Cosmology

Yury Holubeu *

November 12, 2025

This draft is not aimed for distribution. Cosmology is discussed in detail. The note has solved problems and summary of special topics. Readers who have opened this note for the first time are highly recommended to read the preface.

Contents

Preface and main motivation **14**

I —— Typical Cosmology in a Nutshell —— **16**

1 Main concepts of modern cosmology **16**
1.1 Most believed properties of the universe . . . 16
1.1.1 General history of the universe in scope of modern cosmology . . . 16
1.1.2 Properties and objects of the current universe . . . 23
1.1.3 Determination of properties of the universe in a nutshell . . . 23
1.1.4 Concept of shape, expansion of the universe, dark mater, dark energy . . . 24
1.1.5 Main Philosophical Ideas about Universe . . . 24
1.1.6 Validity of modern cosmology, tests, directions of improvement (!?) . . . 25
1.2 Main models of modern cosmology . . . 26
1.2.1 Friedmann universe in a nutshell . . . 26
1.2.2 On distances, expansion, Hubble's law, Hubble Sphere, horizons, redshift . . . 33
1.2.3 Homogeneous inflation in a nutshell . . . 40
1.2.4 Description of equilibrium and non equilibrium processes . . . 46
1.2.5 Nucleosynthesis, baryogenesis, decouplings in a nutshell . . . 51
1.3 Structure formation and anysotropies in a nutshell . . . 58
1.3.1 Overview of fluctuations dynamics, parameters, power spectrum (!!!!!!) . . . 58
1.3.2 Perturbations setup from newtonian and relativisic physics . . . 64
1.3.3 Initial conditions from inflaton fluctuations . . . 72
1.3.4 Derivations of full perturbed Boltzmann and Einstain eq. in a nutshell (!??!) . . . 75
1.3.5 Dynamics of fluctuations, power spectrum and spectral indexes . . . 82
1.3.6 Details of evolution of fluctuations, other approaches in a nutshell . . . 90
1.3.7 Anisotropy predictions, correlations in a nutshell (!!!!!!!!!) . . . 94
1.3.8 Details of anisotropies, other approaches in a nutshell (!!!!!!!!!) . . . 114
1.3.9 Other properties of CMB in a nutshell (!!??) . . . 117
1.4 Mathematics and physical background for applications . . . 118
1.4.1 Physical background for fluctuations, constants, mathematics . . . 118
1.4.2 Basic diffgeom and mathematics for cosmology . . . 120
1.5 Main cosmological parameters and ideas . . . 121
1.5.1 Hubble parameter and tension in a nutshell . . . 121
1.5.2 Dark Matter in a nutshell . . . 121
1.5.3 Cosmological constant (dark energy) in a nutshell . . . 130
1.5.4 Sense of inflanton field . . . 131
1.6 Main experimental facts, their analysis and confirmation of cosmological models . . . 132
1.6.1 Challenges of Λ-CDM . . . 132
1.6.2 Dark Matter detection . . . 133
1.6.3 On experimental data . . . 138
1.6.4 Statistical methods for experiments in cosmology (????) . . . 141

II —— Special Topics in Cosmology in a Nutshell —— 142

2 Other models, theories, properties and data (??) 142
2.1 Main physical background for cosmology . . . 142
2.1.1 Gravity ideas and formalisms for cosmology . . . 142
2.1.2 Gravitational lensing for cosmology in a nutshell (???) . . . 142
2.1.3 On some stars and astrophysics for cosmology . . . 150
2.2 Other models of cosmology in a nutshell . . . 150
2.2.1 Variable Constants models overview . . . 150
2.2.2 Description of formation of Solar System . . . 150
2.2.3 On other models of inflation . . . 151
2.2.4 Primordial phase transitions, quantum bubbles, primordial GWs (????) . . . 151
2.2.5 Cosmic strings, (etc...) . . . 159
2.2.6 On quantum cosmology, wavefunction of universe (????) . . . 160
2.2.7 On bouncing universe model . . . 161
2.2.8 On Conformal cyclic cosmology . . . 161
2.2.9 Other most typical models of cosmology . . . 161
2.2.10 Cosmological models that are considered wrong . . . 163
2.3 On general and more philosophical ideas about physics about cosmology . . . 163
2.3.1 Cosmological paradoxes and philosophical problems . . . 164
2.3.2 What Could be in the Universe if Something Was Different? . . . 164
2.3.3 What is the fate of the universe? . . . 164
2.3.4 What Was in the Beginning of the Universe? . . . 164
2.3.5 Nature of Time, Chronogeometry . . . 164
2.3.6 Some Other Hypothetical Questions . . . 164

3 Some plots from different part of cosmology 165

III Fundamentals of Cosmology 174

4 General Fundamentals of Cosmology 174
4.1 General, Philosophical Approach . . . 174
4.1.1 Why In General We Can Describe a Universe (??) . . . 174
4.1.2 Flatness of the Universe . . . 174
4.1.3 Gravitation on the Scale of the Universe (???) . . . 174
4.1.4 Idea of a Cosmological Constant . . . 174
4.1.5 Gravitational Constant . . . 174
4.1.6 Time in Context of Cosmology (????) . . . 174
4.1.7 Idea of Dark Energy . . . 175
4.1.8 Idea of Dark Matter . . . 175
4.1.9 Redshift . . . 175
4.1.10 Redshift by Landau . . . 177

5 Main Methods of Gravity and Mathematics for Cosmology 183
5.1 Geometry . . . 184
5.1.1 Geodesics . . . 184
5.1.2 Distances . . . 188
5.2 Differential Geometry for Cosmology . . . 190
5.2.1 Killing Vector (??) . . . 190

6 Some Basic Models **190**
6.1 Friedman Universe . . . 190
6.1.1 Cosmic parameters . . . 190
6.1.2 Spacetime Curvature . . . 192
6.1.3 Friedmann Equations . . . 195
6.1.4 Single-Component Universe . . . 200
6.1.5 Two-Component Universe . . . 201
6.1.6 Common misconceptions of horizons and the superluminal expansion . . . 202
6.2 Inflation . . . 217
6.2.1 The Horizon Problem (??) . . . 218
6.2.2 A Shrinking Hubble Sphere . . . 222
6.2.3 The Physics of Inflation . . . 226
6.3 Thermal History . . . 230
6.3.1 The Hot Big Bang . . . 231
6.3.2 Equilibrium . . . 235
6.3.3 Isotropic Space by Landau . . . 238
6.3.4 Closed Isotropic Model by Landau . . . 242
6.3.5 Open Isotropic Model by Landau . . . 246
6.4 Not Popular, but Basic Models . . . 249
6.4.1 Gravitational Stability of Isotropic World . . . 249
6.4.2 Homogeneous Spaces . . . 254
6.4.3 Flat Anisotropic Model . . . 259
6.4.4 Oscillations During Approach to Singularity . . . 263
6.4.5 Singularity in Einstein's Equation for Cosmology (???) . . . 267
6.5 Relics from the Hot Big Bang . . . 270
6.5.1 Introduction . . . 270
6.5.2 Theory . . . 272
6.5.3 Big Bang Cosmology . . . 273
6.5.4 Afterglow of the Big Bang . . . 279
6.5.5 Cosmic Sound Waves . . . 286
6.5.6 Light Relics . . . 291
6.6 Relics from Inflation . . . 300
6.6.1 Inflationary Cosmology . . . 301
6.6.2 Quantum Initial Conditions . . . 306
6.6.3 Primordial Interactions . . . 317
6.6.4 Heavy Relics . . . 325

7 TASI Lectures on Inflation Daniel Baumann **331**
7.1 Classical Dynamics of Inflation . . . 332
7.2 Introduction . . . 333
7.2.1 The Microscopic Origin of Structure . . . 333
7.2.2 Outline of the Lectures . . . 337
7.3 Classical Dynamics of Inflation by Baumann 1th lecture . . . 338
7.3.1 *Review*: The Homogeneous Universe . . . 338
7.3.2 Big Bang Puzzles . . . 345
7.3.3 A First Look at Inflation . . . 348
7.3.4 The Physics of Inflation . . . 353
7.4 Quantum Fluctuations during Inflation by Baumann 2th lecture . . . 360
7.4.1 *Review*: Cosmological Perturbations . . . 361
7.4.2 *Preview*: The Quantum Origin of Structure . . . 366
7.4.3 Quantum Mechanics of the Harmonic Oscillator . . . 368
7.4.4 Quantum Fluctuations in de Sitter Space . . . 371
7.4.5 Primordial Spectra . . . 377
7.5 Contact with Observations by Baumann 3rd lecture . . . 379

7.5.1 Connecting Observations to the Early Universe . . . 379
7.5.2 *Review*: The Cosmic Microwave Background . . . 381
7.5.3 *Review*: Large-Scale Structure . . . 388
7.5.4 Current Evidence for Inflation . . . 390
7.5.5 Future Tests of Inflation . . . 395
7.6 Primordial Non-Gaussianity by Baumann 4th lecture . . . 398
7.6.1 Preliminaries . . . 398
7.6.2 Theoretical Expectations . . . 402
7.6.3 Observational Prospects . . . 405
7.6.4 *Summary*: Lecture 4 . . . 406
7.7 Conclusions . . . 407
7.7.1 *Recap*: TASI Lectures on Inflation . . . 407
7.7.2 Future Prospects and Open Problems . . . 408
7.7.3 Guide to Further Reading . . . 409
7.8 Appendix . . . 411
7.8.1 Cosmological Perturbation Theory . . . 411
7.8.2 Free Field Action for $\mathcal{R}$ . . . 423
7.8.3 A Brief Review of the In-In Formalism . . . 426
7.8.4 Slow-Roll Inflation in the Hamilton-Jacobi Approach . . . 428

8 General Fundamental Questions **431**
8.1 What Cosmology Teaches Us About Our Life? . . . 431
8.2 What Cosmology Teaches Us About Physical Nature of the Word? . . . 432

9 Alternative Fundamental Ideas **432**
9.0.1 Dicke's Explanation of the Redshift . . . 432

10 Cosmology by Weinberg **432**
10.1 The Expansion of the Universe . . . 432
10.1.1 1.1 Spacetime geometry . . . 433
10.1.2 1.1 Spacetime geometry . . . 438
10.1.3 1.2 The cosmological redshift . . . 439
10.1.4 1.2 The cosmological redshift . . . 439
10.1.5 1.3 Distances at small redshift: The Hubble constant . . . 441
10.1.6 1.4 Luminosity distances and angular diameter distances . . . 454
10.1.7 1.5 Dynamics of expansion . . . 456
10.1.8 1.6 Distances at large redshift: Accelerated expansion . . . 464
10.1.9 1.7 Cosmic expansion or tired light? . . . 473
10.1.10 1.8 Ages . . . 475
10.1.11 1.9 Masses . . . 480
10.1.12 1.10 Intergalactic absorption . . . 486
10.1.13 1.11 Number counts . . . 492
10.1.14 1.12 Quintessence . . . 496
10.1.15 1.13 Horizons . . . 503
10.2 The Cosmic Microwave Radiation Background . . . 504
10.2.1 2.1 Expectations and discovery of the microwave background . . . 505
10.2.2 2.2 The equilibrium era . . . 510
10.2.3 2.3 Recombination and last scattering . . . 513
10.2.4 2.4 The dipole anisotropy . . . 524
10.2.5 2.5 The Sunyaev-Zel'dovich effect . . . 526
10.2.6 2.6 Primary fluctuations in the microwave background: A first look . . . 529
10.3 The Early Universe . . . 538
10.3.1 3.1 Thermal history . . . 539
10.3.2 3.2 Cosmological nucleosynthesis . . . 547

10.3.3 3.3 Baryonsynthesis and leptonsynthesis . . . 557
10.3.4 3.4 Cold dark matter . . . 566
10.4 Inflation . . . 576
10.4.1 4.1 Three puzzles . . . 577
10.4.2 4.2 Slow-roll inflation . . . 581
10.4.3 4.3 Chaotic inflation, eternal inflation . . . 587
10.5 General Theory of Small Fluctuations . . . 588
10.5.1 5.1 Field equations . . . 589
10.5.2 5.2 Fourier decomposition and stochastic initial conditions . . . 596
10.5.3 5.3 Choosing a gauge . . . 601
10.5.4 5.4 Conservation outside the horizon . . . 608
10.6 Evolution of Cosmological Fluctuations . . . 616
10.6.1 6.1 Scalar perturbations - kinetic theory . . . 617
10.6.2 6.1 Scalar perturbations - kinetic theory . . . 620
10.6.3 6.2 Scalar perturbations - the hydrodynamic limit . . . 629
10.6.4 6.3 Scalar perturbations - long wavelengths . . . 635
10.6.5 6.4 Scalar perturbations - short wavelengths . . . 640
10.6.6 6.5 Scalar perturbations - interpolation & transfer functions . . . 651
10.6.7 6.5 Scalar perturbations - interpolation & transfer functions . . . 653
10.6.8 6.6 Tensor perturbations . . . 658
10.7 Anisotropies in the Microwave Sky . . . 671
10.7.1 7.1 General formulas for the temperature fluctuation . . . 671
10.7.2 7.2 Temperature multipole coefficients: Scalar modes . . . 682
10.7.3 7.3 Temperature multipole coefficients: Tensor modes . . . 696
10.7.4 7.4 Polarization . . . 702
10.8 The Growth of Structure . . . 725
10.8.1 8.1 Linear perturbations after recombination . . . 726
10.8.2 8.2 Nonlinear growth . . . 739
10.8.3 8.3 Collapse of baryonic matter . . . 744
10.9 Gravitational Lenses . . . 746
10.9.1 9.1 Lens equation for point masses . . . 747
10.9.2 9.2 Magnification: Strong lensing and microlensing . . . 749
10.9.3 9.3 Extended lenses . . . 754
10.9.4 9.3 Extended lenses . . . 754
10.9.5 9.3 Extended lenses . . . 756
10.9.6 9.4 Time delay . . . 757
10.9.7 9.5 Weak lensing . . . 761
10.9.8 9.6 Cosmic strings . . . 773
10.10 Inflation as the Origin of Cosmological Fluctuations . . . 774
10.10.1 10.1 Scalar fluctuations during inflation . . . 774
10.10.2 10.2 Tensor fluctuations during inflation . . . 786
10.10.3 10.3 Fluctuations during inflation: The slow-roll approximation . . . 788
10.10.4 10.3 Fluctuations during inflation: The slow-roll approximation . . . 793
10.10.5 10.4 Multifield inflation . . . 795
10.11 Appendix A Some Useful Numbers . . . 803
10.12 Appendix B Review of General Relativity . . . 804
10.13 Appendix C Energy Transfer between Radiation and Electrons . . . 819
10.14 Appendix D The Ergodic Theorem . . . 823
10.15 Appendix E Gaussian Distributions . . . 825
10.16 Appendix F Newtonian Cosmology . . . 826
10.17 Appendix G Photon Polarization . . . 828
10.18 Appendix H The Relativistic Boltzmann Equation . . . 830
10.19 Glossary of Symbols . . . 840

10.20 Assorted Problems . . . 843

11 Challenges for ΛCDM: An update by Perivolaropoulos, Skara 846
11.1 Introduction . . . 847
11.2 Hubble tension . . . 851
11.2.1 Methods for measuring H_0 and data . . . 851
11.2.2 Theoretical models . . . 882
11.3 Other Tensions - Curiosities . . . 902
11.3.1 Growth tension . . . 902
11.3.2 CMB anisotropy anomalies . . . 911
11.3.3 Cosmic dipoles . . . 918
11.3.4 BAO curiosities . . . 921
11.3.5 Parity violating rotation of CMB linear polarization (Cosmic Birefringence) . . . 922
11.3.6 Small-scale curiosities . . . 923
11.3.7 Age of the Universe . . . 924
11.3.8 The Lithium problem . . . 925
11.3.9 Quasars Hubble diagram . . . 926
11.3.10 Oscillating signals in short range gravity experiments . . . 927
11.3.11 Anomalously low baryon temperature . . . 928
11.3.12 Colliding clusters with high velocity . . . 928
11.4 Conclusions-Discussion-Outlook . . . 930
11.5 Appendix . . . 936

IV Properties of the Universe in Detail 940

12 Theory by Dodelson 940
12.1 The Standard Model and Beyond . . . 940
12.1.1 The Expanding Universe . . . 940
12.1.2 The Hubble Diagram . . . 944
12.1.3 Big Bang Nucleosynthesis . . . 946
12.1.4 The Cosmic Microwave Background . . . 949
12.1.5 Beyond the Standard Model . . . 950
12.2 The Smooth, Expanding Universe . . . 955
12.2.1 General Relativity . . . 956
12.2.2 Distances . . . 964
12.2.3 Evolution of Energy . . . 966
12.2.4 Cosmic Inventory . . . 969
12.3 Beyond Equilibrium . . . 983
12.3.1 Boltzmann Equation for Annihilation . . . 983
12.3.2 Big Bang Nucleosynthesis . . . 986
12.3.3 Recombination . . . 992
12.3.4 Dark Matter . . . 995
12.4 The Boltzmann Equations . . . 1003
12.4.1 The Boltzmann Equation for the Harmonic Oscillator . . . 1004
12.4.2 The Collisionless Boltzmann Equation for Photons . . . 1006
12.4.3 Collision Terms: Compton Scattering . . . 1012
12.4.4 The Boltzmann Equation for Photons . . . 1016
12.4.5 The Boltzmann Equation for Cold Dark Matter . . . 1018
12.4.6 The Boltzmann Equation for Baryons . . . 1022
12.5 Einstein Equations . . . 1028
12.5.1 The Perturbed Ricci Tensor and Scalar . . . 1028
12.5.2 Two Components of the Einstein Equations . . . 1031
12.5.3 Tensor Perturbations . . . 1034

12.5.4 The Decomposition Theorem . . . 1039
12.5.5 from Gauge to Gauge . . . 1040
12.6 Initial Conditions . . . 1042
12.6.1 The Einstein-Boltzmann Equations at Early Times . . . 1042
12.6.2 The Horizon . . . 1045
12.6.3 Inflation . . . 1047
12.6.4 Gravity Wave Production . . . 1055
12.6.5 Scalar Perturbations . . . 1060
12.7 Inhomogeneities . . . 1068
12.7.1 Prelude . . . 1068
12.7.2 Large Scales . . . 1074
12.7.3 Small Scales . . . 1079
12.7.4 Numerical Results and Fits . . . 1086
12.7.5 Growth Function . . . 1088
12.7.6 Beyond Cold Dark Matter . . . 1090
12.8 Anisotropies . . . 1093
12.8.1 Overview . . . 1093
12.8.2 Large-Scale Anisotropies . . . 1098
12.8.3 Acoustic Oscillations . . . 1099
12.8.4 Diffusion Damping . . . 1104
12.8.5 Inhomogeneities to Anisotropies . . . 1107
12.8.6 The Anisotropy Spectrum Today . . . 1114
12.8.7 Cosmological Parameters . . . 1119
12.9 Cosmological perturbations by J. Lesgorgues . . . 1125
12.9.1 Linear cosmological perturbations . . . 1126
12.9.2 CMB temperature anisotropies by Lesgourgues . . . 1135
12.9.3 Matter power spectrum by Lesgourgues . . . 1159
12.10 Probes of Inhomogeneities . . . 1171
12.10.1 Angular Correlations . . . 1172
12.10.2 Peculiar Velocities . . . 1178
12.10.3 Direct Measurements of Peculiar Velocities . . . 1180
12.10.4 Redshift Space Distortions . . . 1183
12.10.5 Galaxy Clusters . . . 1188
12.10.6 Lyth bound (??) . . . 1193
12.11 Weak Lensing and Polarization . . . 1193
12.11.1 Gravitational Distortion of Images . . . 1194
12.11.2 Geodesics and Shear . . . 1197
12.11.3 Ellipticity as an Estimator of Shear . . . 1200
12.11.4 Weak Lensing Power Spectrum . . . 1203
12.11.5 Polarization: The Quadrupole and the Q/U Decomposition . . . 1209
12.11.6 Polarization from a Single Plane Wave . . . 1212
12.11.7 Boltzmann Solution . . . 1217
12.11.8 Polarization Power Spectra . . . 1220
12.11.9 Detecting Gravity Waves . . . 1223

V Problems 1227

13 Typical problems of modern cosmology 1227
13.1 Problems about Homogeneous Dynamics and Thermal History . . . 1227
13.1.1 Mathematical Problems for Basic Preparation to Cosmology . . . 1227
13.1.2 Typical Problems about Friedman Universe (?!??!) . . . 1227
13.1.3 Other Problems about Friedman Universe (?!??!) . . . 1231
13.1.4 Solutions by Dodelson to Chapter 1 . . . 1232

13.1.5 Problems on thermal history (!!?) . . . 1233
13.1.6 Problems on homogeneous inflation 1 . . . 1238
13.1.7 Problems on homogeneous inflation 2 . . . 1241
13.1.8 Problems on Einstein equations . . . 1243
13.2 Problems about Inhomogeneities and Anisotropies . . . 1245
13.2.1 Problems about initial conditions . . . 1245
13.2.2 Problems on inhomogeneities . . . 1251
13.2.3 Problems on Anisotropies . . . 1264
13.2.4 Problems from probes of inhomogeneities by Dodelson (??????) . . . 1270
13.2.5 *Problem Sets* by Baumann's TASI lectures . . . 1272
13.2.6 Solution some problems by Dodelson chapter 2 . . . 1275
13.2.7 Solution some problems by Dodelson chapter 3 . . . 1279
13.2.8 Solution some problems by Dodelson chapter 4 . . . 1280
13.2.9 Solution some problems by Dodelson chapter 5 . . . 1282
13.2.10 Solution some problems by Dodelson chapter 11 . . . 1282

14 Extra Problems about Basic Models 1285
14.1 General questions . . . 1285
14.1.1 Short problems for checking basics of modern cosmology . . . 1285
14.1.2 Short questions and problems for knowledge checking . . . 1286
14.1.3 Problems to Check Deep Understanding of Cosmology . . . 1290
14.1.4 Typical general questions from curious people . . . 1290

15 Problems about Special Modesl 1291
15.0.1 Problems about Weak Lensing and Polarization 1 . . . 1291
15.0.2 Problems about Weak Lensing and Polarization 2 . . . 1293
15.0.3 Problems about Quantum Cosmology (???) . . . 1295

VI Other Topics in Cosmology 1298

16 Stochastic backgrounds of cosmological origin 1298
16.1 22.1 Characteristic frequency of relic GWs . . . 1298
16.1.1 22.2 GW production by classical fields . . . 1300
16.1.2 22.2.1 General formalism . . . 1300
16.1.3 22.2.2 GW generation by a stochastic scalar field . . . 1304
16.1.4 22.3 GWs from preheating after inflation . . . 1307
16.1.5 22.3.1 Parametric resonance in single-field inflation . . . 1307
16.1.6 22.3.2 Tachyonic preheating in hybrid inflation . . . 1309
16.2 22.4 GWs from first-order phase transitions . . . 1310

Experimental Tests

Consequences of High Energy Physics on Cosmology

This note contains a discussion of the cosmological constant, detailed CMB overview, description of quantum bubbles during cosmological phase transitions. Also, there is a popular introduction. I used the following literature.

Let's discuss some minimum knowledge and motivation that would be good to understand for studying the subject.

А как на самом деле устроена Вселенная?

(раскрою мысль, что интересно узнать природу Вселенной)

Что на самом деле было давно в прошлом?

(раскрою мысль, что интересно узнать природу Вселенной)

Квантовая космология - фундаментально очень интересная и возможно верная модель устройства мира в самом его "начале"

Особенно в 2020х годах можно многое узнать про это без особых усилий, потому что это типичная тема многих статей. Квантовая космология - то, где наше интуитивное представление о мире перестает работать и там происходит казалось бы абсолютно непонятно что. Однако есть много исследований про это, и все-таки интересно понять, что же там было. Конечно, ожидать, что эти вопросы будут решены или за пару месяцев станут понятными, абсолютно не разумно, тем не менее, подумать про это особо интересно. В целом, это прекрасное хобби любого физика - подумать про квантовую космологию на досуге. Ну и плюс если что-то там откроешь - то это очень будет актуальным открытием.

Рассказывая о большинстве предметах, можно найти их важные связи и применения в космологии, что очень круто дополнит рассказ, потому что будет казаться, что ты знаешь что-то о глобальном

(распишу потом, что очень круто о таких приложениях говорить и например, о чем можно упоминать! вот например - тут применяется, такой эффект. И такого в космологии полно, редкий предмет в физике не применяется в ней. Классическая механика может быть, и то философский подход такой же)

Головоломки для мотивации

(??? что-то пока не знаю даже, что придумать тут такое для начала? потом напишу, когда нарешаюсь задач.)

С чего начался мир?

(типичный вопрос, который очень мотивирует ответить)

(тут абзац будет, типа мы не знаем, но вот там в доли секунд мы еще знаем что-то. только вот по факту экспериментальное подтверждение - тема на 100 страниц и пары месяцев раздумий про это.)

Какой возраст Вселенной и почему он такой? (????????)

(я не знаю,почему он такой, но это мотивирует учить космологию.)

Derive the age of Universe (??????)

(??? still I have no idea)

Что было 10 миллиардов лет назад?

(я не знаю, что было, но это мотивирует учить космологию.)

Что будет со Вселенной в будущем?

Part I
Typical Cosmology in a Nutshell

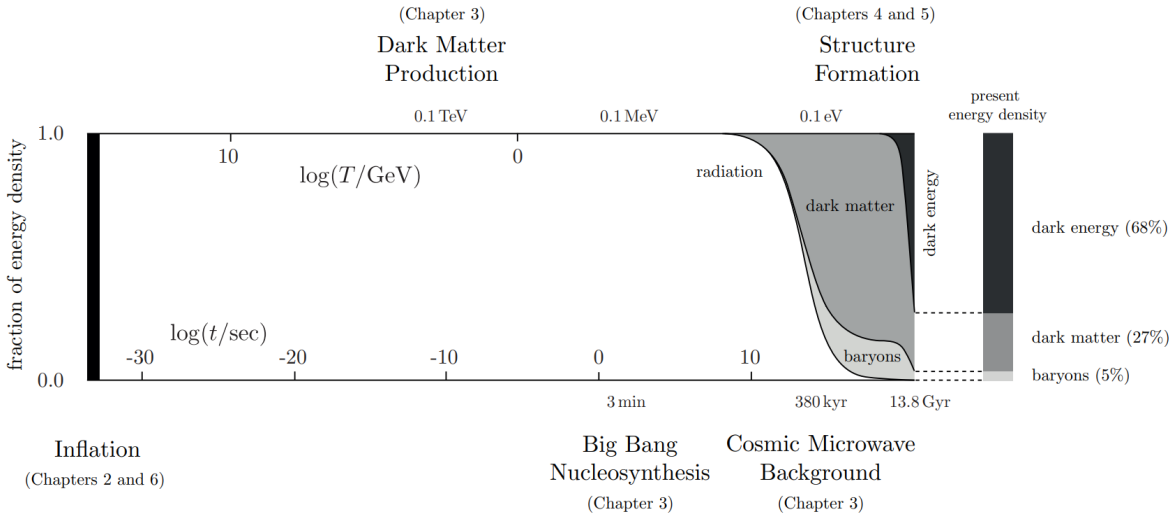
1 Main concepts of modern cosmology

1.1 Most believed properties of the universe

(очень тоже важные указания на то, какой вообще моделью пользоваться и почему? много мнений, много философских соображений, когда-то и я напишу, пока что не спрашивают меня, ну и не до этого.)

1.1.1 General history of the universe in scope of modern cosmology

общая хронология



t	$\rho^{1/4}$	Event
10^{-42} s	10^{18} GeV	Inflation begins?
$10^{-32\pm6}$ s	$10^{13\pm3}$ GeV	Inflation ends, Cold Big Bang begins?
$10^{-18\pm6}$ s	$10^{6\pm3}$ GeV	Hot Big Bang begins?
10^{-10} s	100 GeV	Electroweak phase transition?
10^{-4} s	100 MeV	Quark-hadron phase transition?
10^{-2} s	10 MeV	γ, ν, e, $\bar{e}$, n, and p in thermal equilibrium
1 s	1 MeV	ν decoupling, $e\bar{e}$ annihilation.
100 s	0.1 MeV	Nucleosynthesis (BBN)
10^4 yr	1 eV	Matter-radiation equality
10^5 yr	0.1 eV	Atom formation, photon decoupling (CMB)
$\sim 10^9$ yr	10^{-3} eV	First bound structures form
Now	10^{-4} eV (2.73 K)	The present.

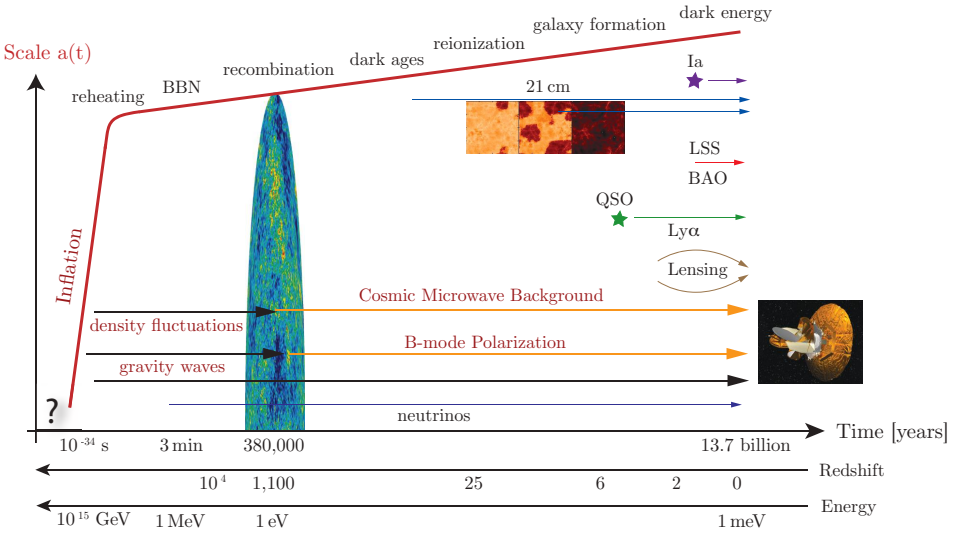
Event	time t	redshift z	temperature T
Inflation	10^{-34} s(?)	–	–
Baryogenesis	?	?	?
EW phase transition	20ps	10^{15}	100GeV
QCD phase transition	20μs	10^{12}	150MeV
Dark matter freeze-out	?	?	?
Neutrino decoupling	1 s	$6 \cdot 10^9$	1MeV
Electron-positron annihilation	6 s	$2 \cdot 10^9$	500keV
Big Bang nucleosynthesis	3 min	$4 \cdot 10^8$	100keV
Matter-radiation equality	60kyr	3400	0.75eV
Recombination	$260 - 380$kyr	$1100 - 1400$	$0.26 - 0.33$eV
Photon decoupling	380kyr	$1000 - 1200$	$0.23 - 0.28$eV
Reionization	$100 - 400$Myr	$11 - 30$	$2.6 - 7.0$meV
Dark energy-matter equality	9 Gyr	0.4	0.33meV
Present	13.8Gyr	0	0.24meV

Epoch	Temperature	Characteristics
Big Bang 0 s	∞K ∞eV	singularity (vacuum fluctuation?)
Planck 0 s $< t \leq 10^{-43}$ s	$> 10^{40}$ K $> 10^{36}$eV	quantum gravity
Grand Unification 10^{-43} s $\leq t \leq 10^{-36}$ s	$10^{36} - 10^{40}$ K $10^{26} - 10^{32}$eV	gravity freezes out the "grand unified force" (GUT)
Inflationary 10^{-36} s $\leq t \leq 10^{-32}$ s	$10^{33} - 10^{36}$ K $10^{29} - 10^{32}$eV	inflation begins strong force freezes out
Electroweak 10^{-32} s $\leq t \leq 10^{-12}$ S	$10^{20} - 10^{33}$ K $10^{16} - 10^{29}$eV	weak force freezes out 4 distinct forces(EM dominates) baryogenesis: baryons and antibaryons annihilate
Quark 10^{-12} s $\leq t \leq 10^{-6}$ s	$10^{16} - 10^{20}$ K $10^{12} - 10^{16}$eV	universe contains hot quark-gluon plasma: quarks, gluons and leptons
Hadron 10^{-6} s $\leq t \leq 1$ s	$10^{12} - 10^{16}$ K $10^{8} - 10^{12}$eV	quarks and gluons bind into hadrons
Lepton 1 s $\leq t \leq 3$ min	$10^{10} - 10^{12}$ K $10^{6} - 10^{8}$eV	universe contains photons (γ), muons ($\mu^{\pm}$), electrons/positrons ($e^{\pm}$), and neutrinos ($\nu, \bar{\nu}$); nucleons n and p in equal numbers
1 s	$\leq 10^{12}$ K $\leq 10^{8}$eV	$\mu^+$and μ^-annihilate; ν and $\bar{\nu}$ decouple; $e^{\pm}, \gamma$ and nucleons remain. Reactions: $e^+ + n \rightleftharpoons p + \nu_e$ $e^- + p \rightleftharpoons n + \nu_e$ $n \rightarrow p + e^- + \bar{\nu}_e$
100 s	10^{10} K, 10^{6}eV	e^+ and e^-annihilate

(!!!!!!!!!!!!! тут напишу важное пояснение, что означает каждый важный процесс из таблицы!)

Reionization is the process that caused electrically neutral atoms in the universe to reionize after the lapse of the "dark ages". It is the second of two major phase transitions of gas in the universe[citation needed] (the first is recombination). While the majority of baryonic matter

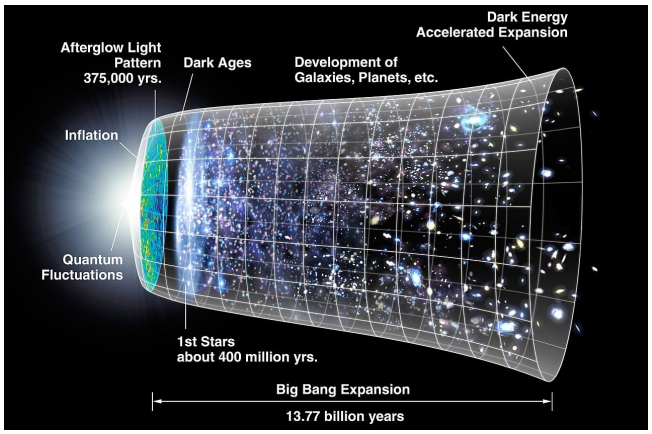
in the universe is in the form of hydrogen and helium, reionization usually refers strictly to the reionization of hydrogen, the element.



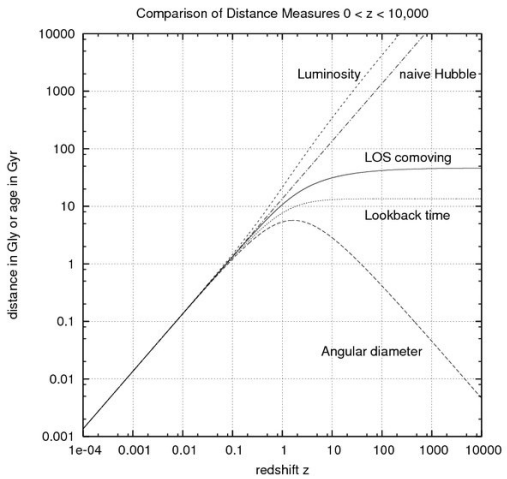
Отдельно подчеркну, что:

• Вначале у Вселенной было очень много энергии, и много света. Как-то появились протоны и электроны, возможно, от инфлятонов. Дальше они собирались в другую материю.

• CMB образовался в именно эпоху доминации материи, не на границе перехода к ней.



Время Вселенной по красоному смещению:



(потом еще додумаю этот график, в целом, можно им и пользоваться)

A Thermal-Particle History of the universe

- Baryogenesis. Particles and antiparticles annihilate through $e^+ + e^- \to \gamma + \gamma$. If initially the universe was filled with equal amounts of matter and anti-matter then we expect these annihilations to lead to a universe dominated by radiation. However, we do observe an overabundance of matter (mostly baryons) over anti-matter in the universe today. Models of baryogenesis try to derive the observed baryon-to-photon ratio

$$\eta := \frac{n_b}{n_\gamma} \sim 10^{-9}$$

from some dynamical mechanism, i.e. without assuming a primordial matter-antimatter asymmetry as an initial condition. Although many ideas for baryogenesis exist, none is singled out by experimental tests.

(!?!?! добавлю ключевую формулу или график!)

- Electroweak phase transition. At 100GeV particles receive their masses through the Higgs mechanism. (????)

(!?!?! добавлю ключевую формулу или график!)

- QCD phase transition to baryons. Below 150MeV the strong interactions between the quarks and the gluons become important (before was only weak interaction). Quarks and gluons then form bound three-quark systems (baryons), and quark-antiquark pairs (mesons). These baryons and mesons are the relevant degrees of freedom below the scale of the QCD phase transition.

(!?!?! добавлю ключевую формулу или график!)

- Dark matter freeze-out. Since dark matter is very weakly interacting with ordinary matter we expect it to decouple relatively early on. In §3.3.2, we will study the example of WIMPs - weakly interacting massive particles that freeze out around 1MeV. We will show that choosing natural values for the mass of the dark matter particles and their interaction cross section with ordinary matter reproduces the observed relic dark matter density surprisingly well.

(!?!?! добавлю ключевую формулу или график!)

- Neutrino decoupling. Neutrinos only interact with the rest of the primordial plasma through the weak interaction. The estimate in (3.1.10) therefore applies and neutrinos decouple at 0.8MeV.

(!?!?! добавлю ключевую формулу или график!)

- Electron-positron annihilation. Electrons and positrons annihilate shortly after neutrino decoupling. The energies of the electrons and positrons gets transferred to the photons, but not the neutrinos. In §3.2.4, we will explain that this is the reason why the photon temperature today is greater than the neutrino temperature.

(!?!?! добавлю ключевую формулу или график!)

- Big Bang nucleosynthesis. Around 3 minutes after the Big Bang, the light elements were formed. In §3.3.4, we will study this process of Big Bang nucleosynthesis (BBN).

(!?!?! добавлю ключевую формулу или график!)

- Recombination. Neutral hydrogen forms through the reaction $e^- + p^+ \to \mathrm{H} + \gamma$ when the temperature has become low enough that the reverse reaction is energetically disfavoured.

At temperatures above about 1 eV, the universe still consisted of a plasma of free electrons and nuclei. Photons were tightly coupled to the electrons via Compton scattering, which in turn strongly interacted with protons via Coulomb scattering. There was very little neutral hydrogen. When the temperature became low enough, the electrons and nuclei combined to form neutral atoms (recombination20), and the density of free electrons fell sharply. The photon mean free path grew rapidly and became longer than the horizon distance. The photons

decoupled from the matter and the universe became transparent. Today, these photons are the cosmic microwave background.

(!?!?! добавлю ключевую формулу или график!)

- Photon decoupling. Before recombination the strongest coupling between the photons and the rest of the plasma is through Thomson scattering, $e^- + \gamma \to e^- + \gamma$. The sharp drop in the free electron density after recombination means that this process becomes inefficient and the photons decouple. They have since streamed freely through the universe and are today observed as the cosmic microwave background (CMB).

(!?!?! добавлю ключевую формулу или график!)

Main temperature properties of the universe

The temperature of the universe 1 second after the Big Bang was about 1MeV, and evolved as $t^{-1/2}$ before that. Because $\frac{T}{1\text{MeV}} \simeq 1.5 g_\star^{-1/4} \left(\frac{1\text{sec}}{t}\right)^{1/2}$. (?? допишу, почему идейно??)

Formation of Solar System

There is evidence that the formation of the Solar System began about 4.6 billion years ago with the gravitational collapse of a small part of a giant molecular cloud.[1] Most of the collapsing mass collected in the center, forming the Sun, while the rest flattened into a protoplanetary disk out of which the planets, moons, asteroids, and other small Solar System bodies formed.

(очень коротко напишу, нужно будет - вдали уже есть раздел про это)

Empirical Evidence for main properties of the universe (???!!!)

(очень хорошая идея их написать тут, позже сделаю)

- The CMBR: probes the recombination era, $t \sim 10^5$yr, $z \sim 1100$, based on a well understood atomic and macroscopic physics

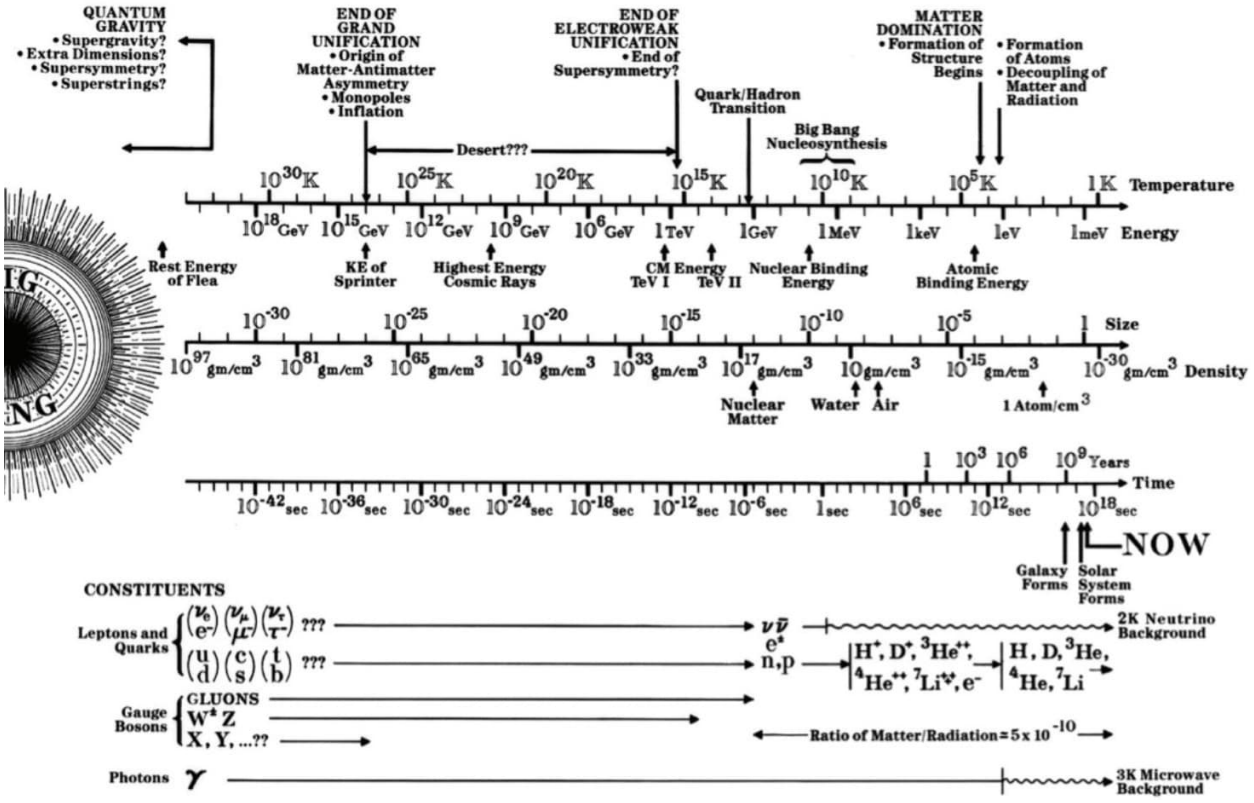
- Nucleosynthesis: probes the $t \sim 10^{-3} - 10^2$ sec era, $z \sim 10^9$, compare the model predictions with observed abundances of the lightest elements, based on a well understood nuclear physics

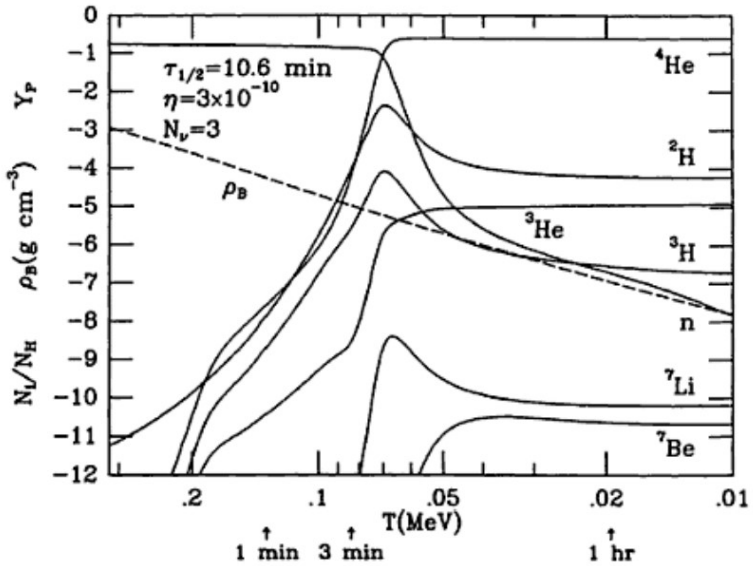
- Matter-antimatter asymmetry: probes the baryogenesis era, $t \sim 10^{-6}$sec, $z \sim 10^{12}$, but only in suggesting that some symmetry breaking did occur

- Predictions of the inflationary scenario: flatness, uniformity of CMBR, absence of monopoles, the right type of density fluctuation spectrum - it all supports the idea that inflation did happen, but does not say a lot about its detailed physics

> Cosmological observations can indicate or constrain physics well outside the reach of laboratory experiments

History of nucleosynthesis





- We will use this to derive the evolution of T as different particle species annihilate in thermal equilibrium

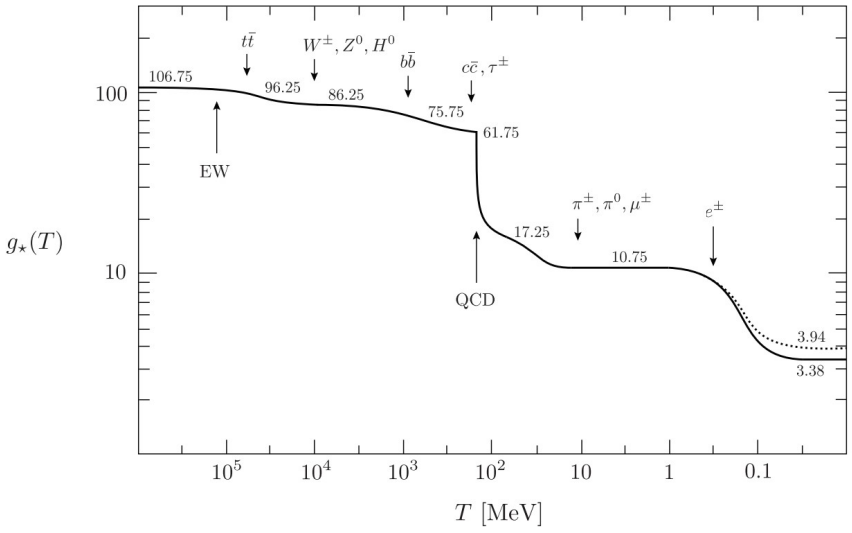
- Setting the entropy density before and after is equivalent to setting

$$g_* T^3\big|_{\text{initial}} = g_* T^3\big|_{\text{final}}$$

- When particle species disappear through annihilation, they dump their entropy into the remaining species and hence raise the temperature

By way of summarizing the features of an expanding universe that I have outlined above and that we will explore in great detail in the coming chapters, let's construct a time line. We

can characterize any epoch in the universe by the time since the Big Bang; by the value of the scale factor at that time; or by the temperature of the cosmic plasma. For example, today, $a = 1; t \simeq 14$ billion years; and $T = 2.725\ \mathrm{K} = 2.35 \cdot 10^{-4}\mathrm{eV}/k_B$.

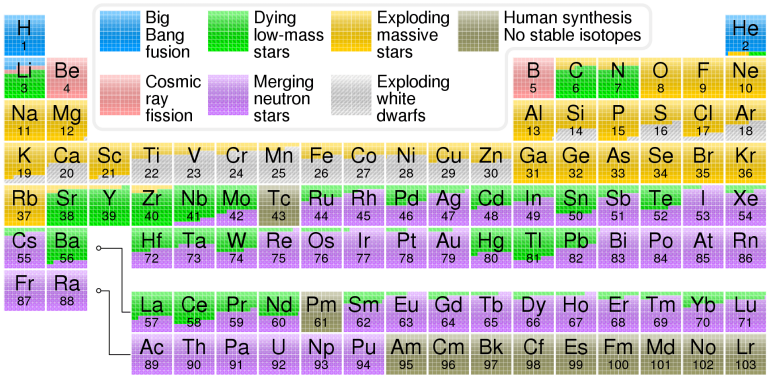


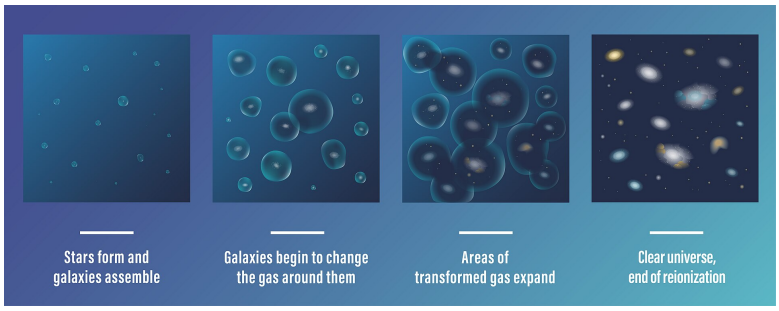
(??? почему график такой - видимо, будет неотвеченным вопросом еще долго, не актуальный вопрос.)

Early on, most of the energy in the universe was in the form of radiation. Eventually, since the energy of a relativistic particle falls as $1/a$ while that of nonrelativistic matter remains constant at m, matter overtook radiation. At relatively recent times, the universe appears to have become dominated not by matter, but by some dark energy, whose density remains relatively constant with time. The evidence for this unexplained form of energy is new and certainly not conclusive, but it is very suggestive.

Light elements formed when the universe was several minutes old, and the CMB decoupled from matter at a temperature of order $k_B T \sim 1/4\mathrm{eV}$. Heavy elementary particles may make up the dark matter in the universe; if they do, their abundance was fixed at very high temperatures of order $k_B T \sim 100\mathrm{GeV}$.

The early end of the time line allows for a brief period of inflation, during which primordial perturbations were produced. These small perturbations began to grow when the universe became dominated by matter. The dark matter grew more and more clumpy, simply because of the attractive nature of gravity. An overdensity of dark matter of 1 part in 1000 when the temperature was 1eV grew to 1 part in 100 by the time the temperature dropped to 0.1eV. Eventually, at relatively recent times, perturbations in the matter ceased to be small; they became the nonlinear structure we see today. Anisotropies in the CMB today tell us what the universe looked like when it was several hundred thousand years old, so they are wonderful probes of the perturbations.



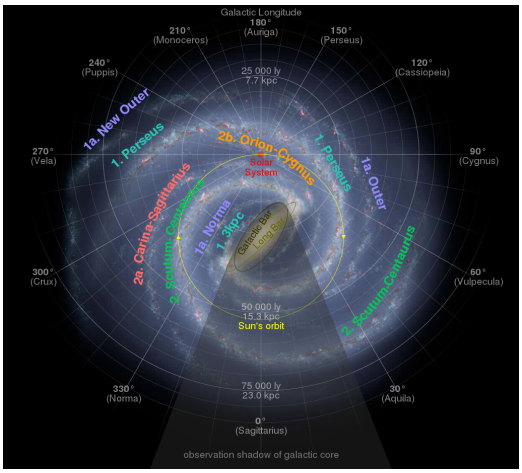


1.1.2 Properties and objects of the current universe

(пока это не пишу, отдельный курс Калтеха про это, нужно будет - недели просижу и доучу)

(об этом пока в записи про астрофизику!)

Overview



Large Scales structures

(см. лекцию Калтеха или мою запись про галлактики, там полно всякого, пока не до этого)

Idea of correlation between galaxies (??)

(вот это важно дописать когда-то будет, пока примерно это понимаю, но уже читал про это)

Voids (????)

(напишу про результаты наблюдений и на чем остановилось объяснение этого???)

1.1.3 Determination of properties of the universe in a nutshell

What is the age of the universe and why? (!??!)

(подробно про то, почему это так?)

There are at least 3 ways that the age of the universe can be estimated:

The age of the chemical elements.

The age of the oldest star clusters.
The age of the oldest white dwarf stars.
(see https://www.astro.ucla.edu/~wright/age.html)

1.1.4 Concept of shape, expansion of the universe, dark mater, dark energy

(самая суть, про все это подробнее ниже будет еще больше указаний)

What is a shape and curvature of universe?

What is a dark energy (Λ)?

What is a dark matter?

Concept of expansion of the universe

Почему космологи считают, что Вселенная расширяется, и почему?

(??? напишу список фактов, приведу также графики из экспериментов для них!)

что сейчас заставляет Вселенную расширяться?

(??? а что сейчас заставляет Вселенную расширяться???? хз, что-то не знаю. сам вакуум - то есть космо постоянная что ли???)

Как это, расширение со сверхсветовой скоростью? (????)

(допишу потом, странно ведь это, да???)

Other important general questions about the universe

Why universe don't fall into one point?

(отвечу потом нормально)

1.1.5 Main Philosophical Ideas about Universe

(main ideas and examples)

What is gravity in a context of universe?

(main statements, formulas and experimental facts)

О границах нашего познания (???)

Возможна ли рациональная космология как наука (???)

(хз, мб и нет, просто тоже важный вопрос)

Принципы метрологии

(услышал, что они важные, иначе херней будешь заниматься, думая, что что-то научное делаешь)

On anthropic principle

(напишу что-то, интересно, но вряд ли это на самом деле важно)
(вики пока)

The anthropic principle (aka the "observation selection effect") is the hypothesis, first proposed in 1957 by Robert Dicke, that the range of possible observations that could be made about the universe is limited by the fact that observations could happen only in a universe capable of developing intelligent life. Proponents of the anthropic principle argue that it explains why the universe has the age and the fundamental physical constants necessary to accommodate conscious life, since if either had been different, no one would have been around to make observations. Anthropic reasoning is often used to deal with the idea that the universe seems to be finely tuned for the existence of life.

There are many different formulations of the anthropic principle. Philosopher Nick Bostrom counts them at thirty, but the underlying principles can be divided into "weak" and "strong" forms, depending on the types of cosmological claims they entail. The weak anthropic principle (WAP), as defined by Brandon Carter, states that the universe's ostensible fine tuning is the result of selection bias (specifically survivorship bias). Most such arguments draw upon some notion of the multiverse for there to be a statistical population of universes from which to select. However, a single vast universe is sufficient for most forms of the WAP that do not specifically deal with fine tuning. Carter distinguished the WAP from the strong anthropic principle (SAP), which considers the universe in some sense compelled to eventually have conscious and sapient life emerge within it. A form of the latter known as the participatory anthropic principle, articulated by John Archibald Wheeler, suggests on the basis of quantum mechanics that the universe, as a condition of its existence, must be observed, thus implying one or more observers. Stronger yet is the final anthropic principle (FAP), proposed by John D. Barrow and Frank Tipler, which views the universe's structure as expressible by bits of information in such a way that information processing is inevitable and eternal.

On metaphysic ideas in cosmology

(их пока не знаю, но очень много наберется, уверен.)

1.1.6 Validity of modern cosmology, tests, directions of improvement (!?)

(Про то, "что и почему не могло бы быть?")

(это подробно в разных разделах будет у меня. подробно ответ на вопрос, не занимаемся ли мы фигней? а то очень даже можем и заниматься! может, нет ничего такого, о чем теоретики говорят, какой-то темной материи, еще чего-то, а просто в принципе мы оторваны от реальности? про это много я буду рассуждать в теории, но тут тоже когда-то укажу основные выводы. пока во все верю, не до сомнений.)

(тут типа такой-то график получили, как его описать? а вот так вот, по сорвеменной космологии. а в такой модификации он тоже описывается, но таки-то особенности тогда. Обзор критический всего будет)

Насколько можно верить в расширение Вселенной и почему?

(потом допишу, вообще, там разные крутые результаты есть, которые отлично подтвердились, кстати...)

Насколько можно верить в термодинамику Вселенной и почему?

Насколько можно верить в инфляцию и почему?

Насколько можно верить в темную материю и темную энергию и почему?

О некоторых альтернативных теориях

О теории Дикке

(указания, что такая есть, и почему она неверная, если так. по не до этого)

1.2 Main models of modern cosmology

1.2.1 Friedmann universe in a nutshell

Main equations and parameters

Robertson-Walker Metric

$$\mathrm{d}s^2 = \mathrm{d}t^2 - a^2(t)\gamma_{ij}\,\mathrm{d}x^i\,\mathrm{d}x^j$$

$$\mathrm{d}s^2 = \mathrm{d}t^2 - a^2(t)\left[\frac{\mathrm{d}r^2}{1-kr^2} + r^2\,\mathrm{d}\Omega^2\right]$$

$$\mathrm{d}s^2 = \mathrm{d}t^2 - a^2(t)\left[\mathrm{d}\chi^2 + S_k^2(\chi)\mathrm{d}\Omega^2\right]$$

$$\mathrm{d}s^2 = a^2(\tau)\left[\mathrm{d}\tau^2 - \left(\mathrm{d}\chi^2 + S_k^2(\chi)\mathrm{d}\Omega^2\right)\right] \quad \text{by} \quad \mathrm{d}\tau := \frac{\mathrm{d}t}{a(t)}$$

$$\mathrm{d}s^2 = \mathrm{d}t^2 - e^{2Ht}\,\mathrm{d}\boldsymbol{x}^2 \quad \text{if} \quad H \equiv \partial_t \ln a = \text{const} \quad \text{(de Sitter)}$$

$$\Gamma^{\mu}_{00} = \Gamma^0_{0\beta} = 0 \qquad \Gamma^0_{ij} = a\dot{a}\gamma_{ij}, \qquad \Gamma^i_{0j} = \frac{\dot{a}}{a}\delta^i_j, \qquad \Gamma^i_{jk} = \frac{1}{2}\gamma^{il}\left(\partial_j\gamma_{kl} + \partial_k\gamma_{jl} - \partial_l\gamma_{jk}\right) \quad \textit{(realt.)}$$

$$R_{00} = -3\frac{\ddot{a}}{a}, \qquad R_{ij} = -\left[\frac{\ddot{a}}{a} + 2\left(\frac{\dot{a}}{a}\right)^2 + 2\frac{k}{a^2}\right]g_{ij}. \qquad R = -6\left[\frac{\ddot{a}}{a} + \left(\frac{\dot{a}}{a}\right)^2 + \frac{k}{a^2}\right]. \quad \textit{(realt.)}$$

Symmetry

$$a \to \lambda a, \quad r \to r/\lambda, \quad k \to \lambda^2 k.$$

Friedmann equations

Считаем, что у нас есть во Вселенной некотрые ρ and P за счет составляющих Вселенную, и просто за счет них и происходит динамика метрики Фридмана по уравнениям Эйнштейна

$G_{\mu\nu} = 8\pi G T_{\mu\nu}$.

$$\left(\frac{\dot a}{a}\right)^2 = \frac{8\pi G}{3}\rho - \frac{k}{a^2}, \qquad \frac{\ddot a}{a} = -\frac{4\pi G}{3}(\rho + 3P). \qquad \text{(real time, } c=1, \Lambda{=}0) \qquad \left[\frac{1}{\text{time}^2}\right]$$

$$(a')^2 + ka^2 = \frac{8\pi G}{3}\rho a^4, \qquad a'' + ka = \frac{4\pi G}{3}(\rho - 3p)a^3. \qquad \text{(conf. time)} \qquad \left(\tfrac{\dot a}{a}\right)^2 = \tfrac{1}{a^2}\left(\tfrac{da}{d\eta}\tfrac{d\eta}{dt}\right)^2 = \tfrac{(a')^2}{a^4}$$

$$\frac{\dot a^2 + kc^2}{a^2} = \frac{8\pi G\rho + \Lambda c^2}{3}, \qquad \frac{\ddot a}{a} = -\frac{4\pi G}{3}\left(\rho + \frac{3p}{c^2}\right) + \frac{\Lambda c^2}{3} \qquad \text{(realt time, } c\neq 1, \Lambda \neq 1)$$

$$H^2 = \frac{8\pi G}{3}\rho - \frac{k}{a^2}. \qquad \text{(real time, by } H := \dot a/a)$$

$$H^2 = \frac{\rho}{3M_{\rm pl}^2} \qquad \text{(real time, flat space)}$$

$$H^2(a) = H_0^2\left[\Omega_{r,0}\left(\frac{a_0}{a}\right)^4 + \Omega_{m,0}\left(\frac{a_0}{a}\right)^3 + \Omega_{k,0}\left(\frac{a_0}{a}\right)^2 + \Omega_{\Lambda,0}\right],$$

$$\frac{H^2}{H_0^2} = \Omega_r a^{-4} + \Omega_m a^{-3} + \Omega_k a^{-2} + \Omega_\Lambda.$$

$$\Omega_{I,0} := \frac{\rho_{I,0}}{\rho_{\text{crit},0}} \qquad \Omega_{k,0} := -\frac{k}{(a_0 H_0)^2} \qquad \Omega_\Lambda = \frac{\rho_\Lambda}{\rho_{\rm crit}}, \quad \rho_{\rm crit} = \frac{3c^2H_0^2}{8\pi G}, \quad \rho_\Lambda = \frac{c^2\Lambda}{8\pi G},$$

(??? выведу еще раз!) Два уравнения Фридмана зависимые: второе получается из первого, однако уравнение второго порядка требует больше начальных условий, так что если решили 1-е, то следует проверить, выполняется ли 2-е (?? встречу в задаче - напишу точнее.)

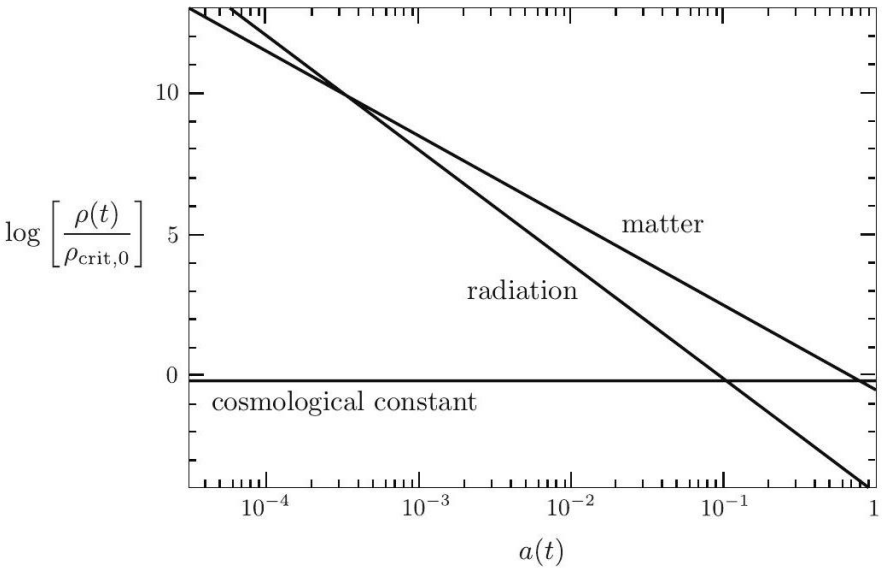
$$\rho_{\text{crit},0} := \frac{3H_0^2}{8\pi G} = 1.9\cdot 10^{-29} h^2 \frac{\text{gr}}{\text{cm}^3} = 2.8\cdot 10^{11} h^2 M_\odot \text{Mpc}^{-3} = 1.1\cdot 10^{-5} h^2 \frac{\text{protons}}{\text{cm}^3}.$$

$$\frac{\rho_0}{\rho_\Lambda} = \frac{\Omega_m}{\Omega_\Lambda} = \frac{\Omega_m}{1-\Omega_m}, \qquad \Omega_\Lambda = \frac{c^2\Lambda}{8\pi G}\frac{8\pi G}{3c^2H_0^2} = \frac{\Lambda}{3H_0^2}, \qquad \sqrt{3\Lambda} = 3H_0\sqrt{\Omega_\Lambda} = 3H_0\sqrt{1-\Omega_m},$$

(?!!! додумаю смысл новых определений!!) we will have

$$|\Omega_k| \le 0.01, \quad \Omega_r = 9.4\cdot 10^{-5}, \quad \Omega_m = 0.32, \quad \Omega_\Lambda = 0.68$$

Идея в том, что константой можно положить параметр в один момент времени в процессе их изменения. (?? где-то в диффурах проверю такой ход, прямо вот такого не встречал там (???))



Качественно: в момент начала Вселенной было много излучения, потом оно собралось в материю, а сейчас Вселенная так расширилась, что вакуума стало более всего. График именно такой из-за логарифмического масштаба. (???? там вроде как-то темная материя из ничего получается еще, а не через свет, но это допишу потом)

(абзац про то, могла ли Вселенная после расширения начать сужаться?)

(абзац про то, могла ли Вселенная иметь два больших взрыва?)

Continuity equation and its implementation to Friedmann equation*

$$\dot{\rho} + 3\frac{\dot{a}}{a}(\rho + P) = 0.$$

Оно получается из $\nabla_\mu T^\mu_\nu = 0$, взяв компоненту $\nu = 0$, putting $T^i{}_0 = 0$ from isotropy, а $\Gamma_{\text{frw}} = \frac{\dot{a}}{a}$ (? еще раз выведу?). Именно через него и входит давление в космологические модели.

Если в ур. Фридмана $H^2 = \rho/(3M_{pl}^2)$ после разных его модификаций вставить ур. непрерывности, то можно получить тождества:

$$\dot{H} = -\frac{\rho_\phi + P_\phi}{2M_{\text{pl}}^2} \qquad \text{(real time, take der of 1 Fr. eq.)}$$

$$\dot{H} + H^2 = -\frac{1}{6M_{\text{pl}}^2}(\rho + 3P) = -\frac{H^2}{2}\left(1 + \frac{3P}{\rho}\right). \qquad \text{(real time, put expr-s to the lhs.)}$$

(про приложения мб укажу)

Conformal time

$$\eta = -\frac{1}{H}e^{-Ht},$$

$$\eta := \int dt/a = \int \frac{da}{a}\frac{1}{H}\frac{a_0}{a}.$$

$$t = \int a d\eta.$$

We just need a preparation for formulas in conf. time:
$\frac{d}{dt} = \frac{d\eta}{dt}\frac{d}{d\eta} = \frac{1}{a}\frac{d}{d\eta}$
prime - the derivative w.r.t. conf. time η.

$$\ddot{a} = \frac{d}{dt}\frac{da}{dt} = \frac{d}{dt}\frac{da}{d\eta}\frac{d\eta}{dt} = \frac{d}{dt}\frac{a'}{a} = \frac{d\eta}{dt}\frac{d}{d\eta}\left(\frac{a'}{a}\right) = \frac{1}{a}\left(-\frac{a'^2}{a^2} + \frac{a''}{a}\right) = -\frac{a'^2}{a^3} + \frac{a''}{a^2}.$$

(?????????) Note that in these $c = 1$ units, the conformal time doubles as the comoving size of the horizon. In an open universe, it is also related to the development angle by

$$\chi = \sqrt{-K}\eta$$

Asymptotic relations are often useful for converting values. Before curvature or Λ domination, the conformal time

$$\eta = \frac{2\sqrt{2}}{k_{eq}}\left(\sqrt{1 + a/a_{eq}} - 1\right) = 2\left(\Omega_0 H_0^2\right)^{-1/2}(a_{eq}/a_0)^{1/2}\left(\sqrt{1 + a/a_{eq}} - 1\right)$$

It also takes on simple asymptotic forms, e.g.

$$t = \frac{2}{3}\left(\Omega_0 H_0^2\right)^{-1/2} a_0^{-3/2}\left[(a + a_{eq})^{1/2}(a - 2a_{eq}) + 2a_{eq}^{3/2}\right]. \quad \text{RD/MD}$$

(!!! абзац про то, почему оно такое удобное. Что оно бежит от 0 до времени Вселенной, т.п. много дописать хорошего можно!)

Величины констант и параметров в FRW

The expansion rate is given by the Hubble parameter

$$H^2 \equiv \left(\frac{1}{a}\frac{da}{dt}\right)^2 = \left(\frac{\dot{a}}{a}\frac{a_0}{a}\right)^2 = \left(\frac{a_0}{a}\right)^4 \frac{a_{eq}+a}{a_{eq}+a_0}\Omega_0 H_0^2 - \left(\frac{a_0}{a}\right)^2 K + \Omega_\Lambda H_0^2,$$

where the curvature is $K = -H_0^2\left(1-\Omega_0-\Omega_\Lambda\right)$.

$H_0 = 100h\mathrm{kms}^{-1}\mathrm{Mpc}^{-1} = 2.13\times10^{-42}h\mathrm{GeV} = (2997.9)^{-1}h\mathrm{Mpc}^{-1} = (3.08\times10^{17})^{-1}\,h\ \mathrm{s}^{-1} = (9.77)^{-1}h\mathrm{Gyr}^{-1}.$

Present day densities in a given particle species X are measured in units of the critical density $\rho_X\left(a_0\right) = \Omega_X\rho_{\mathrm{crit}}$, where

$\rho_{\mathrm{crit}} = \frac{3H_0^2}{8\pi G} = 1.87\cdot10^{-29}h^2\ \mathrm{g\ cm}^{-3} = 8.09\cdot10^{-47}h^2\mathrm{GeV}^4 = 1.05\cdot10^4h^2\mathrm{eVcm}^{-3} = 1.12\cdot10^{-5}h^2\ \mathrm{protons\ cm}^{-3} = 2.77\cdot10^{11}h^2\mathrm{M}_\odot\mathrm{Mpc}^{-3}.$

For the CMB,

$$n_{\gamma0} = 399.3\Theta_{2.7}^3\ \mathrm{cm}^{-3},$$
$$\rho_{\gamma0} = 4.4738\times10^{-34}\Theta_{2.7}^4\ \mathrm{g\ cm}^{-3}$$
$$\Omega_\gamma = 2.3812\times10^{-5}h^{-2}\Theta_{2.7}^4$$

and for the neutrinos

$$\rho_{\nu0} = \left[\left(1-f_\nu\right)^{-1}-1\right]\rho_{\gamma0},$$
$$\Omega_\nu = \left[\left(1-f_\nu\right)^{-1}-1\right]\Omega_\gamma,$$

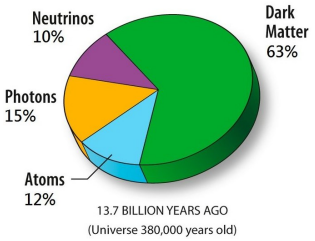
with $\left(1-f_\nu\right)^{-1} = 1.68$ for the standard model, or for the total radiation

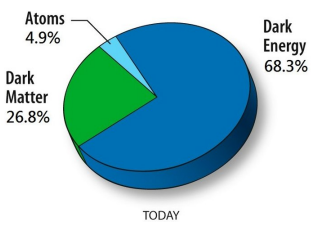
$$\rho_{r0} = \left(1-f_\nu\right)^{-1}\rho_{\gamma0}$$
$$\Omega_r = \left(1-f_\nu\right)^{-1}\Omega_\gamma.$$

Основные свойства компонентов Вселенной (???)

In FRW with flat single-component universe:

	$w := P/\rho$	$\rho(a)\sim a^{-3(1+w)}$	$a(t)$	$a(\tau)$
RD	$\frac{1}{3}$	a^{-4}	$t^{1/2}$	τ
MD	0	a^{-3}	$t^{2/3}$	τ^2
ΛD	-1	a^0	e^{Ht}	$-\tau^{-1}$





(?? тут очень коротко, почему так? вдали обоснование! что на СМБ смотрим - не информативно, нужно более содержательно.)

Matter (including dark matter)

$$|P| \ll \rho.$$

From $\dot{\rho} + 3\frac{\dot{a}}{a}(\rho + P) = 0$

$$\rho \propto a^{-3}$$

Most of the matter in the universe is in the form of invisible dark matter. This is usually thought to be a new heavy particle species, but what it really is, we don't know.

Baryons

(Абзац Что такое темная материя? все равно не место про это рассуждать много, где-то дальше отдельно пр оэто будет)

(важные указания, пусть даже на 1 страницу, но к этому пониманию все и сводится!)

Radiation

Излучение - это фотоны, нейтрино, гравитоны. Нейтрино почти всегда были с почти скоростью света.

$$P = \frac{\rho}{3}$$

$$\rho \propto a^{-4} \qquad \text{or} \qquad E \propto a^{-1}$$

(??? короткий абзац, как доказать формулы? статфиз короткий нужен.) (-4)-я степень ожидаема, потому что (-3) - расширение Вселенной, и еще есть изменеие энергии от изменения длины волны (?? да??)

Dark energy (Λ)

$$P = -\rho$$

$$\rho \propto a^{0}$$

Vacuum energy.

(очень важный абзац Что такое темная энергия?!!!!!! многое напишу как будет время!!!!)

(важные указания, пусть даже на 1 страницу, но к этому пониманию все и сводится!)

О моделях с компонентами Вселенной

Методы анализа вселенной с разными компонентами (!!??!!)

Часто можно ввести a_{eq} в момент совпадения компонент, и через него выражать остальное.

Иногда можно переписать уравнение через конформное время.

(общие важные указания про такие задачи, важный параграф)

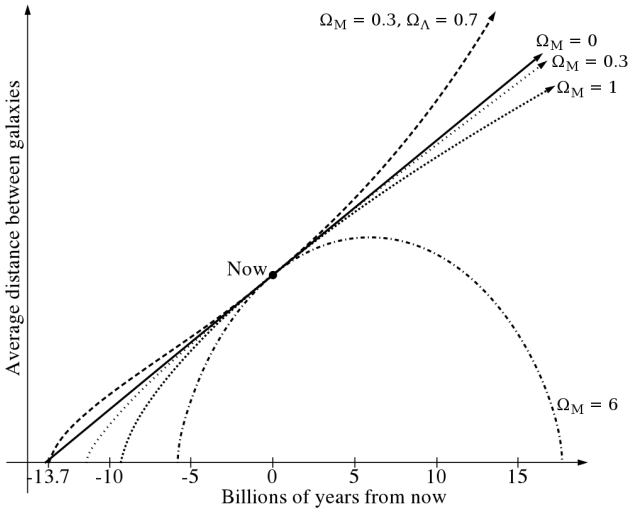
О Вселенной Фридмана с доминацией одной из компонент (???)

$$\frac{\dot{a}}{a} = H_0\sqrt{\Omega_I}a^{-\frac{3}{2}(1+w_I)}.$$

so

$$\text{real t.:}\quad a(t) \propto \begin{cases} t^{2/3(1+w_I)} & w_I \neq -1 & t^{2/3} & \text{MD} \\ & & t^{1/2} & \text{RD} \\ e^{Ht} & w_I = -1 & & \Lambda\text{D} \end{cases}, \quad \text{conf t.:}\quad a(\tau) \propto \begin{cases} \tau^{2/(1+3w_I)} & w_I \neq -1 & \tau^2 & \text{MD} \\ & & \tau & \text{RD} \\ (-\tau)^{-1} & w_I = -1 & & \Lambda\text{D} \end{cases}$$

(потом допишу, тут есть опыт изучения этого уже.)



О Вселенной Фридмана с доминацией двух компонент (???)

(порешаю потом, там разные можно модели придумать.)

$$(a')^2 = \frac{8\pi G}{3}\rho a^4 \qquad a'' = \frac{4\pi G}{3}(\rho - 3P)a^3 \qquad \text{(conf time!)}$$

$$\rho := \rho_m + \rho_r \equiv \frac{\rho_{\rm eq}}{2}\left[\left(\frac{a_{\rm eq}}{a}\right)^3 + \left(\frac{a_{\rm eq}}{a}\right)^4\right].$$

$$C = \left(\frac{4\pi G}{3}\rho_{\rm eq} a_{\rm eq}^4\right)^{1/2}$$

$$a(\tau) = a_{\rm eq}\left[\left(\frac{\tau}{\tau_\star}\right)^2 + 2\left(\frac{\tau}{\tau_\star}\right)\right]$$

$$\tau_\star := \left(\frac{\pi G}{3}\rho_{\rm eq} a_{\rm eq}^2\right)^{-1/2} = \frac{\tau_{\rm eq}}{\sqrt{2}-1}.$$

Другие свойства и уравнения

Perfect fluid

$$T_{\mu\nu} = (\rho + P)U_\mu U_\nu - P g_{\mu\nu},$$

where ρ and P are the energy density and the pressure of the fluid and U^μ is its four-velocity (relative to the observer).

Number Density:

$$\frac{\dot n}{n} = -3\frac{\dot a}{a} \Rightarrow n(t) \propto a^{-3}.$$

because of (????)

$$N^0 = n(t), \quad N^i = 0$$

$$\nabla_\mu N^\mu = \partial_\mu N^\mu + \Gamma^\mu_{\mu\lambda} N^\lambda = 0$$

$$\frac{dn}{dt} + \Gamma^i_{i0} n = 0$$

$$T^\mu{}_\nu = g^{\mu\lambda}T_{\lambda\nu} = \mathrm{diag}\Big[\rho, -P, -P, -P\Big] = (\rho + P)U^\mu U_\nu - P\delta^\mu_\nu,$$

Geodesics in FRW and a change of a momenta and energy of a particle in it

$$\frac{dU^\mu}{ds} + \Gamma^\mu_{\alpha\beta} U^\alpha U^\beta = 0, \qquad \Gamma^\mu_{\alpha\beta} := \frac{g^{\mu\lambda}}{2}\left(\partial_\alpha g_{\beta\lambda} + \partial_\beta g_{\alpha\lambda} - \partial_\lambda g_{\alpha\beta}\right)$$

$$U^\alpha \left(\frac{\partial U^\mu}{\partial X^\alpha} + \Gamma^\mu_{\alpha\beta} U^\beta\right) = 0. \qquad \frac{d}{ds} U^\mu\left(X^\alpha(s)\right) = \frac{dX^\alpha}{ds}\frac{\partial U^\mu}{\partial X^\alpha} = U^\alpha \frac{\partial U^\mu}{\partial X^\alpha}$$

$$P^\alpha \frac{\partial P^\mu}{\partial X^\alpha} = -\Gamma^\mu_{\alpha\beta} P^\alpha P^\beta. \qquad P^\mu := mU^\mu$$

$$\frac{\dot{p}}{p} = -\frac{\dot{a}}{a} \quad \Rightarrow \quad p \propto \frac{1}{a}.$$

$$p = E \propto \frac{1}{a} \quad \text{(massless particles)} \ ,$$

$$p = \frac{mv}{\sqrt{1-v^2}} \propto \frac{1}{a} \quad \text{(massive particles)}$$

The homogeneity of the FRW background implies $\partial_i P^\mu = 0$, so

$$P^0 \frac{dP^\mu}{dt} = -\Gamma^\mu_{\alpha\beta} P^\alpha P^\beta, = -\left(2\Gamma^\mu_{0j} P^0 + \Gamma^\mu_{ij} P^i\right) P^j,$$

so

$$P^j = 0 \Rightarrow \frac{dP^i}{dt} = 0.$$

for $\mu = 0$ because of $\Gamma^0_{0j} = 0$, we have $E\frac{dE}{dt} = -\Gamma^0_{ij} P^i P^j = -\frac{\dot{a}}{a} p^2$, we have that obvious properties.

SUMMARY Smooth Expanding universe

Comoving distance between us and a source at redshift z:

$$\chi(z) = \int_0^z \frac{dz'}{H\left(z'\right)}.$$

How much light could have traveled since $t = 0$, it is conformal time:

$$\eta = \int_0^t \frac{dt'}{a\left(t'\right)} = \int_z^\infty \frac{dz'}{H\left(z'\right)}.$$

Photons in the universe have a Bose-Einstein distribution with zero chemical potential, so their energy density can be determined by measuring their temperature. Neutrinos have a Fermi-Dirac distribution, also probably with zero chemical potential, but there is some ambiguity in their energy density because of our ignorance of the neutrino masses. Early on, this ambiguity is irrelevant since the temperatures are so much larger than the masses and neutrinos behave relativistically. Thus, the uncertainty in neutrino mass does not affect Big Bang nucleosynthesis at temperatures of order 1MeV and probably not even the epoch of matter radiation equality at temperatures of order 1eV. The neutrino temperature is a factor of $(4/11)^{1/3}$ smaller than the photon temperature. This, and the difference in statistics, implies that a species of massless neutrinos has an energy density equal to 0.23 times that of photons. A single neutrino generation with mass m_ν contributes $\Omega_\nu = 0.01\left(m_\nu/0.94\text{eVh}^2\right)$. In addition to photons and neutrinos, the universe consists of baryons, best determined by nucleosynthesis to have $\Omega_b h^2 = 0.0205 \pm 0.0018$; dark matter ($\Omega_m \simeq 0.3$); and dark energy (with $\Omega_{\text{de}} \simeq 0.7$), a new form of energy with negative pressure.

$$a_{\text{eq mt-rad}} = 4.15 \cdot 10^{-5}/\Omega_m h^2.$$

1.2.2 On distances, expansion, Hubble's law, Hubble Sphere, horizons, redshift

Metrics, distances, times

$x^i := \{x^1, x^2, x^3\}$ - comoving coordinates
$x^i_{\text{phys}} = a(t)x^i$ - physical coordinates

$$v^i_{\text{phys}} := \frac{dx^i_{\text{phys}}}{dt} = a(t)\frac{dx^i}{dt} + \frac{da}{dt}x^i := v^i_{\text{pec}} + Hx^i_{\text{phys}} \qquad \text{(physical velocity)}$$
$$v^i_{\text{pec}} := a(t)\dot{x}^i \qquad \text{(peculiar velocity)}$$

$$H := \frac{\dot{a}}{a}$$

О метриках в космологии

Negatively (-) and positively (+) curved space:

$$\mathrm{d}\ell^2 = a^2\left[\ \mathrm{d}\boldsymbol{x}^2 + k\frac{(\boldsymbol{x}\cdot\mathrm{d}\boldsymbol{x})^2}{1-k\boldsymbol{x}^2}\right] := a^2\gamma_{ij}\ \mathrm{d}x^i\ \mathrm{d}x^j$$

$$\gamma_{ij} := \delta_{ij} + k\frac{x_i x_j}{1 - k\cdot x_k x^k}, \qquad k := \begin{cases} 0 & \text{Euclidean} \\ +1 & \text{spherical} \\ -1 & \text{hyperbolic} \end{cases}$$

this is from $\mathrm{d}\ell^2 = a^2\left[\ \mathrm{d}\boldsymbol{x}^2 \pm \mathrm{d}u^2\right], \quad \boldsymbol{x}^2 \pm u^2 = \pm 1.$
Or in polar coordinates:

$$\mathrm{d}\boldsymbol{x}^2 = \mathrm{d}r^2 + r^2\left(\ \mathrm{d}\theta^2 + \sin^2\theta\mathrm{d}\phi^2\right),$$

$$\mathrm{d}\ell^2 = a^2\left[\frac{\mathrm{d}r^2}{1-kr^2} + r^2\ \mathrm{d}\Omega^2\right],$$

where $\mathrm{d}\Omega^2 := \mathrm{d}\theta^2 + \sin^2\theta\mathrm{d}\phi^2$.
Or by χ, which simplifies radial part

$$\mathrm{d}\chi := \mathrm{d}r/\sqrt{1-kr^2}$$

$$\mathrm{d}\ell^2 = a^2\left[\ \mathrm{d}\chi^2 + S_k^2(\chi)\mathrm{d}\Omega^2\right], \qquad S_k(\chi) := \begin{cases} \mathrm{sh}\,\chi & k=-1 \\ \chi & k=0 \\ \sin\chi & k=+1 \end{cases}.$$

Metric, luminosity, angular diameter distances

(потом додумаю, не самые важные понятия)
On metric distance $d_m = S_k(\chi)$

$$\mathrm{d}s^2 = \mathrm{d}t^2 - a^2(t)\left[\mathrm{d}\chi^2 + S_k^2(\chi)\mathrm{d}\Omega^2\right],$$
$$S_k(\chi) := \begin{cases} R_0\,\mathrm{sh}\,(\chi/R_0) & k=-1 \\ \chi & k=0 \\ R_0\sin(\chi/R_0) & k=+1 \end{cases}.$$

$$\chi(z) = \int_{t_1}^{t_0}\frac{\mathrm{d}t}{a(t)} = \int_0^z\frac{\mathrm{d}z}{H(z)}$$

On luminosity distance d_L (??????)

$$d_L = d_m(1+z)$$

$$F = \frac{L}{4\pi\chi^2}.$$

$$F = \frac{L}{4\pi d_m^2(1+z)^2} := \frac{L}{4\pi d_L^2},$$

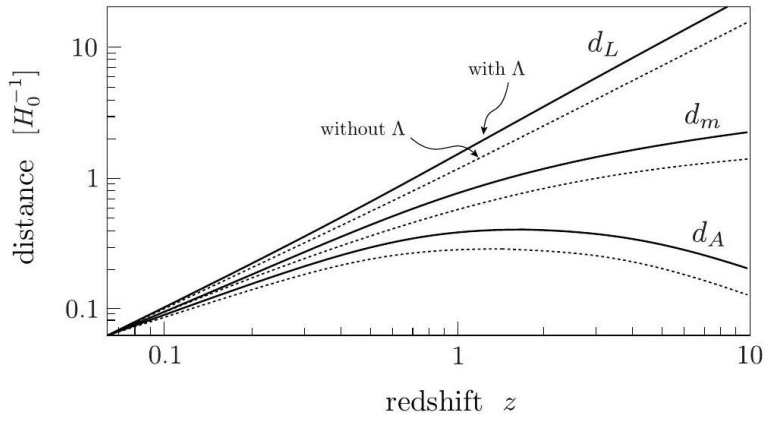
On angular diameter distance

$$d_A = \frac{D}{\delta\theta} = \frac{d_L}{(1+z)^2}$$

$$d_A = \frac{d_m}{1+z}.$$

because $D = a\,(t_1)\,S_k(\chi)\delta\theta = \frac{d_m}{1+z}\delta\theta$

(вставлю мб картинку потом)



(??? этот график я не понимаю, ну и не актуально пока что)

Смысл и общие свойства времен в космологии

Время - проще говоря это просто параметр, который увеличивается. Можно считать, что настоящее время конформное, а то, к которому при привыкли - лишь его приближение. Так или иначе в этих моделях, это просто возрастающий параметр.

(наверняка, что-то потом допишу поглубже)

Standard Candle

- Standard Candle: objects of same luminosity L, measured flux F
- Apply rules again: at emission in conformal-comoving coordinates
- L is the energy per unit time at emission
- Since $E \propto \lambda^{-1}$ and comoving wavelength $\Lambda \propto \lambda/a$ so comoving energy $\mathcal{E} \propto \Lambda^{-1} \propto aE$
- Per unit time at emission $\Delta t = a\Delta\eta$ in conformal time
- So observed luminosity today is $\mathcal{L} = \mathcal{E}/\Delta\eta = a^2 L$
- All photons must pass through the sphere at a given distance, so the comoving surface area is $4\pi D_A^2$
- Put this together to the observed flux at $a = 1$

$$F = \frac{\mathcal{L}}{4\pi D_A^2} = \frac{L}{4\pi D_A^2}\frac{1}{(1+z)^2}$$

Notice the flux is diminished by two powers of $(1+z)$

Standard Ruler

- Standard Ruler: object of known physical size λ
- Let's apply our rule of thumb: at emission the comoving size is Λ:

$$\lambda = a(t)\Lambda$$

Now everything about light is normal: the object of comoving size Λ subtends an observed angle α on the sky α

$$\alpha = \frac{\Lambda}{D_A(z)}$$

- This is the easiest way of thinking about it. But we could also define an effective physical distance $d_A(z)$ which corresponds to what we would infer in a non expanding spacetime

$$\alpha \equiv \frac{\lambda}{d_A(z)} = \frac{a\Lambda}{d_A(z)} = \frac{\Lambda}{D_A(z)} \rightarrow d_A(z) = aD_A(z) = \frac{D_A(z)}{1+z}$$

- Since $D_A \rightarrow D_A\left(D_{\text{horizon}}\right)$ whereas $(1+z)$ unbounded, angular size of a fixed physical scale at high redshift actually increases with radial distance
- Paradox: the further away something is, the bigger it appears - Easily resolved by thinking about comoving coordinates - a fixed physical scale λ as the universe shrinks and $a \rightarrow 0$ will eventually encompass the whole observable universe out to the horizon in comoving coordinates so of course it subtends a big angle on the sky!
- But there are no such bound objects in the early universe there is no causal way such bigger-than-the-horizon objects could form
- Knowing λ or Λ and measuring α and z allows us to infer the comoving angular diameter distance $D_A(z)$

Изотропное пространство

У пространства с положительной кривизной

$$V = \int_0^{2\pi}\int_0^{\pi}\int_0^{\pi} a^3 \sin^2\chi \sin\theta d\chi d\theta d\varphi = 2\pi^2 a^3.$$

Таким образом, пространство положительной кривизны оказывается «замкнутым само в себе» - конечным по объему, но, разумеется, не имеющим границ.
(допишу пл ЛЛ2, интересные соображения)

Закрытая изотропная модель

(допишу пл ЛЛ2, интересные соображения)

Открытая изотропная модель

(допишу пл ЛЛ2, интересные соображения)
(пока идея просто подробно указать эти основные причины таких моделей космологии)

Redshift z, Hubble's law $z \simeq H_0 d$ (!??!)

Красное смещение - увеличение длины волны (уменьшение энерги) для движущегося наблюдателя.

$$\lambda_0 = \frac{a\left(t_0\right)}{a\left(t_1\right)}\lambda_1.$$

Since $a\left(t_0\right) > a\left(t_1\right)$, $\lambda_0 > \lambda_1$.

For classical waves

$$\Delta t_1 = a(\tau_1)\,\Delta\tau \quad \text{and} \quad \Delta t_0 = a(\tau_0)\,\Delta\tau$$

If Δt is the period of the light wave, the light is emitted with wavelength $\lambda_1 = \Delta t_1$ (in units where $c = 1$), but is observed with wavelength $\lambda_0 = \Delta t_0$, so that

$$\frac{\lambda_0}{\lambda_1} = \frac{a(\tau_0)}{a(\tau_1)}$$

$$z := \frac{\lambda_0 - \lambda_1}{\lambda_1} \qquad \text{(Redshift parameter)}$$

λ_0 - wavelenght today, λ_1 - wavelenght at some t_1,

$$1 + z = \frac{1}{a(t_1)}.$$

$$a(t_1) = a(t_0)\left[1 + (t_1 - t_0)\,H_0 + \cdots\right] \qquad H_0 := \frac{\dot{a}(t_0)}{a(t_0)}.$$

parameter h is defined such that

$$H_0 := 100h\mathrm{kms}^{-1}\mathrm{Mpc}^{-1},$$

it is used to keep track of how uncertainties in H_0 propagate into other cosmological parameters.

$$h \approx 0.67 \pm 0.01.$$

Наиболее надёжная оценка постоянной Хаббла на 2013 год составляла

$$H_0 = 67,80 \pm 0,77(\text{км/с})/\text{Мпк}.$$

$$1\text{ пк} = \frac{1}{\operatorname{tg} 1''}\text{ a.e.} \approx \frac{360\cdot 60\cdot 60}{2\pi}\text{ a.e.} \approx 206264,8\text{ a.e.} = 3,08\cdot 10^{16}\text{ м}$$
$$= 30,85\text{ трлн км (петаметров)} = 3,26\text{ св. года.}$$

$$h := H_0/\left(100\text{ km s}^{-1}\mathrm{Mpc}^{-1}\right)$$

$$t_H \equiv \frac{1}{H_0} = \frac{1}{67.8(\text{ km/s})/\text{Mpc}} = 4.55\times 10^{17}\text{ s} = 14.4\text{ billion years (Hubble time).}$$

Вообще, разные есть результаты измерений, так что это отдельное обсуждение - есть ли вообще такой параметр?

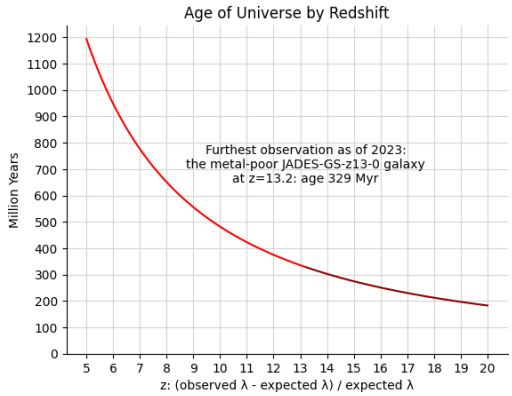
(??? короче говоря, даже тут какие-то проблемы, что разные измерения дают разные значения, так что все это может быть просто неверным. додумаю потом.)

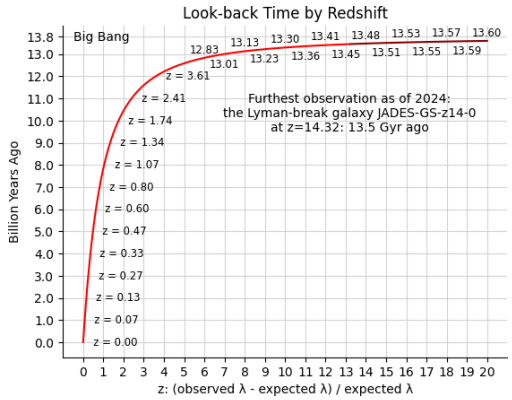
he largest-observed redshift, corresponding to the greatest distance and furthest back in time, is that of the cosmic microwave background radiation; the numerical value of its redshift is about $z = 1089$ ($z = 0$ corresponds to present time), and it shows the state of the universe about 13.7 billion years ago, and 379,000 years after the initial moments of the Big Bang.

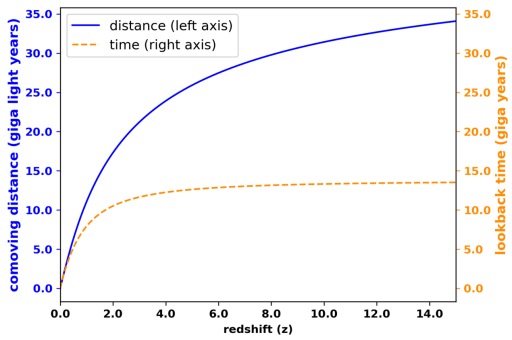
(!?!?!!? абзац, как вообще интерпретируем кр смещ??? почему именно так, почему не через другие модели, через непостоянную скорость света нпр. в теории много про это обсуждения.)

Observations of redshift

(see wiki)







О другом про и других способах объяснения красного смещения z и закона Хабла $z \simeq H_0 d$ (!??!)

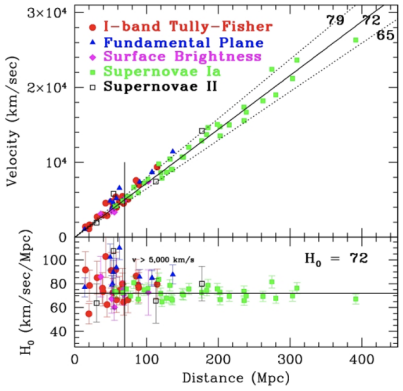
(!!! важный абзац про теорию Дикке, который объяснил с помощью задержки гравитационного замедления света. такое вообще может быть???? у меня в плане оптики неуверенность.)

Redshift surveys

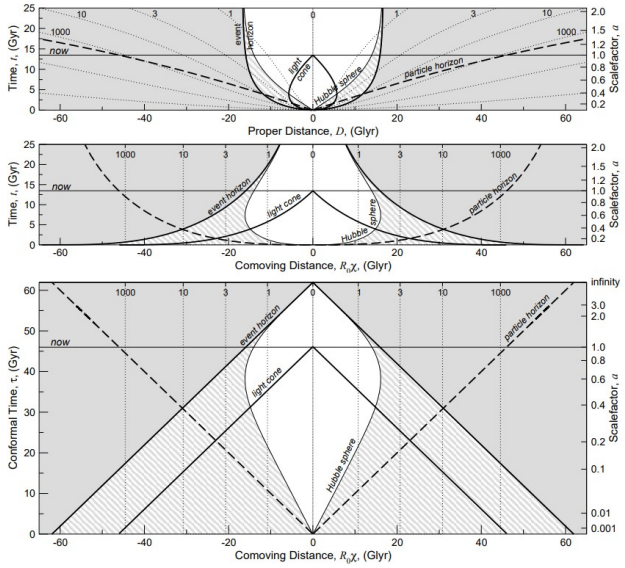
(см лекции Калтеха Physics 217bc: The Standard Model - Cosmology, потом допишу, пока не до этого)

Main about Hubble sphere and horizons (????)

$$\frac{d}{dt}(aH)^{-1} < 0.$$



Light and Horizons



Горизонт частиц - максимальное расстояние, с которого было влияние на настоящий момент пространства-времени. Горизонт событий - максимальное расстояние объектов, на которые мы могли бы повлиять. Если бы не было расширения, то это было бы бесконечностью, а так - там интеграл сходится

(?? я пока остановился на том, что вообще разные есть определения, потому что в статье про это как будто наоборот они. когда-то еще подумаю про это)

The comoving horizon is finite,

$$\chi_{\rm ph}(t) = \frac{2H_0^{-1}}{(1+3w)} a(t)^{\frac{1}{2}(1+3w)} = \frac{2}{(1+3w)}(aH)^{-1}.$$

$$\chi_{\rm eh}(\tau) = \tau_f - \tau = \int_t^{t_f} \frac{{\rm d}t}{a(t)}.$$

Particle horizon.-Eq. (2.1.2) tells us that the maximal comoving distance that light can travel between two times τ_1 and $\tau_2 > \tau_1$ is simply $\Delta\tau = \tau_2 - \tau_1$ (recall that $c := 1$). Hence, if the Big Bang 'started' with the singularity at $t_i := 0$, [2] then the greatest comoving distance

from which an observer at time t will be able to receive signals travelling at the speed of light is given by

$$\chi_{\rm ph}(\tau) = \tau - \tau_i = \int_{t_i}^{t} \frac{{\rm d}t}{a(t)}$$

- Event horizon.-Just as there are past events that we cannot see now, there may be future events that we will never be able to see (and distant regions that we will never be able to influence). In comoving coordinates, the greatest distance from which an observer at time t_f will receive signals emitted at any time later than t is given by

$$\chi_{\rm eh}(\tau) = \tau_f - \tau = \int_{t}^{t_f} \frac{{\rm d}t}{a(t)}$$

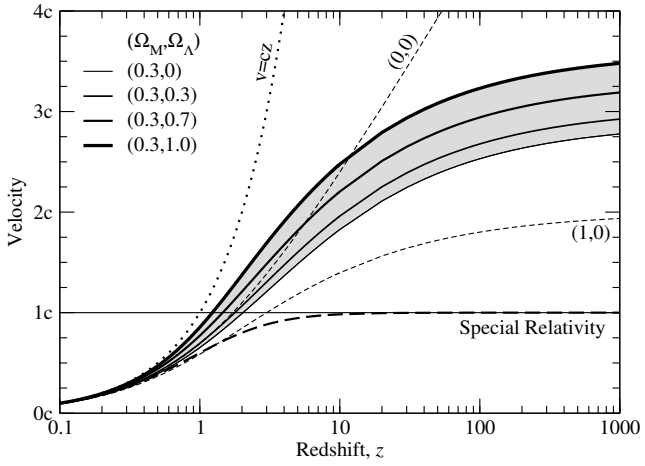
Growing Hubble Sphere

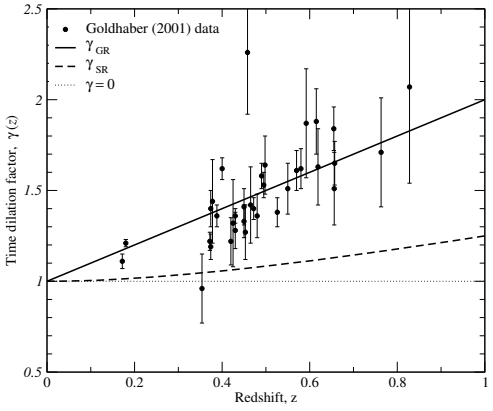
comoving Hubble radius $(aH)^{-1}$.
(????????????????? откуда это??????)

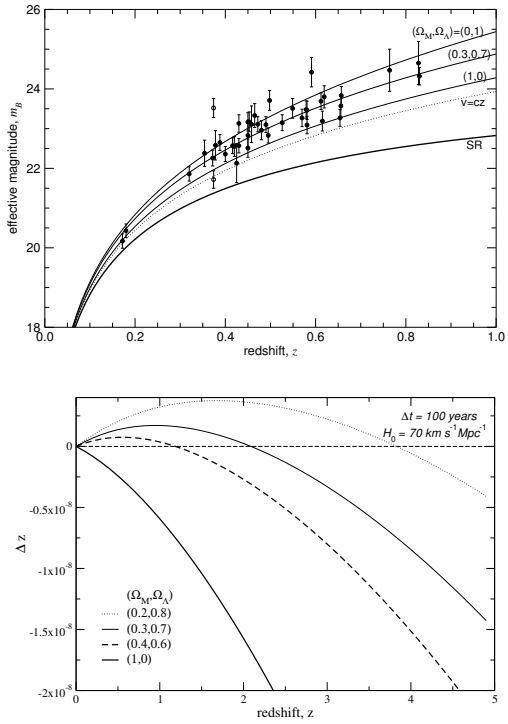
$$(aH)^{-1} = H_0^{-1} a^{\frac{1}{2}(1+3w)}$$

$$\chi_{\rm ph}(a) = \frac{2H_0^{-1}}{(1+3w)} \left[a^{\frac{1}{2}(1+3w)} - a_i^{\frac{1}{2}(1+3w)} \right] := \tau - \tau_i$$

$$\chi_{\rm ph}(\tau) = \int_{t_i}^{t} \frac{{\rm d}t}{a} = \int_{a_i}^{a} \frac{{\rm d}a}{a\dot{a}} = \int_{\ln a_i}^{\ln a} (aH)^{-1} \, {\rm d}\ln a$$







Why is the CMB so uniform?

(??????????????????)
If there wasn't enough time for these regions to communicate, why do they look so similar? This is the horizon problem

Inflation - Solution of the Horizon Problem

$$\tau_i = \frac{2H_0^{-1}}{(1+3w)} a_i^{\frac{1}{2}(1+3w)} \overset{a_i \to 0, w < -\frac{1}{3}}{\longrightarrow} -\infty$$

Hubble Radius vs. Particle Horizon

1.2.3 Homogeneous inflation in a nutshell

Essene and main formulas of inflation

Both the horizon problem and the flatness problem can be traced back to the fact that during the standard Big Bang evolution the comoving Hubble radius, $(aH)^{-1}$, grows monotonically with time. During inflation on the other hand the comoving Hubble radius is temporarily decreasing.

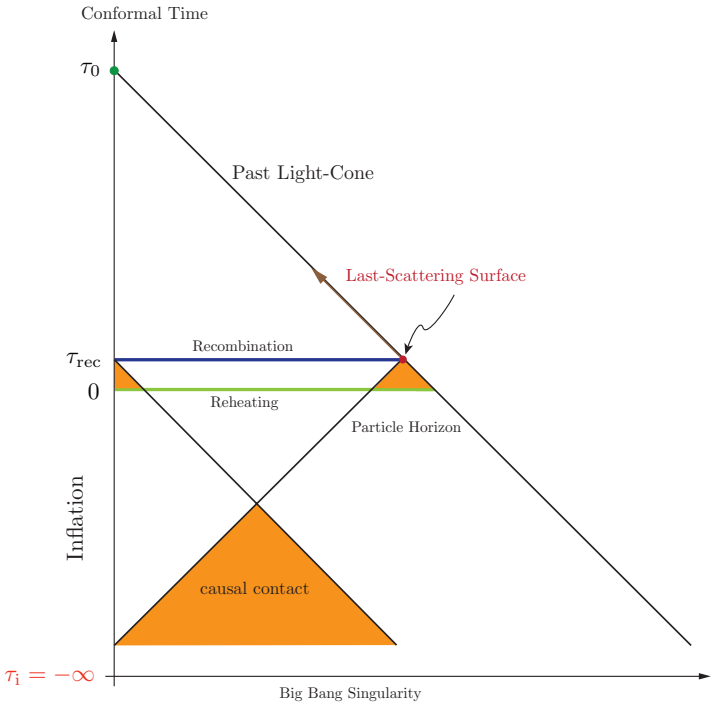


Figure 1: Conformal diagram of inflationary cosmology. Inflation extends conformal time to negative values! The end of inflation creates an "apparent" Big Bang at $\tau = 0$. There is, however, no singularity at $\tau = 0$ and the light cones intersect at an earlier time if inflation lasts for at least 60 e-folds.

This changes the causal structure of the early universe making the horizon problem a fiction of extrapolating the conventional FRW expansion back to arbitrarily early times. From the Einstein Equations one may show that a shrinking Hubble radius corresponds to accelerated expansion as it occurs if the universe is filled with a negative pressure component. The three equivalent conditions for inflation therefore are

$$\frac{d(aH)^{-1}}{dt} < 0 \qquad \Rightarrow \qquad \frac{d^2a}{dt^2} > 0 \qquad \Rightarrow \qquad p < -\frac{\rho}{3} \, .$$

A negative pressure fluid can be modeled by scalar field ϕ, the inflaton, with the following action

$$S = \int \mathrm{d}^4x\sqrt{-g}\left[\frac{1}{2}R + \frac{1}{2}g^{\mu\nu}\partial_\mu\phi\partial_\nu\phi - V(\phi)\right] \, .$$

This will lead to inflation if the slow-roll conditions are satisfied

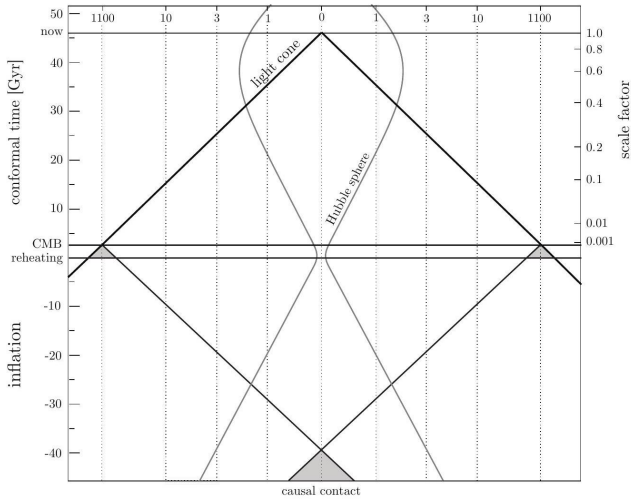
$$\epsilon_{\rm v} = \frac{M_{\rm pl}^2}{2}\left(\frac{V_{,\phi}}{V}\right)^2 , \qquad \eta_{\rm v} = M_{\rm pl}^2\frac{V_{,\phi\phi}}{V} , \qquad \epsilon_{\rm v}, |\eta_{\rm v}| < 1 \, .$$

The number of e-folds of inflationary expansion $N(\phi) = \int_{\phi_{\rm end}}^{\phi} \frac{\mathrm{d}\phi}{\sqrt{2\epsilon_{\rm v}}}$ needs to be at least 60 to solve the horizon problem.

CMB fluctuations are created during four e-folds about 60 e-folds before the end of inflation. Even in the restricted framework for single-field slow-roll inflation described by the above action, there are a multitude of inflationary models characterized by different choices for the inflationary potential $V(\phi)$.

На данный момент нет четкого понимания, каков конкретно смысл модели скалярного поля. Возможно, есть не видимое никем "инфляторное поле", которое и расширяло Вселенную, а к настоящему моменту исчезло. Возможно, у нас такой вакуум сам по себе, что в себе имел потенциал, и поэтому расширял пространство (то есть себя же). Возможно, это вообще что-то другое или вообще не было инфляции. Однако, есть известная модель со

скалярным полем, которая неплохо описывает расширение, которое объясняет экспериментальные данные (CMB или что???)



A defining characteristic of inflation is the behavior of the comoving Hubble radius, $1/(aH)$, which shrinks quasi-exponentially. A mode with comoving wavenumber k is called super-horizon when $k < aH$, and sub-horizon when $k > aH$. The inflaton is taken to be in a vacuum state, defined such that sub-horizon modes approach the Minkowski vacuum for $k \gg aH$. After a mode exits the horizon, it is described by a classical probability distribution with variance given by the power spectrum evaluated at horizon crossing

$$P_{\rm s}(k) = \left.\frac{H^2}{2k^3}\frac{H^2}{\dot\phi^2}\right|_{k=aH}.$$

Inflation also produces fluctuations in the tensor part of the spatial metric. This corresponds to a spectrum of gravitational waves with power spectrum

$$P_{\rm t}(k) = \left.\frac{4}{k^3}\frac{H^2}{M_{\rm pl}^2}\right|_{k=aH}.$$

For slow-roll models the scalar and tensor spectra are expressed purely in terms of $V(\phi)$ and $\epsilon_{\rm v}$ (or $V_{,\phi}$)

$$\Delta^2_{\rm s}(k) \approx \left.\frac{1}{24\pi^2}\frac{V}{M_{\rm pl}^4}\frac{1}{\epsilon_{\rm v}}\right|_{k=aH}, \quad \Delta^2_{\rm t}(k) \approx \left.\frac{2}{3\pi^2}\frac{V}{M_{\rm pl}^4}\right|_{k=aH},$$

where $\Delta^2(k) \equiv \frac{k^3}{2\pi^2}P(k)$. The scale dependence is given by

$$n_{\rm s} - 1 \equiv \frac{d\ln\Delta^2_{\rm s}}{d\ln k} = 2\eta_{\rm v} - 6\epsilon_{\rm v},$$
$$n_{\rm t} \equiv \frac{d\ln\Delta^2_{\rm t}}{d\ln k} = -2\epsilon_{\rm v}.$$

The tensor-to-scalar ratio is

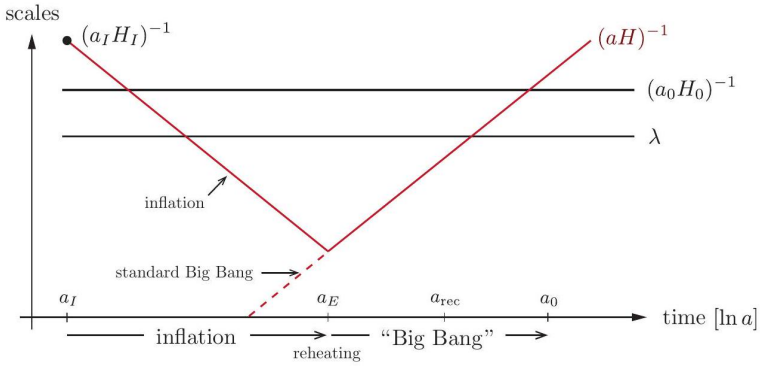
$$r \equiv \frac{\Delta^2_{\rm t}}{\Delta^2_{\rm s}} = 16\epsilon_{\rm v}.$$

By the Lyth bound, r relates directly to total field excursion during inflation

$$\frac{\Delta\phi}{M_{\rm pl}} \approx \left(\frac{r}{0.01}\right)^{1/2}$$

A large value for r therefore correlates both with a high scale for the inflationary energy and a super-Planckian field evolution.

Conditions for Inflation



(!!??? описание очень важного явления: выхода за границы горизонта и заход в него!)

- Accelerated expansion. From $\frac{d}{dt}(aH)^{-1} = \frac{d}{dt}(\dot{a})^{-1} = -\frac{\ddot{a}}{(\dot{a})^2}$, we see that a shrinking comoving Hubble radius implies accelerated expansion

$$\ddot{a} > 0 \qquad \text{(real time)}$$

- Slowly-varying Hubble parameter.

$$\frac{d}{dt}(aH)^{-1} = -\frac{\dot{a}H + a\dot{H}}{(aH)^2} = -\frac{1}{a}(1-\varepsilon), \quad \text{where} \quad \varepsilon := -\frac{\dot{H}}{H^2}. \qquad \text{(real time)}$$

The shrinking Hubble sphere therefore also corresponds to

$$\varepsilon = -\frac{\dot{H}}{H^2} < 1 \qquad \text{(real time)}$$

- Quasi-de Sitter expansion.-For perfect inflation, $\varepsilon = 0$, the spacetime becomes de Sitter space $\mathrm{d}s^2 = \mathrm{d}t^2 - e^{2Ht}\,\mathrm{d}\boldsymbol{x}^2$, where $H = \partial_t \ln a = \text{const}$.

- Negative pressure. Because consider a perfect fluid with pressure P and density ρ. From Friedmann equation, $H^2 = \rho/\left(3M_{\rm pl}^2\right)$, and the continuity equation, $\dot{\rho} = -3H(\rho + P)$, we have

$$\dot{H} + H^2 = -\frac{1}{6M_{\rm pl}^2}(\rho + 3P) = -\frac{H^2}{2}\left(1 + \frac{3P}{\rho}\right). \qquad \text{(real time)}$$

$$-\frac{\dot{H}}{H^2} \equiv \varepsilon = \frac{3}{2}\left(1 + \frac{P}{\rho}\right) < 1 \quad \Leftrightarrow \quad w := \frac{P}{\rho} < -\frac{1}{3}, \qquad \text{(real time)}$$

- Constant density. The continuity equation $\dot{\rho} = -3H(\rho + P)$ with $\dot{H} + H^2 = -\frac{H^2}{2}\left(1 + \frac{3P}{\rho}\right)$ gives (??? check)

$$\left|\frac{d\ln\rho}{d\ln a}\right| = 2\varepsilon < 1.$$

For $\varepsilon \ll 1$, the energy density is therefore nearly constant.

Typical model of scalar field-driven inflation

General Scalar Inflanton Field Dynamics

Пусть есть скалярное поле, которое задает инфляцию, с некоторым потенциалом $V(\phi)$:

$$\rho_\phi = \frac{1}{2}\dot{\phi}^2 + V(\phi). \qquad P_\phi = \frac{1}{2}\dot{\phi}^2 - V(\phi), \qquad H^2 \overset{\text{1F eq}}{=} \frac{1}{3M_{\rm pl}^2}\left[\frac{1}{2}\dot{\phi}^2 + V\right] \qquad \text{(real time)}$$

From here $2H\dot{H} = \frac{1}{3M_{\rm pl}^2}\left[\dot\phi\ddot\phi + V'\dot\phi\right]$, where $V' := dV/d\phi$, and we add from $\dot H \overset{\text{cont+1F}}{=} -\frac{\rho_\phi + P_\phi}{2M_{\rm pl}^2}$ the equation $\dot H = -\frac{1}{2}\frac{\dot\phi^2}{M_{\rm pl}^2}$:

$$\ddot\phi + 3H\dot\phi + V' = 0. \qquad \text{(real time)}$$

The same can be obtained from a Lagrangian $L = a^3\left[\frac{1}{2}\dot\phi^2 - V(\phi)\right]$ which corresponds to metric $\mathrm{d}s^2 = \mathrm{d}t^2 - a^2(t)\mathrm{d}\boldsymbol{x}^2$, (for which $g = -a^6$), if we just use $\frac{d}{dt}\left(\frac{\partial L}{\partial\dot\phi}\right) - \frac{\partial L}{\partial\phi} = 0$.

In particular, if $V = \frac{1}{2}m^2\phi^2$ in terms of $\phi(t) \equiv a^{-3/2}(t)\chi(t)$ we have

$$\ddot\chi + \left(m^2 - \frac{3}{2}\dot H - \frac{9}{4}H^2\right)\chi = 0. \qquad \text{(real time)}$$

Parameters for general inflation

Parameters can be defined differently! The main difference can be in real/confirmal time (so always write them explicitly) and in signs (so before any derivations start in the beginning write, which parameters a certain book uses and wrt which time the derivatives!). Never start without been sure wrt to which time the derivative (write it!) and think that you are in a dead-end, if you haven't written, wrt to what the derivatives! Usually problems can arise only because of definitions of symbols.

$$M_{\rm pl}^2 := \frac{\hbar c}{8\pi G} = 2.4\cdot 10^{18}\ \text{GeV}$$

$$\varepsilon := -\frac{\dot H}{H^2} \equiv -\frac{d\ln H}{dN}$$

$$\eta := \frac{d\ln\varepsilon}{dN} = \frac{\dot\varepsilon}{H\varepsilon} \qquad \mathrm{d}N \equiv \mathrm{d}\ln a = H\ \mathrm{d}t$$

Conditions of SR:

$$\varepsilon < 1, \qquad |\eta| < 1$$

$$\epsilon \equiv \frac{d}{dt}\left(\frac{1}{H}\right) \qquad \text{(from Craps)}$$

$$\delta \equiv \frac{1}{H}\frac{d^2\phi/dt^2}{d\phi/dt} \qquad \text{(from Craps)}$$

$$\epsilon = \frac{1}{16\pi G}\left(\frac{V'}{V}\right)^2, \quad \delta = \epsilon - \frac{1}{8\pi G}\frac{V''}{V}. \qquad \text{(from Craps)}$$

(абзац про то, почему именно такие параметры??? мне так и не объясняли это.)
For a scalar field inflation model we have:

$$\delta := -\frac{\ddot\phi}{H\dot\phi} \qquad \text{(conf.(?????) t.)}$$

$$\varepsilon := \frac{\frac{1}{2}\dot\phi^2}{M_{\rm pl}^2H^2} \qquad \text{(conf.(?????) t.)} \qquad \left(\text{so } \dot\varepsilon = \frac{\dot\phi\ddot\phi}{M_{\rm pl}^2H^2} - \frac{\dot\phi^2\dot H}{M_{\rm pl}^2H^3}\right)$$

$$\eta = 2\frac{\ddot\phi}{H\dot\phi} - 2\frac{\dot H}{H^2} = 2(\varepsilon - \delta). \qquad \text{(conf.(?????) t.)}$$

$$\{\varepsilon, |\delta|\} \ll 1 \qquad \text{implies} \qquad \{\varepsilon, |\eta|\} \ll 1.$$

(!! еще раз решу задачи - пропишу заготовки для них! многое еще указать можно очень нужного)

Slow-Roll Inflation

Slow-roll condition in terms of a potential:

$$\epsilon_{\rm v} := \frac{M_{\rm pl}^2}{2}\left(\frac{V'}{V}\right)^2, \qquad |\eta_{\rm v}| := M_{\rm pl}^2\frac{|V''|}{V}$$

$$\epsilon_{\rm v} \ll 1 \qquad |\eta_{\rm v}| \ll 1.$$

Definition of SR is that:

$$\left(\frac{d\phi}{dt}\right)^2 \ll V(\phi)$$

$$\varepsilon \ll 1$$

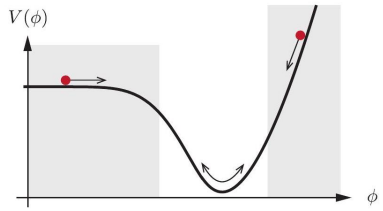
or $\frac{1}{2}\dot\phi^2 \ll V$ and hence

$$H^2 \overset{\text{sl r}}{\approx} \frac{V}{3M_{\rm pl}^2}.$$

and from $|\delta| \ll 1$

$$3H\dot\phi \overset{\text{sl r}}{\approx} -V'.$$

Below two gray regions satisfy slow-roll inflation:



Properties of SR inflation:

$$\frac{V_{,\phi\phi}}{H^2} \approx \frac{3M_{\rm pl}^2 V_{,\phi\phi}}{V} = 3\eta_{\rm v} \ll 1$$

$$\delta + \varepsilon := -\frac{\ddot\phi}{H\dot\phi} - \frac{\dot H}{H^2} \approx M_{\rm pl}^2\frac{V''}{V}.$$

Since $a' = a^2 H$, with $H \approx$ const,

$$\frac{a''}{a} \approx 2a'H = 2a^2H^2 \gg a^2 V_{,\phi\phi}$$

Slow-roll parameters in terms of a potential:

$$\epsilon_{\rm v} := \frac{M_{\rm pl}^2}{2}\left(\frac{V'}{V}\right)^2,$$

$$|\eta_{\rm v}| := M_{\rm pl}^2\frac{|V''|}{V}.$$

Properties of inflation

(collection of useful formulas, see exercises for proofs!?!?!)

$$\frac{d\epsilon}{d\eta} = 2aH\epsilon(\epsilon+\delta)$$

$$4\pi G\left(\dot\phi^{(0)}\right)^2 = \epsilon a^2 H^2,$$

Reheating (giving energy from inflaton to matter fields)

During inflation most of the energy density in the universe is in the form of the inflaton potential $V(\phi)$. Inflation ends when the potential steepens and the inflaton field picks up kinetic energy. The energy in the inflaton sector then has to be transferred to the particles of the Standard Model.

$$\ddot{\phi} + 3H\dot{\phi} = -m^2\phi.$$

$$\dot{\rho}_\phi + 3H\rho_\phi = -3HP_\phi = -\frac{3}{2}H\left(m^2\phi^2 - \dot{\phi}^2\right)$$

(не важно это пока)

О других свойствах типичной инфляции

Amount of inflation

The total number of ' e-folds' of accelerated expansion are

$$N_{\text{tot}} := \int_{a_I}^{a_E} \mathrm{d}\ln a = \int_{t_I}^{t_E} H(t)\mathrm{d}t,$$

(????)

$$N_{\text{tot}} = \int_{\phi_I}^{\phi_E} \frac{1}{\sqrt{2\epsilon_{\text{v}}}} \frac{|\mathrm{d}\phi|}{M_{\text{pl}}},$$

$$N_{\text{cmb}} = \int_{\phi_{\text{cmb}}}^{\phi_E} \frac{1}{\sqrt{2\epsilon_{\text{v}}}} \frac{|\mathrm{d}\phi|}{M_{\text{pl}}} \approx 60$$

Аргументы, почему инфляции не может быть и ответы на них (??!?!?)

(типа там ранее чем 10^{-42}с у нас что-то было кроме большого взрыва? хз, не до этого вопроса.)

1.2.4 Description of equilibrium and non equilibrium processes

(???? статфиз подтяну параллельно, по статфизу уже пробелы, потому что эти темы не очень понятны сразу.)

Laws of local Thermal Equilibrium (??????????????)

We compare the rate of interactions Γ and the rate of expansion H.

$$\text{If } \Gamma \gg H \qquad \text{then} \qquad t_c := \frac{1}{\Gamma} \ll t_H := \frac{1}{H}.$$

Below $T \sim 10^{16}$GeV, but above 100 GeV, it is therefore satisfied.

Из $\sigma \sim$  $\sim \frac{\alpha^2}{T^2}$, ($\alpha := g_A^2/4\pi$ is a structure constant for gauge boson A)

$$\Gamma = n\sigma v \quad \sim \quad T^3 \cdot \frac{\alpha^2}{T^2} = \alpha^2 T.$$

We wish to compare this to the Hubble rate $H \sim \sqrt{\rho}/M_{\rm pl}$, where by dimensional argument (??????) $\rho \sim T^4$, so

$$H \sim \frac{T^2}{M_{\rm pl}^2}.$$

$$\frac{\Gamma}{H} \sim \frac{\alpha^2 M_{\rm pl}}{T} \sim \frac{10^{16}\text{GeV}}{T} \qquad \alpha \sim 0.01.$$

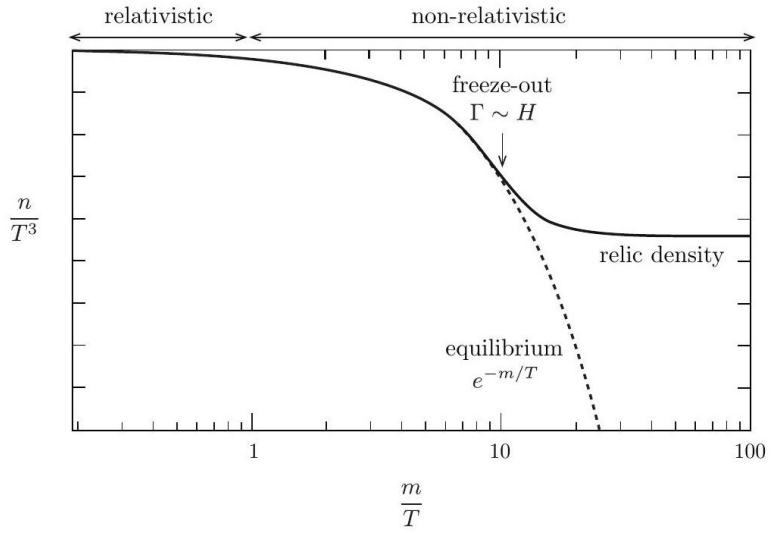
$$f(E) = \frac{1}{e^{E/T} \pm 1},$$

$$\rho_r \propto \sum_i \int \mathrm{d}^3 p f_i(p) E_i(p) = \frac{\pi^2}{30} g_\star(T) T^4,$$

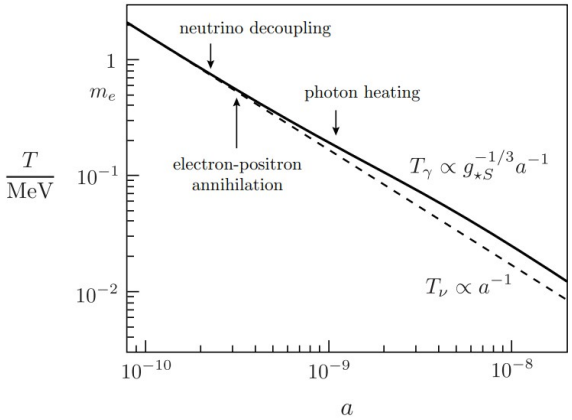
What is an entropy of the universe and what are others entropies, that are used in cosmology? (?!??!)

(отдельно напишу, важный вопрос)

Decoupling and Freeze-Out



(???? выведу еще этот график, пока просто верю, что это так)



Neutrinos are decoupled and their temperature redshifts simply as

$$T_\nu \propto a^{-1}.$$

The energy density of the electron-positron pairs is transferred to the photon gas whose temperature therefore redshifts more slowly,

$$T_\gamma \propto g_{\star S}^{-1/3} a^{-1}.$$

By the weak force $\sigma \sim$ $\sim G_F^2 T^2$,; $G_F \sim \alpha/M_W^2 \sim 1.17 \cdot 10^{-5}\mathrm{GeV}^{-2}$.

$$\frac{\Gamma}{H} \sim \frac{\alpha^2 M_{\rm pl} T^3}{M_W^4} \sim \left(\frac{T}{1\mathrm{MeV}}\right)^3,$$

which drops below unity at $T_{\rm dec} \sim 1\mathrm{MeV}$.

Counting relativistic gases

$$n := \frac{g}{(2\pi)^3}\int \mathrm{d}^3 p f(p) \qquad \text{(particles density)}$$

$$\rho = \frac{g}{(2\pi)^3}\int \mathrm{d}^3 p f(p) E(p) \qquad \text{(energy density)}$$

$$P = \frac{g}{(2\pi)^3}\int \mathrm{d}^3 p f(p)\frac{p^2}{3E} \qquad \text{(pressure)} \qquad f(p) := \frac{1}{e^{(E(p)-\mu)/T} \pm 1}$$

The factor of $p^2/3E$ is the usual $\langle p_x v_x\rangle = \langle \mathbf{p}\cdot\mathbf{v}\rangle/3$ factor from kinetic theory, with $\mathbf{v} = \mathbf{p}/E$.
(?? кст, а там хим пот от T не зависит в этих моделях???)
Chemical equilibrium: $\mu_1 + \mu_2 = \mu_3 + \mu_4$. Thermal equilibrium: T is the same.
For photon: $\mu_\gamma = 0$. For antiparticle: $\mu_{\bar{X}} = -\mu_X$.
At early times all $\mu_i \approx 0$ (???? додумаю, почему, пока верю, мб это и не доказано?)

$$x \equiv m/T \qquad \xi \equiv p/T$$

$$n = \frac{g}{2\pi^2}T^3 I_\pm(x), \qquad I_\pm(x) := \int_0^\infty \mathrm{d}\xi \frac{\xi^2}{\exp\left[\sqrt{\xi^2+x^2}\right] \pm 1}$$

$$\rho = \frac{g}{2\pi^2}T^4 J_\pm(x), \qquad J_\pm(x) := \int_0^\infty \mathrm{d}\xi \frac{\xi^2\sqrt{\xi^2+x^2}}{\exp\left[\sqrt{\xi^2+x^2}\right] \pm 1}$$

$$\int_0^\infty \mathrm{d}\xi \frac{\xi^n}{e^\xi - 1} = \zeta(n+1)\Gamma(n+1), \qquad \zeta(z) \text{ - Riemann zeta-function}$$

$$\int_0^\infty \mathrm{d}\xi \xi^n e^{-\xi^2} = \frac{1}{2}\Gamma\left(\frac{1}{2}(n+1)\right),$$

Relativistic limit

$x \to 0$ ($m \ll T$), so $I_\pm(0) = \int_0^\infty \mathrm{d}\xi \frac{\xi^2}{e^\xi \pm 1}$ and for bosons $I_-(0) = 2\zeta(3) \approx 2 \cdot 1.2$. For fermions, $I_+(0) = I_-(0) - 2 \times \left(\frac{1}{2}\right)^3 I_-(0) = \frac{3}{4} I_-(0)$ (?? ещё раз выведу!)

$$n = \frac{\zeta(3)}{\pi^2} g T^3 \begin{cases} 1 & \text{bosons} \\ \frac{3}{4} & \text{fermions} \end{cases}$$

$$\rho = \frac{\pi^2}{30} g T^4 \begin{cases} 1 & \text{bosons} \\ \frac{7}{8} & \text{fermions} \end{cases}$$

If $\mu \neq 0$ and $T \gg m$, for fermions $n \approx \frac{gT^3}{2\pi^2} \int\limits_0^\infty \mathrm{d}\xi \frac{\xi^2}{e^{\xi-\chi}+1}$ ($\xi := p/T$ and $\chi := \mu/T$), so

$$n - \bar{n} = \frac{g}{2\pi^2} \int\limits_0^\infty \mathrm{d}p p^2 \left(\frac{1}{e^{(p-\mu)/T}+1} - \frac{1}{e^{(p+\mu)/T}+1} \right) = \frac{gT^3}{6\pi^2} \left[\pi^2 \left(\frac{\mu}{T}\right) + \left(\frac{\mu}{T}\right)^3 \right] \quad \mu_{\bar{X}} = -\mu_X$$

We just need to carefully evaluate two approximated integrals.

Non-relativistic Limit

$x \gg 1 (m \gg T)$, so $I_\pm(x) \approx \int\limits_0^\infty \mathrm{d}\xi \frac{\xi^2}{e\sqrt{\xi^2+x^2}} \approx \sqrt{\frac{\pi}{2}} x^{3/2} e^{-x}$. (??? перевыеду еще раз интеграл)

$$n = g \left(\frac{mT}{2\pi} \right)^{3/2} e^{-m/T}$$

$$\rho = mn + \frac{3}{2} nT.$$

$$P = nT \ll \rho = mn.$$

If $\mu \neq 0$, $n = g \left(\frac{mT}{2\pi}\right)^{3/2} e^{-(m-\mu)/T}$,

$$n - \bar{n} = 2g \left(\frac{mT}{2\pi} \right)^{3/2} e^{-m/T} \operatorname{sh}\left(\frac{\mu}{T}\right)$$

(??? строчка, почему? забыл, типичная задача)

Effective Number of Relativistic Species

$$\rho_r = \sum_i \rho_i = \frac{\pi^2}{30} g_\star(T) T^4, \qquad \text{(r - radiation)}$$

$g_\star(T)$ - the effective number of relativistic degrees of freedom at the temperature T. The sum over particle species may receive two types of contributions:

- Relativistic species in thermal equilibrium with the photons, $T_i = T \gg m_i$,

$$g_\star^{th}(T) = \sum_{i=b} g_i + \frac{7}{8} \sum_{i=f} g_i.$$

When the temperature drops below the mass m_i of a particle species, it becomes nonrelativistic and is removed from the sum in (3.2.55). Away from mass thresholds, the thermal contribution is independent of temperature.

- Relativistic species that are not in thermal equilibrium with the photons, $T_i \neq T \gg m_i$,

$$g_\star^{dec}(T) = \sum_{i=b} g_i \left(\frac{T_i}{T} \right)^4 + \frac{7}{8} \sum_{i=f} g_i \left(\frac{T_i}{T} \right)^4.$$

We have allowed for the decoupled species to have different temperatures T_i. This will be relevant for neutrinos after e^+e^-annihilation (see §3.2.4).

$g_b = 28$ photons (2), $W^\pm$and $Z^0(3 \cdot 3)$, gluons $(8 \cdot 2)$, and Higgs (1)
$g_f = 90$ quarks $(6 \cdot 12)$, charged leptons $(3 \cdot 4)$, and neutrinos $(3 \cdot 2)$

$$g_\star = g_b + \frac{7}{8} g_f = 106.75$$

Conservation of Entropy (????????)

(here is a very crazy idea about the change of entropy of the universe. later I'll add a discussion of sense of it!)

Entropy in equilibrium pf particles and acceleration is conserved. It follows from $T\,\mathrm{d}S = \mathrm{d}U + P\,\mathrm{d}V$, $U = \rho V$ and the continuity equation $\dot{\rho} + 3H(\rho + P) = 0$. (because $V \propto a^3$.)

entropy density: $$s := S/V = \frac{\rho + P}{T} = \sum_i \frac{\rho_i + P_i}{T_i} \equiv \frac{2\pi^2}{45} g_{\star S}(T) T^3,$$

Effective degrees of freedom in entropy:

$$g_{\star S}(T) := g^{th}_{\star S}(T) + g^{dec}_{\star S}(T)$$

Note that for species in thermal equilibrium $g^{th}_{\star S}(T) = g^{th}_{\star}(T)$. However, given that $s_i \propto T_i^3$, for decoupled species we get

$$g^{dec}_{\star S}(T) := \sum_{i=b} g_i \left(\frac{T_i}{T}\right)^3 + \frac{7}{8} \sum_{i=f} g_i \left(\frac{T_i}{T}\right)^3 \neq g^{dec}_{\star}(T)$$

The conservation of entropy has two important consequences:

- It implies that $s \propto a^{-3}$. The number of particles in a comoving volume is therefore proportional to the number density n_i divided by the entropy density

$$N_i := \frac{n_i}{s}.$$

If particles are neither produced nor destroyed, then $n_i \propto a^{-3}$ and N_i is constant. This is case, for example, for the total baryon number after baryogenesis, $n_B/s := (n_b - n_{\bar{b}})/s$.

$$T \propto g_{\star S}^{-1/3} a^{-1}.$$

(???????)

Away from particle mass thresholds $g_{\star S}$ is approximately constant and $T \propto a^{-1}$, as expected. The factor of $g_{\star S}^{-1/3}$ accounts for the fact that whenever a particle species becomes non-relativistic and disappears, its entropy is transferred to the other relativistic species still present in the thermal plasma, causing T to decrease slightly less slowly than a^{-1}. We will see an example in the next section (cf. fig. 3.5).

Substituting $T \propto g_{\star S}^{-1/3} a^{-1}$ into the Friedmann equation

$$H = \frac{1}{a}\frac{da}{dt} \simeq \left(\frac{\rho_r}{3M_{\mathrm{pl}}^2}\right)^{1/2} \simeq \frac{\pi}{3}\left(\frac{g_\star}{10}\right)^{1/2} \frac{T^2}{M_{\mathrm{pl}}},$$

we reproduce the usual result for a radiation dominated universe, $a \propto t^{1/2}$, except that there is a change in the scaling every time $g_{\star S}$ changes. For $T \propto t^{-1/2}$, we can integrate the Friedmann equation and get the temperature as a function of time

$$\frac{T}{1\mathrm{MeV}} \simeq 1.5 g_\star^{-1/4} \left(\frac{1\mathrm{sec}}{t}\right)^{1/2}.$$

Boltzmann equation*

$$\frac{dn_i}{dt} + 3\frac{\dot{a}}{a} n_i = 0$$

$$\frac{1}{a^3}\frac{d\left(n_i a^3\right)}{dt} = C_i\left[\{n_j\}\right]$$

$$1+2 \rightleftarrows 3+4,$$

$$\frac{1}{a^3}\frac{d\left(n_1 a^3\right)}{dt} = -\alpha n_1 n_2 + \beta n_3 n_4$$

$$\frac{1}{a^3}\frac{d\left(n_1 a^3\right)}{dt} = -\langle\sigma v\rangle\left[n_1 n_2 - \left(\frac{n_1 n_2}{n_3 n_4}\right)_{\rm eq} n_3 n_4\right]$$

$$\frac{d\ln N_1}{d\ln a} = -\frac{\Gamma_1}{H}\left[1 - \left(\frac{N_1 N_2}{N_3 N_4}\right)_{\rm eq}\frac{N_3 N_4}{N_1 N_2}\right] \qquad \Gamma_1 := n_2\langle\sigma v\rangle \qquad N_i := n_i/s$$

(?????) For $\Gamma_1 \gg H$, the natural state of the system is chemical equilibrium. Imagine that we start with $N_1 \gg N_1^{\rm eq}$ (while $N_i \sim N_i^{\rm eq}, i = 2,3,4$). The r.h.s. of (3.3.86) then is negative, particles of type 1 are destroyed and N_1 is reduced towards the equilibrium value $N_1^{\rm eq}$. Similarly, if $N_1 \ll N_1^{\rm eq}$, the r.h.s. of (3.3.86) is positive and N_1 is driven towards $N_1^{\rm eq}$. The same conclusion applies if several species deviate from their equilibrium values. As long as the interaction rates are large, the system quickly relaxes to a steady state where the r.h.s. of (3.3.86) vanishes and the particles assume their equilibrium abundances.

1.2.5 Nucleosynthesis, baryogenesis, decouplings in a nutshell

Equilibrium properties

Neutrino Decoupling

$$\nu_e + \bar\nu_e \leftrightarrow e^+ + e^-,$$
$$e^- + \bar\nu_e \leftrightarrow e^- + \bar\nu_e$$

The cross section for these interactions was estimated in (3.1.9), $\sigma \sim G_F^2 T^2$, and hence it was found that $\Gamma \sim G_F^2 T^5$. As the temperature decreases, the interaction rate drops much more rapidly that the Hubble rate $H \sim T^2/M_{\rm pl}$:

$$\frac{\Gamma}{H} \sim \left(\frac{T}{1{\rm MeV}}\right)^3.$$

physical momentum of a particle scales as $p \propto a^{-1}$. It is therefore convenient to define the time-independent combination $q := ap$, so that the neutrino number density is

$$n_\nu \propto a^{-3}\int {\rm d}^3 q \frac{1}{\exp\left(q/aT_\nu\right)+1}.$$

Electron-Positron Annihilation

$$e^+ + e^- \leftrightarrow \gamma + \gamma$$

$$g_{\star S}^{th} = \begin{cases} 2 + \frac{7}{8}\cdot 4 = 5.5 & T \gtrsim m_e \\ 2 & T < m_e \end{cases}$$

Since, in equilibrium, $g_{\star S}^{\rm th}\left(aT_\gamma\right)^3$ remains constant, we find that aT_γ increases after electron-positron annihilation, $T < m_e$, by a factor $(11/4)^{1/3}$, while aT_ν remains the same.

that the temperature of neutrinos is slightly lower than the photon temperature after e^+e^- annihilation,

$$T_\nu = \left(\frac{4}{11}\right)^{1/3} T_\gamma.$$

For $T \ll m_e$, the effective number of relativistic species (in energy density and entropy) therefore is

$$g_\star = 2 + \frac{7}{8} \cdot 2N_{\rm eff} \left(\frac{4}{11}\right)^{4/3} = 3.36,$$
$$g_{\star S} = 2 + \frac{7}{8} \cdot 2N_{\rm eff} \left(\frac{4}{11}\right) = 3.94,$$

where we have introduced the parameter $N_{\rm eff}$ as the effective number of neutrino species in the universe. If neutrinos decoupling was instantaneous then we have $N_{\rm eff} = 3$.

Cosmic Neutrino Background

$$n_\nu = \frac{3}{4} N_{\rm eff} \cdot \frac{4}{11} n_\gamma$$

$$\rho_\nu = \frac{7}{8} N_{\rm eff} \left(\frac{4}{11}\right)^{4/3} \rho_\gamma \Rightarrow \Omega_\nu h^2 \approx 1.7 \cdot 10^{-5} \quad (m_\nu = 0)$$

$$\Omega_\nu h^2 \approx \frac{\sum m_{\nu,i}}{94\text{eV}}$$

Dark Matter particle dynamics (!!??)

(скоро это решу!)

Dark Matter Freeze-Out

$$X + \bar{X} \leftrightarrow \ell + \bar{\ell}$$

$$\frac{dN_X}{dt} = -s\langle\sigma v\rangle \left[N_X^2 - (N_X^{\rm eq})^2\right] \qquad N_X^{\rm eq} := n_X^{\rm eq}/s$$

$$x \equiv \frac{M_X}{T}; \qquad \frac{dx}{dt} = \frac{d}{dt}\left(\frac{M_X}{T}\right) = -\frac{1}{T}\frac{{\rm d}T}{dt} x \simeq Hx; \qquad H = \frac{H(M_X)}{x^2} \quad (T \propto a^{-1})$$

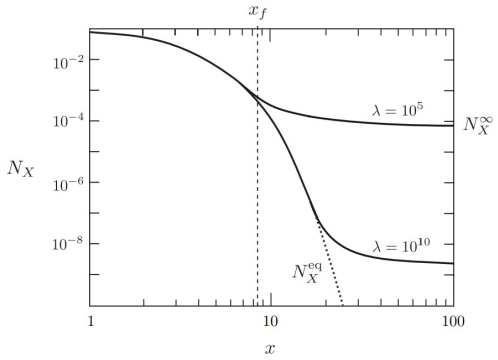
Riccati equation: $$\frac{dN_X}{dx} = -\frac{\lambda}{x^2}\left[N_X^2 - (N_X^{\rm eq})^2\right], \qquad \lambda := \frac{2\pi^2}{45} g_{\star S} \frac{M_X^3 \langle\sigma v\rangle}{H(M_X)}.$$

The final relic abundance, $N_X^\infty := N_X(x = \infty)$, determines the freeze-out density of dark matter.

$$N_X \gg N_X^{\rm eq} \qquad \frac{dN_X}{dx} \simeq -\frac{\lambda N_X^2}{x^2} \quad (x > x_f).$$

$$\frac{1}{N_X^\infty} - \frac{1}{N_X^f} = \frac{\lambda}{x_f} \qquad (N_X^f := N_X(x_f), \quad x \in \{x_f, \infty\})$$

$$N_X^f \gg N_X^\infty \qquad N_X^\infty \simeq \frac{x_f}{\lambda}$$



WIMP Miracle (??????)

We relate the freeze-out abundance of dark matter relics to the dark matter density today:

$$\Omega_X := \frac{\rho_{X,0}}{\rho_{\text{crit },0}} = \frac{M_X n_{X,0}}{3M_{\rm pl}^2 H_0^2} = \frac{M_X N_{X,0} s_0}{3M_{\rm pl}^2 H_0^2} = M_X N_X^\infty \frac{s_0}{3M_{\rm pl}^2 H_0^2}.$$

where we have used that the number of WIMPs is conserved after freeze-out, i.e. $N_{X,0} = N_X^\infty$. Substituting $N_X^\infty = x_f/\lambda$ and $s_0 := s(T_0)$, we get

$$\Omega_X = \frac{H(M_X)}{M_X^2} \frac{x_f}{\langle\sigma v\rangle} \frac{g_{\star S}(T_0)}{g_{\star S}(M_X)} \frac{T_0^3}{3M_{\rm pl}^2 H_0^2}$$

where we have used (3.3.92) and (3.2.62). Using (3.2.67) for $H(M_X)$, gives

$$\Omega_X = \frac{\pi}{9} \frac{x_f}{\langle\sigma v\rangle} \left(\frac{g_\star(M_X)}{10}\right)^{1/2} \frac{g_{\star S}(T_0)}{g_{\star S}(M_X)} \frac{T_0^3}{M_{\rm pl}^3 H_0^2}.$$

Finally, we substitute the measured values of T_0 and H_0 and use $g_{\star S}(T_0) = 3.91$ and $g_{\star S}(M_X) = g_\star(M_X)$:

$$\Omega_X h^2 \sim 0.1 \left(\frac{x_f}{10}\right) \left(\frac{10}{g_\star(M_X)}\right)^{1/2} \frac{10^{-8}\text{GeV}^{-2}}{\langle\sigma v\rangle}.$$

This reproduces the observed dark matter density if

$$\sqrt{\langle\sigma v\rangle} \sim 10^{-4}\text{GeV}^{-1} \sim 0.1\sqrt{G_F}.$$

The fact that a thermal relic with a cross section characteristic of the weak interaction gives the right dark matter abundance is called the WIMP miracle.

(читал, но нужно додумать!!)

Recombination (formation of atoms from electrons and nuclei)

Saha Equilibrium

$$e^- + p^+ \leftrightarrow \text{H} + \gamma$$

Free electron fraction $X_c := \frac{n_e}{n_b}$ n_b is the baryon density, $\eta := 5.5 \cdot 10^{-10} (\Omega_b h^2/0.020)$ is the baryon-to-photon ratio, $B_{\rm H} := m_p + m_c - m_{\rm H} = 13.6\text{eV}$.

The proof is as follows. Since $T < m_i, i = \{e, p, \text{H}\}$,

$$n_i^{\rm eq} = g_i \left(\frac{m_i T}{2\pi}\right)^{3/2} \exp\left(\frac{\mu_i - m_i}{T}\right)$$

$$\mu_p + \mu_c = \mu_{\rm H} \qquad (\mu_\gamma = 0)$$

$$\left(\frac{n_{\rm H}}{n_e^2}\right)_{\rm eq} = \left(\frac{2\pi}{m_e T}\right)^{3/2} e^{B_{\rm H}/T}$$

here we have taken into account $m_{\rm H} \approx m_p$, $B_{\rm H} := m_p + m_c - m_{\rm H} = 13.6{\rm eV}$ and $g_p = g_e = 2$, $g_{\rm H} = 4$.

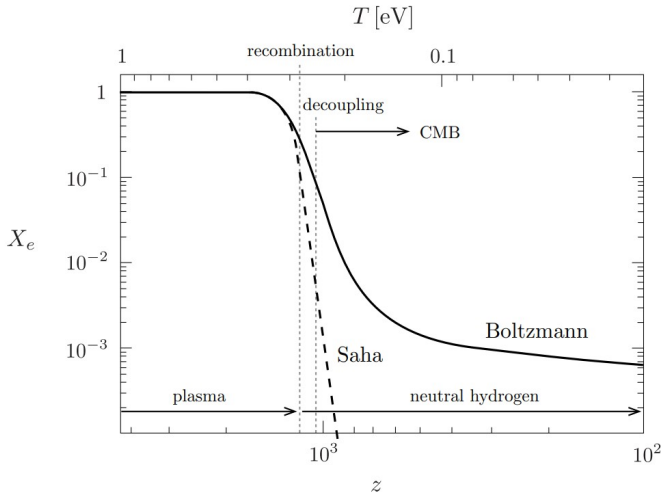
$$n_b = \eta n_\gamma = \eta \cdot \frac{2\zeta(3)}{\pi^2} T^3$$

where $\eta = 5.5 \cdot 10^{-10}\,(\Omega_b h^2/0.020)$ is the baryon-to-photon ratio.

$n_b \approx n_p + n_{\rm H} = n_c + n_{\rm H}$ and hence

$$\frac{1 - X_e}{X_c^2} = \frac{n_H}{n_e^2} n_b$$

$$\left(\frac{1 - X_e}{X_e^2}\right)_{\rm eq} = \frac{2\zeta(3)}{\pi^2}\eta \cdot \left(\frac{2\pi T}{m_e}\right)^{3/2} e^{B_{\rm H}/T} \quad \text{(Saha equation)}$$



(?? как решать ур Саха? Пока просто берем численный график как решение и все.)

Hydrogen Recombination

Let's estimate temperature when a lot of hydrogen is formed.

$$T_{\rm rec}\ \text{is the temperature where } X_e = 10^{-1}$$

From Saha eq.: (? this is the exercise, I'll do it later)

$$T_{\rm rec}\ \approx 0.3{\rm eV} \simeq 3600\ {\rm K}.$$

$T_{\rm rec} \ll B_{\rm H} = 13.6{\rm eV}$ because since there are very many photons for each hydrogen atom ($\eta \sim 10^{-9} \ll 1$), Even when $T < B_{\rm H}$, the high-energy tail of the photon Plank distribution contains photons with energy $E > B_{\rm H}$ so that they are still produces from hydrogen recombination.

(??? потом мб глубже пойму)

From $T_{\rm rec}\ = T_0\,(1 + z_{\rm rec}\,)$, with $T_0 = 2.7$ K

$$z_{rec} \approx 1320.$$

Since matter-radiation equality is at $z_{eq} \simeq 3500$, we conclude that recombination occurred in the matter-dominated era.

From $a(t) = (t/t_0)^{2/3}$,

$$t_{rec} = \frac{t_0}{(1 + z_{rec})^{3/2}} \sim 290000{\rm yrs}$$

Photon Decoupling

Let's estimate temperature when photons will be no more coupled with electrons.

$$e^- + \gamma \leftrightarrow e^- + \gamma$$
$$\Gamma_\gamma \approx n_e \sigma_T \qquad \sigma_T \approx 2 \cdot 10^{-3} \text{MeV}^{-2} \quad \text{(Thomson)}$$

Since $\Gamma_\gamma \propto n_e$, the interaction rate decreases as the density of free electrons drops.

Photons and electrons decouple roughly when the interaction rate becomes smaller than the expansion rate, (???)

$$\Gamma_\gamma (T_{dec}) \sim H (T_{dec})$$
$$\Gamma_\gamma (T_{dec}) = n_b X_e (T_{dec}) \sigma_T = \frac{2\zeta(3)}{\pi^2} \eta \sigma_T X_e (T_{dec}) T_{dec}^3$$
$$H (T_{dec}) = H_0 \sqrt{\Omega_m} \left(\frac{T_{dec}}{T_0} \right)^{3/2}.$$

we have

$$X_e (T_{dec}) T_{dec}^{3/2} \sim \frac{\pi^2}{2\zeta(3)} \frac{H_0 \sqrt{\Omega_m}}{\eta \sigma_T T_0^{3/2}}.$$

Using the Saha equation for $X_e (T_{dec})$, we find

$$T_{dec} \sim 0.27 \text{eV}$$
$$z_{dec} \sim 1100$$
$$t_{dec} \sim 380000 \text{yrs}$$

Although T_{dec} isn't far from T_{rec}, the ionization fraction decreases significantly between recombination and decoupling, $X_e (T_{\text{rec}}) \simeq 0.1 \to X_e (T_{dec}) \simeq 0.01$. This shows that a large degree of neutrality is necessary for the universe to become transparent to photon propagation.

(это в самое начало мб тоже напишу)

Electron Freeze-Out

We will not have Saha's behavior, since there will be no more equilibrium later.

$$\frac{1}{a^3} \frac{d (n_e a^3)}{dt} = -\langle \sigma v \rangle \left[n_e^2 - (n_e^{\text{eq}})^2 \right]$$
$$\langle \sigma v \rangle \simeq \sigma_T \left(\frac{B_{\text{H}}}{T} \right)^{1/2} \qquad \text{(belive in this)}$$

Writing $n_e = n_b X_e$ and using that $n_b a^3 = \text{const.}$, we find

$$\frac{dX_e}{dx} = -\frac{\lambda}{x^2} \left[X_e^2 - (X_e^{\text{eq}})^2 \right]; \qquad x := B_{\text{H}}/T$$
$$\lambda := \left[\frac{n_b \langle \sigma v \rangle}{xH} \right]_{x=1} = 3.9 \cdot 10^3 \left(\frac{\Omega_b h}{0.03} \right)$$

(??? need to derive!!! use matter-domination??)

We use a solution for DM, since there was the same equation

$$X_e^\infty \simeq \frac{x_f}{\lambda} = 0.9 \cdot 10^{-3} \left(\frac{x_f}{x_{rec}} \right) \left(\frac{0.03}{\Omega_b h} \right).$$

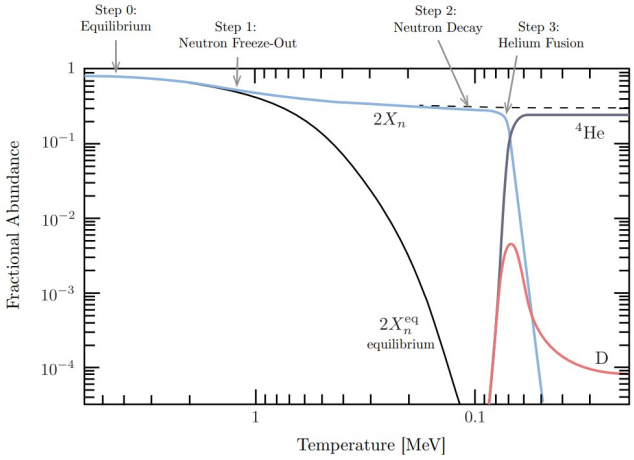
Assuming that freeze-out occurs close to the time of recombination, $x_{rec} \approx 45$, we capture the relic electron abundance pretty well (see fig. 3.8).

From $\Gamma_e (T_f) \sim H (T_f)$,

$$T_f : \qquad X_e (T_f) T_f = \frac{\pi^2}{2\zeta(3)} \frac{H_0 \sqrt{\Omega_m}}{\eta \sigma_T T_0^{3/2} B_{\text{H}}^{1/2}}$$

From Saha equation $T_f \sim 0.25 \text{eV}$ and hence $x_f \sim 54$.

Big Bang Nucleosynthesis (formation of hydrogen, helium, lithium) (????)



Step 0: Equilibrium Abundances

$$\frac{n_{\rm He}}{n_{\rm H}} \sim \frac{1}{16}$$

$$\frac{n_{\rm He}}{n_{\rm H}} \sim \frac{1}{16}$$

1. No elements heavier than helium. Essentially no elements heavier than helium are produced at appreciable levels. So the only nuclei that we need to track are hydrogen and helium, and their isotopes: deuterium, tritium, and ^{3}He.

2. Only neutrons and protons above 0.1MeV. Above $T \approx 0.1$MeV only free protons and neutrons exist, while other light nuclei haven't been formed yet. Therefore, we can first solve for the neutron/proton ratio and then use this abundance as input for the synthesis of deuterium, helium, etc.

Let us demonstrate that we can indeed restrict our attention to neutrons and protons above 0.1MeV. In order to do this, we compare the equilibrium abundances of the different nuclei:

- First, we determine the relative abundances of neutrons and protons. In the early universe, neutrons and protons are coupled by weak interactions, e.g. β-decay and inverse β-decay

$$n + \nu_e \leftrightarrow p^+ + e^-,$$
$$n + e^+ \leftrightarrow p^+ + \bar{\nu}_e.$$

$$\mu_n = \mu_p \qquad \mu_e \approx 0 \qquad \mu_\nu \approx 0$$

$$n_i^{\rm eq} = g_i \left(\frac{m_i T}{2\pi}\right)^{3/2} \exp\left(\frac{\mu_i - m_i}{T}\right)$$

$$\left(\frac{n_n}{n_p}\right)_{\rm eq} = \left(\frac{m_n}{m_p}\right)^{3/2} e^{-(m_n - m_p)/T}$$

$$\left(\frac{n_n}{n_p}\right)_{\rm eq} = e^{-\mathcal{Q}/T} \qquad \mathcal{Q} := m_n - m_p = 1.30\text{MeV}$$

For $T \gg 1$MeV, there are therefore as many neutrons as protons. However, for $T < 1$MeV, the neutron fraction gets smaller. If the weak interactions would operate efficiently enough to maintain equilibrium indefinitely, then the neutron abundance would drop to zero. Luckily, in the real world the weak interactions are not so efficient.

- Next, for deuterium (an isotope of hydrogen (pn)):

$$n + p^+ \leftrightarrow \mathrm{D} + \gamma.$$

$$\mu_n + \mu_p = \mu_{\rm D} \qquad \mu_\gamma = 0.$$

$$\left(\frac{n_{\rm D}}{n_n n_p}\right)_{\rm eq} = \frac{3}{4}\left(\frac{m_{\rm D}}{m_n m_p}\frac{2\pi}{T}\right)^{3/2} e^{-(m_{\rm D}-m_n-m_p)/T},$$

($g_{\rm D} = 3$ and $g_p = g_n = 2$).

$$m_{\rm D} \approx 2m_n \approx 2m_p \approx 1.9{\rm GeV}$$
$$B_{\rm D} := m_n + m_p - m_{\rm D} = 2.22{\rm MeV}$$
$$\left(\frac{n_{\rm D}}{n_p}\right)_{\rm eq} = \frac{3}{4} n_n^{\rm eq}\left(\frac{4\pi}{m_p T}\right)^{3/2} e^{B_{\rm D}/T}.$$
$$n_n \sim n_b = \eta n_\gamma = \eta \cdot \frac{2\zeta(3)}{\pi^2} T^3.$$
$$\left(\frac{n_{\rm D}}{n_p}\right)_{\rm eq} \approx \eta\left(\frac{T}{m_p}\right)^{3/2} e^{B_{\rm D}/T}.$$

The smallness of the baryon-to-photon ratio η inhibits the production of deuterium until the temperature drops well beneath the binding energy $B_{\rm D}$, so that $e^{B_{\rm D}/T}$ can compete with $\eta \sim 10^{-9}$.

The same applies to all other nuclei. At temperatures above 0.1MeV, then, virtually all baryons are in the form of neutrons and protons. Around this time, deuterium and helium are produced, but the reaction rates are by now too low to produce any heavier elements.

Neutron nonequilibrium dynamics and Helium fussion

$$X_n := \frac{n_n}{n_n + n_p}$$

$$\left(\frac{n_n}{n_p}\right)_{\rm eq} = e^{-\mathcal{Q}/T} \qquad X_n^{\rm eq}(T) = \frac{e^{-\mathcal{Q}/T}}{1 + e^{-\mathcal{Q}/T}}$$

$$X_n^{\rm eq}(0.8{\rm MeV}) = 0.17. \qquad (T_{\rm final} \sim T_{\rm dec} \sim 0.8{\rm MeV})$$

$$X_n^\infty \sim X_n^{\rm eq}(0.8{\rm MeV}) \sim \frac{1}{6}$$

(there are more complicated ways for calculation of this in theory, I don't think they are very important)

We need to account for a finite lifetime of the neutron:

$$X_n(t) = X_n^\infty e^{-t/\tau_n} = \frac{1}{6} e^{-t/\tau_n} \qquad \tau_n = 886.7 \pm 0.8{\rm sec}$$

Helium is produced by:

$$n + p^+ \leftrightarrow {\rm D} + \gamma.$$
$${\rm D} + p^+ \leftrightarrow {}^3{\rm He} + \gamma,$$
$${\rm D} + {}^3{\rm He} \leftrightarrow {}^4{\rm He} + p^+.$$

Since the deuterium binding energy is rather small, the deuterium abundance becomes large rather late (at $T < 100{\rm keV}$). So although heavier nuclei have larger binding energies and hence would have larger equilibrium abundances, they cannot be formed until sufficient deuterium has become available. This is the deuterium bottleneck. Only when there is enough deuterium, can helium be produced.

$$T_{\rm nuc}: \qquad (n_{\rm D}/n_p)_{\rm eq} \sim 1$$

$$T_{\rm nuc} \sim 0.06{\rm MeV} \qquad \left(\left(\frac{n_{\rm D}}{n_p}\right)_{\rm eq} \approx \eta \left(\frac{T}{m_p}\right)^{3/2} e^{B_{\rm D}/T}.\right)$$

from $\frac{T}{1{\rm MeV}} \simeq 1.5 g_\star^{-1/4} \left(\frac{1{\rm sec}}{t}\right)^{1/2}$ with $g_\star = 3.38$

$$t_{\rm nuc} = 120{\rm sec} \left(\frac{0.1{\rm MeV}}{T_{\rm nuc}}\right)^2 \sim 330{\rm sec}$$

$$X_n\left(t_{\rm nuc}\right) \sim \frac{1}{8}$$

(??? а ниже - потом додумаю, пока не продумывал)

$$\frac{n_{\rm He}}{n_{\rm H}} = \frac{n_{\rm He}}{n_p} \simeq \frac{\frac{1}{2} X_n\left(t_{\rm nuc}\right)}{1 - X_n\left(t_{\rm nuc}\right)} \sim \frac{1}{2} X_n\left(t_{\rm nuc}\right) \sim \frac{1}{16},$$

Influence of parameters on nucleosynthesis

Changing the input, e.g. by new physics beyond the Standard Model (BSM) in the early universe, would change the predictions of BBN. In this way BBN is a probe of fundamental physics.

- $g_\star$: the number of relativistic degrees of freedom determines the Hubble parameter during the radiation era, $H \propto g_\star^{1/2}$, and hence affects the freeze-out temperature

$$G_F^2 T_f^5 \sim \sqrt{G_N g_\star} T_f^2 \quad \rightarrow \quad T_f \propto g_\star^{1/6}$$

Increasing $g_\star$ increases T_f, which increases the n/p ratio at freeze-out and hence increases the final helium abundance.

- τ_n : a large neutron lifetime would reduce the amount of neutron decay after freeze-out and therefore would increase the final helium abundance.

- $\mathcal{Q}$: a larger mass difference between neutrons and protons would decrease the n/p ratio at freeze-out and therefore would decrease the final helium abundance.

- η: the amount of helium increases with increasing η as nucleosythesis starts earlier for larger baryon density.

- G_N: increasing the strength of gravity would increase the freeze-out temperature, $T_f \propto G_N^{1/6}$, and hence would increase the final helium abundance.

- G_F: increasing the weak force would decrease the freeze-out temperature, $T_f \propto G_F^{-2/3}$, and hence would decrease the final helium abundance.

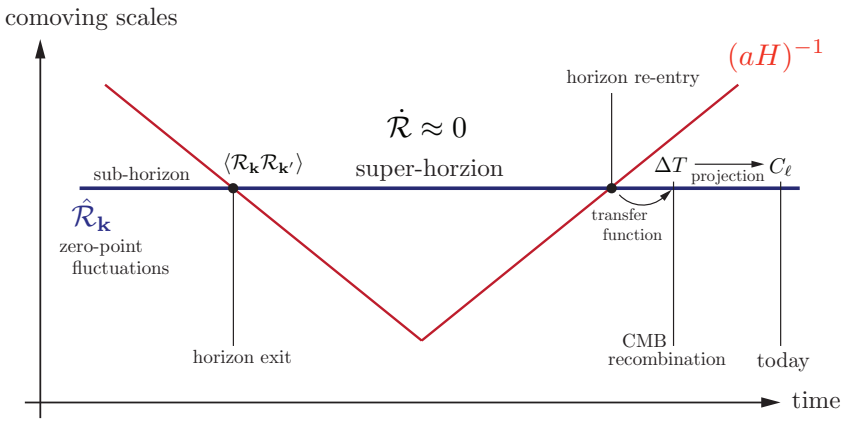
1.3 Structure formation and anysotropies in a nutshell

(тут очень большая и жесткая теория...)

1.3.1 Overview of fluctuations dynamics, parameters, power spectrum (!!!!!!)

Main properties and plots of fluctuation dynamics (??????!!!!)

(!!! только графики, ключевые формулы и ключевые слова!!!)



$$k^2\Phi + 3\frac{\dot{a}}{a}\left(\dot{\Phi} - \Psi\frac{\dot{a}}{a}\right) = 4\pi G a^2\left[\rho_{\rm m}\delta_m + 4\rho_r\Theta_{r,0}\right]$$
$$k^2(\Phi+\Psi) = -32\pi G a^2\rho_r\Theta_{r,2}$$

$m \in \{$ baryons, dark matter$\}$, $r \in \{$ neutrinos, photons$\}$

$$\rho_{\rm m}\delta_m \equiv \rho_{\rm dm}\delta + \rho_b\delta_{\rm b} \quad ; \quad \rho_r\Theta_{r,0} \equiv \rho_\gamma\Theta_0 + \rho_\nu\mathcal{N}_0$$
$$\rho_{\rm m}v_m \equiv \rho_{\rm dm}v + \rho_b v_{\rm b} \quad ; \quad \rho_r\Theta_{r,1} \equiv \rho_\gamma\Theta_1 + \rho_\nu\mathcal{N}_1.$$

A combination of B and E equations leads to an algebraic equation for the potential,

$$k^2\Phi = 4\pi G a^2\left[\rho_{\rm m}\delta_m + 4\rho_r\Theta_{r,0} + \frac{3aH}{k}\left(i\rho_{\rm m}v_m + 4\rho_r\Theta_{r,1}\right)\right].$$

For tensor perturbations, $h_+$and $h_\times$; each of these evolves independently and satisfies

$$\ddot{h}_\alpha + 2\frac{\dot{a}}{a}\dot{h}_\alpha + k^2 h_\alpha = 0 \qquad \alpha \equiv +\times$$

		RD		MD

$k \gg k_{\rm eq}$:	superhorizon	*const.*	*const.* (a^2)	–	–
	subhorizon	a^{-2}	$\ln a$	*const.*	a
$k \ll k_{\rm eq}$:	superhorizon	*const.*	*const.* (a^2)	*const.*	*const.* (a)
	subhorizon	–	–	*const.*	a

Gravitation potential perturbations: They are constant when the modes are outside the horizon. Two of the modes enter the horizon during the radiation era. While they are inside the horizon during the radiation era their amplitudes decrease as a^{-2}. The resulting amplitudes in the matter era are therefore strongly suppressed. During the matter era the potential is constant on all scales. The longest wavelength mode in the figure enters the horizon during the matter era, so its amplitude is only suppressed by the factor of $\frac{9}{10}$ coming from the radiation-to-matter transition.

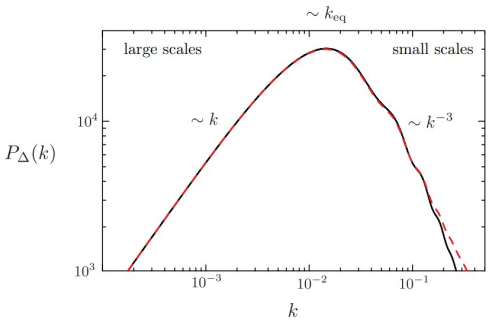
$$\Delta_m := \delta_m - 3\mathcal{H}v_m$$

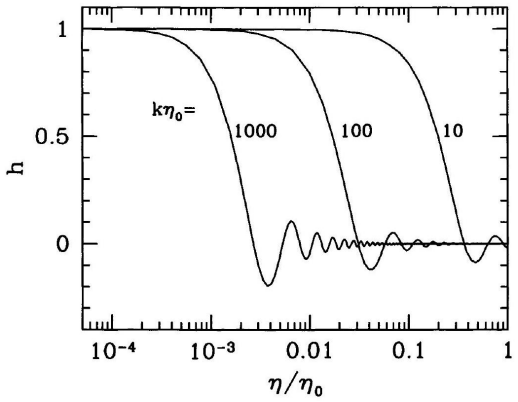
$$\Delta_{m,k}(z) = T(k,z)\mathcal{R}_k.$$

$$P_\Delta(k,z) \equiv |\Delta_{m,k}(z)|^2 = T^2(k,z)\,|\mathcal{R}_k|^2\,.$$



The matter power spectrum $P_\Delta(k)$ at $z = 0$ in linear theory (solid) and with non-linear corrections (dashed). On large scales, $P_\Delta(k)$ grows as k. The power spectrum turns over around $k_{\rm eq} \sim 0.01{\rm Mpc}^{-1}$ corresponding to the horizon size at matter-radiation equality. Beyond the peak, the power falls as k^{-3}. Visible are small amplitude baryon acoustic oscillations in the spectrum.

For gravitational waves:



Summary of evolution of fluctuations during Inflation

A defining characteristic of inflation is the behavior of the comoving Hubble radius, $1/(aH)$, which shrinks quasi-exponentially. A mode with comoving wavenumber k is called super-horizon when $k < aH$, and sub-horizon when $k > aH$. The inflaton is taken to be in a vacuum state, defined such that sub-horizon modes approach the Minkowski vacuum for $k \gg aH$. After a

mode exits the horizon, it is described by a classical probability distribution with variance given by the power spectrum evaluated at horizon crossing

$$P_{\rm s}(k) = \left.\frac{H^2}{2k^3}\frac{H^2}{\dot\phi^2}\right|_{k=aH} .$$

Inflation also produces fluctuations in the tensor part of the spatial metric. This corresponds to a spectrum of gravitational waves with power spectrum

$$P_{\rm t}(k) = \left.\frac{4}{k^3}\frac{H^2}{M_{\rm pl}^2}\right|_{k=aH} .$$

For slow-roll models the scalar and tensor spectra are expressed purely in terms of $V(\phi)$ and $\epsilon_{\rm v}$ (or $V_{,\phi}$)

$$\Delta^2_{\rm s}(k) \approx \left.\frac{1}{24\pi^2}\frac{V}{M_{\rm pl}^4}\frac{1}{\epsilon_{\rm v}}\right|_{k=aH} , \qquad \Delta^2_{\rm t}(k) \approx \left.\frac{2}{3\pi^2}\frac{V}{M_{\rm pl}^4}\right|_{k=aH} ,$$

where $\Delta^2(k) \equiv \frac{k^3}{2\pi^2}P(k)$. The scale dependence is given by

$$\begin{aligned} n_{\rm s} - 1 &\equiv \frac{d\ln\Delta^2_{\rm s}}{d\ln k} = 2\eta_{\rm v} - 6\epsilon_{\rm v} , \\ n_{\rm t} &\equiv \frac{d\ln\Delta^2_{\rm t}}{d\ln k} = -2\epsilon_{\rm v} . \end{aligned}$$

The tensor-to-scalar ratio is

$$r \equiv \frac{\Delta^2_{\rm t}}{\Delta^2_{\rm s}} = 16\epsilon_{\rm v} .$$

By the Lyth bound, r relates directly to total field excursion during inflation

$$\frac{\Delta\phi}{M_{\rm pl}} \approx \left(\frac{r}{0.01}\right)^{1/2} .$$

A large value for r therefore correlates both with a high scale for the inflationary energy and a super-Planckian field evolution.

below SUMMARY AND SPECTRAL INDICES of Initial conditions by Dodelson

In order to understand how scales which should be uncorrelated today are observed to have almost identical temperatures, we are virtually forced into the theory of inflation. In addition to explaining away the nagging fine-tuning problems of the standard cosmology, inflation is also a mechanism for generating primordial perturbations over the smooth universe.

Inflation predicts that quantum-mechanical perturbations in the very early universe are first produced when the relevant scales are causally connected. Then these scales are whisked outside the horizon by inflation, only to reenter much later to serve as initial conditions for the growth of structure and anisotropy in the universe. The perturbations are best described in terms of the Fourier modes. The mean of a given Fourier mode, for example for the gravitational potential, is zero:

$$\langle\Phi(\vec{k})\rangle = 0$$

Further, the perturbations to one Fourier mode are uncorrelated with those to another. However, a given mode has nonzero variance, so

$$\left\langle \Phi(\vec{k})\Phi^*(\vec{k}')\right\rangle = (2\pi)^3 P_\Phi(k)\delta^3\left(\vec{k}-\vec{k}'\right)$$

In the case of scalar perturbations, the ones of most importance for us, the power spectrum is given by Eq. (6.82). Perturbations to the tensor part of the metric are also produced and are also Gaussian with mean zero; the power spectrum of tensor modes is given by Eq. (6.59). The scalar spectrum depends on the slow roll parameter ϵ, defined in Eq. (6.35), which is

proportional to the derivative of the Hubble rate. Since the Hubble rate is close to constant during inflation - because of the dominance of potential energy- ϵ is typically small.

A spectrum in which $k^3 P_\Phi(k)$ is constant (i.e., does not depend on k) is called a scale-invariant (scale-free spectrum). Apart from small deviations encoded in the slow-roll parameters, both the scalar and the tensor perturbations are scale free. This is both a blessing and a curse. It is good because it is a fairly definite prediction, easy to test. It is unfortunate because a scale-free spectrum is what one might have expected even without the complex machinery of inflation. Indeed, a scale-free spectrum is also referred to as a Harrison-Zel'dovich-Peebles spectrum, crediting the smart people who first proposed it as the appropriate distribution for the initial conditions, a proposal that predates inflation by many years. This really is too bad, because if we observe a scale-free spectrum, and most present observations are consistent with this, then inflation cannot fairly claim all the credit. However, if we observe a small mixture of tensor modes and/or a small deviation from a scale-free spectrum, then this will go a long way toward convincing skeptics that inflation is responsible for the primordial perturbations.

To quantify the deviations from scale invariance, it is conventional to write the primordial power spectra as

$$P_\Phi(k) = \frac{8\pi}{9k^3}\frac{H^2}{\epsilon m_{\rm Pl}^2}\bigg|_{aH=k} := \frac{50\pi^2}{9k^3}\left(\frac{k}{H_0}\right)^{n-1}\delta_H^2\left(\frac{\Omega_m}{D_1(a=1)}\right)^2$$
$$P_h(k) = \frac{8\pi}{k^3}\frac{H^2}{m_{\rm Pl}^2}\bigg|_{aH=k} := A_T k^{n_T-3}$$

These equations serve to define the scalar and tensor amplitudes, δ_H (subscript H for amplitude at horizon crossing) and A_T, and the spectral indices, n and n_T. Note that this convention - which has become common - says that a scale-free scalar spectrum corresponds to $n = 1$, while $n_T = 0$ for a scale-free tensor spectrum. The factor of $\Omega_m/D_1(a=1)$, where Ω_m is the fraction of the critical density in matter today and D_1 is the growth function which will be defined in Chapter 7 (Eqs. (7.4) and (7.77)), is part of this convention. It is inconvenient at this stage because we have not even encountered the growth function yet, but it has become standard to include in the definition of δ_H (Liddle and Lyth, 1993; Bunn and White, 1997). The resulting expression for the matter power spectrum today looks much simpler when these factors are included here. We pay the price of complexity now for the benefit of simplicity later.

We can relate the primordial spectral indices n and n_T to the slow-roll parameters ϵ and δ. Consider first the tensor spectrum. By virtue of the definition in Eq. (6.100),

$$\frac{d\ln[P_h]}{d\ln k} = n_T - 3$$

The logarithmic derivative has two terms, first the trivial one $d\ln(k^{-3})/d\ln(k)$ which cancels the -3 here, leaving $n_T = 2d\ln H/d\ln(k)$. The logarithmic derivative of the Hubble rate at horizon crossing is a bit subtle:

$$\frac{d\ln H}{d\ln k}\bigg|_{aH=k} = \frac{k}{H}\frac{dH}{d\eta}\cdot\frac{d\eta}{dk}\bigg|_{aH=k}.$$

By definition (Eq. (6.35)), $\dot H = -aH^2\epsilon$, and $d\eta|_{aH=k}/dk = -\,d(aH)^{-1}|_{aH=k}/dk = 1/k^2$, so

$$\frac{d\ln H}{d\ln k}\bigg|_{aH=k} = -\frac{k}{H}\frac{aH^2\epsilon}{k^2}\bigg|_{aH=k} = -\epsilon.$$

Therefore, the primordial spectral index of tensor perturbations produced by inflation is

$$n_T = -2\epsilon$$

The scalar spectral index follows from a similar argument. Taking the logarithmic derivative of P_Φ leads to

$$n - 1 = \frac{d}{d\ln(k)}\left[\ln\left(H^2\right) - \ln(\epsilon)\right]$$

The derivative of H again gives -2ϵ while the logarithmic derivative of ϵ is $-2(\epsilon+\delta)$ (Exercise 12). So,

$$n = 1 - 4\epsilon - 2\delta.$$

The fact that the tensor index n_T is proportional to ϵ leads to one of the robust predictions of inflation. Many inflationary models have been proposed which offer different predictions for ϵ and δ. Almost all of these, however, maintain the feature that the ratio of tensor to scalar modes (which we saw earlier was proportional to ϵ) is directly related to the tensor spectral index (here also seen to be directly proportional to ϵ).

below Scale invariance and spectral indexes by Craps

A scale-invariant spectrum is one for which $k^3P(k)$ is k-independent. The spectra P_h and P_Ψ are not scale-invariant because the quantities H^2 and ϵ are to be evaluated at the time of horizon crossing, $aH = k$, which depends on k.

Scalar perturbations spectral index (tilt) $n_s \equiv n$: $\quad k^3P_\Psi(k) \sim k^{n-1}$.

The tensor spectral index n_T : $\quad k^3P_h(k) \sim k^{n_T}$.

In these conventions scale-invariant spectra of scalar and tensor perturbations would correspond to $n = 1$ and $n_T = 0$, respectively.

The deviations from scale invariance can be expressed in terms of the slow-roll parameters:

$$n_T = \frac{d\ln H^2}{d\ln k} = \frac{2k}{H}\frac{dH}{d\eta}\frac{d\eta}{dk}\bigg|_{aH=k}. \qquad \left(P_h(k) = \frac{8\pi G H^2}{k^3}\bigg|_{aH=k}\right)$$

$$n_T = \frac{2k}{H}\left(-aH^2\epsilon\right)\eta^2\bigg|_{aH=k} = -2\epsilon \qquad \epsilon = -\dot{H}/\left(aH^2\right); \quad aH \approx -1/\eta$$

So, ϵ controls both the tensor spectral index and the tensor-to-scalar ratio $P_h(k)/P_\Psi(k)$; this is a robust prediction of inflation.

$$n - 1 = \frac{d}{d\ln k}\left(\ln H^2 - \ln\epsilon\right)\bigg|_{aH=k},$$

the first term will again give -2ϵ and because of $\frac{d\epsilon}{d\eta} = 2aH\epsilon(\epsilon+\delta)$ the second term in parentheses will give $-2(\epsilon+\delta)$, so

$$n = 1 - 4\epsilon - 2\delta.$$

1.3.2 Perturbations setup from newtonian and relativisic physics

(суммирую Баумана и круто, минимум флуктуаций сделан)

Perturbed Newtonian fluid equations (continuity, Euler's eq.)

$$\partial_t\rho = -\nabla_{\boldsymbol{r}}\cdot(\rho\boldsymbol{u}), \qquad \text{(Continuity eq.)}$$

$$\left(\partial_t + \boldsymbol{u}\cdot\boldsymbol{\nabla}_{\boldsymbol{r}}\right)\boldsymbol{u} = -\frac{\nabla_{\boldsymbol{r}}P}{\rho} - \nabla_{\boldsymbol{r}}\Phi. \qquad \text{(Euler eq., basically } F = ma)$$

$$\nabla_r^2\Phi = 4\pi G\rho \qquad \text{(Poisson eq.)}$$

$$\rho(t,\boldsymbol{r}) = \bar{\rho}(t) + \delta\rho(t,\boldsymbol{r}).$$

Non-relativistic fluid in static space without gravity:

$$\partial_t\delta\rho = -\nabla_r\cdot(\bar{\rho}\boldsymbol{u}),$$
$$\bar{\rho}\partial_t\boldsymbol{u} = -\nabla_r\delta P.$$

$\partial_t^2\delta\rho - \nabla_r^2\delta P = 0; \qquad \delta P = c_s^2\delta\rho$ (adiab.); $\qquad \left(\partial_t^2 - c_s^2\nabla^2\right)\delta\rho = 0.$ c_s - speed of sound

$\delta\rho(t,\boldsymbol{r}) = \int \frac{\mathrm{d}^3k}{(2\pi)^3} e^{-i\boldsymbol{k}\cdot\boldsymbol{r}}\delta\rho_{\boldsymbol{k}}(t) \qquad \left(\partial_t^2 + c_s^2k^2\right)\delta\rho_{\boldsymbol{k}} = 0, \qquad \delta\rho_{\boldsymbol{k}} = A_{\boldsymbol{k}}e^{i\omega_k t} + B_{\boldsymbol{k}}e^{-i\omega_k t}, \quad \omega_k := c_s k.$

Non-relativistic fluid in static space with gravity:

$$\left(\partial_t^2 - c_s^2\nabla_{\boldsymbol{r}}^2\right)\delta\rho = 4\pi G\bar{\rho}\delta\rho \qquad \nabla^2\delta\Phi = 4\pi G\delta\rho$$

$$\delta\rho = A\exp[i(\omega t - \boldsymbol{k}\cdot\boldsymbol{r})] \qquad \omega^2 = c_s^2k^2 - 4\pi G\bar{\rho}$$

$$\omega = 0 \quad \text{at} \quad k_{\mathrm{J}} := \frac{\sqrt{4\pi G\bar{\rho}}}{c_s}.$$

For small scales (large wavenumber), $k > k_{\mathrm{J}}$, the pressure dominates and we find the same oscillations as before. On large scales, $k < k_{\mathrm{J}}$, gravity dominates, the frequency ω becomes imaginary and the fluctuations grow exponentially.

$$\lambda_{\mathrm{J}} = \frac{2\pi}{k_{\mathrm{J}}} = c_s\sqrt{\frac{\pi}{G\bar{\rho}}}. \qquad \text{(Jeans' lengt)}$$

Non-relativistic fluid in expanding space:

$$\boldsymbol{r}(t) = a(t)\boldsymbol{x} \qquad \boldsymbol{\nabla}_{\boldsymbol{r}} = a^{-1}\nabla_{\boldsymbol{x}} \qquad \left(\frac{\partial}{\partial t}\right)_r \equiv \left(\frac{\partial}{\partial t}\right)_x + \left(\frac{\partial \boldsymbol{x}}{\partial t}\right)_r \cdot \boldsymbol{\nabla}_x = \left(\frac{\partial}{\partial t}\right)_x - H\boldsymbol{x}\cdot\boldsymbol{\nabla}_x$$

Continuity equation:

$$\left[\frac{\partial}{\partial t} - H\boldsymbol{x}\cdot\boldsymbol{\nabla}\right][\bar{\rho}(1+\delta)] + \frac{1}{a}\boldsymbol{\nabla}\cdot[\bar{\rho}(1+\delta)(Ha\boldsymbol{x} + \boldsymbol{v})] = 0$$

$$\delta := \frac{\delta\rho}{\bar{\rho}}$$

$$\frac{\partial\bar{\rho}}{\partial t} + 3H\bar{\rho} = 0 \qquad \text{(0-th order, } \bar{\rho}\propto a^{-3}, \quad \nabla_{\boldsymbol{x}}\cdot\boldsymbol{x} = 3)$$

$$\left[\frac{\partial}{\partial t} - H\boldsymbol{x}\cdot\boldsymbol{\nabla}\right][\bar{\rho}\delta] + \frac{1}{a}\boldsymbol{\nabla}\cdot[\bar{\rho}Ha\boldsymbol{x}\delta + \bar{\rho}\boldsymbol{v}] = 0 \qquad \text{(1-st order)}$$

or $\left[\frac{\partial\bar{\rho}}{\partial t} + 3H\bar{\rho}\right]\delta + \bar{\rho}\frac{\partial\delta}{\partial t} + \frac{\bar{\rho}}{a}\nabla\cdot\boldsymbol{v} = 0$, so

$$\dot{\delta} = -\frac{1}{a}\nabla\cdot\boldsymbol{v}$$

Euler equation:

$$\dot{\boldsymbol{v}} + H\boldsymbol{v} = -\frac{1}{a\bar{\rho}}\boldsymbol{\nabla}\delta P - \frac{1}{a}\boldsymbol{\nabla}\delta\Phi.$$

In the absence of pressure and gravitational perturbations, this equation simply says that $\boldsymbol{v}\propto a^{-1}$, which is something we already discovered in Chapter 1.

Poisson equation:

$$\nabla^2\delta\Phi = 4\pi Ga^2\bar{\rho}\delta$$

Totally we have:

$$\ddot{\delta} + 2H\dot{\delta} - \frac{c_s^2}{a^2}\nabla^2\delta = 4\pi G\bar{\rho}\delta$$

$2H\dot{\delta}$ - friction term, which wasn't in static space without gravity ($(\partial_t^2 - c_s^2\nabla_r^2)\,\delta\rho = 4\pi G\bar{\rho}\delta\rho,$). Below the Jeans' length $\lambda_{\mathrm{J}}(t) = \frac{2\pi}{k_{\mathrm{J}}} = c_s(t)\sqrt{\frac{\pi}{G\bar{\rho}(t)}}$ fluctuations oscillate with decreasing amplitude. Above the Jeans' length, the fluctuations experience power-law growth, rather than the exponential growth we found for static space.

Perturbations from relativistic physics

Relativistic perturbed metric variables and gauges

$$A, B, h_{ij}: \qquad \mathrm{d}s^2 = a^2(\tau)\left[(1+2A)\mathrm{d}\tau^2 - 2B_i\,\mathrm{d}x^i\,\mathrm{d}\tau - (\delta_{ij}+h_{ij})\,\mathrm{d}x^i\,\mathrm{d}x^j\right],$$

$$C, E, E_j, E_{ij}: \qquad h_{ij} = \underbrace{2C\delta_{ij} + 2\partial_{\langle i}\partial_{j\rangle}E}_{\text{scalar}} + \underbrace{2\partial_{(i}\hat{E}_{j)}}_{\text{vector}} + \underbrace{2\hat{E}_{ij}}_{\text{tensor}},$$

$\mathcal{H} := a'/a$ - the Hubble parameter in conformal time.
Gauge-Invariant perturbations - the Bardeen variables:

$$\begin{aligned}
&\Psi := A + \mathcal{H}(B - E') + (B - E')',\\
&\hat{\Phi}_i := \hat{E}_i' - \hat{B}_i,\\
&\hat{E}_{ij},\\
&\Phi := -C - \mathcal{H}(B - E') + \frac{1}{3}\nabla^2 E.
\end{aligned}$$

Because by

$$X^\mu \mapsto \tilde{X}^\mu \equiv X^\mu + \xi^\mu(\tau, x), \quad \text{where} \quad \xi^0 \equiv T, \quad \xi^i \equiv L^i = \partial^i L + \hat{L}^i$$

$$\begin{aligned}
&A \mapsto A - T' - \mathcal{H}T,\\
&B \mapsto B + T - L', \qquad \hat{B}_i \mapsto \hat{B}_i - \hat{L}_i',\\
&C \mapsto C - \mathcal{H}T - \frac{1}{3}\nabla^2 L,\\
&E \mapsto E - L, \qquad \hat{E}_i \mapsto \hat{E}_i - \hat{L}_i, \qquad \hat{E}_{ij} \mapsto \hat{E}_{ij}
\end{aligned}$$

(something about gauge, прямо лень смотреть это, что-то про калибровки... отдельно нужно дочитывать)
(!!! скоро все другое допишу!!!)
10 degrees of freedom of the metric is decomposed into $4 + 4 + 2$ SVT degrees of freedom:
- scalars: A, B, C, E - vectors: $\hat{B}_i, \hat{E}_i$ - tensors: $\hat{E}_{ij}$

$\mathcal{H} := a'/a$ - the Hubble parameter in conformal time.

Newtonian gauge: $B = E = 0$

$$g_{\mu\nu} = a^2 \begin{pmatrix} 1+2\Psi & 0 \\ 0 & -(1-2\Phi)\delta_{ij} \end{pmatrix}$$

Spatially-flat gauge: $C = E = 0$
Clever people say that Π_{ij} is not important, so from now on $\Pi_{ij} = 0$, this enforces $\Phi = \Psi$.

Relativistic Matter perturbation, adiabatic and isocurvature terms

(допишу скоро очень из Бумана тоже формулы про это, с них я и начал)
(у Лесгоргуеса тоже хорошая теория про это, ее тоже тут напишу!!!)
Modes of observational interest were superhorizon when inflation ended, and inflation provides initial conditions for their subsequent evolution. Superhorizon modes undergo very simple evolution, unaffected by local interactions. In single-field inflation, the time-shifting $\delta\eta(\mathbf{x}) \sim \frac{\delta\phi(\mathbf{x})}{\dot{\phi}^{(0)}}$ is the only degree of freedom that determines superhorizon modes. Initial conditions of this type are called adiabatic.

If the universe contains a number of uncoupled perfect fluids (labeled by an index x) with sound speeds $c_x^2 = \delta P_x/\delta\rho_x$, we find for superhorizon modes

$$\rho_x(\eta,\mathbf{x}) = \rho_x^{(0)}(\eta+\delta\eta(\mathbf{x})) = \rho_x^{(0)}(\eta) + \dot\rho_x^{(0)}(\eta)\delta\eta(\mathbf{x}),$$
$$P_x(\eta,\mathbf{x}) = P_x^{(0)}(\eta+\delta\eta(\mathbf{x})) = P_x^{(0)}(\eta) + \dot P_x^{(0)}(\eta)\delta\eta(\mathbf{x}).$$

$$\dot\rho_x^{(0)} = -3\frac{\dot a}{a}\left(\rho_x^{(0)} + P_x^{(0)}\right), \qquad \text{(energy conserv-n.)}$$
$$\frac{\delta\rho_x}{\rho_x^{(0)}+P_x^{(0)}} = -3\frac{\dot a}{a}\frac{\delta\rho_x}{\dot\rho_x^{(0)}} = -3\frac{\dot a}{a}\delta\eta(\mathbf{x}),$$

Using the equations of state for matter and radiation, this implies (still for superhorizon modes)

$$\delta = \delta_b = \frac{3}{4}\delta_\nu = \frac{3}{4}\delta_\gamma.$$

(!!! выведу, это не очевидно вообще!)

Einstein's equations can be used to show that, for superhorizon modes during radiation domination,

$$\Psi = -\frac{1}{2}\delta_\gamma = \text{ constant}.$$

(??? how???)

In general, superhorizon metric and density perturbations are constant except when the equation of state changes.

Perturbed relativistic continuity, Euler and Einstein equations

From the $\nu = 0$ of $\nabla_\mu T^\mu{}_\nu = 0$ we get relativistic continuity eq.:

$$\bar\rho' = -3\mathcal{H}(\bar\rho+\bar P) \qquad \text{0-th or-er cont eq}$$
$$\delta\rho' = -3\mathcal{H}(\delta\rho+\delta P) + 3\Phi'(\bar\rho+\bar P) - \nabla\cdot\boldsymbol{q}. \qquad \text{1-st or-er cont eq}$$

$$\delta \equiv \frac{\delta\rho}{\bar\rho} \quad \text{and} \quad \boldsymbol{v} = \frac{\boldsymbol{q}}{\bar\rho+\bar P}$$
$$\delta' + \left(1+\frac{\bar P}{\bar\rho}\right)(\boldsymbol{\nabla}\cdot\boldsymbol{v} - 3\Phi') + 3\mathcal{H}\left(\frac{\delta P}{\delta\rho} - \frac{\bar P}{\bar\rho}\right)\delta = 0.$$

In the limit $P \ll \rho$, we have corrected Newtonian continuity equation in conformal time $\delta' + \boldsymbol{\nabla}\cdot\boldsymbol{v} - 3\Phi' = 0$.

From $\nabla_\mu T^\mu{}_\nu = 0$ the $\nu = i$ component we get relativistic Euler eq.:

$$\boldsymbol{v}' + \mathcal{H}\boldsymbol{v} - 3\mathcal{H}\frac{\bar P'}{\bar\rho'}\boldsymbol{v} = -\frac{\boldsymbol{\nabla}\delta P}{\bar\rho+\bar P} - \nabla\Psi.$$

Perturbed relativistic Einstein equations

The trace-free part of the ij equation, $G_{ij} = 8\pi G T_{ij}$:

$$\partial_{\langle i}\partial_{j\rangle}(\Phi-\Psi) = 0.$$

(if we have drop anisotropic stress at r.h.s.)

$G_{00} = 8\pi G T_{00}$:

$$\nabla^2\Phi = 4\pi G a^2\bar\rho\delta + 3\mathcal{H}\left(\Phi' + \mathcal{H}\Phi\right)$$

$G_{0i} = 8\pi G T_{0i}$:

$$\Phi' + \mathcal{H}\Phi = -4\pi G a^2(\bar\rho+\bar P)v$$

00-th equation:

$$\nabla^2\Phi = 4\pi G a^2 \bar{\rho}\Delta,$$
$$\bar{\rho}\Delta := \bar{\rho}\delta - 3\mathcal{H}(\bar{\rho}+\bar{P})v$$

trace-part of the ij equation, i.e. $G^i_i = 8\pi G T^i{}_i$.

$$\Phi'' + 3\mathcal{H}\Phi' + \left(2\mathcal{H}' + \mathcal{H}^2\right)\Phi = 4\pi G a^2 \delta P$$

Because

$$\Gamma^0_{00} = \mathcal{H} + \Psi', \qquad \Gamma^0_{0i} = \partial_i\Psi, \qquad \Gamma^i_{00} = \delta^{ij}\partial_j\Psi,$$
$$\Gamma^i_{j0} = \mathcal{H}\delta^i_j - \Phi'\delta^i_j, \qquad \Gamma^i_{jk} = -2\delta^i_{(j}\partial_{k)}\Phi + \delta_{jk}\delta^{il}\partial_l\Phi. \qquad \Gamma^0_{ij} = \mathcal{H}\delta_{ij} - \left[\Phi' + 2\mathcal{H}(\Phi+\Psi)\right]\delta_{ij}$$

$$\begin{aligned}
R_{00} =& -3\mathcal{H}' + \nabla^2\Psi + 3\mathcal{H}\left(\Phi' + \Psi'\right) + 3\Phi'' \\
R_{0i} =& 2\partial_i\Phi' + 2\mathcal{H}\partial_i\Psi \\
R_{ij} =& \mathcal{H}' + 2\mathcal{H}^2 - \Phi'' + \nabla^2\Phi - 2\left(\mathcal{H}' + 2\mathcal{H}^2\right)(\Phi+\Psi) - \mathcal{H}\Psi' - 5\mathcal{H}\Phi'\big]\,\delta_{ij} + \partial_i\partial_j(\Phi - \Psi).
\end{aligned}$$

$$a^2 R = -6\left(\mathcal{H}' + \mathcal{H}^2\right) + 2\nabla^2\Psi - 4\nabla^2\Phi + 12\left(\mathcal{H}' + \mathcal{H}^2\right)\Psi + 6\Phi'' + 6\mathcal{H}\left(\Psi' + 3\Phi'\right)$$

$$\begin{aligned}
G_{00} &= 3\mathcal{H}^2 + 2\nabla^2\Phi - 6\mathcal{H}\Phi' \\
G_{0i} &= 2\partial_i\left(\Phi' + \mathcal{H}\Psi\right). \\
G_{ij} &= -\left(2\mathcal{H}' + \mathcal{H}^2\right)\delta_{ij} + \big[\nabla^2(\Psi - \Phi) + 2\Phi'' + 2\left(2\mathcal{H}' + \mathcal{H}^2\right)(\Phi + \Psi) + 2\mathcal{H}\Psi' + 4\mathcal{H}\Phi'\big]\delta_{ij} + \partial_i\partial_j(\Phi - \Psi)
\end{aligned}$$

Also

$$T_{0i} = g_{0\mu}T^\mu_i = g_{00}T^0_i = \bar{g}_{00}T^0_i = -a^2 q_i$$

$$T^i_i = -3(\bar{P} + \delta P)$$

Summary of Einstein eq. by Dodelson

In this definitions of scalar metric perturbations

$$g_{00}(\vec{x},t) \equiv -1 - 2\Psi(\vec{x},t) \qquad g_{ij}(\vec{x},t) \equiv a^2\delta_{ij}(1 + 2\Phi(\vec{x},t)). \qquad g_{0i}(\vec{x},t) \equiv 0$$

In Fourier space $G_{\mu\nu} = 8\pi G T_{\mu\nu}$ relate perturbations in the metric to perturbations in the matter and radiation by:

$$k^2\Phi + 3\frac{\dot{a}}{a}\left(\dot{\Phi} - \Psi\frac{\dot{a}}{a}\right) = 4\pi G a^2\left[\rho_{\rm m}\delta_m + 4\rho_r\Theta_{r,0}\right]$$
$$k^2(\Phi + \Psi) = -32\pi G a^2\rho_r\Theta_{r,2}$$

"m" - all matter (baryons and dark matter), "r" - all radiation (neutrinos and photons):

$$\rho_{\rm m}\delta_m := \rho_{\rm dm}\delta + \rho_b\delta_{\rm b}; \qquad \rho_r\Theta_{r,0} := \rho_\gamma\Theta_0 + \rho_\nu\mathcal{N}_0$$
$$\rho_{\rm m}v_m := \rho_{\rm dm}v + \rho_b v_{\rm b}; \qquad \rho_r\Theta_{r,1} := \rho_\gamma\Theta_1 + \rho_\nu\mathcal{N}_1$$

Some of the other components of Einstein's equation are redundant, but sometimes one is more useful than another.

For example, one combination of these equations leads to an algebraic equation for the potential,

$$k^2\Phi = 4\pi G a^2\left[\rho_{\rm m}\delta_m + 4\rho_r\Theta_{r,0} + \frac{3aH}{k}\left(i\rho_{\rm m}v_m + 4\rho_r\Theta_{r,1}\right)\right]$$

Other components of Einstein's equation contain information about vector and tensor perturbations. Scalar, vector, and tensor perturbations are decoupled: each evolves independently of the others.

Tensor perturbations are characterized by h_+ and $h_\cdot$; each of these evolves independently and satisfies

$$\ddot{h}_\alpha + 2\frac{\dot{a}}{a}\dot{h}_\alpha + k^2 h_\alpha = 0 \qquad \alpha := +, \times$$

In an expanding universe, this equation tells that amplitude of a gravitational wave falls off once the mode enters the horizon.

On Conserved Curvature Perturbation and its conservation

$$\gamma_{ij} \equiv a^2\left[(1+2C)\delta_{ij} + 2E_{ij}\right] \qquad E_{ij} \equiv \partial_{\langle i}\partial_{j\rangle}E$$

$$\text{curvature perturbation} = C - \frac{1}{3}\nabla^2 E.$$

$${}^{(3)}\Gamma^i_{jk},\ R_{(3)},\ \partial_i\partial_j E^{ij} == \frac{2}{3}\nabla^4 E \Rightarrow \qquad a^2 R_{(3)} = -4\nabla^2\left(C - \frac{1}{3}\nabla^2 E\right).$$

Gauge-invariant comoving curvature perturbation:

$$\mathcal{R} := C - \frac{1}{3}\nabla^2 E + \mathcal{H}(B+v) \quad \text{comoving gauge } \left(B_i = 0 = q^i\right)$$

Because (!!?! see exercises??!??)

$$\mathcal{R} = -\Phi + \mathcal{H}v \qquad (\text{Newtonian gauge } B = E = 0, C \equiv -\Phi)$$

we put v from $0i$ Einstein eq. $\Phi' + \mathcal{H}\Phi = -4\pi G a^2(\bar{\rho} + \bar{P})v$:

$$\mathcal{R} = -\Phi - \frac{\mathcal{H}\left(\Phi' + \mathcal{H}\Phi\right)}{4\pi G a^2(\bar{\rho} + \bar{P})},$$

from it by $\frac{d}{d\eta}$ and not trivial transformations and input of other equations:

$$-4\pi G a^2(\bar{\rho} + \bar{P})\mathcal{R}' = \mathcal{H}\frac{\bar{P}'}{\bar{\rho}'}\nabla^2\Phi + 4\pi G a^2 \mathcal{H}\delta P_{\text{nad}}$$

$$\delta P_{\text{nad}} := \delta P - \frac{\bar{P}'}{\bar{\rho}'}\delta\rho. \quad \text{(non-adiabat pressure perturb-n)}$$

δP_{nad} vanishes, if $P = P(\rho)$ (barotropic liquid). In that case, $\mathcal{H}\frac{\bar{P}'}{\bar{\rho}'}\nabla^2\Phi \sim \mathcal{H}k^2\Phi \sim \mathcal{H}k^2\mathcal{R}$,

$$\frac{d\ln\mathcal{R}}{d\ln a} \sim \left(\frac{k}{\mathcal{H}}\right)^2.$$

Thus $\mathcal{R}$ doesn't evolve on super-Hubble scales, $k \ll \mathcal{H}$ and we use it for connection perturbations in different times.

Setup for Scalar Perturbations from inflation from energy-momenta tensor by Dodelson

Scalar Field Perturbations around a Smooth Background

$$\phi(\vec{x},t) = \phi^{(0)}(t) + \delta\phi(\vec{x},t),$$

$$T^{\mu}_{\nu;\mu} = \frac{\partial T^{\mu}{}_{\nu}}{\partial x^{\mu}} + \Gamma^{\mu}{}_{\alpha\mu}T^{\alpha}{}_{\nu} - \Gamma^{\alpha}_{\nu\mu}T^{\mu}_{\alpha} = 0.$$

$$0 = \frac{\partial \delta T^{0}_{0}}{\partial t} + ik_i \delta T^{i}{}_{0} + 3H\delta T^{0}{}_{0} - H\delta T^{i}{}_{i}.$$

$$\delta T^{i}{}_{0} = \frac{ik_i}{a^3}\dot{\phi}^{(0)}\delta\phi.$$

$$T^{0}{}_{0} = \frac{-1}{2}\left(\phi^{(0)}_{,0} + \delta\phi_{.0}\right)^2 - \frac{1}{2a^2}\delta\phi_{.i}\delta\phi_{.i} - V\left(\phi^{(0)} + \delta\phi\right).$$

$$\delta T^{0}_{0} = \frac{-\dot{\phi}^{(0)}\dot{\delta}\phi}{a^2} - V'\delta\phi.$$

$$\delta T^{i}{}_{j} = \delta_{ij}\left(\frac{\dot{\phi}^{(0)}\dot{\delta}\phi}{a^2} - V'\delta\phi\right).$$

The conservation equation:

$$\left(\frac{1}{a}\frac{\partial}{\partial\eta} + 3H\right)\left(\frac{-\dot{\phi}^{(0)}\dot{\delta}\phi}{a^2} - V'\delta\phi\right) - \frac{k^2}{a^3}\dot{\phi}^{(0)}\delta\phi - 3H\left(\frac{\dot{\phi}^{(0)}\dot{\delta}\phi}{a^2} - V'\delta\phi\right) = 0.$$

Carrying out the time derivatives (the only subtle one is $\partial V'/\partial\eta = V''\dot{\phi}^{(0)}$), multiplying by a^3, and collecting terms leads to

$$-\dot{\phi}^{(0)}\ddot{\delta}\phi + \dot{\delta}\phi\left(-\ddot{\phi}^{(0)} - 4aH\dot{\phi}^{(0)} - a^2V'\right) + \delta\phi\left(-a^2V''\dot{\phi}^{(0)} - k^2\dot{\phi}^{(0)}\right) = 0$$

$$\ddot{\delta\phi} + 2aH\dot{\delta}\phi + k^2\delta\phi = 0.$$

ations to $\delta\phi$ is identical to Eq. is we can trivially copy our rest e power spectrum of fluctuatio

$$P_{\delta\phi} = \frac{H^2}{2k^3}.$$

Super-Horizon Perturbations

$$\frac{\partial \delta T^{0}{}_{0}}{\partial t} + ik_i\delta T^{i}{}_{0} + 3H\delta T^{0}{}_{0} - H\delta T^{i}{}_{i} = -3(\mathcal{P}+\rho)\frac{\partial\Psi}{\partial t}$$

and ρ are the zero-order pressure and energy density.

$$\Psi \ll \frac{\delta T^{0}{}_{0}}{\mathcal{P}+\rho}.$$

$$k^2\Psi + 3aH(\dot{\Psi} + aH\Psi) = 4\pi G a^2 \delta T^{0}{}_{0}.$$

$$\Psi \sim G\frac{\delta T^0{}_0}{H^2} \sim \frac{\delta T^0{}_0}{\rho} = \frac{\mathcal{P}+\rho}{\rho}\left(\frac{\delta T^0{}_0}{\mathcal{P}+\rho}\right).$$

One way to deal with the coupling between the metric perturbations and those to the energy density is to define

$$\zeta \equiv -\frac{ik_i\delta T^0{}_i H}{k^2(\rho+\mathcal{P})} - \Psi.$$

For sub-horizon modes and those which have just left the horizon, Ψ is negligible; $P+\rho = \left(\dot{\phi}^{(0)}/a\right)^2$ from Eqs. (6.26) and (6.27); and Eq. (6.64) fixes the numerator of the first term in ζ. We are left with

$$\zeta = -aH\delta\phi/\dot{\phi}^{(0)}$$

around the time of horizon crossing. After inflation ends, $ik_i\delta T^0{}_i = 4ak\rho_r\Theta_1$, proportional to the dipole of the radiation. Since the pressure of radiation is equal to a third of the energy density,

$$\begin{aligned}\zeta &= -\frac{3aH\Theta_1}{k} - \Psi \\ &= -\frac{3}{2}\Psi \quad \text{(post inflation)}.\end{aligned}$$

The second equality follows from the initial conditions relating the dipole to the potential (Eq. (6.16)).

The variable ζ is so important because it is conserved when the perturbation moves outside the horizon (Figure 6.8). We will show that ζ is conserved shortly, but first let's appreciate the importance of this conservation. Since we know that, after inflation, $\zeta = -3\Psi/2$, we can immediately relate Ψ coming out of inflation to the $\delta\phi$ at horizon crossing,

$$\Psi|_{\text{post inflation}} = \frac{2}{3}aH\frac{\delta\phi}{\dot{\phi}^{(0)}}\bigg|_{\text{horizon crossing}}.$$

$$P_\Psi = \frac{4}{9}\left(\frac{aH}{\dot{\phi}^{(0)}}\right)^2 P_{\delta\phi}\bigg|_{aH=k}$$

It remains to prove that ζ is conserved on super-horizon scales. To see this, let's turn to the conservation equation, Eq. (6.73). On large scales, $k_i\delta T^i{}_0$ is proportional to k^2 and so can be ignored, leaving

$$\frac{\partial\delta T^0{}_0}{\partial t} + 3H\delta T^0{}_0 - H\delta T^i{}_i = -3(\mathcal{P}+\rho)\frac{\partial\Psi}{\partial t}.$$

On large scales, you will show (Exercise 13) that the energy-momentum tensor satisfies

$$\frac{ik_i\delta T^0{}_i H}{k^2} = \frac{\delta T^0{}_0}{3}.$$

Therefore, on large scales

$$\zeta = -\Psi - \frac{1}{3}\frac{\delta T^0{}_0}{\rho+\mathcal{P}}.$$

Eliminating Ψ in favor of ζ in the conservation equation leads to

$$\frac{\partial\delta T^0{}_0}{\partial t} + 3H\delta T^0{}_0 - H\delta T^i{}_i = 3(\mathcal{P}+\rho)\frac{\partial\zeta}{\partial t} + (\rho+\mathcal{P})\frac{\partial}{\partial t}\left[\frac{\delta T^0{}_0}{\rho+\mathcal{P}}\right].$$

The partial derivative on the right acting on $\delta T^0{}_0$ cancels the first term on the left, leaving

$$\delta T^0{}_0 \left[3H + \frac{1}{\rho+\mathcal{P}}\left(\frac{d\rho}{dt} + \frac{d\mathcal{P}}{dt}\right)\right] - H\delta T^i{}_i = 3(\mathcal{P}+\rho)\frac{\partial\zeta}{\partial t}.$$

Recall from Eq. (2.55) that $d\rho/dt = -3H(\rho+\mathcal{P})$, so the first term in brackets cancels the second, and

$$\frac{\partial\zeta}{\partial t} = \frac{-1}{3(\rho+\mathcal{P})^2}\left[H(\rho+\mathcal{P})\delta T^i{}_i - \delta T^0{}_0\frac{d\mathcal{P}}{dt}\right]$$

Spatially Flat Slicing

$$ds^2 = -(1+2A)dt^2 - 2aB_{,i}dx^i dt + \delta_{ij}a^2 dx^i dx^j$$

$$v = ikB - \frac{ik\dot{\phi}^{(0)}\delta\phi}{(\rho+\mathcal{P})a^2} \quad \text{(spatially flat slicing)}$$

where I have evaluated $\delta T^0{}_i$ with Eq. (6.64). Thus, we can create a gauge-invariant variable proportional to $\delta\phi$ in a spatially flat slicing if we subtract off the kB term. Bardeen's Φ_H (Eq. (5.76)) is simply equal to aHB, so the combination

$$\zeta \equiv -\Phi_H - \frac{iaH}{k}v$$

is gauge invariant and in spatially flat slicing is equal to

$$\zeta = -\frac{aH}{\dot{\phi}^{(0)}}\delta\phi \quad \text{(spatially flat slicing).}$$

1.3.3 Initial conditions from inflaton fluctuations

Classical inhomogeneous inflaton field Oscillators and Mukhanov-Sasaki equation

$$\phi(\tau,\boldsymbol{x}) \equiv \bar{\phi}(\tau) + \frac{f(\tau,\boldsymbol{x})}{a(\tau)}$$

$$S = \int \mathrm{d}\tau\mathrm{d}^3x\sqrt{-g}\left[\tfrac{1}{2}g^{\mu\nu}\partial_\mu\phi\partial_\nu\phi - V(\phi)\right] \overset{\text{FRLW}}{=} \int \mathrm{d}\tau\mathrm{d}^3x\left[\tfrac{1}{2}a^2\left((\phi')^2 - (\nabla\phi)^2\right) - a^4V(\phi)\right] \qquad \text{(real t.)}$$

$$S^{(1)} = -\int \mathrm{d}\tau\mathrm{d}^3x a\left[\bar{\phi}'' + 2\mathcal{H}\bar{\phi}' + a^2V_{,\phi}\right]f \qquad \Rightarrow \quad \bar{\phi}'' + 2\mathcal{H}\bar{\phi}' + a^2V_{,\phi} = 0 \qquad \text{(real t.)}$$

$$S^{(2)} \overset{\text{int b p}}{=} \frac{1}{2}\int \mathrm{d}\tau\mathrm{d}^3x\left[(f')^2 - (\nabla f)^2 + \left(\frac{a''}{a} - a^2V_{,\phi\phi}\right)f^2\right]. \qquad \text{(real t.)}$$

Also we neglect the term $a^2V_{,\phi\phi}$, because during slow-roll inflation $\frac{V_{,\phi\phi}}{H^2} \approx \frac{3M_{\rm pl}^2V_{,\phi\phi}}{V} = 3\eta_{\rm v} \ll 1$. Also, since $a' = a^2H$, with $H \approx$ const., we also have $\frac{a''}{a} \approx 2a'H = 2a^2H^2 \gg a^2V_{,\phi\phi}$. For this action the Euler-Lagrange equation gives the Mukhanov-Sasaki equation $f'' - \nabla^2 f - \frac{a''}{a}f = 0$, or for each mode:

$$f_k'' + \left(k^2 - \frac{a''}{a}\right)f_k = 0$$

On subhorizon scales, $k^2 \gg a''/a \approx 2\mathcal{H}^2$, the Mukhanov-Sasaki equation reduces to

$$f_k'' + k^2 f_k \approx 0.$$

We see that each Fourier mode satisfies the equation of motion of a simple harmonic oscillator, with frequency $\omega_k = k$. Quantum zero-point fluctuations of these oscillators provide the origin of structure in the universe.

(?? может, что-то еще допишу, просто вывели уравнения и все.)

Quantum Fluctuations in de Sitter Space

Canonical Quantisation

$$\left[\hat{f}(\tau,\boldsymbol{x}),\hat{\pi}\left(\tau,\boldsymbol{x}'\right)\right]=i\delta\left(\boldsymbol{x}-\boldsymbol{x}'\right)\qquad\left[\hat{f}_k(\tau),\hat{\pi}_{\boldsymbol{k}'}(\tau)\right]=i\delta\left(\boldsymbol{k}+\boldsymbol{k}'\right)$$

$$\hat{f}_k(\tau)=f_k(\tau)\hat{a}_{\boldsymbol{k}}+f_k^*(\tau)a_{\boldsymbol{k}}^\dagger,$$

$$f_k''+\omega_k^2(\tau)f_k=0,\qquad\omega_k^2(\tau):=k^2-\frac{a''}{a}$$

$$\left[\hat{a}_{\boldsymbol{k}},\hat{a}_{\boldsymbol{k}'}^\dagger\right]=\delta\left(\boldsymbol{k}+\boldsymbol{k}'\right)$$

$$\hat{a}_k|0\rangle=0,$$

$$|m_{\boldsymbol{k}_1},n_{\boldsymbol{k}_2},\cdots\rangle=\frac{1}{\sqrt{m!n!\cdots}}\left[\left(a_{\boldsymbol{k}_1}^\dagger\right)^m\left(a_{\boldsymbol{k}_2}^\dagger\right)^n\cdots\right]|0\rangle.$$

Choice of Vacuum

At sufficiently early times (large negative conformal time τ) all modes of cosmological interest were deep inside the horizon, $k/\mathcal{H}\sim|k\tau|\gg1$,

$$\omega_k^2=k^2-\frac{a''}{a}\approx k^2-\frac{2}{\tau^2}\overset{\tau\to-\infty}{\longrightarrow}k^2,$$

and the Mukhanov-Sasaki equation reduces to

$$f_k''+k^2f_k\approx0$$

$$f_k\propto e^{\pm ik\tau}$$

$$\lim_{\tau\to-\infty}f_k(\tau)=\frac{1}{\sqrt{2k}}e^{-ik\tau}\qquad\text{(init. cond, unique physical Bunch-Davies vacuum.)}$$

(???? main words, what is it????)

$$f_k(\tau)=\frac{e^{-ik\tau}}{\sqrt{2k}}\left(1-\frac{i}{k\tau}\right).$$

Zero-Point Fluctuations

$$f_k(\tau)=\frac{e^{-ik\tau}}{\sqrt{2k}}\left(1-\frac{i}{k\tau}\right)=\left\langle|\hat{f}|^2\right\rangle:=\left\langle0\left|\hat{f}^\dagger(\tau,\boldsymbol{0})\hat{f}(\tau,\boldsymbol{0})\right|0\right\rangle$$

$$\Delta_f^2(k,\tau):=\frac{k^3}{2\pi^2}\left|f_k(\tau)\right|^2$$

$$\Delta_{\delta\phi}^2(k)\approx\left.\left(\frac{H}{2\pi}\right)^2\right|_{k=aH}$$

Quantum-to-Classical Transition (??????)

(??? how does it work, in 2 line???)

$$\hat{f}(\tau,\boldsymbol{x}) = \int \frac{\mathrm{d}^3k}{(2\pi)^{3/2}} \left[f_k(\tau)\hat{a}_{\boldsymbol{k}} + f_k^*(\tau)a_{\boldsymbol{k}}^\dagger \right] e^{i\boldsymbol{k}\cdot\boldsymbol{x}}$$
$$\hat{\pi}(\tau,\boldsymbol{x}) = \int \frac{\mathrm{d}^3k}{(2\pi)^{3/2}} \left[f_k'(\tau)\hat{a}_{\boldsymbol{k}} + f_k^{*\prime}(\tau)a_{\boldsymbol{k}}^\dagger \right] e^{i\boldsymbol{k}\cdot\boldsymbol{x}}$$

In the superhorizon limit, $k\tau \to 0$, we have

$$f_k(\tau) \approx -\frac{1}{\sqrt{2}k^{3/2}}\frac{i}{\tau} \qquad \text{and} \qquad f_k'(\tau) \approx \frac{1}{\sqrt{2}k^{3/2}}\frac{i}{\tau^2}$$

$$\hat{f}(\tau,\boldsymbol{x}) = -\frac{i}{\sqrt{2}\tau}\int \frac{\mathrm{d}^3k}{(2\pi)^{3/2}}\frac{1}{k^{3/2}} \left[\hat{a}_{\boldsymbol{k}} - a_{\boldsymbol{k}}^\dagger \right] e^{i\boldsymbol{k}\cdot\boldsymbol{x}},$$
$$\hat{\pi}(\tau,\boldsymbol{x}) = \frac{i}{\sqrt{2}\tau^2}\int \frac{\mathrm{d}^3k}{(2\pi)^{3/2}}\frac{1}{k^{3/2}} \left[\hat{a}_{\boldsymbol{k}} - a_{\boldsymbol{k}}^\dagger \right] e^{i\boldsymbol{k}\cdot\boldsymbol{x}} = -\frac{1}{\tau}\hat{f}(\tau,\boldsymbol{x}).$$

Now,

$$\begin{aligned}\langle 0|\delta\phi(\eta,\mathbf{x})\delta\phi(\eta,\mathbf{y})|0\rangle &= \frac{1}{a^2(\eta)}\int\frac{d^3k}{(2\pi)^{3/2}}\int\frac{d^3k'}{(2\pi)^{3/2}}\chi_{\mathbf{k}}(\eta)\chi_{\mathbf{k}'}^*(\eta)e^{i\mathbf{k}\cdot\mathbf{x}}e^{-i\mathbf{k}'\cdot\mathbf{y}}\delta\left(\mathbf{k}-\mathbf{k}'\right)\\ &= \int\frac{d^3k}{(2\pi)^3}e^{i\mathbf{k}\cdot(\mathbf{x}-\mathbf{y})}\frac{|\chi_{\mathbf{k}}(\eta)|^2}{a^2(\eta)}.\end{aligned}$$

Comparing with $\xi_f(\mathbf{x},\mathbf{y}) = \int \frac{dk}{k}\frac{\sin(kr)}{kr}\frac{k^3\sigma_k^2}{2\pi^2}$, and using $\langle f_{\mathbf{k}}f_{\mathbf{k}'}\rangle \equiv (2\pi)^3 P_f(k)\delta\left(\mathbf{k}+\mathbf{k}'\right)$, $\chi_{\mathbf{k}} = \frac{1}{\sqrt{2k}}\left(1-\frac{i}{k\eta}\right)e^{-ik\eta}$ and $a(\eta) = -\frac{1}{H\eta}$, we get

$$P_{\delta\phi}(k) = \sigma_k^2 = \frac{1}{2k}\left(H^2\eta^2 + \frac{H^2}{k^2}\right) \approx \frac{H^2}{2k^3},$$

where in the last step we ignored the first term. To justify this, note that given a distance $r \equiv |\mathbf{x}-\mathbf{y}|$, the integral (48) will mainly get contributions from $k \leq 1/r$ (the high k contributions tend to cancel each other because of the oscillatory integrand).

From scalar field perturbations to density perturbations

When connecting the theory of inflation to observations, we will be interested in metric perturbations long after inflation has ended, for instance at the time of recombination, when the CMB photons were emitted. At the end of inflation, the energy stored in the potential of the inflaton is converted into radiation and matter (reheating). "Initial conditions" produced by inflation can be reliably propagated to later times by identifying a quantity that is conserved for superhorizon modes, independently of the details of reheating.

For a mode deep inside the horizon during SR inflation:

$$-\frac{k^2}{a^2}\Psi = 4\pi G\delta\rho, \qquad \text{(Poiss. eq for gr pot } \Psi\text{)}$$

and to estimate orders of magnitude we can continue to use this equation up to the time of horizon crossing, $k^2 \sim a^2H^2$. For a mode crossing the horizon:

$$\Psi \sim G\frac{\delta\rho}{H^2} \sim \frac{\delta\rho}{\rho},$$

and before horizon crossing Ψ was even smaller.

For a slowly rolling scalar field, the energy density is dominated by the potential, $\rho = V(\phi)$ (????? this is an important formula, why it is so???), this how the scalar field fluctuations give rise to density perturbations

$$\delta\rho = V'\left(\phi^{(0)}\right)\delta\phi, \qquad \frac{\delta\rho}{\rho} = \frac{V'\left(\phi^{(0)}\right)}{V\left(\phi^{(0)}\right)}\delta\phi \sim \sqrt{G\epsilon}\delta\phi,$$

which thus also have a scale invariant power spectrum.

It can be checked (?? how?) that the resulting metric perturbation Ψ can be ignored in the equation of motion of the scalar field, which justifies a posteriori our computation, where we considered a scalar field in an exponentially expanding homogeneous spacetime, ignoring the backreaction of the scalar on the metric.

Space-dependent fluctuations $\delta\phi$ of the inflaton cause different spatial regions to reach this critical value of the inflaton at different times, with time delay

$$\delta\eta(\mathbf{x}) \sim \frac{\delta\phi(\mathbf{x})}{\dot{\phi}^{(0)}}.$$

More longer inflation in some regions causes space to curve, this curvature will lead to perturbations in the gravitational potential Ψ after inflation has ended.

Общие важные вопросы про квантовые флуктуации в начале Вселенной

Не бред ли, что квантовые осцилляции были настолько большими, что так сильно действовали? (?????)

(тут ответ на этот важный вопрос. наверняка есть большое обсуждение этого)

1.3.4 Derivations of full perturbed Boltzmann and Einstain eq. in a nutshell (!??!)

(это пока не актуально, тут пока углубления Додельсона, и без них можно многое важное понять по упрощенным лекциям. потом тут будут указания про более глубокое решение этой же задачи.)

Method

$$\begin{aligned}
\dot{\Theta}_{r.0} + k\Theta_{r.1} &= -\dot{\Phi} \\
\dot{\Theta}_{r.1} - \frac{k}{3}\Theta_{r,0} &= \frac{-k}{3}\Phi \\
\dot{\delta} + ikv &= -3\dot{\Phi} \\
\dot{v} + \frac{\dot{a}}{a}v &= ik\Phi.
\end{aligned}$$

$$k^2\Phi + 3\frac{\dot{a}}{a}\left(\dot{\Phi} + \frac{\dot{a}}{a}\Phi\right) = 4\pi G a^2\left[\rho_{\mathrm{dm}}\delta + 4\rho_r\Theta_{r,0}\right].$$

$$k^2\Phi = 4\pi G a^2\left[\rho_{\mathrm{dm}}\delta + 4\rho_r\Theta_{r,0} + \frac{3aH}{k}\left(i\rho_{\mathrm{dm}}v + 4\rho_r\Theta_{r,1}\right)\right]$$

Idea of expansion in modes (!!!???)

(общее важное соображение, которое там потом везде и используется, допишу потом)

Boltzmann equations for fluctuations by Dodelson

(это же в доп. кинетике укажу!)

SUMMARY BOLTZMANN EQUATIONS by Dodelson

$$\Theta_0(\vec{x},t) \equiv \frac{1}{4\pi}\int d\Omega' \Theta\left(\hat{p}',\vec{x},t\right). \qquad \text{(monopole)}$$

$$\Theta_1 \equiv i\int_{-1}^{1}\frac{d\mu}{2}\mu\Theta(\mu) \qquad \text{(dipole)}$$

$$\Theta_l := \frac{1}{(-i)^l}\int_{-1}^{1}\frac{d\mu}{2}\mathcal{P}_l(\mu)\Theta(\mu)$$

Photon perturbations can be described either by $\Theta(k,\mu,\eta)$ or by a whole hierarchy of moments, $\Theta_l(k,\eta)$. Same is for neutrino distribution.

strength of the polarization is Θ_P.

$$\dot{\Theta}+ik\mu\Theta = -\dot{\Phi}-ik\mu\Psi-\dot{\tau}\left[\Theta_0-\Theta+\mu v_{\rm b}-\frac{1}{2}\mathcal{P}_2(\mu)\Pi\right] \qquad \text{(Boltz. eq. for photons)}$$

$$\Pi = \Theta_2+\Theta_{P2}+\Theta_{P0}$$

$$\dot{\Theta}_P+ik\mu\Theta_P = -\dot{\tau}\left[-\Theta_P+\frac{1}{2}\left(1-\mathcal{P}_2(\mu)\right)\Pi\right]$$

$$\dot{\delta}+ikv = -3\dot{\Phi}$$

$$\dot{v}+\frac{\dot{a}}{a}v = -ik\Psi$$

$$\dot{\delta}_{\rm b}+ikv_{\rm b} = -3\dot{\Phi}$$

$$\dot{v}_{\rm b}+\frac{\dot{a}}{a}v_{\rm b} = -ik\Psi+\frac{\dot{\tau}}{R}\left[v_{\rm b}+3i\Theta_1\right] \qquad \frac{1}{R} := \frac{4\rho_\gamma^{(0)}}{3\rho_b^{(0)}}$$

$$\dot{\mathcal{N}}+ik\mu\mathcal{N} = -\dot{\Phi}-ik\mu\Psi. \qquad (\mathcal{N}\text{ - neutrinos distr. pert., no scatt.})$$

(!! допишу лучше потом, в чем смысл каждого ур-я???)

THE BOLTZMANN EQUATION FOR THE HARMONIC OSCILLATOR

$$\frac{\partial f}{\partial t}+\frac{p}{m}\frac{\partial f}{\partial x}-kx\frac{\partial f}{\partial p}=0.$$

$$\frac{df(t,x,p)}{dt} = \frac{\partial f}{\partial t}+\frac{\partial f}{\partial x}\frac{dx}{dt}+\frac{\partial f}{\partial p}\frac{dp}{dt}.$$

$$E=\frac{p^2}{2m}+\frac{1}{2}kx^2. \qquad \frac{dx}{dt}\equiv\frac{p}{m}. \qquad \frac{dp}{dt}=-kx$$

$$f(p,x) = f_{\rm EQ}(E)$$

$$\frac{p}{m}\frac{\partial f(E)}{\partial x}-kx\frac{\partial f(E)}{\partial p} = \frac{df}{dE}\left[\frac{p}{m}\frac{\partial E}{\partial x}-kx\frac{\partial E}{\partial p}\right]$$
$$= 0.$$

THE COLLISIONLESS BOLTZMANN EQUATION FOR PHOTONS

$$\frac{df}{dt} = \frac{\partial f}{\partial t} + \frac{\partial f}{\partial x^i}\cdot\frac{dx^i}{dt} + \frac{\partial f}{\partial p}\frac{dp}{dt} + \frac{\partial f}{\partial \hat{p}^i}\cdot\frac{d\hat{p}^i}{dt}$$

$$P^i \equiv C\hat{p}^i.$$

$$\begin{aligned} p^2 &= g_{ij}\hat{p}^i\hat{p}^j C^2 \\ &= a^2(1+2\Phi)\delta_{ij}\hat{p}^i\hat{p}^j C^2 \\ &= a^2(1+2\Phi)C^2 \end{aligned}$$

$C = p(1-\Phi)/a$

$$P^i = p\hat{p}^i\frac{1-\Phi}{a}.$$

$$\frac{dx^i}{dt} = \frac{\hat{p}^i}{a}(1+\Psi-\Phi).$$

$$\frac{d}{dt}[p(1-\Psi)] = -\Gamma^0{}_{\alpha\beta}\frac{P^\alpha P^\beta}{p}(1+\Psi).$$

$$\frac{dp}{dt}(1-\Psi) = p\frac{d\Psi}{dt} - \Gamma^0{}_{\alpha\beta}\frac{P^\alpha P^\beta}{p}(1+\Psi).$$

multiply both sides by $(1+\Psi)$; drop all terms quadratic in Ψ; and reexpress the total time derivative of Ψ in terms of partial derivatives so that

$$\frac{dp}{dt} = p\left\{\frac{\partial\Psi}{\partial t} + \frac{\hat{p}^i}{a}\frac{\partial\Psi}{\partial x^i}\right\} - \Gamma^0{}_{\alpha\beta}\frac{P^\alpha P^\beta}{p}(1+2\Psi).$$

(дальше еще какие-то преобразования, словами напишу потом)

$$\frac{1}{p}\frac{dp}{dt} = -H - \frac{\partial\Phi}{\partial t} - \frac{\hat{p}^i}{a}\frac{\partial\Psi}{\partial x^i}.$$

$$\frac{df}{dt} = \frac{\partial f}{\partial t} + \frac{\hat{p}^i}{a}\frac{\partial f}{\partial x^i} - p\frac{\partial f}{\partial p}\left[H + \frac{\partial\Phi}{\partial t} + \frac{\hat{p}^i}{a}\frac{\partial\Psi}{\partial x^i}\right] \qquad \text{(Boltzmann eq. for photons)}$$

$$f(\vec{x},p,\hat{p},t) = \left[\exp\left\{\frac{p}{T(t)[1+\Theta(\vec{x},\hat{p},t)]}\right\} - 1\right]^{-1}$$

$$\begin{aligned} f &\simeq \frac{1}{e^{p/T}-1} + \left(\frac{\partial}{\partial T}\left[\exp\left\{\frac{p}{T}\right\} - 1\right]^{-1}\right)T\Theta \\ &= f^{(0)} - p\frac{\partial f^{(0)}}{\partial p}\Theta. \qquad f^{(0)} \equiv \left[\exp\left\{\frac{p}{T}\right\} - 1\right]^{-1} \end{aligned}$$

Now,

$$\dot{\tilde{v}}_{\rm b} + \frac{\dot{a}}{a}\tilde{v}_{\rm b} + ik\tilde{\Psi} = \dot{\tau}\frac{4\rho_\gamma}{3\rho_b}\left[3i\tilde{\Theta}_1 + \tilde{v}_{\rm b}\right] \qquad \text{(conf time)}$$

$$\left.\frac{df}{dt}\right|_{\text{zero order}} = \frac{\partial f^{(0)}}{\partial t} - Hp\frac{\partial f^{(0)}}{\partial p} = 0$$

$$\left.\frac{df}{dt}\right|_{\text{first order}} = -p\frac{\partial f^{(0)}}{\partial p}\left[\frac{\partial\Theta}{\partial t} + \frac{\hat{p}^i}{a}\frac{\partial\Theta}{\partial x^i} + \frac{\partial\Phi}{\partial t} + \frac{\hat{p}^i}{a}\frac{\partial\Psi}{\partial x^i}\right].$$

(with words I'll here explain a derivation in Dodelson)

COLLISION TERMS: COMPTON SCATTERING

$$C[f(\vec{p})] = \sum_{\vec{q},\vec{q}',\vec{p}'} \mid \text{Amplitude } \mid^2 \{f_e(\vec{q}')\, f(\vec{p}') - f_e(\vec{q}) f(\vec{p})\}$$

$$C[f(\vec{p})] = \frac{1}{p}\int \frac{d^3q}{(2\pi)^3 2E_e(q)} \int \frac{d^3q'}{(2\pi)^3 2E_e(q')} \int \frac{d^3p'}{(2\pi)^3 2E(p')} |\mathcal{M}|^2 (2\pi)^4 \times$$
$$\times \delta^3[\vec{p}+\vec{q}-\vec{p}'-\vec{q}']\, \delta[E(p)+E_e(q)-E(p')-E_e]\, (q') \left\{f_e(\vec{q}')\, f(\vec{p}') - f_e(\vec{q}) f(\vec{p})\right\}.$$

$$C[f(\vec{p})] = \frac{\pi}{4m_e^2 p}\int \frac{d^3q}{(2\pi)^3}\frac{d^3p'}{(2\pi)^3 p'} \delta\left[p + \frac{q^2}{2m_e} - p' - \frac{(\vec{q}+\vec{p}-\vec{p}')^2}{2m_e}\right] |\mathcal{M}|^2 \Big\{ f_e(\vec{q}+\vec{p}-\vec{p}')\, f(\vec{p}') - f_e(\vec{q}) f(\vec{p}) \Big\}$$

(снова, словами напишу, что происходит, всякие преобразования)

$$C[f(\vec{p})] = \frac{n_e \sigma_T}{p} \int_0^\infty dp' p' \left[\delta(p-p')\left(-p' \frac{\partial f^{(0)}}{\partial p'}\Theta_0 + p \frac{\partial f^{(0)}}{\partial p}\Theta(\hat{p})\right) + \vec{p}\cdot\vec{v}_{\rm b} \frac{\partial \delta(p-p')}{\partial p'}\left(f^{(0)}(p') - f^{(0)}(p)\right)\right]$$

$$C[f(\vec{p})] = -p\frac{\partial f^{(0)}}{\partial p} n_e \sigma_T \left[\Theta_0 - \Theta(\hat{p}) + \hat{p}\cdot\vec{v}_{\rm b}\right]$$

(??? тут картинка есть про монополь, которую я не понимаю.)

THE BOLTZMANN EQUATION FOR PHOTONS

$$\dot{\Theta} + \hat{p}^i \frac{\partial \Theta}{\partial x^i} + \dot{\Phi} + \hat{p}^i \frac{\partial \Psi}{\partial x^i} = n_e \sigma_T a \left[\Theta_0 - \Theta + \hat{p}\cdot\vec{v}_{\rm b}\right]. \qquad \text{(conf. t.)}$$

$$\dot{\tilde{\Theta}} + ik\mu\tilde{\Theta} + \dot{\tilde{\Phi}} + ik\mu\tilde{\Psi} = -\dot{\tau}\left[\tilde{\Theta}_0 - \tilde{\Theta} + \mu\tilde{v}_{\rm b}\right].$$

$$\dot{\tau} \equiv \frac{d\tau}{d\eta} = -n_e\sigma_T a.$$

$$\tau(\eta) \equiv \int_\eta^{\eta_0} d\eta' n_e \sigma_T a$$

(допишу слова про смысл происходящего)

THE BOLTZMANN EQUATION FOR COLD DARK MATTER

$$P^\mu = \left[E(1-\Psi), p\hat{p}^i \frac{1-\Phi}{a}\right].$$

$$\frac{df_{\rm dm}}{dt} = \frac{\partial f_{\rm dm}}{\partial t} + \frac{\partial f_{\rm dm}}{\partial x^i}\frac{dx^i}{dt} + \frac{\partial f_{\rm dm}}{\partial E}\frac{dE}{dt} + \frac{\partial f_{\rm dm}}{\partial \hat{p}^i}\frac{d\hat{p}^i}{dt}$$

$$\frac{\partial f_{\rm dm}}{\partial t} + \frac{\hat{p}^i}{a}\frac{p}{E}\frac{\partial f_{\rm dm}}{\partial x^i} - \frac{\partial f_{\rm dm}}{\partial E}\left[\frac{da/dt}{a}\frac{p^2}{E} + \frac{p^2}{E}\frac{\partial\Phi}{\partial t} + \frac{\hat{p}^i p}{a}\frac{\partial\Psi}{\partial x^i}\right] = 0$$

$$n_{\rm dm} = \int \frac{d^3p}{(2\pi)^3} f_{\rm dm}$$

$$v^i \equiv \frac{1}{n_{\rm dm}}\int \frac{d^3p}{(2\pi)^3} f_{\rm dm}\frac{p\hat{p}^i}{E}$$

$$\frac{\partial n_{\rm dm}}{\partial t}+\frac{1}{a}\frac{\partial\left(n_{\rm dm}v^i\right)}{\partial x^i}+3\left[\frac{da/dt}{a}+\frac{\partial\Phi}{\partial t}\right]n_{\rm dm}=0$$

$$\frac{\partial n^{(0)}_{\rm dm}}{\partial t}+3\frac{da/dt}{a}n^{(0)}_{\rm dm}=0$$

$$n_{\rm dm}=n^{(0)}_{\rm dm}[1+\delta(\vec{x},t)]$$

$$\frac{\partial\delta}{\partial t}+\frac{1}{a}\frac{\partial v^i}{\partial x^i}+3\frac{\partial\Phi}{\partial t}=0$$

(дальше словами)

$$\frac{\partial\left(n_{\rm dm}v^j\right)}{\partial t}+4\frac{da/dt}{a}n_{\rm dm}v^j+\frac{n_{\rm dm}}{a}\frac{\partial\Psi}{\partial x^j}=0.$$

$$\frac{\partial v^j}{\partial t}+\frac{da/dt}{a}v^j+\frac{1}{a}\frac{\partial\Psi}{\partial x^j}=0$$

$$\dot{\tilde{\delta}}+ik\tilde{v}+3\dot{\tilde{\Phi}}=0$$

$$\dot{\tilde{v}}+\frac{\dot{a}}{a}\tilde{v}+ik\tilde{\Psi}=0.$$

THE BOLTZMANN EQUATION FOR BARYONS

Electrons and protons are coupled by Coulomb scattering ($e+p\rightarrow e+p$).

$$\frac{\rho_e-\rho_e^{(0)}}{\rho_e^{(0)}}=\frac{\rho_p-\rho_p^{(0)}}{\rho_p^{(0)}}\equiv\delta_b$$

(словами про вывод)

$$\frac{\partial n_e}{\partial t}+\frac{1}{a}\frac{\partial\left(n_ev^i_{\rm b}\right)}{\partial x^i}+3\left[\frac{da/dt}{a}+\frac{\partial\Phi}{\partial t}\right]n_e=\left\langle c_{ep}\right\rangle_{QQ'q'q}+\left\langle c_{e\gamma}\right\rangle_{pp'q'q}$$

$$\dot{\tilde{\delta}}_b+ik\tilde{v}_{\rm b}+3\dot{\tilde{\Phi}}=0$$

(словами про вывод)

$$\frac{\partial v^j_{\rm b}}{\partial t}+\frac{da/dt}{a}v^j_{\rm b}+\frac{1}{a}\frac{\partial\Psi}{\partial x^j}=\frac{1}{\rho_b}\left\langle c_{e\gamma}q^j\right\rangle_{pp'q'q}$$

$$\dot{v}_{\rm b}+\frac{\dot{a}}{a}\tilde{v}_{\rm b}+ik\tilde{\Psi}=\dot{\tau}\frac{4\rho_\gamma}{3\rho_b}\left[3i\tilde{\Theta}_1+\tilde{v}_{\rm b}\right]$$

THE EINSTEIN-BOLTZMANN EQUATIONS AT EARLY TIMES

(следующая часть Додельсона, просто относится к этой теме)

$$\dot{\Theta}_0 + \dot{\Phi} = 0$$
$$\dot{\mathcal{N}}_0 + \dot{\Phi} = 0.$$
$$\dot{\delta} = -3\dot{\Phi}$$
$$\dot{\delta}_{\rm b} = -3\dot{\Phi}.$$

$$3\frac{\dot{a}}{a}\left(\dot{\Phi} - \frac{\dot{a}}{a}\Psi\right) = 16\pi G a^2 \left(\rho_\gamma \Theta_0 + \rho_\nu \mathcal{N}_0\right)$$

But since radiation dominates, $a \propto \eta$ (recall Eq. (2.100) and the discussion immediately afterward) so $\dot{a}/a = 1/\eta$. Therefore,

$$\frac{\dot{\Phi}}{\eta} - \frac{\Psi}{\eta^2} = \frac{16\pi G\rho a^2}{3}\left(\frac{\rho_\gamma}{\rho}\Theta_0 + \frac{\rho_\nu}{\rho}\mathcal{N}_0\right) = \frac{2}{\eta^2}\left(\frac{\rho_\gamma}{\rho}\Theta_0 + \frac{\rho_\nu}{\rho}\mathcal{N}_0\right)$$

where the last equality follows by virtue of the zero-order Einstein equation.

To simplify further, we can define the ratio of neutrino energy density to the total radiation density as

$$f_\nu \equiv \frac{\rho_\nu}{\rho_\gamma + \rho_\nu}.$$

Then multiplying Eq. (6.4) by η^2 leads to

$$\dot{\Phi}\eta - \Psi = 2\left(\left[1 - f_\nu\right]\Theta_0 + f_\nu \mathcal{N}_0\right).$$

Recall that Eq. (6.1) relates the derivative of the monopoles to the derivative of the potential. We can therefore eliminate both monopoles from Eq. (6.6) by differentiating both right- and left-hand sides. Then,

$$\ddot{\Phi}\eta + \dot{\Phi} - \dot{\Psi} = -2\dot{\Phi}$$

where the right-hand side follows since both $\dot{\Theta}_0$ and $\dot{\mathcal{N}}_0$ are equal to $-\dot{\Phi}$ for these large scale modes.

So far we have used only one Einstein equation. The second, Eq. (5.33), describes how the higher moments of the photon and neutrino distributions cause $\Psi + \Phi$ to be nonzero. Let us here neglect these higher order moments, which cause the sum of the gravitational potentials to be slightly nonzero. [1] Under this approximation, we can eliminate Ψ everywhere by simply setting it to $-\Phi$. Then,

$$\ddot{\Phi}\eta + 4\dot{\Phi} = 0.$$

Setting $\Phi = \eta^p$ leads to the algebraic equation

$$p(p-1) + 4p = 0$$

$$\Theta_1 = \mathcal{N}_1 = \frac{iv_{\rm b}}{3} = \frac{iv}{3}$$
$$= -\frac{k\Phi}{6aH}.$$

ζ conservation for superhorizon modes and power spectrum $P_\Psi(k)$

Fluctuations generated during inflation are related to the metric perturbations that they generate at later times by

$$\zeta := -\Psi + \frac{1}{3}\frac{\delta\rho}{\rho + P} \qquad \text{constant for sup-hor modes.}$$

It doesn't depend on the eq. of state.

During slow-roll inflation, for modes inside the horizon and those which have just left the horizon, $\Psi \approx 0$. From $\delta\rho = V'\left(\phi^{(0)}\right)\delta\phi$ and $d\rho/dt = -3H(\rho + P)$

$$\zeta = -aH\frac{\delta\phi}{\dot{\phi}^{(0)}} \qquad \text{(during inflation).}$$

$$\zeta = -\frac{3}{2}\Psi \qquad \text{(after inflation).} \qquad \Psi = -\frac{1}{2}\delta_\gamma = \text{ constant}$$

(!!! еще раз решу это скоро!!!)

The conservation of ζ for superhorizon modes gives $\Psi(\delta\phi)$, with it from definitions we get a relation between the post-inflation power spectrum of Ψ and the power spectrum of $\delta\phi$ at horizon crossing during inflation:

$$P_\Psi(k) = \frac{4}{9}\left(\frac{aH}{\dot{\phi}^{(0)}}\right)^2 P_{\delta\phi}\bigg|_{aH=k}.$$

$$4\pi G\left(\dot{\phi}^{(0)}\right)^2 = \epsilon a^2 H^2 \qquad \Rightarrow \qquad P_\Psi(k) = \frac{16\pi G}{9\epsilon}P_{\delta\phi}\bigg|_{aH=k} = \frac{8\pi G H^2}{9\epsilon k^3}\bigg|_{aH=k}.$$

Here little ϵ is in the denominator, thus the gravitational potential induced by the time delay much larger than the metric perturbations during inflation. The flatter the potential, the longer it takes to cover an additional distance in ϕ space and the more curvature is generated by additional inflation.

(relations of power spectrum from Dodelson)

We can immediately relate the power in ζ to the power in $\delta\phi$,

$$P_\zeta = \left(\frac{aH}{\dot{\phi}^{(0)}}\right)^2 P_{\delta\phi}.$$

We know $P_{\delta\phi}$ from Eq. (6.72) and the prefactor is $4\pi G/\epsilon$, so

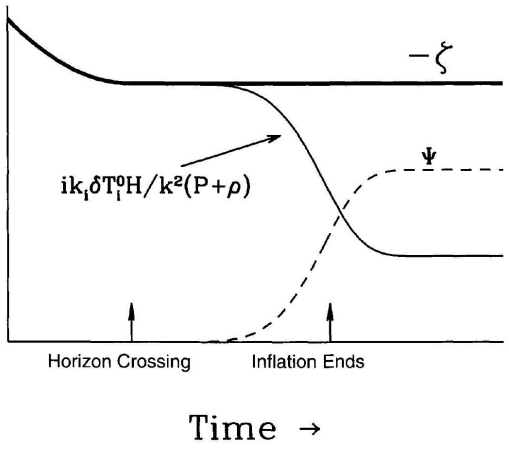
$$P_\zeta = \frac{2\pi G H^2}{\epsilon k^3}\bigg|_{aH=k}.$$

Equation (6.96) is very useful, for it expresses the power spectrum of a gauge invariant quantity. Although we computed it in a gauge of the form in Eq. (6.91), once we have this answer, we can compute ζ in any gauge and then relate the power in the perturbation variables of that gauge to P_ζ.

Throughout this book, we have been working in conformal Newtonian gauge. In this gauge, $\Phi_H = -\Phi$, so ζ as defined in Eq. (6.93) is indeed given by Eq. (6.77). We argued in Section 6.5.2 that in conformal Newtonian gauge, after inflation, $\zeta = 3\Phi/2$, so $P_\Phi = 4P_\zeta/9$, or using Eq. (6.96),

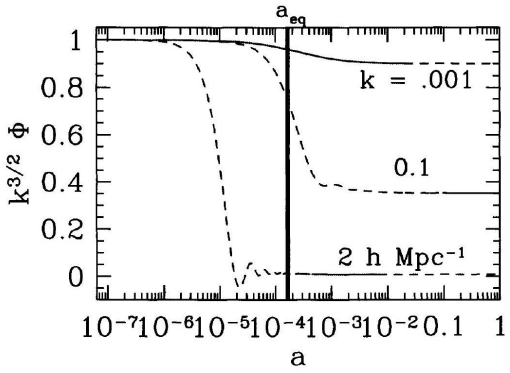
$$P_\Phi = \frac{8\pi G H^2}{9\epsilon k^3}\bigg|_{aH=k}$$

in exact agreement with our earlier calculation finalized in Eq. (6.82).



1.3.5 Dynamics of fluctuations, power spectrum and spectral indexes

Evolution of gravitational potential fluctuations



Inflation sets the initial condition for these superhorizon modes Φ in Newtonian gauge

$$\mathcal{R} = -\Phi - \frac{2}{3(1+w)}\left(\frac{\Phi'}{\mathcal{H}} + \Phi\right)$$

$$\Phi'' + 3(1+w)\mathcal{H}\Phi' + wk^2\Phi = 0$$

Superhorizon Limit

$k \ll \mathcal{H}$,

$$\Phi = \text{ const.} \qquad \text{(superhorizon)}$$

$$\delta = -\frac{2}{3}\frac{k^2}{\mathcal{H}^2}\Phi - \frac{2}{\mathcal{H}}\Phi' - 2\Phi \qquad \text{(Poisson eq)}$$

$$\delta \approx -2\Phi = \text{ const.}$$

$$\delta_m = \frac{3}{4}\delta_r \approx -\frac{3}{2}\Phi_{\rm RD},$$

Radiation-to-Matter Transition

$$\mathcal{R} = -\frac{5+3w}{3+3w}\Phi \quad \text{(superhorizon)} \qquad \mathcal{R} := -\Phi - \frac{\mathcal{H}\left(\Phi' + \mathcal{H}\Phi\right)}{4\pi G a^2(\bar{\rho}+\bar{P})}$$

$$\mathcal{R} = -\frac{3}{2}\Phi_{\rm RD} = -\frac{5}{3}\Phi_{\rm MD} \Rightarrow \Phi_{\rm MD} = \frac{9}{10}\Phi_{\rm RD},$$

Gravitational potential fluctuations in Radiation Era

$w = \frac{1}{3}$, we get

$$\Phi'' + \frac{4}{\tau}\Phi' + \frac{k^2}{3}\Phi = 0$$

$$\Phi_k(\tau) = A_k\frac{j_1(x)}{x} + B_k\frac{n_1(x)}{x}, \quad x := \frac{1}{\sqrt{3}}k\tau$$

here $j_1(x) = \frac{\sin x}{x^2} - \frac{\cos x}{x} = \frac{x}{3} + \mathcal{O}\left(x^3\right)$, $n_1(x) = -\frac{\cos x}{x^2} - \frac{\sin x}{x} = -\frac{1}{x^2} + \mathcal{O}\left(x^0\right)$.

$$\Phi_k(\tau) = -2\mathcal{R}_k(0)\left(\frac{\sin x - x\cos x}{x^3}\right) \quad \text{(all scales)}$$

$$\Phi_{\boldsymbol{k}}(\tau) \approx -6\mathcal{R}_{\boldsymbol{k}}(0)\frac{\cos\left(\frac{1}{\sqrt{3}}k\tau\right)}{(k\tau)^2} \quad \text{(subhorizon)}$$

During the radiation era, subhorizon modes of Φ therefore oscillate with frequency $\frac{1}{\sqrt{3}}k$ and an amplitude that decays as $\tau^{-2} \propto a^{-2}$ (see fig. 5.2). Remember this.

Gravitational potential fluctuations in Matter Era

$w = 0$,

$$\Phi'' + \frac{6}{\tau}\Phi' = 0$$

$$\Phi \propto \begin{cases} \text{const.} \\ \tau^{-5} \propto a^{-5/2} \end{cases}$$

Evolution of radiation fluctuations

Acoustic oscillations in the perturbed radiation density are what gives rise to the peaks in the spectrum of CMB anisotropies
(??? plot???])

radiation fluctuations in Radiation Era

In radiation era for all scales $\Phi_k(\tau) = -2\mathcal{R}_k(0)\left(\frac{\sin x - x\cos x}{x^3}\right)$, so from the Poisson equation

$$\delta_r = -\frac{2}{3}(k\tau)^2\Phi - 2\tau\Phi' - 2\Phi,$$
$$\Delta_r = -\frac{2}{3}(k\tau)^2\Phi.$$

(??? why?? what is Δ_r???)
Outside the horizon δ_r is constant, Δ_r grows as $\tau^2 \propto a^2$.

Inside the horizon,

$$\delta_r \approx \Delta_r = -\frac{2}{3}(k\tau)^2\Phi = 4\mathcal{R}(0)\cos\left(\frac{1}{\sqrt{3}}k\tau\right),$$

which is the solution to

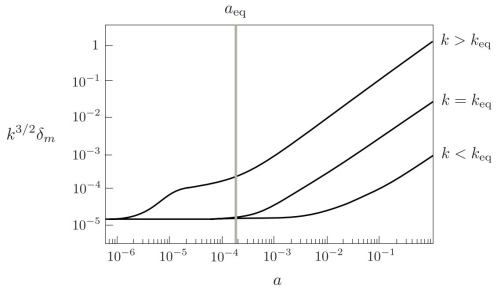
$$\delta_r'' - \frac{1}{3}\nabla^2\delta_r = 0$$

We see that subhorizon fluctuations in the radiation density oscillate with constant amplitude around $\delta_r = 0$.

radiation fluctuations in Matter Era

$$\left.\begin{array}{l}\text{(C) } \delta_r' = -\frac{4}{3}\boldsymbol{\nabla}\cdot\boldsymbol{v}_r \\ \text{(E) } \boldsymbol{v}_r' = -\frac{1}{4}\boldsymbol{\nabla}\delta_r - \boldsymbol{\nabla}\Phi\end{array}\right\} \quad \delta_r'' - \frac{1}{3}\nabla^2\delta_r = \frac{4}{3}\nabla^2\Phi \quad = \text{ const.}$$

Evolution of dark matter fluctuations



The effects we discussed above lead to a post-processing of the primordial perturbations. This evolution is often encoded in the so-called transfer function. For example, the value of the matter perturbation at redshift z is related to the primordial perturbation $\mathcal{R}_{\boldsymbol{k}}$ by

$$\Delta_{m,k}(z) = T(k,z)\mathcal{R}_k$$

$$P_\Delta(k,z) := |\Delta_{m,k}(z)|^2 = T^2(k,z)\,|\mathcal{R}_k|^2$$

Harrison-Zel'dovich plot shows predicted matter power spectrum for scale-invariant initial conditions, $k^3\,|\mathcal{R}_k|^2 = \text{const}$:

$$P_\Delta(k) = \begin{cases} k & k < k_{\rm eq} \\ k^{-3} & k > k_{\rm eq}\end{cases}$$

(??? why sc inv is important??? why inflation gives exactly this spectrum?????)

dark matter fluctuations at Early Times

$$\mathcal{H}^2 = \frac{\mathcal{H}_0^2\Omega_m^2}{\Omega_r}\left(\frac{1}{y}+\frac{1}{y^2}\right), \quad y := \frac{a}{a_{\rm eq}}$$

$$\left.\begin{array}{l}\text{(C) } \delta_m' = -\boldsymbol{\nabla}\cdot\boldsymbol{v}_m \\ \text{(E) } \boldsymbol{v}_m' = -\mathcal{H}\boldsymbol{v}_m - \boldsymbol{\nabla}\Phi\end{array}\right\} \quad \delta_m'' + \mathcal{H}\delta_m' = \nabla^2\Phi$$

$$\delta_m'' + \mathcal{H}\delta_m' - 4\pi G a^2\bar{\rho}_m\delta_m \approx 0$$

or in Mészáros (Meszaros) equation

$$\frac{d^2\delta_m}{dy^2} + \frac{2+3y}{2y(1+y)}\frac{d\delta_m}{dy} - \frac{3}{2y(1+y)}\delta_m = 0.$$

$$\delta_m \propto \begin{cases} 2+3y \\ (2+3y)\ln\left(\frac{\sqrt{1+y}+1}{\sqrt{1+y}-1}\right) - 6\sqrt{1+y} \end{cases}$$

dark matter fluctuations at Intermediate Times

$$\Delta_m = \frac{\nabla^2\Phi}{4\pi G a^2\bar{\rho}} \propto \begin{cases} a \\ a^{-3/2} \end{cases}$$

dark matter fluctuations at Late Times

$$\nabla^2\Phi = 4\pi G a^2 \bar{\rho}_m \Delta_m$$

Pressure fluctuations are negligible, so the Einstein equations give

$$\Phi'' + 3\mathcal{H}\Phi' + \left(2\mathcal{H}' + \mathcal{H}^2\right)\Phi = 0$$

To get an evolution equation for Δ_m, we use a neat trick. Since $a^2\bar{\rho}_m \propto a^{-1}$, we have $\Phi \propto \Delta_m/a$. Hence, eq. (5.2.28) implies

$$\partial_\tau^2\left(\Delta_m/a\right) + 3\mathcal{H}\partial_\tau\left(\Delta_m/a\right) + \left(2\mathcal{H}' + \mathcal{H}^2\right)\left(\Delta_m/a\right) = 0$$

which rearranges to

$$\Delta_m'' + \mathcal{H}\Delta_m' + \left(\mathcal{H}' - \mathcal{H}^2\right)\Delta_m = 0$$

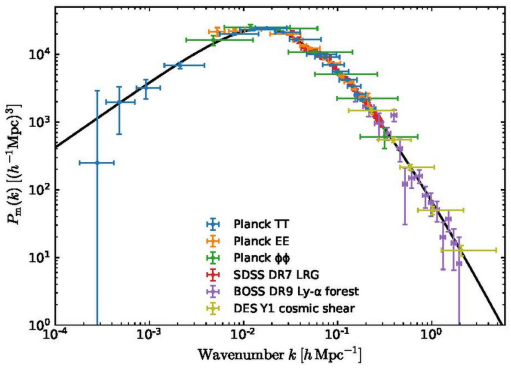
Exercise. - Show that (5.2.30) follows from (5.2.29). Use the Friedmann and conservation equations to show that

$$\mathcal{H}' - \mathcal{H}^2 = -4\pi G a^2(\bar{\rho} + \bar{P}) = -4\pi G a^2\bar{\rho}_m$$

Using (5.2.31), eq. (5.2.30) becomes

$$\Delta_m'' + \mathcal{H}\Delta_m' - 4\pi G a^2\bar{\rho}_m\Delta_m = 0.$$

Power Spectrum from DM



The matter power spectrum $P_\Delta(k)$ at $z = 0$ in linear theory (solid) and with non-linear corrections (dashed). On large scales, $P_\Delta(k)$ grows as k. The power spectrum turns over around

$k_{\rm eq} \sim 0.01{\rm Mpc}^{-1}$ corresponding to the horizon size at matter-radiation equality. Beyond the peak, the power falls as k^{-3}. Visible are small amplitude baryon acoustic oscillations in the spectrum.

(??? описание и качественное объяснение графика!)

From

$$\ddot{h} + 2\frac{\dot{a}}{a}\dot{h} + k^2 h = 0.$$

$$\tilde{h} := \frac{ah}{\sqrt{16\pi G}}$$

$$\hat{\tilde{h}}(\vec{k},\eta) = v(k,\eta)\hat{a}_{\vec{k}} + v^*(k,\eta)a^\dagger_{\vec{k}},$$

where the coefficients of the creation and annihilation operators satisfy the equation

$$\ddot{v} + \left(k^2 - \frac{\ddot{a}}{a}\right) v = 0.$$

$$v = \frac{e^{-ik\eta}}{\sqrt{2k}}\left[1 - \frac{i}{k\eta}\right]$$

$$\left\langle \hat{\tilde{h}}^\dagger(\vec{k},\eta)\hat{\tilde{h}}(\vec{k}',\eta)\right\rangle = |v(\vec{k},\eta)|^2(2\pi)^3\delta^3(\vec{k}-\vec{k}') = \frac{16\pi G}{a^2}|v(k,\eta)|^2(2\pi)^3\delta^3(\vec{k}-\vec{k}')$$
$$:= (2\pi)^3 P_h(k)\delta^3(\vec{k}-\vec{k}')$$

(тут у нас $k\eta \ll 1$ что ли, поэтому числитель 1????)

$$P_h(k) = \frac{16\pi G}{a^2}\frac{1}{2k^3\eta^2}$$
$$= \frac{8\pi G H^2}{k^3}.$$

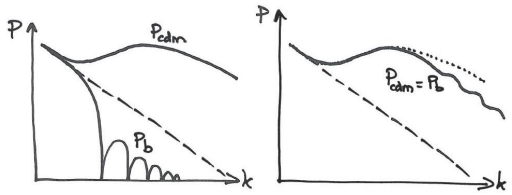


Fig. 14. Shape of the matter power spectrum $P(k)$ (log-log scale) at four different times: (upper left) when initial conditions are imposed (and all wavenumbers are super-Hubble); (upper right) at radiation/matter equality (arrows show the logarithmic growth during radiation domination); (lower left) at matter /Λ equality (lower set of arrows show the growth during matter domination); (lower right) today (lower set of arrows show the growth during Λ domination).

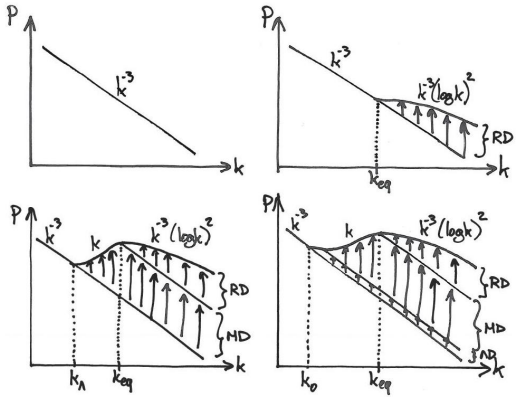
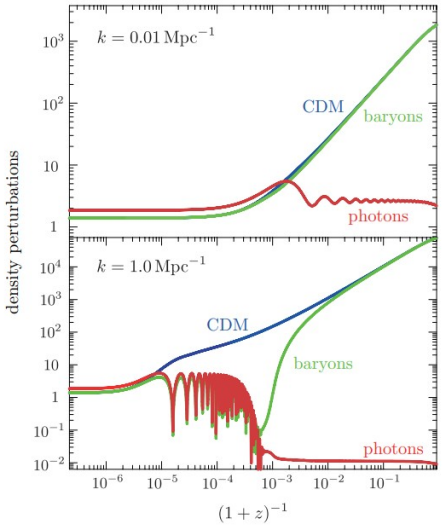


(I'll add description from Lesgourgues later, now it is not needed)

On other topics about fluctuation

Evolution of Baryons fluctuation (?)



(это не нужно, потом мб почитаю, пока не планирую)

$$D'' + \frac{2}{\tau} D' = 0 \Rightarrow D \propto \begin{cases} \text{const.} \\ \tau^{-1} \end{cases},$$

of δ_m is governed

$$\delta_m'' + \frac{2}{\tau}\delta_m' - \frac{6}{\tau^2}\delta_m = 0 \quad \Rightarrow \quad \delta_m \propto \begin{cases} \tau^2 \\ \tau^{-3} \end{cases}.$$

$$\frac{\delta_b}{\delta_c} = \frac{\bar{\rho}_m \delta_m + \bar{\rho}_c D}{\bar{\rho}_m \delta_m - \bar{\rho}_b D} \to \frac{\delta_m}{\delta_m} = 1,$$

Tensors and Lyth bound properties

(here will be a good preparation for section of problems)

The Lyth argument places a theoretical upper bound on the amount of gravitational waves produced during inflation, given the amount of departure from the homogeneity of the cosmic microwave background (CMB).

- During slow-roll inflation, the ratio of gravitational waves to inhomogeneities of the CMB is correlated to the inflationary potential steepness.
- Temperature inhomogeneities of the CMB were successfully and accurately measured in the CMB.
- There are current CMB polarization experiments (see this article for instance for an overview of gravitational wave observatories) aimed at measuring the primordial gravitational wave signature in the CMB.
- However, to date, a significant signal of primordial gravitational waves was not detected. Thus the ratio cannot exceed a certain value.
- Thus the steepness of the inflationary potential is bounded.

$$r \equiv \frac{A_t}{A_s} \overset{\text{SR}}{=} \frac{8\dot{\phi}^2}{M_{\text{pl}}^2 H^2}.$$

The inflaton field travels during (observable) inflation a "distance"

$$\Delta\phi \equiv |\phi_E - \phi_\star| : \qquad \frac{\Delta\phi}{M_{\text{pl}}} = \frac{N_\star}{60}\sqrt{\frac{r}{0.002}},$$

($N_\star$ is the total number of e-folds between the time when the CMB scales exited the horizon and the end of inflation).

$$V^{1/4} = \left(\frac{3\pi^2}{2} r A_s\right)^{1/4} M_{\rm pl.} \approx 3.3 \cdot r^{1/4} \cdot 10^{16}\text{GeV}.$$

This exceeds the highest energy scales that will be probed at the LHC by a factor $\mathcal{O}(10^{13})$!

Dynamics of dark matter on sub-Hubble scales from Newtonian perturbation theory

DM during the radiation-dominated era: from $\ddot{\delta} + 2H\dot{\delta} - \frac{c_s^2}{a^2}\nabla^2\delta = 4\pi G\bar{\rho}\delta$

$$\ddot{\delta}_m + 2H\dot{\delta}_m - 4\pi G \sum_I \bar{\rho}_I \delta_I = 0 \qquad I \in \text{matter, radiation.}$$

$$\ddot{\delta}_m + \frac{1}{t}\dot{\delta}_m - 4\pi G\bar{\rho}_m\delta_m \approx 0.$$

$$\ddot{\delta}_m \sim H^2\delta_m \sim \frac{8\pi G}{3}\bar{\rho}_r\delta_m \gg 4\pi G\bar{\rho}_m\delta_m$$

where we have used that $\bar{\rho}_r \gg \bar{\rho}_m$. We can therefore ignore the last term in (4.1.32) compared to the others. We then find

$$\delta_m \propto \begin{cases} \text{const.} \\ \ln t \propto \ln a \end{cases}.$$

The rapid expansion due to the effectively unclustered radiation reduces the growth of δ_m to only logarithmic. We need to wait until the universe becomes matter dominated in order for the dark matter density fluctuations to grow significantly.

DM during the matter-dominated era: from $\ddot{\delta} + 2H\dot{\delta} - \frac{c_s^2}{a^2}\nabla^2\delta = 4\pi G\bar{\rho}\delta$

$$\ddot{\delta}_m + 2H\dot{\delta}_m - 4\pi G\bar{\rho}_m\delta_m = 0$$

Here $a \propto t^{2/3}$, so $H = 2/3t$ and by $4\pi G\bar{\rho}_m = \frac{3}{2}H^2$

$$\ddot{\delta}_m + \frac{4}{3t}\dot{\delta}_m - \frac{2}{3t^2}\delta_m = 0,$$

$\delta_m \propto t^p$

$$\delta_m \propto \begin{cases} t^{-1} \propto a^{-3/2} \\ t^{2/3} \propto a \end{cases}.$$

Hence, the growing mode of dark matter fluctuations grows like the scale factor during the MD era.

DM during the Λ-dominated era: from $\ddot{\delta} + 2H\dot{\delta} - \frac{c_s^2}{a^2}\nabla^2\delta = 4\pi G\bar{\rho}\delta$

$$\ddot{\delta}_m + 2H\dot{\delta}_m - 4\pi G \sum_i \bar{\rho}_I \delta_I = 0$$

where $I = m, \Lambda$. As far as we can tell, dark energy doesn't cluster (almost by definition), so we can write

$$\ddot{\delta}_m + 2H\dot{\delta}_m - 4\pi G\bar{\rho}_m\delta_m = 0$$

In the Λ dominated regime $H^2 \approx \text{const} \gg 4\pi G\bar{\rho}_m$.

$$\delta_m \propto \begin{cases} \text{const.} \\ e^{-2Ht} \propto a^{-2} \end{cases}$$

Matter fluctuations stop growing once dark energy comes to dominate.

Primordial Perturbations of Curvature

At horizon crossing, we switch from the inflaton fluctuation $\delta\phi$ to the conserved curvature perturbation $\mathcal{R}$. The power spectra of $\mathcal{R}$ and $\delta\phi$ are related via eq. (6.1.7),

$$\Delta^2_{\mathcal{R}} = \frac{1}{2\varepsilon}\frac{\Delta^2_{\delta\phi}}{M^2_{\rm pl}}, \quad \text{where} \quad \varepsilon = \frac{\frac{1}{2}\dot{\phi}^2}{M^2_{\rm pl}H^2}.$$

Substituting (6.4.50), we get

$$\Delta^2_{\mathcal{R}}(k) = \frac{1}{8\pi^2}\frac{1}{\varepsilon}\frac{H^2}{M^2_{\rm pl}}\bigg|_{k=aH}$$

Exercise. - Show that for slow-roll inflation, eq. (6.5.59) can be written as

$$\Delta^2_{\mathcal{R}} = \frac{1}{12\pi^2}\frac{V^3}{M^6_{\rm pl}\left(V'\right)^2}$$

Because the right-hand side of (6.5.59) is evaluated at $k = aH$, the power spectrum is purely a function of k. If $\Delta^2_{\mathcal{R}}(k)$ is k-independent, then we call the spectrum scale-invariant. However, since H and possibly ε are (slowly-varying) functions of time, we predict that the power spectrum will deviate slightly from the scale-invariant form $\Delta^2_{\mathcal{R}} \sim k^0$. Near a reference scale $k_\star$, the k dependence of the spectrum takes a power-law form

$$\Delta^2_{\mathcal{R}}(k) := A_s\left(\frac{k}{k_\star}\right)^{n_s-1}$$

The measured amplitude of the scalar spectrum at $k_\star = 0.05\text{Mpc}^{-1}$ is

$$A_s = (2.196 \pm 0.060)\cdot 10^{-9}$$

To quantify the deviation from scale-invariance we have introduced the scalar spectral index

$$n_s - 1 := \frac{d\ln\Delta^2_{\mathcal{R}}}{d\ln k}$$

where the right-hand side is evaluated at $k = k_\star$ and $n_s = 1$ corresponds to perfect scaleinvariance. We can split (6.5.61) into two factors

$$\frac{d\ln\Delta^2_{\mathcal{R}}}{d\ln k} = \frac{d\ln\Delta^2_{\mathcal{R}}}{dN}\cdot\frac{dN}{d\ln k}$$

The derivative with respect to e-folds is

$$\frac{d\ln\Delta^2_{\mathcal{R}}}{dN} = 2\frac{d\ln H}{dN} - \frac{d\ln\varepsilon}{dN}$$

The first term is just -2ε and the second term is $-\eta$ (see Chapter 2). The second factor in (6.5.62) is evaluated by recalling the horizon crossing condition $k = aH$, or

$$\ln k = N + \ln H$$

Hence, we have

$$\frac{dN}{d\ln k} = \left[\frac{d\ln k}{dN}\right]^{-1} = \left[1 + \frac{d\ln H}{dN}\right]^{-1} \approx 1 + \varepsilon.$$

To first order in the Hubble slow-roll parameters, we therefore find

$$n_s - 1 = -2\varepsilon - \eta.$$

Primordial Perturbations of Gravitational Waves and tensor spectral indexes

$$\mathrm{d}s^2 = a^2(\tau)\left[\mathrm{d}\tau^2 - \left(\delta_{ij} + 2\hat{E}_{ij}\right)\mathrm{d}x^i\ \mathrm{d}x^j\right]$$

$$S = \frac{M_{\rm pl}^2}{2}\int \mathrm{d}^4x\sqrt{-g}R \quad \Rightarrow \quad S^{(2)} = \frac{M_{\rm pl}^2}{8}\int \mathrm{d}\tau\mathrm{d}^3x a^2\left[\left(\hat{E}'_{ij}\right)^2 - \left(\nabla\hat{E}_{ij}\right)^2\right].$$

It is convenient to define

$$\frac{M_{\rm pl}}{2}a\hat{E}_{ij} := \frac{1}{\sqrt{2}}\begin{pmatrix} f_+ & f_\cdot & 0 \\ f_\cdot & -f_+ & 0 \\ 0 & 0 & 0 \end{pmatrix}$$

so that

$$S^{(2)} = \frac{1}{2}\sum_{I=+,\cdot}\int \mathrm{d}\tau\mathrm{d}^3x\left[\left(f'_I\right)^2 - \left(\nabla f_I\right)^2 + \frac{a''}{a}f_I^2\right]$$

$$\Delta_t^2 := 2\cdot\Delta_{\hat{E}}^2 = 2\cdot\left(\frac{2}{aM_{\rm pl}}\right)^2\cdot\Delta_f^2$$

Using (6.4.50), we get

$$\Delta_t^2(k) = \left.\frac{2}{\pi^2}\frac{H^2}{M_{\rm pl}^2}\right|_{k=aH}.$$

This result is the most robust and model-independent prediction of inflation. Notice that the tensor amplitude is a direct measure of the expansion rate H during inflation. This is in contrast to the scalar amplitude which depends on both H and ε.

The scale-dependence of the tensor spectrum is defined by n_t - tensor spectral index:

$$\Delta_t^2(k) := A_t\left(\frac{k}{k_\star}\right)^{n_t}$$

Scale-invariance corresponds to $n_t = 0$.

Tensor-to-scalar ratio is

$$r := \frac{A_t}{A_s}$$

$$r = 16\varepsilon$$
$$n_t = -2\varepsilon$$

Thus always $n_t = -r/8$.

Correlation and concept of power spectrum

(просто мысли Лесгоргуеса впишу и все.)

1.3.6 Details of evolution of fluctuations, other approaches in a nutshell

(now just by Dodelson. это пока не актуально, тут пока углубления Додельсона, и без них можно многое важное понять по упрощенным лекциям. потом тут будут указания про более глубокое решение этой же задачи.)

Transfer Function (!!??!?!?!!?????)

The transfer function for gravity wave evolution as

$$T(k) := \frac{h_\alpha(k,\eta)}{h_\alpha(k,\eta=0)} \left(\frac{k\eta}{3j_1(k\eta)}\right).$$

You should recognize the term in parentheses as the inverse of the matter-dominated solution you derived in Exercise 12. Solve Eq. (5.63) numerically and compute the transfer function. Compare your solution with the fit of Turner, White, and Lidsey (1993),

$$T(y) = \left[1 + 1.34y + 2.5y^2\right]^{1/2}$$

where $y := (k\eta_0/370h)$ (with h parametrizing the Hubble constant). Assume the universe today is flat and matter dominated, but account for transition from matter to radiation.

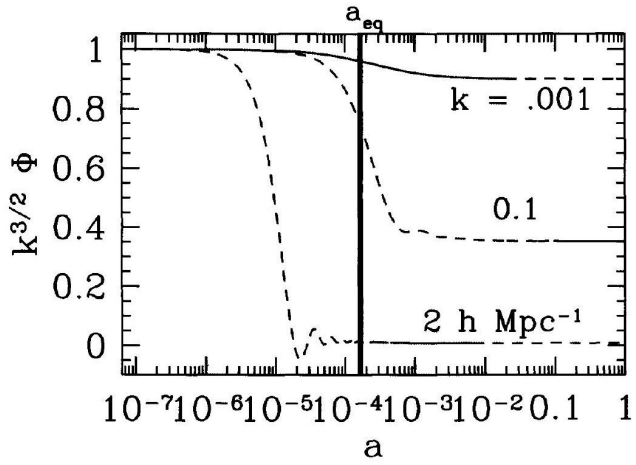


Figure 2: Figure 7.2. The linear evolution of the gravitional potential Φ. Dashed line denotes that the mode has entered the horizon. Evolution through the shaded region is described by the transfer function. The potential is unnormalized, but the relative normalization of the three modes is as it would be for scale-invariant perturbations. Here baryons have been neglected, $\Omega_m = 1$, and $h = 0.5$.

$$\Phi(\vec{k}, a) = \Phi_{\rm p}(\vec{k}) \cdot \{\text{Transfer Function } (k)\} \cdot \{\text{ Growth Function } (a)\}$$

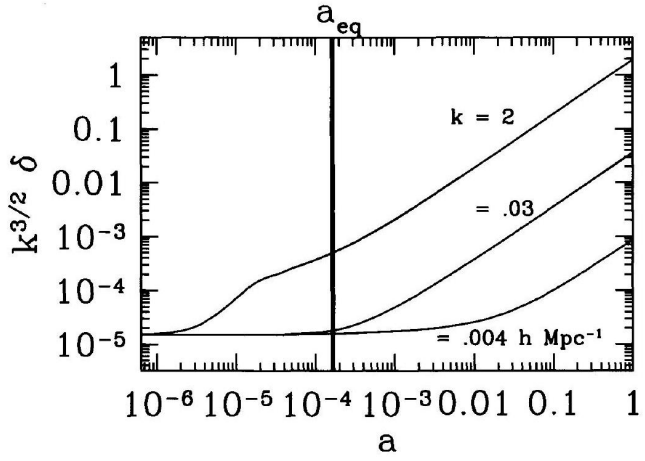
$$T(k) := \frac{\Phi\,(k, a_{\rm late}\,)}{\Phi_{\text{Large-Scale}}\ (k, a_{\rm late}\,)} \qquad \text{(transfer function)}$$

where $a_{\rm late}$ denotes an epoch well after the transfer function regime and the LargeScale solution is the primordial Φ decreased by a small amount. We will derive in Section 7.2 that - neglecting anisotropic stresses - this factor is equal to (9/10). The second caveat concerns the growth function. The ratio of the potential to its value right after the transfer function regime is defined to be

$$\frac{\Phi(a)}{\Phi\,(a_{\rm late}\,)} := \frac{D_1(a)}{a} \quad (a > a_{\rm late}\,),$$

where D_1 is called the growth function. In the flat, matter-dominated case depicted in Figure 7.2, then, the potential is constant so $D_1(a) = a$. With these conventions, we have

$$\Phi(\vec{k}, a) = \frac{9}{10}\Phi_{\rm p}(\vec{k})T(k)\frac{D_1(a)}{a} \quad (a > a_{\rm late}\,)$$



potential at late times is to use Poisson's equation (the large- k, no-radiation limit of Eq. (5.81))

$$\Phi = \frac{4\pi G\rho_{\rm m}a^2\delta}{k^2} \quad (a > a_{\rm late}\,).$$

The background density of matter is $\rho_{\rm m} = \Omega_m\rho_{\rm cr}/a^3$, and $4\pi G\rho_{\rm cr} = (3/2)H_0^2$, so

$$\delta(\vec{k},a) = \frac{k^2\Phi(\vec{k},a)a}{(3/2)\Omega_m H_0^2} \quad (a > a_{\rm late}\,).$$

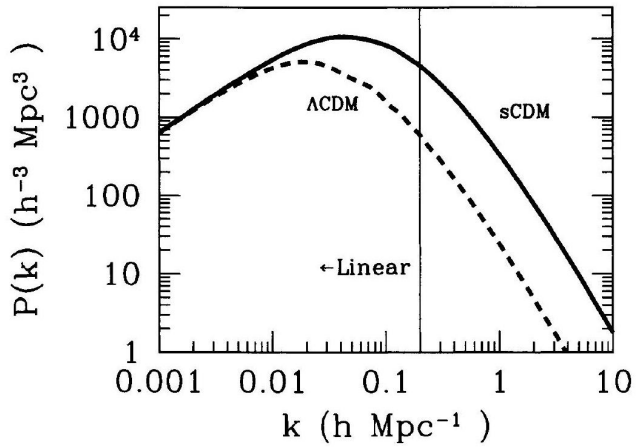
This, together with Eq. (7.5), allows us to relate the overdensity today to the primordial potential

$$\delta(\vec{k},a) = \frac{3}{5}\frac{k^2}{\Omega_m H_0^2}\Phi_{\rm p}(\vec{k})T(k)D_1(a) \quad (a > a_{\rm late}\,).$$

Equation (7.8) holds regardless of how the initial perturbation $\Phi_{\rm p}$ was generated. In the context of inflation, $\Phi_{\rm p}(\vec{k})$ is drawn from a Gaussian distribution with mean zero and variance (Eq. (6.100)) $P_\Phi = (50\pi^2/9k^3)\,(k/H_0)^{n-1}\,\delta_H^2\,(\Omega_m/D_1(a=1))^2$. So the power spectrum of matter at late times is

$$P(k,a) = 2\pi^2\delta_H^2\frac{k^n}{H_0^{n+3}}T^2(k)\left(\frac{D_1(a)}{D_1(a=1)}\right)^2 \quad (a > a_{\rm late}\,).$$

Matter-power spectrum:



(!!!!!! допишу потом асиптотики, так и не понял их!!!)

The power spectrum in two Cold Dark Matter models, with (ACDM) and without (sCDM) a cosmological constant. The spectra have been normalized to agree on large scales. The spectrum in the cosmological constant model turns over on larger scales because of a later aeq. Scales to the left of the vertical line are still evolving linearly.

Evolution of Large Scales perturbations

7.2.1

Super-horizon Solution (!!!)

(тут много важных формул, скоро пропишу их!!!)

$$\dot{\Theta}_{r,0} = -\dot{\Phi}$$
$$\dot{\delta} = -3\dot{\Phi}$$
$$3\frac{\dot{a}}{a}\left(\dot{\Phi} + \frac{\dot{a}}{a}\Phi\right) = 4\pi G a^2 \left[\rho_{\rm dm}\delta + 4\rho_r\Theta_{r,0}\right].$$

(словами про математику тут)

$$\Phi'' + \frac{21y^2 + 54y + 32}{2y(y+1)(3y+4)}\Phi' + \frac{\Phi}{y(y+1)(3y+4)} = 0.$$

7.2.2

Through Horizon Crossing

Evolution of Small Scales perturbations

7.3.1

Horizon Crossing

7.3.2

Sub-horizon Evolution

Numerical Results and Fits (????)

Growth Function (???)

Since radiation can be ignored, the coefficient multiplying δ in Eq. (7.56) is now $4\pi G\rho_{\rm dm} = (3/2)H_0^2\Omega_m a^{-3}$. Also when differentiating Eq. (7.54) previously, we set $(1/aHy)' = -(1+y)^{-1}(2aHy)^{-1}$; here we need to account for other contributions to H' so Eq. (7.57) becomes

$$\delta'' + ikv\left(\frac{d(aHy)^{-1}}{dy} - \frac{1}{aHy^2}\right) = \frac{3\Omega_m H_0^2}{2y^3a^2H^2a_{\rm eq}}\delta.$$

Replacing the velocity term using the continuity equation as before leads to

$$\frac{d^2\delta}{da^2} + \left(\frac{d\ln(H)}{da} + \frac{3}{a}\right)\frac{d\delta}{da} - \frac{3\Omega_m H_0^2}{2a^5H^2}\delta = 0.$$

Here I have divided by $a_{\rm eq}^2$ and we will now use a as the variable instead of y. In this large y limit, all factors of $a_{\rm eq}$ disappear.

$$D_1(a) \propto H(a)\int^a \frac{da'}{\left(a'H\left(a'\right)\right)^3}$$

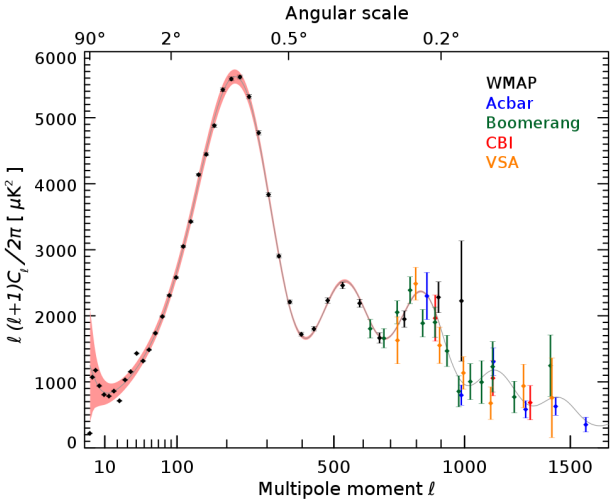
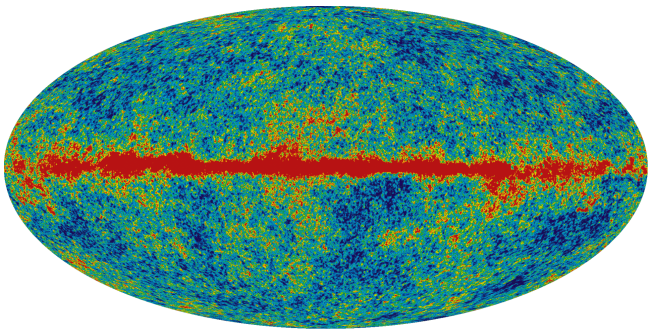
1.3.7 Anisotropy predictions, correlations in a nutshell (!!!!!!!!!)

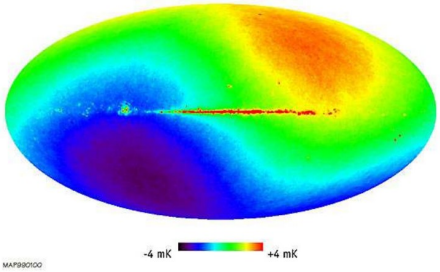
Main properties of CMB and parameters for it



(???? в чем смысл этих параметров тут???)

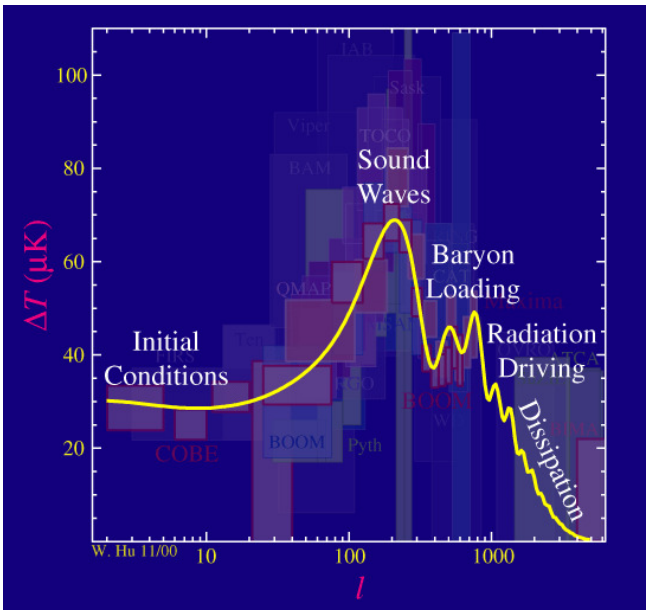


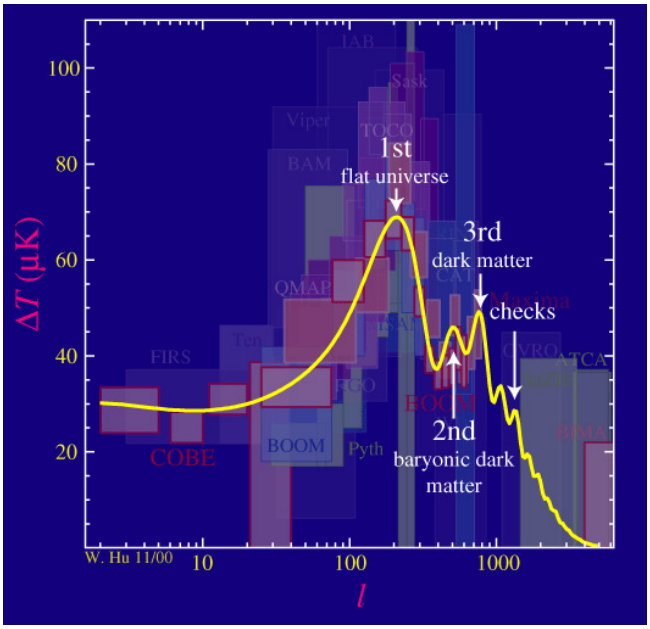
Тут у нас изображена карта звездного неба, и на ней выбраны фотоны с очень малой температурой. Цветом показана их температура.



Можно размыть его, выделить большие круги, посмотреть, насколько они скоррелированы (звучит как вообще бред). Корреляции же можно теоретически посчитать.

$$\Theta_l := \frac{1}{(-i)^l} \int_{-1}^{1} \frac{d\mu}{2} \mathcal{P}_l(\mu)\Theta(\mu)$$





Independent leading effects controlling the shape of the matter power spectrum $P(k)$ in the minimal ΛCDM model.

	Effect	**Relevant quantity**	**Parameter**
(P1)	scale of the maximum	$k_{\rm eq}$	$\omega_{\rm m}, \Omega_\Lambda$
(P2)	slope for $k \gg k_{\rm eq}$ and BAO amplitude	$\Omega_{\rm b}/\Omega_{\rm cdm}$	$\omega_{\rm b}, \omega_{\rm m}$
(P3)	BAO scale	$r_{\rm s}(\eta_{\rm drag})$	$\omega_{\rm b}, \omega_{\rm m}$
(P4)	Global amplitude	amplitude of primordial spectrum and duration of ΛD	$A_{\rm s}, \Omega_\Lambda$
(P5)	Global tilt	tilt of primordial spectrum	$n_{\rm s}$

(!!! here later I'll add explanation!!!)

Independent leading effects controlling the shape of the CMB temperature power spectrum C_l in the minimal ΛCDM model.

	Effect	**Relevant quantity**	**Parameter**
(C1)	Peak scale	$\theta_{\rm peak} = \dfrac{\pi}{l_{\rm peak}} \sim \dfrac{d_{\rm s}\|_{\rm dec}}{d_{\rm a}\|_{\rm dec}}$	$\leftarrow \omega_{\rm m}, \omega_{\rm b}$ $\leftarrow \Omega_\Lambda, \omega_{\rm m}$
(C2)	Odd/even peak amplitude ratio	$R\|_{\rm dec}$	$\omega_{\rm b}$
(C3)	Overall peak amplitude	$\frac{a_{\rm dec}}{a_0}$	$\omega_{\rm m}$
(C4)	Damping enveloppe	$\theta_{\rm d} = \dfrac{\pi}{l_{\rm d}} = \dfrac{a_{\rm dec} r_{\rm d}\|_{\rm dec}}{d_{\rm a}\|_{\rm dec}}$	$\leftarrow \omega_{\rm m}, \omega_{\rm b}$ $\leftarrow \Omega_\Lambda, \omega_{\rm m}$
(C5)	Global amplitude	$\mathcal{P}_\mathcal{R}(k_*)$	$A_{\rm s}$
(C6)	Global tilt	$\frac{d \log \mathcal{P}_\mathcal{R}}{d \log k}$	$n_{\rm s}$
(C7)	Additional plateau tilting (LISW)	$\frac{a_\Lambda}{a_0}$	Ω_Λ
(C8)	Amplitude for $l \geq 40$ only	$\tau_{\rm reio}$	$\tau_{\rm reio}$

(C1) Since all peaks in multipole space correspond to the harmonics of a single correlation length in real space, the scale of the peak is controlled (in good approximation) by a single number $l_{\rm peak}$. It depends on the ratio of the sound horizon at decoupling by the angular diameter distance to decoupling. The first quantity depends on the evolution prior to decoupling, and in particular on the expansion history and sound speed. Hence it depends on $\omega_{\rm m}$ (governing the time of equality) and $\omega_{\rm b}$ (governing $c_{\rm s}^2$ as a function of a). The second quantity depends on the expansion and geometry of the universe after decoupling, i.e. on Ω_Λ and H_0, or in our parameter basis Ω_Λ and $\omega_{\rm m}$.

(C2) When studying the SW contribution to the C_l's, we have seen that the asymmetry between the amplitude of odd and even peaks depends on the shift of the zero-point of acoustic oscillations by a term $-R\psi$. The value of the ratio R at decoupling is governed in our parameter basis by $\omega_{\rm b}$.

(C3) A shift in the time of radiation/matter equality affects the amplitude of all peaks for two reasons: it controls the duration of the intermediate stage between equality and decoupling, during which acoustic oscillations are damped by baryonic effects, and the EISW. Both effects go in the same direction. If equality takes place earlier, there is less time for damping (hence all peaks are increased). The metric fluctuations are also less stabilized at decoupling, and the EISW is larger (hence the first peak is increased even more).

(C4) Diffusion damping near the time of recombination controls the envelope of the peaks (the function $\exp[-(l/l_{\rm d})^2]$ suppresses them, starting essentially from the third one). It depends on the ratio of the damping scale at decoupling by the angular diameter distance to decoupling. The first quantity depends on the Thomson scattering rate prior to decoupling, and in particular on $\omega_{\rm m}$ (governing the value of conformal time at equality) and $\omega_{\rm b}$ (governing the ionization fraction as a function of a). The second quantity depends on the expansion and geometry of the universe after decoupling, i.e. on Ω_Λ and H_0, or in our parameter basis Ω_Λ and $\omega_{\rm m}$. The parameter dependence of effects (C1) and (C4) could be thought to be similar: in fact, it is not, because the sound horizon and the diffusion scale depend on very different combinations of $\omega_{\rm m}$ and $\omega_{\rm b}$.

(C5) The global amplitude of the C_l's depends trivially on that of the primordial spectrum, fixed by $A_{\rm s}$.

(C6) The global slope of the C_l's depends trivially on the tilt of the primordial spectrum, fixed by n_s.

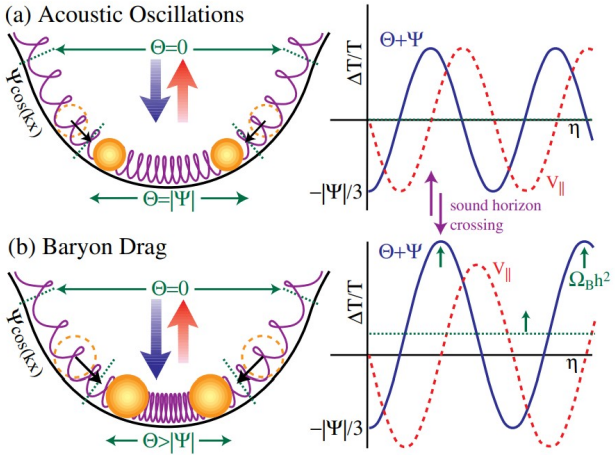
(C7) The LISW effect tilts the Sachs-Wolfe plateau (on top of the effect of n_s). The plateau is more lifted at small l's if Λ domination is longer, i.e. if metric fluctuations decay during a larger amount of time. Hence this effect is enhanced by large values of Ω_Λ.

(C8) The C_l amplitude is suppressed if reionization takes place early, i.e. if $\tau_{\rm reio}$ is large, but without affecting the largest scales (small l's).

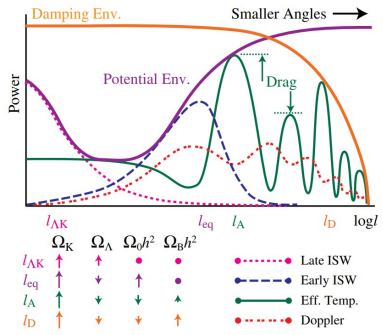
$$D_l := l(l+1)C_l/(2\pi)$$

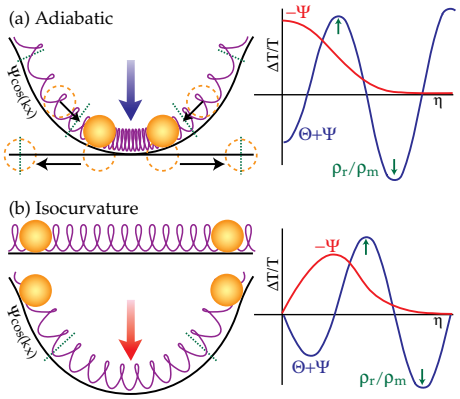
This angular power spectrum is a plot of how much the temperature varies from point to point on the sky (the y-axis variable) vs. the angular frequency ell (the x-axis variable). Ell=10 means that there are ten cycles in the fluctuation around the whole sky, while ell=100 means that there are 100 cycles around the sky.

The acoustic oscillations in the perturbed radiation density are what gives rise to the peaks in the spectrum of CMB anisotropies. (!!! ad eq!!!)



(a) Photon-dominated system. Fluid compression through gravitational infall is resisted by photon pressure setting up acoustic oscillations. Displayed here is a potential well in real space $-\pi/2 \lesssim kx \lesssim \pi/2$. Gravity displaces the zero point so that at the bottom of the well, the temperature is $\Theta_0 = |\Psi| = -\Psi$ at equilibrium with $\Psi/3$ excursions. This displacement is exactly cancelled by the redshift Ψ a photon experiences climbing out from the bottom of the potential well. Velocity oscillations lead to a Doppler effect 90 degrees phase shifted from the temperature perturbation. **(b) Photon-baryon system.** Baryons increase the gravitating mass, causing more infall and a net zero point displacement, even after redshift. Temperature crests (compression) are enhanced over troughs (rarefaction) and velocity contributions. (here from Hu $g_{00} = -[1+2\Psi(\mathbf{x},t)], g_{ij} = (a/a_0)^2\,[1+2\Phi(\mathbf{x},t)]\gamma_{ij}$)





Define the Fourier components of $f(\mathbf{x})$ by

$$f(\mathbf{x}) = \int \frac{d^3k}{(2\pi)^3} f_{\mathbf{k}} e^{i\mathbf{k}\cdot\mathbf{x}}.$$

They satisfy $f_{-\mathbf{k}} = f_{\mathbf{k}}^*$. The simplest inflationary models predict Gaussian perturbations, with probability density formally given by

$$p\left(f_{\mathbf{k}}\right) = \frac{1}{\pi V \sigma_k^2} \exp\left(-\frac{|f_{\mathbf{k}}|^2}{V\sigma_k^2}\right)$$

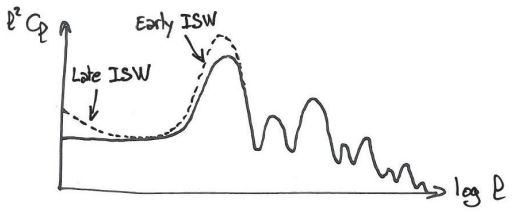
for every Fourier coefficient, where V is the volume of space (which we take to be infinite) and where σ_k only depends on $k = |\mathbf{k}|$ (not to be confused with the parameter k in the spatial curvature!). For the expectation value of the product of two Fourier coefficients, we find

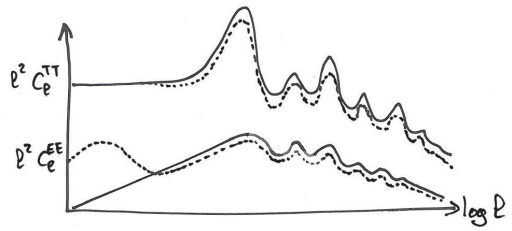
$$\langle f_{\mathbf{k}} f_{\mathbf{k}'} \rangle = V\sigma_k^2 \delta_{\mathbf{k},-\mathbf{k}'} = (2\pi)^3 \sigma_k^2 \delta\left(\mathbf{k}+\mathbf{k}'\right) \equiv (2\pi)^3 P_f(k) \delta\left(\mathbf{k}+\mathbf{k}'\right),$$

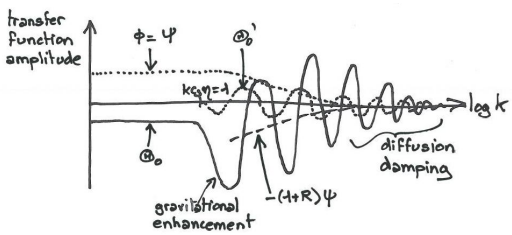
where $P_f(k)$ is the power spectrum.

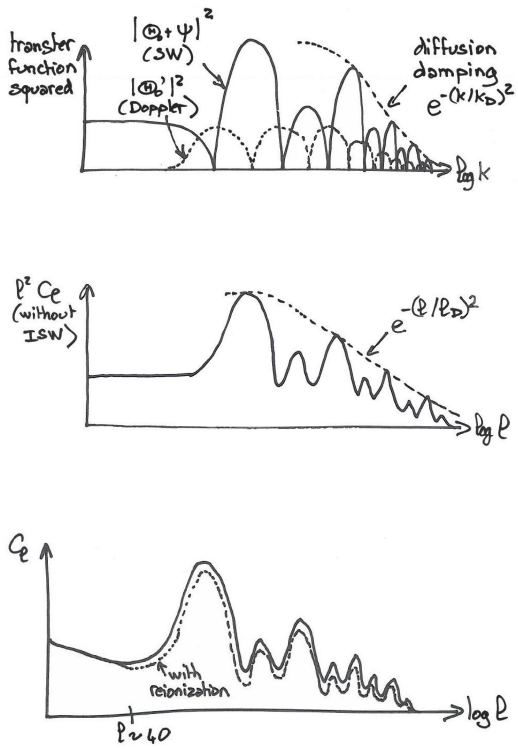
Another way to characterize a Gaussian random field is by its two-point correlation function

$$\xi_f(\mathbf{x},\mathbf{y}) \equiv \langle f(\mathbf{x}) f(\mathbf{y}) \rangle.$$









• It is difficult to measure the full CMB spectrum on the ground due to absorption by water molecules in the atmosphere. The first accurate measurement over all wavelengths was performed by the COBE satellite in 1989, which found that the CMB's spectrum in all directions was very close to that of an ideal blackbody.

• The CMB's temperature was found to be anisotropic due to the Earth's peculiar velocity. By subtracting off Earth's velocity about the Sun, the Sun's velocity in the galaxy, and the galaxy's motion velocity relative to the Local Group, we can measure the peculiar velocity of the Local Group; it is moving quickly towards the nearest supercluster.

• Subtracting off this dipole distortion gives much smaller fluctuations, with

$$\langle T \rangle = 2.725 \text{ K}, \quad (\delta T/T)_{\text{rms}} = 1.1 \times 10^{-5}$$

Thus the CMB is very nearly isotropic, providing strong evidence for the Big Bang.

• The temperature variations can be used to infer the matter distribution on the surface of last scattering, and hence the matter power spectrum at that time. However, this is somewhat subtle. Matter and radiation perturbations are related, since we have adiabatic perturbations, $\delta_r = \frac{4}{3}\delta_m$, and from $\rho \sim t^4$ $\delta_r = 4\frac{\delta T}{T}$, so

$$\frac{\delta T}{T} = \frac{1}{3}\delta_m$$

• We must account for the fact that the photons redshift when they climb out of the gravitational potential. Naively, we would have $\delta T/T = \delta\Phi/c^2$, where Φ is the potential (why????). However, part of this is cancelled by the simultaneous expansion of the universe, and

$$\frac{\delta T}{T} = \frac{\delta\Phi}{3c^2} \text{(Sachs-Wolfe effect)}$$

$$\delta\Phi(\mathbf{k}) = -\frac{4\pi G}{k^2}\bar{\rho}a^2\delta_m(\mathbf{k}) \qquad \text{(Poisson eq, } c = 1\text{)}$$

which means the Sachs-Wolfe effect dominates for modes with $k \lesssim aH$ at last scattering, i.e. superhorizon modes.

$$\frac{\delta T(\hat{\mathbf{n}})}{T} = \sum_{l=0}^{\infty}\sum_{m=-l}^{l} a_{lm}Y_{lm}(\theta,\phi), \quad Y_{lm}(\theta,\phi) = N_{lm}e^{im\phi}P_l^m(\cos\theta)$$

N_{lm} - normalization on the sphere.

The spherical harmonics have $O(1)$ values on the sphere, but vary on angular scales $\theta \sim \pi/l$. (???? what also do they quantitatively do???!!!!? how exactly do they work???)

The Sachs-Wolfe effect dominates for $l \lesssim 50$.

For Gaussian perturbations the coefficients a_{lm} are uncorrelated,

$$\langle a_{lm} a^*_{l'm'} \rangle = C_l \delta_{ll'} \delta_{mm'}$$

(the multipole moments C_l have no m-dependence by isotropy).

(????? how do we average????? do we fix some initial point? or where do we fix a radius???)

For two directions with $\hat{\mathbf{n}} \cdot \hat{\mathbf{n}}' = \cos\theta$,

$$\frac{\langle \delta T(\hat{\mathbf{n}}) \delta T(\hat{\mathbf{n}}') \rangle}{T^2} = \sum_{lml'm'} \langle a_{lm} a_{l'm'} \rangle Y_{lm}(0,0) Y_{l'm'}(\theta, 0) = \sum_l \frac{2l+1}{4\pi} C_l P_l(\cos\theta)$$

(we used $P_l^m(1) = \delta_{m0}$ and $N_{l0} = \sqrt{(2l+1)/4\pi}$).

• For some intuition, the functions $P_l(\cos\theta)$ are about 1 for $\theta \lesssim 1/l$, and oscillate rapidly with lower magnitude for $\theta \gtrsim 1/l$. Thus, the temperature correlation function above is parametrically $l_0^2 C_{l_0}$ where $l_0 \sim 1/\theta$. Alternatively, the variance of the temperature goes roughly as $\int l^2 C_l d\log l$.

• In the plot of $l(l+1)C_l$ the error bars are larger at small l - "cosmic variance" effect. It is because there are fewer of the coefficients a_{lm} available to average over.

• For small l, the Sachs-Wolfe effect dominates. By decomposing $\delta\Phi(\mathbf{k})$ into spherical harmonics, one can show that (!!! this is an important relation, I'll derive it soon!!!!!)

$$C_l = \frac{16\pi T^2}{9} \int dk k^2 P_\Phi(k) j_l^2(kr) \qquad (j_l(kr) \text{ - sph. Bessel f.})$$

For the Harrison-Zel'dovich spectrum, this implies that $C_l \sim 1/l(l+1)$, which is indeed observed in the left part of the plot above, where the curve is flat. The slight tilt of the curve can be used to establish $n_s \approx 0.97$, in agreement with direct measurements of the matter power spectrum.

(!!! maybe I'll write what below in section with illustrations!!!)

• At higher l, we see a pattern of peaks and troughs, associated with baryon acoustic oscillations. The first peak at $l \approx 200$ represents an acoustic wave that had time to undergo a single compression before decoupling. Its l value gives us information about the curvature of the universe, and hence tells us that the universe is nearly flat (???? why???).

• Historically, this was known by the 1990s, and at the time, it was regarded as a puzzle because the amounts of matter and radiation did not add up to the critical density. (???? why????)

Thus, CMB observations lent early evidence to dark energy, which was regarded as established by supernova redshift measurements in 1998, though the CMB itself doesn't directly say anything about it.

• The next two peaks represent oscillations that decoupled at the first rarefaction, and the second compression, respectively. (Oscillations that decoupled in between a rarefaction and a compression, i.e. when at uniform density, correspond to the troughs.) These give information about the amount of baryonic and dark matter in the universe. (why??????)

More dark matter lowers all of the peaks, while more baryonic matter enhances the odd-numbered peaks (why??????).

• For high $l \gtrsim 10^3$, the power spectrum is suppressed. This is because photon decoupling takes a finite time, and during this process, photon diffusion wipes out small-scale fluctuations. (why??????)

• Additional information can be extracted from the polarization pattern of the CMB, which is decomposed into E-modes and B-modes, as mentioned earlier. The E-modes arise automatically from Thomson scattering in an inhomogeneous plasma, and are in accordance with the standard theory of inflationary perturbations. The B-modes are expected to be much weaker, and haven't been observed yet, but would give information about the scale of inflation.

Boltzmann equation

$$\frac{d}{d\eta} f = C\left[f, f_e\right]$$

$$f(\eta, \vec{x}, \vec{p}) = \frac{1}{e^{\frac{p}{T(\eta,\vec{x})}} - 1} \ .$$

$$\bar{f}(\eta, p) = \frac{1}{e^{\frac{p}{\bar{T}(\eta)}} - 1} \ , \qquad \delta f(\eta, \vec{x}, \vec{p}) = \frac{d\bar{f}}{d\log p} \ \frac{\delta T(\eta, \vec{x})}{\bar{T}(\eta)} \ .$$

$\Theta(\eta, \vec{x}) \equiv [\delta T(\eta, \vec{x})/\bar{T}(\eta)]$.

$$\frac{d(a\,p)}{d\eta} = -a\,p\,\phi' - a\,\epsilon\,\hat{n}\cdot\vec{\nabla}\psi \ . \qquad \text{(geodesic eq in Newt g)}$$

$$\frac{d\ln(a\,p)}{d\eta} = -\phi' - \hat{n}\cdot\vec{\nabla}\psi \ .$$

$$f(\eta, \vec{x}, \vec{p}) = \frac{1}{e^{\frac{p}{T(\eta,\vec{x},\hat{n})}} - 1} \ . \qquad (\hat{n} \equiv \vec{p}/p)$$

$(\vec{k}\cdot\hat{n}) = k\cos\theta$.

$$\Theta(\eta, \vec{k}, \theta) = \sum_l (-i)^l (2l+1)\Theta_l(\eta, \vec{k}) P_l(\cos\theta) \ .$$

$$\Theta' + \hat{n}\cdot\vec{\nabla}\Theta - \phi' + \hat{n}\cdot\vec{\nabla}\psi = -\Gamma\left(\Theta - \Theta_0 - \hat{n}\cdot\vec{v}_e\right) \ .$$

Γ is the conformal Thomson scattering rate, Θ_0 the temperature monopole (i.e. the average of $\Theta(\eta, \vec{x}, \hat{n})$ over all directions $\hat{n}$), and $\vec{v}_e$ the bulk velocity of electrons, equal to that of baryons due to tight Coulomb interactions.

This equation is illuminating, since it shows that at early times, when photons, electrons and baryons form a tightly-coupled fluid, the fact that Γ is huge forces Θ to evolve in such way that the parenthesis on the right-hand side vanishes. When this is the case, Θ can only have two non-zero component: a monopole Θ_0, and a dipole equal to $\hat{n}\cdot\vec{v}_\mathrm{b}$. The condition on the dipole can be written equivalently as $\theta_\gamma = \theta_\mathrm{b}$.

In the tightly-coupled regime, the dipole component of $\Theta(\eta, \vec{x}, \hat{n})$ is given by $\hat{n}\cdot\vec{v}_\mathrm{b}$, with $\theta_\mathrm{b} \equiv \vec{\nabla}\cdot\vec{v}_\mathrm{b}$. Hence in Fourier space this component reads $i(\hat{n}\cdot\vec{k})k^{-2}\theta_\mathrm{b} = i(\cos\theta)k^{-1}\theta_\mathrm{b}$. This justifies the fact that initial conditions for Θ in Fourier space depend on θ, but not on the two degrees of freedom of $\hat{n}$. As mentioned above, this property is preserved by the isotropic equations of motion, so that at all times we can study Θ as a function of the arguments $(\eta, \vec{k}, \theta)$ instead of $(\eta, \vec{k}, \hat{n})$.

Photon scattering rate

- The free electron fraction $x_e(\eta)$ (????) starts from one at high redshift. It decreases sharply at the recombination time (corresponding to $z \sim 1080$ or $T \sim 0.3$ eV), and freezes at a very small value (due to departure from thermal equilibrium). Around $z \sim 10$, star formation causes a reionization of the universe, and x_e goes up again to one.

- The Thomson scattering rate $\Gamma = \sigma_T a n_e x_e$ evolves like $a^{-2}x_e$. Before recombination, $\Gamma \gg \frac{a'}{a}$, and the universe is opaque. The sudden drop of x_e at recombination renders the universe transparent: $\Gamma \ll \frac{a'}{a}$. Due to the dilution factor coming from n_e, Γ remains much smaller than $\frac{a'}{a}$ even during reionization, and the universe keeps being transparent (this is why despite of reionization, most photons emitted at recombination do not interact anymore, and allow us to observe anisotropies on the last scattering surface).

- The optical depth $\tau(\eta) \equiv \int_{\eta}^{\eta_0} d\eta \Gamma(\eta)$ represents the opacity of the universe at a given time, when seen from today (when $\eta = \eta_0$). It tends to infinity when $\eta \longrightarrow 0$, falls below one at recombination and stabilize at a value of the order of 0.1 between recombination and reionization. After reionization it decreases smoothly and reaches zero today by definition.

- The visibility function $g(\eta) \equiv -\tau' e^{-\tau}$ gives the probability that a CMB photon seen today experienced its last scattering at time η. It starts from negligible values at high redshift (suppressed by the $e^{-\tau}$ factor). It has a narrow spike around the time of recombination, and then it falls again to negligible values due to the smallness of τ' between recombination and reionization. It develops a second smaller and wider spike around reionization. This function shows that most CMB photons did not interact between the last scattering surface and today, while a minority rescattered at reionization. The width of the recombination spike gives an indication on the thickness of the last scattering "surface".

- The diffusion length $\lambda_{\rm d}(\eta)$ is an important quantity for understanding the damping of temperature anisotropies on small scales. At any given time, the comoving mean free-path (mfp) of photons is given by $r_{\rm mfp} = 1/\Gamma(\eta)$ (still in units where $c = 1$). If the photons experience a random walk analogous to Brownian motion in a gas, the comoving distance over which they travel between time $\eta_{\rm ini}$ and η can be approximated by

$$r_{\rm d} \sim \left[\int_{\eta_{\rm ini}}^{\eta_0} d\eta \; \Gamma \; r_{\rm mfp}^2\right]^{1/2} = \left[\int_{\eta_{\rm ini}}^{\eta_0} d\eta \; \Gamma^{-1}\right]^{1/2} .$$

  This physical diffusion length of photons is given in this approximation by $\lambda_{\rm d} \simeq a r_{\rm d}$. It grows quickly from very small to very large scales (comparable to the Hubble scale) around the time of recombination.

Temperature anisotropy in a given direction

$$ds^2 = -(1+2\psi)dt^2 + (1-2\phi)a^2 d\vec{l}^{\,2} ,$$

$$\frac{\delta T}{\bar{T}}(\hat{n}) = \Theta(\eta, \vec{o}, -\hat{n})$$

(since in a direction $\hat{n}$, we see photons traveling towards $-\hat{n}$).

$$\forall \mathcal{F}(\eta, \vec{x}, \hat{n}) \qquad \frac{d}{d\eta}\mathcal{F}(\eta, \vec{x}, \hat{n}) = \mathcal{F}' + \frac{dx_i}{d\eta}\frac{\partial \mathcal{F}}{\partial x_i} + \frac{dn_i}{d\eta}\frac{\partial \mathcal{F}}{\partial n_i} = \mathcal{F}' + \hat{n}\cdot\vec{\nabla}\mathcal{F} . \qquad)O(1), \frac{dx_i}{d\eta} = \hat{n})$$

$$\mathcal{F}(\eta, \vec{x}, \hat{n}) = e^{-\tau(\eta)} \left(\Theta(\eta, \vec{x}, \hat{n}) + \psi(\eta, \vec{x})\right) .$$

$$\frac{d}{d\eta}\left[e^{-\tau}(\Theta + \psi)\right] = e^{-\tau}\left(\Theta' + \psi' + \hat{n}\cdot\vec{\nabla}(\Theta + \psi)\right) - \tau' e^{-\tau}(\Theta + \psi) .$$

Use linearized Boltzmann equation with (??) $\tau' = -\Gamma$

$$\frac{d}{d\eta}\left[e^{-\tau}(\Theta + \psi)\right] = -e^{-\tau}\tau'(\Theta_0 + \psi + \hat{n}\cdot\vec{v}_{\rm b}) + e^{-\tau}(\phi' + \psi') .$$

$$\frac{d}{d\eta}\left[e^{-\tau}(\Theta + \psi)\right] = g\,(\Theta_0 + \psi + \hat{n}\cdot\vec{v}_{\rm b}) + e^{-\tau}(\phi' + \psi') .$$

$$(\Theta+\psi)|_{\rm obs} = \int_{\eta_{\rm ini}}^{\eta_0} d\eta \left[g\left(\Theta_0+\psi+\hat{n}\cdot\vec{v}_{\rm b}\right) + e^{-\tau}(\phi'+\psi') \right] \ ,$$

$|_{\rm obs} := (\eta_0, \vec{o}, \hat{n})$.

In instantaneous decoupling approximation, in which all photons are assumed to decouple precisely at the time $\eta_{\rm dec}$: we can replace the visibility function g by the Dirac function $\delta_D(\eta - \eta_{\rm dec})$, and $e^{-\tau}$ by the Heaviside function $H(\eta - \eta_{\rm dec})$.

$$(\Theta+\psi)|_{\rm obs} = \left(\Theta_0+\psi+\hat{n}\cdot\vec{v}_{\rm b})\right)|_{\rm dec} + \int_{\eta_{\rm dec}}^{\eta_0} d\eta \left(\phi'+\psi'\right) \ ,$$

$|_{\rm dec} := (\eta_{\rm dec}, -r_{\rm dec}\hat{n}, \hat{n})$

$\Theta|_{\rm obs}$ is the temperature anisotropy measured by the observer in the direction $-\hat{n}$, while $\Theta_0|_{\rm dec}$ is the temperature anisotropy in the point of the last scattering surface seen in the same direction. If only these two terms where present, this relation would simply tell us that that the temperature anisotropy seen today in a given direction is equal to the intrinsic anisotropy in the point where the observed photons last scattered.

$\hat{n}\cdot\vec{v}_{\rm b}|_{\rm dec}$ stands for the correction to this temperature coming from by the usual Doppler. Indeed, this correction is caused by the velocity of the baryon-photon fluid (that we assumed to be tightly coupled until $\eta_{\rm dec}$) projected along the line of sight.

Next, we expect a correction from gravitational effects. The redshifting and blueshifting of the photons traveling along gravitational potential fluctuations should affect the observed temperature anisotropy relatively to the intrinsic one. It turns out that if the gravitational potential was constant in time (but, of course, not in space), this effect would be conservative, and would only depend on $\psi|_{\rm obs} - \psi|_{\rm dec}$. This explains the second term on the left-hand and right-hand sides. But if ψ varies in time, the effect is not conservative anymore: intuitively, the amount of blueshifting and redshifting experienced by photons traveling across a potential well do not compensate each other if the gravitational well gets deeper between the time at which the photon enters and leaves the well. This explains the addition term $\int d\eta\, \psi$. A similar effect is caused by dilation effects along the line-of-sight, and contributes like $\int d\eta\, \phi$.

Finally, we can drop the second term on the left-hand side, because this term represents only a tiny *isotropic* correction to the observed anisotropies. It is impossible to measure it with the CMB map only, because it is formally equivalent to a redefinition of the average temperature $\bar{T}$, but only by a tiny amount of the order of $10^{-5}\bar{T}$.

$$\Theta|_{\rm obs} = \underbrace{(\Theta_0+\psi)|_{\rm dec}}_{\rm SW} + \underbrace{\hat{n}\cdot\vec{v}_{\rm b}|_{\rm dec}}_{\rm Doppler} + \underbrace{\int_{\eta_{\rm dec}}^{\eta_0} d\eta \left(\phi'+\psi'\right)}_{\rm ISW} \ .$$

Sachs-Wolfe (SW) term, and includes the intrinsic temperature term Θ_0 and the "gravitational Doppler shift" term ψ at one point on the last scattering surface. The second term is the conventional Doppler term. The ISW term and contains all non-conservative gravitational effects occurring in a universe with non-static metric fluctuations.

Let us first focus on the term $\Theta_0|_{\rm dec}$. We have seen that on super-Hubble scales, temperature anisotropies only have a monopole and a dipole component, related respectively to δ_γ and θ_γ. We can be more precise now. We know from thermodynamics that the local value of the photon density is proportional to the temperature to the power four. Taking the derivative of $\log\rho_\gamma = \log T^4$, we get $\delta_\gamma = 4\,\delta T/\bar{T}$, where on the right-hand side the temperature anisotropy is averaged over all directions $\hat{n}$: hence $\delta_\gamma = 4\Theta_0$.

Let us now focus on the term $\psi|_{\rm dec}$. on super-Hubble scales for adiabatic initial conditions, $\delta_\gamma = \frac{4}{3}\delta_{\rm b}$, decoupling takes place at the beginning of matter domination, for super-Hubble scales and during matter domination,

$-2\phi = -2\psi = \delta_{\rm tot} = \delta_{\rm b} = \delta_{\rm cdm}$.

Hence, $-2\psi = \frac{3}{4}\delta_\gamma$.

So on the last scattering surface,

$$\Theta_0 + \psi = \frac{1}{4}\delta_\gamma + \psi = (-\frac{1}{4}\,2\,\frac{4}{3} + 1)\,\psi = (-\frac{2}{3} + 1)\,\psi = \frac{1}{3}\psi \ .$$

Moreover, on super-Hubble scales, we can neglect the Doppler term, which can be shown to be important only on sub-Hubble scales. Integrated Sachs-Wolfe term plays a small role on large scales, because ϕ and ψ are static during most of the evolution after decoupling. Hence we get an approximation for CMB anisotropies smoothed over small scales:

$$\Theta|_{\rm obs,\,large\,scales} \simeq \frac{1}{3}\psi|_{\rm dec} = -\frac{1}{8}\delta_\gamma|_{\rm dec} \ .$$

The term ψ wins over the term Θ_0, leading to a minus sign in front of δ_γ in the above relation. This means that an over-density on the last scattering surface ($\delta_\gamma > 0$), corresponding to a potential well ($\psi < 0$), leads to a cold spot in the observed map ($\Theta < 0$). Conversely, a hot spot corresponds to an under-density. Hence, due to the "gravitational Doppler shift" effect accounted by the term ψ (often called the Sachs-Wolfe effect), the patterns that we observe on CMB map are inverted with respect to intrinsic fluctuations on the last scattering surface.

Spectrum of temperature anisotropies

$$\frac{\delta T}{\bar{T}}(\hat{n}) = \Theta(\eta_0, \vec{o}, -\hat{n}) = \sum_{lm} a_{lm} Y_{lm}(\hat{n}) \ .$$

$$a_{lm} = (-i)^l \int \frac{d^3\vec{k}}{2\pi^2} Y_{lm}(\hat{k}) \Theta_l(\eta_0, \vec{k}) \ ,$$

$\hat{k} \equiv \vec{k}/k$. In linear perturbation theory and assuming Gaussian initial conditions, both Θ_l and a_{lm} are Gaussian random variables.

$$\langle a_{lm} a^*_{l'm'} \rangle = \delta^K_{ll'} \delta^K_{mm'} \left[\frac{1}{2\pi^2} \int \frac{dk}{k} \Theta_l^2(\eta_0, k) \mathcal{P}_\mathcal{R}(k) \right] \ .$$

$$C_l \equiv \frac{1}{2\pi^2} \int \frac{dk}{k} \Theta_l^2(\eta_0, k) \mathcal{P}_\mathcal{R}(k) \ .$$

In a universe with linear and Gaussian perturbations, the C_l's encode all the information concerning the cosmological model describing our universe that is contained in the CMB temperature map.

Since the theory of cosmological perturbation is stochastic, the a_{lm}'s should be seen as random numbers, and the averaging symbols $\langle ... \rangle$ is meant over many realizations of the theory. In a sense, "a given realization" means "a given universe", and the average holds over many universes, all obeying to the same cosmological model, which is encoded in the spectrum C_l.

However, we observe CMB anisotropies in our universe, i.e. in only one realization. CMB maps allow us to measure a definite value of each a_{lm}. Hence the squares $|a_{lm}|^2$ are not expected to be equal to C_l, even if we postulated the right model: there should be some scattering around C_l. This scattering limits the possibility to find the best theory matching the observations. However we can reduce considerably the scattering by noticing that for any fixed l, the statistical distribution of $|a_{lm}|^2$ is independent of m. Hence, for an ideal full-sky CMB experiment, the best estimator of the underlying C_l's is the average between all observed coefficients $|a_{lm}|^2$ with fixed l,

$$C_l^{obs} := \frac{1}{2l+1} \sum_{-l \le m \le l} |a_{lm}^{obs}|^2 \ .$$

$$\hat{C}_l := \frac{1}{2l+1} \sum_{-l \le m \le l} |a_{lm}|^2 \ .$$

$$\text{Gaussian } a_{lm}\text{'s} \Rightarrow \qquad \langle \hat{C}_l \rangle = C_l; \qquad\qquad \langle (\hat{C}_l - C_l)^2 \rangle = \frac{2}{2l+1} C_l^2 \ .$$

Since for larger l we perform an average over more values of m, the relative scattering decreases. Cosmic variance can be seen as a theoretical error: because of it, we cannot reconstruct the underlying model with infinite precision, even if we have infinitely precise observations.

(???? still don't fully understand the averaging)

Line-of-sight integral in Fourier space

$$\begin{aligned} \Theta_l(\eta_0, k) &= \int_{\eta_{\rm ini}}^{\eta_0} d\eta \ S_T(\eta, k) \ j_l(k(\eta_0 - \eta)) \ , \\ S_T(\eta, k) &\equiv \underbrace{g \, (\Theta_0 + \psi)}_{\rm SW} + \underbrace{\left(g \, k^{-2} \theta_{\rm b} \right)'}_{\rm Doppler} + \underbrace{e^{-\tau} (\phi' + \psi')}_{\rm ISW} \ . \quad \text{(temperature source f-n)} \end{aligned}$$

In instantaneous decoupling approximation ($e^{-\tau} = H \, (\eta - \eta_{\rm dec}) \, ; g(\eta) = \delta_D \, (\eta - \eta_{\rm dec})$) we integrate the Doppler term by part, and get:

$$\begin{aligned} \Theta_l(\eta_0, k) \ \simeq \ & \left[\Theta_0(\eta_{\rm dec}, k) + \psi(\eta_{\rm dec}, k) \right] j_l(k(\eta_0 - \eta_{\rm dec})) \\ & + k^{-1} \theta_{\rm b}(\eta_{\rm dec}, k) \ j_l'(k(\eta_0 - \eta_{\rm dec})) \\ & + \int_{\eta_{\rm dec}}^{\eta_0} d\eta \ \left[\phi'(\eta, k) + \psi'(\eta, k) \right] j_l(k(\eta_0 - \eta)) \end{aligned}$$

(note that in the second line, i.e. in the Doppler term, the prime stands for the derivative of the function $j_l(x)$ with respect to its argument, not with respect to conformal time). This approximate result can be plugged into Eq. (234) to obtain the final spectrum C_l. We see that each C_l can be decomposed into six terms: the power spectrum $C_l^{\rm SW}$ of the SW term, coming from the first line of Eq. (239) squared, that of the Doppler term, coming from the second line of Eq.(239) squared, that of the Integrated Sachs-Wolfe term, coming from the third line of Eq. (239) squared, and finally the three cross-spectra involving each pair of terms.

For large values of l, the spherical Bessel functions $j_l(x)$ and $j_l'(x)$ are very peaked near $x \simeq l$. Hence, for the Sachs-Wolfe and Doppler contributions to the spectrum C_l, the integral over k in Eq. (234) will pick up mainly modes with $k(\eta_0 - \eta_{\rm dec}) \simeq l$. This shows that the SW contribution to C_l is given by the product of the primordial spectrum with the squared transfer function $(\Theta_0 + \psi)$ at a given value of η and k:

$$C_l^{\rm SW} \sim \left[\Theta_0(\eta_{\rm dec}, k) + \psi(\eta_{\rm dec}, k) \right]^2 \mathcal{P}_{\mathcal{R}}(k) \ , \qquad k \simeq \frac{l}{(\eta_0 - \eta_{\rm dec})}$$

(for simplicity, we did not write numerical factors and powers of l or k in front of this expression). In other words, $C_l^{\rm SW}$ depends on the power spectrum of the perturbation $(\Theta_0 + \psi)$, evaluated at the time of decoupling, and for wavenumbers in the vicinity of $k = \frac{l}{(\eta_0 - \eta_{\rm dec})}$,

$$C_l^{\rm SW} \sim \langle |\Theta_0 + \psi|^2 \rangle_{(\eta, k) \simeq (\eta_{\rm dec}, \, l/(\eta_0 - \eta_{\rm dec}))} \ .$$

We reached this result with mathematical arguments, but it has a very simple geometrical interpretation, illustrated in Fig. 139. The spectrum C_l encodes the correlation between structures on CMB maps seen under an angle $\theta = \pi/l$. This angle subtends a given physical scale on the last scattering surface, namely $\theta \times d_{\rm a}(z_{\rm dec})$, where $d_{\rm a}(z)$ is the angular diameter distance to objects of redshift z. Since the Sachs-Wolfe term $(\Theta_0 + \psi)$ contributes to the temperature map only at the time $\eta \simeq \eta_{\rm dec}$, the spectrum $C_l^{\rm SW}$ should depend on the power spectrum of the Sachs-Wolfe term $\langle |\Theta_0 + \psi|^2 \rangle$ at that time, and for a wavenumber such that

$$\frac{\lambda}{2} = \frac{\pi a(\eta_{\rm dec})}{k} = \theta \, d_{\rm a}(z_{\rm dec}) \ .$$

The reason for which λ has been divided by two is that for spherical harmonics, $\theta = \pi/l$ is the angle between a maximum and a minimum, while for a Fourier mode the distance between a maximum and a minimum is one half of the wavelength, $\frac{\lambda}{2} = \frac{\pi a}{k}$. Eq. (242) leads to

$$\frac{a(\eta_{\rm dec})}{k} = \frac{d_{\rm a}(z_{\rm dec})}{l} \ .$$

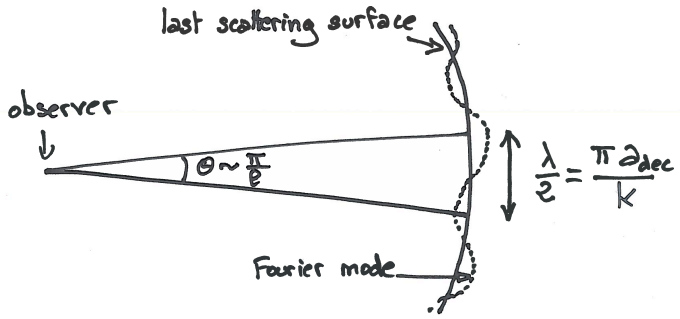


Figure 3: A multipole l refers to structures seen on the last scattering surface under an angle $\theta = \pi/l$. These structures are seeded by Fourier modes with a half wavelength $\frac{\lambda}{2} = \frac{\pi a_{\rm dec}}{k}$.

$$d_{\rm a}(z) := a(t(z)) \int_{t(z)}^{t_0} \frac{dt}{a} \ ,$$

$t(z)$ being the proper time at which an object seen today with a redshift z emitted light. The conformal time $\eta(z)$ is defined similarly. In terms of conformal time,

$$d_{\rm a}(z) = a(\eta(z)) \int_{\eta(z)}^{\eta_0} d\eta = a(\eta(z)) \ [\eta_0 - \eta(z)] \ ,$$

and for the case of a point located on the last scattering surface,

$$d_{\rm a}(z_{\rm dec}) = a(\eta_{\rm dec}) \ (\eta_0 - \eta_{\rm dec}) \ .$$

Hence, Eq. (243) can be written as

$$\frac{1}{k} = \frac{(\eta_0 - \eta_{\rm dec})}{l} \ ,$$

which is the same relation between k and l as in Eqs. (240, 241). In those equations, we implicitly performed a small-angle approximation. For large angles (small l's), it is inaccurate to say that a given angle/mutipole corresponds to a single Fourier mode on the last-scattering surface, and it is important to keep the spherical Bessel function of Eq. (238) and the integral over k of Eq.(234). In summary, Eqs. (240, 241) represent the instantaneous decoupling *and* small-angle limit of the true power spectrum $C_l^{\rm SW}$.

$$C_l^{\rm Doppler} \sim \langle |\theta_{\rm b}|^2 \rangle_{(\eta,k) \simeq (\eta_{\rm dec},\, l/(\eta_0 - \eta_{\rm dec}))} \ ,$$

$$C_l^{\rm ISW} \sim \int_{\eta_{\rm dec}}^{\eta_0} d\eta \, (\eta_0 - \eta) \ \langle |\phi' + \psi'|^2 \rangle_{(\eta,k) \simeq (\eta,\, l/(\eta_0 - \eta))} \ .$$

$$\begin{array}{lcll} \text{SW} & : & \langle|\Theta_0+\psi|^2\rangle & \text{at } (\eta,k)\simeq(\eta_{\rm dec},\ l/(\eta_0-\eta_{\rm dec}))\ , \\ \text{Doppler} & : & \langle|\theta_{\rm b}|^2\rangle & \text{at } (\eta,k)\simeq(\eta_{\rm dec},\ l/(\eta_0-\eta_{\rm dec}))\ , \\ \text{ISW} & : & \langle|\phi'+\psi'|^2\rangle & \text{for all } (\eta,k)\simeq(\eta,\ l/(\eta_0-\eta))\ . \end{array}$$

Before entering into details, we can make a guess. Even if the primordial spectrum $\mathcal{P}_{\mathcal{R}}(k)$ is smooth, the temperature spectrum C_l should contain some structure.

$$d_{\rm s}\equiv a\int_{t_{\rm ini}}^{t}\frac{c_{\rm s}dt}{a}=a\int_{\eta_{\rm ini}}^{\eta}c_{\rm s}d\eta\ , \qquad \text{(sound horison)}$$

$\theta\sim d_{\rm s}(\eta_{\rm dec})/d_{\rm a}(z_{\rm dec})$.
$l\sim\pi/\theta\sim\pi\ d_{\rm a}(z_{\rm dec})/d_{\rm s}(\eta_{\rm dec})$,

Acoustic photon oscillations

An overdense region attracts matter towards it due to gravitational forces, while photon-matter interactions produce a pressure in the opposite direction. Once the overdense region attracts enough matter, the photon-matter interactions become dominant. After a while, after this pressure pushes away enough matter, the gravitational forces kick in again and become dominant. We see that we are in an oscillatory state, in where the counteracting gravity and pressure forces produce sound waves in the early universe.

Consider now a spherical sound wave propagating out from this overdensity. The dark matter stays at the origin of the overdensity since it interacts only through gravitational forces, but the baryons and photons push outwards at some sound speed velocity near half the speed of light (peebles). Once the photons decoupled from matter (at the era of last scattering), the pressure force essentially went to 0 due to the lack of photon-matter interactions. This lack of pressure stopped the baryons from propagating any further outwards, and this distance between the original overdensity site and the effective ring of baryons is called the 'sound horizon'.

During the maximal compression (or rarefaction) in the potential wells, the modes reach an extrema. After recombination, this picture is frozen and those modes will correspond to the peaks of the CMB power spectrum, since those modes will have enhanced temperature.

As long as electrons, baryons and photons are tightly coupled, they form an effective single fluid in which density waves propagate at the sound speed

$$c_{\rm s}^2=\frac{\delta p_\gamma+\delta p_{\rm b}}{\delta\rho_\gamma+\delta\rho_{\rm b}}$$

(the density and pressure of electrons is always negligible with respect to that of photons). The density fluctuation δ_x of each species $x=\gamma,b$ can be inferred from the local value of the equilibrium temperature.

The fact that $\rho_{\rm b}\propto T^3$ and $\rho_\gamma\propto T^4$ implies (by def-s) $\delta_\gamma=\frac{4}{3}\delta_{\rm b}$, and tight coupling imposes $\theta_\gamma=\theta_{\rm b}$.

Using the fact that $|\delta p_{\rm b}|\ll|\delta p_\gamma|$,

$$c_{\rm s}^2=\frac{1}{3(1+R)}\ , \quad R\equiv\frac{4\bar\rho_{\rm b}}{3\bar\rho_\gamma}\propto a\ .$$

In the tightly-coupled regime from Boltzmann and Einstein eq.:

$$\Theta_0''+\frac{R'}{1+R}\Theta_0'+k^2c_{\rm s}^2\Theta_0=-\frac{k^2}{3}\psi+\frac{R'}{1+R}\phi'+\phi''\ .$$

This equation follows from the combination of the continuity and Euler equations for photons and baryons. Given that R is proportional to the scale factor, we could replace R' by $(a'/a)R=aHR$. The second term on the left-hand side is a damping term, increasing with the contribution of baryons to the total energy of the fluid. The third term accounts for pressure forces in the effective fluid. The first term on the right-hand side accounts for the gravitational force, and the last two terms for dilation effects.

$$R = 0, \psi = 0, \phi = 0 \quad \Rightarrow \quad \text{(harm osc)} \quad \Theta_0 = \Theta_{\rm ini}\, \cos(k c_{\rm s} \eta + \varphi) \ ,$$

with two constants of integration $(\Theta_{\rm ini}, \varphi)$. We know that for adiabatic initial conditions and in the Newtonian gauge, photon density/temperature fluctuations should be constant in the super-Hubble limit, $k\eta \ll 1$: this fixes the phase to $\varphi = 0$. In the opposite limit, this solution corresponds to the propagation of acoustic oscillations. Actually, the limit between the constant and oscillatory regime is not set by the value of $k\eta$, but by that of $kc_{\rm s}\eta$. In fact, the condition $kc_{\rm s}\eta \ll 1$ is equivalent to $\lambda \gg d_{\rm s}$, where λ is a physical wavelength ($\lambda = 2\pi a/k$), and $d_{\rm s}$ is the physical sound horizon, given in the case of a constant sound speed by:

$$d_{\rm s} = a \int_{\eta_{\rm ini}}^{\eta} c_{\rm s} d\eta \simeq a c_{\rm s} \eta$$

(assuming $\eta \gg \eta_{\rm ini}$). Hence, the phase $kc_{\rm s}\eta$ of the cosine stands for the ratio $2\pi d_{\rm s}/\lambda$. Modes start oscillating when their wavelength becomes smaller than the sound horizon, and later on, the number of oscillations is given by the ratio between these two scales.

In reality, R grows with time (and crosses one roughly around the time of decoupling). In addition, the gravitational source terms in Eq. (253) can play a role in some regimes. Let us describe qualitatively the evolution of Θ_0 in the different regions in (k, η) space shown in Fig. 141. In this figure, the horizontal axis corresponds to wavenumbers k (large wavelengths are on the left), and the vertical axis to conformal time, flowing from top to bottom. The super-Hubble and sub-Hubble regions are separated by the solid diagonal line corresponding to $k = aH$ (equivalent to $k\eta = 1$ during radiation domination). From top to bottom, the horizontal lines correspond to the time of equality between radiation and matter, to the time of photon decoupling, and to the time today. The upper dashed line separates wavelengths bigger/smaller than the sound horizon in the baryon-photon fluid before decoupling (after decoupling, this notion does not make sense anymore). As we have just seen, this limit corresponds to $\lambda = d_{\rm s}$, or (up to a factor 2π) to $k = (a/d_{\rm s})$. At early times, $c_{\rm s} = 1/\sqrt{3}$, and this condition reads $k\eta = \sqrt{3}$. Just before decoupling, R becomes large, $c_{\rm s}$ goes to zero, and the comoving sound horizon $(d_{\rm s}/a)$ becomes asymptotically constant, explaining the shape of the upper dashed line. Finally, the lower dashed line separates wavelengths bigger/smaller than the diffusion length defined in section 12.9.2: this line corresponds to $k = 1/r_{\rm d}$, where $r_{\rm d}$ is given in first approximation by Eq. (209).

The evolution of Θ_0 in the super-Hubble region is trivial: as long as $k\eta \ll 1$ — and *a fortiori* $kc_{\rm s}\eta \ll 1$ — the fluctuation Θ_0 is frozen, and remains approximately equal to its initial value.

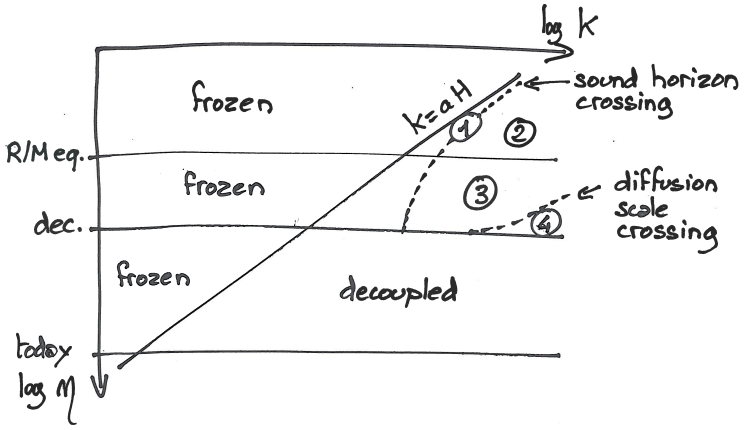

Figure 4: Different regions in (k, η) space, corresponding to qualitatively different behaviors for photon (and baryon) perturbations.

①: in the figure corresponds to modes that are crossing the sound horizon before decoupling. This is precisely the region in which gravitational source terms are important. They shift the

zero point of oscillations, and boost their amplitude (due to gravitational forces and dilution effects). This happens during a limited amount of time, because the metric fluctuations quickly decay inside the sound horizon during radiation domination, making the gravitational source terms negligible. An approximation for the zero-point of oscillations can be found by setting Θ_0'' and Θ_0' to zero in equation (253), and by keeping only the first gravitational term:

$$\Theta_0^{\text{equilibrium}} = -\frac{1}{3c_\text{s}^2}\psi = -(1+R)\psi \ .$$

Since the gravitational potential is non-zero on super-Hubble scales (we have seen that for adiabatic initial conditions $-2\psi = \delta_{\text{tot}}$), the equilibrium point is shifted away from zero on those scales. It reaches asymptotically zero on sub-sound-horizon scales.

②: wavelengths are smaller than the sound horizon during radiation domination. In this regime, the metric fluctuations have decayed, so the source term in Eq. (253) can be neglected. The friction term can also be neglected, because during radiation domination, $R \ll 1$. Finally the effective mass $k^2 c_\text{s}^2$ is constant in time because $R \ll 1$ implies $c_\text{s}^2 = 1/3$. Hence we are in the simple case discussed before, and the solution is proportional to $\cos(kc_\text{s}\eta)$, corresponding to stationary oscillations, symmetric around $\Theta_0 = 0$.

③: wavelengths are smaller than the sound horizon during the intermediate stage between the time of equality and that of photon decoupling. In this region, the metric perturbations have decayed, but R cannot be neglected (baryons and photons contribute to the total energy density with the same order of magnitude). Hence the oscillator equation has a non-negligible friction term (increasing with time), and a time-varying effective mass (decreasing with time). The solution of the equation corresponds to damped oscillations. Physically, this damping is caused by the increasing inertia and decreasing pressure of the baryon-photon fluid when the energy density of non-relativistic baryons takes over.

④: modes with smaller wavelength than the diffusion scale in the photon-baryon fluid. We have defined this scale in section 12.9.2. At early times, in the tightly-coupled limit, the mean free path of particles in the fluid is negligible, and cosmologically interesting scales are all well above the diffusion length. At the approach of decoupling, the diffusion length suddenly increases, and encompasses most of sub-sound-horizon wavelengths. In this regime, the oscillator equaion (253) does not apply anymore, because we cannot describe baryons and photons in terms of a perfect fluid. Perturbations are then strongly damped, since diffusion tends to average out any small-scale fluctuation.

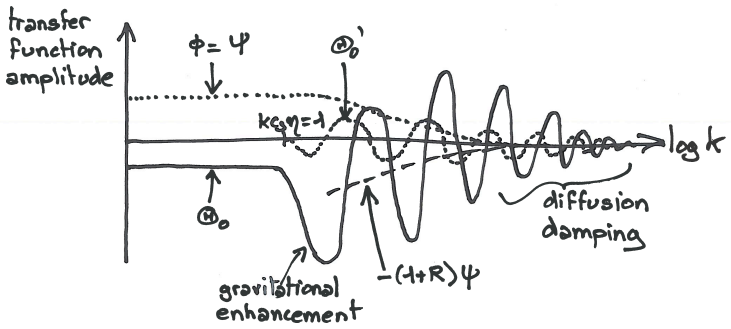

Figure 5: Transfer functions at the time of decoupling.

After describing these different regions, we are ready for understanding the qualitative behavior of the various relevant transfer functions, evaluated at the time of decoupling. Figure 142 shows the transfer functions $\Theta_0(\eta_{\text{dec}}, k)$ (solid line), $\psi(\eta_{\text{dec}}, k)$ (upper dotted line) and $\Theta_0'(\eta_{\text{dec}}, k)$ (middle dotted line) as a function of $\log k$. For simplicity, we neglect the role of the anisotropic stress generated by neutrinos (and to a lesser extent by photons near decoupling time). Hence we can assume $\phi = \psi$ at all times. For scales above the sound horizon ($kc_\text{s}\eta \ll 1$), the transfer functions are constant: indeed we know that, on those scales and in the Newtonian gauge, density and metric fluctuations are frozen. Adiabatic initial conditions impose $-2\psi = \delta_{\text{tot}} \simeq \delta_\text{b} \simeq \frac{3}{4}\delta_\gamma \simeq 3\Theta_0$. The opposite sign of Θ_0 and ψ reflects the fact that an overdensity corresponds to a temperature excess and a gravitational potential well (and vice-versa).

We remember that transfer functions are all normalized to $\mathcal{R}(\vec{k}) = 1$ (see section 12.9.1): this corresponds to a negative δ_γ (and Θ_0) and to a positive ψ, like in the figure.

Because of the decay of metric fluctuations inside the Hubble radius, the ψ curve smoothly decreases and tends towards zero in the small wavelength limit. The behavior of Θ_0 is more complicated. Modes which are just crossing the sound horizon near $\eta = \eta_{\rm dec}$ are experiencing the boost caused by gravitational source terms in Eq. (253): this explains the first bump in the solid line. For smaller wavelengths, we see oscillatory patterns corresponding to acoustic oscillations. Smaller wavelengths crossed the sound horizon earlier, and had more time for oscillating before decoupling. The maxima observed at the time of decoupling correspond to modes that could experience 0.5, 1, 1.5, 2,..., periods of oscillations before that time. The zero point of oscillations follows $-(1+R)\psi$, represented on the figure with a dashed line: this zero point reaches zero well inside the sound horizon. The amplitude of the oscillations is maximal for the first oscillatory pattern, i.e. for modes that crossed the sound horizon very recently. The second oscillatory pattern is reduced by the fact that those modes stayed for a longer time inside the sound horizon during the matter dominated regime, and experienced more damping due to baryons. The third and higher oscillatory patterns are reduced even more by diffusion damping just before photon decoupling. Temperature fluctuations on very small wavelengths are completely suppressed by photon diffusion.

Figure 142 also shows qualitatively the behavior of the time derivative $\Theta_0'(\eta_{\rm dec}, k)$, which exhibits oscillations that are out of phase with respect to those of $\Theta_0(\eta_{\rm dec}, k)$. This will be important in a few paragraphs, when discussing the Doppler effect.

Now that we understand qualitatively the behavior of the metric and photon transfer functions, we can go back to the decomposition of the CMB temperature spectrum C_l in three terms (Sachs-Wolfe, Doppler and integrated Sachs-Wolfe) discussed in section 12.9.2.

Sachs-Wolfe contribution.

We have seen that the Sachs-Wolfe contribution to C_l is approximately given by the power spectrum of the combination $(\Theta_0+\psi)$ at $\eta = \eta_{\rm dec}$, with a correspondence between k and l given by Eq. (247). We know that this power spectrum is given by the product of the primordial spectrum $\mathcal{P}_\mathcal{R}(k)$ (that we can choose to be scale-invariant in first approximation) by the square of the transfer function $(\Theta_0 + \psi)^2$. The qualitative behavior of the latter has no more secrets for us. We can pick up the solid and upper dotted lines in figure 142, add them up, and square the result.

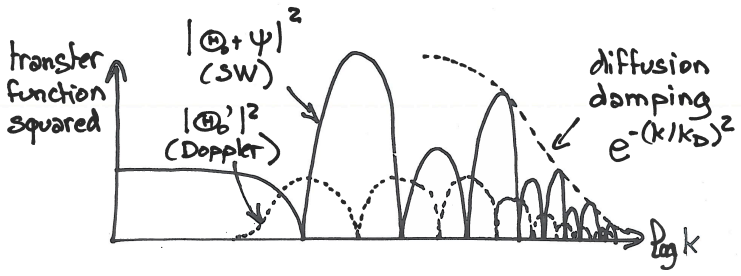

Figure 6: Squared transfer functions at the time of decoupling.

The result is shown in figure 143 as a function of $\log k$. For modes with $kc_s^2\eta \ll 1$, we see a flat plateau: there, our previous calculation of the Sachs-Wolfe effect would apply (this part of the curve is actually called the Sachs-Wolfe plateau). We then observe a series of peaks. Due to the shift of the zero-point of oscillations given by $-(1+R)\psi$ for Θ_0, and hence by $-R\psi$ for the Sachs-Wolfe term $(\Theta_0 + \psi)$, there is an asymmetry between the first few odd and even peaks, with odd peaks being enhanced. Moreover the overall amplitude of the peaks is suppressed in the large k limit by diffusion damping. A bit of algebra would show us that the envelope of the peaks is given in first approximation by the function $\exp[-(k/k_{\rm d})^2]$, where $k_{\rm d}$ is the diffusion wavenumber, related to the diffusion comoving scale of Eq. (209) by $k_{\rm d} r_{\rm d} = 1$.

Doppler contribution.

Next, we know that the C_l's receive a second contribution from the Doppler effect, related to the power spectrum of $\theta_{\rm b}$, which is equal to θ_γ until baryon and photons decouple from each other. It turns out that the photon velocity divergence θ_γ is itself related to the time derivative of the temperature fluctuation Θ_0. At a very qualitative level, we can infer the Doppler contribution from the shape of the transfer function $\Theta_0'(\eta_{\rm dec}, k)$. This contribution is null for scales above the sound horizon, since in this regime there are no oscillations and no significant dynamics in the fluid. On smaller scales, the Doppler contribution has oscillatory patterns, that are out of phase with respect to those of the Sachs-Wolfe term. The Doppler contribution is represented schematically as a dotted line in figure 143.

We can now sum up the Sachs-Wolfe and Doppler contributions. Also, we can transpose our results for power spectra as a function of k in terms of C_l's as a function of l. We have already seen in section 12.9.2 that there is a mapping betwwen the two, at least in the small-angle and instantaneous decoupling approximation, with a correspondence between values of k and l given by Eq. (247).

The result is shows in figure 144. Note that the vertical axis stands for $l^2 C_l$, for the following reason. If the primordial spectrum was scale invariant ($\mathcal{P}_\mathcal{R}(k) =$ constant) and the transfer functions were flat (as it is the case for large wavelengths/small l's), the quantity $l(l+1)C_l$ would also be flat and independent of l. This would follow from Eq. (240) if we had been more carefull in keeping all the factors. It is convenient to plot $l^2 C_l$ or $l(l+1)C_l$ instead of C_l, in order to display a roughly constant curve, just modulated by acoustic oscillations and diffusion damping.

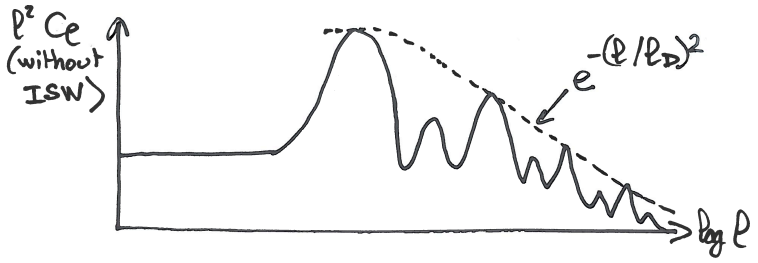

Figure 7: Contribution to the C_l's from the SW and Doppler terms.

Diffusion damping effect.

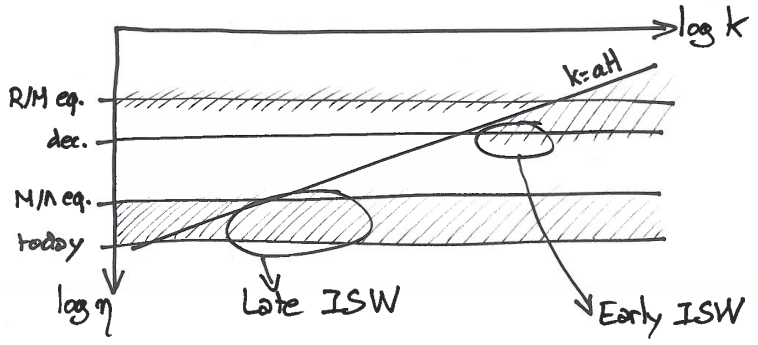

Figure 8: Regions in (k, η) space where metric fluctuations are expected to vary with time (giving rise potentially to an ISW effect after decoupling).

In summary, contribution to the integrated Sachs-Wolfe effect can only come from two regions:

- just after photon decoupling, on sub-sound-horizon scales, and

- during Λ domination, on all scales.

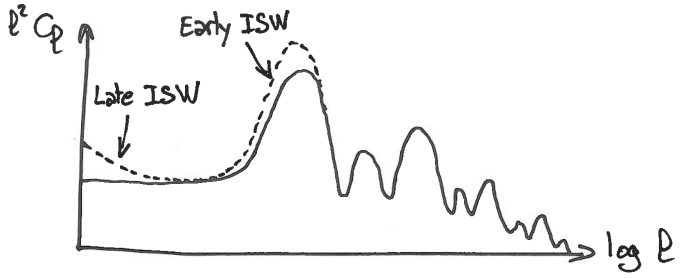

Figure 9: ISW contribution to the temperature spectrum.

Reionization effect.

The last effect that we omitted to describe is that of reionization. We have seen in section 12.9.2 that at small redshift ($z \simeq 10$), the reionization of the universe produces a small secondary bump in the visibility function, corresponding physically to a small probability for CMB photons to rescatter at late times. This rescattering will tend to smooth out any temperature anisotropy pattern. Hence, reionization lowers the overall amplitude of the C_l', but only a small amount (by approximately 15%). Note that the suppression of power is not uniform over the whole multipole range: smoothing effects cannot reach the largest observable scales (corresponding to the smallest values of l). Hence the effect of reionization is step-like shaped, and saturates for l of the order of 40 or so (as illustrated on figure 147).

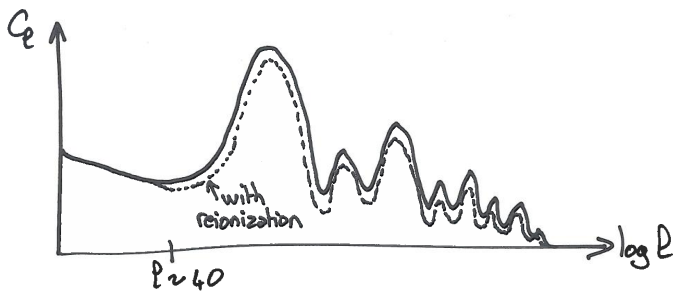

Figure 10: Impact of reionization on the temperature spectrum.

Parameter dependence of the temperature spectrum

$$\mathcal{P}_{\mathcal{R}}(k) = A_{\rm s}(k/k_*)^{n_{\rm s}-1} \ ,$$

$$H_0 \equiv 100\, h\, {\rm km.s^{-1}.Mpc^{-1}}$$

$$\rho_x^0 = \Omega_x \rho_{\rm crit}^0 = \Omega_x \frac{3H_0^2}{8\pi G} = \beta\, \omega_x$$

where $\beta = \frac{3(H_0/h)^2}{8\pi G}$ is a fixed number, with the dimension of an energy per volume.

The six free parameters of the minimal ΛCDM model can be chosen to be

$$\{A_{\rm s}, n_{\rm s}, \omega_{\rm b}, \omega_{\rm m}, \Omega_\Lambda, \tau_{\rm reio}\},$$

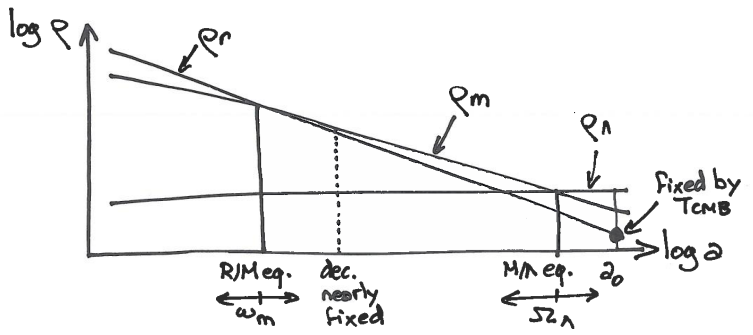

Figure 11: In the minimal ΛCDM model, evolution of the background density of radiation, matter and cosmological constant as a function of the scale factor.

$$\rho_r = \rho_{\rm m} \quad \Longrightarrow \quad \omega_r \left(\frac{a_0}{a_{\rm eq}}\right)^4 = \omega_{\rm m} \left(\frac{a_0}{a_{\rm eq}}\right)^3 \quad \Longrightarrow \quad \frac{a_{\rm eq}}{a_0} = \frac{\omega_r}{\omega_{\rm m}} \,.$$

$$\rho_{\rm m} = \rho_\Lambda \quad \Longrightarrow \quad \omega_{\rm m} \left(\frac{a_0}{a_\Lambda}\right)^3 = \Omega_\Lambda h^2 \quad \Longrightarrow \quad \frac{a_\Lambda}{a_0} = \left(\frac{1-\Omega_\Lambda}{\Omega_\Lambda}\right)^{1/3} \,,$$

A quick word on polarization

The Bolztmann equation presented in Eq. (217) was a bit over-simplified. We did as if the only degree of freedom describing photons with a blackbody spectrum was their temperature. In fact, photons are described by more degrees of freedom, called the Stokes parameters, involving also their polarization. In Eq. (217), the Thomson scattering rate was integrated over polarization parameters, but in reality some polarized correction terms are present.

In general, a vector field can be decomposed into a gradient and a curl component, like the electric and magnetic fields. Similarly, CMB polarization maps can be expanded in two scalar maps called, by analogy, E-type and B-type polarization maps.

One can show that primordial scalar perturbations can produce both temperature anisotropies and E-type polarization anisotropies. If the early universe only features Gaussian scalar perturbations on cosmological scales, all the information contained in CMB maps is encoded in the temperature power spectrum C_l^{TT}, the E-type polarization power spectrum C_l^{EE}, and the cross-correlation power spectrum C_l^{TE}. The later really contains additional independent information, because polarization patterns are only partially correlated with temperature patterns (in mathematical terms, $[C_l^{TE}]^2 \leq C_l^{TT} C_l^{EE}$).

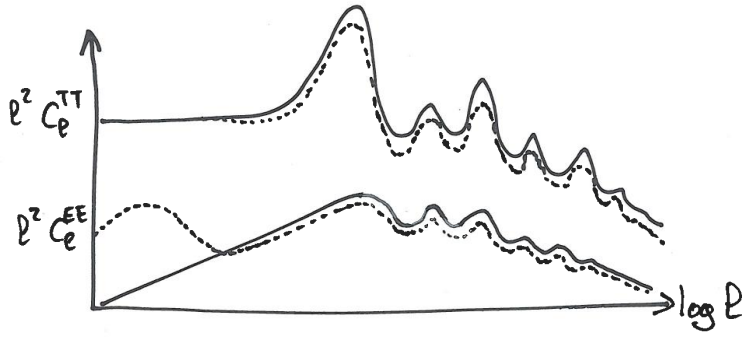

Figure 12: Typical shape of the temperature and E-type polarization power spectra in a ΛCDM model without (solid lines) or with (dotted lines) reionization of the universe at small redshift.

First, reionization has a very distinct effect on the polarization spectrum. The small fraction of photons rescattered around the time of reionization acquire additional polarization that will

show up in the form of a peak in the small-l branch of C_l^{EE} (see figure 149) and C_l^{TE}. We have seen in the previous section that with temperature data only, cosmic variance limits our ability to measure $\tau_{\rm reio}$, and *a fortiori* to constrain additional parameters describing the reionization history. The effect of reionization in the small-l branch of C_l^{EE} and C_l^{TE} is so big that despite of cosmic variance, $\tau_{\rm reio}$ can be well measured using polarization data.

(допишу потом)

A quick word on tensors

We have seen in section 12.9.1 that tensor modes are related to the traceless divergenceless components of the metric and stress-energy tensor, obeying to

$$\sum_i \delta T_{ii} = 0 \qquad \text{and} \qquad \forall j, \quad \sum_i \partial_i \delta T_{ij} = 0 \ .$$

Since these relations impose four constraints on the six degrees of freedom of the 3×3 symmetric matrix δT_{ij} (or δg_{ij}), there are two tensor degrees of freedom in $g_{\mu\nu}$ and $T_{\mu\nu}$.

The two degrees of freedom in δg_{ij} are the two degrees of polarization of gravitational waves, that can propagate even in the vacuum. In the presence of matter with a non-diagonal stress tensor δT_{ij}, gravitational waves can be seeded by the tensor components δT_{ij}.

If tensor perturbations are sufficiently large at recombination or later, they can generate CMB temperature and polarization anisotropies: one can show that they interact with CMB photons, and produce effects similar to the SW and ISW ones. As mentioned in the previous section, gravitational waves can even seed B-type polarization.

Large-Scale Anisotropies by Dodelson

1.3.8 Details of anisotropies, other approaches in a nutshell (!!!!!!!!!)

Acoustic Oscillations by Dodelson (????)

$$\dot\Theta_l + \frac{k}{(-i)^{l+1}} \int_{-1}^{1} \frac{d\mu}{2} \mu \mathcal{P}_l(\mu) \Theta(\mu) = \dot\tau \Theta_l .$$

er terms (e.g., $-\dot\Phi$) have simple μ dependence (sca ments vanish for them. To do the integral, we on for Legendre polynomials, Eq. (C.3), to get

$$\dot\Theta_l - \frac{kl}{2l+1}\Theta_{l-1} + \frac{k(l+1)}{2l+1}\Theta_{l+1} = \dot\tau \Theta_l .$$

(?? слова про смысл перехода)

$$v_{\rm b} \simeq -3i\Theta_1 + \frac{R}{\dot\tau}\left[-3i\dot\Theta_1 - 3i\frac{\dot a}{a}\Theta_1 + ik\Psi\right].$$

$$\ddot\Theta_0 + \frac{\dot a}{a}\frac{R}{1+R}\dot\Theta_0 + k^2c_s^2\Theta_0 = -\frac{k^2}{3}\Psi - \frac{\dot a}{a}\frac{R}{1+R}\dot\Phi - \ddot\Phi \equiv F(k,\eta)$$

where on the right F is a forcing function and $c_s := \sqrt{\frac{1}{3(1+R)}}$ is the sound speed.

$$\left\{\frac{d^2}{d\eta^2} + \frac{\dot R}{1+R}\frac{d}{d\eta} + k^2c_s^2\right\}[\Theta_0+\Phi] = \frac{k^2}{3}\left[\frac{1}{1+R}\Phi - \Psi\right].$$

Tightly Coupled Limit of the Boltzmann Equations (?!!!!)

(!!! короче, додумаю скоро!!!)
In this limit, the two homogeneous solutions (? to what?) are

$$S_1(k,\eta) = \sin\left[kr_s(\eta)\right]; \qquad S_2(k,\eta) = \cos\left[kr_s(\eta)\right]$$

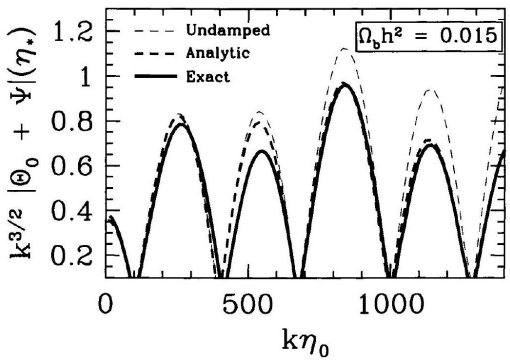
$$r_s(\eta) := \int_0^\eta d\eta' c_s\left(\eta'\right) \qquad \text{(sound horizon),}$$

c_s is the sound speed, the sound horizon is the comoving distance traveled by a sound wave by time η.

The tightly coupled solution for the photon temperature can be constructed from the homogeneous solutions of Eq. (8.21):

$$\Theta_0(\eta) + \Phi(\eta) = C_1S_1(\eta) + C_2S_2(\eta) + \frac{k^2}{3}\int_0^\eta d\eta'\left[\Phi\left(\eta'\right) - \Psi\left(\eta'\right)\right]\frac{S_1\left(\eta'\right)S_2(\eta) - S_1(\eta)S_2\left(\eta'\right)}{S_1\left(\eta'\right)\dot S_2\left(\eta'\right) - \dot S_1\left(\eta'\right)S_2\left(\eta'\right)}$$

$$\Theta_0(\eta) + \Phi(\eta) = \left[\Theta_0(0) + \Phi(0)\right]\cos\left(kr_s\right) + \frac{k}{\sqrt{3}}\int_0^\eta d\eta'\left[\Phi\left(\eta'\right) - \Psi\left(\eta'\right)\right]\sin\left[k\left(r_s(\eta) - r_s\left(\eta'\right)\right)\right]$$



Inhomogeneities to Anisotropies by 8.5.1 Dodelson (!!!)

The C_l's

Effects of CMB by Dodelson

Sachs-Wolfe Effect (8.6.2)

(додумаю когда-то точно!)

ISW effect (??????????!!!)

(додумаю когда-то точно!)

Most of the CMB anisotropy is formed at very high redshift where there are no galaxies. However the ISW effect, which involves changes in the gravitational potential giving energy to (or taking energy from) the CMB photons, is active at late times. The temperature perturbation due to ISW is:

$$\Theta(\hat{\mathbf{n}})|_{\rm ISW} = 2\int \dot{\Phi}(r\hat{\mathbf{n}})dr.$$

This is zero in the matter-dominated era because Φ = constant. However the Poisson equation gives:

$$\Phi = -\frac{4\pi G a^2}{k^2}\bar{\rho}_m\delta,$$

and since $\bar{\rho}_m \propto a^{-3}$ and $\delta \propto D(a)$, the potential varies with time in proportion to $D(a)/a$. Thus in a Λ CDM universe, where D grows more slowly than a, the potentials move toward zero. In overdense regions $\dot{\Phi} > 0$, and in underdense regions $\dot{\Phi} < 0$. This leads to a small additional anisotropy in the CMB, but more importantly it leads to a positive correlation of the CMB with the galaxy distribution. The effect is unique to models with Λ or curvature and its detection rules out Einstein-de Sitter.

This galaxy-CMB cross-correlation was first observed by combining the WMAP CMB data with several galaxy surveys (2MASS, APM, SDSS, NVSS) and the Xray background (HEAO). Two combined analyses of the ISW effect with many galaxy samples have been undertaken by Ho et al. (2008) and Giannantonio et al. (2008) with a total detection significance of 4σ. In the matter+curvature

(wiki????)

The "late-time" ISW effect arises quite recently in cosmic history, as dark energy, or the cosmological constant, starts to govern the universe's expansion. Unfortunately, the nomenclature is a bit confusing. Often, "late-time ISW" implicitly refers to the late-time ISW effect to linear/first order in density perturbations. This linear part of the effect entirely vanishes in a flat universe with only matter, but dominates over the higherorder part of the effect in a universe with dark energy. The full nonlinear [disambiguation needed] (linear + higher-order) late-time ISW effect, especially in the case of individual voids and clusters, is sometimes known as the Rees-Sciama effect, since Martin Rees and Dennis Sciama elucidated the following physical picture.[2]

Accelerated expansion due to dark energy causes even strong large-scale potential wells (superclusters) and hills (voids) to decay over the time it takes a photon to travel through them. A photon gets a kick of energy going into a potential well (a supercluster), and it keeps some of that energy after it exits, after the well has been stretched out and shallowed. Similarly, a photon has to expend energy entering a supervoid, but will not get all of it back upon exiting the slightly reduced potential hill.

A signature of the late-time ISW is a non-zero cross-correlation function between the galaxy density (the number of galaxies per square degree) and the temperature of the CMB, [3] because superclusters gently heat photons, while supervoids gently cool them. This correlation has been detected at moderate to high significance. [4][5][6][7][8]

In May 2008, Granett, Neyrinck & Szapudi showed that the late-time ISW can be pinned to discrete supervoids and superclusters identified in the SDSS Luminous Red Galaxy catalog. [9] Their ISW detection traces the localised ISW effect produced by supervoids and superclusters

have on the CMB. However, the amplitude of this localised detection is controversial, as it is significantly larger than the expectations and depends on several assumptions of the analysis.

Small Scales

(8.6.2 dodelson)

1.3.9 Other properties of CMB in a nutshell (!!??)

(тут именно про всякий бэкграунд, как анализировать данные, которые мы видим???? ну и мб чуть про их получение.)

Polarization of CMB

For polarization one can define a similar decomposition:

$$\begin{pmatrix} Q(\hat{\mathbf{p}}) & U(\hat{\mathbf{p}}) \\ U(\hat{\mathbf{p}}) & -Q(\hat{\mathbf{p}}) \end{pmatrix} = \sum_{lm} \left[a^E_{lm} Y^E_{\mathrm{lm}\,\hat{a}\hat{b}}(\hat{\mathbf{p}}) + a^B_{\mathrm{lm}} Y^B_{lm} \hat{a}\hat{\mathbf{p}}) \right].$$

There are separate E-type and B-type power spectra,

$$\left\langle a^{E*}_{lm} a^E_{l'm'} \right\rangle = C^{EE}_l \delta_{ll'} \delta_{mm'}, \qquad \left\langle a^{B*}_{lm} a^B_{l'm'} \right\rangle = C^{BB}_l \delta_{ll'} \delta_{mm'}.$$

Because E has the same parity as temperature, it is also possible to have a temperature-polarization spectrum:

$$\left\langle a^*_{lm} a^E_{l'm'} \right\rangle = C^{\Theta E}_l \delta_{ll'} \delta_{mm'}.$$

The power spectra for the scalars can be determined using the same method as for the temperature, i.e. integrating over wavenumbers and angles to get:

$$C^{EE}_l = 4\pi \int \Delta^2_\zeta(k) \left| \frac{E_l}{\zeta}(k) \right|^2 d\ln k$$
$$C^{\Theta E}_l = 4\pi \int \Delta^2_\zeta(k) \mathrm{Re} \left[\frac{\Theta^*_l}{\zeta}(k) \frac{E_l}{\zeta}(k) \right] d\ln k.$$

(real part and complex conjugate are technically unnecessary for the scalars since Θ_l/ζ and E_l/ζ are real).

General important questions about CMB

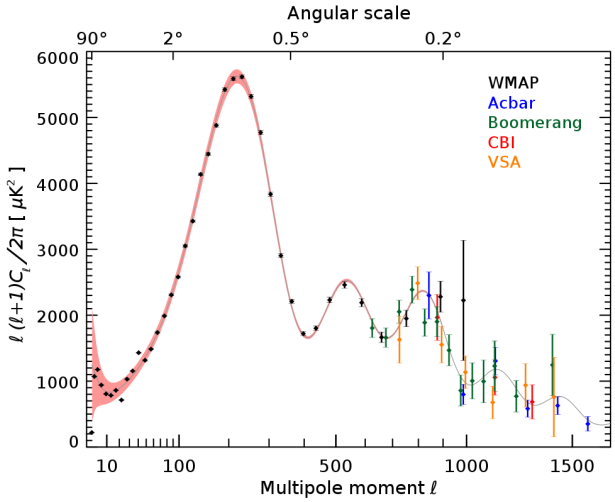
How to obtain the temperature of photons? (!?!?!??!?)

By some distribution (???)
(idk, very interesting question)

Effects of dark matter on CMB and matter spectrum

(see Lesgourgues, not important now)

Observations of CMB (???)



(!!! тут важное описание, того, почему именно такая СМБ, почему именно такие особенности, что по центру чуть ярче???)

(мб картинки добавлю разного анализа СМБ, они есть, просто я все равно их не понимаю, так что когда-то потом займусь ими)

1.4 Mathematics and physical background for applications

1.4.1 Physical background for fluctuations, constants, mathematics

(идея в том, что тут всякая математика и сама собой разумеющаяся физика, потом соберу их)

Constants for cosmology

(I'll add later)

On Gaussian perturbations

A real field $f(\mathbf{x})$ (which could for instance be a density perturbation at the time of recombination) in a region with finite volume V, this field can be Fourier expanded as $f(\mathbf{x}) = \frac{1}{\sqrt{V}} \sum_{\mathbf{k}} f_{\mathbf{k}} e^{i\mathbf{k}\cdot\mathbf{x}}$. Reality of f implies that $f_{-\mathbf{k}} = f^*_{\mathbf{k}}$. If $f_{\mathbf{k}} \equiv a_{\mathbf{k}} + ib_{\mathbf{k}}$, we find $a_{-\mathbf{k}} = a_{\mathbf{k}}$ and $b_{-\mathbf{k}} = -b_{\mathbf{k}}$.

(!?!?!?!?!? why do we want to analyze many regions of CMB sphere??!!)

One way to think about probability distributions is to imagine having a very large number N of such spatial regions, and that the coefficients $a_{\mathbf{k}}$ and $b_{\mathbf{k}}$ can take different values in different regions. In general, a probability distribution function $P\left(\{a_{\mathbf{k}}\}, \{b_{\mathbf{k}}\}\right)$ can be defined by

$$dN = NP\left(\{a'_{\mathbf{k}}\}, \{b'_{\mathbf{k}}\}\right) \prod_{\mathbf{k}} \left(da_{\mathbf{k}} db_{\mathbf{k}}\right),$$

where dN denotes the number of regions with $a'_{\mathbf{k}} < a_{\mathbf{k}} < a'_{\mathbf{k}} + da_{\mathbf{k}}$ and $b'_{\mathbf{k}} < b_{\mathbf{k}} < b'_{\mathbf{k}} + db_{\mathbf{k}}$ for all $\mathbf{k}$. We are interested in situations where the various modes are uncorrelated, meaning that

$$P\left(\{a_{\mathbf{k}}\}, \{b_{\mathbf{k}}\}\right) = \prod_{\mathbf{k}} p\left(a_{\mathbf{k}}, b_{\mathbf{k}}\right).$$

The simplest inflationary models predict homogeneous and isotropic Gaussian distributions,

$$p\left(a_{\mathbf{k}}, b_{\mathbf{k}}\right) = \frac{1}{\pi\sigma_k^2} \exp\left(-\frac{a_{\mathbf{k}}^2}{\sigma_k^2}\right) \exp\left(-\frac{b_{\mathbf{k}}^2}{\sigma_k^2}\right),$$

where σ_k only depends on $k \equiv |\mathbf{k}|$. Now we can compute correlation functions, such as

$$\langle f_{\mathbf{k}} f_{\mathbf{k}'} \rangle = \langle a_{\mathbf{k}} a_{\mathbf{k}'} \rangle - \langle b_{\mathbf{k}} b_{\mathbf{k}'} \rangle + i \langle a_{\mathbf{k}} b_{\mathbf{k}'} \rangle + i \langle b_{\mathbf{k}} a_{\mathbf{k}'} \rangle = \sigma_k^2 \delta_{\mathbf{k},-\mathbf{k}'},$$

(For example, $\langle a_{\mathbf{k}}^2 \rangle = \int\limits_{-\infty}^{\infty} da_{\mathbf{k}} db_{\mathbf{k}} \frac{1}{\pi\sigma_k^2} \exp\left(-\frac{a_{\mathbf{k}}^2}{\sigma_k^2}\right) \exp\left(-\frac{b_{\mathbf{k}}^2}{\sigma_k^2}\right) a_{\mathbf{k}}^2 = \frac{\sigma_k^2}{2}$).

Now, in the infinite volume limit, $V \to \infty$ (????):

$$\sum_{\mathbf{k}} \to \frac{V}{(2\pi)^3} \int d^3\mathbf{k},$$
$$f_{\mathbf{k}}^{\text{old}} \to V^{-1/2} f_{\mathbf{k}}^{\text{new}},$$
$$p_{\text{old}}\ (a_{\mathbf{k}}, b_{\mathbf{k}}) \to V p_{\text{new}}\ (a_{\mathbf{k}}, b_{\mathbf{k}}),$$

so that

$$f(\mathbf{x}) = \int \frac{d^3\mathbf{k}}{(2\pi)^3} f_{\mathbf{k}} e^{i\mathbf{k}\cdot\mathbf{x}},$$
$$p\left(f_{\mathbf{k}}\right) = \frac{1}{\pi V \sigma_k^2} \exp\left(-\frac{|f_{\mathbf{k}}|^2}{V\sigma_k^2}\right),$$
$$\langle f_{\mathbf{k}} f_{\mathbf{k}'} \rangle = V\sigma_k^2 \delta_{\mathbf{k},-\mathbf{k}'} = (2\pi)^3 \sigma_k^2 \delta\left(\mathbf{k} + \mathbf{k}'\right),$$

In the $V \to \infty$ limit the expression for $p\left(f_{\mathbf{k}}\right)$ is only formally defined, but the correlator $\langle f_{\mathbf{k}} f_{\mathbf{k}'} \rangle$ remains well-defined.

(?????? тут важный абзац, физически что вообще мы получаем, когда считаем эти корреляции??? что означает, что две области скореллированы??? что они когда-то были рядом?)

О квантовых полях для космологических возмущений

$$\pi(\mathbf{x}, t) \equiv \frac{\delta L[\phi]}{\delta\dot{\phi}(\mathbf{x}, t)} = \dot{\phi}(\mathbf{x}, t)$$

$$H = \int d^3\mathbf{x} \pi(\mathbf{x}, t)\dot{\phi}(\mathbf{x}, t) - L = \frac{1}{2}\int d^3\mathbf{x} \left[\pi^2 + (\nabla\phi)^2 + m^2\phi^2\right].$$

$$[\hat{\phi}(\mathbf{x}, t), \hat{\pi}(\mathbf{y}, t)] = i\delta(\mathbf{x} - \mathbf{y})$$
$$[\hat{\phi}(\mathbf{x}, t), \hat{\phi}(\mathbf{y}, t)] = 0 \qquad [\hat{\pi}(\mathbf{x}, t), \hat{\pi}(\mathbf{y}, t)] = 0.$$

$$\hat{\phi}(\mathbf{x}, t) = \int \frac{d^3\mathbf{k}}{(2\pi)^{3/2}} \frac{1}{\sqrt{2\omega_k}} \left[e^{-i\omega_k t} e^{i\mathbf{k}\cdot\mathbf{x}} a_{\mathbf{k}} + e^{i\omega_k t} e^{-i\mathbf{k}\cdot\mathbf{x}} a_{\mathbf{k}}^\dagger\right],$$

$$H = \int d^3\mathbf{k} \frac{\omega_k}{2} \left(a_{\mathbf{k}} a_{\mathbf{k}}^\dagger + a_{\mathbf{k}}^\dagger a_{\mathbf{k}}\right) = \int d^3\mathbf{k}\omega_k \left(a_{\mathbf{k}}^\dagger a_{\mathbf{k}} + \frac{1}{2}\delta^{(3)}(0)\right).$$

$$E_0 = \delta^{(3)}(0)\frac{1}{2}\int d^3\mathbf{k}\omega_k.$$

(что нужно будет - то и допишу)

On Wronskian method

(додумаю когда-то его, возможно, и без него можно все делать)

$$\hat{q}(t) = q(t)\hat{a} + q^*(t)\hat{a}^\dagger,$$
$$W\left[q, q^*\right] \times \left[\hat{a}, \hat{a}^\dagger\right] = 1,$$
$$W\left[q_1, q_2^*\right] \equiv -i\left(q_1 \partial_t q_2^* - \left(\partial_t q_1\right) q_2^*\right)$$

$$W\left[q, q^*\right] \equiv 1,$$
$$\left[\hat{a}, \hat{a}^\dagger\right] = 1.$$

On Framework of Zero Point Fluctuations

$$\left\langle |\hat{q}|^2 \right\rangle = |q(t)|^2 = \frac{\hbar}{2\omega}.$$

(может, что-то допишу еще)

On Framework of choosing a vacuum

(про то, какая тут идея вообще?)

1.4.2 Basic diffgeom and mathematics for cosmology

Основы диффгема для космологии

(в диффгеме очень много всего, там сперва отработаю темы, сюда потом вставлю определения и формулы. Тоже полезно, тоже много вопросов может про это быть)

Однородные пространства по Ландау

(тут крутой диффгем, потом додумаю его, пока просто не нужен был он)

$$\eta_{ad}\eta_{be}\eta_{cf}e^{def} = \eta e_{abc}, \quad e_{abf}e^{cdf} = \delta_a^c\delta_b^d - \delta_a^d\delta_b^c.$$

Уравнения Эйнштейна в синхронной системе выражаются, согласно (97.11)-(97.13), через трехмерные тензоры $\varkappa_{\alpha\beta}$ и $P_{\alpha\beta}$. Для первого имеем просто

$$\varkappa_{(a)(b)} = \dot{\eta}_{ab}, \quad \varkappa_{(a)}^{(b)} = \dot{\eta}_{ac}\eta^{cb}$$

(точка означает дифференцирование по t). Компоненты же $P_{(a)(b)}$ можно выразить через величины η_{ab} и структурные константы группы с помощью (98.14). После замены трехиндексовых $\lambda^a{}_{bc} = C^a{}_{bc}$ на двухиндексовые C^{ab} и ряда преобразований [1]) получим:

$$P_{(a)}^{(b)} = \frac{1}{2\eta}\left\{2C^{bd}C_{ad} + C^{db}C_{ad} + C^{bd}C_{da} - C^d{}_d\left(C^b{}_a + C_a{}^b\right) + \delta_a^b\left[\left(C_d^d\right)^2 - 2C^{df}C_{df}\right]\right\}.$$

Тождества Бианки для трехмерного тензора $P_{\alpha\beta}$ в однородном пространстве:

$$P_b^c C^b{}_{ca} + P_a^c C^b{}_{cb} = 0.$$

Реперные составляющие 4-тензора Риччи (????):

$$R_0^0 = -\frac{1}{2}\dot{\varkappa}_{(a)}^{(a)} - \frac{1}{4}\varkappa_{(a)}^{(b)}\varkappa_{(b)}^{(a)},$$
$$R_{(a)}^0 = -\frac{1}{2}\varkappa_{(b)}^{(c)}\left(C_{ca}^b - \delta_a^b C_{dc}^d\right),$$
$$R_{(a)}^{(b)} = -\frac{1}{2\sqrt{n}}\left(\sqrt{\eta}\varkappa_{(a)}^{(b)}\right) \bullet - P_{(a)}^{(b)}.$$

1.5 Main cosmological parameters and ideas

1.5.1 Hubble parameter and tension in a nutshell

(!! это додумать нужно!!! важный вопрос)

Measurements of Hubble constant

(ничего не знаю, потом подумаю и добавлю инфу. пока из лекций Калтеха)

HST Key Project. The basic idea in this measurement is to use Cepheid variable stars to measure distances to nearby galaxies ($\leq$ 20Mpc). Then use these galaxies to calibrate secondary luminosity standards that are used for more distant galaxies ($>$ 20Mpc). Second step is necessary for the Hubble flow ($v = HD$) to dominate over random velocities of galaxies (typically a few hundred km/s).

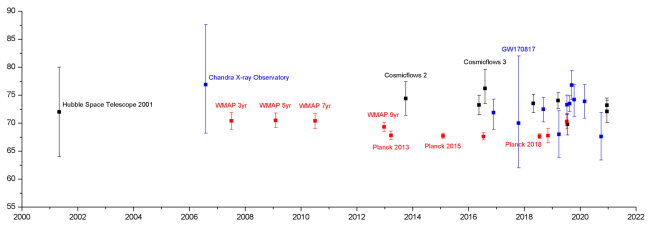
Cepheids are high-mass (typical $\sim 5M_\odot$), luminous (typical $\sim 10^3 L_\odot$) stars near the end of their lives that are unstable against radial pulsations with periods typically of a few days. The radial pulsations are linearly unstable due to the increase of opacity as the star is compressed and He^+ionizes to He^{2+} (traps heat which causes positive work during the expanding part of the cycle). They are stabilized at the nonlinear level which prevents the star from disrupting.

Cepheids have a range of luminosities, so the first step is to calibrate periodluminosity relation for Cepheids. The HST Key Project did this against the Large Magellanic Cloud at distance 50kpc. They find

$$M_V = -2.76 \log_{10} \frac{P}{10\ \mathrm{d}} - 4.22,$$
$$M_I = -2.96 \log_{10} \frac{P}{10\ \mathrm{d}} - 4.90.$$

Does it really exist?

Hubble tension and overview of explanations



1.5.2 Dark Matter in a nutshell

History of DM and Evidence

• In typical galaxies, we infer from the galactic luminosity distribution that the mass is strongly concentrated at the center. So away from the center, stellar velocities should fall off as $v \propto 1/\sqrt{r}$.

• We can measure the function $v(r)$ by measuring redshifts in galaxies tilted relative to us. The result is that $v(r)$ is flat at high distances, or can even increase. Historically, such observations were made in 1939 for the Andromeda galaxy and extended to larger radii in the 1970s by Rubin and Ford. Later, similar measurements were done at radii well beyond the visible disk by measuring 21 cm line emission.

• One should also account for interstellar gas in the calculation of $\rho(r)$, which extends beyond the stars. This can be measured from 21 cm line emission, but in any case is not nearly enough. In addition, there have been decades of searches for baryonic massive compact halo objects (MACHOs) which were just too dim to see, such as cool red and white dwarfs, brown dwarfs, black holes, and rogue planets. But none are present in nearly enough quantity to account for the discrepancy, supporting a nonbaryonic "dark" contribution.

• The curves can be fit by assuming a spherically symmetric DM halo. The halo extends far beyond the galactic disk, with significant density up to order 100kpc from the center. The

density functions $\rho(r)$ can be computed by numerical simulations; at the simplest level, they simply solve the collisionless Boltzmann equation. Some commonly used profiles are

$$\rho(r) = \rho_0 \times \begin{cases} 1/\tilde{r}\,(1+\tilde{r}^2) & \text{Navarro-Frenk-White (NFW)} \\ 1/\tilde{r}^{\gamma}\,(1+\tilde{r}^{3-\gamma}) & \text{generalized NFW} \\ 1/(1+\tilde{r})\,(1+\tilde{r}^2) & \text{Buckert} \\ \exp\left(-2\left(\tilde{r}^{\alpha}-1\right)/\alpha\right) & \text{Einasto} \end{cases}$$

where $\tilde{r} = r/r_s$ and r_s is the scale radius, where $r_s \simeq 20$kpc for our galaxy. Generally, these expressions can't be derived from any analytic model; they empirically fit the results of simulations. Note that a constant $v(r)$ at large radii corresponds to $\rho(r) \propto 1/r^2$.

• Such a wide DM distribution occurs naturally: objects can only gravitationally collapse if they can radiate away energy, while DM only weakly interacts. The collapsing visible matter then becomes a disc, because of the angular momentum barrier, while the DM halo remains spherical.

• We can also infer our local DM density by measuring the local vertical distribution of stars; however, this method is quite noisy and gives a value that could be consistent with zero.

• There are subtleties with modeling galaxies numerically. For example, simulated halo density profiles are often "cuspy" (with a sharp increase at small radii, like the NFW or Einasto profile), but observations suggest "cored" density profiles (flat at small radii, like the Buckert profile).

• However, most DM simulations completely neglected the effects of the baryons, since they are a subdominant fraction of the mass, and have much more complex interactions. But near the center of a galaxy, the baryonic density becomes very high, so they might affect the DM halo.

• Adiabatic contraction. As the baryons slowly collapse, they also pull in the DM (as can be computed using adiabatic invariants). This makes the DM profile more cuspy.

• "Bursty" outflows of baryonic matter, e.g. from supernova and active galactic nuclei, could carry DM outward, coring the profile.

• The DM halo could also be affected by DM self-interactions.

These simulations are difficult, and many parameters must be determined empirically. So far, there's no definitive resolution to the problem, because the uncertainties are large.

• In addition, ΛCDM simulations seem to indicate more small scale structure than is actually observed, specifically more dwarf galaxies bound to the Milky Way; this is called the "too big to fail" or "missing satellites" problem. On the other hand, others argue that this is just observation bias; the satellite galaxies might just be too dim to see, and more are being discovered regularly. Almost all problems with DM are galactic in nature (see this recent review), but galactic dynamics is extraordinarily complex and uncertain.

Note. MOND is an alternative hypothesis that explains galaxy rotation curves well. Here, the gravitational acceleration due to a mass takes the limiting value

$$\lim_{r\to\infty} g = \sqrt{\frac{GMa_0}{r^2}}$$

for a constant a_0. This explains flat rotation curves, because we expect

$$\frac{v^2}{r} = \sqrt{\frac{GMa_0}{r^2}}$$

at large distances, and the factors of r cancel. It also provides a direct explanation of the empirical Tully-Fisher relation $L \propto v^4$, assuming that $M \propto L$. There are several options for g at intermediate values of r which can be adjusted to fit observations at intermediate radii.

In general, MOND seems to do a better job of fitting rotation curves, requiring fewer parameters than galaxy simulations with DM, but completely fails to match evidence from galaxy clusters and the CMB; the only MOND models that work here also use DM. Moreover, galaxy simulations are steadily improving with time, reducing the benefit that MOND provides. This explains the comparatively little interest in MOND: it only gives a minor benefit to the modeling of only one of many aspects of the universe. (However, there are theories of superfluid DM which reduce to MOND on galactic scales. Also, to be fair, one can get the right CMB power spectrum with MOND as long as one puts in a precisely chosen, bumpy initial power spectrum; in this case DM plus inflation has the advantage of working with generic initial

conditions, i.e. being more predictive.) For a deeper look at the debate from a philosophical perspective, see this review.

Evidence for dark matter also comes from observing clusters of galaxies.

• Historically, this was the first evidence for dark matter, proposed in 1933 by Fritz Zwicky to explain observations of the Coma cluster.

• Regarding each galaxy as a point mass, we can show the virial theorem,

$$\ddot{I} = 2T + V, \quad I = \frac{1}{2}\sum_i m_i \mathbf{r}_i \cdot \mathbf{r}_i$$

where I is the virial, T is the total kinetic energy, and V is the total potential energy. In the steady state, $\ddot{I}$ averages to zero and we have

$$T = -\frac{V}{2}$$

which allows us to estimate the mass of a cluster of galaxies from the observed $\langle v^2 \rangle$.

• In practice, we can estimate $\langle v_\perp^2 \rangle$ from redshifts, and multiply by 3 assuming spherical symmetry. We also assume $\rho(r)$ is proportional to the luminosity $L(r)$, allowing us to estimate the average potential energy. Combining these gives a total mass several times higher than the stellar mass inferred by a "census" estimate using luminosity.

• One also needs to know the distance to the cluster. Zwicky did this using the overall Doppler shift and Hubble's law. Though he used an incorrect value for the Hubble constant, overestimating the amount of DM, he did find the right qualitative conclusion.

• The common ground between cluster observations and rotation curves is that they use "tracers", visible collisionless objects that respond to the DM density. Stars are generally excellent tracers because they are very sparse, and hence collisionless.

• DM is also responsible for presence of the hot intracluster gas, which emits X-rays; if DM were not present, most of the gas would be gone. Assuming the gas is in hydrostatic equilibrium and obeys the ideal gas law,

$$\frac{dP}{dr} = -\frac{GM(r)\rho(r)}{r^2}, \quad P = \frac{\rho k T}{m}$$

we find that

$$M(r) = \frac{kT(r)r}{Gm}\left(-\frac{d\log(\rho T)}{d\log r}\right)$$

so that $M(r)$ can be inferred from the functions $T(r)$ and $\rho(r)$, which are measured by X-ray emission. This was done in the 1990s and indicate the same result.

Note. A proof of the virial theorem. We simply differentiate to find

$$\dot{I} = \sum_i \mathbf{r}_i \cdot \mathbf{p}_i, \quad \ddot{I} = \sum_i \mathbf{v}_i \cdot \mathbf{p}_i + \mathbf{r}_i \cdot \mathbf{F}_i$$

The first term in $\ddot{I}$ is simply $2T$. To handle the second term, note that

$$\sum_i \mathbf{r}_i \cdot \mathbf{F}_i = -\sum_{i\neq j} \mathbf{r}_i \cdot \nabla_i V_{ji} = -\sum_{i<j} \mathbf{r}_i \cdot \nabla_i V_{ji} - \sum_{i>j} \mathbf{r}_i \cdot \nabla_i V_{ji}$$

Swapping the index names on the second term, we get

$$-\sum_{i<j} \mathbf{r}_i \cdot \nabla_i V_{ji} + \mathbf{r}_j \cdot \nabla_j V_{ij} = -\sum_{i<j} (\mathbf{r}_i - \mathbf{r}_j) \cdot \nabla_i V_{ji}$$

where we used the fact that $V_{ij} = V_{ji}$ is a function of $\mathbf{r}_i - \mathbf{r}_j$. Now, for any power law potential $V_{ij} \propto (\mathbf{r}_i - \mathbf{r}_j)^n$, the term simplifies using the power rule to $-nV$, giving the result

$$\ddot{I} = 2T - nV.$$

But as long as we work in the CM frame, we expect $\dot{I}$ to be roughly constant over time, giving

$$\langle T \rangle = \frac{n}{2} \langle V \rangle$$

Using the virial theorem, we can also estimate the speed of dark matter in the galactic halo,

$$v \sim \sqrt{\frac{GM_{\text{halo}}}{R_{\text{halo}}}} \sim \sqrt{G\frac{10^{12} M_\odot}{100\text{kpc}}} \sim 200 \text{ km/s}$$

That is, we have $v/c \sim 10^{-3}$.

Note. For generic initial conditions, we estimate the virialization time to be on the order of the gravitational collapse timescale $t \sim 1/\sqrt{G\rho}$, which is on the order of the time it takes the galaxy to rotate; the Milky Way has rotated about 100 times since its formation. There is the possibility of a nonvirialized subcomponent to dark matter. For example, dark matter that has recently been pulled off a satellite galaxy is part of a "stream" with low velocity dispersion.

We can also see evidence for dark matter through gravitational lensing.

• Galaxies and galaxy clusters deflect light. This can be used to measure their masses, giving results in agreement with the observations above.

• Lensing observations can also be used to constrain the nature of dark matter. Baryonic DM could come in the form of MACHOs (massive compact halo objects), i.e. stellar remnants and brown dwarfs. When a MACHO passes exactly between the Earth and a distant star, we see a bright ring around the star. If the object is slightly off center, we instead get a bright arc.

• In practice, these arcs and rings are small enough that we can only detect a momentary brightening of the star. Surveying the sky for these brightening events gives us an estimate of the number of MACHOs in the galaxy. The result is a small fraction of the DM density.

• Gravitational lensing was also used to analyze the Bullet cluster, which was formed by the collision of two large galaxy clusters. It indicated that the interstellar gas, as measured by X-ray spectroscopy, lagged behind most of the gravitational mass, indicating the presence of weakly-interacting DM. (The stars are effectively collisionless and kept going, mostly following the DM.) This was regarded by many as the "nail in the coffin" for MOND.

• However, note that there also are "anti-Bullet cluster" systems, such as the "train wreck cluster" Abell 520, where the DM is in the middle with the interstellar gas; it's not clear how these are to be interpreted, though the data are in some doubt. The Bullet cluster is also unusual, as it has exceptionally high velocity dispersion. Finally, bounds on DM self-interaction from the Bullet cluster are in tension with the self-interaction needed to explain galaxy anomalies.

Finally, cosmological observations give us crucial independent data.

• We can infer the mass density of stars by measuring luminosities, and assuming that a large population of stars has the same mass-to-luminosity ratio as a typical population near us. Additional mass comes from nonluminous stellar remnants, such as white dwarfs, neutron stars, and black holes, as well as brown dwarfs.

• Galaxies also contain significant amounts of interstellar gas, which accounts for 10% of the mass of the Milky Way. For rich clusters of galaxies, the mass of the intergalactic gas can be larger than the mass in the galaxies. This gas is extremely hot and is detected by X-rays using the Sunyaev-Zel'dovich effect.

• By combining all these measurements, a total baryonic density of $\Omega_b = 0.05$ is found, while redshift measurements in the concordance model indicate Ω_m is much larger; in the model the difference is accounted for by DM.

• Stringent independent constraints on Ω_b come from the baryon acoustic oscillation peaks in the CMB, and from the results of BBN, which both yield the same number.

• The DM density also plays an important role in structure formation in the early universe, as we've seen above. Measurements of the matter power spectrum yield yet another independent, consistent value for Ω_m.

• Various modified gravity theories which reduce to MOND in the nonrelativistic limit, such as TeVeS, have also been applied to cosmological scales. However, they currently do a much worse job of fitting the observations than the standard cosmological model. For instance, TeVeS does not produce stable stars.

Models of Dark Matter

• DM candidates can be divided into "cold" and "hot", depending on their typical velocities. Since the 1990s we have known that most, if not all DM must be cold, as hot DM could "freestream" to smooth out small mass fluctuations. Concretely, with cold DM one can first form small structures that merge into larger ones; with hot DM one would first form large structures that fragment into smaller ones. Observations allow only 1% of the DM to be hot.

• One could also consider warm DM, which only suppresses small structures; one could test for this by looking for a cutoff in the matter power spectrum. Other constraints on warm DM come from Lyman α-forest absorption, which provides a map of nearby ($z \sim 5$) hydrogen gas.

• If it's assumed that DM is in thermal equilibrium with the SM thermal bath, then lighter DM particles would automatically be hot. However, there are many nonthermal DM production mechanisms, such as the misalignment mechanism for axions.

• The interactions of DM with the SM are so far consistent with being purely gravitational. Any interactions present must be weak, as they would otherwise contradict, e.g. Bullet cluster observations, and so on. A rough limit for the scattering cross section is $\sigma/m \lesssim (100\text{MeV})^{-3}$. However, adding weak interactions may improve the accuracy of numerical galaxy simulations.

• Decay of DM must be slow. At the simplest level, it must decay slowly enough to still be present today; if the decay is to visible particles, one has stronger constraints from the non-observation of such particles, while if the decay is invisible, one also has stronger constraints due to bounds on how much the DM density can change over time. However, a small amount of decay or annihilation could be used to explain some standing anomalies involves excess detections of energetic SM particles. These should be taken with a grain of salt, because many such anomalies exist, and they frequently vanish.

• DM must have a very small charge, if any at all. The simplest reason is that we can't see it, but stronger constraints come from, e.g. the requirement that the DM be completely decoupled from the thermal bath at recombination. Depending on the mass range, the bound on charge is about $10^{-6}e$. Such a small charge could result from a normal-sized charge under a $U(1)_{A'}$ which weakly kinetically mixes with $U(1)_A$.

• To fit with CMB observations, DM must be present by $z \sim 1000$, eliminating many candidates that form by collapse at late times, such as ordinary black holes. (There aren't enough anyway; they are currently estimated to be about 0.1% of DM.) However, "primordial" black holes, assumed to form early in the universe, are a possibility.

• One generic bound on fermionic DM comes from the exclusion principle. We have

$$\frac{n}{p^3} \sim \frac{\rho_{\text{DM}}/m_{\text{DM}}}{(m_{\text{DM}}v)^3} \lesssim 2$$

which yields $m_{\text{DM}} \gtrsim 1\text{keV}$. This is the Tremaine-Gunn bound. However, bosonic DM can be substantially lighter. On the other hand, composite DM can range up to planetary masses, above which there are lensing bounds, leaving a range of many orders of magnitude in mass.

• The DM does not experience as much dissipation as SM particles, because our galaxy's DM halo seems to be roughly spherical. It's still possible that part of the DM could have collapsed into a "dark disk", and some claim its destabilizing effect could have killed the dinosaurs, though this may have been ruled out with Gaia data.

We now briefly consider some dark matter candidates.

• Many DM candidates fall into one of two classes: light cold bosonic DM (below keV scale) and heavy WIMP-like DM (above MeV scale) produced by freeze-out. Some of these candidates are covered in more detail in the notes on the Standard Model.

• The lightest stable supersymmetric particle, typically a neutralino (but also possibly, e.g. a "mixed sneutrino" or a gravitino), is the canonical example of a WIMP. Many experiments have tried to directly detect WIMPs recoiling on nuclei by the weak force, and have now ruled out most of the "natural" parameter space.

• Neutrinos could account for the DM density if their mass was around 10eV, and they came into thermal equilibrium. This made neutrinos a leading DM candidate in the 1980s, when neutrino oscillations established that they were massless. However, such neutrinos would be hot, and so could not make up the DM by themselves. Today, upper bounds on the neutrino masses from cosmological measurements show that neutrinos are cold DM, but only about 1% of it.

• Sterile neutrinos that don't come into thermal equilibrium could account for the DM density if their mass is on the keV scale; they can be produced via neutrino oscillations in the

DodelsonWidrow or Shi-Fuller mechanisms. Resonant scattering off such sterile neutrinos has been used as an explanation for a deficit of 3.5keV photons emitted from galaxy centers. But they are also strongly constrained, as their decay to normal neutrinos would produce X-rays that haven't been detected.

• Axions are typically extremely light, but can become cold DM because they have a nonthermal production mechanism, the misalignment mechanism. This produces axions in a BEC-like state, with very low velocity dispersion.

• One could also consider axions in a supersymmetric theory, in which case they are part of a chiral supermultiplet. There is another real scalar field, the saxion, and a fermion called the axino. If the axion is the phase of a complex scalar field, the saxion can be thought of as the magnitude. The saxion decays quickly, but the axino can be another WIMP-like DM candidate.

• Some call Primordial black holes (PBHs) the "least speculative" DM candidate, because they don't have nongravitational interactions. But they must be formed by the collapse of large density perturbations in the early universe, which don't appear in the simplest inflation models.

• These perturbations could appear if the inflaton potential had a plateau (the "ultra slow-roll" regime), or in multi-field inflation, where different fields are responsible for the perturbations on small scales and cosmological scales. They could also be formed more violently, such as by the collapse of cosmic strings, bubble collisions from a first-order phase transition, or even by collapse of "dark stars" made of dark sector particles.

• More generally, we could have "macroscopic DM", i.e. DM that comes in discrete chunks, which could have formed through a phase transition or dissipative process. Such objects can have masses ranging from the Planck mass (about a microgram) up to many solar masses. Compared to PBHs, macroscopic DM can be much less compact and doesn't emit Hawking radiation, but it can have nongravitational interactions with the SM.

• Here we overview constraints on ultraheavy DM, including PBHs and macroscopic DM.

• Above $m_{\rm DM} = 10^3 M_\odot$, the gravitational effects of individual DM objects would measurably warp structures by tidal effects.

• The lifetime of a black hole before it evaporates by Hawking radiation is

$$\tau \sim \frac{G^2 M^3}{\hbar c^4} \sim 10^{64} \left(\frac{M}{M_\odot}\right)^3 \text{ yr}$$

Below $m_{\rm DM} \sim 10^{12}$ kg $\sim 10^{-18} M_\odot$, PBHs would have already decayed. (But there is a loophole since extremal BHs are obstructed from decaying.) Black holes above $10^{-7} M_\odot$ aren't evaporating at all; they're actually gaining mass because the CMB is hotter.

• The formation of PBHs requires large density perturbations, which are strongly constrained by the CMB. However, these CMB constraints are only well-measured on large scales, so the small-scale perturbations which would form sub-solar mass PBHs are not constrained. They could be probed in the future by observations of primordial gravitational waves.

• PBHs are also strongly constrained up to $10^{-16} M_\odot$ because of X-rays that would be produced by Hawking radiation, and above $10^{-11} M_\odot$ by lensing constraints. A small window is left in between the two, where PBHs could be all of the DM. (Previously, it was thought much of this range was ruled out by "femtolensing" constraints, but it turns out these are invalidated by finite source size effects.) People also consider cases where PBHs could be a small subcomponent of the DM.

• Macroscopic DM is a bit more complicated, because it is characterized by both a mass and a SM interaction cross section. It is also constrained by lensing above $10^{-10} M_\odot$, and below 10^3 kg or so, there are bounds from terrestrial experiments. But there is a huge "asteroid" range where large interactions with the SM are allowed.

We now list some twists on the collisionless cold dark matter (CCDM) paradigm.

• Warm DM, as mentioned above, smooths out small scale structure.

• Self-interacting DM (SIDM) makes the later stages of structure formation significantly more complicated. Scattering can alleviate the cusp-core problem, and also strips the halos from small clumps of DM orbiting larger structures, reducing their number. It has also been invoked to explain the "train wreck cluster".

• In particle physics, SIDM can also stand for strongly interacting DM. The reason is that the cross sections needed to make self-interacting DM work are of order $\sigma/m \sim \Lambda_{\rm QCD}^{-3}$, which is typical for a particle interacting under the strong force.

• Self-annihilating DM, as mentioned above, can explain standing anomalies and helps alleviate the cusp-core problem, as does decaying DM.

• Fuzzy DM is extremely light bosonic DM with a de Broglie wavelength on the order of the galaxy size; this would provide an additional "poofiness" to DM halos, which could help alleviate the cusp-core problem. Using the uncertainty principle $\Delta x \Delta p \gtrsim 1$ with $\Delta p \sim m_{\rm DM} v$ and Δx the size of a dwarf galaxy halo gives the standard quoted estimate $m_{\rm DM} \gtrsim 10^{-22}$eV. However, over the past ten years, improved data and modeling have pushed up the constraints, which now lie around $m_{\rm DM} \gtrsim 10^{-21}$eV, depending on who you ask.

• Repulsive DM is light bosonic DM which forms a condensate with a repulsive self-interaction, also addressing the cusp-core problem. The idea of "superfluid DM" falls in this category.

• These options are distinguished by their detailed predictions. For example warm DM, fuzzy DM, and repulsive DM all pick out preferred length scales, while decay DM picks out a time scale, and self-interacting and self-annihilating DM pick out densities.

There are many DM production mechanisms beyond freeze-out, and we list some here.

• In the freeze-in scenario, we suppose that the DM is never in thermal equilibrium, but rather has zero abundance in the early universe; the abundance rises monotonically to the desired value throughout cosmological history. Such an initial condition can be achieved if the DM interaction with the SM is very weak, and it is not produced during reheating.

• The freeze-in scenario has different parametrics (the final abundance increases with interaction strength, as opposed to decreasing for freeze-out) and accommodates a wide range of masses. The relevant DM particles are called feebly interacting massive particles (FIMPs).

• Note that if the production rate Γ is set by a dimensionless coupling $g \ll 1$ rather than a suppression by a mass scale, then we have $\Gamma \sim g^2 T$. Since $H \sim T^2$, this means production gets more important later in cosmological evolution. This is nice because the final abundance isn't determined by the reheat temperature, which is free.

• One can modify the freeze-out scenario by considering other DM interactions.

• Coannihilation: there are two DM species, $\chi_i \chi_j \to \phi\phi$, where ϕ is some generic other particle, and χ_i and χ_j are in chemical equilibrium but have different masses. Now the lightest species is the DM, but freeze-out only fixes the cross section for $\chi_i \chi_j$ annihilation, which has absolutely no relation to the cross section for χ_i scattering in WIMP experiments.

• Elastic scattering: $\chi +$ SM $\leftrightarrow \chi +$ SM. This isn't an annihilation process, but it can transfer energy between the DM and SM baths, so its rate can play an important role in some of the more elaborate mechanisms mentioned below.

• Coscattering: $\chi\phi \to \psi\phi$, where the DM converts to another particle in scattering.

• Zombie/pandemic DM: the DM is all converted to another species in reactions like $\chi\phi \to \phi\phi$, which causes the amount of ϕ to increase exponentially.

• Self-annihilation: $n\chi \leftrightarrow \chi\chi$ with $n \geq 3$. These couplings could emerge in a theory with, e.g. χ^3 or χ^4 vertices. (This typically also implies DM self-interactions $\chi\chi \leftrightarrow \chi\chi$, which have astrophysical consequences.) This gives a qualitatively different annihilation rate.

• The above reaction is also called "cannibalization", because for an isolated DM bath, it slows the cooling as rest energy is cannibalized to kinetic energy.

In the standard WIMP freeze-out scenario, self-annihilation isn't present. The abundance is fixed by when the annihilation process decouples. In several newer ideas, the annihilation process is weak and decouples early, while the other processes continue to be effective.

• In strongly interacting massive particle (SIMP) DM, the SM and DM baths are kept in thermal equilibrium by an elastic scattering process, and the DM has a $3 \to 2$ self-annihilation process. Over time, energy is removed from the dark sector by elastic scattering, until the self-annihilation process decouples. The final DM abundance is sensitive to the DM mass and the self-annihilation rate, with typical target masses of $m_{\rm DM} \sim 100$MeV, motivating "light dark matter".

• In elastically decoupling relic (ELDER) DM, the elastic scattering process decouples before selfannihilation. Self-annihilation then keeps the DM bath at approximately a constant temperature for a long period, until it too decouples. It turns out this makes the final DM abundance sensitive to only the elastic scattering cross section, leading to different parametrics.

• Ultralight bosonic DM can be produced nonthermally through the misalignment mechanism, with its abundance thus fixed by initial conditions, or by inflationary fluctuations. Other nonthermal production mechanisms include the decay of heavy particles or topological defects.

• Asymmetric DM is the idea that the relic DM abundance arises from an asymmetry between DM and DM. (For example, in "cogenesis", this asymmetry arises simultaneously with

the baryon-antibaryon symmetry.) This is a tempting idea since the DM and baryon densities are equal up to an $O(1)$ factor. In the simplest version of the idea, $n_{\rm DM}$ and n_B could exactly cancel, with $m_{\rm DM} \approx 5 m_p$.

Example. More about SIMPs, ELDERs, and cannibals, focusing on a $3 \to 2$ annihilation process. (finish)

• The rates for DM annihilation, elastic scattering with the SM, and DM self-annihilation are

$$\Gamma_{\rm ann} \sim n_{\rm DM} \langle \sigma v \rangle_{\rm ann} , \quad \Gamma_{\rm kin} \sim n_{\rm SM} \langle \sigma v \rangle_{\rm kin} , \quad \Gamma_{3\to 2} \sim n_{\rm DM}^2 \left\langle \sigma_{3\to 2} v^2 \right\rangle$$

We can parametrize these rates in terms of couplings, where generically

$$\langle \sigma v \rangle_{\rm kin} \sim \langle \sigma v \rangle_{\rm ann} \equiv \frac{\epsilon^2}{m_{\rm DM}^2}, \quad \left\langle \sigma v^2 \right\rangle_{3\to 2} \equiv \frac{\alpha_{\rm eff}^3}{m_{\rm DM}^5}$$

where the $m_{\rm DM}$ dependence enters by dimensional analysis. We don't have to include powers of T because we have assumed the relevant rates are not dependent on the typical velocity v. This is just the usual assumption of s-wave annihilation for the two-body processes, and its analogue for the three-body annihilation.

• The story of SIMP DM holds as long as

$$\Gamma_{\rm kin} \gtrsim \Gamma_{3\to 2} \gtrsim \Gamma_{\rm ann}$$

until freeze-out. Assuming this is true, freeze-out occurs at

$$\Gamma_{3\to 2} \sim H_F \sim \frac{T_F^2}{M_{\rm pl}}$$

and by similar reasoning to the usual WIMP freeze-out calculation, this means

$$m_{\rm DM} \sim \alpha_{\rm eff} T_{\rm eq}^{2/3} M_{\rm pl}^{1/3}$$

For strong DM self-interactions, $\alpha_{\rm eff} \sim 1$, this points to masses $m_{\rm DM} \sim 100$MeV. The mass scale of the strong force, rather than the weak force, emerges, motivating the name.

• Next, we check the bounds above. After freeze-out, we have

$$\rho_{\rm DM} = m_{\rm DM} n_{\rm DM} \sim T^4 \frac{T_{\rm eq}}{T}$$

since the DM density and radiation density are on the same order at $T_{\rm eq.}$. Then at freeze-out,

$$n_{\rm SM} \sim T_F^3, \quad n_{\rm DM} \sim n_{\rm SM} \frac{T_{\rm eq}}{m_{\rm DM}}$$

which gives

$$\Gamma_{\rm ann} \sim \frac{\epsilon^2 T_F^3}{m_{\rm DM}^2} \frac{T_{\rm eq}}{m_{\rm DM}}, \quad \Gamma_{\rm kin} \sim \frac{\epsilon^2 T_F^3}{m_{\rm DM}^2}, \quad \Gamma_{3\to 2} \sim \frac{\alpha_{\rm eff}^3 T_F^6 T_{\rm eq}^2}{m_{\rm DM}^7}$$

• By using $T_F \sim m_{\rm DM}/20$ and plugging in our expression for $m_{\rm DM}$ above, our bounds become

$$\alpha_{\rm eff}^{1/2} \left(\frac{T_{\rm eq}}{M_{\rm pl}} \right)^{1/3} \lesssim \epsilon \lesssim \alpha_{\rm eff} \left(\frac{T_{\rm eq}}{M_{\rm pl}} \right)^{1/6}$$

For $\alpha_{\rm eff} \sim 1$ this gives a possible range of three orders of magnitude for ϵ.

• Incidentally, if we instead assumed an $n \to 2$ self-annihilation process dominates, then a similar calculation gives $m_{\rm DM} \sim \alpha_{\rm eff} \left(T_{\rm eq}^{n-1} M_{\rm pl} \right)^{1/n}$, so we can further lower the mass.

We now say a bit more about the relatively new paradigm of dark/hidden sectors.

• In the standard WIMP paradigm, we think of the DM as part of a sector that interacts strongly with the SM, such as the superpartners in SUSY. By contrast, a "dark sector" is a group of related particles, one of which is the DM, which interacts only weakly with the SM.

• In principle, a dark sector doesn't have to interact with the SM at all, except gravitationally. This is the worst-case scenario; on the other hand, there is reason for optimism, because many concrete production mechanisms require nongravitational interactions.

• For concreteness, let's suppose that pairs of DM particles couple to a mediator, which in turn couples to pairs of SM particles. In this scenario we can have freeze-out production, where the mediator takes the place of the weak boson for WIMPs.

• The relic abundance scales as $m_{\rm DM}^2/\epsilon^2 g_D^2$, where ϵ is the mediator's coupling to the SM, and g_D is its coupling to DM. Taking g_D to be $O(1)$ and adjusting ϵ, we can accommodate a range of DM masses, from the keV to TeV scale. In SUSY, which in this context is just a concrete way to construct the hidden sector, this was called the "WIMPless miracle". In principle g_D can be adjusted too, but lowering it just increases ϵ, so taking a strong dark sector coupling is a conservative assumption.

• For $m_{\rm DM} \lesssim$ MeV, DM annihilates after neutrinos decouple, which would be detected through $N_{\rm eff.}$. Thus, the window for "light" DM is MeV to GeV.

• Light DM is difficult to search for in direct detection experiments, because such particles deposit little energy in a collision. And since the couplings are low, it is difficult to see the production of such DM in the collider "energy frontier". Instead, for colliders one needs to go to the "intensity frontier", e.g. in beam dump experiments.

• Stepping back, we can ask which interactions between the hidden sector and the SM are "generic". One answer is that it corresponds to the lowest-dimension allowed operators:

• For a vector, there is the dark photon coupling $(\epsilon/2\cos\theta_W)\, B_{\mu\nu}F'^{\mu\nu}$ where F' is the gauge field strength of a dark photon, and B is the $U(1)_Y$ gauge field strength; after electroweak symmetry breaking it is $(\epsilon/2)F_{\mu\nu}F'^{\mu\nu} + (\epsilon/2)\tan\theta_W Z_{\mu\nu}F'^{\mu\nu}$, where $F_{\mu\nu}$ and $Z_{\mu\nu}$ are the photon and Z boson field strengths. The first term is the most important at low energies.

• To understand the phenomenology clearly, we need to refine the fields to remove the kinetic mixing. There are two possibilities. First, we can keep the interactions with other particles the same by setting $A'^{\mu} \to A'^{\mu} + \epsilon A$, in which case we get a mass mixing between the photon and dark photon, allowing them to oscillate into each other. Alternatively, we can remove the mass mixing too, in which case all charged particles pick up a small coupling to the dark photon.

• More general possibilities are also possible with more model building; for example, there are several motivations to gauge $U(1)_{B-L}$: it is non-anomalous in the SM provided sterile neutrinos are introduced, and it can be used to construct R-parity in SUSY models. However, the standard dark photon is distinguished by its minimality.

• There is nothing similar for an axial vector, because the SM has no conserved axial currents; coupling to a nonconserved current would yield issues with unitarity. Of course, a dark axial vector can be accommodated with further model building, which is used for the X17 boson to explain the Beryllium anomaly.

• For a pseudoscalar, there are again no options in the SM. However, if we allow dimension 5 operators, we have the axion couplings $(a/f_a)\, F_{\mu\nu}\tilde{F}^{\mu\nu}$, $(a/f_a)\, G_{\mu\nu}\tilde{G}^{\mu\nu}$, and $(\partial_\mu a/f_a)\, \bar{\psi}\gamma^\mu\gamma^5\psi$. Since the axion is so well-motivated, this is usually included in the standard list.

• For scalars, we have the dark Higgs couplings, $(\mu S + \lambda S^2)\, H^\dagger H$, where the first term isn't allowed for complex scalars. This leads to couplings to SM fermions proportional to their mass. If we allow dimension 5 operators, we can multiply the scalar with any marginal SM operator; in this context, the scalar is often called a "dilaton" in analogy to string theory, since in both cases its value shifts fundamental constants.

• For fermions we have $y_N L H N$, where N is called a sterile neutrino, or heavy neutral lepton. The dark photon, axion, dark Higgs, and sterile neutrino are the "portals". For concreteness, we'll focus on dark photons.

• The dark photon coupling kinetically mixes the SM photon and the dark photon. Upon diagonalizing the kinetic terms with a field redefinition, we can show that the physical degrees of freedom are the familiar photon, along with a massive vector which couples strongly to DM particles, and to SM particles proportional to $\epsilon e Q$.

• The way we would search for such a dark sector depends on the mass of the dark photon.

• If it's in the same "light" mass range as the DM particle, then we could look for its production in a collider experiment. In this case the identity of the DM particle isn't so important, except that it sets a target for the dark photon coupling.

• If it's light, then we can integrate it out. The result is that the DM particles effectively have very small "millicharges". The dark photon itself can also be searched for directly, e.g. through fifth force searches.

• The dark photon itself could be the DM, produced by a nonthermal production mechanism like the axion. This "ultralight" DM could be searched for through precision experiments, such as DM Radio.

• To get a specific target for ϵ, note that if there is a heavy particle that couples to both the photon and dark photon, then it can induce this coupling at one loop. Integrating it out gives $\epsilon \sim 1/16\pi^2 \sim 10^{-3}$, which gives a mass right in the middle of the light DM range.

• A $U(1)_{B-L}$ gauge boson would be searched for in much the same ways as an ordinary dark photon, but the details of the couplings would be different, e.g it would couple equally strongly to neutrons and protons. We could also break family symmetry, e.g. by gauging $U(1)_{L_\mu - L_\tau}$, which would produce no coupling to electrons. On the other hand, these exotic dark photons still pick up a mixing with the SM photon at one loop, albeit a smaller one.

• A similar story holds for a "dark Higgs". In the simplest models, it would couple to SM fermions proportionally to their mass, so it is best probed by the decays of heavy mesons.

• In the standard hidden sector freeze-out scenario, we assume the DM is heavier than the mediator. Forbidden DM is a variant on freeze-out where the DM can only annihilate into heavier particles. In this case, we have $\langle \sigma v \rangle \sim e^{-2\Delta m/T}/m_{\rm DM}^2$ at freeze-out, which can accommodate very light dark matter if Δm is chosen correctly. (To avoid the final particles themselves being a relic, they need to either be SM particles or a decaying hidden sector particle.)

• Another twist is if the DM is heavier than the mediator, but pairs of DM particles couple to pairs of mediator particles. Then DM can annihilate to the mediator, which later decays to SM particles. In this case, the relic density scales as $m_{\rm DM}^2/g_D^4$, where g_D is the mediator-DM coupling. This is called "secluded" annihilation because the extra step means there are much weaker constraints on $m_{\rm DM}$ and g.

• Things could of course be much more complicated. There could be composite objects in the dark sector, resulting from dissipation, phase transitions, or strong interactions. We could have dark atoms, dark molecules, dark mesons and baryons, dark nuclei, or even dark glueballs, leading to a rich phenomenology. As one of infinitely many possible examples, dark pions automatically have a quintic vertex due to the Wess-Zumino-Witten term, providing the self-annihilation process needed for several mechanisms above.

1.5.3 Cosmological constant (dark energy) in a nutshell

More about the discovery of dark energy

Type Ia supernova begin as white dwarfs, which slowly siphon matter from a companion star. When the mass passes the Chandrasekhar limit, a supernova occurs. Since the initial masses of all type Ia supernova are similar, they can be used as standard candles. Strictly speaking, they don't all have the same luminosity, but much of the variance can be accounted for by examining how the luminosity changes over time, in a so-called light-curve shape analysis. Supernova are detected by looking for momentary brightenings of distant galaxies. Their Doppler shift can be used to compute a redshift, while their luminosity can be used to compute a distance. In a uniformly expanding universe, these two are proportional.

Each data point is quite noisy. However, in the 1990s, supernova surveys investigated about 100 supernova at redshifts up to about $z = 1.0$, and observed a deviation from linearity at 5σ, indicating accelerating expansion due to our current period of dark energy dominance. Dark energy can be distinguished from a systematic effect, such as absorption of distant light by dust (i.e. a "tired light" hypothesis), because Λ CDM predicts that for $z \gtrsim 1.0$ we have matter domination, during which the expansion decelerates. However, measurements at such huge distances are extremely difficult, and ongoing. Another line of evidence for dark energy is that the accelerated expansion stunts the growth of galaxies late in the universe, which is indeed observed.

These results remain rather controversial to many. To theorists, dark energy appears difficult to account for in ordinary quantum field theory without tuning, leading to the cosmological constant problem, and it appears difficult to embed into string theory, according to the dS Swampland conjecture. Philosophers are convinced that dark energy is objectionable because of a great variety of vague, metaphysical reasons. Some cosmologists have objected to the original dark energy discovery papers, on the grounds that their analyses overestimated their statistical significance. Finally, late-time measurements of the Hubble constant (including supernova Ia

measurements, but also measurements of quasars) indicate a higher value than that extrapolated from CMB measurements, leading to the "Hubble tension".

Note. None of the discussion above gives direct information about the topology of the universe as a whole. For example, it's possible that the universe is toroidal (i.e. "wraps around") on scales far larger than our Hubble patch. This is scientifically uninteresting, because it produces no observable consequences while making the math more complicated; hence the default assumption is a trivial topology. However, if the topology is on a smaller scale, predictions can be made. In 2003, it was conjectured that the small C_l at $l \lesssim 3$ could be explained by a finite, "Poincare dodecahedral" space, whose volume would be too small for such perturbations to "fit in". This leads to the prediction of "matched circles" in the temperature variations of the CMB, where we see the same part of the surface of last scattering in two different directions; however, a search in 2004 failed to find this. (?? I'll find a ref for it later???)

Main properties of cosmo constant and Vacuum Energy

- In QFT, like the simple harmonic oscillator in ordinary quantum mechanics, there is a zero point energy to the ground state
- For bosons, $\hbar\omega/2 = E(q)/2$, so the most naive version of the cosmological constant problem is that $\rho \propto M^4$ where $M = M_{\rm Pl} = 1/\sqrt{8\pi G}$ if the theory applies out to the Planck scale
- The critical energy density $\rho_c = 3H_0^2/8\pi G \approx 8 \times 10^{-47} h^2 {\rm GeV}^4$ is more than 10^{120} off $M_{\rm Pl}^4 \approx 2 \times 10^{76} {\rm GeV}^4$.
- This is the cosmological constant problem in its basic form - a more sophisticated QFT version is even given renormalization we expect $\rho_{\rm vac} \sim m^4$ for each particle of mass m

Alternatives to Λ

(currently by Hu)
- Alternatives to Λ attempt to have an energy density that is much like vacuum energy in that it remains constant as the universe expands
- For example the potential energy of a field stuck on a hill stays the same even as a grows
- But a field ϕ on a hill can roll converting some of the potential energy V to kinetic energy which does decay with a and make $w > -1$
- Quadratic approximation around minimum of potential: $V = m^2\phi^2/2$ but $m \ll H \sim 10^{-33}$eV.
- Such a field would be a scalar (number at each spacetime position) we'll come back to this possibility in the early universe: inflation
- A light scalar could potentially have exotic long range interactions and coupling to ordinary matter
- Such fifth forces and other modifications to Einstein gravity could also be the explanation of cosmic acceleration

Calculation of cosmo constant in a nutshell

El Gordo galaxy cluster collision

KBC void

The KBC void is an immense, comparatively empty region of space containing the Milky Way approximately 2 billion light-years)600 megaparsecs, Mpc) in diameter [55][56][16] Some authors have said the existence of the KBC void violates the assumption that the CMB reflects baryonic density fluctuations at $z = 1100$ or Einstein's theory of general relativity, either of which would violate the $\wedge$ CDM model [57] while other authors have claimed that supervoids as large as the KBC void are consistent with the Λ CDM model. [58]

Hubble tension

S8 tension

Axis of evil

(wiki)
The $\wedge$ CDM model assumes that the data of the cosmic microwave background and our interpretation of the CMB are correct. However, there exists an apparent correlation between the plane of the Solar System, [78] the rotation of galaxies, and certain aspects of the CMB. This may indicate that there is something wrong with the data or the interpretation of the cosmic microwave background used as evidence for the $\wedge$CDM model, or that the Copernican principle and cosmological principle are violated

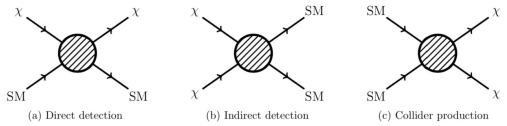
1.6.2 Dark Matter detection

Direct Dark Matter Detection

• The three main paradigms for DM detection are shown below.



(a) Direct detection (b) Indirect detection (c) Collider production

The amplitudes for all three are related by crossing symmetry.

• In a direct detection experiment, one watches for recoils of SM particles (e.g. atomic nuclei) off DM particles. Such experiments are placed deep underground to shield cosmic rays. They were first explored in the mid-1980s by Goodman and Witten. Many experiments have been done since then, placing stringent bounds on WIMP-nucleon cross sections.

• A single experiment, the DAMA collaboration, has seen a significant annual modulation in scattering events, which could be due to the seasonal variation of the Earth's velocity through the DM halo. However, the results are not taken seriously due to possible systematic effects. Since DAMA uses a different material than other experiments, it can be consistent with other experiments if the DM coupling is strongly spin-dependent.

• Astrophysicists typically use indirect detection methods, searching for the produces of annihilating DM. Such signatures include an excess of antimatter, mono-energetic gamma rays, and high-energy neutrinos. The sensitivities of these experiments tend to be complementary to direct direction experiments, e.g. they are more sensitive to higher masses.

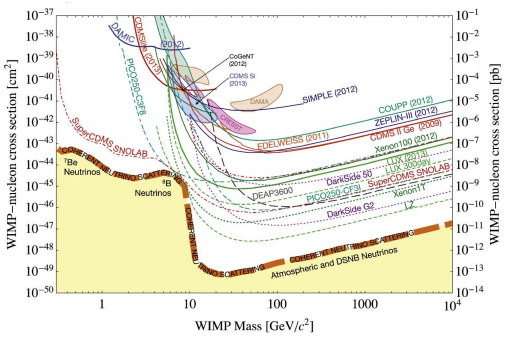
• TeV scale DM could also be produced at the LHC, with the classic signal being missing energy or momentum, such as in the production of a "mono-X" event, where X is a photon, jet, W, Z, h, t or so on. Here, one can take a "top-down" approach, computing results from a full theory such as the MSSM. Alternatively, one could use a simplified model, which gives more generic constraints but which may miss peculiarities that can occur in more complex models. This is done starting from a full model by just removing irrelevant particles, or setting couplings equal or to zero.

• For practicality, LHC results are often phrased in terms of these simplified models, which include the DM particle and the most important mediator. This leaves a reasonable number of parameters, primarily the DM mass, the mediator mass, and, e.g. the mediator's coupling to quarks, which fix the rates for processes such as mono-jets, mediator pair production, or qq scattering via a mediator.

• Various combinations are then possible for the spin and parity of the DM and mediator. For example, a typical figure caption is "axial mediator, Dirac DM, $g_q = 0.25, g_\chi = 1.0$ " with the masses of the mediator and DM on the axes.

Next, we consider direct detection in more detail.

• Standard WIMP direct detection experiments consist of looking for recoils of WIMPs off nuclei. An exclusion plot is shown below.



The basic intuition is that at higher masses, the sensitivity to the cross section falls as 1/m simply because there are fewer DM particles. At lower masses, the sensitivity falls off because the energy deposited by each DM particle is smaller, so not all impacts can be seen; the curve here depends on the details of the high-velocity tail.

• Since the WIMPs would rotate along with the galaxy, there is both a daily modulation of the event rate, due to the spin of the Earth, and a yearly modulation, due to the orbit of the Earth. This is an important way to confirm a WIMP signal, as there are many possible backgrounds, such as radioactivity and cosmic rays. One can also directly measure the WIMP "wind" if the detector is directionally sensitive.

• Suppose a WIMP with mass m_χ and speed v hits a stationary nucleus with mass M. If the nucleus recoils at an angle θ from the original velocity of the WIMP, then some basic classical mechanics gives a recoil energy of

$$E = \frac{2\mu^2 v^2 \cos^2\theta}{M}, \quad \mu = \frac{M m_\chi}{M + m_\chi}$$

The maximum recoil energy has the limits

$$E_{\max} \sim M v^2 \min\left(1, m_\chi^2/M^2\right)$$

For a standard weak-scale WIMP recoiling off a heavy nucleus, the two arguments above are of the same order. Taking $v \sim 10^{-3}$, we have $E_{\max} \sim 10 - 100\text{keV}$.

• Depending on the search, the impact is detected by the resulting ionization, light emitted, calorimetry (i.e. energy deposited into phonons/heat), or a combination of these options. These have varying advantages; for instance, calorimetry reliably gets all the deposited energy, but it is by far the slowest.

• Calculating the differential event rate dR/dE uses input from several fields of physics.

• First, compute the amplitude for WIMPs to scatter off quarks or gluons. This is highly model-dependent.

• Next, use results from nuclear physics to compute the scattering amplitude for protons and neutrons. Usually, we take these to be the same for simplicity; the final experimental bound will get reported in terms of that quantity.

• Infer the amplitude for scattering off the heavy nuclei by summing over the nucleons. At finite momentum transfer, this requires using nuclear form factors, such as the standard simple Helm form factor.

• Compute the scattering rate using the WIMP number density and velocity distribution, e.g. using the standard halo model

$$f(v) = \frac{4}{\sqrt{\pi}} \frac{v^2}{v_0^3} e^{-v^2/v_0^2}$$

This is not exactly true, especially in the high velocity tail; for example, one crude correction would be to set it to zero for velocities greater than the escape velocity of the Milky Way. There is a great variety of halo models, which mostly differ in the tail.

One can substantially change the results by upsetting some of the assumptions made above; this can be used to make the DAMA results consistent with other exclusions.

• An important distinction is between spin-independent and spin-dependent scattering. For spinindependent scattering, in the limit of low momentum transfers, the amplitude contributions of the nucleons add coherently, enhancing the cross section by A^2 where A is the atomic mass number. This works for a decent range of momentum transfers because of the low WIMP velocity. (However, for higher momentum transfers, we must account for a form factor suppression.) The standard WIMP exclusion plots assume spin-independent scattering.

• On the other hand, for spin-dependent scattering, the contributions of nucleons with opposite spins cancel. Since heavy nuclei generally have spin much less than A, this leads to a huge suppression. (DAMA's NaI target is much more sensitive to spin-dependent couplings than other targets, which is why its positive result is not flatly impossible.)

• In general, it's important to have good resolution at low energies, because dR/dE is always monotonically decreasing. It is especially important for experiments detecting light DM, which require light targets and very low energy thresholds.

Example. Suppose the WIMP χ is a Majorana fermion, e.g. the lightest neutralino in a SUSY model. There are two possible leading couplings to quarks: the spin-independent scalar coupling

$$\mathcal{L} \supset \bar{\chi}\chi\bar{q}q$$

which could arise from Higgs exchange, and the spin-dependent axial-vector coupling

$$\mathcal{L} \supset \bar{\chi}\gamma^\mu\gamma_5\chi\bar{q}\gamma_\mu\gamma_5 q$$

which could arise from Z exchange. If χ is a Dirac fermion, we could also have the spin-independent vector coupling

$$\mathcal{L} \supset \bar{\chi}\gamma_\mu\chi\bar{q}\gamma^\mu q.$$

One can extend this discussion to spin 0 or spin 1 WIMPs. Standard WIMP exclusion plots assume a spin-independent scalar coupling.

Indirect Dark Matter Detection

• The standard WIMP miracle calculation fixes the two-body annihilation rate during freeze-out, which can be used to guess the present day annihilation rate. Of course, there are many caveats. Many of the more elaborate DM production mechanisms discussed above completely break this relation: DM relying on $3 \to 2$ self-annihilation might have no $2 \to 2$ annihilation process at all, and coannihilating DM would not have anything to annihilate against today.

• Even if standard $2 \to 2$ annihilation is the dominant process, the annihilation cross section could be effectively different today than during freeze-out, since DM is now more nonrelativistic.

• If s-wave annihilation is forbidden, the leading contribution is usually p-wave annihilation, which has $\langle\sigma v\rangle \propto v^2$, which is much lower today.

• If the DM interacts by a light mediator, its annihilation rate can be higher today due to the Sommerfeld enhancement, a nonperturbative effect due to the exchange of many mediators.

• There could be resonances which enhance the annihilation rate, for appropriate DM velocity.

• We could also consider a one-body decay. It differs qualitatively from annihilation, since it scales only linearly with the density. However, we don't have a solid benchmark for how fast the decay should be.

• One could get rough estimates using an EFT approach with GUTs. For example, if a weak-scale WIMP decays by a dimension 5/6/7 operator from the GUT scale, we would have

$$\tau \sim \begin{cases} m_{\text{GUT}}^2/m_{\text{DM}}^3 \sim 0.1 \text{ s} & \text{dimension 5} \\ m_{\text{GUT}}^4/m_{\text{DM}}^5 \sim 10^{25} \text{ s} & \text{dimension 6} \\ m_{\text{GUT}}^6/m_{\text{DM}}^7 \sim 10^{51} \text{ s} & \text{dimension 7} \end{cases}$$

which are definitely ruled out, possibly observable, and completely unobservable.

• There are a few qualitatively distinct options for the decay/annihilation products. If colored particles or taus are produced, they hadronize and produce many pions, which in turn decay to produce a continuum spectrum of gamma rays. If electrons or muons are produced, we

end up with charged leptons and neutrinos, with only a few photons. Photons can be produced directly, giving a sharp spectral peak, but the branching ratio is expected to be small. Neutrinos can also be produced, but they're very hard to detect.

• Charged particles get strongly deflected by galactic magnetic fields, so experiments looking for such particles are effectively direction blind. Photons and neutrinos aren't deflected, but the detection rates are generically expected to be lower.

• Historically, many indirect detection experiments have reported anomalies which could be explained by DM, but then have been explained by astrophysical effects. This is especially difficult for charged particles, since they could be produced by essentially any nearby new astrophysical phenomenon, such as an unseen population of pulsars. For the uncharged particles, these sources can be localized and ruled out.

Now we focus on detection of uncharged particles.

• Consider DM annihilation in a volume element dV at a distance R from the observer. If the spectrum produced per annihilation is dN/dE, then the spectrum produced per time is

$$\frac{1}{2}\frac{\rho^2}{m_{\rm DM}^2}\langle\sigma v\rangle\frac{dN}{dE}dV$$

where ρ is the DM density and the $1/2$ avoids overcounting. Alternatively, if DM comes in particles and antiparticles symmetrically, then we lose the $1/2$, but we convert ρ^2 to $(\rho/2)^2$, making the result $1/2$ again as large.

• The spectrum per unit time incident on a detector per unit area dA is found by dividing by $4\pi R^2$ and integrating over dV. This quantity splits neatly into a "particle physics" part and "astrophysics" part,

$$\frac{dN_{\rm obs}}{dEdtdA} = \frac{1}{8\pi m_{\rm DM}^2}\langle\sigma v\rangle\frac{dN}{dE}\int\rho^2 dRd\Omega$$

where the integral is called the J-factor. For decaying DM, a similar argument gives

$$\frac{dN_{\rm obs}}{dEdtdA} = \frac{1}{4\pi m_{\rm DM}}\frac{1}{\tau}\frac{dN}{dE}\int\rho dRd\Omega$$

where the integral is called the D-factor. Note, however, that conventions differ on where to put the factors of $1/8\pi$ or $1/4\pi$, and whether to include the angular integral in the J or D-factor.

• Here we have assumed that the cross-section does not depend too strongly on the velocity; otherwise we have to put the $\langle\sigma v\rangle$ under the integral. Also, if we look at distant targets, one should also account for redshift; the line of sight integral dR should be recast as a dz integral.

• Computations of the J-factor depend on the halo model used, especially whether it is cuspy or cored. This makes a significant difference for annihilation because scales quadratically with the density, and hence dominates in the galactic center region. One can estimate local DM densities using oscillations of stars above and below the galactic plane, but this is difficult at the galactic center because one must subtract off a large baryonic matter background.

• For concreteness, plugging in typical WIMP numbers with a cuspy NFW profile gives

$$\frac{dN_{\rm obs}}{dEdt} \sim 10^{-9}\ {\rm cm}^{-2}\ {\rm s}^{-1}$$

for the galactic center. We need about a year with a 100 cm^2 detector to see one photon.

• There are several places that one could look, with various advantages and disadvantages.

• Dwarf galaxies are nearby and have low background, and thus often give the strongest constraints on annihilation.

• The galactic center has high signal, giving it a high potential for discovery. However, it has high background, and the J-factor is uncertain.

• The galactic halo is large and nearby, but has complex backgrounds.

• Other galaxies and galaxy clusters carry a huge amount of DM and also hold redshift information, but are further away. Since they contain a huge total amount of DM, they often give the strongest constraints on decay. However, the J-factor is uncertainty since it depends on DM substructure in the cluster.

• Seemingly empty space could produce a signal, depending on the DM substructure, but it's hard to know where to look.

• Extragalactic background radiation also carries substantial redshift information and averages over a huge region.

• For gamma rays, there are a variety of experiments providing exclusion bounds.

• From 100MeV to 1TeV: Fermi and DAMPE. These are in space, with a relatively small area but wide field of view.

• From 100GeV to 10TeV: HESS, VERITAS, MAGIC. These are ground-based telescopes, with a narrow field of view.

• From 1TeV to 100TeV: HAWC, and later CTA and LHAASO. These ground-based apparatuses have a wide field of view, since they search for the Cherenkov radiation produced when the gamma rays pass through a tank of water.

• For neutrinos, there's also a variety of experiments.

• SuperK probes neutrinos from a few MeV to 1TeV.

• ANTARES reaches 100GeV to 100TeV.

• IceCube reaches 100GeV to 10^9GeV.

• The strongest constraints on GeV-scale DM that annihilates to photon-rich channels come from Fermi looking at gamma rays from dwarf galaxies. The analysis is done by fitting "templates" (i.e. Poisson distributions due to background and candidate signal) using maximum likelihood. A combined analysis rules out thermal relic WIMP DM for masses up to ~ 100GeV, subject to standard assumptions, though the precise bound depends on the annihilation channel.

• Constraints on decaying DM can can probe DM masses up to 10^{10}GeV, or even Hawking radiation from primordial black holes. We can also cover masses down to the keV range using X-ray telescopes such as Chandra, XMM-Newton, INTEGRAL, HXMT, Astrosat, NuSTAR, and Suzaku, or the proposed XRISM, XPoSat, STROBE-X, Athena, and Lynx.

• According to Fermi data, there is a highly significant excess of GeV-scale photons from the galactic center, first noticed by Goodenough and Hooper in 2009. Particle explanations of this excess would have masses in the range $7 - 10$GeV and are generally called "hooperons", but the excess could also be explained by a large population of pulsars. Emission from pulsars would be more "clumpy", but whether the data reflects this is a matter of current controversy which depends on fine statistical details.

• There is also an outstanding 4σ excess of 3.5keV photons from galaxy clusters, found by XMMNewton in 2014, which has been confirmed by other experiments. The simplest DM explanation is a decaying 7keV sterile neutrino, but that hypothesis is in tension with other constraints. In addition, there are many possible non-DM sources in this energy range.

Next, we consider detection of charged particles.

• Charged cosmic rays diffuse through the galactic magnetic field, losing energy as they propagate and escaping at the boundaries; both of these effects soften the spectrum. Protons are usually in the "diffusion-dominated" regime, while electrons and positrons are in the "loss-dominated" regime, sampling only a local regime of about 1kpc. In practice, one uses specialized programs such as GALPROP or DRAGON, or pregenerated results such as PPPC4DMID.

• It is generally better to look for antimatter because DM decay should produce it equally as often, but the background should be much lower; examples include antiprotons, antideuterons, and positrons. Antimatter can be distinguished from matter by how it curves in a magnetic field. If we're using matter, we can still distinguish signal from background, but we need to use spectral features. In general, the backgrounds for charged particles are much harder to model than for photons, so while the bounds tend to be stronger, systematic uncertainties are high.

• The leading experiment for cosmic rays of GeV energies and up is AMS-02, on the International Space Station, and for the purposes of DM detection its sensitivity to antiprotons and positrons is most important.

• Some surprisingly strong limits for sub-GeV cosmic rays come from the Voyager spectrometer. These cosmic rays are usually deflected by the solar wind, but Voyager can see them since it is beyond the heliopause. This provides the best limits on 10MeV to 1GeV DM annihilating or decaying to electrons and positrons.

• Even just considering AMS-02, there are many outstanding anomalies.

• There is a very large, long-standing excess of TeV-scale positrons, which was also seen by AMS-02's predecessor Pamela. But it's so large that it's hard to explain with DM, so it's likely due to a nearby population of pulsars.

• There is an excess of antiprotons around 100GeV at 4.5σ, but the statistical significance is disputed because of possible correlations between energy bins.

• There are tentatively a few events with antihelium, which is supposed to be extremely rare from astrophysical sources. However, it's also tough to get an antihelium signal from DM.

We can also consider "very indirect" DM detection.

• Annihilating or decaying DM would have steadily injected energy into the universe throughout its history. This can modify the results of BBN, and also change the ionization and temperature history, which affects the CMB and 21 cm radiation. Such limits are clean because they don't depend on galactic astrophysics.

• Extra ionization during the cosmic dark ages ($z \sim 10 - 1000$) acts as a "screen" for CMB photons. To estimate the resulting bound, note that during radiation domination and after freeze-out, the fraction of DM that annihilates per Hubble time is

$$n\langle\sigma v\rangle H \propto T$$

and this quantity is order 1 at freeze-out itself.

• Thus, at recombination the fraction is small, $T_{\rm rec}/T_f \sim 10^{-9}$. On the other hand, the massenergy of one DM particle is enough to ionize $(1\text{GeV})/(13.6\text{eV}) \sim 10^8$ hydrogen atoms, assuming all the energy goes into ionization, so at matter-radiation equality a tiny fraction of the DM particles annihilating gives a large effect.

• Planck is sensitive to changes in the ionization of order $\sim 10^{-4}$, so ionization provides a strong bound, especially for lower DM masses. Planck rules out the thermal relic benchmark for masses below 10GeV, though the precise bound depends on the annihilation channel. Ionization also places constraints on decaying DM, which are especially strong from MeV to GeV.

• Annihilation can also heat the universe, and energy injection during recombination distorts the blackbody spectrum of the CMB. However, at matter-radiation equality the change in temperature would be of order $T_{\rm rec}/T_f \sim 10^{-9}$, which is too small for Planck to probe. More promisingly, the energy can also go into heating the baryons in the form of hydrogen gas, which are vastly outnumbered by the photons.

• We can measure the gas temperature over time by measuring the redshifted 21 cm line, with more emission corresponding to a higher temperature. Without a DM effect, we expect the gas to be colder than the CMB after recombination, since nonrelativistic matter cools down more quickly, then heat back up at the cosmic dark ages; DM would appear as a higher temperature at earlier times.

• This line is currently probed by EDGES, HERA, LOFAR, MWA, PAPER, SARAS, SCI-HI, and will be probed further by DARE, LEDA, PRIZM, and SKA. EDGES has seen a deep absorption trough at $z \sim 17$, which is extremely surprising, but the measurement is very difficult and has not yet been confirmed by other experiments.

• The Lyman-alpha forest is a set of emission lines due to the Lyman-alpha transition in neutral hydrogen. It can thus be used to probe the amount of neutral hydrogen. While the CMB is better for probing extra ionization near the beginning of the cosmic dark ages, the Lyman-alpha forest is better for probing extra ionization near the end, before the usual reionization starts. It is not as useful for earlier times because when most hydrogen is neutral, such photons are very efficiently absorbed.

Summary **of Observations**

Observations of the cosmic microwave background (CMB) and the large-scale structure (LSS) may be used to constrain the spectrum of primordial seed fluctuations. This makes CMB and LSS experiments probes of the early universe. To extract this information about the inflationary era the late-time evolution of fluctuations has to be accounted for. This is done with numerical codes such as CMBFAST and CAMB.

Current observations are in beautiful agreement with the basic inflationary predictions: The universe is flat with a spectrum of nearly scale-invariant, Gaussian and adiabatic density fluctuations. The fluctuations show non-zero correlations on scales that were bigger than the horizon at recombination. Furthermore, the peak structure of the CMB spectrum is evidence that the fluctuations we created with coherent phases.

Future tests of inflation will mainly come from measurements of CMB polarization. B-modes of CMB polarization are a unique signature of inflationary gravitational waves. The B-mode amplitude is a direct measure of the energy scale of inflation. In addition, measurements of non-Gaussianty potentially carry a wealth of information about the physics of inflation by constraining interactions of the inflaton field.

Finally, the following measurements would falsify single-field slow-roll inflation:
- Large non-Gaussianity, $f_{\rm NL} > 1$.
- Non-zero isocurvature perturbations, $\alpha \neq 0$.
- Large running of the scalar spectrum, $|\alpha_{\rm s}| > 0.001$.
- Violation of the tensor consistency relation, $r \neq -8n_{\rm t}$.

Special Topics in a Nutshell

2 Other models, theories, properties and data (??)

2.1 Main physical background for cosmology

2.1.1 Gravity ideas and formalisms for cosmology

2.1.2 Gravitational lensing for cosmology in a nutshell (???)

(Додельсон аж книгу по нему написал, да и Вайнберг тоже вставляет его, думаю, не зря это. потом разберу)

Weak lensing by Lee Yoo (lectures in Zurich)

5.1 Gravitational Lensing by a Point Mass

In classical mechanics, the gravitational interaction due to a point mass M provides a perturbation along the transverse direction to a test particle moving with the relative speed $v_{\rm rel}$:

$$\Delta v_\perp = \frac{2GM}{bv_{\rm rel}} \tag{5.1}$$

where G is the Newton's constant and b is the transverse separation (or the impact parameter). The prediction for the light deflection angle $\hat{\alpha}$ in Einstein's general relativity is well-known to follow the same result in classical mechanics, but with additional factor two:

$$\hat{\alpha} = \frac{4GM}{bc^2} = 8.155 \times 10^{-3}\,\text{arcsec}\left(\frac{M}{M_\odot}\right)\left(\frac{b}{\text{AU}}\right)^{-1} \tag{5.2}$$

Given the deflection angle $\hat{\alpha}$, we can readily write down the lens equation in terms of the angular diameter distances

$$\mathcal{D}_s\hat{s} = \mathcal{D}_s\hat{n} - \mathcal{D}_{ls}\hat{\alpha}, \quad \hat{s} = \hat{n} - \theta_E^2/\hat{n} \tag{5.3}$$

where the Einstein radius is

$$\theta_E = \sqrt{\frac{4GM}{c^2}\frac{\mathcal{D}_{ls}}{\mathcal{D}_l\mathcal{D}_s}} = 2.853 \times 10^{-3}\,\text{arcsec}\left(\frac{M}{M_\odot}\right)\left(\frac{\mathcal{D}_l}{\text{kpc}}\right)^{-1/2}\left(1 - \frac{\mathcal{D}_l}{\mathcal{D}_s}\right)^{1/2} \tag{5.4}$$

For a point mass lens and a point source, two lensed image positions are readily obtained as

$$\hat{n}_1 = \frac{1}{2}\left(\hat{s} + \sqrt{\hat{s}^2 + 4\theta_E^2}\right), \quad \hat{n}_2 = \frac{1}{2}\left(\hat{s} - \sqrt{\hat{s}^2 + 4\theta_E^2}\right) < 0, \quad \hat{n}_1 + \hat{n}_2 = \hat{s} \tag{5.5}$$

and when the source and the lens are aligned, the lensed images form a ring with radius θ_E.

- microlensing, probe of MACHOs or exoplanets

5.2 Standard Weak Lensing Formalism

5.2.1 Lens Equation and Distortion Matrix

This light deflection due to a point mass can be generalized to derive the standard weak lensing formalism by considering the gravitational potential fluctuation $\psi = -GM/r$ of the general matter distribution ρ (but still a single lens plane), instead of a point mass (ψ indeed corresponds to the metric fluctuation α_χ). The lensing potential Φ is the line-of-sight integration of the metric fluctuation,

$$\Phi := \frac{1}{c^2}\frac{\mathcal{D}_{ls}}{\mathcal{D}_l\mathcal{D}_s}\int dz 2\psi \tag{5.6}$$

and using the Poisson equation, we can relate the lensing potential with the surface density Σ as

$$\nabla^2\psi = 4\pi G\bar{\rho}a^2\delta, \qquad \hat{\nabla}^2\Phi = 2\frac{\Sigma}{\Sigma_c}, \quad \Phi(\hat{n}) = \int d^2\hat{n}'\frac{\Sigma}{\pi\Sigma_c}\ln|\hat{n}-\hat{n}'| \tag{5.7}$$

where we ignored the boundary term when the Poisson equation is integrated and the critical surface density is defined as

$$\Sigma_c^{-1} := \frac{4\pi G}{c^2}\frac{\mathcal{D}_{ls}\mathcal{D}_l}{\mathcal{D}_s}, \quad \Sigma_c = 1.663\times 10^6 h M_\odot \mathrm{pc}^{-2}\left(\frac{\mathcal{D}_s}{\mathcal{D}_{ls}}\right)\left(\frac{\mathcal{D}_l}{h^{-1}\mathrm{Mpc}}\right)^{-1} \tag{5.8}$$

Though the lensing potential is formally divergent for a point mass, its angular derivative is well defined:

$$\hat{\alpha} = \left(\frac{\mathcal{D}_l\mathcal{D}_s}{\mathcal{D}_{ls}}\right)\nabla_\perp\Phi = \frac{\mathcal{D}_s}{\mathcal{D}_{ls}}\hat{\nabla}\Phi \tag{5.9}$$

such that the lens equation becomes

$$\hat{s} = \hat{\boldsymbol{n}} - \hat{\nabla}\Phi \tag{5.10}$$

where $\hat{\nabla}$ is the angular gradient. When the lensing material is distributed over the redshift, the lensing potential is then obtained by integrating the potential fluctuation over the line-of-sight distance as

$$\Phi = \int_0^{\bar{r}_s} d\bar{r}\left(\frac{\bar{r}_s-\bar{r}}{\bar{r}_s\bar{r}}\right)2\psi \equiv \int_0^{\bar{r}_s} d\bar{r}\frac{g\left(\bar{r},\bar{r}_s\right)}{\bar{r}^2}2\psi \tag{5.11}$$

where we switched to a comoving angular diameter distance $\bar{r}$ and we defined the weight function g for later convenience

$$g := \bar{r}^2\left(\frac{\bar{r}_s-\bar{r}}{\bar{r}_s\bar{r}}\right) \tag{5.12}$$

When the background source galaxies are also spread over some redshift with the distribution $n_g\left(r_s\right)$, the lensing potential can be readily generalized by replacing the weight function with

$$g := \bar{r}^2\int_{\bar{r}}^{\infty} d\bar{r}_s\left(\frac{\bar{r}_s-\bar{r}}{\bar{r}_s\bar{r}}\right)n_g\left(\bar{r}_s\right), \quad \Phi = \int_0^{\infty} d\bar{r}\frac{g(\bar{r})}{\bar{r}^2}2\psi, \quad 1 = \int_0^{\infty} d\bar{r}_s n_g\left(\bar{r}_s\right) \tag{5.13}$$

where the upper limit for the integration is indeed $\bar{r}(z=\infty)$ and the source distribution is normalized. [1]

Using the lens equation, the distortion matrix $\mathbb{D}$ (or sometimes called the amplification matrix) is defined as

$$\mathbb{D}_{ij} \equiv \frac{\partial s_i}{\partial n_j} = \mathbb{I}_{ij} - \begin{pmatrix} \Phi_{11} & \Phi_{12} \\ \Phi_{21} & \Phi_{22} \end{pmatrix}, \quad \Phi_{ij} := \hat{\nabla}_j \hat{\nabla}_i \Phi \tag{5.14}$$

where $\mathbb{I}$ is the two-dimensional identity matrix and we defined a short hand notation for the angular derivatives of the lensing potential. The distortion matrix is conventionally decomposed into the trace, the traceless symmetric and the anti-symmetric matrices:

$$\mathbb{D} := \mathbb{I} - \begin{pmatrix} \kappa & 0 \\ 0 & \kappa \end{pmatrix} - \begin{pmatrix} \gamma_1 & \gamma_2 \\ \gamma_2 & -\gamma_1 \end{pmatrix} - \begin{pmatrix} 0 & \omega \\ -\omega & 0 \end{pmatrix}, \quad \det \mathbb{D} = (1-\kappa)^2 - \gamma^2 + \omega^2 \tag{5.15}$$

where the trace is the gravitational lensing convergence κ and the symmetric traceless part is the lensing shear $\gamma = \sqrt{\gamma_1^2 + \gamma_2^2}$:

$$\begin{aligned} \kappa &\equiv 1 - \frac{1}{2}\operatorname{Tr}\mathbb{D} = \frac{1}{2}\left(\Phi_{11} + \Phi_{22}\right), & \omega &\equiv \frac{\mathbb{D}_{21} - \mathbb{D}_{12}}{2} = 0 \\ \gamma_1 &\equiv \frac{\mathbb{D}_{22} - \mathbb{D}_{11}}{2} = \frac{1}{2}\left(\Phi_{11} - \Phi_{22}\right), & \gamma_2 &\equiv -\frac{\mathbb{D}_{12} + \mathbb{D}_{21}}{2} = \Phi_{12} = \Phi_{21} \end{aligned} \tag{5.16}$$

Since the distortion matrix in Eq. (5.14) is symmetric, the rotation ω vanishes in the standard formalism at all orders.

The standard lensing formalism is based on the lens equation and the lensing potential in Eq. (5.10). However, the source angular position $\hat{s} := (\theta + \delta\theta, \phi + \delta\phi)$ is gauge-dependent, and the lensing potential that is responsible for the angular distortion $(\delta\theta, \delta\phi)$ is also gauge-dependent. Indeed, we already know that 2ψ in Eq. (5.10) should be $(\alpha_\chi - \varphi_\chi)$ to match the leading terms for $\delta\theta$ and the Poisson equation in Eq. (5.21) is indeed an Einstein equation with ψ there replaced by $-\varphi_\chi$.[2] Furthermore, there exist no contributions from the vector and the tensor perturbations in the standard lensing formalism. Finally, while the derivations in this subsection assume no linearity, all formulas of the standard lensing formalism turn out to be valid only at the linear order in perturbations.

5.2.2 Convergence and Shear

While the distortion matrix is defined in terms of angles, it is often assumed in literature that the line-of-sight direction is along z-axis ($\hat{\boldsymbol{n}} // \hat{\boldsymbol{z}}$, i.e., $\theta = 0$), and two angles are aligned with $x - y$ plane. In such a setting, consider two small angular vectors at the source position subtended respectively by $d\theta$ and $d\phi$ at the observer position

$$\Delta s_i^{d\theta} = \mathbb{D}_{i1} d\theta, \quad \Delta s_i^{d\phi} = \mathbb{D}_{i2} d\phi \tag{5.18}$$

The solid angle at the source subtended by these two angular vectors is then related to the solid angle at the observer as

$$d\Omega_s = \left|\Delta s^{d\theta} \times \Delta s^{d\phi}\right| = \det \mathbb{D} d\theta d\phi = \det \mathbb{D} d\Omega_o \tag{5.19}$$

and hence the gravitational lensing magnification μ is then

[1] Sometimes it is normalized when integrated over redshift.

[2] Additional condition of a vanishing anisotropic pressure is needed to guarantee $\alpha_\chi = -\varphi_\chi$ and hence the consistency in the lensing equation.

$$\mu^{-1} \equiv \frac{d\Omega_s}{d\Omega_o} = \det \mathbb{D} \tag{5.20}$$

For this reason, the distortion matrix is often called the inverse magnification matrix. Using the Poisson equation in cosmology,

$$\nabla^2\psi = 4\pi G\bar{\rho}a^2\delta_m = \frac{3H_o^2}{2}\Omega_m\frac{\delta_m}{a} \tag{5.21}$$

the gravitational lensing convergence can be computed in terms of the matter density fluctuation δ_m in the comoving gauge as

$$\kappa = \int_0^{\bar{r}_s} d\bar{r} g\left(\bar{r},\bar{r}_s\right)\nabla_\perp^2\psi = \frac{3H_o^2}{2}\Omega_m\int_0^{\bar{r}_s} d\bar{r}\frac{g\left(\bar{r},\bar{r}_s\right)}{a}\delta_m \tag{5.22}$$

where we used

$$\nabla^2 = \nabla_\perp^2 + \frac{\partial^2}{\partial\bar{r}^2} + \frac{2}{\bar{r}}\frac{\partial}{\partial\bar{r}}, \quad \nabla_\perp^2 = \frac{1}{\bar{r}^2}\hat{\nabla}^2 \tag{5.23}$$

and ignored the boundary terms.
In general, we can compute the individual components of the distortion matrix

$$\gamma_1 = \int_0^{\bar{r}_s} d\bar{r} g\left(\bar{r},\bar{r}_s\right)\left(\nabla_1^2 - \nabla_2^2\right)\psi, \qquad \gamma_2 = 2\int_0^{\bar{r}_s} d\bar{r} g\left(\bar{r},\bar{r}_s\right)\nabla_1\nabla_2\psi \tag{5.24}$$

by using

$$\frac{1}{2}\Phi_{ij} \equiv \frac{1}{2}\hat{\nabla}_i\hat{\nabla}_j\Phi = \int_0^{\bar{r}_s} d\bar{r} g\left(\bar{r},\bar{r}_s\right)\nabla_i\nabla_j\psi \tag{5.25}$$

where the indices i, j represent the perpendicular components.

5.2.3 Angular Power Spectrum and Angular Correlation

Assuming that the survey area is small, we will utilize the angular Fourier transformation in Eq. (2.17) by again computing

$$\Phi(\mathbf{l}) = \int d^2\theta e^{-i\mathbf{l}\cdot\boldsymbol{\theta}}\int_0^{\bar{r}_s} d\bar{r}\frac{g\left(\bar{r},\bar{r}_s\right)}{\bar{r}^2}2\psi = \int_0^{\bar{r}_s} d\bar{r}\frac{g\left(\bar{r},\bar{r}_s\right)}{\bar{r}^4}\int\frac{dk_\parallel}{2\pi}2\psi\left(k_\perp = \frac{l}{\bar{r}}\right)e^{ik_\parallel\bar{r}} \tag{5.26}$$

such that the lensing observables are

$$\kappa(\mathbf{l}) = -\frac{l^2}{2}\Phi(l), \quad \gamma_1(\mathbf{l}) = -\frac{l_1^2 - l_2^2}{2}\Phi(l) = \cos 2\phi_l\kappa(\mathbf{l}), \quad \gamma_2(\mathbf{l}) = -l_1 l_2\Phi(l) = \sin 2\phi_l\kappa(\mathbf{l}) \tag{5.27}$$

where we used $\mathbf{l} = (l_1, l_2) = l\left(\cos\phi_l, \sin\phi_l\right)$. Therefore, the angular power spectra can be readily derived as

$$P_\kappa(l) = \frac{l^4}{4}P_\Phi(l), \quad P_{\gamma_1} = \cos^2 2\phi_l P_\kappa(l), \quad P_{\gamma_2} = \sin^2 2\phi_l P_\kappa(l) \tag{5.28}$$

where the angular power spectrum of the lensing potential is obtained by using the Limber approximation as

$$P_\Phi(l) = \int_0^{\bar{r}_s} d\bar{r} \frac{g^2(\bar{r}, \bar{r}_s)}{\bar{r}^6} 4P_\psi \left(k_\perp = \frac{l}{\bar{r}} \right) \tag{5.29}$$

From the relation of the lensing observables, we find it useful to construct E and B-modes as

$$E(\mathbf{l}) := \cos 2\phi_l \gamma_1(\mathbf{l}) + \sin 2\phi_l \gamma_2(\mathbf{l}), \quad B(\mathbf{l}) := -\sin 2\phi_l \gamma_1(\mathbf{l}) + \cos 2\phi_l \gamma_2(\mathbf{l}) \tag{5.30}$$

We can readily derive

$$E(\mathbf{l}) = \kappa(\mathbf{l}), \quad B(\mathbf{l}) = 0, \quad P_E(l) = P_\kappa(l), \quad P_B(l) = P_{EB}(l) = 0 \tag{5.31}$$

in the absence of any systematics and/or physics other than the gravitational lensing, such that it provides a consistency check of the measurements, where the convergence power spectrum is again related to the matter power spectrum as

$$P_\kappa(l) = \left(\frac{3H_0^2}{2} \Omega_m \right)^2 \int_0^{\bar{r}_s} d\bar{r} \frac{g^2(\bar{r}, \bar{r}_s)}{\bar{r}^2 a^2} P_m \left(k_\perp = \frac{l}{\bar{r}} \right) \tag{5.32}$$

Now we compute the angular correlation function by Fourier transforming the angular power spectrum. Out of two shear components, we construct three angular correlation functions as

$$\begin{aligned} w_{ij}(\theta) := \langle \gamma_i(0) \gamma_j(\theta) \rangle &= \int \frac{d^2 l}{(2\pi)^2} e^{i1\cdot\theta} \begin{pmatrix} \cos^2 2\phi_l & \cos 2\phi_l \sin 2\phi_l \\ \cos 2\phi_l \sin 2\phi_l & \sin^2 2\phi_l \end{pmatrix} P_\kappa(l) \\ &= \frac{1}{2} \int_0^\infty \frac{dl}{2\pi} P_\kappa(l) \begin{pmatrix} J_0(l\theta) + J_4(l\theta) & 0 \\ 0 & J_0(l\theta) - J_4(l\theta) \end{pmatrix} \end{aligned} \tag{5.33}$$

where J_n is the Bessel function and used its integral representation

$$J_0(x) = \int \frac{d\phi}{2\pi} e^{ix\cos\phi}, \quad J_4(x) = \int \frac{d\phi}{2\pi} e^{ix\cos\phi} \cos 4\phi \tag{5.35}$$

5.2.4 Worked Examples

For the simplest case, where the lens and the source are at two definite redshift slices, the lensing observables can be written in a polar coordinate as

$$2\kappa = \Phi_{rr} + \frac{\Phi_r}{r} + \frac{\Phi_{\theta\theta}}{r^2} = 2\frac{\Sigma}{\Sigma_c} \tag{5.36}$$

$$2\gamma_1 = \cos 2\theta \Phi_{rr} - \frac{2\sin 2\theta}{r} \Phi_{r\theta} - \frac{\cos 2\theta}{r} \Phi_r - \frac{\cos 2\theta}{r^2} \Phi_{\theta\theta} + \frac{2\sin 2\theta}{r^2} \Phi_\theta \tag{5.37}$$

$$2\gamma_2 = \sin 2\theta \Phi_{rr} + \frac{2\cos 2\theta}{r} \Phi_{r\theta} - \frac{\sin 2\theta}{r} \Phi_r - \frac{\sin 2\theta}{r^2} \Phi_{\theta\theta} - \frac{2\cos 2\theta}{r^2} \Phi_\theta \tag{5.38}$$

$$\gamma^2 := \gamma_1^2 + \gamma_2^2 = \frac{1}{4} \left(\Phi_{rr} - \frac{\Phi_r}{r} - \frac{\Phi_{\theta\theta}}{r^2} \right)^2 + \left(\frac{\Phi_{r\theta}}{r} - \frac{\Phi_\theta}{r^2} \right)^2 \tag{5.39}$$

For an axisymmetric lens, the lensing observables are further simplified, and the convergence and shear are

$$2\kappa = \hat{\nabla}^2\Phi = \Phi_{rr} + \frac{\Phi_r}{r} = 2\frac{\Sigma}{\Sigma_c}, \quad \gamma = \frac{1}{2}\left(\frac{\Phi_r}{r} - \Phi_{rr}\right) = \frac{\Phi_r}{r} - \frac{\Sigma}{\Sigma_c} = \frac{\bar{\Sigma}(<r) - \Sigma}{\Sigma_c} \tag{5.40}$$

where $\bar{\Sigma}(<r)$ is the average surface density enclosed in radius r and $\bar{\Sigma}(<r) = \Phi_r/r$ from the first relation. The magnification is determined by the surface density of the lensing material, and the gravitational shear is set by the excess surface density of the enclosed mass $\Delta\Sigma := \bar{\Sigma}(<r) - \Sigma(r)$.

For a point mass, the convergence and the shear are

$$\psi = -\frac{GM}{r}, \quad \nabla^2\psi = 4\pi GM\delta^D(x), \quad \kappa = \frac{\Sigma}{\Sigma_c} = \frac{M\delta^D(R)}{\Sigma_c} \tag{5.41}$$

$$\gamma = \frac{\bar{\Sigma}(<R) - \Sigma}{\Sigma_c} = \frac{\bar{\Sigma}}{\Sigma_c} = \frac{\theta_E^2}{\theta^2}, \quad \bar{\Sigma} := \frac{M}{\pi R^2} \tag{5.42}$$

The lensing magnification is then

$$\mu^{-1} = \det\mathbb{D} = 1 - \Phi_{rr} - \frac{\Phi_r}{r} + \frac{\Phi_{rr}\Phi_r}{r} = \frac{s}{r}\frac{\partial s}{\partial r} \tag{5.43}$$

where we used the lens equation

$$s = r - \Phi_r, \quad \partial_r s = 1 - \Phi_{rr} \tag{5.44}$$

For a point mass, there exist two lensed images. When two images are not spatially resolved, the magnification of the lensed images is the sum of two, and we derive the master equation for microlening

$$\mu = \left(\frac{s}{r}\frac{\partial s}{\partial r}\right)_1^{-1} + \left(\frac{s}{r}\frac{\partial s}{\partial r}\right)_2^{-1} = \frac{u^2+2}{u\sqrt{u^2+4}}, \quad u := \frac{s}{\theta_E} \tag{5.45}$$

5.2.5 Galaxy-Galaxy Lensing

Galaxy-galaxy lensing is used to refer to the two-point correlation of the galaxies at one point and the lensing signal measured by background galaxies at the other point. In short, it measures the galaxy-matter cross-correlation. Compared to the cosmic shear measurements, the advantage here is that we have well-defined lenses (lens galaxies) in the foreground, such that the shear measurements in galaxy-galaxy lensing are less susceptible to other systematics.

Assuming spherical symmetry, we can readily derive the lensing convergence and the shear as

$$\kappa(\theta) = \frac{\Sigma(\theta)}{\Sigma_c}, \quad \gamma(\theta) = \bar{\kappa}(\theta) - \kappa(\theta) \tag{5.46}$$

where the "comoving" critical surface density is [3]

$$\Sigma_c(z_1, z_2) = \frac{c^2}{4\pi G}\frac{r_s}{r_l r_{ls}}\frac{1}{1+z_l} = 1.663\times10^{18} h M_\odot \mathrm{Mpc}^{-2}\frac{r_s}{r_l}\left(\frac{r_{ls}}{h^{-1}\mathrm{Mpc}}\right)^{-1}\frac{1}{1+z_l} \tag{5.47}$$

Since we are measuring the excess matter around galaxies, the lensing observables are related to the projected galaxymatter correlation function:

$$w(R) = \int_{-\infty}^{\infty} dz \xi_{\rm gm}\left(r = \sqrt{R^2 + z^2}\right) = \int_0^{\infty} \frac{dk_\perp k_\perp}{2\pi} P_{\rm gm}\left(k_\perp\right) J_0\left(k_\perp R\right) \tag{5.48}$$

where the integration along the line-of-sight is performed. However, note that this is valid only on small angle, as the observed angular separation θ, not the physical separation R is kept fixed. Under the small-angle approximation, the convergence at a given separation can be derived as

$$\kappa(\theta) = \frac{\Sigma(\theta)}{\Sigma_c} = \int dz \frac{\bar{\rho}_m}{\Sigma_c}\left(1 + \xi_{gm}\right) = \frac{\bar{\rho}_m}{\Sigma_c} w(R) \tag{5.49}$$

and the remaining lensing observables are

$$\bar{\kappa}(\theta) = \frac{2\pi}{\pi\theta^2} \int_0^{\theta} d\theta\theta\kappa(\theta) = \frac{3H_0^2\Omega_m}{2} \frac{\left(\bar{r}_s - \bar{r}_l\right)\bar{r}_l}{a_l \bar{r}_s} \int \frac{dk_\perp k_\perp}{2\pi} P_{gm}\left(k_\perp; \bar{r}_l\right) \frac{2J_1\left(k_\perp \bar{r}\theta\right)}{k_\perp \bar{r}\theta} \tag{5.50}$$

$$\gamma_T(\theta) = \bar{\kappa}(\theta) - \kappa(\theta) = \frac{3H_0^2\Omega_m}{2} \frac{\left(\bar{r}_s - \bar{r}_l\right)\bar{r}_l}{a_l \bar{r}_s} \int \frac{dk_\perp k_\perp}{2\pi} P_{gm}\left(k_\perp; \bar{r}_l\right) J_2\left(k_\perp \bar{r}\theta\right) \tag{5.51}$$

$$\Delta\Sigma(R) = \Sigma_c \gamma_T = \bar{\rho}_m \int_{-\infty}^{\infty} dz \left[\frac{2}{R^2} \int_0^R dR' R' \xi_{\rm gm}\left(R', z\right) - \xi_{\rm gm}(R, z)\right] \tag{5.52}$$

5.3 Weak Lensing Observables

5.3.1 Ellipticity of Galaxies

The ellipticity ϵ of galaxies is measured in terms of its semi-major axis a and the semi-minor axis b or in terms of the axis ratio q as

$$\epsilon := \frac{a^2 - b^2}{a^2 + b^2} \equiv \frac{1 - q^2}{1 + q^2} \equiv \frac{\delta - \frac{1}{2}\delta^2}{1 - \delta + \frac{1}{2}\delta^2} \simeq \delta, \quad q := \frac{b}{a} := 1 - \delta \tag{5.53}$$

In an idealized case of round galaxies, the ellipticity ϵ, the axis ratio q, and the distortion δ are a measure of gravitational lensing effects of intervening matter, and they are equivalent in the weak lensing regime. In observations, the center of the galaxy and its ellipticity moment are measured by using some weight function $W\left[I_\nu(\hat{n})\right]$ of the observed intensity as

$$\hat{n}_o := \frac{\int d^2\hat{n}\hat{n}W[\hat{n}]}{\int d^2\hat{n}W[\hat{n}]}, \quad \mathcal{M}_{ij} := \frac{\int d^2\hat{n}\left(\hat{n} - \hat{n}_o\right)_i \left(\hat{n} - \hat{n}_o\right)_j W[\hat{n}]}{\int d^2\hat{n}W[\hat{n}]} \tag{5.54}$$

where the simplest weight function is just the observed intensity $W = I[\hat{n}]$. Given the ellipticity moment, we can define the ellipticity vector and the position angle as

$$\boldsymbol{\epsilon} := \left(\frac{\mathcal{M}_{xx} - \mathcal{M}_{yy}}{\mathcal{M}_{xx} + \mathcal{M}_{yy}}, \frac{2\mathcal{M}_{xy}}{\mathcal{M}_{xx} + \mathcal{M}_{yy}}\right) := \left(\epsilon_+, \epsilon_\times\right) = \epsilon(\cos 2\Theta, \sin 2\Theta), \quad \tan 2\Theta \equiv \frac{2\mathcal{M}_{xy}}{\mathcal{M}_{xx} - \mathcal{M}_{yy}} \tag{5.55}$$

[3] Multiply by $\left(1 + z_l\right)^2$ for physical critical surface density. Note that sometimes people use the physical angular diameter distances, while using comoving coordinates for other quantities, in which $\left(1 + z_l\right)^2$ appears in the equation, instead of $\left(1 + z_l\right)$.

Note that the ellipticity vector is headless, such that it is identical under 180 degree rotation, or spin 2. Since only the ellipticity vector matters, the ellipticity moments $\mathcal{M}$ are often defined without the denominator.

5.3.2 Lensing Polarization

The ellipticity moments of the source galaxies would be what we measure in the absence of gravitational lensing. However, the gravitational lensing changes the observed ellipticity moments. Now, for simplicity, we will ignore rotation ($\omega = 0$) and express the distortion matrix in our coordinate:

$$\mathbb{D} = \mathbb{I} - \begin{pmatrix} \kappa & 0 \\ 0 & \kappa \end{pmatrix} - \begin{pmatrix} \gamma_1 & \gamma_2 \\ \gamma_2 & -\gamma_1 \end{pmatrix} \tag{5.56}$$

and the magnification matrix is then the inverse of the distortion matrix:

$$\mathbf{M}_{ij} := \mathbb{D}^{-1}_{ij} = \frac{1}{|\mathbb{D}|} \begin{pmatrix} 1-\kappa+\gamma_1 & \gamma_2 \\ \gamma_2 & 1-\kappa-\gamma_1 \end{pmatrix}, \quad \mu := |\mathbf{M}| = |\mathbb{D}|^{-1} = \frac{1}{(1-\kappa)^2-\gamma^2} \tag{5.57}$$

Further, assuming the surface brightness conservation due to gravitational lensing (i.e., no frequency change), the observed ellipticity moments are related to those in the source rest-frame as

$$\mathcal{M}^I_{ij} := \int d^2\hat{n}\hat{n}_i\hat{n}_j W[\hat{n}] = \int |\mathbf{M}| d^2\hat{s}\mathbf{M}_{ik}\hat{s}_k\mathbf{M}_{jl}\hat{s}_l W[\hat{s}] \simeq \mu\mathbf{M}_{ik}\mathbf{M}_{jl}\mathcal{M}^s_{kl} \tag{5.58}$$

where we assumed $\hat{n}_o = 0$ and the source size is small that the magnification matrix is constant over the area. Using the definition of the source ellipticity moments

$$\mathcal{M}^s_{11} = \frac{1+\epsilon^s_+}{2}\mathcal{M}, \quad \mathcal{M}^s_{22} = \frac{1-\epsilon^s_+}{2}\mathcal{M}, \quad \mathcal{M}^s_{12} = \frac{\epsilon^s_\times}{2}\mathcal{M}, \quad \mathcal{M} := \mathcal{M}^s_{11} + \mathcal{M}^s_{22} \tag{5.59}$$

the observed ellipticity can be derived in terms of the magnification matrix as

$$\epsilon^I_+ = \frac{\left(1+\epsilon^s_+\right)\mathbf{M}^2_{11} + 2\epsilon^s_\times\mathbf{M}_{12}\left(\mathbf{M}_{11}-\mathbf{M}_{22}\right) - 2\epsilon^s_+\mathbf{M}^2_{12} - \left(1-\epsilon^s_+\right)\mathbf{M}^2_{22}}{\left(1+\epsilon^s_+\right)\mathbf{M}^2_{11} + 2\epsilon^s_\times\mathbf{M}_{12}\left(\mathbf{M}_{11}+\mathbf{M}_{22}\right) + 2\epsilon^s_+\mathbf{M}^2_{12} + \left(1-\epsilon^s_+\right)\mathbf{M}^2_{22}} \tag{5.60}$$

$$\epsilon^I_\times = \frac{2\mathbf{M}_{12}\left[\epsilon^s_\times\mathbf{M}_{12} + \left(1-\epsilon^s_+\right)\mathbf{M}_{22}\right] + 2\mathbf{M}_{11}\left[\left(1+\epsilon^s_+\right)\mathbf{M}_{12} + \epsilon^s_\times\mathbf{M}_{22}\right]}{\left(1+\epsilon^s_+\right)\mathbf{M}^2_{11} + 2\epsilon^s_\times\mathbf{M}_{12}\left(\mathbf{M}_{11}+\mathbf{M}_{22}\right) + 2\mathbf{M}^2_{12} + \left(1-\epsilon^s_+\right)\mathbf{M}^2_{22}} \tag{5.61}$$

where the relation is exact. In terms of the lensing convergence and shear, [4] we derive

$$\epsilon^I_+ = \frac{\epsilon^s_+\left[(1-\kappa)^2+\gamma^2_1-\gamma^2_2\right] + 2\epsilon^s_\times\gamma_1\gamma_2 + 2\gamma_1(1-\kappa)}{2\epsilon^s_+\gamma_1(1-\kappa) + 2\epsilon^s_\times\gamma_2(1-\kappa) + (1-\kappa)^2 + \gamma^2_1 + \gamma^2_2} \tag{5.62}$$

$$\epsilon^I_\times = \frac{\epsilon^s_\times\left[(1-\kappa)^2-\gamma^2_1+\gamma^2_2\right] + 2\epsilon^s_+\gamma_1\gamma_2 + 2\gamma_2(1-\kappa)}{2\epsilon^s_+\gamma_1(1-\kappa) + 2\epsilon^s_\times\gamma_2(1-\kappa) + (1-\kappa)^2 + \gamma^2_1 + \gamma^2_2} \tag{5.63}$$

For circular sources, where $\mathcal{M}^s_{11} = \mathcal{M}^s_{22} \neq 0$, and $\mathcal{M}_{12} = 0$ (or $\epsilon^s_+ = \epsilon^s_\times = 0$), the observed ellipticity becomes

$$\epsilon^I_+ = \frac{2\gamma_1(1-\kappa)}{(1-\kappa)^2+\gamma^2_1+\gamma^2_2} \simeq 2\gamma_1, \quad \epsilon^I_\times = \frac{2\gamma_2(1-\kappa)}{(1-\kappa)^2+\gamma^2_1+\gamma^2_2} \simeq 2\gamma_2 \tag{5.64}$$

where we expanded to the linear order in the last step. Assuming there is no ellipticity correlation of the source galaxies

$$\langle \epsilon_+ \rangle = \langle \epsilon_\times \rangle = \langle \epsilon_+ \epsilon_\times \rangle = \frac{1}{2} \langle \epsilon^2 \rangle \langle \sin 4\phi \rangle = 0 \tag{5.65}$$

$$\langle \epsilon_+^2 \rangle = \langle \epsilon_\times^2 \rangle = \langle \epsilon^2 \rangle \langle \cos^2 2\phi \rangle = \frac{1}{2} \langle \epsilon^2 \rangle \tag{5.66}$$

the observed ellipticity correlation becomes

$$\xi_{\epsilon_+^I}(\theta) = \langle \epsilon_+^I(0) \epsilon_+^I(\theta) \rangle = \xi_\delta(\theta) \left(1 - \sigma_\epsilon^2 + \frac{1}{4}\sigma_\epsilon^4 \right) = \xi_{\epsilon_\times^I},$$

to be compared to the typical ellipticity

$$\sigma_\epsilon = \langle \epsilon^s \rangle^{1/2} \simeq 0.3$$

- modified gravity, no galaxy bias
(???????????)

2.1.3 On some stars and astrophysics for cosmology

(полезные знания, но пока об этом в астрофизике сперва)

Type Ia supernova

(пока только мини инфа из лекций Caltech-a, нужно будет - разберусь потом в теории с этим)

Results from SNe Ia. The SNe Ia were the first technique to directly measure the acceleration of the universe. For low- z observations this is typically quoted in terms of the deceleration parameter q_0, defined by:

$$q_0 = -\left. \frac{a\ddot{a}}{\dot{a}^2} \right|_{a=1} = \frac{1}{2}\Omega_m - \Omega_\Lambda.$$

So $q_0 > 0$ corresponds to a decelerating universe, $q_0 < 0$ to accelerating. From this one can show that

$$H_0 D_L = z + \frac{1 - q_0}{2} z^2 + O\left(z^3\right).$$

In 1998 two supernova teams found that the universe was accelerating, each with ~ 50 SNe:
- High- z Supernova Search: Riess et al. 1998 (AJ 116, 1009). $q_0 = -1.0 \pm 0.4$.
- Supernova Cosmology Project: Perlmutter et al. 1999 (ApJ 517, 565). $0.8\Omega_m - 0.6\Omega_\Lambda = -0.2 \pm 0.1$. (The SCP result is not quite a constraint on q_0 because of the higher-order terms z^3, etc.)

2.2 Other models of cosmology in a nutshell

2.2.1 Variable Constants models overview

(есть статьи про это, посмотрю потом, тут прямо очень все сложно становится)

2.2.2 Description of formation of Solar System

(потом поизучаю, не до этого пока)

[4] With rotation, the magnification matrix is not symmetric, $\mathbf{M}_{12} \neq \mathbf{M}_{21}$.

2.2.3 On other models of inflation

(статья есть, где целая куча моделей собрана, укажу просто тут их, мб графики какие-то приведу, как они отличаются и что эксперимент про них говорит.)

Summary of Inflation in String Theory

Recent work by many authors has led to the emergence of robust mechanisms for inflation in string theory (see Refs. [16, 136, 137, 138, 139, 140] for recent reviews). The primary motivations for these works are the sensitivity of inflationary effective actions to the ultraviolet completion of gravity, and the prospect of empirical tests using precision cosmological data.

In this lecture we illustrated the *UV sensitivity of inflation* with two examples:

• *The eta problem*

The smallness of the eta parameter (or the inflaton mass) is sensitive to dimension-six Planck-suppressed corrections,

$$\Delta V \sim V\frac{\phi^2}{M_{\rm pl}^2} \qquad \Rightarrow \qquad \Delta\eta_{\rm v} \sim 1\,.$$

Such terms arise when integrating out heavy degrees of freedom (above the cutoff) to arrive at the low energy effective theory. For the example of warp brane inflation we showed how this problem is made explicit in string theory calculations [117, 47, 48, 121].

• *Tensor modes in large-field models*

The inflaton field is required to move over a super-Planckian distance for inflation to generate an observable gravitational wave amplitude. Protecting the flatness of the inflationary potential over a super-Planckian range is challenging:

• *No shift symmetry*

In the absence of any special symmetries, the potential in large-field inflation becomes sensitive to an infinite series of Planck-suppressed operators

$$\mathcal{L}_{\rm eff}(\phi) = -\frac{1}{2}(\partial\phi)^2 - \frac{1}{2}m^2\phi^2 - \frac{1}{4}\lambda\phi^4 - \sum_{p=1}^{\infty}\left[\lambda_p\phi^4 + \nu_p(\partial\phi)^2\right]\left(\frac{\phi}{M_{\rm pl}}\right)^{2p} + \cdots\,.$$

In this case, the flatness of the potential over a super-Planckian range requires a fine-tuning of a large number of expansion parameters λ_p (compared to the eta problem which only requires tuning of one mass parameter).

• *Shift symmetry*

If the inflaton field respects a shift symmetry, $\phi \to \phi + const.$, then the action of chaotic inflation

$$\mathcal{L}_{\rm eff}(\phi) = -\frac{1}{2}(\partial\phi)^2 - \lambda_p\,\phi^p\,,$$

with small coefficient λ_p is 'technically natural'.

To construct an inflationary model with detectable gravitational waves, we are therefore interested in finding, in string theory, a configuration that has both a large kinematic range, $\Delta\phi > M_{\rm pl}$, and a potential protected by a shift symmetry that is approximately preserved by the full string theory. Such models have recently been constructed in Refs. [251, 44, 141].

2.2.4 Primordial phase transitions, quantum bubbles, primordial GWs (????)

(выпишу суть уже написанных у меня лекций. Про GW может быть отдельный раздел сделаю потом)

Characteristic frequency of relic GWs

(??? no idea now)

GW production by classical fields

(by the way, this will first be in my note on GWs)

General formalism

GW generation by a stochastic scalar field

GWs from preheating after inflation

Parametric resonance in single-field inflation

$$S=\int d^4x\sqrt{-g}\left[\frac{1}{16\pi G}R-\frac{1}{2}g^{\mu\nu}\partial_\mu\phi\partial_\nu\phi-V(\phi)-\frac{1}{2}g^{\mu\nu}\partial_\mu\chi\partial_\nu\chi-\frac{1}{2}g^2\chi^2\phi^2\right] \tag{22.43}$$

$$\phi(t,\mathbf{x})=\phi(t)+\delta\phi(t,\mathbf{x}) \tag{22.44}$$
$$\chi(t,\mathbf{x})=\delta\chi(t,\mathbf{x}) \tag{22.45}$$

$$\phi(t)=\Phi(t)\sin m_\phi t \tag{22.46}$$

$$R(T) = \frac{2S_1(T)}{|\bar{V}(T)|} \tag{22.134}$$

Bubble dynamics and GW production

GWs from bubble collisions

(I'll make it shorter, just tell here the idea, maybe also some key formulas)

In a first-order phase transition, once these supercritical bubbles have nucleated, their subsequent dynamics depends on their environment. Conceptually, the simplest situation is that of vacuum bubbles, i.e. bubbles that are assumed to expand in the vacuum, neglecting their interaction with the cosmic fluid. In that case, the bubbles expand until their walls move at a speed close to the speed of light. The energy gained in the transition from the metastable state to the ground state is transferred to the kinetic energy of the bubble wall. As the bubble [24] Actually, when the bubble velocity v_b is not close to the speed of light, there are two different time- or lengthscales in the problem. One is the typical time-scale of the phase transition, β^{-1}, which can also identified with the duration of the phase transition. The other is the typical size of the bubbles near the end of the phase transition, when most bubble collisions take place, which is rather given by $R_* = v_b\beta^{-1}$. One should then ask which of these two scales is more appropriate for estimating the peak frequency through eq. (22.6). The answer is quite subtle, and depends on the detailed time evolution of the energy-momentum tensor of the source. It turns out that, in a first approximation, β^{-1} is appropriate for GWs from bubble collisions, while $v_b\beta^{-1}$ is appropriate for turbulence; see the Further Reading. A fit to the dependence on v_b for bubble collisions will be given in eqs. (22.144) and (22.145). expands, more and more regions of space convert to the ground state, and the wall becomes more and more energetic. At the same time, it also becomes thinner, and therefore the energy density stored in the wall increases very rapidly. Of course, as long as we have a single spherical bubble, this large energy cannot be converted to GWs. However, when two bubbles collide, spherical symmetry is broken and GW production can take place.

More realistically, in the cosmological setting in which we are eventually interested, the bubbles interact with the cosmic fluid. This interaction can in principle be quite complex, and results in friction over the bubble wall, which slows down and changes the bubble evolution, while at the same time the cosmic fluid is stirred by the expanding bubbles, with the generation of turbulent motions and acoustic waves. Indeed, three main mechanisms for GW production have been identified, namely GWs from bubble collisions, from turbulence and from colliding acoustic waves in the fluid. We examine them in turn.

19.8 GWs from turbulence in the cosmic fluid 771

2.2.6 On quantum cosmology, wavefunction of universe (????)

(all this is very speculative and I haven't met anyone who would prove me something from here.)

(чуть что есть отдельная про это запись)

Main Formulas of quantum cosmology (??????)

(хз)

Wheeler de Witt equation (??????)

(no one know what is it)

(from Quantum Theory of Gravity. I. The Canonical Theory Bryce S. DeWitt)

$$\pi = \frac{\delta L}{\delta \alpha_{,0}} = 0,$$
$$\pi^i = \frac{\delta L}{\delta \beta_{i,0}} = 0,$$
$$\pi^{ij} = \frac{\delta L}{\delta \gamma_{ij,0}} = -\gamma^{1/2}\left(K^{ij} - \gamma^{ij}K\right),$$
$$H = \int \left(\pi\alpha, 0 + \pi^i\beta_{i,0} + \pi^{ij}\gamma_{ij,0}\right) d^3x - L$$
$$= \int \left(\pi\alpha, 0 + \pi^i\beta_{i,0} + \alpha\mathcal{C} + \beta_i\chi^i\right) d^3x,$$

where

$$\mathcal{HC} \equiv \frac{1}{2}\gamma^{-1/2}\left(\gamma_{ik}\gamma_{jl} + \gamma_{il}\gamma_{jk} - \gamma_{ij}\gamma_{kl}\right)\pi^{ij}\pi^{kl} - \gamma^{1/2(3)}R$$
$$\equiv \gamma^{1/2}\left(K_{ij}K^{ij} - K^2 - {}^{(3)}R\right)$$
$$\chi^i \equiv -2\pi^{ij}{}_{.j} \equiv -2\pi^{ij}{}_{,j} - \gamma^{il}\left(2\gamma_{jl,k} - \gamma_{jk,l}\right)\pi^{jk}$$

Wave function of the universe by J. B. Hartle and S. W. Hawking

(they just wrote some formulas, no one know what do they mean)

$$\psi_0(x, 0) = N \int \delta x(\tau) \exp(-I[x(\tau)]),$$

$$\langle x,0|0,t'\rangle = \sum_n \psi_n(x)\bar{\psi}_n(0)\exp\left(iE_n t'\right)$$
$$= \int \delta x(t)\exp(iS[x(t)]),$$
$$\Psi\left[h_{ij}\right] = N\int_C \delta g(x)\exp\left(iS_E[g]\right)$$

S_E is the classical action for gravity including a cosmological constant Λ and the functional integral is over all four-geometries with a spacelike boundary on which the induced metric is h_{ij} and which to the past of that surface satisfy some appropriate condition to define the state. For this WF we have a diff eq - Wheeler-DeWitt equation which we shall derive from this point of view in Sec. II. With a simple choice of factor ordering it is

$$\left[-G_{ijkl}\frac{\delta^2}{\delta h_{ij}\delta h_{kl}} - {}^3R(h)h^{1/2} + 2\Lambda h^{1/2}\right]\Psi\left[h_{ij}\right] = 0,$$

where G_{ijkl} is the metric on superspace,

$$G_{ijkl} = \frac{1}{2}h^{-1/2}\left(h_{ik}h_{jl} + h_{il}h_{jk} - h_{ij}h_{kl}\right)$$

2.2.7 On bouncing universe model

(напишу потом мб.)

2.2.8 On Conformal cyclic cosmology

(идея Пенроуза, напишу потом. У Турока кст тоже статья про это есть.)

2.2.9 Other most typical models of cosmology

(потом мб пару разделов сделаю, пока на них только тут указания, потому что не были пока нужны мне они)

De Sitter space

(удалю скорее всего, просто еще раз прочитать нужно)

De Sitter space can be defined as a submanifold of a generalized Minkowski space of one higher dimension. Take Minkowski space $\mathbf{R}^{1,n}$ with the standard metric:

$$ds^2 = -dx_0^2 + \sum_{i=1}^{n} dx_i^2.$$

De Sitter space is the submanifold described by the hyperboloid of one sheet

$$-x_0^2 + \sum_{i=1}^{n} x_i^2 = \alpha^2,$$

where α is some nonzero constant with its dimension being that of length. The metric on de Sitter space is the metric induced from the ambient Minkowski metric. The induced metric is nondegenerate and has Lorentzian signature. (Note that if one replaces α^2 with $-\alpha^2$ in the above definition, one obtains a hyperboloid of two sheets. The induced metric in this case is positive-definite, and each sheet is a copy of hyperbolic n-space.

(допишу потом свойства и применения)

Гравитационная устойчивость изотропного мира по Ландау

Плоская анизотропная модель по Ландау

(все это потом буду додумывать.)
Пишем Уравнения Эйнштейна как

$$g_{00} = 1, \quad g_{0\alpha} = 0, \quad g_{\alpha\beta} = -\gamma_{\alpha\beta}(t).$$

Теперь мы можем воспользоваться уравнениями Эйнштейна в виде (97.11)-(97.13). Поскольку величины $\gamma_{\alpha\beta}$, а с ними и компоненты трехмерного тензора $\varkappa_{\alpha\beta} = \dot{\gamma}_{\alpha\beta}$ не зависят от координат x^α, то $R_{0\alpha} \equiv 0$. По той же причине $P_{\alpha\beta} \equiv 0$, и в результате уравнения гравитационного поля в пустоте сводятся к следующей системе:

$$\dot{\varkappa}_\alpha^\alpha + \frac{1}{2}\varkappa_\alpha^\beta \varkappa_\beta^\alpha = 0,$$
$$\frac{1}{\sqrt{\gamma}}\left(\sqrt{\gamma}\varkappa_\alpha^\beta\right)^\bullet = 0.$$

$$\sqrt{\gamma}\varkappa_\alpha^\beta = 2\lambda_\alpha^\beta, \qquad \lambda_\alpha^\beta = \text{ const}$$

$$\varkappa_\alpha^\alpha = \frac{\dot{\gamma}}{\gamma} = \frac{2}{\sqrt{\gamma}}\lambda_\alpha^\alpha,$$

$$\dot{\gamma}_{\alpha\beta} = \frac{2}{t}\lambda_\alpha^\gamma \gamma_{\gamma\beta}$$

Совокупность коэффициентов λ_α^γ можно рассматривать как матрицу некоторой линейной подстановки. Путем соответствующего линейного преобразования координат x^1, x^2, x^3 (или, что эквивалентно, величин $g_{1\beta}, g_{2\beta}, g_{3\beta}$) можно, вообще говоря, привести эту матрицу к диагональному виду. Обозначим ее главные значения посредством p_1, p_2, p_3 и будем считать, что все они вещественны и различны (о других случаях - см. ниже); единичные векторы в соответствующих главных направлениях пусть будут $\mathbf{n}^{(1)}, \mathbf{n}^{(2)}, \mathbf{n}^{(3)}$. Тогда решение уравнений (117.6) можно представить в виде

$$\gamma_{\alpha\beta} = t^{2p_1} n_\alpha^{(1)} n_\beta^{(1)} + t^{2p_2} n_\alpha^{(2)} n_\beta^{(2)} + t^{2p_3} n_\alpha^{(3)} n_\beta^{(3)}$$

(постоянные коэффициенты при степенях t можно обратить в единицу путем соответствующего выбора масштаба координат). Наконец, выбрав направления векторов $\mathbf{n}^{(1)}, \mathbf{n}^{(2)}, \mathbf{n}^{(3)}$ в качестве окончательного направления осей (назовем их x, y, z), приведем метрику к виду

$$ds^2 = dt^2 - t^{2p_1}dx^2 - t^{2p_2}dy^2 - t^{2p_3}dz^2$$

(E. Kasner, 1922). Здесь p_1, p_2, p_3 - любые три числа, удовлетворяющие двум соотношениям:

$$p_1 + p_2 + p_3 = 1, \quad p_1^2 + p_2^2 + p_3^2 = 1$$

The metric in $D > 3$ spacetime dimensions is

$$\mathrm{d}s^2 = -\mathrm{d}t^2 + \sum_{j=1}^{D-1} t^{2p_j} \left[\ \mathrm{d}x^j\right]^2,$$

and contains $D-1$ constants p_j, called the Kasner exponents. The metric describes a spacetime whose equal-time slices are spatially flat, however space is expanding or contracting at different

rates in different directions, depending on the values of the p_j. Test particles in this metric whose comoving coordinate differs by Δx^j are separated by a physical distance $t^{p_j}\Delta x^j$.

The Kasner metric is an exact solution to Einstein's equations in vacuum when the Kasner exponents satisfy the following Kasner conditions,

$$\sum_{j=1}^{D-1} p_j = 1 \qquad\qquad \sum_{j=1}^{D-1} p_j^2 = 1.$$

(???? потом разберу, это модель Казнера по Вики)

Колебательный режим приближения к особой точке по Ландау

(Абзац про достижения В. А. Белинский, Е. М. Лифшиц, И. М. Халатников, 1968, видимо, что-то глубокое, отдельно подумать про это нужно будет много.).

Особенность по времени в общем космологическом решении уравнений Эйнштейна по Ландау

(потом подумаю когда-то)

Факт существования особой точки в общем решении уравнений Эйнштейна был впервые доказан Пенроузом (R. Penrose, 1965) топологическими методами, которые, однако, не дают возможности установить конкретный аналитический характер особенности. Изложение этих методов и полученных с их помощью теорем см. Р. Пенроуз, Структура пространства-времени, «Мир», 1972.

2.2.10 Cosmological models that are considered wrong

(see https://www.astro.ucla.edu/~wright/errors.html, сейчас просто не до этого, там прямо много всякого)

Errors in Tired Light Cosmology

(see https://www.astro.ucla.edu/~wright/tiredlit.htm, there is a lot of info, now it is not important)

Errors in Irving Segal's Chronometric Cosmology

Errors in Eric Lerner's "The Big Bang Never Happened"

Errors in the Steady State and QSSC Models

Eddington did not predict the CMB

2.3 On general and more philosophical ideas about physics about cosmology

(тут то, про что если начнешь думать, то увязнешь в небытии и тупиковости разных идей. поэтому откидываю это подальше, выше - годные идеи, с которыми хоть что-то можно сделать!)

2.3.1 Cosmological paradoxes and philosophical problems

- Bentley's paradox: In a Newtonian universe, gravitation should pull all matter into a single point.

- Boltzmann brain: If the universe we observe resulted from a random thermodynamic fluctuation, it would be vastly more likely to be a simple one than the complex one we observe. The simplest case would be just a brain floating in vacuum, having the thoughts and sensations an ostensible observer has.

- Fermi paradox: If there are, as various arguments suggest, many other sentient species in the universe, then where are they? Should their presence not be obvious?

- Heat death paradox: If the universe were infinitely old, it would be in thermodynamic equilibrium, which contradicts what we observe.

- Olbers' paradox: Why is the night sky dark if there is an infinity of stars, covering every part of the celestial sphere?

2.3.2 What Could be in the Universe if Something Was Different?

(тут обзор разных фантастических идей, их полно.)

2.3.3 What is the fate of the universe?

(потом поизучаю, не до этого пока)

2.3.4 What Was in the Beginning of the Universe?

Как квантовая космология решает вопрос начала Вселенной? (????)

(думаю, это один из не многих вопросов, которые в 1 часть занести нужно.)

2.3.5 Nature of Time, Chronogeometry

Суть

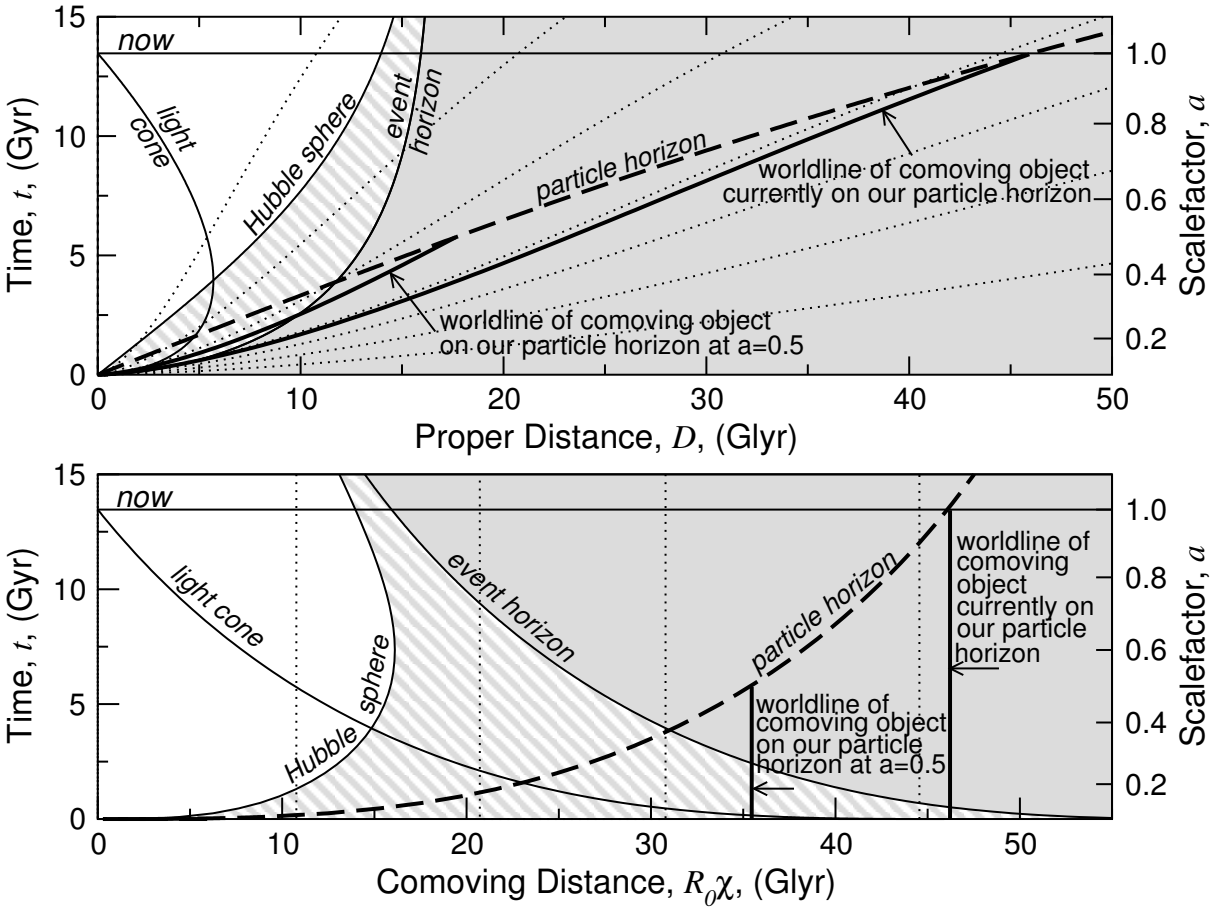
(пока в теорполе это пишу. Гуца и разных схожих авторов мб когда-то почитаю, вот куча записей частично под их влиянием и окажутся.)

2.3.6 Some Other Hypothetical Questions

(???)

О конце света

3 Some plots from different part of cosmology



Plots about relics of inflation

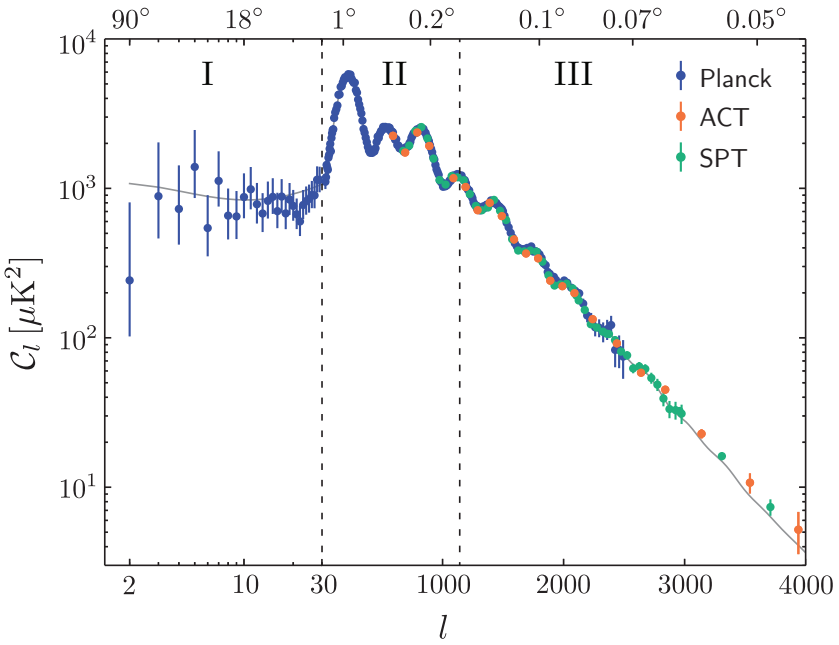


Figure 13: The angular variations of the CMB power spectrum are consequence of the dynamics of sound waves in the photon-baryon fluid. On large scales (region I), the fluctuations are frozen and we directly see the spectrum of the initial conditions. At intermediate scales (region II), we observe the oscillations of the fluid as captured at the moment of last-scattering. Finally, on small scales (region III), fluctuations are damped because their wavelengths are smaller than the mean free path of the photons.

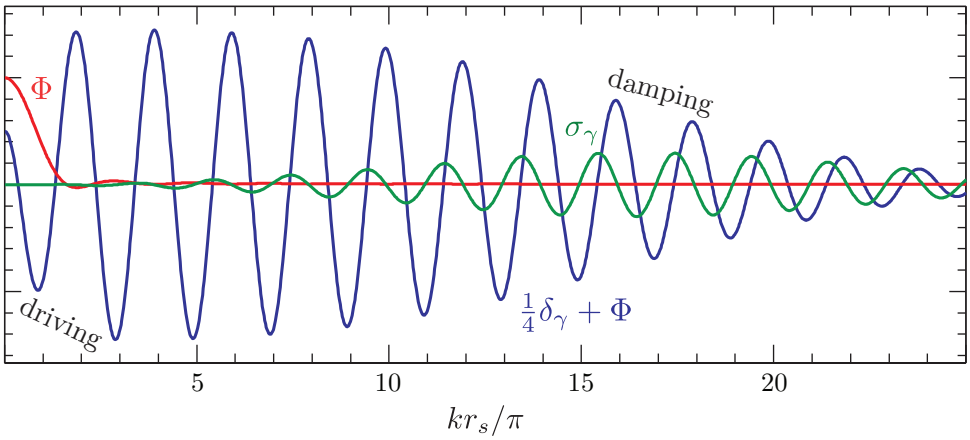

Figure 14: Acoustic oscillations with gravitational forcing and diffusion damping. For a mode that enters the sound horizon during radiation domination, the gravitational potential decays after horizon crossing and drives the acoustic amplitude higher. As the photon diffusion length increases and becomes comparable to the wavelength, viscosity σ_γ is generated and small-scale fluctuations are washed out.

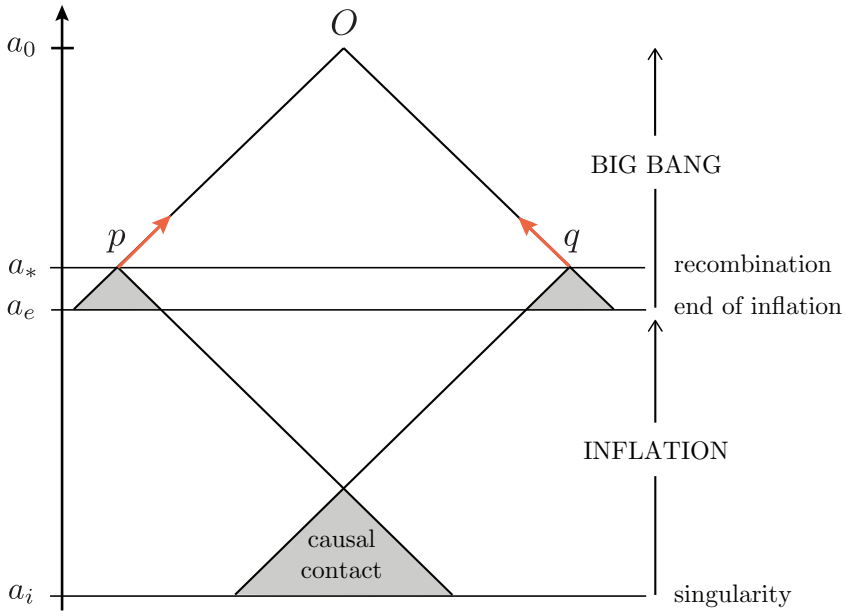

Figure 15: Illustration of the inflationary solution to the horizon problem in comoving coordinates (using conformal time on the vertical axis). The spacelike singularity of the standard Big Bang is replaced by the reheating surface, i.e. rather than marking the beginning of time it now simply corresponds to the transition from the end of inflation to the standard Big Bang evolution. All points in the CMB have overlapping past light cones and therefore originated from a causally connected region of space.

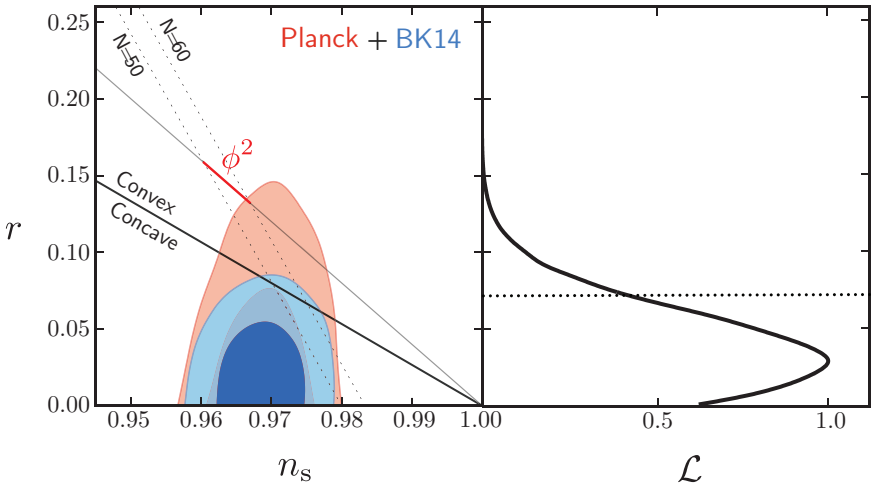

Figure 16: Current constraints on n_s and r from CMB measurements of Planck and BICEP [41].

Part III
Fundamentals of Cosmology

4 General Fundamentals of Cosmology

4.1 General, Philosophical Approach

(see also a section about experiments, there will be a more detailed discussion of the facts which will be mentioned here)

4.1.1 Why In General We Can Describe a Universe (??)

(хз вообще, может ли такое быть)

Почему космология как наука в принципе возможна?

4.1.2 Flatness of the Universe

(???? I'll discuss some ideas)

Почему Вселенная плоская?

(она плоская, а почему так?)

4.1.3 Gravitation on the Scale of the Universe (???)

(??? what is known at all about it???)

4.1.4 Idea of a Cosmological Constant

(see below a big discussion of it)

Как догадаться до косм постоянной?

В уравнении она возможна

Физически (??)

Космологическая постоянная как врожденная кривизна пространства (????)

4.1.5 Gravitational Constant

(see also a note on gravity)

4.1.6 Time in Context of Cosmology (????)

(?? что вообще про него мы думаем?)

if Universe expands than there might be time dilation that will cause time to move slower. Why don't we account for it? (???????)

Imagine 2 particles and Univ accelerates. How would they know if Universe expands, or if they move? There is no way. So time might be changing also.

4.1.7 Idea of Dark Energy

Схожесть темной энергии и эфира (!?!??!)

(ну мб схожа, тут очень много про это подумать нужно.)

4.1.8 Idea of Dark Matter

(???)

4.1.9 Redshift

Redshift in a nutshell

(!!! Отдельный раздел про него сделаю! может, потом очень большим будет, пока просто subsubsection будет.)

Everything we know about the universe is inferred from the light we receive from distant objects. The light emitted by a distant galaxy can be viewed either quantum mechanically as freely-propagating photons, or classically as propagating electromagnetic waves. To interpret the observations correctly, we need to take into account that the wavelength of the light gets stretched (or, equivalently, the photons lose energy) by the expansion of the universe. We now quantify this effect.

Redshifting of photons.

In the quantum mechanical description, the wavelength of light is inversely proportional to the photon momentum, $\lambda = h/p$. Since according to (1.2.51) the momentum of a photon evolves as $a(t)^{-1}$, the wavelength scales as $a(t)$. Light emitted at time t_1 with wavelength λ_1 will be observed at t_0 with wavelength

$$\lambda_0 = \frac{a\left(t_0\right)}{a\left(t_1\right)}\lambda_1.$$

Since $a\left(t_0\right) > a\left(t_1\right)$, the wavelength of the light increases, $\lambda_0 > \lambda_1$.

Redshifting of classical waves.

We can derive the same result by treating light as classical electromagnetic waves. Consider a galaxy at a fixed comoving distance d. At a time τ_1, the galaxy emits a signal of short conformal duration $\Delta\tau$ (see fig. 1.5). According to (1.1.24), the light arrives at our telescopes at time $\tau_0 = \tau_1 + d$. The conformal duration of the signal measured by the detector is the same as at the source, but the physical time intervals are different at the points of emission and detection,

$$\Delta t_1 = a\left(\tau_1\right)\Delta\tau \quad \text{and} \quad \Delta t_0 = a\left(\tau_0\right)\Delta\tau$$

If Δt is the period of the light wave, the light is emitted with wavelength $\lambda_1 = \Delta t_1$ (in units where $c = 1$), but is observed with wavelength $\lambda_0 = \Delta t_0$, so that

$$\frac{\lambda_0}{\lambda_1} = \frac{a\left(\tau_0\right)}{a\left(\tau_1\right)}.$$

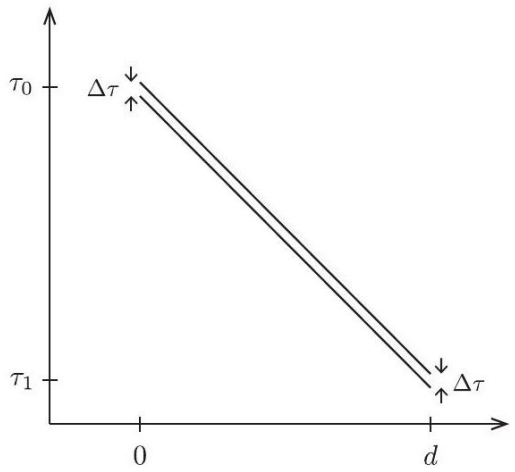

Figure 1.5: In conformal time, the period of a light wave ($\Delta\tau$) is equal at emission (τ_1) and at observation (τ_0). However, measured in physical time ($\Delta t = a(\tau)\Delta\tau$) the period is longer when it reaches us, $\Delta t_0 > \Delta t_1$. We say that the light has redshifted since its wavelength is now longer, $\lambda_0 > \lambda_1$.

It is conventional to define the redshift parameter as the fractional shift in wavelength of a photon emitted by a distant galaxy at time t_1 and observed on Earth today,

$$z \equiv \frac{\lambda_0 - \lambda_1}{\lambda_1}.$$

We then find

$$1 + z = \frac{a\left(t_0\right)}{a\left(t_1\right)}.$$

It is also common to define $a\left(t_0\right) \equiv 1$, so that

$$1 + z = \frac{1}{a\left(t_1\right)}.$$

Hubble's law.-For nearby sources, we may expand $a\left(t_1\right)$ in a power series,

$$a\left(t_1\right) = a\left(t_0\right)\left[1 + \left(t_1 - t_0\right) H_0 + \cdots\right],$$

where H_0 is the Hubble constant

$$H_0 \equiv \frac{\dot{a}\left(t_0\right)}{a\left(t_0\right)}.$$

Eq. (1.2.58) then gives $z = H_0\left(t_0 - t_1\right) + \cdots$. For close objects, $t_0 - t_1$ is simply the physical distance d (in units with $c = 1$). We therefore find that the redshift increases linearly with distance

$$z \simeq H_0 d.$$

The slope in a redshift-distance diagram (cf. fig. 1.8) therefore measures the current expansion rate of the universe, H_0. These measurements used to come with very large uncertainties. Since H_0 normalizes everything else (see below), it became conventional to define [11]

$$H_0 \equiv 100h\mathrm{kms}^{-1}\mathrm{Mpc}^{-1},$$

where the parameter h is used to keep track of how uncertainties in H_0 propagate into other cosmological parameters. Today, measurements of H_0 have become much more precise,[12]

$$h \approx 0.67 \pm 0.01.$$

4.1.10 Redshift by Landau

(лл2 пока)

вкратце о красном смещении

Theory

Основной характерной чертой всех рассмотренных решений является нестационарность метрики: радиус кривизны пространства является функцией времени.

Изменение же радиуса кривизны приводит к изменению всех вообще расстояний между телами в пространстве, как это видно уже из того обстоятельства, что элемент пространственного расстояния dl пропорционален a.

Так, при увеличении a в таком пространстве тела «разбегаются» друг от друга (в открытой модели увеличению a соответствуют $\eta > 0$, а в закрытой $0 < \eta < \pi$).

С точки зрения наблюдателя, находящегося на одном из них, дело будет выглядеть так, как если бы остальные тела двигались в радиальных направлениях, удаляясь от наблюдателя.

Скорость этого «разбегания» (в данный момент t) сама пропорциональна расстоянию между телами.

Это предсказание теории следует поставить в соответствие с фундаментальным астрономическим фактом - эффектом красного смещения линий В спектрах галактик.

Истолковав это смещение как доплеровское, мы приходим к заключению о «разбегании» галактик, т. е. о том, что в настоящее время Вселенная расширяется.

Свет в изотропном пространстве (??)

Рассмотрим распространение лучей света в изотропном пространстве.

Для этого проще всего воспользоваться тем, что вдоль мировой линии распространения светового сигнала интервал $ds = 0$. Точку,

из которой выходит луч света, выберем в качестве начала координат χ, θ, φ. Из соображений симметрии очевидно, что лучи будут распространяться «радиально», т. е. вдоль линии $\theta = \text{const}$, $\varphi = \text{const}$.

Полагая соответственно этому в (112.4) или (113.2)$d\theta = d\varphi = 0$ получим $ds^2 = a^2\,(d\eta^2 - d\chi^2)$. Приравнивая нулю, находим $d\eta = \pm d\chi$ или, интегрируя:

$$\chi = \pm\eta + \text{const}.$$

Знак плюс перед η соответствует лучу, распространяющемуся по направлению от начала координат, а знак минус - лучу, проходящему в начало координат.

В таком виде уравнение (114.1) применимо к распространению лучей как в открытой, так и в закрытой моделях.

С помощью формул предыдущих параграфов можно выразить отсюда проходимое лучом расстояние как функцию времени.

В открытой модели луч света, вышедший из некоторой точки, по мере своего распространения неограниченно удаляется от нее.

В закрытой же модели вышедший из исходной точки луч света в конце концов может дойти до «противоположного полюса» пространства (чему соответствует изменение χ от 0 до π); при дальнейшем распространении луч начнет приближаться к исходной точке.

Обходу луча «вокруг пространства» и возвращению в исходную точку соответствовало бы изменение χ от 0 до 2π. Из (114.1) мы видим, что при этом и η ДОЛЖНО было бы измениться на 2π, что, однако, невозможно (за исключением одного случая - выхода луча в момент, соответствующий $\eta = 0$).

Таким образом, луч не мог бы успеть возвратиться в исходную точку, обойдя «вокруг пространства».

Лучу, приходящему в точку наблюдения (начало координат), соответствует уравнение (114.1) со знаком минус перед η.

Если момент прихода луча в эту точку есть $t(\eta_0)$, то при $\eta = \eta_0$ должно быть $\chi = 0$, так что уравнение распространения таких лучей имеет вид

$$\chi = \eta_0 - \eta$$

Отсюда видно, что к наблюдателю, находящемуся в точке $\chi = 0$, могут дойти к моменту времени $t(\eta_0)$ лучи, вышедшие из точек, находящихся на «расстояниях», не превышающих $\chi = \eta_0$.

Этот результат, относящийся как к открытой, так и к закрытой моделям, весьма существен.

В каждый момент времени $t(\eta)$ в данной точке пространства физическому наблюдению доступно не все пространство, а лишь его часть, соответствующая $\chi \leqslant \eta$. С математической точки зрения «видимая область» пространства представляет собой сечение четырехмерного пространства-времени световым конусом.

Это сечение оказывается конечным как для открытой, так и для закрытой моделей (бесконечным же в открытой модели является сечение гиперповерхностью $t = \text{const}$, соответствующее пространству, рассматриваемому Во всех своих точках в один и тот же момент времени t), В этом смысле разница между открытой и закрытой моделями оказывается менее глубокой, чем это могло бы на первый взгляд показаться.

Чем более удалена от наблюдателя наблюдаемая им в данный момент времени область пространства, тем более ранним моментам времени она соответствует.

Представим себе сферическую поверхность, являющуюся геометрическим местом точек, из которых свет вышел В момент времени $t(\eta - \chi)$ и наблюдается в начале координат в момент $t(\eta)$. Площадь этой поверхности равна $4\pi a^2(\eta - \chi)\sin^2\chi$ (в закрытой модели) или $4\pi a^2(\eta - \chi)\,\mathrm{sh}^2\,\chi$ (в открытой модели).

По мере удаления от наблюдателя площадь «видимой сферы» сначала возрастает от нуля (при $\chi = 0$), затем достигает максимума, после чего снова уменьшается, обращаясь в нуль при $\chi = \eta($ где $a(\eta - \chi) = a(0) = 0)$. Это значит, что сечение световым конусом не только конечно, но и замкнуто.

Оно как бы замыкается в точке, «противоположной» наблюдателю; ее можно увидеть при наблюдении в любом направлении В пространстве.

В этой точке $\varepsilon \to \infty$, так что наблюдению доступна, в принципе, материя на всех ступенях ее эволюции.

Полное наблюдаемое количество материи равно в открытой модели интегралу

$$M_{\text{набл}} = 4\pi \int\limits_0^\eta \mu a^3\,\mathrm{sh}^2\,\chi d\chi$$

Подставив μa^3 из (113.7), Получим:

$$M_{\text{набл}} = \frac{3c^2 a_0}{2k}(\mathrm{sh}\,\eta\,\mathrm{ch}\,\eta - \eta)$$

Эта величина неограниченно возрастает при $\eta \to \infty$. В закрытой же модели возрастание $M_{\text{набл}}$ ограничено, разумеется, полной массой M; аналогичным образом получим в этом случае:

$$M_{\text{набл}} = \frac{M}{\pi}(\eta - \sin\eta\cos\eta)$$

По мере возрастания η от 0 до π эта величина возрастает от 0 до M В дальнейшем же увеличение $M_{\text{набл}}$ согласно полученной формуле фиКтивно и соответствует просто тому, что в «сжимающемся» мире удаленные тела наблюдались бы дважды (по свету, «обошедшему пространство» с двух сторон).

Рассмотрим теперь изменение частоты света при его распространении в изотропном пространстве.

Для этого замечаем предварительно следующее обстоятельство.

Пусть в некоторой точке пространства происходят два события, разделенные промежутком времени $dt = a(\eta)d\eta/$.

Если в моменты этих событий отправляются световые сигналы, наблюдаемые в другой точке пространства, то между моментами их наблюдения пройдет промежуток времени, соответствующий тому же изменению $d\eta$ величины η, что и в точке отправления.

Это следует непосредственно из уравнения (114.1), согласно которому изменение величины η за время распространения луча света из одной точки в другую зависит только от разности координат χ этих точек.

Но поскольку за время распространения сигнала радиус кривизны a изменится, то промежутки времени t между моментами отправления двух сигналов и моментами их наблюдения будут различными; отношение этих промежутков равно отношению соответствующих значений a. Отсюда следует, в частности, что и периоды световых колебаний, измеренные в мировом времени t, меняются вдоль луча пропорционально a.

Частота же света будет, очевидно, обратно пропорциональна a.

Таким образом, при распространении луча света вдоль него постоянно произведение $\omega a = \text{const}$. Предположим, что в момент времени $t(\eta)$ мы наблюдаем свет, излученный источником, находящимся на расстоянии, соответствующем определенному значению координаты χ. Моментом испускания этого света является, согласно (114.1), момент $t(\eta - \chi)$. Если ω_0 есть частота света в момент его испускания, то наблюдаемая нами частота ω равна, согласно (114.5),

$$\omega = \omega_0 \frac{a(\eta - \chi)}{a(\eta)}$$

При монотонно возрастающей функции $a(\eta)$ имеем $\omega < \omega_0$, т. е. происходит уменьшение частоты света.

Это значит, что при наблюдении спектра приходящего света все его линии должны оказаться смещенными в красную сторону по сравнению со спектрами тех же веществ В обычных условиях.

Это явление красного смещения представляет собой, по существу, эффект Доплера от взаимного «разбегания» галактик.

Величина красного смешения, измеряемая отношением ω/ω_0 сдвинутой частоты к несдвинутой, зависит (при данном моменте наблюдения) от расстояния, на котором находится наблюдаемый источник света (в соотношение (114.6) входит координата χ источника света).

При не слишком больших расстояниях можно разложить $a(\eta - \chi)$ в ряд по степеням χ, ограничившись первыми двумя членами:

$$\frac{\omega}{\omega_0} = 1 - \chi\frac{a'(\eta)}{a(\eta)}$$

(Штрих означает дифференцирование по η).

Далее замечаем, что произведение $\chi a(\eta)$ является здесь не чем иным, как расстоянием l до наблюдаемого источника.

Действительно, «радиальный» элемент длины равен $dl = ad\chi$; при интегрировании этого соотношения возникает Вопрос о том, каким способом физического наблюдения определяется расстояние, - в зависимости от этого надо брать значения a в разных точках пути интегрирования в разные моменты времени (интегрирование при $\eta = \text{const}$ соответствовало бы одновременному рассмотрению всех точек пути, что физически неосуществимо).

Но при «малых» расстояниях можно пренебречь изменением a вдоль пути интегрирования И написать просто $l = a\chi$ со значением a, взятым в момент наблюдения.

В результате находим для относительной величины изменения частоты (ее обозначают обычно буквой z) следующую формулу:

$$z = \frac{\omega_0 - \omega}{\omega_0} = \frac{H}{c} l$$

где введено обозначение

$$H = c\frac{a'(\eta)}{a^2(\eta)} = \frac{1}{a}\frac{da}{dt}$$

для так называемой постоянной Хаббла.

Эта величина не зависит при заданном моменте наблюдения от l.

Таким образом, относительный сдвиг спектральных линий пропорционален расстоянию до наблюдаемого источника света.

Рассматривая красное смещение как результат эффекта Доплера, можно определить скорости v галактик, с которыми они удаляются от наблюдателя.

Написав $z = v/c$ и сравнив с (114.7), находим

$$v = Hl$$

(эту формулу можно получить и непосредственно, вычисляя производную $v = d(a\chi)/dt$). Астрономические данные подтверждают закон (114.7), но определение значения постоянной Хаббла затрудняется неопределенностью в установлении масштаба космических расстояний, пригодного для удаленных галактик.

Принятое в настоящее время значение H составляет:

$$H \approx 0,8 \cdot 10^{-10} \text{год}^{-1} = 0,25 \cdot 10^{-17} \text{с}^{-1}$$

$$\frac{1}{H} \approx 4 \cdot 10^{17} \text{с} = 13 \cdot 10^{9} \text{ год.}$$

Это значение H соответствует увеличению «скорости разбегания» на 75 км/с на каждый мегапарсек расстояния.

Подставляя в уравнение (113.4)$\varepsilon = \mu c^2$ и $H = ca'/a^2$, получим для открытой модели следующее соотношение:

$$\frac{c^2}{a^2} = H^2 - \frac{8\pi k}{3}\mu$$

Комбинируя это уравнение с равенством

$$H = \frac{c \operatorname{sh}\eta}{a_0(\operatorname{ch}\eta - 1)^2} = \frac{c}{a}\operatorname{cth}\frac{\eta}{2}$$

получим:

$$\operatorname{ch}\frac{\eta}{2} = H\sqrt{\frac{3}{8\pi k\mu}}$$

Для закрытой модели аналогичным образом получим:

$$\frac{c^2}{a^2} = \frac{8\pi k}{3}\mu - H^2$$
$$\cos\frac{\eta}{2} = H\sqrt{\frac{3}{8\pi k\mu}}$$

Сравнивая (114.11) и (114.13), мы видим, что кривизна пространства отрицательна или положительна, смотря по тому, отрицательна Или положительна разность $8\pi k\mu/3 - H^2$. Эта разность обращается В нуль при $\mu = \mu_k$, где

$$\mu_k = \frac{3H^2}{8\pi k}$$

Со значением (114.10) получим $\mu_k \approx 1.10^{-29}$ г/см ^{3}. При современном состоянии астрономических сведений оценка средней плотности материи в пространстве может быть произведена лишь с весьма небольшой точностью.

Оценки

Для оценки, основанной на подсчете числа галактик и на их средней массе, принимают в настоящее время значение около 3.10$^-$31 г/см ^{3}. Это значение в 30 раз меньше μ_k и, таким образом, свидетельствовало бы в пользу открытой модели.

Однако, не говоря уже о недостаточной достоверности самого этого значения, следует Иметь В виду, что В нем не учитывается возможное существование межгалактического темного газа, учет которого мог бы существенно повысить среднюю плотность материи.

Отметим некоторое неравенство, которое оказывается Возможным ПОлучить при заданном значении величины Н.

Для открытой модели имеем $H = c\,\mathrm{sh}\,\eta/a_0(\mathrm{ch}\,\eta - 1)^2$, и отсюда

$$t = \frac{a_0}{c}(\mathrm{sh}\,\eta - \eta) = \frac{\mathrm{sh}\,\eta(\mathrm{sh}\,\eta - \eta)}{H(\mathrm{ch}\,\eta - 1)^2}$$

Поскольку $0 < \eta < \infty$, то должно быть

$$\frac{2}{3H} < t < \frac{1}{H}$$

Аналогично для закрытой модели получим:

$$t = \frac{\sin\eta(\eta - \sin\eta)}{H(1 - \cos\eta)^2}$$

Возрастанию $a(\eta)$ соответствует интервал $0 < \eta < \pi$; поэтому получаем:

$$0 < t < \frac{2}{3H}$$

Далее определим интенсивность I света, доходящего до наблюдателя от источника, находящегося на расстоянии, соответствующем определенному значению координаты χ. Плотность потока световой энергии в точке наблюдения обратно пропорциональна поверхности сферы, проведенной через рассматриваемую точку с центром в точке

нахождения источника; в пространстве отрицательной кривизны площадь поверхности сферы равна $4\pi a^2\mathrm{sh}^2\chi$. Свет, испущенный источником в течение времени $dt = a(\eta - \chi)d\eta/c$, будет приходить в точку наблюдения в течение времени $a(\eta)dt/a(\eta - \chi) = a(\eta)d\eta/$ с.

Поскольку Интенсивность определяется как поток световой энергии в единицу времени, то, следовательно, в I появится множитель $a(\eta-\chi)/a(\eta)$. Наконец, энергия волнового пакета пропорциональна частоте (см. (53.9)); Поскольку частота меняется при распространении света по закону (114.5), то это приведет к появлению в I еще одного множителя $a(\eta-\chi)/a(\eta)$. В результате окончательно получаем интенсивность В виде

$$I = \text{const} \cdot \frac{a^2(\eta-\chi)}{a^4(\eta)\,\mathrm{sh}^2\,\chi}$$

Для закрытой модели получилось бы аналогично:

$$I = \text{const} \cdot \frac{a^2(\eta-\chi)}{a^4(\eta)\sin^2\chi}$$

Этими формулами устанавливается зависимость видимой яркости наблюдаемого объекта от его расстояния (при заданной абсолютной Яркости).

При малых χ можно положить $a(\eta-\chi)\approx a(\eta)$, и тогда $I\sim 1/a^2(\eta)\chi^2 = 1/l^2$, т. е. обычный закон уменьшения интенсивности обратно пропорционально квадрату расстояния.

Наконец, рассмотрим вопрос о так называемых собственных движениях тел.

Говоря о плотности и движении материи, мы везде подразумевали усредненную плотность и усредненное движение; в частности, В той системе отсчета, которой мы все время пользуемся, скорость усредненного движения равна нулю.

Истинные же скорости тел обнаруживают некоторый разброс вокруг своего среднего значения.

С течением времени скорости собственного движения тел меняются.

Для определения закона этого изменения рассмотрим свободно движущееся тело и выберем начало координат в какой-либо точке его траектории.

Тогда траекторией будет являться радиальная линия $\theta=\text{const}$, $\varphi=\text{const}$.

Уравнение Гамильтона-Якоби (87.6) после подстановки значений g^{ik} примет виД

$$\left(\frac{\partial S}{\partial\chi}\right)^2 - \left(\frac{\partial S}{\partial\eta}\right)^2 + m^2c^2a^2(\eta) = 0$$

Поскольку в коэффициенты этого уравнения χ не входит (т. е. координата χ циклична), то имеет место закон сохранения $dS/d\chi=\text{const}$.

Импульс же p движущегося тела равен, по общему определению, $p=\partial S/\partial l=\partial S/a\partial\chi$. Таким образом, при движении тела остается постоянным произведение $pa=\text{const}$.

Вводя скорость v собственного движения тела согласно

$$p = mv/\sqrt{1-v^2/c^2}$$

получим:

$$\frac{va}{\sqrt{1-\frac{v^2}{c^2}}} = \text{const}.$$

Этим соотношением определяется закон изменения скоростей со временем.

По мере возрастания a скорости v монотонно падают.

ЛЛ2-114.1

Найти первые два члена разложения видимой яркости галактики как функции ее красного смещения; абсолютная яркость галактики меняется со временем по экспоненциальному закону $I_{\text{абс}} = \text{const}\cdot e^{\alpha t}$ (H. Robertson, 1955)

Р е ш е н и е.

Зависимость видимой яркости туманности, наблюдаемой в «момент» η, от расстояния χ дается (для закрытой модели) формулой

$$I = \text{const} \cdot e^{\alpha[t(\eta-\chi)-t(\eta)]} \frac{a^2(\eta-\chi)}{a^4(\eta)\sin^2\chi}$$

Красное смещение, определенное согласно (114.7):

$$z = \frac{\omega_0 - \omega}{\omega} = \frac{a(\eta) - a(\eta-\chi)}{a(\eta-\chi)}$$

Разлагая I и z по степеням χ(с функциями $a(\eta)$ и $t(\eta)$ из (112.9) – (112.10)) и исключая затем χ из получающихся выражений, находим в результате:

$$I = \text{const} \cdot \frac{1}{z^2}\left[1 - \left(1 - \frac{q}{2} + \frac{\alpha}{H}\right) z\right]$$

где введено обозначение

$$q = \frac{2}{1+\cos\eta} = \frac{\mu}{\mu_k} > 1$$

Для открытой модели получается такая же формула с

$$q = \frac{2}{1+\operatorname{ch}\eta} = \frac{\mu}{\mu_k} < 1$$

ЛЛ2-114.2

Найти первые члены разложения числа галактик, находящихся внутри «сферы» заданного радиуса, как функции от красного смещения на границе сферы (в пространственное распределение галактик предполагается однородным).

Р е ш е н и е.

Число N галактик, находящихся на «расстоянии» $\leqslant \chi$, есть (в закрытой модели)

$$N = \text{const} \cdot \int_0^\chi \sin^2\chi d\chi \approx \text{const} \cdot \chi^3$$

Подставляя сюда первые два члена разложения функции $\chi(z)$, получим:

$$N = \text{const} \cdot z^3\left[1 - \frac{3}{4}(2+q)z\right]$$

В таком виде эта формула справедлива и для открытой модели.

Обзор применений красного смещения (??)

(?? пока не знаю.)

5 Main Methods of Gravity and Mathematics for Cosmology

(самая суть и примеры, подробно - в дополнениях)

5.1 Geometry

5.1.1 Geodesics

Geodesics

How do particles evolve in the FRW spacetime? In the absence of additional non-gravitational forces, freely-falling particles in a curved spacetime move along geodesics. I will briefly remind you of some basic facts about geodesic motion in general relativity [8] and then apply it to the FRW spacetime (1.1.16).

Geodesic Equation

Consider a particle of mass m. In a curved spacetime it traces out a path $X^\mu(s)$. The fourvelocity of the particle is defined by

$$U^\mu \equiv \frac{dX^\mu}{ds}.$$

A geodesic is a curve which extremises the proper time $\Delta s/c$ between two points in spacetime. In the box below, I show that this extremal path satisfies the geodesic equation [9]

$$\frac{dU^\mu}{ds} + \Gamma^\mu_{\alpha\beta} U^\alpha U^\beta = 0,$$

where $\Gamma^\mu_{\alpha\beta}$ are the Christoffel symbols $\Gamma^\mu_{\alpha\beta} \equiv \frac{1}{2} g^{\mu\lambda} \left(\partial_\alpha g_{\beta\lambda} + \partial_\beta g_{\alpha\lambda} - \partial_\lambda g_{\alpha\beta}\right)$.

Derivation of the geodesic equation

Consider the motion of a massive particle between to points in spacetime A and B (see fig. 1.4). The relativistic action of the particle is

$$S = -m \int_A^B \mathrm{d}s.$$

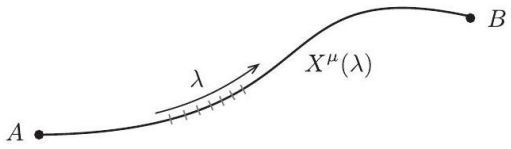

Figure 1.4: Parameterisation of an arbitrary path in spacetime, $X^\mu(\lambda)$.

We label each point on the curve by a parameter λ that increases monotonically from an initial value $\lambda(A) \equiv 0$ to a final value $\lambda(B) \equiv 1$. The action is a functional of the path $X^\mu(\lambda)$,

$$S\left[X^\mu(\lambda)\right] = -m \int_0^1 \left(g_{\mu\nu}(X) \dot{X}^\mu \dot{X}^\nu\right)^{1/2} \mathrm{d}\lambda \equiv \int_0^1 L\left[X^\mu, \dot{X}^\mu\right] \mathrm{d}\lambda,$$

where $\dot{X}^\mu \equiv dX^\mu/d\lambda$. The motion of the particle corresponds to the extremum of this action. The integrand in (1.2.29) is the Lagrangian L and it satisfies the Euler-Lagrange equation

$$\frac{d}{d\lambda}\left(\frac{\partial L}{\partial \dot{X}^\mu}\right) - \frac{\partial L}{\partial X^\mu} = 0.$$

The derivatives in (1.2.30) are

$$\frac{\partial L}{\partial \dot{X}^\mu} = -\frac{1}{L} g_{\mu\nu}\dot{X}^\nu \quad , \quad \frac{\partial L}{\partial X^\mu} = -\frac{1}{2L}\partial_\mu g_{\nu\rho}\dot{X}^\nu \dot{X}^\rho.$$

Before continuing, it is convenient to switch from the general parameterisation λ to the parameterisation using proper time s. (We could not have used s from the beginning since the value of s at B is different for different curves. The range of integration would then have been different for different curves.) Notice that

$$\left(\frac{ds}{d\lambda}\right)^2 = g_{\mu\nu}\dot{X}^\mu \dot{X}^\nu = L^2,$$

and hence $ds/d\lambda = L$. In the above equations, we can therefore replace $d/d\lambda$ with Ld/ds. The Euler-Lagrange equation then becomes

$$\frac{d}{ds}\left(g_{\mu\nu}\frac{dX^\nu}{ds}\right) - \frac{1}{2}\partial_\mu g_{\nu\rho}\frac{dX^\nu}{ds}\frac{dX^\rho}{ds} = 0.$$

Expanding the first term, we get

$$g_{\mu\nu}\frac{d^2X^\nu}{ds^2} + \partial_\rho g_{\mu\nu}\frac{dX^\rho}{ds}\frac{dX^\nu}{ds} - \frac{1}{2}\partial_\mu g_{\nu\rho}\frac{dX^\nu}{ds}\frac{dX^\rho}{ds} = 0.$$

In the second term, we can replace $\partial_\rho g_{\mu\nu}$ with $\frac{1}{2}\left(\partial_\rho g_{\mu\nu} + \partial_\nu g_{\mu\rho}\right)$ because it is contracted with an object that is symmetric in ν and ρ. Contracting (1.2.34) with the inverse metric and relabelling indices, we find

$$\frac{d^2X^\mu}{ds^2} + \Gamma^\mu_{\alpha\beta}\frac{dX^\alpha}{ds}\frac{dX^\beta}{ds} = 0.$$

Substituting (1.2.25) gives the desired result (1.2.26).

Covariant derivative

The derivative term in (1.2.26) can be manipulated by using the chain rule

$$\frac{d}{ds}U^\mu\left(X^\alpha(s)\right) = \frac{dX^\alpha}{ds}\frac{\partial U^\mu}{\partial X^\alpha} = U^\alpha\frac{\partial U^\mu}{\partial X^\alpha},$$

so that we get

$$U^\alpha\left(\frac{\partial U^\mu}{\partial X^\alpha} + \Gamma^\mu_{\alpha\beta}U^\beta\right) = 0.$$

The term in brackets is the covariant derivative of U^μ, i.e. $\nabla_\alpha U^\mu \equiv \partial_\alpha U^\mu + \Gamma^\mu_{\alpha\beta}U^\beta$. This allows us to write the geodesic equation in the following slick way: $U^\alpha\nabla_\alpha U^\mu = 0$. In the GR course you will derive this form of the geodesic equation directly by thinking about parallel transport.

Geodesic equation in 4-momenta

Using the definition of the four-momentum of the particle,

$$P^\mu = mU^\mu,$$

we may also write $U^\alpha\left(\frac{\partial U^\mu}{\partial X^\alpha} + \Gamma^\mu_{\alpha\beta}U^\beta\right) = 0$ as

$$P^\alpha \frac{\partial P^\mu}{\partial X^\alpha} = -\Gamma^\mu_{\alpha\beta} P^\alpha P^\beta.$$

For massless particles, the action (1.2.29) vanishes identically and our derivation of the geodesic equation breaks down. We don't have time to go through the more subtle derivation of the geodesic equation for massless particles. Luckily, we don't have to because the result is exactly the same as (1.2.39). [10] We only need to interpret P^μ as the four-momentum of a massless particle.

Accepting that the geodesic equation (1.2.39) applies to both massive and massless particles, we will move on. I will now show you how to apply the geodesic equation to particles in the FRW universe.

Geodesic Motion in FRW

To evaluate the r.h.s. of $P^\alpha \frac{\partial P^\mu}{\partial X^\alpha} = -\Gamma^\mu_{\alpha\beta} P^\alpha P^\beta$ we need to compute the Christoffel symbols for the FRW metric $\mathrm{d}s^2 = \mathrm{d}t^2 - a^2(t)\gamma_{ij}\,\mathrm{d}x^i\,\mathrm{d}x^j$.

All Christoffel symbols with two time indices vanish, i.e. $\Gamma^\mu_{00} = \Gamma^0_{0\beta} = 0$. The only non-zero components are

$$\Gamma^0_{ij} = a\dot{a}\gamma_{ij}, \quad \Gamma^i_{0j} = \frac{\dot{a}}{a}\delta^i_j, \quad \Gamma^i_{jk} = \frac{1}{2}\gamma^{il}\left(\partial_j\gamma_{kl} + \partial_k\gamma_{jl} - \partial_l\gamma_{jk}\right),$$

or are related to these by symmetry (note that $\Gamma^\mu_{\alpha\beta} = \Gamma^\mu_{\beta\alpha}$).

Derivation of Γ^0_{ij} (????)

-The Christoffel symbol with upper index equal to zero is

$$\Gamma^0_{\alpha\beta} = \frac{1}{2}g^{0\lambda}\left(\partial_\alpha g_{\beta\lambda} + \partial_\beta g_{\alpha\lambda} - \partial_\lambda g_{\alpha\beta}\right).$$

The factor $g^{0\lambda}$ vanishes unless $\lambda = 0$ in which case it is equal to 1. Therefore,

$$\Gamma^0_{\alpha\beta} = \frac{1}{2}\left(\partial_\alpha g_{\beta 0} + \partial_\beta g_{\alpha 0} - \partial_0 g_{\alpha\beta}\right).$$

The first two terms reduce to derivatives of g_{00} (since $g_{i0} = 0$). The FRW metric has constant g_{00}, so these terms vanish and we are left with

$$\Gamma^0_{\alpha\beta} = -\frac{1}{2}\partial_0 g_{\alpha\beta}.$$

The derivative is non-zero only if α and β are spatial indices, $g_{ij} = -a^2\gamma_{ij}$ (don't miss the sign!). In that case, we find

$$\Gamma^0_{ij} = a\dot{a}\gamma_{ij}$$

Analysis of geodesic equation

The homogeneity of the FRW background implies $\partial_i P^\mu = 0$, so that the geodesic equation (1.2.39) reduces to

$$\begin{aligned} P^0\frac{dP^\mu}{dt} &= -\Gamma^\mu_{\alpha\beta}P^\alpha P^\beta \\ &= -\left(2\Gamma^\mu_{0j}P^0 + \Gamma^\mu_{ij}P^i\right)P^j, \end{aligned}$$

[10] One way to think about massless particles is as the zero-mass limit of massive particles. A more rigorous derivation of null geodesics from an action principle can be found in Paul Townsend's Part III Black Holes lectures [arXiv:gr-qc/9707012]. where I have used (1.2.41) in the second line.

- The first thing to notice from (1.2.46) is that massive particles at rest in the comoving frame, $P^j = 0$, will stay at rest because the r.h.s. then vanishes,

$$P^j = 0 \quad \Rightarrow \quad \frac{dP^i}{dt} = 0.$$

- Next, we consider the $\mu = 0$ component of (1.2.46), but don't require the particles to be at rest. The first term on the r.h.s. vanishes because $\Gamma^0_{0j} = 0$. Using (1.2.41), we then find

$$E\frac{dE}{dt} = -\Gamma^0_{ij}P^iP^j = -\frac{\dot{a}}{a}p^2,$$

where we have written $P^0 \equiv E$ and defined the amplitude of the physical three-momentum as

$$p^2 \equiv -g_{ij}P^iP^j = a^2\gamma_{ij}P^iP^j.$$

Momenta of massive and massless particles (?)

Notice the appearance of the scale factor in (1.2.49) from the contraction with the spatial part of the FRW metric, $g_{ij} = -a^2\gamma_{ij}$. The components of the four-momentum satisfy the constraint $g_{\mu\nu}P^\mu P^\nu = m^2$, or $E^2 - p^2 = m^2$, where the r.h.s. vanishes for massless particles. It follows that $E\,\mathrm{d}E = p\,\mathrm{d}p$, so that (1.2.48) can be written as

$$\frac{\dot{p}}{p} = -\frac{\dot{a}}{a} \quad \Rightarrow \quad p \propto \frac{1}{a}.$$

We see that the physical three-momentum of any particle (both massive and massless) decays with the expansion of the universe.

For massless particles, eq. (1.2.50) implies

$$p = E \propto \frac{1}{a} \quad \text{(massless particles)}\ ,$$

i.e. the energy of massless particles decays with the expansion.

- For massive particles, eq. (1.2.50) implies

$$p = \frac{mv}{\sqrt{1-v^2}} \propto \frac{1}{a} \quad \text{(massive particles)}\ ,$$

where $v^i = dx^i/dt$ is the comoving peculiar velocity of the particles (i.e. the velocity relative to the comoving frame) and $v^2 \equiv a^2\gamma_{ij}v^iv^j$ is the magnitude of the physical peculiar velocity, cf. eq. (1.1.17). To get the first equality in (1.2.52), I have used

$$P^i = mU^i = m\frac{dX^i}{ds} = m\frac{dt}{ds}v^i = \frac{mv^i}{\sqrt{1-a^2\gamma_{ij}v^iv^j}} = \frac{mv^i}{\sqrt{1-v^2}}.$$

Eq. (1.2.52) shows that freely-falling particles left on their own will converge onto the Hubble flow.

5.1.2 Distances

For distant objects, we have to be more careful about what we mean by "distance":

Metric distance.

We first define a distance that isn't really observable, but that will be useful in defining observable distances. Consider the FRW metric in the form (1.1.21),

$$\mathrm{d}s^2 = \mathrm{d}t^2 - a^2(t)\left[\mathrm{d}\chi^2 + S_k^2(\chi)\mathrm{d}\Omega^2\right],$$

where [13]

$$S_k(\chi) \equiv \begin{cases} R_0 \sinh\left(\chi/R_0\right) & k=-1 \\ \chi & k=0 \\ R_0 \sin\left(\chi/R_0\right) & k=+1 \end{cases}$$

The distance multiplying the solid angle element $\mathrm{d}\Omega^2$ is the metric distance,

$$d_m = S_k(\chi).$$

[11] A parsec (pc) is 3.26 light-years. Blame astronomers for the funny units in (6.3.29).

[12] Planck 2013 Results - Cosmological Parameters [arXiv:1303.5076].

[13] Notice that the definition of $S_k(\chi)$ contains a length scale R_0 after we chose to make the scale factor dimensionless, $a\left(t_0\right) \equiv 1$. This is achieved by using the rescaling symmetry $a \to \lambda a, \chi \to \chi/\lambda$, and $S_k^2 \to S_k^2/\lambda$. In a flat universe ($k=0$), the metric distance is simply equal to the comoving distance χ. The comoving distance between us and a galaxy at redshift z can be written as

$$\chi(z) = \int_{t_1}^{t_0} \frac{\mathrm{d}t}{a(t)} = \int_0^z \frac{\mathrm{d}z}{H(z)},$$

where the redshift evolution of the Hubble parameter, $H(z)$, depends on the matter content of the universe (see §1.3). We emphasize that the comoving distance and the metric distance are not observables.

Luminosity distance.

Type IA supernovae are called 'standard candles' because they are believed to be objects of known absolute luminosity L (= energy emitted per second). The observed flux F (= energy per second per receiving area) from a supernova explosion can then be used to infer its (luminosity) distance. Consider a source at a fixed comoving distance χ. In a static Euclidean space, the relation between absolute luminosity and observed flux is

$$F = \frac{L}{4\pi\chi^2}.$$

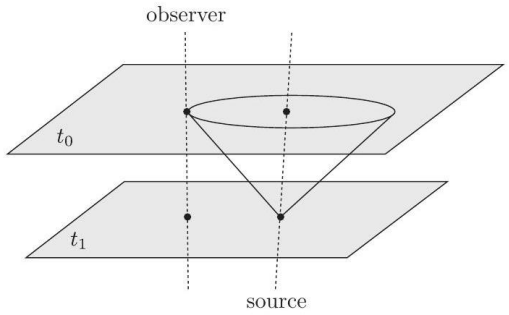

Figure 1.6: Geometry associated with the definition of luminosity distance.
In an FRW spacetime, this result is modified for three reasons:

1. At the time t_0 that the light reaches the Earth, the proper area of a sphere drawn around the supernova and passing through the Earth is $4\pi d_m^2$. The fraction of the light received in a telescope of aperture A is therefore $A/4\pi d_m^2$.

2. The rate of arrival of photons is lower than the rate at which they are emitted by the redshift factor $1/(1+z)$.

3. The energy E_0 of the photons when they are received is less than the energy E_1 with which they were emitted by the same redshift factor $1/(1+z)$.

Hence, the correct formula for the observed flux of a source with luminosity L at coordinate distance χ and redshift z is

$$F = \frac{L}{4\pi d_m^2 (1+z)^2} \equiv \frac{L}{4\pi d_L^2},$$

where we have defined the luminosity distance, d_L, so that the relation between luminosity, flux and luminosity distance is the same as in (1.2.69). Hence, we find

$$d_L = d_m(1+z).$$

Angular diameter distance.

-Sometimes we can make use of 'standard rulers', i.e. objects of known physical size D. (This is the case, for example, for the fluctuations in the CMB.) Let us assume again that the object is at a comoving distance χ and the photons which we observe today were emitted at time t_1. A naive astronomer could decide to measure the distance d_A to the object by measuring its angular size $\delta\theta$ and using the Euclidean formula for its distance, [14]

$$d_A = \frac{D}{\delta\theta}.$$

This quantity is called the angular diameter distance. The FRW metric (1.1.23) implies

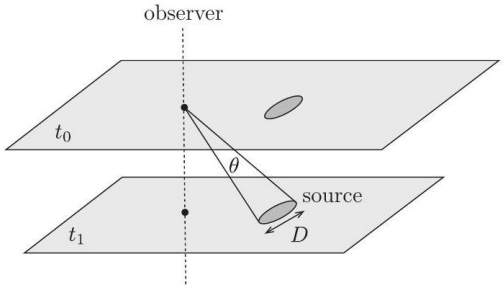

Figure 1.7: Geometry associated with the definition of angular diameter distance.

the following relation between the physical (transverse) size of the object and its angular size on the sky

$$D = a\,(t_1)\,S_k(\chi)\delta\theta = \frac{d_m}{1+z}\delta\theta.$$

Hence, we get

$$d_A = \frac{d_m}{1+z}.$$

The angular diameter distance measures the distance between us and the object when the light was emitted. We see that angular diameter and luminosity distances aren't independent, but related by

$$d_A = \frac{d_L}{(1+z)^2}.$$

Fig. 1.8 shows the redshift dependence of the three distance measures d_m, d_L, and d_A. Notice that all three distances are larger in a universe with dark energy (in the form of a cosmological constant Λ) than in one without. This fact was employed in the discovery of dark energy (see fig. 1.9 in §1.3.3).

5.2 Differential Geometry for Cosmology

(подробно все это - в записи по диффгему)

5.2.1 Killing Vector (??)

(??? discuss it for cosmology)

6 Some Basic Models

6.1 Friedman Universe

6.1.1 Cosmic parameters

The universe is filled with a mixture of different matter components. It is useful to classify the different sources by their contribution to the pressure:

- Matter

We will use the term "matter" to refer to all forms of matter for which the pressure is much smaller than the energy density, $|P| \ll \rho$. As we will show in Chapter 3, this is the case for a gas of non-relativistic particles (where the energy density is dominated by the mass). Setting $P = 0$ in (1.3.98) gives

$$\rho \propto a^{-3}.$$

This dilution of the energy density simply reflects the expansion of the volume $V \propto a^3$.

- Dark matter. Most of the matter in the universe is in the form of invisible dark matter. This is usually thought to be a new heavy particle species, but what it really is, we don't know.

- Baryons. Cosmologists refer to ordinary matter (nuclei and electrons) as baryons. [17]

[17] Of course, this is technically incorrect (electrons are leptons), but nuclei are so much heavier than electrons that most of the mass is in the baryons. If this terminology upsets you, you should ask your astronomer friends what they mean by "metals". 21 1. Geometry and Dynamics

- Radiation

We will use the term "radiation" to denote anything for which the pressure is about a third of the energy density, $P = \frac{1}{3}\rho$. This is the case for a gas of relativistic particles, for which the energy density is dominated by the kinetic energy (i.e. the momentum is much bigger than the mass). In this case, eq. (1.3.98) implies

$$\rho \propto a^{-4}.$$

The dilution now includes the redshifting of the energy, $E \propto a^{-1}$.

- Photons. The early universe was dominated by photons. Being massless, they are always relativistic. Today, we detect those photons in the form of the cosmic microwave background.

- Neutrinos. For most of the history of the universe, neutrinos behaved like radiation. Only recently have their small masses become relevant and they started to behave like matter.

- Gravitons. The early universe may have produced a background of gravitons (i.e. gravitational waves, see §6.5.2). Experimental efforts are underway to detect them.

- Dark energy

We have recently learned that matter and radiation aren't enough to describe the evolution of the universe. Instead, the universe today seems to be dominated by a mysterious negative pressure component, $P = -\rho$. This is unlike anything we have ever encountered in the lab. In particular, from eq. (1.3.98), we find that the energy density is constant,

$$\rho \propto a^{0}.$$

Since the energy density doesn't dilute, energy has to be created as the universe expands. [18]

- Vacuum energy. In quantum field theory, this effect is actually predicted! The ground state energy of the vacuum corresponds to the following stress-energy tensor

$$T^{\rm vac}_{\mu\nu} = \rho_{\rm vac} g_{\mu\nu}.$$

Comparison with eq. (1.3.93), show that this indeed implies $P_{\rm vac} = -\rho_{\rm vac}$. Unfortunately, the predicted size of $\rho_{\rm vac}$ is completely off,

$$\frac{\rho_{\rm vac}}{\rho_{\rm obs}} \sim 10^{120}.$$

- Something else? The failure of quantum field theory to explain the size of the observed dark energy has lead theorists to consider more exotic possibilities (such as time-varying dark energy and modifications of general relativity). In my opinion, none of these ideas works very well.

[18] In a gravitational system this doesn't have to violate the conservation of energy. It is the conservation equation (1.3.98) that counts. Cosmological constant. - The left-hand side of the Einstein equation (1.3.76) isn't uniquely defined. We can add the term $-\Lambda g_{\mu\nu}$, for some constant Λ, without changing the conservation of the stress tensor, $\nabla^\mu T_{\mu\nu} = 0$ (recall, or check, that $\nabla^\mu g_{\mu\nu} = 0$). In other words, we could have written the Einstein equation as

$$G_{\mu\nu} - \Lambda g_{\mu\nu} = 8\pi G T_{\mu\nu}.$$

Einstein, in fact, did add such a term and called it the cosmological constant. However, it has become modern practice to move this term to the r.h.s. and treat it as a contribution to the stress-energy tensor of the form

$$T^{(\Lambda)}_{\mu\nu} = \frac{\Lambda}{8\pi G} g_{\mu\nu} \equiv \rho_\Lambda g_{\mu\nu}.$$

This is of the same form as the stress-energy tensor from vacuum energy, eq. (1.3.102).

Summary

Most cosmological fluids can be parameterised in terms of a constant equation of state: $w = P/\rho$. This includes cold dark matter ($w = 0$), radiation ($w = 1/3$) and vacuum energy ($w = -1$). In that case, the solutions to (1.3.98) scale as

$$\rho \propto a^{-3(1+w)},$$

and hence

$$\rho \propto \begin{cases} a^{-3} & \text{matter} \\ a^{-4} & \text{radiation} \\ a^{0} & \text{vacuum} \end{cases}.$$

6.1.2 Spacetime Curvature

We want to relate these matter sources to the evolution of the scale factor in the FRW metric (1.1.14). To do this we have to compute the Einstein tensor on the l.h.s. of the Einstein equation (1.3.76),

$$G_{\mu\nu} = R_{\mu\nu} - \frac{1}{2} R g_{\mu\nu}.$$

We will need the Ricci tensor

$$R_{\mu\nu} \equiv \partial_\lambda \Gamma^\lambda_{\mu\nu} - \partial_\nu \Gamma^\lambda_{\mu\lambda} + \Gamma^\lambda_{\lambda\rho}\Gamma^\rho_{\mu\nu} - \Gamma^\rho_{\mu\lambda}\Gamma^\lambda_{\nu\rho}$$

and the Ricci scalar

$$R = R^\mu{}_\mu = g^{\mu\nu} R_{\mu\nu}.$$

Again, there is a lot of beautiful geometry behind these definitions. We will simply keep pluggingand-playing: given the Christoffel symbols (1.2.41) nothing stops us from computing (1.3.109).

We don't need to calculate $R_{i0} = R_{0i}$, because it is a 3-vector, and therefore must vanish due to the isotropy of the Robertson-Walker metric. (Try it, if you don't believe it!) The non-vanishing components of the Ricci tensor are

$$R_{00} = -3\frac{\ddot{a}}{a},$$
$$R_{ij} = -\left[\frac{\ddot{a}}{a} + 2\left(\frac{\dot{a}}{a}\right)^2 + 2\frac{k}{a^2}\right] g_{ij}.$$

Notice that we had to find $R_{ij} \propto g_{ij}$ to be consistent with homogeneity and isotropy.

Derivation of R_{00}.

Setting $\mu = \nu = 0$ in (1.3.109), we have

$$R_{00} = \partial_\lambda \Gamma^\lambda_{00} - \partial_0 \Gamma^\lambda_{0\lambda} + \Gamma^\lambda_{\lambda\rho}\Gamma^\rho_{00} - \Gamma^\rho_{0\lambda}\Gamma^\lambda_{0\rho},$$

Since Christoffels with two time-components vanish, this reduces to

$$R_{00} = -\partial_0 \Gamma^i_{0i} - \Gamma^i_{0j}\Gamma^j_{0i}.$$

where in the second line we have used that Christoffels with two time-components vanish. Using $\Gamma^i_{0j} = (\dot{a}/a)\delta^i_j$, we find

$$R_{00} = -\frac{d}{dt}\left(3\frac{\dot{a}}{a}\right) - 3\left(\frac{\dot{a}}{a}\right)^2 = -3\frac{\ddot{a}}{a}.$$

Derivation of R_{ij}

Evaluating (1.3.112) is a bit tedious. A useful trick is to compute $R_{ij}(\boldsymbol{x} = 0) \propto \delta_{ij} \propto g_{ij}(\boldsymbol{x} = 0)$ using (1.1.9) and then transform the resulting relation between 3-tensors to general $\boldsymbol{x}$.

We first read off the spatial metric from (1.1.9),

$$\gamma_{ij} = \delta_{ij} + \frac{k x_i x_j}{1 - k\,(x_k x^k)}.$$

The key point is to think ahead and anticipate that we will set $\boldsymbol{x} = 0$ at the end. This allows us to drop many terms. You may be tempted to use $\gamma_{ij}(\boldsymbol{x} = 0) = \delta_{ij}$ straight away. However, the Christoffel symbols contain a derivative of the metric and the Riemann tensor has another derivative, so there will be terms in the final answer with two derivatives acting on the metric. These terms get a contribution from the second term in (1.3.116). However, we can ignore the denominator in the second term of γ_{ij} and use

$$\gamma_{ij} = \delta_{ij} + k x_i x_j.$$

The difference in the final answer vanishes at $\boldsymbol{x} = 0$ [do you see why?]. The derivative of (1.3.117) is

$$\partial_l \gamma_{ij} = k\left(\delta_{li} x_j + \delta_{lj} x_i\right).$$

With this, we can evaluate

$$\Gamma^i_{jk} = \frac{1}{2}\gamma^{il}\left(\partial_j \gamma_{kl} + \partial_k \gamma_{jl} - \partial_l \gamma_{jk}\right).$$

The inverse metric is $\gamma^{ij} = \delta^{ij} - k x^i x^j$, but the second term won't contribute when we set $\boldsymbol{x} = 0$ in the end [do you see why?], so we are free to use $\gamma^{ij} = \delta^{ij}$. Using (1.3.118) in (1.3.119), we then get

$$\Gamma^i_{jk} = kx^i\delta_{jk}.$$

This vanishes at $\boldsymbol{x} = 0$, but its derivative does not

$$\Gamma^i_{jk}(\boldsymbol{x}=0) = 0 \quad , \quad \partial_l\Gamma^i_{jk}(\boldsymbol{x}=0) = k\delta^i_l\delta_{jk}.$$

We are finally ready to evaluate the Ricci tensor R_{ij} at $\boldsymbol{x} = 0$

$$R_{ij}(\boldsymbol{x}=0) \equiv \underbrace{\partial_\lambda\Gamma^\lambda_{ij} - \partial_j\Gamma^\lambda_{i\lambda}}_{(A)} + \underbrace{\Gamma^\lambda_{\lambda\rho}\Gamma^\rho_{ij} - \Gamma^\rho_{i\lambda}\Gamma^\lambda_{j\rho}}_{(B)}.$$

Let us first look at the two terms labelled (B). Dropping terms that are zero at $\boldsymbol{x} = 0$, I find

$$\begin{aligned}(B) &= \Gamma^l_{l0}\Gamma^0_{ij} - \Gamma^0_{il}\Gamma^l_{j0} - \Gamma^l_{i0}\Gamma^0_{jl} \\ &= 3\frac{\dot{a}}{a}a\dot{a}\delta_{ij} - a\dot{a}\delta_{ij}\frac{\dot{a}}{a}\delta^l_j - \frac{\dot{a}}{a}\delta^l_j a\dot{a}\delta_{jl} \\ &= \dot{a}^2\delta_{ij}.\end{aligned}$$

The two terms labelled (A) in (1.3.122) can be evaluated by using (1.3.121),

$$\begin{aligned}(A) &= \partial_0\Gamma^0_{ij} + \partial_l\Gamma^l_{ij} - \partial_j\Gamma^l_{il} \\ &= \partial_0(a\dot{a})\delta_{ij} + k\delta^l_l\delta_{ij} - k\delta^l_j\delta_{il} \\ &= \left(a\ddot{a} + \dot{a}^2 + 2k\right)\delta_{ij}.\end{aligned}$$

Hence, I get

$$\begin{aligned}R_{ij}(\boldsymbol{x}=0) &= (A) + (B) \\ &= \left[a\ddot{a} + 2\dot{a}^2 + 2k\right]\delta_{ij} \\ &= -\left[\frac{\ddot{a}}{a} + 2\left(\frac{\dot{a}}{a}\right)^2 + 2\frac{k}{a^2}\right]g_{ij}(\boldsymbol{x}=0).\end{aligned}$$

As a relation between tensors this holds for general $\boldsymbol{x}$, so we get the promised result (1.3.112). To be absolutely clear, I will never ask you to reproduce a nasty computation like this.

The Ricci scalar is

$$R = -6\left[\frac{\ddot{a}}{a} + \left(\frac{\dot{a}}{a}\right)^2 + \frac{k}{a^2}\right]$$

Exercise.-Verify eq. (1.3.126).

The non-zero components of the Einstein tensor $G^\mu{}_\nu \equiv g^{\mu\lambda}G_{\lambda\nu}$ are

$$\begin{aligned}G^0_0 &= 3\left[\left(\frac{\dot{a}}{a}\right)^2 + \frac{k}{a^2}\right], \\ G^i_j &= \left[2\frac{\ddot{a}}{a} + \left(\frac{\dot{a}}{a}\right)^2 + \frac{k}{a^2}\right]\delta^i_j.\end{aligned}$$

Exercise.-Verify eqs. (1.3.127) and (1.3.128).

6.1.3 Friedmann Equations

Equations

We combine eqs. (1.3.127) and (1.3.128) with stress-tensor (1.3.92), to get the Friedmann equations,

$$\left(\frac{\dot{a}}{a}\right)^2 = \frac{8\pi G}{3}\rho - \frac{k}{a^2},$$
$$\frac{\ddot{a}}{a} = -\frac{4\pi G}{3}(\rho + 3P).$$

Here, ρ and P should be understood as the sum of all contributions to the energy density and pressure in the universe. We write ρ_r for the contribution from radiation (with ρ_γ for photons and ρ_ν for neutrinos), ρ_m for the contribution by matter (with ρ_c for cold dark matter and ρ_b for baryons) and ρ_Λ for the vacuum energy contribution. The first Friedmann equation is often written in terms of the Hubble parameter, $H \equiv \dot{a}/a$,

$$H^2 = \frac{8\pi G}{3}\rho - \frac{k}{a^2}.$$

Let us use subscripts ' 0 ' to denote quantities evaluated today, at $t = t_0$. A flat universe ($k = 0$) corresponds to the following critical density today

$$\rho_{\text{crit },0} = \frac{3H_0^2}{8\pi G} = 1.9 \times 10^{-29} h^2 \text{ grams cm}^{-3}$$
$$= 2.8 \times 10^{11} h^2 M_\odot \text{Mpc}^{-3}$$
$$= 1.1 \times 10^{-5} h^2 \text{ protons cm}^{-3}.$$

We use the critical density to define dimensionless density parameters

$$\Omega_{I,0} \equiv \frac{\rho_{I,0}}{\rho_{\text{crit },0}}.$$

The Friedmann equation (1.3.131) can then be written as

$$H^2(a) = H_0^2 \left[\Omega_{r,0}\left(\frac{a_0}{a}\right)^4 + \Omega_{m,0}\left(\frac{a_0}{a}\right)^3 + \Omega_{k,0}\left(\frac{a_0}{a}\right)^2 + \Omega_{\Lambda,0}\right],$$

where we have defined a "curvature" density parameter, $\Omega_{k,0} \equiv -k/\left(a_0 H_0\right)^2$. It should be noted that in the literature, the subscript ' 0 ' is normally dropped, so that e.g. Ω_m usually denotes the matter density today in terms of the critical density today. From now on we will follow this convention and drop the ' 0 ' subscripts on the density parameters. We will also use the conventional normalization for the scale factor, $a_0 \equiv 1$. Eq. (1.3.134) then becomes

$$\frac{H^2}{H_0^2} = \Omega_r a^{-4} + \Omega_m a^{-3} + \Omega_k a^{-2} + \Omega_\Lambda.$$

Λ CDM

Observations (see figs. 1.9 and 1.10) show that the universe is filled with radiation (' r '), matter ($'m$ ') and dark energy (' Λ '):

$$|\Omega_k| \leq 0.01, \quad \Omega_r = 9.4 \times 10^{-5}, \quad \Omega_m = 0.32, \quad \Omega_\Lambda = 0.68.$$

The equation of state of dark energy seems to be that of a cosmological constant, $w_\Lambda \approx -1$. The matter splits into 5% ordinary matter (baryons, ' b ') and 27% (cold) dark matter (CDM, ' c '):

$$\Omega_b = 0.05, \quad \Omega_c = 0.27.$$

We see that even today curvature makes up less than 1% of the cosmic energy budget. At earlier times, the effects of curvature are then completely negligible (recall that matter and radiation scale as a^{-3} and a^{-4}, respectively, while the curvature contribution only increases as a^{-2}). For the rest of these lectures, I will therefore set $\Omega_k \equiv 0$. In Chapter 2, we will show that inflation indeed predicts that the effects of curvature should be minuscule in the early universe (see also Problem Set 2).

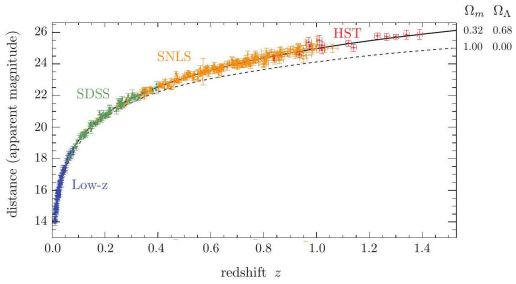

Figure 1.9: Type IA supernovae and the discovery dark energy. If we assume a flat universe, then the supernovae clearly appear fainter (or more distant) than predicted in a matter-only universe ($\Omega_m = 1.0$). (SDSS = Sloan Digital Sky Survey; SNLS = SuperNova Legacy Survey; HST = Hubble Space Telescope.)

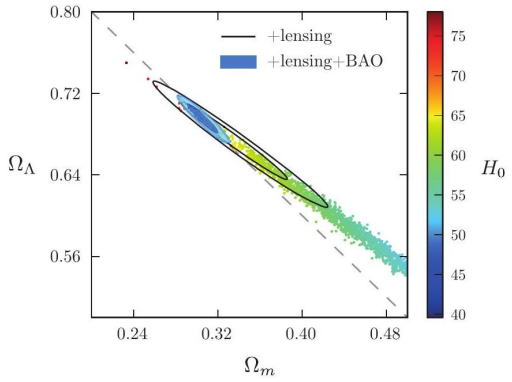

Figure 1.10: A combination CMB and LSS observations indicate that the spatial geometry of the universe is flat. The energy density of the universe is dominated by a cosmological constant. Notice that the CMB data alone cannot exclude a matter-only universe with large spatial curvature. The evidence for dark energy requires additional input.

Dynamics

The dynamics of the universe is determined by the Einstein equation

$$G_{\mu\nu} = 8\pi G T_{\mu\nu}.$$

This relates the Einstein tensor $G_{\mu\nu}$ (a measure of the "spacetime curvature" of the FRW universe) to the stress-energy tensor $T_{\mu\nu}$ (a measure of the "matter content" of the universe). We

[14] This formula assumes $\delta\theta \ll 1$ (in radians) which is true for all cosmological objects. 17 1. Geometry and Dynamics

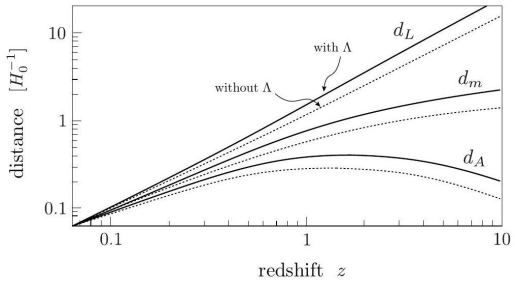

Figure 1.8: Distance measures in a flat universe, with matter only (dotted lines) and with 70% dark energy (solid lines). In a dark energy dominated universe, distances out to a fixed redshift are larger than in a matter-dominated universe.

will first discuss possible forms of cosmological stress-energy tensors $T_{\mu\nu}$(§1.3.1), then compute the Einstein tensor $G_{\mu\nu}$ for the FRW background (§1.3.2), and finally put them together to solve for the evolution of the scale factor $a(t)$ as a function of the matter content (§1.3.3).

Matter Sources

We first show that the requirements of isotropy and homogeneity force the coarse-grained stressenergy tensor to be that of a perfect fluid,

$$T_{\mu\nu} = (\rho + P)U_\mu U_\nu - P g_{\mu\nu},$$

where ρ and P are the energy density and the pressure of the fluid and U^μ is its four-velocity (relative to the observer).

Number Density

In fact, before we get to the stress-energy tensor, we study a simpler object: the number current four-vector N^μ. The $\mu = 0$ component, N^0, measures the number density of particles, where for us a "particle" may be an entire galaxy. The $\mu = i$ component, N^i, is the flux of the particles in the direction x^i. Isotropy requires that the mean value of any 3-vector, such as N^i, must vanish, and homogeneity requires that the mean value of any 3 -scalar [15], such as N^0, is a function only of time. Hence, the current of galaxies, as measured by a comoving observer, has the following components

$$N^0 = n(t), \quad N^i = 0,$$

where $n(t)$ is the number of galaxies per proper volume as measured by a comoving observer. A general observer (i.e. an observer in motion relative to the mean rest frame of the particles), would measure the following number current four-vector

$$N^\mu = nU^\mu$$

where $U^\mu \equiv dX^\mu/ds$ is the relative four-velocity between the particles and the observer. Of course, we recover the previous result (1.3.78) for a comoving observer, $U^\mu = (1, 0, 0, 0)$. For

[15] A 3-scalar is a quantity that is invariant under purely spatial coordinate transformations. $U^\mu = \gamma\,(1, v^i)$, eq. (1.3.79) gives the correctly boosted results. For instance, you may recall that the boosted number density is γn. (The number density increases because one of the dimensions of the volume is Lorentz contracted.)

The number of particles has to be conserved. In Minkowski space, this implies that the evolution of the number density satisfies the continuity equation

$$\dot{N}^0 = -\partial_i N^i,$$

or, in relativistic notation,

$$\partial_\mu N^\mu = 0.$$

Eq. (1.3.81) is generalised to curved spacetimes by replacing the partial derivative ∂_μ with a covariant derivative ∇_μ, [16]

$$\nabla_\mu N^\mu = 0.$$

Eq. (1.3.82) reduces to (1.3.81) in the local intertial frame.

Covariant derivative. - The covariant derivative is an important object in differential geometry and it is of fundamental importance in general relativity. The geometrical meaning of ∇_μ will be discussed in detail in the GR course. In this course, we will have to be satisfied with treating it as an operator that acts in a specific way on scalars, vectors and tensors:

- There is no difference between the covariant derivative and the partial derivative if it acts on a scalar

$$\nabla_\mu f = \partial_\mu f.$$

- Acting on a contravariant vector, V^ν, the covariant derivative is a partial derivative plus a correction that is linear in the vector:

$$\nabla_\mu V^\nu = \partial_\mu V^\nu + \Gamma^\nu_{\mu\lambda} V^\lambda.$$

Look carefully at the index structure of the second term. A similar definition applies to the covariant derivative of covariant vectors, ω_ν,

$$\nabla_\mu \omega_\nu = \partial_\mu \omega_\nu - \Gamma^\lambda_{\mu\nu} \omega_\lambda.$$

Notice the change of the sign of the second term and the placement of the dummy index.

- For tensors with many indices, you just repeat (1.3.84) and (1.3.85) for each index. For each upper index you introduce a term with a single $+\Gamma$, and for each lower index a term with a single $-\Gamma$:

$$\begin{aligned} &+ \Gamma^{\mu_1}{}_{\sigma\lambda} T^{\lambda\mu_2\cdots\mu_k}{}_{\nu_1\nu_2\cdots\nu_l} + \Gamma^{\mu_2}{}_{\sigma\lambda} T^{\mu_1\lambda\cdots\mu_k}{}_{\nu}\nu_2\cdots\nu_l + \cdots \\ &- \Gamma^{\lambda}{}_{\sigma\nu_1} T^{\mu_1\mu_2\cdots\mu_k}{}_{\lambda\nu_2\cdots\nu_l} - \Gamma^{\lambda}{}_{\sigma\nu_2} T^{\mu_1\mu_2\cdots\mu_k}{}_{\nu_1\lambda\cdots\nu_l} - \cdots . \end{aligned}$$

This is the general expression for the covariant derivative. Luckily, we will only be dealing with relatively simple tensors, so this monsterous expression will usually reduce to something managable.

[16] If this is the first time you have seen a covariant derivative, this will be a bit intimidating. Find me to talk about your fears.

$$\nabla_\sigma T^{\mu_1\mu_2\cdots\mu_k}{}_{\nu_1\nu_2\cdots\nu_l} = \partial_\sigma T^{\mu_1\mu_2\cdots\mu_k}{}_{\nu_1\nu_2\cdots\nu_l}$$

19 1. Geometry and Dynamics
Explicitly, eq. (1.3.82) can be written

$$\nabla_\mu N^\mu = \partial_\mu N^\mu + \Gamma^\mu_{\mu\lambda} N^\lambda = 0.$$

Using (1.3.78), this becomes

$$\frac{dn}{dt} + \Gamma^i_{i0} n = 0$$

and substituting (1.2.41), we find

$$\frac{\dot{n}}{n} = -3\frac{\dot{a}}{a} \quad \Rightarrow \quad n(t) \propto a^{-3}.$$

As expected, the number density decreases in proportion to the increase of the proper volume.

Energy-Momentum Tensor

We will now use a similar logic to determine what form of the stress-energy tensor $T_{\mu\nu}$ is consistent with the requirements of homogeneity and isotropy. First, we decompose $T_{\mu\nu}$ into a 3 -scalar, T_{00}, 3-vectors, T_{i0} and T_{0j}, and a 3 -tensor, T_{ij}. As before, isotropy requires the mean values of 3 -vectors to vanish, i.e. $T_{i0} = T_{0j} = 0$. Moreover, isotropy around a point $\boldsymbol{x} = 0$ requires the mean value of any 3 -tensor, such as T_{ij}, at that point to be proportional to δ_{ij} and hence to g_{ij}, which equals $-a^2\delta_{ij}$ at $\boldsymbol{x} = 0$,

$$T_{ij}(\boldsymbol{x} = 0) \propto \delta_{ij} \propto g_{ij}(\boldsymbol{x} = 0).$$

Homogeneity requires the proportionality coefficient to be only a function of time. Since this is a proportionality between two 3-tensors, T_{ij} and g_{ij}, it must remain unaffected by an arbitrary transformation of the spatial coordinates, including those transformations that preserve the form of g_{ij} while taking the origin into any other point. Hence, homogeneity and isotropy require the components of the stress-energy tensor everywhere to take the form

$$T_{00} = \rho(t), \quad \pi_i \equiv T_{i0} = 0, \quad T_{ij} = -P(t) g_{ij}(t, \boldsymbol{x}).$$

It looks even nicer with mixed upper and lower indices

$$T^\mu_\nu = g^{\mu\lambda} T_{\lambda\nu} = \begin{pmatrix} ccccc\rho 0 & & 00 \\ & 0 - P & 00 \\ & 00 & -P0 \\ & 00 & 0 - P \end{pmatrix}.$$

This is the stress-energy tensor of a perfect fluid as seen by a comoving observer. More generally, the stress-energy tensor can be written in the following, explicitly covariant, form

$$T^\mu_\nu = (\rho + P) U^\mu U_\nu - P\delta^\mu_\nu,$$

where $U^\mu \equiv dX^\mu/ds$ is the relative four-velocity between the fluid and the observer, while ρ and P are the energy density and pressure in the rest-frame of the fluid. Of course, we recover the previous result (1.3.92) for a comoving observer, $U^\mu = (1, 0, 0, 0)$.

How do the density and pressure evolve with time? In Minkowski space, energy and momentum are conserved. The energy density therefore satisfies the continuity equation $\dot{\rho} = -\partial_i \pi^i$, i.e. the rate of change of the density equals the divergence of the energy flux. Similarly, the

evolution of the momentum density satisfies the Euler equation, $\dot{\pi}_i = \partial_i P$. These conservation laws can be combined into a four-component conservation equation for the stress-energy tensor

$$\partial_\mu T^\mu_\nu = 0.$$

In general relativity, this is promoted to the covariant conservation equation

$$\nabla_\mu T^\mu_\nu = \partial_\mu T^\mu_\nu + \Gamma^\mu_{\mu\lambda} T^\lambda_\nu - \Gamma^\lambda_{\mu\nu} T^\mu_\lambda = 0.$$

Eq. (1.3.95) reduces to (1.3.94) in the local intertial frame. This corresponds to four separate equations (one for each ν). The evolution of the energy density is determined by the $\nu = 0$ equation

$$\partial_\mu T^\mu_0 + \Gamma^\mu_{\mu\lambda} T^\lambda_0 - \Gamma^\lambda_{\mu 0} T^\mu_\lambda = 0.$$

Since T^i_0 vanishes by isotropy, this reduces to

$$\frac{d\rho}{dt} + \Gamma^\mu_{\mu 0}\rho - \Gamma^\lambda_{\mu 0} T^\mu_\lambda = 0.$$

From eq. (1.2.41) we see that $\Gamma^\lambda_{\mu 0}$ vanishes unless λ and μ are spatial indices equal to each other, in which case it is $\dot{a}/a$. The continuity equation (1.3.97) therefore reads

$$\dot{\rho} + 3\frac{\dot{a}}{a}(\rho + P) = 0.$$

Exercise.-Show that (1.3.98) can be written as, $\mathrm{d}U = -P\ \mathrm{d}V$, where $U = \rho V$ and $V \propto a^3$.

6.1.4 Single-Component Universe

The different scalings of radiation (a^{-4}), matter (a^{-3}) and vacuum energy (a^0) imply that for most of its history the universe was dominated by a single component (first radiation, then matter, then vacuum energy; see fig. 1.11). Parameterising this component by its equation of state w_I captures all cases of interest. For a flat, single-component universe, the Friedmann equation (1.3.135) reduces to

$$\frac{\dot{a}}{a} = H_0 \sqrt{\Omega_I} a^{-\frac{3}{2}(1+w_I)}.$$

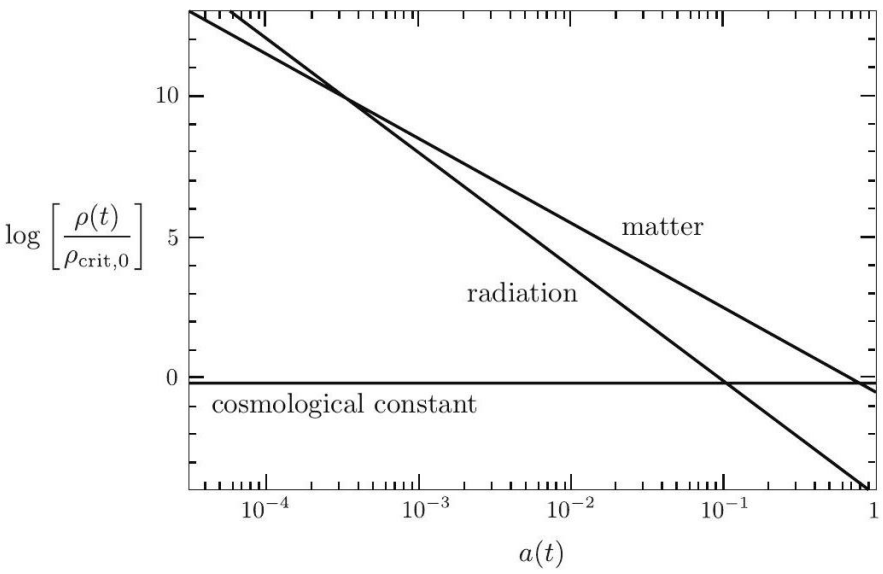

Figure 1.11: Evolution of the energy densities in the universe.

Integrating this equation, we obtain the time dependence of the scale factor

$$a(t) \propto \begin{cases} ccccc t^{2/3(1+w_I)} w_I \neq -1 & t^{2/3}\text{MD} \\ & t^{1/2}\text{RD} \\ e^{Ht} w_I = -1 & \Lambda\text{D} \end{cases}$$

or, in conformal time,

$$a(\tau) \propto \begin{cases} cccc \tau^{2/(1+3w_I)} w_I \neq -1 & \tau^2\text{MD} \\ & \tau\text{RD} \\ (-\tau)^{-1} w_I = -1 & \Lambda\text{D} \end{cases}$$

Exercise.-Derive eq. (1.3.138) from eq. (1.3.137).

Table 1.1 summarises the solutions for a flat universe during radiation domination (RD), matter domination (MD) and dark energy domination (ΛD).

	w	$\rho(a)$	$a(t)$	$a(\tau)$
RD	$\frac{1}{3}$	a^{-4}	$t^{1/2}$	τ
MD	0	a^{-3}	$t^{2/3}$	τ^2
ΛD	-1	a^0	e^{Ht}	$-\tau^{-1}$

Table 1.1: FRW solutions for a flat single-component universe.

6.1.5 Two-Component Universe

Matter and radiation were equally important at $a_{\rm eq} \equiv \Omega_r/\Omega_m \approx 3 \times 10^{-4}$, which was shortly before the cosmic microwave background was released (in §3.3.3, we will show that this happened at $a_{\rm rec} \approx 9 \times 10^{-4}$). It will be useful to have an exact solution describing the transition era. Let us therefore consider a flat universe filled with a mixture of matter and radiation. To solve for the evolution of the scale factor, it proves convenient to move to conformal time. The Friedmann equations (1.3.129) and (1.3.130) then are

$$\begin{aligned} (a')^2 &= \frac{8\pi G}{3}\rho a^4, \\ a'' &= \frac{4\pi G}{3}(\rho - 3P)a^3, \end{aligned}$$

where primes denote derivatives with respect to conformal time and

$$\rho \equiv \rho_m + \rho_r = \frac{\rho_{\rm eq}}{2}\left[\left(\frac{a_{\rm eq}}{a}\right)^3 + \left(\frac{a_{\rm eq}}{a}\right)^4\right].$$

Exercise.-Derive eqs. (1.3.139) and (1.3.140). You will first need to convince yourself that $\dot{a} = a'/a$ and $\ddot{a} = a''/a^2 - (a')^2/a^3$.

Notice that radiation doesn't contribute as a source term in eq. (1.3.140), $\rho_r - 3P_r = 0$. Moreover, since $\rho_m a^3 = \text{const.} = \frac{1}{2}\rho_{\rm eq} a_{\rm eq}^3$, we can write eq. (1.3.140) as

$$a'' = \frac{2\pi G}{3}\rho_{\rm eq} a_{\rm eq}^3.$$

This equation has the following solution

$$a(\tau) = \frac{\pi G}{3}\rho_{\rm eq} a_{\rm eq}^3 \tau^2 + C\tau + D.$$

Imposing $a(\tau = 0) \equiv 0$, fixes one integration constant, $D = 0$. We find the second integration constant by substituting (1.3.143) and (1.3.141) into (1.3.139),

$$C = \left(\frac{4\pi G}{3}\rho_{\rm eq}a_{\rm eq}^4\right)^{1/2}.$$

Eq. (1.3.143) can then be written as

$$a(\tau) = a_{\rm eq}\left[\left(\frac{\tau}{\tau_\star}\right)^2 + 2\left(\frac{\tau}{\tau_\star}\right)\right],$$

where

$$\tau_\star \equiv \left(\frac{\pi G}{3}\rho_{\rm eq}a_{\rm eq}^2\right)^{-1/2} = \frac{\tau_{\rm eq}}{\sqrt{2}-1}.$$

For $\tau \ll \tau_{\rm eq}$, we recover the radiation-dominated limit, $a \propto \tau$, while for $\tau \gg \tau_{\rm eq}$, we agree with the matter-dominated limit, $a \propto \tau^2$.

6.1.6 Expanding Confusion: common misconceptions of cosmological horizons and the superluminal expansion of the universe by Lineweaver

Abstract

We use standard general relativity to illustrate and clarify several common misconceptions about the expansion of the universe. To show the abundance of these misconceptions we cite numerous misleading, or easily misinterpreted, statements in the literature. In the context of the new standard ΛCDM cosmology we point out confusions regarding the particle horizon, the event horizon, the "observable universe" and the Hubble sphere (distance at which recession velocity = c). We show that we can observe galaxies that have, and always have had, recession velocities greater than the speed of light. We explain why this does not violate special relativity and we link these concepts to observational tests. Attempts to restrict recession velocities to less than the speed of light require a special relativistic interpretation of cosmological redshifts. We analyze apparent magnitudes of supernovae and observationally rule out the special relativistic Doppler interpretation of cosmological redshifts at a confidence level of 23σ.

Introduction

The general relativistic (GR) interpretation of the redshifts of distant galaxies, as the expansion of the universe, is widely accepted. However this interpretation leads to several concepts that are widely misunderstood. Since the expansion of the universe is the basis of the big bang model, these misunderstandings are fundamental. Popular science books written by astrophysicists, astrophysics textbooks and to some extent professional astronomical literature addressing the expansion of the Universe, contain misleading, or easily misinterpreted, statements concerning recession velocities, horizons and the "observable universe". Probably the most common misconceptions surround the expansion of the Universe at distances beyond which Hubble's law ($v_{\rm rec} = HD$: recession velocity = Hubble's constant × distance) predicts

recession velocities faster than the speed of light [Appendix B: 1–8], despite efforts to clarify the issue (Murdoch 1977, Harrison 1981, Silverman 1986, Stuckey 1992, Ellis & Rothman 1993, Harrison 1993, Kiang 1997, Davis & Lineweaver 2000, Kiang 2001, Gudmundsson and Björnsson 2002). Misconceptions include misleading comments about the observability of objects receding faster than light [App. B: 9–13]. Related, but more subtle confusions can be found surrounding cosmological event horizons [App. B: 14–15]. The concept of the expansion of the universe is so fundamental to our understanding of cosmology and the misconceptions so abundant that it is important to clarify these issues and make the connection with observational tests as explicit as possible. In Section 6.1.6 we review and illustrate the standard general relativistic description of the expanding universe using spacetime diagrams and we provide a mathematical summary in Appendix 6.1.6. On the basis of this description, in Section 6.1.6 we point out and clarify common misconceptions about superluminal recession velocities and horizons. Examples of misconceptions, or easily misinterpreted statements, occurring in the literature are given in Appendix A.2.6. Finally, in Section 6.1.6 we provide explicit observational tests demonstrating that attempts to apply special relativistic concepts to the Universe are in conflict with observations.

Standard general relativistic description of expansion

The results in this paper are based on the standard general relativistic description of an expanding homogeneous, isotropic universe (Appendix 6.1.6). Here we briefly summarize the main features of the GR description, about which misconceptions often arise. On the spacetime diagrams in Fig. 17 we demonstrate these features for the observationally favoured ΛCDM concordance model: $(\Omega_{\rm M}, \Omega_\Lambda) = (0.3, 0.7)$ with $H_0 = 70\, kms^{-1}Mpc^{-1}$ (Bennett et al. 2003, to one significant figure). The three spacetime diagrams in Fig. 17 plot, from top to bottom, time versus proper distance D, time versus comoving distance $R_0\chi$, and conformal time τ versus comoving distance. They show the relationship between comoving objects, our past light cone, the Hubble sphere and cosmological horizons.

Two types of horizon are shown in Fig. 17. The particle horizon is the distance light can have travelled from $t = 0$ to a given time t (Eq. 27), whereas the event horizon is the distance light can travel from a given time t to $t = \infty$ (Eq. 28). Using Hubble's law ($v_{\rm rec} = HD$), the Hubble sphere is defined to be the distance beyond which the recession velocity exceeds the speed of light, $D_{\rm HS} = c/H$. As we will see, the Hubble sphere is not an horizon. Redshift does not go to infinity for objects on our Hubble sphere (in general) and for many cosmological models we can see beyond it.

In the ΛCDM concordance model all objects with redshift greater than $z \sim 1.46$ are receding faster than the speed of light. This does not contradict SR because the motion is not in any observer's inertial frame. No observer ever overtakes a light beam and all observers measure light locally to be travelling at c. Hubble's law is derived directly from the Robertson-Walker metric (Eq. 15), and is valid for all distances in any homogeneous, expanding universe.

The teardrop shape of our past light cone in the top panel of Fig. 17 shows why we can observe objects that are receding superluminally. Light that superluminally receding objects emit propagates towards us with a local peculiar velocity of c, but since the recession velocity at that distance is greater than c, the total velocity of the light is away from us (Eq. 20). However, since the radius of the Hubble sphere increases with time, some photons that were initially in a superluminally receding region later find themselves in a subluminally receding region. They can therefore approach us and eventually reach us. The objects that emitted the photons however, have moved to larger distances and so are still receding superluminally. Thus we can observe objects that are receding faster than the speed of light (see Section 6.1.6 for more detail).

Our past light cone approaches the cosmological event horizon as $t_0 \to \infty$ (Eqs. 22 and 28).

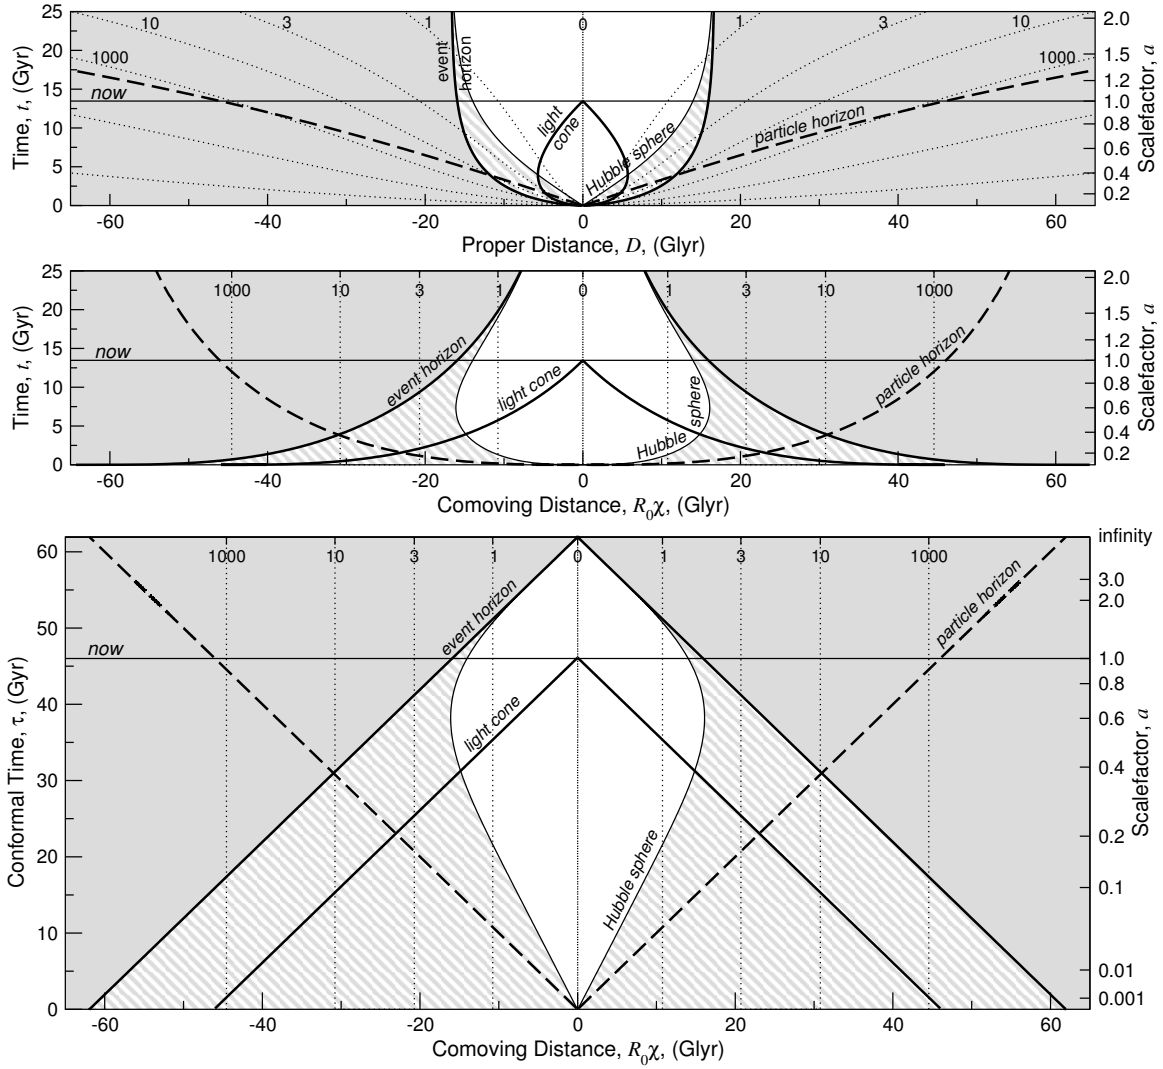

Figure 17: Spacetime diagrams showing the main features of the general relativistic description of the expansion of the universe for the $(\Omega_{\rm M}, \Omega_\Lambda) = (0.3, 0.7)$ model with $H_0 = 70\,km\ s^{-1}Mpc^{-1}$. Dotted lines show the worldlines of comoving objects. We are the central vertical worldline. The current redshifts of the comoving galaxies shown appear labeled on each comoving worldline. The normalized scalefactor, $a = R/R_0$, is drawn as an alternate vertical axis. All events that we currently observe are on our past light cone (with apex at $t =$ now). All comoving objects beyond the Hubble sphere (thin solid line) are receding faster than the speed of light. Top panel (proper distance): The speed of photons relative to us (the slope of the light cone) is not constant, but is rather $v_{\rm rec} - c$. Photons we receive that were emitted by objects beyond the Hubble sphere were initially receding from us (outward sloping lightcone at $t \lesssim 5$ Gyr). Only when they passed from the region of superluminal recession $v_{\rm rec} > c$ (gray crosshatching) to the region of subluminal recession (no shading) can the photons approach us. More detail about early times and the horizons is visible in comoving coordinates (middle panel) and conformal coordinates (lower panel). Our past light cone in comoving coordinates appears to approach the horizontal ($t = 0$) axis asymptotically. However it is clear in the lower panel that the past light cone at $t = 0$ only reaches a finite distance: about 46 Glyr, the current distance to the particle horizon. Currently observable light that has been travelling towards us since the beginning of the universe, was emitted from comoving positions that are now 46 Glyr from us. The distance to the particle horizon as a function of time is represented by the dashed line. Our event horizon is our past light cone at the end of time, $t = \infty$ in this case. It asymptotically approaches $\chi = 0$ as $t \to \infty$. The vertical axis of the lower panel shows conformal time. An infinite proper time is transformed into a finite conformal time so this diagram is complete on the vertical axis. The aspect ratio of $\sim 3/1$ in the top two panels represents the ratio between the radius of the observable universe and the age of the universe, 46 Glyr/13.5 Gyr.

Most observationally viable cosmological models have event horizons and in the ΛCDM model of Fig. 17, galaxies with redshift $z \sim 1.8$ are currently crossing our event horizon. These are the most distant objects from which we will ever be able to receive information about the present day. The particle horizon marks the size of our observable universe. It is the distance to the most distant object we can see at any particular time. The particle horizon can be larger than the event horizon because, although we cannot see *events* that occur beyond our event horizon, we can still see many galaxies that are beyond our current event horizon by light they emitted long ago.

In the GR description of the expansion of the Universe redshifts do not relate to velocities according to any SR expectations. We do not observe objects on the Hubble sphere (that recede at the speed of light) to have an infinite redshift (solve Eq. 24 for z using $\chi = c/\dot{R}$). Instead photons we receive that have infinite redshift were emitted by objects on our particle horizon. In addition, all galaxies become increasingly redshifted as we watch them approach the cosmological *event* horizon ($z \to \infty$ as $t \to \infty$). As the end of the universe approaches, all objects that are not gravitationally bound to us will be redshifted out of detectability.

Since this paper deals frequently with recession velocities and the expansion of the Universe the observational status of these concepts is important and is discussed in Sections 6.1.6 and 6.1.6.

Misconceptions

Misconception #1: Recession velocities cannot exceed the speed of light

A common misconception is that the expansion of the Universe cannot be faster than the speed of light. Since Hubble's law predicts superluminal recession at large distances ($D > c/H$) it is sometimes stated that Hubble's law needs special relativistic corrections when the recession velocity approaches the speed of light [App. B: 6–7]. However, it is well-accepted that general relativity, not special relativity, is necessary to describe cosmological observations. Supernovae surveys calculating cosmological parameters, galaxy-redshift surveys and cosmic microwave background anisotropy tests, all use general relativity to explain their observations. When observables are calculated using special relativity, contradictions with observations quickly arise (Section 6.1.6). Moreover, we know there is no contradiction with special relativity when faster than light motion occurs *outside the observer's inertial frame*. General relativity was specifically derived to be able to predict motion when global inertial frames were not available.

In special relativity, redshifts arise directly from velocities. It was this idea that led Hubble in 1929 to convert the redshifts of the "nebulae" he observed into velocities, and predict the expansion of the universe with the linear velocity-distance law that now bears his name. The general relativistic interpretation of the expansion interprets cosmological redshifts as an indication of velocity since the proper distance between comoving objects increases. However, the velocity is due to the rate of expansion of space, not movement through space, and therefore cannot be calculated with the special relativistic Doppler shift formula. Hubble & Humason's calculation of velocity therefore should not be given special relativistic corrections at high redshift, contrary to their suggestion [App. B: 16].

The general relativistic and special relativistic relations between velocity and cosmological redshift are (e.g. Davis & Lineweaver, 2001):

$$\text{GR} \qquad v_{\rm rec}(t,z) = \frac{c}{R_0}\,\dot{R}(t)\int_0^z \frac{dz'}{H(z')}, \tag{1}$$

$$\text{SR} \qquad v_{\rm pec}(z) = c\,\frac{(1+z)^2-1}{(1+z)^2+1}. \tag{2}$$

These velocities are measured with respect to the comoving observer who observes the receding object to have redshift, z. The GR description is written explicitly as a function of time because when we observe an object with redshift, z, we must specify the epoch at which we wish to calculate its recession velocity. For example, setting $t = t_o$ yields the recession velocity today of the object that emitted the observed photons at $t_{\rm em}$. Setting $t = t_{\rm em}$ yields the recession velocity at the time the photons were emitted (see Eqs. 17 & 24). The changing recession velocity of a comoving object is reflected in the changing slope of its worldline in the top panel of Fig. 17. There is no such time dependence in the SR relation.

Despite the fact that special relativity incorrectly describes cosmological redshifts it has been used for decades to convert cosmological redshifts into velocity because the special relativistic Doppler shift formula (Eq. 2), shares the same low redshift approximation, $v = cz$, as Hubble's Law (Fig. 18). It has only been in the last decade that routine observations have been deep enough that the distinction makes a difference. Figure 18 shows a snapshot at t_0 of the GR velocity-redshift relation for various models as well as the SR velocity-redshift relation and their common low redshift approximation, $v = cz$. Recession velocities exceed the speed of light in all viable cosmological models for objects with redshifts greater than $z \sim 1.5$. At higher redshifts special relativistic "corrections" can be more incorrect than the simple linear approximation (Fig. 21).

Some of the most common misleading applications of relativity arise from the misconception that nothing can recede faster than the speed of light. These include texts asking students to calculate the velocity of a high redshift receding galaxy using the special relativistic Doppler shift equation [App. B: 17–21], as well as the comments that galaxies recede from us at speeds "approaching the speed of light" [App. B: 4–5, 8], or quasars are receding at a certain percentage of the speed of light[1] [App. B: 3, 18–21].

Although velocities of distant galaxies are in principle observable, the set of synchronized comoving observers required to measure proper distance (Weinberg, 1972, p. 415; Rindler, 1977, p. 218) is not practical. Instead, more direct observables such as the redshifts of standard candles can be used to observationally rule out the special relativistic interpretation of cosmological redshifts (Section 6.1.6).

Misconception #2: Inflation causes superluminal expansion of the universe but the normal expansion of the universe does not

Inflation is sometimes described as "superluminal expansion" [App. B: 22–23]. This is misleading because *any* expansion described by Hubble's law has superluminal expansion for sufficiently distant objects. Even during inflation, objects within the Hubble sphere ($D < c/H$) recede at less than the speed of light, while objects beyond the Hubble sphere ($D > c/H$) recede faster than the speed of light. This is identical to the situation during non-inflationary expansion, except the Hubble constant during inflation was much larger than subsequent values. Thus the distance to the Hubble sphere was much smaller. During inflation the proper distance to the Hubble sphere stays constant and is coincident with the event horizon – this is also identical to the asymptotic behaviour of an eternally expanding universe with a cosmological constant $\Omega_\Lambda > 0$ (Fig. 17, top panel).

The oft-mentioned concept of structures "leaving the horizon" during the inflationary period refers to structures once smaller than the Hubble sphere becoming larger than the Hubble sphere. If the exponentially expanding regime, $R = R_0 e^{Ht}$, were extended to the end of time,

[1] Redshifts are usually converted into velocities using $v = cz$, which is a good approximation for $z \lesssim 0.3$ (see Fig. 18) but inappropriate for today's high redshift measurements. When a "correction" is made for high redshifts, the formula used is almost invariably the inappropriate special relativistic Doppler shift equation (Eq. 2).

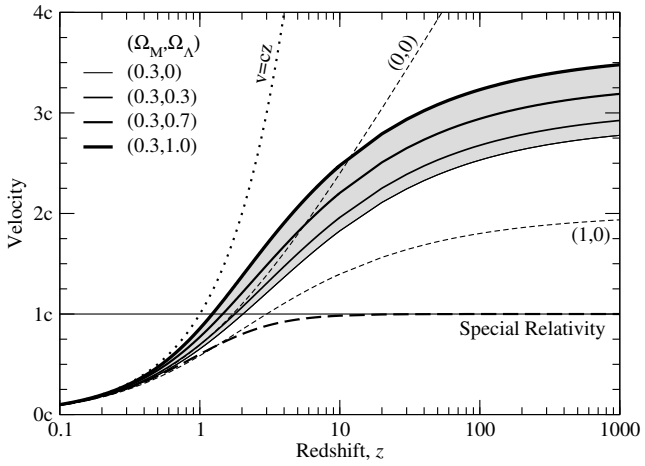

Figure 18: Velocity as a function of redshift under various assumptions. The linear approximation, $v = cz$, is the low redshift approximation of both the GR and SR results. The SR result is calculated using Eq. 2 while the GR result uses Eq. 1 and quotes the recession velocity at the present day, i.e., uses $\dot{R}(t) = \dot{R}_0$. The solid dark lines and gray shading show a range of Fridemann-Robertson-Walker (FRW) models as labeled in the legend. These include the observationally favoured cosmological model $(\Omega_{\rm M}, \Omega_\Lambda) = (0.3, 0.7)$. The recession velocity of all galaxies with $z \gtrsim 1.5$ exceeds the speed of light in all viable cosmological models. Observations now routinely probe regions that are receding faster than the speed of light.

the Hubble sphere would be the event horizon. However, in the context of inflation the Hubble sphere is not a true event horizon because structures that have crossed the horizon can "reenter the horizon" after inflation stops. The horizon they "reenter" is the revised event horizon determined by how far light can travel in a FRW universe without inflation.

It would be more appropriate to describe inflation as superluminal expansion if all distances down to the Planck length, $l_{\rm pl} \sim 10^{-35}m$, were receding faster than the speed of light. Solving $D_{\rm H} = c/H = l_{\rm pl}$ gives $H = 10^{43}s^{-1}$ (inverse Planck time) which is equivalent to $H = 10^{62}kms^{-1}Mpc^{-1}$. If Hubble's constant during inflation exceeded this value it would justify describing inflation as "superluminal expansion".

Misconception #3: Galaxies with recession velocities exceeding the speed of light exist but we cannot see them

Amongst those who acknowledge that recession velocities can exceed the speed of light, the claim is sometimes made that objects with recession velocities faster than the speed of light are not observable [App. B: 9–13]. We have seen that the speed of photons propagating towards us (the slope of our past light cone in the upper panel of Fig. 17) is not constant, but is rather $v_{\rm rec} - c$. Therefore light that is beyond the Hubble sphere has a total velocity away from us. How is it then that we can ever see this light? Although the photons are in the superluminal region and therefore recede from us (in proper distance), the Hubble sphere also recedes. In decelerating universes H decreases as $\dot{a}$ decreases (causing the Hubble sphere to recede). In accelerating universes H also tends to decrease since $\dot{a}$ increases more slowly than a. As long as the Hubble sphere recedes faster than the photons immediately outside it, $\dot{D}_{\rm H} > v_{\rm rec} - c$, the photons end up in a subluminal region and approach us[2]. Thus photons near the Hubble

[2]The behaviour of the Hubble sphere is model dependent. The Hubble sphere recedes as long as the deceleration parameter $q = -\ddot{R}R/\dot{R}^2 > -1$. In some closed eternally accelerating universes (specifically $\Omega_{mM} + \Omega_\Lambda > 1$ and $\Omega_\Lambda > 0$) the deceleration parameter can be less than minus one in which case we see faster-than-exponential

sphere that are receding slowly are overtaken by the more rapidly receding Hubble sphere[3].

Our teardrop shaped past light cone in the top panel of Fig. 17 shows that any photons we now observe that were emitted in the first $\sim$ five billion years were emitted in regions that were receding superluminally, $v_{\rm rec} > c$. Thus their total velocity was away from us. Only when the Hubble sphere expands past these photons do they move into the region of subluminal recession and approach us. The most distant objects that we can see now were outside the Hubble sphere when their comoving coordinates intersected our past light cone. Thus, they were receding superluminally when they emitted the photons we see now. Since their worldlines have always been beyond the Hubble sphere these objects were, are, and always have been, receding from us faster than the speed of light.

Evaluating Eq. 1 for the observationally favoured $(\Omega_{\rm M}, \Omega_\Lambda) = (0.3, 0.7)$ universe shows that all galaxies beyond a redshift of $z = 1.46$ are receding faster than the speed of light (Fig. 18). Hundreds of galaxies with $z > 1.46$ have been observed. The highest spectroscopic redshift observed in the Hubble deep field is $z = 6.68$ (Chen et al., 1999) and the Sloan digital sky survey has identified four galaxies at $z > 6$ (Fan et al., 2003). All of these galaxies have always been receding superluminally. The particle horizon, not the Hubble sphere, marks the size of our observable universe because we cannot have received light from, or sent light to, anything beyond the particle horizon[4]. Our effective particle horizon is the cosmic microwave background (CMB), at redshift $z \sim 1100$, because we cannot see beyond the surface of last scattering. Although the last scattering surface is not at any fixed comoving coordinate, the current recession velocity of the points from which the CMB was emitted is $3.2c$ (Fig. 18). At the time of emission their speed was $58.1c$, assuming $(\Omega_{\rm M}, \Omega_\Lambda) = (0.3, 0.7)$. Thus we routinely observe objects that are receding faster than the speed of light and the Hubble sphere is not a horizon[5].

Ambiguity: The depiction of particle horizons on spacetime diagrams

Here we identify an inconvenient feature of the most common depiction of the particle horizon on spacetime diagrams and provide a useful alternative (Fig. 19). The particle horizon at any particular time is a sphere around us whose radius equals the distance to the most distant object we can see. The particle horizon has traditionally been depicted as the *worldline* or comoving coordinate of the most distant particle that we have ever been able to see (Rindler, 1956; Ellis & Rothman, 1993). The only information this gives is contained in a single point: the current distance of the particle horizon, and this indicates the current radius of the observable universe. The rest of the worldline can be misleading as it does not represent a boundary between events we can see and events we cannot see, nor does it represent the distance to the particle horizon at different times. An alternative way to represent the particle horizon is to plot the distance to the particle horizon as a function of time (Kiang, 1991). The particle horizon at any particular time defines a unique distance which appears as a single point on a

expansion and some subluminally expanding regions can be beyond the event horizon (light that was initially in subluminal regions can end up in superluminal regions and never reach us). Exponential expansion, such as that found in inflation, has $q = -1$. Therefore the Hubble sphere is at a constant proper distance and coincident with the event horizon. This is also the late time asymptotic behaviour of eternally expanding FRW models with $\Omega_\Lambda > 0$ (see Fig. 17, upper panel).

[3]The myth that superluminally receding galaxies are beyond our view, may have propagated through some historical preconceptions. Firstly, objects on our event horizon *do* have infinite redshift, tempting us to apply our SR knowledge that infinite redshift corresponds to a velocity of c. Secondly, the once popular steady state theory predicts exponential expansion, for which the Hubble sphere and event horizon *are* coincident.

[4]The current distance to our particle horizon and its velocity is difficult to say due to the unknown duration of inflation. The particle horizon depicted in Fig. 17 assumes no inflation.

[5]Except in the special cases when the expansion is exponential, $R = R_0 e^{Ht}$, such as the de Sitter universe $(\Omega_{mM} = 0, \Omega_\Lambda > 0)$, during inflation or in the asymptotic limit of eternally expanding FRW universes.

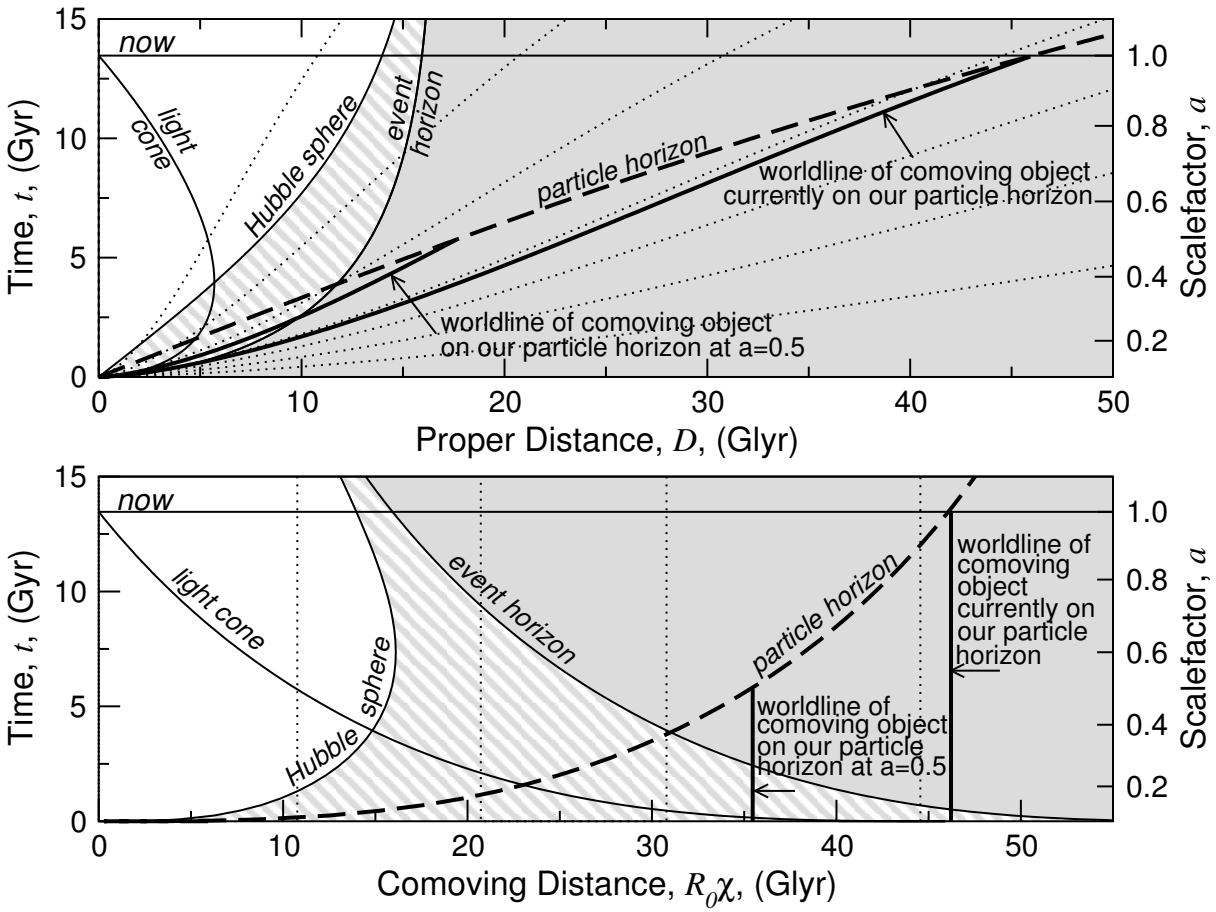

Figure 19: The traditional depiction of the particle horizon on spacetime diagrams is the worldline of the object currently on our particle horizon (thick solid line). All the information in this depiction is contained in a single point, the current distance to the particle horizon. An alternative way to plot the particle horizon is to plot the distance to the particle horizon as a function of time (thick dashed line and Fig. 17). This alleviates the need to draw a new worldline when we need to determine the particle horizon at another time (for example the worldline of the object on our particle horizon when the scalefactor $a = 0.5$).

spacetime diagram. Connecting the points gives the distance to the particle horizon vs time. It is this time dependent series of particle horizons that we plot in Fig. 17. (Rindler (1956) calls this the boundary of our creation light cone – a future light cone starting at the big bang.) Drawn this way, one can read from the spacetime diagram the distance to the particle horizon at any time. There is no need to draw another worldline.

Specifically, what we plot as the particle horizon is $\chi_{\rm ph}(t)$ from Eq. 27 rather than the traditional $\chi_{\rm ph}(t_0)$. To calculate the distance to the particle horizon at an arbitrary time t it is not sufficient to multiply $\chi_{\rm ph}(t_0)$ by $R(t)$ since the comoving distance to the particle horizon also changes with time.

The particle horizon is sometimes distinguished from the event horizon by describing the particle horizon as a "barrier in space" and the event horizon as a "barrier in spacetime". This is not a useful distinction because both the particle horizon and event horizon are surfaces in spacetime – they both form a sphere around us whose radius varies with time. When viewed in comoving coordinates the particle horizon and event horizon are mirror images of each other (symmetry about $z = 10$ in the middle and lower panels of Fig. 17). The traditional depiction of the particle horizon would appear as a straight vertical line in comoving coordinates, i.e., the

comoving coordinate of the present day particle horizon (Fig. 19, lower panel).

The proper distance to the particle horizon is *not* $D_{\rm PH} = ct_0$. Rather, it is the proper distance to the most distant object we can observe, and is therefore related to how much the universe has expanded, i.e. how far away the emitting object has become, since the beginning of time. In general this is $\sim 3ct_0$. The relationship between the particle horizon and light travel time arises because the comoving coordinate of the most distant object we can see *is* determined by the *comoving* distance light has travelled during the lifetime of the universe (Eq. 27).

Observational evidence for the general relativistic interpretaion of cosmological redshifts

Duration-redshift relation for Type Ia Supernovae

Many misconceptions arise from the idea that recession velocities are limited by SR to less than the speed of light so in Section 6.1.6 we present an analysis of supernovae observations yielding evidence against the SR interpretation of cosmological redshifts. But first we would like to present an observational test that *can not* distinguish between special relativistic and general relativistic expansion of the Universe.

General relativistic cosmology predicts that events occurring on a receding emitter will appear time dilated by a factor,

$$\gamma_{\rm GR}(z) = 1 + z. \tag{3}$$

A process that takes Δt_0 as measured by the emitter appears to take $\Delta t = \gamma_{\rm GR}\Delta t_0$ as measured by the observer when the light emitted by that process reaches them. Wilson (1939) suggested measuring this cosmological time dilation to test whether the expansion of the Universe was the cause of cosmological redshifts. Type Ia supernovae (SNe Ia) lightcurves provide convenient standard clocks with which to test cosmological time dilation. Recent evidence from supernovae includes Leibundgut et al. (1996) who gave evidence for GR time dilation using a single high-z supernova and Riess et al. (1997) who showed $1+z$ time dilation for a single SN Ia at the 96.4% confidence level using the time variation of spectral features. Goldhaber et al. (1997) show five data points of lightcurve width consistent with $1 + z$ broadening and extend this analysis in Goldhaber et al. (2001) to rule out any theory that predicts zero time dilation (for example "tired light" scenarios (see Wright, 2001)), at a confidence level of 18σ. All of these tests show that $\gamma = (1 + z)$ time dilation is preferred over models that predict *no* time dilation.

We want to know whether the same observational test can show that GR time dilation is preferred over SR time dilation as the explanation for cosmological redshifts. When we talk about SR expansion of the universe we are assuming that we have an inertial frame that extends to infinity (impossible in the GR picture) and that the expansion involves objects moving through this inertial frame. The time dilation factor in SR is,

$$\gamma_{\rm SR}(z) = (1 - v_{\rm pec}^2/c^2)^{-1/2}, \tag{4}$$

$$= \frac{1}{2}(1 + z + \frac{1}{1+z}) \approx 1 + z^2/2. \tag{5}$$

This time dilation factor relates the proper time in the moving emitter's inertial frame (Δt_0) to the proper time in the observer's inertial frame (Δt_1). To measure this time dilation the observer has to set up a set of synchronized clocks (each at rest in the observer's inertial frame) and take readings of the emitter's proper time as the emitter moves past each synchronized clock. The readings show that the emitter's clock is time dilated such that $\Delta t_1 = \gamma_{\rm SR}\Delta t_0$.

We do not have this set of synchronized clocks at our disposal when we measure time dilation of supernovae and therefore Eq. 5 is not the time dilation we observe. In an earlier version of this paper we mistakenly attempted to use this equation to show SR disagreed with

observational results. This could be classed as an example of an "expanding confusion". For the observed time dilation of supernovae we have to take into account an extra time dilation factor that occurs because the distance to the emitter (and thus the distance light has to propagate to reach us) is increasing. In the time Δt_1 the emitter moves a distance $v\Delta t_1$ away from us. The total proper time we observe (Δt) is Δt_1 plus an extra factor describing how long light takes to traverse this extra distance ($v\Delta t_1/c$),

$$\Delta t = \Delta t_1(1 + v/c). \tag{6}$$

The relationship between proper time at the emitter and proper time at the observer is thus,

$$\begin{aligned} \Delta t &= \Delta t_0\gamma(1 + v/c), & (7)\\ &= \Delta t_0\sqrt{\frac{1 + v/c}{1 - v/c}}, & (8)\\ &= \Delta t_0(1 + z). & (9) \end{aligned}$$

This is identical to the GR time dilation equation. Therefore using time dilation to distinguish between GR and SR expansion is impossible.

Leibundgut et al. (1996), Riess et al. (1997) and Goldhaber et al. (1997, 2001) do provide excellent evidence that expansion is a good explanation for cosmological redshifts. What they can not show is that GR is a better description of the expansion than SR. Nevertheless, other observational tests provide strong evidence against the SR interpretation of cosmological redshifts, and we demonstrate one such test in the next section.

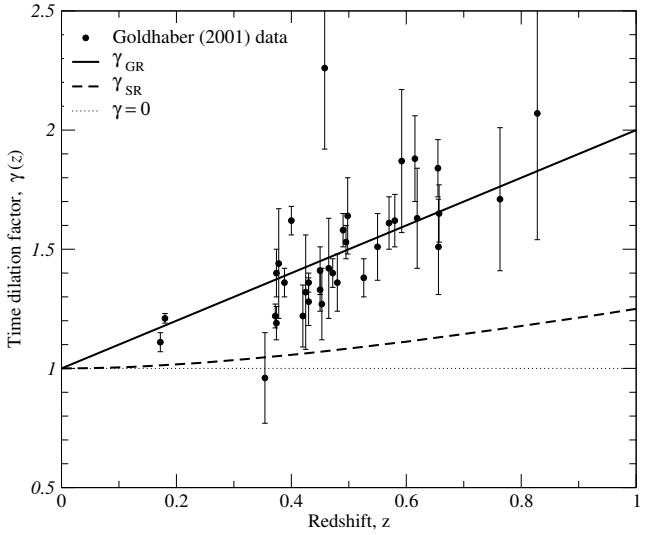

Figure 20: Supernovae time dilation factor vs redshift. The solid line is the time dilation factor predicted by both general relativity and special relativity. The thick dashed line is the special relativistic time dilation factor that a set of synchronized clocks spread throughout our inertial frame would observe, without taking into account the changing distance light has to travel to reach us. Once the change in the emitter's distance is taken into account SR predicts the same time dilation effect as GR, $\gamma = (1 + z)$. The thin dotted line represents any theory that predicts no time dilation (e.g. tired light). The 35 data points are from Goldhaber et al. (2001). They rule out no time dilation at a confidence level of 18σ.

Magnitude-redshift relationship for SNe Ia

Another observational confirmation of the GR interpretation that *is* able to rule out the SR interpretation is the curve in the magnitude-redshift relation. SNe Ia are being used as standard candles to fit the magnitude-redshift relation out to redshifts close to one (Riess et al.,

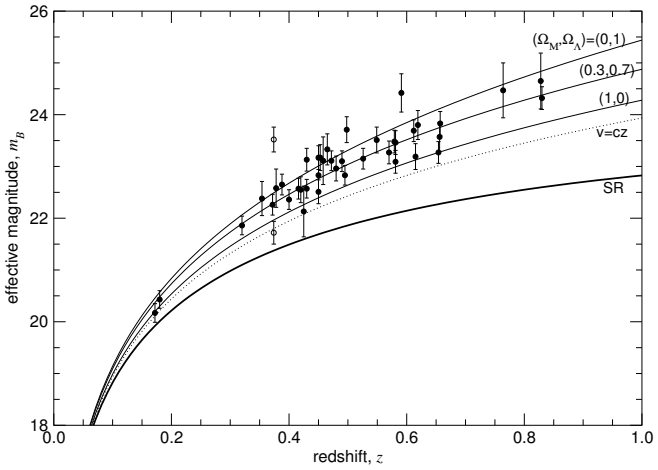

Figure 21: Magnitude-redshift relation for several models with data taken from Perlmutter et al. 1999 [Fig. 2(a)]. The SR prediction has been added (as described in text), as has the prediction assuming a linear $v = cz$ relationship. The interpretation of the cosmological redshift as an SR Doppler effect is ruled out at more than 23σ compared with the ΛCDM concordance model. The linear $v = cz$ model is a better approximation than SR, but is still ruled out at 12σ.

1998; Perlmutter et al., 1999). Recent measurements are accurate enough to put restrictions on the cosmological parameters $(\Omega_{\rm M}, \Omega_\Lambda)$. We perform a simple analysis of the supernovae magnitude-redshift data to show that it also strongly excludes the SR interpretation of cosmological redshifts (Fig. 21).

Figure 21 shows the theoretical curves for several GR models accompanied by the observed SNe Ia data from Perlmutter et al. (1999) [their Fig. 2(a)]. The conversion between luminosity distance, D_L (Eq. 13), and effective magnitude in the B-band given in Perlmutter et al. (1999), is $m_{\rm B}(z) = 5 \log H_0 D_L + M_{\rm B}$ where $M_{\rm B}$ is the absolute magnitude in the B-band at the maximum of the light curve. They marginalize over $M_{\rm B}$ in their statistical analyses. We have taken $M_{\rm B} = -3.45$ which closely approximates their plotted curves.

We superpose the curve deduced by interpreting Hubble's law special relativistically. One of the strongest arguments against using SR to interpret cosmological redshifts is the difficulty in interpreting observational features such as magnitude. We calculate $D(z)$ special relativistically by assuming the velocity in $v = HD$ is related to redshift via Eq. 2, so,

$$D(z) = \frac{c}{H} \frac{(1+z)^2 - 1}{(1+z)^2 + 1}. \tag{10}$$

Since all the redshifting happens at emission in the SR scenario, v should be calculated at the time of emission. However, since SR does not provide a technique for incorporating acceleration into our calculations for the expansion of the Universe, the best we can do is assume that the recession velocity, and thus Hubble's constant, are approximately the same at the time of emission as they are now[6]. We then convert $D(z)$ to $D_L(z)$ using Eq. 13, so $D_L(z) = D(z)(1+z)$. This version of luminosity distance has been used to calculate $m(z)$ for the SR case in Fig. 21.

SR fails this observational test dramatically being 23σ from the general relativistic ΛCDM model $(\Omega_{\rm M}, \Omega_\Lambda) = (0.3, 0.7)$. We also include the result of assuming $v = cz$. Equating this to

[6]There are several complications that this analysis does not address. (1) SR could be manipulated to give an evolving Hubble's constant and (2) SR could be manipulated to give a non-trivial relationship between luminosity distance, D_L, and proper distance, D. However, it is not clear how one would justify these ad hoc corrections.

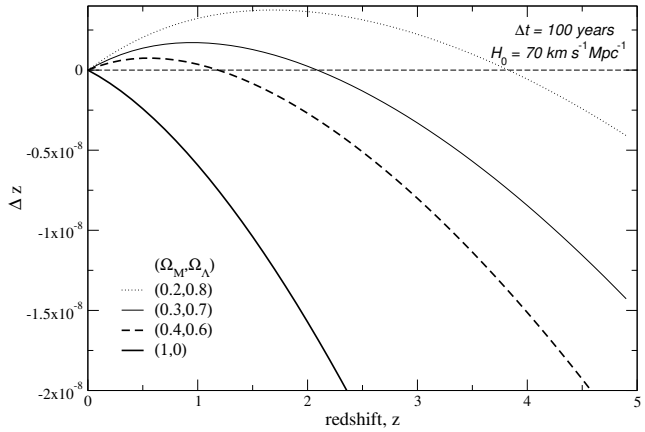

Figure 22: The change in the redshift of a comoving object as predicted by FRW cosmology for various cosmological models. The horizontal axis represents the initial redshifts. The timescale taken for the change is 100 years. The changes predicted are too small for current instrumentation to detect.

Hubble's law gives, $D_L(z) = cz(1+z)/H$. For this observational test the linear prediction is closer to the GR prediction (and to the data) than SR is. Nevertheless the linear result lies 12σ from the ΛCDM concordance result.

Future tests

Current instrumentation is not accurate enough to perform some other observational tests of GR. For example Sandage (1962) showed that the evolution in redshift of distant galaxies due to the acceleration or deceleration of the universe is a direct way to measure the cosmological parameters. The change in redshift over a time interval t_0 is given by,

$$\frac{dz}{dt_0} = H_0(1+z) - H_{\rm em}, \tag{11}$$

where $H_{\rm em} = \dot{R}_{\rm em}/R_{\rm em}$ is Hubble's constant at the time of emission. Unfortunately the magnitude of the redshift variation is small over human timescales. Ebert & Trümper (1975), Lake (1981), Loeb (1998) and references therein each reconfirmed that the technology of the day did not yet provide precise enough redshifts to make such an observation viable. Figure 22 shows the expected change in redshift due to cosmological acceleration or deceleration is only $\Delta z \sim 10^{-8}$ over 100 years. Current Keck/HIRES spectra with iodine cell reference wavelengths can measure quasar absorption line redshifts to an accuracy of $\Delta z \sim 10^{-5}$ (Outram et al., 1999). Thus, this observational test must wait for future technology.

Discussion

Recession velocities of individual galaxies are of limited use in *observational* cosmology because they are not directly observable. For this reason some of the physics community considers recession velocities meaningless and would like to see the issue swept under the rug [App. B: 24–25]. They argue that we should refrain from interpreting observations in terms of velocity or distance, and stick to the observable, redshift. This avoids any complications with superluminal recession and avoids any confusion between the variety of observationally-motivated definitions of distance commonly used in cosmology (e.g. Eqs. 13 and 14).

However, redshift is not the only observable that indicates distance and velocity. The host of low redshift distance measures and the multitude of available evidence for the Big Bang model

all suggest that higher redshift galaxies are more distant from us and receding faster than lower redshift galaxies. Moreover, we cannot currently sweep distance and velocity under the rug if we want to explain the cosmological redshift itself. Expansion has no meaning without well-defined concepts of velocity and distance. If recession velocity were meaningless we could not refer to an "expanding universe" and would have to restrict ourselves to some operational description such as "fainter objects have larger redshifts". However, within general relativity the relationship between cosmological redshift and recession velocity is straightforward. Observations of SNe Ia apparent magnitudes provide independent evidence that the cosmological redshifts are due to the general relativistic expansion of the universe. Understanding distance and velocity is therefore fundamental to the understanding of our Universe.

When distances are large enough that light has taken a substantial fraction of the age of the Universe to reach us there are more observationally convenient distance measures than proper distance, such as luminosity distance and angular-size distance. The most convenient distance measure depends on the method of observation. Nevertheless, these distance measures can be converted between each other, and so collectively define a unique concept[7]. In this paper we have taken proper distance to be the fundamental *radial* distance measure. Proper distance is the spatial geodesic measured along a hypersurface of constant cosmic time (as defined in the Robertson-Walker metric). It is the distance measured along a line of sight by a series of infinitesimal comoving rulers at a particular time, t. Both luminosity and angular-size distances are calculated from observables involving distance perpendicular to the line of sight and so contain the angular coefficient $S_k(\chi)$. They parametrize radial distances but are not geodesic distances along the three dimensional spatial manifold[8]. They are therefore not relevant for the calculation of recession velocity[9]. Nevertheless, if they were used, our results would be similar. Only angular-size distance can avoid superluminal velocities because $D_\theta = 0$ for both $z = 0$ and $z \to \infty$ (Murdoch, 1977). Even then the rate of change of angular-size distance does not approach c for $z \to \infty$.

Throughout this paper we have used proper time, t, as the temporal measure. This is the time that appears in the RW metric and the Friedmann equations. This is a convenient time measure because it is the proper time of comoving observers. Moreover, the homogeneity of the universe is dependent on this choice of time coordinate — if any other time coordinate were chosen (that is not a trivial multiple of t) the density of the universe would be distance dependent. Time can be defined differently, for example to make the SR Doppler shift formula (Eq. 2) correctly calculate recession velocities from observed redshifts (Page, 1993). However, to do this we would have to sacrifice the homogeneity of the universe and the synchronous proper time of comoving objects (Davis & Lineweaver, 2003).

[7]

$$\text{Proper Distance} \quad D = R\chi \tag{12}$$

$$\text{Luminosity Distance} \quad D_L = RS_k(\chi)(1+z) \tag{13}$$

$$\text{Angular-size Distance} \quad D_\theta = RS_k(\chi)(1+z)^{-1} \tag{14}$$

[8]Note also that the standard definition of angular-size distance is purported to be the physical size of an object, divided by the angle it subtends on the sky. The physical size used in this equation is not actually a length along a spatial geodesic, but rather along a line of constant χ (Liske, 2000). The correction is negligible for the small angles usually measured in astronomy.

[9]Murdoch, H. S. 1977, "[McVittie] regards as equally valid other definitions of distance such as luminosity distance and distance by apparent size. But while these are extremely useful concepts, they are really only definitions of observational convenience which extrapolate results such as the inverse square law beyond their range of validity in an expanding universe."

Conclusion

We have clarified some common misconceptions surrounding the expansion of the universe, and shown with numerous references how misleading statements manifest themselves in the literature. Superluminal recession is a feature of all expanding cosmological models that are homogeneous and isotropic and therefore obey Hubble's law. This does not contradict special relativity because the superluminal motion does not occur in any observer's inertial frame. All observers measure light locally to be travelling at c and nothing ever overtakes a photon. Inflation is often called "superluminal recession" but even during inflation objects with $D < c/H$ recede subluminally while objects with $D > c/H$ recede superluminally. Precisely the same relationship holds for non-inflationary expansion. We showed that the Hubble sphere is not a horizon — we routinely observe galaxies that have, and always have had, superluminal recession velocities. All galaxies at redshifts greater than $z \sim 1.46$ today are receding superluminally in the ΛCDM concordance model. We have also provided a more informative way of depicting the particle horizon on a spacetime diagram than the traditional worldline method. An abundance of observational evidence supports the general relativistic big bang model of the universe. The duration of supernovae light curves shows that models predicting no expansion are in conflict with observation. Using magnitude-redshift data from supernovae we were able to rule out the SR interpretation of cosmological redshifts at the $\sim 23\sigma$ level. Together these observations provide strong evidence that the general relativistic interpretation of the cosmological redshifts is preferred over special relativistic and tired light interpretations. The general relativistic description of the expansion of the universe agrees with observations, and does not need any modifications for $v_{\rm rec} > c$.

App: Standard general relativistic definitions of expansion and horizons

The metric for an homogeneous, isotropic universe is the Robertson-Walker (RW) metric,

$$ds^2 = -c^2dt^2 + R(t)^2[d\chi^2 + S_k^2(\chi)d\psi^2], \tag{15}$$

where c is the speed of light, dt is the time separation, $d\chi$ is the comoving coordinate separation and $d\psi^2 = d\theta^2 + \sin^2\theta d\phi^2$, where θ and ϕ are the polar and azimuthal angles in spherical coordinates. The scalefactor, R, has dimensions of distance. The function $S_k(\chi) = \sin\chi$, χ or $\sinh\chi$ for closed ($k = +1$), flat ($k = 0$) or open ($k = -1$) universes respectively (Peacock, 1999, p. 69). The proper distance D, at time t, in an expanding universe, between an observer at the origin and a distant galaxy is defined to be along a surface of constant time ($dt = 0$). We are interested in the radial distance so $d\psi = 0$. The RW metric then reduces to $ds = Rd\chi$ which, upon integration yields,

$$\text{Proper distance,} \qquad D(t) = R(t)\chi. \tag{16}$$

Differentiating this yields the theoretical form of Hubble's law (Harrison, 1993),

$$\text{Recession velocity,} \quad v_{\rm rec}(t,z) = \dot{R}(t)\chi(z), \tag{17}$$

$$= H(t)D(t), \tag{18}$$

where $v_{\rm rec} = \dot{D}$ (for $\dot{\chi} = 0$) and $\chi(z)$ is the fixed comoving coordinate associated with a galaxy observed today at redshift z. Note that the redshift of an object at this fixed comoving coordinate changes with time[10] (Eq. 11). A distant galaxy will have a particular recession velocity when it emits the photon at $t_{\rm em}$ and a different recession velocity when we observe the photon at t_0. Eq. 18 evaluated at t_0 gives the recession velocities plotted in Fig. 18.

[10]In addition, objects that have a peculiar velocity also move through comoving coordinates. Therefore more generally Eq. 17 above should be written with χ explicitly time dependent, $v_{\rm rec}(t,z) = \dot{R}(t)\chi(z,t)$.

The recession velocity of a comoving galaxy is a time dependent quantity because the expansion rate of the universe $\dot{R}(t)$ changes with time. The current recession velocity of a galaxy is given by $v_{\rm rec} = \dot{R}_0\chi(z)$. On the spacetime diagram of Fig. 17 this is the velocity taken at points along the line of constant time marked "now". The recession velocity of an emitter at the time it emitted the light we observe is the velocity at points along our the past light cone[11]. However, we can also compute the recession velocity a comoving object has at *any time* during the history of the universe, having initially calculated its comoving coordinate from its present day redshift.

Allowing χ to vary when differentiating Eq. 16 with respect to time gives two distinct velocity terms (Landsberg & Evans, 1977; Silverman, 1986; Peacock, 1999; Davis et al., 2003),

$$\dot{D} = \dot{R}\chi + R\dot{\chi}, \tag{19}$$

$$v_{\rm tot} = v_{\rm rec} + v_{\rm pec}. \tag{20}$$

This explains the changing slope of our past light cone in the upper panel of Fig. 17. The peculiar velocity of light is always c (Eq. 21) so the total velocity of light whose peculiar velocity is towards us is $v_{\rm tot} = v_{\rm rec} - c$ which is always positive (away from us) when $v_{\rm rec} > c$. Nevertheless we can eventually receive photons that initially were receding from us because the Hubble sphere expands and overtakes the receding photons so the photons find themselves in a region with $v_{\rm rec} < c$ (Section 6.1.6).

Photons travel along null geodesics, $ds = 0$. To obtain the comoving distance, χ, between an observer at the origin and a galaxy observed to have a redshift $z(t)$, set $ds = 0$ (to measure along the path of a photon) and $d\psi = 0$ (to measure radial distances) in the RW metric yielding,

$$c\,dt = R(t)d\chi. \tag{21}$$

This expression confirms our previous statement that the *peculiar* velocity of a photon, $R\dot{\chi}$, is c. Since the velocity of light through comoving coordinates is not constant ($\dot{\chi} = c/R$), to calculate comoving distance we cannot simply multiply the speed of light through comoving space by time. We have to integrate over this changing comoving speed of light for the duration of propagation. Thus, the comoving coordinate of a comoving object that emitted the light we now see at time t is attained by integrating Eq. 21,

$$\text{Past Light Cone, } \chi_{\rm lc}(t_{\rm em}) = c\int_{t_{\rm em}}^{t_0}\frac{dt'}{R(t')}. \tag{22}$$

We can parametrize time using redshift and thus recast Eq. 22 in terms of observables. The cosmological redshift of an object is given by the ratio of the scalefactor at the time of observation, $R(t_0) = R_0$, to the scalefactor at the time of emission, $R(t)$,

$$\text{Redshift, } \quad 1 + z = \frac{R_0}{R(t)}. \tag{23}$$

Differentiating Eq. 23 with respect to t gives $dt/R(t) = -dz/R_0H(z)$ where redshift is used instead of time to parametrize Hubble's constant. $H(z)$ is Hubble's constant at the time an object with redshift, z, emitted the light we now see. Thus, for the limits of the integral in Eq. 22, the time of emission becomes $z = 0$ while the time of observation becomes the observed redshift, z. The comoving coordinate of an object in terms of observables is therefore,

$$\chi(z) = \frac{c}{R_0}\int_o^z\frac{dz'}{H(z')}. \tag{24}$$

[11] The recession velocity at the time of emission is $v_{\rm rec}(t_{\rm em}) = R(t_{\rm em})\chi(z)$ where $R(t_{\rm em}) = R(t)$ as defined in Eq. 23.

Thus, there is a direct one to one relationship between observed redshift and comoving coordinate. Notice that in contrast to special relativity, the redshift does not indicate the velocity, it indicates the distance[12]. That is, the redshift tells us not the velocity of the emitter, but where the emitter sits (at rest locally) in the coordinates of the universe. The recession velocity is obtained by inserting Eq. 24 into Eq. 17 yielding Eq 1.

The Friedmann Equation gives the time dependence of Hubble's constant,

$$H(z) = H_0\,(1+z)\left[1+\Omega_{mM}z+\Omega_\Lambda\left(\frac{1}{(1+z)^2}-1\right)\right]^{1/2}. \tag{25}$$

Expressing Hubble's constant this way is useful because it is in terms of observables. However, it restricts our calculations to objects with redshift $z<\infty$. That is, objects we can currently see. There is no reason to assume the universe ceases beyond our current particle horizon. Expressing Hubble's constant as $H(t)=\dot{R}(t)/R(t)$ allows us to extend the analysis to a time of observation, $t\to\infty$, which is beyond what we can currently observe. Friedmann's equation is then (using the scalefactor normalized to one at the present day $a(t)=R(t)/R_0$),

$$\dot{R}(t) = R_0H_0\left[1+\Omega_{mM}\left(\frac{1}{a}-1\right)+\Omega_\Lambda(a^2-1)\right]^{1/2}, \tag{26}$$

which we use with the identity $dt/R(t)=dR/(\dot{R}R)$ to evaluate Eqs. 22, 27 and 28.

Altering the limits on the integral in Eq. 22 gives the horizons we have plotted on the spacetime diagrams. The time dependent particle horizon we plot in Fig. 17 uses $D_{\rm ph}=R(t)\chi_{\rm ph}(t)$ with,

$$\text{Particle Horizon, } \chi_{\rm ph}(t) = c\int_0^t \frac{dt'}{R(t')}. \tag{27}$$

The traditional depiction of the particle horizon as a worldline uses $D_{\rm ph}=R(t)\chi_{\rm ph}(t_0)$. The comoving distance to the event horizon is given by,

$$\text{Event Horizon, } \chi_{\rm eh}(t) = c\int_t^{t_{\rm end}} \frac{dt'}{R(t')}, \tag{28}$$

where $t_{\rm end}=\infty$ in eternally expanding models or the time of the big crunch in recollapsing models.

A conformal time interval, $d\tau$, is defined as a proper time interval dt divided by the scalefactor,

$$\text{Conformal time, } d\tau = dt/R(t). \tag{29}$$

6.2 Inflation

Обсудим подробно инфляцию.

(пока такой небольшой раздел, у баунмана он не раздут, так что и я пока что не раздуваю его.)

The FRW cosmology described in the previous chapter is incomplete. It doesn't explain why the universe is homogeneous and isotropic on large scales. In fact, the standard cosmology predicts that the early universe was made of many causally disconnected regions of space. The fact that these apparently disjoint patches of space have very nearly the same densities and

[12]Distance is proportional to recession velocity at any particular time, but a particular redshift measured at different times will correspond to different recession velocities.

temperatures is called the horizon problem. In this chapter, I will explain how inflation-an early period of accelerated expansion - drives the primordial universe towards homogeneity and isotropy, even if it starts in a more generic initial state.

Throughout this chapter, we will trade Newton's constant for the (reduced) Planck mass,

$$M_{\rm pl} \equiv \sqrt{\frac{\hbar c}{8\pi G}} = 2.4 \times 10^{18}{\rm GeV},$$

so that the Friedmann equation (1.3.131) is written as $H^2 = \rho/\left(3M_{\rm pl}^2\right)$.

6.2.1 The Horizon Problem (??)

Обзор (?????)

Проблема горизонта возникает, когда мы видим однородность и изотропность распределения космического фонового излучения (теплового излучения, оставшегося после Большого взрыва) на всем небе. Это означает, что эти различные области Вселенной, которые сейчас находятся далеко друг от друга, в прошлом были ближе друг к другу и имели возможность взаимодействовать и достичь термодинамического равновесия. Однако, если эти области находились за горизонтом друг друга на момент Большого взрыва, то как они могли прийти в равновесие, если между ними не было достаточного времени для взаимодействия?

Light and Horizons

The size of a causal patch of space it determined by how far light can travel in a certain amount of time. As we mentioned in §1.1.3, in an expanding spacetime the propagation of light (photons) is best studied using conformal time. Since the spacetime is isotropic, we can always define the coordinate system so that the light travels purely in the radial direction (i.e. $\theta = \phi = $ const.). The evolution is then determined by a two-dimensional line element [1]

$$ds^2 = a^2(\tau)\left[d\tau^2 - d\chi^2\right].$$

Since photons travel along null geodesics, $ds^2 = 0$, their path is defined by

$$\Delta\chi(\tau) = \pm\Delta\tau$$

where the plus sign corresponds to outgoing photons and the minus sign to incoming photons. This shows the main benefit of working with conformal time: light rays correspond to straight lines at 45° angles in the $\chi - \tau$ coordinates. If instead we had used physical time t, then the light cones for curved spacetimes would be curved. With these preliminaries, we now define two different types of cosmological horizons. One which limits the distances at which past events can be observed and one which limits the distances at which it will ever be possible to observe future events.

[1] For the radial coordinate χ we have used the parameterisation of (1.1.23), so that (2.1.1) is conformal to two-dimensional Minkowski space and the curvature k of the three-dimensional spatial slices is absorbed into the definition of the coordinate χ. Had we used the regular polar coordinate r, the two-dimensional line element would have retained a dependence on k. For flat slices, χ and r are of course the same.

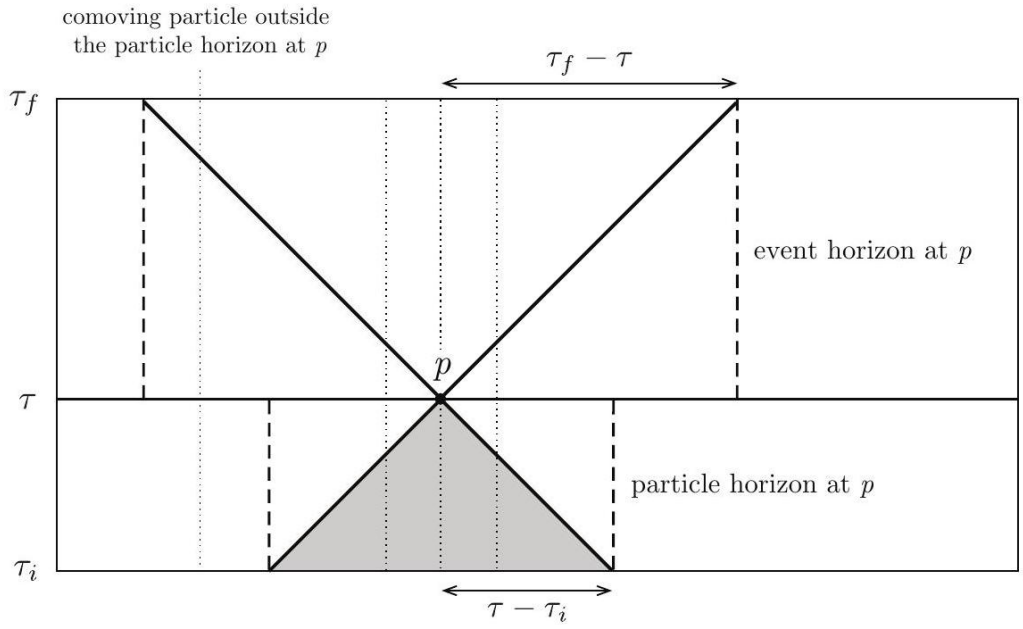

Figure 2.1: Spacetime diagram illustrating the concept of horizons. Dotted lines show the worldlines of comoving objects. The event horizon is the maximal distance to which we can send signal. The particle horizon is the maximal distance from which we can receive signals.

Particle horizon

Eq. (2.1.2) tells us that the maximal comoving distance that light can travel between two times τ_1 and $\tau_2 > \tau_1$ is simply $\Delta\tau = \tau_2 - \tau_1$ (recall that $c \equiv 1$). Hence, if the Big Bang 'started' with the singularity at $t_i \equiv 0$, [2] then the greatest comoving distance from which an observer at time t will be able to receive signals travelling at the speed of light is given by

$$\chi_{\text{ph}}(\tau) = \tau - \tau_i = \int_{t_i}^{t} \frac{\mathrm{d}t}{a(t)}.$$

This is called the (comoving) particle horizon. The size of the particle horizon at time τ may be visualised by the intersection of the past light cone of an observer p with the spacelike surface $\tau = \tau_i$ (see fig. 2.1). Causal influences have to come from within this region. Only comoving particles whose worldlines intersect the past light cone of p can send a signal to an observer at p. The boundary of the region containing such worldlines is the particle horizon at p. Notice that every observer has his of her own particle horizon.

Event horizon

Just as there are past events that we cannot see now, there may be future events that we will never be able to see (and distant regions that we will never be able to influence). In comoving coordinates, the greatest distance from which an observer at time t_f will receive signals emitted at any time later than t is given by

$$\chi_{\text{eh}}(\tau) = \tau_f - \tau = \int_{t}^{t_f} \frac{\mathrm{d}t}{a(t)}.$$

This is called the (comoving) event horizon. It is similar to the event horizon of black holes. Here, τ_f denotes the 'final moment of (conformal) time'. Notice that this may be finite even

if physical time is infinite, $t_f = +\infty$. Whether this is the case or not depends on the form of $a(t)$. In particular, τ_f is finite for our universe, if dark energy is really a cosmological constant.

[2] Notice that the Big Bang singularity is a moment in time, but not a point space. Indeed, in figs. 2.1 and 2.2 we describe the singularity by an extended (possibly infinite) spacelike hypersurface.

Growing Hubble Sphere

It is the particle horizon that is relevant for the horizon problem of the standard Big Bang cosmology. Eq. (2.1.3) can be written in the following illuminating way

$$\chi_{\rm ph}(\tau) = \int_{t_i}^{t} \frac{{\rm d}t}{a} = \int_{a_i}^{a} \frac{{\rm d}a}{a\dot{a}} = \int_{\ln a_i}^{\ln a} (aH)^{-1}\ {\rm d}\ln a,$$

where $a_i \equiv 0$ corresponds to the Big Bang singularity. The causal structure of the spacetime can hence be related to the evolution of the comoving Hubble radius $(aH)^{-1}$. For a universe dominated by a fluid with constant equation of state $w \equiv P/\rho$, we get

$$(aH)^{-1} = H_0^{-1} a^{\frac{1}{2}(1+3w)}.$$

Note the dependence of the exponent on the combination $(1+3w)$. All familiar matter sources satisfy the strong energy condition (SEC), $1+3w > 0$, so it used to be a standard assumption that the comoving Hubble radius increases as the universe expands. In this case, the integral in (2.1.5) is dominated by the upper limit and receives vanishing contributions from early times. We see this explicitly in the example of a perfect fluid. Using (2.1.6) in (2.1.5), we find

$$\chi_{\rm ph}(a) = \frac{2H_0^{-1}}{(1+3w)} \left[a^{\frac{1}{2}(1+3w)} - a_i^{\frac{1}{2}(1+3w)} \right] \equiv \tau - \tau_i.$$

The fact that the comoving horizon receives its largest contribution from late times can be made manifest by defining

$$\tau_i \equiv \frac{2H_0^{-1}}{(1+3w)} a_i^{\frac{1}{2}(1+3w)} \overset{a_i \to 0, w > -\frac{1}{3}}{\longrightarrow} 0.$$

The comoving horizon is finite,

$$\chi_{\rm ph}(t) = \frac{2H_0^{-1}}{(1+3w)} a(t)^{\frac{1}{2}(1+3w)} = \frac{2}{(1+3w)} (aH)^{-1}.$$

We see that in the standard cosmology $\chi_{\rm ph} \sim (aH)^{-1}$. This has lead to the confusing practice of referring to both the particle horizon and the Hubble radius as the "horizon" (see §2.2.2).

Why is the CMB so uniform?

About 380000 years after the Big Bang, the universe had cooled enough to allow the formation of hydrogen atoms and the decoupling of photons from the primordial plasma (see §3.3.3). We observe this event in the form of the cosmic microwave background (CMB), an afterglow of the hot Big Bang. Remarkably, this radiation is almost perfectly isotropic, with anisotropies in the CMB temperature being smaller than one part in ten thousand.

A moment's thought will convince you that the finiteness of the conformal time elapsed between $t_i = 0$ and the time of the formation of the CMB, t_{rec}, implies a serious problem:

it means that most spots in the CMB have non-overlapping past light cones and hence never were in causal contact. This is illustrated by the spacetime diagram in fig. 2.2. Consider two opposite directions on the sky. The CMB photons that we receive from these directions were emitted at the points labelled p and q in fig. 2.2. We see that the photons were emitted sufficiently close to the Big Bang singularity that the past light cones of p and q don't overlap. This implies that no point lies inside the particle horizons of both p and q. So the puzzle is: how do the photons coming from p and q "know" that they should be at almost exactly the same temperature? The same question applies to any two points in the CMB that are separated by more than 1 degree in the sky. The homogeneity of the CMB spans scales that are much larger than the particle horizon at the time when the CMB was formed. In fact, in the standard cosmology the CMB is made of about 10^4 disconnected patches of space. If there wasn't enough time for these regions to communicate, why do they look so similar? This is the horizon problem.

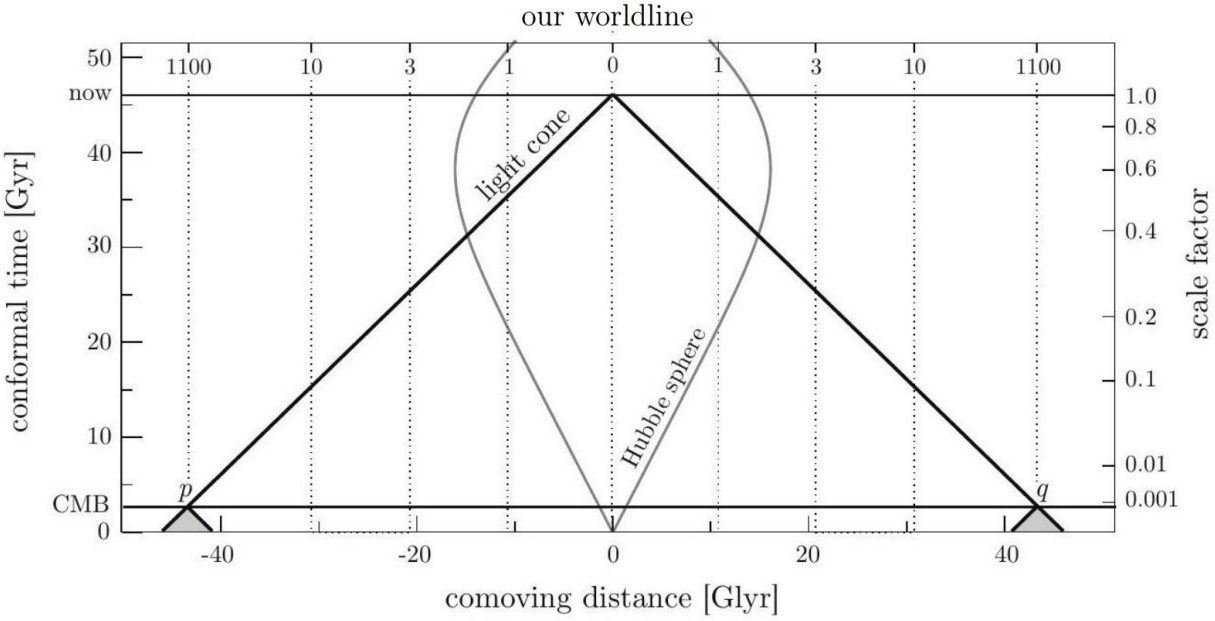

Figure 2.2: The horizon problem in the conventional Big Bang model. All events that we currently observe are on our past light cone. The intersection of our past light cone with the spacelike slice labelled CMB corresponds to two opposite points in the observed CMB. Their past light cones don't overlap before they hit the singularity, $a = 0$, so the points appear never to have been in causal contact. The same applies to any two points in the CMB that are separated by more than 1 degree on the sky.

Физически, как это, выйти за горизонт событий? (????????)

(не знаю, физически плохо это понимаю еще.)

Почему нельзя ответить, что просто системы так эволюционировали, что одинаково и излучали, потому что по сути системы в разных точек галактик аналогичны?

(хз????)

6.2.2 A Shrinking Hubble Sphere

Our description of the horizon problem has highlighted the fundamental role played by the growing Hubble sphere of the standard Big Bang cosmology. A simple solution to the horizon problem therefore suggests itself: let us conjecture a phase of decreasing Hubble radius in the early universe,

$$\frac{d}{dt}(aH)^{-1} < 0.$$

If this lasts long enough, the horizon problem can be avoided. Physically, the shrinking Hubble sphere requires a SEC-violating fluid, $1 + 3w < 0$.

Solution of the Horizon Problem

For a shrinking Hubble sphere, the integral in (2.1.5) is dominated by the lower limit. The Big Bang singularity is now pushed to negative conformal time,

$$\tau_i = \frac{2H_0^{-1}}{(1+3w)} a_i^{\frac{1}{2}(1+3w)} \overset{a_i \to 0, w < -\frac{1}{3}}{\longrightarrow} -\infty.$$

This implies that there was "much more conformal time between the singularity and decoupling than we had thought"! Fig. 2.3 shows the new spacetime diagram. The past light cones of

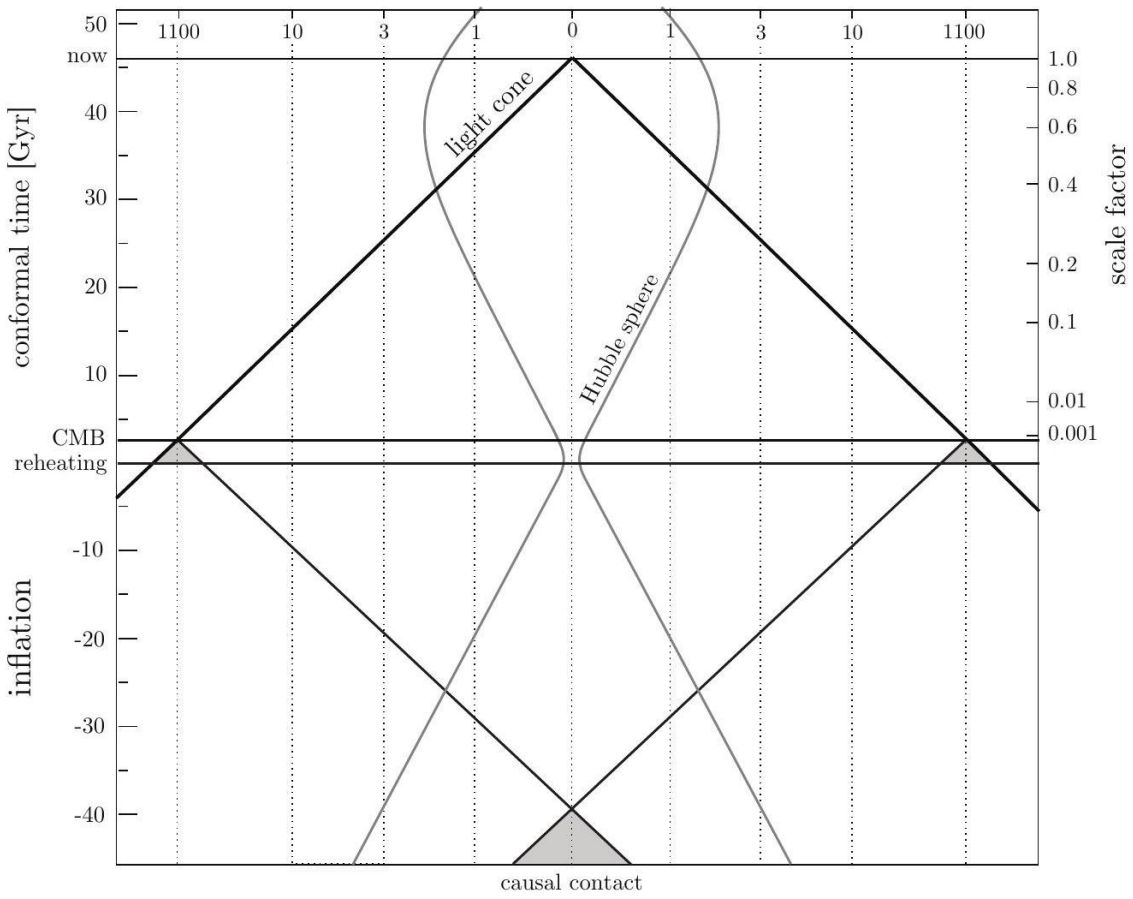

Figure 2.3: Inflationary solution to the horizon problem. The comoving Hubble sphere shrinks during inflation and expands during the conventional Big Bang evolution (at least until dark energy takes over at $a \approx 0.5$). Conformal time during inflation is negative. The spacelike singularity of the standard Big Bang is replaced by the reheating surface, i.e. rather than

marking the beginning of time it now corresponds simply to the transition from inflation to the standard Big Bang evolution. All points in the CMB have overlapping past light cones and therefore originated from a causally connected region of space.

widely separated points in the CMB now had enough time to intersect before the time τ_i. The uniformity of the CMB is not a mystery anymore. In inflationary cosmology, $\tau = 0$ isn't the initial singularity, but instead becomes only a transition point between inflation and the standard Big Bang evolution. There is time both before and after $\tau = 0$.

Hubble Radius vs. Particle Horizon

A quick word of warning about bad (but unfortunately standard) language in the inflationary literature: Both the particle horizon $\chi_{\rm ph}$ and the Hubble radius $(aH)^{-1}$ are often referred to simply as the "horizon". In the standard FRW evolution (with ordinary matter) the two are roughly the same - cf. eq. (2.1.9) - so giving them the same name isn't an issue. However, the whole point of inflation is to make the particle horizon much larger than the Hubble radius.

The Hubble radius $(aH)^{-1}$ is the (comoving) distance over which particles can travel in the course of one expansion time. [3] It is therefore another way of measuring whether particles are causally connected with each other: comparing the comoving separation λ of two particles with $(aH)^{-1}$ determines whether the particles can communicate with each other at a given moment (i.e. within the next Hubble time). This makes it clear that $\chi_{\rm ph}$ and $(aH)^{-1}$ are conceptually very different:

[3] The expansion time, $t_H \equiv H^{-1} = dt/d\ln a$, is roughly the time in which the scale factor doubles. - if $\lambda > \chi_{\rm ph}$, then the particles could never have communicated.

- if $\lambda > (aH)^{-1}$, then the particles cannot talk to each other now.

Inflation is a mechanism to achieve $\chi_{\rm ph} \gg (aH)^{-1}$. This means that particles can't communicate now (or when the CMB was created), but were in causal contact early on. In particular, the shrinking Hubble sphere means that particles which were initially in causal contact with another - i.e. separated by a distance $\lambda < (a_I H_I)^{-1}$ — can no longer communicate after a sufficiently long period of inflation: $\lambda > (aH)^{-1}$; see fig. 2.4. However, at any moment before horizon exit (careful: I really mean exit of the Hubble radius!) the particles could still talk to each other and establish similar conditions. Everything within the Hubble sphere at the beginning of inflation, $(a_I H_I)^{-1}$, was causally connected.

Since the Hubble radius is easier to calculate than the particle horizon it is common to use the Hubble radius as a means of judging the horizon problem. If the entire observable universe was within the comoving Hubble radius at the beginning of inflation-i.e. $(a_I H_I)^{-1}$ was larger than the comoving radius of the observable universe $(a_0 H_0)^{-1}$ - then there is no horizon problem. Notice that this is more conservative than using the particle horizon since $\chi_{\rm ph}(t)$ is always bigger than $(aH)^{-1}(t)$. Moreover, using $(a_I H_I)^{-1}$ as a measure of the horizon problem means that we don't have to assume anything about earlier times $t < t_I$.

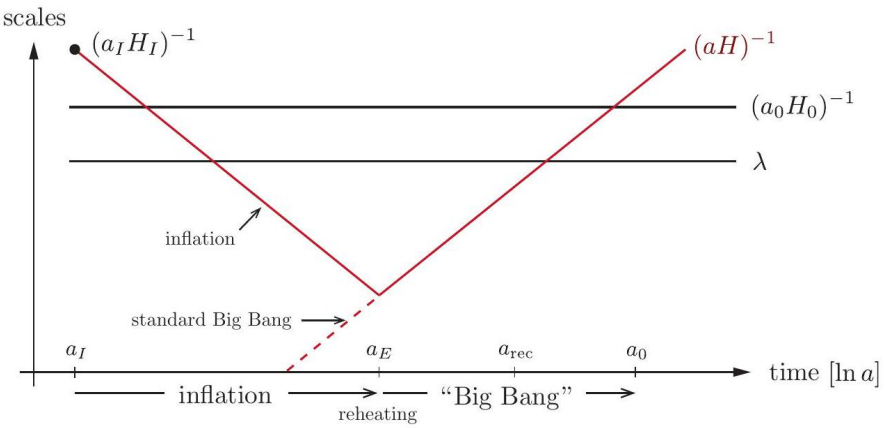

Figure 2.4: Scales of cosmological interest were larger than the Hubble radius until $a \approx 10^{-5}$ (where today is at $a(t_0) \equiv 1$). However, at very early times, before inflation operated, all scales of interest were smaller than the Hubble radius and therefore susceptible to microphysical processing. Similarly, at very late times, the scales of cosmological interest are back within the Hubble radius. Notice the symmetry of the inflationary solution. Scales just entering the horizon today, 60 e-folds after the end of inflation, left the horizon 60 e-folds before the end of inflation.

Duration of inflation.-How much inflation do we need to solve the horizon problem? At the very least, we require that the observable universe today fits in the comoving Hubble radius at the beginning of inflation,

$$(a_0 H_0)^{-1} < (a_I H_I)^{-1} .$$

Let us assume that the universe was radiation dominated since the end of inflation and ignore the relatively recent matter- and dark energy-dominated epochs. Remembering that $H \propto a^{-2}$ during radiation domination, we have

$$\frac{a_0 H_0}{a_E H_E} \sim \frac{a_0}{a_E}\left(\frac{a_E}{a_0}\right)^2 = \frac{a_E}{a_0} \sim \frac{T_0}{T_E} \sim 10^{-28},$$

where in the numerical estimate we used $T_E \sim 10^{15}$GeV and $T_0 = 10^{-3}$eV(~ 2.7 K). Eq. (2.2.12) can then be written as

$$(a_I H_I)^{-1} > (a_0 H_0)^{-1} \sim 10^{28} (a_E H_E)^{-1} .$$

For inflation to solve the horizon problem, $(aH)^{-1}$ should therefore shrink by a factor of 10^{28}. The most common way to arrange this it to have $H \sim$ const. during inflation (see below). This implies $H_I \approx H_E$, so eq. (2.2.14) becomes

$$\frac{a_E}{a_I} > 10^{28} \Rightarrow \ln\left(\frac{a_E}{a_I}\right) > 64.$$

This is the famous statement that the solution of the horizon problem requires about 60e-folds of inflation.

Conditions for Inflation

I like the shrinking Hubble sphere as the fundamental definition of inflation since it relates most directly to the horizon problem and is also key for the inflationary mechanism of generating fluctuations (see Chapter 6). However, before we move on to discuss what physics can lead to a shrinking Hubble sphere, let me show you that this definition of inflation is equivalent to other popular ways of describing inflation.

- Accelerated expansion.-From the relation

$$\frac{d}{dt}(aH)^{-1} = \frac{d}{dt}(\dot{a})^{-1} = -\frac{\ddot{a}}{(\dot{a})^2},$$

we see that a shrinking comoving Hubble radius implies accelerated expansion

$$\ddot{a} > 0.$$

This explains why inflation is often defined as a period of acceleration.

- Slowly-varying Hubble parameter.-Alternatively, we may write

$$\frac{d}{dt}(aH)^{-1} = -\frac{\dot{a}H + a\dot{H}}{(aH)^2} = -\frac{1}{a}(1-\varepsilon), \qquad \text{where } \varepsilon \equiv -\frac{\dot{H}}{H^2}.$$

The shrinking Hubble sphere therefore also corresponds to

$$\varepsilon = -\frac{\dot{H}}{H^2} < 1.$$

- Quasi-de Sitter expansion.-For perfect inflation, $\varepsilon = 0$, the spacetime becomes de Sitter space

$$\mathrm{d}s^2 = \mathrm{d}t^2 - e^{2Ht}\,\mathrm{d}\boldsymbol{x}^2,$$

where $H = \partial_t \ln a = \text{const}$. Inflation has to end, so it shouldn't correspond to perfect de Sitter space. However, for small, but finite $\varepsilon \neq 0$, the line element (2.2.20) is still a good approximation to the inflationary background. This is why we will often refer to inflation as a quasi-de Sitter period. - Negative pressure.-What forms of stress-energy source accelerated expansion? Let us consider a perfect fluid with pressure P and density ρ. The Friedmann equation, $H^2 = \rho/\left(3M_{\rm pl}^2\right)$, and the continuity equation, $\dot{\rho} = -3H(\rho + P)$, together imply

$$\dot{H} + H^2 = -\frac{1}{6M_{\rm pl}^2}(\rho + 3P) = -\frac{H^2}{2}\left(1 + \frac{3P}{\rho}\right).$$

We rearrange this to find that

$$\varepsilon = -\frac{\dot{H}}{H^2} = \frac{3}{2}\left(1 + \frac{P}{\rho}\right) < 1 \quad \Leftrightarrow \quad w \equiv \frac{P}{\rho} < -\frac{1}{3},$$

i.e. inflation requires negative pressure or a violation of the strong energy condition. How this can arise in a physical theory will be explained in the next section. We will see that there is nothing sacred about the strong energy condition and that it can easily be violated.

- Constant density.-Combining the continuitiy equation, $\dot{\rho} = -3H(\rho+P)$, with eq. (2.2.21), we find

$$\left|\frac{d\ln\rho}{d\ln a}\right| = 2\varepsilon < 1.$$

For small ε, the energy density is therefore nearly constant. Conventional matter sources all dilute with expansion, so we need to look for something more unusual.

6.2.3 The Physics of Inflation

We have shown that a given FRW spacetime with time-dependent Hubble parameter $H(t)$ corresponds to cosmic acceleration if and only if

$$\varepsilon \equiv -\frac{\dot{H}}{H^2} = -\frac{d\ln H}{dN} < 1.$$

Here, we have defined $\mathrm{d}N \equiv \mathrm{d}\ln a = H\,\mathrm{d}t$, which measures the number of e-folds N of inflationary expansion. Eq. (2.3.24) implies that the fractional change of the Hubble parameter per e-fold is small. Moreover, in order to solve the horizon problem, we want inflation to last for a sufficiently long time (usually at least $N \sim 40$ to $60e$-folds). To achieve this requires ε to remain small for a sufficiently large number of Hubble times. This condition is measured by a second parameter

$$\eta \equiv \frac{d\ln\varepsilon}{dN} = \frac{\dot{\varepsilon}}{H\varepsilon}.$$

For $|\eta| < 1$, the fractional change of ε per Hubble time is small and inflation persists. In this section, we discuss what microscopic physics can lead to the conditions $\varepsilon < 1$ and $|\eta| < 1$.

Scalar Field Dynamics

As a simple toy model for inflation we consider a scalar field, the inflaton $\phi(t, \boldsymbol{x})$. As indicated by the notation, the value of the field can depend on time t and the position in space $\boldsymbol{x}$. Associated with each field value is a potential energy density $V(\phi)$ (see fig. 2.5). If the field is dynamical (i.e. changes with time) then it also carries kinetic energy density. If the stress-energy associated with the scalar field dominates the universe, it sources the evolution of the FRW background. We want to determine under which conditions this can lead to accelerated expansion.

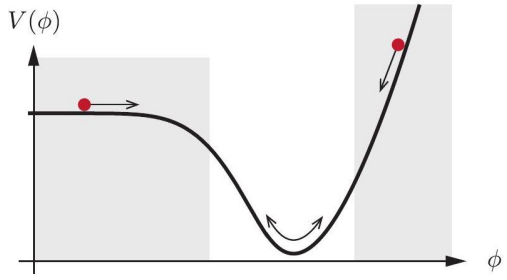

Figure 2.5: Example of a slow-roll potential. Inflation occurs in the shaded parts of the potential.

The stress-energy tensor of the scalar field is [4]

$$T_{\mu\nu} = \partial_\mu\phi\partial_\nu\phi - g_{\mu\nu}\left(\frac{1}{2}g^{\alpha\beta}\partial_\alpha\phi\partial_\beta\phi - V(\phi)\right).$$

Consistency with the symmetries of the FRW spacetime requires that the background value of the inflaton only depends on time, $\phi = \phi(t)$. From the time-time component $T^0_0 = \rho_\phi$, we infer that

$$\rho_\phi = \frac{1}{2}\dot{\phi}^2 + V(\phi).$$

We see that the total energy density, ρ_ϕ, is simply the sum of the kinetic energy density, $\frac{1}{2}\dot{\phi}^2$, and the potential energy density, $V(\phi)$. From the space-space component $T^i_j = -P_\phi\delta^i_j$, we find that the pressure is the difference of kinetic and potential energy densities,

$$P_\phi = \frac{1}{2}\dot{\phi}^2 - V(\phi).$$

We see that a field configuration leads to inflation, $P_\phi < -\frac{1}{3}\rho_\phi$, if the potential energy dominates over the kinetic energy.

Next, we look in more detail at the evolution of the inflaton $\phi(t)$ and the FRW scale factor $a(t)$. Substituting ρ_ϕ from (2.3.27) into the Friedmann equation, $H^2 = \rho_\phi / \left(3M_{\rm pl}^2\right)$, we get

$$H^2 = \frac{1}{3M_{\rm pl}^2}\left[\frac{1}{2}\dot{\phi}^2 + V\right].$$

Taking a time derivative, we find

$$2H\dot{H} = \frac{1}{3M_{\rm pl}^2}\left[\dot{\phi}\ddot{\phi} + V'\dot{\phi}\right],$$

where $V' \equiv dV/d\phi$. Substituting ρ_ϕ and P_ϕ into the second Friedmann equation (2.2.21), $\dot{H} = -\left(\rho_\phi + P_\phi\right) / \left(2M_{\rm pl}^2\right)$, we get

$$\dot{H} = -\frac{1}{2}\frac{\dot{\phi}^2}{M_{\rm pl}^2}.$$

Notice that $\dot{H}$ is sourced by the kinetic energy density. Combining (2.3.30) with (2.3.29) leads to the Klein-Gordon equation

$$\ddot{\phi} + 3H\dot{\phi} + V' = 0.$$

[4] You can derive this stress-energy tensor either from Noether's theorem or from the action of a scalar field. You will see those derivations in the QFT course: David Tong, Part III Quantum Field Theory. This is the evolution equation for the scalar field. Notice that the potential acts like a force, V', while the expansion of the universe adds friction, $H\dot{\phi}$.

Slow-Roll Inflation

Substituting eq. (2.3.30) into the definition of ε, eq. (2.3.24), we find

$$\varepsilon = \frac{\frac{1}{2}\dot{\phi}^2}{M_{\rm pl}^2 H^2}.$$

Inflation ($\varepsilon < 1$) therefore occurs if the kinetic energy, $\frac{1}{2}\dot{\phi}^2$, only makes a small contribution to the total energy, $\rho_\phi = 3M_{\rm pl}^2 H^2$. This situation is called slow-roll inflation.

In order for this condition to persist, the acceleration of the scalar field has to be small. To assess this, it is useful to define the dimensionless acceleration per Hubble time

$$\delta \equiv -\frac{\ddot{\phi}}{H\dot{\phi}}.$$

Taking the time-derivative of (2.3.31),

$$\dot{\varepsilon} = \frac{\dot{\phi}\ddot{\phi}}{M_{\rm pl}^2 H^2} - \frac{\dot{\phi}^2 \dot{H}}{M_{\rm pl}^2 H^3}$$

and comparing to (2.3.25), we find

$$\eta = \frac{\dot{\varepsilon}}{H\varepsilon} = 2\frac{\ddot{\phi}}{H\dot{\phi}} - 2\frac{\dot{H}}{H^2} = 2(\varepsilon - \delta).$$

Hence, $\{\varepsilon, |\delta|\} \ll 1$ implies $\{\varepsilon, |\eta|\} \ll 1$.

Slow-roll approximation.- So far, no approximations have been made. We simply noted that in a regime where $\{\varepsilon, |\delta|\} \ll 1$, inflation occurs and persists. We now use these conditions to simplify the equations of motion. This is called the slow-roll approximation. The condition $\varepsilon \ll 1$ implies $\frac{1}{2}\dot{\phi}^2 \ll V$ and hence leads to the following simplification of the Friedmann equation (F),

$$H^2 \approx \frac{V}{3M_{\rm pl}^2}.$$

In the slow-roll approximation, the Hubble expansion is determined completely by the potential energy. The condition $|\delta| \ll 1$ simplifies the Klein-Gordon equation (KG) to

$$3H\dot{\phi} \approx -V'.$$

($\mathrm{KG_{SR}}$)

This provides a simple relationship between the gradient of the potential and the speed of the inflaton. Substituting ($\mathrm{F_{SR}}$) and ($\mathrm{KG_{SR}}$) into (2.3.31) gives

$$\varepsilon = \frac{\frac{1}{2}\dot{\phi}^2}{M_{\rm pl}^2 H^2} \approx \frac{M_{\rm pl}^2}{2}\left(\frac{V'}{V}\right)^2.$$

Furthermore, taking the time-derivative of ($\mathrm{KG_{SR}}$),

$$3\dot{H}\dot{\phi} + 3H\ddot{\phi} = -V''\dot{\phi},$$

leads to

$$\delta + \varepsilon = -\frac{\ddot{\phi}}{H\dot{\phi}} - \frac{\dot{H}}{H^2} \approx M_{\rm pl}^2\frac{V''}{V}.$$

Hence, a convenient way to assess whether a given potential $V(\phi)$ can lead to slow-roll inflation is to compute the potential slow-roll parameters [5]

$$\epsilon_{\rm v} \equiv \frac{M_{\rm pl}^2}{2}\left(\frac{V'}{V}\right)^2, \quad |\eta_{\rm v}| \equiv M_{\rm pl}^2\frac{|V''|}{V}.$$

Successful slow-roll inflation occurs when these parameters are small, $\{\epsilon_{\rm v}, |\eta_{\rm v}|\} \ll 1$.

Amount of inflation. - The total number of ' e-folds' of accelerated expansion are

$$N_{\rm tot} \equiv \int_{a_I}^{a_E} \mathrm{d}\ln a = \int_{t_I}^{t_E} H(t)\mathrm{d}t,$$

where t_I and t_E are defined as the times when $\varepsilon(t_I) = \varepsilon(t_E) \equiv 1$. In the slow-roll regime, we can use

$$H\ \mathrm{d}t = \frac{H}{\dot{\phi}}\mathrm{d}\phi = \frac{1}{\sqrt{2\varepsilon}}\frac{|\mathrm{d}\phi|}{M_{\rm pl}} \approx \frac{1}{\sqrt{2\epsilon_{\rm v}}}\frac{|\mathrm{d}\phi|}{M_{\rm pl}}$$

to write (2.3.39) as an integral in the field space of the inflaton [6]

$$N_{\rm tot} = \int_{\phi_I}^{\phi_E} \frac{1}{\sqrt{2\epsilon_{\rm v}}}\frac{|\mathrm{d}\phi|}{M_{\rm pl}}$$

where ϕ_I and ϕ_E are defined as the boundaries of the interval where $\epsilon_{\rm v} < 1$. The largest scales observed in the CMB are produced about 60e-folds before the end of inflation

$$N_{\rm cmb} = \int_{\phi_{\rm cmb}}^{\phi_E} \frac{1}{\sqrt{2\epsilon_{\rm v}}} \frac{|{\rm d}\phi|}{M_{\rm pl}} \approx 60.$$

A successful solution to the horizon problem requires $N_{\rm tot} > N_{\rm cmb}$.

Case study: $m^2\phi^2$ inflation.-As an example, let us give the slow-roll analysis of arguably the simplest model of inflation: single-field inflation driven by a mass term

$$V(\phi) = \frac{1}{2} m^2 \phi^2.$$

The slow-roll parameters are

$$\epsilon_{\rm v}(\phi) = \eta_{\rm v}(\phi) = 2\left(\frac{M_{\rm pl}}{\phi}\right)^2.$$

To satisfy the slow-roll conditions $\epsilon_{\rm v}, |\eta_{\rm v}| < 1$, we therefore need to consider super-Planckian values for the inflaton

$$\phi > \sqrt{2} M_{\rm pl} \equiv \phi_E.$$

[5] In contrast, the parameters ε and η are often called the Hubble slow-roll parameters. During slow-roll, the parameters are related as follows: $\epsilon_{\rm v} \approx \varepsilon$ and $\eta_{\rm v} \approx 2\varepsilon - \frac{1}{2}\eta$.

[6] The absolute value around the integration measure indicates that we pick the overall sign of the integral in such a way as to make $N_{\rm tot} > 0$. The relation between the inflaton field value and the number of e-folds before the end of inflation is

$$N(\phi) = \frac{\phi^2}{4M_{\rm pl}^2} - \frac{1}{2}.$$

Fluctuations observed in the CMB are created at

$$\phi_{\rm cmb} = 2\sqrt{N_{\rm cmb}} M_{\rm pl} \sim 15 M_{\rm pl}.$$

Reheating

During inflation most of the energy density in the universe is in the form of the inflaton potential $V(\phi)$. Inflation ends when the potential steepens and the inflaton field picks up kinetic energy. The energy in the inflaton sector then has to be transferred to the particles of the Standard Model. This process is called reheating and starts the Hot Big Bang. We will only have time for a very brief and mostly qualitative description of the absolute basics of the reheating phenomenon. [7] This is non-examinable.

Scalar field oscillations.-After inflation, the inflaton field ϕ begins to oscillate at the bottom of the potential $V(\phi)$, see fig. 2.5. Assume that the potential can be approximated as $V(\phi) = \frac{1}{2}m^2\phi^2$ near the minimum of $V(\phi)$, where the amplitude of ϕ is small. The inflaton is still homogeneous, $\phi(t)$, so its equation of motion is

$$\ddot{\phi} + 3H\dot{\phi} = -m^2\phi.$$

The expansion time scale soon becomes much longer than the oscillation period, $H^{-1} \gg m^{-1}$. We can then neglect the friction term, and the field undergoes oscillations with frequency m. We can write the energy continuity equation as

$$\dot{\rho}_\phi + 3H\rho_\phi = -3HP_\phi = -\frac{3}{2}H\left(m^2\phi^2 - \dot{\phi}^2\right).$$

The r.h.s. averages to zero over one oscillation period. The oscillating field therefore behaves like pressureless matter, with $\rho_\phi \propto a^{-3}$. The fall in the energy density is reflected in a decrease of the oscillation amplitude.

Inflaton decay. - To avoid that the universe ends up empty, the inflaton has to couple to Standard Model fields. The energy stored in the inflaton field will then be transferred into ordinary particles. If the decay is slow (which is the case if the inflaton can only decay into fermions) the inflaton energy density follows the equation

$$\dot{\rho}_\phi + 3H\rho_\phi = -\Gamma_\phi\rho_\phi,$$

where Γ_ϕ parameterizes the inflaton decay rate. If the inflaton can decay into bosons, the decay may be very rapid, involving a mechanism called parametric resonance (sourced by Bose condensation effects). This kind of rapid decay is called preheating, since the bosons thus created are far from thermal equilibrium.

Thermalisation.- The particles produced by the decay of the inflaton will interact, create other particles through particle reactions, and the resulting particle soup will eventually reach thermal

[7] For more details see Baumann, The Physics of Inflation, DAMTP Lecture Notes. equilibrium with some temperature $T_{\rm rh}$. This reheating temperature is determined by the energy density $\rho_{\rm rh}$ at the end of the reheating epoch. Necessarily, $\rho_{\rm rh} < \rho_{\phi,E}$ (where $\rho_{\phi,E}$ is the inflaton energy density at the end of inflation). If reheating takes a long time, we may have $\rho_{\rm rh} \ll \rho_{\phi,E}$. The evolution of the gas of particles into a thermal state can be quite involved. Usually it is just assumed that it happens eventually, since the particles are able to interact. However, it is possible that some particles (such as gravitinos) never reach thermal equilibrium, since their interactions are so weak. In any case, as long as the momenta of the particles are much higher than their masses, the energy density of the universe behaves like radiation regardless of the momentum space distribution. After thermalisation of at least the baryons, photons and neutrinos is complete, the standard Hot Big Bang era begins.

6.3 Thermal History

In this chapter, we will describe the first three minutes [1] in the history of the universe, starting from the hot and dense state following inflation. At early times, the thermodynamical properties of the universe were determined by local equilibrium. However, it are the departures from thermal equilibrium that make life interesting. As we will see, non-equilibrium dynamics allows massive particles to acquire cosmological abundances and therefore explains why there is something rather than nothing. Deviations from equilibrium are also crucial for understanding the origin of the cosmic microwave background and the formation of the light chemical elements.

We will start, in §3.1, with a schematic description of the basic principles that shape the thermal history of the universe. This provides an overview of the story that will be fleshed out in much more detail in the rest of the chapter: in §3.2, will present equilibrium thermodynamics in an expanding universe, while in 3.3, we will introduce the Boltzmann equation and apply it to several examples of non-equilibrium physics. We will use units in which Boltzmann's constant is set equal to unity, $k_{\rm B} \equiv 1$, so that temperature has units of energy.

6.3.1 The Hot Big Bang

The key to understanding the thermal history of the universe is the comparison between the rate of interactions Γ and the rate of expansion H. When $\Gamma \gg H$, then the time scale of particle interactions is much smaller than the characteristic expansion time scale:

$$t_c \equiv \frac{1}{\Gamma} \ll t_H \equiv \frac{1}{H}.$$

Local thermal equilibrium is then reached before the effect of the expansion becomes relevant. As the universe cools, the rate of interactions may decrease faster than the expansion rate. At $t_c \sim t_H$, the particles decouple from the thermal bath. Different particle species may have different interaction rates and so may decouple at different times.

Local Thermal Equilibrium

Let us first show that the condition (3.1.1) is satisfied for Standard Model processes at temperatures above a few hundred GeV. We write the rate of particle interactions as [2]

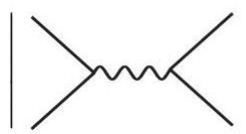
$$\Gamma \equiv n\sigma v$$

where n is the number density of particles, σ is their interaction cross section, and v is the average velocity of the particles. For $T \gtrsim 100\text{GeV}$, all known particles are ultra-relativistic,

[1] A wonderful popular account of this part of cosmology is Weinberg's book The First Three Minutes.

[2] For a process of the form $1+2 \leftrightarrow 3+4$, we would write the interaction rate of species 1 as $\Gamma_1 = n_2\sigma v$, where n_2 is the density of the target species 2 and v is the average relative velocity of 1 and 2. The interaction rate of species 2 would be $\Gamma_2 = n_1\sigma v$. We have used the expectation that at high energies $n_1 \sim n_2 \equiv n.$ and hence $v \sim 1$. Since particle masses can be ignored in this limit, the only dimensionful scale is the temperature T. Dimensional analysis then gives $n \sim T^3$. Interactions are mediated by gauge bosons, which are massless above the scale of electroweak symmetry breaking. The cross sections for the strong and electroweak interactions then have a similar dependence, which also can be estimated using dimensional analysis [3]

$$\sigma \sim \left| \quad \right|^2 \sim \frac{\alpha^2}{T^2},$$



where $\alpha \equiv g_A^2/4\pi$ is the generalized structure constant associated with the gauge boson A. We find that

$$\Gamma = n\sigma v \sim T^3 \times \frac{\alpha^2}{T^2} = \alpha^2 T.$$

We wish to compare this to the Hubble rate $H \sim \sqrt{\rho}/M_{\text{pl}}$. The same dimensional argument as before gives $\rho \sim T^4$ and hence

$$H \sim \frac{T^2}{M_{\text{pl}}^2}.$$

The ratio of (3.1.4) and (3.1.5) is

$$\frac{\Gamma}{H} \sim \frac{\alpha^2 M_{\text{pl}}}{T} \sim \frac{10^{16}\text{GeV}}{T}$$

where we have used $\alpha \sim 0.01$ in the numerical estimate. Below $T \sim 10^{16}$GeV, but above 100 GeV, the condition (3.1.1) is therefore satisfied.

When particles exchange energy and momentum efficiently they reach a state of maximum entropy. It is a standard result of statistical mechanics that the number of particles per unit volume in phase space - the distribution function - then takes the form [4]

$$f(E) = \frac{1}{e^{E/T} \pm 1},$$

where the + sign is for fermions and the - sign for bosons. When the temperature drops below the mass of the particles, $T \ll m$, they become non-relativistic and their distribution function receives an exponential suppression, $f \to e^{-m/T}$. This means that relativistic particles ('radiation') dominate the density and pressure of the primordial plasma. The total energy density is therefore well approximated by summing over all relativistic particles, $\rho_r \propto \sum_i \int \mathrm{d}^3 p f_i(p) E_i(p)$. The result can be written as (see below)

$$\rho_r = \frac{\pi^2}{30} g_\star(T) T^4,$$

where $g_\star(T)$ is the number of relativistic degrees of freedom. Fig. 3.1 shows the evolution of $g_\star(T)$ assuming the particle content of the Standard Model. At early times, all particles are relativistic and $g_\star = 106.75$. The value of $g_\star$ decreases whenever the temperature of the universe drops below the mass of a particle species and it becomes non-relativistic. Today, only photons and (maybe) neutrinos are still relativistic and $g_\star = 3.38$.

[3] Shown in eq. (3.1.3) is the Feynman diagram associated with a $2 \to 2$ scattering process mediated by the exchange of a gauge boson. Each vertex contributes a factor of the gauge coupling $g_A \propto \sqrt{\alpha}$. The dependence of the cross section on α follows from squaring the dependence on α derived from the Feynman diagram, i.e. $\sigma \propto (\sqrt{\alpha} \times \sqrt{\alpha})^2 = \alpha^2$. For more details see the Part III Standard Model course.

[4] The precise formula will include the chemical potential - see below.

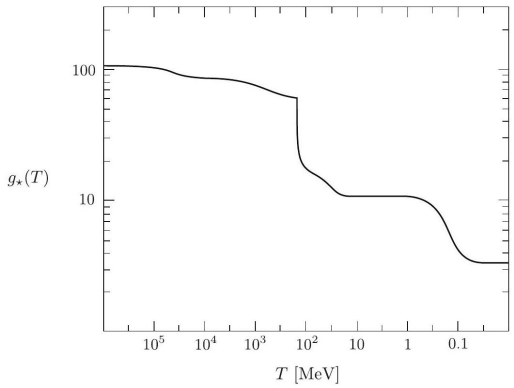


Figure 3.1: Evolution of the number of relativistic degrees of freedom assuming the Standard Model.

Decoupling and Freeze-Out

If equilibrium had persisted until today, the universe would be mostly photons. Any massive particle species would be exponentially suppressed. [5] To understand the world around us, it is therefore crucial to understand the deviations from equilibrium that led to the freeze-out of massive particles (see fig. 3.2).

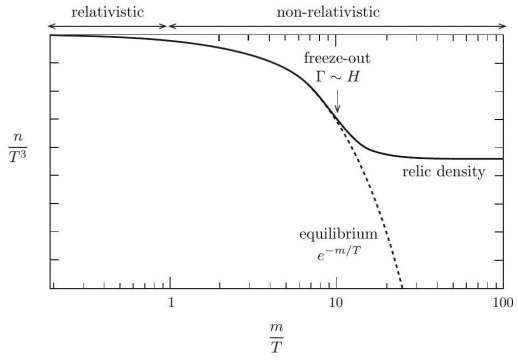

Figure 3.2: A schematic illustration of particle freeze-out. At high temperatures, $T \gg m$, the particle abundance tracks its equilibrium value. At low temperatures, $T \ll m$, the particles freeze out and maintain a density that is much larger than the Boltzmann-suppressed equilibrium abundance.

Below the scale of electroweak symmetry breaking, $T \lesssim 100\text{GeV}$, the gauge bosons of the weak interactions, $W^{\pm}$and Z, receive masses $M_W \sim M_Z$. The cross section associated with

[5] This isn't quite correct for baryons. Since baryon number is a symmetry of the Standard Model, the number density of baryons can remain significant even in equilibrium. processes mediated by the weak force becomes

$$\sigma \sim \left| \quad \times \quad \right|^2 \sim G_F^2 T^2 \ ,$$

where we have introduced Fermi's constant, [6] $G_F \sim \alpha/M_W^2 \sim 1.17 \times 10^{-5}\text{GeV}^{-2}$. Notice that the strength of the weak interactions now decreases as the temperature of the universe drops. We find that

$$\frac{\Gamma}{H} \sim \frac{\alpha^2 M_{\rm pl} T^3}{M_W^4} \sim \left(\frac{T}{1\text{MeV}}\right)^3 ,$$

which drops below unity at $T_{\rm dec} \sim 1\text{MeV}$. Particles that interact with the primordial plasma only through the weak interaction therefore decouple around 1MeV. This decoupling of weak scale interactions has important consequences for the thermal history of the universe.

A Brief History of the Universe

Table 3.1 lists the key events in the thermal history of the universe:

- Baryogenesis. Relativistic quantum field theory requires the existence of anti-particles (see Part III Quantum Field Theory). This poses a slight puzzle. Particles and antiparticles annihilate through processes such as $e^+ + e^- \to \gamma + \gamma$. If initially the universe was filled with equal amounts of matter and anti-matter then we expect these annihilations to lead to a universe dominated by radiation. However, we do observe an overabundance of matter (mostly baryons) over anti-matter in the universe today. Models of baryogenesis try to derive the observed baryon-to-photon ratio

$$\eta \equiv \frac{n_b}{n_\gamma} \sim 10^{-9},$$

from some dynamical mechanism, i.e. without assuming a primordial matter-antimatter asymmetry as an initial condition. Although many ideas for baryogenesis exist, none is singled out by experimental tests. We will not have much to say about baryogenesis in this course.

- Electroweak phase transition. At 100GeV particles receive their masses through the Higgs mechanism. Above we have seen how this leads to a drastic change in the strength of the weak interaction.

- QCD phase transition. While quarks are asymptotically free (i.e. weakly interacting) at high energies, below 150MeV, the strong interactions between the quarks and the gluons become important. Quarks and gluons then form bound three-quark systems, called baryons, and quark-antiquark pairs, called mesons. These baryons and mesons are the relevant degrees of freedom below the scale of the QCD phase transition.

- Dark matter freeze-out. Since dark matter is very weakly interacting with ordinary matter we expect it to decouple relatively early on. In §3.3.2, we will study the example of WIMPs - weakly interacting massive particles that freeze out around 1MeV. We will

[6] The $1/M_W^2$ comes from the low-momentum limit of the propagator of a massive gauge field.

Event	time t	redshift z	temperature T
Inflation	10^{-34} s (?)	–	–
Baryogenesis	?	?	?
EW phase transition	20 ps	10^{15}	100 GeV
QCD phase transition	20 μs	10^{12}	150 MeV
Dark matter freeze-out	?	?	?
Neutrino decoupling	1 s	6×10^9	1 MeV
Electron-positron annihilation	6 s	2×10^9	500 keV
Big Bang nucleosynthesis	3 min	4×10^8	100 keV
Matter-radiation equality	60 kyr	3400	0.75 eV
Recombination	260–380 kyr	1100–1400	0.26–0.33 eV
Photon decoupling	380 kyr	1000–1200	0.23–0.28 eV
Reionization	100–400 Myr	11–30	2.6–7.0 meV
Dark energy-matter equality	9 Gyr	0.4	0.33 meV
Present	13.8 Gyr	0	0.24 meV

Table 3.1: Key events in the thermal history of the universe.

show that choosing natural values for the mass of the dark matter particles and their interaction cross section with ordinary matter reproduces the observed relic dark matter density surprisingly well.

- Neutrino decoupling. Neutrinos only interact with the rest of the primordial plasma through the weak interaction. The estimate in (3.1.10) therefore applies and neutrinos decouple at 0.8MeV.

- Electron-positron annihilation. Electrons and positrons annihilate shortly after neutrino decoupling. The energies of the electrons and positrons gets transferred to the photons, but not the neutrinos. In §3.2.4, we will explain that this is the reason why the photon temperature today is greater than the neutrino temperature.

- Big Bang nucleosynthesis. Around 3 minutes after the Big Bang, the light elements were formed. In §3.3.4, we will study this process of Big Bang nucleosynthesis (BBN).

- Recombination. Neutral hydrogen forms through the reaction $e^- + p^+ \to \mathrm{H} + \gamma$ when the temperature has become low enough that the reverse reaction is energetically disfavoured. We will study recombination in §3.3.3. - Photon decoupling. Before recombination the strongest coupling between the photons and the rest of the plasma is through Thomson scattering, $e^- + \gamma \to e^- + \gamma$. The sharp drop in the free electron density after recombination means that this process becomes inefficient and the photons decouple. They have since streamed freely through the universe and are today observed as the cosmic microwave background (CMB).

In the rest of this chapter we will explore in detail where this knowledge about the thermal history of the universe comes from.

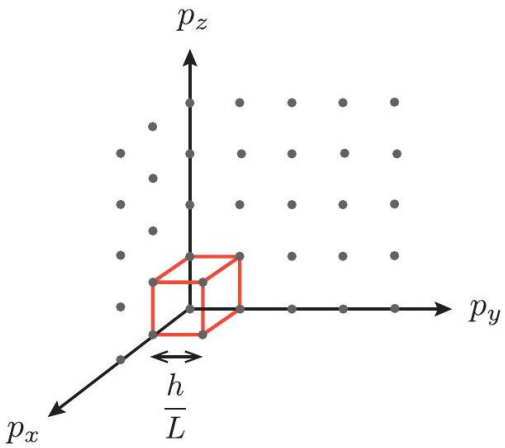
6.3.2 Equilibrium

Equilibrium Thermodynamics

We have good observational evidence (from the perfect blackbody spectrum of the CMB) that the early universe was in local thermal equilibrium. [7] Moreover, we have seen above that the Standard Model predicts thermal equilibrium above 100GeV. To describe this state and the subsequent evolution of the universe, we need to recall some basic facts of equilibrium thermodynamics, suitably generalized to apply to an expanding universe.

Microscopic to Macroscopic

Statistical mechanics is the art of turning microscopic laws into an understanding of the macroscopic world. I will briefly review this approach for a gas of weakly interacting particles. It is convenient to describe the system in phase space, where the gas is described by the positions and momenta of all particles. In quantum mechanics, the momentum eigenstates of a particle in a volume $V = L^3$ have a discrete spectrum:



The density of states in momentum space $\{\boldsymbol{p}\}$ then is $L^3/h^3 = V/h^3$, and the state density in phase space $\{\boldsymbol{x}, \boldsymbol{p}\}$ is

$$\frac{1}{h^3}.$$

If the particle has g internal degrees of freedom (e.g. spin), then the density of states becomes

$$\frac{g}{h^3} = \frac{g}{(2\pi)^3},$$

[7] Strictly speaking, the universe can never truly be in equilibrium since the FRW spacetime doesn't posses a time-like Killing vector. But this is physics not mathematics: if the expansion is slow enough, particles have enough time to settle close to local equilibrium. (And since the universe is homogeneous, the local values of thermodynamics quantities are also global values.)

where in the second equality we have used natural units with $\hbar = h/(2\pi) \equiv 1$. To obtain the number density of a gas of particles we need to know how the particles are distributed amongst the momentum eigenstates. This information is contained in the (phase space) distribution function $f(\boldsymbol{x}, \boldsymbol{p}, t)$. Because of homogeneity, the distribution function should, in fact, be independent of the position $\boldsymbol{x}$. Moreover, isotropy requires that the momentum dependence is only in terms of the magnitude of the momentum $p \equiv |\boldsymbol{p}|$. We will typically leave the time dependence implicitit will manifest itself in terms of the temperature dependence of the distribution functions. The particle density in phase space is then the density of states times the distribution function

$$\frac{g}{(2\pi)^3} \times f(p).$$

The number density of particles (in real space) is found by integrating (3.2.14) over momentum,

$$n = \frac{g}{(2\pi)^3} \int \mathrm{d}^3 p f(p).$$

To obtain the energy density of the gas of particles, we have to weight each momentum eigenstate by its energy. To a good approximation, the particles in the early universe were weakly interacting. This allows us to ignore the interaction energies between the particles and write the energy of a particle of mass m and momentum p simply as

$$E(p) = \sqrt{m^2 + p^2}.$$

Integrating the product of (3.2.16) and (3.2.14) over momentum then gives the energy density

$$\rho = \frac{g}{(2\pi)^3} \int \mathrm{d}^3 p f(p) E(p).$$

Similarly, we define the pressure as

$$P = \frac{g}{(2\pi)^3} \int \mathrm{d}^3 p f(p) \frac{p^2}{3E}$$

Pressure. *-Let me remind you where the $p^2/3E$ factor in (3.2.18) comes from. Consider a small area element of size $\mathrm{d}A$, with unit normal vector $\hat{\boldsymbol{n}}$ (see fig. 3.3). All particles with velocity $|\boldsymbol{v}|$, striking this area element in the time interval between t and $t + \mathrm{d}t$, were located at $t = 0$ in a spherical shell of radius $R = |\boldsymbol{v}|t$ and width $|\boldsymbol{v}|\mathrm{d}t$. A solid angle $\mathrm{d}\Omega^2$ of this shell defines the volume $\mathrm{d}V = R^2 |\boldsymbol{v}| \mathrm{d}t \, \mathrm{d}\Omega^2$ (see the grey shaded region in fig. 3.3). Multiplying the phase space density (3.2.14) by $\mathrm{d}V$ gives the number of particles in the volume (per unit volume in momentum space) with energy $E(|\boldsymbol{v}|)$,

$$\mathrm{d}N = \frac{g}{(2\pi)^3} f(E) \times R^2 |\boldsymbol{v}| \mathrm{d}t \, \mathrm{d}\Omega.$$

Not all particles in $\mathrm{d}V$ reach the target, only those with velocities directed to the area element. Taking into account the isotropy of the velocity distribution, we find that the total number of particles striking the area element $\mathrm{d}A\hat{\boldsymbol{n}}$ with velocity $\boldsymbol{v} = |\boldsymbol{v}|\hat{\boldsymbol{v}}$ is

$$\mathrm{d}N_A = \frac{|\hat{\boldsymbol{v}}\cdot\hat{\boldsymbol{n}}|\mathrm{d}A}{4\pi R^2}\times \mathrm{d}N = \frac{g}{(2\pi)^3}f(E)\times\frac{|\boldsymbol{v}\cdot\hat{\boldsymbol{n}}|}{4\pi}\mathrm{d}A\ \mathrm{d}t\ \mathrm{d}\Omega,$$

where $\boldsymbol{v}\cdot\hat{\boldsymbol{n}}<0$. If these particles are reflected elastically, each transfer momentum $2|\boldsymbol{p}\cdot\hat{\boldsymbol{n}}|$ to the target. Therefore, the contribution of particles with velocity $|\boldsymbol{v}|$ to the pressure is

$$\mathrm{d}P(|\boldsymbol{v}|) = \int \frac{2|\boldsymbol{p}\cdot\hat{\boldsymbol{n}}|}{\mathrm{d}A\ \mathrm{d}t}\ \mathrm{d}N_A = \frac{g}{(2\pi)^3}f(E)\times\frac{p^2}{2\pi E}\int\cos^2\theta\sin\theta\mathrm{d}\theta\mathrm{d}\phi = \frac{g}{(2\pi)^3}\times f(E)\frac{p^2}{3E},$$

where we have used $|\boldsymbol{v}| = |\boldsymbol{p}|/E$ and integrated over the hemisphere defined by $\hat{\boldsymbol{v}}\cdot\hat{\boldsymbol{n}}\equiv-\cos\theta<0$ (i.e. integrating only over particles moving towards $\mathrm{d}A$ - see fig. 3.3). Integrating over energy E (or momentum p), we obtain (3.2.18).

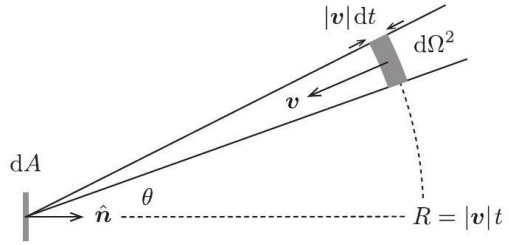


Figure 3.3: Pressure in a weakly interacting gas of particles.

Local Thermal Equilibrium

A system of particles is said to be in kinetic equilibrium if the particles exchange energy and momentum efficiently. This leads to a state of maximum entropy in which the distribution functions are given by the Fermi-Dirac and Bose-Einstein distributions [8]

$$f(p) = \frac{1}{e^{(E(p)-\mu)/T}\pm 1},$$

where the + sign is for fermions and the - sign for bosons. At low temperatures, $T<E-\mu$, both distribution functions reduce to the Maxwell-Boltzmann distribution

$$f(p)\approx e^{-(E(p)-\mu)/T}.$$

The equilibrium distribution functions have two parameters: the temperature T and the chemical potential μ. The chemical potential may be temperature-dependent. As the universe expands, T and $\mu(T)$ change in such a way that the continuity equations for the energy density ρ and the particle number density n are satisfied. Each particle species i (with possibly distinct m_i, μ_i, T_i) has its own distribution function f_i and hence its own n_i, ρ_i, and P_i.

Chemical potential.* - In thermodynamics, the chemical potential characterizes the response of a system to a change in particle number. Specifically, it is defined as the derivative of the entropy with respect to the number of particles, at fixed energy and fixed volume,

$$\mu = -T\left(\frac{\partial S}{\partial N}\right)_{U,V}.$$

[8] We use units where Boltzmann's constant is $k_\mathrm{B}\equiv 1$.

6.3.3 Isotropic Space by Landau

вкратце

Theory

Требования, поставленные в $93 в качестве условий для определения действия гравитационного поля, будут по-прежнему удовлетворены, если к скаляру G добавить постоянный член, т. е. если положить

$$S_g = -\frac{c^3}{16\pi k}\int (G + 2\Lambda)\sqrt{-g}d\Omega$$

где Λ - новая постоянная (с размерностью см $^{-2}$).

Такое изменение приведет к появлению в уравнениях Эйнштейна дополнительного члена Λg_{ik}:

$$R_{ik} - \frac{1}{2}Rg_{ik} = \frac{8\pi k}{c^4}T_{ik} + \Lambda g_{ik}$$

Если приписать «космологической постоянной» Λ очень малое значение, то наличие этого члена не будет сказываться существенным образом на гравитационных полях в не слишком больших областях пространства-времени, но приведет к появлению новых типов «космологических решений», которые могли бы описывать мир в целом.

В настоящее время, однако, нет никаких настоятельных и убедительных оснований - как наблюдательных, так и теоретических для такого видоизменения основных уравнений теории.

(?? да??)

Подчеркнем, что речь шла бы об изменении, имеющем глубокий физический смысл: введение в плотность лагранжевой функции постоянного члена, вообще не зависящего от состояния поля, означало бы приписывание пространству-времени принципиально неустранимой кривизны, не связанной ни с материей, ни с гравитационными волнами.

Все дальнейшее изложение в этой главе основано поэтому на уравнениях Эйнштейна в их виде без космологической постоянной.

Как известно, звезды распределены по пространству весьма неравномерным образом - они сконцентрированы в отдельных звездных системах (галактиках).

Но при исследовании Вселенной «в больших масштабах» следует отвлекаться от «местныХ» неоднородностей, вызванных скоПлением вещества в звезды и звездные системы.

Так, под плотностью масс должна подразумеваться плотность, усредненная по областям пространства, размеры которых велики по сравнению с расстояниями между галактиками.

Рассматриваемые ниже решения уравнений Эйнштейна - так называемая изотропная космологическая модель Фридмана - основаны на предположении об однородности и изотропии распределения вещества по пространству.

Существующие астрономические данные не противоречат такому предположению,

и в настоящее время есть все основания считать,

что изотропная модель дает в общих чертах адекватное описание не только современного состояния Вселенной,

но и значительной доли ее эволюции в прошлом.

Мы увидим ниже, что основным свойством этой модели является ее нестационарность.

Нет сомнения в том, что это свойство («расширяющаяся Вселенная») дает правильное объяснение фундаментального для космологической проблемы явления красного смещения ($ 114).

В то же время ясно, что предположение об однородности и изотропии Вселенной уже по самому своему существу неизбежно может иметь лишь приближенный характер, поскольку эти свойства заведомо нарушаются при переходе к меньшим масштабам.

К вопросу о возможной роли неоднородности Вселенной в различных аспектах космологической проблемы мы вернемся в \$115 – \$119.

Однородность и изотропия пространства означают, что можно выбрать такое мировое время, чтобы в каждый его момент метрика пространства была одинаковой во всех точках и по всем направлениям.

Займемся прежде всего изучением метрики изотропного пространства как таковой, не интересуясь пока его возможной зависимостью от времени.

Скалярная кривизна

Как мы уже делали выше, обозначим трехмерный метрический тензор как $\gamma_{\alpha\beta}$, т. е. напишем элемент пространственного расстояния в виде

$$dl^2 = \gamma_{\alpha\beta} dx^\alpha dx^\beta$$

Кривизна пространства полностью определяется его трехмерным тензором кривизны, который мы обозначаем как $P_{\alpha\beta\gamma\delta}$, в отличие от четырехмерного тензора R_{iklm}. В случае полной изотропии тензор $P_{\alpha\beta\gamma\delta}$ должен, очевидно, выражаться только через метрический тензор $\gamma_{\alpha\beta}$, а потому в силу своих свойств симметрии должен иметь вид

$$P_{\alpha\beta\gamma\delta} = \lambda \left(\gamma_{\alpha\gamma}\gamma_{\beta\delta} - \gamma_{\alpha\delta}\gamma_{\beta\gamma}\right)$$

где λ - постоянная.

Тензор Риччи $P_{\alpha\beta} = P^\gamma_{\alpha\gamma\beta}$ равен соответственно

$$P_{\alpha\beta} = 2\lambda\gamma_{\alpha\beta}$$

а скалярная кривизна

$$P = 6\lambda$$

Таким образом, свойства кривизны изотропного пространства определяются лишь одной постоянной.

Три типа метрики

Соответственно этому возможны всего три существенных различных случая пространственной метрики

1) так называемое пространство постоянной положительной кривизны (при $\lambda > 0$),

2) пространство постоянной отрицательной кривизны (при $\lambda < 0$) и

3) пространство с кривизной, равной нулю ($\lambda = 0$).

Из них последнее представляет собой плоское, т.

е.

евклидово пространство.

При изучении метрики удобно исходить из геометрической аналогии,

рассматривая геометрию изотропного трехмерного пространства как геометрию на заведомо изотропной гиперповерхности (в некотором фиктивном четырехмерном пространстве).

Такой поверхностью является гиперсфера; соответствующее ей трехмерное пространство и является пространством положительной постоянной кривизны.

Уравнение гиперсферы с радиусом a в четырехмерном пространстве x_1, x_2, x_3, x_4 имеет вид

$$x_1^2 + x_2^2 + x_3^2 + x_4^2 = a^2$$

а элемент длины на ней выражается как

$$dl^2 = dx_1^2 + dx_2^2 + dx_3^2 + dx_4^2$$

Рассматривая координаты x_1, x_2, x_3 как три пространственные координаты и исключая из dl^2 фиктивную координату x_4 с помощью первого уравнения,

находим элемент пространственного расстояния в виде

$$dl^2 = dx_1^2 + dx_2^2 + dx_3^2 + \frac{(x_1 dx_1 + x_2 dx_2 + x_3 dx_3)^2}{a^2 - x_1^2 - x_2^2 - x_3^2}$$

Из этого выражения легко вычислить постоянную λ В (111.2).

Поскольку нам заранее известно, что тензор $P_{\alpha\beta}$ имеет вид (111.3)

во всем пространстве, то достаточно вычислить его только для точек, находящихся вблизи начала координат, где $\gamma_{\alpha\beta}$ равны

$$\gamma_{\alpha\beta} = \delta_{\alpha\beta} + \frac{x_\alpha x_\beta}{a^2}$$

Так как первые производные от $\gamma_{\alpha\beta}$, а значит, и величины $\lambda^\alpha_{\beta\gamma}$ (ср.

задачу 1 §88) - трехмерные символы Кристоффеля, соответствующие метрике $\gamma_{\alpha\beta}$, - в начале координат обращаются в нуль, то вычисление по общей формуле (92.7) оказывается очень простым и дает в результате

$$\lambda = \frac{1}{a^2}$$

Величину a можно назвать «радиусом кривизны» пространства.

Введем вместо координат x_1, x_2, x_3 соответствующие им «сферические» координаты r, θ, φ. Тогда элемент длины примет вид

$$dl^2 = \frac{dr^2}{1 - \frac{r^2}{a^2}} + r^2 \left(\sin^2\theta d\varphi^2 + d\theta^2\right)$$

Начало координат может быть выбрано в любой точке пространства.

Длина окружности в этих координатах равна $2\pi r$, а поверхность сферы $4\pi r^2$. Длина же «радиуса» окружности (или сферы) равна

$$\int_0^r \frac{dr}{\sqrt{1 - \frac{r^2}{a^2}}} = a \arcsin\frac{r}{a}$$

т.

е.

больше r. Таким образом, отношение длины окружности к радиусу в таком пространстве меньше, чем 2π.

Другую удобную форму dl^2 имеет в «четырехмерных сферических координатах»,

получающихся, если ввести вместо координаты r «угол» χ согласно $r = a\sin\chi$(χменяется в предел

Тогда

$$dl^2 = a^2\left[d\chi^2 + \sin^2\chi\left(\sin^2\theta d\varphi^2 + d\theta^2\right)\right]$$

Координата χ измеряет расстояние от начала координат, равное $a\chi$. Поверхность сферы в этих координатах равна $4\pi a^2 \sin^2\chi$. Мы видим, что по мере удаления от начала координат величина поверхности сферы увеличивается, пока не достигнет на расстоянии $\pi a/2$ максимального значения, равного $4\pi a^2$. Вслед за этим она начинает уменьшаться, пока не превратится в точку на «противоПоложном полюсе» простран-

ства на расстоянии πa - наибольшем расстоянии, которое вообще может существовать в таком пространстве (все это видно, конечно, И из (111.7), если заметить, что координата r не может принимать значений больших, чем a).

Объем пространства с положительной кривизной равен

$$V = \int_0^{2\pi}\int_0^{\pi}\int_0^{\pi} a^3 \sin^2\chi \sin\theta d\chi d\theta d\varphi$$

откуда

$$V = 2\pi^2 a^3$$

Таким образом, пространство положительной кривизны оказывается «замкнутым само в себе» - конечным по объему,

но, разумеется, не имеющим границ.

Интересно отметить, что в замкнутом пространстве полный электрический заряд должен быть равен нулю.

Действительно, всякая замкнутая поверхность в конечном пространстве с обеих своих сторон охватывает конечные же области пространства.

Поэтому поток электрического поля через эти поверхности равен, с одной стороны, полному заряду, находящемуся внутри поверхности, а с другой, равен находящемуся вне ее заряду, взятому с обратным знаком.

Сумма же зарядов с обеих сторон поверхности равна, следовательно,

нулю.

Аналогичным образом, из выражения (96.16) 4-импульса в виде интеграла по поверхности следует обращение в нуль полного 4-импульса P^i во всем пространстве.

Пространство постоянной отрицательной кривизны

Перейдем теперь к рассмотрению геометрии пространства,

обладающего постоянной отрицательной кривизной.

$_3$(111.6) мы видим, что постоянная λ становится отрицательной, если a мнимо.

Поэтому все формулы для пространства отрицательной кривизны можно непосредственно получить из предыдущих, заменив в них a на ia.

Другими словами, геометрия пространства отрицательной кривизны получается математически как геометрия на четырехмерной псевдосфере с мнимым радиусом.

Таким образом, постоянная λ равна теперь

$$\lambda = -\frac{1}{a^2}$$

а элемент длины в пространстве отрицательной кривизны в координатах r, θ, φ имеет вид

$$dl^2 = \frac{dr^2}{1+\frac{r^2}{a^2}} + r^2\left(\sin^2\theta d\varphi^2 + d\theta^2\right)$$

где координата r может пробегать все значения от 0 до ∞.

Отношение длины окружности к радиусу теперь больше, чем 2π. Выражение

Для dl^2, соответствующее (111.8), получится,

если ввести координату χ согласно $r = a\,\mathrm{sh}\,\chi$(χ меняется здесь от 0 до ∞).

Тогда

$$dl^2 = a^2\left\{d\chi^2 + \mathrm{sh}^2\chi\left(\sin^2\theta d\varphi^2 + d\theta^2\right)\right\}$$

Поверхность сферы равна теперь $4\pi a^2\mathrm{sh}^2\chi$ при удалении от начала координат (увеличении χ) возрастает неограниченно.

Объем пространства отрицательной кривизны, очевидно, бесконечен.

получение конформино-евклидовых координат

Преобразовать элемент длины

$$dl^2 = dr^2\left(1 - \frac{r^2}{a^2}\right) + r^2\left(\sin^2\theta d\varphi^2 + d\theta^2\right)$$

к виду, в котором он был бы пропорционален своему евклидову выражению (конформно-евклидовы координаты).

Ре ш е н и е.

Подстановка

$$r = \frac{r_1}{1 + \frac{r_1^2}{4a^2}}$$

приводит к результату:

$$dl^2 = \left(1 + \frac{r_1^2}{4a^2}\right)^{-2}\left(dr_1^2 + r_1^2 d\theta^2 + r_1^2\sin^2\theta d\varphi^2\right)$$

и кстати, это важно, это отвечает на вопрос, можно ли было бы заменить как-то координаты, чтобы убрать особенности.

какой-то такой там важный вопрос, Володя говорил.

6.3.4 Closed Isotropic Model by Landau

вкратце

Theory

Переходя к исследованию пространственно-временной метрики изотропной модели, мы должны прежде всего условиться о выборе системы отсчета.

Наиболее удобна «сопутствующая» система отсчета, Движущаяся в каждой точке пространства вместе с находящимся В ней веществом.

Другими словами, системой отсчета является сама заполняющая пространство материя; скорость вещества в этой системе По определению равна везде нулю.

Очевидно, что такой выбор системы отсчета для изотропной модели естествен: при другом выборе направленность скоростей материи создавала бы кажущуюся неэквивалентность различных направлений в пространстве.

Временная координата должна быть выбрана указанным в начале предыдущего параграфа образом, т.е. так, чтобы в каждый данный момент времени метрика во всем пространстве была одинаковой.

Ввиду полной эквивалентности всех направлений, компоненты $g_{0\alpha}$ метрического тензора в выбранной нами системе отсчета равны нулю.

Действительно, три компоненты $g_{0\alpha}$ можно рассматривать как Компоненты трехмерного вектора, который, будучи отличен от нуля, создавал бы неравноценность различных направлений.

Таким образом, ds^2 должно иметь вид $ds^2 = g_{00}\left(dx^0\right)^2 - dl^2$. Компонента g_{00} является здесь функцией только от x^0. Поэтому можно всегда выбрать временную координату так, чтобы g_{00} обратилось в 1.

Обозначая ее через ct, имеем

$$ds^2 = c^2dt^2 - dl^2$$

Переменная t является синхронным собственным временем в каждой точке пространства.

Начнем с рассмотрения пространства положительной кривизны ниже мы будем для краткости говорить о соответствующем решении уравнений Эйнштейна как о закрытой модели.

Для dl воспользуемся выражением (111.8), в котором радиус кривизны a является, вообще говоря, функцией времени.

Таким образом, ds^2 пишем в виде

$$ds^2 = c^2dt^2 - a^2(t)\left\{d\chi^2 + \sin^2\chi\left(d\theta^2 + \sin^2\theta d\varphi^2\right)\right\}$$

Функция $a(t)$ определяется уравнениями Эйнштейна.

Для решения этих уравнений удобно воспользоваться вместо времени величиной η, определяемой соотношением

$$cdt = ad\eta$$

Тогда ds^2 напишется в виде

$$ds^2 = a^2(\eta)\left\{d\eta^2 - d\chi^2 - \sin^2\chi\left\{d\theta^2 + \sin^2\theta d\varphi^2\right)\right\}$$

Для составления уравнений поля надо начать с вычисления компонент тензора R_{ik} (координатами x^0, x^1, x^2, x^3 являются $\eta, \chi, \theta, \varphi$). С помощью значений компонент метрического тензора

$$g_{00} = a^2, \quad g_{11} = -a^2, \quad g_{22} = -a^2\sin^2\chi, \quad g_{33} = -a^2\sin^2\chi\sin^2\theta$$

вычисляем величины Γ^i_{kl} :

$$\Gamma^0_{00} = \frac{a'}{a}, \quad \Gamma^0_{\alpha\beta} = -\frac{a'}{a^3}g_{\alpha\beta}, \quad \Gamma^\alpha_{0\beta} = \frac{a'}{a}\delta^\alpha_\beta, \quad \Gamma^0_{\alpha 0} = \Gamma^\alpha_{00} = 0$$

гДе Штрих означает дифференцирование по η (компоненты $\Gamma^\alpha_{\beta\gamma}$ нет надобности вычислять в явном виде).

С помощью этих значений по общей формуле (92.7) получим:

$$R^0_0 = \frac{3}{a^4}\left(a'^2 - aa''\right)$$

Из тех же соображений симметрии, которые были применены выше К $g_{0\alpha}$, заранее очевидно, что компоненты $R_{0\alpha} = 0$. Для вычисления же компонент R^β_α замечаем, что если выделить в них члены, содержащие только $g_{\alpha\beta}$ (т.

е.

только $\Gamma^\alpha_{\beta\gamma}$), то эти члены должны составить компоненты трехмерного тензора $-P^\beta_\alpha$, значения которых заранее известны из (111.3) и (111.6)

$$R^\beta_\alpha = -P^\beta_\alpha + \ldots = -\frac{2}{a^2}\delta^\beta_\alpha + \ldots$$

гДе многоточие подразумевает члены, содержащие наряду с $g_{\alpha\beta}$ также и g_{00}. В результате вычисления последних получим:

$$R^\beta_\alpha = -\frac{1}{a^4}\left(2a^2 + a^2 + aa''\right)\delta^\beta_\alpha$$

Н 3аТеМ

$$R = R^0_0 + R^\alpha_\alpha = -\frac{6}{a^3}\left(a + a''\right)$$

Поскольку в выбранной нами системе отсчета материя неподвижна, то $u^\alpha = 0, u^0 = 1/a$ и из (94.9) имеем $T^0_0 = \varepsilon$, где ε - плотность энергиИ материи.

Подставляя полученные выражения в уравнение

$$R^0_0 - \frac{1}{2}R = \frac{8\pi k}{c^4}T^0_0$$

получИм:

$$\frac{8\pi k}{c^4}\varepsilon = \frac{3}{a^4}\left(a^2 + a^{22}\right)$$

Сюда входят две неизвестные функции ε и a; поэтому необходимо получить еще одно уравнение.

В качестве него удобно выбрать (вместо пространственных компонент уравнений Эйнштейна) уравнение $T^i_{0:i} = 0$ - одно из четырех уравнений (94.7), содержашихся, как мы знаем, в уравнениях поля.

Это уравнение можно вывести и непосредственно с помощью термодинамических соотношений следующим образом.

Пользуясь в уравнениях поля выражением (94.9) ДлЯ тензора энергиИ-импульса, мы тем самым пренебрегаем всеми процессами диссипации энергии,

приводящими к возрастанию энтропии.

Такое пренебрежение, разумеется, здесь вполне законно, поскольку дополнительные члены, которые надо было бы прибавить к T^i_k в связи с диссипаЦией энергии,

ничтожно малы по сравнению с плотностью энергии ε,

включающей в себя энергию покоя материальных тел.

Таким образом, при выводе уравнений поля мы можем считать полную энтропию постоянной.

Воспользуемся теперь известным термодинамическим соотношением $d\mathscr{E} = TdS - pdV$, где $\mathscr{E}, S, V$ - энергия, энтропия и объем системы, а p, T - давление и температура.

При постоянной энтропии имеем просто $d\mathscr{E} = -pdV$. Вводя плотность энергии $\varepsilon = \mathscr{E}/V$, без труда находим:

$$d\varepsilon = -(\varepsilon + p)\frac{dV}{V}$$

Объем пространства V пропорционален, согласно (111.9), кубу радиуса кривизны a. Поэтому $dV/V = 3da/a = 3d\ln a$ и мы можем написать:

$$-\frac{d\varepsilon}{\varepsilon + p} = 3d\ln a$$

или, интегрируя,

$$3\ln a = -\int \frac{d\varepsilon}{p + \varepsilon} + \text{const}$$

(нижний предел в интеграле постоянен).

Если связь между ε и p (уравнение состояния материи) известна, то уравнение (112.6) определяет ε как функцию от a. Тогда из (112.5) мы можем определить η в виде

$$\eta = \pm\int \frac{da}{a\sqrt{\frac{8\pi k}{3c^4}\varepsilon a^2 - 1}}$$

Уравнения (112.6) – (112.7) решают в общем виде задачу об определении метрики в изотропной закрытой модели.

Если материя распределена в пространстве в виде отдельных макроскопических тел, то при определении создаваемого ею гравитационного поля мы можем рассматривать эти тела как материальные частицы,

обладающие определенными массами, не интересуясь вовсе их внутренним строением.

Считая скорости тел сравнительно малыми (малыми по сравнению с c), можно положить просто $\varepsilon = \mu c^2$, где μ - сумма масс тел, отнесенная к единице объема.

По той же причине давление «газа», состоящего из этих тел, крайне мало по сравнению с ε и им можно пренебречь (давления же внутри тел,

согласно сказанному, не имеют отношения к рассматриваемому вопросу).

Что касается имеющегося в пространстве излучения, то его количество относительно мало и его энергией и давлением тоже можно пренебречь.

Таким образом, для описания в терминах рассматриваемой модели современного состояния Вселенной следует пользоваться уравнением состояния «пылевидной» материи

$$\varepsilon = \mu c^2, \quad p = 0$$

Интегрирование в (112.6) дает тогда $\mu a^3 = \text{const}$.

Это равенство можно было бы написать и сразу,

так как оно выражает собой просто постоянство суммы M масс тел во всем пространстве, как и должно было быть в рассматриваемом случае пылевидной материи.

Поскольку объем пространства в замкнутой модели равен $V = 2\pi^2 a^3$, То $\text{const} = M/2\pi^2$. Таким образом,

$$\mu a^3 = \text{const} \ = \frac{M}{2\pi^2}$$

Подставив (112.8) в уравнение (112.7) и произведя интегрирование, получим:

$$a = a_0(1 - \cos\eta)$$

где постоянная

$$a_0 = \frac{2kM}{3\pi c^2}$$

Наконец, для связи между t и η находим из (112.3):

$$t = \frac{a_0}{c}(\eta - \sin\eta)$$

Уравнения (112.9)−(112.10) определяют в параметрическом виде зависимость $a(t)$. Функция $a(t)$ возрастает от нуля при $t = 0(\eta = 0)$ до максимального значения $a = 2a_0$, достигаемого при $t = \pi a_0/c(\eta = \pi)$, и затем снова убывает до нуля при $t = 2\pi a_0/c(\eta = 2\pi)$. При $\eta \ll 1$ имеем приближенно $a = a_0\eta^2/2, t = a_0\eta^3/6c$, так что

$$a \approx \left(\frac{9a_0c^2}{2}\right)^{1/3} t^{2/3}$$

При этом плотность вещества

$$\mu = \frac{1}{6\pi k t^2} = \frac{8 \cdot 10^5}{t^2}$$

(численное значение коэффициента дано для плотности в г $\cdot$ см $^{-3}$ при t в секундах).

Обратим внимание на то, что в этом пределе зависимость $\mu(t)$ имеет универсальный характер в том смысле, что не зависит от параметра a_0.

При $a \to 0$ плотность μ обращается в бесконечность.

Но при $\mu \to \infty$ давление тоже становится большим, и потому для исследования метрики в этой области надо рассмотреть противоположный случай наибольшего возможного (при данной плотности энергии ε) давления, т. е. описывать материю уравнением состояния

$$p = \frac{\varepsilon}{3}$$

(см. примечание на с. 119).

Из формулы (112.6) получим тогда

$$\varepsilon a^4 = \text{const} \ \equiv \frac{3c^4 a_1^2}{8\pi k}$$

(a_1- новая постоянная), после чего уравнения (112.3) и приводят к зависимости

$$a = a_1 \sin\eta, \quad t = \frac{a_1}{c}(1 - \cos\eta)$$

Поскольку это решение имеет смысл рассматривать только при очень больших значениях ε (т. е. малых a), то положим $\eta \ll 1$. Тогда $a \approx a_1\eta$, $t \approx a_1\eta^2/2c$, так что

$$a = \sqrt{2a_1 ct}$$

При этом

$$\frac{\varepsilon}{c^2} = \frac{3}{32\pi k t^2} = \frac{4.5 \cdot 10^5}{t^2}$$

(эта зависимость снова не содержит никаких параметров).

Таким образом, и здесь $a \to 0$ при $t \to 0$, так что значение $t = 0$ действительно является особой точкой пространственно-временной метрики изотропной модели (и то же самое относится к закрытой модели и ко второй точке, в которой $a = 0$).

Мы видим также из (112.14), что при изменении знака t величина $a(t)$ сделалась бы мнимой, а ее квадрат - отрицательным.

Все четыре компоненты g_{ik} в (112.2) стали бы при этом положительными, так же как и определитель g. Но такая метрика физически бессмысленна.

Это значит, что не имеет физического смысла аналитически продолжать метрику за особую точку.

6.3.5 Open Isotropic Model by Landau

вкратце

В открытой изотропной модели метрика имеет вид:

$$ds^2 = c^2dt^2 - a^2(t)\left\{d\chi^2 + \mathrm{sh}^2\,\chi\left(d\theta^2 + \sin^2\theta d\varphi^2\right)\right\}$$

актуальность и применения открытой изотропной модели

хз, насколько нужна она?

Theory

Решение, соответствующее изотропному пространству отрицательной кривизны (открытая модель), получается вполне аналогично предыдущему.

Рассмотрим метрику вида

$$ds^2 = c^2dt^2 - a^2(t)\left\{d\chi^2 + \mathrm{sh}^2\,\chi\left(d\theta^2 + \sin^2\theta d\varphi^2\right)\right\}$$

Вводим снова вместо t переменную η согласно $cdt = ad\eta$; тогда получаем:

$$ds^2 = a^2(\eta)\left\{d\eta^2 - d\chi^2 - \mathrm{sh}^2\,\chi\left(d\theta^2 + \sin^2\theta d\varphi^2\right)\right\}$$

Это выражение может быть формально получено из (112.4) заменой η, χ, a соответственно на $i\eta, i\chi$, ia.

Поэтому и уравнения поля можно получить просто путем этой же замены из (112.5) – (112.6). Уравнение (112.6) сохраняет при этом свой прежний вид:

$$3\ln a = | - \int \frac{d\varepsilon}{\varepsilon + p} + \mathrm{const}$$

а вместо (112.5) имеем:

$$\frac{8\pi k}{c^4}\varepsilon = \frac{3}{a^4}\left(a'^2 - a^2\right)$$

Соответственно этому находим вместо (112.7)

$$\eta = \pm \int \frac{da}{a\sqrt{\frac{8\pi k}{3c^4}\varepsilon a^2 + 1}}$$

Для пылевидной материи получаем отсюда:

$$a = a_0(\operatorname{ch}\eta - 1), \quad t = \frac{a_0}{c}(\operatorname{sh}\eta - \eta)$$

$$\mu a^3 = \frac{3c^2}{4\pi k}a_0$$

Формулы (113.6) определяют в параметрическом виде зависимость $a(t)$. В отличие от замкнутой модели, здесь радиус кривизны меняется монотонно, возрастая от нуля при $t = 0(\eta = 0)$ до бесконечности при $t \to \infty$ ($\eta \to \infty$). Плотность же материи, соответственно, монотонно убывает от бесконечного значения при $t = 0$ (при $\eta \ll 1$ закон этого убывания дается той же приближенной формулой (112.12), что и в закрытой модели).

Для больших плотностей решение (113.6)−(113.7) неприменимо, и надо снова обратиться к случаю $p = \varepsilon/3$. При этом снова получается

$$\varepsilon a^4 = \text{const} \equiv \frac{3c^4 a_1^2}{8\pi k}$$

а для зависимости $a(t)$ находим:

$$a = a_1 \operatorname{sh}\eta, \quad t = \frac{a_1}{c}(\operatorname{ch}\eta - 1)$$

или при $\eta \ll 1$:

$$a = \sqrt{2a_1 ct}$$

(и прежняя формула (112.15) для $\varepsilon(t)$). Таким образом, и в открытой модели метрика имеет особую точку (но в отличие от закрытой модели - лишь одну).

Наконец, предельным случаем рассмотренных решений, соответствующим бесконечному радиусу кривизны пространства, является

модель с плоским (евклидовым) пространством.

Интервал ds^2 в этой модели можно написать в виде

$$ds^2 = c^2dt^2 - b^2(t)\left(dx^2 + dy^2 + dz^2\right)$$

(в качестве пространственных координат выбраны «декартовы» координаты x, y, z). Зависящий от времени множитель в элементе пространственного расстояния не меняет, очевидно, евклидовости пространственной метрики, так как при заданном t этот множитель постоянен и простым преобразованием координат может быть приведен к единице.

Вычисления, аналогичные произведенным в предыдущем параграфе, приводят к следующим уравнениям:

$$\frac{8\pi k}{c^2}\varepsilon = \frac{3}{b^2}\left(\frac{db}{dt}\right)^2, \quad 3\ln b = -\int \frac{d\varepsilon}{p+\varepsilon} + \text{const}.$$

Для случая малых давлений находим:

$$\mu b^3 = \text{const}, \quad b = \text{const}\, t^{2/3}$$

При малых t опять надо рассматривать случай $p = \varepsilon/3$, при котором получаем:

$$\varepsilon b^4 = \text{const}, \quad b = \text{const}\,\sqrt{t}.$$

Таким образом, и в этом случае метрика имеет особую точку ($t = 0$).

Отметим, что все найденные изотропные решения существуют лишь при отличной от нуля плотности материи; для пустого пространства уравнения Эйнштейна не имеют такого рода решений 1).

Упомянем также, что в математическом отношении они являются частным случаем более общего класса решений, содержащего три физически различные произвольные функции пространственных координат (см. задачу).

Вид квазиоднородным образом расширяющейся метрики вблизи особой точки

Найти общий вид вблизи особой точки для метрики, в которой расширение пространства происходит «квазиоднородным» образом, т.е. так, что все компоненты $\gamma_{\alpha\beta} = -g_{\alpha\beta}$ (в синхронной системе отсчета) стремятся к нулю по одинаковому закону.

Пространство заполнено материей с уравнением состояния $p = \varepsilon/3$

Ищем решение вблизи особой точки ($t = 0$) в виде

$$\gamma_{\alpha\beta} = t a_{\alpha\beta} + t^2 b_{\alpha\beta} + \dots$$

где $a_{\alpha\beta}, b_{\alpha\beta}$ - функции координат (пространственных); ниже полагаем $c = 1$. Обратный тензор

$$\gamma_{\alpha\beta} = \frac{1}{t} a^{\alpha\beta} - b^{\alpha\beta}$$

где тензор $a^{\alpha\beta}$ обратен $a_{\alpha\beta}$, а $b^{\alpha\beta} = a^{\alpha\gamma} a^{\beta\delta} b_{\gamma\delta}$; ниже все операции поднимания индексов и ковариантного дифференцирования производятся при помощи не зависящей от времени метрики $a_{\alpha\beta}$.

Вычисляя левые стороны уравнений (97.11) и (97.12) с необходимой точностью до $1/t$, Получим:

$$-\frac{3}{4t^2} + \frac{1}{2t} b = \frac{8\pi k}{3} \varepsilon \left(-4u_0^2 + 1\right), \quad \frac{1}{2}\left(b; \alpha - b^{\beta}_{\alpha;\beta}\right) = -\frac{32\pi k}{3} \varepsilon u_\alpha u_0$$

(где $b = b^\alpha_\alpha$).

Учитывая также тождество

$$1 = u_i u^i \approx u_0^2 - \frac{1}{t} u_\alpha u_\beta a^{\alpha\beta}$$

найдем:

$$8\pi k \varepsilon = \frac{3}{4t^2} - \frac{b}{2t}, \quad u_\alpha = -\frac{t^2}{2}\left(b_{;\alpha} - b^{\beta}_{\alpha;\beta}\right)$$

Трехмерные символы Кристоффеля, а с ними и тензор $P_{\alpha\beta}$ в первом по $1/t$ приближении не зависят от времени; при этом $P_{\alpha\beta}$ совпадают с выражениями, получающимися при вычислении с метрикой просто $a_{\alpha\beta}$. Учитывая это, найдем, что в уравнении (97.13) члены порядка t^{-2} взаимно сокращаются, а члены $\sim 1/t$ дают

$$P^\beta_\alpha + \frac{3}{4} b^\beta_\alpha + \frac{5}{12} \delta^\beta_\alpha b = 0$$

откуда

$$b^\beta_\alpha = -\frac{4}{3} P^\beta_\alpha + \frac{5}{18} \delta^\beta_\alpha P$$

(где $P = a^{\beta\gamma}P_{\beta\gamma}$).

Ввиду тождества

$$P^{\beta}_{\alpha;\beta} - \frac{1}{2}P_{;\alpha} = 0$$

(см.

(92.10)) имеет место соотношение

$$b^{\beta}_{\alpha;\beta} = \frac{7}{9}b_{;\alpha}$$

и потому u_α можно переписать в виде

$$u_\alpha = -\frac{t^2}{9}b_{;\alpha}$$

Таким образом, все шесть функций $a_{\alpha\beta}$ остаются произвольными, а по ним определяются коэффициенты $b_{\alpha\beta}$ следующего члена разложения (1).

Выбор времени в метрике (1) полностью определен условием $t = 0$ в особой точке; пространственные же координаты допускают еще произвольные преобразования,

не затрагивающие времена (ими можно воспользоваться, например, для приведения тензора $a_{\alpha\beta}$ к диагональному виду).

Поэтому полученное решение содержит всего три «физически различные» произвольные функции.

Отметим, что в этом решении пространственная метрика неоднородна и анизотропна, а распределение плотности материи стремится при $t \to 0$ к однородному.

Трехмерная скорость v имеет (в приближении(4)) равный нулю ротор, а ее величина стремится к нулю по закону

$$v^2 = v_\alpha v_\beta \gamma^{\alpha\beta} \sim t^3$$

6.4 Not Popular, but Basic Models

6.4.1 Gravitational Stability of Isotropic World

(???!!! it is a good idea to discuss gravitational stability!!!)

вкратце

??? а в чем вопрос, собственно??

Theory

Рассмотрим вопрос о поведении малых возмущений в изотропной модели, то есть о ее гравитационной устойчивости.

При этом мы ограничимся рассмотрением возмущений в сравнительно небольших областях пространства - областях, линейные размеры которых малы по сравнению с радиусом a.

В каждой такой области пространственная метрика может быть принята в первом приближении евклидовой, т.е. метрика $dl^2 = a^2\left[d\chi^2 + \sin^2\chi\left(\sin^2\theta d\varphi^2 + d\theta^2\right)\right]$ или $dl^2 = a^2\left\{d\chi^2 + \mathrm{sh}^2\,\chi\left(\sin^2\theta d\varphi^2 + d\theta^2\right)\right\}$ заменится метрикой

$$dl^2 = a^2(\eta)\left(dx^2 + dy^2 + dz^2\right)$$

где x, y, z - декартовы координаты, измеренные в единицах радиуса a.

В качестве временной координаты будем по-прежнему пользоваться переменной η.

возмущение метрики - описание его (???)

Без ограничения общности будем описывать возмущенное поле по-прежнему в синхронной системе отсчета, т.е. наложим на изменения δg_{ik} метрического тензора условия $\delta g_{00} = \delta g_{0\alpha} = 0$.

(???? мб она все-таки нужна?)

Варьируя при этих условиях тождество $g_{ik}u^i u^k = 1$ и имея в виду, что невозмущенные значения компонент 4-скорости материи $u^0 = 1/a, u^\alpha = 0$, получим $g_{00}u^0\delta u^0 = 0$, откуда $\delta u^0 = 0$.

Возмущения же δu^α, вообще говоря, отличны от нуля, так что система отсчета - уже не сопутствующая.

Возмущения пространственного метрического тензора обозначим посредством $h_{\alpha\beta} = \delta\gamma_{\alpha\beta} = -\delta g_{\alpha\beta}$.

Тогда $\delta\gamma^{\alpha\beta} = -h^{\alpha\beta}$, причем поднимание индексов у $h_{\alpha\beta}$ осуществляется с помощью невозмущенной метрики $\gamma_{\alpha\beta}$.

В линейном приближении малые возмущения гравитационного поля удовлетворяют уравнениям

$$\delta R_i^k - \frac{1}{2}\delta_i^k \delta R = \frac{8\pi k}{c^4}\delta T_i^k$$

В сихронной системе отсчета вариации компонент тензора энергии-импульса (94.9) равны:

$$\delta T_\alpha^\beta = -\delta_\alpha^\beta \delta p, \quad \delta T_0^\alpha = a(p+\varepsilon)\delta u^\alpha, \quad \delta T_0^0 = \delta\varepsilon$$

Ввиду малости $\delta\varepsilon$ и δp можно написать $\delta p = \frac{dp}{d\varepsilon}\delta\varepsilon$, и мы получаем соотношения

$$\delta T_\alpha^\beta = -\delta_\alpha^\beta \frac{dp}{d\varepsilon}\delta T_0^0$$

Формулы для δR_i^k можно получить варьированием выражений (97.10).

Поскольку невозмущенный метрический тензор $\gamma_{\alpha\beta} = a^2\delta_{\alpha\beta}$, то невозмущенные значения

$$\varkappa_{\alpha\beta} = \frac{2\dot{a}}{a}\gamma_{\alpha\beta} = \frac{2a'}{a^2}\gamma_{\alpha\beta}, \quad \varkappa_\alpha^\beta = \frac{2a'}{a}\delta_\alpha^\beta$$

где точка означает дифференцирование по ct, а штрих - по η. Возмущения же величин $\varkappa_{\alpha\beta}$ и $\S_\alpha^\beta = \varkappa_{\alpha\gamma\gamma}\gamma^{\gamma\beta}$

$$\delta\varkappa_{\alpha\beta} = \dot{h}_{\alpha\beta} = \frac{1}{a}h'_{\alpha\beta}, \quad \delta\varkappa_\alpha^\beta = -h^{\beta\gamma}{}_{\alpha\gamma} + \gamma^{\beta\gamma}\dot{h}_{\alpha\gamma} = \dot{h}_\alpha^\beta = \frac{1}{a}h_\alpha^{\beta\prime}$$

где $h_\alpha^\beta = \gamma^{\beta\gamma}h_{\alpha\gamma}$. Невозмущенные значения трехмерного тензора P_α^β для евклидовой метрики (115.1) равны нулю.

Вариации же δP_α^β вычисляются по формулам (108.3) – (108.4); очевидно, что δP_α^β выражается через $\delta\gamma_{\alpha\beta}$ так же, как 4-тензор δR_{ik} выражается через δg_{ik}, причем все тензорные операции производятся в трехмерном пространстве с метрикой (115.1); ввиду евклидовости этой метрики все ковариантные дифференцирования сводятся к простым дифференцированиям по координатам x^α (контравариантные же дифференцирования - еще и к делению на a^2).

Имея все это в виду (и переходя везде от производных по t к производным по η), получим после простого вычисления:

$$\delta R_\alpha^\beta = -\frac{1}{2a^2}\left(h_{\alpha,\gamma}^{\gamma,\beta} + h_{\gamma,\alpha}^{\beta,\gamma} - h_{\gamma\alpha}^{,\beta,\gamma} - h_{,\alpha}^{,\beta}\right) - \frac{1}{2a^2}h_\alpha^{\beta\prime\prime} - \frac{a'}{a^3}h_\alpha^{\beta\prime} - \frac{a'}{2a^3}h'\delta_\alpha^\beta$$

$$\delta R_0^0 = -\frac{1}{2a^2}h'' - \frac{a'}{2a^3}h',$$

$$\delta R_0^\alpha = \frac{1}{2a^2}\left(h^{,\alpha} - h_\beta^{\alpha,\beta}\right)'$$

($h \equiv h^\alpha_\alpha$). Здесь как нижние, так и верхние индексы после запятой означают простые дифференцирования по координатам x^α (мы продолжаем Писать индексы вверху и внизу лишь для сохранения единообразия обозначений).

Окончательные уравнения для возмущения h^β_α мы получим, подставив в (115.4) компоненты δT^k_i, выраженные через δR^k_i согласно (115.2). В качестве этих уравнений удобно выбрать уравнения, получающиеся из (115.4) при $\alpha \neq \beta$ при упрощении по индексам α, β. Они гласят:

$$\left(h^{\gamma,\beta}_{\alpha,\gamma} + h^{\beta,\gamma}_{\gamma,\alpha} - h^{\beta}_{,\alpha} - h^{\beta,\gamma}_{\alpha,\gamma}\right) + h^{\beta''}_\alpha + 2\frac{a'}{a}h^{\beta'}_\alpha = 0, \quad \alpha \neq \beta$$

$$\frac{1}{2}\left(h^{\delta,\gamma}_{\gamma,\delta} - h^{\gamma}_{,\gamma}\right)\left(1 + 3\frac{dp}{d\varepsilon}\right) + h'' + h'\frac{a'}{a}\left(2 + 3\frac{dp}{d\varepsilon}\right) = 0$$

Возмущения плотности и скорости материи могут быть определены по известным h^β_α с помощью формул (115.2)-(115.3).

Так, для относительного изменения плотности имеем:

$$\frac{\delta\varepsilon}{\varepsilon} = \frac{c^4}{8\pi k\varepsilon}\left(\delta R^0_0 - \frac{1}{2}\delta R\right) = \frac{c^4}{16\pi k\varepsilon a^2}\left(h^{\beta,\alpha}_{\alpha,\beta} - h^{,\alpha}_{,\alpha} + \frac{2a'}{a}h'\right)$$

Среди решений уравнений (115.6) есть такие, которые могут быть исключены простым преобразованием системы отсчета (не нарушающим ее синхронности) и поэтому не представляют собой реального физического изменения метрики.

Вид таких решений может быть заранее установлен с помощью полученных в задаче 3 $ 97 формул (1) и (2).

Подставив в них невозмущенные значения $\gamma_{\alpha\beta} = a^2\delta_{\alpha\beta}$, получим следующие выражения для фиктивных возмущений метрики:

$$h^\beta_\alpha = f^{,\beta}_{0,\alpha}\int\frac{d\eta}{a} + \frac{a'}{a^2}f_0\delta^\beta_\alpha + \left(f^{,\beta}_\alpha + f^\beta_{,\alpha}\right)$$

где f_0, f_α - произвольные (малые) функции координат x, y, z. Поскольку метрика в рассматриваемых нами небольших областях пространства предполагается евклидовой, то произвольное возмущение в каждой такой области может быть разложено по плоским волнам.

Понимая под x, y, z декартовы координаты, измеренные в единицах a, мы можем написать пространственный периодический множитель плоских волн в виде $e^{i\mathbf{nr}}$, где $\mathbf{n}$ - безразмерный вектор, представляющий собой волновой вектор, измеренный в единицах 1/a (волновой вектор $\mathrm{k} = \mathbf{n}/a$).

Если мы имеем возмущение в участке пространства с размерами $\sim l$, то в его разложение войдут в основном волны с длинами $\lambda = 2\pi a/n \sim l$. Ограничиваясь возмущениями в областях с размерами $l \ll a$, мы тем самым предполагаем число n достаточно большим ($n \gg 2\pi$).

Классификация гравитационных возмущений.

Гравитационные возмущения можно разделить на три типа по возможных типах плоских волн, в виде которых может быть представлен симметричный тензор $h_{\alpha\beta}$.

1.

С помощью скалярной функций

$$Q = e^{i\mathbf{n}r}$$

можно составить вектор $\mathrm{P} = \mathrm{n}Q$ и тензоры

$$Q^\beta_\alpha = \frac{1}{3}\delta^\beta_\alpha Q, \quad P^\beta_\alpha = \left(\frac{1}{3}\delta^\beta_\alpha - \frac{n_\alpha n^\beta}{n^2}\right)Q$$

Таким плоским волнам отвечают возмущения, в которых наряду с гравитационным полем испытывают изменении также скорость и плотность материи, т. е. мы имеем дело с возмущениями, сопровождающимися возникновением сгущений или разрежений материи.

Возмущение h_α^β выражается при этом через тензоры Q_α^β и P_α^β, возмущение скорости - через вектор P, а возмущение плотности - через скаляр Q.

2.

С помощью поперечной векторной волны

$$\mathbf{S} = \mathbf{s}e^{i\mathbf{nr}}, \quad \mathbf{sn} = 0$$

можно составить тензор $\left(n^\beta S_\alpha + n_\alpha S^\beta\right)$; соответствующего же скаляра не существует, поскольку nS = 0. Этим волнам отвечают возмущения, В которых наряду с гравитационным полем испытывает изменение скорость, но не плотность материи; их можно назвать вращательными возмущениями.

3.

Поперечная тензорная волна

$$G_\alpha^\beta = g_\alpha^\beta e^{i\mathrm{nr}}, \quad g_\alpha^\beta n_\beta = 0$$

С ее помощью нельзя составить ни вектора, ни скаляра.

Этим волнам отвечают возмущения гравитационного поля, при которых материя остается неподвижной и однородно распределенной в пространстве.

Другими словами, это - гравитационные волны в изотропном мире.

Наиболее интересны возмущения первого типа.

Полагаем

$$h_\alpha^\beta = \lambda(\eta)P_\alpha^\beta + \mu(\eta)Q_\alpha^\beta, \quad h = \mu Q$$

Из (115.7) получим для относительного изменения плотности

$$\frac{\delta\varepsilon}{\varepsilon} = \frac{c^4}{24\pi k\varepsilon a^2}\left[n^2(\lambda+\mu) + \frac{3a'}{a}\mu'\right]Q$$

Уравнения, определяющие функции λ и μ, получаются подстановкой (115.13) в (115.6)

$$\lambda'' + 2\frac{a'}{a}\lambda' - \frac{n^2}{3}(\lambda+\mu) = 0$$
$$\mu'' + \mu'\frac{a'}{a}\left(2 + 3\frac{dp}{d\varepsilon}\right) + \frac{n^2}{3}(\lambda+\mu)\left(1 + 3\frac{dp}{d\varepsilon}\right) = 0$$

Эта уравнения имеют прежде всего следующие два частных интеграла, соответствующие тем фиктивным изменениям метрики, которые могут быть исключены преобразованием системы отсчета:

$$\lambda = -\mu = \mathrm{const}$$
$$\lambda = -n^2\int\frac{d\eta}{a}, \quad \mu = n^2\int\frac{d\eta}{a} - \frac{3a'}{a^2}$$

(первый из них получается из (115.8) выбором $f_0 = 0, f_\alpha = P_\alpha$, Второй - выбором $f_0 = Q, f_\alpha = 0$). На ранних стадиях расширения мира, когда материя описывается уравнением состояниЯ $p = \varepsilon/3$, имеем $a \approx a_1\eta, \eta \ll 1$ (как в открытой, так и в закрытой моделях).

Уравнения (115.15) принимают вид

$$\lambda'' + \frac{2}{\eta}\lambda' - \frac{n^2}{3}(\lambda+\mu) = 0, \quad \mu'' + \frac{3}{\eta}\mu' + \frac{2n^2}{3}(\lambda+\mu) = 0$$

Исследование этих уравнений удобно производить раздельно длЯ двух предельных случаев в зависимости от взаимного соотношения между двумя большими величинами n и $1/\eta$.

Предположим сначала, что число n не слишком велико (или η достаточно мало), так что $n\eta \ll 1$. С той точностью, с которой справедливы уравнения (115.18), находим из них в данном случае:

$$\lambda = \frac{3C_1}{\eta} + C_2\left(1 + \frac{n^2}{9}\eta^2\right), \quad \mu = -\frac{2n^2}{3}C_1\eta + C_2\left(1 - \frac{n^2}{6}\eta^2\right)$$

где C_1, C_2 - постоянные; отсюда исключены решения вида (115.16) К (115.17) (в данном случае это - решение, в котором $\lambda = -\mu = \text{const}$ И В котором $\lambda + \mu \sim 1/\eta^2$).

Вычислив также $\delta\varepsilon/\varepsilon$ согласно (115.14) И (112.15), получим следующие выражения для возмущений метрики и плотности:

$$h_\alpha^\beta = \frac{3C_1}{\eta}P_\alpha^\beta + C_2\left(Q_\alpha^\beta + P_\alpha^\beta\right)$$

$$\frac{\delta\varepsilon}{\varepsilon} = \frac{n^2}{9}\left(C_1\eta + C_2\eta^2\right)Q \qquad \text{при} \qquad p = \frac{\varepsilon}{3}, \eta \ll \frac{1}{n}$$

Постоянные C_1, C_2 должны удовлетворять определенным условиям, выражающим малость возмущения в момент η_α его возникновения: должно быть $h_\alpha^\beta \ll 1$(откуда $\lambda \ll 1, \mu \ll 1$) и $\delta\varepsilon/\varepsilon \ll 1$. В применении к (115.19) эти условия приводят к неравенствам $C_1 \ll \eta_0, C_2 \ll 1$.

В выражениях (115.19) имеются члены, возрастающие в расширяющемся мире как различные степени радиуса $a = a_1\eta$. Однако это возрастание не приводит к тому, чтобы возмущение могло стать большим: если применить формулы (115.19) по порядку величины при $\eta \sim 1/n$, то мы увидим, что (в силу полученных выше неравенств для C_1, C_2) возмущения остаются малыми даже на верхнем пределе действия этих формул.

Пусть теперь число n настолько велико, что $n\eta \gg 1$. Решая уравнения (115.18) при этом условии, найдем, что главные члены в λ и μ равны:

$$\lambda = -\frac{\mu}{2} = \text{const}\,\frac{1}{\eta^2}e^{in\eta/\sqrt{3}}$$

Отсюда находим для возмущений метрики и плотности:

$$h_\alpha^\beta = \frac{C}{n^2\eta^2}\left(P_\alpha^\beta - 2Q_\alpha^\beta\right)e^{in\eta/\sqrt{3}}, \quad \frac{\delta\varepsilon}{\varepsilon} = -\frac{C}{9}Qe^{in\eta/\sqrt{3}}$$

$$\text{при } p = \frac{\varepsilon}{3}, \quad \frac{1}{n} \ll \eta \ll 1$$

где C - комплексная постоянная, удовлетворяющая условию $|C| \ll 1$. Наличие периодического множителя в этих выражениях вполне естественно.

При больших n мы имеем дело с возмущением, пространственная периодичность которого определяется большим волновым вектором $k = n/$ а.

Такие возмущения должны распространяться как звуковые волны со скоростью

$$u = \sqrt{\frac{dp}{d\left(\varepsilon/c^2\right)}} = \frac{c}{\sqrt{3}}$$

Соответственно временная часть фазы определяется, как полагается В геометрической акустике, большим интегралом $\int kudt = n\eta/\sqrt{3}$.

Амплитуда относительного изменения плотности остается, как мы видим, постоянной, амплитуды же возмущений метрики при расширений мира убывают как a^{-2}.

Далее, рассмотрим более поздние стадии расширения, когда материя разрежена уже настолько, что можно пренебречь ее давлением ($p = 0$). При этом мы ограничимся здесь лишь случаем малых η соответствующих тем стадиям расширения, когда радиус a еще очень мал по сравнению с его современным значением, но все же материя уже достаточно разрежена.

При $p = 0$ и $\eta \ll 1$ имеем $a \approx a_0\eta^2/2$ и уравнения (115.15) принимают вид

$$\lambda'' + \frac{4}{\eta}\lambda' - \frac{n^2}{3}(\lambda + \mu) = 0, \quad \mu'' + \frac{4}{\eta}\mu' + \frac{n^2}{3}(\lambda + \mu) = 0$$

Решение этих уравнений:

$$\lambda + \mu = 2C_1, \quad \lambda - \mu = 2n^2\left(\frac{C_1\eta^2}{15} + \frac{2C_2}{\eta^3}\right)$$

Вычислив также $\delta\varepsilon/\varepsilon$ (с помощью (115.14) и (112.12)), находим:

$$h_\alpha^\beta = C_1\left(P_\alpha^\beta + Q_\alpha^\beta\right) + \frac{2n^2C_2}{\eta^3}\left(P_\alpha^\beta - Q_\alpha^\beta\right) \text{ при } \eta \ll \frac{1}{n}$$

$$h_\alpha^\beta = \frac{C_1}{15}n^2\eta^2\left(P_\alpha^\beta - Q_\alpha^\beta\right) + \frac{2n^2C_2}{\eta^3}\left(P_\alpha^\beta - Q_\alpha^\beta\right) \text{ при } \frac{1}{n} \ll \eta \ll 1$$

$$\frac{\delta\varepsilon}{\varepsilon} = \left(\frac{C_1n^2\eta^2}{30} + \frac{C_2n^2}{\eta^3}\right)Q$$

Мы видим, что $\delta\varepsilon/\varepsilon$ содержит член, возрастающий пропорционально a.

Однако если $n\eta \ll 1$, то $\delta\varepsilon/\varepsilon$ не становится все же большим даже при $\eta \sim 1/n$ в силу условия $C_1 \ll 1$. Если же $\eta n \gg 1$, то при $\eta \sim 1$ относительное изменение плотности становится порядка C_1n^2, между тем как малость начального возмущения требует лишь, чтобы было $C_1n^2\eta_0^2 \ll 1$. Таким образом, хотя возрастание возмущений происходит и медленно, но общее увеличение может быть значительным и в результате возмущение может стать сравнительно большим.

Аналогичным образом могут быть рассмотрены возмущения второго и третьего из перечисленных выше типов.

Однако законы затухания этих возмущений могут быть найдены и без детальных вычислений исходя из следующих простых соображений.

Если в небольшом участке вещества (с линейными размерами l) имеется вращательное возмущение со скоростью δv, то момент импульса этого участка $\sim (\varepsilon/c^2)\, l^3 \cdot l \cdot v$. При расширении мира l растет пропорционально a, а ε убывает как a^{-3} (в случае $p = 0$) или как a^{-4} (при $p = \varepsilon/3$).

В силу сохранения момента имеем поэтому

$$\delta v = \text{const при } p = \frac{\varepsilon}{3}, \quad \delta v \propto \frac{1}{a} \text{при } p = 0$$

Наконец, плотность энергии гравитационных волн должна убывать при расширении мира как a^{-4}. С другой стороны, эта плотность, выражается через возмущение метрики как $\sim k^2\left(h_\alpha^\beta\right)^2$, где $k = n/a$ - волновой вектор возмущения.

Отсюда следует, что амплитуда возмущения типа гравитационной волны убывает со временем как 1/a.

6.4.2 Homogeneous Spaces

вкратце

(хз вообще, что это, я и близко не на этом уровне)

Theory

Предположение об однородности и изотропиИ пространства определяет его метрику полностьЮ (оставляя свободным лишь знак кривизны).

Значительно больше свободы оставляет предположение об одной только однородности пространства, без какой-либо еще дополнительной симметрии.

Рассмотрим вопрос о том, каковы могут быть метрические свойства однородного пространства.

Речь будет идти о метрике пространства, рассматриваемой в заданный момент времени t.

При этом предполагается, что пространственновременная система отсчета выбрана синхронной, так что t есть единое для всего пространства синхронизованное время.

Однородность означает одинаковость метрических свойств во всех точках пространства.

Точное определение этого понятия связано с рассмотрением совокупности преобразований координат, которые совмещают пространство само с собой, т. е. оставляют его метрику неизменной: если до преобразования элемент длины

$$dl^2 = \gamma_{\alpha\beta}\left(x^1, x^2, x^3\right) dx^\alpha dx^\beta$$

то после преобразования тот же элемент

$$dl^2 = \gamma_{\alpha\beta}\left(x'^1, x'^2, x'^3\right) dx'^\alpha dx'^\beta$$

с той же функциональной зависимостью $\gamma_{\alpha\beta}$ от новых координат.

Пространство однородно, если оно допускает совокупность преобразований (или, как говорят, группу движений), позволяющих совместить любую заданную его точку с любой другой точкой.

В силу трехмерности пространства очевидно, что для этого различные преобразования группы должны определяться значениями трех независимых параметров.

Так, в евклидовом пространстве однородность выражается инвариантностью метрики по отношению к параллельным переносам (трансляциям) декартовой системы координат.

Каждая трансляция определяется тремя параметрами - компонентами вектора смещения начала координат.

Все эти преобразования оставляют инвариантными три независимых дифференциала (dx, dy, dz), из которых и строится элемент длины.

В общем случае неевклидова однородного пространства преобразования его группы движений тоже оставляют инвариантными три независимые линейные дифференциальные формы, не сводящиеся, однако, к полным дифференциалам каких-либо координатных функций.

Напишем эти формы в виде

$$e_\alpha^{(a)} dx^\alpha$$

где латинский индекс (a) нумерует три независимых реперных вектора (функции координат).

С помощью форм (116.1) инвариантная по отношению к данной группе движений пространственная метрика строится как

$$dl^2 = \eta_{ab}\left(e_\alpha^{(a)} dx^\alpha\right)\left(e_\beta^{(b)} dx^\beta\right)$$

где метрический тензор

$$\gamma_{\alpha\beta} = \eta_{ab} e_\alpha^{(a)} e_\beta^{(b)}$$

где симметричные по индексам a, b коэффициенты η_{ab} - функции времени.

Таким образом, мы приходим к «триадному»| представлению пространственной метрики с помощью тройки реперных векторов; к этому представлению применимы все полученные в & 98 формулы.

При этом выбор реперных векторов диктуется свойствами симметрии пространства и, вообще говоря, эти векторы не ортогональны (так что матрица η_{ab} не диагональна).

Как и в \$98, наряду с тройкой векторов $e_\alpha^{(a)}$ введем тройку взаимных с ними векторов $e_{(a)}^\alpha$, для которых

$$e_{(a)}^\alpha e_\alpha^{(b)} = \delta_a^b, \quad e_{(a)}^\alpha e_\beta^{(a)} = \delta_\beta^\alpha$$

В трехмерном случае связь между теми и другими векторами может быть представлена в явном виде как

$$\mathbf{e}_{(1)} = \frac{1}{v}\left[\mathbf{e}^{(2)}\mathbf{e}^{(3)}\right], \quad \mathbf{e}_{(2)} = \frac{1}{v}\left[\mathbf{e}^{(3)}\mathbf{e}^{(1)}\right], \quad \mathbf{e}_{(3)} = \frac{1}{v}\left[\mathbf{e}^{(1)}\mathbf{e}^{(2)}\right]$$

где

$$v = \left|e_\alpha^{(a)}\right| = \left(\mathbf{e}^{(1)}\left[\mathbf{e}^{(2)}\mathbf{e}^{(3)}\right]\right)$$

а $\mathrm{e}_{(a)}$ и $\mathrm{e}^{(a)}$ надо понимать как декартовы векторы с компонентами соответственно $e_{(a)}^\alpha$ и $e_\alpha^{(a)}$ Определитель метрического тензора (116.3)

$$\gamma = \eta v^2$$

где η - определитель матрицы η_{ab}.

Инвариантность дифференциальных форм (116.1) означает, что

$$e_\alpha^{(a)}(x)dx^\alpha = e_\alpha^{(a)}(x')\,dx'^\alpha$$

причем $e_\alpha^{(a)}$ в обеих сторонах равенства - одни и те же функции соответственно от старых и новых координат.

Умножив это равенство на $e_{(\alpha)}^\beta(x')$, заменив $dx'^\beta = \left(\partial x'^\beta/\partial x^\alpha\right)dx^\alpha$ и сравнив коэффициенты при одинаковых дифференциалах dx^α, получим

$$\frac{\partial x'^\beta}{\partial x^\alpha} = e_{(a)}^\beta(x')\,e_\alpha^{(a)}(x).$$

Эти равенства представляют собой систему дифференциальных уравнений, определяющих функции $x'^\beta(x)$ по заданным реперным векторам. Для того чтобы быть интегрируемыми, уравнения (116.8) должны тождественно удовлетворять условиям

$$\frac{\partial^2 x'^\beta}{\partial x^\alpha \partial x^\gamma} = \frac{\partial^2 x'^\beta}{\partial x^\gamma \partial x^\alpha}$$

Вычислив производные, получим:

$$\left[\frac{\partial e_{(a)}^\beta(x')}{\partial x'^\delta} - \frac{\partial e_{(b)}^\beta(x')}{\partial x'^\delta}e_{(a)}^\delta(x')\right]e_\gamma^{(b)}(x)e_\alpha^{(a)}(x) = e_{(a)}^\beta(x')\left[\frac{\partial e_\gamma^{(a)}(x)}{\partial x^\alpha} - \frac{\partial e_\alpha^{(a)}(x)}{\partial x^\gamma}\right]$$

Умножив обе стороны равенства на $e_{(d)}^\alpha(x)e_{(c)}^\gamma(x)e_\beta^{(f)}(x')$ и перенеся Дифференцирования с одних множителей на другие с учетом (116.4), Получим в левой стороне:

$$e_\beta^{(f)}(x')\left[\frac{\partial e_{(d)}^\beta(x')}{\partial x'^\delta}e_{(c)}^\delta(x') - \frac{\partial e_{(c)}^\beta(x')}{\partial x'^\delta}e_{(d)}^\delta(x')\right] = e_{(c)}^\beta(x')\,e_{(d)}^\delta(x')\left[\frac{\partial e_\beta^{(f)}(x')}{\partial x'^\delta} - \frac{\partial e_\delta^{(f)}(x')}{\partial x'^\beta}\right],$$

а в правой - такое же выражение как функцию от x. Поскольку x и x' произвольны, то эти выражения должны сводиться к постоянным:

$$\left(\frac{\partial e_\alpha^{(c)}}{\partial x^\beta} - \frac{\partial e_\beta^{(c)}}{\partial x^\alpha}\right)e_{(a)}^\alpha e_{(b)}^\beta = C_{ab}^c$$

Постоянные C^c_{ab} называются структурными константами группы Умножив на $e^\gamma_{(c)}$ можно переписать (116.9) в виде

$$e^\alpha_{(a)}\frac{\partial e^\gamma_{(b)}}{\partial x^\alpha} - e^\beta_{(b)}\frac{\partial e^\gamma_{(a)}}{\partial x^\beta} = C^c_{ab}e^\gamma_{(c)}$$

Это и есть искомые условия однородности пространства.

(!!!!!?????)

Выражение в левой стороне равенства (116.9) совпадает с определением величин λ^c_{ab}, которые, таким образом, оказываются постоянными.

По своему определению структурные константы антисимметричны по нижним индексам:

$$C^c_{ab} = -C^c_{ba}$$

Еще одно условие для них можно получить, заметив, что равенство (116.10) эквивалентно правилу коммутации

$$[X_a, X_b] \equiv X_aX_b - X_bX_a = C^c_{ab}X_c$$

для линейных дифференциальных операторов

$$X_a = e^\alpha_{(a)}\frac{\partial}{\partial x^\alpha}$$

Тогда упомянутое соотношение возникнет из тождества

$$[[X_a, X_b], X_c] + [[X_b, X_c], X_a] + [[X_c, X_a], X_b] = 0$$

(так называемое тождество Якоби) и имеет вид

$$C^f_{ab}C^d_{cf} + C^f_{bc}C^d_{af} + C^f_{ca}C^d_{bf} = 0$$

Определенное преимущество перед трехиндексовыми константами $C^c{}_{ab}$ представляют двухиндексовые величины, получающиеся путем дуального преобразования

$$C^c_{ab} = e_{abd}C^{dc}$$

где $e_{abc} = e^{abc}$ - единичный антисимметричный символ (причем $e_{123} = +1$). Правила коммутации (116.12) с помощью таких констант запишутся в виде

$$e^{abc}X_bX_c = C^{ad}X_d$$

Свойство (116.11) уже учтено в определении (116.15), а свойство (116.14) примет вид

$$e_{bcd}C^{cd}C^{ba} = 0$$

Укажем также, что определение (116.9) для величин Cab можно представить в векторном виде:

$$C^{ab} = -\frac{1}{v}\mathbf{e}^{(a)}\,\mathrm{rot}\,\mathbf{e}^{(b)}$$

где снова векторные операции производятся так, как если бы координаты x^α были декартовыми.

Выбор трех реперных векторов в дифференциальных формах (116.1) (а с ними и операторов X_a), разумеется, не однозначен.

Они могут быть подвергнуты любому линейному преобразованию с постоянными коэффициентами

$$\mathbf{e}_{(a)} = A^b_a\mathbf{e}_{(b)}$$

По отношению к таким преобразованиям величины η_{ab} и C^{ab} ведут себя как тензоры.

Условия (116.17) - единственные, которым должны удовлетворять структурные константы C^{ab}. Но среди допускаемых этими условиями наборов констант есть эквивалентные - в том смысле, что различие связано лишь с преобразованиями (116.19).

Вопрос о классификации однородных пространств сводится к определению всех неэквивалентных наборов структурных констант.

Это можно сделать, воспользовавшись «тензорными» свойствами величин C^{ab}, следующим простым способом (C. G. Behr, 1962).

Несимметричный «тензор» C^{ab} можно разложить на симметричную и антисимметричную части.

Первую обозначим посредством n^{ab}, а вторую выразим через дуальный ей «вектор» a_c :

$$C^{ab} = n^{ab} + e^{abc}a_c$$

Подстановка этого выражения в (116.17) приводит к условию

$$n^{ab}a_b = 0$$

Преобразованиями (116.19) симметричный «тензор» n^{ab} может быть приведен к диагональному виду; пусть n_1, n_2, n_3 - его главные значения.

Равенство $n^{ab}a_b = 0$ показывает, что «вектор» a_b (если он существует) лежит в одном из главных направлений «тензора» n^{ab}, - в том, которое отвечает нулевому главному значению.

Не уменьшая общности, можно поэтому положить $a_b = (a, 0, 0)$. Тогда $n^{ab}a_b = 0$ сводится к $an_1 = 0$, т. е. одна из величин a или n_1 должна быть нулем.

Правила же коммутации (116.16) примут виД

$$[X_1, X_2] = -aX_2 + n_3X_3, \quad [X_2, X_3] = n_1X_1, \quad [X_3, X_1] = n_2X_2 + aX_3$$

После этого остается еще свобода в изменении знака операторов X_a и в произвольных их масштабных преобразованиях (умножению на постоянные).

Это дозволяет одновременно изменить знак всех n_1, n_2, n_3, а также сделать величину a положительной (если она отлична от нуля).

Можно также обратить все структурные константы в ± 1, если по крайней мере одна из величин a, n_2, n_3 равна нулю.

Если же все эти три величины отличны от нуля, то масштабные преобразования оставляют инвариантным отношение a^2/n_2n_3 ").

Таким образом, мы приходим к следующему перечислению возможных типов однородных пространств; в первом столбце таблицы римской Цифрой указан номер, которым принято обозначать типы по классификации Бианки (L. Bianchi, 1918)

(тут таблица, которую мб потом перепишу)

ТиП I - евклидово пространство; все компоненты пространственного тензора кривизны (см.

ниже формулу (116.24)) обращаются в нуль.

Помимо тривиального случая галилеевой метрики, сюда относится зависящая от времени метрика, которая будет рассмотрена в следующем параграфе.

ТиП IX содержит в себе как частный случай пространство постоянной положительной кривизны.

Оно получается, если в элементе длИны (116.2) положить $\eta_{ab} = \delta_{ab}/4\lambda$, где λ - положительная постоЯнная.

Действительно, вычисление по (116.24)с$C^{11} = C^{22} = C^{33} = 1$ (структурные константы типа IX) дает $P_{(a)(b)} = 1/2\delta_{ab}$ и затем

$$P_{\alpha\beta} = P_{(a)(b)}e^{(a)}_{\alpha}e^{(b)}_{\beta} = 2\lambda\gamma_{\alpha\beta}$$

что как раз и соответствует указанному пространству (ср.
(111.3)).

Аналогичным образом пространство постоянной отрицательной кривизны содержится как частный случай в типе V.

Действительно, положив $\eta_{ab} = \delta_{ab}/\lambda$ и вычислив $P_{(a)(b)}$ по (116.24)с$C^{23} = -C^{32} = 1$ ПОЛучИМ

$$P_{(a)(b)} = -2\delta_{ab}, \quad P_{\alpha\beta} = -2\lambda\gamma_{\alpha\beta}$$

что и отвечает постоянной отрицательной кривизне.

Наконец, покажем, каким образом уравнения Эйнштейна для мира с однородным пространством сводятся к системе обыКновенных Дифференциальных уравнений, содержащих только функЦиИ времени.

ДлЯ этого пространственные компоненты 4-векторов и 4-тензоров надо разложить по тройке реперных векторов данного пространства:

$$R_{(a)(b)} = R_{\alpha\beta}e^{\alpha}_{(a)}e^{\beta}_{(b)}, \quad R_{0(a)} = R_{0\alpha}e^{\alpha}_{(a)}, \quad u^{(a)} = u^{\alpha}e^{(a)}_{\alpha}$$

причем все эти величины являются уже фунКциями только от t; фунКЦиЯми времени являются также и скалярные величины - плотность энергиИ ε и давление p материИ.

Уравнения Эйнштейна в синхронной системе выражаются, согласно (97.11) – (97.13), через трехмерные тензоры $_{\alpha\beta}$ и $P_{\alpha\beta}$. Для первого имеем просто

$$\mathscr{K}_{(a)(b)} = \dot{\eta}_{ab}, \quad x^{(b)}_{(a)} = \dot{\eta}_{ac}\eta^{cb}$$

(точка означает дифференцирование по t).

Компоненты же $P_{(a)(b)}$ можНО Выразить через величины η_{ab} и структурные константы групПы с помощью (98.14).

После замены трехиндексовых $\lambda_{bc} = C^{a}_{bc}$ на двухиндексовые C^{ab} и ряда преобразований 1) получим:

$$P^{(b)}_{(a)} = \frac{1}{2\eta}\left\{2C^{bd}C_{ad} + C^{db}C_{ad} + C^{bd}C_{da} - C^{d}_{d}\left(C^{b}_{a} + C^{b}_{a}\right) + \right.$$
$$\left. + \delta^{b}_{a}\left[\left(C^{d}_{d}\right)^{2} - 2C^{df}C_{df}\right]\right\}$$

Здесь, в соответствии с обШим правилом,

$$C^{b}_{a} = \eta_{ac}C^{cb}, \quad C_{ab} = \eta_{ac}\eta_{bd}C^{cd}$$

Отметим также, что тождества Бианки для трехмерного тензора $P_{\alpha\beta}$ В однородном пространстве принимают виД

$$P^{c}_{b}C^{b}_{ca} + P^{c}_{a}C^{b}_{cb} = 0$$

Окончательные выражения для реперных составляющих 4-тензора Риччи [2])

Подчеркнем, что для составления уравнений Эйнштейна нет, таким образом, необходимости в использовании явных выражений для репер- ных векторов как функций координат.

6.4.3 Flat Anisotropic Model

вкратце

Theory

Адекватность изотропной модели для описания поздних этапов эволюции Вселенной сама по себе не дает оснований ожидать, что она столь же пригодна и для описания ранних стадий эволюции, вблизи особой точки по времени. Этот вопрос будет детально обсужден

в пар 119, а в этом и следующем параграфах будут предварительно рассмотрены решения уравнений Эйнштейна, тоже обладающие особой точкой по времени, но принципиально отличных (от фридмановской особенности) типов.

Будем искать решение, в котором все компоненты метрического тензора являются, при надлежащем выборе системы отсчета, функциями лишь одной переменной - времени $x^0 = t^1$).

Такой вопрос рассматривался уже в $ 109, где, однако, был рассмотрен только случай, когда определитель $|g_{\alpha\beta}| = 0$. Теперь уже будем считать этот определитель отличным от нуля.

Как было показано в $ 109, в таком случае можно, без ограничения общности, положить все $g_{0\alpha} = 0$. Преобразованием переменной t, согласно $\sqrt{g_{00}}dt \to dt$ можно затем обратить g_{00} В единицу, так что мы получим синхронную систему отсчета, в которой

$$g_{00} = 1, \quad g_{0\alpha} = 0, \quad g_{\alpha\beta} = -\gamma_{\alpha\beta}(t)$$

Теперь мы можем воспользоваться уравнениями Эйнштейна в виде (97.11)−(97.13). Поскольку величины $\gamma_{\alpha\beta}$, а с ними и компоненты трехмерного тензора $\mathcal{X}_{\alpha\beta} = \dot{\gamma}_{\alpha\beta}$ не зависят от координат x^α, то $R_{0\alpha} \equiv 0$.

По той же причине $P_{\alpha\beta} \equiv 0$, и в результате уравнения гравитационного поля в пустоте сводятся к следующей системе:

$$l\dot{x}^\alpha_\alpha + \frac{1}{2}x^\beta_\alpha x^\alpha_\beta = 0$$
$$\frac{1}{\sqrt{\gamma}}\left(\sqrt{\gamma}x^\beta_\alpha\right)^\bullet = 0$$

Из (117.3) следует, что

$$\sqrt{\gamma}x^\beta_\alpha = 2\lambda^\beta_\alpha$$

где λ^β_α - постоянные величины.

Упрощая по индексам α и β, Получим:

$$x^\alpha_\alpha = \frac{\dot{\gamma}}{\gamma} = \frac{2}{\sqrt{\gamma}}\lambda^\alpha_\alpha$$

откуда видно, что $\gamma = \text{const}\ t^2$. Без ограничения общности можно положить const $= 1$ (это достигается просто изменением масштаба координат x^α), тогда $\lambda^\alpha_\alpha = 1$. Подстановка (117.4) в уравнение (117.2) дает теперь соотношение

$$\lambda^\beta_\alpha\lambda^\alpha_\beta = 1$$

связывающее между собой постоянные λ^β_α.

Далее, опустив в (117.4) индекс β, перепишем эта равенства в виде системы обыкновенных дифференциальных уравнений для $\gamma_{\alpha\beta}$:

$$\dot{\gamma}_{\alpha\beta} = \frac{2}{t}\lambda^\gamma_\alpha\gamma_{\gamma\beta}$$

Совокупность коэффициентов λ^γ_α можно рассматривать как матрицу некоторой линейной подстановки.

Путем соответствующего линейного преобразования координат x^1, x^2, x^3 (или, что эквивалентно, величин $g_{1\beta}, g_{2\beta}, g_{3\beta}$) можно, вообще говоря, привести эту матрицу к диагональному виду.

Обозначим ее главные значения посредством p_1, p_2, p_3 И будем считать, что все они вещественны и различны (о других случаях - см. ниже); единичные векторы в соответствующих

главных направлениях пусть будут $\mathbf{n}^{(1)}, \mathbf{n}^{(2)}, \mathbf{n}^{(3)}$. Тогда решение уравнений (117.6) можно представить в виде

$$\gamma_{\alpha\beta} = t^{2p_1} n_\alpha^{(1)} n_\beta^{(1)} + t^{2p_2} n_\alpha^{(2)} n_\beta^{(2)} + t^{2p_3} n_\alpha^{(3)} n_\beta^{(3)}$$

(постоянные коэффициенты при степенях t можно обратить в единицу путем соответствующего выбора масштаба координат).

Наконец, выбрав направления векторов $\mathbf{n}^{(1)}, \mathbf{n}^{(2)}, \mathbf{n}^{(3)}$ в качестве окончательного направления осей (назовем их x, y, z), приведем метрику к виду

$$ds^2 = dt^2 - t^{2p_1} dx^2 - t^{2p_2} dy^2 - t^{2p_3} dz^2$$

(E. Kasner, 1922).

Здесь p_1, p_2, p_3 - любые три числа, удовлетворяющие двум соотношениям:

$$p_1 + p_2 + p_3 = 1, \quad p_1^2 + p_2^2 + p_3^2 = 1$$

(первое следует из $-g = t^2$, а второе получается затем из (117.5)). Три числа p_1, p_2, p_3 не могут, очевидно, иметь одинаковые значения.

Равенство двух из них имеет место в тройках значений (0,0,1) и $(-1/3, 2/3, 2/3)$. Во всех других случаях числа p_1, p_2, p_3 различны причем одно из них отрицательно, а два других положительны.

Если расположить их в порядке $p_1 < p_2 < p_3$, то их значения будут лежать в интервалах

$$-\frac{1}{3} \leqslant p_1 \leqslant 0, \quad 0 \leqslant p_2 \leqslant \frac{2}{3}, \quad \frac{2}{3} \leqslant p_3 \leqslant 1$$

Таким образом, метрика (117.8) соответствует плоскому однородному, но анизотропному пространству, все объемы в котором растут (с увеличением времени) пропорционально t, причем линейные расстояния вдоль двух осей (y, z) увеличиваются, а вдоль одной (x) убывают.

Момент $t = 0$ является особой точкой решения; метрика имеет в ней особенность, не устранимую никаким преобразованием системы отсчета, причем инварианты тензора четырехмерной кривизны обращаются в бесконечность.

Исключением является лишь случай $p_1 = p_2 = 0, p_3 = 1$; при этих значениях мы имеем дело просто с плоскИм пространством-временем: преобразованием $t \operatorname{sh} z = \zeta, t \operatorname{ch} z = \tau$ метрика (117.8) приводится к галилеевой 1).

Метрика (117.8) является точным решением уравнений Эйнштейна ДлЯ пустого пространства.

Но вблизи особой точки, при малых t, она остается приближенным (с точностьЮ до членов главного порядка по $1/t$) решением уравнений и при наличии равномерно распределенной В пространстве материи.

Скорость и ход изменения плотности материи определяются при этом просто уравнениями ее движения в заданном гравитационном поле, а обратное влияние материи на поле оказывается пренебрежимым.

Плотность материи стремится к бесконечности при $t \to 0$ - в соответствии с физическим характером особенности (см. задачу 3).

ЛЛ2-117.1

Найти решение уравнений (117.6), соответствующее случаю, когда матрица λ_α^β имеет одно вещественное (p_3) и два комплексных $(p_{1,2} = p' \pm ip'')$ главных значения.

Р е ш е н и е.

В этом случае переменная x^0, от которой зависят все величины, должна иметь пространственный характер; обозначим ее как

$x^0 = x$. Соответственно в (117.1) должно быть теперь $g_{00} = -1$. Уравнения же (117.2)–(117.3) не меняются.

Векторы $\mathbf{n}^{(1)}, \mathbf{n}^{(2)}$ В (117.7) становятся комплексными: $\mathbf{n}^{(1,2)} = (\mathbf{n}' \pm \pm i\mathbf{n}'')/\sqrt{2}$, где $\mathbf{n}', \mathbf{n}''$ - единичные векторы.

Выбирая оси x^1, x^2, x^3 в направлениях $\mathbf{n}', \mathbf{n}'', \mathbf{n}^{(3)}$, получим решение в виде

$$-g_{11} = g_{22} = x^{2p'} \cos\left(2p'' \ln \frac{x}{a}\right), \quad g_{12} = -x^{2p'} \sin\left(2p'' \ln \frac{x}{a}\right)$$
$$g_{33} = -x^{2p_3}, \quad -g = -g_{00}\,|g_{\alpha\beta}| = x^2$$

где a - постоянная (которую уже нельзя устранить выбором масштаба вдоль оси x, не изменив других коэффициентов в написанных выражениях).

Числа p_1, p_2, p_3 по-прежнему удовлетворяют соотношениям (117.9), причем вещественное число p_3 либо меньше $-1/3$, либо больше единицы.

ЛЛ2-117.2

То же в случае совпадающих двух главных значений ($p_2 = p_3$).

Р е ш е н и е.

Как известно, из общей теории линейных дифференциальных уравнений, в этом случае система (117.6) может быть приведена к следующему каноническому виду:

$$\dot{g}_{11} = \frac{2p_1}{x} g_{11}, \quad \dot{g}_{2\alpha} = \frac{2p_2}{x} g_{2\alpha}, \quad \dot{g}_{3\alpha} = \frac{2p_2}{x} g_{3\alpha} = a_\alpha + \frac{\lambda}{x} g_{2\alpha}, \quad \alpha = 2, 3$$

где λ - постоянная.

При $\lambda = 0$ мы возвращаемся к (117.8).

При $\lambda \neq 0$ можно положить $\lambda = 1$; тогда

$$g_{11} = -x^{2p_1}, \quad g_{2\alpha} = a_\alpha x^{2p_2}, \quad g_{3\alpha} = a_\alpha x^{2p_2} \ln x + b_\alpha x^{2p_2}$$

Из условия $g_{32} = g_{23}$ находим, что $a_2 = 0, a_3 = b_2$. Надлежащим выбором масштаба вдоль осей x^2, x^3 окончательно приводим метрику к следующему виду:

$$ds^2 = -dx^2 - x^{2p_1} \left(dx^1\right)^2 \pm 2x^{2p_2} dx^2 dx^3 \pm x^{2p_2} \ln \frac{x}{a} \left(dx^3\right)^2$$

Числа p_1, p_2 могут иметь значения 1,0 или $-1/3, 2/3$.

ЛЛ2-117.3

Вблизи особой точки $t = 0$ найти закон изменения со временем плотности материи, равномерно распределенной в пространстве с метрикой (117.8).

Р е ш е н и е.

Пренебрегая обратным влиянием материи на поле, исходим из гидродинамических уравнений движения

$$\frac{1}{\sqrt{-q}} \frac{\partial}{\partial x^i} \left(\sqrt{-g}\sigma u^i\right) = 0$$

$$(p+\varepsilon)u^k\left(\frac{\partial u_i}{\partial x^k}-\frac{1}{2}u^l\frac{\partial g_{kl}}{dx^i}\right)=-\frac{\partial p}{\partial x^i}-u_iu^k\frac{\partial p}{\partial x^k}$$

содержащихся в уравнениях $T^k_{i;k}=0$ (см. «Гидродинамика», \$ 134).

Здесь σ - плотность энтропии; вблизи особенности надо пользоваться ультрарелятивистским уравнением состояния $p=\varepsilon/3$, и тогда $\sigma\propto e^{3/4}$.

Обозначим временные множители в (117.8) посредством $a=t^{p_1}, b=t^{p_2}$, $c=t^{p_3}$. Поскольку все величины зависят только от времени, а $\sqrt{-g}=abc$, уравнения (1) дают

$$\frac{d}{dt}\left(abcu_0\varepsilon^{3/4}\right)=0,\quad 4\varepsilon\frac{du_\alpha}{dt}+u_\alpha\frac{d\varepsilon}{dt}=0$$

Отсюда

$$abcu_0\varepsilon^{3/4}=\text{const}$$
$$u_\alpha\varepsilon^{1/4}=\text{const}.$$

Согласно (3) все ковариантные составляющие u_α - одинакового порядка величины.

Из контравариантных же компонент наиболее велика (при $t\to 0$) $u^3\approx u_3/c^2$. Сохранив в тождестве $u_iu^i=1$ лишь наибольшие члены, получим поэтому $u_0^2\approx u_3u^3=(u_3)^2/c^2$ и затем из (2) и (3):

$$\varepsilon\propto\frac{1}{a^2b^2},\quad u_\alpha\propto\sqrt{ab}$$

или

$$\varepsilon\propto t^{-2(p_1+p_2)}=t^{-2(1-p_3)},\quad u_\alpha\propto t^{(1-p_3)/2}$$

Как и следовало, ε стремится при $t\to 0$ к бесконечности для всех значений p_3, за исключением лишь $p_3=1$, - в соответствии с тем, что особенность в метрике с показателями (0,0,1) фиктивна.

Справедливость использованного приближения проверяется оценкой компонент T^k_i, опущенных в правых частях уравнений (117.2)-(117.3).

Главные члены в них:

$$llT^0_0\sim\varepsilon u_0^2\propto t^{-(1+p_3)},T^1_1\sim\varepsilon\propto t^{-2(1-p_3)}$$
$$T^2_2\sim\varepsilon u_2u^2\propto t^{-(1+2p_2-p_3)},T^3_3\sim\varepsilon u_3u^3\propto t^{-(1+p_3)}$$

Все они действительно растут при $t\to 0$ медленнее, чем левые стороны уравнений, возрастающие как t^{-2}.

6.4.4 Oscillations During Approach to Singularity

вкратце

Есть модель Кнезера, в которой какие-то есть колебания.

Theory

На примере модели мира с однородным пространством типа IX изучим особенность метрики по времени, имеющую колебательный характер.

Мы увидим в следующем параграфе, что такой характер имеет весьма общее значение.

Нас будет интересовать поведение модели вблизи особой точки (которую выберем в качестве начала отсчета времени, $t=0$).

Как и в рассмотренном в \$ 117 решении Казнера, наличие материи не отражается на качественных свойствах этого поведения, и для упрощения исследования будем предполагать пространство пустым.

Положим в (116.3)????? матрицу величин $\eta_{ab}(t)$ диагональной, обозначив ее диагональные элементы через a^2, b^2, c^2; три реперных вектора $\mathbf{e}^{(1)}, \mathbf{e}^{(2)}, \mathbf{e}^{(3)}$ обозначим теперь посредством $1, \mathbf{m}, \mathbf{n}$.

Тогда пространственная метрика запишется в виде

$$\gamma_{\alpha\beta} = a^2 l_\alpha l_\beta + b^2 m_\alpha m_\beta + c^2 n_\alpha n_\beta$$

Для пространства типа IX?????? структурные константы

$$C^{11} = C^{22} = C^{33} = 1$$

при этом $C^1_{23} = C^2_{31} = C^3_{12} = 1$

Из (116.26) видно, что для таких констант и при диагональной матрице η_{ab} компоненты $R^0_{(a)}$ тензора Риччи в синхронной системе отсчета обращаются в нуль тождественно.

Согласно (116.24) обращаются в нуль также и недиагональные компоненты $P_{(a)(b)}$.

Остальные компоненты уравнений Эйнштейна дают для функций $a(t), b(t), c(t)$ систему уравнений:

$$\begin{aligned}
\frac{(\dot{a}bc)^{\cdot}}{abc} &= \frac{1}{2a^2b^2c^2}\left[\left(b^2-c^2\right)^2 - a^4\right] \\
\frac{(abc)^2}{abc} &= \frac{1}{2a^2b^2c^2}\left[\left(a^2-c^2\right)^2 - b^4\right] \\
\frac{(ab\dot{c})^{-}}{abc} &= \frac{1}{2a^2b^2c^2}\left[\left(a^2-b^2\right)^2 - c^4\right] \\
&\frac{\ddot{a}}{a} + \frac{\ddot{b}}{b} + \frac{\ddot{c}}{c} = 0
\end{aligned}$$

((118.3) - уравнения $R^{(1)}_{(1)} = R^{(2)}_{(2)} = R^{(3)}_{(3)} = 0$; (118.4) - уравнение $R^0_0 = 0$)

Производные по времени в системе (118.3) – (118.4) принимают более простой вид, если ввести вместо функций a, b, c их логарифмы α, β, γ :

$$a = e^\alpha, \quad b = e^\beta, \quad c = e^\gamma$$

а вместо t - переменную τ согласно

$$dt = abcd\tau$$

Тогда:

$$\begin{aligned}
2\alpha_{,\tau,\tau} &= \left(b^2-c^2\right)^2 - a^4 \\
2\beta_{,\tau,\tau} &= \left(a^2-c^2\right)^2 - b^4 \\
2\gamma_{,\tau,\tau} &= \left(a^2-b^2\right)^2 - c^4 \\
\frac{1}{2}(\alpha+\beta+\gamma)_{,\tau,\tau} &= \alpha_{,\tau}\beta_{,\tau} + \alpha_{,\tau}\gamma_{,\tau} + \beta_{,\tau}\gamma_{,\tau}
\end{aligned}$$

где индекс τ означает дифференцирование по τ. Сложив почленно уравнения (118.7) и заменив в левой стороне сумму вторых производных согласно (118.8), получим:

$$\alpha_{,\tau}\beta_{,\tau} + \alpha_{,\tau}\gamma_{,\tau} + \beta_{,\tau}\gamma_{,\tau} = \frac{1}{4}\left(a^4 + b^4 + c^4 - 2a^2b^2 - 2a^2c^2 - 2b^2c^2\right)$$

Это соотношение содержит только первые производные и представляет собой первый интеграл уравнений (118.7).

Уравнения (118.3) – (118.4) не могут быть решены точно в аналитическом виде, но вблизи особой точки допускают детальное качественное исследование.

Прежде всего замечаем, что в отсутствие правых частей в уравнениях (118.3) (или, что то же, в уравнениях (118.7)) система имела бы точное решение, в котором

$$a \sim t^{p_l}, \quad b \sim t^{p_m}, \quad c \sim t^{p_n}, \quad (118.10)$$

где p_l, p_m, p_n - числа, связанные соотношениями

$$p_l + p_m + p_n = p_l^2 + p_m^2 + p_n^2 = 1$$

(аналог решения Казнера (117.8) для однородного плоского пространства).

Мы обозначили здесь показатели степеней как p_l, p_m, p_n, не предопределяя их последовательности в порядке возрастания; обозначение же p_1, p_2, p_3 из §117 сохраним за тройками чисел, расположенных в порядке $p_1 < p_2 < p_3$ и соответственно пробегающими значения в интервалах (117.10).

Эти числа могут быть представлены в параметрическом виде как

$$p_1(u) = \frac{-u}{1+u+u^2}, \quad p_2(u) = \frac{1+u}{1+u+u^2}, \quad p_3(u) = \frac{u(1+u)}{1+u+u^2}$$

Все различные значения p_1, p_2, p_3 (с соблюдением условного порядка) Получаются, если параметр u пробегает значения в области $u \geqslant 1$. Значения же $u < 1$ приводятся к той же области согласно

$$p_1\left(\frac{1}{u}\right) = p_1(u), \quad p_2\left(\frac{1}{u}\right) = p_3(u), \quad p_3\left(\frac{1}{u}\right) = p_2(u)$$

На рис. 25 изображены графики p_1, p_2, p_3 в зависимости от $1/u$.

Предположим, что в некотором интервале времени правые части В уравнениях (118.7) действительно малы, так что ими можно пренебречь и имеет место казнеровский режим (118.10).

Такая ситуация не может продолжаться (при $t \to 0$) неограниченно, так как среди указанных членов всегда имеются возрастающие.

Так, если отрицательный показатель степени относится к функции $a(t)$ $(p_l = p_1 < 0)$, то возмущение казнеровского режима возникает от членов a^4; остальные же члены при уменьшении t будут убывать.

Сохранив в правых частях (118.7) лишь эти члены, получим систему уравнений

$$\alpha_{,\tau,\tau} = -\frac{1}{2}e^{4\alpha}, \quad \beta_{,\tau,\tau} = \gamma_{,\tau,\tau} = \frac{1}{2}e^{4\alpha}$$

Решение этих уравнений должно описывать эволюцию метрики из «начального» состояния, в котором оно описывается формулами (118.10) с определенным набором показателей (причем $p_l < 0$); пусть $p_l = p_1, p_m = p_2, p_n = p_3$, так что

$$a = t^{p_1}, \quad b = t^{p_2}, \quad c = t^{p_3}$$

(коэффициенты пропорциональности в этих выражениях можно положить равными 1 без ограничения общности получаемого ниже результата).

При этом $abc = t, \tau = \ln t +$ const, поэтому начальные условия длЯ уравнений (118.14) формулируются в виде

$$\alpha_{,\tau} = p_1, \quad \beta_{,\tau} = p_2, \quad \gamma_{,\tau} = p_3$$

Первое из уравнений (118.14) имеет вид уравнения одномерного движения частицы в поле экспоненциальной потенциальной стенки, причем α играет роль координаты.

В этой аналогии начальному казнеровскому режиму соответствует свободное движение с постоянной скоростью $\alpha_{,\tau} = p_1$. Отразившись от стенки, частица будет снова двигаться свободно со скоростью обратного знака: $\alpha_{,\tau} = -p_1$. Заметив также, что в силу всех трех уравнений (118.14)

$$\alpha_{,\tau} + \beta_{,\tau} = \text{const}, \quad \alpha_{,\tau} + \gamma_{,\tau} = \text{const}$$

найдем, что $\beta_{,\tau}$ и $\gamma_{,\tau}$ приобретут значения $\beta_{,\tau} = p_2 + 2p_1, \gamma_{,\tau} = p_3 + 2p_1$ Определив отсюда α, β, γ и затем t согласно (118.6), Получим:

$$e^{\alpha} \sim e^{-p_1\tau}, \quad e^{\beta} \sim e^{(p_2+2p_1)\tau}, \quad e^{\gamma} \sim e^{(p_3+2p_1)\tau}, \quad t \sim e^{(1+2p_1)\tau}$$

Т. е. $a \sim t^{p'_l}, b \sim t^{p'_m}, c \sim t'^{p}_{n}$, где

$$p'_l = \frac{|p_1|}{1-2|p_1|}, \quad p'_m = -\frac{2|p_1| - p_2}{1-2|p_1|}, \quad p'_n = \frac{p_3 - 2|p_1|}{1-2|p_1|}$$

Таким образом, воздействие возмущения приводит к смене одной «Казнеровской эпохи» другой, причем отрицательная степень t перебрасывается с направления l на направление m : если было $p_l < 0$, то теперь $p'_m < 0$. В процессе смены функция $a(t)$ проходит через максимум, а $b(t)$ - через минимум: убывавшая прежде величина $b(t)$ начинает возрастать, возраставшая $a(t)$ - падать, а функция $c(t)$ продолжает убывать.

Само возмущение (члены a^4 в уравнениях (118.7)), прежде возраставшее, начинает убывать и затухает.

Дальнейшая эволюция метрики приведет аналогичным образом к возрастанию возмущения, выражающегося членами b^4 в уравнениях (118.7), следующей смене казнеровских показателей, и т.д.

Правило смены показателей (118.15) удобно представить с помощью параметризации (118.12): если

$$p_l = p_1(u), \quad p_m = p_2(u), \quad p_n = p_3(u)$$

то

$$p'_l = p_2(u-1), \quad p'_m = p_1(u-1), \quad p'_n = p_3(u-1)$$

Остается положительным больший из двух положительных показателей.

В этом процессе смен казнеровских эпох лежит ключ к пониманию характера эволюции метрики при приближении к особой точке.

Последовательные смены (118.16) с перебросом отрицательного показателя степени (p_1) между направлениями 1 и m продолжаются до тех пор, пока не исчерпается целая часть начального значения и И не станет $u < 1$. Значение $u < 1$ преобразуется В $u > 1$ согласно (118.13); в этот момент отрицателен показатель p_l Или p_m, а p_n становится меньшим из двух положительных чисел ($p_n = p_2$). СледуюЩая серия смен будет уже перебрасывать отрицательный показатель между направлениями **n** и 1 или между **n** и **m**. При произвольном (иррациональном) начальном значении u процесс смен продолжается неограниченно.

При точном решении уравнений показатели p_1, p_2, p_3 теряют, конечно, свой буквальный смысл.

Отметим, что вносимая этим обстоятельством некоторая «размытость» в определении этих чисел (а с ними и параметра u), хотя она и мала, лишает смысла рассмотрение как-либо выделенных (например, рациональных) значений и.

Именно поэтому реальным смыслом обладают лишь те закономерности, которые свойственны общему случаю произвольных иррациональных значений и.

Таким образом, процесс эволюции модели в направлении к особой точке складывается из последовательных серий колебаний, в течение Каждой из которых расстояния вдоль

двух пространственных осей осциллируют, а вдоль третьей - монотонно убывают; объем убывает по закону, близкому К $\sim t$. При переходе от одной серии к следущая серия смен будет уже перебрасывать отрицательный показатель (иррациональном) начальном значении и процесс смен продолжается неограниченно.

При точном решении уравнений показатели p_1, p_2, p_3 теряют, конечно, свой буквальный смысл.

Отметим, что вносимая этим обстоятельством некоторая «размытость» в определении этих чисел (а с ними и параметра u), хотя она и мала, лишает смысла рассмотрение как-либо выделенных (например, рациональных) значений и.

Именно поэтому реальным смыслом обладают лишь те закономерности, которые свойственны общему случаю произвольных иррациональных значений и.

Таким образом, процесс эволюцИи модели в направлении к особой точке складывается из последовательных серий колебаний, в течение Каждой из которых расстояния вдоль двух пространственных осей осциллируют, а вдоль третьей - монотонно убывают; объем убывает по закону, близкому К $\sim$ t.

При переходе от одной серии к следуюЩей направление, вдоль которого происходит монотонное убывание расстояний, переходит с одной оси на другую.

Порядок этих переходов приобретает асимптотически характер случайного процесса.

Такой же характер приобретает и порядок чередования длин последовательных серий колебаний (т. е. чисел сменяющихся в каждой серии «казнеровских эпох»).

Последовательные серии колебаний сгущаются по мере приближения к особой точке.

Между любым конечным моментом мирового времени t и моментом $t = 0$ заключено бесконечное множество колебаний.

Естественной переменной для описания временного хода этой эволюции оказывается не само время t, а его логарифм, $\ln t$, по которому весь процесс приближения к особой точке растянут до - ∞.

В изложенном решении мы с самого начала несколько упростили задачу, предположив матрицу $\eta_{ab}(t)$ в (116.3) диагональной.

Включение в метрику недиагональных компонент η_{ab} не меняет описанного колебательного характера эволюции метрики и закона (118.16) смен показателей p_l, p_m, p_n чередующихся казнеровских эпох.

Оно приводит, однако, к появлению дополнительного свойства: смена показателей сопровождается также и изменением направлений осей, к которым эти показатели относятся.

6.4.5 Singularity in Einstein's Equation for Cosmology (???)

вкратце особенности

Theory

Уже было отмечено, что адекватность модели Фридмана для описания современного состояния Вселенной сама по себе еще не дает оснований ожидать, что она столь же пригодна и для описания ранних стадий эволюции мира.

В этой связи возникает прежде всего вопрос о том, в какой степени существование особой точки по времени вообще является обязательным свойством космологических моделей; и не связано ли оно со специфическими упрощающими предположениями (в первую очередь с симметрией), лежащими в их основе.

Подчеркнем, что, говоря об особой точке, мы имеем в виду физическую особенность — обращение в бесконечность плотности материи и инвариантов тензора четырехмерной кривизны.

Независимость от специфических предположений означала бы, что наличие особенности присуще не только частным, но и общему решению уравнений Эйнштейна.

Критерием общности является число содержащихся в решений «физически произвольных» функций. В общем решении число таких функций должно быть достаточным для произвольного задания начальных условий в какой-либо выбран- ный момент времени (4 для пустого пространства, 8 для пространства, заполненного материей, — см. пар 95).

Нахождение общего решения в точном виде для всего пространства в течение всего времени, разумеется, невозможно.

Но для решения поставленного вопроса в этом нет необходимости: достаточно исследовать вид решения вблизи особенности. Особенность, которую имеет решение Фридмана, характерна тем, что обращение в нуль пространственных расстояний происходит по одинаковому закону во всех направлениях.

Такой тип особенности не является достаточно общим: он свойствен классу решений, содержащему лишь три произвольные функции координат (см. задачу к пар 113).

Отметим также, что эти решения существуют только для пространства, заполненного материей. Особенность же колебательного типа, рассмотренная в предыдущем параграфе, имеет общий характер — существует решение уравнений Эйнштейна с такой особенностью, содержащее всю требуемую совокупность произвольных функций.

Мы обрисуем здесь кратко способ построения такого решения, не вникая в детали вычислений 1). Как и в однородной модели (пар 118), режим приближения к особой точке в общем решении складывается из чередующихся серий сменяющих друг друга «казнеровских эпох».

В течение каждой такой эпохи главные (по $1/t$) члены в пространственном метрическом тензоре (в синхронной системе отсчета) имеют вид (118.1) с функциями времени a, b, c из (118.10), но векторы l, m, n являются теперь произвольными (а не вполне определенными, как в однородной модели) функциями пространственных координат.

Такими же функциями (а не просто числами) являются теперь показатели pl, pm, pn, по-прежнему связанные друг с другом соотношениями (118.11).

Построенная таким образом метрика удовлетворяет уравнениям $R_0^0 = 0$ и $R_\alpha^\beta = 0$ для поля в пустоте (В иХ Главных членах) в течение некоторого конечного интервала времени.

Уравнения же $R_\alpha^0 = 0$ приводят к трем соотношениям (не содержащим времени), которые должны быть наложены на содержащиеся В $\gamma_{\alpha\beta}$ произвольные функции пространственных координат.

Эти соотношения связывают между собой 10 различных фунКций: по три степеней времени (какая-либо из трех функций p_l, p_m, p_n, связанных Двумя условиями (118.11)).

При определении числа физически проИзвольных функций надо учесть также, что синхронная система отсчета допускает еще произвольные преобразования трех пространственных Координат, не затрагивающие времени.

поэтому метрика содержит всего $10-3-3 = 4$ произвольные функции - именно столько, сколько должно быть в обшем решении для поля в пустоте.

Смена одной казнеровской эпохи на другую происходит (как и в однородной модели) благодаря наличию в трех из шести уравнений $r_\alpha^\beta = 0$ членов, которые при уменьшении t растут быстрее других, играя, таким образом, роль возмущения, разрушающего казнеровский режим. эти уравнения в общем случае имеют вид, отличающийся от уравнений (118. 14) лишь зависящим от пространственных координат множителем $(\mathrm{lrot}\, 1/\mathbf{l}[\mathbf{mn}])^2$ в их правых сторонах (подразумевается, что из трех показателей p_l, p_m, p_n отрицателен p_l) 1). поскольку, однако, уравнения (118. 14) составляют систему обыкновенных дифференциальных уравнений по отношению ко времени, это отличие никак не сказывается на их решении и на следуюшем из этого решения законе смены казнеровских показателей (118. 16), а тем самым и на всех дальнейших следствиях, изложенных в \$118[2]). степень общности

решения не уменьшается при введении материи: материя «вписывается» в метрику со всеми вносимыми ею 4 новыми координатными функциями, необходимыми для задания начальных распределений ее плотности и трех компонент скорости. тензор энергии-импульса материи T_i^k привносит в уравнения поля члены, оказывающиеся более высокого порядка по $1/t$, чем главные члены (в точности аналогично тому, как это было показано в задаче 3 к \$117 для плоской однородной модели).

Таким образом, существование особой точки по времени является весьма общим свойством решений уравнений Эйнштейна, причем режим приближения к особой точке имеет в общем случае колебательный характер [3]). Подчеркнем, что этот характер не связан с наЛичием материи (а потому и с ее уравнением состояния) и свойствен уже самому по себе пустому пространству-времени. Зависящая же

От присутствия материи особенность монотонного изотропного тиПа, свойственная решению Фридмана, имеет лишь частное значение.

Говоря об особенностях в космологическом аспекте, мы имеем В виду особую точку, достигаемую всем пространством, а не лишь его ограниченной частью, как при гравитационном коллапсе конечного тела. Но общность колебательного решения дает основание полагать,

что такой же характер имеет и особенность, достигаемая конечным те- лом в его коллапсе под горизонтом событий в сопутствующей системе отсчета. Мы везде говорили о направлении приближения к особой точке как о направлении уменьшения времени; но ввиду симметрии уравнений Эйнштейна по отношению к изменению знака времени, с тем же правом могла бы идти речь о приближении к особенности в направлении уве- личения времени.

В действительности, однако, ввиду физической неэк- вивалентности будущего и прошедшего между этими двумя случаями имеется существенное отличие в отношении самой постановки вопроса. Особенность в будущем может иметь физический смысл, лишь если она допустима при произвольных начальных условиях, задаваемых в какой-либо предшествующий момент времени.

Ясно, что нет никаких оснований для того, чтобы распределение материи и поля, достигаемое в какой-либо момент в процессе эволюции Вселенной, соответствовало бы специфическим условиям, требуемым для осуществления того или иного частного решения уравнений Эйнштейна. На вопрос же о типе особенности в прошлом исследование, основанное на одних лишь уравнениях гравитации, вряд ли вообще может дать однозначный ответ.

Естественно думать, что отбор решения, отвечающего реальному миру, связан с какими-то глубокими физиче- скими требованиями, установление которых на основании одной лишь существующей теории гравитации невозможно и которые смогут быть выяснены лишь в результате дальнейшего синтеза физических теорий. В этом смысле в принципе может оказаться, что этому отбору соответ- ствует какой-либо частный (например, изотропный) тип особенности. Наконец, необходимо сделать еще следующее замечание.

Область применимости уравнений Эйнштейна самих по себе никак не ограни- чена со стороны малых расстояний или больших плотностей материи в том смысле, что уравнения не приводят в этом пределе ни к каким внутренним противоречиям (в отличие, например, от классических уравнений электродинамики).

В этом смысле исследование особенно- стей пространственно-временной метрики на базе уравнений Эйнштей- на вполне корректно.

Нет сомнений, однако, в том, что в действитель- ности в указанном пределе должны стать существенными квантовые явления, о которых при современном состоянии теорий мы еще ничего не можем сказать.

Лишь в будущем синтезе теории тяготения и кван- товой теории сможет выясниться, чт´о именно из результатов класси- ческой теории сохранит реальный смысл.

В то же время нет сомнений и в том, что самый факт возникновения особенностей в решениях урав- нений Эйнштейна (как в космологическом аспекте, так и для коллапса конечных тел) имеет глубокий физический смысл.

Не надо забывать и о том, что достижение в процессе гравитационного коллапса уже тех огромных плотностей, при которых еще нет оснований для сомнений в законности классической теории тяготения, достаточны для того, чтобы говорить о физически «особом» явлении.

6.5 Relics from the Hot Big Bang

6.5.1 Introduction

There are many reasons to believe that our current understanding of fundamental physics is incomplete. For example, the nature of dark matter and dark energy are still unknown, the stability of the Higgs mass remains unsolved, the origin of neutrino masses is unexplained, the strong CP problem is still there, the physics of inflation remains elusive, and the origin of the matter-antimatter asymmetry is still to be discovered. Attempts to address these shortcomings of the Standard Model (hereafter SM) often involve new degrees of freedom. These new particles can escape detection in terrestrial experiments either because they are too *heavy* to be produced at the energies available or because they are too *weakly coupled* to be created in sufficiently large numbers. However, in astrophysical systems and in the early universe the small cross sections can be compensated for by probing environments with large densities and by following the evolution over long time scales. For example, the high densities at the cores of stars allow a significant production of new weakly coupled species. Integrated over the long lifetime of stars this can lead to large deviations from the standard stellar evolution. Observations of the lifecycles of stars have therefore put interesting constraints on the couplings of new light species to the SM. Similarly, in the hot environment of the early universe, even extremely weakly coupled particles can be produced prolifically and their gravitational influence becomes detectable in the cosmic microwave background (CMB). Moreover, during inflation even very massive particles can be created by the rapid expansion of the spacetime. When these particles decay they produce distinctive signatures in cosmological observables. Observing these effects could teach us a great deal about the physics driving the inflationary expansion.

New physics can affect cosmological observables in two distinct ways: *i*) it may affect the *initial conditions* of the hot big bang, or *ii*) it may affect the *evolution* of these initial conditions through changes to the thermal history of the universe. These opportunities for probing new physics with cosmological observations are illustrated in the following schematic:

$$\begin{array}{ccc} & \text{new physics?} & \\ & \downarrow & \\ \underset{\text{initial conditions}}{\langle \zeta_{\mathbf{k}_1} \zeta_{\mathbf{k}_2} \ldots \rangle} & \xrightarrow{\qquad \text{evolution} \qquad} & \underset{\text{cosmological correlators}}{\langle O_1 O_2 \ldots \rangle} \\ \uparrow & & \\ \text{new physics?} & & \end{array}$$

where ζ denotes the primordial curvature perturbations and O stands for late-time observables, which may be the temperature variations δT of the CMB or the density fluctuations $\delta\rho_g$ in the distribution of galaxies. In these lectures, we will give examples from both of these avenues of tests for physics beyond the Standard Model (BSM).

The initial fluctuations were drawn from a probability distribution $P[\zeta]$ and hence are

characterized by the following correlation functions

$$\langle \zeta_{\mathbf{k}_1} \zeta_{\mathbf{k}_2} \ldots \rangle = \int \mathcal{D}\zeta \, P[\zeta] \, \zeta_{\mathbf{k}_1} \zeta_{\mathbf{k}_2} \cdots \, .$$

By tracing the observed correlations $\langle O_1 O_2 \ldots \rangle$ back in time, cosmologists try to measure the initial correlations $\langle \zeta_{\mathbf{k}_1} \zeta_{\mathbf{k}_2} \ldots \rangle$ and use them to extract information about the initial probability distribution $P[\zeta]$ and about the physics that gave rise to it. If the early universe went through a period of inflation then these initial correlations were produced dynamically *before* the hot big bang. New physics during inflation, such as the existence of new degrees of freedom X, can leave imprints in the spectrum of primordial perturbations, i.e. $P[\zeta] \to P[\zeta, X]$.

New physics may also affect how the initial correlations evolve into the late-time observables. For example, the evolution equations for fluctuations in the primordial plasma can be affected by the presence of new degrees of freedom X:

$$G_{\mu\nu} = 8\pi G \left(T^{\rm SM}_{\mu\nu} + T^{X}_{\mu\nu} \right) \, , \qquad \nabla^\mu \left(T^{\rm SM}_{\mu\nu} + T^{X}_{\mu\nu} \right) = 0 \, .$$

As we will see, much of the evolution in the early universe is very well understood and probed by very precise observations. The possibilities for new physics are therefore highly constrained.

The most conservative way to parameterize physics beyond the Standard Model is in terms of an *effective field theory* (EFT). The basic input of an EFT are the field content and the symmetries that are relevant at a given energy scale. The effective Lagrangian is then the sum of all operators consistent with the symmetries,

$$\mathcal{L}_{\rm eff} \, \subset \, \sum g \, \mathcal{O}_X \mathcal{O}_{\rm SM} \, ,$$

where $\mathcal{O}_{\rm SM}$ denotes operators made from the SM degrees of freedom and $\mathcal{O}_X$ stands for operators constructed from any additional fields. The couplings g parameterize the strengths of the interactions between the fields X and the SM. Deviations from the SM predictions then scale with the size of the couplings g. In these lectures, I will show how cosmological observations put constraints on these couplings.

Outline

The goal of these lectures is to show that cosmology is becoming an increasingly sensitive probe of BSM physics. The presentation is divided into two parts: In Part I, we study the production of new light particles in the hot big bang and describe their effects on the anisotropies of the cosmic microwave background. In Part II, we investigate the possibility of very massive particles being created during inflation and determine their imprints in higher-order cosmological correlations.

Notation and conventions

Throughout these lectures, we will use natural units, $c = \hbar = 1$, with reduced Planck mass $M_{\rm pl}^2 = 1/8\pi G$. Our metric signature is $(-+++)$. Greek letters will stand for spacetime indices, $\mu, \nu, \ldots = 0, 1, 2, 3$, and Latin letters for spatial indices, $i, j, \ldots = 1, 2, 3$. Three-dimensional vectors will be written in boldface, $\mathbf{k}$, and unit vectors will be hatted, $\hat{\mathbf{k}}$. Overdots and primes will denote derivatives with respect to conformal time τ and physical time t, respectively. The dimensionless power spectrum of a Fourier mode $\zeta_{\mathbf{k}}$ will be defined as

$$\mathcal{P}_\zeta(k) \equiv \frac{k^3}{2\pi^2} \langle \zeta_{\mathbf{k}} \zeta_{-\mathbf{k}} \rangle' \, ,$$

where the prime on the expectation value indicates that the overall momentum-conserving delta function has been dropped.

Acknowledgements

I am grateful to the organizers Igor Klebanov and Mirjam Cvetic for the invitation to lecture at TASI 2017. Thanks to my students and collaborators for many helpful discussions on the material presented in these lectures. I am especially grateful to Daniel Green, Joel Meyers, Benjamin Wallisch and Matias Zaldarriaga for collaboration on topics covered in Part I, and to Nima Arkani-Hamed, Valentin Assassi, Garrett Goon, Daniel Green, Hayden Lee, Liam McAllister and Guilherme Pimentel for collaboration on work described in Part II. Finally, thanks to Benjamin Wallisch and Swagat Saurav Mishra for comments on a preliminary version of the manuscript.

6.5.2 Theory

Consider a $2 \to N$ scattering process producing a new particle species X. Assume that X is very weakly coupled to the Standard Model degrees of freedom. The production of particles X then carries energy and momentum away from the interaction region. Such missing energy, of course, famously led to the discovery of neutrinos. However, particles that are more weakly coupled than neutrinos are produced very rarely in colliders and their missing energy signatures are hard to detect. Fortunately, the creation of new species may be enhanced in astrophysical systems and in the early universe. To see this, consider the change in the number densities of the particles involved in the above interaction. Schematically, this is given by

$$\frac{\Delta n}{n} \sim n\sigma \times \Delta t \,,$$

i.e. the fractional change in the number density is equal to the interaction rate, $\Gamma \sim n\sigma$, times the interaction time, Δt. We see that small cross sections σ can be compensated for by high densities and long time scales. This explains why observations of the lifecycles of stars have put interesting constraints on the existence of extra species. Taking the typical number density inside of stars to be $n \sim (1\,\mathrm{keV})^3$ and integrating over the typical lifetime of a star, $\Delta t \sim 10^{16}\,\mathrm{sec} \approx 1.5 \times 10^{31}\,\mathrm{eV}^{-1}$, we find significant changes in the stellar evolution if

$$\sigma > (n\Delta t)^{-1} \sim (10^{10}\,\mathrm{GeV})^{-2} \,.$$

Similar constraints can be derived from the observed energy loss in supernova explosions. In that case, the relevant time scales are much shorter, $\Delta t \sim 10\,\mathrm{sec}$, but the densities are much higher, $n \sim (30\,\mathrm{MeV})^3$.

These order of magnitude estimates also give us a sense for the power of cosmological constraints. In the early universe, the interaction time scales are short, $\Delta t < 1\,\mathrm{sec}$, but the densities can be very high, $n \sim T^3 \gg (1\,\mathrm{MeV})^3$. For temperatures above $10^4\,\mathrm{GeV}$, we expect cosmological constraints to be stronger than those from astrophysics. In this part of the lectures, we will show that primordial cosmology is indeed a highly sensitive probe of new light particles produced in the hot Big Bang.

We will begin, in Section 6.5.3, with a quick review of FRW cosmology. In Section 7.5.2, we will introduce the cosmic microwave background as a tool for precision cosmology. In Section 6.5.5, we will discuss the physics of the acoustic oscillations observed in the CMB anisotropy spectrum. Finally, in Section 6.5.6, we will show that extra relativistic particles leave a unique signature in the CMB spectrum.

6.5.3 Big Bang Cosmology

We will begin with a lightning review of some elementary concepts in cosmology. I will assume that you have seen most, if not all, of this material before, so I will cite many results without detailed derivations. Further details can be found in my *Cosmology* course [1] or in any of the standard textbooks (e.g. [2, 3]).

Geometry and Dynamics

The Friedmann-Robertson-Walker (FRW) metric of a homogenous and isotropic spacetime is

$$\mathrm{d}s^2 = -\mathrm{d}t^2 + a^2(t)\gamma_{ij}\,\mathrm{d}x^i\mathrm{d}x^j\,, \tag{30}$$

where γ_{ij} denotes the metric of a maximally symmetric 3-space and $a(t)$ is the scale factor. Throughout these lectures, we will restrict to the special case of flat spatial slices, i.e. $\gamma_{ij} = \delta_{ij}$, and define $\mathrm{d}\mathbf{x}^2 \equiv \delta_{ij}\mathrm{d}x^i\mathrm{d}x^j$. We will also introduce conformal time, $\mathrm{d}\tau = \mathrm{d}t/a(t)$, so that the metric becomes

$$\mathrm{d}s^2 = a^2(\tau)\left(-\mathrm{d}\tau^2 + \mathrm{d}\mathbf{x}^2\right). \tag{31}$$

We will first discuss the kinematics of particles in an FRW spacetime for an arbitrary scale factor $a(\tau)$. After that, we will show how the Einstein equations determine $a(\tau)$ in terms of the matter content of the universe.

Kinematics

Particles in the FRW spacetime evolve according to the geodesic equation

$$P^\nu\nabla_\nu P^\mu = P^\nu\left(\frac{\partial P^\mu}{\partial x^\nu} + \Gamma^\mu_{\nu\rho}P^\rho\right) = 0\,, \tag{32}$$

where $P^\mu \equiv dx^\mu/d\lambda$ is the four-momentum of the particle. In an expanding spacetime, it is convenient to write the components of the four-momentum as

$$P^\mu = a^{-1}[E, \mathbf{p}]\,. \tag{33}$$

For massless particles, such as photons, we have the constraint $g_{\mu\nu}P^\mu P^\nu = -E^2 + |\mathbf{p}|^2 = 0$, so we can write $\mathbf{p} = E\,\hat{\mathbf{p}}$, where $\hat{\mathbf{p}}$ is a unit vector in the direction of propagation.

Exercise.—Show that the non-zero connection coefficients associated with the metric (328) are

$$\Gamma^0_{00} = \mathcal{H}\,, \quad \Gamma^0_{ij} = \mathcal{H}\delta_{ij}\,, \quad \Gamma^i_{j0} = \mathcal{H}\delta^i_j\,, \tag{34}$$

where $\mathcal{H} \equiv \dot{a}/a$ is the conformal Hubble parameter.

The $\mu = 0$ component of the geodesic equation (32) becomes

$$P^0\frac{dP^0}{d\tau} = -\Gamma^0_{\alpha\beta}P^\alpha P^\alpha\,. \tag{35}$$

Using (33) and (34), we get

$$(a^{-1}E)\frac{d}{d\tau}(a^{-1}E) = -\mathcal{H}a^{-2}E^2 - \mathcal{H}a^{-2}|\mathbf{p}|^2\,, \tag{36}$$

which simplifies to

$$\frac{1}{E}\frac{dE}{d\tau} = -\frac{1}{a}\frac{da}{d\tau}\,. \tag{37}$$

This describes the *redshifting* of the photon energy in an expanding spacetime, $E \propto a^{-1}$.

Dynamics

The evolution of the scale factor is determined by the Friedmann equations

$$3\mathcal{H}^2 = 8\pi G a^2 \bar{\rho}\,, \tag{38}$$

$$2\dot{\mathcal{H}} + \mathcal{H}^2 = -8\pi G a^2\, \bar{P}\,, \tag{39}$$

where $\bar{\rho}$ and $\bar{P}$ are the background density and pressure, respectively.

Exercise.—By substituting (34) into

$$R_{\mu\nu} \equiv \partial_\lambda \Gamma^\lambda_{\mu\nu} - \partial_\nu \Gamma^\lambda_{\mu\lambda} + \Gamma^\lambda_{\lambda\rho}\Gamma^\rho_{\mu\nu} - \Gamma^\rho_{\mu\lambda}\Gamma^\lambda_{\nu\rho} \tag{40}$$

show that

$$R_{00} = -3\dot{\mathcal{H}}\,, \quad R_{ij} = (\dot{\mathcal{H}} + 2\mathcal{H}^2)\delta_{ij} \quad \Rightarrow \quad a^2 R \equiv a^2 g^{\mu\nu} R_{\mu\nu} = -6(\dot{\mathcal{H}} + \mathcal{H}^2)\,. \tag{41}$$

Hence, show that the non-zero components of the Einstein tensor, $G_{\mu\nu} \equiv R_{\mu\nu} - \frac{1}{2} R g_{\mu\nu}$, are

$$G_{00} = 3\mathcal{H}^2\,, \quad G_{ij} = -(2\dot{\mathcal{H}} + \mathcal{H}^2)\delta_{ij}\,. \tag{42}$$

Use this to confirm that the 00-Einstein equation, $G_{00} = 8\pi G T_{00}$, implies (A.122) and the ij-Einstein equation, $G_{ij} = 8\pi G T_{ij}$, leads to (39).

Combining (A.122) and (39), we can write an evolution equation for the density

$$\dot{\bar{\rho}} = -3\mathcal{H}(\bar{\rho} + \bar{P})\,. \tag{43}$$

For pressureless matter ($\bar{P}_m \approx 0$) this implies $\bar{\rho}_m \propto a^{-3}$, while for radiation ($\bar{P}_r = \frac{1}{3}\bar{\rho}_r$) we have $\bar{\rho}_r \propto a^{-4}$.

Exercise.—Derive the continuity equation (43) from the conservation of the stress tensor, $\nabla^\mu T_{\mu\nu} = 0$. By integrating the Friedmann equation (A.122) for matter and radiation show that

$$a(\tau) = \begin{cases} \tau^2 & \text{matter} \\ \tau & \text{radiation} \end{cases}\,. \tag{44}$$

Cosmic inventory

The universe is filled with several different species of particles:

$$\underbrace{\text{photons } (\gamma) \quad \text{neutrinos } (\nu)}_{\text{radiation } (r)} \qquad \overbrace{\underbrace{\text{electrons } (e) \quad \text{protons } (p)}_{\text{baryons } (b)} \quad \text{cold dark matter } (c)}^{\text{matter } (m)}\,.$$

The number density, energy density and pressure of each species a can be written as

$$n_a = g_a \int \frac{\mathrm{d}^3 p}{(2\pi)^3}\, f_a(\mathbf{x}, \mathbf{p})\,, \tag{45}$$

$$\rho_a = g_a \int \frac{\mathrm{d}^3 p}{(2\pi)^3}\, f_a(\mathbf{x}, \mathbf{p})\, E(p)\,, \tag{46}$$

$$P_a = g_a \int \frac{\mathrm{d}^3 p}{(2\pi)^3}\, f_a(\mathbf{x}, \mathbf{p})\, \frac{p^2}{3E(p)}\,, \tag{47}$$

where $f_a(\mathbf{x}, \mathbf{p})$ is the (phase space) distribution function of the species a, and g_a is the number of internal degrees of freedom. In the unperturbed universe, the distribution functions should not depend on the position and the direction of the momentum, i.e. $f_a(\mathbf{x}, \mathbf{p}) \to \bar{f}_a(E(p))$.

At early times, particle interactions were efficient enough to keep the different species in local equilibrium. They then shared a common temperature T and the distribution functions take the following maximum entropy form

$$\bar{f}_a(E) = \frac{1}{e^{(E_a - \mu_a)/T} \pm 1}\,, \tag{48}$$

with + for fermions and - for bosons. The chemical potential μ_a vanishes for photons and is (likely) small for all other species. We will henceforth set it to zero. When the temperature drops below the mass of a particle species, $T \ll m_a$, they become non-relativistic and their distribution function receives an exponential (Boltzmann) suppression, $f_a \to e^{-m_a/T}$. This means that relativistic particles ('radiation') dominate the density and pressure of the primordial plasma. By performing the integrals (46) and (47) in the limit $E \to p$, one finds

$$\bar{\rho}_a = \frac{\pi^2}{30}\, g_a T^4 \begin{cases} 1 & \text{bosons} \\ \frac{7}{8} & \text{fermions} \end{cases} \qquad \text{and} \quad \bar{P}_a = \frac{1}{3}\bar{\rho}_a\,. \tag{49}$$

The total radiation density is

$$\bar{\rho}_r = \frac{\pi^2}{30}\, g_* T^4\,, \quad \text{where} \quad g_* \equiv \sum_{a=b} g_a + \frac{7}{8}\sum_{a=f} g_a\,. \tag{50}$$

If equilibrium had persisted until today, all species with masses greater than $10^{-3}\,\text{eV}$ would be exponentially suppressed. This would not be a very interesting world. Fortunately, many massive particle species (e.g. dark matter) are weakly interacting and decoupled from the primordial plasma at early times.

Thermal History

The key to understanding the thermal history of the universe is understanding the competition between the interaction rate of particles, Γ, and the expansion rate of the universe, H. Particles maintain equilibrium as long as $\Gamma \gg H$ and freeze out when $\Gamma \lesssim H$ (see Fig. 23).

Neutrinos are the most weakly interacting particles of the Standard Model and therefore decoupled first (around 0.8 MeV or 1 sec after the Big Bang). Shortly after neutrino decoupling, electrons and positrons annihilated. The energies of the electrons and positrons got transferred to the photons, but not the neutrinos. The temperature of the photons today is therefore slightly larger than that of the neutrinos (see insert below). At around the same time, neutron-proton interactions became inefficient, leading to a relic abundance of neutrons. These neutrons were essential for the formation of the light elements during Big Bang nucleosynthesis (BBN), which occurred around 3 minutes after the Big Bang.

Cosmic neutrino background. After the neutrinos decouple, their momenta redshift, $p_\nu \propto a^{-1}$, and their distribution functions f_ν maintain their shape. The combination of these two facts requires that the neutrino temperature evolves as $T_\nu \propto a^{-1}$. We would like to compare this to the evolution of the photon temperature T_γ, since this is what has been measured by observations of the CMB. We will use the fact that the *comoving entropy* is conserved in equilibrium [1]:

$$s a^3 = \frac{\rho + P}{T} a^3 = \frac{2\pi^2}{45} g_* (aT)^3 = const\,. \tag{51}$$

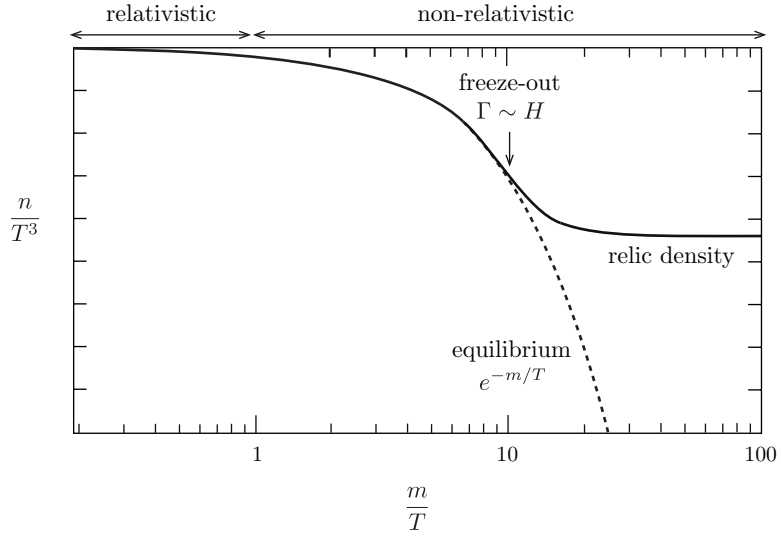

Figure 23: A schematic illustration of particle freeze-out. At high temperatures, the particle abundance tracks its equilibrium value. At low temperatures, the particles freeze out and maintain a relic density that is much larger than the Boltzmann-suppressed equilibrium abundance.

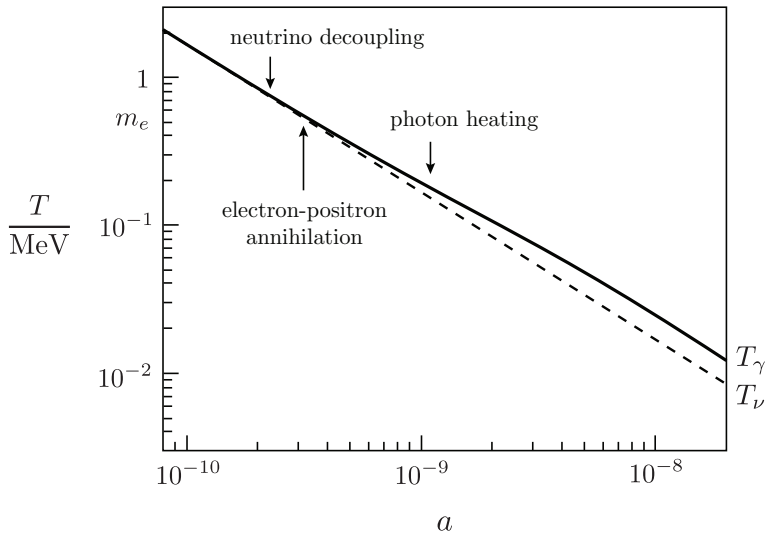

Figure 24: Thermal history through electron-positron annihilation. Neutrinos are decoupled and their temperature redshifts simply as $T_\nu \propto a^{-1}$. The energy density of the electron-positron pairs is transferred to the photon gas whose temperature therefore redshifts more slowly, $T_\gamma \propto g_*^{-1/3} a^{-1}$.

Since entropy is separately conserved for the thermal bath and the decoupled species, we only need to consider the change in the effective number of relativistic degrees of freedom in equilibrium with the photons. Before e^+e^- annihilation, i.e. at $T_+ > m_e$, we have

$$g_*(T_+) = 2 + \frac{7}{8} \times (2 \times 2) = \frac{11}{2}\,, \tag{52}$$

where we have counted photons, electrons and positrons. After e^+e^- annihilation, i.e. at $T_- < m_e$, only the two polarization degrees of freedom of the photons contribute,

$$g_*(T_-) = 2\,. \tag{53}$$

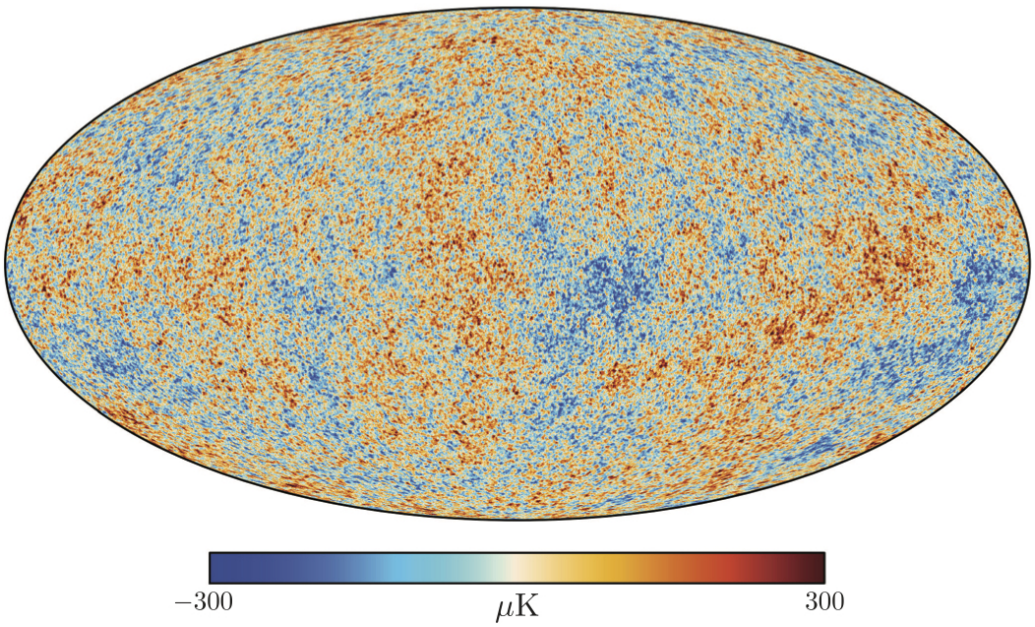

Figure 25: Planck measurement of the temperature variations in the CMB sky.

Comparing $g_*(aT_\gamma)^3 = const.$ to $aT_\nu = const.$, we get

$$T_\nu = \left(\frac{g_*(T_-)}{g_*(T_+)}\right)^{1/3} T_\gamma = \left(\frac{4}{11}\right)^{1/3} T_\gamma \,. \tag{54}$$

Given the measured temperature of the CMB today, $T_{\gamma,0} = 2.7\,\mathrm{K}$, this tells us that the present temperature of the cosmic neutrino background (CνB) is $T_{\nu,0} = 1.9\,\mathrm{K}$.

While the neutrinos are still relativistic (i.e. for most of the history of the universe), each species carries the following energy density

$$\frac{\rho_\nu}{\rho_\gamma} = \frac{\frac{7}{8} \times 2 \times T_\nu^4}{2 \times T_\gamma^4} = \frac{7}{8}\left(\frac{4}{11}\right)^{4/3} \equiv a_\nu \approx 0.227 \,. \tag{55}$$

The $N_\nu = 3$ neutrino species of the Standard Model therefore contribute a significant amount to the total radiation density in the early universe:

$$\frac{\sum \rho_\nu}{\rho_r} = \frac{N_\nu \rho_\nu}{N_\nu \rho_\nu + \rho_\gamma} = \frac{N_\nu a_\nu}{N_\nu a_\nu + 1} \approx 41\% \,. \tag{56}$$

Although the neutrinos are decoupled, their gravitational effects are significant and have recently been observed in the CMB [4, 5].

Below about 1 eV, or 380,000 years after the Big Bang, the temperature became low enough for neutral hydrogen atoms to form through the reaction $e^- + p^+ \to \mathrm{H} + \gamma$. This is the moment of *recombination*. At this point the density of free electrons dropped dramatically. Before recombination the strongest coupling between the photons and the rest of the plasma was through Thomson scattering, $e^- + \gamma \to e^- + \gamma$. The sharp drop in the free electron density after recombination means that this process became inefficient and the photons decoupled. After *decoupling* the photons streamed freely through the universe and are observed today as the CMB.

Structure Formation

The CMB is an almost perfect blackbody with an average temperature of 2.7 K. Small variations in the CMB temperature across the sky (see Fig. 25), reflect spatial variations in the density of the primordial plasma, $\delta\rho_a \equiv \rho_a - \bar{\rho}_a$ (see Section 7.5.2), and related perturbations of the spacetime geometry, $\delta g_{\mu\nu} \equiv g_{\mu\nu} - \bar{g}_{\mu\nu}$. During the radiation-dominated phase of the early universe, the growth of matter perturbations was inhibited by the large pressure provided by the radiation. Perturbations in the coupled photon and baryon fluids were oscillating with constant amplitude (see Section 6.5.5). Shortly before recombination, however, the universe became matter dominated and the radiation pressure disappeared, so that density fluctuations could start to grow under the influence of gravity. This growth of the matter perturbations eventually led to the large-scale structure (LSS) of the universe.

Initial Conditions

At sufficiently early times, all scales of interest to current observations were outside the Hubble radius, $k < \mathcal{H}$. On super-Hubble scales, the evolution of perturbations becomes very simple, especially for adiabatic initial conditions.

Adiabatic perturbations

Adiabatic perturbations have the property that the local state of matter (determined, for example, by the energy density ρ and the pressure P) at some spacetime point $(\tau, \mathbf{x})$ of the perturbed universe is the same as in the *background* universe at some slightly different time $\tau + \delta\tau(\mathbf{x})$. (Notice that the time shift varies with position $\mathbf{x}$.) If the universe is filled with multiple fluids, adiabatic perturbations correspond to perturbations induced by a *common, local shift in time* of all background quantities; e.g. adiabatic density perturbations are defined as

$$\delta\rho_a(\tau, \mathbf{x}) \equiv \bar{\rho}_a(\tau + \delta\tau(\mathbf{x})) - \bar{\rho}_a(\tau) \approx \dot{\bar{\rho}}_a \delta\tau(\mathbf{x}) \,, \tag{57}$$

where $\delta\tau$ is the same for all species a. This implies that all matter perturbations can be characterized by a single degree of freedom. It also means that we can perform a local time reparameterization to set all matter perturbations to zero, e.g. $\delta\rho_a \equiv 0$. In that gauge, the information about fluctuations is carried by the following perturbation of the metric

$$g_{ij}(\tau, \mathbf{x}) = a^2(\tau)\, e^{2\zeta(\tau,\mathbf{x})}\, \delta_{ij} \,, \tag{58}$$

where ζ is called the *curvature perturbation*. An attractive property of the curvature perturbation is that it is conserved on super-Hubble scales.

Statistics

The initial conditions for the hot Big Bang are believed to have been created by quantum fluctuations during a period of inflationary expansion [6]. As we will see in Section 6.6.2, this mechanism predicts the statistics of the initial conditions, i.e. it predicts the correlations between the CMB fluctuations in different directions in the sky, rather than the specific value of the temperature fluctuation in a specific direction. For Gaussian initial conditions, these correlations are completely specified by the two-point correlation function

$$\langle \zeta(\mathbf{x})\zeta(\mathbf{x}')\rangle \equiv \xi_\zeta(\mathbf{x}, \mathbf{x}') = \xi_\zeta(|\mathbf{x}' - \mathbf{x}|) \,, \tag{59}$$

where the last equality holds as a consequence of statistical homogeneity and isotropy. The Fourier transform of ζ then satisfies

$$\langle \zeta(\mathbf{k})\zeta^*(\mathbf{k}')\rangle = \frac{2\pi^2}{k^3}\mathcal{P}_\zeta(k)\, \delta_D(\mathbf{k} - \mathbf{k}') \,, \tag{60}$$

where $\mathcal{P}_\zeta(k)$ is the (dimensionless) *power spectrum*.

Exercise.—Show that

$$\xi_\zeta(\mathbf{x}, \mathbf{x}') = \int \frac{\mathrm{d}k}{k} \mathcal{P}_\zeta(k) \,\mathrm{sinc}(k|\mathbf{x} - \mathbf{x}'|)\,. \tag{61}$$

In Section 6.6.2, we will explicitly compute the form of $\mathcal{P}_\zeta(k)$ predicted by inflation. However, before we do that, we will show, in Sections 7.5.2 and 6.5.5, how generic scale-invariant initial conditions, $\mathcal{P}_\zeta(k) \approx const.$, evolve into the anisotropies of the cosmic microwave background. We will first do this in the context of the Standard Model of particle physics, before asking, in Section 6.5.6, what kind of deviations can arise in theories beyond the SM.

6.5.4 Afterglow of the Big Bang

Observations of the temperature fluctuations in the cosmic microwave background have played a pivotal role in establishing the standard cosmological model. We now have a detailed understanding of the geometry and composition of the universe, and there is growing evidence that the primordial fluctuations originated from quantum fluctuations during a period of inflation. In this section and the next, we will give a simplified analytical treatment of the physics of the CMB anisotropies. Our goal is to present just enough details to be able to explain how the CMB can be used as a probe of BSM physics.

CMB Anisotropies

The first thing one sees when looking at the microwave scy is the motion of the Solar System with respect to the rest frame of the CMB (cf. Fig. 26).

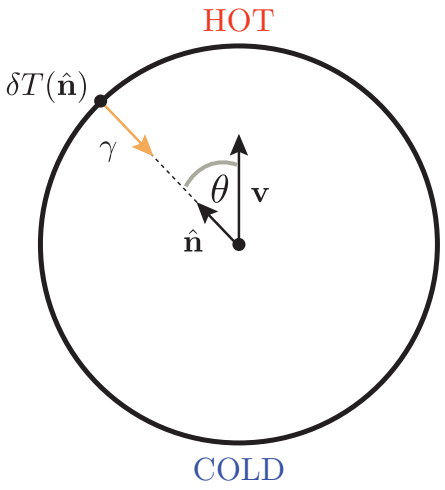

Figure 26: The motion of the Solar System relative to the CMB rest frame produces a dipolar pattern in the observed CMB temperature.

Consider a photon entering our detectors from a direction $\hat{\mathbf{n}}$. In the rest frame of the CMB, it has momentum $\mathbf{p} = -p\hat{\mathbf{n}}$. Due to the Doppler effect, the observed momentum is

$$p_0(\hat{\mathbf{n}}) = \frac{p}{\gamma(1 - \hat{\mathbf{n}} \cdot \mathbf{v})} \approx p\,(1 + \hat{\mathbf{n}} \cdot \mathbf{v})\,, \tag{62}$$

where $\mathbf{v}$ is our velocity relative to the CMB rest frame, p is the momentum of the photon in the CMB rest frame and $\gamma = (1 - v^2)^{-1/2}$ is the Lorentz factor. We have also shown an

approximation at leading order in $|\mathbf{v}| \ll 1$. As expected, the momentum is higher if we move towards the photon ($\hat{\mathbf{n}} \cdot \mathbf{v} = v$) and smaller if we move away from it ($\hat{\mathbf{n}} \cdot \mathbf{v} = -v$). Since the CMB has a blackbody spectrum, we can relate the change in the observed momentum of photons to a change in the observed temperature:

$$\frac{\delta T(\hat{\mathbf{n}})}{T} \equiv \frac{T_0(\hat{\mathbf{n}}) - T}{T} = \frac{p_0(\hat{\mathbf{n}}) - p}{p} = \hat{\mathbf{n}} \cdot \mathbf{v} = v \cos\theta \,. \tag{63}$$

Fitting this dipolar anisotropy to the data, we find that the speed of the Solar System relative to the CMB is

$$v = 368\,\mathrm{km/s}. \tag{64}$$

After subtracting the dipole, we are left with the *primordial anisotropy*.

Perturbed photon geodesics

Let us trace the life of a photon after decoupling. Its (physical) momentum will redshift due to the expansion of the universe. In addition, the momentum will change in response to the inhomogeneities of the universe. We will study these effects by solving the geodesic equation (32) in the perturbed spacetime.

We will treat perturbations in the metric in (conformal) Newtonian gauge

$$\mathrm{d}s^2 = a^2(\tau)\big[-(1+2\Phi)\mathrm{d}\tau^2 + (1-2\Psi)\delta_{ij}\mathrm{d}x^i\mathrm{d}x^j\big]\,, \tag{65}$$

where the perturbation $\Phi \approx \Psi$ plays the role of the gravitational potential.

Exercise.—Show that the connection coefficients associated with the metric (65) are

$$\begin{aligned}
\Gamma^0_{00} &= \mathcal{H} + \dot{\Phi}\,,\\
\Gamma^0_{i0} &= \partial_i\Phi\,,\\
\Gamma^i_{00} &= \delta^{ij}\partial_j\Phi\,,\\
\Gamma^0_{ij} &= \mathcal{H}\delta_{ij} - \big[\dot{\Psi} + 2\mathcal{H}(\Phi+\Psi)\big]\delta_{ij}\,,\\
\Gamma^i_{j0} &= \big[\mathcal{H} - \dot{\Psi}\big]\delta^i_j\,,\\
\Gamma^i_{jk} &= -2\delta^i_{(j}\partial_{k)}\Psi + \delta_{jk}\delta^{il}\partial_l\Psi\,.
\end{aligned} \tag{66}$$

As we will show in the following insert, the geodesic equation then leads to the following evolution equation for the photon momentum:

$$\boxed{\frac{d}{d\tau}\ln(ap) = -\frac{d\Phi}{d\tau} + \frac{\partial(\Phi+\Psi)}{\partial\tau}}\,. \tag{67}$$

In the absence of the source terms on the right-hand side, this implies $p \propto a^{-1}$, which is the expected redshifting due to the expansion of the universe, cf. eq. (37). The inhomogeneous source terms describe how photons lose (gain) energy as they move out of (into) potential wells.

,

Derivation.—We will derive eq. (67) from the geodesic equation for photons,

$$\frac{dP^0}{d\lambda} = -\Gamma^0_{\alpha\beta} P^\alpha P^\beta \,, \tag{68}$$

where $P^\mu = dx^\mu/d\lambda$ is the four-momentum of the photons. We need expressions for the components of the four-momentum in the presence of metric perturbations.

- We first consider the P^0 component. Since photons are massless we have

$$\begin{aligned} P^2 = g_{\mu\nu} P^\mu P^\nu &= 0 \\ &= -a^2(1+2\Phi)(P^0)^2 + p^2 \,, \end{aligned} \tag{69}$$

  where we have substituted the metric (65) and defined $p^2 \equiv g_{ij} P^i P^j$. Solving (69) for P^0, we find

$$P^0 = \frac{p}{a}(1-\Phi) \,. \tag{70}$$

- We then write the spatial component of the four-momentum as

$$P^i \equiv \alpha\, \hat{p}^i \,. \tag{71}$$

  To determine the constant of proportionality α, we use

$$\begin{aligned} p^2 = g_{ij} P^i P^j &= a^2(1-2\Psi)\delta_{ij}\hat{p}^i\hat{p}^j\alpha^2 \\ &= a^2(1-2\Psi)\alpha^2 \,, \end{aligned} \tag{72}$$

  where the last equality holds because the direction vector is a unit vector. Solving (72) for α, we get $\alpha = p(1+\Psi)/a$, or

$$P^i = \frac{p\hat{p}^i}{a}(1+\Psi) \,. \tag{73}$$

Substituting these results into the geodesic equation (68), we get

$$\frac{p}{a}(1-\Phi)\frac{d}{d\tau}\left[\frac{p}{a}(1-\Phi)\right] = -\Gamma^0_{\alpha\beta} P^\alpha P^\beta \,, \tag{74}$$

where we have used the standard trick of rewriting the derivative with respect to λ as a derivative with respect to time multiplied by $d\tau/d\lambda = P^0$. We expand out the time derivative to get

$$\frac{dp}{d\tau}(1-\Phi) = \mathcal{H} p(1-\Phi) + p\frac{d\Phi}{d\tau} - \Gamma^0_{\alpha\beta} P^\alpha P^\beta \frac{a^2}{p}(1+\Phi) \,. \tag{75}$$

Multiplying both sides by $(1+\Phi)/p$ and dropping all quadratic terms in Φ, we find

$$\frac{1}{p}\frac{dp}{d\tau} = \mathcal{H} + \frac{d\Phi}{d\tau} - \Gamma^0_{\alpha\beta} P^\alpha P^\beta \frac{a^2}{p^2}(1+2\Phi) \,. \tag{76}$$

To evaluate the last term on the right-hand side, we use the perturbed Christoffel symbols (6.5.4). After a bit of algebra, we get

$$-\Gamma^0_{\alpha\beta}\frac{P^\alpha P^\beta}{p^2}(1+2\Phi) = -2\mathcal{H} + \frac{\partial\Psi}{\partial\tau} - \frac{\partial\Phi}{\partial\tau} - 2\hat{p}^i\frac{\partial\Phi}{\partial x^i} \,. \tag{77}$$

Equation (76) then becomes

$$\frac{1}{p}\frac{dp}{dt} \tag{78}$$

$$= -\mathcal{H} + \frac{d\Phi}{d\tau} - 2\left(\frac{\partial\Phi}{\partial\tau} + \hat{p}^i\frac{\partial\Phi}{\partial x^i}\right) + \frac{\partial(\Phi+\Psi)}{\partial\tau} \,. \tag{79}$$

At leading order, the term in brackets is equal to the total time derivative of Φ:

$$\frac{d\Phi}{d\tau} = \frac{\partial\Phi}{\partial\tau} + \frac{dx^i}{d\tau}\frac{\partial\Phi}{\partial x^i} = \frac{\partial\Phi}{\partial\tau} + \hat{p}^i\frac{\partial\Phi}{\partial x^i}\,, \tag{80}$$

where we used

$$\frac{dx^i}{d\tau} = \frac{dx^i}{d\lambda}\frac{d\lambda}{d\tau} = \frac{P^i}{P^0} = \hat{p}^i(1+\Psi+\Phi) = \hat{p}^i + \mathcal{O}(1)\,. \tag{81}$$

Substituting (80) into (79), we get

$$\frac{1}{p}\frac{dp}{d\tau} = -\frac{1}{a}\frac{da}{d\tau} - \frac{d\Phi}{d\tau} + \frac{\partial(\Phi+\Psi)}{\partial\tau}\,, \tag{82}$$

which confirms the result (67).

Line-of-sight solution

By integrating the geodesic equation (67) along a line-of-sight, we can relate the observed CMB temperature anisotropies to the fluctuations at recombination. To simplify matters, we will therefore work with the idealised approximation of *instantaneous recombination*. The CMB photons were then emitted at a fixed time τ_*. This moment is often called *last scattering*. Integrating (67) from the time of emission τ_* to the time of observation τ_0, we then get

$$\ln(ap)_0 = \ln(ap)_* + (\Phi_* - \Phi_0) + \int_{\tau_*}^{\tau_0} \mathrm{d}\tau\,\frac{\partial}{\partial\tau}(\Phi+\Psi)\,. \tag{83}$$

To relate this to the temperature anisotropy, we note that

$$ap \propto a\bar{T}\left(1 + \frac{\delta T}{\bar{T}}\right), \tag{84}$$

where $\bar{T}(\tau)$ is the mean temperature. Taylor-expanding the logarithms in (83) to first order in $\delta T/\bar{T}$, and keeping in mind that $a_0\bar{T}_0 = a_*\bar{T}_*$, we find

$$\left.\frac{\delta T}{\bar{T}}\right|_0 = \left.\frac{\delta T}{\bar{T}}\right|_* + (\Phi_* - \Phi_0) + \int_{\tau_*}^{\tau_0} \mathrm{d}\tau\,\frac{\partial}{\partial\tau}(\Phi+\Psi)\,. \tag{85}$$

The term Φ_0 only affects the monopole perturbation, so it is unobservable and therefore usually dropped from the equation. The fractional temperature perturbation at last-scattering can be expressed in terms of the density contrast of photons, $\delta_\gamma \equiv \delta\rho_\gamma/\rho_\gamma$, as

$$\left.\frac{\delta T}{\bar{T}}\right|_* = \frac{1}{4}(\delta_\gamma)_*\,, \tag{86}$$

where the factor of $\frac{1}{4}$ arises because $\rho_\gamma \propto T^4$. Equation (85) then reads

$$\left.\frac{\delta T}{\bar{T}}\right|_0 = \left(\frac{1}{4}\delta_\gamma + \Phi\right)_* + \int_{\tau_*}^{\tau_0} \mathrm{d}\tau\,\frac{\partial}{\partial\tau}(\Phi+\Psi)\,. \tag{87}$$

Each term on the right-hand side has a simple physical interpretation:

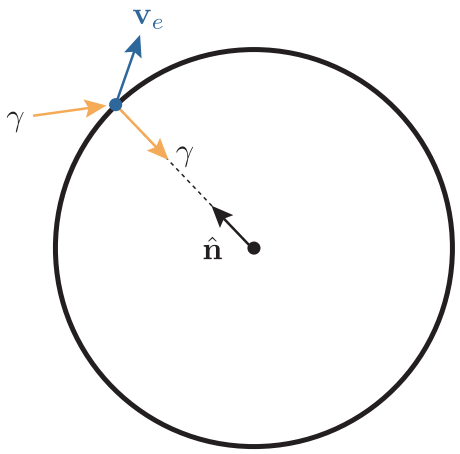

Figure 27: The motion of electrons at the surface of last-scattering produces an additional temperature anisotropy.

- The term $\frac{1}{4}\delta_\gamma$ can be thought of as the intrinsic temperature variation over the background last-scattering surface.
- The term Φ arises from the gravitational redshift that the photons experience when climbing out of a potential well at last-scattering. The combination $\frac{1}{4}\delta_\gamma + \Phi$ is often called the *Sachs-Wolfe* (SW) term.
- Finally, the *integrated Sachs-Wolfe* (ISW) term describes the effect of gravitational redshifting from evolution of the potentials along the line-of-sight. During matter domination, $\dot{\Phi} \approx \dot{\Psi} = 0$ and this term vanishes.

So far, we have ignored the motion of the electrons at the surface of last-scattering. Including this effect leads to an extra Doppler shift in the received energy of photons when referenced to an observer comoving with the electrons at last-scattering (see Fig. 27),

$$\left.\frac{\delta T}{\bar{T}}\right|_0 \subset (\hat{\mathbf{n}} \cdot \mathbf{v}_e)_* \,. \tag{88}$$

Putting everything together, we obtain the following important result

$$\boxed{\frac{\delta T}{\bar{T}}(\hat{\mathbf{n}}) = \left(\frac{1}{4}\delta_\gamma + \Phi + \hat{\mathbf{n}} \cdot \mathbf{v}_e\right)_* + \int_{\tau_*}^{\tau_0} \mathrm{d}\tau \, (\dot{\Phi} + \dot{\Psi})} \tag{89}$$

where we have dropped the subscript '0' on the observed $\delta T/\bar{T}$ to avoid clutter. Figure 28 illustrates the contributions that each of the terms in (89) makes to the power spectrum of the CMB temperature anisotropies (see §6.5.4). We see that the ISW contribution is subdominant and that the shape of the power spectrum is mostly determined by the Sachs-Wolfe and Doppler contributions.

Large scales.—For adiabatic initial conditions, the superhorizon initial condition is $\delta_\gamma \approx \frac{4}{3}\delta_m \approx -\frac{8}{3}\Psi$. The Sachs-Wolfe term then becomes

$$\frac{1}{4}\delta_\gamma + \Phi = -\frac{2\Psi}{3} + \Phi \approx \frac{1}{3}\Phi \,. \tag{90}$$

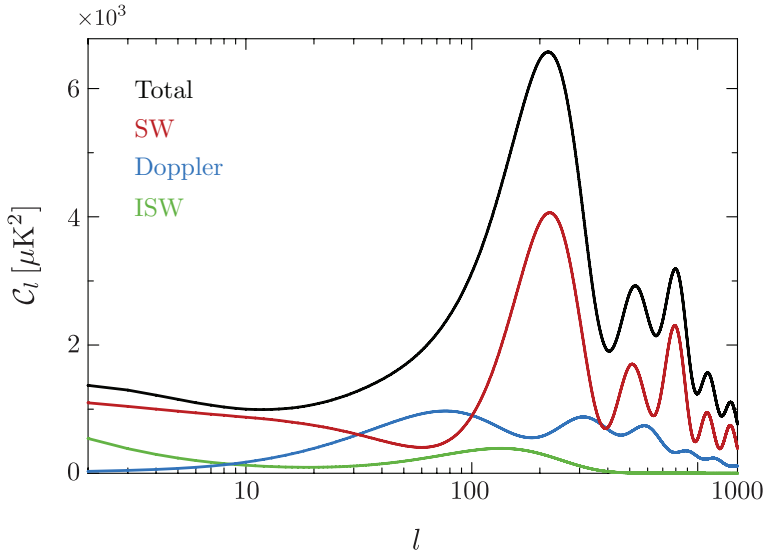

Figure 28: Contributions of the various terms in (89) to the (rescaled) power spectrum of CMB anisotropies, $\mathcal{C}_l \equiv l(l+1)C_l$.

This shows that, on large scales, an overdense region ($\Psi \approx \Phi < 0$) appears as a cold spot in the sky. While the temperature at the bottom of the potential well is hotter than the average ($-\frac{2}{3}\Psi$), photons lose more energy (Φ) as they climb out of the potential well, resulting in a cold spot ($\frac{1}{3}\Phi < 0$).

CMB Power Spectrum

A map of the cosmic microwave background radiation describes the variation of the CMB temperature as a function of direction, $\delta T(\hat{\mathbf{n}})$. We will be interested in the statistical correlations between temperature fluctuations in two different directions $\hat{\mathbf{n}}$ and $\hat{\mathbf{n}}'$ (see Fig. 29), averaged over the entire sky.

If the initial conditions are statistically isotropic, then we expect these correlations only to depend on the relative orientation of $\hat{\mathbf{n}}$ and $\hat{\mathbf{n}}'$. In that case, we can write the two-point correlation function as

$$\left\langle \delta T(\hat{\mathbf{n}})\, \delta T(\hat{\mathbf{n}}') \right\rangle = \sum_l \frac{2l+1}{4\pi} C_l P_l(\cos\theta)\,, \tag{91}$$

where $\hat{\mathbf{n}} \cdot \hat{\mathbf{n}}' \equiv \cos\theta$ and P_l are Legendre polynomials. The expansion coefficients C_l are the *angular power spectrum*. If the fluctuations are Gaussian, then the power spectrum contains the entire information of the CMB map.

The right panel of Fig. 29 illustrates the temperature variations created by a single plane wave inhomogeneity. The CMB anisotropies observed on the sky are a *superposition* of many such plane waves with amplitudes that are weighted by the spectrum of primordial curvature perturbations $\mathcal{P}_\zeta(k)$. In Section 6.6.2, we will show that the initial conditions of the primordial perturbations are expected to be featureless, $\mathcal{P}_\zeta(k) \approx const.$ The observed features in the CMB anisotropy spectrum arise from the subhorizon evolution of perturbations in the photon density and the metric. This evolution takes the form of cosmic sound waves (see Section 6.5.5). These waves are *captured* at recombination and *projected* onto the sky. The observed oscillations in the CMB power spectrum are therefore a snapshot of primordial sound waves caught at different phases in their evolution at the time when photons last scattered off electrons. The beautiful physics of the CMB fluctuations is described in detail in my *Advanced Cosmology* course [7].

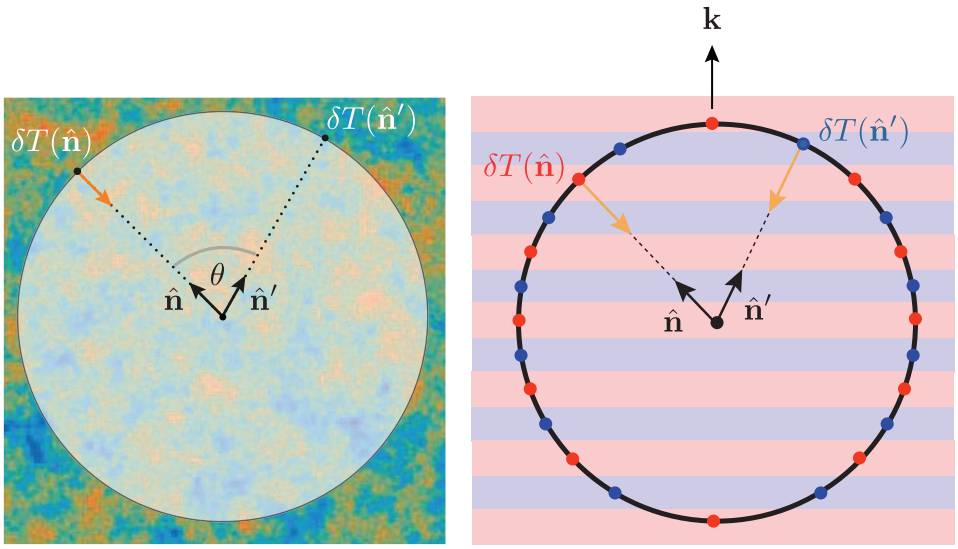

Figure 29: *Left*: Illustration of the two-point correlation function of the temperature anisotropy $\delta T(\hat{\mathbf{n}})$. *Right*: Illustration of the temperature anisotropy created by a single plane wave inhomogeneity are recombination.

Substituting the line-of sight solution (89) into the definition of the angular power spectrum (91), we find (see insert below)

$$\boxed{C_l = \frac{4\pi}{(2l+1)^2}\int \mathrm{d}\ln k\; T_l^2(k)\,\mathcal{P}_\zeta(k)}\,. \tag{92}$$

The *transfer function* $T_l(k)$ captures both the *evolution* of the initial fluctuations until recombination and the *projection* onto the surface of last-scattering. Ignoring the subdominant ISW contribution, we can write the transfer function as follows:

$$\boxed{T_l(k) = T_{\rm SW}(k)\,j_l(kr_*) + T_{\rm D}(k)\,j_l'(kr_*)}\,, \quad \text{where} \quad \begin{aligned} T_{\rm SW}(k) &\equiv \frac{(\frac{1}{4}\delta_\gamma + \Phi)_*}{\zeta(\mathbf{k})}\,, \\ T_{\rm D}(k) &\equiv -\frac{(v_e)_*}{\zeta(\mathbf{k})}\,. \end{aligned} \tag{93}$$

The subscript $*$ denotes quantities evaluated at recombination, with r_* being the distance to last-scattering. The Bessel function $j_l(kr_*)$ and its derivative $j_l'(kr_*)$ act almost like delta functions and map the Fourier modes k to the harmonic moments $l \sim kr_*$. Given that $\mathcal{P}_\zeta(k)$ is expected to be nearly constant, the angular power spectrum C_l therefore measures the square of the transfer function $T_l(k)$ evaluated at $k = l/r_*$:

$$C_l \;\sim\; \frac{4\pi}{(2l+1)^2}\Big[T_{\rm SW}^2(k) + T_{\rm D}^2(k)\Big]\Big|_{k\sim l/r_*}\,, \tag{94}$$

where we have dropped the cross term $T_{\rm SW}(k)\,T_{\rm D}(k)$ because it is negligible. In the next section, we will discuss the evolution effects that determine the transfer function and hence the CMB power spectrum.

Projection.—To understand the origin of the Bessel functions in (93), let us consider the projection of the Sachs-Wolfe term onto the surface of last-scattering. Assuming instantaneous recombination,

we can write

$$\delta T(\hat{\mathbf{n}}) = \int \mathrm{d}r\, \delta T(\mathbf{x}, \mathbf{n})\, \delta_D(r - r_*) \tag{95}$$

$$= \int \frac{\mathrm{d}^3 k}{(2\pi)^3}\, e^{i(kr_*)\hat{\mathbf{k}}\cdot\hat{\mathbf{n}}}\, \delta T(\mathbf{k})\,, \tag{96}$$

where we substituted the Fourier expansion of the temperature field in the second line. The exponential in (96) can be written in a Rayleigh plane wave expansion,

$$e^{i(kr_*)\hat{\mathbf{k}}\cdot\hat{\mathbf{n}}} = \sum_l (-i)^l (2l+1) j_l(kr_*) P_l(\hat{\mathbf{k}}\cdot\hat{\mathbf{n}})\,. \tag{97}$$

The two-point function of temperature anisotropies then becomes

$$\langle \delta T(\hat{\mathbf{n}})\, \delta T(\hat{\mathbf{n}}')\rangle = \int \frac{\mathrm{d}^3 k}{(2\pi)^3} \int \frac{\mathrm{d}^3 k'}{(2\pi)^3} \sum_l \sum_{l'} (-i)^{l+l'} (2l+1)(2l'+1)\, j_l(kr_*) j_{l'}(k'r_*) \times P_l(\hat{\mathbf{k}}\cdot\hat{\mathbf{n}}) P_{l'}(\hat{\mathbf{k}}'\cdot\hat{\mathbf{n}}')\, \langle \delta T(\mathbf{k})\, \delta T(\mathbf{k}')\rangle\,. \tag{98}$$

The power spectrum of the temperature field can be written in terms of the power spectrum of the primordial curvature perturbations, cf. (60),

$$\langle \delta T(\mathbf{k})\, \delta T(\mathbf{k}')\rangle = T_{\rm SW}(k) T_{\rm SW}(k') \langle \zeta(\mathbf{k})\, \zeta(\mathbf{k}')\rangle$$

$$= T^2_{\rm SW}(k)\, \frac{2\pi^2}{k^3}\, \mathcal{P}_\zeta(k)\, \delta_D(\mathbf{k} - \mathbf{k}')\,. \tag{99}$$

The delta function allows us to trivially perform one of the momentum integrals in (98). To evaluate the angular part of the second momentum integral, we use the following identity

$$\int \mathrm{d}^2\hat{\mathbf{k}}\, P_l(\hat{\mathbf{k}}\cdot\hat{\mathbf{n}}) P_{l'}(\hat{\mathbf{k}}\cdot\hat{\mathbf{n}}') = \frac{4\pi}{2l+1} P_l(\hat{\mathbf{n}}\cdot\hat{\mathbf{n}}')\, \delta_{ll'}\,. \tag{100}$$

The two-point function then takes the form (91) with the angular power spectrum given by

$$C_l^{\rm SW} = \frac{4\pi}{(2l+1)^2} \int \mathrm{d}\ln k\; \underset{\text{projection}}{\underset{\uparrow}{j_l^2(kr_*)}}\; \underset{\text{evolution}}{\underset{\uparrow}{T^2_{\rm SW}(k)}}\; \underset{\text{initial conditions}}{\underset{\uparrow}{\mathcal{P}_\zeta(k)}}\,. \tag{101}$$

A similar derivation gives the form of the Doppler contribution.

6.5.5 Cosmic Sound Waves

In the early universe, photons and electrons were strongly interacting, while the electrons were strongly coupled to protons. The combined system is often called the *photon-baryon fluid*. In this section, we will study the evolution of sound waves in this medium. These waves will evolve in an inhomogeneous spacetime whose perturbations are sourced by all forms of matter in the universe (see Fig. 30).

Our treatment in this section will be rather telegraphic and is just meant to give a flavor for the beautiful physics underlying the CMB. Further details can be found in the notes of my *Advanced Cosmology* course [7], or in the following textbooks [2, 8] and review articles [9, 921, 11, 12].

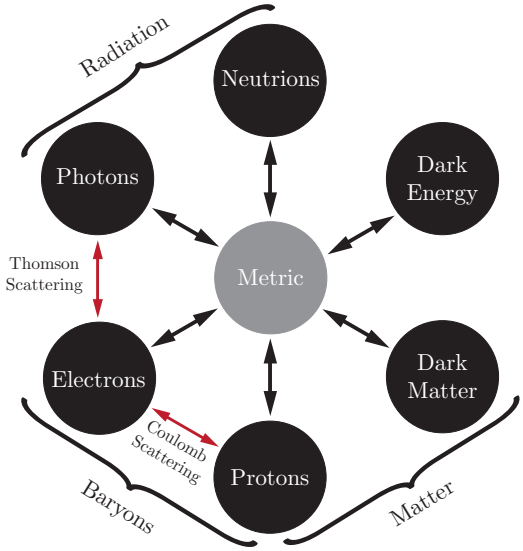

Figure 30: Interactions between the different forms of matter in the universe.

Photon-Baryon Fluid

Combining the continuity and Euler equations for the photon-baryon fluid leads to an evolution equation for the photon density perturbations [7]:

$$\boxed{\ddot{\delta}_\gamma + \frac{\mathcal{H}R}{1+R}\,\dot{\delta}_\gamma - c_s^2\nabla^2\delta_\gamma \;=\; \frac{4}{3}\nabla^2\Phi + 4\ddot{\Psi} + \frac{4\mathcal{H}R}{1+R}\,\dot{\Psi}}$$

$$\begin{array}{cccc} \uparrow & \uparrow & \uparrow & \uparrow \\ \text{friction} & \text{pressure} & \text{gravity} & \text{time dilation} \end{array} \tag{102}$$

where $R \equiv \frac{3}{4}\bar{\rho}_b/\bar{\rho}_\gamma$ is the ratio of the momentum densities of baryons and photons, and the sound speed of the photon-baryon fluid is defined as

$$c_s^2 \equiv \frac{1}{3(1+R)}\,. \tag{103}$$

Equation (B.4) is the master equation describing the entire CMB phenomenology. The most important terms in the equation are the photon pressure term on the left-hand side and the gravitational forcing term on the right-hand side. In addition, we have a friction term proportional to the baryon density R on the left-hand side and two terms related to time dilation effects on the right-hand side. The metric potentials Φ and Ψ are determined by the Einstein equations (which include important contributions from dark matter).

In practice, the equations describing the many coupled fluctuations in the primordial plasma have to be solved numerically. To gain some intuition, however, it is nevertheless useful to obtain approximate analytic results. In the following, we will solve equation (B.4) by making several (more or less justified) approximations. Our goal is to understand the main features of the CMB power spectrum shown in Fig. 31.

Acoustic Oscillations

During radiation domination, the baryon density is subdominant, $R \ll 1$, so for the moment we will set $R = 0$. For simplicity, we will also ignore the time dilation terms in (B.4); we will include their effects in §6.5.6. Equation (B.4) can then be written as

$$\ddot{\Theta} - c_s^2\nabla^2\Theta \;=\; 0\,, \tag{104}$$

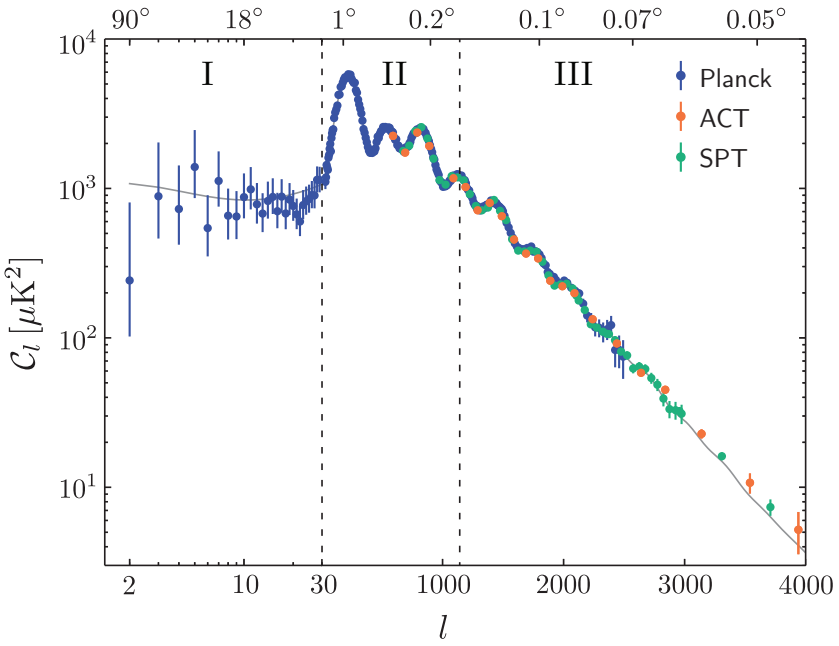

Figure 31: The angular variations of the CMB power spectrum are consequence of the dynamics of sound waves in the photon-baryon fluid. On large scales (region I), the fluctuations are frozen and we directly see the spectrum of the initial conditions. At intermediate scales (region II), we observe the oscillations of the fluid as captured at the moment of last-scattering. Finally, on small scales (region III), fluctuations are damped because their wavelengths are smaller than the mean free path of the photons.

where $c_s^2 \approx \frac{1}{3}$ and $\Theta \equiv \frac{1}{4}\delta_\gamma + \Phi$ is precisely the combination of the Sachs-Wolfe term appearing in (89). Solving (104) for a single Fourier mode, we get

$$\Theta(\mathbf{k},\tau) \;=\; A_{\mathbf{k}}\cos(c_s k\tau) + B_{\mathbf{k}}\sin(c_s k\tau)\,, \tag{105}$$

where $A_{\mathbf{k}}$ and $B_{\mathbf{k}}$ are parameters that are fixed by the initial conditions. For adiabatic initial conditions, all perturbations in the limit $\tau \to 0$ are analytic functions of k^2, which is only the case for the cosine part of the solution above. We therefore set $B_{\mathbf{k}} = 0$. Moreover, the matching to the superhorizon initial conditions implies $A_{\mathbf{k}} = 3\zeta_{\mathbf{k}}$ [7] and we get

$$\Theta(\mathbf{k},\tau) \;=\; 3\zeta_{\mathbf{k}}\cos(c_s k\tau)\,. \tag{106}$$

Evaluating this solution at recombination, $\tau = \tau_*$, gives the Sachs-Wolfe transfer function, $T_{\rm SW}(k) \equiv \Theta(\mathbf{k},\tau_*)/\zeta_{\mathbf{k}} = 3\cos(c_s k\tau_*)$. As we have seen in §6.5.4, the CMB power spectrum is roughly given by the square of the transfer function. The oscillatory k-dependence of the transfer function then maps to the observed oscillations in the CMB power spectrum in harmonic space, cf. eq. (94).

Sound horizon

Modes caught at extrema of their oscillations will have enhanced fluctuations

$$k_n = n\pi/s_*\,, \tag{107}$$

where $s_* \equiv c_s\tau_* \approx \frac{1}{\sqrt{3}}\tau_*$ is the sound horizon at recombination. We see that the peaks occur at multiples of the fundamental scale $k_* \equiv \pi/s_* \approx \sqrt{3}\pi/\tau_*$. This scale becomes a characteristic

angular scale by simple projection

$$\theta_* = \frac{\lambda_*}{D_A}\,, \tag{108}$$

$$, \tag{109}$$

$$l_* = k_* D_A \approx \frac{\tau_*}{\tau_0}\,, \tag{110}$$

where D_A is the angular diameter distance (which in a flat universe is $D_A = \tau_0 - \tau_* \approx \tau_0$). Assuming a purely matter-dominated universe after recombination, we have $\tau \propto a^{1/2}$ and therefore find

$$\theta_* \approx \left(\frac{1}{1100}\right)^{1/2} \approx 2^\circ\,, \tag{111}$$

$$l_* \approx 200\,. \tag{112}$$

The presence of dark energy and spatial curvature would slightly change this result. Measurements on the CMB spectrum have now determined θ_* to better than 0.05%, which puts strong constraints on the geometry and composition of the universe. Keeping the physical densities of dark matter, baryons, photons and neutrinos fixed, i.e. $\Omega_i h^2 = const.$, the scale θ_* is a measure of the curvature parameter Ω_k through its effect on the angular diameter distance to last-scattering. The observed value of θ_* is found to be consistent with a flat universe. Allowing the matter density and the Hubble parameter to vary, one finds $\theta_* \approx f(\Omega_m h^3)$, i.e. there is a specific degeneracy between variations in Ω_m and h. This degeneracy is broken by measurements of the peak morphology of the CMB spectrum and by external data sets (BAO, supernovae, etc.).

Baryon loading

Let me briefly comment on the effects of baryons on the CMB spectrum. The baryon-to-photon ratio increases with time, $R \propto a$, reaching an order one value at recombination. This decreases the sound speed, cf. (103). Instead of (104), we now have

$$\frac{d^2}{d\tau^2}(\Theta + R\Phi) - \frac{1}{3}\nabla^2(\Theta + R\Phi) = 0\,, \tag{113}$$

where we have ignored the time variation of R relative to the much faster evolution of the acoustic oscillations. We see that the finite baryon density, $R \neq 0$, changes the equilibrium point of the oscillations from $\Theta = 0$ to $\Theta = -R\Phi$. Since the CMB spectrum depends on the square of the solution, the shift of the equilibrium of the oscillating solution leads to odd and even peaks in the CMB having unequal heights. The relative heights of the CMB spectrum therefore provide a measure of the baryon density Ω_b.

Radiation driving

One important effect is not included in our highly simplified treatment. During the radiation era the gravitational potential Φ decays inside the horizon. Counterintuitively, the decaying potential actually enhances temperature fluctuations through a subtle resonance effect (see Fig. 32). Since the potential Φ decays after sound horizon crossing, it drives the first compression of the photon-baryon fluid without a counterbalancing effect on the subsequent rarefaction stage. The higher peaks in the CMB spectrum correspond to fluctuations that began their oscillations in the radiation-dominated era and therefore have enhanced amplitudes. This effect is sensitive to the ratio of radiation to matter, Ω_r/Ω_m. Since the radiations density Ω_r is fixed by the observed CMB temperature, measuring the peak heights relative to the Sachs-Wolf plateau determines the matter density of the universe Ω_m.

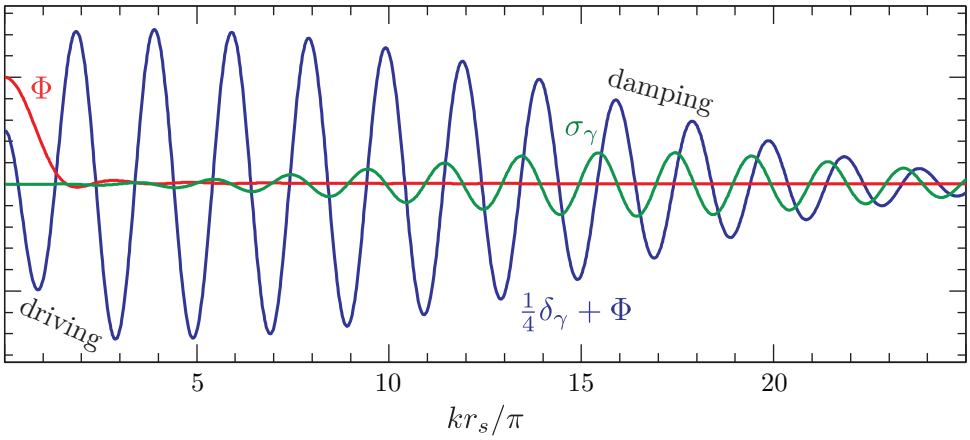

Figure 32: Acoustic oscillations with gravitational forcing and diffusion damping. For a mode that enters the sound horizon during radiation domination, the gravitational potential decays after horizon crossing and drives the acoustic amplitude higher. As the photon diffusion length increases and becomes comparable to the wavelength, viscosity σ_γ is generated and small-scale fluctuations are washed out.

Diffusion damping

So far, we have treated photons and baryons as a single perfect fluid, i.e. we took the mean free path of the photons to be zero. In reality, the coupling between electrons and photons is imperfect and the photons have a finite mean free path:

$$\lambda_C = \frac{1}{n_e \sigma_T a}\,, \tag{114}$$

where n_e is the electron density and σ_T is the Thomson cross section. Accounting for this leads to the damping of small-scale fluctuations: see Fig. 31. As the photons random walk through the baryons, hot and cold regions are mixed. By this process, fluctuations will be erased below the diffusion length:

$$\lambda_D = \sqrt{N}\,\lambda_C = \sqrt{\tau/\lambda_C}\,\lambda_C = \sqrt{\tau \lambda_C}\,, \tag{115}$$

which is the geometric mean between the horizon scale and the mean free path. As we will show in the following insert, the transfer function for the photon density fluctuations will receive an exponential suppression for modes with $k > k_D \equiv 2\pi/\lambda_D$. As shown in the insert below, the photon transfer function receives the following correction:

$$T(k) \to \mathcal{D}(k) T(k)\,, \tag{116}$$

where $\mathcal{D}(k) = e^{-k^2/k_D^2}$.

Imperfect fluid.—Diffusion causes heat conduction and generates viscosity in the fluid. Incorporating these effects into the dynamics leads to a modified oscillator equation [7],

$$\ddot{\Theta} + \mu\, c_s^2 k^2\, \dot{\Theta} + c_s^2 k^2\, \Theta = 0\,, \tag{117}$$

where we have ignored the gravitational source terms and defined

, (118)

$$\mu \equiv \left[\frac{16}{15} + \frac{R^2}{1+R}\right] \lambda_C\,. \tag{119}$$

Using the WKB ansatz

$$\Theta \propto \exp\left(i \int \omega \, \mathrm{d}\tau\right), \tag{120}$$

we get

$$-\omega^2 + \mu \, c_s^2 k^2 \, i\omega + c_s^2 k^2 = 0\,, \tag{121}$$

which we can write as

$$\omega = \pm c_s k \Big[1 + i\omega\mu\Big]^{1/2} \approx \pm c_s k \Big[1 \pm \frac{i}{2}\mu \, c_s k\Big]\,. \tag{122}$$

Substituting this back into (120), we get

$$\Theta \propto= e^{\pm i k r_s} \exp\left[-\frac{1}{2}(k/k_D)^2\right], \tag{123}$$

where we have defined the diffusion wavenumber as

$$k_D^{-2} = \int \mathrm{d}\eta \, \mu \, c_s^2 = \int \mathrm{d}\tau \, \frac{1}{3(1+R)} \left[\frac{16}{15} + \frac{R^2}{1+R}\right] \lambda_C\,. \tag{124}$$

In the limit $R \to 0$, this becomes

$$k_D^{-2} \approx \frac{16}{45} \int \mathrm{d}\tau \, \lambda_C \sim \tau \lambda_C\,, \tag{125}$$

which agrees with our previous estimate (115).

Within the Standard Model, the physics of the CMB anisotropies is understood extremely well. In the next section, we will explore what can be learned about physics beyond the Standard Model by looking for subtle deviations in the CMB spectrum.

6.5.6 Light Relics

Future cosmological observations will measure the radiation density of the early universe at the percent level. In this section, I will show how these observations will probe the physics of neutrinos, as well as the possible existence of extra light particles that are more weakly coupled to the SM than neutrinos. Examples of light relics that can be constrained in this way are the QCD axion [13, 14, 15], axion-like particles (ALPs) [16], dark photons [17] and light sterile neutrinos [8]. These particles may be so weakly coupled that they are hard to detect in terrestrial experiments, but the large number densities in the early universe make their gravitational imprints observable.

Dark Radiation

Let us assume that some physics beyond the Standard Model adds an extra radiation density ρ_X to the early universe. It is conventional to measure this density relative to the density of a SM neutrino species:

$$\Delta N_{\text{eff}} \equiv \frac{\rho_X}{\rho_\nu} = \frac{1}{a_\nu} \frac{\rho_X}{\rho_\gamma}\,, \tag{126}$$

and define $N_{\text{eff}} = N_\nu + \Delta N_{\text{eff}}$ as the *effective number of neutrinos*, although ρ_X may have nothing to do with neutrinos. Current measurements of the CMB anisotropies and the light

element abundances find

$$N_{\rm eff}^{\rm CMB} = 3.04 \pm 0.18\,, \tag{127}$$

$$N_{\rm eff}^{\rm BBN} = 2.85 \pm 0.28\,, \tag{128}$$

which is consistent with the SM prediction,[13] $N_{\rm eff} = 3.046$. Future CMB observations have the potential to improve these constraints by an order of magnitude [1].

A natural source for $\Delta N_{\rm eff} \neq 0$ are extra relativistic particles. Let us therefore consider a light species X as the only additional particle in some BSM theory. Assuming that this species was in thermal equilibrium with the SM at some point in the history of the universe, we can compute its contribution to $N_{\rm eff}$ in the same way as we derived the relic density of neutrinos in §6.5.3. For concreteness, let us assume that the particles of the species X decouple before neutrino decoupling, $T_{{\rm dec},X} > 10$ MeV. Particle-antiparticle annihilations until neutrino decoupling will lead to a difference between the temperature associated with the species X and that of neutrinos:

$$\begin{aligned} T_X = \left(\frac{g_*(T_{{\rm dec},\nu})}{g_*(T_{{\rm dec},X})}\right)^{1/3} T_\nu &= \left(\frac{10.75}{106.75}\right)^{1/3} \left(\frac{106.75}{g_*(T_{{\rm dec},X})}\right)^{1/3} T_\nu \\ &= 0.465 \left(\frac{106.75}{g_*(T_{{\rm dec},X})}\right)^{1/3} T_\nu\,. \end{aligned} \tag{129}$$

After neutrino decoupling, T_X and T_ν evolve in the same way, with both receiving the same suppression relative to T_γ from e^+e^- annihilation. As long as both X and ν are relativistic, they therefore maintain a constant energy ratio

$$\Delta N_{\rm eff} \equiv \frac{\rho_X}{\rho_\nu} = \frac{g_{*,X}}{g_{*,\nu}} \left(\frac{T_X}{T_\nu}\right)^4 = 0.027\, g_{*,X} \left(\frac{106.75}{g_*(T_{{\rm dec},X})}\right)^{4/3}\,, \tag{130}$$

where $g_{*,\nu} = \frac{7}{4}$ and $g_{*,X} = \{1, \frac{7}{4}, 2, \ldots\}$ are the internal degrees of freedom for spin $\{0, \frac{1}{2}, 1, \ldots\}$ particles. Figure 33 shows the contribution of a single decoupled species as a function of its decoupling temperature. We see that the contributions asymptote to fixed values for decoupling temperatures above the mass of the top quark (the heaviest particle of the SM). Using $g_*(T_{{\rm dec},X}) \leq 106.75$ in expression (130), we find that the extra species X contributes the following minimal amount[14]

$$\boxed{\Delta N_{\rm eff} > 0.027\, g_{*,X}} \;=\; \begin{cases} 0.054 & \text{gauge boson} \\ 0.047 & \text{Weyl fermion} \\ 0.027 & \text{Goldstone boson} \end{cases} \tag{131}$$

As we will see, this is an interesting target for future CMB experiments.

[13] The predicted value of $N_{\rm eff} = 3.046$ accounts for plasma corrections of quantum electrodynamics, flavour oscillations and, in particular, the fact that neutrinos have not fully decoupled when electrons and positrons annihilated.

[14] In deriving this bound, we assumed an extension of the SM in which there is no significant entropy production after decoupling and that the species X is the only addition to the SM particle content. Additional particles may both increase $\Delta N_{\rm eff}$ is there are light enough, or decrease it if they are relativistic at the decoupling of X, but become non-relativistic before neutrino decoupling. While entropy production typically dilutes the effects of extra relativistic species, it can also lead to additional effects that can be looked for in cosmological observations. For a more detailed discussion of these issues, see [20].

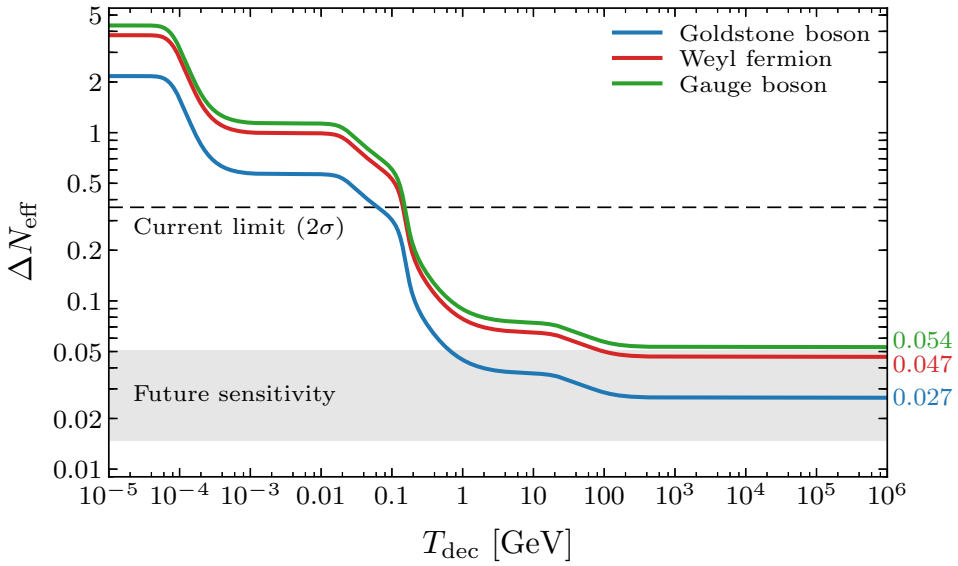

Figure 33: Contributions of a single thermally-decoupled Goldstone boson, Weyl fermion or massless gauge boson to the effective number of neutrinos, $\Delta N_{\rm eff}$, as a function of its decoupling temperature $T_{\rm dec}$.

Imprints in the CMB

Adding extra relativistic species will change the shape of the CMB spectrum. Precise measurements of the spectrum therefore make the CMB an accurate tool for probing this type of BSM physics.

Diffusion damping

The main effect of adding radiation density to the early universe is to increase the damping of the CMB spectrum [913] (see Fig. 34). Increasing $N_{\rm eff}$ increases H_*, the expansion rate at recombination. This would change both the damping scale θ_D and the peak location θ_*. Using

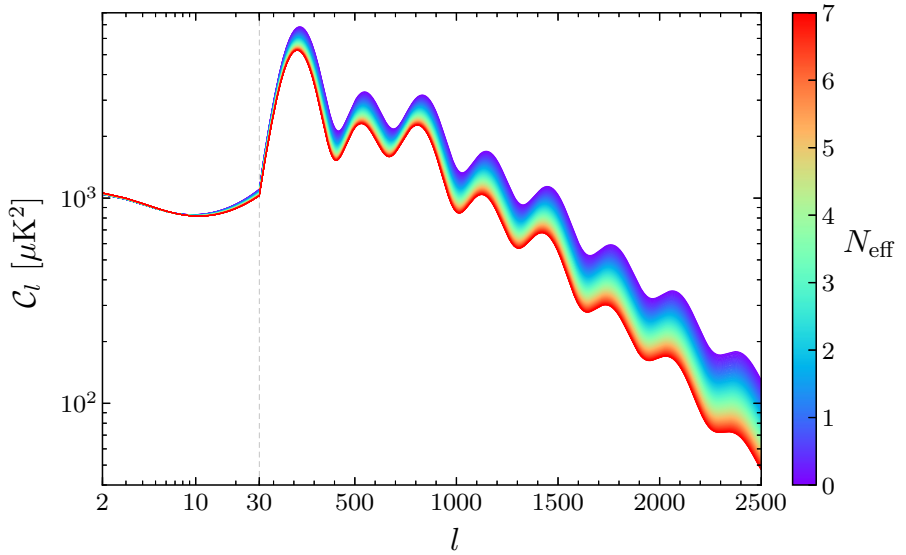

Figure 34: Variation of the CMB spectrum $\mathcal{C}_l \equiv l(l+1)C_l$ as a function of $N_{\rm eff}$ for fixed θ_*.

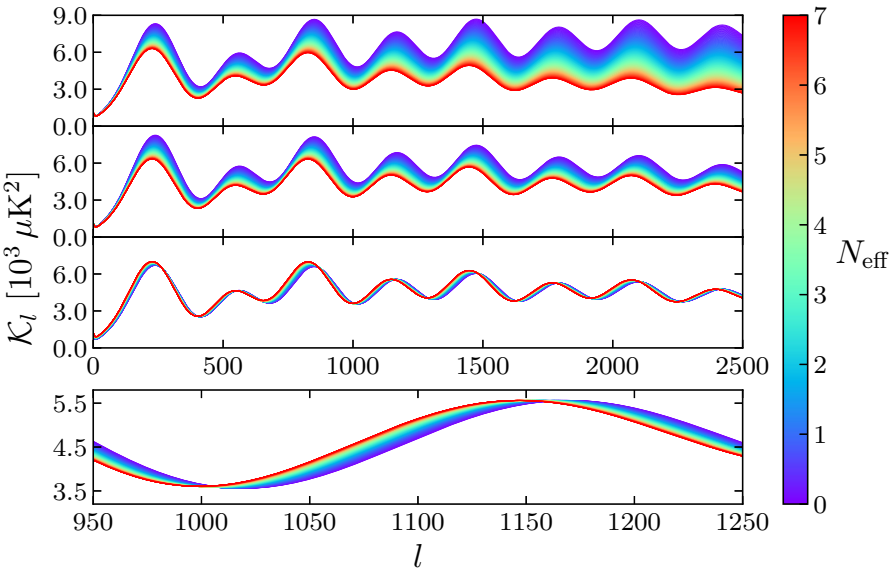

Figure 35: Variation of the undamped power spectra, $\mathcal{K}_l \equiv \mathcal{D}_l^{-1}\mathcal{C}_l$, as a function of $N_{\rm eff}$. The physical baryon density ω_b, the matter-to-radiation ratio ρ_m/ρ_r and the angular size of the sound horizon θ_* are held fixed in all panels. The dominant effect in the first panel is the variation of the damping scale θ_D. In the second panel, we fixed θ_D by adjusting the Helium fraction Y_P. The dominant variation is now the amplitude perturbation δA. In the third panel, the spectra are normalized at the fourth peak. The remaining variation is the phase shift φ (see the zoom-in in the fourth panel).

the estimates presented in §6.5.5, the ratio of θ_D and θ_* scales as

$$\frac{\theta_D}{\theta_*} = \frac{1}{r_{s,*}\,k_D} \propto \frac{1}{H_*^{-1}H_*^{1/2}} = H_*^{1/2}\,. \tag{132}$$

Since θ_* is measured very accurately, we need to keep it fixed. This can be done, for example, by simultaneously increasing the Hubble constant H_0. Increasing $N_{\rm eff}$ (and hence H_*) at fixed θ_* then implies larger θ_D, i.e. the damping kicks in at larger scales reducing the power in the damping tail (see Fig. 34). By accurately measuring the small-scale CMB anisotropies, observations therefore put a constraint on the number of relativistic species at recombination, cf. eq. (127).

The main limiting factor in these measurements is a degeneracy with the primordial Helium fraction $Y_P \equiv n_{\rm He}/n_b$. At fixed $\omega_b \equiv \Omega_b h^2$, increasing Y_P decreases the number density of free electrons. This increases the diffusion length, cf. eq. (114), and hence reduces the power in the damping tail. The parameters Y_P and $N_{\rm eff}$ are therefore anti-correlated. As we will discuss next, this degeneracy is broken by a more subtle effect of free-streaming relativistic species on the CMB spectrum.

Phase shift

Recently, CMB experiments have started to become sensitive to perturbations in the gas of relativistic particles. As we will see, perturbations in the density of free-streaming relativistic particles (e.g. neutrinos) leave a small imprint in the temporal phase of the acoustic oscillations and hence a coherent shift in the peak locations of the CMB spectrum (see Fig. 35). To get some intuition for the physical origin of this effect, let us return to the master equation (B.4), but now solve it slightly more accurately. Since the effect occurs during the radiation-dominated era, we

can still assume perfect radiation domination with $R = 0$. Equation (B.4) then becomes [22]

$$\ddot{d}_\gamma - c_s^2 \nabla^2 d_\gamma \;=\; \nabla^2 \Phi_+ \tag{133}$$

where we have defined $d_\gamma \equiv \frac{3}{4}\delta_\gamma - 3\Phi$ and $\Phi_\pm \equiv \Phi \pm \Psi$. The solution for a single Fourier mode can be written as

$$d_\gamma(y) = A\cos(y) - c_s^{-2} \int_0^y \mathrm{d}y'\, \Phi_+(y')\, \sin(y - y')\,, \tag{134}$$

where $y \equiv c_s k\tau$ and we have dropped the argument $\mathbf{k}$ on d_γ, A, and Φ_+ to avoid clutter. Using $\sin(y - y') = \sin(y)\cos(y') - \cos(y)\sin(y')$, we can write this as

$$d_\gamma(y) = \left[A + c_s^{-2}\alpha(y)\right]\cos(y) - c_s^{-2}\beta(y)\sin(y)\,, \tag{135}$$

where

$$\alpha(y) \equiv \int_0^y \mathrm{d}y'\, \Phi_+(y')\, \sin(y')\,, \tag{136}$$

$$\beta(y) \equiv \int_0^y \mathrm{d}y'\, \Phi_+(y')\, \cos(y')\,. \tag{137}$$

To obtain the CMB spectrum, we need to evaluate the solution at recombination. For the high-l modes of the CMB, it is a good approximation to use $y \to \infty$ for the limit of integration. The solution (135) can then be written as

$$d_\gamma(y) = \tilde{A}\cos(y + \varphi)\,, \tag{138}$$

where $\tilde{A} \equiv A + c_s^{-2}\alpha$ and

$$\sin\varphi \equiv \frac{\beta}{\sqrt{\beta^2 + (\alpha + c_s^2 A)^2}}\,. \tag{139}$$

We see that $\beta \neq 0$ corresponds to a constant phase shift of the acoustic oscillations.

To diagnose when such a phase shift can occur, it is useful to write the parameter β as follows

$$\begin{aligned}\beta \;&=\; \int_0^\infty \mathrm{d}y'\, \Phi_+(y')\cos(y') \\ &=\; \frac{1}{2}\int_{-\infty}^{+\infty} \mathrm{d}y' \left[\Phi_+^{(\mathrm{s})}(y')\right] e^{iy'}\,,\end{aligned} \tag{140}$$

where, in the second line, we have analytically continued the integrand and defined the symmetric part of the potential, $\Phi_+^{(\mathrm{s})}(y) \equiv \Phi_+(y) + \Phi_+(-y)$. For adiabatic modes, we expect $\Phi_+^{(\mathrm{s})}(y)$ to be an analytic function. Closing the contour in the upper-half plane, we find $\beta = 0$ if the contour at infinity vanishes. This is the case if $\Phi_+^{(\mathrm{s})}$ is sourced by fluctuations that travel at $c < c_s$. Neutrinos or other free-streaming particles, on the other hand, travel at the speed of light. This induces a mode in $\Phi_+^{(\mathrm{s})}$ of the form $e^{-ick\eta} = e^{-i(c/c_s)y}$, with $c = 1 > c_s$, and therefore leads to a finite phase shift.

Neutrino free-streaming.—We will briefly sketch how free-streaming relativistic particles, such as neutrinos, produce a phase shift in the CMB anisotropy spectrum. Details can be found in [22, 5].

The evolution of Φ_+ is related to that of Φ_- via the following Einstein equation:

$$\Phi_+'' + \frac{4}{y}\Phi_+' + \Phi_+ \;=\; \Phi_-'' + \frac{2}{y}\Phi_-' + 3\Phi_- \;\equiv\; \mathcal{S}[\Phi_-]\,, \tag{141}$$

where Φ_- is sourced by the anisotropic stress π_ν created by the neutrinos:

$$\Phi_-(y) = -\frac{2k^2}{y^2} f_\nu \pi_\nu(y)\,. \tag{142}$$

Here, we have introduced the fractional neutrino density $f_\nu \equiv \sum \rho_\nu/\rho_r \approx 0.41$. The evolution of π_ν follows from the Boltzmann equation for the neutrino distribution function. The solution can be written as [22]

$$\frac{k^2}{2}\pi_\nu(y) \approx -\zeta\, j_2(c_s^{-1}y) + c_s^{-1}\int_0^y \mathrm{d}y'\,\Phi_+(y')\left[\frac{2}{5}j_1(c_s^{-1}(y-y')) - \frac{3}{5}j_3(c_s^{-1}(y-y'))\right]. \tag{143}$$

We see that the solution involves an integral over Φ_+. Moreover, the solution depends on $c_s^{-1}y = k\tau$, i.e. it contains modes travelling at the speed of light. Following [22], the system of equations can be solved order by order in the fractional neutrino density:

- At zeroth order in f_ν, the potential Φ_- vanishes and the homogeneous solution is a function only of y, i.e. it doesn't contain modes travelling faster than the sound speed of the photon-baryon fluid. No phase shift is generated.
- At first order in f_ν, the potential Φ_- is non-zero. Note that the right-hand side of (142) is proportional to f_ν, so only the zeroth-order solution for π_ν (and Φ_+) is needed to determine the first-order solution for Φ_-. Computing the induced first-order correction to Φ_+, one finds [22, 5]

  $$\beta \approx 0.60\,\zeta\, f_\nu \quad \text{and} \quad \varphi \approx 0.19\,\pi\, f_\nu\,. \tag{144}$$

  As expected, a finite phase shift is generated. This phase shift has recently been detected in the CMB data [4, 5]. It has also been measured in the clustering of galaxies via its imprint in the spectrum of baryon acoustic oscillations [23].

CMB Stage 4

The sensitivity of ground-based CMB experiments can be characterized by the number of detectors that are mounted onto the telescope. The current generation of experiments has about 10^3 detectors, but there are plans to increase the number of detectors by up to two orders of magnitude [1]. This would lead to a significant improvement in the sensitivity of CMB experiments (see Fig. 36). What is particularly exciting about this is that it will lead to an order of magnitude improvement in constraints on $N_{\rm eff}$, allowing us to probe particles that decoupled before the QCD phase transition (cf. Fig. 33). If these so-called CMB Stage 4 experiments can reach the threshold $\Delta N_{\rm eff} = 0.027$, they would be sensitive to any light relics that have ever been in thermal equilibrium with the Standard Model (modulo the constraints described in footnote 14). As we will show in the next section, even the absence of a detection would be informative since it would put strong constraints on the couplings of extra light species to the SM.

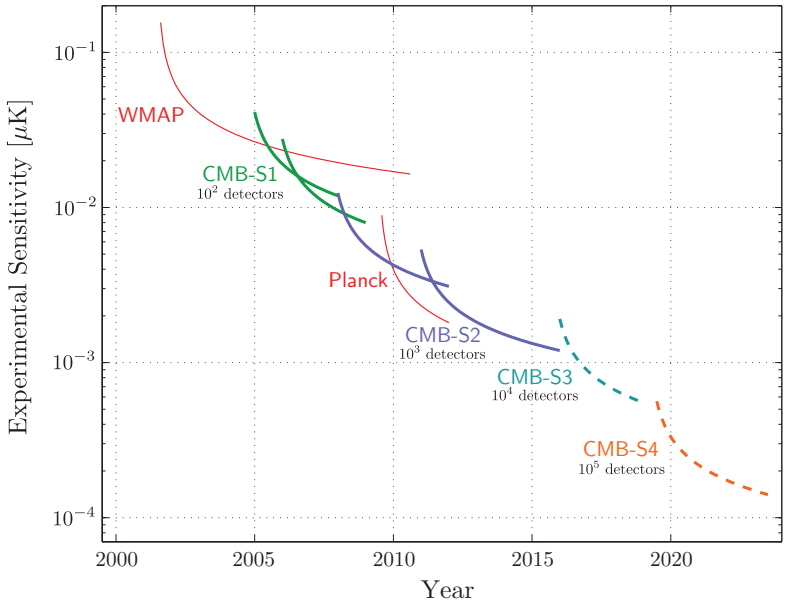

Figure 36: Evolution of the sensitivity of past and future CMB experiments (figure adapted from [1]).

EFT of Light Species

Extra light species arise in many models of physics beyond the Standard Model. Rather than studying these models one by one, it is more efficient to pass directly to an effective field theory for the couplings of the new light fields X to the SM,

$$\mathcal{L} \subset \sum g\, \mathcal{O}_X \mathcal{O}_{\rm SM}\,. \tag{145}$$

The strength of the couplings g determines the decoupling temperature, $T_{\rm dec}(g)$, and hence the thermal abundance of the species X, cf. Fig. 33.

Following [24], we consider EFTs that are minimal and technically natural. Minimality here means that the additional particle content is as small as possible, usually consisting of only one additional elementary particle. Naturalness requires the small masses of the extra particles to be protected by symmetries, which also restricts the allowed interactions in (145). Since the available symmetries depend on the spin of the new particles, it is convenient to organize the EFT according to spin.

Spin-0

A particularly well-motivated example of light particles are *Goldstone bosons* created by the spontaneous breaking of additional global symmetries. Goldstone bosons are either massless (if the broken symmetry was exact) or naturally light (if it was approximate). Examples of light pseudo-Nambu-Goldstone bosons (pNGBs) are *axions* [13, 14, 15], *familons* [25, 26, 27], and *majorons* [28, 29], associated with spontaneously broken Peccei-Quinn, family and lepton-number symmetry, respectively. Axion, familon and majoron models are characterized by different couplings in (145).

Axions arise naturally in many areas of high-energy physics, the QCD axion being a famous example. They are a compelling example of a new particle that is experimentally elusive because of its weak coupling rather than due to kinematic constraints. What typically distinguishes axions from other pNGBs are their unique couplings to the SM gauge fields. Below the scale

of electroweak symmetry breaking, the shift-symmetric couplings of the axion to the SM gauge fields are

$$\mathcal{L} = -\frac{1}{4}\left(\frac{a}{\Lambda_\gamma} F_{\mu\nu}\tilde{F}^{\mu\nu} + \frac{a}{\Lambda_g} G^a_{\mu\nu}\tilde{G}^{\mu\nu,a}\right), \tag{146}$$

where $X_{\mu\nu} \equiv \{F_{\mu\nu}, G^a_{\mu\nu}\}$ are the field strengths of photons and gluons, and $\tilde{X}^{\mu\nu} \equiv \frac{1}{2}\epsilon^{\mu\nu\rho\sigma}X_{\rho\sigma}$ are their duals. Axion models will typically include couplings to all SM gauge fields, but only the coupling to gluons is strictly necessary to solve the strong CP problem.

Spin-$\frac{1}{2}$

Light *fermions* are a natural possibility because Weyl and Dirac mass terms are protected by chiral and axial symmetries, respectively. A hidden Weyl fermion χ then couples to the SM through an anapole moment, $\chi^\dagger\bar{\sigma}^\mu\chi\partial^\nu B_{\mu\nu}$, or a four-fermion interaction, $\chi^\dagger\bar{\sigma}^\mu\chi\psi\gamma_\mu\psi$, while a Dirac fermion Ψ can couple through a dipole interaction, $\bar{\Psi}\sigma^{\mu\nu}\Psi B_{\mu\nu}$.

Spin-1

Massless spin-1 particles are technically natural because they have fewer degrees of freedom than their massive counterparts. The dominant coupling of *dark photons* A'_μ to the SM is through the dipole interaction $H\bar{\psi}\sigma^{\mu\nu}\psi F'_{\mu\nu}$.

Spin-$\frac{3}{2}$

The *gravitino* is a universal prediction of supergravity. Its mass is set by the SUSY breaking scale, $m_{3/2} = F/M_{\rm pl}$, and can be very small in low-scale SUSY breaking scenarios. The coupling of the longitudinal component of the gravitino to the SM is equivalent to the Goldstino coupling $\chi^\dagger\sigma_\mu\partial_\nu\chi\, T^{\mu\nu}$. The strength of the coupling is set by the SUSY-breaking scale F rather than $M_{\rm pl}$.

Spin-2

The *graviton* interacts only through Planck-suppressed gravitational interactions and hence has never been in thermal equilibrium with the SM. Its thermal abundance is therefore negligible.

Cosmic axions

Let us illustrate the power of future CMB observations through the example of axions [30]. To simplify the narrative, I will assume that a future CMB-S4 mission will be sensitive enough to exclude the minimal abundance of thermal axions, $\Delta N_{\rm eff} > 0.027$. In practice, this will probably require additional data from large-scale structure surveys [31].

At high energies, the rate of axion production is through the gauge field interactions (146) and can be expressed as [32]

$$\Gamma(\Lambda_n, T) = \sum_n \gamma_n(T)\,\frac{T^3}{\Lambda_n^2}\,. \tag{147}$$

The prefactors $\gamma_n(T)$ have their origin in the running of the couplings and are only weakly dependent on temperature. We will ignore this temperature dependence in the following. We see that the production rate, $\Gamma \propto T^3$, decreases faster than the expansion rate during the radiation era, $H \propto T^2$. To avoid producing a thermal axion abundance requires that the

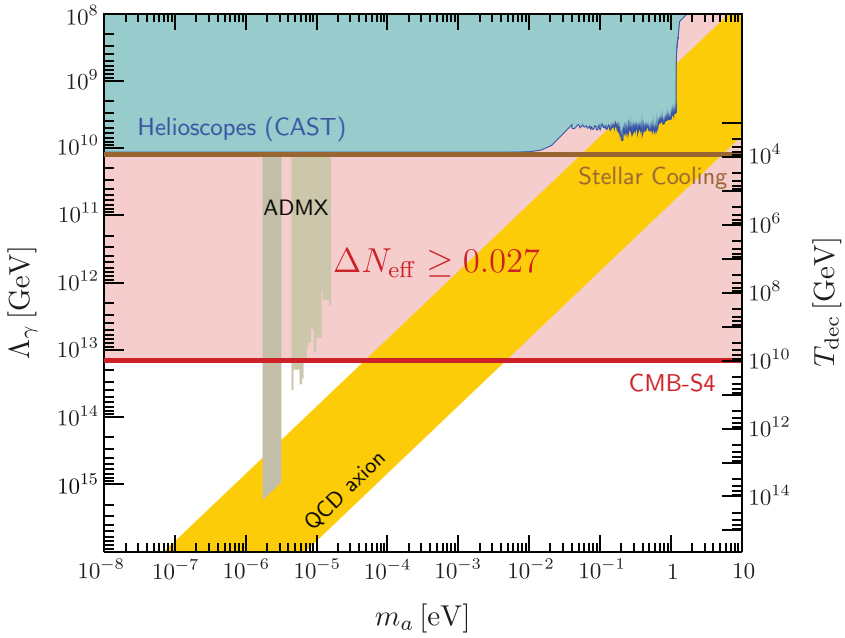

Figure 37: Comparison between current constraints on the axion-photon coupling and the sensitivity of a future CMB-S4 mission (figure adapted from [33]). The yellow band indicates a range of representative models for the QCD axion. The future CMB bound is a function of the reheating temperature T_R. We note that ADMX assumes that the axion is all of the dark matter, while all other constraints do not have this restriction.

interaction rate was never larger than the expansion rate. Denoting the reheating temperature of the universe by T_R, this implies

$$\Gamma(\Lambda_n, T_R) < H(T_R) = \frac{\pi}{\sqrt{90}} \sqrt{g_{*,R}} \frac{T_R^2}{M_{\rm pl}}\,, \tag{148}$$

where $g_{*,R} \equiv g_*(T_R)$. For a given reheating temperature, this is a constraint on the couplings Λ_n in (147). Treating the different axion couplings separately, we can write

$$\Lambda_n \;>\; \left(\frac{\pi^2}{90} g_{*,R}\right)^{-1/4} \sqrt{\gamma_{n,R} T_R M_{\rm pl}}\,, \tag{149}$$

where $\gamma_{n,R} \equiv \gamma_n(T_R)$.

The operator that has been most actively investigated experimentally is the coupling to photons. Photons are easily produced in large numbers in both the laboratory and in many astrophysical settings which makes this coupling a particularly fruitful target for axion searches. The couplings in the high-energy theory prior to electroweak symmetry breaking are related to the photon coupling Λ_γ through the Weinberg mixing angle. To be conservative, I will present the weakest constraint which arises when the axion only couples to the $U(1)_Y$ gauge field. A specific axion model is likely to also couple to the $SU(2)_L$ sector and the constraint on Λ_γ would then be stronger. Using $\gamma_{\gamma,R} \approx \gamma_\gamma(10^{10}\,\text{GeV}) = 0.029$ and $g_{*,R} = 106.75 + 1$, we find

$$\Lambda_\gamma \;>\; 1.4 \times 10^{13}\,\text{GeV}\,\sqrt{T_{R,10}}\,, \tag{150}$$

where $T_{R,10} \equiv T_R/10^{10}\,\text{GeV}$. For a reheating temperature of about $10^{10}\,\text{GeV}$, the bound in (150) is three orders of magnitude stronger than the best current constraints (cf. Fig. 37). Even for a reheating temperature as low as $10^4\,\text{GeV}$ the bound from the CMB would still marginally improve over existing constraints.

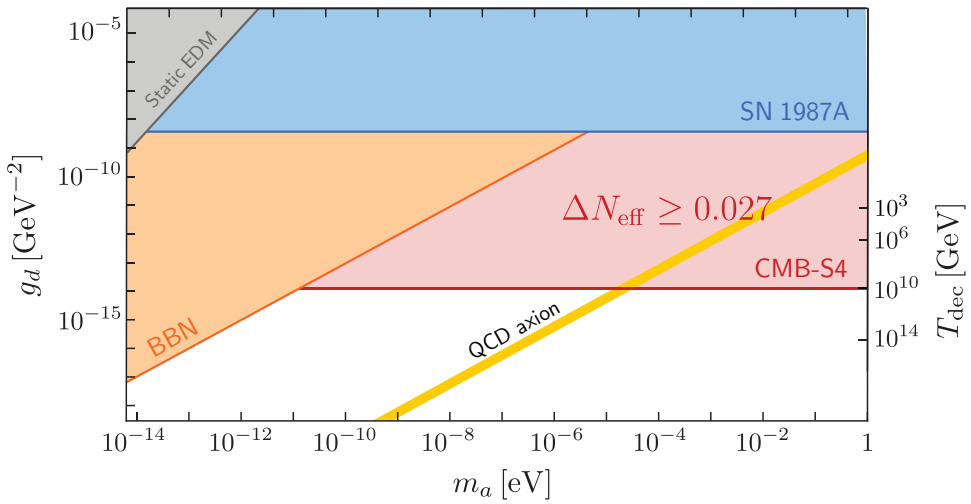

Figure 38: Comparison between current constraints on the axion-gluon coupling and the sensitivity of a future CMB-S4 mission (figure adapted from [34, 35]). We note that the static EDM [34] and BBN constraints [35] assume that the axion is all of the dark matter, while SN 1987A [36] and the future CMB constraint do not have this restriction.

The coupling to gluons is especially interesting for the QCD axion since it has to be present in order to solve the strong CP problem. The axion production rate associated with the gluon interaction in (146) is $\Gamma_g \simeq 0.41 T^3/\Lambda_g^2$ [32]. The bound (149) then implies

$$\Lambda_g > 5.4 \times 10^{13}\,\mathrm{GeV}\,\sqrt{T_{R,10}}\,. \tag{151}$$

Laboratory constraints on the axion-gluon coupling are usually phrased in terms of the induced electric dipole moment (EDM) of nucleons: $d_n = g_d a_0$, where a_0 is the value of the local axion field. For the QCD axion, the coupling g_d is given by [37, 34]

$$g_d \approx \frac{2\pi}{\alpha_s} \times \frac{3.8 \times 10^{-3}\,\mathrm{GeV}^{-1}}{\Lambda_g}\,. \tag{152}$$

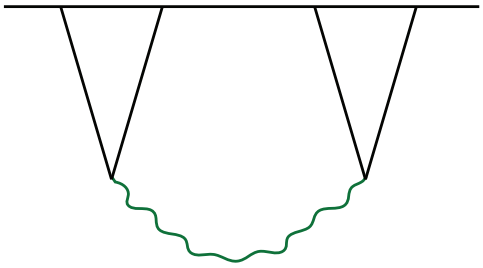
Constraints on g_d (and hence Λ_g) are shown in Fig. 38. We see that future CMB-S4 observations can improve over existing constraints on Λ_g by up to six orders of magnitude if $T_R = \mathcal{O}(10^{10}\,\mathrm{GeV})$. Even if the reheating temperature is as low as $10^4\,\mathrm{GeV}$, the future CMB constraints will be tighter by three orders of magnitude.

Deriving similar constraints for the other axion couplings and for the couplings of fields with spin is left as an exercise for the reader.

6.6 Relics from Inflation

Inflation predicts that the quantum fluctuations of any massless fields get amplified by the rapid expansion of the spacetime. Two massless fields that are guaranteed to exist in all inflationary models are the curvature perturbation ζ and the tensor fluctuations γ_{ij}. In Part I of these lectures, we assumed a nearly scale-invariant spectrum of curvature perturbations as a source for the density fluctuations in the late universe. In the following, I will show that these initial conditions indeed naturally arise from inflation. I will also demonstrate that the same effect produces tensor fluctuations. The search for this stochastic background of primordial gravitational waves is a very active area of observational cosmology.

Inflation also excites massive particles as long as their masses aren't far above the inflationary Hubble scale. Since the Hubble scale during inflation may be as high as 10^{14} GeV, this gives us the opportunity to probe the particle spectrum at energies far beyond the reach of conventional particle colliders. Once produced, these massive particles quickly decay into the massless modes ζ and γ_{ij}, creating higher-order correlations in the inflatonary fluctuations:



As we will see, this effect leads to a characteristic non-locality in cosmological correlators.

We will start with a brief review of slow-roll inflation. In Section 6.6.1, we will discuss the dynamics of the inflationary background, while in Section 6.6.2 we will explicitly compute the spectrum of quantum fluctuations. In Section 6.6.3, we will extend this treatment to include interactions and show that they lead to a characteristic non-Gaussianity in cosmological correlators. In Section 6.6.4, we will discuss the imprints of extra fields, showing how the masses and spins are encoded in the momentum dependence of higher-order correlation functions.

6.6.1 Inflationary Cosmology

A key fact about the universe is that on large scales it is described by the FRW metric (328). But why? A naive extrapolation of the radiation-dominated Big Bang cosmology suggests that the early universe consisted of many causally disconnected regions of space. The fact that these apparently disjoint patches of space are observed to have nearly the same densities and temperatures is called the *horizon problem*. In this section, I will explain how inflation—an early period of accelerated expansion—drives the primordial universe towards homogeneity and isotropy, even if it started in a more generic initial state.

Horizon Problem

The *particle horizon* is the maximal distance that a signal can travel between the time corresponding to the initial singularity, $t_i \equiv 0$, and a later time t. In physical coordinates, this distance is given by

$$D(t) \;=\; a(t)\int_0^t \frac{\mathrm{d}t}{a(t)} = a(t)\int_0^a \frac{\mathrm{d}\ln a}{a'}\,. \tag{153}$$

If the early universe was filled by ordinary matter, then $a'' < 0$. In that case, the integral in (153) is dominated by late times and converges to a finite value:

$$\text{e.g.}\quad a(t) \propto \begin{cases} t^{2/3} \\ t^{1/2} \end{cases} \quad\to\quad D(t) \;=\; \begin{cases} 3t & \text{matter} \\ 2t & \text{radiation} \end{cases} \tag{154}$$

This leads to a puzzle: because the age of the universe (t_0) is much larger than the time of recombination (t_*), the CMB naively consists of many causally disconnected patches (see Fig. 39). The following questions immediately arise: Why is the CMB so homogeneous? And, more importantly, why are the observed CMB fluctuations correlated on large scales and not just random noise?

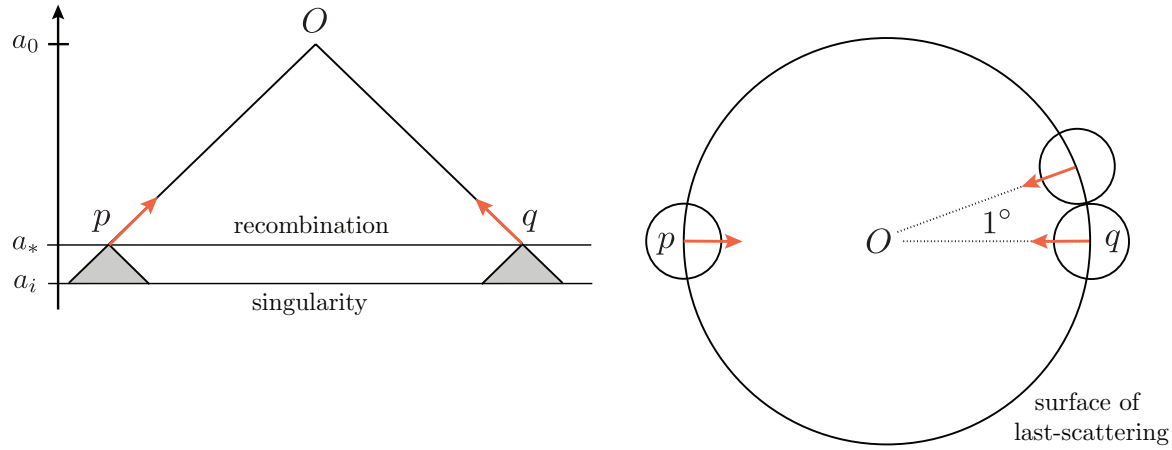


Figure 39: Illustration of the horizon problem in the conventional Big Bang model. All events that we currently observe are on our past light cone. The intersection of our past light cone with the spacelike slice labelled "recombination" corresponds to the "surface of last-scattering". Any two points on the surface of last-scattering that are separated by more than 1 degree, appear never to have been in causal contact. This means that their past light cones do not overlap before the singularity. This is illustrated for opposite points on the sky labelled p and q.

The horizon problem is solved if the early universe experienced a sustained period of accelerated expansion (= inflation), $a'' > 0$. In that case, the integral in (153) is dominated by early times and the particle horizon diverges in the past. Signals were therefore able to travel a much larger distance than suggested by the naive extrapolation of the standard FRW expansion (see Fig. 40).

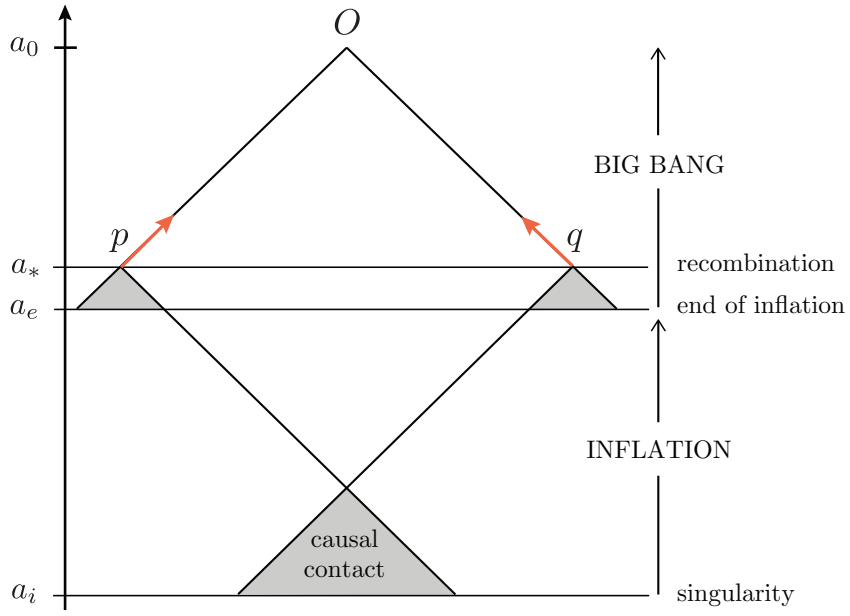

Figure 40: Illustration of the inflationary solution to the horizon problem in comoving coordinates (using conformal time on the vertical axis). The spacelike singularity of the standard Big Bang is replaced by the reheating surface, i.e. rather than marking the beginning of time it now simply corresponds to the transition from the end of inflation to the standard Big Bang evolution. All points in the CMB have overlapping past light cones and therefore originated from a causally connected region of space.

Exercise.—A special case of accelerated expansion is the quasi-de Sitter limit, which is characterized by a nearly constant expansion rate, $H = a'/a \approx const.$, so that $a(t) = e^{H(t-t_0)}$, where t_0 is some fiducial time at which $a(t_0) \equiv 1$. Show that

$$a(\tau) = -\frac{1}{H\tau}\,, \tag{155}$$

for $\tau < 0$. Notice that the initial singularity has been pushed to $\tau = -\infty$ (cf. Fig. 40).

Exercise.—Show that $a'' > 0$ is equivalent to a slow variation of the Hubble parameter

$$\varepsilon \equiv -\frac{H'}{H^2} < 1\,. \tag{156}$$

Notice that $\varepsilon \approx 0$ corresponds to a quasi-de Sitter spacetime with a nearly constant expansion rate, $H \approx const.$ Using the Friedmann equations, show that

$$\varepsilon = \frac{3}{2}\left(1 + \frac{P}{\rho}\right) < 1 \quad \Leftrightarrow \quad w \equiv \frac{P}{\rho} < -\frac{1}{3}\,. \tag{157}$$

The last condition corresponds to a violation of the strong energy condition.

Slow-Roll Inflation

As a simple toy model for inflation, let us consider the dynamics of a scalar field, the *inflaton* $\phi(t, \mathbf{x})$. As indicated by the notation, the value of the field can depend on time t and the position in space $\mathbf{x}$. Associated with each field value is a potential energy density $V(\phi)$ (see Fig. 63). If the field is dynamical (i.e. changes with time) then it also carries a kinetic energy density. If the energy density associated with the scalar field dominates the universe, it sources the evolution of the FRW background. We want to determine under which conditions this can lead to accelerated expansion.

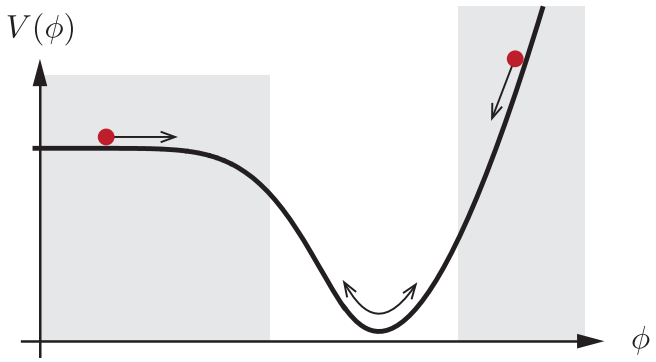

Figure 41: Example of a slow-roll potential. Inflation occurs in the shaded parts of the potential.

The stress-energy tensor of the scalar field is

$$T_{\mu\nu} \;=\; \partial_\mu\phi\partial_\nu\phi - g_{\mu\nu}\left(\frac{1}{2}g^{\alpha\beta}\partial_\alpha\phi\partial_\beta\phi - V(\phi)\right). \tag{158}$$

Consistency with the symmetries of the FRW spacetime requires that the background value of the inflaton only depends on time, $\phi = \phi(t)$. From the time-time component $T^0{}_0 = -\rho_\phi$, we

infer that the energy density of the field is

$$\rho_\phi \;=\; \frac{1}{2}(\phi')^2 + V)\phi)\,. \tag{159}$$

We see that this is simply the sum of the kinetic energy density, $\frac{1}{2}(\phi')^2$, and the potential energy density, $V(\phi)$. From the space-space component $T^i{}_j = P_\phi\,\delta^i_j$, we find that the pressure is the *difference* of kinetic and potential energy densities,

$$P_\phi \;=\; \frac{1}{2}(\phi')^2 - V)\phi)\,. \tag{160}$$

A field configuration therefore leads to inflation, $P_\phi < -\frac{1}{3}\rho_\phi$, if the potential energy dominates over the kinetic energy. i.e. if the field *rolls slowly*.

Exercise.—Using the Einstein equations (A.122) and (39), show that

$$\left.\begin{aligned} 3M_{\rm pl}^2H^2 &= \tfrac{1}{2}(\phi')^2 + V \\ M_{\rm pl}^2H' &= -\tfrac{1}{2}(\phi')^2 \end{aligned}\right\} \quad\Rightarrow\quad \varepsilon = \frac{\frac{1}{2}(\phi')^2}{M_{\rm pl}^2H^2} < 1\,, \tag{161}$$

where $M_{\rm pl} = (8\pi G)^{-1/2}$ is the reduced Planck mass.

Equation (161) corresponds to the *first slow-roll condition*:

$$(\phi')^2 < V\,. \tag{162}$$

This condition alone, however, does not guarantee successful inflation. We also need to assure that inflation does not just occur for an instant, but lasts long enough to solve the horizon problem.

Combining the two Friedmann equations in (161) leads to the Klein-Gordon equation for the evolution of the scalar field

$$\phi'' + 3H\phi' = -V_{,\phi}\,, \tag{163}$$

where $V_{,\phi}$ denotes the derivative of the potential with respect to the field value. To maintain the slow-roll condition (162) for a sufficient period of time, we require that the acceleration of the field is small. This is quantified by the *second slow-roll condition*:

$$\phi'' < 3H\phi'\,. \tag{164}$$

The evolution of the scalar field is then friction dominated, with the velocity of the field determined by the slope of the potential.

The two slow-roll conditions (162) and (164) can be expressed as conditions on the shape of the inflaton potential:

$$\varepsilon_V \equiv \frac{M_{\rm pl}^2}{2}\left(\frac{V_{,\phi}}{V}\right)^2 < 1\,, \qquad \eta_V \equiv M_{\rm pl}^2\left|\frac{V_{,\phi\phi}}{V}\right| < 1\,. \tag{165}$$

We will refer to the parameters in (165) as the *(potential) slow-roll parameters*.

Exercise.—Applying the slow-roll conditions (162) and (164) to the Friedmann equation (161) and the Klein-Gordon equation (163), we get

$$3M_{\rm pl}^2H^2 \approx V\,, \tag{166}$$

$$3H\phi' \approx -V_{,\phi}\,. \tag{167}$$

Use this to show that $\varepsilon \approx \varepsilon_V$ during slow-roll inflation.

Inflation ends when the first slow-roll condition is violated, $\varepsilon_V(\phi_e) \equiv 1$. The amount of inflation is measured in terms of 'e-folds' of expansion, $\mathrm{d}N = \mathrm{d}\ln a$. The total number of e-folds between a point ϕ on the potential and the end of inflation at ϕ_e is

$$N(\phi) \equiv \int_a^{a_e} \mathrm{d}\ln a = \int_t^{t_e} H\,\mathrm{d}t = \int_\phi^{\phi_e} \frac{H}{\phi'}\,\mathrm{d}\phi$$
$$= \int_\phi^{\phi_e} \frac{1}{\sqrt{2\varepsilon}} \frac{|\mathrm{d}\phi|}{M_{\rm pl}} \approx \int_\phi^{\phi_e} \frac{1}{\sqrt{2\varepsilon_V}} \frac{|\mathrm{d}\phi|}{M_{\rm pl}}\,. \tag{168}$$

To solve the horizon problem requires at least between 40 and 60 e-folds (with the precise value depending on the reheating temperature).

Case study: $m^2\phi^2$ inflation.—As an example, let us give the slow-roll analysis of arguably the simplest model of inflation: single-field inflation driven by a mass term

$$V(\phi) = \frac{1}{2}m^2\phi^2\,. \tag{169}$$

The slow-roll parameters are

$$\varepsilon_V(\phi) = \eta_V(\phi) = 2\left(\frac{M_{\rm pl}}{\phi}\right)^2\,. \tag{170}$$

To satisfy the slow-roll conditions $\{\varepsilon_V, |\eta_V|\} < 1$, we therefore need to consider super-Planckian values for the inflaton

$$\phi > \sqrt{2}M_{\rm pl} \equiv \phi_e\,. \tag{171}$$

The relation between the inflaton field value and the number of e-folds before the end of inflation is

$$N(\phi) = \frac{\phi^2}{4M_{\rm pl}^2} - \frac{1}{2}\,. \tag{172}$$

Solving the horizon problem then requires that the initial value of the field, ϕ_i, satisfies

$$\phi_i > \phi_{60} \equiv 2\sqrt{60}\,M_{\rm pl} \sim 15\,M_{\rm pl}\,. \tag{173}$$

We note that the total field excursion is super-Planckian, $\Delta\phi = \phi_i - \phi_e \gg M_{\rm pl}$.

Effective Field Theory

In the absence of a complete microscopic theory of inflation, we describe inflation in the context of an effective field theory. We are then obliged to include in the inflationary action all operators consistent with the assumed symmetries of the inflaton,

$$\mathcal{L}_{\rm eff}(\phi) \;=\; -\frac{1}{2}(\partial_\mu\phi)^2 - V(\phi) \;+\; \sum_n c_n V(\phi)\frac{\phi^{2n}}{\Lambda^{2n}} + \sum_n d_n \frac{(\partial\phi)^{2n}}{\Lambda^{4n}} + \cdots\,. \tag{174}$$

One of the remarkable features of inflation is that it is sensitive even to Planck-suppressed operators.

Eta problem

Successful inflation requires that the inflaton mass m_ϕ is parametrically smaller than the Hubble scale H:

$$\eta_V = \frac{m_\phi^2}{3H^2} \ll 1\,. \tag{175}$$

It is difficult to protect this hierarchy against high-energy corrections. We know that some new degrees of freedom must appear at $\Lambda \lesssim M_{\rm pl}$ to give a UV-completion of gravity. In string theory, this scale is often found to be significantly below the Planck scale, $\Lambda \lesssim M_s \ll M_{\rm pl}$. If ϕ has order-one couplings to any massive fields ψ (with $m_\psi \sim \Lambda$), then integrating out the fields ψ yields the effective action (1350) for ϕ with order-one couplings c_n and d_n. The above argument makes us worry that integrating out the massive fields ψ yields corrections to the potential of the form

$$\Delta V = c_1\, V(\phi)\frac{\phi^2}{\Lambda^2}\,, \tag{176}$$

where $c_1 \sim \mathcal{O}(1)$. If this term arises, then the eta parameter receives the following correction

$$\Delta\eta_V = \frac{M_{\rm pl}^2}{V})\Delta V)'' \approx 2c_1\left(\frac{M_{\rm pl}}{\Lambda}\right)^2 > 1\,, \tag{177}$$

where the final inequality follows from $\Lambda \lesssim M_{\rm pl}$. Notice that this problem is independent of the energy scale of inflation. All inflationary models have to address the eta problem.

Large-field inflation

The Planck-scale sensitivity of inflation is dramatically enhanced in models with observable gravitational waves, $r \gtrsim 0.01$. In this case, the inflaton field moves over a super-Planckian range during the last 60 e-folds of inflation, $\Delta\phi > M_{\rm pl}$ (see §6.6.2), and an infinite number of operators contribute equally to the effective action (1350). This observation makes an effective field theorist nervous and a string theorist curious [38].

6.6.2 Quantum Initial Conditions

One of the most remarkable features of inflation is that it provides a natural mechanism for producing the initial conditions for the hot big bang. To see this, recall that the evolution of the inflaton field $\phi(t)$ governs the energy density of the early universe $\rho(t)$ and, hence, controls the end of inflation (see Fig. 42). Essentially, the field ϕ plays the role of a "clock" reading off the amount of inflationary expansion still to occur. By the uncertainty principle, arbitrarily precise timing is not possible in quantum mechanics. Instead, quantum-mechanical clocks necessarily have some variance, so the inflaton will have spatially varying fluctuations $\delta\phi(t,\mathbf{x})$. There will therefore be local differences in the time when inflation ends, $\delta t(\mathbf{x})$, so that different regions of space inflate by different amounts. These differences in the local expansion histories lead to differences in the local densities after inflation, $\delta\rho(t,\mathbf{x})$, and to curvature perturbations in comoving gauge, $\zeta(\mathbf{x})$. It is worth remarking that the theory was not engineered to produce these fluctuations, but that their origin is instead a natural consequence of treating inflation quantum mechanically.

Quantum Fluctuations

Free Scalar in de Sitter

Before attacking the real problem of interest, namely the quantization of coupled inflaton-metric fluctuations during inflation, we will consider the simpler case of a free scalar field in

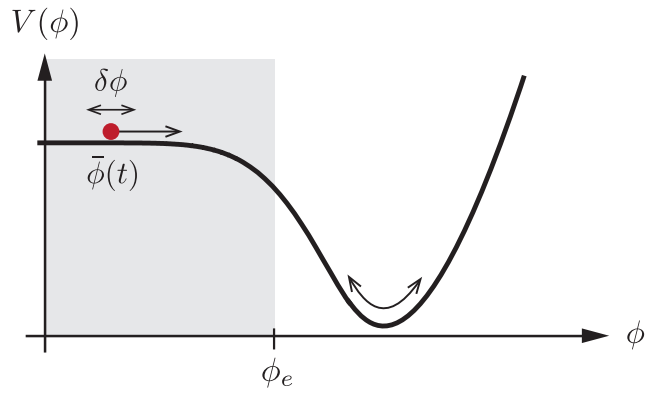

Figure 42: Quantum fluctuations $\delta\phi(t, \mathbf{x})$ around the classical background evolution $\bar{\phi}(t)$. Regions acquiring negative fluctuations $\delta\phi$ remain potential-dominated longer than regions with positive $\delta\phi$. Different parts of the universe therefore undergo slightly different evolutions. After inflation, this induces density fluctuations $\delta\rho(t, \mathbf{x})$.

de Sitter space. We will assume that the scalar field carries an insignificant amount of the total energy density and, hence, doesn't backreact on the de Sitter geometry. Such a field is sometimes called a *spectator field*.

The action of a massless, free scalar field in de Sitter space is

$$\begin{aligned} S &= \frac{1}{2}\int \mathrm{d}^4x\sqrt{-g}\, g^{\mu\nu}\partial_\mu\varphi\partial_\nu\varphi \\ &= \frac{1}{2}\int \mathrm{d}\tau\, \mathrm{d}^3x\, a^2\left[\dot{\varphi}^2 - (\partial_i\varphi)^2\right], \end{aligned} \tag{178}$$

where $a(\tau) = -1/(H\tau)$. It is useful to define the canonically normalized field $v \equiv a\varphi$, so that

$$S = \frac{1}{2}\int \mathrm{d}\tau\, \mathrm{d}^3x\left[\dot{v}^2 - (\partial_i v)^2 + \frac{\ddot{a}}{a}v^2\right]. \tag{179}$$

This action implies the following equation of motion for the Fourier modes of the field

$$\boxed{\ddot{v}_{\mathbf{k}} + \left(k^2 - \frac{\ddot{a}}{a}\right)v_{\mathbf{k}} = 0}\,. \tag{180}$$

Sometimes this is called the *Mukhanov-Sasaki (MS) equation.*

We see that the expansion of the universe is captured by the time dependence of the effective mass of the canonically-normalized field, $m^2_{\text{eff}}(\tau) \equiv \ddot{a}/a = 2/\tau^2$. At early times, $-\tau \gg k^{-1}$, this mass is much smaller than the momentum k of the relevant Fourier modes. The dynamics then reduces to that of a simple harmonic oscillator in flat space,

$$\ddot{v}_{\mathbf{k}} + k^2 v_{\mathbf{k}} \approx 0\,. \tag{181}$$

In this limit, the quantum fluctuations of the field v therefore follow from the standard quantization of a simple harmonic oscillator.

Canonical quantization

From the action (179), we read off the the momentum conjugate to v:

$$\pi \equiv \frac{\partial\mathcal{L}}{\partial\dot{v}} = \dot{v}\,. \tag{182}$$

We promote the fields $v(\tau, \mathbf{x})$ and $\pi(\tau, \mathbf{x})$ to quantum operators $\hat{v}(\tau, \mathbf{x})$ and $\hat{\pi}(\tau, \mathbf{x})$. These operators satisfy the equal time commutation relation

$$\boxed{[\hat{v}(\tau, \mathbf{x}), \hat{\pi}(\tau, \mathbf{x}')] = i\delta_D(\mathbf{x} - \mathbf{x}')} \tag{183}$$

in units where $\hbar \equiv 1$. The delta function is required by *locality*: modes at different points in space are independent and the corresponding operators therefore commute. In Fourier space, this becomes

$$\begin{aligned}
[\hat{v}_{\mathbf{k}}(\tau), \hat{\pi}_{\mathbf{k}'}(\tau)] &= \int \mathrm{d}^3x \int \mathrm{d}^3x' \underbrace{[\hat{v}(\tau, \mathbf{x}), \hat{\pi}(\tau, \mathbf{x}')]}_{i\delta_D(\mathbf{x} - \mathbf{x}')} e^{-i\mathbf{k}\cdot\mathbf{x}} e^{-i\mathbf{k}'\cdot\mathbf{x}'} \\
&= i \int \mathrm{d}^3x \, e^{-i(\mathbf{k}+\mathbf{k}')\cdot\mathbf{x}} \\
&= i\,(2\pi)^3 \delta_D(\mathbf{k} + \mathbf{k}')\,,
\end{aligned} \tag{184}$$

where the delta function implies that modes with different wavelengths commute.

Note that we are using the Heisenberg picture where operators vary in time while states are time independent. The operator solution $\hat{v}_{\mathbf{k}}(\tau)$ is determined by two initial conditions $\hat{v}_{\mathbf{k}}(\tau_i)$ and $\hat{\pi}_{\mathbf{k}}(\tau_i) = \partial_\tau \hat{v}_{\mathbf{k}}(\tau_i)$. Since the evolution equation is linear, the solution is linear in these operators. It is convenient to trade $\hat{v}_{\mathbf{k}}(\tau_i)$ and $\hat{\pi}_{\mathbf{k}}(\tau_i)$ for a single time-independent non-Hermitian operator $\hat{a}_{\mathbf{k}}$, in terms of which the solution can be written as

$$\boxed{\hat{v}_{\mathbf{k}}(\tau) = v_k(\tau)\,\hat{a}_{\mathbf{k}} + v_k^*(\tau)\,a^\dagger_{-\mathbf{k}}} \tag{185}$$

where the (complex) mode function $v_k(\tau)$ satisfies the classical equation of motion (180). Of course, $v_k^*(\tau)$ is the complex conjugate of $v_k(\tau)$ and $\hat{a}^\dagger_{\mathbf{k}}$ is the Hermitian conjugate of $\hat{a}_{\mathbf{k}}$. As indicated by dropping the vector notation $\mathbf{k}$ on the subscript, the mode functions, $v_k(\tau)$ and $v_k^*(\tau)$, are the same for all Fourier modes with $k \equiv |\mathbf{k}|$.[15]

We choose the normalization of the mode functions, so that $v_k \dot{v}_k^* - \dot{v}_k v_k^* \equiv i$. Substituting (185) into (184), we then get

$$\boxed{[\hat{a}_{\mathbf{k}}, \hat{a}^\dagger_{\mathbf{k}'}] = (2\pi)^3 \delta_D(\mathbf{k} + \mathbf{k}')} \tag{186}$$

which is the standard commutation relation for the *raising* and *lowering operators* of a harmonic oscillator. The quantum states in the Hilbert space are constructed by defining the vacuum state $|0\rangle$ via

$$\hat{a}_{\mathbf{k}}|0\rangle = 0\,, \tag{187}$$

and by producing excited states through repeated application of the creation operators $a^\dagger_{\mathbf{k}}$.

Choice of vacuum

The most general solution of equation (180) is

$$v_k(\tau) = c_1 \left(1 - \frac{i}{k\tau}\right) e^{-ik\tau} + c_2 \left(1 + \frac{i}{k\tau}\right) e^{ik\tau}\,, \tag{188}$$

[15] Since the frequency $\omega_k(\tau) \equiv k^2 - \ddot{a}/a$ in (180) depends only on $k \equiv |\mathbf{k}|$, the evolution does not depend on direction. The constant operators $\hat{a}_{\mathbf{k}}$ and $\hat{a}^\dagger_{\mathbf{k}}$, on the other hand, define initial conditions which may depend on direction.

where the constraint on the overall normalisation of the mode functions, $v_k\dot{v}_k^* - \dot{v}_k v_k^* \equiv i$, implies

$$|c_1|^2 - |c_2|^2 = \frac{1}{2k}\,. \tag{189}$$

At this point, we still have a one-parameter family of solutions for the mode function $v_k(\tau)$. A change in $v_k(\tau)$ could be accompanied by a change in $\hat{a}_{\mathbf{k}}$ that keeps the solution $\hat{v}_{\mathbf{k}}(\tau)$ unchanged. Each such solution corresponds to a different vacuum state, cf. eq. (187). However, a special choice of $v_k(\tau)$ is selected if we require the vacuum state $|0\rangle$ to be the ground state of the Hamiltonian.

To see this, consider the Hamiltonian operator

$$\hat{H} = \int \mathrm{d}^3x \left[\frac{1}{2}\hat{\pi}^2 + \frac{1}{2}(\nabla\hat{v})^2 + \frac{1}{2}\frac{\ddot{a}}{a}\,\hat{v}^2\right]. \tag{190}$$

Substituting the mode expansion (185) into this, we find

$$\hat{H} = \frac{1}{4}\int \mathrm{d}^3k \left[a_{\mathbf{k}}a_{-\mathbf{k}}F_k^* + a_{\mathbf{k}}^\dagger a_{-\mathbf{k}}^\dagger F_k + \Big(2a_{\mathbf{k}}^\dagger a_{\mathbf{k}} + \delta_D(0)\Big)\,E_k\right], \tag{191}$$

where

$$E_k(\tau) = |\dot{v}_k|^2 + \omega_k^2|v_k|^2\,, \tag{192}$$

$$F_k(\tau) = \dot{v}_k^2 + \omega_k^2 v_k^2\,. \tag{193}$$

The vacuum expectation value of the Hamiltonian is

$$\langle 0|\hat{H}|0\rangle = \frac{1}{4}\delta_D(0)\int \mathrm{d}^3k\, E_k(\tau)\,, \tag{194}$$

where the divergent factor $\delta_D(0)$ is an artefact of integrating over an infinite volume. The energy density of the vacuum is

$$\varepsilon_k \equiv \frac{1}{4}\int \mathrm{d}^3k\, E_k(\tau)\,. \tag{195}$$

At early times, we have

$$\lim_{\tau\to-\infty} v_k(\tau) = c_1\, e^{-ik\tau} + c_2\, e^{ik\tau}\,, \tag{196}$$

$$\lim_{\tau\to-\infty} E_k(\tau) = 4\left(|c_1|^2 + |c_2|^2\right)k^2\,. \tag{197}$$

Given the constraint (604), the function in (197) is minimized for

$$|c_1| = \frac{1}{\sqrt{2k}}\,, \quad c_2 = 0\,. \tag{198}$$

Up to an irrelevant phase, this uniquely determines the *Bunch-Davies* mode function

$$\boxed{v_k(\tau) = \frac{1}{\sqrt{2k}}\left(1 - \frac{i}{k\tau}\right)e^{-ik\tau}}\,. \tag{199}$$

Note that (198) implies

$$\lim_{\tau\to-\infty} E_k(\tau) = 2k\,, \tag{200}$$

$$\lim_{\tau\to-\infty} F_k(\tau) = 0\,, \tag{201}$$

and hence

$$\lim_{\tau\to-\infty} \hat{H} = \int \mathrm{d}^3k \left[a_{\mathbf{k}}^\dagger a_{\mathbf{k}} + \frac{1}{2}\delta_D(0)\right]\hbar\omega_k\,, \tag{202}$$

where we have reinstated Planck's constant $\hbar$. We see that the vacuum state $|0\rangle$ is the state of minimum energy $\frac{1}{2}\hbar\omega_k$. If any function other than (199) had been chosen as the mode function, then the state annihilated by $\hat{a}_{\mathbf{k}}$ would *not* be the ground state of the oscillator.

Zero-point fluctuations

Finally, we can predict the quantum statistics of the operator

$$\hat{v}(\tau,\mathbf{x}) = \int \frac{\mathrm{d}^3k}{(2\pi)^3}\left[v_k(\tau)\,\hat{a}_{\mathbf{k}} + v_k^*(\tau)\,a^\dagger_{-\mathbf{k}}\right]e^{i\mathbf{k}\cdot\mathbf{x}}. \tag{203}$$

The expectation value of $\hat{v}$ vanishes, i.e. $\langle\hat{v}\rangle \equiv \langle 0|\hat{v}|0\rangle = 0$. However, the variance of inflaton fluctuations receives non-zero quantum fluctuations:

$$\begin{aligned}
\langle|\hat{v}|^2\rangle &\equiv \langle 0|\hat{v}(\tau,\mathbf{0})\hat{v}(\tau,\mathbf{0})|0\rangle \\
&= \int \frac{\mathrm{d}^3k}{(2\pi)^3}\int \frac{\mathrm{d}^3k'}{(2\pi)^3}\,\langle 0|\big)\overbrace{v_k^*(\tau)\hat{a}^\dagger_{\mathbf{k}} + v_k(\tau)\hat{a}_{\mathbf{k}}\big)\big(v_{k'}(\tau)\hat{a}_{\mathbf{k}'} + v^*_{k'}(\tau)\hat{a}^\dagger_{\mathbf{k}'}\big)}|0\rangle \\
&= \int \frac{\mathrm{d}^3k}{(2\pi)^3}\int \frac{\mathrm{d}^3k'}{(2\pi)^3}\,v_k(\tau)v^*_{k'}(\tau)\,\langle 0|[\hat{a}_{\mathbf{k}},\hat{a}^\dagger_{\mathbf{k}'}]|0\rangle \\
&= \int \frac{\mathrm{d}^3k}{(2\pi)^3}\,|v_k(\tau)|^2 \\
&= \int \mathrm{d}\ln k\;\frac{k^3}{2\pi^2}|v_k(\tau)|^2.
\end{aligned} \tag{204}$$

We define the (dimensionless) *power spectrum* as

$$\boxed{\mathcal{P}_v(k,\tau) \equiv \frac{k^3}{2\pi^2}|v_k(\tau)|^2}. \tag{205}$$

We see that the square of the classical solution determines the variance of quantum fluctuations. Substituting the Bunch-Davies mode function (199) into (205), we find

$$\mathcal{P}_\varphi(k,\tau) = \frac{\mathcal{P}_v(k,\tau)}{a^2(\tau)} = \left(\frac{H}{2\pi}\right)^2\left[1+(k\tau)^2\right] \xrightarrow{k\tau\to 0} \left(\frac{H}{2\pi}\right)^2. \tag{206}$$

Note that in the superhorizon limit, $k\tau \to 0$, the dimensionless power spectrum $\mathcal{P}_\varphi$ approaches the same constant for all momenta. This is the characteristic of a *scale-invariant* spectrum.

Massive fields

The above discussion is easily generalized to massive spectator fields. The modified equation of motion is

$$\ddot{v}_k + \left(k^2 + m^2a^2 - \frac{\ddot{a}}{a}\right)v_k = 0\,, \tag{207}$$

which, in de Sitter space, becomes

$$\ddot{v}_k + \left(k^2 - \frac{\nu^2-1/4}{\tau^2}\right)v_k = 0\,, \quad \text{where} \quad \nu^2 \equiv \frac{9}{4} - \frac{m^2}{H^2}\,. \tag{208}$$

The most general solution of (208) is

$$v_k(\tau) = \sqrt{-\tau}\,\left[c_1 H_\nu^{(1)}(|k\tau|) + c_2 H_\nu^{(2)}(|k\tau|)\right], \tag{209}$$

where $H_\nu^{(1)}$ and $H_\nu^{(2)}$ are Hankel functions of the first and second kind. Imposing the Bunch-Davies initial condition, we find

$$c_1 = \frac{\sqrt{\pi}}{2}e^{i(2\nu+1)\frac{\pi}{4}}\,, \quad c_2 = 0\,. \tag{210}$$

For the moment, let us assume $m < \frac{3}{2}H$, so that ν is real. We then find

$$\mathcal{P}_\varphi(k,\tau) = \frac{\mathcal{P}_v(k,\tau)}{a^2(\tau)} \xrightarrow{k\tau\to 0} \left(\frac{H}{2\pi}\right)^2 (k\tau)^{3/2-\nu} . \tag{211}$$

We observe that the superhorizon limit of the spectrum is scale-dependent and evolves in time. The scale-dependence takes a power law form with the following *spectral index*

$$n_\varphi \equiv \frac{d\ln \mathcal{P}_\varphi}{d\ln k} = \frac{3}{2} - \nu \xrightarrow{m\ll H} \frac{1}{3}\frac{m^2}{H^2} . \tag{212}$$

In the limit $m \to 0$, we recover the scale-invariant spectrum of a massless field in de Sitter.

For $m > \frac{3}{2}H$, the degree of the Hankel function becomes imaginary, $\nu \equiv i\mu$, where

$$\mu \equiv \sqrt{m^2/H^2 - 9/4} \xrightarrow{m\gg H} m/H . \tag{213}$$

What used to be an irrelevant phase factor in (210), now becomes an exponential suppression of the amplitude of the mode function

$$|v_k(\tau)| = \frac{\sqrt{\pi}}{2} e^{-\pi\mu/2}\sqrt{-\tau}\,|H^{(1)}_{i\mu}(|k\tau|)| . \tag{214}$$

The power spectrum of very massive fields in de Sitter is therefore highly suppressed, $\mathcal{P}_\varphi \propto e^{-\pi m/H}$, for $m \gg \frac{3}{2}H$.

Fluctuations during Inflation

We now move to studying the fluctuations in the inflaton field during inflation. These fluctuations cannot be treated independently from fluctuations in the metric, since the two are coupled by the Einstein equations. This leads to some technical complications, but conceptually the quantization of the coupled inflaton-metric fluctuations is the same as before.

Metric fluctuations

We will treat the fluctuations of the metric in the so-called *ADM formalism* [168]. We start by writing the perturbed line element as

$$\mathrm{d}s^2 = -N^2\mathrm{d}t^2 + h_{ij}(N^i\mathrm{d}t + \mathrm{d}x^i)(N^j\mathrm{d}t + \mathrm{d}x^j) , \tag{215}$$

where $N \equiv N(t,\mathbf{x})$ is the lapse function, $N^i \equiv N^i(t,\mathbf{x})$ is the shift vector, and $h_{ij} \equiv h_{ij}(t,\mathbf{x})$ is the induced metric on three-dimensional hypersurfaces of constant time t. The geometry of the spatial slices is characterized by the intrinsic curvature, $R^{(3)}_{ij}$, i.e. the Ricci tensor of the induced metric, and by the extrinsic curvature

$$K_{ij} \equiv \frac{1}{2N}\left(h'_{ij} - \nabla_i N_j - \nabla_j N_i\right) \equiv \frac{1}{N}E_{ij} . \tag{216}$$

The four-dimensional Ricci scalar, R, can be written in terms of the three-dimensional Ricci scalar, $R^{(3)}$, and the extrinsic curvature tensor as

$$R = R^{(3)} + N^{-2}\left(E^{ij}E_{ij} - E^2\right) , \tag{217}$$

where indices are raised with h^{ij}, and $E \equiv h^{ij}E_{ij}$.

The inflaton action can then be written as

$$S = \frac{1}{2}\int \mathrm{d}^4x\sqrt{-g}\left[R - g^{\mu\nu}\partial_\mu\phi\partial_\nu\phi - 2V\right]$$
$$= \frac{1}{2}\int \sqrt{h}N\left[R^{(3)} - 2V + N^{-2}\left(E^{ij}E_{ij} - E^2\right) + N^{-2}\left(\phi' - N^i\partial_i\phi\right)^2 - h^{ij}\partial_i\phi\partial_j\phi\right], \quad (218)$$

where for the moment we have set $M_{\rm pl} \equiv 1$. Note that N and N_i do not have time derivatives acting on them and are therefore non-dynamical fields that will be fixed by constraint equations. Indeed, varying the action with respect to N and N^i, we find

$$R^{(3)} - 2V - h^{ij}\partial_i\phi\partial_j\phi - N^2[E_{ij}E^{ij} - E^2 - (\phi' - N^i\partial_i\phi)^2] = 0\,, \quad (219)$$
$$\nabla_i[N^{-1}(E^i_j - E\delta^i_j)] = 0\,. \quad (220)$$

Plugging the solutions for N and N^i back into the action leaves ϕ and h_{ij} as the only dynamical variables. We will perform this procedure in perturbation theory. For the time being, we will focus on scalar perturbations. To fix time and space reparameterizations, we will have to choose a gauge for ϕ and h_{ij}. We will present the results for two different gauges: spatially flat gauge and comoving gauge.

Spatially flat gauge

As the name suggests, in spatially flat gauge the induced metric is taken to be unperturbed:

$$h_{ij} = a^2\delta_{ij}\,. \quad (221)$$

We then consider the perturbations of the inflaton, the lapse and the shift:

$$\phi \equiv \bar{\phi}(t) + \varphi(t,\mathbf{x})\,, \quad N \equiv 1 + \alpha(t,\mathbf{x})\,, \quad N_i \equiv \partial_i\beta(t,\mathbf{x})\,. \quad (222)$$

Substituting (221) and (222) into the constraint equations (219) and (220), we obtain [40] [16]

$$\alpha = \frac{\bar{\phi}'}{2H}\varphi\,, \quad \partial^2\beta = \frac{(\bar{\phi}')^2}{2H^2}\frac{d}{dt}\left(-\frac{H}{\bar{\phi}'}\varphi\right). \quad (223)$$

Plugging this solution into the action (218), expanding to second order and performing a few integrations by parts, we find

$$S_2 = \frac{1}{2}\int \mathrm{d}t\,\mathrm{d}^3x\; a^3\left[(\varphi')^2 - \frac{1}{a^2}(\partial\varphi)^2 - \left[V'' - 2(3\varepsilon - \varepsilon^2 + \varepsilon\eta)H^2\right]\varphi^2\right]. \quad (224)$$

Switching to conformal time, the equation of motion for the Fourier components of the canonically normalized field $v \equiv a\varphi$ is

$$\ddot{v}_k + \left(k^2 + a^2\left[V'' - 6\varepsilon H^2\right] - \frac{\ddot{a}}{a}\right)v_k = 0\,, \quad (225)$$

where we have dropped terms in the effective mass that are higher order in slow-roll parameters. Note that the term $a^2\left[V'' - 6\varepsilon H^2\right] \sim \mathcal{O}(\varepsilon,\eta)(aH)^2$ is always smaller than $\ddot{a}/a = 2(aH)^2$. However, it is the only source of time evolution on superhorizon scales and even a small evolution can accumulate over time. In order not to have to follow the evolving field on superhorizon

[16] To find the quadratic action, we only have to solve the constraints to linear order. The second order terms in N and N_i will multiply the zeroth order constraints which vanish when the background equations of motion are imposed.

scales, it is useful to evaluate the solution at horizon crossing, $k = aH$, and then map it to a field that is known not to evolve outside the horizon. This constant mode is the *comoving curvature perturbation*, which in spatially flat gauge is defined as

$$\zeta = -\frac{H}{\bar{\phi}'}\varphi\,. \tag{226}$$

The power spectrum of ζ is

$$\mathcal{P}_\zeta(k) = \left(\frac{H}{\bar{\phi}'}\right)^2 \mathcal{P}_\varphi(k,\tau)\Big|_{k=aH}\,. \tag{227}$$

Dropping the slow-roll suppressed terms in (225), the equation of motion reduces to that of a massless field in de Sitter space. The power spectrum $\mathcal{P}_\varphi(k,\eta)$ is therefore given by (206) and we get

$$\boxed{\mathcal{P}_\zeta(k) = \left(\frac{H}{\bar{\phi}'}\right)^2 \left(\frac{H}{2\pi}\right)^2\Big|_{k=aH}}\,. \tag{228}$$

Another advantage of using ζ rather than φ to characterize the initial conditions is that ζ remains well-defined after inflation.

Comoving gauge

In comoving gauge the inflaton field is taken to be unperturbed:

$$\phi = \bar{\phi}(t)\,. \tag{229}$$

All perturbations are then carried by the metric:

$$h_{ij} = a^2(1+2\zeta(t,\mathbf{x}))\delta_{ij}\,, \quad N \equiv 1+\alpha(t,\mathbf{x})\,, \quad N_i \equiv \partial_i\beta(t,\mathbf{x})\,, \tag{230}$$

where ζ is the comoving curvature perturbation. Substituting this ansatz into the constraint equations (219) and (220), we obtain [40]

$$\alpha = \frac{\zeta'}{H}\,, \quad \partial^2\beta = -\frac{\partial^2\zeta}{H} + a^2\frac{(\bar{\phi}')^2}{2H^2}\zeta'\,. \tag{231}$$

Plugging this solution into the action (218), expanding to second order, performing integrations by parts and using the background equations of motion, we get a remarkably simple result

$$S_2 = \int \mathrm{d}t\,\mathrm{d}^3x\,a^3\varepsilon\left((\zeta')^2 - \frac{1}{a^2}(\partial\zeta)^2\right). \tag{232}$$

Note that there is no mass term, so ζ is conserved outside the horizon. Consider the equation of motion

$$\zeta_k'' + (3+\eta)H\zeta_k' + \frac{k^2}{a^2}\zeta_k = 0\,. \tag{233}$$

On super-Hubble scales, $k \ll aH$, this becomes $\zeta_k'' + (3+\eta)H\zeta_k' \approx 0$, which clearly has a constant mode as a solution.

The equation of motion of the canonically normalized field, $v \equiv a\sqrt{2\varepsilon}\,\zeta \equiv z\,\zeta$, is

$$\ddot{v}_k + \left(k^2 - \frac{\ddot{z}}{z}\right)v_k = 0\,, \tag{234}$$

where the effective mass can be written as

$$\frac{\ddot{z}}{z} = \frac{\nu^2 - 1/4}{\tau^2}\,, \quad \text{with} \quad \nu \approx \frac{3}{2} + \varepsilon + \frac{\eta}{2}\,. \tag{235}$$

Recall that we have seen eq. (234) before when we considered a massive scalar field in de Sitter space, cf. eq. (208). The Bunch-Davies mode function therefore is

$$|v_k(\tau)| = \frac{\sqrt{\pi}}{2}\sqrt{-\tau}\,|H_\nu^{(1)}(-k\tau)| \xrightarrow{k\tau\to 0} \frac{2^\nu \Gamma(\nu)}{2\sqrt{\pi}}\frac{1}{\sqrt{k}}\,(-k\tau)^{-\nu+1/2}\,, \tag{236}$$

and the superhorizon limit of the power spectrum of ζ is

$$\begin{aligned}\mathcal{P}_\zeta(k) \equiv \lim_{k\tau\to 0}\frac{k^3}{2\pi^2}|\zeta_k(\tau)|^2 &= \frac{1}{z^2(\tau)}\lim_{k\tau\to 0}\frac{k^3}{2\pi^2}|v_k(\tau)|^2 \\ &= \frac{1}{2a^2\varepsilon}\frac{k^2}{4\pi^2}\,(-k\tau)^{-2\nu+1} \;=\; \frac{1}{16\pi^2}\frac{H^2(\tau)}{\varepsilon(\tau)}\,(-k\tau)^{-2\nu+3}\,.\end{aligned} \tag{237}$$

Note that the time dependence of $H(\tau)$ and $\varepsilon(\tau)$ precisely cancels the time dependence of the final factor in (237), so that the power spectrum is time independent. Let k_* be a reference scale that exits the horizon at time $\tau_* = -1/k_*$. Equation (237) can then be written as

$$\boxed{\mathcal{P}_\zeta(k) = \frac{1}{8\pi^2}\frac{1}{\varepsilon_*}\frac{H_*^2}{M_{\rm pl}^2}\,(k/k_*)^{-2\varepsilon_*-\eta_*}} \tag{238}$$

where $H_* \equiv H(\tau_*)$ and $\varepsilon_* \equiv \varepsilon(\tau_*)$.

Curvature Perturbations

For ease of reference, we briefly summarize the results of the previous section. The power spectrum of the curvature perturbation ζ, cf. eqs. (228) and (238), takes a power law form

$$\mathcal{P}_\zeta(k) = A_{\rm s}\left(\frac{k}{k_*}\right)^{n_{\rm s}-1}\,, \tag{239}$$

where the amplitude and the spectral index are

$$A_{\rm s} \equiv \frac{1}{8\pi^2}\frac{1}{\varepsilon_*}\frac{H_*^2}{M_{\rm pl}^2}\,, \tag{240}$$

$$n_{\rm s} \equiv 1 - 2\varepsilon_* - \eta_*\,. \tag{241}$$

The observational constraint on the scalar spectral index is $n_{\rm s} = 0.9603 \pm 0.0073$. The observed percent-level deviation from the scale-invariant value, $n_{\rm s} = 1$, are the first direct measurement of time dependence in the inflationary dynamics.

Exercise.—Show that for slow-roll inflation, the results (240) and (460) can be written as

$$A_{\rm s} = \frac{1}{24\pi^2}\frac{1}{\varepsilon_V}\frac{V}{M_{\rm pl}^4}\,, \tag{242}$$

$$n_{\rm s} = 1 - 6\varepsilon_V + 2\eta_V\,, \tag{243}$$

where ε_V and η_V are the potential slow-roll parameters defined in (165). This expresses the amplitude of curvature perturbations and the spectral index in terms of the shape of the inflaton potential.

Gravitational Waves

Arguably the cleanest prediction of inflation is a spectrum of primordial gravitational waves. These are tensor perturbations to the spatial metric,

$$\mathrm{d}s^2 = a^2(\tau)\left[-\mathrm{d}\tau^2 + (\delta_{ij} + 2\gamma_{ij})\mathrm{d}x^i\mathrm{d}x^j\right], \tag{244}$$

where γ_{ij} is transverse and traceless. Substituting (244) into the Einstein-Hilbert action and expanding to second order gives

$$S = \frac{M_{\rm pl}^2}{2}\int \mathrm{d}^4x\sqrt{-g}\,R \qquad \Rightarrow \qquad S_2 = \frac{M_{\rm pl}^2}{8}\int \mathrm{d}\tau\,\mathrm{d}^3x\,a^2\left[\dot\gamma_{ij}^2 - (\partial\gamma_{ij})^2\right]. \tag{245}$$

It is convenient to use rotational symmetry to align the z-axis of the coordinate system with the momentum of the mode, i.e. $\mathbf{k} \equiv (0,0,k)$, and write

$$\frac{M_{\rm pl}}{2}\,a\gamma_{ij} \equiv \frac{1}{\sqrt{2}}\begin{pmatrix} v_+ & v_\times & 0 \\ v_\times & -v_+ & 0 \\ 0 & 0 & 0 \end{pmatrix}. \tag{246}$$

The action (245) then becomes

$$S_2 = \frac{1}{2}\sum_{\lambda=+,\times}\int \mathrm{d}\tau\,\mathrm{d}^3x\left[\dot v_\lambda^2 - (\partial v_\lambda)^2 + \frac{\ddot a}{a}v_\lambda^2\right], \tag{247}$$

which is just two copies of the action of a massless scalar field, one for each polarization mode of the gravitational wave, $v_{+,\times}$. The equation of motion for each polarization is

$$\ddot v_k + \left(k^2 - \frac{\ddot a}{a}\right)v_k = 0\,, \tag{248}$$

where the effective mass can be written as

$$\frac{\ddot a}{a} = \frac{\nu^2 - 1/4}{\tau^2}\,, \quad \text{with} \quad \nu \approx \frac{3}{2} + \varepsilon\,. \tag{249}$$

The Bunch-Davies mode function is then given by (236). The superhorizon limit of the power spectrum of the tensor flucutations then is

$$\begin{aligned}\mathcal{P}_\gamma(k) = 2\times\lim_{k\tau\to 0}\frac{k^3}{2\pi^2}|\gamma_k(\tau)|^2 &= 2\times\left(\frac{2}{aM_{\rm pl}}\right)^2\lim_{k\tau\to 0}\frac{k^3}{2\pi^2}|v_k(\tau)|^2 \\ &= \frac{2}{\pi^2}\frac{H^2(\tau)}{M_{\rm pl}^2}\,(-k\tau)^{-2\nu+3}\,,\end{aligned} \tag{250}$$

where the factor of 2 accounts for the sum over the two polarization modes. Introducing the reference scale k_*, this can be written as

$$\boxed{\mathcal{P}_\gamma(k) = \frac{2}{\pi^2}\frac{H_*^2}{M_{\rm pl}^2}(k/k_*)^{-2\varepsilon_*}}\,. \tag{251}$$

This result is arguably the most robust and model-independent prediction of inflation. We see that the form of the tensor power spectrum is again a power law,

$$\mathcal{P}_\zeta(k) = A_{\rm t}\left(\frac{k}{k_*}\right)^{n_{\rm t}}\,, \tag{252}$$

where the amplitude and the spectral index are

$$A_{\rm t} \equiv \frac{2}{\pi^2}\frac{H_*^2}{M_{\rm pl}^2}\,, \tag{253}$$

$$n_{\rm t} \equiv -2\varepsilon_*\,. \tag{254}$$

Notice that the tensor amplitude is a direct measure of the expansion rate H during inflation. This is in contrast to the scalar amplitude which depends on both H and ε. The tensor tilt is a direct measure of ε, whereas the scalar tilt depends both on ε and η. Observationally, a small value for $n_{\rm t}$ is hard to distinguish from zero. The tensor amplitude is often normalized with respect to the measured scalar amplitude, $A_{\rm s} = (2.196 \pm 0.060) \times 10^{-9}$ (at $k_* = 0.05$ Mpc^{-1}):

$$\boxed{r \equiv \frac{A_{\rm t}}{A_{\rm s}} = 16\varepsilon_*} \tag{255}$$

where r is the *tensor-to-scalar ratio*. Inflationary models make predictions for $(n_{\rm s}, r)$. The latest observational constraints on these parameters are shown in Fig. 80.

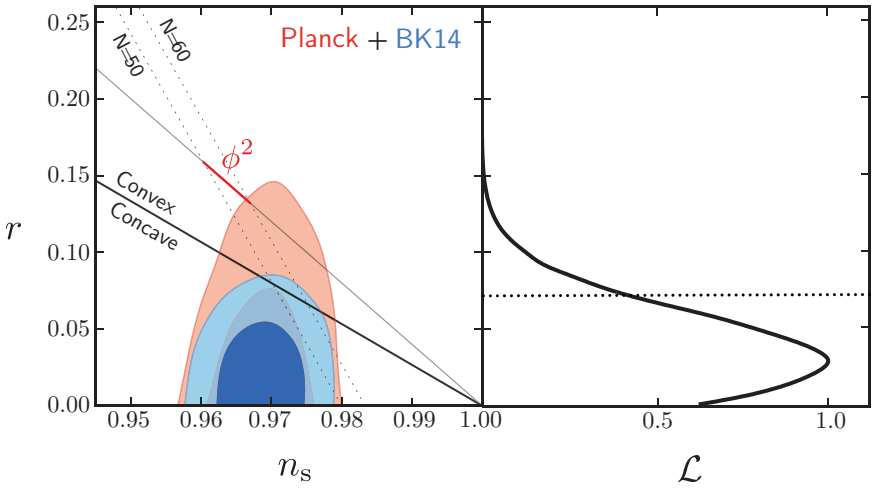

Figure 43: Current constraints on $n_{\rm s}$ and r from CMB measurements of Planck and BICEP [41].

Case study: $m^2\phi^2$ inflation.—In Section 6.6.1, we showed that the slow-roll parameters of $m^2\phi^2$ inflation are

$$\varepsilon_V(\phi) = \eta_V(\phi) = 2\left(\frac{M_{\rm pl}}{\phi}\right)^2\,, \tag{256}$$

and the number of e-folds before the end of inflation is

$$N(\phi) = \frac{\phi^2}{4M_{\rm pl}^2} - \frac{1}{2} \approx \frac{\phi^2}{4M_{\rm pl}^2}\,. \tag{257}$$

At the time when the CMB fluctuations crossed the horizon at $\phi = \phi_*$, we have

$$\varepsilon_{V,*} = \eta_{V,*} \approx \frac{1}{2N_*}\,. \tag{258}$$

The spectral tilt and the tensor-to-scalar ratio therefore are

$$n_{\rm s} \equiv 1 - 6\varepsilon_{V,*} + 2\eta_{V,*} = 1 - \frac{2}{N_*} \approx 0.97\,, \tag{259}$$

$$r \equiv 16\varepsilon_{V,*} = \frac{8}{N_*} \approx 0.13\,, \tag{260}$$

where the final equalities are for $N_* \approx 60$. Comparison with Fig. 80 shows that these predictions are in conflict with the latest CMB data.

The Lyth bound.—During $m^2\phi^2$ inflation, the inflaton field value varies by $\Delta\phi \approx 15\, M_{\rm pl}$ from the time the mode observed in the CMB exited the horizon until the end of inflation. This super-Planckian field variation is, in fact, a general feature of all inflationary models with observable gravitational waves.
Combining (161) and (255), the tensor-to-scalar ratio can be related to the evolution of the inflaton:

$$r = \frac{8}{M_{\rm pl}^2}\left(\frac{d\phi}{dN}\right)^2 , \tag{261}$$

where $\mathrm{d}N = H\mathrm{d}t$. The total field excursion between the time when CMB fluctuations exited the horizon at N_* and the end of inflation at N_e can therefore be written as the integral

$$\frac{\Delta\phi}{M_{\rm pl}} = \int_{N_e}^{N_*} \mathrm{d}N \sqrt{\frac{r}{8}} . \tag{262}$$

During slow-roll evolution, $r(N)$ doesn't evolve much and one may obtain the following approximate relation, called the *Lyth bound* :

$$\frac{\Delta\phi}{M_{\rm pl}} = \mathcal{O}(1) \times \left(\frac{r}{0.01}\right)^{1/2} , \tag{263}$$

where $r \equiv r(N_*)$ is the tensor-to-scalar ratio on CMB scales. Large values of the tensor-to-scalar ratio, $r > 0.01$, therefore correlate with super-Planckian field excursions, $\Delta\phi > M_{\rm pl}$.

A major goal of current efforts in observational cosmology is to detect the tensor component of the primordial fluctuations. Its amplitude depends on the energy scale of inflation and is therefore not predicted (i.e. it varies between models). While this makes the search for primordial tensor modes difficult, it is also what makes it exciting. Detecting tensors would reveal the energy scale at which inflation occurred, providing an important clue about the physics driving the inflationary expansion.

Most searches for tensors focus on the imprint that tensor modes leave in the polarization of the CMB. Polarization is generated through the scattering of the anisotropic radiation field off the free electrons just before decoupling. The presence of a gravitational wave background creates an anisotropic stretching of the spacetime which induces a special type of polarization pattern, the so-called B-mode pattern (a pattern whose "curl" doesn't vanish). Such a pattern cannot be created by scalar (density) fluctuations and is therefore a unique signature of primordial tensors (gravitational waves). A large number of ground-based, balloon and satellite experiments are currently searching for the B-mode signal predicted by inflation. A B-mode detection would be a milestone towards a complete understanding of the origin of all structure in the universe.

6.6.3 Primordial Interactions

In the previous section, we have computed the two-point function of primordial curvature perturbations, or its Fourier equivalent, the power spectrum. If the initial conditions are drawn from a Gaussian distribution function, then the power spectrum contains all of the information

about the primordial perturbations. In general, however, higher-order correlations can encode a significant amount of new information. In particular, these correlations are sensitive to nonlinear interactions while the power spectrum only probes the free theory.

In this section, I will introduce the basic formalism for computing the non-Gaussianity produced by inflation. I will apply this to single-field slow-roll inflation and show that gravitational nonlinearities produce a robust (but small) non-Gaussian signature. In Section 6.6.4, I will show that extra massive fields can get excited during inflation and that their decays lead to distinctive signatures in cosmological correlation functions.

For further reading I highly recommend the classic papers by Maldacena [40] and Weinberg [89], as well as the wonderfully clear reviews by Chen [43], Wang [44], Lim [45] and Komatsu [46].

Non-Gaussianity

The leading non-Gaussian signature is the three-point correlation function, or its Fourier equivalent, the bispectrum

$$B_\zeta(\mathbf{k}_1, \mathbf{k}_2, \mathbf{k}_3) \equiv \langle \zeta_{\mathbf{k}_1} \zeta_{\mathbf{k}_2} \zeta_{\mathbf{k}_3} \rangle \,. \tag{264}$$

For perturbations around an FRW background, the momentum dependence of the bispectrum simplifies considerably: Because of homogeneity, or *translation invariance*, the bispectrum is proportional to a delta function of the sum of the momenta, $B_\zeta(\mathbf{k}_1, \mathbf{k}_2, \mathbf{k}_3) \propto \delta_D(\mathbf{k}_1 + \mathbf{k}_2 + \mathbf{k}_3)$, i.e. the sum of the momentum three-vectors must form a closed triangle. Because of isotropy, or *rotational invariance*, the bispectrum only depends on the magnitudes of the momentum vectors, but not on their orientations,

$$B_\zeta(\mathbf{k}_1, \mathbf{k}_2, \mathbf{k}_3) = (2\pi)^3 \delta_D(\mathbf{k}_1 + \mathbf{k}_2 + \mathbf{k}_3)\, B_\zeta(k_1, k_2, k_3) \,. \tag{265}$$

It is convenient to define the dimensionless bispectrum as

$$\mathcal{B}_\zeta(k_1, k_2, k_3) \equiv \frac{(k_1 k_2 k_3)^2}{(2\pi^2)^2} B_\zeta(k_1, k_2, k_3) \,. \tag{266}$$

The *amplitude* of the non-Gaussianity is then defined as the size of the bispectrum in the equilateral momentum configuration:

$$f_{\rm NL}(k) \equiv \frac{5}{18} \frac{\mathcal{B}_\zeta(k, k, k)}{\mathcal{P}_\zeta^2(k)} \,, \tag{267}$$

where we have indicated that $f_{\rm NL}$ can in general depend on the overall momentum. On the other hand, if the fluctuations are *scale-invariant*, then $f_{\rm NL}$ is a constant and we can write

$$\mathcal{B}_\zeta(k_1, k_2, k_3) \equiv \frac{18}{5} f_{\rm NL} \times \mathcal{S}(x_2, x_3) \times \mathcal{P}_\zeta^2 \,, \tag{268}$$

where $x_2 \equiv k_2/k_1$ and $x_3 \equiv k_3/k_1$. The shape function $\mathcal{S}(x_2, x_3)$ is normalized so that $\mathcal{S}(1, 1) \equiv 1$.

As we will discuss in detail below, the *shape* of the non-Gaussianity contains a lot of information about the microphysics of inflation. A divergence of the signal for squeezed triangles is a signature for extra degrees of freedom during inflation (see Fig. 83 and Sec. 6.6.4), while a peak in the signal for equilateral triangles arises from higher-derivative inflaton self-interactions (see Fig. 45).

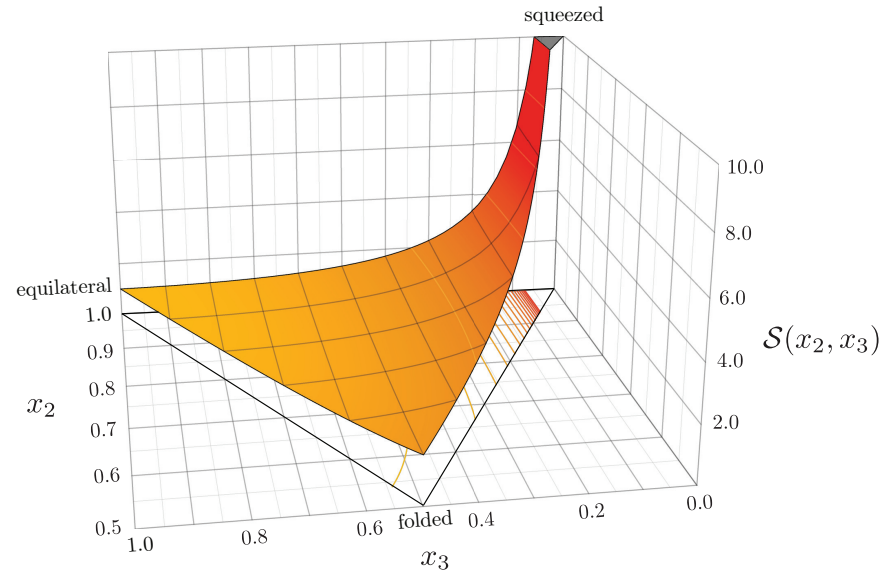

Figure 44: Bispectrum of local non-Gaussianity. The signal is peaked for squeezed triangles.

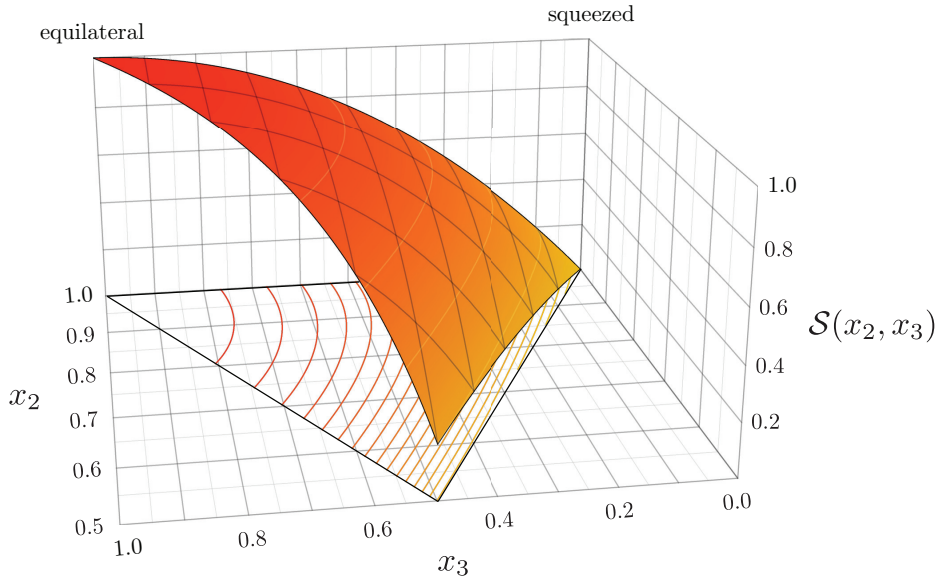

Figure 45: Bispectrum for the interaction $\dot{\zeta}^3$. The signal is peaked for equilateral triangles.

In-In Formalism

The problem of computing correlation functions in cosmology differs in important ways from the corresponding analysis of quantum field theory applied to particle physics.

In particle physics, the main observable is the S-matrix, i.e. the transition probability for a state $|in\rangle$ in the far past to become some state $|out\rangle$ in the far future,

$$\langle out|\, S|in\rangle = \langle out(+\infty)|in(-\infty)\rangle. \tag{269}$$

The scattering particles are taken to be non-interacting at very early and very late times, when they are far from the interaction region, and the asymptotic states can be taken to be vacuum states of the free Hamiltonian H_0.

In cosmology, on the other hand, the task is to determine the expectation values of products of operators *at a fixed time*. Boundary conditions are only imposed at very early times when their wavelengths are much smaller than the horizon and the interaction picture fields should have the same form as in Minkowski space. As we have seen in the previous section, this

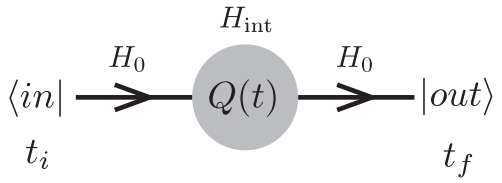

Figure 46: Particle physicists compute in-out transition amplitudes.

leads to the definition of the Bunch–Davies vacuum. In this section, we will describe the *in-in* formalism[17] to compute cosmological correlation functions as expectation values in two $|in\rangle$ states.

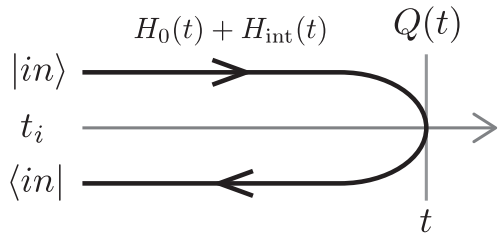

Figure 47: Cosmologists compute in-in expectation values.

Our goal is to compute n-point functions of the curvature perturbation ζ or the gravitational wave polarization modes $\gamma^\times$ and γ^+. We will collectively denote these fluctuations by the field $\psi = \{\zeta, \gamma^\times, \gamma^+\}$ and consider expectation values of operators such as $\hat{Q} = \hat{\psi}_{\mathbf{k}_1}\hat{\psi}_{\mathbf{k}_2}\cdots\hat{\psi}_{\mathbf{k}_n}$,

$$\langle \hat{Q}(\tau)\rangle = \langle in|\, \hat{Q}(\tau)\, |in\rangle\,, \tag{270}$$

where $|in\rangle$ is the vacuum of the interacting theory at some moment τ_i in the far past, and $\tau > \tau_i$ is some later time, such as horizon crossing or the end of inflation. To compute the matrix element in (270) we evolve $Q(\tau)$ back to τ_i using the perturbed Hamiltonian δH. Computing this time evolution is complicated by the interactions inside of $\delta H = H_0 + H_{\rm int}$, which lead to nonlinear equations of motion. We therefore introduce the *interaction picture* in which the leading time dependence of the fields is determined by the quadratic Hamiltonian H_0 (or linear equations of motion). Corrections arising from the interactions are then treated as a power series in $H_{\rm int}$.

This leads to the following important result:

$$\boxed{\langle \hat{Q}(\tau)\rangle \;=\; \langle 0|\, \bar{T} e^{\,i\int_{-\infty(1-i\epsilon)}^{\tau} \hat{H}^I_{\rm int}(\tau')\,{\rm d}\tau'}\, \hat{Q}^I(\tau)\, T e^{\,-i\int_{-\infty(1+i\epsilon)}^{\tau} \hat{H}^I_{\rm int}(\tau'')\,{\rm d}\tau''}\, |0\rangle} \tag{271}$$

where T ($\bar{T}$) is the (anti-)time-ordering symbol. Note that both $\hat{Q}^I$ and $\hat{H}^I_{\rm int}$ are evaluated using interaction picture operators. The standard $i\epsilon$ prescription has been used to effectively turn off the interaction in the far past and project the interacting $|in\rangle$ state onto the free vacuum $|0\rangle$. By expanding the exponentials, we can compute the correlation function perturbatively in $\hat{H}_{\rm int}$. For example, at leading order, we find

$$\boxed{\langle \hat{Q}(\tau)\rangle \;=\; -i\int_{-\infty}^{\tau} {\rm d}\tau'\; \langle 0|\, [\hat{Q}^I(\tau), \hat{H}^I_{\rm int}(\tau')]\, |0\rangle}\,. \tag{272}$$

[17] This is also referred to as the Schwinger–Keldysh formalism [86]. The use of the *in-in* formalism in cosmology was pioneered in [87, 88, 40, 89] (see also [169, 170]) and is reviewed in [43, 44].

We can use Feynman diagrams to organize the power series, drawing interaction vertices for every power of $\hat{H}_{\rm int}$.

In the following insert, I will derive the *in-in* master formula (271). Readers who are more interested in applications of the result, may skip this part.

Derivation.—The time evolution of the operators in the Heisenberg picture is determined by

$$\frac{d\hat{\psi}}{d\tau} = i[\hat{H}, \hat{\psi}]\,, \quad \frac{d\hat{p}_\psi}{d\tau} = i[\hat{H}, \hat{p}_\psi]\,, \tag{273}$$

where $\hat{H} = \hat{H}_0 + \hat{H}_{\rm int}$ is the perturbed Hamiltonian. This time evolution is complicated by the interactions inside $\hat{H}$, which lead to nonlinear equations of motion. We therefore introduce the *interaction picture* in which the leading time dependence of the fields is determined by the quadratic Hamiltonian $\hat{H}_0$ (or, equivalently, by the linear equations of motion):

$$\frac{d\hat{\psi}^I}{d\tau} = i[\hat{H}_0, \hat{\psi}^I] \quad \frac{d\hat{p}^I_\psi}{d\tau} = i[\hat{H}_0, \hat{p}^I_\psi]\,. \tag{274}$$

The solution to these equations can be written as

$$\hat{\psi}^I_{\mathbf{k}}(\tau) = \psi^I_k(\tau)\,\hat{a}_{\mathbf{k}} + h.c.\,, \tag{275}$$

where $\psi^I_k(\tau)$ is the solution to the free-field equation and the operators $\hat{a}_{\mathbf{k}}$ define the free-field vacuum $|0\rangle$. Corrections to the evolution of the operators can then be treated perturbatively in $\hat{H}_{\rm int}$. Relatively straightforward algebraic manipulations of (273) and (274) allow us to express an operator in the Heisenberg picture in terms of operators in the interaction picture [89],

$$\hat{Q}(\tau) = \hat{F}^{-1}(\tau, \tau_i)\,\hat{Q}^I(\tau)\,\hat{F}(\tau, \tau_i)\,, \tag{276}$$

where

$$\hat{F}(\tau, \tau_i) \equiv T e^{-i\int_{\tau_i}^{\tau} \hat{H}^I_{\rm int}(\tau'')\,{\rm d}\tau''}\,. \tag{277}$$

We can think of $\hat{F}(\tau, \tau_i)$ as an operator evolving quantum states in the interaction picture,

$$|\Omega(\tau)\rangle = \hat{F}(\tau, \tau_i)|\Omega(\tau_i)\rangle\,, \tag{278}$$

where $|\Omega(\tau_i)\rangle \equiv |\Omega\rangle$. We would like to relate the vacuum of the interacting theory, $|\Omega\rangle$, to the vacuum of the free theory, $|0\rangle$. Inserting a complete set of energy eigenstates $\{|\Omega\rangle, |n\rangle\}$ of the full theory, where $|n\rangle$ are the excited states, we have

$$|0\rangle = |\Omega\rangle\langle\Omega|0\rangle + \sum_n |n\rangle\langle n|0\rangle\,, \tag{279}$$

and correspondingly

$$e^{-i\hat{H}(\tau-\tau_i)}|0\rangle = e^{-i\hat{H}(\tau-\tau_i)}|\Omega\rangle\langle\Omega|0\rangle + \sum_n e^{-iE_n(\tau-\tau_i)}|n\rangle\langle n|0\rangle\,. \tag{280}$$

Adding a small imaginary part to the initial time, $\tau_i \to -\infty(1-i\epsilon) \equiv -\infty^-$, will project out the excited states, $e^{-iE_n(\tau-\tau_i)} \to e^{-\infty\times\epsilon E_n}(\cdots) \to 0$. We are then left with

$$\hat{F}(\tau, -\infty^-)|\Omega\rangle = \frac{\hat{F}(\tau, -\infty^-)|0\rangle}{\langle\Omega|0\rangle}\,. \tag{281}$$

The $i\epsilon$ prescription has effectively turned off the interactions in the far past and projected the interacting vacuum $|\Omega\rangle$ onto the free vacuum $|0\rangle$. Setting $|\langle\Omega|0\rangle| \to 1$, we arrive at the *in-in* master formula

$$\langle\hat{Q}(\tau)\rangle \;=\; \langle 0|\,\bar{T} e^{i\int_{-\infty^+}^{\tau} \hat{H}^I_{\rm int}(\tau')\,{\rm d}\tau'}\;\hat{Q}^I(\tau)\;T e^{-i\int_{-\infty^-}^{\tau} \hat{H}^I_{\rm int}(\tau'')\,{\rm d}\tau''}\,|0\rangle\,, \tag{282}$$

where $\infty^\pm \equiv \infty(1\pm i\epsilon)$. The integration contour goes from $-\infty(1-i\epsilon)$ to τ (where the correlation function is evaluated) and back to $-\infty(1+i\epsilon)$.

Gravitational Floor

Let us now apply this formalism to the calculation of the bispectrum of curvature perturbations in single-field slow-roll inflation [40]. The nonlinearities of the gravitational evolution produce a minimal amount of non-Gaussianity which we will call the "gravitational floor". Unfortunately, the amplitude of the signal is too small to be detectable in the foreseeable future.

To compute the bispectrum we need to expand the inflationary action (218) to third order in perturbations. It is convenient to perform the computation in comoving gauge, cf. eqs. (229) and (230). In §6.6.2, we solved the lapse N and the shift N_i to first order in ζ. This is sufficient also for the cubic action since second-order and third-order perturbations in N and N_i will multiply the first-order and zeroth-order constraint equation, respectively. Substituting (231) into (218) and expanding to third order, we find [40]

$$S_3 = \frac{1}{2}\int \mathrm{d}t\,\mathrm{d}^3x\,a^3\Big(2\varepsilon^2\,\zeta(\zeta')^2 - 4a^{-2}\varepsilon^2\,\zeta'(\partial\zeta)(\partial\zeta) + 2a^{-2}\varepsilon^2\,\zeta(\partial\zeta)^2 \\ + a^{-2}\varepsilon\eta'\,\zeta^2\zeta' + a^{-2}\varepsilon\,\partial\zeta\partial\beta\partial^2\beta + \frac{1}{2}a^{-2}\varepsilon\,\partial^2\zeta(\partial\beta)^2 + 2f(\zeta)\frac{\delta L_2}{\delta\zeta}\Big)\,, \tag{283}$$

where we have defined

$$\frac{\delta L_2}{\delta\zeta} \equiv (a^3\varepsilon\,\zeta')' - a\varepsilon\partial^2\zeta\,, \tag{284}$$

$$f(\zeta) \equiv \frac{\eta}{4}\zeta^2 + \frac{\zeta\zeta'}{H} + \frac{-(\partial\zeta)^2 + \partial^{-2}(\partial_i\partial_j(\partial_i\zeta\partial_j\zeta))}{4a^2H^2} + \frac{\partial\zeta\partial\beta - \partial^{-2}(\partial_i\partial_j(\partial_i\zeta\partial_j\beta))}{2a^2H^2}\,. \tag{285}$$

Maldacena showed that the term proportional to $f(\zeta)$ in (283) can be removed by a field redefinition,

$$\zeta \to \tilde\zeta + f(\tilde\zeta)\,. \tag{286}$$

This field redefinition has the following effect on the correlation function:

$$\langle\zeta(\mathbf{x}_1)\zeta(\mathbf{x}_2)\zeta(\mathbf{x}_3)\rangle = \langle\tilde\zeta(\mathbf{x}_1)\tilde\zeta(\mathbf{x}_2)\tilde\zeta(\mathbf{x}_3)\rangle + \frac{\eta}{2}\Big(\langle\tilde\zeta(\mathbf{x}_1)\tilde\zeta(\mathbf{x}_2)\rangle\langle\tilde\zeta(\mathbf{x}_1)\tilde\zeta(\mathbf{x}_3)\rangle + \text{cyclic}\Big) + \cdots\,. \tag{287}$$

The term proportional to $f(\zeta)$ in (283) therefore leads to a contribution to $f_{\rm NL}$ of order $\eta \ll 1$. The effect of the remaining interactions is computed by expanding the *in-in* master formula (271) to first order in $H_{\rm int} = -L_3 + \mathcal{O}(\zeta^4)$,

$$\langle\zeta_{\mathbf{k}_1}\zeta_{\mathbf{k}_2}\zeta_{\mathbf{k}_3}\rangle = -i\int_{-\infty}^{0}\mathrm{d}\tau\;\langle 0|\big[\hat\zeta_{\mathbf{k}_1}\hat\zeta_{\mathbf{k}_2}\hat\zeta_{\mathbf{k}_3}(0), \hat H_{\rm int}(\tau)\big]|0\rangle\,, \tag{288}$$

where we have switched to conformal time and taken the superhorizon limit $k\tau \to 0$.

Back-of-the-envelope estimate.—Before embarking on a lengthy calculation of the bispectrum, it is often advisable to perform an order-of-magnitude estimate of the expected size of the signal, i.e. to estimate (288) without explicitly performing the integral. For example, the first term in (283), can be written as

$$\int \mathrm{d}\tau\, H_{\rm int}(\tau) \subset -\int \mathrm{d}\tau\mathrm{d}^3x\,a^2\varepsilon^2\zeta\dot\zeta^2. \tag{289}$$

We only need to keep track of factors of H and ε. Any time- and momentum-dependence will work itself out and only contributes to the shape function. Using $a \propto H^{-1}$ and $\zeta \propto \dot\zeta \propto \mathcal{P}_\zeta^{1/2} \sim H/\sqrt{\varepsilon}$,

we estimate that the contribution from the three-point vertex is $\sim H\sqrt{\varepsilon}$. Combining this with estimates for the size of the three external legs, $\zeta^3 \sim H^3\varepsilon^{-3/2}$, we find

$$\langle\zeta^3\rangle = -i\int \mathrm{d}\tau\,\langle[\hat{\zeta}^3, \hat{H}_{\rm int}(\tau)]\rangle \propto \frac{H^4}{\varepsilon} \propto \mathcal{O}(\varepsilon)\,\mathcal{P}_\zeta^2 \sim f_{\rm NL}\,\mathcal{P}_\zeta^2. \tag{290}$$

Similar results are obtained for the other interactions in (283), $f_{\rm NL} \sim \mathcal{O}(\varepsilon)$. We also include the contribution from the field redefinition in (287), $f_{\rm NL} \sim \mathcal{O}(\eta)$. We conclude that the non-Gaussianity in slow-roll inflation is slow-roll suppressed,

$$f_{\rm NL} \sim \mathcal{O}(\varepsilon,\eta) \ll 1\,. \tag{291}$$

This small amount of non-Gaussianity will be unobservable in the CMB.

To get the full momentum-dependence of the bispectrum, we actually have to do some real work and compute the integral in (288) using the free-field mode functions for ζ. The final result for the dimensionless bispectrum is [40]

$$\begin{aligned}\frac{\mathcal{B}_\zeta(k_1,k_2,k_3)}{\mathcal{P}_\zeta^2} &= \frac{\varepsilon}{2}\left[-\left(\frac{k_1^2}{k_2k_3} + 2\,\text{perms.}\right) + \left(\frac{k_1}{k_2} + 5\,\text{perms.}\right) + \frac{8}{k_t}\left(\frac{k_1k_2}{k_3} + 2\,\text{perms.}\right)\right] \\ &\quad + \frac{\eta}{2}\left(\frac{k_1^2}{k_2k_3} + 2\,\text{perms.}\right),\end{aligned} \tag{292}$$

where $k_t \equiv k_1 + k_2 + k_3$. It is interesting to take the *squeezed limit*, $k_3 \ll k_1 \approx k_2$, of the result:

$$\lim_{k_3\to 0}\frac{\mathcal{B}_\zeta(k_1,k_2,k_3)}{\mathcal{P}_\zeta^2} = (2\varepsilon+\eta)\,\frac{k_1}{k_3}\,. \tag{293}$$

Note that the coefficient in the squeezed limit equals the deviation from scale invariance of the power spectrum, $1 - n_{\rm s} = 2\varepsilon + \eta$. In fact, this is a general result that applies to all models of single-field inflation, not necessarily just to slow-roll models. The *single-field consistency relation* states that [40, 94]

$$\boxed{\lim_{k_3\to 0} B_\zeta(k_1,k_2,k_3) = (1-n_{\rm s})\,P_\zeta(k_1)P_\zeta(k_3)} \tag{294}$$

i.e. the squeezed limit of the three-point function is suppressed by $(1 - n_{\rm s})$ and vanishes for perfectly scale-invariant perturbations.

Proof.—The squeezed triangle correlates one long-wavelength mode, $k_{\rm L} = k_3$, to two short-wavelength modes, $k_{\rm S} = k_1 \approx k_2$,

$$\langle\zeta_{\mathbf{k}_1}\zeta_{\mathbf{k}_2}\zeta_{\mathbf{k}_3}\rangle \;\to\; \langle(\zeta_{\mathbf{k}_{\rm S}})^2\zeta_{\mathbf{k}_{\rm L}}\rangle\,. \tag{295}$$

Modes with longer wavelengths freeze earlier. The long mode $\zeta_{\mathbf{k}_{\rm L}}$ will therefore already be frozen and act as a classical background wave when the two short modes $\zeta_{\mathbf{k}_{\rm S}}$ exit the horizon. This provides an intuitive way to study the correlations between long and short modes.

Why should $(\zeta_{\mathbf{k}_{\rm S}})^2$ be correlated with $\zeta_{\mathbf{k}_{\rm L}}$? The theorem says that it isn't correlated if $\zeta_{\mathbf{k}}$ is precisely scale-invariant, but that the short scale power does get modified by the long-wavelength mode if $n_{\rm s} \neq 1$. Let's see why. We decompose the evaluation of (295) into two steps:

i) we calculate the power spectrum of short fluctuations $\langle\zeta_{\rm S}^2\rangle_{\zeta_{\rm L}}$ in the presence of a long mode $\zeta_{\rm L}$;

ii) we then calculate the correlation $\langle(\zeta_{\rm S})^2\zeta_{\rm L}\rangle$, i.e. average the short-scale power spectrum over realizations of the long modes.

The calculation of $\langle\zeta_{\rm S}^2\rangle_{\zeta_{\rm L}}$ is simplest in real space: When the background mode is homogeneous, $\zeta_{\rm L}(x)\equiv\bar\zeta_{\rm L}$, it can be reabsorbed simply by a rescaling of the spatial coordinates, $\tilde x^i = e^{\bar\zeta_{\rm L}}x^i$ (recall that $\mathrm{d}s^2 = -\mathrm{d}t^2 + a^2(t)e^{2\zeta(\mathbf{x},t)}\mathrm{d}\mathbf{x}^2$). After this rescaling, $\bar\zeta_{\rm L}$ no longer appears in the action, so that the two-point function in the new coordinates is the same as in the absence of $\bar\zeta_{\rm L}$. In other words, in the limit of constant $\bar\zeta_{\rm L}$, we have

$$\langle\zeta_{\rm S}(\mathbf{x}_1)\zeta_{\rm S}(\mathbf{x}_2)\rangle_{\bar\zeta_{\rm L}} = \langle\zeta_{\rm S}(\tilde{\mathbf{x}}_1)\zeta_{\rm S}(\tilde{\mathbf{x}}_2)\rangle\,. \tag{296}$$

When $\zeta_{\rm L}$ is slowly varying, we can evaluate it at the middle point $\mathbf{x}_+\equiv\frac12(\mathbf{x}_1+\mathbf{x}_2)$ to get

$$\tilde{\mathbf{x}}_- \simeq \mathbf{x}_- + \zeta_{\rm L}(\mathbf{x}_+)\cdot\mathbf{x}_- + \cdots\,, \tag{297}$$

where we defined $\mathbf{x}_-\equiv\mathbf{x}_1-\mathbf{x}_2$. The two-point function at linear order in $\zeta_{\rm L}$ therefore is

$$\langle\zeta_{\rm S}(\mathbf{x}_2)\zeta_{\rm S}(\mathbf{x}_3)\rangle_{\zeta_{\rm L}(x)} \simeq \xi_{\rm S}(|\mathbf{x}_-|) + \zeta_{\rm L}(\mathbf{x}_+)[\mathbf{x}_-\cdot\nabla\xi_{\rm S}(|\mathbf{x}_-|)] \tag{298}$$

where

$$\xi_{\rm S}(|\mathbf{x}_-|)\equiv\int\frac{\mathrm{d}^3k_{\rm S}}{(2\pi)^3}\,P_\zeta(k_{\rm S})\,e^{i\mathbf{k}_{\rm S}\cdot\mathbf{x}_-}\,. \tag{299}$$

The three-point function then is

$$\begin{aligned}\langle\zeta_{\rm S}(\mathbf{x}_1)\zeta_{\rm S}(\mathbf{x}_2)\zeta_{\rm L}(\mathbf{x}_3)\rangle &\simeq \langle\zeta_{\rm L}(\mathbf{x}_3)\zeta_{\rm L}(\mathbf{x}_+)\rangle[\mathbf{x}_-\cdot\nabla\xi_{\rm S}(|\mathbf{x}_-|)]\,,\\ &= \int\frac{\mathrm{d}^3k_{\rm L}}{(2\pi)^3}\int\frac{\mathrm{d}^3k_{\rm S}}{(2\pi)^3}\,e^{i\mathbf{k}_{\rm L}\cdot(\mathbf{x}_3-\mathbf{x}_+)}P_\zeta(k_{\rm L})P_\zeta(k_{\rm S})\left[\mathbf{k}_{\rm S}\cdot\frac{\partial}{\partial\mathbf{k}_{\rm S}}\right]e^{i\mathbf{k}_{\rm S}\cdot\mathbf{x}_-}\,.\end{aligned} \tag{300}$$

Integrating by parts, inserting $1=\int\mathrm{d}^3k_3\,\delta_D(\mathbf{k}_3+\mathbf{k}_{\rm L})$ and using

$$\frac{\partial}{\partial\mathbf{k}_{\rm S}}\cdot[\mathbf{k}_{\rm S}P_\zeta(k_{\rm S})] = P_\zeta)k_{\rm S})\,\frac{d\ln(k_{\rm S}^3P_\zeta(k_{\rm S}))}{d\ln k_{\rm S}}\,, \tag{301}$$

we get

$$\begin{aligned}\langle\zeta_{\rm S}(\mathbf{x}_1)\zeta_{\rm S}(\mathbf{x}_2)\zeta_{\rm L}(\mathbf{x}_3)\rangle = -\int\frac{\mathrm{d}^3k_3}{(2\pi)^3}\int\frac{\mathrm{d}^3k_{\rm L}}{(2\pi)^3}\int\frac{\mathrm{d}^3k_{\rm S}}{(2\pi)^3}\;e^{-i\mathbf{k}_1\cdot\mathbf{x}_1-i\mathbf{k}_{\rm L}\cdot\mathbf{x}_++i\mathbf{k}_{\rm S}\cdot\mathbf{x}_-}\\ \times\left[(2\pi)^3\delta_D(\mathbf{k}_1+\mathbf{k}_{\rm L})P_\zeta(k_1)P_\zeta(k_{\rm S})\,\frac{d\ln(k_{\rm S}^3P_\zeta(k_{\rm S}))}{d\ln k_{\rm S}}\right].\end{aligned} \tag{302}$$

Letting $\mathbf{k}_{\rm L}=\mathbf{k}_2+\mathbf{k}_3$ and $\mathbf{k}_{\rm S}=\frac12(\mathbf{k}_2-\mathbf{k}_3)$, we get $-i\mathbf{k}_{\rm L}\cdot\mathbf{x}_+ + i\mathbf{k}_{\rm S}\cdot\mathbf{x}_- = -i\mathbf{k}_2\cdot\mathbf{x}_2 - i\mathbf{k}_3\cdot\mathbf{x}_3$. Changing variables in the integration and Fourier transforming, we get

$$\begin{aligned}\lim_{k_3\to0}\langle\zeta_{\mathbf{k}_1}\zeta_{\mathbf{k}_2}\zeta_{\mathbf{k}_3}\rangle &= -(2\pi)^3\delta_D(\mathbf{k}_1+\mathbf{k}_2+\mathbf{k}_3)\,P_\zeta(k_1)P_\zeta(k_3)\,\frac{d\ln k_3^3P_\zeta(k_3)}{d\ln k_3}\,,\\ &= (2\pi)^3\delta_D(\mathbf{k}_1+\mathbf{k}_2+\mathbf{k}_3)\,(1-n_{\rm s})\,P_\zeta(k_1)P_\zeta(k_3)\,.\end{aligned} \tag{303}$$

This completes the proof.

The fact that the squeezed limit of the bispectrum for single-field inflation vanished implies that it can be used as a clean diagnostic for extra fields during inflation. In the next section, we will expand on this view of the squeezed limit as a particle detector.

6.6.4 Heavy Relics

As we have seen in the previous sections, computing the quantum correlations in single-field slow-roll inflation is a well-defined problem leading to clean predictions for the cosmological correlation functions. In this final section, we will look for deviations from those predictions associated with the existence of extra particles during inflation.

We will begin, in §6.6.4, with a review of the allowed spectrum of particles in de Sitter space, highlighting the qualitative differences to the corresponding results in flat space. In §6.6.4 and §6.6.4, we derive the basic observational imprints that these massive fields create when they are excited during inflation. For further details we refer the reader to the vast literature on the subject, e.g. [53, 54, 55, 56, 57, 38, 58, 59, 60, 97, 62, 63].

Massive Fields in de Sitter

Particles in Minkowski space are classified as unitary irreducible representations of the Poincaré group [64, 65]. The eigenvalues of the Casimir operators of the Poincaré group are related as follows to the mass m and the spin s of the particles:

$$\mathcal{C}_1 \equiv P_\mu P^\mu = m^2\,, \tag{304}$$
$$\mathcal{C}_2 \equiv W_\mu W^\mu = -s(s+1)m^2\,, \tag{305}$$

where P_μ is the four-momentum and W_μ is the Pauli-Lubanski pseudovector. We distinguish between massive and massless particles. Massive particles carry $2s+1$ degrees of freedom (transverse and longitudinal polarizations), while massless particles have only two transverse polarizations.

Similarly, particles in de Sitter space are classified as unitary irreducible representations of the de Sitter group $SO(1,4)$. The Casimir operators of the de Sitter group have the following eigenvalues [66, 67]:

$$\mathcal{C}_1 \equiv \frac{1}{2}M_{AB}M^{AB} = m^2 - 2(s-1)(s+1)H^2\,, \tag{306}$$
$$\mathcal{C}_2 \equiv W_A W^A = -s(s+1)\left[m^2 - \left(s^2+s-\frac{1}{2}\right)H^2\right], \tag{307}$$

where M_{AB} are the generators of $SO(1,4)$, with $A,B = \{0,\dots,4\}$. Notice that this time the Casimir (306) is not just proportional to the mass alone, but also has a term that depends on spin. For $s \geq 1$, the representations of de Sitter space fall into three distinct categories [68, 69, 70]:

principal series	complementary series	discrete series
$\frac{m^2}{H^2} \geq \left(s-\frac{1}{2}\right)^2$	$s(s-1) < \frac{m^2}{H^2} < \left(s-\frac{1}{2}\right)^2$	$\frac{m^2}{H^2} = s(s-1) - t(t+1)\,,$

for $t = 0, 1, 2, ..., s-1$, which is called the depth of the field. Masses that are not associated with one of the above categories correspond to non-unitary representations and are therefore not allowed in the spectrum (see Fig. 48). At the specific mass values corresponding to the discrete series, the system gains an additional gauge invariance and some of the lowest helicity modes become pure gauge modes; this phenomenon is called partial masslessness [71]. We see that unitarity demands the existence of a lower bound

$$m^2 \geq s(s-1)H^2\,, \tag{308}$$

on the masses of fields except those that belong to the discrete series. For $s = 2$, this is known as the Higuchi bound [72].

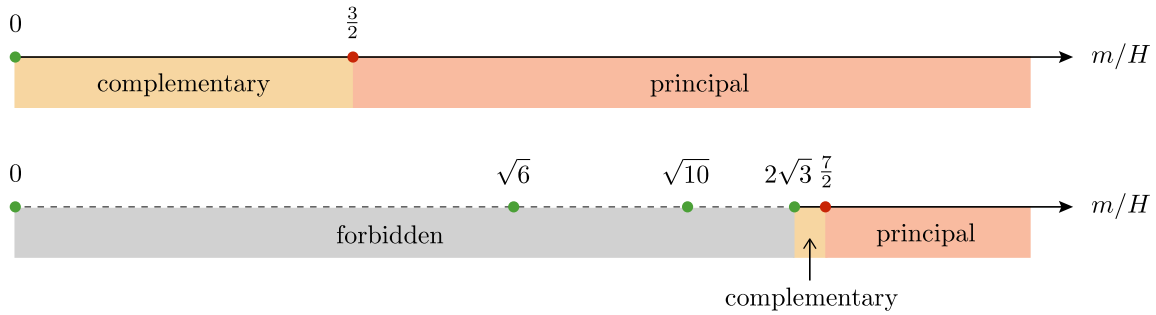

Figure 48: Spectrum of spin-0 (top) and spin-4 fields (bottom) in de Sitter space. The green points correspond to masses in the discrete series.

The Lagrangian for massive fields with arbitrary spin in flat space was constructed by Singh and Hagen in [73, 74], and generalized to (A)dS spaces in [75]. For massive fields with spin greater than 2, the action is rather complex and requires introducing auxiliary fields of lower spins. An alternative, which we will follow, is to use a group theoretical approach to find the equations of motion directly [66]. In four spacetime dimensions, a massive bosonic spin-s field is described by a totally symmetric rank-s tensor, $\sigma_{\mu_1\cdots\mu_s}$, subject to the constraints

$$\nabla^{\mu_1}\sigma_{\mu_1\cdots\mu_s} = 0\,, \quad \sigma^{\mu}{}_{\mu\mu_3\cdots\mu_s} = 0\,. \tag{309}$$

The conditions in (309) project out the components of the tensor which transform as fields with lower spins. The Casimir eigenvalue equation of the de Sitter group then gives the on-shell wave equation satisfied by these fields:

$$\big(\Box - m_s^2\big)\sigma_{\mu_1\cdots\mu_s} = 0\,, \tag{310}$$

where $\Box \equiv \nabla_\mu\nabla^\mu$ is the Laplace-Beltrami operator on dS_4 and $m_s^2 \equiv m^2 - (s^2-2s-2)H^2$. The shift in the mass arises from the mismatch between the Casimir and Laplace-Beltrami operators in de Sitter space and is necessary to describe the correct representations for massless fields. Explicit solutions to the equation of motion (310) can be found in Appendix A of [59]. The spatial components contain all the physical degrees of freedom, while the other components are constrained variables or pure gauge modes.[18] The late-time behaviour of the solution is

$$\lim_{\tau\to 0}\sigma_{i_1\cdots i_s}(\tau,\mathbf{x}) = \sum_{\pm}\tau^{\Delta_\pm - s}\sigma^{\pm}_{i_1\cdots i_s}(\mathbf{x})\,, \tag{311}$$

where $\Delta_\pm$ is the conformal dimension of the field

$$\Delta_\pm = \frac{3}{2} \pm i\mu\,, \quad \mu \equiv \sqrt{\frac{m^2}{H^2} - \left(s-\frac{1}{2}\right)^2}\,. \tag{312}$$

Note that, for $s=0$, the value $m=0$ corresponds to a conformally-coupled scalar field. In the limit $m \gg sH$, the parameter μ becomes the mass of the particle in Hubble units, $\mu \to m/H$. Particles belonging to the principal series correspond to $\mu \geq 0$, which covers the largest mass range. For real μ, the asymptotic scaling is given by a complex-conjugate pair, resulting in a wavefunction that oscillates logarithmically in conformal time. The complementary series has imaginary μ and corresponds to the interval $-i\mu = (0, 1/2)$. In that case, only the growing mode survives in the late-time limit.

[18] This can be seen by solving the equation of motion (310) explicitly, where the normalizations of non-physical components become singular [59].

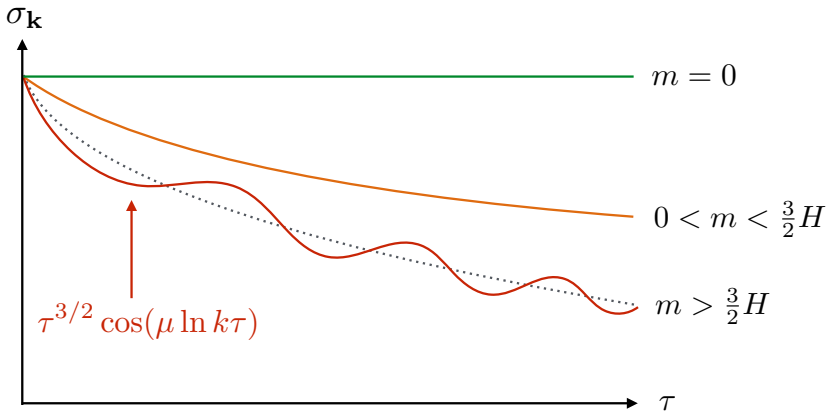

Figure 49: Superhorizon evolution of a massive scalar field. The decay of the field amplitude is determined by the mass of the field.

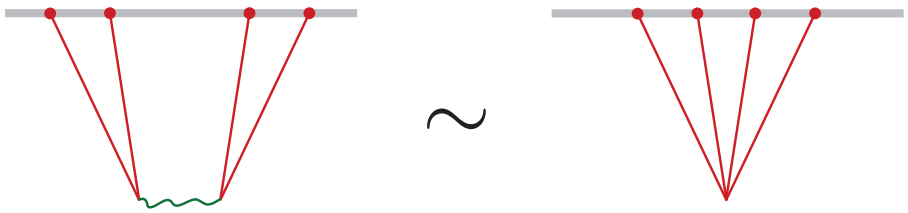
Local and Non-Local

In the remainder of this section, we will study the imprints of massive particles on inflationary correlations functions. Massive particles during inflation can have two types of effects:

- Particles with masses $M \gg H$ can be integrated out, leading to an EFT of inflaton interactions:



These *local* interactions create characteristic imprints in the non-Gaussianity of the inflaton fluctuations. In particular, the soft limits of the resulting correlation functions must satisfy the single-field consistency relation discussed in the previous section.

- Particles with masses $M \lesssim \text{few} \times H$ cannot be integrated out completely, but are produced nonperturbatively by the expanding spacetime. When these particles decay, they produce characteristic *non-local* signatures in cosmological correlators. The single-field consistency relation will be violated.

Local effects

To illustrate the local effects arising from massive particles, we consider the following two-field example:

$$\mathcal{L} = -\frac{1}{2}(\partial_\mu\phi)^2 - V(\phi) - \frac{1}{2}(\partial_\mu\sigma)^2 - \frac{1}{2}M^2\sigma^2 + \frac{\sigma(\partial_\mu\phi)^2}{\tilde{\Lambda}}\,, \tag{313}$$

where $M \gg H$. Integrating out the massive field σ gives

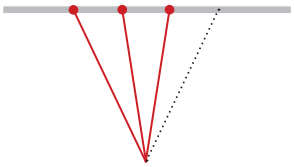
$$\begin{aligned}\mathcal{L}_{\text{eff}} &= -\frac{1}{2}(\partial_\mu\phi)^2 - V(\phi) + \frac{1}{8\tilde{\Lambda}^2}(\partial_\mu\phi)^2\,\frac{1}{\Box + M^2}\,(\partial_\mu\phi)^2 + \cdots \\ &= -\frac{1}{2}(\partial_\mu\phi)^2 - V(\phi) + \frac{1}{8\tilde{\Lambda}^2 M^2}\left((\partial_\mu\phi)^4 + (\partial_\mu\phi)^2\,\frac{\Box}{M^2}\,(\partial_\mu\phi)^2 + \cdots\right),\end{aligned} \tag{314}$$

where the second line is written as an expansion in $(H/M)^2$, with H being the Hubble scale during inflation. Truncating the expansion of EFT operators at the lowest order, we obtain the Lagrangian [80]

$$\mathcal{L}_{\rm eff} = \mathcal{L}_0(\phi) + \frac{(\partial_\mu \phi)^4}{8\Lambda^4}\,, \tag{315}$$

where $\mathcal{L}_0$ is the canonical slow-roll Lagrangian and $\Lambda^2 \equiv \tilde{\Lambda} M$. Following [80], we will compute the bispectrum induced by the interaction in (315).

This time it is useful to work in spatially flat gauge. At leading order in the slow-roll parameters, the action for the inflaton perturbation $\varphi \equiv \phi - \bar{\phi}(t)$ can then be calculated from (315) without including the contributions from $\sqrt{-g}R$. The intuitive reason for this simplification is that in the limit of a flat potential the perturbation φ does not induce a perturbation in the spacetime curvature. Evaluating one of the legs of the interaction $(\partial_\mu\phi)^4$ on the background solution, we get



$$\Leftrightarrow \qquad \mathcal{L}_{\rm eff,3} = -\frac{\phi'}{4\Lambda^4}\,\varphi'(\partial_\mu\varphi)^2\,. \tag{316}$$

Using this interaction, we can compute the bispectrum $\langle\varphi\varphi\varphi\rangle$. We will relate the result to $\langle\zeta\zeta\zeta\rangle$ at horizon crossing to avoid the error that would be induced by the superhorizon evolution of φ. To perform this matching, we, in principle, need to know the relation between φ and ζ up to second order. However, the quadratic term is slow-roll suppressed, so it suffices to use the linear relationship

$$\zeta = -\frac{H}{\phi'}\,\varphi\,. \tag{317}$$

Feeding $\mathcal{H}_{\rm int} = -\mathcal{L}_{\rm eff,3}$ into the *in-in* master formula (282), we find

$$\rangle' = \left(-\frac{H}{\bar{\phi}'}\right)^3 \langle\varphi_{\mathbf{k}_1}\varphi_{\mathbf{k}_2}\varphi_{\mathbf{k}_3}\rangle' \frac{\mathcal{B}_\zeta(k_1,k_2,k_3)}{\mathcal{P}_\zeta^2} \tag{318}$$

$$\begin{aligned} &= -\frac{4i}{k_1k_2k_3}\frac{(\phi')^2}{\Lambda^4}\int_{-\infty}^{0} \mathrm{d}\tau\left(-k_1^2k_2^2k_3^3\,\tau^2 - (\mathbf{k}_1\cdot\mathbf{k}_2)k_3^2(1-ik_1\tau)(1-ik_2\tau)\right)e^{ik_t\tau} \\ &\quad + \text{perms.} + c.c.\,, \qquad \begin{array}{cc} \uparrow & \uparrow \\ (\varphi')^3 & (\varphi')(\partial_i\varphi)^2 \end{array} \end{aligned} \tag{319}$$

where $k_t \equiv k_1 + k_2 + k_3$. Evaluating the integral, we get [80]

$$\frac{\mathcal{B}_\zeta(k_1,k_2,k_3)}{\mathcal{P}_\zeta^2} = \frac{8}{k_1k_2k_3}\frac{(\phi')^2}{\Lambda^4}\frac{1}{k_t^2}\left(\sum_i k_i^5 + \sum_{i\neq j}(2k_i^4k_j - 3k_i^3k_j^2) + \sum_{i\neq j\neq l}(k_i^3k_jk_l - 4k_i^2k_j^2k_l)\right). \tag{320}$$

The following features of this result are worth noting:

- The signal peaks in the equilateral configuration (cf. Fig. 45).
- The squeezed limit, $\lim_{k_{\rm L}\to 0}\langle\zeta_{\mathbf{k}_{\rm S}}\zeta_{\mathbf{k}_{\rm S}}\zeta_{\mathbf{k}_{\rm L}}\rangle$, is an analytic function of $k_{\rm L}/k_{\rm S}$. This is a consequence of the interaction being local.
- The amplitude is bounded,

$$f_{\rm NL} = \frac{35}{108}\frac{(\phi')^2}{\Lambda^4} < 1\,, \tag{321}$$

  where the final inequality follows from $\phi' < \Lambda^2$, as required by consistency of the truncation used in (315).

Nonlocal effects

For $M \lesssim$ few $\times H$, there are effects of massive particles that cannot be captured by local inflaton interactions, i.e. the field cannot be integrated out completely. The non-locality of the effective inflaton interactions will be reflected in a characteristic non-analyticity in its correlation functions.

As a concrete example, we consider a massive scalar field σ. Its two-point function in de Sitter space is

$$\langle \sigma_{\mathbf{k}}(\tau)\sigma_{\mathbf{k}'}(\tau')\rangle' = \frac{\pi}{4}H^2(\tau\tau')^{3/2}e^{-\pi\mu}H_{i\mu}(-k\tau)H^*_{i\mu}(-k\tau')\,, \tag{322}$$

where $H_{i\mu} \equiv H^{(1)}_{i\mu}$ is the Hankel function of the first kind and $\mu \equiv \sqrt{m^2/H^2 - 9/4}$. For now, let us focus on particles belonging to the principal series, so that μ is real. The local part of the two-point function has support only at coincident points in position space, while the non-local part describes correlations over long distances. In Fourier space, the local and non-local parts of the two-point function are analytic and non-analytic in the momentum k, respectively. In the late-time limit, we can split (322) into its local and non-local parts

$$\lim_{\tau,\tau'\to 0}\langle \sigma_{\mathbf{k}}(\eta)\sigma_{\mathbf{k}'}(\tau')\rangle'_{\text{local}} = \frac{H^2(\tau\tau')^{3/2}}{4\pi}\Gamma(-i\mu)\Gamma(i\mu)\left[e^{\pi\mu}\left(\frac{\tau}{\tau'}\right)^{i\mu} + e^{-\pi\mu}\left(\frac{\tau}{\tau'}\right)^{-i\mu}\right], \tag{323}$$

$$\lim_{\tau,\tau'\to 0}\langle \sigma_{\mathbf{k}}(\tau)\sigma_{\mathbf{k}'}(\tau')\rangle'_{\text{non-local}} = \frac{H^2(\tau\tau')^{3/2}}{4\pi}\left[\Gamma(-i\mu)^2\left(\frac{k^2\tau\tau'}{4}\right)^{i\mu} + \Gamma(i\mu)^2\left(\frac{k^2\tau\tau'}{4}\right)^{-i\mu}\right]. \tag{324}$$

Note that $\Gamma(\pm i\mu) \to e^{-\pi\mu/2}$ for large μ, resulting in an overall suppression of $e^{-\pi\mu}$ of the non-local contribution (324). In the next section, we will see how the non-analyticity of the non-local part of the two-point function of σ is reflected in the inflationary correlators.

Cosmological Collider Physics

The correlations in the massive field σ become observable when they get converted to inflaton fluctuations through interactions such as the mixing term in (313):

$$\mathcal{L} \supset \frac{\sigma(\partial_\mu\phi)^2}{\Lambda}\,. \tag{325}$$

Evaluating one of the legs of the inflaton field on the background solution, $\bar{\phi}$, leads to a bispectrum for the inflaton fluctuations φ (and hence of the curvature perturbations ζ); cf. Fig. 50. The derivation of the bispectrum of curvature perturbations can be found in [58, 59]. Here, we summarize the main features of the result:

- The non-local effect associated with the massive particle exchange shows up as a non-analyticity in the squeezed limit, $\lim_{k_{\rm L}\to 0}\langle\zeta_{\mathbf{k}_{\rm S}}\zeta_{-\mathbf{k}_{\rm S}}\zeta_{\mathbf{k}_{\rm L}}\rangle$. Between the horizon crossing times of the long mode $\zeta_{\rm L}$ and the short modes $\zeta_{\rm S}$ the amplitude of the massive field oscillates with a frequency set by the mass of the field. This leads to distinct oscillations in the bispectrum of curvature perturbations:

$$\lim_{k_{\rm L}\to 0}\langle\zeta_{\mathbf{k}_{\rm S}}\zeta_{-\mathbf{k}_{\rm S}}\zeta_{\mathbf{k}_{\rm L}}\rangle \propto \left(\frac{k_{\rm L}}{k_{\rm S}}\right)^{3/2}\cos\left[\frac{M}{H}\ln\left(\frac{k_{\rm L}}{k_{\rm S}}\right) + \delta\right], \tag{326}$$

  where δ is a computable phase [58]. We see that the mass M of the field is encoded in the frequency of the oscillations (see Fig. 51).

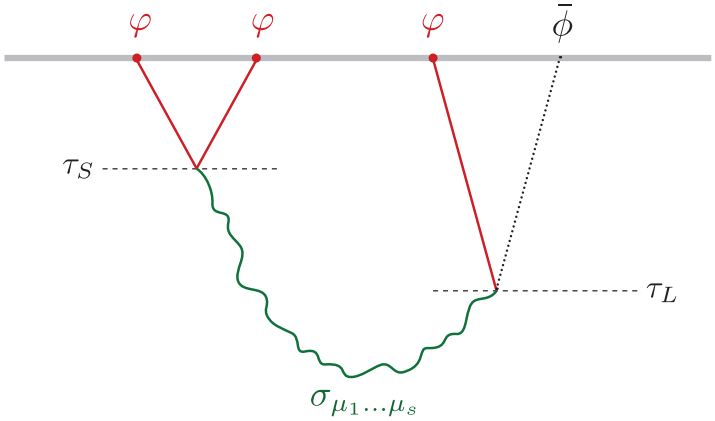


Figure 50: The spontaneous creation and decay of a massive particle σ produces a four-point function for the inflaton field ϕ. Evaluating one of the legs on the background solution, $\bar{\phi}$, leads to a three-point function for the inflaton fluctuations φ.

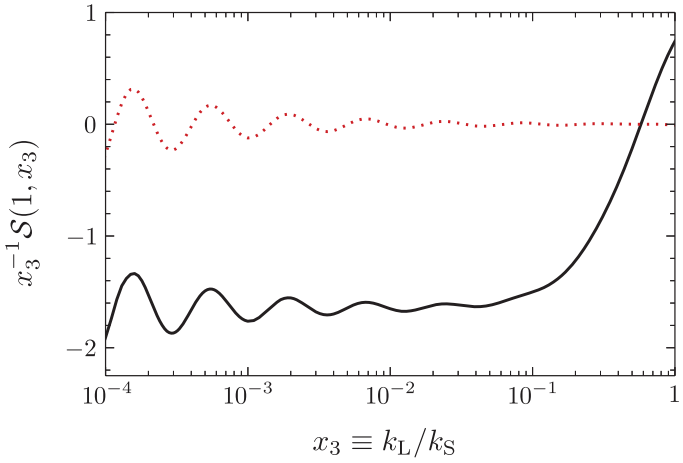

Figure 51: Shape function for the bispectrum arising from the exchange of a spin-2 particle with $\mu = 5$, evaluated in the isosceles-triangle configuration, $x_2 \equiv k_2/k_1 = 1$ (figure adapted from [59]). The dotted line is the non-local part of the signal.

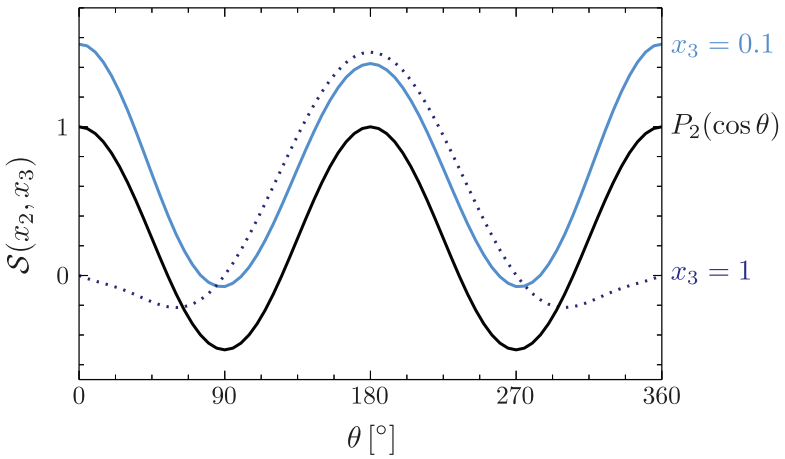

Figure 52: Shape function for the bispectrum arising from the exchange of a spin-2 particle with $\mu = 5$, as a function of the base angle $\theta = \cos^{-1}(\hat{\mathbf{k}}_1 \cdot \hat{\mathbf{k}}_3)$ for fixed ratios of $x_3 \equiv k_3/k_1$ (figure adapted from [59]).

- Particles with spin s lead to a unique angular dependence (see Fig. 52):

$$\lim_{k_{\rm L}\to 0} \langle \zeta_{\mathbf{k}_{\rm S}} \zeta_{-\mathbf{k}_{\rm S}} \zeta_{\mathbf{k}_{\rm L}} \rangle \;\propto\; P_s(\cos\theta)\,, \tag{327}$$

where $\cos\theta \equiv \mathbf{k}_{\rm S}\cdot\mathbf{k}_{\rm L}$ and P_s is a Legendre polynomial of degree s.

There are several effects that determine the amplitude of the signal:

- If we make the conservative assumption that the interaction in (325) is only of gravitational strength [58], then the scale determining the mixing between σ and ϕ is $\Lambda = M_{\rm pl}$. In that case, the amplitude of the bispectrum is at most of order the gravitational floor, $f_{\rm NL} \lesssim \mathcal{O}(\varepsilon)$. However, in principle, the mixing can be much larger. In particular, the mixing interaction in (325) remains perturbative as long as $\Lambda \geq (\phi')^{1/2}$, allowing for non-Gaussianity of order $f_{\rm NL} \lesssim \mathcal{O}(1)$ [53, 54, 77, 59]. Finally, in the EFT for the inflationary fluctuations [78] the cutoff Λ can even be below $(\phi')^{1/2}$ and the non-Gaussianity can be much larger, $f_{\rm NL} \lesssim \mathcal{O}(\mathcal{P}_\zeta^{-1/2})$.

- In addition, the spontaneous production of massive particles in the principal series is exponentially suppressed. This Boltzmann suppression is inherited by the amplitude of the bispectrum, $f_{\rm NL} \propto e^{-\pi M/H}$. The creation of particles in the complementary series, on the other hand, does not receive the same suppression and the signal can be large [53, 54]. Instead of oscillations, the squeezed limit in that case has a monotonic scaling $(k_{\rm L}/k_{\rm S})^{\Delta}$, where the scaling dimension Δ carries the information about the mass of the particle.

- For particles in the principal series, the squeezed limit is suppressed by a factor of $(k_{\rm L}/k_{\rm S})^{3/2}$. This is to be compared to the squeezed limit for equilateral non-Gaussianity which scales as $(k_{\rm L}/k_{\rm S})^2$. The signal from particles in the complementary series can be larger in the squeezed limit, $(k_{\rm L}/k_{\rm S})^{\Delta}$, where $0 < \Delta < 3/2$. Finally, partially massless particles do not decay on superhorizon scales and may therefore induce signals that are not suppressed in the squeezed limit [63].

Figure 53 is a schematic illustration of current and future constraints on (scale-invariant) primordial non-Gaussianities. We see that the perturbatively interesting regime spans about seven orders of magnitude in $f_{\rm NL}$. Of this regime, three orders of magnitude have been ruled out by current CMB observations, leaving a window of opportunity of about four orders of magnitude to be explored. Accessing these low levels of non-Gaussianity will be challenging. Even optimistic projections for future CMB observations won't reduce the constraints by more than an order of magnitude. Digging deeper will require new cosmological probes, such as observations of the large-scale structure of the universe [79] and the tomography of the 21cm transition of neutral hydrogen gas [80].

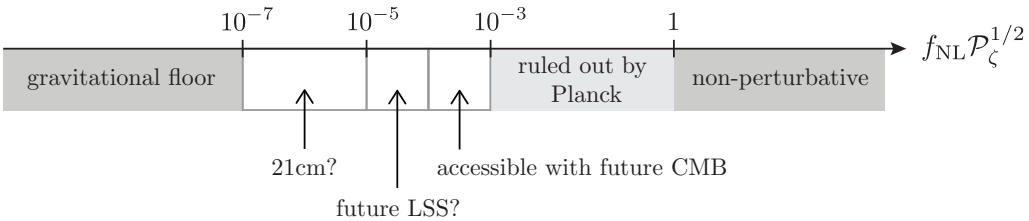

Figure 53: Schematic illustration of current and future constraints on (scale-invariant) primordial non-Gaussianity. The "gravitational floor" denotes the minimal level of non-Gaussianity created by purely gravitational interactions during inflation [40] (see §6.6.3).

7 TASI Lectures on Inflation Daniel Baumann

In a series of five lectures I review inflationary cosmology. I begin with a description of the initial conditions problems of the Friedmann-Robertson-Walker (FRW) cosmology and then

explain how inflation, an early period of accelerated expansion, solves these problems. Next, I describe how inflation transforms microscopic quantum fluctuations into macroscopic seeds for cosmological structure formation. I present in full detail the famous calculation for the primordial spectra of scalar and tensor fluctuations. I then define the inverse problem of extracting information on the inflationary era from observations of cosmic microwave background fluctuations. The current observational evidence for inflation and opportunities for future tests of inflation are discussed. Finally, I review the challenge of relating inflation to fundamental physics by giving an account of inflation in string theory.

7.1 Classical Dynamics of Inflation

The aim of this lecture is a first-principles introduction to the classical dynamics of inflationary cosmology. After a brief review of basic FRW cosmology we show that the conventional Big Bang theory leads to an initial conditions problem: the universe as we know it can only arise for very special and finely-tuned initial conditions. We then explain how inflation (an early period of accelerated expansion) solves this initial conditions problem and allows our universe to arise from generic initial conditions. We describe the necessary conditions for inflation and explain how inflation modifies the causal structure of spacetime to solve the Big Bang puzzles. Finally, we end this lecture with a discussion of the physical origin of the inflationary expansion.

Lecture 2: Quantum Fluctuations during Inflation

In this lecture we review the famous calculation of the primordial fluctuation spectra generated by quantum fluctuations during inflation. We present the calculation in full detail and try to avoid 'cheating' and approximations. After a brief review of fundamental aspects of cosmological perturbation theory, we first give a qualitative summary of the basic mechanism by which inflation converts microscopic quantum fluctuations into macroscopic seeds for cosmological structure formation. As a pedagogical introduction to quantum field theory in curved spacetime we then review the quantization of the simple harmonic oscillator. We emphasize that a unique vacuum state is chosen by demanding that the vacuum is the minimum energy state. We then proceed by giving the corresponding calculation for inflation. We calculate the power spectra of both scalar and tensor fluctuations.

Lecture 3: Contact with Observations

In this lecture we describe the inverse problem of extracting information on the inflationary perturbation spectra from observations of the cosmic microwave background and the large-scale structure. We define the precise relations between the gauge-invariant scalar and tensor power spectra computed in the previous lecture and the observed CMB anisotropies and galaxy power spectra. We give the transfer functions that relate the primordial fluctuations to the late-time observables. We then use these results to discuss the current observational evidence for inflation. Finally, we indicate opportunities for future tests of inflation.

Lecture 4: Primordial Non-Gaussianity

In this lecture we summarize key theoretical results in the study of primordial non-Gaussianity. Most results are stated without proof, but their significance for constraining the fundamental physical origin of inflation is explained. After introducing the bispectrum as a basic diagnostic of non-Gaussian statistics, we show that its momentum dependence is a powerful probe of the inflationary action. Large non-Gaussianity can only arise if inflaton interactions are significant during inflation. In single-field slow-roll inflation non-Gaussianity is therefore predicted to be unobservably small, while it can be significant in models with multiple fields, higher-derivative

interactions or non-standard initial states. Finally, we end the lecture with a discussion of the observational prospects for detecting or constraining primordial non-Gaussianity.

Lecture 5: Inflation in String Theory
We end this lecture series with a discussion of a slightly more advanced topic: inflation in string theory. We provide a pedagogical overview of the subject based on a recent review article with Liam McAllister. The central theme of the lecture is the sensitivity of inflation to Planck-scale physics, which we argue provides both the primary motivation and the central theoretical challenge for realizing inflation in string theory. We illustrate these issues through two case studies of inflationary scenarios in string theory: warped D-brane inflation and axion monodromy inflation. Finally, we indicate opportunities for future progress both theoretically and observationally.

7.2 Introduction

"I'm astounded by people who want to 'know' the Universe
when it's hard enough to find your way around Chinatown"
Woody Allen

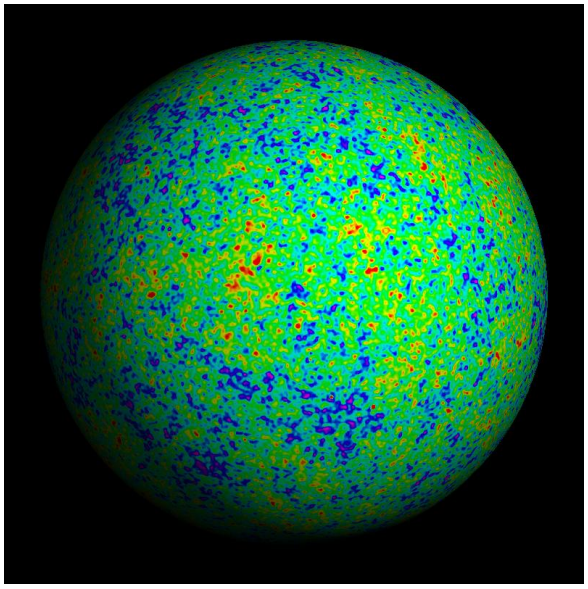

Figure 54: Fluctuations in the Cosmic Microwave Background (CMB). What produced them?

7.2.1 The Microscopic Origin of Structure

TASI 2009: *The Physics of the Large and the Small*

The fluctuations in the temperature of the cosmic microwave background (CMB) (see Fig. 54) tell an amazing story. Measured now almost routinely by experiments like the Wilkinson Microwave Anisotropy Probe (WMAP), the temperature variations of the microwave sky bear testimony of minute fluctuations in the density of the primordial universe. These fluctuations grew via gravitational instability into the large-scale structures (LSS) that we observe in the universe today. The success in relating observations of the thermal afterglow of the Big

Bang to the formation of structures billions of years later motivates us to ask an even bolder question: what is the fundamental microphysical origin of the CMB fluctuations? An answer to this question would provide us with nothing less than a fundamental understanding of the physical origin of all structure in the universe.

In these lectures, I will describe the currently leading working hypothesis that a period of cosmic *inflation* was integral part of this picture for the formation and evolution of structure. Inflation [119, 170, 15], a period of exponential expansion in the very early universe, is believed to have taken place some 10^{-34} seconds after the Big Bang singularity. Remarkably, inflation is thought to be responsible both for the large-scale homogeneity of the universe and for the small fluctuations that were the seeds for the formation of structures like our own galaxy.

The central focus of this lecture series will be to explain in full detail the physical mechanism by which inflation transformed microscopic quantum fluctuations into macroscopic fluctuations in the energy density of the universe. In this sense inflation provides the most dramatic example for the theme of *TASI 2009*: the connection between the 'physics of the large and the small'. We will calculate explicitly the statistical properties and the scale dependence of the spectrum of fluctuations produced by inflation. This result provides the input for all studies of cosmological structure formation and is one of the great triumphs of modern theoretical cosmology.

Structure and Evolution of the Universe

There is undeniable evidence for the expansion of the universe: the light from distant galaxies is systematically shifted towards the red end of the spectrum [4], the observed abundances of the light elements (H, He, and Li) matches the predictions of Big Bang Nucleosynthesis (BBN) [5], and the only convincing explanation for the CMB is a relic radiation from a hot early universe [6].

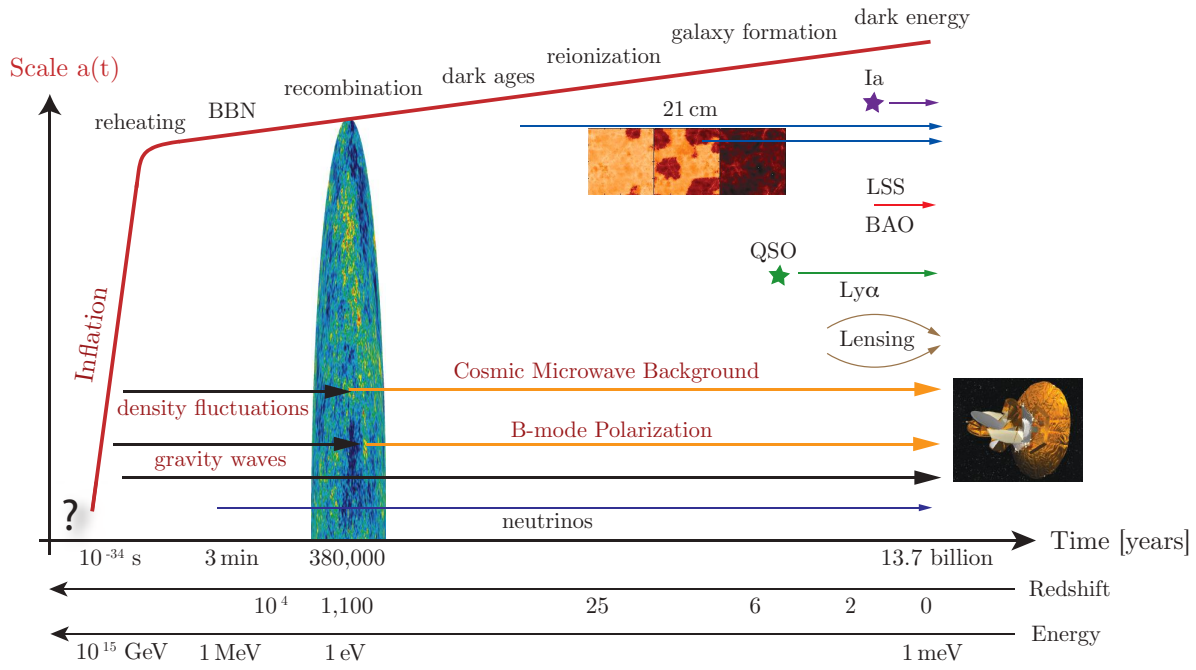

Figure 55: History of the universe. In this schematic we present key events in the history of the universe and their associated time and energy scales. We also illustrate several cosmological probes that provide us with information about the structure and evolution of the universe. *Acronyms*: BBN (Big Bang Nucleosynthesis), LSS (Large-Scale Structure), BAO (Baryon Acoustic Oscillations), QSO (Quasi-Stellar Objects = Quasars), Lyα (Lyman-alpha), CMB (Cosmic Microwave Background), Ia (Type Ia supernovae), 21cm (hydrogen 21cm-transition).

Two principles characterize thermodynamics and particle physics in an expanding universe: *i)* interactions between particles freeze out when the interaction rate drops below the expansion rate, and *ii)* broken symmetries in the laws of physics may be restored at high energies. Table 1 shows the thermal history of the universe and various phase transitions related to symmetry breaking events. In the following we will give a quick qualitative summary of these milestones in the evolution of our universe. We will emphasize which aspects of this cosmological story are based on established physics and which require more speculative ideas.

Table 1: Major Events in the History of the Universe.

	Time	Energy	
Planck Epoch?	$< 10^{-43}$ s	10^{18} GeV	
String Scale?	$\gtrsim 10^{-43}$ s	$\lesssim 10^{18}$ GeV	
Grand Unification?	$\sim 10^{-36}$ s	10^{15} GeV	
Inflation?	$\gtrsim 10^{-34}$ s	$\lesssim 10^{15}$ GeV	
SUSY Breaking?	$< 10^{-10}$ s	> 1 TeV	
Baryogenesis?	$< 10^{-10}$ s	> 1 TeV	
Electroweak Unification	10^{-10} s	1 TeV	
Quark-Hadron Transition	10^{-4} s	10^2 MeV	
Nucleon Freeze-Out	0.01 s	10 MeV	
Neutrino Decoupling	1 s	1 MeV	
BBN	3 min	0.1 MeV	
			Redshift
Matter-Radiation Equality	10^4 yrs	1 eV	10^4
Recombination	10^5 yrs	0.1 eV	1,100
Dark Ages	$10^5 - 10^8$ yrs		> 25
Reionization	10^8 yrs		$25 - 6$
Galaxy Formation	$\sim 6 \times 10^8$ yrs		~ 10
Dark Energy	$\sim 10^9$ yrs		~ 2
Solar System	8×10^9 yrs		0.5
Albert Einstein born	14×10^9 yrs	1 meV	0

From 10^{-10} seconds to today the history of the universe is based on well understood and experimentally tested laws of particle physics, nuclear and atomic physics and gravity. We are therefore justified to have some confidence about the events shaping the universe during that time.

Let us enter the universe at 100 GeV, the time of the electroweak phase transition (10^{-10} s). Above 100 GeV the electroweak symmetry is restored and the Z and $W^{\pm}$ bosons are massless. Interactions are strong enough to keep quarks and leptons in thermal equilibrium. Below 100 GeV the symmetry between the electromagnetic and the weak forces is broken, Z and $W^{\pm}$ bosons acquire mass and the cross-section of weak interactions decreases as the temperature of the universe drops. As a result, at 1 MeV, neutrinos decouple from the rest of the matter. Shortly after, at 1 second, the temperature drops below the electron rest mass and electrons and positrons annihilate efficiently. Only an initial matter-antimatter asymmetry of one part in a billion survives. The resulting photon-baryon fluid is in equilibrium. Around 0.1 MeV the strong interaction becomes important and protons and neutrons combine into the light elements (H, He, Li) during Big Bang nucleosynthesis (~ 200 s). The successful prediction of the H, He and Li abundances is one of the most striking consequences of the Big Bang theory.

The matter and radiation densities are equal around 1 eV (10^{11} s). Charged matter particles and photons are strongly coupled in the plasma and fluctuations in the density propagate as cosmic 'sound waves'. Around 0.1 eV (380,000 yrs) protons and electrons combine into neutral hydrogen atoms. Photons decouple and form the free-streaming cosmic microwave background. 13.7 billion years later these photons give us the earliest snapshot of the universe. Anisotropies in the CMB temperature provide evidence for fluctuations in the primordial matter density.

These small density perturbations, $\rho(\mathbf{x}, t) = \bar{\rho}(t)[1 + \delta(\mathbf{x}, t)]$, grow via gravitational instability to form the large-scale structures observed in the late universe. A competition between the background pressure and the universal attraction of gravity determines the details of the growth of structure. During radiation domination the growth is slow, $\delta \sim \ln a$ (where $a(t)$ is the scale factor describing the expansion of space). Clustering becomes more efficient after matter dominates the background density (and the pressure drops to zero), $\delta \sim a$. Small scales become non-linear first, $\delta \gtrsim 1$, and form gravitationally bound objects that decouple from the overall expansion. This leads to a picture of hierarchical structure formation with small-scale structures (like stars and galaxies) forming first and then merging into larger structures (clusters and superclusters of galaxies). Around redshift $z \sim 25$ ($1 + z = a^{-1}$), high energy photons from the first stars begin to ionize the hydrogen in the inter-galactic medium. This process of 'reionization' is completed at $z \approx 6$. Meanwhile, the most massive stars run out of nuclear fuel and explode as 'supernovae'. In these explosions the heavy elements (C, O, ...) necessary for the formation of life are created, leading to the slogan "we are all stardust". At $z \approx 1$, a negative pressure 'dark energy' comes to dominate the universe. The background spacetime is accelerating and the growth of structure ceases, $\delta \sim$ const.

The First 10^{-10} Seconds

The history of the universe from 10^{-10} seconds (1 TeV) to today is based on observational facts and tested physical theories like the Standard Model of particle physics, general relativity and fluid dynamics, *e.g.* the fundamental laws of high energy physics are well-established up to the energies reached by current particle accelerators ($\sim$ 1 TeV). Before 10^{-10} seconds, the energy of the universe exceeds 1 TeV and we lose the comfort of direct experimental guidance. The physics of that era is therefore as speculative as it is fascinating.

To explain the fluctuations seen in the CMB temperature requires an input of primordial seed fluctuations. In these lectures we will explain the conjecture that these primordial fluctuations were generated in the very early universe ($\sim 10^{-34}$ seconds) during a period of inflation. We will explain how microscopic quantum fluctuations in the energy density get stretched by the inflationary expansion to macroscopic scales, larger than the physical horizon at that time. After a perturbation exits the horizon no causal physics can affect it and it remains frozen with constant amplitude until it re-enters the horizon at a later time during the conventional (non-accelerating) Big Bang expansion. The fluctuations associated with cosmological structures re-enter the horizon when the universe is about 100,000 years olds, a short time before the decoupling of the CMB photons. Inside the horizon causal physics can affect the perturbation amplitudes and in fact leads to the acoustic peak structure of the CMB and the collapse of high-density fluctuations into galaxies and clusters of galaxies. Since we understand (and can calculate) the evolution of perturbations after they re-enter the horizon we can use the late time observations of the CMB and the LSS to infer the primordial input spectrum. Assuming this spectrum was produced by inflation, this gives us an observational probe of the physical conditions when the universe was 10^{-34} seconds old. This fascinating opportunity to use cosmology to probe physics at the highest energies will be the subject of these lectures.

7.2.2 Outline of the Lectures

In Lecture 1 we introduce the *classical* background dynamics of inflation. We explain how inflation solves the horizon and flatness problems. We discuss the slow-roll conditions and reheating and speculate on the physical origin of the inflationary expansion. In Lecture 2 we describe how *quantum* fluctuations during inflation become the seeds for the formation of large-scale structures. We present in full detail the derivation of the inflationary power spectra of scalar and tensor perturbations, $\mathcal{R}$ and h_{ij}. In Lecture 3 we relate the results of Lecture 2 to observations of the cosmic microwave background and the distribution of galaxies, *i.e.* we explain how to measure $P_{\mathcal{R}}(k)$ and $P_h(k)$ in the sky! We describe current observational constraints and emphasize future tests of inflation. In Lecture 4 we present key results in the study of non-Gaussianity of the primordial fluctuations. We explain how non-Gaussian correlations can provide important information on the inflationary action. We reserve Lecture 5 for the study of an advanced topic that is at the frontier of current research: inflation in string theory. We describe the main challenges of the subject and summarize recent advances.

To make each lecture self-contained, the necessary background material is presented in a short *review* section preceeding the core of each lecture. Every lecture ends with a *summary* of the most important results. An important part of every lecture are problems and exercises that appear throughout the text and (for longer problems) as a separate *problem set* appended to the end of the lecture. The exercises were carefully chosen to complement the material of the lecture or to fill in certain details of the computations.

A number of appendices collect standard results from cosmological perturbation theory and details of the inflationary perturbation calculation. It is hoped that the appendices provide a useful reference for the reader.

Notation

We have tried hard to keep the notation of these lectures coherent and consistent:
Throughout we will use the God-given natural units

$$c = \hbar \equiv 1\,.$$

We use the reduced Planck mass

$$M_{\rm pl} = (8\pi G)^{-1/2}\,,$$

and often set it equal to one. Our metric signature is $(-+++)$. Greek indices will take the values $\mu, \nu = 0, 1, 2, 3$ and latin indices stand for $i, j = 1, 2, 3$. Our Fourier convention is

$$\mathcal{R}_{\mathbf{k}} = \int \mathrm{d}^3\mathbf{x}\, \mathcal{R}(\mathbf{x}) e^{-i\mathbf{k}\cdot\mathbf{x}}\,,$$

so that the power spectrum is

$$\langle \mathcal{R}_{\mathbf{k}} \mathcal{R}_{\mathbf{k}'} \rangle = (2\pi)^3 \delta(\mathbf{k}+\mathbf{k}') P_{\mathcal{R}}(k)\,, \qquad \Delta^2_{\mathcal{R}}(k) \equiv \frac{k^3}{2\pi^2} P_{\mathcal{R}}(k)\,.$$

For conformal time we use the letter τ (and caution the reader not confuse it with the astrophysical parameter for optical depth). We reserve the letter η for the second slow-roll parameter. Derivatives with respect to physical time are denoted by overdots, while derivatives with respect to conformal time are indicated by primes. Partial derivatives are denoted by commas, covariant derivatives by semi-colons.

Acknowledgements

I am most grateful to Scott Dodelson and Csaba Csaki for the invitation to give these lectures at the Theoretical Advanced Study Institute in Elementary Particle Physics (*TASI*).

In past few years I have learned many things from my teachers Liam McAllister, Paul Steinhardt, and Matias Zaldarriaga and my collaborators Igor Klebanov, Anatoly Dymarsky, Shamit Kachru, Hiranya Peiris, Alberto Nicolis and Asantha Cooray. Thanks to all of them for generously sharing their insights with me. The input from the members of the *CMBPol* Inflation Working Group [7] was very much appreciated. Their expert opinions on many of the topics described in these lectures were most valuable to me. I learned many things in discussions with Richard, Easther, Eva Silverstein, Eiichiro Komatsu, Mark Jackson, Licia Verde, David Wands, Paolo Creminelli, Leonardo Senatore, Andrei Linde, and Sarah Shandera.

The Aspen Center for Physics, Trident Cafe, Boston and Dado Tea, Cambridge are acknowledged for their hospitality while these lecture notes were written.

Finally, I wish to thank the students at *TASI 2009* for challenging me with their questions and for comments on a draft of these notes.

7.3 Classical Dynamics of Inflation by Baumann 1th lecture

Abstract

The aim of this lecture is a first-principles introduction to the classical dynamics of inflationary cosmology. After a brief review of basic FRW cosmology we show that the conventional Big Bang theory leads to an initial conditions problem: the universe as we know it can only arise for very special and finely-tuned initial conditions. We then explain how inflation (an early period of accelerated expansion) solves this initial conditions problem and allows our universe to arise from generic initial conditions. We describe the necessary conditions for inflation and explain how inflation modifies the causal structure of spacetime to solve the Big Bang puzzles. Finally, we end this lecture with a discussion of the physical origin of the inflationary expansion.

7.3.1 *Review*: The Homogeneous Universe

To set the stage, we review basic aspects of the homogeneous universe. Since this material was covered in Prof. Turner's lectures at *TASI 2009* and is part of any textbook treatment of cosmology (*e.g.* [8, 9, 10]), we will be brief and recall many of the concepts via exercises for the reader. We will naturally focus on the elements most relevant for the study of inflation.

FRW Spacetime

Cosmology describes the structure and evolution of the universe on the largest scales. Assuming *homogeneity* and *isotropy* [19] on large scales one is lead to the Friedmann-Robertson-Walker (FRW) metric for the spacetime of the universe (see **Problem 1**):

$$\boxed{\mathrm{d}s^2 = -\mathrm{d}t^2 + a^2(t)\left(\frac{\mathrm{d}r^2}{1-kr^2} + r^2(\mathrm{d}\theta^2 + \sin^2\theta\mathrm{d}\phi^2)\right)}. \tag{328}$$

[19] A *homogeneous* space is one which is translation invariant, or the same at every point. An *isotropic* space is one which is rotationally invariant, or the same in every direction. A space which is everywhere isotropic is necessarily homogeneous, but the converse is not true; *e.g.* a space with a uniform electric field is translationally invariant but not rotationally invariant.

Here, the scale factor $a(t)$ characterizes the relative size of spacelike hypersurfaces Σ at different times. The curvature parameter k is $+1$ for positively curved Σ, 0 for flat Σ, and -1 for negatively curved Σ. Eqn. (328) uses comoving coordinates – the universe expands as $a(t)$ increases, but galaxies/observers keep fixed coordinates r, θ, ϕ as long as there aren't any forces acting on them, *i.e.* in the absence of peculiar motion. The corresponding physical distance is obtained by multiplying with the scale factor, $R = a(t)r$, and is time-dependent even for objects with vanishing peculiar velocities. By a coordinate transformation the metric (328) may be written as

$$\boxed{\mathrm{d}s^2 = -\mathrm{d}t^2 + a^2(t)\left(\mathrm{d}\chi^2 + \Phi_k(\chi^2)(\mathrm{d}\theta^2 + \sin^2\theta\mathrm{d}\phi^2)\right)}, \tag{329}$$

where

$$r^2 = \Phi_k(\chi^2) \equiv \begin{cases} \sinh^2\chi & k=-1 \\ \chi^2 & k=0 \\ \sin^2\chi & k=+1 \end{cases}. \tag{330}$$

For the FRW ansatz the evolution of the homogeneous universe boils down to the single function $a(t)$. Its form is dictated by the matter content of the universe via the Einstein field equations (see §7.3.1). An important quantity characterizing the FRW spacetime is the expansion rate

$$\boxed{H \equiv \frac{\dot{a}}{a}}. \tag{331}$$

The *Hubble parameter* H has unit of inverse time and is positive for an expanding universe (and negative for a collapsing universe). It sets the fundamental scale of the FRW spacetime, *i.e.* the characteristic time-scale of the homogeneous universe is the Hubble time, $t \sim H^{-1}$, and the characteristic length-scale is the Hubble length, $d \sim H^{-1}$ (in units where $c = 1$). The Hubble scale sets the scale for the age of the universe, while the Hubble length sets the size of the observable universe.

Kinematics: Conformal Time and Horizons

Having defined the metric for the average spacetime of the universe we can now study kinematical properties of the propagation of light and matter particles.

Conformal Time and Null Geodesics

The causal structure of the universe is determined by the propagation of light in the FRW spacetime (328). Massless photons follows null geodesics, $\mathrm{d}s^2 = 0$. These photon trajectories are studied most easily if we define conformal time[20]

$$\boxed{\tau = \int \frac{\mathrm{d}t}{a(t)}}, \tag{332}$$

for which the FRW metric becomes

$$\mathrm{d}s^2 = a(\tau)^2\left[-\mathrm{d}\tau^2 + \left(\mathrm{d}\chi^2 + \Phi_k(\chi^2)(\mathrm{d}\theta^2 + \sin^2\theta\mathrm{d}\phi^2)\right)\right]. \tag{333}$$

In an isotropic universe we may consider radial propagation of light as determined by the two-dimensional line element

$$\mathrm{d}s^2 = a(\tau)^2\left[-\mathrm{d}\tau^2 + \mathrm{d}\chi^2\right]. \tag{334}$$

[20] Conformal time may be interpreted as a "clock" which slows down with the expansion of the universe.

The metric has factorized into a static Minkowski metric multiplied by a time-dependent conformal factor $a(\tau)$. Expressed in conformal time the radial null geodesics of light in the FRW spacetime therefore satisfy

$$\chi(\tau) = \pm\tau + \text{const.}\,, \tag{335}$$

i.e. they correspond to straight lines at angles $\pm 45°$ in the τ–χ plane (see Fig. 56). If instead we had used physical time t to study light propagation, then the light cones for curved spacetimes would be curved.

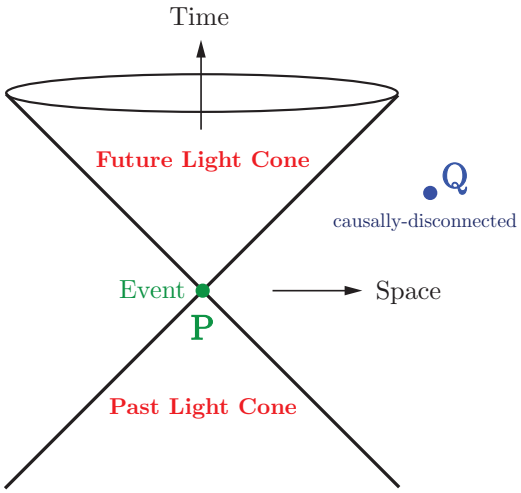

Figure 56: Light cones and causality. Photons travel along world lines of zero proper time, $\mathrm{d}s^2 = 0$, called *null geodesics*. Massive particles travel along world lines with real proper time, $\mathrm{d}s^2 > 0$, called *timelike geodescis*. Causally disconnected regions of spacetime are separated by *spacelike* intervals, $\mathrm{d}s^2 < 0$. The set of all null geodesics passing through a given point (or *event*) in spacetime is called the *light cone*. The interior of the light cone, consisting of all null and timelike geodesics, defined the region of spacetime causally related to that event.

Particle Horizon

The maximum comoving distance light can propagate between an initial time t_i and some later time t is

$$\chi_p(\tau) = \tau - \tau_\mathrm{i} = \int_{t_\mathrm{i}}^{t} \frac{\mathrm{d}t}{a(t)}\,. \tag{336}$$

This is called the (comoving) particle horizon. The initial time t_i is often taken to be the 'origin of the universe', $t_\mathrm{i} \equiv 0$, defined by the initial singularity, $a(t_\mathrm{i} \equiv 0) \equiv 0$.[21] The physical size of the particle horizon is

$$d_p(t) = a(t)\chi_p\,. \tag{337}$$

The particle horizon is of crucial importance to understanding the causal structure of the universe and it will be fundamental to our discussion of inflation. As we will see, the conventional Big Bang model 'begins' at a finite time in the past and at any time in the past the particle horizon was finite, limiting the distance over which spacetime region could have been in causal contact. This feature is at the heart of the 'Big Bang puzzles'.

[21] Whether $t_\mathrm{i} = 0$ also corresponds to $\tau_\mathrm{i} = 0$ depends on the evolution of the scale factor $a(t)$; *e.g.* for inflation $t_\mathrm{i} = 0$ will *not* be $\tau_\mathrm{i} = 0$.

Event Horizon

An event horizon defines the set of points from which signals sent at a given moment of time τ will never be received by an observer in the future. In comoving coordinates these points satisfy

$$\chi \; > \; \chi_e = \int_{\tau}^{\tau_{\rm max}} {\rm d}\tau = \tau_{\rm max} - \tau \,, \tag{338}$$

where $\tau_{\rm max}$ denotes the 'final moment of time' (this might be infinite or finite). The physical size of the event horizon is

$$d_e(t) = a(t)\chi_e \,. \tag{339}$$

Angular Diameter and Luminosity Distances

Conformal time (or comoving distance) relates in a simple way to angular diameter and luminosity distances which are important for the discussion of CMB anisotropies and supernova distances, respectively. These details won't concern us here, but may be found in the standard books [8, 9, 10].

Dynamics: Einstein Equations

The dynamics of the universe as characterized by the evolution of the scale factor of the FRW spacetime $a(t)$ is determined by the Einstein Equations

$$\boxed{G_{\mu\nu} = 8\pi G\, T_{\mu\nu}} \,. \tag{340}$$

We will often work in units where $8\pi G \equiv 1$.

Einstein Gravity

For convenience we here recall the definition of the Einstein tensor

$$G_{\mu\nu} \equiv R_{\mu\nu} - \frac{1}{2} g_{\mu\nu} R \,, \tag{341}$$

in terms of the Ricci tensor $R_{\mu\nu}$ and the Ricci scalar R,

$$R_{\mu\nu} = \Gamma^{\alpha}_{\ \mu\nu,\alpha} - \Gamma^{\alpha}_{\ \mu\alpha,\nu} + \Gamma^{\alpha}_{\ \beta\alpha}\Gamma^{\beta}_{\ \mu\nu} - \Gamma^{\alpha}_{\ \beta\nu}\Gamma^{\beta}_{\ \mu\alpha} \,, \qquad R \equiv g^{\mu\nu} R_{\mu\nu} \,, \tag{342}$$

where

$$\Gamma^{\mu}_{\ \alpha\beta} \equiv \frac{g^{\mu\nu}}{2} \left[g_{\alpha\nu,\beta} + g_{\beta\nu,\alpha} - g_{\alpha\beta,\nu} \right] \,. \tag{343}$$

Commas denote partial derivatives, *e.g.* $(\dots)_{,\mu} = \frac{\partial(\dots)}{\partial x^{\mu}}$. We will continue to follow this notation in the rest of these lectures.

Energy, Momentum and Pressure

To define the energy-momentum tensor of the universe, $T_{\mu\nu}$, we introduce a set of observers whose worldlines are tangent to the timelike velocity 4-vector

$$u^{\mu} \equiv \frac{dx^{\mu}}{d\tau} \,, \tag{344}$$

where τ is the proper time of the observers, so that $g_{\mu\nu}u^{\mu}u^{\nu} = -1$. We define the tensor $\gamma_{\mu\nu} \equiv g_{\mu\nu} + u_{\mu}u_{\nu}$ as the metric of the 3-dimensional spatial sections orthogonal to u_{μ}. We

use $\gamma_{\mu\nu}$ to project quantities orthogonal to the 4-velocity into the observers' instantaneous rest space. The energy-momentum tensor of a general (imperfect) fluid can then be written as

$$T_{\mu\nu} = \rho u_\mu u_\nu + p\gamma_{\mu\nu} + 2q_{(\mu}u_{\nu)} + \Sigma_{\mu\nu}\,, \tag{345}$$

where $\rho = T_{\mu\nu}u^\mu u^\nu$ is the matter energy density, $p = \frac{1}{3}T_{\mu\nu}\gamma^{\mu\nu}$ is the isotropic pressure, $q_\mu = -\gamma_\mu{}^\alpha T_{\alpha\beta}u^\beta$ is the energy-flux vector, and $\Sigma_{\mu\nu} = \gamma_{\langle\mu}{}^\alpha\gamma_{\nu\rangle}{}^\beta T_{\alpha\beta}$ is the symmetric and trace-free anisotropic stress tensor.[22] For a perfect fluid there exists a unique 4-velocity so that $q_\mu = \Sigma_{\mu\nu} = 0$, *i.e.* for the case of a perfect fluid the stress-energy tensor is

$$T^\mu{}_\nu = g^{\mu\alpha}T_{\alpha\nu} = (\rho + p)\,u^\mu u_\nu - p\,\delta^\mu_\nu\,, \tag{346}$$

where ρ and p are the proper energy density and pressure in the fluid rest frame and u^μ is the 4-velocity of the fluid. In a frame that is comoving with the fluid we may choose $u^\mu = (1,0,0,0)$, *i.e.*

$$T^\mu{}_\nu = \begin{pmatrix} \rho & 0 & 0 & 0 \\ 0 & -p & 0 & 0 \\ 0 & 0 & -p & 0 \\ 0 & 0 & 0 & -p \end{pmatrix}. \tag{347}$$

The Einstein Equations then take the form of two coupled, non-linear ordinary differential equations, also called the the *Friedmann Equations* (see **Problem 3**)

$$\boxed{H^2 \equiv \left(\frac{\dot{a}}{a}\right)^2 = \frac{1}{3}\rho - \frac{k}{a^2}}\,, \tag{348}$$

and

$$\boxed{\dot{H} + H^2 = \frac{\ddot{a}}{a} = -\frac{1}{6}(\rho + 3p)}\,, \tag{349}$$

where overdots denote derivatives with respect to physical time t. Notice, that in an expanding universe (*i.e.* $\dot{a} > 0$) filled with ordinary matter (*i.e.* matter satisfying the strong energy condition: $\rho + 3p \geq 0$) Eqn. (349) implies $\ddot{a} < 0$. This indicates the existence of a singularity in the finite past: $a(t \equiv 0) = 0$. Of course, this conclusion relies on the assumption that General Relativity and the Friedmann Equations are applicable up to arbitrary high energies and that no exotic forms of matter become relevant at high energies. More likely the singularity signals the breakdown of General Relativity.

Eqns. (348) and (349) may be combined into the continuity equation

$$\boxed{\frac{d\rho}{dt} + 3H(\rho + p) = 0}\,. \tag{350}$$

This may also be written as

$$\frac{d\ln\rho}{d\ln a} = -3(1 + w)\,, \tag{351}$$

if we define the equation of state parameter

$$w \equiv \frac{p}{\rho}\,. \tag{352}$$

Eqn. (351) may be integrated to give

$$\rho \propto a^{-3(1+w)}\,. \tag{353}$$

[22] Here we use the notation $t_{\langle\mu\nu\rangle} = \gamma_{(\mu}{}^\alpha\gamma_{\nu)}{}^\beta t_{\alpha\beta} - \frac{1}{3}\gamma^{\alpha\beta}t_{\alpha\beta}\gamma_{\mu\nu}$ and $t_{(\mu\nu)} = \frac{1}{2}(t_{\mu\nu} + t_{\nu\mu})$.

Together with the Friedmann Equation (348) this leads to the time evolution of the scale factor

$$a(t) \propto \begin{cases} t^{2/3(1+w)} & w \neq -1\,, \\ e^{Ht} & w = -1\,, \end{cases} \tag{354}$$

i.e. $a(t) \propto t^{2/3}$, $a(t) \propto t^{1/2}$ and $a(t) \propto \exp(Ht)$, for the scale factor of a flat ($k = 0$) universe dominated by non-relativistic matter ($w = 0$), radiation or relativistic matter ($w = \frac{1}{3}$) and a cosmological constant ($w = -1$), respectively.

Table 2: FRW solutions for a flat universe dominated by radiation, matter or a cosmological constant.

	w	$\rho(a)$	$a(t)$	$a(\tau)$	$\tau_{\rm i}$
MD	0	a^{-3}	$t^{2/3}$	τ^2	0
RD	$\frac{1}{3}$	a^{-4}	$t^{1/2}$	τ	0
Λ	-1	a^0	e^{Ht}	$-\tau^{-1}$	$-\infty$

If more than one matter species (baryons, photons, neutrinos, dark matter, dark energy, etc.) contributes significantly to the energy density and the pressure, ρ and p refer to the sum of all components

$$\rho \equiv \sum_i \rho_i\,, \qquad p \equiv \sum_i p_i\,. \tag{355}$$

For each species 'i' we define the *present* ratio of the energy density relative to the *critical energy density* $\rho_{\rm crit} \equiv 3H_0^2$

$$\Omega_i \equiv \frac{\rho_0^i}{\rho_{\rm crit}}\,, \tag{356}$$

and the corresponding equations of state

$$w_i \equiv \frac{p_i}{\rho_i}\,. \tag{357}$$

Here and in the following the subscript '0' denotes evaluation of a quantity at the present time t_0. We normalize the scale factor such that $a_0 = a(t_0) \equiv 1$. This allows us to write the Friedmann Equation (348) as

$$\left(\frac{H}{H_0}\right)^2 = \sum_i \Omega_i a^{-3(1+w_i)} + \Omega_k a^{-2}, \tag{358}$$

with $\Omega_k \equiv -k/a_0^2H_0^2$ parameterizing curvature. Evaluating Eqn. (358) today implies the consistency relation

$$\sum_i \Omega_i + \Omega_k = 1\,. \tag{359}$$

The second Friedmann Equation (349) evaluated at $t = t_0$ becomes

$$\frac{1}{a_0 H_0^2}\frac{d^2 a_0}{dt^2} = -\frac{1}{2}\sum_i \Omega_i(1 + 3w_i). \tag{360}$$

This defines the condition for accelerated expansion today.

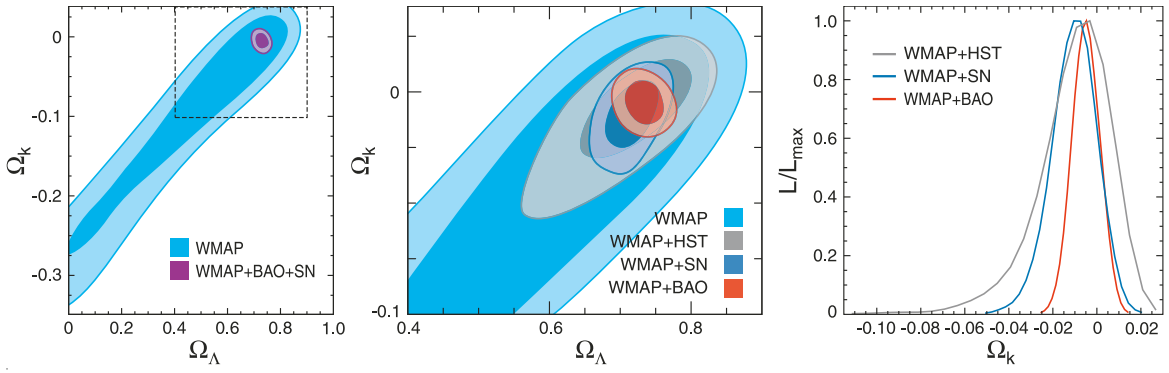

Figure 57: A combination CMB and LSS observations indicate that the spatial geometry of the universe is flat [11]. Note that the evidence for flatness cannot be obtained from CMB observations alone.

The Concordance Model

Observations of the cosmic microwave background and the large-scale structure find that the universe is flat (see Fig. 57)

$$\Omega_k \sim 0\,, \tag{361}$$

and composed of 4% atoms (or baryons, 'b'), 23% (cold) dark matter ('dm') and 73% dark energy (Λ) (see Fig. 58):

$$\Omega_b = 0.04\,, \quad \Omega_{dm} = 0.23\,, \quad \Omega_\Lambda = 0.72\,, \tag{362}$$

with $w_\Lambda \approx -1$ (see Fig. 59).

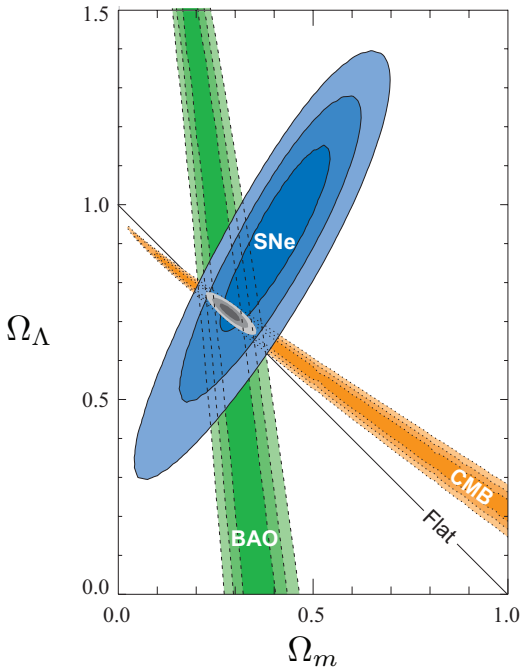

Figure 58: Evidence for dark energy. Shown are a combination of observations of the cosmic microwave background (CMB), supernovae (SNe) and baryon acoustic oscillations (BAO) [12].

It is also found that the universe has tiny ripples of adiabatic, scale-invariant, Gaussian density fluctuations. In the bulk of this lecture series I will describe how quantum fluctuations during inflation can explain the observed cosmological perturbations.

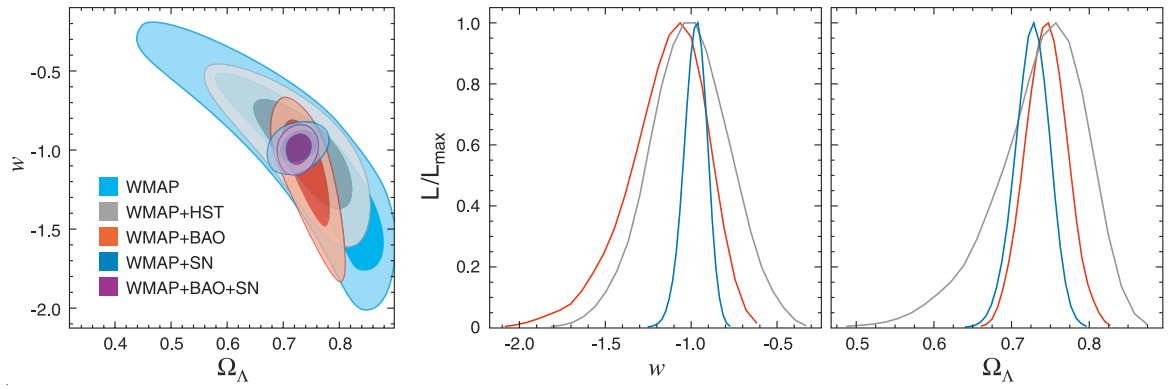

Figure 59: The properties of dark energy are close to a cosmological constant, $w_\Lambda \approx -1$ [11].

7.3.2 Big Bang Puzzles

It is somewhat of a philosophical questions whether initial conditions form part of a physical theory or should be considered separately. The purpose of physics is to predict the future evolution of a system given a set of initial conditions; *e.g.* Newton's laws of gravity will predict the path of a projectile if we define its initial position and velocity. It is therefore far from clear whether cosmology should predict or even just explain the initial conditions of the universe. On the other hand, it would be very disappointing if only very special and finely-tuned initial conditions would lead to the universe as we see it, making the observed universe an 'improbable accident'.

In this section we will explain that the conventional Big Bang theory requires precisely such a fine-tuned set of initial conditions to allow the universe to evolve to its current state. One of the major achievements of inflation is that it explains the initial conditions of the universe. Via inflation, the universe we know and love grew out of generic initial conditions.

The Cauchy Problem of the Universe

To specify the initial condition of the universe we consider a spatial slice of constant time Σ (we here won't worry about the gauge-dependence of the choice of Σ). On the 3-surface Σ we define the positions and velocities of all matter particles. The laws of gravity and fluid dynamics are then used to evolve the system forward in time.

- Initial Homogeneity

  We describe the spatial distribution of matter by its density and pressure as a function of coordinates $\mathbf{x}$, *i.e.* $\rho(\mathbf{x})$ and $p(\mathbf{x})$. In the previous section we assumed homogeneity and isotropy of the universe. Why is this a good assumption? Inhomogeneities are gravitationally unstable and therefore grow with time. Observations of the cosmic microwave background show that the inhomogeneities were much smaller in the past (at last-scattering) than today. One thus expects that these inhomogeneities were even smaller at yet earlier times. How do we explain the smoothness of the early universe?

  This is particularly surprising since we will show in §7.3.2 that in the conventional Big Bang picture the early universe (*e.g.* the CMB at last-scattering) consisted of a large number of causally-disconnected regions of space. In the Big Bang theory, there is no dynamical reason to explain why these causally-separated patches show such similar physical conditions. The homogeneity problem is therefore often called the *horizon problem*.

- Initial Velocities

In addition to specifying the initial density distribution, the complete characterization of the Cauchy problem of the universe requires the fluid velocities at every point in space. As we will see, to ensure that the universe remains homogeneous at late times requires the initial fluid velocities to take very precise values. If the initial velocities are just slightly too small, the universe recollapses within a fraction of a second. If they are just slightly too big, the universe expands too rapidly and quickly becomes nearly empty. The fine-tuning of initial velocities is made more dramatic by considering it in combination with the horizon problem. The fluid velocities need to be fine-tuned across causally-separated regions of space.

Since the difference between the potential energy and the kinetic energy defines the local curvature of a region of space (see **Exercise 1**), this fine-tuning of initial velocities is often called the *flatness problem*.

Horizon Problem

In the previous section, we defined the *comoving (particle) horizon*, τ, as the causal horizon or the maximum distance a light ray can travel between time 0 and time t

$$\boxed{\tau \equiv \int_0^t \frac{\mathrm{d}t'}{a(t')} = \int_0^a \frac{\mathrm{d}a}{Ha^2} = \int_0^a \mathrm{d}\ln a \left(\frac{1}{aH}\right)}. \tag{363}$$

Here, we have expressed the comoving horizon as an integral of the *comoving Hubble radius*, $(aH)^{-1}$, which plays a crucial role in inflation.

For a universe dominated by a fluid with equation of state w, we have

$$(aH)^{-1} = H_0^{-1} a^{\frac{1}{2}(1+3w)}\,. \tag{364}$$

Notice the dependence of the exponent on the combination $(1+3w)$. The qualitative behavior therefore depends on whether $(1+3w)$ is positive or negative. During the conventional Big Bang expansion ($w \gtrsim 0$) $(aH)^{-1}$ *grows* monotonically and the comoving horizon τ or the *fraction of the universe in causal contact increases with time*

$$\tau \propto a^{\frac{1}{2}(1+3w)}\,. \tag{365}$$

Again, the qualitative behavior depends on whether $(1+3w)$ is positive of negative. In particular, for radiation-dominated (RD) and matter-dominated (MD) universes we find

$$\tau = \int_0^a \frac{\mathrm{d}a}{Ha^2} \propto \begin{cases} a & \text{RD} \\ a^{1/2} & \text{MD} \end{cases}\,. \tag{366}$$

This means that the comoving horizon grows monotonically with time which implies that comoving scales entering the horizon today have been far outside the horizon at CMB decoupling.[23] But the near-homogeneity of the CMB tells us that the universe was extremely homogeneous at the time of last-scattering on scales encompassing many regions that *a priori* are causally independent. How is this possible?

[23] Recall that the comoving wavelength of a fluctuations is time-independent, while the comoving Hubble radius is time-dependent.

Flatness Problem

Exercise 1 (Flatness and Kinetic Energy)**.** *Show that the curvature parameter*

$$\Omega_k \equiv \Omega - 1 = \frac{\rho - \rho_{\rm crit}}{\rho_{\rm crit}}\,, \qquad \text{where} \quad \rho_{\rm crit} \equiv 3H^2\,,$$

may be interpreted as the difference between the average potential energy and the average kinetic energy of a region of space.

Spacetime in General Relativity is dynamical, curving in response to matter in the universe. Why then is the universe so closely approximated by flat Euclidean space? To quantify the problem we consider the Friedmann Equation

$$H^2 = \frac{1}{3}\rho(a) - \frac{k}{a^2}\,, \tag{367}$$

written as

$$\boxed{1 - \Omega(a) = \frac{-k}{(aH)^2}}\,, \tag{368}$$

where

$$\Omega(a) \equiv \frac{\rho(a)}{\rho_{\rm crit}(a)}\,, \qquad \rho_{\rm crit}(a) \equiv 3H(a)^2\,. \tag{369}$$

Notice that $\Omega(a)$ is now defined to be time-dependent, whereas the Ω's in the previous sections were constants, $\Omega(a_0)$. In standard cosmology the comoving Hubble radius, $(aH)^{-1}$, grows with time and from Eqn. (368) the quantity $|\Omega - 1|$ must thus diverge with time. The critical value $\Omega = 1$ is an *unstable fixed point*. Therefore, in standard Big Bang cosmology without inflation, the near-flatness observed today, $\Omega(a_0) \sim 1$, requires an extreme fine-tuning of Ω close to 1 in the early universe. More specifically, one finds that the deviation from flatness at Big Bang Nucleosynthesis (BBN), during the GUT era and at the Planck scale, respectively has to satisfy the following conditions

$$|\Omega(a_{\rm BBN}) - 1| \;\leq\; \mathcal{O}(10^{-16})\,, \tag{370}$$
$$|\Omega(a_{\rm GUT}) - 1| \;\leq\; \mathcal{O}(10^{-55})\,, \tag{371}$$
$$|\Omega(a_{\rm pl}) - 1| \;\leq\; \mathcal{O}(10^{-61})\,. \tag{372}$$

Another way of understanding the flatness problem is from the following differential equation

$$\frac{d\Omega}{d\ln a} = (1 + 3w)\Omega(\Omega - 1)\,. \tag{373}$$

Eqn. (373) is derived by differentiating Eqn. (368) and using the continuity equation (351). This makes it apparent that $\Omega = 1$ is an unstable fixed point if the strong energy condition is satisfied

$$\frac{d|\Omega - 1|}{d\ln a} > 0 \quad \Leftrightarrow \quad 1 + 3w > 0\,. \tag{374}$$

Again, why is $\Omega(a_0) \sim \mathcal{O}(1)$ and not much smaller or much larger?

On the Problem of Initial Conditions

We should emphasize that the flatness and horizon problems are *not* strict inconsistencies in the standard cosmological model. If one assumes that the initial value of Ω was extremely close to unity and that the universe began homogeneously over superhorizon distances (but with just the right level of inhomogeneity to explain structure formation) then the universe will continue

to evolve homogeneously in agreement with observations. The flatness and horizon problems are therefore really just severe shortcomings in the predictive power of the Big Bang model. The dramatic flatness of the early universe cannot be predicted by the standard model, but must instead be assumed in the initial conditions. Likewise, the striking large-scale homogeneity of the universe is not explained or predicted by the model, but instead must simply be assumed. A theory that explains these initial conditions dynamically seems very attractive.

7.3.3 A First Look at Inflation

The Shrinking Hubble Sphere

In §7.3.2 and §7.3.2 we emphasized the fundamental role of the comoving Hubble radius, $(aH)^{-1}$, in the horizon and flatness problems of the standard Big Bang cosmology. Both problems arise since in the conventional cosmology the comoving Hubble radius is strictly increasing. This suggest that all the Big Bang puzzles are solved by a beautifully simple idea: *invert the behavior of the comoving Hubble radius*, *i.e.* make is *decrease sufficiently in the very early universe.*

Comoving Horizon during Inflation

The evolution of the comoving horizon is of such crucial importance to the whole idea of inflation that it is worth being explicit about a few important points.

Recall the definition of the comoving horizon (= conformal time) as a logarithmic integral of the comoving Hubble radius

$$\boxed{\tau = \int_0^a \mathrm{d}\ln a' \, \frac{1}{a'H(a')}} \,. \tag{375}$$

Let us emphasize a subtle distinction between the comoving horizon τ and the comoving Hubble radius $(aH)^{-1}$ [8]:

> If particles are separated by distances greater than τ, they *never* could have communicated with one another; if they are separated by distances greater than $(aH)^{-1}$, they cannot talk to each other *now*! This distinction is crucial for the solution to the horizon problem which relies on the following: It is possible that τ is much larger than $(aH)^{-1}$ now, so that particles cannot communicate today but were in causal contact early on. From Eqn. (375) we see that this might happen if the comoving Hubble radius in the early universe was much larger than it is now so that τ got most of its contribution from early times. Hence, we require a phase of decreasing Hubble radius. Since H is approximately constant while a grows exponentially during inflation we find that the comoving Hubble radius decreases during inflation just as advertised.

Besides solving the Big Bang puzzles the decreasing comoving horizon during inflation is the key feature required for the quantum generation of cosmological perturbations described in the second lecture. I will describe how quantum fluctuations are generated on subhorizon scales, but exit the horizon once the Hubble radius becomes smaller than their comoving wavelength. In physical coordinates this corresponds to the superluminal expansion stretching perturbations to acausal distances. They become classical superhorizon density perturbations which re-enter the horizon in the subsequent Big Bang evolution and then gravitationally collapse to form the large-scale structure in the universe.

With this understanding of how the comoving horizon and the comoving Hubble radius evolve during inflation it is now almost trivial to explain how inflation solves the Big Bang puzzles.

Flatness Problem Revisited

Recall the Friedmann Equation (368) for a non-flat universe

$$|1 - \Omega(a)| = \frac{1}{(aH)^2} \,. \tag{376}$$

If the comoving Hubble radius decreases this *drives the universe toward flatness* (rather than away from it). This solves the flatness problem! The solution $\Omega = 1$ is an attractor during inflation.

Horizon Problem Revisited

A decreasing comoving horizon means that large scales entering the present universe were inside the horizon before inflation (see Figure 2). Causal physics before inflation therefore established spatial homogeneity. With a period of inflation, the uniformity of the CMB is not a mystery.

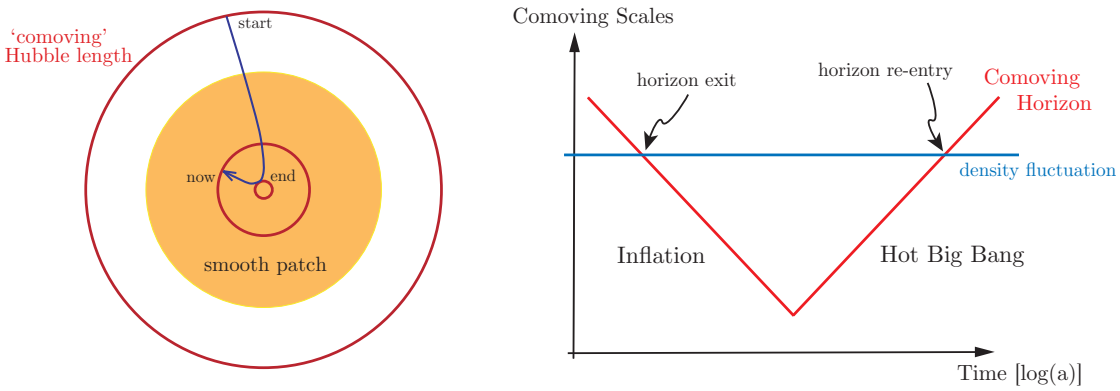

Figure 60: *Left:* Evolution of the comoving Hubble radius, $(aH)^{-1}$, in the inflationary universe. The comoving Hubble sphere shrinks during inflation and expands after inflation. Inflation is therefore a mechanism to 'zoom-in' on a smooth sub-horizon patch. *Right:* Solution of the horizon problem. All scales that are relevant to cosmological observations today were larger than the Hubble radius until $a \sim 10^{-5}$. However, at sufficiently early times, these scales were smaller than the Hubble radius and therefore causally connected. Similarly, the scales of cosmological interest came back within the Hubble radius at relatively recent times.

Conditions for Inflation

Via the Friedmann Equations a shrinking comoving Hubble radius can be related to the acceleration and the the pressure of the universe

$$\boxed{\frac{d}{dt}\left(\frac{H^{-1}}{a}\right) < 0 \quad \Rightarrow \quad \frac{d^2a}{dt^2} > 0 \quad \Rightarrow \quad \rho + 3p < 0} \,. \tag{377}$$

The three equivalent conditions for inflation therefore are:

- **Decreasing comoving horizon**

The shrinking Hubble sphere is defined as

$$\frac{d}{dt}\left(\frac{1}{aH}\right) < 0\,. \tag{378}$$

We used this as our fundamental definition of inflation since it most directly relates to the flatness and horizon problems and is key for the mechanism to generate fluctuations.

- **Accelerated expansion**

  From the relation

  $$\frac{d}{dt}(aH)^{-1} = \frac{-\ddot{a}}{(aH)^2}\,, \tag{379}$$

  we see immediately that a shrinking comoving Hubble radius implies accelerated expansion

  $$\frac{d^2a}{dt^2} > 0\,. \tag{380}$$

  This explains why inflation is often defined as a period of accelerated expansion. The second time derivative of the scale factor may of course be related to the first time derivative of the Hubble parameter H

  $$\frac{\ddot{a}}{a} = H^2(1-\varepsilon)\,, \qquad \text{where} \quad \varepsilon \equiv -\frac{\dot{H}}{H^2}\,. \tag{381}$$

  Acceleration therefore corresponds to

  $$\boxed{\varepsilon = -\frac{\dot{H}}{H^2} = -\frac{d\ln H}{dN} < 1} \tag{382}$$

  Here, we have defined $\mathrm{d}N = H\mathrm{d}t = \mathrm{d}\ln a$, which measures the number of e-folds N of inflationary expansion. Eqn. (382) therefore means that the fractional change of the Hubble parameter per e-fold is small.

- **Negative pressure**

  What stress-energy can source acceleration? Consulting Eqn. (349) we infer that $\ddot{a} > 0$ requires

  $$p < -\frac{1}{3}\rho\,, \tag{383}$$

  i.e. negative pressure or a violation of the strong energy condition (SEC). How this can arise in a physical theory will be explained in §7.3.4. We will see that there is nothing sacred about the SEC and it can easily be violated.

Conformal Diagram of Inflation

A truly illuminating way of visualizing inflation is with the aid of a conformal spacetime diagram. Recall from §7.3.1 the flat FRW metric in conformal time $\mathrm{d}\tau = \mathrm{d}t/a(t)$

$$\mathrm{d}s^2 = a^2(\tau)\left[-\mathrm{d}\tau^2 + \mathrm{d}\mathbf{x}^2\right]\,. \tag{384}$$

Also recall that in conformal coordinates null geodesics ($\mathrm{d}s^2 = 0$) are always at 45° angles, $\mathrm{d}\tau = \pm\sqrt{\mathrm{d}\mathbf{x}^2} \equiv \pm\mathrm{d}r$. Since light determines the causal structure of spacetime this provides a nice way to study horizons in inflationary cosmology.

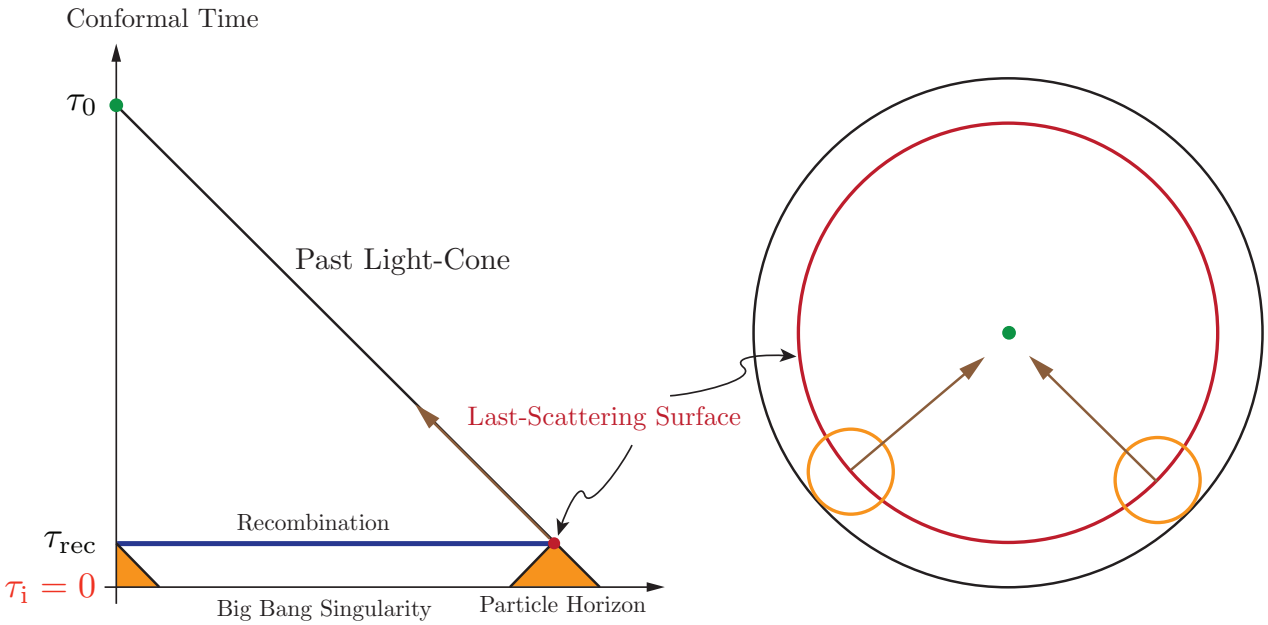

Figure 61: Conformal diagram of Big Bang cosmology. The CMB at last-scattering (recombination) consists of 10^5 causally disconnected regions!

During matter or radiation domination the scale factor evolves as

$$a(\tau) \propto \begin{cases} \tau & \text{RD} \\ \tau^2 & \text{MD} \end{cases} . \tag{385}$$

If and only if the universe had always been dominated by matter or radiation, this would imply the existence of the *Big Bang singularity* at $\tau_{\rm i} = 0$

$$a(\tau_{\rm i} \equiv 0) = 0 \, . \tag{386}$$

The conformal diagram corresponding to standard Big Bang cosmology is given in Figure 61. The horizon problem is apparent. Each spacetime point in the conformal diagram has an associated past light cone which defines its causal past. Two points on a given τ = constant surface are in causal contact if their past light cones intersect at the Big Bang, $\tau_{\rm i} = 0$. This means that the surface of last-scattering ($\tau_{\rm CMB}$) consisted of many causally disconnected regions that won't be in thermal equilibrium. The uniformity of the CMB on large scales hence becomes a serious puzzle.

During inflation ($H \approx$ const.), the scale factor is

$$a(\tau) = -\frac{1}{H\tau} \, , \tag{387}$$

and the singularity, $a = 0$, is pushed to the infinite past, $\tau_{\rm i} \to -\infty$. The scale factor (387) becomes infinite at $\tau = 0$! This is because we have assumed de Sitter space with $H =$ const., which means that inflation will continue forever with $\tau = 0$ corresponding to the infinite future $t \to +\infty$. In reality, inflation ends at some finite time, and the approximation (387) although valid at early times, breaks down near the end of inflation. So the surface $\tau = 0$ is not the Big Bang, but the end of inflation. The initial singularity has been pushed back arbitrarily far in conformal time $\tau \ll 0$, and light cones can extend through the apparent Big Bang so that apparently disconnected points are in causal contact. In other words, because of inflation, 'there was more (conformal) time before recombination than we thought'. This is summarized in the conformal diagram in Figure 62.

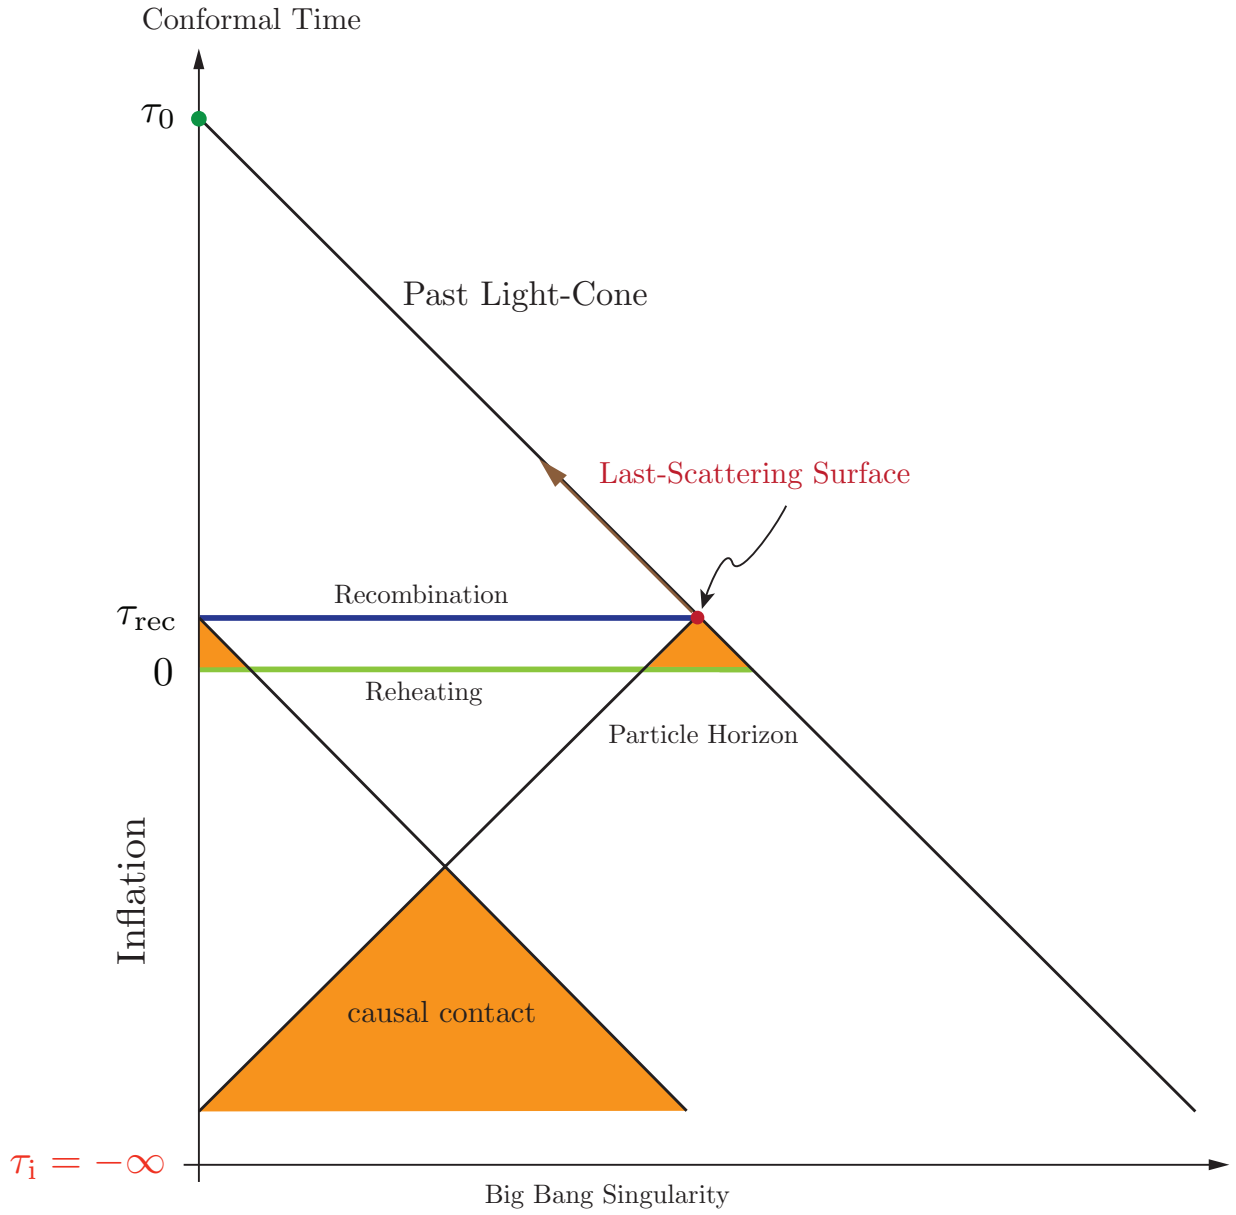

Figure 62: Conformal diagram of inflationary cosmology. Inflation extends conformal time to negative values! The end of inflation creates an "apparent" Big Bang at $\tau = 0$. There is, however, no singularity at $\tau = 0$ and the light cones intersect at an earlier time if inflation lasts for at least 60 e-folds.

7.3.4 The Physics of Inflation

Inflation is a very unfamiliar physical phenomenon: within a fraction a second the universe grew exponential at an accelerating rate. In Einstein gravity this requires a negative pressure source or equivalently a nearly constant energy density. In this section we describe the physical conditions under which this can arise.

Scalar Field Dynamics

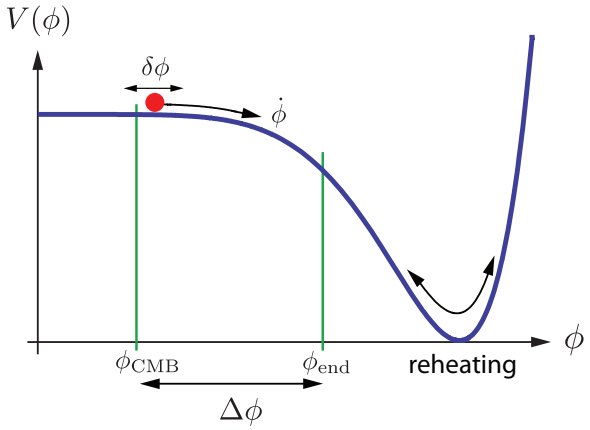

Figure 63: Example of an inflaton potential. Acceleration occurs when the potential energy of the field, $V(\phi)$, dominates over its kinetic energy, $\frac{1}{2}\dot{\phi}^2$. Inflation ends at $\phi_{\rm end}$ when the kinetic energy has grown to become comparable to the potential energy, $\frac{1}{2}\dot{\phi}^2 \approx V$. CMB fluctuations are created by quantum fluctuations $\delta\phi$ about 60 e-folds before the end of inflation. At reheating, the energy density of the inflaton is converted into radiation.

The simplest models of inflation involve a single scalar field ϕ, the *inflaton*. Here, we don't specify the physical nature of the field ϕ, but simply use it as an order parameter (or clock) to parameterize the time-evolution of the inflationary energy density. The dynamics of a scalar field (minimally) coupled to gravity is governed by the action

$$\boxed{S = \int \mathrm{d}^4x\sqrt{-g}\left[\frac{1}{2}R + \frac{1}{2}g^{\mu\nu}\partial_\mu\phi\,\partial_\nu\phi - V(\phi)\right]} = S_{\rm EH} + S_\phi\,. \tag{388}$$

The action (388) is the sum of the gravitational Einstein-Hilbert action, $S_{\rm EH}$, and the action of a scalar field with canonical kinetic term, S_ϕ. The potential $V(\phi)$ describes the self-interactions of the scalar field. The energy-momentum tensor for the scalar field is

$$T^{(\phi)}_{\mu\nu} \equiv -\frac{2}{\sqrt{-g}}\frac{\delta S_\phi}{\delta g^{\mu\nu}} = \partial_\mu\phi\partial_\nu\phi - g_{\mu\nu}\left(\frac{1}{2}\partial^\sigma\phi\partial_\sigma\phi + V(\phi)\right). \tag{389}$$

The field equation of motion is

$$\frac{\delta S_\phi}{\delta\phi} = \frac{1}{\sqrt{-g}}\partial_\mu(\sqrt{-g}\partial^\mu\phi) + V_{,\phi} = 0\,, \tag{390}$$

where $V_{,\phi} = \frac{dV}{d\phi}$. Assuming the FRW metric (328) for $g_{\mu\nu}$ and restricting to the case of a homogeneous field $\phi(t,\mathbf{x}) \equiv \phi(t)$, the scalar energy-momentum tensor takes the form of a perfect fluid (347) with

$$\rho_\phi = \frac{1}{2}\dot{\phi}^2 + V(\phi)\,, \tag{391}$$

$$p_\phi = \frac{1}{2}\dot{\phi}^2 - V(\phi)\,. \tag{392}$$

The resulting equation of state

$$\boxed{w_\phi \equiv \frac{p_\phi}{\rho_\phi} = \frac{\frac{1}{2}\dot{\phi}^2 - V}{\frac{1}{2}\dot{\phi}^2 + V}}\,, \tag{393}$$

shows that a scalar field can lead to negative pressure ($w_\phi < 0$) and accelerated expansion ($w_\phi < -1/3$) if the potential energy V dominates over the kinetic energy $\frac{1}{2}\dot{\phi}^2$. The dynamics of the (homogeneous) scalar field and the FRW geometry is determined by

$$\ddot{\phi} + 3H\dot{\phi} + V_{,\phi} = 0 \qquad \text{and} \qquad H^2 = \frac{1}{3}\left(\frac{1}{2}\dot{\phi}^2 + V(\phi)\right)\,. \tag{394}$$

For large values of the potential, the field experiences significant Hubble friction from the term $H\dot{\phi}$.

Slow-Roll Inflation

The acceleration equation for a universe dominated by a homogeneous scalar field can be written as follows

$$\frac{\ddot{a}}{a} = -\frac{1}{6}(\rho_\phi + 3p_\phi) = H^2(1-\varepsilon)\,, \tag{395}$$

where

$$\varepsilon \equiv \frac{3}{2}(w_\phi + 1) = \frac{1}{2}\frac{\dot{\phi}^2}{H^2}\,. \tag{396}$$

The so-called *slow-roll parameter* ε may be related to the evolution of the Hubble parameter

$$\boxed{\varepsilon = -\frac{\dot{H}}{H^2}} = -\frac{d\ln H}{dN}\,, \tag{397}$$

where $\mathrm{d}N = H\mathrm{d}t$. Accelerated expansion occurs if $\varepsilon < 1$. The de Sitter limit, $p_\phi \to -\rho_\phi$, corresponds to $\varepsilon \to 0$. In this case, the potential energy dominates over the kinetic energy

$$\dot{\phi}^2 \ll V(\phi)\,. \tag{398}$$

Accelerated expansion will only be sustained for a sufficiently long period of time if the second time derivative of ϕ is small enough

$$|\ddot{\phi}| \;\ll\; |3H\dot{\phi}|\,,\, |V_{,\phi}|\,. \tag{399}$$

This requires smallness of a second slow-roll parameter

$$\eta = -\frac{\ddot{\phi}}{H\dot{\phi}} = \varepsilon - \frac{1}{2\varepsilon}\frac{d\varepsilon}{dN}\,, \tag{400}$$

where $|\eta| < 1$ ensures that the fractional change of ε per e-fold is small. The slow-roll conditions, $\varepsilon, |\eta| < 1$, may also be expressed as conditions on the shape of the inflationary potential

$$\boxed{\epsilon_{\rm v}(\phi) \equiv \frac{M_{\rm pl}^2}{2}\left(\frac{V_{,\phi}}{V}\right)^2}\,, \tag{401}$$

and

$$\boxed{\eta_{\rm v}(\phi) \equiv M_{\rm pl}^2\frac{V_{,\phi\phi}}{V}}\,. \tag{402}$$

Here, we temporarily reintroduced the Planck mass to make $\epsilon_{\rm v}$ and $\eta_{\rm v}$ manifestly dimensionless. In the following we will set $M_{\rm pl}$ to one again. In the slow-roll regime

$$\epsilon_{\rm v}, |\eta_{\rm v}| \ll 1\,, \tag{403}$$

the background evolution is

$$H^2 \approx \frac{1}{3}V(\phi) \approx \text{const.}\,, \tag{404}$$

$$\dot\phi \approx -\frac{V_{,\phi}}{3H}\,, \tag{405}$$

and the spacetime is approximately *de Sitter*

$$a(t) \sim e^{Ht}\,. \quad H \approx \text{const}\,. \tag{406}$$

The parameters $\epsilon_{\rm v}$ and $\eta_{\rm v}$ are called the *potential slow-roll parameters* to distinguish them from the *Hubble slow-roll parameters* ε and η. In the slow-roll approximation the Hubble and potential slow-roll parameters are related as follows (see Appendix 7.8.4)

$$\varepsilon \approx \epsilon_{\rm v}\,, \qquad \eta \approx \eta_{\rm v} - \epsilon_{\rm v}\,. \tag{407}$$

Inflation ends when the slow-roll conditions are violated

$$\varepsilon(\phi_{\rm end}) \equiv 1\,, \qquad \epsilon_{\rm v}(\phi_{\rm end}) \approx 1\,. \tag{408}$$

The number of e-folds before inflation ends is

$$\begin{aligned} N(\phi) &\equiv \ln\frac{a_{\rm end}}{a} \\ &= \int_t^{t_{\rm end}} H{\rm d}t = \int_\phi^{\phi_{\rm end}} \frac{H}{\dot\phi}{\rm d}\phi \approx \int_{\phi_{\rm end}}^{\phi} \frac{V}{V_{,\phi}}{\rm d}\phi\,, \end{aligned} \tag{409}$$

where we used the slow-roll results (404) and (405). The result (409) may also be written as

$$\boxed{N(\phi) = \int_{\phi_{\rm end}}^{\phi} \frac{{\rm d}\phi}{\sqrt{2\varepsilon}} \approx \int_{\phi_{\rm end}}^{\phi} \frac{{\rm d}\phi}{\sqrt{2\epsilon_{\rm v}}}}\,. \tag{410}$$

To solve the horizon and flatness problems requires that the total number of inflationary e-folds exceeds about 60,

$$N_{\rm tot} \equiv \ln\frac{a_{\rm end}}{a_{\rm start}} \gtrsim 60\,. \tag{411}$$

The precise value depends on the energy scale of inflation and on the details of reheating after inflation. The fluctuations observed in the CMB are created $N_{\rm cmb} \approx 40-60$ e-folds before the end of inflation (the precise value again depending on the details of reheating and the post-inflationary thermal history of the universe). The following integral constraint gives the corresponding field value $\phi_{\rm cmb}$

$$\int_{\phi_{\rm end}}^{\phi_{\rm cmb}} \frac{{\rm d}\phi}{\sqrt{2\epsilon_{\rm v}}} = N_{\rm cmb} \approx 40-60\,. \tag{412}$$

Case Study: $m^2\phi^2$ Inflation

As an example, let us give the slow-roll analysis of arguably the simplest model of inflation: single field inflation driven by a mass term

$$V(\phi) = \frac{1}{2}m^2\phi^2\,. \tag{413}$$

The slow-roll parameters are

$$\epsilon_{\rm v}(\phi) = \eta_{\rm v}(\phi) = 2\left(\frac{M_{\rm pl}}{\phi}\right)^2\,. \tag{414}$$

To satisfy the slow-roll conditions $\epsilon_{\rm v}, |\eta_{\rm v}| < 1$, we need to consider super-Planckian values for the inflaton

$$\phi > \sqrt{2}M_{\rm pl} \equiv \phi_{\rm end}\,. \tag{415}$$

The relation between the inflaton field value and the number of e-folds before the end of inflation is

$$N(\phi) = \frac{\phi^2}{4M_{\rm pl}^2} - \frac{1}{2}\,. \tag{416}$$

Fluctuations observed in the CMB are created at

$$\phi_{\rm cmb} = 2\sqrt{N_{\rm cmb}}\,M_{\rm pl} \sim 15M_{\rm pl}\,. \tag{417}$$

In the next lecture we will come back to this example when we compute the fluctuation spectrum generate by $m^2\phi^2$ inflation.

Exercise 2 ($m^2\phi^2$ Inflation)**.** *Verify the above slow-roll results for $m^2\phi^2$ inflation.*

Reheating

After inflation ends the scalar field begins to oscillate around the minimum of the potential. During this phase of coherent oscillations the scalar field acts like pressureless matter

$$\frac{d\bar{\rho}_\phi}{dt} + 3H\bar{\rho}_\phi = 0\,. \tag{418}$$

Exercise 3 (Coherent Scalar Field Oscillations)**.** *Confirm Eqn. (418) from the equations of motion for ϕ.*

The coupling of the inflaton field to other particles leads to a decay of the inflaton energy

$$\frac{d\bar{\rho}_\phi}{dt} + (3H + \Gamma_\phi)\bar{\rho}_\phi = 0\,. \tag{419}$$

The coupling parameter Γ_ϕ depends on complicated and model-dependent physical processes that we do not have the time to review. Eventually, the inflationary energy density is converted into standard model degrees of freedom and the hot Big Bang commences.

Reheating is a rich and complicated subject to which we couldn't do justice to in these lectures. We refer the interested reader to the review by Bassett *et al.* [13] for more details.

Models of Inflation

The fundamental microscopic origin of inflation is still a mystery. Basic questions like: what is the inflaton? what is the shape of the inflationary potential? and why did the universe start in a high energy state? remain unanswered. The challenge to explain the physics of inflation is considerable. Inflation is believed to have occurred at an enormous energy scale (maybe as high as $\sim 10^{15}$ GeV), far out of reach of terrestrial particle accelerators. Any description of the inflationary era therefore requires a considerable extrapolation of the known laws of physics, and until recently, only a phenomenological parameterization of the inflationary dynamics was possible.[24] In this approach, a suitable inflationary potential function $V(\phi)$ is postulated (see Figures 63 and 64 for two popular examples) and the experimental predictions are computed from that. As we will see in the next lecture, details of the primordial fluctuation spectra will depend on the precise shape of the inflaton potential.

Single-Field Slow-Roll Inflation

The definition of an inflationary model amounts to a specification of the inflaton action (potential and kinetic terms) and its coupling to gravity. So far we have phrased our discussion of inflation in terms of the simplest models, single-field slow-roll inflation, characterized by the following action

$$S = \int \mathrm{d}^4x\sqrt{-g}\left[\frac{1}{2}R + \frac{1}{2}g^{\mu\nu}\partial_\mu\phi\,\partial_\nu\phi - V(\phi)\right] . \tag{420}$$

The dynamics of the inflaton field, from the time when CMB fluctuations were created (see **Lecture 2**) at $\phi_{\rm cmb}$ to the end of inflation at $\phi_{\rm end}$, is determined by the shape of the inflationary potential $V(\phi)$. The different possibilities for $V(\phi)$ can be classified in a useful way by determining whether they allow the inflaton field to move over a large or small distance $\Delta\phi \equiv \phi_{\rm cmb} - \phi_{\rm end}$, as measured in Planck units.

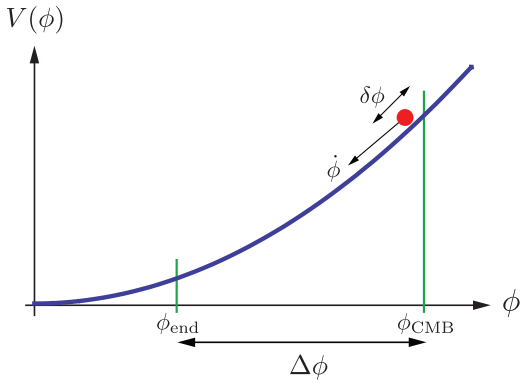

Figure 64: Large-field inflation. In an important class of inflationary models the inflationary dynamics is driven by a single monomial term in the potential, $V(\phi) \propto \phi^p$. In these models the inflaton field evolves over a super-Planckian range during inflation, $\Delta\phi > M_{\rm pl}$, and a large amplitude of gravitational waves is produced by quantum mechanical fluctuations (see **Lecture 2**).

1. *Small-Field Inflation*

   In small-field models the field moves over a small (sub-Planckian) distance: $\Delta\phi < M_{\rm pl}$. This is relevant for future observations because small-field models predict that the amplitude of the gravitational waves produced during inflation is too small to be detected

[24] Recently, progress has been made both in a systematic effective field theory description of inflation [14, 15] and in top-down derivations of inflationary potentials from string theory [16].

(see **Lecture 2**). The potentials that give rise to such small-field evolution often arise in mechanisms of *spontaneous symmetry breaking*, where the field rolls off an unstable equilibrium toward a displaced vacuum (see Fig. 63). A simple example is the Higgs-like potential

$$V(\phi) = V_0 \left[1 - \left(\frac{\phi}{\mu}\right)^2\right]^2 . \tag{421}$$

More generally, small-field models can be locally approximated by the following expansion

$$V(\phi) = V_0 \left[1 - \left(\frac{\phi}{\mu}\right)^p\right] + \cdots \tag{422}$$

where the dots represent higher-order terms that become important near the end of inflation and during reheating.

Historically, a famous inflationary potential is the *Coleman-Weinberg potential* [170, 15]

$$V(\phi) = V_0 \left[\left(\frac{\phi}{\mu}\right)^4 \left(\ln\left(\frac{\phi}{\mu}\right) - \frac{1}{4}\right) + \frac{1}{4}\right] , \tag{423}$$

which arises as the potential for radiatively-induced symmetry breaking in electroweak and grand unified theories. Although the original values of the parameters V_0 and μ based on the $SU(5)$ theory are incompatible with the small amplitude of inflationary fluctuations, the Coleman-Weinberg potential remains a popular phenomenological model (see *e.g.* [17]).

2. *Large-Field Inflation*

In large-field models the inflaton field starts a large field values and then evolves to a minimum at the origin $\phi = 0$. If the field evolution is super-Planckian, $\Delta\phi > M_{\rm pl}$, the gravitational waves produced by inflation should be observed in the near future.

The prototypical large-field model is *chaotic inflation* where a single monomial term dominates the potential (see Fig. 64)

$$V(\phi) = \lambda_p \phi^p . \tag{424}$$

For such a potential the slow-roll parameters are small for super-Planckian field values, $\phi \gg M_{\rm pl}$ (notice that the slow-roll conditions are independent of the coupling constant λ_p). However, to arrange for a small amplitude of density fluctuations (see **Lecture 2**) the inflaton self-coupling has to be very small, $\lambda_p \ll 1$. This condition automatically guarantees that the potential energy (density) is sub-Planckian, $V \ll M_{\rm pl}^4$, and quantum gravity effects are not necessarily important (but see §29.2 in **Lecture 5**).

One of the most elegant inflationary models is *natural inflation* where the potential takes the following form (see Fig. 65)

$$V(\phi) = V_0 \left[\cos\left(\frac{\phi}{f}\right) + 1\right] . \tag{425}$$

This potential often arises if the inflaton field is taken to be an axion. Depending on the parameter f the model can be of the small-field or large-field type. However, it is particularly attractive to consider natural inflation for large-field variations, $2\pi f > M_{\rm pl}$, since for axions a shift symmetry can be employed to protect the potential from correction terms even over large field ranges (see §29.2).

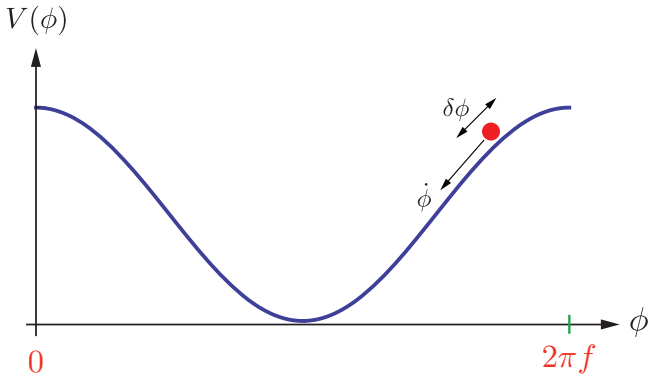

Figure 65: Natural Inflation. If the periodicity $2\pi f$ is super-Planckian the model can naturally support a large gravitational wave amplitude.

The Overshoot Problem

The Patch Problem

Beyond Single-Field Slow-Roll

The possibilities for getting inflationary expansion are (maybe frustratingly) varied. Inflation is a paradigm, a framework for a theory of the early universe, but it is not a unique theory. A large number of phenomenological models has been proposed with different theoretical motivations and observational predictions. For the majority of these lectures we will focus on the simplest single-field slow-roll models that we just described. However, in this short section we want to relieve ourselves from the sin of not mentioning the broader landscape of inflationary model-building (see also Ref. [18]).

The simplest inflationary actions (420) may be extended in a number of obvious ways:

1. *Non-minimal coupling to gravity.*

   The action (420) is called minimally coupled in the sense that there is no direct coupling between the inflaton field and the metric. In principle, we could imagine a non-minimal coupling between the inflaton and the graviton, however, in practice, non-minimally coupled theories can be written as minimally coupled theories by a field redefinition.

2. *Modified gravity.*

   Similarly, we could entertain the possibility that the Einstein-Hilbert part of the action is modified at high energies. However, the simplest examples for this UV modification of gravity, so-called $f(R)$ theories, can again be transformed into a minimally coupled scalar field with potential $V(\phi)$.

3. *Non-canonical kinetic term.*

   The action (420) has a canonical kinetic term

   $$\mathcal{L}_\phi = X - V(\phi)\,, \qquad X \equiv \frac{1}{2} g^{\mu\nu}\partial_\mu\phi\partial_\nu\phi\,. \tag{426}$$

   Inflation can then only occur if the potential $V(\phi)$ is very flat. More generally, however, we could imagine that the high-energy theory has fields with non-canonical kinetic terms

   $$\mathcal{L}_\phi = F(\phi, X) - V(\phi)\,, \tag{427}$$

   where $F(\phi, X)$ is some function of the inflaton field and its derivatives. For actions such as (427) it is possible that inflation is driven by the kinetic term and occurs even in the presence of a steep potential.

4. *More than one field.*

   If we allow more than one field to be dynamically relevant during inflation, then the possibilities for the inflationary dynamics (and the mechanisms for the production of fluctuations) expand dramatically and the theory loses a lot of its predictive power. Some of the large number of possibilities of multi-field inflationary models are reviewed in Ref. [19].

Multi-Field Inflation

Non-Trival Kinetic Terms

7.4 Quantum Fluctuations during Inflation by Baumann 2th lecture

Abstract

In this lecture we present the famous calculation of the primordial fluctuation spectra generated by quantum fluctuations during inflation. We present the calculation in full detail and try to avoid 'cheating' and approximations. After a brief review of fundamental aspects of cosmological perturbation theory, we first give a qualitative summary of the basic mechanism by which inflation converts microscopic quantum fluctuations into macroscopic seeds for cosmological structure formation. As a pedagogical introduction to quantum field theory in curved spacetime we then review the quantization of the simple harmonic oscillator. We emphasize that a unique vacuum state is chosen by demanding that the vacuum is the minimum energy state. We then proceed by giving the corresponding calculation for inflation. We calculate the power spectra of both scalar and tensor fluctuations and discuss their dependence on scale.

In the last lecture we studied the classical ($\hbar = 0$) dynamics of a scalar field rolling down a potential with speed $\dot{\phi}$ (see Fig. 66). In this lecture we study the effects of quantum ($\hbar \neq 0$) fluctuations around the classical background evolution $\bar{\phi}(t)$. These fluctuations lead to a local time delay in the time at which inflation ends, *i.e.* different parts of the universe will end inflation at slightly different times. For instance, for the potential shown in Fig. 66 regions acquiring a negative frozen fluctuations $\delta\phi$ remain potential-dominated longer than regions with positive $\delta\phi$. Different parts of the universe therefore undergo slightly different evolutions. This induces relative density fluctuations $\delta\rho(t, \mathbf{x})$.

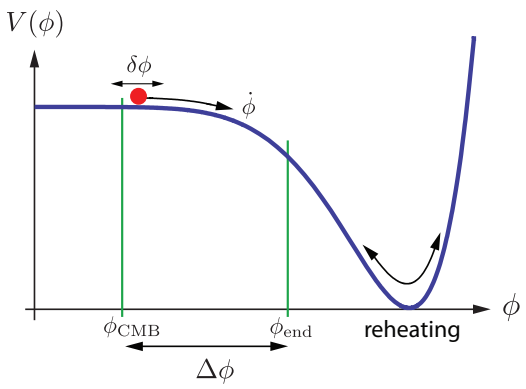

Figure 66: Quantum fluctuations $\delta\phi(t, \mathbf{x})$ around the classical background evolution $\bar{\phi}(t)$.

In this lecture we will discuss the technical details underlying this basic picture for the quantum origin of large-scale structure.

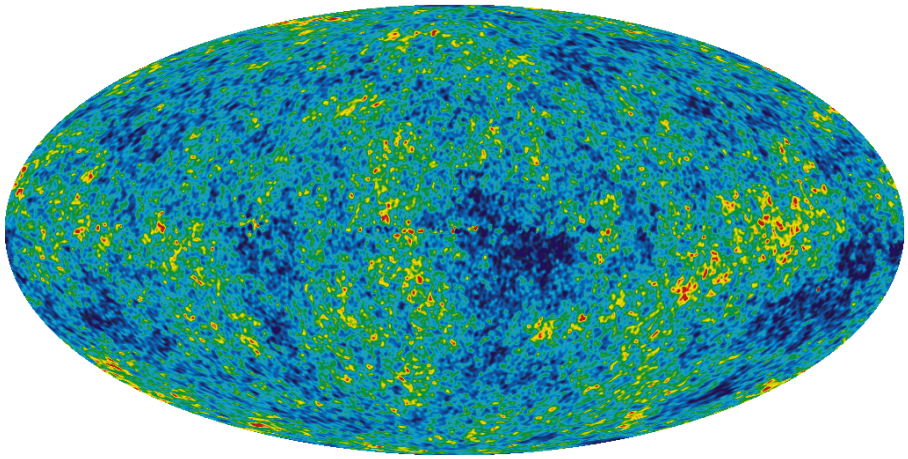

Figure 67: Observations of the CMB anisotropies prove that the early universe wasn't perfectly homogeneous. However, the observations also show that the inhomogeneities were small and can therefore be analyzed as linear perturbations around a homogenous background.

7.4.1 *Review*: Cosmological Perturbations

In this lecture we present in detail the generation of cosmological perturbations from quantum fluctuations during inflation. This discussion will require some background in cosmological perturbation theory which we now briefly review. More details may be found in Appendix A.

Generalities

Linear Perturbations

Observations of the CMB (Fig. 67) explain the success of cosmological perturbation theory. At the time of decoupling the universe was very nearly homogeneously with small inhomogeneities at the 10^{-5} level. A natural strategy therefore is to split all quantities $X(t, \mathbf{x})$ (metric $g_{\mu\nu}$ and matter fields $T_{\mu\nu} \to \phi$ ρ, p, etc.) into a homogeneous background $\bar{X}(t)$ that depends only on cosmic time and a spatially dependent perturbation

$$\delta X(t, \mathbf{x}) \equiv X(t, \mathbf{x}) - \bar{X}(t) \,. \tag{428}$$

Because the perturbations are small, $\delta X \ll \bar{X}$, expanding the Einstein Equations at linear order in perturbations approximates the full non-linear solution to very high accuracy

$$\delta G_{\mu\nu} = 8\pi G \, \delta T_{\mu\nu} \,. \tag{429}$$

Gauge Choice

A crucial subtlety in the study of cosmological perturbations is the fact that the split into background and perturbations, Eqn. (428), is not unique, but depends on the choice of coordinates or the *gauge choice*.[25] When we described the homogeneous universe in **Lecture 1** we introduced coordinates t and $\mathbf{x}$ to define the FRW metric. The spacelike hypersurfaces

[25]The perturbation δX in any relevent quantity, say represented by a tensor field X, is define as the difference between the value X has in the physical spacetime (the perturbed spacetime), and the value X_0 the same quantity has in the given (unperturbed) background spacetime. However, it is a basic fact of differential geometry that, in order to make the comparison of tensors meaningful, they can be compared only after a prescription for

of constant time t defined the *slicing* to the four-dimensional spacetime, while the timelike worldlines of constant $\mathbf{x}$ defined the *threading*. The FRW threading corresponds to the motion of comoving observers who see zero momentum density at their location. These observers a free-falling and the expansion defined by them is isotropic. The slicing is orthogonal to the threading with each spacelike slice corresponding to a homogeneous universe. These features made our coordinate choice so distinguished that we never worried about other coordinates (in which the universe would not look homogeneous and isotropic). However, now that we are considering perturbations it is important to realize that the slicing and threading of the perturbed spacetime is not unique. Furthermore, when describing an inhomogeneous spacetime there is often not a preferred coordinate choice. When we make a gauge choice to define the slicing and threading of the spacetime we implicitly also define the perturbations. If we aren't careful this gauge dependence of perturbations can lead to some confusion. To demonstrate this fact most dramatically consider an *unperturbed* homogeneous and isotropic universe, where the energy density is only a function of time, $\rho(t, \mathbf{x}) = \rho(t)$. We now show that a change of the time coordinate can introduce *fictitious* perturbations $\delta\rho$. Consider a new time coordinate $\tilde{t} = t + \delta t(t, \mathbf{x})$. In general, the energy density on the new time-slice will not be homogeneous, $\tilde{\rho}(\tilde{t}, \mathbf{x}) = \rho(t(\tilde{t}, \mathbf{x}))$. These perturbations in the energy density aren't physical, but entirely due to the choice of new time-slicing. Similarly, we can remove a *real* perturbation in the energy density by choosing the hypersurface of constant time to coincide with the hypersurface of constant energy density. Then $\delta\tilde{\rho} = 0$ although there are real inhomogeneities. To resolve ambiguities between real and fake perturbations in general relativity, we need to consider the complete set of perturbations, *i.e.* we need both the matter field perturbations and the metric perturbations and by a gauge transformation we can trade one for the other. To avoid misinterpretation of fictitious gauge modes it will also be useful to study gauge-invariant combinations of perturbations. By definition, fluctuations of gauge-invariant quantities cannot be removed by a coordinate transformation.

Scalars, Vectors and Tensors

The spatially flat, homogeneous and isotropic background spacetime possesses a great deal of symmetry. These symmetries allow a decomposition of the metric and the stress-energy perturbations into independent scalar (S), vector (V) and tensor (T) components. This *SVT decomposition* is most easily described in Fourier space

$$X_{\mathbf{k}}(t) = \int \mathrm{d}^3\mathbf{x}\; X(t, \mathbf{x})\, e^{i\mathbf{k}\cdot\mathbf{x}}\,, \qquad X \equiv \delta\phi,\, \delta g_{\mu\nu}, \text{etc}\,. \tag{430}$$

We note that *translation invariance* of the linear equations of motion for the perturbations means that the different Fourier modes do not interact (see Appendix 7.8.1 for the proof). Different Fourier modes can therefore be studied independently. This often simplifies the differential equations for the perturbations. Next we consider rotations around a single Fourier wavevector $\mathbf{k}$. A perturbation is said to have helicity m if its amplitude is multiplied by $e^{im\psi}$ under rotation of the coordinate system around the wavevector by an angle ψ

$$X_{\mathbf{k}} \to e^{im\psi} X_{\mathbf{k}}\,. \tag{431}$$

identifying points of these two different spacetimes is given. A *gauge choice* is precisely this, *i.e.* a one-to-one correspondence (map) between the background spacetime and the physical spacetime. A change of this map is then a gauge transformation, and the freedom one has in choosing it gives rise to an arbitrariness in the value of the perturbation of X at any given spacetime point, unless X is gauge-invariant.

Scalar, vector and tensor perturbations have helicity 0, ± 1 and ± 2, respectively.[26] The importance of the SVT decomposition is that the perturbations of each type evolve independently (at the linear level) and can therefore be treated separately (see Appendix 7.8.1 for the proof). This considerably simplifies the study of cosmological perturbations.

After these general remarks, let us now become more specific and explicitly define the perturbations around the homogenous and isotropic FRW universe.

The Inhomogeneous Universe

Metric Perturbations

During inflation we define perturbations around the homogeneous background solutions for the inflaton $\bar{\phi}(t)$ and the metric $\bar{g}_{\mu\nu}(t)$,

$$\phi(t, \mathbf{x}) = \bar{\phi}(t) + \delta\phi(t, \mathbf{x}) \,, \qquad g_{\mu\nu}(t, \mathbf{x}) = \bar{g}_{\mu\nu}(t) + \delta g_{\mu\nu}(t, \mathbf{x}) \,, \tag{432}$$

where

$$\begin{aligned} \mathrm{d}s^2 &= g_{\mu\nu}\, \mathrm{d}x^\mu \mathrm{d}x^\nu \\ &= -(1+2\Phi)\mathrm{d}t^2 + 2aB_i \mathrm{d}x^i \mathrm{d}t + a^2[(1-2\Psi)\delta_{ij} + E_{ij}]\mathrm{d}x^i \mathrm{d}x^j \,. \end{aligned} \tag{433}$$

In real space, the SVT decomposition of the metric perturbations (433) is[27]

$$B_i \equiv \partial_i B - S_i \,, \qquad \text{where} \quad \partial^i S_i = 0 \,, \tag{434}$$

and

$$E_{ij} \equiv 2\partial_{ij} E + 2\partial_{(i} F_{j)} + h_{ij} \,, \qquad \text{where} \quad \partial^i F_i = 0 \,, \quad h^i_i = \partial^i h_{ij} = 0 \,. \tag{435}$$

The vector perturbations S_i and F_i aren't created by inflation (and in any case decay with the expansion of the universe). For this reason we ignore vector perturbations in these lectures. Our focus will be on scalar and tensor fluctuations which are observed as density fluctuations and gravitational waves in the late universe.

Tensor fluctuations are gauge-invariant, but scalar fluctuations change under a change of coordinates. Consider the gauge transformation

$$t \;\to\; t + \alpha \tag{436}$$

$$x^i \;\to\; x^i + \delta^{ij}\beta_{,j} \,. \tag{437}$$

Under these coordinate transformations the scalar metric perturbations transform as

$$\Phi \;\to\; \Phi - \dot{\alpha} \tag{438}$$

$$B \;\to\; B + a^{-1}\alpha - a\dot{\beta} \tag{439}$$

$$E \;\to\; E - \beta \tag{440}$$

$$\Psi \;\to\; \Psi + H\alpha \,. \tag{441}$$

Exercise 4 (Linear Gauge Transformations)**.** *Derive the gauge transformations of the scalar metric perturbations (438)–(441). Hint: use invariance of the spacetime interval,*

$$\mathrm{d}s^2 = g_{\mu\nu}\mathrm{d}x^\mu \mathrm{d}x^\nu = \tilde{g}_{\mu\nu}\mathrm{d}\tilde{x}^\mu \mathrm{d}\tilde{x}^\nu \,. \tag{442}$$

[26] Should this abstract definition of scalar, vector and tensor perturbations in terms of their helicities be confusing, the reader may want to test those rules on the explicit metric and stress-energy perturbations introduced in the next section.

[27] SVT decomposition in real space corresponds to the distinct transformation properties of scalars, vectors and tensors on spatial hypersurfaces.

Matter Perturbations

During inflation the inflationary energy is the dominant contribution to the stress-energy of the universe, so that the inflaton perturbations $\delta\phi$ backreact on the spacetime geometry. This coupling between matter perturbations and metric perturbations is described by the Einstein Equations (see Appendix 7.8.1).

After inflation, the perturbations to the total stress-energy tensor of the universe are

$$\begin{aligned} T^0_0 &= -(\bar\rho + \delta\rho) && (443)\\ T^0_i &= (\bar\rho + \bar p)\, a v_i && (444)\\ T^i_0 &= -(\bar\rho + \bar p)(v^i - B^i)/a && (445)\\ T^i_j &= \delta^i_j(\bar p + \delta p) + \Sigma^i_j\,. && (446) \end{aligned}$$

The anisotropic stress Σ^i_j is gauge-invariant while the density, pressure and momentum density ($(\delta q)_{,i} \equiv (\bar\rho + \bar p)v_i$) transform as follows

$$\begin{aligned} \delta\rho &\to \delta\rho - \dot{\bar\rho}\,\alpha && (447)\\ \delta p &\to \delta p - \dot{\bar p}\,\alpha && (448)\\ \delta q &\to \delta q + (\bar\rho + \bar p)\,\alpha\,. && (449) \end{aligned}$$

Gauge-Invariant Variables

As we explained above, to avoid the pitfall of fictitious gauge modes, it useful to introduce gauge-invariant combinations of metric and matter perturbations [219]. An important gauge-invariant scalar quantity is the *curvature perturbation on uniform-density hypersurfaces* [21]

$$\boxed{-\zeta \equiv \Psi + \frac{H}{\dot{\bar\rho}}\delta\rho}\,. \tag{450}$$

Geometrically, ζ measures the spatial curvature of constant-density hypersurfaces, $R^{(3)} = 4\nabla^2\Psi/a^2$. An important property of ζ is that it remains constant outside the horizon for adiabatic matter perturbations, *i.e.* perturbations that satisfy

$$\boxed{\delta p_{en} \equiv \delta p - \frac{\dot{\bar p}}{\dot{\bar\rho}}\delta\rho} = 0\,. \tag{451}$$

Notice that the definition of δp_{en} is gauge-invariant. In the single-field inflation models studied in this lecture the condition (600) is always satisfy, so the perturbation $\zeta_{\mathbf{k}}$ doesn't evolve outside the horizon, $k \ll aH$.

In a gauge defined by spatially flat hypersurfaces, Ψ, the perturbations ζ is the dimensionless density perturbation $\frac{1}{3}\delta\rho/(\bar\rho+\bar p)$. Taking into account appropriate transfer functions to describe the sub-horizon evolution of the fluctuations, CMB and LSS observations can therefore be related to the primordial value of ζ (see **Lecture 3**). During slow-roll inflation

$$-\zeta \approx \Psi + \frac{H}{\dot{\bar\phi}}\delta\phi\,. \tag{452}$$

Another gauge-invariant scalar is the *comoving curvature perturbation*

$$\boxed{\mathcal{R} \equiv \Psi - \frac{H}{\bar\rho + \bar p}\delta q}\,, \tag{453}$$

where δq is the scalar part of the 3-momentum density $T^0_i = \partial_i \delta q$. During inflation $T^0_i = -\dot{\bar{\phi}}\,\partial_i \delta\phi$ and hence

$$\mathcal{R} = \Psi + \frac{H}{\dot{\bar{\phi}}}\delta\phi\,. \tag{454}$$

Geometrically, $\mathcal{R}$ measures the spatial curvature of comoving (or constant-ϕ) hypersurfaces.

The linearized Einstein equations relate ζ and $\mathcal{R}$ as follows (see Appendix 7.8.1)

$$-\zeta = \mathcal{R} + \frac{k^2}{(aH)^2}\frac{2\bar{\rho}}{3(\bar{\rho}+\bar{p})}\Psi_{\rm B}\,, \tag{455}$$

where

$$\Psi_{\rm B} \equiv \psi + a^2 H(\dot{E} - B/a)\,, \tag{456}$$

is one of the Bardeen potentials [219]. ζ and $\mathcal{R}$ are therefore equal on superhorizon scales, $k \ll aH$. ζ and $\mathcal{R}$ are also equal during slow-roll inflation, *cf.* Eqs. (452) and (454). The correlation functions of ζ and $\mathcal{R}$ are therefore equal at horizon crossing and both ζ and $\mathcal{R}$ are conserved on superhorizon scales. In this lecture we will compute the primordial spectrum of $\mathcal{R}$ at horizon crossing.

Finally, a gauge-invariant measure of inflaton perturbations is the *inflaton perturbation on spatially flat slices*

$$\boxed{Q \equiv \delta\phi + \frac{\dot{\bar{\phi}}}{H}\Psi}\,. \tag{457}$$

Exercise 5 (Gauge-Invariant Perturbations)**.** *Using the linear gauge transformations for the metric and matter perturbations, confirm that ζ, $\mathcal{R}$ and Q are gauge-invariant.*

Superhorizon (Non-)Evolution

The Einstein equations (see Appendix 7.8.1) give the evolution equation for the gauge-invariant curvature perturbation

$$\dot{\mathcal{R}} = -\frac{H}{\bar{\rho}+\bar{p}}\,\delta p_{en} + \frac{k^2}{(aH)^2}\Big(\dots\Big)\,. \tag{458}$$

Adiabatic matter perturbations satisfy $\delta p_{en} = 0$ and $\mathcal{R}$ is conserved on superhorizon scales, $k < aH$.

Exercise 6 (Separate Universe Approach)**.** *Read about the separate universe approach [22] for proving conservation of the curvature perturbation $\mathcal{R}$ on superhorizon scales.*

Statistics of Cosmological Perturbations

A crucial statistical measure of the primordial scalar fluctuations is the power spectrum of $\mathcal{R}$ (or ζ)[28]

$$\langle \mathcal{R}_{\mathbf{k}}\mathcal{R}_{\mathbf{k}'}\rangle = (2\pi)^3\,\delta(\mathbf{k}+\mathbf{k}')\,P_{\mathcal{R}}(k)\,, \qquad \Delta^2_{\rm s} \equiv \Delta^2_{\mathcal{R}} = \frac{k^3}{2\pi^2}P_{\mathcal{R}}(k)\,. \tag{459}$$

Here, $\langle\,\dots\,\rangle$ defines the ensemble average of the fluctuations. The scale-dependence of the power spectrum is defined by the scalar spectral index (or tilt)

$$n_{\rm s} - 1 \equiv \frac{d\ln\Delta^2_{\rm s}}{d\ln k}\,, \tag{460}$$

[28] The normalization of the dimensionless power spectrum $\Delta^2_{\mathcal{R}}(k)$ is chosen such that the variance of $\mathcal{R}$ is $\langle\mathcal{R}\mathcal{R}\rangle = \int_0^\infty \Delta^2_{\mathcal{R}}(k)\,{\rm d}\ln k$.

where scale-invariance corresponds to the value $n_{\rm s} = 1$. We may also define the running of the spectral index by

$$\alpha_{\rm s} \equiv \frac{dn_{\rm s}}{d\ln k}\,. \tag{461}$$

The power spectrum is often approximated by a power law form

$$\Delta^2_{\rm s}(k) = A_{\rm s}(k_\star)\left(\frac{k}{k_\star}\right)^{n_{\rm s}(k_\star)-1+\frac{1}{2}\alpha_{\rm s}(k_\star)\ln(k/k_\star)}\,, \tag{462}$$

where $k_\star$ is an arbitrary reference or pivot scale.

If $\mathcal{R}$ is Gaussian then the power spectrum contains all the statistical information. Primordial non-Gaussianity is encoded in higher-order correlation functions of $\mathcal{R}$. In single-field slow-roll inflation the non-Gaussianity is predicted to be small [23, 22], but non-Gaussianity can be significant in multi-field models or in single-field models with non-trivial kinetic terms and/or violation of the slow-roll conditions. We will return to primordial non-Gaussianity in **Lecture 4**. In this lecture we restrict our computation to Gaussian fluctuations and the associated power spectra.

The power spectrum for the two polarization modes of h_{ij}, *i.e.* $h \equiv h^+, h^\times$, is defined as

$$\langle h_{\mathbf{k}} h_{\mathbf{k}'}\rangle = (2\pi)^3\,\delta(\mathbf{k}+\mathbf{k}')\,P_h(k)\,, \qquad \Delta^2_h = \frac{k^3}{2\pi^2}P_h(k)\,. \tag{463}$$

We define the power spectrum of tensor perturbations as the sum of the power spectra for the two polarizations

$$\Delta^2_{\rm t} \equiv 2\Delta^2_h\,. \tag{464}$$

Its scale-dependence is defined analogously to Eqn. (460) but for historical reasons without the -1,

$$n_{\rm t} \equiv \frac{d\ln\Delta^2_{\rm t}}{d\ln k}\,, \tag{465}$$

i.e.

$$\Delta^2_{\rm t}(k) = A_{\rm t}(k_\star)\left(\frac{k}{k_\star}\right)^{n_{\rm t}(k_\star)}\,. \tag{466}$$

Aim of this Lecture

It will be the aim of this lecture to compute the power spectra of scalar and tensor fluctuations, $P_{\mathcal{R}}(k)$ and $P_h(k)$, from first principles. This is one of the most important calculations in modern theoretical cosmology, so to understand it will be well worth our efforts.

Uniform Density Gauge

Comoving Gauge

Spatially-Flat Gauge

7.4.2 *Preview*: The Quantum Origin of Structure

In the last lecture we discussed the classical evolution of the inflaton field. Something remarkable happens when one considers quantum fluctuations of the inflaton: inflation combined with quantum mechanics provides an elegant mechanism for generating the initial seeds of all structure in the universe. In other words, quantum fluctuations during inflation are the source of the primordial power spectra of scalar and tensor fluctuations, $P_{\rm s}(k)$ and $P_{\rm t}(k)$. In this section we sketch the mechanism by which inflation relates microscopic physics to macroscopic observables. In §7.4.4 we present the full calculation.

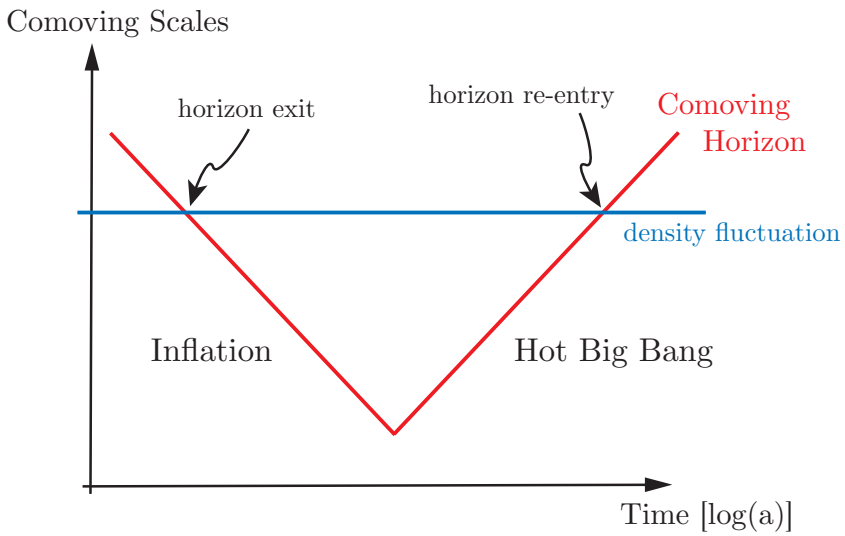

Figure 68: Creation and evolution of perturbations in the inflationary universe. Fluctuations are created quantum mechanically on subhorizon scales. While comoving scales, k^{-1}, remain constant the comoving Hubble radius during inflation, $(aH)^{-1}$, shrinks and the perturbations exit the horizon. Causal physics cannot act on superhorizon perturbations and they freeze until horizon re-entry at late times.

Quantum Zero-Point Fluctuations

As we will explain quantitatively in §7.4.4 quantum fluctuations during inflation induce a non-zero variance for fluctuations in all light fields (like the inflaton or the metric perturbations). This is very similar to the variance in the amplitude of a harmonic oscillator induced by zero-point fluctuations in the ground state; see §7.4.3. The amplitude of fluctuations scales with the expansion parameter H during inflation. This relates to the de Sitter horizon, H^{-1}, and the quantum fluctuations during inflation may also be interpreted as thermal fluctuations in de Sitter space in close analogy to the Hawking radiation for black holes.

Fluctuations are created on all length scales, *i.e.* with a spectrum of wavenumbers k. Cosmologically relevant fluctuations start their lives inside the horizon (Hubble radius),

$$\text{subhorizon}: \quad k \gg aH\,. \tag{467}$$

However, while the comoving wavenumber is constant the comoving Hubble radius shrinks during inflation (recall this is how we 'defined' inflation!), so eventually all fluctuations *exit the horizon*

$$\text{superhorizon}: \quad k < aH\,. \tag{468}$$

Horizon Exit and Re-Entry

Cosmological inhomogeneity is characterized by the intrinsic curvature of spatial hypersurfaces defined with respect to the matter, $\mathcal{R}$ or ζ. Both $\mathcal{R}$ and ζ have the attractive feature that they remain constant outside the horizon, *i.e.* when $k < aH$. In particular, their amplitude is *not* affected by the unknown physical properties of the universe shortly after inflation (recall that we know next to nothing about the details of reheating; it is the constancy of $\mathcal{R}$ and ζ outside the horizon that allows us to nevertheless predict cosmological observables). After inflation, the comoving horizon grows, so eventually all fluctuations will re-enter the horizon. After horizon re-entry, $\mathcal{R}$ or ζ determine the perturbations of the cosmic fluid resulting in the observed CMB anisotropies and the LSS.

In **Lecture 1** we explained the evolution of the comoving horizon during inflation and in the standard FRW expansion after inflation. In this lecture (**Lecture 2**) we will compute the primordial power spectrum of comoving curvature fluctuations $\mathcal{R}$ at horizon exit. In the next lecture (**Lecture 3**) we will compute the relation of curvature fluctuations $\mathcal{R}$ to fluctuations in cosmological observables after horizon re-entry. Together these three lectures therefore provide a complete account of both the generation and the observational consequences of the quantum fluctuations produced by inflation. It is a beautiful story. Let us begin to unfold it.

7.4.3 Quantum Mechanics of the Harmonic Oscillator

> "The career of a young theoretical physicist consists of treating the harmonic oscillator in ever-increasing levels of abstraction."
>
> *Sidney Coleman*

The computation of quantum fluctuations generated during inflation is algebraically quite intensive and it is therefore instructive to start with a simpler example which nevertheless contains most of the relevant physics. We therefore warm up by considering the quantization of a one-dimensional simple harmonic oscillator. Harmonic oscillators are one of the few physical systems that physicists know how to solve exactly. Fortunately, almost all more complicated physical systems can be represented by a collection of simple harmonic oscillators with different amplitudes and frequencies. This is of course what Fourier analysis is all about. We will show below that free fields in curved spacetime (and de Sitter space in particular) are similar to collections of harmonic oscillators with time-dependent frequencies. The detailed treatment of the quantum harmonic oscillator in this section will therefore not be in vain, but will provide important intuition for the inflationary calculation. This section is based on the excellent treatment of [26].

Action

The classical action of a harmonic oscillator with time-dependent frequency is

$$S = \int \mathrm{d}t \left(\frac{1}{2}\dot{x}^2 - \frac{1}{2}\omega^2(t)x^2 \right) \equiv \int \mathrm{d}t\, L\,, \tag{469}$$

where x is the deviation of the particle from its equilibrium state, $x \equiv 0$, and for convenience we have set the particle mass to one, $m \equiv 1$. For concreteness one may wish to consider a particle of mass m on a spring which is heated by an external source so that its spring constant depends on time, $k(t)$, where $\omega^2 = k/m$. The classical equation of motion follows from variation of the action with respect to the particle coordinate x

$$\frac{\delta S}{\delta x} = 0 \quad \Rightarrow \quad \boxed{\ddot{x} + \omega^2(t)\, x = 0}\,. \tag{470}$$

Canonical Quantization

Canonical quantization of the system proceeds in the standard way: We define the momentum conjugate to x

$$p \equiv \frac{dL}{d\dot{x}} = \dot{x}, \tag{471}$$

which agrees with the standard notion of the particle's momentum $p = mv$. We then promote the classical variables x, p to quantum operators $\hat{x}$, $\hat{p}$ and impose the canonical commutator

$$\boxed{[\hat{x}, \hat{p}] = i\hbar}\,, \tag{472}$$

where $[\hat{x}, \hat{p}] \equiv \hat{x}\hat{p} - \hat{p}\hat{x}$. The equation of motion implies that the commutator holds at all times if imposed at some initial time. In particular, for our present example

$$[x(t), \dot{x}(t)] = i\hbar\,. \tag{473}$$

Note that we are in the Heisenberg picture where operators vary in time while states are time-independent. The operator $\hat{x}$ is then expanded in terms of creation and annihilation operators

$$\boxed{\hat{x} = v(t)\,\hat{a} + v^*(t)\,\hat{a}^\dagger}\,, \tag{474}$$

where the (complex) mode function satisfies the classical equation of motion

$$\ddot{v} + \omega^2(t)v = 0\,. \tag{475}$$

The commutator (472) becomes

$$\langle v, v\rangle[\hat{a}, \hat{a}^\dagger] = 1\,, \tag{476}$$

where

$$\langle v, w\rangle \equiv \frac{i}{\hbar}\left(v^*\partial_t w - (\partial_t v^*)w\right)\,. \tag{477}$$

Without loss of generality, let us assume that the solution v is chosen so that the real number $\langle v, v\rangle$ is positive. The function v can then be rescaled such that $\langle v, v\rangle \equiv 1$ and hence

$$\boxed{[\hat{a}, \hat{a}^\dagger] = 1}\,. \tag{478}$$

Eqn. (478) is the standard relation for the raising and lowering operators of a harmonic oscillator. We have hence identified the following annihilation and creation operators

$$\hat{a} = \langle v, \hat{x}\rangle \tag{479}$$

$$\hat{a}^\dagger = -\langle v^*, \hat{x}\rangle\,, \tag{480}$$

and can define the vacuum state $|0\rangle$ via the prescription

$$\boxed{\hat{a}|0\rangle = 0}\,, \tag{481}$$

i.e. the vacuum is annihilated by $\hat{a}$. Excited states of the system are created by repeated application of creation operators

$$|n\rangle \equiv \frac{1}{\sqrt{n!}}(\hat{a}^\dagger)^n|0\rangle\,. \tag{482}$$

These states are eigenstates of the number operator $\hat{N} = \hat{a}^\dagger\hat{a}$ with eigenvalue n, *i.e.*

$$\hat{N}|n\rangle = n|n\rangle\,. \tag{483}$$

Non-Uniqueness of the Mode Functions

We haven't yet determined unique mode functions and hence we haven't fixed the vacuum state. Any change in $v(t)$ that keeps the solution $x(t)$ unchanged will lead to a change in the creating operator $\hat{a} = \langle v, \hat{x}\rangle$ and hence a change in the definition of the vacuum. For the simple harmonic oscillator with time-dependent frequency $\omega(t)$ (and for quantum fields in curved spacetime) there is in fact *no* unique choice for the mode function $v(t)$. Hence, there is *no* unique decomposition of $\hat{x}$ into annihilation and creation operators and *no* unique notion of the vacuum. Different choices for the solution $v(t)$ give different vacuum solutions. This problem

and its standard (but not uncontested) resolution in the case of inflation will be discussed in more detail below.

In the present case we can make progress by considering the special case of a constant-frequency harmonic oscillator[29] $\omega(t) = \omega$. In that case a preferred choice of $v(t)$ is the one that makes the vacuum state $|0\rangle$ the ground state of the Hamiltonian. First, we evaluate the Hamiltonian for a general mode function $v(t)$,

$$\begin{aligned} \hat{H} &= \frac{1}{2}\hat{p}^2 + \frac{1}{2}\omega^2\hat{x}^2 \\ &= \frac{1}{2}\left[(\dot{v}^2 + \omega^2 v^2)\hat{a}\hat{a} + (\dot{v}^2 + \omega^2 v^2)^*\,\hat{a}^\dagger\hat{a}^\dagger + (|\dot{v}|^2 + \omega^2|v|^2)(\hat{a}\hat{a}^\dagger + \hat{a}^\dagger\hat{a})\right] . \end{aligned} \tag{484}$$

Using $\hat{a}|0\rangle = 0$ and $[\hat{a}, \hat{a}^\dagger] = 1$, we hence find the following action of the Hamiltonian operator on the vacuum state

$$\hat{H}|0\rangle = \frac{1}{2}(\dot{v}^2 + \omega^2 v^2)^*\,\hat{a}^\dagger\hat{a}^\dagger|0\rangle + \frac{1}{2}(|\dot{v}|^2 + \omega^2|v|^2)|0\rangle\,. \tag{485}$$

The requirement that $|0\rangle$ be an eigenstate of $\hat{H}$ means that the first term must vanish which implies the condition

$$\dot{v} = \pm i\omega v\,, \tag{486}$$

and hence

$$\langle v, v\rangle = \mp\frac{2\omega}{\hbar}|v|^2\,. \tag{487}$$

Positivity of the normalization condition $\langle v, v\rangle > 0$ selects the minus sign in Eqn. (486)

$$\dot{v} = -i\omega v\,. \tag{488}$$

Properly normalized ($\langle v, v\rangle = 1$) this gives the following *positive-frequency solution*

$$\boxed{v(t) = \sqrt{\frac{\hbar}{2\omega}}\,e^{-i\omega t}}\,. \tag{489}$$

With this choice of mode function v the Hamiltonian is

$$\hat{H} = \hbar\omega\left(\hat{N} + \frac{1}{2}\right)\,, \tag{490}$$

for which the vacuum $|0\rangle$ is the state of minimum energy $\hbar\omega/2$.

Exercise 7 (Non-Uniqueness for Time-Dependent Oscillators)**.** *What goes wrong with the above argument for the case of a simple harmonic oscillator with time-dependent frequency?*

Zero-Point Fluctuations in the Ground State

Consider the mean square expectation value of the position operator $\hat{x}$ in the ground state $|0\rangle$

$$\begin{aligned} \langle|\hat{x}|^2\rangle &\equiv \langle 0|\hat{x}^\dagger\hat{x}|0\rangle \\ &= \langle 0|(v^*\hat{a}^\dagger + v\hat{a})(v\hat{a} + v^*\hat{a}^\dagger)|0\rangle \\ &= |v(\omega,t)|^2\langle 0|\hat{a}\hat{a}^\dagger|0\rangle \\ &= |v(\omega,t)|^2\langle 0|[\hat{a}, \hat{a}^\dagger]|0\rangle \\ &= |v(\omega,t)|^2\,. \end{aligned} \tag{491}$$

[29] It will turn out that this is the relevant case for inflation at very early times when all modes are deep inside the horizon.

This characterizes the zero-point fluctuations of the position in the vacuum state as the square of the mode function

$$\boxed{\langle|\hat{x}|^2\rangle = |v(\omega,t)|^2} = \frac{\hbar}{2\omega}\,. \tag{492}$$

This is all we need to know about quantum mechanics to compute the fluctuation spectrum created by inflation. However, first we need to do quite a bit of work to derive the mode equation for the scalar mode of cosmological perturbations, *i.e.* the analogue of Eqn. (475).

7.4.4 Quantum Fluctuations in de Sitter Space

We have finally come to the highlight of this lecture: the full computation of the quantum-mechanical fluctuations generated during inflation and their relation to cosmological perturbations. Our calculation follows closely the treatment by Maldacena [22].

Summary of the Computational Strategy

The last two sections might have bored you, but they provided important background for the computation of inflationary fluctuations. We have defined the gauge-invariant curvature perturbation $\mathcal{R}$. It is conserved outside of the horizon, so we can compute it at horizon exit and remain ignorant about the subhorizon physics during and after reheating until horizon re-entry of a given $\mathcal{R}$-mode. We have recalled the quantization of the simple harmonic oscillator, so by writing the equation of motion for $\mathcal{R}$ in simple harmonic oscillator form we are in the position to study the quantization of scalar fluctuations during inflation.

Here is a summary of the steps we will perform in the following sections:

1. We expand the action for single-field slow-roll inflation to second order in fluctuations. Specially, we derive the second-order expansion of the action in terms of $\mathcal{R}$. The action approach guarantees the correct normalization for the quantization of fluctuations.

2. From the action we derive the equation of motion for $\mathcal{R}$ and show that it is of SHO form.

3. The mode equations for $\mathcal{R}$ will be hard to solve exactly so we consider several approximate solutions valid during slow-roll evolution.

4. We promote the classical field $\mathcal{R}$ to a quantum operator and quantize it. Imposing the canonical commutation relation for quantum operators will lead to a boundary condition on the mode functions. This doesn't fix the mode function completely.

5. We define the vacuum state by matching our solutions to the Minkowski vacuum in the ultraviolet, *i.e.* on small scales when the mode is deep inside the horizon. This fixes the mode functions completely and their large-scale limit is hence determined.

6. We then compute the power spectrum of curvature fluctuations at horizon crossing. In **Lecture 3** we will relate the power spectrum at horizon crossing during inflation to the angular power spectrum of CMB fluctuations at recombination.

Enough talking, let's compute!

Scalar Perturbations

We consider single-field slow-roll models of inflation defined by the action

$$S = \frac{1}{2}\int \mathrm{d}^4x\sqrt{-g}\,\left[R - (\nabla\phi)^2 - 2V(\phi)\right]\,, \tag{493}$$

in units where $M_{\rm pl}^{-2} \equiv 8\pi G = 1$. To fix time and spatial reparameterizations we choose the following gauge for the dynamical fields g_{ij} and ϕ

$$\delta\phi = 0\,, \qquad g_{ij} = a^2[(1-2\mathcal{R})\delta_{ij} + h_{ij}]\,, \qquad \partial_i h_{ij} = h^i_i = 0\,. \tag{494}$$

In this gauge the inflaton field is unperturbed and all scalar degrees of freedom are parameterized by the metric fluctuation $\mathcal{R}(t,\mathbf{x})$. An important property of $\mathcal{R}$ is that it remains constant outside the horizon. We can therefore restrict our computation to correlation functions of $\mathcal{R}$ at horizon crossing. The remaining metric perturbations Φ and B are related to $\mathcal{R}$ by the Einstein Equations; in the ADM formalism (see Appendix 7.8.2) these are pure constraint equations.

Free Field Action

With quite some effort (see Appendix 7.8.2) one may expand the action (493) to second order in $\mathcal{R}$

$$\boxed{S_{(2)} = \frac{1}{2}\int \mathrm{d}^4x\, a^3\frac{\dot\phi^2}{H^2}\left[\dot{\mathcal{R}}^2 - a^{-2}(\partial_i\mathcal{R})^2\right]}\,. \tag{495}$$

Defining the *Mukhanov variable*

$$v \equiv z\mathcal{R}\,, \qquad \text{where} \qquad z^2 \equiv a^2\frac{\dot\phi^2}{H^2} = 2a^2\varepsilon\,, \tag{496}$$

and transitioning to conformal time τ leads to the action for a canonically normalized scalar

$$\boxed{S_{(2)} = \frac{1}{2}\int \mathrm{d}\tau\mathrm{d}^3x\,\left[(v')^2 + (\partial_i v)^2 + \frac{z''}{z}v^2\right]}\,, \qquad (...)' \equiv \partial_\tau(...)\,. \tag{497}$$

Exercise 8 (Mukhanov Action)**.** *Confirm Eqn. (497). Hint: use integration by parts.*

We define the Fourier expansion of the field v

$$v(\tau,\mathbf{x}) = \int\frac{\mathrm{d}^3k}{(2\pi)^3}\,v_{\mathbf{k}}(\tau)e^{i\mathbf{k}\cdot\mathbf{x}}\,, \tag{498}$$

where

$$\boxed{v_k'' + \left(k^2 - \frac{z''}{z}\right)v_k = 0}\,. \tag{499}$$

Here, we have dropped to vector notation $\mathbf{k}$ on the subscript, since (499) depends only on the magnitude of k. The Mukhanov Equation (499) is hard to solve in full generality since the function z depends on the background dynamics. For a given inflationary background one may solve (499) numerically. However, to gain a more intuitive understanding of the solutions we will discuss approximate analytical solutions in the pure de Sitter limit (§7.4.4) and in the slow-roll approximation (**Problem 7**).

Quantization

The quantization of the field v is performed in completely analogy with our treatment of the quantum harmonic oscillator in §7.4.3.

As before we promote the field v and its conjugate momentum v' to quantum operator

$$v \quad \rightarrow \quad \hat{v} = \int \frac{\mathrm{d}\mathbf{k}^3}{(2\pi)^3} \left[v_k(\tau)\hat{a}_{\mathbf{k}} e^{i\mathbf{k}\cdot\mathbf{x}} + v_k^*(\tau)\hat{a}_{\mathbf{k}}^\dagger e^{-i\mathbf{k}\cdot\mathbf{x}} \right] . \tag{500}$$

Alternatively, the Fourier components $v_{\mathbf{k}}$ are promoted to operators and expressed via the following decomposition

$$v_{\mathbf{k}} \quad \rightarrow \quad \hat{v}_{\mathbf{k}} = v_k(\tau)\hat{a}_{\mathbf{k}} + v_{-k}^*(\tau)\hat{a}_{-\mathbf{k}}^\dagger \,, \tag{501}$$

where the creation and annihilation operators $\hat{a}_{-\mathbf{k}}^\dagger$ and $\hat{a}_{\mathbf{k}}$ satisfy the canonical commutation relation

$$[\hat{a}_{\mathbf{k}}, \hat{a}_{\mathbf{k}'}^\dagger] = (2\pi)^3 \delta(\mathbf{k} - \mathbf{k}') \,, \tag{502}$$

if and only if the mode functions are normalized as follows

$$\langle v_k, v_k \rangle \equiv \frac{i}{\hbar}(v_k^* v_k' - v_k^{*\prime} v_k) = 1 \,. \tag{503}$$

Eqn. (503) provides one of the boundary conditions on the solutions of Eqn. (499). The second boundary conditions that fixes the mode functions completely comes from *vacuum selection*.

Boundary Conditions and Bunch-Davies Vacuum

We must choose a vacuum state for the fluctuations,

$$\hat{a}_{\mathbf{k}}|0\rangle = 0 \,, \tag{504}$$

which corresponds to specifying an additional boundary conditions for v_k (see *e.g.* Chapter 3 in Birell and Davies [25]). The standard choice is the Minkowski vacuum of a comoving observer in the far past (when all comoving scales were far inside the Hubble horizon), $\tau \rightarrow -\infty$ or $|k\tau| \gg 1$ or $k \gg aH$. In this limit the mode equation (499) becomes

$$v_k'' + k^2 v_k = 0 \,. \tag{505}$$

This is the equation of a simple harmonic oscillator with time-independent frequency! For this case we showed that a unique solution (489) exists if we require the vacuum to be the minimum energy state. Hence we impose the initial condition

$$\boxed{\lim_{\tau \rightarrow -\infty} v_k = \frac{e^{-ik\tau}}{\sqrt{2k}}} \,. \tag{506}$$

The boundary conditions (503) and (506) completely fix the mode functions on *all* scales.

Solution in de Sitter Space

Consider the de Sitter limit $\varepsilon \rightarrow 0$ ($H = \text{const.}$) and

$$\frac{z''}{z} = \frac{a''}{a} = \frac{2}{\tau^2} \,. \tag{507}$$

In a de Sitter background we therefore wish to solve the mode equation

$$\boxed{v_k'' + \left(k^2 - \frac{2}{\tau^2} \right) v_k = 0} \,. \tag{508}$$

Exercise 9 (de Sitter Mode Functions)**.** *Verify by direct substitution that an exact solution to Eqn. (508) is*

$$v_k = \alpha \frac{e^{-ik\tau}}{\sqrt{2k}}\left(1 - \frac{i}{k\tau}\right) + \beta \frac{e^{ik\tau}}{\sqrt{2k}}\left(1 + \frac{i}{k\tau}\right). \tag{509}$$

The free parameters α and β characterize the non-uniqueness of the mode functions. However, we may fix α and β to unique values by considering the quantization condition (503) together with the subhorizon limit, $|k\tau| \gg 1$, Eqn. (506). This fixes $\alpha = 1$, $\beta = 0$ and leads to the unique Bunch-Davies mode functions

$$\boxed{v_k = \frac{e^{-ik\tau}}{\sqrt{2k}}\left(1 - \frac{i}{k\tau}\right)}. \tag{510}$$

Power Spectrum in Quasi-de Sitter

We then compute the power spectrum of the field $\hat{\psi}_{\mathbf{k}} \equiv a^{-1}\hat{v}_{\mathbf{k}}$,

$$\langle \hat{\psi}_{\mathbf{k}}(\tau)\hat{\psi}_{\mathbf{k}'}(\tau)\rangle = (2\pi)^3\delta(\mathbf{k}+\mathbf{k}')\frac{|v_k(\tau)|^2}{a^2} \tag{511}$$

$$= (2\pi)^3\delta(\mathbf{k}+\mathbf{k}')\frac{H^2}{2k^3}(1+k^2\tau^2)\,. \tag{512}$$

On superhorizon scales, $|k\tau| \ll 1$, this approaches a constant

$$\langle \hat{\psi}_{\mathbf{k}}(\tau)\hat{\psi}_{\mathbf{k}'}(\tau)\rangle \to (2\pi)^3\delta(\mathbf{k}+\mathbf{k}')\frac{H^2}{2k^3}\,. \tag{513}$$

or

$$\Delta^2_\psi = \left(\frac{H}{2\pi}\right)^2. \tag{514}$$

The de Sitter result for $\psi = v/a$, Eqn. (513), allows us to compute the power spectrum of $\mathcal{R} = \frac{H}{\dot{\phi}}\psi$ at horizon crossing, $a(t_\star)H(t_\star) = k$,

$$\langle \mathcal{R}_{\mathbf{k}}(t)\mathcal{R}_{\mathbf{k}'}(t)\rangle = (2\pi)^3\delta(\mathbf{k}+\mathbf{k}')\frac{H_\star^2}{2k^3}\frac{H_\star^2}{\dot{\phi}_\star^2}\,. \tag{515}$$

Here, $(...)_\star$ indicates that a quantity is to be evaluated at horizon crossing. We define the dimensionless power spectrum $\Delta^2_{\mathcal{R}}(k)$ by

$$\langle \mathcal{R}_{\mathbf{k}}\mathcal{R}_{\mathbf{k}'}\rangle = (2\pi)^3\delta(\mathbf{k}+\mathbf{k}')P_{\mathcal{R}}(k)\,, \qquad \Delta^2_{\mathcal{R}}(k) \equiv \frac{k^3}{2\pi^2}P_{\mathcal{R}}(k)\,, \tag{516}$$

such that the real space variance of $\mathcal{R}$ is $\langle \mathcal{R}\mathcal{R}\rangle = \int_0^\infty \Delta^2_{\mathcal{R}}(k)\,\mathrm{d}\ln k$. This gives

$$\boxed{\Delta^2_{\mathcal{R}}(k) = \frac{H_\star^2}{(2\pi)^2}\frac{H_\star^2}{\dot{\phi}_\star^2}}. \tag{517}$$

Since $\mathcal{R}$ approaches a constant on super-horizon scales the spectrum at horizon crossing determines the future spectrum until a given fluctuation mode re-enters the horizon.

The fact that we computed the power spectrum at a specific instant (horizon crossing, $a_\star H_\star = k$) implicitly extends the result for the pure de Sitter background to a slowly time-evolving quasi-de Sitter space. Different modes exit the horizon as slightly different times when $a_\star H_\star$ has a different value. This procedure gives the correct result for the power spectrum during slow-roll inflation (we prove this more rigorously in **Problem 7**.). For non-slow-roll inflation the background evolution will have to be tracked more precisely and the Mukhanov Equation typically has to be integrated numerically.

Spatially-Flat Gauge

In the previous sections we followed Maldacena and used the comoving gauge ($\delta\phi = 0$) to compute the scalar power spectrum. A popular alternative to obtain the same result is to use *spatially-flat gauge*. In spatially-flat gauge, perturbations in $\mathcal{R}$ are related to perturbations in the inflaton field value[30] $\delta\phi$, *cf.* Eqn. (454) with $\Psi = 0$

$$\mathcal{R} = H\frac{\delta\phi}{\dot{\phi}} \equiv -H\delta t\,. \tag{518}$$

The power spectrum of $\mathcal{R}$ and the power spectrum of inflaton fluctuations $\delta\phi$ are therefore related as follows

$$\langle \mathcal{R}_{\mathbf{k}}\mathcal{R}_{\mathbf{k}'}\rangle = \left(\frac{H}{\dot{\phi}}\right)^2 \langle \delta\phi_{\mathbf{k}}\,\delta\phi_{\mathbf{k}'}\rangle\,. \tag{519}$$

Finally, in the case of slow-roll inflation, quantum fluctuations of a light scalar field ($m_\phi \ll H$) in quasi-de Sitter space ($H \approx$ const.) scale with the Hubble parameter H, *cf.* Eqn. (514),

$$\langle \delta\phi_{\mathbf{k}}\,\delta\phi_{\mathbf{k}'}\rangle = (2\pi)^3\,\delta(\mathbf{k}+\mathbf{k}')\,\frac{2\pi^2}{k^3}\left(\frac{H}{2\pi}\right)^2, \qquad \Delta^2_{\delta\phi} = \left(\frac{H}{2\pi}\right)^2. \tag{520}$$

Inflationary quantum fluctuations therefore produce the following power spectrum for $\mathcal{R}$

$$\Delta^2_{\mathcal{R}}(k) = \frac{H^2_\star}{(2\pi)^2}\frac{H^2_\star}{\dot{\phi}^2_\star}\,. \tag{521}$$

This is consistent with our result (517).

Tensor Perturbations

Having discussed the quantization of scalar perturbation is some details, the corresponding calculation for tensor perturbations will appear almost trivial.

Action

By expansion of the Einstein-Hilbert action one may obtain the second-order action for tensor fluctuations is

$$S_{(2)} = \frac{M^2_{\rm pl}}{8}\int \mathrm{d}\tau\mathrm{d}x^3 a^2\left[(h'_{ij})^2 - (\partial_l h_{ij})^2\right]\,. \tag{522}$$

Here, we have reintroduced explicit factors of $M_{\rm pl}$ to make h_{ij} manifestly dimensionless. Up to a normalization factor of $\frac{M_{\rm pl}}{2}$ this is the same as the action for a massless scalar field in an FRW universe.

We define the following Fourier expansion

$$h_{ij} = \int \frac{\mathrm{d}^3k}{(2\pi)^3}\sum_{s=+,\times}\epsilon^s_{ij}(k)h^s_{\mathbf{k}}(\tau)e^{i\mathbf{k}\cdot\mathbf{x}}\,, \tag{523}$$

where $\epsilon_{ii} = k^i\epsilon_{ij} = 0$ and $\epsilon^s_{ij}(k)\epsilon^{s'}_{ij}(k) = 2\delta_{ss'}$. The tensor action (522) becomes

$$S_{(2)} = \sum_s \int \mathrm{d}\tau\mathrm{d}\mathbf{k}\frac{a^2}{4}M^2_{\rm pl}\left[h^{s\prime}_{\mathbf{k}}h^{s\prime}_{\mathbf{k}} - k^2 h^s_{\mathbf{k}}h^s_{\mathbf{k}}\right]\,. \tag{524}$$

[30] Intuitively, the curvature perturbation $\mathcal{R}$ is related to a spatially varying time-delay $\delta t(\mathbf{x})$ for the end of inflation. This time-delay is induced by the inflaton fluctuation $\delta\phi$.

We define the canonically normalized field

$$v_{\mathbf{k}}^s \equiv \frac{a}{2} M_{\rm pl} h_{\mathbf{k}}^s \,, \tag{525}$$

to get

$$\boxed{S_{(2)} = \sum_s \frac{1}{2} \int {\rm d}\tau {\rm d}^3\mathbf{k} \left[(v_{\mathbf{k}}^{s\prime})^2 - \left(k^2 - \frac{a''}{a} \right) (v_{\mathbf{k}}^s)^2 \right]}, \tag{526}$$

where

$$\frac{a''}{a} = \frac{2}{\tau^2} \tag{527}$$

holds in de Sitter space. This should be recognized as effectively two copies of the action (497).

Quantization

Each polarization of the gravitational wave is therefore just a renormalized massless field in de Sitter space

$$h_{\mathbf{k}}^s = \frac{2}{M_{\rm pl}} \psi_{\mathbf{k}}^s \,, \qquad \psi_{\mathbf{k}}^s \equiv \frac{v_{\mathbf{k}}}{a} \,. \tag{528}$$

Since we computed the power spectrum of $\psi = v/a$ in the previous section, $\Delta_\psi^2 = (H/2\pi)^2 {\rm m}$ we can simply right down the answer for Δ_h^2, the power spectrum for a single polarization of tensor perturbations,

$$\Delta_h^2(k) = \frac{4}{M_{\rm pl}^2} \left(\frac{H_\star}{2\pi} \right)^2 \,. \tag{529}$$

Again, the r.h.s. is to be evaluated at horizon exit. .

Power Spectrum

The dimensionless power spectrum of tensor fluctuations therefore is

$$\boxed{\Delta_{\rm t}^2 = 2\Delta_h^2(k) = \frac{2}{\pi^2} \frac{H_\star^2}{M_{\rm pl}^2}} \,. \tag{530}$$

The Tensor-to-Scalar Ratio

The Energy Scale of Inflation

Tensor fluctuations are often normalized relative to the (measured) amplitude of scalar fluctuations, $\Delta_{\rm s}^2 \equiv \Delta_{\mathcal{R}}^2 \sim 10^{-9}$. The *tensor-to-scalar ratio* is

$$r \equiv \frac{\Delta_{\rm t}^2(k)}{\Delta_{\rm s}^2(k)} \,. \tag{531}$$

Since $\Delta_{\rm s}^2$ is fixed and $\Delta_{\rm t}^2 \propto H^2 \approx V$, the tensor-to-scalar ratio is a direct measure of the energy scale of inflation

$$\boxed{V^{1/4} \sim \left(\frac{r}{0.01} \right)^{1/4} 10^{16}\,{\rm GeV}} \,. \tag{532}$$

Large values of the tensor-to-scalar ratio, $r \geq 0.01$, correspond to inflation occuring at GUT scale energies.

The Lyth Bound

Note from Eqns. (517) and (530) that the tensor-to-scalar ratio relates directly to the evolution of the inflaton as a function of e-folds N

$$r = \frac{8}{M_{\rm pl}^2}\left(\frac{d\phi}{dN}\right)^2 . \tag{533}$$

The total field evolution between the time when CMB fluctuations exited the horizon at $N_{\rm cmb}$ and the end of inflation at $N_{\rm end}$ can therefore be written as the following integral

$$\frac{\Delta\phi}{M_{\rm pl}} = \int_{N_{\rm end}}^{N_{\rm cmb}} {\rm d}N \sqrt{\frac{r}{8}} . \tag{534}$$

During slow-roll evolution, $r(N)$ doesn't evolve much and one may obtain the following approximate relation [26]

$$\boxed{\frac{\Delta\phi}{M_{\rm pl}} = \mathcal{O}(1) \times \left(\frac{r}{0.01}\right)^{1/2}}, \tag{535}$$

where $r(N_{\rm cmb})$ is the tensor-to-scalar ratio on CMB scales. Large values of the tensor-to-scalar ratio, $r > 0.01$, therefore correlate with $\Delta\phi > M_{\rm pl}$ or *large-field inflation*.

7.4.5 Primordial Spectra

The results for the power spectra of the scalar and tensor fluctuations created by inflation are

$$\Delta_{\rm s}^2(k) \equiv \Delta_{\mathcal{R}}^2(k) = \left.\frac{1}{8\pi^2}\frac{H^2}{M_{\rm pl}^2}\frac{1}{\varepsilon}\right|_{k=aH} , \tag{536}$$

$$\Delta_{\rm t}^2(k) \equiv 2\Delta_h^2(k) = \left.\frac{2}{\pi^2}\frac{H^2}{M_{\rm pl}^2}\right|_{k=aH} , \tag{537}$$

where

$$\varepsilon = -\frac{d\ln H}{dN} . \tag{538}$$

The horizon crossing condition $k = aH$ makes (536) and (537) functions of the comoving wavenumber k. The tensor-to-scalar ratio is

$$r \equiv \frac{\Delta_{\rm t}^2}{\Delta_{\rm s}^2} = 16\,\varepsilon_\star . \tag{539}$$

Scale-Dependence

The scale dependence of the spectra follows from the time-dependence of the Hubble parameter and is quantified by the spectral indices

$$n_{\rm s} - 1 \equiv \frac{d\ln\Delta_{\rm s}^2}{d\ln k} , \qquad n_{\rm t} \equiv \frac{d\ln\Delta_{\rm t}^2}{d\ln k} . \tag{540}$$

We split this into two factors

$$\frac{d\ln\Delta_{\rm s}^2}{d\ln k} = \frac{d\ln\Delta_{\rm s}^2}{dN} \times \frac{dN}{d\ln k} . \tag{541}$$

The derivative with respect to e-folds is

$$\frac{d\ln\Delta_{\rm s}^2}{dN} = 2\frac{d\ln H}{dN} - \frac{d\ln\varepsilon}{dN}\,. \tag{542}$$

The first term is just -2ε and the second term may be evaluated with the following result from Appendix 7.8.4

$$\frac{d\ln\varepsilon}{dN} = 2(\varepsilon-\eta)\,, \qquad \text{where} \quad \eta = -\frac{d\ln H_{,\phi}}{dN}\,. \tag{543}$$

The second factor in Eqn. (541) is evaluated by recalling the horizon crossing condition $k = aH$, or

$$\ln k = N + \ln H\,. \tag{544}$$

Hence

$$\frac{dN}{d\ln k} = \left[\frac{d\ln k}{dN}\right]^{-1} = \left[1 + \frac{d\ln H}{dN}\right]^{-1} \approx 1+\varepsilon\,. \tag{545}$$

To first order in the Hubble slow-roll parameters we therefore find

$$n_{\rm s} - 1 = 2\eta_\star - 4\varepsilon_\star\,. \tag{546}$$

Similarly, we find

$$n_{\rm t} = -2\varepsilon_\star\,. \tag{547}$$

Any deviation from perfect scale-invariance ($n_{\rm s} = 1$ and $n_{\rm t} = 0$) is an indirect probe of the inflationary dynamics as quantified by the parameters ε and η.

Slow-Roll Results

In the slow-roll approximation the Hubble and potential slow-roll parameters are related as follows

$$\varepsilon \approx \epsilon_{\rm v}\,, \qquad \eta \approx \eta_{\rm v} - \epsilon_{\rm v}\,. \tag{548}$$

The scalar and tensor spectra are then expressed purely in terms of $V(\phi)$ and $\epsilon_{\rm v}$ (or $V_{,\phi}$)

$$\Delta_{\rm s}^2(k) \approx \frac{1}{24\pi^2}\frac{V}{M_{\rm pl}^4}\frac{1}{\epsilon_{\rm v}}\bigg|_{k=aH}\,, \qquad \Delta_{\rm t}^2(k) \approx \frac{2}{3\pi^2}\frac{V}{M_{\rm pl}^4}\bigg|_{k=aH}\,. \tag{549}$$

The scalar spectral index is

$$\boxed{n_{\rm s} - 1 = 2\eta_{\rm v}^\star - 6\epsilon_{\rm v}^\star}\,. \tag{550}$$

The tensor spectral index is

$$\boxed{n_{\rm t} = -2\epsilon_{\rm v}^\star}\,, \tag{551}$$

and the tensor-to-scalar ratio is

$$\boxed{r = 16\epsilon_{\rm v}^\star}\,. \tag{552}$$

We see that single-field slow-roll models satisfy a consistency condition between the tensor-to-scalar ratio r and the tensor tilt $n_{\rm t}$

$$\boxed{r = -8n_{\rm t}}\,. \tag{553}$$

In the slow-roll approximation measurements of the scalar and tensor spectra relate directly to the shape of the potential $V(\phi)$, *i.e.* H is a measure of of the scale of the potential, $\epsilon_{\rm v}$ of its first derivative $V_{,\phi}$, $\eta_{\rm v}$ of its second derivative $V_{,\phi\phi}$, etc. Measurements of the amplitude and the scale-dependence of the cosmological perturbations therefore encode information about the potential driving the inflationary expansion. This allows to reconstruct a power series expansion of the potential around $\phi_{\rm cmb}$ (corresponding to the time when CMB fluctuations exited the horizon).

Case Study: $m^2\phi^2$ Inflation

Recall from **Lecture 1** the slow-roll parameters for $m^2\phi^2$ inflation evaluated at $\phi_\star = \phi_{\rm cmb}$, *i.e.* $N_{\rm cmb} \sim 60$ e-folds before the end of inflation

$$\epsilon_{\rm v}^\star = \eta_{\rm v}^\star = 2\left(\frac{M_{\rm pl}}{\phi_{\rm cmb}}\right)^2 = \frac{1}{2N_{\rm cmb}}\,. \tag{554}$$

To satisfy the normalization of scalar fluctuations, $\Delta_{\rm s}^2 \sim 10^{-9}$, we need to fix the inflaton mass to $m \sim 10^{-6}M_{\rm pl}$. To see this note that Eqn. (549) implies

$$\Delta_{\rm s}^2 = \frac{m^2}{M_{\rm pl}^2}\frac{N_{\rm cmb}^2}{3}\,. \tag{555}$$

The scalar spectral index $n_{\rm s}$ and the tensor-to-scalar ratio r evaluated at CMB scales are

$$\boxed{n_{\rm s}} = 1 + 2\eta_{\rm v}^\star - 6\epsilon_{\rm v}^\star = 1 - \frac{2}{N_{\rm cmb}} \approx \boxed{0.96}\,, \tag{556}$$

and

$$\boxed{r} = 16\epsilon_{\rm v}^\star = \frac{8}{N_{\rm cmb}} \approx \boxed{0.1}\,. \tag{557}$$

These predictions of one of the simplest inflationary models are something to look out for in the near future.

7.5 Contact with Observations by Baumann 3rd lecture

Abstract

In this lecture we describe the inverse problem of extracting information on the inflationary perturbation spectra from observations of the cosmic microwave background and the large-scale structure. We define the precise relations between the scalar and tensor power spectra computed in the previous lecture and the observed CMB anisotropies and the galaxy power spectrum. We describe the transfer functions that relate the primordial fluctuations to the late-time observables. We then use these results to discuss the current observational evidence for inflation. Finally, we indicate opportunities for future tests of inflation.

7.5.1 Connecting Observations to the Early Universe

> "It doesn't matter how beautiful your theory is, it doesn't matter how smart you are or what your name is. If it doesn't agree with experiment, it's wrong."
>
> *Richard Feynman*

In the last lecture we computed the power spectra of the primordial scalar and tensor fluctuations $\mathcal{R}$ and h at horizon exit. In this lecture we relate these results to observations of the cosmic microwave background (CMB) and the large-scale structure (LSS). Making this correspondence explicit is crucial for constraining the inflationary predictions.

The curvature perturbation $\mathcal{R}$ and the gravitational wave amplitude h both freeze at constant values once the mode exits the horizon, $k = a(\tau_\star)H(\tau_\star)$. In the previous lecture we therefore computed the primordial perturbations at the time of horizon exit, $\tau_\star$. To relate this to a cosmological observable (like the CMB temperature or the density of galaxies) we need to

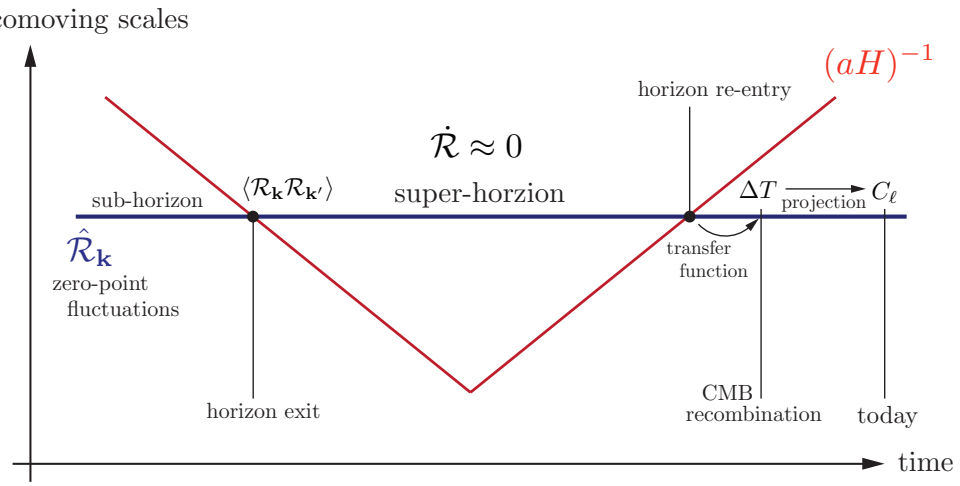

Figure 69: Creation and evolution of perturbations in the inflationary universe. Fluctuations are created quantum mechanically on subhorizon scales (see **Lecture 2**). While comoving scales, k^{-1}, remain constant the comoving Hubble radius during inflation, $(aH)^{-1}$, shrinks and the perturbations exit the horizon and freeze until horizon re-entry at late times. After horizon re-entry the fluctuations evolve into anisotropies in the CMB and perturbations in the LSS. This time-evolution has to be accounted for to relate cosmological observations to the primordial perturbations laid down by inflation (see **Lecture 3**).

i) relate $\mathcal{R}$ (or h) to the quantity $\mathcal{Q}$ that is actually measured in an experiment and

ii) take into account the time evolution of $\mathcal{R}$ (and $\mathcal{Q}$) once it re-enters the horizon.

Schematically, we may write

$$\boxed{\mathcal{Q}_{\mathbf{k}}(\tau) = T_{\mathcal{Q}}(k, \tau, \tau_\star)\, \mathcal{R}_{\mathbf{k}}(\tau_\star)}\,, \tag{558}$$

where $T_{\mathcal{Q}}$ is the *transfer function* between $\mathcal{R}$ fluctuations at time $\tau_\star$ and $\mathcal{Q}$ fluctuations at some later time τ. As we have indicated the transfer function may depend on scale. The quantity $\mathcal{Q}$ may be the temperature fluctuations measured by a CMB satellite such as the Wilkinson Microwave Anisotropy Probe (WMAP) or the galaxy density inferred in a galaxy survey such as the Sloan Digital Sky Survey (SDSS).

CMB anisotropies

The main result of §7.5.2 will be the following relation between the inflationary input spectra $P(k) \equiv \{P_{\mathcal{R}}(k), P_h(k)\}$ and the angular power spectra of CMB temperature fluctuations and polarization

$$\boxed{C_\ell^{XY} = \frac{2}{\pi} \int k^2 \mathrm{d}k \underbrace{P(k)}_{\text{Inflation}} \underbrace{\Delta_{X\ell}(k) \Delta_{Y\ell}(k)}_{\text{Anisotropies}}}\,, \tag{559}$$

where

$$\Delta_{X\ell}(k) = \int_0^{\tau_0} \mathrm{d}\tau \underbrace{S_X(k, \tau)}_{\text{Sources}} \underbrace{P_{X\ell}(k[\tau_0 - \tau])}_{\text{Projection}}\,. \tag{560}$$

The labels X, Y refer to temperature T and polarization modes E and B (see §7.5.2). The integral (559) relates the inhomogeneities predicted by inflation, $P(k)$, to the anisotropies observed in the CMB, C_ℓ^{XY}. The correlations between the different X and Y modes are related by the transfer functions $\Delta_{X\ell}(k)$ and $\Delta_{Y\ell}(k)$. The transfer functions may be written as the line-of-sight integral (560) which factorizes into physical source terms $S_X(k, \tau)$ and geometric

projection factors $P_{X\ell}(k[\tau_0 - \tau])$ (combinations of Bessel functions). A derivation of the source terms and the projection factors is beyond the scope of this lecture, but may be found in Dodelson's book [8]. An intuitive explanation for these results may be found in the animations on Wayne Hu's website [27].

Our interest in this lecture lies in experimental constraints on the primordial power spectra $P_{\mathcal{R}}(k)$ and $P_h(k)$. To measure the primordial spectra the observed CMB anisotropies C_ℓ^{XY} need to be *deconvolved* by taking into account the appropriate transfer functions and projection effects, *i.e.* for a given background cosmology we can compute the evolution and projection effects in Eqn. (559) and therefore extract the inflationary initial conditions $P(k)$. By this deconvolution procedure, the CMB provides a fascinating probe of the early universe.

Large-scale structure

To study fluctuations in the matter distribution (as measured *e.g.* by the distribution of galaxies on the sky) we define the density contrast $\delta \equiv \delta\rho/\bar{\rho}$. We distinguish between fluctuations in the density of galaxies δ_g and the dark matter density δ. A common assumption is that galaxies are (biased) tracers of the underlying dark matter distribution, $\delta_g = b\,\delta$. If we have an independent way of determining the *bias* parameter b, we can use observations of the galaxy density contrast δ_g to infer the underlying dark matter distribution δ. The late-time power spectrum of dark matter density fluctuations is related to the primordial spectrum of curvature fluctuations as follows

$$\boxed{P_\delta(k,\tau) = \frac{4}{25}\left(\frac{k}{aH}\right)^4 T_\delta^2(k,\tau) P_{\mathcal{R}}(k)}\,. \tag{561}$$

The numerical factor and the k-scaling that have been factored out from the transfer function is conventional. The transfer function T_δ reflects the relative growth of fluctuations during matter domination, $\delta \sim a$, and radiation domination, $\delta \sim \ln a$. It usually has to be computed numerically using codes such as CMBFAST [28] or CAMB [166], however, in §7.5.3 we will cite useful fitting functions for T_δ. Again, since for a fixed background cosmology the transfer function can be assumed as given, observations of the matter power spectrum can be a probe of the initial fluctuations from the early universe.

7.5.2 *Review*: The Cosmic Microwave Background

We give a very brief review of the physics and the statistical interpretation of CMB fluctuations. More details may be found in Dodelson's book [8] or Prof. Pierpaoli's lectures at *TASI 2009*.

Temperature Anisotropies

Harmonic Expansion

Figure 70 shows a map of the measured CMB temperature fluctuations $\Delta T(\hat{n})$ relative to the background temperature $T_0 = 2.7$ K. Here the unit vector $\hat{n}$ denotes the direction in sky. The harmonic expansion of this map is

$$\Theta(\hat{n}) \equiv \frac{\Delta T(\hat{n})}{T_0} = \sum_{\ell m} a_{\ell m} Y_{\ell m}(\hat{n})\,, \tag{562}$$

where

$$a_{\ell m} = \int \mathrm{d}\Omega\, Y^*_{\ell m}(\hat{n})\Theta(\hat{n})\,. \tag{563}$$

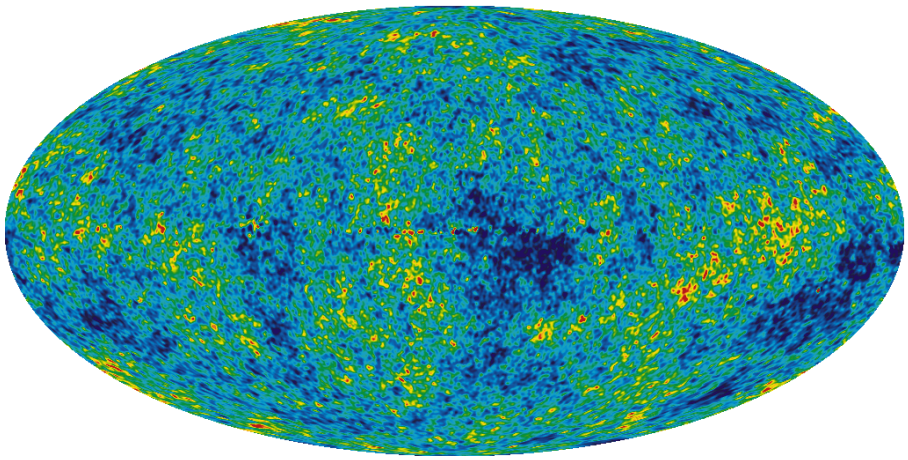

Figure 70: Temperature fluctuations in the CMB. Blue spots represent directions on the sky where the CMB temperature is $\sim 10^{-5}$ below the mean, $T_0 = 2.7$ K. This corresponds to photons losing energy while climbing out of the gravitational potentials of overdense regions in the early universe. Yellow and red indicate hot (underdense) regions. The statistical properties of these fluctuations contain important information about both the background evolution and the initial conditions of the universe.

Here, $Y_{\ell m}(\hat{n})$ are the standard spherical harmonics on a 2-sphere with $\ell = 0$, $\ell = 1$ and $\ell = 2$ corresponding to the monopole, dipole and quadrupole, respectively. The magnetic quantum numbers satisfy $m = -\ell, \ldots, +\ell$. The multipole moments $a_{\ell m}$ may be combined into the rotationally-invariant angular power spectrum

$$C_\ell^{TT} = \frac{1}{2\ell+1} \sum_m \langle a_{\ell m}^* a_{\ell m} \rangle \,, \qquad \text{or} \qquad \langle a_{\ell m}^* a_{\ell' m'} \rangle = C_\ell^{TT} \delta_{\ell\ell'} \delta_{mm'} \,. \tag{564}$$

The angular power spectrum is an important tool in the statistical analysis of the CMB. It describes the cosmological information contained in the millions of pixels of a CMB map in terms of a much more compact data representation. Figure 71 shows the most recent measurements of the CMB angular power spectrum. The figure also shows a fit of the theoretical prediction for the CMB spectrum to the data. The theoretical curve depends both on the background cosmological parameters and on the spectrum of initial fluctuations. We hence can use the CMB as a probe of both.

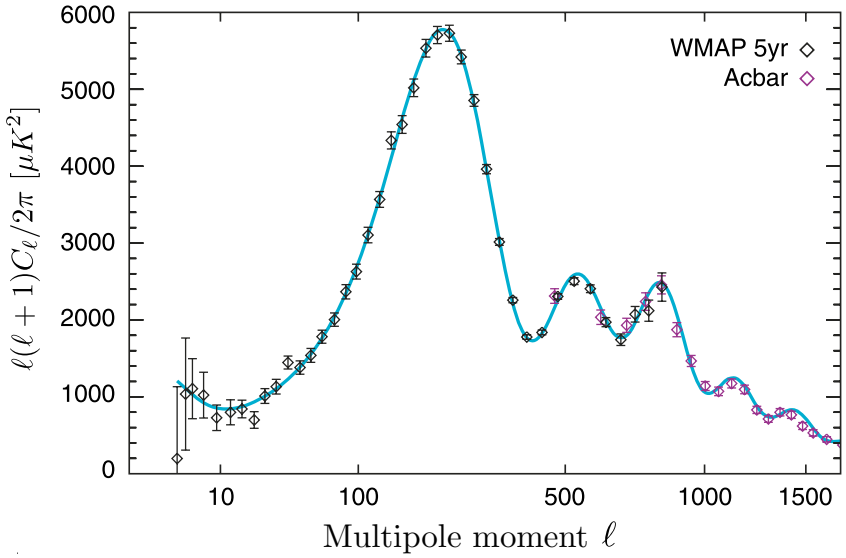

Figure 71: Angular power spectrum of CMB temperature fluctuations.

CMB temperature fluctuations are dominated by the *scalar* modes $\mathcal{R}$ (at least for the values of the tensor-to-scalar ratio now under consideration, $r < 0.3$). The linear evolution which relates $\mathcal{R}$ and ΔT is mediated by the transfer function $\Delta_{T\ell}(k)$ through the k-space integral [8]

$$\boxed{a_{\ell m} = 4\pi(-i)^\ell \int \frac{\mathrm{d}^3k}{(2\pi)^3}\, \Delta_{T\ell}(k)\, \mathcal{R}_{\mathbf{k}}\, Y_{\ell m}(\hat{\mathbf{k}})}\,. \tag{565}$$

Substituting (565) into (564) and using the identity

$$\sum_{m=-\ell}^{\ell} Y_{\ell m}(\hat{\mathbf{k}}) Y_{\ell m}(\hat{\mathbf{k}}') = \frac{2\ell+1}{4\pi} P_\ell(\hat{\mathbf{k}}\cdot\hat{\mathbf{k}}')\,, \tag{566}$$

we find

$$C_\ell^{TT} = \frac{2}{\pi}\int k^2 \mathrm{d}k \underbrace{P_{\mathcal{R}}(k)}_{\text{Inflation}} \underbrace{\Delta_{T\ell}(k)\Delta_{T\ell}(k)}_{\text{Anisotropies}}\,. \tag{567}$$

The transfer functions $\Delta_{T\ell}(k)$ generally have to be computed numerically using Boltzmann-codes such as CMBFAST [28] or CAMB [166]. They depend on the parameters of the background cosmology. Assuming a fixed background cosmology the shape of the power spectrum C_ℓ^{TT} contains information about the initial conditions as described by the primoridial power spectrum $P_{\mathcal{R}}(k)$.[31] Of course, learning from observations about $P_{\mathcal{R}}(k)$ and hence about inflation is the primary objective of this lecture.

Large Scales

On large scales, modes were still outside of the horizon at recombination. The large-scale CMB spectrum has therefore not been affected by subhorizon evolution and is simply the geometric projection of the primordial spectrum from recombination to us today. In this *Sachs-Wolfe regime* the transfer function $\Delta_{T\ell}(k)$ is simply a Bessel function [8]

$$\Delta_{T\ell}(k) = \frac{1}{3} j_\ell(k[\tau_0 - \tau_{\mathrm{rec}}])\,. \tag{568}$$

The angular power spectrum on large scales (small ℓ) therefore is

$$C_\ell^{TT} = \frac{2}{9\pi}\int k^2 \mathrm{d}k\, P_{\mathcal{R}}(k)\, j_\ell^2(k[\tau_0 - \tau_{\mathrm{rec}}])\,. \tag{569}$$

The Bessel projection function is peaked at $k[\tau_0 - \tau_{\mathrm{rec}}] \approx \ell$ and so effectively acts like a δ-function mapping between k and ℓ. Given that modes with wavenumber $k \approx \ell/(\tau_0 - \tau_{\mathrm{rec}})$ domintate the integral in Eqn. (569), we can write

$$C_\ell^{TT} \propto k^3 P_{\mathcal{R}}(k)\big|_{k\approx\ell/(\tau_0-\tau_{\mathrm{rec}})} \underbrace{\int \mathrm{d}\ln x\; j_\ell^2(x)}_{\propto \ell(\ell+1)}\,. \tag{570}$$

Hence,

$$\ell(\ell+1)C_\ell^{TT} \propto \Delta_{\mathrm{s}}^2(k)\big|_{k\approx\ell/(\tau_0-\tau_{\mathrm{rec}})} \propto \ell^{n_{\mathrm{s}}-1}\,. \tag{571}$$

For a scale-invariant input spectrum, $n_{\mathrm{s}} = 1$, the quantity

$$\mathcal{C}_\ell \equiv \frac{\ell(\ell+1)}{2\pi} C_\ell^{TT} \tag{572}$$

is independent of ℓ (except for a rise at very low ℓ due to the integrated Sachs-Wolfe effect arising from the late-time evolution of the gravitational potential in a dark energy dominated universe). This explains why the CMB power spectrum is often plotted for $\mathcal{C}_\ell$ instead of C_ℓ^{TT}.

[31] In practice, the CMB data is fit simultaneously to the background cosmology and a spectrum of fluctuations.

Non-Gaussianity

So far we have shown that the angular power spectrum of CMB fluctuations essentially is a measure of the primordial power spectrum $P_{\mathcal{R}}(k)$ if we take into account subhorizon evolution and geometric projection effects

$$\langle a^*_{\ell m} a_{\ell' m'} \rangle = C_\ell^{TT} \delta_{\ell\ell'} \delta_{mm'} \quad \Leftrightarrow \quad \langle \mathcal{R}_{\mathbf{k}} \mathcal{R}_{\mathbf{k}'} \rangle = (2\pi)^3 P_{\mathcal{R}}(k)\, \delta(\mathbf{k} + \mathbf{k}') \,. \tag{573}$$

If the primordial fluctuations are Gaussian then $P_{\mathcal{R}}(k)$ contains all the information. Single-field slow-roll inflation in fact predicts that $\mathcal{R}$ should be Gaussian to a very high degree [22]. However, as we explain in **Lecture 4**, even a small amount of non-Gaussianity would provide crucial information about the inflationary action as it would require to go beyond the simplest single-field slow-roll models.

The primary measure of non-Gaussianity is the *three-point function* or equivalently the *bispectrum*

$$\langle \mathcal{R}_{\mathbf{k}_1} \mathcal{R}_{\mathbf{k}_2} \mathcal{R}_{\mathbf{k}_3} \rangle = (2\pi)^3 B_{\mathcal{R}}(k_1, k_2, k_3)\, \delta(\mathbf{k}_1 + \mathbf{k}_2 + \mathbf{k}_3) \,. \tag{574}$$

In the CMB a non-zero bispectrum $B_{\mathcal{R}}(k_1, k_2, k_3)$ leaves a signature in the angular bispectrum

$$B^{\ell_1 \ell_2 \ell_3}_{m_1 m_2 m_3} = \langle a_{\ell_1 m_1} a_{\ell_2 m_2} a_{\ell_3 m_3} \rangle \,. \tag{575}$$

Substituting (565) into (575) we may relate the primordial bispectrum to the observed CMB bispectrum [30].[32]

Note that the primordial bispectrum $B_{\mathcal{R}}(k_1, k_2, k_3)$ is a function of three momenta subject only to momentum conservation (*i.e.* the three vectors $\mathbf{k}_i$ form a closed triangle). This makes observational constraints on non-Gaussianity challenging (there are many different forms of non-Gaussianity to consider), but also means that if detected non-Gaussianity contains a lot of information about the physics of the early universe.

A simple model of primoridal non-Gaussianity is *local non-Gaussianity* defined by a Taylor expansion of the curvature perturbation around the Gaussian part $\mathcal{R}_g$

$$\mathcal{R}(\mathbf{x}) = \mathcal{R}_g(\mathbf{x}) + \frac{3}{5} f^{\mathcal{R}}_{\rm NL} \star \mathcal{R}_g^2(\mathbf{x}) \,. \tag{576}$$

This is local in real space and the parameter $f^{\mathcal{R}}_{\rm NL}$ characterizes the level of non-Gaussianity. The reader is invited to show that Eqn. (576) implies the following simple form for the bispectrum

$$B_{\mathcal{R}}(k_1, k_2, k_3) = \frac{6}{5} f^{\mathcal{R}}_{\rm NL} \Big[P_{\mathcal{R}}(k_1) P_{\mathcal{R}}(k_2) + P_{\mathcal{R}}(k_2) P_{\mathcal{R}}(k_3) + P_{\mathcal{R}}(k_3) P_{\mathcal{R}}(k_1) \Big] \,. \tag{577}$$

Present observational constraints on non-Gaussianity are therefore often phrased as constraints on the parameter $f^{\mathcal{R}}_{\rm NL}$ (see §7.5.4).

Polarization

CMB polarization is likely to become one of the most important tools to probe the physics governing the early universe. In addition to anisotropies in the CMB temperature, we expect the CMB to become polarized via Thomson scattering [8]. As we now explain, this polarization contains crucial information about the primordial fluctuations and hence about inflation [7].

[32] Non-linear evolution can lead to additional non-Gaussianity (see **Lecture 4**).

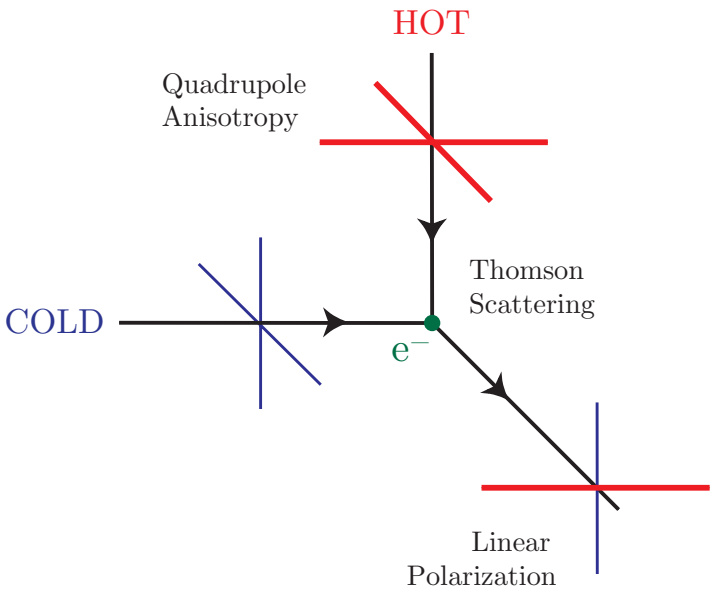

Figure 72: Linear polarization is generation via Thomson scattering of radiation with a quadrupolar anisotropy. Here, the red (thick) lines represent hot radiation and the blue (thin) line cold radiation.

Polarization via Thomson Scattering

Let us see how polarization is generated by the scattering between photons and free electrons. If the incident radiation pattern is isotropic (in the rest frame of the electron), then the outgoing radiation remains unpolarized because orthogonal polarization directions cancel out. A net linear polarization only arises if the incoming radiation field has a quadrupole component (see Fig. 72). Such a quadrupole moment is generated when photons decouple from the electrons and protons just before recombination. Since the temperature anisotropies are created by primordial density fluctuations, a component of the polarization should be correlated with the temperature anisotropy.

Characterization of the Radiation Field

The mathematical characterization of CMB polarization anisotropies is slightly more involved than that the description of temperature fluctuations because polarization is not a scalar field so the standard expansion in terms of spherical harmonics is not applicable.

The anisotropy field is defined in terms of a 2×2 intensity tensor $I_{ij}(\hat{n})$, where as before $\hat{n}$ denotes the direction on the sky. The components of I_{ij} are defined relative to two orthogonal basis vectors $\hat{\mathbf{e}}_1$ and $\hat{\mathbf{e}}_2$ perpendicular to $\hat{n}$. Linear polarization is then described by the Stokes parameters $Q = \frac{1}{4}(I_{11} - I_{22})$ and $U = \frac{1}{2}I_{12}$, while the temperature anisotropy is $T = \frac{1}{4}(I_{11} + I_{22})$. The polarization magnitude and angle are $P = \sqrt{Q^2 + U^2}$ and $\alpha = \frac{1}{2}\tan^{-1}(U/Q)$. The quantity T is invariant under a rotation in the plane perpendicular to $\hat{n}$ and hence may be expanded in terms of scalar (spin-0) spherical harmonics (562). The quantities Q and U, however, transform under rotation by an angle ψ as a spin-2 field $(Q \pm iU)(\hat{n}) \to e^{\mp 2i\psi}(Q \pm iU)(\hat{n})$. The harmonic analysis of $Q \pm iU$ therefore requires expansion on the sphere in terms of tensor (spin-2) spherical harmonics [197, 1888, 33]

$$(Q \pm iU)(\hat{n}) = \sum_{\ell,m} a_{\pm 2,\ell m}\, {}_{\pm 2}Y_{\ell m}(\hat{n})\,. \tag{578}$$

A description of the mathematical properties of these tensor spherical harmonics, ${}_{\pm 2}Y_{\ell m}$, would

take us too far off the main track of this lecture, so we refer the reader to the classic papers [197, 1888] or Dodelson's book [8].

E and B-modes

Instead of the moments $a_{\pm 2,\ell m}$ it is convenient to introduce the linear combinations

$$a_{E,\ell m} \equiv -\frac{1}{2}\left(a_{2,\ell m} + a_{-2,\ell m}\right) , \qquad a_{B,\ell m} \equiv -\frac{1}{2i}\left(a_{2,\ell m} - a_{-2,\ell m}\right) . \tag{579}$$

Then one can define two scalar (spin-0) fields instead of the spin-2 quantities Q and U

$$E(\hat{n}) = \sum_{\ell,m} a_{E,\ell m}\, Y_{\ell m}(\hat{n}) , \qquad B(\hat{n}) = \sum_{\ell,m} a_{B,\ell m}\, Y_{\ell m}(\hat{n}) . \tag{580}$$

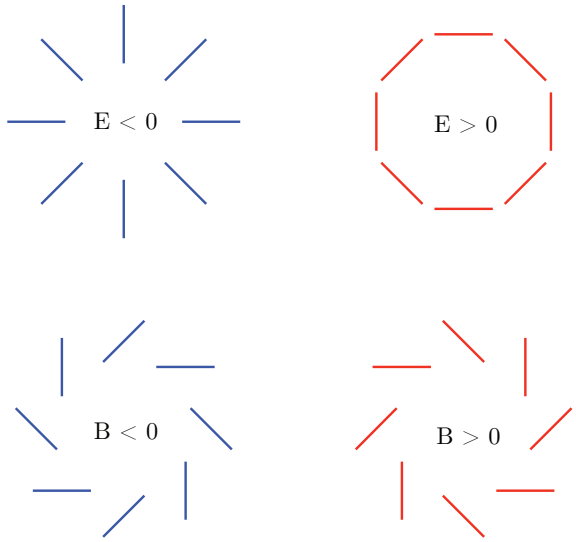

Figure 73: Examples of E-mode and B-mode patterns of polarization. Note that if reflected across a line going through the center the E-mode patterns are unchanged, while the positive and negative B-mode patterns get interchanged.

The scalar quantities E and B completely specify the linear polarization field. E-mode polarization is often also characterized as a *curl-free* mode with polarization vectors that are radial around cold spots and tangential around hot spots on the sky. In contrast, B-mode polarization is *divergence-free* but has a *curl*: its polarization vectors have vorticity around any given point on the sky.[33] Fig. 73 gives examples of E- and B-mode patterns. Although E and B are both invariant under rotations, they behave differently under parity transformations. Note that when reflected about a line going through the center, the E-mode patterns remain unchanged, while the B-moe patterns change sign.

The symmetries of temperature and polarization (E- and B-mode) anisotropies allow four types of correlations: the autocorrelations of temperature fluctuations and of E- and B-modes denoted by TT, EE, and BB, respectively, as well as the cross-correlation between temperature fluctuations and E-modes: TE. All other correlations (TB and EB) vanish for symmetry reasons.

The angular power spectra are defined as before

$$C_\ell^{XY} \equiv \frac{1}{2\ell+1}\sum_m \langle a^*_{X,\ell m} a_{Y,\ell m}\rangle , \qquad X, Y = T, E, B . \tag{581}$$

[33] Evidently the E and B nomenclature reflects the properties familiar from electrostatics, $\nabla \times \mathbf{E} = 0$ and $\nabla \cdot \mathbf{B} = 0$.

In Fig. 74 we show the latest measurement of the TE cross-correlation [11]. The EE spectrum has now begun to be measured, but the errors are still large. So far there are only upper limits on the BB spectrum, but no detection.

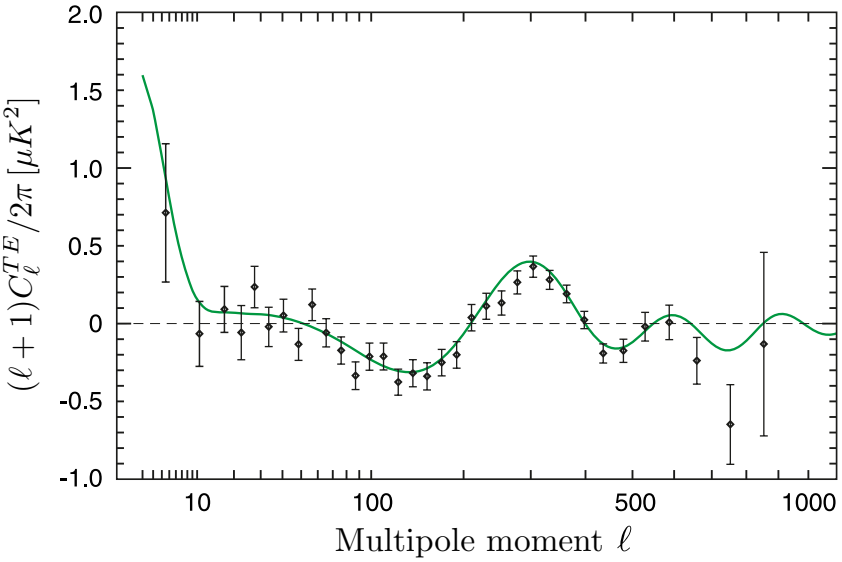

Figure 74: Power spectrum of the cross-correlation between temperature and E-mode polarization anisotropies [11]. The anti-correlation for $\ell = 50 - 200$ (corresponding to angular separations $5^\circ > \theta > 1^\circ$) is a distinctive signature of adiabatic fluctuations on superhorizon scales at the epoch of decoupling [34, 35], confirming a fundamental prediction of the inflationary paradigm.

The cosmological significance of the E/B decomposition of CMB polarization was realized by the authors of Refs. [197, 1888], who proved the following remarkable facts:

i) scalar (density) perturbations create only E-modes and *no* B-modes.

ii) vector (vorticity) perturbations create mainly B-modes.[34]

iii) tensor (gravitational wave) perturbations create both E-modes and B-modes.

The fact that *scalars do not produce B-modes* while *tensors do* is the basis for the statement that detection of B-modes is a smoking gun of tensor modes, and therefore of inflation.

E-modes and Scalars

The power spectrum of E-modes and the TE cross-correlation is dominated by inflationary *scalar* modes, *i.e.*

$$C_\ell^{EE} \approx (4\pi)^2 \int k^2 \mathrm{d}k \overbrace{P_{\mathcal{R}}(k)}^{\text{Inflation}} \Delta_{E\ell}^2(k)\,, \tag{582}$$

$$C_\ell^{TE} \approx (4\pi)^2 \int k^2 \mathrm{d}k \underbrace{P_{\mathcal{R}}(k)}_{\text{Inflation}} \Delta_{T\ell}(k)\Delta_{E\ell}(k)\,. \tag{583}$$

Like C_ℓ^{TT}, the spectra C_ℓ^{EE} and C_ℓ^{TE} provide information about $P_{\mathcal{R}}(k)$. However, since the primordial spectrum is convolved with different transfer functions in each case (polarization is generated only by scattering from free electrons), the signals are usefully complementary.

[34] However, vectors decay with the expansion of the universe and are therefore believed to be subdominant at recombination. We therefore do not consider them here.

B-modes and Tensors

B-modes are only generated by *tensor* modes, *i.e.*

$$C_\ell^{BB} = (4\pi)^2 \int k^2 \mathrm{d}k \underbrace{P_h(k)}_{\text{Inflation}} \Delta^2_{B\ell}(k)\,. \tag{584}$$

Measuring C_ℓ^{BB} is therefore a unique opportunity to access information about primordial tensor fluctuations.

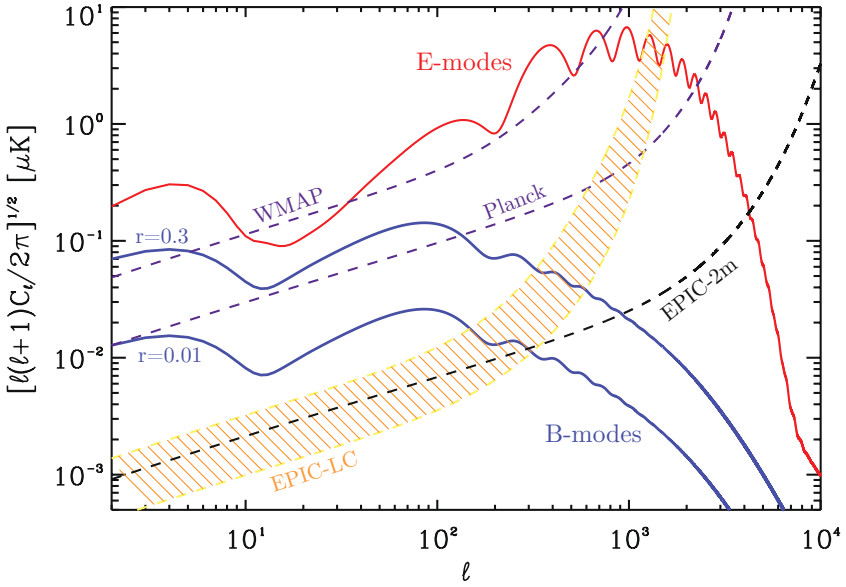

Figure 75: *E*- and *B*-mode power spectra for a tensor-to-scalar ratio saturating current bounds, $r = 0.3$, and for $r = 0.01$. Shown are also the experimental sensitivities for *WMAP*, *Planck* and two different realizations of a future CMB satellite (*CMBPol*) (EPIC-LC and EPIC-2m) [36].

7.5.3 *Review*: Large-Scale Structure

The galaxy (or dark matter) power spectrum is a measure of the spectrum of primordial curvature fluctuations

$$P_\delta(k, z) \quad \Rightarrow \quad P_{\mathcal{R}}(k)\,, \tag{585}$$

if the effects of subhorizon evolution are accounted for. This is done by the dark matter transfer function.

Dark Matter Transfer Functions

Density fluctuations evolve under the competing influence of pressure and gravity. During radiation domination the large radiation pressure prevents the rapid growth of fluctuations; the density contrast only grows logarithmically, $\delta \sim \ln a$. During matter domination the background pressure is negligible and gravitational collapse operates more effectively, $\delta \sim a$.

Under the simplifying assumption that there is no significant growth of perturbations between the time of horizon entry and matter domination one may derive the following approximate transfer function

$$T_\delta(k) \approx \begin{cases} 1 & k < k_{\rm eq} \\ (k_{\rm eq}/k)^2 & k > k_{\rm eq} \end{cases}\,. \tag{586}$$

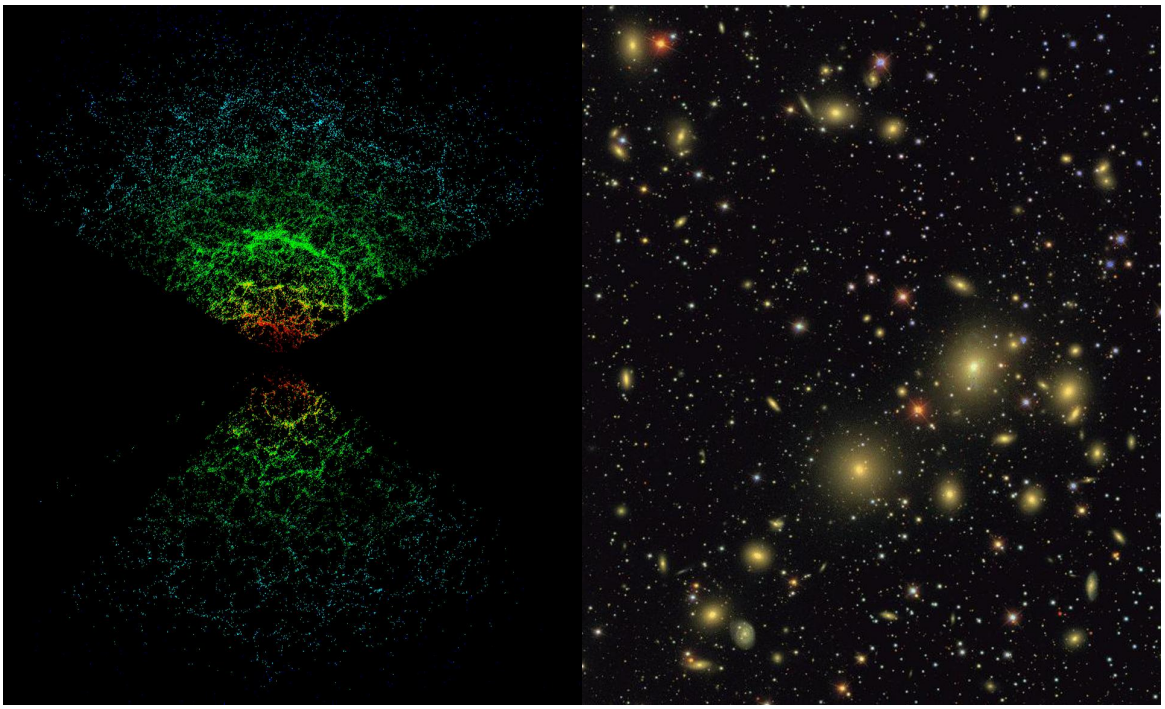

Figure 76: Distribution of galaxies. The Sloan Digital Sky Survey (SDSS) has measured the positions and distances (redshifts) of nearly a million galaxies. Galaxies first identified on 2d images, like the one shown above on the right, have their distances measured to create the 3d map. The left image shows a slice of such a 3d map. The statistical properties of the measured distribution of galaxies reveal important information about the structure and evolution of the late time universe.

Although Eqn. (586) is intuitively appealing for understanding the qualitative shape of the spectrum (*i.e.* the break in the spectrum at $k \approx k_{\rm eq}$), it is not accurate enough for most applications. A famous fitting function for the matter transfer function was given by Bardeen *et al.* (BBKS) [37]

$$T_\delta(q) = \frac{\ln(1+2.34q)}{2.34q}\left[1+3.89q+(1.61q)^2+(5.46q)^3+(6.71q)^4\right]^{-1/4}\,, \tag{587}$$

where $q = k/\Gamma h\,\mathrm{Mpc}^{-1}$ and we defined the shape parameter

$$\Gamma \equiv \Omega h \exp(-\Omega_b - \sqrt{2h}\Omega_b/\Omega)\,. \tag{588}$$

More accurate transfer functions may be found in Eisenstein and Hu [38]. Finally, exact transfer functions may be computed numerically with CMBFAST [28] or CAMB [166].

For our purposes it is only important to note that (give the background cosmological parameters) the dark matter transfer function can be computed and used to relate the dark matter power spectrum $P_\delta(k,z)$ to the inflationary spectrum $P_{\mathcal{R}}(k)$.

Galaxy Bias

With the exception of gravitational lensing we unfortunately can't observe the dark matter directly. What we observe (*e.g.* in galaxy surveys like the Sloan Digital Sky Survey (SDSS)) is luminous or baryonic matter. On large scales the following phenomenological ansatz for relating the galaxy distribution and the dark matter has proven useful

$$\delta_g = b\,\delta\,, \tag{589}$$

or

$$P_{\delta_g} = b^2 P_\delta \,. \tag{590}$$

Here, b is called the (linear) bias parameter. It may be viewed as a parameter describing the ill-understood physics of galaxy formation. The bias parameter b can be obtained by measuring the galaxy bispectrum B_{δ_g}.

Modulo these complications the galaxy power spectrum $P_{\delta_g}(k)$ is an additional probe of inflationary scalar fluctuations $P_{\mathcal{R}}(k)$. As it probes smaller scales it is complementary to observations of the CMB fluctuations.

7.5.4 Current Evidence for Inflation

Inflation is a hypothesis. In order to increase our confidence that inflation describes the physical reality of the early universe, we compare the predictions of inflation to cosmological observations. In this section we describe the current observational evidence for inflation, before discussing future tests in the next section.

Flatness

The universe is filled with baryons, dark matter, photons, neutrinos and dark energy

$$\Omega_{\rm tot} = \Omega_b + \Omega_{\rm cdm} + \Omega_\gamma + \Omega_\nu + \Omega_\Lambda \,. \tag{591}$$

The value of $\Omega_{\rm tot}$ determines the spatial geometry of the universe with $\Omega_{\rm tot} = 1$ corresponding to a flat universe, $\Omega_{\rm tot} < 1$ to a negatively curved universe and $\Omega_{\rm tot} > 1$ to a positively curved universe. Inflation predicts

$$\Omega_{\rm tot} = 1 \pm 10^{-5} \,, \tag{592}$$

while the data shows [11]

$$\Omega_{\rm tot} = 1 \pm 0.02 \,. \tag{593}$$

Although this agreement between theory and data is impressive, one could argue that inflation achieves the flatness of the universe somewhat 'by design'.[35] We should therefore search for additional tests of the inflationary idea.

Coherent Phases and Superhorizon Fluctuations

As we have repeatedly emphasized in these lectures, the observations of the inhomogeneous universe allow detailed test of the inflationary dynamics. In this subsection, we discuss non-trivial qualitative features of the observations that inflation explains naturally, before giving quantitative results in the next subsection.

The following is a trivialization of arguments that have been explained beautifully by Dodelson in [35].

The Peaks of the TT Spectrum

Inflation produces a nearly scale-invariant spectrum of perturbations,

$$\langle \mathcal{R}_{\mathbf{k}} \mathcal{R}_{\mathbf{k}'} \rangle = (2\pi)^3 \delta(\mathbf{k} + \mathbf{k}') P_{\mathcal{R}}(k) \,, \tag{594}$$

where $k^3 P_{\mathcal{R}}(k) \propto k^{n_{\rm s}-1}$ with $n_{\rm s} \approx 1$.

[35] However, it is worth pointing out that when Guth introduced inflation in 1980, the flatness of the universe was a non-trivial prediction that at the time was inconsistent with observations!

> You might think then that the shape of the power spectrum can be measured in observations, and this is what convinces us that inflation is right. Well, it is true that we can measure the power spectrum, both of the matter and of the radiation, and it is true that the observations agree with the theory. But this is not what tingles our spines when we look at the data. Rather, the truly striking aspect of perturbations generated during inflation is that *all Fourier modes have the same phase* [35].

Consider a Fourier mode with physical wavelength λ. While the mode is inside the horizon during inflation it oscillates with a frequency given by $k = 2\pi/\lambda$. However, before inflation ends, the mode exits the horizon, *i.e.* its physical wavelength gets stretched to a length greater than the instantaneous Hubble radius, $\lambda > H^{-1}$. After that its amplitude remains constant. Only at a much later time when the mode re-enters the horizon can causal physics affect it and lead to a time-evolution. Since the fluctuation amplitude was constant outside the horizon, $\dot{\mathcal{R}}$ is very small at horizon re-entry. In general, each Fourier mode could be a linear combination of a sine and a cosine mode. However, the special feature of inflation is that excites only the cosine mode (defining horizon re-entry as $t \equiv 0$).

Once inside the horizon the curvature perturbation $\mathcal{R}$ sources density fluctuations δ which evolve under the influence of gravity and pressure

$$\ddot{\delta} - c_s^2 \nabla^2 \delta = F_g[\mathcal{R}]\,, \tag{595}$$

where c_s is the sound speed and F_g is the gravitational source term. This leads to oscillations in the density field. In the plasma of the early universe, fluctuations in the matter density were strongly coupled to fluctuations in the radiation. The CMB fluctuations therefore provide a direct snapshot of the conditions of the underlying density field at the time of recombination. Imagine that recombination happens instantaneously (this is not a terrible approximation). Fluctuations with different wavelengths would be captured at different phases in their oscillations. Modes of a certain wavelength would be captured at maximum or minimum amplitude, while others would be captured at zero amplitude. If all Fourier modes of a given wavelength had the same phases they would interfere coherently and the spectrum of all Fourier would produce a series of peaks and troughs in the CMB power spectrum as seen on the last-scattering surface. This is of course what we see in Fig. 70. However, in order for the theory of initial fluctuations to explain this it needs to involve a mechanism that produces coherent initial phases for all Fourier modes. Inflation does precisely that! Because fluctuations freeze when the exit the horizon the phases for the Fourier modes were set well before the modes of interest entered the horizon. When were are admiring the peak structure of the CMB power spectrum we are really admiring the ability of the primordial mechanism for generating flucutations to coordinate the phases of all Fourier modes. Without this coherence, the CMB power spectrum would simply be white noise with no peaks and troughs (in fact, this is precisely why cosmic strings or topological defects are ruled out at the primary sources for the primordial fluctuations.).

$\ell < 100$ in the TE Spectrum

The skeptic might not be convinced by the above argument. The peaks and troughs of the CMB temperature fluctuation spectrum are at $\ell > 200$ corresponding to angular scales $\theta < 1^\circ$. All of these scales were within the horizon at the time of recombination. So it is in principle possible (and people have tried in the 90s) to engineer a theory of structure formation which obeys causality and still manages to produce only the 'cosine mode'. Such a theory would explain the CMB peaks without appealing to inflation. This doesn't sound like the most elegant thing in the world but it can't be excluded as a logical possibility.

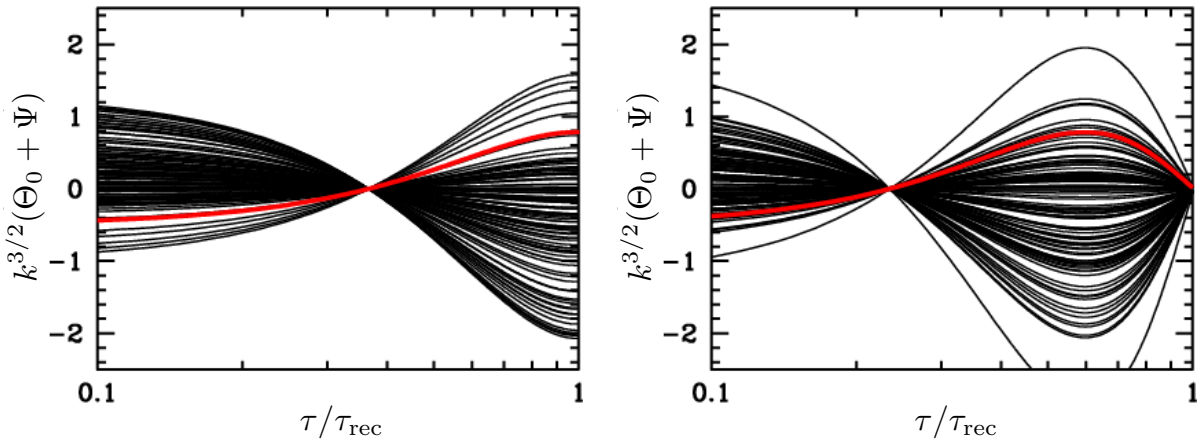

Figure 77: Evolution of modes with the same wavelength. Recombination is at $\tau = \tau_{\rm rec}$. The left figure illustrates the wavelength corresponding to the first peak in the CMB angular power spectrum, while the right figure shows the wavelength corresponding to the first trough. Since all modes start with the same phase, the ones on the left all reach maximum amplitude at recombination, while the ones on the right all go to zero at recombination. This explains to the peaks of the CMB power spectrum.

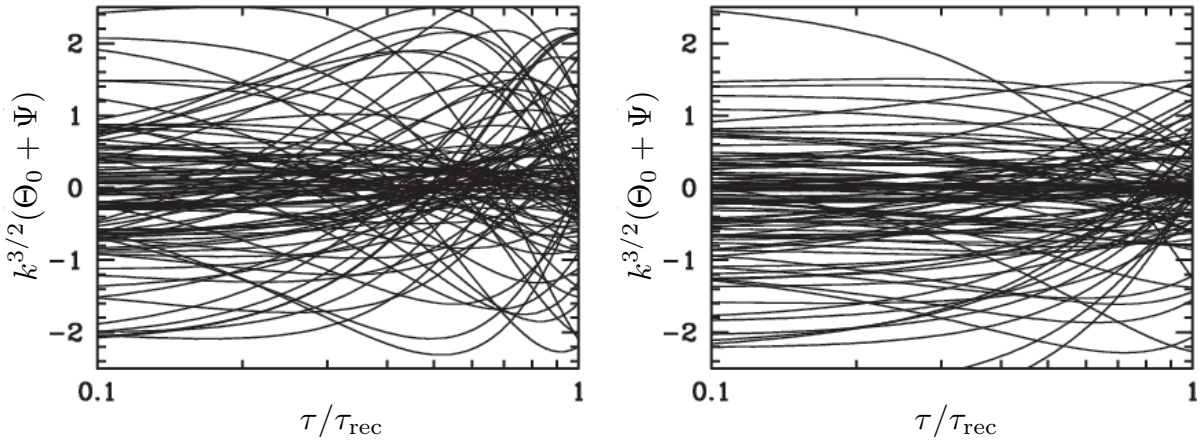

Figure 78: Modes corresponding to the same two wavelengths as in Fig. 77, but this time with random initial phases. We see that the angular peak structure of the CMB would be washed away.

However, we now show that when considering CMB polarization, then even these highly-tuned alternatives to inflation can be ruled out. Looking at Fig. 74 we see that the cross-correlation between CMB temperature fluctuations and the E-mode polarization has a negative peak around $100 < \ell < 200$. This anti-correlation signal is also the result of phase coherence, but now the scales involved were *not* within the horizon at recombination. Hence, there is *no* causal mechanism (after $\tau = 0$) that could have produced this signal. One is almost forced to consider something like inflation with its shrinking comoving horizon leading to horizon exit and re-entry.[36]

As Dodelson explains [35]

> At recombination, [the phase difference between the monopole (sourcing T) and the dipole (sourcing E) of the density field] causes the product of the two to be negative

[36]It should be mentioned here that there are two ways to get a shrinking comoving Hubble radius, $1/(aH)$. During inflation H is nearly constant and the scale factor a grows exponentially. However, in a *contracting* spacetime a shrinking horizon can be achieved if H grows with time. This is the mechanism employed by ekpyrotic/cyclic cosmology [39, 40, 41]. When viewed in terms of the evolution of the comoving Hubble scale inflation and ekpyrosis appear very similar, but there are important differences, *e.g.* in ekyprosis it is a challenge to match the contracting phase to our conventional Big Bang expansion.

for $100 < \ell < 200$ and positive on smaller scales until $\ell \sim 400$. But this is precisely what WMAP has observed! We have clear evidence that the monopole and the dipole were out of phase with each other at recombination.

This evidence is exciting for the small scale modes ($\ell > 200$). Just as the acoustic peaks bear testimony to coherent phases, the cross-correlation of polarization and temperatures speaks to the coherence of the dipole as well. It solidifies our picture of the plasma at recombination. The evidence from the larger scale modes ($\ell < 200$) though is positively stupendous. For, these modes were not within the horizon at recombination. So the *only* way they could have their phases aligned is if some primordial mechanism did the job, when they were in causal contact. Inflation is just such a mechanism.

Scale-Invariant, Gaussian and Adiabatic

We now describe quantitative constraints on the primordial fluctuations. The simplest versions of inflation predict that the scalar perturbations are nearly *scale-invariant*, *Gaussian* and *adiabatic*. In this section we give the latest quantitative constraints on these fundamental predictions of the theory.

Parameter	5-year *WMAP*	*WMAP*+BAO+SN
n_s	$0.963^{+0.014}_{-0.015}$	$0.960^{+0.013}_{-0.013}$
n_s	0.986 ± 0.022	0.970 ± 0.015
r	< 0.43	< 0.22
n_s	$1.031^{+0.054}_{-0.055}$	$1.017^{+0.042}_{-0.043}$
α_s	-0.037 ± 0.028	$-0.028^{+0.020}_{-0.020}$
n_s	$1.087^{+0.072}_{-0.073}$	$1.089^{+0.070}_{-0.068}$
r	< 0.58	< 0.55
α_s	-0.050 ± 0.034	-0.058 ± 0.028

Table 3: 5-year *WMAP* constraints on the primordial power spectra in the power law parameterization [11]. We present results for (n_s), (n_s, r), (n_s, α_s) and (n_s, r, α) marginalized over all other parameters of a flat Λ CDM model.

Spectral Index

As we explained in detail above, observations of the CMB relate to the inflationary spectrum of curvature perturbations $\mathcal{R}$

$$\boxed{C_\ell^{TT}, C_\ell^{TE}, C_\ell^{EE} \quad \Rightarrow \quad P_{\mathcal{R}}(k)}\,. \tag{596}$$

Here, we present the latest quantitative constraints on $P_{\mathcal{R}}(k)$ in the standard power-law parameterization

$$\Delta^2_{\rm s}(k) \equiv \frac{k^3}{2\pi^2} P_{\mathcal{R}}(k) = A_{\rm s} \left(\frac{k}{k_\star}\right)^{n_{\rm s}-1}\,. \tag{597}$$

Measurements of $n_{\rm s}$ are degenerate with the tensor-to-scalar ratio r so constraints on $n_{\rm s}$ are often shown as confidence contours in the $n_{\rm s}$-r plane. The latest WMAP 5-year constraints on the scalar spectral index are shown in Fig. 79 and Table 3. Two facts may be noted: i) the spectrum is nearly scale-invariant, $n_{\rm s} \approx 1$, just as inflation predicts and ii) there are already interesting indications that the spectrum is not perfectly scale-invariant, but slightly red, $n_{\rm s} < 1$. This

deviation from scale-invariance provides the first test of the detailed time-dependence of the inflationary expansion. In fact, as we have seen in **Lecture 2**, inflation predicts this percent level deviation from scale-invariance.[37]

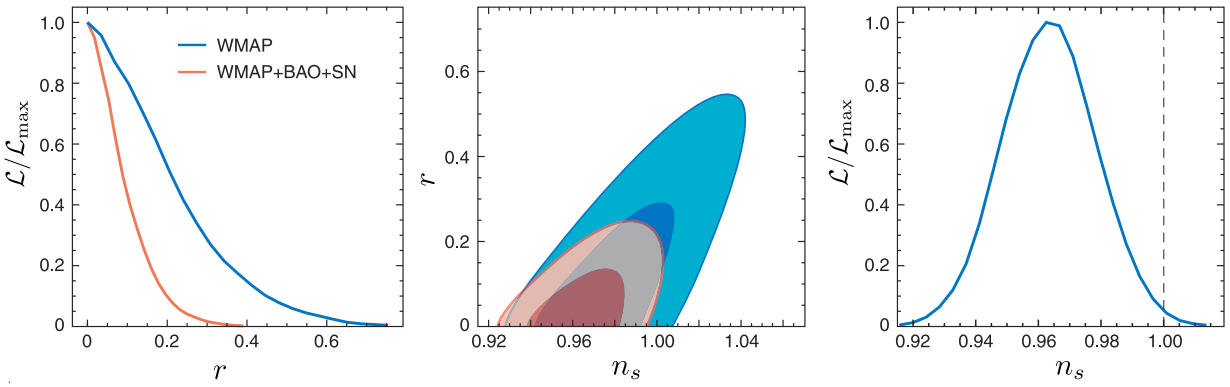

Figure 79: *WMAP* 5-year constraints on the inflationary parameters n_s and r [11]. The *WMAP*-only results are shown in blue, while constraints from *WMAP* plus other cosmological observations are in red. The third plot assumes that r is negligible.

Gaussianity

If $\mathcal{R}$ is Gaussian then the power spectrum $P_{\mathcal{R}}(k)$ (two-point correlations in real space) is the end of the story. However, if $\mathcal{R}$ is *non-Gaussian* then the fluctuations have a non-zero bispectrum $B_{\mathcal{R}}(k_1, k_2, k_3)$ (corresponding to three-point correlations in real space). There is only one way to be Gaussian but many ways to be non-Gaussian, so constraints on non-Gaussianity are a bit hard to describe. One of the simplest forms of non-Gaussianity is described by the parameterization

$$\mathcal{R}(\mathbf{x}) = \mathcal{R}_g(\mathbf{x}) + \frac{3}{5} f_{\rm NL} \star \mathcal{R}_g^2(\mathbf{x})\,. \tag{598}$$

where $\mathcal{R}_g$ is Gaussian. In this *local model* for non-Gaussianity, the information is reduced to a single number $f_{\rm NL}$. The latest constraint on $f_{\rm NL}$ by Smith, Senatore, and Zaldarriaga [42] is

$$-4 \;<\; f_{\rm NL} \;<\; 80 \quad \text{at} \quad 95\%\ \text{CL}\,. \tag{599}$$

Notice that an $f_{\rm NL}$ value of order 100 corresponds to a 0.1% correction to $\mathcal{R}_g \sim 10^{-5}$ in Eq. (598). The constraint (599) therefore implies that the CMB is Gaussian to 0.1%! This is better than our constraint on the curvature of the universe which is usually celebrated as the triumph of inflation. The CMB is highly Gaussian and it didn't have to be that way. However, if inflation is correct then the observed Gaussianity is a rather natural consequence.[38]

Adiabaticity

In single-field inflation, the fluctuations of the inflaton field on large scales (where spatial gradients can be neglected) can be identified with a local shift backwards or forwards along the the trajectory of the homogeneous background field. These shifts along the inflaton trajectory affect the total density in different parts of the universe after inflation, but cannot give rise

[37] For inflation to end, the Hubble parameter H has to change in time. This time-dependence changes the conditions at the time when each fluctuation mode exits the horizon and therefore gets translated into a scale-dependence of the fluctuations.

[38] Non-Gaussianity is a measure of *interactions* of the inflaton field. However, for slow-roll dynamics to occur, the inflaton has to be very weakly self-interacting (the potential is very flat) and the non-Gaussianity is necessarily small, $f_{\rm NL} \sim \mathcal{O}(0.01)$ [22].

to variations in the relative density between different components. Hence, single-field inflation produces purely *adiabatic* primordial density perturbations characterized by an overall curvature perturbations, $\mathcal{R}$. This means that all perturbations of the cosmological fluid (photons, neutrinos, baryons and cold dark matter (CDM) particles) originate from the same curvature perturbation $\mathcal{R}$ and satisfy the adiabaticity property, $\delta(n_m/n_r) = 0$, or

$$\frac{\delta\rho_m}{\rho_m} = \frac{3}{4}\frac{\delta\rho_r}{\rho_r}\,, \tag{600}$$

where the index m collectively stands for non-relativistic species (baryons or CDM) and r for relativistic species (photons or neutrinos). The latest data shows no violation of the condition (600) [11]. If such a violation were to be found this would be a clear signature of multi-field inflation (see §7.5.5).

Testing Slow-Roll Models

In Figure 80 we present current observational constraints on some of the simplest single-field slow-roll models of inflation (see **Lecture 1**). Future measurements will significantly cut into the parameter space of allowed models.

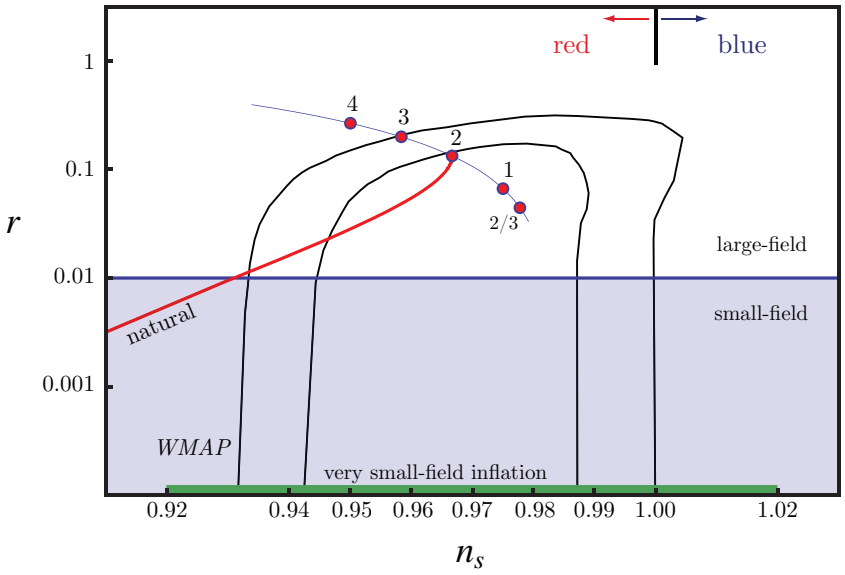

Figure 80: Constraints on single-field slow-roll models in the n_s-r plane. The value of r determines whether the models involve large or small field variations. The value of n_s classifies the scalar spectrum as red or blue. Combinations of the values of r and n_s determine whether the curvature of the potential was positive ($\eta_{\rm v} > 0$) or negative ($\eta_{\rm v} < 0$) when the observable universe exited the horizon. Also shown are the *WMAP* 5-year constraints on n_s and r [11] as well as the predictions of a few representative models of single-field slow-roll inflation: *chaotic inflation*: $\lambda_p\,\phi^p$, for general p (thin solid line) and for $p = 4, 3, 2, 1, \frac{2}{3}(\bullet)$; models with $p = 2$ [43], $p = 1$ [44] and $p = \frac{2}{3}$ [251] have recently been obtained in string theory; *natural inflation*: $V_0[1-\cos(\phi/\mu)]$ (solid line); *very small-field inflation*: models of inflation with a very small tensor amplitude, $r \ll 10^{-4}$ (green bar); examples of such models in string theory include warped D-brane inflation [46, 47, 48], Kähler inflation [49], and racetrack inflation [50].

7.5.5 Future Tests of Inflation

We are only at the beginning of really testing the inflationary paradigm. The flatness of the universe and the near scale-invariance, Gaussianity and adiabaticity of the density fluctuations

are encouraging evidence for inflation[39], but they are not proof that inflation really occurred.[40] Let us therefore look into the future and describe how future experiments can provide further tests of inflationary physics.

Amplitude of Tensor Modes

Probably the single most important piece of evidence for inflation would come from a measurement of a primordial tensor amplitude. We showed above that a detection of primordial CMB B-modes would be virtually impossible to explain by anything other inflationary gravitational waves [51]

$$\boxed{C_\ell^{BB} \quad \Rightarrow \quad P_h(k)}\,, \tag{601}$$

where

$$\Delta_{\rm t}^2(k) \equiv \frac{k^3}{2\pi^2} P_h(k) = A_{\rm t} \left(\frac{k}{k_\star}\right)^{n_{\rm t}} . \tag{602}$$

We also explained in **Lecture 2** that the tensor amplitude A_t is directly linked with the energy scale of inflation. As a single clue about the physics of inflation, what could be more important and higher on the wish-list of inflationary theorists? In addition, a detection of tensor modes would imply that the inflaton field moved over a super-Planckian distance in field space, making string theorists and quantum gravity affectionatos think hard about Planck-suppressed corrections to the inflaton potential (see **Lecture 5**).

Scale Dependence of Scalar Modes

The variation of the spectral index $n_{\rm s}$ with scale (also called the "running" of the spectral index) arises only at second-order in slow-roll and is therefore expected to be small

$$\alpha_{\rm s} \equiv \frac{dn_{\rm s}}{d\ln k} \sim \mathcal{O}(\varepsilon^2)\,. \tag{603}$$

On the other hand, an unexpected large positive or negative running would force us to rethink some of our simplest notions about inflation and the generation of perturbations.

Scale Dependence of Tensor Modes

Measuring the amplitude of primordial tensor fluctuations from inflation will be a significant observational challenge. Hoping to measure its dependence on scale seems unrealistic unless the tensor amplitude is near its current upper limit. In single-field slow-roll models the tensor-to-scalar ratio r and the tensor spectral index $n_{\rm t}$ are related by the *consistency relation*

$$r = -8n_{\rm t}\,. \tag{604}$$

Measuring (604) would offer another way to falsify single-field slow-roll inflation.

Non-Gaussianity

The primordial fluctuations are to a high degree Gaussian. However, as we now describe, even a small non-Gaussianity would encode a tremendous amount of information about the inflationary action. We mentioned that the three-point function of inflationary fluctuations is

[39] Note that at any stage we could have made measurements that would have falsified the whole idea of inflation.

[40] I know, I used the word 'proof' when Karl Popper taught us that we can never prove a theory.

the prime diagnostic of non-Gaussian statistics. In momentum space, the three-point correlation function can be written generically as

$$\langle \mathcal{R}_{\mathbf{k}_1} \mathcal{R}_{\mathbf{k}_2} \mathcal{R}_{\mathbf{k}_3} \rangle = (2\pi)^3 \, \delta(\mathbf{k}_1 + \mathbf{k}_2 + \mathbf{k}_3) \; f_{\rm NL} \; F(k_1, k_2, k_3) \, . \tag{605}$$

Here, $f_{\rm NL}$ is a dimensionless parameter defining the amplitude of non-Gaussianity, while the function $F(k_1, k_2, k_3)$ captures the momentum dependence. The amplitude and sign of $f_{\rm NL}$, as well as the shape and scale dependence of $F(k_1, k_2, k_3)$, depend on the details of the interaction generating the non-Gaussianity, making the three-point function a powerful discriminating tool for probing models of the early universe [30].

Two simple and distinct shapes $F)k_1, k_2, k_3)$ are generated by two very different mechanisms [52]: The *local shape* is a characteristic of multi-field models and takes its name from the expression for the primordial curvature perturbation $\mathcal{R}$ in real space,

$$\mathcal{R}(\mathbf{x}) = \mathcal{R}_g(\mathbf{x}) + \frac{3}{5} f_{\rm NL}^{\rm local} \mathcal{R}_g(\mathbf{x})^2 \, , \tag{606}$$

where $\mathcal{R}_g(\mathbf{x})$ is a Gaussian random field. Fourier transforming this expression shows that the signal is concentrated in "squeezed" triangles where $k_3 \ll k_1, k_2$. Local non-Gaussianity arises in multi-field models where the fluctuations of an isocurvature field (see below) are converted into curvature perturbations. As this conversion happens outside of the horizon, when gradients are irrelevant, one generates non-linearities of the form (606). Specific models of this type include multi-field inflation [53, 54, 55, 56, 57, 58, 52, 60, 61, 62, 63, 64, 65], the curvaton scenario [173, 67], inhomogeneous reheating [68, 69], and New Ekpyrotic models [70, 71, 72, 73, 74, 75, 76].

The second important shape is called *equilateral* as it is largest for configurations with $k_1 \sim k_2 \sim k_3$. The equilateral form is generated by single-field models with non-canonical kinetic terms such as DBI inflation [77], ghost inflation [78, 79] and more general models with small sound speed [80, 81].

Isocurvature Fluctuations

In inflationary models with more than one field the perturbations are not necessarily adiabatic. With more than one field, fluctuations orthogonal to the background trajectory can affect the relative density between different matter components even if the total density and therefore the spatial curvature is unperturbed [111]. There are various different possibilities for such *isocurvature* perturbations (also called non-adiabitic or entropic perturbations), *e.g.* we may define relative perturbations between CDM and photons

$$\mathcal{S}_m \equiv \frac{\delta\rho_m}{\rho_m} - \frac{3}{4} \frac{\delta\rho_\gamma}{\rho_\gamma} \, . \tag{607}$$

Adiabatic and isocurvature perturbations lead to a different peak structure in the CMB fluctuations. CMB measurements can therefore distinguish between the different types of fluctuations and in fact already show that isocurvature perturbations have to be a subdominant component (if at all present).

Isocurvature perturbations could be correlated with the adiabatic perturbations. To capture this we define the following correlation parameter

$$\beta \equiv \frac{P_{\mathcal{S}\mathcal{R}}}{\sqrt{P_{\mathcal{S}} P_{\mathcal{R}}}} \, , \tag{608}$$

where $P_{\mathcal{R}}$ and $P_{\mathcal{S}}$ are the power spectra of adiabatic and isocurvature fluctuations and $P_{\mathcal{S}\mathcal{R}}$ is their cross-correlation. Parameterizing the relative amplitude between the two types of perturbations by a coefficient α

$$\frac{P_{\mathcal{S}}}{P_{\mathcal{R}}} \equiv \frac{\alpha}{1-\alpha} \, , \tag{609}$$

the present constraints on the isocurvature contribution are $\alpha_0 < 0.067$ (96% CL) in the uncorrelated case ($\beta = 0$) and $\alpha_{-1} < 0.0037$ (95% CL) in the totally anti-correlated case ($\beta = -1$).

Theoretical predictions for the amplitude of isocurvature perturbations are complicated by the fact that they are strongly model-dependent: the isocurvature amplitude does not depend entirely on the multi-field inflationary dynamics, but also on the post-inflationary evolution. If all particle species are in thermal equilibrium after inflation and their local densities are uniquely given by their temperature (with vanishing chemical potential) then the primordial perturbations are adiabatic [176, 84]. Thus, it is important to note that the existence of primordial isocurvature modes requires at least one field to decay into some species whose abundance is not determined by thermal equilibrium (*e.g.* CDM after decoupling) or respects some conserved quantum numbers, like baryon or lepton numbers.

7.6 Primordial Non-Gaussianity by Baumann 4th lecture

Abstract

In this lecture we summarize key theoretical results in the study of primordial non-Gaussianity. Most results are stated without proof, but their significance for constraining the fundamental physical origin of inflation is explained. After introducing the bispectrum as a basic diagnostic of non-Gaussian statistics, we show that its momentum dependence is a powerful probe of the inflationary action. Large non-Gaussianity can only arise if inflaton interactions are significant during inflation. In single-field slow-roll inflation non-Gaussianity is therefore predicted to be unobservably small, while it can be significant in models with multiple fields, higher-derivative interactions or non-standard initial states. Finally, we end the lecture with a discussion of the observational prospects for detecting or constraining primordial non-Gaussianity.

7.6.1 Preliminaries

Non-Gaussianity, *i.e.* the study of non-Gaussian contributions to the correlations of cosmological fluctuations, is emerging as an important probe of the early universe [85]. Being a direct measure of inflaton *interactions*, constraints on primordial non-Gaussianities will teach us a great deal about the inflationary dynamics. It also puts strong constraints on alternatives to the inflationary paradigm [70, 71, 72, 73, 74, 75, 76].

In **Lecture 2** we expanded the inflationary action to second order in the comoving curvature perturbation $\mathcal{R}$. This free-field action allowed us to compute the power spectrum $P_{\mathcal{R}}(k)$. As we mentioned in **Lecture 3**, if the fluctuations $\mathcal{R}$ are drawn from a Gaussian distribution, then the power spectrum (or two-point correlation function) contains all the information.[41] However, for non-Gaussian fluctuations higher-order correlation functions beyond the two-point function contain additional information about inflation. Computing the leading non-Gaussian effects requires expansion of the action to third order in order to capture the leading non-trivial interaction terms. These computations can be algebraically quite challenging, so we will limit this lecture to a review of the main results and their physical interpretations. For more details and derivations we refer the reader to the comprehensive review by Bartolo *et al.* [30] and the references cited therein.

[41] The three-point function and all odd higher-point correlation functions vanish for Gaussian fluctuations, while all even higher-point functions can be expressed in terms of the two-point function. In other words, all *connected* higher-point functions vanish for Gaussian fluctuations.

The Bispectrum and Local Non-Gaussianity

Bispectrum

The Fourier transform of the two-point function is the power spectrum

$$\langle \mathcal{R}_{\mathbf{k}_1} \mathcal{R}_{\mathbf{k}_2} \rangle = (2\pi)^3 \delta(\mathbf{k}_1 + \mathbf{k}_2) P_{\mathcal{R}}(k_1) \,. \tag{610}$$

Similarly, the Fourier equivalent of the three-point function is the *bispectrum*

$$\boxed{\langle \mathcal{R}_{\mathbf{k}_1} \mathcal{R}_{\mathbf{k}_2} \mathcal{R}_{\mathbf{k}_3} \rangle = (2\pi)^3 \delta(\mathbf{k}_1 + \mathbf{k}_2 + \mathbf{k}_3) B_{\mathcal{R}}(\mathbf{k}_1, \mathbf{k}_2, \mathbf{k}_3)} \,. \tag{611}$$

Here, the delta function (enforcing momentum conservation) is a consequence of translation invariance of the background. The function $B_{\mathcal{R}}$ is symmetric in its arguments and for scale-invariant fluctuations it is a homogeneous function of degree -6

$$B_{\mathcal{R}})\lambda \mathbf{k}_1, \lambda \mathbf{k}_2, \lambda \mathbf{k}_3) = \lambda^{-6} B_{\mathcal{R}}(\mathbf{k}_1, \mathbf{k}_2, \mathbf{k}_3) \,. \tag{612}$$

Rotational invariance further reduces the number of independent variables to just two, *e.g.* the two ratios k_2/k_1 and k_3/k_1.

To compute the three-point function for a specific inflationary model requires a careful treatment of the time-evolution of the vacuum in the presence of interactions (while for the two-point function this effect is higher-order). In Appendix C we describe the "in-in" formalism for computing cosmological correlation functions [86, 87, 88, 22, 89]. In practice, computing three-point functions can be algebraically very cumbersome, so in the lecture we restrict us to citing the final results. The details on how to compute these three-point functions deserves a review of its own.

Local Non-Gaussianity

One of the first ways to parameterize non-Gaussianity phenomenologically was via a non-linear correction to a Gaussian perturbation $\mathcal{R}_g$ [90],

$$\boxed{\mathcal{R}(\mathbf{x}) = \mathcal{R}_g(\mathbf{x}) + \frac{3}{5} f_{\rm NL}^{\rm local} \left[\mathcal{R}_g(\mathbf{x})^2 - \langle \mathcal{R}_g(\mathbf{x})^2 \rangle \right]} \,. \tag{613}$$

This definition is local in real space and therefore called *local non-Gaussianity*. Experimental constraints on non-Gaussianity (see **Lecture 3**) are often set on the parameter $f_{\rm NL}^{\rm local}$ defined via Eqn. (613).[42] Using Eqn. (613) the bispectrum of local non-Gaussianity may be derived

$$B_{\mathcal{R}}(k_1, k_2, k_3) = \frac{6}{5} f_{\rm NL}^{\rm local} \times \left[P_{\mathcal{R}}(k_1) P_{\mathcal{R}}(k_2) + P_{\mathcal{R}}(k_2) P_{\mathcal{R}}(k_3) + P_{\mathcal{R}}(k_3) P_{\mathcal{R}}(k_1) \right] \,. \tag{614}$$

Exercise 10 (Local Bispectrum)**.** *Derive Eqn. (614) from Eqns. (611) and (613).*

For a scale-invariant spectrum, $P_{\mathcal{R}}(k) = A k^{-3}$, this is

$$B_{\mathcal{R}}(k_1, k_2, k_3) = \frac{6}{5} f_{\rm NL}^{\rm local} \times A^2 \left[\frac{1}{(k_1 k_2)^3} + \frac{1}{(k_2 k_3)^3} + \frac{1}{(k_3 k_1)^3} \right] \,. \tag{615}$$

Without loss of generality, let us order the momenta such that $k_3 \leq k_2 \leq k_1$. The bispectrum for local non-Gaussianity is then largest when the smallest k (*i.e.* k_3) is very small, $k_3 \ll k_1 \sim k_2$. The other two momenta are then nearly equal. In this *squeezed* limit, the bispectrum for local non-Gaussianity becomes

$$\lim_{k_3 \ll k_1 \sim k_2} B_{\mathcal{R}}(k_1, k_2, k_3) = \frac{12}{5} f_{\rm NL}^{\rm local} \times P_{\mathcal{R}}(k_1) P_{\mathcal{R}}(k_3) \,. \tag{616}$$

[42] The factor of $3/5$ in Eqn. (613) is conventional since non-Gaussianity was first defined in terms of the Newtonian potential, $\Phi(\mathbf{x}) = \Phi_g(\mathbf{x}) + f_{\rm NL}^{\rm local} \left[\Phi_g(\mathbf{x})^2 - \langle \Phi_g(\mathbf{x})^2 \rangle \right]$, which during the matter era is related to $\mathcal{R}$ by a factor of $3/5$.

Shapes of Non-Gaussianity

The delta function in Eqn. (611) enforces that the three Fourier modes of the bispectrum form a closed triangle. Different inflationary models predict maximal signal for different triangle configurations. This *shape of non-Gaussianity* [52] is potentially a powerful probe of the mechanism that laid down the primordial perturbations.

It will be convenient to define the shape function

$$\mathcal{S}(k_1, k_2, k_3) \equiv N(k_1 k_2 k_3)^2 B_{\mathcal{R}}(k_1, k_2, k_3)\,, \tag{617}$$

where N is an appropriate normalization factor. Two commonly discussed shapes are the *local* model, *cf.* Eqn. (615),

$$\mathcal{S}^{\rm local}(k_1, k_2, k_3) \propto \frac{K_3}{K_{111}}\,, \tag{618}$$

and the *equilateral* model,

$$\mathcal{S}^{\rm equil}(k_1, k_2, k_3) \propto \frac{\tilde{k}_1 \tilde{k}_2 \tilde{k}_3}{K_{111}}\,. \tag{619}$$

Here, we have introduced a notation first defined by Fergusson and Shellard [87],

$$K_p = \sum_i (k_i)^p \quad \text{with} \quad K = K_1 \tag{620}$$

$$K_{pq} = \frac{1}{\Delta_{pq}} \sum_{i \neq j} (k_i)^p (k_j)^q \tag{621}$$

$$K_{pqr} = \frac{1}{\Delta_{pqr}} \sum_{i \neq j \neq l} (k_i)^p (k_j)^q (k_l)^q \tag{622}$$

$$\tilde{k}_{ip} = K_p - 2(k_i)^p \quad \text{with} \quad \tilde{k}_i = \tilde{k}_{i1}\,, \tag{623}$$

where $\Delta_{pq} = 1 + \delta_{pq}$ and $\Delta_{pqr} = \Delta_{pq}(\Delta_{qr} + \delta_{pr})$ (no summation). This notation significantly compresses the increasingly complex expressions for the bispectra discussed in the literature.

We have argued above that for scale-invariant fluctuations the bispectrum is only a function of the two ratios k_2/k_1 and k_3/k_1. We hence define the rescaled momenta

$$x_i \equiv \frac{k_i}{k_1}\,. \tag{624}$$

We have ordered the momenta such that $x_3 \leq x_2 \leq 1$. The triangle inequality implies $x_2 + x_3 > 1$. In the following we plot $\mathcal{S}(1, x_2, x_3)$ (see Figs. 81, 83, and 84). We use the normalization, $\mathcal{S}(1, 1, 1) \equiv 1$. To avoid showing equivalent configurations twice $\mathcal{S}(1, x_2, x_3)$ is set to zero outside the triangular region $1 - x_2 \leq x_3 \leq x_2$. We see in Fig. 81 that the signal for the local shape is concentrated at $x_3 \approx 0$, $x_2 \approx 1$, while the equilateral shape peaks at $x_2 \approx x_3 \approx 1$. Fig. 82 illustrates how the different triangle shapes are distributed in the x_2-x_3 plane.

Physically motivated models for producing non-Gaussian perturbations often produce signals that peak at special triangle configurations. Three important special cases are:

i) *squeezed triangle* ($k_1 \approx k_2 \gg k_3$)

This is the dominant mode of models with multiple light fields during inflation [53, 54, 55, 56, 57, 58, 52, 60, 61, 62, 63, 64, 65], the curvaton scenario [173, 67], inhomogeneous reheating [68, 69], and New Ekpyrotic models [70, 71, 72, 73, 74, 75, 76].

ii) *equilateral triangle* ($k_1 = k_2 = k_3$)

Signals that peak at equilateral triangles arise in models with higher-derivative interactions and non-trivial speeds of sound [92, 81].

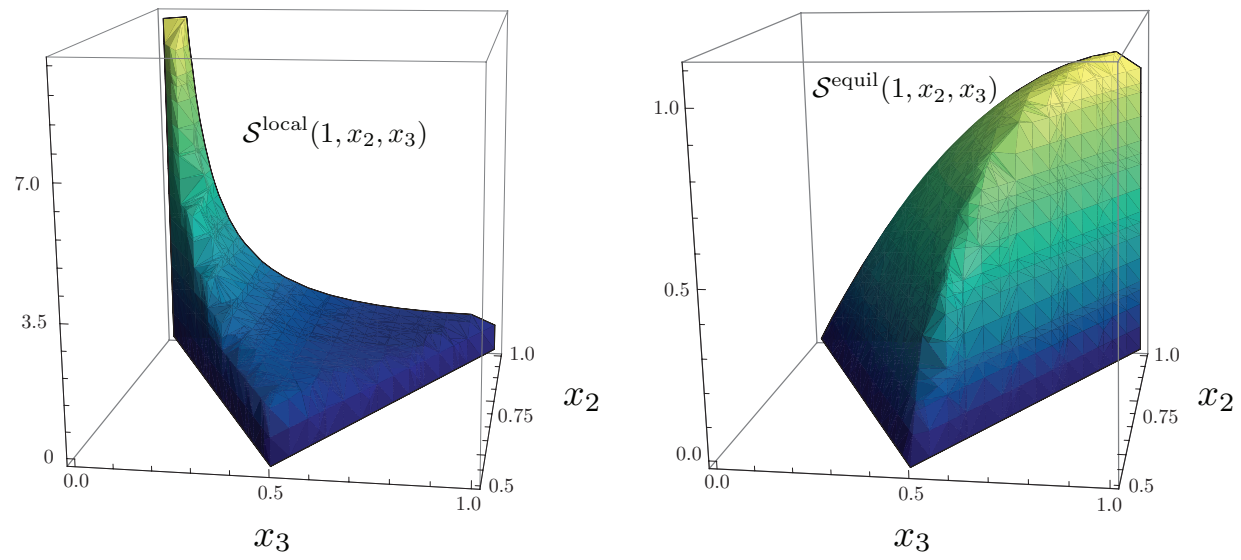

Figure 81: 3D plots of the *local* and *equilateral* bispectra. The coordinates x_2 and x_3 are the rescaled momenta k_2/k_1 and k_3/k_1, respectively. Momenta are order such that $x_3 < x_2 < 1$ and satsify the triangle inequality $x_2 + x_3 > 1$.

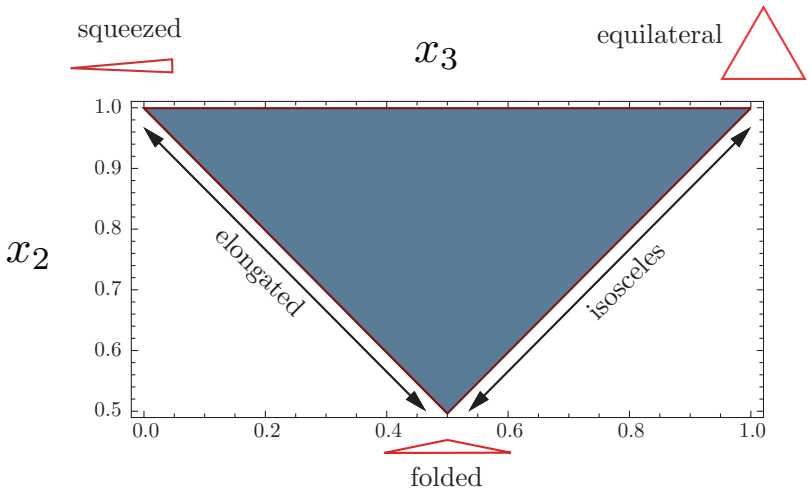

Figure 82: Shapes of Non-Gaussianity. The coordinates x_2 and x_3 are the rescaled momenta k_2/k_1 and k_3/k_1, respectively. Momenta are order such that $x_3 < x_2 < 1$ and satsify the triangle inequality $x_2 + x_3 > 1$.

iii) *folded triangle* ($k_1 = 2k_2 = 2k_3$)

Folded triangles arise in models with non-standard initial states [93, 81].

In addition, there are the intermediate cases: *elongated triangles* ($k_1 = k_2 + k_3$) and *isosceles triangles* ($k_1 > k_2 = k_3$).

$f_{\rm NL}$: The Amplitude of Non-Gaussianity

For arbitrary shape functions we measure the magnitude of non-Gaussianity by defining the generalized $f_{\rm NL}$ parameter

$$\boxed{f_{\rm NL} \equiv \frac{5}{18}\frac{B_{\mathcal{R}}(k,k,k)}{P_{\mathcal{R}}(k)^2}}\,. \tag{625}$$

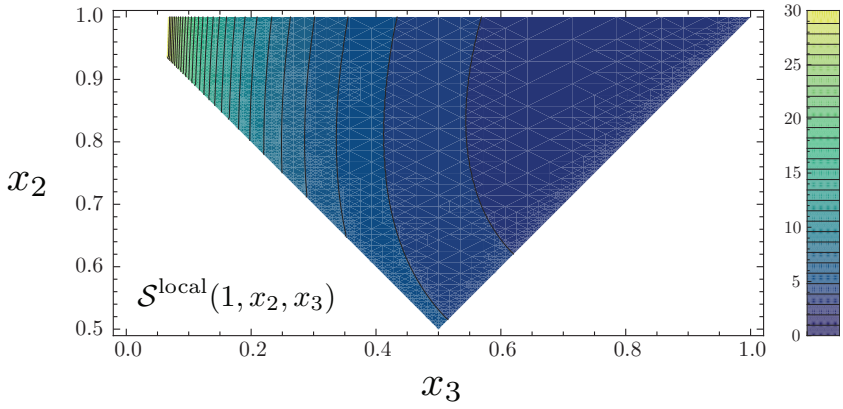

Figure 83: Contour plot of the *local* bispectrum.

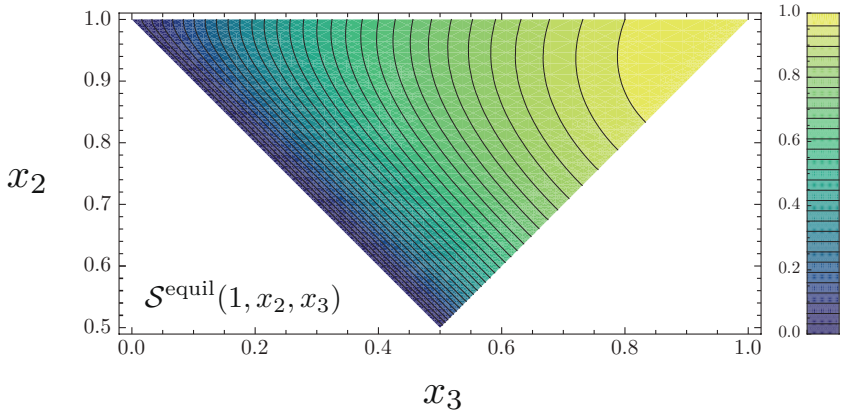

Figure 84: Contour plot of the *equilateral* bispectrum.

In this definition the amplitude of non-Gaussianity is normalized in the equilateral configuration.

Exercise 11 ($f_{\rm NL}$)**.** *Show from Eqn. (614) that the definition (625) is consistent with our definition of* $f_{\rm NL}^{\rm local}$*, Eqn. (613).*

7.6.2 Theoretical Expectations

Single-Field Slow-Roll Inflation

Successful slow-roll inflation demands that the interactions of the inflaton field are weak. Since the wave function of free fields in the ground state is Gaussian, the fluctuations created during slow-roll inflation are expected to be Gaussian. Maldacena [22] first derived the bispectrum for slow-roll (SR) inflation

$$\mathcal{S}^{\rm SR}(k_1, k_2, k_3) \quad \propto \quad)\varepsilon - 2\eta)\frac{K_3}{K_{111}} + \varepsilon\left(K_{12} + 8\frac{K_{22}}{K}\right) \tag{626}$$

$$\approx \quad (4\varepsilon - 2\eta)\,\mathcal{S}^{\rm local}(k_1, k_2, k_3) + \frac{5}{3}\varepsilon\,\mathcal{S}^{\rm equil}(k_1, k_2, k_3)\,, \tag{627}$$

where $\mathcal{S}^{\rm local}$ and $\mathcal{S}^{\rm equil}$ are normalized so that $\mathcal{S}^{\rm local}(k, k, k) = \mathcal{S}^{\rm equil}(k, k, k)$. The bispectrum for slow-roll inflation peaks at squeezed triangles and has an amplitude that is suppressed by slow-roll parameters [22]

$$f_{\rm NL}^{\rm SR} = \mathcal{O}(\varepsilon, \eta)\,. \tag{628}$$

This makes intuitive sense since the slow-roll parameters characterize deviations of the inflaton from a free field.

The Maldacena Theorem

Under the assumption of single-field inflation, but *no* other assumptions about the inflationary action, Creminelli and Zaldarriaga [94] were able to prove a powerful theorem:

$$\boxed{\lim_{k_3\to 0}\langle \mathcal{R}_{\mathbf{k}_1}\mathcal{R}_{\mathbf{k}_2}\mathcal{R}_{\mathbf{k}_3}\rangle = (2\pi)^3\delta(\mathbf{k}_1+\mathbf{k}_2+\mathbf{k}_3)\,\underline{\underline{(1-n_{\rm s})}}\,P_{\mathcal{R}}(k_1)P_{\mathcal{R}}(k_3)}\,, \tag{629}$$

where

$$\langle \mathcal{R}_{\mathbf{k}_i}\mathcal{R}_{\mathbf{k}_j}\rangle = (2\pi)^3\delta(\mathbf{k}_i+\mathbf{k}_j)P_{\mathcal{R}}(k_i)\,. \tag{630}$$

Eqn. (629) states that for single-field inflation, the squeezed limit of the three-point function is suppressed by $(1-n_{\rm s})$ and vanishes for perfectly scale-invariant perturbations. A detection of non-Gaussianity in the squeezed limit can therefore rule out single-field inflation! In particular, this statement is independent of: the form of the potential, the form of the kinetic term (or sound speed) and the initial vacuum state.

Proof:

The squeezed triangle correlates one long-wavelength mode, $k_{\rm L}=k_3$ to two short-wavelength modes, $k_{\rm S}=k_1\approx k_2$,

$$\langle \mathcal{R}_{\mathbf{k}_1}\mathcal{R}_{\mathbf{k}_2}\mathcal{R}_{\mathbf{k}_3}\rangle \approx \langle (\mathcal{R}_{\mathbf{k}_{\rm S}})^2\mathcal{R}_{\mathbf{k}_{\rm L}}\rangle\,. \tag{631}$$

Modes with longer wavelengths freeze earlier. Therefore, $k_{\rm L}$ will be already frozen outside the horizon when the two smaller modes freeze and acts as a background field for the two short-wavelength modes.

Why should $(\mathcal{R}_{\mathbf{k}_{\rm S}})^2$ be correlated with $\mathcal{R}_{\mathbf{k}_{\rm L}}$? The theorem says that "it isn't correlated if $\mathcal{R}_{\rm k}$ is precisely scale-invariant". The proof is simplest in real-space (see Creminelli and Zaldarriaga [94]): The long-wavelength curvature perturbation $\mathcal{R}_{\mathbf{k}_{\rm L}}$ rescales the spatial coordinates (or changes the effective scale factor) within a given Hubble patch

$$\mathrm{d}s^2 = -\mathrm{d}t^2 + a(t)^2e^{2\mathcal{R}}\mathrm{d}\mathbf{x}^2\,. \tag{632}$$

The two-point function $\langle \mathcal{R}_{\mathbf{k}_1}\mathcal{R}_{\mathbf{k}_2}\rangle$ will depend on the value of the background fluctuations $\mathcal{R}_{\mathbf{k}_{\rm L}}$ already frozen outside the horizon. In position space the variation of the two-point function given by the long-wavelength fluctuations $\mathcal{R}_{\rm L}$ is at linear order

$$\frac{\partial}{\partial\mathcal{R}_{\rm L}}\langle\mathcal{R}(x)\mathcal{R}(0)\rangle\cdot\mathcal{R}_{\rm L} = x\frac{d}{dx}\langle\mathcal{R}(x)\mathcal{R}(0)\rangle\cdot\mathcal{R}_{\rm L}\,. \tag{633}$$

To get the three-point function Creminelli and Zaldarriaga multiply Eqn. (633) by $\mathcal{R}_{\rm L}$ and average over it. Going to Fourier space gives Eqn. (629).[43] QED.

Models with Large Non-Gaussianity

Higher-Derivative Interactions

Although Maldacena proved that for single-field *slow-roll* inflation non-Gaussianity is always small, single-field models can still give large non-Gaussianity if higher-derivative terms are important during inflation (as opposed to assuming a canonical kinetic term and no higher-derivative corrections as in slow-roll inflation). Consider the following action

$$S = \frac{1}{2}\int \mathrm{d}^4x\sqrt{-g}\,[R-P(X,\phi)]\;,\quad \text{where}\quad X\equiv(\partial_\mu\phi)^2\,. \tag{634}$$

[43] For more details see Cheung *et al.* [95].

Here, $P(X,\phi)$ is an arbitrary function of the kinetic term $X = (\partial_\mu\phi)^2$ and hence can contain higher-derivative interactions. These models in general have a non-trivial sound speed for the propagation of fluctuations

$$c_s^2 \equiv \frac{P_{,X}}{P_{,X} + 2XP_{,XX}}\,. \tag{635}$$

The second-order action for $\mathcal{R}$ (giving $P_\mathcal{R}$) is [81]

$$S_{(2)} = \int \mathrm{d}^4x\, \varepsilon \left[a^3(\dot{\mathcal{R}})^2/\underline{\underline{c_s^2}} - a(\partial_i\mathcal{R})^2\right] + \mathcal{O}(\varepsilon^2) \tag{636}$$

The third-order action for $\mathcal{R}$ (giving $B_\mathcal{R}$; see Appendix 7.8.3 and Ref. [81]) is

$$S_{(3)} = \int \mathrm{d}^4x\, \underline{\underline{\varepsilon^2}} \left[\ldots a^3(\dot{\mathcal{R}})^2\mathcal{R}/\underline{\underline{c_s^2}} + \ldots a(\partial_i\mathcal{R})^2\mathcal{R} + \ldots a^3(\dot{\mathcal{R}})^3/\underline{\underline{c_s^2}}\right] + \mathcal{O}(\varepsilon^3) \tag{637}$$

We notice that the third-order action is surpressed by an extra factor of ε relative to the second-order action. This is a reflection of the fact that non-Gaussianity is small in the slow-roll limit: $P(X,\phi) = X - V(\phi)$, $c_s^2 = 1$. However, away from the slow-roll limit, for small sound speeds, $c_s^2 \ll 1$, a few interaction terms in Eqn. (637) get boosted and non-Gaussianity can become significant. The signal is peaked at equilateral triangles, with

$$f_{\rm NL}^{\rm equil} = -\frac{35}{108}\left(\frac{1}{c_s^2} - 1\right) + \frac{5}{81}\left(\frac{1}{c_s^2} - 1 - 2\Lambda\right)\,, \tag{638}$$

where

$$\Lambda \equiv \frac{X^2P_{,XX} + \frac{2}{3}X^3P_{,XXX}}{XP_{,X} + 2X^2P_{,XX}}\,. \tag{639}$$

Whether actions with arbitrary $P(X,\phi)$ exist in consistent high-energy theories is an important challenge for these models. It is encouraging that one of the most interesting models of inflation in string theory, DBI inflation [92] (see **Lecture 5**), has precisely such a structure with

$$P_{\rm DBI}(X,\phi) = -f^{-1}(\phi)\sqrt{1 - 2f(\phi)X} + f^{-1}(\phi) - V(\phi)\,. \tag{640}$$

In this case, the second term in Eqn. (641) is identically zero and we find

$$f_{\rm NL}^{\rm DBI} = -\frac{35}{108}\left(\frac{1}{c_s^2} - 1\right)\,. \tag{641}$$

The shape function for DBI inflation is

$$\mathcal{S}^{\rm DBI}(k_1,k_2,k_3) \propto \frac{1}{K_{111}K^2}(K_5 + 2K_{14} - 3K_{23} + 2K_{113} - 8K_{122})\,. \tag{642}$$

Multiple Fields

In single-field slow-roll inflation interactions of the inflaton are constrained by the requirement that inflation should occur. However, if more than one field was relevant during inflation this constraint may be circumvented. Models like the *curvaton mechanism* [173, 67] or *inhomogeneous reheating* [68, 69] exploit this to create non-Gaussian fluctuations via fluctuations is a second field that is not the inflaton. The signal is peaked at squeezed triangles.

For more details on these mechanisms to produce local-type non-Gaussianity we refer the reader to the review by Bartolo *et al.* [30].

Non-Standard Vacuum

If inflation started in an excited state rather than in the Bunch-Davies vacuum, remnant non-Gaussianity may be observable [93] (unless inflation lasted much more than the minimal number of e-folds, in which case the effect is exponentially diluted). The signal is peaked at folded triangles with a shape function

$$\mathcal{S}^{\rm folded}(k_1,k_2,k_3) \propto \frac{1}{K_{111}}(K_{12}-K_3)+4\frac{K_2}{(\tilde{k}_1\tilde{k}_2\tilde{k}_3)^2}\,. \tag{643}$$

For a more detailed discussion of this effect the reader may consult the paper by Holman and Tolley [93].

7.6.3 Observational Prospects

Observational constraints on primordial non-Gaussianity are beginning to reach interesting levels. Precision CMB experiments now probe the regime of parameter space where some inflationary models [173, 67, 68, 69] and most models of New Ekpyrosis [70, 71, 72, 73, 74, 75, 76] predict a signal.

Cosmic Microwave Background

The latest constraint on $f_{\rm NL}^{\rm local}$ and $f_{\rm NL}^{\rm equil}$ by Smith, Senatore, and Zaldarriaga [42, 96] are

$$-4 \;<\; f_{\rm NL}^{\rm local} \;<\; +80 \quad \text{at} \;\; 95\%\ \text{CL}\,, \tag{644}$$

$$-125 \;<\; f_{\rm NL}^{\rm equil} \;<\; +435 \quad \text{at} \;\; 95\%\ \text{CL}\,. \tag{645}$$

The Planck satellite and the proposed CMBPol mission are projected to give $\sigma(f_{\rm NL}^{\rm local})\sim 5$ and $\sigma(f_{\rm NL}^{\rm local})\sim 2$, respectively. At the level of $f_{\rm NL}\sim\mathcal{O}(1)$ we, in fact, expect to see a signal from secondary effects not associated with inflation. In order, not to confuse these effects with the primordial signal, one needs to compute in detail how the non-linear evolution of fluctuations can induce its own non-Gaussianity. To date, the effects haven't been fully computed (but see, *e.g.* Refs.[97, 98, 99]). Often only their order of magnitude is estimated. A systematic characterization of all effects inducing observable levels of non-Gaussianity is clearly timely.

Large-Scale Structure

Non-Gaussianity also leaves signatures in the large-scale structure in the universe. In general, extracting primordial non-Gaussianity from large-scale structure observations is complicated by the fact that non-linear fluctuations produce a non-Gaussianity that completely dominates over the signal from primordial origin. However, recently, the concept of a *scale-dependent bias* has been introduced as a promising probe of primordial non-Gaussianity [91, 101]. It has been shown [91, 101] that for highly biased tracers of the underlying density field, the bias parameter depends on scale and on $f_{\rm NL}$

$$P_{\delta_g}(k) = \left[b+\Delta b(k,f_{\rm NL}^{\rm local})\right]^2 P_\delta(k)\,. \tag{646}$$

The details of the method are beyond the scope of this lecture but may be found *e.g.* in Ref. [101]. Application of the method to the luminous red galaxies (LRGs) sample of SDSS yields [101]

$$-29 \;<\; f_{\rm NL}^{\rm local} \;<\; +70 \quad \text{at} \;\; 95\%\ \text{CL}\,. \tag{647}$$

Note that this limit is competitive with the constraints obtained from the CMB. Although more work is needed to make this a truly robust test of primordial non-Gaussianity, the preliminary results by Slosar *et al.* [101] provide an encouraging proof-of-principle demonstration of the method.

7.6.4 *Summary*: Lecture 4

The study of non-Gaussian contributions to the correlations of cosmological fluctuations, is emerging as an important probe of the early universe [85]. Being a direct measure of inflaton interactions non-Gaussianity can potentially teach us a great deal about the inflationary dynamics.

The basic diagnostic for non-Gaussian fluctuations is the three-point function or bispectrum

$$\langle \mathcal{R}_{\mathbf{k}_1} \mathcal{R}_{\mathbf{k}_2} \mathcal{R}_{\mathbf{k}_3} \rangle = (2\pi)^3 \delta(\mathbf{k}_1 + \mathbf{k}_2 + \mathbf{k}_3) B_{\mathcal{R}}(k_1, k_2, k_3) \,.$$

Physically motivated models for producing non-Gaussian perturbations often produce signals that peak at special triangle configurations. Three special cases are:

i) *squeezed triangle* ($k_1 \approx k_2 \gg k_3$)

This is the dominant mode of models with multiple light fields during inflation [53, 54, 55, 56, 57, 58, 52, 60, 61, 62, 63, 64, 65], the curvaton scenario [173, 67], inhomogeneous reheating [68, 69], and New Ekpyrotic models [70, 71, 72, 73, 74, 75, 76].

ii) *equilateral triangle* ($k_1 = k_2 = k_3$)

Signals that peak at equilateral triangles arise in models with higher-derivative interactions [92].

iii) *folded triangle* ($k_1 = 2k_2 = 2k_3$)

Folded triangles arise in models with non-standard initial states [93].

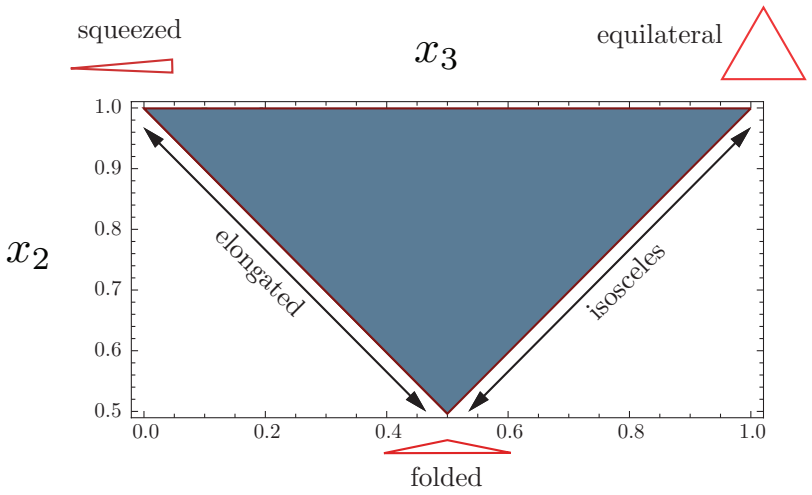

Figure 85: Shapes of Non-Gaussianity. The triangle shapes are parameterized by the rescaled momenta, $x_2 = k_2/k_1$, $x_3 = k_3/k_1$.

The single-field consistency relation is

$$\lim_{k_3 \to 0} \langle \mathcal{R}_{\mathbf{k}_1} \mathcal{R}_{\mathbf{k}_2} \mathcal{R}_{\mathbf{k}_3} \rangle = (2\pi)^3 \delta(\mathbf{k}_1 + \mathbf{k}_2 + \mathbf{k}_3) \underline{\underline{(1 - n_{\rm s})}} P_{\mathcal{R}}(k_1) P_{\mathcal{R}}(k_3) \,.$$

This states that the squeezed limit of the bispectrum for single-field inflation is proportional to the deviation from scale-invariance, $1 - n_{\rm s}$.

7.7 Conclusions

7.7.1 *Recap*: TASI Lectures on Inflation

Fig. 86 summarizes many of the key concepts described in these lectures.

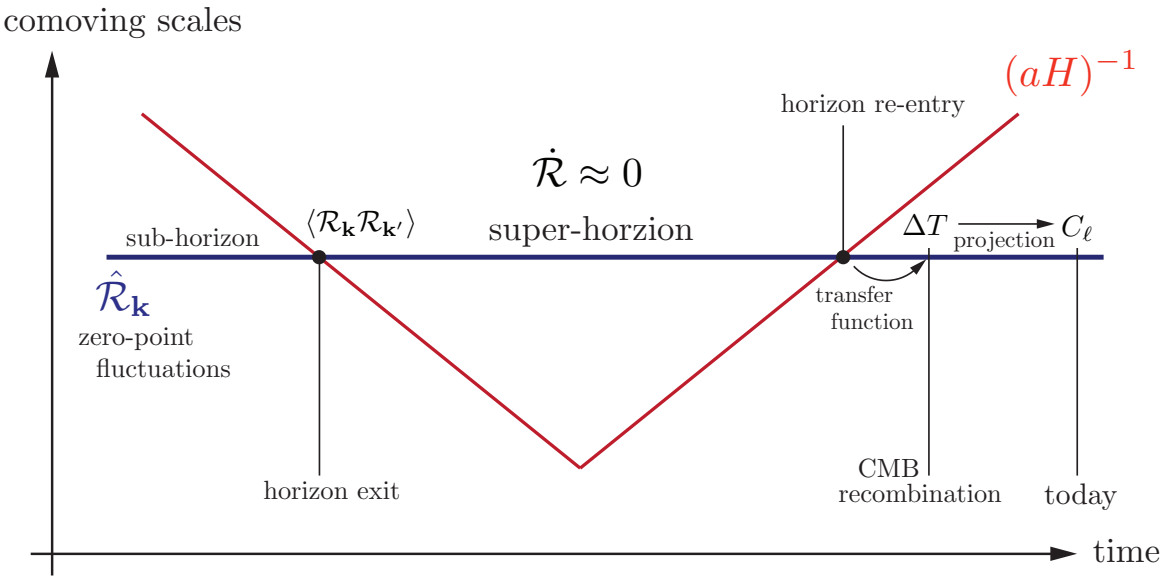

Figure 86: Evolution of the horizon and generation of perturbations in the inflationary universe.

- **Lecture 1**: We defined inflation as a phase in the very early universe when the comoving Hubble radius, $(aH)^{-1}$, was decreasing. We explained that this key characteristic of inflation was at the heart of the solution to the horizon and flatness problems. The apparent acausal correlations of CMB fluctuations on super-horizon scales at recombination are explained by those scales being inside the horizon during inflation (and hence causally-connected).

- **Lecture 2**: Modes exit the horizon during inflation and re-enter at later times during the conventional FRW expansion. We described scalar fluctuations during inflation in terms of the comoving curvature perturbation $\mathcal{R}$. A crucial feature of $\mathcal{R}$ is that it freezes on super-horizon scales, $\dot{\mathcal{R}} \approx 0$. The initial conditions for $\mathcal{R}$ can therefore be computed at horizon exit during inflation and translated without change to horizon re-entry (under fairly weak assumptions this is independent of the unknown physics of reheating). In Lecture 2 we computed the power spectrum of curvature perturbations, $\langle \mathcal{R}_{\mathbf{k}} \mathcal{R}_{\mathbf{k}'} \rangle = (2\pi)^3 \delta(\mathbf{k} + \mathbf{k}') P_{\mathcal{R}}(k)$, at horizon exit.

- **Lecture 3**: After horizon re-entry, the curvature perturbation $\mathcal{R}$ evolves into fluctuations of the CMB temperature ΔT at recombination. This sub-horizon evolution is captured by the transfer functions discussed in Lecture 3. Finally, today we see a projection of the CMB fluctuations from the last-scattering-surface to us. Experiments measure the angular power spectrum of CMB temperature fluctuations, C_ℓ. In Lecture 3 we explained how to relate the observed angular power spectrum of CMB anisotropies to the power spectrum of primordial curvature fluctuations, $P_{\mathcal{R}}(k)$, generated during inflation. Inverting the sub-horizon evolution and removing projection effects, CMB observations therefore provide a powerful probe of the inflationary perturbations.

- **Lecture 4**: The three-point function of primordial curvature perturbations, $\langle \mathcal{R}_{\mathbf{k}_1} \mathcal{R}_{\mathbf{k}_2} \mathcal{R}_{\mathbf{k}_3} \rangle = (2\pi)^3 \delta(\mathbf{k}_1 + \mathbf{k}_2 + \mathbf{k}_3) B_{\mathcal{R}}(k_1, k_2, k_3)$, can be an additional probe of the physics of inflation if the primordial fluctuations are sufficiently non-Gaussian.

7.7.2 Future Prospects and Open Problems

We have described the present observational evidence for inflation and highlighted future observational opportunities for further tests of the physics of inflation. Two of the most direct probes of inflation are primordial tensor modes and primordial non-Gaussianity:

- **B-modes**

  Detecting primordial B-modes (the CMB polarization signature of inflationary tensor modes) is clearly the most distinctive observation we could make to confirm inflation. We would measure the energy scale of inflation and learn that the inflaton field moved over a super-Planckian distance. The European *Planck* satellite [142], many ground-based or balloon experiments [143, 144, 145, 146, 147, 148, 149, 150], as well as the planned *CMBPol* mission [7, 151], all hope to detect this signal from the inflationary era. The theoretical community is awaiting the results from these experiments with great anticipation.

- **Non-Gaussianity**

  A slightly more model-dependent signature of the physics of inflation is the possible existence of non-Gaussianity in the primordial fluctuations. While predicted to be small for single-field slow-roll models, models with multiple fields, higher-derivative interactions or non-trivial vacuum states may leave non-Gaussian signatures. The momentum dependence of the Fourier-space signal is a powerful diagnostic of the mechanism that laid down the primordial fluctuations. The *Planck* satellite will be a sensitive probe of primordial non-Gaussianity.

In these lectures we have presented a rather optimistic view on inflation. While this illustrates the significant theoretical and observational advances that have been made in recent years in understanding and constraining the physics of inflation, it ignores important conceptual problems that the theory still faces. Here we mention some of these theoretical challenges and point to the relevant literature for more details:

- **Initial Conditions**

  The lectures have mentioned the initial conditions required to start inflation only in a very superficial way. Partly this is a reflection of the fact that the inflationary initial conditions aren't very well understood.

  Our simple slow-roll analysis of inflation has *assumed* that the initial inflaton velocities are small and that initial inhomogeneities in the inflaton field aren't large enough to prevent inflation:

  - *The overshoot problem*

    If the initial inflaton velocity near the region of the potential where inflation is supposed to occur is non-negligible, it is possible that the field will *overshoot* that region without sourcing accelerated expansion. This problem is stronger for small-field models where Hubble friction is often not efficient enough to slow the field before it reaches the region of interest.

  - *The patch problem*

    Initial inhomogeneities in the inflaton field provide gradient energy that also hinders accelerated expansion. Numerical analysis for specific examples shows that typically the inflaton field has to be smooth over a few times the horizon size at that time to start inflation.

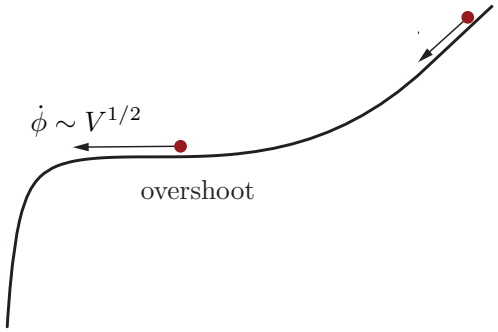

Figure 87: Graphical illustration of the overshoot problem.

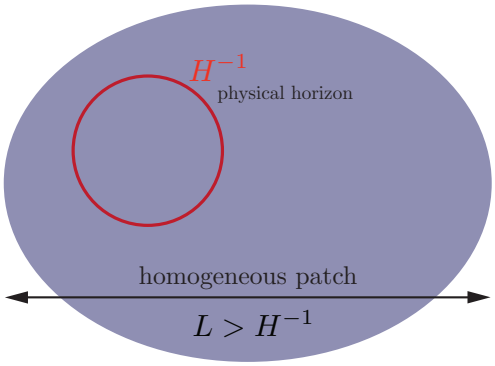

Figure 88: Graphical illustration of the patch problem.

How severe the fine-tuning of initial conditions really is for inflation cannot be discussed outside of the incompletely understood topic of eternal inflation and the measure problem.

- **Eternal Inflation and the Measure Problem**

  The modern view of inflation is that globally it never ends! Inflation ends locally to produce pockets of FRW universes, but there are always region where quantum fluctuations keep the field at high values of the potential energy. Those regions keep expanding exponentially and produce more volume of inflationary regions.

  How likely the initial conditions for inflation are and even what the inflationary predictions themselves are depends on the relative probabilities of the inflationary and non-inflationary patches of the universe (or multiverse). This is the measure problem. Different probability measures can significantly affect the probability of inflationary initial conditions and the likelihood of FRW universes with certain observable characteristics (like flatness, scale-invariant fluctuations, etc.)

  For more on eternal inflation and the measure problem see Refs. [152, 153, 154, 155, 156, 157, 158, 159, 160, 161, 162, 163, 164, 165].

These problems illustrate that there is still room for increasing our theoretical understanding of inflation and cosmological initial conditions. At the same time, the advent of high-precision measurements of CMB polarization and small-scale temperature fluctuations promises real experimental test of the inflationary hypothesis.

7.7.3 Guide to Further Reading

The following textbooks, reviews and papers have been useful to me in the preparation of these lectures. The student will find valuable further details about inflation in those works.

Textbooks

- Mukhanov, *Physical Foundations of Cosmology*

  A nice treatment of early universe cosmology and the theory of cosmological perturbations.

- Dodelson, *Modern Cosmology*

  An excellent book about cosmology with a strong focus on the cosmic microwave background. Very readable, *i.e.* you can read it while lying down.

- Weinberg, *Cosmology*

  It is by Steven Weinberg!

- Liddle and Lyth, *Cosmological Inflation and Large-Scale Structure*

  A comprehensive review of inflationary cosmology.

- Longair, *Galaxy Formation*

  A more astrophysical perspective of cosmology.

- Birrell and Davies, *Quantum Field Theory in Curved Spacetime*

  The classic treatment of quantum field theory in curved spacetime.

Reviews

- Baumann et al., *Probing Inflation with CMB Polarization*

  White paper of the Inflation Working Group of the CMBPol Mission Concept Study. More than 60 experts on inflation combined to write this very comprehensive review.

- Baumann and Peiris, *Cosmological Inflation: Theory and Observations*

  In this review Hiranya Peiris and I summarize the basics of inflation and CMB observations for a non-expert audience. The level might be too elementary for the readers of these lectures, but could be of interest to readers looking for some bedtime reading.

- Baumann and McAllister, *Advances in String Inflation*

  In this review Liam McAllister and I describe the challenge of realizing inflation in string theory.

- Lyth and Riotto, *Particle Physics Models of Inflation*

  What these lectures lack on inflationary model-building may be found here.

- Bassett et al., *Inflation Dynamics and Reheating*

  What these lectures lack on reheating may be found here.

- Kinney, *TASI Lectures on Inflation*

  Will Kinney's lectures at *TASI 2008* are perfect as a first read on inflation. It is hoped that these *TASI 2009* lectures make a good second read. I tried to complement Will's lectures by giving more technical details.

- Malik and Wands, *Cosmological Perturbations*

  A nice review of first and second-order perturbation theory. Many useful formulas.

- Komatsu, *The Pursuit of Non-Gaussian Fluctuations in the Cosmic Microwave Background*

  Eiichiro Komatsu's PhD thesis contains a useful review of non-Gaussian fluctuations from inflation.

Papers

Some of the original papers on inflation are very accessible and well worth reading:

- Guth, *Inflationary Universe: A Possible Solution to the Horizon and Flatness Problems*

  This classic is of course a must-read. It provides a very clear explanation of the Big Bang puzzles.

- Maldacena, *Non-Gaussian Features of Primordial Fluctuations in Single Field Inflationary Models*

  This paper provided the first rigorous computation of the three-point function for slow-roll inflation. It also gives one of the clearest and most elegant expositions of the calculation of the power spectra of inflationary fluctuations. My treatment in these lectures was heavily inspired by Maldacena's paper.

7.8 Appendix

7.8.1 Cosmological Perturbation Theory

In this appendix we summarize basic facts of cosmological perturbation theory. This is based on unpublished lecture notes of a course at Princeton University by Uros Seljak and Chris Hirata as well as a review by Malik and Wands [166].

The Perturbed Universe

We consider perturbations to the homogeneous background spacetime and the stress-energy of the universe.

Metric Perturbations

The most general first-order perturbation to a spatially flat FRW metric is

$$\mathrm{d}s^2 = -(1+2\Phi)\mathrm{d}t^2 + 2a(t)B_i\mathrm{d}x^i\mathrm{d}t + a^2(t)[(1-2\Psi)\delta_{ij} + 2E_{ij}]\mathrm{d}x^i\mathrm{d}x^j \tag{A.1}$$

where Φ is a 3-scalar called the *lapse*, B_i is a 3-vector called the *shift*, Ψ is a 3-scalar called the spatial *curvature* perturbation, and E_{ij} is a spatial *shear* 3-tensor which is symmetric and traceless, $E^i_i = \delta^{ij}E_{ij} = 0$. 3-surfaces of constant time t are called *slices* and curves of constant spatial coordinates x^i but varying time t are called *threads*.

Stress-Energy Perturbations

The stress-energy tensor may be described by a density ρ, a pressure p, a 4-velocity u^μ (of the frame in which the 3-momentum density vanishes), and an anisotropic stress $\Sigma^{\mu\nu}$.

Density and pressure perturbations are defined in an obvious way

$$\delta\rho(t,x^i) \equiv \rho(t,x^i) - \bar{\rho}(t)\,, \qquad \text{and} \qquad \delta p(t,x^i) \equiv p(t,x^i) - \bar{p}(t)\,. \tag{A.2}$$

Here, the background values have been denoted by overbars. The 4-velocity has only three independent components (after the metric is fixed) since it has to satisfy the constraint $g_{\mu\nu}u^\mu u^\nu = -1$. In the perturbed metric (A.1) the perturbed 4-velocity is

$$u_\mu \equiv (-1-\Phi, a v_i)\,, \qquad \text{or} \qquad u^\mu \equiv (1-\Phi, a^{-1}(v^i - B^i))\,. \tag{A.3}$$

Here, u_0 is chosen so that the constraint $u_\mu u^\mu = -1$ is satisfied to first order in all perturbations. Anisotropic stress vanishes in the unperturbed FRW universe, so $\Sigma^{\mu\nu}$ is a first-order perturbation. Furthermore, $\Sigma^{\mu\nu}$ is constrained by

$$\Sigma^{\mu\nu}u_\nu = \Sigma^\mu_\mu = 0\,. \tag{A.4}$$

The orthogonality with u_μ implies $\Sigma^{00} = \Sigma^{0j} = 0$, *i.e.* only the spatial components Σ^{ij} are non-zero. The trace condition then implies $\Sigma^i_i = 0$. Anisotropic stress is therefore a traceless symmetric 3-tensor.

Finally, with these definitions the perturbed stress-tensor is

$$\begin{aligned} T^0_0 &= -(\bar\rho + \delta\rho) && \text{(A.5)}\\ T^0_i &= (\bar\rho + \bar p)\, a v_i && \text{(A.6)}\\ T^i_0 &= -(\bar\rho + \bar p)(v^i - B^i)/a && \text{(A.7)}\\ T^i_j &= \delta^i_j(\bar p + \delta p) + \Sigma^i_j\,. && \text{(A.8)} \end{aligned}$$

If there are several contributions to the stress-energy tensor (*e.g.* photons, baryons, dark matter, etc.), they are added: $T_{\mu\nu} = \sum_I T^I_{\mu\nu}$. This implies

$$\begin{aligned} \delta\rho &= \sum_I \delta\rho_I && \text{(A.9)}\\ \delta p &= \sum_I \delta p_I && \text{(A.10)}\\ (\bar\rho + \bar p)v^i &= \sum_I (\bar\rho_I + \bar p_I) v^i_I && \text{(A.11)}\\ \Sigma^{ij} &= \sum_I \Sigma^{ij}_I\,. && \text{(A.12)} \end{aligned}$$

Density, pressure and anisotropic stress perturbations simply add. However, velocities do not add, which motivates defining the 3-momentum density

$$\delta q^i \equiv (\bar\rho + \bar p)\, a v^i\,, \tag{A.13}$$

such that

$$\delta q^i = \sum_I \delta q^i_I\,. \tag{A.14}$$

Scalars, Vectors and Tensors

The Einstein Equations relate metric perturbations to the stress-energy perturbations. Einstein's Equations are both complicated (coupled second-order partial differential equations) and non-linear. Fortunately, the symmetries of the flat FRW background spacetime allow perturbations to be decomposed into independent scalar, vector and tensor components. This reduces the Einstein Equations to a set of uncoupled ordinary differential equations.

Helicity and SVT-Decomposition in Fourier Space

The decomposition into scalar, vector and tensor perturbations is most elegantly explained in Fourier space. We define the Fourier components of a general perturbation $\delta Q(t, \mathbf{x})$ as follows

$$\delta Q(t, \mathbf{k}) = \int \mathrm{d}^3\mathbf{x}\, \delta Q(t, \mathbf{x}) e^{-i\mathbf{k}\cdot\mathbf{x}}\,. \tag{A.15}$$

First note that as a consequence of translation invariance different Fourier modes (different wavenumbers k) evolve independently.[44]

Proof:

Consider the linear evolution of N perturbations δQ_I, $I = 1, \ldots, N$ from an initial time t_1 to a final time t_2

$$\delta Q_I(t_2, \mathbf{k}) = \sum_{J=1}^{N} \int \mathrm{d}^3\bar{\mathbf{k}}\; T_{IJ}(t_2, t_1, \mathbf{k}, \bar{\mathbf{k}}) \delta Q_J(t_1, \bar{\mathbf{k}})\,, \tag{A.16}$$

where the transfer matrix $T_{IJ}(t_2, t_1, \mathbf{k}, \bar{\mathbf{k}})$ follows from the Einstein Equations and we have allowed for the possibility of a mixing of k-modes. We now show that translation invariance in fact forbids such couplings. Consider the coordinate transformation

$$x^{i'} = x^i + \Delta x^i\,, \qquad \text{where} \quad \Delta x^i = const. \tag{A.17}$$

You may convince yourself that the Fourier amplitude gets shifted as follows

$$\delta Q'_I(t, \mathbf{k}) = e^{-ik_j \Delta x^j} \delta Q_I(t, \mathbf{k})\,. \tag{A.18}$$

Thus the evolution equation in the primed coordinate system becomes

$$\delta Q'_I(t_2, \mathbf{k}) = \sum_{J=1}^{N} \int \mathrm{d}^3\bar{\mathbf{k}}\; e^{-ik_j \Delta x^j} T_{IJ}(t_2, t_1, \mathbf{k}, \bar{\mathbf{k}}) e^{i\bar{k}_j \Delta x^j}\, \delta Q'_J(t_1, \bar{\mathbf{k}}) \tag{A.19}$$

$$\equiv \sum_{J=1}^{N} \int \mathrm{d}^3\bar{\mathbf{k}}\; T'_{IJ}(t_2, t_1, \mathbf{k}, \bar{\mathbf{k}}) \delta Q_J(t_1, \bar{\mathbf{k}})\,. \tag{A.20}$$

By translation invariance the equations of motion must be the same in both coordinate systems, *i.e.* the transfer matrices T_{IJ} and T'_{IJ} must be the same

$$T_{IJ}(t_2, t_1, \mathbf{k}, \bar{\mathbf{k}}) = e^{i(\bar{k}_j - k_j)\Delta x^j} T_{IJ}(t_2, t_1, \mathbf{k}, \bar{\mathbf{k}})\,. \tag{A.21}$$

This must hold for all Δx^j. Hence, either $\bar{\mathbf{k}} = \mathbf{k}$ or $T_{IJ}(t_2, t_1; \mathbf{k}, \bar{\mathbf{k}}) = 0$, *i.e.* the perturbation $\delta Q_I(t_2, \mathbf{k})$ of wavevector $\mathbf{k}$ depends only on the initial perturbations of wavevector $\mathbf{k}$. At linear order there is no coupling of different k-modes. QED.

Now consider rotations around the Fourier vector $\mathbf{k}$ by an angle ψ. We classify perturbations according to their *helicity* m: a perturbation of helicity m has its amplitude multiplied by $e^{im\psi}$ under the above rotation. We define scalar, vector and tensor perturbations as having helicities 0, ± 1, ± 2, respectively.

Consider a Fourier mode with wavevector $\mathbf{k}$. Without loss of generality we may assume that $\mathbf{k} = (0, 0, k)$ (or use rotational invariance of the background). The spatial dependence of any perturbation then is

$$\delta Q \propto e^{ikx^3}\,. \tag{A.22}$$

[44] The following proof was related to me by Uros Seljak and Chris Hirata.

To study rotations around $\mathbf{k}$ it proves convenient to switch to the helicity basis

$$\mathbf{e}_\pm \equiv \frac{\mathbf{e}_1 \pm i\mathbf{e}_2}{\sqrt{2}}\,, \qquad \mathbf{e}_3\,, \tag{A.23}$$

where $\{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\}$ is the Cartesian basis. A rotation around the 3-axis by an angle ψ has the following effect

$$\begin{pmatrix} x^{1'} \\ x^{2'} \end{pmatrix} = \begin{pmatrix} \cos\psi & \sin\psi \\ -\sin\psi & \cos\psi \end{pmatrix} \begin{pmatrix} x^1 \\ x^2 \end{pmatrix}\,, \qquad x^{3'} = x^3\,, \tag{A.24}$$

and

$$\mathbf{e}'_\pm = e^{\pm i\psi}\mathbf{e}_\pm\,, \qquad \mathbf{e}'_3 = \mathbf{e}_3\,. \tag{A.25}$$

The contravariant components of any tensor $T_{i_1 i_2 \ldots i_n}$ transform as

$$T'_{i_1 i_2 \ldots i_n} = e^{i(n_+ - n_-)\psi} T_{i_1 i_2 \ldots i_n} \equiv e^{im\psi} T_{i_1 i_2 \ldots i_n} \tag{A.26}$$

where n_+ and n_- count the number of plus and minus indices in $i_1 \ldots i_n$, respectively. Helicity is defined as the difference $m \equiv n_+ - n_-$.

In the helicity basis $\{\mathbf{e}_\pm, \mathbf{e}_3\}$, a 3- scalar α has a single component with no indicies and is therefore obviously of helicity 0; a 3-vector β_i has 3 components $\beta_+, \beta_-, \beta_3$ of helicity ± 1 and 0; a symmetric and traceless 3-tensor γ_{ij} has 5 components $\gamma_{--}, \gamma_{++}, \gamma_{-3}, \gamma_{+3}, \gamma_{33}$ (the tracelessness condition makes γ_{-+} redundant), of helicity ± 2, ± 1 and 0.

Rotational invariance of the background implies that helicity scalars, vectors and tensors evolve independently.[45]

Proof:

Consider N perturbations δQ_I, $I = 1, \ldots, N$ of helicity m_I. The linear evolution is

$$\delta Q_I(t_2, \mathbf{k}) = \sum_{J=1}^{N} T_{IJ}(t_2, t_1, \mathbf{k}) \delta Q_J(t_1, \mathbf{k})\,, \tag{A.27}$$

where the transfer matrix $T_{IJ}(t_2, t_1, \mathbf{k})$ follows from the Einstein Equations. Under rotation the perturbations transform as

$$\delta Q'_I(t, \mathbf{k}) = e^{im_I\psi} \delta Q_I(t, \mathbf{k}) \tag{A.28}$$

and

$$\delta Q'_I(t_2, \mathbf{k}) = \sum_{J=1}^{N} e^{im_I\psi}\, T_{IJ}(t_2, t_1, \mathbf{k})\, e^{-im_J\psi} \delta Q'_J(t_1, \mathbf{k})\,. \tag{A.29}$$

By rotational invariance of the equations of motion

$$T_{IJ}(t_2, t_1, \mathbf{k}) = e^{im_I\psi}\, T_{IJ}(t_2, t_1, \mathbf{k})\, e^{-im_J\psi} = e^{i(m_I - m_J)\psi} T_{IJ}(t_2, t_1, \mathbf{k})\,, \tag{A.30}$$

which has to hold for any angle ψ; it follows that eithers $m_I = m_J$, *i.e.* δQ_I and δQ_J have the same helicity or $T_{IJ}(t_2, t_1, \mathbf{k}) = 0$. This proves that the equations of motion don't mix modes of different helicity. QED.

[45] The following proof was related to me by Uros Seljak and Chris Hirata.

Real Space SVT-Decomposition

In the last section we have seen that 3-scalars correspond to helicity scalars, 3-vectors decompose into helicity scalars and vectors, and 3-tensors decompose into helicity scalars, vectors and tensors. We now look at this from a different perspective.

A 3-scalar is obviously also a helicity scalar

$$\alpha = \alpha^S \,. \tag{A.31}$$

Consider a 3-vector β_i. We argue that it can be decomposed as

$$\beta_i = \beta_i^S + \beta_i^V \,, \tag{A.32}$$

where

$$\beta_i^S = \nabla_i \hat{\beta} \,, \qquad \nabla^i \beta_i^V = 0 \,, \tag{A.33}$$

or, in Fourier space,

$$\beta_i^S = -\frac{ik_i}{k}\beta \,, \qquad k_i \beta_i^V = 0 \,. \tag{A.34}$$

Here, we have defined $\beta \equiv k\hat{\beta}$. .

Exercise 12 (Helicity Vector)**.** *Show that β_i^V is a helicity vector.*

Similarly, a traceless, symmetric 3-tensor can be written as

$$\gamma_{ij} = \gamma_{ij}^S + \gamma_{ij}^V + \gamma_{ij}^T \,, \tag{A.35}$$

where

$$\gamma_{ij}^S = \left(\nabla_i\nabla_j - \frac{1}{3}\delta_{ij}\nabla^2\right)\hat{\gamma} \tag{A.36}$$

$$\gamma_{ij}^V = \frac{1}{2}\left(\nabla_i\hat{\gamma}_j + \nabla_j\hat{\gamma}_i\right) \,, \quad \nabla_i\hat{\gamma}_i = 0 \tag{A.37}$$

$$\nabla_i\gamma_{ij}^T = = 0 \,. \tag{A.38}$$

or

$$\gamma_{ij}^S = \left(-\frac{k_ik_j}{k^2} + \frac{1}{3}\delta_{ij}\right)\gamma \tag{A.39}$$

$$\gamma_{ij}^V = -\frac{i}{2k}\left(k_i\gamma_j + k_j\gamma_i\right) \,, \quad k_i\gamma_i = 0 \tag{A.40}$$

$$k_i\gamma_{ij}^T = = 0 \,. \tag{A.41}$$

Here, we have defined $\gamma \equiv k^2\hat{\gamma}$ and $\gamma_i \equiv k\hat{\gamma}_i$.

Exercise 13 (Helicity Vectors and Tensors)**.** *Show that γ_{ij}^V and γ_{ij}^T are a helicity vector and a helicity tensor, respectively.*

Choosing $\mathbf{k}$ along the 3-axis, *i.e.* $\mathbf{k} = (0, 0, k)$ we find

$$\gamma_{ij}^S = \frac{1}{3}\begin{pmatrix} \gamma & 0 & 0 \\ 0 & \gamma & 0 \\ 0 & 0 & -2\gamma \end{pmatrix} \tag{A.42}$$

$$\gamma_{ij}^V = -\frac{i}{2}\begin{pmatrix} 0 & 0 & \gamma_1 \\ 0 & 0 & \gamma_2 \\ \gamma_1 & \gamma_2 & 0 \end{pmatrix} \tag{A.43}$$

$$\gamma_{ij}^T = \begin{pmatrix} \gamma^\times & \gamma^+ & 0 \\ \gamma^+ & -\gamma^\times & 0 \\ 0 & 0 & 0 \end{pmatrix} \,. \tag{A.44}$$

Scalars

Metric Perturbations

Four scalar metric perturbations Φ, $B_{,i}$, $\Psi\delta_{ij}$ and $E_{,ij}$ may be constructed from 3-scalars, their derivatives and the background spatial metric, *i.e.*

$$\mathrm{d}s^2 = -(1+2\Phi)\mathrm{d}t^2 + 2a(t)B_{,i}\mathrm{d}x^i\mathrm{d}t + a^2(t)[(1-2\Psi)\delta_{ij} + 2E_{,ij}]\mathrm{d}x^i\mathrm{d}x^j \tag{A.45}$$

Here, we have absorbed the $\nabla^2 E\,\delta_{ij}$ part of the helicity scalar E^S_{ij} in $\Psi\,\delta_{ij}$.

The intrinsic Ricci scalar curvature of constant time hypersurfaces is

$$R_{(3)} = \frac{4}{a^2}\nabla^2\Psi\,. \tag{A.46}$$

This explains why Ψ is often referred to as the curvature perturbation.

There are two scalar gauge transformations

$$t \;\rightarrow\; t+\alpha \tag{A.47}$$
$$x^i \;\rightarrow\; x^i + \delta^{ij}\beta_{,j}\,. \tag{A.48}$$

Under these coordinate transformations the scalar metric perturbations transform as

$$\Phi \;\rightarrow\; \Phi - \dot{\alpha} \tag{A.49}$$
$$B \;\rightarrow\; B + a^{-1}\alpha - a\dot{\beta} \tag{A.50}$$
$$E \;\rightarrow\; E - \beta \tag{A.51}$$
$$\Psi \;\rightarrow\; \Psi + H\alpha\,. \tag{A.52}$$

Note that the combination $\dot{E} - B/a$ is independent of the spatial gauge and only depends on the temporal gauge. It is called the scalar potential for the anisotropic shear of world lines orthogonal to constant time hypersurfaces. To extract physical results it is useful to define gauge-invariant combinations of the scalar metric perturbations. Two important gauge-invariant quantities were introduced by Bardeen [219]

$$\Phi_{\mathrm{B}} \;\equiv\; \Phi - \frac{d}{dt}[a^2(\dot{E} - B/a)] \tag{A.53}$$
$$\Psi_{\mathrm{B}} \;\equiv\; \Psi + a^2 H(\dot{E} - B/a)\,. \tag{A.54}$$

Matter Perturbations

Matter perturbations are also gauge-dependent, *e.g.* density and pressure perturbations transform as follows under temporal gauge transformations

$$\delta\rho \rightarrow \delta\rho - \dot{\bar{\rho}}\,\alpha\,, \qquad \delta p \rightarrow \delta p - \dot{\bar{p}}\,\alpha\,. \tag{A.55}$$

Adiabatic pressure perturbations are defined as

$$\delta p_{ad} \equiv \frac{\dot{\bar{p}}}{\dot{\bar{\rho}}}\,\delta\rho\,. \tag{A.56}$$

The non-adiabiatic, or entropic, part of the pressure perturbations is then gauge-invariant

$$\delta p_{en} \equiv \delta p - \frac{\dot{\bar{p}}}{\dot{\bar{\rho}}}\,\delta\rho\,. \tag{A.57}$$

The scalar part of the 3-momentum density, $(\delta q)_{,i}$, transforms as

$$\delta q \to \delta q + (\bar{\rho} + \bar{p})\,\alpha\,. \tag{A.58}$$

We may then define the gauge-invariant comoving density perturbation

$$\delta\rho_m \equiv \delta\rho - 3H\delta q\,. \tag{A.59}$$

Finally, two important gauge-invariant quantities are formed from combinations of matter and metric perturbations. The *curvature perturbation on uniform density hypersurfaces* is

$$-\zeta \equiv \Psi + \frac{H}{\dot{\bar{\rho}}}\delta\rho\,. \tag{A.60}$$

The *comoving curvature perturbation* is

$$\mathcal{R} = \Psi - \frac{H}{\bar{\rho}+\bar{p}}\delta q\,. \tag{A.61}$$

We will show that ζ and $\mathcal{R}$ are equal on superhorizon scales, where they become time-independent. The computation of the inflationary perturbation spectrum is most clearly phrased in terms of ζ and $\mathcal{R}$.

Einstein Equations

To relate the metric and stress-energy perturbations, we consider the perturbed Einstein Equations

$$\delta G_{\mu\nu} = 8\pi G\,\delta T_{\mu\nu}\,. \tag{A.62}$$

We work at linear order. This leads to the *energy and momentum constraint equations*

$$3H(\dot{\Psi} + H\Phi) + \frac{k^2}{a^2}\left[\Psi + H(a^2\dot{E} - aB)\right] = -4\pi G\,\delta\rho \tag{A.63}$$

$$\dot{\Psi} + H\Phi = -4\pi G\,\delta q\,. \tag{A.64}$$

These can be combined into the gauge-invariant *Poisson Equation*

$$\frac{k^2}{a^2}\Psi_{\rm B} = -4\pi G\delta\rho_m\,. \tag{A.65}$$

The Einstein equation also yield two *evolution equations*

$$\ddot{\Psi} + 3H\dot{\Psi} + H\dot{\Phi} + (3H^2 + 2\dot{H})\Phi = 4\pi G\left(\delta p - \frac{2}{3}k^2\delta\Sigma\right) \tag{A.66}$$

$$(\partial_t + 3H)(\dot{E} - B/a) + \frac{\Psi - \Phi}{a^2} = 8\pi G\,\delta\Sigma\,. \tag{A.67}$$

The last equation may be written as

$$\Psi_{\rm B} - \Phi_{\rm B} = 8\pi G\,a^2\delta\Sigma\,. \tag{A.68}$$

In the absence of anisotropic stress this implies, $\Psi_{\rm B} = \Phi_{\rm B}$.

Energy-momentum conservation, $\nabla_\mu T^{\mu\nu} = 0$, gives the *continuity equation* and the *Euler Equation*

$$\dot{\delta\rho} + 3H(\delta\rho + \delta p) = \frac{k^2}{a^2}\delta q + (\bar{\rho}+\bar{p})[3\dot{\Psi} + k^2(\dot{E} + B/a)]\,, \tag{A.69}$$

$$\dot{\delta q} + 3H\delta q = -\delta p + \frac{2}{3}k^2\delta\Sigma - (\bar{\rho}+\bar{p})\Phi\,. \tag{A.70}$$

Expressed in terms of the curvature perturbation on uniform-density hypersurfaces, ζ, Eqn. (A.69) reads

$$\dot{\zeta} = -H\frac{\delta p_{en}}{\bar{\rho}+\bar{p}} - \Pi\,, \tag{A.71}$$

where δp_{en} is the non-adiabatic component of the pressure perturbation, and Π is the scalar shear along comoving worldlines

$$\frac{\Pi}{H} \equiv -\frac{k^2}{3H}\left[\dot{E} - B/a + \frac{\delta q}{a^2(\bar{\rho}+\bar{p})}\right] \tag{A.72}$$

$$= -\frac{k^2}{3a^2H^2}\left[\zeta - \Psi_{\rm B}\left(1 - \frac{2\bar{\rho}}{9(\bar{\rho}+\bar{p})}\frac{k^2}{a^2H^2}\right)\right]\,. \tag{A.73}$$

For adiabative perturbations, $\delta p_{en} = 0$ on superhorizon scales, $k/(aH) \ll 1$ (*i.e.* $\Pi/H \to 0$ for finite ζ and $\Psi_{\rm B}$), the curvature perturbation ζ is constant. This is a crucial result for our computation of the inflationary spectrum of ζ in **Lecture 2**. It justifies computing ζ at horizon exit and ignoring superhorizon evolution.

Popular Gauges

For reference we now give the Einstein Equations and the conservation equations is various popular gauges:

- **Synchronous gauge**

  A popular gauge, especially for numerical implementation of the perturbation equations (*cf.* CMBFAST [28] or CAMB [166]), is synchronous gauge. It is defined by

  $$\Phi = B = 0\,. \tag{A.74}$$

  The Einstein Equations become

  $$3H\dot{\Psi} + \frac{k^2}{a^2}\left[\Psi + Ha^2\dot{E}\right] = -4\pi G\,\delta\rho \tag{A.75}$$

  $$\dot{\Psi} = -4\pi G\,\delta q \tag{A.76}$$

  $$\ddot{\Psi} + 3H\dot{\Psi} = 4\pi G\left(\delta p - \frac{2}{3}k^2\delta\Sigma\right) \tag{A.77}$$

  $$(\partial_t + 3H)\dot{E} + \frac{\Psi}{a^2} = 8\pi G\,\delta\Sigma\,. \tag{A.78}$$

  The conservation equation are

  $$\dot{\delta\rho} + 3H(\delta\rho + \delta p) = \frac{k^2}{a^2}\delta q + (\bar{\rho}+\bar{p})[3\dot{\Psi} + k^2\dot{E}] \tag{A.79}$$

  $$\dot{\delta q} + 3H\delta q = -\delta p + \frac{2}{3}k^2\delta\Sigma\,. \tag{A.80}$$

- **Newtonian gauge**

  The Newtonian gauge has its name because it reduces to Newtonian gravity in the small-scale limit. It is popular for analytic work since it leads to algebraic relations between metric and stress-energy perturbations.

  Newtonian gauge is defined by

  $$B = E = 0\,, \tag{A.81}$$

and

$$\mathrm{d}s^2 - (1+2\Phi)\mathrm{d}t^2 + a^2(t)(1-2\Psi)\delta_{ij}\mathrm{d}x^i\mathrm{d}x^j\,. \tag{A.82}$$

The Einstein Equations are

$$\begin{aligned} 3H(\dot{\Psi} + H\Phi) + \frac{k^2}{a^2}\Psi &= -4\pi G\,\delta\rho & \text{(A.83)}\\ \dot{\Psi} + H\Phi &= -4\pi G\,\delta q & \text{(A.84)}\\ \ddot{\Psi} + 3H\dot{\Psi} + H\dot{\Phi} + (3H^2 + 2\dot{H})\Phi &= 4\pi G\left(\delta p - \frac{2}{3}k^2\delta\Sigma\right) & \text{(A.85)}\\ \frac{\Psi - \Phi}{a^2} &= 8\pi G\,\delta\Sigma\,. & \text{(A.86)} \end{aligned}$$

The continuity equations are

$$\begin{aligned} \dot{\delta\rho} + 3H(\delta\rho + \delta p) &= \frac{k^2}{a^2}\delta q + 3(\bar{\rho} + \bar{p})\dot{\Psi}\,, & \text{(A.87)}\\ \dot{\delta q} + 3H\delta q &= -\delta p + \frac{2}{3}k^2\delta\Sigma - (\bar{\rho} + \bar{p})\Phi\,. & \text{(A.88)} \end{aligned}$$

- **Uniform density gauge**

  The uniform density gauge is useful for describing the evolution of perturbations on superhorizon scales. As its name suggests it is defined by

$$\delta\rho = 0\,. \tag{A.89}$$

  In addition, it is convenient to take

$$E = 0\,, \qquad -\Psi \equiv \zeta\,. \tag{A.90}$$

  The Einstein Equations are

$$\begin{aligned} 3H(-\dot{\zeta} + H\Phi) - \frac{k^2}{a^2}\left[\zeta + aHB\right] &= 0 & \text{(A.91)}\\ -\dot{\zeta} + H\Phi &= -4\pi G\,\delta q & \text{(A.92)}\\ -\ddot{\zeta} - 3H\dot{\zeta} + H\dot{\Phi} + (3H^2 + 2\dot{H})\Phi &= 4\pi G\left(\delta p - \frac{2}{3}k^2\delta\Sigma\right) & \text{(A.93)}\\ (\partial_t + 3H)B/a + \frac{\zeta + \Phi}{a^2} &= -8\pi G\,\delta\Sigma\,. & \text{(A.94)} \end{aligned}$$

  The continuity equations are

$$\begin{aligned} 3H\delta p &= \frac{k^2}{a^2}\delta q + (\bar{\rho} + \bar{p})[-3\dot{\zeta} + k^2 B/a]\,, & \text{(A.95)}\\ \dot{\delta q} + 3H\delta q &= -\delta p + \frac{2}{3}k^2\delta\Sigma - (\bar{\rho} + \bar{p})\Phi\,. & \text{(A.96)} \end{aligned}$$

- **Comoving gauge**

  Comoving gauge is defined by the vanishing of the scalar momentum density,

$$\delta q = 0\,, \qquad E = 0\,. \tag{A.97}$$

  It is also conventional to set $-\Psi \equiv \mathcal{R}$ in this gauge.

The Einstein Equations are

$$3H(-\dot{\mathcal{R}} + H\Phi) + \frac{k^2}{a^2}\left[-\mathcal{R} - aHB\right] = -4\pi G\,\delta\rho \tag{A.98}$$

$$-\dot{\mathcal{R}} + H\Phi = 0 \tag{A.99}$$

$$-\ddot{\mathcal{R}} - 3H\dot{\mathcal{R}} + H\dot{\Phi} + (3H^2 + 2\dot{H})\Phi = 4\pi G\left(\delta p - \frac{2}{3}k^2\delta\Sigma\right) \tag{A.100}$$

$$(\partial_t + 3H)B/a + \frac{\mathcal{R} + \Phi}{a^2} = -8\pi G\,\delta\Sigma\,. \tag{A.101}$$

The continuity equations are

$$\dot{\delta\rho} + 3H(\delta\rho + \delta p) = (\bar{\rho} + \bar{p})[-3\dot{\mathcal{R}} + k^2 B/a]\,. \tag{A.102}$$

$$0 = -\delta p + \frac{2}{3}k^2\delta\Sigma - (\bar{\rho} + \bar{p})\Phi\,. \tag{A.103}$$

Equations (A.103) and (A.99) may be combined into

$$\Phi = \frac{-\delta p + \frac{2}{3}\Sigma}{\bar{\rho} + \bar{p}}\,, \qquad kB = \frac{4\pi G a^2\delta\rho - k^2\mathcal{R}}{aH}\,. \tag{A.104}$$

- **Spatially-flat gauge**

  A convenient gauge for computing inflationary perturbation is spatially-flat gauge

$$\Psi = E = 0\,. \tag{A.105}$$

  During inflation all scalar perturbations are then described by $\delta\phi$.

  The Einstein Equations are

$$3H^2\Phi + \frac{k^2}{a^2}\left[-aHB)\right] = -4\pi G\,\delta\rho \tag{A.106}$$

$$H\Phi = -4\pi G\,\delta q \tag{A.107}$$

$$H\dot{\Phi} + (3H^2 + 2\dot{H})\Phi = 4\pi G\left(\delta p - \frac{2}{3}k^2\delta\Sigma\right) \tag{A.108}$$

$$(\partial_t + 3H)B/a + \frac{\Phi}{a^2} = -8\pi G\,\delta\Sigma\,. \tag{A.109}$$

  The continuity equations are

$$\dot{\delta\rho} + 3H(\delta\rho + \delta p) = \frac{k^2}{a^2}\delta q + (\bar{\rho} + \bar{p})[k^2 B/a]\,, \tag{A.110}$$

$$\dot{\delta q} + 3H\delta q = -\delta p + \frac{2}{3}k^2\delta\Sigma - (\bar{\rho} + \bar{p})\Phi\,. \tag{A.111}$$

Vectors

Metric Perturbations

Vector type metric perturbations are defined as

$$\mathrm{d}s^2 = -\mathrm{d}t^2 + 2a(t)S_i\mathrm{d}x^i\mathrm{d}t + a^2(t)[\delta_{ij} + 2F_{(i,j)}]\mathrm{d}x^i\mathrm{d}x^j\,, \tag{A.112}$$

where $S_{i,i} = F_{i,i} = 0$. The vector gauge transformation is

$$x^i \to x^i + \beta^i\,, \qquad \beta_{i,i} = 0\,. \tag{A.113}$$

They lead to the transformations

$$S_i \to S_i + a\dot{\beta}_i\,, \tag{A.114}$$

$$F_i \to F_i - \beta_i\,. \tag{A.115}$$

The combination $\dot{F}_i + S_i/a$ is called the gauge-invariant vector shear perturbation.

Matter Perturbations

We define the vector part of the anisotropic stress by

$$\delta\Sigma_{ij} = \partial_{(i}\Sigma_{j)}\,, \tag{A.116}$$

where Σ_i is divergence-free, $\Sigma_{i,i} = 0$.

Einstein Equations

For vector perturbations there are only two Einstein Equations,

$$\dot{\delta q_i} + 3H\delta q_i = k^2\delta\Sigma_i\,, \tag{A.117}$$

$$k^2(\dot{F}_i + S_i/a) = 16\pi G\,\delta q_i\,. \tag{A.118}$$

In the absence of anisotropic stress ($\delta\Sigma_i = 0$) the divergence-free momentum δq_i decays with the expansion of the universe; see Eqn. (A.117). The shear perturbation $\dot{F}_i + S_i/a$ then vanishes by Eqn. (A.118). Under most circumstances vector perturbations are therefore subdominant. They won't play an important role in these lectures. In particular, vector perturbations aren't created by inflation.

Tensors

Metric Perturbations

Tensor metric perturbations are defined as

$$\mathrm{d}s^2 = -\mathrm{d}t^2 + a^2(t)[\delta_{ij} + h_{ij}]\mathrm{d}x^i\mathrm{d}x^j\,, \tag{A.119}$$

where $h_{ij,i} = h^i_i = 0$. Tensor perturbations are automatically gauge-invariant (at linear order). It is conventional to decompose tensor perturbations into eigenmodes of the spatial Laplacian, $\nabla^2 e_{ij} = -k^2 e_{ij}$, with comoving wavenumber k and scalar amplitude $h(t)$,

$$h_{ij} = h(t)e_{ij}^{(+,\times)}(x)\,. \tag{A.120}$$

Here, $+$ and $\times$ denote the two possible polarization states.

Matter Perturbations

Tensor perturbations are sourced by anisotropic stress Σ_{ij}, with $\Sigma_{ij,i} = \Sigma^i_i = 0$. It is typically a good approximation to assume that the anisotropic stress is negligible, although a small amplitude is induced by neutrino free-streaming.

Einstein Equations

For tensor perturbations there is only one Einstein Equation. In the absence of anisotropic stress this is

$$\ddot{h} + 3H\dot{h} + \frac{k^2}{a^2}h = 0\,. \tag{A.121}$$

This is a wave equation describing the evolution of gravitational waves in an expanding universe. Gravitational waves are produced by inflation, but then decay with the expansion of the universe. However, at recombination their amplitude may still be large enough to leave distinctive signatures in B-modes of CMB polarization.

Statistics

We recall some basic facts about statistics. More details may be found in Licia Verde's notes [167].

Fourier Conventions

Different conventions exist for the normalization of Fourier transforms. Defining

$$\mathcal{R}_{\mathbf{k}} = A \int \mathrm{d}^3x\, \mathcal{R}(\mathbf{x})\, \mathbf{e}^{-\mathbf{i}\mathbf{k}\cdot\mathbf{x}}\,, \tag{A.122}$$

$$\mathcal{R}(\mathbf{x}) = B \int \mathrm{d}^3k\, \mathcal{R}_{\mathbf{k}}\, e^{i\mathbf{k}\cdot\mathbf{x}}\,, \tag{A.123}$$

implies that the Dirac delta function is

$$\delta(\mathbf{k}) = BA \int \mathrm{d}^3x\, e^{\pm i\mathbf{k}\cdot\mathbf{x}}\,, \qquad BA = \frac{1}{(2\pi)^3}\,. \tag{A.124}$$

Except for the constraint $BA = 1/(2\pi)^3$ different conventions are possible for the values of A and B. These conventions can lead to some confusion about factors of 2π in the normalization of the power spectrum. In the main text we follow the convention $A = 1$, $B = 1/(2\pi)^3$ (the other common convention is $A = B = 1/(2\pi)^{3/2}$; it is nice, since it makes the basis function $e^{i\mathbf{k}\mathbf{x}}$ orthonormal rather than just orthogonal.), but in this appendix we will keep things general in order to help identifying normalization errors in the literature.

Two-Point Correlation Function

We make frequent use of the two-point correlation function

$$\xi_{\mathcal{R}}(r) \equiv \langle \mathcal{R}(\mathbf{x})\mathcal{R}(\mathbf{x}+\mathbf{r})\rangle\,. \tag{A.125}$$

Here, we have made the assumption that by isotropy ξ depends only on $r \equiv |\mathbf{r}|$ (distance not orientation).

Power Spectrum

Consider the following ensemble average

$$\langle \mathcal{R}_{\mathbf{k}}\, \mathcal{R}_{\mathbf{k}'}\rangle\,, \tag{A.126}$$

where $\mathcal{R}^*_{\mathbf{k}} = \mathcal{R}_{-\mathbf{k}}$ because $\mathcal{R}(\mathbf{x})$ is real. Substituting (A.122) gives

$$\langle \mathcal{R}_{\mathbf{k}}\, \mathcal{R}_{\mathbf{k}'}\rangle = A^2 \int \mathrm{d}^3x\, e^{-i(\mathbf{k}+\mathbf{k}')\mathbf{x}} \int \mathrm{d}^3r\, \xi_{\mathcal{R}}(r) e^{-i\mathbf{k}\mathbf{r}} \tag{A.127}$$

$$= \frac{A}{B}\delta(\mathbf{k}+\mathbf{k}') \int \mathrm{d}^3r\, \xi_{\mathcal{R}}(r) e^{-i\mathbf{k}\mathbf{r}}\,. \tag{A.128}$$

If we *define* the power spectrum as the Fourier transform of the two-point correlation function

$$P_{\mathcal{R}}(k) \equiv A \int \mathrm{d}^3r\, \xi_{\mathcal{R}}(r)\, e^{-i\mathbf{k}\cdot\mathbf{r}}\,, \tag{A.129}$$

then we get

$$\langle \mathcal{R}_{\mathbf{k}}\, \mathcal{R}_{\mathbf{k}'}\rangle = \frac{1}{B} P_{\mathcal{R}}(k)\delta(\mathbf{k}+\mathbf{k}')\,. \tag{A.130}$$

Notice that often the power spectrum is defined as

$$\langle \mathcal{R}_{\mathbf{k}}\, \mathcal{R}_{\mathbf{k}'} \rangle = (2\pi)^3 P_{\mathcal{R}}(k) \delta(\mathbf{k} + \mathbf{k}') \,. \tag{A.131}$$

In the present discussion we realize that this implies a fixed Fourier convention, $B = 1/(2\pi)^3$, if we mean by the power spectrum really the Fourier transform of the two-point function; this is often not done correctly in the literature.

Consider the variance

$$\sigma^2_{\mathcal{R}} \equiv \langle \mathcal{R}^2(x) \rangle = \xi_{\mathcal{R}}(0) = B \int \mathrm{d}^3k\, P_{\mathcal{R}}(k) \,. \tag{A.132}$$

This is often defined as

$$\sigma^2_{\mathcal{R}} \equiv \int \mathrm{d} \ln k\, \Delta^2_{\mathcal{R}}(k) \,, \tag{A.133}$$

where

$$\Delta^2_{\mathcal{R}}(k) \equiv 4\pi B\, k^3 P_{\mathcal{R}}(k) \,. \tag{A.134}$$

In the common Fourier convention $B = 1/(2\pi)^3$ this becomes

$$\Delta^2_{\mathcal{R}}(k) \equiv \frac{k^3}{2\pi^2} P_{\mathcal{R}}(k) \,. \tag{A.135}$$

For other Fourier conventions the relation between $\Delta^2_{\mathcal{R}}(k)$ and $P_{\mathcal{R}}(k)$ will differ by a numerical factor.

Bispectrum

For Gaussian perturbations the power spectrum contains all the information (all higher-order correlation functions can be expressed in terms of the two-point function). Non-Gaussianity is measured by a non-zero three-point function, or equivalently in Fourier space the bispectrum

$$\langle \mathcal{R}_{\mathbf{k}_1} \mathcal{R}_{\mathbf{k}_2} \mathcal{R}_{\mathbf{k}_3} \rangle = (2\pi)^3 B_{\mathcal{R}}(k_1, k_2, k_3) \delta(\mathbf{k}_1 + \mathbf{k}_2 + \mathbf{k}_3) \,. \tag{A.136}$$

7.8.2 Free Field Action for $\mathcal{R}$

In this appendix we compute the second-order action for the comoving curvature perturbation $\mathcal{R}$. This is a basic element for the quantization of cosmological scalar perturbations in **Lecture 2**.

We consider slow-roll models of inflation which are described by a canonical scalar field ϕ minimally coupled to gravity

$$S = \frac{1}{2} \int \mathrm{d}^4x \sqrt{-g}\, \left[R - (\nabla\phi)^2 - 2V(\phi) \right] \,, \tag{A.137}$$

in units where $M_{\rm pl}^{-2} \equiv 8\pi G = 1$. We will study perturbations of this action due to fluctuations in the scalar field $\delta\phi(t, x^i) \equiv \phi(t, x^i) - \bar{\phi}(t)$ and the metric. We will treat metric fluctuations in the ADM formalism (Arnowitt-Deser-Misner) [168].

Slow-Roll Background

We consider a flat background metric

$$\mathrm{d}s^2 = -\mathrm{d}t^2 + a(t)^2\delta_{ij}\mathrm{d}x^i\mathrm{d}x^j = a^2(\tau)(-\mathrm{d}\tau^2 + \delta_{ij}\mathrm{d}x^i\mathrm{d}x^j)\,, \tag{A.138}$$

with scale factor $a(t)$ and Hubble parameter $H(t) \equiv \partial_t \ln a$ satisfying the Friedmann Equations

$$3H^2 = \frac{1}{2}\dot{\phi}^2 + V(\phi)\,, \qquad \dot{H} = -\frac{1}{2}\dot{\phi}^2\,. \tag{A.139}$$

The scalar field satisfies the Klein-Gordon Equation

$$\ddot{\phi} + 3H\dot{\phi} + V_{,\phi} = 0\,. \tag{A.140}$$

The standard slow-roll parameters are

$$\epsilon_{\rm v} = \frac{1}{2}\Big(\frac{V_{,\phi}}{V}\Big)^2 \approx \frac{1}{2}\frac{\dot{\phi}^2}{H^2}\,, \qquad \eta_{\rm v} = \frac{V_{,\phi\phi}}{V} \approx -\frac{\ddot{\phi}}{H\dot{\phi}} + \frac{1}{2}\frac{\dot{\phi}^2}{H^2}\,. \tag{A.141}$$

ADM Formalism

We treat fluctuations in the ADM formalism [168] where spacetime is sliced into three-dimensional hypersurfaces

$$\mathrm{d}s^2 = -N^2\mathrm{d}t^2 + g_{ij}(\mathrm{d}x^i + N^i\mathrm{d}t)(\mathrm{d}x^j + N^j\mathrm{d}t)\,. \tag{A.142}$$

Here, g_{ij} is the three-dimensional metric on slices of constant t. The lapse function $N(\mathbf{x})$ and the shift function $N_i(\mathbf{x})$ contain the same information as the metric perturbations Φ and B in (A.45). However, they were chosen in such a way that they appear as non-dynamical Lagrange multipliers in the action, *i.e.* their equations of motion are purely algebraic. The action (A.137) becomes

$$S = \frac{1}{2}\int \mathrm{d}^4x\sqrt{-g}\Big[NR^{(3)} - 2NV + N^{-1}(E_{ij}E^{ij} - E^2) + N^{-1}(\dot{\phi} - N^i\partial_i\phi)^2 - Ng^{ij}\partial_i\phi\partial_j\phi - 2V\Big]\,, \tag{A.143}$$

where

$$E_{ij} \equiv \frac{1}{2}(\dot{g}_{ij} - \nabla_i N_j - \nabla_j N_i)\,, \qquad E = E^i_i\,. \tag{A.144}$$

E_{ij} is related to the extrinsic curvature of the three-dimensional spatial slices $K_{ij} = N^{-1}E_{ij}$.

Exercise 14 (ADM Action)**.** *Confirm Eqn. (A.143).*

Comoving Gauge

To fix time and spatial reparameterizations we choose the following gauge for the dynamical fields g_{ij} and ϕ

$$\delta\phi = 0\,, \qquad g_{ij} = a^2[(1-2\mathcal{R})\delta_{ij} + h_{ij}]\,, \qquad \partial_i h_{ij} = h^i_i = 0\,. \tag{A.145}$$

In this gauge the inflaton field is unperturbed and all scalar degrees of freedom are parameterized by the metric fluctuation $\mathcal{R}(t,\mathbf{x})$. Geometrically, $\mathcal{R}$ measures the spatial curvature of constant-ϕ hypersurfaces, $R^{(3)} = 4\nabla^2\mathcal{R}/a^2$. An important property of $\mathcal{R}$ is that it remains constant outside the horizon. This allows us in **Lecture 2** to restrict our computation to correlation functions at horizon crossing.

Constraint Equations

The ADM action (A.143) implies the following constraint equations for the Lagrange multipliers N and N^i

$$\nabla_i[N^{-1}(E^i_j - \delta^i_j E)] = 0\,, \tag{A.146}$$
$$R^{(3)} - 2V - N^{-2}(E_{ij}E^{ij} - E^2) - N^{-2}\dot{\phi}^2 = 0\,. \tag{A.147}$$

Exercise 15 (Constraint Equations)**.** *Derive the constraint equations (A.146) and (A.147) from the ADM action (A.143).*

To solve the constraints, we split the shift vector N_i into irrotational (scalar) and incompressible (vector) parts

$$N_i \equiv \psi_{,i} + \tilde{N}_i\,, \quad \text{where} \quad \tilde{N}_{i,i} = 0\,, \tag{A.148}$$

and define the lapse perturbation as

$$N \equiv 1 + \alpha\,. \tag{A.149}$$

The quantities α, ψ and $\tilde{N}_i$ then admit expansions in powers of $\mathcal{R}$,

$$\begin{aligned} \alpha &= \alpha_1 + \alpha_2 + \dots\,, \\ \psi &= \psi_1 + \psi_2 + \dots\,, \\ \tilde{N}_i &= \tilde{N}_i^{(1)} + \tilde{N}_i^{(2)} + \dots\,, \end{aligned} \tag{A.150}$$

where, *e.g.* $\alpha_n = \mathcal{O}(\mathcal{R}^n)$. The constraint equations may then be set to zero order-by-order.

Exercise 16 (First-Order Solution of Constraint Equations)**.** *Show that at first order (A.147) implies*

$$\alpha_1 = \frac{\dot{\mathcal{R}}}{H}\,, \qquad \partial^2 \tilde{N}_i^{(1)} = 0\,. \tag{A.151}$$

With an appropriate choice of boundary conditions one may set $\tilde{N}_i^{(1)} \equiv 0$. Show that at first order Eqn. (A.146) implies

$$\psi_1 = -\frac{\mathcal{R}}{H} + \frac{a^2}{H}\epsilon_{\rm v}\,\partial^{-2}\dot{\mathcal{R}}\,, \tag{A.152}$$

where ∂^{-2} is defined via $\partial^{-2}(\partial^2\phi) = \phi$.

The Free Field Action

Substituting the first-order solutions for N and N_i back into the action, one finds the following second-order action [22]

$$\boxed{S_2 = \frac{1}{2}\int \mathrm{d}^4x\, a^3 \frac{\dot{\phi}^2}{H^2}\left[\dot{\mathcal{R}}^2 - a^{-2}(\partial_i\mathcal{R})^2\right]}\,. \tag{A.153}$$

Exercise 17 (Second-Order Action)**.** *Confirm Eqn. (A.153). Hint: use integration by parts and the background equations of motion.*

The quadratic action (A.153) for $\mathcal{R}$ is the main result of this appendix and forms the basis for the quantization of cosmological perturbations in **Lecture 2**.

7.8.3 A Brief Review of the In-In Formalism

The problem of computing correlation functions in cosmology differs in important ways from the corresponding analysis of quantum field theory applied to particle physics. In particle physics the central object is the S-matrix describing the transition probability for a state in the far past $|\psi\rangle$ to become some state $|\psi'\rangle$ in the far future, $\langle\psi'|S|\psi\rangle = \langle\psi'(+\infty)|\psi(-\infty)\rangle$. Imposing asymptotic conditions at very early *and* very late times makes sense in this case, since in Minkowski space, states are assumed to non-interacting in the far past and the far future, *i.e.* the asymptotic state are taken to be vacuum state of the free Hamiltonian H_0.

In cosmology, however, we evaluate the expectation values of products of fields *at a fixed time*. Conditions are *not* imposed on the fields at both very early and very late times, but only at very early times, when the wavelength is deep inside the horizon. As we argued in **Lecture 2**, in this limit (according to the equivalence principle) the interaction picture fields should have the same firm as in Minkowski space. This lead us to the definition of the Bunch-Davies vacuum (the free vacuum in Minkowski space).

In this appendix we describe the Schwinger-Keldysh "in-in" formalism [86] to compute cosmological correlation functions. After pioneering work by Calzetta and Hu [87] and Jordan [88] the application of the "in-in" formalism to cosmological problems was recently revived by Maldacena [22] and Weinberg [89] (see also [169, 170]).

Time Evolution in the Interaction Picture

To describe the time evolution of cosmological perturbations we split the Hamiltonian into a free part and an interacting part

$$\boxed{H = H_0 + H_{\rm int}}\,. \tag{A.154}$$

The free-field Hamiltonian H_0 is quadratic in perturbations. Quadratic order was sufficient to compute the two-point correlations of **Lecture 2**. However, the higher-order correlations that concerned us in our study of non-Gaussianity in **Lecture 4** require going beyond quadratic order and defining the interaction Hamiltonian $H_{\rm int}$. The interaction Hamiltonian defines the evolution of states via the well-known time-evolution operator

$$U(\tau_2,\tau_1) = T\exp\left(-i\int_{\tau_1}^{\tau_2}{\rm d}\tau' H_{\rm int}(\tau')\right)\,, \tag{A.155}$$

where T denotes the time-ordering operator. The time-evolution operator U may be used to relate the interacting vacuum at arbitrary time $|\Omega(\tau)\rangle$ to the free (Bunch-Davies) vacuum $|0\rangle$. We first expand $\Omega(\tau)$ in eigenstates of the free Hamiltonian,

$$|\Omega\rangle = \sum_n |n\rangle\langle n|\Omega(\tau)\rangle\,. \tag{A.156}$$

Then we evolve $|\Omega(\tau)\rangle$ as

$$|\Omega(\tau_2)\rangle = U(\tau_2,\tau_1)|\Omega(\tau_1)\rangle = |0\rangle\langle 0|\Omega\rangle + \sum_{n\geq 1} e^{+iE_n(\tau_2-\tau_1)}|n\rangle\langle n|\Omega(\tau_1)\rangle\,. \tag{A.157}$$

$|{\rm in}\rangle$ Vacuum

From Eqn. (A.157) we see that the choice $\tau_2 = -\infty(1-i\epsilon)$ projects out all excited states. Hence, we have the following relation between the interacting vacuum at $\tau = -\infty(1-i\epsilon)$ and the free vacuum $|0\rangle$

$$|\Omega(-\infty(1-i\epsilon))\rangle = |0\rangle\langle 0|\Omega\rangle\,. \tag{A.158}$$

Finally, the interacting vacuum at an arbitrary time τ is

$$|\text{in}\rangle \equiv |\Omega(\tau)\rangle = U(\tau, -\infty(1-i\epsilon))|\Omega(-\infty(1-i\epsilon))\rangle \tag{A.159}$$

$$= T\exp\left(-i\int_{-\infty(1-i\epsilon)}^{\tau} \mathrm{d}\tau' H_{\rm int}(\tau')\right)|0\rangle\langle 0|\Omega\rangle\,. \tag{A.160}$$

Expectation Values

In the "in-in" formalism, the expectation value $\langle W(\tau)\rangle$, of a product of operators $W(\tau)$ at time τ, is evaluated as[46]

$$\langle W(\tau)\rangle \equiv \frac{\langle \text{in}|W(\tau)|\text{in}\rangle}{\langle \text{in}|\text{in}\rangle} \tag{A.161}$$

$$= \left\langle 0\right|\left(\bar{T}e^{-i\int_{-\infty^+}^{\tau} H_{\rm int}(\tau')\mathrm{d}\tau'}\right)^{\dagger} W(\tau)\left(Te^{-i\int_{-\infty^+}^{\tau} H_{\rm int}(\tau'')\mathrm{d}\tau''}\right)\left|0\right\rangle, \tag{A.162}$$

or

$$\boxed{\langle W(\tau)\rangle = \left\langle 0\right|\left(\bar{T}e^{-i\int_{-\infty^-}^{\tau} H_{\rm int}(\tau')\mathrm{d}\tau'}\right) W(\tau)\left(Te^{-i\int_{-\infty^+}^{\tau} H_{\rm int}(\tau'')\mathrm{d}\tau''}\right)\left|0\right\rangle,} \tag{A.163}$$

where we defined the anti-time-ordering operator $\bar{T}$ and the notation $-\infty^{\pm} \equiv -\infty(1\mp i\epsilon)$. This definition of the correlation functions $\langle W(\tau)\rangle$ in terms of the interaction Hamiltonian $H_{\rm int}$ is the main result of the "in-in" formalism. The interaction Hamiltonian is computed in the ADM approach to General Relativity [22] and $\langle W(\tau)\rangle$ is then evaluated perturbatively.

In **Lecture 4** this formalism was implicitly used to compute the three-point functions for various inflationary models,

$$\boxed{\langle \mathcal{R}_{\mathbf{k}_1}\mathcal{R}_{\mathbf{k}_2}\mathcal{R}_{\mathbf{k}_3}\rangle(\tau) = \left\langle 0\right|\left(\bar{T}e^{-i\int_{-\infty^-}^{\tau} H_{\rm int}(\tau')\mathrm{d}\tau'}\right)\mathcal{R}_{\mathbf{k}_1}(\tau)\mathcal{R}_{\mathbf{k}_2}(\tau)\mathcal{R}_{\mathbf{k}_3}(\tau)\left(Te^{-i\int_{-\infty^+}^{\tau} H_{\rm int}(\tau'')\mathrm{d}\tau''}\right)\left|0\right\rangle.} \tag{A.164}$$

Interaction Hamiltonian

Let us sketch how the interaction Hamiltonian is computed:[47] The inflationary action is expanded perturbatively

$$S = S_0[\bar{\phi}, \bar{g}_{\mu\nu}] + S_2[\mathcal{R}^2] + S_3[\mathcal{R}^3] + \cdots\,. \tag{A.165}$$

Here, we have defined a background part S_0, a quadratic free-field part S_2 and a non-linear interaction term S_3. The background action S_0 defines the Hubble parameter H and the slow-roll parameters ε and η. The free-field action S_2 defines the time-evolution of the mode functions $\mathcal{R}(\tau)$ in the interaction picture (often denoted by $\mathcal{R}_{\rm I}(\tau)$). The non-linear part of the action defines the interaction Hamiltonian, *e.g.* at cubic order $S_3 = -\int \mathrm{d}\tau H_{\rm int}(\mathcal{R}_{\rm I})$. Schematically, the interaction Hamiltonian takes the following form

$$H_{\rm int} = \sum_i f_i(\varepsilon, \eta, \ldots)\mathcal{R}_{\rm I}^3(\tau)\,. \tag{A.166}$$

[46] For a derivation of this result see Weinberg [89].

[47] For a sample calculation that shows the full (painful) details see Maldacena [22].

Perturbative Expansion

In **Lecture 2** we defined the expansion of the operator corresponding to the Mukhanov variable, $v = 2a^2\varepsilon\,\mathcal{R}$, in terms of creation and annihilation operators

$$\hat{v}_{\mathbf{k}}(\tau) = v_k(\tau)\hat{a}_{\mathbf{k}} + v_k^*(\tau)\hat{a}^\dagger_{-\mathbf{k}}\,. \tag{A.167}$$

The mode functions $v_k(\tau)$ were defined uniquely by initial state boundary conditions when all modes were deep inside the horizon

$$v_k(\tau) = \frac{e^{-ik\tau}}{\sqrt{2k}}\left(1 - \frac{i}{k\tau}\right)\,. \tag{A.168}$$

The free two-point correlation function is

$$\langle 0|\hat{v}_{\mathbf{k}_1}(\tau_1)\hat{v}_{\mathbf{k}_2}(\tau_2)|0\rangle = (2\pi)^3\delta(\mathbf{k}_1 + \mathbf{k}_2)G_{k_1}(\tau_1,\tau_2)\,, \tag{A.169}$$

with

$$G_{k_1}(\tau_1,\tau_2) \equiv v_k(\tau_1)v_k^*(\tau_2)\,. \tag{A.170}$$

Expansion of Eqn. (A.164) in powers of $H_{\rm int}$ gives:

- at zeroth order
$$\langle W(\tau)\rangle^{(0)} = \langle 0|W(\tau)|0\rangle\,, \tag{A.171}$$
where $W(\tau) \equiv \mathcal{R}_{\mathbf{k}_1}(\tau)\mathcal{R}_{\mathbf{k}_2}(\tau)\mathcal{R}_{\mathbf{k}_3}(\tau)$.
- at first order
$$\langle W(\tau)\rangle^{(1)} = 2\,\mathrm{Re}\left[-i\int_{-\infty^+}^{\tau}\mathrm{d}\tau'\langle 0|W(\tau)H_{\rm int}(\tau')|0\rangle\right]\,. \tag{A.172}$$
- at second order
$$\begin{aligned}\langle W(\tau)\rangle^{(2)} \;=\; & -2\,\mathrm{Re}\left[\int_{-\infty^+}^{\tau}\mathrm{d}\tau'\int_{-\infty^+}^{\tau'}\mathrm{d}\tau''\langle 0|W(\tau)H_{\rm int}(\tau')H_{\rm int}(\tau'')|0\rangle\right] \\ & + \int_{-\infty^-}^{\tau}\mathrm{d}\tau'\int_{-\infty^+}^{\tau}\mathrm{d}\tau''\langle 0|H_{\rm int}(\tau')W(\tau)H_{\rm int}(\tau'')|0\rangle\,.\end{aligned} \tag{A.173}$$

In the bispectrum calculations of **Lecture 2** the zeroth-order term (A.171) vanishes for Gaussian initial conditions. The leading result therefore comes from Eqn. (A.172). Evaluating Eqn. (A.172) makes use of Wick's theorem to expresses the result as products of two-point functions (A.170).

7.8.4 Slow-Roll Inflation in the Hamilton-Jacobi Approach

In these lectures we have defined *exact* slow-roll conditions via the parameters

$$\varepsilon = -\frac{\dot{H}}{H^2}\,, \qquad \eta = -\frac{\ddot{\phi}}{H\dot{\phi}}\,, \tag{B.1}$$

and *approximate* conditions via

$$\epsilon_{\rm v} = \frac{M_{\rm pl}^2}{2}\left(\frac{V_{,\phi}}{V}\right)^2\,, \qquad \eta_{\rm v} = M_{\rm pl}^2\frac{V_{,\phi\phi}}{V}\,. \tag{B.2}$$

In this appendix we explore their relationship in more detail.

Hamilton-Jacobi Formalism

The Hamilton-Jacobi approach treats the Hubble expansion rate $H(\phi) = \mathcal{H}/a$ as the fundamental quantity, considered as a function of time. Consider

$$H_{,\phi} = \frac{H'}{\phi'} = \frac{-(\mathcal{H}^2 - \mathcal{H}')/a}{\phi'} = -\frac{\phi'}{2a}\,, \tag{B.3}$$

where we used $\mathcal{H}^2 - \mathcal{H}' = a^2(\rho + p)/2 = (\phi')^2/2$ and primes are derivatives with respect to conformal time. This gives the master equation

$$\boxed{\frac{d\phi}{dt} = \frac{\phi'}{a} = -2H_{,\phi}}\,. \tag{B.4}$$

This allows us to rewrite the Friedmann Equation

$$H^2 = \frac{1}{3}\left[\frac{1}{2}\left(\frac{d\phi}{dt}\right)^2 + V(\phi)\right] \tag{B.5}$$

in the following way

$$\boxed{[H_{,\phi}]^2 - \frac{3}{2}H^2 = -\frac{1}{2}V(\phi)}\,. \tag{B.6}$$

Notice the following important consequence of the Hamilton-Jacobi Equation (B.6): For any specified function $H(\phi)$, it produces a potential $V(\phi)$ which admits the given $H(\phi)$ as an exact inflationary solution. Integrating Eqn. (B.4)

$$\int \mathrm{d}t = -\frac{1}{2}\int \frac{\mathrm{d}\phi}{H'(\phi)} \tag{B.7}$$

relates ϕ to proper time t. This enables us to obtain $H(t)$, which can be integrated to give $a(t)$. The Hamilton-Jacobi formalism can therefore be used to generate infinitely many inflationary models with exactly known analytic solutions for the background expansion. However, here we are more concerned with the fact that it allows an elegant and intuitive definition of the slow-roll parameters.

Hubble Slow-Roll Parameters

During slow-roll inflation the background spacetime is approximately de Sitter. Any deviation of the background equation of state

$$w = \frac{p}{\rho} = \frac{(\phi')^2/2a^2 - V}{(\phi')^2/2a^2 + V} \tag{B.8}$$

from the perfect de Sitter limit $w = -1$ may be defined by the parameter

$$\boxed{\varepsilon \equiv \frac{3}{2}(1 + w)}\,. \tag{B.9}$$

We can express the Friedmann Equations

$$\mathcal{H}^2 = \frac{1}{3}a^2\rho \tag{B.10}$$

$$\mathcal{H}' = -\frac{1}{6}a^2(\rho + 3p) \tag{B.11}$$

in terms of ε

$$\mathcal{H}^2 = \frac{1}{3}\frac{(\phi')^2}{\varepsilon} \tag{B.12}$$

$$\mathcal{H}' = \mathcal{H}^2(1-\varepsilon)\,. \tag{B.13}$$

Hence,

$$\varepsilon = 1 - \frac{\mathcal{H}'}{\mathcal{H}^2} = \frac{d(H^{-1})}{dt} = -\frac{\dot{H}}{H^2}\,. \tag{B.14}$$

Note that this can be interpreted as the rate ot change of the Hubble parameter H with respect to the number of e-foldings $\mathrm{d}N = H\mathrm{d}t = -\frac{1}{2}\frac{H(\phi)}{H_{,\phi}}\mathrm{d}\phi$

$$\boxed{\varepsilon = -\frac{d\ln H}{dN} = 2\left(\frac{H_{,\phi}}{H}\right)^2}\,. \tag{B.15}$$

Analogously we define the second slow-roll parameter as the rate of change of $H_{,\phi}$

$$\boxed{\eta = -\frac{d\ln|H_{,\phi}|}{dN} = 2\frac{H_{,\phi\phi}}{H}}\,. \tag{B.16}$$

Using Eqn. (B.4) this is also

$$\eta = \frac{d\ln|\dot{\phi}|}{dN}\,. \tag{B.17}$$

Slow-Roll Inflation

By definition, slow-roll corresponds to a regime where all dynamical characteristics of the universe, measured in physical (proper) units, change little over a single e-folding of expansion. This ensures that the primordial perturbations are generated with approximately equal power on all scales, leading to a scale-invariant perturbation spectrum.

Since ε and η characterize the rate of change of H and $H_{,\phi}$ with e-foldings, slow-roll is naturally defined by

$$\varepsilon \ll 1\,, \quad |\eta| \ll 1\,. \tag{B.18}$$

The first slow-roll condition implies

$$\varepsilon \ll 1 \qquad \Rightarrow \qquad \mathcal{H}^2 = \frac{1}{3}\frac{(\phi')^2}{\varepsilon} \gg (\phi')^2\,, \tag{B.19}$$

so that the slow-roll limit of the first Friedmann Equation is

$$\mathcal{H}^2 \approx \frac{1}{3}a^2V\,. \tag{B.20}$$

The second slow-roll condition implies

$$\eta = \frac{d\ln|\dot{\phi}|]}{dN} = \frac{\ddot{\phi}}{H|\dot{\phi}|} \ll 1 \qquad \Rightarrow \qquad |\ddot{\phi}| \ll H|\dot{\phi}|\,, \tag{B.21}$$

so that the Klein-Gordon Equation reduces to

$$\dot{\phi} \approx -\frac{a^2V'}{3\mathcal{H}}\,. \tag{B.22}$$

In **Lecture 1** we defined a second set of common slow-roll parameters in terms of the local shape of the potential $V(\phi)$

$$\epsilon_{\rm v} \equiv \frac{1}{2}\left(\frac{V_{,\phi}}{V}\right)^2 \tag{B.23}$$

$$\eta_{\rm v} \equiv \frac{V_{,\phi\phi}}{V}\,. \tag{B.24}$$

We note that $\varepsilon(\phi_{\rm end}) \equiv 1$ is an exact definition of the end of inflation, while $\epsilon_{\rm v}(\phi_{\rm end}) = 1$ is only an approximation. In the slow-roll regime the following relations hold

$$\varepsilon \approx \epsilon_{\rm v} \tag{B.25}$$

$$\eta \approx \eta_{\rm v} - \epsilon_{\rm v}\,. \tag{B.26}$$

Inflationary Attractor Solution

We now show that the slow-roll condition, $\varepsilon < 1$, also implies that inflation is an attractor solution.

Let $\bar{H}(\phi)$ be a solution of the Hamilton-Jacobi Equation (B.6) (at this point we don't demand that this is an inflationary solution). Now consider a small perturbation $\delta H(\phi)$, *i.e.*

$$H(\phi) = \bar{H}(\phi) + \delta H(\phi)\,. \tag{B.27}$$

We linearize Eqn. (B.6) to find

$$\bar{H}_{,\phi}\,\delta H_{,\phi} \approx \frac{3}{2}\bar{H}\delta H\,, \tag{B.28}$$

or

$$\frac{d}{d\phi}(\ln \delta H) = \frac{3}{2}\frac{\bar{H}}{\bar{H}_{,\phi}}\,. \tag{B.29}$$

This has the solution

$$\delta H(\phi) = \delta H(\phi_{\rm i}) \exp\left[\frac{3}{2}\int_{\phi_{\rm i}}^{\phi} \frac{\bar{H}}{\bar{H}_{,\phi}} {\rm d}\phi\right]\,. \tag{B.30}$$

Recalling that

$${\rm d}N = -\frac{1}{2}\frac{H}{H_{,\phi}}{\rm d}\phi = \frac{|{\rm d}\phi|}{\sqrt{2\varepsilon}} > 0\,, \tag{B.31}$$

this may be written as

$$\delta H(\phi) = \delta H(\phi_i) \exp\left[-3(N - N_i)\right]\,. \tag{B.32}$$

During inflation, $\varepsilon < 1$, the number of e-folds of expansion N rapidly becomes large and any perturbation to the inflationary solution δH gets diluted exponentially. $H(\phi)$ then approaches $\bar{H}(\phi)$.

8 General Fundamental Questions

8.1 What Cosmology Teaches Us About Our Life?

(??? actually, this is a very important question. it is better to write an answer to it, and not pretend "oh, we don't want even to ask this question". I'll write some ideas later)

8.2 What Cosmology Teaches Us About Physical Nature of the Word?

(also, it is a good question, and these ideas will tell us something about)

9 Alternative Fundamental Ideas

(not valuable - at the end of this note. here, there will be only very fundamentally valuable ones.)

9.0.1 Dicke's Explanation of the Redshift

(????вопрос - верная эта теория или нет? подумаю, хороший вопрос)

10 Cosmology by Weinberg

10.1 The Expansion of the Universe

The visible universe seems the same in all directions around us, at least if we look out to distances larger than about 300 million light years. [1] The isotropy is much more precise (to about one part in 10^{-5}) in the cosmic microwave background, to be discussed in Chapters 2 and 7. As we will see there, this radiation has been traveling to us for about 14 billion years, supporting the conclusion that the universe at sufficiently large distances is nearly the same in all directions.

It is difficult to imagine that we are in any special position in the universe, so we are led to conclude that the universe should appear isotropic to observers throughout the universe. But not to all observers. The universe does not seem at all isotropic to observers in a spacecraft whizzing through our galaxy at half the speed of light. Such observers will see starlight and the cosmic microwave radiation background coming toward them from the direction toward which they are moving with much higher intensity than from behind. In formulating the assumption of isotropy, one should specify that the universe seems the same in all directions to a family of "typical" freely falling observers: those that move with the average velocity of typical galaxies in their respective neighborhoods. That is, conditions must be the same at the same time (with a suitable definition of time) at any points that can be carried into each other by a rotation about any typical galaxy. But any point can be carried into any other by a sequence of such rotations about various typical galaxies, so the universe is then also homogeneous - observers in all typical galaxies at the same time see conditions pretty much the same. [2]

The assumption that the universe is isotropic and homogeneous will lead us in Section 1.1 to choose the spacetime coordinate system so that the metric takes a simple form, first worked out by Friedmann [3] as a solution of the Einstein field equations, and then derived on the basis of isotropy and homogeneity alone by Robertson [4] and Walker. [5] Almost all of modern cosmology is based on this Robertson-Walker metric, at least as a first

[2] The Sloan Digital Sky Survey provides evidence that the distribution of galaxies is homogeneous on scales larger than about 300 light years; see J. Yadav, S. Bharadwaj, B. Pandey, and T. R. Seshadri, Mon. Not. Roy. Astron. Soc. 364, 601 (2005) [astro-ph/0504315].

[3] A. Friedmann, Z. Phys. 10, 377 (1922); ibid. 21, 326 (1924).

approximation. The observational implications of these assumptions are discussed in Sections 1.2-1.4, without reference to any dynamical assumptions. The Einstein field equations are applied to the Robertson-Walker metric in Section 1.5, and their consequences are then explored in Sections 1.6-1.13.

10.1.1 1.1 Spacetime geometry

As preparation for working out the spacetime metric, we first consider the geometry of a three-dimensional homogeneous and isotropic space. As discussed in Appendix B, geometry is encoded in a metric $g_{ij}(\mathbf{x})$ (with i and j running over the three coordinate directions), or equivalently in a line element $ds^2 \equiv g_{ij}dx^i dx^j$, with summation over repeated indices understood. (We say that ds is the proper distance between $\mathbf{x}$ and $\mathbf{x} + d\mathbf{x}$, meaning that it is the distance measured by a surveyor who uses a coordinate system that is Cartesian in a small neighborhood of the point $\mathbf{x}$.) One obvious homogeneous isotropic three-dimensional space with positive definite lengths is flat space, with line element

$$ds^2 = d\mathbf{x}^2. \tag{1.1.1}$$

The coordinate transformations that leave this invariant are here simply ordinary three-dimensional rotations and translations. Another fairly obvious possibility is a spherical surface in four-dimensional Euclidean space with some radius a, with line element

$$ds^2 = d\mathbf{x}^2 + dz^2, \quad z^2 + \mathbf{x}^2 = a^2. \tag{1.1.2}$$

Here the transformations that leave the line element invariant are fourdimensional rotations; the direction of $\mathbf{x}$ can be changed to any other direction by a four-dimensional rotation that leaves z unchanged (that is, an ordinary three-dimensional rotation), while $\mathbf{x}$ can be carried into any other point by a four-dimensional rotation that does change z. It can be proved [6] that the only other possibility (up to a coordinate transformation) is a hyperspherical surface in four-dimensional pseudo-Euclidean space, with line element

$$ds^2 = d\mathbf{x}^2 - dz^2, \quad z^2 - \mathbf{x}^2 = a^2, \tag{1.1.3}$$

where a^2 is (so far) an arbitrary positive constant. The coordinate transformations that leave this invariant are four-dimensional pseudo-rotations, just like Lorentz transformations, but with z instead of time.

We can rescale coordinates

$$\mathbf{x}' \equiv a\mathbf{x}, \quad z' \equiv az \tag{1.1.4}$$

Dropping primes, the line elements in the spherical and hyperspherical cases are

$$ds^2 = a^2\left[d\mathbf{x}^2 \pm dz^2\right], \quad z^2 \pm \mathbf{x}^2 = 1 \tag{1.1.5}$$

The differential of the equation $z^2 \pm \mathbf{x}^2 = 1$ gives $zdz = \mp\mathbf{x}\cdot d\mathbf{x}$ so

$$ds^2 = a^2\left[d\mathbf{x}^2 \pm \frac{(\mathbf{x}\cdot d\mathbf{x})^2}{1 \mp \mathbf{x}^2}\right] \tag{1.1.6}$$

We can extend this to the case of Euclidean space by writing it as

[4] H. P. Robertson, Astrophys. J. 82, 284 (1935); ibid., 83, 187, 257 (1936).
[5] A. G. Walker, Proc. Lond. Math. Soc. (2) 42, 90 (1936).
[476] See S. Weinberg, Gravitation and Cosmology (John Wiley & Sons, New York, 1972) [quoted below as G&Cl, Sec. 13.2.

$$ds^2 = a^2 \left[d\mathbf{x}^2 + K \frac{(\mathbf{x} \cdot d\mathbf{x})^2}{1 - K\mathbf{x}^2} \right] \tag{1.1.7}$$

where

$$K = \begin{cases} +1 & \text{spherical} \\ -1 & \text{hyperspherical} \\ 0 & \text{Euclidean} \end{cases} \tag{1.1.8}$$

(The constant K is often written as k, but we will use upper case for this constant throughout this book to avoid confusion with the symbols for wave number or for a running spatial coordinate index.) Note that we must take $a^2 > 0$ in order to have ds^2 positive at $\mathbf{x} = 0$, and hence everywhere.

There is an obvious way to extend this to the geometry of spacetime: just include a term (1.1.7) in the spacetime line element, with a now an arbitrary function of time (known as the Robertson-Walker scale factor):

$$d\tau^2 \equiv -g_{\mu\nu}(x) dx^\mu dx^\nu = dt^2 - a^2(t) \left[d\mathbf{x}^2 + K \frac{(\mathbf{x} \cdot d\mathbf{x})^2}{1 - K\mathbf{x}^2} \right] \tag{1.1.9}$$

Another theorem [7] tells us that this is the unique metric (up to a coordinate transformation) if the universe appears spherically symmetric and isotropic to a set of freely falling observers, such as astronomers in typical galaxies. The components of the metric in these coordinates are:

$$g_{ij} = a^2(t) \left(\delta_{ij} + K \frac{x^i x^j}{1 - K\mathbf{x}^2} \right), \quad g_{i0} = 0, \quad g_{00} = -1 \tag{1.1.10}$$

with i and j running over the values 1,2 , and 3 , and with $x^0 \equiv t$ the time coordinate in our units, with the speed of light equal to unity. Instead of the quasi-Cartesian coordinates x^i, we can use spherical polar coordinates, for which

$$d\mathbf{x}^2 = dr^2 + r^2 d\Omega, \quad d\Omega \equiv d\theta^2 + \sin^2\theta d\phi^2$$

so

$$d\tau^2 = dt^2 - a^2(t) \left[\frac{dr^2}{1 - Kr^2} + r^2 d\Omega \right] \tag{1.1.11}$$

in which case the metric becomes diagonal, with

$$g_{rr} = \frac{a^2(t)}{1 - Kr^2}, \quad g_{\theta\theta} = a^2(t) r^2, \quad g_{\phi\phi} = a^2(t) r^2 \sin^2\theta, \quad g_{00} = -1 \tag{1.1.12}$$

We will see in Section 1.5 that the dynamical equations of cosmology depend on the overall normalization of the function $a(t)$ only through a term $K/a^2(t)$, so for $K = 0$ this normalization has no significance; all that matters are the ratios of the values of $a(t)$ at different times.

The equation of motion of freely falling particles is given in Appendix B by Eq. (B.12):

$$\frac{d^2 x^\mu}{du^2} + \Gamma^\mu_{\nu\kappa} \frac{dx^\nu}{du} \frac{dx^\kappa}{du} = 0 \tag{1.1.13}$$

where $\Gamma^\mu_{\nu\kappa}$ is the affine connection, given in Appendix B by Eq. (B.13),

$$\Gamma^\mu_{\nu\kappa} = \frac{1}{2} g^{\mu\lambda} \left[\frac{\partial g_{\lambda\nu}}{\partial x^\kappa} + \frac{\partial g_{\lambda\kappa}}{\partial x^\nu} - \frac{\partial g_{\nu\kappa}}{\partial x^\lambda} \right] \tag{1.1.14}$$

[477] G&C, Sec. 13.5.

and u is a suitable variable parameterizing positions along the spacetime curve, proportional to τ for massive particles. (A spacetime path $x^\mu = x^\mu(u)$ satisfying Eq. (1.1.13) is said to be a geodesic, meaning that the integral $\int d\tau$ is stationary under any infinitesimal variation of the path that leaves the endpoints fixed.) Note in particular that the derivatives $\partial_i g_{00}$ and $\dot{g}_{0i}$ vanish, so $\Gamma^i_{00} = 0$. A particle at rest in these coordinates will therefore stay at rest, so these are co-moving coordinates, which follow the motion of typical observers. Because $g_{00} = -1$, the proper time interval $(-g_{\mu\nu}dx^\mu dx^\nu)^{1/2}$ for a co-moving clock is just dt, so t is the time measured in the rest frame of a co-moving clock.

The meaning of the Robertson-Walker scale factor $a(t)$ can be clarified by calculating the proper distance at time t from the origin to a co-moving
object at radial coordinate r :

$$d(r,t) = a(t)\int_0^r \frac{dr}{\sqrt{1-Kr^2}} = a(t)\times\begin{cases}\sin^{-1} r & K=+1\\ \sinh^{-1} r & K=-1\\ r & K=0\end{cases} \tag{1.1.15}$$

In this coordinate system a co-moving object has r time-independent, so the proper distance from us to a co-moving object increases (or decreases) with $a(t)$. Since there is nothing special about our own position, the proper distance between any two co-moving observers anywhere in the universe must also be proportional to $a(t)$. The rate of change of any such proper distance $d(t)$ is just

$$\dot{d} = d\dot{a}/a \tag{1.1.16}$$

We will see in the following section that in fact $a(t)$ is increasing.
We also need the non-zero components of the affine connection, given by Eq. (1.1.14) as:

$$\begin{aligned}\Gamma^0_{ij} =& -\frac{1}{2}\left(g_{0i,j}+g_{0j,i}-g_{ij,0}\right) = a\dot{a}\left(\delta_{ij}+K\frac{x^i x^j}{1-K\mathbf{x}^2}\right)\\ =& \, a\dot{a}\tilde{g}_{ij} \qquad (1.1.17)\\ \Gamma^i_{0j} =& \frac{1}{2}g^{il}\left(g_{l0,j}+g_{lj,0}-g_{0j,l}\right) = \frac{\dot{a}}{a}\delta_{ij} \qquad (1.1.18)\\ \Gamma^i_{jl} =& \frac{1}{2}\tilde{g}^{im}\left(\frac{\partial\tilde{g}_{jm}}{\partial x^l}+\frac{\partial\tilde{g}_{lm}}{\partial x^j}-\frac{\partial\tilde{g}_{jl}}{\partial x^m}\right)\equiv\tilde{\Gamma}^i_{jl} \qquad (1.1.19)\end{aligned}$$

Here $\tilde{g}_{ij}$ and $\tilde{\Gamma}^i_{jl}$ are the purely spatial metric and affine connection, and $\tilde{g}^{ij}$ is the reciprocal of the 3×3 matrix $\tilde{g}_{ij}$, which in general is different from the ij component of the reciprocal of the 4×4 matrix $g_{\mu\nu}$. In quasi-Cartesian coordinates,

$$\tilde{g}_{ij} = \delta_{ij}+K\frac{x^i x^j}{1-K\mathbf{x}^2}, \quad \tilde{\Gamma}^i_{jl} = K\tilde{g}_{jl}x^i \tag{1.1.20}$$

We can use these components of the affine connection to find the motion of a particle that is not at rest in the co-moving coordinate system. First, let's calculate the rate of change of the momentum of a particle of non-zero mass m_0. Consider the quantity

$$P \equiv m_0\sqrt{g_{ij}\frac{dx^i}{d\tau}\frac{dx^j}{d\tau}} \tag{1.1.21}$$

where $d\tau^2 = dt^2 - g_{ij}dx^i dx^j$. In a locally inertial Cartesian coordinate system, for which $g_{ij} = \delta_{ij}$, we have $d\tau = dt\sqrt{1-\mathbf{v}^2}$ where $v^i = dx^i/dt$,
so Eq. (1.1.21) is the formula given by special relativity for the magnitude of the momentum.

On the other hand, the quantity (1.1.21) is evidently invariant under arbitrary changes in the spatial coordinates, so we can evaluate it just as well in co-moving Robertson-Walker coordinates. This can be done directly, using Eq. (1.1.13), but to save work, suppose we adopt a spatial coordinate system in which the particle position is near the origin $x^i = 0$, where $\tilde{g}_{ij} = \delta_{ij} + O(\mathbf{x}^2)$, and we can therefore ignore the purely spatial components Γ^i_{jk} of the affine connection. General relativity gives the equation of motion

$$\frac{d^2x^i}{d\tau^2} = -\Gamma^i_{\mu\nu}\frac{dx^\mu}{d\tau}\frac{dx^\nu}{d\tau} = -\frac{2}{a}\frac{da}{dt}\frac{dx^i}{d\tau}\frac{dt}{d\tau}$$

Multiplying with $d\tau/dt$ gives

$$\frac{d}{dt}\left(\frac{dx^i}{d\tau}\right) = -\frac{2}{a}\frac{da}{dt}\frac{dx^i}{d\tau}$$

whose solution is

$$\frac{dx^i}{d\tau} \propto \frac{1}{a^2(t)} \tag{1.1.22}$$

Using this in Eq. (1.1.21) with a metric $g_{ij} = a^2(t)\delta_{ij}$, we see that

$$P(t) \propto 1/a(t) \tag{1.1.23}$$

This holds for any non-zero mass, however small it may be compared to the momentum. Hence, although for photons both m_0 and $d\tau$ vanish, Eq. (1.1.23) is still valid.

It is important to characterize the paths of photons and material particles in interpreting astronomical observations (especially of gravitational lenses, in Chapter 9). Photons and particles passing through the origin of our spatial coordinate system obviously travel on straight lines in this coordinate system, which are spatial geodesics, curves that satisfy the condition

$$\frac{d^2x^i}{ds^2} + \tilde{\Gamma}^i_{jl}\frac{dx^j}{ds}\frac{dx^l}{ds} = 0 \tag{1.1.24}$$

where ds is the three-dimensional proper length

$$ds^2 \equiv \tilde{g}_{ij}dx^i dx^j \tag{1.1.25}$$

But the property of being a geodesic is invariant under coordinate transformations (since it states the vanishing of a vector), so the path of the photon
or particle will also be a spatial geodesic in any spatial coordinate system, including those in which the photon or particle's path does not pass through the origin. (This can be seen in detail as follows. Using Eqs. (1.1.17) and (1.1.18), the equations of motion (1.1.13) of a photon or material particle are

$$\begin{aligned} 0 &= \tfrac{d^2x^i}{du^2} + \Gamma^i_{jl}\tfrac{dx^j}{du}\tfrac{dx^l}{du} + \tfrac{2\dot{a}}{a}\tfrac{dx^i}{du}\tfrac{dt}{du} \\ 0 &= \tfrac{d^2t}{du^2} + a\dot{a}\tilde{g}_{ij}\tfrac{dx^i}{du}\tfrac{dx^j}{du} \end{aligned} \tag{1.1.27}$$

Eq. (1.1.26) can be written

$$0 = \left(\frac{ds}{du}\right)^2\left[\frac{d^2x^i}{ds^2} + \Gamma^i_{jl}\frac{dx^j}{ds}\frac{dx^l}{ds}\right] + \left[\frac{d^2s}{du^2} + \frac{2\dot{a}}{a}\frac{dt}{du}\frac{ds}{du}\right]\frac{dx^i}{ds} \tag{1.1.28}$$

where s is so far arbitrary. If we take s to be the proper length (1.1.25) in the spatial geometry, then as we have seen

$$du^2 \propto d\tau^2 \propto dt^2 - a^2ds^2$$

Dividing by du^2, differentiating with respect to u, and using Eq. (1.1.27) shows that

$$\frac{d^2s}{du^2} + \frac{2\dot{a}}{a}\frac{dt}{du}\frac{ds}{du} = 0$$

so that Eq. (1.1.28) gives Eq. (1.1.24).)

There are various smoothed-out vector and tensor fields, like the current of galaxies and the energy-momentum tensor, whose mean values satisfy the requirements of isotropy and homogeneity. Isotropy requires that the mean value of any three-vector v^i must vanish, and homogeneity requires the mean value of any three-scalar (that is, a quantity invariant under purely spatial coordinate transformations) to be a function only of time, so the current of galaxies, baryons, etc. has components

$$J^i = 0, \quad J^0 = n(t) \tag{1.1.29}$$

with $n(t)$ the number of galaxies, baryons, etc. per proper volume in a comoving frame of reference. If this is conserved, in the sense of Eq. (B.38), then

$$0 = J^\mu_{;\mu} = \frac{\partial J^\mu}{\partial x^\mu} + \Gamma^\mu_{\mu\nu}J^\nu = \frac{dn}{dt} + \Gamma^i_{i0}n = \frac{dn}{dt} + 3\frac{da}{dt}\frac{n}{a}$$

so

$$n(t) = \frac{\text{constant}}{a^3(t)} \tag{1.1.30}$$

This shows the decrease of number densities due to the expansion of the co-moving coordinate mesh for increasing $a(t)$.

Likewise, isotropy requires the mean value of any three-tensor t^{ij} at $\mathbf{x} = 0$ to be proportional to δ_{ij} and hence to g^{ij}, which equals $a^{-2}\delta_{ij}$ at $\mathbf{x} = 0$. Homogeneity requires the proportionality coefficient to be some function only of time. Since this is a proportionality between two three-tensors t^{ij} and g^{ij} it must remain unaffected by an arbitrary transformation of space coordinates, including those transformations that preserve the form of g^{ij} while taking the origin into any other point. Hence homogeneity and isotropy require the components of the energy-momentum tensor everywhere to take the form

$$T^{00} = \rho(t), \quad T^{0i} = 0, \quad T^{ij} = \tilde{g}^{ij}(\mathbf{x})a^{-2}(t)p(t) \tag{1.1.31}$$

(These are the conventional definitions of proper energy density ρ and pressure p, as given by Eq. (B.43) in the case of a velocity four-vector with $u^i = 0$, $u^0 = 1$.) The momentum conservation law $T^{i\mu}{}_{;\mu} = 0$ is automatically satisfied for the Robertson-Walker metric and the energy-momentum tensor (1.1.31), but the energy conservation law gives the useful information

$$\begin{aligned} 0 = T^{0\mu}_{;\mu} &= \frac{\partial T^{0\mu}}{\partial x^\mu} + \Gamma^0_{\mu\nu}T^{\nu\mu} + \Gamma^\mu_{\mu\nu}T^{0\nu} \\ &= \frac{\partial T^{00}}{\partial t} + \Gamma^0_{ij}T^{ij} + \Gamma^i_{i0}T^{00} = \frac{d\rho}{dt} + \frac{3\dot{a}}{a}(p+\rho), \end{aligned}$$

so that

$$\frac{d\rho}{dt} + \frac{3\dot{a}}{a}(p+\rho) = 0 \tag{1.1.32}$$

This can easily be solved for an equation of state of the form

$$p = w\rho \tag{1.1.33}$$

with w time-independent. In this case, Eq. (1.1.32) gives

$$\rho \propto a^{-3-3w}. \tag{1.1.34}$$

In particular, this applies in three frequently encountered extreme cases:

- Cold Matter (e.g. dust): $p = 0$

$$\rho \propto a^{-3} \tag{1.1.35}$$

- Hot Matter (e.g. radiation): $p = \rho/3$

$$\rho \propto a^{-4} \tag{1.1.36}$$

10.1.2 1.1 Spacetime geometry

- Vacuum energy: As we will see in Section 1.5, there is another kind of energy-momentum tensor, for which $T^{\mu\nu} \propto g^{\mu\nu}$, so that $p = -\rho$, in which case the solution of Eq. (1.1.32) is that ρ is a constant, known (up to conventional numerical factors) either as the cosmological constant or the vacuum energy.

These results apply separately for coexisting cold matter, hot matter, and a cosmological constant, provided that there is no interchange of energy between the different components. They will be used together with the Einstein field equations to work out the dynamics of the cosmic expansion in Section 1.5.

So far, we have considered only local properties of the spacetime. Now let us look at it in the large. For $K = +1$ space is finite, though like any spherical surface it has no boundary. The coordinate system used to derive Eq. (1.1.7) with $K = +1$ only covers half the space, with $z > 0$, in the same way that a polar projection map of the earth can show only one hemisphere. Taking account of the fact that z can have either sign, the circumference of the space is $2\pi a$, and its volume is $2\pi^2 a^3$.

The spaces with $K = 0$ or $K = -1$ are usually taken to be infinite, but there are other possibilities. It is also possible to have finite spaces with the same local geometry, constructed by imposing suitable conditions of periodicity. For instance, in the case $K = 0$ we might identify the points $\mathbf{x}$ and $\mathbf{x} + n_1\mathbf{L}_1 + n_2\mathbf{L}_2 + n_3\mathbf{L}_3$, where n_1, n_2, n_3 run over all integers, and $\mathbf{L}_1, \mathbf{L}_2$, and $\mathbf{L}_3$ are fixed non-coplanar three-vectors that characterize the space. This space is then finite, with volume $a^3\mathbf{L}_1 \cdot (\mathbf{L}_2 \times \mathbf{L}_3)$. Looking out far enough, we should see the same patterns of the distribution of matter and radiation in opposite directions. There is no sign of this in the observed distribution of galaxies or cosmic microwave background fluctuations, so any periodicity lengths such as $|\mathbf{L}_i|$ must be larger than about 10^{10} light years. [8]

There are an infinite number of possible periodicity conditions for $K = -1$ as well as for $K = +1$ and $K = 0$.[9] We will not consider these possibilities further here, because they seem ill-motivated. In imposing conditions of periodicity we give up the rotational (though not translational) symmetry that led to the Robertson-Walker metric in the first place, so there seems little reason to impose these periodicity conditions while limiting the local spacetime geometry to that described by the Robertson-Walker metric.

10.1.3 1.2 The cosmological redshift

The general arguments of the previous section gave no indication whether the scale factor $a(t)$ in the Robertson-Walker metric (1.1.9) is increasing, decreasing, or constant. This information comes to us from the observation of a shift in the frequencies of spectral lines from distant galaxies as compared with their values observed in terrestrial laboratories.

To calculate these frequency shifts, let us adopt a Robertson-Walker coordinate system in which we are at the center of coordinates, and consider a light ray coming to us along the radial direction. A ray of light obeys the equation $d\tau^2 = 0$, so for such a light ray Eq. (1.1.11) gives

$$dt = \pm a(t)\frac{dr}{\sqrt{1-Kr^2}} \tag{1.2.1}$$

For a light ray coming toward the origin from a distant source, r decreases as t increases, so we must choose the minus sign in Eq. (1.2.1). Hence if light leaves a source at co-moving coordinate r_1 at time t_1, it arrives at the origin $r = 0$ at a later time t_0, given by

$$\int_{t_1}^{t_0}\frac{dt}{a(t)} = \int_0^{r_1}\frac{dr}{\sqrt{1-Kr^2}} \tag{1.2.2}$$

Taking the differential of this relation, and recalling that the radial coordinate r_1 of co-moving sources is time-independent, we see that the interval δt_1 between departure of subsequent light signals is related to the interval δt_0 between arrivals of these light signals by

$$\frac{\delta t_1}{a\left(t_1\right)} = \frac{\delta t_0}{a\left(t_0\right)} \tag{1.2.3}$$

If the "signals" are subsequent wave crests, the emitted frequency is $v_1 = 1/\delta t_1$, and the observed frequency is $v_0 = 1/\delta t_0$, so

$$v_0/v_1 = a\left(t_1\right)/a\left(t_0\right) \tag{1.2.4}$$

If $a(t)$ is increasing, then this is a redshift, a decrease in frequency by a factor $a\left(t_1\right)/a\left(t_0\right)$, equivalent to an increase in wavelength by a factor conventionally called $1+z$:

$$1 + z = a\left(t_0\right)/a\left(t_1\right) \tag{1.2.5}$$

Alternatively, if $a(t)$ is decreasing then we have a blueshift, a decrease in wavelength given by the factor Eq. (1.2.5) with z negative. These results are frequently interpreted in terms of the familiar Doppler effect; Eq. (1.1.15)

10.1.4 1.2 The cosmological redshift

shows that for an increasing or decreasing $a(t)$, the proper distance to any comoving source of light like a typical galaxy increases or decreases with time, so that such sources are receding from us or approaching us, which naturally produces a redshift or blueshift. For this reason, galaxies with redshift (or blueshift) z are often said to have a cosmological radial velocity cz. (The meaning of relative velocity is clear only for $z \ll 1$, so the existence of distant sources with $z > 1$ does not imply any violation of special relativity.) However, the interpretation of the cosmological redshift as a Doppler shift can only take us so far. In particular, the increase of wavelength from emission to absorption of light does not depend on the rate of change of $a(t)$ at the times of emission or absorption, but on the increase of $a(t)$ in the whole period from emission to absorption.

We can also understand the frequency shift (1.2.4) by reference to the quantum theory of light: The momentum of a photon of frequency v is hv/c (where h is Planck's constant), and we saw in the previous section that this momentum varies as $1/a(t)$.

For nearby sources, we may expand $a(t)$ in a power series, so

$$a(t) \simeq a\left(t_0\right)\left[1+\left(t-t_0\right)H_0+\ldots\right] \tag{1.2.6}$$

where H_0 is a coefficient known as the Hubble constant:

$$H_0 \equiv \dot{a}\left(t_0\right)/a\left(t_0\right) \tag{1.2.7}$$

Eq. (1.2.5) then gives the fractional increase in wavelength as

$$z = H_0\left(t_0-t_1\right)+\ldots \tag{1.2.8}$$

Note that for close objects, $t_0 - t_1$ is the proper distance d (in units with $c = 1$). We therefore expect a redshift (for $H_0 > 0$) or blueshift (for $H_0 < 0$) that increases linearly with the proper distance d for galaxies close enough to use the approximation (1.2.6):

$$z = H_0 d + \ldots \tag{1.2.9}$$

The redshift of light from other galaxies was first observed in the 1910s by Vesto Melvin Slipher at the Lowell Observatory in Flagstaff, Arizona. In 1922, he listed 41 spiral nebulae, of which 36 had positive z up to 0.006 , and only 5 had negative z, the most negative being the Andromeda nebula M31, with $z = -0.001$.[1] From 1918 to 1925 C. Wirtz and K. Lundmark [2]

discovered a number of spiral nebulae with redshifts that seemed to increase with distance. But until 1923 it was only possible to infer the relative distances of the spiral nebulae, using observations of their apparent luminosity or angular diameter. With the absolute luminosity and physical dimensions unknown, it was even possible that the spiral nebulae were outlying parts of our own galaxy, as was in fact believed by many astronomers. Edwin Hubble's 1923 discovery of Cepheid variable stars in the Andromeda nebula M31 (discussed in the next section) allowed him to estimate its distance and size, and made it clear that the spiral nebulae are galaxies like our own, rather than objects in our own galaxy.

No clear linear relation between redshift and distance could be seen in the early data of Slipher, Wirtz, and Lundmark, because of a problem that has continued to bedevil measurements of the Hubble constant down to the present. Real galaxies generally do not move only with the general expansion or contraction of the universe; they typically have additional "peculiar" velocities of hundreds of kilometers per second, caused by gravitational fields of neighboring galaxies and intergalactic matter. To see a linear relation between redshift and distance, it is necessary to study galaxies with $|z| \gg 10^{-3}$, whose cosmological velocities zc are thousands of kilometers per second.

In 1929 Hubble [3] announced that he had found a "roughly linear" relation between redshift and distance. But at that time redshifts and distances had been measured only for galaxies out to the large cluster of galaxies in the constellation Virgo, whose redshift indicates a radial velocity of about $1,000$ km/sec, not much larger than typical peculiar velocities. His data points were therefore spread out widely in a plot of redshift versus distance, and did not really support a linear relation. But by the early 1930s he had measured redshifts and distances out to the Coma cluster, with redshift $z \simeq 0.02$, corresponding to a recessional velocity of about

[471] V. M. Slipher, table prepared for A. S. Eddington, The Mathematical Theory of Relativity, 2nd ed. (Cambridge University Press, London, 1924): 162.

[2] C. Wirtz, Astr. Nachr. 206, 109 (1918); ibid. 215, 349 (1921); ibid. 216, 451 (1922); ibid. 222, 21 (1924); Scientia 38, 303 (1925); K. Lundmark, Stock. Hand. 50, No. 8 (1920); Mon. Not. Roy. Astron. Soc. 84, 747 (1924); ibid. 85, 865 (1925).

7,000 km/sec, and a linear relation between redshift and distance was evident. The conclusion was clear (at least, to some cosmologists): the universe really is expanding. The correctness of this interpretation of the redshift is supported by observations to be discussed in Section 1.7.

From Hubble's time to the present galaxies have been discovered with ever larger redshifts. Galaxies were found with redshifts of order unity, for which expansions such as Eq. (1.2.9) are useless, and we need formulas that take relativistic effects into account, as discussed in Sections 1.4 and 1.5. At the time of writing, the largest accurately measured redshift is for a galaxy observed with the Subaru telescope. [4] The Lyman alpha line from

this galaxy (emitted in the transition from the $2p$ to $1s$ levels of hydrogen), which is normally at an ultraviolet wavelength of $1,215$Å, is observed at the infrared wavelength of $9,682$Å, indicating a redshift $1+z = 9682/1215$, or $z = 6.96$.

It may eventually become possible to measure the expansion rate $H(t) \equiv \dot{a}(t)/a(t)$ at times t earlier than the present, by observing the change in very accurately measured redshifts of individual galaxies over times as short as a decade. [5] By differentiating Eq. (1.2.5) we see that the rate of change of redshift with the time of observation is

$$\frac{dz}{dt_0} = \frac{\dot{a}\,(t_0)}{a\,(t_1)} - \frac{a\,(t_0)\,\dot{a}\,(t_1)}{a^2\,(t_1)}\frac{dt_1}{dt_0} = \left[H_0 - H\,(t_1)\,\frac{dt_1}{dt_0}\right](1+z)$$

From the same argument that led to Eq. (1.2.3) we have $dt_1/dt_0 = 1/(1+z)$, so if we measure dz/dt_0 we can find the expansion rate at the time of light emission from the formula

$$H\,(t_1) = H_0(1+z) - \frac{dz}{dt_0} \tag{1.2.10}$$

10.1.5 1.3 Distances at small redshift: The Hubble constant

We must now think about how astronomical distances are measured. In this section we will be considering objects that are relatively close, say with z not much greater than 0.1 , so that effects of the spacetime curvature and cosmic expansion on distance determinations can be neglected. These measurements are of cosmological importance in themselves, as they are used to learn the value of the Hubble constant H_0. Also, distance measurements at larger redshift, which are used to find the shape of the function $a(t)$, rely on the observations of "standard candles," objects of known intrinsic luminosity, that must be identified and calibrated by studies at these relatively small redshifts. Distance determinations at larger redshift will be discussed in Section 1.6, after we have had a chance to lay a foundation in Sections 1.4 and 1.5 for an analysis of the effects of expansion and spacetime geometry on measurements of distances of very distant objects.

It is conventional these days to separate the objects used to measure distances in cosmology into primary and secondary distance indicators. The absolute luminosities of the primary distance indicators in our local group

of galaxies are measured either directly, by kinematic methods that do not depend on an a priori knowledge of absolute luminosities, or indirectly, by observation of primary distance indicators in association with other primary distance indicators whose distance is measured by kinematic methods. The sample of these relatively close primary distance indicators is large enough to make it possible to work out empirical rules that give their absolute luminosities as functions of various observable properties. Unfortunately, the primary distance indicators are

[475] A. Loeb, Astrophys. J. 499, L111 (1998) [astro-ph/9802122]; P-S. Corasaniti, D. Huterer, and A. Melchiorri, Phys. Rev. D 75, 062001 (2007) [astro-ph/0701433]. For an earlier suggestion along this line, see A. Sandage, Astrophys. J. 139, 319 (1962).

not bright enough for them to be studied at distances at which z is greater than about 0.01 , redshifts at which cosmological velocities cz would be greater than typical random departures of galactic velocities from the cosmological expansion, a few hundred kilometers per second. Thus they cannot be used directly to learn about $a(t)$. For this purpose it is necessary to use secondary distance indicators, which are bright enough to be studied at these large distances, and whose absolute luminosities are known through the association of the closer ones with primary distance indicators.

A. Primary distance indicators [1]

Almost all distance measurements in astronomy are ultimately based on measurements of the distance of objects within our own galaxy, using one or the other of two classic kinematic methods.

1. Trigonometric parallax

The motion of the earth around the sun produces an annual motion of the apparent position of any star around an ellipse, whose maximum angular radius π is given in radians (for $\pi \ll 1$, which is the case for all stars) by

$$\pi = \frac{d_E}{d} \tag{1.3.1}$$

where d is the star's distance from the solar system, and d_E is the mean distance of the earth from the sun, [2] defined as the astronomical unit,

$1\text{AU} = 1.496 \times 10^8$ km. A parsec (pc) is defined as the distance at which $\pi = 1''$; there are 206,264.8 seconds of arc per radian so

$$1\text{pc} = 206,264.8\text{AU} = 3.0856 \times 10^{13} \text{ km} = 3.2616 \text{ light years.}$$

The parallax in seconds of arc is the reciprocal of the distance in parsecs.
The first stars to have their distances found by measurement of their trigonometric parallax were α Centauri, by Thomas Henderson in 1832, and 61 Cygni, by Friedrich Wilhelm Bessel in 1838. These stars are at distances 1.35 pc and 3.48 pc , respectively. The earth's atmosphere makes it very difficult to measure trigonometric parallaxes less than about $0.03''$ from ground-based telescopes, so that for many years this method could be used to find the distances of stars only out to about 30 pc , and at these distances only for a few stars and with poor accuracy.

This situation has been improved by the launching of a European Space Agency satellite known as Hipparcos, used to measure the apparent positions and luminosities of large numbers of stars in our galaxy. [3] For stars of sufficient brightness, parallaxes could be measured with an accuracy (standard deviation) in the range of 7 to 9×10^{-4} arc seconds. Of the 118,000 stars in the Hipparcos Catalog, it was possible in this way to find distances with a claimed uncertainty of no more than 10% for about 20,000 stars, some at distances over 100 pc.

[471] For a survey, see M. Feast, in Nearby Large-Scale Structures and the Zone of Avoidance, eds. A. P. Fairall and P. Woudt (ASP Conference Series, San Francisco, 2005) [astro-ph/0405440].

[2] The history of measurements of distances in the solar system goes back to Aristarchus of Samos (circa 310 BC-230 BC). From the ratio of the breadth of the earth's shadow during a lunar eclipse to the angular diameter of the moon he estimated the ratio of the diameters of the moon and earth; from the angular diameter of the moon he estimated the ratio of the diameter of the moon to its distance from the earth; and from the angle between the lines of sight to the sun and moon when the moon is half full he estimated the ratio of the distances to the sun and moon; and in this way he was able to measure the distance to the sun in units of the diameter of the earth. Although the method of Aristarchus was correct, his observations were poor, and his result for the distance to the sun was far too low. [For an account of Greek astronomy before Aristarchus and a translation of his work, see T. L. Heath, Aristarchus of

2. Proper motions

A light source at a distance d with velocity $v_\perp$ perpendicular to the line of sight will appear to move across the sky at a rate μ in radians/time given by

$$\mu = v_\perp/d \tag{1.3.2}$$

This is known as its proper motion. Of course, astronomers generally have no way of directly measuring the transverse velocity $v_\perp$, but they can measure the component v_r of velocity along the line of sight from the Doppler shift of the source's spectral lines. The problem is to infer $v_\perp$ from the measured value of v_r. This can be done in a variety of special cases:

- Moving clusters are clusters of stars that were formed together and hence move on parallel tracks with equal speed. (These are open

clusters, in the sense that they are not held together by gravitational attraction, in distinction to the much larger globular clusters whose spherical shape indicates a gravitationally bound system.) The most important such cluster is the Hyades (called by Tennyson's Ulysses the "rainy Hyades"), which contains over 100 stars. The velocities of these stars along the line of sight are measured from their Doppler shifts, and if we knew the distance to the cluster then the velocities of its stars at right angles to the line of sight could be measured from their proper motions. The distance to the cluster was determined long ago to be about 40 pc by imposing the constraint that all these velocities are parallel. Distances measured in this way are often expressed as moving cluster parallaxes. Since the advent of the Hipparcos satellite, the moving cluster method has been supplemented with a direct measurement of the trigonometric parallax of some of these clusters, including the Hyades.

- A second method is based on the statistical analysis of the Doppler shifts and proper motions of stars in a sample whose relative distances are all known, for instance because they all have the same (unknown) absolute luminosity, or because they all at the same (unknown) distance. The Doppler shifts give the velocities along the line of sight, and the proper motions and the relative distances give the velocities transverse to the line of sight, up to a single overall factor related to the unknown absolute luminosity or distance. This factor can be determined by requiring that the distribution of velocities transverse to the line of sight is the same as the distribution of velocities along the line of sight. Distances measured in this way are often called statistical parallaxes, or dynamical distances.

- The distance to the Cepheid variable star ζ Geminorum has been measured [4] by comparing the rate of change of its physical diameter, as found from the Doppler effect, with the rate of change of its angular diameter, measured using an optical interferometer. (About Cepheids, more below.) The distance was found to be 336 ± 44pc, much greater than could have been found from a trigonometric parallax. This method has subsequently been extended to eight other Cepheids. [5]

- It is becoming possible to measure distances by measuring the proper motion of the material produced by supernovae, assuming a

[47]Samos (Oxford University Press, Oxford, 1913).] The first reasonably accurate determination of the distance of the earth to the sun was made by the measurement of a parallax. In 1672 Jean Richer and Giovanni Domenico Cassini measured the distance from the earth to Mars, from which it was possible to infer the distance from the earth to the sun, by observing the difference in the apparent direction to Mars as seen from Paris and Cayenne, which are separated by a known distance of 6,000 miles. Today distances within the solar system are measured very accurately by measurement of the timing of radar echoes from planets and of radio signals from transponders carried by spacecraft.

[3] M. A. C. Perryman et al., Astron. Astrophys. 323, L49 (1997).

more-or-less cylindrically symmetric explosion, so that the transverse velocity $v_\perp$ can be inferred from the radial velocity v_r measured by Doppler shifts. This method has been applied [6] to the ring around the supernova SN1987A, observed in 1987 in the Large Magellanic Cloud, with the result that its distance is 52 kpc (thousand parsecs).

- The measurement of the time-varying Doppler shift and proper motion of an object in orbit around a central mass can be used to find the distance to the object. For instance, if the line of sight happens to be in the plane of the orbit, and if the orbit is circular, then the Doppler shift is a maximum when the object is moving along the line of sight, and hence gives the orbital velocity ν, while the proper motion μ is a maximum when the object is moving with the same velocity at right angles to the line of sight, and gives the distance as ν/μ. This method can also be used for orbits that are inclined to the line of sight and not circular, by studying the time-variation of the Doppler shift and proper motion. The application of this method to the star S2, which orbits the massive black hole in the galactic center, gives what is now the best value for the distance of the solar system from the galactic center, [7] as 8.0 ± 0.4kpc. This method also allows the measurement of some distances outside our galaxy, by using the motion of masers - point microwave sources - in the accretion disks of gas and dust in orbit around black holes at the centers of galaxies. The orbital velocity can be judged from the Doppler shifts of masers at the edge of the accretion disk, which are moving directly toward us or away from us, and if this is the same as the orbital velocities of masers moving transversely to the line of sight, then the ratio of this orbital velocity to their observed proper motion gives the distance to the galaxy. So far, this method has been used to measure the distance to the galaxy NGC 4258, [8] as 7.2 ± 0.5Mpc (million parsecs), and to the galaxy M33, [9] as 0.730 ± 0.168 Mpc .

These kinematic methods have limited utility outside the solar neighborhood. We need a different method to measure larger distances.

3. Apparent luminosity

The most common method of determining distances in cosmology is based on the measurement of the apparent luminosity of objects of known (or

supposedly known) absolute luminosity. The absolute luminosity L is the energy emitted per second, and the apparent luminosity ℓ is the energy received per second per square centimeter of receiving area. If the energy is emitted isotropically, then we can find the relation between the absolute and apparent luminosity in Euclidean geometry by imagining the luminous object to be surrounded with a sphere whose radius is equal to the distance d between the object and the earth. The total energy per second passing through the sphere is $4\pi d^2 \ell$, so

$$\ell = \frac{L}{4\pi d^2} \tag{1.3.3}$$

This relation is subject to corrections due to interstellar and/or intergalactic absorption, as well as possible anisotropy of the source, which though important in practice involve too many technicalities to go into here.

Astronomers unfortunately use a traditional notation for apparent and absolute luminosity in terms of apparent and absolute magnitude. [10] In the second century A.D., the Alexandrian astronomer Claudius Ptolemy published a list of 1,022 stars, labeled by categories of apparent brightness, with bright stars classed as being of first magnitude, and stars just barely visible being of sixth magnitude. [11] This traditional brightness scale was made quantitative in 1856 by Norman Pogson, who decreed that a difference of five magnitudes should correspond to a ratio of a factor 100 in apparent luminosities, so that $\ell \propto 10^{-2m/5}$. With the advent of photocells at the beginning of the twentieth century, it became possible to fix the constant of proportionality: the apparent bolometric luminosity (that is, including all wavelengths) is given in terms of the apparent bolometric magnitude m by

$$\ell = 10^{-2m/5} \times 2.52 \times 10^{-5} \text{erg cm}^{-2} \text{ s}^{-1} \tag{1.3.4}$$

For orientation, Sirius has a visual magnitude $m_{\rm vis} = -1.44$, the Andromeda nebula M31 has $m_{\rm vis} = 0.1$, and the large galaxy M87 in the nearest large cluster of galaxies has $m_{\rm vis} = 8.9$. The absolute magnitude in any wavelength band is defined as the apparent magnitude an object would have at a distance of 10 pc , so that the absolute bolometric luminosity is given in terms of the absolute bolometric magnitude M by

$$L = 10^{-2M/5} \times 3.02 \times 10^{35} \text{erg s}^{-1} \tag{1.3.5}$$

For comparison, in the visual wavelength band the absolute magnitude $M_{\rm vis}$ is +4.82 for the sun, +1.45 for Sirius, and -20.3 for our galaxy. Eq. (1.3.3) may be written as a formula for the distance in terms of the distance-modulus $m - M$:

$$d = 10^{1+(m-M)/5} \text{pc} \tag{1.3.6}$$

There are several different kinds of star that have been used in measurements of distance through the observation of apparent luminosity:

- Main Sequence: Stars that are still burning hydrogen at their cores obey a characteristic relation between absolute luminosity and color, both depending on mass. This is known as the main sequence, discovered in the decade before the First World War by Ejnar Hertzsprung and Henry Norris Russell. The luminosity is greatest for blue-white stars, and then steadily decreases for colors tending toward yellow and red. The shape of the main sequence is found by observing the apparent luminosities and colors of large numbers of stars in clusters, all of which in each cluster may be assumed to be at the same distance from us, but we need to know the distances to the clusters to calibrate absolute luminosities on the main sequence. For many years the calibration of the main sequence absolute luminosities was based on observation of a hundred or so main sequence stars in the Hyades cluster, whose distance was measured by the moving cluster method described above. With the advent of the Hipparcos satellite, the calibration of the main sequence has been greatly improved through the observation of colors and apparent luminosities of nearly 100,000 main sequence stars whose distance is known through measurement of their trigonometric parallax. Including in this sample are stars in open clusters such as the Hyades, Praesepe, the Pleiades, and NGC 2516; these clusters yield consistent main sequence absolute magnitudes if care is taken to take proper account of the varying chemical compositions of the stars in different clusters. [12] With the main sequence calibrated

[4710] For the history of the apparent magnitude scale, see J. B. Hearnshaw, The Measurement of Starlight: Two centuries of astronomical photometry (Cambridge University Press, Cambridge, 1996); K. Krisciunas, astro-ph/0106313.

[11] For the star catalog of Ptolemy, see M. R. Cohen and I. E. Drabkin, A Source Book in Greek Science (Harvard University Press, Cambridge, MA, 1948): p. 131.

in this way, we can use Eq. (1.3.3) to measure the distance of any star cluster or galaxy in which it is possible to observe stars exhibiting the main sequence relation between apparent luminosity and color. Distances measured in this way are sometimes known as photometric parallaxes.
The analysis of the Hipparcos parallax measurements revealed a discrepancy between the distances to the Pleiades star cluster measured by observations of main sequence stars and by measurements of

trigonometric parallax. [13] The traditional method, using a main sequence calibration based on the application of the moving cluster method to the closer Hyades cluster, gave a distance to the Pleiades [14] of 132 ± 4pc. Then trigonometric parallaxes of a number of stars in the Pleiades measured by the Hipparcos satellite gave a distance [15] of 118 ± 4pc, in contradiction with the results of main sequence fitting. More recently, these Hipparcos parallaxes have been contradicted by more accurate measurements of the parallaxes of three stars in the Pleiades with the Fine Guidance Sensor of the Hubble Space Telescope, [16] which gave a distance of 133.5 ± 1.2pc, in good agreement with the main sequence results. At the time of writing, the balance of astronomical opinion seems to be favoring the distances given by main sequence photometry. [17]

- Red Clump Stars: The color-magnitude diagram of clusters in metalrich [18] parts of the galaxy reveals distinct clumps of red giant stars in a small region of the diagram, with a spread of only about 0.2 in visual magnitude. These are stars that have exhausted the hydrogen at their cores, with helium taking the place of hydrogen as the fuel for nuclear reactions at the stars' cores. The absolute magnitude of the red clump stars in the infrared band (wavelengths around 800 nm) has been determined [19] to be $M_I = -0.28 \pm 0.2$mag, using the distances and apparent magnitudes measured with the Hipparcos satellite and in an earlier survey. [20] In this band there is little dependence of absolute magnitude on color, but it has been argued that even the infrared magnitude may depend significantly on metallicity. [21]

- RR Lyrae Stars: These are variable stars that have been used as distance indicators for many decades. [22] They can be recognized by their periods, typically 0.2 to 0.8 days. The use of the statistical parallax, trigonometric parallax and moving cluster methods (with data

from both ground-based observatories and the Hipparcos satellite) give respectively [23] an absolute visual magnitude for RR Lyrae stars in our galaxy's halo of $0.77 \pm 0.13, 0.71 \pm 0.15$, and 0.67 ± 0.10, in good agreement with an earlier result [24] $M_{\rm vis} = 0.71 \pm 0.12$ for halo RR Lyrae stars and 0.79 ± 0.30 for RR Lyrae stars in the thick disk of the galaxy. RR Lyrae stars are mostly too

far for a measurement of their trigonometric parallax, but recently measurements [25] with the Hubble Space Telescope have given a value of 3.82×10^{-3} arcsec for the trigonometric parallax of the eponymous star RR Lyr itself, implying an absolute visual magnitude of $0.61^{-0.11}_{+0.10}$.

- Eclipsing Binaries: In favorable cases it is possible to estimate the intrinsic luminosity of a star that is periodically partially eclipsed by a smaller companion, without the use of any intermediate distance indicators. The velocity of the companion can be inferred from the Doppler shift of its spectral lines (with the ellipticity of the orbit inferred from the variation of the Doppler shift with time), and the radius of the primary star can then be calculated from the duration of the eclipse. The temperature of the primary can be found from measurement of its spectrum, typically from its apparent luminosity in various wavelength bands. Knowing the radius, and hence the area, and the temperature of the primary, its absolute luminosity can then be calculated from the Stefan-Boltzmann law for black body radiation. This method has been applied to measure distances to two neighboring dwarf galaxies, the Large Magellanic Cloud (LMC) [26] and the Small Magellanic Cloud (SMC), [27] and to the Andromeda galaxy M31 [28] and its satellite M33. [29]

- Cepheid variables: Because they are so bright, these are by far the most important stars used to measure distances outside our galaxy. Named after the first such star observed, δ Cephei, they can be

recognized from the characteristic time dependence of their luminosity, with periods ranging from 2 to 45 days. (Cepheids in other galaxies have been observed with periods extending up to 100 days.) In 1912 Henrietta Swan Leavitt discovered that the Cepheid variables in the Small Magellanic Cloud (SMC) have apparent luminosities given by a smooth function of the period of the variation in luminosity, but the distance to the SMC was not known. Having measured the distances and apparent luminosities of several Cepheids in open clusters, and hence their absolute luminosities, it became possible to calibrate the relation between period and luminosity. Cepheid variables thus became a "standard candle" that could be used to measure the distance to any galaxy close enough for Cepheids to be seen. It was the discovery of Cepheids in M31, together with Leavitt's calibration of the Cepheid period-luminosity relation, that allowed Edwin Hubble in 1923 to measure the distance of M31, and show that it was far outside our own galaxy, and hence a galaxy in its own right.

Today the form of the Cepheid period-luminosity relation is derived more from the Large Magellanic Cloud (LMC), where there are many Cepheids, and the dependence of the absolute luminosity on color is also taken into account. The calibration of Cepheid absolute luminosities can therefore be expressed as (and often in fact amounts to) a measurement of the distance to the LMC. Main sequence photometry and other methods gave what for some years was a generally accepted LMC distance modulus of 18.5 mag , corresponding according to Eq. (1.3.6) to a distance of 5.0×10^4pc. The use of red clump stars [30] has given a distance modulus of

18.47 , with a random error ±0.01, and a systematic error $^{+0.05}_{-0.06}$. A large catalog [31] of Cepheids in the LMC has been interpreted by the members of the Hubble Space Telescope Key Project [32] to give the Cepheid visual and infrared absolute magnitudes as functions of the period P in days:
$M_V = -2.760 \log_{10} P - 1.458, \quad M_I = -2.962 \log_{10} P - 1.942,$
under the assumption that the LMC distance modulus is 18.5 .
This result was challenged in two distinct ways, which illustrate the difficulty of this sort of distance measurement:

First, there have been discordant measurements of the distance to the LMC. Under the assumption that red clump stars in the LMC

have the same infrared luminosity as those in the local galactic disk, a distance modulus was found [33] that was 0.45 magnitudes smaller, giving a distance to the LMC that is smaller by a factor 0.8 . This has in turn been challenged on the grounds that the stars in the LMC have distinctly lower metallicity than in the local disk; two groups taking this into account [34] have given LMC distance moduli of 18.36± 0.17 mag and 18.28 ± 0.18mag, in fair agreement with the previously accepted value. This also agrees with the measurement of the distance to the LMC inferred [35] from observations of RR Lyrae stars, which gives a distance modulus of 18.33 ± 0.06mag. This distance modulus for the LMC is further confirmed by the measurement of the distance of the eclipsing binary HV2274; taking account of its distance from the center of the LMC gives [36] a distance modulus for the LMC of 18.30 ± 0.07.

Second, there have been new calibrations of the Cepheid periodluminosity relation, that do not rely on Cepheids in the LMC, which together with observations of Cepheids in the LMC can be used to give an independent estimate of the LMC distance. [37] In recent years the satellite Hipparcos [38] has measured trigonometric parallaxes for 223 Cepheid variables in our galaxy, of which almost 200 can be used to calibrate the period-luminosity relation, without relying on main sequence photometry, red clump stars, or RR Lyrae stars. The nearest Cepheids are more than 100 pc away from us (the distance to Polaris is about 130 pc), so the parallaxes are just a few milliarcseconds, and individual measurements are not very accurate, but with about 200 Cepheids measured it has been possible to get pretty good accuracy. One early result [39] gave the relation between the absolute visual magnitude M_V and the period P (in days) as

$$M_V = -2.81 \log_{10} P - 1.43 \pm 0.10$$

This was a decrease of about 0.2 magnitudes from previous results, i.e., an increase of the intrinsic luminosity of Cepheids by a factor $10^{0.2 \times 2/5} = 1.20$ leading to a 10% increase in all cosmic distances based

directly or indirectly on the Cepheid period-luminosity relation. With this value of Cepheid absolute luminosity, the LMC distance modulus would be 18.66, or slightly less with corrections for the metallicity of the LMC (though with the absolute luminosity of Cepheids calibrated

by Hipparcos observations, the only relevance of the LMC for the Cepheid period-luminosity relation is to determine its shape.) This result for the Cepheid absolute luminosities has in turn been contradicted. [40]

These uncertainties may now have been resolved by measurements of the trigonometric parallax of Cepheids in our galaxy with the Fine Guidance Sensor of the Hubble Space Telescope. First, the trigonometric parallax of δ Cephei [41] gave a distance of 273 ± 11pc, corresponding to an LMC distance modulus of 18.50 ± 0.13. More recently, trigonometric parallaxes have been measured for nine Galactic Cepheids, giving an LMC distance modulus of 18.50 ± 0.03, or with metallicity corrections, 18.40 ± 0.05.[42]

There has also been an independent calibration of the Cepheid period-luminosity relation through observations [43] of Cepheids in the galaxy NGC 4258, whose distance 7.2 ± 0.5Mpc has been measured using the observations of proper motions of masers in this galaxy mentioned above. This distance is in satisfactory agreement with the distance 7.6 ± 0.3Mpc obtained from the Cepheids in NGC 4258 under the assumption that these Cepheids have the period-luminosity relation (1.3.7) obtained under the assumption that the LMC distance modulus is 18.5 , which tends to confirm this period-luminosity relation. But there are differences in the metallicity of the Cepheids in NGC 4258 and in the LMC, which makes this conclusion somewhat controversial. [44] A 2006 calibration of the Cepheid period-luminosity relation based on the study of 281 Cepheids in NGC 4258[45] (whose distance, as we have seen, is known from observations of maser Doppler shifts and proper motions) gave an LMC distance modulus 18.41 ± 0.10 (stat.) ± 0.13 (syst.). This study includes both a field that is metal rich, like our Galaxy, and a field that is metal poor, like the LMC, so

it provides a calibration of the metallicity dependence of the Cepheid period-luminosity relation.

In a 2003 survey [46] the LMC distance modulus measured using a variety of distance indicators other than Cepheid variables (including RR Lyrae stars, red clump stars, etc.) was found to be 18.48 ± 0.04, in very good agreement with the earlier value 18.52 ± 0.05 found by observation of Cepheids, with the corrections adopted by the Hubble Space Telescope group.

B. Secondary distance indicators

None of the above distance indicators are bright enough to be used to measure distances at redshifts large enough so that peculiar velocities can be neglected compared with the expansion velocity, say, $z > 0.03$. For this we need what are called secondary distance indicators that are brighter than Cepheids, such as whole galaxies, or supernovae, which can be as bright as whole galaxies.

For many years Cepheids could be used as distance indicators only out to a few million parsecs (Mpc), which limited their use to the Local Group (which consists of our galaxy and the Andromeda nebula M31, and a dozen or so smaller galaxies like M33 and the LMC and SMC) and some other nearby groups (the M81, M101, and Sculptor groups). This was not enough to calibrate distances to an adequate population of galaxies or supernovae, and so it was necessary to use a variety of intermediate distance indicators: globular clusters, HII regions, brightest stars in galaxies, etc. Now the Hubble Space Telescope allows us to observe

Cepheids in a great many galaxies at much greater distances, out to about 30 Mpc , and so the secondary distance indicators can now be calibrated directly, without the use of intermediate distance indicators. Four chief secondary distance indicators have been developed:

1. The Tully-Fisher relation

Although whole galaxies can be seen out to very large distances, it has not been possible to identify any class of galaxies with the same absolute luminosity. However, in 1977 Tully and Fisher [47] developed a method for estimating the absolute luminosity of suitable spiral galaxies. The 21 cm absorption line in these galaxies (arising in transitions of hydrogen atoms from lower to the higher of their two hyperfine states) is widened by the

Doppler effect, caused by the rotation of the galaxy. The line width W gives an indication of the maximum speed of rotation of the galaxy, which is correlated with the mass of the galaxy, which in turn is correlated with the galaxy's absolute luminosity. [48] (It is also possible to apply the Tully-Fisher relation using the width of other lines, such as a radio frequency transition in the carbon monoxide molecule. [49])

In one application of this approach [50] the shape of the function $L_I(W)$ that gives the infrared band absolute luminosity as a function of 21 cm line width (that is, the absolute luminosity up to a common constant factor) was found from a sample of 555 spiral galaxies in 24 clusters, many with redshifts less than 0.01 . (The relative distances to these galaxies were found from the ratios of their redshifts, using Eq. (1.2.9), so that the peculiar velocities of these galaxies introduced considerable errors into the estimated ratios of absolute luminosities of individual pairs of galaxies, but with 555 galaxies in the sample it could be assumed that these errors would cancel in a leastsquares fit of the measured relative values of absolute luminosity to a smooth curve.) Roughly speaking, $L_I(W)$ turned out to be proportional to W^3. The overall scale of the function $L_I(W)$ was then found by fitting it to the absolute luminosities of 15 spiral galaxies whose distances were accurately known from observations of Cepheid variables they contain. (These 15 galaxies extended out only to 25 Mpc , not far enough for them to be used to measure the Hubble constant directly.) The Hubble constant could then be found by using the function $L_I(W)$ calibrated in this way to find the distances to galaxies in 14 clusters with redshifts ranging from 0.013 to 0.03 , and comparing the results obtained with Eq. (1.2.8). (These redshifts may not be large enough to ignore peculiar velocities altogether, but again, this problem is mitigated by the use of a fairly large number of galaxies.) The Hubble constant found in this way was 70 ± 5 km s^{-1}Mpc^{-1}. More recently, the Hubble Space Telescope Key Project to Measure the Hubble Constant has used Cepheid variables to recalibrate the Tully-Fisher relation (assuming an LMC distance of 50 kpc) and then found H_0 by plotting distances found from the Tully-Fisher relation against redshift for a sample of 19 clusters with redshifts from 0.007 to 0.03,[51] taken from the G97 survey of Giovanelli et al. [52] The result was $H_0 = 71 \pm 3 \pm 7$ km s^{-1}Mpc^{-1}, with the first quoted uncertainty statistical and the second systematic.

2. Faber-Jackson relation

Just as the Tully-Fisher method is based on a correlation of orbital velocities with absolute luminosities in spiral galaxies, the Faber-Jackson method is based on a correlation of random velocities with absolute luminosities in elliptical galaxies. [53] An advantage of this method over the Tully-Fisher method is that it has a firmer theoretical foundation, provided by the virial theorem to be discussed in Section 1.9, which directly relates the mean square random velocity to the galaxy mass.

3. Fundamental plane

The Faber-Jackson method was improved by the recognition that the correlation between orbital velocity and absolute luminosity depends also on the surface brightness of the cluster, and hence on its area. [54] (The term "fundamental plane" refers to the way that data on elliptical galaxies are displayed graphically.) This method has been used [55] to estimate that $H_0 = 78 \pm 5$ (stat.) ± 9 (syst.) kmsec^{-1}Mpc^{-1}.

4. Type Ia supernovae

Supernovae of Type Ia are believed to occur when a white dwarf star in a binary system accretes sufficient matter from its partner to push its mass close to the Chandrasekhar limit, the maximum possible mass that can be supported by electron degeneracy pressure. [56] When this happens the white dwarf becomes unstable, and the increase in temperature and density allows the conversion of carbon and oxygen into ^{56}Ni, triggering a thermonuclear explosion that can be seen at distances of several thousand megaparsecs. The exploding star always has a mass close to the Chandrasekhar limit, so there is little variation in the absolute luminosity of these explosions, making them nearly ideal distance indicators. [57] What variation there is seems

to be well correlated with the rise time and decline time of the supernova light: the slower the decline, the higher the absolute luminosity. [58]

This relation has been calibrated by measurements of Type Ia supernovae in several galaxies of known distance. From 1937 to 1999 there were ten supernovae in galaxies whose distance had been measured by observation of Cepheid variables they contain. [59] Of these, six Type Ia supernovae were used by the HST Key H_0 Group [60] to calibrate the relation between absolute luminosity and decline time. This relation was then used to calculate distances to a sample

[56] W. A. Fowler and F. Hoyle, Astrophys. J. 132, 565 (1960). Calling a supernova Type I simply means that hydrogen lines are not observed in its spectrum. In addition to Type Ia supernovae, there are other Type I supernovae that occur in the collapse of the cores of stars much more massive than white dwarfs, whose outer layer of hydrogen has been lost in stellar winds, as well as Type II supernovae, produced by core collapse in massive stars that have not lost their outer layer of hydrogen. For a discussion of the Chandrasekhar limit, see G&C, Section 11.3.

[57] The use of Type Ia supernovae as distance indicators was pioneered by A. Sandage and G. A. Tammann, Astrophys. J. 256, 339 (1982), following an earlier observation that they had fairly uniform luminosity by C. T. Kowal, Astron. J. 73, 1021 (1968). In 1982 it was necessary to use brightest supergiant stars as intermediate distance indicators, to bridge the gap between the distances that could then be measured using Cepheids and the distances at which the Type Ia supernova could be found. For reviews of the use of type Ia supernovae as standard candles, see D. Branch, Ann. Rev. Astron. & Astrophys. 36, 17 (1998); P. Höflich, C. Gerardy, E. Linder, and H. Marion, in Stellar Candles, eds. W. Gieren et al. (Lecture Notes in Physics) [astro-ph/0301334].

of 29 Type Ia supernovae in galaxies with redshifts extending from 0.01 to 0.1 , observed at the Cerro Tololo Inter-American Observatory. [61] Plotting these distances against measured redshifts gave a Hubble constant [62] of 71 ± 2 (statistical) ± 6 (systematic) $\mathrm{kms}^{-1}\mathrm{Mpc}^{-1}$. This agrees well with an older determination using Type Ia supernovae by a Harvard group, [63] which found $H_0 = 67 \pm 7$ km $\mathrm{s}^{-1}\mathrm{Mpc}^{-1}$. Members of this group have superceded this result, [64] now giving a Hubble constant $H_0 = 73 \pm 4$ (stat.) ± 5 (syst.) $\mathrm{kms}^{-1}\mathrm{Mpc}^{-1}$. On the other hand, a group headed by Sandage using Type Ia supernovae and the Tully-Fisher relation has consistently found lower values of H_0.[65] The gap seems to be narrowing; in 2006, this group quoted [66] a value $H_0 = 62.3 \pm 1.3$ (stat.) ± 5.0 (syst.) $\mathrm{kms}^{-1}\mathrm{Mpc}^{-1}$. (According to Sandage et al., the difference between these results is due to a difference in the Cepheid period-luminosity relation used to measure distances to the galaxies that host the supernovae that are used to calibrate the relation between supernova absolute luminosity and decline time. Sandage et al. use a metallicity-dependent period-luminosity relation. However Macri et al. [45] subsequently reported no difference in the period-luminosity relation for Cepheids in a metal-rich and a metal-poor region of NGC 4258.)

It is an old hope that with a sufficient theoretical understanding of supernova explosions, it might be possible to measure their distance

without use of primary distance indicators. A 2003 comparison [67] of observed light curves (apparent magnitude as a function of time) and spectra with theory for 26 Type Ia supernovae with redshifts extending up to 0.05 , plus one with redshift 0.38 , gave $H_0 = 67$ $\mathrm{kmsec}^{-1}\mathrm{Mpc}^{-1}$, with a two standard deviation uncertainty of 8 $\mathrm{kmsec}^{-1}\mathrm{Mpc}^{-1}$. It is too soon for this method to replace the older method based on the use of primary distance indicators to calibrate the supernova absolute luminosities, but the agreement between the values of H_0 found in these two ways provides some reassurance that no large error is being made with the older method.

It is instructive to consider a fifth secondary distance indicator that is also used to measure the Hubble constant:

5. Surface brightness fluctuations

In 1988 Tonry and Schneider [68] suggested using the fluctuations in the observed surface brightness of a galaxy from one part of the image to another as a measure of the galaxy's distance. Suppose that the stars in a galaxy can be classified in luminosity classes, all the stars in a luminosity class i having the same absolute luminosity L_i. The rate of receiving energy per unit area of telescope aperture in a small part of the galactic image (as for instance, a single pixel in a charge-coupled device) is

$$\ell = \sum_i \frac{N_i L_i}{4\pi d^2} \tag{1.3.8}$$

where N_i the number of stars of class i in this part of the galaxy's image, and d is the distance of the galaxy. Usually only the brightest stars can be resolved, so it is not possible to measure all the N_i directly, but one can measure the fluctuations in ℓ from one part of the image to another due to the finite values of the N_i. Suppose that the different N_i fluctuate independently from one small part of the galaxy's image to another, and obey the rules of Poisson statistics, so that

$$\langle (N_i - \langle N_i \rangle)\,(N_j - \langle N_j \rangle) \rangle = \delta_{ij}\,\langle N_i \rangle\,, \tag{1.3.9}$$

with brackets denoting an average over small parts of the central portion of the galaxy's image. It follows then that

$$\frac{\langle (\ell - \langle \ell \rangle)^2 \rangle}{\langle \ell \rangle} = \frac{\bar{L}}{4\pi d^2} \tag{1.3.10}$$

where $\bar{L}$ is a luminosity-weighted mean stellar luminosity

$$\bar{L} \equiv \frac{\sum_i \langle N_i \rangle\, L_i^2}{\sum_i \langle N_i \rangle\, L_i} \tag{1.3.11}$$

which is expected to vary much less from one galaxy to another than the luminosities of the galaxies themselves. Eq. (1.3.10) can be used to measure distances once this relation is calibrated by measuring $\bar{L}$. By studying surface brightness fluctuations in a survey of galaxies whose distances were found by observations of Cepheids they contain, Tonry et al. [69] found an absolute magnitude $\bar{M}_I$ that in the infrared band is equivalent to the absolute luminosity $\bar{L}$:

$$\bar{M}_I = (-1.74 \pm 0.07) + (4.5 \pm 0.25)\,[m_V - m_I - 1.15] \tag{1.3.12}$$

where $m_V - m_I$ is a parameter characterizing the color of the galaxy, equal to the difference of its apparent magnitudes in the infrared and visual bands, assumed here to lie between 1.0 and 1.5. Using Eq. (1.3.10) to find distances of galaxies of higher redshift, they obtained a Hubble constant 81 ± 6 km s^{-1}Mpc^{-1}.

There are other phenomena that are used to measure the Hubble constant, including the comparison of apparent and absolute luminosity of supernovae of other types, novae, globular clusters, and planetary nebulae, the diameter-velocity dispersion relation for elliptical galaxies, gravitational lenses (discussed in Section 1.12), the Sunyaev-Zel'dovich effect (discussed in Section 2.3), etc. [70] The HST Key H_0 Group have put together their results of measurements of the Hubble constant using the Tully-Fisher relation, Type Ia supernovae, and several of these other secondary distance indicators, and conclude that [71]

$$H_0 = 71 \pm 6 \text{ km s}^{-1}\text{Mpc}^{-1}$$

As we will see in Section 7.2, the study of anisotropies in the cosmic microwave background has given a value $H_0 = 73 \pm 3$ km s^{-1}Mpc^{-1}. This does not depend on any of the tools discussed in this section, but it does depend on some far-reaching cosmological assumptions: including flat spatial geometry, time-independent vacuum energy, and cold dark matter. For this reason, the increasingly precise measurement of H_0 provided by the

cosmic microwave background will not supplant the older measurements discussed in this section - rather, the agreement (or possible future disagreement) between the values of H_0 provided by these very different methods will serve to validate (or possibly invalidate) the cosmological assumptions made in the analysis of the cosmic microwave background.

To take account of the remaining uncertainty in the Hubble constant, it is usual these days to take

$$H_0 = 100h \text{ km s}^{-1}\text{Mpc}^{-1} \tag{1.3.13}$$

with the dimensionless parameter h assumed to be in the neighborhood of 0.7. This corresponds to a Hubble time

$$1/H_0 = 9.778 \times 10^9 h^{-1} \text{ years} \tag{1.3.14}$$

10.1.6 1.4 Luminosity distances and angular diameter distances

We must now consider the measurement of distances at large redshifts, say $z > 0.1$, where the effects of cosmological expansion on the determination of distance can no longer be neglected. It is these measurements that can tell us whether the expansion of the universe is accelerating or decelerating, and how fast. Before we can interpret these measurements, we will need to consider in this section how to define distance at large redshifts, and we will have to apply Einstein's field equations to the Robertson-Walker metric in the following section. After that, we will return in Section 1.6 to the measurements of distances for large redshift, and their interpretation.

In the previous section we derived the familiar relation $\ell = L/4\pi d^2$ for the apparent luminosity ℓ of a source of absolute luminosity L at a distance d. At large distances this derivation needs modification for three reasons:

1. At the time t_0 that the light reaches earth, the proper area of a sphere drawn around the luminous object and passing through the earth is given by the metric (1.1.10) as $4\pi r_1^2 a^2(t_0)$, where r_1 is the coordinate distance of the earth as seen from the luminous object, which is just the same as the coordinate distance of the luminous object as seen from the earth. The fraction of the light received in a telescope of aperture A on earth is therefore $A/4\pi r_1^2 a^2(t_0)$, and so the factor $1/d^2$ in the formula for ℓ must be replaced with $1/r_1^2 a^2(t_0)$.

2. The rate of arrival of individual photons is lower than the rate at which they are emitted by the redshift factor $a(t_1)/a(t_0) = 1/(1+z)$.

3. The energy hv_0 of the individual photons received on earth is less than the energy hv_1 with which they were emitted by the same redshift factor $1/(1+z)$.

Putting this together gives the correct formula for apparent luminosity of a source at radial coordinate r_1 with a redshift z of any size:

$$\ell = \frac{L}{4\pi r_1^2 a^2(t_0)(1+z)^2} \tag{1.4.1}$$

It is convenient to introduce a "luminosity distance" d_L, which is defined so that the relation between apparent and absolute luminosity and luminosity distance is the same as Eq. (1.3.3):

$$\ell = \frac{L}{4\pi d_L^2} \tag{1.4.2}$$

Eq. (1.4.1) can then be expressed as

$$d_L = a\left(t_0\right) r_1 (1+z) \tag{1.4.3}$$

For objects with $z \ll 1$, we can usefully write the relation between luminosity distance and redshift as a power series. The redshift $1+z \equiv a\left(t_0\right)/a\left(t_1\right)$ is related to the "look-back time" $t_0 - t_1$ by

$$z = H_0\left(t_0 - t_1\right) + \frac{1}{2}\left(q_0+2\right) H_0^2 \left(t_0 - t_1\right)^2 + \ldots \tag{1.4.4}$$

where H_0 is the Hubble constant (1.2.7) and q_0 is the deceleration parameter

$$q_0 \equiv \frac{-1}{H_0^2 a\left(t_0\right)} \frac{d^2 a(t)}{dt^2}\bigg|_{t=t_0} \tag{1.4.5}$$

This can be inverted, to give the look-back time as a power series in the redshift

$$H_0\left(t_0 - t_1\right) = z - \frac{1}{2}\left(q_0+2\right) z^2 + \ldots \tag{1.4.6}$$

The coordinate distance r_1 of the luminous object is given by Eq. (1.2.2) as

$$\frac{t_0 - t_1}{a\left(t_0\right)} + \frac{H_0\left(t_0 - t_1\right)^2}{2a\left(t_0\right)} + \cdots = r_1 + \ldots \tag{1.4.7}$$

with the dots on the right-hand side denoting terms of third and higher order in r_1. Using Eq. (1.4.6), the solution is

$$r_1 a\left(t_0\right) H_0 = z - \frac{1}{2}\left(1+q_0\right) z^2 + \cdots \tag{1.4.8}$$

This gives the luminosity distance (1.4.3) as a power series

$$d_L = H_0^{-1}\left[z + \frac{1}{2}\left(1-q_0\right) z^2 + \cdots\right]. \tag{1.4.9}$$

We can therefore measure q_0 as well as H_0 by measuring the luminosity distance as a function of redshift to terms of order z^2. The same reasoning has been used to extend the expression (1.4.9) to fourth order in z :[1]

$$\begin{aligned} d_L(z) =& H_0^{-1}\left[z + \frac{1}{2}\left(1-q_0\right) z^2 - \frac{1}{6}\left(1 - q_0 - 3q_0^2 + j_0 + \frac{K}{H_0^2 a_0^2}\right) z^3 \right. \\ &+ \frac{1}{24}\left(2 - 2q_0 - 15q_0^2 - 15q_0^3 + 5j_0 + 10q_0 j_0 \right. \\ &\left.\left. + s_0 + \frac{2K\left(1+3q_0\right)}{H_0^2 a_0^2}\right) z^4 + \cdots\right], \end{aligned}$$

where j_0 and s_0 are parameters known as the jerk and snap:

$$j_0 \equiv \frac{1}{H_0^3 a\left(t_0\right)} \frac{d^3 a(t)}{dt^3}\bigg|_{t=t_0}, \quad s_0 \equiv \frac{1}{H_0^4 a\left(t_0\right)} \frac{d^4 a(t)}{dt^4}\bigg|_{t=t_0}.$$

Years ago cosmology was called "a search for two numbers," H_0 and q_0. The determination of H_0 is still a major goal of astronomy, as discussed in the previous section. On the other hand, there is less interest now in q_0. Instead of high-precision distance determinations at moderate redshifts, of order 0.1 to 0.2 , which would give an accurate value of q_0, we now have distance determinations of only moderate precision at high redshifts, of order unity, which depend on

the whole form of the function $a(t)$ over the past few billion years. For redshifts of order unity, it is not very useful to expand in powers of redshift. In order to interpret these measurements, we will need a dynamical theory of the expansion, to be developed in the next section. As we will see there, modern observations suggest strongly that there are not two but at least three parameters that need to be measured to calculate $a(t)$.

Before turning to this dynamical theory, let's pause a moment to clarify the distinction between different measures of distance. So far, we have encountered the proper distance (1.1.15) and the luminosity distance (1.4.3). There is another sort of distance, which is what we measure when we compare angular sizes with physical dimensions. Inspection of the metric

(1.1.12) shows that a source at co-moving radial coordinate r_1 that emits light at time t_1 and is observed at present to subtend a small angle θ will extend over a proper distance s (normal to the line of sight) equal to $a(t_1)\, r_1\theta$. The angular diameter distance d_A is defined so that θ is given by the usual relation of Euclidean geometry

$$\theta = s/d_A \tag{1.4.10}$$

and we see that

$$d_A = a(t_1)\, r_1 \tag{1.4.11}$$

Comparison of this result with Eq. (1.4.3) shows that the ratio of the luminosity and angular-diameter distances is simply a function of redshift:

$$d_A/d_L = (1+z)^{-2} \tag{1.4.12}$$

Therefore if we have measured the luminosity distance at a given redshift (and if we are convinced of the correctness of the Robertson-Walker metric), then we learn nothing additional about $a(t)$ if we also measure the angular diameter distance at that redshift. Neither galaxies nor supernovas have well-defined edges, so angular diameter distances are much less useful in studying the cosmological expansion than are luminosity distances. However, as we shall see, they play an important role in the theoretical analysis of both gravitational lenses in Chapter 9 and of the fluctuations in the cosmic microwave radiation background in Chapters 2 and 7 . We will see in Section 8.1 that the observation of acoustic oscillations in the matter density may allow a measurement of yet another distance, a structure distance, equal to $a(t_0)\, r_1 = (1+z)d_A$.

10.1.7 1.5 Dynamics of expansion

All our results up to now have been very general, not depending on assumptions about the dynamics of the cosmological expansion. To go further we will need now to apply the gravitational field equations of Einstein, with various tentative assumptions about the cosmic energy density and pressure.

The expansion of the universe is governed by the Einstein field equations (B.71), which can be put in the convenient form

$$R_{\mu\nu} = -8\pi G S_{\mu\nu} \tag{1.5.1}$$

where $R_{\mu\nu}$ is the Ricci tensor:

$$R_{\mu\nu} = \frac{\partial \Gamma^\lambda_{\lambda\mu}}{\partial x^\nu} - \frac{\partial \Gamma^\lambda_{\mu\nu}}{\partial x^\lambda} + \Gamma^\lambda_{\mu\sigma}\Gamma^\sigma_{\nu\lambda} - \Gamma^\lambda_{\mu\nu}\Gamma^\sigma_{\lambda\sigma} \tag{1.5.2}$$

[471] M. Visser, Class. Quant. Grav. 21, 2603 (2004) [gr-qc/0309109]. The term of third order in z was previously calculated by T. Chiba and T. Nakamura, Prog. Theor. Phys. 100, 1077 (1998).

and $S_{\mu\nu}$ is given in terms of the energy-momentum tensor $T_{\mu\nu}$ by

$$S_{\mu\nu} \equiv T_{\mu\nu} - \frac{1}{2} g_{\mu\nu} T^{\lambda}_{\lambda} \tag{1.5.3}$$

As we saw in Section 1.1, for the Robertson-Walker metric the components of the affine connection with two or three time indices all vanish, so

$$\begin{aligned} R_{ij} =& \frac{\partial \Gamma^k_{ki}}{\partial x^j} - \left[\frac{\partial \Gamma^k_{ij}}{\partial x^k} + \frac{\partial \Gamma^0_{ij}}{\partial t} \right] \\ &+ \left[\Gamma^0_{ik} \Gamma^k_{j0} + \Gamma^k_{i0} \Gamma^0_{jk} + \Gamma^l_{ik} \Gamma^k_{jl} \right] \\ &- \left[\Gamma^k_{ij} \Gamma^l_{kl} + \Gamma^0_{ij} \Gamma^l_{0l} \right] \end{aligned} \tag{1.5.4}$$

$$R_{00} = \frac{\partial \Gamma^i_{i0}}{\partial t} + \Gamma^i_{0j} \Gamma^j_{0i} \tag{1.5.5}$$

We don't need to calculate $R_{i0} = R_{0i}$, because it is a three-vector, and therefore must vanish due to the isotropy of the Robertson-Walker metric. Using the formulas (1.1.17)-(1.1.19) for the non-vanishing components of the affine connection gives

$$\begin{array}{ll} \frac{\partial \Gamma^0_{ij}}{\partial t} = \tilde{g}_{ij} \frac{d}{dt}(a\dot{a}), & \Gamma^0_{ik} \Gamma^k_{j0} = \tilde{g}_{ij} \dot{a}^2, \quad \Gamma^0_{ij} \Gamma^l_{0l} = 3 \tilde{g}_{ij} \dot{a}^2 \\ \frac{\partial \Gamma^i_{i0}}{\partial t} = 3 \frac{d}{dt} \left(\frac{\dot{a}}{a} \right), & \Gamma^i_{0j} \Gamma^j_{i0} = 3 \left(\frac{\dot{a}}{a} \right)^2 \end{array} \tag{1.5.6}$$

where dots denote time derivatives. Using this in Eqs. (1.5.4) and (1.5.5), we find that the non-vanishing components of the Ricci tensor are

$$R_{ij} = \tilde{R}_{ij} - 2\dot{a}^2 \tilde{g}_{ij} - a\ddot{a} \tilde{g}_{ij} \tag{1.5.7}$$

$$R_{00} = 3 \frac{d}{dt} \left(\frac{\dot{a}}{a} \right) + 3 \left(\frac{\dot{a}}{a} \right)^2 = 3 \frac{\ddot{a}}{a} \tag{1.5.8}$$

where $\tilde{R}_{ij}$ is the purely spatial Ricci tensor

$$\tilde{R}_{ij} = \frac{\partial \Gamma^k_{ki}}{\partial x^j} - \frac{\partial \Gamma^k_{ij}}{\partial x^k} + \Gamma^l_{ik} \Gamma^k_{jl} - \Gamma^l_{ij} \Gamma^k_{kl}. \tag{1.5.9}$$

According to Eq. (1.1.19), the spatial components Γ^i_{jk} of the four-dimensional affine connection are here the same as those of the affine connection that would be calculated in three dimensions from the three-metric $\tilde{g}_{ij}$:

$$\Gamma^k_{ij} = K x^k \tilde{g}_{ij} \tag{1.5.10}$$

To calculate $\tilde{R}_{ij}$, we use a trick used earlier in calculating particle trajectories: we calculate $\tilde{R}_{ij}$ where the calculation is simplest, at $\mathbf{x} = 0$, and express the result as a relation that is invariant under all transformations of the spatial coordinates, so that the homogeneity of the three-dimensional metric insures that this relation is valid everywhere. The spatial Ricci tensor at $\mathbf{x} = 0$ is

$$\tilde{R}_{ij} = \frac{\partial \Gamma^l_{li}}{\partial x^j} - \frac{\partial \Gamma^l_{ji}}{\partial x^l} = K\delta_{ij} - 3K\delta_{ij} = -2K\delta_{ij} \tag{1.5.11}$$

At $\mathbf{x} = 0$ the spatial metric $\tilde{g}_{ij}$ is just δ_{ij}, so this can be rewritten as

$$\tilde{R}_{ij} = -2K \tilde{g}_{ij} \tag{1.5.12}$$

which, since it is an equality between two three-tensors, is then true in all spatial coordinate systems, including systems in which the point $\mathbf{x} = 0$ is transformed into any other point. Hence Eq. (1.5.12) is true everywhere, and together with Eq. (1.5.7) gives

$$R_{ij} = -\left[2K + 2\dot{a}^2 + a\ddot{a}\right]\tilde{g}_{ij} \tag{1.5.13}$$

We also need the values of S_{ij} and S_{00}. For this, we use Eq. (1.1.31) in the form

$$T_{00} = \rho, \quad T_{i0} = 0, \quad T_{ij} = a^2 p\tilde{g}_{ij} \tag{1.5.14}$$

where $\rho(t)$ and $p(t)$ are the proper energy density and pressure. Eq. (1.5.3) gives then

$$S_{ij} = T_{ij} - \frac{1}{2}\tilde{g}_{ij}a^2\left(T^k{}_k + T^0_0\right) = a^2 p\tilde{g}_{ij} - \frac{1}{2}a^2\tilde{g}_{ij}(3p - \rho) = \frac{1}{2}(\rho - p)a^2\tilde{g}_{ij} \tag{1.5.15}$$

$$S_{00} = T_{00} + \frac{1}{2}\left(T^k{}_k + T^0_0\right) = \rho + \frac{1}{2}(3p - \rho) = \frac{1}{2}(\rho + 3p) \tag{1.5.16}$$

and $S_{i0} = 0$. The Einstein equations are therefore

$$-\frac{2K}{a^2} - \frac{2\dot{a}^2}{a^2} - \frac{\ddot{a}}{a} = -4\pi G(\rho - p) \tag{1.5.17}$$

$$\frac{3\ddot{a}}{a} = -4\pi G(3p + \rho) \tag{1.5.18}$$

We can eliminate the second derivative terms by adding three times the first equation to the second, and find

$$\dot{a}^2 + K = \frac{8\pi G\rho a^2}{3} \tag{1.5.19}$$

This is the fundamental Friedmann equation [1] governing the expansion of the universe.

The remaining information in Eqs. (1.5.17) and (1.5.18) just reproduces the conservation law (1.1.32):

$$\dot{\rho} = -\frac{3\dot{a}}{a}(\rho + p) \tag{1.5.20}$$

(This should come as no surprise. Under all circumstances, the energymomentum conservation law may be derived as a consequence of the Einstein field equations.) Given p as a function of ρ, we can solve Eq. (1.5.20) to find ρ as a function of a, and then use this in Eq. (1.5.19) to find a as a function of t.

There is another way of deriving Eq. (1.5.19), at least for the case of nonrelativistic matter. Imagine a co-moving ball cut out from the expanding universe, with some typical galaxy at its center, and suppose it then emptied of the matter it contains. According to Birkhoff's theorem, [2] in any system that is spherically symmetric around some point, the metric in an empty ball centered on this point must be that of flat space. This holds whatever is happening outside the empty ball, as long as it is spherically symmetric. Now imagine putting the matter back in the ball, with a velocity proportional to distance from the center of symmetry, taken as $\mathbf{X} = 0$:

$$\dot{\mathbf{X}} = H(t)\mathbf{X} \tag{1.5.21}$$

(Here the components X^i of $\mathbf{X}$ are ordinary Cartesian coordinates, not the co-moving coordinates x^i used in the Robertson-Walker metric. Note that this is the one pattern of velocities consistent with the principle of homogeneity: The velocity of a co-moving particle at $\mathbf{X}_1$ relative to a co-moving particle at $\mathbf{X}_2$ is $\dot{\mathbf{X}}_1 - \dot{\mathbf{X}}_2 = H(t)\left(\mathbf{X}_1 - \mathbf{X}_2\right)$.) The solution of Eq. (1.5.21) is

$$\mathbf{X}(t) = \left(\frac{a(t)}{a\left(t_0\right)} \right) \mathbf{X}\left(t_0\right), \tag{1.5.22}$$

where $a(t)$ is the solution of the equation

$$\dot{a}(t)/a(t) = H(t) \tag{1.5.23}$$

As long as the radius of the ball is chosen to be not too large, the expansion velocity (1.5.21) of the matter we put into it will be non-relativistic, and the gravitational field will be weak, so that we can follow its motion using Newtonian mechanics. The kinetic energy of a co-moving particle of mass m at $\mathbf{X}$ is

$$K.E. = \frac{1}{2} m \dot{\mathbf{X}}^2 = \frac{m \dot{a}^2 \mathbf{X}^2}{2a^2} \tag{1.5.24}$$

The mass interior to the position of the particle is $M(\mathbf{X}) = 4\pi\rho|\mathbf{X}|^3/3$, so the potential energy of the particle is

$$P.E. = -\frac{GmM(\mathbf{X})}{|\mathbf{X}|} = -\frac{4\pi G m \rho |\mathbf{X}|^2}{3} \tag{1.5.25}$$

The condition of energy conservation thus tells us that

$$E = K.E. + P.E. = \frac{m\left|\mathbf{X}\left(t_0\right)\right|^2}{a^2\left(t_0\right)} \left[\frac{\dot{a}^2}{2} - \frac{4\pi G \rho a^2}{3} \right] = \text{ constant} \tag{1.5.26}$$

This is the same as Eq. (1.5.19), providing we identify the particle energy as

$$E = -\frac{Km\left|\mathbf{X}\left(t_0\right)\right|^2}{2a^2\left(t_0\right)} \tag{1.5.27}$$

Particles will be able to escape to infinity if and only if $E \geq 0$, which requires $K = 0$ or $K = -1$. For $K = +1$ they have less than escape velocity, so the expansion eventually stops, and particles fall back toward each other.

Returning now to the relativistic formalism and an arbitrary dependence of ρ on a, even without knowing this dependence we can use Eq. (1.5.19) to draw important consequences about the general features of the expansion. First, as long as ρ remains positive, it is only possible for the expansion of the universe to stop if $K = +1$, the case of spherical geometry. Also, for any value of the Hubble constant $H_0 \equiv \dot{a}\left(t_0\right)/a\left(t_0\right)$, we may define a critical present density

$$\rho_{0,\text{ crit}} \equiv \frac{3H_0^2}{8\pi G} = 1.878 \times 10^{-29} h^2 \text{ g/cm}^3 \tag{1.5.28}$$

where h is the Hubble constant in units of 100 km s^{-1}Mpc^{-1}. According to Eq. (1.5.19), whatever we assume about the constituents of the universe, the curvature constant K will be $+1$ or 0 or -1 according to whether the present density ρ_0 is greater than, equal to, or less than $\rho_{0,\text{ crit}}$. If the quantity $3p + \rho$ is positive (as it is for any mixture of matter and radiation, in the absence of a vacuum energy density) then Eq. (1.5.18) shows that $\ddot{a}/a \leq 0$, so the expansion must have started with $a = 0$ at some moment in the past; the present age of the universe t_0 is less than the Hubble time

$$t_0 < H_0^{-1} \tag{1.5.29}$$

[471] A. Friedmann, Z. Phys. 16, 377 (1922); ibid 21, 326 (1924).

[2] G&C, Section 11.7.

Also, if $K = +1$ and the expansion stops, then with $\ddot{a}/a \leq 0$ the universe will again contract to a singularity at which $a = 0$.

We can use Eq. (1.5.18) to give a general formula for the deceleration parameter $q_0 \equiv -\ddot{a}\left(t_0\right) a\left(t_0\right) / \dot{a}^2\left(t_0\right)$:

$$q_0 = \frac{4\pi G\left(\rho_0 + 3p_0\right)}{3H_0^2} = \frac{\rho_0 + 3p_0}{2\rho_{0,\text{crit}}} \tag{1.5.30}$$

with a subscript 0 denoting a present value. If the present density of the universe were dominated by non-relativistic matter then $p_0 \ll \rho_0$, and the curvature constant K would be $+1$ or 0 or -1 according to whether $q_0 > \frac{1}{2}$ or $q_0 = \frac{1}{2}$ or $q_0 < \frac{1}{2}$. On the other hand, if the present density of the universe were dominated by relativistic matter then $p_0 = \rho_0/3$, and the critical value of the deceleration parameter at which $K = 0$ would be $q_0 = 1$. Finally, if the present density of the universe were dominated by vacuum energy then $p_0 = -\rho_0$, and the value of the deceleration parameter at which $K = 0$ would be $q_0 = -1$.

There is a peculiar aspect to these results. The contribution of nonrelativistic and relativistic matter to the quantity ρa^2 in Eq. (1.5.19) grows as a^{-1} and a^{-2}, respectively, as $a \to 0$, so at sufficiently early times in the expansion we may certainly neglect the constant K, and Eq. (1.5.19) gives

$$\frac{\dot{a}^2}{a^2} \to \frac{8\pi G\rho}{3} \tag{1.5.31}$$

That is, at these early times the density becomes essentially equal to the critical density $3H^2/8\pi G$, where $H \equiv \dot{a}/a$ is the value of the Hubble "constant" at those times. On the other hand, we will see later that the total energy density of the present universe is still a fair fraction of the critical density. How is it that after billions of years, ρ is still not very different from ρ_{crit} ? This is sometimes called the flatness problem.

The simplest solution to the flatness problem is just that we are in a spatially flat universe, in which $K = 0$ and ρ is always precisely equal to ρ_{crit} . A more popular solution is provided by the inflationary theories discussed in Chapter 4. In these theories K may not vanish, and ρ may not start out close to ρ_{crit} , but there is an early period of rapid growth in which ρ/ρ_{crit} rapidly approaches unity. In inflationary theories it is expected though not required that ρ should now be very close to ρ_{crit} , in which case it is a good approximation to take $K = 0$.

For $K = 0$ we get very simple solutions to Eq. (1.5.19) in the three special cases listed in Section 1.1:

Non-relativistic matter: Here $\rho = \rho_0\left(a/a_0\right)^{-3}$, and the solution of Eq. (1.5.19) with $K = 0$ is

$$a(t) \propto t^{2/3} \tag{1.5.32}$$

This gives $q_0 \equiv -a\ddot{a}/\dot{a}^2 = 1/2$, and a simple relation between the age of the universe and the Hubble constant

$$t_0 = \frac{2}{3H_0} = 6.52 \times 10^9 h^{-1}\text{yr} \tag{1.5.33}$$

Eqs. (1.5.32) and (1.5.18) show that for $K = 0$, the energy density at time t is $\rho = 1/6\pi G t^2$. This is known as the Einstein-de Sitter model. It was for many years the most popular cosmological model, though as we shall see, the age (1.5.33) is uncomfortably short compared with the ages of certain stars.

Relativistic matter: Here $\rho = \rho_0\left(a/a_0\right)^{-4}$, and the solution of Eq. (1.5.19) with $K = 0$ is

$$a(t) \propto \sqrt{t} \tag{1.5.34}$$

This gives $q_0 = +1$, while the age of the universe and the Hubble constant are related by

$$t_0 = \frac{1}{2H_0} \tag{1.5.35}$$

The energy density at time t is $\rho = 3/32\pi G t^2$.
Vacuum energy: Lorentz invariance requires that in locally inertial coordinate systems the energy-momentum tensor $T_V^{\mu\nu}$ of the vacuum must be proportional to the Minkowski metric $\eta^{\mu\nu}$ (for which $\eta^{ij} = \eta_{ij} = \delta_{ij}, \eta^{i0} = \eta_{i0} = \eta^{0i} = \eta_{0i} = 0, \eta^{00} = \eta_{00} = -1$), and so in general coordinate systems $T_V^{\mu\nu}$ must be proportional to $g^{\mu\nu}$. Comparing this with Eq. (B.43) shows that the vacuum has $p_V = -\rho_V$, so that $T_V^{\mu\nu} = -\rho_V g^{\mu\nu}$. In the absence of any other form of energy this would satisfy the conservation law $0 = T_{V\ ;\mu}^{\mu\nu} = g^{\mu\nu}\partial\rho_V/\partial x^\mu$, so that ρ_V would be a constant, independent of spacetime position. Eq. (1.5.19) for $K = 0$ requires that $\rho_V > 0$, and has the solutions

$$a(t) \propto \exp(Ht) \tag{1.5.36}$$

where H is the Hubble constant, now really a constant, given by

$$H = \sqrt{\frac{8\pi G\rho_V}{3}} \tag{1.5.37}$$

Here $q_0 = -1$, and the age of the universe in this case is infinite. This is known as the de Sitter model. [3] Of course, there is some matter in the universe, so even if the energy density of the universe is now dominated by a constant vacuum energy, there was a time in the past when matter and/or radiation were more important, and so the expansion has a finite age, although greater than it would be without a vacuum energy.

More generally, for arbitrary K and a mixture of vacuum energy and relativistic and non-relativistic matter, making up fractions Ω_Λ, Ω_M, and Ω_R of the critical energy density, [4] we have

$$\rho = \frac{3H_0^2}{8\pi G}\left[\Omega_\Lambda + \Omega_M\left(\frac{a_0}{a}\right)^3 + \Omega_R\left(\frac{a_0}{a}\right)^4\right], \tag{1.5.38}$$

where the present energy densities in the vacuum, non-relativistic matter, and and relativistic matter (i.e., radiation) are, respectively,

$$\rho_{V0} \equiv \frac{3H_0^2\Omega_\Lambda}{8\pi G}, \quad \rho_{M0} \equiv \frac{3H_0^2\Omega_M}{8\pi G}, \quad \rho_{R0} \equiv \frac{3H_0^2\Omega_R}{8\pi G} \tag{1.5.39}$$

and, according to Eq. (1.5.19),

$$\Omega_\Lambda + \Omega_M + \Omega_R + \Omega_K = 1, \quad \Omega_K \equiv -\frac{K}{a_0^2H_0^2} \tag{1.5.40}$$

Using this in Eq. (1.5.19) gives

$$\begin{aligned} dt &= \frac{dx}{H_0 x\sqrt{\Omega_\Lambda + \Omega_K x^{-2} + \Omega_M x^{-3} + \Omega_R x^{-4}}} \\ &= \frac{-dz}{H_0(1+z)\sqrt{\Omega_\Lambda + \Omega_K(1+z)^2 + \Omega_M(1+z)^3 + \Omega_R(1+z)^4}} \end{aligned} \tag{1.5.41}$$

where $x \equiv a/a_0 = 1/(1+z)$. Therefore, if we define the zero of time as corresponding to an infinite redshift, then the time at which light was emitted that reaches us with redshift z is given by

$$t(z) = \frac{1}{H_0}\int_0^{1/(1+z)} \frac{dx}{x\sqrt{\Omega_\Lambda + \Omega_K x^{-2} + \Omega_M x^{-3} + \Omega_R x^{-4}}} \tag{1.5.42}$$

In particular, by setting $z = 0$, we find the present age of the universe:

$$t_0 = \frac{1}{H_0}\int_0^{1} \frac{dx}{x\sqrt{\Omega_\Lambda + \Omega_K x^{-2} + \Omega_M x^{-3} + \Omega_R x^{-4}}} \tag{1.5.43}$$

In order to calculate luminosity or angular diameter distances, we also need to know the radial coordinate $r(z)$ of a source that is observed now with redshift z. According to Eqs. (1.2.2) and (1.5.41), this is

$$\begin{aligned} r(z) &= S\left[\int_{t(z)}^{t_0} \frac{dt}{a(t)}\right] \\ &= S\left[\frac{1}{a_0 H_0}\int_{1/(1+z)}^{1} \frac{dx}{x^2\sqrt{\Omega_\Lambda + \Omega_K x^{-2} + \Omega_M x^{-3} + \Omega_R x^{-4}}}\right] \end{aligned}$$

where

$$S[y] \equiv \begin{cases} \sin y & K = +1 \\ y & K = 0 \\ \sinh y & K = -1 \end{cases}$$

This can be written more conveniently by using Eq. (1.5.40) to express $a_0 H_0$ in terms of Ω_K. We then have a single formula

$$\begin{aligned} a_0 r(z) =& \frac{1}{H_0 \Omega_K^{1/2}} \\ & \times \sinh\left[\Omega_K^{1/2}\int_{1/(1+z)}^{1} \frac{dx}{x^2\sqrt{\Omega_\Lambda + \Omega_K x^{-2} + \Omega_M x^{-3} + \Omega_R x^{-4}}}\right] \end{aligned} \tag{1.5.44}$$

which can be used for any curvature. (Eq. (1.5.43) has a smooth limit for $\Omega_K \to 0$, which gives the result for zero curvature. Also, for $\Omega_K < 0$, the argument of the hyperbolic sine is imaginary, and we can use $\sinh ix = i \sin x$.) Using Eq. (1.5.44) in Eq. (1.4.3) gives the luminosity distance of a source observed with redshift z as

$$\begin{aligned} d_L(z) =& a_0 r(z)(1+z) = \frac{1+z}{H_0 \Omega_K^{1/2}} \\ & \times \sinh\left[\Omega_K^{1/2}\int_{1/(1+z)}^{1} \frac{dx}{x^2\sqrt{\Omega_\Lambda + \Omega_K x^{-2} + \Omega_M x^{-3} + \Omega_R x^{-4}}}\right] \end{aligned} \tag{1.5.45}$$

For $K = 0$ we have $\Omega_K = 0$ and Eq. (1.5.45) becomes

$$d_L(z) = a_0 r_1(1+z) = \frac{1+z}{H_0}\int_{1/(1+z)}^{1} \frac{dx}{x^2\sqrt{\Omega_\Lambda + \Omega_M x^{-3} + \Omega_R x^{-4}}} \tag{1.5.46}$$

[473] W. de Sitter, Proc. Roy. Acad. Sci. (Amsterdam), 19, 1217 (1917); ibid. 20, 229 (1917); ibid. 20, 1309 (1917); Mon. Not. Roy. Astron. Soc., 78, 2 (1917).

[4] The use of the symbol Ω_Λ instead of Ω_V for the ratio of the vacuum energy density to the critical energy density has become standard, because of a connection with the cosmological constant discussed in a historical note below.

As we will see in Section 2.1, Ω_R is much less than Ω_M, and the integral (1.5.46) converges at its lower bound for $z \to \infty$ whether or not Ω_R vanishes, so it is a good approximation to take $\Omega_R = 0$ here.

It is of some interest to express the deceleration parameter q_0 in terms of the Ω s. The p/ρ ratio w for vacuum, matter, and radiation is $-1, 0$, and $1/3$, respectively, so Eq. (1.5.39) gives the present pressure as

$$p_0 = \frac{3H_0^2}{8\pi G}\left(-\Omega_\Lambda + \frac{1}{3}\Omega_R\right). \tag{1.5.47}$$

Eq. (1.5.30) then gives

$$q_0 = \frac{4\pi G\left(3p_0 + \rho_0\right)}{3H_0^2} = \frac{1}{2}\left(\Omega_M - 2\Omega_\Lambda + 2\Omega_R\right) \tag{1.5.48}$$

One of the reasons for our interest in the values of Ω_K, Ω_M, etc. is that they tell us whether the present expansion of the universe will ever stop. According to Eq. (1.5.38), the expansion can only stop if there is a real root of the cubic equation

$$\Omega_\Lambda u^3 + \Omega_K u + \Omega_M = 0 \tag{1.5.49}$$

where $u \equiv a(t)/a\left(t_0\right)$ is greater than one. (We are ignoring radiation here, since it will become even less important as the universe expands.) This expression has the value $+1$ for $u = 1$. If $\Omega_\Lambda < 0$ then the left-hand side of Eq. (1.5.49) becomes negative for sufficiently large u, so it must take the value zero at some intermediate value of u, and the expansion will stop when this value of u is reached. Even for $\Omega_\Lambda \geq 0$ it is still possible for the expansion to stop, provided $\Omega_K = 1 - \Omega_\Lambda - \Omega_M$ is sufficiently negative (which, among other things, requires that $K = +1$).

Historical Note 1: If we express the total energy momentum tensor $T_{\mu\nu}$ as the sum of a possible vacuum term $-\rho_V g_{\mu\nu}$ and a term $T_{\mu\nu}^M$ arising from matter (including radiation), then the Einstein equations take the form

$$R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}R_\lambda^\lambda = -8\pi G T_{\mu\nu}^M + 8\pi G\rho_V g_{\mu\nu}. \tag{1.5.50}$$

Thus the effect of a vacuum energy is equivalent to modifying the Einstein field equations to read

$$R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}R - \Lambda g_{\mu\nu} = -8\pi G T_{\mu\nu}^M \tag{1.5.51}$$

where

$$\Lambda = 8\pi G\rho_V \tag{1.5.52}$$

The quantity Λ is known as the cosmological constant. It was introduced into the field equation by Einstein in 1917 in order to satisfy a condition that at the time was generally regarded as essential, that the universe should be static. [5] According to Eqs. (1.5.18) and (1.5.19), a static universe is only possible if $3p + \rho = 0$ and $K = 8\pi G\rho a^2/3$. If the contents of the universe are limited to vacuum energy and non-relativistic matter, then $\rho = \rho_M + \rho_V$, $p = -\rho_V$, and $\rho_M \geq 0$. It follows that $\rho_M = 2\rho_V \geq 0$, so $K > 0$, which by convention means $K = +1$, so that a takes the value $a_E = 1/\sqrt{8\pi G\rho_V} = 1/\sqrt{\Lambda}$. This is known as the Einstein model.

Einstein did not realize it, but his cosmology was unstable: If a is a little less than a_E then ρ_M is a little larger than $2\rho_V$, so Eq. (1.5.18) shows that $\ddot{a}/a < 0$, and a thus begins to decrease. Likewise, if a is a little greater than a_E then it begins to increase. The models with $K = +1$

and $\Lambda > 0$ in which a starts at the Einstein radius $a = a_E$ with $\rho_M = 2\rho_V$ and then expands to infinity (or starts at $a = 0$ and approaches a_E as $t \to \infty$ with just enough matter so that $\rho_M = 2\rho_V$ at the Einstein radius), are known as Eddington-Lemaître models. [6] There are also models with $K = +1$ and a little more matter, that start at $a = 0$, spend a long time near the Einstein radius, and then expand again to infinity, approaching a de Sitter model. These are known as Lemaître models. [7]

Oddly, de Sitter also invented his cosmological model (with $a \propto \exp(Ht)$) in order to satisfy a supposed need for a static universe. He originally proposed a time-independent metric, given by

$$d\tau^2 = \left(1 - r^2/R^2\right) dt^2 - \frac{dr^2}{1 - r^2/R^2} - r^2 d\theta^2 - r^2 \sin^2\theta d\phi^2 \tag{1.5.53}$$

or equivalently, setting $r = R \sin\chi$,

$$d\tau^2 = \cos^2\chi dt^2 - R^2 \left(d\chi^2 + \sin^2\chi d\theta^2 + \sin^2\chi \sin^2\theta d\phi^2\right) \tag{1.5.54}$$

with $R = \sqrt{3/\Lambda}$ constant. De Sitter did not realize at first that this metric has $\Gamma^i_{00} \neq 0$, so that his coordinate system was not co-moving. [8] Only later was it noticed that, using co-moving spatial coordinates and cosmological standard time, de Sitter's model is equivalent to a Robertson-Walker metric with $K = 0$ and $a \propto \exp(t/R)$.

After the discovery of the expansion of the universe, cosmologists lost interest in a static universe, and Einstein came to regret his introduction of a cosmological constant, calling it his greatest mistake. But as we shall see in the next section, there are theoretical reasons to expect a non-vanishing vacuum energy, and there is observational evidence that in fact it does not vanish. Einstein's mistake was not that he introduced the cosmological constant - it was that he thought it was a mistake.

Historical Note 2: There is a cosmological model due to Bondi and Gold [9] and in a somewhat different version to Hoyle, [10] known as the steady state theory. In this model nothing physical changes with time, so the Hubble constant really is constant, and hence $a(t) \propto \exp(Ht)$, just as in the de Sitter model. To keep the curvature constant, it is necessary to take $K = 0$. In this model new matter must be continually created to keep ρ constant as the universe expands. Since the discovery of the cosmic microwave background (discussed in Chapter 2) the steady state theory in its original form has been pretty well abandoned.

10.1.8 1.6 Distances at large redshift: Accelerated expansion

We now return to our account of the measurement of distances as a function of redshift, considering now redshifts $z > 0.1$, which are large enough so that we can ignore the peculiar motions of the light sources, and also large enough so that we need to take into account the effects of cosmological expansion on distance determination.

For many years, the chief "standard candles" used at large redshift were the brightest galaxies in rich clusters. It is now well established that the

[478] A. S. Eddington, The Mathematical Theory of Relativity, 2nd ed. (Cambridge University Press, Cambridge, 1924), Section 70. It is interesting that Eddington interpreted Slipher's observation that most spiral nebulae exhibit redshifts rather than blueshifts in terms of the de Sitter model, rather than Friedmann's models.

[9] H. Bondi and T. Gold, Mon. Not. Roy. Astron. Soc. 108, 252 (1948).

absolute luminosity of these brightest galaxies evolves significantly over cosmological time scales. There are also severe selection effects: there is a tendency to pick out larger clusters with brightest galaxies of higher absolute luminosity at large distances. The evolution of brightest galaxies is of interest in itself, and continues to be the object of astronomical study, [1] but the use of these galaxies as distance indicators has been pretty well abandoned. Similarly, although the Tully-Fisher relation discussed in Section 1.3 has been applied to galaxies with redshifts of order unity, at these redshifts it is used to study galactic evolution, rather than to measure cosmological parameters. [2]

Fortunately, the Type Ia supernovae discussed in Section 1.3 provide an excellent replacement as standard candles. [3] They are very bright; the peak blue absolute magnitude averages about -19.2 , which compares well with the absolute magnitude -20.3 estimated for our own galaxy. Also, as described in Section 1.3, a Type Ia supernova typically occurs when a white dwarf member of a binary pair has accreted just enough mass to push it over the Chandrasekhar limit, so that the nature of the explosion does not depend much on when in the history of the universe this happens, or on the mass with which the white dwarf started or the nature of the companion star. But it might depend somewhat on the metallicity (the proportion of elements heavier than helium) of the white dwarf, which can depend on the epoch of the explosion. The absolute luminosity of Type Ia supernovae is observed to vary with environmental conditions, but fortunately in the use of supernovae as distance indicators the bulk of this variation is correctable empirically.

Observations of Type Ia supernovae have been compared with theoretical predictions (equivalent to Eq. (1.5.45)) for luminosity distance as a function of redshift at about the same time by two groups: The Supernova Cosmology Project [4] and the High- z Supernova Search Team. [5]

The Supernova Cosmology Project analyzed the relation between apparent luminosity and redshift for 42 Type Ia supernovae, with redshifts z ranging from 0.18 to 0.83 , together with a set of closer supernovae from another supernova survey, at redshifts below 0.1 . Their original results are shown in Figure 1.1.

With a confidence level of 99%, the data rule out the case $\Omega_\Lambda = 0$ (or $\Omega_\Lambda < 0$). For a flat cosmology with $\Omega_K = \Omega_R = 0$, so that $\Omega_\Lambda + \Omega_M = 1$, the data indicate a value

$$\Omega_M = 0.28^{+0.09}_{-0.08}(1\sigma \text{ statistical })^{+0.05}_{-0.04} \text{ (identified systematics)}$$

(These results are independent of the Hubble constant or the absolute calibration of the relation between supernova absolute luminosity and time scale, though they do depend on the shape of this relation.) This gives the age (1.5.43) as

$$t_0 = 13.4^{+1.3}_{-1.0} \times 10^9 \left(\frac{70 \text{ km s}^{-1}\text{Mpc}^{-1}}{H_0} \right) \text{yr}.$$

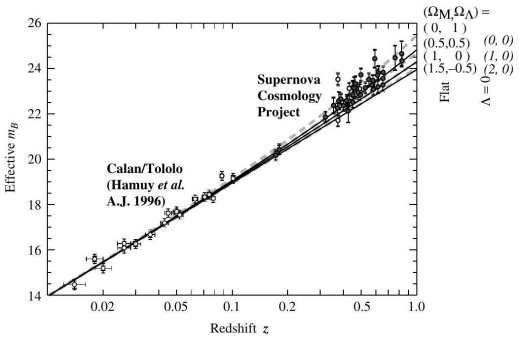

Figure 1.1: Evidence for dark energy, found in 1998 by the Supernova Cosmology Project, from S. Perlmutter et al., Astrophys. J. 517, 565 (1999) [astro-ph/9812133]. Here the effective blue apparent magnitude (corrected for variations in absolute magnitude, as indicated by supernova light curves) are plotted versus redshift for 42 high redshift Type Ia supernovae observed by the Supernova Cosmology Project, along with 18 lower redshift Type Ia supernovae from the Calán-Tololo Supernovae Survey. Horizontal bars indicate the uncertainty in cosmological redshift due to an assumed peculiar velocity uncertainty of \$300 \mathrm{˜km} \mathrm{sec}ˆ{-1}\$. Dashed and solid curves give the theoretical effective apparent luminosities for cosmological models with $\Omega_K = 0$ or $\Omega_\Lambda = 0$, respectively, and various possible values of Ω_M.

For $\Omega_M = 0.28$ and $\Omega_\Lambda = 1 - \Omega_M$, Eq. (1.5.48) gives a negative deceleration parameter, $q_0 = -0.58$, indicating that the expansion of the universe is accelerating.

The High-z Supernova Search Team originally studied 16 Type Ia supernovae of high redshift (with redshifts ranging from 0.16 to 0.97), including 2 from the Supernova Cosmology Project, together with 34 nearby supernovae, and conclude that $\Omega_\Lambda > 0$ at the 99.7% confidence level, with no assumptions about spatial curvature. Their original results are shown in Figure 1.2.

Their best fit for a flat cosmology is $\Omega_M = 0.28 \pm 0.10$ and $\Omega_\Lambda = 1 - \Omega_M$, giving an age of about $(14.2 \pm 1.5) \times 10^9$ years, including uncertainties in the Cepheid distance scale. Assuming only $\Omega_M \geq 0$, and with a conservative

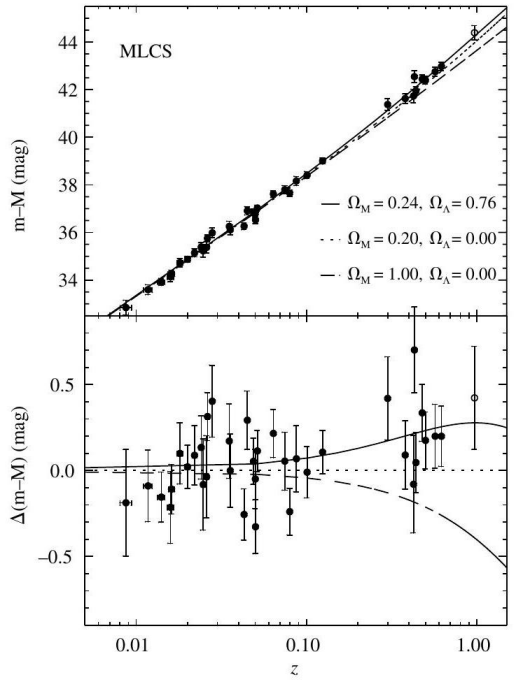

Figure 1.2: Evidence for dark energy, found in 1998 by the High-z Supernova Search Team, from A. G. Riess et al., Astron. J. 116, 1009 (1998) [astro-ph/9805201]. In the upper panel distance modulus is plotted against redshift for a sample of Type Ia supernovae. The curves give the theoretical results for two cosmologies with $\Omega_{\Lambda}=0$ and a good-fit flat cosmology with $\Omega_M = 0.24$ and $\Omega_\Lambda = 0.76$. The bottom panel shows the difference between data and a formerly popular Einstein-de Sitter model with $\Omega_M = 0.2$ and $\Omega_\Lambda = 0$, represented by the horizontal dotted line.

fitting method, with 99.5% confidence they conclude that $q_0 < 0$, again strongly indicating an accelerated expansion. Including 8 new supernovae in a sample of 230 supernovae of Type Ia gave [6] $1.4\Omega_M - \Omega_\Lambda = -0.35 \pm 0.14$, providing further evidence that $\Omega_\Lambda > 0$. The case for vacuum energy was then strenghtened when the Supernova Cosmology Project, [7] including a new set of supernova, found for a flat universe that $\Omega_\Lambda = 0.75^{+0.06}_{-0.07}$ (stat.) $\pm$ 0.032(syst.).

Both groups agree that their results are chiefly sensitive to a linear combination of Ω_Λ and Ω_M, given as $0.8\Omega_M - 0.6\Omega_\Lambda$ by the Supernova Cosmology Project and $\Omega_M - \Omega_\Lambda$ or $1.4\Omega_M - \Omega_\Lambda$ by the High- z Supernova Search Team. The minus sign in these linear combinations, as in Eq. (1.5.48), reflects the fact that matter and vacuum energy have opposite effects on the cosmological acceleration: Matter causes it to slow down, while a positive vacuum energy causes it to accelerate. The negative values found for these linear combinations shows the presence of a component of energy something like vacuum energy, with $p \simeq -\rho$. This is often called dark energy.

Incidentally, these linear combinations of Ω_Λ and Ω_M are quite different from the expression $\Omega_M/2 - \Omega_\Lambda$, which according to Eq. (1.5.48) gives the deceleration parameter q_0 that was the target of much cosmological work of the past. Thus the observations of Type Ia supernovae at cosmological distances should not be regarded as simply measurements of q_0.

The High-z Supernova Search Team subsequently began to use the same survey observations to follow the time development of supernovae that were used to find them. [8] They discovered 23 new high redshift supernovae of Type Ia, including 15 with $z > 0.7$. Using these new supernovae along with the 230 used earlier by Tonry et al., and with the assumption that $\Omega_M + \Omega_\Lambda = 1$, they found the best-fit values $\Omega_M = 0.33$ and $\Omega_\Lambda = 0.67$.

The crucial feature of the supernova data that indicates that $\Omega_\Lambda > \Omega_M$ is that the apparent

luminosity of Type Ia supernovae falls off more rapidly with redshift than would be expected in an Einstein-de Sitter cosmology with $\Omega_M = 1$ and $\Omega_\Lambda = 0$. We can see the effect of vacuum energy on apparent luminosity by comparing the luminosity distance calculated in two extreme cases, both with no matter or radiation. For a vacuumdominated flat model with $\Omega_\Lambda = 1$ and $\Omega_K = \Omega_M = \Omega_R = 0$, Eq. (1.5.46) gives

$$d_L(z) = \frac{z + z^2}{H_0} \quad \text{(vacuum dominated)} , \tag{1.6.1}$$

while for an empty model with $\Omega_K = 1$ and $\Omega_\Lambda = \Omega_M = \Omega_R = 0$, Eq, (1.5.46) gives

$$d_L(z) = \frac{z + z^2/2}{H_0} \quad \text{(empty)}, \tag{1.6.2}$$

Evidently for all z, vacuum energy increases the luminosity distance. The same increase is seen if we compare the more realistic case $\Omega_\Lambda = 0.7, \Omega_M = 0.3$, $\Omega_K = \Omega_R = 0$ with the corresponding case without vacuum energy and $\Omega_K = 0.7, \Omega_M = 0.3, \Omega_\Lambda = \Omega_R = 0$, as can be seen in Figure 1.3.

Both the Supernova Cosmology Project and the High-z Supernova Search Team found that curve of measured luminosity distances vs. redshift of Type Ia supernovae was closer to the upper than the lower curve in Figure 1.3. Indeed, according to Eq. (1.4.9), the negative value of q_0 found by all groups corresponds to the fact that the apparent luminosity of the type Ia supernovae seen at moderate redshifts is less than in the empty model, for which $q_0 = 0$, in contrast with what had been expected, that the expansion is dominated by matter, in which case we would have had $q_0 > 0$, and the apparent luminosities at moderate redshifts would have been larger than for $q_0 = 0$.

The connection between an accelerating expansion and a reduced apparent luminosity can be understood on the basis of the naive Newtonian cosmological model discussed in Section 1.5. In this model, the redshift we observe from a distant galaxy depends on the speed the galaxy had when the light we observe was emitted, but the apparent luminosity is inversely proportional to the square of the distance of this galaxy now, because the galaxy's light is now spread over an area equal to 4π times this squared distance. If the galaxies we observe have been traveling at constant speed since the beginning, as in the empty model, then the distance of any galaxy from

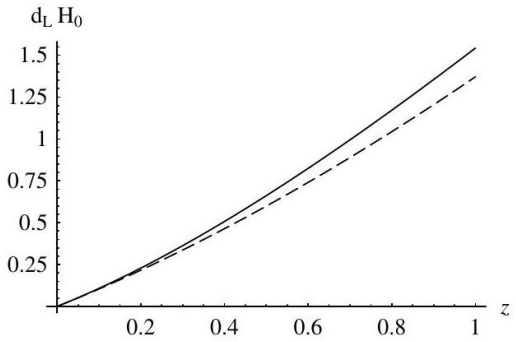

Figure 1.3: Luminosity distance versus redshift for two cosmological models. The upper solid curve is for the case \$\Omega_{\Lambda}=0.7, \Omega_{M}=0.3, \Omega_{K}=\Omega_{R}=0\$; the lower dashed curve is for an empty model, with $\Omega_K = 1, \Omega_\Lambda = \Omega_M = \Omega_R = 0$. The vertical axis gives the luminosity distance times the Hubble constant.

us now would be proportional to its speed when the light was emitted. In the absence of a vacuum energy, we would expect the galaxies to be slowing down under the influence of their mutual gravitational attraction, so that the speed we observe would be greater than the speed they have had since the light was emitted, and their distances now would therefore be smaller than they would be if the speeds were constant. Thus in the absence of vacuum energy we would expect an enhanced apparent luminosity of the supernovae in these galaxies. In fact, it seems that the luminosity distances of supernovae are larger than they would be if the speeds of their host galaxies were constant, indicating that these galaxies have not been slowing down, but speeding up. This is just the effect that would be expected from a positive vacuum energy.

Of course, it is also possible that the reduction in apparent luminosity is due to absorption or scattering of light by intervening material rather than an accelerated expansion. It is possible to distinguish such effects from a true increase in luminosity distance by the change in the apparent color produced by such absorption or scattering, but this is a complicated business. [9] This concern has been allayed by careful color measurements. [10] But it is still possible to invent intergalactic media (so-called gray dust) that would reduce the apparent luminosity while leaving the color unchanged.

This concern has been largely put to rest, first by the study [11] of the supernovae SN1997ff found in the Hubble Deep Field [12] in a galaxy with a redshift $z = 1.7 \pm 0.1$, the greatest yet found for any supernova, and then by the discovery and analysis by a new team, the Higher-z Supernova Team, [13] of 16 new Type Ia supernovae, of which six have $z > 1.25$. These redshifts are so large that during a good part of the time that the light from these supernovae has been on its way to us, the energy density of the universe would have been dominated by matter rather than by a cosmological constant, and so the expansion of the universe would have been decelerating rather than accelerating as at present. Thus if the interpretation of the results of the two groups at smaller redshifts in terms of Ω_M and Ω_Λ is correct, then the apparent luminosity of these supernovae should be larger than would be given by a linear relation between luminosity distance and redshift, a result that could not be produced by absorption or scattering of light. We see this in Figure 1.4, which shows the difference between the luminosity distance (in units H_0^{-1}) for the realistic case with $\Omega_\Lambda = 0.7, \Omega_M = 0.3, \Omega_K = \Omega_R = 0$ and for

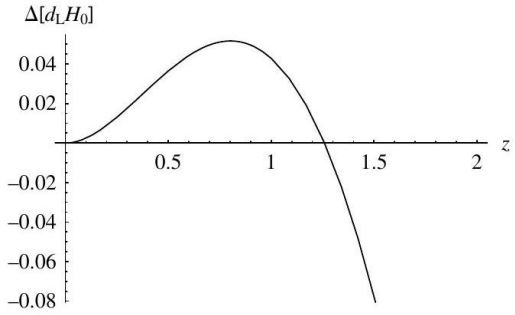

Figure 1.4: The luminosity distance times H_{0} for the realistic case $\Omega_\Lambda = 0.7, \Omega_M = 0.3$, $\Omega_K = \Omega_R = 0$, minus its value for the empty case $\Omega_K = 1, \Omega_\Lambda = \Omega_M = \Omega_R = 0$, plotted against redshift.

the empty model with $\Omega_K = 1, \Omega_M = \Omega_K = \Omega_R = 0$. We see that luminosity distances for the realistic model are greater than for the empty model for moderate redshift, but become less than for the empty model for $z > 1.25$. This is just what is seen. The apparent luminosity of all supernovae is consistent with the parameters $\Omega_M \approx 0.3, \Omega_\Lambda \approx 0.7$ found in the 1998 studies, but not consistent with what would be expected for gray dust and $\Omega_\Lambda = 0$. These conclusions have subsequently been strengthened by the measurement of luminosity distances of additional Type Ia supernovae with redshifts near 0.5. [14] In 2006 Riess et al. [15] announced the discovery with the Hubble Space Telescope of 21 new Type Ia supernovae, which included 13 supernovae with redshifts $z \geq 1$ measured spectroscopically (not just photometrically). Their measured luminosity distances and redshifts, together with data on previously discovered Type Ia supernovae, gave further evidence of a transition from a matter-dominated to a vacuum energy-dominated expansion, and showed that the pressure/density ratio of the vacuum energy for $z > 1$ is consistent with $w = -1$, and not rapidly evolving.

Another serious concern arises from the possibility that the absolute luminosity of Type Ia supernovae may depend on when the supernovae occur. Because Type Ia supernovae occur at a characteristic moment in the history of a star, evolution effects on the luminosities of these supernovae are not expected to be as important as for whole galaxies, which at great distances are seen at an earlier stage in their history. [16] Even so, the absolute luminosity of a Type Ia supernova is affected by the chemical composition

of the two progenitor stars of the supernova, which is in turn affected by the evolution of the host galaxy. [17] Such effects are mitigated by taking account of the correlation of supernova absolute luminosity with decay time and with intrinsic color, both of which presumably depend on the progenitor's chemical composition. Also, evidence for dark energy has been found in studies of subsets of Type Ia supernovae found in very different environments with very different histories. [18] The study of the seven supernovae with $z > 1.25$ mentioned above rules out models with $\Omega_\Lambda = 0$ and any sort of dramatic monotonic evolution of supernovae absolute luminosities that would mimic the effects of dark energy.

There are other effects that might possibly impact the observed relation between supernova apparent luminosities and redshifts:

1. The effect of weak gravitational lensing on the implications of the supernova observations is expected to be small, [19] except perhaps for small area surveys. [20] (Gravitational lensing

is discussed in Chapter 9.) It had been thought that the apparent luminosity of the most distant observed supernova, SN1997ff, may be enhanced by gravitational lensing, [21] conceivably reopening the possibility that the reduction of the apparent luminosity of the nearer supernovae is due to gray dust. However, a subsequent analysis by the same group [22] reported that the magnification of this supernova due to gravitational lensing is less than had been thought, and that the effect of the corrections due to gravitational lensing on current cosmological studies is small. Members of the High-z Supernova project have reported that instead this effect is likely to improve agreement with the estimate that $\Omega_M = 0.35$ and $\Omega_\Lambda = 0.65$.[23]

2. It has been argued that inhomogeneities in the cosmic distribution of matter could produce an accelerating expansion, without the need for any sort of exotic vacuum energy. [24] Given the high degree of

homogeneity of the universe when averaged over sufficiently large scales, this seems unlikely. [25]

3. There is some evidence for two classes of type Ia supernovae, [26] with the minority associated perhaps with merging white dwarfs, or with a variation in explosion physics. The effect on cosmological studies remains to be evaluated.
4. Other uncertainties that can degrade the accuracy of measurements of dark energy (without casting doubt on its existence) arise from the circumstance that the shape of the curve of luminosity distance versus redshift is found by numerous observatories, both ground-based and space-based, and there are various flux calibration errors that can arise between these different observatories.
5. The measurement of luminosity distance of any source of light at large redshift has historically been plagued by the fact that measurements are not "bolometric," that is, equally sensitive to all wavelengths, but are rather chiefly sensitive to wavelengths in a limited range. The cosmological redshift changes the apparent colors of sources, and thereby changes the sensitivity with which apparent luminosity is measured. To take this into account, the observed apparent magnitude is corrected with a so-called K-correction. [27] The K -correction for supernovae were worked out before the discovery of dark energy, [28] and has been refined subsequently. [29] As the precision of supernovae observations improves, further improvements may also be needed in the K-correction.

These observations of an accelerated expansion are consistent with the existence of a constant vacuum energy, but do not prove that this energy density really is constant. According to Eq. (1.5.18), the existence of an accelerated expansion does however require that a large part of the energy density of the universe is in a form that has $\rho + 3p < 0$, unlike ordinary matter or radiation. This has come to be called dark energy. [30]

To take into account the possibility that the dark energy density is not constant, it has become conventional to analyze observations in terms of its pressure/density ratio $p_{\rm D.E.}/\rho_{\rm D.E.} \equiv w$. Except in the case of a constant vacuum energy density, for which $w = -1$, there is no special reason why w should be time-independent. (A different, more physical, possibility is explored at the end of Section 1.12.) Still, it is popular to explore cosmological models with w constant but not necessarily equal to -1 . As long as the dark energy density and Ω_K are non-negative, the expansion of the universe will continue, with $\dot{a}$ always positive. As shown in Eq. (1.1.34), the dark energy density in this case goes as a^{-3-3w}, so if w is negative (as indicated by the supernova observations) the energy density of radiation and matter must eventually become negligible compared with the dark energy density. For $w < -1/3$, the effect of a possible curvature in the Friedmann equation (1.5.19) also eventually becomes negligible. The solution of this equation for $w > -1$ with $\dot{a} > 0$ then becomes $t - t_1 \to Ca^{(3+3w)/2}$, with $C > 0$, and t_1 an integration constant. This is a continued expansion, with a decreasing expansion rate. But for $w < -1$, sometimes known as the case of phantom energy, the solution with $\dot{a} > 0$ is instead $t_1 - t \to Ca^{(3+3w)/2}$, again with $C > 0$. This solution has the remarkable feature that $a(t)$ becomes infinite at the time t_1. In contrast with the case $w \geq -1$, for $w < -1$ all structures - galaxy clusters, galaxy clusters, stars, atoms, atomic nuclei, protons and neutrons - eventually would be ripped apart by the repulsive forces associated with dark energy. [31]

To further study the time dependence of the dark energy, a five year supernova survey, the Supernova Legacy Survey, [32] was begun in 2003 at the Canada-France-Hawaii telescope on Mauna Kea. At the end of the first year, 71 high redshift Type Ia supernovae had been discovered and studied, with the result that $\Omega_M = 0.263 \pm 0.042$ (stat) ± 0.032 (sys). Combining this supernova data with data from the Sloan Digital Sky Survey (discussed in Chapter 8), and assuming that the dark energy has $w \equiv p/\rho$ timeindependent, it is found that if w is constant then $w = -1.023 \pm 0.09$ (stat) $\pm$ 0.054 (sys), consistent with the value $w = -1$ for a constant vacuum energy. At the time of writing, results have just become available for 60 Type Ia supernovae from another supernova survey, ESSENCE. [33] (The acronym is for Equation of State: Supernovae trace Cosmic Expansion). Combining these with the results of the Supernova Legacy Survey, the ESSENCE group found that if w is constant then $w = -1.07 \pm 0.09$ (stat, 1σ) ± 0.13 (syst), and $\Omega_M = 0.267^{0.028}_{-0.018}$ (stat, 1σ).

The conclusion that dark energy makes up a large fraction of the energy of the universe has been confirmed by observations of the cosmic microwave background, as discussed in Section 7.2. This conclusion has also received support from the use of a different sort of secondary distance indicator, the emission of X-rays from hot gas in galaxy clusters. In Section 1.9 we will see that the measurement of redshift, temperature, apparent X-ray luminosity and angular diameter of a cluster allows a determination of the ratio of hot gas ("baryons") to all matter in the cluster, with this ratio proportional to $d_A^{-3/2}$, where d_A is the assumed angular-diameter distance of the cluster. This can be turned around: under the assumption that the ratio of hot gas to all matter is the same for all clusters in a sample, X-ray observations can be used to find the dependence of

the cluster angular diameter distances on redshift. [34] In this way, observations by the Chandra satellite of X-rays from 26 galaxy clusters with redshifts in the range $0.07 < z < 0.9$ have been used to determine that in a cosmology with a constant vacuum energy and cold dark matter, $\Omega_\Lambda = 0.94^{+0.21}_{-0.25}$, within 68% confidence limits. [35] Relaxing the assumption that the cosmological dark energy density is constant, but assuming $\Omega_K = 0$ and a constant w, and taking the baryon density to have the value indicated by cosmological nucleosynthesis (discussed in Section 3.2), this analysis of the Chandra data yields $1-\Omega_M = 0.76\pm0.04$ and a dark energy pressure/density ratio $w = -1.20^{+0.24}_{-0.28}$.

It is possible that measurements of luminosity distance can be pushed to much larger redshifts by the use of long gamma ray bursts as secondary distance indicators. These bursts definitely do not have uniform absolute luminosity, but there are indications that the absolute gamma ray luminosity is correlated with the peak gamma ray energy and a characteristic time scale. [36]

The discovery of dark energy is of great importance, both in interpreting other observations and as a challenge to fundamental theory. It is profoundly puzzling why the dark energy density is so small. The contribution of quantum fluctuations in known fields up to 300 GeV , roughly the highest energy at which current theories have been verified, gives a vacuum energy

density of order $(300\text{GeV}),$ [4] or about 10^{27} g/cm^3. This of course is vastly larger than the observed dark energy density, $\Omega_V \rho_{0,\,\text{crit}} \simeq 10^{-29}$ g/cm^3, by a factor of order 10^{56}. There are other unknown contributions to the vacuum energy that might cancel this contribution, coming from fluctuations in fields at higher energies or from the field equations themselves, but this cancelation would have to be precise to about 56 decimal places. There is no known reason for this remarkable cancelation. [37] The discovery of dark energy now adds a second problem: why is the dark energy density comparable to the matter energy density at this particular moment in the history of the universe?

In thinking about these problems, it is crucial to know whether the vacuum energy is really time-independent, or varies with time, a question that may be answered by future studies of distant Type Ia supernovae or other measurements at large redshift. The possibility of a varying dark energy (known as quintessence) will be considered further in Section 1.12.

10.1.9 1.7 Cosmic expansion or tired light?

In comparing observations of redshifts and luminosity distances with theory, we rely on the general understanding of redshifts and luminosities outlined in Sections 1.2 and 1.4. One thing that might invalidate this understanding is absorption or scattering, which reduces the number of photons reaching us from distant sources. This possibility is usually taken into account by measuring the color of the source, which would be affected by absorption or scattering, though as mentioned in the previous section there is a possibility of gray dust, which could not be detected in this way. Another possible way that apparent luminosities could be reduced is through the conversion of photons into particles called axions by intergalactic magnetic fields.

Rines et al., Astrophys. J. 517, 70 (1999); S. Ettori and A. Fabian, Astron. Soc. Pac. Conf. Ser. 200, 369 (2000); S. W. Allen, R. W. Schmidt, and A. C. Fabian, Mon. Not. Roy. Astron. Soc. 334, L11 (2002); S. Ettori, P, Tozzi, and P. Rosati, Astron. & Astrophys. 398, 879 (2003). The possibility of a variable ratio of hot gas to all matter is explored by R. Sadat et al., Astron. & Astrophys. 437, 310 (2005); L. D. Ferramacho and A. Blanchard, Astron. & Astrophys. 463, 423 (2007) [astro-ph/0609822].

[36] C. Firmani, V. Avila-Reese, G. Ghisellini, and G. Ghirlanda, Mon. Not. Roy. Astron. Soc. 372, 28 (2006) [astro-ph/0605430]; G. Ghirlanda, G. Ghisellini, and C. Firmani, New J. Phys. 8, 123 (2006) [astro-ph/0610248].

There is also a more radical possibility. Ever since the discovery of the cosmological redshift, there has been a nagging doubt about its interpretation as evidence of an expanding universe. Is it possible that the universe is really static, and that photons simply suffer a loss of energy and hence a decrease in frequency as they travel to us, the loss of energy and hence the redshift naturally increasing with the distance that the photons have to travel?

It is possible to rule out all these possibilities by comparing the luminosity distance $d_L(z)$ with the angular diameter distance $d_A(z)$ of the same distant source. None of the possibilities mentioned above can affect the angular diameter distance, while the conventional interpretation of

redshifts and luminosities provides the model-independent result (1.4.12), that $d_L(z)/d_A(z) = (1+z)^2$, so a verification of this ratio can confirm the conventional understanding of $d_L(z)$.

We can check this formula for $d_L(z)/d_A(z)$ by a "surface brightness test" suggested long ago by Tolman. [1] If a light source has an absolute luminosity per proper area $\mathcal{L}$, then the apparent luminosity of a patch of area A will be $\ell = \mathcal{L}A/4\pi d_L^2$. This patch will subtend a solid angle $\Omega = A/d_A^2$. The surface brightness B is defined as the apparent luminosity per solid angle, so

$$B \equiv \frac{\ell}{\Omega} = \frac{\mathcal{L} d_A^2}{4\pi d_L^2} \tag{1.7.1}$$

In the conventional big bang cosmology the ratio d_A/d_L is given by Eq. (1.4.12), so

$$B = (1+z)^{-4} \left(\frac{\mathcal{L}}{4\pi}\right) \tag{1.7.2}$$

If we can find a class of light sources with a common value for the absolute luminosity per proper area $\mathcal{L}$, then their surface brightness should be found to decrease with redshift precisely as $(1+z)^{-4}$.

For instance, one important difference between "tired light" theories and the conventional big bang theory is that in the conventional theory all rates at the source are decreased by a factor $(1+z)^{-1}$, while in tired light theories there is no such slowing down. One rate that is slowed down at large redshifts in the conventional theory is the rate at which photons are emitted by the source. This is responsible for one of the two factors of $(1+z)^{-1}$ in formula (1.4.1) for apparent luminosity, the other factor being due to the reduction of energy of individual photons. On the other hand, if the rate of photon emission is not affected by the redshift, then in a static Euclidean universe in which photons lose energy as they travel to us, the apparent luminosity of a distant source L at a distance d will be given by $L/4\pi(1+z)d^2$, with only a single factor $1+z$ in the denominator to take account of the photon energy loss. That is, the luminosity distance will be $(1+z)^{1/2}d$, while the angular diameter distance in a Euclidean universe is just d, so here $d_L/d_A = (1+z)^{1/2}$, and the surface brightness of distant galaxies should decrease as $(1+z)^{-1}$.

Lubin and Sandage [2] have used the Hubble Space Telescope to compare the surface brightness of galaxies in three distant clusters with redshifts

$0.76, 0.90$, and 0.92 with the surface brightness measured in closer galaxies. They detect a decrease of B with increasing z that is consistent with Eq. (1.7.2) with reasonable corrections for the effects of galaxy evolution, and is quite inconsistent with the behavior $B \propto (1+z)^{-1}$ expected in a static universe with "tired light."

[4737] For a survey of efforts to answer this question, see S. Weinberg, Rev. Mod. Phys. 61, 1 (1989).

[471] R. C. Tolman, Proc. Nat. Acad. Sci 16, 5111 (1930); Relativity, Thermodynamics, and Cosmology (Oxford Press, Oxford, 1934): 467.

[2] L. M. Lubin and A. Sandage, Astron. J. 122, 1084 (2001) [astro-ph/0106566]. Their earlier work is described in A. Sandage and L. M. Lubin, Astron. J. 121, 2271 (2001); L. M. Lubin and A. Sandage, ibid, 2289 (2001) and Astron. J. 122, 1071 (2001) [astro-ph/0106563.]

In the standard big bang cosmology all rates observed from a distant source are slowed by a factor $1/(1+z)$, not just the rate at which photons are emitted. This slowing has been confirmed [3] for the rate of decline of light from some of the Type Ia supernovae used by the Supernova Cosmology Project discussed in the previous section. The hypothesis that the absolute luminosity is simply correlated with the intrinsic decline time is found to work much better if the observed decline time is taken to be the intrinsic decline time stretched out by a factor $1+z$. Nothing like this would be expected in a static Euclidean universe with redshifts attributed to tired light.

10.1.10 1.8 Ages

As we have seen, a knowledge of the Hubble constant and of the matter and vacuum density parameters Ω_M and Ω_Λ allows us to estimate the age of the universe. In this section we will discuss independent estimates of the age of the universe, based on calculations of the ages of some of the oldest things it contains.

Since metals (elements heavier than helium) found in the outer parts of stars arise chiefly from earlier generations of stars, the oldest stars are generally those whose spectra show small abundances of metals. These are the so-called Population II stars, found in the halo of our galaxy, and in particular in globular clusters. There are two main ways of estimating ages of old stars:

A. Heavy element abundances

If a nucleus decays with decay rate λ, and has an initial abundance $A_{\rm init}$, then the abundance A after a time T is $A = A_{\rm init}\, \exp(-\lambda T)$. Hence if we knew $A_{\rm init}$ and could measure A, we could determine T from $T = \lambda^{-1} \ln\left(A_{\rm init}\,/A\right)$. Unfortunately neither condition is likely to be satisfied. On the other hand, it is often possible to calculate the ratio of the initial abundances $A_{1\ {\rm init}}$ and $A_{2\ {\rm init}}$ of two nuclei, and to measure their relative present abundance A_1/A_2.

This relative abundance is given by

$$\frac{A_1}{A_2} = \left(\frac{A_{1\ {\rm init}}}{A_{2\ {\rm init}}}\right) \exp\left(\left(\lambda_2 - \lambda_1\right) T\right),$$

so

$$T = \frac{1}{\lambda_2 - \lambda_1}\left[\ln\left(\frac{A_1}{A_2}\right) - \ln\left(\frac{A_{1\ {\rm init}}}{A_{2\ {\rm init}}}\right)\right] \tag{1.8.1}$$

If the initial abundances are similar and the observed abundances are very different, then the estimated value of T will be insensitive to the precise value of the initial abundance ratio.

The initial relative abundances of heavy, radioactive elements are estimated on the well-founded assumption that these elements are made in the so-called r-process, the rapid addition of neutrons to lighter elements such as iron in core-collapse supernova explosions, after which the neutron-rich isotopes formed in this way undergo multiple beta decays, transforming them to the most deeply bound nuclei with the same number of nucleons. This method has been used to put a lower bound on the age of our galaxy from the terrestrial abundance of ^{235}U, which has a decay rate of 0.971×10^{-9}/yr. To avoid uncertainties in the distribution of ^{235}U in earth, its abundance is measured relative to the isotope ^{238}U, which has a slower decay rate of 0.154×10^{-9}/yr, but behaves the same chemically and is presumably distributed in the same way. The initial abundance ratio of ^{235}U to ^{238}U is estimated to be 1.65 ± 0.15; it is larger than

[473] B. Leibundgut et al., Astrophys. J. 466, L21 (1996); G. Goldhaber et al. (Supernova Cosmology Project), Astrophys. J. 558, 359 (2001) [astro-ph/0104382].

one because three additional neutrons must be added to the progenitor of ^{235}U to form the progenitor of ^{238}U. On the other hand, the larger decay rate of ^{235}U makes it (fortunately) less abundant than ^{238}U now. The present abundance ratio of uranium isotopes on earth is 0.00723 , so this uranium has been decaying for a time

$$\frac{\ln(1.65) - \ln(.00723)}{0.971 \times 10^{-9}/\text{yr} - 0.154 \times 10^{-9}/\text{yr}} = 6.6\text{Gyr} \quad \left[1\text{Gyr} = 10^9\text{yr}\right]$$

But the sun is a second (or perhaps third) generation (called "Population I") star, and presumably its uranium was being produced over a long time interval before the formation of the solar system. The uranium abundance ratio has been supplemented with measurements of other abundance ratios on the earth and meteorites, such as ^{232}Th/^{238}U and ^{187}Re/^{187}Os ratios, and analyzed with the length of the period of heavy element formation left as a free parameter. This gives a more stringent (but less certain) lower bound of 9.6Gyr[1] on the age of the heavy elements in the neighborhood of the solar system.

A much more stringent lower bound on the age of the galaxy is given by applying these methods to heavy elements in metal-poor stars beyond the solar system. First thorium was observed spectroscopically in a very metal-poor star (and hence presumably old) K giant star, CS 22892-052. [2] The relative abundances in this star of the more stable elements produced in the r-process, as measured from the intensity of absorption lines in the star's spectrum, matches those of the same elements in the solar system, except for a much lower abundance of the heaviest detected element thorium, which (for ^{232}Th) has a half life 14 Gyr . Attributing the decrease in thorium to its radioactive decay, the age of the thorium in this star is estimated as 14.1 ± 3 Gyr. Other estimates of the ages of CS 22892-052 and other metalpoor stars have been made using the measured abundance ratios of thorium to europium and lanthanum. [3]

Uranium-238 decays more rapidly than ^{232}Th, so we can get a more sensitive estimate of the age of a star by using both its uranium and its thorium abundances, providing of course that uranium as well as thorium lines can be observed in the star's spectrum. No uranium absorption lines were observed in the spectrum of CS 22892-052, but absorption lines from singly ionized uranium were subsequently observed in two other metal-poor star with an abundance of r-process elements, CS31082-001 and BD + 17°3248. The observed abundance ratio of uranium to thorium in CS31082-001 is $10^{-0.74\pm0.15}$, while the initial abundance ratio has been variously estimated as $10^{-0.255}$ or $10^{-0.10}$. Using these numbers in Eq. (1.8.1) gives this star an age of 12.5 ± 3 Gyr. [4] Subsequent observations indicated ages of 14 ± 2Gyr, [5] 15.5 ± 3.2Gyr, [6] and 14.1 ± 2.5Gyr.[7] In a similar way, the age of BD + 17°3248 has been calculated as 13.8 ± 4Gyr.[8] (See Figure 1.5.) More recently, both uranium and thorium lines have been found in the spectrum of the newly discovered metal-poor star HE 1523-0903; the ratio of thorium and uranium abundance to the abundances of other r-process elements, and to each other, was used to give an age of the star as 13.2 Gyr. Figure 1.5: Abundances of elements produced by the r-process in the star $\mathrm{BD}+17^{\circ} 3248$, obtained by ground-based and Hubble Space Telescope spectroscopic observations. For comparison, the solid curve gives theoretical initial abundances, based on solar system data. Note the low observed abundances of thorium and uranium, compared with the theoretical initial abundances, which indicate an age for BD + 17°3248 of 13.8 ± 4 Gyr. From J. J. Cowan et al., Astrophys. J. 572, 861 (2002) [astro-ph/0202429].

B. Main sequence turn-off

The stars that satisfy the main sequence relation between absolute luminosity and surface temperature are still burning hydrogen at their core. When the hydrogen is exhausted at the core, hydrogen-burning continues in a shell around a (temporarily) inert helium core. The star then moves off the main sequence, toward higher luminosity and lower surface temperature. The heavier a star is, the more luminous it is on the main sequence, and the faster it evolves. Thus as time passes, the main sequence of a cluster of stars of different masses but the same age shows a turn-off that moves to lower and lower luminosities. (See Figure 1.6). Roughly, the absolute luminosity of stars at the turn-off point is inversely proportional to the age of the cluster. In particular, observations of the main sequences of a number of globular clusters gave ages variously calculated [10] as 11.5 ± 1.3Gyr, 12 ± 1Gyr, 11.8 ± 1.2Gyr, 14.0 ± 1.2Gyr, 12 ± 1Gyr, and 12.2 ± 1.8Gyr. A summary by Schramm [11] found that most of the discrepancies disappear when

[11] D. Schramm, in Critical Dialogues in Cosmology, N. Turok, ed. (World Scientific, Singapore, 1997): 81

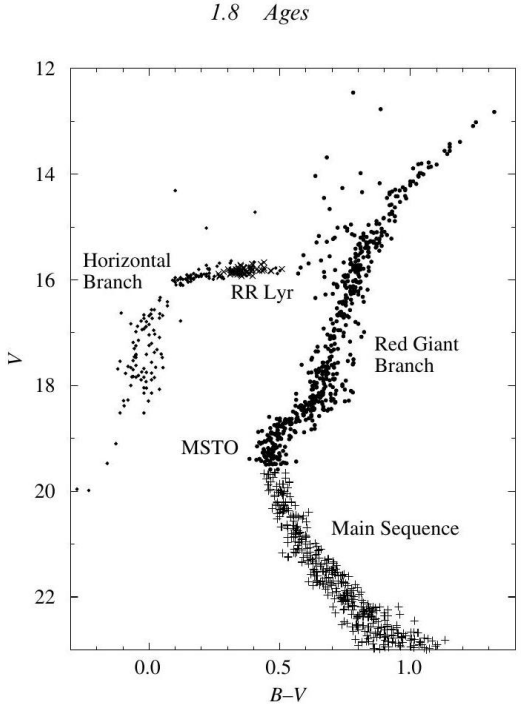

Figure 1.6: Color-magnitude diagram for the globular cluster M15. Visual apparent magnitudes of M15 stars are plotted on the vertical axis. Since all stars in M15 are at about the same distance from earth, the apparent visual magnitude differs from the absolute visual magnitude by a constant term, with absolute luminosities increasing upwards. The difference of apparent blue and visual magnitudes is plotted on the horizontal axis. This is a measure of surface temperature, with temperature decreasing to the right. If M15 were young, the main sequence would continue upwards and to the left; the position of the main sequence turn-off (MSTO) and other features of the diagram indicate that the age of the cluster is 15 ± 3 Gyr. Diagram from B. Chaboyer, Phys. Rep. 307, 23 (1998), based on data of P. R. Durrell and W. E. Harris, Astron. J. 105, 1420 (1993) [astro-ph/9808200].

the various calculations are done with the same input values for parameters like the initial abundance of helium, oxygen, and iron, and gave a consensus value as 14 ± 2 (statistical) ± 2 (systematic) Gyr. Note that all these ages are sensitive to the distance scale; a fractional change $\delta d/d$ in estimates of distances would produce a fractional change $\delta L/L = -2\delta d/d$ in estimates of absolute luminosities, and hence a fractional change $\delta t/t \approx +2\delta d/d$ in estimates of ages. Using measurements of distances to nine globular clusters with the Hipparcos satellite yields an estimated galactic age [12] of 13.2 ± 2.0 Gyr.

These ages would pose a problem for what used to be the most popular model, with $\Omega_M = 1$ and no vacuum energy. In this case, the age of the universe is

$$t_0 = \frac{2}{3H_0} = 9.3 \left(\frac{70 \text{ km/sec/Mpc}}{H_0} \right) \text{Gyr}$$

which is somewhat younger than the oldest objects in the galaxy, though not by many standard deviations. Inclusion of a constant vacuum energy helps to avoid this problem; as remarked in Section 1.5, with nothing else in the universe we would have $a(t) \propto \exp(Ht)$, and the age of the universe would be infinite. As we saw in Section 1.6, the supernovae distance-redshift relation indicates that the vacuum energy is now roughly twice the matter energy,

[4712] E. Carretta, R. G. Gratton, G. Clementini, and F. F. Pecci, Astrophys. J. 533, 215 (2000) [astro-ph/9902086].

giving an age much longer than $2/3H_0$:

$$t_0 = 13.4^{+1.3}_{-1.0}\left(\frac{70\ \text{km/sec/Mpc}}{H_0}\right)\text{Gyr}$$

This removes the danger of a conflict, provided that the globular clusters in our galaxy are not much younger than the universe itself. In fact, there is now a truly impressive agreement between the age of the oldest stars and star clusters on one hand and the cosmic age calculated using values of H_0, Ω_M, and Ω_Λ found from the redshift-distance relation. As we will see in Section 7.2, there is also an excellent agreement between these ages and the age calculated using parameters measured in observations of anisotropies in the cosmic microwave background.

So far in this section, we have considered only the present age of our own galaxy. It is also possible to estimate the ages of other galaxies at high redshift, at the time far in the past when the light we now observe left these galaxies. Of course, it is not possible to distinguish individual stars or globular clusters in these galaxies, but the spectrum of the galaxy gives a good idea of the age. We need the whole spectrum to separate the effects of metallicity, scattering, etc., but roughly speaking, the redder the galaxy, the more of its bright bluer stars have left the main sequence, and hence the older it is. In this way, it has been found [13] that the radio galaxies 53 W091($z = 1.55$) and 53 W069($z = 1.43$) have ages $\simeq 3.5$Gyr and 3 to 4 Gyr , respectively. This sets useful lower bounds on the vacuum energy. In a model with non-relativistic matter and a constant vacuum energy, the age of the universe at the time of emission of light that is seen at present with

redshift z is given by Eq. (1.5.42) as

$$t(z) = \frac{1}{H_0}\int_0^{\frac{1}{1+z}} \frac{dx}{x\sqrt{\Omega_\Lambda + \Omega_K x^{-2} + \Omega_M x^{-3} + \Omega_R x^{-4}}} \tag{1.8.2}$$

Any galaxy observed with redshift z must have been younger than this at the time that its light was emitted. For instance, for a flat universe with $\Omega_K = \Omega_R = 0$, so that $\Omega_M = 1 - \Omega_\Lambda$, the existence of a galaxy at $z = 1.55$ with age $\simeq 3.5$Gyr sets a lower bound [14] on Ω_Λ of about 0.6 for $H_0 = 70\text{kms}^{-1}\text{Mpc}^{-1}$.

Eventually the accuracy of these age determinations may become good enough to allow us to measure at least the dependence of redshift on the cosmic age. Of course, galaxies form at various times in the history of the universe, so the age of any one galaxy does not allow us to infer the age of the universe at the time light we now see left that galaxy. However, the homogeneity of the universe implies that the distribution of cosmic times of formation for any one variety of galaxy is the same anywhere in the universe. From differences in the distributions of ages of a suitable species of galaxy at different redshifts, we can then infer the difference of cosmic age t at these redshifts. The Robertson-Walker scale factor $a(t)$ is related to the redshift $z(t)$ observed now of objects that emitted light when the cosmic age was t by $1 + z(t) = a\left(t_0\right)/a(t)$, so $\dot{z} = -H(t)(1+z)$. To calculate $\ddot{z}$, we note that for $K = 0, H^2(t) = 8\pi G\rho(t)/3$, and $\dot{\rho} = -3H(\rho + p)$,

$$\dot{H}(t) = -4\pi G(\rho(t) + p(t)) \tag{1.8.3}$$

Then for $K = 0$

$$\ddot{z} = \frac{\dot{z}^2}{1+z}\left(\frac{5}{2} + \frac{3p}{2\rho}\right) \tag{1.8.4}$$

Thus measurements of differences in t for various differences in redshift may allow a measurement of the ratio p/ρ at various times in the recent history of the universe. [15]

10.1.11 1.9 Masses

We saw in Section 1.6 that the observed dependence of luminosity distance on redshift suggests that the fraction Ω_M of the critical density provided by

non-relativistic matter is roughly 30%. In this section we will consider other independent ways that Ω_M is measured.

A. Virialized clusters of galaxies

The classic approach [1] to the measurement of Ω_M is to use the virial theorem to estimate the masses of various clusters of galaxies, calculate a mean ratio of mass to absolute luminosity, and then use observations of the total luminosity of the sky to estimate the total mass density, under the assumption that the mass-to-light ratio of clusters of galaxies is typical of the universe as a whole.

To derive the virial theorem, consider a non-relativistic gravitationally bound system of point masses m_n (either galaxies, or stars, or single particles) with positions relative to the center of mass (in an ordinary Cartesian coordinate system) $\mathbf{X}_n$. The equations of motion are

$$m_n \ddot{X}_n^i = -\frac{\partial V}{\partial X_n^i}, \tag{1.9.1}$$

where the potential energy V is

$$V = -\frac{1}{2}\sum_{n\neq\ell} \frac{G m_n m_\ell}{|\mathbf{X}_n - \mathbf{X}_\ell|} \tag{1.9.2}$$

Multiplying Eq. (1.9.1) with X_n^i and summing over n and i gives

$$-\sum_n X_n^i \frac{\partial V}{\partial X_n^i} = \sum_n m_n \mathbf{X}_n \cdot \ddot{\mathbf{X}}_n = \frac{1}{2}\frac{d^2}{dt^2}\sum_n m_n \mathbf{X}_n^2 - 2T, \tag{1.9.3}$$

where T is the internal kinetic energy (not counting any motion of the center of mass)

$$T = \frac{1}{2}\sum_n m_n \dot{\mathbf{X}}_n^2 \tag{1.9.4}$$

Let us assume that the system has reached a state of equilibrium ("become virialized"), so that although the individual masses are moving there is no further statistical evolution, and in particular that

$$0 = \frac{d^2}{dt^2}\sum_n m_n \mathbf{X}_n^2 \tag{1.9.5}$$

(This is why it was important to specify that $\mathbf{X}_n$ is measured relative to the center of mass; otherwise a motion of the whole cluster would give the sum a term proportional to t^2, invalidating Eq. (1.9.5).) But V is of order -1 in the coordinates, so the left-hand side of Eq. (1.9.3) is just V, giving the virial theorem:

$$2T + V = 0 \tag{1.9.6}$$

[4714] L. M. Krauss, Astrophys. J. 489, 486 (1997); J. S. Alcaniz and J. A. S. Lima, Astrophys. J. 521, L87 (1999) [astro-ph/9902298].

[15] R. Jiminez and A. Loeb, Astrophys. J. 573, 37 (2002) [astro-ph/0106145].

[471] F. Zwicky, Astrophys. J. 86, 217 (1937); J. H. Oort, in La Structure et l'Evolution de l'Universe (Institut International de Physique Solvay, R. Stoops, Brussels, 1958): 163.

We may express T and V as

$$T = \frac{1}{2}M\left\langle v^2\right\rangle, \quad V = -\frac{1}{2}GM^2\left\langle\frac{1}{r}\right\rangle \tag{1.9.7}$$

where $\langle v^2\rangle$ is the mean (mass weighted) square velocity relative to the center of mass, $\langle 1/r\rangle$ is the mean inverse separation, and $M = \sum_n m_n$ is the total mass. Eq. (1.9.6) thus gives the virial formula for M :

$$M = \frac{2\left\langle v^2\right\rangle}{G\langle 1/r\rangle} \tag{1.9.8}$$

This derivation does not apply to irregular clusters of galaxies, like the nearby one in Virgo. Clusters like this do not seem to have settled into a configuration in which the condition (1.9.5) is satisfied, and therefore probably do not satisfy the virial theorem. On the other hand, the virial theorem probably does apply at least approximately to other clusters of galaxies, like the one in Coma, which appear more or less spherical. According to general ideas of statistical equilibrium, we may expect the rms velocity dispersion $\sqrt{\langle v^2\rangle}$ of the dominant masses in such clusters to equal the velocity dispersion of the visible galaxies in the cluster, which can be measured from the spread of their Doppler shifts, and also to equal the velocity dispersion of the ionized intergalactic gas in the cluster, which since the advent of X-ray astronomy can be measured from the X-ray spectrum of the gas. The values obtained in these ways for $\langle v^2\rangle$ are independent of the distance scale. On the other hand, values for $\langle 1/r\rangle$ are obtained from angular separations: the true transverse proper distance d is given in terms of the angular separation θ by $d = \theta d_A$, where d_A is the angular diameter distance (1.4.11). For clusters with $z \ll 1$, Eqs. (1.4.9) and (1.4.11) give $d_A \simeq z/H_0$, so $d \simeq \theta z/H_0$. Thus the estimated values of $\langle 1/r\rangle$ for galaxy clusters with $z \ll 1$ scale as H_0, and the values of M inferred from Eq. (1.9.8) scale as $1/H_0$. The absolute luminosity L of a cluster of galaxies with redshift z and apparent luminosity ℓ is given for $z \ll 1$ by Eqs. (1.4.2) and (1.4.9) as $L = 4\pi z^2\ell/H_0^2$, so the values of L scale as H_0^{-2}, and the mass-to-light ratios obtained in this way therefore scale as $H_0^{-1}/H_0^{-2} = H_0$.

Estimates of M/L for rich clusters have generally given results of order 200 to $300hM_\odot/L_\odot$, where h is the Hubble constant in units of 100 km s^{-1}Mpc^{-1}, and $M_\odot$ and $L_\odot$ are the mass and absolute luminosity of the sun. For instance, a 1996 study [2] of 16 clusters of galaxies with redshifts between 0.17 and 0.55 gave $M/L = (295 \pm 53)hM_\odot/L_\odot$. Some of the same group [3] have corrected this result for various biases, and now find $M/L = (213 \pm 59)hM_\odot/L_\odot$. A more recent application [4] of the virial theorem to 459 clusters has found a value $M/L \simeq 348hM_\odot/L_\odot$.

All these values of M/L for clusters of galaxies are very much larger than the mass-to-light ratios of the visible regions of individual galaxies. [5] The mass-to-light ratios of individual elliptical galaxies can be measured using the virial theorem, with $\sqrt{\langle v^2\rangle}$ taken as the velocity dispersion of stars contained in the galaxy; this gives mass-to-light ratios generally in the range of 10 to $20hM_\odot/L_\odot$.[6] All of the visible light from clusters comes from their galaxies, so we must conclude that most of the mass in clusters of galaxies is in some non-luminous form, either in the outer non-luminous parts of galaxies or in intergalactic space. It has been argued that this mass is in large dark halos surrounding galaxies, extending to 200 kpc for bright galaxies. [7] The nature of this dark matter is an outstanding problem of cosmology, to which we will frequently return.

Incidentally, the large value of M/L given by the virial theorem for elliptical galaxies shows that most of the mass of these galaxies is not in the form of stars as bright as the sun. It is harder to estimate M/L for spiral galaxies, but since the work of Vera Rubin [8] it has been known that most of their mass is also not in luminous stars. [9] If most of the mass of a spiral galaxy were in the luminous central regions of the galaxy, then the rotational speeds of stars

outside this region would follow the Kepler law, $v \propto r^{-1/2}$. Instead, it is observed that v outside the central region is roughly constant, even beyond the visible disk of the galaxy, which is what would be expected for a spherical halo with a mass density that decreases only as $1/r^2$, in which case most of the mass of the galaxy would be in the dark outer

parts of the halo. There is some evidence from the absence of gravitational microlensing by the halo (discussed in Section 9.2) that this mass is not in the form of dark stars either, but it is still possible that most of the matter in galaxies is baryonic. We will not go into this in detail, because the formation of galaxies involves cooling processes that requires baryonic matter of the same sort as in stars, so that we would only expect the value of M/L for galaxies to be similar to the value for the universe as a whole if the matter of the universe were mostly baryonic.

In using the value of M/L derived from the virial theorem for clusters of galaxies to find the mass density of the universe, we cannot just add up the luminosity per volume of clusters, because most of the light of the universe comes from "field" galaxies that are not in clusters. Instead, if we assume that the field galaxies are accompanied by the same amount of dark matter as the galaxies in clusters, as argued in ref. 7 , then we can find Ω_M by using the value of M/L for clusters together with an estimate of the total luminosity density $\mathcal{L}$ to estimate the total mass density as

$$\rho_M = (M/L)\mathcal{L} \tag{1.9.9}$$

Since values of absolute luminosities inferred from apparent luminosities and redshifts scale as H_0^{-2}, and distances inferred from redshifts scale as H_0^{-1}, the total luminosity density of the universe calculated by adding up the absolute luminosities of galaxies per volume scales as $H_0^{-2}/\left(H_0^{-1}\right)^3 = H_0$. For example, a 1999 estimate [10] gave $\mathcal{L} = 2 \pm 0.2 \times 10^8 h L_\odot \mathrm{Mpc}^{-3}$. For the purpose of calculating Ω_M it is more convenient to write this as a ratio of the critical mass density to the luminosity density:

$$\rho_{0,\,\mathrm{crit}}\,/\mathcal{L} = (1390 \pm 140) h M_\odot/L_\odot$$

(Here we use $M_\odot = 1.989 \times 10^{33}$ g, $1\mathrm{Mpc} = 3.0857 \times 10^{24}$ cm, and $\rho_{0,\,\mathrm{crit}} = 1.878 \times 10^{-29} h^2$ g/cm^3.) Taking $M/L = (213 \pm 53) h M_\odot/L_\odot$ gives then

$$\Omega_M = \frac{M/L}{\rho_{0,\,\mathrm{crit}}\,/\mathcal{L}} = 0.15 \pm 0.02 \pm .04$$

with the first uncertainty arising from $\mathcal{L}$ and the second from M/L. It is important to note that this is independent of the Hubble constant, as both $\mathcal{L}M/L$ and $\rho_{0,\,\mathrm{crit}}$ scale as H_0^2.

This estimate of Ω_M is somewhat lower than those derived from the redshift-luminosity relation of supernovae and from the anisotropies in the

cosmic microwave background, to be discussed in Section 2.6 and Chapter 7. But all these estimates agree that Ω_M is distinctly less than unity.

B. X-ray luminosity of clusters of galaxies

Does the dark matter in clusters of galaxies consist of ordinary nuclei and electrons? We can find the ratio of the fraction Ω_B of the critical density provided by baryonic matter (nuclei and electrons) to the fraction Ω_M provided by all forms of non-relativistic matter by studying the X-rays from clusters of galaxies, for it is only the collisions of ordinary baryonic particles that produces these X-rays. Because these collision processes involve pairs of particles of baryonic matter, the absolute X-ray luminosity per unit proper volume takes the form

$$\mathcal{L}_X = \Lambda\left(T_B\right)\rho_B^2 \tag{1.9.10}$$

where T_B and ρ_B are the temperature and density of the baryonic matter, and $\Lambda(T)$ is a known function of temperature and fundamental constants. The baryonic density satisfies the equation of hydrostatic equilibrium, which (assuming spherical symmetry) follows from the balance of pressure and gravitational forces acting on the baryons in a small area A and between radii r and $r+\delta r$:

$$A\left(p_B(r+\delta r)-p_B(r)\right) = -\frac{A\delta r\rho_B(r)G}{r^2}\int_0^r 4\pi r^2\rho_M(r)dr$$

or, canceling factors of A and δr and using the ideal gas law $p_B = k_{\mathcal{B}}T_B\rho_B/m_B$,

$$\frac{d}{dr}\left(\frac{k_{\mathcal{B}}T_B(r)\rho_B(r)}{m_B}\right) = -\frac{G\rho_B(r)}{r^2}\int_0^r 4\pi r^2\rho_M(r)dr$$

where $\rho_M(r)$ is the total mass density, $k_{\mathcal{B}}$ is Boltzmann's constant, m_B is a characteristic mass of the baryonic gas particles, and r is here the proper distance to the center of the cluster. Multiplying by $r^2/\rho_B(r)$ and differentiating with respect to r yields

$$\frac{d}{dr}\left[\frac{r^2}{\rho_B(r)}\frac{d}{dr}\left(\frac{k_{\mathcal{B}}T_B(r)\rho_B(r)}{m_B}\right)\right] = -4\pi G r^2\rho_M(r) \tag{1.9.11}$$

If we make the assumption that cold dark matter particles, or whatever particles dominate the dark intergalactic matter, have an isotropic velocity
distribution (which is not very well motivated), then the same derivation applies to these particles, and their density $\rho_D = \rho_M - \rho_B$ satisfies the non-linear differential equation

$$\frac{d}{dr}\left[\frac{r^2}{\rho_D(r)}\frac{d}{dr}\left(\frac{k_{\mathcal{B}}T_D(r)\rho_D(r)}{m_D}\right)\right] = -4\pi G r^2\rho_M(r) \tag{1.9.12}$$

where $T_D(r)$ and m_D are the temperature and mass of the dark matter particles. With perfect X-ray data and a knowledge of the distance of the source, one could measure the X-ray luminosity density $\mathcal{L}_X(r)$ and (using the Xray spectrum) the baryon temperature $T_B(r)$ at each point in the cluster, then use Eq. (1.9.10) to find the baryon density $\rho_B(r)$ at each point, and then use Eq. (1.9.11) to find the total mass density at each point. We could then calculate the fractional baryon density ρ_B/ρ_M, and if we were interested we could also use Eq. (1.9.12) to find the velocity dispersion $k_{\mathcal{B}}T_D(r)/m_D$ of the dark matter.

In practice, it is usually necessary to use some sort of cluster model. In the simplest sort of model, one assumes an isothermal sphere: the temperatures T_B and T_D are taken to be independent of position, at least near the center of the cluster where most of the X-rays come from. It is also often assumed that the same gravitational effects that causes the

concentration of the hot intergalactic gas in the cluster is also responsible for the concentration of the dark matter, so that the densities $\rho_B(r)$ and $\rho_M(r)$ are the same, up to a constant factor, which represents the cosmic ratio Ω_B/Ω_M of baryons to all non-relativistic matter. (These gravitational effects are believed to be a so-called "violent relaxation," [11] caused by close encounters of clumps of matter whose gravitational attraction cannot be represented as an interaction with a smoothed average gravitational field. The condensation of galaxies out of this mixture requires quite different cooling processes that can affect only the baryonic gas, which is why galaxies have a lower proportion of dark matter and a lower mass-to-light ratio.) Comparison of Eqs. (1.9.11) and (1.9.12) shows that $\rho_B(r)$ and $\rho_D(r)$ will be proportional to each other, and hence also to $\rho_M(r)$ if the velocity dispersions of the dark matter and hot baryonic gas are the same:

$$k_{\mathcal{B}}T_M/m_M = k_{\mathcal{B}}T_D/m_D \equiv \sigma^2 \tag{1.9.13}$$

Equations (1.9.11) and (1.9.12) both then tell us that

$$\rho_M(r) = \rho_M(0)F\left(r/r_0\right) \tag{1.9.14}$$

where $F(0) \equiv 1; r_0$ is a core radius, defined conventionally by

$$r_0 \equiv \sqrt{\frac{9\sigma^2}{4\pi G\rho_M(0)}}; \tag{1.9.15}$$

and $F(u)$ is a function satisfying the differential equation

$$\frac{d}{du}\left(\frac{u^2}{F(u)}\frac{dF(u)}{du}\right) = -9u^2F(u). \tag{1.9.16}$$

We must also impose the boundary condition that ρ_M is analytic in the coordinate $\mathbf{X}$ at $\mathbf{X} = 0$, which for a function only of r means that it is given near $r = 0$ by a power series in r^2, so that $F(u)$ is given near $u = 0$ by a power series in $u^2, F(u) = 1 + O\left(u^2\right)$. Together with this boundary condition, Eq. (1.9.16) defines a unique function [12] that for small u has the approximate behavior [13]

$$F(u) \simeq \left(1 + u^2\right)^{-3/2}. \tag{1.9.17}$$

The solution to Eq. (1.9.16) is shown together with the approximation (1.9.17) in Figure 1.7.

For large $u, F(u)$ approaches the exact solution $2/9u^2$. Taken literally, this would make the integral for the total mass diverge at large r, which shows that the assumption of constant σ^2 must break down at some large radius. Often the function $F(u)$ is taken simply as [14]

$$F(u) = \left(1 + u^2\right)^{-3\beta/2},$$

where β is an exponent of order unity.

[4711] D. Lynden-Bell, Mon. Not. Roy. Astron. Soc. 136, 101 (1967).

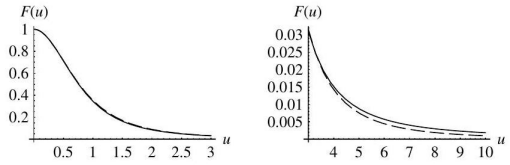

Figure 1.7: The solution to Eq. (1.9.16) (solid line) and the approximation (1.9.17) (dashed line). For the lower values of u in the figure at the left, the two curves are indistinguishable.

Also, Eq. (1.9.11) has the solution

$$\rho_B(r) = \rho_B(0) F\left(r/r_0\right) \tag{1.9.18}$$

with the same function $F(u)$ and the same core radius r_0. We can measure the core radius from the X-ray image of the cluster, and measure σ^2 from the X-ray spectrum, so that Eq. (1.9.15) can be used to find the central density $\rho_M(0)$ of all non-relativistic matter. The central density $\rho_B(0)$ of the baryonic matter can then be found from the total X-ray luminosity, which with these approximations (and using Eq. (1.9.10)) is

$$L_X \equiv \int d^3x \mathcal{L}_X = 4\pi\Lambda\left(T_B\right) r_0^3 \rho_B(0)^2 \mathcal{I} \tag{1.9.19}$$

where

$$\mathcal{I} \equiv \int_0^\infty u^2 F^2(u) du \tag{1.9.20}$$

Even though the solution of Eq. (1.9.16) gives an infinite mass, it gives a finite total X-ray luminosity, with $\mathcal{I} = 0.1961$. (The approximation (1.9.17) would give $\mathcal{I} = \pi/16 = 0.1963$.)

For a cluster at redshift z, the core radius r_0 inferred from observation of the angular size of the cluster will be proportional to the angular diameter distance $d_A(z)$, while the temperature and velocity dispersion found from the X-ray spectrum will not depend on the assumed distance. Thus the value of the central total matter density $\rho_M(0)$ given by Eq. (1.9.15) will be proportional to $1/d_A^2(z)$. On the other hand, the absolute X-ray luminosity L_X inferred from the apparent X-ray luminosity will (like all absolute luminosities) be proportional to the value assumed for $d_L^2(z)$, the square of the luminosity distance, so with $r_0 \propto d_A$, the central baryon density $\rho_B(0)$ given by Eq. (1.9.19) will be proportional to $[d_L^2(z)/d_A^3(z)]^{1/2}$. The value of the ratio of central densities inferred from observations of a given cluster at redshift z will therefore have a dependence on the distance assumed for the cluster given by

$$\frac{\rho_B(0)}{\rho_M(0)} \propto d_L(z) d_A^{1/2}(z) = (1+z)^2 d_A^{3/2}(z) \tag{1.9.21}$$

in which we have used the relation (1.4.12) between luminosity and angular diameter distances.

For $z \ll 1$, we have $d_A(z) \simeq d_L(z) \simeq z/H_0$, and so according to Eq. (1.9.21) the value of $\rho_B(0)/\rho_M(0)$ obtained from observations of clusters of small redshift will be proportional to the assumed value of $H_0^{-3/2}$. It is believed that most of the baryonic mass in a cluster of galaxies is in the

[4712] For a tabulation of values of $F(u)$, see e.g. J. Binney and S. Tremaine, Galactic Dynamics (Princeton University, Princeton, 1987): Table 4.1.
[13] I. R. King, Astron. J. 67, 471 (1962).
[14] A. Cavaliere and R. Fusco-Fermiano, Astron. Astrophys. 49, 137 (1976).

hot gas outside the galaxies, and if we suppose that this mass is the same fraction of the total mass as in the universe as a whole, [15] then we should get the same value of $\rho_B(0)/\rho_M(0)$, equal to Ω_B/Ω_M, for all clusters, whatever value we assume for H_0, but this value of Ω_B/Ω_M will be proportional to the assumed value of $H_0^{-3/2}$. For example, Schindler [16] quotes various studies that give $\rho_B(0)/\rho_M(0)$ as $0.14, 0.11, 0.12$, and 0.12 for $H_0 = 65$ km s^{-1}Mpc^{-1}, so if we take the average 0.12 of these values as the cosmic value of Ω_B/Ω_M for $H_0 = 65$ km s^{-1}Mpc^{-1}, then for a general Hubble constant we find

$$\Omega_B/\Omega_M \simeq 0.06h^{-3/2} \tag{1.9.22}$$

where h as usual is Hubble's constant in units of 100 km s^{-1}Mpc^{-1}. We can thus conclude pretty definitely that only a small fraction of the mass in clusters of galaxies is in a baryonic form that can emit X-rays.

On the other hand, when we study clusters with a range of redshifts that are not all small, we will not get a uniform value of $\rho_B(0)/\rho_M(0)$ unless we use values of $d_A(z)$ with the correct dependence on z. As remarked in Section 1.6, observations of clusters have been used in this way to learn about the z-dependence of $d_A(z)$.

It should be mentioned that computer simulations that treat galaxy clusters as assemblages of collisionless particles do not show evidence for a central core, [17] but instead indicate that the dark matter density at small distances r from the center should diverge as r^{-1} to $r^{-3/2}$. On the other hand, it has been shown [18] that the density of a baryonic gas in hydrostatic equilibrium in the gravitational field of such a distribution of dark matter does exhibit the core expected from Eq. (1.9.18). In any case, the dark matter and baryonic gas densities do have the same distributions at distances from the center that are larger than r_0.

As we will see in Section 3.2, it is possible to infer a value for $\Omega_B h^2$ from the abundances of deuterium and other light isotopes, which together with Eq. (1.9.22) can be used to derive a value for $\Omega_M h^{1/2}$. There are several other methods for estimating Ω_M or $\Omega_M h^2$ that will be discussed elsewhere

in this book, using gravitational lenses (Section 9.3), the Sunyaev-Zel'dovich effect (Section 2.5), and anisotropies in the cosmic microwave background (Sections 2.6 and 7.2), the last of which also gives a value for $\Omega_B h^2$. In addition to these, there are methods [19] based on the evolution of clusters of galaxies, cosmic flows, cluster correlations, etc., that depend on detailed dynamical theories of structure formation.

10.1.12 1.10 Intergalactic absorption

Some of the cosmic gas of nuclei and electrons from which the first galaxies and clusters of galaxies condensed must be still out there in intergalactic space. Atoms or molecules in this gas could be observed through the resonant absorption of light or radio waves from more distant galaxies or quasars, but it is believed that most of the gas was ionized by light from a first generation of hot massive stars, now long gone, that are sometimes called stars of Population III. It now appears that some quasars formed before this ionization was complete, giving us

[4715] This is argued by S. D. M. White, J. F. Navarro, A. E. Evrard, and C. S. Frenk, Nature 366, 429 (1993). Calculations supporting this assumption are described in Section 8.3.

[18] N. Makino, S. Sasaki, and Y. Suto, Astrophys. J. 497, 555 (1998). Also see Y. Suto, S. Sasaki, and M. Makino, Astrophys. J. 509, 544 (1998); E. Komatsu and U. Seljak, Mon. Not. Roy. Astron. Soc. 327, 1353 (2001).

the opportunity to observe the intergalactic gas through resonant absorption of the light from these very distant quasars.

Let us suppose that an atomic transition in a distant source produces a ray of light of frequency v_1 that leaves the source at time t_1 and arrives at the Earth with frequency v_0 at time t_0. At time t along its journey the light will have frequency redshifted to $v_1 a(t_1)/a(t)$, so if the intergalactic medium absorbs light of frequency ν at a rate (per proper time) $\Lambda(\nu, t)$, and does not emit light, then the intensity $I(t)$ of the light ray will decrease according to the equation

$$\dot{I}(t) = -\Lambda\left(v_1 a(t_1)/a(t), t\right) I(t)$$

But if the intergalactic gas is at a non-zero temperature $T(t)$, then photons will also be added to the light ray through the process of stimulated emission, as a rate per photon given by the Einstein formula [1] $\exp(-hv/k_{\mathcal{B}}T)\,\Lambda(v,t)$, so the intensity of the light ray will satisfy

$$\dot{I}(t) = -\left[1 - \exp\left(-\frac{hv_1 a(t_1)}{k_{\mathcal{B}} T(t) a(t)}\right)\right] \Lambda\left(v_1 a(t_1)/a(t), t\right) I(t) \tag{1.10.1}$$

The intensity observed at the earth will then be

$$I(t_0) = \exp(-\tau) I(t_1) \tag{1.10.2}$$

where τ is the optical depth:

$$\tau = \int_{t_1}^{t_0} \left[1 - \exp\left(-\frac{hv_1 a(t_1)}{k_{\mathcal{B}} T(t) a(t)}\right)\right] \Lambda\left(v_1 a(t_1)/a(t), t\right) dt \tag{1.10.3}$$

The absorption rate is given by

$$\Lambda(v,t) = n(t)\sigma(v) \tag{1.10.4}$$

where $\sigma(v)$ is the absorption cross section at frequency v, and $n(t)$ is the number density (per proper volume) of absorbing atoms. Often the absorption cross section is sharply peaked at some frequency v_R, so the absorption takes place only close to a time t_R, given by

$$a(t_R) = v_1 a(t_1)/v_R \tag{1.10.5}$$

Therefore the optical depth can be approximated as

$$\tau \simeq n(t_R)\left[1 - \exp\left(-hv_R/k_{\mathcal{B}}T(t_R)\right)\right] \int \sigma\left(v_1 a(t_1)/a(t)\right) dt$$

By changing the variable of integration from time to frequency, we can write this as

$$\tau \simeq n(t_R)\left[1 - \exp\left(-hv_R/k_{\mathcal{B}}T(t_R)\right)\right]\left[a(t_R)/\dot{a}(t_R)\right]\mathcal{I}_R \tag{1.10.6}$$

where

$$\mathcal{I}_R \equiv \frac{1}{v_R}\int \sigma(v) dv \tag{1.10.7}$$

Olive, lectures given at Theoretical Advanced Study Institute on Elementary Particle Physics, Boulder, June 2002 [astro-ph/0301505].

[1] A. Einstein, Phys. Z. 18, 121 (1917).

the integral being taken over a small range of frequencies containing the absorption line. The only thing in the formula for τ that depends on a cosmological model is the Hubble expansion rate $\dot{a}(t_R)/a(t_R)$ at the time of absorption, given by Eq. (1.5.19) and (1.5.38) as

$$\frac{\dot{a}(t_R)}{a(t_R)} = H_0\sqrt{\Omega_\Lambda + \Omega_K(1+z_R)^2 + \Omega_M(1+z_R)^3 + \Omega_R(1+z_R)^4} \tag{1.10.8}$$

where $z_R = a(t_0)/a(t_R) - 1 = v_R/v_0 - 1$ is the redshift of the location of the resonant absorption. For a source at redshift z, the absorption takes place over a range of observed frequencies $v_0 = v_1/(1+z)$ given by the condition that the time t_R defined by Eq. (1.10.5) should be between t_1 and t_0 :

$$v_R/(1+z) \leq v_0 \leq v_R. \tag{1.10.9}$$

For example, in 1959 Field [2] suggested looking for the effects of absorption of radio frequencies in the 21 cm transition in hydrogen atoms, caused in transitions from the spin zero to spin one hyperfine states in the $1s$ state of intergalactic hydrogen. Here $v_R = 1420$MHz, so the radio spectrum of the galaxy Cygnus A at a redshift $z = 0.056$ should show an absorption trough (1.10.9) from 1342 MHz to 1420 MHz . Unfortunately, the temperature of neutral hydrogen in intergalactic space is much larger than $hv_R/k_{\mathcal{B}} = 0.068$ K, so the optical depth (1.10.6) is suppressed by a factor $\simeq 0.068\text{ K}/T(t_R)$. No sign of this absorption trough has been discovered. It is hoped that in the future a new generation of low frequency radio telescopes with good angular resolution may be able to use the emission and absorption of 21 cm radiation at large redshifts to study both the growth of structure and primordial density perturbations from which they grew. [3] For instance, by 2010 the Low Frequency Array (LOFAR) should be able to study 21 cm radiation from sources at redshift between 5 and 15 with good sensitivity and high angular resolution. [4]

For the present, a much better probe of intergalactic hydrogen atoms is provided by absorption of photons in the Lyman α transition from the $1s$ ground state to the $2p$ excited state, known as the Gunn-Peterson effect. [5] This has a resonant frequency in the ultraviolet, $v_R = 2.47\times10^{15}$ Hz, corresponding to a wavelength $1,215$Å, but for a source of redshift $z > 1.5$ the lower part or the absorption trough (1.10.9) will be observable on the Earth's surface at wavelengths greater than $3,000$Å, in the visible or infrared part of the spectrum. Here $hv_R/k_{\mathcal{B}} = 118,000$ K, which is likely to be larger than the temperature of the intergalactic medium, in which case the factor $1-\exp(-hv_R/k_{\mathcal{B}}T(t_R))$ in Eq. (1.10.6) can be set equal to unity. The integral (1.10.7) here has the value 4.5×10^{-18} cm^2, so Eq. (1.10.6) gives the optical depth just above the lower end of the absorption trough (1.10.9) as

$$\tau_{v_0=v_R/(1+z)+} = \left(\frac{n(t_R)}{2.4h\times10^{-11}\text{ cm}^{-3}}\right)\left(\Omega_\Lambda + \Omega_K(1+z)^2 + \Omega_M(1+z)^3 + \Omega_R(1+z)^4\right)^{-1/2} \tag{1.10.10}$$

where again h is Hubble's constant in units of 100 km s^{-1}Mpc^{-1}. For instance, if a fraction f of the baryons of the universe at a time corresponding

to $z = 5$ were in the form of neutral intergalactic hydrogen atoms, and $\Omega_B h^2 = 0.02$, then the number density of hydrogen atoms at $z = 5$ would be $4.8f \times 10^{-5}$ cm^{-3}. Taking $h = 0.65, \Omega_\Lambda = 0.7, \Omega_M = 0.3$, and $\Omega_K = \Omega_R = 0$, the optical depth (1.10.10) would be $3.8f \times 10^5$. Thus with these parameters intergalactic neutral hydrogen that makes up a fraction of baryonic matter $f \gg 2.6 \times 10^{-6}$ would completely block any light with a frequency above the redshifted Lyman α line from sources beyond $z = 5$. Evidently the Gunn-Peterson effect provides a very sensitive probe of even a small proportion of neutral hydrogen atoms.

For many years the search for the Lyman α absorption trough was unsuccessful. Quasar spectra show numerous Lyman α absorption lines, forming what are sometimes called "Lyman α forests," which are believed to arise from clouds of neutral hydrogen atoms along the line of sight, but for quasars out to $z \approx 5$ there was no sign of a general suppression of frequencies above the redshifted Lyman α frequency, [6] that would be produced by even a small fraction f of the baryons in the universe in the form of neutral intergalactic hydrogen atoms. Then in 2001 the spectrum of the quasar SDSSp J103027.10+052455.0 with redshift $z = 6.28$ discovered by the Sloan Digital Sky Survey was found to show clear signs of a complete suppression of light in the wavelength range from just below the redshifted Lyman α wavelength at $8,845$Å down to $8,450$Å, indicating a significant fraction f of baryons in the form of neutral intergalactic hydrogen atoms at redshifts greater than $8,450/1,215 - 1 = 5.95$.[7] (See Figure 1.8.) Thus a redshift of order 6 may mark the end of a "dark age," in which the absorption of light by neutral hydrogen atoms made the universe opaque to light with frequencies above the redshifted Lyman α frequency. Further evidence for this conclusion is supplied by the spectrum of intense gamma ray sources, known as gamma ray bursters, at large redshifts. [8]

This does not mean that all or even most of the hydrogen in the universe was in the form of neutral atoms at $z > 6$. As we have seen, even small concentrations of neutral hydrogen could have produced an absorption trough in the spectrum of distant quasars. In fact, we shall see in Chapter 7 that there is now some evidence from the study of the cosmic microwave background that hydrogen became mostly ionized at redshifts considerably larger than $z \approx 6$, perhaps around $z \approx 10$.

The clouds of neutral hydrogen at redshifts $z < 6$ which produce the Lyman α forest can provide an independent means of measuring Ω_M and Ω_Λ. The idea goes back to a 1979 paper of Alcock and Paczyński. [9] Suppose we observe a luminous object at a redshift z that extends a proper distance $D_\perp$ perpendicular to the line of sight and a proper distance $D_\parallel$along the line of sight. According to the definition of the angular diameter distance, the object will subtend an angle

$$\Delta\theta = D_\perp / d_A(z) \tag{1.10.11}$$

Also, when we observe light from the whole object at the same time t_0, the difference in the time t_1 that the light was emitted from the far and near points of the object will be $\Delta t_1 = D_\parallel$. The redshift is $a(t_0)/a(t_1) - 1$, so the absolute value of the difference of redshift from the far and near points of the object will be

$$\Delta z = \frac{a(t_0)}{a^2(t_1)} \dot{a}(t_1) \Delta t_1 = (1+z) H(z) D_\parallel \tag{1.10.12}$$

where $H(z) \equiv \dot{a}(t_1)/a(t_1)$ is the Hubble constant at the time of emission. Taking the ratio, we have

[476] A. Songalia, E. Hu, L. Cowie, and R. McMahon, Astrophys. J. 525, L5 (1999).

[7] R. H. Becker et al., Astron. J. 122, 2850 (2001) [astro-ph/0108097]. See S. G. Djorgovski et al., Astrophys. J. 560, L5 (2001) [astro-ph/0108069], for a hint of absorption by neutral hydrogen at slightly smaller redshifts. Also see X. Fan et al., Astrophys. J. 123, 1247 (2002) [astro-ph/0111184].

[8] T. Totani et al., Publ. Astron. Soc. Pacific 58, 485 (2006) [astro-ph/0512154].

$$\frac{\Delta z}{\Delta\theta} = (1+z)H(z)d_A(z)\left(D_\parallel/D_\perp\right) \tag{1.10.13}$$

It is then only necessary to use Eq. (1.5.19) to write $H(z)$ as

$$\begin{aligned} H(z) &= \sqrt{\left(\frac{8\pi G}{3}\right)(\rho_{M0}(1+z)^3 + \rho_V + \rho_{R0}(1+z)^4) - \frac{K}{a_0^2}(1+z)^2} \\ &= H_0\sqrt{\Omega_M(1+z)^3 + \Omega_\Lambda + \Omega_R(1+z)^4 + \Omega_K(1+z)^2} \end{aligned} \tag{1.10.14}$$

and use Eqs. (1.4.12) and (1.5.45) to write $d_A(z)$ as

$$\begin{aligned} d_A(z) =& \frac{1}{(1+z)H_0\Omega_K^{1/2}} \\ &\times \sinh\left[\Omega_K^{1/2}\int_{1/(1+z)}^1 \frac{dx}{x^2\sqrt{\Omega_\Lambda + \Omega_K x^{-2} + \Omega_M x^{-3} + \Omega_R x^{-4}}}\right] \end{aligned} \tag{1.10.15}$$

The Hubble constant H_0 cancels in the product, and we find a result that depends only on $z, D_\parallel/D_\perp$, and the Ω s:

$$\begin{aligned} \frac{\Delta z}{\Delta\theta} =& \left(D_\parallel/D_\perp\right)\Omega_K^{-1/2}\sqrt{\Omega_M(1+z)^3 + \Omega_\Lambda + \Omega_R(1+z)^4 + \Omega_K(1+z)^2} \\ &\times \sinh\left[\Omega_K^{1/2}\int_{1/(1+z)}^1 \frac{dx}{x^2\sqrt{\Omega_\Lambda + \Omega_K x^{-2} + \Omega_M x^{-3} + \Omega_R x^{-4}}}\right] \end{aligned} \tag{1.10.16}$$

For instance, if the object is known to be a sphere, such as a spherical cluster of galaxies, then $D_\parallel/D_\perp = 1$, and we can use a measurement of Δz and $\Delta\theta$ to set a model-independent constraint on the Ωs, with no need to worry about effects of evolution or intergalactic absorption.

Unfortunately, it is not so easy to find spherical objects at large redshift. But there are various objects whose distribution functions are spherically symmetric. For instance, the distribution of field galaxies is presumably spherically symmetric about any point in space, and it has been proposed that the application of the Alcock-Paczyński method to galaxies might allow a determination of the cosmological constant. [10] This method has been applied [11] instead to the distribution of quasars measured in the 2 dF QSO Redshift Survey. [12] Assuming $K = 0$, this analysis gives $\Omega_\Lambda = 0.71^{0.09}_{-0.17}$.

Recently the Alcock-Paczyński idea has been applied to the distribution function of Lyman α clouds. [13] As already mentioned, these are intergalactic clouds containing neutral hydrogen atoms, which absorb light from more distant quasars along the line of sight in $1s \to 2p$ transitions, showing up as dark lines in the spectrum of the quasar at wavelengths $1215(1+z)$Å for clouds at redshift z. Suppose we measure the number density $N(z,\hat{n})$ of Lyman α clouds at various redshifts z in various directions $\hat{n}$. Assuming a spherically symmetric distribution of Lyman α clouds, the mean value of the product of the number densities of these clouds at two nearby points with redshifts z and $z+\Delta z$ (with $\Delta z \ll 1$) and directions $\hat{n}$ and $\hat{n}+\Delta\hat{n}$ separated by a small angle $\Delta\theta$ will be a function only of z and the proper distance between the points, and will be analytic in the components of the vector

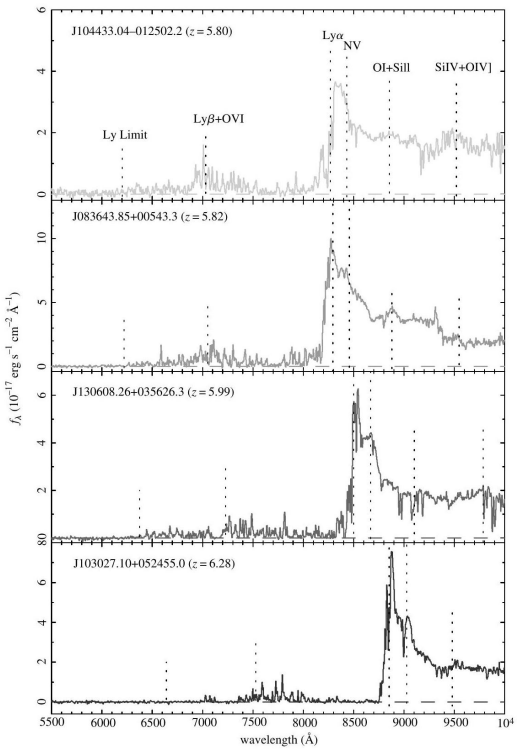

Figure 1.8: Observed intensity versus wavelength for four high-redshift quasars, from R. H. Becker et al., Astron. J. 122, 2850 (2001) [astro-ph/0108097]. Vertical dashed lines indicate the redshifted wavelengths for various spectral lines. In the direction of the quasar with $z = 6.28$ the intensity drops to zero within experimental accuracy just to the left of the Lyman α line at 8845Å, a feature not seen for the quasar with $z = 5.99$, indicating the onset of patches of nearly complete ionization at a redshift between 5.99 and 6.28.

separating these components, so for small separations it can be written

$$\langle N(z,\hat{n})N(z+\Delta z,\hat{n}+\Delta\hat{n})\rangle \simeq \left\langle N^2(z,\hat{n})\right\rangle \left[1-\frac{D_\perp^2+D_\parallel^2}{L^2(z)}\right] \tag{1.10.17}$$

where $D_\perp$ and $D_\parallel$are given by Eqs. (1.10.11) and (1.10.12), and L is some correlation length. This can be written in terms of the observed Δz and $\Delta\theta$, as

$$\langle N(z,\hat{n})N(z+\Delta z,\hat{n}+\Delta\hat{n})\rangle \simeq \left\langle N^2(z,\hat{n})\right\rangle \left[1-\frac{\Delta z^2}{L_z^2(z)}-\frac{\Delta\theta^2}{L_\theta^2(z)}\right] \tag{1.10.18}$$

where L_z and L_θ are correlation lengths for redshift and angle

$$L_\theta(z)=\frac{L(z)}{d_A(z)},\quad L_z(z)=L(z)(1+z)H(z) \tag{1.10.19}$$

By measuring this product for various redshifts and directions, we can infer a value for the ratio of correlation lengths, which is independent of L :

[13] L. Hui, A. Stebbins, and S. Burles, Astrophys. J. 511, L5 (1999); P. McDonald and J. MiraldaEscudeé, Astrophys. J. 518, 24 (1999); W-C. Lin and M. L. Norman, talk at the Theoretical Astrophysics in Southern California meeting, Santa Barbara, October 2002 [astro-ph/0211177]; P. McDonald, Astrophys. J. 585, 34 (2003).

$$\frac{L_z(z)}{L_\theta(z)} = \Omega_K^{-1/2}\sqrt{\Omega_M(1+z)^3+\Omega_\Lambda+\Omega_R(1+z)^4+\Omega_K(1+z)^2} \times \sinh\left[\Omega_K^{1/2}\int_{1/(1+z)}^{1}\frac{dx}{x^2\sqrt{\Omega_\Lambda+\Omega_K x^{-2}+\Omega_M x^{-3}+\Omega_R x^{-4}}}\right] \tag{1.10.20}$$

This method has been applied [14] to five pairs of close quasars, with redshifts in the range from 2.5 to 3.5 and separations ranging from 33 to 180 arcseconds. Use of this limited sample sets only weak constraints on the Ωs, but it rules out $\Omega_\Lambda = 0$ at the level of 2 standard deviations.

10.1.13 1.11 Number counts

A uniform distribution of sources with a smooth distribution of absolute luminosity leads in ordinary Euclidean space to a unique distribution in apparent luminosity. If there are $N(L)dL$ sources per unit volume with absolute luminosity between L and $L + dL$, then the number $n(> \ell)$ of

sources observed with apparent luminosity greater than ℓ is given by

$$\begin{aligned} n(>\ell) &= \int_0^\infty N(L)dL\int_0^{\sqrt{L/4\pi\ell}} 4\pi r^2 dr \\ &= \frac{1}{3\sqrt{4\pi}\ell^{3/2}}\int_0^\infty L^{3/2}N(L)dL \end{aligned} \tag{1.11.1}$$

Thus whatever the distribution in absolute luminosity, we expect that $n(> \ell) \propto \ell^{-3/2}$.

This analysis needs several changes in a cosmological setting:

1. Instead of the volume element $r^2\sin\theta dr d\theta d\phi$, the proper volume element here is $\left(\mathrm{Det}\, g^{(3)}\right)^{1/2} dr d\theta d\phi$, where $g^{(3)}_{ij} \equiv a^2\tilde{g}_{ij}$ is the three-dimensional metric, with non-vanishing components $g^{(3)}_{rr} = a^2/\left(1-Kr^2\right), g^{(3)}_{\theta\theta} = a^2r^2, g^{(3)}_{\phi\phi} = a^2r^2\sin^2\theta$, so

$$dV = \frac{a^3(t)r^2\sin\theta dr d\theta d\phi}{\sqrt{1-Kr^2}} \tag{1.11.2}$$

2. The apparent luminosity is related to the absolute luminosity by

$$\ell = \frac{L}{4\pi d_L^2(z)} \tag{1.11.3}$$

where $d_L(z)$ is the luminosity distance (1.4.3).

3. Except in the steady state cosmology, the number density of sources changes with time, even if only through the cosmic expansion.

4. We can often measure the redshift z as well as the apparent luminosity.

Eq. (1.11.2) gives the number of sources with redshift between z and $z + dz$ and apparent luminosity between ℓ and $\ell + d\ell$ as

$$n(z,\ell)dzd\ell = 4\pi\mathcal{N}(t,L)dL\frac{a^3(t)r^2dr}{\sqrt{1-Kr^2}} \tag{1.11.4}$$

[4714] A. Lidz, L. Hui, A. P. S. Crotts, and M. Zaldarriaga, astro-ph/0309204 (unpublished).

where $\mathcal{N}(t, L)dL$ is the number of sources per proper volume at time t with absolute luminosity between L and $L + dL$; t and z are related by $1 + z = a\,(t_0)\,/a(t)$, and t and r are related by Eq. (1.2.2):

$$\int_t^{t_0} \frac{dt'}{a\,(t')} = \int_0^r \frac{dr'}{\sqrt{1 - Kr'^2}} \tag{1.11.5}$$

We use (1.11.5) to express the differential dr in terms of dt, and then express dt in terms of dz :

$$\frac{dr}{\sqrt{1 - Kr^2}} = -\frac{dt}{a(t)} = \frac{dz}{H(z)a_0}$$

where $H(z) \equiv \dot{a}(t)/a(t)$ and $a_0 \equiv a\,(t_0)$. As a reminder, for a universe containing radiation, matter, and a constant vacuum energy, Eq. (1.5.41) gives

$$H(z) = H_0\sqrt{\Omega_\Lambda + \Omega_K(1 + z)^2 + \Omega_M(1 + z)^3 + \Omega_R(1 + z)^4}$$

Canceling dz in Eq. (1.11.4), we then have

$$n(z, \ell)d\ell = \frac{4\pi\mathcal{N}(t(z), L)r^2(z)a_0^2 dL}{(1 + z)^3 H(z)}$$

We next use Eq. (1.11.3) to write (with z now held fixed):

$$dL = 4\pi d_L^2(z)d\ell$$

so that canceling $d\ell$ gives

$$n(z, \ell) = \frac{16\pi^2\mathcal{N}\,(t(z), 4\pi d_L^2(z)\ell)\,d_L^4(z)}{H(z)(1 + z)^5} \tag{1.11.6}$$

in which we have used Eq. (1.4.3) to express $a_0 r$ in terms of d_L.
In particular, for a sample of sources that are not evolving at a time $t(z)$, the time dependence of the number density $\mathcal{N}$ is just proportional to $a^{-3} \propto (1 + z)^3$:

$$\mathcal{N}(t(z), L) = (1 + z)^3\mathcal{N}_0(L) \tag{1.11.7}$$

If all members of this sample are bright enough to be visible at a redshift z, then the total number of sources observed with redshifts between z and $z + dz$ will be $n(z)dz$, where

$$n(z) \equiv \int_0^\infty n(z, \ell)d\ell = \frac{4\pi\mathcal{N}_0 d_L^2(z)}{H(z)(1 + z)^2} \tag{1.11.8}$$

where $d_L(z)$ is given by Eq. (1.5.45), and

$$\mathcal{N}_0 \equiv \int_0^\infty \mathcal{N}_0(L)dL \tag{1.11.9}$$

In principle, even without knowing $\mathcal{N}_0$ or H_0, if $n(z)$ were accurately measured we could compare the observed shape of this function with Eq. (1.11.8) to find the Ω s.

There are several obvious dangers in using Eq. (1.11.8) in this way. For one thing, it is necessary to avoid missing sources that have high redshift and hence low apparent luminosity. Also, evolution in the number of sources can introduce an additional dependence on the light emission time t, and hence on z. In 1986 Loh and Spillar [1] carried out a survey of galaxy numbers as a function of redshift. The redshifts were measured photometrically (i. e., from their luminosities at various colors rather than by the shift of specific spectral lines), which

generally gives less reliable results. Comparing their results with Eq. (1.11.8) in the case $\Omega_K = \Omega_R = 0$ (so that $\Omega_\Lambda + \Omega_M = 1$), they found that $\Omega_\Lambda/\Omega_M = 0.1^{-0.4}_{+0.2}$. By now it has been realized that the evolution of sources cannot be neglected at redshifts large enough for $n(z)$ to be sensitive to cosmological parameters, and this result for Ω_Λ/Ω_M has been abandoned. [2]

Useful results can be obtained when evolution is taken into account. One group [3] used number counts of very faint galaxies [4] as a function of apparent luminosity to estimate the free parameters in a model of galactic luminosity evolution (assuming the number of galaxies per coordinate volume to be constant), and then used this model together with a redshift survey [5] extending to $z \simeq 0.47$ to conclude that Ω_M is small and that Ω_Λ is in the range of 0.5 to 1 . More recently, several surveys [6] of numbers of galaxies at different redshifts that yield important results about galactic evolution, and with the use of dynamical models they can yield information about Ω_M and Ω_Λ.[7] But it appears that number counts of galaxies will be more useful in learning about galactic evolution than in making precise determinations of cosmological parameters. In a dramatic application of this approach, [8] a

search at the Lick Observatory for galaxies with redshifts in the range $z \approx 7$ to 8 found at most just one galaxy, while it is estimated that if Eq. (1.11.7) were valid then, on the basis of the number of galaxies observed (with the same conservative selection criteria) at redshifts $z \approx 6$, ten galaxies should have been found with $z \approx 7$ to 8 . The implication is that there must have been a spurt in the formation of luminous galaxies at a redshift in the range 6 to 7. This fits in well with the conclusion discussed in Section 1.10, that the ionization of intergalactic hydrogen became essentially complete at a redshift of order 6, presumably due to ultraviolet radiation from massive stars formed around that time.

Historically the first important application of number counts was in radio source surveys, where redshifts are not generally available. These surveys take place at a fixed receiving frequency ν, corresponding to a variable emitted frequency $v(1+z)$, so the source counts are affected by the frequency dependence of the distribution of intrinsic source powers.

If a source with a redshift z emits a power [9]$P(v)dv$ between frequencies v and $v + dv$, then the power received at the origin per unit antenna area between frequencies ν and $\nu + d\nu$ is

$$S(v)dv = \frac{P(v(1+z))dv(1+z)}{4\pi d_L^2(z)} \tag{1.11.10}$$

Many radio sources have a "straight" spectrum, i.e.

$$P(v) \propto v^{-\alpha} \tag{1.11.11}$$

with the spectral index α typically about 0.7 to 0.8 . This allows a great simplification in Eq. (1.11.10):

$$S(v)dv = \frac{P(v)dv}{4\pi d_L^2(z)(1+z)^{\alpha-1}} \tag{1.11.12}$$

From now on we will take the observed frequency v as fixed, and write $S(v) = S$ and $P(v) = P$. Canceling dv, Eq. (1.11.12) then reads

$$S = \frac{P}{4\pi d_L^2(z)(1+z)^{\alpha-1}} \tag{1.11.13}$$

If at time t there are $N(P,t)dP$ sources per proper volume with power between P and $P + dP$, then the number of sources observed with power per antenna area greater than S is

$$n(>S) = \int_0^\infty dP \int N(P,t)\frac{4\pi r^2 a^3(t)dr}{\sqrt{1-Kr^2}} \tag{1.11.14}$$

with the upper limit on the integral over r set by the condition that

$$a_0^2 r^2 (1+z)^{1+\alpha} < \frac{P}{4\pi S} \tag{1.11.15}$$

Of course, r, z, and t are related by the familiar formulas

$$\int_0^r \frac{dr'}{\sqrt{1-Kr'^2}} = \int_t^{t_0} \frac{dt'}{a\left(t'\right)}, \quad 1 + z = a\left(t_0\right)/a(t) \tag{1.11.16}$$

This becomes much simpler if we assume that the time-dependence of the source number density can be parameterized as

$$N(P,t) = N(P)\left(\frac{a(t)}{a_0}\right)^\beta \tag{1.11.17}$$

For instance, if sources do not evolve and are neither created nor destroyed, then $\beta = -3$, while in the steady-state model $\beta = 0$. Eq. (1.11.14) now reads

$$n(>S) = a_0^3 \int_0^\infty N(P)dP \int \frac{4\pi r^2 (1+z)^{-\beta-3} dr}{\sqrt{1-Kr^2}} \tag{1.11.18}$$

with the same P/S-dependent upper limit (1.11.15) on r.
The coordinate r is given in terms of z by the power series (1.4.8)

$$a_0 H_0 r = z - \frac{1}{2}\left(1 + q_0\right) z^2 + \ldots \tag{1.11.19}$$

We can then convert the integral over r to one over z, with

$$a_0 H_0 dr = dz\left[1 - \left(1 + q_0\right) z + \ldots\right] \tag{1.11.20}$$

and the upper limit on z is given by

$$z^2\left[1 + z\left(\alpha - q_0\right) + \ldots\right] < \frac{PH_0^2}{4\pi S}$$

or, in other words,

$$z < \sqrt{\frac{PH_0^2}{4\pi S}}\left[1 - \frac{1}{2}\left(\alpha - q_0\right)\sqrt{\frac{PH_0^2}{4\pi S}} + \ldots\right] \tag{1.11.21}$$

[479] In G&C, P was defined as the power emitted per solid angle, while here it is the power emitted in all directions.

Then Eq. (1.11.18) becomes

$$n(>S) = \frac{4\pi}{H_0^3}\int_0^\infty N(P)dP \times\left[\frac{1}{3}\left(\frac{PH_0^2}{4\pi S}\right)^{3/2}\left(1-\frac{3}{2}(\alpha-q_0)\left(\frac{PH_0^2}{4\pi S}\right)^{1/2}+\ldots\right) -\frac{1}{4}\left(\frac{PH_0^2}{4\pi S}\right)^2(\beta+5+2q_0)+\ldots\right]$$

or, collecting terms,

$$n(>S) = \frac{1}{3\sqrt{4\pi}S^{3/2}}\int_0^\infty P^{3/2}N(P)dP \times\left[1-\frac{3}{4}(5+\beta+2\alpha)\left(\frac{PH_0^2}{4\pi S}\right)^{1/2}+\ldots\right] \tag{1.11.22}$$

We see that $n(>S)$ has a term with the familiar $S^{-3/2}$ dependence, plus a correction proportional to S^{-2} with a coefficient proportional to $5+\beta+2\alpha$. It is noteworthy that this coefficient is independent of q_0 or K. For the standard cosmology with no evolution of sources $\beta=-3$, and we have mentioned that $\alpha\approx 0.75$, so $5+\beta+2\alpha=3.5$. Although the precise value is uncertain, this coefficient is definitely positive, which means that for faint sources $n(>S)$ should fall off more slowly than $S^{-3/2}$. This is definitely not what is observed. [10] It has been known for many years that for $S>5\times10^{-26}\mathrm{Wm}^{-2}/\mathrm{Hz}$, the source count function $N(>S)$ falls off more rapidly than $S^{-3/2}$. The conclusion is inevitable that the number of radio sources per co-moving volume is decreasing, with $\beta<-6.5$. Radio source counts are useful in studying this evolution, but not for measuring cosmological parameters.

On the other hand, for the steady state cosmology (discussed in Section 1.5) we have $\beta=0$, so the coefficient $5+\beta+2\alpha\approx 6.5$, and the predicted number count $N(>S)$ decreases even more slowly with S, making the disagreement with experiment even worse than for the standard cosmology with no evolution of sources. Here it is not possible to save the situation by appealing to evolution, because the essence of the steady state model is that on the average there is no evolution. This observation

discredited the steady state model even before the discovery of the cosmic microwave radiation background.

10.1.14 1.12 Quintessence

So far, we have taken into account only non-relativistic matter, radiation, and a constant vacuum energy in calculating the rate of expansion of the universe. It appears that the vacuum energy is not only much smaller than would be expected from order-of-magnitude estimates based on the quantum theory of fields, but is only a few times greater than the present matter density. This has led to a widespread speculation that the vacuum energy is not in fact constant; it may now be small because the universe is old. A time-varying vacuum energy is sometimes called quintessence. [1]

The natural way to introduce a varying vacuum energy is to assume the existence of one or more scalar fields, on which the vacuum energy depends, and whose cosmic expectation values change with time. Scalar fields of this sort play a crucial part in the modern theory of weak

[4][7][10] For a list of major radio source surveys, and references to the original literature, see G&C, Sec. 14.8.

and electromagnetic interactions, and are also introduced in theories of inflation, as discussed in Chapters 4 and 10.

For simplicity, let us consider a single real scalar field $\varphi(\mathbf{x}, t)$. We will be concerned here with fields that are vary little on elementary particle spacetime scales, so the action of these field is taken to have a minimum number of spacetime derivatives:

$$I_\varphi = -\int d^4x \sqrt{-\operatorname{Det} g}\left[\frac{1}{2} g^{\lambda\kappa}\frac{\partial\varphi}{\partial x^\lambda}\frac{\partial\varphi}{\partial x^\kappa} + V(\varphi)\right] \tag{1.12.1}$$

with an unspecified potential function $V(\varphi)$. We are interested here in the case of a Robertson-Walker metric, and a scalar field that depends only on time, not position. In this case the formulas (B.66) and (B.67) for the scalar field energy density and pressure become

$$\rho_\varphi = \frac{1}{2}\dot{\varphi}^2 + V(\varphi) \tag{1.12.2}$$

$$p_\varphi = \frac{1}{2}\dot{\varphi}^2 - V(\varphi). \tag{1.12.3}$$

It follows immediately that $(1 + w)\rho_\varphi \geq 0$, where $w \equiv p_\varphi/\rho_\varphi$, so as long as $\rho_\varphi \geq 0$ this model has $w \geq -1$, and the phantom energy disaster discussed in Section 1.6 does not occur.

The equation (1.1.32) of energy conservation here reads

$$\ddot{\varphi} + 3H\dot{\varphi} + V'(\varphi) = 0, \tag{1.12.4}$$

(where as usual $H(t) \equiv \dot{a}(t)/a(t)$), which is the same as the field equation derived from the action (1.12.1). This is the equation of a particle of unit mass with one-dimensional coordinate φ, moving in a potential $V(\varphi)$ with a frictional force $-3H\dot{\varphi}$. The field will run toward lower values of $V(\varphi)$, finally coming to rest if it can reach any field value where $V(\varphi)$ is at least a local minimum. Unfortunately, we do not know any reason why the value of $V(\varphi)$ where it is stationary should be small.

Nevertheless, there are potentials that have some attractive properties once we adjust an additive constant in the potential to make them vanish at their stationary point. The original and simplest example is provided by a potential [2]

$$V(\varphi) = M^{4+\alpha}\varphi^{-\alpha} \tag{1.12.5}$$

where α is positive but otherwise arbitrary, and M is a constant with the units of mass (taking $\hbar = c = 1$), which gives $V(\varphi)$ the dimensions of an energy density. There is no special reason to believe that the potential has this form, and in particular there is no known reason for excluding an additive constant (including effects of quantum fluctuations in all other fields), which would give the potential a non-zero value at its stationary point, at $\varphi = \infty$. Nevertheless, it may be illuminating to work out the consequences of this one specific model of quintessence.

For any potential it is necessary to assume that at sufficiently early times ρ_φ was much less than the energy density ρ_R of radiation because, as we will see in Section 3.2, any appreciable increase in the energy density at the time of cosmological nucleosynthesis would lead to a helium abundance exceeding what is observed. At these early times the energy density of radiation (including particles like neutrinos with masses less than $k_B T$) is also greater than that of non-relativistic matter, so Eq. (1.5.34) gives $a(t) \propto t^{1/2}$, and therefore $H = 1/2t$. The field equation (1.12.4) with potential (1.12.5) then reads

[471] For reviews with references to the original literature, see B. Ratra and P. J. E. Peebles, Rev. Mod. Phys. 75, 559 (2003); E. V. Linder, 0704.2064.

$$\ddot{\varphi} + \frac{3}{2t}\dot{\varphi} - \alpha M^{4+\alpha}\varphi^{-\alpha-1} = 0 \tag{1.12.6}$$

This has a solution

$$\varphi = \left(\frac{\alpha(2+\alpha)^2 M^{4+\alpha} t^2}{6+\alpha}\right)^{\frac{1}{2+\alpha}} \tag{1.12.7}$$

Both $\dot{\varphi}^2$ and $V(\varphi)$ then go as $t^{-2\alpha/(2+\alpha)}$, and therefore at very early times ρ_φ must have been less than ρ_R, which goes as t^{-2}. This solution is not unique, but it is an attractor, in the sense that any other solution that comes close to it will approach it as t increases. (To see this, note that a small perturbation $\delta\varphi$ of the solution (1.12.7) will satisfy
$0 = \delta\ddot{\varphi} + \frac{3}{2t}\delta\dot{\varphi} + \alpha(1+\alpha)M^{4+\alpha}\varphi^{-\alpha-2}\delta\varphi = \delta\ddot{\varphi} + \frac{3}{2t}\delta\dot{\varphi} + \frac{(6+\alpha)(1+\alpha)}{(2+\alpha)^2 t^2}\delta\varphi$.
This has two independent solutions of the form

$$\delta\varphi \propto t^\gamma, \quad \gamma = -\frac{1}{4} \pm \sqrt{\frac{1}{16} - \frac{(6+\alpha)(1+\alpha)}{(2+\alpha)^2}}.$$

The square root is imaginary for $\alpha > 0$, so both solutions for $\delta\varphi$ decay as $t^{-1/4}$ for increasing t, while φ itself is increasing.) For this reason, the particular solution of Eq. (1.12.6) that goes as Eq. (1.12.7) for $t \to 0$ is known as the tracker solution. There is no particular physical reason to require that the initial conditions for the scalar field are such that the scalar field has approached the tracker solution by the present moment (the set of such initial conditions is called the "basin of attraction"), but since this requirement would make the present evolution of the scalar field insensitive to the initial conditions, it has the practical advantage of providing a model of quintessence with just two free parameters: M and α.

Nothing much changes when the radiation energy density drops below the energy density of non-relativistic matter. The tracker solution for the scalar field continues to grow as $t^{2/(2+\alpha)}$ (though with a different constant factor), so $\dot{\varphi}^2$ and $V(\varphi)$ continue to fall as $t^{-2\alpha/(2+\alpha)}$. But ρ_M and ρ_R are decreasing faster, like t^{-2} and $t^{-8/3}$, respectively, so eventually ρ_M and ρ_R will fall below ρ_φ. It is interesting that the value of φ where ρ_φ becomes equal to ρ_M is independent of the unknown constant M. When the expansion is dominated by matter ρ_M is given by Eq. (1.5.31) as $1/6\pi G t^2$, while (1.1.2), (1.12.5) and (1.12.7) give $\rho_\varphi \approx M^{2(4+\alpha)/(2+\alpha)} t^{-2\alpha/(2+\alpha)}$, so the time t_c at which $\rho_\varphi = \rho_M$ is of order

$$t_c \approx M^{-(4+\alpha)/2} G^{-(2+\alpha)/4} \tag{1.12.8}$$

Using this in Eq. (1.12.7) then gives

$$\varphi(t_c) \approx G^{-1/2} \tag{1.12.9}$$

Once ρ_M falls well below ρ_φ, the equation of motion of $\varphi(t)$ becomes

$$\ddot{\varphi} + \sqrt{24\pi G\rho_\varphi}\,\dot{\varphi} - \alpha M^{4+\alpha}\varphi^{-\alpha-1} = 0 \tag{1.12.10}$$

with ρ_φ given by Eq. (1.12.2). The tracker solution in this era has a complicated time dependence, but it becomes simple again at sufficiently late times, times that may be later than the present. We can guess that the damping term proportional to $\dot{\varphi}$ in this equation will eventually slow the growth of φ, so that $\dot{\varphi}^2$ will become less than $V(\varphi)$, and also guess that the

[472] P. J. E. Peebles and B. Ratra, Astrophys. J. 325, L17 (1988); B. Ratra and P. J. E. Peebles, Phys. Rev. D 37, 3406 (1988); C. Wetterich, Nucl. Phys. B302, 668 (1988). Quintessence models with this potential were intensively studied by I. Zlatev, L. Wang, and P. J. Steinhardt, Phys. Rev. Lett. 82, 896 (1999); P. J. Steinhardt, L. Wang, and I. Zlatev, Phys. Rev. D 59, 123504 (1999).

inertial term proportional to $\ddot{\varphi}$ will become negligible compared to the damping and potential terms. (Similar "slow roll" conditions will play an important role in the theory of inflation, described in Chapters 4 and 10.) Equation (1.12.10) then becomes

$$\sqrt{24\pi G M^{4+\alpha}\varphi^{-\alpha}}\dot{\varphi} = \alpha M^{4+\alpha}\varphi^{-\alpha-1}$$

and so

$$\dot{\varphi} = \frac{\alpha M^{2+\alpha/2}\varphi^{-\alpha/2-1}}{\sqrt{24\pi G}} \tag{1.12.11}$$

The solution is

$$\varphi = M\left(\frac{\alpha(2+\alpha/2)t}{\sqrt{24\pi G}}\right)^{1/(2+\alpha/2)} \tag{1.12.12}$$

(In general this involves a redefinition of the zero of time, to avoid a possible integration constant that might be added to t.) We can now check the approximations used in deriving Eq. (1.12.11), of which this is the solution. From Eq. (1.12.12) we see that $\dot{\varphi}^2 \propto t^{-(2+\alpha)/(2+\alpha/2)}$ while $V(\varphi) \propto t^{-\alpha/(2+\alpha/2)}$, so the kinetic energy term in Eq. (1.12.2) does become small compared with the potential term at late times. Also, $\ddot{\varphi} \propto t^{-(3+\alpha)/(2+\alpha/2)}$ while $V'(\varphi) \propto t^{-(1+\alpha)/(2+\alpha/2)}$, so the inertial term in Eq. (1.12.10) does become small compared with the potential term at late times. Eq. (1.12.12) is therefore a valid asymptotic solution of Eq. (1.12.10) for $t \to \infty$. Numerical calculations show that it is not only a solution for $t \to \infty$; it is the asymptotic form approached for $t \to \infty$ by the tracker solution.

With $\rho_\varphi \propto t^{-\alpha/(2+\alpha/2)}$ dominating the expansion rate at late times, we have $\dot{a}/a \propto t^{-\alpha/2(2+\alpha/2)}$, so

$$\ln a \propto t^{2/(2+\alpha/2)} \tag{1.12.13}$$

This is a similar but less rapid growth of a than would be produced by a cosmological constant, for which $\ln a \propto t$. The difference between the deceleration parameter q_0 and the value -1 for an expansion dominated by a cosmological constant vanishes as $t^{-(2+\alpha)/(2+\alpha/2)}$. Note that the radiation and matter densities decrease as $1/a^4$ and $1/a^3$ respectively, and the curvature decreases as $1/a^2$, all of which have a much faster rate of decrease with time than the power-law decrease of ρ_φ, so the expansion rate is indeed dominated by ρ_φ at late times, justifying the derivation of Eq. (1.12.10).

We have found that, at least for a range of initial conditions, the potential (1.12.5) leads to an expansion that is dominated by radiation and then matter at early times, but becomes dominated by the scalar field energy at late times. But to get agreement with observation it is necessary arbitrarily to exclude a large constant term that might be added to (1.12.5), and also to adjust the value of M to make the critical time (1.12.8) at which the values of ρ_φ and ρ_M cross be close to the present moment $t_0 \approx 1/H_0$. Specifically, Eq. (1.12.8) shows that we need the constant factor in $V(\varphi)$ to take the value

$$M^{4+\alpha} \approx G^{-1-\alpha/2}H_0^2. \tag{1.12.14}$$

There is no known reason why this should be the case.

Several groups of observers are now planning programs to discover whether the vacuum energy density is constant, as in the case of a cosmological constant, or changing with time. In such programs, one would compare the observed luminosity distance (or angular diameter distance) with a formula obtained by replacing the term Ω_Λ in the argument of the square root in Eq. (1.5.45) with a time-varying dark energy term. These observations will not actually measure

the value w_0 of w at the present time, much less the present time derivatives $\dot{w}_0, \ddot{w}_0$, etc., because for that purpose it would be necessary to have extremely precise measurements of the luminosity distance or angular-diameter distance for small redshifts. Instead, measurements will be made with only moderate precision, but over a fairly large range of redshifts. To compare such measurements with theory, one needs a model of the time-variation of the dark energy. One model is simply to assume that w is constant, or perhaps varying linearly with time or redshift, but there is no physical model that entails such behavior. [3] It seems preferable to compare observation with the model of a scalar field rolling down a potential, which (whatever reservations may have about its naturalness) at least provides a physically possible model of varying dark

energy. [4] Because these observations are difficult, it pays to adopt scalar field models with just two parameters, which can if we like be expressed in terms of $\Omega_\Lambda = 1 - \Omega_M$ (assuming flatness and neglecting the radiation energy density) and w_0.

One possibility is to suppose that over the latest e-folding of cosmic expansion the scalar field φ has taken values for which $V(\varphi)$ is only slowly varying. If $V(\varphi)$ were constant, we would have a constant vacuum energy, with $w = -1$, and the only parameter to measure would be Ω_V. For a two-parameter fit, we can take $V(\varphi)$ to vary linearly with φ :

$$V(\varphi) = V_0 + (\varphi - \varphi_0)\, V_0' \tag{1.12.15}$$

This is valid if the fractional change in $V'(\varphi)$ in a time interval of order $1/H_0$ is small; that is, if $|V_0''\dot{\varphi}_0| \ll H_0\, |V_0'|$.

The field equation (1.12.4) for $\varphi(t)$ can be put in a convenient dimensionless form by replacing the dependent variable t and independent variable φ with dimensionless variables x and ω, defined by

$$x \equiv H_0\sqrt{\Omega_M}t, \quad \omega \equiv \frac{8\pi G V(\varphi)}{3\Omega_M H_0^2} \tag{1.12.16}$$

Because V is linear in φ, we have

$$\dot{\varphi} = \frac{3\Omega_M H_0^2 \dot{\omega}}{8\pi G V_0'} = \frac{3\Omega_M^{3/2} H_0^3}{8\pi G V_0'}\frac{d\omega}{dx}$$

Then Eq. (1.12.4) becomes

$$\frac{d^2\omega}{dx^2} + 3\mathcal{H}\frac{d\omega}{dx} + \lambda = 0 \tag{1.12.17}$$

where λ is the dimensionless parameter

$$\lambda \equiv \frac{8\pi G V_0'^2}{3H_0^4\Omega_M^2} \tag{1.12.18}$$

and $\mathcal{H}$ is a function of ω and $d\omega/dx$:

$$\mathcal{H} \equiv \frac{H}{H_0\sqrt{\Omega_M}} = \sqrt{(1+z)^3 + \omega + \frac{1}{2\lambda}\left(\frac{d\omega}{dx}\right)^2} \tag{1.12.19}$$

We will also need the differential equation for the redshift:

[473] Other assumptions about the form of w as a function of redshift that can mimic scalar field models have been considered by J. Weller and A. Albrecht, Phys. Rev. D 65, 103512 (2002); E. V. Linder, Phys. Rev. Lett. 90, 091301 (2003) [astro-ph/0208512].

[474] This approach is followed by D. Huterer and H. V. Peiris, Phys. Rev. D 75, 083502 (2007) [astroph/0610427]; R. Crittenden, E. Majerotto, and F. Piazza, astro-ph/0702003.

$$\frac{dz}{dx} = -\mathcal{H}(1+z) \tag{1.12.20}$$

In general, even if we wrote all derivatives with respect to x in terms of derivatives with respect to z, to solve these equations we would need initial conditions for ω and $d\omega/dz$ at some initial z, which with λ would give a threeparameter set of solutions. However, assuming that for large redshift the energy density is dominated by matter rather than vacuum energy (which as we shall see is the case), the derivative $d\omega/dx$ sufficiently late in the matterdominated era becomes quite insensitive to initial conditions. [5] For $z \gg 1$, Eq. (1.12.19) gives

$$\mathcal{H} \to (1+z)^{3/2} \tag{1.12.21}$$

and (1.12.17) and (1.12.20) then have the solution

$$1 + z \to \left(\frac{3x}{2}\right)^{-2/3}, \quad \frac{d\omega}{dx} \to -\frac{\lambda x}{3} \tag{1.12.22}$$

(An integration constant in the solution for z has been absorbed into the definition of x, setting the zero of time. An integration constant in the solution for $d\omega/dx$ has been dropped, because it gives a term in $d\omega/dx$ that dies away with increasing time as $x^{-2} \propto t^{-2}$.) The free parameters in our solution are then λ, together with the value of ω at some arbitrary initial value x_1 of x, taken sufficiently small so that at x_1 the energy density is dominated by matter rather than vacuum energy. (Note that the constant V_0 appears nowhere in these equations; it contributes a term to $\omega(x_1)$, but there is no need to isolate this term.) One must adopt various trial values of λ and $\omega(x_1)$; use Eq. (1.12.22) to calculate $1+z$ and $d\omega/dx$ at $x = x_1$; with these initial conditions, integrate the differential equations (1.12.17) and (1.12.20) numerically from x_1 to a value x_0 where $z = 0$; and then if we like calculate the values of $\Omega_V = 1 - \Omega_M$ and the present value w_0 of the ratio p_φ/ρ_φ for this particular solution, [6] using

$$\frac{\Omega_\Lambda}{\Omega_M} = \omega(x_0) + \frac{1}{2\lambda}\left(\frac{d\omega}{dx}\right)^2_{x=x_0}, \quad w_0 = \frac{(d\omega/dx)^2_{x=x_0} - 2\lambda\omega(x_0)}{(d\omega/dx)^2_{x=x_0} + 2\lambda\omega(x_0)} \tag{1.12.23}$$

The ratio of the dark energy at a given time to its value at the present is

$$\xi \equiv \frac{\rho_V(t)}{\rho_V(t_0)} = \frac{(d\omega(x)/dx)^2 + 2\lambda\omega(x)}{(d\omega/dx)^2_{x=x_0} + 2\lambda\omega(x_0)} \tag{1.12.24}$$

For instance, if we take $\Omega_\Lambda = 1 - \Omega_M = 0.76$ and $w_0 = -0.777$, the ratio ξ of the dark energy density to its value at present rises to 1.273 at $z = 1$ and to 1.340 at infinite redshift. [7] The leveling off of $\xi(z)$ for large z occurs because the growth of the matter density for increasing redshift makes the expansion rate grow, so that the friction term $3H\dot{\varphi}$ in Eq. (1.12.4) freezes the value of the scalar field at early times.

It should not be thought that the leveling off of the dark energy for large z for the potential (1.12.15) means that in analyzing dark energy observations with this potential one must give up the idea motivating theories of quintessence, that the vacuum energy is now small because the universe is old. In fact, for the potential $V(\varphi) \propto \varphi^{-\alpha}$, for typical initial conditions the quintessence energy drops at first precipitously, and then levels off while the scalar field rolls slowly down the potential until the field approaches the tracker solution, with the tracker

[475] R. Cahn, private communication. Cahn has also shown that the approximation of neglecting the second derivative term in the field equation does not work well in this context.

[6] As already mentioned, with models of this sort one can only have $w_0 > -1$. To compare the case $w_0 < -1$ with observation, it is necessary to adopt a model with the opposite sign for the derivative term in the action (1.12.1). The analysis given here can then be applied, with only obvious sign changes here and there.

solution not reached by the present time if α is small. [8] The condition $|V_0''\dot{\varphi}_0| \ll H_0\,|V_0'|$ for treating this potential as linear over a time of order $1/H_0$ is satisfied if $\alpha(1+\alpha)\varphi_0^{-2} \ll 8\pi G$, which in light of Eq. (1.12.9) is likely to be satisfied if $\alpha < 1$.

Another possible two-parameter model is provided by the same potential, $V(\varphi) \propto \varphi^{-\alpha}$, but now under the assumption that the tracker solution is reached by some early time (say, for $z \leq 10$) in the matter-dominated era. With this assumption the observable history of dark energy is insensitive to initial conditions, so the model has just two parameters: M and α. The equations of this model can be put in dimensionless form by writing the coupling constant of this potential in terms of a dimensionless parameter β as

$$M^{4+\alpha} \equiv \beta\Omega_M H_0^2 (8\pi G)^{-1-\alpha/2} \tag{1.12.25}$$

and replacing the dependent variable t and independent variable φ with dimensionless variables x and f, defined by

$$t \equiv x/H_0\sqrt{\Omega_M}, \quad \varphi(t) \equiv f(x)/\sqrt{8\pi G} \tag{1.12.26}$$

The field equation (1.12.4) (with no slow roll approximation) in the era dominated by matter and vacuum energy then takes the form

$$\frac{d^2 f}{dx^2} + 3\mathcal{H}\frac{df}{dx} - \alpha\beta f^{-\alpha-1} = 0 \tag{1.12.27}$$

where

$$\mathcal{H} \equiv H/\sqrt{\Omega_M}H_0 = \sqrt{\frac{1}{6}\left(\frac{df}{dx}\right)^2 + \frac{\beta}{3}f^{-\alpha} + (1+z)^3} \tag{1.12.28}$$

in which we also need

$$\frac{dz}{dx} = -\mathcal{H}(1+z) \tag{1.12.29}$$

Because the large z solution (1.12.7) is an attractor, the initial conditions introduce no new free parameters; in terms of these dimensionless variables, the initial conditions are that, for $x \to 0$,

$$f \to \left[\frac{\alpha\beta(\alpha+2)^2 x^2}{2(\alpha+4)}\right]^{1/(\alpha+2)}, \quad 1+z \to \left(\frac{2}{3x}\right)^{2/3} \tag{1.12.30}$$

We need to integrate the equations (1.12.27) and (1.12.29) from some small x (say, $x = 0.01$) to a value x_0 at which $z = 0$, with the initial conditions (1.12.30), and then evaluate $\Omega_M = 1 - \Omega_\Lambda$ from the condition that $\mathcal{H}(x_0) = 1/\sqrt{\Omega_M}$. We can also evaluate the present value w_0 of $w \equiv p_\varphi/\rho_\varphi$ from the formula

$$w_0 = \frac{f'^2(x_0)\, f(x_0)^\alpha/2\beta - 1}{f'^2(x_0)\, f(x_0)^\alpha/2\beta + 1} \tag{1.12.31}$$

and then replace the parameters α and β with Ω_M and w_0. For instance, if we arbitrarily take $\alpha = 1$, then to get the realistic value $\Omega_M = 0.24$ we must take $\beta = 9.93$, in which case $w_0 = -0.777$. Of course, we can get any other values of w_0 greater than -1 by choosing different values of α and re-adjusting β to give the same value of Ω_M (though for small α, the range

[477] Numerical results for various values of redshift are given in Table 1.1. These results for the linear potential were calculated by R. Cahn, private communication.

[8] Steinhardt, Wang, and Zlatev, ref. 2.

of initial conditions that allow the tracker solution to be reached well before the present is relatively small.) For instance, for $\alpha = 1/2$ we must take $\beta = 7.82$ to have $\Omega_M = 0.24$, and in this case we calculate that $w_0 = -0.87$. (For the case $w < -1$, see footnote 6.) The ratios of dark energy to its value at present calculated in this way for $\Omega_M = 0.24$ and $w_0 = -0.777$ are shown in Table 1.1, along with the values calculated with the same choice of Ω_M and w_0 for both the case of constant w and for the linear potential (1.12.15). The tracker and linear models evidently represent opposite extreme assumptions about the time-dependence of dark

Table 1.1: Ratio of dark energy to its present value, for the tracker solution with the potential (1.12.5), and for the linear potential (1.12.15), calculated for $\Omega_{M}=1-\Omega_{\Lambda}=0.24$ and $w_0 = -0.777$, compared with the results for a constant $w = -0.777$.

z	tracker	linear	constant w
0	1	1	1

energy, but both are better motivated physically than the assumption of a constant w.

10.1.15 1.13 Horizons

Modern cosmological theories can exhibit horizons of two different types, which limit the distances at which past events can be observed or at which it will ever be possible to observe future events. These are called by Rindler [1] particle horizons and event horizons, respectively.

According to Eq. (1.2.2), if the big bang started at a time $t = 0$, then the greatest value $r_{\rm max}\,(t)$ of the Robertson-Walker radial coordinate from which an observer at time t will be able to receive signals traveling at the speed of light is given by the condition

$$\int_0^t \frac{dt'}{a\,(t')} = \int_0^{r_{\rm max}(t)} \frac{dr}{\sqrt{1-Kr^2}} \tag{1.13.1}$$

Thus there is a particle horizon unless the integral $\int dt/a(t)$ does not converge at $t = 0$. It does converge in conventional cosmological theories; whatever the contribution of matter or vacuum energy at the present, it is likely that the energy density will be dominated by radiation at early times, in which case $a(t) \propto t^{1/2}$, and the integral converges. The proper distance of the horizon is given by Eq. (1.1.15) and (1.13.1) as

$$d_{\rm max}(t) = a(t)\int_0^{r_{\rm max}(t)} \frac{dr}{\sqrt{1-Kr^2}} = a(t)\int_0^t \frac{dt'}{a\,(t')} \tag{1.13.2}$$

For instance, during the radiation-dominated era $a(t) \propto t^{1/2}$, so $d_{\rm max}\,(t) = 2t = 1/H$. Well into the matter-dominated era most of the integral over time in Eq. (1.13.1) comes from a time when $a \propto t^{2/3}$, so that $d_{\rm max}(t) \simeq 3t = 2/H$. At present most of the integral over t' comes

[471] W. Rindler, Mon. Not. Roy. Astron. Soc. 116, 663 (1956).

from a period when the expansion is dominated by matter and the vacuum energy, and perhaps curvature as well. According to Eq. (1.5.41), the particle horizon distance at present is

$$d_{\max}(t_0) = \frac{1}{H_0}\int_0^1 \frac{dx}{x^2\sqrt{\Omega_\Lambda + \Omega_K x^{-2} + \Omega_M x^{-3}}} \tag{1.13.3}$$

We will see in Chapter 4 that there may have been a time before the radiationdominated era in which there was nothing in the universe but vacuum energy, in which case the particle horizon distance would actually be infinite. But as far as telescopic observations are concerned, Eq. (1.13.3) gives the proper distance beyond which we cannot now see.

Just as there are past events that we cannot now see, there may be events that we never will see. Again returning to Eq. (1.2.2), if the universe re-collapses at a time T, then the greatest value $r_{\rm MAX}$ of r from which an observer will be able to receive signals traveling at the speed of light emitted at any time later than t is given by the condition

$$\int_t^T \frac{dt'}{a(t')} = \int_0^{r_{\rm MAX}(t)} \frac{dr}{\sqrt{1-Kr^2}} \tag{1.13.4}$$

Even if the future is infinite, if the integral $\int dt/a(t)$ converges at $t = \infty$ there will be an event horizon given by

$$\int_t^\infty \frac{dt'}{a(t')} = \int_0^{r_{\rm MAX}(t)} \frac{dr}{\sqrt{1-Kr^2}} \tag{1.13.5}$$

Since co-moving sources are labeled with a fixed value of r, the condition $r < r_{\rm MAX}$ limits the events occurring at time t that we can ever observe. In the case where the universe does not recollapse, the proper distance to the event horizon is given by

$$d_{\rm MAX}(t) = a(t)\int_0^{r_{\rm MAX}(t)} \frac{dr}{\sqrt{1-Kr^2}} = a(t)\int_t^\infty \frac{dt'}{a(t')} \tag{1.13.6}$$

In the absence of a cosmological constant, $a(t)$ grows like $t^{2/3}$, and the integral diverges, so that there is no event horizon. But with a cosmological constant $a(t)$ will eventually grow as $\exp(Ht)$ with $H = H_0\Omega_\Lambda^{1/2}$ constant, and there really is an event horizon, which approaches the value $d_{\rm MAX}(\infty) = 1/H$. As time passes all sources of light outside our gravitationally bound Local Group will move beyond this distance, and become unobservable. The same is true for the quintessence theory described in the previous section. In that case $a(t)$ eventually grows as $\exp(\text{ constant } \times t^{2/(2+\alpha/2)})$, so for any $\alpha \geq 0$ the integral (1.13.6) again converges.

If a source is at a radial coordinate r in a Robertson-Walker coordinate system based on us, then we are at a radial coordinate r in a RobertsonWalker coordinate system based on the source. Hence Eq. (1.13.4) or (1.13.5) also gives the greatest radial coordinate to which, starting at time t, we will ever be able to travel.

10.2 The Cosmic Microwave Radiation Background

Before the mid-1960s by far the greatest part of our information about the structure and evolution of the universe came from observations of the redshifts and distances of distant galaxies, discussed in the previous chapter. In 1965 a nearly isotropic background of microwave radiation was discovered, which has provided a wealth of new cosmological data. After reviewing the expectations and discovery of this radiation, this chapter will explore some of its implications. We will only be able to give a first look at the anisotropies in this radiation in this chapter. In Chapter 7 we will return to this very important topic, applying the analysis of the evolution of cosmological perturbations presented in Chapters 5 and 6, and in Chapter 10 we will consider the origin of these perturbations in the very early universe.

10.2.1 2.1 Expectations and discovery of the microwave background

The work done by pressure in an expanding fluid uses heat energy drawn from the fluid. The universe is expanding, so we expect that in the past matter was hotter as well as denser than at present. If we look far enough backward in time we come to an era when it was too hot for electrons to be bound into atoms. At sufficiently early times the rapid collisions of photons with free electrons would have kept radiation in thermal equilibrium with the hot dense matter. The number density of photons in equilibrium with matter at temperature T at photon frequency between ν and $\nu + d\nu$ is given by the black-body spectrum:

$$n_T(v)dv = \frac{8\pi v^2 dv}{\exp\left(hv/k_{\mathcal{B}}T\right) - 1} \tag{2.1.1}$$

where h is the original Planck's constant (which first made its appearance in a formula equivalent to this one), and $k_{\mathcal{B}}$ is Boltzmann's constant. (Recall that we are using units with $c = 1$.)

As time passed, the matter became cooler and less dense, and eventually the radiation began a free expansion, but its spectrum has kept the same form. We can see this most easily under an extreme assumption, that there was a time t_L when radiation suddenly went from being in thermal equilibrium with matter to a free expansion. (The subscript L stands for "last scattering.") Under this assumption, a photon that has frequency v at some later time t when photons are traveling freely would have had frequency
$va(t)/a\left(t_L\right)$ at the time the radiation went out of equilibrium with matter, and so the number density at time t of photons with frequency between v and $v + dv$ would be

$$n(v,t)dv = \left(a\left(t_L\right)/a(t)\right)^3 n_{T(t_L)}\left(va(t)/a\left(t_L\right)\right) d\left(va(t)/a\left(t_L\right)\right) \tag{2.1.2}$$

with the factor $\left(a\left(t_L\right)/a(t)\right)^3$ arising from the dilution of photons due to the cosmic expansion. Using Eq. (2.1.1) in (2.1.2), we see that the redshift factors $a(t)/a\left(t_L\right)$ all cancel except in the exponential, so that the number density at time t is given by

$$n(v,t)dv = \frac{8\pi v^2 dv}{\exp\left(hv/k_{\mathcal{B}}T(t)\right) - 1} = n_{T(t)}(v)dv \tag{2.1.3}$$

where

$$T(t) = T\left(t_L\right) a\left(t_L\right)/a(t) \tag{2.1.4}$$

Thus the photon density has been given by the black-body form even after the photons went out of equilibrium with matter, but with a redshifted temperature (2.1.4).

This conclusion is obviously unchanged if the transition from opacity to transparency occupied a finite time interval, as long as the interactions of photons with matter during this interval are limited to elastic scattering processes in which photon frequencies are not changed. This is a very good approximation. We will see in Section 2.3 that the last interaction of photons with matter (until near the present) took place at a time when the cosmic temperature T was of order $3,000$ K, when by far the most important interaction was the elastic scattering of photons with electrons, in which the fractional shift of photon frequency was of order $k_{\mathcal{B}}T/m_e c^2 \approx 3 \times 10^{-7}$. In the following section we shall show that, because of the large photon entropy, even the small shift of photon frequency in elastic scattering and the relatively infrequent inelastic interactions of photons with hydrogen atoms had almost no effect on the photon spectrum.

It was George Gamow and his collaborators who first recognized in the late 1940s that the universe should now be filled with black-body radiation. [1] The first plausible estimate of the

present temperature of this radiation was

made in 1950 by Ralph Alpher and Robert Herman. [2] On the basis of considerations of cosmological nucleosynthesis, to be discussed in Section 3.2, they found a present temperature of 5 K . This work was largely forgotten in subsequent decades, until in 1965 a group at Princeton started to search for a cosmic radiation background left over from the early universe. They had only a rough idea of the temperature to be expected, based on a nucleosynthesis calculation of P. J. E. Peebles, which suggested a value of 10 K.[3] Before they could complete their experiment the radiation was discovered in a study of noise backgrounds in a radio telescope by Arno Penzias and Robert Wilson, [4] who published their work along with a companion article [5] by the Princeton group explaining its possible cosmological significance. [6]

Originally Penzias and Wilson could only report that the antenna temperature at a wavelength 7.5 cm was 3.5 ± 1.0 K, meaning that the intensity of the radiation at this one wavelength agreed with Eq. (2.1.1) for this temperature. This of course did not show that they were observing black-body radiation. Then Roll and Wilkinson [7] measured the radiation intensity at a wavelength of 3.2 cm , finding an antenna temperature of 3.0 ± 0.5 K, in agreement with what would be expected for black-body radiation at the temperature measured by Penzias and Wilson. In the following few years a large number of measurements were made by other radio astronomers at other wavelengths. These measurements also gave antenna temperatures at the wavelengths being studied around 3 K , with uncertainties that gradually improved to of order 0.2 K . But this also did not establish the black-body nature of the radiation, because these measurements were all at wavelengths greater than about 0.3 cm , where the black-body energy distribution $h\nu n_T(\nu)$ with $T \approx 3$ K has its maximum. For these long wavelengths the argument of the exponential is small, and Eq. (2.1.1) gives

$$h\nu n_T(\nu) \simeq 8\pi\nu^2 k_{\mathcal{B}} T, \tag{2.1.5}$$

This is the Rayleigh-Jeans formula of classical statistical mechanics, but it describes the long-wavelength distribution of radiant energy under various circumstances more general than black-body radiation. For instance, black-body radiation diluted by an expansion that preserves the energy of individual photons also has $h\nu n(\nu) \propto \nu^2$ for low frequencies. [8] To confirm that the cosmic microwave background radiation is really described by the black-body formula, it was necessary to see at least the beginning of the exponential fall-off of $n_T(\nu)$ for wavelengths shorter than about 0.3 cm .

This was difficult because the earth's atmosphere becomes increasingly opaque at wavelengths shorter than about 0.3 cm . However, there had been a measurement of the radiation temperature at a wavelength 0.264 cm in 1941, long before the discovery by Penzias and Wilson. In between the star ζ Oph and the earth there is a cloud of cold molecular gas, whose absorption of light produces dark lines in the spectrum of the star. In 1941 W. S. Adams, [9]

following a suggestion of Andrew McKellar, found two dark lines in the spectrum of ζ Oph that could be identified as due to absorption of light by cyanogen (CN) in the molecular cloud. The first line, observed at a wavelength of $3,874.62$Å, could be attributed to absorption of light from the CN ground state, with rotational angular momentum $J = 0$, leading to the component of the first vibrationally excited state with $J = 1$. But the second line, at $3,874.00$Å, represented absorption from the $J = 1$ rotationally excited vibrational ground state, leading to the $J = 2$ component of the first vibrationally excited state. [10] From this, McKellar concluded [11] that a fraction of the CN molecules in the cloud were in the first excited rotational component of the vibrational ground state, which is above the true $J = 0$ ground state by an energy $hc/(0.264$ cm). and from this fraction he estimated an equivalent molecular temperature of 2.3 K. Of course, he did not know that the CN molecules were being excited by radiation, much less by black-body radiation. After the discovery by Penzias and Wilson several astrophysicists [12] independently noted that the old Adams-McKellar result could be explained by radiation with a

black-body temperature at wavelength 0.264 cm in the neighborhood of 3 K . Theoretical analysis showed that nothing else could explain the excitation of this rotational state. [13] This interpretation was then borne out by continuing observations on this and other absorption lines in CN as well as CH and CH^+in the spectrum of ζOph and other stars. [14]

The black-body spectrum of the cosmic microwave radiation background began to be established by balloon-borne and rocket-borne observations above the earth's atmosphere at wavelengths below 0.3 cm . For some years there were indications of an excess over the black-body formula at these short wavelengths. It was clearly necessary to do these observations from space, but this is difficult; to measure the absolute value of the microwave radiation intensity it is necessary to compare the radiation received from space with that emitted by a "cold load" of liquid helium, which rapidly evaporates. Finally, the Planck spectrum of the microwave background was settled in the 1990s by observations with the FIRAS radiometer carried by the Cosmic Background Explorer Satellite (COBE), launched in November 1989. [15] When a slide showing the agreement of the observed spectrum with the Planck black-body spectrum was shown by J. C. Mather at a meeting of the American Astronomical Society in January 1990, it received a standing ovation. It was found that the background radiation has a nearly exact black-body spectrum in the wavelength range from 0.5 cm to 0.05 cm.[16] The comparison of observation with the black-body spectrum is shown in Figure 2.1. After six years of further analysis, the temperature was given as 2.725 ± 0.002 K (95% confidence). [17] Other observations at wavelengths between 3 cm and 75 cm and at 0.03 cm are all consistent with a Planck distribution at this temperature. [18]

The energy density in this radiation is given by

$$\int_0^\infty h\nu n(\nu)d\nu = a_{\mathcal{B}}T^4 \tag{2.1.6}$$

where $a_{\mathcal{B}}$ is the radiation energy constant; in c.g.s. units,

[478] The sunlight falling on the earth's surface provides a pretty good example of dilute black-body radiation; it is described by the Planck formula (2.1.1), with $T \approx 6,000$ K the temperature of the sun's surface, but with the right-hand side of Eq. (2.1.1) multiplied by a factor $(R_\odot/r)^2$, where $R_\odot$ is the radius of the sun and r is the distance from the sun to the earth.

[9] W. S. Adams, Astrophys. J. 93, 11 (1941)

[10] Today the wavelengths of these two lines are more accurately known to be $3,874.608$ and $3,873.998$Å. There is another line at 3875.763Å, produced by transitions from the $J = 1$ rotationally excited vibrational ground state to the $J = 0$ component of the first vibrationally excited state.

$$a_{\mathcal{B}} = \frac{8\pi^5 k_{\mathcal{B}}^4}{15h^3c^3} = 7.56577(5) \times 10^{-15}\text{erg cm}^{-3}\text{deg}^{-4} \tag{2.1.7}$$

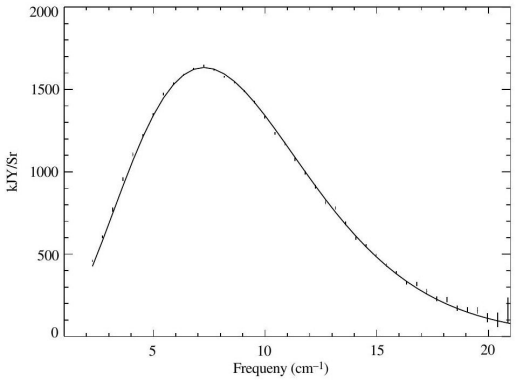

Figure 2.1: Comparison of the intensity of radiation observed with the FIRAS radiometer carried by COBE with a black-body spectrum with temperature 2.728 K , from D . J . Fixsen et al., Astrophys. J. 473, 576 (1996) [astro-ph/9605054]. The vertical axis gives the intensity in kiloJansky per steradian (one Jansky equals \$10ˆ{-23} \mathrm{erg} \mathrm{cm}ˆ{-2} \mathrm{˜s}ˆ{-1} \mathrm{˜Hz}ˆ{-1}\$); the horizontal axis gives the reciprocal wavelength in cm^{-1}. The 1σ experimental uncertainty in intensity is indicated by the tiny vertical bars; the uncertainty in wavelength is negligible.

Using $T = 2.725$ K, this gives an equivalent mass density (reverting to $c = 1$)

$$\rho_{\gamma 0} = a_{\mathcal{B}} T_{\gamma 0}^4 = 4.64 \times 10^{-34}\text{ g cm}^{-3}.$$

Taking the ratio of this with the critical density (1.5.28) gives

$$\Omega_\gamma \equiv \frac{\rho_{\gamma 0}}{\rho_{0\text{ crit}}} = 2.47 \times 10^{-5} h^{-2} \tag{2.1.8}$$

We will see in Section 3.1 that the photons are accompanied with neutrinos and antineutrinos of three different types, giving a total energy density in radiation (that is, in massless or nearly massless particles):

$$\rho_{R0} = \left[1 + 3\left(\frac{7}{8}\right)\left(\frac{4}{11}\right)^{4/3}\right]\rho_{\gamma 0} = 7.80 \times 10^{-34}\text{ g cm}^{-3}, \tag{2.1.9}$$

or in other words, using Eq. (1.5.28),

$$\Omega_R \equiv \frac{\rho_{R0}}{\rho_{0,\text{ crit}}} = 4.15 \times 10^{-5} h^{-2} \tag{2.1.10}$$

[astroph/9902027], gave a temperature 2.7377 ± 0.0038 K (95% confidence), but the result of Mather et al. seems to be the one usually quoted.

[18] For a review, see G. Sironi et al., in Proc. Third Sakharov Conf. - Moscow 2002 [astro-ph/0301354].

We see that ρ_{R0} is much less than the critical mass density needed to give $K = 0$, and much less even than the mass density of ordinary matter seen in stars. It is for this reason that we have generally neglected Ω_R in calculating luminosity distances as a function of redshift.

On the other hand, even at present the number density of photons is relatively very large. Eq. (2.1.1) gives

$$\begin{aligned} n_{\gamma 0} &= \int_0^\infty \frac{8\pi v^2 dv}{\exp\left(hv/k_{\mathcal{B}}T\right) - 1} = \frac{30\zeta(3)}{\pi^4}\frac{a_{\mathcal{B}}T^3}{k_{\mathcal{B}}} \\ &= 0.3702\frac{a_{\mathcal{B}}T^3}{k_{\mathcal{B}}} = 20.28[T(\deg K)]^3 \text{ cm}^{-3} \end{aligned} \tag{2.1.11}$$

where $\zeta(3) = 1.202057\ldots$ For $T = 2.725$ K this gives a present number density

$$n_{\gamma 0} = 410 \text{ photons } /\text{cm}^3 \tag{2.1.12}$$

This is much larger than the present number density n_{B0} of nucleons, given by

$$n_{B0} = \frac{3\Omega_B H_0^2}{8\pi G m_N} = 1.123 \times 10^{-5}\Omega_B h^2 \text{ nucleons } /\text{cm}^3 \tag{2.1.13}$$

Both n_γ and n_B vary with time as $a^{-3}(t)$, so the ratio n_γ/n_B has been the same at least during the whole period that photons have been traveling freely.

There is an effect of the cosmic microwave background that has long been expected but has been difficult to observe. A cosmic ray proton of moderate energy striking a photon in the cosmic microwave background can only scatter the photon, a process whose rate is proportional to the square of the fine structure constant $\alpha \simeq 1/137$. However, if the proton has sufficiently high energy then it is also possible for the photon to be converted into a π meson in the reactions $\gamma + p \to \pi^0 + p$ or $\gamma + p \to \pi^+ + n$, processes whose rate is proportional to α, not α^2. Assuming that high energy cosmic rays come to us from outside our galaxy, we therefore expect a dip in the spectrum of cosmic ray protons at an energy where the cross section for these processes becomes appreciable. [19] Although some pions can be produced at lower energy, the effective threshold is at a value of the total energy W of the

initial proton and photon in the center-of-mass system equal to $m_\Delta = 1232$ MeV , the mass of the pion-nucleon resonance with spin-parity $3/2^+$and isospin 3/2. The center of mass energy is

$$\begin{aligned} W &= \left(\left(q + \sqrt{p^2 + m_p^2}\right)^2 - |\mathbf{q} + \mathbf{p}|^2\right)^{1/2} \\ &\simeq \left(2qp(1 - \cos\theta) + m_p^2\right)^{1/2}, \end{aligned} \tag{2.1.14}$$

where $\mathbf{q}$ and $\mathbf{p}$ are the initial photon and proton momenta (with $p \gg m_p \gg q$) and θ is the angle between them. The threshold condition that $W > m_\Delta$ thus requires that

$$qp(1 - \cos\theta) > m_\Delta^2 - m_p^2. \tag{2.1.15}$$

The typical energy of photons in black-body radiation at temperature $T_{\gamma 0} = 2.725$ K is $\rho_{\gamma 0}/n_{\gamma 0} \simeq 6 \times 10^{-4}$eV, while the largest value for $1 - \cos\theta$ is 2 , so the effective threshold is roughly at a proton energy

[4719] K. Greisen, Phys. Rev. Lett. 16, 748 (1966); G. T. Zatsepin and V. A. Kuzmin, Pis'ma Sh. Exsp. Teor. Fiz. 4, 114 (1966) [transl. Sov. Phys. JETP Lett. 4, 78 (1966)]; F. W. Stecker, Phys. Rev. Lett. 21, 1016 (1968).

$$p_{\rm threshold} \approx \frac{m_\Delta^2 - m_p^2}{2\rho_{\gamma 0}/n_{\gamma 0}} \simeq 10^{20}{\rm eV} \tag{2.1.16}$$

This effect is not easy to see. The flux of cosmic ray protons with energies between E and $E + dE$ goes roughly as $E^{-3}dE$, so there are few protons at these very high energies, roughly one per square kilometer per year above 10^{19}eV and 0.01 per square kilometer per year above 10^{20}eV. At these rates, direct observation is clearly impossible, and the cosmic rays have had to be studied indirectly by observation at ground level of the large showers of photons and charged particles that they produce. Also, there is a smooth distribution of photon energies and directions, so one is not looking for a sharp cut-off at 10^{20}eV, but rather for a dip below the E^{-3} curve at around this energy. [20] No such effect was observed by the Akeno Giant Air Shower Array, [21] but a subsequent analysis of this and other observations showed the effect. [22] More recently signs of a drop appeared in the High Resolution Fly's Eye experiment. [23] In 2006 this group announced the observation of a "sharp suppression" of the primary cosmic ray spectrum at an energy of 6×10^{19}GeV, just about where expected. [24]

10.2.2 2.2 The equilibrium era

As already remarked in the previous section, if we look back in time sufficiently far, we surely must come to an era when the temperature and density were sufficiently high so that radiation and matter were in thermal equilibrium. We will now consider this era, jumping over the intermediate time when radiation was going out of equilibrium with matter, which will be the subject of the next section.

As we saw in the previous section, in a free expansion of photons, the frequency distribution preserves the Planck black-body form (2.1.1), but with a temperature that falls as $1/a(t)$. On the other hand, in a free expansion of non-relativistic particles such as electrons or nuclei, the momentum distribution preserves the Maxwell-Boltzmann form, $n(p)dp \propto \exp\left(-p^2/2mk_{\mathcal{B}}T\right)$, but since (as shown in Eq. (1.1.23)) the momentum of any particle decreases as the universe expands with $p \propto 1/a$, the temperature of the Maxwell-Boltzmann distribution decreases as $1/a^2(t)$. So if radiation is in equilibrium with matter, who wins? Does the temperature decrease as $1/a(t)$, or $1/a^2(t)$, or something more complicated?

The issue is settled democratically, on the basis of one particle, one vote. Since there are so many more photons than electrons or nucleons, the photons win, and the temperature decreases almost exactly as $1/a(t)$.

We can see this in more detail by applying the second law of thermodynamics. In equilibrium both the entropy and the baryon number (that is, at temperatures $\ll 10^{13}$ K, the number of protons and neutrons) in any co-moving volume were constant, and so their ratio, the entropy per baryon, was also constant. It is convenient to write the entropy per baryon as $k_{\mathcal{B}}\sigma$, with $k_{\mathcal{B}}$ the Boltzmann constant and σ dimensionless. The second law of thermodynamics tells us that this satisfies

$$d\left(k_{\mathcal{B}}\sigma\right) = \frac{d\left(\epsilon/n_B\right) + pd\left(1/n_B\right)}{T}, \tag{2.2.1}$$

[24] G. B. Thompson, for HiRes Collaboration, in Proc. Quarks '06 Conf. [astro-ph/0609403]; R. U. Abbasi et al., astro-ph/0703099.

where n_B is the baryon number density (so that $1/n_B$ is the volume per baryon), ϵ is the thermal energy density and p is the pressure. For simplicity, let us consider an ideal gas of photons and non-relativistic particles (mostly protons, helium nuclei, and electrons), with a fixed number (of order unity) $\mathcal{N}$ of the non-relativistic particles per baryon. Then

$$\epsilon = a_{\mathcal{B}} T^4 + \frac{3}{2} n_B \mathcal{N} k_{\mathcal{B}} T, \quad p = \frac{1}{3} a_{\mathcal{B}} T^4 + n_B \mathcal{N} k_{\mathcal{B}} T, \tag{2.2.2}$$

with $a_{\mathcal{B}}$ the radiation energy constant (2.1.7). The solution of Eq. (2.2.1) is here

$$\sigma = \frac{4 a_{\mathcal{B}} T^3}{3 n_B k_{\mathcal{B}}} + \mathcal{N} \ln \left(\frac{T^{3/2}}{n_B C} \right) \tag{2.2.3}$$

where C is an arbitrary constant of integration. It is the quantity σ that remains constant in thermal equilibrium.

We saw in the previous section that the first term in Eq. (2.2.3) is larger than 10^8 at present. (Compare Eqs. (2.1.12) and (2.1.13).) Let us tentatively assume that this quantity was also much larger than unity when photons were in equilibrium with matter. Since σ was constant in this era, this means that the ratio T^3/n_B would also have been very close to constant during the era of equilibrium, unless the quantity $T^{3/2}/n_B$ changed by an enormous amount. For instance, if at some time in the equilibrium era the first term in Eq. (2.2.3) were of order 10^8, then in order for the first term in Eq. (2.2.3) to have changed by even 0.01%, to keep σ constant the value of $T^{3/2}/n_B$ would have had to change by a factor $e^{10000/\mathcal{N}}$. We are not going to be considering such enormous density or temperature ratios here, so we can conclude that T^3/n_B was essentially constant in thermal equilibrium. We saw in the previous section that this ratio was also constant when the photons were traveling freely, and also when photons were interacting only by purely elastic Thomson scattering, so it has been close to constant from the beginning of the era considered here to the present. If we define the constant C in Eq. (2.2.3) to equal the value of $T^{3/2}/n_B$ at some typical time during the era of equilibrium, then the entropy per baryon throughout this era can be taken as

$$\sigma = \frac{4 a_{\mathcal{B}} T^3}{3 n_B k_{\mathcal{B}}} = \frac{3.60 n_{\gamma 0}}{n_{B0}} = 1.31 \times 10^8 h^{-2} \Omega_B^{-1} \tag{2.2.4}$$

The conservation of baryon number tells us that $n_B a^3$ is constant, so the constancy of (2.2.3) has the consequence that $T \propto 1/a$. (Note incidentally that if the first term in Eq. (2.2.3) were of order 10^{-8} instead of greater than 10^8, then it would be the logarithm in the second term that would have to remain constant during thermal equilibrium, in which case $T \propto n_B^{2/3} \propto a^{-2}$, as expected if non-relativistic particles dominate the thermal evolution.)

We can now see why the black-body spectrum with $T \propto 1/a$ is preserved as photons go out of equilibrium with matter, even when we take into account small inelastic effects, like the loss of energy to electron recoil in photon-electron scattering. Photons effectively stop gaining or losing energy to matter when $\Gamma_\gamma < H$, where $H \equiv \dot{a}/a$ and Γ_γ is the rate at which an individual photon loses or gains an energy $k_{\mathcal{B}} T$ through scattering on electrons (to be calculated later). But the rate Γ_e at which an individual electron would gain or lose an energy $k_{\mathcal{B}} T$ by scattering on photons is greater than Γ_γ by a factor $n_\gamma/n_e > 10^8$, so at the time that Γ_γ drops below H we still have $\Gamma_e \gg H$. Thus instead of the electron kinetic energies decreasing like $1/a^2$, as they would in a free expansion, they continue to remain in thermal equilibrium with the photons. While in equilibrium with matter
the photon temperature goes as $1/a$, and we saw in the previous section that when they stop interacting with matter the temperature continues to drop like $1/a$, so through this whole period the electron temperature also drops as $1/a$, and the last few exchanges of energy that photons have with electrons do not affect the photon energy distribution.

According to results quoted in the previous section, the present ratio of the equivalent photon and neutrino mass density and the total matter mass density $\rho_{M0} = \Omega_M \rho_{0,\,\mathrm{crit}}$ is

$$\frac{\rho_{R0}}{\rho_{M0}} = \frac{\Omega_R}{\Omega_M} = 4.15 \times 10^{-5} \Omega_M^{-1} h^{-2} \tag{2.2.5}$$

As we have seen, the photon and neutrino energy density varied as $T^4 \propto a^{-4}$ even before the photons began their free expansion, while the density of pressureless matter varied as a^{-3}, so ρ_R/ρ_M varied as $1/a \propto T$. Therefore the energy density of photons and neutrinos was equal to that of matter when the temperature was

$$T_{\mathrm{EQ}} = \frac{T_{\gamma 0} \Omega_M}{\Omega_R} = 6.56 \times 10^4 \text{ K} \times \Omega_M h^2 \tag{2.2.6}$$

and ρ_R was greater than ρ_M at earlier times. For $\Omega_M h^2 \simeq 0.15, T_{\mathrm{EQ}}$ is about 10^4 K.

Although collisions cannot change the distribution of photon energies as long as the photon number is much greater than the number of charged particles, at sufficiently high temperatures collisions can drastically change the energy of an individual photon. It is of some interest to work out when photons stopped exchanging energies of order $k_{\mathcal{B}} T$ with electrons. The rate at which any individual photon is scattered by electrons is $\Lambda_\gamma = \sigma_{\mathcal{T}} n_e c$, where n_e is the number density of electrons, and $\sigma_{\mathcal{T}} = 0.66525 \times 10^{-24} \mathrm{cm}^2$ is the cross section for Thomson scattering, the elastic scattering of photons by non-relativistic electrons. As we will see in Section 3.2, about 76% of the matter of the universe in this era was ionized hydrogen, with the rest helium, completely ionized at temperatures above $20,000$ K, so with one electron per nucleon for hydrogen and half an electron per nucleon for helium, the net number of electrons per nucleon is $0.76 + (1/2)0.24 = 0.88$, and the number density of electrons at temperature T is $n_e \simeq 0.88 n_B = 0.88 n_{B0} \left(T/T_{\gamma 0}\right)^3$, with a subscript zero as usual indicating the present moment. Using Eq. (2.1.13), the rate at which a photon is scattered by electrons is

$$\Lambda_\gamma = 0.88 n_{B0} \left(\frac{T}{T_{\gamma 0}}\right)^3 \sigma_{\mathcal{T}} c = 1.97 \times 10^{-19} \text{ s}^{-1} \times \Omega_B h^2 \left(\frac{T}{T_{\gamma 0}}\right)^3 \tag{2.2.7}$$

But this is not the rate that governs the effectiveness of the energy exchange between matter and radiation. A photon with energy much less than $m_e c^2$ that strikes a non-relativistic electron will transfer a momentum to the electron of the order of its own momentum, typically about $k_{\mathcal{B}} T$ (in units with $c = 1$), and so it will gain or lose an energy of order $\left(k_{\mathcal{B}} T\right)^2 / m_e$. (This agrees with Eq. (C.20) for $\omega \approx k_{\mathcal{B}} T \ll m_e$.) Hence the rate for energy transfer of order $k_{\mathcal{B}} T$ between a given photon and the electrons equals the rate of collisions times the fraction of the energy $k_{\mathcal{B}} T$ that is transferred per collision:

$$\Gamma_\gamma \simeq \left(\frac{k_{\mathcal{B}} T}{m_e}\right) \Lambda_\gamma \approx 9.0 \times 10^{-29} \text{ s}^{-1} \Omega_B h^2 \left(\frac{T}{T_{\gamma 0}}\right)^4 . \tag{2.2.8}$$

We have to compare this with the cosmic expansion rate. Let's tentatively assume that at the time that concerns us here the density of the universe was dominated by photons and neutrinos, not matter, in which case the cosmic expansion rate was

$$H \equiv \frac{\dot{a}}{a} = H_0 \sqrt{\Omega_R T^4 / T_{\gamma 0}^4} = 2.1 \times 10^{-20} \text{ s}^{-1} \left(\frac{T}{T_{\gamma 0}}\right)^2 . \tag{2.2.9}$$

Therefore Γ_γ was greater than H until the temperature dropped to a value of order

$$T_{\mathrm{freeze}} = 1.5 \times 10^4 \text{ K} \left(\Omega_B h^2\right)^{-1/2} \tag{2.2.10}$$

For $\Omega_B h^2 \simeq 0.02$, this is about 10^5 K. (Comparison with Eq. (2.2.6) shows that for plausible values of $\Omega_M h^2$ and $\Omega_B h^2$, as for instance $\Omega_M h^2 \simeq 0.15$ and $\Omega_B h^2 \simeq 0.02$, we have $T_{\rm freeze} > T_{\rm EQ}$, so the temperature (2.2.10) was reached while the expansion rate was still dominated by radiation, as we have been assuming.)

After the temperature dropped below about 10^5 K photons no longer exchanged appreciable energy with electrons, but at this temperature the rate (2.2.7) of elastic scattering was still roughly 10^5 times greater than H. If Eq. (2.2.7) remained valid then Λ_γ would remain larger than H until the temperature dropped to much lower temperature. For 3 K $\ll T \ll 10^4$ K the universe was matter-dominated, with

$$H = H_0 \sqrt{\Omega_M T^3/T_{\gamma 0}^3} = 3.3 \times 10^{-18} \text{ s}^{-1} \sqrt{\Omega_M h^2} \left(\frac{T}{T_{\gamma 0}}\right)^{3/2} .$$

This became equal to the rate given by Eq. (2.2.7) at a temperature $T \simeq 18 \text{ K} \left(\Omega_M h^2\right)^{1/3} / \left(\Omega_B h^2\right)^{2/3}$, or about 130 K for $\Omega_M h^2 = 0.15$ and $\Omega_B h^2 =$
0.02 , and until then each photon would be scattered many times by electrons in each doubling of $a(t)$. This is not what actually happens, because when the temperature became low enough for electrons and nuclei to hold together as neutral atoms, the elastic scattering rate Λ_γ dropped sharply below the value (2.2.7). As we shall see in the next section, this was at a temperature of about 3,000 K, which marked the end of the era of rapid scattering of photons by electrons.

10.2.3 2.3 Recombination and last scattering

We saw in the previous section that photons stopped exchanging energy effectively with electrons when the temperature of the expanding universe dropped to about 10^5 K. After that, photons continued to be scattered by free electrons, but without appreciable gain or loss of energy. This terminated when the free electrons became bound into hydrogen and helium atoms, ending the scattering of photons. This is called recombination. [1] Let's consider when this happened.

We start our calculation at a time early enough so that protons, electrons, and hydrogen and helium atoms were in thermal equilibrium at the temperature of the radiation. In a gas in equilibrium at temperature T, the number density of any non-relativistic non-degenerate particle of type i is given by the Maxwell-Boltzmann formula:

$$n_i = g_i (2\pi\hbar)^{-3} e^{\mu_i/k_{\mathcal{B}}T} \int d^3q \exp\left[-\left(m_i + \frac{q^2}{2m_i}\right)/k_{\mathcal{B}}T\right] \tag{2.3.1}$$

where m_i is the particle mass, g_i is the number of its spin states, and μ_i is a characteristic of the gas known as the chemical potential of particles of type i. (The generalization of Eq. (2.3.1) to include the effects of relativity and/or degeneracy is given in the following chapter.) The property of the chemical potentials that make this a useful formula is that they are conserved in any reaction that is occurring rapidly in the gas. In our case, the particles are protons, electrons, and hydrogen atoms in any bound state, for which we take i as $p, e, 1s, 2s, 2p$, etc. (As already mentioned, about 24% of the mass of the early universe was in the form of helium nuclei, but helium atoms are more tightly bound than hydrogen atoms, so that at the time that concerns us now, say for $T < 4,400$ K, almost all the helium was locked up in the form of neutral atoms, and therefore played no role here.) The electron and proton

have spin one-half, so $g_p = g_e = 2$, while the $1s$ ground state of the hydrogen atom has two hyperfine states with spins 0 and 1 , so $g_{1s} = 1 + 3 = 4$. At first the recombination and

[471] The "re" in "recombination" may be misleading; before this time electrons and protons had never been combined into atoms. This has become the standard term throughout astrophysics for the capture of electrons into atoms.

ionization reactions $p + e \rightleftharpoons H_{1s}$ occurred rapidly by cascades of radiative transitions through excited states, so the chemical potentials satisfied

$$\mu_p + \mu_e = \mu_{1s} \tag{2.3.2}$$

(Photons can be freely created and destroyed in reactions like $e + p \rightleftharpoons e + p + \gamma$, so their chemical potential vanishes.) The integrals are

$$(2\pi\hbar)^{-3} \int d^3p \exp\left(-\frac{p^2}{2mk_{\mathcal{B}}T}\right) = \left(\frac{mk_{\mathcal{B}}T}{2\pi\hbar^2}\right)^{3/2}$$

so the conservation law (2.3.2) gives

$$\frac{n_{1s}}{n_p n_e} = \left(\frac{m_e k_{\mathcal{B}}T}{2\pi\hbar^2}\right)^{-3/2} \exp\left(B_1/k_{\mathcal{B}}T\right) \tag{2.3.3}$$

where $B_1 \equiv m_p + m_e - m_H = 13.6\text{eV}$ is the binding energy of the $1s$ ground state of hydrogen. (Here we ignore the difference between the hydrogen mass and the proton mass, except in the exponential.) Also, the charge neutrality of cosmic matter requires that

$$n_e = n_p \tag{2.3.4}$$

Further, in equilibrium the number density of hydrogen atoms in any one excited state is less than the number density in the ground states by a factor of order $\exp\left(-\Delta E/k_{\mathcal{B}}T\right)$, where ΔE is the excitation energy, which is necessarily not less than the difference 10.6 eV in the binding energies of the $n = 1$ and $n = 2$ states of hydrogen. (Excited states had the same chemical potential as the ground state, since in equilibrium the atom could go rapidly from one to the other by emitting or absorbing photons.) For temperatures below $4,200$ K this exponential factor is less than 6×10^{-13}, so that to a good approximation we can neglect the presence of excited hydrogen atoms as long as thermal equilibrium persisted. As we will see in Section 3.2, the matter at the time of recombination was about 76% by weight neutral or ionized hydrogen, so we can take

$$n_p + n_{1s} = 0.76 n_B \tag{2.3.5}$$

where n_B is the number density of baryons (i.e. at the temperatures of interest here, of neutrons and protons.) The fractional hydrogen ionization $X \equiv n_p/\left(n_p + n_{1s}\right)$ therefore satisfies the Saha equation:

$$X(1 + SX) = 1 \tag{2.3.6}$$

where

$$S \equiv \frac{\left(n_p + n_{1s}\right) n_{1s}}{n_p^2} = 0.76 n_B \left(\frac{m_e k_{\mathcal{B}}T}{2\pi\hbar^2}\right)^{-3/2} \exp\left(B_1/k_{\mathcal{B}}T\right). \tag{2.3.7}$$

One might think that the fractional ionization in equilibrium would become small when the temperature drops below the value $B_1/k_{\mathcal{B}} = 157,894$ K , but even in equilibrium the recombination is considerably delayed, because of the small value of the coefficient of the exponential in Eq. (2.3.7). With $n_B = n_{B0}\left(T/T_{\gamma 0}\right)^3$ and n_{B0} given by Eq. (2.1.13), we have

$$S = 1.747 \times 10^{-22} e^{157894/T} T^{3/2} \Omega_B h^2, \tag{2.3.8}$$

where h is here again the Hubble constant in units of 100 km $s^{-1}Mpc^{-1}$, and T is the temperature in degrees Kelvin. This function of temperature is extremely rapidly varying where it is of order unity, so the Saha equation gives a quite sharp temperature of recombination, as shown in Table 2.1. We see from Table 2.1 that the equilibrium value of the ionization dropped from over 97% for $T = 4,200$ K to less than 1% for $T = 3,000$ K.

This gives the correct order of magnitude of the temperature of the steep decline in fractional ionization, but it is not correct in detail, because

Table 2.1: Equilibrium hydrogen ionization X for various values of the temperature T and $\Omega_{B} h^{2}$.

T(K)	$\Omega_B h^2 = 0.01$	$\Omega_B h^2 = 0.02$	$\Omega_B h^2 = 0.03$

2.725	2.8×10^{-12571}	2.0×10^{-12571}	1.6×10^{-12571}

equilibrium was not actually maintained for low ionization levels. The photon that is emitted when a free electron is captured by a proton into the ground state has more than enough energy to ionize another hydrogen atom, so this process produces no net decrease in ionization. Similarly, the photon emitted when an electron in a high orbit of the hydrogen atom with principal quantum number $n \geq 3$ falls into the ground state has more than enough energy to lift an electron in the ground state of some other hydrogen atom to the $n = 2$ excited state, so this process also produces no net increase in the number of electrons in the ground state. The ground state of hydrogen is typically reached by formation of excited states H^* in the reaction $e + p \rightarrow H^* + \gamma$, followed by a cascade of radiative decays down to the $n = 2$ excited state. The final transition from the $2p$ excited state to the $1s$ ground state by emission of a single Lyman α photon is impeded by the same effect that impedes the transition of free electrons or electrons in higher excited states to the ground state: the Lyman α photon does not simply merge into the thermal radiation background; it has a large resonant cross section for exciting another hydrogen atom from the ground state to the first excited state, from which it is most often reionized (as shown by the small equilibrium numbers of hydrogen atoms in excited states). But in cosmology this process is not entirely ineffective, because the Lyman α photon emitted by one atom will have just barely enough energy to excite another hydrogen atom in its ground state to the $2p$ state, so if it does not interact very soon with another atom then the cosmological redshift will take its energy outside the resonant line, after which it no longer has enough energy to excite a hydrogen atom in its ground state. Even so, the formation of the ground state by radiative decay from the $2p$ state is so inefficient that we also have to consider slower pathways to the ground state, such as the formation of the $2s$ excited state, which can only decay into the ground state by emitting two photons, neither of which has enough energy to re-excite a hydrogen atom in its ground state. When the ionization became small the rate of these reactions could no longer compete with the cosmic expansion rate, and

the ionization no longer fell as fast as it would in thermal equilibrium. [2]

This is a complicated business, but it is not hard to see the main outlines of the recombination process. We make the following approximations:

1. Collisions between hydrogen atoms and radiative transitions between the states of these atoms are sufficiently rapid so that all states of the atoms are in equilibrium with each other at the temperature T of the radiation, except for the $1s$ ground state, which as already mentioned is reached only through slow or inefficient processes. This has the consequence that the number density of states $n\ell$ of hydrogen having principal quantum number n (with $n > 1$) and orbital angular momentum ℓ can be expressed in terms of the number density of any one state, say the $2s$ state: [3]

$$n_{n\ell} = (2\ell + 1) n_{2s} \exp\left(\left(B_2 - B_n\right)/k_{\mathcal{B}}T\right) \tag{2.3.9}$$

where B_n is the binding energy [4] of the state with principal quantum number n.

2. The net rate of change in the population of hydrogen atoms in their $1s$ state is given by the rate of radiative decay from the $2s$ and $2p$ states, minus the rate of excitation of these states from the $1s$ state. In accordance with the discussion above, all other processes leading to the ground state are assumed to be canceled by the reionization or re-excitation of other atoms by the emitted photon. Because recombination occurs in collisions of electrons and protons, it decreases the number $n_e a^3$ of free electrons in a co-moving volume a^3 at a rate $\alpha(T) n_p n_e a^3$ that is proportional both to $n_p = n_e$ and $n_e a^3$, with the coefficient $\alpha(T)$ depending only on temperature, not on n_e or a. (We do not include recombination directly to the ground state here, since it is canceled by the ionization of other atoms by the emitted photon, so $\alpha(t)$ is what in astrophysics is called the "case B recombination coefficient.") Also, leaving aside ionization from the ground state which just cancels recombination to the ground state, the ionization from excited states of hydrogen increases $n_e a^3$ at a rate given by a sum of terms proportional to the $n_{n\ell} a^3$ with $n > 1$, with coefficients depending only on temperature. Eq. (2.3.9) gives all the $n_{n\ell}$ with $n > 1$ as proportional to n_{2s}, with coefficients that also depend only on temperature, so ionization increases the number of electrons in a co-moving volume a^3 at a rate that can be written as $\beta(T) n_{2s} a^3$, with $\beta(T)$

a function only of temperature, not of a or n_e or any of the $n_{n\ell}$. Putting these rates together, we have

$$\frac{d}{dt}\left(n_e a^3\right) = -\alpha n_e^2 a^3 + \beta n_{2s} a^3$$

Dividing by the constant na^3 (where $n \equiv n_p + n_H = n_p + \sum_{n\ell} n_{n\ell} = 0.76 n_B$), this gives

[472] The classic paper on this subject is by P. J. E. Peebles, Astrophys. J. 153, 1 (1968). Also see Ya. B. Zel'dovich, V. G. Kurt, and R. A. Sunyaev, Soviet Physics JETP 28, 146 (1969). At the time of writing the most thorough analysis known to me is that of S. Seager, D. D. Sasselov, and D. Scott , Astrophys. J. 523, L1 (1999); Astrophys. J. Suppl. Ser. 128, 407 (2000) [astro-ph/9909275]. Corrections of the order of a percent of the calculated value due to additional transitions and stimulated emission were subsequently found by V. K. Dubrovich and S. I. Grachev, Astron. Lett. 31, 359 (2005) [astro-ph/051672]; J. Chluba and R. A. Sunyaev, Astron. Astrophys. 446, 39 (2006) [astro-ph/0508144]; W. Y. Wong and D. Scott, Mon. Not. Roy. Astron. Soc. 375, 1441 (2007) [astro-ph/0610691]. The possible use of observations of the cosmic microwave background to resolve these uncertainties is discussed by A. Lewis, J. Weller, and R. Battye, Mon. Not. Roy. Astron. Soc. 373, 561 (2006) [astro-ph/0606552]. For the sake of simplicity here I will make the same approximations as Peebles, but will use the "escape probability"

[47]method discussed by Seager et al., which seems to me more direct and easier to justify.

[3] This formula does not apply to hydrogen atoms in very high excited states, which have such large radii and small binding energies that they cannot be treated as free particles. See, e.g., D. Mihalas, Stellar Atmospheres, 2nd edition (Freeman, San Francisco, 1978).

[4] We are here neglecting the fine structure, hyperfine structure, and Lamb energy shifts, which give the binding energies a very small dependence on ℓ and on the total (including spin) angular momentum j.

$$\frac{d}{dt}\left(\frac{n_e}{n}\right) = -\frac{\alpha n_e^2}{n} + \frac{\beta n_{2s}}{n} \tag{2.3.10}$$

Further, this must vanish under conditions of equilibrium, where (since the transitions $e + p \rightleftharpoons 2s$ occur rapidly) instead of Eq. (2.3.3) we would have

$$\frac{n_{2s}}{n_e^2} = \left(\frac{m_e k_{\mathcal{B}} T}{2\pi\hbar^2}\right)^{-3/2} \exp\left(B_2/k_{\mathcal{B}}T\right)$$

so the coefficients in Eq. (2.3.10) are related by

$$\beta/\alpha = \left(\frac{n_e^2}{n_{2s}}\right)_{\text{equilibrium}} = \left(\frac{m_e k_{\mathcal{B}} T}{2\pi\hbar^2}\right)^{3/2} \exp\left(-B_2/k_{\mathcal{B}}T\right) \tag{2.3.11}$$

In order for Eq. (2.3.10) to be useful, we need to relate n_{2s} to the total number density n of protons and hydrogen atoms.

3. The total number of excited hydrogen atoms in a co-moving volume $1/n$ changes so much more slowly than individual radiative processes that the net increase in this number due to recombination and reionization of hydrogen is balanced by the net decrease in this number by transitions to and from the $1s$ state. That is,

$$\alpha n_e^2 - \beta n_{2s} = \left(\Gamma_{2s} + 3P\Gamma_{2p}\right) n_{2s} - \mathcal{E} n_{1s} \tag{2.3.12}$$

where Γ_{2s} and Γ_{2p} are the rates for the radiative decay processes $2s \to 1s + \gamma + \gamma$ and $2p \to 1s + \gamma$, respectively; [5]P is the probability that the Lyman α photon emitted in the decay $2p \to 1s + \gamma$ will escape to infinity without exciting some other hydrogen atom in the $1s$ state back to the $2p$ state (to be calculated below); and $\mathcal{E}$ is the rate at which hydrogen atoms in the $1s$ state are excited to the $2s$ or $2p$ state, not including those that are excited to the $2p$ state by Lyman α photons from the decays $2p \to 1s + \gamma$, which we take into account with the factor P. (The factor 3 in Eq. (2.3.12)

enters because Eq. (2.3.9) gives $n_{2p} = 3n_{2s}$.) From this, we obtain the needed formula for n_{2s} :

$$n_{2s} = \frac{\alpha n_e^2 + \mathcal{E} n_{1s}}{\Gamma_{2s} + 3P\Gamma_{2p} + \beta} \tag{2.3.13}$$

We will be concerned here with temperatures $T \ll \left(B_2 - B_3\right)/k_{\mathcal{B}} = 21,900$ K, so according to Eq. (2.3.9) all $n_{n\ell}$ with $n > 2$ are much less than n_{2s}, and hence to a very good approximation the total number of hydrogen atoms is

$$n_H = n_{1s} + n_{2s} + n_{2p} = n_{1s} + 4n_{2s}. \tag{2.3.14}$$

We can therefore eliminate n_{1s} in favor of n_H in Eq. (2.3.13), so

$$n_{2s} = \frac{\alpha n_e^2 + \mathcal{E} n_H}{\Gamma_{2s} + 3P\Gamma_{2p} + \beta + 4\mathcal{E}} \tag{2.3.15}$$

Further, in equilibrium the number of hydrogen atoms in the $1s$ state would be constant, so the coefficients on the right-hand side of Eq. (2.3.12) (which gives the net rate of increase of the number density of hydrogen atoms in the ground state) must have the ratio

$$\frac{\mathcal{E}}{\Gamma_{2s} + 3P\Gamma_{2p}} = \left(\frac{n_{2s}}{n_{1s}}\right)_{\text{equilibrium}} = \exp\left(-\left(B_1 - B_2\right)/k_{\mathcal{B}}T\right). \tag{2.3.16}$$

[475] We neglect the process $2p \to 1s + \gamma + \gamma$, which is much slower than $2s \to 1s + \gamma + \gamma$.

Using Eqs. (2.3.15) and (2.3.16) in Eq. (2.3.10) now gives the rate equation in a more useful form

$$\frac{d}{dt}\left(\frac{n_e}{n}\right) = \frac{\Gamma_{2s} + 3P\Gamma_{2p}}{\left(\Gamma_{2s} + 3P\Gamma_{2p}\right)\left[1 + 4\exp\left(-\left(B_1 - B_2\right)/k_{\mathcal{B}}T\right)\right] + \beta} \times \left(-\left[1 + 4\exp\left(-\left(B_1 - B_2\right)/k_{\mathcal{B}}T\right)\right]\frac{\alpha n_e^2}{n} + \exp\left(-\left(B_1 - B_2\right)/k_{\mathcal{B}}T\right)\frac{\beta n_H}{n}\right)$$

At the temperatures of interest the factor $1 + 4\exp\left(-\left(B_1 - B_2\right)/k_{\mathcal{B}}T\right)$ can be replaced with unity. Using Eq. (2.3.11) and the definition of fractional ionization $X \equiv n_e/n = n_p/n = 1 - n_H/n$, we have at last

$$\frac{dX}{dt} = \left(\frac{\Gamma_{2s} + 3P\Gamma_{2p}}{\Gamma_{2s} + 3P\Gamma_{2p} + \beta}\right)\alpha n\left(-X^2 + S^{-1}(1 - X)\right), \tag{2.3.17}$$

where $S(T)$ is the function (2.3.7) appearing in the Saha equation. Note that if the temperature were constant then this would be satisfied by any solution of the Saha equation (2.3.6). In fact, X is always larger than the value given by the Saha equation, so Eq. (2.3.17) gives a monotonically decreasing fractional ionization. The first factor in Eq. (2.3.17) represents the suppression of recombination that occurs when the transitions of the $2s$ and $2p$ states to the ground state are slower than the reionization of the atom.

It remains to calculate the photon survival probability P. This is given in general by

$$P(t) = \int_{-\infty}^{+\infty} d\omega \mathcal{P}(\omega) \exp\left[-\int_t^{\infty} dt' n_{1s}\left(t'\right) c\sigma\left(\omega a(t)/a\left(t'\right)\right)\right] \tag{2.3.18}$$

where $\mathcal{P}(\omega)d\omega$ is the probability that a photon emitted in the transition $2p \to 1s$ has energy between $\hbar\omega$ and $\hbar(\omega + d\omega)$, normalized so that $\int \mathcal{P}(\omega)d\omega = 1$, and $\sigma(\omega)$ is the cross section for the excitation $1s \to 2p$ by a photon of energy $\hbar\omega$. The factor $a(t)/a\left(t'\right)$ arises from the cosmological redshift of the photon. The cross section is given by the Breit-Wigner formula [6]

$$\sigma(\omega) = \left(\frac{3}{2}\right)\left(\frac{2\pi^2\Gamma_{2p}}{k_\alpha^2}\right)\mathcal{P}(\omega) \tag{2.3.19}$$

where k_α is the mean wave number $\left(B_1 - B_2\right)/\hbar c$ of the Lyman α photon emitted in the transition $2p \to 1s$. The probability density here is

$$\mathcal{P}(\omega) = \frac{\Gamma_{2p}}{2\pi}\frac{1}{\left(\omega - \omega_\alpha\right)^2 + \Gamma_{2p}^2/4} \tag{2.3.20}$$

where ω_α is the circular frequency ck_α corresponding to the wave number k_α.

Now, if a photon is captured at all then it is captured in a time much less than the characteristic expansion time of the universe, so we can set the density $n_{1s}\left(t'\right)$ in Eq. (2.3.18) equal to $n_{1s}(t)$. The cross section $\sigma(\omega)$ varies very rapidly with ω, so we cannot neglect the time-dependence of $a(t)$, but we can take the expansion rate to be constant in the integral over t', so that $a(t)/a\left(t'\right) = 1 - H(t)\left(t' - t\right)$, where $H(t) = \dot{a}(t)/a(t)$. It is convenient then

[476] See, e.g., S. Weinberg, The Quantum Theory of Fields, (Cambridge University Press, Cambridge, UK, 1995, 1996, 2000) [referred to henceforth as QTF]: Vol. I, Eq. (3.8.16). The factor 3/2 arises from the number $2\ell + 1 = 3$ of $2p$ angular momentum states, and the number 2 of photon helicity states. If the spin of the electron and proton are taken into account then the numerator is 12 and the denominator is 8 , but the ratio is the same.

to change the variable of integration in the exponential in Eq. (2.3.18) from t' to $\omega' = (1 - H(t)\,(t' - t))\,\omega$, so that Eq. (2.3.18) reads

$$P(t) = \int_{-\infty}^{+\infty} d\omega \mathcal{P}(\omega) \exp\left[-\frac{3\pi^2 \Gamma_{2p} n_{1s}(t) c}{\omega H(t) k_\alpha^2} \int_{-\infty}^{\omega} d\omega' \mathcal{P}\left(\omega'\right)\right] \tag{2.3.21}$$

The function $\mathcal{P}(\omega)$ is negligible except for ω very near ω_α, so we can replace ω with ω_α in the factor $1/\omega$ in the argument of the exponential (but not in the upper limit of the integral over ω', which rises steeply from zero to one for ω in the neighborhood of ω_α.) The integral over ω is now trivial, and gives

$$P(t) = F\left(\frac{3\pi^2 \Gamma_{2p} n_{1s}(t) c}{\omega_\alpha H(t) k_\alpha^2}\right) \tag{2.3.22}$$

where

$$F(x) \equiv \left(1 - e^{-x}\right)/x \tag{2.3.23}$$

The Lyman α transition rate [7] is $\Gamma_{2p} = 4.699 \times 10^8\ \mathrm{s}^{-1}$, so that the argument of the function $F(x)$ in Eq. (2.3.22) is very large. For instance, if we take $\Omega_M h^2 = 0.15$ and $\Omega_B h^2 = 0.01$, then for $T < 6,000$ K the argument x is greater than 10. Hence for the temperatures of interest here we can drop the exponential in Eq. (2.3.23), and find

$$P = \frac{\omega_\alpha H k_\alpha^2}{3\pi^2 \Gamma_{2p} n_{1s} c} = \frac{8\pi H}{3\lambda_\alpha^3 \Gamma_{2p} n_{1s}}, \tag{2.3.24}$$

where $\lambda_\alpha = 1215.682 \times 10^{-8}$ cm is the wavelength of Lyman α photons, and the argument t is now understood. We see that the quantity $3P\Gamma_{2p}$ in the rate equation (2.3.17) is independent of Γ_{2p} :

$$3P\Gamma_{2p} = \frac{8\pi H}{\lambda_\alpha^3 n_{1s}} \tag{2.3.25}$$

With this result for P, equation (2.3.17) is the same as the rate equation found in a different way by Peebles. [2] In this equation we may use the approximation that at the temperatures of interest, which are much less than $(B_1 - B_2)/k_{\mathcal{B}} = 118,420$ K, even though n_{1s}/n_{2s} is less than it would be in thermal equilibrium it is still much larger than unity, so that we can replace n_{1s} with $n_H = (1 - X)n$. We also replace time with temperature as the independent variable, using

$$\frac{dt}{dT} = -\frac{1}{HT} \tag{2.3.26}$$

The rate equation (2.3.17) then becomes

$$\frac{dX}{dT} = \frac{\alpha n}{HT}\left(1 + \frac{\beta}{\Gamma_{2s} + 8\pi H/\lambda_\alpha^3 n(1 - X)}\right)^{-1} \left[X^2 - (1 - X)/S\right] \tag{2.3.27}$$

Now we must put in some numbers. In calculating the expansion rate we need to include both the energy density of non-relativistic matter and that of neutrinos and photons, but at temperatures where neutrinos are important their mass is negligible, and for temperatures $T > 30$ K we may neglect vacuum energy, so

[477] W. L. Wiese, M. W. Smith, and R. M. Glennon, Atomic Transition Probabilities, Vol. I, National Standard Reference Data Series NBS 4 (1966).

$$H = H_0 \left[\Omega_M \left(\frac{T}{T_{\gamma 0}} \right)^3 + \Omega_R \left(\frac{T}{T_{\gamma 0}} \right)^4 \right]^{1/2}$$
$$= 7.204 \times 10^{-19} T^{3/2} \sqrt{\Omega_M h^2 + 1.523 \times 10^{-5} T} \text{ s}^{-1} \quad (2.3.28)$$

where again in all numerical expressions T is the temperature in degrees Kelvin. The number density of ionized and un-ionized hydrogen is

$$n = 0.76 \times \frac{3H_0^2 \Omega_B}{8\pi G m_p} \left(\frac{T}{T_{\gamma 0}} \right)^3 = 4.218 \times 10^{-7} \Omega_B h^2 T^3 \text{ cm}^{-3} \quad (2.3.29)$$

The two-photon decay rate of the $2s$ state is [8]

$$\Gamma_{2s} = 8.22458 \text{ s}^{-1} \quad (2.3.30)$$

The coefficient of the proton number density in the electron recombination rate used by Peebles is [9]

$$\alpha = 2.84 \times 10^{-11} T^{-1/2} \text{ cm}^3 \text{ s}^{-1}$$

The factor $T^{-1/2}$ here is what would be expected from a factor velocity $^{-1}$ that generally appears in the cross sections for exothermic reactions like $e+p \to H+\gamma$.[10] Actually α represents a chain of reactions more complicated than just the radiative capture of an electron, including the cascade of radiative decays down to the $2s$ and $2p$ states, and so it has a more complicated temperature dependence. A variety of detailed numerical calculations of the effective rate of recombination to the $2s$ and $2p$ states can be fit

with the simple formula: [11]

$$\alpha = \frac{1.4377 \times 10^{-10} T^{-0.6166} \text{ cm}^3 \text{ s}^{-1}}{1 + 5.085 \times 10^{-3} T^{0.5300}}. \quad (2.3.31)$$

The value of β is given in terms of α by Eq. (2.3.11):
$\beta = \left(\frac{m_e k_{\mathcal{B}} T}{2\pi\hbar^2}\right)^{3/2} \exp\left(-B_2/k_{\mathcal{B}} T\right) \alpha = 2.4147 \times 10^{15} \text{ cm}^{-3} T^{3/2} e^{-39474/T} \alpha.$

Finally, the function $S[T]$ is given by Eq. (2.3.8).

The values of $X[T]$ calculated [12] from the differential equation (2.3.27) with the inputs (2.3.28)-(2.3.32) (and Eq. (2.3.8) for $S[T]$) are given in Table 2.2 for $\Omega_M h^2 = 0.15$ and a range of values of $\Omega_B h^2$. The initial condition here is taken to be that $X[T]$ is given by the solution of the Saha equation (2.3.6) for thermal equilibrium at the highest temperature considered, which we take to be $T = 4,226$ K (i.e. $z = 1,550$), high enough so that thermal equilibrium should be a good approximation (because the equilibrium value of X is very close to one, while the true value must be between one and the equilibrium value), but low enough so that hardly any of the helium is still ionized. (Almost all helium was doubly ionized until the temperature dropped below $20,000$ K, and there was still appreciable singly ionized helium until the temperature dropped below about $4,400$ K.) The actual value of $X[4226]$ is slightly higher than the equilibrium value, but to three significant figures there would be no effect on the results at lower temperatures if we increased the assumed value of $X[4226]$ by a small amount, as say from 0.984 to 0.99 for $\Omega_B h^2 = 0.02$.

[478] S. P. Goldman, Phys. Rev. A40, 1185 (1989). Peebles used an earlier value, 8.227 s^{-1}, given by L. Spitzer and J. L. Greenstein, Astrophys. J. 114, 407 (1951).

[10] See, e.g., QTF, Vol. I, p. 157.

Comparison of Tables 2.1 and 2.2 shows that for the small values of $\Omega_B h^2$ considered here, the Saha equation stopped giving a good approximation to the fractional ionization as soon as the equilibrium ionization dropped appreciably below unity. In particular, although in equilibrium the fractional ionization would have dropped to vanishingly small values for temperatures below $2,000$ K, the ionization calculated from Eq. (2.3.27) leveled off at low temperatures to a small but non-zero asymptotic value,

Table 2.2: Hydrogen ionization X calculated from Eq. (2.3.27) and time t for the temperature to drop to T from \$10\hat{}\{6\{ \}\^{}\{\circ\} \mathrm\{K\}\$ calculated from Eq. (2.3.26). The fourth through sixth columns give results for various values of $\Omega_B h^2$, with $\Omega_M h^2 = 0.15$. The last column gives results for parameters $\Omega_B h^2 = 0.02238, \Omega_M h^2 = 0.13229$ used in Section 7.2 to compare the analytic calculation of microwave background anisotropies with a numerical calculation.

[4711] D. Péquignot, P. Petijean, and C. Boisson, Astron. Astrophys. 251, 680 (1991). This includes an over-all "fudge factor" of 1.14 recommended by S. Seager, D. D. Sasselov, and D. Scott, Astrophys. J. 523, L1 (1999). Eq. (2.3.31) agrees well with subsequent calculations of D. G. Hummer, Mon. Not. Roy. Astron. Soc. 268, 109 (1994).

[12] I thank D. Dicus for the calculation of these numerical results. The calculation is stopped at $z = 10$, because at later times hydrogen is reionized by the first generation of stars, and also the rate of expansion is affected by the vacuum energy.

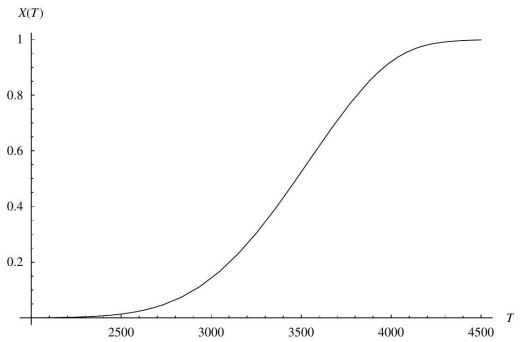

Figure 2.2: The fractional ionization given by the rate equation (2.3.17) as a function of temperature in degrees Kelvin, for $\Omega_{M} h^{2}=0.132, \Omega_{B} h^{2}=0.0224$.

due to the increasing rarity of encounters of the few remaining free protons and electrons. This residual ionization played an important role in the formation of the first stars.

The fractional ionization given by Eq. (2.3.17) for a currently favored set of cosmological parameters is also shown in Figure 2.2. On the scale of this figure, the results are indistinguishable from those given by the more elaborate calculations of Seager, Sasselov, and Scott, [2] except for temperatures above $T > 4,300$ K, where the contribution of electrons from the ionization of helium (ignored in Eq. (2.3.17)) was still significant.

The most important application of these results for the fractional ionization is the calculation of the opacity $\mathcal{O}(T)$, the probability that a photon present at a time $t(T)$ when the temperature is T will undergo at least one more scattering before the present, given by

$$\mathcal{O}(T) = 1 - \exp\left[-\int_{t(T)}^{t_0} c\sigma_{\mathcal{T}} n_e(t) dt\right] \tag{2.3.33}$$

This rises from near zero at low temperature, where the integral in the exponent is small, to near one at high temperature, where the integral becomes large.

It is convenient to convert the integral over time to an integral over temperature, again using Eq. (2.3.26):

$$\mathcal{O}(T) = 1 - \exp\left[-c\sigma_{\mathcal{T}} \int_{2.725}^{T} n_e\left(T'\right) dT' / H\left(T'\right) T'\right] \tag{2.3.34}$$

We use Eq. (2.3.28) for H and take $n_e = Xn$ with n given by Eq. (2.3.29), so

$$\begin{aligned}\mathcal{O}(T) &= 1 - \exp\left[-c\sigma_{\mathcal{T}} \int_{2.725}^{T} n_e\left(T'\right) dT' / H\left(T'\right) T'\right] \\ &= 1 - \exp\left[-\int_{2.725}^{T} \frac{0.01168 \Omega_B h^2 T'^{1/2} X\left(T'\right) dT'}{\sqrt{\Omega_M h^2 + 1.523 \times 10^{-5} T'}}\right]\end{aligned} \tag{2.3.35}$$

In studies of anisotropies in the cosmic microwave background we are particularly interested in when the photons observed today were last scattered. The probability that the last scattering of a photon was before the temperature dropped to T is $1 - \mathcal{O}(T)$, and the probability that the last scattering was after the temperature dropped further to $T - dT$ is $\mathcal{O}(T - dT)$, so the probability that the last scattering of a photon was at a temperature between T and $T - dT$ is

$$1 - (1 - \mathcal{O}(T)) - \mathcal{O}(T - dT) = \mathcal{O}'(T) dT \tag{2.3.36}$$

The opacity function $\mathcal{O}(T)$ increases monotonically with temperature from $\mathcal{O} = 0$ at $T = T_0$ to $\mathcal{O} \to 1$ for $T \to \infty$, so $\mathcal{O}'(T)$ is a positive normalized probability distribution, with unit

integral. Values [12] of $\mathcal{O}'(T)$ for $\Omega_M h^2 = 0.15$ and a range of values of $\Omega_B h^2$ are given in Table 2.3. The distribution $\mathcal{O}'(T)$ is peaked at a temperature T_L, with a standard deviation σ, given in the two bottom rows of Table 2.3.

It may be useful to note an approximation [13] for the fractional ionization, even though it was not used in the calculations of Tables 2.2 or 2.3. In equilibrium the fractional ionization depends only on the temperature and $\Omega_B h^2$. But as soon as the Saha equation stopped giving a good approximation to the fractional ionization, the ionization then depended not only on $\Omega_B h^2$, but also on $\Omega_M h^2$. The approximation derived below shows that at sufficiently low temperatures the fractional ionization depends on $\Omega_B h^2$ and $\Omega_M h^2$ chiefly through a multiplicative factor $(\Omega_M h^2)^{1/2}/\Omega_B h^2$, while the opacity $\mathcal{O}'(T)$ is nearly independent of these parameters.

Table 2.3: The normalized probability distribution $\mathcal{O}'(T)$ of the temperature of last scattering, as a function of the temperature T (in degrees Kelvin), calculated from Eq. (2.3.35). The second through fourth columns give results for various values of $\Omega_B h^2$, with $\Omega_M h^2 = 0.15$. The last column gives results for parameters $\Omega_B h^2 = 0.02238$, $\Omega_M h^2 = 0.13229$ used in Section 7.2 to compare the analytic calculation of microwave background anisotropies with a numerical calculation. The bottom two rows give the parameters for a fit of $\mathcal{O}'(T)$ to the Gaussian $\exp\left[-(T-T_L)^2/2\sigma^2\right]/\sigma\sqrt{2\pi}$, found by setting T_L equal to temperature at which $\mathcal{O}'$ is a maximum, and $1/\sigma\sqrt{2\pi}$ equal to the value of $\mathcal{O}'$ at that maximum.

T(K)	$\mathcal{O}'_{\Omega_B h^2=0.01}$	$\mathcal{O}'_{\Omega_B h^2}=0.02$	$\mathcal{O}'_{\Omega_B h^2=0.03}$	$\mathcal{O}'_{\text{Sec.7.2}}$

1000	9.50×10^{-6}	9.76×10^{-6}	9.87×10^{-6}	9.84×10^{-6}
T_L(K)	3017	2954	2930	2941
σ(K)	287	253	241	248

To derive this approximation, note first that as soon as the fractional ionization dropped well below its equilibrium value, the term $(1-X)/S$ in the square brackets in Eq. (2.3.27) (which would equal X^2 in equilibrium) became much less than the term X^2. Comparison of Tables 2.1 and 2.2 shows that for a plausible range of cosmological parameters, this is the case for $T < 3,400$ K. At such temperatures we can also neglect the radiation
energy density compared with the mass density, so that the expansion rate (2.3.28) becomes simply $7.2\times10^{-19}\sqrt{\Omega_M h^2}$ s^{-1}. Also, for temperatures in the range from 3,400 K down to 2000 K the effective $2p$ decay rate $3P\Gamma_{2p}$ was less than the $2s$ decay rate, while for $T < 2,000$ K the reionization rate β was less than either $3P\Gamma_{2p}$ or Γ_{2s}, so for all temperatures below $T < 3,400$ K, Eq. (2.3.27) took the form

[4713] B. J. T. Jones and R. F. Wyse, Astron. Astrophys. 149, 144 (1985).

$$\frac{dX}{dT} = f(T)X^2 \tag{2.3.37}$$

where

$$f(T) = \frac{\alpha n}{HT}\left(1 + \frac{\beta}{\Gamma_{2s}}\right)^{-1} = \frac{\Omega_B h^2}{(\Omega_M h^2)^{1/2}} g(T), \tag{2.3.38}$$

with $g(T)$ a function of temperature alone

$$g(T) = \frac{84.2 T^{-0.1166}}{1 + 5.085 \times 10^{-3} T^{0.53} + 4.22 \times 10^4 T^{.8834} e^{-39474/T}} \tag{2.3.39}$$

The solution is

$$X(T) \simeq \left[X(3400)^{-1} + \frac{\Omega_B h^2}{(\Omega_M h^2)^{1/2}} \int_T^{3400} g\left(T'\right) dT'\right]^{-1} \tag{2.3.40}$$

Comparison of this formula with the results shown in Table 2.2 for $\Omega_M = 0.15$ and $\Omega_B = 0.02$ shows that the error introduced by these approximations rises to about 25% as the temperature drops from $3,400$ K to $\simeq 2,500$ K, and then drops to less than 10% for $T < 1,400$ K. For temperatures less than about $2,600$ K the fractional ionization is so much less than at $3,400$ K that we can neglect the term $X(3400)^{-1}$ in the denominator of Eq. (2.3.36) without introducing any appreciable additional error, giving

$$X(T) \simeq \frac{(\Omega_M h^2)^{1/2}}{\Omega_B h^2} \left[\int_T^{3400} g\left(T'\right) dT'\right]^{-1} \tag{2.3.41}$$

so that $X(T)$ is proportional at sufficiently low temperature to $(\Omega_M h^2)^{1/2} / \Omega_B h^2$, as was to be shown. Inspection of Table 2.2 confirms that for $T < 1,700$ K and with $\Omega_M h^2 = 0.15$ fixed, the fractional ionization is indeed inversely proportional to $\Omega_B h^2$ with fair accuracy, but this is not a good approximation in the neighborhood of $3,000$ K.

It is striking that the values of $\mathcal{O}'(T)$ depend only weakly on $\Omega_B h^2$ for $T < 3,200$ K. The reason, as noted by Jones and Wyse, [13] is that at temperatures low enough to neglect the radiation energy density, Eq. (2.3.35) gives
$\ln \mathcal{O}(T)$ as proportional to $\Omega_B h^2 / \sqrt{\Omega_M h^2}$ times an integral of $T^{1/2} X(T)$, while the approximate formula (2.3.41) gives $X(T)$ proportional at low temperature to $\sqrt{\Omega_M h^2} / \Omega_B h^2$, so at sufficiently low temperature $\mathcal{O}(T)$ and hence $\mathcal{O}'(T)$ are independent of $\Omega_B h^2$ and also of $\Omega_M h^2$. Table 2.3 shows that for plausible values of cosmological parameters, the temperature T_L of last scattering is always close to $3,000$ K, with a spread (in the sense of standard deviation) of about 10%.

10.2.4 2.4 The dipole anisotropy

In the previous sections of this chapter we have treated the cosmic microwave background as perfectly isotropic and homogeneous. This is certainly a good approximation. Indeed, in the discovery of the cosmic microwave background in 1965, the one thing that enabled Penzias and Wilson to distinguish the background radiation from radiation emitted by earth's atmosphere was that the microwave background did not seem to vary with direction in the sky.

Of course, the cosmic microwave background does have small variations in direction that are too small to have been detected by Penzias and Wilson. The departures from perfect isotropy provides some of the most important information we have about the evolution of the universe. This section deals with the simplest and earliest detected departure from isotropy of the observed cosmic microwave background, arising from the earth's motion. The following

two sections deal with anisotropies due to scattering of photons by intergalactic electrons in clusters of galaxies, and with the primary anisotropies left over from the early universe.

To the extent that the cosmic microwave background is itself perfectly homogeneous and isotropic, it provides a frame of reference for the whole universe, with respect to which we can measure the peculiar velocities of individual galaxies. To analyze the measurement of our own galaxy through the cosmic microwave background, it is useful to consider the density $N_\gamma(\mathbf{p})$ of photons in phase space, defined by specifying that there are $N_\gamma(\mathbf{p})d^3p$ photons of each polarization (right or left circularly polarized) per unit spatial volume in a momentum-space volume d^3p centered at $\mathbf{p}$. Since $|\mathbf{p}| = hv/c$ and the momentum-space volume between frequencies v and dv is $4\pi h^3 v^2 dv/c^3$, Eq. (2.1.1) gives

$$N_\gamma(\mathbf{p}) = \frac{1}{2}\frac{n_T(c|\mathbf{p}|/h)}{4\pi h^3 v^2/c^3} = \frac{1}{h^3}\frac{1}{\exp(|\mathbf{p}|c/kT) - 1}, \tag{2.4.1}$$

(The factor 1/2 takes account of the fact that n_T includes both possible photon polarization states.) This is of course the density that would be measured
by an observer at rest in the radiation background. The phase space volume is Lorentz invariant, and the number of photons is also Lorentz invariant, so N_γ is a scalar, in the sense that a Lorentz transformation to a coordinate system moving with respect to the radiation background that takes $\mathbf{p}$ to $\mathbf{p}'$ also takes N_γ to N'_γ, where

$$N'_\gamma(\mathbf{p}') = N_\gamma(\mathbf{p}) \tag{2.4.2}$$

If the earth is moving in the three-direction with a velocity (in units of c) of β, and we take $\mathbf{p}$ to be the photon momentum in the frame at rest in the cosmic microwave background and $\mathbf{p}'$ to be the photon momentum measured on the earth, then

$$\begin{pmatrix} p_1 \\ p_2 \\ p_3 \\ |\mathbf{p}| \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & \gamma & \beta\gamma \\ 0 & 0 & \beta\gamma & \gamma \end{pmatrix} \begin{pmatrix} p'_1 \\ p'_2 \\ p'_3 \\ |\mathbf{p}'| \end{pmatrix} \tag{2.4.3}$$

where as usual $\gamma \equiv (1-\beta^2)^{-1/2}$. In particular

$$|\mathbf{p}| = \gamma(1 + \beta\cos\theta)\,|\mathbf{p}'| \tag{2.4.4}$$

where θ is the angle between $\mathbf{p}'$ and the three-axis. Thus

$$N'_\gamma(\mathbf{p}') = \frac{1}{h^3}\frac{1}{\exp\left(|\mathbf{p}'|\,c/kT'\right) - 1} \tag{2.4.5}$$

where the temperature is a function of the angle between the direction of the photon and the earth's velocity

$$T' = \frac{T}{\gamma(1 + \beta\cos\theta)} \tag{2.4.6}$$

Since the galaxy can be expected to be moving at a velocity of several hundred kilometers per second, comparable to the peculiar velocities observed for other galaxies relative to the mean Hubble flow, and the solar system is moving with a similar velocity within the galaxy, we expect β to be roughly of order 10^{-3}, in which case γ is essentially unity. The apparent temperature is greatest if we observe photons coming from the direction toward which the earth is moving, for which $\cos\theta = -1$, where it is greater than the intrinsic temperature by a fractional amount β_{earth} . It is least if we observe photons moving in the same direction as the earth, for which $\cos\theta = +1$, and the temperature is decreased by the same fractional amount.

This effect was first observed in 1969 with a ground-based radiometer, but at the time it was only possible to measure the component of the earth's velocity in the earth's equatorial plane, found to be 350 km/sec in a direction corresponding to right ascension 11 h20 m.[1] The full velocity vector of the earth was measured in 1977 by a Berkeley group, [2] using measurements from a U2 aircraft flying above most of the earth's atmosphere. Our knowledge of this effect has been greatly improved by measurements from the COBE satellite. The Far Infrared Absolute Spectrophotometer group [3] found a maximum temperature increase ΔT of 3.372 ± 0.014mK (95% confidence level) in a direction with galactic coordinates [4] $\ell = 264^\circ.14 \pm 0^\circ.30, b = 48^\circ.26 \pm 0^\circ.30$; the Differential Microwave Interferometer group [5] found $\Delta T = 3.353 \pm 0.024$mK (95% confidence level) in a direction with galactic coordinates $\ell = 264^\circ.26 \pm 0^\circ.33, b = 48^\circ.22 \pm 0^\circ.13$, corresponding to right ascension $11^{\rm h}12^{\rm m}.2 \pm 0^{\rm m}.8$, declination $-7^\circ.06 \pm 0^\circ.16$.

More recently, the WMAP satellite experiment [6] (discussed in detail in Chapter 7) has given a maximum temperature increase of 3.346 ± 0.017mK in a direction $\ell = 263^\circ.85 \pm 0^\circ.1, b = 48^\circ.25 \pm 0^\circ.04$. These results indicate a motion of the solar system with a velocity $(0.00335)c/(2.725) = 370$ km/sec, not quite in the direction of the Virgo cluster, which has $\ell \approx 284$ and $b \approx 74$. For comparison, the rotation of the galaxy gives the earth a velocity relative to the center of the galaxy of about 215 km/sec, more or less in the opposite direction. Taking this into account gives a net velocity of the local group of galaxies [7] relative to the microwave background of 627 ± 22 km/sec in a direction ($\ell = 276^\circ \pm 3^\circ, b = 30^\circ \pm 3^\circ$) between the Hydra and Centaurus clusters of galaxies.

Expanding Eq. (2.4.6) in powers of β, the temperature shift can be expressed as a sum of Legendre polynomials

$$\Delta T \equiv T' - T = T\left[-\frac{\beta^2}{6} - \beta P_1(\cos\theta) + \frac{2\beta^2}{3}P_2(\cos\theta) + \dots\right] \tag{2.4.7}$$

Because $\beta = 370$ km/sec$/c = 0.0013$ is small, the temperature shift is primarily a dipole, but Eq. (2.4.7) also exhibits a "kinematic quadrupole"

term that is not much smaller than the intrinsic quadrupole term in the temperature, to be discussed in Section 2.6.

10.2.5 2.5 The Sunyaev-Zel'dovich effect

There is another contribution to the anisotropy of the cosmic microwave radiation background, due to the scattering of this radiation by electrons in intergalactic space within clusters of galaxies along the line of sight. This is known as the Sunyaev-Zel'dovich effect. [1] Eq. (C.26) (the Kompaneets equation) of Appendix C shows that scattering of the cosmic microwave background by a non-relativistic [2] electron gas changes the observed photon occupation number $N(\omega)$ (defined so that $4\pi\omega^2 N(\omega)d\omega$ is the number of photons of each of the two polarization states with energy between $\hbar\omega$ and $\hbar(\omega + d\omega)$) at photon energy $\hbar\omega \ll m_e c^2$ at a rate (here in cgs units)

$$\dot{N}(\omega) = \frac{n_e \sigma_{\mathcal{T}}}{m_e c \omega^2} \frac{\partial}{\partial \omega} \left[k_{\mathcal{B}} T_e \omega^4 \frac{\partial N(\omega)}{\partial \omega} + \hbar \omega^4 N(\omega)(1 + N(\omega)) \right],$$

where $\sigma_{\mathcal{T}}$ is the Thomson scattering cross section, n_e is the electron number density, and T_e is the electron temperature. This formula can be used directly in calculating the rate of change of the occupation number $N(\omega)$ of a homogeneous isotropic photon gas through interactions with a MaxwellBoltzmann distribution of electrons at temperature T_e. In the application that concerns us now, we are interested instead in the change of the appearance to us of the cosmic microwave background due to scattering by a cloud of electrons along the line of sight. In this context, we rewrite the Kompaneets equation as

$$\begin{aligned} \frac{\partial}{\partial \ell} N(\omega, \ell) =& \frac{n_e(\ell) \sigma_{\mathcal{T}}}{m_e c^2 \omega^2} \frac{\partial}{\partial \omega} \\ & \times \left[k_{\mathcal{B}} T_e(\ell) \omega^4 \frac{\partial N(\omega, \ell)}{\partial \omega} + \hbar \omega^4 N(\omega, \ell)(1 + N(\omega, \ell)) \right] \end{aligned} \tag{2.5.1}$$

where ℓ is the proper distance coordinate along the line of sight through the cloud.

The ionized plasma in clusters of galaxies is typically at temperatures greater than 10^6 degrees, so that $k_{\mathcal{B}} T_e$ is very much greater than the typical

value of the photon energy $\hbar\omega$, which for the cosmic microwave background is 10^{-4}eV to 10^{-3}eV. In this case Eq. (2.5.1) simplifies to

$$\frac{\partial}{\partial \ell} N(\omega, \ell) = \frac{n_e(\ell) \sigma_{\mathcal{T}} k_{\mathcal{B}} T_e(\ell)}{m_e c^2 \omega^2} \frac{\partial}{\partial \omega} \left[\omega^4 \frac{\partial N(\omega, \ell)}{\partial \omega} \right]. \tag{2.5.2}$$

This is now a linear differential equation, so it can be solved exactly, [3] but in the usual case this is unnecessary, because the cloud of electrons is optically thin. Eq. (2.5.2) then tells us that the change in the occupation number due to passage of the radiation through the cloud is simply

$$\Delta N(\omega) = \frac{y}{\omega^2} \frac{\partial}{\partial \omega} \left[\omega^4 \frac{\partial N(\omega)}{\partial \omega} \right] \tag{2.5.3}$$

where y is the dimensionless parameter

$$y \equiv \frac{\sigma_{\mathcal{T}}}{m_e c^2} \int d\ell n_e(\ell) k_{\mathcal{B}} T_e(\ell) \tag{2.5.4}$$

the integral being taken along the line of sight through the cloud. For black-body radiation at temperature T_γ we have

$$N(\omega) = \frac{1}{\exp\left(\hbar\omega / k_{\mathcal{B}} T_\gamma\right) - 1} \tag{2.5.5}$$

Using this in Eq. (2.5.3) gives

$$\Delta N = y \left(\frac{-x + (x^2/4) \coth(x/2)}{\sinh^2(x/2)} \right), \tag{2.5.6}$$

[2] The ionized gas in galaxy clusters is hot, so that relativistic corrections, though small, are not negligible; see Y. Rephaeli, Astrophys. J. 445, 33 (1995); A. Challinor and A. Lasenby, Astrophys. J. 499, 1 (1998); N. Itoh, U. Kohyama, and S. Nozawa, Astrophys. J. 502, 7 (1998).

where $x \equiv \hbar\omega/k_{\mathcal{B}}T_\gamma$. We see that in general the scattering changes the shape of the photon energy distribution, not just the effective temperature. The characteristic dependence on ω of Eq. (2.5.6) makes it possible in principle for radio astronomers to distinguish between anisotropies due to the Sunyaev-Zel'dovich effect and the primary anisotropies discussed in Section 2.6 and Chapter 7.

But in the Rayleigh-Jeans part of the spectrum, where $x \ll 1$, Eq. (2.5.6) gives $\Delta N \to -2y/x$, while Eq. (2.5.5) gives $N \to 1/x$, so the shape of the spectrum is preserved, with a fractional change in photon temperature equal to

$$\frac{\Delta T_\gamma}{T_\gamma} = \frac{\Delta N}{N} = -2y. \tag{2.5.7}$$

It may seem surprising that scattering of photons by a cloud of electrons with much higher temperature would lower the photon temperature, but this is only in the Rayleigh-Jeans part of the spectrum. Far beyond the peak in the black-body spectrum, where $x \gg 1$, Eqs. (2.5.5) and (2.5.6) give $\Delta N/N$ the positive value yx^2; the cooling observed in the Rayleigh-Jeans region is due to the transfer of photons from low to high energy. Indeed, Eq. (2.5.3) shows that $\int \Delta N(\omega)\omega^2 d\omega$ vanishes, so scattering by the electron cloud preserves the total number of photons we receive.

Eq. (2.5.7) gives the fractional change in photon temperature observed at low frequency due to scattering in a cloud of electrons, typically associated with a cluster of galaxies. If the cluster is at a redshift z, then both T_γ and ΔT_γ are reduced by a factor $(1+z)^{-1}$, but the ratio is independent of z, and independent also of the Hubble constant and other cosmological parameters, except in so far as these quantities are needed in estimating n_e and proper lengths. The electron temperature T_e can be measured from observations of the luminosity of the cluster as a function of photon wavelength, with a result that is independent of the cluster redshift or H_0, but the proper length along the line of sight has to be inferred from the angular size of the cluster and the angular diameter distance d_A, which is inversely proportional to H_0, so the electron density calculated from measurements of the SunyaevZel'dovich parameter y is proportional to the value assumed for H_0.

Measurements of the Sunyaev-Zel'dovich effect can usefully be combined with measurements of the X-ray luminosity of the cluster of galaxies. [4] The cross section [5] $d\sigma$ for the bremsstrahlung of photons of energy between $\hbar\omega$ and $\hbar(\omega + d\omega)$ (with $\hbar\omega$ comparable to but not very close to $m_e v^2/2$) in collisions between non-relativistic electrons of velocity v (with $1/137 \ll v \ll 1$) and atomic nuclei of small velocity is proportional to $v^{-2}d\omega/\omega$; the density of protons equals the density of electrons; and v is typically of order $(k_{\mathcal{B}}T/m_e)^{1/2}$; so the rate at which an antenna of radius R receives bremsstrahlung photons of wavelength λ in this energy range and in the resolution solid angle $(\lambda/R)^2$ from an optically thin plasma cloud with electron temperature T_e and number density n_e is

$$\left[R^2/d_A^2\right]\left[d_A^2(\lambda/R)^2\right]\int d\ell\langle v d\sigma\rangle n_e^2 \propto \lambda^2\left(\frac{d\omega}{\omega}\right)\int d\ell T_e^{-1/2} n_e^2 \tag{2.5.8}$$

Hence the value of n_e inferred from measurements of the X-ray luminosity and the angular size of the cluster is proportional to the assumed value of $H_0^{1/2}$. The requirement that the value of n_e inferred from the

[5] See, e.g., V. B. Berestetskii, E. M. Lifshitz, and L. P. Pitaevskii, Quantum Electrodynamics, 2nd edition, transl. by J. B. Sykes and J. S. Bell (Pergamon, Oxford, 1982).

X-ray luminosity should agree with the value obtained from the SunyaevZel'dovich effect thus allows an estimate of H_0. For example, study of two galaxy clusters with $z \simeq 0.55$ (with d_A calculated assuming $\Omega_M = 0.3$ and $\Omega_\Lambda = 0.7$) has given a Hubble constant of $63^{+12}_{-9} \pm 21$ km/sec/Mpc, with the first uncertainty statistical and the second systematic, both with 68% confidence. [6] Any such measurement depends so much on assumptions about the shape of the galaxy cluster and about the clumpiness of the electron distribution, that it seems likely that measurements of the SunyaevZel'dovich effect and X-ray luminosities will be more useful in providing information about galaxy clusters than in fixing the Hubble constant. In one respect, the Sunyaev-Zel'dovich effect is a nuisance - it will interfere with future measurements of the correlation between the primary temperature fluctuations at very small angular separation. [7] But if combined with a model of structure formation, such as discussed in Chapter 8, observations of the Sunyaev-Zel'dovich effect in small angle correlations of the microwave background temperature fluctuations can provide useful cosmological information. [8] Observations of such small-angle correlations [9] have been interpreted as due to the Sunyaev-Zel'dovich effect. [10]

10.2.6 2.6 Primary fluctuations in the microwave background: A first look

In the two previous sections we have considered anisotropies in the cosmic microwave background that arise from effects in the recent universe: the motion of the earth relative to the cosmic microwave background, and the scattering of light by intergalactic electrons in clusters of galaxies along the line of sight. Now we turn to general anisotropies, including the highly revealing primary anisotropies that have their origin in the early universe. [1]

It is convenient to expand the difference $\Delta T(\hat{n})$ between the microwave radiation temperature observed in a direction given by the unit vector $\hat{n}$ and the present mean value T_0 of the temperature in spherical harmonics $Y_\ell^m(\hat{n})$:

$$\Delta T(\hat{n}) \equiv T(\hat{n}) - T_0 = \sum_{\ell m} a_{\ell m} Y_\ell^m(\hat{n}), \quad T_0 \equiv \frac{1}{4\pi} \int d^2\hat{n} T(\hat{n}) \tag{2.6.1}$$

the sum over ℓ running over all positive-definite integers, and the sum over m running over integers from $-\ell$ to ℓ. Since $\Delta T(\hat{n})$ is real, the coefficients $a_{\ell m}$ must satisfy the reality condition

$$a^*_{\ell m} = a_{\ell -m} \tag{2.6.2}$$

(We are defining the spherical harmonics so that $Y_\ell^m(\hat{n})^* = Y_\ell^{-m}(\hat{n})$.) As we saw in Section 2.4, the earth's motion contributes to $\Delta T(\hat{n})$ an anisotropy that to a good approximation is proportional to $P_1(\cos\theta) \propto Y_1^0(\theta, \phi)$ (with the z-axis taken in the direction of the earth's motion), so the main $a_{\ell m}$ produced by this effect is that with $\ell = 1$ and $m = 0$.

The coefficients $a_{\ell m}$ reflect not only what was happening at the time of last scattering, but also the particular position of the earth in the universe. No cosmological theory can tell us this. The quantities of greatest cosmological interest are averages, which may be regarded either as

averages over the possible positions from which the radiation could be observed, or averages over the historical accidents that produced a particular pattern of fluctuations. The ergodic theorem described in Appendix D shows that, under reasonable assumptions, these two kinds of average are the same. These averages will be denoted $\langle \cdots \rangle$. As discussed in Chapter 10, for anisotropies that arise from quantum fluctuations during inflation, it is these averages over historical accidents that are related to quantum mechanical expectation values. We will return shortly to the question of how to use observations from one position in a universe produced by one specific sequence of accidents to learn about these averages, but first we must introduce some notation.

We assume that the universe is rotationally invariant on the average, so all averages $\langle \Delta T\left(\hat{n}_1\right) \Delta T\left(\hat{n}_2\right) \Delta T$ are rotationally invariant functions of the directions $\hat{n}_1, \hat{n}_2$, etc. In particular, $\langle \Delta T(\hat{n}) \rangle$ is independent of $\hat{n}$, Since $\Delta T(\hat{n})$ is defined as the departure of the temperature from its angular average, its angular average $\int \Delta T(\hat{n}) d^2\hat{n}/4\pi$ vanishes. Averaging over the position of the observer, we have $\int \langle \Delta T(\hat{n}) \rangle d^2\hat{n} = 0$, so since $\langle \Delta T(\hat{n}) \rangle$ is independent of $\hat{n}$, it too vanishes.

The simplest non-trivial quantity characterizing the anisotropies in the microwave background is the average of a product of two ΔT s. Rotational invariance requires that the product of two a s takes the form

$$\langle a_{\ell m} a_{\ell' m'} \rangle = \delta_{\ell \ell'} \delta_{m -m'} C_\ell \tag{2.6.3}$$

for in this case the average of the product of two ΔT s is rotationally invariant:

$$\langle \Delta T(\hat{n}) \Delta T\left(\hat{n}'\right) \rangle = \sum_{\ell m} C_\ell Y_\ell^m(\hat{n}) Y_\ell^{-m}\left(\hat{n}'\right) = \sum_\ell C_\ell \left(\frac{2\ell+1}{4\pi} \right) P_\ell\left(\hat{n} \cdot \hat{n}'\right) \tag{2.6.4}$$

where P_ℓ is the usual Legendre polynomial. Given the left-hand side, we can find C_ℓ by inverting the Legendre transformation

$$C_\ell = \frac{1}{4\pi} \int d^2\hat{n} d^2\hat{n}' P_\ell\left(\hat{n} \cdot \hat{n}'\right) \langle \Delta T(\hat{n}) \Delta T\left(\hat{n}'\right) \rangle \tag{2.6.5}$$

Instead of Eq. (2.6.3), we could equivalently define the multipole coefficients C_ℓ by

$$\langle a_{\ell m} a^*_{\ell' m'} \rangle = \delta_{\ell \ell'} \delta_{m m'} C_\ell$$

which shows that the C_ℓ are real and positive. For perturbations ΔT that are Gaussian in the sense described in Appendix E, a knowledge of the C_ℓ tells us all we need to know about averages of all products of ΔT s.

Of course, we cannot average over positions from which to view the microwave background. What is actually observed is a quantity averaged over m but not position:

$$C_\ell^{\rm obs} \equiv \frac{1}{2\ell+1} \sum_m a_{\ell m} a_{\ell -m} = \frac{1}{4\pi} \int d^2\hat{n} d^2\hat{n}' P_\ell\left(\hat{n} \cdot \hat{n}'\right) \Delta T(\hat{n}) \Delta T\left(\hat{n}'\right) \tag{2.6.6}$$

The fractional difference between the cosmologically interesting C_ℓ and the observed $C_\ell^{\rm obs}$ is known as the cosmic variance. Fortunately, for Gaussian perturbations, the mean square cosmic variance decreases with ℓ. The mean square fractional difference is

$$\left\langle \left(\frac{C_\ell - C_\ell^{\rm obs}}{C_\ell} \right)^2 \right\rangle = 1 - 2 + \frac{1}{(2\ell+1)^2 C_\ell^2} \sum_{m m'} \langle a_{\ell m} a_{\ell -m} a_{\ell m'} a_{\ell -m'} \rangle \,. \tag{2.6.7}$$

If ΔT is governed by a Gaussian distribution, then so are its multipole coefficients $a_{\ell m}$ (but not quantities quadratic in the $a_{\ell m}$, such as C_ℓ.) It follows then that [2]

$$\begin{aligned}\langle a_{\ell m}a_{\ell -m}a_{\ell m'}a_{\ell -m'}\rangle = &\langle a_{\ell m}a_{\ell -m}\rangle\langle a_{\ell m'}a_{\ell -m'}\rangle \\ &+\langle a_{\ell m}a_{\ell m'}\rangle\langle a_{\ell -m}a_{\ell -m'}\rangle \\ &+\langle a_{\ell m}a_{\ell -m'}\rangle\langle a_{\ell -m}a_{\ell m'}\rangle \end{aligned} \tag{2.6.8}$$

Using Eq. (2.6.3), we find that the first term on the right-hand side of Eq. (2.6.8) contributes $(2\ell+1)^2C_\ell^2$ to the sum in Eq. (2.6.7), while the second and third terms each contribute $(2\ell+1)C_\ell^2$ to the sum, so that

$$\left\langle \left(\frac{C_\ell - C_\ell^{\rm obs}}{C_\ell}\right)^2 \right\rangle = \frac{2}{2\ell+1} \tag{2.6.9}$$

This sets a limit on the accuracy with which we can measure C_ℓ for small values of ℓ. On the other hand, the same analysis shows that for $\ell \neq \ell'$,

$$\left\langle \left(\frac{C_\ell - C_\ell^{\rm obs}}{C_\ell}\right)\left(\frac{C_{\ell'} - C_{\ell'}^{\rm obs}}{C_{\ell'}}\right) \right\rangle = 0, \tag{2.6.10}$$

so the fluctuations of $C_\ell^{\rm obs}$ away from the smoothly varying quantity C_ℓ are uncorrelated for different values of ℓ. This means that when $C_\ell^{\rm obs}$ is measured for all ℓ in some range $\Delta\ell$ in which C_ℓ actually varies little, the uncertainty due to cosmic variance in the value of C_ℓ obtained in this range is reduced by a factor $1/\sqrt{\Delta\ell}$. Even so, measurements of C_ℓ for $\ell < 5$ probably tell us little about cosmology. Also, measurements for $\ell > 2,000$ are corrupted by foreground effects, such as the Sunyaev-Zel'dovich effect discussed in the previous section. Fortunately there is lots of structure in C_ℓ at values of ℓ between 5 and 2,000 that provides invaluable cosmological information.

The primary anisotropies in the cosmic microwave background arise from several sources:

1. Intrinsic temperature fluctuations in the electron-nucleon-photon plasma at the time of last scattering, [3] at a redshift of about 1,090 .

2. The Doppler effect due to velocity fluctuations in the plasma at last scattering.

3. The gravitational redshift or blueshift due to fluctuations in the gravitational potential at last scattering. This is known as the SachsWolfe effect. [4]

[472] Non-Gaussian terms in the probability distribution of anisotropies would show up as non-vanishing averages of products of odd numbers of the $a_{\ell m}$, as well as corrections to formulas like Eq. (2.6.8) for the averages of products of even numbers of the $a_{\ell m}$. Such non-Gaussian terms are produced both in the early universe and at relatively late times. For a review, see N. Bartolo, E. Komatsu, S. Matarrese, and A. Riotto, Phys. Rep. 402, 103 (2004). Non-Gaussian terms produced by quantum fluctuations during inflation were calculated in the tree graph approximation by J. Maldacena, J. High Energy Phys.

[47]05 (2003) 013. The effect of loop graphs is considered by S. Weinberg, Phys. Rev. D 72, 043514 (2005) [hep-ph/0506236]; Phys. Rev. D. 74, 023508 (2006) [hep-ph/0605244]; K. Chaicherdsakul, Phys. Rev. D 75, 063522 (2007) [hep-th/0611352]. For late-time contributions, see M. Liguori, F. K. Hansen, E. Komatsu, S. Matarrese, and A. Riotto, Phys. Rev. D 73, 043505 (2006) [astro-ph/0509098]. The weakness of microwave background anisotropies indicates that any non-Gaussian terms are likely to be quite small. So far, there is no observational evidence of such terms.

[3] Strictly speaking, in the approximation of a sudden drop in opacity at a fixed temperature $T_L \simeq 3,000$ K, it is not the intrinsic fluctuation in temperature we observe, but the consequent fluctuation in the redshift z_L of last scattering. Since the unperturbed temperature $\bar{T}(t)$ goes as $1/a(t)$, the value a_L of $a(t)$ at which the total temperature $\bar{T}(t) + \delta T(t)$ reaches a fixed value T_L is shifted by an amount δa_L such that $-(T_L/a_L)\,\delta a_L + \delta T(t_L) = 0$. The observed temperature (leaving aside other effects) is $T_L a(t_L)/a_0$, so to first order this is shifted by a fractional amount $T_L\delta a_L/a_0T_0 = \delta T(t_L)\,a_L/a_0T_0 = \delta T(t_L)/T_L$, just as if it were the intrinsic temperature fluctuation that we observe.

4. Gravitational redshifts or blueshifts due to time-dependent fluctuations in the gravitational potential between the time of last scattering and the present. (It is necessary that the fluctuations be time-dependent; a photon falling into a time-independent potential well will lose the energy it gains when it climbs out of it.) This is known, somewhat confusingly, as the integrated Sachs-Wolfe effect. [4]

A proper treatment of these effects requires the use of general relativity. This will be the subject of Chapters 5-7. On the other hand, from the time the temperature dropped below 10^4 K until vacuum energy became important at a redshift of order unity, the gravitational field of the universe was dominated to a fair approximation by cold dark matter, which can be treated by the methods of Newtonian physics. Therefore in this introductory section we will concentrate on the Sachs-Wolfe and integrated Sachs-Wolfe effect, which turn out to dominate the multipole coefficients C_ℓ for relatively small ℓ, less than about 40 . We will make only a few tentative remarks in this section about the contribution of intrinsic temperature fluctuations and of the Doppler effect.

In considering the Sachs-Wolfe and integrated Sachs-Wolfe effects, we return to the Newtonian approach to cosmology outlined in Eqs. (1.5.21)(1.5.27). The treatment of perturbations to a homogeneous isotropic cosmology in this approach is presented in Appendix F. For the moment, we need only one result of this analysis, that the perturbation to the gravitational potential, when expressed as a function of the co-moving coordinate $\mathbf{x}$, is a time-independent function $\delta\phi(\mathbf{x})$. This perturbation has two effects. First, there is the usual gravitational redshift: A photon emitted at a point $\mathbf{x}$ at the time of last scattering will have its frequency and hence its energy shifted by a fractional amount $\delta\phi(\mathbf{x})$, so the temperature seen when we look in a direction $\hat{n}$ will be shifted from the average over the whole sky by an amount

$$\left(\frac{\Delta T(\hat{n})}{T_0}\right)_1 = \delta\phi\left(\hat{n}r_L\right) \tag{2.6.11}$$

Here r_L is the radial coordinate of the surface of last scattering, given by Eq. (1.5.44) as

$$r_L = \frac{1}{\Omega_K^{1/2} H_0 a\left(t_0\right)} \sinh\left[\Omega_K^{1/2}\int_{1/(1+z_L)}^{1}\frac{dx}{\sqrt{\Omega_\Lambda x^4+\Omega_K x^2+\Omega_M x+\Omega_R}}\right] \tag{2.6.12}$$

where $\Omega_K = 1-\Omega_\Lambda-\Omega_M-\Omega_R$; $z_L \simeq 1090$ is the redshift of last scattering; and t_0 is the present. The perturbation to the gravitational potential also has the effect of changing the rate at which the universe expands by a fractional amount $\delta\phi(\mathbf{x})$, and since the temperature in a matter-dominated universe is falling like $a^{-1} \propto t^{-2/3}$, this shifts the value of the redshift at which the universe reaches the temperature $\simeq 3,000$ K of last scattering in direction $\hat{n}$ by a fractional amount

$$\left(\frac{\delta z}{1+z}\right)_{T=3000\text{ K}} = -\left(\frac{\delta a(t)}{a(t)}\right)_{T=3000\text{ K}} = \left(\frac{\dot{a}}{a}\right)_{T=3000\text{ K}}$$
$$\delta\phi\left(r_L\hat{n}\right)t_L = \frac{2}{3}\delta\phi\left(r_L\hat{n}\right)$$

With all other effects neglected, the temperature observed in direction $\hat{n}$ would be $3,000$ K divided by $1+z$, so this fractional shift in $1+z$ changes the observed temperature by a fractional amount

$$\left(\frac{\Delta T(\hat{n})}{T_0}\right)_2 = -\frac{2}{3}\delta\phi\left(\hat{n}r_L\right) \tag{2.6.13}$$

The sum of the fractional shifts (2.6.11) and (2.6.13) gives the Sachs-Wolfe effect:

[474] R. K. Sachs and A. M. Wolfe, Astrophys. J. 147, 73 (1967).

$$\left(\frac{\Delta T(\hat{n})}{T_0}\right)_{\rm SW} = \frac{1}{3}\delta\phi\left(\hat{n}r_L\right) \tag{2.6.14}$$

The factor 1/3 will be obtained in Chapter 7 as a result of a better-grounded relativistic treatment.

It is convenient to write $\delta\phi(\mathbf{x})$ as a Fourier transform

$$\delta\phi(\mathbf{x}) = \int d^3q e^{i\mathbf{q}\cdot\mathbf{x}}\delta\phi_{\mathbf{q}} \tag{2.6.15}$$

We make use of the well-known Legendre expansion of the exponential

$$e^{i\mathbf{q}\cdot\mathbf{x}} = \sum_\ell (2\ell+1) i^\ell P_\ell(\hat{q}\cdot\hat{n}) j_\ell(qr) \tag{2.6.16}$$

where j_ℓ is the spherical Bessel function, defined in terms of the usual Bessel function $J_\nu(z)$ by $j_\ell(z) \equiv (\pi/2z)^{1/2} J_{\ell+1/2}(z)$. Eq. (2.6.14) then
gives

$$\left(\frac{\Delta T(\hat{n})}{T_0}\right)_{\rm SW} = \frac{1}{3}\sum_{\ell=0}^{\infty}(2\ell+1)i^\ell \int d^3q \delta\phi_{\mathbf{q}} j_\ell\left(qr_L\right) P_\ell(\hat{q}\cdot\hat{n}) \tag{2.6.17}$$

Now we must consider how to calculate the average of a product of two of these fractional temperature shifts in two different directions. Although $\delta\phi(\mathbf{x})$ depends on position, the probability distribution of $\delta\phi(\mathbf{x})$ as seen by observers in different parts of the universe is invariant under spatial rotations and translations. This implies among other things that

$$\langle \delta\phi_{\mathbf{q}} \delta\phi_{\mathbf{q}'}\rangle = \mathcal{P}_\phi(q)\delta^3\left(\mathbf{q}+\mathbf{q}'\right) \tag{2.6.18}$$

where $\mathcal{P}_\phi(q)$ is a function only of the magnitude of $\mathbf{q}$. (The delta function is needed so that $\langle\delta\phi(\mathbf{x})\delta\phi(\mathbf{y})\rangle$ should be only a function of $\mathbf{x}-\mathbf{y}$.) Because $\delta\phi(\mathbf{x})$ is real, its Fourier transform satisfies the reality condition $\delta\phi^*_{\mathbf{q}} = \delta\phi_{-\mathbf{q}}$, which together with Eq. (2.6.18) tells us that $\mathcal{P}_\phi(q)$ is real and positive.

Now, using Eqs. (2.6.17) and (2.6.18), together with the reflection property $P_\ell(-z) = (-1)^\ell P_\ell(z)$ and the orthogonality property of Legendre polynomials

$$\int d\Omega_{\hat{q}} P_\ell(\hat{n}\cdot\hat{q}) P_{\ell'}\left(\hat{n}'\cdot\hat{q}\right) = \left(\frac{4\pi}{2\ell+1}\right)\delta_{\ell\ell'} P_\ell\left(\hat{n}\cdot\hat{n}'\right) \tag{2.6.19}$$

we have
$\langle\Delta T(\hat{n})\Delta T\left(\hat{n}'\right)\rangle_{\rm SW} = \frac{4\pi T_0^2}{9}\sum_\ell (2\ell+1) P_\ell\left(\hat{n}\cdot\hat{n}'\right)\int_0^\infty q^2 dq \mathcal{P}_\phi(q) j_\ell^2\left(qr_L\right)$,
or, comparing with Eq. (2.6.4),

$$C_{\ell,\rm SW} = \frac{16\pi^2 T_0^2}{9}\int_0^\infty q^2 dq \mathcal{P}_\phi(q) j_\ell^2\left(qr_L\right) \tag{2.6.21}$$

To the extent that the gravitational potential is produced by pressureless cold dark matter, the differential equation for $\delta\phi$ does not involve gradients, and so the differential equation for its Fourier transform does not involve the wave vector $\mathbf{q}$. (See Eqs. (F.12) and (F.18).) The dependence of $\delta\phi_{\mathbf{q}}$ on $\boldsymbol{q}$ then can arise only from the initial conditions for these differential equations. [5] It is therefore natural to try the hypothesis that the function

[475] This is not true even for the Sachs-Wolfe effect if q is so large that q/a became greater than H before the density of the universe became dominated by cold matter. As we will see in Chapter 7, this qualification affects C_ℓ SW only for $\ell > 100$.

$\mathcal{P}_\phi(q)$ has a simple form, such as a power of q. This power is conventionally written as $n-4$:

$$\mathcal{P}_\phi(q) = N_\phi^2 q^{n-4} \tag{2.6.22}$$

where N_ϕ^2 is a positive constant. Then we can use a standard formula:

$$\int_0^\infty j_\ell^2(s) s^{n-2} ds = \frac{2^{n-4}\pi\Gamma(3-n)\Gamma\left(\ell+\frac{n-1}{2}\right)}{\Gamma^2\left(\frac{4-n}{2}\right)\Gamma\left(\ell+2-\frac{n-1}{2}\right)} \tag{2.6.23}$$

and find that for $\ell < 100$, Eq. (2.6.21) gives

$$C_{\ell \mathrm{SW}} \to \frac{16\pi^3 2^{n-4}\Gamma(3-n) r_L^{1-n} N_\phi^2 T_0^2}{9\Gamma^2\left(\frac{4-n}{2}\right)} \frac{\Gamma\left(\ell+\frac{n-1}{2}\right)}{\Gamma\left(\ell+2-\frac{n-1}{2}\right)}. \tag{2.6.24}$$

In particular, even before the discovery of primary fluctuations in the cosmic microwave background there was a general expectation about the values of n and N, based not on the microwave background, but on the large scale structure of matter observed relatively close to the present. The perturbation $\delta\rho$ in the total mass density is related to the Sachs-Wolfe effect through the Poisson equation, which gives

$$a^{-2}\nabla^2\delta\phi = 4\pi G\delta\rho \tag{2.6.25}$$

with the factor $a^{-2}(t)$ inserted because it is $\mathbf{X} = a(t)\mathbf{x}$ that measures proper distances. (See Eq. (F.12).) Expressing the Fourier transform of $\delta\rho$ in terms of the Fourier transform of $\delta\phi$, we find the correlation function of the density fluctuations to be

$$\langle \delta\rho(\mathbf{x},t)\delta\rho\left(\mathbf{x}',t'\right)\rangle = \left(4\pi G a(t) a\left(t'\right)\right)^{-2} \int d^3q q^4 \mathcal{P}_\phi(q) e^{i\mathbf{q}\cdot(\mathbf{x}-\mathbf{x}')} \tag{2.6.26}$$

The use of this formula to measure $\mathcal{P}_\phi$ is discussed in Chapter 8. For the present, it is enough to note that observations of the density correlation function long ago led to the expectation that $\mathcal{P}_\phi$ takes the so-called Harrison-Zel'dovich form [6] with $n = 1$, and that $N_\phi \approx 10^{-5}$. As we will see in Chapter 10, inflationary theories generally predict that n is close but not

precisely equal to unity. For $n = 1$, we obtain a result that is scale-invariant, in the sense of being independent of r_L :

$$C_{\ell,\mathrm{SW}} \to \frac{8\pi^2 N_\phi^2 T_0^2}{9\ell(\ell+1)} \tag{2.6.27}$$

This is why experimental data on the cosmic microwave background anisotropies is usually presented as a plot of $\ell(\ell+1)C_\ell$ versus ℓ.

What about the other contributions to C_ℓ ? Pressure gradients are important in the dynamics of the photon-nucleon-electron plasma, so in estimating the contributions of the Doppler effect and intrinsic temperature fluctuations we must deal with differential equations in which the wave number q enters in an important way. Whatever sort of perturbation we are considering, we can always write it as a Fourier integral like Eq. (2.6.15) and use Eq. (2.6.16) to express $e^{i\mathbf{q}\cdot\hat{n}r_L}$ as a series of Legendre polynomials $P_\ell(\hat{q}\cdot\hat{n})$ with coefficients proportional to $j_\ell\left(qr_L\right)$. The integral over q is then dominated by values of q of order ℓ/r_L in the case $\ell \gg 1$. (This is the most interesting case because Eq. (2.6.9) shows that it is only for $\ell \gg 1$ that cosmic variance can be neglected in measurements of C_ℓ.) This is because for $\ell \gg 1$, the spherical

[476] E. R. Harrison, Phys. Rev. D1, 2726 (1970); Ya. B. Zel'dovich, Mon. Not. Roy. Astron. Soc. 160, 1P (1972).

Bessel function $j_\ell(z)$ is peaked at $z \simeq \ell$. Specifically, for $v \equiv \ell + 1/2 \to \infty$ and $z \to \infty$ with v/z fixed at a value other than unity, we have

$$j_\ell(z) \to \begin{cases} 0 & z < v \\ z^{-1/2}\left(z^2 - v^2\right)^{-1/4} \cos\left(\sqrt{z^2 - v^2} - v \arccos(v/z) - \frac{\pi}{4}\right) & z > v. \end{cases} \tag{2.6.28}$$

Hence C_ℓ for large ℓ chiefly reflects the behavior of the Fourier components of perturbations for $q \approx \ell/r_L$. To put this another way, the physical wave number at time t_L is $\mathbf{k}_L \equiv \mathbf{q}/a\left(t_L\right)$ (because it is $a\left(t_L\right)\mathbf{x}$ that measures proper distances at this time) so C_ℓ for large ℓ reflects the behavior of the perturbations for $k_L \approx \ell/d_A$, where d_A is the angular diameter distance of the surface of last scattering

$$\begin{aligned} d_A \equiv r_L a\left(t_L\right) = & \frac{1}{\Omega_K^{1/2} H_0\left(1 + z_L\right)} \\ & \times \sinh\left[\Omega_K^{1/2} \int_{\frac{1}{1+z_L}}^1 \frac{dx}{\sqrt{\Omega_\Lambda x^4 + \Omega_K x^2 + \Omega_M x + \Omega_R}}\right] \end{aligned} \tag{2.6.29}$$

with $1 + z_L \equiv a\left(t_0\right)/a\left(t_L\right)$.

For physical wave numbers q/a that are much less than the expansion rate H the differential equation governing any one perturbation is essentially independent of the wave number q, so that the whole dependence of the perturbation on q comes from the initial conditions. (Ratios of different perturbations, such as $\delta\phi_q$ and $\delta\rho_q$, may of course depend on q.) Such perturbations are said to be "outside the horizon" because the wavelength $2\pi a/q$ is much larger than the horizon distance (strictly speaking, the "particle horizon" distance), which we saw in Section 1.13 is roughly of order $1/H$. During the radiation- or matter-dominated eras q/a decreased like $t^{-1/2}$ or $t^{-2/3}$, while H decreased faster, like $1/t$, so perturbations that were outside the horizon at early times subsequently came within the horizon, those with high wave number entering the horizon earlier than those with lower wave numbers.

We need to be a little more precise about the horizon distance. At the time of last scattering the universe was largely matter dominated, so as shown in Section 1.13 the horizon distance at that time was approximately $2/H\left(t_L\right)$. But this is the maximum proper distance that light could have traveled since the beginning of the present phase of the expansion of the universe. As we will see in Chapters 5 and 6, the dominant perturbations to the plasma of nucleons, electrons, and photons that are relevant to the anisotropies in the cosmic microwave background are sound waves, so we need to take into account the smaller speed of sound. During the era before recombination, when radiation and matter were in thermal equilibrium, the speed of sound was $v_s = (\delta p/\delta\rho)^{1/2}$, where δp and $\delta\rho$ are infinitesimal variations in the pressure and density in an adiabatic fluctuation. In such a perturbation, the entropy per baryon remains unperturbed:

$$0 = \delta\sigma \propto \delta\left(\frac{\epsilon}{n_B}\right) + p\delta\left(\frac{1}{n_B}\right),$$

where ϵ is the thermal energy density, n_B is the baryon number density, and p is the pressure. As we saw in Section 2.2, there are so many more photons than baryons that both ϵ and p are dominated by radiation:

$$\epsilon = a_{\mathcal{B}} T^4, \quad p = \frac{1}{3} a_{\mathcal{B}} T^4,$$

and therefore for adiabatic perturbations

$$3\frac{\delta T}{T} = \frac{\delta n_B}{n_B} = \frac{\delta \rho_B}{\rho_B}, \tag{2.6.30}$$

where ρ_B is the baryonic mass density. This gives a sound speed

$$v_s = \left(\frac{4a_{\mathcal{B}}T^3\delta T/3}{\delta\rho_B + 4a_{\mathcal{B}}T^3\delta T}\right)^{1/2} = \frac{1}{\sqrt{3(1+R)}}, \tag{2.6.31}$$

where $R \equiv 3\rho_B/4a_{\mathcal{B}}T^4$. Since $\rho_B \propto a^{-3}$ and $T \propto a^{-1}$, we have $R \propto a$, and hence $dt = dR/HR$, or in more detail,

$$dt = \frac{dR}{RH_0\sqrt{\Omega_M\left(R_0/R\right)^3 + \Omega_R\left(R_0/R\right)^4}} = \frac{RdR}{H_0\sqrt{\Omega_M}R_0^{3/2}\sqrt{R_{\rm EQ}+R}}$$

where $R_{\rm EQ} \equiv \Omega_R R_0/\Omega_M = 3\Omega_R\Omega_B/4\Omega_M\Omega_\gamma$ is the value of R at matterradiation equality. The acoustic horizon distance is then

$$\begin{aligned} d_H &\equiv a_L\int_0^{t_L}\frac{dt}{a\sqrt{3(1+R)}} = R_L\int_0^{t_L}\frac{dt}{R\sqrt{3(1+R)}} \\ &= \frac{2}{H_0\sqrt{3R_L\Omega_M}\left(1+z_L\right)^{3/2}}\ln\left(\frac{\sqrt{1+R_L}+\sqrt{R_{\rm EQ}+R_L}}{1+\sqrt{R_{\rm EQ}}}\right) \end{aligned} \tag{2.6.32}$$

where $R_L = 3\Omega_B/4\Omega_\gamma\left(1+z_L\right)$ is the value of R at last scattering. Gradients become important when $k_L \approx 1/d_H$, and since in C_ℓ the integral over wave number is dominated by $k_L \approx \ell/d_A$, gradients become important when ℓ reaches the value ℓ_H, where $\ell_H \equiv d_A/d_H$. Both d_A and d_H are proportional to $1/H_0$, so H_0 cancels in the ratio.

For a crude estimate of ℓ_H, we note that d_A is proportional to $\left(1+z_L\right)^{-1}$, while d_H is proportional to $\left(1+z_L\right)^{-3/2}$, so ℓ_H is of the order of $\left(1+z_L\right)^{1/2} = 33$. To get a closer estimate, we will take cosmological parameters to have sample values suggested by supernova observations and cosmological nucleosynthesis (discussed in Section 3.2): $\Omega_M = 0.26, \Omega_\Lambda = 0.74, \Omega_B = 0.043$. This gives $R_L = 0.62, R_{\rm EQ} = 0.21, d_A = 3.38H_0^{-1}\left(1+z_L\right)^{-1}$ and $d_H = 1.16H_0^{-1}\left(1+z_L\right)^{-3/2}$, and hence $\ell_H = 2.9\sqrt{1+z_L} = 96$.

We can now estimate the relative magnitude of the contributions to C_ℓ other than the Sachs-Wolfe effect:

- Doppler effect: Like any vector field, the plasma velocity can be decomposed into a term given by the gradient of a scalar, plus a "vector" term whose divergence vanishes. Appendix F shows that the vector term decays as $1/a$, so the dominant perturbations are compressional modes, for which the velocity is the gradient of a scalar. We can therefore expect that in the integral over wave numbers q for $\Delta T/T_0$, the contribution of the Doppler effect will be suppressed for small wave numbers by a factor of order $\mathbf{k}_L d_H$. We will see in Chapter 7 that, because it is proportional to the vector $\mathbf{k}_L$, the Doppler effect contribution does not interfere with the contribution of the SachsWolfe effect, so for a multipole order $\ell \ll \ell_H$, the contribution of the Doppler effect will be less than that of the Sachs-Wolfe effect by a factor of order $\left[\left(\ell/d_A\right)d_H\right]^2 = \ell^2/\ell_H^2$.

- Intrinsic temperature fluctuations: As we have seen in Eq. (2.6.30) the intrinsic fractional temperature fluctuation at the time of last scattering will be just one-third the intrinsic fractional perturbation in the plasma density. As discussed in Chapters 5 and 6, the particular perturbations that are believed to dominate outside the horizon are adiabatic

in the further sense that the fractional perturbation in the plasma density is equal to the fractional perturbation $\delta\rho/\bar{\rho}$ in the total matter density. But the perturbation to the total matter density is related to the perturbation to the gravitational potential by Poisson's equation (2.6.25), which if evaluated at the time of last scattering gives for the Fourier transform:

$$\delta\rho_{\mathbf{q}}(t_L) = -\frac{q^2}{4\pi G a^2(t_L)}\delta\phi_{\mathbf{q}} = -\frac{k_L^2}{4\pi G}\delta\phi_{\mathbf{q}}$$

where, as before, $k = q/a(t_L)$. Also, the mean total mass density $\bar{\rho}(t_L)$ at last scattering is related to the horizon size d_H by

$$\bar{\rho}(t_L) \simeq \frac{3H^2(t_L)}{8\pi G} \approx \frac{1}{2\pi G d_H^2}$$

so the order of magnitude of the intrinsic fractional temperature perturbation is related to the perturbation to the gravitational potential by

$$\frac{\delta T(t_L)}{\bar{T}(t_L)} = \frac{\delta\rho(t_L)}{3\bar{\rho}(t_L)} \approx k_L^2 d_H^2 \delta\phi_q \tag{2.6.33}$$

Thus we expect that in the integral over wave numbers q for $\Delta T/T_0$, the contribution of intrinsic temperature fluctuations will be suppressed for small wave numbers by a factor $\mathbf{k}_L^2 d_H^2$. The interference of this contribution with the Sachs-Wolfe term then makes a contribution to C_ℓ for $\ell \ll \ell_{\text{horizon}}$ that, like the contribution of the Doppler effect, is smaller than the Sachs-Wolfe contribution by a factor of order $[(\ell/d_A)\, d_H]^2 \approx \ell^2/\ell^2_{\text{horizon}}$. (It should be noted that the distinction between the Sachs-Wolfe effect and the effect of intrinsic temperature fluctuations depends on how the time coordinate is defined. The nonrelativistic estimates made here correspond to what in the relativistic treatment of Chapters $5-7$ would be the use of what are called Newtonian gauge coordinates.)

- Integrated Sachs-Wolfe effect: As already mentioned, to the extent that $\delta\phi$ is truly time independent, there is no integrated Sachs-Wolfe effect. The blueshift caused by a photon falling into a time-independent gravitational potential well along the line of sight would be canceled by
  the redshift caused when the photon climbs out of the well. [7] In fact, the perturbation to the gravitational field is not strictly time-independent, both because radiation continues to make a non-negligible contribution to the gravitational field for some time after last scattering, and also because at late times vacuum energy requires modifications to the Newtonian treatment presented in Appendix F. The late-time integrated Sachs-Wolfe effect chiefly affects C_ℓ for ℓ less than about 10 .

It is reasonable then to assume that for $10 < \ell < 50$, the dominant contribution to C_ℓ is from the Sachs-Wolfe effect.

Apart from observation of the $\ell = 1$ anisotropy due to the earth's motion through the microwave background, the first detection of an anisotropy in the cosmic microwave radiation background was achieved by the COBE satellite in 1992. [8] This experiment scanned the sky with two microwave antennae separated by 60°, at frequencies $31.5, 53$, and 90 GHz near the minimum of emission from our galaxy and the maximum of the Planck distribution for 2.7 K . The 1992 data showed an rms fluctuation in the temperature with angle of $30 \pm 5\mu$ K, with an angular distribution consistent with $n = 1$. After four years, values of C_ℓ had been measured [9] with the same instruments at values of ℓ ranging from $\ell = 2$ to $\ell = 40$. For $\ell \geq 4$ the results

were fit to the ℓ-dependence given by Eq. (2.6.24), with the result that $n = 1.13^{+0.3}_{-0.4}$, which is consistent with the value $n = 1$ for what is called a Harrison-Zel'dovich spectrum. This result is often written as

$$C_\ell = \frac{24\pi Q^2}{5\ell(\ell+1)} \tag{2.6.34}$$

with Q known as the quadrupole moment. Fitting the values of C_ℓ for $10 \leq \ell \leq 40$, the 1996 COBE results gave $Q = 18 \pm 1.4\mu$ K. Comparing Eq. (2.6.34) with (2.6.27), we see that

$$N_\phi = \sqrt{\frac{27}{5\pi}}\frac{Q}{T_0} = (8.7 \pm 0.7) \times 10^{-6} \tag{2.6.35}$$

Surprisingly, the multipole coefficients for $\ell = 2$ and $\ell = 3$ were found to be much less than would be expected by extrapolation of Eq. (2.6.34) from

the fit for $\ell \geq 4$, [10] as shown by the apparent absence of two-point correlations for angles greater than about 60°. The discrepancy with theory is even worse when the integrated Sachs-Wolfe effect is taken into account. This result has since been confirmed by observations with the WMAP satellite, [11] to be discussed in Chapter 7. It is quite possible that this discrepancy is due to a combination of foreground contamination and cosmic variance, [12] which according to Eq. (2.6.9) is 63% for $\ell = 2$.

We will have to wait to discuss calculations of C_ℓ for large ℓ, above the range of validity of Eq. (2.6.34), until Chapter 7, after we have developed the general relativistic theory of cosmological fluctuations in Chapters 5 and 6. In Chapter 7 we will also come back to the observations over the past decade that have refined the COBE measurements and extended them to higher ℓ.

10.3 The Early Universe

We have been exploring the period in the history of the universe when the radiation temperature dropped from a little over 10^4 K down to its present value of 2.725 K . We now want to look back to the era when the temperature was greater than about 10^4 K, well before the energy density in radiation fell below that of baryons and cold dark matter. We will carry the story back to when the temperature was above 10^{10} K, when electron-positron pairs were abundant and neutrinos were in equilibrium with these pairs, and even farther back, as far as our current knowledge of the laws of physics will take us.

[477] There is also an anisotropy produced by time-dependent fluctuations in the gravitational potential of cosmological inhomogeneities (such as concentrations of cold dark matter), known as the Rees-Sciama effect; M. J. Rees and D. W. Sciama, Nature 217, 511 (1968). This is expected to be quite small; see U. Seljak, Astrophys. J. 460, 549 (1996). For possible larger effects due to local structures, see A. Rakić, Syksy Räsänen, and D. J. Schwarz, Mon. Not. Roy. Astron. Soc. 363, L27 (2006) [astro-ph/0601445].

10.3.1 3.1 Thermal history

We first want to work out the history of the falling temperature of the early universe. In this section we will look back only to a time when the temperature was between 10^4 K and 10^{11} K, which is low enough so that muon-antimuon and hadron-antihadron pairs were no longer being produced in appreciable numbers.

There are two circumstances that greatly simplify this task. The first is that the collision rate of photons with electrons and other charged particles during this era was so much greater than the expansion rate of the universe that the photons and charged particles can be assumed to have been in thermal equilibrium, with a common falling temperature. At sufficiently early times even the neutrinos and perhaps the cold dark matter particles were also in thermal equilibrium with the photons and charged particles; later, when no longer colliding rapidly with other particles, they can be treated separately as free particles. The other circumstance is that the number density of baryons (or more strictly, the number density of baryons minus the number density of antibaryons) is so much less than the number density of photons that we can ignore the chemical potential associated with baryon number. Baryons will be put back into the picture in the following section. Also, because the electron/photon number ratio is so small now, it is reasonable to assume that the universe has always had a very small net lepton number density (the number density of leptons of all sorts minus that of antileptons) per photon. This means that even at temperatures of order 10^{10} K, when electron-positron pairs were abundant and the energy density and pressure were not simply proportional to T^4 and the entropy density was not simply proportional to T^3, the entropy density, energy density, and pressure were functions $s(T), \rho(T)$, and $p(T)$ of the temperature alone.
(The possibility of a non-negligible net lepton number is discussed at the end of this section.)

Before studying the history of the universe during this era we will have to take a brief look at the thermodynamics and statistical mechanics of this sort of matter, in thermal equilibrium with negligible chemical potentials. The condition of thermal equilibrium tells us that the entropy in a co-moving volume is fixed

$$s(T)a^3 = \text{ constant} \tag{3.1.1}$$

The second law of thermodynamics says that any adiabatic change in a system of volume V produces a change in the entropy given by

$$d(s(T)V) = \frac{d(\rho(T)V) + p(T)dV}{T} \tag{3.1.2}$$

Equating the coefficients of dV gives our formula for the entropy density

$$s(T) = \frac{\rho(T) + p(T)}{T} \tag{3.1.3}$$

Also, equating the coefficients of VdT and using Eq. (3.1.3) give the law of conservation of energy:

$$T\frac{dp(T)}{dT} = \rho(T) + p(T) \tag{3.1.4}$$

(For instance, for radiation we have $p(T) = \rho(T)/3$, so Eq. (3.1.4) gives the Stefan-Boltzmann law $\rho = a_{\mathcal{B}}T^4$ with $a_{\mathcal{B}}$ a constant that cannot be determined from thermodynamics alone; Eq. (3.1.3) then gives the entropy density for radiation as $s(T) = 4a_{\mathcal{B}}T^3/3$. This is why in we said in Section 2.2 that the constant $\sigma k_{\mathcal{B}} \equiv 4a_{\mathcal{B}}T^3/3n_B$ may be interpreted as the radiation entropy per baryon.)

With equal numbers of particles and antiparticles, the number density $n(p)dp$ of a species of fermions (such as electrons) or bosons (like photons) of mass m and momentum between p and $p+dp$ is given by the Fermi-Dirac or Bose-Einstein distributions (with zero chemical potential)

$$n(p,T) = \frac{4\pi g p^2}{(2\pi\hbar)^3}\left(\frac{1}{\exp\left(\sqrt{p^2+m^2}/k_{\mathcal{B}}T\right)\pm 1}\right) \tag{3.1.5}$$

where g is the number of spin states of the particle and antiparticle, and the sign is + for fermions and - for bosons. For instance, for photons $g = 2$ (and of course $m = 0$), because photons have two polarization states and they are their own antiparticles, while for electrons and positrons $g = 4$, because they have two spin states and electrons and positrons are distinct particle species. The energy density and pressure of a particle of mass m are given by the integrals [1]

$$\rho(T) = \int_0^\infty n(p,T)dp\sqrt{p^2+m^2} \tag{3.1.6}$$

$$p(T) = \int_0^\infty n(p,T)dp\frac{p^2}{3\sqrt{p^2+m^2}} \tag{3.1.7}$$

The entropy density of this particle is then given by Eq. (3.1.3) as

$$s(T) = \frac{1}{T}\int_0^\infty n(p,T)dp\left[\sqrt{p^2+m^2}+\frac{p^2}{3\sqrt{p^2+m^2}}\right] \tag{3.1.8}$$

In particular, for massless particles Eq. (3.1.6) gives

$$\begin{aligned}\rho(T) &= g\int_0^\infty \frac{4\pi p^3 dp}{(2\pi\hbar)^3}\left(\frac{1}{\exp\left(p/k_{\mathcal{B}}T\right)\pm 1}\right)\\ &= \begin{cases} g a_{\mathcal{B}} T^4/2 & \text{bosons}\\ 7g a_{\mathcal{B}} T^4/16 & \text{fermions}\end{cases}\end{aligned} \tag{3.1.9}$$

and of course $p(T) = \rho(T)/3$ and $s(T) = 4\rho(T)/3T$. In other words, each species and spin of massless fermions makes a contribution to the energy density, pressure, and entropy density that is just the same as for each polarization state of photons, except for an additional factor 7/8.

During a period of thermal equilibrium, the variation with time of the temperature is governed by the equation (3.1.1) of entropy conservation and the Einstein field equation, with curvature neglected,

$$\frac{\dot{a}^2}{a^2} = \frac{8\pi G\rho(T)}{3}. \tag{3.1.10}$$

Combining these gives

$$t = -\int \frac{s'(T)dT}{s(T)\sqrt{24\pi G\rho(T)}} + \text{ constant} \tag{3.1.11}$$

(The minus sign is inserted in taking the square root of $\dot{T}^2$, to take account of the fact that the temperature decreases as time passes.) In particular, during any epoch in which the

dominant constituent of the universe is a highly relativistic ideal gas, the entropy and energy densities are

given by

$$s(T) = \frac{2\mathcal{N}a_{\mathcal{B}}T^3}{3} \tag{3.1.12}$$

$$\rho(T) = \frac{\mathcal{N}a_{\mathcal{B}}T^4}{2} \tag{3.1.13}$$

where $\mathcal{N}$ is the number of particle types, counting particles and antiparticles and each spin state separately, and with an extra factor of 7/8 for fermions. Then Eq. (3.1.11) becomes

$$t = \sqrt{\frac{3}{16\pi G\mathcal{N}a_{\mathcal{B}}}}\frac{1}{T^2} + \text{ constant} \tag{3.1.14}$$

With this background, let us now start our history at a time when the temperature was around 10^{11} K, which is in the range $m_\mu \gg k_{\mathcal{B}}T \gg m_e$. Even though it was too cold at this time for reactions like $\upsilon_\mu + e \to \mu + \upsilon_e$ or $\nu_\tau + e \to \tau + \nu_e$, the μ and τ neutrinos and antineutrinos were kept in thermal equilibrium by neutral current reactions, like neutrino-electron scattering or $e^+ + e^- \rightleftharpoons \nu + \bar{\nu}$. Hence the constituents of the universe at this time were photons with two spin states, plus three species of neutrinos and three of antineutrinos, each with one spin state, plus electrons and positrons, each with two spin states, all in equilibrium and all highly relativistic, giving

$$\mathcal{N} = 2 + \frac{7}{8}(6+4) = \frac{43}{4} \tag{3.1.15}$$

so that Eq. (3.1.14) gives, in cgs units:

$$t = \sqrt{\frac{3c^2}{172\pi G a_{\mathcal{B}}}}\frac{1}{T^2} + \text{ constant } = 0.994\,\text{sec}\left[\frac{T}{10^{10}\text{ K}}\right]^{-2} + \text{ constant .} \tag{3.1.16}$$

For instance, with muons ignored and the mass of the electron neglected, it took 0.0098 sec for the temperature to drop from a value 10^{12} K to 10^{11} K, and another 0.98 sec for the temperature to drop to 10^{10} K.

At a temperature of about 10^{10} K neutrinos were just going out of equilibrium and beginning a free expansion. The weak interaction cross section for neutrino-electron scattering is roughly $\sigma_{\text{wk}} \approx (\hbar G_{\text{wk}} k_{\mathcal{B}}T)^2$, where $G_{\text{wk}} \simeq 1.16 \times 10^{-5}\text{GeV}^{-2}$ is the weak interaction coupling constant, and the factor $\hbar^2$ is included to convert a quantity with the units (energy) $^{-2}$ to a quantity with the units (length) ^{2} of a cross section. (Recall that we are using units with $c = 1$.) The number density of electrons at temperatures above 10^{10} K is roughly given by $n_e \approx (k_{\mathcal{B}}T/\hbar)^3$, so the collision rate of a neutrino with electrons or positrons at such temperatures is

$$\Gamma_\upsilon = n_e\sigma_{\text{wk}} \approx G_{\text{wk}}^2\left(k_{\mathcal{B}}T\right)^5/\hbar$$

This may be compared with the expansion rate, which during the radiationdominated era is of the order

$$H \approx \sqrt{G\left(k_{\mathcal{B}}T\right)^4/\hbar^3},$$

[471] Eq. (3.1.6) follows directly from the definition of $n(p,T)$, and Eq. (3.1.7) can then be derived from Eq. (3.1.4). Or both Eqs. (3.1.6) and (3.1.7) can be obtained from Eqs. (B.41) and (B.43).

with the factor $\hbar^{-3}$ included to convert a quantity with the units (energy) ^{4} to a quantity with the units mass/length ^{3} of a mass density. The ratio of the collision rate to the expansion rate is thus

$$\frac{\Gamma_\nu}{H} \approx G_{\rm wk}^2(\hbar/G)^{1/2}\,(k_{\mathcal B}T)^3 \simeq \left(\frac{T}{10^{10}\ {\rm K}}\right)^3$$

Hence neutrinos were scattered rapidly enough to remain in thermal equilibrium at temperatures above 10^{10} K. This is just a little greater than $m_e/k_{\mathcal B}$, so for lower temperatures electrons and positrons rapidly disappeared from equilibrium, the collision rate dropped rapidly below $G_{\rm wk}^2\,(k_{\mathcal B}T)^5\,/\hbar$, and hence the ratio Γ_ν/H dropped rapidly below unity. The neutrinos then began a free expansion, in which (as we saw in Section 2.1) the number density distribution n_ν continued to keep the form (3.1.5), with a temperature $T_\nu \propto 1/a$.

At lower temperatures we must take into consideration the finite mass of the electron, so the temperature T of the electrons, positrons, and photons (which were still in equilibrium with each other) no longer fell as $1/a$. On the other hand, the freely expanding massless neutrinos preserved a FermiDirac momentum distribution, ^{2} with a temperature that continued to drop as $1/a$. We must therefore now distinguish between the photon temperature T, and the neutrino temperature T_ν.

The entropy density of the photons, electrons, and positrons is

$$\begin{aligned} s(T) =& \frac{4a_{\mathcal B}T^3}{3} + \frac{4}{T}\int_0^\infty \frac{4\pi p^2 dp}{(2\pi\hbar)^3}\left(\sqrt{p^2+m_e^2} + \frac{p^2}{3\sqrt{p^2+m_e^2}}\right) \\ & \times \frac{1}{\exp\left(\sqrt{p^2+m_e^2}/k_{\mathcal B}T\right)+1} \\ =& \frac{4a_{\mathcal B}T^3}{3}\mathcal{S}\left(m_e/k_{\mathcal B}T\right) \end{aligned} \tag{3.1.17}$$

where, recalling that $a_{\mathcal B} = \pi^2 k_{\mathcal B}^4/15\hbar^3$,
$\mathcal{S}(x) \equiv 1 + \frac{45}{2\pi^4}\int_0^\infty y^2 dy\left(\sqrt{y^2+x^2} + \frac{y^2}{3\sqrt{y^2+x^2}}\right)\frac{1}{\exp\sqrt{y^2+x^2}+1}$.

The entropy conservation law (3.1.1) gives $a^3T^3\mathcal{S}\left(m_e/k_{\mathcal B}T\right)$ constant, and since $T_\nu \propto 1/a$, this means that T_ν is proportional to $T\mathcal{S}^{1/3}\left(m_e/k_{\mathcal B}T\right)$. The temperatures were equal for $k_{\mathcal B}T \gg m_e$, and

$$\mathcal{S}(0) = 1 + 2\frac{7}{8} = 11/4 \tag{3.1.19}$$

so

$$T_v = (4/11)^{1/3}T\mathcal{S}^{1/3}\left(m_e/k_{\mathcal B}T\right) \tag{3.1.20}$$

The ratio T/T_ν rose from very close to unity for $T > 10^{11}$ K to 1.008 at $T = 10^{10}$ K and to 1.346 at $T = 10^9$ K. To find the asymptotic value of T/T_ν without a computer calculation, we note that $\mathcal{S}(\infty) = 1$, so for $k_{\mathcal B}T \ll m_e$, Eq. (3.1.20) gives

^{472} This is not exact; even at temperatures under 10^{10} K, the neutrino distribution was slightly affected by weak interaction processes, such as $e^- + e^+ \to \upsilon + \bar{\upsilon}$. See A. D. Dolgov, S. H. Hansen, and D. V. Semikoz, Nucl. Phys. B 503, 426 (1997); 543, 269 (1999); G. Mangano, G. Miele, S. Pastor, and M. Peioso, Phys. Lett. B534, 8 (2002). For a review, see A. D. Dolgov, Phys. Rep. 370, 333 (2002). The weak interactions provide some thermal contact between the neutrinos and the plasma, which is being heated by electron-positron annihilation, so the effect is to slightly increase the neutrino energy density, by an amount usually represented as an increase in the effective number of neutrino species, from 3 to 3.04. This effect is neglected in what follows.

$$T/T_v \to (11/4)^{1/3} = 1.401 \tag{3.1.21}$$

In particular, at the present time, when $T = 2.725$ K, the neutrino temperature is 1.945 K . Unfortunately there does not seem to be any way of detecting such a neutrino background.

With three flavors of neutrinos and antineutrinos, the total energy density during this period is

$$\begin{aligned}\rho(T) &= 6 \cdot \frac{7}{8} \cdot \frac{a_{\mathcal{B}} T_v^4}{2} + a_{\mathcal{B}} T^4 + 4 \int_0^\infty \frac{4\pi p^2 dp}{(2\pi\hbar)^3} \frac{\sqrt{p^2 + m_e^2}}{\exp\left(\sqrt{p^2 + m_e^2}/k_{\mathcal{B}} T\right) + 1} \\ &= a_{\mathcal{B}} T^4 \mathcal{E}\left(m_e/k_{\mathcal{B}} T\right)\end{aligned} \tag{3.1.22}$$

where

$$\mathcal{E}(x) = 1 + \frac{21}{8}\left(\frac{4}{11}\right)^{4/3} \mathcal{S}^{4/3}(x) + \frac{30}{\pi^4} \int_0^\infty \frac{y^2 \sqrt{y^2 + x^2} dy}{\exp \sqrt{y^2 + x^2} + 1} \tag{3.1.23}$$

We insert Eqs. (3.1.17) and (3.1.22) in Eq. (3.1.11), and find

$$\begin{aligned}t &= \int \left(\frac{\left(m_e/k_{\mathcal{B}} T\right) \mathcal{S}'\left(m_e/k_{\mathcal{B}} T\right)}{\mathcal{S}\left(m_e/k_{\mathcal{B}} T\right)} - 3 \right) \frac{dT}{T\sqrt{24\pi G a_{\mathcal{B}} T^4 \mathcal{E}\left(m_e/k_{\mathcal{B}} T\right)}} \\ &= t_e \int \left(3 - \frac{x\mathcal{S}'(x)}{\mathcal{S}(x)}\right) \mathcal{E}^{-1/2}(x) x dx\end{aligned} \tag{3.1.24}$$

where $x \equiv m_e/k_{\mathcal{B}} T$, and in cgs units

$$t_e \equiv \left(24\pi G c^6 a_{\mathcal{B}} m_e^4/k_{\mathcal{B}}^4\right)^{-1/2} = 4.3694\text{sec}. \tag{3.1.25}$$

The values of T/T_ν and of the time required for the temperature to fall to T (calculated from Eq. (3.1.11)) are given for various values of T in Table 3.1.

After the era of electron-positron annihilation, the energy density of the universe was dominated for a long while by photons, neutrinos, and antineutrinos, all of them highly relativistic, so during this period we have $s(T) \propto T^3$, and

$$\rho(T) = a_{\mathcal{B}} T^4 + \frac{7}{8} \cdot 3 \cdot a_{\mathcal{B}} T_v^4 = a_{\mathcal{B}} T^4 \left(1 + \frac{7}{8} \cdot 3 \cdot (4/11)^{4/3}\right) = 3.363 a_{\mathcal{B}} T^4/2. \tag{3.1.26}$$

Table 3.1: Ratio of electron-photon temperature T to neutrino temperature T_{ν} and the time t required for the temperature to drop from 10^{11} K to T, for various values of T.

T(K)	T/T_v	t(sec)
10^{11}	1.000	0
6×10^{10}	1.000	0.0177
3×10^{10}	1.001	0.101
2×10^{10}	1.002	0.239
10^{10}	1.008	0.998
6×10^{9}	1.022	2.86
3×10^{9}	1.080	12.66
2×10^{9}	1.159	33.1
10^{9}	1.345	168
3×10^{8}	1.401	1980
10^{8}	1.401	1.78×10^{4}
10^{7}	1.401	1.78×10^{6}
10^{6}	1.401	1.78×10^{8}

That is, during this period the effective number of particle species is $\mathcal{N} = 3.363$. Using Eq. (3.1.14) then gives, in cgs units:

$$t = \sqrt{\frac{3c^2}{3.363 \cdot 16 \cdot \pi a_{\mathcal{B}} G}} \frac{1}{T^2} + \text{ constant } = 1.78\,\text{sec} \left[\frac{T}{10^{10}\text{ K}}\right]^{-2} + \text{ constant .} \tag{3.1.27}$$

For instance, the time required for the universe to cool from a temperature of 10^9 K (where electrons and positrons have mostly annihilated) to a temperature of 10^8 K is 1.76×10^4sec, or 4.9 hours.

According to Eq. (3.1.27), the time required for the temperature to drop to 10^6 K from much higher values is 1.78×10^8sec, or 5.64 years. At lower temperatures we must take into account the energy density of nonrelativistic matter, and Eq. (3.1.27) no longer applies. We saw in Section 2.3 that for $\Omega_M h^2 = 0.15$, it took an additional 360,000 years for the universe to cool to the temperature 3,000 K of last scattering.

So far in this section we have been assuming that neutrinos are massless, and that the net neutrino number of each of the three types (that is, the number of neutrinos minus the number of antineutrinos) is much less than the number of photons. In the general case of an ideal gas of particles of mass m, the number $n(p)dp$ of particles of momentum between p and $p + dp$ is given by the Fermi-Dirac and Bose-Einstein distributions

$$n(p, T, \mu)dp = \frac{4\pi g p^2 dp}{(2\pi\hbar)^3} \left(\frac{1}{\exp\left[\left(\sqrt{p^2 + m^2} - \mu\right)/k_{\mathcal{B}}T\right] \pm 1} \right) \tag{3.1.28}$$

where μ is the chemical potential for the particle in question, a quantity that is conserved in any reaction occurring rapidly in thermal equilibrium, and again g is the number of spin states of the particle and antiparticle, and the sign is + for fermions and - for bosons. This reduces to Eq. (3.1.5) in the case of zero chemical potential, and it yields the number density (2.3.1) for non-relativistic particles with $p \ll m$ and $k_{\mathcal{B}}T \ll m$. During the whole of the era of interest here, electrons and positrons rapidly annihilated into photons, so their chemical potentials were equal and opposite, and since we are assuming charge neutrality and neglecting

the tiny number of baryons per photon, we can conclude that the chemical potentials of the electrons and photons were much less than $k_{\mathcal{B}}T$. At temperatures at which neutrinos and antineutrinos were in thermal equilibrium with electrons, positrons, and photons, reactions like $e^+ + e^- \rightleftharpoons v_i + \bar{v}_i$ were occurring rapidly (where $i = e, \mu, \tau$ label the three types of neutrino), so the chemical
potential μ_i of each type of neutrino was equal and opposite to the chemical potential of the corresponding antineutrino. But if we do not assume zero net neutrino (or lepton) number, then there is no a priori reason why the μ_i had to be less than $k_{\mathcal{B}}T$.

If neutrino masses are less than about 1 eV , then they may be neglected at the temperatures of interest in this section. The observations of oscillations between different flavors of neutrinos from the sun, nuclear reactors, and cosmic rays shows [3] that the two differences in the squares of the masses of the three types of neutrinos of definite mass (which are mixtures of neutrinos of electron, muon, and tau flavor) are $8.0^{+0.4}_{-0.3} \times 10^{-5}\text{eV}^2$ and between 1.9 and 3.0 times 10^{-3}eV^2. Thus the neutrino masses are all much less than 1 eV , unless they are highly degenerate, which there is no reason to expect. If degenerate, then from the absence of anomalies in the low-energy beta decay of tritium, their common mass must be less than 2eV.[3] Whether degenerate or not, it is clear from this that all three neutrino types (if there are only three) have masses very much less than 1 MeV , and were therefore highly relativistic at the time that they went of thermal equilibrium with electrons and positrons, at a temperature of about 10^{10} K. Once out of equilibrium, their momentum simply decayed as $1/a$ (as shown in Section 1.1), so if their chemical potential was negligible their momentum distribution remained the same as that of photons, with a temperature less by a factor $(4/11)^{1/3}$. Thus once $k_{\mathcal{B}}T$ dropped below the smallest neutrino mass, their energy density became just $n_\nu \sum_\nu m_\nu = (3/11) n_\gamma \sum_\nu m_\nu$. (For $k_{\mathcal{B}}T$ much larger than the mass, the integral for the number density of each spin state of fermions is 3/4 the corresponding integral for bosons, and after neutrinos decouple $T_\nu^3 = (4/11)T_\gamma^3$.) With a non-zero chemical potential the energy density is larger. The agreement between theory (with massless neutrinos) and observation for the cosmic microwave background anisotropies discussed in Sections 2.6 and 7.2 and for the large scale structure discussed in Chapter 8 shows that the sum of the three neutrino masses is less than 0.68 eV (95% confidence level), [4] so if they are degenerate the common mass is less than 0.23 eV . This result has been contradicted by the observation of neutrinoless double beta decay in a Heidelberg-Moscow experiment, [5] which suggests a value greater than 1.2 eV for the sum of neutrino masses. [6] There has not yet been an opportunity to confirm the double beta decay results, and for the present it seems reasonable to continue to neglect neutrino masses.

With neutrino masses neglected, the energy density, pressure, and net lepton number density of neutrinos and antineutrinos of type i is

$$\begin{aligned}
\rho_i =& 3p_i \\
=& \frac{4\pi}{(2\pi\hbar)^3} \int p^3 dp \left(\frac{1}{\exp\left[(p-\mu_i)/k_{\mathcal{B}}T\right]+1} + \frac{1}{\exp\left[(p+\mu_i)/k_{\mathcal{B}}T\right]+1} \right) \\
=& 4\pi \frac{(k_{\mathcal{B}}T)^4}{(2\pi\hbar)^3} \mathcal{P}\left(\mu_i/k_{\mathcal{B}}T\right) \qquad (3.1.29) \\
n_i =& \frac{4\pi}{(2\pi\hbar)^3} \int p^2 dp
\end{aligned}$$

$$\times\left(\frac{1}{\exp\left[\left(p-\mu_i\right)/k_{\mathcal{B}}T\right]+1}-\frac{1}{\exp\left[\left(p+\mu_i\right)/k_{\mathcal{B}}T\right]+1}\right)$$
$$=4\pi\frac{\left(k_{\mathcal{B}}T\right)^3}{(2\pi\hbar)^3}\mathcal{M}\left(\mu_i/k_{\mathcal{B}}T\right) \tag{3.1.30}$$

where

$$\mathcal{P}(x)\equiv\int_0^\infty\left[\left(e^{y-x}+1\right)^{-1}+\left(e^{y+x}+1\right)^{-1}\right]y^3dy \tag{3.1.31}$$
$$\mathcal{M}(x)\equiv\int_0^\infty\left[\left(e^{y-x}+1\right)^{-1}-\left(e^{y+x}+1\right)^{-1}\right]y^2dy \tag{3.1.32}$$

As we have seen, at temperatures above 10^{10} K the energy density of the photons and electron-positron pairs is $11a_{\mathcal{B}}T^4/4$, and the pressure is one-third as great, so the total energy density and pressure are given by

$$\rho=3p=T^4\left[\frac{11a_{\mathcal{B}}}{4}+\frac{4\pi k_{\mathcal{B}}^4}{(2\pi\hbar)^3}\sum_{i=e,\mu,\tau}\mathcal{P}\left(\mu_i/k_{\mathcal{B}}T\right)\right]. \tag{3.1.33}$$

The equation (1.5.20) of energy conservation tells us that under these circumstances ρa^4 is constant, while the conservation of each type of neutrino number also tells us that n_ia^3 is constant. Since ρ and n_i depend in different ways on the chemical potentials, this requires that as the universe expands in this era the $\mu_i/k_{\mathcal{B}}T$ remain constant, and also $T\propto 1/a$, just as in the case of zero chemical potential.

As the temperature dropped below 10^{10} K the temperature of the photons and electron-positron pairs no longer varied as $1/a$, but as we have seen the neutrinos and antineutrinos entered on a free expansion. With each neutrino's momentum p varying as $1/a$, the form of the Fermi-Dirac distributions for each type of massless neutrino was preserved, with a temperature $T_\nu\propto 1/a$ and $\mu_i/k_{\mathcal{B}}T$ constant, just as before decoupling. We
conclude that to a good approximation $T_\nu\propto 1/a$ and each $\mu_i\propto 1/a$ throughout the whole era of interest here.

The only effect that a non-zero neutrino chemical potential would have on the calculations of this section is that it would increase the total energy density and hence shorten the time scale. For any non-zero μ the function $\mathcal{P}\left(\mu/k_{\mathcal{B}}T\right)$ is greater than $\mathcal{P}(0)=7\pi^4/60$, so if $\mu_i\neq 0$ then $\rho_i>7\pi^2\left(k_{\mathcal{B}}T\right)^4/120(\hbar)^3=(7/8)a_{\mathcal{B}}T^4$. In particular, if $|\mu_i|\gg k_{\mathcal{B}}T$ then $\mathcal{P}\left(\mu_i/k_{\mathcal{B}}T\right)\simeq\left(\mu_i/k_{\mathcal{B}}T\right)^4/4$, so $\rho_i\simeq\pi\left(\mu_i\right)^4/(2\pi\hbar)^3\gg a_{\mathcal{B}}T^4$, and these neutrinos (or antineutrinos, if $\exp\left(-\mu_i/k_{\mathcal{B}}T\right)$ is large) dominated the energy density of the universe, at least until the cross-over of non-relativistic matter and radiation. Inspection of Eq. (3.1.28) shows that for a chemical potential $\mu\gg k_{\mathcal{B}}T$, the fermion distribution function $n(p,T,\mu)dp$ is equal to $4\pi gp^2dp/(2\pi\hbar)^3$ for particle energies less than μ, and then falls off rapidly for higher energies, indicating that all fermion energy levels up to energy μ are filled, while higher energy levels are empty. This is the case of complete neutrino degeneracy. [7] Experiments on the beta decay of tritium, ${}^3\mathrm{H}\rightarrow{}^3\mathrm{He}+e^-+\bar{\nu}_e$ show that $|\mu_e|$ is less than a few eV , because otherwise for $\mu_e>0$ there would be a rise in the electron spectrum beyond the expected endpoint $m\left({}^3\mathrm{H}\right)-m\left({}^3\mathrm{He}\right)$, due to absorption of degenerate cosmic neutrinos in the reaction $\nu_e+{}^3\mathrm{H}\rightarrow{}^3\mathrm{He}+e^-$, while for $\mu_e<0$ the Pauli exclusion principle would produce a dip in the electron spectrum within a few eV of its expected endpoint, where antineutrino energies are less than a few eV, putting them within the degenerate antineutrino sea. (The absence of a dip within a few eV of the expected electron spectrum endpoint also sets a limit of a few eV on the electron neutrino mass.) This yields an upper bound on the timeindependent quantity $|\mu_e|/k_{\mathrm{B}}T$ of order 10^4, which is very much

weaker than the upper bound that will be provided in the following section by considerations of cosmological nucleosynthesis.

10.3.2 3.2 Cosmological nucleosynthesis

We have worked out the thermal history of the universe from temperatures above 10^{10} K down to the crossover temperature $\approx 10^4$ K, ignoring the presence of a small number of nucleons (and a small excess of electrons over positrons). Now let us consider what happens to the nucleons during this era. [1]

The weak interactions allow neutron-proton conversion through six processes:

$$n + v \rightleftharpoons p + e^-, \quad n + e^+ \rightleftharpoons p + \bar{v}, \quad n \rightleftharpoons p + e^- + \bar{v} \tag{3.2.1}$$

(Here v is v_e; the other neutrino flavors do not contribute to these reactions.) In this range of temperatures $k_{\mathcal{B}}T \ll m_N$, so the nucleons can be treated as essentially at rest. The initial and final lepton energies are therefore simply related, by

$$\begin{array}{ll} E_e - E_v = Q & \text{for } n + v \rightleftharpoons p + e^-, \\ E_v - E_e = Q & \text{for } n + e^+ \rightleftharpoons p + \bar{v} \\ E_v + E_e = Q & \text{for } n \rightleftharpoons p + e^- + \bar{v}, \end{array} \tag{3.2.2}$$

where

$$Q = m_n - m_p = 1.293\text{MeV} \tag{3.2.3}$$

The total rates at which an individual neutron is converted to a proton or a proton to a neutron take the form

$$\lambda(n \to p) = A \int \left(1 - \frac{m_e^2}{(Q+q)^2}\right)^{1/2} \frac{(Q+q)^2 q^2 dq}{(1 + e^{q/k_{\mathcal{B}}T_v})\,(1 + e^{-(Q+q)/k_{\mathcal{B}}T})} \tag{3.2.4}$$

[477] The possibility of cosmic neutrino degeneracy was raised by S. Weinberg, Phys. Rev. 128, 1457 (1962).

[1] I outlined the history of these calculations in The First Three Minutes (Basic Books, 1977, 1988). Briefly, the first calculations of cosmological nucleosynthesis were undertaken by Ralph Alpher, George Gamow, and Robert Herman in the late 1940s; see G&C, Chapter 15, footnotes 51 and 52. In this

[47]work it was assumed that nucleons start as pure neutrons, which then convert to protons by the process of neutron beta decay. It was then pointed out that the conversion of neutrons into protons and vice versa occurs primarily through two-particle collisions, and that the rapid rate of these processes at very early times has the consequence that nucleons start as 50% neutrons and 50% protons, by C. Hayashi, Prog. Theor. Phys. (Japan) 5, 224 (1950). Following this, a modern calculation of the evolution of the neutron/proton ratio was presented by R. A. Alpher, J. W. Follin, Jr., and R. C. Herman, Phys. Rev. 92, 1347 (1953), but the results were not applied to the problem of cosmological nucleosynthesis. Several authors noted that the abundance of helium in the universe is too large to be accounted for by stellar nucleosynthesis; see G. Burbidge, Pub. Astron. Soc. Pacific 70, 83 (1958); F. Hoyle and R. J. Tayler, Nature 203, 1108 (1964). The modern theory of cosmological nucleosynthesis is due to P. J. E. Peebles, Astron. J. 146, 542 (1966). (Related calculations done by Ya. B. Zel'dovich, Adv. Astron. Astrophys. 3, 241 (1965) were not known in the West until much later.) Nucleosynthesis calculations were then extended to more nuclides and reactions by R. V. Wagoner, W. A. Fowler, and F. Hoyle, Astrophys. J. 148, 3 (1967), and many small corrections were included by D. A. Dicus, E. W. Kolb, A. M. Gleeson, E. C. G. Sudarshan, V. L. Teplitz, and M. S. Turner, Phys. Rev. D 26, 2694 (1982). Modern reviews are given by G. Steigman, in Measuring and Modeling the Universe - Carnegie Observatories Astrophysics Series, Volume 2, ed. W. Freedman (Cambridge University Press, Cambridge, UK) [astro-ph/0307244]; in The Local Group as an Astrophysical Laboratory - Proceedings of the May 2003 STScI Symposium [astro-ph/0308511]; in Chemical Abundances and Mixing in Stars in the Milky Way and its Satellites Proceedings of the ESO/Arcetrei Workshop, eds. L. Pasquini and S. Randich (Springer-Verlag) [astroph/0501591]; and Int. J. Mod. Phys. E15, 1 (2006) [astro-ph/0511534]. For discussions emphasizing analytic calculations, see G&C, Section 15.7, and V. Mukhanov, Int. J. Theor. Phys. 43, 669 (2004) [astro-ph/0303073].

$$\lambda(p \to n) = A \int \left(1 - \frac{m_e^2}{(Q+q)^2}\right)^{1/2} \frac{(Q+q)^2 q^2 dq}{(1+e^{-q/k_{\mathcal{B}}T_v})\,(1+e^{(Q+q)/k_{\mathcal{B}}T})} \tag{3.2.5}$$

where [2]

$$A \equiv \frac{G_{\rm wk}^2\,(1+3g_A^2)\cos^2\theta_C}{2\pi^3\hbar} \tag{3.2.6}$$

and the integrals over q run from $-\infty$ to $+\infty$, leaving out a gap from $q = -Q - m_e$ to $q = -Q + m_e$, where the square root would be imaginary. These rates include the effect of the Pauli Principle in the presence of partly filled lepton seas. For instance, the cross section for the process $n + e^+ \to p + \bar{v}$ is $2\pi^2\hbar^3 A E_v^2/v_e$, the number density of positrons of each helicity with momentum between p_e and $p_e + dp_e$ is $4\pi p_e^2 dp_e (2\pi\hbar)^{-3}\left[\exp\left(E_e/k_{\mathcal{B}}T\right)+1\right]^{-1}$, and the fraction of unfilled antineutrino levels with energy E_ν is

$$1 - \left[\exp\left(E_\nu/k_{\mathcal{B}}T_\nu\right)+1\right]^{-1} = \left[\exp\left(-E_\nu/k_{\mathcal{B}}T_\nu\right)+1\right]^{-1}$$

so the total rate per neutron of the process $n + e^+ \to p + \bar{v}$ is

$$\begin{aligned}\lambda\left(n + e^+ \to p + \bar{v}\right) =& A \int_0^\infty E_v^2 p_e^2 dp_e \left[\exp\left(E_e/k_{\mathcal{B}}T\right)+1\right]^{-1} \\ & \times \left[\exp\left(-E_v/k_{\mathcal{B}}T_v\right)+1\right]^{-1}\end{aligned}$$

Changing the variable of integration to $q \equiv -E_v = -Q - E_e$, we see that this partial rate is just the part of the integral (3.2.4) that runs from $q = -\infty$ to $q = -Q - m_e$. Likewise, the part of the integral that runs from $q = -Q + m_e$ to $q = 0$ is supplied by the neutron-decay process $n \to p + e^- + \bar{\nu}$, with $q = -E_\nu$, and the part of the integral that runs from $q = 0$ to $q = +\infty$ arises from the process $n + v \to p + e^-$, with $q = E_v$. Similar remarks apply to the integral (3.2.5).

With the rates (3.2.4)-(3.2.5) known in principle, we can calculate the change in the ratio X_n of neutrons to all nucleons from the differential equation

$$\frac{dX_n}{dt} = -\lambda(n \to p) X_n + \lambda(p \to n)\,(1 - X_n) \tag{3.2.7}$$

As a check, note that for a time-independent temperature T equal to T_ν, the two rates (3.2.4) and (3.2.5) would have the ratio

$$\frac{\lambda(p \to n)}{\lambda(n \to p)} = \exp\left(-Q/k_{\mathcal{B}}T\right) \qquad \text{for } T = T_v \tag{3.2.8}$$

It follows then that in this case, Eq. (3.2.7) would have the time-independent solution expected in thermal equilibrium

$$\frac{X_n}{X_p} = \frac{X_n}{1 - X_n} = \exp\left(-Q/k_{\mathcal{B}}T\right) \tag{3.2.9}$$

It is the inequality of T and T_ν as well as the time-dependence of these temperatures that drives X_n/X_p away from its equilibrium value (3.2.9).

For $k_{\mathcal{B}}T \gg Q$ we can evaluate the integrals (3.2.4)-(3.2.5) by setting $T_\nu = T$ and $Q = m_e = 0$, so in this case

[472] Here $G_{\rm wk} = 1.16637(1) \times 10^{-5}{\rm GeV}^{-2}$ is the weak coupling constant, measured from the rate of the decay process $\mu^+ \to e^+ + \nu_e + \bar{\nu}_\mu$; $g_A = 1.257$ is the axial vector coupling of beta decay, measured from the rate of neutron decay; and θ_C is the Cabibbo angle, with $\cos\theta_C = 0.9745$ (6), measured from the rate of O^{14} beta decay and other $0^+ \to 0^+$transitions.

$$\lambda(n \to p) = \lambda(p \to n) = A \int_{-\infty}^{+\infty} \frac{q^4 dq}{(1 + e^{q/k_{\mathcal{B}}T})(1 + e^{-q/k_{\mathcal{B}}T})}$$
$$= \frac{7}{15}\pi^4 A (k_{\mathcal{B}}T)^5 = 0.400\text{sec}^{-1} \left(\frac{T}{10^{10}\text{ K}}\right)^5 \tag{3.2.10}$$

For comparison, the time t for the temperature to drop to T from much higher values is given by Eq. (3.1.16) as $0.99\text{sec}\,(T/10^{10}\text{ K})^{-2}$. Also, $H \simeq 1/2t$. The ratio λ/H is therefore

$$\lambda/H \simeq 0.8 \times \left(\frac{T}{10^{10}\text{ K}}\right)^3 \tag{3.2.11}$$

This ratio is larger than 1 for $T > 1.1 \times 10^{10}$ K. It is true that temperatures near this lower bound are not much larger than Q/k, and T_ν at this epoch is not precisely equal to T, so the rates $\lambda(n \to p)$ and $\lambda(p \to n)$ are not precisely equal, and neither is given precisely by Eq. (3.2.10). Nevertheless Eq. (3.2.10) gives the order of magnitude of these rates in this temperature range, so we can still rely on the conclusion that $\lambda(n \to p)/H$ and $\lambda(p \to n)/H$ are large down to these temperatures. This means that the initial value of X_n at temperatures larger than about 3×10^{10} K is given by the condition that the right-hand side of Eq. (3.2.7) should vanish:

$$X_n \to \frac{\lambda(p \to n)}{\lambda(p \to n) + \lambda(n \to p)} \tag{3.2.12}$$

If X_n were larger or smaller than this, then the right-hand side of Eq. (3.2.7) would be large and respectively negative or positive, so X_n would be rapidly driven to the value (3.2.12). For $T > 10^{10}$ K the neutrino temperature was within 1% of the photon-electron-positron temperature, so at these temperatures the rates have the ratio (3.2.8). Thus at the temperatures $T > 3 \times 10^{10}$ K at which the neutron fraction is given by the equilibrium formula (3.2.12), this formula gives simply

$$X_n = \frac{1}{1 + \exp(Q/k_{\mathcal{B}}T)} \tag{3.2.13}$$

It is crucially important that this ratio is fixed at high temperatures by the condition of zero lepton chemical potential, so that we do not need to make any a priori assumptions about the initial neutron/proton ratio. The results of a numerical integration of Eq. (3.2.7) with initial condition provided by Eq. (3.2.13) are presented in Table 3.2. [3]

We have seen that for $k_{\mathcal{B}}T > m_e$ the ratios $\lambda(p \to n)/H$ and $\lambda(n \to p)/H$ varied roughly as T^3, so there was a rather sharp end to the equilibrium era, in which $\lambda \gg H$, at a temperature between 3×10^{10} K and 10^{10} K. A little later, at a temperature between 10^{10} K and 3×10^9 K the two-body and threebody neutron-proton conversion reaction rates became negligible, due in part to the disappearance of electron-positron pairs. Neutron-proton conversion continued mostly through the process of neutron decay, with a mean lifetime τ_n of 885.7 ± 0.9sec, so the neutron fraction became proportional to $\exp(-t/\tau_n)$. This is confirmed by fitting the numerical results presented in Table 3.2 with an exponential that decays with the observed rate of neutron decay, which gives

$$X_n \to 0.1609 \exp\left(\frac{-t}{885.7\text{sec}}\right) \tag{3.2.14}$$

The conversion of neutrons into protons was eventually stopped by the formation of complex nuclei, in which neutrons are stable. As a guide to this process, note that in thermal (and

chemical) equilibrium the number density of a nuclear species i is given by formulas like Eqs. (2.3.1):

$$n_i = g_i e^{\mu_i/k_{\mathcal{B}}T} \left(\frac{2\pi m_i k_{\mathcal{B}} T}{h^2}\right)^{3/2} \exp\left(-m_i/k_{\mathcal{B}}T\right) \tag{3.2.15}$$

where m_i is the mass of nucleus i and g_i is the number of its spin states. If these nuclei can be built up rapidly out of Z_i protons and $A_i - Z_i$ neutrons,

Table 3.2: Neutron fraction X_{n} as a function of temperature or time (with neglect of the formation of complex nuclei).

T(K)	t(sec)	X_n
10^{12}	0.0001	0.4962
3×10^{11}	0.0011	0.4875
10^{11}	0.0099	0.4626
3×10^{10}	0.1106	0.3798
10^{10}	1.008	0.2386
3×10^{9}	12.67	0.1654
1.3×10^{9}	91.09	0.1458
1.2×10^{9}	110.2	0.1425
1.1×10^{9}	135.1	0.1385
10^{9}	168.1	0.1333
9×10^{8}	212.7	0.1268
8×10^{8}	274.3	0.1182
7×10^{8}	362.6	0.1070
6×10^{8}	496.3	0.0919
3×10^{8}	1980	0.0172
10^{8}	17780	3.07×10^{-10}

then the chemical potential of nuclei of type i is

$$\mu_i = Z_i \mu_p + (A_i - Z_i)\, \mu_n. \tag{3.2.16}$$

We can eliminate the unknown nucleon chemical potentials by forming the quantities

$$\frac{n_i}{n_p^{Z_i} n_n^{A_i - Z_i}} = \frac{g_i}{2^{A_i}} A_i^{3/2} \left(\frac{2\pi m_N k_{\mathcal{B}} T}{h^2}\right)^{3(1-A_i)/2} e^{B_i/k_{\mathcal{B}}T}, \tag{3.2.17}$$

where B_i is the binding energy, defined by

$$m_i = Z_i m_p + (A_i - Z_i)\, m_n - B_i. \tag{3.2.18}$$

(In deriving Eq. (3.2.17), we neglect the binding energy and the neutronproton mass difference outside the exponential.) Eq. (3.2.17) can be expressed in terms of the dimensionless ratios

$$X_i \equiv n_i/n_N, \quad X_p \equiv n_p/n_N, \quad X_n \equiv n_n/n_N \tag{3.2.19}$$

[473] These results are somewhat different from those given in Table 15.5 of G&C, because in 1972 only two types of neutrinos were known, and we are now assuming three types of massless neutrinos, which increases the expansion rate at a given temperature. We are also using the modern value 1.257 for the axial vector coupling constant of beta decay in Eq. (3.2.6), instead of the value 1.18 used in G&C.

where n_N is here the number density of all nucleons. In these terms,

$$X_i = \frac{g_i}{2} X_p^{Z_i} X_n^{A_i - Z_i} A_i^{3/2} \epsilon^{A_i - 1} e^{B_i/k_{\mathcal{B}}T} \tag{3.2.20}$$

where ϵ is the dimensionless quantity

$$\begin{aligned} \epsilon &\equiv \frac{1}{2} n_N h^3 \left(2\pi m_N k_{\mathcal{B}} T\right)^{-3/2} \\ &= 2.96 \times 10^{-11} \left(\frac{a}{10^{-10} a_0}\right)^{-3} \left(\frac{T}{10^{10}\ \mathrm{K}}\right)^{-3/2} \Omega_B h^2 \end{aligned} \tag{3.2.21}$$

in which we have used $n_N = 3\Omega_B H_0^2 \left(a_0/a\right)^3 / 8\pi G m_N$ for the number density of nucleons, bound or free. During the period of interest (after electronpositron annihilation) the temperature T goes as $1/a$, so Eq. (3.2.21) may be written

$$\epsilon = 1.46 \times 10^{-12} \left(\frac{T}{10^{10}\ \mathrm{K}}\right)^{+3/2} \Omega_B h^2 \tag{3.2.22}$$

The coefficient ϵ is very small for temperatures in the range of interest, so in equilibrium a nuclear species i is nearly absent until the temperature drops to the value

$$T_i \simeq \frac{B_i}{k\left(A_i - 1\right) \left|\ln \epsilon\right|} \tag{3.2.23}$$

For $\Omega_B h^2 \simeq 0.02$ this temperature is 0.75×10^9 K for deuterium, 1.4×10^9 K for H^3, 1.3×10^9 K for He^3, and 3.1×10^9 K for He^4, with only a very weak dependence on $\Omega_B h^2$. The binding energy per nucleon for heavier nuclei is similar to that of He^4, so they have similar values of T_i.

If thermal and chemical equilibrium were really maintained during the time that the temperature drops from around 10^{10} K to below 10^9 K, then during this time He^4 and heavier nuclei would appear first, followed by He^3 and H^3 (which would later beta decay to He^3), followed finally by H^2. But this is not what happens. The density at this time is too low for any but two-body reactions to compete with the expansion rate, so nuclei are built up by a chain of two-body processes: first $p + n \to d + \gamma$, then $d + d \to H^3 + p$ and $d + d \to He^3 + n$, and next $d + H^3 \to He^4 + n$ and $d + He^3 \to He^4 + p$, as well as slower processes involving photons.

There is no trouble with the first step. The rate of deuterium production per free neutron is

$$\begin{aligned} \lambda_d &= 4.55 \times 10^{-20}\ \mathrm{cm}^3/\mathrm{sec} \times n_p = 511 \mathrm{sec}^{-1} \left(\frac{a}{10^{-9} a_0}\right)^{-3} X_p \Omega_B h^2 \\ &= 2.52 \times 10^4 \mathrm{sec}^{-1} \left(\frac{T}{10^{10}\ \mathrm{K}}\right)^3 X_p \Omega_B h^2 \end{aligned} \tag{3.2.24}$$

Multiplying by the time (3.1.27), this gives

$$\lambda_d t \simeq 4.5 \times 10^4 \left(\frac{T}{10^{10}\ \mathrm{K}}\right) X_p \Omega_B h^2, \tag{3.2.25}$$

which remains substantially greater than unity until well after the temperature drops below 10^9 K. Therefore the deuterium abundance during the period of interest is given to a good approximation by its equilibrium value, which according to Eq. (3.2.20) is

$$X_d = 3\sqrt{2} X_p X_n \epsilon \exp\left(\frac{B_d}{k_{\mathcal{B}} T}\right). \tag{3.2.26}$$

The trouble is that, because of the small binding energy of the deuteron, the temperature $T_d \approx 0.7 \times 10^9$ K is quite small, so deuterons remained rare until long after He^4 would have been abundant in thermal equilibrium. With deuterons rare, the two-deuteron processes $d + d \to H^3 + p$ and $d + d \to He^3 + n$ had small rates per deuteron, blocking further nucleosynthesis. (The rarity of deuterons had no effect on the rate per deuteron of radiative processes like $p + d \to He^3 + \gamma$ and $n + d \to H^3 + \gamma$, and these reactions are included in modern nucleosynthesis calculations, but they have intrinsically small cross sections.) When finally the temperature dropped below T_d the neutrons that were still extant were very rapidly assembled into the most deeply bound of the light elements, He^4. Further cosmological nucleosynthesis was blocked by the non-existence of stable nuclear species with atomic weight 5 or 8 . (In stars this blockage is overcome [4] by the brief formation of the unstable Be^8 nucleus in collisions of two He^4 nuclei, followed by resonant capture of another He^4 nucleus to form an excited state of C^{12}, but the time available in the early universe was too short for this to have been effective then.) Thus, to a good approximation, the fraction by weight Y of He^4 formed in the early universe is just equal to twice [5] the fraction X_n of all nucleons that are neutrons (because in He^4 each neutron is accompanied with a bound proton) at the time that deuterium becomes abundant enough to allow the build-up of heavier nuclei.

This actually occurs at a temperature somewhat above T_d. The first steps in building up heavier elements from deuterium are the reactions $d + d \to H^3 + p$ and $d + d \to He^3 + n$. These are exothermic processes, so for initial velocity $v \to 0$ these have cross sections proportional to $1/v$. At the temperatures of interest here, we have

$$\left\langle \sigma \left(d + d \to H^3 + p \right) v \right\rangle \simeq 1.8 \times 10^{-17} \text{ cm}^3/\text{sec}$$
$$\left\langle \sigma \left(d + d \to He^3 + n \right) v \right\rangle \simeq 1.6 \times 10^{-17} \text{ cm}^3/\text{sec}$$

so the total rate of these processes per deuteron is [6]

$$\begin{aligned} \Lambda &= \left[\left\langle \sigma \left(d + d \to H^3 + p \right) v \right\rangle + \left\langle \sigma \left(d + d \to He^3 + n \right) v \right\rangle \right] X_d n_N \\ &\simeq 1.9 \times 10^7 \left(T/10^{10} \text{ K} \right)^3 \left(\Omega_B h^2 \right) X_d \text{sec}^{-1} \end{aligned}$$

This may be compared with the expansion rate, which after electron-positron annihilation is given by Eq. (3.1.27) as $H = 1/2t = 0.28 \left(T/10^{10} \text{ K}\right)^2 \text{sec}^{-1}$, so for T in the neighborhood of 10^9 K, we have $\Lambda = H$ at $X_d \simeq 1.2 \times 10^{-7}/\Omega_B h^2$, which is 0.6×10^{-5} for $\Omega_B h^2 = 0.02$. This value is reached in thermal equilibrium at a temperature $\simeq 10^9$ K, with only a weak dependence on $\Omega_B h^2$, so nucleosynthesis began at around 10^9 K, not at 0.75×10^9 K. According to table 3.2, this happened when $t = 168$ seconds, so according to Eq. (3.2.14), the abundance by weight of helium formed at this time was about

$$Y_p \simeq 2 \times 0.1609 \times \exp(-168/885) \simeq 0.27$$

(The conventional subscript p stands for "primordial.") The larger the nucleon density, the higher the temperature at which nucleosynthesis began, and so the less time there was for neutron decay before nucleosynthesis, leading to a higher final He^4 abundance. The results of modern calculations are usually given for different values of η, the ratio of nucleons to photons, which according to Eqs. (2.1.12) and (2.1.13) is related to $\Omega_B h^2$ by

[474] E. E. Salpeter, Astrophys. J. 115, 326 (1952).

[5] In a little more detail, with n_{He} helium nuclei and n_{H} hydrogen nuclei per unit proper volume, the helium mass per unit proper volume in atomic mass units is $4n_{\text{He}}$, while the total mass per unit proper

$$\Omega_B h^2 = 3.65\eta \times 10^7,$$

so for instance $\Omega_B h^2 = 0.02$ corresponds to $\eta = 5.5 \times 10^{-10}$. (The nucleon density at a given temperature can be expressed in terms of η without knowing the present microwave background temperature, which made η a more convenient parameter than $\Omega_B h^2$ before the 1990s, when the present microwave background temperature was not yet accurately known.) Detailed calculations [7] give $Y_p = 0.232$ for $\eta = 2 \times 10^{-10}$ and $Y_p = 0.240$ for $\eta = 4 \times 10^{-10}$.

The primordial helium/hydrogen ratio is inferred from spectroscopic study of HII regions (regions of ionized hydrogen) containing low abundances of "metals" (elements other than hydrogen or helium), especially in blue compact galaxies which have not yet formed many stars. Observations in the 1990s were divided between those giving lower values [8] $Y_p = 0.234 \pm 0.002 \pm 0.005$, and higher values [9] $Y_p = 0.243 \pm 0.003$. Even with this division among the observers, the helium abundance clearly called for a hot universe, with η in the range of 10^{-10} to 5×10^{-10}. More recent observations of HII regions, combined with new atomic data used to interpret the spectroscopic observations, have led to a more precise determination: [10] $Y_p = 0.2477 \pm 0.0029$, corresponding to $\eta = (5.813 \pm 1.81) \times 10^{-10}$. The uncertainty in the value of η given by observations of helium abundance is still quite large, because Y_p is only weakly dependent on the baryon/photon ratio.

Helium abundance is more useful as a test of the expansion rate than of the value of η. For instance, if there were four flavors of massless neutrinos that went out of equilibrium at temperatures between 10^{11} K and 10^{10} K, then at temperatures below 3×10^9 K, the effective number of particle species would have been $2+(7/8)\cdot 8\cdot(4/11)^{4/3} = 3.817$ instead of 3.363 , so the time required to drop from 3×10^9 K to any lower temperature would have been shortened by a factor $\sqrt{3.363/3.817} = 0.94$. Shortening the time to reach a given temperature increases the neutron fraction at that temperature, and hence increases the abundance of helium produced at the temperature $T \simeq 10^9$ K of nucleosynthesis. It is actually the shortening of the time scale at temperatures between 3×10^{10} K and 3×10^9 K, when electronpositron pairs were disappearing, that would have the largest effect on the helium abundance. Detailed calculations show [11] that for each additional

neutrino species this effect increases Y by an amount 0.01276 for $\eta = 10^{-10}$, and by 0.01369 for $\eta = 5 \times 10^{-10}$. The agreement between theory and observation for the helium abundance gave an upper bound of four light neutrino flavors before this was accurately measured to be just three flavors in measurements of the Z^0 decay width, part of which is due to the unobserved processes $Z^0 \to v + \bar{\nu}$. (Strictly speaking, the Z^0 width measures the number of neutrinos with masses less than $m_Z/2 = 45.6$GeV, while the helium abundance measures the number of neutrinos with masses less than about 1 MeV .) Although the number of light neutrino flavors is now definitely known on the basis of Z^0 decay to be no greater than three, there may be other light particles left over from the very early universe that contribute to the expansion rate,

[47] volume is $4n_{\rm He} + n_{\rm H}$, so the fractional abundance by weight of helium is $Y = 4n_{\rm He}/\left(4n_{\rm He} + n_{\rm H}\right)$. But the numbers of protons and neutrons per unit proper volume are $n_p = 2n_{\rm He} + n_{\rm H}$ and $n_n = 2n_{\rm He}$, so the fraction of nucleons that are neutrons is $X_n = 2n_{\rm He}/\left(4n_{\rm He} + n_{\rm H}\right)$. Hence $Y = 2X_n$.

and for these the helium abundance continues to provide useful upper bounds.

The nuclear reactions that built up helium from free neutrons at $T \approx 10^9$ K were not perfectly efficient, but left over a small residue, [12] like an unburned ash, of the light elements H^2, H^3, He^3, Li^7, and Be^7. The nuclei of H^3 decayed later by β^+decay to He^3, and the nuclei of Be^7 decayed later by electron capture to Li^7, leaving us with H^2, He^3, and Li^7, as well as protons and He^4. The calculated abundances are shown in Figure 3.1.

The higher the baryon density, the more complete will be the incorporation of neutrons into He^4, and hence the smaller the resulting abundance of deuterium. We saw earlier that nucleosynthesis began when $X_d \simeq 1.2 \times 10^{-7}/\Omega_B h^2$, or $X_d \simeq 0.6 \times 10^{-5}$ for $\Omega_B h^2 = 0.02$. The deuterium fraction continued to rise for a while, as the temperature dropped and the exponential in Eq. (3.2.26) increased, but X_d then decreased again as the incorporation of free neutrons into deuterium reduced the factor X_n in Eq. (3.2.26), and deuterium was converted to H^3 and He^3, and thence to He^4. The final results, shown in Figure 3.1, are not very different from the deuterium fraction $X_d \simeq 1.2 \times 10^{-7}/\Omega_B h^2$ that we found at $T = 10^9$ K, and in particular exhibit a strong decline with increasing values of $\Omega_B h^2$.

The measurement of the deuterium abundance is complicated by the fact that deuterium has a small binding energy, and can readily be destroyed in stars. Any measurement of the deuterium abundance therefore gives a lower bound on the primordial deuterium abundance, and hence an upper bound on the baryon density.

In the past, the deuterium/hydrogen ratio was measured in various ways:

1. Interstellar medium. Spectroscopic studies of the interstellar medium gave a deuterium/hydrogen ratio [13] of $\left(1.60 \pm 0.09^{+0.05}_{-0.10}\right) \times 10^{-5}$.

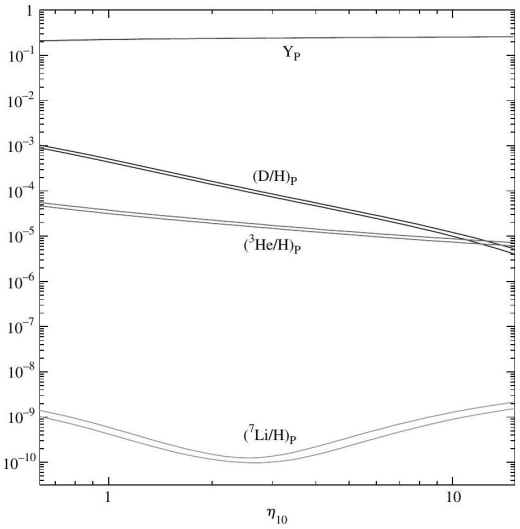

Figure 3.1: Calculated primordial abundances of deuterium, He^{3}, and Li^7 relative to hydrogen, and the fraction Y_P of the primordial mass of the universe in He^4, as functions of $\eta_{10} \equiv 10^{10}\eta$, where η is the ratio of nucleons to photons in the present universe. The widths of the bands indicate the effect of uncertainties in nuclear reaction rates. From G. Steigman, Int. J. Mod. Phys. E15, 1 (2006) [astro-ph/0511534].

2. Solar wind. Deuterium was converted to He^3 in the sun before it went onto the main sequence, so measurements of He^3 in the solar wind and meteorites is believed to give the

[4712] The calculated abundances cited below are given by S. Burles, K. M. Nollett, and M. S. Turner, Astrophys. J. 552, L1 (2001).

[13] J. L. Linsky et al., Astrophys. J. 402, 694 (1993); 451, 335 (1995).

total pre-solar value of He^3 and deuterium. Subtracting the abundance of He^3 obtained in other ways gave [14] a deuterium/hydrogen ratio of $(2.6 \pm 0.6 \pm 1.4) \times 10^{-5}$.

3. Jovian atmosphere. Spectroscopic studies of the Jovian atmosphere gave [15] a deuterium/hydrogen ratio of $(5 \pm 2) \times 10^{-5}$.

More recently, it has been possible to measure the deuterium/hydrogen ratio in very early intergalactic matter, by observing deuterium as well as hydrogen absorption lines in the spectra of quasistellar objects, due to

Table 3.3: Five quasi-stellar objects in whose spectra deuterium and hydrogen absorption lines are observed, together with the redshift of the intergalactic cloud responsible for the absorption, and the ratio of the numbers of deuterium and hydrogen atoms in the clouds inferred from the relative strength of the absorption lines, from ref. 17. (Observational uncertainties represent one standard deviation.)

QSO	z	D/H
PKS 1937-1009	3.572	$3.25 \pm 0.3 \times 10^{-5}$
Q1009+299	2.504	$3.98^{+0.59}_{-0.67} \times 10^{-5}$
HS 0105+1619	2.536	$2.54 \pm 0.23 \times 10^{-5}$
Q1243+3047	2.525675	$2.42^{+0.35}_{-0.25} \times 10^{-5}$
Q2206-199	2.0762	$1.65 \pm 0.35 \times 10^{-5}$

absorption in intervening intergalactic clouds of large redshift. [16] In 2003 the results of several years of observations of deuterium and hydrogen absorption lines in the spectra of four quasi-stellar objects were put together with results for one more QSO, [17] with the results shown in Table 3.3. The best value of the deuterium/hydrogen number ratio was found to be $2.78^{+0.44}_{-0.38} \times 10^{-5}$, from which is inferred a baryon/photon ratio $\eta = 5.9 \pm 0.5 \times 10^{-10}$, corresponding to

$$\Omega_B h^2 = 0.0214 \pm 0.0020.$$

Even for H_0 as small as 50 km/sec/Mpc, it was clear that Ω_B is much less than the fraction that all non-relativistic matter contributes to the critical density, which we have seen had been given as $\Omega_M \simeq 0.2$ by studies of galaxy clusters and as $\Omega_M \simeq 0.3$ by the redshift-distance relation of type Ia supernovae. It is this discrepancy that provided the original evidence for non-baryonic dark matter in the universe.

The discrepancy has become sharper through measurements of anisotropies in the cosmic microwave background. As we will see in Section 7.2, from these measurements it is possible to infer that $\Omega_B h^2 = 0.0223^{+0.0007}_{-0.0009}$ and $\Omega_M h^2 = 0.127^{+0.007}_{-0.013}$, indicating a total mass density that is from 5 to 6 times larger than the density of ordinary baryonic matter. The nature of the missing matter is discussed in Section 3.4.

The primordial abundance of He^3, like that of deuterium, is a monotonically decreasing function of the baryon/photon ratio. On the basis of a long term study of galactic HII regions

and planetary nebula, a 2002 study [18] concluded that the He^3/H ratio in interstellar space is less than $1.1 \pm 0.2 \times 10^{-5}$, which is consistent with the value $1.04 \pm 0.06 \times 10^{-5}$ calculated for $\Omega_B h^2 = 0.0214$. But, unlike deuterium, He^3 is both produced and destroyed in stars, so it is not clear whether the observed interstellar abundance really represents the primordial abundance of He^3. Indeed, it had been thought that low-mass stars would inject a good deal of He^3 into the interstellar medium, in which case the apparent agreement between the amount observed in the interstellar medium and the amount expected from cosmological nucleosynthesis would actually represent a discrepancy. [19] This apparent discrepancy may have been removed by detailed calculations [20] of the movement of He^3 into the interior of these low-mass stars, which indicate that these stars do not in fact emit much He^3.

Some Li^6 is produced cosmologically, but in such small quantities (an abundance of about 10^{-13} to 10^{-14} that of hydrogen) that it has generally not been considered useful as a test of cosmological theories. [21] Much more attention has been given to Li^7. Its abundance has a more complicated dependence on the baryon/photon ratio, because Li^7 was formed in two different ways: directly, by the reactions $H^3 + He^4 \rightarrow Li^7 + \gamma$, and indirectly by $He^3 + He^4 \rightarrow Be^7 + \gamma$, followed much later by $e^- + Be^7 \rightarrow v + Li^7$. As we go to higher baryon densities, the amount of Li^7 produced directly increases at first, but then begins to decrease as Li^7 is destroyed in the reaction $p + Li^7 \rightarrow He^4 + He^4$. Eventually the indirect reaction takes over, and the Li^7 abundance rises again. The minimum Li^7/ hydrogen ratio is calculated to be about 2×10^{-10}, and is reached at a baryon/photon ratio of about 3×10^{-10}, corresponding to $\Omega_B h^2 = 0.01$. The observed Li^7/H ratio was reported [22] in 2000 to be $2.07^{+0.15}_{-0.04} \times 10^{-10}$, close to this minimum. A subsequent study [23] of 63 dwarf stars in the galactic halo gave a Li^7/H ratio of $(2.37 \pm 0.05) \times 10^{-10}$. Either result is less than the value 3×10^{-10} predicted for $\Omega_B h^2 = 0.0214$, but it is plausible that although

Li^7 is produced in stars and in the interaction of cosmic rays with matter, the Li^7 abundance has been depleted by convection in stellar atmospheres. Observation of Li^7 abundances in stars of varying temperature in the globular cluster NGC 6397 gave results in agreement with a theory of convective depletion of Li^7, with an assumed initial Li^7/H ratio equal to the expected value 3×10^{-10} (calculated taking $\Omega_B h^2$ to have the value estimated from deuterium abundance and microwave background anisotropies). [24] With the one possible exception of Li^7, there is now complete agreement between observations of light element abundances and calculations of cosmological nucleosynthesis, adopting the value $\Omega_B h^2$ provided by observations of anisotropies in the cosmic microwave background.

Although the baryon mass density inferred from cosmological nucleosynthesis and the cosmic microwave background is considerably less than the total mass density, it is also considerably greater than the density of baryonic matter observed in stars and luminous interstellar matter. [25] Some of this dark baryonic matter is in intergalactic space, but a fair fraction is believed to be present in galaxies, in the form of brown dwarf stars and clouds of hydrogen molecules. [26] But this is more a problem for the astrophysics of galaxies than for cosmology.

10.3.3 3.3 Baryonsynthesis and leptonsynthesis

We saw in the previous section that the ratio η of nucleons to photons at the time of nucleosynthesis had the tiny value $\simeq 5 \times 10^{-10}$. At earlier times, when the temperature was above 10^{13} K, nucleons would not yet have formed from their three constituent quarks, and there would have been roughly as many quark-antiquark pairs in thermal equilibrium as photons. But the conservation of baryon number (one-third the number of quarks minus the number of antiquarks) during the annihilation process tells us that before annihilation there must have been a slight excess, roughly of order η per photon, of quarks over antiquarks, so that some quarks would survive to form nucleons when all the antiquarks had annihilated with quarks. There was also a slight excess of electrons over positrons, to maintain the charge neutrality of the universe. It is conceivable that there is a compensating excess of antineutrinos over neutrinos, so that the total lepton number density (the number density of electrons, muons, tauons, and neutrinos, minus the number density of their antiparticles) vanishes, but it seems more natural to assume that before lepton-antilepton annihilation

there was also a slight imbalance of leptons and antileptons, comparable to the excess of quarks over antiquarks.

These tiny imbalances in the numbers of quarks and antiquarks and of leptons and antileptons might be explained if the baryon and lepton number densities were generated by physical processes in a universe that at some early time had equal number of particles and antiparticles of all sorts. We could then hope to calculate η from first principles, and understand why it is so small. In 1967 Sakharov [1] outlined three conditions that must be met for this to be possible:

1. Obviously, in order for an excess of baryons over antibaryons or an inequality of leptons and antileptons to arise in a universe that begins with equal numbers of particles and antiparticles of each type, some physical processes must violate the conservation of baryon number or lepton number.

2. A universe with equal numbers of particles and antiparticles of each type (and each momentum and helicity) is invariant under the symmetry operators C (the exchange of particles with antiparticles) and CP (the exchange of particles with antiparticles, combined with a change of sign of all three-dimensional coordinate vectors), while a state with an excess of baryons over antibaryons or an imbalance of leptons and antileptons is clearly not invariant under either C or CP. Hence to produce such an state, some physical process must violate invariance under both C and CP . It is true that, whether or not C and/or CP are conserved, any relativistic quantum field theory will respect a symmetry [2] under CPT, the simultaneous exchange of particle with antiparticles, combined with a change of sign of all three-dimensional coordinate vectors, combined with a change in the direction of time's flow, but this does not prevent the production of baryon or lepton number, because the time-reversal symmetry T is violated by the expansion of the universe.

3. A little less obviously, in order to produce an excess of baryons over antibaryons or an imbalance of leptons and antileptons out of a state with equal numbers of particles and antiparticles, the universe must at some time depart from a state of thermal (including chemical) equilibrium. This is because in a state of thermal equilibrium, if baryon and/or lepton conservation are not respected, and all conserved quantities like electric charge vanish, then since chemical potentials must be conserved in all reactions, all chemical

[4][7][24] A. J. Korn et al., Nature 442, 657 (2006) [astro-ph/0608201].
[25] M. Fukugita, C. J. Hogan, and P. J. E. Peebles, Astrophys. J. 503, 518 (1998).
[26] See e.g. M. Roncadelli, Recent Research Devel. Astron. & Astrophys. 1, 407 (2003).

potentials must vanish. The CPT symmetry implies that even if C and CP are not conserved, the masses of particles and their

antiparticles are precisely equal, so with vanishing chemical potentials particles and antiparticles will have identical distribution functions, such as (3.1.28) with $\mu = 0$ for ideal gases. Thus, whatever the rates for various processes, no net baryon or lepton number will be produced. [3] An exception to this reasoning is presented at the end of this section.

All three conditions are now known to be satisfied:

(1) There is no direct experimental evidence for the nonconservation of baryon number, but a very weak baryon number nonconservation is expected according to modern views of the standard model of elementary particles. According to these views, the standard model is not a fundamental theory, which might be expected to be contain only interactions whose coupling parameters are either dimensionless or proportional to positive powers of mass, so that all infinities that arise in the standard model can be absorbed into a renormalization of these coupling parameters. Rather, we now think that the standard model is only an effective field theory, valid at energies much less than some fundamental mass scale M, which might be the Planck mass $M_{\mathcal{P}} \equiv G^{-1/2} = 1.22 \times 10^{19}$GeV, or perhaps the energy scale $\approx 10^{15}$ to 10^{16}GeV at which the three independent (suitably normalized) gauge coupling parameters of the standard model become equal. We would expect such an effective field theory to contain every possible interaction allowed by the gauge symmetries of the strong, weak, and electromagnetic interactions, but all but a finite number of these coupling parameters will have the dimensions of negative powers of mass. These "non-renormalizable" couplings are thus suppressed at energy $E \ll M$ by powers of E/M. Now, the gauge symmetries of the standard model do not allow any unsuppressed interactions among quarks and leptons that violate baryon or lepton number, so this picture makes it plausible that baryon and lepton number would be automatically conserved to a good approximation for energies $E \ll M$, even if baryon and lepton conservation are not respected by whatever fundamental theory describes physics at energies of order M. In other words, baryon and lepton number conservation may be mere "accidental" symmetries. In this case, there is no reason to exclude any suppressed interactions that violate conservation of baryon and lepton number. The least suppressed interactions of this sort are an interaction involving two lepton doublets and two scalar doublets, which is suppressed by a factor M^{-1} and violates lepton but not baryon conservation, and an interaction suppressed by a factor M^{-2} involving three quark fields and one lepton field, which violates both lepton and baryon

conservation. [4] (Also, as we shall see below, there is a quantum-mechanical violation of baryon-number and lepton-number conservation in the standard electroweak theory.) There is experimental evidence for the first but not the second interaction. With a coupling parameter of order $1/\,(10^{16}\text{GeV})$, when the neutral scalar fields are replaced by their vacuum expectation values, this interaction provides a neutrino mass of order 10^{-2}eV, in good agreement with the results of neutrino oscillation experiments. (The existence of non-zero neutrino masses means that helicity $+1/2$ neutrinos, which are conventionally assigned lepton number $+1$, can be changed to helicity $-1/2$ neutrinos with lepton number -1 by a Lorentz transformation.) The second interaction would lead to decay processes like $p \to \pi^0 + e^+$, with decay rates of order $m_p^5/M^4\hbar$. Such events have not been seen, but could easily have escaped detection.

(2) The violation of invariance under C was discovered in 1957, while the violation of invariance under CP was discovered in 1964.[5]

(3) The expansion of the universe tends to pull states out of thermal equilibrium, either because the cooling temperature makes reaction rates decrease below the expansion rate, or because

[471] A. D. Sakharov, JETP Lett. 5, 24 (1967).

[2] See QTF, Vol. I, Sec. 5.8.

[473] For a more detailed argument and references to earlier discussions, see S. Weinberg, Phys. Rev. Lett. 42, 850 (1978).

as it cools the universe goes through first-order phase transitions, similar to the condensation of water vapor or the freezing of liquid water. Although this in itself does not violate the conservation of baryon or lepton number, it opens the door for physical processes that do violate these conservation laws, as well as C and CP conservation, to create an imbalance between baryons and antibaryons and/or between leptons and antileptons.

All this just goes to show that it is possible for physical processes to produce a non-zero cosmological baryon and lepton number. It remains to find a specific theory in which the observed ratio of baryons to photons could be produced. [6] There are several theories of this type:

1. Delayed decay of heavy particles [7]

Suppose there is a species of heavy " X " particle, which decays into a pair of different channels, with baryon numbers B_1 and B_2 and lepton numbers L_1 and L_2, and branching ratios r and $1-r$. (For instance, in some grand

unified theories there are "leptoquarks" with mass of order 10^{15}GeV, that decay into either two quarks, with baryon number 2/3 and lepton number zero, or into a lepton and antiquark, with baryon number $-1/3$ and lepton number $+1$.) The antiparticle will then decay into channels with baryon numbers $-B_1$ and $-B_2$ and lepton numbers $-L_1$ and $-L_2$, with branching ratios $\bar{r}$ and $1-\bar{r}$. (Invariance under CPT tells us that any particle has the same total decay rate as its antiparticle, but as long as C and CP conservation are violated, it is possible for particles and antiparticles to have different branching ratios for their different decay channels.) The average total baryon number produced in the decay of one X particle and the decay of one of the corresponding antiparticles is then

$$\Delta B = rB_1 + (1-r)B_2 - \bar{r}B_1 - (1-\bar{r})B_2 = (r-\bar{r})\,(B_1 - B_2)\,, \tag{3.3.1}$$

and likewise for lepton number.
Similarly, there may be some heavy " N " particle that is its own antiparticle, and that decays with branching ratio r into one channel with baryon number B_1 and lepton number L_1, and with branching ratio $1-r$ into the antichannel with baryon number $-B_1$ and lepton number $-L_1$. On the average, each decay produces a baryon number

$$\Delta B = rB_1 - (1-r)B_1 \tag{3.3.2}$$

and likewise for lepton number. If C and CP conservation are violated, then it is possible to have $r \neq 1-r$, so that a net baryon number and lepton number may be produced. For instance, in some grand unified theories there are neutral fermions that decay both into scalar particles and leptons and into their antiparticles, producing a net lepton number if the branching ratios for these channels are unequal.

Such processes do not produce any net baryon or lepton number in equilibrium, because the inverse to the decay processes will destroy precisely as much baryon and lepton number as the decay processes create. The conditions for thermal equilibrium will be violated if H falls below the X-particle decay rate, but as long as $k_{\mathcal{B}}T$ remained above all particle masses,

[474] For a review, with references to the original literature, see QTF, Vol. II, Section 21.5.

Lett. 81B, 416 (1979); A. Yu. Ignatiev, N. V. Krosnikov, V. A. Kuzmin, and A. N. Tavkhelidze, Phys. Lett. 76B, 436 (1978); B. Toussaint, S. B. Treiman, F. Wilczek, and A. Zee, Phys. Rev. D 19, 1036 (1978); J. Ellis, M. K. Gaillard, and D. V. Nanopoulos, Phys. Lett. 80B, 360 (1979); 82B, 464(E) (1979).
[7] S. Weinberg, Phys. Rev. Lett. 42, 850 (1978).

whatever the rates of various processes, the expansion preserved the equilibrium form for all particle distributions, with a redshifted temperature $T \propto 1/a$. Specifically, if $k_{\mathcal{B}}T$ was still above all particle masses when $H \equiv \dot{a}/a$ fell below the decay rate Γ_X, the inverse decay process would re-create as many X particles as had decayed. On the other hand, if at the time that $H \approx \Gamma_X, k_{\mathcal{B}}T$ was less than the mass m_X of the X particles, then the Boltzmann factor $e^{-m_X/k_{\mathcal{B}}T}$ would have blocked the inverse decay, and the X particles and antiparticles would have disappeared, yielding a net baryon number $(r-\bar{r})(B_1 - B_2)$ for each original heavy particle-antiparticle pair.

The condition for this to work is then that $k_{\mathcal{B}}T \leq m_X$ at the temperature when $H = \Gamma_X$. We can estimate that (here taking $\hbar = c = 1$)

$$H = \sqrt{\frac{8\pi G a_{\mathcal{B}} T^4 (\mathcal{N}/2)}{3}} = 1.66\,(k_{\mathcal{B}}T)^2\,\mathcal{N}^{1/2}/m_{\mathcal{P}} \tag{3.3.3}$$

where $m_{\mathcal{P}} \equiv G^{-1/2} = 1.22 \times 10^{19}$GeV, and $\mathcal{N}$ is the total number of helicity states of all elementary particles and antiparticles, with an extra factor 7/8 for fermions. (We assume here that the main contribution to the energy density of the universe at these temperatures comes from the large number $\mathcal{N}$ of highly relativistic particle types, rather than from the X particles themselves.) The decay rate of the X particle will be m_X times some dimensionless parameter α_X, which characterizes the strength of the interactions responsible for the decay and the number of decay channels. Hence decays start to be significant at a temperature T_X, given by

$$k_{\mathcal{B}}T_X \approx \sqrt{\alpha_X m_X m_{\mathcal{P}}/\mathcal{N}^{1/2}} \tag{3.3.4}$$

For this to be less than m_X, we must have

$$m_X \geq \mathcal{N}^{-1/2}\alpha_X m_{\mathcal{P}} \tag{3.3.5}$$

This is a fairly severe lower bound on m_X. For instance, if the X particles decay through ordinary electroweak interactions, then $\alpha_X \approx 10^{-2}$, so if $\mathcal{N} \approx 100$ we must have m_X greater than about 10^{16}GeV. From the point of view of theories that unify the strong and electroweak interactions, this is not an unreasonable value for the mass.

Assuming that this condition is satisfied, we can easily use Eq. (3.3.1) to make an estimate of η. At temperatures far above the heavy particle mass the number density of pairs of X particles and antiparticles is of the same order as the number density of photons. The entropy density (using energy units for temperature, with $k_{\mathcal{B}} = 1$) at this time is of the order of $\mathcal{N}$ times the number density of photons, so the ratio of the number densities of X and $\bar{X}$ pairs to the entropy density is of the order of $1/\mathcal{N}$. With Eq. (3.3.4) satisfied, after the disappearance of these pairs the ratio of the baryon number to the entropy densities will be of order $(r-\bar{r})(B_1 - B_2)/\mathcal{N}$. The entropy density varies as a^{-3}, and provided that baryon number is subsequently conserved so does the baryon number density, and so the baryon number to entropy ratio will remain unchanged. The present entropy density is of the order of the photon number density, and at present the only baryons are nucleons, with no antinucleons, so we expect a nucleon to photon ratio

$$\eta \approx (r-\bar{r})(B_1 - B_2)/\mathcal{N} \tag{3.3.6}$$

Typically $B_1 - B_2$ is of order unity (in the leptoquark example mentioned above, it is equal to unity) but $r-\bar{r}$ is generally very small, both because CP conservation is weakly violated, and because the CPT theorem tells us that $r = \bar{r}$ in the lowest order of perturbation theory. The precise value of $r - \bar{r}$ is very model-dependent, but values of η of the desired order, 5×10^{-10},

appear quite natural. [8] This idea runs into difficulty in inflationary theories, which as we will see in Chapter 10 generally require that the temperature was never high enough to produce particles with masses satisfying Eq. (3.3.5).

2. Nonperturbative electroweak baryon and lepton number nonconservation

In the standard model of weak, electromagnetic, and strong interactions baryon and lepton number are automatically conserved to all orders of perturbation theory, but not when certain non-perturbative effects are taken into account. [9] This produces reactions that violate baryon and lepton number conservation, but such reactions are suppressed at low temperatures by a factor $\exp(-8\pi^2/g^2) \simeq 10^{-162}$, where g is the $SU(2)$ electroweak coupling constant. This tiny exponential is actually a barrier penetration factor, which accompanies the quantum mechanical tunneling transition through the barrier between topologically different configurations of the gauge fields. At high temperatures, above about 300 GeV , thermal fluctuations allow passage over this barrier, and the exponential suppression disappears. [10] Nevertheless, by themselves these reactions do not produce an appreciable net baryon or lepton number, both because they take place at a time of nearly perfect thermal equilibrium, [11] and because they are suppressed by small parameters associated with the need to violate CP conservation as well as the conservation of baryon and lepton number. [12]

3. Leptogenesis [13]

Although the non-perturbative effects of electroweak interactions described in the previous paragraph do not by themselves provide a way of accounting

for the observed baryon/photon ratio, they can convert a cosmological lepton number density into a baryon number density, or vice versa. The only truly conserved quantum numbers in the $SU(3) \times SU(2) \times U(1)$ standard model are those associated with gauge symmetries - the electroweak isospin generator T_3, the electroweak hypercharge Y (defined so that the electric charge in units of e is $T_3 - Y$), and a pair of generators of the $SU(3)$ gauge group of quantum chromodynamics - together with $B-L$, the total baryon number minus the total lepton number, which is conserved because of a cancelation between Feynman diagrams containing loops of quarks or leptons. This creates a further problem for the proposal that the observed baryon number density of the universe is created in the decay of a leptoquark into both two quarks and into a lepton and antiquark. Although these channels have different values for B and L, they both have the same value (equal to 2/3) for $B - L$. Hence if the universe starts with equal numbers of particles and antiparticles of all types, then even if leptoquark decay produces equal non-zero baryon and lepton number densities, all truly conserved quantities will remain zero, so when thermal equilibrium is established at lower temperatures it will be with zero values

for all chemical potentials. (This is demonstrated below.) Such a state has equal numbers of particles and antiparticles, and hence zero densities of B and L as well as $B-L$.

On the other hand, if some heavy particle (such as the N particle mentioned above) in the early universe decays in such a way as to produce a non-zero density of $B-L$ this will persist through the period of thermal equilibrium, though the relative densities of B and L may change. In general, whatever mixture of baryon and lepton number is produced when the heavy particle decay, and even if only lepton number is produced, we would expect the densities of baryon and lepton number to be comparable in a subsequent period of thermal equilibrium.

This can be made quantitative. [14] Suppose in thermal equilibrium there are a set of conserved quantum numbers Q_a, such as T_3, Y, and $B-L$. Suppose also that there are several species i of particles in equilibrium, such as quarks, leptons, etc., each carrying a value q_{ai} for the quantum number Q_a. The chemical potentials μ_i for these particles must be conserved for all reactions in thermal equilibrium, which requires that they be linear combinations of the conserved quantum numbers:

$$\mu_i = \sum_a q_{ai}\mu_a \tag{3.3.7}$$

with coefficients μ_a that can be regarded as chemical potentials for the different conserved quantities. The densities of the different particle species

can then be expressed as functions of the μ_a and the temperature, and these relations can be used to calculate the densities n_a of the different conserved quantum numbers as functions of the μ_a and the temperature. But there are just as many n_a as there are μ_a, so these relations can be inverted to give the μ_a in terms of the n_a and the temperature, from which we can calculate the density of anything else as functions of the n_a and the temperature, including the density of a nonconserved quantity like baryon or lepton number that is not among the Q_a.

In the case that interests us here, at temperatures above about 10^{16} K, all particles of the Standard Model are highly relativistic, so that their masses can be neglected. The number density of particle species i is then

$$\begin{aligned} n_i &= \frac{g_i}{(2\pi\hbar)^3}\int \frac{d^3p}{e^{(p-\mu_i)/k_{\mathcal{B}}T}\mp 1} \\ &= 4\pi g_i\left(\frac{k_{\mathcal{B}}T}{2\pi\hbar}\right)^3\int_0^\infty \frac{x^2dx}{e^{x-\mu_i/k_{\mathcal{B}}T}\mp 1} \end{aligned} \tag{3.3.8}$$

where g_i is the number of helicity (and other sources of multiplicity) states for each species, and the $\mp$ sign is - for bosons and + for fermions. The antiparticle density $\bar{n}_i$ will be given by the same formula, but with μ_i replaced with $-\mu_i$, so the difference is

$$n_i - \bar{n}_i = 8\pi g_i\left(\frac{k_{\mathcal{B}}T}{2\pi\hbar}\right)^3 \sinh\left(\frac{\mu_i}{k_{\mathcal{B}}T}\right)\int_0^\infty \frac{x^2e^x dx}{e^{2x}\mp 2e^x\cosh\left(\mu_i/k_{\mathcal{B}}T\right)+1} \tag{3.3.9}$$

In the situation that concerns us here, the imbalance between particles and antiparticles of all sorts is small, so $|\mu_i| \ll 1$ for all particle species. In this case,

$$n_i - \bar{n}_i = 8\pi g_i\left(\frac{k_{\mathcal{B}}T}{2\pi\hbar}\right)^3 \frac{\mu_i}{k_{\mathcal{B}}T}\int_0^\infty \frac{x^2e^x dx}{\left(e^x\mp 1\right)^2} \tag{3.3.10}$$

The integral over x has the value $\pi^2/3$ for bosons and $\pi^2/6$ for fermions, so we can write this as

[4714] J. A. Harvey and M. S. Turner, Phys. Rev. D 42, 3344 (1990).

$$n_i - \bar{n}_i = f(T)\tilde{g}_i\mu_i \tag{3.3.11}$$

where

$$f(T) \equiv \frac{4\pi^3}{3}\frac{(k_{\mathcal{B}}T)^2}{(2\pi\hbar)^3} \tag{3.3.12}$$

and $\tilde{g}_i$ is the number of spin states, but with an extra factor of 2 for bosons. Using Eq. (3.3.7), Eq. (3.3.11) becomes

$$n_i - \bar{n}_i = f(T)\tilde{g}_i \sum_a q_{ai}\mu_a \tag{3.3.13}$$

In particular, the density of the conserved quantum number Q_a is

$$n_a = \sum_i q_{ai}\,(n_i - \bar{n}_i) = f(T)\sum_b M_{ab}\mu_b, \tag{3.3.14}$$

where M is the matrix

$$M_{ab} \equiv \sum_i \tilde{g}_i q_{ai} q_{bi} \tag{3.3.15}$$

This matrix is positive-definite (in the sense that, for any set of real numbers ξ_a, we have $\sum_{ab} M_{ab}\xi_a\xi_b > 0$, unless all ξ_a vanish), and therefore it has an inverse M^{-1}. We can thus invert the relation (3.3.14), and find $\mu_a = \sum_b M^{-1}_{ab} n_b/f(T)$. Using this in Eq. (3.3.13) gives

$$n_i - \bar{n}_i = \sum_{ab} \tilde{g}_i q_{ai} M^{-1}_{ab} n_b \tag{3.3.16}$$

for any particle species i. Note in particular that if the densities n_b of all the conserved quantum numbers vanish, then there is an equal number of particles and antiparticles of every kind, as mentioned above.

In order to deal with the case where some conserved quantities such as $B-L$ have non-zero densities, we need to calculate the matrix M_{ab}. The particles of the Standard Model are listed in Table 3.4. For N_g generations of quarks and leptons and N_d scalar doublets, the independent elements of the matrix M_{ab} are

$$M_{B-LB-L} = \frac{13N_g}{3}, \quad M_{B-LY} = -\frac{8N_g}{3}, \quad M_{YY} = \frac{10N_g}{3} + N_d \tag{3.3.17}$$

We don't need any of the matrix elements involving T_3, because the sum of the T_3 values vanishes for all the particles with any given values of $B-L$ and Y, so that $M_{B-LT_3} = M_{YT_3} = 0$. That is, the matrix M_{ab} is blockdiagonal, with a 2×2 block having a and b running over $B-L$ and Y. This has the consequence that without bothering to calculate $M_{T_3T_3}$, we can calculate that

$$M^{-1}_{B-LB-L} = \frac{10N_g}{3D} + \frac{N_d}{D}, \quad M^{-1}_{B-LY} = \frac{8N_g}{3D}, \quad M^{-1}_{YY} = \frac{13N_g}{3D} \tag{3.3.18}$$

where D is the determinant

$$D = \frac{22N_g^2}{3} + \frac{13N_gN_d}{3} \tag{3.3.19}$$

(Similarly, because the sum of the color quantum numbers vanishes for all the particles with any given values of $B-L$ and Y, we do not need to take

Table 3.4: Particles of the Standard Model, together with the number $\tilde{g}$ of their helicity and color states (with an extra factor 2 for bosons), and the values of their baryon number, lepton number, and gauge quantum numbers. Only one "generation" of quarks and leptons and only one doublet of scalar fields are shown. The subscripts L and R denote the helicity states of quarks u and d and leptons v and e. Antiparticles are not shown separately, and the photon and Z^0 are not shown because they are their own antiparticles, and so do not contribute to the densities of any quantum numbers. Color quantum numbers are not shown, for reasons given in the text.

Particle	$\tilde{g}$	B	L	T_3	Y
u_L	3	1/3	0	1/2	-1/6
d_L	3	1/3	0	-1/2	-1/6
u_R	3	1/3	0	0	-2/3
d_R	3	1/3	0	0	1/3
v_L	1	0	1	1/2	1/2
e_L	1	0	1	-1/2	1/2
e_R	1	0	1	0	1
W^+	4	0	0	1	0
φ^+	2	0	0	1/2	-1/2
φ^0	2	0	0	-1/2	-1/2
gluons	4	0	0	0	0

the color quantum numbers into account here.) Thus if $B-L$ is the only conserved quantum number with a non-vanishing number density, then Eqs. (3.3.16) and (3.3.18) tell us that the baryon number density in thermal equilibrium is

$$\begin{aligned} n_B &\equiv \sum_i B_i \left(n_i - \tilde{n}_i\right) = \sum_i \tilde{g}_i B_i \left((B-L)_i M^{-1}_{B-LB-L} + Y_i M^{-1}_{YB-L}\right) n_{B-L} \\ &= \left(\frac{4}{3} M^{-1}_{B-LB-L} - \frac{2}{3} M^{-1}_{YB-L}\right) N_g n_{B-L} \\ &= \left(\frac{8N_g + 4N_d}{22N_g + 13N_d}\right) n_{B-L} \end{aligned} \tag{3.3.20}$$

For instance, in the minimal experimentally allowed case, with $N_g = 3$ and $N_d = 1$, this gives $n_B = (28/79)n_{B-L}$. In any case, n_B turns out to be of
the same order of magnitude as n_{B-L}, as anticipated above. The reason for the smallness of n_B/n_γ in this scenario would be traced to the smallness of CP violation in the out-of-equilibrium heavy particle decay that produces a non-vanishing density of $B - L$.

4. Affleck-Dine mechanism [15]

It is possible for baryon number nonconservation to occur in the nonequilibrium dynamics of a scalar field that carries a non-zero baryon number. Both baryon-number conservation and CP-invariance need to be violated in the Lagrangian of the scalar field. Such theories find their motivation in supersymmetry, which lies outside the scope of this book.

5. Equilibrium baryon synthesis

The violation of CPT by the expansion of the universe means that the part of the Hamiltonian that is odd in C and CP can have a non-zero expectation value ΔE_i in the state of a single

baryon of type i, and of course opposite expectation value $-\Delta E_i$ in the state of the corresponding antibaryon. Then even the universe starts in a state of zero baryon number, if it enters a state of thermal equilibrium in which baryon-number nonconserving processes occur rapidly, although there will be no chemical potential associated with baryon number, the difference in energy of baryons and antibaryons will lead to a net baryon number. When baryon-number nonconserving processes become ineffective the resulting baryon number density will survive, simply decreasing as a^{-3}. As long as baryon-conserving collisions remain sufficiently rapid, the one-particle distribution will have the form appropriate for thermal equilibrium, but now with a non-vanishing baryonic chemical potential.

As a general class of theories of this sort, suppose that in the expanding universe, there is a term in the Lagrangian density of the form

$$\Delta\mathcal{L}(x) = -\sqrt{-\operatorname{Det} g}V_\mu(x)J_B^\mu(x), \tag{3.3.21}$$

where $V_\mu(x)$ is a classical vector field and $J_B^\mu(x)$ is the current associated with baryon number (for which $J_B^0(x)$ is the baryon density, which is odd under C and CP). Two proposals of this sort have been made: the vector field could be $V_\mu = M^{-1}\partial_\mu\varphi$, where φ is some scalar field [16] and M is some large mass; or the vector field could be $V_\mu = M^{-2}\partial_\mu R$, where R is the curvature scalar [17] and again M is some large mass. In any case, the isotropy and homogeneity of the Robertson-Walker metric requires that

V_i vanishes, while V_0 is a function only of time. This interaction then shifts the energy of the state of a single particle of type i with baryon number b_i by an amount $\Delta E_i = V_0(t)b_i$. In thermal (including chemical) equilibrium, the baryon number density will be

$$n_B(t) = \sum_i b_i g_i \int \frac{4\pi p^2 dp}{(2\pi\hbar)^3}\left[e^{\left(\sqrt{p^2+m_i^2}+b_iV_0(t)\right)/k_{\mathcal{B}}T(t)} \mp 1\right]^{-1} \tag{3.3.22}$$

where the sum over i runs over all particle (and antiparticle) types; g_i and b_i are the number of spin states and the baryon number of a particle of type i; and the upper and lower signs again apply to bosons and fermions, respectively. If baryon non-conserving collisions shut off suddenly at time t_1, then subsequently the baryon number density will be

$$n_B(t) = \left(\frac{a\left(t_1\right)}{a(t)}\right)^3 \sum_i b_i g_i \int \frac{4\pi p^2 dp}{(2\pi\hbar)^3}\left[e^{\left(\sqrt{p^2+m_i^2}+b_iV_0(t_1)\right)/k_{\mathcal{B}}T(t_1)} \mp 1\right]^{-1} \tag{3.3.23}$$

For $V_0 = 0$ the cancelation between baryons and antibaryons of course makes this vanish. Since the baryon/entropy ratio is known to be small, we expect $V_0\left(t_1\right)$ to be small; to first order in $V_0\left(t_1\right)$, the baryon number density for $t > t_1$ will be

$$\begin{aligned} n_B(t) = &\left(\frac{a\left(t_1\right)}{a(t)}\right)^3 \frac{V_0\left(t_1\right)}{k_{\mathcal{B}}T\left(t_1\right)} \sum_i b_i^2 g_i \\ &\times \int \frac{4\pi p^2 dp}{(2\pi\hbar)^3} e^{\sqrt{p^2+m_i^2}/k_{\mathcal{B}}T(t_1)}\left[e^{\sqrt{p^2+m_i^2}/k_{\mathcal{B}}T(t_1)} \mp 1\right]^{-2} \end{aligned} \tag{3.3.24}$$

[4715] L. Affleck and M. Dine, Nucl. Phys. B 249, 361 (1985); M. Dine, L. Randall, and S. Thomas, Phys. Rev. Lett. 75, 398 (1995); Nucl. Phys. B 458, 291 (1996).

[16] A. G. Cohen and D. B. Kaplan, Phys. Lett. B 199, 251 (1987). The production of baryon number is suppressed when the scalar field oscillates rapidly; see A. Dolgov, K. Freese, R. Rangarajan, and M. Srednicki, Phys. Rev. D 56, 6155 (1997) [hep-ph/9610405].

[17] H. Davoudiasl, R. Kitano, G. D. Kribs, H. Murayama, and P. J. Steinhardt, Phys. Rev. Lett. 93, 201301 (2004).

A similar mechanism could also be responsible for lepton synthesis.
The crucial confirmation of any theory of baryon synthesis would be a successful prediction of the present baryon/photon ratio. So far, none of the proposals discussed here are anywhere near this goal.

10.3.4 3.4 Cold dark matter

We saw in Section 3.2 that considerations of cosmological nucleosynthesis lead to the conclusion that most of the mass in the universe is not in the form of ordinary baryonic matter, i.e. atomic nuclei and electrons. We will see in Chapter 7 that this conclusion is powerfully reinforced by observations of anisotropies in the cosmic microwave background. So we face the question, if the particles that make up most of the mass of the universe are not baryons, then what are they?

We know that this matter is dark, in the sense that it does not interact significantly with radiation, both because we don't see it, and also because it has not lost its kinetic energy sufficiently to relax into the disks of galaxies, as has baryonic matter. This means in particular that these particles must be electrically neutral. [1] Detailed studies of the dynamics of galaxy clusters indicate that the dark matter particles must also be cold, in the sense that their velocities are highly non-relativistic. [2]

The study of a double galaxy cluster 1E0657-558 (the "bullet cluster," with $z = 0.296$) has provided vivid direct evidence of the existence of dark matter, which does not have non-gravitational interactions with itself or with ordinary baryonic matter. [3] The galaxies in this cluster are mostly grouped into two distinct subclusters, while hot gas (observed through its emission of X-rays) is concentrated between these subclusters. The interpretation is that two clusters of galaxies have collided; the galaxies which have little chance of close encounters have mostly continued on their original paths, while the two clouds of hot gas that previously accompanied them have collided and remained closer to the center of the double cluster. The total matter density in 1E0657-558 is mapped out through its effect in gravitationally deflecting light from more distant galaxies along the same line of sight. (Gravitational lensing is discussed in Chapter 9.) In this way, it is found that most of the matter in 1E0657-558 is not associated with the hot gas, but like the galaxies forms two subclusters that have evidently passed through each other without appreciable interaction. The ratio of the mass in hot gas to the mass in all matter is estimated to be about 1/6, in line with the value of Ω_B/Ω_M previously inferred from measurements of deuterium abundance and luminosity distance as a function of redshift, or from anisotropies in the cosmic microwave background.

Elementary particle theory offers several candidates for the particles making up the cold dark matter.

A. Weakly interacting massive particles (WIMPs)

Massive particles may survive to the present if they carry some sort of conserved additive or multiplicative quantum number. If there is a non-zero

[471] There are particularly strong limitations on the number density of any sort of charged stable particles that might be left over from the big bang, which are set by mass spectroscopy, the analysis of the charged particles contained in samples of matter according to their ratio of mass to charge. The number of electrically charged exotic particles with masses in the range of 6 GeV to 330 GeV has been found to be less than 10^{-21} of the number of nucleons, by P. F. Smith and J. R. J. Bennett, Nucl. Phys. B 149, 525 (1979).
[2] P. J. E. Peebles, Astrophys. J. 263, L1 (1983); G. R. Blumenthal, S. M. Faber, J. R. Primack, and M. J. Rees, Nature 311, 517 (1984).
[3] D. Clowe et al., Astrophys. J. 648, L109 (2006) [astro-ph/0608407].

chemical potential associated with this quantum number, then of course some particles (or antiparticles) must be left over after all the antiparticles (or particles) have annihilated. But even if there are no non-zero chemical potentials for these particles, so that the initial number densities of particles and antiparticles are equal, if they can only annihilate with their antiparticles then once their number density becomes sufficiently low the collision rate eventually becomes too small to reduce the density further. [4] We will call these particles L-particles (for "left-over"), to distinguish them from the other particles into which they may annihilate, which we will assume are all approximately in thermal and chemical equilibrium during the period of annihilation. The annihilation rate per particle of the L particles and antiparticles is $n\langle\sigma v\rangle$, where n is their number density, and $\langle\sigma v\rangle$ is the average value of the product of annihilation cross section and relative velocity. The rate of decrease in the number of L particles in a co-moving volume a^3 is then $na^3 \times n\langle\sigma v\rangle$. There is also an n-independent rate of creation of these particle-antiparticle pairs from the thermal background. Since this must balance the annihilation rate when everything is in equilibrium, in general the creation rate per volume a^3 must equal $n_{\rm eq}^2\, a^3\langle\sigma v\rangle$, where $n_{\rm eq}$ is the number density of L particles and of antiparticles in equilibrium. The number na^3 of L particles and of antiparticles in a co-moving volume a^3 is therefore governed by a Boltzmann equation

$$\frac{d\,(na^3)}{dt} = -\left(n^2 - n_{\rm eq}^2\right) a^3\langle\sigma v\rangle. \tag{3.4.1}$$

For very high temperatures with $k_{\mathcal{B}}T \gg m_L$ the equilibrium density $n_{\rm eq}$ varies as T^3, and T varies as $1/a$, so Eq. (3.4.1) has a solution $n = n_{\rm eq}$. Eventually, with the decrease in temperature below the L-particle mass, the equilibrium density drops so low that the creation term in Eq. (3.4.1) becomes negligible, and we have

$$\frac{d\,(na^3)}{dt} = -n^2a^3\langle\sigma v\rangle. \tag{3.4.2}$$

The solution of Eq. (3.4.2) is

$$\frac{1}{n(t)a^3(t)} = \text{ constant } + \int \frac{\langle\sigma v\rangle dt}{a^3(t)}$$

or, in other words,

$$n(t)a^3(t) = \frac{n\,(t_1)\,a^3\,(t_1)}{1 + n\,(t_1)\,a^3\,(t_1)\int_{t_1}^{t}\langle\sigma v\rangle a^{-3}\,(t')\,dt'}$$

where t_1 is any convenient time chosen late enough so that the creation term in Eq. (3.4.1) may be neglected for $t' > t_1$.

The important point here is that the integral in the denominator converges for $t \to \infty$. The denominator $a^3(t)$ increases like $t^{3/2}$ when the energy density is dominated by relativistic particles, and even faster later, when it is dominated by non-relativistic particles and/or vacuum energy. Also, if annihilation is possible from states of zero orbital angular momentum then σv approaches a constant for low energies, so its thermal average $\langle\sigma v\rangle$ approaches a constant for low temperatures, and hence for late times. The contribution of states of higher orbital angular momentum decreases with decreasing temperature, so if s wave annihilation is forbidden by selection rules the integral converges even faster. Because the integral converges, the particle number in a co-moving volume a^3 approaches a finite limit:

[474] B. W. Lee and S. Weinberg, Phys. Rev. Lett. 39, 165 (1977); D. D. Dicus, E. W. Kolb, and V. L. Teplitz, Phys. Rev. Lett. 39, 168 (1977); E. W. Kolb and K. A. Olive, Phys. Rev. D 33, 1202 (1986).

$$n(t)a^3(t) \to \frac{n\left(t_1\right)a^3\left(t_1\right)}{1+n\left(t_1\right)a^3\left(t_1\right)\int_{t_1}^{\infty}\langle\sigma v\rangle a^{-3}\left(t'\right)dt'} \tag{3.4.3}$$

Let us assume that the annihilation of L particles and antiparticles took place during a time when the density of the universe was dominated by relativistic particles, so that $a \propto 1/T$, and the time is given by Eq. (3.1.14):

$$dt = -2\sqrt{\frac{3}{16\pi G\mathcal{N}a_{\mathcal{B}}}}\frac{dT}{T^3}$$

or, using the formula $a_{\mathcal{B}} = \pi^2 k_{\mathcal{B}}^4/15$ with $\hbar = c = 1$,

$$dt = -\sqrt{\frac{45}{4\pi^3 G\mathcal{N}}}m_L^{-2}\frac{dx}{x^3} \tag{3.4.4}$$

where $x \equiv k_{\mathcal{B}}T/m_L$. Eq. (3.4.1) therefore takes the form

$$\frac{du(x)}{dx} = B\left[u^2(x) - u_{\rm eq}^2(x)\right] \tag{3.4.5}$$

where $u(x)$ is the dimensionless quantity of interest

$$u \equiv n/\left(k_{\mathcal{B}}T\right)^3 \tag{3.4.6}$$

$u_{\rm eq}\ (k_{\mathcal{B}}T/m_L)$ is its equilibrium value, and B is the dimensionless parameter

$$B = \sqrt{\frac{45}{4\pi^3 G\mathcal{N}}}m_L\langle\sigma v\rangle \tag{3.4.7}$$

We see that the left-over value of $n/\left(k_{\mathcal{B}}T\right)^3$ depends only on B, and on the spin of the L particles, which we need to know to give a formula for $u_{\rm eq}\left(x\right)$:

$$u_{\rm eq}(x) = \frac{2s_L+1}{(2\pi)^3}\int_0^{\infty}\frac{4\pi y^2 dy}{\exp\sqrt{x^{-2}+y^2}\pm 1} \tag{3.4.8}$$

where $y \equiv p/k_{\mathcal{B}}T$, and as usual the sign is $+1$ for fermions and -1 for bosons.

For instance, for $k_{\mathcal{B}}T \ll m_L$ the heavy particles are non-relativistic, and the mean value of the low-energy annihilation cross section times velocity is a constant,

$$\langle\sigma v\rangle = G_{\rm wk}^2 m_L^2\mathcal{F}/2\pi \tag{3.4.9}$$

where $G_{\rm wk} = 1.1664\times 10^{-5}{\rm GeV}^{-2}$ is the weak coupling constant, and $\mathcal{F}$ is a fudge factor to take account of the number of annihilation channels and the details of the interaction responsible for the annihilation. This gives

$$B = 1.59\times 10^8\left(m_L[{\rm GeV}]\right)^3\mathcal{F}\mathcal{N}^{-1/2} \tag{3.4.10}$$

The solution of Eq. (3.4.5) for various values of B and $s_L = 1/2$ is shown in Figure 3.2. We see that $u(x)$ drops steeply from a constant B-independent value for $x > 1$ to a constant B-dependent value for $x < 0.01$.

For m_L in the GeV range B is quite large, and for such values of B (and $s_L = 1/2$) the asymptotic value of u is well approximated by [4]

$$u(0) \simeq 6.1B^{-0.95} \tag{3.4.11}$$

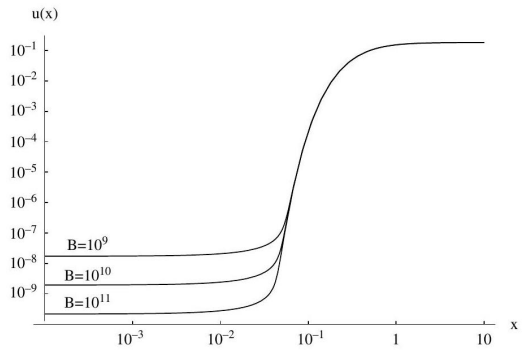

Figure 3.2: The function $u(x) \equiv n /\left(k_{\mathcal{B}} T\right)^{3}$ vs $x \equiv k_{\mathcal{B}}T/m_L$, for a dark matter particle of spin 1/2 and mass m_L, with various values of the parameter B defined by Eq. (3.4.7).

(A value $u(0) \propto B^{-1}$ is what we would expect if the second term in the denominator in Eq. (3.4.3) were much greater than unity.) The present mass density of these heavy particles and antiparticles is then (recalling that electron-positron annihilation increases the photon temperature by a factor $(11/4)^{1/3}$)

$$\begin{aligned}\rho_L &= 2m_L u(0)(4/11)\left(k_{\mathcal{B}}T_{\gamma 0}\right)^3 \\ &= \left(2.15\times 10^{-28}\ \mathrm{g/cm^3}\right)\left(m_L(\mathrm{GeV})\right)^{-1.85}\left(\mathcal{F}/\sqrt{\mathcal{N}}\right)^{-0.95}\end{aligned} \tag{3.4.12}$$

or in other words

$$\Omega_L \equiv 8\pi G\rho_L/3H_0^2 = 11.5h^{-2}\left(m_L(\mathrm{GeV})\right)^{-1.85}\left(\mathcal{F}/\sqrt{\mathcal{N}}\right)^{-0.95} \tag{3.4.13}$$

Note that Ω_L is a decreasing function of m_L, because heavy L particles annihilate more effectively than light ones. If we assume that the left-over heavy particles make up most of the cosmic mass density, then $\Omega_M \simeq \Omega_L$, and so

$$m_L(\mathcal{F}/\sqrt{\mathcal{N}})^{0.51} \simeq 3.7\left(\Omega_M h^2\right)^{-.54}\,\mathrm{GeV} \tag{3.4.14}$$

which is 10 GeV for $\Omega_M h^2 = 0.15$. Otherwise this provides a lower bound on the mass of these particles.

Incidentally, similar arguments apply to the annihilation of nucleons and antinucleons, if the universe has zero net baryon number. The difference here of course is that instead of $\langle\sigma v\rangle$ being of order $G_F^2 m_L^2$, it is roughly of order m_π^{-2}. We can thus estimate the density of left-over baryon-antibaryon pairs by taking $m_L = m_N, \mathcal{N} \approx 10$, and replacing $\mathcal{F}$ in Eq. (3.4.13) with $2\pi m_\pi^{-2}/G_F^2 m_N^2 = 2.7\times 10^{12}$, so that Eq. (3.4.13) would give a baryonantibaryon density parameter $\Omega_{B+\bar{B}}h^2 \approx 6\times 10^{-11}$. This is much less than the present observed density parameter of baryons, ruling out the possibility that the baryons around us are just those that missed being annihilated in an initially baryon-antibaryon symmetric universe, and then somehow became segregated from the antibaryons.

Returning to the cold dark matter, originally it was thought that the L particles might be heavy neutrinos. They could not be any of the three known neutrino types, which as discussed at the end of Section 3.1 have masses at most of the order of 1 eV , but there could be a fourth generation of very heavy leptons that have negligible mixing with the known leptons. The mass of a new heavy neutrino would have to be greater than $m_Z/2 = 45$ GeV , to block the decay of the Z^0 into a heavy neutrino and antineutrino, which if it occurred would destroy the present excellent agreement between theory and experiment for the total decay rate of the Z^0 particle.

If the
L particles were heavy neutrinos, then the fudge factor $\mathcal{F}$ in Eq. (3.4.9) would be of the order of the number of types of particles into which the L particles might annihilate. If we assume very roughly that $\mathcal{F} \approx \mathcal{N} \approx 100$, then Eq. (3.4.13) gives $\Omega_L h^2 \leq 10^{-3}$. So it does not seem that the cold dark matter could consist of a new heavy neutrino.

The most plausible candidate for the L particle is one of the new particles required by supersymmetry. [5] In many supersymmetric theories there is a multiplicatively conserved quantum number R, which takes the value $+1$ for all the known particles of the Standard Model, and -1 for their supersymmetric partners. (Multiplicative conservation means that the product of the Rs for all the particles in the final state of any reaction is the same as for the initial state.) Among other things, this conservation law tells us that the lightest particle with $R = -1$ (which is often called the LSP, for "lightest supersymmetric particle") is stable, although two of these particles could annihilate into ordinary particles with $R = +1$. To judge which is the lightest particle with $R = -1$, it is necessary to distinguish between two possible pictures of supersymmetry breaking. [6] In both pictures supersymmetry is spontaneously broken by non-perturbative effects in some hidden sector of particles with a large typical mass M_S, which interact through some strong force that is not felt by the known particles of the Standard Model or their superpartners. The supersymmetry breaking in the hidden sector also gives the gravitino (the superpartner of the graviton with spin 3/2) a mass $m_g \approx \sqrt{G} M_S^2$.

In one picture of supersymmetry breaking, the breakdown of supersymmetry is communicated to the particles of the Standard Model and their superpartners by the electroweak and ordinary strong forces of the Standard Model. In this case M_S would have to be of the order of 100 GeV to 100 TeV , and the gravitino mass would be at most of order 1 eV . The lightest particle with $R = -1$ would be the gravitino, which would be too light to furnish the cold dark matter. Even if gravitinos were once in equilibrium with other particles, and did not annihilate or decay, by the same arguments as in Section 3.1 their number density now would be less than the number density of photons by a factor of order $2/\mathcal{N}$, where $\mathcal{N}$ is the effective number of relativistic particle states at the time that gravitinos went out of thermal equilibrium. Photons with typical energy $k_{\mathcal{B}} T_{\gamma 0}$ have an energy density parameter given by Eq. (2.1.8) as $\Omega_\gamma h^2 = 2.47 \times 10^{-5}$, so in order for gravitinos to furnish cold dark matter with $\Omega_M h^2 \simeq 0.15$, the mass of the gravitino would have to be of order

$0.15 \mathcal{N} k_{\mathcal{B}} T_\gamma 0 / 2 \Omega_\gamma h^2$, which for $\mathcal{N} \approx 100$ is roughly 70eV.[7] Thus in this picture of supersymmetry breaking, gravitinos are not likely to be the cold dark matter, though this is not absolutely ruled out. The next-to-lightest particles with $R = -1$ would all presumably decay over billions of years into gravitinos and ordinary particles, so they could not furnish the cold dark matter either. (The rate of decay into relativistic gravitinos with helicity $\pm 3/2$ would be suppressed by a factor G, but particles with $R = -1$ could decay into gravitinos with helicity $\pm 1/2$ with the decay rate suppressed only by a factor M_S^{-2} and by some powers of the gauge couplings of the Standard Model.)

In the other picture, supersymmetry breaking is mediated by the gravitational field and its superpartners, and because these interactions are very weak M_S must be correspondingly large, of order 10^{11} to 10^{13}GeV. The gravitino mass would be of the same order of magnitude as the masses of the superpartners of the known particles of the Standard Model, so it might or might not be the lightest particle with $R = -1$.

If the lightest particle with $R = -1$ is not a gravitino, then it could be either a sneutrino, the spin 0 superpartner of the neutrino, or a neutralino, the spin 1/2 superpartner of some mixture of the neutral gauge and scalar bosons of the Standard Model. [8] Whichever of these is the

[475] This and other possibilities are discussed in a comprehensive review by G. Bertone, D. Hooper, and J. Silk, Phys. Rep. 405, 279 (2005) [hep-ph/0404175].
[6] See QTF, Vol. III, Sec. 28.3.

lightest, the decay process will involve the exchange of a particle with $R = -1$, having a mass $\tilde{M}$ that is expected to be of the order of a TeV or so. Hence its annihilation amplitude (aside from factors of 2 and π) will be of order $g^2/\tilde{M}^2$, where g is a typical electroweak coupling. This is smaller than the weak coupling constant $G_{\rm wk}$ by a factor of order $m_W^2/\tilde{M}^2$, so the fudge factor $\mathcal{F}$ in the annihilation rate constant (3.4.9) will be of order $m_W^4\mathcal{N}_A/\tilde{M}^4 \approx 10^{-4}\mathcal{N}_A$, where $\mathcal{N}_A$ is the number of annihilation channels. Taking $\mathcal{N}_A/\sqrt{\mathcal{N}} \approx 1$, Eq. (3.4.14) tells us that to furnish cold dark matter with $\Omega_M h^2 \simeq 0.15$, the lightest particle with $R = -1$ (if not the gravitino) would have to have a mass of order 1 TeV . This is similar to estimates of the masses of the superpartners of the particles of the Standard Model in typical supersymmetric models, a circumstance that greatly encourages the hope that the particles of dark matter will be found to be created in experiments at high energy accelerators.

Cosmological considerations rule out the possibility that the lightest particle with $R = -1$ in this picture of supersymmetry breaking is the gravitino. Unlike the superpartners of the particles of the Standard Model, the

gravitino has a two-body annihilation amplitude proportional to two factors [9] of the gravitational coupling constant $\sqrt{G}$, so the annihilation rate is proportional to G^2, and is therefore much too small for annihilation to play any significant role in reducing the number density of gravitinos. If, because of particle annihilations after gravitino decoupling, the number density of gravitinos were now, say, 1% of the number density of photons, then, as we have seen, in order for their mass density now not to exceed cosmological bounds their mass would have to be less than roughly 100 eV . This is quite inconsistent with the gravitino masses expected in theories of gravity mediated supersymmetry breaking. But if the gravitinos are not the lightest particles with $R = -1$ then they can decay, reducing their present mass density to acceptable values even if their masses are quite high. [10] The coupling of the gravitino to other fields is proportional to $\sqrt{G}$, so on dimensional grounds the decay rate Γ_g of a gravitino at rest is roughly of the order of Gm_g^3. This is to be compared with the rate of expansion of the universe, which at temperature T is of order $\sqrt{G\left(k_{\mathcal{B}}T\right)^4}$. (We are here ignoring factors of order 10-100, including those involving non-gravitational coupling constants and the number of particle species.) When the cosmic temperature drops to the value $k_{\mathcal{B}}T \approx m_g$ at which gravitinos become non-relativistic, the ratio of their decay rate to the expansion rate is of order $\sqrt{G}m_g = m_g/m_{\rm Planck} \ll 1$, so gravitino decay becomes significant only after this time, when the gravitinos are highly non-relativistic. As we have seen, their number density will be of order $\left(k_{\mathcal{B}}T\right)^3$, so their energy density will then be of order $m_g\left(k_{\mathcal{B}}T\right)^3$, which is greater than the energy density of order $\left(k_{\mathcal{B}}T\right)^4$ of the photons and other relativistic particles in thermal equilibrium at temperature T, and therefore makes the dominant contribution to the cosmic gravitational field that governs the rate of expansion of the universe. The expansion rate under these conditions is therefore of order $\sqrt{Gm_g\left(k_{\mathcal{B}}T\right)^3}$, and gravitino decay becomes significant when this equals the gravitino decay rate of order Gm_g^3, and therefore at a temperature

$$k_{\mathcal{B}}T_g \approx G^{1/3}m_g^{5/3}$$

After they decay, their energy must go into the energy of photons and other relativistic particles, so the temperature T_g' after decay is related to the temperature T_g calculated above by the energy conservation condition

[477] H. Pagels and J. R. Primack, Phys. Rev. Lett. 48, 223 (1982) first remarked that in order for the gravitino not to give $\Omega_M \gg 1$, its mass would have to be less than about 1 keV .

[8] S. Weinberg, Phys. Rev. Lett. 50, 387 (1983).

[479] This does not include a factor of $\sqrt{G}$ in the gravitino mass, because this factor is multiplied by the scale of supersymmetry breaking, which for gravitationally mediated supersymmetry breaking is very large, giving a gravitino mass that is comparable to the mass of other supersymmetric particles.

[10] S. Weinberg, Phys. Rev. Lett. 48, 223 (1982).

$m_g T_g^3 \approx T_g'^4$, and hence

$$k_{\mathcal{B}} T_g' \approx G^{1/4} m_g^{3/2}$$

In particular, since $k_{\mathcal{B}} T_g \ll m_g$, we have $T_g' \gg T_g$. If T_g were less than the temperature $T_n \simeq 0.1$MeV at which cosmological nucleosynthesis can occur, then gravitinos would still be abundant before nucleosynthesis, giving a higher energy density and hence a faster expansion, so that there would be less time for free neutrons to decay before being incorporated into complex nuclei, and hence more helium would be produced when nucleosynthesis occurs. Also, the ratio of the photon and baryon densities would have been subsequently increased by gravitino decay, so this ratio at the time of nucleosynthesis would have been considerably less than is usually estimated from the present cosmic microwave background temperature, and so nuclear reactions would have incorporated neutrons more completely into helium, and less deuterium would be left today. The present agreement between theory and observation for the cosmic helium and deuterium abundances would thus be destroyed. This problem is avoided if $T_g > 0.1$MeV, but it can also be avoided under the much weaker condition that $T_g' > 0.4$MeV, because then after the gravitinos decay the temperature would have been high enough to break up the excess helium and give cosmological nucleosynthesis a fresh start as the universe recools. This condition requires that $m_g > 10$TeV. This limit on m_g corresponds to a supersymmetry breaking scale $M_S > 10^{11}$GeV for $m_g \approx \sqrt{G} M_S^2$.

It may be possible to detect cosmic WIMPs through observation of the recoil of atomic nuclei from which they scatter elastically, [11] as for instance the scattering of heavy neutrinos through the neutral current weak interaction. [12] This is being pursued by a number of collaborations: DAMA, [13] CRESST, [14] EDELWEISS, [15] UK Dark Matter, [16] CDMS, [17] and WARP. [18] Assuming that WIMPs are more or less at rest in the halo of our galaxy, the motion of the solar system through the halo produces a WIMP "wind" with

a speed v_w of about 220 km/s. A nucleus of mass Am_N when struck with a WIMP of mass $m_w \gg Am_N$ traveling at this velocity will recoil with a typical velocity of order v_w, and hence a kinetic energy of order $Am_N v_w^2/2 \approx 100A$ eV . These recoils can be detected by observing the ionization of atoms struck by the recoiling nucleus, or by detecting light emitted by these atoms, or by detecting vibrations in the crystal lattice of the detector. The mass density ρ_h in the halo of our galaxy near earth is estimated from observations of stellar motions to be about 0.3GeV/cm^3, giving a number density for WIMP mass m_w of ρ_h/m_w, from which the elastic scattering rate can be calculated for any assumed values of the WIMP mass and the scattering cross section. Failing to observe nuclear recoil events then excludes some region of the m_w-cross-section plane.

The greatest problem in these experiments is distinguishing true WIMP events from background, caused by natural radioactivity and cosmic rays. The best hope for distinguishing events from background is to exploit the motion of the earth around the sun. [19] This orbital motion adds about 15 km/s to the speed of the WIMP wind in summer, and subtracts an

equal amount in winter (though this depends on the halo model), so one may expect a 7% seasonal modulation of true WIMP events. The DAMA collaboration reported just such a modulation, but almost all of the region in the m_w-cross-section plane that would account for this observation was subsequently apparently excluded (using a different detection scheme) by the CDMS collaboration. So far, experiments set an upper bound on the effective cross section of about 10^{-42} to 10^{-43} cm^2 for $m_w > 50$GeV, and much larger for $m_w < 50$GeV, the precise bound depending on assumptions about the distribution of WIMPs in the galactic halo. [20] (For comparison, the effective cross section for the low energy scattering of the neutralinos of supersymmetric theories on nucleons is expected to be less than about 10^{-41} cm^2.)

There is also a possibility of an indirect detection of WIMPs, through observation of gamma rays or other particles produced when pairs of WIMPs annihilate in regions of high WIMP concentration. [21] Gamma rays do not penetrate the earth's atmosphere, so they have to be detected either through the observation of showers of charged particles produced in the atmosphere, as for instance by the Cerenkov radiation associated with these particles, or by gamma ray telescopes carried by balloons or by satellites in orbit above the earth's atmosphere. If WIMP-WIMP annihilation produces

just a pair of gamma rays, then each will carry a unique energy equal to the WIMP mass, giving a very clear WIMP signal. So far, there has been no sign of such a monochromatic gamma ray. Of course the annihilation may produce other particles along with gamma rays, or particles whose decay then produces gamma rays, but in either case this would yield a continuum of gamma ray energies, which would be much harder to identify as coming from WIMP annihilation. The Cangaroo-II [22] and HESS [23] atmospheric Cerenkov detector collaborations have both reported continuum sources of gamma rays coming from near the center of our galaxy, but with very different spectra, which can be interpreted as coming from annihilation of WIMPs with a mass of about 1 TeV or 19 TeV , respectively.

For decades there has been evidence of monochromatic gamma rays coming from the galactic center, but at the energy of 511 keV expected from electron-positron annihilation, rather than WIMP-WIMP annihilation. In 1970 a balloon-borne pair of gamma ray detectors found evidence of a gamma ray line around 500 keV coming more-or-less from the direction of the galactic center. [24] The evidence for this has since become much stronger through observations made by the INTEGRAL (International GammaRay Astrophysics Laboratory) satellite, [25] which found a gamma ray line coming from the galactic center with an energy within about 3 keV of 511 keV . It is possible that this is due to the decay of a relatively light WIMP into electron-positron pairs, with the positrons then losing energy by ionization, after which they annihilate with ambient electrons. [26]

There is also a report of an excess of positrons in cosmic rays found by the HEAT balloon experiment, [27] which might or might not come from WIMP annihilation. Very recently it has been suggested that an excess of microwave emission from the direction of the center of our galaxy observed by the WMAP satellite may come from synchrotron emission by relativistic electrons and positrons produced in WIMP annihilation. [28]

It is too early to reach any definite conclusions from any of these experiments about WIMPs as candidates for the particles of dark matter.

B. Axions and axinos

Axions [29] are light neutral spinless particles that are made necessary [30] by the spontaneous breakdown of a symmetry that first appeared in a model [31] that was proposed to explain why non-perturbative effects of the strong interactions do not violate CP invariance. For our present purposes, all we need to know is that the dominant part of the effective action (with $\hbar = c = 1$) that describes the axion field φ takes the form (B.44) with potential $V(\varphi) = m_a^2\varphi^2/2$:

$$I[\varphi] = \int d^4x \sqrt{-\det g}\left(-\frac{1}{2}g^{\mu\nu}\partial_\mu\varphi\partial_\nu\varphi - \frac{1}{2}m_a^2\varphi^2\right) \tag{3.4.15}$$

The axion mass m_a is a complicated function of temperature, but for temperatures well below 10^{12} K it takes a well-known constant value, related to the energy scale M at which the Peccei-Quinn symmetry is broken by

$$m_{a0} = \frac{F_\pi m_\pi}{M}\frac{\sqrt{m_d m_u}}{m_d + m_u} \simeq \frac{13\text{MeV}}{M[\text{GeV}]} \tag{3.4.16}$$

(Here $F_\pi = 184$MeV is the pion decay amplitude, and m_d and m_u are the down and up quark masses appearing in the Lagrangian of quantum chromodynamics, for which $m_d/m_u \simeq 1.85$.) In the original Peccei-Quinn model, [31] M was of the order of the electroweak symmetry breaking scale, $M \approx 100$GeV, but it was soon realized that this is experimentally ruled out. Axion fields interact with ordinary matter through factors $\partial_\mu\varphi/M$, so with $M \geq 100$GeV axions interact so weakly that they emerge without attenuation from reactor cores or stellar interiors. The production rate of axions is proportional to $1/M^2$, so the failure to observe effects of axion emission from stars or nuclear reactors sets a lower bound on M, and hence an upper bound on m_a. In particular, limits on the rate of cooling of red giant stars by axion emission give [32] $M > 10^7$GeV, while observations of the supernova SN1987A indicate [33] that $M > 10^{10}$GeV. A generalization of the Peccei-Quinn model was then proposed, [34] in which M is an arbitrary parameter. As we shall see, cosmological considerations provide an upper bound [35] on M, which together with the above lower bounds leaves a narrow window of allowed values.

The cosmological axion field is supposed to be spatially homogeneous. [36] In a Robertson-Walker metric, the energy density and pressure are given by Eq. (B.66) and (B.67) as

$$\rho_a = \frac{1}{2}\dot{\varphi}^2 + \frac{1}{2}m_a^2\varphi^2, \quad p_a = \frac{1}{2}\dot{\varphi}^2 - \frac{1}{2}m_a^2\varphi^2, \tag{3.4.17}$$

so the equation (1.1.32) of energy conservation (or the Euler-Lagrange equation derived directly from the action (3.4.15)) gives the field equation

$$\ddot{\varphi} + 3H(t)\dot{\varphi} + m_a^2(t)\varphi = 0 \tag{3.4.18}$$

At early times $H(t) \gg m_a(t)$, so we can ignore $m_a(t)$, and Eq. (3.4.17) has solutions $\varphi =$ constant, and $\varphi \propto 1/a^3$. Rejecting the singular solution, we see that at early times $\varphi(t)$ is frozen at a value φ_0, which (absent fine tuning) would be expected to be of order M. Later, when $H(t)$ dropped below $m_a(t), \varphi(t)$ began a rapid oscillation, so that in this case Eq. (3.4.18) can be solved using the WKB approximation, which gives

$$\varphi(t) \to \varphi_1 \left(\frac{a\,(t_1)}{a(t)}\right)^{3/2} \cos\left(\int_0^t m_a(t)dt + \alpha\right) \tag{3.4.19}$$

where t_1 is the time at which $H\,(t_1) = m_{a0}, \varphi_1$ is a constant of order $\varphi_0 \approx M$, and α is a phase that cannot be determined without a more detailed study, but which fortunately we do not need to know. (For instance, if $m_a(t)$ has the constant value m_{a0} and the universe is radiation-dominated in the era of interest, then $\varphi_1 = 2^{3/2}\pi^{-1/2}\Gamma(5/4)\varphi_0 = 1.446\varphi_0$, and $\alpha = -3\pi/8$.) Since $a(t)$ for $m_a \gg H$ was varying much more slowly than the phase of the cosine, the energy density at late times is given by Eq. (3.4.17) as

$$\rho_a(t) \to \frac{1}{2}m_a^2\varphi_1^2 \left(\frac{a\,(t_1)}{a(t)}\right)^3 \tag{3.4.20}$$

In order to project this forward to the present, we note that if the universe was radiation-dominated at time t_1, with $\mathcal{N}_1$ the effective number of types of particles with masses much less than $k_{\mathcal{B}}T\,(t_1)$ (counting each spin state

of particles and antiparticles separately, and including an extra factor 7/8 for fermions), then the photon temperature at present is

$$T_{\gamma 0} = \mathcal{N}_1^{1/3} T\,(t_1)\, a\,(t_1)\,/a\,(t_0)$$

the factor $\mathcal{N}_1^{1/3}$ being inserted to take account of the heating of photons by the annihilation of particles and antiparticles between times t_1 and t_0. The temperature $T\,(t_1)$ may be determined by noting that the expansion rate at time t_1 is

$$m_a \equiv H\,(t_1) = \sqrt{\frac{8\pi G\mathcal{N}_1 a_{\mathcal{B}} T^4/2}{3}} = \sqrt{\frac{4\pi^3 G\mathcal{N}_1}{45}}\,(k_{\mathcal{B}}T_1)^2\,.$$

Using these results in Eq. (3.4.20) then gives the present axion energy density

$$\rho_a\,(t_0) \simeq \frac{1}{2}m_a^{1/2}\mathcal{N}_1^{-1/4}\varphi_0^2 \left(\frac{4\pi^3 G}{45}\right)^{3/4} (k_{\mathcal{B}}T_{\gamma_0})^3 \tag{3.4.21}$$

We expect φ_0 to be of the same order of magnitude as the symmetry breaking scale M, so using Eq. (3.4.16) and ignoring all factors of order unity,

$$\rho_a \approx \frac{F_\pi^2 m_\pi^2 G^{3/4}\,(k_{\mathcal{B}}T_{\gamma 0})^3}{m_a^{3/2}} \tag{3.4.22}$$

Equivalently, the axion density provides a fraction Ω_a of the critical density given by

[4735] J. Preskill, M. B. Wise, and F. Wilczek, Phys. Lett. 120B, 127 (1983); L. F. Abbott and P. Sikivie, Phys. Lett. 120B, 127 (1983); M. Dine and W. Fischler, Phys. Lett. 120B, 137 (1983). For reviews, see J. E. Kim, Phys. Rep. 150, 1 (1987); M. S. Turner, Phys. Rep. 197, 68 (1990).

[36] Components with non-zero wave number are doubtless present, but their energy density decays more rapidly than the energy density of the spatially homogeneous coherent field $\varphi(t)$.

$$\Omega_a h^2 \approx \left(m_a/10^{-5}\text{eV}\right)^{-3/2} \tag{3.4.23}$$

Because the axion field is spatially homogeneous, for $m_a \gg H$ its energy takes the form of massive particles that are essentially at rest. If axions furnish the whole of the cold dark matter, then $m_a \approx 10^{-5}$eV, corresponding to $M \approx 10^{12}$GeV. Otherwise, these numbers provide a lower bound on m_a and an upper bound on M.

Axions are much too weakly interacting to be detected in the sort of nuclear recoils looked for in searches for WIMPs. One possibility is to observe the conversion of cosmic axions into photons in intense magnetic fields. [37] This approach has already been used to put a limit on the parameters of axions that would be produced by the sun. [38] The axion field $\varphi(x)$ would be expected to have an interaction with the electromagnetic field of

the form $g_{a\gamma}\varphi\mathbf{E}\cdot\mathbf{B}$, with $g_{a\gamma}$ of order $\alpha/2\pi M$, so that photons in the sun could convert into axions in the presence of the strong electric fields around atomic nuclei, and these solar axions would then convert back into photons in intense laboratory magnetic fields. No such photons were seen, indicating that for axions with mass less than 0.02eV, $|g_{a\gamma}| < 1.16 \times 10^{-10}\text{GeV}^{-1}$, a much more restrictive limit than provided by earlier experiments of this sort. [39] In a different sort of search, [40] the Axion Dark Matter Experiment, a microwave cavity was used to search for axions in our galactic halo, and put upper limits on the axion density in the narrow mass range (1.98 to 2.17) $\times 10^{-6}$eV. None of these experiments are in conflict with axion models of dark matter, but a plausible improvement in the sensitivity of this sort of experiment may rule out these models, or perhaps find axions.

In supersymmetric theories, the axion would be partnered with a spin one-half particle, the axino, which would probably be the lightest particle with $R = -1$, and hence stable. Axinos could be produced non-thermally, [41] through the decay of other particles with $R = -1$, or thermally. [42] It appears that the axino provides another plausible candidate for the particle of cold dark matter.

10.4 Inflation

We can have some confidence in the story of the evolution of the universe from the time of electron-positron annihilation to the present, as told in the previous three chapters. About earlier times, so far we can only speculate. In the past quarter century these speculations have centered on the idea that before the period of radiation domination, during which the RobertsonWalker scale factor $a(t)$ was growing as $\sqrt{t}$, there was an earlier period of inflation, when the energy density of the universe was dominated by a slowly varying vacuum energy, and $a(t)$ grew more-or-less exponentially. The possibility of an early exponential expansion had been noticed by several authors, [1] but at first it attracted little attention. It was Alan Guth [2] who incited interest in the possibility of inflation by noting what it was good for.

Guth noticed that, in a model of grand unification he was considering (with Henry Tye), scalar fields could get caught in a local minimum of the potential, which in his work corresponded to a state with an unbroken grand unified symmetry. The energy of empty space would then have remained constant for a while as the universe expanded, which would produce

a constant rate of expansion, meaning that $a(t)$ would have grown exponentially. Eventually this inflation would be stopped by quantum-mechanical barrier penetration, after which the scalar field would start rolling down the potential toward a global minimum, corresponding to the present universe. In itself this would have been a result of no great immediate importance. But then it occurred to Guth that the existence of an era of inflation would solve one of the outstanding problems of cosmology, mentioned here in Section 1.5. It is known as the "flatness problem:" Why was the curvature of space was so small in the early universe? Guth soon also discovered that inflation would solve other cosmological puzzles, some of which he had not even realized were puzzles. These problems along with the flatness problem will be discussed in Section 4.1.

As Guth and others soon realized, his version of inflation had a fatal problem, to be described in Section 4.2. Guth's "old inflation" was soon replaced with a "new inflation" model, due to Andrei Linde [3] and Andreas Albrecht and Paul Steinhardt. [4] The essential element introduced by

theories of new inflation was a nearly exponential expansion during the slow roll of one or more scalar fields down a potential hill, which is the main subject of Section 4.2. This provided a basis for "chaotic inflation" and "eternal inflation" and other variants, some of which are briefly described in Section 4.3.

So far, the details of inflation are unknown, and the whole idea of inflation remains a speculation, though one that is increasingly plausible. Aside from the classic problems that inflation solved at the beginning, it has had one significant experimental success: a prediction of some of the properties of the fluctuations in the cosmic microwave background and large scale structure. We will come to this in Chapter 10, after we take up the evolution of fluctuations in the early universe in Chapters 5 and 6 and the observation of these fluctuations in Chapters 7 and 8 and Section 9.5.

10.4.1 4.1 Three puzzles

In this section we will outline three classic cosmological problems, and work out the extent of the inflation required to solve each of them. For this purpose we will here simply assume that the universe went through an early period of exponential expansion, without worrying yet about how this came about.

A. Flatness

As we saw in Section 1.6 and 1.8, the observed Type Ia supernova redshiftdistance relation and measurements of the ages of the oldest stars are consistent with a vanishing spatial curvature parameter Ω_K, though a nonvanishing curvature can be accommodated by changing Ω_M. Including data from the cosmic microwave background temperature fluctuations, discussed in Section 7.2, favors $\Omega_K = 0$. Although there is still room for a small non-zero Ω_K, it seems quite safe to conclude from these observations that $|\Omega_K| < 1$. But Ω_K is just the present value of the dimensionless time dependent curvature parameter $-K/a^2H^2 = -K/\dot{a}^2$, with K constant. From the time the temperature dropped to about 10^4 K until near the present, $a(t)$ has been increasing as $t^{2/3}$, so $|K|/\dot{a}^2$ has also been increasing as $t^{2/3} \propto T^{-1}$. Thus, if $|\Omega_K| < 1$, then at 10^4 K the curvature parameter $|K|/\dot{a}^2$ could not have been greater than about 10^{-4}. Earlier,

[2] A. Guth, Phys. Rev. D 23, 347 (1981). Guth tells the story of this work in The Inflationary Universe: The Quest for a New Theory of Cosmic Origins (Helix Books/Addison Wesley, 1997).

[3] A. D. Linde, Phys. Lett. B 108, 389 (1982); 114, 431 (1982); Phys. Rev. Lett. 48, 335 (1982).

[4] A. Albrecht and P. Steinhardt, Phys. Rev. Lett. 48, 1220 (1982).

$a(t)$ was increasing as $t^{1/2}$, so $|K|/\dot{a}^2$ was increasing as $t \propto T^{-2}$. In order for $|K|/\dot{a}^2$ at 10^4 K to be no greater than about 10^{-4}, it is necessary that $|K|/\dot{a}^2$ was at most about 10^{-16} at the temperature $T \approx 10^{10}$ K of electron-positron annihilation (roughly, the beginning of the period of neutron-proton conversion that results in the observed helium abundance), and even smaller at earlier times. [5] This is not a paradox-there is no reason why the curvature should not have been very small-but it is the sort of thing physicists would like to explain if we can.

What Guth realized was that during inflation $\dot{a}/a$ would have been roughly constant, so $|K|/a^2H^2$ would have been decreasing more or less like a^{-2}. So to understand why space was so flat at the beginning of the present big bang it is not necessary to make any arbitrary assumptions; if the radiation-dominated big bang was preceded by a sufficient period of inflation, it would necessarily have started with negligible curvature.

To put this quantitatively, suppose the universe began with a period of inflation during which $a(t)$ increased by some large factor $e^{\mathcal{N}}$, followed by a period of radiation dominance lasting until the time of radiation-matter equality, followed in turn by a period of matter dominance and then a period dominated by vacuum energy. If $|K|/a^2H^2$ had a value of order unity at the beginning of inflation, then at the time t_I of the end of inflation $|K|/a^2H^2$ would have had a value $|K|/a_I^2H_I^2$ of order $e^{-2\mathcal{N}}$ (where a_I and H_I are the Robertson-Walker scale factor and expansion rate at this time), and today we will have

$$|\Omega_K| = \frac{|K|}{a_0^2H_0^2} = e^{-2\mathcal{N}}\left(\frac{a_IH_I}{a_0H_0}\right)^2, \tag{4.1.1}$$

Thus the flatness problem is avoided if the expansion during inflation has the lower bound

$$e^{\mathcal{N}} > \frac{a_IH_I}{a_0H_0}. \tag{4.1.2}$$

To evaluate this we will make the somewhat risky assumption that not much happens to the cosmic scale factor and expansion rate from the end of inflation to the beginning of the radiation-dominated era, so that

$$a_IH_I \simeq a_1H_1, \tag{4.1.3}$$

the subscript 1 denoting the beginning of the radiation-dominated era. We can express the expansion a_0/a_1 of the universe since the start of the radiation-dominated era in terms of ratios of expansion rates by noting that over the whole of the radiation and matter-dominated era, the expansion

rate was

$$H = \frac{H_{\rm EQ}}{\sqrt{2}}\sqrt{\left(\frac{a_{\rm EQ}}{a}\right)^3 + \left(\frac{a_{\rm EQ}}{a}\right)^4},$$

where $a_{\rm EQ} = a_0\Omega_R/\Omega_M$ and $H_{\rm EQ} = \sqrt{2\Omega_M}H_0\,(a_0/a_{\rm EQ})^{3/2}$ are the scale factor and expansion rate at matter-radiation equality. Setting $a = a_1 \ll a_{\rm EQ}$ gives

$$H_1 = \frac{H_{\rm EQ}}{\sqrt{2}}\left(\frac{a_{\rm EQ}}{a_1}\right)^2. \tag{4.1.4}$$

Using this relation to eliminate a_1, we can put the bound (4.1.2) in the more useful form

$$e^{\mathcal{N}} > \left(\frac{\Omega_M a_{\rm EQ}}{a_0}\right)^{1/4}\sqrt{\frac{H_1}{H_0}} = \Omega_R^{1/4}\sqrt{\frac{H_1}{H_0}} = \left(\Omega_R\frac{\rho_1}{\rho_{0,\,\rm crit}}\right)^{1/4} = \frac{[\rho_1]^{1/4}}{0.037h{\rm eV}}, \tag{4.1.5}$$

[475] R. H. Dicke and P. J. E. Peebles, in General Relativity - An Einstein Centenary Survey, eds. S. Hawking and W. Israel (Cambridge University Press, 1979).

where ρ_1 is the energy density at the beginning of the radiation-dominated era, and $\rho_{0,\,\mathrm{crit}} = [3.00 \times 10^{-3}\mathrm{eV}]^4\, h^2$ is the critical density (1.5.28).

To go further, we need some idea of the energy density at the end of inflation. The success of the theory of cosmological nucleosynthesis shows that ρ_1 cannot be less than the energy density at the time of the beginning of neutron-proton conversion, roughly $[\,1\ \mathrm{MeV}]^4$, in which case Eq. (4.1.5) with $h = 0.7$ requires that the universe expanded during inflation by at least a factor 4×10^7, or $17e$-foldings. At the other extreme, we would not expect ρ_1 to be greater than the Planck energy density $G^{-2} = [1.22 \times 10^{19}\mathrm{GeV}]^4$, in which case Eq. (4.1.5) with $h = 0.7$ would require that the expansion during inflation was at least by a factor 5×10^{29}, or $68e$-foldings. We will see some evidence in Section 10.3 that ρ_1 is of order $[2 \times 10^{16}\mathrm{GeV}]^4$, in which case $e^{\mathcal{N}}$ for $h = 0.7$ would have to be at least 8×10^{26}, so that $\mathcal{N} > 62$.

This is the least convincing of the arguments for inflation, because the small value of $|K|/\dot{a}^2$ in the past could be explained by the assumption (one that was often made before anyone heard of inflation) that space is precisely flat, so that $K = 0$ now and always. On the other hand, as we will discuss in Section 4.3, inflation opens up the interesting possibility that the universe in the large is not at all homogeneous and isotropic, and that its apparent flatness of the cosmic metric is just the result of inflation.

It would be quite a coincidence if inflation lasted for precisely the right number of e-foldings so that $|K|/\dot{a}^2$ would have decreased during inflation from an initial value of order unity just enough so that its subsequent increase during the radiation and matter-dominated eras would have
brought it back to a value of order unity now. It seems more likely that the present value $|\Omega_K|$ would be either much larger or much smaller than unity, and since observations tell us that it is not much larger than unity, inflationary theories suggest that $|\Omega_K| \ll 1$. (But this sort of reasoning would also suggest that the vacuum energy is much less than the present matter density, which we now know is not the case.)

B. Horizons

From the beginning the observed high degree of isotropy of the cosmic microwave radiation background posed a problem. Recall that the horizon size in a matter- or radiation-dominated universe is of order t, which, because $a(t)$ has increased as $t^{2/3}$ since the time of last scattering, was of order $d_H \approx H_0^{-1}\,(1+z_L)^{-3/2}$ at the time of last scattering. (See Eq. (2.6.32).) Also, according to Eq. (2.6.29), the angular diameter distance d_A to the surface of last scattering is of order $H_0^{-1}\,(1+z_L)^{-1}$, so the horizon at the time of last scattering now subtends an angle of order $d_H/d_A \approx (1+z_L)^{-1/2}$ radians, which for $z_L \simeq 1100$ is about 1.6°. Therefore in a matter- or radiation-dominated universe no physical influence could have smoothed out initial inhomogeneities and brought points at a redshift z_L that are separated by more than a few degrees to the same temperature, in contradiction with the nearly perfect isotropy of the microwave background at large angular scales observed ever since the background radiation was discovered. Inflation provides an explanation: during the inflationary era the part of the universe that we can observe would have occupied a tiny space, and there would have been plenty of time for everything in this space to be homogenized.

To work out what this means for the expansion during inflation, first recall that as discussed in Section 1.13, the proper horizon size at the time t_L of last scattering is

$$d_H\,(t_L) \equiv a\,(t_L) \int_{t_*}^{t_L} \frac{dt}{a(t)} \tag{4.1.6}$$

with t_* (possibly equal to $-\infty$) the beginning of the era of inflation. We have seen that the contribution to the integral from the radiation and matterdominated eras is much too small

to account for the isotropy of the microwave radiation background, so we will assume that the integral is dominated by an era of inflation. For definiteness, we assume that during inflation $a(t)$ increased exponentially at a rate H_I, so that

$$a(t) = a(t_*) \exp(H_I(t - t_*)) = a_I \exp(-H_I(t_I - t))$$

where t_I is again the time of the end of inflation, and $a_I = a(t_I)$. With $\mathcal{N} \equiv H_I(t_I - t_*)$ the number of e-foldings of expansion during inflation, Eq. (4.1.6) gives

$$d_H(t_L) = \frac{a(t_L)}{a_I H_I}\left[e^{\mathcal{N}} - 1\right] \tag{4.1.7}$$

In order to have any hope of solving the horizon problem, we must have $e^{\mathcal{N}} \gg 1$, so we can drop the term -1 in square brackets in Eq. (4.1.7).

To account for the observed high degree of isotropy of the cosmic microwave background at large angular scales we need $d_H(t_L) > d_A(t_L)$, where $d_A(t_L)$ is the angular-diameter distance of the surface of last scattering. According to Eq. (2.6.29),

$$d_A(t_L) \approx \frac{a(t_L)}{H_0 a_0} \tag{4.1.8}$$

The condition $d_H(t_L) > d_A(t_L)$ for the isotropy of the cosmic microwave background is then

$$e^{\mathcal{N}} > \frac{a_I H_I}{a_0 H_0}. \tag{4.1.9}$$

This is the same as the condition (4.1.2) for the solution of the flatness problem. If we again make the assumption that not much happens between the end of inflation and the beginning of the radiation-dominated era, and use Eq. (4.1.3), then to solve the horizon problem we again need $\mathcal{N} > 17$ if $\rho_1 \simeq [1\text{MeV}]^4$, $\mathcal{N} > 62$ if $\rho_1 \simeq [2 \times 10^{16}\text{GeV}]^4$, and $\mathcal{N} > 68$ if $\rho_1 \simeq G^{-2}$. We will see in Chapter 10 that whether 17 or 62 or 68e-foldings are needed to solve the horizon problem, it is only that number of e-foldings before the end of inflation that can be explored through observations of nonuniformities in the present universe.

It should be noted that the time t_L of last scattering does not enter in the bound (4.1.9) on $\mathcal{N}$, so this is also the condition that the whole sky at any redshift $z < z_{\text{EQ}}$ was within the horizon at the time that light observed now with that redshift left its source. Indeed, Eq. (4.1.9) is also the condition that the horizon size at the present should be greater than the size of the observable universe, which is roughly $1/H_0$.

C. Monopoles

In grand unified theories local symmetry under some simple symmetry group is spontaneously broken at an energy $M \approx 10^{16}$GeV to the gauge symmetry of the Standard Model under the group $SU(3) \times SU(2) \times U(1)$.

In all such cases, the scalar fields that break the symmetry can be left in twisted configurations that carry non-zero magnetic charge and that cannot be smoothed out through any continuous processes. [6] This poses a problem for some cosmological models. [7] The scalar fields before this phase transition would have necessarily been uncorrelated at distances larger than the horizon distance, the farthest distance that light could have traveled since the initial singularity. At an early time t in the standard big bang theory the horizon distance was of order $t \approx \left(G(k_{\mathcal{B}}T)^4\right)^{-1/2}$ (where $G \simeq (10^{19}\text{GeV})^{-2}$ is Newton's constant), so the number density of monopoles produced at the time that the temperature drops to $M/k_{\mathcal{B}}$ would have been of

order $t^{-3} \approx (GM^4)^{3/2}$, which is smaller than the photon density $\approx M^3$ at $T \approx M/k_{\mathcal{B}}$ by a factor of order $(GM^2)^{3/2}$. For $M \approx 10^{16}$GeV this factor is of order 10^{-9}. If monopoles did not find each other to annihilate, then this ratio would remain roughly constant to the present, but with at least 10^9 microwave background photons per nucleon today, this would give at least one monopole per nucleon, in gross disagreement with what is observed.

This potential paradox was one of the factors leading to interest in inflationary cosmological models. In such models, a period of exponential expansion that occurred before the monopoles were produced would have greatly extended the horizon, and an exponential expansion that occurred after the production of monopoles (but before photons were created in a period of reheating) would have greatly reduced the monopole to photon ratio. To be specific, the search for monopoles in iron ore, seawater, etc. shows that there are fewer than 10^{-6} per gram, or about 10^{-30} monopoles per nucleon, and hence fewer than about 10^{-39} monopoles per photon. [8] (With this abundance, even if the monopole mass were as large as 10^{19}GeV, they would make a negligible contribution to the cosmic mass density.) In order for inflation to have reduced the monopole/photon ratio by a factor 10^{-30}, it must have increased the horizon size (at some time before the reheating that creates photons) by a factor 10^{10}. That is, the horizon size $e^{\mathcal{N}}/H_1$ after inflation must be greater than the previous estimate $(GM^4)^{-1/2}$ by at least a factor 10^{10}. For $H_1 \approx (GM^4)^{1/2}$ this requires the number $\mathcal{N}$ of e-foldings to be greater than $\ln 10^{10} = 23$. Of course, another possible solution of the monopole problem is that inflation ends at a temperature below the grand unification scale M, so that there never was a time when the grand unification group was unbroken. An even simpler possibility, which does not rely on inflation, is that there may be no simple gauge group that is

spontaneously broken to the gauge group $SU(3) \times SU(2) \times U(1)$ of the Standard Model.

The most serious of the above three problems is the horizon problem. As we have seen, there are possible solutions of the flatness and monopole problems that do not rely on inflation. Also, any number of e-foldings of inflation that solves the horizon problem automatically solves not only the flatness problem, but also the monopole problem. If the radiationdominated era begins with an energy density $\rho_1 > [10^{15}\text{GeV}]^4$ then for inflation to solve the flatness and horizon problems we need at least 59 e-foldings of inflation, which is more than enough to avoid the monopole problem, while if $\rho_1 < [10^{15}\text{GeV}]^4$ GeV then in the usual picture of grand unification there would be no monopoles at all.

10.4.2 4.2 Slow-roll inflation

In Guth's original work, inflation was conceived to be due to a delayed first-order phase transition, in which a scalar field was initially trapped in a local minimum of some potential, and then leaked through the potential barrier and rolled toward a true minimum of the potential. It was soon realized [1] that this idea does not work, because of what has come to be called the graceful exit problem. The transition from the supercooled initial "false vacuum" phase to the lower energy "true vacuum" phase could not have occurred everywhere simultaneously, but here and there in small bubbles of true vacuum, which rapidly expanded into the background of false vacuum, in which the scalar field would have been still trapped in its local minimum, [2] like water droplets forming in supercooled water vapor. The trouble is that the latent heat released in the phase transition would have wound up in the bubble walls, leaving the interiors of the bubbles essentially empty, so that the only places where there would be energy that could grow into the present contents of the universe would be highly inhomogeneous and anisotropic.

[476] For a discussion, see QTF, Vol. II, Sec. 23.3.

[7] Ya. B. Zel'dovich and M. Yu. Khlopov, Phys. Lett. B 79, 239 (1978); J. Preskill, Phys. Rev. Lett. 43, 1365 (1979). For a review, see J. Preskill, Annual Rev. Nucl. Part. Science 34, 461 (1984).

[8] For a review, see Particle Data Group, Phys Lett. B 582, 1001 (2004).

At first Guth thought the bubbles in inflationary cosmologies would have merged, leading to our present more-or-less homogeneous universe, but this could not have happened; because the background false-vacuum space continued to inflate, the bubble walls would have moved too fast away from each other ever to have coalesced.

Guth's version of inflation was soon supplanted by a version due to Linde and to Albrecht and Steinhardt, known as 'new inflation. [3] Originally new inflation was formulated in a particular model of the breakdown of a grand unified symmetry, using a symmetry-breaking mechanism introduced by Coleman and E. Weinberg. [4] With this mechanism the zero-temperature potential for a scalar field φ is artificially adjusted to have zero second derivative at $\varphi = 0$. One-loop radiative corrections then give a potential equal to a known positive factor times $\varphi^4 \ln(\varphi/M)$, where M is a free constant; changing the value of M amounts to changing the φ^4 coupling constant. This potential has an unstable stationary point at $\varphi = 0$ and a minumum at $\varphi_0 = Me^{-1/4}$. At finite temperature T there is also a quadratic term in the potential, proportional to $T^2\varphi^2$, which makes the stationary point at $\varphi = 0$ into a local minimum. Again the phase transition occurs by forming bubbles, but for low temperature the potential barrier is very small, and so the scalar field in the interior of the bubble starts with φ nearly zero. The field then rolls slowly down the potential, in the manner discussed in Section 1.12, while the universe (including the bubble) undergoes an exponential expansion. Eventually the field energy is converted into ordinary particles, filling the bubble. Our observable universe is supposed to occupy a small part of one such bubble.

The consequences of the new inflationary theories turned out to depend on the slow roll of the scalar field after bubble formation, rather than the process of bubble formation itself. Indeed, the important aspects of inflation do not really require any assumptions about grand unification or the Coleman-E. Weinberg mechanism. All we need to assume is that there is a scalar field φ, known as the inflaton, which at some early time takes a value at which the potential $V(\varphi)$ is large but quite flat. The scalar field "rolls" very slowly at first down this potential, so that the Hubble constant decreases only slowly, and the universe experiences a more-or-less exponential inflation before the field changes very much.

To put this quantitatively, recall that the energy density (B.66) and pressure (B.67) of a spatially homogeneous scalar field $\varphi(t)$ with potential $V(\varphi)$ in a Robertson-Walker spacetime take the form (with $\hbar = c = 1$)

$$\rho = \frac{1}{2}\dot{\varphi}^2 + V(\varphi), \quad p = \frac{1}{2}\dot{\varphi}^2 - V(\varphi),$$

so the energy conservation equation $\dot{\rho} = -3H(\rho + p)$ takes the form:

$$\ddot{\varphi} + 3H\dot{\varphi} + V'(\varphi) = 0, \tag{4.2.1}$$

where $H \equiv \dot{a}/a$ is the time dependent expansion rate, which during the period of scalar field energy dominance is given by

$$H = \sqrt{\frac{8\pi G\rho}{3}} = \sqrt{\frac{8\pi G}{3}\left(\frac{1}{2}\dot{\varphi}^2 + V(\varphi)\right)} \tag{4.2.2}$$

[2] For a description of this process and references to the original literature on bubble formation in quantum field theory, see QTF II, Section 23.8.

[473] A. D. Linde, Phys. Lett. B 108, 389 (1982); 114, 431 (1982); Phys. Rev. Lett. 48, 335 (1982); A. Albrecht and P. Steinhardt, Phys. Rev. Lett. 48, 1220 (1982).

[4] S. Coleman and E. Weinberg, Phys. Rev. D 7, 1888 (1973).

From Eqs. (4.2.1) and (4.2.2) we can derive an extremely useful formula for $\dot{H}$. By taking the time derivative of the square of Eq. (4.2.2) and then using Eq. (4.2.1), we have

$$2H\dot{H} = \frac{8\pi G}{3}\left(\dot{\varphi}\ddot{\varphi} + V'(\varphi)\dot{\varphi}\right) = -8\pi G H\dot{\varphi}^2,$$

and therefore

$$\dot{H} = -4\pi G\dot{\varphi}^2 \tag{4.2.3}$$

Now, in order to have a nearly exponential expansion, the fractional change $|\dot{H}/H|(1/H)$ in H during an expansion time $1/H$ must be much less than unity. That is, we must have

$$|\dot{H}| \ll H^2. \tag{4.2.4}$$

With Eqs. (4.2.3) and (4.2.2), this requires that

$$\dot{\varphi}^2 \ll |V(\varphi)|. \tag{4.2.5}$$

This has the consequence that $p \simeq -\rho$, and also

$$H \simeq \sqrt{\frac{8\pi G V(\varphi)}{3}} \tag{4.2.6}$$

Usually it is also assumed that the fractional change $|\ddot{\varphi}/\dot{\varphi}|(1/H)$ in $\dot{\varphi}$ during an expansion time $1/H$ is much less than unity. That is,

$$|\ddot{\varphi}| \ll H|\dot{\varphi}|. \tag{4.2.7}$$

This has the consequence that we may drop the inertial term $\ddot{\varphi}$ in Eq. (4.2.1), which then becomes

$$\dot{\varphi} = -\frac{V'(\varphi)}{3H} = -\frac{V'(\varphi)}{\sqrt{24\pi G V(\varphi)}}. \tag{4.2.8}$$

The fractional change of the expansion rate H in an expansion time $1/H$ will then be

$$\frac{|\dot{H}|}{H^2} = \frac{1}{2}\sqrt{\frac{3}{8\pi G}}\left|\frac{V'(\varphi)\dot{\varphi}}{V^{3/2}(\varphi)}\right| = \frac{1}{16\pi G}\left(\frac{V'(\varphi)}{V(\varphi)}\right)^2, \tag{4.2.9}$$

so the exponential expansion of the universe will last for many e-foldings if

$$\left|\frac{V'(\varphi)}{V(\varphi)}\right| \ll \sqrt{16\pi G}. \tag{4.2.10}$$

According to Eq. (4.2.8), the condition on the potential for the inequality (4.2.5) to be satisfied is that

$$\left|\frac{V'(\varphi)}{V(\varphi)}\right| \ll \sqrt{24\pi G}, \tag{4.2.11}$$

which is guaranteed by the inequality (4.2.10). Also, Eq. (4.2.8) gives

$$\ddot{\varphi} = -\frac{V''(\varphi)\dot{\varphi}}{3H} + \frac{V'(\varphi)\dot{H}}{3H^2} = \frac{V''(\varphi)V'(\varphi)}{9H^2} - \frac{V'^3}{48\pi G V^2}. \tag{4.2.12}$$

The inequality (4.2.10) ensures that the absolute value of the last term on the right-hand side is much less than $|V'(\varphi)|$, so the condition for $|\ddot{\varphi}|$ to be much less than $|V'(\varphi)|$ is that $|V''(\varphi)| \ll 9H^2$, or, in other words,

$$\left|\frac{V''(\varphi)}{V(\varphi)}\right| \ll 24\pi G. \tag{4.2.13}$$

Eqs. (4.2.10) and (4.2.13) are the two "flatness" conditions needed to insure the slow roll of both φ and $\dot{\varphi}$. It is possible in principle that the second flatness condition (4.2.13) may not be satisfied for a potential that does satisfy the first flatness condition (4.2.10), but this is unusual, and in particular is not possible for the simple potentials discussed below.

Under these conditions the expansion is generally not strictly exponential, but it can easily be exponentially large. Suppose that during some time interval the field $\varphi(t)$ shifts from an initial value φ_1 to a final value φ_2, with $0 < V(\varphi_2) < V(\varphi_1)$, with both inequalities (4.2.10) and (4.2.13) assumed valid over this range of φ. The Robertson-Walker scale factor will increase during this period by a factor

$$\begin{aligned}\frac{a(t_2)}{a(t_1)} &= \exp\left[\int_{t_1}^{t_2} H dt\right] = \exp\left[\int_{\varphi_1}^{\varphi_2} \frac{H d\varphi}{\dot{\varphi}}\right] \\ &\simeq \exp\left[-\int_{\varphi_1}^{\varphi_2}\left(\frac{8\pi G V(\varphi)}{V'(\varphi)}\right) d\varphi\right]\end{aligned} \tag{4.2.14}$$

In this range the potential is positive and decreases as $\varphi(t)$ runs from φ_1 to φ_2, so the argument of the exponential in Eq. (4.2.14) is positive. Condition (4.2.10) tells us that this argument is much greater than $\sqrt{4\pi G}\,|\varphi_1 - \varphi_2|$, so this flatness condition guarantees that we get a large number of e-foldings
in any time interval in which φ changes by an amount at least as large as $1/\sqrt{4\pi G} = 3.4 \times 10^{18}$GeV.

It is important to note that such large values of the scalar field do not necessarily rule out the classical treatment of gravitation on which we have been relying. The condition that allows us to neglect quantum gravitational effects is that the energy density should be much less than the Planck energy density:

$$|V(\varphi)| \ll (4\pi G)^{-2} \tag{4.2.15}$$

This condition can be satisfied, even if φ is comparable to the Planck mass $\approx G^{-1/2}$, by supposing that $V(\varphi)$ is proportional to a sufficiently small coupling constant. Neither the flatness conditions (4.2.10), (4.2.13) nor the growth (4.2.14) of $a(t)$ for a given change in $\varphi(t)$ depend on the value of such a coupling constant.

Depending on the potential shape, the flatness conditions (4.2.10) and (4.2.13) may provide either conditions on the initial value of the scalar field or on the parameters of the potential itself. As an example of the first sort, consider the power-law potential

$$V(\varphi) = g\varphi^{\alpha} \tag{4.2.16}$$

with g and α arbitrary real parameters, except that we assume that $g > 0$ and take $|\alpha|$ larger but not orders of magnitude larger than unity. The flatness conditions (4.2.10) and (4.2.13) are then both satisfied for $|\varphi| \gg 1/\sqrt{4\pi G}$, irrespective of the value of the coupling constant g. The number of e foldings of expansion for a scalar field that starts at a value φ_1 and ends at a much smaller value is given by Eq. (4.2.14) as $8\pi G\varphi_1^2/\alpha$, so for instance for $\alpha = 4$ we get the $62e$-foldings needed to avoid the horizon problem for inflation ending at a temperature $2 \times 10^{16}\text{GeV}/k_{\mathcal{B}}$ if $|\varphi_1| > \sqrt{31/\pi G}$. On the other hand, for this potential the condition (4.2.15) for the neglect of quantum gravitational effects does put an upper bound on $|g|$. For instance, in the case $\alpha = 4$, the potential (4.2.16) will satisfy condition (4.2.15) if $g \ll (\sqrt{4\pi G}|\varphi|)^{-4}$ so, with $|\varphi|$ just large enough to get $62e$ foldings of exponential expansion, to avoid quantum

gravity corrections we need $g \ll 2 \times 10^{-5}$. The need for a very small coupling can be avoided in theories with more than one scalar field, such as "hybrid inflation" theories, [5] in which the effective self-coupling of one scalar field is very small because the other scalar field has a very small mass and hence a small expectation value.

There is a well-known example of a rather different sort for which Eqs. (4.2.1) and (4.2.2) can be solved exactly, the exponential potential: [6]

$$V(\varphi) = g \exp(-\lambda\varphi), \tag{4.2.17}$$

with g and λ arbitrary constants. It is easy to verify that Eqs. (4.2.1) and (4.2.2) are satisfied by [7]

$$\varphi(t) = \frac{1}{\lambda} \ln\left(\frac{8\pi G g \epsilon^2 t^2}{3-\epsilon}\right), \tag{4.2.18}$$

and

$$a \propto t^{1/\epsilon}, \quad H = 1/\epsilon t, \tag{4.2.19}$$

where ϵ is the positive dimensionless quantity

$$\epsilon \equiv \frac{\lambda^2}{16\pi G}. \tag{4.2.20}$$

The flatness conditions (4.2.10) and (4.2.13) here respectively read $\epsilon \ll 1$ and $\epsilon \ll 3/2$, so both are satisfied if and only if

$$\epsilon \ll 1, \tag{4.2.21}$$

with no constraint on the values of either g or φ. This exact solution is useful as a check of approximate calculations for more general potentials. For instance, Eq. (4.2.18) may be compared with the solution of the approximate equation (4.2.8), which for the exponential potential is

$$\varphi(t) = \frac{1}{\lambda} \ln\left(\frac{8\pi G g \epsilon^2 t^2}{3}\right), \tag{4.2.22}$$

The difference between this and the exact solution (4.2.18) is evidently negligible for $\epsilon \ll 1$. Likewise, the increase in the Robertson-Walker scale factor during a time interval from t_1 to t_2 in which the field drops from φ_1 to φ_2 is

$$\frac{a(t_2)}{a(t_1)} = \left(\frac{t_2}{t_1}\right)^{1/\epsilon} = e^{(\varphi_2-\varphi_1)\lambda/2\epsilon}, \tag{4.2.23}$$

which is exactly the same as the "slow-roll" result (4.2.14) for the exponential potential.

It is assumed in these theories that when $V(\varphi)$ dropped sufficiently far, the inequalities (4.2.10) and (4.2.13) were in general no longer be satisfied, and φ began a damped oscillation around the minimum of $V(\varphi)$, which is at the present value φ_0. Eventually φ would have approached close enough to φ_0 so that we can approximate the potential as a quadratic,

[475] A. D. Linde, Phys. Lett. B 259, 38 (1991); Phys. Rev. D 49, 748 (1994) [astro-ph/9307002].

[476] L. F. Abbott and M. B. Wise, Nucl. Phys. B 244, 541 (1984); F. Lucchin and S. Matarrese, Phys. Rev. D 32, 1316 (1985); Phys. Lett. B 164, 282 (1985); D. H. Lyth and E. D. Stewart, Phys. Lett. B 274, 168 (1992).

[7] This is an exact solution for all values of t, but it is not the most general solution. Since Eqs. (4.2.1) is a second-order differential equation, it has a two-parameter set of solutions. The particular solution (4.2.18) is an attractor, which the general solutions approach for large t.

$$V(\varphi) = \frac{1}{2} m^2 (\varphi - \varphi_0)^2 \tag{4.2.24}$$

(In order to account for the small present value of the vacuum energy, it is necessary to assume that, for reasons that remain entirely mysterious, the minimum value of the potential is very close to zero.) This is just like the field theory of spinless particles with mass m and negligible velocity. In order to have ended inflation, there must also be some coupling of the inflaton scalar field to other fields, including the fields of ordinary matter and radiation, so that the energy density of the inflaton field decreased as

$$\rho_\varphi(t) = \rho_\varphi(t_I) \left(\frac{a(t_I)}{a(t)} \right)^3 e^{-\Gamma(t-t_I)} \tag{4.2.25}$$

where Γ is the rate of decay of the φ quanta into other particles, and t_I is taken at the beginning of the inflaton oscillation and decay. This is known as the period of reheating. [8] It is this period in which the entropy observed in the present universe is supposed to be generated. [9]

The energy density ρ_M of the particles into which φ decayed satisfies a conservation equation like Eq. (1.1.32), but corrected to take account of the flow of energy from the inflaton:

$$\dot{\rho}_M + 3H(\rho_M + p_M) = \Gamma \rho_\varphi \tag{4.2.26}$$

For definiteness, we will assume that the decay products of the inflaton are highly relativistic, so that $p_M = \rho_M/3$. Then the solution of Eq. (4.2.26) is

$$\rho_M(t) = \frac{\rho_\varphi(t_I)\,\Gamma a^3(t_I)}{a^4(t)} \int_{t_I}^{t} a(t')\, e^{-\Gamma(t'-t_I)} dt' \tag{4.2.27}$$

In contemporary models of inflation this is the source of all the matter and radiation in the present universe. (In using this relation it is important

to keep in mind the possibility of parameteric amplification of the density $\rho_\varphi(t_I)$. That is, scalar field expectation values can increase the effective mass of the inflaton field φ, and thereby increase its energy density. [10])

The matter energy density (4.2.27) starts equal to zero at $t = t_I$, then rises at first, and finally falls as the density is attenuated by the expansion of the universe. It is of some interest to find the value of $\rho_M(t)$ at its maximum, because this tells us the maximum temperature ever reached, which controls the kinds of relics - cold dark matter, baryons, monopoles, axions - left over from the early universe. This maximum density can be easily calculated in two extreme cases, for $\Gamma \gg H(t_I)$ and $\Gamma \ll H(t_I)$.

For $\Gamma \gg H(t_I)$, we can express Eq. (4.2.27) as a power series in $H(t_I)/\Gamma$ by repeated integration by parts

$$\rho_M(t) = \rho_\varphi(t_I) \left(\frac{a(t_I)}{a(t)} \right)^4 \left(1 + \frac{H(t_I)}{\Gamma} + \ldots \right) \tag{4.2.28}$$

We see that in this case ρ_M jumped up almost immediately to the value $\rho_\varphi(t_I)$, and then decreased with the usual a^{-4} factor, so in this case all the energy of the inflaton field at the end of inflation went into ordinary matter and radiation. This was the assumption made in deriving lower bounds on the number of e-foldings of inflation in the previous section.

[478] The term reheating is a historical relic of early theories of inflation in which it was assumed that the zero-temperature slow roll of the inflaton field followed an earlier period of high temperature.

[9] A. D. Dolgov and A. D. Linde, Phys. Lett. 116B, 329 (1982); L. F. Abbott, E. Farhi, and M. B. Wise, Phys. Lett. 117B, 29 (1982).

For $\Gamma \ll H(t_I)$, the maximum value of $\rho_M(t)$ was reached at a time when the exponential $e^{-\Gamma(t'-t_I)}$ in Eq. (4.2.27) had not yet begun to decay. (This will be checked below.) Setting this factor equal to unity, we have

$$\rho_M(t) \simeq \frac{\rho_\varphi(t_I)\,\Gamma a^3(t_I)}{a^4(t)} \int_{t_I}^{t} a(t')\,dt' \tag{4.2.29}$$

At this time the energy density of the universe was still dominated by the inflaton, so $a(t) = a(t_I)(t/t_I)^{2/3}$, and Eq. (4.2.29) becomes

$$\rho_M(t) \simeq \frac{3}{5}\Gamma t_I \rho_\varphi(t_I) \left(\frac{t_I}{t}\right)^{8/3} \left(\left(\frac{t}{t_I}\right)^{5/3} - 1\right). \tag{4.2.30}$$

This reached a maximum at $t = (8/3)^{3/5} t_I$, which incidentally confirms that, under the assumption that $\Gamma \ll H(t_I) = 2/3t_I$, the argument of the exponential in Eq. (4.2.27) at this maximum was still negligible. At this maximum, the matter density is

$$\rho_{M,\max} = (3/8)^{8/5}\Gamma t_I \rho_\varphi(t_I) = 0.139\,(\Gamma/H(t_I))\,\rho_\varphi(t_I). \tag{4.2.31}$$

In this case the maximum energy density at the beginning of the radiationdominated era would have been much less than the energy density in the inflaton field at the end of inflation.

10.4.3 4.3 Chaotic inflation, eternal inflation

It was soon realized that some "new inflation" models actually entail an endless production of inflating bubbles. [1] This has come to be called "eternal inflation." [2] To take one example, if the inflaton scalar field at a given point in space once had a value of unstable equilibrium (like at the top of a potential hill) then the probability that the inflaton field was still at this value after a time t decreased as $\exp(-\gamma t)$. However, the volume in which the scalar field had this value was meanwhile increasing as $\exp(+3Ht)$, so as long as $3H > \gamma$ the volume of space that still undergoes inflation eternally increases exponentially.

We have been assuming that the scalar field is initially independent of position, aside from small perturbations, about which more in Chapter 10. Soon after the introduction of new inflation, the possibilities of inflationary theory were greatly expanded and improved when Linde [3] proposed the theory of "chaotic inflation," in which initially one or more scalar fields varied in a random way with position. Here and there one would have found patches of space in which an inflaton field took a nearly uniform value at which the potential satisfied the slow-roll conditions (4.2.10) and (4.2.13), as for instance a value substantially greater than the Planck mass for a power-law potential. Inflation will then have occured in such a patch, provided the patch was initially sufficiently large.

It is necessary to require that the uniform patch be sufficiently large, because the scalar field Lagrangian density given by Eq. (B.63) contains a term involving spatial derivatives, which for a non-uniform scalar field contributes a term $-a^{-2}\nabla^2\varphi$ on the left-hand side of Eq. (4.2.1). In order for this term not to interfere with the slow-roll analysis of the previous section, we need the scale L of proper distances over which φ takes a roughly constant initial value to be greater than $|\varphi/V'(\varphi)|^{1/2}$. For instance, for the

[4][7][1][0] L. Kofman, A. D. Linde, and A. A. Starobinsky, Phys. Rev. Lett. 73, 3195 (1994); Phys. Rev. D 56, 3258 (1997).

[471] P. J. Steinhardt, in The Very Early Universe - Proceedings of the Nuffield Workshop, 1982, eds. G. W. Gibbon S. W. Hawking, and S. T. C. Siklos (Cambridge University Press, 1983): 251; A. Vilenkin, Phys. Rev. D 27, 2848 (1983).

[2] For reviews of this and other variants of inflation, see A. Guth, talk given at the Pritzker Symposium on

potential $V(\varphi) = g\varphi^4$, this condition gives

$$L \gg \frac{1}{2\sqrt{g}|\varphi|} = \left(\frac{1}{g(4\pi G)^2\varphi^4}\right)^{1/2} (\sqrt{\pi G}\varphi)\sqrt{4\pi G} \tag{4.3.1}$$

The classical field theory condition (4.2.15) makes the first factor much larger than unity, while the slow-roll condition (4.2.10) makes the second factor also much larger than unity, so the patch size must be very much greater than the third factor, which is essentially the Planck length. Such relatively large uniform patches may be quite rare, but that is no argument against this hypothesis, because life can only arise in big bangs that stem from such patches.

A sufficiently large patch will inflate to an enormous size, which to observers deep inside seems highly homogeneous and isotropic. In this way, chaotic inflation solves a puzzle that had not generally been realized to be a puzzle, even when the first inflation theories were being developed. It explains not just why the Robertson-Walker metric in which we find ourselves was remarkably flat in the past; it also explains why we find ourselves in a Robertson-Walker metric at all. Unfortunately, it is hard to see how we will ever observe any part of the universe beyond our inflated patch. The validity of the idea of chaotic inflation will probably have to come from progress in fundamental physics, which may verify the existence of a suitable inflaton field, rather than from astronomical observation.

Even when the scalar field in a patch of the space was large enough to start a slow roll inflation, quantum fluctuations in smaller regions within that patch would subsequently have driven the inflaton field to even higher values, so that these regions will begin an earlier stage of inflation. [4] In this way, chaotic inflation turns out also to be eternal.

10.5 General Theory of Small Fluctuations

In most of the work described in the previous chapters, the universe has been treated as isotropic and homogeneous, with a gravitational field described by the Robertson-Walker metric. This is of course just an approximation, which ignores many of the most interesting things in the universe: galaxy clusters, galaxies, stars, us. We now turn to an analysis of these departures from homogeneity and isotropy.

In this chapter we will lay a foundation for this analysis, by deriving the general relativistic equations that govern small fluctuations, and drawing general conclusions about their implications. Chapter 6 will apply this formalism to the evolution of structure, from the radiation-dominated era to near the present. In Chapters 7 and 8 we apply the results obtained in Chapter 6 to the observed fluctuations in the cosmic microwave background and to the growth of structure. Chapter 9 deals with gravitational lensing, which may in the long run provide the best tool for analyzing the large scale structure of dark matter. These chapters are kept at a general level, independent of detailed assumptions about an inflationary era before the radiation-dominated era. Chapter 10 will then explore the implications of inflationary theories for the calculations of Chapters 6 through 9. Some readers may prefer to skip on immediately to Chapter 6, using the present chapter as a source of useful formulas, while others will do better to read these chapters in order.

10.5.1 5.1 Field equations

As an essential feature of the analysis presented here, we assume that during most of the history of the universe all departures from homogeneity and isotropy have been small, so that they can be treated as first-order perturbations. [1] Because the observable universe is nearly homogeneous, and its spatial curvature either vanishes or is negligible until very near the present, we will take the unperturbed metric to have the Robertson-Walker form (1.1.11), with curvature constant $K = 0$. (Effects of a possible finite curvature at times close to the present will be included in Chapters 7 through 9

where they are relevant.) The total perturbed metric is then

$$g_{\mu\nu} = \bar{g}_{\mu\nu} + h_{\mu\nu}, \tag{5.1.1}$$

where $\bar{g}_{\mu\nu}$ is the unperturbed $K = 0$ Robertson-Walker metric

$$\bar{g}_{00} = -1, \quad \bar{g}_{i0} = \bar{g}_{0i} = 0, \quad \bar{g}_{ij} = a^2(t)\delta_{ij}, \tag{5.1.2}$$

and $h_{\mu\nu} = h_{\nu\mu}$ is a small perturbation. (Here and from now on, a bar over any quantity denotes its unperturbed value.) The perturbation to the inverse of a general matrix M is $\delta M^{-1} = -M^{-1}(\delta M)M^{-1}$, so the inverse metric is perturbed by

$$h^{\mu\nu} \equiv g^{\mu\nu} - \bar{g}^{\mu\nu} = -\bar{g}^{\mu\rho}\bar{g}^{\nu\sigma}h_{\rho\sigma}, \tag{5.1.3}$$

with components

$$h^{ij} = -a^{-4}h_{ij}, \quad h^{i0} = a^{-2}h_{i0}, \quad h^{00} = -h_{00} \tag{5.1.4}$$

Note the - sign in the last expression in Eq. (5.1.3); in our notation, the perturbation $\delta g^{\mu\nu}$ to $g^{\mu\nu}$ is not given by simply using the unperturbed metric to raise the indices on $\delta g_{\mu\nu}$.

The metric perturbation produces a perturbation to the affine connection

$$\delta\Gamma^{\mu}_{\nu\lambda} = \frac{1}{2}\bar{g}^{\mu\rho}\left[-2h_{\rho\sigma}\bar{\Gamma}^{\sigma}_{\nu\lambda} + \partial_\lambda h_{\rho\nu} + \partial_\nu h_{\rho\lambda} - \partial_\rho h_{\lambda\nu}\right]. \tag{5.1.5}$$

For $K = 0$, the only non-vanishing components of the unperturbed affine connection are given by Eqs. (1.1.17)-(1.1.19) as

$$\bar{\Gamma}^{i}_{j0} = \bar{\Gamma}^{i}_{0j} = \frac{\dot{a}}{a}\delta_{ij}, \quad \bar{\Gamma}^{0}_{ij} = a\dot{a}\delta_{ij}$$

Thus Eq. (5.1.5) gives the components of the perturbed affine connection as

[471] The study of first-order cosmological fluctuations was initiated by E. Lifshitz, J. Phys. U.S.S.R. 10, 116 (1946). Classical second-order corrections were worked out by K. Tomita, Prog. Theor. Phys. 37, 831 (1967); 45, 1747 (1970); 47, 416 (1971). For recent work, see K. Tomita, Phys. Rev. D 71, 3504 (2005); N. Bartolo, S. Matarrese, and A. Riotto, J. Cosm. & Astropart. Phys. 0606, 024 (2006) [astro-ph/0604416].

$$\delta\Gamma^i_{jk} = \frac{1}{2a^2}\left(-2a\dot{a}h_{i0}\delta_{jk} + \partial_k h_{ij} + \partial_j h_{ik} - \partial_i h_{jk}\right) \tag{5.1.6}$$

$$\delta\Gamma^i_{j0} = \frac{1}{2a^2}\left(-\frac{2\dot{a}}{a}h_{ij} + \dot{h}_{ij} + \partial_j h_{i0} - \partial_i h_{j0}\right) \tag{5.1.7}$$

$$\delta\Gamma^0_{ij} = \frac{1}{2}\left(2a\dot{a}\delta_{ij}h_{00} - \partial_j h_{i0} - \partial_i h_{j0} + \dot{h}_{ij}\right) \tag{5.1.8}$$

$$\delta\Gamma^i_{00} = \frac{1}{2a^2}\left(2\dot{h}_{i0} - \partial_i h_{00}\right) \tag{5.1.9}$$

$$\delta\Gamma^0_{i0} = \frac{\dot{a}}{a}h_{i0} - \frac{1}{2}\partial_i h_{00} \tag{5.1.10}$$

$$\delta\Gamma^0_{00} = -\frac{1}{2}\dot{h}_{00} \tag{5.1.11}$$

In particular, we will need

$$\delta\Gamma^\lambda_{\lambda\mu} = \partial_\mu\left[\frac{1}{2a^2}h_{ii} - \frac{1}{2}h_{00}\right].$$

To write the Einstein equations, we need the perturbation to the Ricci tensor

$$\begin{aligned}\delta R_{\mu\kappa} =& \frac{\partial\delta\Gamma^\lambda_{\mu\lambda}}{\partial x^\kappa} - \frac{\partial\delta\Gamma^\lambda_{\mu\kappa}}{\partial x^\lambda} \\ &+ \delta\Gamma^\eta_{\mu\nu}\bar{\Gamma}^v_{\kappa\eta} + \delta\Gamma^v_{\kappa\eta}\bar{\Gamma}^\eta_{\mu\nu} - \delta\Gamma^\eta_{\mu\kappa}\bar{\Gamma}^v_{\nu\eta} - \delta\Gamma^v_{\nu\eta}\bar{\Gamma}^\eta_{\mu\kappa}\end{aligned} \tag{5.1.12}$$

with components

$$\begin{aligned}\delta R_{jk} =& -\frac{1}{2}\partial_j\partial_k h_{00} - \left(2\dot{a}^2 + a\ddot{a}\right)\delta_{jk}h_{00} - \frac{1}{2}a\dot{a}\delta_{jk}\dot{h}_{00} \\ &+ \frac{1}{2a^2}\left(\nabla^2 h_{jk} - \partial_i\partial_j h_{ik} - \partial_i\partial_k h_{ij} + \partial_j\partial_k h_{ii}\right) \\ &- \frac{1}{2}\ddot{h}_{jk} + \frac{\dot{a}}{2a}\left(\dot{h}_{jk} - \delta_{jk}\dot{h}_{ii}\right) + \frac{\dot{a}^2}{a^2}\left(-2h_{jk} + \delta_{jk}h_{ii}\right) + \frac{\dot{a}}{a}\delta_{jk}\partial_i h_{i0} \\ &+ \frac{1}{2}\left(\partial_j\dot{h}_{k0} + \partial_k\dot{h}_{j0}\right) + \frac{\dot{a}}{2a}\left(\partial_j h_{k0} + \partial_k h_{j0}\right)\end{aligned} \tag{5.1.13}$$

$$\begin{aligned}\delta R_{0j} =& \delta R_{j0} = \frac{\dot{a}}{a}\partial_j h_{00} + \frac{1}{2a^2}\left(\nabla^2 h_{j0} - \partial_j\partial_i h_{i0}\right) - \left(\frac{\ddot{a}}{a} + \frac{2\dot{a}^2}{a^2}\right)h_{j0} \\ &+ \frac{1}{2}\frac{\partial}{\partial t}\left[\frac{1}{a^2}\left(\partial_j h_{kk} - \partial_k h_{kj}\right)\right]\end{aligned} \tag{5.1.14}$$

$$\begin{aligned}\delta R_{00} =& \frac{1}{2a^2}\nabla^2 h_{00} + \frac{3\dot{a}}{2a}\dot{h}_{00} - \frac{1}{a^2}\partial_i\dot{h}_{i0} \\ &+ \frac{1}{2a^2}\left[\ddot{h}_{ii} - \frac{2\dot{a}}{a}\dot{h}_{ii} + 2\left(\frac{\dot{a}^2}{a^2} - \frac{\ddot{a}}{a}\right)h_{ii}\right]\end{aligned} \tag{5.1.15}$$

In general, we can put the Einstein field equations (B.71) in the form

$$R_{\mu\nu} = -8\pi G S_{\mu\nu}, \tag{5.1.16}$$

where

$$S_{\mu\nu} = T_{\mu\nu} - \frac{1}{2}g_{\mu\nu}g^{\rho\sigma}T_{\rho\sigma}. \tag{5.1.17}$$

(A cosmological constant can be accommodated by including a term in $T_{\mu\nu}$ proportional to $g_{\mu\nu}$, with a constant coefficient.) The perturbation to the
energy-momentum tensor and metric produces a perturbation to the source tensor $S_{\mu\nu}$:

$$\delta S_{\mu\nu} = \delta T_{\mu\nu} - \frac{1}{2}\bar{g}_{\mu\nu}\delta T^{\lambda}_{\lambda} - \frac{1}{2}h_{\mu\nu}\bar{T}^{\lambda}_{\lambda}. \tag{5.1.18}$$

We are not assuming that the contents of the universe form a perfect fluid, but the rotational and translational invariance of the unperturbed energymomentum tensor $\bar{T}^{\mu\nu}$ require that it takes the perfect fluid form (B.42):

$$\bar{T}_{\mu\nu} = \bar{p}\bar{g}_{\mu\nu} + (\bar{p}+\bar{\rho})\bar{u}_{\mu}\bar{u}_{\nu} \tag{5.1.19}$$

where $\bar{\rho}(t), \bar{p}(t)$, and $\bar{u}^{\mu}$ are the unperturbed energy density, pressure, and velocity four-vector, respectively, with $\bar{u}^0 = 1$ and $\bar{u}^i = 0$. Also, we use the unperturbed Einstein equations (1.5.17) and (1.5.18) to write $\bar{\rho}$ and $\bar{p}$ in terms of the Robertson-Walker scale factor and its derivatives

$$\bar{\rho} = \frac{3}{8\pi G}\left(\frac{\dot{a}^2}{a^2}\right), \quad \bar{p} = -\frac{1}{8\pi G}\left(\frac{2\ddot{a}}{a} + \frac{\dot{a}^2}{a^2}\right). \tag{5.1.20}$$

It follows in particular that the unperturbed energy-momentum tensor has the trace

$$\bar{T}^{\lambda}_{\lambda} = 3\bar{p} - \bar{\rho} = -\frac{3}{4\pi G}\left(\frac{\ddot{a}}{a} + \frac{\dot{a}^2}{a^2}\right).$$

Thus Eq. (5.1.18) gives

$$\delta S_{jk} = \delta T_{jk} - \frac{a^2}{2}\delta_{jk}\delta T^{\lambda}_{\lambda} + \frac{3}{8\pi G}\left(\frac{\ddot{a}}{a} + \frac{\dot{a}^2}{a^2}\right)h_{jk}, \tag{5.1.21}$$

$$\delta S_{j0} = \delta T_{j0} + \frac{3}{8\pi G}\left(\frac{\ddot{a}}{a} + \frac{\dot{a}^2}{a^2}\right)h_{j0} \tag{5.1.22}$$

$$\delta S_{00} = \delta T_{00} + \frac{1}{2}\delta T^{\lambda}_{\lambda} + \frac{3}{8\pi G}\left(\frac{\ddot{a}}{a} + \frac{\dot{a}^2}{a^2}\right)h_{00}. \tag{5.1.23}$$

The Einstein equations (5.1.16) thus take the form

$$\begin{aligned}
-8\pi G\left(\delta T_{jk} - \frac{a^2}{2}\delta_{jk}\delta T^{\lambda}_{\lambda}\right) &= -\frac{1}{2}\partial_j\partial_k h_{00} - \left(2\dot{a}^2 + a\ddot{a}\right)\delta_{jk}h_{00} \\
&\quad -\frac{1}{2}a\dot{a}\delta_{jk}\dot{h}_{00} + \frac{1}{2a^2}\left(\nabla^2 h_{jk} - \partial_i\partial_j h_{ik} - \partial_i\partial_k h_{ij} + \partial_j\partial_k h_{ii}\right) \\
-\frac{1}{2}\ddot{h}_{jk} + \frac{\dot{a}}{2a}\left(\dot{h}_{jk} - \delta_{jk}\dot{h}_{ii}\right) + \left(\frac{\dot{a}^2}{a^2} + \frac{3\ddot{a}}{a}\right)h_{jk} + \left(\frac{\dot{a}^2}{a^2}\right)\delta_{jk}h_{ii} \\
+\frac{\dot{a}}{a}\delta_{jk}\partial_i h_{i0} + \frac{1}{2}\left(\partial_j\dot{h}_{k0} + \partial_k\dot{h}_{j0}\right) + \frac{\dot{a}}{2a}\left(\partial_j h_{k0} + \partial_k h_{j0}\right) &\qquad (5.1.24) \\
-8\pi G\delta T_{j0} = \frac{\dot{a}}{a}\partial_j h_{00} + \frac{1}{2a^2}\left(\nabla^2 h_{j0} - \partial_j\partial_i h_{i0}\right) + \left(\frac{\dot{a}^2}{a^2} + \frac{2\ddot{a}}{a}\right)h_{j0} \\
+\frac{1}{2}\frac{\partial}{\partial t}\left[\frac{1}{a^2}\left(\partial_j h_{kk} - \partial_k h_{kj}\right)\right] &\qquad (5.1.25) \\
-8\pi G\left(\delta T_{00} + \frac{1}{2}\delta T^{\lambda}_{\lambda}\right) = \frac{1}{2a^2}\nabla^2 h_{00} + \frac{3\dot{a}}{2a}\dot{h}_{00} - \frac{1}{a^2}\partial_i\dot{h}_{i0} \\
+\frac{1}{2a^2}\left[\ddot{h}_{ii} - \frac{2\dot{a}}{a}\dot{h}_{ii} + 2\left(\frac{\dot{a}^2}{a^2} - \frac{\ddot{a}}{a}\right)h_{ii}\right] + 3\left(\frac{\dot{a}^2}{a^2} + \frac{\ddot{a}}{a}\right)h_{00}. &\qquad (5.1.26)
\end{aligned}$$

The components of the energy momentum tensor are subject to the conservation condition that $T^{\mu}{}_{\nu;\mu} = 0$, which to first order in perturbations gives

$$\partial_\mu \delta T^\mu_\nu + \bar{\Gamma}^\mu_{\mu\lambda}\delta T^\lambda_\nu - \bar{\Gamma}^\lambda_{\mu\nu}\delta T^\mu_\lambda + \delta\Gamma^\mu_{\mu\lambda}\bar{T}^\lambda_\nu - \delta\Gamma^\lambda_{\mu\nu}\bar{T}^\mu_\lambda = 0 \tag{5.1.27}$$

in which the perturbations to the energy-momentum tensor $\delta T^{\mu}{}_{\nu}$ with mixed indices can be calculated from

$$\delta T^\mu_\nu = \bar{g}^{\mu\lambda}\left[\delta T_{\lambda\nu} - h_{\lambda\kappa}\bar{T}^\kappa_\nu\right] \tag{5.1.28}$$

Setting v equal to a spatial coordinate index j gives the equation of momentum conservation

$$\partial_0 \delta T^0_j + \partial_i \delta T^i_j + \frac{2\dot{a}}{a}\delta T^0_j - a\dot{a}\delta T^j_0 - (\bar{\rho}+\bar{p})\left(\frac{1}{2}\partial_j h_{00} - \frac{\dot{a}}{a}h_{j0}\right) = 0, \tag{5.1.29}$$

while setting v equal to the time coordinate index 0 gives the equation of energy conservation

$$\partial_0 \delta T^0_0 + \partial_i \delta T^i_0 + \frac{3\dot{a}}{a}\delta T^0_0 - \frac{\dot{a}}{a}\delta T^i_i - \left(\frac{\bar{\rho}+\bar{p}}{2a^2}\right)\left(-\frac{2\dot{a}}{a}h_{ii} + \dot{h}_{ii}\right) = 0. \tag{5.1.30}$$

As remarked in Appendix B, these conservation equations are not independent conditions, but may be derived from the Einstein field equations. However, it is often convenient to use either or both in place of one or two of the field equations. Also, in the frequently encountered case where the constituents of the universe are non-interacting fluids (such as one fluid consisting of cold dark matter and another consisting of ordinary matter
and radiation) these conservation equations are satisfied separately by each fluid, information that could not be derived from the field equations.

The results obtained so far are repulsively complicated. Fortunately, the spatial isotropy and homogeneity of the unperturbed metric and energymomentum tensor allow us to simplify these results by decomposing the perturbations into scalars, divergenceless vectors, and divergenceless traceless symmetric tensors, which are not coupled to each other by the field equations or conservation equations. The perturbation to the metric can always be put in the form [2]

$$h_{00} = -E \tag{5.1.31}$$

$$h_{i0} = a\left[\frac{\partial F}{\partial x^i} + G_i\right] \tag{5.1.32}$$

$$h_{ij} = a^2\left[A\delta_{ij} + \frac{\partial^2 B}{\partial x^i \partial x^j} + \frac{\partial C_i}{\partial x^j} + \frac{\partial C_j}{\partial x^i} + D_{ij}\right] \tag{5.1.33}$$

where the perturbations $A, B, C_i, D_{ij} = D_{ji}, E, F$, and G_i are functions of $\mathbf{x}$ and t, satisfying the conditions

$$\frac{\partial C_i}{\partial x^i} = \frac{\partial G_i}{\partial x^i} = 0, \quad \frac{\partial D_{ij}}{\partial x^i} = 0, \quad D_{ii} = 0 \tag{5.1.34}$$

To carry out a similar decomposition of the energy-momentum tensor, we first note that for a perfect fluid we would have

$$T_{\mu\nu} = p g_{\mu\nu} + (\rho + p)u_\mu u_\nu \tag{5.1.35}$$

with

$$g^{\mu\nu}u_\mu u_\nu = -1 \tag{5.1.36}$$

Recalling that $\bar{u}_i = 0$ and $\bar{u}_0 = -1$, we find that the normalization condition Eq. (5.1.36) gives

$$\delta u^0 = \delta u_0 = h_{00}/2 \tag{5.1.37}$$

while δu_i is an independent dynamical variable. (Note that $\delta u^\mu \equiv \delta\left(g^{\mu\nu}u_\nu\right)$ is not given by $\bar{g}^{\mu\nu}\delta u_\nu$.) Then the first-order perturbation to the energymomentum tensor for a perfect fluid is

$$\delta T_{ij} = \bar{p}h_{ij} + a^2\delta_{ij}\delta p, \quad \delta T_{i0} = \bar{p}h_{i0} - (\bar{\rho}+\bar{p})\delta u_i, \quad \delta T_{00} = -\bar{\rho}h_{00} + \delta\rho \tag{5.1.38}$$

More generally, we can always put the perturbed energy-momentum tensor in a form like that of the perturbed metric. In general, we define $\delta\rho$ just as for a perfect fluid, as the difference between δT_{00} and $-\bar{\rho}h_{00}$, but $\delta\rho$ is not necessarily given by varying the temperature and chemical potentials in the formula for ρ that applies in thermal equilibrium. Also, in general we define the velocity perturbation δu_i times $\bar{\rho}+\bar{p}$ as for a perfect fluid, as the difference between $-\delta T_{i0}$ and $\bar{p}h_{i0}$, and we decompose δu_i into the gradient of a scalar velocity potential δu and a divergenceless vector δu_i^V. Finally, we define $a^2\delta p$ as the coefficient of δ_{ij} in the difference between δT_{ij} and $\bar{p}\delta_{ij}$, again without assuming that δp is given by varying the temperature and chemical potentials in the formula for p that applies in thermal equilibrium. The other terms in δT_{ij}, denoted $\partial_i\partial_j\pi^S, \partial_i\pi_j^V + \partial_j\pi_i^V$, and π_{ij}^T, represent dissipative corrections to the inertia tensor. That is, we write

$$\delta T_{ij} = \bar{p}h_{ij} + a^2\left[\delta_{ij}\delta p + \partial_i\partial_j\pi^S + \partial_i\pi_j^V + \partial_j\pi_i^V + \pi_{ij}^T\right] \tag{5.1.39}$$

$$\delta T_{i0} = \bar{p}h_{i0} - (\bar{\rho}+\bar{p})\left(\partial_i\delta u + \delta u_i^V\right) \tag{5.1.40}$$

$$\delta T_{00} = -\bar{\rho}h_{00} + \delta\rho \tag{5.1.41}$$

where π_i^V, π_{ij}^T, and δu_i^V satisfy conditions analogous to the conditions (5.1.34) satisfied by C_i, D_{ij}, and G_i :

$$\partial_i\pi_i^V = \partial_i\delta u_i^V = 0, \quad \partial_i\pi_{ij}^T = 0, \quad \pi_{ii}^T = 0 \tag{5.1.42}$$

To repeat, these formulas can be taken as a definition of the quantities $\delta\rho$, δp, and $\delta u_i \equiv \partial_i\delta u + \delta u_i^V$, as well as of the anisotropic inertia terms π^S, π^V, and π^T, which characterize departures from the perfect fluid form of the energy-momentum tensor. The perturbed mixed components (5.1.28) of the energy-momentum tensor, which are needed in the conservation laws, now take the form

$$\begin{aligned}
\delta T_j^i &= \delta_{ij}\delta p + \partial_i\partial_j\pi^S + \partial_i\pi_j^V + \partial_j\pi_i^V + \pi_{ij}^T \\
\delta T_0^i &= a^{-2}(\bar{\rho}+\bar{p})\left(a\partial_i F + aG_i - \partial_i\delta u - \delta u_i^V\right) \\
\delta T_i^0 &= (\bar{\rho}+\bar{p})\left(\partial_i\delta u + \delta u_i^V\right), \quad \delta T_0^0 = -\delta\rho, \\
\delta T_\lambda^\lambda &= 3\delta p - \delta\rho + \nabla^2\pi^S.
\end{aligned} \tag{5.1.43}$$

With these decompositions, and again using Eqs. (5.1.20), the Einstein field equations (5.1.24)-(5.1.26) and conservation equations (5.1.29) and (5.1.30) fall into three classes of coupled equations:

[472] To see this, we define F, A, and B, as the solutions of $\nabla^2 F = a^{-1}\partial_i h_{i0}, \nabla^2 A + \nabla^4 B = a^{-2}\partial_i\partial_j h_{jk}$, and $3A + \nabla^2 B = a^{-2}h_{ii}$, then define C_i as the solution of $\nabla^2 C_i = a^{-2}\partial_j h_{jk} - \partial_i\left[A + \nabla^2 B\right]$, and then use Eqs. (5.1.32) and (5.1.33) to define G_i and D_{jk}.

Scalar (compressional) modes

These are the most complicated, involving the eight scalars $E, F, A, B, \delta\rho,\ \delta p, \pi^S$, and δu. The part of Eq. (5.1.24) proportional to δ_{jk} gives

$$\begin{aligned}-4\pi G a^2\left[\delta\rho-\delta p-\nabla^2\pi^S\right] =&\frac{1}{2}a\dot{a}\dot{E}+\left(2\dot{a}^2+a\ddot{a}\right)E+\frac{1}{2}\nabla^2 A-\frac{1}{2}a^2\ddot{A}\\ &-3a\dot{a}\dot{A}-\frac{1}{2}a\dot{a}\nabla^2\dot{B}+\dot{a}\nabla^2 F\end{aligned} \tag{5.1.44}$$

The part of Eq. (5.1.24) of the form $\partial_j\partial_k S$ (where S is any scalar) gives

$$\partial_j\partial_k\left[16\pi G a^2\pi^S+E+A-a^2\ddot{B}-3a\dot{a}\dot{B}+2a\dot{F}+4\dot{a}F\right]=0 \tag{5.1.45}$$

The part of Eq. (5.1.25) of the form $\partial_j S$ (where S is again any scalar) gives

$$8\pi G a(\bar{\rho}+\bar{p})\partial_j\delta u=-\dot{a}\partial_j E+a\partial_j\dot{A} \tag{5.1.46}$$

Eq. (5.1.26) gives

$$\begin{aligned}-4\pi G\left(\delta\rho+3\delta p+\nabla^2\pi^S\right)=&-\frac{1}{2a^2}\nabla^2 E-\frac{3\dot{a}}{2a}\dot{E}-\frac{1}{a}\nabla^2\dot{F}-\frac{\dot{a}}{a^2}\nabla^2 F\\ &+\frac{3}{2}\ddot{A}+\frac{3\dot{a}}{a}\dot{A}-\frac{3\ddot{a}}{a}E+\frac{1}{2}\nabla^2\ddot{B}+\frac{\dot{a}}{a}\nabla^2\dot{B}\end{aligned} \tag{5.1.47}$$

The part of the momentum conservation condition (5.1.29) that is a derivative ∂_j is

$$\partial_j\left[\delta p+\nabla^2\pi^S+\partial_0[(\bar{\rho}+\bar{p})\delta u]+\frac{3\dot{a}}{a}(\bar{\rho}+\bar{p})\delta u+\frac{1}{2}(\bar{\rho}+\bar{p})E\right]=0 \tag{5.1.48}$$

and the energy-conservation condition (5.1.30) is

$$\begin{aligned}&\delta\dot{\rho}+\frac{3\dot{a}}{a}(\delta\rho+\delta p)+\nabla^2\left[-a^{-1}(\bar{\rho}+\bar{p})F+a^{-2}(\bar{\rho}+\bar{p})\delta u+\frac{\dot{a}}{a}\pi^S\right]\\ &+\frac{1}{2}(\bar{\rho}+\bar{p})\partial_0\left[3A+\nabla^2 B\right]=0.\end{aligned} \tag{5.1.49}$$

In Eqs. (5.1.48) and (5.1.49), $\delta\rho, \delta p$, and π^S are elements of the perturbation to the total energy-momentum tensor, but the same equations apply to each constituent of the universe that does not exchange energy and momentum with other constituents.

Vector (vortical) modes

These involve the four divergenceless vectors $G_i, C_i, \delta u_i^V$, and π_i^V. The part of Eq. (5.1.24) of the form $\partial_k V_j$ (where V_j is any vector satisfying $\partial_j V_j = 0$) gives

$$\partial_k\left[16\pi G a^2\pi_j^V-a^2\ddot{C}_j-3a\dot{a}\dot{C}_j+a\dot{G}_j+2\dot{a}G_j\right]=0, \tag{5.1.50}$$

while the part of Eq. (5.1.25) of the form V_j (where V_j is again any vector satisfying $\partial_j V_j = 0$) gives

$$8\pi G(\bar{\rho}+\bar{p})a\delta u_j^V=\frac{1}{2}\nabla^2 G_j-\frac{a}{2}\nabla^2\dot{C}_j. \tag{5.1.51}$$

The part of the momentum conservation equation (5.1.29) that takes the form of a divergenceless vector is

$$\nabla^2\pi_j^V + \partial_0\left[(\bar\rho+\bar p)\delta u_j^V\right] + \frac{3\dot a}{a}(\bar\rho+\bar p)\delta u_j^V = 0, \tag{5.1.52}$$

In particular, for a perfect fluid $\pi_i^V = 0$, and Eq. (5.1.52) tells us that $(\ \bar\rho+\bar p)\delta u_j^V$ decays as $1/a^3$. In this case, both Eqs. (5.1.50) and (5.1.51) imply that the quantity $G_j - a\dot C_j$ (which we will see in Section 5.3 is the only physically relevant combination of metric components for vector perturbations) decays as $1/a^2$. Because they decay, vector modes have not played a large role in cosmology.

Tensor (radiative) modes

These involve only the two traceless divergenceless symmetric tensors D_{ij} and π_{ij}^T. There is only one field equation here: the part of Eq. (5.1.24) of the form of a divergenceless traceless tensor is the wave equation for gravitational radiation

$$-16\pi G a^2\pi_{ij}^T = \nabla^2 D_{ij} - a^2\ddot D_{ij} - 3a\dot a\dot D_{ij}. \tag{5.1.53}$$

The above equations for scalar, vector, and tensor perturbations do not form a complete set. This is in part because we still have the freedom to make changes in the coordinate system, of the same order as the physical perturbations. In Section 5.3 we will see how to remove this freedom by a choice of "gauge."

But even after the gauge has been fixed, the equations for the scalar modes will still not form a complete set, unless the pressure p and anisotropic inertia π^S can be expressed as functions of the energy density ρ. This is the
case, for instance, for a constituent of the universe such as cold dark matter, whose particles have negligible velocities, and do not interact with other constituents. For such constituents, we can simply set p and π^S equal to zero. Things are only a little more complicated for constituents of the universe whose particles' velocities cannot be neglected, but which experience collisions that are sufficiently rapid to maintain local thermal equilibrium. In such cases, π^S can be neglected, and if the particles are highly relativistic p is simply $\rho/3$. Even where the particles are only moderately relativistic, the pressure in thermal equilibrium can usually be expressed as a function of ρ and one or more number densities n that satisfy the condition that the current nu^μ is conserved

$$(nu^\mu)_{;\mu} = 0. \tag{5.1.54}$$

This condition tells us that the unperturbed number density satisfies $\bar n \propto a^{-3}$, while the perturbation satisfies

$$\frac{\partial}{\partial t}\left(\frac{\delta n}{\bar n}\right) + \frac{1}{a^2}\nabla^2\delta u + \frac{1}{2}\left(3\dot A + \nabla^2\dot B\right) - \frac{1}{a}\nabla^2 F = 0. \tag{5.1.55}$$

With p given as a function of ρ and n, after gauge fixing the field equations and conservation equations (5.1.48), (5.1.49), and (5.1.55) form a complete set of equations for the scalar modes.

Similarly, even after gauge fixing, the equations for vector and tensor modes do not form a complete set unless we have formulas for π_i^V and π_{ij}^T, respectively. This is no problem for perfect fluids, for which $\pi_i^V = \pi_{ij}^T = 0$.

In the general case local thermal equilibrium is not maintained, and we must calculate $\delta\rho, \delta p, \pi^S, \pi_i^V$ and π_{ij}^T by following changes in the distribution of individual particle positions and momenta, which are governed by Boltzmann equations. The Boltzmann equations for photons and neutrinos are derived in Appendix H, and used in Chapters 6 and 7.

10.5.2 5.2 Fourier decomposition and stochastic initial conditions

In order to simplify our work we want to make full use of the symmetries of the problem. We have already used the rotational symmetry of the field and conservation equations in sorting out perturbations into scalar, vector, and tensor modes, and we will apply rotational symmetry again later in this section. The equations also have a symmetry under translations in space, which can best be exploited by working with the Fourier components of the perturbations. As long as we treat perturbations as infinitesimal, there is no coupling between the Fourier components of different wave number.

Further, only the initial conditions but not the equations themselves depend on the direction of the co-moving wave number $\mathbf{q}$.

Let us first see how this works out for the scalar modes. Because the unperturbed metric, energy density, etc. are independent of position, the general solution for the corresponding perturbed quantities may be written as a superposition of plane wave solutions, whose spatial variation is given by factors $\exp(i\mathbf{q}\cdot\mathbf{x})$, where $\mathbf{q}$ is a real wave vector, over which we must integrate. The coefficient of $\exp(i\mathbf{q}\cdot\mathbf{x})$ in each of the scalar perturbations $A(\mathbf{x},t), B(\mathbf{x},t)$, etc. is a solution of coupled ordinary differential equations with time as the independent variable, obtained by replacing $\partial/\partial x^j$ with iq_j everywhere in the equations presented in Section 5.1. The differential equations obtained in this way depend on $q \equiv |\mathbf{q}|$, but not on the direction of $\mathbf{q}$, so the solutions can be written as superpositions of independent q-dependent normal modes, each characterized by a set of perturbations $A_{nq}(t), B_{nq}(t)$, etc., with an overall normalization factor $\alpha_n(\mathbf{q})$ carrying a discrete index n that labels the various independent solutions. These normalization factors depend on the initial conditions, which of course are not rotationally invariant - if they were then there would be no galaxies or stars - so the $\alpha_n(\mathbf{q})$ depend on the direction of $\mathbf{q}$, but the solutions $A_{nq}(t), B_{nq}(t)$ can be chosen to depend only on $q \equiv |\mathbf{q}|$. That is, we write

$$A(\mathbf{x},t) = \sum_n \int d^3q \alpha_n(\mathbf{q}) A_{nq}(t) e^{i\mathbf{q}\cdot\mathbf{x}}$$
$$B(\mathbf{x},t) = \sum_n \int d^3q \alpha_n(\mathbf{q}) B_{nq}(t) e^{i\mathbf{q}\cdot\mathbf{x}} \tag{5.2.1}$$

and likewise (with the same $\alpha_n(\mathbf{q})$) for E and F as well as for $\delta\rho, \delta p, \delta u, \pi^S$ and any other rotational scalars.

Now, as discussed in Section 2.6, we expect the scalar variables $A(\mathbf{x},t)$, $B(\mathbf{x},t)$, etc. to be stochastic variables, characterized by averages of their products. The solutions $\{A_{nq}(t), B_{nq}(t), \ldots\}$ are ordinary fixed functions, not stochastic variables, so the stochastic nature of the scalar variables arises from the stochastic character of the initial conditions, embodied in the factors $\alpha_n(\mathbf{q})$. Under the assumption that the scalar variables are governed by Gaussian distributions, of the sort discussed in Appendix E, all averages of scalar quantities can be expressed in terms of bilinear averages $\langle A(\mathbf{x},t)A(\mathbf{y},t)\rangle, \langle A(\mathbf{x},t)B(\mathbf{y},t)\rangle$, etc. Let us consider the average of the product of any two real scalar quantities $X(\mathbf{x},t)$ and $Y(\mathbf{y},t)$. It turns out to be very convenient to use Eq. (5.2.1) for X and its complex conjugate for Y, so that

$$\langle X(\mathbf{x},t)Y(\mathbf{y},t)\rangle = \sum_{nm} \int d^3q \int d^3q' X_{nq}(t) Y^*_{mq}(t) \left\langle \alpha_n(\mathbf{q}) \alpha^*_m(\mathbf{q}') \right\rangle e^{i\mathbf{q}\cdot\mathbf{x}} e^{-i\mathbf{q}'\cdot\mathbf{y}}$$

We assume that although the initial conditions are not translationally invariant, they are governed by a translationally invariant probability distribution function, so that $\langle X(\mathbf{x},t)Y(\mathbf{y},t)\rangle$ should be a function only of $\mathbf{x}-\mathbf{y}$. This immediately tells us that $\langle \alpha_n(\mathbf{q})\alpha^*_m(\mathbf{q}')\rangle$ must be proportional to a delta function, $\delta^3(\mathbf{q}-\mathbf{q}')$. Furthermore, although the initial conditions are not

rotationally invariant, we also assume that they are governed by a rotationally invariant probability distribution, so that the function of $\mathbf{q}$ multiplying this delta function can only depend on the magnitude $q \equiv |\mathbf{q}|$ of the wave vector, not on its direction. That is, we can write

$$\langle \alpha_n(\mathbf{q}) \alpha_m^*(\mathbf{q}') \rangle = \mathcal{P}_{nm}(q) \delta^3(\mathbf{q} - \mathbf{q}'), \tag{5.2.2}$$

and so

$$\langle X(\mathbf{x}, t) Y(\mathbf{y}, t) \rangle = \sum_{nm} \int d^3q X_{nq}(t) Y_{mq}^*(t) \mathcal{P}_{nm}(q) \exp(i\mathbf{q} \cdot (\mathbf{x} - \mathbf{y}) \tag{5.2.3}$$

The task of the theory of cosmological perturbations is twofold: to find the solutions $A_{nq}(t), B_{nq}(t)$, etc. of the differential equations under suitable assumptions about the constituents of the universe, and to calculate the spectral functions $\mathcal{P}_{nm}(q)$ in a theory of the origin of fluctuations in the very early universe.

Inspection of Eq. (5.2.2) shows immediately that $\mathcal{P}_{mn}(q)$ is a Hermitian matrix

$$\mathcal{P}_{nm}^*(q) = \mathcal{P}_{mn}(q) \tag{5.2.4}$$

and it is positive, in the sense that

$$\sum_{nm} \mathcal{P}_{nm}(q) \xi_n \xi_m^* > 0 \tag{5.2.5}$$

for any set of complex numbers ξ_n (or functions of q) that are not all zero.
In general, for an arbitrary choice of independent solutions, there is no reason why $\mathcal{P}_{nm}(q)$ should also be diagonal, so in general there will be interference between the different modes. However, it is sometimes convenient to choose the solutions so that $\mathcal{P}_{nm}(q)$ is simply equal to δ_{nm}. To see that this can always be done, we recall a theorem of matrix algebra, which says that, because it is positive and Hermitian, $\mathcal{P}_{nm}(q)$ can be put in the form

$$\mathcal{P}_{nm}(q) = \sum_r Z_{nr}(q) Z_{mr}^*(q) \tag{5.2.6}$$

for some square matrix $Z_{nr}(q)$, with r running over as many values as n. (That is, in matrix notation, $\mathcal{P} = ZZ^\dagger$.) We can then redefine the
independent solutions, defining

$$\tilde{A}_{rq}(t) \equiv \sum_n Z_{nr}(q) A_{nq}(t), \quad \tilde{B}_{rq}(t) \equiv \sum_n Z_{nr}(q) B_{nq}(t), \text{ etc. },$$

with a corresponding redefinition of the normalization factors

$$\alpha_n(q) \equiv \sum_r Z_{nr}(q) \tilde{\alpha}_r(q)$$

chosen so that

$$A(\mathbf{x}, t) = \sum_r \int d^3q \tilde{\alpha}_r(\mathbf{q}) \tilde{A}_{rq}(t) e^{i\mathbf{q}\cdot\mathbf{x}}$$

and likewise (with the same $\tilde{\alpha}_r(\mathbf{q})$) for B, E, and F, as well as for $\delta\rho, \delta p, \delta u$, etc. The advantage of this is that now the relevant bilinear averages are

$$\langle \tilde{\alpha}_r(\mathbf{q}) \tilde{\alpha}_s^*(\mathbf{q}') \rangle = \delta_{rs} \delta^3(\mathbf{q} - \mathbf{q}') \tag{5.2.7}$$

This is the result that was to be proved. With the solutions $\tilde{A}_{rq}(t)$, etc. chosen so that the $\tilde{\alpha}_r(\mathbf{q})$ satisfy Eq. (5.2.7), the different modes are uncorrelated. That is, any binary average is a sum over the individual modes. For instance,

$$\langle A(\mathbf{x},t)A(\mathbf{y},t)\rangle = \sum_r \int d^3q e^{i\mathbf{q}\cdot(\mathbf{x}-\mathbf{y})} \left|\tilde{A}_{rq}(t)\right|^2 \tag{5.2.8}$$

In this way, the problem of calculating the spectral function $\mathcal{P}_{nm}(q)$ is traded for the problem of finding the correct linear combination of solutions for which Eq. (5.2.7) applies.

Incidentally, there is no problem in calculating the averages $\langle\alpha_n\alpha_m\rangle$ if we know the averages $\langle\alpha_n\alpha_m^*\rangle$, because the α_n satisfy a reality condition. To derive this condition, note that the differential equations for $A_{nq}(t)$, $B_{nq}(t)$, etc. are real, so the set of complex conjugates $A_{nq}^*(t), B_{nq}^*(t)$, etc. of solution n is also a solution, and can therefore be expressed as a set of linear combinations $\sum_m c_{nm}(q)A_{mq}(t), \sum_m c_{nm}(q)B_{mq}(t)$, etc. (Of course, in the case of a real solution, $c_{nm}(q) = \delta_{nm}$.) The functions $A(\mathbf{x},t), B(\mathbf{x},t)$ are real, so by taking the complex conjugate of Eqs. (5.2.1) and replacing the integration variable $\boldsymbol{q}$ with $-\boldsymbol{q}$ we see that

$$\sum_n \alpha_n^*(\mathbf{q})c_{nm}(q) = \alpha_m(-\mathbf{q}) \tag{5.2.9}$$

In particular, it follows that

$$\langle\alpha_n(\mathbf{q})\alpha_m(\mathbf{q}')\rangle = \sum_l \mathcal{P}_{nl}(q)c_{lm}(q)\delta^3(\mathbf{q}+\mathbf{q}')$$

Now let us consider the tensor modes. These are completely characterized by the traceless divergenceless symmetric tensor $D_{ij}(\mathbf{x},t)$. (The stress tensor $\pi_{ij}^T(\mathbf{x},t)$ is not an independent dynamical quantity but, as we will see in Section 6.6, it is given by a linear functional of $\dot{D}_{ij}$-specifically, the solution of a linear integral equation with $\dot{D}_{ij}$ as the inhomogeneous term.) If we write D_{ij} as a Fourier integral

$$D_{ij}(\mathbf{x},t) = \int d^3q e^{i\mathbf{q}\cdot\mathbf{x}}\mathcal{D}_{ij}(\mathbf{q},t), \tag{5.2.10}$$

then the Fourier transform $\mathcal{D}$ must satisfy the conditions

$$\mathcal{D}_{ij} = \mathcal{D}_{ji}, \quad \mathcal{D}_{ii} = 0, \quad q_i\mathcal{D}_{ij} = 0. \tag{5.2.11}$$

For a given wave vector $\mathbf{q}$, there are just two independent matrices satisfying these conditions. For instance, for $\mathbf{q}$ in the three-direction, Eq. (5.2.11) requires that

$$\mathcal{D}_{11} = -\mathcal{D}_{22}, \quad \mathcal{D}_{12} = \mathcal{D}_{21}, \quad \mathcal{D}_{i3} = \mathcal{D}_{3i} = 0, \tag{5.2.12}$$

so all $\mathcal{D}_{ij}$ can be expressed in terms of the two independent components $\mathcal{D}_{11}$ and $\mathcal{D}_{12}$. (These components are frequently denoted $h^+ = \mathcal{D}_{11}$ and $h^\times = \mathcal{D}_{12}$.) It is convenient to classify the possible $\mathcal{D}_{ij}$ by their transformation properties under a rotation by an angle θ around the three-axis. [1] It is easily seen that under such a rotation,

$$\begin{aligned}
\mathcal{D}_{11} &\to \cos^2\theta\mathcal{D}_{11} + \cos\theta\sin\theta\mathcal{D}_{12} + \sin\theta\cos\theta\mathcal{D}_{21} + \sin^2\theta\mathcal{D}_{22} \\
&= \cos 2\theta\mathcal{D}_{11} + \sin 2\theta\mathcal{D}_{12} \\
\mathcal{D}_{12} &\to \cos^2\theta\mathcal{D}_{12} - \cos\theta\sin\theta\mathcal{D}_{11} + \sin\theta\cos\theta\mathcal{D}_{22} - \sin^2\theta\mathcal{D}_{21} \\
&= -\sin 2\theta\mathcal{D}_{11} + \cos 2\theta\mathcal{D}_{12},
\end{aligned}$$

or more succinctly

$$\mathcal{D}_{11} \mp i\mathcal{D}_{12} \to e^{\pm 2i\theta}\left[\mathcal{D}_{11} \mp i\mathcal{D}_{12}\right] \tag{5.2.13}$$

For this reason, the linear combinations $\mathcal{D}_{11} \mp i\mathcal{D}_{12}$ are said to have helicity ± 2. (A wave of helicity λ consists of quanta with angular momentum in the direction of motion equal to $\hbar\lambda$.) We will write $\mathcal{D}_{ij}(\mathbf{q}, t)$ as a sum over helicities:

$$\mathcal{D}_{ij}(\mathbf{q}, t) = \sum_{\lambda=\pm 2} e_{ij}(\hat{q}, \lambda)\mathcal{D}(\mathbf{q}, \lambda, t), \tag{5.2.14}$$

where for $\mathbf{q}$ in the three-direction

$$\begin{aligned} e_{11}(\hat{z}, \pm 2) = -e_{22}(\hat{z}, \pm 2) = \mp ie_{12}(\hat{z}, \pm 2) = \mp ie_{21}(\hat{z}, \pm 2) = \frac{1}{\sqrt{2}} \\ e_{i3} = e_{3i} = 0 \end{aligned} \tag{5.2.15}$$

while for $\hat{q}$ in any other direction $e_{ij}(\hat{q}, \pm 2)$ is defined by applying on each of the indices i and j a standard rotation, that takes the three-direction into the direction of $\hat{q}$.

For $\mathbf{q}$ in the three-direction, the combination $\mathcal{D}_{11}(\mathbf{q}, t) \mp i\mathcal{D}_{12}(\mathbf{q}, t)$ is proportional to $\mathcal{D}(\mathbf{q}, \pm 2, t)$, so according to the transformation rule (5.2.13), a rotation by an angle θ around the direction of $\mathbf{q}$ changes $\mathcal{D}(\mathbf{q}, \pm 2, t)$ by a factor $\exp(\pm 2i\theta)$. There is nothing special about the three-direction, and the same is true for $\mathbf{q}$ in any direction.

The quantities $\mathcal{D}(\mathbf{q}, \lambda, t)$ in Eq. (5.2.14) satisfy the λ-independent second-order field equation (5.1.53), with the Laplacian ∇^2 replaced with $-q^2 \equiv -\mathbf{q}^2$:

$$\ddot{\mathcal{D}}(\mathbf{q}, \lambda, t) + 3\frac{\dot{a}}{a}\dot{\mathcal{D}}(\mathbf{q}, \lambda, t) + \frac{q^2}{a^2}\mathcal{D}(\mathbf{q}, \lambda, t) = 16\pi G\pi^T(\mathbf{q}, \lambda, t) \tag{5.2.16}$$

where $\pi^T(\mathbf{q}, \lambda, t)$ is the Fourier transform of the tensor part of the anisotropic inertia tensor:

$$\pi^T_{ij}(\mathbf{x}, t) = \sum_{\lambda=\pm 2}\int d^3q e^{i\mathbf{q}\cdot\mathbf{x}} e_{ij}(\hat{q}, \lambda)\pi^T(\mathbf{q}, \lambda, t) \tag{5.2.17}$$

As already mentioned, $\pi^T(\mathbf{q}, \lambda, t)$ is a helicity-independent linear functional of $\dot{\mathcal{D}}(\mathbf{q}, \lambda, t)$. Therefore, just as in the absence of anisotropic inertia, there are two independent solutions (distinguished by a label N) that, aside from normalization factors β, are independent of λ and of the direction of $\mathbf{q}$. Thus we can write

$$\mathcal{D}(\mathbf{q}, \lambda, t) = \sum_N \beta_N(\mathbf{q}, \lambda)\mathcal{D}_{Nq}(t) \tag{5.2.18}$$

and

$$\pi^T(\mathbf{q}, \lambda, t) = \sum_N \beta_N(\mathbf{q}, \lambda)\pi^T_{Nq}(t) \tag{5.2.19}$$

the sum over N running over the labels of the two independent solutions $\mathcal{D}_{Nq}(t)$ of the field equation

$$\ddot{\mathcal{D}}_{Nq}(t) + 3\frac{\dot{a}}{a}\dot{\mathcal{D}}_{Nq}(t) + \frac{q^2}{a^2}\mathcal{D}_{Nq}(t) = 16\pi G\pi^T_{Nq}(t) \tag{5.2.20}$$

Putting together Eqs. (5.2.10), (5.2.14), and (5.2.18), we have

[471] See, for instance, G&C, Sec. 10.2.

$$D_{ij}(\mathbf{x},t) = \sum_{N,\lambda} \int d^3q e^{i\mathbf{q}\cdot\mathbf{x}} e_{ij}(\hat{q},\lambda)\beta_N(\mathbf{q},\lambda)\mathcal{D}_{Nq}(t) \tag{5.2.21}$$

The normalization factors $\beta_N(\mathbf{q},\lambda)$ like the $\alpha_n(\mathbf{q})$ are stochastic variables. The translational invariance of the probability distribution governing these factors tells us that $\langle \beta_N(\mathbf{q},\lambda)\beta^*_{N'}(\mathbf{q}',\lambda')\rangle$ is proportional to $\delta^3(\mathbf{q}-\mathbf{q}')$. Under a rotation by an angle θ around the direction of $\mathbf{q}$, the product $\beta_N(\mathbf{q},\lambda)\beta^*_{N'}(\mathbf{q},\lambda')$ is changed by a factor $\exp(i\theta(\lambda-\lambda'))$, so the rotational invariance of the probability distribution requires further that $\langle \beta_N(\mathbf{q},\lambda)\beta^*_{N'}(\mathbf{q}',\lambda')\rangle$ is also proportional to $\delta_{\lambda\lambda'}$. For the most part, we will also assume that the probability distribution is invariant under the space-inversion operator P . This operator reverses the direction of momentum but not of angular momentum, so it changes the sign of the helicity, and therefore with this assumption, aside from the factor $\delta_{\lambda\lambda'}$, the mean value $\langle \beta_N(\mathbf{q},\lambda)\beta^*_{N'}(\mathbf{q}',\lambda')\rangle$ is independent of helicity. [2] We have then

$$\langle \beta_N(\mathbf{q},\lambda)\beta^*_{N'}(\mathbf{q}',\lambda')\rangle = \mathcal{P}^{\rm grav}_{NN'}(q)\delta_{\lambda\lambda'}\delta^3(\mathbf{q}-\mathbf{q}') \tag{5.2.22}$$

Rotational and translational invariance also tell us that there is no correlation between the normalization factors for scalar and tensor modes:

$$\langle \beta_N(\mathbf{q},\lambda)\alpha^*_n(\mathbf{q}')\rangle = 0 \tag{5.2.23}$$

Just as in the case of scalar modes, it is always possible to choose the two tensor modes so that $\mathcal{P}^{\rm grav}_{NN'}(q)$ is just $\delta_{NN'}$, but we need to know the probability distribution governing initial conditions in order to decide which linear combination of modes have this property.

The average of a product of two tensor perturbations is given by Eqs. (5.2.21) and (5.2.22) as

$$\begin{aligned}\langle D_{ij}(\mathbf{x},t)D_{kl}(\mathbf{y},t)\rangle =& \sum_{NN'}\int d^3q \mathcal{P}^{\rm grav}_{NN'}(q)e^{i\mathbf{q}\cdot(\mathbf{x}-\mathbf{y})} \\ & \times \Pi_{ij,k\ell}(\hat{q})\mathcal{D}_{Nq}(t)\mathcal{D}^*_{N'q}(t)\end{aligned} \tag{5.2.24}$$

where [3]

$$\begin{aligned}\Pi_{ij,k\ell}(\hat{q}) \equiv& \sum_\lambda e_{ij}(\hat{q},\lambda)e^*_{k\ell}(\hat{q},\lambda) \\ =& \delta_{ik}\delta_{j\ell} + \delta_{i\ell}\delta_{jk} - \delta_{ij}\delta_{k\ell} + \delta_{ij}\hat{q}_k\hat{q}_\ell + \delta_{k\ell}\hat{q}_i\hat{q}_j \\ & - \delta_{ik}\hat{q}_j\hat{q}_\ell - \delta_{i\ell}\hat{q}_j\hat{q}_k - \delta_{jk}\hat{q}_i\hat{q}_\ell - \delta_{j\ell}\hat{q}_i\hat{q}_k + \hat{q}_i\hat{q}_j\hat{q}_k\hat{q}_\ell\end{aligned} \tag{5.2.25}$$

Formulas like Eqs. (5.2.24) and (5.2.3) will be applied to the cosmic microwave background in Section 7.4.

We will see in Section 5.4 that the anisotropic inertia π_{Nq} becomes negligible during the era when the physical wave number q/a is much less than the expansion rate $\dot{a}/a$. In this case, one tensor mode becomes dominant. In the absence of anisotropic inertia, the gravitational wave equation (5.2.20) in the limit $q/a \ll H$ becomes

$$\ddot{\mathcal{D}}_{Nq}(t) + 3\frac{\dot{a}}{a}\dot{\mathcal{D}}_{Nq}(t) = 0$$

[472] The same conclusion follows if we assume that the probability distribution is invariant under CP, where C is the charge conjugation operator. Neither P nor CP is an exact symmetry of nature, but CP-invariance is a better approximation than P -invariance. The product CPT (where T is the reversal of the direction of time) is an exact symmetry in any quantum field theory, but T -invariance is broken by the expansion of the universe.

This has two obvious solutions:

$$\mathcal{D}_{1q}(t) = 1, \quad \mathcal{D}_{2q}(t) = \int_t^\infty \frac{dt'}{a^3(t')}$$

(The integral in the second solution converges, because $a(t) \propto t^{1/2}$ in the radiation-dominated era, and grows even faster in the matter-dominated and vacuum-dominated eras.) Since $\mathcal{D}_{2q}(t) \to 0$ at late times, for generic initial conditions the gravitational waves will eventually be dominated by the first solution. Thus in this case, to evaluate bilinear averages like (5.2.24), we only need to know $\mathcal{P}_{11}^{\rm grav}(q)$. Alternatively, we could take $\mathcal{D}_{1q}(t)$ to be a constant $\mathcal{D}_q^o$ (the o superscript denoting "outside the horizon"), chosen so that $\mathcal{P}_{11}^{\rm grav}(q) = 1$. In Section 5.4 we will see that similar remarks usually apply to the scalar modes.

10.5.3 5.3 Choosing a gauge

The equations derived in Section 5.1 have two unsatisfactory features. First, even with the simplifications introduced by decomposing the equations into

scalar, vector, and tensor modes, the equations for the scalar modes are still fearsomely complicated. Second, among the solutions of these equations are unphysical scalar and vector modes, corresponding to a mere coordinate transformation of the unperturbed Robertson-Walker metric and energy-momentum tensor. We can eliminate the second problem and ameliorate the first by fixing the coordinate system, adopting suitable conditions on the full perturbed metric and/or energy-momentum tensor. We will deal here with the coordinate-dependent perturbations $A(\mathbf{x}, t), B(\mathbf{x}, t)$, etc., but all of the results of this section could be applied just as well to the Fourier components $A_{nq}(t), B_{nq}(t)$, etc., by simply replacing each Laplacian with $-q^2$.

Consider a spacetime coordinate transformation

$$x^\mu \to x'^\mu = x^\mu + \epsilon^\mu(x) \tag{5.3.1}$$

with $\epsilon^\mu(x)$ small in the same sense that $h_{\mu\nu}, \delta\rho$, and other perturbations are small. Under this transformation, the metric tensor will be transformed to

$$g'_{\mu\nu}(x') = g_{\lambda\kappa}(x)\frac{\partial x^\lambda}{\partial x'^\mu}\frac{\partial x^\kappa}{\partial x'^\nu} \tag{5.3.2}$$

Instead of working with such transformations, which affect the coordinates and unperturbed fields as well as the perturbations to the fields, it is more convenient to work with so-called gauge transformations, which affect only the field perturbations. For this purpose, after making the coordinate transformation (5.3.1), we relabel coordinates by dropping the prime on the coordinate argument, and we attribute the whole change in $g_{\mu\nu}(x)$ to a change in the perturbation $h_{\mu\nu}(x)$. The field equations should thus be invariant under the gauge transformation $h_{\mu\nu}(x) \to h_{\mu\nu}(x) + \Delta h_{\mu\nu}(x)$, where

$$\Delta h_{\mu\nu}(x) \equiv g'_{\mu\nu}(x) - g_{\mu\nu}(x) \tag{5.3.3}$$

with the unperturbed Robertson-Walker metric $\bar{g}_{\mu\nu}(x)$ left unchanged, and corresponding gauge transformations of other perturbations. To first order in $\epsilon(x)$ and $h_{\mu\nu}(x)$, Eq. (5.3.3) is

[473] To obtain the final formula for $\Pi_{ij,k\ell}(\hat{q})$, one can use the conditions that $\Pi_{ij,k\ell}(\hat{q})$ is a tensor function of $\hat{q}$, symmetric in i and j and in k and ℓ, that $\Pi_{ij,k\ell}(\hat{q}) = \Pi^*_{k\ell,ij}(\hat{q})$, and that $\hat{q}_i\Pi_{ij,k\ell}(\hat{q}) = 0$, to show that $\Pi_{ij,k\ell}(\hat{q})$ is proportional to the quantity on the right-hand side of Eq. (5.2.25). The constant of proportionality can then be found by using Eq. (5.2.15), letting $\hat{q}$ be in the three-direction and setting i, j, k, and ℓ all equal to 1 .

$$\Delta h_{\mu\nu}(x) = g'_{\mu\nu}(x') - \frac{\partial g_{\mu\nu}(x)}{\partial x^\lambda}\epsilon^\lambda(x) - g_{\mu\nu}(x)$$
$$= -\bar{g}_{\lambda\mu}(x)\frac{\partial \epsilon^\lambda(x)}{\partial x^\nu} - \bar{g}_{\lambda\nu}(x)\frac{\partial \epsilon^\lambda(x)}{\partial x^\mu} - \frac{\partial \bar{g}_{\mu\nu}(x)}{\partial x^\lambda}\epsilon^\lambda(x), \tag{5.3.4}$$

or in more detail

$$\Delta h_{ij} = -\frac{\partial \epsilon_i}{\partial x^j} - \frac{\partial \epsilon_j}{\partial x^i} + 2a\dot{a}\delta_{ij}\epsilon_0 \tag{5.3.5}$$
$$\Delta h_{i0} = -\frac{\partial \epsilon_i}{\partial t} - \frac{\partial \epsilon_0}{\partial x^i} + 2\frac{\dot{a}}{a}\epsilon_i \tag{5.3.6}$$
$$\Delta h_{00} = -2\frac{\partial \epsilon_0}{\partial t} \tag{5.3.7}$$

with all quantities evaluated at the same spacetime coordinate point, and indices now raised and lowered with the Robertson-Walker metric, so that $\epsilon_0 = -\epsilon^0$ and $\epsilon_i = a^2\epsilon^i$. The field equations will be invariant only if the same gauge transformation is applied to all tensors, and in particular to the energy-momentum tensor, so that we must transform $\delta T_{\mu\nu}(x) \to \delta T_{\mu\nu}(x) + \Delta\delta T_{\mu\nu}(x)$, where $\Delta\delta T_{\mu\nu}$ is given by a formula [1] analogous to Eq. (5.3.4):

$$\Delta\delta T_{\mu\nu} = -\bar{T}_{\lambda\mu}(x)\frac{\partial \epsilon^\lambda(x)}{\partial x^\nu} - \bar{T}_{\lambda\nu}(x)\frac{\partial \epsilon^\lambda(x)}{\partial x^\mu} - \frac{\partial \bar{T}_{\mu\nu}(x)}{\partial x^\lambda}\epsilon^\lambda(x) \tag{5.3.8}$$

or in more detail

$$\Delta\delta T_{ij} = -\bar{p}\left(\frac{\partial \epsilon_i}{\partial x^j} + \frac{\partial \epsilon_j}{\partial x^i}\right) + \frac{\partial}{\partial t}\left(a^2\bar{p}\right)\delta_{ij}\epsilon_0 \tag{5.3.9}$$
$$\Delta\delta T_{i0} = -\bar{p}\frac{\partial \epsilon_i}{\partial t} + \bar{\rho}\frac{\partial \epsilon_0}{\partial x^i} + 2\bar{p}\frac{\dot{a}}{a}\epsilon_i \tag{5.3.10}$$
$$\Delta\delta T_{00} = 2\bar{\rho}\frac{\partial \epsilon_0}{\partial t} + \dot{\bar{\rho}}\epsilon_0 \tag{5.3.11}$$

Note that we use δ to signify a perturbation, while Δ here denotes the change in a perturbation associated with a gauge transformation.

In order to write these gauge transformations in terms of the scalar, vector, and tensor components introduced in Section 5.1, it is necessary to decompose the spatial part of ϵ^μ into the gradient of a spatial scalar plus a divergenceless vector:

$$\epsilon_i = \partial_i\epsilon^S + \epsilon_i^V, \quad \partial_i\epsilon_i^V = 0 \tag{5.3.12}$$

Then the transformations (5.3.5)-(5.3.7) and (5.3.9)-(5.3.11) give the gauge transformations of the metric perturbation components defined by

Eqs. (5.1.31)-(5.1.33):

$$\Delta A = \frac{2\dot{a}}{a}\epsilon_0, \quad \Delta B = -\frac{2}{a^2}\epsilon^S,$$
$$\Delta C_i = -\frac{1}{a^2}\epsilon_i^V, \quad \Delta D_{ij} = 0, \quad \Delta E = 2\dot{\epsilon}_0 \tag{5.3.13}$$
$$\Delta F = \frac{1}{a}\left(-\epsilon_0 - \dot{\epsilon}^S + \frac{2\dot{a}}{a}\epsilon^S\right), \quad \Delta G_i = \frac{1}{a}\left(-\dot{\epsilon}_i^V + \frac{2\dot{a}}{a}\epsilon_i^V\right)$$

[471] The right-hand sides of Eqs. (5.3.4) and (5.3.8) are known as the Lie derivatives of the metric and energy-momentum tensor, respectively. For a discussion of Lie derivatives, see G&C, Secs. 10.9 and 12.3.

and of the perturbations (5.1.39)-(5.1.41) to the pressure, energy density, and velocity potential

$$\Delta\delta p = \dot{\bar{p}}\epsilon_0, \quad \Delta\delta\rho = \dot{\bar{\rho}}\epsilon_0, \quad \Delta\delta u = -\epsilon_0 \tag{5.3.14}$$

The other ingredients of the energy-momentum tensor are gauge invariant:

$$\Delta\pi^S = \Delta\pi_i^V = \Delta\pi_{ij}^T = \Delta\delta u_i^V = 0 \tag{5.3.15}$$

Note in particular that the conditions $\pi^S = \pi_i^V = \pi_{ij}^T = 0$ for a perfect fluid and the condition $\delta u_i^V = 0$ for potential (i.e., irrotational) flow are gauge invariant.

For the field equations to be gauge-invariant, similar transformations must of course be made on any other ingredients in these equations. For instance, any four-scalar $s(x)$ for which $s'(x') = s(x)$ under arbitrary fourdimensional coordinate transformations would undergo the change $\Delta\delta s(x) \equiv s'(x) - s(x) = s'(x) - s'(x')$, which to first order in perturbations is

$$\Delta\delta s(x) = s(x) - s(x') = -\frac{\partial\bar{s}(t)}{\partial x^\mu}\epsilon^\mu(x) = \dot{\bar{s}}(t)\epsilon_0 \tag{5.3.16}$$

This applies for instance to the number density n or a scalar field φ. For a perfect fluid both p and ρ are defined as scalars, and the gauge transformations in Eq. (5.3.14) of δp and $\delta\rho$ are other special cases of Eq. (5.3.16). Likewise, for a perfect fluid the gauge transformation in Eq. (5.3.14) of δu can be derived from the vector transformation law of u_μ. Because the gauge transformation properties of $\delta\rho, \delta p, \delta u$, etc. do not depend on the conservation laws, Eqs. (5.3.14) and (5.3.15) apply to each individual constituent of the universe in any case in which the energy-momentum tensor is a sum of terms for different constituents of the universe, even if these individual terms are not separately conserved.

We can eliminate the gauge degrees of freedom either by working only with gauge-invariant quantities, [2] or by choosing a gauge. The tensor

quantities π_{ij}^T and D_{ij} appearing in Eq. (5.1.53) are already gauge invariant, and no gauge-fixing is necessary or possible. For the vector quantities π_i^V, δu_i^V, C_i and G_i, we can write Eqs. (5.1.50)-(5.1.52) in terms of the gaugeinvariant quantities π_i^V, δu_i^V and $\tilde{G}_i \equiv G_i - a\dot{C}_i$, or we can fix a gauge for these quantities by choosing ϵ_i^V so that either C_i or G_i vanishes. (Note that $\tilde{G}_i$ is the vector field that we showed in Section 5.1 to decay as $1/a^2$ in the absence of anisotropic inertia.) For the scalar perturbations it is somewhat more convenient to fix a gauge. There are several frequently considered possibilities.

A. Newtonian gauge

Here we choose ϵ^S so that $B = 0$, and then choose ϵ_0 so that $F = 0$. Both choices are unique, so that after choosing Newtonian gauge, there is no remaining freedom to make gauge transformations. It is conventional to write E and A in this gauge as

$$E \equiv 2\Phi, \quad A \equiv -2\Psi, \tag{5.3.17}$$

so that (now considering only scalar perturbations) the perturbed metric has components

$$g_{00} = -1 - 2\Phi, \quad g_{0i} = 0, \quad g_{ij} = a^2\delta_{ij}[1 - 2\Psi]. \tag{5.3.18}$$

The gravitational field equations (5.1.44)-(5.1.47) then take the form

[472] J. M. Bardeen, Phys. Rev. D 22, 1882 (1980).

$$-4\pi G a^2\left[\delta\rho - \delta p - \nabla^2\pi^S\right] = a\dot{a}\dot{\Phi} + \left(4\dot{a}^2 + 2a\ddot{a}\right)\Phi - \nabla^2\Psi + a^2\ddot{\Psi} + 6a\dot{a}\dot{\Psi} \tag{5.3.19}$$

$$-8\pi G a^2\partial_i\partial_j\pi^S = \partial_i\partial_j[\Phi - \Psi] \tag{5.3.20}$$

$$4\pi G a(\bar{\rho} + \bar{p})\partial_i\delta u = -\dot{a}\partial_i\Phi - a\partial_i\dot{\Psi} \tag{5.3.21}$$

$$4\pi G\left(\delta\rho + 3\delta p + \nabla^2\pi^S\right) = +\frac{1}{a^2}\nabla^2\Phi + \frac{3\dot{a}}{a}\dot{\Phi} + 3\ddot{\Psi} + \frac{6\dot{a}}{a}\dot{\Psi} + \frac{6\ddot{a}}{a}\Phi \tag{5.3.22}$$

and the equations (5.1.48) and (5.1.49) of momentum and energy conservation become (aside from modes of zero wave number)

$$\delta p + \nabla^2\pi^S + \partial_0[(\bar{\rho} + \bar{p})\delta u] + \frac{3\dot{a}}{a}(\bar{\rho} + \bar{p})\delta u + (\bar{\rho} + \bar{p})\Phi = 0 \tag{5.3.23}$$

$$\delta\dot{\rho} + \frac{3\dot{a}}{a}(\delta\rho + \delta p) + \nabla^2\left[a^{-2}(\bar{\rho} + \bar{p})\delta u + \frac{\dot{a}}{a}\pi^S\right] - 3(\bar{\rho} + \bar{p})\dot{\Psi} = 0 \tag{5.3.24}$$

In particular, Eq. (5.3.20) shows that Φ and Ψ are not physically independent fields; they differ only by a term arising from the anisotropic part of the stress tensor, and in particular they are equal for a perfect fluid, for which $\pi^S = 0$. The perturbation to the number density of a species of particle whose total number is conserved will satisfy relation (5.1.55), which in Newtonian gauge reads

$$\frac{\partial}{\partial t}\left(\frac{\delta n}{\bar{n}}\right) + \frac{1}{a^2}\nabla^2\delta u - 3\dot{\Psi} = 0 \tag{5.3.25}$$

Given an equation of state for p as a function of ρ (or, if p depends also on other quantities like n, then given also field equations for those quantities) and given also a formula for π^S as a linear combination of the other perturbations (such as for instance the formula $\pi^S = 0$ for a perfect fluid) we can regard Eqs. (5.3.21), (5.3.23), and (5.3.24) (and, where needed, Eq. (5.3.25)) as equations of motion for $\Psi, \delta u$, and $\delta\rho$, respectively, with Φ given in terms of Ψ by Eq. (5.3.20). The remaining equations provide a constraint on the solution of this coupled system of equations. By subtracting $3/a^2$ times Eq. (5.3.19) from Eq. (5.3.22) and then using Eqs. (5.3.20) and (5.3.21) to eliminate π^S and Φ, we find that [2]

$$a^3\delta\rho - 3Ha^3(\bar{\rho} + \bar{p})\delta u - \left(\frac{a}{4\pi G}\right)\nabla^2\Psi = 0 \tag{5.3.26}$$

This is a constraint rather than an equation of motion, because the equations of motion (5.3.21), (5.3.23), and (5.3.24) imply that the left-hand side of Eq. (5.3.26) is time-independent, so that Eq. (5.3.26) only has to be imposed as an initial condition.

B. Synchronous gauge

Here we choose ϵ_0 so that $E = 0$, and then choose ϵ^S so that again $F = 0$. Considering only scalar perturbations, the complete perturbed metric is then

$$g_{00} = -1, \quad g_{0i} = 0, \quad g_{ij} = a^2\left[(1 + A)\delta_{ij} + \frac{\partial^2 B}{\partial x^i\partial x^j}\right] \tag{5.3.27}$$

In this gauge, the Einstein field equations (5.1.44)-(5.1.47) take the form

$$-4\pi G a^2\left[\delta\rho-\delta p-\nabla^2\pi^S\right]=\frac{1}{2}\nabla^2 A-\frac{1}{2}a^2\ddot{A}-3a\dot{a}\dot{A}-\frac{1}{2}a\dot{a}\nabla^2\dot{B} \tag{5.3.28}$$

$$-16\pi G a^2\pi^S=A-a^2\ddot{B}-3a\dot{a}\dot{B} \tag{5.3.29}$$

$$8\pi G a(\bar{\rho}+\bar{p})\delta u=a\dot{A} \tag{5.3.30}$$

$$-4\pi G\left(\delta\rho+3\delta p+\nabla^2\pi^S\right)=\frac{3}{2}\ddot{A}+\frac{3\dot{a}}{a}\dot{A}+\frac{1}{2}\nabla^2\ddot{B}+\frac{\dot{a}}{a}\nabla^2\dot{B} \tag{5.3.31}$$

and the equations (5.1.48) and (5.1.49) of momentum and energy conservation read

$$\delta p+\nabla^2\pi^S+\partial_0[(\bar{\rho}+\bar{p})\delta u]+\frac{3\dot{a}}{a}(\bar{\rho}+\bar{p})\delta u=0, \tag{5.3.32}$$

$$\delta\dot{\rho}+\frac{3\dot{a}}{a}(\delta\rho+\delta p)+\nabla^2\left[a^{-2}(\bar{\rho}+\bar{p})\delta u+\frac{\dot{a}}{a}\pi^S\right]+\frac{1}{2}(\bar{\rho}+\bar{p})\partial_0\left[3A+\nabla^2 B\right]=0. \tag{5.3.33}$$

Note that in this gauge the equation of momentum conservation, which furnishes the equation of motion (the Navier-Stokes equation) for an imperfect fluid, does not depend at all on the perturbed metric, while the equation of energy conservation may be written as

$$\delta\dot{\rho}+\frac{3\dot{a}}{a}(\delta\rho+\delta p)+\nabla^2\left[a^{-2}(\bar{\rho}+\bar{p})\delta u+\frac{\dot{a}}{a}\pi^S\right]+(\bar{\rho}+\bar{p})\psi=0 \tag{5.3.34}$$

where

$$\psi\equiv\frac{1}{2}\left[3\dot{A}+\nabla^2\dot{B}\right]=\frac{\partial}{\partial t}\left(\frac{h_{ii}}{2a^2}\right). \tag{5.3.35}$$

We need A and B separately to calculate the motion of individual particles, but the effect of gravitation on a perfect or imperfect fluid is entirely governed by the quantity ψ. Inspection of the field equation (5.3.31) shows that it provides a differential equation for just this combination of scalar fields:

$$-4\pi G a^2\left(\delta\rho+3\delta p+\nabla^2\pi^S\right)=\frac{\partial}{\partial t}\left(a^2\psi\right) \tag{5.3.36}$$

Also, in synchronous gauge the equation (5.1.55) for particle conservation takes the form

$$\frac{\partial}{\partial t}\left(\frac{\delta n}{\bar{n}}\right)+a^{-2}\nabla^2\delta u+\psi=0. \tag{5.3.37}$$

Given an equation of state for p as a function of ρ (and perhaps n) and a formula expressing π^S as a linear combination of the other scalar perturbations we can use Eqs. (5.3.32), (5.3.34), (5.3.36) (and perhaps

Eq. (5.3.37)) to find solutions for the three independent perturbations δu, $\delta\rho$, and ψ, respectively. The left-over equations (5.3.28)-(5.3.30) are not needed, for a reason given in Section 5.1: the full set of equations (5.3.28)(5.3.33) are not independent, because the equations of energy and momentum conservation can be derived from the Einstein field equations.

If we need to know A and B separately we can find them from ψ and $\delta\rho$. By adding 3 times Eq. (5.3.28), plus 1/2 the Laplacian of Eq. (5.3.29), plus a^2 times Eq. (5.3.31), we obtain the simple relation

$$\nabla^2 A = -8\pi G a^2 \delta\rho + 2Ha^2\psi, \tag{5.3.38}$$

where as usual $H \equiv \dot{a}/a$. After A is found in this way, we can find B from A and ψ by solving Eq. (5.3.35).

Synchronous gauge was widely used in early calculations of the evolution of perturbations in cosmology, starting with the ground-breaking work of Lifshitz in 1946.[3] In the 1980s synchronous gauge became unpopular, because of a feature emphasized by Bardeen: [2] even after we impose the conditions $E = F = 0$, we are left with a residual gauge invariance. We can see from Eq. (5.3.13) that E and F are not affected by a gauge transformation with

$$\epsilon_0(\mathbf{x}, t) = -\tau(\mathbf{x}), \quad \epsilon^S(\mathbf{x}, t) = a^2(t)\tau(\mathbf{x}) \int a^{-2}(t)dt \tag{5.3.39}$$

where $\tau(\mathbf{x})$ is an arbitrary function of $\mathbf{x}$, but not of t. But under this transformation A and B do change

$$\Delta A = -\frac{2\dot{a}\tau}{a}, \quad \Delta B = -2\tau \int a^{-2}(t)dt \tag{5.3.40}$$

In particular, the combination (5.3.35) undergoes the change

$$\Delta\psi = -3\tau \frac{d}{dt}\left(\frac{\dot{a}}{a}\right) - a^{-2}\nabla^2\tau. \tag{5.3.41}$$

Also, the changes in the perturbations to the energy density, pressure, and velocity potential are given by Eqs. (5.3.14) and (5.3.39) as

$$\Delta\delta p = -\dot{\bar{p}}\tau, \quad \Delta\delta\rho = -\dot{\bar{\rho}}\tau, \quad \Delta\delta u = \tau, \tag{5.3.42}$$

while π^S is invariant. The same transformation rules apply for any one of the individual constituents of the universe. Any scalar perturbation δs such as the number density perturbation δn or a scalar field perturbation

$\delta\varphi$ undergoes a change like that of the pressure and density perturbations:

$$\Delta\delta s = -\dot{\bar{S}}\tau \tag{5.3.43}$$

The reader can check that all of the equations (5.3.28)-(5.3.34) and (5.3.37) are invariant under these residual gauge transformations. This being the case, for any solution $\psi, \delta p, \delta\rho, \delta u, \delta n$, etc. of these equations there will be another solution $\psi + \Delta\psi, \delta p + \Delta\delta p, \delta\rho + \Delta\delta\rho, \delta u + \Delta\delta u, n + \Delta\delta n$, etc., and since the field equations are linear, this means that $\Delta\psi, \Delta\delta p, \Delta\delta\rho, \Delta\delta u, \Delta\delta n$, etc., is also a solution. (For this solution there is no scalar anisotropic inertia, because π^S is gauge invariant.) This is a nuisance, because in finding solutions of the field equations we keep having to check that our solution represents a physical disturbance, not a mere change of gauge.

However, this is not a problem if we can remove the residual gauge symmetry in any natural way. This is the case if the universe contains a fluid (such as cold dark matter) whose individual particles are moving at speeds much less than that of light. In this case, the space-space components T_D^{ij} of the energy-momentum tensor for that fluid are negligible, so we can take $\bar{p}_D = 0$, $\bar{\rho}_D \propto a^{-3}$, and $\delta p_D = \pi_D^S = 0$ in the equation (5.3.32) of momentum conservation for this fluid, which tells us then that δu_D is time-independent. According to Eq. (5.3.42) (which

[473] E. Lifshitz, J. Phys. USSR 10, 116 (1946). Also see G&C, Sec. 15.10.

applies separately to each constituent of the universe) a time-independent velocity potential δu_D can always be removed in synchronous gauge by a residual gauge transformation, with $\tau = -\delta u_D$. There is then no longer any ambiguity in the choice of gauge. These features make synchronous gauge particularly convenient in dealing with the later stages of cosmological evolution, when cold dark matter plays a prominent role.

C. Newtonian/synchronous conversion

We will find it convenient to do calculations using Newtonian gauge in some eras, and synchronous gauge in others. To connect results for different eras, we need to be able to convert them from one gauge to another. [4]

Suppose first that we begin in Newtonian gauge, and make an infinitesimal coordinate transformation $x^\mu \to x^\mu + \epsilon^\mu$, with $\epsilon_i = \partial_i \epsilon^S$ so as not to induce vector perturbations. According to Eqs. (5.3.13) and (5.3.17), in order to give E the synchronous gauge value $E = 0$, we need

$$\dot{\epsilon}_0 = -\Phi \tag{5.3.44}$$

Then according to Eq. (5.3.13), to keep $F = 0$ we need

$$\frac{\partial}{\partial t}\left(\frac{\epsilon^S}{a^2}\right) = -\frac{\epsilon_0}{a^2}. \tag{5.3.45}$$

The A and B components of the spatial metric in synchronous gauge are given by Eqs. (5.3.13) and (5.3.17):

$$A = -2\Psi + 2H\epsilon_0, \quad B = -\frac{2}{a^2}\epsilon^S, \tag{5.3.46}$$

where $H \equiv \dot{a}/a$. In particular, the field ψ is

$$\psi = -3\dot{\Psi} + 3\frac{\partial}{\partial t}(H\epsilon_0) + \frac{\nabla^2 \epsilon_0}{a^2}. \tag{5.3.47}$$

Also, Eq. (5.3.14) allows us to calculate the synchronous gauge pressure perturbation δp^s, energy density perturbation $\delta\rho^s$, and velocity potential δu^s from the corresponding quantities $\delta p, \delta\rho$, and δu in Newtonian gauge:

$$\delta p^s = \delta p + \epsilon_0 \dot{\bar{p}}, \quad \delta\rho^s = \delta\rho + \epsilon_0 \dot{\bar{\rho}}, \quad \delta u^s = \delta u - \epsilon_0. \tag{5.3.48}$$

Given Φ we can calculate ϵ_0 from Eq. (5.3.44), and then given Ψ we can obtain ψ from Eq. (5.3.47) and the synchronous gauge pressure, energy density, and velocity potential perturbations from Eq. (5.3.48). The quantity ϵ_0 is determined by Eq. (5.3.44) only up to a time-independent function of position, so the values of the synchronous gauge quantities A, B, ψ, $\tilde{p}, \tilde{\rho}$, and $\delta\tilde{u}$ are only determined up to a residual gauge transformation (5.3.40)-(5.3.42).

Next suppose that we begin in synchronous gauge, with metric fields A and B, and want to convert to Newtonian gauge. According to Eq. (5.3.13), to make g_{ij} proportional to δ_{ij} we need to take

$$\epsilon^S = a^2 B/2. \tag{5.3.49}$$

Then to keep $g_{i0} = 0$, Eq. (5.3.13) tells us that we must take

$$\epsilon_0 = -a^2 \dot{B}/2 \tag{5.3.50}$$

[474] See, for instance, C.-P. Ma and E. Bertschinger, Astrophys. J. 455, 7 (1995).

Using Eq. (5.3.13) again together with the definitions (5.3.18), we have then

$$\Phi = \dot{\epsilon}_0 = -\frac{1}{2}\frac{\partial}{\partial t}\left(a^2\dot{B}\right) \tag{5.3.51}$$

$$\Psi = -\frac{1}{2}\left(A + \frac{2\dot{a}}{a}\epsilon_0\right) = -\frac{1}{2}A + \frac{a\dot{a}}{2}\dot{B}. \tag{5.3.52}$$

In contrast to the previous case, Eqs. (5.3.51) and (5.3.52) give Φ and Ψ uniquely. Not only that - it is easy to see that the results for Φ and Ψ are unaffected if the A and B with which we start are subjected to the residual gauge transformation (5.3.40).

D. Other gauges

In choosing a gauge, it is not necessary to impose conditions only on the scalar fields appearing in the metric tensor. [5] Instead, some of the gauge conditions can impose constraints on the scalars appearing in the energymomentum tensor. For instance, in co-moving gauge we choose ϵ_0 so that $\delta u = 0$ (which for scalar perturbations makes the velocity perturbation δu^i vanish). Where the only "matter" is a single scalar field, as in popular theories of inflation, this means that the time coordinate is defined so that at any given time the scalar field equals its unperturbed value, with all perturbations relegated to components of the metric. [6] In the constant density gauge we choose ϵ_0 so that $\delta\rho = 0$. In either case, after fixing ϵ_0 we can make F vanish with a suitable choice of ϵ^S, so that the scalar perturbations still have $g_{i0} = 0$. Note that although this procedure fixes ϵ_0, it only fixes ϵ^S up to terms of the form $a^2(t)\tau(\mathbf{x})$, so these gauges share the drawback of synchronous gauge, of leaving a residual gauge symmetry.

10.5.4 5.4 Conservation outside the horizon

The perturbations that concern us are believed to have originated in quantum fluctuations during an era of inflation in the very early universe, discussed in Chapter 10. That early time and the much later time when these perturbations are observed are separated by a time interval in which the equations governing perturbations are not well known. For instance, at the end of the era of inflation there was a time of so-called reheating, during which the energy of the vacuum was transferred to ordinary matter and radiation, but we have no idea what particles were first created during reheating or how the energy transfer took place. Later, there was presumably a time when some particles effectively stopped interacting with the rest of matter and radiation, and became what is now observed as cold dark matter, but we can only guess when this was and how it happened.

The only reason that we are able to use inflationary theories to make any predictions at all about observable perturbations despite these uncertainties is that the wavelengths of the perturbations that concern us were outside the horizon during a period that extends from well before the end of inflation until relatively near the present (and hence includes the times of reheating and cold dark matter decoupling), in the sense that the physical wave number q/a during this period was much less than the expansion rate $H \equiv \dot{a}/a$. During inflation q/a decreases with time more-or-less exponentially while H is roughly constant, so all perturbations originally had $q/a \gg H$ but except for very short wavelengths eventually have $q/a \ll H$. Then during the radiation and matter-dominated eras a increases like $t^{1/2}$ or $t^{2/3}$ while H falls like

[475] A great variety of different gauges are described by H. Kodama and M. Sasaki, Prog. Theor. Phys. Suppl. 78, 1 (1984).

[6] For instance, this gauge was used in calculations of non-Gaussian corrections to cosmological correlations by J. Maldacena, J. High Energy Phys. 0305, 013 (2003) [astro-ph/0210603].

$1/t$, so except for the longest wavelengths the perturbations that had $q/a \ll H$ at the end of inflation eventually again have $q/a \gg H$. During the intervening period when perturbations were outside the horizon, the scalar and tensor fluctuations were subject to certain conservation laws, that allow us to connect the distant past to the relatively recent past.

As we shall see below, for scalar modes it is the quantity defined in Newtonian gauge by [1]

$$\mathcal{R}_q \equiv -\Psi_q + H\delta u_q \tag{5.4.1}$$

that in certain circumstances is conserved outside the horizon. (Recall that δu is the velocity potential for the total energy-momentum tensor.) Equivalently, there is another quantity [2]

$$\zeta_q \equiv -\Psi_q + \frac{\delta\rho_q}{3(\bar{\rho}+\bar{p})} \tag{5.4.2}$$

that according to the constraint (5.3.26) is related to $\mathcal{R}_q$ by

$$\zeta_q = \mathcal{R}_q - \frac{q^2\Psi_q}{12\pi G(\bar{\rho}+\bar{p})a^2} \tag{5.4.3}$$

The difference is of relative order $(q/aH)^2$, so for $q/a \ll H$ the quantity ζ_q is conserved outside the horizon if $\mathcal{R}_q$ is.

The importance of $\mathcal{R}_q$ in the work of ref. 1 is that (as will be shown below) it is conserved outside the horizon in inflation driven by a single scalar

field. But this is not enough for our purposes. After inflation, the universe becomes filled with a number of types of matter and radiation, and $\mathcal{R}_q$ is not necessarily conserved outside the horizon under these circumstances. What we need is a theorem that says that, whatever the constituents of the universe, there is always a solution of the field equations for which $\mathcal{R}_q$ and ζ_q are conserved outside the horizon. Such a solution is called "adiabatic," for reasons explained later. If cosmological fluctuations are described by such a solution during inflation, then they will continue to be described by such a solution and $\mathcal{R}_q$ and ζ_q will remain constant as long as the perturbation is outside the horizon, because this is a solution under all circumstances.

This result (and a corresponding result for tensor modes) is contained in the following theorem: [3] Whatever the contents of the universe, there are two independent adiabatic physical scalar solutions of the Newtonian gauge field equations for which the quantity $\mathcal{R}_q$ is time-independent in the limit $q/a \ll H$, and there is one tensor mode for which the tensor amplitude $\mathcal{D}_q$ is time-independent in the limit $q/a \ll H$. In this limit one of the scalar modes has $\mathcal{R}_q \neq 0$; the scalar metric components are

$$\Phi_q(t) = \Psi_q(t) = \mathcal{R}_q\left[-1 + \frac{H(t)}{a(t)}\int_{\mathcal{T}}^{t} a\left(t'\right)dt'\right] \tag{5.4.4}$$

the perturbation to any four-scalar $s(x)$ (such as the energy density, pressure, inflaton field, etc.) is given by

$$\delta s_q(t) = -\frac{\mathcal{R}_q\dot{\bar{s}}(t)}{a(t)}\int_{\mathcal{T}}^{t} a\left(t'\right)dt' \tag{5.4.5}$$

and the perturbation to the velocity potential is

[471] The constancy of $\mathcal{R}$ was noted in various special cases by J. M. Bardeen, Phys. Rev. D 22, 1882 (1980); D. H. Lyth, Phys. Rev. D 31, 1792 (1985). For reviews, see J. Bardeen, in Cosmology and Particle Physics, eds. Li-zhi Fang and A. Zee (Gordon & Breach, New York, 1988); A. R. Liddle and D. H. Lyth, Cosmological Inflation and Large Scale Structure (Cambridge University Press, Cambridge, UK, 2000).

[2] J. M. Bardeen, P. J. Steinhardt, and M. S. Turner, Phys. Rev. D 28, 679 (1983). This quantity was re-introduced by D. Wands, K. A. Malik, D. H. Lyth, and A. R. Liddle, Phys. Rev. D 62, 043527 (2000).

$$\delta u_q(t) = \frac{\mathcal{R}_q}{a(t)} \int_{\mathcal{T}}^{t} a\,(t')\,dt' \tag{5.4.6}$$

where $\mathcal{T}$ is an arbitrary initial time, the same in all integrals. The other scalar mode has $\mathcal{R}_q = 0$, and

$$\Phi_q(t) = \Psi_q(t) = \frac{\mathcal{C}_q H(t)}{a(t)}, \quad \delta s_q(t) = -\frac{\mathcal{C}_q \dot{\bar{s}}(t)}{a(t)}, \quad \delta u_q(t) = \frac{\mathcal{C}_q}{a(t)} \tag{5.4.7}$$

where $\mathcal{C}_q$ is time-independent. For $q/a \ll H$, the anisotropic inertia components π_q^S, π_{iq}^V, and π_{ijq}^T vanish in both adiabatic scalar modes and in the conserved tensor mode, even when some mean free times are comparable

with the Hubble time. These are physical solutions for scalar as well as tensor modes, because the choice of Newtonian gauge leaves no remaining gauge freedom.

The proof of the theorem is based on the observation that in the special case of a spatially homogeneous universe, the coordinate space Newtonian gauge field equations and dynamical equations for matter and radiation (as well as the condition of spatial homogeneity) are invariant under coordinate transformations that are not symmetries of the unperturbed metric. [4] In Newtonian gauge, general first-order spatially homogeneous scalar and tensor perturbations to the metric take the form

$$h_{00} = -2\Phi(t), \quad h_{i0} = 0, \quad h_{ij} = -2\delta_{ij}a^2(t)\Psi(t) + a^2(t)D_{ij}(t)$$

with D_{ij} subject to the condition that $D_{ii} = 0$. Spatial homogeneity also requires that all pressures, densities, velocity potentials, etc. are functions only of time. The Newtonian gauge field equations for these spatially homogeneous perturbations are necessarily invariant under those gauge transformations of the form (5.3.4)-(5.3.7), (5.3.14)-(5.3.16) that preserve the conditions for Newtonian gauge and spatial homogeneity. Eq. (5.3.7) shows that in order for h_{00} to remain spatially homogeneous, ϵ_0 must be of the form

$$\epsilon_0(\mathbf{x}, t) = \epsilon(t) + \chi(\mathbf{x}),$$

so that

$$\Delta\Phi = \dot{\epsilon}$$

Eq. (5.3.6) then shows that in order for the h_{i0} to remain equal to zero, ϵ_i must have the form

$$\epsilon_i(\mathbf{x}, t) = a^2(t)f_i(\mathbf{x}) - a^2(t)\frac{\partial\chi(\mathbf{x})}{\partial x^i}\int \frac{dt}{a^2(t)}$$

Eq. (5.3.5) then shows that

$$\Delta h_{ij} = -a^2\left(\frac{\partial f_i}{\partial x^j} + \frac{\partial f_j}{\partial x^i}\right) + 2\delta_{ij}a\dot{a}[\epsilon + \chi] - 2\frac{\partial^2\chi}{\partial x^i \partial x^j}\int \frac{dt}{a^2}$$

In order not to introduce any $\mathbf{x}$-dependence in h_{ij}, we must take χ constant, in which case by shifting it into ϵ it can be taken to be zero, and we must also take f_i to have the form

[473] S. Weinberg, Phys. Rev. D 67, 123504 (2003) [astro-ph/0302326]. Also see the appendix of S. Weinberg, Phys. Rev. D 69, 023503 (2004) [astro-ph/0306304].

$f_i(\mathbf{x}) = \omega_{ij}x^j$, with ω_{ij} a constant matrix. (An $\mathbf{x}$-independent term in f_i would have no effect on the metric or anything

else, and so can be ignored here.) Then

$$\Delta h_{ij} = -a^2\left[\omega_{ij} + \omega_{ji}\right] + 2\delta_{ij}a\dot{a}\epsilon.$$

We compare this with Eq. (5.1.33) (with the Newtonian gauge conditions $B = C_i = 0$ and $A = -2\Psi$), which gives

$$\Delta h_{ij} = -2a^2\delta_{ij}\Delta\Psi + a^2\Delta D_{ij}$$

Matching the terms in Δh_{ij} that are either proportional to δ_{ij} or traceless gives

$$\Delta\Psi = \frac{1}{3}\omega_{ii} - H\epsilon,$$
$$\Delta D_{ij} = -\omega_{ij} - \omega_{ji} + \frac{2}{3}\delta_{ij}\omega_{kk}.$$

(Note that an antisymmetric term in ω_{ij} would have no effect, because the unperturbed metric is invariant under three-dimensional rotations.) The corresponding gauge transformations of the quantities appearing in the energy-momentum tensor and of general scalars are given by Eqs. (5.3.14)(5.3.16). Since $\{h_{\mu\nu}, T_{\mu\nu}\}$ and $\{h_{\mu\nu} + \Delta h_{\mu\nu}, T_{\mu\nu} + \Delta T_{\mu\nu}\}$ are both solutions of the field equations and conservation equations, their difference must also be such a solution. We conclude that there is always a spatially homogeneous solution of the Newtonian gauge field and conservation equations, with scalar perturbations

$$\Psi = H\epsilon - \omega_{ii}/3, \quad \Phi = -\dot{\epsilon} \tag{5.4.8}$$
$$\delta p = -\dot{\bar{p}}\epsilon, \quad \delta\rho = -\dot{\bar{\rho}}\epsilon, \quad \delta u = \epsilon, \quad \pi^S = 0 \tag{5.4.9}$$

and more generally for any four-scalar s

$$\delta s = -\dot{\bar{S}}\epsilon. \tag{5.4.10}$$

(The reader can check that when we drop all spatial gradients, then the perturbations (5.4.8)-(5.4.10) satisfy the Newtonian gauge field equations (5.3.19)-(5.3.22), the conservation laws (5.3.23)-(5.3.24) and (5.3.25), and the constraint (5.3.26).) There is also a spatially homogeneous solution with a tensor perturbation

$$D_{ij} \propto \omega_{ij} - \frac{1}{3}\delta_{ij}\omega_{kk}, \quad \pi^T_{ij} = 0. \tag{5.4.11}$$

(This is obviously a solution of Eq. (5.1.53), but it includes the not so obvious information that the equations that determine π^T_{ij} necessarily give $\pi^T_{ij} = 0$ for D_{ij} constant, even if some particle collision rates become comparable

with H.) Equivalently, Eqs. (5.4.8)-(5.4.11) are solutions for the Fourier transforms of the perturbations with zero wave number.

So far, ϵ is an arbitrary function of time, and ω_{ij} is an unrelated arbitrary constant 4×4 matrix. But these are just gauge modes for zero wave number. On the other hand, if they can be extended to non-zero wave number they become physical modes, since the choice of

[474] In this respect, the theorem proved here is similar to the Goldstone theorem of quantum field theory; see J. Goldstone, Nuovo Cimento 9, 154 (1961); J. Goldstone, A. Salam, and S. Weinberg, Phys. Rev. 127, 965 (1962). The modes for which $\mathcal{R}_q$ or $\mathcal{D}_q$ are constant outside the horizon take the place here of the Goldstone bosons that become free particles for long wavelength.

Newtonian gauge leaves no residual gauge symmetries except for zero wave number. For the tensor modes there is no problem; in this case there are no field equations that disappear for zero wave number, so the solution with D_{ij} timeindependent automatically has an extension to a physical mode for non-zero wave number. But matters are more complicated for the scalar modes.

For the scalar modes the field equation (5.3.20) disappears in the limit of zero wave number, so to get a physical mode we must impose on the perturbations the condition

$$\Phi = \Psi \tag{5.4.12}$$

(The condition $\delta u = \epsilon$ that is required for Eq. (5.3.21) to be satisfied for $q \neq 0$ is already satisfied, according to Eq. (5.4.9).) Inserting Eq. (5.4.8) in (5.4.12) gives a differential equation for ϵ :

$$\dot{\epsilon} = -H\epsilon + \omega_{kk}/3 \tag{5.4.13}$$

Also, Eq. (5.4.8) for Ψ and Eq. (5.4.9) for δu give the quantity $\mathcal{R}$ defined by Eq. (5.4.1) the time-independent value

$$\mathcal{R} = \omega_{kk}/3 \tag{5.4.14}$$

There is a general solution of Eq. (5.4.13) for $\epsilon(t)$ with $\mathcal{R} \neq 0$:

$$\epsilon(t) = \frac{\mathcal{R}}{a(t)} \int_{\mathcal{T}}^{t} a\left(t'\right) dt' \tag{5.4.15}$$

with $\mathcal{T}$ arbitrary. Using Eq. (5.4.15) in Eq. (5.4.8) gives the explicit solution (5.4.4) for large wavelengths

$$\Psi = \Phi = \mathcal{R}\left[-1 + \frac{H(t)}{a(t)} \int_{\mathcal{T}}^{t} a\left(t'\right) dt'\right] \tag{5.4.16}$$

Eq. (5.4.9) gives

$$\frac{\delta p}{\dot{\bar{p}}} = \frac{\delta \rho}{\dot{\bar{\rho}}} = -\delta u = -\frac{\mathcal{R}}{a(t)} \int_{\mathcal{T}}^{t} a\left(t'\right) dt' \tag{5.4.17}$$

and more generally for any four-scalar Eq. (5.4.10) gives

$$\frac{\delta s}{\dot{\bar{s}}} = -\frac{\mathcal{R}}{a(t)} \int_{\mathcal{T}}^{t} a\left(t'\right) dt' \tag{5.4.18}$$

Because for any $\mathcal{T}$, Eq. (5.4.15) is a solution of Eq. (5.4.13) with the same value of $\mathcal{R}$, the difference of two of these solutions with different values of $\mathcal{T}$ is also a solution, but with $\mathcal{R} = 0$. For this solution

$$\epsilon(t) = \frac{\mathcal{C}}{a(t)} \tag{5.4.19}$$

with $\mathcal{C}$ another constant, and

$$\Psi = \Phi = \frac{\mathcal{C}H(t)}{a(t)} \tag{5.4.20}$$

$$\frac{\delta \rho}{\dot{\bar{\rho}}} = \frac{\delta p}{\dot{\bar{p}}} = -\delta u = \frac{\delta s}{\dot{\bar{s}}} = -\frac{\mathcal{C}}{a(t)} \tag{5.4.21}$$

and likewise for individual constituents of the universe. (Since $a(t)$ increases and $H(t)$ decreases with time, this is a decaying mode, which is usually assumed to play no significant role at late times.) Note in particular that these scalar modes have equal values for $\delta\rho_\alpha/\dot{\bar{\rho}}_\alpha$ for all individual constituents α of the universe, whether or not energy is separately conserved for these constituents. For this reason, such perturbations are called adiabatic. [5] For the same reason, any other solutions are called entropic. (Sometimes such other solutions are called zero-curvature modes, but this is misleading, because setting $\Phi = \Psi = 0$ does not usually give a solution at all.)

We have shown that for sufficiently small wave number (in practice, this means $q/a \ll H$) there are always two adiabatic physical solutions for scalar perturbations that take the form (5.4.16)-(5.4.18) and (5.4.20)-(5.4.21), with $\mathcal{R}$ and $\mathcal{C}$ arbitrary constants, and a physical solution for tensor perturbations that takes the form (5.4.11) with ω_{ij} an arbitrary constant matrix. Since the equations we have solved are homogeneous, it follows that there are also solutions of the same form for which $\mathcal{R}, \mathcal{C}$, and ω_{ij} are arbitrary timeindependent functions of q. This concludes the proof. [6]

This theorem shows that if the perturbations produced during inflation are actually in the modes found above at the end of inflation, then they stay in these modes as long as the perturbations remain outside the horizon, and in particular $\mathcal{R}_q$ and $\mathcal{D}_q$ remain constant, since these modes are solutions of the equations whatever the constituents of the universe may become. In particular, the wavelengths that will interest us are far outside the horizon during the era of reheating that is supposed to follow inflation, so if the scalar perturbations are adiabatic at the end of inflation, then reheating cannot generate entropic perturbations. [7]

The question that is left unanswered by this theorem is whether the scalar perturbations produced during inflation are actually in these modes at the end of inflation. This is often a matter of counting. We know that there are always two independent adiabatic solutions of the differential equations governing the scalar fluctuations, so if these equations have no more than two independent solutions, then any perturbations must be adiabatic. As we will see in Chapter 10, this counting shows that all solutions are adiabatic for inflation with a single inflaton field.

But it must not be thought that if observation of the cosmic microwave background reveals purely adiabatic perturbations at the time of last scattering, then the perturbations must have been adiabatic at the end of inflation. In a state of complete local thermal equilibrium in which all conserved quantum numbers vanish (such as is usually assumed to have existed at some early time in theories of cosmological baryonsynthesis or leptonsynthesis, like those discussed in Section 3.3) there are only two scalar degrees of freedom, the temperature and the gravitational potential $\Phi = \Psi$. They are governed by coupled first-order ordinary differential equations, so there are just two independent solutions, which must be adiabatic since there are always at least two adiabatic solutions. Thus whatever happens during inflation, if the universe subsequently spends sufficient time in a state of local thermal equilibrium with no non-zero conserved quantities, then the perturbations become adiabatic, and they remain adiabatic subsequently, even when the conditions of local thermal equilibrium are no longer satisfied. [8]

[475] For instance, if several constituents (such as an electron-positron plasma, and photons) each have a density and pressure that depends (even when perturbed) only on the temperature, then $\delta\rho_\alpha(T) = \rho'_\alpha(T)\delta T$ and $d\bar{\rho}_\alpha(T)/dt = \rho'_\alpha(T)\dot{\bar{T}}$, so $\delta\rho_\alpha/\dot{\bar{\rho}}_\alpha = \delta T/\dot{\bar{T}}$, and likewise for pressure and any other scalars.

[6] The existence of solutions with $\delta s_q/\dot{\bar{s}}$ equal for all four-scalars s such as energy densities, pressures, etc. (but not the detailed solutions (5.4.4)-(5.4.7)) seems to have been generally accepted for a long time. An intuitive "separate universe" argument for the existence of solutions for which $\delta\rho_{\alpha q}/\dot{\bar{\rho}}_\alpha$ are equal for all constituents α of the universe has been given by D. H. Lyth and D. Wands, Phys. Rev. D 68, 103516 (2003); also see D. Wands, K. A. Malik, D. H. Lyth, and A. R. Liddle, Phys. Rev. D 62, 043627 (2000); A. R. Liddle and D. H. Lyth, Cosmological Inflation and Large-Scale Structure (Cambridge University Press, 2000). This reasoning has been extended beyond perturbation theory by D. H. Lyth, K. A. Malik, and M. Sasaki, J. Cosm. & Astropart. Phys. 0505, 004 (2005) [astro-ph/0411220]. But this

The use of conservation laws to connect different cosmological eras is not limited to Newtonian gauge. Indeed, both ζ_q and $\mathcal{R}_q$ can be put in

a gauge invariant form. It is only necessary to remark that according to Eqs. (5.3.13) and (5.3.14), the quantities $A/2 - H\delta\rho/\dot{\bar{\rho}}$ and $A/2 + H\delta u$ are gauge invariant, and that they reduce in Newtonian gauge to the quantities (5.4.2) and (5.4.1), respectively, so in any gauge

$$\zeta_q = A_q/2 - H\delta\rho_q/\dot{\bar{\rho}}, \quad \mathcal{R}_q = A_q/2 + H\delta u_q, \tag{5.4.22}$$

provided of course that $A, \delta\rho$, and δu are all calculated in the same gauge.
For instance, in synchronous gauge Eq. (5.3.38) gives

$$q^2 A_q = 8\pi G a^2 \delta\rho_q - 2Ha^2\psi_q, \tag{5.4.23}$$

so in this gauge ζ_q and $\mathcal{R}_q$ can be expressed in terms of the convenient gravitational variable ψ_q by

$$\begin{aligned} q^2\zeta_q &= -a^2 H\psi_q + 4\pi G a^2\delta\rho_q - q^2 H\delta\rho_q/\dot{\bar{\rho}} \\ q^2\mathcal{R}_q &= -a^2 H\psi_q + 4\pi G a^2\delta\rho_q + q^2 H\delta u_q \end{aligned} \tag{5.4.24}$$

of course with the understanding that $\delta\rho_q$ and δu_q are here calculated in synchronous gauge. This result can also be derived directly from the Newtonian gauge formulas (5.4.1) and (5.4.2) by using the rules for transforming from Newtonian to synchronous gauge given in the previous section.

There is a convenient general formula for the rate of change of ζ_q and $\mathcal{R}_q$ that holds for $q/a \ll H$ whether or not the cosmological fluctuations are in an adiabatic mode. To derive this formula, we use the Newtonian gauge energy-conservation law (5.3.24), which for $q/a \ll H$ gives

$$\delta\dot{\rho}_q + 3H\left(\delta\rho_q + \delta p_q\right) = 3(\bar{\rho} + \bar{p})\dot{\Psi}_q, \tag{5.4.25}$$

and the corresponding unperturbed conservation law

$$\dot{\bar{\rho}} = -3H(\bar{\rho} + \bar{p}). \tag{5.4.26}$$

It is then a matter of simple algebra to calculate that for $q/a \ll H$

$$\dot{\zeta}_q = \frac{\dot{\bar{\rho}}\delta p_q - \dot{\bar{p}}\delta\rho_q}{3(\bar{\rho} + \bar{p})^2}. \tag{5.4.27}$$

For $q/a \ll H$, the same formula then also gives $\dot{\mathcal{R}}_q$. It should be noted that according to Eq. (5.3.14) the quantity on the right-hand side is gaugeinvariant, so we can check whether or not ζ_q and $\mathcal{R}_q$ are time-independent by evaluating $\dot{\bar{\rho}}\delta p_q - \dot{\bar{p}}\delta\rho_q$ in any gauge.

In particular, if for arbitrary perturbations $\bar{p} + \delta p$ is a function $F(\bar{\rho} + \delta\rho)$ of the perturbed energy density alone, then $\dot{\bar{p}} = F'(\bar{\rho})\dot{\bar{\rho}}$ and $\delta p_q = F'(\bar{\rho})\delta\rho_q$, so the terms in the numerator of

[47] sort of argument only shows that there is a solution satisfying this condition for zero wave number. As we have seen, there are indeed many such solutions for zero wave number, most of which have no physical significance because they cannot be extended to finite wave number. The proof presented here shows that the requirement that the solution can be extended to finite wave number yields just two solutions, described by Eqs. (5.4.4)-(5.4.7). It is this requirement that makes it necessary for the infinitesimal redefinition of the time coordinate, used in the "separate universe" argument to generate the solutions for zero wave number, to be accompanied with an infinitesimal rescaling of the space coordinate.

[7] S. Weinberg, Phys. Rev. D 70, 043541 (2004) (astro-ph/0401313).

[8] S. Weinberg, Phys. Rev. D 70, 083522 (2004) (astro-ph/0405397).

the right-hand side of Eq. (5.4.27) cancel,
and so ζ_q and $\mathcal{R}_q$ are conserved outside the horizon, even if the fluctuations are not in an adiabatic mode. [9] This is the case for instance if all abundant particles are highly relativistic, in which case the total perturbed pressure is 1/3 the total perturbed energy density, or if they are highly non-relativistic, in which case the total perturbed pressure is negligible. On the other hand, the theorem proved earlier in this section tells us that ζ_q and $\mathcal{R}_q$ are conserved outside the horizon in the adiabatic modes, even in cases (such as inflation with a single scalar field) for which the perturbed pressure is not given as a function only of the perturbed energy density.

The proof of Eq. (5.4.27) depended only on the energy conservation equations (5.4.25) and (5.4.26), not on the gravitational field equations. Therefore, if there is a constituent α of the universe that is energetically isolated, in the sense of not exchanging energy with the rest of the matter and radiation of the universe, then for $q/a \ll H$ the quantity

$$\zeta_{\alpha q} \equiv -\Psi_q + \delta\rho_{\alpha q}/3\left(\bar{\rho}_\alpha + \bar{p}_\alpha\right) \tag{5.4.28}$$

calculated using the energy density ρ_α and pressure p_α of the isolated constituent, satisfies the gauge-invariant relation [10]

$$\dot{\zeta}_{\alpha q} = \frac{\dot{\bar{\rho}}_\alpha \delta p_{\alpha q} - \dot{\bar{p}}_\alpha \delta\rho_{\alpha q}}{3\left(\bar{\rho}_\alpha + \bar{p}_\alpha\right)^2} \tag{5.4.29}$$

In particular, $\zeta_{\alpha q}$ (and hence also $\mathcal{R}_{\alpha q}$) is conserved outside the horizon if the perturbed pressure of the isolated constituent is a function only of its perturbed energy density. [11] (As we will see in Section 6.1, this is actually a good approximation for each of the individual constituents of the universe at times after the temperature dropped below about 10^{10} K, when neutrinos and antineutrinos no longer had significant interactions with matter and radiation.) In this case, Eq. (5.4.28) can be regarded as a convenient formula for the fractional density fluctuation outside the horizon in Newtonian gauge

$$\frac{\delta\rho_{\alpha q}}{3\left(\bar{\rho}_\alpha + \bar{p}_\alpha\right)} = \zeta_{\alpha q} + \Psi_q \tag{5.4.30}$$

with $\zeta_{\alpha q}$ time-independent.

There is a corresponding result in synchronous gauge: For long wavelengths the energy conservation equation (5.3.34) for an energetically isolated component of the universe takes the form

$$\delta\dot{\rho}^s_{\alpha q} + 3H\left(\delta\rho^s_{\alpha q} + \delta p^s_{\alpha q}\right) + \left(\bar{\rho}_\alpha + \bar{p}_\alpha\right)\psi_q = 0, \tag{5.4.31}$$

the superscript s denoting synchronous gauge. If also p_α is either negligible or a function only of ρ_α, then this can be written as

$$\frac{d}{dt}\left(\frac{\delta\rho^S_{\alpha q}}{\bar{\rho}_\alpha + \bar{p}_\alpha}\right) = -\psi_q,$$

[479] If the total pressure is a function only of the total energy density, then the three first-order differential equations (5.3.21), (5.3.23) and (5.3.24) form a closed set of equations for $\Psi = \Phi, \delta u$, and $\delta\rho$, so with the constraint (5.3.26) there must be just two independent solutions for these quantities, which therefore must take the adiabatic form (5.4.4) and (5.4.6), or (5.4.7). But the complete solution is not necessarily adiabatic, because other four-scalars (such as the energy densities or pressures of individual components of the universe) may not be given by Eq. (5.4.9).

[10] S. Bashinsky and U. Seljak, Phys. Rev. D 69, 083002 (2004) [astro-ph/0310198].

[11] D. Wands et al., ref. 2.

so that

$$\frac{\delta\rho^s_{\alpha q}}{\bar\rho_\alpha + \bar p_\alpha} = -\int \psi_q dt + c_{\alpha q} \tag{5.4.32}$$

The integration constants $c_{\alpha q}$ depend on what we take as the lower limit on the integral of ψ_q, but their differences have an absolute significance, and are simply related to the differences of the $\zeta_{\alpha q}$. The gauge transformation equation (5.3.14) and the equation $\dot{\bar\rho}_\alpha = -3H\left(\bar\rho_\alpha + \bar p_\alpha\right)$ for separate energy conservation shows that for any two components of the universe whose energy is separately conserved, we have

$$\frac{\delta\rho^S_{\alpha q}}{\bar\rho_\alpha + \bar p_\alpha} - \frac{\delta\rho^S_{\beta q}}{\bar\rho_\beta + \bar p_\beta} = \frac{\delta\rho_{\alpha q}}{\bar\rho_\alpha + \bar p_\alpha} - \frac{\delta\rho_{\beta q}}{\bar\rho_\beta + \bar p_\beta} \tag{5.4.33}$$

Comparing Eqs. (5.4.30) and (5.4.33), we see that

$$c_{\alpha q} - c_{\beta q} = 3\left(\zeta_{\alpha q} - \zeta_{\beta q}\right). \tag{5.4.34}$$

In the special case in which the perturbations are adiabatic, according to Eq. (5.4.9) the quantities $\delta\rho_{\alpha q}/\left(\bar\rho_\alpha + \bar p_\alpha\right) = -3H\delta\rho_{\alpha q}/\dot{\bar\rho}_\alpha$ are all equal, and hence the $\zeta_{\alpha q}$ are all equal, and in fact equal to ζ_q. According to Eq. (5.4.34), the $c_{\alpha q}$ will then also be all equal. The cosmic microwave background can be used to measure the differences of the $\zeta_{\alpha q}$ or $c_{\alpha q}$ before perturbations re-enter the horizon, and hence to decide whether the cosmological fluctuations are truly adiabatic. So far, as we will see in Section 7.2, it seems they are.

10.6 Evolution of Cosmological Fluctuations

We will now apply the formalism developed in the previous chapter to work out the evolution of cosmological fluctuations, from a temperature $\approx 10^9$ K when electron positron annihilation is substantially complete and neutrinos have decoupled from matter and radiation, down to the relatively recent time when the matter fluctuations become too large to be treated as firstorder perturbations. Our results will be applied to analyze the observed fluctuations in the cosmic microwave background in the next chapter, and large scale structure in Chapter 8.

For reasons discussed in Section 5.4, the connection between the evolution of fluctuations in this era and what happened at earlier times will appear in a few parameters including $\mathcal{R}_q$ (or ζ_q), which are conserved during the many e-foldings of expansion when the perturbations to the various constituents of the universe were still outside the horizon - that is, when the physical wave number q/a was much less than the expansion rate $\dot a/a$. The values of these parameters when outside the horizon thus characterize the strength of the various perturbations. In Chapter 10 we will see what can be understood about these parameters from a study of the much earlier era of inflation, and in this way work out what large scale structure and fluctuations in the cosmic microwave background can tell us about the era of inflation.

Section 6.1 presents the equations governing scalar perturbations. These equations take a simple hydrodynamic form for cold dark matter and the baryonic plasma, but for calculations of high accuracy it is necessary to use the Boltzmann equations of kinetic theory to follow the detailed distribution of photons and neutrinos in phase space. [1] These equations are too complicated for an analytic treatment; that is a task for comprehensive computer programs such as CMBfast [2] and CAMB. [3] Unfortunately such computer programs do not lend themselves to an exposition aimed at an

[471] P. J. E. Peebles and J. T. Yu, Astrophys. J. 162, 815 (1970); R. A. Sunyaev and Ya. B. Zel'dovich, Astrophys. Space Sci. 7, 3 (1970).

[2] The original code for the Boltzmann equations for photons and neutrinos and the other dynamical and

understanding of the physical phenomena involved. Therefore in subsequent sections we will present hydrodynamic calculations that are simple enough to be done analytically, aside from a few numerical integrations, and yet realistic enough so that the results are a good approximation to the more accurate results of computer programs.

The general equations and initial conditions for our analytic treatment of scalar modes are given in Section 6.2. Our analytic treatment of scalar modes then divides into the study of two wavelength regimes: wavelengths long enough to have come within the horizon during the matter-dominated era, to be considered in Section 6.3, and wavelengths short enough to have come within the horizon during the radiation-dominated era, considered in Section 6.4. Section 6.5 will show how to interpolate between the solutions found for these long and short wavelengths. Section 6.6 treats the evolution of tensor perturbations.

In Chapter 7 the results of this chapter for both scalar and tensor modes are applied to the anisotropies and polarization of the cosmic microwave background. Chapter 8 takes the treatment of matter perturbations beyond the time of last scattering, with results applied to observations of the cosmic distribution of matter.

10.6.1 6.1 Scalar perturbations - kinetic theory

It seems highly likely that from the beginning of the period of interest here, from just after $e^+ - e^-$annihilation at a temperature $T \approx 10^9$ K, down to the time of last scattering when $T \simeq 3,000$ K, the universe consisted of just four components: photons, cold dark matter, neutrinos, and a baryonic plasma consisting of free electrons, ions, and neutral atoms. In this section we will consider the perturbations in scalar modes to each of these four constituents in turn, adopting for this purpose the synchronous gauge described in Section 5.3. Each perturbed quantity $X(\mathbf{x}, t)$ (such as $\delta\rho, \delta p,\ A, B,$ etc.) is written as a Fourier integral and a sum over modes, as in Eq. (5.2.1):

$$X(\mathbf{x}, t) = \sum_n \int d^3q \alpha_n(\mathbf{q}) X_{nq}(t) e^{i\mathbf{q}\cdot\mathbf{x}} \tag{6.1.1}$$

where $\alpha_n(\mathbf{q})$ is the stochastic parameter for the n-th mode. In particular, the metric perturbation in synchronous gauge is given by $\delta g_{00} = 0, \delta g_{i0} = 0$, and

$$\delta g_{ij}(\mathbf{x}, t) = a^2(t) \sum_n \int d^3q \alpha_n(\mathbf{q}) \left[A_{nq}(t)\delta_{ij} - q_i q_j B_{nq}(t)\right] e^{i\mathbf{q}\cdot\mathbf{x}} \tag{6.1.2}$$

(Note that q is the co-moving wave number, related to the physical wave number k by $k = q/a$. It is common to define a so that $a = 1$ at the present time, so that the co-moving wave number equals the present value of the physical wave number, in which case the co-moving wave number is often denoted k. We will instead leave the normalization of a arbitrary, and reserve the symbol k for the physical wave number q/a.) In this section we will consider any one mode, dropping the label n; the equations we find will have a number of solutions, which define the various modes.

gravitational equations on which CMBfast is based was written by C.-P. Ma and E. Bertschinger, Astrophys. J. 455, 7 (1995) [astro-ph/9506072]. An important element discussed below was added by U. Seljak and M. A. Zaldarriaga, Astrophys. J. 469, 437 (1996).[astro-ph/9603033]. Also see M. Zaldarriaga, U. Seljak, and E. Bertschinger, Astrophys. J. 494, 491 (1998); M. Zaldarriaga and U. Seljak, Astrophys. J. 129, 431 (2000). The program is available on the website www. cmbfast. org.

[3] This program is based on CMBfast. It was written by A. Lewis and A. Challinor, and is available at camb.info/.

Cold dark matter

The individual cold dark matter particles are assumed to move too slowly for them to produce an appreciable pressure or anisotropic inertia, and, as shown in Section 5.3, the absence of pressure or anisotropic inertia allows us to adopt a particular synchronous gauge in which the cold dark matter fluid velocity u^i_D vanishes. That is, the coordinate mesh is tied to the dark matter particles in such a way that they remain at rest despite fluctuations in the gravitational field in which they move. Cold dark matter is therefore characterized solely by a total density $\bar{\rho}_D(t) + \delta\rho_D(\mathbf{x}, t)$, with the unperturbed density $\bar{\rho}_D(t)$ simply decreasing as $a^{-3}(t)$, and the Fourier transform of the perturbation $\delta\rho_D(\mathbf{x}, t)$ governed by the equation (5.3.34) of energy conservation with zero pressure and velocity

$$\delta\dot{\rho}_{Dq} + 3H\delta\rho_{Dq} = -\bar{\rho}_D\psi_q \tag{6.1.3}$$

(Recall that $\psi_q \equiv \left(3\dot{A}_q - q^2\dot{B}_q\right)/2$.)

Baryonic plasma

The Coulomb interactions of electrons and atomic nuclei are sufficiently strong so that they act together as a single perfect fluid. In the era of interest both electrons and nuclei are highly non-relativistic, so the baryonic plasma has negligible pressure and anisotropic inertia, and therefore the unperturbed density $\bar{\rho}_B(t)$ goes as $a^{-3}(t)$, and the Fourier transform of the density perturbation $\delta\rho_B(\mathbf{x}, t)$ is governed by the energy-conservation equation (5.3.34), but now with a non-zero velocity potential $\delta u_B(\mathbf{x}, t)$:

$$\delta\dot{\rho}_{Bq} + 3H\delta\rho_{Bq} - \left(q^2/a^2\right)\bar{\rho}_B\delta u_{Bq} = -\bar{\rho}_B\psi_q. \tag{6.1.4}$$

On the other hand, Thomson scattering allows the baryonic plasma to exchange momentum with photons, so it is the combination of photons and plasma that satisfies the equation (5.3.32) of momentum conservation, which here reads

$$\delta p_{\gamma q} - q^2\pi^S_{\gamma q} + [\partial_0 + 3H]\left[\bar{\rho}_B\delta u_{Bq} + \frac{4}{3}\bar{\rho}_\gamma\delta u_{\gamma q}\right] = 0 \tag{6.1.5}$$

where δp_γ and δu_γ are the pressure perturbation and velocity potential of the photons. We can regard this as the equation of motion of the baryonic plasma, with the photonic quantities $\pi^S_{\gamma q}, p_{\gamma q}, \delta u_{\gamma q}$ calculated as described in the next subsection.

Photons

Well before the time of recombination the density of free electrons was high enough so that photons could be described hydrodynamically: Thomson scattering gave the photons a total momentum locked to that of the baryonic plasma, so that $\delta u_{\gamma q} = \delta u_{Bq}$, and a momentum distribution that was isotropic in the co-moving frame, so that $\delta p_{\gamma q} = \delta\rho_{\gamma q}/3$ and $\pi^S_{\gamma q} = 0$. But for a highly accurate treatment of photons around the time of recombination it is necessary to treat them kinetically, studying the distribution of photons in momentum space, and taking account of photon polarization. As discussed in Appendix H, this distribution is an Hermitian number density matrix $n^{ij}(\mathbf{x}, \mathbf{p}, t)$, defined so that the number of photons in a space volume $\prod_i dx^i$ with momenta in a momentum-space volume $\prod_i dp_i$, weighted with the probability of their having polarization e^i, is $e_i e^*_j n^{ij}(\mathbf{x}, \mathbf{p}, t)\prod_k dx^k dp_k$, and $p_i n^{ij} = 0$. (The polarization vectors satisfy the normalization condition $g_{ij}e^i e^{j*} = 1$ and the transversality condition $p_i e^i = 0$,

and $e_i \equiv g_{ik}e^k$. For further discussion of polarization, see Appendix G.) For small perturbations, this distribution is conveniently written in the form

$$n^{ij}(\mathbf{x},\mathbf{p},t) = \frac{1}{2}\bar{n}_\gamma\left(a(t)p^0(\mathbf{x},\mathbf{p},t)\right)\left[g^{ij}(\mathbf{x},t) - \frac{g^{ik}(\mathbf{x},t)g^{jl}(\mathbf{x},t)p_k p_l}{\left[p^0(\mathbf{x},\mathbf{p},t)\right]^2}\right] + \delta n^{ij}(\mathbf{x},\mathbf{p},t) \tag{6.1.6}$$

where

$$p^0(\mathbf{x},\mathbf{p},t) \equiv \sqrt{g^{ij}(\mathbf{x},t)p_i p_j} \tag{6.1.7}$$

Here $\bar{n}_\gamma(p)$ is the equilibrium phase space number density

$$\bar{n}_\gamma(p) \equiv \frac{1}{(2\pi)^3}\left[\exp\left(p/k_{\mathcal{B}}a(t)\bar{T}(t)\right) - 1\right]^{-1} \tag{6.1.8}$$

with $\bar{T}(t)$ the unperturbed temperature of the baryonic plasma, and δn^{ij} is a small intrinsic perturbation. The first term in Eq. (6.1.6) is just the distribution matrix for unpolarized photons in thermal equilibrium at temperature $\bar{T}(t)$, written in a general spatial coordinate system, so δn includes the dynamical rather than the purely geometric effect of metric perturbations on the photon distribution. (Note that the factor $a(t)$ in the argument of $\bar{n}_\gamma$ in

Eq. (6.1.6) is canceled by the factor $a(t)$ multiplying $\bar{T}(t)$ in Eq. (6.1.8); this factor is introduced because in the era of interest $\bar{T}(t) \propto a^{-1}(t)$, so that as we have defined it, $\bar{n}_\gamma$ is a time-independent function of its argument.)

Since the sum over polarizations of $e_i e_j^*$ is g_{ij}, the phase space density of photons is $g_{ij}n^{ij}$. Hence the total energy-momentum tensor of the photons is

$$T^\mu_{\gamma\nu} = \frac{1}{\sqrt{\text{Det}\, g}}\int\left[\prod_{k=1}^{3}dp_k\right] g_{ij}n^{ij}\frac{p^\mu p_v}{p^0} \tag{6.1.9}$$

The first term in Eq. (6.1.6) contains first-order perturbations arising from the metric perturbations in $p^i = g^{ij}p_j$ and $p^0 = -p_0 = \sqrt{g^{ij}p_i p_j}$, in the metric determinant Detg, and in the factor g_{ij} in $g_{ij}n^{ij}$. It is straightforward though tedious to show directly that all these contributions to $\delta T^\mu_{\gamma\,\nu}$ cancel, but this can be seen more easily by noting that Eq. (6.1.9) shows that the contribution of the first term in Eq. (6.1.6) to $\delta T^i_{\gamma j}(\mathbf{x},t)$, $\delta T^0_{\gamma j}(\mathbf{x},t)$, $\delta T^j_{\gamma 0}(\mathbf{x},t)$, and $\delta T^0_{\gamma 0}(\mathbf{x},t)$ are local functions of the three-metric $g_{ij}(\mathbf{x},t)$ that transform under general spatial coordinate transformations as a mixed three-tensor, a covariant three-vector, a contravariant three-vector, and a three-scalar, respectively. But there are no non-trivial local functions of the three-metric that transform in this way under spatial coordinate transformations! This leaves only the contribution from the trace of δn^{ij}_γ. That is, the total first-order perturbations to the mixed components of the energy-momentum tensor are

$$\delta T^i_{\gamma j}(\mathbf{x},t) = \frac{1}{a^4(t)}\int\left(\prod_{k=1}^{3}dp_k\right)a^2(t)\delta n^{kk}_\gamma(\mathbf{x},\mathbf{p},t)\frac{p_i p_j}{\sqrt{p_k p_k}} \tag{6.1.10}$$

$$\delta T^0_{\gamma j}(\mathbf{x},t) = \frac{1}{a^3(t)}\int\left(\prod_{k=1}^{3}dp_k\right)a^2(t)\delta n^{kk}_\gamma(\mathbf{x},\mathbf{p},t)p_j \tag{6.1.11}$$

$$\delta T^0_{\gamma 0}(\mathbf{x},t) = -\frac{1}{a^4(t)}\int\left(\prod_{k=1}^{3}dp_k\right)a^2(t)\delta n^{kk}_\gamma(\mathbf{x},\mathbf{p},t)\sqrt{p_k p_k} \tag{6.1.12}$$

Evidently, all we need to calculate these perturbations is the integral of $\delta n_\gamma^{kk}(\mathbf{x},\mathbf{p},t)$ over photon energy, weighted with a single factor of energy. We therefore introduce a dimensionless intensity matrix $J_{ij}(\mathbf{x},\hat{p},t)$, defined by

$$a^4(t)\bar{\rho}_\gamma(t)J_{ij}(\mathbf{x},\hat{p},t) \equiv a^2(t)\int_0^\infty \delta n_\gamma^{ij}(\mathbf{x},p\hat{p},t)4\pi p^3 dp \tag{6.1.13}$$

where $\bar{\rho}_\gamma(t) \equiv a^{-4}(t)\int 4\pi p^3 \bar{n}_\gamma(p)dp$ is the unperturbed photon energy density. The components (6.1.10)-(6.1.12) then become

$$\delta T_{\gamma j}^i(\mathbf{x},t) = \bar{\rho}_\gamma(t)\int \frac{d^2\hat{p}}{4\pi} J_{kk}(\mathbf{x},\hat{p},t)\hat{p}_i\hat{p}_j \tag{6.1.14}$$

$$\delta T_{\gamma j}^0(\mathbf{x},t) = a(t)\bar{\rho}_\gamma(t)\int \frac{d^2\hat{p}}{4\pi} J_{kk}(\mathbf{x},\hat{p},t)p_j \tag{6.1.15}$$

$$\delta T_{\gamma 0}^0(\mathbf{x},t) = -\bar{\rho}_\gamma(t)\int \frac{d^2\hat{p}}{4\pi} J_{kk}(\mathbf{x},\hat{p},t) \tag{6.1.16}$$

As shown in Eq. (H.37) of Appendix H, the perturbation δn^{ij} is governed by the Boltzmann equation

$$\begin{aligned}
&\frac{\partial \delta n^{ij}(\mathbf{x},\mathbf{p},t)}{\partial t} + \frac{\hat{p}_k}{a(t)}\frac{\partial \delta n^{ij}(\mathbf{x},\mathbf{p},t)}{\partial x^k} + \frac{2\dot{a}(t)}{a(t)}\delta n^{ij}(\mathbf{x},\mathbf{p},t) \\
&\quad -\frac{1}{4a^2(t)}p\bar{n}'_\gamma(p)\hat{p}_k\hat{p}_l\frac{\partial}{\partial t}\left(a^{-2}(t)\delta g_{kl}(\mathbf{x},t)\right)(\delta_{ij}-\hat{p}_i\hat{p}_j) \\
&\quad = -\omega_c(t)\delta n^{ij}(\mathbf{x},\mathbf{p},t) + \frac{3\omega_c(t)}{8\pi}\int d^2\hat{p}_1 \\
&\times\left[\delta n^{ij}(\mathbf{x},p\hat{p}_1,t) - \hat{p}_i\hat{p}_k\delta n^{kj}(\mathbf{x},p\hat{p}_1,t) - \hat{p}_j\hat{p}_k\delta n^{ik}(\mathbf{x},p\hat{p}_1,t)\right. \\
&\qquad \left. +\hat{p}_i\hat{p}_j\hat{p}_k\hat{p}_l\delta n^{kl}(\mathbf{x},p\hat{p}_1,t)\right] \\
&\quad -\frac{\omega_c}{2a^3}p_k\delta u_{Bk}\bar{n}'_\gamma(p)(\delta_{ij}-\hat{p}_i\hat{p}_j)
\end{aligned} \tag{6.1.17}$$

where now $p \equiv \sqrt{p_i p_i}, \hat{p} \equiv \mathbf{p}/p; \omega_c(t)$ is the collision rate of a photon with electrons in the baryonic plasma; and δu_{Bk} is the peculiar velocity of the baryonic plasma. We can derive a Boltzmann equation for the dimensionless intensity matrix by multiplying Eq. (6.1.17) with $4\pi p^3$ and integrating over $p \equiv \sqrt{p_i p_i}$, using

$$4\pi\int_0^\infty p^4\bar{n}'_\gamma(p)dp = -16\pi\int_0^\infty p^3\bar{n}_\gamma(p)dp = -4a^4(t)\rho_\gamma(t)$$

Writing the intensity matrix and plasma velocity as Fourier transforms

$$J_{ij}(\mathbf{x},\hat{p},t) = \int d^3q J_{ij}(\mathbf{q},\hat{p},t)e^{i\mathbf{q}\cdot\mathbf{x}}, \quad \delta u_{Bk}(\mathbf{x},t) = \int d^3q\,\delta u_{Bi}(\mathbf{q},t)e^{i\mathbf{q}\cdot\mathbf{x}} \tag{6.1.18}$$

10.6.2 6.1 Scalar perturbations - kinetic theory

we find

$$\begin{aligned}
&\frac{\partial J_{ij}(\mathbf{q},\hat{p},t)}{\partial t}+i\frac{\hat{p}\cdot\mathbf{q}}{a(t)}J_{ij}(\mathbf{q},\hat{p},t)\\
&\quad+\alpha(\mathbf{q})\left[\dot{A}_q(t)-(\mathbf{q}\cdot\hat{p})^2\dot{B}_q(t)\right](\delta_{ij}-\hat{p}_i\hat{p}_j)\\
&=-\omega_c(t)J_{ij}(\mathbf{q},\hat{p},t)+\frac{3\omega_c(t)}{8\pi}\int d^2\hat{p}_1\\
&\quad\times\left[J_{ij}\left(\mathbf{q},\hat{p}_1,t\right)-\hat{p}_i\hat{p}_kJ_{kj}\left(\mathbf{q},\hat{p}_1,t\right)-\hat{p}_j\hat{p}_kJ_{ik}\left(\mathbf{q},\hat{p}_1,t\right)\right.\\
&\quad\left.+\hat{p}_i\hat{p}_j\hat{p}_k\hat{p}_lJ_{kl}\left(\mathbf{q},\hat{p}_1,t\right)\right]\\
&\quad+\frac{2\omega_c(t)}{a(t)}\left[\delta_{ij}-\hat{p}_i\hat{p}_j\right]\hat{p}_k\delta u_{Bk}(\mathbf{q},t)
\end{aligned}\tag{6.1.19}$$

in which we have used Eqs. (5.3.27) and (6.1.2) for the metric perturbation.
The intensity matrix and plasma velocity are proportional to the stochastic parameter $\alpha(\mathbf{q})$ for whatever mode is under consideration, which contains all information about initial conditions. Apart from this factor, there are no preferred directions in the problem, so the coefficient of $\alpha(\mathbf{q})$ in the intensity matrix can be decomposed into a sum of terms proportional to the two symmetric three-dimensional tensors $\delta_{ij}-\hat{p}_i\hat{p}_j$ and $(\hat{q}_i-(\hat{q}\cdot\hat{p})\hat{p}_i)(\hat{q}_j-(\hat{q}\cdot\hat{p})\hat{p}_j)$ that vanish when contracted with $\hat{p}_i$ or $\hat{p}_j$, with coefficients that depend on the directions $\hat{q}$ and $\hat{p}$ only through the scalar product $\hat{q}\cdot\hat{p}$. This decomposition is conventionally written as

$$\begin{aligned}
J_{ij}(\mathbf{q},\hat{p},t)=\alpha(\mathbf{q})\left\{\frac{1}{2}\left(\Delta_T^{(S)}(q,\hat{q}\cdot\hat{p},t)-\Delta_P^{(S)}(q,\hat{q}\cdot\hat{p},t)\right)(\delta_{ij}-\hat{p}_i\hat{p}_j)\right.\\
\left.+\Delta_P^{(S)}(q,\hat{q}\cdot\hat{p},t)\right)\left[\frac{(\hat{q}_i-(\hat{q}\cdot\hat{p})\hat{p}_i)(\hat{q}_j-(\hat{q}\cdot\hat{p})\hat{p}_j)}{1-(\hat{p}\cdot\hat{q})^2}\right]\Bigg\}.
\end{aligned}\tag{6.1.20}$$

(The subscripts T and P stand for "temperature" and "polarization." Note that the trace J_{ii}, which is all that appears in the energy-momentum tensor, is proportional solely to $\Delta_T^{(S)}$, but we need to keep track of $\Delta_P^{(S)}$ because it is linked to $\Delta_T^{(S)}$ through the dynamical equations.) Similarly, the integral over $\hat{p}$ appearing on the right-hand side of Eq. (6.1.19) may be expressed in terms of a pair of "source functions" $\Phi(q,t)$ and $\Pi(q,t)$ as

$$\int\frac{d^2\hat{p}}{4\pi}J_{ij}(\mathbf{q},\hat{p},t)=\alpha(\mathbf{q})\left[\delta_{ij}\Phi(q,t)+\frac{1}{2}\hat{q}_i\hat{q}_j\Pi(q,t)\right],\tag{6.1.21}$$

and as usual we write

$$\delta u_{Bi}(\mathbf{q},t)=i\alpha(\mathbf{q})q_i\delta u_{Bq}(t)\tag{6.1.22}$$

Inserting Eqs. (6.1.20)-(6.1.22) in Eq.(6.1.19) yields the coupled Boltzmann equations for $\Delta_T^{(S)}$ and $\Delta_P^{(S)}$:

$$\begin{aligned}
&\dot{\Delta}_P^{(S)}(q,\mu,t)+i\left(\frac{q\mu}{a(t)}\right)\Delta_P^{(S)}(q,\mu,t)=-\omega_c(t)\Delta_P^{(S)}(q,\mu,t)\\
&\quad+\frac{3}{4}\omega_c(t)\left(1-\mu^2\right)\Pi(q,t)
\end{aligned}\tag{6.1.23}$$

$$\begin{aligned}
&\dot{\Delta}_T^{(S)}(q,\mu,t)+i\left(\frac{q\mu}{a(t)}\right)\Delta_T^{(S)}(q,\mu,t)=-\omega_c(t)\Delta_T^{(S)}(q,\mu,t)\\
&\quad-2\dot{A}_q(t)+2q^2\mu^2\dot{B}_q(t)\\
&\quad+3\omega_c(t)\Phi(q,t)+\frac{3}{4}\omega_c(t)\left(1-\mu^2\right)\Pi(q,t)+4iq\mu\omega_c(t)\delta u_{Bq}(t)
\end{aligned}\tag{6.1.24}$$

with Φ and Π defined by Eq. (6.1.21).
The usual approach [4] to the solution of these Boltzmann equations is through an expansion of $\Delta_T^{(S)}$ and $\Delta_P^{(S)}$ in partial wave amplitudes:

$$\Delta_T^{(S)}(q,\mu,t) = \sum_{\ell=0}^{\infty} i^{-\ell}(2\ell+1)P_\ell(\mu)\Delta_{T,\ell}^{(S)}(q,t) \tag{6.1.25}$$

$$\Delta_P^{(S)}(q,\mu,t) = \sum_{\ell=0}^{\infty} i^{-\ell}(2\ell+1)P_\ell(\mu)\Delta_{P,\ell}^{(S)}(q,t) \tag{6.1.26}$$

To derive the Boltzmann equations for the partial wave amplitudes, we use the recursion and normalization relations for Legendre polynomials
$(2\ell+1)\mu P_\ell(\mu) = (\ell+1)P_{\ell+1}(\mu) + \ell P_{\ell-1}(\mu)$, $\quad \int_{-1}^{+1} P_\ell^2(\mu)d\mu = \frac{2}{2\ell+1}$.
Multiplying Eqs. (6.1.23) and (6.1.24) by $P_\ell(\mu)$ and integrating over μ then gives

$$\begin{aligned}
&\dot{\Delta}_{P,\ell}^{(S)} + \frac{q}{a(2\ell+1)}\left[(\ell+1)\Delta_{P,\ell+1}^{(S)} - \ell\Delta_{P,\ell-1}^{(S)}\right] \\
&\quad = -\omega_c\Delta_{P,\ell}^{(S)} + \frac{1}{2}\omega_c\Pi\left(\delta_{\ell 0} + \frac{\delta_{\ell 2}}{5}\right),
\end{aligned} \tag{6.1.27}$$

$$\begin{aligned}
&\dot{\Delta}_{T,\ell}^{(S)} + \frac{q}{a(2\ell+1)}\left[(\ell+1)\Delta_{T,\ell+1}^{(S)} - \ell\Delta_{T,\ell-1}^{(S)}\right] \\
&\quad = -2\dot{A}_q\delta_{\ell 0} + 2q^2\dot{B}_q\left(\frac{\delta_{\ell 0}}{3} - \frac{2\delta_{\ell 2}}{15}\right) \\
&\quad - \omega_c\Delta_{T,\ell}^{(S)} + \omega_c\left(3\Phi + \frac{1}{2}\Pi\right)\delta_{\ell 0} + \frac{1}{10}\omega_c\Pi\delta_{\ell 2} \\
&\quad - \frac{4}{3}q\omega_c\delta u_{Bq}\delta_{\ell 1}
\end{aligned} \tag{6.1.28}$$

We can express the source functions in terms of $\Delta_{T,\ell}^{(S)}$ and $\Delta_{P,\ell}^{(S)}$ by inserting Eq.(6.1.20) in Eq. (6.1.21), and using the integral formula, that for any function $f(\hat{q}\cdot\hat{p})$,

$$\frac{1}{4\pi}\int d^2\hat{p} f(\hat{q}\cdot\hat{p})\hat{p}_i\hat{p}_j = \mathcal{A}\delta_{ij} + \mathcal{B}\hat{q}_i\hat{q}_j$$

where

$$\mathcal{A} = \frac{1}{4}\int_{-1}^{1} d\mu f(\mu)\left(1-\mu^2\right) = \frac{1}{6}\int_{-1}^{1} d\mu f(\mu)\left(P_0(\mu) - P_2(\mu)\right)$$
$$\mathcal{B} = \frac{1}{4}\int_{-1}^{1} d\mu f(\mu)\left(3\mu^2-1\right) = \frac{1}{2}\int_{-1}^{1} d\mu f(\mu)P_2(\mu)$$

(The general form of the integrals is dictated by rotational invariance, while the formulas for the coefficients are found by contracting the integral with δ_{ij} and with $\hat{q}_i\hat{q}_j$, and then solving the resulting pair of linear equations for $\mathcal{A}$ and $\mathcal{B}$.) Using this, we can easily evaluate the two terms in the integral (6.1.21) (here dropping the arguments q and t):

[474] M. L. Wilson and J. Silk, Astrophys. J. 243, 14 (1981); J. R. Bond and G. Efstathiou, Astrophys. J. 285, L45 (1984); R. Crittenden, J. R. Bond, R. L. Davis, G. Efstathiou, and P. Steinhardt, Phys. Rev. Lett. 71, 324 (1993); C. -P. Ma and E. Bertschinger, Astrophys. J. 455, 7 (1995).

$$\frac{1}{8\pi}\int d^2\hat{p}\left(\Delta_T^{(S)}(\hat{q}\cdot\hat{p})-\Delta_P^{(S)}(\hat{q}\cdot\hat{p})\right)(\delta_{ij}-\hat{p}_i\hat{p}_j)$$
$$=\int_{-1}^{+1}d\mu\left(\Delta_T^{(S)}(\mu)-\Delta_P^{(S)}(\mu)\right)\left[\left(\frac{1}{6}P_0(\mu)+\frac{1}{12}P_2(\mu)\right)\delta_{ij}-\frac{1}{4}P_2(\mu)\hat{q}_i\hat{q}_j\right]$$
$$\frac{1}{4\pi}\int d^2\hat{p}\Delta_P^{(S)}(\hat{q}\cdot\hat{p})\frac{(\hat{q}_i-(\hat{q}\cdot\hat{p})\hat{p}_i)\,(\hat{q}_j-(\hat{q}\cdot\hat{p})\hat{p}_j)}{1-(\hat{q}\cdot\hat{p})^2}$$
$$=\int_{-1}^{+1}d\mu\Delta_P^{(S)}(\mu)\left[\left(\frac{1}{12}P_0(\mu)+\frac{1}{6}P_2(\mu)\right)\delta_{ij}+\left(\frac{1}{4}P_0(\mu)-\frac{1}{2}P_2(\mu)\right)\hat{q}_i\hat{q}_j\right]$$

In this way, and using the partial wave expansions (6.1.25) and (6.1.26), we find

$$\Phi=\frac{1}{6}\left[2\Delta_{T,0}^{(S)}-\Delta_{P,0}^{(S)}-\Delta_{T,2}^{(S)}-\Delta_{P,2}^{(S)}\right] \tag{6.1.29}$$
$$\Pi=\Delta_{P,0}^{(S)}+\Delta_{T,2}^{(S)}+\Delta_{P,2}^{(S)} \tag{6.1.30}$$

In the same way, using Eq. (6.1.20) in Eqs. (6.1.14)-(6.1.16) gives

$$\delta T^i_{\gamma j}(\mathbf{x},t)=\bar{\rho}_\gamma(t)\int d^3q e^{i\mathbf{q}\cdot\mathbf{x}}\alpha(\mathbf{q})\int_{-1}^{1}d\mu\Delta_T^{(S)}(q,\mu,t)$$
$$\times\left[\frac{1}{6}\left(P_0(\mu)-P_2(\mu)\right)\delta_{ij}+\frac{1}{2}P_2(\mu)\hat{q}_i\hat{q}_j\right]$$
$$\delta T^0_{\gamma j}(\mathbf{x},t)=a(t)\bar{\rho}_\gamma(t)\int d^3q e^{i\mathbf{q}\cdot\mathbf{x}}\alpha(\mathbf{q})\frac{\hat{q}_i}{2}\int_{-1}^{1}d\mu\Delta_T^{(S)}(q,\mu,t)P_1(\mu)$$
$$\delta T^0_{\gamma 0}(\mathbf{x},t)=-\frac{1}{2}\bar{\rho}_\gamma(t)\int d^3q e^{i\mathbf{q}\cdot\mathbf{x}}\alpha(\mathbf{q})\int_{-1}^{1}d\mu\Delta_T^{(S)}(q,\mu,t)P_0(\mu)$$

in which we have used the formula

$$\frac{1}{4\pi}\int d^2\hat{p}f(\hat{q}\cdot\hat{p})\hat{p}_i=\frac{\hat{q}_i}{2}\int_{-1}^{1}d\mu f(\mu)P_1(\mu)$$

Comparing this with the first three of Eqs. (5.1.43), and again using the partial wave expansions (6.1.25) and (6.1.26), we find

$$\delta p_{\gamma q}=\frac{\bar{\rho}_\gamma}{3}\left(\Delta_{T,0}^{(S)}+\Delta_{T,2}^{(S)}\right) \tag{6.1.31}$$
$$q^2\pi^S_{\gamma q}=\bar{\rho}_\gamma\Delta_{T,2}^{(S)} \tag{6.1.32}$$
$$\delta\rho_{\gamma q}=\bar{\rho}_\gamma\Delta_{T,0}^{(S)} \tag{6.1.33}$$
$$q\delta u_{\gamma q}=-\frac{3}{4}\Delta_{T,1}^{(S)} \tag{6.1.34}$$

As a check of Eqs. (6.1.31)-(6.1.33), note that when used in the last of Eqs. (5.1.43) these results give $\delta T^\lambda_\gamma\lambda=0$, a necessary consequence of the masslessness of the photon for any distribution of photon momenta.

Eqs. (6.1.31)-(6.1.34) show that to work out the cosmological evolution of the gravitational field and its effect on other perturbations in scalar modes, all we need to know about photons is $\Delta_{T,\ell}^{(S)}$ for $\ell\leq 2$. But of course the evolution of these three amplitudes is coupled by the Boltzmann equations (6.1.27)-(6.1.30) to both $\Delta_{T,\ell}^{(S)}$ and $\Delta_{P,\ell}^{(S)}$ for all higher ℓ. In computer

programs like CMBfast and CAMB, the partial wave expansion is cut off at a sufficiently high value of ℓ; in the latest version of CMBfast, the maximum value of ℓ is taken as $\ell_{\max} = 12$, in which case the computer has to solve $2(\ell_{\max}+1) = 26$ coupled ordinary differential equations for each value of q, not counting the other equations that describe the evolution of the baryonic plasma, cold dark matter, neutrinos, and the gravitational field.

As we will see in the next chapter, the interpretation of observations of the cosmic microwave radiation background requires calculation of $\Delta^{(S)}_{T,\ell}$ and $\Delta^{(S)}_{P,\ell}$ for ℓ ranging to values well over 1,000 . Originally this was done by a direct use of the coupled Boltzmann equations (6.1.27) and (6.1.28), [4] but this required hours or even days of computer time for each theoretical model. A great improvement was introduced with the suggestion to use instead a formal solution of the Boltzmann equation (6.1.19), in the form of a "line-of-sight" integral, [5] which in matrix notation takes the form

$$\begin{aligned} J_{ij}(\mathbf{q},\hat{p},t) = \alpha(\mathbf{q})\int_{t_1}^{t} dt' \exp\left(-i\mathbf{q}\cdot\hat{p}\int_{t'}^{t}\frac{dt''}{a(t'')} - \int_{t'}^{t} dt''\omega_c(t'')\right) \\ \times\Big[-(\delta_{ij}-\hat{p}_i\hat{p}_j)\left(\dot{A}_q(t') - (\hat{p}\cdot\mathbf{q})^2\dot{B}_q(t')\right) \\ + \frac{3\omega_c(t')}{2}(\delta_{ij}-\hat{p}_i\hat{p}_j)\,\Phi(q,t') \\ + \frac{3\omega_c(t')}{4}\Pi(q,t')\,(\hat{q}_i-\hat{p}_i(\hat{q}\cdot\hat{p}))\,(\hat{q}_j-\hat{p}_j(\hat{q}\cdot\hat{p})) \\ + \frac{2\omega_c(t')}{a(t')}\left[\delta_{ij}-\hat{p}_i\hat{p}_j\right]\hat{p}_k\delta u_k(\mathbf{q},t')\Big] \\ + J_{ij}(\mathbf{q},\hat{p},t_1)\exp\left(-i\mathbf{q}\cdot\hat{p}\int_{t_1}^{t}\frac{dt'}{a(t')} - \int_{t_1}^{t} dt'\omega_c(t')\right) \end{aligned} \tag{6.1.35}$$

where t_1 is any arbitrary initial time. If we choose t_1 to be sufficiently early, before recombination, so that $\omega_c(t_1) \gg H(t_1)$, and take t at any time

after recombination, the final term in Eq. (6.1.35) may be neglected, and we have

$$\begin{aligned} J_{ij}(\mathbf{q},\hat{p},t) = \alpha(\mathbf{q})\int_{t_1}^{t} dt' \exp\left(-i\mathbf{q}\cdot\hat{p}\int_{t'}^{t}\frac{dt''}{a(t'')} - \int_{t'}^{t} dt''\omega_c(t'')\right) \\ \times\Big[-(\delta_{ij}-\hat{p}_i\hat{p}_j)\left(\dot{A}_q(t') - (\hat{p}\cdot\mathbf{q})^2\dot{B}_q(t')\right) \\ + \frac{3\omega_c(t')}{2}(\delta_{ij}-\hat{p}_i\hat{p}_j)\,\Phi(q,t') \\ + \frac{3\omega_c(t')}{4}\Pi(q,t')\,(\hat{q}_i-\hat{p}_i(\hat{q}\cdot\hat{p})\,(\hat{q}_j-\hat{p}_j(\hat{q}\cdot\hat{p}) \\ + \frac{2\omega_c(t')}{a(t')}\left[\delta_{ij}-\hat{p}_i\hat{p}_j\right]\hat{p}_k\delta u_k(\mathbf{q},t')\Big] \end{aligned} \tag{6.1.36}$$

In terms of the temperature and polarization amplitudes defined by the decomposition (6.1.20), the line-of-sight solution reads

[475] U. Seljak and M. A. Zaldarriaga, Astrophys. J. 469, 437 (1996). [astro-ph/9603033].

$$\Delta_T^{(S)}(q,\mu,t) = \Delta_P^{(S)}(q,\mu,t) + 2\int_{t_1}^{t} dt' \exp\left[-iq\mu\int_{t'}^{t}\frac{dt''}{a\,(t'')} - \int_{t'}^{t}\omega_c\,(t'')\,dt''\right]$$
$$\times\left[-\dot{A}_q\,(t') + \mu^2 q^2 \dot{B}_q\,(t') + \frac{3}{2}\omega_c\,(t')\,\Phi\,(q,t') + \frac{2i\mu q\omega_c\,(t')}{a\,(t')}\delta u_q\,(t')\right] \tag{6.1.37}$$

$$\Delta_P^{(S)}(q,\mu,t) = \frac{3}{4}\left(1-\mu^2\right)\int_{t_1}^{t} dt' \exp\left[-iq\mu\int_{t'}^{t}\frac{dt''}{a\,(t'')} - \int_{t'}^{t}\omega_c\,(t'')\,dt''\right]$$
$$\times\,\omega_c\,(t')\,\Pi\,(q,t') \tag{6.1.38}$$

where δu_q is the scalar velocity potential, defined by $\delta u_k(\mathbf{q},t) = iq_k u_q(t)$. Once Φ and Π have been calculated from Eqs. (6.1.29) and (6.1.30), Eqs. (6.1.37) and (6.1.38) can be used to calculate $\Delta_{T,\ell}^{(S)}$ and $\Delta_{P,\ell}^{(S)}$ for arbitrarily high values of ℓ. (It is also possible to use Eq. (6.1.36) as a substitute for the partial wave expansion in calculating the source terms Φ and Π. Integrating Eq. (6.1.36) over $\hat{p}$ yields integral equations: [6] expressions for $\Phi(q,t)$ and $\Pi(q,t)$ as integrals from t_1 to t in which the integrand is a linear function of $\Phi\,(q.t')$ and $\Pi\,(q,t')$ for $t' < t$. This approach will be applied to tensor modes in Section 6.6.)

Neutrinos

The number density $n_\nu(\mathbf{x},\mathbf{p},t)$ of each species of massless neutrinos (or antineutrinos) in phase space can be conveniently expressed in terms of an intrinsic perturbation $\delta n_\nu(\mathbf{x},\mathbf{p},t)$ by a formula like Eq. (6.1.6):

$$n_v(\mathbf{x},\mathbf{p},t) = \bar{n}_v\left(a(t)p^0(\mathbf{x},\mathbf{p},t)\right) + \delta n_v(\mathbf{x},\mathbf{p},t) \tag{6.1.39}$$

where $\bar{n}_\nu$ is the equilibrium phase space density of each neutrino species

$$\bar{n}_v(p) \equiv \frac{1}{(2\pi)^3}\left[\exp\left(p/k_{\mathcal{B}}a(t)\bar{T}(t)\right)+1\right]^{-1} \tag{6.1.40}$$

As shown in Appendix H, the perturbation $\delta n_\nu(\mathbf{x},\mathbf{p},t)$ satisfies the same Boltzmann equation as the photon phase space density $a^2(t)n_\gamma^{kk}(\mathbf{x},\mathbf{p},t)$, except that for $T \ll 10^{10}$ K, the terms proportional to the collision frequency are absent:

$$0 = \frac{\partial\delta n_v(\mathbf{x},\mathbf{p},t)}{\partial t} + \frac{\hat{p}_k}{a(t)}\frac{\partial\delta n_v(\mathbf{x},\mathbf{p},t)}{\partial x^k}$$
$$-\frac{1}{2}p\bar{n}_v'(p)\hat{p}_k\hat{p}_l\frac{\partial}{\partial t}\left(a^{-2}(t)\delta g_{kl}(\mathbf{x},t)\right) \tag{6.1.41}$$

The contribution of each species of neutrino to the perturbations to the energy-momentum tensor is given by formulas (6.1.10)-(6.1.12), except that $\delta n_v(\mathbf{x},\mathbf{p},t)$ appears instead of $a^2(t)\delta n_\gamma^{kk}(\mathbf{x},\mathbf{p},t)$. Once again, all we need for this purpose is a dimensionless direction-dependent intensity, defined by a formula like Eq. (6.1.13):

$$a^4(t)\bar{\rho}_v(t)J(\mathbf{x},\hat{p},t) \equiv N_v\int_0^\infty \delta n_v(\mathbf{x},\mathbf{p},t)4\pi p^3 dp \tag{6.1.42}$$

where N_v is the number of species of neutrino, counting antineutrinos separately, and $\bar{\rho}_\nu \equiv N_\nu a^{-4}\int 4\pi p^3\bar{n}_\nu(p)dp$. Then the total neutrino and antineutrino contribution to the energy-momentum tensor is

[476] S. Weinberg, Phys. Rev. D 74, 063517 (2006) [astro-ph/0607076]; D. Baskaran, L. P. Grishchuk, and A. G. Polnarev, Phys. Rev. D 74, 063517 [gr-qc/0605100].

$$\delta T^i_{vj}(\mathbf{x},t) = \bar{\rho}_v(t)\int \frac{d^2\hat{p}}{4\pi} J(\mathbf{x},\hat{p},t)\hat{p}_i\hat{p}_j \tag{6.1.43}$$

$$\delta T^0_{vj}(\mathbf{x},t) = a(t)\bar{\rho}_v(t)\int \frac{d^2\hat{p}}{4\pi} J(\mathbf{x},\hat{p},t)p_j \tag{6.1.44}$$

$$\delta T^0_{v0}(\mathbf{x},t) = -\bar{\rho}_v(t)\int \frac{d^2\hat{p}}{4\pi} J(\mathbf{x},\hat{p},t) \tag{6.1.45}$$

just as in Eqs. (6.1.14)-(6.1.16). Rotational and translational invariance allow us to express $J(\mathbf{x},\hat{p},t)$ as a Fourier integral of the form

$$J(\mathbf{x},\hat{p},t) = \int \alpha(\mathbf{q})\Delta^{(S)}_v(q,\hat{q}\cdot\hat{p},t)e^{i\mathbf{q}\cdot\mathbf{x}}d^3q \tag{6.1.46}$$

To derive a Boltzmann equation for $\Delta^{(S)}_\nu$, we multiply Eq. (6.1.41) with $4\pi|\mathbf{p}|^3$ and integrate over $|\mathbf{p}|$, and find

$$\frac{\partial\Delta^{(S)}_v(q,\mu,t)}{\partial t} + i\frac{q\mu}{a(t)}\Delta^{(S)}_v(q,\mu,t) = -2\dot{A}_q(t) + 2q^2\mu^2\dot{B}_q(t) \tag{6.1.47}$$

In computer programs like CMBfast, the Boltzmann equation for neutrinos as well as for photons is solved by a partial wave expansion. One writes

$$\Delta^{(S)}_v(q,\mu,t) = \sum_{\ell=0}^{\infty} i^{-\ell}(2\ell+1)P_\ell(\mu)\Delta^{(S)}_{v,\ell}(q,t) \tag{6.1.48}$$

Inserting this in Eq. (6.1.46) and then in Eqs. (6.1.43)-(6.1.45) and then comparing the results with the first three of Eqs. (5.1.43) gives the perturbed pressure, scalar anisotropic inertia, perturbed energy density, and velocity potential of the neutrinos

$$\delta p_{vq}(t) = \frac{\bar{\rho}_v(t)}{3}\left(\Delta^{(S)}_{v,0}(q,t) + \Delta^{(S)}_{v,2}(q,t)\right) \tag{6.1.49}$$

$$q^2\pi^S_{vq}(t) = \bar{\rho}_v(t)\Delta^{(S)}_{v,2}(q,t) \tag{6.1.50}$$

$$\delta\rho_v q(t) = \bar{\rho}_v(t)\Delta^{(S)}_{v,0}(q,t) \tag{6.1.51}$$

$$q\delta u_v q = -\frac{3}{4}\Delta^{(S)}_{v,1}(q,t) \tag{6.1.52}$$

To derive the Boltzmann equations for the partial wave amplitudes, we multiply Eq. (6.1.47) with $P_\ell(\mu)$ and integrate over μ :

$$\begin{aligned}\dot{\Delta}^{(S)}_{v,\ell}(q,t) + \frac{q}{a(2\ell+1)}\left[(\ell+1)\Delta^{(S)}_{v,\ell+1}(q,t) - \ell\Delta^{(S)}_{v,\ell-1}(q,t)\right] \\ = -2\dot{A}_q(t)\delta_{\ell 0} + q^2\dot{B}_q(t)\left(\frac{2\delta_{\ell 0}}{3} - \frac{4\delta_{\ell 2}}{15}\right)\end{aligned} \tag{6.1.53}$$

In the current version of CMBfast, this equation is cut off at a maximum value of ℓ equal to 25 . Instead of relying on a truncated partial wave expansion, it is possible to write a solution (here not merely a formal solution) of Eq. (6.1.47) as another line-of-sight integral:

$$\Delta_v^{(S)}(q,\mu,t) = -2\int_{t_1}^{t} \exp\left(-iq\mu\int_{t'}^{t}\frac{dt''}{a(t'')}\right)\left(\dot{A}_q(t') - \mu^2 q^2 \dot{B}_q(t')\right) + \Delta_v^{(S)}(q,\mu,t_1)\exp\left(-iq\mu\int_{t_1}^{t}\frac{dt'}{a(t')}\right) \tag{6.1.54}$$

where t_1 is any arbitrary initial time. If t_1 is taken at some time after the neutrinos went out of thermal equilibrium with the baryonic plasma, but early enough so that gravitational field perturbations have not yet had a chance to distort the neutrino distribution, then $\Delta_\nu^{(S)}(q,\mu,t_1)$ arises only from the temperature perturbation at time t_1 :

$$\Delta_v^{(S)}(q,\mu,t_1) = 4\left[\frac{\delta T_q(t_1)}{\bar{T}(t_1)} + i\frac{\mu q \delta u_q(t_1)}{a(t_1)}\right] \tag{6.1.55}$$

in which the second term in square brackets arises from the Doppler effect due to the streaming of the electron-positron-photon plasma.

The integrals over direction in Eqs. (6.1.43)-(6.1.45) can be done analytically; for this purpose we need the formulas

$$\int\frac{d^2\hat{p}}{4\pi}\hat{p}_i\hat{p}_j\hat{p}_k\hat{p}_l e^{-i\hat{p}\cdot\mathbf{v}} = (\delta_{ij}\delta_{kl}+\delta_{ik}\delta_{jl}+\delta_{il}\delta_{kj})\,j_2(v)/v^2 - (\delta_{ij}\hat{v}_k\hat{v}_l+\delta_{ik}\hat{v}_j\hat{v}_l+\delta_{il}\hat{v}_k\hat{v}_j+\delta_{jk}\hat{v}_i\hat{v}_l+\delta_{jl}\hat{v}_k\hat{v}_i+\delta_{kl}\hat{v}_i\hat{v}_j)\,j_3(v)/v + \hat{v}_i\hat{v}_j\hat{v}_k\hat{v}_l j_4(v)$$

$$\int\frac{d^2\hat{p}}{4\pi}\hat{p}_i\hat{p}_j\hat{p}_k e^{-i\hat{p}\cdot\mathbf{v}} = -i\,(\delta_{ij}\hat{v}_k+\delta_{jk}\hat{v}_i+\delta_{ki}\hat{v}_j)\,j_2(v)/v + i\hat{v}_i\hat{v}_j\hat{v}_k j_3(v)$$

$$\int\frac{d^2\hat{p}}{4\pi}\hat{p}_i\hat{p}_j e^{-i\hat{p}\cdot\mathbf{v}} = \delta_{ij}j_1(v)/v - \hat{v}_i\hat{v}_j j_2(v) \tag{6.1.56}$$

$$\int\frac{d^2\hat{p}}{4\pi}\hat{p}_i e^{-i\hat{p}\cdot\mathbf{v}} = -i\hat{v}_i j_1(v)$$

$$\int\frac{d^2\hat{p}}{4\pi}e^{-i\hat{p}\cdot\mathbf{v}} = j_0(v), \tag{6.1.57}$$

here $v\equiv|\mathbf{v}|$, and $j_\ell(v)$ is the usual spherical Bessel function. Again (6.1.58)

omparing the results with the first three of Eqs. (5.1.43), we obtain explicit (6.1.59)

ormulas for the perturbed pressure, scalar anisotropic inertia, perturbed (6.1.60)

energy density, and velocity potential of the neutrinos: [7]

$$\delta p_{\nu q}(t) = -2\bar{\rho}_\nu(t)\int_{t_1}^{t}dt' \times\left[\dot{A}_q(t')\,K_1\left(q\int_{t'}^{t}\frac{dt''}{a(t'')}\right) - q^2\dot{B}_q(t')\,K_2\left(q\int_{t'}^{t}\frac{dt''}{a(t'')}\right)\right] \tag{6.1.61}$$

$$q^2\pi_{\nu q}^S(t) = -2\bar{\rho}_\nu(t)\int_{t_1}^{t}dt' \times\left[\dot{A}_q(t')\,j_2\left(q\int_{t'}^{t}\frac{dt''}{a(t'')}\right) - q^2\dot{B}_q(t')\,K_3\left(q\int_{t'}^{t}\frac{dt''}{a(t'')}\right)\right] \tag{6.1.62}$$

$$q\delta u_\nu q(t) = \frac{3a(t)}{2}\int_{t_1}^{t}dt'$$

$$\times \left[\dot{A}_q(t') j_1\left(q \int_{t'}^{t} \frac{dt''}{a(t'')} \right) - q^2 \dot{B}_q(t') K_4\left(q \int_{t'}^{t} \frac{dt''}{a(t'')} \right) \right] \tag{6.1.63}$$

$$\delta\rho_\nu q(t) = -2\bar{\rho}_\nu(t) \int_{t_1}^{t} dt' \times \left[\dot{A}_q(t') j_0\left(q \int_{t'}^{t} \frac{dt''}{a(t'')} \right) - q^2 \dot{B}_q(t') K_5\left(q \int_{t'}^{t} \frac{dt''}{a(t'')} \right) \right] \tag{6.1.64}$$

where

$$K_1(v) \equiv j_1(v)/v \tag{6.1.65}$$
$$K_2(v) \equiv j_2(v)/v^2 - j_3(v)/v \tag{6.1.66}$$
$$K_3(v) \equiv -2j_2(v)/v^2 + 5j_3(v)/v - j_4(v) \tag{6.1.67}$$
$$K_4(v) \equiv 3j_2(v)/v - j_3(v) \tag{6.1.68}$$
$$K_5(v) \equiv j_1(v)/v - j_2(v) \tag{6.1.69}$$

Using these formulas, one no longer needs the truncated partial wave expansion for neutrinos.

Gravitation

It only remains to give the equations of motion for the scalar gravitational field components $\dot{A}$ and $\dot{B}$. (Note that A and B themselves are nowhere needed.) It is convenient to take one of these as Eq. (5.3.31), written as

$$\frac{\partial}{\partial t}\left[a^2\psi_q\right] = -4\pi G a^2 \times \left(\delta\rho_{Dq} + \delta\rho_{Bq} + \delta\rho_{\gamma q} + \delta\rho_{\nu q} + 3\delta p_{\gamma q} + 3\delta p_{\nu q} - q^2\pi^S_{\gamma q} - q^2\pi^S_{\nu q}\right) \tag{6.1.70}$$

where

$$\psi_q \equiv \frac{1}{2}\left(3\dot{A}_q - q^2\dot{B}_q\right) \tag{6.1.71}$$

The other can be taken from Eq. (5.3.30)

$$\dot{A}_q = 8\pi G\left[\frac{4}{3}\bar{\rho}_\gamma \delta u_{\gamma q} + \frac{4}{3}\bar{\rho}_\nu \delta u_{\nu q} + \bar{\rho}_B \delta u_{Bq}\right]. \tag{6.1.72}$$

(Recall that we have adopted the particular synchronous gauge in which $\delta u_{Dq} = 0$.) After solving the first-order differential equation (6.1.70) for ψ_q and using Eq. (6.1.72) to find $\dot{A}_q$, the other component is trivially given by the definition Eq. (6.1.71) as

$$q^2\dot{B}_q = 3\dot{A}_q - 2\psi_q. \tag{6.1.73}$$

With this, as long as we truncate the partial wave expansions used for photons and neutrinos, we have a closed system of ordinary differential equations for all the perturbations, which can be straightforwardly solved by computer for any given initial conditions.

To find initial conditions, we note that at a sufficiently early time t_1, well before the era of recombination, (say, for $\bar{T}(t_1) > 10^5$ K), the collision rate of photons with the baryonic plasma

[477] These formulas are given also for massive neutrinos by S. Weinberg, ref. 6.

is so great that photons are in thermal and kinetic equilibrium with the plasma. Under these conditions, the photon distribution δn^{ij} arises only from a perturbation to the temperature in the first term of Eq. (H.31), including the Doppler shift due to the photon streaming velocity, which in equilibrium is the same as the baryonic plasma velocity $\delta \mathbf{u}_B$:
$\delta n_\gamma^{ij}(\mathbf{x}, \mathbf{p}, t_1) = -\frac{1}{2} a^{-2}(t_1) [\delta_{ij} - \hat{p}_i \hat{p}_j] \bar{n}'_\gamma(p) p \left[\frac{\delta T(\mathbf{x}, t_1)}{\bar{T}(t_1)} + \frac{\hat{p}_k \delta u_{Bk}(\mathbf{x}, t_1)}{a(t_1)} \right]$.
(The factor $1/a(t_1)$ in the Doppler term in Eq. (6.1.74) was explained in connection with Eq. (H.13).) Note that for ω_c very large, the coefficients of ω_c on the right-hand side of equation (6.1.17) must cancel, which gives an
initial condition consistent with Eq. (6.1.74). Multiplying with $4\pi p^3$ and integrating over p, we find a corresponding condition on J_{ij} :

$$J_{ij}(\mathbf{x}, \hat{p}, t_1) = 2 [\delta_{ij} - \hat{p}_i \hat{p}_j] \left[\frac{\delta T(\mathbf{x}, t_1)}{\bar{T}(t_1)} + \frac{\hat{p}_k \delta u_k(\mathbf{x}, t_1)}{a(t_1)} \right] \tag{6.1.75}$$

Note that $J_{ij}(\mathbf{x}, \hat{p}, t_1)$ receives contributions only from scalar and vector perturbations, not from tensor perturbations.

Similar remarks apply to neutrinos, except that we must go back to an earlier time, when the temperature was a little below 10^{10} K, so that neutrinos were already traveling freely, but not enough time had elapsed for the gravitational field perturbation to have altered the equilibrium form of the neutrino phase space distribution.

This still leaves us with the necessity of stipulating initial values for A_q, $B_q, \delta_{Dq}, \delta_{Bq}, \delta u_{Bq}$, and δT_q. For this, we must go back to a time early enough so that the wave numbers of interest were outside the horizon, in the sense that $q/a \ll H$. In the following section the needed initial values will be worked out for the dominant adiabatic mode, with a normalization expressed in terms of the quantity $\mathcal{R}_q$, given in synchronous gauge outside the horizon by Eq. (5.4.24).

10.6.3 6.2 Scalar perturbations - the hydrodynamic limit

The system of equations described in the previous section is much too complicated to allow an analytic solution. Fortunately, until near the time of recombination the rate of collisions of photons with free electrons was so great that photons were in local thermal equilibrium with the baryonic plasma, and so photons at these times can be treated hydrodynamically, like the plasma and cold dark matter. This approach loses its validity around the time of recombination, but a fair degree of accuracy will be preserved in Section 6.4 by taking into account the damping caused by the growing mean free times in this era. After the time of recombination photons traveled more or less freely, and their path can be followed by solving their equation of motion. Neutrinos are more of a problem, but at very early times perturbations were outside the horizon, so at these times $q^2 \pi_{\nu q}^S$ and $q \delta u_{\nu q}$ were negligible and Eqs. (6.1.49)-(6.1.51) show that $\delta \rho_{\nu q} = 3 \delta p_{\nu q}$, just as if the neutrinos were in local thermal equilibrium, while at late times the universe became matter dominated and neutrinos made only a small contribution to the cosmic gravitational field.

With these justifications, in order to allow an analytic treatment, in this and the next three sections we will adopt a hydrodynamic approach. [1] To be specific, for the most part we will neglect anisotropic inertia, take $\delta u_{\gamma q}$ equal to δu_{Bq}, and take $p_{\gamma q} = \rho_{\gamma q}/3$ and $p_{\nu q} = \rho_{\nu q}/3$. This necessarily entails the loss of some accuracy, but our aim in this chapter (and in the next two chapters) is not to calculate the course of cosmic evolution and its observational consequences with the high level of accuracy that would optimize the extraction of cosmological parameters from the latest data on the cosmic microwave background and large scale structure. Rather, we wish here to elucidate the physics of cosmic evolution, and clarify the dependence of observables on cosmological assumptions. Fortunately, the results we obtain from this analytic treatment

will turn out in Chapter 7 to yield predictions for anisotropies in the cosmic microwave background that are quite similar to those obtained by comprehensive computer programs, using the full Boltzmann equations described in the previous section. We are thereby reassured that the hydrodynamic approach captures the essence of what is going on in the early universe.

Under the above assumptions, the Fourier transforms with co-moving wave number q of the synchronous gauge perturbations are governed by the gravitational field equation (5.3.36):

$$\frac{d}{dt}\left(a^2\psi_q\right) = -4\pi G a^2\left(\delta\rho_{Dq} + \delta\rho_{Bq} + 2\delta\rho_{\gamma q} + 2\delta\rho_{\nu q}\right) \tag{6.2.1}$$

the equations (5.3.34) of energy conservation for each of the four fluids

$$\delta\dot{\rho}_{\gamma q} + 4H\delta\rho_{\gamma q} - \left(4q^2/3a^2\right)\bar{\rho}_\gamma\delta u_{\gamma q} = -(4/3)\bar{\rho}_\gamma\psi_q \tag{6.2.2}$$

$$\delta\dot{\rho}_{Dq} + 3H\delta\rho_{Dq} = -\bar{\rho}_D\psi_q \tag{6.2.3}$$

$$\delta\dot{\rho}_{Bq} + 3H\delta\rho_{Bq} - \left(q^2/a^2\right)\bar{\rho}_B\delta u_{\gamma q} = -\bar{\rho}_B\psi_q \tag{6.2.4}$$

$$\delta\dot{\rho}_{\nu q} + 4H\delta\rho_{\nu q} - \left(4q^2/3a^2\right)\bar{\rho}_\nu\delta u_{\nu q} = -(4/3)\bar{\rho}_\nu\psi_q \tag{6.2.5}$$

and the equations (5.3.32) of momentum conservation for the photonbaryon plasma and the neutrinos:

$$\frac{d}{dt}\left(\left(\frac{4}{3}\bar{\rho}_\gamma + \bar{\rho}_B\right)\delta u_{\gamma q}\right) + 3H\left(\left(\frac{4}{3}\bar{\rho}_\gamma + \bar{\rho}_B\right)\delta u_{\gamma q}\right) = -(1/3)\delta\rho_{\gamma q} \tag{6.2.6}$$

$$\frac{d}{dt}\left(\bar{\rho}_\nu\delta u_{\nu q}\right) + 3H\bar{\rho}_\nu\delta u_{\nu q} = -(1/4)\delta\rho_{\nu q} \tag{6.2.7}$$

It is very convenient to rewrite these equations in terms of the dimensionless fractional perturbations [2]

$$\delta_{\alpha q} \equiv \frac{\delta\rho_{\alpha q}}{\bar{\rho}_\alpha + \bar{p}_\alpha} \tag{6.2.8}$$

where α runs over γ, D, B, and ν. Taking into account that $a^4\bar{\rho}_\gamma, a^3\bar{\rho}_D$, $a^3\bar{\rho}_B$, and $a^4\bar{\rho}_\nu$ are all time-independent, Eqs. (6.2.1)-(6.2.7) now read

$$\frac{d}{dt}\left(a^2\psi_q\right) = -4\pi G a^2\left(\bar{\rho}_D\delta_{Dq} + \bar{\rho}_B\delta_{Bq} + \frac{8}{3}\bar{\rho}_\gamma\delta_{\gamma q} + \frac{8}{3}\bar{\rho}_\nu\delta_{\nu q}\right) \tag{6.2.9}$$

$$\dot{\delta}_{\gamma q} - \left(q^2/a^2\right)\delta u_{\gamma q} = -\psi_q \tag{6.2.10}$$

$$\dot{\delta}_{Dq} = -\psi_q \tag{6.2.11}$$

$$\dot{\delta}_{Bq} - \left(q^2/a^2\right)\delta u_{\gamma q} = -\psi_q \tag{6.2.12}$$

$$\dot{\delta}_{\nu q} - \left(q^2/a^2\right)\delta u_{\nu q} = -\psi_q \tag{6.2.13}$$

$$\frac{d}{dt}\left(\frac{(1+R)\delta u_{\gamma q}}{a}\right) = -\frac{1}{3a}\delta_{\gamma q} \tag{6.2.14}$$

$$\frac{d}{dt}\left(\frac{\delta u_{\nu q}}{a}\right) = -\frac{1}{3a}\delta_{\nu q} \tag{6.2.15}$$

[47]1 Other analytic or semi-analytic treatments of the evolution of fluctuations have been given by W.Hu and N. Sugiyama, Astrophys. J. 444, 489 (1995); 471, 542 (1996); V. Mukhanov, Int. J. Theor. Phys. 43, 623 (2004) [astro-ph/0303072]. The treatment given here is in my opinion more transparent though somewhat less accurate than that of Hu and Sugiyama, and (because we allow ourselves the use of a computer to do numerical integrals) it is more accurate than that of Mukhanov.

where $R \equiv 3\bar{\rho}_B/4\bar{\rho}_\gamma$. Eqs. (6.2.1)-(6.2.7) or (6.2.9)-(6.2.15) form a closed system of seven first-order differential equations for ψ_q, the four density perturbations, and the plasma and neutrino velocity potentials, so there must be seven independent solutions.

Before trying to find solutions valid up to the time of recombination, we must first consider the initial conditions to be imposed. These initial conditions will distinguish the different independent solutions. At sufficiently early times the universe was in a radiation-dominated era, when $\bar{\rho}_M \ll \bar{\rho}_R$, where

$$\bar{\rho}_M \equiv \bar{\rho}_D + \bar{\rho}_B, \quad \bar{\rho}_R \equiv \bar{\rho}_\gamma + \bar{\rho}_v \tag{6.2.16}$$

so that to a good approximation $a \propto \sqrt{t}$ and $8\pi G\bar{\rho}_R/3 = 1/4t^2$, while $R \ll 1$. (This fixes our definition of the zero of time.) If we take $a \propto \sqrt{t}$ and $R \ll 1$, Eqs. (6.2.9)-(6.2.15) become

$$\frac{d}{dt}\left(t\psi_q\right) = -4\pi G t\left(\bar{\rho}_D\delta_{Dq} + \bar{\rho}_B\delta_{Bq} + \frac{8}{3}\bar{\rho}_\gamma\delta_{\gamma q} + \frac{8}{3}\bar{\rho}_\nu\delta_{\nu q}\right) \tag{6.2.17}$$

$$\dot{\delta}_{\gamma q} = \dot{\delta}_{Bq} = -\psi_q + \left(q^2/a^2\right)\delta u_{\gamma q} \tag{6.2.18}$$

$$\dot{\delta}_{Dq} = -\psi_q \tag{6.2.19}$$

$$\dot{\delta}_{vq} = -\psi_q + \left(q^2/a^2\right)\delta u_{vq} \tag{6.2.20}$$

$$\frac{d}{dt}\left(\frac{\delta u_{\gamma q}}{\sqrt{t}}\right) = -\frac{1}{3\sqrt{t}}\delta_{\gamma q} \tag{6.2.21}$$

$$\frac{d}{dt}\left(\frac{\delta u_{vq}}{\sqrt{t}}\right) = -\frac{1}{3\sqrt{t}}\delta_{vq} \tag{6.2.22}$$

At very early times the perturbation was outside the horizon, in this sense that $q/aH \ll 1$, but we have not yet dropped the terms in Eqs. (6.2.18) and (6.2.20) proportional to q^2, because in some modes there are cancelations in the calculation of the conserved quantity $\mathcal{R}_q$ outside the horizon that require us to take such terms into account. Also, we have not dropped the terms on the right-hand side of Eq. (6.2.17) proportional to $\bar{\rho}_D$ or $\bar{\rho}_B$, because even though we are now assuming that $\bar{\rho}_D$ and $\bar{\rho}_B$ are much less than $\bar{\rho}_\gamma$ and $\bar{\rho}_\nu$, we want to leave open the possibility of modes in which the fractional fluctuations in the dark matter and/or baryon density are much larger than the fractional fluctuations in the photon and neutrino densities.

Mode 1

This is the dominant adiabatic mode - adiabatic, in the sense that all the $\delta_{\alpha q}$ become equal at very early times. (As discussed in Section 5.4, only these modes are present in inflationary theories with a single scalar field, or if the universe was ever earlier in a state of complete local thermal equilibrium with no non-zero conserved quantities.) Inspection of Eqs. (6.2.17)-(6.2.22) shows that, if we make the ansatz,

$$\delta_{\gamma q} = \delta_{Bq} = \delta_{Dq} = \delta_{\nu q} \equiv \delta_q, \quad \delta u_{\gamma q} = \delta u_{\nu q} \equiv \delta u_q \tag{6.2.23}$$

and if we now drop the baryon and dark matter-dominated terms in Eq. (6.2.17), and consider times early enough so that we can drop the q^2/a^2 terms in Eqs. (6.2.18) and (6.2.20), then Eqs. (6.2.18)-(6.2.22) and (6.2.17) become

[472] Note that this differs from a commonly used convention, according to which $\delta_{\alpha q}$ would be defined as $\delta\rho_{\alpha q}/\bar{\rho}_\alpha$.

$$\dot{\delta}_q = -\psi_q, \tag{6.2.24}$$

$$\frac{d}{dt}\left(\frac{\delta u_q}{\sqrt{t}}\right) = -\frac{1}{3\sqrt{t}}\delta_q, \tag{6.2.25}$$

and

$$\frac{d}{dt}\left(t\psi_q\right) = -\frac{1}{t}\delta_q \tag{6.2.26}$$

Combining Eqs. (6.2.24) and (6.2.26) gives a second-order differential equation for δ_q :

$$\frac{d}{dt}\left(t\frac{d}{dt}\delta_q\right) - \frac{1}{t}\delta_q = 0$$

This has two solutions, with $\delta_q \propto t$ and $\delta_q \propto 1/t$, and for each solution Eqs. (6.2.24) and (6.2.25) give solutions for ψ_q and δu_q. The growing solution has $\delta_q \propto t$ and $\delta u_q \propto t^2$, and gives our first adiabatic mode:

$$\delta_{\gamma q} = \delta_{Bq} = \delta_{\nu q} = \delta_{Dq} = \frac{q^2 t^2 \mathcal{R}_q^o}{a^2}, \tag{6.2.27}$$

$$\psi_q = -\frac{t q^2 \mathcal{R}_q^o}{a^2}, \tag{6.2.28}$$

$$\delta u_{\gamma q} = \delta u_{\nu q} = -\frac{2t^3 q^2 \mathcal{R}_q^o}{9a^2}, \tag{6.2.29}$$

We have normalized this mode so that the quantity given by Eq. (5.4.24) as

$$q^2\mathcal{R}_q \equiv -a^2 H\psi_q + 4\pi G a^2 \delta\rho_q + q^2 H\delta u_q \tag{6.2.30}$$

takes the time-independent value $q^2\mathcal{R}_q^o$ for $q/a \ll H$ (the superscript o standing for "outside the horizon").

Mode 2

The solution of Eqs. (6.2.24)-(6.2.26) which goes as $\delta_q \propto 1/t$ for $t \to 0$ gives us our second adiabatic solution:

$$\delta_{\gamma q} = \delta_{Bq} = \delta_{\nu q} = \delta_{Dq} = \epsilon_q/t, \quad \psi_q = \epsilon_q/t^2, \quad \delta u_{\gamma q} = \delta u_{\nu q} = \frac{2\epsilon_q}{3} \tag{6.2.31}$$

with ϵ_q an arbitrary time-independent function of q. The calculation of $\mathcal{R}_q$ for this solution has the problem that the first two terms in Eq. (6.2.30) for $q^2\mathcal{R}_q$ cancel to zeroth order in q^2/a^2H^2, leaving us with an unknown residue in $q^2\mathcal{R}_q$ of order q^2/a^2H^2, and hence an unknown term in $\mathcal{R}_q$ of zeroth order in q^2/a^2H^2. Fortunately, in this mode we can find a solution to Eqs. (6.2.17)-(6.2.22) that is valid to all orders in q/aH, as long as
$\rho_M \ll \rho_R$:

$$\delta_{\gamma q} = \delta_{Bq} = \delta_{\nu q} = \epsilon_q/t, \quad \delta_{Dq} = \frac{\epsilon_q}{t}\left[1 - \frac{q^2}{3H^2a^2}\ln\left(\frac{q}{Ha}\right)\right] \tag{6.2.32}$$

$$\psi_q = \frac{\epsilon_q}{t^2}\left[1 + \frac{2q^2t^2}{3a^2}\right] \tag{6.2.33}$$

$$\delta u_{\gamma q} = \delta u_{\nu q} = \frac{2\epsilon_q}{3} \tag{6.2.34}$$

Using this in Eq. (6.2.30) shows that this mode has $\mathcal{R}_q = 0$ to all orders in q/aH as long as $\bar{\rho}_M \ll \bar{\rho}_R$.

The other five modes are non-adiabatic, in the sense that some of the $\delta_{\alpha q}$ are unequal even for $q/a \ll H$. One particularly simple mode can serve as an illustration:

Mode 3

$$\begin{gathered} \delta_{Dq} = \frac{\epsilon_q \bar{\rho}_B}{\bar{\rho}_B + \bar{\rho}_D}, \quad \delta_{Bq} = -\frac{\epsilon_q \bar{\rho}_D}{\bar{\rho}_B + \bar{\rho}_D} \\ \psi_q = 0, \quad \delta_{\gamma q} = \delta_{\nu q} = 0, \quad \delta u_{\gamma q} = \delta u_{\nu q} = 0 \end{gathered} \tag{6.2.36}$$

again with ϵ_q time-independent but otherwise arbitrary. This just amounts to a perturbation in the time-independent ratio of the densities of baryons and dark matter, and is an exact solution for all times. It is an isocurvature mode, in both the sense that $\mathcal{R}_q = 0$, and also that $\psi_q = 0$.

As already indicated, these results apply only at times early enough so that $\bar{\rho}_M \ll \bar{\rho}_R$ (and, for mode 1, $q/a \ll H$). As an aid to extending these early-time solutions to later times, note that for all times before recombination, the difference of Eqs. (6.2.10) and (6.2.12) gives

$$\frac{d}{dt}\left(\delta_{Bq} - \delta_{\gamma q}\right) = 0 \tag{6.2.37}$$

We see that any solution that satisfies the adiabatic condition, that $\delta_{Bq} = \delta_{\gamma q}$ at early times, when the perturbation is far outside the horizon, will continue thereafter to have

$$\delta_{Bq} = \delta_{\gamma q} \tag{6.2.38}$$

Eqs. (6.2.9)-(6.2.15) are then reduced to

$$\frac{d}{dt}\left(a^2 \psi_q\right) = -4\pi G a^2 \left[\bar{\rho}_D \delta_{Dq} + \left(\bar{\rho}_B + \frac{8}{3}\bar{\rho}_\gamma\right)\delta_{\gamma q} + \frac{8}{3}\bar{\rho}_\nu \delta_{\nu q}\right] \tag{6.2.39}$$

$$\dot{\delta}_{\gamma q} - \left(q^2/a^2\right)\delta u_{\gamma q} = -\psi_q \tag{6.2.40}$$

$$\dot{\delta}_{Dq} = -\psi_q \tag{6.2.41}$$

$$\dot{\delta}_{\nu q} - \left(q^2/a^2\right)\delta u_{\nu q} = -\psi_q \tag{6.2.42}$$

$$\frac{d}{dt}\left(\frac{(1+R)\delta u_{\gamma q}}{a}\right) = -\frac{1}{3a}\delta_{\gamma q} \tag{6.2.43}$$

$$\frac{d}{dt}\left(\frac{\delta u_{\nu q}}{a}\right) = -\frac{1}{3a}\delta_{\nu q} \tag{6.2.44}$$

where again $R \equiv 3\bar{\rho}_B/4\bar{\rho}_R$. These equations apply to modes 1 and 2 at all times before recombination. We will be chiefly interested in mode 1 , since the perturbations of mode 2 decay by a factor $1/t^2$ relative to those of mode 1 during the part of the radiation dominated era when the perturbation is still outside the horizon.

It is not possible to find an analytic solution of even the reduced set of equations (6.2.39)-(6.2.44) that would be valid for all times and wave numbers. They can be treated analytically, however, in two wavelength regimes: long wavelengths, for which $q \ll q_{\rm EQ}$, and short wavelengths, for which $q \gg q_{\rm EQ}$, where $q_{\rm EQ}$ is the wave number for which $q/a = H$ at matter-radiation equality. Recall that, once inflation is over, q/a decreases more slowly than H, so that for long wavelengths, the wave number is so small that $\bar{\rho}_M$ becomes equal to $\bar{\rho}_R$ when q/a is still much less than H, while for short wavelengths, the wave number is so large that q/a becomes equal to H when $\bar{\rho}_M$ is still much less than $\bar{\rho}_R$. For long wavelengths we will be able

to find analytic solutions of Eqs. (6.2.39)-(6.2.44) in both the early era, when the perturbation is outside the horizon, and in the later era, when the expansion is dominated by non-relativistic matter, and patch them together in the era of overlap, when the perturbation is still outside the horizon and the universe is already matter dominated. Conversely, for short wavelengths we will be able to find analytic solutions of these equations in the early era when the universe is radiation dominated and in the later era when the perturbation is deep inside the horizon, and patch them together in the era of overlap, when the universe is still radiation dominated and the perturbation is already deep inside the horizon. The two cases of long and short wavelength are considered in Sections 6.3 and 6.4, respectively.

To calculate the critical wave number $q_{\rm EQ}$ for which $q/a = H$ at matter-radiation equality, we recall that the redshift of matter-radiation equality is given by Eq. (2.2.5) as $1 + z_{\rm EQ} = \Omega_M/\Omega_R = \Omega_M h^2/4.15 \times 10^{-5}$.

Eq. (2.2.9) gives the Hubble rate during the radiation dominated era as $H = 2.1 \times 10^{-20}(1+z)^2 s^{-1}$, but at radiation-matter equality the contribution of matter to the total energy density makes H larger by a factor $\sqrt{2}$, so for fluctuations that just enter the horizon at matter-radiation equality the physical wave number and Hubble rate at that time are given by Eq. (2.2.9) as $q_{\rm EQ}/a_{\rm EQ} = H_{\rm EQ} = \sqrt{2} \times 2.1 \times 10^{-20}\,(1 + z_{\rm EQ})^2\, s^{-1} = 1.72 \times 10^{-11}\,(\Omega_M h^2)^2$ s^{-1}.
This corresponds to a critical physical wavelength at present given by

$$\lambda_0 \equiv \frac{2\pi}{q_{\rm EQ}/a_0} = \frac{2\pi\,(1 + z_{\rm EQ})}{q_{\rm EQ}/a_{\rm EQ}} = 85\left(\Omega_M h^2\right)^{-1} {\rm Mpc} \tag{6.2.45}$$

For comparison, the size of the local supercluster, estimated from the distance between our galaxy and the Virgo cluster, is about 15 Mpc . Perturbations that are now observed to extend over distances that are larger or smaller than $\lambda_{\rm EQ}$ came within the horizon before or after matter-radiation equality, respectively. Using the present mass density ρ_{M0} given by Eq. (1.5.28) and (1.5.39), the average mass now contained within a sphere of diameter λ_0 is

$$\frac{\pi}{6}\rho_{M0}\lambda_0^3 = 0.9 \times 10^{17}\left(\Omega_M h^2\right)^{-2} M_\odot \tag{6.2.46}$$

This may be compared with the mass of a large galaxy, about $10^{12} M_\odot$. Thus any perturbation that is relevant to the formation of galaxies or even clusters of galaxies would have been well within the horizon at the time of radiation-matter equality.

We can also identify a corresponding critical multipole order $\ell_{\rm EQ}$ of anisotropies in the cosmic microwave background. As remarked in Section 2.6, the integral over wave numbers for the multipole coefficient C_ℓ is dominated by co-moving wave numbers of order ℓ/r_L, where r_L is the radial coordinate of the surface of last scattering, and hence the integral for C_ℓ is dominated by wave numbers of order $q_{\rm EQ}$ that just come into the horizon at matter-radiation equality if ℓ is of order $\ell_{\rm EQ} = q_{\rm EQ} r_L$. This can be written

$$\ell_{\rm EQ} = \left(\frac{q_{\rm EQ}}{a_{\rm EQ}}\right)\left(\frac{a_{\rm EQ}}{a_0}\right)\left(\frac{a_0}{a_L}\right) a_L r_L = \frac{H_{\rm EQ}\,(1 + z_L)}{(1 + z_{\rm EQ})} a_L r_L$$

where a_L is the Robertson-Walker scale factor at last scattering. We recall that $H_{\rm EQ} = \sqrt{2\Omega_M}\,(1 + z_{\rm EQ})^{3/2}\, H_0$, and $a_L r_L = d_A$, the angular diameter distance of the surface of last scattering. Also, $1 + z_{\rm EQ} = \Omega_M/\Omega_R$. Hence

$$\ell_{\rm EQ} = \Omega_M \sqrt{2/\Omega_R} H_0 d_A\,(1 + z_L) \tag{6.2.47}$$

For instance, if we take sample parameters $\Omega_M = 0.26$ and $\Omega_\Lambda = 0.74$, then as noted in Section 2.6 $d_A = 3.38 H_0^{-1}\,(1 + z_L)^{-1}$. Taking $\Omega_R = 8.01 \times 10^{-5}$ (corresponding to $T_0 = 2.725$ K and $H_0 = 72$ kmsec^{-1}Mpc^{-1}), Eq. (6.2.47) gives a critical multipole order $\ell_{\rm EQ} = 140$.

Multipole coefficients for larger values of ℓ arise only from perturbations that entered the horizon during the radiation dominated era.

In what follows, for both scalar and tensor modes,we will find it convenient to introduce a dimensionless rescaled wave number,

$$\kappa \equiv \frac{\sqrt{2}q}{q_{\rm Eq}} = \frac{(q/a_0)\sqrt{\Omega_R}}{H_0\Omega_M} = \frac{q/a_0}{0.052\Omega_M h^2 {\rm Mpc}^{-1}}. \tag{6.2.48}$$

In the cases of long and short wavelength, we have $\kappa \ll 1$ and $\kappa \gg 1$, respectively.

The calculations of the next three sections are necessarily complicated and perhaps tedious. As a guide, it may help to say that the results at which we are aiming are Eqs. (6.5.15) and (6.5.16) for the perturbations to the dark matter density and gravitational field in the whole of the matter-dominated era, and Eqs. (6.5.17) and (6.5.18) for the perturbations to the photon and baryonic plasma density and velocity potential in the matter-dominated era, up to the time of the decoupling of matter and radiation.

10.6.4 6.3 Scalar perturbations - long wavelengths

We first consider perturbations with wavelengths that are long enough so that they are still outside the horizon at the time of radiation-matter equality. As discussed at the end of the previous section, such perturbations are responsible for multipole moments of the cosmic microwave background anisotropies with $\ell < 140$. Because $q\bar\rho_R/aH\bar\rho_M$ is constant during the radiation dominated era, when $a \propto \sqrt{t}$ and $H \propto a^{-2}$, and we are here assuming it is much less than one when $\bar\rho_M = \bar\rho_R$, it follows that for these wavelengths we have

$$\frac{q}{aH} \ll \frac{\bar\rho_M}{\bar\rho_R} \tag{6.3.1}$$

throughout the radiation-dominated era. (Recall that $\bar\rho_M \equiv \bar\rho_D + \bar\rho_B$ and $\bar\rho_R \equiv \bar\rho_\gamma + \bar\rho_\nu$.) On the other hand, during the matter-dominated era when $a \propto t^{2/3}$ and $H \propto a^{-3/2}$, it is $q^2\bar\rho_R/a^2H^2\bar\rho_M$ that remains constant, and since this quantity is assumed to be much less than one when $\bar\rho_M = \bar\rho_R$, for these wavelengths we have

$$\frac{q^2}{a^2H^2} \ll \frac{\bar\rho_M}{\bar\rho_R} \tag{6.3.2}$$

throughout the matter-dominated era.

We cannot give a single analytic formula for these perturbations during the whole era from just after electron-positron annihilation until near the present, but fortunately we can find analytic solutions in two eras: first, the era when the perturbations are outside the horizon, and, second, the era when the energy density of the universe is dominated by non-relativistic matter. (The anisotropic inertia due to neutrinos can be neglected in both eras, because it is negligible outside the horizon, and irrelevant when the energy density of neutrinos is much less than that of matter.) For the long wavelengths considered in this section, that are still outside the horizon at the time that the matter density becomes equal to that of radiation, these eras overlap. This allows us to take the initial condition in the second era from the results for the first era in the period in which they overlap.

A. Outside the horizon

The perturbations of greatest interest, corresponding to adiabatic modes, are governed by Eqs. (6.2.39)-(6.2.44), with the fractional perturbations $\delta_{\alpha q}$ defined by Eq. (6.2.8), and with $\delta_{Bq} = \delta_{\gamma q}$. For $q/a \ll H$, this gives

$$\frac{d}{dt}\left(a^2\psi_q\right) = -4\pi G a^2\left[\bar{\rho}_D\delta_{Dq} + \left(\bar{\rho}_B + \frac{8}{3}\bar{\rho}_\gamma\right)\delta_{\gamma q} + \frac{8}{3}\bar{\rho}_\nu\delta_{\nu q}\right] \tag{6.3.3}$$

$$\dot{\delta}_{\gamma q} = \dot{\delta}_{\nu q} = \dot{\delta}_{Dq} = -\psi_q \tag{6.3.4}$$

$$\frac{d}{dt}\left(\frac{(1+R)\delta u_{\gamma q}}{a}\right) = -\frac{1}{3a}\delta_{\gamma q} \tag{6.3.5}$$

$$\frac{d}{dt}\left(\frac{\delta u_{\nu q}}{a}\right) = -\frac{1}{3a}\delta_{\nu q} \tag{6.3.6}$$

These can be solved analytically, at least for some of the modes described in the previous section. Most importantly, for the adiabatic solutions with all $\delta_{\alpha q}$ equal outside the horizon, Eqs. (6.3.3) and (6.3.4) become

$$\frac{d}{dt}\left(a^2\psi_q\right) = -4\pi G a^2\left[\bar{\rho}_M + \frac{8}{3}\bar{\rho}_R\right]\delta_q \tag{6.3.7}$$

$$\dot{\delta}_q = -\psi_q \tag{6.3.8}$$

where

$$\delta_q \equiv \delta_{\gamma q} = \delta_{\nu q} = \delta_{Bq} = \delta_{Dq} \tag{6.3.9}$$

and we recall that $\bar{\rho}_M \equiv \bar{\rho}_B + \bar{\rho}_D$ and $\bar{\rho}_R \equiv \bar{\rho}_\gamma + \bar{\rho}_\nu$. Inserting Eq. (6.3.8) in (6.3.7) then gives a second-order differential equation for δ_q :

$$\frac{d}{dt}\left(a^2\frac{d}{dt}\delta_q\right) = 4\pi G a^2\left[\bar{\rho}_M + \frac{8}{3}\bar{\rho}_R\right]\delta_q \tag{6.3.10}$$

To solve Eq. (6.3.10), it is very convenient to replace the dependent variable t with $y \equiv a/a_{\rm EQ} = \bar{\rho}_M/\bar{\rho}_R$, where $a_{\rm EQ}$ is the Robertson-Walker scale factor at matter-radiation equality. Then $\bar{\rho}_M = \rho_{\rm EQ}/y^3$ and $\bar{\rho}_R = \rho_{\rm EQ}/y^4$, where $\rho_{\rm EQ}$ is the common density of matter and radiation when they are equal. Using the Friedmann formula for the expansion rate, we have then

$$\frac{d}{dt} = \frac{H_{\rm EQ}}{\sqrt{2}}\frac{\sqrt{1+y}}{y}\frac{d}{dy} \tag{6.3.11}$$

and Eq. (6.3.10) becomes

$$y\sqrt{1+y}\frac{d}{dy}\left(y\sqrt{1+y}\frac{d}{dy}\delta_q\right) - \frac{3}{2}\left(y+\frac{8}{3}\right)\delta_q = 0 \tag{6.3.12}$$

This has two independent solutions,

$$\delta^{(a)} = y^{-2}\left(16 + 8y - 2y^2 + y^3\right), \quad \delta^{(b)} = y^{-2}\sqrt{1+y}$$

We are looking for a solution that, as found for Mode 1 in the previous section, vanishes like $t \propto y^2$ for $t \to 0$, so we must take our solution to be proportional to $\delta^{(a)} - 16\delta^{(b)}$, which for $y \to 0$ approaches $5y^2/8$. Adjusting the normalization of this solution to match Eq. (6.2.27), we have then

$$\delta_q = \frac{4q^2\mathcal{R}_q^o}{5H_{\rm EQ}^2 a_{\rm EQ}^2 y^2}\left(16+8y-2y^2+y^3-16\sqrt{1+y}\right), \tag{6.3.13}$$

$$\delta u_{\gamma q} = -\frac{\sqrt{2}y}{3H_{\rm EQ}(1+R)}\int_0^y \frac{dy'}{\sqrt{1+y'}}\delta_q\left(y'\right), \tag{6.3.14}$$

$$\delta u_{\nu q} = -\frac{\sqrt{2}y}{3H_{\rm EQ}}\int_0^y \frac{dy'}{\sqrt{1+y'}}\delta_q\left(y'\right), \tag{6.3.15}$$

$$\psi_q = \frac{\sqrt{2}q^2\mathcal{R}_q^o}{5H_{\rm EQ}a_{\rm EQ}^2 y^4}\left(2\sqrt{1+y}\left(32+8y-y^3\right)-64-48y\right). \tag{6.3.16}$$

With this normalization factor, $\mathcal{R}_q$ takes the time-independent value $\mathcal{R}_q^o$ outside the horizon.

B. The matter-dominated era

We can also solve Eqs. (6.2.39)-(6.2.44) analytically in the matter-dominated era, when $\bar\rho_M \gg \bar\rho_R$, whether or not the perturbation is outside the horizon. For simplicity, we will also assume that $\bar\rho_B \ll \bar\rho_D$. (Their ratio is actually
about 0.2.) However, since $\bar\rho_\gamma$ is also much less than $\bar\rho_D$ in the matterdominated era, we will not assume that $\bar\rho_B$ is negligible compared with $\bar\rho_\gamma$ in this era. Recall that in the matter-dominated era ${}^1a \propto t^{2/3}$ and $8\pi G\bar\rho_M/3 = H^2 = 4/9t^2$. If we keep only the term in Eq. (6.2.39) proportional to $\bar\rho_D$, but now make no assumption about the relative magnitude of q/a and H, then Eqs. (6.2.39)-(6.2.44) become

$$\frac{d}{dt}\left(t^{4/3}\psi_q\right) = -\frac{2}{3}t^{-2/3}\delta_{Dq} \tag{6.3.17}$$

$$\dot\delta_{\gamma q} - \left(q^2/a^2\right)\delta u_{\gamma q} = -\psi_q \tag{6.3.18}$$

$$\dot\delta_{\nu q} - \left(q^2/a^2\right)\delta u_{\nu q} = -\psi_q \tag{6.3.19}$$

$$\dot\delta_{Dq} = -\psi_q \tag{6.3.20}$$

$$\frac{d}{dt}\left(t^{-2/3}(1+R)\delta u_{\gamma q}\right) = -\frac{1}{3}t^{-2/3}\delta_{\gamma q} \tag{6.3.21}$$

$$\frac{d}{dt}\left(t^{-2/3}\delta u_{\nu q}\right) = -\frac{1}{3}t^{-2/3}\delta_{\nu q} \tag{6.3.22}$$

where once again $R \equiv 3\bar\rho_B/4\bar\rho_R \propto a$.
There are two solutions to Eqs. (6.3.17) and (6.3.20), one with $\psi_q \propto t^{-1/3}$ and $\delta_{Dq} \propto t^{2/3}$, the other with $\psi_q \propto t^{-2}$ and $\delta_{Dq} \propto t^{-1}$. To evaluate the coefficients of these solutions in mode 1 , we must compare these results with those given by Eqs. (6.3.13) and (6.3.16) in the era where both sets of results apply, the era (which exists because of our assumption of long wavelength) when both $q/a \ll H$ and $\bar\rho_R \ll \bar\rho_M$, i. e., $y \gg 1$. Eqs. (6.3.13) and (6.3.16) give in mode 1

$$\delta_{Dq} = \frac{4q^2 y\mathcal{R}_q^o}{5H_{\rm EQ}^2 a_{\rm EQ}^2} = \frac{9q^2t^2\mathcal{R}_q^o}{10a^2} \tag{6.3.23}$$

$$\psi_q = \frac{-2\sqrt{2}q^2\mathcal{R}_q^o}{5H_{\rm EQ}a_{\rm EQ}^2 y^{1/2}} = -\frac{3q^2t\mathcal{R}_q^o}{5a^2} \tag{6.3.24}$$

(The final expression in Eqs. (6.3.23)-(6.3.24) is derived using the result that for $\bar\rho_R \ll \bar\rho_D$, the Hubble rate is $H = 2/3t = H_{\rm EQ}/\sqrt{2}y^{3/2}$, and eliminating $H_{\rm EQ}$.) For $a \propto t^{2/3}$, these match

the solution with $\delta_{Dq} \propto t^{2/3}$ and $\psi_q \propto t^{-1/3}$, while it is easy to see that Mode 2 gives the other solution in the matter-dominated era, the one with $\psi_q \propto t^{-2}$ and $\delta_{Dq} \propto t^{-1}$. We conclude that if Mode 1 is dominant outside the horizon, then the dark

matter density perturbation and gravitational field perturbation are given in the matter-dominated era by Eqs. (6.3.23) and (6.3.24).

This is a good place to pause, and make contact with the more elementary treatment of Section 2.6. Under the assumption that the fluctuation in the Newtonian gravitational potential $\phi(\mathbf{x}, t)$ at around the time of last scattering is dominated by fluctuations in the dark matter density, its Fourier transform is given by using Poisson's equation, with the Laplacian replaced with $-q^2/a^2$:

$$\delta\phi(\mathbf{q}, t) = -4\pi G \left(a^2(t)/q^2\right) \delta\rho_D(\mathbf{q}, t) = -4\pi G \left(a^2(t)/q^2\right) \bar{\rho}_D(t)\delta_{Dq}(t)$$

Using the Mode 1 solution Eq. (6.3.23) and the Friedmann equation $H^2 = (2/3t)^2 = 8\pi G\bar{\rho}_D/3$, we see that $\delta\phi(\mathbf{q}, t)$ takes the time-independent value

$$\delta\phi(\mathbf{q}) = -\frac{3}{5}\alpha(\mathbf{q})\mathcal{R}_q^o$$

Then $\langle\delta\phi(\mathbf{q})\delta\phi\left(\mathbf{q}'\right)\rangle = \mathcal{P}_\phi(q)\delta^3\left(\mathbf{q}+\mathbf{q}'\right)$, with the correlation function $\mathcal{P}_\phi$ introduced in Section 2.6 equal to

$$\mathcal{P}_\phi(q) = \frac{9}{25}\left|\mathcal{R}_q^o\right|^2.$$

The behavior $\mathcal{P}_\phi(q) = N_\phi^2 q^{-3}$ that was found in Section 2.6 to yield a temperature multipole coefficient $C_\ell = 8\pi N_\phi^2/9\ell(\ell+1)$ thus corresponds to the assumption that $\left|\mathcal{R}_q^o\right|^2 = N^2 q^{-3}$, with $N_\phi^2 = 9N^2/25$.

Even if we assume that the gravitational field is dominated by cold dark matter, we must still consider the perturbations to the photon density and the photon-baryon velocity as preparation for calculating the contribution of intrinsic temperature fluctuations and Doppler effect to the cosmic microwave background anisotropies in the next chapter. Equations (6.3.18) and (6.3.21) are a pair of coupled inhomogeneous first-order differential equations for the two unknowns $\delta_{\gamma q}$ and $\delta u_{\gamma q}$, with a forcing term proportional to ψ_q. Surprisingly, with ψ_q given by Eq. (6.3.24), there is a simple exact solution of these equations:

$$\delta_{\gamma q}^{(1)} = \frac{3q^2t^2(1+3R)\mathcal{R}_q^o}{5a^2\left(t^2q^2/a^2+2R\right)}, \quad \delta u_{\gamma q}^{(1)} = -\frac{3t^3q^2\mathcal{R}_q^o}{5a^2\left(t^2q^2/a^2+2R\right)} \tag{6.3.25}$$

(We will not be concerned with the remaining equations, (6.3.19) and (6.3.22), which are needed only to calculate the neutrino perturbations.)

To the particular solution (6.3.25), we must add a suitable solution of the homogeneous version of Eqs. (6.3.18) and (6.3.21),

$$\dot{\delta}_{\gamma q}^{(2)} = \left(q^2/a^2\right)\delta u_{\gamma q}^{(2)}, \quad \frac{d}{dt}\left(t^{-2/3}(1+R)\delta u_{\gamma q}^{(2)}\right) = -\frac{1}{3}t^{-2/3}\delta_{\gamma q}^{(2)}, \tag{6.3.26}$$

or, eliminating the velocity potential,

$$\frac{d}{dt}\left(t^{-2/3}(1+R)a^2\frac{d}{dt}\delta_{\gamma q}^{(2)}\right) + \frac{q^2}{3}t^{-2/3}\delta_{\gamma q}^{(2)} = 0 \tag{6.3.27}$$

[471] The zero of time is chosen in this subsection so that in the matter-dominated era $a \propto t^{2/3}$. In other words, t could here be defined as $2/3H$.

with coefficients chosen so that $\delta^{(1)}_{\gamma q} + \delta^{(2)}_{\gamma q}$ matches the solution found earlier outside the horizon, when $q^2t^2/a^2 \ll 1$.

Using the fact that in the matter dominated era $R \propto a \propto t^{2/3}$, we can find a general solution of Eq. (6.3.27) as a linear combination of the functions

$$F\left(\tfrac{1}{4} - \tfrac{1}{4}\sqrt{1-16\eta}, \tfrac{1}{4} + \tfrac{1}{4}\sqrt{1-16\eta}, \tfrac{1}{2}, -R\right),$$
$$\sqrt{R}F\left(\tfrac{3}{4} - \tfrac{1}{4}\sqrt{1-16\eta}, \tfrac{3}{4} + \tfrac{1}{4}\sqrt{1-16\eta}, \tfrac{3}{2}, -R\right),$$

where F is the Gauss hypergeometric function (also known as ${}_2F_1$), and η is the quantity

$$\eta \equiv \frac{3q^2t^2}{4a^2R}$$

which is time-independent during the matter-dominated era. Unfortunately, this does not provide much insight into the behavior of the solutions. Instead, at this point we will make the further assumption that the wavelength is only moderately long, in the sense that $\eta \gg 1$. That is, although q is small enough so that $q/aH \ll 1$ at matter-radiation equality, we assume that it is sufficiently large so that throughout the matter-dominated era we have

$$R \ll t^2q^2/a^2 \ll \bar{\rho}_M/\bar{\rho}_R \tag{6.3.28}$$

Each term in this inequality is proportional to $t^{2/3}$ during the matterdominated era, so if Eq. (6.3.28) holds at any time during this era, then it holds throughout it. This assumption will allow us to find solutions of Eq. (6.3.27) in terms of elementary functions. In the opposite case of extremely long wavelengths, for which $t^2q^2/a^2 \ll R$ throughout the matterdominated era, we can solve the general solution of Eqs. (6.3.18) and (6.3.21)
as a power series in the quantity t^2q^2/a^2R. We are more interested here in the case of moderately long wavelengths, because as we will see in Section 6.5, it is this case that can be connected to the case of short wavelengths by a smooth extrapolation.

For perturbations satisfying the inequality (6.3.28), when the perturbation is outside the horizon and for some time after it re-enters the horizon, we will have $R \ll 1$. During the period when $R \ll 1$, the homogeneous equations (6.3.26) have the exact solution:

$$\delta^{(2)}_{\gamma q} = c_q \cos(\sqrt{3}qt/a) + d_q \sin(\sqrt{3}qt/a) \tag{6.3.29}$$
$$\delta u^{(2)}_{\gamma q} = \frac{a}{\sqrt{3}q}\left[-c_q \sin(\sqrt{3}qt/a) + d_q \cos(\sqrt{3}qt/a)\right] \tag{6.3.30}$$

with c_q and d_q constant. To this, we must add the inhomogeneous solution (6.3.25), in the limit $R \ll q^2t^2/a^2$:

$$\delta^{(1)}_{\gamma q} = \frac{3(1+3R)\mathcal{R}^o_q}{5}, \quad \delta u^{(1)}_{\gamma q} = -\frac{3t\mathcal{R}^o_q}{5}. \tag{6.3.31}$$

We can evaluate the constants c_q and d_q by requiring that for $qt/a \ll 1$ (which according to Eq. (6.3.28) also implies that $R \ll 1$), the total photon density perturbation $\delta^{(1)}_{\gamma q} + \delta^{(2)}_{\gamma q}$ must approach $\delta_{Dq} \to 9q^2t\mathcal{R}^o_q/10a^2$. This gives

$$c_q = -\frac{3\mathcal{R}^o_q}{5}, \quad d_q = 0 \tag{6.3.32}$$

so that, as long as $R \ll 1$,

$$\delta^{(2)}_{\gamma q} = -\frac{3\mathcal{R}^o_q}{5}\cos(\sqrt{3}qt/a), \tag{6.3.33}$$

Eventually R becomes non-negligible, but under the assumption (6.3.28), by then qt/a will be much larger than one, and we can solve the homogeneous equations (6.3.26) using the WKB approximation. Inspection of Eq. (6.3.27) suggests that for $qt/a \gg 1$ the density fluctuation will oscillate rapidly, with phase

$$\varphi \equiv \int_0^t \frac{q dt}{a\sqrt{3(1+R)}} = \frac{\sqrt{3}qt}{a\sqrt{R}} \ln(\sqrt{R} + \sqrt{1+R}) \tag{6.3.34}$$

Using φ as the independent variable instead of t, and recalling that during the matter-dominated era $a \propto t^{2/3}$, Eq. (6.3.27) becomes

$$\frac{d^2\delta_{\gamma q}}{d\varphi^2} + \frac{1}{2}\left(\frac{d\ln(1+R)}{d\varphi}\right)\frac{d\delta_{\gamma q}}{d\varphi} + \delta_{\gamma q} = 0.$$

We try for a solution of the form $\mathcal{A}e^{\pm i\varphi}$, with $\mathcal{A}$ varying slowly with φ, so that we can neglect the second derivative of $\mathcal{A}$ in the first term on the left and neglect the first derivative of $\mathcal{A}$ in the second term on the left, which is already small because of the factor $d\ln(1+R)/d\varphi$. This gives $dA/d\varphi \simeq -(A/4)d\ln(1+R)/d\varphi$, and hence the general WKB solutions of Eq. (6.3.27) are

$$\delta_{\gamma q}^{(2\pm)} \propto (1+R)^{-1/4}\exp(\pm i\varphi).$$

Clearly, the linear combination of these solutions that merge smoothly with the results for $R \ll 1$ is obtained by replacing the argument of the cosine in Eq. (6.3.33) with φ, and multiplying with $(1+R)^{-1/4}$. Adding the inhomogeneous term (6.3.25), the total photon and baryon fractional density perturbations for moderately long wavelengths in the matter-dominated era are

$$\delta_{\gamma q} = \delta_{Bq} = \frac{3\mathcal{R}_q^o}{5}\left[1 + 3R - (1+R)^{-1/4}\cos\varphi\right] \tag{6.3.35}$$

We can then use Eqs. (6.3.18) and (6.3.24) to calculate the velocity potential

$$\delta u_{\gamma q} = \frac{3t\mathcal{R}_q^o}{5}\left[-1 + \frac{a}{\sqrt{3}qt(1+R)^{3/4}}\sin\varphi\right] \tag{6.3.36}$$

(Here we neglect a term in square brackets of order Ra^2/t^2q^2.) As a check, note that early in the matter-dominated era, when $qt/a \ll 1$, we have $R \ll 1$, so $\varphi \to \sqrt{3}qt/a \to 0$, and hence Eq. (6.3.35) gives $\delta_{\gamma q} = \delta_{Bq} \to 9q^2t^2\mathcal{R}_q^o/10a^2$, in agreement with Eq. (6.3.23) and the condition that for adiabatic modes all $\delta_{\alpha q}$ are equal outside the horizon. This condition is satisfied by Eq. (6.3.35) even if the inequality (6.3.28) is not satisfied, as long as both $R \ll 1$ and $qt/a \ll 1$.

The results (6.3.35) and (6.3.36) for $\delta_{\gamma q} = \delta_{Bq}$ and $\delta u_{\gamma q}$ in the case of moderately long wavelengths all apply only up to the time of last scattering. On the other hand, to the extent that the energy density after last scattering is dominated by dark matter, δ_{Dq} and ψ_q are unaffected by the decoupling of radiation from the baryonic plasma, and continue to be given by Eq. (6.3.23) and (6.3.24) until either vacuum energy and possibly spatial curvature become significant or the perturbations become too strong to be treated as first-order perturbations.

10.6.5 6.4 Scalar perturbations - short wavelengths

We next consider adiabatic perturbations with wavelengths that are short enough so that they are already well within the horizon at the time of
radiation-matter equality. As discussed at the end of Section 6.2, such perturbations are responsible for multipole moments of the cosmic microwave background anisotropies with $\ell \gg 140$,

and also for the onset of gravitational condensations that lead to the formation of structures on the scale of galaxies or clusters of galaxies. Following the same reasoning as at the beginning of the previous section, for these wavelengths in the radiationdominated era

$$\frac{q}{aH} \gg \frac{\bar{\rho}_M}{\bar{\rho}_R}, \tag{6.4.1}$$

and in the matter-dominated era

$$\frac{q^2}{a^2H^2} \gg \frac{\bar{\rho}_M}{\bar{\rho}_R}, \tag{6.4.2}$$

where as before $\bar{\rho}_M \equiv \bar{\rho}_D + \bar{\rho}_B$ and $\bar{\rho}_R \equiv \bar{\rho}_\gamma + \bar{\rho}_\nu$.
As shown in Section 6.2, because we are considering adiabatic perturbations, the fractional perturbations $\delta_{\alpha q} \equiv \delta\rho_{\alpha q}/\left(\bar{\rho}_\alpha + \bar{p}_\alpha\right)$ are subject to the condition $\delta_{Bq} = \delta_{\gamma q}$. Consequently the perturbations are governed by Eqs. (6.2.39)-(6.2.44). Again, we cannot give a single analytic solution of these equations during the whole era from just after electron-positron annihilation until near the present, but fortunately we can find analytic solutions in two overlapping eras: first, the era when the energy density of the universe is dominated by radiation (photons and neutrinos), and second, the era when perturbations are well within the horizon.

A. The radiation-dominated era

We can solve Eqs. (6.2.39)-(6.2.44) analytically in the radiation-dominated era, when $\bar{\rho}_R \gg \bar{\rho}_M$. We will assume tentatively that at this time the photon and neutrino density fluctuations on the right-hand side of the gravitational field equation (6.2.39) dominate over the dark matter density fluctuations, an assumption we will check later in this section. In this era $a \propto t^{1/2}$, so Eqs. (6.2.39)-(6.2.44) take the form

$$\frac{d}{dt}\left(t\psi_q\right) = -\frac{32\pi G t}{3}\left(\bar{\rho}_\gamma\delta_{\gamma q} + \bar{\rho}_\nu\delta_{\nu q}\right) \tag{6.4.3}$$

$$\dot{\delta}_{\gamma q} - \left(q^2/a^2\right)\delta u_{\gamma q} = -\psi_q \tag{6.4.4}$$

$$\dot{\delta}_{Dq} = -\psi_q \tag{6.4.5}$$

$$\frac{d}{dt}\left(t^{-1/2}\delta u_{\gamma q}\right) = -\frac{1}{3}t^{-1/2}\delta_{\gamma q} \tag{6.4.6}$$

$$\dot{\delta}_{vq} - \left(q^2/a^2\right)\delta u_{vq} = -\psi_q \tag{6.4.7}$$

$$\frac{d}{dt}\left(t^{-1/2}\delta u_{vq}\right) = -\frac{1}{3}t^{-1/2}\delta_{vq} \tag{6.4.8}$$

We are interested in adiabatic solutions for which all $\delta_{\alpha q}$ and $\delta u_{\alpha q}$ become equal at early times, so since the differential equations here are the same for photons and neutrinos, these adiabatic solutions have

$$\delta_{\gamma q} = \delta_{\nu q}, \quad \delta u_{\gamma q} = \delta u_{\nu q}$$

For these modes, Eq. (6.4.3) now simplifies to

$$\frac{d}{dt}\left(t\psi_q\right) = -\frac{32\pi G\bar{\rho}_R t}{3}\delta_{\gamma q} = -\frac{1}{t}\delta_{\gamma q}$$

Also, assuming that the cosmological perturbations are in the growing adiabatic mode, Mode 1, they satisfy the initial conditions (6.2.27)-(6.2.30): For $q/aH \ll 1$

$$\delta_{\gamma q} = \delta_{Bq} = \delta_{\nu q} \to \frac{q^2 t^2 \mathcal{R}_q^o}{a^2}, \quad \delta_{Dq} \to \frac{q^2 t^2 \mathcal{R}_q^o}{a^2} \tag{6.4.9}$$

$$\psi_q \to -\frac{t q^2 \mathcal{R}_q^o}{a^2}, \quad \delta u_{\gamma q} = \delta u_{\nu q} \to -\frac{2 t^3 q^2 \mathcal{R}_q^o}{9 a^2} \tag{6.4.10}$$

where $\mathcal{R}_q^o$ is the value of $\mathcal{R}_q$ outside the horizon. The reader can check that the solution of Eqs. (6.4.3)-(6.4.8) satisfying these initial conditions is [1]

$$\delta_{\gamma q} = \delta_{Bq} = \delta_{\nu q} = 3\mathcal{R}_q^o \left(\frac{2}{\Theta} \sin\Theta - \left(1 - \frac{2}{\Theta^2}\right) \cos\Theta - \frac{2}{\Theta^2} \right) \tag{6.4.11}$$

$$\psi_q = \frac{3\mathcal{R}_q^o}{t} \left(\frac{2}{\Theta} \sin\Theta + \frac{2}{\Theta^2} \cos\Theta - \frac{2}{\Theta^2} - 1 \right) \tag{6.4.12}$$

$$\delta_{Dq} = -6\mathcal{R}_q^o \int_0^\Theta \left(\frac{2}{\vartheta^3} \sin\vartheta + \frac{2}{\vartheta^4} \cos\vartheta - \frac{2}{\vartheta^4} - \frac{1}{\vartheta^2} \right) \vartheta d\vartheta \tag{6.4.13}$$

$$\delta u_{\gamma q} = \delta u_{\nu q} = 4t\mathcal{R}_q^0 \left(\frac{\sin\Theta}{2\Theta} - \frac{1 - \cos\Theta}{\Theta^2} \right) \tag{6.4.14}$$

where

$$\Theta \equiv \frac{2qt}{\sqrt{3}a} \tag{6.4.15}$$

Note that the fractional perturbations $\delta_{\alpha q}$ are all of the same order of magnitude for moderate values of Θ. This justifies the neglect of the matter terms in Eq. (6.2.39) when $\bar{\rho}_R$ is much greater than $\bar{\rho}_D$ and q/aH is not very much larger than unity. The condition for continuing to neglect the matter terms in Eq. (6.2.39) for perturbations deep inside the horizon, when Θ becomes large, will be discussed below.

B. Deep inside the horizon

We can also find a solution of Eqs. (6.2.39)-(6.2.44) when the wavelength is well within the horizon, in the sense that $q/a \gg H$, whether or not $\bar{\rho}_D$ is negligible compared with $\bar{\rho}_R$. For $q/a \gg H$ we can distinguish two different kinds of solutions: "slow modes," for which time derivatives yield factors of order H, and "fast modes," for which time derivatives acting on the perturbations yield factors of order of q/a, as well as other terms with factors of H instead. Eqs. (6.2.39)-(6.2.44) are a sixth-order system of differential equations, so they have six independent solutions. We are going to identify four independent fast solutions and two independent slow solutions, so we can be sure that there are no solutions other than what we have called fast and slow modes.

[471] By replacing t with Θ as the dependent variable, Eqs. (6.4.3), (6.4.4), and (6.4.6) are put in the form of a parameter-free third-order system of differential equations for $\delta_{\gamma q} = \delta_{Bq} = \delta_{\nu q}, \delta u_{\gamma q}/t = \delta u_{\nu q}/t$ and $t\psi_q$. After finding the solution that matches the initial conditions (6.4.9), (6.4.10), we can solve Eq. (6.4.5) for δ_{Dq} by an integration. Aside from normalization, this solution for the various fluctuations is equivalent to that given for the Newtonian potential in a different gauge in Eq. (48) of S. Bashinsky & E. Bertschinger Phys. Rev. D 65, 123008 (2002).

1. Fast modes

Up to now we have ignored the neutrino anisotropic inertia, but for the rapidly oscillating fast modes we must take into account its effect of the long neutrino mean free path in damping the neutrino density and velocity perturbations. In considering the fast modes deep inside the horizon, we shall simply assume that this damping allows us to ignore δ_{vq} in Eq. (6.2.39). Turning to the other perturbations in a fast mode with fractional rates of change of order q/a, Eq. (6.2.41) shows that δ_{Dq} is of order $\psi_q/(q/a)$, so the dark-matter term on the right-hand side of Eq. (6.2.39) is of order

$$4\pi G a^2 \overline{\rho_D}\psi_q/(q/a) \leq 3H^2 a^2 \psi_q/2(q/a)$$

while the left-hand side of Eq. (6.2.39) is of order $(q/a)a^2\psi_q$, and the dark matter term is therefore less than the left-hand side of Eq. (6.2.39) by a factor less than of order $\leq H^2/(q/a)^2$, which deep in the horizon is much less than unity. Dropping the dark matter term in Eq. (6.2.39), we see that $\delta_{\gamma q}$ must be at least of order $(q/a)\psi_q/H^2$. Eq. (6.2.43) then shows that $\delta u_{\gamma q}$ is of order $\delta_{\gamma q}/(q/a)$, and hence at least of order ψ_q/H^2. Both terms
on the left-hand side of Eqs. (6.2.42) are then larger than ψ_q by factors of order $q^2/a^2H^2 \gg 1$, so we can drop ψ_q on the right-hand side. (That is, because the wavelength is short, pressure gradients exert a much larger force on the baryon-photon plasma than gravitation.) Hence if we neglect all terms in Eqs. (6.2.40), (6.2.43), (6.2.39), and (6.2.41) that are suppressed by factors $H^2/(q/a)^2$ (but not terms arising from derivatives of a that are only suppressed by factors $H/(q/a)$), these equations become

$$\dot{\delta}_{\gamma q} = \left(q^2/a^2\right)\delta u_{\gamma q} \tag{6.4.16}$$

$$\frac{d}{dt}\left(\frac{(1+R)\delta u_{\gamma q}}{a}\right) = -\frac{1}{3a}\delta_{\gamma q} \tag{6.4.17}$$

$$\frac{d}{dt}\left(a^2\psi_q\right) = -\frac{16\pi G a^2}{3}\bar{\rho}_\gamma(R+2)\delta_{\gamma q} \tag{6.4.18}$$

$$\dot{\delta}_{Dq} = -\psi_q \tag{6.4.19}$$

where, as before, $R \equiv 3\bar{\rho}_B/4\bar{\rho}_\gamma$. Equations (6.4.16) and (6.4.17) have two independent solutions for $\delta_{\gamma q}$ and $\delta u_{\gamma q}$. Given these solutions, and looking only for fast modes, Eq. (6.4.18) then has a unique solution for ψ_q, and Eq. (6.4.19) then has a unique solution for δ_{Dq}. (Possible constant terms that might be included in the solutions for $a^2\psi_q$ or δ_{Dq} would contribute to the slow modes, not the fast modes.) Together with the two strongly damped solutions of Eqs. (6.2.42) and (6.2.44) for the neutrino perturbations, there are four independent fast modes, as promised.

By eliminating $\delta u_{\gamma q}$ from Eqs. (6.4.16) and (6.4.17), we obtain a secondorder differential equation for $\delta_{\gamma q}$ alone

$$\frac{d}{dt}\left(a(1+R)\frac{d}{dt}\delta_{\gamma q}\right) + \frac{q^2}{3a}\delta_{\gamma q} = 0 \tag{6.4.20}$$

If a and R were constant, this would be just the wave equation for a sound wave, with physical wave number q/a and velocity ${}^2v_s = 1/\sqrt{3(1+R)}$. With a and R varying at a relatively slow fractional rate H, Eq. (6.4.20) can be solved for $q/a \gg H$ by the WKB approximation. For this purpose, we introduce a new independent variable, the phase $\varphi \equiv q\int_0^t dt/a\sqrt{3(1+R)}$, and rewrite Eq. (6.4.20) as

$$\frac{d^2\delta_{\gamma q}}{d\varphi^2} + \frac{1}{2}\frac{d\ln(1+R)}{d\varphi}\frac{d\delta_{\gamma q}}{d\varphi} + \delta_{\gamma q} = 0$$

Writing $\delta_{\gamma q} = \mathcal{A}\exp(\pm i\varphi)$, and neglecting $d^2\mathcal{A}/d\varphi^2$ in the first term on the left and neglecting $d\mathcal{A}/d\varphi$ in the second term (which is already small because of the factor $d\ln(1+R)/d\varphi$), we find $d\mathcal{A}/d\varphi = -(\mathcal{A}/4)d\ln(1+R)/d\varphi$, so the WKB solutions are [3]

$$\delta^{\pm}_{\gamma q} = (1+R)^{-1/4}\exp\left[\pm iq\int_0^t \frac{dt}{a\sqrt{3(1+R)}}\right] \tag{6.4.21}$$

There is a further complication that must be taken into account for fast modes, though it is not important for slow modes. The amplitude of a sound wave whose physical wave number k is larger than the inverse mean path of the particles in a relativistic medium is damped by viscosity and heat conduction, at a rate given in general by [4]

$$\Gamma = \frac{k^2}{2(\rho+p)}\left\{\zeta + \frac{4}{3}\eta + \chi\left(\frac{\partial\rho}{\partial T}\right)_n^{-1} \right.$$
$$\left.\left[\rho + p - 2T\left(\frac{\partial p}{\partial T}\right)_n + v_s^2 T\left(\frac{\partial\rho}{\partial T}\right)_n - \frac{n}{v_s^2}\left(\frac{\partial p}{\partial n}\right)_T\right]\right\}, \tag{6.4.22}$$

where η, χ, and ζ are the coefficients of shear viscosity, heat conduction, and bulk viscosity, respectively, defined in Appendix B; v_s is the sound speed; n is any number density on which the fluid properties may depend; and subscripts indicate the quantities held constant in taking partial derivatives. For the baryon-photon fluid, for which n is the baryon number density, we have $\rho = \rho_B + \rho_\gamma, p = \rho_\gamma/3$, with $\rho_B \propto n$ and $\rho_\gamma \propto T^4$. Also, as we have seen $v_s^2 = 1/\sqrt{3(1+R)}$. Hence, (setting $k = q/a$) the damping rate becomes

$$\Gamma = \frac{3q^2}{8a^2\bar{\rho}_\gamma(1+R)}\left\{\zeta + \frac{4}{3}\eta + \frac{\chi T R^2}{3(1+R)}\right\}. \tag{6.4.23}$$

The viscosity and heat conduction coefficients for photons interacting with a non-relativistic plasma with mean free time $t_\gamma = 1/\sigma_{\mathcal{T}} n_e$ are

$$\eta = \frac{16}{45}\bar{\rho}_\gamma t_\gamma, \quad \chi T = \frac{4}{3}\bar{\rho}_\gamma t_\gamma, \quad \zeta = 0 \tag{6.4.24}$$

so in this case the damping rate is [5]

$$\Gamma = \frac{q^2 t_\gamma}{6a^2(1+R)}\left\{\frac{16}{15} + \frac{R^2}{1+R}\right\}. \tag{6.4.25}$$

The effect is to replace Eq. (6.4.21) for the fast mode amplitudes with

$$\delta^{\pm}_{\gamma q} = (1+R)^{-1/4}\exp\left[\pm iq\int_0^t \frac{dt}{a\sqrt{3(1+R)}} - \int_0^t \Gamma dt\right] \tag{6.4.26}$$

This damping of the fast modes is known as Silk damping. [6] With this result, $\delta u^{\pm}_{\gamma q}$for these fast modes can be obtained from Eq. (6.4.16), $\psi^{\pm}_q$can be obtained from Eq. (6.4.18), and then $\delta^{\pm}_{Dq}$can be obtained from Eq. (6.4.19).

[472] Note that the condition of constant entropy gives $d\rho_B/\bar{\rho}_B = d\rho_\gamma/(\bar{\rho}_\gamma + \bar{p}_\gamma) = (3/4)d\rho_\gamma/\bar{\rho}_\gamma$, so $v_s^2 = dp/d\rho = d\rho_\gamma/3(d\rho_\gamma + d\rho_B) = 1/3(1+R)$.

2. Slow modes

For solutions whose fractional rate of change is of order $H = O(1/t)$, we can run through the same sort of counting of powers of q/aH as for fast modes, but with very different results. From Eqs. (6.2.41), (6.2.43), and (6.2.44), we see that δ_{Dq} is of order ψ_q/H while $\delta_{\gamma q}$ and $\delta_{\nu q}$ are of order $H\delta u_{\gamma q}$ and $H\delta u_{\nu q}$, respectively. The terms $\dot{\delta}_{\gamma q}$ and $\dot{\delta}_{\nu q}$ on the left-hand side of Eqs. (6.2.40) and (6.2.42) are then of order $H^2\delta u_{\gamma q}$ and $H^2\delta u_{\nu q}$, and hence are less than the terms $(q^2/a^2)\,\delta u_{\gamma q}$ and $(q^2/a^2)\,\delta u_{\nu q}$ by factors of order H^2a^2/q^2, and may be dropped, giving instead

$$\left(q^2/a^2\right)\delta u_{\gamma q} = \left(q^2/a^2\right)\delta u_{\nu q} = \psi_q, \tag{6.4.27}$$

so Eqs. (6.2.43) and (6.2.44) show that $\delta_{\gamma q}$ and $\delta_{\nu q}$ are of order $(a^2H/q^2)\,\psi_q$.
The ratios of the photon and neutrino terms on the right-hand side of Eq. (6.2.39) to the dark matter term are then of order

$$\frac{\text{photons \& neutrinos}}{\text{dark matter}} = O\left[\left(\frac{\bar{\rho}_B + 8\bar{\rho}_R/3}{\bar{\rho}_D}\right)\left(\frac{a^2H^2}{q^2}\right)\right],$$

where as before $\bar{\rho}_R \equiv \bar{\rho}_\gamma + \bar{\rho}_\nu$. The term in the numerator proportional to $\bar{\rho}_B$ contributes much less than unity to this ratio, because $\bar{\rho}_B/\bar{\rho}_D \approx 1/5$ and we are now assuming that $aH/q \ll 1$. According to Eq. (6.4.2), the contribution of the term proportional to $\bar{\rho}_R$ is much less than unity throughout the matter-dominated era. It actually begins to be much less than unity during the radiation-dominated era, when the ratio of radiation density to dark matter density falls below the critical value $(\bar{\rho}_R/\bar{\rho}_D)_{\rm crit}$, given by

$$\left(\frac{\bar{\rho}_R}{\bar{\rho}_D}\right)_{\rm crit} = \left(\frac{3}{8}\right)^{1/3}\left(\frac{q}{aH}\frac{\bar{\rho}_R}{\bar{\rho}_D}\right)^{2/3}. \tag{6.4.28}$$

According to Eqs. (6.4.1), the right-hand side is constant and much greater than unity throughout the radiation-dominated era for the wavelengths considered in this section, so $\bar{\rho}_R/\bar{\rho}_D$ will fall below this critical value well before radiation-matter equality. (That is, strong pressure forces keep perturbations to the baryon-photon plasma density small enough so that their effect on the gravitational field is negligible once $\bar{\rho}_\gamma/\bar{\rho}_B$ falls below the critical value (6.4.28), even though the unperturbed radiation density is at first still larger than the dark matter density.) From then on the photon and neutrino terms may be neglected in Eq. (6.2.39) for the slow modes, yielding

$$\frac{d}{dt}\left(a^2\psi_q\right) = -4\pi G\bar{\rho}_D a^2\delta_{Dq} \tag{6.4.29}$$

The remaining equations, (6.2.41), (6.2.43) and (6.2.44) are unchanged:

[475] This damping rate was first calculated by N. Kaiser, Mon. Not. Roy. Astron. Soc. 202, 1169 (1983), and is derived here in Appendix H. The formulas for the shear viscosity and heat conduction coefficients are obtained by comparing formulas (6.4.23) and (6.4.25) for the acoustic damping rate, taking into account that the bulk viscosity vanishes because energy and momentum are transported by relativistic particles; see ref. 4. The damping rate calculated by ref. 4 had given the correct values for χ and ζ, but it gave a value for η that was 3/4 the correct value of Kaiser, quoted here in Eq. (6.4.24). This was because its results were based on calculations of L. H. Thomas, Quart. J. Math. (Oxford) 1, 239 (1930), that had assumed isotropic scattering and ignored photon polarization. (The same value for η had been given earlier by C. Misner, Astrophys. J. 151, 431 (1968).) Kaiser's results are calculated using the correct differential cross section for Thomson scattering and take photon polarization into account, and therefore supersede the value for η quoted in ref. 4 and Chapter 15 of G&C.

[6] J. Silk, Nature 215, 1155 (1972).

$$\dot{\delta}_{Dq} = -\psi_q \tag{6.4.30}$$

$$\frac{d}{dt}\left(\frac{(1+R)\delta u_{\gamma q}}{a}\right) = -\frac{1}{3a}\delta_{\gamma q} \tag{6.4.31}$$

$$\frac{d}{dt}\left(\frac{\delta u_{\nu q}}{a}\right) = -\frac{1}{3a}\delta_{\nu q} \tag{6.4.32}$$

Using Eq. (6.4.30) in Eq. (6.4.29) yields a second-order differential equation for δ_{Dq} :[7]

$$\frac{d}{dt}\left(a^2\frac{d\delta_{Dq}}{dt}\right) = 4\pi G a^2 \bar{\rho}_D \delta_{Dq}. \tag{6.4.33}$$

It is convenient once again to convert the independent variable from t to $y \equiv a/a_{\rm EQ} = \bar{\rho}_M/\bar{\rho}_R$, using the Friedmann equation

$$\frac{\dot{y}^2}{y^2} = \frac{8\pi G}{3}\left(\bar{\rho}_M + \bar{\rho}_R\right) = \frac{8\pi G \rho_{\rm EQ}}{3}\left(y^{-3} + y^{-4}\right) \tag{6.4.34}$$

with $\rho_{\rm EQ}$ the values of $\bar{\rho}_M$ and $\bar{\rho}_R$ when they are equal. Then (6.4.33) becomes what is sometimes known as the Mészáros equation:

$$y(1+y)\frac{d^2\delta_D}{dy^2} + \left(1+\frac{3y}{2}\right)\frac{d\delta_D}{dy} - \frac{3}{2}(1-\beta)\delta_D = 0 \tag{6.4.35}$$

where $\beta \equiv \bar{\rho}_B/\bar{\rho}_M = \Omega_B/\Omega_M$. The independent solutions of Eq. (6.4.35) for $\beta = 0$ were given by Mészáros, [7] and by Groth and Peebles [8]

$$\delta_{Dq}^{(1)} = 1 + \frac{3y}{2}, \quad \delta_{Dq}^{(2)} = \left(1+\frac{3y}{2}\right)\ln\left(\frac{\sqrt{1+y}+1}{\sqrt{1+y}-1}\right) - 3\sqrt{1+y}. \tag{6.4.36}$$

Subsequently Hu and Sugiyama [9] gave two independent solutions for general β :

$$\delta_{Dq} \propto (1+y)^{-\alpha_\pm} F\left(\alpha_\pm, \alpha_\pm + \frac{1}{2}, 2\alpha_\pm + \frac{1}{2}; \frac{1}{1+y}\right)$$

where F is the Gauss hypergeometric function and

$$\alpha_\pm = \frac{1 \pm \sqrt{1+24\beta}}{4}$$

In order to obtain our final results in an analytic form, we will continue to drop corrections proportional to $\beta \equiv \bar{\rho}_B/\bar{\rho}_M \approx 1/6$, while keeping those proportional to $R \equiv 3\bar{\rho}_B/4\bar{\rho}_\gamma$, so we shall use the slow solutions (6.4.36) for $\beta = 0$. (Corrections for the finite value of β are discussed in the following section.) From these two solutions, we can find unique corresponding slow solutions for $\psi_q, \delta u_{\gamma q}, \delta u_{\nu q}, \delta_{\gamma q}$ and $\delta_{\nu q}$ by successive use of Eqs. (6.4.30), (6.4.27), (6.4.31) and (6.4.32). (The neutrino perturbations are of no known observational interest.) We have thus found two slow modes, giving six in all.

[477] Eq. (6.4.33) was first derived by P. Mészáros, Astron. Astrophys. 37, 225 (1974), who simply ignored fluctuations in the radiation energy density. The argument given here for the neglect of perturbations in the radiation density in Eq. (6.4.33) was given by S. Weinberg, Astrophys. J. 581, 810 (2002). It applies only to the slow mode part of the solution; in the fast mode it is the perturbations in the dark matter density that become negligible for small wavelength. This paper also gives comments on other attempts to justify the neglect of perturbations in the radiation density in Eq. (6.4.33).

C. Matching

Fortunately, for small wavelength there is an overlap in the two eras in which we have found solutions for δ_D, etc., satisfying both conditions $q/a \gg \dot{a}/a$

and $\bar{\rho}_M \ll \bar{\rho}_R$. In this period the solution (6.4.11)-(6.4.14) found for the radiation-dominated era can be decomposed into a fast and a slow mode. Since the variable Θ defined by Eq. (6.4.15) is here much larger than unity, we have

$$\delta^{\rm fast}_{\gamma q} = \delta^{\rm fast}_{Bq} = \delta^{\rm fast}_{\nu q} = 3\mathcal{R}^o_q \left(\frac{2}{\Theta} \sin\Theta - \left(1 - \frac{2}{\Theta^2}\right) \cos\Theta \right),$$
$$\rightarrow -3\mathcal{R}^o_q \cos\Theta \tag{6.4.37}$$

$$\psi^{\rm fast}_q = \frac{3\mathcal{R}^o_q}{t} \left(\frac{2}{\Theta} \sin\Theta + \frac{2}{\Theta^2} \cos\Theta \right) \rightarrow \frac{6\mathcal{R}^o_q}{t\Theta} \sin\Theta, \tag{6.4.38}$$

$$\delta^{\rm fast}_{Dq} = -6\mathcal{R}^o_q \int_{\Theta_1}^{\Theta} \left(\frac{2}{\vartheta^3} \sin\vartheta + \frac{2}{\vartheta^4} \cos\vartheta \right) \vartheta d\vartheta \rightarrow \frac{12\mathcal{R}^o_q}{\Theta^2} \cos\Theta, \tag{6.4.39}$$

$$\delta u^{\rm fast}_{\gamma q} = \delta u^{\rm fast}_{\nu q} = 4t\mathcal{R}^0_q \left(\frac{\sin\Theta}{2\Theta} + \frac{\cos\Theta}{\Theta^2} \right) \rightarrow \frac{2t\mathcal{R}^0_q}{\Theta} \sin\Theta, \tag{6.4.40}$$

and

$$\delta^{\rm slow}_{\gamma q} = \delta^{\rm slow}_{Bq} = \delta^{\rm slow}_{\nu q} = -\frac{6\mathcal{R}^o_q}{\Theta^2} \tag{6.4.41}$$

$$\psi^{\rm slow}_q = -\frac{3\mathcal{R}^o_q}{t} \left(\frac{2}{\Theta^2} + 1 \right) \rightarrow -\frac{3\mathcal{R}^o_q}{t} \tag{6.4.42}$$

$$\delta^{\rm slow}_{Dq} = -6\mathcal{R}^o_q \int_0^{\Theta_1} \left(\frac{2}{\vartheta^3} \sin\vartheta + \frac{2}{\vartheta^4} \cos\vartheta - \frac{2}{\vartheta^4} - \frac{1}{\vartheta^2} \right) \vartheta d\vartheta$$
$$+ 6\mathcal{R}^o_q \left[-\frac{1}{\Theta^2} + \frac{1}{\Theta_1^2} + \ln\left(\Theta/\Theta_1\right) \right]$$
$$\rightarrow 6\mathcal{R}^o_q \left(-\frac{1}{2} + \gamma + \ln\Theta \right) \tag{6.4.43}$$

$$\delta u^{\rm slow}_{\gamma q} = \delta u^{\rm slow}_{\nu q} = -\frac{4t\mathcal{R}^0_q}{\Theta^2} \tag{6.4.44}$$

where again $\Theta \equiv 2qt/\sqrt{3}a$, Θ_1 is any constant in the range $1 \ll \Theta_1 \ll \Theta$, and $\gamma = 0.5772\ldots$ is the Euler constant. [10]

Matching the solutions in the radiation-dominated era and deep within the horizon is straightforward for the fast modes. In the radiation-dominated era, when $R \ll 1$, damping is negligible (because the mean free time is very short), and $a \propto \sqrt{t}$, the argument of the cosine in Eq. (6.4.37) may be expressed as the integral

[478] E. J. Groth and P. J. E. Peebles, Astron. Astrophys. 41, 143 (1975).

[9] W. Hu and N. Sugiyama, Astrophys. J. 471, 542 (1996).

[4710] To evaluate the asymptotic limit of the integral in Eq. (6.4.43), we can rewrite this integral as the sum of three terms, each of which converges at $\vartheta = 0$:

$$\int_0^{\Theta_1} \left(\frac{2}{\vartheta^3} \sin\vartheta + \frac{2}{\vartheta^4} \cos\vartheta - \frac{2}{\vartheta^4} - \frac{1}{\vartheta^2} \right) \vartheta d\vartheta = \int_0^{\Theta_1} \left(\frac{1}{\vartheta^2} \sin\vartheta + \frac{2}{\vartheta^3} \cos\vartheta - \frac{2}{\vartheta^3} \right) d\vartheta$$
$$+ \int_0^{\Theta_1} \left(\frac{\sin\vartheta}{\vartheta} - \frac{1}{1+\vartheta} \right) \frac{d\vartheta}{\vartheta} + \int_0^{\Theta_1} \left(\frac{1}{1+\vartheta} - 1 \right) \frac{d\vartheta}{\vartheta}$$

$$q\int_0^t \frac{dt}{a\sqrt{3(1+R)}} \to \frac{2qt}{a\sqrt{3}} = \Theta$$

Hence the linear combination of the two fast solutions (6.4.26) that fits smoothly with the result (6.4.37) is:

$$\delta_{\gamma q}^{\rm fast} = -\frac{3\mathcal{R}_q^o}{(1+R)^{1/4}} e^{-\int_0^t \Gamma dt} \cos\left(\int_0^t \frac{qdt}{a\sqrt{3(1+R)}}\right) \tag{6.4.45}$$

By a successive use of Eqs. (6.4.16), (6.4.18), and (6.4.19) (and ignoring the time dependence of all factors except the rapidly oscillating sines and cosines), we then also find that for $q/a \gg H$:

$$\delta u_{\gamma q}^{\rm fast} = \frac{a\sqrt{3}\mathcal{R}_q^o}{q(1+R)^{3/4}} e^{-\int_0^t \Gamma dt} \sin\left(\int_0^t \frac{qdt}{a\sqrt{3(1+R)}}\right). \tag{6.4.46}$$

$$\psi_q^{\rm fast} = 16\sqrt{3}\pi G\bar\rho_\gamma(2+R)(1+R)^{1/4}(a/q)\mathcal{R}_q^o e^{-\int_0^t \Gamma dt} \sin\left(\int_0^t \frac{qdt}{a\sqrt{3(1+R)}}\right),$$

$$\delta_{Dq}^{\rm fast} = 48\pi G\bar\rho_\gamma(2+R)(1+R)^{3/4}(a/q)^2\mathcal{R}_q^o e^{-\int_0^t \Gamma dt} \cos\left(\int_0^t \frac{qdt}{a\sqrt{3(1+R)}}\right).$$

We will use Eqs. (6.4.45)-(6.4.48) in dealing with baryon acoustic oscillations in Section 8.1.

The reader can easily check that in the overlap era, when the universe is radiation dominated, the perturbation is deep inside the horizon, and damping is negligible, Eqs. (6.4.45) and (6.4.46) give the same results for $\delta_{\gamma q}^{\rm fast}$ and $\delta u_{\gamma q}^{\rm fast}$ as Eqs. (6.4.37) and (6.4.40). On the other hand, Eqs. (6.4.47) and (6.4.48) give results for $\psi_q^{\rm fast}$ and $\delta_{Dq}^{\rm fast}$ that differ from

Eqs. (6.4.38) and (6.4.39) by a factor $\bar\rho_\gamma/\bar\rho_R$. This is because in deriving Eqs. (6.4.38) and (6.4.39) we treated the neutrinos as a perfect fluid throughout the radiation-dominated era, although this is valid only outside the horizon when anisotropic inertia is negligible, while in deriving Eqs. (6.4.47) and (6.4.48) we assumed that deep inside the horizon neutrino density fluctuations are so damped by anisotropic inertia that they can be neglected as a source of gravitational field perturbations. This discrepancy is a small price to pay for the simplicity gained by these approximations, especially since it will turn out that the slow contributions to ψ_q and δ_{Dq} are much larger than the fast contributions.

Next let us consider the slow modes. Here there is a complication in matching solutions in the radiation-dominated era and deep inside the horizon. In deriving Eqs. (6.4.41)-(6.4.43) we have assumed that in the radiation dominated era we can neglect perturbations in the baryon and dark matter densities as a source of the gravitational field perturbations, but in exploring the solutions deep inside the horizon we found that this assumption is violated for the slow modes once the radiation/dark matter density ratio drops below the limit (6.4.28), even if this ratio is still much larger than unity. Indeed, we can see from Eqs. (6.4.41) and (6.4.43) that for large Θ, $\delta_{Dq}^{\rm slow}/\delta_{\gamma q}^{\rm slow} \to -\Theta^2\ln\Theta$, so the assumption under which Eqs. (6.4.41)(6.4.44) were derived breaks down once $\Theta^2\ln\Theta$ becomes comparable to $\bar\rho_R/\bar\rho_D$, which is close to when $\bar\rho_\gamma/\bar\rho_D$ falls below the critical value (6.4.28). Therefore we have to interpolate between the results (6.4.41)-(6.4.44), which are valid early in the radiation-dominated era, when $q^2t^2/a^2 \ll \bar\rho_R/\bar\rho_D$,

[47] For large Θ_1, these three integrals approach the values $-1/2, 1-\gamma$, and $-\ln\Theta_1$, respectively, giving a total of $1/2-\gamma-\ln\Theta_1$, which when combined with the term on the second line of Eq. (6.4.43) yields the quoted result.

and the results later in the radiation-dominated era and in the matter-dominated era, when the Mészáros equation (6.4.35) applies.

This is easiest for the dark matter density perturbation, because its timedependence turns out to have the same form deep in the horizon in the radiation-dominated era both before and after $\bar{\rho}_R/\bar{\rho}_D$ falls below the critical value (6.4.28). Before this time in the radiation-dominated era $\delta_{Dq}^{\rm slow}$ is given by Eq. (6.4.43). After this time, the gravitational field perturbation becomes dominated by dark matter, and the dark matter density perturbation becomes a linear combination of the solutions (6.4.36) of the Mészáros equation, which in the radiation-dominated era when $y \ll 1$ become

$$\delta_{Dq}^{(1)} \to 1, \quad \delta_{Dq}^{(2)} \to -\ln(y/4) - 3 \tag{6.4.49}$$

The linear combination of these two solutions that fits smoothly with Eq. (6.4.43) is then

$$\delta_{Dq}^{\rm slow} = 6\mathcal{R}_q^0 \left\{ \left[-\frac{7}{2} + \gamma + \ln\left(\frac{4q\sqrt{2}}{\sqrt{3}H_{\rm EQ}a_{\rm EQ}} \right) \right] \delta_{Dq}^{(1)} - \delta_{Dq}^{(2)} \right\} \tag{6.4.50}$$

where $H_{\rm EQ}$ and $a_{\rm EQ}$ are the expansion rate and Robertson-Walker scale factor at matter-radiation equality. (Here we use $t = 1/2H = y^2/\sqrt{2}H_{\rm EQ}$.) The slow part of the gravitational field, radiation velocity potential, and radiation density perturbations are given by a successive use of Eqs. (6.4.30), (6.4.27), and (6.4.31) as

$$\psi_q^{\rm slow} = -\dot{\delta}_{Dq}^{\rm slow} \tag{6.4.51}$$

$$\delta u_{\gamma q}^{\rm slow} = -\left(a^2/q^2\right) \dot{\delta}_{Dq}^{\rm slow} \tag{6.4.52}$$

$$\delta_{\gamma q}^{\rm slow} = \frac{3a}{q^2}\frac{d}{dt}\left(a(1+R)\frac{d}{dt}\delta_{Dq}^{\rm slow} \right). \tag{6.4.53}$$

In particular, in the matter-dominated era we have $y \gg 1, \delta_{Dq}^{(1)} \to 3y/2$, and $\delta_{Dq}^{(2)} \to 4/15y^{3/2}$, so Eqs. (6.4.50)-(6.4.53) become

$$\delta_{Dq}^{\rm slow} \to \frac{9\mathcal{R}_q^0 a}{a_{\rm EQ}} \left[-\frac{7}{2} + \gamma + \ln\left(\frac{4\kappa}{\sqrt{3}} \right) \right], \tag{6.4.54}$$

$$\psi_q^{\rm slow} \to -\frac{6\mathcal{R}_q^0 a}{a_{\rm EQ}t} \left[-\frac{7}{2} + \gamma + \ln\left(\frac{4\kappa}{\sqrt{3}} \right) \right]. \tag{6.4.55}$$

$$\delta u_{\gamma q}^{\rm slow} \to -\frac{6\mathcal{R}_q^0 a^3}{a_{\rm EQ}tq^2} \left[-\frac{7}{2} + \gamma + \ln\left(\frac{4\kappa}{\sqrt{3}} \right) \right], \tag{6.4.56}$$

$$\delta_{\gamma q}^{\rm slow} \to \frac{6\mathcal{R}_q^o a^3(1+3R)}{a_{\rm EQ}t^2q^2} \left[-\frac{7}{2} + \gamma + \ln\left(\frac{4\kappa}{\sqrt{3}} \right) \right]. \tag{6.4.57}$$

We have here again introduced a dimensionless rescaled wave number

$$\kappa \equiv \frac{q\sqrt{2}}{a_{\rm EQ}H_{\rm EQ}} = \frac{(q/a_0)\sqrt{\Omega_R}}{H_0\Omega_M} = \frac{19.3\,(q/a_0)\left[{\rm Mpc}^{-1}\right]}{\Omega_M h^2}, \tag{6.4.58}$$

in which we have used the relations $H_{\rm EQ} = \sqrt{2}\left(H_0\sqrt{\Omega_M}\right)(a_0/a_{\rm EQ})^{3/2}$ and $a_0/a_{\rm EQ} = \Omega_M/\Omega_R$. In terms of the wave number $q_{\rm EQ}$ introduced in Section 6.2, for which the perturbation just comes into the horizon at matter-radiation equality, we have $\kappa = \sqrt{2}q/q_{\rm EQ}$, so the assumption of short wavelength made in this section essentially amounts to the condition that $\kappa \gg 1$.

The full solution up to the time of recombination is given by adding the contributions of the fast mode and slow mode:

$$\begin{aligned}\delta_{Dq} \to & \frac{9\mathcal{R}_q^0 a}{a_{\rm EQ}}\left[-\frac{7}{2}+\gamma+\ln\left(\frac{4\kappa}{\sqrt{3}}\right)\right] \\ & + 48\pi G\bar{\rho}_\gamma(2+R)(1+R)^{3/4}(a/q)^2\mathcal{R}_q^o \\ & \times e^{-\int_0^t \Gamma dt}\cos\left(\int_0^t \frac{qdt}{a\sqrt{3(1+R)}}\right) \end{aligned} \tag{6.4.59}$$

$$\begin{aligned}\psi_q \to & -\frac{6\mathcal{R}_q^0 a}{a_{\rm EQ}t}\left[-\frac{7}{2}+\gamma+\ln\left(\frac{4\kappa}{\sqrt{3}}\right)\right] \\ & + 16\sqrt{3}\pi G\bar{\rho}_\gamma(2+R)(1+R)^{1/4}(a/q)\mathcal{R}_q^o \\ & \times e^{-\int_0^t \Gamma dt}\sin\left(\int_0^t \frac{qdt}{a\sqrt{3(1+R)}}\right) \end{aligned} \tag{6.4.60}$$

$$\begin{aligned}\delta u_{\gamma q} \to & -\frac{6\mathcal{R}_q^0 a^3}{a_{\rm EQ}tq^2}\left[-\frac{7}{2}+\gamma+\ln\left(\frac{4\kappa}{\sqrt{3}}\right)\right] \\ & + \frac{a\sqrt{3}\mathcal{R}_q^o}{q(1+R)^{3/4}}e^{-\int_0^t \Gamma dt}\sin\left(\int_0^t \frac{qdt}{a\sqrt{3(1+R)}}\right) \end{aligned} \tag{6.4.61}$$

$$\begin{aligned}\delta_{Bq}=\delta_{\gamma q} \to & \frac{6\mathcal{R}_q^o a^3(1+3R)}{a_{\rm EQ}t^2q^2}\left[-\frac{7}{2}+\gamma+\ln\left(\frac{4\kappa}{\sqrt{3}}\right)\right] \\ & - \frac{3\mathcal{R}_q^o}{(1+R)^{1/4}}e^{-\int_0^t \Gamma dt}\cos\left(\int_0^t \frac{qdt}{a\sqrt{3(1+R)}}\right) \end{aligned} \tag{6.4.62}$$

with Γ and κ given by Eqs. (6.4.25) and (6.4.58).
Each of the different perturbations (6.4.59)-(6.4.62) is dominated by either its fast or slow term. First, let us consider δ_{Dq} and ψ_q. Comparison of Eqs. (6.4.48) and (6.4.47) with Eqs. (6.4.54) and (6.4.55) shows that the ratios of the fast and slow contributions to δ_{Dq} and ψ_q are of order

$$\frac{\delta_{Dq}^{\rm fast}}{\delta_{Dq}^{\rm slow}} \sim \frac{a^2H^2}{q^2}\left(\frac{\bar{\rho}_R}{\bar{\rho}_M}\right)^2, \quad \frac{\psi_q^{\rm fast}}{\psi_q^{\rm slow}} \sim \frac{aH}{q}\left(\frac{\bar{\rho}_R}{\bar{\rho}_M}\right)^2. \tag{6.4.63}$$

We are assuming in this section that the wavelengths are short enough so that perturbations enter the horizon during the radiation-dominated era, so these ratios are much less than one at matter-radiation equality. Subsequently the ratio of fast to slow contributions to δ_{Dq} decreases as $1/a^3$, while for ψ_q the ratio of fast to slow contributions decreases as $1/a^{5/2}$. Hence it is a good approximation to take $\delta_{Dq}=\delta_{Dq}^{\rm slow}$ and $\psi_q=\psi_q^{\rm slow}$ throughout the matter-dominated era. Nevertheless, because the fast terms in Eqs. (6.4.59) and (6.4.60) have an oscillatory dependence on q, we will need to take them into account when we consider baryon acoustic oscillations in Section 8.1.

We also need $\delta_{\gamma q}$ and $\delta u_{\gamma q}$ in calculations of the cosmic microwave background anisotropies. Comparison of Eqs. (6.4.45) and (6.4.46) with Eqs. (6.4.57) and (6.4.56) shows that the ratios of the fast and slow contributions to $\delta_{\gamma q}$ and $u_{\gamma q}$ are (apart from the damping of the fast terms) of order

$$\frac{\delta_{\gamma q}^{\rm fast}}{\delta_{\gamma q}^{\rm slow}} \sim \frac{q^2}{a^2H^2}\frac{\bar{\rho}_R}{\bar{\rho}_M}, \quad \frac{\delta u_{\gamma q}^{\rm fast}}{\delta u_{\gamma q}^{\rm slow}} \sim \frac{q}{aH}\frac{\bar{\rho}_R}{\bar{\rho}_M}. \tag{6.4.64}$$

These ratios are much larger than unity at horizon entry, and remain so until matter-radiation equality. After that the ratio of fast to slow contributions to $\delta_{\gamma q}$ remains of the same order of magnitude, while for $\delta u_{\gamma q}$ the ratio of fast to slow terms decreases like $1/\sqrt{a}$. Hence, once the wavelength enters the horizon, the slow contribution to $\delta_{\gamma q}$ is nominally smaller than the fast term, while the slow contribution to $\delta u_{\gamma q}$ remains nominally smaller than the fast term until late in the matter-dominated era. Nevertheless, we will keep the slow as well as fast terms here, because they are not affected by the damping that suppresses the fast terms. Also, even though it is relatively small, the slow term in δ_{Rq} will be found in Section 7.2 to produce a characteristic effect in the plot of the cosmic microwave background multipole coefficients C_ℓ vs. ℓ that would not be present with the fast term alone.

10.6.6 6.5 Scalar perturbations - interpolation & transfer functions

In the previous two sections we found analytic results for wavelengths that are long enough to enter the horizon well after matter-radiation equality, or short enough to enter the horizon well before matter-radiation equality. Unfortunately, this leaves out wavelengths that enter the horizon around the time of matter-radiation equality. It is wavelengths of this magnitude that make the dominant contributions to the first acoustic peak at around $\ell = 200$ in the multipole coefficients of the cosmic microwave background anisotropies. In this section we will consider how to construct formulas for the fluctuations that interpolate between the results of Sections 6.3 and 6.4, concentrating on results in the matter-dominated era, which are of the greatest observational interest.

We can get a good clue to this interpolation by first considering the limit of negligible baryon mass density and negligible damping, for which the form of the solution in the matter-dominated era can be found exactly, with no limitations on wavelength. In this limit, and leaving aside the neutrinos, the equations for the perturbations in the matter-dominated era are given for
all wavelengths by Eqs. (6.3.17), (6.3.18), (6.3.20) and (6.3.21), with $R = 0$:

$$\frac{d}{dt}\left(t^{4/3}\psi_q\right) = -\frac{2}{3}t^{-2/3}\delta_{Dq} \tag{6.5.1}$$

$$\dot{\delta}_{\gamma q} - \left(q^2/a^2\right)\delta u_{\gamma q} = -\psi_q \tag{6.5.2}$$

$$\dot{\delta}_{Dq} = -\psi_q \tag{6.5.3}$$

$$\frac{d}{dt}\left(t^{-2/3}\delta u_{\gamma q}\right) = -\frac{1}{3}t^{-2/3}\delta_{\gamma q} \tag{6.5.4}$$

with $a \propto t^{2/3}$. These have four independent exact solutions, three of which are quite simple:

Solution 1:

$$\delta_{Dq} = \frac{3q^2t^2}{2a^2}, \psi_q = -\frac{q^2t}{a^2}$$
$$\delta_{\gamma q} = 1, \delta u_{\gamma q} = -t$$

Solution 2:

$$\delta_{Dq} = \psi_q = 0$$
$$\delta_{\gamma q} = -\cos\left(q\int_0^t \frac{dt}{\sqrt{3}a}\right), \quad \delta u_{\gamma q} = \frac{a}{\sqrt{3}q}\sin\left(q\int_0^t \frac{dt}{\sqrt{3}a}\right).$$

Solution 3:

$$\delta_{Dq} = \psi_q = 0$$
$$\delta_{\gamma q} = \sin\left(q\int_0^t \frac{dt}{\sqrt{3}a}\right), \quad \delta u_{\gamma q} = \frac{a}{\sqrt{3}q}\cos\left(q\int_0^t \frac{dt}{\sqrt{3}a}\right).$$

The fourth solution is more complicated; it decays, with $\delta_{Dq} \propto 1/t$ and $\psi_q \propto 1/t^2$. As we will see, the initial conditions are satisfied by a linear combination of the first three solutions, so the fourth solution will not concern us here.

Without any loss of generality, we can write the linear combination of solutions 1, 2, and 3 that fits the solution at earlier time in a form that simplifies this fit, as [1]

$$\delta_{Dq} = \frac{9q^2t^2\mathcal{R}_q^o\mathcal{T}(\kappa)}{10a^2} \tag{6.5.5}$$
$$\psi_q = -\frac{3q^2t\mathcal{R}_q^o\mathcal{T}(\kappa)}{5a^2} \tag{6.5.6}$$

$$\delta_{\gamma q} = \delta_{\nu q} = \frac{3\mathcal{R}_q^o}{5}\left[\mathcal{T}(\kappa) - \mathcal{S}(\kappa)\cos\left(q\int_0^t \frac{dt}{\sqrt{3}a} + \Delta(\kappa)\right)\right] \tag{6.5.7}$$
$$\delta u_{\gamma q} = \delta u_{\nu q} = \frac{3t\mathcal{R}_q^o}{5}\left[-\mathcal{T}(\kappa) + \mathcal{S}(\kappa)\frac{a}{\sqrt{3}qt}\sin\left(q\int_0^t \frac{dt}{\sqrt{3}a} + \Delta(\kappa)\right)\right] \tag{6.5.8}$$

where $\mathcal{S}(\kappa), \mathcal{T}(\kappa)$, and $\Delta(\kappa)$ are time-independent dimensionless functions of the dimensionless rescaled wave number introduced in Sections 6.2 and 6.4 :

$$\kappa \equiv \frac{q\sqrt{2}}{a_{\rm EQ}H_{\rm EQ}} = \frac{(q/a_0)\sqrt{\Omega_R}}{H_0\Omega_M} = \frac{19.3\,(q/a_0)\left[{\rm Mpc}^{-1}\right]}{\Omega_M h^2} \tag{6.5.9}$$

in which $a_{\rm EQ}$ and $H_{\rm EQ}$ are respectively the Robertson-Walker scale factor and expansion rate at matter-radiation equality. These are known as transfer functions. (These functions can only depend on κ because they must be independent of the normalization of the spatial coordinates and are dimensionless.) The division we made in the previous two sections between long and short wavelengths can be expressed in terms of the parameter κ. In the matter-dominated era we have $t = 2/3H = (t/3H_{\rm EQ})\,(a/a_{\rm EQ})^{3/2}$ and $\bar\rho_R/\bar\rho_M = a_{\rm EQ}/a$, so

$$\frac{t^2q^2}{a^2}\frac{\bar\rho_R}{\bar\rho_M} = \frac{4\kappa^2}{9}$$

Hence t^2q^2/a^2 is much less or much greater than $\bar\rho_M/\bar\rho_R$, according as the parameter κ is much less or much greater than one.

We choose to write the linear combination of solutions 1,2 , and 3 in the form (6.5.5)-(6.5.8) because it leads to simple values for the coefficients $\mathcal{S}(\kappa), \mathcal{T}(\kappa)$, and $\Delta(\kappa)$ for $\kappa \ll 1$. For $\bar\rho_B = 0$, the results (6.3.23), (6.3.24), (6.3.35), (6.3.36) obtained earlier for moderately long wavelengths satisfying $t^2q^2/a^2 \ll \bar\rho_M/\bar\rho_R$, or in other words in the limit $\kappa \ll 1$, are consistent with Eqs. (6.5.5)-(6.5.8), and tell us that in this limit [2]

[471] From now on, we define the zero of time so that $a \propto t^{1/2}$ in the radiation-dominated era. This is different from the definition of the zero of time in Solutions 1 and 2, where time is defined so that $a \propto t^{2/3}$ in the matter-dominated era. However, the difference this makes in the integral $\int_0^t dt/a$ is just a constant, which can be absorbed into $\Delta(\kappa)$.

$$\mathcal{T}(\kappa) \to 1, \quad \mathcal{S}(\kappa) \to 1, \quad \Delta(\kappa) \to 2\kappa/\sqrt{3}. \tag{6.5.10}$$

(The case of extremely long wavelengths does not arise here, because it requires that $t^2q^2/a^2 \ll R$, and for the present we are taking $R = 0$.)

Similarly, for $\bar{\rho}_B = 0$ and $\Gamma = 0$, the results (6.4.59)-(6.4.62) obtained earlier for short wavelengths satisfying $t^2q^2/a^2 \gg \bar{\rho}_M/\bar{\rho}_R$, or in other words

in the limit $\kappa \gg 1$, are consistent with Eqs. (6.5.5)-(6.5.8), and tell us that in this limit [3]

$$\mathcal{T}(\kappa) \to \frac{45}{2\kappa^2}\left[-\frac{7}{2} + \gamma + \ln\left(\frac{4\kappa}{\sqrt{3}}\right)\right], \quad \mathcal{S}(\kappa) \to 5, \quad \Delta(\kappa) \to 0 \tag{6.5.11}$$

As we shall see in Chapter 8, the decrease of $\mathcal{T}(\kappa)$ for large κ is very important in determining the intensity of fluctuations in the dark matter density at various wavelengths. (We can understand this decrease qualitatively by following the history of the dark matter density fluctuations. According to Eq. (6.2.27), for all wavelengths δ_{Dq} grows like t at early times, when the universe is radiation dominated and the wavelength is outside the horizon. For $\kappa \ll 1$ this growth continues until the universe becomes matter dominated, after which Eqs. (6.3.13) and (6.3.23) tell us that δ_{Dq} grows like $t^{2/3}$ both before and after the wavelength enters the horizon. In contrast, for $\kappa \gg 1$ the growth of δ_{Dq} like t continues only until the wavelength enters the horizon, which in this case is during the radiation-dominated era, after which according to Eq. (6.4.50) δ_{Dq} grows only logarithmically with time until the universe becomes matter dominated, after which according to Eq. (6.4.54) it grows as $t^{2/3}$, just as in the case $\kappa \ll 1$. The end of the period of growth proportional to t is at the time when $q/a \approx 1/t$, which since $a \propto \sqrt{t}$ is at $t \propto 1/q^2$, so the growth until matter-radiation equality is proportional to $\ln q/q^2$, accounting for the asymptotic behavior of $\mathcal{T}(\kappa)$. That is, the smallness of $\mathcal{T}(\kappa)$ for $\kappa \gg 1$ reflects not a decay of δ_{Dq}, but rather the failure of δ_{Dq} to grow appreciably during the interval from horizon-entry to matter-radiation equality.)

For values of κ of order unity, we have to find some way of interpolating between these two limiting cases. This can be done almost "by hand"; it turns out that almost any smooth interpolation between the limits $\kappa \ll 1$ and $\kappa \gg 1$ gives reasonable results for the cosmic microwave background anisotropies. For better precision, we need to solve the full coupled equations (6.2.9)-(6.2.15) (still with $\bar{\rho}_B = 0$) numerically for general wavelengths and general values of $y \equiv \bar{\rho}_M/\bar{\rho}_R$, imposing the initial conditions found in Section 6.1 for $y \ll 1$, and then comparing this solution for $y \gg 1$ with Eqs. (6.5.5)-(6.5.8). These equations can be put in a dimensionless form by using y as the independent variable, and writing

$$\delta_{Dq} = \kappa^2\mathcal{R}_q^0 d(y)/4, \quad \delta_{\gamma q} = \delta_{\nu q} = \kappa^2\mathcal{R}_q^0 r(y)/4$$
$$\psi_q = \left(\kappa^2 H_{\rm EQ}/4\sqrt{2}\right)\mathcal{R}_q^0 f(y), \quad \delta u_{\gamma q} = \delta u_{\nu q} = \left(\kappa^2\sqrt{2}/4H_{\rm EQ}\right)\mathcal{R}_q^0 g(y)$$

10.6.7 6.5 Scalar perturbations - interpolation & transfer functions

Eqs. (6.2.9)-(6.2.15) then become

[472] The limit $2\kappa/\sqrt{3}$ for $\Delta(\kappa)$ is the difference for $y \equiv \bar{\rho}_M/\bar{\rho}_R \gg 1$ between the phase $\sqrt{3}qt/a = 2\kappa\sqrt{y}/\sqrt{3}$ in Eq. (6.3.34) (for $R \ll 1$), and the phase $q\int_0^t dt/\sqrt{3}a = 2\kappa[\sqrt{1+y}-1]/\sqrt{3}$ in Eqs. (6.5.7) and (6.5.8).

[473] This result for $T(\kappa)$ was given by S. Weinberg, Astrophys. J. 581, 810 (2002) [astro-ph/0207375]. The fact that the Mészáros equation (6.4.35) implies a fall-off of the transfer function for large wave number k like $\ln k/k^2$ had been pointed out by W. Hu and N. Sugiyama, Astrophys. J. 444, 489 (1995).

$$\sqrt{1+y}\frac{d}{dy}\left(y^2 f(y)\right) = -\frac{3d(y)}{2} - \frac{4r(y)}{y}$$

$$\sqrt{1+y}\frac{d}{dy}d(y) = -yf(y)$$

$$\sqrt{1+y}\frac{d}{dy}r(y) - \frac{\kappa^2}{y}g(y) = -yf(y)$$

$$\sqrt{1+y}\frac{d}{dy}\left(\frac{g(y)}{y}\right) = -\frac{1}{3}r(y)$$

In this notation, the initial conditions (6.2.27)-(6.2.29) read

$$d(y) \to r(y) \to y^2,$$

$$f(y) \to -2, \quad g(y) \to -\frac{y^4}{9}.$$

When evaluated for $y \gg 1$, the numerical solutions of these equations [4] match Eqs. (6.5.5)-(6.5.8), with transfer functions given in Table 6.1. Inspection of this table shows that these numerical results agree with the analytic results (6.5.10) and (6.5.11) in the limits $\kappa \ll 1$ and $\kappa \gg 1$, respectively, although κ must be quite large before the asymptotic results (6.5.11) are reached.

As we will see in the following two chapters, the microwave background anisotropies and the correlation function of large scale structure are given by integrals involving one or more of these transfer functions, so it will be useful to give approximate analytic formulas for these functions. Dicus [5] has found "fitting formulas," which to a good approximation agree with the asymptotic formulas (6.5.10) and (6.5.11) for $\kappa \ll 1$ and $\kappa \gg 1$, and (except for $\Delta(\kappa)$ at large κ) generally match the numerical results of Table 6.1 at intermediate values of κ to better than 2% :

$$\mathcal{T}(\kappa) \simeq \frac{\ln\left[1+(0.124\kappa)^2\right]}{(0.124\kappa)^2}\left[\frac{1+(1.257\kappa)^2+(0.4452\kappa)^4+(0.2197\kappa)^6}{1+(1.606\kappa)^2+(0.8568\kappa)^4+(0.3927\kappa)^6}\right]^{1/2}_{(6.5.12)} \tag{6.5.12}$$

$$\mathcal{S}(\kappa) \simeq \left[\frac{1+(1.209\kappa)^2+(0.5116\kappa)^4+5^{1/2}(0.1657\kappa)^6}{1+(0.9459\kappa)^2+(0.4249\kappa)^4+(0.1657\kappa)^6}\right]^2 \tag{6.5.13}$$

[474] I thank D. Dicus for this numerical calculation.

[5] D. Dicus, private communication.

$$\Delta(\kappa) \simeq \left[\frac{(0.1585\kappa)^2 + (0.9702\kappa)^4 + (0.2460\kappa)^6}{1 + (1.180\kappa)^2 + (1.540\kappa)^4 + (0.9230\kappa)^6 + (0.4197\kappa)^8}\right]^{1/4}. \tag{6.5.14}$$

These transfer functions are shown in Figure 6.1. A fitting formula for $\mathcal{T}(\kappa)$ that includes the effects of neutrino anisotropic inertia and fits the

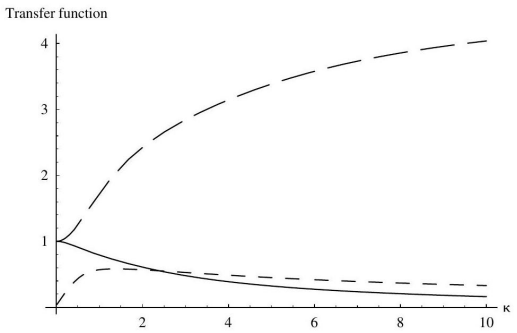

Figure 6.1: The transfer functions $\mathcal{T}(\kappa)$ (solid curve), $\mathcal{S}(\kappa)$ (long dashes), and $\Delta(\kappa)$ (short dashes), as functions of the rescaled wave number κ.

CAMB numerical results is given by Eisenstein and Hu. [6] Because of the neglect of neutrino anisotropic inertia, the results for $\mathcal{T}(\kappa)$ of Eq. (6.5.12) and Table 6.1 are about 4% too low.

Now we have to consider how to take damping and the non-zero ratio of baryon to photon density into account. Eqs. (6.3.23), (6.3.24) and (6.4.59), (6.4.60) show that in the limits of either short or long wavelength, the leading terms in δ_{Dq} and ψ_q are unaffected by either damping or baryons, so in leading order we can simply use Eqs. (6.5.5) and (6.5.6):

$$\delta_{Dq} = \frac{9q^2t^2\mathcal{R}_q^o\mathcal{T}(\kappa)}{10a^2} \tag{6.5.15}$$

$$\psi_q = -\frac{3q^2t\mathcal{R}_q^o\mathcal{T}(\kappa)}{5a^2} \tag{6.5.16}$$

Damping affects the short-wavelength results (6.4.61) and (6.4.62) for $\delta u_{\gamma q}$ and $\delta_{\gamma q}$ by multiplying the sines and cosines with a factor $\exp\left(-\int_0^t \Gamma dt\right)$. This factor is absent in the long-wavelength results (6.3.36) and (6.3.35) for these perturbations, but this factor is essentially unity anyway for long wavelengths, because $\Gamma \propto q^2$. Hence for all wavelengths we can take damping into account by simply multiplying the sines and cosines in Eqs. (6.5.7) and (6.5.8) by $\exp\left(-\int_0^t \Gamma dt\right)$. Finally, in both the short-wavelength results (6.4.62) and (6.4.61) and the long-wavelength results (6.3.35) and (6.3.36),

the effect of the non-zero baryon density is to multiply the non-oscillatory term in $\delta_{\gamma q}$ with $1+3R$, multiply the cosine in $\delta_{\gamma q}$ with $(1+R)^{-1/4}$, and multiply the sine in $\delta u_{\gamma q}$ with $(1+R)^{-3/4}$, so it is highly plausible that a finite ratio of baryon density to photon density can be taken into account at all wavelengths by making the same alterations in Eqs. (6.5.7) and (6.5.8):

$$
\begin{aligned}
\delta_{\gamma q}=\delta_{B q} &= \frac{3 \mathcal{R}_{q}^{o}}{5}\left[\mathcal{T}(\kappa)(1+3 R)\right. \\
&\left.(1+R)^{-1 / 4} e^{-\int_{0}^{t} \Gamma d t} \mathcal{S}(\kappa) \cos \left(\int_{0}^{t} \frac{q d t}{a \sqrt{3(1+R)}}+\Delta(\kappa)\right)\right] \tag{6.5.17}
\end{aligned}
$$

[476] D. J. Eisenstein and W. Hu, Astrophys. J. 496, 605 (1998).

$$\delta u_{\gamma q} = \delta_{Bq} = \frac{3\mathcal{R}_q^o}{5}[-t\mathcal{T}(\kappa) + \frac{a}{\sqrt{3}q(1+R)^{3/4}} e^{-\int_0^t \Gamma dt} \mathcal{S}(\kappa) \sin\left(\int_0^t \frac{qdt}{a\sqrt{3(1+R)}} + \Delta(\kappa)\right)] \tag{6.5.18}$$

To repeat, these results agree with the results of Section 6.4 for short wavelength, they agree with the results of Section 6.3 for long wavelength (for which Γ is negligible), and they agree with the results found in this section for all wavelengths when damping and the baryon density are neglected.

We must say a little more about the function $\mathcal{T}(\kappa)$, which is commonly known as the transfer function. It is conventional to write this transfer function as a function of a variable Q :

$$Q \equiv \frac{q}{a_0} \times \frac{1\text{Mpc}}{\Omega_M h^2}, \tag{6.5.19}$$

which according to Eq. (6.5.9) is the same as $\kappa/19.3$. In these terms, Eqs. (6.5.10) and (6.5.11) for $\mathcal{T}(\kappa)$ now read

$$\mathcal{T}(\kappa) \to \begin{cases} 1 & Q \to 0 \\ \frac{\ln(2.40Q)}{(4.07Q)^2} & Q \to \infty \end{cases} \tag{6.5.20}$$

A numerical solution of the equations for growth of dark matter density fluctuations has been fit for large Q with the formula [7]

$$\mathcal{T}_{\text{BBKS}}(\kappa) \simeq \frac{\ln(1+2.34Q)}{2.34Q} \times \left[1 + 3.89Q + (16.1Q)^2 + (5.46Q)^3 + (6.71Q)^4\right]^{-1/4} \tag{6.5.21}$$

This goes to $\ln(2.34Q)/(3.96Q)^2$ for large Q, in excellent agreement with the analytic result (6.5.20). However, it should be noted that although the BBKS transfer function (6.5.21) is correctly normalized at $Q = 0$, it does not give a good account of the behavior of the transfer function for $Q \ll 1$. The power series expansion of Eq. (6.5.21) contains odd as well as even terms in Q, which is not consistent with the requirement that it must be an analytic function of the three-vector $\mathbf{q}$. The Dicus fitting formula (6.5.12) was constructed to be analytic in the three-vector $\mathbf{q}$ at $\mathbf{q} = 0$, and in fact fits the numerical results of Table 6.1 better than the BBKS transfer function (6.5.21). In our analysis of cosmic microwave background anisotropies, we will use the fitting formula (6.5.12) instead of Eq. (6.5.21).

All this has been for $\beta \equiv \bar{\rho}_B/\bar{\rho}_M \ll 1$, though we have now taken into account a non-negligible ratio $R = 3\bar{\rho}_B/4\bar{\rho}_\gamma$. The corrections to the transfer function for finite values of β are roughly 10%; they have been calculated analytically [8] for $\kappa \gg 1$ to lowest order in β, and numerically [9] for general κ and for selected values of β to all orders in β. In using the transfer function in calculations of large scale structure, it is common to use a simple modification of the fitting formula. Peacock and Dodds [10] proposed in effect that the same fitting formula could be used for finite baryon density, but with $\kappa = \left(k\sqrt{\Omega_R}/H_0\Omega_M\right)\exp\left(\Omega_B\right)$. This worked well for the limited range of cosmological parameters studied, but it is physically impossible for the transfer function to have this sort of dependence on Ω_B. There is no way that the physical processes during the radiation-dominated era that are responsible for the transfer function to know anything about the time at which we happen to measure cosmological parameters like $\bar{\rho}_M$.

[477] J. M. Bardeen, J. R. Bond, N. Kaiser, & A. S. Szalay, Astrophys. J. 304, 15 (1986).

Aside from κ, the transfer function can only depend on quantities such as $\beta \equiv \bar{\rho}_B/\bar{\rho}_M = \Omega_B/\Omega_M$, which is constant, or $\Omega_M h^2$, which (for a known present radiation temperature) tells us the matter density at any given temperature. Indeed, Sugiyama [11] pointed out that the correction factor $\exp(\Omega_B)$ actually works well only for values of Ω_M close to unity. As an alternative that would apply for smaller values of Ω_M, he proposed a correction factor $\exp(\Omega_B + \Omega_B/\Omega_M)$, which is physically impossible for the same reason as $\exp(\Omega_B)$. Another difficulty with all these suggestions is that the baryon correction must disappear for small wave number, because in this case pressure forces are negligible, and baryons behave just like cold dark matter. A baryon correction that satisfies all these physical criteria has been proposed by Eisenstein and Hu: [6] The transfer function is evaluated

with κ taken as

$$\kappa = \left(\frac{k\sqrt{\Omega_R}}{H_0\Omega_M}\right)\left[\alpha + \frac{1-\alpha}{1+(0.43ks)^4}\right]^{-1}, \tag{6.5.22}$$

where

$$\alpha = 1 - 0.328\ln\left(431\Omega_M h^2\right)\beta + 0.38\ln\left(22.3\Omega_M h^2\right)\beta^2,$$

and s is the acoustic horizon at the time $t = t_L$ of last scattering, projected (as is k) to the present:

$$s \equiv a(t_0)\int_0^{t_L}\frac{v_s dt}{a(t)} = (1+z_L)\,d_H$$

with d_H given by Eq. (2.6.32).

10.6.8 6.6 Tensor perturbations

We next turn to the tensor modes. These are considerably simpler to study than the scalar modes, so what took five sections to analyze for the scalar modes will be treated here in just one section. As in the case of scalar modes, we begin by setting down the full set of equations used in computer programs like CMBfast, and then move on to approximations.

A. Cold dark matter and baryonic plasma

As already mentioned, the particles of both the cold dark matter and baryonic plasma move too slowly to contribute any anisotropic inertia. In tensor modes there are no perturbations to densities or streaming velocities, so there are no perturbations to either the cold dark matter or baryonic plasma that need to be followed here.

B. Gravitation

According to Section 5.1, in tensor modes the gravitational perturbation takes the form:

$$\delta g_{ij}(\mathbf{x},t) = a^2(t)D_{ij}(\mathbf{x},t) \tag{6.6.1}$$

with $D_{ij}(\mathbf{x},t)$ satisfying the wave equation (5.1.53):

$$\ddot{D}_{ij} + 3H\dot{D}_{ij} - a^{-2}\nabla^2 D_{ij} = 16\pi G\pi^T_{ij}, \tag{6.6.2}$$

and the trace and transversality conditions

[478] S. Weinberg, ref. 2.
[9] J. A. Holtzman, Astrophys. J. Suppl. 71, 1 (1989).
[10] J. A. Peacock and S.J. Dodds, Mon. Not. Roy. Astron. Soc. 267, 1020 (1994).
[11] N. Sugiyama, Astrophys. J. 100, 281 (1995).

$$D_{ii} = 0, \quad \partial_i D_{ij} = 0 \tag{6.6.3}$$

We will see that the anisotropic inertia tensor π_{ij}^T is a linear functional of $\dot{D}_{ij}$, so Eq. (6.6.2) has two independent solutions. During the period when the perturbation is outside the horizon, the anisotropic inertia tensor π_{ij}^T and the $a^{-2}\nabla^2 D_{ij}$ term are negligible, and Eq. (6.6.2) becomes

$$\ddot{D}_{ij} + 3H\dot{D}_{ij} = 0.$$

Hence outside the horizon one of the solutions is constant, while the other decays as $\int a^{-3}dt$, which in the radiation dominated era goes as $t^{-1/2}$. For all interesting wave numbers the perturbation remains outside the horizon during many e-foldings of cosmic expansion, so the decaying mode becomes negligible, and we can consider only the other mode. The metric perturbation and anisotropic inertia can therefore be put in the form

$$D_{ij}(\mathbf{x}, t) = \sum_{\lambda=\pm 2} \int d^3q e^{i\mathbf{q}\cdot\mathbf{x}} \beta(\mathbf{q}, \lambda) e_{ij}(\hat{q}, \lambda) \mathcal{D}_q(t), \tag{6.6.4}$$

$$\pi_{ij}^T(\mathbf{x}, t) = \sum_{\lambda=\pm 2} \int d^3q e^{i\mathbf{q}\cdot\mathbf{x}} \beta(\mathbf{q}, \lambda) e_{ij}(\hat{q}, \lambda) \pi_q^T(t). \tag{6.6.5}$$

where $\beta(\mathbf{q}, \lambda)$ is a stochastic parameter for the single non-decaying mode with wave number $\mathbf{q}$ and helicity λ; $e_{ij}(\hat{q}, \lambda)$ is the corresponding polarization tensor, defined in Section 5.2, with $e_{ii} = q_i e_{ij} = 0$; and $\mathcal{D}_q(t)$ is the solution of the wave equation

$$\ddot{\mathcal{D}}_q + 3H\dot{\mathcal{D}}_q + a^{-2}q^2\mathcal{D}_q = 16\pi G\pi_q^T. \tag{6.6.6}$$

We will return later to the solution of this equation.

C. Photons

The Boltzmann equation for the photon density matrix perturbation $\delta n^{ij}(\mathbf{x}, t)$ in the tensor mode is given by Eq. (H.35) as

$$\begin{aligned}
&\frac{\partial \delta n_\gamma^{ij}(\mathbf{x}, \mathbf{p}, t)}{\partial t} + \frac{\hat{p}_k}{a(t)} \frac{\partial \delta n_\gamma^{ij}(\mathbf{x}, \mathbf{p}, t)}{\partial x^k} + \frac{2\dot{a}(t)}{a(t)} \delta n_\gamma^{ij}(\mathbf{x}, \mathbf{p}, t) \\
&- \frac{1}{4a^2(t)} p\bar{n}_\gamma'(p) \hat{p}_k \hat{p}_l \dot{D}_{kl}(\mathbf{x}, t) \left(\delta_{ij} - \hat{p}_i \hat{p}_j\right) \\
&= -\omega_c(t) \delta n_\gamma^{ij}(\mathbf{x}, \mathbf{p}, t) + \frac{3\omega_c(t)}{8\pi} \int d^2\hat{p}_1 \\
&\times \left[\delta n_\gamma^{ij}\left(\mathbf{x}, p\hat{p}_1, t\right) - \hat{p}_i \hat{p}_k \delta n_\gamma^{kj}\left(\mathbf{x}, p\hat{p}_1, t\right) - \hat{p}_j \hat{p}_k \delta n_\gamma^{ik}\left(\mathbf{x}, p\hat{p}_1, t\right)\right. \\
&\left. + \hat{p}_i \hat{p}_j \hat{p}_k \hat{p}_l \delta n_\gamma^{kl}\left(\mathbf{x}, p\hat{p}_1, t\right)\right]
\end{aligned} \tag{6.6.7}$$

in which we have used Eq. (6.6.1) for the metric perturbation. As in the case of scalar modes, instead of $\delta n_\gamma^{ij}(\mathbf{x}, \mathbf{p}, t)$, we will concentrate on the fractional intensity matrix defined by the analog of Eq. (6.1.13):

$$a^4(t)\bar{\rho}_\gamma(t) J_{ij}(\mathbf{x}, \hat{p}, t) \equiv a^2(t) \int_0^\infty \delta n_\gamma^{ij}(\mathbf{x}, p\hat{p}, t) 4\pi p^3 dp \tag{6.6.8}$$

We seek a solution in the form

$$J_{ij}(\mathbf{x},\hat{p},t)=\sum_{\lambda=\pm 2}\int d^3q e^{i\mathbf{q}\cdot\mathbf{x}}\beta(\mathbf{q},\lambda)J_{ij}(\mathbf{q},\hat{p},t,\lambda) \tag{6.6.9}$$

The Boltzmann equation (6.6.7) then takes the form

$$\begin{aligned}\frac{\partial J_{ij}(\mathbf{q},\hat{p},t,\lambda)}{\partial t}+i\frac{\mathbf{q}\cdot\hat{p}}{a(t)}J_{ij}(\mathbf{q},\hat{p},t,\lambda)\\ +\hat{p}_k\hat{p}_l e_{kl}(\hat{q},\lambda)\dot{\mathcal{D}}_q(t)\left(\delta_{ij}-\hat{p}_i\hat{p}_j\right)\\ =-\omega_c(t)J_{ij}(\mathbf{q},\hat{p},t,\lambda)+\frac{3\omega_c(t)}{2}\\ \times\left[\mathcal{J}_{ij}(\mathbf{q},t,\lambda)-\hat{p}_i\hat{p}_k\mathcal{J}_{kj}(\mathbf{q},t,\lambda)-\hat{p}_j\hat{p}_k\mathcal{J}_{ik}(\mathbf{q},t,\lambda)\right.\\ \left.+\hat{p}_i\hat{p}_j\hat{p}_k\hat{p}_l\mathcal{J}_{kl}(\mathbf{q},t,\lambda)\right]\end{aligned} \tag{6.6.10}$$

where

$$\mathcal{J}_{ij}(\mathbf{q},t,\lambda)\equiv\int\frac{d^2\hat{p}}{4\pi}J_{ij}(\mathbf{q},\hat{p},t,\lambda) \tag{6.6.11}$$

Furthermore, because $J_{ij}(\mathbf{q},\hat{p},t,\lambda)$ for a given helicity λ must be a linear combination of the polarization tensor components $e_{kl}(\hat{q},\lambda)$ with the same λ, while $\hat{q}_k e_{kl}(\hat{q},\lambda)$ and $e_{kk}(\hat{q},\lambda)$ both vanish, the only possible form of $\mathcal{J}_{ij}(\mathbf{q},t,\lambda)$ allowed by rotational invariance is just $e_{ij}(\hat{q},\lambda)$ times some function of $q\equiv|\mathbf{q}|$ and t. This relation is conventionally written

$$\mathcal{J}_{ij}(\mathbf{q},t,\lambda)=-\frac{2}{3}e_{ij}(\hat{q},\lambda)\Psi(q,t) \tag{6.6.12}$$

Rotational invariance allows the intensity matrix perturbation to be written in the form

$$\begin{aligned}J_{ij}(\mathbf{q},\hat{p},t,\lambda)=&\frac{1}{2}\left(\delta_{ij}-\hat{p}_i\hat{p}_j\right)\hat{p}_k\hat{p}_l e_{kl}(\hat{q},\lambda)\\ &\times\left(\Delta_T^{(T)}(q,\hat{p}\cdot\hat{q},t)+\Delta_P^{(T)}(q,\hat{p}\cdot\hat{q},t)\right)\\ &+\left(e_{ij}(\hat{q},\lambda)-\hat{p}_i\hat{p}_k e_{kj}(\hat{q},\lambda)-\hat{p}_j\hat{p}_k e_{ik}(\hat{q},\lambda)+\hat{p}_i\hat{p}_j\hat{p}_k\hat{p}_l e_{kl}(\hat{q},\lambda)\right)\\ &\times\Delta_P^{(T)}(q,\hat{p}\cdot\hat{q},t)\end{aligned} \tag{6.6.13}$$

(Here the superscript T stands for "tensor," while the subscript T stands for "temperature." The coefficients are chosen so that J_{ii} is proportional to Δ_T, and the polarization is proportional to Δ_P.) A third term proportional to $\left(\hat{q}_i-\hat{p}_i(\hat{p}\cdot\hat{q})\right)\left(\hat{q}_j-\hat{p}_j(\hat{p}\cdot\hat{q})\right)\hat{p}_k\hat{p}_l e_{kl}$ would be allowed by symmetry principles, but is not generated in the Boltzmann equation by Thomson scattering. Using Eq. (6.6.13) in Eq. (6.6.10) yields separate Boltzmann equations for $\Delta_T^{(T)}$ and $\Delta_P^{(T)}$:

$$\begin{aligned}&\frac{\partial}{\partial t}\Delta_T^{(T)}(q,\mu,t)+ia^{-1}(t)q\mu\Delta_T^{(T)}(q,\mu,t)\\ &\quad=-2\dot{\mathcal{D}}_q(t)-\omega_c(t)\Delta_T^{(T)}(q,\mu,t)+\omega_c(t)\Psi(q,t)\end{aligned} \tag{6.6.14}$$

$$\begin{aligned}&\frac{\partial}{\partial t}\Delta_P^{(T)}(q,\mu,t)+ia^{-1}(t)q\mu\Delta_P^{(T)}(q,\mu,t)\\ &\quad=-\omega_c(t)\Delta_P^{(T)}(q,\mu,t)-\omega_c(t)\Psi(q,t)\end{aligned} \tag{6.6.15}$$

The functions $\Delta_T^{(T)}$ and $\Delta_P^{(T)}$ may be expanded in Legendre polynomials

$$\Delta_T^{(T)}(q,\hat{p}\cdot\hat{q},t)=\sum_{\ell=0}^{\infty}i^{-\ell}(2\ell+1)P_\ell(\hat{q}\cdot\hat{p})\Delta_{T,\ell}^{(T)}(q,t) \tag{6.6.16}$$

$$\Delta_P^{(T)}(q,\hat{p}\cdot\hat{q},t)=\sum_{\ell=0}^{\infty}i^{-\ell}(2\ell+1)P_\ell(\hat{q}\cdot\hat{p})\Delta_{P,\ell}^{(T)}(q,t) \tag{6.6.17}$$

Using the familiar recursion relation

$$zP_\ell(z)=\frac{\ell+1}{2\ell+1}P_{\ell+1}(z)+\frac{\ell}{2\ell+1}P_{\ell-1}(z)$$

we find that the Boltzmann equations (6.6.14) and (6.6.15) now read

$$\begin{aligned}&\dot{\Delta}_{T,\ell}^{(T)}+\frac{q}{a(2\ell+1)}\left((\ell+1)\Delta_{T,\ell+1}^{(T)}-\ell\Delta_{T,\ell-1}^{(T)}\right)\\&\quad=\left(-2\dot{\mathcal{D}}_q+\omega_c\Psi\right)\delta_{\ell,0}-\omega_c\Delta_{T,\ell}^{(T)}\end{aligned} \tag{6.6.18}$$

$$\begin{aligned}&\dot{\Delta}_{P,\ell}^{(T)}+\frac{q}{a(2\ell+1)}\left((\ell+1)\Delta_{P,\ell+1}^{(T)}-\ell\Delta_{P,\ell-1}^{(T)}\right)\\&\quad=-\omega_c\Psi\delta_{\ell,0}-\omega_c\Delta_{P,\ell}^{(T)}\end{aligned} \tag{6.6.19}$$

To calculate the source term $\Psi(q,t)$ in terms of partial waves, one first integrates Eq. (6.6.13) over $\hat{p}$, using the formulas

$$\int d^2\hat{p}f(\hat{p}\cdot\hat{q})\hat{p}_i\hat{p}_k e_{jk}(\hat{q})=\frac{1}{2}e_{ij}(\hat{q})\int d^2\hat{p}f(\hat{p}\cdot\hat{q})\left(1-(\hat{p}\cdot\hat{q})^2\right)$$

$$\int d^2\hat{p}f(\hat{p}\cdot\hat{q})\hat{p}_i\hat{p}_j\hat{p}_k\hat{p}_l e_{kl}(\hat{q})=\frac{1}{4}e_{ij}(\hat{q})\int d^2\hat{p}f(\hat{p}\cdot\hat{q})\left(1-(\hat{p}\cdot\hat{q})^2\right)^2$$

where f is any function of $\hat{p}\cdot\hat{q}$ and e_{ij} is any symmetric traceless matrix function of $\hat{q}$ with $\hat{q}_i e_{ij}=0$ and $e_{ii}=0$. The integral gives

$$\begin{aligned}\Psi(q,t)=-\frac{3}{2}\int\frac{d^2\hat{p}}{4\pi}\Bigg[&-\frac{1}{8}\left(1-(\hat{p}\cdot\hat{q})^2\right)^2\Delta_T^{(T)}(q,\hat{p}\cdot\hat{q},t)\\&+\left((\hat{p}\cdot\hat{q})^2+\frac{1}{8}\left(1-(\hat{p}\cdot\hat{q})^2\right)^2\right)\Delta_P^{(T)}(q,\hat{p}\cdot\hat{q},t)\Bigg].\end{aligned} \tag{6.6.20}$$

Inserting the partial wave expansions (6.6.16) and (6.6.17) then gives: [1]

$$\begin{aligned}\Psi(q,t)=&\frac{1}{10}\Delta_{T,0}^{(T)}(q,t)+\frac{1}{7}\Delta_{T,2}^{(T)}(q,t)+\frac{3}{70}\Delta_{T,4}^{(T)}(q,t)-\frac{3}{5}\Delta_{P,0}^{(T)}(q,t)\\&+\frac{6}{7}\Delta_{P,2}^{(T)}(q,t)-\frac{3}{70}\Delta_{P,4}^{(T)}(q,t)\end{aligned} \tag{6.6.21}$$

Eqs. (6.6.18) and (6.6.19) thus form a closed system of coupled differential equations for the partial wave amplitudes produced by a given gravitational field perturbation $\mathcal{D}_q(t)$. Of course, their solution requires a truncation of the partial wave expansion at some maximum ℓ.

The solution is of interest in itself, because we can measure anisotropies in the cosmic microwave background. It will be applied to these anisotropies in Chapter 7. It is also needed in calculations of the tensor anisotropic inertia. In tensor modes, the only non-vanishing contribution of photons to the energy-momentum tensor is to the space-space component (6.1.10)

$$\begin{aligned}\delta T^i_{\gamma j}(\mathbf{x},t) =& a^{-4}(t)\int d^3p a^2(t)\delta n^{kk}(\mathbf{x},\mathbf{p},t)p\hat{p}_i\hat{p}_j\\ =&\bar{\rho}_\gamma(t)\sum_\lambda\int d^3q\beta(\mathbf{q},\lambda)e^{i\mathbf{q}\cdot\mathbf{x}}\int\frac{d^2\hat{p}}{4\pi}J_{kk}(\mathbf{q},\hat{p},t,\lambda)\hat{p}_i\hat{p}_j\\ =&\bar{\rho}_\gamma(t)\sum_\lambda\int d^3q\beta(\mathbf{q},\lambda)e^{i\mathbf{q}\cdot\mathbf{x}}e_{kl}(\hat{q},\lambda)\\ &\times\int\frac{d^2\hat{p}}{4\pi}\Delta^{(T)}_T(q,\hat{p}\cdot\hat{q},t)\hat{p}_i\hat{p}_j\hat{p}_k\hat{p}_l\\ =&\bar{\rho}_\gamma(t)\sum_\lambda\int d^3q\beta(\mathbf{q},\lambda)e^{i\mathbf{q}\cdot\mathbf{x}}e_{ij}(\hat{q},\lambda)\\ &\times\frac{1}{4}\int\frac{d^2\hat{p}}{4\pi}\Delta^{(T)}_T(q,\hat{p}\cdot\hat{q},t)\left(1-(\hat{p}\cdot\hat{q})^2\right)^2\end{aligned}\tag{6.6.22}$$

For tensor modes there is no pressure perturbation, so according to Eq. (5.1.43), this is the same as the anisotropic inertia tensor $\pi^T_{\gamma ij}(\mathbf{x},t)$. Comparing Eq. (6.6.22) with Eq. (6.6.5) thus gives

$$\begin{aligned}\pi^T_{\gamma q}(t) &= \frac{\bar{\rho}_\gamma(t)}{4}\int\frac{d^2\hat{p}}{4\pi}\Delta^{(T)}_T(q,\hat{p}\cdot\hat{q},t)\left(1-(\hat{p}\cdot\hat{q})^2\right)^2\\ &= 2\bar{\rho}_\gamma(t)\left[\frac{1}{15}\Delta^{(T)}_{T,0}(q,t)+\frac{2}{21}\Delta^{(T)}_{T,2}(q,t)+\frac{1}{35}\Delta^{(T)}_{T,4}(q,t)\right].\end{aligned}\tag{6.6.23}$$

Experience shows that to accurately calculate the partial wave amplitudes up to $\ell=4$, which appear in Eqs. (6.6.21) and (6.6.23), one needs to solve the Boltzmann equations for the partial wave amplitudes up to larger values of ℓ, up to $\ell=10$. Once Ψ is calculated in this way, we can calculate $J_{ij}(\mathbf{q},\hat{p},t,\lambda)$ for very much higher values of ℓ by using the "line of sight" solution of Eq. (6.6.10):

$$\begin{aligned}J_{ij}(\mathbf{q},\hat{p},t,\lambda) = &\int_{t_1}^t dt'\exp\left(-i\mathbf{q}\cdot\hat{p}\int_{t'}^t\frac{dt''}{a\left(t''\right)}-\int_{t'}^t dt''\omega_c\left(t''\right)\right)\\ &\times\left[-\hat{p}_k\hat{p}_l\left(\delta_{ij}-\hat{p}_i\hat{p}_j\right)e_{kl}(\hat{q},\lambda)\dot{\mathcal{D}}_q\left(t'\right)-\omega_c\left(t'\right)\Psi\left(q,t'\right)\right.\\ &\left.\left(e_{ij}(\hat{q},\lambda)-\hat{p}_i\hat{p}_k e_{kj}(\hat{q},\lambda)-\hat{p}_j\hat{p}_k e_{ik}(\hat{q},\lambda)+\hat{p}_i\hat{p}_j\hat{p}_k\hat{p}_l e_{kl}(\hat{q},\lambda)\right)\right]\end{aligned}\tag{6.6.24}$$

where t_1 is any time that is early enough before recombination so that $\omega_c\left(t_1\right)\gg H\left(t_1\right)$, which allows us to drop a term proportional to $J_{ij}\left(\mathbf{q},\hat{p},t_1,\lambda\right)$. In terms of the temperature and polarization amplitudes defined by the decomposition (6.6.13), the line-of-sight integrals read

$$\begin{aligned}\Delta^{(T)}_T(q,\mu,t) =& -\Delta^{(T)}_P(q,\mu,t)-2\int_{t_1}^t dt'\exp\left[-iq\mu\int_{t'}^t\frac{dt''}{a\left(t''\right)}\right.\\ &\left.-\int_{t'}^t\omega_c\left(t''\right)dt''\right]\times\mathcal{D}_q\left(t'\right)\end{aligned}\tag{6.6.25}$$

$$\begin{aligned}\Delta^{(T)}_P(q,\mu,t) =& -\int_{t_1}^t dt'\exp\left[-iq\mu\int_{t'}^t\frac{dt''}{a\left(t''\right)}-\int_{t'}^t\omega_c\left(t''\right)dt''\right]\\ &\times\omega_c\left(t'\right)\Psi\left(q,t'\right)\end{aligned}\tag{6.6.26}$$

[471] R. Crittenden, J. R. Bond, R. L. Davis, G. Efstathiou, and P. J. Steinhardt, Phys. Rev. Lett. 71, 324 (1993) [astro-ph/9303014].

This line of sight integral also provides an alternative to the use of the truncated partial wave expansion. [2] We can derive an integral equation for

$\Psi(q,t)$ by simply analytically integrating Eq. (6.6.24) over $\hat{p}$. Equating the coefficients of e_{ij} on both sides gives the integral equation

$$\Psi(q,t) = \frac{3}{2}\int_{t_1}^{t} dt' \exp\left[-\int_{t'}^{t} \omega_c\left(t''\right) dt''\right] \times \left[-2\dot{\mathcal{D}}_q\left(t'\right) K\left(q\int_{t'}^{t}\frac{dt''}{a\left(t''\right)}\right) + \omega_c\left(t'\right) F\left(q\int_{t'}^{t}\frac{dt''}{a\left(t''\right)}\right)\Psi\left(q,t'\right)\right] \tag{6.6.27}$$

where $K(v)$ and $F(v)$ are the functions

$$K(v) \equiv j_2(v)/v^2, \quad F(v) \equiv j_0(v) - 2j_1(v)/v + 2j_2(v)/v^2. \tag{6.6.28}$$

Eq. (6.6.27) can be solved efficiently either by iteration, or by numerical recipes appropriate for integral equations of the Volterra type. Once $\Psi(q,t)$ is calculated in this way, the complete photon intensity matrix can be obtained by a numerical integration in Eq. (6.6.24).

Neutrinos

The Boltzmann equation for the perturbation $\delta n_\nu(\mathbf{x},\mathbf{p},t)$ to the neutrino phase space density is given by Eq. (H.14) as

$$\frac{\partial \delta n_v(\mathbf{x},\mathbf{p},t)}{\partial t} + \frac{\hat{p}_i}{a(t)}\frac{\partial \delta n_v(\mathbf{x},\mathbf{p},t)}{\partial x^i} = \frac{p\bar{n}'(p)}{2}\hat{p}_i\hat{p}_j\dot{D}_{ij}(\mathbf{x},t), \tag{6.6.29}$$

in which we have used Eq. (6.6.1) for the metric perturbation. As in the case of scalar modes, instead of δn_ν, we find it more convenient to deal with a dimensionless intensity perturbation J, defined by the analog of Eq. (6.1.42):

$$a^4(t)\bar{\rho}_v(t)J(\mathbf{x},\hat{p},t) \equiv N_v\int_0^\infty \delta n_v(\mathbf{x},\mathbf{p},t)4\pi p^3 dp \tag{6.6.30}$$

where N_ν is the number of species of neutrino, counting antineutrinos separately, and $\bar{\rho}_\nu \equiv N_\nu a^{-4}\int 4\pi p^3 \bar{n}_\nu(p)$. This satisfies a Boltzmann equation

$$\frac{\partial J(\mathbf{x},\hat{p},t)}{\partial t} + \frac{\hat{p}_i}{a(t)}\frac{\partial J(\mathbf{x},\hat{p},t)}{\partial x^i} = -2\hat{p}_i\hat{p}_j\dot{D}_{ij}(\mathbf{x},t), \tag{6.6.31}$$

with D_{ij} given by Eq. (6.6.4). We will be able to find a solution in the form

$$J(\mathbf{x},\hat{p},t) = \sum_{\lambda=\pm 2}\int d^3q e^{i\mathbf{q}\cdot\mathbf{x}}\beta(\mathbf{q},\lambda)e_{ij}(\hat{q},\lambda)\hat{p}_i\hat{p}_j\Delta_v^{(T)}(q,\hat{p}\cdot\hat{q},t) \tag{6.6.32}$$

Then Eq. (6.6.29) becomes an equation for $\Delta_\nu^{(T)}$:

$$\dot{\Delta}_v^{(T)}(q,\mu,t) + \frac{iq\mu}{a(t)}\Delta_v^{(T)}(q,\mu,t) = -2\dot{\mathcal{D}}_q(t) \tag{6.6.33}$$

This can be solved by a partial wave expansion

$$\Delta_v^{(T)}(q,\mu,t) = \sum_\ell i^{-\ell}(2\ell+1)\Delta_{v,\ell}^{(T)}(q,t) \tag{6.6.34}$$

[472] S. Weinberg, Phys. Rev. D 74, 063517 (2006) [astro-ph/0607076]; D. Baskaran, L. P. Grishchuk, and A. G. Polnarev, Phys. Rev. D 74, 083008 (2006) [gr-qc/0605100].

with $\Delta^{(T)}_{\nu,\ell}(q,t)$ satisfying

$$\dot{\Delta}^{(T)}_{v,\ell} + \frac{q}{a(2\ell+1)}\left((\ell+1)\Delta^{(T)}_{v,\ell+1} - \ell\Delta^{(T)}_{T,\ell-1}\right) = -2\dot{\mathcal{D}}_q(t)\delta_{\ell 0}. \tag{6.6.35}$$

This of course needs to be truncated at some more-or-less arbitrary maximum value of ℓ. But instead we can find a direct solution of Eq. (6.6.33), as a line of sight integral

$$\Delta^{(T)}_v(q,\mu,t) = -2\int_{t_1}^{t} dt' \exp\left(-iq\mu\int_{t'}^{t}\frac{dt''}{a\,(t'')}\right)\dot{\mathcal{D}}_q\,(t') \tag{6.6.36}$$

We take t_1 soon enough after the decoupling of neutrinos at $T \approx 10^{10}$ K so that at this time the distribution of neutrinos is still essentially that of local thermal equilibrium. In this case the perturbation to this distribution arises only from the perturbations δT_ν and $\delta\mathbf{u}_\nu$ to the neutrino temperature and streaming velocity, which do not have tensor components, so we do not need to include an initial value term $\Delta^{(T)}_v\,(q,\mu,t_1)$ on the right-hand side of Eq. (6.6.36).

It will be a long while before anyone measures the angular distribution of cosmic neutrinos, so the only use to be made of calculations of δn_ν is in calculating components of the energy momentum tensor. In the tensor mode, the only non-vanishing component is $\delta T^i_{\nu j}$, given by the same formula (6.6.22) as for photons, except that $\Delta^{(T)}_\nu$ appears instead of $\Delta^{(T)}_T$:

$$\begin{aligned}
\delta T^i_{vj}(\mathbf{x},t) =& a^{-4}(t)\int d^3p\,\delta n_v(\mathbf{x},\mathbf{p},t)p\hat{p}_i\hat{p}_j\\
=&\bar{\rho}_v(t)\sum_\lambda\int d^3q\,\beta(\mathbf{q},\lambda)e^{i\mathbf{q}\cdot\mathbf{x}}\int\frac{d^2\hat{p}}{4\pi}J(\mathbf{q},\hat{p},t,\lambda)\hat{p}_i\hat{p}_j\\
=&\bar{\rho}_v(t)\sum_\lambda\int d^3q\,\beta(\mathbf{q},\lambda)e^{i\mathbf{q}\cdot\mathbf{x}}e_{kl}(\hat{q},\lambda)\\
&\times\int\frac{d^2\hat{p}}{4\pi}\Delta^{(T)}_v(q,\hat{p}\cdot\hat{q},t)\hat{p}_i\hat{p}_i\hat{p}_j\hat{p}_k\\
\\
=&\bar{\rho}_v(t)\sum_\lambda\int d^3q\,\beta(\mathbf{q},\lambda)e^{i\mathbf{q}\cdot\mathbf{x}}e_{ij}(\hat{q},\lambda)\\
&\times\frac{1}{4}\int\frac{d^2\hat{p}}{4\pi}\Delta^{(T)}_v(q,\hat{p}\cdot\hat{q},t)\left(1-(\hat{p}\cdot\hat{q})^2\right)^2
\end{aligned} \tag{6.6.37}$$

This is the neutrino contribution to the anisotropic inertia tensor π^T_{ij}. Comparing this with Eq. (6.6.5) then gives

$$\pi^T_{vq}(t) = \frac{\bar{\rho}_v(t)}{4}\int\frac{d^2\hat{p}}{4\pi}\Delta^{(T)}_v(q,\hat{p}\cdot\hat{q},t)\left(1-(\hat{p}\cdot\hat{q})^2\right)^2. \tag{6.6.38}$$

As for photons, this can be evaluated using the partial wave expansion:

$$\pi^T_{vq}(t) = 2\bar{\rho}_v(t)\left[\frac{1}{15}\Delta^{(T)}_{v,0}(q,t) + \frac{2}{21}\Delta^{(T)}_{v,2}(q,t) + \frac{1}{35}\Delta^{(T)}_{v,4}(q,t)\right]. \tag{6.6.39}$$

But for neutrinos it is easier to use the explicit solution (6.6.36). Using Eqs. (6.6.36) and (6.1.55) in the third expression of Eq. (6.6.35) and comparing with Eq. (6.6.5) gives [3]

$$\pi^T_{vq}(t) = -4\bar{\rho}_\gamma(t)\int_{t_1}^{t}dt'K\left(q\int_{t'}^{t}\frac{dt''}{a\,(t'')}\right)\dot{\mathcal{D}}_q\,(t') \tag{6.6.40}$$

where

$$K(v) \equiv j_2(v)/v^2 = -\frac{\sin v}{v^3} - \frac{3\cos v}{v^4} + \frac{3\sin v}{v^5}. \tag{6.6.41}$$

We will use this below in calculating the decay of gravitational waves that exit from the horizon in the radiation-dominated era.

We have found a complete set of differential equations for the tensor perturbations. Now we shall turn to the calculation of $\mathcal{D}_q(t)$, which provides the essential input in the calculation of tensor anisotropies in the cosmic microwave background. We begin by neglecting the tensor anisotropic inertia π_{ij}^T, returning to a consideration of its effects at the end of this section. The anisotropic inertia is negligible during most of the history of the universe, when the cosmic energy density is dominated by one or more perfect fluids, and it is never very large. With this approximation, the field equation (6.6.6) governing the Fourier components of the tensor component D_{ij} of the metric perturbation is simply

$$\ddot{\mathcal{D}}_q(t) + 3\frac{\dot{a}}{a}\dot{\mathcal{D}}_q(t) + \frac{q^2}{a^2}\mathcal{D}_q(t) = 0. \tag{6.6.42}$$

As already mentioned earlier in this section, at very early times when $q/a \ll \dot{a}/a$ one solution is constant while the other decays, so as long as this era lasts sufficiently long we can neglect the decaying solution, and take our initial condition that $\mathcal{D}_q(t)$ goes to a constant $\mathcal{D}_q^o$ at early times.

To treat the evolution of $\mathcal{D}_q(t)$ at later times, it is convenient once again to change the independent variable from t to $y \equiv a/a_{\rm EQ} = \bar{\rho}_M/\bar{\rho}_R$, where $a_{\rm EQ}$ is the value of the Robertson-Walker scale factor at matter-radiation equality. Assuming that the energy density of the universe is governed by radiation and non-relativistic matter, [4] we can put Equation (6.3.11) in the form

$$\frac{H_{\rm EQ}dt}{\sqrt{2}} = \frac{ydy}{\sqrt{1+y}} \tag{6.6.43}$$

where $H_{\rm EQ}$ is the expansion rate at matter-radiation equality. Then Eq. (6.6.42) becomes

$$(1+y)\frac{d^2\mathcal{D}_q}{dy^2} + \left(\frac{2(1+y)}{y} + \frac{1}{2}\right)\frac{d\mathcal{D}_q}{dy} + \kappa^2\mathcal{D}_q = 0 \tag{6.6.44}$$

where κ is the dimensionless rescaled wave number (6.5.9):

$$\kappa \equiv \frac{\sqrt{2}q}{a_{\rm EQ}H_{\rm EQ}} = \frac{(q/a_0)\sqrt{\Omega_R}}{H_0\Omega_M} = \frac{19.3\,(q/a_0)\left[{\rm Mpc}^{-1}\right]}{\Omega_M h^2}. \tag{6.6.45}$$

We also have the initial condition, that $\mathcal{D}_q \to \mathcal{D}_q^o$ for $y \ll 1$. As in the case of scalar modes, we can find analytic solutions in two extreme cases, for $\kappa \ll 1$ and $\kappa \gg 1$.

Consider first the case $\kappa \gg 1$. In this limit we already have $q/a \gg \dot{a}/a$ at matter-radiation equality, so horizon entry occurs early in the radiationdominated era. Hence for $\kappa \gg 1$ there are two overlapping eras; an era when the universe is radiation dominated extending to early times when the perturbation is outside the horizon, and an era when the perturbation is well inside the horizon extending to the present, in both of which we will be able to find analytic solutions. Because these eras overlap, we will be able to match the analytic solutions in the era of overlap, and in this way relate the gravitational wave amplitude at late times to the initial condition when the perturbation is outside the horizon.

First, in the era when the universe is radiation dominated $y \ll 1$, and Eq. (6.6.44) becomes

[473] S. Weinberg, Phys. Rev. D 69, 023503 (2004) [astro-ph/0306304].

$$\frac{d^2\mathcal{D}_q}{dy^2} + \left(\frac{2}{y}\right)\frac{d\mathcal{D}_q}{dy} + \kappa^2\mathcal{D}_q = 0 \tag{6.6.46}$$

The solution which approaches a constant $\mathcal{D}_q^o$ for $y \to 0$ is

$$D_q = \frac{\sin(\kappa y)}{\kappa y}\mathcal{D}_q^o \tag{6.6.47}$$

Next, consider the case of perturbations deep inside the horizon, that is, for which $q/a \gg H$. In this case we can find solutions using the WKB approximation for a completely arbitrary dependence of $a(t)$ on time, so that our results will apply even in the presence of vacuum energy, whether or not it is constant. For this purpose, we must put Eq. (6.6.42) into a standard form with no first derivative term [5] by introducing a new independent variable,

$$x \equiv \int a^{-3}(t)dt$$

so that Eq. (6.6.42) becomes

$$\frac{d^2\mathcal{D}_q}{dx^2} + q^2a^4\mathcal{D}_q = 0 \tag{6.6.48}$$

We write $\mathcal{D}_q = A\exp\left(\pm iq\int a^2dx\right)$, and keep only terms in Eq. (6.6.48) of order q^2 and q. This gives $dA/dx = -\left(A/2a^2\right)da^2/dx$, so $A \propto 1/a$, and the WKB solutions for $\mathcal{D}_q$ are $a^{-1}\exp\left(\pm iq\int a^2dx\right) = a^{-1}\exp\left(\pm iq\int a^{-1}dt\right)$. The factor $1/a$ gives a gravitational wave energy density that decreases as a^{-4}, a factor of a^{-1} representing the redshift of individual gravitons, and a factor a^{-3} arising from the dilution of gravitons as the universe expands. [6]

To find the correct linear combination of the two WKB solutions, we have to match them to the solution (6.6.47) in the radiation-dominated era, by considering these solutions in the intermediate range where both $q/a \gg H$ and $y \ll 1$. In the radiation-dominated era vacuum energy is presumably negligible, so here $q/aH = \kappa a_{\rm EQ}H_{\rm EQ}/\sqrt{2}aH = \kappa y$, and for $\kappa \gg 1$ there does exist a range of y for which $\kappa y \gg 1$ even though $y \ll 1$. In this range of y, we have

$$q\int\frac{dt}{a} = q\int\frac{da}{Ha^2} = \kappa\int\frac{yda}{a} = \kappa y$$

so (recalling that $y \propto a$) the linear combination of $a^{-1}\exp\left(+iq\int a^{-1}dt\ \right)$ and $a^{-1}\exp\left(-iq\int a^{-1}dt\right)$ that matches Eq. (6.6.47) where both are valid is

$$\mathcal{D}_q = \frac{1}{\kappa y}\sin\left(q\int_0^t\frac{dt'}{a\left(t'\right)}\right)\mathcal{D}_q^o. \tag{6.6.49}$$

To repeat, this is the solution deep in the horizon, whatever the contents of the universe. For times near the present, this is

$$\mathcal{D}_q = \frac{\sqrt{\Omega_R H_0^2}}{k}\sin\left(\eta + k\left(t - t_0\right)\right)\mathcal{D}_q^o, \tag{6.6.50}$$

[474] The evolution of the tensor amplitude under more general assumptions is considered by L . A. Boyle and P. J. Steinhardt, astro-ph/0512014.

[475] The standard way of eliminating the first derivative term in Eq. (6.6.42) is to change the dependent instead of the independent variable. For instance, see V. S. Mukhanov, H. A. Feldman, and R. H. Brandenberger, Phys. Rep. 215, 203 (1992); K. Ng and A. Speliotopoulos, Phys. Rev. D 52, 2112 (1995); and more recently, J. R. Pritchard and M. Kamionkowski, Ann. Phys. 318, 2 (2005). The results obtained in this section are much simpler than with this standard method, because by changing the independent rather than the dependent variable we encounter no turning point in the WKB solution.

[6] See G&C, Sec. 15.10.

where $k \equiv q/a_0$, and $\eta \equiv k a_0 \int_0^{t_0} dt/a(t)$.
It is possible that cosmological gravitational waves might be detected directly. [7] Tensor modes detectable in this way would certainly have $\kappa \gg 1$, the case we have been considering, so that they would enter the horizon much earlier than the time of recombination, and hence could provide an opportunity for a direct observation of the universe at very early times, and even for the exploration of physics at higher energies than can be reached by conventional particle accelerators. The existing ground-based Laser Interferometer Gravitational-Wave Observatory (LIGO) operates at about 100 Hz ; perturbations with this frequency re-entered the horizon when the cosmic temperature was about 10^8GeV, but LIGO does not have the sensitivity required to detect cosmological gravitational waves. But cosmological gravitational waves might be detected by space-borne laser interferometers. For instance, two detectors of cosmological gravitational waves have been under consideration: the Big Bang Observer in the U.S., and the Decihertz Laser Interferometer Gravitational Wave Observatory in Japan. Both operate at frequencies around 0.01 to 0.1 Hz , and according to Eq. (6.6.43), a gravitational wave with a frequency of $qc/2\pi a_0 = 10^{-2}$ Hz would have $\kappa = 1.3 \times 10^{15}/\Omega_M h^2 \gg 1$. The wavelengths to which such detectors would be sensitive would short enough to have come into the horizon when the cosmic temperature was 10^4 to 10^5GeV. In this case, the changes in the time dependence of $a(t)$ associated with changes in the equation of state of matter at various annihilation thresholds produce distinctive features in the spectrum of the tensor modes. [8] For reasonable assumptions about the pri-

mordial tensor spectrum, it seems likely [9] that a tensor perturbation strong enough to be detected directly at short wavelengths would be detected also indirectly at longer wavelengths through its effect on the polarization of the cosmic microwave background, to be discussed in Section 7.4.

In calculating the effect of cosmological gravitational waves on the cosmic microwave background, we need also to consider values of κ of order unity or less. Let us therefore turn to the other case that can be treated analytically, the case $\kappa \ll 1$. Here we still have $q/a \ll \dot{a}/a$ at matter-radiation equality, so the perturbation remains outside the horizon and $\mathcal{D}_q(t)$ remains equal to the constant value $\mathcal{D}_q^0$ until well into the matter-dominated era, when $y \gg 1$. In the limit $y \gg 1$, and whatever the value of κ, Eq. (6.6.42) becomes

$$y\frac{d^2\mathcal{D}_q}{dy^2} + \frac{5}{2}\frac{d\mathcal{D}_q}{dy} + \kappa^2\mathcal{D}_q = 0 \tag{6.6.51}$$

This has two independent solutions, which can be written as functions of $\kappa\sqrt{y}$:

$$\begin{aligned} \frac{2j_1(2\kappa\sqrt{y})}{\kappa\sqrt{y}} &= \frac{-\cos(2\kappa\sqrt{y})}{\kappa^2 y} + \frac{\sin(2\kappa\sqrt{y})}{2\kappa^3 y^{3/2}} \\ -\frac{2n_1(2\kappa\sqrt{y})}{\kappa\sqrt{y}} &= \frac{\sin(2\kappa\sqrt{y})}{\kappa^2 y} + \frac{\cos(2\kappa\sqrt{y})}{2\kappa^3 y^{3/2}} \end{aligned} \tag{6.6.52}$$

In the matter-dominated era, $q/aH = \kappa a_{\rm EQ} H_{\rm EQ}/\sqrt{2}aH = \kappa\sqrt{y}$, so we must impose the condition that the solution should approach the constant value $\mathcal{D}_q^o$ for $\kappa\sqrt{y} \ll 1$. In order to satisfy this condition, we must exclude the second solution, which becomes singular for

[477] For recent studies, see N. Seto, S. Kawamura, and T. Nakamura, Phys. Rev. Lett. 87, 221103 (2001) [astro-ph/0108011]; A. Buonanno, gr-qc/0303085; A. Cooray, astro-ph/0503118; T. L. Smith, M. Kamionkowski, and A. Cooray, Phys. Rev. D 73, 023504 (2006) [astro-ph/0506422]; G. Efstathiou and S. Chongchitnan, Prog. Theor. Phys. Suppl. 163, 204 (2006) [astro-ph/0603118]; B. Friedman, A. Cooray, and A. Melchiorri, Phys. Rev. D 74, 123509 (2006) [astro-ph/0610220]. Also see NASA web page universe.nasa.gov/program/bbo.html.
[8] Y. Watanabe and E. Komatsu, Phys. Rev. D 73, 123515 (2006) [astro-ph/0604176].

$\kappa\sqrt{y} \to 0$. In this limit the first solution approaches the constant 4/3, so the correct solution when $\kappa \ll 1$ is

$$\mathcal{D}_q \to \frac{3\mathcal{D}_q^o}{4}\left(\frac{-\cos(2\kappa\sqrt{y})}{\kappa^2 y} + \frac{\sin(2\kappa\sqrt{y})}{2\kappa^3 y^{3/2}}\right). \tag{6.6.53}$$

(Note that although Eq. (6.6.51) applies only for $y \gg 1$, Eq. (6.6.53) is valid for $\kappa \ll 1$ and any y, because it correctly gives $\mathcal{D}_q(t) = \mathcal{D}_q^o$ as long as $\kappa\sqrt{y} \ll 1$, which for $\kappa \ll 1$ applies until $y \gg 1$.)

The interpolation between the cases $\kappa \gg 1$ and $\kappa \ll 1$ is simplest in the matter-dominated era, when $y \gg 1$. This is only a fair approximation at the time of the decoupling of matter and radiation, when $y \approx 3$, but it

becomes a good approximation thereafter. In this case the tensor modes are governed by Eq. (6.6.51), and the general solution is a linear combination of the two solutions (6.6.52), which for any κ can conveniently be written

$$\mathcal{D}_q = \frac{3\mathcal{D}_q^o\mathcal{U}(\kappa)}{4\kappa^2}\left(\frac{-\cos(2\kappa\sqrt{y}+\Xi(\kappa))}{y} + \frac{\sin(2\kappa\sqrt{y}+\Xi(\kappa))}{2\kappa y^{3/2}}\right), \tag{6.6.54}$$

where $\mathcal{U}$ and Ξ are real dimensionless functions of κ. From Eq. (6.6.53) we see that for $\kappa \ll 1$,

$$\mathcal{U}(\kappa) \to 1, \quad \Xi(\kappa)/\kappa^3 \to 0 \tag{6.6.55}$$

which is why we chose to write the physical solution in the form (6.6.54). Also, for $y \gg 1$ Eq. (6.6.49) becomes

$$\mathcal{D}_q = \frac{\sin(2\kappa(\sqrt{1+y}-1))}{\kappa y}\mathcal{D}_q^o \tag{6.6.56}$$

and therefore for $\kappa \gg 1$,

$$\mathcal{U}(\kappa) \to \frac{4\kappa}{3}, \quad \Xi(\kappa) \to \frac{\pi}{2} - 2\kappa \tag{6.6.57}$$

The values of $\mathcal{U}(\kappa)$ and $\Xi(\kappa)$ for general κ must be found by a computer calculation of the solution of Eq. (6.6.44). The results [10] are presented in Table 6.2. It can be seen that the analytic asymptotic limits (6.6.55) and (6.6.57) agree quite well with the computer calculation for $\kappa \ll 1$ and $\kappa \gg 1$, respectively.

Now let us consider the effect of anisotropic inertia. [11] The anisotropic inertia tensor is the sum of the contributions from photons and neutrinos, but photons are have a short mean free time before the era of recombination, and make only a small contribution to the total energy density afterwards, so their contribution to the anisotropic inertia is small. This leaves neutrinos (including antineutrinos), which have been travelling essentially without collisions [12] since the temperature dropped below

[479] Smith, Kamionkowski, and Cooray, ref. 7.

[4710] D. Dicus, private communication.

[11] S. Weinberg, ref. 3. For results of an earlier computer calculation, see J. R. Bond, in Cosmology and Large Scale Structure, Les Houches Session LX, eds. R. Schaeffer, J. Silk, and J. Zinn-Justin (Elsevier, Amsterdam, 1996).

[12] For very short wavelengths that entered the horizon before the time of electron-positron annihilation, it is necessary to take into account collisions of neutrinos with each other and with electrons and positrons. This is considered by M. Lattanzi and G. Montani, Mod. Phys. Lett. A 20, 2607 (2005) [astro-ph/0508364].

about 10^{10} K, and which make up a good fraction of the energy density of the universe until cold dark matter becomes important, at a temperature about 10^4 K. The tensor part of the anisotropic inertia tensor is given by Eq. (6.6.40), so the gravitational wave equation (6.6.6) now becomes an
integro-differential equation [13]
$\ddot{\mathcal{D}}_q(t) + 3\frac{\dot{a}}{a}\dot{\mathcal{D}}_q(t) + \frac{q^2}{a^2}\mathcal{D}_q(t) = -64\pi G\bar{\rho}_\nu(t)\int_0^t K\left(q\int_{t'}^t \frac{dt''}{a(t'')}\right)\dot{\mathcal{D}}_q(t')\,dt'$,
with $K(v)$ given by Eq. (6.6.41). Note that despite the presence of anisotropic inertia, for $q/a \ll H$ this has a solution with $\mathcal{D}_q(t)$ time-independent, in accordance with the general theorem of Section 5.4.

This wave equation becomes particularly simple for wavelengths short enough to enter the horizon during the radiation-dominated era (though well after $e^+ - e^-$annihilation), that is, for

$\kappa \gg 1$. We will define the zero of time so that in this era $a \propto \sqrt{t}$. It is convenient now to write $\mathcal{D}_q$ as a function of the variable

$$u \equiv q \int_0^t \frac{dt'}{a\,(t')} = \frac{2qt}{a(t)}, \tag{6.6.59}$$

instead of t. Using the Friedmann equation $8\pi G\bar{\rho}/3 = H^2 = 1/4t^2$, the gravitational wave equation (6.6.58) in the radiation-dominated era becomes

$$\frac{d^2}{du^2}\mathcal{D}_q(u) + \frac{2}{u}\frac{d}{du}\mathcal{D}_q(u) + \mathcal{D}_q(u) = -\frac{24 f_v}{u^2}\int_0^u K\,(u-u')\,\frac{d\mathcal{D}_q\,(u')}{du'}du' \tag{6.6.60}$$

where

$$f_v \equiv \frac{\bar{\rho}_v}{\bar{\rho}_v + \bar{\rho}_\gamma} = \frac{3\cdot(7/8)\cdot(4/11)^{4/3}}{1+3\cdot(7/8)\cdot(4/11)^{4/3}} = 0.4052. \tag{6.6.61}$$

Late in the radiation-dominated era, the factor $1/u^2$ makes the right-hand side negligible, so $\mathcal{D}_q(u)$ approaches a solution of the homogeneous equation. In general, one might expect a linear combination of $\sin u/u$ and $\cos u/u$, but in fact no $\cos u/u$ term appears in the solution. [14] A numerical solution of Eq. (6.6.60) shows that if $\mathcal{D}_q(u)$ takes the value $\mathcal{D}_q^o$ for $u \ll 1$ then for $u \gg 1$ (but still in the radiation-dominated era)

$$\mathcal{D}_q(u) \to \mathcal{D}_q^o \alpha \frac{\sin(u)}{u}, \tag{6.6.62}$$

where $\alpha = 0.8026$. This then serves instead of Eq. (6.6.47) as an initial condition for the subsequent evolution of the gravitational wave amplitude, so that later, during the matter-dominated era, the effect of damping on the amplitude (neglecting δ) is simply to multiply the result given in Eq. (6.6.54) by a factor α. [15]

The damping of gravitational waves of longer wavelength is considerably more complicated. Because of a shift in the phase of the oscillation, the effect of anisotropic inertia on the amplitude of gravitational waves at the time of decoupling is a sensitive function of wave number, and for some wave numbers can even be an enhancement instead of a damping, but typically the amplitude is damped for $\kappa = O(1)$ by roughly 5%.

Because the damping effect is small anyway for $\kappa \ll 1$, it will be an adequate approximation for all wavelengths to take the gravitational wave amplitude in the matter dominated era to be given by multiplying the result (6.6.54) with a factor $\alpha(\kappa)$:

$$\mathcal{D}_q = \frac{3\mathcal{D}_q^o \mathcal{U}(\kappa)\alpha(\kappa)}{4\kappa^2}\left(\frac{-\cos(2\kappa\sqrt{y}+\Xi(\kappa))}{y} + \frac{\sin(2\kappa\sqrt{y}+\Xi(\kappa))}{2\kappa y^{3/2}}\right) \tag{6.6.63}$$

with $\alpha(\kappa)$ some function of κ that rises smoothly from $\alpha(\kappa) = 0.8026$ for $\kappa \gg 1$ to $\alpha(\kappa) \simeq 1$ for $\kappa \ll 1$. For instance, we can take $\alpha(\kappa) \simeq (1 + .8026\kappa)/(1+\kappa)$. All observable effects of cosmological gravitational waves will be reduced by this factor $\alpha(\kappa)$.

[4713] The lower bound on this integral should in principle be taken as the time of neutrino decoupling, at a temperature of about 10^{10} K, but it is a good approximation to take it at a time $t = 0$, defined by writing the scale factor during the radiation-dominated era as $a \propto t^{1/2}$.

[14] D. Dicus and W. Repko, Phys. Rev. 72, 088302(2005) [astro-ph/0509096] have shown analytically that no $\cos u/u$ term appears in this solution, and have given an analytic solution as a rapidly convergent sum of spherical Bessel functions. The absence of a $\cos u/u$ term was shown very generally on causality grounds by S. Bashinsky, astro-ph/0505502.

[4715] The effect of possible neutrino masses and/or chemical potentials is considered by K. Ichiki, M. Yamaguchi, and J. Yokayama, Pub. Astron. Soc. Pacific 119, 30 (2007) [hep-ph/0611121].

10.7 Anisotropies in the Microwave Sky

We will now return to the theory of anisotropies in the cosmic microwave background, introduced in Section 2.6. In Section 7.1 we derive general formulas for the observed temperature fluctuation. Then in Sections 7.2 and 7.3 we combine these results with the analysis of cosmic evolution in Chapter 6 and introduce a series of approximations that simplify the evaluation of the multipole coefficients for scalar and tensor modes, respectively. Section 7.4 deals with the polarization of the microwave background.

10.7.1 7.1 General formulas for the temperature fluctuation

In this section we will derive general formulas for the contribution of scalar and tensor modes to the observed temperature fluctuation. We begin by carrying the solution of the Boltzmann equations in synchronous gauge given in Section 6.1 forward to the present. When implemented with computer programs such as CMBfast or CAMB, the approach provides numerical results of great accuracy, but neither the derivation of the formulas for temperature fluctuations nor the computer programs are physically very transparent. We will then show how these results can be simplified by making the approximation of a sharp transition from thermal equilibrium to complete transparency at a moment t_L of last scattering. This ignores the scattering of photons by matter that becomes reionized at a redshift of order 10. For temperature correlations, the corrections due to reionization are very simple for multipole orders ℓ greater than about 20, and will be included in Section 7.2. In Section 7.2 we will also partly make up for the approximation of a sharp drop from opacity to transparency by including effects of viscous damping during this transition, and by including effects of averaging over t_L. (At the end of this section we will show how the same simplified results can also be obtained in a more general gauge by following photon trajectories from t_L to the present, with no need to use the Boltzmann equation.) The results of the sudden-decoupling approximation obtained here will be used together with other approximations in Section 7.2 to derive analytic expressions for the temperature multipole coefficients, that require computer calculations only to carry out a single numerical integration.

Because the proper energy density of black body radiation is proportional to the fourth power of the temperature, the fractional perturbation in temperature of radiation coming from a direction $\hat{n}$ is one-fourth the
fractional perturbation in the proper energy density of photons travelling in direction $\hat{p} = -\hat{n}$ at our position $\mathbf{x} = 0$ and time $t = t_0$. Eqs. (6.1.13) or (6.6.8) thus give

$$\frac{\Delta T(\hat{n})}{T_0} = \frac{1}{4} J_{ii}\left(\mathbf{x} = 0, -\hat{n}, t_0\right), \tag{7.1.1}$$

where $J_{ij}(\mathbf{x}, \hat{p}, t)$ is the fractional density matrix, defined by Eqs. (6.1.13) for scalar modes and (6.6.8) for tensor modes. Using the decompositions (6.1.18), (6.1.20) for scalar modes or (6.6.9), (6.6.13) for tensor modes, the scalar and tensor contributions to the temperature fluctuation are

$$\left(\frac{\Delta T(\hat{n})}{T_0}\right)^{(S)} = \frac{1}{4}\int d^3q \alpha(\mathbf{q}) \Delta_T^{(S)}\left(q, -\hat{q}\cdot\hat{n}, t_0\right), \tag{7.1.2}$$

and

$$\left(\frac{\Delta T(\hat{n})}{T_0}\right)^{(T)} = \frac{1}{4}\sum_{\lambda=\pm 2}\int d^3q \beta(\mathbf{q},\lambda)\hat{n}_k\hat{n}_l e_{kl}(\hat{q},\lambda)\Delta_T^{(T)}\left(q, -\hat{q}\cdot\hat{n}, t_0\right), \tag{7.1.3}$$

where $\alpha(\mathbf{q})$ and $\beta(\mathbf{q},\lambda)$ are the stochastic parameters for whatever modes are assumed to dominate the scalar and tensor perturbations, respectively; $e_{kl}(\hat{q},\lambda)$ is the polarization

tensor defined in Section 6.6 for a gravitational wave with wave number $\mathbf{q}$ and helicity λ; and $\Delta_T^{(S)}(q,\mu,t)$ and $\Delta_T^{(T)}(q,\mu,t)$ are amplitudes appearing in the decompositions (6.1.20) and (6.6.13) of the scalar and tensor contributions to the fractional density matrix J_{ij}.

In order to display the angular dependence of the temperature shift, we use the line-of-sight integrals (6.1.37) and (6.1.38) for scalar modes and (6.6.25) and (6.6.26) for tensor modes, which give, for the scalar modes

$$\begin{aligned}\left(\frac{\Delta T(\hat{n})}{T_0}\right)^{(S)} =& \frac{1}{4}\int d^3q\alpha(\mathbf{q}) \\ & \times \int_{t_1}^{t_0} dt \exp\left[i\mathbf{q}\cdot\hat{n}\int_t^{t_0}\frac{dt'}{a\left(t'\right)} - \int_t^{t_0} dt'\omega_c\left(t'\right)\right] \\ & \times \Big[-2\dot{A}_q(t) + 2(\mathbf{q}\cdot\hat{n})^2\dot{B}_q(t) + 3\omega_c(t)\Phi(q,t) \\ & - 4i(\mathbf{q}\cdot\hat{n})\omega_c(t)\delta u_{Bq}(t)/a(t) \\ & + \frac{3}{4}\left(1-(\hat{q}\cdot\hat{n})^2\right)\omega_c(t)\Pi(q,t)\Big] \end{aligned} \tag{7.1.4}$$

and for the tensor modes

$$\begin{aligned}\left(\frac{\Delta T(\hat{n})}{T_0}\right)^{(T)} =& \frac{1}{4}\sum_{\lambda=\pm 2}\int d^3q\beta(\mathbf{q},\lambda)\hat{n}_k\hat{n}_l e_{kl}(\hat{q},\lambda) \\ & \times \int_{t_1}^{t_0} dt \exp\left[i\mathbf{q}\cdot\hat{n}\int_t^{t_0}\frac{dt'}{a\left(t'\right)} - \int_t^{t_0} dt'\omega_c\left(t'\right)\right] \\ & \times \Big[-2\dot{\mathcal{D}}_q(t) + \omega_c(t)\Psi(q,t)\Big] \end{aligned} \tag{7.1.5}$$

As a reminder: t_1 is any time sufficiently early before recombination so that any photon present then would have been scattered many times before the present; $\omega_c(t)$ is the photon collision rate at time t; $A_q(t)$ and $B_q(t)$ are the scalar fields in the perturbation to the metric in synchronous gauge, defined in Section 5.2; $\Phi(q,t)$ and $\Pi(q,t)$ are the scalar source functions, defined by Eq. (6.1.21); $\delta u_{Bq}(t)$ is the scalar velocity potential of the baryonic plasma; $\mathcal{D}_q(t)$ is the gravitational wave amplitude, defined in Section 5.2; and $\Psi(q,t)$ is the tensor source function, defined by Eqs. (6.6.11) and (6.6.12).

Eq. (7.1.4) does not give the expression for the scalar temperature fluctuation in its most convenient form. When we pass to the limit of a sharp moment of last scattering, its terms will not correspond to the decomposition of the fluctuation into Sachs-Wolfe, Doppler, intrinsic, and integrated Sachs-Wolfe terms, discussed in Section 2.6. The individual terms in Eq. (7.1.4) are not even invariant under the limited class of gauge transformations (5.3.39)-(5.3.42) that preserve the conditions for synchronous gauge. We will therefore rewrite Eq. (7.1.4) by using the identity

$$\begin{aligned}&\exp\left(i\mathbf{q}\cdot\hat{n}\int_t^{t_0}\frac{dt'}{a\left(t'\right)}\right)(\mathbf{q}\cdot\hat{n})^2\dot{B}_q(t) = \\ &-\exp\left(i\mathbf{q}\cdot\hat{n}\int_t^{t_0}\frac{dt'}{a\left(t'\right)}\right)\frac{d}{dt}\left(a^2(t)\ddot{B}_q(t) + a(t)\dot{a}(t)\dot{B}(t)\right) \\ &+\frac{d}{dt}\left\{\exp\left(i\mathbf{q}\cdot\hat{n}\int_t^{t_0}\frac{dt'}{a\left(t'\right)}\right)\right. \\ &\left.\times\left[a^2(t)\ddot{B}_q(t) + a(t)\dot{a}(t)\dot{B}_q(t) + ia(t)\mathbf{q}\cdot\hat{n}\dot{B}_q(t)\right]\right\} \end{aligned} \tag{7.1.6}$$

Using this in Eq. (7.1.4) and integrating by parts, yields our final formula for the scalar temperature fluctuation

$$\left(\frac{\Delta T(\hat{n})}{T_0}\right)^{(S)} = \left(\frac{\Delta T(\hat{n})}{T_0}\right)^{(S)}_{\rm early} + \left(\frac{\Delta T(\hat{n})}{T_0}\right)^{(S)}_{\rm ISW}, \tag{7.1.7}$$

where the first, "early," term receives contributions only from times with an appreciable free electron density, before recombination and after reionization,

$$\begin{aligned}\left(\frac{\Delta T(\hat{n})}{T_0}\right)^{(S)}_{\rm early} &= \int d^3q\alpha(\mathbf{q}) \\ &\times \int_{t_1}^{t_0} dt \exp\left[i\mathbf{q}\cdot\hat{n}\int_t^{t_0}\frac{dt'}{a\,(t')} - \int_t^{t_0} dt'\omega_c\,(t')\right] \\ &\times \omega_c(t)\left[\frac{3}{4}\Phi(q,t) + \frac{3}{16}\left(1-(\hat{q}\cdot\hat{n})^2\right)\Pi(q,t)\right. \\ &- \frac{1}{2}a^2(t)\ddot{B}_q(t) - \frac{1}{2}a(t)\dot{a}(t)\dot{B}_q(t) \\ &\left.-i(\mathbf{q}\cdot\hat{n})\left(\delta u_{Bq}(t)/a(t) + a(t)\dot{B}_q(t)/2\right)\right]\end{aligned} \tag{7.1.8}$$

and the second, "integrated Sachs-Wolfe term," receives contributions from the whole period from t_1 to the present,

$$\begin{aligned}\left(\frac{\Delta T(\hat{n})}{T_0}\right)^{(S)}_{\rm ISW} &= -\frac{1}{2}\int d^3q\alpha(\mathbf{q})\int_{t_1}^{t_0} dt \\ &\times \exp\left[i\mathbf{q}\cdot\hat{n}\int_t^{t_0}\frac{dt'}{a\,(t')} - \int_t^{t_0} dt'\omega_c\,(t')\right] \\ &\times \frac{d}{dt}\left[A_q(t) + a^2(t)\ddot{B}_q(t) + a(t)\dot{a}(t)\dot{B}_q(t)\right]\end{aligned} \tag{7.1.9}$$

(Here we are ignoring a surface term in the integration by parts at $t = t_0$, because it is linear in $\hat{n}$, and therefore just contributes to the $\ell = 0$ and $\ell = 1$ partial waves. This "late" term is calculated by a different method later in this section, and given in Eq.(7.1.38).)

The integrated Sachs-Wolfe term (7.1.9) represents the effect of changing gravitational fields during the passage of the microwave photons from last scattering to the present. As already noted in Section 2.6, the ISW term would vanish if the gravitational field from last scattering to the present (or more precisely, at times t when the transparency $\exp\left(-\int_t^{t_0}\omega_c\,(t')\,dt'\right)$ was non-negligible) arose solely from the density of cold matter. (This feature provides another reason, apart from gauge invariance, for the rearrangement of terms that led to Eq. (7.1.7).) Under this approximation, Eqs. (6.5.15) and (6.5.16) show that $\delta_{Dq} \propto t^{2/3}$ and $\psi_q \propto t^{-1/3}$. Eq. (5.3.38) gives $q^2A_q = 8\pi a^2\bar{\rho}_D\delta_{Dq} - 2Ha^2\psi_q$, both terms of which are constant in the matter-dominated era, so $\dot{A}_q$ does not contribute to Eq. (7.1.9). With $\dot{A}_q$ negligible, $\psi_q = -q^2\dot{B}_q$, so $\dot{B}_q \propto t^{-1/3}$, and therefore both terms $a^2\ddot{B}_q$ and $a\dot{a}\dot{B}_q$ in Eq. (7.1.9) are time-independent, and therefore do not contribute to the ISW effect either. For this reason the ISW term (7.1.9) is relatively small. The early-time ISW effect depends sensitively on the ratio of matter to radiation at last scattering, which is an aid in using observations of temperature fluctuations to measure $\Omega_M h^2$. The late-time ISW effect receives its main contribution from times near the present, when the dark matter density falls below the vacuum energy density. Anisotropies subtend larger angles when viewed nearby than from great distances, so the late-time ISW term in the temperature

anisotropy contributes to the temperature multipole coefficients C_ℓ only for relatively small ℓ, say $\ell < 20$. It is the integrated Sachs-Wolfe effect that causes the predicted values of $\ell(\ell+1)C_\ell$ to rise as ℓ drops from around 20 to smaller values. This effect has been difficult to see in present data on the cosmic microwave background temperature fluctuations. [1]

It is the "early" term (7.1.8) that makes the largest contribution to the scalar temperature fluctuation for $\ell > 20$. The terms in Eq. (7.1.8) proportional to $\mathbf{q} \cdot \hat{n}$ represent the Doppler effect, [2] while the other terms give the combined effect of gravitational time dilation and intrinsic temperature fluctuations.

Let's pause to check invariance under the limited set of gauge transformations that preserve the conditions for synchronous gauge. These transformations induce the changes $\Delta \dot{B}_q = -2\tau/a^2$ and $\Delta \delta u_{Bq} = \tau$, where τ is an arbitrary function of $\mathbf{x}$, so the Doppler term proportional to $i\mathbf{q} \cdot \hat{n}$ in

Eq. (7.1.8) is separately gauge invariant. Also, ${}^3\Delta\Phi = -(4/3)\dot{\bar{T}}\tau/\bar{T} = (4/3)\dot{a}\tau/a$ and $\Delta\Pi = 0$, so the other terms in Eq. (7.1.8) are also gauge invariant; and $\Delta A = -2\dot{a}\tau/a$, so also Eq. (7.1.9) is invariant under this limited set of gauge transformations.

Our results so far are exact, aside from the use of first-order perturbation theory and the assumption that photons interact only through purely elastic Thomson scattering. (In Eqs. (7.1.2) and (7.1.3) we are assuming that the scalar and tensor fluctuations are each dominated by a single mode, but it would be trivial to introduce a sum over modes in these expressions.) These results are equivalent to those given by Seljak and Zaldarriaga, [4] which are used in computer programs like CMBfast and CAMB. At the cost of only a small loss of numerical accuracy, they can be greatly simplified if we now make the approximation of a sharp transition from thermal equilibrium to perfect transparency at a definite time t_L.

The integrand of the "early" contribution (7.1.8) to the scalar temperature perturbation contains a factor $P(t)$ equal to the probability distribution of the last photon scattering

$$P(t) = \omega_c(t) \exp\left(- \int_t^{t_0} dt' \omega_c\left(t'\right) \right) \tag{7.1.10}$$

Assuming that $\omega_c(t)$ drops sharply at time t_L from a value much greater than the expansion rate to zero, the function $P(t)$ is non-zero only in a narrow interval around t_L. But $P(t)$ is a normalized probability distribution:

[471] The ISW effect can be detected through its correlation with inhomogeneities in the distribution of matter (which are also linear in $\alpha(\mathbf{q})$), as suggested by R. G. Crittenden and N. Turok, Phys. Rev. Lett. 76, 575 (1996) [astro-ph/9510072]. This effect has been seen in the correlation of data from the WMAP satellite (discussed in the next section) with various surveys, by P. Fosalba and E. Gaztañaga, Mon. Not. Roy. Astron. Soc. 350, L37 (2004) [astro-ph/0305468]; P. Fosalba, E. Gaztañaga, and F. Castander, Astrophys. J. 597, L89 (2003) [astro-ph/0307249]; N. Ashfordi, Y-S. Loh, and M. A. Strauss, astro-ph/0308260; S. P. Boughn and R. G. Crittenden, New Astron. Rev. 49, 75 (2005) [astroph/0404470]; N. Padmanabhan, C. M. Hirata, U. Seljak, D. Schlegel, J. Brinkmann and D. P. Schneider, Phys. Rev. D 72, 043525 (2005) [astro-ph/0410360]. More recent cross-correlations of anisotropies seen by the three-year Wilkinson Microwave Anisotropy Probe (discussed in the next section) with galaxies in the Sloan Digital Sky Survey and with radio galaxy data from the NRAO VLA Sky Survey give $0.7 \leq \Omega_V \leq 0.82$ and $0.3 \leq \Omega_V \leq 0.8$ at a 95% confidence level, respectively; see A. Cabré et al., astro-ph/0603690; D. Pietrobon, A. Balbi, and D. Marinucci, Phys. Rev. D 74, 043524 (2006) [astroph/0606475]. Unfortunately, cosmic variance limits the accuracy with which this approach can be used to study the time dependence of the vacuum energy.

[2] In a gauge in which cold dark matter remains at rest, the effect of gravitational perturbations on the cold dark matter particles is canceled by the definition of surfaces of equal time, so in this gauge the velocity perturbations of the baryonic plasma arise solely from pressure forces, not from gravitational forces. This is why the gravitational term proportional to $\dot{B}_q$ appears accompanying the plasma velocity potential in Eq. (7.1.8); it represents the velocity that in a different gauge would be given to the photonbaryon plasma by gravitational forces.

$$\int_{t_1}^{t_0} P(t)dt = 1 \tag{7.1.11}$$

so the integral over t in Eq. (7.1.8) can be evaluated by dropping the factor $P(t)$ and setting $t = t_L$:

$$\left(\frac{\Delta T(\hat{n})}{T_0}\right)^{(S)}_{\text{early}} \simeq \int d^3q\alpha(\mathbf{q}) \exp\left[i\mathbf{q}\cdot\hat{n}\int_{t_L}^{t_0}\frac{dt'}{a\,(t')}\right]$$
$$\times\left[\frac{3}{4}\Phi\,(q,t_L) + \frac{3}{16}(1-(\hat{q}\cdot\hat{n}))^2\Pi\,(q,t_L)\right.$$

7.1 General formulas for the temperature fluctuation

$$-\frac{1}{2}a^2(t)\ddot{B}_q\,(t_L) - \frac{1}{2}a\,(t_L)\,\dot{a}\,(t_L)\,\dot{B}_q\,(t_L)$$
$$\left.-i(\mathbf{q}\cdot\hat{n})\left(\delta u_q\,(t_L)\,/a\,(t_L) + a\,(t_L)\,\dot{B}_q\,(t_L)\,/2\right)\right]. \tag{7.1.12}$$

Under the same assumption of a rapid drop in $\omega_c(t)$ from a large value for $t < t_L$ to a negligible value for $t > t_L$, the factor $\exp\left(-\int_t^{t_0} dt'\omega_c\,(t')\right)$ in Eq. (7.1.9) rises sharply from zero for $t < t_L$ to unity for $t > t_L$, so Eq (7.1.9) becomes

$$\left(\frac{\Delta T(\hat{n})}{T_0}\right)^{(S)}_{\text{ISW}} \simeq -\frac{1}{2}\int d^3q\alpha(\mathbf{q})\int_{t_L}^{t_0} dt\exp\left[i\mathbf{q}\cdot\hat{n}\int_t^{t_0}\frac{dt'}{a\,(t')}\right]$$
$$\times\frac{d}{dt}\left[A_q(t) + a^2(t)\ddot{B}_q(t) + a(t)\dot{a}(t)\dot{B}_q(t)\right] \tag{7.1.13}$$

The same approximation applied to the tensor contribution (7.1.5) gives

$$\left(\frac{\Delta T(\hat{n})}{T_0}\right)^{(T)} = \frac{1}{4}\sum_{\lambda\simeq\pm2}\int d^3q\beta(\mathbf{q},\lambda)\hat{n}_k\hat{n}_l e_{kl}(\hat{q},\lambda)$$
$$\times\left[-2\int_{t_L}^{t_0} dt\dot{\mathcal{D}}_q(t)\exp\left(i\mathbf{q}\cdot\hat{n}\int_t^{t_0}\frac{dt'}{a\,(t')}\right)\right.$$
$$\left.+\Psi\,(q,t_L)\exp\left(i\mathbf{q}\cdot\hat{n}\int_{t_L}^{t_0}\frac{dt'}{a\,(t')}\right)\right] \tag{7.1.14}$$

Further, in local thermal equilibrium photons are unpolarized and have an isotropic momentum distribution, so $\Delta^{(S)}_{P,\ell}$, $\Delta^{(T)}_{P,\ell}$, and $\Delta^{(T)}_{T,\ell}$ vanish for all ℓ, and $\Delta^{(S)}_{T,\ell}$ vanishes for all ℓ except $\ell = 0$, so that the formulas (6.1.29), (6.1.30), and (6.6.21) for the source functions give $\Pi = \Psi = 0$

[473] This follows from the rule (5.3.42), that the change $\Delta\delta s$ in the perturbation δs to a scalar s with unperturbed value $\bar{s}$ is $\Delta s = -\dot{\bar{s}}\tau$. In using this rule, we note that the unperturbed photon distribution is isotropic and unpolarized, so that, of the terms in Eqs. (6.1.29) and (6.1.30) for Φ and Π, the only one that has an unperturbed value is $\Delta^{(S)}_{T,0}/3$. For the purposes of assessing the gauge transformation property of this term, we must define the unperturbed value of $\Delta^{(S)}_{T,0}$ so that its perturbation is the fractional photon density fluctuation $4\delta T/\bar{T}$, and so its unperturbed value is $4\ln\bar{T}$.

[4] U. Seljak and M. Zaldarriaga, Astrophys. J. 459, 437 (1996) [astro-ph/9603033].

and $\Phi = \Delta_{T,0}^{(S)}/3 = 4\delta T/3\bar{T}$ in local thermal equilibrium. [5] The assumption of a sharp drop from a very high to a very low photon collision frequency then

allows Eqs. (7.1.12) and (7.1.14) to be further simplified to

$$\left(\frac{\Delta T(\hat{n})}{T_0}\right)_{\text{early}}^{(S)} \simeq \int d^3q\alpha(\mathbf{q}) \exp\left[i\mathbf{q}\cdot\hat{n}\int_{t_L}^{t_0}\frac{dt'}{a\left(t'\right)}\right] \times \left[F(q) + i(\hat{q}\cdot\hat{n})G(q)\right] \tag{7.1.15}$$

where $F(q)$ and $G(q)$ are the form factors

$$F(q) = \frac{\delta T_q\left(t_L\right)}{\bar{T}\left(t_L\right)} - \frac{1}{2}a^2(t)\ddot{B}_q\left(t_L\right) - \frac{1}{2}a\left(t_L\right)\dot{a}\left(t_L\right)\dot{B}_q\left(t_L\right) \tag{7.1.16}$$

$$G(q) = -q\left(\delta u_{\gamma q}\left(t_L\right)/a\left(t_L\right) + a\left(t_L\right)\dot{B}_q\left(t_L\right)/2\right) \tag{7.1.17}$$

and

$$\left(\frac{\Delta T(\hat{n})}{T_0}\right)^{(T)} = -\frac{1}{2}\sum_{\lambda\simeq\pm 2}\int d^3q\beta(\mathbf{q},\lambda)\hat{n}_k\hat{n}_l e_{kl}(\hat{q},\lambda) \times \int_{t_L}^{t_0} dt\dot{\mathcal{D}}_q(t)\exp\left(i\mathbf{q}\cdot\hat{n}\int_t^{t_0}\frac{dt'}{a\left(t'\right)}\right) \tag{7.1.18}$$

We will now make the same approximation, of a sudden drop in opacity at t_L, and use it to derive formulas for the scalar and tensor temperature fluctuations by following photon trajectories, without needing to use the Boltzmann equation formalism of Section 6.1. Because it is easy, we will carry out this derivation in a more general class of gauges. After this derivation, we will check that it yields the results (7.1.15) and (7.1.13) for scalar fluctuations in synchronous gauge, and (7.1.18) for tensor fluctuations. The reader who is comfortable with the derivation of these formulas using the Boltzmann equation in synchronous gauge may want to skip the rest of this section.

We start with some general remarks, that apply equally to scalar and tensor perturbations, and that for scalar perturbations apply in any gauge in which $g_{i0} = 0$, including both Newtonian and synchronous gauge. Continuing to neglect a possible unperturbed spatial curvature, we write the perturbed metric in any gauge with $g_{i0} = 0$ in the form

$$g_{00} = -1 - E(\mathbf{x},t), \quad g_{i0} = 0, \quad g_{ij} = a^2(t)\delta_{ij} + h_{ij}(\mathbf{x},t). \tag{7.1.19}$$

A light ray travelling toward the center of the Robertson-Walker coordinate system from the direction $\hat{n}$ will have a co-moving radial coordinate r related to t by

$$0 = g_{\mu\nu}dx^\mu dx^\nu = -(1+E(r\hat{n},t))dt^2 + \left(a^2(t) + h_{rr}(r\hat{n},t)\right)dr^2 \tag{7.1.20}$$

[475] This can be seen formally by taking the limit $\omega_c \to \infty$ in the Boltzmann equations (6.1.27), (6.1.28), (6.6.18), and (6.6.19). This gives

$$\Delta_{P,\ell}^{(S)} = \frac{1}{2}\Pi\left(\delta_{\ell 0} + \delta_{\ell 2}\right), \quad \Delta_{T,\ell}^{(S)} = \left(3\Phi + \frac{1}{2}\Pi\right)\delta_{\ell 0} + \frac{1}{2}\Pi\delta_{\ell 2}$$
$$\Delta_{T,\ell}^{(T)} = \delta_{\ell 0}\Psi, \quad \Delta_{P,\ell}^{(T)} = -\delta_{\ell 0}\Psi$$

The formulas (6.1.29), (6.1.30), and (6.6.21) for the source functions then read $\Phi = \Phi - \Pi/12, \Pi = 3\Pi/5$, and $\Psi = 7\Psi/10$, which require that $\Pi = \Psi = 0$ and $\Phi = \Delta_{T,0}^{(S)}/3$.

or in other words

$$\frac{dr}{dt} = -\left(\frac{a^2 + h_{rr}}{1+E}\right)^{-1/2} \simeq -\frac{1}{a} + \frac{h_{rr}}{2a^3} - \frac{E}{2a}. \tag{7.1.21}$$

(To first order in perturbations we don't have to worry about a deflection of the ray from the radial direction, because $\bar{g}_{r\theta} = \bar{g}_{r\phi} = 0$, so that any deflection would have to be of first order, and its effect in the term $h_{ij}dx^i dx^j$ would therefore be of second order.)

We now make the approximation that the transition of cosmic matter from opacity to transparency occurred suddenly at a time t_L of last scattering, at a red shift $1 + z_L \simeq 1090$. With this approximation, the relevant first-order solution of Eq. (7.1.21) is

$$r(t) = s(t) + \int_{t_L}^{t} \frac{dt'}{a\,(t')} N\left(s\,(t')\,\hat{n}, t'\right) \tag{7.1.22}$$

where

$$N(\mathbf{x}, t) \equiv \frac{1}{2}\left[\frac{h_{rr}(\mathbf{x}, t)}{a^2(t)} - E(\mathbf{x}, t)\right], \tag{7.1.23}$$

and $s(t)$ is the zeroth order solution for the radial coordinate which has the value r_L at $t = t_L$:

$$s(t) = r_L - \int_{t_L}^{t} \frac{dt'}{a\,(t')} = \int_{t}^{t_0} \frac{dt'}{a\,(t')} \tag{7.1.24}$$

In particular, if the ray reaches $r = 0$ at a time t_0, then Eq. (7.1.22) gives

$$0 = s\,(t_0) + \int_{t_L}^{t_0} \frac{dt}{a(t)} N(s(t)\hat{n}, t) = r_L + \int_{t_L}^{t_0} \frac{dt}{a(t)} (N(s(t)\hat{n}, t) - 1). \tag{7.1.25}$$

A time interval δt_L between the departure of successive light wave crests at the time t_L of last scattering produces a time interval δt_0 between arrival of successive crests at t_0 given by the variation of Eq. (7.1.25):

$$\begin{aligned} 0 = \quad & \frac{\delta t_L}{a\,(t_L)}\Big[1 - N\,(r_L\hat{n}, t_L) + \int_{t_L}^{t_0} \frac{dt}{a(t)} \left(\frac{\partial N(r\hat{n}, t)}{\partial r}\right)_{r=s(t)}\Big] \\ & + \delta t_L \delta u_\gamma^r\,(r_L\hat{n}, t_L) + \frac{\delta t_0}{a\,(t_0)}\left[-1 + N\,(0, t_0)\right]. \end{aligned} \tag{7.1.26}$$

(The term on the right-hand side involving the radial velocity δu_γ^r of the photon gas or photon-electron-nucleon fluid arises from the change with
time of the radial coordinate r_L of the light source in Eq. (7.1.25). We don't consider the variation of the argument $s(t)\hat{n}$ in N, because to zeroth order r_L and t_L are related in such a way that $s(t) = 0$ for all r_L, so its variation with r_L is of first order, and the effect of this variation on N would be of second order.) The total rate of change of the quantity $N(s(t)\hat{n}, t)$ in Eq. (7.1.25) is

$$\frac{d}{dt} N(s(t)\hat{n}, t) = \left(\frac{\partial}{\partial t} N(r\hat{n}, t)\right)_{r=s(t)} - \frac{1}{a(t)} \left(\frac{\partial N(r\hat{n}, t)}{\partial r}\right)_{r=s(t)}$$

so Eq. (7.1.26) may be written

$$0 = \frac{\delta t_L}{a(t_L)}\left[1 - N(0,t_0) + \int_{t_L}^{t_0} dt \left\{\frac{\partial}{\partial t} N(r\hat{n},t)\right\}_{r=s(t)}\right] + \delta t_L \delta u_\gamma^r(r_L\hat{n},t_L) + \frac{\delta t_0}{a(t_0)}\left[-1 + N(0,t_0)\right] \tag{7.1.27}$$

This gives the ratio of the coordinate time interval between crests when emitted and received, but what we want is the ratio of the proper time intervals

$$\delta\tau_L = \sqrt{1 + E(r_L,t_L)}\delta t_L, \quad \delta\tau_0 = \sqrt{1 + E(0,t_0)}\delta t_0 \tag{7.1.28}$$

which to first order gives the ratio of the received and emitted frequencies as

$$\frac{v_0}{v_L} = \frac{\delta\tau_L}{\delta\tau_0} = \frac{a(t_L)}{a(t_0)}\left[1 + \frac{1}{2}\left(E(r_L\hat{n},t_L) - E(0,t_0)\right) - \int_{t_L}^{t_0}\left\{\frac{\partial}{\partial t} N(r\hat{n},t)\right\}_{r=s(t)} dt - a(t_L)\,\delta u_\gamma^r(r_L\hat{n},t_L)\right] \tag{7.1.29}$$

The temperature observed at the present time t_0 coming from direction $\hat{n}$ is then

$$T(\hat{n}) = (v_0/v_L)\left(\bar{T}(t_L) + \delta T(r_L\hat{n},t_L)\right)$$

where now we have added a term δT to take account of the intrinsic temperature fluctuation at time t_L. Likewise, in the absence of perturbations the temperature observed in all directions would be

$$T_0 = \left(a(t_L)/a(t_0)\right)\bar{T}(t_L)$$

so the fractional shift in the radiation temperature observed coming from direction $\hat{n}$ from its unperturbed value is [6]

$$\frac{\Delta T(\hat{n})}{T_0} \equiv \frac{T(\hat{n}) - T_0}{T_0} = \frac{v_0}{a(t_L)\,v_L/a(t_0)} - 1 + \frac{\delta T(r_L\hat{n},t_L)}{\bar{T}(t_L)} = \frac{1}{2}\left(E(r_L\hat{n},t_L) - E(0,t_0)\right) - \int_{t_L}^{t_0} dt\left\{\frac{\partial}{\partial t} N(r\hat{n},t)\right\}_{r=s(t)} - a(t_L)\,\delta u_\gamma^r(r_L\hat{n},t_L) + \frac{\delta T(r_L\hat{n},t_L)}{\bar{T}(t_L)} \tag{7.1.30}$$

Because tensor and scalar perturbations are uncorrelated, we will treat their contribution to C_ℓ independently.

For scalar perturbations in any gauge with $h_{i0} = 0$, the metric perturbation is given by Eqs. (5.1.31)-(5.1.33) as

$$h_{00} = -E, \quad h_{ij} = a^2\left[A\delta_{ij} + \frac{\partial^2 B}{\partial x^i \partial x^j}\right] \tag{7.1.31}$$

Also for scalar perturbations the radial photon fluid velocity is given in terms of a velocity potential δu_γ as

$$\delta u_\gamma^r = \bar{g}^{r\mu}\frac{\partial \delta u_\gamma}{\partial x^\mu} = \frac{1}{a^2}\frac{\partial \delta u_\gamma}{\partial r} \tag{7.1.32}$$

Thus Eq. (7.1.30) gives the scalar contribution to the temperature fluctuation

$$\begin{aligned}\left(\frac{\Delta T(\hat{n})}{T_0}\right)^S &= \frac{1}{2}\left(E\left(r_L\hat{n}, t_L\right) - E\left(0, t_0\right)\right) - \int_{t_L}^{t_0} dt \left\{\frac{\partial}{\partial t}N(r\hat{n}, t)\right\}_{r=s(t)} \\ &- \frac{1}{a\left(t_L\right)}\left(\frac{\partial \delta u_\gamma\left(r\hat{n}, t_L\right)}{\partial r}\right)_{r=r_L} + \frac{\delta T\left(r_L\hat{n}, t_L\right)}{\bar{T}\left(t_L\right)}\end{aligned} \tag{7.1.33}$$

where now

$$N = \frac{1}{2}\left[A + \frac{\partial^2 B}{\partial r^2} - E\right]. \tag{7.1.34}$$

Eq. (7.1.33) is not in the form that is most useful for our purposes. The total temperature fluctuation given by Eq. (7.1.33) is invariant with respect to the limited class of gauge transformations that leave $g_{i0} = 0$, but this is not true of its individual terms, including even the integral of $(\partial N/\partial t)_{r=s(t)}$.

It will be much more convenient to rewrite Eq. (7.1.33) in a way that leaves the integral term separately gauge invariant.

For this purpose, we make use of an identity corresponding to Eq. (7.1.6):

$$\begin{aligned}&\left\{\frac{\partial^2 \dot{B}(r\hat{n}, t)}{\partial r^2}\right\}_{r=s(t)} \\ &= -\frac{d}{dt}\left[\left\{a^2(t)\ddot{B}(r\hat{n}, t) + a(t)\dot{a}(t)\dot{B}(r\hat{n}, t) + a(t)\frac{\partial \dot{B}(r\hat{n}, t)}{\partial r}\right\}_{r=s(t)}\right] \\ &\quad + \left\{\frac{\partial}{\partial t}\left(a^2(t)\ddot{B}(r\hat{n}, t) + a(t)\dot{a}(t)\dot{B}(r\hat{n}, t)\right)\right\}_{r=s(t)}.\end{aligned}$$

Together with Eq. (7.1.34), this gives the integrand in Eq. (7.1.33) as

$$\begin{aligned}\left\{\frac{\partial}{\partial t}N(r\hat{n}, t)\right\}_{r=s(t)} &= -\frac{1}{2}\frac{d}{dt}\left[\left\{a^2(t)\ddot{B}(r\hat{n}, t) + a(t)\dot{a}(t)\dot{B}(r\hat{n}, t) + a(t)\frac{\partial \dot{B}(r\hat{n}, t)}{\partial r}\right\}_{r=s(t)}\right] \\ &\quad + \frac{1}{2}\left\{\frac{\partial}{\partial t}\left(a^2(t)\ddot{B}(r\hat{n}, t) + a(t)\dot{a}(t)\dot{B}(r\hat{n}, t)\right.\right. \\ &\quad \left.\left. + A(r\hat{n}, t) - E(r\hat{n}, t)\right)\right\}_{r=s(t)}\end{aligned}$$

The scalar fractional temperature fluctuation (7.1.33) may therefore be written

$$\left(\frac{\Delta T(\hat{n})}{T_0}\right)^S = \left(\frac{\Delta T(\hat{n})}{T_0}\right)^S_{\text{early}} + \left(\frac{\Delta T(\hat{n})}{T_0}\right)^S_{\text{late}} + \left(\frac{\Delta T(\hat{n})}{T_0}\right)^S_{\text{ISW}}, \tag{7.1.36}$$

where

[476] This result is essentially that first found by R. K. Sachs and A. M. Wolfe, Astrophys. J. 147, 73 (1967).
