Suppose Alice encodes message M as $\rho_M = \rho_1^M \otimes \cdots \otimes \rho_n^M$ with corresponding outputs denoted using σ instead of ρ, and Bob decodes using a POVM $\{E_M\}$ which, without loss of generality, we may suppose contains an element E_M for each message, and possibly an extra element E_0 to ensure that the completeness relation $\sum_M E_M = I$ is satisfied. This gives an average error probability:

$$p_{\text{av}} = \frac{\sum_M \left(1 - \text{tr}\left(\sigma_M E_M\right)\right)}{2^{nR}} \tag{12.96}$$

From Exercise 12.3 we know that $R \leq \log(d)$, where d is the dimension of the input to the channel, and thus the POVM $\{E_M\}$ contains at most $d^n + 1$ elements. By Fano's inequality it follows that

$$H\left(p_{\text{av}}\right) + p_{\text{av}} \log\left(d^n\right) \geq H(M \mid Y) \tag{12.97}$$

where Y is the measurement outcome from Bob's decoding, and thus

$$np_{\text{av}} \log d \geq H(M) - H(M:Y) - H\left(p_{\text{av}}\right) = nR - H(M:Y) - H\left(p_{\text{av}}\right) \tag{12.98}$$

Applying first the Holevo bound and then the subadditivity of entropy gives

$$H(M:Y) \leq S(\bar{\sigma}) - \sum_M \frac{S\left(\sigma_1^M \otimes \cdots \otimes \sigma_n^M\right)}{2^{nR}} \tag{12.99}$$

$$\leq \sum_{j=1}^{n} \left(S\left(\bar{\sigma}^j\right) - \sum_M \frac{S\left(\sigma_j^M\right)}{2^{nR}} \right) \tag{12.100}$$

where $\bar{\sigma}^j \equiv \sum_M \sigma_j^M / 2^{nR}$. Each of the n terms in the sum on the right hand side is no greater than $\chi(\mathcal{E})$ as defined in (12.71), so

$$H(M:Y) \leq n\chi(\mathcal{E}) \tag{12.101}$$

Substituting into (12.98) gives $np_{\text{av}} \log d \geq n(R - \chi(\mathcal{E})) - H\left(p_{\text{av}}\right)$, and thus in the limit as n becomes large we obtain

$$p_{\text{av}} \geq \frac{(R - \chi(\mathcal{E}))}{\log(d)} \tag{12.102}$$

which is bounded away from zero when $R > \chi(\mathcal{E})$, which completes the proof that $\chi(\mathcal{E})$ is an upper bound on the product state capacity.

Box 12.5: HSW theorem: the error estimate

The most technically complicated part of the proof of the HSW theorem is obtaining an estimate for p_{av}. We outline the details of how this is done here; missing steps should be regarded as exercises to be filled in. Suppose we define $\left|\tilde{E}_K^M\right\rangle \equiv P \left|E_K^M\right\rangle$. Then

$$E_M = \left(\sum_{M'} \sum_{K \in T_{M'}} \left| \tilde{E}_K^{M'} \right\rangle \left\langle \tilde{E}_K^{M'} \right| \right)^{-1/2} \sum_{K \in T_M} \left| \tilde{E}_K^{M} \right\rangle \left\langle \tilde{E}_K^{M} \right| \left(\sum_{M'} \sum_{K \in T_{M'}} \left| \tilde{E}_K^{M'} \right\rangle \left\langle \tilde{E}_K^{M'} \right| \right)^{-1/2} \tag{12.84}$$

Defining

$$\alpha_{(M,K),(M',K')} \equiv \left\langle \tilde{E}_K^M \right| \left(\sum_{M''} \sum_{K'' \in T_{M''}} \left| \tilde{E}_{K''}^{M''} \right\rangle \left\langle \tilde{E}_{K''}^{M''} \right| \right)^{-1/2} \left| \tilde{E}_{K'}^{M'} \right\rangle, \tag{12.85}$$

the average probability of error can be written

$$p_{\text{av}} = \frac{1}{2^{nR}} \sum_M \left[1 - \sum_K \sum_{K' \in T_M} \lambda_K^M \left| \alpha_{(M,K),(M,K')} \right|^2 \right]. \tag{12.86}$$

Using $\sum_K \lambda_K^M = 1$ and omitting non-positive terms, we see that

$$p_{\text{av}} \leq \frac{1}{2^{nR}} \sum_M \left[\sum_{K \in T_M} \lambda_K^M \left(1 - \alpha^2_{(M,K),(M,K)} \right) + \sum_{K \notin T_M} \lambda_K^M \right]. \tag{12.87}$$

Define a matrix Γ with entries $\gamma_{(M,K),(M',K')} \equiv \left\langle \tilde{E}_K^M \mid \tilde{E}_{K'}^{M'} \right\rangle$, where the indices are such that $K \in T_M$ and $K' \in T_{M'}$. It is convenient to work in the matrix space defined by these index conventions, to let E denote the unit matrix with respect to these indices, and to use sp (for *spur*) to denote the trace operations with respect to these indices. A calculation shows that $\Gamma^{1/2} = \left[\alpha_{(M,K),(M',K')} \right]$ and it follows that $\alpha^2_{(M,K),(M,K)} \leq \gamma_{(M,K),(M,K)} \leq 1$. Using the observation that $1 - x^2 = (1+x)(1-x) \leq 2(1-x)$ when $0 \leq x \leq 1$ together with (12.87) gives

$$p_{\text{av}} \leq \frac{1}{2^{nR}} \sum_M \left[2 \sum_{K \in T_M} \lambda_K^M \left(1 - \alpha_{(M,K),(M,K)} \right) + \sum_{K \notin T_M} \lambda_K^M \right]. \tag{12.88}$$

Define the diagonal matrix $\Lambda \equiv \text{diag}\left(\lambda_K^M \right)$ and observe that

$$\begin{aligned} 2\left(E - \Gamma^{1/2} \right) &= \left(E - \Gamma^{1/2} \right)^2 + (E - \Gamma) && (12.89) \\ &= (E - \Gamma)^2 \left(E + \Gamma^{1/2} \right)^{-2} + (E - \Gamma) && (12.90) \\ &\leq (E - \Gamma)^2 + (E - \Gamma) && (12.91) \end{aligned}$$

Thus,

$$\begin{aligned} 2 \sum_M \sum_{K \in T_M} \lambda_K^M \left(1 - \alpha_{(M,K),(M,K)} \right) &= 2 \,\text{sp}\left(\Lambda \left(E - \Gamma^{1/2} \right) \right) && (12.92) \\ &\leq \text{sp}\left(\Lambda (E - \Gamma)^2 \right) + \text{sp}(\Lambda (E - \Gamma)). && (12.93) \end{aligned}$$

(continued)

Box 12.5 (continued):

Calculating the spurs on the right hand side, substituting into (12.88), and doing some simple algebra gives

$$p_{\text{av}} \leq \frac{1}{2^{nR}} \sum_M \left[\sum_K \lambda_K^M \left(2 - 2\gamma_{(M,K),(M,K)} + \sum_{K' \neq K} \left|\gamma_{(M,K),(M,K')}\right|^2 + \sum_{M' \neq M, K' \in T_{M'}} \left|\gamma_{(M,K),(M',K')}\right|^2 \right) + \sum_{K \notin T_M} \lambda_K^M \right] \tag{12.94}$$

Substituting definitions and doing some simple algebra gives

$$p_{\text{av}} \leq \frac{1}{2^{nR}} \sum_M \left[2\,\text{tr}\left(\sigma_M(I-P)\right) + \text{tr}\left(\sigma_M(I-P)P_M(I-P)\right) + \sum_{M' \neq M} \text{tr}\left(P\sigma_M P P_{M'}\right) + \text{tr}\left(\sigma_M\left(I - P_M\right)\right) \right] \tag{12.95}$$

The second term is less than $\text{tr}\left(\sigma_M(I-P)\right)$, which gives the desired error estimate, (12.79).

Examples

An interesting implication of the HSW theorem is that any quantum channel $\mathcal{E}$ whatsoever can be used to transmit classical information, provided the channel is not simply a constant. For if the channel is not a constant then there exist pure states $|\psi\rangle$ and $|\varphi\rangle$ such that $\mathcal{E}(|\psi\rangle\langle\psi|) \neq \mathcal{E}(|\varphi\rangle\langle\varphi|)$. Substituting the ensemble made up of these two states with equal probabilities $1/2$ into the expression (12.71) for the product state capacity we see that

$$C^{(1)}(\mathcal{E}) \geq S\left(\frac{\mathcal{E}(|\psi\rangle\langle\psi|) + \mathcal{E}(|\varphi\rangle\langle\varphi|)}{2}\right) - \frac{1}{2}\mathcal{E}(|\psi\rangle\langle\psi|) - \frac{1}{2}\mathcal{E}(|\varphi\rangle\langle\varphi|) > 0 \tag{12.103}$$

where the second inequality follows from the strict concavity of the entropy established in Section 11.3.5.

Let's look at a simple example where the product state capacity can be calculated exactly, the case of the depolarizing channel with parameter p. Let $\{p_j, |\psi_j\rangle\}$ be an ensemble of quantum states. Then we have

$$\mathcal{E}\left(|\psi_j\rangle\langle\psi_j|\right) = p\,|\psi_j\rangle\langle\psi_j| + (1-p)\frac{I}{2} \tag{12.104}$$

a quantum state which has eigenvalues $(1+p)/2$ and $(1-p)/2$ from which it follows that

$$S\left(\mathcal{E}\left(|\psi_j\rangle\langle\psi_j|\right)\right) = H\left(\frac{1+p}{2}\right) \tag{12.105}$$

which does not depend on $|\psi_j\rangle$ at all. Thus the maximum in (12.71) is achieved by maximizing the entropy $S\left(\sum_j \mathcal{E}\left(|\psi_j\rangle\langle\psi_j|\right)\right)$, which may be done by simply choosing the $|\psi_j\rangle$ to form an orthonormal basis (say $|0\rangle$ and $|1\rangle$) for the state space of a single qubit, giving a value for the entropy of one bit, and a product state capacity of

$$C(\mathcal{E}) = 1 - H\left(\frac{1+p}{2}\right) \tag{12.106}$$

for the depolarizing channel with parameter p.

Exercise 12.12: Adapt the proof of the HSW theorem to find a proof of Shannon's noisy channel coding theorem, simplifying the proof wherever possible.

9.5.10 12.4 Quantum information over noisy quantum channels

How much quantum information can be reliably transmitted over a noisy quantum channel? This problem of determining the quantum channel capacity is less well understood than is the problem of determining the capacity for sending classical information through a noisy quantum channel. We now present some of the information-theoretic tools that have been developed to understand the capacity of a quantum channel for quantum information, most notably quantum information-theoretic analogues to the Fano inequality (Box 12.2 on page 536), data processing inequality (Section 11.2.4 on page 509) and Singleton bound (Exercise 10.21 on page 449).

As for quantum data compression, our point of view in studying these problems is to regard a quantum source as being a quantum system in a mixed state ρ which is entangled with another quantum system, and the measure of reliability for transmission of quantum information by the quantum operation $\mathcal{E}$ is the entanglement fidelity $F(\rho, \mathcal{E})$. It is useful to introduce, as in Chapter 9, labels Q for the system ρ lives in and R, the reference system, which initially purifies Q. In this picture the entanglement fidelity is a measure of how well the entanglement between Q and R was preserved by the action of $\mathcal{E}$ on system Q.

9.5.11 12.4.1 Entropy exchange and the quantum Fano inequality

How much noise does a quantum operation cause when applied to the state ρ of a quantum system Q ? One measure of this is the extent to which the state of RQ, initially pure, becomes mixed as a result of the quantum operation. We define the entropy exchange of the operation $\mathcal{E}$ upon input of ρ by

$$S(\rho, \mathcal{E}) \equiv S\left(R', Q'\right) \tag{12.107}$$

Suppose that the action of the quantum operation $\mathcal{E}$ is mocked up by introducing an environment E, initially in a pure state, and then causing a unitary interaction between Q and E, as described in Chapter 8. Then the state of RQE after the interaction is a pure state, whence $S\left(R', Q'\right) = S\left(E'\right)$, so the entropy exchange may also be identified with the amount of entropy introduced by the operation $\mathcal{E}$ into an initially pure environment E.

Note that the entropy exchange does not depend upon the way in which the initial state of Q, ρ, is purified into RQ. The reason is because any two purifications of Q into RQ are related by a unitary operation on the system R, as shown in Exercise 2.81 on page 111. This unitary operation on R obviously commutes with the action of the
quantum operation on Q, and thus the final states of $R'Q'$ induced by the two different purifications are related by a unitary transformation on R, and thus give rise to the same value for the entropy exchange. Furthermore, it follows from these results that $S\left(E'\right)$ does not depend upon the particular environmental model for $\mathcal{E}$ which is used, provided the model starts with E in a pure state.

A useful explicit formula for the entropy exchange can be given based upon the operator-sum representation for quantum operations. Suppose a trace-preserving quantum operation $\mathcal{E}$ has operation elements $\{E_i\}$. Then, as shown in Section 8.2.3, a unitary model for this quantum operation is given by defining a unitary operator U on QE such that

$$U|\psi\rangle|0\rangle = \sum_i E_i|\psi\rangle|i\rangle \tag{12.108}$$

where $|0\rangle$ is the initial state of the environment, and $|i\rangle$ is an orthonormal basis for the environment. Note that the state of E' after application of $\mathcal{E}$ is:

$$\rho^{E'} = \sum_{i,j} \mathrm{tr}\left(E_i \rho E_j^\dagger\right) |i\rangle\langle j| \tag{12.109}$$

That is, $\mathrm{tr}\left(E_i \rho E_j^\dagger\right)$ are the matrix elements of E' in the $|i\rangle$ basis. Given a quantum operation with operation elements $\{E_i\}$ it is therefore natural to define a matrix W (the w-matrix) with matrix elements $W_{ij} \equiv \mathrm{tr}\left(E_i \rho E_j^\dagger\right)$, that is, W is the matrix of E' in an appropriate basis. This representation for $\rho^{E'}$ gives rise to a formula for the entropy exchange which is useful in making explicit calculations,

$$S(\rho, \mathcal{E}) = S(W) \equiv -\mathrm{tr}(W \log W) \tag{12.110}$$

Given a quantum operation $\mathcal{E}$ and a state ρ, it is always possible to choose operation elements $\{F_j\}$ for $\mathcal{E}$ such that W is diagonal; we say W is in canonical form. To see that such a set of operation elements exists, recall from Chapter 8 that a quantum operation may have many different sets of operation elements. In particular, two sets of operators $\{E_i\}$ and $\{F_j\}$ are operation elements for the same quantum operation if and only if $F_j = \sum_j u_{ji} E_i$, where u is a unitary matrix of complex numbers, and it may be necessary to append 0 operators to the sets E_i or F_j so that the matrix u is a square matrix. Let W be the w-matrix associated to a particular choice of operation elements $\{E_i\}$ for $\mathcal{E}$.W is a matrix representation of the environmental density operator, and thus is a positive matrix which may be diagonalized by a unitary matrix $v, D = vWv^\dagger$, where D is a diagonal matrix with non-negative entries. Define operators F_j by the equation $F_j \equiv \sum_i v_{ji} E_i$, so the F_j are also a set of operation elements for $\mathcal{E}$, giving rise to a new w-matrix $\widetilde{W}$ with matrix elements

$$\widetilde{W}_{kl} = \mathrm{tr}\left(F_k \rho F_l^\dagger\right) = \sum_{mn} v_{km} v_{ln}^* W_{mn} = D_{kl} \tag{12.111}$$

Thus, the w -matrix is diagonal if calculated with respect to the operation elements $\{F_j\}$. Any such set of operation elements $\{F_j\}$ for $\mathcal{E}$ for which the corresponding w-matrix is diagonal is said to be a canonical representation for $\mathcal{E}$ with respect to the input ρ. We see later that canonical representations turn out to have a special significance for quantum error-correction.

Many properties of the entropy exchange follow easily from properties of the entropy discussed in Chapter 11. For example, working in a canonical representation for a trace-preserving quantum operation $\mathcal{E}$ on a d-dimensional space, we see immediately that $S(I/d, \mathcal{E}) = 0$ if and only if $\mathcal{E}$ is a unitary quantum operation. Therefore, $S(I/d, \mathcal{E})$ can be thought of as quantifying the extent to which incoherent quantum noise occurs on the system as a whole. A second example is that the matrix W is linear in ρ, and by the concavity of the entropy it follows that $S(\rho, \mathcal{E})$ is concave in ρ. Since the system RQ can always be chosen to be at most d^2-dimensional, where d is the dimension of Q, it follows that the entropy exchange is bounded above by $2 \log d$.

Exercise 12.13: Show that the entropy exchange is concave in the quantum operation $\mathcal{E}$.

Intuitively, if the quantum source Q is subject to noise which results in the entanglement RQ becoming mixed, then the fidelity of the final state $R'Q'$ with the initial state RQ cannot be perfect. Moreover, the greater the noise the worse the fidelity. In Section 12.1.1 an analogous situation arose in the study of classical channels, where the uncertainty $H(X \mid Y)$ about the input of a channel, X, given the output, Y, was related to the probability of being able to recover the state of X from Y by the Fano inequality. There is a very useful quantum analogue of this result, relating the entropy exchange $S(\rho, \mathcal{E})$ to the entanglement fidelity $F(\rho, \mathcal{E})$.

Theorem 12.9: (Quantum Fano inequality) Let ρ be a quantum state and $\mathcal{E}$ a trace-preserving quantum operation. Then

$$S(\rho, \mathcal{E}) \leq H(F(\rho, \mathcal{E})) + (1 - F(\rho, \mathcal{E})) \log \left(d^2 - 1\right) \tag{12.112}$$

where $H(\cdot)$ is the binary Shannon entropy.
Inspection of the quantum Fano inequality reveals an attractive intuitive meaning: if the entropy exchange for a process is large, then the entanglement fidelity for the process must necessarily be small, indicating that the entanglement between R and Q has not been well preserved. Moreover, we note that in the quantum Fano inequality the entropy exchange $S(\rho, \mathcal{E})$ plays a role analogous to the role played by the conditional entropy $H(X \mid Y)$ in classical information theory.

Proof

To prove the quantum Fano inequality, let $|i\rangle$ be an orthonormal basis for the system RQ chosen so the first state in the set $|1\rangle = |RQ\rangle$. If we form the quantities $p_i \equiv \langle i|\rho^{R'Q'}|i\rangle$, then from the results of Section 11.3.3 it follows that

$$S\left(R', Q'\right) \leq H\left(p_1, \ldots, p_{d^2}\right) \tag{12.113}$$

where $H\left(p_i\right)$ is the Shannon information of the set $\{p_i\}$. Elementary algebra shows that

$$H\left(p_1, \ldots, p_{d^2}\right) = H\left(p_1\right) + \left(1 - p_1\right) H\left(\frac{p_2}{1 - p_1}, \ldots, \frac{p_{d^2}}{1 - p_1}\right) \tag{12.114}$$

Combining this with the observation that $H\left(\frac{p_2}{1-p_1}, \ldots, \frac{p_{d^2}}{1-p_1}\right) \leq \log\left(d^2 - 1\right)$ and $p_1 = F(\rho, \mathcal{E})$ by definition gives,

$$S(\rho, \mathcal{E}) \leq H(F(\rho, \mathcal{E})) + (1 - F(\rho, \mathcal{E})) \log \left(d^2 - 1\right) \tag{12.115}$$

which is the quantum Fano inequality.

9.5.12 12.4.2 The quantum data processing inequality

In Section 11.2.4 we discussed the classical data processing inequality. Recall that the data processing inequality states that for a Markov process $X \rightarrow Y \rightarrow Z$,

$$H(X) \geq H(X : Y) \geq H(X : Z) \tag{12.116}$$

with equality in the first stage if and only if the random variable X can be recovered from Y with probability one. Thus the data processing inequality provides informationtheoretic necessary and sufficient conditions for error-correction to be possible.

There is a quantum analogue to the data processing inequality applicable to a two stage quantum process described by quantum operations $\mathcal{E}_1$ and $\mathcal{E}_2$,

$$\rho \stackrel{\mathcal{E}_1}{\rightarrow} \rho' \stackrel{\mathcal{E}_2}{\rightarrow} \rho''. \tag{12.117}$$

We define the quantum coherent information by

$$I(\rho, \mathcal{E}) \equiv S(\mathcal{E}(\rho)) - S(\rho, \mathcal{E}) \tag{12.118}$$

This quantity, coherent information, is suspected (but not known) to play a role in quantum information theory analogous to the role played by the mutual information $H(X : Y)$ in classical

information theory. One reason for this belief is that the coherent information satisfies a quantum data processing inequality analogous to the classical data processing inequality.

Theorem 12.10: (Quantum data processing inequality) Let ρ be a quantum state and $\mathcal{E}_1$ and $\mathcal{E}_2$ trace-preserving quantum operations. Then

$$S(\rho) \geq I\left(\rho, \mathcal{E}_1\right) \geq I\left(\rho, \mathcal{E}_2 \circ \mathcal{E}_1\right) \tag{12.119}$$

with equality in the first inequality if and only if it is possible to perfectly reverse the operation $\mathcal{E}_1$, in the sense that there exists a trace-preserving reversal operation $\mathcal{R}$ such that $F(\rho, \mathcal{R} \circ \mathcal{E}) = 1$.

Comparison with the classical data processing inequality shows that the coherent information plays a role in the quantum data processing inequality identical to the role played by the mutual information in the classical data processing inequality. Of course, such a heuristic argument cannot be regarded as any sort of a rigorous justification for the view that the coherent information is the correct quantum analogue of the classical mutual information. In order to obtain such a justification, the coherent information ought to be related to the quantum channel capacity in a similar way to the relation between classical mutual information and classical channel capacity, and such a relationship has not yet been established. (See the end of chapter 'History and further reading' for some partial progress.)

How is the notion of perfect reversibility defined in the quantum data processing inequality connected with more familiar notions such as that arising in the context of quantum error-correction? By definition, we say a trace-preserving quantum operation $\mathcal{E}$ is perfectly reversible upon input of ρ if there exists a trace-preserving quantum operation $\mathcal{R}$ such that

$$F(\rho, \mathcal{R} \circ \mathcal{E}) = 1 \tag{12.120}$$

But from item (4) on page 423, it follows that a quantum operation is perfectly reversible if and only if for every state $|\psi\rangle$ in the support of ρ,

$$(\mathcal{R} \circ \mathcal{E})(|\psi\rangle\langle\psi|) = |\psi\rangle\langle\psi|. \tag{12.121}$$

This observation connects the notion of perfect reversibility to quantum error-correcting codes. Recall that a quantum error-correcting code is a subspace of some larger Hilbert space spanned by logical codewords. To be resilient against the noise induced by a quantum operation $\mathcal{E}$ it is necessary that the quantum operation $\mathcal{E}$ be reversible by a trace-preserving reversal operation $\mathcal{R}$ in the sense that for all states $|\psi\rangle$ in the code, $(\mathcal{R} \circ \mathcal{E})(|\psi\rangle\langle\psi|) = |\psi\rangle\langle\psi|$. This condition is equivalent to the criterion of perfect reversibility in the statement of the data processing inequality, that $F(\rho, \mathcal{R} \circ \mathcal{E}) = 1$, for some ρ whose support is the code space.

Proof

The quantum data processing inequality is proved using a four system construction: R and Q appear in their familiar roles, while E_1 and E_2 are systems initially in pure states, chosen such that a unitary interaction between Q and E_1 generates the dynamics $\mathcal{E}_1$, and a unitary interaction between Q and E_2 generates the dynamics $\mathcal{E}_2$. The proof of the first stage of the quantum data processing inequality is to apply the subadditivity inequality $S\left(R', E_1'\right) \leq S\left(R'\right) + S\left(E_1'\right)$ to obtain

$$I(\rho, \mathcal{E}_1) = S(\mathcal{E}_1(\rho)) - S(\rho, \mathcal{E}_1) \tag{12.122}$$
$$= S(Q') - S(E_1') \tag{12.123}$$
$$= S(R', E_1') - S(E_1') \tag{12.124}$$
$$\leq S(R') + S(E_1') - S(E_1') = S(R') \tag{12.125}$$
$$= S(R) = S(Q) = S(\rho) \tag{12.126}$$

The proof of the second part of the data processing inequality is to apply the strong subadditivity inequality,

$$S(R'', E_1'', E_2'') + S(E_1'') \leq S(R'', E_1'') + S(E_1'', E_2'') \tag{12.127}$$

From the purity of the total state of $R''Q''E_1''E_2''$ it follows that

$$S(R'', E_1'', E_2'') = S(Q'') \tag{12.128}$$

Neither of the systems R or E_1 are involved in the second stage of the dynamics in which Q and E_2 interact unitarily. Thus, their state does not change during this stage: $\rho^{R''E_1''} = \rho^{R'E_1'}$. But from the purity of RQE_1 after the first stage of the dynamics,

$$S(R'', E_1'') = S(R', E_1') = S(Q') \tag{12.129}$$

The remaining two terms in the strong subadditivity inequality (12.127) are now recognized as entropy exchanges,

$$S(E_1'') = S(E_1') = S(\rho, \mathcal{E}_1); \quad S(E_1'', E_2'') = S(\rho, \mathcal{E}_2 \circ \mathcal{E}_1) \tag{12.130}$$

Making these substitutions into (12.127) yields

$$S(Q'') + S(\rho, \mathcal{E}_1) \leq S(Q') + S(\rho, \mathcal{E}_2 \circ \mathcal{E}_1) \tag{12.131}$$

which can be rewritten as the second stage of the data processing inequality, $I(\rho, \mathcal{E}_1) \geq I(\rho, \mathcal{E}_2 \circ \mathcal{E}_1)$.

To complete the proof we need to show that $\mathcal{E}$ is perfectly reversible upon input of ρ if and only if the first inequality in the quantum data processing inequality is satisfied with equality,

$$S(\rho) = I(\rho, \mathcal{E}) = S(\rho') - S(\rho, \mathcal{E}) \tag{12.132}$$

To prove the necessity of this condition for reversal, suppose that $\mathcal{E}$ is perfectly reversible upon input of ρ, with reversal operation $\mathcal{R}$. From the second stage of the quantum data processing inequality it follows that

$$S(\rho') - S(\rho, \mathcal{E}) \geq S(\rho'') - S(\rho, \mathcal{R} \circ \mathcal{E}) \tag{12.133}$$

From the reversibility requirement it follows that $\rho'' = \rho$. Furthermore, from the quantum Fano inequality (12.112) and the perfect reversibility requirement $F(\rho, \mathcal{R} \circ \mathcal{E}) = 1$ it follows that $S(\rho, \mathcal{R} \circ \mathcal{E}) = 0$. Thus the second stage of the quantum data processing inequality when applied to $\rho \to \mathcal{E}(\rho) \to (\mathcal{R} \circ \mathcal{E})(\rho)$ may be rewritten

$$S(\rho') - S(\rho, \mathcal{E}) \geq S(\rho) \tag{12.134}$$

Combining this with the first part of the quantum data processing inequality, $S(\rho) \geq S(\rho') - S(\rho, \mathcal{E})$, we deduce that

$$S(\rho') = S(\rho) - S(\rho, \mathcal{E}) \tag{12.135}$$

for any $\mathcal{E}$ which is perfectly reversible upon input of ρ.
Next, we give a constructive proof that satisfaction of the condition

$$S(\rho) = S(\rho') - S(\rho, \mathcal{E}) \tag{12.136}$$

implies that the quantum operation $\mathcal{E}$ is reversible upon input of ρ. Noting that $S(\rho) = S(Q) = S(R) = S(R'), S(\rho') = S(Q') = S(R', E')$ and $S(\rho, \mathcal{E}) = S(E')$, we see that $S(R') + S(E') = S(R', E')$, which we saw in Section 11.3.4 is equivalent to the condition that $\rho^{R'E'} = \rho^{R'} \otimes \rho^{E'}$. Suppose the initial state of Q is $\rho = \sum_i p_i |i\rangle\langle i|$, and that we purify this state into RQ as $|RQ\rangle = \sum_i \sqrt{p_i}|i\rangle|i\rangle$, where the first system is R and the second system is Q. Note that $\rho^{R'} = \rho^R = \sum_i p_i |i\rangle\langle i|$. Furthermore, suppose that $\rho^{E'} = \sum_j q_j |j\rangle\langle j|$ for some orthonormal set $|j\rangle$, so that

$$\rho^{R'E'} = \sum_{ij} p_i q_j |i\rangle\langle i| \otimes |j\rangle\langle j|. \tag{12.137}$$

This has eigenvectors $|i\rangle|j\rangle$ so by the Schmidt decomposition we may write the total state of $R'Q'E'$ after the quantum operation $\mathcal{E}$ has been applied as

$$|R'Q'E'\rangle = \sum_{ij} \sqrt{p_i q_j}|i\rangle|i,j\rangle|j\rangle \tag{12.138}$$

where $|i,j\rangle$ is some orthonormal set of states for system Q. Define projectors P_j by $P_j \equiv \sum_i |i,j\rangle\langle i,j|$. The idea of the restoration operation is to first perform a measurement described by the projectors P_j, which reveals the state $|j\rangle$ of the environment, and then do a unitary rotation U_j conditional on j which restores the state $|i,j\rangle$ to $|i\rangle : U_j|i,j\rangle \equiv |i\rangle$.

That is, j is the measurement syndrome, and U_j the corresponding recovery operation. The complete recovery operation may be written

$$\mathcal{R}(\sigma) \equiv \sum_j U_j P_j \sigma P_j U_j^\dagger \tag{12.139}$$

The projectors P_j are orthogonal, by the orthogonality of the states $|i,j\rangle$, but may not be complete. If this is the case, then to ensure that the quantum operation $\mathcal{R}$ is tracepreserving, it is necessary to add an extra projector $\tilde{P} \equiv I - \sum_j P_j$ to the set of projectors to make the operation trace-preserving.

The final state of the system RQE after the reversal operation is given by

$$\begin{aligned}
&\sum_j U_j P_j \left|R'Q'E'\right\rangle \left\langle R'Q'E'\right| P_j U_j^\dagger \\
&\qquad = \sum_j \sum_{i_1 i_2} \sqrt{p_{i_1} p_{i_2}} q_j \left|i_1\right\rangle \left\langle i_2\right| \otimes \left(U_j \left|i_1, j\right\rangle \left\langle i_2, j\right| U_j^\dagger\right) \otimes |j\rangle\langle j| \qquad (12.140) \\
&\qquad = \sum_{i_1, i_2} \sqrt{p_{i_1} p_{i_2}} \left|i_1\right\rangle \left\langle i_2\right| \otimes \left|i_1\right\rangle \left\langle i_2\right| \otimes \rho^{E'}, \qquad (12.141)
\end{aligned}$$

from which we see that $\rho^{R''Q''} = \rho^{RQ}$, and thus $F(\rho, \mathcal{R} \circ \mathcal{E}) = 1$, that is, the operation $\mathcal{E}$ is perfectly reversible upon input of the state ρ, as we desired to show.

This completes the proof of the information-theoretic reversibility conditions for tracepreserving quantum operations. Intuition about the result may be obtained by imagining that Q

is a memory element in a quantum computer, R is the remainder of the quantum computer, and E is an environment whose interaction with Q causes noise. The information-theoretic reversibility condition is most elegantly understood as the statement that the state of the environment E' after the noise has occurred should not be correlated with the state of the remainder of the quantum computer, R'. To state it in more anthropomorphic terms, error-correction is possible precisely when the environment does not learn anything about the remainder of the quantum computer through interacting with Q !

Even more concretely, suppose Q is an n qubit system and C is an $[n, k]$ quantum error-correcting code living in the system Q with orthonormal codewords $|x\rangle$ and projector P onto the codespace. Consider the density matrix $P/2^k$, which may be purified to a pure state of RQ :

$$\frac{1}{\sqrt{2^k}} \sum_x |x\rangle |x\rangle. \tag{12.142}$$

Imagine this code is able to correct arbitrary errors on some subset Q_1 of the qubits. Then, in particular, it must be able to correct that error which simply swaps those qubits out into the environment and replaces them with some standard state. The informationtheoretic reversibility condition that $\rho^{R'E'} = \rho^{R'} \otimes \rho^{E'}$ can in this case be rephrased as the condition $\rho^{RQ_1} = \rho^R \otimes \rho^{Q_1}$. Thus the reference system R and subsystem Q_1 on which errors can be corrected must initially be uncorrelated if correction is to be possible!

Exercise 12.14: Show that the condition $\rho^{RQ_1} = \rho^R \otimes \rho^{Q_1}$ is also sufficient to be able to correct errors on the subsystem Q_1.

The reasoning used in the proof of the quantum data processing inequality can be adapted to prove a wide variety of other inequalities. For example, suppose we have a quantum system Q in a state ρ that is subjected to the quantum operation $\mathcal{E}$. The first stage of the data processing inequality follows by applying the subadditivity inequality for entropy to the systems $R'E'$. What if instead we applied the subadditivity inequality to the systems $Q'E'$, obtaining

$$S(\rho) = S(R) = S\left(R'\right) = S\left(Q', E'\right) \leq S\left(Q'\right) + S\left(E'\right) = S(\mathcal{E}(\rho)) + S(\rho, \mathcal{E}) \tag{12.143}$$

That is,

$$\Delta S + S(\rho, \mathcal{E}) \geq 0 \tag{12.144}$$

where $\Delta S \equiv S(\mathcal{E}(\rho)) - S(\rho)$ is the change in entropy caused by the process $\mathcal{E}$. Loosely speaking, this inequality says that the change in entropy of the system plus the change in entropy of the environment must be non-negative, an eminently reasonable statement in accord with the second law of thermodynamics, and one which will aid us in Section 12.4.4 in our thermodynamic analysis of quantum error-correction!

Exercise 12.15: Apply all possible combinations of the subadditivity and strong subadditivity inequalities to deduce other inequalities for the two stage quantum process $\rho \to \rho' = \mathcal{E}_1(\rho) \to \rho'' = \left(\mathcal{E}_2 \circ \mathcal{E}_1\right)(\rho)$, expressing the results whenever possible in terms of entropy exchanges and the entropies $S(\rho), S\left(\rho'\right), S\left(\rho''\right)$. When it is not possible to express a quantity appearing in such an inequality in these terms, give a prescription for calculating the quantity using only a knowledge of ρ and operation elements $\{E_j\}$ for $\mathcal{E}_1$ and $\{F_k\}$ for $\mathcal{E}_2$.

9.5.13 12.4.3 Quantum Singleton bound

The information-theoretic approach to quantum error-correction can be used to prove a beautiful bound on the ability of quantum error-correcting codes to correct errors, the quantum

Singleton bound. Recall that an $[n, k, d]$ code uses n qubits to encode k qubits, and is able to correct located errors (Exercise 10.45) on up to $d-1$ of the qubits. The quantum Singleton bound states that we must have $n-k \geq 2(d-1)$. Contrast this with the classical Singleton bound, Exercise 10.21 on page 449, which states that for an $[n, k, d]$ classical code we must have $n-k \geq d-1$. Because a quantum code to correct errors on up to t qubits must have distance at least $2t+1$ it follows that $n-k \geq 4t$. Thus, for example, a code to encode $k=1$ qubits and capable of correcting errors on $t=1$ of the qubits must satisfy $n-1 \geq 4$, that is, n must be at least 5 , so the five qubit code described in Chapter 10 is the smallest possible code for this task.

The proof of the quantum Singleton bound is an extension of the information-theoretic techniques we have been using to analyze quantum error-correction. Suppose the code is a 2^k-dimensional subspace associated with the system Q, with orthonormal basis denoted by $|x\rangle$. Introduce a 2^k-dimensional reference system R also with 2^k orthonormal basis vectors denoted $|x\rangle$, and consider the entangled state of RQ,

$$|RQ\rangle = \frac{1}{\sqrt{2^k}} \sum_x |x\rangle |x\rangle \tag{12.145}$$

We divide the n qubits of Q up into three disjoint blocks, the first and second, Q_1 and Q_2, consisting of $d-1$ qubits each, and the third Q_3 consisting of the remaining $n-2(d-1)$ qubits. Because the code has distance d any set of $d-1$ located errors may be corrected, and thus it is possible to correct errors on either Q_1 or Q_2. It follows that R and Q_1 must be uncorrelated, as are R and Q_2. By this observation, the overall purity of the state of $RQ_1Q_2Q_3$, and the subadditivity of entropy we have:

$$S(R) + S(Q_1) = S(R, Q_1) = S(Q_2, Q_3) \leq S(Q_2) + S(Q_3) \tag{12.146}$$

$$S(R) + S(Q_2) = S(R, Q_2) = S(Q_1, Q_3) \leq S(Q_1) + S(Q_3). \tag{12.147}$$

Adding these two inequalities gives

$$2S(R) + S(Q_1) + S(Q_2) \leq S(Q_1) + S(Q_2) + 2S(Q_3) \tag{12.148}$$

Canceling terms and substituting $S(R) = k$ gives $k \leq S(Q_3)$. But Q_3 is $n-2(d-1)$ qubits in size, so $S(Q_3) \leq n-2(d-1)$, giving $k \leq n-2(d-1)$, whence $2(d-1) \leq n-k$, the quantum Singleton bound.

As an example of the quantum Singleton bound in action, consider the depolarizing channel $\mathcal{E}(\rho) = p\rho + (1-p)/3(X\rho X + Y\rho Y + Z\rho Z)$. Suppose the depolarizing channel acts independently on a large number n of qubits. If $p < 3/4$ then more than one quarter of those qubits will suffer errors, so any code capable of recovering from the errors must have $t > n/4$. But the quantum Singleton bound implies that $n-k \geq 4t > n$, and thus k must be negative, that is, it is not possible to encode any qubits at all in this case. Thus, when $p < 3/4$, the quantum Singleton bound implies that the capacity of the depolarizing channel for quantum information is zero!

9.5.14 12.4.4 Quantum error-correction, refrigeration and Maxwell's demon

Quantum error-correction may be thought of as a type of refrigeration process, capable of keeping a quantum system at a constant entropy, despite the influence of noise processes which tend to change the entropy of the system. Indeed, quantum error-correction may even appear rather puzzling from this point of view, as it appears to allow a reduction in entropy of the quantum system in apparent violation of the second law of thermodynamics! To understand

why there is no violation of the second law we do an analysis of quantum error-correction similar to that used to analyze Maxwell's demon in Box 3.5 on page 162. Quantum error-correction is essentially a special type of Maxwell's demon we can imagine a 'demon' performing syndrome measurements on the quantum system, and then correcting errors according to the result of the syndrome measurement. Just as in the analysis of the classical Maxwell's demon, the storage of the syndrome in the demon's memory carries with it a thermodynamic cost, in accordance with Landauer's principle. In particular, because any memory is finite, the demon must eventually begin erasing information from its memory, in order to have space for new measurement results. Landauer's principle states that erasing one bit of information from the memory increases the total entropy of the system - quantum system, demon, and environment by at least one bit.

Rather more precisely, we can consider a four-stage error-correction 'cycle' as depicted in Figure 12.9:
(1) The system, starting in a state ρ, is subjected to a noisy quantum evolution that takes it to a state ρ'. In typical scenarios for error-correction, we are interested in cases where the entropy of the system increases, $S(\rho') > S(\rho)$, although this is not necessary.
(2) A demon performs a (syndrome) measurement on the state ρ' described by measurement operators $\{M_m\}$, obtaining result m with probability $p_m = \mathrm{tr}\left(M_m \rho' M_m^\dagger\right)$, resulting in the posterior state $\rho'_m = M_m \rho' M_m^\dagger / p_m$.
(3) The demon applies a unitary operation V_m (the recovery operation) that creates a final system state

$$\rho''_m = V_m \rho'_m V_m^\dagger = \frac{V_m M_m \rho' M_m^\dagger V_m^\dagger}{p_m} \tag{12.149}$$

(4) The cycle is restarted. In order that this actually be a cycle and that it be a successful error-correction, we must have $\rho''_m = \rho$ for each measurement outcome m.

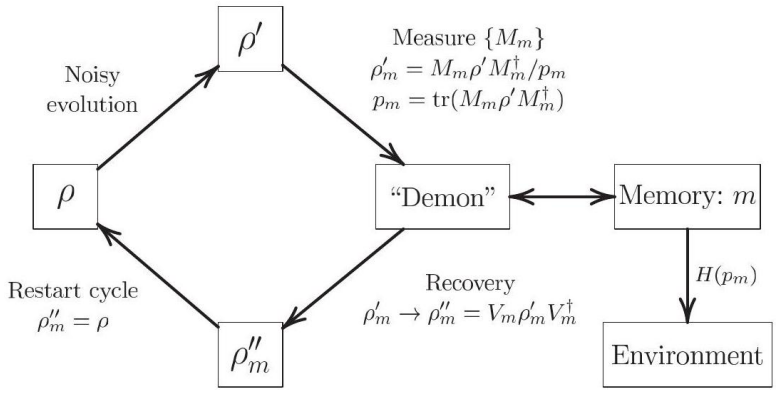

Figure 12.9. The quantum error-correction cycle.

We now show that any reduction in entropy during the second and third stages - the error-correction stages - comes at the expense of entropy production in the environment which is at least as large as the entropy reduction in the quantum system being errorcorrected. After the third stage the only record of the measurement result m is the record kept in the demon's memory. To reset its memory for the next cycle, the demon must erase its record of the measurement result, causing a net increase in the entropy of the environment by Landauer's principle. The number of bits that must be erased is determined by the representation the demon uses to store the measurement result m; by Shannon's noiseless channel coding theorem, at least $H(p_m)$ bits are required, on average, to store the measurement result, and thus a single error-correction cycle on average involves the dissipation of $H(p_m)$ bits of entropy into the environment when the measurement record is erased.

Before error-correction the state of the quantum system is ρ'. After error-correction the state of the quantum system is ρ, so the net change in entropy of the system due to the error-correction is $\Delta S \equiv S(\rho) - S(\rho')$. There is an additional entropic cost of $H(p_m)$ (on average) associated with erasing the measurement record, for a total cost of $\Delta(S) + H(p_m)$. Our goal is to bound this thermodynamic cost, and in so doing demonstrate that the second law of thermodynamics is never violated. To do so, it helps to introduce two items of notation: let $\mathcal{E}$ represent the noise process occurring during stage 1 of the error-correction cycle, $\rho \rightarrow \rho' = \mathcal{E}(\rho)$, and let $\mathcal{R}$ be the quantum operation representing
the error-correction operation,

$$\mathcal{R}(\sigma) \equiv \sum_m V_m M_m \sigma M_m^\dagger V_m^\dagger \tag{12.150}$$

With input ρ' the w-matrix for this process has elements $W_{mn} = \mathrm{tr}\left(V_m M_m \rho' M_n^\dagger V_n^\dagger\right)$, and thus has diagonal elements $W_{mm} = \mathrm{tr}\left(V_m M_m \rho' M_m^\dagger V_m^\dagger\right) = \mathrm{tr}\left(M_m \rho' M_m^\dagger\right)$, which is just the probability p_m the demon obtains measurement outcome m when measuring the error syndrome. By Theorem 11.9 on page 515 the entropy of the diagonal elements of W is at least as great as the entropy of W, so

$$H(p_m) \geq S(W) = S(\rho', \mathcal{R}), \tag{12.151}$$

with equality if and only if the operators $V_m M_m$ are a canonical decomposition of $\mathcal{R}$ with respect to ρ' so that the off-diagonal terms in W vanish. By Equation (12.144) on page 568 it follows that

$$\Delta S + S(\rho', \mathcal{R}) = S(\rho) - S(\rho') + S(\rho', \mathcal{R}) \geq 0. \tag{12.152}$$

Combining this result with (12.151) we deduce that $\Delta S + H(p_m) \geq 0$. But $\Delta S + H(p_m)$ was the total entropy change caused by the error-correction procedure. We conclude that error-correction can only ever result in a net increase in total entropy, with any decrease in system entropy due to error-correction being paid for with entropy production when the error syndrome produced during error-correction is erased.

Exercise 12.16: Show that in the case where $\mathcal{R}$ perfectly corrects $\mathcal{E}$ for the input ρ, the inequality

$$S(\rho) - S(\rho') + S(\rho', \mathcal{R}) \geq 0 \tag{12.153}$$

must actually be satisfied with equality.

9.5.15 12.5 Entanglement as a physical resource

Thus far our study of quantum information has been focused on resources that are not too far distant from the resources considered in classical information theory. For your convenience Figure 12.10 summarizes many of these results in both their quantum and classical guises. One of the delights of quantum computation and quantum information is that quantum mechanics also contains essentially new types of resource that differ vastly from the sort of resource traditionally regarded as information in classical information theory. Perhaps the best understood of these is quantum entanglement, and it is to this resource that we now turn.

We say 'best understood', but that is not saying a whole lot! We are a long way from having a general theory of quantum entanglement. Nevertheless, some encouraging progress towards such a general theory has been made, revealing an intriguing structure to the entangled states, and some quite remarkable connections between the properties of noisy quantum channels and various types of entanglement transformation. We are just going to take a quick peek at what

is known, focusing on the transformation properties of entanglement distributed between two systems ('bi-partite' entanglement), Alice and Bob. There is, of course, a great deal of interest in developing a general theory of entanglement for multi-partite systems, but how to do this is not well understood.

$$S(\rho) \geq I(\rho, \mathcal{E}_1) \geq I(\rho, \mathcal{E}_2 \circ \mathcal{E}_1)$$

Figure 12.10. Summary of some important classical information relations, and quantum analogues of those relations.

9.5.16 12.5.1 Transforming bi-partite pure state entanglement

The starting point for our investigation is the following simple question: given that Alice and Bob share an entangled pure state $|\psi\rangle$, into what other types of entanglement $|\varphi\rangle$ may they transform $|\psi\rangle$, given that they can each perform arbitrary operations on their local systems, including measurement, but can only communicate using classical communication? No quantum communication between Alice and Bob is allowed, constraining the class of transformations they may achieve.

As an example, imagine that Alice and Bob share an entangled pair of qubits in the Bell state $(|00\rangle + |11\rangle)/\sqrt{2}$. Alice performs a two outcome measurement described by measurement operators M_1 and M_2 :

$$M_1 = \begin{bmatrix} \cos\theta & 0 \\ 0 & \sin\theta \end{bmatrix}; \quad M_2 = \begin{bmatrix} \sin\theta & 0 \\ 0 & \cos\theta \end{bmatrix}. \tag{12.154}$$

After the measurement the state is either $\cos\theta|00\rangle + \sin\theta|11\rangle$ or $\cos\theta|11\rangle + \sin\theta|00\rangle$, depending on the measurement outcome, 1 or 2 . In the latter case, Alice applies a not gate after the measurement, resulting in the state $\cos\theta|01\rangle + \sin\theta|10\rangle$. She then sends the measurement result (1 or 2) to Bob, who does nothing to the state if the measurement result is 1 , and performs a NOT gate if the result is 2 . The final state of the joint system is therefore $\cos\theta|11\rangle + \sin\theta|00\rangle$, regardless of the measurement outcome obtained by Alice. That is, Alice and Bob have transformed their initial entangled resource $(|00\rangle + |11\rangle)/\sqrt{2}$ into the state $\cos\theta|00\rangle + \sin\theta|11\rangle$ using only local operations on their individual systems, and classical communication.

It is perhaps not immediately obvious what is the significance of the problem of entanglement transformation. There is a certain intrinsic interest to the class of transformations we are allowing - local operations and classical communication (LOCC) - however, it is by no means clear a priori that this is truly an interesting problem. It turns out, however, that generalizations of this entanglement transformation problem exhibit deep and unexpected connections to quantum error-correction. Furthermore, the techniques introduced in the solution to the problem are of quite considerable interest, and give unexpected insight into the properties of entanglement. In particular, we will discover a close connection between entanglement and the theory of majorization, an area of mathematics that actually predates quantum mechanics!

Before jumping into the study of entanglement transformation, let's first acquaint ourselves with a few relevant facts about majorization. Majorization is an ordering on d-dimensional real vectors intended to capture the notion that one vector is more or less disordered than another. More precisely, suppose $x = (x_1, \ldots, x_d)$ and $y = (y_1, \ldots, y_d)$ are two d-dimensional vectors. We use the notation $x^{\downarrow}$ to mean x re-ordered so the components are in decreasing order so, for example, $x_1^{\downarrow}$ is the largest component of x. We say x is majorized by y, written $x \prec y$, if $\sum_{j=1}^{k} x_j^{\downarrow} \leq \sum_{j=1}^{k} y_j^{\downarrow}$ for $k = 1, \ldots, d$, with equality instead of inequality when $k = d$. What this definition has to do with notions of disorder will become clear shortly!

The connection between majorization and entanglement transformation is easily stated yet rather surprising. Suppose $|\psi\rangle$ and $|\varphi\rangle$ are states of the joint Alice-Bob system. Define $\rho_\psi \equiv \mathrm{tr}_B(|\psi\rangle\langle\psi|), \rho_\varphi \equiv \mathrm{tr}_B(|\varphi\rangle\langle\varphi|)$ to be the corresponding reduced density matrices of Alice's system, and let λ_ψ and λ_φ be the vectors whose entries are the eigenvalues of ρ_ψ and ρ_φ. We will show that $|\psi\rangle$ may be transformed to $|\varphi\rangle$ by LOCC if and only if $\lambda_\psi \prec \lambda_\varphi$! To demonstrate this we need first a few simple facts about majorization.

Exercise 12.17: Show that $x \prec y$ if and only if for all real t, $\sum_{j=1}^{d} \max(x_j - t, 0) \leq \sum_{j=1}^{d} \max(y_j - t, 0)$, and $\sum_{j=1}^{d} x_j = \sum_{j=1}^{d} y_j$.

Exercise 12.18: Use the previous exercise to show that the set of x such that $x \prec y$ is convex.

The following proposition gives a more intuitive meaning to the notion of majorization, showing that $x \prec y$ if and only if x can be written as a convex combination of permutations of y. Intuitively, therefore, $x \prec y$ if x is more disordered than y in the sense that x can be obtained by permuting the elements of y and mixing the resulting vectors. This representation theorem is one of the most useful results in the study of majorization.

Proposition 12.11: $x \prec y$ if and only if $x = \sum_j p_j P_j y$ for some probability distribution p_j and permutation matrices P_j.

Proof

Suppose $x \prec y$. Without loss of generality we may suppose $x = x^{\downarrow}$ and $y = y^{\downarrow}$. We will prove that $x = \sum_j p_j P_j y$ by induction on the dimension d. For $d = 1$ the result is clear. Suppose x and y are $d+1$-dimensional vectors such that $x \prec y$. Then $x_1 \leq y_1$. Choose j such that $y_j \leq x_1 \leq y_{j-1}$, and define t in the range $[0, 1]$ such that $x_1 = t y_1 + (1-t) y_j$. Define a convex combination of permutations $D \equiv tI + (1-t)T$, where T is the permutation matrix which transposes the 1st and j th matrix elements. Then

$$Dy = (x_1, y_2, \ldots, y_{j-1}, (1-t)y_1 + t y_j, y_{j+1}, \ldots, y_{d+1}) \tag{12.155}$$

Define $x' \equiv (x_2, \ldots, x_{d+1})$ and $y' \equiv (y_2, \ldots, y_{j-1}, (1-t)y_1 + t y_j, y_{j+1}, \ldots, y_{d+1})$. In Exercise 12.19 on this page you show $x' \prec y'$, so by the inductive hypothesis $x' = \sum_j p'_j P'_j y'$ for probabilities p'_j and permutation matrices P'_j, whence $x = \left(\sum_j p'_j P'_j\right) Dy$, where the P'_j are extended to $d+1$ dimensions by acting trivially on the first entry. Since $D = (tI + (1-t)T)$, and a product of permutation matrices is a permutation matrix, the result follows.

Exercise 12.19: Verify that $x' \prec y'$.

Conversely, suppose $x = \sum_j p_j P_j y$. It is clear that $P_j y \prec y$ and by Exercise 12.18 it follows that $x = \sum_j p_j P_j y \prec y$.

Matrices which are convex combinations of permutation matrices have many interesting properties. Notice, for example, that the entries of such a matrix must be non-negative, and that each of the rows and columns must sum to one. A matrix with these properties is known as a doubly stochastic matrix, and there is a result known as Birkhoff's theorem which implies that the doubly stochastic matrices correspond exactly to the set of matrices which can be written as convex combinations of permutation matrices. We won't prove Birkhoff's theorem here (see the end of chapter 'History and further reading'), but merely state it:

Theorem 12.12: (Birkhoff's theorem) A d by d matrix D is doubly stochastic (that is, has non-negative entries and each row and column sums to 1) if and only if D can be written as a convex combination of permutation matrices, $D = \sum_j p_j P_j$.

From Birkhoff's theorem and Proposition 12.11 it follows that $x \prec y$ if and only if $x = Dy$ for some doubly stochastic D. This result allows us to prove a striking and useful operator generalization of Proposition 12.11. Suppose H and K are two Hermitian operators. Then we say $H \prec K$ if $\lambda(H) \prec \lambda(K)$, where we use $\lambda(H)$ to denote the vector of eigenvalues of a Hermitian operator H. Then we have:

Theorem 12.13: Let H and K be Hermitian operators. Then $H \prec K$ if and only if there is a probability distribution p_j and unitary matrices U_j such that

$$H = \sum_j p_j U_j K U_j^\dagger. \tag{12.156}$$

Proof

Suppose $H \prec K$. Then $\lambda(H) = \sum_j p_j P_j \lambda(K)$ by Proposition 12.11. Let $\Lambda(H)$ denote the diagonal matrix whose entries are the eigenvalues of H. Then the vector equation $\lambda(H) = \sum_j p_j P_j \lambda(K)$ may be re-expressed as

$$\Lambda(H) = \sum_j p_j P_j \Lambda(K) P_j^\dagger \tag{12.157}$$

But $H = V\Lambda(H)V^\dagger$ and $\Lambda(K) = WKW^\dagger$ for some unitary matrices V and W, giving $H = \sum_j p_j U_j K U_j^\dagger$ where $U_j \equiv V P_j W$ is a unitary matrix, completing the proof in the forward direction.

Conversely, suppose $H = \sum_j p_j U_j K U_j^\dagger$. Similarly to before, this is equivalent to $\Lambda(H) = \sum_j p_j V_j \Lambda(K) V_j^\dagger$ for some unitary matrices V_j. Writing the matrix components of V_j as $V_{j,kl}$, we have:

$$\lambda(H)_k = \sum_{jl} p_j V_{j,kl} \lambda(K)_l V_{j,lk}^\dagger = \sum_{jl} p_j \left|V_{j,kl}\right|^2 \lambda(K)_l. \tag{12.158}$$

Define a matrix D with entries $D_{kl} \equiv \sum_j p_j \left|V_{j,kl}\right|^2$ so we have $\lambda(H) = D\lambda(K)$. The entries of D are non-negative by definition, and the rows and columns of D all sum to one because the rows and columns of the unitary matrices V_j are unit vectors, so D is doubly stochastic and thus $\lambda(H) \prec \lambda(K)$.

We now have in hand all the facts about majorization needed in the study of LOCC transformations of bipartite pure state entanglement. The first step of the argument is to reduce the problem from the study of general protocols, which may involve two way classical communication, to protocols involving only one-way classical communication.

Proposition 12.14: Suppose $|\psi\rangle$ can be transformed to $|\varphi\rangle$ by LOCC. Then this transformation can be achieved by a protocol involving just the following steps: Alice performs a single measurement described by measurement operators M_j, sends the result j to Bob, who performs a unitary operation U_j on his system.

Proof

Without loss of generality we may suppose the protocol consists of Alice performing a measurement, sending the result to Bob, who performs a measurement (whose nature may depend on the information received from Alice), and sends the result back to Alice, who performs a measurement... and so on. The idea of the proof is simply to show that the
effect of any measurement Bob can do may be simulated by Alice (with one small caveat) so all Bob's actions can actually be replaced by actions by Alice! To see that this is the case, imagine Bob performs a measurement with measurement operators M_j on a pure state $|\psi\rangle$. Suppose this pure state has Schmidt decomposition $|\psi\rangle = \sum_l \sqrt{\lambda_l}\,|l_A\rangle\,|l_B\rangle$ and define operators N_j on Alice's system to have a matrix representation with respect to Alice's Schmidt basis which is the same as the matrix representation of Bob's operators M_j with respect to his Schmidt basis. That is, if $M_j = \sum_{kl} M_{j,kl}\,|k_B\rangle\,\langle l_B|$ then we define

$$N_j \equiv \sum_{kl} M_{j,kl}\,|k_A\rangle\,\langle l_A| \tag{12.159}$$

Suppose Bob performs the measurement defined by the measurement operators M_j. Then the post-measurement state is $|\psi_j\rangle \propto M_j|\psi\rangle = \sum_{kl} M_{j,kl}\sqrt{\lambda_l}\,|l_A\rangle\,|k_B\rangle$, with probability $\sum_{kl} \lambda_l\,|M_{j,kl}|^2$. On the other hand, if Alice had measured N_j then the post-measurement state is $|\varphi_j\rangle \propto N_j|\psi\rangle = \sum_{kl} M_{j,kl}\sqrt{\lambda_l}\,|k_A\rangle\,|l_B\rangle$, also with probability $\sum_{kl} \lambda_l\,|M_{j,kl}|^2$. Note furthermore that $|\psi_j\rangle$ and $|\varphi_j\rangle$ are the same states up to interchange of Alice and Bob's systems via the map $|k_A\rangle \leftrightarrow |k_B\rangle$, and therefore must have the same Schmidt components. It follows from Exercise 2.80 on page 111 that there exists a unitary U_j on Alice's system and V_j on Bob's system such that $|\psi_j\rangle = (U_j \otimes V_j)\,|\varphi_j\rangle$. Therefore, Bob performing a measurement described by measurement operators M_j is equivalent to Alice performing the measurement described by measurement operators $U_j N_j$ followed by Bob performing the unitary transformation V_j. Summarizing, a measurement by Bob on a known pure state can be simulated by a measurement by Alice, up to a unitary transformation by Bob.

Imagine then that Alice and Bob engage in a multi-round protocol transforming $|\psi\rangle$ to $|\varphi\rangle$. Without loss of generality, we may suppose that the first round of the protocol consists of Alice performing a measurement and sending the result to Bob. The second round consists of Bob performing a measurement (perhaps with the type of measurement determined by the result of the first) and sending the result to Alice. Instead, however, we can suppose that this measurement is simulated by a measurement performed by Alice, up to a unitary transformation by Bob. Indeed, we can replace all the measurements by Bob and communication from Bob to Alice by measurements by Alice, with a unitary to be done by Bob conditional on Alice's measurement result. Finally, all the measurements performed by Alice can be combined into one single measurement (Exercise 2.57 on page 86), whose result determines a unitary transformation to be performed by Bob; the net effect of this protocol is exactly the same as the original protocol with two-way communication.

Theorem 12.15: A bipartite pure state $|\psi\rangle$ may be transformed to another pure state $|\varphi\rangle$ by LOCC if and only if $\lambda_\psi \prec \lambda_\varphi$.

Proof

Suppose $|\psi\rangle$ may be transformed to $|\varphi\rangle$ by LOCC. By Proposition 12.14 we may assume that the transformation is effected by Alice performing a measurement with measurement operators M_j, then sending the result to Bob, who performs a unitary transformation U_j. From Alice's point of view she starts with the state ρ_ψ and ends with the state ρ_φ regardless of the measurement outcome, so we must have

$$M_j \rho_\psi M_j^\dagger = p_j \rho_\varphi \tag{12.160}$$

where p_j is the probability of outcome j. Polar decomposing $M_j \sqrt{\rho_\psi}$ implies that there exists a unitary V_j such that

$$M_j \sqrt{\rho_\psi} = \sqrt{M_j \rho_\psi M_j^\dagger} V_j = \sqrt{p_j \rho_\varphi} V_j. \tag{12.161}$$

Premultiplying this equation by its adjoint gives

$$\sqrt{\rho_\psi} M_j^\dagger M_j \sqrt{\rho_\psi} = p_j V_j^\dagger \rho_\varphi V_j. \tag{12.162}$$

Summing on j and using the completeness relation $\sum_j M_j^\dagger M_j = I$ gives

$$\rho_\psi = \sum_j p_j V_j^\dagger \rho_\varphi V_j \tag{12.163}$$

whence $\lambda_\psi \prec \lambda_\varphi$ by Theorem 12.13.

The proof of the converse is essentially to run the proof in the forwards direction backwards. Suppose $\lambda_\psi \prec \lambda_\varphi$, so $\rho_\psi \prec \rho_\varphi$ and by Theorem 12.13 there exist probabilities p_j and unitary operators U_j such that $\rho_\psi = \sum_j p_j U_j \rho_\varphi U_j^\dagger$. Assume for now that ρ_ψ is invertible (this assumption is easily removed; see Exercise 12.20) and define operators M_j for Alice's system by

$$M_j \sqrt{\rho_\psi} \equiv \sqrt{p_j \rho_\varphi} U_j^\dagger \tag{12.164}$$

To see that these operators define a measurement we need to check the completeness relation. We have $M_j = \sqrt{p_j \rho_\varphi} U_j^\dagger \rho_\psi^{-1/2}$ and thus

$$\sum_j M_j^\dagger M_j = \rho_\psi^{-1/2} \left(\sum_j p_j U_j \rho_\varphi U_j^\dagger \right) \rho_\psi^{-1/2} = \rho_\psi^{-1/2} \rho_\psi \rho_\psi^{-1/2} = I, \tag{12.165}$$

which is the completeness relation. Suppose Alice performs the measurement described by the operators M_j, obtaining the outcome j and the corresponding state $|\psi_j\rangle \propto M_j |\psi\rangle$. Let ρ_j denote Alice's reduced density matrix corresponding to the state $|\psi_j\rangle$, so

$$\rho_j \propto M_j \rho_\psi M_j^\dagger = p_j \rho_\varphi \tag{12.166}$$

by substitution of (12.164), and thus $\rho_j = \rho_\varphi$. It follows by Exercise 2.81 that Bob may convert $|\psi_j\rangle$ into $|\varphi\rangle$ by application of a suitable unitary transformation V_j.

Exercise 12.20: Show that the assumption that ρ_ψ is invertible may be removed from the proof of the converse part of Theorem 12.15.

Exercise 12.21: (Entanglement catalysis) Suppose Alice and Bob share a pair of four level systems in the state $|\psi\rangle = \sqrt{0.4}|00\rangle + \sqrt{0.4}|11\rangle + \sqrt{0.1}|22\rangle + \sqrt{0.1}|33\rangle$. Show that it is not possible for them to convert this state by LOCC to the state $|\varphi\rangle = \sqrt{0.5}|00\rangle + \sqrt{0.25}|11\rangle + \sqrt{0.25}|22\rangle$. Imagine, however, that a friendly bank is willing to offer them the loan of a catalyst, an entangled pair of qubits in the state $|c\rangle = \sqrt{0.6}|00\rangle + \sqrt{0.4}|11\rangle$. Show that it is possible for Alice and Bob to convert the state $|\psi\rangle|c\rangle$ to $|\varphi\rangle|c\rangle$ by local operations and classical communication, returning the catalyst $|c\rangle$ to the bank after the transformation is complete.

Exercise 12.22: (Entanglement conversion without communication) Suppose Alice and Bob are trying to convert a pure state $|\psi\rangle$ into a pure state $|\varphi\rangle$ using local operations only - no classical communication. Show that this is possible if
and only if $\lambda_\psi \cong \lambda_\varphi \otimes x$, where x is some real vector with non-negative entries summing to 1 , and ' $\cong$ ' means that the vectors on the left and the right have identical non-zero entries.

9.5.17 12.5.2 Entanglement distillation and dilution

Suppose that instead of being supplied with a single copy of a state $|\psi\rangle$ Alice and Bob are supplied with a large number of copies. What types of entanglement transformation can they accomplish with all these copies? We are going to focus on two particular types of entanglement transformation, known as entanglement distillation and entanglement dilution. The idea of entanglement distillation is for Alice and Bob to convert some large number of copies of a known pure state $|\psi\rangle$ into as many copies of the Bell state $(|00\rangle + |11\rangle)/\sqrt{2}$ as possible using local operations and classical communication, requiring not that they succeed exactly, but only with high fidelity. Entanglement dilution is the reverse process of using LOCC to convert a large number of copies of the Bell state $(|00\rangle + |11\rangle)/\sqrt{2}$ into copies of $|\psi\rangle$, again with high fidelity in the limit where a large number of copies of the Bell state are initially available.

What motivates the study of entanglement distillation and dilution? Suppose we take seriously the idea that entanglement is a physical resource and that as such it should be possible to quantify entanglement, much as we quantify other physical resources such as energy or entropy. Suppose we decide to pick the Bell state $(|00\rangle + |11\rangle)/\sqrt{2}$ as our standard unit of entanglement - the basic measure, rather like the standard kilogram or the standard meter. We can associate a measure of entanglement to a quantum state $|\psi\rangle$ in a similar way to the way we associate a mass to an object. Suppose, for instance, that it takes 15 chocolate biscuits of a particular brand to attain a mass equivalent to the standard kilogram; we say that the chocolate biscuits have a mass of 1/15 th of a kilogram. Now, strictly speaking, if the chocolate biscuits had a mass of 1/14.8 kilograms we'd be in a bit of trouble, because no integer number of chocolate biscuits is going to balance the standard kilogram, and it's not so obvious how to define a non-integer number of chocolate biscuits. Fortunately, what we do is notice that 148 chocolate biscuits exactly balances 10 standard kilograms, so the mass of the chocolate biscuits is 10/148 kilograms. But what if the real mass is not 1/14.8 kilograms, but is something even more esoteric, like 1/14.7982... kilograms? Well, we simply go to the limit of balancing a large number m of chocolate biscuits with another large number n of standard kilograms, and declare the mass of a chocolate biscuit to be the limiting ratio n/m as both m and n become very large.

In a similar way, a potential approach to defining the amount of entanglement present in a pure state $|\psi\rangle$ is to imagine that we are given a large number n of Bell states $(|00\rangle + |11\rangle)/\sqrt{2}$, and are asked to produce as many (high-fidelity) copies of $|\psi\rangle$ as possible using local operations and classical communication. If the number of copies of $|\psi\rangle$ that can be produced is m then we define the limiting ratio of n/m to be the entanglement of formation of the state $|\psi\rangle$. Alternately, we might imagine performing the process in reverse, going from m copies of $|\psi\rangle$ to n copies of $(|00\rangle + |11\rangle)/\sqrt{2}$ using LOCC, and defining the limiting ratio n/m to be the distillable entanglement of the state $|\psi\rangle$. It is by no means obvious that these two definitions give the same number for the quantity of entanglement; we will see that for pure states $|\psi\rangle$ the entanglement of formation and the distillable entanglement are in fact exactly the same!

Let's take a look at a simple protocol for entanglement dilution, and another for entanglement distillation. Suppose an entangled state $|\psi\rangle$ has Schmidt decomposition

$$|\psi\rangle = \sum_x \sqrt{p(x)}\, |x_A\rangle\, |x_B\rangle\,. \tag{12.167}$$

We write the squared Schmidt co-efficients $p(x)$ in the form we usually reserve for probability distributions, both because the co-efficients satisfy the usual rules of probability distributions (non-negative and sum to one), and because ideas from probability theory turn out to be useful in understanding entanglement distillation and dilution. The m-fold tensor product $|\psi\rangle^{\otimes m}$ may be written

$$|\psi\rangle^{\otimes m} = \sum_{x_1,x_2,\ldots,x_m} \sqrt{p(x_1)\,p(x_2)\ldots p(x_m)}\,|x_{1A}x_{2A}\ldots x_{mA}\rangle\,|x_{1B}x_{2B}\ldots x_{mB}\rangle\,. \tag{12.168}$$

Suppose that we defined a new quantum state $|\varphi_m\rangle$ by omitting all those terms $x_1,\ldots,x_m$ which are not ϵ-typical, in the sense defined in Section 12.2.1:

$$|\varphi_m\rangle \equiv \sum_{x\in\text{-typical}} \sqrt{p(x_1)\,p(x_2)\ldots p(x_m)}\,|x_{1A}x_{2A}\ldots x_{mA}\rangle\,|x_{1B}x_{2B}\ldots x_{mB}\rangle\,. \tag{12.169}$$

The state $|\varphi_m\rangle$ is not quite a properly normalized quantum state; to normalize it we define $|\varphi'_m\rangle \equiv |\varphi_m\rangle / \sqrt{\langle\varphi_m \mid \varphi_m\rangle}$. By part 1 of the theorem of typical sequences the fidelity $F(|\psi\rangle^{\otimes m}, |\varphi'_m\rangle) \rightarrow 1$ as $m \rightarrow \infty$. Furthermore, by part 2 of the theorem of typical sequences the number of terms in the sum (12.169) is at most $2^{m(H(p(x))+\epsilon)} = 2^{m\left(S\left(\rho_\psi\right)+\epsilon\right)}$, where ρ_ψ is the result of tracing out Bob's part of $|\psi\rangle$.

Suppose then that Alice and Bob are in joint possession of $n = m\left(S\left(\rho_\psi\right)+\epsilon\right)$ Bell states. Alice prepares 'both parts' of $|\varphi'_m\rangle$ locally, and then uses the Bell states shared with Bob to teleport what should be Bob's half of the state $|\varphi'_m\rangle$ over to Bob. In this way, Alice and Bob can dilute their n Bell states to obtain $|\varphi'_m\rangle$, a pretty good approximation to $|\psi\rangle^{\otimes m}$. This entanglement dilution procedure has $n = m\left(S\left(\rho_\psi\right)+\epsilon\right)$, so the ratio n/m tends to $S\left(\rho_\psi\right)+\epsilon$. We may choose ϵ as small as we like, so we conclude that the entanglement of formation for the state $|\psi\rangle$ is no larger than $S\left(\rho_\psi\right)$, since we have just shown that (asymptotically) $S\left(\rho_\psi\right)$ Bell states may be converted into a single copy of $|\psi\rangle$.

An entanglement distillation protocol for converting copies of $|\psi\rangle$ into Bell states also follows along similar lines. Suppose that Alice and Bob are in possession of m copies of $|\psi\rangle$. By performing a measurement onto the ϵ-typical subspace of ρ_ψ Alice may, with high fidelity, convert the state $|\psi\rangle^{\otimes m}$ into the state $|\varphi'_m\rangle$. The largest Schmidt co-efficient appearing in $|\varphi_m\rangle$ is at most $2^{-m\left(S\left(\rho_\psi\right)-\epsilon\right)}$ by the definition of typical sequences. The renormalized state $|\varphi'_m\rangle$ has Schmidt co-efficients at most a factor $1/\sqrt{(1-\delta)}$ larger, since the theorem of typical sequences tells us that $1-\delta$ is a lower bound on the probability that a sequence is ϵ-typical, and may be made arbitrarily close to 1 for sufficiently large m. Thus, the largest eigenvalue of the state $\rho_{\varphi'_m}$ is at most $2^{-m\left(S\left(\rho_\psi\right)-\epsilon\right)}/(1-\delta)$. Suppose we choose any n such that

$$\frac{2^{-m\left(S\left(\rho_\psi\right)-\epsilon\right)}}{1-\delta} \leq 2^{-n}. \tag{12.170}$$

Then the vector of eigenvalues for $\rho_{\varphi'_m}$ is majorized by the vector $(\,2^{-n}, 2^{-n}, \ldots, 2^{-n}\,)$, and thus by Theorem 12.15 the state $|\varphi'_m\rangle$ may be converted to n Bell states by local operations and classical communication. Examining (12.170) we see that this is possible provided $n \approx mS\left(\rho_\psi\right)$, and thus the entanglement of distillation is at least $S\left(\rho_\psi\right)$.

We have exhibited strategies for distilling $|\psi\rangle$ into $S\left(\rho_\psi\right)$ Bell states and for diluting $S\left(\rho_\psi\right)$ Bell states into a copy of $|\psi\rangle$. In fact, it is not very difficult to see that the procedures we have described are really the optimal methods for doing entanglement dilution and distillation! Suppose, for example, that a more efficient protocol for entanglement dilution existed, that could dilute $|\psi\rangle$ into $S > S\left(\rho_\psi\right)$ Bell states. Then starting with $S\left(\rho_\psi\right)$ Bell states Alice and Bob

could produce a copy of $|\psi\rangle$ using the protocol already described, and then use the hypothetical protocol to produce S Bell states. Thus, by local operations and classical communication, Alice and Bob have taken $S(\rho_\psi)$ Bell states and turned them into $S > S(\rho_\psi)$ Bell states! It is not very difficult to convince yourself (and see Exercise 12.24) that increasing the number of Bell states present using local operations and classical communication is not possible, so such a hypothetical dilution protocol can not exist. In a similar way we can see that the procedure for entanglement distillation is optimal. Thus, the entanglement of formation and entanglement of distillation for the state $|\psi\rangle$ are the same, and both equal $S(\rho_\psi)$!

Exercise 12.23: Prove that the procedure for entanglement distillation we have described is optimal.

Exercise 12.24: Recall that the Schmidt number of a bi-partite pure state is the number of non-zero Schmidt components. Prove that the Schmidt number of a pure quantum state cannot be increased by local operations and classical communication. Use this result to argue that the number of Bell states shared between Alice and Bob cannot be increased by local operations and classical communication.

We've learned how to transform Bell states of a bipartite quantum system into copies of another entangled state, $|\psi\rangle$, and back again, in an optimal fashion, motivating us to define the amount of entanglement present in that quantum state to be the number of Bell states into which copies of $|\psi\rangle$ may be inter-converted, that is, $S(\rho_\psi)$. What do we learn from this definition? Below we will see that it is possible to obtain some interesting insights into quantum error-correction by further generalizing the notion of distillable entanglement. Nevertheless, at the time of writing it seems fair to say that the study of entanglement is in its infancy, and it is not yet entirely clear what advances in our understanding of quantum computation and quantum information can be expected as a result of the study of quantitative measures of entanglement. We have a reasonable understanding of the properties of pure states of bi-partite quantum systems, but a very poor understanding of systems containing three or more components, or even of mixed states for bi-partite systems. Developing a better understanding of entanglement and connecting that understanding to topics such as quantum algorithms, quantum error-correction and quantum communication is a major outstanding task of quantum computation and quantum information!

9.5.18 12.5.3 Entanglement distillation and quantum error-correction

We defined entanglement distillation for pure states, but there is no reason that definition cannot be extended to mixed states. More precisely, suppose ρ is a general state of a bi-partite quantum system belonging to Alice and Bob. They are supplied with a large number m of copies of these states, and using local operations and classical communication attempt to convert these states to the largest possible number n of Bell states, with high fidelity. The distillable entanglement $D(\rho)$ of ρ is the limiting value of the ratio n/m
for the best possible distillation protocol; for pure states $|\psi\rangle$ we have already shown that $D(|\psi\rangle) = S(\rho_\psi)$, but we do not yet know how to evaluate $D(\rho)$ for a mixed state.

A considerable number of techniques for doing entanglement distillation have been developed, giving lower bounds on the value for $D(\rho)$ for specific classes of states ρ. We won't review these techniques here (see the end of chapter 'History and further reading'). What we will describe is a fascinating connection between distillable entanglement and quantum error-correction.

Imagine that Alice is attempting to send Bob quantum information through a noisy quantum channel $\mathcal{E}$. We suppose the channel is a qubit channel such as the depolarizing channel, although the same basic ideas adapt easily to non-qubit channels. One method for sending quantum

information through the channel is as follows. Alice prepares a large number m of Bell states, and sends half of each Bell pair through the channel. Suppose the result of applying $\mathcal{E}$ to half a Bell pair is to create the state ρ, so Alice and Bob end up sharing m copies of ρ. Alice and Bob now perform entanglement distillation, producing $mD(\rho)$ Bell pairs. Alice can now prepare an $mD(\rho)$ qubit state and teleport it to Bob using the $mD(\rho)$ Bell pairs which they share.

Thus, entanglement distillation protocols can be used as a type of error-correction for quantum communications channels between two parties Alice and Bob, enabling Alice to reliably send $mD(\rho)$ qubits of information to Bob, where $D(\rho)$ is the distillable entanglement of ρ, the state that results when one half of a Bell pair is sent through the noisy channel $\mathcal{E}$ connecting Alice and Bob.

What is truly remarkable is that this method of communication using entanglement distillation may sometimes work even when conventional quantum error-correction techniques fail. For example, for the depolarizing channel with $p = 3/4$ we saw in Section 12.4.3 that no quantum information may be transmitted through the channel. However, entanglement distillation protocols are known which can produce a non-zero rate of transmission $D(\rho)$ even for this channel! The reason this is possible is because the entanglement distillation protocols allow classical communication back and forth between Alice and Bob, whereas conventional quantum error-correction does not allow any such classical communication.

This example allows us to explain the claim we made way back in Chapter 1, illustrated in Figure 12.11, that there are channels with zero capacity for quantum information which, when one such channel is connecting Alice to Bob, and another connects Bob to Alice, can be used to achieve a net flow of quantum information! The way this is done is very simple and is based on entanglement distillation. Now, in order that entanglement distillation be possible, we need Alice and Bob to be able to communicate classically, so we set aside half the forward uses of the channel, and all the backward uses of the channel to be used for the transmission of classical information used by the distillation protocol; these channels have non-zero rate for classical information transmission by the HSW theorem. The remaining forward uses of the channel are used to transmit halves of Bell pairs from Alice to Bob, with entanglement distillation being used to extract good Bell pairs out of the resulting states, and then teleportation with the good Bell pairs to achieve a net transmission of quantum information, providing yet another vivid demonstration of the remarkable properties of quantum information!

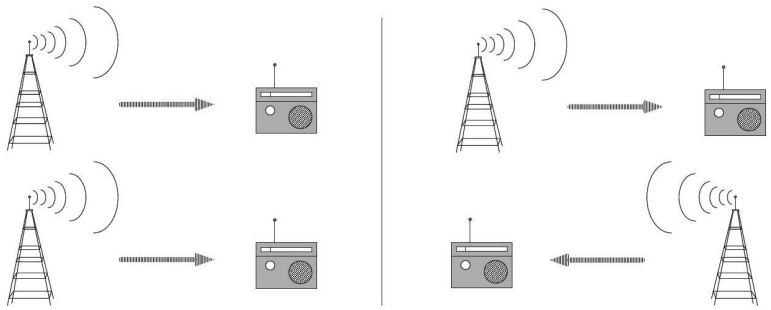

Figure 12.11. Classically, if we have two very noisy channels of zero capacity running side by side, then the combined channel has zero capacity to send information. Not surprisingly, if we reverse the direction of one of the channels, we still have zero capacity to send information. Quantum mechanically, reversing one of the zero capacity channels can actually allow us to send information!

9.5.19 12.6 Quantum cryptography

A fitting conclusion to this chapter is provided by a most remarkable application of quantum information. As we saw in Chapter 5, quantum computers can be used to break some of the best public key cryptosystems. Fortunately, however, what quantum mechanics takes away with one hand, it gives back with the other: a procedure known as quantum cryptography or quantum key distribution exploits the principles of quantum mechanics to enable provably secure distribution of private information. In this section we describe this procedure, and discuss its security. We begin by explaining the basic ideas of a classical technique, private key cryptography, in Section 12.6.1. Private key cryptography is a much older form of cryptography than the public key cryptosystems (mentioned in Chapter 5), and the principles of private key cryptography are used in quantum cryptosystems. Two other important classical techniques, privacy amplification and information reconciliation, which are also used in the quantum systems, are described in Section 12.6.2. Three different protocols for quantum key distribution are then presented in Section 12.6.3. How secure are these protocols? It turns out, as we see in Section 12.6.4, that the coherent information, a measure of quantum information we first encountered in Section 12.4.1, gives an information-theoretic lower bound on the in-principle ability to use a quantum communication channel to send private information! This suggests that ideas of quantum information may be useful in proving the security of specific quantum key distribution protocols, and indeed, they are: we conclude the chapter in Section 12.6.5 with a sketch of how the theory of quantum error-correction provides proof of the security of quantum cryptography.

9.5.20 12.6.1 Private key cryptography

Until the invention of public key cryptography in the 1970s, all cryptosystems operated on a different principle, now known as private key cryptography. In a private key cryptosystem, if Alice wishes to send messages to Bob then Alice must have an encoding key, which allows her to encrypt her message, and Bob must have a matching decoding key, which allows Bob to decrypt the encrypted message. A simple, yet highly effective private key cryptosystem is the Vernam cipher, sometimes called a one time pad. Alice
and Bob begin with n-bit secret key strings, which are identical. Alice encodes her n-bit message by adding the message and key together, and Bob decodes by subtracting to invert the encoding, as illustrated in Figure 12.12.

The great feature of this system is that as long as the key strings are truly secret, it is provably secure. That is, when the protocol used by Alice and Bob succeeds, it does so with arbitrarily high probability (an eavesdropper Eve can always jam the communication channel, but Alice and Bob can detect this jamming and declare failure). And for any eavesdropping strategy employed by Eve, Alice and Bob can guarantee that Eve's mutual information with their unencoded message can be made as small as desired. In contrast, the security of public key cryptography (Appendix 5) relies on unproven mathematical assumptions about the difficulty of solving certain problems like factoring (with classical computers!), even though it is widely used and more convenient.

Original message	Q	U	A	N	T	U
	+	+	+	+	+	+
Encryption key	G	Q	Y	R	W	□
Encrypted message	|| W	"	"	|| F	" Q	"
Received message	W	L	□ Y	□ F	□ Q	□ U
	-	-	____	-	-	-
Decryption key	G	□ Q	Y	□ R	W	A
Decrypted message	|| Q	"U	"A	" N	"T	"U

Figure 12.12. The Vernam cipher. Alice encrypts by adding the random key bits (or in this example, letters of the alphabet) to the original message. Bob decrypts by subtracting the key bits to recover the message.

The major difficulty of private key cryptosystems is secure distribution of key bits. In

particular, the Vernam cipher is secure only as long as the number of key bits is at least as large as the size of the message being encoded, and key bits cannot be reused! Thus, the large amount of key bits needed makes such schemes impractical for general use. Furthermore, key bits must be delivered in advance, guarded assiduously until used, then destroyed afterwards; otherwise, in principle, such classical information can be copied without disturbing the originals, thus compromising the security of the whole protocol. Despite these drawbacks, private key cryptosystems such as the Vernam cipher continue to be used because of their provable security, with key material delivered by clandestine meetings, trusted couriers, or private secured communication links.

Exercise 12.25: Consider a system with n users, any pair of which would like to be able to communicate privately. Using public key cryptography how many keys are required? Using private key cryptography how many keys are required?

9.5.21 12.6.2 Privacy amplification and information reconciliation

The first step in private key cryptography is distribution of the key string. What if Alice and Bob start out with imperfect keys? Specifically, suppose that Alice and Bob share correlated random classical bit strings X and Y, and they also have an upper bound on Eve's mutual information with X and Y. From these imperfect keys, how can they obtain a good enough key to conduct a secure cryptographic protocol? We now show that by performing two steps, information reconciliation, followed by privacy amplification, they can systematically increase the correlation between their key strings, while reducing eavesdropper Eve's mutual information about the result, to any desired level of security. These classical steps will be used in the next section, in the quantum key distribution protocol.

Information reconciliation is nothing more than error-correction conducted over a public channel, which reconciles errors between X and Y to obtain a shared bit string W while divulging as little as possible to Eve. After this procedure, suppose Eve has obtained a random variable Z which is partially correlated with W. Privacy amplification is then used by Alice and Bob to distill from W a smaller set of bits S whose correlation with Z is below a desired threshold. Since this last step is conceptually new, let us consider it first.

A detailed proof of why privacy amplification succeeds is beyond the scope of this book, but we will describe the basic method and present the main theorem. One way to accomplish privacy amplification uses the class of universal hash functions $\mathcal{G}$, which map the set of n-bit strings $\mathcal{A}$ to the set of m-bit strings $\mathcal{B}$, such that for any distinct $a_1, a_2 \in \mathcal{A}$, when g is chosen uniformly at random from $\mathcal{G}$, then the probability that $g(a_1) = g(a_2)$ is at most $1/|\mathcal{B}|$,

The collision entropy of the random variable X with probability distribution $p(x)$ is defined as

$$H_c(X) = -\log\left[\sum_x p(x)^2\right]. \tag{12.171}$$

(This is sometimes known as the Rènyi entropy of order 2.) Using the concavity of the log function, it is not difficult to show that the Shannon entropy provides an upper bound on this quantity: $H(X) \geq H_c(X)$.H_c is important in the following theorem about universal hash functions:

Theorem 12.16: Let X be a random variable on alphabet $\mathcal{X}$ with probability distribution $p(x)$ and collision entropy $H_c(X)$, and let G be the random variable corresponding to the random choice (with uniform distribution) of a member of the universal class of hash functions from $\mathcal{X}$ to $\{0,1\}^m$. Then

$$H(G(X) \mid G) \geq H_c(G(X) \mid G) \geq m - 2^{m-H_c(X)} \tag{12.172}$$

Theorem 12.16 can be applied to privacy amplification in the following manner. Alice and Bob publicly select $g \in \mathcal{G}$ and each apply it to W, giving a new bit string S, which they choose as their secret key. If Eve's uncertainty about W given her knowledge $Z = z$ (about a specific instance of the protocol) is known in terms of the collision entropy to be bounded below by some number, say $H_c(W \mid Z = z) > d$, then it follows from Theorem 12.16 that

$$H_c(S \mid G, Z = z) \geq m - 2^{m-d} \tag{12.173}$$

In other words, m may be chosen small enough such that $H_c(S \mid G, Z = z)$ is nearly equal to m. This maximizes Eve's uncertainty about the key S, making it a secure secret.

Information reconciliation further reduces the number of bits that Alice and Bob can obtain, but this can be bounded as follows. By computing a series of parity checks on subsets of her bits X, Alice can compose a (classical) message u consisting of subset specifications and parities, which, when transmitted to Bob, allows him to correct the errors in his string Y, after which both have the same string W. Clearly, this will require sending $k > H(W \mid Y)$ bits of information in u. However, this procedure gives Eve additional knowledge $U = u$, thus increasing her collision entropy to $H_c(W \mid Z = z, U = u)$. On average (over possible reconciliation messages u), this increase is bounded below by $H_c(W \mid Z = z, U = u) \geq H_c(W \mid Z = z) - H(U)$, where $H(U)$ is the usual Shannon entropy of U, but this bound is too weak, because it implies that the probability that the leaked information $U = u$ decreases H_c by more than $mH(U)$ is only at most $1/m$. A stronger bound is provided by this theorem:

Theorem 12.17: Let X and U be random variables with alphabets $\mathcal{X}$ and $\mathcal{U}$, respectively, where X has probability distribution $p(x)$, and U is jointly distributed with X according to $p(x, u)$. Also let $s > 0$ be an arbitrary parameter. Then, with probability at least $1 - 2^{-s}, U$ takes on a value u for which

$$H_c(X \mid U = u) \geq H_c(X) - 2 \log |\mathcal{U}| - 2s. \tag{12.174}$$

Here, s is known as a security parameter. Applying this to the reconciliation protocol gives the conclusion that Alice and Bob can choose s such that Eve's collision entropy is bounded from below by $H_c(W \mid Z = z, U = u) \geq d - 2(k + s)$, with probability better than $1 - 2^{-s}$. Following this step with privacy amplification allows them to distill m secret key bits S, for which Eve's total information is less than $2^{m-d+2(k+s)}$ bits.

CSS code privacy amplification $^{\mathcal{G}}$ information reconciliation

As we noted above, information reconciliation is nothing more than error-correction; it turns out that privacy amplification is also intimately related to error-correction, and both tasks can be implemented by using classical codes. This viewpoint provides a simple conceptual picture which will be useful in the proof of the security of quantum key distribution, in Section 12.6.5, since we have a well-developed theory of quantum errorcorrection codes. With this in mind, it is useful to observe the following.

Decoding from a randomly chosen CSS code (see Section 10.4.2) can be thought of as performing information reconciliation and privacy amplification. Although CSS codes are usually used to encode quantum information, for our present purpose we can just consider their classical properties. Consider two classical linear codes C_1 and C_2 which satisfy the conditions for a t error-correcting $[n, m]$ CSS code: $C_2 \subset C_1$ and C_1 and $C_2^{\perp}$ both correct t errors. Alice chooses a random n bit string X and transmits it to Bob, who receives Y.

Let us assume that a priori it is known that along a communication channel between Alice and Bob, the expected number of errors per code block caused by all noise sources including eavesdropping is less than t; in practice, this can be established by random testing of the

channel. Furthermore, suppose that Eve knows nothing about the codes C_1 and C_2; this can be ensured by Alice choosing the code randomly. Finally, suppose that Alice and Bob have an upper bound on the mutual information between Eve's data Z, and their own data, X and Y.

Bob receives $Y = X + \epsilon$, where ϵ is some error. Since it is known that less than t errors occurred, if Alice and Bob both correct their states to the nearest codeword in C_1, their results $X', Y' \in C_1$ are identical, $W = X' = Y'$. This step is nothing more than information reconciliation. Of course, Eve's mutual information with W may still be unacceptably large. To reduce this, Alice and Bob identify which of the 2^m cosets of C_2 in C_1 their state W belongs to; that is, that they compute the coset of $W + C_2$ in C_1. The result is their m bit key string, S. By virtue of Eve's lack of knowledge about C_2, and the error-correcting properties of C_2, this procedure can reduce Eve's mutual information with S to an acceptable level, performing privacy amplification.

9.5.22 12.6.3 Quantum key distribution

Quantum key distribution (QKD) is a protocol which is provably secure, by which private key bits can be created between two parties over a public channel. The key bits can then be used to implement a classical private key cryptosystem, to enable the parties to communicate securely. The only requirement for the QKD protocol is that qubits can be communicated over the public channel with an error rate lower than a certain threshold. The security of the resulting key is guaranteed by the properties of quantum information, and thus is conditioned only on fundamental laws of physics being correct!

The basic idea behind QKD is the following fundamental observation: Eve cannot gain any information from the qubits transmitted from Alice to Bob without disturbing their state. First of all, by the no-cloning theorem (Box 12.1), Eve cannot clone Alice's qubit. Second, we have the following proposition:

Proposition 12.18: (Information gain implies disturbance) In any attempt to distinguish between two non-orthogonal quantum states, information gain is only possible at the expense of introducing disturbance to the signal.

Proof

Let $|\psi\rangle$ and $|\varphi\rangle$ be the non-orthogonal quantum states Eve is trying to obtain information about. By the results of Section 8.2, we may assume without loss of generality that the process she uses to obtain information is to unitarily interact the state ($|\psi\rangle$ or $|\varphi\rangle$) with an ancilla prepared in a standard state $|u\rangle$. Assuming that this process does not disturb the states, in the two cases one obtains

$$|\psi\rangle|u\rangle \rightarrow |\psi\rangle|v\rangle \tag{12.175}$$
$$|\varphi\rangle|u\rangle \rightarrow |\varphi\rangle\,|v'\rangle \tag{12.176}$$

Eve would like $|v\rangle$ and $|v'\rangle$ to be different so that she can acquire information about the identity of the state. However, since inner products are preserved under unitary transformations, it must be that

$$\langle v \mid v'\rangle\,\langle\psi \mid \varphi\rangle = \langle u \mid u\rangle\langle\psi \mid \varphi\rangle \tag{12.177}$$
$$\langle v \mid v'\rangle = \langle u \mid u\rangle = 1, \tag{12.178}$$

which implies that $|v\rangle$ and $|v'\rangle$ must be identical. Thus, distinguishing between $|\psi\rangle$ and $|\varphi\rangle$ must inevitably disturb at least one of these states.

We make use of this idea by transmitting non-orthogonal qubit states between Alice and Bob. By checking for disturbance in their transmitted states, they establish an upper bound on any noise or eavesdropping occurring in their communication channel. These 'check' qubits are interspersed randomly among data qubits (from which key bits are later extracted), so that the upper bound applies to the data qubits as well. Alice and Bob then perform information reconciliation and privacy amplification to distill a shared secret key string. The threshold for the maximum tolerable error rate is thus determined by the efficacy of the best information reconciliation and privacy amplification protocols. Three different QKD protocols which work in this way are presented below.

The BB84 protocol

Alice begins with a and b, two strings each of $(4+\delta)n$ random classical bits. She then encodes these strings as a block of $(4+\delta)n$ qubits,

$$|\psi\rangle = \bigotimes_{k=1}^{(4+\delta)n} |\psi_{a_k b_k}\rangle \tag{12.179}$$

where a_k is the k^{th} bit of a (and similarly for b), and each qubit is one of the four states

$$|\psi_{00}\rangle = |0\rangle \tag{12.180}$$
$$|\psi_{10}\rangle = |1\rangle \tag{12.181}$$
$$|\psi_{01}\rangle = |+\rangle = (|0\rangle + |1\rangle)/\sqrt{2} \tag{12.182}$$
$$|\psi_{11}\rangle = |-\rangle = (|0\rangle - |1\rangle)/\sqrt{2} \tag{12.183}$$

The effect of this procedure is to encode a in the basis X or Z, as determined by b. Note that the four states are not all mutually orthogonal, and therefore no measurement can distinguish between (all of) them with certainty. Alice then sends $|\psi\rangle$ to Bob, over their public quantum communication channel.

Bob receives $\mathcal{E}(|\psi\rangle\langle\psi|)$, where $\mathcal{E}$ describes the quantum operation due to the combined effect of the channel and Eve's actions. He then publicly announces this fact. At this point, Alice, Bob, and Eve each have their own states described by separate density matrices. Note also that at this point, since Alice hasn't revealed b, Eve has no knowledge of what basis she should have measured in to eavesdrop on the communication; at best, she can only guess, and if her guess was wrong, then she would have disturbed the state received by Bob. Moreover, whereas in reality the noise $\mathcal{E}$ may be partially due to the environment (a poor channel) in addition to Eve's eavesdropping, it doesn't help Eve to have complete control over the channel, so that she is entirely responsible for $\mathcal{E}$.

Of course, Bob also finds $\mathcal{E}(|\psi\rangle\langle\psi|)$ uninformative at this point, because he does not know anything about b. Nevertheless, he goes ahead and measures each qubit in basis X or Z, as determined by a random $(4+\delta)n$ bit string b' which he creates on his own. Let

Bob's measurement result be a'. After this, Alice publicly announces b, and by discussion over a public channel, Bob and Alice discard all bits in $\{a', a\}$ except those for which corresponding bits of b' and b are equal. Their remaining bits satisfy $a' = a$, since for these bits Bob measured in the same basis Alice prepared in. Note that b reveals nothing about either a, or the bits a' resulting from Bob's measurement, but it is important that Alice not publish b until after Bob announces reception of Alice's qubits. For simplicity in the following explanation, let Alice and Bob keep just $2n$ bits of their result; δ can be chosen sufficiently large so that this can be done with exponentially high probability.

Now Alice and Bob perform some tests to determine how much noise or eavesdropping happened during their communication. Alice selects n bits (of their $2n$ bits) at random, and publicly announces the selection. Bob and Alice then publish and compare the values of these check bits. If more than t bits disagree, then they abort and re-try the protocol from the start. t is selected such that if the test passes, then they can apply information reconciliation and privacy amplification algorithms to obtain m acceptably secret shared key bits from the remaining n bits.

This protocol, known as BB84 after its inventors (see the end of chapter 'History and further reading'), is summarized in Figure 12.13, and an experimental realization is described in Box 12.7. Related versions of this protocol, such as using fewer check bits, are also known by the same name.

The BB84 QKD protocol

1: Alice chooses $(4+\delta)n$ random data bits.
2: Alice chooses a random $(4+\delta)n$-bit string b. She encodes each data bit as $\{|0\rangle, |1\rangle\}$ if the corresponding bit of b is 0 or $\{|+\rangle, |-\rangle\}$ if b is 1 .
3: Alice sends the resulting state to Bob.
4: Bob receives the $(4+\delta)n$ qubits, announces this fact, and measures each qubit in the X or Z basis at random.
5: Alice announces b.
6: Alice and Bob discard any bits where Bob measured a different basis than Alice prepared. With high probability, there are at least $2n$ bits left (if not, abort the protocol). They keep $2n$ bits.
7: Alice selects a subset of n bits that will to serve as a check on Eve's interference, and tells Bob which bits she selected.
8: Alice and Bob announce and compare the values of the n check bits. If more than an acceptable number disagree, they abort the protocol.
9: Alice and Bob perform information reconciliation and privacy amplification on the remaining n bits to obtain m shared key bits.

Figure 12.13. The four state quantum key distribution protocol known as BB84.

Exercise 12.26: Let a'_k be Bob's measurement result of qubit $|\psi_{a_k b_k}\rangle$, assuming a noiseless channel with no eavesdropping. Show that when $b'_k \neq b_k, a'_k$ is random and completely uncorrelated with a_k. But when $b'_k = b_k, a'_k = a_k$.

Exercise 12.27: (Random sampling tests) The random test of n of $2n$ check bits allows Alice and Bob to place an upper bound on the number of errors in their untested bits, with high probability. Specifically, for any $\delta > 0$, the probability of obtaining less than δn errors on the check bits, and more than $(\delta+\epsilon)n$ errors on the remaining n bits is asymptotically less than $\exp\left[-O\left(\epsilon^2 n\right)\right]$, for large n. We prove this claim here.
(1) Without loss of generality, you may assume that there are μn errors in the $2n$ bits, where $0 \leq \mu \leq 2$. Now, if there are δn errors on the check bits, and $(\delta+\epsilon)n$ errors on the rest, then $\delta = (\mu - \epsilon)/2$. The two conditional statements in the claim thus imply the following:

$$\begin{array}{lcl} < \delta n \text{ errors on check bits} & \Rightarrow & < \delta n \text{ errors on check bits} \\ > (\delta+\epsilon)n \text{ errors on rest} & \Rightarrow & > (\mu-\delta)n \text{ errors on rest} \end{array} \tag{12.185}$$

and in fact, the top claim on the right implies the bottom one on the right.
Using this, show that the probability p which we would like to bound satisfies

$$p < \binom{2n}{n}^{-1} \binom{\mu n}{\delta n} \binom{(2-\mu)n}{(1-\delta)n} \delta n. \tag{12.186}$$

(2) Show that for large n, you can bound

$$\frac{1}{an+1}2^{anH(b/a)} \leq \binom{an}{bn} \leq 2^{anH(b/a)} \tag{12.187}$$

where $H(\cdot)$ is the binary entropy function, Equation (11.8). Apply this to the above bound for p.
(3) Apply the bound $H(x) < 1-2(x-1/2)^2$ to obtain the final result, $p < \exp\left[-O\left(\epsilon^2 n\right)\right]$. You may replace μ by a constant which expresses the worst possible case.
(4) Compare the result with the Chernoff bound, Box 3.4. Can you come up with a different way to derive an upper bound on p ?

The B92 protocol

The BB84 protocol can be generalized to use other states and bases, and similar conclusions hold. In fact, a particularly simple protocol exists in which only two states are used. For simplicity, it is sufficient to consider what happens to a single bit at a time; the description easily generalizes to block tests just as is done in BB 84 .

Suppose Alice prepares one random classical bit a, and, depending on the result, sends Bob

$$|\psi\rangle = \begin{cases} |0\rangle & \text{if } a = 0 \\ \frac{|0\rangle+|1\rangle}{\sqrt{2}} & \text{if } a = 1. \end{cases} \tag{12.188}$$

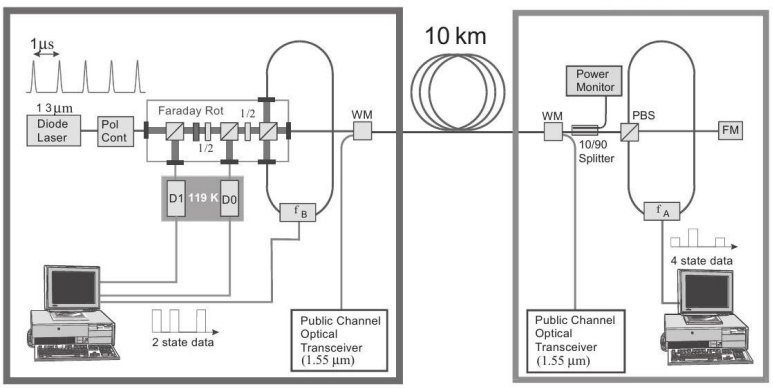
Depending on a random classical bit a' which he generates, Bob subsequently measures the qubit he receives from Alice in either the Z basis $|0\rangle, |1\rangle$ (if $a' = 0$), or in the X basis $|\pm\rangle = (|0\rangle \pm |1\rangle)/\sqrt{2}$ (if $a' = 1$). From his measurement, he obtains the result b, which is 0 or 1 , corresponding to the -1 and +1 eigenstates of X and Z. Bob then publicly announces b (but keeps a' secret), and Alice and Bob conduct a public discussion keeping

Box 12.7: Experimental quantum cryptography

Quantum key distribution is particularly interesting and astonishing because it is easily experimentally realized. Here is a schematic diagram of one system employing commercial fiber-optic components to deliver key bits over a ten kilometer distance, which has been built at IBM:

Alice

Bob



Bob initially generates strong coherent states $|\alpha\rangle$ using a diode laser emitting light at a wavelength of 1.3μ m, and transmits them to Alice, who attenuates them to (approximately)

generate a single photon. She also polarizes the photon in one of the four states of the BB84 protocol, using as $|0\rangle$ and $|1\rangle$ states horizontal and vertical polarization. She then returns the photon to Bob, who measures it using a polarization analyzer, in a random basis. By using this special configuration in which the photon traverses the same path twice, the apparatus can be made to autocompensate for imperfections (such as slowly fluctuating path lengths and polarization shifts) along the fiber link. Alice and Bob then select the subset of results in which they used the same basis, reconcile their information, and perform privacy amplification, communicating over a public channel with photons (over the same fiber) of 1.55 μm wavelength. Key bits can be exchanged at the rate of a few hundred per second. Ultimately, improvements in the light source and detector should allow the rate to be improved by a few orders of magnitude. Quantum key distribution over distances exceeding 40 kilometers, and also in installed telecommunication fiber (under Lake Geneva) has been demonstrated.
only those pairs $\{a, a'\}$ for which $b = 1$. Note that when $a = a'$, then $b = 0$ always. Only if $a' = 1 - a$ will Bob obtain $b = 1$, and that occurs with probability 1/2. The final key is a for Alice, and $1 - a'$ for Bob.

This protocol, known as B92 (see the end of chapter 'History and further reading'), highlights how the impossibility of perfect distinction between non-orthogonal states lies at the heart of quantum cryptography. As in BB84, because it is impossible for any eavesdropper to distinguish between Alice's states without disrupting the correlation between the bits Alice and Bob finally keep, this protocol allows Alice and Bob to created shared
key bits while also placing an upper bound on the noise and eavesdropping during their communication. They can then apply information reconciliation and privacy amplification to extract secret bits from their resulting correlated random bit strings.

Exercise 12.28: Show that when $b = 1$, then a and a' are perfectly correlated with each other.

Exercise 12.29: Give a protocol using six states, the eigenstates of X, Y, and Z, and argue why it is also secure. Discuss the sensitivity of this protocol to noise and eavesdropping, in comparison with that of BB 84 and B 92 .

The EPR protocol

The key bits generated in the BB 84 and B 92 protocols may appear to have been originated by Alice. However, it turns out that the key can be seen to arise from a fundamentally random process involving the properties of entanglement. This is illustrated by the following protocol.

Suppose Alice and Bob share a set of n entangled pairs of qubits in the state

$$\frac{|00\rangle + |11\rangle}{\sqrt{2}} \tag{12.189}$$

These states are known as EPR pairs. Obtaining these states could have come about in many different ways; for example, Alice could prepare the pairs and then send half of each to Bob, or vice versa. Alternatively, a third party could prepare the pairs and send halves to Alice and Bob. Or they could have met a long time ago and shared them, storing them until the present. Alice and Bob then select a random subset of the EPR pairs, and test to see if they violate Bell's inequality (Equation (2.225), on page 115 in Section 2.6), or some other appropriate test of fidelity. Passing the test certifies that they continue to hold sufficiently pure, entangled quantum states, placing a lower bound on the fidelity of the remaining EPR pairs (and thus any noise or eavesdropping). And when they measure these in jointly determined random bases, Alice and Bob obtain correlated classical bit strings from which they can obtain secret key bits as in the B92 and BB84 protocols. Using an argument based on Holevo's bound, the fidelity of their EPR pairs can be used to establish an upper bound on Eve's accessible information about the key bits.

Where do the key bits come from in this EPR protocol? Since it is symmetric - Alice and Bob perform identical tasks on their qubits, even possibly simultaneously - it cannot be said that either Alice or Bob generates the key. Rather, the key is truly random. In fact the same applies to the BB84 protocol, since it can be reduced to an instance of a generalized version of the EPR protocol. Suppose that Alice prepares a random classical bit b, and according to it, measures her half of the EPR pair in either the $|0\rangle, |1\rangle$ basis, or in the basis $|\pm\rangle = (|0\rangle \pm |1\rangle)/\sqrt{2}$, obtaining a. Let Bob do identically, measuring in (his randomly chosen) basis b' and obtaining a'. Now they communicate b and b' over a public classical channel, and keep as their key only those $\{a, a'\}$ for which $b = b'$. Note that this key is undetermined until Alice or Bob performs a measurement on their EPR pair half. Similar observations can be made about the B92 protocol. For this reason, quantum cryptography is sometimes thought of not as secret key exchange or transfer, but rather as secret key generation, since fundamentally neither Alice nor Bob can pre-determine the key they will ultimately end up with upon completion of the protocol.

9.5.23 12.6.4 Privacy and coherent information

Thus far, we have described the basic protocol for QKD and argued that it is secure, but we have not provided quantitative bounds. How secure is it? It turns out there is an interesting and fundamental connection between the basic quantitative measures of quantum information discussed in this chapter, and the in-principle obtainable security of quantum cryptography, which we describe below.

The quantum coherent information $I(\rho, \mathcal{E})$ gives a lower bound on the ability of a quantum channel to send private information. In the most general circumstance, Alice prepares states ρ_k^A, where $k = 0, 1, \ldots$ denotes the different possible states she may send, each with some probability p_k. Bob receives states $\rho_k^B = \mathcal{E}\left(\rho_k^A\right)$ which may be different from ρ_k^A because of channel noise or an eavesdropper, Eve. The mutual information between the result of any measurement Bob may do, and Alice's value k, H_{bobalice} , is bounded above by Holevo's bound, (12.6),

$$H_{\text{bob:alice}} \leq \chi^B = S\left(\rho^B\right) - \sum_k p_k S\left(\rho_k^B\right) \tag{12.190}$$

where $\rho^B = \sum_k p_k \rho_k^B$. Similarly, Eve's mutual information is bounded above,

$$H_{\text{eve:alice}} \leq \chi^E = S\left(\rho^E\right) - \sum_k p_k S\left(\rho_k^E\right) \tag{12.191}$$

Since any excess information Bob has relative to Eve (at least above a certain threshold) can in principle be exploited by Bob and Alice to distill a shared secret key using techniques such as privacy amplification, it makes sense to define the quantity

$$\mathcal{P} = \sup\left[H_{\text{bob:alice}} - H_{\text{eve:alice}}\right] \tag{12.192}$$

as the guaranteed privacy of the channel, where the supremum is taken over all strategies Alice and Bob may employ to use the channel. This is the maximum excess classical information that Bob may obtain relative to Eve about Alice's quantum signal. By the HSW theorem, Alice and Bob can employ a strategy such that $H_{\text{bob:alice}} = \chi^B$, while for any strategy Eve may employ, $H_{\text{eve:alice}} \leq \chi^E$. Thus, $\mathcal{P} \geq \chi^B - \chi^E$, for a suitable choice of strategy.

From Exercise 12.11, it follows that a lower bound on the privacy $\mathcal{P}$ can be obtained by assuming that all of Alice's signal states $\rho_k^A = \left|\psi_k^A\right\rangle\left\langle\psi_k^A\right|$ are pure states, which are initially unentangled with Eve, who starts out in some state $\left|0^E\right\rangle$ (that may also be assumed to be pure, without loss of generality). In general, the channel from Alice to Bob will include interactions

with some environment other than Eve, but to give Eve the greatest possible advantage, all such interactions may be attributed to her, such that the final joint state received by Eve and Bob after transmission is

$$\left|\psi^{EB}\right\rangle = U\left|\psi_k^A\right\rangle\left|0^E\right\rangle. \tag{12.193}$$

Since this is a pure state, the reduced density matrices ρ_k^E and ρ_k^B will have the same non-zero eigenvalues, and thus the same entropies, $S\left(\rho_k^E\right) = S\left(\rho_k^B\right)$. Thus,

$$\begin{aligned}
\mathcal{P} &\geq \chi^B - \chi^E && (12.194)\\
&= S\left(\rho^B\right) - \sum_k p_k S\left(\rho_k^B\right) - S\left(\rho^E\right) + \sum_k p_k S\left(\rho_k^E\right) && (12.195)\\
&= S\left(\rho^B\right) - S\left(\rho^E\right) && (12.196)\\
&= I(\rho, \mathcal{E}). && (12.197)
\end{aligned}$$

That is, a lower bound on the guaranteed privacy of the channel $\mathcal{E}$ is given by the quantum coherent information $I(\rho, \mathcal{E})$, as defined in Equation (12.118). Note that this result is not specific to any protocol (which may have its own security flaws). Also, the protocol must perform tests, which are not considered in this calculation, to actually determine properties of the channel $\mathcal{E}$, after which this bound can be applied. So although the information-theoretic bound we have arrived at here is quite elegant, we still have a way to go before being able to quantify the security of QKD!

9.5.24 12.6.5 The security of quantum key distribution

How secure is quantum key distribution? Because of the inevitability of disturbance of the communicated state, upon information gain by an eavesdropper, we have good reason to believe in the security of QKD. What we need, however, to conclude that the protocol truly is secure, is a quantifiable definition of security which explicitly bounds Eve's knowledge about the final key, given some measure of Alice and Bob's effort. The following criterion is acceptable:

> A QKD protocol is defined as being secure if, for any security parameters $s > 0$ and $\ell > 0$ chosen by Alice and Bob, and for any eavesdropping strategy, either the scheme aborts, or it succeeds with probability at least $1 - O\left(2^{-s}\right)$, and guarantees that Eve's mutual information with the final key is less than $2^{-\ell}$. The key string must also be essentially random.

In this final section, we give the main elements of a proof that BB 84 is secure. This proof serves as a fitting conclusion to the chapter, because of its elegant use of many concepts of quantum information in providing an argument that is sufficiently simple and transparent so as to be incontestable. The origin of this proof, intriguingly, comes from the observation that after information reconciliation and privacy amplification are performed, the ultimately obtainable key rate turns out to coincide with the achievable qubit transmission rate for CSS codes (Section 10.4.2) over noisy communication channels!

Here is the main idea, in outline. It is relatively straightforward to exhaustively establish that the BB84, B92, and EPR protocols are secure if Eve can only attack the transmission one qubit at a time. The difficulty lies in dealing with the possibility of collective attacks, in which Eve manipulates and possibly stores large blocks of the transmitted qubits. To address this, we need a more general and powerful argument. Suppose we somehow know that Eve

never introduces more than t qubit errors per block. Then Alice could encode her qubits in a t error-correcting quantum code, such that all of Eve's meddling could be removed by Bob decoding the code. Two things must be established to make this feasible: first, how can an upper bound be placed on t ? This turns out to be possible by sampling the channel in the appropriate manner, leaving us with a protocol which is secure, even against collective attacks! Unfortunately, this protocol generally requires a fault-tolerant quantum computer in order to encode and decode qubits robustly. The second challenge is thus to choose a quantum code such that the full sequence of encoding, decoding, and measurement can be performed using no quantum computation or storage - just single qubit preparation and measurement. Using CSS codes does the trick (after some simplification), and in fact gives just the BB 84 protocol. Below, we begin with a manifestly secure EPR pair based QKD protocol, and then apply solutions to the two challenges to systematically simplify the initial protocol into BB84.

Requirements for a secure QKD protocol

Suppose that Alice has n pairs of entangled qubits, each in the state

$$|\beta_{00}\rangle = \frac{|00\rangle + |11\rangle}{\sqrt{2}}. \tag{12.198}$$

Denote this state as $|\beta_{00}\rangle^{\otimes n}$. Alice then transmits half of each pair to Bob; because of noise and eavesdropping on the channel, the resulting state may be impure, and can be described as the density matrix ρ. Alice and Bob then perform local measurements to obtain a key, as described previously. The following Lemma can be used to show that the fidelity of ρ with respect to $|\beta_{00}\rangle^{\otimes n}$ places an upper bound on the mutual information Eve has with the key.

Lemma 12.19: (High fidelity implies low entropy) If $F\left(\rho, |\beta_{00}|^{\otimes n}\right)^2 > 1 - 2^{-s}$, then $S(\rho) < (2n + s + 1/\ln 2)2^{-s} + O\left(2^{-2s}\right)$.

Proof

If $F\left(\rho, |\beta_{00}\rangle^{\otimes n}\right)^2 = {}^{\otimes n}\langle\beta_{00}|\,\rho\,|\beta_{00}\rangle^{\otimes n} > 1 - 2^{-s}$, then the largest eigenvalue of ρ must be larger than $1 - 2^{-s}$. Therefore, the entropy of ρ is bounded above by the entropy of a diagonal density matrix $\rho_{\max}$ with diagonal entries $1 - 2^{-s}, 2^{-s}/\left(2^{2n} - 1\right), 2^{-s}/\left(2^{2n} - 1\right), \ldots, 2^{-s}/\left(2^{2n} - 1\right)$, that is, $\rho_{\max}$ has a large entry $1 - 2^{-s}$, and the remaining probability is distributed equally among the remaining $2^{2n} - 1$ entries. Since

$$S\left(\rho_{\max}\right) = -\left(1 - 2^{-s}\right)\log\left(1 - 2^{-s}\right) - 2^{-s}\log\frac{2^{-s}}{2^{2n} - 1} \tag{12.199}$$

the desired result follows.

By Holevo's bound (12.6), $S(\rho)$ is an upper bound on the information accessible to Eve, resulting from Alice and Bob's measurements of ρ. This implies that if a QKD protocol can provide Alice and Bob with EPR pairs of fidelity at least $1 - 2^{-s}$ (with high probability), then it is secure.

Exercise 12.30: Simplify (12.199) to obtain the expression for $S(\rho)$ given in the statement of the Lemma.

Exercise 12.31: It may be unclear why $S(\rho)$ bounds Eve's mutual information with Alice and Bob's measurement results. Show that this follows from assuming the worst about Eve, giving her all the control over the channel.

Random sampling can upper-bound eavesdropping

How can a protocol place a lower bound on the fidelity of Alice and Bob's EPR pairs? The key idea is a classical argument, based on random sampling, which we encountered in the description of the BB84 protocol (Exercise 12.27). Arguments based on classical probability, however, need not apply when considering outcomes of quantum measurements. This is vividly demonstrated by Bell's inequality (Section 2.6). On the other hand, quantum experiments do allow a classical interpretation whenever measurement observables that refer to only one basis are considered. And fortunately, it happens that measurements in only one basis are required for Alice and Bob to bound the fidelity of their EPR pairs.

According to (10.14), a qubit transmitted through a noisy quantum channel can be described as having had one of four things happen to it: nothing (I), a bit flip (X), a phase flip (Z), or a combined bit and phase flip (Y). Recall that the Bell basis is defined by the four states

$$|\beta_{00}\rangle = \frac{|00\rangle + |11\rangle}{\sqrt{2}}, \quad |\beta_{10}\rangle = \frac{|00\rangle - |11\rangle}{\sqrt{2}}, \quad |\beta_{01}\rangle = \frac{|01\rangle + |10\rangle}{\sqrt{2}}, \quad |\beta_{11}\rangle = \frac{|01\rangle - |10\rangle}{\sqrt{2}}. \tag{12.200}$$

Let the second qubit in each pair be the one that Alice sends to Bob. If a bit flip error occurs to this qubit, then $|\beta_{00}\rangle$ is transformed into $|\beta_{01}\rangle$. Similarly, a phase flip gives $|\beta_{10}\rangle$, and a combination of the two errors gives $|\beta_{11}\rangle$ (up to irrelevant overall phases). A natural measurement which detects if a bit flip has occurred is given by projectors $\Pi_{\rm bf} = |\beta_{01}\rangle\langle\beta_{01}| + |\beta_{11}\rangle\langle\beta_{11}|$ and $I - \Pi_{\rm bf}$, and likewise, the measurement described by projectors $\Pi_{\rm pf} = |\beta_{10}\rangle\langle\beta_{10}| + |\beta_{11}\rangle\langle\beta_{11}|$ and $I - \Pi_{\rm pf}$ detects phase flips. Since both these measurements commute with the Bell basis, their outcomes obey classical probability arguments. In fact, any measurement which commutes with the Bell basis will also satisfy the same classical arguments.

More precisely, Alice and Bob and can bound the fidelity of their EPR pairs by randomly sampling a subset of them. Suppose Alice sends $2n$ EPR pair halves to Bob. They subsequently randomly select n of them and check these qubits by jointly measuring either $\Pi_{\rm bf}$ or $\Pi_{\rm pf}$ (again, chosen randomly). By the same classical arguments used in the random sampling tests in BB 84 (Exercise 12.27), if δn bit or phase flip errors are detected, then the remaining n EPR pairs would be exponentially certain to have the same number of errors, were they also to be measured in the Bell basis.

Bell states are nonlocal, and generally measurements in the Bell basis require nonlocal operations, which can be difficult. Fortunately, however, they are not required in the present scheme, because $\Pi_{\rm bf} = (I \otimes I - Z \otimes Z)/2$, and $\Pi_{\rm pf} = (I \otimes I - X \otimes X)/2$. Thus, Alice and Bob can perform the desired checks with local measurements of Pauli operators, either by both measuring Z, or both measuring X.

Exercise 12.32: Note that the local measurements that Alice and Bob perform, such as $I \otimes X$ and $X \otimes I$, do not commute with the Bell basis. Show that despite this, the statistics which Alice and Bob compile from their measurements are the same as those which they would have obtained had they actually measured $\Pi_{\rm bf}$ and Π_{pf}.

The modified Lo-Chau protocol

Random sampling in the Bell basis thus provides Alice and Bob with EPR pairs ρ with known fidelity to the ideal state $|\beta_{00}\rangle^{\otimes n}$, and as previously discussed, this bounds Eve's mutual information with any measurements that might be performed on ρ. For ρ to be useful for key generation, however, Alice and Bob must reduce Eve's mutual information with their state until it is exponentially small. This task can be achieved by applying classical privacy amplification to their measurement results. Equivalently, Alice and Bob can first perform entanglement distillation, as introduced in Section 12.5.2, to obtain ρ' which is very close to $|\beta_{00}\rangle^{\otimes m}$ for some

$m < n$, then measure the final state. This sort of 'quantum privacy amplification' will be useful to us.

A rough argument is as follows. Entanglement distillation can be accomplished by performing quantum error-correction. Since ρ is nearly certain to have δn errors, encoding these qubits in a δn correcting quantum error-correction code allows up to δn errors to be perfectly corrected. As we saw in Sections 10.5.5 and 10.5.8, if an $[n, m]$ stabilizer code is used, then encoding, syndrome measurement and error recovery can be performed by measurements of Pauli operators determined by the rows of the check matrix for the code. Alice and Bob simply perform identical measurements and recovery operations on their respective n qubit halves of ρ, producing an error-corrected state which has a fidelity relative to $|\beta_{00}\rangle^{\otimes m}$ that is on the order of one minus the the probability of more than δn errors occurring. By construction, the syndrome measurements turn out to commute with the Bell basis, since Alice and Bob perform identical tasks.

Putting the random sampling and entanglement distillation pieces together gives us the modified Lo-Chau protocol, presented in Figure 12.14. A few notes about this protocol are in order. The random Hadamard transforms performed in steps 3 and 7 create a symmetry in Eve's strategy between detecting information encoded in the X and Z bases (and thus causing X and Z errors). They also enable random selection of a measurement of $\Pi_{\rm bf}$ or $\Pi_{\rm pf}$ on the check qubits. The specific procedure employed in step 9 can be justified for the case of any stabilizer code, as in Exercise 12.34. The Gilbert-Varshamov bound for CSS codes, Equation (10.74), shows that good quantum codes exist for large block lengths, so that n can be chosen sufficiently large that for a δn error-correcting $[\ n, m\ ]$ quantum code, the criteria for security can be satisfied.

QKD protocol: modified Lo-Chau

1: Alice creates $2n$ EPR pairs in the state $|\beta_{00}\rangle^{\otimes 2n}$.
2: Alice randomly selects n of the $2n$ EPR pairs to serve as checks to check for Eve's interference. She does not do anything with them yet.
3: Alice selects a random $2n$-bit string b, and performs a Hadamard transform on the second qubit of each pair for which b is 1 .
4: Alice sends the second qubit of each pair to Bob.
5: Bob receives the qubits and publicly announces this fact.
6: Alice announces b and which n qubits are to provide check bits.
7: Bob performs Hadamards on the qubits where b is 1 .
8: Alice and Bob each measure their n check qubits in the $|0\rangle, |1\rangle$ basis, and publicly share the results. If more than t of these disagree, they abort the protocol.
9: Alice and Bob measure their remaining n qubits according to the check matrix for a predetermined $[n, m]$ quantum code correcting up to t errors. They share the results, compute the syndromes for the errors, and then correct their state, obtaining m nearly perfect EPR pairs.
10: Alice and Bob measure the m EPR pairs in the $|0\rangle, |1\rangle$ basis to obtain a shared secret key.

Figure 12.14. A QKD protocol which is secure, by virtue of use of perfect quantum computers, error-correction, and random testing of EPR pairs.

Exercise 12.33: Let $\{M_1, M_2, \ldots, M_n\}$ be a set of measurement observables which produce respective results X_i when an input state ρ is measured. Argue that the random variables X_i obey classical probability arguments if $[M_i, M_j] = 0$, that is, they commute with each other.

Exercise 12.34: (Entanglement distillation by error-correction) In
Section 10.5.8, we saw that codewords of an $[n, m]$ qubit stabilizer code can be constructed by measuring its generators $g_1, \ldots, g_{n-m}$ on an arbitrary n qubit quantum state, then applying Pauli operations to change the result to be a simultaneous $+1$ eigenstate of the generators.

Using that idea, show that if we start out with n EPR pairs in the state $|\beta_{00}\rangle^{\otimes n}$, and perform identical generator measurements on the two n qubit halves of the pairs, followed by Pauli operations to correct for differences in the measurement results between the pairs, then we obtain an encoded $|\beta_{00}\rangle^{\otimes m}$ state. Also show that if the stabilizer code corrects up to δn errors, then even if δn errors are suffered by an n qubit half, we still obtain $|\beta_{00}\rangle^{\otimes m}$.

A quantum error-correction protocol

The modified Lo-Chau protocol makes use of quantum error-correction to perform entanglement distillation, and is built essentially upon the EPR protocol. Entanglement is a frail resource, and quantum error-correction generally requires robust quantum computers, which are challenging to realize. Fortunately, however, this protocol can be systematically simplified in a series of steps, each of which provably does not compromise the security of the scheme. Let us begin by removing the need to distribute EPR pairs.

Note that the measurements which Alice perform at the end of the modified Lo-Chau protocol can be performed at the very start, with no change in any of the states held by the rest of the world. Alice's measurements of her halves of the check EPR pairs in step 8 collapse the pairs into n single qubits, so instead of sending entangled states, Alice can simply send single qubits. This gives us the modified steps
$1'$: Alice creates n random check bits, and n EPR pairs in the state $|\beta_{00}\rangle^{\otimes n}$. She also encodes n qubits as $|0\rangle$ or $|1\rangle$ according to the check bits.
$2'$: Alice randomly chooses n positions (out of $2n$) and puts the check qubits in these positions and half of each EPR pair in the remaining positions.
$8'$: Bob measures the n check qubits in the $|0\rangle, |1\rangle$ basis, and publicly shares the results with Alice. If more than t of these disagree, they abort the protocol.

Similarly, Alice's measurements in steps 9 and 10 collapse EPR pairs into random qubits encoded in a random quantum code. This can be seen in the following manner. A particularly convenient choice of code, which we shall employ for the remainder of this section, is an $[n, m]$ CSS code of C_1 over C_2, $\mathrm{CSS}\,(C_1, C_2)$, which encodes m qubits in n qubits and corrects up to t errors. Recall from Section 10.4.2 that for this code, H_1 and $H_2^{\perp}$ are the parity check matrices corresponding to the classical codes C_1 and $C_2^{\perp}$, in which each of the codeword states is

$$\frac{1}{\sqrt{|C_2|}} \sum_{w \in C_2} |v_k + w\rangle\,, \tag{12.201}$$

for v_k being a representative of one of the 2^m cosets of C_2 in C_1 (the notation v_k is chosen to suggest a vector v indexed by a key string k). Also recall that there exists a family of codes equivalent to this one, $\mathrm{CSS}_{z,x}\,(C_1, C_2)$, with codeword states

$$|\xi_{v_k,z,x}\rangle = \frac{1}{\sqrt{|C_2|}} \sum_{w \in C_2} (-1)^{z \cdot w} |v_k + w + x\rangle \tag{12.202}$$

These states form an orthonormal basis for a 2^n-dimensional Hilbert space (see Exercise 12.35), and thus we may write Alice's n EPR pair state as

$$|\beta_{00}\rangle^{\otimes n} = \sum_{j=0}^{2^n} |j\rangle|j\rangle = \sum_{v_k,z,x} |\xi_{v_k,z,x}\rangle\, |\xi_{v_k,z,x}\rangle \tag{12.203}$$

Note that in this expression, we have separated the labels into two kets, where the first denotes the qubits Alice keeps, and the second, the qubits which are sent to Bob. When Alice measures the stabilizer generators corresponding to H_1 and $H_2^{\perp}$ on her qubits in step 9, she obtains random values for x and z, and similarly, her final measurement in step 10 gives her

a random choice of v_k. The remaining n qubits are thus left in the state $|\xi_{v_k,z,x}\rangle$, which is the codeword for v_k in $\mathrm{CSS}_{z,x}(C_1, C_2)$. This is just the encoded counterpart of a 2^m qubit state $|k\rangle$. Therefore, as claimed above, Alice's measurements produce random qubits encoded in a random code.

Thus, instead of sending halves of EPR pairs, Alice can equivalently randomly choose x, z, and k, then encode $|k\rangle$ in the code $\mathrm{CSS}_{z,x}(C_1, C_2)$, and send Bob the encoded n qubits. This gives us the modified steps

$1''$: Alice creates n random check bits, a random m bit key k, and two random n bit strings x and z. She encodes $|k\rangle$ in the code $\mathrm{CSS}_{z,x}(C_1, C_2)$. She also encodes n qubits as $|0\rangle$ or $|1\rangle$ according to the check bits.

$2''$: Alice randomly chooses n positions (out of $2n$) and puts the check qubits in these positions and encoded qubits in the remaining positions.

6′ : Alice announces b, x, z, and which n qubits are to provide check bits.

9': Bob decodes the remaining n qubits from $\mathrm{CSS}_{z,x}(C_1, C_2)$.

10′ : Bob measures his qubits to obtain the shared secret key k.

The resulting scheme, known as the CSS codes protocol, is shown in Figure 12.15.

Exercise 12.35: Show that the states $|\xi_{v_k,z,x}\rangle$ defined in (12.202) form an orthonormal basis for a 2^n-dimensional Hilbert space, that is,

$$\sum_{v_k,z,x} |\xi_{v_k,z,x}\rangle \langle \xi_{v_k,z,x}| = I \tag{12.204}$$

Hint: for C_1 an $[n, k_1]$ code, C_2 an $[n, k_2]$ code, and $m = k_1 - k_2$, note that there are 2^m distinct values of v_k, 2^{n-k_1} distinct x, and 2^{k_2} distinct z.

Exercise 12.36: Verify Equation (12.203).

Exercise 12.37: This is an alternative way to understand why Alice's measurements in steps 9 and 10 collapse EPR pairs into random qubits encoded in a random quantum code. Suppose Alice has an EPR pair $(|00\rangle + |11\rangle)/\sqrt{2}$. Show that if she measures the first qubit in the X basis, then the second qubit collapses into an eigenstate of X determined by the measurement result. Similarly, show that if

she measures in the Z basis, then the second qubit is left in a Z eigenstate labeled by the measurement result. Using this observation and the results of Section 10.5.8, conclude that Alice's measurements of $H_1, H_2^{\perp}$, and $\bar{Z}$ on her EPR pair halves result in a random codeword of $\mathrm{CSS}_{z,x}(C_1, C_2)$ determined by her measurement results.

QKD protocol: CSS codes

$1''$: Alice creates n random check bits, a random m bit key k, and two random n bit strings x and z. She encodes $|k\rangle$ in the code $\mathrm{CSS}_{z,x}(C_1, C_2)$. She also encodes n qubits as $|0\rangle$ or $|1\rangle$ according to the check bits.

$2''$: Alice randomly chooses n positions (out of $2n$) and puts the check qubits in these positions and the encoded qubits in the remaining positions.

3: Alice selects a random $2n$-bit string b, and performs a Hadamard transform on each qubit for which b is 1 .

4: Alice sends the resulting qubits to Bob.

5: Bob receives the qubits and publicly announces this fact.

$6'$: Alice announces b, x, z, and which n qubits are to provide check bits.

7: Bob performs Hadamards on the qubits where b is 1 .

$8'$: Bob measures the n check qubits in the $|0\rangle, |1\rangle$ basis, and publicly shares the results with Alice. If more than t of these disagree, they abort the protocol.

9': Bob decodes the remaining n qubits from $\mathrm{CSS}_{z,x}(C_1, C_2)$.

10′ : Bob measures his qubits to obtain the shared secret key k.

Figure 12.15. A QKD protocol which is secure, by virtue of simplification of the modified Lo-Chau protocol via CSS codes.

Reduction to BB84

The CSS codes QKD protocol is secure by virtue of direct reduction from the modified Lo-Chau protocol, and is much simpler because it does not make any evident use of EPR pairs. Unfortunately, it is still unsatisfactory, because it requires perfect quantum computation to perform the encoding and decoding (instead of just single qubit preparation and measurements), and Bob needs to temporarily store qubits in a quantum memory while waiting for communication from Alice. The use of CSS codes, however, enables these two requirements to be removed, essentially because they decouple phase flip correction from bit flip correction.

First, note that Bob measures his qubits in the Z basis immediately after decoding; thus, the phase correction information Alice sends as z is unnecessary. Thus, since C_1 and C_2 are classical codes, instead of decoding then measuring, he can immediately measure to obtain $v_k + w + x + \epsilon$ (where ϵ represents some possible error, due to the channel and to Eve), then decode classically: he subtracts Alice's announced value of x, then corrects the result to a codeword in C_1, which is definitely $v_k + w$, if the distance of the code is
not exceeded. The final key k is the coset of v_k+w+C_2 in C_1 (see Appendix 2 for an explanation of cosets, and this notation). This gives us:
$\mathbf{9}''$: Bob measures the remaining qubits to get $v_k + w + x + \epsilon$, and subtracts x from the result, correcting it with code C_1 to obtain $v_k + w$.
$10''$: Bob computes the coset of $v_k + w + C_2$ in C_1 to obtain the key k.
Second, since Alice need not reveal z, the state she effectively sends is a mixed state, averaged over random values of z,

$$\rho_{v_k,x} = \frac{1}{2^n} \sum_z |\xi_{v_k,z,x}\rangle \langle \xi_{v_k,z,x}| \tag{12.205}$$

$$= \frac{1}{2^n |C_2|} \sum_z \sum_{w_1,w_2 \in C_2} (-1)^{z\cdot(w_1+w_2)} |v_k + w_1 + x\rangle \langle v_k + w_2 + x| \tag{12.206}$$

$$= \frac{1}{|C_2|} \sum_{w \in C_2} |v_k + w + x\rangle \langle v_k + w + x| \tag{12.207}$$

This state is simple to create: Alice need only classically choose $w \in C_2$ at random, and construct $|v_k + w + x\rangle$, using her randomly determined x and k. We thus have:
$1'''$: Alice creates n random check bits, a random n bit string x, a random $v_k \in C_1/C_2$, and a random $w \in C_2$. She encodes n qubits in the state $|0\rangle$ or $|1\rangle$ according to $v_k + w + x$, and similarly, n qubits according to the check bits.

Steps $\mathbf{1}'''$ and $\mathbf{9}''$ can be simplified further, by changing step $\mathbf{6}'$ slightly. Currently, Alice sends $|v_k + w + x\rangle$, Bob receives and measures to obtain $v_k + w + x + \epsilon$, then Alice sends x, which Bob subtracts to obtain $v_k + w + \epsilon$. But if Alice chooses $v_k \in C_1$ (as opposed to C_1/C_2), then w is unnecessary. Moreover, $v_k + x$ is then a completely random n bit string, and instead of the above protocol, it is equivalent if Alice chooses x at random, sends $|x\rangle$, Bob receives and measures to obtain $x + \epsilon$, then Alice sends $x - v_k$, which Bob subtracts to obtain $v_k + \epsilon$. Now, there is no difference between the random check bits and the code bits! This gives us:
$1''''$: Alice chooses a random $v_k \in C_1$, and creates $2n$ qubits in the state $|0\rangle$ or $|1\rangle$ according to $2n$ random bits.
$2'''$: Alice randomly chooses n positions (out of $2n$) and designates these as the check qubits, and the remainder as $|x\rangle$.

6″ : Alice announces $b, x - v_k$, and which n qubits are to provide check bits.
9‴ : Bob measures the remaining qubits to get $x + \epsilon$, and subtracts $x - v_k$ from the result, correcting it with code C_1 to obtain v_k.
10″ : Alice and Bob compute the coset of $v_k + C_2$ in C_1 to obtain the key k.
Next, note that Alice need not perform Hadamard operations (although in practice, single qubit operations are not so difficult to accomplish with photons). She can instead encode her qubits directly in either the $|0\rangle, |1\rangle(Z)$ basis or in the $|+\rangle, |-\rangle(X)$ basis, depending on the bits of b :
1⁗ : Alice creates $(4 + \delta)n$ random bits. For each bit, she creates a qubit in either the $|0\rangle, |1\rangle$ basis, or the $|+\rangle, |-\rangle$ basis, according to a random bit string b.

We are almost done: encoding and decoding are now performed classically. The remaining problem is to remove the need for a quantum memory. To solve this problem, suppose that Bob goes ahead and measures immediately after receiving qubits from Alice, choosing randomly to measure in either the X or Z bases. When Alice subsequently announces b, they can keep only those bits for which their bases happened to be the same. This allows Bob to do away completely with his quantum storage device. Note that with high probability they discard half their bits, so in order to obtain the same number of key bits as before, they should start with a little (say, δ) more than twice the number of original random bits. Of course, Alice now must delay her choice of which bits are to be check bits, until after the discarding step. This gives us the final protocol, shown in Figure 12.16. This protocol is exactly the same as BB84, with only minor cosmetic differences. Note how the use of the classical code C_1 performs information reconciliation, and computing the coset of $v_k + C_2$ in C_1 performs privacy amplification (see Section 12.6.2).

QKD protocol: Secure BB84

1: Alice creates $(4 + \delta)n$ random bits.
2: For each bit, she creates a qubit in either the Z basis, or the X basis, according to a random bit string b.
3: Alice sends the resulting qubits to Bob.
4: Alice chooses a random $v_k \in C_1$.
5: Bob receives the qubits, publicly announces this fact, and measures each in the Z or X bases at random.
6: Alice announces b.
7: Alice and Bob discard those bits Bob measured in a basis other than b. With high probability, there are at least $2n$ bits left; if not, abort the protocol. Alice decides randomly on a set of $2n$ bits to continue to use, randomly selects n of these to be check bits, and announces the selection.
8: Alice and Bob publicly compare their check bits. If more than t of these disagree, they abort the protocol. Alice is left with the n bit string x, and Bob with $x + \epsilon$.
9: Alice announces $x - v_k$. Bob subtracts this from his result, correcting it with code C_1 to obtain v_k.
10: Alice and Bob compute the coset of $v_k + C_2$ in C_1 to obtain the key k.

Figure 12.16. The final QKD protocol arrived at by systematic reduction of the CSS codes protocol, which is exactly the same as BB 84 (up to minor cosmetic differences). For clarity, we have dropped the ' notation.

In summary, we have systematically proven the security of the BB84 quantum key distribution protocol, by starting with a manifestly secure scheme requiring perfect quantum computation and quantum memories, and systematically reducing it to BB84. By virtue of having only made modifications which manifestly leave Eve's quantum state (conditioned on all revealed classical information) unchanged, we conclude that BB84 is secure. Naturally, there are some caveats. This proof only applies to an ideal situation, where the states sent are those described.

In practice, qubit sources are imperfect; for example,
such sources are often lasers attenuated to approximately generate single photons, representing qubits (as described in Section 7.4.1). Furthermore, the proof does not place any bounds on the amount of effort Alice and Bob must go to in decoding; for practical key distribution, C_1 must be efficiently decodable. This proof also does not provide an upper bound on the tolerable eavesdropping; it utilizes CSS codes, which are not optimal. It is estimated that a rate of bit and phase errors up to 11% is acceptable using a protocol similar to BB84, but with the aid of quantum computers to encode and decode, higher error rates may be tolerable. The ultimate capability of quantum cryptography is an interesting open issue, and we expect such fundamental questions about the physical limits of computation and communication to continue to intrigue and challenge researchers in the future.

Exercise 12.38: Show that if you had the ability to distinguish non-orthogonal states, then it would be possible to compromise the security of BB84, and indeed, all of the QKD protocols we have described.

Problem 12.1: In this problem we will work through an alternate proof of the Holevo bound. Define the Holevo chi quantity,

$$\chi \equiv S(\rho) - \sum_x p_x S(\rho_x) \tag{12.208}$$

(1) Suppose the quantum system consists of two parts, A and B. Show that

$$\chi_A \leq \chi_{AB} \tag{12.209}$$

(Hint: Introduce an extra system which is correlated with AB, and apply strong subadditivity.)
(2) Let $\mathcal{E}$ be a quantum operation. Use the previous result to show that

$$\chi' \equiv S(\mathcal{E}(\rho)) - \sum_x p_x S(\mathcal{E}(\rho_x)) \leq \chi \equiv S(\rho) - \sum_x p_x S(\rho_x) \tag{12.210}$$

That is, the Holevo chi quantity decreases under quantum operations. This is an important and useful fact in its own right.
(3) Let E_y be a set of POVM elements. Augment the quantum system under consideration with an 'apparatus' system, M, with an orthonormal basis $|y\rangle$. Define a quantum operation by

$$\mathcal{E}(\rho \otimes |0\rangle\langle 0|) \equiv \sum_y \sqrt{E_y}\rho\sqrt{E_y} \otimes |y\rangle\langle y|, \tag{12.211}$$

where $|0\rangle$ is some standard pure state of M. Prove that after the action of $\mathcal{E}$, $\chi_M = H(X : Y)$. Use this and the previous two results to show that

$$H(X : Y) \leq S(\rho) - \sum_x p_x S(\rho_x) \tag{12.212}$$

which is the Holevo bound.
Problem 12.2: This result is an extension of the previous problem. Provide a proof of the no-cloning theorem by showing that a cloning process for non-orthogonal pure states would necessarily increase χ.

Problem 12.3: For a fixed quantum source and rate $R > S(\rho)$, design a quantum circuit implementing a rate R compression scheme.

Problem 12.4: (Linearity forbids cloning) Suppose we have a quantum machine with two slots, A and B. Slot A, the data slot, starts out in an unknown quantum state ρ. This is the

state to be copied. Slot B, the target slot, starts out in some standard quantum state, σ. We will assume that any candidate copying procedure is linear in the initial state,

$$\rho \otimes \sigma \rightarrow \mathcal{E}(\rho \otimes \sigma) = \rho \otimes \rho, \tag{12.213}$$

where $\mathcal{E}$ is some linear function. Show that if $\rho_1 \neq \rho_2$ are density operators such that

$$\mathcal{E}(\rho_1 \otimes \sigma) = \rho_1 \otimes \rho_1 \tag{12.214}$$

$$\mathcal{E}(\rho_2 \otimes \sigma) = \rho_2 \otimes \rho_2 \tag{12.215}$$

then any mixture of ρ_1 and ρ_2 is not copied correctly by this procedure.

Problem 12.5: (Classical capacity of a quantum channel - Research) Is the product state capacity (12.71) the true capacity of a noisy quantum channel for classical information, that is, the capacity when entangled inputs to the channel are allowed?

Problem 12.6: (Methods for achieving capacity - Research) Find an efficient construction for codes achieving rates near the product state capacity (12.71) of a noisy quantum channel for classical information.

Problem 12.7: (Quantum channel capacity - Research) Find a method to evaluate the capacity of a given quantum channel $\mathcal{E}$ for the transmission of quantum information.

9.5.25 Summary of Chapter 12: Quantum information theory

- No-cloning: No quantum device can be constructed which outputs $|\psi\rangle|\psi\rangle$, given $|\psi\rangle$, for arbitrary $|\psi\rangle$.
- Holevo's bound: The maximum accessible classical information when trying to distinguish between quantum states ρ_x sent with probability distribution p_x is

$$H(X:Y) \leq \chi \equiv S\left(\sum_x p_x \rho_x\right) - \sum_x p_x S(\rho_x)$$

- Schumacher's quantum noiseless channel coding theorem: $S(\rho)$ can be interpreted as the number of qubits needed to faithfully represent a quantum source described by ρ.
- The Holevo-Schumacher-Westmoreland theorem: The capacity of a noisy quantum channel $\mathcal{E}$ for classical information is given by:

$$C(\mathcal{E}) = \max_{\{p_x, |\psi_x\rangle\}} S\left(\sum_x p_x \mathcal{E}(|\psi_x\rangle\langle\psi_x|)\right) - \sum_x p_x S(\mathcal{E}(|\psi_x\rangle\langle\psi_x|)) \tag{12.216}$$

- Majorization condition for entanglement transformation: Alice and Bob can transform $|\psi\rangle$ to $|\varphi\rangle$ by local operations and classical communication if and only if $\lambda_\psi \prec \lambda_\varphi$, where λ_ψ is a vector of the eigenvalues of the reduced density matrix of $|\psi\rangle$ (similarly for λ_φ).
- Pure state entanglement distillation and dilution: Alice and Bob can convert between n copies of a joint state $|\psi\rangle$ and $nS(\rho)$ Bell pairs, by local operations and classical communication alone, as $n \rightarrow \infty$, where ρ is the reduced density matrix.
- Quantum cryptography: Provably secure key distribution is possible by communicating using non-orthogonal quantum states, with a protocol such as BB84. Eavesdropping on the channel will cause a detectable increase in the error rate, because information gain implies disturbance.

History and further reading

The book of Cover and Thomas [CT91] is a terrific introduction to classical information theory. The reader looking for a more advanced yet still readable treatment of information theory should consult Csiszár and Körner [CK81] . Also well worth the read are Shannon's original papers, among the most influential in twentieth century science. These have been reprinted together in a single volume by Shannon and Weaver [*SW*49]. Bennett and Shor [BS98] and Bennett and DiVincenzo [BD00] have written excellent review articles on quantum information theory.

The no-cloning theorem is due to Dieks [Die82] and to Wootters and Zurek [WZ82]. An enormous amount of work has been done extending these results. By far the majority of the papers consider various schemes for cloners which are interesting in some particular way - they optimize some measure of cloning fidelity, or some other property one might wish a cloner to have. We will not attempt to give a full review of this work here, but
note that many of these papers may be found on the internet at http://arXiv.org/ in the quant-ph archive. Some papers of especial interest include the work of Barnum, Caves, Fuchs, Jozsa and Schumacher [BCF+96] extending the range of application of the no-cloning theorem to mixed states and non-unitary cloning devices; by Mor [Mor 98] on the cloning of states of composite systems; by Westmoreland and Schumacher [WS98] on a possible equivalence between cloning and faster-than-light communication; and a rebuttal by van Enk [van 98 b].

The Holevo bound was conjectured by Gordon in 1964[Gor64], and proved by Holevo in 1973[Hol73]. The conceptually simple proof we have given is based upon the difficult-toprove strong subadditivity inequality, however Holevo used a more direct approach which has been simplified by Fuchs and Caves [*FC*94]. The approach via strong subadditivity is due to Yuen and Ozawa [YO93]; see also Schumacher, Westmoreland and Wootters [SWW96].

The classical noiseless channel coding theorem is due to Shannon [Sha48, *SW*49]. The quantum noiseless channel coding theorem is due to Schumacher [*Sch*95], and is described in a pioneering paper that introduced in an integrated fashion many of the fundamental notions of quantum information theory, including sources, fidelity measures, and the notion of quantum states as a resource that could be treated in information-theoretic terms. This last observation, simple but profound, was driven home by Schumacher's introduction in the paper of the now-ubiquitous term qubit, attributed to a conversation between Schumacher and Wootters. A paper by Jozsa and Schumacher [JS94] simplified Schumacher's original approach; this paper was published earlier than [Sch95], but was was written at a later time. These papers were based on the ensemble-average fidelity measure discussed in Exercise 12.8, rather than the entanglement fidelity based proof we have given here, which is based on the approach of Nielsen [Nie98]. A slight hole in the original papers by Schumacher, and Schumacher and Jozsa was filled by the work of Barnum, Fuchs, Jozsa and Schumacher [BFJS96]. M. Horodecki[Hor97] subsequently provided a more powerful proof of the same result that also points the way towards a theory of quantum data compression of ensembles of mixed states. The compression scheme described in Box 12.4, which is the quantum analogue of Cover's enumerative coding method [CT91], is originally attributed to Schumacher [Sch95], and quantum circuits for it are explicitly given by Cleve and DiVincenzo [CD96]. Braunstein, Fuchs, Gottesman, and Lo have generalized this to provide a quantum analogue to Huffman encoding[BFGL98], and Chuang and Modha to arithmetic coding[CM00].

The Holevo-Schumacher-Westmoreland (HSW) theorem has an interesting history. The problem it addresses was first discussed by Holevo [Hol79] in 1979, who made some partial progress on the problem. Unaware of this work, Hausladen, Jozsa, Schumacher, Westmoreland, and Wootters [HJS+96] solved a special case of the problem in 1996. Independently, and shortly thereafter, Holevo [Hol98] and Schumacher and Westmoreland[SW97] proved the HSW theorem giving the product state capacity of a noisy quantum channel for classical information. Fuchs

[Fuc97] has described some interesting examples of the product state capacity, where the ensemble of states maximizing the expression (12.71) for the capacity contains non-orthogonal members. King and Ruskai [$KR99$] have made some promising headway on the problem of showing that the product state capacity is the same as the capacity unrestricted to product states, but the general problem remains open.

The entropy exchange was defined by Lindblad [Lin 91], and rediscovered by Schumacher [$Sch96$ b], who proved the quantum Fano inequality. The coherent information was introduced by Lloyd [Llo97] and by Schumacher and Nielsen [SN96] in the context of the capacity of a noisy quantum channel; [SN96] proves the quantum data processing inequality. A table containing the inequalities mentioned in Exercise 12.15 may be found in Nielsen's Ph.D. dissertation [Nie98]. The as yet unsolved problem of determining the quantum channel capacity (Problem 12.7) has an interesting history. Initial work on the subject came from several different perspectives, as may be seen from the papers of Barnum, Nielsen and Schumacher [BNS98], of Bennett, DiVincenzo, Smolin, and Wootters [BDSW96], of Lloyd [Llo97] , of Schumacher [Sch96b] and of Schumacher and Nielsen [SN96]. The equivalence of several of these points of view has been understood through the work of Barnum, Knill and Nielsen[BKN98], and Barnum, Smolin and Terhal[BST98]. The capacity has been established for some specific channels (most notably the quantum erasure channel) by Bennett, DiVincenzo and Smolin [BDS97] , and a lower bound on the capacity of the depolarizing channel making intriguing use of degenerate quantum codes has been obtained by Shor and Smolin [$SS96$], and refined by DiVincenzo, Shor and Smolin [$DSS98$]. Zurek[Zur89], Milburn [Mil96], and Lloyd[Llo96] analyzed examples of quantum Maxwell's demons, though not in the context of error-correction. The analysis here is based on the work of Nielsen, Caves, Schumacher and Barnum [NCSB98]. This point of view has also been pursued by Vedral[Ved99] to obtain limits on entanglement distillation procedures. The quantum Singleton bound is due to Knill and Laflamme[KL97]. The proof we give is due to Preskill[Pre98b].

The study of entanglement has blossomed into a major area of research, and there are far too many papers on the subject to even begin to give an account here. Once again, see the quant-ph archive at http://arXiv.org/. The conditions for entanglement transformation based on majorization (Theorem 12.15) are due to Nielsen [Nie99]. Theorem 12.13 is due to Uhlmann[Uhl71, Uhl72, Uhl73]. Proposition 12.14 is due to Lo and Popescu[LP97]. Entanglement catalysis was discovered by Jonathan and Plenio [JP99]. Marshall and Olkin [MO79] is a comprehensive introduction to majorization, including the proof of Birkhoff's theorem. The limits for entanglement dilution and distillation are due to Bennett, Bernstein, Popescu and Schumacher [BBPS96]. Entanglement distillation protocols for mixed states were introduced by Bennett, Brassard, Popescu, Schumacher, Smolin and Wootters [$BBP^{+}96$], and the connection to quantum error-correction developed in a ground-breaking paper by Bennett, DiVincenzo, Smolin and Wootters[BDSW96] that has stimulated a lot of subsequent research. The example illustrated in Figure 12.11 was noted by Gottesman and Nielsen (unpublished). We mention just a few more papers on entanglement of exceptional interest that may serve as an entry-point to the literature; unfortunately many papers of note are omitted as a result. A series of papers by members of the Horodecki family (Michal, Pawel and Ryszard) have investigated the properties of entanglement in depth; of especial note are [HHH96, HHH98, HHH99a, HHH99b, HHH99c]. Also of great interest are the papers by Vedral and Plenio [$VP98$] and by Vidal [$Vid98$].

For an excellent (early) overview of quantum cryptography at the lay level see the article by Bennett, Brassard, and Ekert in Scientific American [$8BE92$]. Quantum cryptographic ideas were first put forward by Wiesner in the late 1960s. Unfortunately, Wiesner's ideas were not accepted for publication, and it wasn't until the early 1980s that the ideas became known. Wiesner proposed that (entangled) quantum states, if they could be stored for long periods of time, could be used as a kind of counterfeit-proof money[Wie, Wie83]. Bennett developed sev-

eral further protocols, one of which lead to the first experimental implementation, by Bennett, Bessette, Brassard, Salvail, and Smolin [BBB+92], which is
of historical interest (in principle) since it transmitted its information less than a meter and, moreover, eavesdropping was facilitated by a loud buzzing sound which emanated from the power supply whenever a 'one' was sent! The concept of privacy amplification was first introduced by Bennett, Brassard, and Robert [BBR88]. For information reconciliation protocols see [BBB+92] and [BS94]. Theorem 12.16 is stated and proved in Bennett, Brassard, Crèpeau, and Maurer [BBCM95], in a very readable general treatment of privacy amplification. Note that the information disclosed during reconciliation has an important impact on the threshold for privacy amplification, as bounded in Theorem 12.17, proven by Cachin and Maurer [CM97] . Privacy amplification has applications to classical key generation using distant correlated random sources such as starlight sensed by satellites[Mau93]. The four state protocol known as BB84 is named after the authors, Bennett and Brassard [BB84], and similarly, the two state B92 protocol is named after Bennett [Ben92] . The EPR protocol was devised by Ekert [Eke91]. The proof of the random sampling bound in Exercise 12.27 is due to Ambainis. The limitations and security of quantum cryptography have been discussed in depth in many publications. For a sample, see the works by Barnett and Phoenix [BP93] ; Brassard [Bra93] ; Ekert, Huttner, Palma, and Peres [EHPP94] ; also [Phy92] . The connection between coherent information and privacy was recognized by Schumacher and Westmoreland [SW98]. Numerous papers have been published on experimental implementations of quantum cryptographic systems. For a good introduction, see Hughes, Alde, Dyer, Luther, Morgan, and Schauer [HAD+95]; the demonstration of quantum cryptography under Lake Geneva was by Muller, Zbinden, and Gisin [MZG96]. The experiment described in Box 12.7 was performed at IBM, by Bethune and Risk [BR98, BR00], and we thank them for the schematic of their apparatus. A large number of proofs of the security of various quantum key distribution protocols, under different circumstances, have been presented. Of particular note is a complete (and extensive, but somewhat complicated) proof of the security of QKD with BB84 given by Mayers[May98]. Biham, Boyer, Brassard, van de Graaf, and Mor have also considered attacks against BB84 [BBB+98]. A simpler proof, which uses EPR states and requires perfect quantum computation has been given by Lo and Chau [LC99]; this is the protocol we began with in Section 12.6.5. Lo has simplified it to begin with a test which ascertains the error rate, before transmitting key material [Lo99]. The even simpler (and beautiful!) proof given in Section 12.6.5 is due to Shor and Preskill [SP00], who also give the 11% estimate mentioned in Section 12.6.5. Our presentation of this proof also benefited greatly from conversations with Gottesman.

10 Quantum Systems, Channels, Information by Holevo

10.0.1 Preface

Quantum information theory studies the general laws of transfer, storage, and processing of information in systems obeying the laws of quantum mechanics. It took shape as a self-consistent area of research in the 1990s, while its origin can be traced back to the 1950-1960s, which was when the basic ideas of reliable data transmission and of Shannon's information theory were developed. At the first stage, which covers the period 1960-1980, the main issue consisted of the fundamental restrictions on the possibilities of information transfer and processing caused by the quantum mechanical nature of its carrier. Modern technological developments, relying upon the achievements of quantum electronics and quantum optics, suggest that in the foreseeable future such restrictions will become the main obstacle limiting further extrapolation of existing technologies and principles of information processing.

The emergence, in the 1980-1990s, of the ideas of quantum computing, quantum cryptography, and the new communication protocols, on the other hand, allowed discussing not only the restrictions, but also the new possibilities created by the use of specific quantum resources, such as quantum entanglement, quantum complementarity, and quantum parallelism. Quantum information theory provides the clue to understanding these fundamental issues and stimulates the development of experimental physics, with potential importance to new, effective applications. At present, investigations in the area of quantum information science, including information theory, its experimental aspects, and technological developments, are ongoing in advanced research centers throughout the world.

The mathematical toolbox of "classical" information theory contains methods based on probability theory, combinatorics, and modern algebra, including algebraic geometry. For a mathematician sensible to the impact of his research on the natural sciences, information theory can be a source of deep ideas and new, challenging problems, with sound motivation and applications. This equally, if not to a greater extent, applies to quantum information theory, the scope of which turns out to be closely connected to multilinear algebra and noncommutative analysis, convexity, and asymptotic theory of finite-dimensional normed spaces, subtle aspects of positivity and tensor products in operator algebras, and the methods of random matrices. Nowadays, the intimate connections to operator spaces and so-called "quantum functional analysis" have been revealed and explored.

In 2002, the Moscow Independent University published the author's lecture notes (in Russian), in which an attempt was made at a mathematician's introduction to problems of quantum information theory. In 2010, a substantially expanded text was published with the title "Quantum systems, channels, information." The author's intention was to provide a widely accessible and self-contained introduction to the subject, starting from primary structures and leading up to nontrivial results with rather de-
tailed proofs, as well as to some open problems. The present English text is a further step in that direction, extending and improving the Russian version of 2010.

The exposition is organized in concentric circles, the N th round consisting of Parts I to N, where each circle is self-contained. The reader can restrict himself to any of these circles, depending on the depth of presentation that he or she demands. In particular, in Part I to Part IV, we consider finite-dimensional systems and channels, whereas the infinite-dimensional case is treated in the final Part V.

Part I starts with a description of the statistical structure of quantum theory. After introducing the necessary mathematical prerequisites in Chapter 1, the central focus in Chapters 2, 3 is on discussing the key features of quantum complementarity and entanglement. The former is reflected by the noncommutativity of the algebra of observables of the system, while the latter is reflected by the tensor product structure of composite quantum systems. Chapter 3 also contains the first applications of the information-theoretic approach to quantum systems.

In information theory, the notions of a channel and its capacity, giving a measure of ultimate information-processing performance of the channel, play a central role. In Chapter 4 of Part II, a review of the basic concepts and necessary results from classical information theory is provided, the quantum analogs of which are the main subject of the following chapters. The concepts of random coding and typicality are introduced and then extended to the quantum case in Chapter 5. That chapter contains direct and self-consistent proofs of the quantum information bound and of the primary coding theorems for the classical-quantum channels, which will later serve as a basis for the more advanced capacity results in Chapter 8.

Part III is devoted to the study of quantum channels and their entropy characteristics. In Chapter 6, we discuss the general concept and structure of a quantum channel, with the help of a variety of examples. From the point of view of operator algebras, these are normalized completely positive maps, the analog of Markov maps in noncommutative probability theory,

and they play the role of morphisms in the category of quantum systems. From the point of view of statistical mechanics, a channel gives an overall description of the evolution of an open quantum system interacting with an environment - a physical counterpart of the mathematical dilation theorem. Various entropic quantities essential to the characterization of the information-processing performance, as well as the irreversibility of the channel, are investigated in Chapter 7.

Part IV is devoted to the proofs of advanced coding theorems, which give the main capacities of a quantum channel. Remarkably, in the quantum case, the notion of the channel capacity splits, giving a whole spectrum of information-processing characteristics, depending on the kind of data transmitted (classical or quantum), as well as on the additional communication resources. In Chapter 8, we discuss the classical capacity of a quantum channel, i. e., the capacity for transmitting classical data. We touch upon the tremendous progress made recently in the solution of the related additivity problem and point out the remaining questions. Chapter 9 is devoted to the classical entanglement-assisted capacity and its comparison with unassisted capacity. In

Chapter 10, we consider reliable transmission of quantum information (i. e., quantum states), which turns out to be closely related to the private transmission of classical information. The corresponding coding theorems provide the quantum capacity and the private classical capacity of a quantum channel.

In Part V, we pass from finite-dimensional to separable Hilbert space. Chapter 11 deals with the new obstacles characteristic for infinite-dimensional channels - singular behavior of the entropy (infinite values, discontinuity) and the emergence of the input channel constraints (e.g., finiteness of the signal energy) and of the continuous optimizing state ensembles. Chapter 12 treats the bosonic Gaussian systems and channels on the canonical commutation relations (many experimental demonstrations of quantum information processing were realized in such "continuous-variables" systems, based in particular on the principles of quantum optics). We assume the reader has some minor background in the field and start with a rather extended introduction at the beginning of Chapter 12. Next, we describe and study in detail the Gaussian states and channels. The main mathematical problems here are the structure of the multimode quantum Gaussian channels and the computation of the various entropic quantities characterizing their performance. While the classical entanglementassisted capacity is, in principle, computable for a general Gaussian channel, the quantum capacity is found only for restricted classes of channels, and the unassisted classical capacity in general presents an open analytical problem, namely, that of verifying the conjecture of "quantum Gaussian optimizers," which is comparable in complexity to the additivity problem (also open for the class of Gaussian channels) and appears to be closely related to it.

This book does not intend to be an all-embracing text in quantum information theory and its content definitely reflects the author's personal research interests and preferences. For example, the important topics of entanglement quantification and error correction are mentioned only briefly. An interested reader can find an account of these in other sources, listed in the notes and references to the individual chapters. Quantum information theory is in a stage of fast development and new, important results continue to appear. Yet, we hope the present text will be a useful addition to the existing literature, particularly for mathematically inclined readers eager to penetrate the fascinating world of quantum information.

The basis for these lecture notes was a course taught by the author at the Moscow Institute of Physics and Technology, Moscow State University, and several Western institutions. The author acknowledges stimulating discussions, collaborations, and invaluable support of R. Ahlswede, A. Barchielli, C. H. Bennett, G. M. D'Ariano, C. Fuchs, V. Giovannetti, O. Hirota, R. Jozsa, L. Lanz, O. Melsheimer, H. Neumann, M. B. Ruskai, P. W. Shor, Yu. M. Suhov, K. A. Valiev, R. Werner, A. Winter, and M. Wolf.

I extend special thanks to my colleagues Maxim Shirokov and Andrey Bulinsky for their careful reading of the manuscript and the suggestions for numerous improvements.

This work was supported by the Russian Foundation for Basic Research, Fundamental Research Programs of the Russian Academy of Sciences, and the Cariplo Fellowship organized by the Landau Network - Centro Volta.

10.0.2 Preface to the Second Edition

A major change in the second edition of the book is Chapter 12. The new version includes a solution of the long-standing problem of quantum Gaussian optimizers, which appeared soon after publication of the first edition. This result enables one to explicitly compute the classical capacity for the most usable mathematical models of quantum communication channels in continuous-variables systems, making the whole content of the book more complete.

In Chapters 1-11 several textual amendments were made. Circa thirty new references were added which are strictly relevant to the main content of the monograph. The author is grateful to Maxim Shirokov, whose careful reading and comments contributed substantially to the improvement of the presentation.

10.1 1 Vectors and Operators

We will deal with quantum-mechanical systems described by finite-dimensional Hilbert spaces. On the one hand, one can see already in that case, and perhaps most manifestly, the distinctive features of quantum statistics. On the other hand, finite-level systems are of the main interest for applications such as quantum communication, cryptography, and computing (although in the field of quantum information theory attention was recently attracted by the "continuous-variables systems," which are described by infinite-dimensional spaces; see Chapters 11, 12).

10.1.1 1.1 Hilbert Space

Let $\mathcal{H}$ be a d-dimensional complex linear space, $\dim \mathcal{H} = d < \infty$, with the inner product $\langle \phi \mid \psi \rangle, \phi, \psi \in \mathcal{H}$, satisfying the axioms of unitary space (see, e. g., [156]). However, following physical rather than mathematical traditions, we assume $\langle \phi \mid \psi \rangle$ to be linear with respect to the second argument ψ and antilinear with respect to ϕ. Again following a tradition in physics literature, we shall call it a Hilbert space (although emphasis of the mathematical Hilbert space theory is on the infinite-dimensional case).

We shall use Dirac's notations: a vector $\psi \in \mathcal{H}$ (which conventionally should be thought of as a column vector) will often be denoted as $|\psi\rangle$. Correspondingly, $\langle \phi|$ will denote the linear function on $\mathcal{H}$, defined by the inner product

$$\langle \phi| : \psi \to \langle \phi \mid \psi \rangle, \quad \psi \in \mathcal{H}$$

These linear functions themselves form another Hilbert space-the dual space $\mathcal{H}^*$ of $\mathcal{H}$ (they should be thought of as row vectors $\langle \phi| = |\phi\rangle^*$, the Hermitian conjugate [adjoint] to $|\phi\rangle$). The space $\mathcal{H}^*$ is antiisomorphic to $\mathcal{H}$ via the correspondence $|\psi\rangle \leftrightarrow \langle \psi|$. Then the inner product $\langle \phi \mid \psi \rangle$ is naturally thought of as the product of the "bra" and "ket" vectors $\langle \phi|$ and $|\psi\rangle$. The square of the norm, both in $\mathcal{H}$ and $\mathcal{H}^*$, is $\langle \psi \mid \psi \rangle = \|\psi\|^2$.

This notation also allows for a convenient description of operators. For example, the "outer product" of "ket" and "bra" vectors $A = |\psi\rangle\langle\phi|$ describes the rank one operator, which acts onto vector $|\chi\rangle$ according to the formula $A|\chi\rangle = |\psi\rangle\langle\phi \mid \chi\rangle$. Let $\{e_i\}_{i=1,d}$ be an orthonormal basis in $\mathcal{H}$. The decomposition of arbitrary vector $\psi \in \mathcal{H}$ can then be written as

$$|\psi\rangle = \sum_{i=1}^{d} |e_i\rangle \langle e_i \mid \psi\rangle \tag{1.1}$$

which is the same as

$$\sum_{i=1}^{d} |e_i\rangle \langle e_i| = I \tag{1.2}$$

where I is the unit operator in $\mathcal{H}$.

Exercise 1.1 Write the matrix representation for operators in $\mathcal{H}$, similar to the representation (1.1) for vectors.

An additional advantage of Dirac's notations is that we do not need to write the symbol of the vector, leaving only the label(s), e. g., we may write $|i\rangle$ instead of $|e_i\rangle$.

Sometimes we shall consider a real Hilbert (i. e., Euclidean) space. A fundamental difference with the complex case is revealed by the polarization identity

$$\beta(\phi, \psi) = \frac{1}{4} \sum_{k=0}^{3} (-i)^k \beta\left(\phi + i^k \psi, \phi + i^k \psi\right), \tag{1.3}$$

which allows us to uniquely restore all values of the form $\beta(\phi, \psi)$, which is linear with respect to the second argument and antilinear with respect to the first, from its diagonal values $\beta(\psi, \psi), \psi \in \mathcal{H}$ (in the real case, such a restoration is possible only for symmetric forms). Due to this, in order to prove an operator equality $A = B$, it is sufficient to establish the equality for all diagonal values, i. e., $\langle \psi \mid A\psi\rangle = \langle \psi \mid B\psi\rangle, \psi \in \mathcal{H}$.

10.1.2 1.2 Operators

If A is an operator in $\mathcal{H}$ (throughout this book we deal only with linear operators), then A^* denotes its adjoint, defined by

$$\langle \phi \mid A^*\psi\rangle = \langle A\phi \mid \psi\rangle, \quad \phi, \psi \in \mathcal{H}. \tag{1.4}$$

An operator A is called Hermitian if $A = A^*$. An (orthogonal) projector is a Hermitian operator P such that $P^2 = P$. The range of projector P is the subspace

$$\mathcal{L} = \{\psi : P|\psi\rangle = |\psi\rangle\}.$$

If $\|\psi\| = 1$, then $|\psi\rangle\langle\psi|$ is the projector onto the unit vector $|\psi\rangle$. More generally, for an orthonormal system $\{e_i\}_{i\in I}$, the operator $\sum_{i\in I} |e_i\rangle \langle e_i| = P$ is the projector onto the subspace generated by $\{e_i\}_{i\in I}$.

A unitary operator is an operator U such that $U^*U = I$. In the finite-dimensional case, which we here consider, this implies $UU^* = I$. A partial isometry is an operator U such that $U^*U = P$ is a projector. In this case $UU^* = Q$ also is a projector; U maps the range of P onto the range of Q isometrically, i. e., preserving inner products and norms of vectors.

Theorem 1.2 (Spectral decomposition). For a Hermitian operator A, there is an orthonormal basis of eigenvectors to which correspond real eigenvalues a_i, such that

$$A = \sum_{i=1}^{d} a_i |e_i\rangle \langle e_i| . \tag{1.5}$$

Another useful form of the spectral decomposition is obtained if we consider the distinct eigenvalues $\{a\}$ and the corresponding spectral projectors, i.e.,

$$E_a = \sum_{i:a_i=a} |e_i\rangle \langle e_i| .$$

The collection of distinct eigenvalues $\mathrm{spec}(A) = \{a\}$ is called the spectrum of the operator A. Then

$$A = \sum_{a\in \mathrm{spec}(A)} aE_a. \tag{1.6}$$

This representation is unique up to the ordering of the eigenvalues. The collection of projectors $\{E_a\}$ forms an orthogonal resolution of the identity, i.e.,

$$E_a E_{a'} = \delta_{aa'} E_a, \qquad \sum_{a\in \mathrm{spec}(A)} E_a = I. \tag{1.7}$$

The Hilbert space $\mathcal{H}$ splits into the direct orthogonal sum of the ranges of the projectors $\{E_a\}$, on which A acts as multiplication by a.

Both unitary and Hermitian operators are special cases of normal operators, satisfying $A^*A = AA^*$. For normal operators, the spectral decomposition (1.5) holds, with complex eigenvalues a_i.

10.1.3 1.3 Positivity

A Hermitian operator A is called positive, $A \geq 0$, if $\langle \psi \mid A\psi \rangle \geq 0$ for all $\psi \in \mathcal{H}$. The eigenvalues of a positive operator are all nonnegative, i.e., $a \geq 0$ for $a \in \mathrm{spec}(A)$.

The operator is positive if and only if it can be represented as $A = B^*B$ for some operator B. A positive operator has a unique positive square root, i. e., for any positive operator A there exists one and only one positive operator B, denoted by $\sqrt{A} = A^{1/2}$ such that $B^2 = A$.

For an arbitrary Hermitian operator A, we have

$$A = A_+ - A_-, \tag{1.8}$$

where $A_+ = \sum_{a>0} aE_a, A_- = -\sum_{a<0} aE_a$ are positive operators called the positive and negative part of the operator A.

Theorem 1.3 (Polar decomposition). Any operator A in $\mathcal{H}$ allows the decomposition

$$A = U|A| = |A^*|\, U, \tag{1.9}$$

where $|A| = \sqrt{A^*A}$ is a positive operator and U is unitary.

The support $\mathrm{supp}\, A$ of a positive operator A is the span of eigenvectors of A corresponding to positive eigenvalues. In the polar decomposition, the unitary operator is uniquely defined only on $\mathrm{supp}\, A$.

Occasionally, we will make use of a real Hilbert space, i. e., Euclidean space, and the operators in it. In that case, the Hermitian operators are replaced by symmetric operators, and unitary operators by orthogonal ones, with formally similar definitions. The polar decomposition of an operator A holds, with $|A|$ symmetric positive and U an orthogonal operator.

10.1.4 1.4 Trace and Duality

The trace of an operator T is defined by

$$\mathrm{Tr}\, T = \sum_{i=1}^{d} \langle e_i \mid Te_i \rangle , \tag{1.10}$$

where $\{e_i\}$ is an arbitrary orthonormal basis.

Exercise 1.4 Show that the definition does not depend on the choice of basis and that

$$\operatorname{Tr} A^* = \overline{\operatorname{Tr} A}, \quad \operatorname{Tr} AB = \operatorname{Tr} BA, \tag{1.11}$$

where the bar denotes the complex conjugate. Show that

$$\operatorname{Tr} |\psi\rangle\langle\varphi| A = \langle\varphi \mid A\psi\rangle. \tag{1.12}$$

Show that for $A, B \geq 0$

$$\operatorname{Tr} AB \geq 0, \tag{1.13}$$

with equality if and only if $AB = 0$.

The expression

$$\|T\|_1 = \operatorname{Tr} |T| \tag{1.14}$$

defines the trace norm on the complex linear space of all operators in $\mathcal{H}$. Note that for Hermitian T

$$\|T\|_1 = \sum_{i=1}^{d} |t_i| \tag{1.15}$$

where t_i are the eigenvalues of T. Another important norm is the operator norm

$$\|A\| \equiv \|A\|_\infty = \max_{\psi:\|\psi\|=1} \|A\psi\| \tag{1.16}$$

which for a Hermitian A is equal to

$$\|A\| = \max_{a \in \operatorname{spec}(A)} |a|. \tag{1.17}$$

There is an important inequality,

$$|\operatorname{Tr} TA| \leq \|T\|_1 \|A\|, \tag{1.18}$$

where equality can be attained either for any fixed T or for any fixed A : for a fixed T take $A = U^*$, where U is the unitary from the polar decomposition $T = U|T|$. Thus,

$$\|T\|_1 = \max_U |\operatorname{Tr} TU| = \max_{\|A\|=1} |\operatorname{Tr} TA|. \tag{1.19}$$

Similarly, for given A equality is attained for $T = |\psi\rangle\langle\psi|U^*$, where U is the unitary from the polar decomposition $A = U|A|$, and ψ is the normalized eigenvector of $|A|$, with the maximal eigenvalue. It follows that

$$\|A\| = \max_{\|T\|_1=1} |\operatorname{Tr} TA|. \tag{1.20}$$

These facts underly an important duality relation. The space of all operators in $\mathcal{H}$, equipped with the trace norm, becomes the complex Banach space $\mathfrak{T}(\mathcal{H})$. The same space equipped with the operator norm (and the product operation) is the Banach algebra $\mathfrak{B}(\mathcal{H})$. These two Banach spaces are in mutual duality, which means that every linear function on $\mathfrak{T}(\mathcal{H})$ has the form $T \to \operatorname{Tr} TA$ for some $A \in \mathfrak{B}(\mathcal{H})$, with the norm given by (1.20), and, conversely, every linear function on $\mathfrak{B}(\mathcal{H})$ has the form $A \to \operatorname{Tr} TA$ for some $T \in \mathfrak{T}(\mathcal{H})$ with the norm (1.19).

The subscript h will be applied to spaces of operators to denote the corresponding real Banach spaces of Hermitian operators. Then the real Banach spaces $\mathfrak{T}_h(\mathcal{H})$ and $\mathfrak{B}_h(\mathcal{H})$ are again in the mutual duality, provided by the bilinear form $T, A \to \operatorname{Tr} TA$. It follows from (1.11) that this form is real-valued for Hermitian T, A.

In the finite-dimensional case the spaces $\mathfrak{T}(\mathcal{H})$ and $\mathfrak{B}(\mathcal{H})$ coincide with the space of all operators in $\mathcal{H}$ and differ only by the norms. In the infinite-dimensional case, however, they are substantially different (just as the classical l^1 and l^∞ spaces over finite versus infinite sets).

Exercise 1.5 Show that the complex dimensionality of the space of all operators in $\mathcal{H}$ is d^2, while the real dimensionality of the subspace of all Hermitian operators in $\mathcal{H}$ is again d^2. If $\mathcal{H}$ is a real d-dimensional Hilbert space, the dimensionality of the space of all operators in $\mathcal{H}$ is d^2, while the dimensionality of the subspace of all symmetric operators in $\mathcal{H}$ is $d(d+1)/2$.

10.1.5 1.5 Convexity

A subset $\mathfrak{S}$ of a real linear space is convex if, for any finite collection of points $\{S_j\} \subset \mathfrak{S}$ and any probability distribution $\{p_j\}$, the convex combination $S = \sum_{j=1} p_j S_j$ is in $\mathfrak{S}$ (it is sufficient to impose this requirement only on collections of two points, which means that if the set $\mathfrak{S}$ contains two points, it must contain the whole segment connecting these points). In a convex set, a special role is played by extreme points, which cannot be represented as a nontrivial convex combination of other points. This is equivalent to the fact that $S = pS_1 + (1-p)S_2, 0 < p < 1$, implies $S = S_1 = S_2$, which means that there is no segment in $\mathfrak{S}$ containing S as its interior point. We denote by $\operatorname{ext}(\mathfrak{S})$ the set of all extreme points of a convex set $\mathfrak{S}$. The following general result holds.

Theorem 1.6 (Carathéodory). Let $\mathfrak{S}$ be a compact convex subset of $\mathbb{R}^n$. Then every point $S \in \mathfrak{S}$ can be represented as a convex combination of at most $n+1$ extreme points $S_j \in \operatorname{ext}(\mathfrak{S})$. We have

$$S = \sum_{j=1}^{n+1} p_j S_j, \quad S_j \in \operatorname{ext}(\mathfrak{S}). \tag{1.21}$$

As an example, consider the convex set $\mathfrak{P}_n$ of all probability distributions $P = \{p_1, \ldots, p_{n+1}\}$ on a set of $n+1$ points. Its extreme points are the degenerate distributions, for which all p_j are zero, except for one which is equal to 1 . There are $n+1$ extreme points and every point of $\mathfrak{P}_n$ is uniquely represented as their convex combination, with the coefficients p_j. This set is called simplex, and uniqueness of the representation is the characteristic feature of this convex set.

A real function $\mathcal{F}$ on a convex subset $\mathfrak{S}$ of a finite-dimensional linear space is convex (concave) if

$$\mathcal{F}\left(\sum_j p_j S_j\right) \leq (\geq) \sum_j p_j \mathcal{F}(S_j),$$

for an arbitrary convex combination of points $S_j \in \mathfrak{S}$. It is affine if it is both convex and concave. More generally, a map $\mathcal{F}$ from one convex set into another is called affine if it preserves convex combinations, i.e.,

$$\mathcal{F}\left(\sum_j p_j S_j\right) = \sum_j p_j \mathcal{F}(S_j).$$

Exercise 1.7 A continuous convex (in particular, affine) function on a compact convex set $\mathfrak{S}$ attains its maximum at an extreme point of this set.

10.1.6 1.6 Notes and References

The basics of the operator formalism of quantum mechanics were laid down in Dirac's classical treatise [64]. An excellent introduction to finite quantum systems is given in

Feynman's lectures [70]. From the vast variety of textbooks on linear algebra, we mention the modern course of Kostrikin and Manin [156], which takes into account the needs of quantum theory, and the book of Glazman and Ljubich [83], which is aimed at the active study of noncommutative, finite-dimensional analysis through solving problems. A variety of topics in modern matrix analysis, including many matrix inequalities, is covered in the book of Bhatia [31]. The fundamentals of convex analysis are exposed in, e.g., the books of Magaril-Il'jaev and Tikhomirov [172] and Rockafellar [194].

10.2 2 States, Observables, Statistics

10.2.1 2.1 Structure of Statistical Theories

10.2.2 2.1.1 Classical Systems

A classical system is described in terms of its phase space Ω, the points ω of which label deterministic states of the system. For simplicity, we consider in what follows finite sets Ω. By classical (statistical) state we denote a probability distribution $P = \{p_\omega\}$ on Ω. The collection of all probability distributions is the simplex $\mathfrak{P}(\Omega)$, in which every point is uniquely represented as a convex combination of extreme points - pure states, given by probability distributions that are degenerated in the points $\omega \in \Omega$. The simplest nontrivial system is the bit, the system with two pure states 0,1 , for which the set of statistical states is isomorphic to the unit segment of the real line.

Any random variable is a function $X = \{x_\omega\}$ on the phase space Ω, defining a decomposition of the space Ω into nonintersecting subsets Ω_x, in which X takes on the values x. The indicators $E_x(\omega)$ of these subsets satisfy the conditions

$$E_x(\omega)E_y(\omega) = \delta_{x,y}E_x(\omega), \quad \sum_x E_x(\omega) \equiv 1.$$

Along with random variables, which will henceforth be called sharp observables, one can consider unsharp observables which take the values x with probabilities $M(x \mid \omega)$ (such as observables with random error or intentionally randomized). The collection of conditional probabilities $M = \{M(x \mid \omega)\}$ is characterized by the properties

$$M(x \mid \omega) \geq 0, \quad \sum_x M(x \mid \omega) = 1.$$

For a sharp observable the probabilities $M(x \mid \omega) = E_x(\omega)$ are equal to 0 or 1 , i.e., $M(x \mid \omega)^2 = M(x \mid \omega)$.

The probability distribution for the observable M in the state P is given by the formula

$$\mu_P^M(x) = \sum_\omega p_\omega M(x \mid \omega). \tag{2.1}$$

For a smooth transition to quantum systems it is useful to introduce a matrix representation of the classical quantities. Consider the Hilbert space spanned by a fixed orthonormal basis $\{|\omega\rangle; \omega \in \Omega\}$. Given any function f_ω defined on Ω, we consider the diagonal operator

$$f = \sum_\omega f_\omega |\omega\rangle\langle\omega|.$$

Then a classical state gives rise to the operator $P = \sum_\omega p_\omega |\omega\rangle\langle\omega|$, characterized by the properties

$$P \geq 0, \quad \operatorname{Tr} P = 1. \tag{2.2}$$

A classical observable gives rise to the resolution of the identity, i. e., a collection of operators $M = \{M_x\}$, where

$$M_x = \sum_\omega M(x \mid \omega)|\omega\rangle\langle\omega|,$$

satisfying the conditions

$$M_x \geq 0, \quad \sum_x M_x = I. \tag{2.3}$$

For a sharp observable, the operators $M_x = E_x$ are pairwise orthogonal projectors. The relation (2.1) for the probability distribution of an observable can be rewritten as

$$\mu_P^M(x) = \operatorname{Tr} P M_x. \tag{2.4}$$

10.2.3 2.1.2 Axioms of Statistical Description

At the basis of the mathematical structure of quantum theory, as well as of any other statistical theory, lies the separation of a statistical experiment into the two stages of preparation and measurement, which underlies the duality between states and observables (Figure 2.1). The following set of axioms, which is applicable to any statistical theory, stresses the parallel between the statistical description of classical and quantum systems.

Figure 2.1: A quantum state described by a density operator S characterizes the preparation of a system, whereas the statistics of a measurement is described by a probability measure $\mu_S^M(x)$, where x labels the possible outcomes.

Axiom 1. Let there be a given set $\mathfrak{S}$, whose elements are called states, and a set $\mathfrak{M}$, whose elements are called (finite-valued) observables. For arbitrary $M \in \mathfrak{M}$, there is a finite set $\mathcal{X}^M$ of outcomes. For arbitrary $S \in \mathfrak{S}$ and $M \in \mathfrak{M}$, there is a probability distribution μ_S^M on $\mathcal{X}^M$, called the probability distribution of the observable M in the state S.

The state S is interpreted as a more or less detailed description of the preparation of a statistical ensemble, i. e., a sample of independent individual representatives of the system under consideration, and the observable M, as a quantity that can be measured by a definite apparatus for each representative in the given ensemble. Axiom 1 thus presupposes the reproducibility of the individual experiments and the stability of frequencies under independent repetitions.

The following axiom expresses the possibility of the mixing of statistical ensembles.

Axiom 2. For arbitrary $S_1, S_2 \in \mathfrak{S}$ and an arbitrary number $p, 0 < p < 1$, there exists an $S \in \mathfrak{S}$ such that $\mu_S^M = p\mu_{S_1}^M + (1-p)\mu_{S_2}^M$ for all $M \in \mathfrak{M}$; S is called the mixture of states S_1 and S_2 with weights $p, 1-p$.

The next axiom describes the possibility of processing the information obtained from a measurement of an observable. Let $M_1, M_2 \in \mathfrak{M}$, and let f be a function from $\mathcal{X}^{M_1}$ to $\mathcal{X}^{M_2}$ such that, for all $S \in \mathfrak{S}$,

$$\mu_S^{M_2}(y) = \sum_{x:f(x)=y} \mu_S^{M_1}(x)$$

where observable M_2 is called the coarse-graining of the observable M_1. In this case, we write $M_2 = f \circ M_1$.

Axiom 3. For an arbitrary observable $M_1 \in \mathfrak{M}$ and an arbitrary (necessarily, finitevalued) function f on $\mathcal{X}^{M_1}$, there exists an observable $M_2 \in \mathfrak{M}$, such that $M_2 = f \circ M_1$.

A pair of nonempty sets $(\mathfrak{S}, \mathfrak{M})$ satisfying Axioms $1 - 3$ will be called statistical model. The statistical model is said to be separated if the following Axiom holds.

Axiom 4. From the fact that $\mu_{S_1}^M = \mu_{S_2}^M$ for all $M \in \mathfrak{M}$ it follows that $S_1 = S_2$, and from $\mu_S^{M_1} = \mu_S^{M_2}$ for all $S \in \mathfrak{S}$ it follows that $M_1 = M_2$.

For a separated model both the operation of mixing in $\mathfrak{S}$ and the coarse-graining in $\mathfrak{M}$ are uniquely defined. Thus, the set of states $\mathfrak{S}$ obtains a convex structure, and the set of observables $\mathfrak{M}$ has the structure of a partial order.

Observables $M_1, \ldots, M_m$ are called compatible if they are all coarse-grainings of some observable M, that is, $M_j = f_j \circ M$ for $j = 1, \ldots, m$. The outcome of compatible observables can be obtained as a result of data post-processing in a single-measurement experiment. Statistical models in which all observables are compatible are, in fact, classical.

Proposition 2.1. Let $(\mathfrak{S}, \mathfrak{M})$ be a separated statistical model in which there exists the maximal observable M^*, such that all other observables are obtained by coarsegrainings of this maximal observable. Then there exist a finite set Ω, a one-to-one affine map $S \to P_S$ of the convex set of states $\mathfrak{S}$ into the set of all probability distributions on Ω, and a one-to-one map $M \to f_M$ of the set of observables $\mathfrak{M}$ onto a subset of random variables on Ω, preserving the relation of coarse-graining, such that

$$\mu_S^M(x) = \sum_{\omega:f_M(\omega)=x} P_S(\omega) \tag{2.5}$$

Proof. Let Ω be the set of outcomes of the maximal observable M^*, and let $P_S(\omega)$ be its probability distribution in a state S. According to the assumption of maximality, for any observable M there is a function f_M, such that the relation (2.5) holds. The fact that the maps $S \to P_S$ and $M \to f_M$ are one-to-one follows from the separatedness of the model. Checking the properties of the maps is left as an exercise to the reader. $\square$

Thus the outcome of this "maximal observable" constitutes the phase space Ω of the system, and all states are represented by probability measures on Ω. The main classical model is the Kolmogorov model, in which the set of states is a collection of all probability distributions $\mathfrak{P}(\Omega)$, and observables are described by random variables on Ω. The above proposition means that a statistical model in which all the observables are compatible can be embedded into the Kolmogorov model.

Another important classical model, which we call the Wald model, differs from Kolmogorov's model in that it embraces "unsharp" or "randomized" classical observables (see Section 2.1.1; randomization was consistently used by Wald in statistical decision theory and by von Neumann in game theory). To obtain a result similar to Proposition 2.1, one should introduce stochastic versions of coarse-graining and compatibility. Let $M_1, M_2 \in \mathfrak{M}$, and let Π be a transition probability from $\mathcal{X}^{M_1}$ to $\mathcal{X}^{M_2}$, such that for all $S \in \mathfrak{S}$

$$\mu_S^{M_2}(y) = \sum_x \Pi(y \mid x) \mu_S^{M_1}(x).$$

In this case, observable M_2 is called the stochastic coarse-graining of the observable M_1. Observables $M_1, \ldots, M_m$ are stochastically compatible, if they are all stochastic coarse-grainings of one observable M. In the Wald model, all observables are stochastically compatible and any separated model with this property can be embedded within a Wald model.

In the statistical model of quantum mechanics, states and observables are described by operators in a Hilbert space. Many efforts were spent on obtaining a reasonable axiomatic scheme, leading to the Hilbert space formalism of quantum mechanics. However, this is not our goal here and we will proceed in a different way. We take for granted the description of quantum states as density operators in a Hilbert space and derive from it the most general concept of quantum observable (including both "sharp" and "unsharp" observables), following from the axioms of the statistical model.

10.2.4 2.2 Quantum States

A state of a quantum-mechanical system represents a statistical ensemble of independent, identically prepared copies of the system.

Definition 2.2. A quantum state is described by a density operator, i.e., a Hermitian operator S in a Hilbert space $\mathcal{H}$ of the system, satisfying the conditions

$$S \geq 0, \quad \operatorname{Tr} S = 1.$$

Let $\mathfrak{S}(\mathcal{H})$ be the set of all density operators. It is a convex subset of the real linear space of all Hermitian operators in $\mathcal{H}$. A convex combination $S = \sum_j p_j S_j$ of density operators will describe the mixture of the corresponding statistical ensembles, obtained by taking ensembles prepared in the states S_j and mixing them with weights p_j. In a quantum-statistical ensemble there are two kinds of randomness. One is due to fluctuations in the classical parameters of the preparation procedure. The other one is the intrinsically quantum irreducible randomness, present in any quantum state. The following theorem characterizes states without classical randomness.

Theorem 2.3. Extreme points of the set of quantum states $\mathfrak{S}(\mathcal{H})$, called pure states, are precisely one-dimensional projectors.

Proof. The spectral decomposition of the Hermitian operator S reads

$$S = \sum_{i=1}^{d} s_i \left|e_i\right\rangle \left\langle e_i\right|, \quad s_j \geq 0, \sum s_j = 1 \tag{2.6}$$

where s_i are the eigenvalues and $|e_i\rangle$ are the eigenvectors of S. If S is extreme, this sum can contain only one nonzero term, implying that S is a one-dimensional projector. Conversely, let S be a one-dimensional projector, and

$$S = pS_1 + (1-p)S_2, \quad 0 < p < 1$$

Taking the square, we obtain

$$0 = S - S^2 = pS_1\left(I - S_1\right) + (1-p)S_2\left(I - S_2\right) + p(1-p)\left(S_1 - S_2\right)^2. \tag{2.7}$$

This equation is the sum of three positive operators, each of which must therefore be equal to zero. But this implies $S_1 = S_2 = S$, i. e., S is extreme.

From the viewpoint of probability theory, one-dimensional projectors are the noncommutative analog of distributions that are degenerated at some phase space point, while the role of the uniform distribution is played by the chaotic state, with the density operator $S = \frac{1}{d} I$.

Exercise 2.4 Show that if $\dim \mathcal{H} = d, \mathfrak{S}(\mathcal{H})$ can be embedded into the real vector space of dimensionality $n = d^2 - 1$. If $\mathcal{H}$ is a Euclidean (real Hilbert) space, then $n = d(d+1)/2 - 1$.

The spectral decomposition (2.6) shows that every quantum state is a mixture of no more than d pure states, where $d = \dim \mathcal{H}$. Thus, in the case of a set of quantum states, the Carathéodory theorem overestimates the number of extreme points that are actually present in the mixture(1.21). On the other hand, this theorem gives the exact value for the simplex of probability distributions on a "phase space" $\Omega = \{1, \dots, n+1\}$, representing the statistical states of a classical system. This suggests an idea of interpreting quantum theory as a probabilistic model with specific nonclassical constraints (a hidden-variable theory). For a single quantum system, such a viewpoint is possible, although up to now it did not prove to be productive compared to standard quantum mechanics. On the other hand, for composite systems this viewpoint leads to an inevitable contradiction with the physical principle of locality (separability) (see Section 3.2.1).

The simplest, and yet fundamental example is qubit - a two-level quantum system, $\dim \mathcal{H} = 2$. We use the canonical basis, i.e., $\begin{bmatrix} 1 \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ 1 \end{bmatrix}$. It is convenient to introduce the basis in the real space of 2×2 Hermitian matrices, called Pauli matrices,

$$I \equiv \sigma_0 = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad \sigma_x = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad \sigma_y = \begin{bmatrix} 0 & -i \\ i & 0 \end{bmatrix}, \quad \sigma_z = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}.$$

In particular, a density operator $S \in \mathfrak{S}(\mathcal{H})$ can be represented as

$$S = \frac{1}{2}\left(I + a_x\sigma_x + a_y\sigma_y + a_z\sigma_z\right) = \frac{1}{2}\begin{bmatrix} 1+a_z & a_x - ia_y \\ a_x + ia_y & 1-a_z \end{bmatrix}. \tag{2.8}$$

The condition $\det S \geq 0$ imposes the following constraint onto the Stokes parameters $\vec{a} = (a_x, a_y, a_z)$:

$$|\vec{a}|^2 \equiv a_x^2 + a_y^2 + a_z^2 \leq 1.$$

Thus, $\mathfrak{S}(\mathcal{H})$ as a convex set is isomorphic to the unit ball in $\mathbb{R}^3$, which we shall call the Bloch ball.

Exercise 2.5 Show that the density operator (2.8) has the eigenvalues $\frac{1 \pm |\vec{a}|}{2}$.

The pure states are characterized by the condition $a_x^2 + a_y^2 + a_z^2 = 1$ and form the Bloch sphere. By introducing Euler angles θ, ϕ, so that $a_z = \cos\theta, a_x + ia_y = \sin\theta e^{i\phi}$, we have $S = |\psi(\vec{a})\rangle\langle\psi(\vec{a})|$, where

$$|\psi(\vec{a})\rangle = \begin{bmatrix} \cos\frac{\theta}{2}e^{-i\phi/2} \\ \sin\frac{\theta}{2}e^{i\phi/2} \end{bmatrix}. \tag{2.9}$$

For an electron, which is a spin-1/2 particle, the vector $\psi(\vec{a})$ describes the pure state with the spin direction $\vec{a}$ produced by a Stern-Gerlach filter with this direction
of the magnetic field gradient. The mixed state, with $a_x = a_y = a_z = 0$, described by the density operator $S = \frac{1}{2}I$ for which all spin directions are equiprobable, is the chaotic state (see the Feynman lectures [70] for more detail).

Another important example of a two-level system is the polarization of a monochromatic photon, as visualized in classical optics experiments. In this case, the parameter $\frac{\theta}{2}$ is the angle of linear polarization, while $\frac{\phi}{2}$ characterizes circular polarization. For a linearly polarized photon $\phi = 0$. In particular, for a vertically polarized photon $\theta = 0$, while for a horizontally polarized one $\theta = \pi$.

10.2.5 2.3 Quantum Observables

10.2.6 2.3.1 Quantum Observables from the Axioms

Consider a statistical model in which the state space is the convex set $\mathfrak{S}(\mathcal{H})$ of all density operators in a Hilbert space $\mathcal{H}$. Let M be an observable. Now, by Axiom 2, the probabilities of the outcome of the measurement $\mu_S^M(x)$ should be affine functions of state.

Theorem 2.6. Let the map $S \to \mu_S$ be an affine function on $\mathfrak{S}(\mathcal{H})$ such that $0 \le \mu_S \le 1$. Then there exists an operator M on $\mathcal{H}$ with $0 \le M \le I$ such that, for every $S \in \mathfrak{S}(\mathcal{H})$,

$$\mu_S = \operatorname{Tr} SM \tag{2.10}$$

Proof (Sketch). Let us show that it is possible to extend the map $S \to \mu_S$ to a welldefined linear function on the space $\mathfrak{T}_h(\mathcal{H})$ of all Hermitian operators in $\mathcal{H}$.

First, we note that by separating positive and negative parts in the spectral decomposition (1.6), every Hermitian operator A can be represented as the difference of two positive operators, e. g., as in (1.8). Normalizing by the traces, we can always write

$$A = t_+ S_+ - t_- S_-, \quad t_\pm \ge 0, \quad S_\pm \in \mathfrak{S}(\mathcal{H}). \tag{2.11}$$

The representation of an operator A in the form of (2.11) is, of course, not unique.

Exercise 2.7 Using the affinity of the function $S \to \mu_S$, show that the value $\mu_A = t_+\mu_{S_+} - t_-\mu_{S_-}$ is uniquely defined (i.e., depends solely on the operator A, but not on the concrete decomposition of A into the difference of positive operators), and that $A \to \mu_A$ is a real, linear function.

Next, every operator A can be represented as $A = A_1 + iA_2$, where $A_1 = \frac{1}{2}(A + A^*)$, $A_2 = \frac{1}{2i}(A - A^*)$ are Hermitian operators. This representation is unique, and by setting $\mu_A = \mu_{A_1} + i\mu_{A_2}$, we obtain the unique complex linear extension of the function μ_A to the space of all linear operators in $\mathcal{H}$. Any such function apparently has the form

$$\mu_A = \operatorname{Tr} AM \tag{2.12}$$

where M is an operator in H. Taking $A = |\psi\rangle\langle\psi|$, where ψ is a unit vector and using (1.12), we have, by assumption, $0 \le \langle\psi \mid M\psi\rangle \le 1$ for all ψ, hence $0 \le M \le I$. □

A collection of operators $\{M_x, x \in \mathcal{X}\}$ is called the resolution of the identity or probability operator-valued measure [1] (POVM) on $\mathcal{X}$ if

$$M_x^* = M_x \ge 0, \quad \sum_x M_x = I$$

Corollary 2.8. Let $S \to \{\mu_S(x), x \in \mathcal{X}\}$ be an affine map of the convex set of quantum states $\mathfrak{S}(\mathcal{H})$ into the set of probability distributions on a finite set $\mathcal{X}$. Then there exists a POVM $M = \{M_x\}$ in $\mathcal{H}$ such that

$$\mu_S(x) = \operatorname{Tr} SM_x, \quad x \in \mathcal{X}. \tag{2.13}$$

The proof of the corollary is left as an exercise to the reader. This corollary leads to the following.

Definition 2.9. A quantum observable with outcomes in $\mathcal{X}$ is described by a POVM $\{M_x, x \in \mathcal{X}\}$. The probability distribution μ_S^M of the observable $M = \{M_x\}$ in a state S is given by formula (2.13).

By accepting this definition of a quantum observable, we introduce the maximal statistical model, with the state space coinciding with the set of all density operators and with the set of

observables consisting of all POVMs in $\mathcal{H}$. In the standard expositions of quantum mechanics, the more restricted notion of quantum observable is used.

Definition 2.10. The quantum observable is called sharp if all operators $M_x = E_x$ are projectors, i. e., $E_x^2 = E_x$.

Exercise 2.11 Show that the condition $E_x^2 = E_x$, for all outcomes x, is equivalent to $E_x E_y = \delta_{xy} E_x$ for all x, y, i. e., the projectors E_x are mutually orthogonal.

The corresponding resolutions of the identity are called orthogonal. Sharp observables are thus described by orthogonal resolutions of the identity in $\mathcal{H}$. Observables for which the outcomes are real numbers, i.e., $\mathcal{X} \subset \mathbb{R}$, are called real. The spectral decomposition

$$X = \sum_{x \in \mathcal{X}} x E_x$$

sets a one-to-one correspondence between sharp real observables $E = \{E_\chi\}$ and Hermitian operators X in $\mathcal{H}$ (which are also called observables). Coarse-graining for such

observables takes the form of functional calculus. Namely, for a function $f : \mathbb{R} \to \mathbb{R}$, an observable $f \circ E$ corresponds to the Hermitian operator $f(X)$ (exercise).

The expectation (mean value) of a sharp real observable X in the state S is given by the Born-von Neumann statistical formula

$$\mathrm{E}_S(X) = \sum x \mu_S^E(x) = \mathrm{Tr}\, SX.$$

The relation (2.13) can be regarded as an extension of this formula.
The statistical model in which states are described by density operators and observables - by Hermitian (self-adjoint) operators - was considered in great detail by von Neumann [237].

10.2.7 2.3.2 Compatibility and Complementarity

Definition 2.12. The commutator of the operators X, Y is $[X, Y] = XY - YX$. Operators X, Y commute if $[X, Y] = 0$.

Theorem 2.13. Let $E = \{E_x\}$ and $F = \{F_y\}$ be sharp observables. In this case, the following are equivalent:
i. E, F are compatible;
ii. projectors E_x and F_y commute for all x, y.

If E, F are real observables, this is equivalent to
iii. the corresponding Hermitian operators $X = \sum_x x E_x, Y = \sum_y y F_y$ commute.

Proof. ii $\Rightarrow$ i Put $M_{x,y} = E_x F_y = F_y E_x$. Since the product of commuting projections is a projector, $M = \{M_{x,y}\}$ is a (sharp) observable. Moreover, $E = f \circ M, F = g \circ M$, where $f(x, y) = x, g(x, y) = y$. Thus, E, F are compatible.
i $\Rightarrow$ ii If E, F are compatible, there exists an observable $M = \{M_z\}$ such that

$$E_x = \sum_{z : f(z) = x} M_z, \quad F_y = \sum_{z : g(z) = y} M_z$$

for some functions f, g (we agree to set M_z to zero if there is no z satisfying the condition in question).

Lemma 2.14. Let $0 \leq A \leq P$, where P is a projector. Then $[A, P] = 0$.
Proof. We have $(I - P)A(I - P) = 0$, hence $\sqrt{A}(I - P) = 0$, hence $A(I - P) = 0$, hence $A = AP$, hence $PA = (AP)^* = AP$. $\square$

[0]1 The term "positive operator-valued measure" is also used in the literature, which is however less precise, as it does not reflect the normalization of the measure.

Now, if $f(z) = x$, then $E_x \geq M_z$ and by Lemma 2.14 $[E_x, M_z] = 0$. If $f(z) \neq x$, $I - E_x \geq M_z$, and again $[E_x, M_z] = 0$. Thus, E_x commute with all M_z and hence with $F_y = \sum_{z:g(z)=y} M_z$.
ii $\Rightarrow$ iii This is obvious. Conversely, let $[X, Y] = 0$. In this case, $[f(X), g(Y)] = 0$ for arbitrary polynomials f, g. Taking the polynomials, which vanish at all points of the corresponding spectra except x (resp. y), we obtain $[E_x, F_y] = 0$. $\square$

If E, F are compatible, then denoting $\hat{M}_{xy} = \sum_{z:f(z)=x,g(z)=y} M_z$, we have

$$E_x = \sum_y \hat{M}_{xy}, \quad F_y = \sum_x \hat{M}_{xy}.$$

Observable $\hat{M}$ describes the statistics of joint measurement of E, F. Their joint probability distribution in the state S is given by

$$\mu_S^{EF}(x, y) = \operatorname{Tr} S\hat{M}_{xy}.$$

One can similarly define a joint measurement and probability distribution for an arbitrary finite collection of compatible observables.

Exercise 2.15 Show that the only observable compatible with all quantum observables is a constant, i.e., the observable equal to a scalar multiple of the unit operator.

Existence of (the vast variety of) incompatible observables is a manifestation of the quantum feature of complementarity. Physical measurements on micro-objects are implemented by macroscopic experimental devices, each of which requires a specific organization of the environment in space and time (such as, e.g., Stern-Gerlach experiments). Different ways of organization, corresponding to measurements of different observables, may be mutually exclusive (despite the fact that they relate to the identically prepared micro-object), i. e., complementary. Complementarity is the first fundamental distinction between quantum and classical statistical models.

Example 2.16. Consider a spin-1/2 particle, and let the unit vector $\vec{a} = (a_x, a_y, a_z)$ give a direction. Then

$$\sigma(\vec{a}) = a_x\sigma_x + a_y\sigma_y + a_z\sigma_z = \begin{bmatrix} a_z & a_x - ia_y \\ a_x + ia_y & -a_z \end{bmatrix} \tag{2.14}$$

is the observable of the projection of the spin[2] onto the direction $\vec{a}$. Indeed, the operator $\sigma(\vec{a})$ has the eigenvalues ± 1 (spin along and opposite the direction $\vec{a}$), and the spectral decomposition is given by

$$\sigma(\vec{a}) = |\psi(\vec{a})\rangle\langle\psi(\vec{a})| - |\psi(-\vec{a})\rangle\langle\psi(-\vec{a})|. \tag{2.15}$$

Recall that $\vec{a}$ has the Euler angles (θ, ϕ), and $\psi(\vec{a})$, given by (2.9), is the vector of the pure state in $\mathcal{H}$, with the spin direction $\vec{a}$. The corresponding density operator, which is the one-dimensional projector onto $\psi(\vec{a})$, is

$$S(\vec{a}) = |\psi(\vec{a})\rangle\langle\psi(\vec{a})| = \frac{I + \sigma(\vec{a})}{2}.$$

Exercise 2.17 Prove

$$\sigma(\vec{a}_1)\,\sigma(\vec{a}_2) = (\vec{a}_1 \cdot \vec{a}_2) / + i\sigma(\vec{a}_1 \times \vec{a}_2). \tag{2.16}$$

Written for the basis vectors this amounts to

[0]2 In physical applications there is a dimensional factor $\hbar/2$, which can be removed by an appropriate choice of units.

$$\sigma_x^2 = I, \qquad \sigma_y^2 = I, \qquad \sigma_z^2 = I$$
$$\sigma_x\sigma_y = i\sigma_z, \qquad \sigma_y\sigma_z = i\sigma_x, \qquad \sigma_z\sigma_x = i\sigma_y \tag{2.17}$$

Taking into account that $\operatorname{Tr}\sigma(\vec{a}) = 0$, the relation (2.16) implies the following formula for the mean value of $\sigma(\vec{b})$:

$$\operatorname{Tr} S(\vec{a})\sigma(\vec{b}) = \vec{a}\cdot\vec{b}$$

Another corollary of (2.16) is

$$[\sigma(\vec{a}_1), \sigma(\vec{a}_2)] = 2i\sigma(\vec{a}_1 \times \vec{a}_2), \tag{2.18}$$

which implies that $\sigma(\vec{a}_1), \sigma(\vec{a}_2)$ are compatible if and only if $\vec{a}_1 = \pm\vec{a}_2$. In particular, the spin components $\sigma_x, \sigma_y, \sigma_z$ are incompatible observables.

10.2.8 2.3.3 The Uncertainty Relation

If X, Y are two operators, we can write

$$XY = X \circ Y + \frac{1}{2}[X, Y]$$

where $X \circ Y = \frac{1}{2}(XY + YX)$ is the symmetrized or Jordan product of X, Y.
Let S be some state. For an arbitrary collection $X = \{X_1, \ldots, X_n\}$ of sharp, real observables we introduce two real matrices, one symmetric and another skew-symmetric,

$$\mathrm{B}_S(X) = \left[\operatorname{Tr} SX_j^0 \circ X_k^0\right]_{j,k=1,\ldots,n}, \quad \mathrm{C}_S(X) = \left[i\operatorname{Tr} S[X_j, X_k]\right]_{j,k=1,\ldots,n}, \tag{2.19}$$

where $X_j^0 = X_j - I\mathrm{E}_S(X_j)$. The matrix $\mathrm{B}_S(X)$ is called the covariance matrix, while $\mathrm{C}_S(X)$ is called the commutation matrix of X. We have

$$\mathrm{B}_S(X) \geq \pm\frac{i}{2}\mathrm{C}_S(X) \tag{2.20}$$

in the sense of an inequality between complex Hermitian matrices. Indeed, the Hermitian matrix

$$\mathrm{B}_S(X) - \frac{i}{2}\mathrm{C}_S(X) = \left[\operatorname{Tr} SX_j^0X_k^0\right]_{j,k=1,\ldots,n}$$

is positive definite, since for arbitrary $c_j \in \mathbb{C}$

$$\sum_{j,k=1}^{n} \bar{c}_j c_k \operatorname{Tr} SX_j^0X_k^0 = \operatorname{Tr} SZ^*Z \geq 0$$

where $Z = \sum_{j=1}^n c_jX_j^0$. This produces inequality (2.20) with the $+$sign. The inequality with the minus sign follows after taking the transposes.

For two observables $X_1 = X - I\mathrm{E}_S(X)$ and $X_2 = Y - I\mathrm{E}_S(Y)$, inequality (2.20) is equivalent to the Schrödinger-Robertson uncertainty relation

$$D_S(X)D_S(Y) \geq \{E_S((X - IE_S(X)) \circ (Y - IE_S(Y)))\}^2 + \frac{1}{4}|E_S[X, Y]|^2, \tag{2.21}$$

where

$$\mathrm{D}_S(X) = \mathrm{Tr}\, S\left(X - I\mathrm{E}_S(X)\right)^2 \tag{2.22}$$

is the variance of the sharp real observable X in the state S. The quantity

$$\mathrm{E}_S\left(X - I\mathrm{E}_S(X)\right) \circ \left(Y - I\mathrm{E}_S(Y)\right) \tag{2.23}$$

represents the covariance of X, Y in the state S. If the observables X, Y are compatible, this quantity coincides with the covariance of random variables, in the sense of probability theory, with respect to their joint probability distribution. In this case, $\mathrm{E}_S[X, Y] = 0$ and (2.21) reduces to the Cauchy-Schwarz inequality for the covariance of random variables. However, if X, Y are not compatible, X, Y are not measurable in a single experiment and the variances $\mathrm{D}_S(X), \mathrm{D}_S(Y)$ in the uncertainty relation refer to the two different measurements performed over different representatives of the same statistical ensemble, while the covariance is just a formal characteristic of the state.

Exercise 2.18 Prove the noncommutative Cauchy-Schwarz inequality

$$\left|\mathrm{Tr}\, SX^*Y\right|^2 \leq \mathrm{Tr}\, SX^*X\ \mathrm{Tr}\, SY^*Y, \tag{2.24}$$

for arbitrary state S and operators X, Y in $\mathcal{H}$.

10.2.9 2.3.4 Convex Structure of Observables

The set of all (finite-valued) quantum observables in a Hilbert space $\mathcal{H}$ will be denoted by $\mathfrak{M}(\mathcal{H})$. Given a Hilbert space $\mathcal{H}$, the sets $\mathfrak{S}(\mathcal{H})$ of quantum states and $\mathfrak{M}(\mathcal{H})$ of quantum observables, by construction, together with the generalized Born-von Neumann statistical rule (2.13), satisfy the axioms of separated statistical models. However, this model has an additional convexity structure in $\mathfrak{M}(\mathcal{H})$, which is to some extent similar to that of $\mathfrak{S}(\mathcal{H})$.

Let $\{M^j\}$ be a finite collection of observables with the same space of outcomes $\mathcal{X}$. Given a probability distribution $\{p_j\}$, we can define the mixture $M = \{M_x; x \in \mathcal{X}\}$ of these observables in an obvious way, i.e.,

$$M_x = \sum_j p_j M_x^j, \quad x \in \mathcal{X}. \tag{2.25}$$

Thus, the set $\mathfrak{M}_\mathcal{X}$ of all observables with a given space of outcomes $\mathcal{X}$ is a convex set. Similar to what is the case with states, mixtures of observables describe measurements with fluctuations in the classical parameters of the measuring procedure.

The following result describes the relation between observables without classical randomness and sharp observables.

Theorem 2.19. Any sharp observable $M \in \mathfrak{M}_\mathcal{X}$ is an extreme point of $\mathfrak{M}_\mathcal{X}$. In the reverse direction, an extreme observable $M \in \mathfrak{M}_\mathcal{X}$, with commuting components, $[M_X, M_{X'}] \equiv 0$, is sharp.

Proof. Let M be sharp, and assume $M = pM^1 + (1-p)M^2, 0 < p < 1$. In this case, similar to (2.7),

$$pM_x^1\left(I - M_x^1\right) + (1-p)M_x^2\left(I - M_x^2\right) + p(1-p)\left(M_x^1 - M_x^2\right)^2 = 0, \tag{2.26}$$

and therefore $M_x^1 \equiv M_x^2 \equiv M_x$, and M is extreme.
Now note that in all cases, $M_x \leq I$ and hence $M_x^2 \leq M_x$. Taking some $x \in \mathcal{X}$ we have

$$M_x = \frac{1}{2}M_x^2 + \frac{1}{2}\left(2M_x - M_x^2\right), \tag{2.27}$$

$$M_{x'} = \frac{1}{2}M_{x'}\left(I + M_x\right) + \frac{1}{2}M_{x'}\left(I - M_x\right), \quad x' \neq x. \tag{2.28}$$

If $[M_x, M_{x'}] \equiv 0$, these relations represent M as a convex combination (with equal weights) of two other observables. If M is extreme, they should coincide with M, in particular $M_x^2 = M_x$. Hence, M is sharp. $\square$

It follows that in the classical case extreme observables coincide with the sharp ones, giving them a very clear characterization as observables without randomness in the measuring procedure. In the quantum statistical model, things are not so simple (and much more interesting). We call the two-valued observables tests (they are also called propositions, questions, effects in the literature, and they play a central role in various axiomatic approaches although, they have a rather special property
as concerns the important issue of extremity). The set of extreme quantum observables is exhausted by sharp observables only in this case of two outcomes. This fact follows from the theorem, because any test necessarily has commuting components $\{M_0, M_1 = I - M_0\}$. Thus, any extreme test is completely determined by the projector $P = M_0$.

For observables with more than two values, we consider the following construction.

Definition 2.20. Let $\{|\psi_x\rangle\}$ be an arbitrary finite collection of not necessarily normalized vectors in $\mathcal{H}$ such that $\sum_x |\psi_x\rangle \langle\psi_x| = I$. Such a collection is called an overcomplete system.

If $\{|\psi_x\rangle\}$ is an overcomplete system, an arbitrary vector $|\psi\rangle \in \mathcal{H}$ can be represented as a linear combination

$$|\psi\rangle = \sum_x c_x |\psi_x\rangle \qquad \text{with } c_x = \langle\psi_x \mid \psi\rangle, \tag{2.29}$$

where the coefficients $\{c_x\}$ need not be unique, because the vectors $|\psi_x\rangle$ may be linearly dependent. There also is a corresponding matrix representation of the operators. In a d-dimensional Hilbert space, overcomplete systems with more than d vectors always exist, and they can be built from any complete (possibly, linearly dependent) system as follows. Let $\{|\phi_x\rangle\}$ be a complete system of vectors in $\mathcal{H}$. The corresponding Gram operator is defined by

$$G = \sum_x |\phi_x\rangle \langle\phi_x|. \tag{2.30}$$

Completeness implies that G is nondegenerate. Now, $\{|\psi_x\rangle\}$, with $|\psi_x\rangle = G^{-1/2}|\phi_x\rangle$, is an overcomplete system because

$$\sum_x |\psi_x\rangle \langle\psi_x| = G^{-1/2} \sum_x |\phi_x\rangle \langle\phi_x| G^{-1/2} = I. \tag{2.31}$$

An overcomplete system determines a quantum observable M with the components

$$M_x = |\psi_x\rangle \langle\psi_x|, \quad x \in \mathcal{X}. \tag{2.32}$$

In particular, for any orthonormal basis $\{e_x\}$, the observable $M = \{|e_x\rangle \langle e_x|\}$ is sharp and, hence, an extreme observable.

Theorem 2.21. An observable (2.32) is extreme if and only if the operators M_x are linearly independent in the real vector space $\mathfrak{B}_h(\mathcal{H})$.

Proof. Let M be extreme and assume that

$$\sum_x c_x \left|\psi_x\right\rangle \left\langle\psi_x\right| = 0 \tag{2.33}$$

For $\epsilon > 0$ small enough, we define

$$M_x^{\pm} = (1 \pm \epsilon c_x)\, M_x \geq 0, \quad x \in \mathcal{X}.$$

Then $M^{\pm}$are observables and, by construction, $M = \frac{1}{2}M^+ + \frac{1}{2}M^-$. Therefore, $M_x^+ = M_x^- = M_x$ since M is extreme. Thus, (2.33) implies $c_x = 0$, i. e., the components of M are linearly independent.

Conversely, let

$$\left|\psi_x\right\rangle \left\langle\psi_x\right| = pM_x^1 + (1-p)M_x^2$$

be a convex decomposition of M. In this case, $0 \leq pM_x^1 \leq \left|\psi_x\right\rangle \left\langle\psi_x\right|$. By Lemma 2.14,

$$M_x^1 \left|\psi_x\right\rangle \left\langle\psi_x\right| = \left|\psi_x\right\rangle \left\langle\psi_x\right| M_x^1 = \left\langle\psi_x \mid \psi_x\right\rangle M_x^1,$$

whence $M_x^1 = \lambda_x \left|\psi_x\right\rangle \left\langle\psi_x\right|$, with $\lambda_x = \left\langle\psi_x\right| M_x^1 \left|\psi_x\right\rangle / \left\langle\psi_x \mid \psi_x\right\rangle^2$. Now, $\sum_x \lambda_x \left|\psi_x\right\rangle \left\langle\psi_x\right| = I$, i. e.,

$$\sum_x (\lambda_x - 1) \left|\psi_x\right\rangle \left\langle\psi_x\right| = 0.$$

Due to the linear independence of M_x, we must have $\lambda_x = 1$, and $M_x^1 = M_x$ for all x, which means that M is extreme.

From the result of Exercise 1.5, it follows that the dimensionality of the real space of Hermitian operators is equal to d^2. Thus, all overcomplete systems with n linearly independent components, $d < n \leq d^2$, determine unsharp extremal observables. A concrete example of such an observable with $n = 3, d = 2$ will be considered in the next section.

10.2.10 2.4 Statistical Discrimination Between Quantum States

10.2.11 2.4.1 Formulation of the Problem

In this section, we consider a statistical decision problem which will allow us to pass to the optimal information transmission via quantum channels in Part II of the book.

Let a quantum system be prepared in one of the states $S_x, x = 1, \ldots, n$. The observer is allowed to perform arbitrary measurements aimed at determining, in the best possible way, in which of these states, given a priori, the system was actually prepared. This kind of decision problem is typical for mathematical statistics and its applications in communication theory, where we deal with the optimal signal detection or estimation (see Section 3.3.1). On the other hand, in high-precision experiments, researchers are already able to operate with elementary quantum systems such as single ions, atoms, and photons. This leads to potentially important applications, such as quantum communication and quantum cryptography. A quite important issue is that of extracting the maximum possible information about the state of a given quantum system. In proposals currently under discussion for application to quantum computing, the information is written into states of elementary quantum cells, qubits, and is read via quantum measurements. From a statistical point of view, a measurement gives an estimate for the quantum state, either as a whole, or for some of its components (parameters), and the problem of finding the most informative measurement arises.

The statistic of the whole measurement procedure is described by an observable, i. e., by resolution of the identity $M = \{M_x\}$ in the system space $\mathcal{H}$. The probability to make a decision y, under the condition that the system was in the state S_x, is equal to $p_M(y \mid x) = \operatorname{Tr} S_x M_y$. In particular, the probability of making a correct decision is equal to $p_M(x \mid x)$. Let us additionally assume that the states S_x appear with probabilities π_x (e.g., in the case of equiprobable states $\pi_x = 1/n$). In this case, the average probability of making a correct decision is equal to

$$\mathcal{P}\{M\} = \sum_{x=1}^{n} \pi_x p_M(x \mid x)$$

and the problem is to maximize it with respect to all possible observables M.

10.2.12 2.4.2 Optimal Observables

Denoting by $W_x = \pi_x S_x \geq 0$ the average probability of a correct decision can be written explicitly as an affine function,

$$\mathcal{P}\{M\} = \sum_{x=1}^{n} \operatorname{Tr} W_x M_x$$

on the convex set of observables with n outcomes

$$\mathfrak{M}_n = \left\{ M = \{M_x\}_{x=1,\ldots,n} : M_x \geq 0, \sum_{x=1}^{n} M_x = I \right\}.$$

Maximization of an affine function defined on a compact convex set is a typical convex programming problem.

Theorem 2.22. The average probability of a correct decision $\mathcal{P}\{M\}$ attains its maximum at an extreme point of the set $\mathfrak{M}_n$. An observable M^0 is optimal if and only if there exists a Hermitian operator Λ, such that

i. $(\Lambda - W_x)\, M_x^0 = 0$;

ii. $\Lambda \geq W_x$.

The following duality relation holds:

$$\max\{\mathcal{P}\{M\} : M \in \mathfrak{M}_n\} = \min\{\operatorname{Tr}\Lambda : \Lambda \geq W_x, x = 1, \ldots, n\} \tag{2.34}$$

Proof. Since $\mathcal{P}\{M\}$ is a continuous affine function on a compact convex set $\mathfrak{M}_n$, the first statement follows from the result of Exercise 1.7.

Let us first prove the sufficiency of the conditions i, ii. Let Λ be a Hermitian operator satisfying the conditions i, ii. By using these conditions and the property (1.13), we obtain

$$\mathcal{P}\{M\} = \operatorname{Tr} \sum_x W_x M_x \leq \operatorname{Tr} \sum_x \Lambda M_x = \operatorname{Tr}\Lambda. \tag{2.35}$$

From i , we have $\Lambda M_x^0 = W_x M_x^0$. If we sum over x and take the trace of the resulting equation, we obtain

$$\operatorname{Tr}\Lambda = \operatorname{Tr}\Lambda \sum_x M_x^0 = \operatorname{Tr} \sum_x W_x M_x^0 = \mathcal{P}\left\{M^0\right\}. \tag{2.36}$$

Hence, we obtain

$$\mathcal{P}\{M\} \leq \mathcal{P}\left\{M^0\right\}, \quad \text{for all } M, \tag{2.37}$$

and therefore M^0 maximizes $\mathcal{P}$. Note that

$$\Lambda = \sum_x W_x M_x^0 = \sum_x M_x^0 W_x.$$

Now, we prove the necessity. Put $M_x = A_x^2$, where A_x are Hermitian operators satisfying the condition $\sum_x A_x^2 = I$. Applying the method of Lagrange multipliers, we can reduce the problem of maximizing $\mathcal{P}\{M\}$ on the set $\mathfrak{M}_n$ to the problem of maximizing the function

$$\operatorname{Tr} \sum_x W_x A_x^2 - \operatorname{Tr} \Lambda \left(\sum_x A_x^2 - I \right), \tag{2.38}$$

where Λ is a Hermitian operator, over all collections of Hermitian operators A_x. Here, the matrix elements of the Hermitian operator Λ represent the array of the Lagrange multipliers for this problem. Let A_x^0 be the optimal collection. In addition, let $A_x = A_x^0 + \epsilon Y_x$, with Hermitian Y_x, and consider (2.38) as a function of ϵ. By considering the coefficients of ϵ and ϵ^2, we obtain the conditions

$$\operatorname{Tr} \left[(W_x - \Lambda) A_x^0 + A_x^0 (W_x - \Lambda) \right] Y_x = 0$$
$$\operatorname{Tr} (W_x - \Lambda) Y_x^2 \leq 0$$

for an arbitrary Hermitian Y_χ, i.e.,

$$(W_x - \Lambda) A_x^0 + A_x^0 (W_x - \Lambda) = 0, \quad \Lambda - W_x \geq 0.$$

The second inequality is just condition ii of the theorem. By putting $M_x^0 = (A_x^0)^2$, the first relation implies $\operatorname{Tr} (\Lambda - W_x) M_x^0 = 0$, which, together with the second inequality, leads to condition i. □

Exercise 2.23 Prove that the operator Lagrange multiplier Λ is the unique solution Λ^0 of the dual problem on the right side of (2.34).

Let us illustrate the meaning and applications of these conditions with some examples.

Example 2.24. Consider the classical case where all density operators S_x, and hence the operators W_x, commute. In this case, there is a common orthonormal basis $\{|\omega\rangle\}$ in which they are all diagonal,

$$W_x = \sum_\omega W_x(\omega) |\omega\rangle\langle\omega|.$$

In this case, the dual problem has the unique solution

$$\Lambda^0 = \sum_\omega \max_x W_x(\omega) |\omega\rangle\langle\omega|,$$

where $\max_x W_x(\omega)$ is the upper envelope of the family of functions $W_x(\omega), x = 1, \ldots, n$. A solution of the initial problem is given by the formula

$$M_x^0 = \sum_\omega \mathbf{1}_{\Omega_x}(\omega) |\omega\rangle\langle\omega|,$$

where $\mathbf{1}_{\Omega_x}$ denotes the indicator of the subset Ω_x, where subsets $\Omega_x \subseteq \{\omega : \Lambda^0(\omega) = W_X(\omega)\}$ are assumed to be nonintersecting and to constitute a partition of the set $\Omega = \{\omega\}$.

This solution amounts to the principle of maximal likelihood in classical statistics. The decision x should be taken for those observations ω for which the posterior gain $W_x(\omega)$ is maximal. Thus, in the classical case, the optimal observable can always be chosen sharp. This is directly related to the fact that in the commutative case extreme points of the set $\mathfrak{M}_n$ are precisely the orthogonal resolutions of the identity (cf. Theorem 2.19).

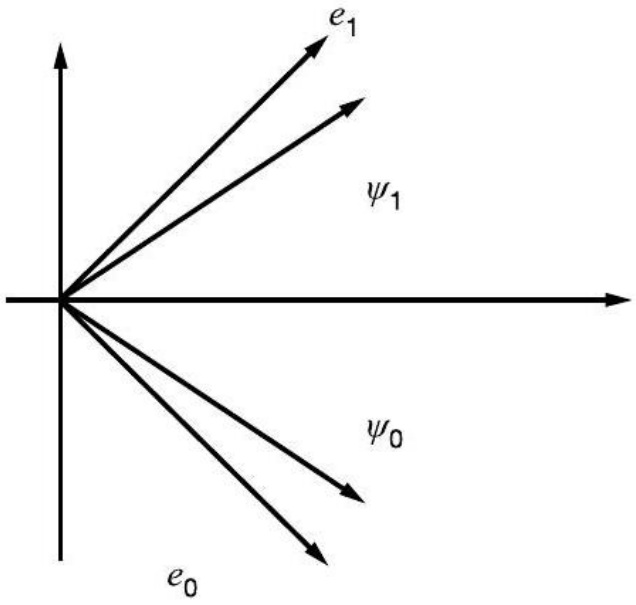


Figure 2.2: Discrimination between two pure states.

Example 2.25 (Discrimination Between the Two States). Let S_0, S_1 be two density operators, with π_0, π_1 their a priori probabilities. An observable (test) is given by resolution of the identity $\{M_0, M_1\}$, so that $M_0 + M_1 = I$. This case can be reduced to the previous one, by representing

$$W_0 = \pi_1 S_1 + W_0', \quad W_1 = \pi_1 S_1 + W_1',$$

where the operators $W_0' = \pi_0 S_0 - \pi_1 S_1, W_1' = 0$ commute. Thus

$$\mathcal{P}\{M\} = \pi_1 + \mathrm{Tr}\,(W_0' M_0 + W_1' M_1)\,, \tag{2.39}$$

and

$$\Lambda^0 = \max\{\pi_0 S_0 - \pi_1 S_1, 0\} = (\pi_0 S_0 - \pi_1 S_1)_+\,. \tag{2.40}$$

Any optimal M_0^0 has the form

$$M_0^0 = \mathbf{1}_{(0,\infty)}\,(\pi_0 S_0 - \pi_1 S_1) + X_0, \tag{2.41}$$

where the first term is the projector onto the positive part of the spectrum of $\pi_0 S_0 - \pi_1 S_1$, and the second is an operator supported by the null subspace of $\pi_0 S_0 - \pi_1 S_1$, such that $0 \le X_0 \le I$. The maximum is given by

$$\mathcal{P}\{M\} = \pi_1 + \mathrm{Tr}\,(\pi_0 S_0 - \pi_1 S_1)_+\,. \tag{2.42}$$

By using the relation

$$(\pi_0 S_0 - \pi_1 S_1)_+ = \frac{1}{2}\,|\pi_0 S_0 - \pi_1 S_1| + \frac{1}{2}\,(\pi_0 S_0 - \pi_1 S_1)\,,$$

we obtain

$$\max \mathcal{P}\{M\} = \frac{1}{2}\,(1 + \|\pi_0 S_0 - \pi_1 S_1\|_1)\,.$$

In particular, taking $\pi_0 = \pi_1 = \frac{1}{2}$, we have

$$\max \mathcal{P}\{M\} = \frac{1}{2}\left(1 + \frac{1}{2}\left\|S_0 - S_1\right\|_1\right),$$

so that the more distinguishable the density operators S_0 and S_1 are in the sense of the trace norm, the greater the maximum will be.

Proposition 2.26. Let $S_0 = |\psi_0\rangle\langle\psi_0|, S_1 = |\psi_1\rangle\langle\psi_1|$ be pure states. In this case, the maximum of $\mathcal{P}\{M\}$ is given by

$$\max_M \mathcal{P}\{M\} = \frac{1}{2}\left(1 + \sqrt{1 - 4\pi_0\pi_1 |\langle\psi_0 \mid \psi_1\rangle|^2}\right), \tag{2.43}$$

and is achieved on a sharp observable. In particular, if $\pi_0 = \pi_1 = 1/2$, the maximum is equal to

$$\max_M \mathcal{P}\{M\} = \frac{1}{2}\left(1 + \sqrt{1 - |\langle\psi_0 \mid \psi_1\rangle|^2}\right). \tag{2.44}$$

Proof. Consider the eigenvalue problem for the rank two operator

$$\pi_0 |\psi_0\rangle\langle\psi_0| - \pi_1 |\psi_1\rangle\langle\psi_1|.$$

This operator may have eigenvalue zero, corresponding to the orthogonal complement to its support, which is just the linear span $\mathcal{L}$ of the vectors $|\psi_0\rangle, |\psi_1\rangle$. The relevant part of the optimal observable is also supported by $\mathcal{L}$, so we can restrict ourselves to the eigenvectors that are linear combinations, i.e.,

$$|\psi\rangle = c_0 |\psi_0\rangle + c_1 |\psi_1\rangle.$$

Substituting this into the eigenvector equation results in

$$\pi_0 (c_0 + \langle\psi_0 \mid \psi_1\rangle c_1) = \lambda c_0 \tag{2.45}$$
$$-\pi_1 (\langle\psi_1 \mid \psi_0\rangle c_0 + c_1) = \lambda c_1 \tag{2.46}$$

whence the eigenvalues are

$$\lambda_{0,1} = \frac{1}{2}\left[\pi_0 - \pi_1 \pm \sqrt{1 - 4\pi_0\pi_1 |\langle\psi_0 \mid \psi_1\rangle|^2}\right]$$

with the corresponding orthonormal basis of eigenvectors $|e_0\rangle, |e_1\rangle$. Now,

$$\|\pi_0 |\psi_0\rangle\langle\psi_0| - \pi_1 |\psi_1\rangle\langle\psi_1|\|_1 = \lambda_0 - \lambda_1 = \sqrt{1 - 4\pi_0\pi_1 |\langle\psi_0 \mid \psi_1\rangle|^2}$$

and we get (2.43).

The sharp optimal observable in the subspace $\mathcal{L}$ is just $\{|e_0\rangle\langle e_0|, |e_1\rangle\langle e_1|\}$. If $\pi_0 = \pi_1 = 1/2$, the optimal basis is situated symmetrically with respect to $|\psi_0\rangle, |\psi_1\rangle$ (see Figure 2.2).

Example 2.27. On a plane (considered as a real subspace of two-dimensional complex space), consider an "equiangular" configuration of the three vectors (see Figure 2.3)

$$|\psi_j\rangle = \begin{bmatrix} \cos\frac{2j\pi}{3} \\ \sin\frac{2j\pi}{3} \end{bmatrix}, \quad j = 0, 1, 2 \tag{2.47}$$

The corresponding density matrices $S_j = |\psi_j\rangle\langle\psi_j|$ describe the states of a two-level quantum system such as a linearly polarized photon or a spin-1/2 particle.

We have

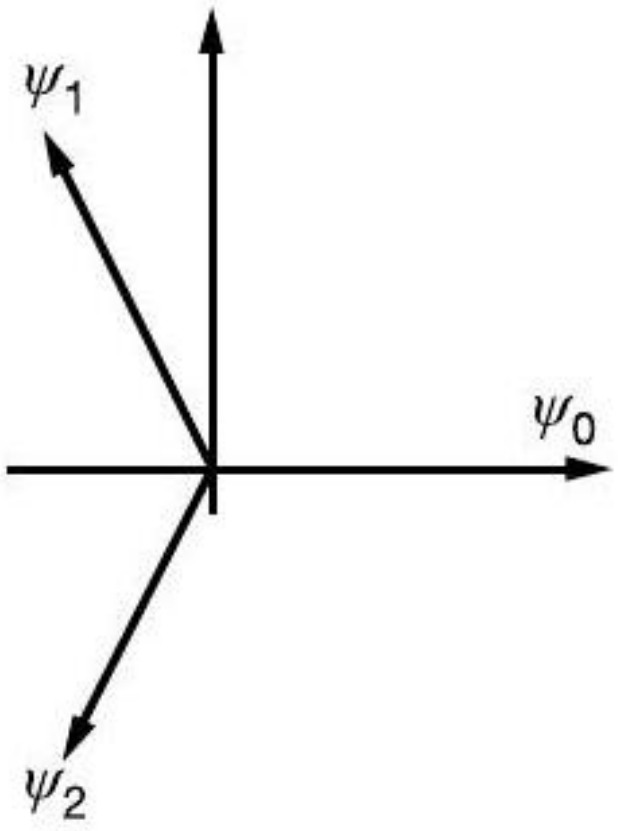

Figure 2.3: Trine on the plane.

$$S_j = \frac{1}{2}\left(I + \begin{bmatrix} \cos\frac{4j\pi}{3} & \sin\frac{4j\pi}{3} \\ \sin\frac{4j\pi}{3} & -\cos\frac{4j\pi}{3} \end{bmatrix}\right), \tag{2.48}$$

so that

$$\sum_{j=0}^{2} S_j = \frac{3}{2} I$$

because $\sum_{j=0}^{2} e^{i\frac{4\pi j}{3}} = 0$.

It follows that $M_k^0 = \frac{2}{3} S_k, k = 0, 1, 2$, is the resolution of the identity that corresponds to the overcomplete system $\left\{\sqrt{\frac{2}{3}}\,|\psi_k\rangle\,; k = 0, 1, 2\right\}$. The corresponding observable is extremal, since it satisfies the conditions of Theorem 2.21.

Let us show that, in the case of equiprobable states $\pi_j = 1/3$, observable $\{M_k^0\}$ is optimal, by checking the conditions of Theorem 2.22. Since $S_j^2 = S_j$,

$$\Lambda^0 = \sum_{j=0}^{2} \frac{1}{3} S_j M_j^0 = \frac{2}{9} \sum_{j=0}^{2} S_j = \frac{1}{3} I$$

so that condition ii is satisfied; $I/3 = \Lambda^0 \geq S_j/3$. Condition i is also satisfied since

$$\left(\Lambda^0 - \frac{1}{3} S_j\right) M_j^0 = \frac{1}{3}\left(I - S_j\right) S_j = 0.$$

Thus, $\max \mathcal{P}\{M\} = \operatorname{Tr} \Lambda^0 = 2/3$. Let us now find the maximum over all sharp observables with three outcomes. A nontrivial orthogonal resolution of the identity with three components

in the two-dimensional space has the form $M_0 = |e_0\rangle\langle e_0|$, $M_1 = |e_1\rangle\langle e_1|, M_2 = 0$, where $|e_0\rangle, |e_1\rangle$ is an arbitrary basis. Thus, the problem reduces to the optimal discrimination of the two equiprobable states S_0, S_1. Applying relation (2.44) to the case $\langle\psi_0 \mid \psi_1\rangle = -\frac{1}{2}$, we obtain

$$\max_{M-\text{ sharp}} \mathcal{P}\{M\} = \frac{2}{3}\frac{1+\sqrt{3}/2}{2} < \frac{2}{3} = \max_{M\in\mathfrak{M}} \mathcal{P}\{M\}.$$

Thus, in the quantum state discrimination, using unsharp observables can lead to an improvement in comparison with the sharp ones. Let us stress that in the similar classical problem (of discrimination between probability distributions) unsharpness or randomization can never lead to such an improvement. From a geometrical point of view, the reason for this phenomenon is, of course, that in the quantum case not all extremal observables (among which the optimal one is found) are sharp ones.

10.2.13 2.5 Notes and References

1. Among the texts devoted to the mathematical foundations of quantum mechanics let us mention the monographs of von Neumann [237], Mackey [171], Segal [204], Faddeev and Yakubovsky [68]. A survey of axiomatic approaches is given in the paper of Wightman [246] and also in the Comments to Chapter VIII of the book of Reed and Simon [193]. One aim of any axiomatics that is longed for is a derivation of the Hilbert space formalism. Such a derivation within the framework of the operational approach (see below) was realized, in the finite-dimensional case, in the paper of Araki [8] (for a more recent approach, see Hardy [92]). However, this is a separate topic; for our purposes it will suffice to postulate the state space $\mathfrak{S} = \mathfrak{S}(\mathcal{H})$.

The description of mixed states by density operators (matrices) was introduced independently by von Neumann, Weyl, and Landau (see footnote 172 in Section IV. 2 of von Neumann's book [237]).

The axiomatic approach, in which the central role is played by the duality between the two partially ordered linear spaces, generated by a convex set of quantum states, and by the order interval $[0, I]$ of two-valued observables (effects or tests), was developed by the school of Ludwig [170], [73]; see also Davies [56] (this approach is usually called operational). A detailed investigation of the statistical structure of quantum theory, based on the operational approach, is undertaken in the books [122], [115], where one can find a detailed bibliography.

In Proposition 2.1, we had to assume the existence of the maximal observable for the sole reason that, for simplicity, from the beginning we restricted ourselves to observables with finite sets of outcomes. With an appropriate generalization the existence of the maximal observable (in general, with an infinite Ω) can be deduced from compatibility of all observables of the model. Essentially, this is the message of the famous Kolmogorov extension theorem for a random process defined by system of compatible finite-dimensional distributions. A detailed study of the notion of stochastic compatibility, including the proof that the separated model, in which all observables are stochastically compatible, can be embedded within the Wald model, can be found in the paper [112].

A brief introduction to the basic notions of quantum theory targeted at quantum information science is given in the books of Nielsen and Chuang [179] and Hayashi [95]. The papers of Fuchs [75], Chiribella et al. [45], Masanes and Müller [175] and the book of D'Ariano et al. [54] elaborate on information-theoretical approaches to the foundations of quantum theory.

2. The generalized concept of a quantum observable presented here was developed by Ludwig [170], Davies and Lewis [56], and Holevo [122]. As concerns the convex structure of the set of observables, see Kraus [157]. In analysis and in signal theory, overcomplete systems are known under the name "(rigid) frames."

The spin of a quantum particle is intrinsically related to representations of the group of rotations of three-dimensional Euclidean space [245], [70], [171]. Results related to Theorem 2.21 are discussed in the paper of Davies [55].

3. The problem of discriminating the two pure quantum states was treated, in 1968, in the paper of Bakut and Shchurov [16]. Such problems arise naturally in connection with the detection of weak light sources, and in quantum optics [103]. A physical device that achieves the bound (2.43) for two coherent states of a radiation field (see Chapter 12), called Dolinar receiver, was described in [103]. It uses photon counting as a measurement, together with an ingenious feedback from the output of the photon detector to the input field of the counter.

General detection and estimation theory for quantum states was developed in the 1970s in works of Helstrom [102], Holevo [107], Yuen and Lax [260], Stratonovich [228], Belavkin [20], and other authors. Example 2.27, with the three equiangular states, was proposed in [110]. For further details and extensive references, see the monographs [103], [122]. The new interest in quantum estimation theory emerged in connection with the ideas of quantum computation. Any such computation is completed by measuring parameters of the final state of the quantum computer, which should be maximally precise. The achievements of modern quantum estimation theory, including asymptotic theory, are presented in the books of Hayashi [95] and Petz [190]. The Bayes problem is a convex programming problem (see [172], [194]), and Theorem 2.22 could be proved basing on the corresponding duality theorem. An interesting variation of this problem proposed by Peres [187] concerns the unambiguous discrimination between quantum states when an inconclusive result is allowed. For a survey of the recent status of the field see, e. g., Herzog [104].

10.3 3 Composite Systems and Entanglement

10.3.1 3.1 Composite Systems

10.3.2 3.1.1 Tensor Products

The new possibilities that are offered by quantum information are to a large extent due to the unusual features of composite quantum systems. Let $\mathcal{H}_j, j = 1, 2$, be the Hilbert spaces of two finite quantum systems with inner products $\langle \cdot \mid \cdot \rangle_j$. The combination of the two systems is described by the tensor product of the Hilbert spaces, which is defined as follows.

According to Section 1.1, the element $\psi \in \mathcal{H}$ defines the antilinear function $\psi(\phi) = \langle \phi \mid \psi \rangle$ of the argument $\phi \in \mathcal{H}$. For any two elements $\psi_j \in \mathcal{H}_j, j = 1, 2$, we denote by $\psi_1 \otimes \psi_2$ the bi-antilinear function of the arguments $\phi_1 \in \mathcal{H}_1, \phi_2 \in \mathcal{H}_2$, defined by the relation

$$(\psi_1 \otimes \psi_2)(\phi_1, \phi_2) = \langle \phi_1 \mid \psi_1 \rangle_1 \langle \phi_2 \mid \psi_2 \rangle_2 .$$

Consider the vector space $\mathcal{L}$ of finite linear combinations of such functions $\sum_j c_j \psi_1^j \otimes \psi_2^j$. Introduce the inner product in $\mathcal{L}$ by letting

$$\langle \varphi_1 \otimes \varphi_2 \mid \psi_1 \otimes \psi_2 \rangle = \langle \varphi_1 \mid \psi_1 \rangle_1 \langle \varphi_2 \mid \psi_2 \rangle_2$$

on the generating elements $|\psi_1 \otimes \psi_2\rangle \equiv |\psi_1\rangle \otimes |\psi_2\rangle$ and extending, by linearity, to $\mathcal{L}$.

Exercise 3.1 Show that such a linear extension is possible and that it is unique and satisfies all the properties of an inner product.

Definition 3.2. The space $\mathcal{L}$ with the inner product defined above is called the tensor product $\mathcal{H}_1 \otimes \mathcal{H}_2$ of the Hilbert spaces $\mathcal{H}_1, \mathcal{H}_2$.

Exercise 3.3 Prove the following statement. If $\{e_1^j\}, \{e_2^k\}$ are orthonormal bases in $\mathcal{H}_1, \mathcal{H}_2$, then $\{e_1^j \otimes e_2^k\}$ is an orthonormal basis in $\mathcal{H}_1 \otimes \mathcal{H}_2$ and $\dim \mathcal{H}_1 \otimes \mathcal{H}_2 = \dim \mathcal{H}_1 \times \dim \mathcal{H}_2$.

It follows that any vector $\psi \in \mathcal{H}_1 \otimes \mathcal{H}_2$ is uniquely represented in the form

$$|\psi\rangle = \sum_{j,k} c_{jk} \left|e_1^j\right\rangle \otimes \left|e_2^k\right\rangle,$$

where c_{jk} are complex numbers. Summing with respect to j and denoting $|\psi_k\rangle = \sum_{j=1}^{d_1} c_{jk} \left|e_1^j\right\rangle \in \mathcal{H}_1$, we obtain

$$|\psi\rangle = \sum_{k=1}^{d_2} |\psi_k\rangle \otimes \left|e_2^k\right\rangle,$$

which means that the space $\mathcal{H}_1 \otimes \mathcal{H}_2$ is isomorphic to the direct orthogonal sum $\mathcal{H}_1 \oplus \cdots \oplus \mathcal{H}_1$ of $d_2 = \dim \mathcal{H}_2$ copies of the space $\mathcal{H}_1$.

For the operators X_j in the spaces $\mathcal{H}_j$ we define the tensor product by putting

$$(X_1 \otimes X_2)(\psi_1 \otimes \psi_2) = X_1\psi_1 \otimes X_2\psi_2,$$

and extending by linearity. Let a basis in $\mathcal{H}_2$ be fixed, so that $\mathcal{H}_1 \otimes \mathcal{H}_2$ is realized as $\mathcal{H}_1 \oplus \cdots \oplus \mathcal{H}_1$. In this case, $X_1 \otimes X_2$ is realized as the block matrix $\left[X_1 x_2^{jk}\right]$, where $\left[x_2^{jk}\right]$ is the matrix of the operator X_2. Now, a general operator X in $\mathcal{H}_1 \otimes \mathcal{H}_2$ is given by a block matrix $[X_{jk}]$ whose entries are operators in $\mathcal{H}_1$.

Let us recall that in Section 1.4 we denoted by $\mathfrak{B}_h(\mathcal{H})$ the real linear space of all Hermitian operators (i. e., sharp real observables) in $\mathcal{H}$. From the result of Exercise 1.5, in the case of complex Hilbert spaces $\mathcal{H}_1\mathcal{H}_2$ we have

$$\dim \mathfrak{B}_h(\mathcal{H}_1 \otimes \mathcal{H}_2) = \dim \mathfrak{B}_h(\mathcal{H}_1) \cdot \dim \mathfrak{B}_h(\mathcal{H}_2)$$

while in the case of real Hilbert spaces $\mathcal{H}_1, \mathcal{H}_2$ the dimensionalities of spaces of symmetric operators are related by the inequality $>$. [1]

Exercise 3.4 Prove the following statement. If S_j are the density operators in $\mathcal{H}_j$, then $S_1 \otimes S_2$ is a density operator in $\mathcal{H}_1 \otimes \mathcal{H}_2$.

Definition 3.5. Let T be an operator in $\mathcal{H} = \mathcal{H}_1 \otimes \mathcal{H}_2$. The partial trace of T (with respect to $\mathcal{H}_2$) is defined as an operator $\mathrm{Tr}_{\mathcal{H}_2} T$ in $\mathcal{H}_1$, satisfying

$$\langle\phi| (\mathrm{Tr}_{\mathcal{H}_2} T) |\psi\rangle = \sum_k \left\langle \phi \otimes e_2^k \right| T \left| \psi \otimes e_2^k \right\rangle, \quad \phi, \psi \in \mathcal{H}_1.$$

If S_{12} is a density operator corresponding to a state of the composite system, then $S_1 = \mathrm{Tr}_{\mathcal{H}_2} S_{12}$ and the similarly defined S_2 are called partial states of the first or second subsystem, respectively.

Partial states are the noncommutative analog of marginal probability distributions in probability theory.

Exercise 3.6 Show that this definition does not depend on the choice of the orthonormal basis $\left\{e_2^k\right\}$. If $T = T_1 \otimes T_2$, then $\mathrm{Tr}_{\mathcal{H}_2}(T_1 \otimes T_2) = (\mathrm{Tr}\, T_2)\, T_1$.

Let $\mathcal{H}_1 \otimes \mathcal{H}_2$ be realized as $\mathcal{H}_1 \oplus \cdots \oplus \mathcal{H}_1$, so that $T = [T_{jk}]$. Then $\mathrm{Tr}_{\mathcal{H}_2} T = \sum_{j=1}^{d_2} T_{jj}$ and $\mathrm{Tr}_{\mathcal{H}_1} T = [\mathrm{Tr}\, T_{jk}]$.

10.3.3 3.1.2 Naimark's Dilation

The fundamental relation between orthogonal and nonorthogonal resolutions of the identity is established by the following theorem.

[1] It is possible to consider quaternionic Hilbert spaces, in which case the inequality changes to $<$; see [8].

Theorem 3.7 (Naimark). Let $\{M_x\}$ be a resolution of the identity in $\mathcal{H}$ with m outcomes, $\dim \mathcal{H} = d$. Then there exist a Hilbert space $\mathcal{K}$ of dimensionality $\dim \mathcal{K} \leq md$, an isometry $V : \mathcal{H} \to \mathcal{K}$, and an orthogonal resolution of the identity $\{E_x\}$ in $\mathcal{K}$ such that

$$M_x = V^* E_x V, \quad x \in \mathcal{X}. \tag{3.1}$$

An isometry is a linear map that preserves the norms and hence the inner products of vectors in the Hilbert spaces. For arbitrary $|\phi\rangle, |\psi\rangle \in \mathcal{H}, \langle\phi|V^*V|\psi\rangle = \langle\phi \mid \psi\rangle$ holds, i. e., $V^*V = I$. The isometric embedding V allows us to identify $\mathcal{H}$ with the subspace $V\mathcal{H}$ of the space $\mathcal{K}$ and consider $\mathcal{H} \subset \mathcal{K}$. Then M_x can be considered as a restriction of E_χ onto $\mathcal{H}$, i.e.,

$$E_x = \begin{bmatrix} M_x & \dots \\ \dots & \dots \end{bmatrix}.$$

Proof. The construction of $\mathcal{K}$ is done in two steps. First, we define vectors $|\Psi\rangle \in \mathcal{H}_m$ with

$$|\Psi\rangle = \begin{bmatrix} |\psi_1\rangle \\ \vdots \\ |\psi_m\rangle \end{bmatrix}, \quad |\psi_x\rangle \in \mathcal{H}. \tag{3.2}$$

In addition, we define the pre-inner product, i.e., a form satisfying all the properties of the inner product except nondegeneracy, by the relation

$$\langle \Psi' \mid \Psi \rangle = \sum_x \langle \psi'_x | \, M_x \, |\psi_x\rangle \, . \tag{3.3}$$

The properties follow from the definition of the resolution of the identity.
In order to ensure that the norm induced by this pre-inner product is nondegenerate, one considers the quotient space $\mathcal{K} = \mathcal{H}_m/\mathcal{H}_0$, where

$$\mathcal{H}_0 = \{\Psi_0 \in \mathcal{H}_m : \langle \Psi_0 \mid \Psi_0 \rangle = 0\},$$

i. e., we identify the vectors whose difference has zero norm. Now, the map $V : \mathcal{H} \to \mathcal{H}_m$, defined as

$$V|\psi\rangle = \begin{bmatrix} |\psi\rangle \\ \vdots \\ |\psi\rangle \end{bmatrix}, \tag{3.4}$$

is an isometry because

$$\langle\psi|V^*V|\psi\rangle = \sum_{x=1}^{m} \langle\psi|M_x|\psi\rangle = \langle\psi \mid \psi\rangle. \tag{3.5}$$

For the orthogonal resolution of the identity $\{E_x\}$ in $\mathcal{K}$, we introduce $E_x|\Psi\rangle = [0, \dots, |\psi_x\rangle, \dots, 0]^\top$, where the only nonzero component is on the x th place. Hence,

$$\langle V\phi|E_x|V\psi\rangle = \langle\phi|M_x|\psi\rangle, \quad \phi, \psi \in \mathcal{H},$$

which concludes the proof. □

We now consider an important corollary of Naimark's dilation theorem, which provides us with a statistical interpretation of an arbitrary resolution of the identity and establishes that the generalized definition of a quantum observable is just an extension of the standard one.

Corollary 3.8. Let $\{M_x\}$ be an observable in $\mathcal{H}$. Then there exist a Hilbert space $\mathcal{H}_0$, a unit vector $\psi_0 \in \mathcal{H}_0$, and a sharp observable $\{E_x\}$ in $\mathcal{H} \otimes \mathcal{H}_0$, such that

$$M_x = \mathrm{Tr}_{\mathcal{H}_0} \left(I \otimes |\psi_0\rangle \langle\psi_0| \right) E_x. \tag{3.6}$$

Proof. According to Naimark's theorem, $M_x = V^* E_x V$, where $V : \mathcal{H} \to \mathcal{K}$ is an isometric embedding. Let us identify $\mathcal{H}$ with the subspace $V\mathcal{H} \subseteq \mathcal{K}$. By extending, if necessary, the space $\mathcal{K}$, we can take $\dim \mathcal{K} = \dim \mathcal{H} \cdot d_0$, and hence

$$\mathcal{K} \simeq \mathcal{H} \oplus \cdots \oplus \mathcal{H} \simeq \mathcal{H} \otimes \mathcal{H}_0,$$

where $\mathcal{H}_0 = \mathbb{C}^{d_0}$ is the coordinate complex Hilbert space of dimensionality d_0, and $\mathcal{H}$ is identified with the first term in the direct sum, or with the subspace $\mathcal{H} \otimes |\psi_0\rangle$, where $|\psi_0\rangle = [1, 0, \ldots, 0]^\top$. Then

$$\left(I \otimes |\psi_0\rangle \langle\psi_0| \right) E_x = \begin{bmatrix} M_x & \cdots \\ 0 & 0 \end{bmatrix},$$

so that (3.6) indeed holds. □

Thus, every observable can be realized as a sharp observable in the composite system by introducing an auxiliary system in a fixed state $S_0 = |\psi_0\rangle \langle\psi_0|$. Such a way of realization can be called quantum randomization.

In classical statistics, randomization, i. e., the introduction of a "roulette" can be a useful trick, but it can never increase the information about the state of the observed system. From the result of Section 2.4.2 it follows that in quantum statistics this is no longer true. Paradoxically, quantum randomization allows us to extract more information about the state of the observed system than is contained in the sharp observables when we are not using an auxiliary system.

10.3.4 3.1.3 Schmidt Decomposition and Purification

Consider a state S_{12} in the Hilbert space of the composite system $\mathcal{H}_1 \otimes \mathcal{H}_2$.

Definition 3.9. A pure state S_{12} is called entangled if it cannot be represented as a product state $S_1 \otimes S_2$.

Thus, any unit vector $\psi_{12} \in \mathcal{H}_1 \otimes \mathcal{H}_2$ that is a nontrivial superposition of product vectors generates a pure entangled state. An important example is the maximally entangled state, generated by the vector

$$|\psi_{12}\rangle = \frac{1}{\sqrt{d}} \sum_{j=1}^{d} \left| e_j^1 \right\rangle \otimes \left| e_j^2 \right\rangle \tag{3.7}$$

in the space $\mathcal{H}_1 \otimes \mathcal{H}_2$, where $d = \dim \mathcal{H}_1 = \dim \mathcal{H}_2$ and $\left\{ e_j^{1,2} \right\}$ are orthonormal bases in $\mathcal{H}_{1,2}$. The meaning of this name will be clarified in Section 7.5. Meanwhile, note that the partial states of the maximally entangled state are the chaotic states in $\mathcal{H}_1$ and $\mathcal{H}_2$:

$$\mathrm{Tr}_{\mathcal{H}_2} |\psi_{12}\rangle \langle\psi_{12}| = \frac{I_1}{d}$$

and similarly for $\mathcal{H}_2$.

We shall often make use of the following result.

Theorem 3.10 (Schmidt Decomposition). Let $S_{12} = |\psi\rangle\langle\psi|$ be a pure state in the Hilbert space $\mathcal{H}_1 \otimes \mathcal{H}_2$ and $S_1 = \mathrm{Tr}_{\mathcal{H}_2} S_{12}, S_2 = \mathrm{Tr}_{\mathcal{H}_1} S_{12}$ be its partial states. Then the density operators S_1, S_2 have the same nonzero eigenvalues λ_j. Furthermore,

$$|\psi\rangle = \sum_j \sqrt{\lambda_j} \left| e_j^1 \right\rangle \otimes \left| e_j^2 \right\rangle, \tag{3.8}$$

where $\left\{e_j^{1,2}\right\}$ are orthonormal eigenvectors of S_1, resp. of S_2.

Proof. Taking the orthonormal basis $\left\{e_j^1\right\}$ of eigenvectors in $\mathcal{H}_1$, we can write $|\psi\rangle$ as

$$|\psi\rangle = \sum_j \left|e_j^1\right\rangle \otimes \left|h_j^2\right\rangle, \tag{3.9}$$

with some vectors $\left|h_j^2\right\rangle \in \mathcal{H}_2$. Computation of the partial trace gives

$$\sum_{j,k} \left\langle h_j^2 \mid h_k^2\right\rangle \left|e_k^1\right\rangle \left\langle e_j^1\right| = \sum_j \lambda_j \left|e_j^1\right\rangle \left\langle e_j^1\right| \equiv S_1, \tag{3.10}$$

and therefore $\left\langle h_j^2 \mid h_k^2\right\rangle = \lambda_j \delta_{jk}$ (Kronecker's delta). Thus, we can put $\left|e_j^2\right\rangle = \frac{1}{\sqrt{\lambda_j}} \left|h_j^2\right\rangle$ for $\lambda_j > 0$ and complete this orthonormal system to a basis in $\mathcal{H}_2$, consisting of eigenvectors of the operator S_2. □

Conversely, an arbitrary mixed state of a quantum system can be "purified," i. e., extended to a pure state of a larger system.

Theorem 3.11 (Purification). Let S_1 be a state in $\mathcal{H}_1$. Then there exist a reference Hilbert space $\mathcal{H}_2$ of the same dimensionality as $\mathcal{H}_1$ and a pure state $|\psi\rangle\langle\psi|$ in $\mathcal{H}_1 \otimes \mathcal{H}_2$ such that $S_1 = \mathrm{Tr}_{\mathcal{H}_2} |\psi\rangle\langle\psi|$.

For any other pure state $|\psi'\rangle \langle\psi'|$ in $\mathcal{H}_1 \otimes \mathcal{H}_2$ that has this property, there is a unitary operator U_2 in $\mathcal{H}_2$ such that $|\psi'\rangle = (I_1 \otimes U_2) |\psi\rangle$.

Proof. Diagonalize S_1 and take $|\psi\rangle$ as in (3.8), with an arbitrary basis $\left\{e_j^2\right\}$ in a Hilbert space $\mathcal{H}_2$ isomorphic to $\mathcal{H}_1$. Any other $|\psi'\rangle$ has a decomposition (3.8) with a different basis in $\mathcal{H}_2$, and any two bases in the same space are related by a unitary transformation. □

Corollary 3.12. Let S_{12} be a state in $\mathcal{H}_1 \otimes \mathcal{H}_2$ such that the partial state S_1 is pure. In this case, $S_{12} = S_1 \otimes S_2$.

Proof. For a pure state S_{12} the statement obviously follows from Theorem 3.10. For an arbitrary state S_{12}, we can apply the same argument to its purification. □

From Theorem 3.10, it also follows that the purification is essentially unique. Any two purifications with reference spaces $\mathcal{H}_2, \mathcal{H}_2'$, such that $\dim \mathcal{H}_2 \leq \dim \mathcal{H}_2'$, are related by an isometric embedding of $\mathcal{H}_2$ into $\mathcal{H}_2'$.

Remarkably, there is one universal Hilbert space that contains purifications of all states in $\mathcal{H}$. Consider the Hilbert space $L^2(\mathcal{H})$ of all operators $X, Y, \ldots$ in $\mathcal{H}$, equipped with the inner product

$$(X, Y) = \mathrm{Tr}\, X^* Y.$$

Then the bilinear correspondence

$$|\psi\rangle\langle\varphi| \leftrightarrow |\psi\rangle \otimes \langle\varphi|, \tag{3.11}$$

where $\langle\varphi| \in \mathcal{H}^*$ (the dual space of linear functions on $\mathcal{H}$) is uniquely extended to the isometry between the Hilbert spaces $L^2(\mathcal{H})$ and $\mathcal{H} \otimes \mathcal{H}^*$. Denoting by L_A (resp. R_B) the operation of left multiplication by A (resp. of right multiplication by B), we have for $X = |\psi\rangle\langle\varphi|$

$$L_A R_B X \equiv AXB \leftrightarrow |A\psi\rangle \otimes \langle B^*\varphi| .$$

For an arbitrary density operator S in $\mathcal{H}$ consider the unit vector $\sqrt{S}W \in L^2(\mathcal{H})$, where W is arbitrary unitary in $\mathcal{H}$. Then

$$\left(\sqrt{S}W, L_A R_B \sqrt{S}W\right) = \mathrm{Tr}\, \sqrt{S} A \sqrt{S} W B W^*,$$

whence, letting $B = I$,

$$\operatorname{Tr} SA = \left(\sqrt{S}W, \left(A \otimes I_{\mathcal{H}^*}\right)\sqrt{S}W\right).$$

Therefore $\sqrt{S}W$ is a purification of S in $L^2(\mathcal{H})$ identified with $\mathcal{H}\otimes\mathcal{H}^*$ via the correspondence (3.11). Moreover, all purifications of S are obtained in this way.

Note that purification is a mathematical construct that does not correspond to any physical operation. Indeed, it would imply cloning the quantum state S_1.

Definition 3.13. A general mixed state $S_{12} \in \mathfrak{S}\left(\mathcal{H}_1 \otimes \mathcal{H}_2\right)$ is called separable (unentangled) if it belongs to the convex hull of the set of all product states, i. e., if it has the form of the convex combination

$$S_{12} = \sum_x \pi_x S_1^x \otimes S_2^x,$$

where $S_j^x \in \mathfrak{S}\left(\mathcal{H}_j\right), j = 1, 2$, and $\{\pi_x\}$ is a finite probability distribution. The states that are not separable are called entangled.

A simple necessary condition for separability is that the state S_{12} has a positive partial transpose (PPT). An arbitrary operator in $\mathcal{H}_1 \otimes \mathcal{H}_2$ can be represented as $A_{12} = \sum_j A_1^j \otimes A_2^j$. Its partial transpose with respect to the second system is correctly defined as

$$A_{12}^{\tau_2} = \sum_j A_1^j \otimes \left[A_2^j\right]^{\tau_2},$$

where ${}^{\top}{}_2$ is a transposition in the second system. In general, this condition is not sufficient, so there exist PPT entangled states.

10.3.5 3.2 Quantum Entanglement vs. "Local Realism"

10.3.6 3.2.1 Paradox of Einstein-Podolski-Rosen and Bell's Inequalities

Entanglement, along with complementarity, constitutes the principal structural difference between the classical and the quantum description of systems.

The pure state of a classical system is described by a point in the phase space (practically, this is a complete set of parameter values describing "inner properties" of the system). If the classical system under consideration consists of several subsystems, an arbitrary pure state is necessarily a product of the pure states of the subsystems. By fixing the values of the parameters of the system we ipso facto fix the values of the parameters of all its subsystems. In this case, there is no need to involve a statistical treatment.

For quantum systems the situation is different. As Corollary 3.12 shows, for any pure entangled state S_{12} of a composite system, the partial states $S_{1,2}$ are necessarily mixed, i. e., they require a statistical description.

Such behavior is quite unusual from a classical point of view and, as will be shown in this section, is entirely incompatible with the classical mode of description (which is often called "realism").

The key example of the unusual behavior of composite quantum systems was provided by Einstein, Podolski, and Rosen (EPR) in 1935. In the 1950s Bohm presented it in a clearer form, using spin degrees of freedom instead of spatial ones, and in the 1960s it was substantially clarified by J. S. Bell, who suggested a fundamental inequality, which holds for classical composite systems satisfying a natural requirement of "locality" (separability), but is violated in quantum systems and which, in principle, can be verified experimentally.

Consider two particles with spin 1/2, each of which is described by the Hilbert space $\mathcal{H}$ with $\dim \mathcal{H} = 2$. Initially, the particles interact, resulting in the common spin state described by the vector

$$|\psi\rangle = \frac{1}{\sqrt{2}}[|\uparrow\rangle \otimes |\downarrow\rangle - |\downarrow\rangle \otimes |\uparrow\rangle],$$

where the basis vectors

$$|\uparrow\rangle = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \quad |\downarrow\rangle = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$$

describe the states of each particle, with the spin along the positive (resp. negative) direction of the z axis. Usually, one writes briefly

$$|\psi\rangle = \frac{1}{\sqrt{2}}[|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle]. \tag{3.12}$$

Every component denotes the state with the spins in opposite directions, while $|\psi\rangle$ is their superposition, which cannot be represented as a tensor product of state vectors related to different particles. This state is called "singlet" and is a canonical example of an entangled state of two quantum systems.

Suppose that the particles travel apart along the y axis at a macroscopic distance, while preserving the entangled state of their spins. Consider an experiment in which simultaneous measurements of spin observables $\sigma(\vec{a})$ for one particle and $\sigma(\vec{b})$ for another particle are made simultaneously in remote laboratories A and B. Operators $X = \sigma(\vec{a}) \otimes I, Y = I \otimes \sigma(\vec{b})$ commute. Hence, the corresponding observables are compatible and their covariance is given by expression (2.23).

Exercise 3.14 By using expressions for the matrix elements

$$\langle\uparrow |\sigma(\vec{a})| \uparrow\rangle = a_z, \quad \langle\downarrow |\sigma(\vec{a})| \uparrow\rangle = a_x + ia_y, \quad \langle\downarrow |\sigma(\vec{a})| \downarrow\rangle = -a_z, \tag{3.13}$$

which follows from (2.14), show that in the singlet state the mean value and the variance of the spin observable in any direction are given by

$$\mathrm{E}(\sigma(\vec{a}) \otimes I) = 0, \quad \mathrm{D}(\sigma(\vec{a}) \otimes I) = 1,$$

while the covariance between the spins is given by the formula

$$\langle\psi|\sigma(\vec{a}) \otimes \sigma(\vec{b})|\psi\rangle = -\vec{a} \cdot \vec{b} \tag{3.14}$$

It follows that for $\vec{b} = \vec{a}$, the correlation coefficient is equal to -1 . Hence, there is a deterministic relation $a = -b$ between the outcomes a, b of the measurements. The formulas (3.13) and the fact that $\sigma(\vec{a})^2 = I$ imply

$$\langle\psi|[\sigma(\vec{a}) \otimes I + I \otimes \sigma(\vec{a})]^2|\psi\rangle = 0,$$

whence

$$[\sigma(\vec{a}) \otimes I + I \otimes \sigma(\vec{a})]|\psi\rangle = 0. \tag{3.15}$$

If the spins were classical random variables, this would mean that measuring the spin of the first particle in some arbitrarily chosen direction $\vec{a}$ would "instantaneously" bring the spin of the second particle into the opposite direction.

Exercise 3.15 Prove the following statement. For any direction $\vec{a}$,

$$|\psi\rangle = \frac{\epsilon}{\sqrt{2}}[|\vec{a}\rangle \otimes |-\vec{a}\rangle - |-\vec{a}\rangle \otimes |\vec{a}\rangle], \tag{3.16}$$

where ϵ is inessential factor of modulus one.

Thus, one has to choose between the following alternatives.

(1) In quantum mechanics, like in the classical case, the (pure) state describes "real" inner properties of a system. However, in this case, in order to explain how the second particle "gets to know" the chosen spin direction of the first particle, one has to accept instantaneous action at a distance, contradicting the physical "locality principle."

(2) The state vector is only an expression of the information about the preparation procedure. In that case there is no contradiction with locality, but one has to abandon the complete mechanistic description of a system state as the totality of its "inner properties."

However, a thorough consideration of the EPR experiment led Bell to a much deeper conclusion: if one tries to describe the quantum correlations classically and simultaneously attempts to satisfy the principle of locality, one cannot achieve the level of correlation between systems A and B predicted by quantum theory. "Local realism" and the correlations (3.14) predicted by quantum theory are incompatible.

This is established with the help of the Clauser-Horne-Shimony-Holt inequality, which is a convenient modification of Bell's original inequality.

Let $X_j, Y_k (j, k = 1, 2)$ be arbitrary random variables on one probability space Ω, such that $|X_j| \leq 1, |Y_k| \leq 1$. In this case, for any probability distribution P on Ω, the correlations of these random variables satisfy

$$|\mathrm{E}X_1Y_1 + \mathrm{E}X_1Y_2 + \mathrm{E}X_2Y_1 - \mathrm{E}X_2Y_2| \leq 2, \tag{3.17}$$

where E is the expectation corresponding to the distribution P.

The proof is obtained by averaging the elementary inequality over the distribution P,

$$-2 \leq X_1Y_1 + X_1Y_2 + X_2Y_1 - X_2Y_2 \leq 2,$$

which in turn follows from

$$|X_1Y_1 + X_1Y_2 + X_2Y_1 - X_2Y_2| \leq |Y_1 + Y_2| + |Y_1 - Y_2| \leq 2\max\{|Y_1|, |Y_2|\}.$$

Let us go back to the system of two qubits and consider the four different experiments in which the spin observables $\sigma(\vec{a}_j)\,(j = 1, 2)$ are measured over the first qubit, and $\sigma\left(\vec{b}_k\right)\,(k = 1, 2)$ over the second, while the directions $\vec{a}_j, \vec{b}_k (j, k = 1, 2)$ will be chosen later. In all four experiments the system is prepared in the singlet state (3.12). Assume that there exists a "local" classical description reproducing the statistical results of all these four experiments. This means that there is a probability space Ω, a probability distribution on Ω describing the statistical ensemble in the singlet state, and the random variables $X_j, Y_k, j, k = 1, 2$, taking values ± 1, which classically describe the spin observables $\sigma(\vec{a}_j), \sigma\left(\vec{b}_k\right), j, k = 1, 2$. In this case, the quantum correlations (3.14) have to satisfy inequality (3.17). The requirement of "locality" (or, better to say, separability of the two subsystems) is expressed by the fact that the random variables that describe the spin of the first particle (X_1 in the first two correlations and X_2 in the other two cases) are assumed to be the same for the experiments with different directions of spin of the second particle (Y_1 or Y_2), and vice vers a for Y_1 and Y_2, which allows us to apply inequality (3.17). Omitting this requirement would mean that the given classical description allows the choice of a measurement on the second particle to influence the inner characteristics of the first particle (the term "locality" is used in connection with the fact that the two particles are supposed to be spatially separated).

Now, choose the spin directions as shown in Figure 3.1. Substituting the correlations given by formula (3.14) into the left-hand side of (3.17) gives the value $2\sqrt{2}$, which breaks the inequality. Thus, assuming the possibility of a classical "local" description is incorrect. The requirement of separability appears to be so natural that it is not so easy to perceive. However, it is this condition which forbids instantaneous influence of measurements in one subsystem on another. If this condition is abandoned, the four correlations in question can be arbitrary numbers in $[-1, 1]$, and the left-hand side of inequality (3.17) can be bounded only by the value 4, which does not contradict quantum theory.

Therefore, one has a dilemma: either quantum theory gives incorrect predictions for the correlations, or the composite system of two qubits has no classical local (separable) description. Several experiments were made, starting with Aspect's experiments in 1981-1982, the results of which essentially confirm the predictions of quantum theory.

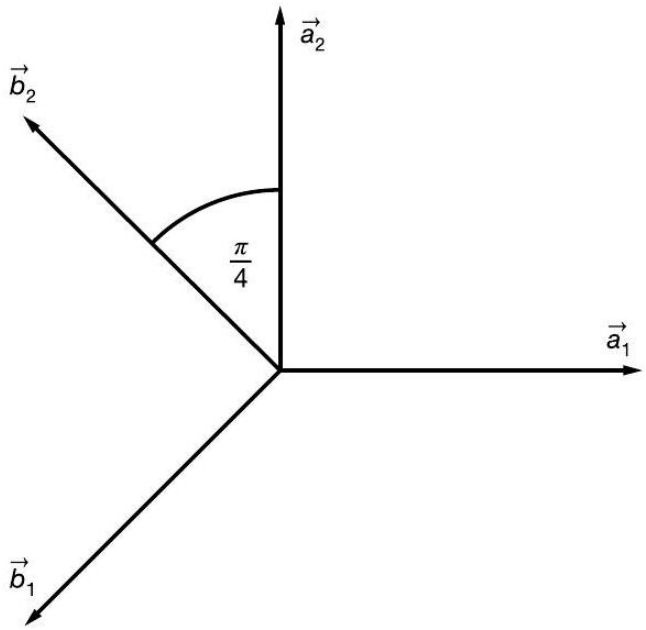

Figure 3.1: Choice of the vectors $\vec{a}_{j}$ and $\vec{b}_k$.

10.3.7 3.2.2 Mermin-Peres Game

The fact that quantum entanglement between parts of a composite system is profoundly different from any kind of classical connection, and in some situations can provide a real advantage over the latter, is demonstrated in a most spectacular, nearly grotesque, way by "quantum pseudotelepathy games." We will describe one of these, the Mermin-Peres magic square game, which uses nothing but the basic postulates of quantum theory.

In the following game, a team of two players, A (Alice) and B (Bob), tries to win against a croupier C. Imagine a 3×3-matrix in which C chooses a row and a column and announces the number i of the row to A and the number j of the column to B. A and B are allowed to agree on any joint strategy prior to this announcement, but cannot communicate after it has been made. Thus, A does not know the number of the column for B and viceversa. Then A must put $+1$ or -1 in each cell of her row, subject to the constraint that the product of elements must be 1 . Similarly B must put $+1$ or -1 in each cell of his row subject to the constraint that the product of elements must be -1 . They win if their choices coincide on the intersection ij of the row and the column chosen by the croupier.

In order to win, players A and B could agree a priori on some fixed 3×3-matrix with elements ± 1. However, it is easy to see that there is no matrix that satisfies the imposed constraints: from the constraint on A (resp. B) the product of all matrix elements should be equal to 1 (resp. -1). They could adopt a randomized strategy, but the probability of success will always be strictly less than 1 .

However, assuming that they are capable of producing and sharing an entangled quantum state before C makes his announcement and make pre-agreed quantum measurements on their respective parts of this state after the announcement, they will al-
ways be able to win! Of course, both the entangled state and the measurements are independent of the choices of C, as it should be. Hence, the rules of the game are perfectly respected and it is the use of advanced quantum information technology that produces a result that is unachievable by solely classical means. From the point of view of a purely classical observer it looks like there is some immaterial connection between A and B, hence the name "pseudotelepathy."

For a pair of qubits A and B, let us introduce the Bell state

$$|\Psi\rangle_{AB} = \frac{1}{\sqrt{2}}(|\uparrow\uparrow\rangle + |\downarrow\downarrow\rangle),$$

which is similar to the singlet state (3.12).
The prepared entangled state is the tensor product of two Bell states of two pairs of qubits A_1B_1 and A_2B_2, i. e.,

$$|\Psi\rangle = |\Psi\rangle_{A_1B_1} \otimes |\Psi\rangle_{A_2B_2}.$$

Before C makes his announcement, qubits A_1 and A_2 are distributed to player A, while qubits B_1 and B_2 are given to B. Players A and B also agree in advance that, as soon as they receive the numbers of the row i and the column j, respectively, they will perform the spin measurements on their pairs of qubits, according to the table

$$\begin{bmatrix} \sigma_0 \otimes \sigma_z & \sigma_z \otimes \sigma_0 & \sigma_z \otimes \sigma_z \\ \sigma_x \otimes \sigma_0 & \sigma_0 \otimes \sigma_x & \sigma_x \otimes \sigma_x \\ -\sigma_x \otimes \sigma_z & -\sigma_z \otimes \sigma_x & \sigma_y \otimes \sigma_y \end{bmatrix},$$

and write the outcome of the measurement in the corresponding cell. At this point, we should expand on the special properties of this array of operators.

Denoting by X_{ij} the operator on the intersection of the i th row and the j th column, one has
i. $X_{ij} = X_{ij}^*$ and $X_{ij}^2 = \sigma_0 \otimes \sigma_0 \equiv I$, so that all X_{ij} are (sharp) real observables with eigenvalues ± 1;
ii. in any row i, the operators $X_{ij}, j = 1, 2, 3$, commute. Hence, the observables are compatible. Moreover, $X_{i1}X_{i2}X_{i3} = I$. Hence for any value $i = 1, 2, 3$ given by C, player A can make a joint measurement of the observables $X_{ij}, j = 1, 2, 3$, obtaining the outcomes $+1$ or -1 , which obey the constraint for A. Next, A writes these outcomes in row i. A similar description applies to player B and any column j.
iii. miraculously, the numbers written on the intersection of the i th row and the j th column by A and B always coincide. This follows from the identity

$$\left(X_{ij}^A \otimes X_{ij}^B\right)|\Psi\rangle = |\Psi\rangle, \quad i, j = 1, 2, 3,$$

where X_{ij}^A (resp. X_{ij}^B) is the operator X_{ij} in system $A = A_1A_2$ (resp. $B = B_1B_2$). Indeed, this identity means that, if the whole system $A_1A_2B_1B_2$ is prepared in the state $|\Psi\rangle$, the product of the outcomes of the (compatible) measurements of A and B, in any cell ij, will be equal to 1 , i.e., the outcomes coincide.

Exercise 3.16 Prove the properties i, ii by using the multiplication table (2.17) for the Pauli matrices. Prove the property iii by using the identities

$$(\sigma_{x,z} \otimes \sigma_0) |\Psi\rangle_{AB} = (\sigma_0 \otimes \sigma_{x,z}) |\Psi\rangle_{AB}$$
$$(\sigma_y \otimes \sigma_0) |\Psi\rangle_{AB} = -(\sigma_0 \otimes \sigma_y) |\Psi\rangle_{AB}$$

similar to (2.17).

10.3.8 3.3 Quantum Systems as Information Carriers

10.3.9 3.3.1 Transmission of Classical Information

If the information carrier is a classical system with a finite number of states d, the maximal number of binary digits, or bits, which can be recorded or transmitted by such a carrier is equal to $\log_2 d$. If the transmission is without errors, one speaks of an ideal communication channel. In general, a noisy classical channel is described by the conditional probabilities $p(y \mid x)$ for receiving the signal y at the output, if the value at the input was x. For the ideal channel $p(y \mid x) = \delta_{xy}$. The opposite case is the channel for which the probabilities $p(y \mid x) = p(y)$ do not depend on the transmitted signal x and hence the information is not transmitted at all. More detailed account of classical channels will be given in Chapter 4.

Let us now consider how classical information can be transmitted with a quantum carrier described by a Hilbert space $\mathcal{H}$. The carrier's state S is prepared with macroscopic devices. By changing the parameters of a device, one changes the parameters of the state, thus having a possibility to "record" classical information into the quantum state. Let there be n different signals and let S_x be the quantum state corresponding to the signal $x = 1, \ldots, n$. The mapping $x \to S_x$ describes the net result of a physical process that generates the state S_x. A detailed description of such a process is beyond the scope of information theory, for which only the resulting states S_x are relevant.

To extract the classical information contained in the output state of a channel, one has to perform a measurement. If one measures the observable $M = \{M_y\}$, the conditional probability of obtaining a signal y at the output given the input signal x is equal to

$$p_M(y \mid x) = \operatorname{Tr} S_x M_y \tag{3.18}$$

Thus, for a fixed quantum measurement, we have the usual classical channel. Assume that one manages to prepare states and perform a measurement in such a way that $S_x = |e_x\rangle \langle e_x|$, $M_y = |e_y\rangle \langle e_y|$. Then $P_M(y \mid x) = \delta_{xy}$, i. e., one has an ideal classical channel, capable of transmitting $\log_2 d$ bits, where $d = \dim \mathcal{H}$. Later, in Chapter 5, we will establish that this quantity is the upper bound for the amount of classical information that can in principle be transmitted with the given quantum carrier. This implies the following important consequences:
(1) The fact that Hilbert space contains infinitely many different state vectors does not aid us in transmitting an unlimited amount of information. The more states are used for transmission, the closer they are to each other and hence they become less and less distinguishable.
(2) The dimensionality of the Hilbert space is a measure of the ultimate information resource of the corresponding quantum system.

10.3.10 3.3.2 Entanglement and Local Operations

In this section, we will need elementary knowledge about quantum evolutions. Later, in Chapter 6, we will provide a detailed discussion of this question from the viewpoint of the general theory. Meanwhile, it is sufficient to know that reversible evolutions of a quantum system are

described by unitary operators U. The vector of the initial pure state ψ is transformed into $U\psi$. Correspondingly, a density operator S is transformed into USU^*.

Consider now the following question. The nonlocal, from a classical viewpoint, nature of the EPR correlations suggests to attempt using them for instantaneous information transmission. Let us show that this is not possible within the quantum mechanical framework, so that the EPR correlations do not contradict locality. Consider two quantum systems A and B, in the corresponding spaces $\mathcal{H}_A$ and $\mathcal{H}_B$, which are in an entangled state S_{AB}. In the case of practical interest, the systems are sufficiently spatially separated, although this is not reflected by the formulas. The system A (transmitter) uses the classical messages x, which should be transmitted to B (receiver), in order to perform certain unitary operations U_x in the space $\mathcal{H}_A$ (such operations are called local, i.e., acting nontrivially only in one of the two systems). This brings the state of the system AB into $S_x = (U_x \otimes I_B)\, S_{AB}\, (U_x \otimes I_B)^*$, and in this way the classical information is written into the quantum state of the composite system. After that, observer B makes a local measurement of an observable in $\mathcal{H}_B$, corresponding to the resolution of the identity $M = \{I_A \otimes M_y\}$ in the space of the composite system $\mathcal{H}_A \otimes \mathcal{H}_B$. The resulting conditional probability (3.18) is

$$p_M(y \mid x) = \operatorname{Tr} (U_x \otimes I_B)\, S_{AB}\, (U_x \otimes I_B)^*\, (I_A \otimes M_y) = \operatorname{Tr} S_B M_y,$$

where $S_B = \operatorname{Tr}_A S_{AB}$ is the partial state of the system B, which does not depend on x. This means that local operations of observer A do not in any way influence the state of B, and hence, no information is transmitted.

Consider now the different scenario where observer A makes a local measurement of observable M_x^A and sends the outcome to observer B, who takes this into account by selecting the subensemble where this outcome x has appeared. In this case, the posterior state $S_B(x)$ of party B will depend on the outcome of the measurement x. To find the posterior state, assume that B performs his local measurement M_y^B, and consider the joint probability distribution of the two measurements

$$p_{x,y} = \operatorname{Tr} S_{AB} \left(M_x^A \otimes M_y^B\right).$$

By introducing the conditional probabilities $p(y \mid x) = p_{x,y}/p_x$ (assuming $p_x > 0$), we have

$$\begin{aligned} p_x &= \operatorname{Tr} S_{AB} \left(M_x^A \otimes I_B\right) = \operatorname{Tr} S_A M_x^A, \\ p(y \mid x) &= \operatorname{Tr} S_B(x) M_x^B, \end{aligned}$$

where

$$S_B(x) = p_x^{-1} \operatorname{Tr}_{\mathcal{H}_A} S_{AB} \left(M_x^A \otimes I_B\right)$$

are the posterior states.

The change of the state of observer B from S_B to $S_B(x)$ means a reduction of the full statistical ensemble of B to the subensemble characterized by the value x of the outcome of the measurement of observer A. If this outcome is not taken into account (for example, A does not send it to B, hence B makes no selection), then the state of B is not changed, i.e.,

$$S_B = \sum_x p_x S_B(x).$$

Exercise 3.17 Let $S_{AB} = |\psi\rangle\langle\psi|$ be a pure entangled state,

$$|\psi\rangle = \sum_x \left|e_x^A\right\rangle \otimes \left|\psi_x^B\right\rangle,$$

where e_x^A is an orthonormal basis in $\mathcal{H}_A, \sum_x \left\|\psi_x^B\right\|^2 = 1$. Assume that A measures the observable $M_x^A = \left|e_x^A\right\rangle \left\langle e_x^A\right|$ and sends the measurement outcome x to party B. Prove that $p_x = \left\|\psi_x^B\right\|^2$ and the posterior states of B are

$$S_B(x) = p_x^{-1} \left|\psi_x^B\right\rangle \left\langle \psi_x^B\right| . \tag{3.19}$$

Coming back to the EPR experiment, we obtain from the relation (3.16) that, in the case where A measures the spin observable $\sigma(\vec{a})$ and sends the outcome ± 1 to observer B, the posterior state of B (i. e., the state of the corresponding statistical subensemble) is $|\mp\vec{a}\rangle\langle\mp\vec{a}|$. On the other hand, if there is no communication between A and B, the state of B remains chaotic, independently of the measurement of A. Thus, quantum theory does not contradict the principle of locality.

10.3.11 3.3.3 Superdense Coding

Although EPR correlations cannot aid in transmitting information from A to B, it appears that using these correlations as additional resource allows one to double the
amount of classical information transmitted from A to B if they are connected by an ideal quantum channel enabling perfect transmission of a quantum state from A to B. Hence, EPR correlations appear as a "catalyst" for classical information transmission and from this viewpoint can be considered a unit of a specific information resource (sometime called an ebit).

Consider the two systems A and B, each of which is a qubit, connected by an ideal quantum channel. The maximum amount of classical information that can be transmitted from A to B is equal to 1 bit and is obtained by encoding this bit into two orthogonal vectors, say,

$$0 \to |0\rangle, 1 \to |1\rangle,$$

where $|0\rangle, |1\rangle$ is the canonical basis for one qubit.
The protocol of "superdense coding," which allows us to double the amount of transmitted classical information, is based on the following simple mathematical fact. All vectors of the Bell basis

$$|e_+\rangle = |00\rangle + |11\rangle, \quad |e_-\rangle = |00\rangle - |11\rangle, \quad |h_+\rangle = |10\rangle + |01\rangle, \quad |h_-\rangle = |10\rangle - |01\rangle$$

in the system of two qubits AB (we will systematically omit the normalizing factor $1/\sqrt{2}$) can be obtained from one of these vectors by the action of "local" unitary operators, i. e., operators acting nontrivially only on qubit A. Namely,

$$|e_-\rangle = (\sigma_z \otimes I) |e_+\rangle , \quad |h_+\rangle = (\sigma_x \otimes I) |e_+\rangle , \quad |h_-\rangle = -i (\sigma_y \otimes I) |e_+\rangle .$$

Thus, if AB is initially in the state $|e_+\rangle$, A can encode 2 bits of classical information into 4 states of the Bell basis by mere local operations $\sigma_y, y = 0, x, y, z$, and then (physically) send its qubit to B via the ideal quantum channel. Then, making the measurement in the Bell basis, B receives 2 bits of classical information.

10.3.12 3.3.4 Quantum Teleportation

So far, we considered transmission of classical information. This information can be "written" into a quantum state and transmitted through a physical channel. However, the quantum state itself is an information resource, since it carries statistical uncertainty. The information carried by an unknown quantum state is qualitatively different from the classical one and

deserves the special name quantum information. The most apparent distinction of quantum information is impossibility of copying (no cloning). While classical information can be reproduced in an arbitrary number of copies, there is no room for a physical device that could perform the same task for quantum information. Indeed, the cloning transformation

$$|\psi\rangle \to \underbrace{|\psi\rangle \otimes \cdots \otimes |\psi\rangle}_{n}$$

is nonlinear, and hence cannot be implemented by a unitary operator. Of course, any fixed state (or even a collection of orthogonal states) may be copied by a specific device, but there is no universal device which would do this for an arbitrary state.

Let us briefly discuss the question of how a quantum state can be transmitted. A straightforward way is to just send the quantum system itself. Much more interesting and nontrivial is teleportation of the state, where the system itself is not transmitted, but instead a certain classical message is sent. An essential additional resource are the EPR correlations between the input and the output, which again play the role of "catalyst." Note that teleportation of a quantum state cannot be accomplished by merely sending classical information without using the entanglement. Since the classical information can be copied, this would mean the possibility of cloning quantum information.

Let there be two quantum systems A and B, describing input and output of the communication channel, respectively. In the simplest and basic version, the systems A and B are just qubits.
i. Before the transmission, the system AB is prepared in the state $|00\rangle + |11\rangle$ (recall that we omit the normalizing factor $1/\sqrt{2}$).
ii. The third party C provides A with an arbitrary pure state

$$|\psi\rangle = a|0\rangle + b|1\rangle,$$

which should be transmitted to B. Now, the combination of the three systems CAB is in the state

$$(a|0\rangle + b|1\rangle) \otimes (|00\rangle + |11\rangle).$$

iii. Then observer A performs a certain reversible local transformation of the state of CA.
iv. Observer A performs a measurement in CA with 4 outcomes (comprising 2 bits of classical information) and transmits the outcome of its measurement to B by using the ideal classical communication channel. The transformation and the measurement will be described below.
v. Depending on the outcome received, observer B performs a certain transformation of its state, obtaining the required state vector $|\psi\rangle$.

The necessary transformations are examples of quantum "gates," used in quantum computations. In step iii the state of CA is transformed by the operation CNOT (controlled "not"), i. e.,

$$|00\rangle \to |00\rangle, \quad |01\rangle \to |01\rangle, \quad |10\rangle \to |11\rangle, \quad |11\rangle \to |10\rangle,$$

when the state of the first qubit is unchanged, whilst the state of the second qubit is changed to its opposite if and only if the state of the first qubit is $|1\rangle$. As this transformation turns one basis into another basis, it is a unitary operator in the four-dimensional
space of CA. Next, the qubit C is transformed by the Hadamard gate H, implemented by the unitary matrix

$$H = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}.$$

Then the basis is rotated by the angle $\pi/4$, i. e.,

$$|0\rangle \to \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle), \quad |1\rangle \to \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle).$$

The initial state of the total system CAB is

$$a|000\rangle + b|100\rangle + a|011\rangle + b|111\rangle.$$

The action of CNOT on CA results in

$$a|000\rangle + b|110\rangle + a|011\rangle + b|101\rangle.$$

Then the Hadamard gate H acts on C, and we obtain

$$a(|000\rangle + |100\rangle) + b(|010\rangle - |110\rangle) + a(|011\rangle + |111\rangle) + b(|001\rangle - |101\rangle).$$

Singling out the state of the subsystem CA we have

$$|00\rangle(a|0\rangle + b|1\rangle) + |01\rangle(a|1\rangle + b|0\rangle) + |10\rangle(a|0\rangle - b|1\rangle) + |11\rangle(a|1\rangle - b|0\rangle).$$

Now, in step iv, the measurement in the subsystem CA is performed, which projects onto one of four basis vectors $|00\rangle, |01\rangle, |10\rangle, |11\rangle$. According to formula (3.19), the posterior state of the system B, depending on the obtained measurement outcome, is described by one of the vectors

$$a|0\rangle + b|1\rangle, a|1\rangle + b|0\rangle, a|0\rangle - b|1\rangle, a|1\rangle - b|0\rangle.$$

The outcome of the measurement is sent to B through the ideal classical channel. In step v, depending on the outcome, B applies one of the unitary Pauli operators $\sigma_0 = I, \sigma_x, \sigma_z, \sigma_y$, in each case transforming the state of B into $a|0\rangle + b|1\rangle$. Thus, observer B is transformed to the state in which observer C was initially, while the state of C is irreversibly lost (otherwise cloning of the quantum information would be possible).

10.3.13 3.4 Notes and References

1. For more details about tensor products of Hilbert spaces, see Chapter II. 4 of the book [193], where one can also find solutions to the exercises in this section. For a general formulation of Naimark's dilation theorem, see [180], where it was proved for an arbitrary resolution of the identity (probability operator-valued measure, see Definition 11.29) in infinite-dimensional Hilbert space. The motivation was to obtain selfadjoint extensions of symmetric operators but it was later recognized that this was just the first discovery of the remarkable general phenomenon that the properties of various operator objects can be improved by extension to a wider underlying space. In quantum information theory this principle received the colorful name "the Church of Larger Hilbert Space." The purification of quantum states and the unitary dilation of irreversible quantum dynamics in Section 6.3 are two of its other manifestations.

An analog of the decomposition (3.8) in separable Hilbert space dates back to Schmidt's paper of 1907, which is devoted to integral equations. The "purification map" was introduced by Powers and Størmer [191] and studied by Woronowicz [259] in connection with the problem of the quasi-equivalence of states on a C^*-algebra. The trick of purifying mixed states, which is widely used in quantum information theory, also appeared in the paper of Lindblad [167].

The observation that the PPT condition is necessary for separability is due to Peres [188] and Horodeckis [136], while the latter has shown that this condition is also sufficient for separability of states in 2×2 - and 2×3-dimensional composite systems. In higher dimensions there exist PPT states that are not separable, but their entanglement (called bound entanglement) is "weak," since it does not allow for distillation, i. e., transformation to maximally entangled Bell states by using local operations and classical communication (LOCC) (P. Horodecki [137], Horodeckis [140]).

2. The term "entanglement" (German "Verschränktheit") was introduced by Schrödinger, who was the first to note the unusual properties of entangled states. The careful logical analysis of the EPR experiment is due to Bell [21], who in particular established an inequality related to (3.17) and applied it to analyze the EPR paradox. "Loophole-free" experimental tests of the CHSH inequality were reported recently by Zeilinger et al. [262], Shalm et al. [205], Hanson et al. [91]. In the discussion of the Mermin-Peres game, we followed Aravind [9], where one can find further references. Experimental demonstrations of the quantum gain were also reported; see Zu et al. [261].

3. The protocol of superdense coding was proposed by Bennett and Wiesner [30]. The protocol of quantum teleportation was proposed in the famous publication of Bennett, Brassard, Crépeau, Jozsa, Peres, and Wootters [22]. The possibility of teleportation of the polarization state of a photon was experimentally demonstrated by the group of Zeilinger in 1997. Since then, a number of further successful experiments were performed, both on photons and on atoms.

10.4 4 Classical Entropy and Information

10.4.1 4.1 Entropy of a Random Variable and Data Compression

Let X be a random variable with values in a finite set $\mathcal{X}$ and let $P = \{p_x, x \in \mathcal{X}\}$ be its probability distribution. The entropy $H(X) = H(P)$ is defined as

$$H(X) = \sum_{x \in \mathcal{X}} \eta\left(p_x\right), \tag{4.1}$$

where

$$\eta(t) = \begin{cases} -t \log t, & t > 0, \\ 0, & t = 0. \end{cases} \tag{4.2}$$

Here and in what follows $\log = \log_2$ denotes the binary logarithm. The entropy $H(X)$ is a measure of uncertainty, of variability, or of the information content in the random variable X, as we shall see below. Without loss of generality we will assume in what follows that $p_x > 0$ for all x.

Let d be the number of elements in the set $\mathcal{X}$. One has

$$0 \leq H(P) \leq \log d \tag{4.3}$$

with the minimum value attained on degenerate distributions $\{1, 0, \ldots, 0\}, \ldots, \{0, \ldots, 0, 1\}$ and the maximum value on the uniform distribution $\left\{\frac{1}{d}, \ldots, \frac{1}{d}\right\}$. The first inequality follows from the nonnegativity of the function $\eta(t)$ in the domain $[0, 1]$, and the second follows from the concavity of the function $t \to \log t$, i.e.,

$$H(P) = \sum_{x=1}^{d} p_x \log \frac{1}{p_x} \leq \log \sum_{x=1}^{d} p_x \frac{1}{p_x} = \log d.$$

Let us now explain the operational interpretation of the entropy $H(X)$ as a measure of the information content in the random variable X. Consider a "random source" which produces independent, identically distributed (i.i.d.) random variables with distribution P. A sequence $w = (x_1, \ldots, x_n)$ of n letters from the alphabet $\mathcal{X}$ is called a word of length n. The total number of such words is $|\mathcal{X}|^n = 2^{n \log |\mathcal{X}|}$. Hence it is possible to encode all these words using binary strings of length $n \log |\mathcal{X}|$, i. e., $n \log |\mathcal{X}|$ bits. [1] However, by using the fact that the probability distribution P of X is in general nonuniform, one can in general achieve a much better encoding. The possibility of the data compression is closely connected with the asymptotic equipartition property.

Theorem 4.1. If $X_1, \ldots, X_n$ are i. i. d. random variables with distribution P, then

$$-\frac{1}{n} \sum_{i=1}^{n} \log p_{X_i} \longrightarrow H(X) \quad \text{in probability.} \tag{4.4}$$

This means that for any $\delta, \epsilon > 0$ there exists an n_0, such that for all $n \geq n_0$ we have

$$\mathrm{P}\left\{ \left| -\frac{1}{n} \sum_{i=1}^{n} \log p_{X_i} - H(X) \right| < \delta \right\} > 1 - \epsilon. \tag{4.5}$$

This is a direct consequence of the law of large numbers applied to the i.i.d. random variables $-\log p_{X_i}, i = 1, \ldots, n$, taking into account that $\mathrm{E}\,(-\log p_{X_i}) = H(X)$.

Noting that the probability of the occurrence of a word $w = (x_1, \ldots, x_n)$ is

$$p_w = p_{x_1} \cdots p_{x_n} = 2^{-n\left(-\frac{1}{n}\sum_{i=1}^{n} \log p_{x_i}\right)}, \tag{4.6}$$

we can now use relation (4.5) to introduce a basic notion of the typical word.

Definition 4.2. A word w, having probability p_w, is called δ-typical if

$$2^{-n(H(X)+\delta)} < p_w < 2^{-n(H(X)-\delta)} \tag{4.7}$$

in other words, if it satisfies the event in formula (4.5).

The collection of all δ-typical words of length n will be denoted by $T^{n,\delta}$. By using (4.5), (4.7), it is straightforward to see that δ-typical words have the following properties (where δ, ϵ are fixed positive numbers).

Exercise 4.3 Prove the following statements:

i. There are at most $2^{n(H(X)+\delta)}$ typical words, i. e., $\left|T^{n,\delta}\right| \leq 2^{n(H(X)+\delta)}$.

ii. For sufficiently large n, the set of all nontypical words has a probability $\mathrm{P}\left(\overline{T^{n,\bar{\delta}}}\right) \leq \epsilon$.

iii. For sufficiently large n, there are at least $(1-\epsilon)2^{n(H(X)-\delta)}$ typical words.

Now, one can do efficient data compression by using all binary sequences of length $n(H(X)+\delta)$ to encode all δ-typical words and all nontypical words into one additional (idle) symbol. Then the error probability of such a coding scheme will be less than or equal to ϵ.

Conversely, any code that uses only binary sequences of length $n(H(X)-\delta)$ has an asymptotically nonvanishing error probability, which in fact can be made arbitrarily close to 1 for n large enough. Indeed, let C be the collection of words that are used for the encoding into $n(H(X)-\delta)$ binary strings, while all other words are encoded into
the idle symbol. In this case, the error probability is $1 - \mathrm{P}(C)$, where

[1] To avoid inessential complications, we shall systematically neglect the fact that this number is not necessarily an integer.

$$\mathrm{P}(C) = \mathrm{P}\left(C \cap T^{n,\delta/2}\right) + \mathrm{P}\left(C \cap \overline{T^{n,\delta/2}}\right) \tag{4.8}$$

$$\leq |C| 2^{-n(H(X)-\delta/2)} + \mathrm{P}\left(\overline{T^{n,\delta/2}}\right) \tag{4.9}$$

$$\leq 2^{-n\delta/2} + \epsilon, \tag{4.10}$$

which can be made arbitrarily small for n large enough.
Since we need asymptotically $N \sim 2^{nH(X)}$ codewords for efficient encoding, $H(X)$ can be interpreted as a measure of the information content of the source in bits per letter. It is also clear that if we start with a uniform distribution $p_x = \frac{1}{|\mathcal{X}|}$, then $H(X) = \log|\mathcal{X}|$ and no data compression is possible.

Exercise 4.4 Let $\mathcal{X}$ be a finite subset of $\mathbb{R}$ and let $X_1, \ldots, X_n, \ldots$ be i. i. d. random variables with values in $\mathcal{X}$. Assuming the conditions of Theorem 4.1, prove the following large deviations inequality:

$$\mathrm{P}\left\{\frac{1}{n}\sum_{i=1}^{n}(X_i - \mathrm{E}X) \geq \delta\right\} \leq \exp\left\{-n \sup_{s>0}[s\delta - \mu(s)]\right\}, \tag{4.11}$$

where

$$\mu(s) = \ln Ee^{s(X-EX)} = o(s) \quad \text{for } s \to 0$$

This implies the law of large numbers with exponential decay of tails, since $s\delta - \mu(s) > 0$ for small $s > 0$.

Hint: prove and apply the following version of the Markov inequality:

$$\mathrm{P}\{X \geq x\} = \mathrm{P}\left\{\mathrm{e}^{\mathrm{s}X} \geq \mathrm{e}^{\mathrm{s}X}\right\} \leq \exp(-sx)\mathrm{E}\mathrm{e}^{\mathrm{s}X}$$

for any $x \in \mathbb{R}$ and $s > 0$.

10.4.2 4.2 Conditional Entropy and the Shannon Information

Let X, Y be random variables on one probability space with joint probability distribution $\{p_{x,y}\}$. In this case, one can define their joint entropy $H(XY)$ similar to relation (4.1). The conditional entropy $H(Y \mid X)$ is defined as

$$\begin{aligned} H(Y \mid X) &= \sum_x p_x H(Y \mid X = x) \\ &= -\sum_x p_x \sum_y p(y \mid x) \log p(y \mid x) \\ &= -\sum_{x,y} p_{x,y} \log p_{x,y} + \sum_x p_x \log p_x \\ &= H(XY) - H(X) \end{aligned} \tag{4.12}$$

There is a useful general rule stating that any linear relation for (conditional) entropies continues to hold if, in every term, a condition is supplemented with one and the same extra condition. For example, (4.12) implies

$$H(XY \mid Z) = H(X \mid Z) + H(Y \mid XZ). \tag{4.13}$$

A noisy communication channel is described by the transition probability $p(y \mid x)$ from the input alphabet $\mathcal{X}$ to the output alphabet $\mathcal{Y}$, i.e., a collection of conditional probabilities that a letter $y \in \mathcal{Y}$ is received when a letter $x \in \mathcal{X}$ is sent. An input probability distribution $P = \{p_x\}$ is transformed by the channel to the output probability distribution $P' = \{p'_y\}$, where $p'_y = \sum_x p(y \mid x)p_x$. The Shannon information (about the random variable X contained in Y) is defined as

$$I(X;Y) = H(Y) - H(Y \mid X), \tag{4.14}$$

where the entropy $H(Y)$ can be interpreted as the information content of the output, while the conditional entropy $H(Y \mid X)$ is interpreted as its useless component that arises from the noise in the channel. Substituting (4.12) into this expression for the Shannon information, we see that it is symmetric in X and Y, and hence it can also be called the mutual information

$$I(X;Y) = H(X) + H(Y) - H(XY). \tag{4.15}$$

Furthermore, $I(X;Y) = H(X) - H(X \mid Y)$, where $H(X)$ can now be interpreted as the information content of the input, and $H(X \mid Y)$ is sometimes referred to as loss. An explicit expression for the Shannon information via the input distribution and the channel transition probabilities is given by

$$I(X;Y) = \sum_{xy} p_x p(y \mid x) \log \left(\frac{p(y \mid x)}{\sum_{x'} p\left(y \mid x'\right) p_{x'}} \right). \tag{4.16}$$

A very useful quantity from classical statistics is the relative entropy of two probability distributions $P = \{p_x\}, Q = \{q_x\}$ (the Kullback-Leibler-Sanov entropy):

$$H(P;Q) = \begin{cases} \sum_{x:p_x>0} p_x \log \frac{p_x}{q_x}, & \text{if } \{x : p_x > 0\} \subseteq \{x : q_x > 0\}, \\ +\infty, & \text{otherwise .} \end{cases}$$

By using the inequality $\ln t \leq t - 1$, we obtain

$$H(P;Q) \geq -\log \mathrm{e} \sum_{x:p_x>0} p_x \left(\frac{q_x}{p_x} - 1 \right) \geq 0, \tag{4.17}$$

with equality if and only if $P = Q$.
The quantity $H(P;Q)$ plays an important role as an "asymmetric distance" between the probability distributions. It has the following monotonicity property. Consider the channel $r(y \mid x)$ and two input probability distributions $P = \{p_x\}, Q = \{q_x\}$, which are transformed to the output distributions $P' = \left\{p'_y\right\}, Q' = \left\{q'_y\right\}$,

$$p'_y = \sum_x r(y \mid x)p_x, \quad q'_y = \sum_x r(y \mid x)q_x.$$

In this case,

$$H\left(P';Q'\right) \leq H(P;Q). \tag{4.18}$$

In fact,

$$
\begin{aligned}
H(P;Q) &= \sum_{xy} p_x r(y \mid x) \log \frac{r(y \mid x) p_x}{r(y \mid x) q_x} \\
&= \sum_{xy} p_{x,y} \left(\log \frac{p'_y}{q'_y} + \log \frac{p(x \mid y)}{q(x \mid y)} \right) \\
&= H\left(P';Q'\right) + \sum_y p'_y H(p(x \mid y); q(x \mid y)) \\
&\geq H\left(P';Q'\right)
\end{aligned}
$$

Exercise 4.5 Prove that $I(X;Y) = H\left(p_{x,y}; p_x \cdot p_y\right)$. Hence, due to (4.17), $I(X;Y) \geq 0$, while $I(X;Y) = 0$ if and only if X and Y are independent random variables, i. e., $p_{x,y} = p_x \cdot p_y$.

This also implies monotonicity of the conditional entropy,

$$
0 \leq H(Y \mid X) \leq H(Y),
$$

and subadditivity of the entropy,

$$
H(XY) \leq H(X) + H(Y). \tag{4.19}
$$

Exercise 4.6 Consider the concatenation of two channels $p(y \mid x)$ and $q(z \mid y)$, defined as $r(z \mid x) = \sum_y q(z \mid y) p(y \mid x)$. Let X be a random variable at the input of the channel $p(y \mid x)$ having the probability distribution $\{p(x)\}$, and denote by Y and Z the output of the channel $p(y \mid x)$ and $r(z \mid x)$, resp., so that $X \to Y \to Z$ is a Markov chain. In this case, the data-processing inequalities hold,

$$
I(X;Z) \leq \min\{I(X;Y), I(Y;Z)\}. \tag{4.20}
$$

Hint: $I(X;Z) \leq I(X;YZ) = I(X;Y)$ follows from $H(X \mid Z) \geq H(X \mid YZ) = H(X \mid Y)$ and analogously for the second quantity.

The Shannon information has the following expression, in terms of the relative entropy:

$$
I(X;Y) = \sum_x p_x H\left(P'_x; P'\right), \tag{4.21}
$$

where $P'_x = \{p(y \mid x)\}$ for fixed $x \in \mathcal{X}$, and $P' = \sum_x p_x P'_x$ is the distribution of Y.

10.4.3 4.3 The Shannon Capacity of the Classical Noisy Channel

Consider the classical channel $X \to Y$ determined by the transition probability $p(y \mid x)$. The most important characteristic of the channel is the Shannon capacity

$$
C_{\text{Shan}} = \max_X I(X;Y), \tag{4.22}
$$

where the maximum is taken over all possible distributions $P = \{p_x\}$ of the input X. It will later be identified as the operationally defined information transmission capacity of the channel.

As an example, let us consider the binary symmetric channel. Assume that $\mathcal{X}$ and $\mathcal{Y}$ consist of two letters 0,1 , which are transmitted with probability p and flipped with probability $1-p$. Introducing the binary entropy

$$
h_2(p) = -p \log p - (1-p) \log(1-p), \tag{4.23}
$$

the mutual information can be written as $I(X;Y) = H(Y) - H(Y \mid X) = H(Y) - h_2(p)$, and is thus bounded by the quantity

$$C_{\text{Shan}} = 1 - h_2(p), \tag{4.24}$$

which is achieved for the uniform input distribution: $p_0 = p_1 = \frac{1}{2}$.
In general, $I(X;Y)$ is a concave function of the input probability distribution $P = \{p_x\}$. Hence, the Kuhn-Tucker conditions from convex analysis (see, e. g., [47]) can be applied to characterize the optimal input distribution P that maximizes $I(X;Y)$.

Exercise 4.7 Show that the entropy $H(P)$ is a concave function of the probability distribution P. Hint: use concavity of the function $t \to \eta(t)$. Therefore, the output entropy $H(Y) = H(P')$ is also concave, while the conditional entropy $H(Y \mid X)$ is affine. Use formula (4.14) to conclude that $I(X;Y)$ is concave.

Exercise 4.8 (Kuhn-Tucker Conditions) Let $F(P)$ be a concave function of probability distribution P, continuously differentiable at the interior of the simplex of all probability distributions on $\mathcal{X}$, and having possibly infinite limits of the partial derivatives at its boundary. Prove the following statement: a necessary and sufficient condition for the point P^0 to be the maximizer for $F(P)$ is that there exists a λ such that

$$\frac{\partial F(P^0)}{\partial p_x} \begin{cases} = \lambda, & \text{if } p_x^0 > 0, \\ \leq \lambda, & \text{if } p_x^0 = 0. \end{cases}$$

In the case of Shannon information (4.21), we find

$$\frac{\partial I}{\partial p_x} = H(P'_x; P') - \log \mathrm{e},$$

which leads to the following "maximal distance" characterization of the optimal input distribution $P^0 = \{p_x^0\}$: there exists a μ such that

$$H\left(P'_x; \left(P^0\right)'\right) \begin{cases} = \mu, & \text{if } p_x^0 > 0, \\ \leq \mu, & \text{if } p_x^0 = 0, \end{cases} \tag{4.25}$$

in which case, necessarily $\mu = C_{\text{Shan}}$.
Assume that two channels $\{p_j(y_j \mid x_j)\}, j = 1, 2$, are given, and consider the composite parallel channel consisting of the independent use of these two channels, described by the transition probability $\{p_1(y_1 \mid x_1)\, p_2(y_2 \mid x_2)\}$.

Proposition 4.9. The Shannon capacity of the composite channel is

$$(C_{\text{Shan}})_{12} = (C_{\text{Shan}})_1 + (C_{\text{Shan}})_2 . \tag{4.26}$$

Thus the Shannon capacity is additive for the parallel channels.
Proof. Let P^j be the optimal input probability distributions for the j th channel. Then they satisfy the condition (4.25) with constants $\mu_j = (C_{\text{Shan}})_j$. Using the fact that in general

$$H\left(P^1 \times P^2; Q^1 \times Q^2\right) = H\left(P^1; Q^1\right) + H\left(P^2; Q^2\right),$$

we obtain that the probability distribution $P = P^1 \times P^2$ satisfies the condition (4.25) for the composite channel, with the constant $\mu = (C_{\text{Shan}})_1 + (C_{\text{Shan}})_2$. □

10.4.4 4.4 The Channel Coding Theorem

Given the channel $p(y \mid x)$, one can consider the composite memoryless channel

$$p\left(y^n \mid x^n\right) = p\left(y_1 \mid x_1\right) \cdots p\left(y_n \mid x_n\right), \tag{4.27}$$

which transmits words of length n, by using the initial channel n times, with each use being independent of the others,

$$x^n \left\{ \begin{array}{ccc} x_1 & \longrightarrow & y_1 \\ x_2 & \longrightarrow & y_2 \\ \vdots & & \vdots \\ x_n & \longrightarrow & y_n \end{array} \right\} y^n.$$

By X^n, Y^n, we denote the random variables at the input and the output of the composite channel.

Following (4.22), consider the quantity

$$C_n = \max_{X^n} I\left(X^n; Y^n\right)$$

for the composite channel. Inductively applying property (4.26), we find that the sequence $\{C_n\}$ is additive for memoryless channels, whence

$$C_n = nC_{\text{Shan}}\,. \tag{4.28}$$

To reduce the effect of noise, one uses encoding of the messages at the input and, correspondingly, decoding at the output. The whole process of information transmission is given by the following diagram:

$$i \xrightarrow{\text{encoding}} x^n \xrightarrow{\text{channel}} y^n \xrightarrow{\text{decoding}} j, \tag{4.29}$$

where i (resp. j) denotes transmitted (resp. received) messages. One can simply assume that $i, j \in \{1, \ldots, N\}$ are the indices of the messages, since only the quantity N of the transmitted messages is of importance.

The aim is to choose an encoding and decoding that maximizes the transmission rate $R = \frac{\log N}{n}$, equal to the number of bits per transmitted symbol, while keeping the error probability small. Let us proceed to the exact formulation.

Definition 4.10. A code (W, V) of size N for the classical memoryless channel consists of a codebook W, which is a collection of N codewords $w^{(1)}, \ldots, w^{(N)}$ of length n, and a decision rule that is a decomposition of $\mathcal{Y}^n$ into $N+1$ nonintersecting subsets $V = \left\{V^{(0)}, V^{(1)}, \ldots, V^{(N)}\right\}$. The subsets $V^{(1)}, \ldots, V^{(N)}$ can be interpreted as decision domains. Whenever $y^n \in V^{(j)}$ is received, we decide that the word $w^{(j)}$ was transmitted. If $y^n \in V^{(0)} = \overline{\bigcup_{j=1}^N V^{(j)}}$, no definite decision is made.

Thus, the maximal error probability of such a code is

$$P_e(W, V) = \max_{1 \le j \le N} \left(1 - p\left(V^{(j)} \mid w^{(j)}\right)\right), \tag{4.30}$$

where $p\left(V^{(j)} \mid w^{(j)}\right) = \mathrm{P}\left(Y^n \in V^{(j)} \mid X^n = w^{(j)}\right)$ are the probabilities of correct decisions. The mean error probability is equal to

$$\bar{P}_e(W, V) = \frac{1}{N} \sum_{j=1}^{N} \left(1 - p\left(V^{(j)} w^{(j)}\right)\right) \le P_e(W, V). \tag{4.31}$$

The following useful statement implies that criteria for information transmission based on the average error probability $\bar{P}_e(W,V)$ and on the maximal error probability $P_e(W,V)$ are asymptotically the same.

Lemma 4.11. For any code (W,V) of size $2N$ with average error probability $\bar{P}_e(W,V)$ there exists a subcode $(\tilde{W},\tilde{V})$ of size N which has a maximal error probability $P_e(\tilde{W},\tilde{V}) \le 2\bar{P}_e(W,V)$.

Proof. Put $\epsilon = \bar{P}_e(W,V)$ and assume that there are at least $N+1$ codewords with error probability $p\left(V^{(j)} \mid w^{(j)}\right) \ge 2\epsilon$, so that it would not be possible to construct the required N-code. In this case, the average error probability of the $2N$-code would be bounded from below, since

$$\bar{P}_e(W,V) > \frac{1}{2N} 2\epsilon(N+1) > \epsilon$$

which contradicts the assumption. □

Denote by $p_e(n,N)$ (resp. by $\bar{p}_e(n,N)$) the maximal (resp. average) error probability minimized over all codes of length n and size N. Then

$$\frac{1}{2} p_e(n,N) \le \bar{p}_e(n,2N) \le p_e(n,2N) \tag{4.32}$$

Definition 4.12. The number $R \ge 0$ is called the achievable transmission rate if

$$\lim_{n\to\infty} p_e\left(n, 2^{nR}\right) = 0$$

The supremum of all achievable rates is called the information capacity C of the channel $p(y \mid x)$.

Theorem 4.13 (Shannon's channel coding theorem). For a memoryless channel,

$$C = C_{\text{Shan}} .$$

Thus, the operationally (and asymptotically) defined transmission capacity is equal to the "one-letter" characteristic of the channel as defined by (4.22). The inequality $C \ge C_{\text{Shan}}$ will follow from the statement

$$\lim_{n\to\infty} p_e\left(n, 2^{nR}\right) = 0, \quad \text{if } R < C_{\text{Shan}} ,$$

which is called the direct statement of the coding theorem, while the weak converse amounts to

$$\liminf_{n\to\infty} p_e\left(n, 2^{nR}\right) > 0, \quad \text{if } R > C_{\text{Shan}} , \tag{4.33}$$

which implies $C \le C_{\text{Shan}}$. In fact, one can prove a stronger result, i.e.,

$$\lim_{n\to\infty} p_e\left(n, 2^{nR}\right) = 1, \quad \text{if } R > C_{\text{Shan}}$$

Proof. The weak converse. Due to inequality (4.32), it is sufficient to prove the analog of the statement (4.33) for the average error probability $\bar{p}_e(n,N)$.

Lemma 4.14 (Fano's Inequality). Let X, Y be two random variables and $\hat{X} = \hat{X}(Y)$ be an estimator of X with error probability $p_e = \mathrm{P}(\hat{X}(Y) \ne X)$. In this case,

$$H(X \mid Y) \le h_2(p_e) + p_e \log(|\mathcal{X}| - 1) \le 1 + p_e \log|\mathcal{X}|. \tag{4.34}$$

Proof. Let E denote an indicator of the estimation error,

$$E = \begin{cases} 0, & \text{if } \hat{X}(Y) = X, \\ 1, & \text{otherwise} . \end{cases} \tag{4.35}$$

Since E is a function of $(X, \hat{X})$ and thus is fixed for a given value of X, Y, we have $H(X \mid Y) = H(E, X \mid Y)$. But (4.13) implies

$$H(EX \mid Y) = H(E \mid Y) + H(X \mid EY) \tag{4.36}$$

Here $H(E \mid Y) \leq H(E) = h_2(p_e)$ and

$$H(X \mid EY) = (1 - p_e) H(X \mid E = 0, Y) + p_e H(X \mid E = 1, Y) \leq p_e \log(|\mathcal{X}| - 1),$$

where we have used the notion that $H(X \mid E = 0, Y) = 0$, since $E = 0$ means that, given Y, we know X exactly. The condition $E = 1$ is the same as $X \neq \hat{X}(Y)$, which leaves the possibility for $|\mathcal{X}| - 1$ values of X. Hence, the maximal possible value of the entropy is $\log(|\mathcal{X}| - 1)$. $\square$

Consider an arbitrary code (W, V) of size N, with codewords $w^{(1)}, \ldots, w^{(N)}$ of length n and a decomposition of $\mathcal{Y}^n$ into $N + 1$ decision domains

$$V^{(0)}, V^{(1)}, \ldots, V^{(N)} \subset \mathcal{Y}^n.$$

Denote by X^n a random variable taking the values $w^{(1)}, \ldots, w^{(N)}$ with equal probabilities $\frac{1}{N}$ and let $\hat{X}^n = \hat{X}(Y^n)$ be an estimate for X^n such that $\hat{X}^n = w^{(j)}$ if $Y^n \in V^{(j)}$. In this case,

$$\begin{aligned} C_n &\geq I(X^n; Y^n) = H(X^n) - H(X^n \mid Y^n) \\ &\geq \log N \left(1 - \mathrm{P}\left\{\hat{X}^n \neq X^n\right\}\right) - 1, \end{aligned} \tag{4.37}$$

by Fano's inequality, where $\mathrm{P}\left\{\hat{X}^n \neq X^n\right\} = \bar{P}_e(W, V)$. Substituting $N = 2^{nR}$ and dividing by nR leads to

$$\bar{P}_e(W, V) \geq 1 - \frac{C_n}{nR} - \frac{1}{nR}. \tag{4.38}$$

Taking the minimum of all possible codes, and using the additivity (4.28), we have in the limit $n \to \infty$

$$\liminf_{n \to \infty} \bar{p}_e\left(n, 2^{nR}\right) \geq 1 - \frac{C_{\text{Shan}}}{R} > 0$$

for $R > C_{\text{Shan}}$.

Proof of the direct statement. The main idea, due to Shannon, is to use random coding. Take N independent codewords $w^{(1)}, \ldots, w^{(N)}$ with the same probability distribution

$$\mathrm{P}\left\{w^{(i)} = (x_1, \ldots, x_n)\right\} = p_{x_1} \cdots p_{x_n}, \tag{4.39}$$

where the input distribution $P = \{p_x\}$ is chosen such that it maximizes $I(X; Y)$. Note that we have $2^{nH(X)}$ $\left(2^{nH(Y)}\right)$ typical codewords for the input (output) and on average $2^{nH(Y|X)}$ typical outputs for every input codeword w. In order for the error in the discrimination between different words at the output to tend to zero, it is necessary that the sets of typical output words corresponding to different input words do not intersect asymptotically. Hence, the size of the code is

$$N \approx \frac{2^{nH(Y)}}{2^{nH(Y|X)}} = 2^{n(H(Y) - H(Y|X))} = 2^{nI(X;Y)} = 2^{nC_{\text{Shan}}} \tag{4.40}$$

To make this argument precise, let us call an output word y^n conditionally typical for the input word $w = x^n$ if

$$2^{-n(H(Y|X)+\delta)} < p\left(y^n \mid w\right) < 2^{-n(H(Y|X)-\delta)}. \tag{4.41}$$

Denote by $T_w^{n,\delta} \subset \mathcal{Y}^n$ the subset of all conditionally typical words for the given input word w.

Exercise 4.15 Assuming that w is random, with distribution (4.39), show, by using the law of large numbers, that $\mathrm{P}\left\{Y^n \in \overline{T_w^{n,\bar{\delta}}}\right\} \le \varepsilon$ for arbitrary $\varepsilon > 0$ and sufficiently large n.

For a given encoding $W = \left\{w^{(1)}, \ldots, w^{(N)}\right\}$, we construct a special suboptimal decoding. The subsets $T_{w^{(j)}}^{n,\delta}$ may be intersecting for different j. Hence, to obtain nonintersecting decision domains we put

$$V^{(j)} = T_{w^{(j)}}^{n,\delta} \cap \overline{\left(\bigcup_{k:k\neq j} T_{w^{(k)}}^{n,\delta}\right)}. \tag{4.42}$$

Now, if, e. g., the word $w^{(1)}$ was transmitted, the error occurs if and only if

$$y^n \in \overline{V^{(1)}} = \overline{T_{w^{(1)}}^{n,\delta}} \cup \left(\bigcup_{k=2}^{N} T_{w^{(k)}}^{n,\delta}\right). \tag{4.43}$$

We now assume that the codewords $w^{(1)}, \ldots, w^{(N)}$ are selected randomly, as described above, i. e., independently, each with distribution (4.39), and let us evaluate the expectation of the mean error probability $\bar{P}_e(W, V)$. This will give us the required estimate, since obviously

$$\bar{p}_e(n, N) \le \mathrm{E}\bar{P}_e(W, V).$$

Denote by $\mathrm{P}_w\{B\}$ the probability $\mathrm{P}\left\{Y^n \in B \mid X^n = w\right\}$, where B is some, possibly random, subset of $\mathcal{Y}^n$. Due to the complete symmetry between the codewords,

$$\begin{aligned} \mathrm{E}\bar{P}_e(W, V) &= \mathrm{EP}_{w^{(1)}}\left\{\overline{V^{(1)}}\right\} \\ &= \mathrm{EP}_{w^{(1)}}\left\{\overline{V^{(1)}} \cap T^{n,\delta}(Y)\right\} + \mathrm{EP}_{w^{(1)}}\left\{\overline{V^{(1)}} \cap \overline{T^{n,\delta}(Y)}\right\} \end{aligned} \tag{4.44}$$

where $T^{n,\delta}(Y)$ is the set of the output δ-typical sequences y^n, defined similarly to Definition 4.2 with the replacement of $H(X)$ by $H(Y)$. Then, taking into account (4.43),

$$\mathrm{E}\bar{P}_e(W, V) \le \mathrm{P}\left\{Y^n \in \overline{T_{w^{(1)}}^{n,\delta}}\right\} + \sum_{k=2}^{N} \mathrm{EP}_{w^{(1)}}\left\{T_{w^{(k)}}^{n,\delta} \cap T^{n,\delta}(Y)\right\} + \mathrm{P}\left\{\overline{T^{n,\delta}(Y)}\right\}. \tag{4.45}$$

The first and third terms are $\le \varepsilon$ for sufficiently large n by the corresponding properties of the (conditionally) nontypical words. Each term in the second sum is evaluated as

$$\begin{aligned} &\sum_{w^{(1)}} \sum_{w^{(k)}} \sum_{y^n \in T_{w^{(k)}}^{n,\delta} \cap T^{n,\delta}(Y)} p\left(y^n \mid w^{(1)}\right) p_{w^{(1)}} p_{w^{(k)}} \\ &\quad \le 2^{n(H(Y|X)+\delta)} \sum_{w^{(1)}} \sum_{w^{(k)}} \sum_{y^n \in T^{n,\delta}(Y)} p\left(y^n \mid w^{(1)}\right) p_{w^{(1)}} p\left(y^n \mid w^{(k)}\right) p_{w^{(k)}} \\ &\quad = 2^{n(H(Y|X)+\delta)} \sum_{y^n \in T^{n,\delta}(Y)} (p_{y^n})^2 \le 2^{n(H(Y|X)-H(Y)+2\delta)}. \end{aligned}$$

Here, the first inequality is obtained by introducing the factor

$$2^{n(H(Y|X)+\delta)} p\left(y^n \mid w^{(k)}\right) > 1$$

on the set $T^{n,\delta}_{w^{(k)}}$, while the last one follows from the second inequality in the definition of a typical word y^n and the fact that $\mathrm{P}\left\{T^{n,\delta}(Y)\right\} \leq 1$. Finally,

$$E\bar{P}_e(W,V) \leq 2\varepsilon + (N-1)2^{n(H(Y|X)-H(Y)+2\delta)} \leq 2\varepsilon + N2^{-n(C_{\text{Shan}}-2\delta)},$$

which can be made less than 3ε if $N = 2^{nR}$, with $R < C_{\text{Shan}}$ and δ sufficiently small. □

It should be noted that the method of random encoding that allows us to prove the existence of asymptotically optimal codes and which discloses their nature is unfortunately not very suitable for practical applications. Its realization even for moderate values of n requires a huge (exponentially growing) amount of computation for the decoding. The development of practically acceptable methods of encoding and decoding is the subject of a special topic in information theory - coding theory - which makes ample use of the methods of modern algebra and combinatorics.

10.4.5 4.5 Wiretap Channel

Another important issue in modern information theory is the study of multiple user systems - networks - such as the internet. A specific example of a system with a malicious party is the wiretap channel, which we will briefly discuss here, since it will be used in Chapter 10, which is devoted to quantum information transmission.

Let $\mathcal{X}, \mathcal{Y}, \mathcal{Z}$ be finite alphabets, where alphabet $\mathcal{X}$ is associated with the transmitter, $\mathcal{Y}$ with the receiver, and $\mathcal{Z}$ with an eavesdropper. A wiretap channel is determined by a pair of channels $p(y \mid x), q(z \mid x)$, one from transmitter to receiver and another from transmitter to eavesdropper. The transmitter sends the words $w = (x_1, \ldots, x_n)$ of length n through the channels $p\left(y^n \mid x^n\right), q\left(z^n \mid x^n\right)$, and the goal is to achieve asymptotically exact transmission of a maximal amount of information to the receiver, subject to the condition that the eavesdropper receives an asymptotically negligible amount of information.

Definition 4.16. For a composite wiretap channel, the code $(\mathcal{M}, r, V)$ of size N consists of a collection of messages $\mathcal{M} = \{1, \ldots, N\}$, the transition probability $r\left(x^n \mid m\right)$ from $\mathcal{M}$ to $\mathcal{X}^n$, defining the randomized encoding of the messages $m \in \mathcal{M}$ into words x^n, and a decoding V for the receiver, given by a decomposition of the set $\mathcal{Y}^n$ into $N+1$ pairwise nonintersecting subsets $V^{(0)}, V^{(1)}, \ldots, V^{(N)} \subset \mathcal{Y}^n$.

The maximal error probability of such a code is equal to

$$P_e(\mathcal{M}, r, V) = \max_{1 \leq m \leq N} \left(1 - p\left(V^{(m)} \mid m\right)\right), \tag{4.46}$$

where $p\left(V^{(m)} \mid m\right) = \sum_{x^n} \mathrm{P}\left(Y^n \in V^{(m)} \mid x^n\right) r\left(x^n \mid m\right)$ is the probability of a correct decision for the receiver. We call R achievable rate for the wiretap channel if there exists a sequence of codes $\left(\mathcal{M}^{(n)}, r^{(n)}, V^{(n)}\right)$ of sizes $N = 2^{nR}$ such that

$$\lim_{n\to\infty} P_e\left(\mathcal{M}^{(n)}, r^{(n)}, V^{(n)}\right) = 0$$

and

$$\lim_{n\to\infty} I\left(M^n; Z^n\right) = 0,$$

where M^n is a random variable, uniformly distributed over the set of messages $\mathcal{M}^{(n)}$. The last condition expresses the requirement that the eavesdropper's information about the transmitted messages should tend to zero. The supremum of the achievable rates is called the private capacity C_p of the wiretap channel.

The coding theorem for the wiretap channel provides the following expression:

$$C_p = \max[I(M;Y) - I(M;Z)], \tag{4.47}$$

where the maximum is taken over all possible triples of random variables M, Y, Z, such that the sequence $M, X, (Y, Z)$ is a Markov chain, while the couples X, Y and X, Z are related correspondingly via channels $p(y \mid x)$ and $q(z \mid x)$.

The proof is based on the following idea. Let us fix $\delta, \varepsilon > 0$ and a distribution for X and let $T^{n,\delta}$ be the set of δ-typical words of length n. Consider the "pruned" random encoding $W^{(n)}$ which uses N independent words, each uniformly distributed over the set $T^{n,\delta}$. Let $V^{(n)}$ be the suboptimal decoding for Y constructed as in (4.42). A modification of the proof of Theorem 4.13 allows us to prove that for $N = 2^{n[I(X;Y)-\delta]}$ the inequality

$$\bar{P}_e\left(W^{(n)}, V^{(n)}\right) \leq \varepsilon \tag{4.48}$$

holds with a high probability.

To make the code secret, the transmitter has to sacrifice $n[I(X;Z) + \delta/2]$ bits of information by additional randomization of the messages. Assuming $I(X;Y) - I(X;Z) > 0$, let

$$N_{\mathcal{Z}} = 2^{n[I(X;Z)+\delta/2]}, \quad N_{\mathcal{Y}} = 2^{n[I(X;Y)-I(X;Z)-3\delta/2]},$$

so that $N_{\mathcal{Z}} N_{\mathcal{Y}} = N$. Let us arrange the array of all codewords $W^{(n)}$ as a matrix with $N_{\mathcal{Y}}$ rows and $N_{\mathcal{Z}}$ columns. In this case,

$$W^{(n)} = \left\{w^{mj}; m = 1, \ldots, N_{\mathcal{Y}}; j = 1, \ldots, N_{\mathcal{Z}}\right\}.$$

Next, let for any message m the transmitter choose the values j randomly, with equal probabilities. It can be shown that such a randomization makes almost all transmitted information hidden for the eavesdropper. For every m the collection of codewords

$$\left\{w^{mj}; j = 1, \ldots, N_{\mathcal{Z}}\right\} \tag{4.49}$$

with high probability contains almost maximal possible information $I(X;Z)$, subject to the condition that the eavesdropper uses optimal decoding. In other words, for every value of m, the sets of conditionally typical words corresponding to (4.49) cover almost the whole set of typical words for Z. The mutual information between the collections of codewords with different values of m is close to zero, so that randomization inside each collection erases almost all information going to the eavesdropper. This argument, together with relation (4.48), shows that the rate $I(X;Y) - I(X;Z) - \delta$ should be achievable, while randomization is equivalent to using an additional channel $M \to X$. A modification of a similar argument for any triple M, X, YZ satisfying the conditions of the coding theorem allows us to show that $I(M;Y) - I(M;Z) - \delta$ is also an achievable rate.

10.4.6 4.6 Gaussian Channel

Consider the continuous analog of the memoryless channel (4.27), with the real line $\mathbb{R}$ as the input and output alphabets. The channel is defined by the transition probability density

$$p\left(y_i \mid x_i\right) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left[-\frac{\left(y_i - x_i\right)^2}{2\sigma^2}\right], \quad i = 1, \ldots, n.$$

Equivalently, one obtains the output random variables Y_i by addition of the noise given by i.d.d. Gaussian random variables Z_i to the input signal x_i, with $\mathrm{E}Z_i = 0$ and $\mathrm{E}Z_i^2 = \sigma^2$, i.e.,

$$Y_i = x_i + Z_i, \quad i = 1, \ldots, n$$

Clearly, the naturally defined information capacity of such a channel is infinite if one does not introduce constraints on the signal. Usually, the quadratic constraint is considered, i. e.,

$$\sum_{i=1}^{n} x_i^2 \le ns^2 \tag{4.50}$$

motivated by the finiteness of the signal power. Under this constraint the channel capacity is computed as

$$C = \frac{1}{2} \log \left(1 + \frac{s^2}{\sigma^2} \right) \tag{4.51}$$

This formula also belongs to Shannon and it also has a simple heuristic explanation. The inequalities

$$\frac{1}{n} \sum_{i=1}^{n} Z_i^2 \le \sigma^2 + \varepsilon, \quad \frac{1}{n} \sum_{i=1}^{n} Y_i^2 \le s^2 + \sigma^2 + \varepsilon$$

hold with high probability for arbitrary $\varepsilon > 0$ and sufficiently large n.

Exercise 4.17 Prove this statement by using the Markov inequality $\mathrm{P}\{X \ge \varepsilon\} \le \mathrm{E}X/\varepsilon$ for a nonnegative random variable X and the relation (4.50).

The first of these inequalities means that, for any input word $w = (x_1, \ldots, x_n)$, the output vector $Y^n = (Y_1, \ldots, Y_n)$ lies in an n-dimensional ball with radius $\sqrt{n\,(\sigma^2 + \varepsilon)}$ and center w, while the second tells us that the output vectors for arbitrary inputs that satisfy constraint (4.50) lie in an n-dimensional ball of radius $\sqrt{n\,(s^2 + \sigma^2 + \varepsilon)}$, with its center at the origin. The ratio of the volumes of these balls gives an approximate value for the quantity of balls of the first type within the big ball,

$$N = \left[\frac{\sqrt{n\,(s^2 + \sigma^2 + \varepsilon)}}{\sqrt{n\,(\sigma^2 + \varepsilon)}} \right]^n = 2^{nR}$$

where $R = \frac{1}{2} \log \left(1 + \frac{s^2}{\sigma^2 + \varepsilon} \right)$, which can be made arbitrarily close to (4.51).

10.4.7 4.7 Notes and References

1. The ideas of reliable data transmission have been promoted since the 1930s and even earlier (see Verdú [236] for a detailed historical survey). Remarkably, Kotelnikov, the Russian pioneer in the field, maintained a deep interest in the foundations of quantum mechanics throughout his life. The mathematical tradition in information theory goes back to the 1950s, when Khinchin and Kolmogorov gave insights into Shannon's discoveries from the viewpoint of advanced probability theory. Nowadays, there are many excellent texts on information theory. Here, we mainly follow the book of Cover and Thomas [47], which provides an enlightening, nontechnical introduction to the subject. The method of types was systematically developed by Cziszar and Körner [50].

2. The idea of using the exponential function in the Markov inequality with subsequent large deviation estimates goes back to Bernstein, followed by Cramér. Its importance to information theory and statistics was emphasized in the work of Chernoff, see, e. g., [47], Lemma 12.9.1, and also [78].

3. For a complete proof of Exercise 4.8 and its application to the additivity of the Shannon capacity, see Gallager [78], Theorems 4.4.1, 4.5.1.

4. The heuristic argument for the direct coding theorem was already present in Shannon's pioneering paper [206]. Our proof differs from the one given in the book [47] in that it uses conditional rather than joint typicality. It is this approach that allows for the noncommutative extension; see Section 5.6.

5. Theory of multiuser systems is presented in the books of Cziszar and Körner [50] and Cover and Thomas [47]. The proof of the coding theorem for the wiretap channel is given in [50].

6. For a rigorous proof of formula (4.51), see, e. g., [47]. The quantum analog of the channel with additive Gaussian noise is considered in Section 12.1.4.

10.5 5 The Classical-Quantum Channel

10.5.1 5.1 Codes and Achievable Rates

As was explained in Section 3.3.1, a simple mathematical model of a quantum communication channel is given by a map $x \to S_x$ that transforms the letters x of a (finite) input alphabet $\mathcal{X}$ into the quantum states at the channel output. We will call such a model a classical-quantum (c-q) channel. If an observable $M = \{M_y\}$ is measured at the output of such a channel, the conditional probability to obtain the outcome y, under the condition that the signal x was sent, is given by the formula

$$p(y \mid x) = \operatorname{Tr} S_x M_y. \tag{5.1}$$

Thus, for a fixed quantum measurement we have a usual classical channel. This leads to the question as to the maximum amount of classical information that can be transmitted through the quantum communication channel with asymptotically vanishing error, i.e., its "classical capacity." This question will be considered in detail in the present chapter.

Consider the composite c-q channel which maps a word $w = (x_1, \dots, x_n)$ into the product state $S_w = S_{x_1} \otimes \cdots \otimes S_{x_n}$ in the space $\mathcal{H}^{\otimes n}$. The process of transmission of classical information is described by the diagram

$$i \xrightarrow{\text{encoding}} w \xrightarrow{\text{channel}} S_w \xrightarrow{\text{decoding}} j. \tag{5.2}$$

The assumption that a word w is mapped into the tensor product of states S_{x_j} corresponds to the definition of a memoryless channel in the classical case. At the channel output, there is a receiver which performs a measurement of an observable $M = \left\{ M_j^{(n)} \right\}$ in the space $\mathcal{H}^{\otimes n}$ (the outcome j means that the receiver decides that the signal j was sent). Thus, the resolution of the identity in the space $\mathcal{H}^{\otimes n}$ describes the overall statistics of the decision procedure, including both the physical measurement and the subsequent classical information processing. The choice of the observable M is formally similar to the choice of the decision rule in the classical case, but here it plays a much more significant role, as we shall see.

Definition 5.1. A code (W, M) of size N consists of a classical codebook $W = \left\{ w^{(i)}; i = 1, \dots, N \right\}$, which is a collection of N codewords of length n, and a quantum decision rule given by an observable $M = \{M_j; j = 0, 1, \dots, N\}$ in $\mathcal{H}^{\otimes n}$. An outcome $j = 1, \dots, N$ corresponds to the decision that the word w^j was sent, while $j = 0$ means no definite decision.

The probability of decoding the signal i as j is equal to

$$p_{WM}(j \mid i) = \operatorname{Tr} S_{w^{(i)}} M_j, \quad j = 0, 1, \ldots, N. \tag{5.3}$$

Then the probability of a correct decision is $p_{WM}(i \mid i) = \operatorname{Tr} S_{w^{(i)}} M_i$, while the maximal error probability of the code $(\ W, M\ )$ is equal to

$$P_e(W, M) = \max_{1 \le j \le N} \left[1 - p_{WM}(j \mid j)\right]. \tag{5.4}$$

The average error probability is

$$\bar{P}_e(W, M) = \frac{1}{N} \sum_{j=1}^{N} \left[1 - p_{WM}(j \mid j)\right]. \tag{5.5}$$

In what follows we denote by

$$p_e(n, N) = \min_{W,M} P_e(W, M), \quad \bar{p}_e(n, N) = \min_{W,M} \bar{P}_e(W, M) \tag{5.6}$$

the maximal and the average error, respectively, minimized over all codes $(\ W, M\ )$ of size N, using words of length n.

Definition 5.2. The classical capacity C of the c−q channel $x \to S_x$ is equal to the supremum of the transmission rates R that are achievable, in the sense that $\lim_{n\to\infty} p_e\left(n, 2^{nR}\right) = 0$ or, equivalently (by inequalities (4.32)), that $\lim_{n\to\infty} \bar{p}_e(n,\ 2^{nR}) = 0$.

10.5.2 5.2 Formulation of the Coding Theorem

The notion of the entropy of a quantum state is a natural extension of the entropy of a probability distribution. Let S be a density operator in d-dimensional Hilbert space $\mathcal{H}$, and let

$$S = \sum_{j=1}^{d} s_j \left|e_j\right\rangle \left\langle e_j\right|$$

be its spectral decomposition. Its eigenvalues s_j form a probability distribution. The von Neumann entropy of the density operator S is defined as

$$H(S) = -\sum_{j=1}^{d} s_j \log s_j = \operatorname{Tr} \eta(S) \tag{5.7}$$

where the function $\eta(\cdot)$ is given by (4.2), and is equal to the Shannon entropy of the probability distribution $\{s_j\}$. In what follows we use a more spectacular expression $H(S) = -\operatorname{Tr} S \log S$, although the logarithm is not defined for degenerate density operators. As in the case of distributions, this will not lead to ambiguities. From (4.3) it follows that

$$0 \le H(S) \le \log d$$

with the minimum achieved on pure states, and the maximum on the chaotic state $\bar{S} = \frac{1}{d} I$. As in the classical case, the entropy is a measure of the uncertainty and also of the information content of the state (this last statement will be substantiated in Section 5.5).

The following properties of the quantum entropy are easy to check.

Exercise 5.3

i. Unitary invariance: $H(VSV^*) = H(S)$, where V is a unitary operator. Moreover, this equality holds for any operator V, isometric on the support of S.
ii. Additivity: $H(S_1 \otimes S_2) = H(S_1) + H(S_2)$.

In earlier works on quantum communications, the quantity

$$\chi(\{\pi_\chi\}; \{S_\chi\}) = H\left(\sum_x \pi_\chi S_x\right) - \sum_x \pi_x H(S_x), \tag{5.8}$$

with $\pi = \{\pi_x\}$ a probability distribution on $\mathcal{X}$, was used to evaluate the capacity of the c -q channel $x \to S_x$ on heuristic grounds. The quantity (5.8) can be considered a formal quantum analog of the Shannon information, where the first term plays the role of the output entropy, and the second that of the conditional entropy of the output with respect to the input. Remarkably, this quantity appears to be strictly related to the classical capacity of the $c - q$ channel as defined in the previous section. When the states $\{S_x\}$ are fixed and there is no risk of confusion, we shall abbreviate the notation (5.8) as $\chi(\pi)$ and put

$$C_\chi = \max_\pi \chi(\pi). \tag{5.9}$$

The main goal of the next sections will be the proof of the following coding theorem.

Theorem 5.4 (Holevo [113]; Schumacher and Westmoreland [200]). The classical capacity C of the $c - q$ channel $x \to S_x$, defined as in Definition 5.2, is equal to C_x.

Note that the quantum entropy is continuous on the compact set of quantum states, hence χ is continuous in π and the maximum in the above formula is indeed achieved. Let us introduce the notation

$$\bar{S}_\pi = \sum_x \pi_x S_x \tag{5.10}$$

for the average output state. In general,

$$\chi(\pi) \le H\left(\bar{S}_\pi\right),$$

with equality in the case of the pure-state channel $S_x = |\psi_x\rangle\langle\psi_x|$. Since the maximum possible value of the entropy is $\log \dim \mathcal{H}$, this theorem implies an absolute upper bound on the classical capacity, i.e.,

$$C \le \log \dim \mathcal{H}. \tag{5.11}$$

Thus, in spite of the fact that in a Hilbert space there are infinitely many different pure states, the finite-dimensional quantum carrier cannot be used to transmit an unlimited amount of classical information. The upper bound (5.11) is achieved for the channel with orthogonal pure states $S_x = |e_x\rangle\langle e_x|, x = 1, \ldots, d$, where $\{e_x\}$ is an orthonormal basis in $\mathcal{H}, d = \dim \mathcal{H}$, and for the uniform distribution $\pi_x \equiv 1/d$. Note that such states, as a rule, cannot be obtained at the output of a realistic communication channel. It is remarkable, however, that orthogonality of the output states is not necessary in order to attain the capacity of the ideal quantum channel.

Example 5.5. Consider the trine channel with the three equiangular pure states ψ_0, ψ_1, ψ_2 in a two-dimensional Hilbert space as in Example 2.27. Taking the equal probabilities $\pi_x = \frac{1}{3}$, we obtain the chaotic average output state

$$\bar{S}_\pi = \sum_{x=0}^{2} \pi_x |\psi_x\rangle\langle\psi_x| = \frac{1}{2} I, \tag{5.12}$$

implying $C_\chi = \log 2 = 1$ bit, i. e., the capacity of the ideal channel.
More generally, if $\{\psi_x\}$ is an arbitrary overcomplete system in a Hilbert space $\mathcal{H}$, the pure state channel $x \to \frac{|\psi_x\rangle\langle\psi_x|}{\langle\psi_x|\psi_x\rangle}$ has the maximum possible capacity $\log d$, and the maximum is attained on the distribution $\pi_x = \langle\psi_x \mid \psi_x\rangle / d$.

Example 5.6. Consider a binary channel with two pure states with unit vectors ψ_0, ψ_1 as in Example 2.25. In this case,

$$C_\chi = h_2\left(\frac{1+\epsilon}{2}\right), \tag{5.13}$$

where $\epsilon = |\langle\psi_0 \mid \psi_1\rangle|$. Indeed, the entropy $H\left(\bar{S}_\pi\right)$ is maximized by the uniform distribution $\pi_0 = \pi_1 = \frac{1}{2}$ since, by concavity of the quantum entropy (see Corollary 7.17 in Chapter 7),

$$H\left(\frac{1}{2}|\psi_0\rangle\langle\psi_0| + \frac{1}{2}|\psi_1\rangle\langle\psi_1|\right) = H\left(\frac{S+S'}{2}\right) \geq \frac{1}{2}\left(H(S) + H\left(S'\right)\right),$$

where

$$S = \pi_0|\psi_0\rangle\langle\psi_0| + \pi_1|\psi_1\rangle\langle\psi_1|, \quad S' = \pi_1|\psi_0\rangle\langle\psi_0| + \pi_0|\psi_1\rangle\langle\psi_1|,$$

and $H\left(S'\right) = H(S)$ due to the reflection symmetry with respect to the bisector of the angle between the two vectors. Similar to the solution of Exercise 2.26, the eigenvalues of the density operator $\frac{1}{2}|\psi_0\rangle\langle\psi_0| + \frac{1}{2}|\psi_1\rangle\langle\psi_1|$ are equal to $\frac{1\pm\epsilon}{2}$, whence (5.13) follows.

10.5.3 5.3 The Upper Bound

Consider an arbitrary c-q channel $x \to S_x$ and an observable $M = \{M_y\}$ at its output. Note that the alphabets $\mathcal{X}$ and $\mathcal{Y}$ need not coincide. The variables x and y are related by the classical channel $p_M(y \mid x) = \operatorname{Tr} S_x M_y$. Denote by

$$\mathcal{I}_1(\pi, M) = \sum_{xy} \pi_x p_M(y \mid x) \log\left(\frac{p_M(y \mid x)}{\sum_{x'} p_M\left(y \mid x'\right)\pi_{x'}}\right) \tag{5.14}$$

the Shannon information between the variables x and y corresponding to some input distribution $\pi = \{\pi_x\}$.

> Exercise 5.7 Prove that for given π and $\mathcal{Y}$ the information quantity $\mathcal{I}_1(\pi, M)$ is a continuous and convex function of the transition probability $p_M(y \mid x)$, and hence of M. Hint: use the corresponding property of the Shannon information $I(X;Y)$.

For given distribution π on the input alphabet, consider the accessible information

$$A(\pi) = \sup_M \mathcal{I}_1(\pi, M),$$

where the supremum is taken over all possible observables at the output of the channel $x \to S_x$.

Proposition 5.8 (Davies [55]). The supremum of the information quantity $\mathcal{I}_1(\pi, M)$ is attained by the observable M^0 of the form

$$M^0_y = |\phi_y\rangle\langle\phi_y|, \quad y = 1, \ldots, m, \tag{5.15}$$

where $m \leq d^2$ in the case of complex $\mathcal{H}$ $\left(m \leq \frac{d(d+1)}{2}\right.$ in the case of real $\left.\mathcal{H}\right)$.
Proof. For any $k = 2, 3, \ldots$ the set $\mathfrak{M}_k$ of observables with k outcomes is compact, and the

continuous convex functional $\mathcal{I}_1(\pi, M)$ attains its maximum on the set $\mathfrak{M}_k$. Assume that $\hat{M}^0$ maximizes $\mathcal{I}_1(\pi, M)$ on $\mathfrak{M}_k$. By throwing off, if necessary, zero components, we obtain the observable $\tilde{M}^0 \in \mathfrak{M}_l, l \leq k$, for which $\mathcal{I}_1\left(\pi, \tilde{M}^0\right) = \mathcal{I}_1\left(\pi, \hat{M}^0\right)$. By making the spectral decomposition of the components of the observable $\tilde{M}^0$ into rank one operators, we can construct the new observable M^0 of the form (5.15), with $m \geq l$, for which $\tilde{M}^0$ is a coarse-graining,

$$\underbrace{M_1, M_2, \ldots}_{=\tilde{M}_1}, \underbrace{i_1}_{=\tilde{M}_2} \cdots, \underbrace{\ldots, M_m}_{=\tilde{M}_l}.$$

Then $\mathcal{I}_1(\pi, M^0) \geq \mathcal{I}_1\left(\pi, \tilde{M}^0\right)$. In fact, this is a statement about the classical Shannon information, $I(X; f(Y)) \leq I(X; Y)$ or, equivalently, $H(X \mid f(Y)) \geq H(X \mid Y)$, which follows from the monotonicity of the classical conditional entropy, since $H(X \mid Y) = H(X \mid f(Y), Y)$.

The function $M \to \mathcal{I}(\pi, M)$ is convex. Therefore, we can assume that the maximizing observable $M^0 = \left\{M_y^0\right\}$ is an extreme point of the set $\mathfrak{M}_m$. Then, according to Theorem 2.21, the operators M_y^0 are linearly independent and Exercise 1.5 implies the estimate $m \leq d^2$. Since k was arbitrary, it follows that $\sup_M \mathcal{I}_1(\pi, M)$ is attained on an observable from the compact convex set $\mathfrak{M}_{d^2}$. □

Theorem 5.9 (Holevo [111]). For an arbitrary distribution π

$$A(\pi) \equiv \max_M \mathcal{I}_1(\pi, M) \leq \chi(\pi), \tag{5.16}$$

with equality attained if and only if the operators $\pi_x S_x, x \in \mathcal{X}$ all commute.

In Chapter 7, we will obtain the information bound (5.16) as a corollary of the rather general monotonicity property of the quantum relative entropy. Here we give instead an outline of the original proof, based on the comparison of the convexity of the classical and quantum entropies. This proof reveals a connection between the quantum entropy and the noncommutative analog of the Fisher information, and moreover allows us to obtain a necessary and sufficient condition for equality. The latter condition will be used in the next section, in order to establish the nonclassical property of superadditivity of the Shannon information for the c-q channel.

Proof. Without loss of generality, we assume all $\pi_x > 0$. In this case, the condition for equality amounts to the commutativity of all operators S_x. Now, equality in (5.16) is apparently achieved by the common spectral measure M of the operators S_x.

To prove the inequality let us first consider the case of two states S_0, S_1. Denote

$$\chi(t) = H\left((1-t)S_0 + tS_1\right) - (1-t)H\left(S_0\right) - tH\left(S_1\right), \quad t \in [0, 1]. \tag{5.17}$$

Also set $S_t = (1-t)S_0 + tS_1, D = S_1 - S_0$ and let $S_t = \sum_k s_k E_k$ be the spectral decomposition of the operator S_t. Here and in what follows, s_k will denote strictly positive eigenvalues.

By using Cauchy's integral formula, we have

$$S_t \log S_t = \frac{1}{2\pi i} \oint (Iz - S_t)^{-1} z \log z dz,$$

where $z \log z$ is the branch of the function, analytic in the right halfplane, and the integral is taken over a closed contour embracing the segment $[\varepsilon, 1], \varepsilon > 0$, which contains all positive eigenvalues of S_t. Differentiating twice with respect to t,

$$[S_t \log S_t]'' = \frac{1}{2\pi i} \oint \left[(Iz - S_t)^{-1}\right]'' z \log z dz,$$

where, using the resolvent expansion and taking into account that $S_t' = D$,

$$\left[(Iz - S_t)^{-1}\right]'' = 2\left(Iz - S_t\right)^{-1} D \left(Iz - S_t\right)^{-1} D \left(Iz - S_t\right)^{-1}.$$

By using the fact that $\operatorname{Tr} E_k D E_j D = \operatorname{Tr} E_j D E_k D$ due to (1.11), we have

$$\begin{aligned}\chi''(t) &= -\frac{1}{\pi i}\oint \operatorname{Tr}\left(Iz - S_t\right)^{-2} D \left(Iz - S_t\right)^{-1} D z \log z dz \\ &= -\frac{1}{\pi i}\oint \sum_{k,j} \frac{\operatorname{Tr} E_k D E_j D}{\left(z - s_k\right)^2 \left(z - s_j\right)} z \log z dz \\ &= -\sum_{k,j} \left(\operatorname{Tr} E_k D E_j D\right) f\left(s_k, s_j\right) \end{aligned} \tag{5.18}$$

where

$$\begin{aligned} f(a,b) &= \frac{1}{2\pi i}\oint \left[\frac{1}{(z-a)^2(z-b)} + \frac{1}{(z-b)^2(z-a)}\right] z \log z dz \\ &= \frac{\log a - \log b}{a-b}, \quad a \neq b, f(a,a) = a^{-1} \end{aligned} \tag{5.19}$$

Note that $\operatorname{Tr} E_k D E_j D = \operatorname{Tr} E_k D E_j D E_k \geq 0$. By using the inequality

$$f(a,b) \geq \frac{2}{a+b}, \quad 0 < a, 0 < b \tag{5.20}$$

in which equality is obtained if and only if $a = b$, we have

$$\chi''(t) \leq -\sum_{k,j} \operatorname{Tr} E_k D E_j D \frac{2}{s_k + s_j}, \tag{5.21}$$

with equality attained if and only if $\operatorname{Tr} E_k D E_j D = 0$ for all $k \neq j$. The latter condition is equivalent to $[D, S_t] = 0$, i. e., $[S_0, S_1] = 0$, because of the identity

$$\operatorname{Tr}\left[D, S_t\right]^* \left[D, S_t\right] = \sum_{k,j} \left(s_k - s_j\right)^2 \operatorname{Tr} E_k D E_j D$$

Exercise 5.10 Prove relation (5.19) and inequality (5.20).
Exercise 5.11 Show that the operator

$$L_t = \sum_{k,j} E_k D E_j \frac{2}{s_k + s_j}$$

is a solution of the equation

$$S_t \circ L_t \equiv \frac{1}{2}\left[S_t L_t + L_t S_t\right] = D$$

Moreover, show that

$$\sum_{k,j} \operatorname{Tr} E_k D E_j D \frac{2}{s_k + s_j} = \operatorname{Tr} D L_t = \operatorname{Tr} S_t L_t^2. \tag{5.22}$$

The operator L_t is a noncommutative (symmetric) analog of the logarithmic derivative of the operator-valued function S_t, while (5.22) is an analog of the Fisher information quantity in mathematical statistics. From (5.21), (5.22) it follows that

$$\chi''(t) \leq -\operatorname{Tr} D L_t = -\operatorname{Tr} S_t L_t^2, \quad 0 < t < 1; \tag{5.23}$$

in particular, $\chi''(t) \leq 0$, so that $\chi(t)$ is concave on the segment [0,1] with $\chi(0) = \chi(1) = 0$. Moreover, equality in (5.23) is achieved if and only if $[S_0, S_1] = 0$.

Now let $M = \{M_y\}$ be an arbitrary observable, let $P_t(y) = \operatorname{Tr} S_t M_y = (1-t)P_0(y) + tP_1(y)$ be its distribution in the state S_t, and $J_M(t) = \mathcal{I}_1(\pi, M)$, where $\pi = \{1-t, t\}$. In other words,

$$J_M(t) = H\left((1-t)P_0 + tP_1\right) - (1-t)H\left(P_0\right) - tH\left(P_1\right),$$

where $H(P)$ is the Shannon entropy of the probability distribution P. Also denote $D(y) = P_1(y) - P_0(y)$. Applying the previous argument to the diagonal matrix $\operatorname{diag}[P_t(y)]$ instead of the state S_t, we obtain

$$J''_M(t) = -\sum_y \frac{D(y)^2}{P_t(y)} = -\operatorname{Tr} D\Lambda_t, \tag{5.24}$$

where

$$\Lambda_t = \sum_y M_y \frac{D(y)}{P_t(y)}.$$

The first equality in (5.24) diagonal matrices. The right-hand side of (5.24) is equal to minus the classical Fisher information for the family of measurement probability distributions. We have $J''_M(t) \leq 0$, so that the function $J_M(t)$ is concave on $[0, 1]$, and $J_M(0) = J_M(1) = 0$.

Finally, let us prove that

$$J''_M(t) \geq \chi''(t), \tag{5.25}$$

and hence

$$J_M(t) \leq \chi(t), \quad 0 < t < 1, \tag{5.26}$$

with the sharp inequality if $[S_0, S_1] \neq 0$.

Proof of inequality (5.25). First note that

$$\operatorname{Tr} DM_y = \operatorname{Tr}\left(S_t \circ L_t\right) M_y = \operatorname{Re} \operatorname{Tr} S_t L_t M_y,$$

hence by using the noncommutative Cauchy-Schwarz inequality

$$\left(\operatorname{Tr} DM_y\right)^2 \leq \left|\operatorname{Tr} S_t \left(L_t \sqrt{M_y}\right) \sqrt{M_y}\right|^2 \leq \left(\operatorname{Tr} S_t L_t M_y L_t\right) \cdot \left(\operatorname{Tr} S_t M_y\right).$$

By using (5.24),

$$-J''_M(t) \leq \sum_y \operatorname{Tr} S_t L_t M_y L_t = \operatorname{Tr} S_t L_t^2 \leq -\chi''(t)$$

where in the last inequality (which is sharp if $[S_0, S_1] \neq 0$) we invoked (5.23). This implies (5.25) and hence (5.26).

This completes the proof of Theorem 5.9 in the case of two states. The case of several states $S_x, x = 0, 1, \ldots, k$, with distribution $\pi = \{\pi_x; x = 0, 1, \ldots, k\}$ is reduced to the case of two states with the help of the following recurrent formula.

Exercise 5.12 Prove that

$$X(\pi) = \sum_{m=1}^{k} \left(\pi_0 + \cdots + \pi_m\right) X_m\left(t_m\right),$$

where

$$X_m(t) = H\left((1-t)S_0^m + tS_m\right) - (1-t)H\left(S_0^m\right) - tH\left(S_m\right),$$
$$t_m = \frac{\pi_m}{\pi_0 + \cdots + \pi_m},$$
$$S_0^m = \sum_{j=0}^{m-1} \frac{\pi_j S_j}{\pi_0 + \cdots + \pi_{m-1}}.$$

Similarly,

$$\mathcal{I}_1(\pi, M) = \sum_{m=1}^{k} \left(\pi_0 + \cdots + \pi_m\right) J_M^m\left(t_m\right)$$

where $J_M^m\left(t_m\right)$ are defined in the same way as $\chi_m\left(t_m\right)$, via the Shannon entropies of the measurement probability distributions. From the proven result for two states, $J_M^m\left(t_m\right) \leq \chi_m\left(t_m\right)$. Hence, inequality (5.16) follows. If there is at least a pair of noncommuting states, we can take them as S_0, S_1, and the sharp inequality follows.

10.5.4 5.4 Proof of the Weak Converse

The bound (5.16) is the main tool for proving the weak converse of the quantum coding theorem, which implies $C \leq C_\chi$.

Theorem 5.13 (Weak Converse). If $R > C_\chi$, then

$$\liminf_{n\to\infty} \bar{p}_e\left(n, 2^{nR}\right) > 0. \tag{5.27}$$

Proof. Consider the composite, memoryless c-q channel $w \to S_w$, where $w = x^{(n)}$ denote words of length n. Let $\mathcal{I}_n\left(\pi^{(n)}, M^{(n)}\right)$ be the Shannon information defined for this composite channel similarly to $\mathcal{I}_1(\pi, M)$, where $\pi^{(n)} = \{\pi_w\}$ is a probability distribution of codewords of length n and $M^{(n)}$ is an observable in $\mathcal{H}^{\otimes n}$. Then (5.16) implies

$$\mathcal{I}_n\left(\pi^{(n)}, M^{(n)}\right) \leq C_\chi^{(n)}, \tag{5.28}$$

where

$$C_\chi^{(n)} = \max_{\pi^{(n)}} \chi\left(\{\pi_w\}; \{S_w\}\right) = \max_{\pi^{(n)}} \left[H\left(\sum_w \pi_w S_w\right) - \sum_w \pi_w H\left(S_w\right)\right]. \tag{5.29}$$

Lemma 5.14. The sequence $C_\chi^{(n)}$ is additive, i.e., $C_\chi^{(n)} = nC_\chi$.

Proof. The inequality $C_\chi^{(n)} \geq nC_\chi$ follows from the additivity of the entropy by using the product input probability distributions $\pi^{(n)}$. The proof of the converse inequality $C_\chi^{(n)} \leq nC_\chi$ follows from subadditivity of the von Neumann entropy with respect to the tensor products (see Corollary 7.4), which implies

$$\chi_n\left(\pi^{(n)}\right) \leq \sum_{k=1}^{n} \chi\left(\pi^{(n,k)}\right) \tag{5.30}$$

where $\pi^{(n,k)}$ is the k th marginal distribution of π on $\mathcal{X}$. □

Defining

$$C_n = \max_{\pi^{(n)}, M^{(n)}} \mathcal{I}_n\left(\pi^{(n)}, M^{(n)}\right), \tag{5.31}$$

we thus have $C_n \leq nC_\chi$ and, applying the classical Fano inequality (4.34), we obtain, similar to (4.38),

$$\bar{P}_e(W, M) \geq 1 - \frac{C_n}{nR} - \frac{1}{nR} \geq 1 - \frac{C_\chi}{R} - \frac{1}{nR}, \tag{5.32}$$

and hence, (5.27) follows. □

The quantity C_n is the maximal Shannon information accessible through n uses of the c-q channel when arbitrary decodings are allowed on the quantum output $\mathcal{H}^{\otimes n}$. The following result clarifies its relation to the classical capacity.

Proposition 5.15. The classical capacity C of the channel $x \to S_x$ is equal to

$$\sup_n \frac{1}{n} C_n = \lim_n \frac{1}{n} C_n. \tag{5.33}$$

Proof. The equality in (5.33) follows from superadditivity of the sequence $\{C_n\}$.

Exercise 5.16 Show that the sequence C_n is superadditive, i. e., $C_{n+m} \geq C_n + C_m$, by taking product probability distributions $\pi^{(n+m)} = \pi^{(n)} \times \pi^{(m)}$.

The inequality $C \leq \sup_n \frac{1}{n} C_n$ follows from the first relation in (5.32). The opposite inequality $C \geq \sup_n \frac{1}{n} C_n$ follows from the direct statement of Shannon's coding theorem 4.13 applied to composite channels. Indeed, let us show that any $R < \sup_n \frac{1}{n} C_n$ is an achievable rate. We have $n_0 R < C_{n_0}$ for some n_0. Hence, we can choose an observable $M^{(n_0)}$ in $\mathcal{H}^{\otimes n_0}$ such that

$$n_0 R < \max_{\pi^{(n_0)}} \mathcal{I}_n \left(\pi^{(n_0)}, M^{(n_0)} \right) \equiv C \left(M^{(n_0)} \right).$$

The quantity $C\left(M^{(n_0)}\right)$ is the Shannon capacity of the classical channel

$$p_M^{(n_0)} \left(j \mid x^{n_0} \right) = \operatorname{Tr} S_{x^{n_0}} M_j^{(n_0)}. \tag{5.34}$$

Therefore, the minimal error probability for this channel satisfies $\tilde{p}_e\left(n, 2^{n(n_0 R)}\right) \to 0$ as $n \to \infty$. Apparently, $\bar{p}_e\left(nn_0, 2^{n(n_0 R)}\right) \leq \tilde{p}_e\left(n, 2^{n(n_0 R)}\right)$, since the channel (5.34) corresponds to a certain block decoding for the initial c-q channel. Thus, $\bar{p}_e\left(nn_0, 2^{n(n_0 R)}\right) \to 0$ as $n \to \infty$. For arbitrary n', one can find n such that $nn_0 \leq n' \leq (n+1)n_0$. Then

$$\bar{p}_e\left(n', 2^{n' R}\right) \leq \bar{p}_e\left(nn_0, 2^{(n+1)n_0 R}\right) \leq \bar{p}_e\left(nn_0, 2^{n(n_0 R')}\right) \to 0, \tag{5.35}$$

if R' is chosen such that $R(1 + 1/n) \leq R' < \sup_n \frac{1}{n} C_n$ for sufficiently large n. □

The quantity

$$C_1 = \max_{\pi, M} \mathcal{I}_1(\pi, M),$$

which we call the Shannon capacity of the c-q channel $x \to S_x$, is of special interest. Similar to the proof of Proposition 5.15, it can be shown to be equal to the capacity of the c-q channel $x \to S_x$, with the additional restriction that only product observables $\left\{M_{y_1}^1 \otimes \cdots \otimes M_{y_n}^n\right\}$ are allowed at the output of the composite channel. More generally, we call the decoding $M^{(n)} = \left\{M_j^{(n)}\right\}$ in $\mathcal{H}^{\otimes n}$ unentangled if

$$M_j^{(n)} = \sum_{y^n} p\left(j \mid y^n\right) M_{y_1}^1 \otimes \cdots \otimes M_{y_n}^n, \tag{5.36}$$

where $\left\{M_{y_k}^k\right\}$ is a quantum observable for the k th copy of the space $\mathcal{H}$, and $p\left(j \mid y^n\right)$ is a conditional probability describing the classical (stochastic) transformation of the measurement outcomes of a product observable

$$\left\{M_{y_1}^1 \otimes \cdots \otimes M_{y_n}^n\right\} \tag{5.37}$$

at the output.

Exercise 5.17 Denoting by C_{ud} the supremum of achievable rates for the codes (W, M), with the additional constraint (5.36) on the decoding M, show that $C_{ud} = C_1$. Hint: the effect of the decoding (5.36) can be described by concatenation of the classical composite channel corresponding to the product observable (5.37) and the channel $p(j \mid y^n)$. Use the data-processing inequality (4.20) and the analog of the first inequality in (5.32) to prove that $C_{ud} \leq C_1$. For the proof of the converse inequality, use the direct statement of the classical coding theorem for the channel $p_M(y \mid x) = \operatorname{Tr} S_x M_y$ to prove that any rate $R < \max_\pi \mathcal{I}_1(\pi, M)$ is achievable. Since the decoding M in $\mathcal{H}$ is arbitrary, it follows that any rate $R < C_1$ is achievable. Hence, $C_1 \leq C_{ud}$.

So far, we have shown that

$$C_1 \leq C \leq C_\chi.$$

The direct statement of the coding theorem, which will be proven below, implies $C = C_\chi$. The following result means that $C_1 < C$ for channels with essentially quantum output. Thus, for the memoryless c-q channels the capacity can be increased by using entangled decodings. It follows that, while $C_n = nC_1$ for a classical memoryless channel (see Proposition 4.9), in the quantum case strict superadditivity of the classical information $C_n > nC_1$ is possible, the reason being the existence of entangled observables at the output of the composite quantum channel. One can say that this is a dual manifestation of the EPR correlations. The latter arise when the state of a composite quantum system is entangled, while the measurements are local, i. e., unentangled. Here, the strict superadditivity of the information appears for the product states and entangled measurements.

Proposition 5.18. The equality $C_1 = C$ holds if and only if the operators $\pi_x^0 S_x$ commute for a probability distribution π^0 that maximizes $\chi(\pi)$.

Proof. The sufficiency of the condition is obvious. Conversely, let $C_1 = C$. In this case, by using Proposition 5.8, compactness of the set of probability distributions $\{\pi\}$, and continuity of the Shannon information $\mathcal{I}_1(\pi^1, M^1)$, we have $C_1 = \mathcal{I}_1(\pi^1, M^1)$ for some distribution π^1 and observable M^1. Hence, $\mathcal{I}_1(\pi^1, M^1) = \chi(\pi^0)$. It follows that $\chi(\pi^1) = \chi(\pi^0)$; otherwise, by using inequality (5.16), we would have

$$\mathcal{I}_1\left(\pi^1, M^1\right) \leq \chi\left(\pi^1\right) < \chi\left(\pi^0\right).$$

Thus, we can replace π^0 with $\pi^1, \mathcal{I}_1(\pi^1, M^1) = \chi(\pi^1)$, and necessity follows from the second statement of Theorem 5.9. □

The following examples (more detailed references and discussion are given in Section 5.8) illustrate the inequality $C_1 < C$.

Example 5.19. For the trine channel,

$$C_1 = 1 - h_2\left(\frac{1 + \sqrt{3}/2}{2}\right) \approx 0.645\text{bit}, \tag{5.38}$$

which is obtained for the nonuniform distribution $\pi = [1/2, 1/2, 0]$ and for the optimal measurement for the two equiprobable states ψ_0, ψ_1, see Sasaki et al. [199]. Thus, $C_1 < C$ and the sequence $\{C_n\}$ is strictly superadditive. Note that taking the uniform distribution $\pi = [1/3, 1/3, 1/3]$ and the information optimal observable results in the smaller quantity $\log(3/2) \approx 0.585$ bit.

Example 5.20. The Shannon capacity of the c − q channel with two pure states is given by

$$C_1 = \max_{\pi, M} \mathcal{I}(\pi, M) = 1 - h_2\left(\frac{1+\sqrt{1-\epsilon^2}}{2}\right), \tag{5.39}$$

where the maximum is achieved for the uniform distribution ($\pi_0 = \pi_1 = \frac{1}{2}$) and for the sharp observable M given by the orthonormal basis situated symmetrically with respect to the vectors $|\psi_0\rangle, |\psi_1\rangle$; see Levitin [162]. Here, $\epsilon = |\langle\psi_0 \mid \psi_1\rangle| = \cos\alpha$, where α is the angle between the vectors. Note that in this case the optimal observable is the same as the one obtained by the maximum likelihood criterion (Example 2.26), while C_1 is just the capacity (4.24) of the classical binary symmetric channel, with error probability

$$p = \sin^2(\pi/4 - \alpha/2) = \frac{1-\sin\alpha}{2}$$

The plot of the quantities C_1, C as functions of ϵ is given in Figure 5.1.

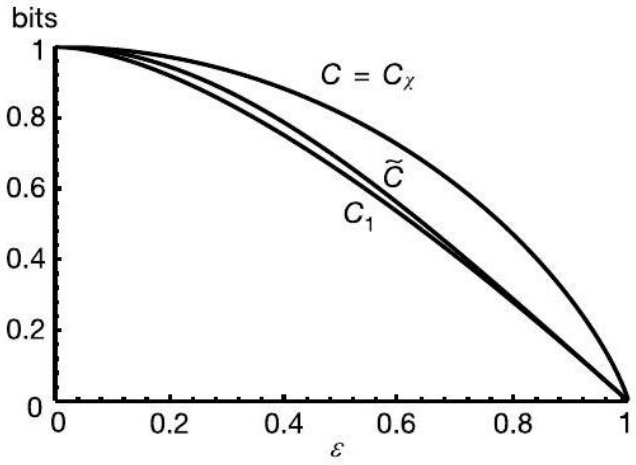

Figure 5.1: The capacity of the binary pure-state channel.

10.5.5 5.5 Typical Projectors

Before proving the direct statement of the coding theorem for the quantity C_χ, we shall consider the important notion of the typical subspace due to Schumacher and Jozsa [146].

Consider the tensor degree of a density operator

$$S^{\otimes n} = S \otimes \cdots \otimes S$$

in the space $\mathcal{H}^{\otimes n}$. Let

$$S = \sum_j \lambda_j |e_j\rangle \langle e_j|$$

be the spectral decomposition of the operator S, where $\{e_j\}$ is an orthonormal basis of eigenvectors and λ_j are the corresponding eigenvalues. Note that λ_j form a probability distribution with entropy

$$\sum_j \eta(\lambda_j) = H(S).$$

Then the spectral decomposition of the product state

$$S^{\otimes n} = S \otimes \cdots \otimes S$$

can be written as

$$S^{\otimes n} = \sum_J \lambda_J \left|e_J\right\rangle \left\langle e_J\right|,$$

where $J = (j_1, \ldots, j_n)$, with eigenvectors $|e_J\rangle = |e_{j_1}\rangle \otimes \cdots \otimes |e_{j_n}\rangle$ and eigenvalues $\lambda_J = \lambda_{j_1} \cdots \lambda_{j_n}$, describing a probability distribution of i.i.d. classical random variables. In accordance with Definition 4.2, the eigenvector $|e_j\rangle$ will be called δ-typical if

$$2^{-n(H(S)+\delta)} < \lambda_J < 2^{-n(H(S)-\delta)}$$

From the spectral decomposition of $S^{\otimes n}$ we can now construct the projector $P^{n,\delta}$ onto the typical subspace $\mathcal{H}^{n,\delta} = P^{n,\delta}\mathcal{H}^{\otimes n}$ by the relation

$$P^{n,\delta} = \sum_{J \in T^{n,\delta}} \left|e_J\right\rangle \left\langle e_J\right|.$$

We also call $P^{n,\delta}$ the typical projector.
The properties of the typical subspace $\mathcal{H}^{n,\delta}$ are analogous to the properties of the set $T^{n,\delta}$ of typical words (see Section 4.1) and easily follow from the latter.
i. The dimensionality $\dim \mathcal{H}^{n,\delta} = \operatorname{Tr} P^{n,\delta} = \left|T^{n,\delta}\right|$ satisfies the inequality

$$\dim \mathcal{H}^{n,\delta} \leq 2^{n(H(S)+\delta)}.$$

ii. The contribution of the non- δ-typical eigenvectors to the operator $S^{\otimes n}$ can be made arbitrarily small, i. e., for given $\delta, \varepsilon > 0$ and large enough n

$$\operatorname{Tr} S^{\otimes n} \left(I - P^{n,\delta}\right) < \varepsilon \tag{5.40}$$

To see this, we evaluate the trace in the basis of the eigenvectors of the operator $S^{\otimes n}$, and we find that it is equal to

$$\begin{aligned} \sum_{J \in \overline{T^{n,\delta}}} \lambda_J &= \mathrm{P}\left\{\left|-\frac{1}{n}\log \lambda_J - H(S)\right| \geq \delta\right\} \\ &= \mathrm{P}\left\{\left|-\frac{1}{n}\sum_{k=1}^{n} \log \lambda_{j_k} - H(S)\right| \geq \delta\right\}, \end{aligned} \tag{5.41}$$

where P corresponds to the probability distribution $\{\lambda_J\}$ and, by the law of large numbers, the last probability can be made arbitrarily small for n large.
iii. For sufficiently large n

$$(1-\varepsilon)2^{n(H(S)-\delta)} \leq \dim \mathcal{H}^{n,\delta}.$$

Now, we can formulate the noncommutative version of the asymptotic equipartition property: for large n the state $S^{\otimes n}$ approaches the chaotic state in the subspace $\mathcal{H}^{n,\delta}$ of dimensionality $\approx 2^{nH(S)}$.

An immediate application of this property is the quantum analog of data compression. As we have seen, the dimensionality of the underlying Hilbert space reflects the potential classical information resource of the quantum system. On the other hand, e. g., in quantum computation, the logarithm of the dimensionality measures the size of the memory, i.e., the

number of qubits in the register, which is the most important characteristic that one would like to minimize. Consider the problem of encoding quantum states into other states in a Hilbert space of the smallest possible dimensionality without essential loss of the "quantum information" carried by the states. To this end, we consider a quantum source that produces the pure states $S_x = |\psi_x\rangle \langle\psi_x|$ with probabilities p_x. The words $w = (x_1, \ldots, x_n)$ generate the product states $S_w = |\psi_w\rangle \langle\psi_w|$, where $|\psi_w\rangle = |\psi_{x_1}\rangle \otimes \cdots \otimes |\psi_{x_n}\rangle \in \mathcal{H}^{\otimes n}$, which are then encoded in some other states S'_w in a subspace $\mathcal{H}_d \subset \mathcal{H}^{\otimes n}$, the dimensionality of which $d = \dim \mathcal{H}_d$ should be as small as possible. The fidelity of the encoding is measured by the quantities $\langle\psi_w| S'_w |\psi_w\rangle$. The closer they are to 1 , the better the encoding. We require that the average fidelity

$$F_n = \sum_w \pi_w \langle\psi_w| S'_w |\psi_w\rangle$$

converges to 1 as $n \to \infty$.
Let

$$\bar{S}_\pi = \sum_{x=1}^{d} \pi_x |\psi_x\rangle \langle\psi_x|$$

be the average state of the source.
The following is called the quantum data compression theorem.

Theorem 5.21 (Schumacher and Jozsa [146]).
i. For all small enough $\varepsilon, \delta > 0$ there exist a Hilbert space $\mathcal{H}_d \subset \mathcal{H}^{\otimes n}$ of dimensionality $d = 2^{n\left(H\left(\bar{S}_\pi\right)+\delta\right)}$ and density operators S'_w in $\mathcal{H}_d$, such that the fidelity $F_n > 1 - \varepsilon$ for n large enough.
ii. For any choice of the subspace $\mathcal{H}_d \subset \mathcal{H}^{\otimes n}$ with $d = 2^{n\left(H\left(\bar{S}_\pi\right)-\delta\right)}$ and of the density operators S'_w in $\mathcal{H}_d$ we have $F_n < \varepsilon$ for n large enough.

Proof.
i. Consider the source state $|\psi_w\rangle = |\psi_{x_1}\rangle \otimes \cdots \otimes |\psi_{x_n}\rangle$. We now define the "compressed" state as

$$S'_w = \frac{P^{n,\delta} |\psi_w\rangle \langle\psi_w| P^{n,\delta}}{\langle\psi_w \mid P^{n,\delta}\psi_w\rangle}, \tag{5.42}$$

where $P^{n,\delta}$ is the typical projector of the state $\bar{S}_\pi^{\otimes n}$. The operator S'_w acts in the typical subspace $\mathcal{H}^{n,\delta}$, which has a dimensionality of at most $d = 2^{n\left(H\left(\bar{S}_\pi\right)+\delta\right)}$. For the average fidelity we obtain

$$\begin{aligned} F_n &= \sum_w \pi_w \langle\psi_w \mid S'_w \psi_w\rangle \\ &= \sum \pi_w \left\langle\psi_w \mid P^{n,\delta}\psi_w\right\rangle = \operatorname{Tr} \bar{S}_\pi^{\otimes n} P^{n,\delta} \end{aligned}$$

because $\bar{S}_\pi^{\otimes n} = \sum \pi_w |\psi_w\rangle \langle\psi_w|$. Due to the second property of $P^{n,\delta}$, we can bound this quantity from below by $1 - \varepsilon$.
ii. Taking into account the fact that the inequality $S'_w \leq P_d$ holds for all S'_w in $\mathcal{H}_d = P_d \mathcal{H}^{\otimes n}$, we have

$$\begin{aligned} F_n &= \sum \pi_w \langle\psi_w \mid S'_w \psi_w\rangle \leq \operatorname{Tr} \bar{S}_\pi^{\otimes n} P_d \\ &= \operatorname{Tr} \bar{S}_\pi^{\otimes n} P^{\frac{\delta}{2},n} P_d + \operatorname{Tr} \bar{S}_\pi^{\otimes n} \left(I - P^{\frac{\delta}{2},n}\right) P_d \\ &\leq \left\| \bar{S}_\pi^{\otimes n} P^{\frac{\delta}{2},n} \right\| \cdot \operatorname{Tr} P_d + \operatorname{Tr} \bar{S}_\pi^{\otimes n} \left(I - P^{\frac{\delta}{2},n}\right). \end{aligned}$$

Here we also used the following general property of the trace: if $T, X \geq 0, \operatorname{Tr} TX \leq \operatorname{Tr} T\|X\|$, which follows from (1.18). By the definition of typical eigenvectors, the corresponding eigenvalues are upper-bounded by

$$\left\|\bar{S}_{\pi}^{\otimes n} P^{n,\delta}\right\| < 2^{-n(H(S)-\delta)}. \tag{5.43}$$

By using this inequality and property ii of the typical projector, we obtain that for n large enough the quantity F_n does not exceed

$$2^{-n\left(H\left(\bar{S}_{\pi}\right)-\delta/2\right)} d + \varepsilon.$$

Thus, if we take $d = 2^{n\left(H\left(\bar{S}_{\pi}\right)-\delta\right)}$, then $F_n \leq 2^{-n\delta/2} + \varepsilon \leq 2\varepsilon$ for n large enough. $\square$

For the proof of the direct statement of the coding theorem in the next section, we will also need the notion of a conditionally typical projector. Consider the product states $S_w = S_{x_1} \otimes \cdots \otimes S_{x_n}$, where S_x is now an arbitrary (not necessarily pure) state and $w = (x_1, \ldots, x_n)$ is a word in the input alphabet. Denote by

$$\bar{H}_{\pi}\left(S_{(\cdot)}\right) = \sum_x \pi_x H\left(S_x\right)$$

the quantum analog of the conditional entropy of the output with respect to the input. Let $P_w = P_w^{n,\delta}$ be the spectral projector of S_w corresponding to the eigenvalues in the interval $\left(2^{-n\left[\bar{H}_{\pi}\left(S_{(\cdot)}\right)+\delta\right]}, 2^{-n\left[\bar{H}_{\pi}\left(S_{(\cdot)}\right)-\delta\right]}\right)$. In more detail, consider the spectral decomposition

$$S_x = \sum_j \lambda_j^x \left|e_j^x\right\rangle \left\langle e_j^x\right|.$$

Then the spectral decomposition of the operator S_w has the form

$$S_w = \sum_J \lambda_J^w \left|e_J^w\right\rangle \left\langle e_J^w\right|$$

where $\lambda_J^w = \lambda_{j_1}^{x_1} \cdots \lambda_{j_n}^{x_n}$ are the eigenvalues and $\left|e_J^w\right\rangle = \left|e_{j_1}^{x_1}\right\rangle \otimes \cdots \otimes \left|e_{j_n}^{x_n}\right\rangle$ are the corresponding eigenvectors. The conditionally typical projector is defined as

$$P_w = \sum_{J \in T_w^{n,\delta}} \left|e_J^w\right\rangle \left\langle e_J^w\right|$$

where

$$T_w^{n,\delta} = \left\{J : 2^{-n\left[\bar{H}_{\pi}\left(S_{(\cdot)}\right)+\delta\right]} < \lambda_J^w < 2^{-n\left[\bar{H}_{\pi}\left(S_{(\cdot)}\right)-\delta\right]}\right\}.$$

The essential properties of the projector P_w are:

i. from the definition,

$$P_w \leq S_w 2^{n\left[\bar{H}_{\pi}\left(S_{(\cdot)}\right)+\delta\right]} \tag{5.44}$$

ii. for $\varepsilon > 0$ and sufficiently large n

$$\mathrm{E} \operatorname{Tr} S_w \left(I - P_w\right) \leq \varepsilon \tag{5.45}$$

where E is the expectation corresponding to the probability distribution

$$\mathrm{P}\left\{w = (x_1, \ldots, x_n)\right\} = \pi_{x_1} \cdots \pi_{x_n}. \tag{5.46}$$

To prove the second property, consider the sequence of independent trials with outcomes $(x_l, j_l), l = 1, \ldots, n$, where the probability of an outcome (x, j) is, in each trial, equal to $\pi_x \lambda_j^x$. In this case,

$$\mathrm{E}\,\mathrm{Tr}\, S_w (I - P_w) = \mathrm{P}\left\{J \in \overline{T_w^{n,\delta}}\right\} \tag{5.47}$$

which tends to 0 as $n \to \infty$, according to the law of large numbers; see Exercise 4.15.

10.5.6 5.6 Proof of the Direct Coding Theorem

According to Definition 5.2, it is sufficient to show that the minimal average error probability $\bar{p}_e\left(n, 2^{nR}\right)$ tends to zero, as $n \to \infty$, provided $R < C_\chi$.

Consider the average state

$$\bar{S}_\pi = \sum_x \pi_x S_x$$

and the typical projector $P = P^{n,\delta}$ of the state $\bar{S}_\pi^{\otimes n}$, defined in the previous section. For a given codebook $W = \left\{w^{(1)}, \ldots, w^{(N)}\right\}$, we can also define the conditionally typical projectors $P_{w^{(}}, j = 1, \ldots, N$. We now introduce the special suboptimal observable M. The classical Shannon coding theorem, Theorem 4.13, corresponds to the case of diagonal density operators S_x with conditional probabilities $p(y \mid x)$ on the diagonal. The projector P is a quantum analog of the indicator of the subset of all δ-typical output words, while $P_{w^{(j)}}$ is the same for the subset of all conditionally typical words, given the input word $w^{(j)}$. However, in the quantum case these projectors need not commute, which makes a straightforward generalization of the decision domains (4.43) and the corresponding measure-theoretic argument impossible. Therefore, we introduce the following observable M in $\mathcal{H}^{\otimes n}$ by letting

$$M_j = \left(\sum_{l=1}^N P P_{w^{(l)}} P\right)^{-1/2} P P_{w^{(j)}} P \left(\sum_{l=1}^N P P_{w^{(l)}} P\right)^{-1/2}, \quad j = 1, \ldots, N. \tag{5.48}$$

The normalization with the square root is necessary, because the sum of the operators $P P_{w^{(j)}} P$ may not be equal to the unit operator, and the replacement of $P_{w^{(j)}}$ by $P P_{w^{(j)}} P$ plays the role of intersection with the set of all typical words in formula (4.44). The operator $\left(\sum_{l=1}^N P P_{w^l} P\right)^{-1/2}$ is to be understood as the generalized inverse of $\left(\sum_{l=1}^N P P_{w^l} P\right)^{1/2}$, equal to 0 on the null subspace of that operator, which contains the range of the projector $I - P$. Denoting by $\hat{P}$ the projector onto the support of $\sum_{l=1}^N P P_{w^l} P$, we have

$$P P_{w^{(l)}} P \le \hat{P} \le P, \quad l = 1, \ldots, N. \tag{5.49}$$

To avoid cumbersome notations, we shall further enumerate words by the variable w, omitting the indices j, l. By denoting

$$A_w = P_w P \left(\sum_{w'=1}^N P P_{w'} P\right)^{-1/2}$$

and using the Cauchy-Schwarz inequality (2.24),

$$\left|\mathrm{Tr}\, S_w A_w\right|^2 \le \mathrm{Tr}\, S_w A_w{}^* A_w,$$

we obtain

$$\bar{P}_e(W,M) \le \frac{1}{N}\sum_{w=1}^{N}\left[1-|\operatorname{Tr} S_w A_w|^2\right] \le \frac{2}{N}\sum_{w=1}^{N}\left[1-\operatorname{Tr} S_w A_w\right]$$

where $\operatorname{Tr} S_w A_w = \operatorname{Tr} P S_w P_w P \left(\sum_{w'=1}^{N} P P_{w'} P\right)^{-1/2}$ is a real number between 0 and 1 (note that $S_w P_w = P_w S_w \ge 0$). Applying the inequality

$$-2x^{-1/2} \le -3 + x, \quad x > 0, \tag{5.50}$$

we obtain by (5.49)

$$-2\left(\sum_{w'=1}^{N} P P_{w'} P\right)^{-1/2} \le -3\hat{P} + \sum_{w'=1}^{N} P P_{w'} P \le -3 P P_w P + \sum_{w'=1}^{N} P P_{w'} P.$$

Therefore, by using inequality (1.13),

$$\begin{aligned}\bar{P}_e(W,M) &\le \frac{1}{N}\sum_{w=1}^{N}\left[2\operatorname{Tr} S_w - 3\operatorname{Tr} S_w P_w P P_w P + \sum_{w'=1}^{N}\operatorname{Tr} S_w P_w P P_{w'} P\right] \\ &= \frac{1}{N}\sum_{w=1}^{N}\left[2\operatorname{Tr} S_w\left(I - P_w P P_w P\right) + \sum_{w':w'\ne w}\operatorname{Tr} S_w P_w P P_{w'} P\right]\end{aligned}$$

Taking into account that

$$\begin{aligned}\operatorname{Tr} S_w\left(I - P_w P P_w P\right) =& \operatorname{Tr} S_w\left(I - P_w\right) P P_w P + \operatorname{Tr} S_w (I-P) P_w \\ &- \operatorname{Tr} S_w (I-P) P_w (I-P) + \operatorname{Tr} S_w\left(I - P_w\right) P \\ &+ \operatorname{Tr} S_w (I-P) \\ \le& 2\left[\operatorname{Tr} S_w\left(I - P_w\right) + \operatorname{Tr} S_w (I-P)\right]\end{aligned}$$

where we used (1.13), we can write

$$\bar{P}_e(W,M) \le \frac{1}{N}\sum_{w=1}^{N}\left[4\operatorname{Tr} S_w (I-P) + 4\operatorname{Tr} S_w\left(I - P_w\right) + \sum_{w':w'\ne w}\operatorname{Tr} P S_w P P_{w'}\right] \tag{5.51}$$

which is our final basic estimate, similar to (4.45) in the classical case.
We now again apply Shannon's random coding scheme, assuming that the words $w^{(1)}, \dots, w^{(N)}$ are chosen at random, independently, and with the probability distribution (5.46) for each word, where π is the optimal distribution for which

$$H\left(\bar{S}_\pi\right) - \bar{H}_\pi\left(S_{(\cdot)}\right) = C_\chi.$$

Then

$$E S_w = \sum_{x_1 \cdots x_n} \pi_{x_1} \cdots \pi_{x_n} S_{x_1} \otimes \cdots \otimes S_{x_n} = \bar{S}_\pi^{\otimes n}$$

Taking the expectations in (5.51) and using the independence of random operators $S_w, P_{w'}$, we obtain

$$\begin{aligned}\mathrm{E}\bar{P}_e(W,M) \le& 4\operatorname{Tr}\bar{S}_\pi^{\otimes n}(I-P) + 4\mathrm{E}\operatorname{Tr} S_w\left(I - P_w\right) \\ &+ (N-1)\operatorname{Tr}\bar{S}_\pi^{\otimes n} P E P_{w'}.\end{aligned} \tag{5.52}$$

By inequalities (5.40), (5.45), expressing typicality of the projectors P, P_w, and by inequality (1.18) we have

$$E\bar{P}_e(W,M) \le 8\epsilon + (N-1)\left\|\bar{S}_\pi^{\otimes n}P\right\| \operatorname{Tr} EP_{w'},$$

for $n \ge n(\pi,\epsilon,\delta)$. By the property (5.43) of the projector P,

$$\left\|\bar{S}_\pi^{\otimes n}P\right\| \le 2^{-n\left[H\left(\bar{S}_\pi\right)-\delta\right]}$$

and by property i of the projector P_w,

$$\operatorname{Tr} \mathrm{E}P_{w'} = \mathrm{E}\operatorname{Tr} P_{w'} \le \mathrm{E}\operatorname{Tr} S_{w'} \cdot 2^{n\left[\bar{H}_\pi\left(S_{(\cdot)}\right)+\delta\right]} = 2^{n\left[\bar{H}_\pi\left(S_{(\cdot)}\right)+\delta\right]}$$

Recalling that $H\left(\bar{S}_\pi\right) - \bar{H}_\pi\left(S_{(\cdot)}\right) = C_\chi$, we obtain

$$\bar{p}_e(n,N) \le \mathrm{E}\bar{P}_e(W,M) \le 8\epsilon + N2^{-n[C_x-2\delta]}$$

Thus, if $R \le C_\chi - 3\delta$,

$$\bar{p}_e\left(n,2^{nR}\right) \le 8\epsilon + 2^{-n\delta}$$

hence, the direct coding theorem follows.

A slight modification of this argument shows exponential decay of the average error probability. Namely, there exists a $\beta > 0$, such that

$$\mathrm{E}\bar{P}_e(W,M) \le 2^{-n\beta} \tag{5.53}$$

Indeed, we already have such an estimate for the last term in (5.52), provided $N \le 2^{n[C_x-3\delta]}$, so we have to establish it for the first two terms. But this follows by application of inequality (4.11) to the probabilities of large deviations (5.41), (5.47) (Exercise).

10.5.7 5.7 The Reliability Function for Pure-State Channel

In the classical case, pure signal states correspond to degenerate distributions, and the coding theorem trivially implies the maximal value of the channel capacity $\log|\mathcal{X}|$. However, for pure quantum nonorthogonal states, the coding theorem remains nontrivial, although the situation is simplified, allowing us to obtain a stronger result. Here, we give a different proof of the direct statement of the coding theorem in the case of pure states $S_x = |\psi_x\rangle\langle\psi_x|$, which does not use the notion of typicality but, due to a more sophisticated analysis, gives the estimate for the exponential speed of decay of the error probability.

Theorem 5.22 (Burnashev and Holevo [37]). For $R < C_\chi$, the following inequality holds:

$$\bar{p}_e\left(n,2^{nR}\right) \le 2\cdot 2^{-nE(R)},$$

where

$$E(R) = \max_{0\le r\le 1}\left[-Rr + \max_\pi\left(-\log\operatorname{Tr}\bar{S}_\pi^{1+r}\right)\right] > 0. \tag{5.54}$$

The function $E(R)$ gives a lower bound for the so-called reliability function of the channel, characterizing the exponential speed of decay of the error probability $\bar{p}_e\left(n,2^{nR}\right)$ as $n\to\infty$.

Proof. Consider the subspace of the space $\mathcal{H}^{\otimes n}$, spanned by the code vectors $\psi_{w^{(1)}},\ldots,$ $\psi_{w^{(N)}}$. As shown in Section 2.3.4, we can use the Gram operator $G = \sum_j |\psi_{w^{(j)}}\rangle\langle\psi_{w^{(j)}}|$ to construct the overcomplete system

$$\left|\hat{\psi}_j\right\rangle = G^{-\frac{1}{2}}\left|\psi_{w^{(j)}}\right\rangle, \quad j=1,\ldots,N,$$

and hence the observable M with the components

$$M_j = \left|\hat{\psi}_j\right\rangle \left\langle\hat{\psi}_j\right|, \quad j = 1, \ldots, N, \tag{5.55}$$

which can be extended to the whole space $\mathcal{H}^{\otimes n}$ by adjoining the projector M_0 onto the orthogonal complement to $\psi_{w^{(1)}}, \ldots, \psi_{w^{(N)}}$. This will be our suboptimal decoding for the composite channel. Note that it differs from (5.48), in that it does not contain the typical projector P (while the conditionally typical projectors in the case of pure states are $P_w = |\psi_w\rangle \langle\psi_w|$). In this way, we obtain the upper bound for the average error probability expressed via the Gram operator of the code vectors, i.e.,

$$\begin{aligned}
\bar{P}_e(W, M) &= \frac{1}{N} \sum_{j=1}^{N} \left(1 - \left\langle\hat{\psi}_j\right| G^{\frac{1}{2}} \left|\hat{\psi}_j\right\rangle^2\right) \\
&\leq \frac{2}{N} \sum_{j=1}^{N} \left(1 - \left\langle\hat{\psi}_j\right| G^{\frac{1}{2}} \left|\hat{\psi}_j\right\rangle\right) \\
&= \frac{2}{N} \left(N - \operatorname{Tr} G^{\frac{1}{2}}\right)
\end{aligned} \tag{5.56}$$

Assuming that the codewords $\left\{w^{(j)}\right\}$ are randomly chosen, independently of each other, with the distribution (5.46), we obtain

$$\mathrm{E}\bar{P}_e(W, M) \leq \frac{2}{N} \left(N - \mathrm{E} \operatorname{Tr} G^{\frac{1}{2}}\right). \tag{5.57}$$

By using the inequality

$$-2x^{\frac{1}{2}} \leq x^2 - 3x, \quad x \geq 0,$$

which follows from (5.50), in combination with the obvious one $-2x^{\frac{1}{2}} \leq 0$, we have

$$-2G^{\frac{1}{2}} \leq \begin{cases} G^2 - 3G, \\ 0. \end{cases} \tag{5.58}$$

The expectation of the Gram operator is equal to

$$\begin{aligned}
\mathrm{E}G &= \mathrm{E} \sum_{j=1}^{N} |\psi_{w^{(j)}}\rangle \langle\psi_{w^{(j)}}| = N\mathrm{E} |\psi_{w^{(j)}}\rangle \langle\psi_{w^{(j)}}| \\
&= N \sum_{x_1 \ldots x_n} \pi_{x_1} \ldots \pi_{x_n} \left(|\psi_{x_1}\rangle \otimes \cdots \otimes |\psi_{x_n}\rangle\right) \left(\langle\psi_{x_1}| \otimes \cdots \otimes \langle\psi_{x_n}|\right) \\
&= N \left[\sum_x \pi_x |\psi_x\rangle \langle\psi_x|\right]^{\otimes n} = N \bar{S}_\pi^{\otimes n}
\end{aligned} \tag{5.59}$$

Similarly

$$\begin{aligned}\mathrm{E}\left(G^2-G\right)=&\mathrm{E}\left(\sum_{j,k=1}^{N}|\psi_{w^{(j)}}\rangle\langle\psi_{w^{(j)}}\mid\psi_{w^{(k)}}\rangle\langle\psi_{w^{(k)}}|\right.\\&\left.-\sum_{j=1}^{N}|\psi_{w^{(j)}}\rangle\langle\psi_{w^{(j)}}|\right)\\=&\mathrm{E}\left(\sum_{j\neq k}|\psi_{w^{(j)}}\rangle\langle\psi_{w^{(j)}}\mid\psi_{w^{(k)}}\rangle\langle\psi_{w^{(k)}}|\right)\\=&N(N-1)\left(\bar{S}_{\pi}^{\otimes n}\right)^2,\end{aligned}\tag{5.60}$$

so that in combination with (5.58) we obtain

$$-2\mathrm{E}G^{\frac{1}{2}}\leq\begin{cases}N(N-1)\left(\bar{S}_{\pi}^{\otimes n}\right)^2-2N\bar{S}_{\pi}^{\otimes n}\\0\end{cases}\tag{5.61}$$

Let $\{|e_J\rangle\}$ be the orthonormal basis of eigenvectors and $\{\lambda_J\}$ the corresponding eigenvalues of the operator $\bar{S}_{\pi}^{\otimes n}$. Then

$$-2\langle e_J|\,\mathrm{E}G^{\frac{1}{2}}\,|e_J\rangle\leq\begin{cases}N(N-1)\lambda_J^2-2N\lambda_J,\\0,\end{cases}\tag{5.62}$$

hence, using the inequalities $\min(a,b)\leq a^r b^{1-r}$ and $2^{1-r}\leq 2$ for $0\leq r\leq 1$, we obtain

$$N\lambda_J\min\left[(N-1)\lambda_J,2\right]-2N\lambda_J\leq 2N(N-1)^r\lambda_J^{1+r}-2N\lambda_J,\tag{5.63}$$

whence

$$-2\mathrm{E}\,\mathrm{Tr}\,G^{\frac{1}{2}}\leq-2N+2N(N-1)^r\,\mathrm{Tr}\left(\bar{S}_{\pi}^{\otimes n}\right)^{1+r}.$$

Coming back to (5.57), we can evaluate the average error probability minimized over all codes as

$$\bar{p}_e(n,N)\leq 2N^r\left(\mathrm{Tr}\,\bar{S}_{\pi}^{1+r}\right)^n$$

for any $0\leq r\leq 1$. Putting $N=2^{nR}$, we obtain

$$\bar{p}_e\left(n,2^{nR}\right)\leq 2\cdot 2^{n\left(Rr+\log\mathrm{Tr}\,\bar{S}_{\pi}^{1+r}\right)}\tag{5.64}$$

Now, we can use the freedom in the choice of the parameters r and π. Note that $-\log\mathrm{Tr}\,\bar{S}_{\pi}^{1+r}$ is a concave function of r, which can be established by showing that the second derivative is negative (Exercise). Also,

$$\frac{d}{dr}\left(-\log\mathrm{Tr}\,\bar{S}_{\pi}^{1+r}\right)\Big|_{r=0}=-\,\mathrm{Tr}\,\bar{S}_{\pi}\log\bar{S}_{\pi}=H\left(\bar{S}_{\pi}\right)\tag{5.65}$$

Take for π the optimal distribution, for which $H\left(\bar{S}_{\pi}\right)=C_{\chi}$. Then, for $R<C_{\chi}$ we have $\bar{p}_e\left(n,2^{nR}\right)\leq 2\cdot 2^{-nE(R)}$, where $E(R)$ is given by expression (5.54).

10.5.8 5.8 Notes and References

1. The issue of the information capacity of quantum communication channels arose in the 1960s in the papers of Gordon [85], [86], Forney [72], Lebedev and Levitin [160], and Stratonovich [227] and goes back to even earlier, classical works of Gabor and Brillouin, that ask for fundamental physical limits on the rate and quality of information transmission (for detailed reference, see the surveys [43], [114] and the books [103], [122]). These works laid a physical foundation and raised the question of consistent quantum information treatment of the problem.

2. The proof of Theorem 5.9, including the criterion for the equality, based on comparison of the convexity of the quantities in (5.16), was given in [111]. The symmetric logarithmic derivative of a family of quantum states and the corresponding quantum Fisher information were introduced by Helstrom in the context of quantum estimation theory [103]. The information inequality (5.16) has a number of applications: from evaluation of eavesdropper information in quantum cryptography to entropic Heisenberg limits and uncertainty relations (Hall [90]).

3. A detailed comparison of the capacities C_1, C_χ for different channels was made in the paper of Hirota et al. [148].

The strong converse

$$\lim_{n\to\infty} \bar{p}_e\left(n, 2^{nR}\right) = 1 \quad \text{for } R \geq C_\chi$$

was obtained by Winter [253] and Ogawa and Nagaoka [181]; see also the book [95]. Exact strong converse exponent was obtained by Mosonyi and Ogawa [177]. It is expressed in terms of "sandwiched" Rényi divergence (Wilde, Winter and Yang [251]).

Formula (5.39) follows from the work of Levitin [162], who showed that for two pure states and arbitrary π the maximum $\max_M \mathcal{I}(\pi, M)$ over the two-valued sharp observables in the plane is attained by the observable that maximizes the average probability of correct decision, and from the work of Shor [217], who proved that the twovalued sharp observables are sufficient in this case, and the maximum $\max_M \mathcal{I}(\pi, M)$ is a concave symmetric function of π, implying that the optimal distribution is uniform.

The trine channel was introduced by Holevo [110], who proved that for the uniform distribution π, the maximum $\max_M \mathcal{I}(\pi, M)$ over all observables is strictly greater than the maximum over sharp observables ($\log\left(\sqrt{3}/\sqrt[3]{2}\right) \approx 0.459$). It is interesting that the information-optimal observable in this problem differs from the maximal likelihood observable (see Section 2.4.2) by rotation by the angle $\pi/2$, the latter being the least informative observable. A complete treatment of $\max_M \mathcal{I}(\pi, M)$ for an arbitrary symmetric family of pure states in two-dimensional Hilbert space was given by Sasaki, Barnett, Jozsa, Osaki, and Hirota [199], who also discussed experimental implementation of the optimal measuring procedures. Conjecture (5.38) was confirmed numerically in [147], and an additional argument was given in [217]. A remarkable study of the "lifted trine" channel, i. e., the channel with three linearly independent, equiangular state vectors in three-dimensional Hilbert space, was given by Shor [217]. It was shown, in particular, that the information-optimal observable in this case has in general 6 outcomes, i. e., the maximal value admitted by Proposition 5.8 in the case $d = 3$ (although the gain, as compared to 3 outcomes, is tiny).

4. The idea of quantum data compression, originally due to Schumacher, is one of the central ones in quantum information theory. Theorem 5.21 is proved by Jozsa and Schumacher [146]. For a survey of more recent results, from different authors, on the much more complicated problem of data compression for sources with mixed states, see the book of Hayashi [95], papers of

Winter [254] and Wilde et al. [249]. The topic of reverse Shannon theorem, both for classical and quantum channels was elaborated in the work of Bennett et al. [23].
5. The proof of the coding theorem for a general c − q channel was given by Holevo [113] and by Schumacher and Westmoreland [200]. See Winter [253] for a different proof in the spirit of Cziszar and Körner's approach [50] to the classical coding theorem. This was preceded by the consideration of the pure-state channel in the work of Hausladen, Josza, Schumacher, Westmoreland, and Wootters [94], who used the technique of typical subspaces discussed in Section 5.5. It should be noted that Shannon's method of random coding for the channel with pure, almost orthogonal states was first applied by Stratonovich and Vancian [229], who used the first term in the minimal error probability in the asymptotics $\varepsilon \to 1$ (almost orthogonal states) to conclude that this method allows us to obtain the so-called cut-off rate

$$\tilde{C} = -\log \min_{\pi} \operatorname{Tr} \bar{\rho}_{\pi}^{2} < C. \tag{5.66}$$

As shown by Burnashev and Holevo [37], the properly used method of random coding allows us to obtain not only the classical capacity C, but also the exponential estimate for the error probability, in the spirit of the classical results in Gallager [78]. Dalai [51], [52] was able to extend the classical sphere packing bound of Fano, Shannon, Gallager, and Berlecamp to the pure-state c-q channel, to obtain the upper bound on the reliability function, which coincides, at high rates, with the lower bound $E(R)$ of [37]. The paper [37] also contains a formulation of the hypothesis concerning the reliability function for an arbitrary mixed-state channel. In this case, like in the others, a mixed-state problem is much more complex than its pure-state analog. Among further variations and refinements of the coding theorem we mention here nonasymptotic approach of Wang and Renner [239] and second order asymptotic results by Tomamichel and Tan [231].

10.6 6 Quantum Evolutions and Channels

10.6.1 6.1 Quantum Evolutions

In this section, the notion of quantum communication channel will be considered from a general point of view. As we have seen in Chapter 4, a classical communication channel is completely characterized by the transition probability matrix

$$\mathcal{X} \xrightarrow{p(y|x)} \mathcal{Y}.$$

Such a channel describes an affine transformation $p_x \to p'_y = \sum_x p(y \mid x) p_x$ of classical states (probability distributions) $p = \{p_x\}$ on the input alphabet $\mathcal{X}$, into the classical states $p' = \{p'_y\}$ on the output alphabet $\mathcal{Y}$.

To have a proper quantum analog of a channel we will therefore first look for maps taking density operators into density operators, which respect convex combinations, i. e., affine maps $\Phi : \mathfrak{S}(\mathcal{H}) \to \mathfrak{S}(\mathcal{H})$,

$$\Phi\left[\sum_j p_j S_j\right] = \sum_j p_j \Phi\left[S_j\right], \quad p_j \geq 0, \quad \sum_j p_j = 1, \quad S_j \in \mathfrak{S}(\mathcal{H}).$$

Exercise 6.1 Prove the following statement: an affine map Φ of $\mathfrak{S}(\mathcal{H})$ into itself can be uniquely extended to a map of the linear space $\mathfrak{T}(\mathcal{H})$ with the following properties:
i. Φ is linear: $\Phi\left[\sum_j c_j S_j\right] = \sum_j c_j \Phi\left[S_j\right], c_j \in \mathbb{C}, S_j \in \mathfrak{T}(\mathcal{H})$;
ii. Φ is positive: $S \in \mathfrak{T}(\mathcal{H}), S \geq 0 \Rightarrow \Phi[S] \geq 0$;
iii. Φ is trace-preserving: $\operatorname{Tr} \Phi[S] = \operatorname{Tr} S, S \in \mathfrak{T}(\mathcal{H})$.

Hint: follow the proof of Theorem 2.6 to obtain the linear extension of Φ to $\mathfrak{T}(\mathcal{H})$. Properties ii, iii then are straightforward.

Definition 6.2. For every map $\Phi : \mathfrak{T}(\mathcal{H}) \to \mathfrak{T}(\mathcal{H})$, satisfying properties i-iii, the dual map $\Phi^* : \mathfrak{B}(\mathcal{H}) \to \mathfrak{B}(\mathcal{H})$ is defined by the formula

$$\operatorname{Tr} \Phi[S]X = \operatorname{Tr} S\Phi^*[X], \quad S \in \mathfrak{T}(\mathcal{H}), X \in \mathfrak{B}(\mathcal{H}). \tag{6.1}$$

Exercise 6.3 Prove the following statement: the properties of the map Φ from Exercise 6.1 are equivalent to the following:

i. Φ^* is linear;

ii. Φ^* is positive: $X \geq 0 \Rightarrow \Phi^*[X] \geq 0$;

iii. Φ^* is unital: $\Phi^*[I] = I$.

The map Φ describes an evolution of the quantum system in terms of states (the Schrödinger picture), while the map Φ^* does this in terms of observables (the Heisenberg picture). Note that positive linear maps transform Hermitian operators into Hermitian operators. In the case of a finite-dimensional $\mathcal{H}$ that we are considering, the linear space $\mathfrak{T}(\mathcal{H})$ and the algebra $\mathfrak{B}(\mathcal{H})$ coincide with the space of all linear operators in $\mathcal{H}$, but we use different notations to stress that $\mathfrak{T}(\mathcal{H})$ is the arena for the states and the Schrödinger picture, while $\mathfrak{B}(\mathcal{H})$ is that of the observables and the Heisenberg picture. This distinction becomes quite substantial in the infinite-dimensional case considered in Chapters 11, 12.

Example 6.4. Let U be a unitary operator. In this case, $\Phi[S] = USU^*$ is an affine, one-to-one mapping of the set of quantum states $\mathfrak{S}(\mathcal{H})$ onto itself (i.e., affine bijection), describing reversible evolution in the Schrödinger picture. In the Heisenberg picture $\Phi^*[X] = U^*XU$.

The following result, going back to the famous Wigner theorem, characterizes all reversible evolutions.

Theorem 6.5. Let Φ be an affine bijection of the convex set $\mathfrak{S}(\mathcal{H})$. Then

$$\Phi[S] = USU^*, \quad \text{or} \quad \Phi[S] = US^\top U^*, \tag{6.2}$$

where U is a unitary operator and $S^\top$ is the matrix transposition in some basis. Equivalently, $\Phi[S] = USU^*$, where U is a unitary or antiunitary operator.

An antiunitary operator U is characterized by the following properties:

i. $\|U\psi\| = \|\psi\|, \psi \in \mathcal{H}$;

ii. $U\left(\sum c_j\psi_j\right) = \sum \bar{c}_j U\psi_j$.

Such an operator can always be represented in the form $U = \tilde{U}\Lambda$, where $\tilde{U}$ is a unitary operator and $\Lambda = \Lambda^*$ is the antiunitary operator of the complex conjugation, in a fixed basis. The corresponding evolution of states is given by the matrix transposition in this basis

$$S^\top = \Lambda S \Lambda^*.$$

In physics, transposition and complex conjugation are associated with time inversion.

Proof. We rely on the case of the qubit ($\dim \mathcal{H} = 2$), for which the proof will be given in Section 6.8. Let ψ_1, ψ_2 be some linearly independent vectors in $\mathcal{H}$. Since an affine bijection of a convex set maps extreme points into extreme points, we have

$$\Phi\left[|\psi_j\rangle\langle\psi_j|\right] = |\phi_j\rangle\langle\phi_j|, \quad j = 1, 2. \tag{6.3}$$

Denote by $\mathcal{H}_2$ the two-dimensional subspace generated by ψ_1, ψ_2. Then for any $|\psi\rangle \in \mathcal{H}_2$ we have

$$|\psi\rangle\langle\psi| \leq c\left(|\psi_1\rangle\langle\psi_1| + |\psi_2\rangle\langle\psi_2|\right).$$

On the other hand, similar to (6.3),

$$\Phi[|\psi\rangle\langle\psi|] = |\phi\rangle\langle\phi|.$$

Because of the positivity of Φ

$$|\phi\rangle\langle\phi| \leq c\left(|\phi_1\rangle\langle\phi_1| + |\phi_2\rangle\langle\phi_2|\right),$$

i. e., $|\phi\rangle$ belongs to a two-dimensional subspace that contains the vectors ϕ_1, ϕ_2. By an additional unitary transformation, we can make this subspace coincide with $\mathcal{H}_2$. Hence, we can apply the aforementioned result for the qubit to the restriction of Φ onto the subset of states supported by the two-dimensional subspace $\mathcal{H}_2 \subset \mathcal{H}$ to conclude that this restriction is given by formula (6.2), where U may, however, depend on that subspace.

The proof in the general case is obtained by performing appropriate transformations of the subspace $\mathcal{H}_2$ to show that this dependence reduces to an inessential phase factor. Let $\{e_j; j = 1, \ldots, d\}$ be an orthonormal basis in $\mathcal{H}$. Then

$$\Phi\left[|e_j\rangle\langle e_j|\right] = |h_j\rangle\langle h_j|.$$

By applying the aforementioned result for $\mathcal{H}_2$ generated by the vectors e_j, e_k, we obtain that $\{h_j\}$ is an orthonormal basis. Moreover,

$$\Phi\left[|e_j\rangle\langle e_k|\right] = z_{jk}|h_j\rangle\langle h_k| \quad \text{or} \quad z_{kj}|h_k\rangle\langle h_j|, \tag{6.4}$$

where $|z_{jk}| = 1$. If $\Phi\left[|e_1\rangle\langle e_2|\right] = z_{12}|h_1\rangle\langle h_2|$ but $\Phi\left[|e_1\rangle\langle e_3|\right] = z_{31}|h_3\rangle\langle h_1|$, then

$$\Phi\left[|e_1\rangle\langle e_2 + e_3|\right] = z_{12}|h_1\rangle\langle h_2| + z_{31}|h_3\rangle\langle h_1|$$

is an operator of rank two, which contradicts (6.4). Repeating this argument, we obtain that in relation (6.4) one and the same alternative takes place for all j, k.

Consider the first alternative, when

$$\Phi\left[|e_j\rangle\langle e_k|\right] = z_{jk}|h_j\rangle\langle h_k|.$$

Now, putting $\psi = e_1 + \cdots + e_d$, we obtain that the operator

$$\Phi[|\psi\rangle\langle\psi|] = \sum_{j,k=1}^{d} z_{jk}|h_j\rangle\langle h_k|$$

has rank one, hence $z_{jk} = a_j\bar{a}_k$, where $|a_j| = 1$ for all j. Denoting by U the unitary operator for which $U|e_j\rangle = a_j|h_j\rangle$, we obtain $\Phi[S] = USU^*$. Similarly, in the case of the second alternative we obtain $\Phi[S] = US^\top U^*$, where $^\top$ is a transposition in the basis $\{e_j\}$. □

10.6.2 6.2 Completely Positive Maps

Generalizing the previous considerations, we shall consider a linear map Φ, acting from $\mathfrak{T}(\mathcal{H}_A)$ to $\mathfrak{T}(\mathcal{H}_B)$, where $\mathcal{H}_A, \mathcal{H}_B$ are, in general, different spaces. In this case, the dual map Φ^* acts from $\mathfrak{B}(\mathcal{H}_B)$ to $\mathfrak{B}(\mathcal{H}_A)$.

Definition 6.6. The map $\Phi^*(\Phi)$ is called completely positive (CP) if one of the two equivalent conditions holds:

i. $\Phi^* \otimes \mathrm{Id}_n$ is positive for all $n = 1, 2, \ldots$, where Id_n denotes the identity map of the algebra of all $n \times n$-matrices $\mathfrak{B}(\mathbb{C}^n)$;

ii. for arbitrary finite sets of vectors $\{\varphi_j\} \subset \mathcal{H}_B, \{\psi_j\} \subset \mathcal{H}_A$ the following inequality holds:

$$\sum_{j,k} \langle\varphi_j \mid \Phi\left[|\psi_j\rangle\langle\psi_k|\right]\varphi_k\rangle \geq 0.$$

To see the equivalence of the above conditions, let us introduce the spaces $\mathcal{H}_i^{(n)}$, which are direct orthogonal sums of n copies of $\mathcal{H}_i, i = A, B$, where n is the size of given sets of vectors $\{\varphi_j\}, \{\psi_j\}$. As we have seen in Section 3.1.1, $\mathcal{H}_i^{(n)}$ can be identified with $\mathcal{H}_i \otimes \mathbb{C}^n$. In this case, denoting

$$\varphi^{(n)} = \sum_{j=1}^{n} \oplus \varphi_j, \quad \psi^{(n)} = \sum_{j=1}^{n} \oplus \psi_j$$

we have

$$\sum_{j,k} \langle \varphi_j \mid \Phi\left[|\psi_j\rangle \langle \psi_k|\right] \varphi_k \rangle = \left\langle \psi^{(n)} \right| \left(\Phi^* \otimes \mathrm{Id}_n\right) \left[\left|\varphi^{(n)}\right\rangle \left\langle \varphi^{(n)}\right|\right] \left|\psi^{(n)}\right\rangle,$$

from which the implication i $\Rightarrow$ ii follows. Conversely, any positive operator $X^{(n)}$ in $\mathcal{H}_B^{(n)} \simeq \mathcal{H}_B \otimes \mathbb{C}^n$ can be represented as a sum of positive rank one operators of the form $\left|\varphi^{(n)}\right\rangle \left\langle \varphi^{(n)}\right|$. Hence, condition ii, which means positivity of $\Phi^* \otimes \mathrm{Id}_n$ on such operators, implies i.

Exercise 6.7 Prove the following statement: if the map Φ^* satisfies condition i for $n = 2$, the Kadison inequality holds,

$$\Phi^*[X]^* \Phi^*[X] \leq \|\Phi^*[I]\| \, \Phi^*\left[X^* X\right] \tag{6.5}$$

for arbitrary operator X.

Exercise 6.8 Show that for the transposition map $S \to S^\top$ in some basis, condition i already breaks for $n = 2$. Hint: consider condition ii where $\{\psi_j\}$ is the orthonormal basis in which the transposition is made.

The notion of complete positivity was introduced by Stinespring [226], who proved an important result, generalizing Naimark's theorem. We shall give the proof of Stinespring's dilation theorem in the special finite-dimensional case.

Theorem 6.9. For every completely positive map $\Phi^* : \mathfrak{B}(\mathcal{H}_B) \to \mathfrak{B}(\mathcal{H}_A)$ there exist a Hilbert space $\mathcal{H}_E$ and an operator $V : \mathcal{H}_A \to \mathcal{H}_B \otimes \mathcal{H}_E$ such that

$$\Phi^*[X] = V^* (X \otimes I_E) V, \quad X \in \mathfrak{B}(\mathcal{H}_B). \tag{6.6}$$

Dually,

$$\Phi[S] = \mathrm{Tr}_E \, V S V^*, \quad S \in \mathfrak{T}(\mathcal{H}_A).$$

The map Φ^* is unital, i.e., $\Phi^*[I_B] = I_A$ (the map Φ preserves the trace) if and only if the operator V is isometric.

In relation (6.7) and in what follows we use the abbreviated notation for the partial trace: $\mathrm{Tr}_E = \mathrm{Tr}_{\mathcal{H}_E}$, etc.

Proof. Consider the algebraic tensor product $\mathcal{L} = \mathcal{H}_A \otimes \mathfrak{B}(\mathcal{H}_B)$, generated by the elements $\Psi = \psi \otimes X, \psi \in \mathcal{H}_A, X \in \mathfrak{B}(\mathcal{H}_B)$. Let us introduce a pre-inner product in $\mathcal{L}$ with the corresponding square of the norm

$$\left\| \sum_j \psi_j \otimes X_j \right\|^2 = \sum_{j,k} \langle \psi_j | \, \Phi^*\left[X_j^* X_k\right] |\psi_k\rangle$$

This quantity is nonnegative because the block operator $X^{(n)} = \left[X_j^* X_k\right]_{j,k=\overline{1,n}}$ in $\mathcal{H}_B^{(n)}$ is positive and the map Φ is CP . Taking the quotient with respect to the subspace $\mathcal{L}_0$ of zero norm, we obtain the Hilbert space $\mathcal{K} = \mathcal{L}/\mathcal{L}_0$. Define V and π by the relations $V\psi = \psi \otimes I$ and $\pi[Y]\Psi = \pi[Y](\psi \otimes X) = \psi \otimes YX$. It is easy to check that these definitions agree with

taking the quotient. Then π is a *-homomorphism of the algebra $\mathfrak{B}(\mathcal{H}_B)$ into $\mathfrak{B}(\mathcal{K})$, i. e., a linear map that preserves the algebraic operations and the involution, i.e.,

$$\pi[XY] = \pi[X]\pi[Y], \pi[X^*] = \pi[X]^*.$$

The map π is unital. Moreover,

$$\langle\varphi|\Phi^*[X]|\psi\rangle = \langle\varphi\otimes I \mid \psi\otimes X\rangle = \langle\varphi|V^*\pi[X]V|\psi\rangle, \quad X\in\mathfrak{B}(\mathcal{H}_B),$$

that is,

$$\Phi^*[X] = V^*\pi[X]V. \tag{6.8}$$

However, by Lemma 6.10 proved below any *-homomorphism of the algebra $\mathfrak{B}(\mathcal{H}_B)$ is unitary equivalent to the ampliation $\pi[X] = X\otimes I_E$, where I_E is the unit
operator in a Hilbert space $\mathcal{H}_E$, i. e., we can take $\mathcal{K} = \mathcal{H}_B\otimes\mathcal{H}_E$, and the Stinespring representation (6.8) takes the form (6.6).

The dual representation (6.7) follows from (6.6) and from the definition of the dual map (6.1). □

In this construction, the dimensionality of the space $\mathcal{H}_E$ satisfies

$$\dim\mathcal{H}_E \le d_A d_B, \tag{6.9}$$

where $d_A = \dim\mathcal{H}_A, d_B = \dim\mathcal{H}_B$. Indeed, $\dim\mathcal{H}_E = \dim\mathcal{K}/d_B \le \dim\mathcal{L}/d_B$ and $\dim\mathcal{L} = d_A d_B^2$. However, there is no a priori restriction and any map of the form (6.6) is completely positive as concatenation of ampliation $X\to X\otimes I$ and conjugation $X\to V^*XV$, the complete positivity of which follows from Definition 6.6.

Lemma 6.10. Let π be a unital *-homomorphism of the algebra $\mathfrak{B}(\mathcal{H})$ into the algebra $\mathfrak{B}(\mathcal{K})$. Then there exist a Hilbert space $\mathcal{H}_E$ and an isometric map U of the space $\mathcal{K}$ onto $\mathcal{H}\otimes\mathcal{H}_E$ such that

$$\pi[X] = U^*(X\otimes I_E)U, \quad X\in\mathfrak{B}(\mathcal{H}). \tag{6.10}$$

Proof. Choose an orthonormal basis $\{e_j; j = 1,\dots,d\}$ in $\mathcal{H}$, and consider the matrix units $|e_j\rangle\langle e_k|$ and their images

$$V_{jk} = \pi[|e_j\rangle\langle e_k|]\in\mathfrak{B}(\mathcal{K}).$$

Since π is *-homomorphism, the operators V_{jk} satisfy the same algebraic relations as the matrix units

$$V_{jk}V_{lm} = \delta_{kl}V_{jm}, \quad V_{jk}^* = V_{kj}. \tag{6.11}$$

Consider the subspace $\mathcal{H}_E = V_{11}\mathcal{K}\subseteq\mathcal{K}$ and define $U:\mathcal{K}\to\mathcal{H}\otimes\mathcal{H}_E$ by the relation

$$U\psi = \sum_j |e_j\rangle\otimes V_{1j}\psi$$

(note that $V_{1j}\psi = V_{11}V_{1j}\psi\in\mathcal{H}_E$). Then

$$\langle U\psi_1 \mid (X\otimes I_E)U\psi_2\rangle = \sum_{j,k}\langle e_j \mid Xe_k\rangle\langle V_{1j}\psi_1 \mid V_{1k}\psi_2\rangle. \tag{6.12}$$

By (6.11)

$$\langle V_{1j}\psi_1 \mid V_{1k}\psi_2\rangle = \langle\psi_1 \mid V_{jk}\psi_2\rangle = \langle\psi_1 \mid \pi[|e_j\rangle\langle e_k|]\psi_2\rangle.$$

Therefore, the right-hand side of (6.12) is equal to

$$\sum_{j,k} \langle e_j \mid Xe_k \rangle \langle \psi_1 \mid \pi \left[|e_j\rangle \langle e_k| \right] \psi_2 \rangle = \langle \psi_1 \mid \pi[X]\psi_2 \rangle .$$

This implies (6.10). Taking $X = I$ and using the unitality of π, we obtain that U is an isometric map of $\mathcal{K}$ into $\mathcal{H} \otimes \mathcal{H}_E$.

Exercise 6.11 Show that the image of $\mathcal{K}$ under the map U coincides with $\mathcal{H} \otimes \mathcal{H}_E$. □

The Stinespring representation (6.6) for a given CP map is not unique. Representations for which $\dim \mathcal{H}_E$ is minimal are called minimal. In this case, the number $\dim \mathcal{H}_E$ is called the rank of the map Φ.

Theorem 6.12. Let

$$\Phi^*[X] = \tilde{V}^* \left(X \otimes \tilde{I}_E \right) \tilde{V}, \quad X \in \mathfrak{B}\left(\mathcal{H}_B\right) \tag{6.13}$$

be another Stinespring representation, where $\tilde{I}_E$ is the unit operator in $\tilde{\mathcal{H}}_E$. Then there exists a partial isometry W_E from $\mathcal{H}_E$ to $\tilde{\mathcal{H}}_E$, such that

$$\left(I_B \otimes W_E\right) V = \tilde{V}; \tag{6.14}$$

if both representations are minimal, then W_E isometrically maps $\mathcal{H}_E$ onto $\tilde{\mathcal{H}}_E$.

Proof. For the representation (6.6), consider the subspace

$$\mathcal{M} = \operatorname{lin} \left\{ \left(X \otimes I_E\right) V\psi : \psi \in \mathcal{H}_A, X \in \mathfrak{B}\left(\mathcal{H}_B\right) \right\} \subset \mathcal{K} = \mathcal{H}_B \otimes \mathcal{H}_E.$$

It is invariant under multiplication by operators of the form $Y \otimes I_E$. Hence, it has the form $\mathcal{M} = \mathcal{H}_B \otimes \mathcal{M}_E$, where $\mathcal{M}_E \subseteq \mathcal{H}_E$. For a minimal representation we should have $\mathcal{M}_E = \mathcal{H}_E$, because otherwise there would be a proper subrepresentation.

Consider a similar subspace $\tilde{\mathcal{M}} = \mathcal{H}_B \otimes \tilde{\mathcal{M}}_E$ of the space $\tilde{\mathcal{K}} = \mathcal{H}_B \otimes \tilde{\mathcal{H}}_E$ for the second representation (6.13). Define the operator W from $\mathcal{M}$ to $\tilde{\mathcal{M}}$ by the relation

$$W \left(X \otimes I_E\right) V\psi = \left(X \otimes \tilde{I}_E \right) \tilde{V}\psi. \tag{6.15}$$

Then W is isometric by polarization, since the norms of the vector $\left(X \otimes I_E\right) V\psi$ and of its image under W are both equal to $\langle \psi | \Phi^* \left[X^* X\right] | \psi \rangle$ by (6.6), (6.13).

From (6.15) we obtain, for all $Y \in \mathfrak{B}\left(\mathcal{H}_B\right)$,

$$W \left(YX \otimes I_E\right) V\psi = \left(Y \otimes \tilde{I}_E \right) W \left(X \otimes I_E\right) V\psi$$

and hence

$$W \left(Y \otimes I_E\right) = \left(Y \otimes \tilde{I}_E \right) W \tag{6.16}$$

on $\mathcal{M}$. Extend W to the whole of $\mathcal{K}$ by setting it equal to zero on the orthogonal complement to $\mathcal{M}$. Then (6.16) holds on $\mathcal{K}$. Therefore, $W = I_B \otimes W_E$, where W_E isometrically maps $\mathcal{M}_E$ onto $\tilde{\mathcal{M}}_E$. Relation (6.15) implies (6.14). If the first representation is minimal, W_E is an isometry of $\mathcal{H}_E$ into $\tilde{\mathcal{H}}_E$, and if both representations are minimal, W_E is unitary onto $\tilde{\mathcal{H}}_E$. □

Corollary 6.13. A map Φ^* is completely positive if and only if it can be represented in the form

$$\Phi^*[X] = \sum_{k=1}^{\tilde{d}} V_k^* X V_k, \quad X \in \mathfrak{B}\left(\mathcal{H}_B\right), \tag{6.17}$$

where $V_k : \mathcal{H}_A \to \mathcal{H}_B$, or dually

$$\Phi[S] = \sum_{k=1}^{\tilde{d}} V_k S V_k^*, \quad S \in \mathfrak{T}(\mathcal{H}_A). \tag{6.18}$$

The map Φ^* is unital (Φ is trace-preserving) if and only if

$$\sum_{k=1}^{\tilde{d}} V_k^* V_k = I. \tag{6.19}$$

This representation is often called the Kraus representation.

Proof. By writing $I_E = \sum_{k=1}^{\tilde{d}} |e_k^0\rangle \langle e_k^0|$, where $\{e_k^0\}$ is an orthonormal basis in $\mathcal{H}_E$ and $\tilde{d} = \dim \mathcal{H}_E$, consider the operators V_k acting from $\mathcal{H}_A$ to $\mathcal{H}_B$, defined by

$$\langle \phi | V_k | \psi \rangle = \left\langle \phi \otimes e_k^0 \right| V |\psi\rangle, \quad \phi \in \mathcal{H}_B, \psi \in \mathcal{H}_A. \tag{6.20}$$

For the operators defined like in (6.20) we shall sometimes use the notation $V_k = \langle e_k^0 | V$. The representation (6.17) then follows from formula (6.6). □

Given a representation (6.17) or (6.18), we can always restore the Stinespring representation by letting $\mathcal{H}_E = \mathbb{C}^{\tilde{d}}$ and

$$V|\psi\rangle = \sum_{k=1}^{\tilde{d}} V_k |\psi\rangle \otimes \left| e_k^0 \right\rangle.$$

Not surprisingly, the Kraus representation of a given completely positive map is not unique. Representations with a minimal number of components come from the minimal Stinespring representations and are also called minimal.

Exercise 6.14 Prove the following statement: the Kraus representation is minimal if and only if the operators $\{V_k\}$ are linearly independent. Hint: from (6.20)

$$\langle \phi | X \left(\sum_{k=1}^{\tilde{d}} c_k V_k \right) |\psi\rangle = \left\langle \phi \otimes \left(\sum_{k=1}^{\tilde{d}} \bar{c}_k e_k^0 \right) \right| (X \otimes I_E) V |\psi\rangle,$$

for all $\phi \in \mathcal{H}_B, \psi \in \mathcal{H}_A, X \in \mathfrak{B}(\mathcal{H}_B)$. Hence, $\sum_{k=1}^{\tilde{d}} c_k V_k = 0$ is equivalent to $\sum_{k=1}^{\tilde{d}} \bar{c}_k e_k^0 \perp \mathcal{M}_E$.

Exercise 6.15 Basing on Theorem 6.12, show that for any two Kraus representations of the same completely positive map, with the operators $V_j, \tilde{V}_k$, there exists a rectangular, partially isometric matrix $[u_{kj}]$, such that $\tilde{V}_k = \sum_j u_{kj} V_j$. If both representations are minimal, the matrix is unitary.

Exercise 6.16 Let $M = \{M_x\}$ be an observable. Show that if

$$M_x = V^* E_x V = \tilde{V}^* \tilde{E}_x \tilde{V} \tag{6.21}$$

are two Naimark dilations of M in $\mathcal{K}, \tilde{\mathcal{K}}$, then there exists a partial isometry $W : \mathcal{K} \to \tilde{\mathcal{K}}$, such that

$$WV = \tilde{V}, \quad W E_x = \tilde{E}_x W.$$

If the dilations are minimal in the sense of the dimensionality of $\mathcal{K}, \tilde{\mathcal{K}}$, then W is isometry of $\mathcal{K}$ onto $\tilde{\mathcal{K}}$.

The set of all CP maps that satisfy the normalization condition (6.19) is apparently convex. Extreme points of this set are given by the following Proposition.

Proposition 6.17 (Choi [46]). The unital CP map Φ^* is extreme if and only if it has a representation (6.17) where the system $\left\{V_j^* V_k\right\}$ is linearly independent.

Proof. Let Φ^* be extreme and let (6.17) be its minimal representation. Let $\sum_{jk} y_{jk} V_j^* V_k = 0$ and denote $Y = \sum_{jk} y_{jk} \left|e_j^0\right\rangle \left\langle e_k^0\right|$. Without loss of generality, we can assume that $Y = Y^*$ and $\|Y\| \leq 1$. Define

$$\Phi_{\pm}^*[X] = V^* \left(X \otimes \left(I_B \pm Y\right)\right) V = \sum_{jk} \left(\delta_{jk} \pm y_{jk}\right) V_j^* X V_k.$$

Then $\Phi_{\pm}^*$ are completely positive maps and $\Phi_{\pm}^*\left[I_B\right] = I_A$ by the assumption. Since Φ^* is extreme, one has $\Phi^* = \Phi_{\pm}^*$, implying $V^*(X \otimes Y)V = 0$ for all X, Y. It follows that

$$\left\langle\psi_2\right| V^* \left(X_2^* \otimes I_E\right) \left(I_B \otimes Y\right) \left(X_1 \otimes I_E\right) V \left|\psi_1\right\rangle \equiv 0.$$

Hence, the bilinear form of the operator $I_B \otimes Y$ vanishes on $\mathcal{M}$ and hence $Y = 0$, by the minimality of the representation. Thus, $y_{jk} \equiv 0$, i. e., the system $\left\{V_j^* V_k\right\}$ is linearly independent.

Conversely, let the system $\left\{V_j^* V_k\right\}$ be linearly independent. Let $\Phi^* = \frac{1}{2}\left(\Phi_1^* + \Phi_2^*\right)$, where Φ_j^* are unital CP maps. In this case, the Kraus operators for Φ_1^*, Φ_2^* are also Kraus operators for some representation of Φ^*, and hence are linearly expressible through $\{V_k\}$, by Exercise 6.15, so that $\Phi_1^*[X] = \sum_{jk} z_{jk} V_j^* X V_k$. Since $\Phi_1^*\left[I_B\right] = I_A$, we have

$$\sum_{jk} z_{jk} V_j^* V_k = \sum_{jk} \delta_{jk} V_j^* V_k.$$

Hence, $z_{jk} = \delta_{jk}$ by linear independence. Therefore, $\Phi_1^* = \Phi^*$ and thus Φ^* is extreme.

By Exercise 1.5, the dimensionality of $\mathfrak{B}\left(\mathcal{H}_A\right)$ is d_A^2. Hence, the rank $\tilde{d}$ of an extreme map should satisfy $\tilde{d}^2 \leq d_A^2$, i. e., $\tilde{d} \leq d_A$ as compared to $\tilde{d} \leq d_A d_B$ (see (6.9)) for an arbitrary map.

10.6.3 6.3 Definition of the Channel

Let us provide a physical interpretation of the property of complete positivity, via the picture of the (irreversible) evolution of an open system interacting with the environment. Let $\mathcal{H}$ be the Hilbert space of the system, $\mathcal{H}_E$ the Hilbert space of its environment, and S_E the initial state of the environment. Assume that the system interacts with the environment via a unitary operator U. The evolution of the system is then given by the formula

$$\Phi[S] = \operatorname{Tr}_E U \left(S \otimes S_E\right) U^*. \tag{6.22}$$

Theorem 6.18. Every linear trace-preserving completely positive map, with $\mathcal{H}_A = \mathcal{H}_B = \mathcal{H}$, can be extended to the evolution of an open system interacting with an environment so that relation (6.22) holds.

Proof. Consider the space $\mathcal{H}_E$ of $\tilde{d}$-dimensional vectors, where $\tilde{d}$ is the number of components in the Kraus representation of Φ. In this case, $\mathcal{H} \otimes \mathcal{H}_E$ can be considered as the direct sum of $\tilde{d}$ copies of $\mathcal{H}$, consisting of column vectors $\left[\psi_1, \ldots, \psi_{\tilde{d}}\right]^\top$, $\psi_j \in \mathcal{H}$, while operators in this space are the block matrices $\left[X_{jk}\right]_{j,k=1,\ldots,\tilde{d}}$, $X_{jk} \in \mathfrak{B}(\mathcal{H})$. Consider the vector $\left|\psi_E\right\rangle = [1, 0, \ldots, 0]^\top$. Then

$$S \otimes \left|\psi_E\right\rangle \left\langle\psi_E\right| = \begin{bmatrix} S & \ldots & 0 \\ \ldots & \ldots & \ldots \\ 0 & \ldots & 0 \end{bmatrix}.$$

Introduce the operator

$$U = \begin{bmatrix} V_1 & \dots & \dots \\ \dots & \dots & \dots \\ V_{\tilde{d}} & \dots & \dots \end{bmatrix}, \tag{6.23}$$

where the first column consists of $V_1, \dots, V_{\tilde{d}}$ and the rest of the columns are chosen to complement it to a unitary operator, which is possible due to (6.19). Now,

$$U\left(S \otimes |\psi_E\rangle \langle\psi_E|\right) U^* = \left[V_j S V_k^*\right]_{j,k=1,\dots,\tilde{d}}$$

The partial trace in $\mathcal{H} \otimes \mathcal{H}_E$, with respect to $\mathcal{H}_E$, is just the sum of the diagonal elements of this matrix, which coincides with the Kraus representation for the map Φ. $\square$

The preceding discussion motivates the following definition. We denote by A the input system of the channel and by B the output system.

Definition 6.19. A channel in the Schrödinger picture is a linear, completely positive trace-preserving map $\Phi : \mathfrak{T}(\mathcal{H}_A) \to \mathfrak{T}(\mathcal{H}_B)$. Dually, a channel in the Heisenberg picture is a linear, completely positive unital map $\Phi^* : \mathfrak{B}(\mathcal{H}_B) \to \mathfrak{B}(\mathcal{H}_A)$.

The channel Φ is called bistochastic if it maps the chaotic state in $\mathcal{H}_A$ into the chaotic state in $\mathcal{H}_B, \Phi[I_A/d_A] = I_B/d_B$. If the input and output systems have equal dimensionalities ($d_A = d_B$), the bistochastic channel Φ is unital. In this case, Φ^* is also trace-preserving, so that both Φ and Φ^* are channels in both the Schrödinger and the Heisenberg picture.

Let $S = S_A$ be an input state of a channel Φ. Denote by $\mathcal{L} = \operatorname{supp} S$ the support of the density operator S. Consider a purification $S_{AR} = |\psi_{AR}\rangle \langle\psi_{AR}|$ of the state S_A, where R labels the purifying system and

$$|\psi_{AR}\rangle = \sum_j \sqrt{\lambda_j}\, |e_j\rangle \otimes |h_j\rangle, \quad \lambda_j > 0, e_j \in \mathcal{L},$$

cf. (3.9). Let Id_R be the identity map in $\mathfrak{T}(\mathcal{H}_R)$. Then the tensor product $\Phi \otimes \mathrm{Id}_R$ describes a channel from AR to BR, transforming A into B and leaving R intact. Therefore, R is called the reference system. The output state of this channel is

$$(\Phi \otimes \mathrm{Id}_R)[S_{AR}] = S_{BR}. \tag{6.24}$$

Since the state S_{AR} is, in general, entangled, this operation is sometimes called "entanglement transmission." Note that by the trace preservation property of Φ, the state S_{BR} has the same partial state S_R as the input state S_{AR}. Since S_R is a copy of the state S_A, the state S_{BR} can be considered a quantum substitute of the joint distribution of the input A and the output B of the channel Φ.

Proposition 6.20. The state S_{BR} uniquely determines the restriction $\Phi_{\mathcal{L}}$ of the channel Φ to the states S with $\operatorname{supp} S \subset \mathcal{L}$. In particular, if S_A is nondegenerate, S_{BR} uniquely determines the channel Φ.

Proof. One has

$$(\Phi \otimes \mathrm{Id}_R)[S_{AR}] = \sum_{j,k} \sqrt{\lambda_j}\sqrt{\lambda_k}\, \Phi\left[|e_j\rangle \langle e_k|\right] \otimes |h_j\rangle \langle h_k|. \tag{6.25}$$

The collection of operators $\Phi[|e_j\rangle \langle e_k|]$ uniquely determines $\Phi_{\mathcal{L}}$. Hence, the statement follows. $\square$

In particular, taking the maximally entangled state

$$S_{AR} = \frac{1}{d} \sum_{j,k} |e_j\rangle \langle e_k| \otimes |h_j\rangle \langle h_k|,$$

we obtain from (6.25), for arbitrary state S,

$$\Phi[S] = d \operatorname{Tr}_R S_{BR} \left(I_B \otimes S_R^\top \right), \tag{6.26}$$

where $S_R^\top = \sum_{j,k} \langle e_k | S | e_j \rangle | h_j \rangle \langle h_k |$ and the state S_{BR} satisfies the characteristic condition $\operatorname{Tr}_B S_{BR} = \bar{S}_R = I_R/d$. This one-to-one correspondence between channels and states is called the Choi-Jamiołkowski correspondence.

10.6.4 6.4 Entanglement-Breaking and PPT Channels

In quantum information theory one often has to deal with both quantum and classical information. A usual device is to embed the classical system into a quantum system, as in Section 2.1.1, by representing classical states and observables on the phase space Ω as diagonal operators in the artificial Hilbert space $\mathcal{H}$ spanned by the orthonormal basis $\{|\omega\rangle; \omega \in \Omega\}$.
i. Any classical-quantum (c-q) channel $x \to S_x$ describing an encoding of the classical input x into the quantum state S_x, as considered in Chapter 5, can then be extended to the quantum channel,

$$\Phi[S] = \sum_x \langle e_x | S | e_x \rangle S_x, \quad S \in \mathfrak{S}(\mathcal{H}_A),$$

where $\{e_x\}$ is an orthonormal basis in $\mathcal{H}_A$.
ii. The quantum-classical ($\mathrm{q}-\mathrm{c}$) channel corresponding to the measurement of observable $M = \{M_y\}$ in $\mathcal{H}_A$ (see Section 6.5), which produces the probability distribution from a quantum state, gives rise to the quantum channel

$$\Phi[S] = \sum_y |e_y\rangle \langle e_y| \operatorname{Tr} S M_y, \quad S \in \mathfrak{S}(\mathcal{H}_A),$$

where $\{e_y\}$ is an orthonormal basis in $\mathcal{H}_B$. The dual channel acts as

$$\Phi^*[X] = \sum_y \langle e_y | X | e_y \rangle M_y. \tag{6.27}$$

The Stinespring representation (6.6) in this case provides Naimark's dilation for the observable M. By taking $X = |e_y\rangle \langle e_y|$, we obtain

$$M_y = V^* (|e_y\rangle \langle e_y| \otimes I_E) V,$$

where $E = \{|e_y\rangle \langle e_y| \otimes I_E\}$ is the sharp observable.
iii. Taking a composition of $\mathrm{q}-\mathrm{c}$ and $\mathrm{c}-\mathrm{q}$ channels with the same orthonormal basis $\{e_j\}$, we obtain the q-c-q channel

$$\Phi[S] = \sum_j S_j \operatorname{Tr} S M_j \tag{6.28}$$

of which i and ii are particular cases. Such channels have a classical system between the input and the output (represented by symbol j).

Definition 6.21. Channel Φ from A to B is entanglement-breaking if for an arbitrary input state S_{AR} of the channel $\Phi \otimes \mathrm{Id}$, its output state S_{BR} is separable (Definition 3.13), i. e., a mixture of product states

$$S_{BR} = \sum_j p_j S_B^j \otimes S_R^j \tag{6.29}$$

where $\{p_j\}$ is a probability distribution.

The following characterization is due to M. Horodecki, Shor, and Ruskai [142].

Proposition 6.22. The following properties are equivalent:

i. channel Φ is entanglement-breaking;

ii. the state S_{BR} in the Choi-Jamiotkowski representation (6.26) is separable;

iii. Φ is $q-c-q$ channel (6.28).

Proof.

i. $\Rightarrow$ ii. This is trivial.

ii. $\Rightarrow$ iii. Taking for S_{AR} the maximally entangled state, and using relations (6.29) and (6.26), we obtain the representation (6.28), in which $S_j = S_B^j, M_j = dp_j \left(S_R^j\right)^\top$.

iii. $\Rightarrow$ i. For a channel (6.28) and any input state S_{AR} of the channel $\Phi \otimes \mathrm{Id}_R$, relation (6.29) holds, with $S_B^j = S_j, p_j S_R^j = \mathrm{Tr}_A\, S_{AR}\,(M_j \otimes I_R)$. $\square$

Example 6.23. An important extreme case of a c – q channel is the completely depolarizing channel, describing the irreversible evolution to some final state S_f, i.e.,

$$\Phi[S] = S_f \cdot \mathrm{Tr}\, S, \quad S \in \mathfrak{T}(\mathcal{H}). \tag{6.30}$$

Exercise 6.24 Prove complete positivity and find a Kraus representation in the examples above.

Definition 6.25. Channel Φ from A to B is PPT if, for an arbitrary input state S_{AR} of the channel $\Phi\otimes$ Id, its output state S_{BR} has a positive partial transpose in the space $\mathcal{H}_R$ (see the end of Section 3.1.3).

Apparently, every entanglement-breaking channel is PPT (but not vice versa, see Horodeckis' paper [139]; a PPT channel which is not entanglement-breaking is called entanglement-binding). If the channel Φ is given by the Kraus decomposition (6.18), the channel $\Phi^\top$ is defined by the relation

$$\Phi^\top[S] = \sum_k V_k^{*\top} S V_k^\top$$

assuming some bases are fixed in the input and output spaces of the channel. Taking into account that $S_{AR}^\top = S_{AR}$, we obtain from (6.24), for the transposition in the basis $\{e_j \otimes h_k\}$,

$$\left(\Phi^\top \otimes \mathrm{Id}_R\right)[S_{AR}] = S_{BR}^\top.$$

It follows that the channels Φ and $\Phi^\top$ are simultaneously PPT or not PPT.

Exercise 6.26 Prove the relation

$$\Phi \circ T_A = T_B \circ \Phi^\top \tag{6.31}$$

where T_A, T_B denote transpositions in the corresponding spaces.

Proposition 6.27. The following conditions are equivalent:

i. the channel Φ is PPT;

ii. the state S_{BR} in the Choi-Jamiotkowski representation (6.26) has a positive partial transpose;

iii. $\Phi \circ T_A$ or $T_B \circ \Phi$ is a channel.

Proof. Again, i $\Rightarrow$ ii is trivial.

ii. $\Rightarrow$ iii. Taking for S_{AR} the maximally entangled state and using the relation (6.26), we obtain

$$(\Phi \circ T_A)[S] = d\,\mathrm{Tr}_R\, S_{BR}\,(I_B \otimes S_R) = d\,\mathrm{Tr}_R\, S_{BR}^{\top_R}\left(I_B \otimes S_R^\top\right)$$

which is a channel, because $S_{BR}^{\top_R} \geq 0$. By relation (6.31) and the remark preceding it, this is equivalent to $T_B \circ \Phi$ being a channel.
iii. $\Rightarrow$ i. Let $T_B \circ \Phi$ be a channel. In this case, for any input state S_{AR} of the channel $\Phi \otimes \mathrm{Id}_R$ we have

$$(\Phi \otimes \mathrm{Id}_R [S_{AR}])^{\top_R} = (T_B \circ \Phi \otimes \mathrm{Id}_R) [S_{AR}]^{\top} \geq 0.$$

10.6.5 6.5 Quantum Measurement Processes

An important example of irreversible evolution is the state change of the system due to a quantum measurement. A complete ideal quantum measurement is associated with an orthonormal basis $|e_x\rangle$, indexed by the measurement outcomes x. It is postulated that the initial state S of the system after such a measurement is transformed into one of the states $|e_x\rangle \langle e_x|$ with probability $\langle e_x| S |e_x\rangle$. Thus, the post-measurement statistical ensemble splits into subensembles corresponding to different measurement outcomes x, and, as a whole, is described by the density operator

$$S' = \sum_x |e_x\rangle \langle e_x| S |e_x\rangle \langle e_x| \tag{6.32}$$

Note that the map $S \to S'$ is a particular case of a q-c channel corresponding to the measurement of an observable $M = \{|e_x\rangle \langle e_x|\}$.

Under an incomplete ideal measurement some outcomes are joined together (coarse-grained), forming the orthogonal resolution of the identity $E = \{E_x\}$,

$$E_x E_{x'} = \delta_{xx'} E_x, \quad \sum_x E_x = I,$$

in other words, a sharp observable in the space $\mathcal{H}$. According to the von NeumannLüders projection postulate, the ideal measurement of the sharp observable E gives an outcome x with the probability

$$p_x = \mathrm{Tr}\, S E_x = \mathrm{Tr}\, E_x S E_x,$$

and the posterior state, i. e., the post-measurement state of the subensemble in which the outcome x has occurred, is

$$S_x = \frac{E_x S E_x}{\mathrm{Tr}\, E_x S E_x}, \quad \text{if } p_x > 0$$

We then have the quantum analog of the Bayes formula for the state of the whole ensemble

$$S' = \sum_x p_x S_x = \sum_x E_x S E_x = \mathcal{E}[S]. \tag{6.33}$$

Note that, as distinct from the classical Bayes formula, the quantum state (6.33) of the whole ensemble after the ideal measurement can be different from the initial state S. Thus, even an ideal quantum measurement does not reduce to a simple reading of the outcome and involves an inevitable interaction, which changes the state of the system. This is a fundamental difference between quantum observables and classical random variables, the observation of which does not change the statistical ensemble and reduces to mere selection of its representatives according to the values of a random variable.

In the Heisenberg picture, the transformation of observables due to an ideal measurement is described by the completely positive map

$$\mathcal{E}^*[X] = \sum_X E_X X E_X = \mathcal{E}[X], \tag{6.34}$$

which can be interpreted as a conditional expectation onto the algebra of operators commuting with all of E_x, characterized by the following properties:

i. $\mathcal{E}^2 = \mathcal{E}$,

ii. $\mathcal{E}[X\mathcal{E}[Y]] = \mathcal{E}[X]\mathcal{E}[Y], X, Y \in \mathfrak{B}(\mathcal{H})$.

An ideal quantum measurement satisfies the repeatability hypothesis: the outcome of the repeated measurement is equal, with probability one, to the outcome of the first measurement (provided no evolution occurred between the two measurements). Most of the real measurement procedures do not fulfill this requirement, and we pass to a mathematical description of nonideal measurements.

Consider the process of indirect measurement, when the system $\mathcal{H}$ in the state S first interacts with a probe system $\mathcal{H}_E$ in the initial state S_E, and next an ideal measurement of a sharp observable $\{E_x^0\}$ is made over the probe system. In this case, according to the above, the probability of an outcome x equals

$$p_x = \operatorname{Tr} U\left(S \otimes S_E\right) U^*\left(I \otimes E_x^0\right),$$

and the posterior state is described by the density operator S_x, such that

$$p_x S_x = \operatorname{Tr}_E U\left(S \otimes S_E\right) U^*\left(I \otimes E_x^0\right) \equiv \Phi_x[S]. \tag{6.35}$$

Thus, the state of the system after the measurement can be written as

$$\Phi[S] = \sum_x p_x S_x = \sum_x \Phi_x[S].$$

The maps Φ_x are completely positive, and their sum Φ is trace-preserving. Any such family $\{\Phi_x\}$ is called an instrument. The instruments describe the statistics and posterior states of nonideal measurements, which in general need not satisfy the repeatability hypothesis.

Note that

$$p_x = \operatorname{Tr} S M_x, \qquad \text{where } M_x = \Phi_x^*[I]$$

is the resolution of the identity describing the observable associated with the instrument and the indirect measurement. Conversely, given an observable $M = \{M_x\}$, one can construct a (nonunique) instrument and indirect measurement with which it is associated. Consider a decomposition $M_x = V_x^* V_x$ and the corresponding unitary operator (6.23) in the space $\mathcal{H} \otimes \mathcal{H}_E$. Then the family of completely positive maps

$$\Phi_x[S] = \operatorname{Tr}_E U\left(S \otimes |\psi_E\rangle\langle\psi_E|\right) U^*\left(I \otimes |e_x\rangle\langle e_x|\right), \tag{6.36}$$

where $|e_x\rangle$ is the column vector with 1 in the x th place and zeroes otherwise, so that $|\psi_E\rangle = |e_1\rangle$, forms an instrument. Further,

$$M_x = \operatorname{Tr}_E\left(I \otimes |\psi_E\rangle\langle\psi_E|\right) U^*\left(I \otimes |e_x\rangle\langle e_x|\right) U = \Phi_x^*[I]. \tag{6.37}$$

Thus, the process of indirect measurement of the observable M is realized by the probe system $\mathcal{H}_E$ in the initial state $|\psi_E\rangle\langle\psi_E|$, the unitary operator U in the space $\mathcal{H} \otimes \mathcal{H}_E$, and the sharp observable $\{|e_x\rangle\langle e_x|\}$ in $\mathcal{H}_E$.

Exercise 6.28 For a complete ideal measurement with $M_x = |e_x\rangle\langle e_x|$, set $V_x = M_x$ and construct the unitary operator U by use of formula (6.23) (in this case $\mathcal{H}_E = \mathcal{H}$). Show that

$$U\left(|e_x\rangle \otimes |e_1\rangle\right) = |e_x\rangle \otimes |e_x\rangle\,.$$

For an arbitrary vector $\psi \in \mathcal{H}$

$$U\left(|\psi\rangle \otimes |e_1\rangle\right) = \sum_x \langle e_x \mid \psi\rangle \left(|e_x\rangle \otimes |e_x\rangle\right),$$

thus, an interaction U produces entanglement between the main and the probe systems, which allows us to reduce the ideal measurement in the main system to the measurement of the sharp observable $\{|e_x\rangle\langle e_x|\}$ in the probe system.

10.6.6 6.6 Complementary Channels

Given three quantum systems A, B, C with the spaces $\mathcal{H}_A, \mathcal{H}_B, \mathcal{H}_C$ and a linear operator $V : \mathcal{H}_A \to \mathcal{H}_B \otimes \mathcal{H}_C$, the relations

$$\Phi_B[S] = \mathrm{Tr}_C\, VSV^*, \quad \Phi_C[S] = \mathrm{Tr}_B\, VSV^*, \quad S \in \mathfrak{T}\left(\mathcal{H}_A\right) \tag{6.38}$$

define two CP maps $\Phi_B : \mathfrak{T}\left(\mathcal{H}_A\right) \to \mathfrak{T}\left(\mathcal{H}_B\right), \Phi_C : \mathfrak{T}\left(\mathcal{H}_A\right) \to \mathfrak{T}\left(\mathcal{H}_C\right)$, which will be called mutually complementary (see Fig. 6.1). If V is an isometry, both maps are trace preserving, i. e., channels.

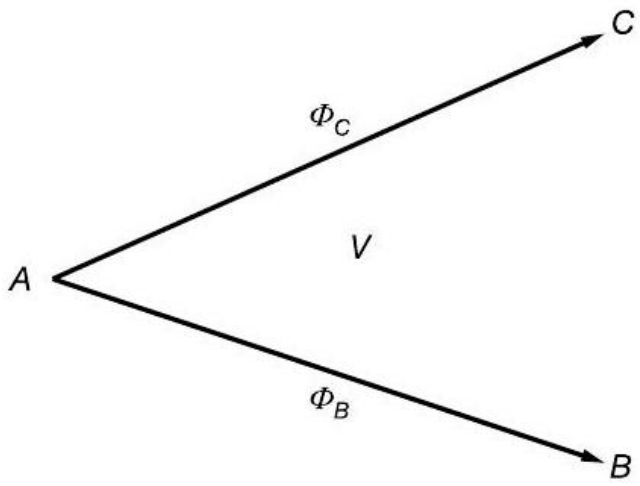

Figure 6.1: Complementary channel.

The Stinespring dilation theorem implies that for a given CP map (channel) a complementary always exists. Moreover, the complementary map is unique in the following sense: for a given CP map Φ_B, any two maps $\Phi_C, \Phi_{C'}$ complementary to Φ_B are isometrically equivalent in the sense that there is a partial isometry $W : \mathcal{H}_C \to \mathcal{H}_{C'}$ such that

$$\Phi_{C'}(S) = W\Phi_C(S)W^*, \quad \Phi_C(S) = W^*\Phi_{C'}(S)W, \tag{6.39}$$

for all S. This is a consequence of Theorem 6.12. If the dimensionalities of $\mathcal{H}_C, \mathcal{H}_{C'}$ are minimal, W is an isometry from $\mathcal{H}_C$ onto $\mathcal{H}_{C'}$. In this case, the complementary map is called minimal.

If $A = B$ is an open quantum system that interacts with the environment $C = E$ in an arbitrary initial state S_E, and Φ_B is the corresponding channel

$$\Phi_B[S] = \mathrm{Tr}_E\, U\left(S \otimes S_E\right) U^*, \tag{6.40}$$

describing the state change of A, the final state of the environment is the output of the channel

$$\Phi_E[S] = \mathrm{Tr}_B\, U\,(S \otimes S_E)\, U^*. \tag{6.41}$$

We will call the channels Φ_B, Φ_E mutually weakly complementary. If the state of the environment is pure, $S_E = |\psi_E\rangle\langle\psi_E|$, then introducing the isometry $V = U\,|\psi_E\rangle : \mathcal{H}_A \to \mathcal{H}_B \otimes \mathcal{H}_E$, which acts as follows:

$$V|\psi\rangle = U\,(|\psi\rangle \otimes |\psi_E\rangle)\,, \quad \psi \in \mathcal{H}_A.$$

We see that Φ_E is the complementary of Φ_B. If S_E is not pure, then by taking its purification $S_{E'}$ in the space $\mathcal{H}_{E'} = \mathcal{H}_E \otimes \mathcal{H}_R$ and letting $U' = U \otimes I_R$, we obtain a representation of the type (6.41), with E replaced by E', where $S_{E'}$ is a pure state. Hence, $\Phi_{E'}$ is the complementary of Φ_B and $\Phi_E[S] = \mathrm{Tr}_R\, \Phi_{E'}[S]$. In contrast to the complementary map, the weak complementary is not unique and depends on the representation (6.40).

To simplify the formulas we shall also use the notation $\tilde{\Phi}$ for the map that is complementary to Φ.

Assume that a CP map $\Phi : \mathfrak{T}(\mathcal{H}_A) \to \mathfrak{T}(\mathcal{H}_B)$ is given by the Kraus representation

$$\Phi[S] = \sum_{k=1}^{\tilde{d}} V_k S V_k^*$$

In this case, a complementary map $\tilde{\Phi} : \tilde{\mathfrak{T}}(\mathcal{H}) \to \mathfrak{M}_{\tilde{d}}$ is given by

$$\tilde{\Phi}[S] = [\mathrm{Tr}\, V_k S V_l^*]_{k,l=1,\tilde{d}} = \sum_{k,l=1}^{\tilde{d}} (\mathrm{Tr}\, S V_l^* V_k)\, |e_k\rangle\langle e_l|\,, \tag{6.42}$$

where $\{e_k\}$ is the canonical basis for the coordinate space $\mathbb{C}^d$, which plays the role of $\mathcal{H}_C$, so that $\tilde{d} = d_C$. This statement follows from the fact that

$$V = \sum_{k=1}^{\tilde{d}} \oplus V_k$$

is a map from $\mathcal{H}_A$ to $\sum_{k=1}^{\tilde{d}} \oplus \mathcal{H}_B \simeq \mathcal{H}_B \otimes \mathcal{H}_C$, for which $\Phi, \tilde{\Phi}$ are given by the partial traces (6.38); see Exercise 3.6.

Exercise 6.29 Check by direct computation that, applying the same procedure to $\tilde{\Phi}$, one obtains the map $\tilde{\tilde{\Phi}}$, which is isometrically equivalent in the sense of (6.39) to Φ.

Exercise 6.30 Prove the following statement: channel Φ is extreme if and only if there exists a complementary channel $\tilde{\Phi}$ such that $\mathrm{Ker}\, \tilde{\Phi}^* = 0$. Hint: prove the relation $\tilde{\Phi}^*[Y] = \sum_{jk} y_{jk} V_j^* V_k$, where $y_{jk} = \langle e_j^0 |\, Y\, |e_k^0\rangle$, and use Proposition 6.17.

Example 6.31. Consider the channel

$$\Phi(S) = S \otimes S_C, \tag{6.43}$$

where S_C is a fixed state in the space $\mathcal{H}_C$. By writing the spectral decomposition

$$S_C = \sum_{k=1}^{\tilde{d}} \lambda_k\, |e_k\rangle\langle e_k|\,,$$

one arrives at the Kraus representation with the operators $V_k = \sqrt{\lambda_k}\,(I \otimes |e_k\rangle) : \mathcal{H}_A \to \mathcal{H}_A \otimes \mathcal{H}_C$. Hence, one obtains from (6.42)

$$\tilde{\Phi}(S) = [\lambda_k \delta_{kl} \operatorname{Tr} S]_{k,l=1,\tilde{d}} \simeq S_C \operatorname{Tr} S,$$

which is a completely depolarizing channel. If S_C is pure, (6.43) is essentially the same as the ideal (identity) channel Id and $\tilde{\Phi}$ is its complementary. Whatever the state S_C, the ideal channel Id is weakly complementary for this channel.

This example illustrates the fact that perfect transmission of quantum information from input A to output B is equivalent to no information going from A to the environment C, and vice versa. Later in this book, we shall see that an approximate version of this complementarity plays a basic role in quantum capacity theorems: the closer channel Φ is to an ideal one, the closer its complement $\tilde{\Phi}$ is to the completely depolarizing one.

The completely depolarizing channel is an instance of entanglement-breaking (q-c-q) channel (see Section 6.4); the construction of the complementary channel can be generalized to the whole of this class. For this, we need the following characterization of entanglement-breaking channels.

Proposition 6.32. Channel $\Phi : \mathfrak{T}(\mathcal{H}_A) \to \mathfrak{T}(\mathcal{H}_B)$ is entanglement-breaking if and only if it has a Kraus representation with rank one operators V_k, i.e.,

$$\Phi[S] = \sum_{k=1}^{\tilde{d}} |\varphi_k\rangle \langle\psi_k| S |\psi_k\rangle \langle\varphi_k|, \tag{6.44}$$

where

$$\sum_{k=1}^{\tilde{d}} |\psi_k\rangle \langle\varphi_k \mid \varphi_k\rangle \langle\psi_k| = I.$$

Proof. Let the channel Φ admit the representation (6.44). In this case, making a renormalization, we can always assume that $\langle\varphi_k \mid \varphi_k\rangle = 1$, in which case $\{|\psi_k\rangle\}$ is an overcomplete system. Denoting $S_k = |\varphi_k\rangle \langle\varphi_k|$ and $M_k = |\psi_k\rangle \langle\psi_k|$, we rewrite (6.44) in the form (6.28). Hence, Φ is entanglement-breaking.

Conversely, by making the spectral decompositions of the operators S_j, M_j in (6.28), we obtain a Kraus representation of the form (6.44). □

The complementary channel $\tilde{\Phi} : \mathfrak{T}(\mathcal{H}_A) \to \mathfrak{T}\left(\mathbb{C}^{\tilde{d}}\right)$ has the form

$$\tilde{\Phi}[S] = [c_{kl} \langle\psi_k| S |\psi_l\rangle]_{k,l=\overline{1,\tilde{d}}} = \sum_{k,l=1}^{\tilde{d}} c_{kl} |e_k\rangle \langle\psi_k| S |\psi_l\rangle \langle e_l|, \tag{6.45}$$

where $c_{kl} = \langle\varphi_l \mid \varphi_k\rangle$. In the special case where the system $\{\psi_k\}_{k=\overline{1,\tilde{d}}}$ is an orthonormal basis in $\mathcal{H}_A$, (6.45) is a channel called dephasing. The reason for this name is that such channels describe the suppression of the off-diagonal elements of the density matrix, due to the fact that $|c_{kl}| \leq 1$. In particular, the completely dephasing channel corresponds to $c_{kl} = \delta_{kl}$. From (6.44) we see that the dephasing channels are complementary to c-q channels. Note that using the Schur (element-wise) product of matrices *, formula (6.45) can in this case be written in the compact form

$$\tilde{\Phi}[S] = C * S,$$

where $C = [c_{kl}]$ and S is the density matrix in the orthonormal basis $\{\psi_k\}$.
For q-c channels, $\{\varphi_k\}_{k=1,\tilde{d}}$ is an orthonormal basis in $\mathcal{H}$, so that $c_{kl} = \delta_{kl}$, and the complementary channel is again a q-c channel.

Noting that an arbitrary positive definite matrix $[c_{kl}]$ can be represented as $c_{kl} = \sum_j \bar{v}_{lj} v_{kj}$, and denoting

$$\tilde{V}_j = \sum_{k=1}^{\tilde{d}} v_{kj} \left|e_k\right\rangle \left\langle\psi_k\right|, \tag{6.46}$$

we have the Kraus representation

$$\tilde{\Phi}[S] = \sum_{j=1}^{d_B} \tilde{V}_j S \tilde{V}_j^* \tag{6.47}$$

for the complementary map. For the dephasing channel, we can take $|e_k\rangle = |\psi_k\rangle$. Hence, one sees from (6.46) that the dephasing maps are characterized by the property of having a Kraus representation with simultaneously diagonalizable (i. e., commuting normal) operators $\tilde{V}_j$.

Definition 6.33. Let $\{p_j\}$ be a finite probability distribution and $\Phi_j : \mathfrak{T}(\mathcal{H}) \to \mathfrak{T}\left(\mathcal{H}'_j\right)$ a collection of channels. Channel $\Phi : \mathfrak{T}(\mathcal{H}) \to \mathfrak{T}\left(\sum_j \oplus \mathcal{H}'_j\right)$ will be called orthogonal convex sum of the channels Φ_j,

$$\Phi = \sum_j \oplus p_j \Phi_j$$

if $\Phi[S] = \sum_j \oplus p_j \Phi_j[S]$ for all $S \in \mathfrak{S}(\mathcal{H})$.

Example 6.34. Quantum erasure channel. Let $p \in [0,1]$. Now, the channel $\Phi : \mathfrak{T}(\mathcal{H}) \to \mathfrak{T}(\mathcal{H} \oplus \mathbb{C})$, defined by the relation

$$\Phi(S) = \begin{bmatrix} (1-p)S & 0 \\ 0 & p \operatorname{Tr} S \end{bmatrix}$$

transmits the input state S with probability $1-p$ and "erases" it with probability p sending the erasure signal. This channel is the orthogonal convex sum of the ideal channel and the completely depolarizing channel (6.30), with a pure final state S_f.

Exercise 6.35 Show that the complementary to the orthogonal convex sum of the channels is the orthogonal convex sum of the complementary channels for the components, i. e.,

$$\widetilde{\sum_j \oplus p_j \Phi_j} = \sum_j \oplus p_j \tilde{\Phi}_j$$

Hint: write the Kraus representation for the orthogonal convex sum, basing on those for the summands, and then use the relation (6.42).

In particular, by using Example 6.31 (with $\tilde{d} = \dim \mathcal{H}_C = 1$), show that the complementary to the erasure channel Φ_p is unitarily equivalent to the erasure channel Φ_{1-p}.

10.6.7 6.7 Covariant Channels

Recall that a projective unitary representation of the group G is a family of unitary operators $\{V_g; g \in G\}$ in a Hilbert space $\mathcal{H}$, satisfying

$$V_g V_h = \lambda(g,h) V_{gh}$$

where $\lambda(g,h)$ is a complex multiplier (of modulus one). If $\lambda(g,h) \equiv 1$, we call it a unitary representation (see, e. g., [171] for more detail).

Let G be a group and $g \to V_g^{(j)}, g \in G$, be two (projective) unitary representations of G in $\mathcal{H}_j, j = A, B$. The channel $\Phi : \mathfrak{T}(\mathcal{H}_A) \to \mathfrak{T}(\mathcal{H}_B)$ is covariant if

$$\Phi\left[V_g^A S\left(V_g^A\right)^*\right] = V_g^B \Phi[S]\left(V_g^B\right)^* \tag{6.48}$$

for all $g \in G$ and S. If the representation V_g^B is irreducible, the channel Φ is bistochastic. Indeed, $V_g^B \Phi\left[I_A\right] = \Phi\left[I_A\right] V_g^B$ (for all g), and irreducibility of V_g^B implies that $\Phi\left[I_A\right]$ is proportional to I_B, with the coefficient obtained by taking the traces.

Definition 6.36. The depolarizing channel in $\mathcal{H}$ is defined by the relation

$$\Phi[S] = (1-p)S + p\frac{I}{d}\operatorname{Tr} S, \quad 0 \leq p \leq \frac{d^2}{d^2-1} \tag{6.49}$$

If $p \leq 1$, this describes a mixture of the ideal channel Id and the completely depolarizing channel which maps an arbitrary state to the chaotic state $\bar{S} = \frac{I}{d}$. For the whole range $0 \leq p \leq \frac{d^2}{d^2-1}$ complete positivity can be demonstrated by the explicit Kraus representation (see (6.54)).

Exercise 6.37 Show that the depolarizing channel can be characterized by the property of unitary covariance, $\Phi\left[USU^*\right] = U\Phi[S]U^*$ for an arbitrary unitary operator U in $\mathcal{H}$.

The depolarizing channel satisfies $\Phi^* = \Phi$ and is thus unital and bistochastic.

Exercise 6.38 Show that the channel complementary to a covariant channel is itself covariant, i.e.,

$$\Phi\left[V_g^A S\left(V_g^A\right)^*\right] = V_g^E \Phi[S]\left(V_g^E\right)^*$$

where $g \to V_g^E$ is a (projective) unitary representation of the group G in $\mathcal{H}_E$. Hint: use the fact that an arbitrary covariant channel has a Kraus representation (6.18), in which operators V_j satisfy the relations

$$V_g^B V_j \left(V_g^A\right)^* = \sum_k d_{jk}(g) V_k$$

where $g \to D(g) = [d_{jk}(g)]$ is a matrix unitary representation of the group G. It follows that the complementary map (6.42) is covariant and the role of the second representation V_g^E is played by $D(g)$.

For future use we introduce here an important general construction, namely, a discrete version of the Weyl operators and canonical commutation relations (CCRs) in a finite-dimensional Hilbert space. Fix an orthonormal basis $\{e_k; k = 1, \ldots, d\}$ in $\mathcal{H}$. The discrete Weyl operators are the unitary operators in $\mathcal{H}$ defined as

$$W_{\alpha\beta} = U^\alpha V^\beta, \quad \alpha, \beta = 0, \ldots, d-1, \tag{6.50}$$

where

$$V\left|e_k\right\rangle = \exp\left(\frac{2\pi i k}{d}\right)\left|e_k\right\rangle, \quad U\left|e_k\right\rangle = \left|e_{k+1(\bmod d)}\right\rangle, \quad k = 0, \ldots, d-1. \tag{6.51}$$

Note that $W_{00} = I$. These operators satisfy the discrete analog of the Weyl-Segal CCR for bosonic systems, which will appear in Chapter 12:

$$\begin{aligned} W_{\alpha\beta} W_{\alpha'\beta'} &= \exp\frac{2\pi i \beta\alpha'}{d} W_{\alpha+\alpha', \beta+\beta'} \\ &= \exp\frac{2\pi i\left(\beta\alpha' - \beta'\alpha\right)}{d} W_{\alpha'\beta'} W_{\alpha\beta}. \end{aligned} \tag{6.52}$$

The first equality expresses the fact that $(\alpha, \beta) \to W_{\alpha\beta}$ is a projective representation of the additive cyclic group $\mathbb{Z}_d \times \mathbb{Z}_d$.

The representation is irreducible: any operator A that commutes with all $W_{\alpha,\beta}$ is a multiple of the unit operator. Indeed, $[A,V]=0$ implies, by (6.51), that $A\left|e_k\right\rangle = a_k\left|e_k\right\rangle$ and $[A,U]=0$ implies $a_k \equiv a$. We then have an important identity: for all states S

$$\sum_{\alpha,\beta=0}^{d-1} W_{\alpha\beta} S W_{\alpha\beta}^* = d(\operatorname{Tr} S) I \tag{6.53}$$

since it follows from (6.52) that the left side commutes with all Weyl operators. The constant on the right is obtained by comparing traces. In fact, the identity (6.53) is a very special case of a general identity, following from orthogonality relations for an arbitrary irreducible representation (see, e. g., Section IV. 2 in [122]).

Exercise 6.39 Prove the Kraus representation for the depolarizing channel (6.49),

$$\Phi[S] = \left(1 - p\frac{d^2-1}{d^2}\right) S + \frac{p}{d^2} \sum_{\alpha+\beta>0} W_{\alpha\beta} S W_{\alpha\beta}^*, \tag{6.54}$$

where all coefficients are nonnegative, provided $0 \leq p \leq \frac{d^2}{d^2-1}$. Hint: substitute the expression for $\operatorname{Tr} S$ from (6.53) into (6.49).

Proposition 6.40. The depolarizing channel is entanglement-breaking for $p \geq \frac{d}{d+1}$.

Proof. To avoid notational confusion with the differential, in this proof we denote the dimensionality as $d_A = \dim \mathcal{H}$. Let Θ be the unit sphere in $\mathcal{H}$ and let $v(d\theta)$ be the uniform distribution on Θ. Thus, $|\theta\rangle \in \Theta$ is a unit vector in $\mathcal{H}$. Now, as we show below,

$$d_A \int_\Theta |\theta\rangle\langle\theta| v(d\theta) = I, \tag{6.55}$$

so that we have a continuous overcomplete system in $\mathcal{H}$. Then as we shall see in Section 11.7, the relation $M(d\theta) = d_A|\theta\rangle\langle\theta|v(d\theta)$ defines an observable in $\mathcal{H}$, with values in Θ, in the sense of Definition 11.29. Its probability distribution in the state S is given by

$$\mu_S^M(d\theta) = d_A\langle\theta|S|\theta\rangle v(d\theta).$$

We prove the statement by using the continuous analog of Proposition 6.32, which will be established later, in Section 11.7.

It is sufficient to prove the statement for $p = \frac{d_A}{d_A+1}$. Then the depolarizing channel for $p > \frac{d_A}{d_A+1}$ can be represented as a mixture of this channel and a completely depolarizing channel $S \to \frac{I}{d_A}\operatorname{Tr} S$, which are both entanglement-breaking. For $p = \frac{d_A}{d_A+1}$, we will prove

$$\Phi[S] \equiv \frac{1}{d_A+1} S + \frac{d_A}{d_A+1}\frac{I}{d_A} = d_A \int_\Theta |\theta\rangle\langle\theta|S|\theta\rangle\langle\theta| v(d\theta) \tag{6.56}$$

for all density operators S, which is a continuous analog of the Kraus representation (6.44), meaning that the channel is entanglement-breaking. We will use Lemma IV.4.1 from [122], according to which, for any continuous function F and a fixed $|\theta'\rangle$,

$$\int_\Theta F\left(|\langle\theta \mid \theta'\rangle|\right) v(d\theta) = -\int_0^1 F(r) d\left(1-r^2\right)^{d_A-1} \tag{6.57}$$

It suffices to establish (6.56) for all $S = |\theta'\rangle\langle\theta'|, \theta' \in \Theta$. Consider the operator

$$\sigma = d_A \int_\Theta |\theta\rangle \langle\theta \mid \theta'\rangle \langle\theta' \mid \theta\rangle \langle\theta| v(d\theta) \tag{6.58}$$

It has unit trace, since

$$\operatorname{Tr}\sigma = d_A \int_\Theta |\langle\theta \mid \theta'\rangle|^2 \, v(d\theta) = -d_A \int_0^1 r^2 d\left(1-r^2\right)^{d_A-1} = 1$$

by (6.57). From this, (6.55) follows by polarization.
Next, σ commutes with all unitaries leaving invariant $|\theta'\rangle$. Hence, it must have the form

$$\sigma = (1-p)\,|\theta'\rangle\,\langle\theta'| + p\frac{I}{d_A}$$

To find p take $\langle\theta'|\,\sigma\,|\theta'\rangle$. We then obtain from (6.58)

$$(1-p) + \frac{p}{d_A} = d_A \int_\Theta |\langle\theta \mid \theta'\rangle|^4 \, v(d\theta) = -d_A \int_0^1 r^4 d\left(1-r^2\right)^{d_A-1}$$

Computing the integral with formula (6.57) we obtain the value $\frac{2}{d_A+1}$, whence $p = \frac{d_A}{d_A+1}$. □

10.6.8 6.8 Qubit Channels

Let us consider channels in the qubit space $\mathcal{H}_2$ which are affine maps of the Bloch ball in $\mathbb{R}^3$, satisfying an additional restriction imposed by complete positivity.

Proposition 6.41. An arbitrary linear, positive, trace-preserving map Φ of the space $\mathfrak{T}(\mathcal{H}_2)$ can be represented in the form

$$\Phi[S] = U_2 \Lambda\left[U_1 S U_1^*\right] U_2^* \tag{6.59}$$

where U_1, U_2 are unitary operators and Λ has the following canonical form, in the basis of Pauli matrices:

$$\Lambda[I] = I + \sum_{y=x,y,z} t_y \sigma_y, \quad \Lambda\left[\sigma_y\right] = \lambda_y \sigma_y, \quad \gamma = x, y, z, \tag{6.60}$$

with λ_y, t_y real.
Proof. The restriction of Φ onto the qubit state space is an affine map, hence it maps the state $S(\vec{a})$, given by (2.8), into the state $S(T\vec{a}+\vec{b})$, where T is a real 3×3-matrix, $\vec{b}$ is a vector in $\mathbb{R}^3$. By using the polar decomposition for T and then the spectral decomposition for $|T|$, we have

$$T = O|T| = O_2 L O_1,$$

where O, O_1, O_2 are orthogonal matrices, $\det O_1 = \det O_2 = 1$, and $L = \operatorname{diag}\left[\lambda_x, \lambda_y, \lambda_z\right]$ is diagonal, with the λ s real but not necessarily nonnegative. Thus,

$$\Phi[S(\vec{a})] = S\left(O_2\left[L\left(O_1\vec{a}\right) + \vec{t}\right]\right), \tag{6.61}$$

where $\vec{t} = O_2^{-1}\vec{b}$.
The matrices O_1, O_2 describe rotations of the Bloch ball in $\mathbb{R}^3$. Let us show that they correspond to reversible evolutions in $\mathcal{H}$, generated by unitary operators U in $\mathcal{H}$ according to formula (6.2). It is sufficient to consider rotation O by an angle φ around the z axis. In this case, a unit vector $\vec{a}$ with the Euler angles θ, ϕ is rotated to $O\vec{a}$, with the angles $\theta, \phi+\varphi$ so that the corresponding state vector (2.9) in $\mathcal{H}$ is transformed into

$$|\psi(O\vec{a})\rangle = \begin{bmatrix} \cos\frac{\theta}{2} e^{-i(\phi+\varphi)/2} \\ \sin\frac{\theta}{2} e^{i(\phi+\varphi)/2} \end{bmatrix} = U|\psi(\vec{a})\rangle, \tag{6.62}$$

where $U = \operatorname{diag}\left[e^{-i\varphi/2}, e^{i\varphi/2}\right]$ is a unitary matrix. Then

$$S(O\vec{a}) = US(\vec{a})U^* \tag{6.63}$$

for all $\vec{a}$.

By using (6.61) we obtain the required statement (6.59). □

Exercise 6.42 Show that a rotation of the Bloch ball around the axis $\vec{a}$ by the angle φ is implemented by the unitary operator

$$U = \exp\left[-\frac{i\varphi}{2}\sigma(\vec{a})\right] = \cos\frac{\varphi}{2}I - i\sin\frac{\varphi}{2}\sigma(\vec{a}).$$

Let us focus our attention on the maps of the form (6.60). Of course, complete positivity imposes nontrivial restrictions on the parameters λ_y, t_y [197]. Especially simple is the case where $t_y \equiv 0$, when the map Φ, and hence Λ, is unital. In this case Λ is a contraction of the Bloch ball along the x, y, z axes, with coefficients $|\lambda_x|, |\lambda_y|, |\lambda_z|$, combined with reflections in case some of the numbers λ_y are negative (for example, $\lambda_y < 0$ implies reflection with respect to the xz plane). Transposition of the density matrix $S(\vec{a})$, which is not completely positive, corresponds to Λ with the parameters $\lambda_x = 1$, $\lambda_y = -1, \lambda_z = 1$. It follows, in particular, that the relation of the type (6.63) also holds for orthogonal matrices O with $\det O = -1$, but with antiunitary operator U. Since any affine bijection of the Bloch ball is apparently implemented by an orthogonal matrix O, this implies Theorem 6.5 in the case of qubits.

Exercise 6.43 By using the multiplication rules (2.17), show that in the case $t_\gamma \equiv 0$

$$\Lambda[S] = \sum_{\gamma=0,x,y,z} \mu_\gamma \sigma_\gamma S \sigma_\gamma, \tag{6.64}$$

where

$$\mu_0 = \tfrac{1}{4}(1 + \lambda_x + \lambda_y + \lambda_z), \quad \mu_x = \tfrac{1}{4}(1 + \lambda_x - \lambda_y - \lambda_z),$$
$$\mu_y = \tfrac{1}{4}(1 - \lambda_x + \lambda_y - \lambda_z), \quad \mu_z = \tfrac{1}{4}(1 - \lambda_x - \lambda_y + \lambda_z).$$

Nonnegativity of these numbers is the necessary and sufficient condition for the complete positivity of Λ and hence of Φ.

In the case $d = 2$, the "discrete Weyl operators" are nothing but the Pauli matrices, namely, with the convention $|e_0\rangle = |\uparrow\rangle, |e_1\rangle = |\downarrow\rangle$, we have

$$W_{01} = V = \sigma_z, \quad W_{10} = U = \sigma_x, \quad W_{11} = UV = -i\sigma_y, \tag{6.65}$$

and the "discrete CCR" are the multiplication rules (2.17).

Exercise 6.44 Show that qubit unital channels (6.64) are covariant with respect to the projective unitary representation of the group $\mathbb{Z}_2 \times \mathbb{Z}_2$ defined by (6.65).

10.6.9 6.9 Notes and References

1. The proof of Theorem 6.5, going back to the famous Wigner theorem [247], follows the book of Davies (see Section 2.3 and Comments in [56]).

2. The notion of a completely positive map, introduced by Stinespring [226] in the more general context of C^*-algebras, was thoroughly studied in the paper of Arveson [10]. A useful survey of the properties of CP maps, including the proof of the inequality from Exercise 6.7, is in the paper of Størmer (pp. 85-106 in the volume [73]). In the finite-dimensional case, which has its own special features, CP maps were considered in detail in the work of Choi [46]. In these works one can find the conditions for extremality of CP maps.

This proof of Theorem 6.9 relies upon Gelfand-Naimark-Segal (GNS) construction, where from an object having a positivity property, one constructs a representation in a Hilbert space. The above proof, with a minor modification, works for CP maps of C^*-algebras in infinite dimensions. In the case of the algebra $\mathfrak{B}(\mathcal{H})$, Lemma 6.10 allows us to obtain the more special result (6.6).

3. The characteristic CP property of the dynamics of an open quantum system was observed in particular by Lindblad [166] and Holevo [108]. However, it was already implicit in the notion of "dynamical matrix" introduced by Sudarshan et al. [230], as well as the representation (6.18). Equivalence of this representation with complete positivity was proved by Choi [46]. Later it was independently considered in great detail in the book of Kraus [157]. Some authors use the name operator-sum representation for (6.17), (6.18). The correspondence (6.26) was introduced by Jamiołkowski [144] for positive maps and by Choi [46] in the case of CP maps. Many interesting applications of this correspondence in the field of quantum information theory are considered by Verstraete and Verschelde [238].

Extensive literature is devoted to the Markovian dynamics of an open system described by a quantum dynamical semigroup, i. e., the semigroup of normalized positive or completely positive maps. A survey of quantum dynamical semigroups and closely related quantum stochastic processes can be found in the books [56], [115].

4. Q-c-q channels were introduced in the paper [114]. A detailed study of entan-glement-breaking channels, including proof of Proposition 6.22, is given in the paper of M. Horodecki, Shor, and Ruskai [142].

Entanglement-binding channels were introduced in Horodeckis' paper [139], where examples of PPT channels that are not entanglement-breaking are given.

5. For detailed discussions of mathematical models for the quantum measurement process, see the books of Ludwig [170], Davies [56], Kraus [157], and Holevo [115] and the papers of Lindblad [164] and Ozawa [184].

6. The notion of complementary channel was introduced in the paper of Devetak and Shor [63]. The results in this section are due to Holevo [118] and to King, Matsumoto, Natanson, and Ruskai [152].

7. Discrete Weyl operators were used in the famous paper of Bennett, Brassard, Crépeau, Jozsa, Peres, and Wootters [22] on quantum teleportation. Concerning the covariance of the complementary channel (Exercise 6.38) see [118]. The ChoiJamiołkowski state of the depolarizing channel is the isotropic state (a mixture of chaotic and maximally entangled states) [192], and a usual way to prove Proposition 6.40, as well as its converse, is to study the separability of that state (see, e. g., [149]).

8. Realistic examples of qubit channels are considered in detail in the book of Nielsen and Chuang [179]. The structure of general qubit channels is described in detail by Ruskai, Szarek, and E. Werner [197]; see also Verstraete and Verschelde [238].

10.7 7 Quantum Entropy and Information Quantities

10.7.1 7.1 Quantum Relative Entropy

The classical relative entropy was considered in Section 4.2, where its monotonicity property and relation to the Shannon mutual information were established. The following definition introduces the noncommutative analog of the relative entropy, which plays an important role in quantum information theory. Many properties of the relative entropy are generalized to the quantum case, but some proofs become much more involved.

Definition 7.1. Let S, T be two density operators. If T is nondegenerate, the quantum relative entropy is defined by the formula

$$H(S;T) = -H(S) - \operatorname{Tr} S \log T = \operatorname{Tr} S(\log S - \log T) \tag{7.1}$$

The case where $\operatorname{supp} S \subseteq \operatorname{supp} T$($\operatorname{supp} S$ denotes support of S, see Section 1.3) is reduced to the previous situation by considering the restrictions of the operators S, T to $\operatorname{supp} T$, where T is nondegenerate. If however $\operatorname{supp} S \nsubseteq \operatorname{supp} T$, then, by definition, $H(S;T) = +\infty$.

Exercise 7.2 Let λ_j, μ_k be the eigenvalues and $|e_j\rangle, |h_k\rangle$ the respective eigenvectors of the density operators S, T. Prove the formula

$$H(S;T) = \sum_{j,k} |\langle e_j \mid h_k\rangle|^2 (\lambda_j \log \lambda_j - \lambda_j \log \mu_k). \tag{7.2}$$

Proposition 7.3. We have

$$H(S;T) \geq \frac{\log e}{2} \operatorname{Tr}(S-T)^2 \geq 0, \tag{7.3}$$

with equalities if and only if $S = T$.

Proof. By using the formula

$$\eta(\lambda) - \eta(\mu) = (\lambda - \mu)\eta'(\mu) + \frac{1}{2}(\lambda - \mu)^2 \eta''(\xi),$$

where ξ lies between λ and μ, we obtain for (4.2) the inequality

$$\lambda \log \lambda - \lambda \log \mu \geq \log \mathrm{e} \left[(\lambda - \mu) + \frac{1}{2}(\lambda - \mu)^2 \right].$$

Substituting this into (7.2), we get the result. □

Corollary 7.4 (Subadditivity of Quantum Entropy). Let S_{12} be a density operator in $\mathcal{H}_1 \otimes \mathcal{H}_2$, with partial states $S_1 = \operatorname{Tr}_{\mathcal{H}_2} S_{12}$ and $S_2 = \operatorname{Tr}_{\mathcal{H}_1} S_{12}$. Then

$$H(S_{12}) \leq H(S_1) + H(S_2), \tag{7.4}$$

with equality if and only if $S_{12} = S_1 \otimes S_2$.

Proof. This follows from the equality

$$H(S_1) + H(S_2) - H(S_{12}) = H(S_{12}; S_1 \otimes S_2)$$

and inequality (7.3). □

Similar to the ordinary entropy (see Exercise 5.3), the relative entropy has the following elementary properties, to be proved in the following exercise.

Exercise 7.5

i. Isometry invariance: $H(VSV^*; VS'V^*) = H(S; S')$ for an arbitrary operator V isometric on the supports of S, S'.

ii. Additivity: $H(S_1 \otimes S_2; S_1' \otimes S_2') = H(S_1; S_1') + H(S_2; S_2')$.

10.7.2 7.2 Monotonicity of the Relative Entropy

The following key property is the noncommutative analog of inequality (4.18).

Theorem 7.6 (Lindblad [166]). For arbitrary density operators S, T in $\mathcal{H}_1$ and arbitrary channel $\Phi : \mathfrak{T}(\mathcal{H}_1) \to \mathfrak{T}(\mathcal{H}_2)$

$$H(\Phi[S]; \Phi[T]) \leq H(S;T). \tag{7.5}$$

This important result follows from Theorem 7.7, to be proved below, which establishes a similar monotonicity property for a whole class of functions of a pair of quantum states.

Consider the Hilbert space $L^2(\mathcal{H})$ of linear operators in $\mathcal{H}$, with the inner product

$$(X, Y) = \operatorname{Tr} X^* Y.$$

Let S, T be nondegenerate operators. In $L^2(\mathcal{H})$, we introduce the operator L_T of left multiplication by T and the operator R_S of right multiplication by S, namely, $L_T X = TX, R_S X = XS$. They are positive commuting Hermitian operators in the Hilbert space $L^2(\mathcal{H})$.

The relative g-entropy of operators S, T is defined by the relation

$$H_g(S;T) = \left(S^{1/2}, g\left(L_T R_S^{-1}\right) S^{1/2}\right), \tag{7.6}$$

for any function $g \in \mathcal{G}$, where $\mathcal{G}$ is the class of functions of the form

$$g(w) = a(w-1) + b(w-1)^2 + \int_0^\infty \frac{(w-1)^2}{w+s} dv(s) \tag{7.7}$$

with a real, $b \geq 0$, and v a positive measure on $[0, \infty)$ such that $\int_0^\infty \frac{1}{s+1} dv(s) < \infty$ (concerning the inner characterization of $\mathcal{G}$ as the class of operator-convex functions such that $g(1) = 0$, see Section 7.8). For the proof of the following theorem it is only important that the function $g(w)$ admits such a representation.

Theorem 7.7 (Petz [189]). For arbitrary $g \in \mathcal{G}$, the relative g-entropy $H_g(S;T)$ has the monotonicity property

$$H_g(\Phi[S]; \Phi[T]) \leq H_g(S;T), \tag{7.8}$$

where Φ is an arbitrary channel.

Theorem 7.6 then follows from the two following observations:

i. the function $g(w) = -\log w$ belongs to the class $\mathcal{G}$. Indeed, by performing integration by parts, one can check that

$$-\ln w = \int_0^\infty \left[\frac{1}{w+s} - \frac{1}{1+s}\right] ds = -(w-1) + \int_0^\infty \frac{(w-1)^2}{(w+s)(s+1)^2} ds$$

ii.

$$H_{-\log}(S;T) = H(S;T).$$

We have

$$-\log\left(L_T R_S^{-1}\right) X = (\log R_S) X - (\log L_T) X = X(\log S) - (\log T)X$$

because of the commutativity of the operators L_T, R_S, whence we obtain $-\log\left(L_T R_S^{-1}\right) S^{1/2} = (\log S - \log T) S^{1/2}$, and the result follows from (7.6).

Proof of Theorem 7.7.

Lemma 7.8. For an arbitrary function $g \in \mathcal{G}$,

$$\begin{aligned} H_g(S;T) =& b \operatorname{Tr}(T-S) S^{-1} (T-S) \\ &+ \int_0^\infty \operatorname{Tr}(T-S) \left(L_T + s R_S\right)^{-1} (T-S) dv(s) \end{aligned} \tag{7.9}$$

Proof. By introducing the notation $\Delta_{T,S} = L_T R_S^{-1}$, we see that

$$(\Delta_{T,S} - I)\, S^{1/2} = (T-S)S^{-1/2} = R_{S^{-1/2}}(T-S), \tag{7.10}$$

hence,

$$H_{w-1}(S;T) = \operatorname{Tr} S^{1/2}(T-S)S^{-1/2} = 0, \tag{7.11}$$

so that the linear term in (7.7) does not contribute to (7.9). For $g(w) = \frac{(w-1)^2}{(w+s)}, s > 0$, we find, by using (7.10),

$$\begin{aligned} H_g(S;T) &= \left((\Delta_{T,S} - I)\, S^{1/2}, (\Delta_{T,S} + SI)^{-1} (\Delta_{T,S} - I)\, S^{1/2}\right) \\ &= \operatorname{Tr}\left[(T-S)\,(\Delta_{T,S} + sI)^{-1} R_{S^{-1}}(T-S)\right] \\ &= \operatorname{Tr}(T-S)\,(L_T + sR_S)^{-1}\,(T-S) \end{aligned} \tag{7.12}$$

For $s = 0$ we get

$$H_{(w-1)^2/w}(S;T) = \operatorname{Tr}(T-S)T^{-1}(T-S) = H_{(w-1)^2}(T;S). \tag{7.13}$$

By substituting this into (7.7), we get (7.9). □

If we neglect the first term in (7.7) (which does not contribute to $H_g(S;T)$), the functions (7.7) are "continual convex combinations" of the functions $(w-1)^2$ and $\frac{(w-1)^2}{w+s}$, $s \geq 0$. Thus, it is sufficient to prove monotonicity of the relative g-entropy for such functions g, i. e., for (7.12).

The proof of Theorem 7.7 now follows from the integral representation (7.9) and the following.

Lemma 7.9. For an arbitrary channel $\Phi, s \geq 0$, and an operator A

$$\operatorname{Tr} A^* \,(L_T + sR_S)^{-1}\, A \geq \operatorname{Tr} \Phi\,[A^*]\left(L_{\Phi[T]} + sR_{\Phi[S]}\right)^{-1} \Phi[A]. \tag{7.14}$$

Proof. Note that positive maps respect Hermitian conjugation, so that $\Phi\,[X^*] = \Phi[X]^*$, and similarly for Φ^*.

Since L_T, R_S are positive operators in $L^2(\mathcal{H})$, the operator $L_T + sR_S$ is also positive. Set $X = (L_T + sR_S)^{-1/2}\, A - (L_T + sR_S)^{1/2}\, \Phi^*[B]$, where $B = \left(L_{\Phi[T]} + sR_{\Phi[S]}\right)^{-1} \Phi[A]$. Then $\operatorname{Tr} X^*X \geq 0$, so that

$$\begin{aligned} &\operatorname{Tr} A^* \,(L_T + sR_S)^{-1}\, A - \operatorname{Tr} A^*\Phi^*[B] \\ &\quad - \operatorname{Tr} \Phi^*\,[B^*]\, A + \operatorname{Tr} \Phi^*\,[B^*]\,(L_T + sR_S)\,\Phi^*[B] \geq 0. \end{aligned} \tag{7.15}$$

We have

$$\operatorname{Tr} A^*\Phi^*[B] + \operatorname{Tr} \Phi^*\,[B^*]\, A = 2 \operatorname{Tr} \Phi\,[A^*]\left(L_{\Phi[T]} + sR_{\Phi[S]}\right)^{-1} \Phi[A]$$

and therefore, in order to prove the lemma, it is sufficient to show that the last term in (7.15) is less than or equal to the right-hand side of (7.14). Thus,

$$\begin{aligned} \operatorname{Tr} \Phi^*\,[B^*]\,(L_T + sR_S)\,\Phi^*[B] &= \operatorname{Tr}\left[s\Phi^*\,[B^*]\,\Phi^*[B]S + \Phi^*\,[B^*]\,T\Phi^*[B]\right] \\ &= \operatorname{Tr}\left[s\Phi^*\,[B^*]\,\Phi^*[B]S + \Phi^*[B]\Phi^*\,[B^*]\,T\right] \\ &\leq \operatorname{Tr}\left[s\Phi^*\,[B^*B]\,S + \Phi^*\,[BB^*]\,T\right] \end{aligned}$$

where the inequality follows from the positivity of S, T and the Kadison inequality (6.5), which in the case of a channel Φ takes the form

$$\Phi^*[B^*]\,\Phi^*[B] \le \Phi^*[B^*B].$$

Then by using the relation $\operatorname{Tr}\Phi^*[B^*B]\,S = \operatorname{Tr} B^*B\Phi[S]$, we find

$$\begin{aligned}\operatorname{Tr}\Phi^*[B^*]\,(L_T + sR_S)\,\Phi^*[B] &\le \operatorname{Tr}\left(sB^*B\Phi[S] + BB^*\Phi[T]\right)\\ &= \operatorname{Tr} B^*(sB\Phi[S] + \Phi[T]B)\\ &= \operatorname{Tr} B^*\left(L_{\Phi[T]} + sR_{\Phi[S]}\right)(B) = \operatorname{Tr} B^*\Phi[A]\\ &= \operatorname{Tr}\Phi[A^*]\left(L_{\Phi[T]} + sR_{\Phi[S]}\right)^{-1}\Phi[A]\end{aligned}$$

□

This proves Theorem 7.7 in the case of nondegenerate S, T. In the general case, either $H(S;T) = +\infty$ and inequality (7.5) is trivial, or $\operatorname{supp} S \subseteq \operatorname{supp} T$, in which case we can assume that $\operatorname{supp} T = \mathcal{H}$, i. e., the operator T is nondegenerate and for $H(S;T)$ formula (7.1) holds. Approximating an arbitrary operator S by nondegenerate operators and using the continuity of the entropy (see Section 7.4), the statement of the theorem in the general case can be proved. □

We now consider a number of useful corollaries of the monotonicity theorem, Theorem 7.6.

Corollary 7.10 (Generalized H-Theorem). Let Φ be a bistochastic (unital) channel in $\mathcal{H} = \mathcal{H}_1 = \mathcal{H}_2$. Then, for any state S,

$$H(\Phi[S]) \ge H(S). \tag{7.16}$$

Proof. From (7.1) it follows that

$$H(S) = \log d - H(S;\bar{S}) \tag{7.17}$$

where $\bar{S} = \frac{1}{d}I$ is the chaotic state, hence

$$H(\Phi[S]) = \log d - H(\Phi[S];\Phi[\bar{S}])$$

because $\Phi[\bar{S}] = \bar{S}$. The corollary now follows by virtue of the monotonicity Theorem 7.6. □

Corollary 7.11. The quantity (5.8) is monotone under the action of the arbitrary channel Φ, i.e.,

$$\chi(\{\pi_\chi\};\Phi[\{S_\chi\}]) \le \chi(\{\pi_\chi\};\{S_\chi\}). \tag{7.18}$$

Proof. By introducing the average state $\bar{S}_\pi = \sum \pi_x S_x$, we obtain the important identity generalizing (4.21)

$$\chi(\{\pi_x\};\{S_x\}) \equiv H\left(\bar{S}_\pi\right) - \sum \pi_x H(S_x) = \sum_x \pi_x H\left(S_x;\bar{S}_\pi\right). \tag{7.19}$$

Therefore (7.18) follows directly from (7.5). □

In particular, Theorem 7.6 implies the bound (5.16) on the Shannon information. Take an arbitrary basis $\{e_y\}$ in $\mathcal{H}$ and consider the q-c channel

$$\Psi[S] = \sum_y \operatorname{Tr} SM_y\,|e_y\rangle\langle e_y|,$$

corresponding to the measurement of the observable $M = \{M_y\}$. Then

$$\Psi\left[S_x\right]=\sum_y p_M(y\mid x)\left|e_y\right\rangle\left\langle e_y\right|,$$

$$\Psi\left[\bar{S}_\pi\right]=\sum_y\left(\sum_x \pi_x p_M(y\mid x)\right)\left|e_y\right\rangle\left\langle e_y\right|,$$

where $p_M(y\mid x)=\operatorname{Tr} S_x M_y$ are the density operators that are diagonal in the basis $\{e_y\}$. Therefore, the quantum relative entropy at the output of the channel Ψ becomes the classical relative entropy, and relation (4.21) implies

$$\sum_x \pi_x H\left(\Psi\left[S_x\right];\Psi\left[\bar{S}_\pi\right]\right)=\mathcal{I}_1(\pi,M).$$

By using the relation (7.18) for the channel Ψ we obtain the required inequality.
A useful quantity, motivated by Corollary 7.10, is the entropy gain

$$G_\Phi[S]=H(\Phi[S])-H(S). \tag{7.20}$$

Corollary 7.12. The entropy gain is convex as a function of S and is superadditive, i.e.,

$$G_{\Phi_1\otimes\Phi_2}\left[S_{12}\right]\geq G_{\Phi_1}\left[S_1\right]+G_{\Phi_2}\left[S_2\right]. \tag{7.21}$$

Proof. Taking into account the first identity in (7.19), the convexity of $G_\Phi[S]$ is just a reformulation of relation (7.18). The superadditivity (7.21) is equivalent to the relation

$$H\left(\left(\Phi_1\otimes\Phi_2\right)\left[S_{12}\right];\left(\Phi_1\otimes\Phi_2\right)\left[S_1\otimes S_2\right]\right)\leq H\left(S_{12};S_1\otimes S_2\right),$$

which follows from the monotonicity theorem, Theorem 7.6. □

10.7.3 7.3 Strong Subadditivity of the Quantum Entropy

Theorem 7.13. The following properties are equivalent:
i. monotonicity of the quantum relative entropy;
ii. strong subadditivity of the quantum entropy; let S_{123} be a density operator in $\mathcal{H}_1\otimes\mathcal{H}_2\otimes\mathcal{H}_3$; in this case, with the obvious notations for the partial states,

$$H\left(S_{123}\right)+H\left(S_2\right)\leq H\left(S_{12}\right)+H\left(S_{23}\right) \tag{7.22}$$

iii. joint convexity of the quantum relative entropy $H(S;T)$ with respect to the arguments S,T.

Proof. i. $\Rightarrow$ ii. Denoting by $\bar{S}_\alpha=\left(\dim\mathcal{H}_\alpha\right)^{-1}I_\alpha$ the chaotic state in $\mathcal{H}_\alpha$, we have

$$H\left(S_{123};\bar{S}_{123}\right)=H\left(S_{123};S_{12}\otimes\bar{S}_3\right)+H\left(S_{12};\bar{S}_{12}\right)$$
$$H\left(S_{23};\bar{S}_{23}\right)=H\left(S_{23};S_2\otimes\bar{S}_3\right)+H\left(S_2;\bar{S}_2\right)$$

Performing subtraction and using (7.17), we get

$$H\left(S_{12}\right)+H\left(S_{23}\right)-H\left(S_{123}\right)-H\left(S_2\right)=H\left(S_{123};S_{12}\otimes\bar{S}_3\right)-H\left(S_{23};S_2\otimes\bar{S}_3\right)$$

Consider the partial trace channel $\Phi\left[S_{123}\right]=S_{23}$. Applying Theorem 7.6 to it, we deduce the nonnegativity of the right-hand side, i. e., the strong subadditivity.
ii. $\Rightarrow$ iii. Consider the density operator in $\mathcal{H}_1\otimes\mathcal{H}_2\otimes\mathcal{H}_3$ of the form

$$S_{123} = \sum_{kl} |e_k\rangle \langle e_k| \otimes A_{kl} \otimes |h_l\rangle \langle h_l| ,$$

where $\{e_k\}$ is an orthonormal basis in $\mathcal{H}_1$, $\{h_l\}$ is an orthonormal basis in $\mathcal{H}_3$, and A_{kl} are positive operators in $\mathcal{H}_2$, which become density operators with an appropriate normalization. Then

$$S_{12} = \sum_k |e_k\rangle \langle e_k| \otimes \sum_l A_{kl}, \quad S_{23} = \sum_{kl} A_{kl} \otimes |h_l\rangle \langle h_l| , \quad S_2 = \sum_{kl} A_{kl},$$

and the strong subadditivity implies

$$-\sum_{kl} H(A_{kl}) + \sum_k H\left(\sum_l A_{kl}\right) + \sum_l H\left(\sum_k A_{kl}\right) - H\left(\sum_{kl} A_{kl}\right) \geq 0,$$

where we denoted $H(A) = -\operatorname{Tr} A \log A$ for a positive operator A. In particular, for arbitrary positive operators A_1, A_2, B_1, B_2,

$$\begin{aligned} & H(A_1 + A_2 + B_1 + B_2) \\ -H(A_1 + A_2) - H(B_1 + B_2) \leq & H(A_1 + B_1) - H(A_1) - H(B_1) \\ & + H(A_2 + B_2) - H(A_2) - H(B_2) \end{aligned}$$

which is equivalent to the joint convexity of the function

$$\Delta(A, B) = H(A + B) - H(A) - H(B)$$

with respect to A, B. On the other hand, the following lemma implies that $H(A; B)$ is convex as a supremum of a family of convex functions.

Lemma 7.14. For any two density operators A, B

$$H(A; B) = \sup_{\lambda > 0} \lambda^{-1} \chi_\lambda(A; B), \tag{7.23}$$

where

$$\begin{aligned} \chi_\lambda(A; B) &= H(\lambda A + (1 - \lambda)B) - \lambda H(A) - (1 - \lambda)H(B) \\ &= \Delta(\lambda A, (1 - \lambda)B) + h(\lambda). \end{aligned}$$

Proof. From the proof above, it follows that the function $\chi_\lambda(A; B)$ is convex with respect to A, B. As a function of $\lambda \in [0, 1]$ it is concave and equal to zero for $\lambda = 0, 1$ (this was proved in Section 5.3). Hence, for fixed A, B

$$\sup_{\lambda > 0} \lambda^{-1} \chi_\lambda(A; B) = \lim_{\lambda \to +0} \lambda^{-1} \chi_\lambda(A; B) = \frac{d}{d\lambda} \chi_\lambda(A; B) \Big|_{\lambda = 0}.$$

Exercise 7.15 Let F be a continuously differentiable function on $(\ 0, +\infty\ )$. Show that for any two positive operators A, B the following holds:

$$\frac{d}{d\lambda} \operatorname{Tr} F(\lambda A + (1 - \lambda)B) = \operatorname{Tr} F'(\lambda A + (1 - \lambda)B)(A - B). \tag{7.24}$$

Hint: prove (7.24) for the case where $F(x) = x^k$, implying the result for polynomials, and then use the Weierstrass uniform approximation theorem.

Now let $\operatorname{supp} A \subseteq \operatorname{supp} B$, so that $H(A; B) < +\infty$. Without loss of generality we assume that the operator B is nondegenerate. Computing the derivative of

$$H(\lambda A + (1-\lambda)B) = \operatorname{Tr} \eta(\lambda A + (1-\lambda)B)$$

by formula (7.24) we obtain

$$\frac{d}{d\lambda}\chi_\lambda(A;B)\Big|_{\lambda=0} = \operatorname{Tr} A(\log A - \log B) + (\log \mathrm{e}) \operatorname{Tr}(B-A) = H(A;B),$$

from which (7.23) follows. □

Exercise 7.16 Prove the statement (7.23) for the case $H(A;B) = +\infty$.

iii. ⇒ i. Consider the density operator S_{12} in $\mathcal{H}_1 \otimes \mathcal{H}_2$ and let $S_1 = \operatorname{Tr}_2 S_{12}$. From the property (6.53) of the discrete Weyl operators, we obtain

$$S_1 \otimes \bar{S}_2 = \frac{1}{d^2} \sum_{\alpha,\beta=0}^{d-1} (I_1 \otimes W_{\alpha\beta})\, S_{12}\, (I_1 \otimes W_{\alpha\beta})^*$$

The joint convexity of the relative entropy and the properties from Exercise 7.5 then imply

$$H\left(S_1; S_1'\right) \leq H\left(S_{12}; S_{12}'\right),$$

which is monotonicity with respect to the partial trace channel. But, according to Theorem 6.9, every channel can be represented as a concatenation of an isometric embedding (preserving the relative entropy) and a partial trace. This proves i. □

By using (7.17) and the convexity of the relative entropy we also obtain the following.

Corollary 7.17. The quantum entropy is concave, i.e., for arbitrary states S_j and probability distribution $\{p_j\}$,

$$H\left(\sum_j p_j S_j\right) \geq \sum_j p_j H\left(S_j\right).$$

Exercise 7.18 Find a direct proof of the concavity, using the spectral decomposition of the operator $\sum_j p_j S_j$ and the concavity of the function $\eta(t)$.

10.7.4 7.4 Continuity Properties

In the finite-dimensional case that we consider here, the quantum entropy is a continuous function of a state. Indeed, the function $\eta(x) = -x \log x$ is (uniformly) continuous on the segment $[0,1]$. Hence, $S_n \to S$ implies $\|\eta(S_n) - \eta(S)\| \to 0$, where $\|\cdot\|$ is the operator norm. Therefore,

$$|H(S_n) - H(S)| = |\operatorname{Tr}(\eta(S_n) - \eta(S))| \leq d\,\|\eta(S_n) - \eta(S)\| \to 0.$$

A more precise estimate, which we will need later, is given by the following.

Lemma 7.19 (Fannes [69]). Let S_1, S_2 be two density operators in d-dimensional Hilbert space, such that $\|S_1 - S_2\|_1 \leq \frac{1}{e}$. In this case,

$$|H(S_1) - H(S_2)| \leq \log d \cdot \|S_1 - S_2\|_1 + \eta\left(\|S_1 - S_2\|_1\right). \tag{7.25}$$

Since the function $\eta(x)$ is monotonously increasing for $x \in \left[0, \frac{1}{e}\right]$, the lemma implies the estimate

$$|H(S_1) - H(S_2)| \leq \log d \cdot \|S_1 - S_2\|_1 + \frac{\log e}{e}. \tag{7.26}$$

Proof. Let $\lambda_1 \geq \lambda_2 \geq \cdots (\mu_1 \geq \mu_2 \geq \cdots)$ be the eigenvalues of S_1 (correspondingly, S_2). Lemma 7.20. Denoting $\Delta_i = |\lambda_i - \mu_i|$, one has

$$\Delta = \sum_{i=1}^{d} \Delta_i \leq \|S_1 - S_2\|_1 . \tag{7.27}$$

Proof. Let $v_1 \geq v_2 \geq \cdots$ be the eigenvalues of the operator

$$A = S_1 + [S_1 - S_2]_- = S_2 + [S_1 - S_2]_+ .$$

Since $A \geq S_1, S_2$, we have $v_i \geq \lambda_i, \mu_i$, so that

$$|\lambda_i - \mu_i| \leq 2v_i - \lambda_i - \mu_i.$$

Therefore,

$$\begin{aligned}\Delta \leq \sum_{i=1}^{d} (2v_i - \lambda_i - \mu_i) &= \operatorname{Tr}(2A - S_1 - S_2) = \operatorname{Tr}[S_1 - S_2]_+ + \operatorname{Tr}[S_1 - S_2]_- \\ &= \|S_1 - S_2\|_1 .\end{aligned}$$

□

Exercise 7.21 Prove the inequality

$$|\eta(y) - \eta(x)| \leq \eta(y - x), \quad 0 \leq x \leq y \leq 1.$$

Combining these statements, we obtain

$$\begin{aligned}|H(S_1) - H(S_2)| &\leq \sum_{i=1}^{d} |\eta(\lambda_i) - \eta(\mu_i)| \leq \sum_{i=1}^{d} \eta(\Delta_i) \\ &= \Delta \sum_{i=1}^{d} \eta(\Delta_i/\Delta) + \eta(\Delta) \leq \Delta \log d + \eta(\Delta)\end{aligned}$$

Taking into account the monotonicity of $\eta(x)$ and combining this with (7.27) produces (7.25). □

Exercise 7.22 Show that the relative entropy is lower semicontinuous in the following sense: if $S_n \to S$ and $S'_n \to S'$, then

$$\lim_{n\to\infty} \inf_n H(S_n; S'_n) \geq H(S; S') .$$

Hint: use the continuity of the entropy, representation (7.23), and the fact that the supremum of a family of continuous functions is lower semicontinuous.

As we shall in Chapter 11, this property holds for both the entropy and the relative entropy in the infinite-dimensional Hilbert space, while the global continuity of the entropy no longer holds.

10.7.5 7.5 Information Correlation, Entanglement of Formation, and Conditional Entropy

In the classical case, the amount of information transmitted by the channel $X \to Y$ is measured by the quantity $I(X;Y) = H(X) + H(Y) - H(XY)$. In quantum statistics there is no general analog of the quantity $H(XY)$, as the joint distribution of observables exists only in special cases. One such case is that of the composite system.

Let S_{12} be a state of a bipartite quantum system in the Hilbert space $\mathcal{H}_1 \otimes \mathcal{H}_2$. In this situation, an obvious quantum analogue of the Shannon mutual information is

$$I(1;2) = H(S_1) + H(S_2) - H(S_{12}) = H(S_{12}; S_1 \otimes S_2). \tag{7.28}$$

We call this information correlation. From Corollary 7.4, it follows that $I(1;2) \geq 0$ and $I(1;2) = 0$ if and only if $S_{12} = S_1 \otimes S_2$.

Take a bipartite system and perform the measurements of observables M_1, M_2 in the corresponding subsystems. Their joint distribution exists and is given by the formula $p(x,y) = \operatorname{Tr} S_{12}(M_{1x} \otimes M_{2y})$. Let $I(M_1; M_2)$ denote the Shannon mutual information between the outcomes of these measurements.

Exercise 7.23 Show that for a pure state $S_{12} = |\psi\rangle\langle\psi|$

$$I(1;2) = 2 \max_{M_1, M_2} I(M_1, M_2). \tag{7.29}$$

In the case of the pure state S_{12} we have $H(S_{12}) = 0$, and Theorem 3.10 implies that

$$H(S_1) = H(S_2)$$

and

$$I(1;2) = H(S_1) + H(S_2) = 2H(S_1). \tag{7.31}$$

The quantity $H(S_1) = H(S_2) = \max I(M_1, M_2)$ then is a natural measure of entanglement of a pure bipartite state S_{12}. It is equal to zero for unentangled states and takes the maximal value $\log d$ for the state (3.7), which explains the name "maximally entangled state."

The question of measures of entanglement for mixed states is substantially more complicated than that for pure states. Unlike the case of pure states there are many
different measures of entanglement for mixed states. Of main interest for us will be entanglement of formation, which is defined for an arbitrary state S_{12} in $\mathcal{H}_1 \otimes \mathcal{H}_2$ as

$$E_F(S_{12}) = \inf \sum_j \pi_j H\left(\operatorname{Tr}_2 S_{12}^j\right), \tag{7.32}$$

where the infimum is taken over all possible decompositions of the density operator

$$S_{12} = \sum_j \pi_j S_{12}^j$$

as convex combinations of some density operators S_{12}^j (in terms of convex analysis, $E_F(S_{12})$ is the convex hull of the continuous function $S_{12} \to H(S_1)$).

Proposition 7.24. The function $S_{12} \to E_F(S_{12})$ is continuous and convex, and the infimum in (7.32) is attained on a convex combination of no more than $(d_1 d_2)^2$ pure states S_{12}^j. Moreover, the duality relation holds, i.e.,

$$E_F(S_{12}) = \max_{A_{12}} \operatorname{Tr} S_{12} A_{12}, \tag{7.33}$$

where the maximization is over the Hermitian operators A_{12} in $\mathcal{H}_1 \otimes \mathcal{H}_2$, satisfying

$$\operatorname{Tr} T_{12} A_{12} \leq H(\operatorname{Tr}_2 T_{12}), \tag{7.34}$$

for all (pure) states T_{12} in $\mathcal{H}_1 \otimes \mathcal{H}_2$.

Proof. Let $\mathcal{H} = \mathcal{H}_1 \otimes \mathcal{H}_2, S = S_{12}$, and $f(S) = H(\operatorname{Tr}_2 S_{12})$. In this case, f is a continuous concave function on the compact convex set of quantum states $\mathfrak{S} = \mathfrak{S}(\mathcal{H})$. The proof below uses

very few of the other special properties of f and $\mathfrak{S}$, and could be entirely based on references to the convex duality theory. However, we here provide a selfcontained proof.

A finite collection of states with the corresponding probabilities is usually called an ensemble. [1] For our proof it is useful to consider "continual" generalization of ensembles, described by the probability measures $\pi(dS)$ on the set $\mathfrak{S}(\mathcal{H})$ (the concept of a generalized ensemble will be systematically explored in Chapter 11). Now, the usual ensembles correspond to finitely supported measures. By using general facts from measure theory (see, e. g., [186]) one can show that the set $\mathcal{P}(\mathfrak{S}(\mathcal{H}))$ of all probability measures on $\mathfrak{S}(\mathcal{H})$ is itself compact with respect to the topology of weak convergence, which is defined as the convergence of integrals of all bounded continuous functions on $\mathfrak{S}(\mathcal{H})$.

Consider the functional

$$F(\pi) = \int_{\mathfrak{S}} f(T)\pi(dT) \tag{7.35}$$

on $\mathcal{P}(\mathfrak{S}(\mathcal{H}))$, which for finitely supported π coincides with the minimized expression in (7.32). From the definition, it is a continuous, affine functional. We are interested in the minimization of this functional, on the closed convex subset $\mathcal{P}_S$ of probability measures π with the given barycenter

$$S = \int_{\mathfrak{S}(\mathcal{H})} T\pi(dT). \tag{7.36}$$

The continuous functional $F(\pi)$ attains its minimum on the compact set $\mathcal{P}_S$. The concavity of f then implies that we can choose the minimizing measure π to be supported by the pure states, since we can always perform decompositions of all density operators $T = T_{12}$ into pure states, without changing the barycenter and without increasing the value $F(\pi)$.

Let us now show that such an extreme π is supported by no more than $(d_1 d_2)^2$ states. Note that the states supporting π are linearly independent in the sense that if

$$\int_{\mathfrak{S}(\mathcal{H})} c(T)T\pi(dT) = 0 \tag{7.37}$$

for some real bounded measurable function $c(T)$, then $c(T) = 0$ almost everywhere with respect to π. Indeed, it follows from (7.37) that $\pi = \frac{1}{2}\pi_+ + \frac{1}{2}\pi_-$, where

$$\pi_\pm(dT) = (1 \pm \varepsilon c(T))\pi(dT)$$

for sufficiently small ε, so that extremality implies $\pi_\pm(dT) = \pi(dT)$, and hence $c(T) = 0(\mathrm{mod}\pi)$, i. e., almost everywhere with respect to the measure π. By taking the matrix elements of (7.37), we see that the real Hilbert space $L^2_{\mathbb{R}}(\pi)$ is spanned by $(d_1 d_2)^2$ functions

$$\begin{aligned} T &\to \mathrm{Re}\,\langle e_j|\,T\,|e_k\rangle\,, \quad 1 \le j \le k \le d_1 d_2 \\ T &\to \mathrm{Im}\,\langle e_j|\,T\,|e_k\rangle\,, \quad 1 \le j < k \le d_1 d_2. \end{aligned}$$

Indeed, any function $c(T)$ that is orthogonal to all these functions in $L^2_{\mathbb{R}}(\pi)$ must be zero $(\mathrm{mod}\pi)$. The rest follows from the following exercise.

Exercise 7.25 Show that if $\dim L^2_{\mathbb{R}}(\pi) = n$, then π is finitely supported by n points.

The inequality $\ge$ in the duality relation follows from integrating the inequality $f(T) \ge \mathrm{Tr}\,TA$ with respect to an arbitrary probability measure π that satisfies the constraint (7.36). In the proof of the reverse inequality we can consider only those measures which have a fixed (but arbitrary) finite support, containing the support of the optimal (minimizing) measure π^0. In

[0]1 This notion is different from the "statistical ensemble" in Section 2.1.2, which means a statistical sample of identically prepared systems.

this case, the minimization in (7.32) becomes a finitedimensional problem with a finite number of linear constraints, defined by (7.36). Note
that these constraints also imply the constraint expressed by the normalization of a probability measure. Applying the elementary Lagrange method, we then obtain that there exists a Hermitian operator Λ such that π^0 minimizes the functional

$$F(\pi) - \operatorname{Tr}\left(\int_{\mathfrak{S}} \mathrm{T}\,\pi(dT)\right)\Lambda = \int_{\mathfrak{S}} [f(T) - \operatorname{Tr} T\Lambda]\pi(dT) \tag{7.38}$$

over all (nonnormalized) positive measures π with the given finite support. Here, the Hermitian operator Λ simply describes the collection of real Lagrange multipliers for the constraints (7.36). It follows that

$$f(T) - \operatorname{Tr} T\Lambda \geq 0, \tag{7.39}$$

$$f(T) - \operatorname{Tr} T\Lambda = 0 \left(\operatorname{mod}\pi^0\right). \tag{7.40}$$

Inequality (7.39) follows from the fact that otherwise the infimum of the functional (7.38) would be $-\infty$, while equality (7.40) guarantees that the infimum, equal to 0 , is attained. By integrating the second equality with respect to π^0, and taking into account (7.36), we obtain $\operatorname{Tr} S\Lambda = \int_{\mathfrak{S}} f(T)\pi^0(dS)$, which, together with inequality (7.39), implies that Λ is the solution of the dual problem, and (7.33) holds with the common value $\operatorname{Tr} S\Lambda$.

The duality relation implies that the function $E_F(S)$ is lower semicontinuous, as the maximum of the family of continuous (affine) functions $S \to \operatorname{Tr} SA$. It now suffices to show that it is upper semicontinuous, i.e.,

$$\limsup_{n\to\infty} E_F\left(S^{(n)}\right) \leq E_F(S),$$

for any sequence of states $S^{(n)} \to S$. In this proof we follow Shirokov [210]. Let

$$E_F(S) = \sum_{j=1}^{N} \pi_j^0 H\left(\operatorname{Tr}_{\mathcal{H}_2} S_j\right), \tag{7.41}$$

where $S = \sum_{j=1}^{N} \pi_j^0 S_j$. Now, if S is nondegenerate, put

$$S^{(n)} = \sum_{j=1}^{N} \pi_j^{(n)} S_j^{(n)},$$

where

$$\pi_j^{(n)} = t_j^{(n)}\pi_j^0$$
$$S_j^{(n)} = \left(t_j^{(n)}\right)^{-1} \left(S^{(n)}\right)^{1/2} S^{-1/2} S_j S^{-1/2} \left(S^{(n)}\right)^{1/2},$$

and

$$t_j^{(n)} = \operatorname{Tr}\left(S^{(n)}\right)^{1/2} S^{-1/2} S_j S^{-1/2} \left(S^{(n)}\right)^{1/2}.$$

These expressions also make sense for degenerate S, if by $S^{-1/2}$ we denote the generalized inverse of $S^{1/2}$, i. e., the operator that is equal to the inverse on the support of S and zero on its orthogonal complement (see [210] for detail). Now,

$$E_F\left(S^{(n)}\right) \leq \sum_{j=1}^{N} \pi_j^{(n)} H\left(\mathrm{Tr}_{\mathcal{H}_2} S_j^{(n)}\right)$$

and the right-hand side tends to (7.41). Therefore

$$\limsup_{n\to\infty} E_F\left(S^{(n)}\right) \leq E_F(S),$$

that is, E_F is upper semicontinuous, and hence continuous. □

Let us come back to the case of the pure state S_{12}. Note that in classical statistics, partial states of a pure state (marginal distributions of a degenerate distribution) are again pure, and purification has no classical counterpart. Related to this fact is the following unusual property of the quantum analog of conditional entropy. In the classical case, the conditional entropy is always nonnegative, i.e.,

$$H(X \mid Y) = H(XY) - H(Y) = \sum_y p_y H(X \mid Y = y) \geq 0. \tag{7.42}$$

Defining the quantum conditional entropy as

$$H(1 \mid 2) = H\left(S_{12}\right) - H\left(S_2\right),$$

we see that it is negative if S_{12} is a pure entangled state. In other words, unlike the classical entropy, the quantum entropy is not monotone with respect to enlargement of the system, i. e., $H\left(S_1\right) \not\leq H\left(S_{12}\right)$. Nevertheless, similar to the classical case, the following properties hold:
i. monotonicity of the conditional entropy: $H(1 \mid 23) \leq H(1 \mid 2)$;
ii. $H(1 \mid 2) + H(1 \mid 3) \geq 0$.

Exercise 7.26 Show that these properties are reformulations of the strong subadditivity of the quantum entropy (7.22). Hint: use purification of the total state.

Another useful property of the quantum conditional entropy is the following.
Corollary 7.27. The conditional entropy $H(1 \mid 2)$ is a concave function of the state S_{12}. It is subadditive in the following sense:

$$H(13 \mid 24) \leq H(1 \mid 2) + H(3 \mid 4). \tag{7.43}$$

The statements follow from Corollary 7.12 by observing that the conditional entropy is equal to minus the entropy gain that corresponds to the partial trace channel, i.e., $H(1 \mid 2) = -G_{\mathrm{Tr}_1}\left(S_{12}\right)$.

These properties make the conditional entropy a useful tool in quantum information theory.

10.7.6 7.6 Entropy Exchange

Let Φ be a channel from the input system A to the output system B, and let $S = S_A$ be a density operator in $\mathcal{H}_A$ denoting the input state. By Theorem 6.9, the channel admits the Stinespring representation

$$\Phi\left[S_A\right] = \mathrm{Tr}_E\, V S_A V^*, \tag{7.44}$$

where V is an isometric operator from $\mathcal{H}_A$ to $\mathcal{H}_{BE} = \mathcal{H}_B \otimes \mathcal{H}_E$ and $\mathcal{H}_E$ can be thought of as the "environment" of the channel. Transmission of the state S_A produces the state of the environment

$$S_E = \mathrm{Tr}_B\, V S_A V^* = \tilde{\Phi}\left[S_A\right], \tag{7.45}$$

where $\tilde{\Phi}$ is the complementary channel from the input to the environment. In what follows we will simplify notations for the entropies by omitting the notation for the state, i.e., replace $H(S_A)$ by $H(A)$, etc., as we already did in the previous section.

Definition 7.28. The quantity $H(S_E) = H\left(\tilde{\Phi}[S_A]\right)$, which is equal to the output entropy of the environment, is called the entropy exchange and will be denoted $H(S, \Phi)$, or simply $H(E)$.

By using the construction of the complementary channel from (6.42), we see that S_E is given by the density matrix $\left[\operatorname{Tr} SV_j^* V_k\right]_{j,k=\overline{1,N}}$. Hence, we obtain the following result.

Proposition 7.29. Let $\Phi[S] = \sum_{j=1}^N V_j S V_j^*$, with $\sum_{j=1}^N V_j^* V_j = I$. Then

$$H(S, \Phi) = H\left(\left[\operatorname{Tr} SV_j^* V_k\right]_{j,k=\overline{1,N}}\right). \tag{7.46}$$

To obtain another useful expression for $H(S, \Phi)$, we take a reference system $\mathcal{H}_R$. Then we can purify the state S_A to $|\psi_{AR}\rangle\langle\psi_{AR}|$ in $\mathcal{H}_A \otimes \mathcal{H}_R$. Next, compute (see Fig. 7.1)

$$H\left((\Phi \otimes \mathrm{Id}_R)|\psi_{AR}\rangle\langle\psi_{AR}|\right) = H(S_{BR}). \tag{7.47}$$

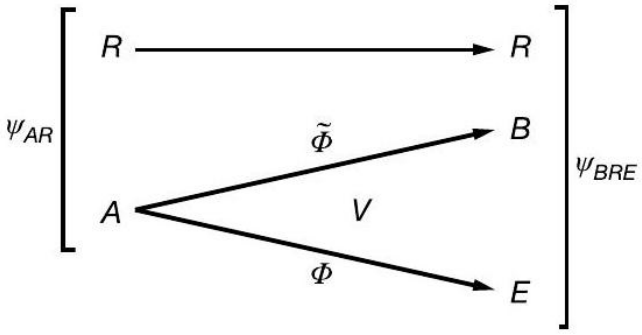

Figure 7.1: Purification with the reference system.

Now, the tripartite system BRE described by the Hilbert space $\mathcal{H}_{BRE} = \mathcal{H}_B \otimes \mathcal{H}_R \otimes \mathcal{H}_E$ is in the pure state

$$|\psi_{BRE}\rangle = (V \otimes I_R)|\psi_{AR}\rangle \tag{7.48}$$

Looking at the split $BR \mid E$ we have a bipartite system in the pure state and therefore, by (7.30),

$$H(S_E) = H(S_{BR}) \tag{7.49}$$

Formula (7.49) provides an alternative expression for the entropy exchange as the output entropy of the extended channel $\Phi \otimes \mathrm{Id}_R$ applied to the purified input state S_{AR}. Since the left-hand side does not involve R, this also shows that $H(S_{BR})$ does not depend on a particular way of purification of the state $S = S_A$.

The entropy exchange satisfies a simple but useful inequality. Let $S = \sum_j p_j S_j$ be a mixture of pure states S_j. In this case,

$$H(S, \Phi) \geq \sum_j p_j H(\Phi[S_j]) \tag{7.50}$$

Indeed, by concavity of the quantum entropy,

$$H(S, \Phi) = H\left(\tilde{\Phi}\left[\sum_j p_j S_j\right]\right) \geq \sum_j p_j H\left(\tilde{\Phi}[S_j]\right)$$

But $H\left(\tilde{\Phi}\left[S_j\right]\right) = H\left(\Phi\left[S_j\right]\right)$, because the system BE is in a pure state as soon as the input S_j is pure.

Example 7.30. Consider the depolarizing channel (6.49) and the input chaotic state $\bar{S} = I_d/d$. By using representation (6.54) with the Kraus operators $V_{\alpha\beta}$ and the properties of discrete Weyl operators, we find

$$\operatorname{Tr} \bar{S} V_{\alpha\beta}^* V_{\alpha'\beta'} = \delta_{(\alpha\beta),(\alpha'\beta')} \begin{cases} \frac{p}{d^2}, & (\alpha\beta) \neq (00) \\ 1 - p\frac{d^2-1}{d^2}, & (\alpha\beta) = (00) \end{cases}$$

Hence,

$$H(\bar{S}, \Phi) = -\left(1 - p\frac{d^2-1}{d^2}\right) \log \left(1 - p\frac{d^2-1}{d^2}\right) - p\frac{d^2-1}{d^2} \log \frac{p}{d^2} \tag{7.51}$$

10.7.7 7.7 Quantum Mutual Information

So far, we have encountered three entropic quantities: the input entropy $H(S)$, the output entropy $H(\Phi[S])$, and the entropy exchange $H(S, \Phi)$. The relation between them allows us to interpret them as the sides of a triangle: the sum of any two of them is larger than the third. For example, the difference in length of the upper two sides of the triangle and its basis can be seen as the information correlation between R and B, i. e.,

$$\begin{aligned} I(S, \Phi) &= H(S) + H(\Phi[S]) - H(S, \Phi) \\ &= H(A) + H(B) - H(E) \\ &= H(R) + H(B) - H(BR) \geq 0 \end{aligned} \tag{7.52}$$

by the subadditivity of the quantum entropy.
Since R has the same entropy as A, this quantity can be thought of as the quantum mutual information between the input and output. The mutual information $I(S, \Phi)$ has a number of nice properties, similar to that of the Shannon information.

Proposition 7.31. The quantum mutual information $I(S, \Phi)$
i. is concave in S;
ii. is convex in Φ;
iii. is subadditive: $I\left(S_{12}, \Phi_1 \otimes \Phi_2\right) \leq I\left(S_1, \Phi_1\right) + I\left(S_2, \Phi_2\right)$;
iv. satisfies the data processing inequalities, i.e.,

$$I\left(S, \Phi_2 \circ \Phi_1\right) \leq \min\left\{I\left(S, \Phi_1\right), I\left(\Phi_1(S), \Phi_2\right)\right\}$$

Proof. The proof is based on playing with different splits of the tripartite system BRE, which is in the pure state (7.48), and on the properties of the conditional entropy.
i. We have

$$\begin{aligned} I(S, \Phi) &= H(R) + H(B) - H(E) \\ &= H(BE) + H(B) - H(E) \\ &= H(B \mid E) + H(B) \end{aligned} \tag{7.53}$$

where the first term is concave in S_{BE} by Corollary 7.27, and the second is concave in S_B. It remains for us to observe that the maps $S \to S_{BE}$ and $S \to S_B$ are affine.
ii. We have

$$
\begin{aligned}
I(S,\Phi) &= H(R) + H(B) - H(E) \\
&= H(R) + H(B) - H(BR) \\
&= H(R) - H(R \mid B)
\end{aligned}
$$

where the first term does not depend on Φ, while the second is concave in $S_{BR} = (\Phi \otimes \mathrm{Id}_R)[S_{AR}]$, which is affine in Φ.

iii. This follows from the expression $I(S,\Phi) = H(B \mid E) + H(B)$ (see (7.53)), the subadditivity (7.43) of the conditional entropy $H(B \mid E)$, and the subadditivity (7.4) of the quantum entropy $H(B)$.

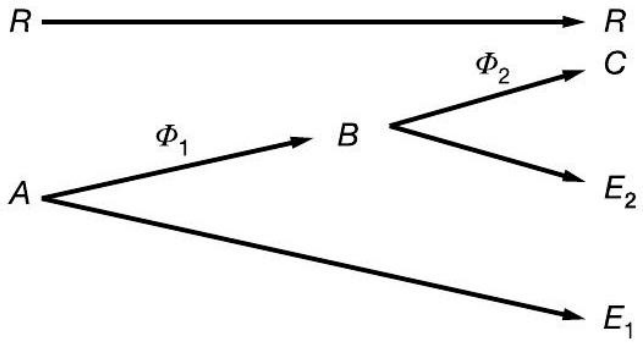

Figure 7.2: Composition of channels.

iv. Denote by A the input of Φ_1, by B the common output of Φ_1 and input of Φ_2, and by C the output of Φ_2. Let also $E_{1,2}$ denote the environments for $\Phi_{1,2}$ (see Fig. 7.2). We have

$$
I(S, \Phi_2 \circ \Phi_1) = H(R) + H(C) - H(E_1 E_2). \tag{7.54}
$$

To prove the first data processing inequality, note that

$$
I(S, \Phi_1) = H(R) + H(B) - H(E_1), \tag{7.55}
$$

so we have to show that $H(C) - H(E_1 E_2) \leq H(B) - H(E_1)$. But since the systems CRE_1E_2 and BRE_1 are in pure states, this is equivalent to

$$
H(R \mid E_1 E_2) \leq H(R \mid E_1),
$$

which is true because of the monotonicity of the conditional entropy. To prove the second data processing inequality, note that

$$
I(\Phi_1[S], \Phi_2) = H(B) + H(C) - H(E_2), \tag{7.56}
$$

so we have to show that $H(R) - H(E_1 E_2) \leq H(B) - H(E_2)$. But since the systems BRE_1 and CRE_1E_2 are in pure states, this is the same as $H(R) - H(CR) \leq H(RE_1) - H(CRE_1)$ or

$$
H(C \mid RE_1) \leq H(C \mid R).
$$

However, the last inequality holds due to the monotonicity of the conditional entropy. □

10.7.8 7.8 Notes and References

1. The entropy of a density operator was introduced by von Neumann [237]. A detailed survey of the properties of the quantum entropy and the quantum relative entropy can be found in the article of Wehrl [242] and in the books of Ohya and Petz [182] and Petz [190].

Inequality (7.3) can be strengthened by replacing $\mathrm{Tr}(S-T)^2$ by $\|S-T\|_1^2$; see [203]. The proof is based on the corresponding classical Pinsker's inequality; see Lemma 12.6.1 in [47].

2. A real function g, defined on the interval $I \subseteq \mathbb{R}$, is called operator-monotone if, for arbitrary natural n and Hermitian $n \times n$-matrices $A \leq B$ with spectra in I, the inequality $g(A) \leq g(B)$ holds. Operator-convex functions are defined in a similar fashion. The main results concerning operator-monotone and operator-convex functions, as well as a number of useful matrix inequalities, can be found in the book of Bhatia [31]. By using the classical results from the theory of operator-monotone and operatorconvex functions one can show that the class $\mathcal{G}$, defined by the relation (7.7), consists of operator-convex functions g on $(0,\infty)$ such that $g(1)=0$.

There are several proofs of the monotonicity theorem, Theorem 7.6. A usual approach is to derive it as a corollary of the celebrated "Lieb concavity" [182], [179]. In a series of papers [164], [165], and [166], Lindblad obtained a number of approximations to the monotonicity property and finally proved its equivalence to the strong subadditivity of the quantum entropy, established earlier by Lieb and Ruskai [163]. Uhlmann [234] gave a different proof based on an interpolation method. Quantum "quasi-entropies," including the relative g-entropies, were introduced by Petz [189], who gave a proof of Theorem 7.7 for maps satisfying (6.5), based on an operator generalization of the Jensen inequality. Here, we follow the paper of Lesniewski and Ruskai [161], where a direct proof of the monotonicity is given that makes no use of the Lieb concavity. This proof is based, after all, on a generalization of the CauchySchwarz inequality and allows us to establish the monotonicity of a whole class of invariants of pairs of states in quantum "geometro-statistics," initiated by Morozova and Chentzov [44]. Effros pointed to the connection of these problems with the notion of the matrix perspective of an operator-convex function [67]. The condition for the equality in the monotonicity property was established by Petz (see also the survey of Ruskai [196]).

A new, "natural" proof of the monotonicity property of the relative entropy was suggested by Bjelaković and Siegmund-Schultze [32] (see also Hayashi [95]), based on the operational interpretation of the quantum relative entropy as the optimal error exponent in the problem of asymptotic discrimination between two quantum states (for the quantum analog of Stein's lemma in mathematical statistics, see Theorem 12.8.1 in [47]). In the paper [178], basing on the properties of "sandwiched Renyi divergence" introduced and studied by Beigi [19], the authors extended the monotonicity property (7.5) to positive maps.

The entropy gain was introduced and studied by Alicki [7].

3. In this section we follow Lindblad [166]; see also the book of Ohya and Petz [182].

4. Lemma 7.19 is due to Fannes [69]. Audenaert [14] obtained the sharp bound

$$|H(S_1) - H(S_2)| \leq \log(d-1) \cdot \|S_1 - S_2\|_1 + h_2\left(\|S_1 - S_2\|_1\right).$$

The connection of this inequality with Fano's lemma, Lemma 4.14, is indicated in the book of Petz [190].

5. The information correlation was considered by Stratonovich [227] and by Lindblad [164]. The entanglement of formation was introduced in the fundamental work of Bennett, DiVincenzo, Smolin, and Wootters [25]. For mixed states, there is a whole variety of measures of entanglement. The quantitative theory of entanglement is another separate chapter of quantum information science, in which the mathematical methods are substantially applied and

developed; see, e. g., the surveys of Keyl [149] and Alber et al. [6] and the book of Hayashi [95].

The definition and properties of the convex hull, as well as the general duality theorem of convex programming, are presented in, e. g., the books of Rockafellar [194] and Magaril-Il'yaev and Tikhomirov [172]. The proof of upper semicontinuity of the entanglement of formation is based on a construction from the work of Shirokov [210].

The quantum conditional entropy was introduced by Adami and Cerf [2]. The operational interpretation of the negative values of the conditional entropy as a "credit" for future quantum communication based on state merging protocol was proposed by M. Horodecki, Oppenheim, and Winter [141].

6. Entropy exchange was introduced (without using this name) by Lindblad [167] and later, independently, in the context of quantum information theory, by Barnum, Nielsen, and Schumacher [18].

7. The quantum mutual information also first appeared in the paper of Lindblad [167] and later, independently, in the paper of Adami and Cerf [2], who studied its properties in detail in an information-theoretic context.

10.8 8 The Classical Capacity of Quantum Channels

10.8.1 8.1 The Coding Theorem

In Chapter 5, the basic coding theorem for a classical-quantum (c-q) communication channel was established. In this chapter, we will use this result to obtain the coding theorem for an arbitrary quantum channel.

Consider the channel $\Phi : \mathfrak{T}(\mathcal{H}_A) \to \mathfrak{T}(\mathcal{H}_B)$ and the corresponding composite, "memoryless" channel $\Phi^{\otimes n} = \Phi \otimes \cdots \otimes \Phi : \mathfrak{T}\left(\mathcal{H}_A^{\otimes n}\right) \to \mathfrak{T}\left(\mathcal{H}_B^{\otimes n}\right)$. The block code for such a composite channel comprises a c-q channel $i \to S_i^{(n)}$ encoding classical messages i into input states $S_i^{(n)}$ in the space $\mathcal{H}_A^{\otimes n}$, and a q-c channel (observable $M^{(n)}$) in the space $\mathcal{H}_B^{\otimes n}$, decoding the output states $\Phi^{\otimes n}\left[S_i^{(n)}\right]$ into classical messages j, i. e.,

$$i \to S_i^{(n)} \to \Phi^{\otimes n}\left[S_i^{(n)}\right] \to j.$$

This leads to the following definition.

Definition 8.1. A code $\left(\Sigma^{(n)}, M^{(n)}\right)$ of length n and of size N for the composite channel $\Phi^{\otimes n}$ consists of an encoding, given by a collection of states $\Sigma^{(n)} = \left\{S_i^{(n)}; i = 1, \ldots, N\right\}$ in $\mathcal{H}_A^{\otimes n}$, and a decoding, described by an observable $M^{(n)} = \left\{M_j^{(n)}; j = 0, 1, \ldots, N\right\}$ in $\mathcal{H}_B^{\otimes n}$.

The maximal error probability of the code is equal to

$$P_e\left(\Sigma^{(n)}, M^{(n)}\right) = \max_{i=1,\ldots,N}\left[1 - p_{\Sigma M}(i \mid i)\right] \tag{8.1}$$

where

$$p_{\Sigma M}(j \mid i) = \operatorname{Tr} \Phi^{\otimes n}\left[S_i^{(n)}\right] M_j^{(n)} \tag{8.2}$$

is the probability to make a decision j under the condition that a message i was sent. The minimum of the error $P_e\left(\Sigma^{(n)}, M^{(n)}\right)$ over all codes of length n and size N is again denoted $p_e(n, N)$. The classical capacity $C(\Phi)$ of the quantum channel Φ is defined as the least upper bound of the rates R for which

$$\lim_{n\to\infty} p_e\left(n, 2^{nR}\right) = 0$$

Let us recall that a finite probability distribution π on the set of quantum states $\mathfrak{S}(\mathcal{H})$, that assigns the probabilities π_i to states S_i, is called an ensemble. If an ensemble $\pi^{(n)}$ with probabilities $\left\{\pi_i^{(n)}\right\}$ of the input states $S_i^{(n)}$ is given, then using the transition probability $p_{\Sigma M}(j \mid i)$, we can find the joint distribution of input i and output j and
compute the Shannon information $\mathcal{I}_n\left(\pi^{(n)}, M^{(n)}\right)$ according to formula (5.14). Applying Shannon's coding theorem, we obtain, as in Proposition 5.15,

$$C(\Phi) = \lim_{n\to\infty} \frac{1}{n} \sup_{\left\{\pi^{(n)}, M^{(n)}\right\}} \mathcal{I}_n\left(\pi^{(n)}, M^{(n)}\right). \tag{8.3}$$

In contrast to the case of c − q channels, there is no fixed alphabet here, and one has to optimize not only with respect to the output observable $M^{(n)}$ and the input distribution $\left\{\pi_i^{(n)}\right\}$, but also with respect to all possible states $S_i^{(n)}$ at the input of the channel $\Phi^{\otimes n}$.

Proposition 8.2. The classical capacity of channel Φ is equal to

$$C(\Phi) = \lim_{n\to\infty} \frac{1}{n} C_\chi\left(\Phi^{\otimes n}\right), \tag{8.4}$$

where

$$C_\chi(\Phi) = \sup_\pi \chi\left(\{\pi_i\}; \{\Phi[S_i]\}\right), \tag{8.5}$$

the quantity χ is defined by the relation (5.8), and the supremum is taken over all input ensembles $\pi = \{\pi_i, S_i\}$ in $\mathfrak{S}(\mathcal{H})$.

Note that, similar to Proposition 5.15, the limit in the relations (8.3), (8.4) as $n \to \infty$ is equal to the supremum over n, due to superadditivity of the corresponding sequences.

Proof. From the upper bound of Theorem 5.9

$$\mathcal{I}_n\left(\pi^{(n)}, M^{(n)}\right) \le C_\chi\left(\Phi^{\otimes n}\right).$$

The inequality $\le$ in (8.4) then follows from (8.3).
Let us show that

$$C(\Phi) \ge \lim_{n\to\infty} \frac{1}{n} C_\chi\left(\Phi^{\otimes n}\right) \equiv \bar{C}(\Phi). \tag{8.6}$$

Take $R < \bar{C}(\Phi)$. In this case, we can choose n_0 and an ensemble $\pi^{(n_0)} = \left\{\pi_i^{(n_0)}, S_i^{(n_0)}\right\}$ in $\mathcal{H}_A^{\otimes n_0}$ such that

$$n_0 R < \chi\left(\left\{\pi_i^{(n_0)}\right\}; \left\{\Phi^{\otimes n_0}\left[S_i^{(n_0)}\right]\right\}\right). \tag{8.7}$$

Consider the c-q channel $\tilde{\Phi}$ in $\mathcal{H}_B^{\otimes n_0}$ defined by the formula

$$i \to \Phi^{\otimes n_0}\left[S_i^{(n_0)}\right]. \tag{8.8}$$

By the coding theorem, Theorem 5.4, for c-q channels, the capacity of $\tilde{\Phi}$ is

$$C(\tilde{\Phi}) = \max_{\{\pi_i\}} \chi\left(\{\pi_i\}; \left\{\Phi^{\otimes n_0}\left[S_i^{(n_0)}\right]\right\}\right), \tag{8.9}$$

where the states $S_i^{(n_0)}$ are fixed and the maximum is taken over the probability distributions $\{\pi_i\}$. By (8.7), this is greater than $n_0 R$. Denoting by $\tilde{p}_e(n, N)$ the minimal error probability for $\tilde{\Phi}$, we have

$$p_e\left(nn_0, 2^{(nn_0)R}\right) \leq \tilde{p}_e\left(n, 2^{n(n_0R)}\right), \tag{8.10}$$

since every code of size N for $\tilde{\Phi}$ is also a code of the same size for Φ. Thus, having chosen $R < \bar{C}(\Phi)$, we can make the right-hand side and hence the left-hand side of (8.10) tend to zero as $n \to \infty$. Via the same argument as in Proposition 5.15 we can prove that $p_e\left(n', 2^{n'R}\right) \to 0$, when $n' \to \infty$, and hence (8.6) follows. □

10.8.2 8.2 The χ-Capacity

We shall call the quantity $C_\chi(\Phi)$, defined in (8.5), the χ-capacity of the channel Φ. Thus,

$$C_\chi(\Phi) = \sup_\pi \left[H\left(\sum_i \pi_i \Phi\left[S_i\right]\right) - \sum_i \pi_i H\left(\Phi\left[S_i\right]\right)\right], \tag{8.11}$$

where $\pi = \{\pi_i, S_i\}$. It can also be rewritten as

$$C_\chi(\Phi) = \sup_{S \in \mathfrak{S}(\mathcal{H})} \left[H(\Phi(S)) - \hat{H}_\Phi(S)\right] \tag{8.12}$$

where the new channel characteristic

$$\hat{H}_\Phi[S] = \inf_{\pi: \sum_i \pi_i S_i = S} \sum_i \pi_i H\left(\Phi\left[S_i\right]\right) \tag{8.13}$$

was introduced, which is called the convex hull of the output entropy $H(\Phi[S])$. Here, the infimum is taken over all ensembles $\pi = \{\pi_i, S_i\}$, with the fixed average state $\sum_i \pi_i S_i = S$. Note that, by concavity of the quantum entropy, it is sufficient to take the infimum with respect to the convex decompositions of S into the pure states S_i.

Exercise 8.3 Prove that for the ideal channel $\hat{H}_{\mathrm{id}}(S) \equiv 0$. Hint: consider the spectral decomposition of S.

The quantity (8.13) is closely related to the entanglement of formation (7.32), namely,

$$\hat{H}_\Phi(S) = E_F\left(VSV^*\right),$$

where V is the isometry in the Stinespring representation (6.7) of the channel Φ, so that VSV^* is the state of the composite system "output-environment." The proof of the following lemma is similar to that of Proposition 7.24, with the dimensionality $d_1 d_2$ of $\mathcal{H}_1 \otimes \mathcal{H}_2$ replaced with the dimensionality d_1 of $\mathcal{H}_1$.

Lemma 8.4. The convex hull of the output entropy $\hat{H}_\Phi(S)$ is a continuous convex function on $\mathfrak{S}(\mathcal{H})$. The infimum in (8.13) is attained on an ensemble consisting of no more than d_A^2 pure states, $d_A = \dim \mathcal{H}_A$.

Corollary 8.5. The supremum in the expression (8.11) for the χ-capacity is attained on an ensemble consisting of no more than d_A^2 pure states.

Exercise 8.6 By using Exercise 4.8, show that an ensemble $\pi = \{\pi_i, S_i\}$ with the average state $\bar{S}_\pi = \sum_i \pi_i S_i$ is optimal for the supremum in expression (8.11) if and only if the following maximal distance condition holds: there exists a positive μ such that

$$H\left(\Phi[S]; \Phi\left[\bar{S}_\pi\right]\right) \leq \mu, \qquad \text{for all (pure) input states } S, \tag{8.14}$$

with equality for members $S = S_i$ of the ensemble with $\pi_i > 0$. In this case, necessarily, $\mu = C_X(\Phi)$. Hint:

$$\frac{\partial}{\partial \pi_j} \chi\left(\{\pi_i\}; \{\Phi\left[S_i\right]\}\right) = H\left(\Phi\left[S_j\right]; \Phi\left[\bar{S}_\pi\right]\right) - \log \mathrm{e}.$$

The χ-capacity can be computed for a number of interesting channels.

Exercise 8.7 Show that $C_X(\mathrm{Id}) = \log d$ for the ideal channel in d-dimensional Hilbert space. For the quantum erasure channel $C_X(\Phi_p) = (1-p)\log d$, where p is the probability of erasure. In both cases the optimal ensemble consists of equiprobable pure states corresponding to an orthonormal basis in $\mathcal{H}$.

Proposition 8.8. Let Φ be a covariant channel (see Section 6.7),

$$\Phi\left[U_g^A S \left(U_g^A\right)^*\right] = U_g^B \Phi[S] \left(U_g^B\right)^*.$$

If the representation U_g^A is irreducible (in which case Φ is called irreducibly covariant),

$$C_\chi(\Phi) = H\left(\Phi\left[\frac{I_A}{d_A}\right]\right) - \min_S H(\Phi[S]), \tag{8.15}$$

where the minimum is taken over the set of pure states.

Proof. Assume first that the symmetry group is finite. Irreducibility of the representation means that it has no nontrivial invariant subspaces, which is equivalent to the following: any operator that commutes with all U_g^A is a multiple of the unit operator. It follows, similar to the proof of relation (6.53), that for all states S

$$\frac{1}{|G|}\sum_{g\in G} U_g^A S \left(U_g^A\right)^* = \frac{I_A}{d_A}. \tag{8.16}$$

Let us show that

$$\max_{S\in\mathfrak{S}(\mathcal{H})} H(\Phi[S]) = H\left(\Phi\left[\frac{I_A}{d_A}\right]\right). \tag{8.17}$$

This follows from the fact that the function $S \to H(\Phi[S])$ is concave and invariant with respect to the transformations $S \to U_g^A S U_g^{A*}$. Therefore, for arbitrary state S,

$$\begin{aligned} H(\Phi[S]) &= |G|^{-1}\sum_{g\in G} H\left(\Phi\left[U_g^A S \left(U_g^A\right)^*\right]\right) \\ &\le H\left(\Phi\left[|G|^{-1}\sum_{g\in G} U_g^A S \left(U_g^A\right)^*\right]\right) \end{aligned}$$

The inequality $\le$ in (8.15) then follows from (8.16), and it is sufficient to show that

$$C_\chi(\Phi) \ge H\left(\Phi\left[\frac{I_A}{d_A}\right]\right) - \min_S H(\Phi[S]). \tag{8.18}$$

Let us choose a state S_0 that minimizes the output entropy. Since the entropy is concave, it attains the minimum on pure states. Then the value in the right-hand side of (8.15) is attained for the ensemble of states $S_g = U_g^A S_0 U_g^{A*}$, $g \in G$, with equal probabilities $\pi_g = |G|^{-1}$.

If the group is continuous, a similar argument applies, but the optimizing distribution will be continuous, namely, the uniform distribution on G. One can then use a finite approximation and the continuity of the entropy.

Example 8.9. For the depolarizing channel (6.49)

$$C_\chi(\Phi) = \log d + \left(1 - p\frac{d-1}{d}\right)\log\left(1 - p\frac{d-1}{d}\right) + p\frac{d-1}{d}\log\frac{p}{d} \tag{8.19}$$

which is achieved for an ensemble of equiprobable, orthogonal pure states forming an orthonormal basis in $\mathcal{H}$.

Indeed, the channel is irreducibly covariant, hence (8.15) applies. The output entropy is concave. Hence, it achieves the minimum on the set of pure states. For an arbitrary pure input state, the output $\Phi[|\psi\rangle\langle\psi|]$ has the simple eigenvalue $\left(\ 1-p\frac{d-1}{d}\ \right)$ and $d-1$ eigenvalues $\frac{p}{d}$. Hence, the output entropy has the same value

$$-\left(1-p\frac{d-1}{d}\right)\log\left(1-p\frac{d-1}{d}\right)-p\frac{d-1}{d}\log\frac{p}{d}$$

for all pure input states, and (8.19) follows.

Example 8.10. Let us compute the χ-capacity of an arbitrary qubit unital channel Φ. Such a channel is irreducibly covariant with respect to the representation (6.65) (see Exercise 6.44). Hence, we can again apply Proposition 8.8.

In computing $\min_{S\in\mathfrak{S}(\mathcal{H})} H(\Phi(S))$ it is sufficient to consider $\Phi=\Lambda$, by taking into account the unitary invariance of the quantum entropy. We also remark that by Exercise 2.5 the entropy of the qubit state (2.8) is equal to

$$H(S(\vec{a}))=h_2\left(\frac{1-|\vec{a}|}{2}\right) \tag{8.20}$$

Now, the Bloch ball is contracted, by the channel Λ, to the ellipsoid with lengths of the axes $|\lambda_y|\,,\gamma=x,y,z$, and the minimal output entropy is attained at the top of the longest axis, which corresponds to the state with the eigenvalues $\frac{1\pm\max_y|\lambda_y|}{2}$. This gives the χ-capacity

$$C_\chi(\Phi)=1-h_2\left(\frac{1-\max_y|\lambda_y|}{2}\right). \tag{8.21}$$

10.8.3 8.3 The Additivity Problem

10.8.4 8.3.1 The Effect of Entanglement in Encoding and Decoding

Several interesting and difficult mathematical problems in quantum information theory are related to the proof or disproof of the additivity property, i.e.,

$$C_\chi\left(\Phi_1\otimes\Phi_2\right)=C_\chi\left(\Phi_1\right)+C_\chi\left(\Phi_2\right), \tag{8.22}$$

for some channels Φ_1,Φ_2. Obviously, always

$$C_\chi\left(\Phi_1\otimes\Phi_2\right)\geq C_\chi\left(\Phi_1\right)+C_\chi\left(\Phi_2\right).$$

If (8.22) is fulfilled for the channel $\Phi=\Phi_1$ and an arbitrary channel Φ_2, then

$$C_\chi\left(\Phi^{\otimes n}\right)=nC_\chi(\Phi) \tag{8.23}$$

and due to relation (8.4) the classical capacity of the channel Φ is equal to the χ-capacity,

$$C(\Phi)=C_\chi(\Phi) \tag{8.24}$$

Property (8.22) was established for some important classes of channels $\Phi=\Phi_1$ (and arbitrary Φ_2) such as entanglement-breaking channels (Shor [215]), unital qubit channels (King [150]), depolarizing channels (King [151]), and several others. In particular, equality (8.24) holds for the classical capacity of all these channels. There was a strong belief that the additivity should hold for arbitrary channels Φ_1,Φ_2, supported by the absence of counterexamples and intensive numerical search in low dimensions. However, it was finally shown that in very high dimensions there exist channels that violate (8.22), (8.23), (8.24). We will discuss these results in Section 8.3.5.

The additivity of the Shannon capacity for classical channels, after all, relies upon the absence of entanglement in the classical systems. To see this, let us try to generalize the classical proof based on the Kuhn-Tucker conditions (see Proposition 4.9) to the quantum case. Let Φ_1, Φ_2 be two channels with the optimal ensembles having averages $\bar{S}_{\pi^1}, \bar{S}_{\pi^2}$. We wish to prove that

$$C_\chi(\Phi_1 \otimes \Phi_2) \leq C_\chi(\Phi_1) + C_\chi(\Phi_2). \tag{8.25}$$

Then condition (8.14), applied to the product channel $\Phi_1 \otimes \Phi_2$, requires the inequality

$$H\left((\Phi_1 \otimes \Phi_2)[S_{12}]; (\Phi_1 \otimes \Phi_2)\left[\bar{S}_{\pi^1} \otimes \bar{S}_{\pi^2}\right]\right) \leq C_\chi(\Phi_1) + C_\chi(\Phi_2) \tag{8.26}$$

to hold for all pure input states S_{12} of the product channel. Moreover, equality must hold for the tensor products of the members of the optimal ensembles with positive probabilities, which easily follows from the corresponding equalities for the channels Φ_1, Φ_2, as well as inequality (8.26) for product states. However, proving (8.26) for entangled states is no simpler than proving the inequality

$$C_\chi(\Phi_1 \otimes \Phi_2) \leq C_\chi(\Phi_1) + C_\chi(\Phi_2)$$

which is the main problem with (8.22), since the opposite inequality follows from the definition of C_χ.

Additivity of $C_\chi(\Phi)$ would have a surprising physical consequence - it would mean that using entangled input states does not increase the classical capacity of a quantum channel. However, as shown in Section 5.4, using entangled observables at the output of any essentially quantum channel (i.e., a channel with noncommuting output states) increases the capacity. From this point of view it is surprising that the additivity of $C_\chi(\Phi)$ is a rather widespread phenomenon. Let us discuss entangled inputs in more detail.

The encoding $\Sigma^{(n)} = \left\{S_i^{(n)}\right\}$ in Definition 8.1 of a code will be called unentangled if

$$S_i^{(n)} = \sum_{\chi^n} p(\chi^n \mid i)\, S_{x_1} \otimes \cdots \otimes S_{x_n} \tag{8.27}$$

where S_{x_k} is a state in the k th copy of the space $\mathcal{H}_A$ and $p(x^n \mid i)$ is a conditional probability describing preliminary processing of the input message. Let us recall that a decoding $M^{(n)}$ is unentangled if it has the form (5.36).

Given a quantum channel Φ, one can define the four classical capacities $C_{1,1}, C_{1,\infty}$, $C_{\infty,1}, C_{\infty,\infty}$, where the first (second) index refers to the inputs (outputs), ∞ means using arbitrary entangled inputs (outputs), and 1 means restriction to unentangled inputs (outputs) in Definition 8.1 and correspondingly in formula (8.3). By definition,

$$C_{\infty,\infty} = C(\Phi)$$

Exercise 8.11 Show, by using (8.27), the data-processing inequality (4.20), and the Shannon coding theorem, Theorem 4.13, that

$$C_{1,1} = \max_{\pi, M} \mathcal{I}_1(\pi, M).$$

Here, π is an arbitrary ensemble at the input of the channel Φ, and M is an arbitrary observable at the output.

The quantity $C_{1,1}$ is sometimes called the Shannon capacity of the quantum channel Φ.

Exercise 8.12 By using the coding theorem, Theorem 5.4 for c-q channels, show that

$$C_{1,\infty} = C_X(\Phi).$$

The relations between these four capacities are shown in the following diagram:

$$\begin{array}{c} C_{\infty,1} \leq C_{\infty,\infty} (= C) \\ \| \quad \| \\ C_{1,1} \leq C_{1,\infty} \, (= C_\chi) \, , \end{array} \tag{8.28}$$

where $\leq$ should be understood as "always less than or equal to, and strictly less for some channels."

The equality

$$C_{1,1} = C_{\infty,1} \tag{8.29}$$

shows that using entangled input states with unentangled output measurements does not increase the accessible information. It will be proved below. The upper inequality $C_{\infty,1} \neq C_{\infty,\infty}$ follows from this and from the lower inequality, which expresses the strict superadditivity with respect to the output measurements demonstrated in Section 5.4.

Proof of equality (8.29). Let Φ be a channel, let π be a probability distribution, assigning probability π_k to a state S_k at the input of the channel, and let $M = \{M_j\}$ be the observable measured at the output of the channel. Denote by $\mathcal{I}_\Phi(\pi, M)$ the Shannon information corresponding to the input probability distribution $\{\pi_k\}$ and transition probability $p(j \mid k) = \operatorname{Tr} \Phi \left[S_k\right] M_j = \operatorname{Tr} S_k \Phi^* \left[M_j\right]$. In order to prove (8.29), it is sufficient to establish the inequality

$$\begin{aligned} \max_{\{\pi, M^1, M^2\}} \mathcal{I}_{\Phi_1 \otimes \Phi_2} \left(\pi, M^1 \otimes M^2\right) \leq & \max_{\{\pi^1, M^1\}} \mathcal{I}_{\Phi_1} \left(\pi^1, M^1\right) \\ & + \max_{\{\pi^2, M^2\}} \mathcal{I}_{\Phi_2} \left(\pi^2, M^2\right) \end{aligned} \tag{8.30}$$

In terms of the classical mutual information

$$\mathcal{I}_\Phi(\pi, M) = I(X; Y),$$

where X is the input random variable, taking values k, and Y is the output random variable, taking values j. In order to prove (8.30), consider the states S_k in the Hilbert space $\mathcal{H}_1 \otimes \mathcal{H}_2$ of the channel $\Phi_1 \otimes \Phi_2$, with a product observable $M^1 \otimes M^2$. In this case, the conditional probability is

$$p\left(j_1, j_2 \mid k\right) = \operatorname{Tr} S_k \left(\Phi_1^* \left[M_{j_1}^1\right] \otimes \Phi_2^* \left[M_{j_2}^2\right]\right) = p^1 \left(j_1 \mid j_2, k\right) p^2 \left(j_2 \mid k\right), \tag{8.31}$$

where

$$p^1 \left(j_1 \mid j_2, k\right) = \operatorname{Tr} S_{j_2,k}^1 \Phi_1^* \left[M_{j_1}^1\right], \quad p^2 \left(j_2 \mid k\right) = \operatorname{Tr} S_k^2 \Phi_2^* \left[M_{j_2}^2\right]$$

and

$$S_k^2 = \operatorname{Tr}_1 S_k, \quad S_{j_2,k}^1 = \frac{\operatorname{Tr}_2 S_k \left(I \otimes \Phi_2^* \left[M_{j_2}^2\right]\right)}{\operatorname{Tr} S_k \left(I \otimes \Phi_2^* \left[M_{j_2}^2\right]\right)}$$

Here, Tr_s denotes the partial trace in the sth subsystem ($s = 1, 2$) in $\mathcal{H}_1 \otimes \mathcal{H}_2$.
We then have

$$I\left(X; Y_1 Y_2\right) = H\left(Y_1 Y_2\right) - H\left(Y_1 Y_2 \mid X\right)$$

where $H(\cdot), H(\cdot \mid \cdot)$ are the entropy and conditional entropy, respectively, of the random variables describing the common classical input (X) and the outputs (Y_1, Y_2) of the two channels. By the subadditivity of the classical entropy,

$$H(Y_1Y_2) \leq H(Y_1) + H(Y_2)$$

On the other hand,

$$H(Y_1Y_2 \mid X) = H(Y_1 \mid Y_2X) + H(Y_2 \mid X).$$

Combining, we get

$$I(X; Y_1Y_2) \leq I(XY_2; Y_1) + I(X; Y_2),$$

which, due to (8.31), amounts to

$$\mathcal{I}_{\Phi_1 \otimes \Phi_2}\left(\pi, M^1 \otimes M^2\right) \leq \mathcal{I}_{\Phi_1}\left(\pi^1, M^1\right) + \mathcal{I}_{\Phi_2}\left(\pi^2, M^2\right)$$

where π^1 is the probability distribution that assigns a probability $\pi_k p^2(j_2 \mid k)$ to the state $S^1_{j_2,k}$, and π^2 is the probability distribution that assigns probability π_k to the state S^2_k. Taking the maximum over π and S gives (8.30).

10.8.5 8.3.2 A Hierarchy of Additivity Properties

An important characteristic of a quantum channel Φ, which already appeared in Section 8.2, is the minimal output entropy

$$\check{H}(\Phi) = \min_{S \in \mathfrak{S}(\mathcal{H})} H(\Phi[S]). \tag{8.32}$$

The corresponding hypothetical additivity property is

$$\check{H}(\Phi_1 \otimes \Phi_2) = \check{H}(\Phi_1) + \check{H}(\Phi_2). \tag{8.33}$$

By the concavity of the entropy, the minimum in (8.32) is attained on a pure state $S \in \operatorname{extr} \mathfrak{S}(\mathcal{H})$. Therefore, the classical analog of the quantity $\check{H}(\Phi)$ is additive, because any pure state of a composite classical system is a product of the pure states of the subsystems. Instead, for a tensor product $\mathcal{H}_1 \otimes \mathcal{H}_2$ describing a composite quantum system, one has

$$\operatorname{extr} \mathfrak{S}(\mathcal{H}_1 \otimes \mathcal{H}_2) \supsetneqq \operatorname{extr} \mathfrak{S}(\mathcal{H}_1) \times \operatorname{extr} \mathfrak{S}(\mathcal{H}_2), \tag{8.34}$$

due to the presence of the entangled states. Hence, there is no obvious reason for the additivity (8.33) in the quantum case.

Clearly, inequality $\leq$ always holds in (8.33). This implies that (8.33) obviously holds for channels with zero minimal output entropy, i.e., those for which there exists a pure output state, such as an ideal channel.

Exercise 8.13 Prove the following statement: the additivity properties (8.22) and (8.33) are equivalent for a pair of covariant channels satisfying the conditions of Proposition 8.8. Hint: use the fact that the tensor product of the irreducible representations of two symmetry groups G_1, G_2 is an irreducible representation of the group $G_1 \times G_2$.

Exercise 8.14 Consider the minimal entropy gain

$$\check{G}(\Phi) = \min_{S \in \mathfrak{S}(\mathcal{H})} (H(\Phi[S]) - H(S)).$$

Use the superadditivity property (7.21) to show that it is additive, i.e.,

$$\check{G}\left(\Phi_1 \otimes \Phi_2\right) = \check{G}\left(\Phi_1\right) + \check{G}\left(\Phi_2\right). \tag{8.35}$$

Now consider the convex hull $\hat{H}_\Phi(S)$ of the output entropy, defined by relation (8.13). The hypothetical superadditivity property for this quantity is formulated in the following way: for arbitrary state $S_{12} \in \mathfrak{S}\left(\mathcal{H}_1 \otimes \mathcal{H}_2\right)$ and channels Φ_1, Φ_2

$$\hat{H}_{\Phi_1 \otimes \Phi_2}\left(S_{12}\right) \geq \hat{H}_{\Phi_1}\left(S_1\right) + \hat{H}_{\Phi_2}\left(S_2\right), \tag{8.36}$$

where S_1, S_2 are the partial traces of S_{12} in $\mathcal{H}_1, \mathcal{H}_2$.
This superadditivity property is maximal in the sense that its validity for a pair of channels Φ_1, Φ_2 implies all the other additivity properties for this pair of channels.

Proposition 8.15. For two given channels Φ_1, Φ_2 the superadditivity property (8.36) implies both the additivity of the minimal output entropy (8.33) and of the χ-capacity (8.22).

Proof. Indeed, let S_{12}^0 be a minimizer for $H\left(\left(\Phi_1 \otimes \Phi_2\right)\left[S_{12}\right]\right)$. In this case,

$$\begin{aligned}\check{H}\left(\Phi_1 \otimes \Phi_2\right) &= H\left(\left(\Phi_1 \otimes \Phi_2\right)\left[S_{12}^0\right]\right) = \hat{H}_{\Phi_1 \otimes \Phi_2}\left(S_{12}^0\right) \\ &\geq \hat{H}_{\Phi_1}\left(S_1^0\right) + \hat{H}_{\Phi_2}\left(S_2^0\right) \geq \check{H}\left(\Phi_1\right) + \check{H}\left(\Phi_2\right),\end{aligned}$$

from which (8.33) follows. On the other hand, (8.36) and the subadditivity of the quantum entropy imply

$$\begin{aligned}&H\left(\left(\Phi_1 \otimes \Phi_2\right)\left[S_{12}\right]\right) - \hat{H}_{\Phi_1 \otimes \Phi_2}\left(S_{12}\right) \\ &\quad \leq H\left(\left(\Phi_1 \otimes \Phi_2\right)\left[S_{12}\right]\right) - \hat{H}_{\Phi_1}\left(S_1\right) - \hat{H}_{\Phi_2}\left(S_2\right) \\ &\quad \leq \left[H\left(\Phi_1\left[S_1\right]\right) - \hat{H}_{\Phi_1}\left(S_1\right)\right] + \left[H\left(\Phi_2\left[S_2\right]\right) - \hat{H}_{\Phi_2}\left(S_2\right)\right]\end{aligned} \tag{8.37}$$

By using (8.12), we get

$$C_\chi\left(\Phi_1 \otimes \Phi_2\right) \leq C_\chi\left(\Phi_1\right) + C_\chi\left(\Phi_2\right),$$

i. e., (8.22). □

Moreover, the property (8.36) is closely related to the additivity of the χ-capacity with input constraints. Let F be a positive operator in the input Hilbert space $\mathcal{H}$ of the channel, and let E be a positive constant. Consider the χ-capacity under the linear constraint $\operatorname{Tr} SF \leq E$ on the input state S, i.e.,

$$C_\chi(\Phi, F, E) = \max_{S:\operatorname{Tr} SF \leq E}\left[H(\Phi[S]) - \hat{H}_\Phi(S)\right]. \tag{8.38}$$

Exercise 8.16 Assume that we have two channels Φ_1, Φ_2 with corresponding constraint operators F_1, F_2. Then inequality (8.36), along with (8.12), implies

$$\begin{aligned}C_X\left(\Phi_1 \otimes \Phi_2, F_1 \otimes I_2 + I_1 \otimes F_2, E\right) = \max_{E_1+E_2=E}[&C_X\left(\Phi_1, F_1, E_1\right) \\ &+C_X\left(\Phi_2, F_2, E_2\right)].\end{aligned} \tag{8.39}$$

The property of superadditivity (8.36) is closely related to the following hypothetical property of the entanglement of formation: let $\mathcal{H}_1 = \mathcal{H}_1^A \otimes \mathcal{H}_1^B$ and $\mathcal{H}_2 = \mathcal{H}_2^A \otimes \mathcal{H}_2^B$, and let S_{12}^{AB} be a state in $\mathcal{H}_1 \otimes \mathcal{H}_2$; then

$$E_F\left(S_{12}^{AB}\right) \geq E_F\left(S_1^{AB}\right) + E_F\left(S_2^{AB}\right), \tag{8.40}$$

where the entanglement of formation is defined relative to the subdivision $A \mid B$. Namely, if property (8.40) would hold for all states S_{12}^{AB}, this would imply (8.36) for all channels Φ_1, Φ_2 and all states S_{12}, while if (8.36) would hold for all states S_{12} and partial trace channels, (8.40) would hold for all states S_{12}^{AB}.

The most complete conditional result in this direction is the following,

Theorem 8.17. The conjectured properties (8.33), (8.22), (8.23), and (8.36) are globally equivalent in the following sense: assuming that one of them holds for all channels Φ_1, Φ_2, any other is also true for all channels. Moreover, they are globally equivalent to the superadditivity of the entanglement of formation (8.40) and to the additivity of the χ-capacity with arbitrary input constraints.

When (parts of this) theorem were proved, there was hope that it would help to reduce the proof of more complicated global conjectures, such as additivity of the χ-capacity or superadditivity of entanglement of formation to a seemingly less complicated one - the global additivity of the minimal output entropy. However, with the disproof of the last conjecture, this theorem implies that none of the additivity properties holds globally (see Section 8.4 for more detail).

We will not consider the proof of this theorem here; instead we discuss some restricted classes of channels for which the maximal property (8.36) can be proved.

10.8.6 8.3.3 Some Entropy Inequalities

Here, we obtain inequalities that allow us to prove, in some cases, the superadditivity of the convex hull (8.36) and hence the additivity of the minimal output entropy (8.33) and of the χ-capacity (8.22).

Consider a state S and a nonideal measurement, described by a collection of operators A_k that satisfy the normalization condition $\sum_k A_k^* A_k = I$, so that an outcome k occurs with probability $\pi_k = \operatorname{Tr} S A_k^* A_k$, resulting in a posterior state of the system $S_k = A_k S A_k^* / \pi_k$. The entropies of the initial and posterior states are related by the Lindblad-Ozawa inequality

$$H(S) \geq \sum_k \pi_k H\left(S_k\right). \tag{8.41}$$

Proof. To prove this, take $\mathcal{H} = \mathcal{H}_1$ and consider a purification $|\psi\rangle$ of the state S in $\mathcal{H}_1 \otimes \mathcal{H}_2$. Then

$$\pi_k S_k = \operatorname{Tr}_{\mathcal{H}_2} \left(A_k \otimes I\right) |\psi\rangle\langle\psi| \left(A_k \otimes I\right)^*,$$

and $S_2 = \operatorname{Tr}_{\mathcal{H}_1} |\psi\rangle\langle\psi| = \sum_k \pi_k S_2^k$, where

$$\pi_k S_2^k = \operatorname{Tr}_{\mathcal{H}_1} \left(A_k \otimes I\right) |\psi\rangle\langle\psi| \left(A_k \otimes I\right)^*.$$

Using Theorem 3.10 twice and applying the concavity of the quantum entropy,

$$H(S) = H\left(S_2\right) = H\left(\sum_k \pi_k S_2^k\right) \geq \sum_k \pi_k H\left(S_2^k\right) = \sum_k \pi_k H\left(S_k\right).$$

□

A particular case of the above is the following inequality for composite systems. Let S_{12} be a state of the composite system 12 and let $\{|e_k^2\rangle\}$ be an orthonormal basis in $\mathcal{H}_2$. Taking $A_k = I_1 \otimes |e_k^2\rangle \langle e_k^2|$, one obtains

$$H\left(S_{12}\right) \geq \sum_k \pi_k H\left(S_1^k\right), \tag{8.42}$$

where $\pi_k S_1^k = \langle e_k^2| S_{12} |e_k^2\rangle$. This can be used to prove a particular case of the additivity conjecture.

Proposition 8.18. The maximal property (8.36) holds in the case where $\Phi_1 = \Phi$ is an arbitrary channel in $\mathcal{H}_1$ and $\Phi_2 = \mathrm{Id}_2$ is the ideal channel in $\mathcal{H}_2$.

Proof. Since $\hat{H}_{\mathrm{Id}}(S) \equiv 0$, according to Exercise 8.3, we have to prove that

$$\hat{H}_{(\Phi\otimes I\ \mathrm{d}_2)}(S_{12}) \geq \hat{H}_\Phi(S_1). \tag{8.43}$$

Let $S_{12} = \sum_i \pi_i S_{12}^i$ be the optimal decomposition, i. e.,

$$\hat{H}_{(\Phi\otimes \mathrm{Id}_2)}(S_{12}) = \sum_i \pi_i H\left((\Phi\otimes \mathrm{Id}_2)\left[S_{12}^i\right]\right).$$

By using (8.42), we obtain

$$\sum_i \pi_i H\left((\Phi\otimes \mathrm{Id}_2)\left[S_{12}^i\right]\right) \geq \sum_{ik} \pi_i\pi_{ik} H\left(\Phi\left[S_1^{ik}\right]\right) \tag{8.44}$$

where $\pi_{ik} S_1^{ik} = \langle e_k^2| S_{12}^i |e_k^2\rangle$. Now, we have the decomposition of S_1 into the states S_1^{ik} with probabilities $\pi_i\pi_{ik}$ for channel Φ. Hence, the right-hand side of (8.44) is greater than or equal to $\hat{H}_\Phi(S_1)$. □

Proposition 8.19. The maximal property (8.36) (and hence the additivity of the minimal output entropy (8.33) and of the χ-capacity (8.22)) holds in the case where $\Phi_1 = \Phi$ is an entanglement-breaking channel (see Section 6.4) and $\Phi_2 = \Psi$ is an arbitrary channel.

Lemma 8.20. Let $\pi_j \geq 0, \sum \pi_j = 1$, and S_1^j, S_2^j be arbitrary states of the systems 1,2 . Then

$$H\left(\sum_j \pi_j S_1^j \otimes S_2^j\right) \geq H\left(\sum_j \pi_j S_1^j\right) + \sum_j \pi_j H\left(S_2^j\right).$$

Proof. We introduce the notation

$$\left(\bar{S}_{12}\right)_\pi = \sum_j \pi_j S_1^j \otimes S_2^j, \quad \left(\bar{S}_1\right)_\pi = \sum_j \pi_j S_1^j$$

Now, using the additivity of the entropy, the inequality can be rewritten as

$$H\left(\left(\bar{S}_{12}\right)_\pi\right) - \sum_j \pi_j H\left(S_1^j \otimes S_2^j\right) \geq H\left(\left(\bar{S}_1\right)_\pi\right) - \sum_j \pi_j H\left(S_1^j\right),$$

which by identity (7.19) is equivalent to

$$\sum_j \pi_j H\left(S_1^j \otimes S_2^j; \left(\bar{S}_{12}\right)_\pi\right) \geq \sum_j \pi_j H\left(S_1^j; \left(\bar{S}_1\right)_\pi\right).$$

However, the last inequality follows from the monotonicity of the relative entropy (with respect to partial trace in the second system). □

Proof. Coming back to the proof of the proposition, assume that Φ is an entanglement-breaking channel, so that $\Phi[S] = \sum_j S_1^j \operatorname{Tr} S M_1^j$, where $\left\{M_1^j\right\}$ is an observable in system 1 . In this case,

$$(\Phi\otimes \mathrm{Id}_2)[S_{12}] = \sum_j p_j S_1^j \otimes S_2^j, \tag{8.45}$$

where $p_j S_2^j = \operatorname{Tr}_{\mathcal{H}_1} S_{12}\left(M_1^j \otimes I_2\right)$ for an arbitrary state S_{12} of the composite system. Taking the partial trace, we obtain, in particular,

$$\Phi\left[S_1\right] = \sum_j p_j S_1^j, \quad S_2 = \sum_j p_j S_2^j. \tag{8.46}$$

If Ψ is an arbitrary channel in system 2,

$$(\Phi \otimes \Psi)\left[S_{12}\right] = \sum_j p_j S_1^j \otimes \Psi\left[S_2^j\right]. \tag{8.47}$$

We have

$$\hat{H}_{\Phi\otimes\Psi}\left(S_{12}\right) = \inf \sum_i \pi_i H\left((\Phi \otimes \Psi)\left[S_{12}^i\right]\right), \tag{8.48}$$

where $S_{12} = \sum_i \pi_i S_{12}^i$ is an arbitrary decomposition. By writing relation (8.45) for S_{12}^i we obtain

$$(\Phi \otimes \mathrm{Id}_2)\left[S_{12}^i\right] = \sum_j p_{ij} S_1^{ij} \otimes S_2^{ij}$$

along with the decompositions

$$S_1 = \sum_i \pi_i S_1^i, \quad S_2 = \sum_{ij} \pi_i p_{ij} S_2^{ij}. \tag{8.49}$$

By using (8.47), the lemma that we just proved, and (8.46), we obtain

$$\begin{aligned} H\left((\Phi \otimes \Psi)\left[S_{12}^i\right]\right) &= H\left(\sum_j p_{ij} S_1^{ij} \otimes \Psi\left[S_2^{ij}\right]\right) \\ &\geq H\left(\sum_j p_{ij} S_1^{ij}\right) + \sum_j p_{ij} H\left(\Psi\left[S_2^{ij}\right]\right) \\ &\geq H\left(\Phi\left[S_1^i\right]\right) + \sum_j p_{ij} H\left(\Psi\left[S_2^{ij}\right]\right) \end{aligned}$$

which in combination with (8.48) and (8.49) implies

$$\hat{H}_{\Phi\otimes\Psi}\left(S_{12}\right) \geq \hat{H}_\Phi\left[S_1\right] + \hat{H}_\Psi\left[S_2\right].$$

□

10.8.7 8.3.4 Additivity for Complementary Channels

Lemma 8.21. If S is a pure state, then it holds for any channel Φ,

$$H(\Phi[S]) = H(\tilde{\Phi}[S]), \tag{8.50}$$

where $\tilde{\Phi}$ is the complementary of Φ. Therefore, if either of the properties (8.36), (8.33) holds for channels Φ_1, Φ_2, the similar property holds for the complementary channels $\tilde{\Phi}_1, \tilde{\Phi}_2$.

Proof. As follows from the definition (6.38) of the complementary channels, the states $\Phi[S]$ and $\tilde{\Phi}[S]$ are partial states of the pure state VSV^*. Hence, by equality (7.30), they have equal entropies.

From (8.50) we conclude

$$\check{H}(\Phi) = \check{H}(\tilde{\Phi}), \quad \hat{H}_\Phi(S) = \hat{H}_{\tilde{\Phi}}(S)$$

for an arbitrary state S, due to the expressions for $\check{H}(\Phi), \hat{H}_\Phi(S)$ in terms of the output entropies for pure input states. Hence, the second statement follows. □

Proposition 8.19 then implies the following.

Corollary 8.22. The maximal property (8.36) (and hence the additivity of the minimal output entropy (8.33) and of the χ-capacity (8.22)) hold in the case where $\Phi_1 = \Phi$ is the channel (6.45), in particular, a dephasing channel, and $\Phi_2 = \Psi$ is an arbitrary channel.

Proposition 8.23. Let Φ_2 be an arbitrary channel. The maximal property (8.36) holds for Φ_1, Φ_2 if Φ_1 is an orthogonal convex sum (see Definition 6.33) of the ideal channel and a channel $\Phi^{(0)}$ such that the maximal property holds for $\Phi^{(0)}$ and Φ_2.

It follows that such a Φ_1 fulfills the additivity of the minimal output entropy (8.33) and of the χ-capacity (8.22), with an arbitrary Φ_2. For example, this holds for the erasure channel, because it is an orthogonal convex sum of the ideal channel and an entanglement-breaking channel for which the property (8.36) was established in Section 8.3.3.

Proof. Denote $\Phi^{(q)} = q\,\mathrm{Id} \oplus (1-q)\Phi^{(0)}$. Now,

$$H\left(\Phi^{(q)}[S]\right) = qH(S) + (1-q)H\left(\Phi^{(0)}[S]\right) + h_2(q),$$

where $h_2(q) = -q\log q - (1-q)\log(1-q)$ is the binary entropy and

$$\hat{H}_{\Phi^{(q)}}(S) = (1-q)\hat{H}_{\Phi^{(0)}}(S) + h_2(q), \tag{8.51}$$

because the minimum in the expression for $\hat{H}_{\Phi^{(0)}}(S)$ is attained for an ensemble of pure states S_j for which $H(S_j) = 0$. For an arbitrary channel Φ_2 we have

$$\Phi^{(q)} \otimes \Phi_2 = q\,(\mathrm{Id} \otimes \Phi_2) \oplus (1-q)\left(\Phi^{(0)} \otimes \Phi_2\right).$$

Then

$$\begin{aligned}\hat{H}_{\Phi^{(q)}\otimes\Phi_2}(S_{12}) &\geq q\hat{H}_{\mathrm{Id}\otimes\Phi_2}(S_{12}) + (1-q)\hat{H}_{\Phi^{(0)}\otimes\Phi_2}(S_{12}) + h_2(q)\\ &\geq q\hat{H}_{\Phi_2}(S_2) + (1-q)\left[\hat{H}_{\Phi^{(0)}}(S_1) + \hat{H}_{\Phi_2}(S_2)\right] + h_2(q),\end{aligned}$$

where we have used the superadditivity of $\hat{H}_{\mathrm{Id}\otimes\Phi_2}(S_{12}), \hat{H}_{\Phi^{(0)}\otimes\Phi_2}(S_{12})$ and the fact that $\hat{H}_{\mathrm{Id}}(S_1) \equiv 0$. By using (8.51), we obtain that the right-hand side is equal to $\hat{H}_{\Phi^{(q)}}(S_1) + \hat{H}_{\Phi_2}(S_2)$. □

Corollary 8.22 implies that Proposition 8.23 holds with the replacement of the ideal channel by its complementary, the completely depolarizing channel.

10.8.8 8.3.5 Nonadditivity of Quantum Entropy Quantities

The quantum Rényi entropy of order $p > 1$ of a density operator S is defined as

$$R_p(S) = \frac{1}{1-p}\log \mathrm{Tr}\, S^p, \tag{8.52}$$

and in the limit $p \to 1$ the quantum Rényi entropies converge uniformly to the von Neumann entropy of a density operator S,

$$\lim_{p\to 1} R_p(S) = -\mathrm{Tr}\, S\log S \equiv H(S).$$

Defining the minimal output Rényi entropy of the channel Φ as

$$\check{R}_p(\Phi) = \min_{S\in\mathfrak{S}(\mathcal{H})} R_p(\Phi[S]),$$

one may ask for an additivity property similar to (8.33), namely,

$$\check{R}_p\left(\Phi_1 \otimes \Phi_2\right) = \check{R}_p\left(\Phi_1\right) + \check{R}_p\left(\Phi_2\right). \tag{8.53}$$

Again, inequality $\leq$ is obvious here. Note that the validity of (8.53) for some specific channels Φ_1, Φ_2 and p close to 1 implies (8.33) for these Φ_1, Φ_2. This raised interest in the problem (8.53) in the hope that its solution could shed light on the additivity problems in quantum information theory.

A counterexample of the transpose-depolarizing channel [243] soon appeared, i. e.,

$$\Phi[S] = \frac{1}{d-1}\left(I - S^T\right), \tag{8.54}$$

for which (8.53) with $\Phi_1 = \Phi_2 = \Phi$ fails to hold for $d = \dim \mathcal{H} \geq 3$ and large enough p.

Exercise 8.24 Prove the complete positivity of the map (8.54) by establishing the Kraus representation

$$\Phi[S] = \frac{1}{2(d-1)} \sum_{j,k=1}^{d} \left(|e_j\rangle\langle e_k| - |e_k\rangle\langle e_j|\right) S \left(|e_k\rangle\langle e_j| - |e_j\rangle\langle e_k|\right), \tag{8.55}$$

where $\{e_j\}$ is an orthonormal basis.

A breakthrough in the negative solution of the global conjecture (8.53) came in 2007. Winter [255] had shown that in very high dimensions there always exist channels for which (8.53) does not hold for any $p > 2$. Next, Hayden [97] proved this for any $1 < p < 2$. Winter showed that the additivity of the Rényi entropy with $p > 2$ breaks for the pair of channels $\Phi, \bar{\Phi}$ (complex conjugate in a fixed basis), where

$$\Phi[S] = \frac{1}{n} \sum_{j=1}^{n} U_j S U_j^* \tag{8.56}$$

is the uniform mixture of unitary evolutions in $\mathcal{H}$ and $n, d = \dim \mathcal{H}$ are large enough. The proof relies upon the two estimates. A simple but efficient upper bound for $\check{R}_p(\Phi \otimes \bar{\Phi})$ is given by the inequality

$$\check{R}_p(\Phi \otimes \bar{\Phi}) \leq R_p(\Phi \otimes \bar{\Phi})[|\Omega\rangle\langle\Omega|] \leq \frac{p}{p-1} \log n, \tag{8.57}$$

where $|\Omega\rangle$ is the maximally entangled vector in the same basis. Indeed,

$$\begin{aligned}
(\Phi \otimes \bar{\Phi})[|\Omega\rangle\langle\Omega|] &= \frac{1}{n^2} \sum_{j,k=1}^{n} \left(U_j \otimes \bar{U}_k\right) |\Omega\rangle\langle\Omega| \left(U_j \otimes \bar{U}_k\right)^* \\
&= \frac{1}{n}|\Omega\rangle\langle\Omega| + \frac{1}{n^2} \sum_{j \neq k} \left(U_j \otimes \bar{U}_k\right) |\Omega\rangle\langle\Omega| \left(U_j \otimes \bar{U}_k\right)^* \\
&\geq \frac{1}{n}|\Omega\rangle\langle\Omega|,
\end{aligned}$$

where in the second equality we used the property $(U \otimes \bar{U})|\Omega\rangle = |\Omega\rangle$ for arbitrary unitary U. It follows that the maximal eigenvalue of the density operator $(\Phi \otimes \bar{\Phi})[|\Omega\rangle\langle\Omega|]$, i. e., its operator norm, is greater than or equal to $\frac{1}{n}$, i.e.,

$$\|(\Phi \otimes \bar{\Phi})[|\Omega\rangle\langle\Omega|]\| \geq \frac{1}{n}. \tag{8.58}$$

Hence,

$$R_p((\Phi\otimes\bar\Phi)[|\Omega\rangle\langle\Omega|]) \le \frac{1}{1-p}\log\left(\frac{1}{n}\right)^p = \frac{p}{p-1}\log n, \tag{8.59}$$

and (8.57) follows.

The next step is to consider random independent unitary operators $U_j, j = 1,\dots,n$, distributed according to the normalized Haar measure on the group of unitaries in $\mathcal{H}$. In this case, the expectation of each term in (8.56) is $\mathrm{E}U_jSU_j^* = I/d$, since it is the only density operator that is invariant under unitary conjugations, and one can expect that $\Phi[S]$ is close to I/d in a probabilistic sense for n large enough. A key ingredient of the proof is the large deviation estimate for the sums of random operators, inspired by the classical Bernstein-Chernoff-Hoeffding inequality, which implies that the probability of the inequality

$$\left\|\Phi[S] - \frac{I}{d}\right\| \le \frac{\varepsilon}{d} \tag{8.60}$$

tends to 1 when $d\to\infty, n\sim d\log d$ (compare this result with Theorem 10.34). From inequality (8.60) it follows that $\|\Phi[S]\| \le \frac{1+\varepsilon}{d}$ and hence

$$\operatorname{Tr}\Phi[S]^p = \operatorname{Tr}\Phi[S]\Phi[S]^{p-1} \le \|\Phi[S]\|^{p-1}\operatorname{Tr}\Phi[S] \le \left(\frac{1+\varepsilon}{d}\right)^{p-1} \tag{8.61}$$

so that

$$\check R_p(\Phi) = -\frac{1}{p-1}\max_{S\in\mathfrak{S}(\mathcal{H})}\log\operatorname{Tr}\Phi[S]^p \ge \log\frac{d}{1+\varepsilon}.$$

This implies the probabilistic lower bound

$$\lim_{d\to\infty}\mathrm{P}\left\{\check R_p(\Phi) \ge \log\frac{d}{1+\varepsilon}\right\} = 1$$

for random Φ of the form (8.56), with $n\sim d\log d$. Taking into account that $\check R_p(\Phi) = \check R_p(\bar\Phi)$, and comparing with (8.57), one sees that with probability close to 1 ,

$$\check R_p(\Phi\otimes\bar\Phi) \le \frac{p}{p-1}\log n < 2\log\left(\frac{d}{1+\varepsilon}\right) \le \check R_p(\Phi) + \check R_p(\bar\Phi)$$

if $p>2, d\to\infty, n\sim d\log d$.

The estimate (8.58) can be generalized to an arbitrary channel Φ as follows.

Lemma 8.25. Let Φ be a quantum channel from A to B which has the Kraus representation with d_E components, and let $|\Omega_{AA}\rangle$ be the maximally entangled vector in $\mathcal{H}_A\otimes\mathcal{H}_A$. Then

$$\left\|(\Phi\otimes\bar\Phi)\left[|\Omega_{AA}\rangle\langle\Omega_{AA}|\right]\right\| \ge \frac{d_A}{d_Bd_E} \equiv D. \tag{8.62}$$

Proof. We have

$$(\Phi\otimes\bar\Phi)\left[|\Omega_{AA}\rangle\langle\Omega_{AA}|\right] = \sum_{r,S=1}^{d_E}\left(V_r\otimes\bar V_S\right)|\Omega_{AA}\rangle\langle\Omega_{AA}|\left(V_r\otimes\bar V_S\right)^*$$

and

$$\langle\Omega_{BB}|\left(X\otimes Y\right)|\Omega_{AA}\rangle = \frac{1}{d_Ad_B}\operatorname{Tr}Y^\top X,$$

for any operators X, Y acting from $\mathcal{H}_A$ to $\mathcal{H}_B$.

By using these identities, we have

$$\begin{aligned}
\left\|(\Phi\otimes\bar{\Phi})\left[|\Omega_{AA}\rangle\langle\Omega_{AA}|\right]\right\| &\geq \langle\Omega_{BB}|\,(\Phi\otimes\bar{\Phi})\left[|\Omega_{AA}\rangle\langle\Omega_{AA}|\right]|\Omega_{BB}\rangle \\
&= \sum_{r,s=1}^{d_E}\left|\langle\Omega_{BB}|\left(V_r\otimes\bar{V}_s\right)|\,\Omega_{AA}\right\rangle|^2 \\
&= \frac{1}{d_A d_B}\sum_{r,s=1}^{d_E}|\mathrm{Tr}\,V_s^*V_r|^2 \\
&\geq \frac{1}{d_A d_B}\sum_{r=1}^{d_E}|\mathrm{Tr}\,V_r^*V_r|^2 \\
&\geq \frac{1}{d_A d_B d_E}\left|\mathrm{Tr}\sum_{r=1}^{d_E}V_r^*V_r\right|^2 \\
&= \frac{1}{d_A d_B d_E}|\mathrm{Tr}\,I_A|^2 = \frac{d_A}{d_B d_E}
\end{aligned}$$

where the Cauchy-Schwarz inequality was used. □

This estimate is one part of proving that in very high dimensions there exist channels that violate the additivity of the minimal Rényi entropies for all $p>1$ (Winter and Hayden [100]). To this end one considers the pair of channels $\Phi,\bar{\Phi}$, where Φ is a generic channel given by a general open system representation (6.22) with the random unitary evolution operator uniformly distributed over the group of unitaries. Moreover, $d_B=d_E=d\longrightarrow\infty$, and $d_A\sim d^{1+1/p}$ so that $D\sim d^{1/p-1}$. The upper bound

$$\check{R}_p(\Phi\otimes\bar{\Phi})\leqslant\log d \tag{8.63}$$

then follows from (8.62) similarly to (8.59).

The most difficult part of the proof is the probabilistic lower estimate

$$\lim_{d\to\infty}\mathrm{P}\left\{\check{R}_p(\Phi)\geq\log d-c\right\}=1, \tag{8.64}$$

which is also based on a large deviation phenomenon, namely, the measure concentration, used to establish the concentration of the output entropy. This is closely related to the early observations that, given a random uniformly distributed pure state vector $|\psi_{AB}\rangle$ of a composite system AB, the entropy of the partial state S_B of the smaller
system tends to its maximal value $\log d_B$ as $d_A\to\infty$, and hence S_B becomes almost chaotic while $|\psi_{AB}\rangle$ is almost maximally entangled.

The relations (8.63) and (8.64), together with $\check{R}_p(\Phi)=\check{R}_p(\Phi)$, imply that

$$\check{R}_p(\Phi\otimes\bar{\Phi})<\check{R}_p(\Phi)+\check{R}_p(\bar{\Phi})$$

with probability close to 1 .

Notably, these estimates for $p>1$ are not strong enough to imply the violation of additivity for $p\to1$ and the case of the minimal von Neumann entropy requires additional efforts which were accomplished by Hastings [93]. His original argument was improved and simplified in subsequent works [76], [34], and [13]. Following [34], consider the random unitary evolution channels with $d_B=d\longrightarrow\infty$, and $d_E=d_A\gg d$. In this case $D=1/d$, and Lemma 8.25 implies that the density operator $(\Phi\otimes\bar{\Phi})\left[|\Omega_{AA}\rangle\langle\Omega_{AA}|\right]$, acting in the space of dimensionality d^2, has an eigenvalue greater than or equal to $1/d$.

Exercise 8.26 Let $P=[\lambda_1,\ldots,\lambda_{d^2}]$ run through all probability distributions, such that $\lambda_1\geq1/d$. Then

$$\max_P H(P) = \log d + \frac{d-1}{d}\log(d+1) \leq 2\log d - \frac{\log(d/\mathrm{e})}{d},$$

where the maximum is attained for the distribution P such that $\lambda_1 = 1/d$ and all other probabilities are equal to $1/d(d+1)$.

It follows that

$$\check{H}(\Phi \otimes \bar{\Phi}) \leq H\left((\Phi \otimes \bar{\Phi})\left[|\Omega_{AA}\rangle\langle\Omega_{AA}|\right]\right) \leq 2\log d - \frac{\log(d/\mathrm{e})}{d}, \tag{8.65}$$

which gives the "easier" part of the argument. The difficult part is again the probabilistic estimate, exploring at full strength the phenomenon of entropy concentration,

$$\mathbf{P}\left\{\check{H}(\Phi) > \log d - \frac{C}{d}\right\} > 0$$

for $d, d_A/d$ large enough, where C is a positive constant. Together with (8.65), this proves the existence of channels violating the additivity of the minimal von Neumann entropy.

Although, when combined with Theorem 8.17, this gives a definite negative answer to all global additivity conjectures, including the one which concerns the χ-capacity, several important issues remain open. All the above proofs use the technique of random unitary operators or random states and, as such, are not constructive. They only provide evidence for existence of counterexamples but do not allow us to actually produce them. Attempts at providing estimates for the dimensions in which
nonadditivity can happen have so far led to overwhelmingly high values. The detailed estimates made in [76] gave $d \approx 3.9\times10^4, d_A \approx 7.8\times10^{32}$, breaking the additivity by a quantity of the order of 10^{-5}. While this does not exclude the possibility of better estimates, perhaps to be based on a different (but yet unknown) approach, it casts doubt on finding concrete counterexamples by computer simulation of random unitary channels. It remains a mystery what happens in realistic dimensions. Perhaps, for some unknown reason, the additivity still holds generically or its violation is so tiny that it cannot be caught by numerical simulations.

From this point of view, the following explicit construction is of interest. Following [88], we shall consider an explicit example of a simple channel closely related to (8.54), for which the minimal Rényi entropies are nonadditive for all $p > 2$ and sufficiently large d. This more recent explicit construction thus achieves the same goal as the first Winter proposal (8.56). However, it is not clear if it could be extended to the most interesting range $p \geq 1$.

Exercise 8.27 By using formula (6.42) and the Kraus representation (8.55), show that the complementary channel of (8.54) is

$$\tilde{\Phi}[S] = \frac{2}{(d-1)} P_-\,(S \otimes I_2)\,P_- \tag{8.66}$$

where $P_- = \frac{I_{12}-F}{2}$ is the projector onto the antisymmetric subspace $\mathcal{H}_-$of $\mathcal{H}\otimes\mathcal{H}$, which has dimensionality $\frac{d(d-1)}{2}$, and F is the flip operator acting as

$$F\,(|\psi_1\rangle \otimes |\psi_2\rangle) = |\psi_2\rangle \otimes |\psi_1\rangle \tag{8.67}$$

By Lemma 8.21, this channel shares the additivity properties with the channel (8.54).
Now consider the completely positive map $\frac{(d-1)}{2}\tilde{\Phi}^*$, where $\tilde{\Phi}^*$ is the dual to the channel (8.66), i. e.,

$$S_{12} \longrightarrow \frac{(d-1)}{2}\tilde{\Phi}^*\left[S_{12}\right] = \mathrm{Tr}_2\, P_- S_{12} P_- \tag{8.68}$$

Its restriction to operators with support in the subspace $\mathcal{H}_-$is trace-preserving and hence it is a channel, which we denote Φ_-. For this channel, the input dimensionality is $\dim \mathcal{H}_- = \frac{d(d-1)}{2}$, while the output dimensionality is d and the environment dimensionality also is d, because (8.68) involves the partial trace with respect to the second copy of $\mathcal{H}$. Thus, we have $d_A = \frac{d(d-1)}{2}, d_B = d_E = d$, whence $D = \frac{(d-1)}{2d}$ in (8.62), so that

$$\operatorname{Tr}(\Phi \otimes \bar{\Phi}) \left[|\Omega_{AA}\rangle \langle \Omega_{AA}|\right]^p \geq \left\|(\Phi \otimes \bar{\Phi}) \left[|\Omega_{AA}\rangle \langle \Omega_{AA}|\right]\right\|^p \geq D^p$$

and

$$\check{R}_p(\Phi \otimes \bar{\Phi}) \leq \frac{p}{p-1} \log D. \tag{8.69}$$

The channel (8.68) breaks the additivity of the quantum Rényi entropies for $p > 2$.

Proposition 8.28. For any $p > 2$ and $d > \left(1 - 2^{2/p-1}\right)^{-1}$

$$\check{R}_p \left(\Phi_- \otimes \Phi_-\right) < \check{R}_p \left(\Phi_-\right) + \check{R}_p \left(\bar{\Phi}_-\right).$$

Proof. Let us show that

$$\check{R}_p \left(\Phi_-\right) = 1. \tag{8.70}$$

Let $S_{12} = |\psi_{12}\rangle \langle \psi_{12}|$ be a pure input state of the channel (8.68), where the vector $|\psi_{12}\rangle \in \mathcal{H}_-$has the Schmidt decomposition $|\psi_{12}\rangle = \sum_{j=1}^d \sqrt{\lambda_j} |e_j \otimes h_j\rangle$. From the definition (8.68) of the channel,

$$\Phi_- \left[S_{12}\right] = S_1 = \sum_{j=1}^d \lambda_j |e_j\rangle \langle e_j|.$$

We have

$$\begin{aligned}
\lambda_j &= |\langle \psi_{12} \mid e_j \otimes h_j \rangle|^2 \\
&\leq \langle e_j \otimes h_j| P_- |e_j \otimes h_j\rangle \\
&= \frac{1}{2} \langle e_j \otimes h_j| \left(I_{12} - F\right) |e_j \otimes h_j\rangle \\
&= \frac{1}{2} \left(1 - |\langle e_j \mid h_j \rangle|^2\right) \leq \frac{1}{2},
\end{aligned}$$

with equality in the last inequality if $\langle e_j \mid h_j \rangle = 0$. Therefore,

$$\|\Phi_- \left[S_{12}\right]\| = \max_j \lambda_j \leq \frac{1}{2}.$$

Hence, similar to (8.61),

$$\operatorname{Tr} \Phi_- \left[S_{12}\right]^p = \operatorname{Tr} \Phi_- \left[S_{12}\right] \Phi_- \left[S_{12}\right]^{p-1} \leq \|\Phi_- \left[S_{12}\right]\|^{p-1} \operatorname{Tr} \Phi_- \left[S_{12}\right] \leq \left(\frac{1}{2}\right)^{p-1}$$

and $R_p \left(\Phi_- \left[S_{12}\right]\right) = \frac{1}{1-p} \log \operatorname{Tr} \Phi_- \left[S_{12}\right]^p \geq 1$. Equality is attained for $|\psi_{12}\rangle = \frac{1}{\sqrt{2}}(|e\rangle \otimes |h\rangle - |h\rangle \otimes |e\rangle)$, where $\langle e \mid h \rangle = 0$. This proves (8.70).

Now, (8.69) together with $\Phi = \bar{\Phi}$ implies

$$\check{R}_p \left(\Phi_- \otimes \Phi_-\right) \leq \frac{p}{p-1} \log \frac{(d-1)}{2d} < 2 = \check{R}_p \left(\Phi_-\right) + \check{R}_p \left(\bar{\Phi}_-\right),$$

provided p, d satisfy the conditions of the proposition. □

10.8.9 8.4 Notes and References

1. The memoryless channel model is the simplest, yet is basic in information theory. Already for this case, the coding theorems are not at all trivial. At the same time they give a basis for considering more complicated and realistic scenarios, taking into account memory effects. Moreover, the effects of entanglement are demonstrated in the memoryless case in a most spectacular way. Therefore, in our presentation throughout the book we concentrate on the memoryless configurations. Proposition 8.2, proved in the paper [114], was later generalized to memory channels by Kretschmann and Werner [159]. A generalization to arbitrary channels in the spirit of Han and Verdú's information spectrum approach was given by Hayashi and Nagaoka [96], [95].

2. The fruitful connection between the χ-capacity and the relative entropy, in particular the maximal distance property, was observed by Schumacher and Westmoreland [202].

3. One of the first mentions of the additivity problem was in the paper of Bennett, Fuchs, and Smolin [26]. The formulation in terms of the four capacities was given by Bennett and Shor [27]. Remarkably, as shown by Shor [217], there is an intermediate capacity, which is obtained by allowing adaptive measurement on the output, and which lies strictly between $C_{1,1}$ and $C_{1,\infty}$ for the "lifted trines" channel.

Theorem 8.17 consists of several implications, some of which are individual, i. e., hold for any fixed pair of channels, while others only hold globally, e. g., "if the minimal output entropy is additive for all channels, so is the (constrained) χ-capacity." Matsumoto, Shimono, and Winter [176] observed the relation between a constrained version of the χ-capacity and the entanglement of formation. Audenaert and Braunstein [15] demonstrated the relevance of the methods of convex analysis, while the most profound global implications were established by Shor, who developed an ingenious extension construction that allows one to strengthen the individual channel's properties. See the paper of Shor [218] for a detailed account as well as for further references. Additional information on the equivalences of various additivity properties can be found in Chapter 9 of Hayashi's book [95]. The fact that global validity of the property (8.23) implies additivity (8.22) for all pairs of channels Φ_1, Φ_2 (and a similar implication for the minimal output entropy) was proved by Fukuda and Wolf [77].

The relation between the additivity properties of complementary channels was noticed and studied by Holevo [118] and by King, Matsumoto, Natanson, and Ruskai [152]. Proposition 8.23 is proved in the paper of Holevo and Shirokov [129], where a mathematical description was given to the channel extension construction, and the superadditivity conjecture (8.36) and its equivalence to the additivity of constrained χ-capacity were studied systematically.

The Lindblad-Ozawa inequality was established in its final form in [183]. The validity of the additivity conjecture for entanglement-breaking channels was established by Shor [215]. Other notable results include King's proofs of conjectures (8.22) and (8.33) for unital qubits [150] and depolarizing channels, as well as their complementary channels [118], [152]. Most of these results can be derived by proving the additivity of the minimal output Renýi entropies (8.53) for all values of p. A significant role in these proofs is played by the Lieb-Thirring inequality (see [31], Section X.2). For a detailed account of these and other partial results on the additivity problem, see the survey [119].

The counterexample of a transpose-depolarizing channel was proposed by Werner and Holevo [243]. A breakthrough came with the results of Winter [255] and Hayden [97], who showed that the additivity of the minimal Renýi entropy with parameter values $p > 2$ and $1 < p \leq 2$, correspondingly, does not hold in sufficiently high dimensions. The phenomenon of entropy concentration was explored in [99], basing on a noncommutative generalization of the Bernstein-Chernoff-Hoeffding inequality. Basing himself on the methods of these works,

Hastings [93] considered mixtures of random unitary operators and sketched a proof of the violation of additivity for the minimal von Neumann entropy for large $n, n/d$. By Theorem 8.17, this implies the existence of counterexamples to all forms of the additivity, as well as to equality (8.24), as follows from [77]. The original argument of Hastings was improved and simplified in the subsequent works of Fukuda, King, and Moser [76] and Brandão and M. Horodecki [34]. Aubrun, Szarek, and E. Werner [13] pointed out a profound connection of these results to Dvoretzky-Milman's theorem in the asymptotic theory of finite-dimensional Banach spaces. The constructive counterexample to the additivity of minimum output Rényi entropy of quantum channels for $p > 2$ is due to Grudka, M. Horodecky, and Pankowski [88].

An important corollary of these negative results is that, in general, the classical capacity $C(\Phi) \neq C_\chi(\Phi)$. By definition, $C\left(\Phi^{\otimes n}\right) = nC(\Phi)$. However, whether the classical capacity $C(\Phi)$ can be nonadditive for a pair of different quantum channels Φ_1, Φ_2 remains an open question. Further discussion of the additivity problem can be found in the books of Aubrun and Szarek [12] and of Watrous [240].

10.9 9 Entanglement-Assisted Classical Communication

10.9.1 9.1 The Gain of Entanglement Assistance

The construction of the superdense coding protocol (Section 3.3.3) allows for generalization to the case of a nonideal channel Φ between arbitrary finite-dimensional quantum systems A and A'. Consider the following protocol of the classical information transmission through the channel Φ. Systems A (transmitter) and B (receiver) share an entangled (pure) state S_{AB}, which is distributed to them with a procedure of the kind described in Section 3.2.1. We shall assume that $\dim \mathcal{H}_A \leq \dim \mathcal{H}_B$. System A does some encoding of classical messages i, arriving with probabilities π_i, into operations (channels) $\mathcal{E}_A^i$ acting in $\mathcal{H}_A$. These operations are applied by A to its part of the state S_{AB}, so that the state of the system AB is transformed into $\left(\mathcal{E}_A^i \otimes \mathrm{Id}_B\right)[S_{AB}]$. After that, A sends its part of this state through the channel Φ, thus driving the whole system AB into the state $\left(\Phi \circ \mathcal{E}_A^i \otimes \mathrm{Id}_B\right)[S_{AB}]$, accessible to B. Next, B makes a measurement in the space $\mathcal{H}_{A'B}$ in order to extract the classical information. In fact, block encoding is allowed, so that the whole of this description refers to the nth tensor degree of $\mathcal{H}_{A'B}$. We are interested in the classical capacity of this protocol, which is called the entanglement-assisted classical capacity of the channel Φ.

The maximum over measurements of B can be evaluated using the coding theorem, Theorem 5.4, for the classical capacity. First, we introduce the quantity

$$C_{ea}^{(1)}(\Phi) = \sup_{\pi_i, \mathcal{E}_A^i, S_{AB}^i} \chi\left(\{\pi_i\}; \left(\Phi \otimes \mathrm{Id}_B\right)\left[S_{AB}^i\right]\right), \tag{9.1}$$

which takes into account measurements in the system $A'B$. Using the channel n times and allowing arbitrary collective (entangled) measurement on B 's side, one gets

$$C_{ea}^{(n)}(\Phi) = C_{ea}^{(1)}\left(\Phi^{\otimes n}\right) \tag{9.2}$$

Now, the full entanglement-assisted classical capacity is

$$C_{ea}(\Phi) = \lim_{n\to\infty} \frac{1}{n} C_{ea}^{(1)}\left(\Phi^{\otimes n}\right). \tag{9.3}$$

The following theorem gives a simple "one-letter" expression for $C_{ea}(\Phi)$ in terms of quantum mutual information.

Theorem 9.1 (Bennett, Shor, Smolin, and Thapliyal [28]). The entanglement-assisted classical capacity of the channel Φ is equal to

$$C_{ea}(\Phi) = \max_{S_A} I\left(S_A, \Phi\right) = \max_{S_A} \left[H\left(S_A\right) + H\left(\Phi\left[S_A\right]\right) - H\left(S_A; \Phi\right)\right]. \tag{9.4}$$

The proof of this theorem will be given in the following sections. Here, we wish to compare entanglement-assisted and (unassisted) classical capacities.

Example 9.2. Consider the quantum erasure channel Φ_p. We have

$$H\left(\Phi_p\left[S_A\right]\right) = (1-p)H\left(S_A\right) + h_2(p)$$

Using the fact that the complementary channel $\tilde{\Phi}_p = \Phi_{1-p}$ (see Exercise 6.35) together with Definition 7.28 of the entropy exchange, we have $H\left(S_A; \Phi\right) = H\left(\tilde{\Phi}\left[S_A\right]\right) = pH\left(S_A\right) + h_2(p)$. Hence,

$$I\left(S_A, \Phi_p\right) = H\left(S_A\right) + (1-p)H\left(S_A\right) - pH\left(S_A\right) = 2(1-p)H\left(S_A\right)$$

whence $C_{ea}\left(\Phi_p\right) = 2(1-p)\log d$, which is twice as large as the classical capacity of the erasure channel.

Proposition 9.3. If the channel Φ is covariant, the maximum in (9.4) is attained for an invariant state S_A. In particular, if Φ is irreducibly covariant, it is attained on the chaotic state.

Proof. Let the channel Φ satisfy the covariance condition (6.48). In this case,

$$I\left(V_g^A S_A V_g^{A*}, \Phi\right) = I\left(S_A, \Phi\right) \tag{9.5}$$

This follows from the expression (7.52) for the mutual information, unitary covariance of the input and output entropies, and the corresponding property of the entropy exchange,

$$H\left(V_g^A S_A V_g^{A*}, \Phi\right) = H\left(S_A, \Phi\right) \tag{9.6}$$

To prove this last property, consider formula (7.47) for the entropy exchange and note that purification of the state $V_g^A S_A V_g^{A*}$ is given by the vector $\left(V_g^A \otimes I_R\right)|\psi_{AR}\rangle$. Substituting this into (7.47) and again using the covariance of Φ and the unitary invariance of the entropy gives (9.6).

Now, let S_A be an optimal state for the channel Φ. Consider the V_g^A-invariant state

$$\bar{S} = \frac{1}{|G|}\sum_{g\in G} V_g^A S_A V_g^{A*}$$

By Proposition 7.31, the function $S \to I(S, \Phi)$ is concave, and therefore

$$I(\bar{S}, \Phi) \geq \frac{1}{|G|}\sum_{g\in G} I\left(V_g^A S_A V_g^{A*}, \Phi\right) = I\left(S_A, \Phi\right)$$

where the last equality follows from (9.5).

Example 9.4. Consider the depolarizing channel (6.49). By using unitary covariance, one sees that $I(S, \Phi)$ achieves its maximum at the chaotic state $\bar{S} = \frac{I}{d}$, for which $H(\bar{S}) = H(\Phi[\bar{S}]) = \log d$. The entropy exchange $H(\bar{S}, \Phi)$ is given by the relation (7.51), whence

$$C_{ea}(\Phi) = \log d^2 + \left(1 - p\frac{d^2-1}{d^2}\right)\log\left(1 - p\frac{d^2-1}{d^2}\right) + p\frac{d^2-1}{d^2}\log\frac{p}{d^2}. \tag{9.7}$$

This should be compared with the unassisted classical capacity C, which is equal to C_X, given by formula (8.19).

One can see, in particular, that the gain of entanglement assistance $C_{\rm ea}\,/C \to d+1$ in the limit of strong noise $p \to 1$ (note that both capacities tend to zero!). Moreover, taking the maximal possible value $p = \frac{d^2}{d^2-1}$, we obtain

$$\begin{aligned} C_{ea} &= \log \frac{d^2}{d^2-1} \\ C = C_\chi &= \frac{1}{d+1}\log\frac{d}{d+1} + \frac{d}{d+1}\log\frac{d^2}{d^2-1} \end{aligned} .$$

The ratio C_{ea}/C increases monotonically from the value 5.08 for $d=2$, tightly approaching the asymptotic line $2(d+1)$ as d grows. Recall (Proposition 6.40) that the depolarizing channel is entanglement-breaking for all $p \geq d/(d+1)$. Nevertheless, $C_{ea} > C$ also in this case. In the next section we will show that this inequality holds generically even for q-c channels.

Here, entanglement again appears as a "catalyst" of the transmission of classical information through the quantum channel - it may indefinitely increase the classical capacity of noisy channels, while being unable to transmit the information on its own.

Exercise 9.5 Show that for a qubit unital channel of the form (6.59) with Λ given by (6.64),

$$C_{ea}(\Phi) = I(\bar{S},\Phi) = 2\log 2 + \sum_{\gamma=0,x,y,z} \mu_\gamma \log \mu_\gamma$$

Hint: the entropy exchange $H(\bar{S},\Phi)$ can be computed by using Proposition 7.29 and the Kraus representation (6.64), resulting in

$$H(\bar{S},\Phi) = -\sum_{\gamma=0,x,y,z} \mu_\gamma \log \mu_\gamma$$

Compare this with the capacity $C_X(\Phi)$, given by formula (8.21).

In general, there are simple inequalities relating entanglement-assisted and unassisted classical capacities, i. e.,

$$C_\chi(\Phi) \leq C_{ea}(\Phi) \leq \log d + C_\chi(\Phi) \tag{9.8}$$

Take S_A to be a mixture of arbitrary pure states S_j with probabilities p_j. In this case, (7.50) implies

$$I\left(S_A,\Phi\right) \leq H\left(\sum_j p_j S_j\right) + H\left(\sum_j p_j \Phi\left(S_j\right)\right) - \sum_j p_j H\left(\Phi\left(S_j\right)\right)$$

Taking the maxima in both sides and using (9.4), we obtain the second inequality in (9.8).

Although the entanglement-assisted protocol uses additional resources compared to unassisted transmission of classical information, the first inequality in (9.8) is not quite obvious, because of the special nature of the encoding procedure used by A. To avoid this, let us show that the definition of $C_{ea}^{(1)}(\Phi)$, and hence of $C_{ea}(\Phi)$, can be formulated without explicit introduction of the encoding operations $\mathcal{E}_A^i$, namely,

$$\begin{aligned} C_{ea}^{(1)}(\Phi) = \sup_{\pi_i,\left\{S_{AB}^i\right\}\in\Sigma_B} \Big[& H\left(\sum_i \pi_i \left(\Phi\otimes \mathrm{Id}_B\right)\left[S_{AB}^i\right]\right) \\ & - \sum_i p i_i H\left(\left(\Phi\otimes\mathrm{Id}_B\right)\left[S_{AB}^i\right]\right)\Big] \end{aligned} \tag{9.9}$$

where Σ_B is the collection of families of the states $\{S^i_{AB}\}$ that satisfy the condition that their partial states S^i_B do not depend on $i, S^i_B = S_B$.

The first inequality in (9.8) then follows by taking $S^i_{AB} = S^i_A \otimes S_B$. To prove (9.9), it is sufficient to establish the following fact.

Lemma 9.6. Let $\{S^i_{AB}\}$ be a family of the states satisfying the condition $S^i_B = S_B$. Then there exist a pure state S_{AB} and encodings $\mathcal{E}^i_A$ such that

$$S^i_{AB} = \left(\mathcal{E}^i_A \otimes \mathrm{Id}_B\right)[S_{AB}]\,. \tag{9.10}$$

Proof. For simplicity assume first that S_B is nondegenerate. In this case,

$$S_B = \sum_{k=1}^{d} \lambda_k \left|e^B_k\right\rangle \left\langle e^B_k\right|,$$

where $\lambda_k > 0$ and $\left\{\left|e^B_k\right\rangle\right\}$ is an orthonormal basis in $\mathcal{H}_B$. Let $\left\{\left|e^A_k\right\rangle\right\}$ be an orthonormal basis in $\mathcal{H}_A$. For a vector $\left|\psi^A\right\rangle = \sum_{k=1}^d c_k \left|e^A_k\right\rangle$ we denote $\left|\bar{\psi}^B\right\rangle = \sum_{k=1}^d \bar{c}_k \left|e^B_k\right\rangle$. The map $\left|\psi^A\right\rangle \to \left|\bar{\psi}^B\right\rangle$ is an antiisomorphism of $\mathcal{H}_A$ and $\mathcal{H}_B$. Set

$$|\psi_{AB}\rangle = \sum_{k=1}^{d} \sqrt{\lambda_k}\left|e^A_k\right\rangle \otimes \left|e^B_k\right\rangle,$$

so that $S_{AB} = |\psi_{AB}\rangle\langle\psi_{AB}|$, and define encodings by the relation

$$\mathcal{E}^i_A\left[\left|\psi^A\right\rangle\left\langle\phi^A\right|\right] = \left\langle\bar{\psi}^B\right| S_B^{-1/2} S^i_{AB} S_B^{-1/2} \left|\bar{\phi}^B\right\rangle, \quad \left|\psi^A\right\rangle, \left|\phi^A\right\rangle \in \mathcal{H}_A.$$

Then one can check that $\mathcal{E}^i_A$ are indeed channels fulfilling formula (9.10).
In the case where S_B is degenerate, the above construction should be modified by replacing $S_B^{-1/2} S^i_{AB} S_B^{-1/2}$ in the above formula with $\sqrt{S_B^-} S^i_{AB} \sqrt{S_B^-} + P^0_B$, where $S_B^-$is the generalized inverse of S_B and P^0_B is the projection onto the null subspace of S_B. □

10.9.2 9.2 The Classical Capacities of Quantum Observables

In this section, we wish to compare the classical capacities C, C_{ea} for the special class of q-c channels, when it is possible to establish a necessary and sufficient condition for their coincidence. Let $M = \{M_y; y \in \mathcal{Y}\}$ be a quantum observable in a Hilbert space $\mathcal{H}$. Consider the measurement channel

$$\mathcal{M}[S] = \sum_y |e_y\rangle\langle e_y| \operatorname{Tr} S M_y. \tag{9.11}$$

Since any q − c channel is entanglement-breaking, its classical capacity is given by the one-letter expression

$$C(\mathcal{M}) = C_\chi(\mathcal{M}) = \max_\pi \mathcal{I}(\pi; M),$$

where $\pi = \{\pi_x, S_x\}$ is an ensemble that assigns the probabilities π_x to states S_x and

$$\mathcal{I}(\pi; M) = H\left(P_{\bar{S}_\pi}\right) - \sum_x \pi_x H\left(P_{S_x}\right)$$

is the Shannon information between the input x and the output y. Here, $\bar{S}_\pi = \sum_x \pi_x S_x$, $P_S = \{\operatorname{Tr} S M_y\}$ is the probability distribution of the measurement outcomes and $H(P)$ is the Shannon entropy of a probability distribution P. This can be rewritten as

$$C(\mathcal{M}) = \max_S \left[H(P_S) - \min_{\pi:\bar{S}_\pi = S} \sum_x \pi_x H(P_{S_x}) \right], \tag{9.12}$$

where the minimum is over input ensembles π with the fixed average state $\bar{S}_\pi = S$.
Next, consider the entanglement-assisted capacity which, according to Theorem 9.1, is given by the formula

$$C_{ea}(\mathcal{M}) = \max_S I(S; \mathcal{M}), \tag{9.13}$$

where

$$I(S; \mathcal{M}) = H(S) + H(\mathcal{M}[S]) - H(S, \mathcal{M})$$

is the quantum mutual information. Here, $H(\cdot)$ is the von Neumann entropy and $H(S, \mathcal{M})$ is the entropy exchange. Let $p_y = \operatorname{Tr} SM_y$ and let V_y be an operator satisfying $M_y = V_y^* V_y$, for example, $V_y = M_y^{1/2}$. Then the density operator $\frac{V_y S V_y^*}{p_y} = S(y \mid M)$ can be interpreted as posterior state of the measurement of observable M with instrument $S \to \left\{V_y S V_y^*\right\}$ in state S. We use the following formula [211]:

$$I(S; \mathcal{M}) = H(S) - \sum_y (\operatorname{Tr} SM_y) H(S(y \mid M)). \tag{9.14}$$

Indeed, writing the Kraus decomposition

$$\mathcal{M}[S] = \sum_{y,j} |e_y\rangle \langle h_j| V_y S V_y^* |h_j\rangle \langle e_y|$$

and applying Proposition 7.29, we obtain

$$\begin{aligned} H(S, \mathcal{M}) &= H\left(\sum_y V_y S V_y^* \otimes |e_y\rangle \langle e_y| \right) \\ &= H\left(\sum_y p_y S(y \mid M) \otimes |e_y\rangle \langle e_y| \right) \\ &= H(P_S) + \sum_y p_y H(S(y \mid M)), \end{aligned}$$

while $H(\mathcal{M}[S]) = H(P_S)$, hence (9.14). The entanglement-assisted classical capacity of the channel $\mathcal{M}$ follows by substituting this expression into (9.13).

Let us now describe the ensemble-observable duality. If $M = \{M_y; y \in \mathcal{Y}\}$ is a quantum observable and $\pi = \{p_x, S_x; x \in \mathcal{X}\}$ an ensemble of quantum states, then

$$p_{xy} = p_x \operatorname{Tr} S_x M_y$$

is a probability distribution on $\mathcal{X} \times \mathcal{Y}$. On the other hand,

$$p_{xy} = p'_y \operatorname{Tr} S'_y M'_x,$$

where, denoting $\bar{S}_\pi = \sum_x p_x S_x$, we have $p'_y S'_y = {\bar{S}_\pi}^{1/2} M_y {\bar{S}_\pi}^{1/2}$ so that $p'_y = \operatorname{Tr} \bar{S}_\pi M_y$ and $M'_x = p_x {\bar{S}_\pi}^{-1/2} S_x {\bar{S}_\pi}^{-1/2}$. Here $M'_\pi = \{M'_x; x \in \mathcal{X}\}$ is the new observable, and $\pi' = \left\{p'_y, S'_y; y \in \mathcal{Y}\right\}$ is the new ensemble. Therefore, the Shannon information between x, y is

$$\mathcal{I}(\pi, M) = \mathcal{I}(\pi', M'_\pi).$$

Introducing the ensemble $\pi'_S = \left\{\operatorname{Tr} SM_y, \frac{S^{1/2}M_yS^{1/2}}{\operatorname{Tr} SM_y}\right\}$, for a given state S, we have the following duality relations.

Proposition 9.7. Denoting $A(\pi'_S) = \max_{M''} \mathcal{I}(\pi'_S, M'')$ the accessible information and $\chi(\pi'_S) = H\left(\sum_y p'_y S'_y\right) - \sum_y p'_y H\left(S'_y\right)$ the χ-quantity of the dual ensemble π'_S, we have

$$C(\mathcal{M}) \equiv \max_{\pi} \mathcal{I}(\pi, M) = \max_{S} A(\pi'_S) \tag{9.15}$$

$$C_{ea}(\mathcal{M}) \equiv \max_{S} I(S; \mathcal{M}) = \max_{S} \chi(\pi'_S) \tag{9.16}$$

Proof. Relation (9.15) follows from

$$\begin{aligned}
\max_{\pi} \mathcal{I}(\pi, M) &= \max_{S} \max_{\pi:\bar{S}_\pi = S} \mathcal{I}(\pi, M) \\
&= \max_{S} \max_{M'_\pi \cdot \bar{S}_\pi = S} \mathcal{I}(\pi'_S, M'_\pi) \\
&= \max_{S} \max_{M''} \mathcal{I}(\pi'_S, M'') \\
&= \max_{S} A(\pi'_S),
\end{aligned}$$

where in the third equality we used the fact that for any observable $M'' = \{M_y\}$ there is an ensemble $\pi = \left\{\frac{\operatorname{Tr} SM_y}{d}, \frac{M_y}{\operatorname{Tr} SM_y}\right\}$ such that $M'' = M'_\pi$ for this ensemble.

Note that $\sum_y p'_y S'_y = S$, and $H\left(S'_y\right) = H\left(\frac{V_y S V_y^*}{p'_y}\right)$, where V_y is an arbitrary operator that satisfies $M_y = V_y^* V_y$, because the operators $V_y S V_y^* = V_y S^{1/2} S^{1/2} V_y^*$ and $S^{1/2} V_y^* V_y S^{1/2} = S^{1/2} M_y S^{1/2} = p'_y S'_y$ are unitarily equivalent via polar decomposition and hence have the same spectrum. The density operator $\frac{V_y S V_y^*}{p'_y} = S(y \mid M)$ is the posterior state of the measurement of the observable M with the instrument $\{V_y\}$ in the state S. Thus, the χ-quantity of the dual ensemble is

$$\chi(\pi'_S) = H(S) - \sum_y p'_y H(S(y \mid M)) = I(S; \mathcal{M}) \tag{9.17}$$

and hence, in addition to (9.15), we have, via (9.14), the duality relation (9.16). □

Let us now recall the bound of Theorem 5.9,

$$A(\pi) \leq H\left(\sum_y p_y S_y\right) - \sum_y p_y H(S_y) \equiv \chi(\pi), \tag{9.18}$$

with equality attained if and only if the operators $p_y S_y$ all commute. Applying this to the dual situation, we obtain

$$A(\pi'_S) \leq H\left(\sum_y p'_y S'_y\right) - \sum_y p'_y H\left(S'_y\right) = \chi(\pi'_S).$$

Then the necessary and sufficient condition for the equality becomes

$$S^{1/2} M_y S M_{y'} S^{1/2} = S^{1/2} M_{y'} S M_y S^{1/2} \tag{9.19}$$

for all y, y'. Therefore, by (9.15), (9.16), the necessary and sufficient condition for the equality $C_{ea}(\mathcal{M}) = C(\mathcal{M})$ is that condition (9.19) is fulfilled for a density operator S maximizing the quantity (9.17). In particular, in the case of a covariant observable $M_g = V_g M_0 V_g^*$, where V_g is an irreducible representation of a symmetry group G, Proposition 9.3 implies $S = I/d$

and condition (9.19) reduces to the fact that all components of the observable commute, i. e., it is essentially a classically randomized observable.

Consider the case of an overcomplete system $M_y = |\psi_y\rangle\langle\psi_y|$ in d-dimensional Hilbert space $\mathcal{H}$, where $S = I/d$. The corresponding ensemble of pure states is $\pi'_S \equiv \bar{\pi} = \left\{\frac{\langle\psi_y|\psi_y\rangle}{d}, \frac{|\psi_y\rangle\langle\psi_y|}{\langle\psi_y|\psi_y\rangle}\right\}$ and $\chi(\bar{\pi}) = \log d = C_{ea}(\mathcal{M})$ (note that this is also equal to the classical capacity of the c-q channel $y \longrightarrow \frac{|\psi_y\rangle\langle\psi_y|}{\langle\psi_y|\psi_y\rangle}$, since this is the maximal possible value). Condition (9.19) amounts to

$$|\psi_y\rangle\langle\psi_y \mid \psi_{y'}\rangle\langle\psi_{y'}| = |\psi_{y'}\rangle\langle\psi_{y'} \mid \psi_y\rangle\langle\psi_y|.$$

We can always assume that the vectors $|\psi_y\rangle$ are all pairwise linearly independent. In this case, the last condition is equivalent to the fact that they form an orthonormal basis.

Thus we conclude that $C_{ea}(\mathcal{M}) > C(\mathcal{M})$, unless $\{\psi_y\}$ is an orthonormal basis.
Now, let Θ be the unit sphere in $\mathcal{H}$ and let $v(d\theta)$ be the uniform distribution on Θ. To avoid notational confusion with the differential, we denote in the argument below the dimensionality with $d_A = \dim \mathcal{H}$. According to relation (6.55), the family of unit vectors $\{|\theta\rangle; \theta \in \Theta\}$ can be considered a continuous overcomplete system. The corresponding measurement channel $\mathcal{M}$ maps the density operator S to the probability distribution on Θ, i. e.,

$$\mathcal{M} : S \longrightarrow d_A\langle\theta|S|\theta\rangle v(d\theta). \tag{9.20}$$

It can be shown that, similar to the discrete overcomplete systems considered above, $C_{ea}(\mathcal{M}) = \log d_A$. Let us show that

$$C(\mathcal{M}) = \log d_A - \log e \sum_{k=2}^{d_A} \frac{1}{k}. \tag{9.21}$$

Thus, for $d_A \to \infty$ we have $C(\mathcal{M}) \to \log e(1-\gamma)$, where $\gamma \approx 0.577$ is Euler's constant. At the same time, $C_{ea}(\mathcal{M}) = \log d_A \to \infty$.

All outcome probability distributions (9.20) are absolutely continuous with respect to $v(d\theta)$, and hence we can use the differential entropy

$$h(p_S) = -\int_\Theta p_S(\theta) \log p_S(\theta) v(d\theta),$$

where $p_S(\theta) = d_A\langle\theta|S|\theta\rangle$, to get the continuous analog of formula (9.12)

$$C(\mathcal{M}) = C_\chi(\mathcal{M}) = \max_S \left[h(p_S) - \min_{\pi: S_\pi = S} \sum_x \pi_x h(p_{S_x}) \right]. \tag{9.22}$$

The channel $\mathcal{M}$ is covariant with respect to the irreducible action of the unitary group, in the sense that

$$\mathcal{M}(USU^*) = d_A \langle U^*\theta| S |U^*\theta\rangle v(d\theta).$$

Therefore, similar to (8.15)

$$C_\chi(\mathcal{M}) = h\left(\mathcal{M}\left(\frac{I}{d_A}\right)\right) - \min_{\theta'} h\left(\mathcal{M}\left(|\theta'\rangle\langle\theta'|\right)\right). \tag{9.23}$$

But $\mathcal{M}\left(\frac{I}{d_A}\right)$ is the uniform distribution over Θ, with density $p(\theta) \equiv 1$. Hence, $h\left(\mathcal{M}\left(\frac{I}{d_A}\right)\right) = 0$. On the other hand,

$$-h\left(\mathcal{M}\left(|\theta'\rangle\langle\theta'|\right)\right)=\int_{\Theta}d_A\left|\langle\theta\mid\theta'\rangle\right|^2\log\left[d_A\left|\langle\theta\mid\theta'\rangle\right|^2\right]v(d\theta). \tag{9.24}$$

By the unitary invariance of v, this quantity is the same for all θ'. Hence, there is no need for minimization in (9.23). For its computation, we use relation (6.57). With this, (9.24) becomes

$$-\int_0^1\left(d_Ar^2\right)\log\left(d_Ar^2\right)d\left(1-r^2\right)^{d_A-1}=\int_0^1\left[d_A(1-u)\right]\log\left[d_A(1-u)\right]d\left(u^{d_A-1}\right),$$

where $u=1-r^2$, which, after integrations by parts, gives (9.21).

10.9.3 9.3 Proof of the Converse Coding Theorem

Now, we finally come to the proof of Theorem 9.1.
To prove the inequality

$$C_{ea}(\Phi)\leq\max_{S_A}I\left(S_A,\Phi\right), \tag{9.25}$$

we first prove that

$$C_{ea}^{(1)}(\Phi)\leq\max_{S_A}I\left(S_A,\Phi\right) \tag{9.26}$$

Let us denote by $\mathcal{E}_A^i$ the encodings used by A. Let S_{AB} be the pure state, initially shared between A and B. Then the state of the system AB (resp. A) after the encoding is

$$S_{AB}^i=\left(\mathcal{E}_A^i\otimes\mathrm{Id}_B\right)\left[S_{AB}\right],\quad S_A^i=\mathcal{E}_A^i\left[S_A\right]. \tag{9.27}$$

Note that the partial state of B does not change after the encoding, i.e., $S_B^i=S_B$. We will prove that

$$H\left(\sum_i\pi_i\left(\Phi\otimes\mathrm{Id}_B\right)\left[S_{AB}^i\right]\right)-\sum_i\pi_iH\left(\left(\Phi\otimes\mathrm{Id}_B\right)\left[S_{AB}^i\right]\right)\leq I\left(\sum_i\pi_iS_A^i,\Phi\right). \tag{9.28}$$

The maximum of the left-hand side with respect to all possible $\pi_i,\mathcal{E}_A^i$ is just $C_{ea}^{(1)}(\Phi)$, from which (9.26) follows.

By using the subadditivity of the quantum entropy, we can upperbound the first term in the left-hand side of (9.28) as

$$H\left(\sum_i\pi_i\Phi\left[S_A^i\right]\right)+H\left(S_B\right)=H\left(\Phi\left[\sum_i\pi_iS_A^i\right]\right)+\sum_i\pi_iH\left(S_B\right).$$

Here, the first term already provides us with the output entropy from $I\left(\sum_i\pi_iS_A^i;\Phi\right)$. Let us proceed with the evaluation of the remainder

$$\sum_i\pi_i\left[H\left(S_B\right)-H\left(\left(\Phi\otimes\mathrm{Id}_B\right)\left[S_{AB}^i\right]\right)\right].$$

We first show that the term in squared brackets does not exceed $H\left(S_A^i\right)-H((\Phi\otimes\mathrm{Id}_{R^i})\left[S_{AR^i}^i\right]$, where R^i is the purifying (reference) system for S_A^i, and $S_{AR^i}^i$ is the purified state. To this end consider the unitary extension of the encoding $\mathcal{E}_A^i$ with the environment E_i, which is initially in a pure state, according to Theorem 6.18. From (9.27) we

see that we can take $R^i = BE_i$ (after the unitary interaction, which involves only AE_i). Then again denoting by primes states after the application of the channel Φ, we have

$$H(S_B) - H\left((\Phi \otimes \mathrm{Id}_B)\left[S^i_{AB}\right]\right) = H(S_B) - H\left(S^i_{A'B}\right) = -H_i(A' \mid B), \tag{9.29}$$

where the lower index i of the conditional entropy refers to the joint state $S^i_{A'B'}$. Similarly,

$$\begin{aligned} H\left(S^i_A\right) - H\left((\Phi \otimes \mathrm{Id}_{R^i})\left[S^i_{AR^i}\right]\right) &= H\left(S^i_{R^i}\right) - H\left(S^i_{A'R^i}\right) \\ &= -H_i\left(A' \mid R^i\right) = -H_i(A' \mid BE_i), \end{aligned}$$

which is greater than or equal to (9.29), by the monotonicity of the conditional entropy (Exercise 7.26).

Using the concavity of the function $S_A \to H(S_A) - H((\Phi \otimes \mathrm{Id}_R)[S_{AR}])$, to be shown below, we get

$$\begin{aligned} \sum_i \pi_i \left[H\left(S^i_A\right) - H\left((\Phi \otimes \mathrm{Id}_{R^i})\left[S^i_{AR^i}\right]\right)\right] \leq & H\left(\sum_i \pi_i S^i_A\right) \\ & - H\left((\Phi \otimes \mathrm{Id}_R)\left[\hat{S}_{AR}\right]\right) \end{aligned}$$

where $\hat{S}_{AR}$ is the state purifying $\sum_i \pi_i S^i_A$ with a reference system R, thus arriving to (9.28).

To complete this proof, it remains to show the above concavity. By introducing the environment E for the channel Φ, we have

$$\begin{aligned} H(S_A) - H((\Phi \otimes \mathrm{Id}_R)[S_{AR}]) &= H(S_R) - H(S_{A'R}) \\ &= H(S_{A'E'}) - H(S_{E'}) = H(A' \mid E'). \end{aligned}$$

Now, $H(A' \mid E')$ is a concave function of $S_{A'E'}$ by Corollary 7.27. The map $S_A \to S_{A'E'}$ is affine and therefore $H(A' \mid E')$ is a concave function of S_A.

Applying the same argument to the channel $\Phi^{\otimes n}$ gives

$$C^{(n)}_{ea}(\Phi) \leq \max_{S_A} I\left(S_A, \Phi^{\otimes n}\right) \tag{9.30}$$

Then, from the subadditivity of the quantum mutual information (property iii in Proposition 7.31) we have

$$\max_{S_{12}} I(S_{12}, \Phi_1 \otimes \Phi_2) = \max_{S_1} I(S_1, \Phi_1) + \max_{S_2} I(S_2, \Phi_2),$$

whence the remarkable additivity follows, and we have

$$\max_{S_{A^n}} I\left(S_{A^n}, \Phi^{\otimes n}\right) = n \max_{S_A} I(S_A, \Phi).$$

Therefore, we finally obtain (9.25). □

10.9.4 9.4 Proof of the Direct Coding Theorem

Here, we prove the inequality

$$C_{ea}(\Phi) \geq \max_{S_A} I(S_A, \Phi). \tag{9.31}$$

First, let us show by generalizing the dense coding protocol that

$$C^{(1)}_{ea}\left(\Phi^{\otimes n}\right) \geq I\left(\frac{P}{\dim P}, \Phi^{\otimes n}\right) \tag{9.32}$$

for an arbitrary projection P in $\mathcal{H}_A^{\otimes n}$.
Indeed, let $P = \sum_{k=1}^m |e_k\rangle\langle e_k|$, where $\{e_k; k = 1, \ldots, m = \dim P\}$ is an orthonormal system. Consider the discrete Weyl system $\{W_{\alpha\beta}; \alpha, \beta = 0, \ldots, m-1\}$, defined by the relations (6.50) on the subspace $\mathcal{H}_P = P\mathcal{H}_A^{\otimes n}$.

Since $\dim \mathcal{H}_A \leq \dim \mathcal{H}_B$, we can assume that $\mathcal{H}_A \subseteq \mathcal{H}_B$. Let

$$|\psi_{AB}\rangle = \frac{1}{\sqrt{m}} \sum_{k=1}^m |e_k\rangle \otimes |e_k\rangle .$$

Exercise 9.8 Show that the system $\{(W_{\alpha\beta} \otimes I_B) |\psi_{AB}\rangle ; \alpha, \beta = 0, \ldots, m-1\}$ is an orthonormal basis in $\mathcal{H}_p \otimes \mathcal{H}_p$. In particular,

$$\sum_{\alpha,\beta=0}^{m-1} (W_{\alpha\beta} \otimes I_B) |\psi_{AB}\rangle \langle\psi_{AB}| (W_{\alpha\beta} \otimes I_B)^* = P \otimes P. \tag{9.33}$$

The operators $W_{\alpha\beta}$ will play a role similar to the Pauli matrices in the dense coding protocol for qubits. Take the classical signal to be transmitted as $i = (\alpha, \beta)$, with equal probabilities $1/m^2$, the entangled state $|\psi_{AB}\rangle\langle\psi_{AB}|$, and the unitary encodings $\mathcal{E}_A^i[S] = W_{\alpha\beta} S W_{\alpha\beta}^*$. Now, we have

$$C_{ea}^{(1)}\left(\Phi^{\otimes n}\right) \geq H\left(\frac{1}{m^2}\sum_{\alpha,\beta} (\Phi \otimes \mathrm{Id}_B)^{\otimes n}\left[S_{AB}^{\alpha\beta}\right]\right) - \frac{1}{m^2}\sum_{\alpha,\beta} H\left((\Phi \otimes \mathrm{Id}_B)^{\otimes n}\left[S_{AB}^{\alpha\beta}\right]\right),$$

where $S_{AB}^{\alpha\beta} = \left(W_{\alpha\beta} \otimes I_B^{\otimes n}\right) |\psi_{AB}\rangle\langle\psi_{AB}| \left(W_{\alpha\beta} \otimes I_B^{\otimes n}\right)^*$. By (9.33) the first term in the right-hand side is equal to $H\left((\Phi \otimes \mathrm{Id}_B)\left[\frac{P}{m} \otimes \frac{P}{m}\right]\right) = H\left(\frac{P}{m}\right) + H\left(\Phi\left[\frac{P}{m}\right]\right)$. Since $S_{AB}^{\alpha\beta}$ is a purification of $\frac{P}{m}$, the entropies in the second term are all equal to $H\left(\frac{P}{m}, \Phi\right)$. By the expression for the quantum mutual information

$$I(S_A, \Phi) = H(S_A) + H(\Phi[S_A]) - H(S_A; \Phi)$$

with $S_A = \frac{P}{m}$, this proves (9.32). For future use, note that the last term in the quantum mutual information - the entropy exchange - is equal to the final environment entropy $H(S'_E) = H\left(\tilde{\Phi}[S_A]\right)$, where $\tilde{\Phi}$ is the complementary channel from the system to the environment.

Now let $S_A = S$ be an arbitrary state in $\mathcal{H}_A$ and let $\hat{P}^{n,\delta}$ be the strongly typical projector of the state $S^{\otimes n}$ in the space $\mathcal{H}_A^{\otimes n}$, defined below. We shall prove that for an arbitrary channel Ψ from $\mathcal{H}_A$ to a possibly other Hilbert space $\tilde{\mathcal{H}}$ the following relation holds:

$$\lim_{\delta\to 0}\lim_{n\to\infty} \frac{1}{n} H\left(\Psi^{\otimes n}\left[\frac{\hat{P}^{n,\delta}}{\dim \hat{P}^{n,\delta}}\right]\right) = H(\Psi[S]).$$

This would imply, by the above expressions for the mutual information and the entropy exchange, that

$$\lim_{\delta\to 0}\lim_{n\to\infty} \frac{1}{n} I\left(\frac{\hat{P}^{n,\delta}}{\dim \hat{P}^{n,\delta}}, \Phi^{\otimes n}\right) = I(S, \Phi), \tag{9.34}$$

and hence, by (9.32), the required inequality (9.31).
Definition 9.9. Let us fix small positive δ, and let λ_j be the eigenvalues and $|e_j\rangle$ the eigenvectors of the density operator S. Then the eigenvalues and eigenvectors of $S^{\otimes n}$ are $\lambda_J = \lambda_{j_1} \cdots \lambda_{j_n}, |e_J\rangle = |e_{j_1}\rangle \otimes \cdots \otimes |e_{j_n}\rangle$, where $J = (j_1, \ldots, j_n)$. The sequence J is called strongly typical if the numbers $N(j \mid J)$ of times that the symbol j appears in J satisfy the condition

$$\left|\frac{N(j \mid J)}{n} - \lambda_j\right| < \delta, \quad j = 1, \ldots, d,$$

and $N(j \mid J) = 0$ if $\lambda_j = 0$. Let us denote the collection of all strongly typical sequences as $\hat{T}^{n,\delta}$. The strongly typical projector is defined as the following spectral projector of the density operator $S^{\otimes n}$:

$$\hat{P}^{n,\delta} = \sum_{J \in \hat{T}^{n,\delta}} |e_J\rangle \langle e_J| .$$

Let P^n be the probability distribution given by the eigenvalues λ_J. Then, by the law of large numbers, $\mathrm{P}^n\left(\hat{T}^{n,\delta}\right) \to 1$ as $n \to \infty$. For an arbitrary function $f(j), j = 1, \ldots, d$, and a sequence $J = (j_1, \ldots, j_n) \in \hat{T}^{n,\delta}$,

$$\left|\frac{f(j_1) + \cdots + f(j_n)}{n} - \sum_{j=1}^{d} \lambda_j f(j)\right| < \delta d \max f. \tag{9.35}$$

In particular, any strongly typical sequence is typical: taking $f(j) = -\log \lambda_j$ gives

$$n\left[H(S) - \delta_1\right] < -\log \lambda_J < n\left[H(S) + \delta_1\right], \tag{9.36}$$

where $\delta_1 = \delta d \max_{\lambda_j > 0}(-\log \lambda_j)$ (the converse is not true - not every typical sequence is strongly typical).

We shall need the following combinatorial result, the proof of which can be found in [50].

Exercise 9.10 Show that the size of the set $\hat{T}^{n,\delta}$ is estimated as

$$2^{n[H(S) - \Delta_n(\delta)]} < \left|\hat{T}^{n,\delta}\right| < 2^{n[H(S) + \Delta_n(\delta)]}, \tag{9.37}$$

where $H(S) = -\sum_{j=1}^{d} \lambda_j \log \lambda_j$, and $\lim_{\delta \to 0} \lim_{n \to \infty} \Delta_n(\delta) = 0$.

Proof of the relation (9.34). Denote $d_{n,\delta} = \dim \hat{P}^{n,\delta} = \left|\hat{T}^{n,\delta}\right|$ and $\bar{S}^{n,\delta} = \frac{\hat{P}^{n,\delta}}{d_{n,\delta}}$. We will prove that

$$\lim_{\delta \to 0} \lim_{n \to \infty} \frac{1}{n} H\left(\Psi^{\otimes n}\left[\bar{S}^{n,\delta}\right]\right) = H(\Psi[S]) \tag{9.38}$$

for an arbitrary channel Ψ. We have

$$\begin{aligned} nH(\Psi[S]) - H\left(\Psi^{\otimes n}\left[\bar{S}^{n,\delta}\right]\right) =& H\left(\Psi[S]^{\otimes n}\right) - H\left(\Psi^{\otimes n}\left[\bar{S}^{n,\delta}\right]\right) \\ =& H\left(\Psi^{\otimes n}\left[\bar{S}^{n,\delta}\right]; \Psi^{\otimes n}\left[S^{\otimes n}\right]\right) \\ &+ \operatorname{Tr} \log \Psi[S]^{\otimes n}\left(\Psi^{\otimes n}\left[\bar{S}^{n,\delta}\right] - \Psi[S]^{\otimes n}\right). \end{aligned} \tag{9.39}$$

Strictly speaking, this formula is correct if the density operator $\Psi[S]^{\otimes n}$ is nondegenerate, which we will assume for the moment. Later we shall show how the argument can be modified to the general case.

For the first term, by the monotonicity of the relative entropy, we have the estimate

$$H\left(\Psi^{\otimes n}\left[\bar{S}^{n,\delta}\right]; \Psi^{\otimes n}\left[S^{\otimes n}\right]\right) \leq H\left(\bar{S}^{n,\delta}; S^{\otimes n}\right),$$

with the right-hand side computed explicitly as

$$H\left(\bar{S}^{n,\delta}; S^{\otimes n}\right) = \sum_{J \in \hat{T}^{n,\delta}} \frac{1}{d_{n,\delta}} \log \frac{1}{d_{n,\delta} \lambda_J} = -\log d_{n,\delta} - \sum_{J \in \hat{T}^{n,\delta}} \frac{1}{d_{n,\delta}} \log \lambda_J,$$

which, divided by n, by (9.36), (9.37) is less than or equal to the quantity ($\delta_1 + \Delta_n(\delta)$), converging to zero as $n \to \infty, \delta \to 0$.

By using the identity

$$\log \Psi[S]^{\otimes n} = \log \Psi[S] \otimes I \otimes \cdots \otimes I + \cdots + I \otimes \cdots \otimes I \otimes \log \Psi[S]$$

and introducing the operator $F = \Psi^*[\log \Psi[S]]$, where Ψ^* is the dual channel, we can rewrite the second term as

$$\begin{aligned} & n \operatorname{Tr} \frac{(F \otimes I \otimes \cdots \otimes I + \cdots + I \otimes \cdots \otimes I \otimes F)}{n} \left(\bar{S}^{n,\delta} - S^{\otimes n}\right) \\ & = \frac{n}{d_{n,\delta}} \sum_{J \in \hat{T}^{n,\delta}} \left[\frac{f(j_1) + \cdots + f(j_n)}{n} - \sum_{j=1}^{d} \lambda_j f(j) \right] \end{aligned} \tag{9.40}$$

where $f(j) = \langle e_j | F | e_j \rangle$, which is evaluated by $n\delta d \max f$ via (9.35). This establishes (9.38) in the case of a nondegenerate $\Psi[S]$.

Coming back to the general case, let us denote by P_Ψ the supporting projector of $\Psi[S]$. Then the supporting projector of $\Psi[S]^{\otimes n}$ is $P_\Psi^{\otimes n}$, and the support of $\Psi^{\otimes n}\left(\bar{S}^{n,\delta}\right)$ is contained in the support of $\Psi[S]^{\otimes n} = \Psi^{\otimes n}\left[S^{\otimes n}\right]$, because the support of $\bar{S}^{n,\delta}$ is contained in that of $S^{\otimes n}$. Thus, the second term in (9.39) can be understood as

$$\operatorname{Tr} P_\Psi^{\otimes n} \log \left[P_\Psi^{\otimes n} \Psi[S]^{\otimes n} P_\Psi^{\otimes n}\right] P_\Psi^{\otimes n} \left(\Psi^{\otimes n}\left[\bar{S}^{n,\delta}\right] - \Psi[S]^{\otimes n}\right),$$

where now we have the logarithm of a nondegenerate operator in $P_\Psi^{\otimes n} \mathcal{H}_{A'}^{\otimes n}$. We can then repeat the argument, with F defined as $\Psi^*\left[P_\Psi \log\left(P_\Psi \Psi[S] P_\Psi\right) P_\Psi\right]$. This completes the proof of (9.34), from which (9.31) follows. □

10.9.5 9.5 Notes and References

1. Theorem 9.1 was announced by Bennett, Shor, Smolin, and Thapliyal in [28] and was proved in the paper [29] by the same authors. The case of limited amount of entanglement was studied by Shor [219].

2. Information capacities of quantum observables were studied by Dall'Arno, D'Ariano, and Sacchi [53] and by Holevo [123]. The identity (9.15) was obtained in [53] and (9.16) was obtained in [123]. Relation (9.14) is due to Shirokov [211], who also obtained a general criterion for the coincidence $C_{ea} = C_\chi$, saying that the essential part of the channel should be the c-q channel [212]. The duality between quantum observables and ensembles was introduced by Hall [89]. The value (9.21) was obtained in the paper of Jozsa, Robb, and Wootters [145] as the "subentropy" of the chaotic state $S = I/d$.

3. We here provide a simplified proof, following [116]. Concerning strongly typical projectors and the solution of Exercise 9.10, see [50].

10.10 10 Transmission of Quantum Information

As was already stressed, a quantum state is itself a special kind of information resource, insofar as it contains statistical uncertainty. Statistical mechanics studies irreversible state changes of a physical system that result from its interaction with the environment (and are accompanied by loss of information). Information theory in a sense solves a reverse problem, namely, that of how to reduce these losses to a negligible quantity by using a special processing

of the system state - encoding before and decoding after the irreversible evolution described by a noisy channel. This chapter is devoted to this kind of problems.

We shall start with a brief review of the methods of encoding the quantum information resilient to a certain specific kind of errors (e.g., an arbitrary error in one arbitrary qubit), when complete error correction is possible. We then pass to an approximate setting, where some measure of fidelity for the processing of a quantum state is introduced. In this situation, the aim is to asymptotically achieve an exact transmission of the quantum state through the composite channel $\Phi^{\otimes n}$ with maximal possible rate as $n \to \infty$. In this way, another analog of the Shannon coding theorem emerges, concerning the transmission of quantum information. This leads to the notion of the quantum capacity, expressed in terms of an entropic quantity called coherent information. On the other hand, the quantum capacity of a channel turns out to be closely related to its cryptographic characteristics, such as the capacity for the secret transmission of classical information (the private classical capacity). The role of the eavesdropper in such scenarios is played by the environment of the quantum system.

10.10.1 10.1 Quantum Error-Correcting Codes

10.10.2 10.1.1 Error Correction by Repetition

When transmitting information, one would like to have a code that is robust against errors. In the classical case, the existence of such codes for rates below the capacity follows from the Shannon coding theorem. However, this theorem does not provide a constructive method for the design of such codes, and a practical solution to this problem is the subject of extensive research in classical information theory.

A straightforward method of reducing errors is repetition of messages, which, of course, reduces the rate of transmission. Take the binary alphabet 0,1 and assume that the probability p of a bit flip in the process of transmission is small, so that the probability of a change in more than one bit is negligible. Consider the code $0 \to 00$, $1 \to 11$. In this case, having received 00 or 11 , one can conclude with a high degree of certitude that the encoded symbol was 0 or, correspondingly, 1 . However, if 01 or

10 was received, one can only ascertain an error but not recover the encoded symbol. However, this defect is easily remedied by adding one more bit to the code, $0 \to 000$ and $1 \to 111$. The last code corrects the error in one arbitrary bit of the received message.

A direct generalization of this recipe to the quantum case is impossible, because quantum information cannot be copied. By the very nature of quantum information, one should be able to transmit robustly not only the basis states but also their superposition. Although at first glance this seems not feasible, the problem has an ingenious solution. Let us consider an example of solving such a problem in an important model case.

Assume that one wants to transmit an arbitrary pure state of a qubit $\psi = a|0\rangle + b|1\rangle$, provided that encoding by states of several qubits is allowed. The encoding in the quantum case is just an isometric mapping. Following the classical analogy, consider first the code that maps the basis vectors as follows:

$$|0\rangle \to |000\rangle, \quad |1\rangle \to |111\rangle. \tag{10.1}$$

Such a code corrects the "bit flip," i.e., the change $|0\rangle \leftrightarrow |1\rangle$ in any one of the qubits. We are interested in the arbitrary state $a|0\rangle + b|1\rangle$, which is now encoded into $a|000\rangle + b|111\rangle$. Let, for example, the bit flip occur in the first qubit, i.e.,

$$a|0\rangle + b|1\rangle \to a|100\rangle + b|011\rangle,$$

In this case, the states $a|000\rangle + b|111\rangle, a|100\rangle + b|011\rangle$ are orthogonal, and hence can be perfectly distinguished to correct the error.

However, such a code does not correct a "phase flip" $|0\rangle \leftrightarrow |0\rangle, |1\rangle \leftrightarrow -|1\rangle$. Indeed, after such a phase error in one bit, we have $a|000\rangle - b|111\rangle$ instead of $a|000\rangle + b|111\rangle$, and in general these states are not orthogonal, and hence not perfectly distinguishable.

Now remark that the Hadamard transform

$$|0\rangle \to \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle), \quad |1\rangle \to \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle)$$

maps a phase flip into a bit flip and vice versa. By converting the code (10.1), we obtain another code,

$$\begin{aligned} |0\rangle &\to \frac{1}{2^{3/2}}(|0\rangle + |1\rangle)(|0\rangle + |1\rangle)(|0\rangle + |1\rangle), \\ |1\rangle &\to \frac{1}{2^{3/2}}(|0\rangle - |1\rangle)(|0\rangle - |1\rangle)(|0\rangle - |1\rangle), \end{aligned} \tag{10.2}$$

which corrects a phase flip in one arbitrary qubit, but does not correct bit flips.
The Shor code, which corrects both phase and bit flips in one qubit, is obtained by concatenation of the codes (10.1), (10.2), and requires nine qubits, i.e.,

$$\begin{aligned} |0\rangle &\to \frac{1}{2^{3/2}}(|000\rangle + |111\rangle)(|000\rangle + |111\rangle)(|000\rangle + |111\rangle), \\ |1\rangle &\to \frac{1}{2^{3/2}}(|000\rangle - |111\rangle)(|000\rangle - |111\rangle)(|000\rangle - |111\rangle). \end{aligned} \tag{10.3}$$

Remarkably, it turns out that this code corrects not only bit and phase errors but also an arbitrary error in one of the nine qubits, since it can be represented as a combination of these two basic errors. This follows from the fact that the general conditions for error correction discussed in Section 10.1.3 are satisfied.

10.10.3 10.1.2 General Formulation

Let S be an arbitrary state in a Hilbert space $\mathcal{M}$. A quantum code is an isometric map $V : \mathcal{M} \to \mathcal{N}$, transforming states S into encoded states VSV^* in another Hilbert space $\mathcal{N}$. The system $\mathcal{N}$ is subject to errors, the effect of which is described by completely positive maps Φ in $\mathfrak{T}(\mathcal{N})$, that belong to a certain class $\mathcal{E}$. As we know, irreversible evolutions are described by CP maps that satisfy the normalization $\Phi(I) \leqslant I$ (see Section 6.5), but in the present situation this restriction is not essential, since the effect of an error is determined up to a constant factor.

Thus, transformations of the quantum information are given by the diagram

$$S \longrightarrow VSV^* \longrightarrow \Phi\left(VSV^*\right), \quad \Phi \in \mathcal{E}.$$

Definition 10.1. The code V is correcting errors from $\mathcal{E}$, if there exists a reverse channel $\mathcal{D}$ such that

$$\mathcal{D}\left[\Phi\left(VSV^*\right)\right] = c(\Phi)S \tag{10.4}$$

for an arbitrary state S and an arbitrary $\Phi \in \mathcal{E}$, where $c(\Phi)$ is a constant depending only on Φ.

In fact, the code is determined by the subspace $\mathcal{L} = V\mathcal{M} \subset \mathcal{N}$ and can be defined as such, without introducing $\mathcal{M}$ and V.

Example 10.2. Storage of quantum information in the memory of a quantum computer. Let $\mathcal{N} = \mathcal{H}_2^{\otimes n}$ be the quantum register in which the quantum information from the subspace $\mathcal{M}$ is to be stored. Consider errors involving no more than m qubits of the register. The corresponding class $\mathcal{E}(n,m)$ consists of the maps $\Phi = \Phi_1 \otimes \cdots \otimes \Phi_n$, where the number of $\Phi_k \neq \mathrm{Id}$ is not greater than m, while the error Φ_k in the k th qubit can be an arbitrary completely positive map. Operators of elementary errors in each qubit are usually given by the Pauli matrices, with σ_x describing the bit flip, σ_z the phase flip, and $\sigma_y = i\sigma_x\sigma_z$ their combination. Together with the unit operator $\sigma_0 = I$, corresponding to absence of error, they form a basis in the algebra of observables of the qubit.

The Shor code demonstrates the possibility of error-correction for the class $\mathcal{E}(n,1)$, if n is large enough (one can show that the smallest possible value of n for a code that corrects one error is 5). Restriction to the correction of only one error is, of course, essential here. However, it can be shown that there exist codes that correct errors from $\mathcal{E}(n,m)$, where the ratio m/n is greater than a certain positive number for large enough n.

10.10.4 10.1.3 Necessary and Sufficient Conditions for Error Correction

The class $\mathcal{E}$ of errors usually has the following structure. It consists of mappings of the form $\Phi(S) = \sum_j V_j S V_j^*$, where $V_j \in \mathrm{Lin}\,(B_1, \ldots, B_p)$, and B_j are the fixed, linearly independent operators of elementary errors.

Theorem 10.3 (Knill and Laflamme [153]). The following statements are equivalent:
i. the code $\mathcal{L}$ corrects errors from $\mathcal{E}$;
ii. the code $\mathcal{L}$ corrects the error $\Phi[S] = \sum_{j=1}^p B_j S B_j^*$;
iii. for all $\phi, \psi \in \mathcal{L}$ such that $\langle \phi \mid \psi \rangle = 0$, one has $\langle \phi | B_i^* B_j | \psi \rangle = 0$ for all $i, j = 1, \ldots p$;
iv. for an orthonormal basis $\{|k\rangle\}$ in $\mathcal{L}$ one has

$$\langle k|B_i^* B_j|k\rangle = \langle l|B_i^* B_j|l\rangle, \quad \text{for all } i,j;k,l,$$
$$\langle k|B_i^* B_j|l\rangle = 0, \quad \text{for } k \neq l;$$

v. $P_{\mathcal{L}} B_i^* B_j P_{\mathcal{L}} = b_{ij} P_{\mathcal{L}}$, where $P_{\mathcal{L}}$ is the projector onto $\mathcal{L}$.

Proof.
i. $\Rightarrow$ ii. This is obvious.
ii. $\Rightarrow$ iii. Let there exist a reverse channel $\mathcal{D}[S] = \sum_r R_r S R_r^*$ for the error Φ. Consider a pure input state $S = |\psi\rangle\langle\psi|, |\psi\rangle \in \mathcal{L}$. In this case,

$$\sum_r \sum_j R_r B_j |\psi\rangle\langle\psi| B_j^* R_r^* = c|\psi\rangle\langle\psi|.$$

But this is possible only if $R_r B_j |\psi\rangle = c_{jr}|\psi\rangle$, in which case $c = \sum_r \sum_j |c_{jr}|^2$.
Let $|\phi\rangle, |\psi\rangle \in \mathcal{L}$ be two orthogonal vectors. Since the reverse channel is tracepreserving, we have $I = \sum_r R_r^* R_r$. Therefore,

$$\langle \phi | B_i^* B_j | \psi \rangle = \sum_r \langle \phi | B_i^* R_r^* R_r B_j | \psi \rangle = \left(\sum_r \overline{c_{ir}} c_{jr} \right) \langle \phi \mid \psi \rangle = 0.$$

iii. $\Rightarrow$ iv. The second equality follows trivially, while the first one is obtained by letting $|\phi\rangle = |k+l\rangle, |\psi\rangle = |k-l\rangle$.
iv. $\Rightarrow$ v. Denoting $b_{ij} = \langle k|B_i^* B_j|k\rangle$, we can write condition iv as

$$\langle k|B_i^* B_j|l\rangle = \delta_{kl} b_{ij}$$

which is equivalent to v .

v. $\Rightarrow$ i. The matrix $[b_{ij}]$ is Hermitian positive, hence there exists a unitary matrix $[u_{ij}]$ such that

$$\sum_{ij} \bar{u}_{ir} b_{ij} u_{js} = \delta_{rs} \lambda_r,$$

where $\lambda_r \geq 0$. Introducing $\tilde{B}_s = \sum_j u_{js} B_j$, we have $\Phi[S] = \sum_{s=1}^{p} \tilde{B}_s S \tilde{B}_s^*$ and

$$P_{\mathcal{L}} \tilde{B}_r^* \tilde{B}_s P_{\mathcal{L}} = \delta_{rs} \lambda_r P_{\mathcal{L}}.$$

Thus, for $\lambda_s > 0$ we have

$$\lambda_s^{-1/2} \tilde{B}_s P_{\mathcal{L}} = U_s P_{\mathcal{L}},$$

where U_s are the partially isometric operators that map $\mathcal{L}$ onto mutually orthogonal subspaces $\mathcal{L}_s \subset \mathcal{H}$. It follows that

$$\Phi[S] = \sum_S \lambda_s U_S S U_s^* \tag{10.5}$$

for any state S with $\operatorname{supp} S \subset \mathcal{L}$.

Let P_s be the projectors onto the subspaces $\mathcal{L}_s$, and denote $P_0 = I - \sum_s P_s$. We define the channel

$$\mathcal{D}[S] = \sum_s U_s^* P_s S P_s U_s + P_0 S P_0$$

and wish to show that it is the reverse for all errors in $\mathcal{E}$. However, a linear combination of elementary errors B_j is also a linear combination of $\tilde{B}_r$ and, taking into account that $U_s^* P_s \tilde{B}_r P_{\mathcal{L}} = \lambda_r^{1/2} \delta_{sr} P_{\mathcal{L}}$, we obtain (10.4) for arbitrary $\Phi \in \mathcal{E}$. $\square$

Exercise 10.4 Check condition iv for the Shor code (10.3) and the elementary error operators given by the Pauli matrices in arbitrary one qubit.

10.10.5 10.1.4 Coherent Information and Perfect Error Correction

We now consider an arbitrary channel Φ from A to B. Let $S = S_A$ be an input state of the channel. Introduce the reference system R so that $S_{AR} = |\psi_{AR}\rangle \langle \psi_{AR}|$ is a purification of S_A. Let $V : \mathcal{H}_A \to \mathcal{H}_B \otimes \mathcal{H}_E$ be the Stinespring isometry (6.7) for the channel Φ, where E is the environment.

An important component of the mutual information $I(S, \Phi)$ is the coherent information

$$\begin{aligned} I_c(S, \Phi) &= H(\Phi[S]) - H(S; \Phi) \\ &= H(B) - H(E) \\ &= H(B) - H(RB) \\ &= -H(R \mid B). \end{aligned}$$

As we shall see later, it is closely related to the quantum capacity of the channel Φ. Somewhat disappointingly, the coherent information does not have several "natural" information properties, such as concavity in S, subadditivity, or the second chain rule. Moreover, it can take negative values. Its classical analog is never positive, $H(Y) - H(XY) = -H(X \mid Y) \leq 0$. However, $I_c(S, \Phi)$ is convex in Φ and satisfies the first chain rule, i.e.,

$$I_c(S, \Phi_2 \circ \Phi_1) \leq I_c(S, \Phi_1) \tag{10.6}$$

as can be seen from the relation $I_c(S,\Phi) = I(S,\Phi) - H(S)$ and from the corresponding properties for the quantum mutual information $I(S,\Phi)$. Let us see why one should not expect the second chain rule, $I_c(S, \Phi_2 \circ \Phi_1) \leq I_c(\Phi_1[S], \Phi_2)$. Assuming that this holds, we would have

$$H(\Phi_2 \circ \Phi_1[S]) - H(S, \Phi_2 \circ \Phi_1) \leq H(\Phi_2 \circ \Phi_1[S]) - H(\Phi_1[S], \Phi_2)$$

i. e., $H(S, \Phi_2 \circ \Phi_1) \geq H(\Phi_1[S], \Phi_2)$. But this is the same as $H(E_1E_2) \geq H(E_2)$, where E_j is the environment for the j th channel. However, such a monotonicity does not hold in general for quantum entropy, as we have noted in Section 7.5.

Exercise 10.5 Show that subadditivity of $I_c(S,\Phi)$ is equivalent to the following inequality:

$$H(B_1B_2) - H(B_1) - H(B_2) \leq H(E_1E_2) - H(E_1) - H(E_2),$$

which need not hold in general.

There is a close relationship between the perfect transmission of quantum information, error correction, and the coherent information.

Definition 10.6. The channel Φ is called perfectly reversible on the state $S = S_A$ if there is a reverse channel $\mathcal{D}$ from B to A, such that

$$(\mathcal{D} \circ \Phi \otimes \mathrm{Id}_R)[S_{AR}] = S_{AR}$$

Proposition 10.7. The following conditions are equivalent:
i. the channel Φ is perfectly reversible on the state S;
ii. $I(R;E) = 0$, i.e., $S_{RE} = S_R \otimes S_E$ (where $S_{RE} = \mathrm{Tr}_B S_{BRE}$);
iii. $I_c(S,\Phi) = H(S)$;
iv. the channel Φ admits a representation (10.5) on the support of the state S.

The meaning of condition ii is that no information goes to the environment, i.e., the channel is "private." Thus, the perfect reversibility of the channel and its perfect privacy are equivalent. Condition iii means that for perfect transmission by the channel Φ of the state S, the coherent information $I_c(S,\Phi)$ should reach its maximal possible value $H(S)$. In particular, by taking $S = \bar{S}_A = I_A/d_A$ - the chaotic state - we obtain the condition $\log d_A = I_C\left(\bar{S}_A, \Phi\right)$. This indicates that the coherent information is the quantity relevant to the quantum capacity of the channel Φ, i.e., the capacity for perfect transmission of quantum states. In the next sections, we shall see that for approximately perfect transmission by the memoryless channel $\Phi^{\otimes n}$, an appropriate analog of these conditions should hold asymptotically, with $n \to \infty$.

Proof.
i. $\Rightarrow$ ii. The vector $|\psi_{BRE}\rangle = (V \otimes I_R)|\psi_{AR}\rangle$ is a vector of the pure state S_{BRE} of the composite system BRE. The perfect reversibility implies

$$(\mathcal{D} \otimes \mathrm{Id}_{RE})[S_{BRE}] = S_{ARE}.$$

Since the partial state S_{AR} is pure, by Corollary 3.12 $S_{ARE} = S_{AR} \otimes S_E$. Taking the partial trace with respect to A, we obtain

$$S_{RE} = S_R \otimes S_E, \tag{10.7}$$

that is, ii.
ii. $\Rightarrow$ iii. We have

$$H(S) - I_c(S,\Phi) = H(A) + H(E) - H(B) \tag{10.8}$$
$$= H(R) + H(E) - H(RE) = I(R;E) \geq 0, \tag{10.9}$$

with equality if and only if $I(R;E)=0$, i. e., $S_{RE}=S_R\otimes S_E$.
ii. $\Rightarrow$ i. The vector $|\psi_{BRE}\rangle=(V\otimes I_R)\,|\psi_{AR}\rangle$ is the vector of joint pure state S_{BRE} of the system BRE, which is a purification of the state S_{RE}. Starting from the right-hand side of (10.7), we obtain another purification $|\psi_{AR}\rangle\otimes|\psi_{EE'}\rangle$, where E' is a purifying system for S_E. By choice of E' we can always assume that this second purification has dimensionality not less than that of the first. Hence, by the remark after Theorem 3.10, there is an isometric operator $W:\mathcal{H}_B\to\mathcal{H}_A\otimes\mathcal{H}_{E'}$ such that

$$(I_{RE}\otimes W)\,|\psi_{BRE}\rangle=|\psi_{AR}\rangle\otimes|\psi_{EE'}\rangle\,. \tag{10.10}$$

Taking the partial trace with respect to E,E' of the corresponding density operator, we obtain the perfect reversibility

$$(\mathrm{Id}_R\otimes\mathcal{D}\circ\Phi)\,[S_{AR}]=S_{AR} \tag{10.11}$$

where the reverse channel is defined as

$$\mathcal{D}\,[S_B]=\mathrm{Tr}_{E'}\,WS_BW^*. \tag{10.12}$$

i. $\Rightarrow$ iv. Later, we shall prove Corollary 10.14, the statement i. $\Leftrightarrow$ iii. of which, with the replacement of Φ by $\mathcal{D}\circ\Phi$, implies that the channel Φ is perfectly reversible on the state S if and only if

$$\mathcal{D}\circ\Phi[\tilde{S}]=\tilde{S}$$

for all $\tilde{S}$ with $\mathrm{supp}\,\tilde{S}\subset\mathcal{L}\equiv\mathrm{supp}\,S$, where $\mathrm{supp}\,S$ is the support of the density operator S (see Section 1.3). We can reformulate this property by saying that Φ is perfectly reversible on the subspace $\mathcal{L}$. In other words, the subspace $\mathcal{L}$ is a quantum code that corrects the error Φ (and hence, all errors of the associated class $\mathcal{E}$). The statement then follows from the proof of Theorem 10.3.

The following proposition provides yet another characterization in terms of complementary channels (see Section 6.6), which prepares the ground for the coding theorem for the private classical capacity of a quantum channel, in Section 10.4.1.

Proposition 10.8. For a given Stinespring dilation of the channel Φ the following conditions are equivalent:
i. the channel Φ is perfectly reversible on the subspace $\mathcal{L}$;
ii. the complementary channel $\tilde{\Phi}$ is completely depolarizing on $\mathcal{L}$, i.e.,

$$\tilde{\Phi}[\tilde{S}]=S_E, \tag{10.13}$$

for any state $\tilde{S}$ with $\mathrm{supp}\,\tilde{S}\subset\mathcal{L}$, where S_E is a fixed state.

Proof.

i. $\Rightarrow$ ii. Assuming Φ is perfectly reversible, the relation (10.10) holds, with an isometric W for all $|\psi_{RA}\rangle$ having a tensor decomposition with A-components in $\mathcal{L}$. Here, $|\psi_{EE'}\rangle$ cannot depend on the input $|\psi_{RA}\rangle$, since otherwise the right-hand side would be nonlinear in $|\psi_{RA}\rangle$. Taking the partial trace with respect to RAE' of the corresponding density operators, we obtain (10.13).
ii. $\Rightarrow$ i. We have a Stinespring dilation $\tilde{\Phi}[\tilde{S}]=\mathrm{Tr}_B\,V\tilde{S}V^*$, where B plays the role of an "environment" for the environment system. Let (10.13) hold and let $|\psi_{EE'}\rangle$ be a purification of S_E. Then there is another Stinespring dilation for the restriction of the channel
$\tilde{\Phi}$ to the states with support in $\mathcal{L}$, i. e.,

$$\tilde{\Phi}[\tilde{S}] = \mathrm{Tr}_{AE'}\, V'\tilde{S}V'^{*}, \tag{10.14}$$

where $V' = I_A \otimes |\psi_{EE'}\rangle$ is an isometric operator from $\mathcal{H}_A$ to $\mathcal{H}_{AEE'} = \mathcal{H}_E \otimes \mathcal{H}_{AE'}$, acting as $V'|\psi\rangle = |\psi\rangle \otimes |\psi_{EE'}\rangle$. In this dilation, the role of an "environment" for the environment E is now played by AE'. By Theorem 6.12, there is a partial isometry $W : \mathcal{H}_B \to \mathcal{H}_{AE'}$ such that

$$(W \otimes I_E)\, V = V' = I_A \otimes |\psi_{EE'}\rangle\,.$$

It follows that relation (10.10) holds for all $|\psi_{RA}\rangle$ having a tensor decomposition with A-components in $\mathcal{L}$. By possibly extending the space $\mathcal{H}_{E'}$ we can replace W with an isometry that preserves relation (10.10). Following a similar argument as in the proof of the previous proposition, we take the partial trace of the corresponding density operator with respect to REE' and obtain the perfect reversibility on $\mathcal{L}$, i.e.,

$$\mathcal{D} \circ \Phi[\tilde{S}] = \tilde{S}, \tag{10.15}$$

where the reverse channel is defined by (10.12). □

10.10.6 10.2 Fidelities for Quantum Information

As a measure of exactness of the transmission of a quantum state S by the channel Φ one could take the trace norm $\|S - \Phi[S]\|_1$. However, in quantum information theory there are a number of other useful quantities playing the same role as the probability of a correct decision in the classical case. Let us first consider these quantities and study the relations between them.

10.10.7 10.2.1 Fidelities for Pure States

Lemma 10.9. Let ψ be a unit vector and S an arbitrary state. Then the following inequalities hold:

$$2[1 - \langle\psi|S|\psi\rangle] \leqslant \||\psi\rangle\langle\psi| - S\|_1 \leqslant 2\sqrt{1 - \langle\psi|S|\psi\rangle}. \tag{10.16}$$

If $S = |\phi\rangle\langle\phi|$ is a pure state, the second inequality turns into equality, i.e.,

$$\||\psi\rangle\langle\psi| - |\phi\rangle\langle\phi|\|_1 = 2\sqrt{1 - |\langle\psi \mid \phi\rangle|^2}. \tag{10.17}$$

Proof. By using (1.19) we have

$$\||\psi\rangle\langle\psi| - S\|_1 = \max_U |\,\mathrm{Tr}(|\psi\rangle\langle\psi| - S)U|,$$

where the maximum is over all unitary operators U. Taking $U = 2|\psi\rangle\langle\psi| - I$ produces the first inequality.

Equality (10.17) is obtained similar to relation (2.44). To compute the trace norm, it is sufficient to find the eigenvalues of the operator $|\psi\rangle\langle\psi| - |\phi\rangle\langle\phi|$, which has rank two (see Proposition 2.26).

Now, let S be an arbitrary density operator and consider its spectral decomposition $S = \sum \lambda_i S_i$. By using the convexity of the norm, the concavity of the square root, and relation (10.17), we obtain

$$\begin{aligned}\||\psi\rangle\langle\psi| - S\|_1 &\leq \sum_i \lambda_i \||\psi\rangle\langle\psi| - S_i\|_1 \\ &= 2\sum_i \lambda_i \sqrt{1 - \langle\psi|S_i|\psi\rangle} \leq 2\sqrt{1 - \langle\psi|S|\psi\rangle}.\end{aligned}$$

□

For a pure state $|\psi\rangle\langle\psi|$ and an arbitrary state S, the quantity

$$F(|\psi\rangle\langle\psi|, S) = \langle\psi|S|\psi\rangle \tag{10.18}$$

is called the fidelity between the pure state $|\psi\rangle\langle\psi|$ and the state S. Clearly, $F \leq 1$, with equality if and only if $S = |\psi\rangle\langle\psi|$. Note that in quantum data compression (Section 5.5) we in fact used the fidelity (10.18). There, the state $|\psi_i\rangle\langle\psi_i|$ appeared with probability p_i. Hence, the average fidelity is just $\bar{F} = \sum_i p_i \langle\psi_i| S_i |\psi_i\rangle$.

In connection with error-correcting codes, a natural definition of fidelity is as follows. Let a subspace (quantum code) $\mathcal{L} \subset \mathcal{H}$ and a channel Φ in $\mathcal{H}$, for which the input and output spaces coincide $\mathcal{H}_B = \mathcal{H}_A = \mathcal{H}$, be given. The subspace fidelity is defined as

$$\begin{aligned} F_s(\mathcal{L}, \Phi) &= \min_{\psi\in\mathcal{L}, \|\psi\|=1} F(|\psi\rangle\langle\psi|, \Phi[|\psi\rangle\langle\psi|]) \\ &= \min_{\psi\in\mathcal{L}, \|\psi\|=1} \langle\psi|\Phi[|\psi\rangle\langle\psi|]|\psi\rangle. \end{aligned}$$

By Lemma 10.9,

$$2\left[1 - F_s(\mathcal{L}, \Phi)\right] \leq \max_{\psi\in\mathcal{L}, \|\psi\|=1} \| |\psi\rangle\langle\psi| - \Phi[|\psi\rangle\langle\psi|] \|_1 \leq 2\sqrt{1 - F_s(\mathcal{L}, \Phi)}. \tag{10.19}$$

Another important quantity is the entanglement fidelity $F_e(S, \Phi)$, defined as follows. Let us purify the state $S = S_A$ to $|\psi_{AR}\rangle\langle\psi_{AR}|$ in the Hilbert space $\mathcal{H}_A \otimes \mathcal{H}_R$ and consider the fidelity for this pure state under the action of the trivial extension of the channel

$$F_e(S, \Phi) = \langle\psi_{AR}| \left(\Phi \otimes \mathrm{Id}_R\right) \left(|\psi_{AR}\rangle\langle\psi_{AR}|\right) |\psi_{AR}\rangle .$$

There is another convenient expression for $F_e(S, \Phi)$, which also shows independence of this definition of the way of purification of the initial state.

Lemma 10.10. Let the channel have the Kraus representation

$$\Phi[S] = \sum_i V_i S V_i^* \tag{10.20}$$

Then

$$F_e(S, \Phi) = \sum_i |\mathrm{Tr}\, V_i S|^2 \tag{10.21}$$

Proof. Indeed,

$$\begin{aligned} \langle\psi_{AR}| \sum_i \left(V_i \otimes I_R\right) |\psi_{AR}\rangle\langle\psi_{AR}| \left(V_i \otimes I_R\right)^* |\psi_{AR}\rangle &= \sum_i \left| \langle\psi_{AR}| \left(V_i \otimes I_R\right) \right| \psi_{AR} \Big\rangle \Big|^2 \\ &= \sum_i |\mathrm{Tr}\, V_i S|^2 . \end{aligned}$$

□

Note that for a pure state $S = |\psi\rangle\langle\psi|$,

$$F_e(S, \Phi) = \langle\psi|\Phi[|\psi\rangle\langle\psi|]|\psi\rangle = F(|\psi\rangle\langle\psi|, \Phi[|\psi\rangle\langle\psi|]).$$

Exercise 10.11 Prove that $F_e(S, \Phi)$ is a convex function of S. Hint: by (10.21), $F_e(S, \Phi)$ is the sum of squares of affine functions of S.

10.10.8 10.2.2 Relations Between the Fidelity Measures

Lemma 10.12. For an arbitrary state S

$$1 - F_e(S, \Phi) \leq 4\sqrt{1 - F_S(\operatorname{supp} S, \Phi)}$$

Proof. We have

$$\begin{aligned} 1 - F_e(S, \Phi) &= 1 - \langle \psi_{AR}| \left(\Phi \otimes \mathrm{Id}_R\right) \left(|\psi_{AR}\rangle \langle \psi_{AR}|\right) |\psi_{AR}\rangle \\ &= \langle \psi_{AR}| \left((\mathrm{Id}_A - \Phi) \otimes \mathrm{Id}_R\right) \left[|\psi_{AR}\rangle \langle \psi_{AR}|\right] |\psi_{AR}\rangle \end{aligned}$$

Representing $|\psi_{AR}\rangle = \sum_j |\psi_j\rangle \otimes |e_j\rangle$, where $\{|e_j\rangle\}$ is an orthonormal basis in $\mathcal{H}_R$, $\sum_j \|\psi_j\|^2 = 1, \psi_j \in \operatorname{supp} S$, we obtain the equivalent relation

$$\sum_{jk} \langle \psi_j| \left(\mathrm{Id} - \Phi\right) \left[|\psi_j\rangle \langle \psi_k|\right] |\psi_k\rangle = \sum_{jk} \operatorname{Tr} |\psi_k\rangle \langle \psi_j| \left(|\psi_j\rangle \langle \psi_k| - \Phi\left[|\psi_j\rangle \langle \psi_k|\right]\right).$$

Taking into account inequality (1.18) and the fact that the operators $|\psi_j\rangle \langle \psi_k|$ all have both trace and operator norms equal to $\|\psi_j\| \, \|\psi_k\|$, we obtain that this does not exceed

$$\max_T \frac{\|T - \Phi[T]\|_1}{\|T\|_1},$$

where the maximum is taken over all nonzero operators T acting in $\mathcal{L} = \operatorname{supp} S$. By decomposing $T = T_1 + iT_2$, where $T_1^* = T_1, T_2^* = T_2$ again act in $\mathcal{L}$, and taking into account that $\|T_{1,2}\|_1 \leq \|T\|_1$, as well as the triangle inequality, we infer that this does not exceed the following quantity:

$$2 \max_{T^* = T} \frac{\|T - \Phi[T]\|_1}{\|T\|_1} = 2 \max_{S : \operatorname{supp} S \in \mathcal{L}} \|S - \Phi[S]\|_1. \tag{10.22}$$

Here, the inequality $\geq$ is obtained by restricting ourselves to positive T. On the other hand,

$$\max_{T^* = T} \frac{\|T - \Phi[T]\|_1}{\|T\|_1} \leq \|S_+ - \Phi\left[S_+\right]\|_1 \frac{p_+}{p_+ + p_-} + \|S_- - \Phi\left[S_-\right]\|_1 \frac{p_-}{p_+ + p_-}, \tag{10.23}$$

where we denoted $p_\pm = \operatorname{Tr} T_\pm; S_\pm = p_\pm^{-1} T_\pm$. Here, the right-hand side is less than or equal to the right-hand side in the relation (10.22), which is thus proved. Finally,

$$\max_{S : \operatorname{supp} S \in \mathcal{L}} \|S - \Phi[S]\|_1 = \max_{\psi : \psi \in \mathcal{L}, \|\psi\| = 1} \| |\psi\rangle\langle\psi| - \Phi[|\psi\rangle\langle\psi|]\|_1,$$

since the maximum of a convex function is attained at an extreme point of the convex set. By using the second inequality from (10.19), we obtain that the expression does not exceed $4\sqrt{1 - F_s(\mathcal{L}, \Phi)}$. $\square$

Exercise 10.13 By using the convexity property from Exercise 10.11, prove the inequality

$$1 - F_s(\mathcal{L}, \Phi) \leq 1 - \min_{S : \operatorname{supp} S \subset \mathcal{L}} F_e(S, \Phi). \tag{10.24}$$

Now, let $\mathcal{L} = \mathcal{H}$. In this case,

$$\max_T \frac{\|T - \Phi[T]\|_1}{\|T\|_1} = \|\mathrm{Id} - \Phi\|.$$

From the proof of Lemma 10.12, we have the chain of inequalities

$$1 - \min_S F_e(S,\Phi) \le \|\mathrm{Id} - \Phi\| \le 2 \max_{\|\psi\|=1} \| |\psi\rangle\langle\psi| - \Phi[|\psi\rangle\langle\psi|] \|_1 \le 2\| \mathrm{Id} - \Phi\|. \tag{10.25}$$

Together with relation (10.24) this means that a deviation of the channel Φ from the ideal channel Id is equivalently described by one of the quantities

$$\|\mathrm{Id} - \Phi\|, \quad \max_S \|S - \Phi[S]\|_1, \quad 1 - F_S(\mathcal{H},\Phi), \quad 1 - \min_S F_e(S,\Phi)$$

In the consideration of the quantum capacity we will need the following obvious corollary of Lemma 10.12:

$$1 - F_e(\bar{S},\Phi) \le 4\sqrt{1 - F_s(\mathcal{H},\Phi)}, \tag{10.26}$$

where $\bar{S}$ is the chaotic state in $\mathcal{H}$.

It is instructive to consider the "ideal" case of the unit fidelities.

Corollary 10.14. The following conditions are equivalent:

i. $F_e(S,\Phi) = 1$;

ii. $F_S(\mathrm{supp}\, S,\Phi) = 1$;

iii. $\Phi[\tilde{S}] = \tilde{S}$ for arbitrary state $\tilde{S}$ with $\mathrm{supp}\,\tilde{S} \subset \mathrm{supp}\, S$;

iv. $F_e(\tilde{S},\Phi) = 1$ for arbitrary state $\tilde{S}$ with $\mathrm{supp}\,\tilde{S} \subset \mathrm{supp}\, S$.

Proof. Let us prove i. $\Rightarrow$ ii. Let $|\psi\rangle \in \mathrm{supp}\, S$. In this case, we can write

$$S = p|\psi\rangle\langle\psi| + (1-p)S',$$

where $p > 0$ and S' is a density operator. By Exercise 10.11, the function $S \to F_e(S,\Phi)$ is convex. Therefore,

$$pF_e(|\psi\rangle\langle\psi|,\Phi) + (1-p)F_e\,(S',\Phi) \ge F_e(S,\Phi) = 1$$

and hence $F_e(|\psi\rangle\langle\psi|,\Phi) = 1$. But this means that

$$\langle\psi|\Phi[|\psi\rangle\langle\psi|]|\psi\rangle = 1$$

for all $|\psi\rangle \in \mathrm{supp}\, S$ and $F_s(\mathrm{supp}\, S,\Phi) = 1$.

Lemma 10.12 implies ii. $\Rightarrow$ i. Moreover, since ii obviously implies the same condition, with $\mathrm{supp}\,\tilde{S}$ instead of $\mathrm{supp}\, S$, it also implies iv, which is formally stronger than i.

By the definition of F_S, ii is equivalent to iii for pure, and, hence, for mixed states $\tilde{S}$.

10.10.9 10.2.3 Fidelity and the Bures Distance

Here, we discuss the fidelity between two arbitrary mixed states. This material will be needed only in Section 10.4.4.

For pure states $S = |\phi\rangle\langle\phi|, T = |\psi\rangle\langle\psi|$, the fidelity is equal to $F(T,S) = |\langle\phi \mid \psi\rangle|^2$, and formula (10.17) provides the relation between the fidelity and the trace norm distance between S, T. Now, let S, T be arbitrary density operators.

Definition 10.15. The fidelity between the density operators S, T is defined by the relation

$$F(T,S) = \max |\langle\psi_T \mid \psi_S\rangle|^2 \tag{10.27}$$

where the maximum is taken over all possible purifications ψ_S, ψ_T of the states S, T (in the same Hilbert space $\mathcal{H} \otimes \mathcal{H}'$).

By using Theorem 3.11, we see that

$$F(T,S) = \max_W |\langle \psi_T \mid (I \otimes W)\psi_S \rangle|^2 , \tag{10.28}$$

where now ψ_S, ψ_T are fixed purifications of the states S, T in a fixed Hilbert space $\mathcal{H} \otimes \mathcal{H}'$, and the maximum is taken over all unitary operators W in $\mathcal{H}'$. In particular, taking the purifications $\sqrt{S}, \sqrt{T}$ in $L^2(\mathcal{H}) \simeq \mathcal{H} \otimes \mathcal{H}^*$ we obtain

$$F(T,S) = \max_W |\operatorname{Tr} \sqrt{S}\sqrt{T}W|^2,$$

where the maximum is over all unitary operators W in $\mathcal{H}$. By using the polar decomposition of the operator $\sqrt{S}\sqrt{T} = U|\sqrt{S}\sqrt{T}|$, one sees that the maximum is achieved for $W = U^*$ and is equal to

$$F(T,S) = (\operatorname{Tr} |\sqrt{S}\sqrt{T}|)^2 = \|\sqrt{S}\sqrt{T}\|_1^2.$$

This coincides with (10.18) for $T = |\psi\rangle\langle\psi|$. Note that the above argument implies that in the definition (10.27) we can restrict ourselves to maximization with respect to all purifications of only one of the states, with a fixed purification of another.

Exercise 10.16 Show that $F(T,S) \leq 1$, with equality if and only if $T = S$.

Related to the fidelity (10.27), there is a metric on the set of all states, called the Bures distance, namely,

$$\beta(T,S) = \min \|\psi_T - \psi_S\| , \tag{10.29}$$

where the minimum is again taken over all possible purifications ψ_S, ψ_T of the states S, T. Taking the square of the norm and using the definition (10.27), one obtains

$$\beta(T,S) = \sqrt{2(1 - \sqrt{F(T,S)})} = \sqrt{2\left(1 - \|\sqrt{S}\sqrt{T}\|_1\right)}. \tag{10.30}$$

In particular, for pure states $T = |\psi\rangle\langle\psi|, S = |\phi\rangle\langle\phi|$,

$$\beta(T,S) = \sqrt{2(1 - |\langle\psi \mid \phi\rangle|)}.$$

It also follows that, just as in the definition of fidelity, in the definition (10.29) we can restrict ourselves to minimization with respect to all purifications of only one of the states, with a fixed purification of another.

The triangle inequality for $\beta(T,S)$ then follows from the definition (10.29) and the corresponding inequality for the norm. For pure states, it reduces to

$$\sqrt{1 - |\langle\varphi \mid \psi\rangle|} \leq \sqrt{1 - |\langle\varphi \mid \chi\rangle|} + \sqrt{1 - |\langle\chi \mid \psi\rangle|}, \tag{10.31}$$

where φ, χ, ψ are arbitrary unit vectors.

Lemma 10.17. For any two density operators S_1, S_2 in $\mathcal{H}$,

$$\beta\left(S_1, S_2\right)^2 \leq \|S_1 - S_2\|_1 \leq 2\beta\left(S_1, S_2\right), \tag{10.32}$$

The first inequality, combined with (10.30) and (10.28), implies the following.

Corollary 10.18. For any two density operators S_1, S_2 in $\mathcal{H}$ and their given purifications ψ_{S_1}, ψ_{S_2} in $\mathcal{H} \otimes \mathcal{H}'$,

$$\|S_1 - S_2\|_1 \geq 2\left(1 - \max_W |\langle\psi_{S_1} \mid (I \otimes W)\psi_{S_2}\rangle|\right), \tag{10.33}$$

where the maximum is taken over all unitary operators W in $\mathcal{H}'$.

Proof of Lemma 10.17. Since $\operatorname{Tr}\sqrt{S_1}\sqrt{S_2} \le \operatorname{Tr}\left|\sqrt{S_1}\sqrt{S_2}\right|$, to prove the first inequality in (10.32) it is sufficient to prove that

$$2\left(1 - \operatorname{Tr}\sqrt{S_1}\sqrt{S_2}\right) \le \|S_1 - S_2\|_1 .$$

This in turn follows from the more general inequality

$$\operatorname{Tr}\left(\sqrt{S_1} - \sqrt{S_2}\right)^2 \le \|S_1 - S_2\|_1 ,$$

valid for arbitrary positive S_1, S_2. To prove this, for a Hermitian operator K, we denote by $1_+(K)$ (resp. $1_-(K)$) the spectral projector corresponding to positive (resp. nonpositive) eigenvalues. In this case, $\sigma(K) = 1_+(K) - 1_-(K)$ is a unitary Hermitian operator that satisfies $\sigma(K)K = K\sigma(K) = |K|$. Denoting $K = \sqrt{S_1} - \sqrt{S_2}, L = \sqrt{S_1} + \sqrt{S_2}$, we have $S_1 - S_2 = \frac{1}{2}(KL + LK) \equiv K \circ L$. Hence,

$$\begin{aligned}\|S_1 - S_2\|_1 \ge |\operatorname{Tr}\sigma(K)K \circ L| &= \operatorname{Tr}|K|L \\ &= \operatorname{Tr}|K|\left(1_+(K)L1_+(K) + 1_-(K)L1_-(K)\right).\end{aligned}$$

Since $L \ge K \ge -L$, we have $1_+(K)L1_+(K) \ge 1_+(K)K$ and $1_-(K)L1_-(K) \ge -1_-(K)K$. Thus, $(1_+(K)L1_+(K) + 1_-(K)L1_-(K)) \ge |K|$, and therefore

$$\|S_1 - S_2\|_1 \ge \operatorname{Tr}|K|^2 = \operatorname{Tr}\left(\sqrt{S_1} - \sqrt{S_2}\right)^2 .$$

To prove the second inequality in (10.32), let $S_1 = T_1^*T_1, S_2 = T_2^*T_2$ for some not necessarily Hermitian T_1, T_2. Denoting $K = T_1 - T_2, L = T_1 + T_2$, we have

$$\begin{aligned}\|S_1 - S_2\|_1 &= \operatorname{Tr}\sigma\left(S_1 - S_2\right)\left(S_1 - S_2\right) \\ &= \frac{1}{2}\left[\operatorname{Tr}\sigma\left(S_1 - S_2\right)K^*L + \operatorname{Tr}\sigma\left(S_1 - S_2\right)L^*K\right]\end{aligned}$$

By using the Cauchy-Schwarz inequality for the trace, we obtain

$$\left|\operatorname{Tr}\sigma\left(S_1 - S_2\right)K^*L\right| \le \left[\operatorname{Tr}\sigma\left(S_1 - S_2\right)^2 K^*K \cdot \operatorname{Tr}L^*L\right]^{\frac{1}{2}} = \left[\operatorname{Tr}K^*K \cdot \operatorname{Tr}L^*L\right]^{\frac{1}{2}},$$

and similarly for the second term. Thus, $\|S_1 - S_2\|_1 \le \left[\operatorname{Tr}K^*K \cdot \operatorname{Tr}L^*L\right]^{\frac{1}{2}}$. Using the normalization of S_1, S_2, we obtain

$$\operatorname{Tr}K^*K = 2\left(1 - \operatorname{Re}\operatorname{Tr}T_1^*T_2\right), \quad \operatorname{Tr}L^*L = 2\left(1 + \operatorname{Re}\operatorname{Tr}T_1^*T_2\right).$$

Take $T_1 = \sqrt{S_1}, T_2 = U\sqrt{S_2}$, where U is the unitary from the polar decomposition of $\sqrt{S_1}\sqrt{S_2}$. Then $\operatorname{Re}\operatorname{Tr}T_1^*T_2 = \operatorname{Re}\operatorname{Tr}T_2^*T_1 = \operatorname{Tr}\left|\sqrt{S_1}\sqrt{S_2}\right|$. Thus,

$$\begin{aligned}\operatorname{Tr}K^*K &= 2\left(1 - \left\|\sqrt{S_1}\sqrt{S_2}\right\|_1\right) = \beta\left(S_1, S_2\right)^2 \\ \operatorname{Tr}L^*L &= 2\left(1 + \left\|\sqrt{S_1}\sqrt{S_2}\right\|_1\right) \le 4\end{aligned}$$

and the second inequality in (10.32) follows.

10.10.10 10.3 The Quantum Capacity

10.10.11 10.3.1 Achievable Rates

Let $\Phi : \mathfrak{T}(\mathcal{H}_A) \to \mathfrak{T}(\mathcal{H}_B)$ be a quantum channel. Consider the composite channel $\Phi^{\otimes n} : \mathfrak{T}\left(\mathcal{H}_A^{\otimes n}\right) \to \mathfrak{T}\left(\mathcal{H}_B^{\otimes n}\right)$.

Definition 10.19. A number $R \geq 0$ is called the achievable rate (for the transmission of quantum information) if there exist a sequence of spaces $\mathcal{H}^{(n)}$ such that

$$\overline{\lim_{n\to\infty}} \frac{1}{n} \log \dim \mathcal{H}^{(n)} = R$$

and sequences of channels $\mathcal{E}^{(n)} : \mathfrak{T}\left(\mathcal{H}^{(n)}\right) \to \mathfrak{T}\left(\mathcal{H}_A^{\otimes n}\right)$ (encodings) and $\mathcal{D}^{(n)} : \mathfrak{T}\left(\mathcal{H}_B^{\otimes n}\right) \to \mathfrak{T}\left(\mathcal{H}^{(n)}\right)$ (decodings) such that

$$\lim_{n\to\infty} F_s\left(\mathcal{H}^{(n)}, \mathcal{D}^{(n)} \circ \Phi^{\otimes n} \circ \mathcal{E}^{(n)}\right) = 1 \tag{10.34}$$

The least upper bound of achievable rates will be denoted $Q(\Phi)$ and called the quantum capacity of the channel Φ.

The following data-processing inequality is useful for obtaining bounds on the quantum capacity.

Proposition 10.20. For any two channels Φ_1, Φ_2

$$Q(\Phi_2 \circ \Phi_1) \leq \min\{Q(\Phi_1), Q(\Phi_2)\}. \tag{10.35}$$

In particular, if one of these channels has zero quantum capacity, so does their concatenation.

Proof. To show that $Q(\Phi_2 \circ \Phi_1) \leq Q(\Phi_2)$, it suffices to observe that $Q(\Phi_2 \circ \Phi_1)$ is equal to the supremum of the achievable rates for channel Φ_2 over the special class of encodings, including post-processing with channel Φ_1. Hence, it does not exceed $Q(\Phi_2)$. The inequality $Q(\Phi_2 \circ \Phi_1) \leq Q(\Phi_1)$ is proved similarly by considering decodings for Φ_1, including preprocessing with channel Φ_2. □

Note that essentially the same reasoning implies a similar inequality for the classical capacity,

$$C(\Phi_2 \circ \Phi_1) \leq \min\{C(\Phi_1), C(\Phi_2)\}, \tag{10.36}$$

while for the classical entanglement-assisted capacity C_{ea} this can be derived from the data-processing inequality for quantum mutual information (Proposition 7.31, property iv), taking into account expression (9.4).

In the proof of the classical coding theorem it was much more convenient to use the average error probability instead of the maximal error probability, as the two criteria were shown to be equivalent in Lemma 4.11. In the quantum case, the role of the average error is played by the quantity $1 - F_e\left(\bar{S}^{(n)}, \mathcal{D}^{(n)} \circ \Phi^{\otimes n} \circ \mathcal{E}^{(n)}\right)$, where $\bar{S}^{(n)} = \frac{1}{d_n} I_{\mathcal{H}^{(n)}}$ is the chaotic state in $\mathcal{H}^{(n)}$, while the analog of the maximal error is $1 - F_s\left(\mathcal{H}^{(n)}, \mathcal{D}^{(n)} \circ \Phi^{\otimes n} \circ \mathcal{E}^{(n)}\right)$. Indeed, $F_S\left(\mathcal{H}^{(n)}, \mathcal{D}^{(n)} \circ \Phi^{\otimes n} \circ \mathcal{E}^{(n)}\right) \to 1$ implies $F_e\left(\bar{S}^{(n)}, \mathcal{D}^{(n)} \circ \Phi^{\otimes n} \circ \mathcal{E}^{(n)}\right) \to 1$ (according to Lemma 10.12). In the reverse direction, there is the following noncommutative analog of Lemma 4.11.

Lemma 10.21. Let $\mathcal{H}$ be a Hilbert space of dimensionality $2d$ and Φ a channel in $\mathcal{H}$. There exists a subspace $\mathcal{H}'$ of dimensionality d such that

$$1 - F_S(\mathcal{H}', \mathcal{D}' \circ \Phi) \leq 2\left(1 - F_e(\bar{S}, \Phi)\right)$$

where $\bar{S} = \frac{1}{2d} I_{\mathcal{H}}$, and $\mathcal{D}'[S] = P'SP' + \frac{P'}{d} \operatorname{Tr}(I - P')S$ for all $S \in \mathfrak{S}(\mathcal{H})$ with P' being the projector onto $\mathcal{H}'$.

Proof. On the unit ball of $\mathcal{H}$, consider the continuous function $|\psi\rangle \to f(\psi) = \langle\psi|\Phi[|\psi\rangle\langle\psi|]|\psi\rangle = F_e(|\psi\rangle\langle\psi|, \Phi)$. Let $|\psi_1\rangle$ be a vector minimizing $f(\psi)$. Define

the orthonormal basis $\{|\psi_j\rangle\,; j = 1, \ldots, 2d\}$ in $\mathcal{H} \equiv \mathcal{H}_0$ by the following recurrent procedure: $|\psi_{j+1}\rangle$ is the vector in the subspace $\mathcal{H}_j = \{|\psi_1\rangle, \ldots, \psi_j\rangle\}^\perp$ that minimizes $f(\psi)$. Then $\mathcal{H}_j \supset \mathcal{H}_{j+1}$ and $\dim \mathcal{H}_j = 2d - j$. By the convexity of $F_e(S, \Phi)$ (see Exercise 10.11), we obtain

$$\begin{aligned} 1 - F_e(\bar{S}, \Phi) &\geq \frac{1}{2d} \sum_{j=1}^{2d} \left(1 - F_e\left(|\psi_j\rangle \langle\psi_j|, \Phi\right)\right) \\ &\geq \frac{1}{2d} \sum_{j=d+1}^{2d} \left(1 - f\left(\psi_j\right)\right) \\ &\geq \frac{1}{2} \left(1 - \min_{|\psi\rangle \in \mathcal{H}_d} f(\psi)\right) \\ &\geq \frac{1}{2} \left(1 - F_s\left(\mathcal{H}', \mathcal{D}' \circ \Phi\right)\right), \end{aligned}$$

where $\mathcal{H}' = \mathcal{H}_d$.

From this lemma, together with inequality (10.26), it follows that in the definition of achievable rates we can replace (10.34) by

$$\lim_{n\to\infty} F_e\left(\bar{S}^{(n)}, \mathcal{D}^{(n)} \circ \Phi^{\otimes n} \circ \mathcal{E}^{(n)}\right) = 1 \tag{10.37}$$

Corollary 10.22. Any PPT channel (in particular, an entanglement-breaking channel) has zero quantum capacity.

Proof. In this proof, we denote by T the operations of transposition in different spaces, which will be clear from the context. By using (6.31), we have

$$\begin{aligned} F_e\left(\bar{S}^{(n)}, \mathcal{D}^{(n)} \circ \Phi^{\otimes n} \circ \mathcal{E}^{(n)}\right) &= F_e\left(\bar{S}^{(n)}, \mathcal{D}^{(n)} \circ T \circ T \circ \Phi^{\otimes n} \circ \mathcal{E}^{(n)}\right) \\ &= F_e\left(\bar{S}^{(n)}, T \circ \Phi_n\right) \end{aligned}$$

where $\Phi_n = \left(\mathcal{D}^{(n)}\right)^\top \circ (T \circ \Phi^{\otimes n}) \circ \mathcal{E}^{(n)}$ is a channel, because by Proposition 6.27 $T \circ \Phi^{\otimes n}$ is a channel. Now,

$$\begin{aligned} F_e\left(\bar{S}^{(n)}, T \circ \Phi_n\right) &= \left\langle \Omega^{(n)} \right| \left(\mathrm{Id}_{\mathcal{H}^{(n)}} \otimes T \circ \Phi_n\right) \left[\left|\Omega^{(n)}\right\rangle \left\langle \Omega^{(n)}\right|\right] \left|\Omega^{(n)}\right\rangle \\ &= \mathrm{Tr} \left|\Omega^{(n)}\right\rangle \left\langle \Omega^{(n)}\right| \left(\mathrm{Id}_{\mathcal{H}^{(n)}} \otimes T \circ \Phi_n\right) \left[\left|\Omega^{(n)}\right\rangle \left\langle \Omega^{(n)}\right|\right] \\ &= \mathrm{Tr} \left(\mathrm{Id}_{\mathcal{H}^{(n)}} \otimes T\right) \left[\left|\Omega^{(n)}\right\rangle \left\langle \Omega^{(n)}\right|\right] \left(\mathrm{Id}_{\mathcal{H}^{(n)}} \otimes \Phi_n\right) \left[\left|\Omega^{(n)}\right\rangle \left\langle \Omega^{(n)}\right|\right], \end{aligned}$$

where

$$\left|\Omega^{(n)}\right\rangle = \frac{1}{\sqrt{d_n}} \sum_{m=1}^{d_n} |m\rangle \otimes |m\rangle \tag{10.38}$$

is the maximally entangled vector in $\mathcal{H}^{(n)} \otimes \mathcal{H}^{(n)}$.

Introducing the Kraus decomposition $\Phi_n[S] = \sum_k V_k S V_k^*$, we obtain, by using (10.38), that the last expression for F_e is evaluated as

$$\begin{aligned} \frac{1}{d_n^2} \sum_k \sum_{l,m=1}^{d_n} \langle m|V_k|l\rangle \langle m|V_k^*|l\rangle \leq \frac{1}{d_n^2} \sum_k \sum_{l,m=1}^{d_n} \left|\langle m|V_k|\, l\right\rangle|^2 &= \frac{1}{d_n^2} \sum_k \mathrm{Tr}\, V_k^* V_k \\ &= \frac{1}{d_n} \end{aligned}$$

Thus, for arbitrary encodings and decodings $F_e\left(\bar{S}^{(n)}, \mathcal{D}^{(n)} \circ \Phi^{\otimes n} \circ \mathcal{E}^{(n)}\right) = d_n^{-1} \leq 1/2$ implying $Q(\Phi) = 0$.

Now, let us show that in the definition of the quantum capacity we can restrict ourselves to isometric encodings, i.e., to those which have the form

$$\mathcal{E}[S] = \operatorname{Ad} V[S] \equiv VSV^*, \tag{10.39}$$

where V is an isometric mapping of the space $\mathcal{H}^{(n)}$ into the input space $\mathcal{H}^{\otimes n}$ of the channel. We shall prove that if there is an encoding of a general form which achieves high fidelity for a given state, there also is an isometric encoding with a similar property. To explain this on an intuitive level, consider the case of perfect transmission. If the concatenation encoding-channel-decoding perfectly reproduces some state S, the encoding channel $\mathcal{E}$ is perfectly reversible on S, with the concatenation channel-decoding as the reverse channel. In this case, according to Proposition 10.7 the channel $\mathcal{E}$ on $\operatorname{supp} S$ can be represented in the form (10.5) as a convex combination of isometric encodings $\mathcal{U}_j = \operatorname{Ad} U_j$. Hence, any channel $\mathcal{U}_j$ is perfectly reversible on S with the same reverse channel.

Lemma 10.23. Let S be a state in a Hilbert space $\mathcal{L}, \mathcal{L} = \operatorname{supp} S$, let $\mathcal{E}$ be a completely positive map from $\mathfrak{T}(\mathcal{L})$ to $\mathfrak{T}(\mathcal{H})$, such that $\operatorname{Tr} \mathcal{E}[S] = 1$, and let $\mathcal{A}$ be a channel from $\mathfrak{T}(\mathcal{H})$ to $\mathfrak{T}(\mathcal{L})$. Assume that $\dim \mathcal{L} \leq \dim \mathcal{H}$. Then there exists an isometry V from $\mathcal{L}$ to $\mathcal{H}$ such that

$$F_e(S, \mathcal{A} \circ \operatorname{Ad} V) \geq F_e(S, \mathcal{A} \circ \mathcal{E})^2. \tag{10.40}$$

This lemma will be used in the situation where $\mathcal{E}$ is the encoding map, while $\mathcal{A}$ is the concatenation channel-decoding. For the proof, we need the following generalization of the polar decomposition. If X is an operator from $\mathcal{L}$ to $\mathcal{H}, \dim \mathcal{L} \leq \dim \mathcal{H}$, then $X = V|X|$, where $|X| = \sqrt{X^*X}$ is a positive operator in $\mathcal{L}$ and V is an isometry from $\mathcal{L}$ to $\mathcal{H}$. This implies the following representation for an arbitrary square matrix X : $X = VDU$, where D is a diagonal matrix with nonnegative elements, and V, U are unitary matrices.

Proof. Let $A_i : \mathcal{H} \to \mathcal{L}$ and $E_j : \mathcal{L} \to \mathcal{H}$ be the components of the Kraus decomposition for the maps $\mathcal{A}$ and $\mathcal{E}$, respectively. Denote by X the matrix with the elements $X_{ij} = \operatorname{Tr} A_i E_j S$. Then, by (10.21),

$$F_e(S, \mathcal{A} \circ \mathcal{E}) = \sum_{ij} |X_{ij}|^2 .$$

Complementing the Kraus decompositions, if necessary, with additional zero components, we may assume that X is a square matrix. The decomposition $X = VDU$ implies that by transforming the Kraus decompositions for $\mathcal{A}$ and $\mathcal{E}$, we can make the matrix X diagonal. Then again using (10.21), we obtain $F_e(S, \mathcal{A} \circ \mathcal{E}) = \sum_k |\operatorname{Tr} A_k E_k S|^2$. We denote $\lambda_k = \operatorname{Tr} S E_k^* E_k$, and we restrict ourselves to $\lambda_k > 0$. Then $\sum_k \lambda_k \left(|\operatorname{Tr} A_k E_k S|^2 / \lambda_k \right) =$
$F_e(S, \mathcal{A} \circ \mathcal{E})$ and $\sum_k \lambda_k = 1$, so that there exists a k such that $|\operatorname{Tr} A_k E_k S|^2 / \lambda_k \geq F_e(S, \mathcal{A} \circ \mathcal{E})$. Setting $E = E_k / \sqrt{\lambda_k} : \mathcal{L} \to \mathcal{H}, A = A_k : \mathcal{H} \to \mathcal{L}$, we have $A^*A \leq I_{\mathcal{H}}, \operatorname{Tr} S E^* E = 1$, and

$$F_e(S, \mathcal{A} \circ \mathcal{E}) \leq F_e(S, \operatorname{Ad} A \circ \operatorname{Ad} E) = |\operatorname{Tr} AES|^2.$$

Let $A^* = V |A^*|$ be the polar decomposition of the operator $A^* : \mathcal{L} \to \mathcal{H}$, where $V : \mathcal{L} \to \mathcal{H}$ is an isometry. According to the noncommutative Cauchy-Schwarz inequality (2.24)

$$|\operatorname{Tr} AES|^2 = |\operatorname{Tr} SAE|^2 \leq \operatorname{Tr} SAA^* \operatorname{Tr} SE^*E = \operatorname{Tr} S |A^*|^2 . \tag{10.41}$$

Since $A^*A \leq I_{\mathcal{H}}$, also $AA^* \leq I_{\mathcal{L}}$. Hence, $|A^*|^2 \leq |A^*|$ and therefore

$$\operatorname{Tr} S |A^*|^2 \leq \operatorname{Tr} S |A^*| = \operatorname{Tr} AVS.$$

Then

$$|\operatorname{Tr} AVS|^2 \le \sum_k |\operatorname{Tr} A_k VS|^2 = F_e(S, \mathcal{A}\circ \operatorname{Ad} V)$$

This chain of inequalities implies (10.40).
Now, let some sequences of subspaces $\mathcal{H}^{(n)}$, encodings $\mathcal{E}^{(n)}$, and decodings $\mathcal{D}^{(n)}$ be given, for which (10.37) holds. In this case, by Lemma 10.23, there exists a sequence of isometric encodings $\mathcal{V}^{(n)} = \operatorname{Ad} V^{(n)}$ such that

$$\lim_{n\to\infty} F_e\left(\bar{S}^{(n)}, \mathcal{D}^{(n)}\circ\Phi^{\otimes n}\circ\mathcal{V}^{(n)}\right) = 1 \tag{10.42}$$

It follows that in the definition of the quantum capacity we can restrict ourselves to the isometric encodings.

10.10.12 10.3.2 The Quantum Capacity and the Coherent Information

The following fundamental result is the coding theorem for the quantum capacity, which relates it to the coherent information.

Theorem 10.24 (Lloyd, Shor, Devetak). For any channel Φ, the quantum capacity is given by the expression

$$Q(\Phi) = \lim_{n\to\infty}\frac{1}{n}\max_S I_c\left(S, \Phi^{\otimes n}\right), \tag{10.43}$$

where $I_c(S,\Phi)$ is the coherent information.

Existence of the limit can be shown, just like in the case of the classical capacity, by using superadditivity of the sequence $\bar{Q}_n = \max_S I_c\left(S, \Phi^{\otimes n}\right)$. Let us check that (10.43) implies the inequality relating the quantum and the classical capacities of the channel

$$Q(\Phi) \le C(\Phi) \tag{10.44}$$

which is proved the same way as the second inequality in (9.8). Indeed, take S to be a mixture of arbitrary pure states S_j with probabilities p_j. Then (7.50) implies

$$I_c(S,\Phi) = H(\Phi[S]) - H(S,\Phi) \le H\left(\sum_j p_j \Phi\left[S_j\right]\right) - \sum_j p_j H\left(\Phi\left[S_j\right]\right) = \chi\left(\{p_j\}, \{\Phi\left[S_j\right]\}\right)$$

Taking the maximum gives $\max_S I_c(S,\Phi) \le C_\chi(\Phi)$. Applying this to $\Phi^{\otimes n}$ leads to (10.44).
Proof of the inequality $\le$. Denote by $\bar{Q}(\Phi)$ the right-hand side of (10.43). A simpler part of the theorem is the proof of the inequality

$$Q(\Phi) \le \bar{Q}(\Phi) \tag{10.45}$$

i. e., the weak converse of the coding theorem. Let $\mathcal{H}^{(n)}$ be the input space of dimensionality $d_n = \dim \mathcal{H}^{(n)} = 2^{nR}$ and let $\mathcal{E}^{(n)}, \mathcal{D}^{(n)}$ be an encoding and decoding such that

$$1 - F_e\left(\bar{S}^{(n)}, \mathcal{D}^{(n)}\circ\Phi^{\otimes n}\circ\mathcal{E}^{(n)}\right) \le \varepsilon$$

where $\bar{S}^{(n)} = \frac{1}{d_n} I_{\mathcal{H}^{(n)}}$ is the chaotic state in $\mathcal{H}^{(n)}$, with the entropy $H\left(\bar{S}^{(n)}\right) = \log d_n = nR$. Here, we are using the requirement (10.37) in the definition of the achievable rate. According to Lemma 10.23, we can assume that $\mathcal{E}^{(n)}$ are isometric encodings. Since

$$F_e\left(\bar{S}^{(n)}, \mathcal{D}^{(n)} \circ \Phi^{\otimes n} \circ \mathcal{E}^{(n)}\right)$$
$$= \left\langle \Omega^{(n)} \right| \left(\mathrm{Id}_{\mathcal{H}^{(n)}} \otimes \mathcal{D}^{(n)} \circ \Phi^{\otimes n} \circ \mathcal{E}^{(n)}\right) \left[\left|\Omega^{(n)}\right\rangle \left\langle \Omega^{(n)}\right|\right] \left|\Omega^{(n)}\right\rangle,$$

where $\left|\Omega^{(n)}\right\rangle$ is the maximally entangled vector, it follows by Lemma 10.9 that for the maximally entangled state $\left|\Omega^{(n)}\right\rangle \left\langle \Omega^{(n)}\right|$ in $\mathcal{H}^{(n)} \otimes \mathcal{H}^{(n)}$ the following holds:

$$\| \left|\Omega^{(n)}\right\rangle \left\langle \Omega^{(n)}\right| - \left(\mathrm{Id}_{\mathcal{H}^{(n)}} \otimes \mathcal{D}^{(n)} \circ \Phi^{\otimes n} \circ \mathcal{E}^{(n)}\right) \left[\left|\Omega^{(n)}\right\rangle \left\langle \Omega^{(n)}\right|\right] \|_1 \leq 2\sqrt{\varepsilon}. \tag{10.46}$$

This means that the rate R is achievable for asymptotically perfect transmission of the chaotic state in $\mathcal{H}^{(n)}$.

Denoting $S^{(n)} = \mathcal{E}^{(n)}\left[\bar{S}^{(n)}\right]$ and using the chain rule (10.6) for the coherent information, we have

$$I_c\left(S^{(n)}, \Phi^{\otimes n}\right) \geq I_c\left(S^{(n)}, \mathcal{D}^{(n)} \circ \Phi^{\otimes n}\right) = H\left(S_{B'}\right) - H\left(S_{B'R'}\right) \tag{10.47}$$

where $S_{B'R'} = \left(\mathrm{Id}_{\mathcal{H}^{(n)}} \otimes \left(\mathcal{D}^{(n)} \circ \Phi^{\otimes n} \circ \mathcal{E}^{(n)}\right)\right) \left[\left|\Omega^{(n)}\right\rangle \left\langle \Omega^{(n)}\right|\right]$, so that

$$S_{B'} = \left(\mathcal{D}^{(n)} \circ \Phi^{\otimes n} \circ \mathcal{E}^{(n)}\right) \left[\bar{S}^{(n)}\right].$$

The equality $H\left(S_{B'R'}\right) = H\left(S^{(n)}, \mathcal{D}^{(n)} \circ \Phi^{\otimes n}\right)$ follows from the fact that, due to the isometric nature of the encoding $\mathcal{E}^{(n)}$, the state $\left(\mathrm{Id}_{\mathcal{H}^{(n)}} \otimes \mathcal{E}^{(n)}\right) \left[\left|\Omega^{(n)}\right\rangle \left\langle \Omega^{(n)}\right|\right]$ is pure and can be regarded as a purification of $S^{(n)}$. According to (10.46)

$$\left\|\bar{S}^{(n)} - S_{B'}\right\|_1 \leq \| \left|\Omega^{(n)}\right\rangle \left\langle \Omega^{(n)}\right| - S_{B'R'} \|_1 \leq 2\sqrt{\varepsilon}.$$

Here the first inequality follows from a simple observation, to be proved in the following exercise.

Exercise 10.25 Prove the following statement: the trace norm does not increase under partial trace, i.e.,

$$\|\mathrm{Tr}_{\mathcal{H}_0} T\|_1 \leq \|T\|_1,$$

for any positive operator $T \in \mathcal{H} \otimes \mathcal{H}_0$. Hint: use expression (1.19) for the trace norm.

By using twice the estimate (7.26) for the continuity of the entropy, we have

$$\begin{aligned} H\left(S_{B'}\right) - H\left(S_{B'R'}\right) =& H\left(\bar{S}^{(n)}\right) + \left[H\left(S_{B'}\right) - H\left(\bar{S}^{(n)}\right)\right] \\ &+ \left[H\left(\left|\Omega^{(n)}\right\rangle \left\langle \Omega^{(n)}\right|\right) - H\left(S_{B'R'}\right)\right] \\ \geq& H\left(\bar{S}^{(n)}\right) - 6 \log \dim \mathcal{H}^{(n)} \sqrt{\varepsilon} - \frac{2 \log e}{e} \\ =& nR(1 - 6\sqrt{\varepsilon}) - \frac{2 \log e}{e}. \end{aligned}$$

Therefore, taking into account (10.47),

$$\bar{Q}_n = \max_{S^{(n)}} I_c\left(S^{(n)}, \Phi^{\otimes n}\right) \geq nR(1 - 6\sqrt{\varepsilon}) - \frac{2 \log e}{e},$$

whence $R \leq \lim_{n\to\infty} \frac{1}{n} \bar{Q}_n = \bar{Q}(\Phi)$.

This completes the proof of inequality (10.45), i.e., the weak converse for the quantum capacity. The proof of the direct coding theorem is postponed to Section 10.4.4. □

10.10.13 10.3.3 Degradable Channels

First of all, we obtain important relations between the coherent information and the quantity

$$\chi\left(\{\pi_x\},\{S_x\}\right)=H\left(\sum_x \pi_x S_x\right)-\sum_x \pi_x H\left(S_x\right),$$

giving the upper bound (5.16) for the amount of classical information and, as a consequence, a relation between the quantum and the classical capacities of a channel and its complementary.

Consider a channel $\Phi:\mathfrak{T}\left(\mathcal{H}_A\right)\to\mathfrak{T}\left(\mathcal{H}_B\right)$, its Stinespring dilation with the isometry $V:\mathcal{H}_A\to\mathcal{H}_B\otimes\mathcal{H}_E$, and the complementary channel (see Section 6.6)

$$\tilde{\Phi}[S]=\mathrm{Tr}_{\mathcal{H}_B} VSV^*,\quad S\in\mathfrak{T}\left(\mathcal{H}_A\right). \tag{10.48}$$

Let $S=\sum_x \pi_x S_x$ be an arbitrary decomposition of the state S into pure states. Then the following equalities hold:

$$\begin{aligned}
I_c(S,\Phi)&=H(\Phi[S])-H(\tilde{\Phi}[S])\\
&=\left[H(\Phi[S])-\sum_x \pi_x H\left(\Phi\left[S_x\right]\right)\right] &(10.49)\\
&-\left[H(\tilde{\Phi}[S])-\sum_x \pi_x H\left(\tilde{\Phi}\left[S_x\right]\right)\right]\\
&=\chi\left(\{\pi_x\},\{\Phi\left[S_x\right]\}\right)-\chi\left(\{\pi_x\},\left\{\tilde{\Phi}\left[S_x\right]\right\}\right) &(10.50)\\
&=\sum_x \pi_x\left[H\left(\Phi\left[S_x\right];\Phi[S]\right)-H\left(\tilde{\Phi}\left[S_x\right];\tilde{\Phi}[S]\right)\right] &(10.51)
\end{aligned}$$

Here, equality (10.49) follows from the fact that the state VS_xV^* is pure and hence

$$H\left(\Phi\left[S_x\right]\right)=H\left(\tilde{\Phi}\left[S_x\right]\right)$$

for all x, and (10.51) follows from identity (7.19). Taking the upper and the lower bounds in (10.50), with respect to all possible ensembles of pure states, we obtain

$$-Q_1(\tilde{\Phi})\le C_\chi(\Phi)-C_\chi(\tilde{\Phi})\le Q_1(\Phi), \tag{10.52}$$

where we introduced the notation

$$Q_1(\Phi)=\max_S I_c(S,\Phi). \tag{10.53}$$

Applying (10.52) to channel $\Phi^{\otimes n}$, taking the limit $n\to\infty$, and using the coding theorems, we obtain

$$-Q(\tilde{\Phi})\le C(\Phi)-C(\tilde{\Phi})\le Q(\Phi).$$

Now, we introduce an important class of channels for which the quantum capacity is given by the "one-letter" expression (10.53).

Definition 10.26. The channel Φ is called degradable if there exists a channel Γ such that $\tilde{\Phi}=\Gamma\circ\Phi$ (Fig. 10.1) and antidegradable if there exists a channel Γ' such that $\Phi=\Gamma'\circ\tilde{\Phi}$.

Obviously, Φ is degradable if and only if $\tilde{\Phi}$ is antidegradable. From relation (10.51), by using the monotonicity of the relative entropy, we deduce that if Φ is an antidegradable channel, then

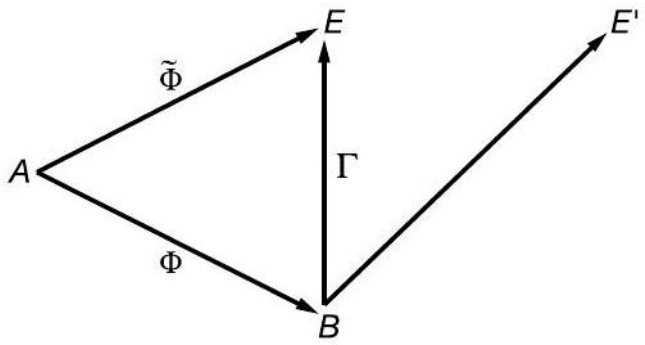

Figure 10.1: Degradable channel.

$$I_c(S,\Phi) \le 0 \quad \text{for all states } S \tag{10.54}$$

(correspondingly, $I_c(S,\Phi) \ge 0$ for a degradable channel).

Proposition 10.27. If Φ is an antidegradable channel, then $Q(\Phi) = 0$. If Φ is degradable, then

$$Q(\Phi) = Q_1(\Phi) = \max_S I_c(S,\Phi). \tag{10.55}$$

Proof. The first statement follows from (10.54) and the weak converse (10.45).

Let Φ be a degradable channel and $W : \mathcal{H}_B \to \mathcal{H}_E \otimes \mathcal{H}_{E'}$ be the Stinespring isometry for the channel $\Gamma : \mathfrak{T}(\mathcal{H}_B) \to \mathfrak{T}(\mathcal{H}_E)$. Then $I_c(S,\Phi) = H(B) - H(E) = H(EE') - H(E)$, so that

$$I_c(S,\Phi) = H(E' \mid E).$$

For two degradable channels Φ_1, Φ_2 and for an arbitrary state S_{12} in $\mathcal{H}_{A_1} \otimes \mathcal{H}_{A_2}$, we have

$$I_c(S_{12}, \Phi_1 \otimes \Phi_2) = H(E_1' E_2' \mid E_1 E_2).$$

Hence, by subadditivity (7.43) of the conditional entropy

$$I_c(S_{12}, \Phi_1 \otimes \Phi_2) \le I_c(S_1, \Phi_1) + I_c(S_2, \Phi_2)$$

implying

$$I_c\left(S^{(n)}, \Phi^{\otimes n}\right) \le n \max_S I_c(S,\Phi) \tag{10.56}$$

and hence, by the weak converse, (10.55). □

Consider an entanglement-breaking channel

$$\Phi[S] = \sum_{k=1}^{\tilde{d}} |\varphi_k\rangle \langle\psi_k| S |\psi_k\rangle \langle\varphi_k|,$$

where $\{\psi_k\}$ is an overcomplete system in $\mathcal{H}$ and $\{\varphi_k\}$ is a system of unit vectors in the output space $\mathcal{H}'$. The complementary channel is

$$\tilde{\Phi}[S] = \sum_{k,l=1}^{\tilde{d}} c_{kl} |e_k\rangle \langle\psi_k| S |\psi_l\rangle \langle e_l|,$$

where $c_{kl} = \langle\varphi_l \mid \varphi_k\rangle$, while $\{e_k\}$ is the standard basis in $\tilde{\mathbb{C}}^{\tilde{d}}$. We have $\Phi = \Gamma' \circ \tilde{\Phi}$, where

$$\Gamma'[S] = \sum_{k=1}^{\tilde{d}} |\varphi_k\rangle \langle e_k| S |e_k\rangle \langle \varphi_k| .$$

This proves the following.

Corollary 10.28. Any entanglement-breaking channel Φ is antidegradable.

The first statement of Proposition 10.27 again implies $Q(\Phi) = 0$, thus reconfirming Corollary 10.22.

Example 10.29. Consider the quantum erasure channels Φ_p. For $q \geq p$,

$$\Phi_q = \Gamma_{(1-q)/(1-p)} \circ \Phi_p,$$

where $\Gamma_\alpha : \mathfrak{T}(\mathcal{H} \oplus \mathbb{C}) \to \mathfrak{T}(\mathcal{H} \oplus \mathbb{C})$ is the channel acting as

$$\Gamma_\alpha \left[\begin{bmatrix} S & 0 \\ 0 & S \end{bmatrix} \right] = \alpha \begin{bmatrix} S & 0 \\ 0 & S \end{bmatrix} + (1-\alpha) \begin{bmatrix} 0 & 0 \\ 0 & \operatorname{Tr} S + s \end{bmatrix}.$$

Combining this with the fact that $\tilde{\Phi}_p = \Phi_{1-p}$ (see Exercise 6.35), we find that Φ_p is degradable for $p \in [0, 1/2]$ and antidegradable for $p \in [1/2, 1]$. Therefore, by Theorem 10.27, we obtain

$$Q(\Phi_p) = \begin{cases} (1-2p) \log d, & p \in [0, 1/2], \\ 0, & p \in [1/2, 1]. \end{cases} \tag{10.57}$$

Here, the first line follows from (10.55) together with the fact that $H(\Phi_p[S]) = (1-p)H(S) + h_2(p)$. Hence, $I_c(S, \Phi_p) = H(\Phi_p[S]) - H\left(\tilde{\Phi}_p[S]\right) = (1-p)H(S) - pH(S) = (1-2p)H(S)$. Maximizing over S gives (10.57).

10.10.14 10.4 The Private Classical Capacity and the Quantum Capacity

10.10.15 10.4.1 The Quantum Wiretap Channel

Consider the situation where the quantum communication channel is accessed by three parties, i. e., a sender A, a receiver B, and an eavesdropper E. The mathematical model of the quantum wiretap channel consists of three Hilbert spaces $\mathcal{H}_A, \mathcal{H}_B, \mathcal{H}_E$
and an isometric map $V : \mathcal{H}_A \to \mathcal{H}_B \otimes \mathcal{H}_E$, so that the input state S_A is mapped to the state $S_{BE} = \Phi_{BE}[S_A] \equiv V S_A V^*$ of the system BE, with the partial states

$$S_B = \Phi_B[S_A] = \operatorname{Tr}_E V S_A V^*, \quad S_E = \Phi_E[S_A] = \operatorname{Tr}_B V S_A V^*$$

Recall that the notation E was used previously for the environment. This is a consistent change, if we regard the whole environment as accessible to the eavesdropper.

Assume that the party A chooses an ensemble of states $\left\{S_A^X\right\}$ with probabilities $\{\pi_\chi\}$, so that B and E receive states $\{S_B^\chi\}$ and $\{S_E^\chi\}$, respectively. In this case, the upper bounds for the Shannon informations of B and E are, correspondingly, $\chi\left(\{\pi_x\}, \left\{S_B^X\right\}\right)$ and $\chi(\{\pi_x\}, \{S_E^x\})$. By analogy with the classical wiretap channel (see Section 4.5), the "quantum privacy" can be characterized by the quantity $\chi(\{\pi_x\}, \{S_B^x\}) - \chi(\{\pi_x\}, \{S_E^x\})$. Assuming that the input states S_A^X are pure and denoting by $\bar{S}_A = \sum_x \pi_x S_A^X$ the average of the input ensemble, we obtain, from (10.50), a key relation (Schumacher and Westmoreland [201]),

$$I_c\left(\bar{S}_A, \Phi_B\right) = \chi(\{\pi_\chi\}, \{S_B^x\}) - \chi(\{\pi_\chi\}, \{S_E^x\}) \tag{10.58}$$

This points to the profound connection between the quantum capacity and the private classical capacity, which provides a hint to a proof of the direct coding theorem.

To define the private classical capacity, let us consider block coding for the quantum wiretap channel. The goal is to transmit the maximum amount of classical information from A to B in a private way, so that E can receive only an asymptotically negligible amount of information. A code $\left(\Sigma^{(n)}, M^{(n)}\right)$ of length n and of size N is defined as in Definition 8.1, i. e., as a collection of states $\Sigma^{(n)} = \left\{S^i_{A^{(n)}}; i = 1, \ldots, N\right\}$ in $\mathcal{H}_A^{\otimes n}$, together with an observable $M^{(n)} = \{M_j; j = 0, 1, \ldots, N\}$ in $\mathcal{H}_B^{\otimes n}$. Along with its error probability $P_e\left(\Sigma^{(n)}, M^{(n)}\right)$, defined by (8.1), we consider the new quantity

$$v_E\left(\Sigma^{(n)}\right) = \max_{i,k=1,\ldots,N} \left\|S^i_{E^{(n)}} - S^k_{E^{(n)}}\right\|_1$$

which characterizes the variability, and hence the information content of the output states for the eavesdropper E. Note that, by the triangle inequality for the norm, we have

$$\left\|\bar{S}_{E^{(n)}} - S^i_{E^{(n)}}\right\|_1 \leq v_E\left(\Sigma^{(n)}\right) \qquad \text{for all } i$$

where $\bar{S}_{E^{(n)}} = \frac{1}{N}\sum_{i=1}^N S^i_{E^{(n)}}$. Applying inequality (7.25), we obtain

$$\begin{aligned} \frac{1}{n}\chi\left(\left\{\frac{1}{N}\right\}, \left\{S^i_{E^{(n)}}\right\}\right) &= \frac{1}{nN}\sum_{i=1}^N \left[H\left(\bar{S}_{E^{(n)}}\right) - H\left(S^i_{E^{(n)}}\right)\right] \\ &\leq \log\dim\mathcal{H}_E \cdot v_E\left(\Sigma^{(n)}\right) + \frac{1}{n}\eta\left(v_E\left(\Sigma^{(n)}\right)\right) \end{aligned} \tag{10.59}$$

provided that $v_E\left(\Sigma^{(n)}\right)$ is small enough. Therefore, if the variability is small, the Shannon mutual information between A and E, with equiprobable encoding, is also small.

We call R the achievable rate for the wiretap channel if there exists a sequence of codes $\left(\Sigma^{(n)}, M^{(n)}\right)$ of sizes $N = 2^{nR}$, such that

$$\lim_{n\to\infty} P_e\left(\Sigma^{(n)}, M^{(n)}\right) = 0$$

and

$$\lim_{n\to\infty} v_E\left(\Sigma^{(n)}\right) = 0. \tag{10.60}$$

The least upper bound of the achievable rates is called the private classical capacity $C_p\left(\Phi_{BE}\right)$ of the wiretap channel. By (10.59), condition (10.60) implies asymptotic vanishing of the mutual information between A and E. It is possible to show that these conditions are, in fact, equivalent, but condition (10.60) is more convenient technically and is also more useful for later application to the quantum capacity.

Theorem 10.30 (Devetak [62] and Cai, Winter, and Yeung [38]). We have

$$C_p\left(\Phi_{BE}\right) = \lim_{n\to\infty}\frac{1}{n}\max_{\pi^{(n)},\Sigma^{(n)}}\left[\chi\left(\left\{\pi^{(n)}_i\right\}, \left\{S^i_{B^{(n)}}\right\}\right) - \chi\left(\left\{\pi^{(n)}_i\right\}, \left\{S^i_{E^{(n)}}\right\}\right)\right], \tag{10.61}$$

where the maximization is over all ensembles, i. e., finite collections of states $\Sigma^{(n)} = \left\{S^i_{A^{(n)}}\right\}$ in $\mathcal{H}_A^{\otimes n}$ with probability distributions $\pi^{(n)} = \left\{\pi^{(n)}_i\right\}$ (we use the notations $S^i_{B^{(n)}} = \Phi_B^{\otimes n}\left[S^i_{A^{(n)}}\right]$, $S^i_{E^{(n)}} = \Phi_E^{\otimes n}\left[S^i_{A^{(n)}}\right]$).

Formulas (10.43), (10.58), and (10.61) imply an important relation between the quantum and the private classical capacities

$$Q\left(\Phi_B\right) \leq C_p\left(\Phi_{BE}\right) \tag{10.62}$$

following from the fact that $C_p\left(\Phi_{BE}\right)$ involves arbitrary state ensembles for A, while $Q\left(\Phi_B\right)$ involves only pure ones. In general, the inequality can be strict. Therefore, the following statement is of special interest.

Proposition 10.31. If the channel Φ_B is degradable,

$$C_p\left(\Phi_{BE}\right) = Q\left(\Phi_B\right) = Q_1\left(\Phi_B\right). \tag{10.63}$$

Proof. By using equality (10.50), we have

$$\begin{aligned}
&\chi\left(\left\{\pi_i^{(n)}\right\}, \left\{S_{B^{(n)}}^i\right\}\right) - \chi\left(\left\{\pi_i^{(n)}\right\}, \left\{S_{E^{(n)}}^i\right\}\right) \\
&= H\left(\sum_i \pi_i^{(n)} S_{B^{(n)}}^i\right) - H\left(\sum_i \pi_i^{(n)} S_{E^{(n)}}^i\right) \\
&\quad - \sum_i \pi_i^{(n)}\left[H\left(S_{B^{(n)}}^i\right) - H\left(S_{E^{(n)}}^i\right)\right] \\
&= I_c\left(\sum_i \pi_i^{(n)} S_{A^{(n)}}^i, \Phi_B^{\otimes n}\right) - \sum_i \pi_i^{(n)} I_c\left(S_{A^{(n)}}^i, \Phi_B^{\otimes n}\right) \\
&\leq I_c\left(\sum_i \pi_i^{(n)} S_{A^{(n)}}^i, \Phi_B^{\otimes n}\right)
\end{aligned}$$

since channel $\Phi_B^{\otimes n}$, along with Φ_B, is degradable and hence, $I_c\left(S_{A^{(n)}}^i, \Phi_B^{\otimes n}\right) \geq 0$. Therefore, by using (10.62)

$$\max_{\pi^{(n)}, \Sigma^{(n)}}\left[\chi\left(\left\{\pi_i^{(n)}\right\}, \left\{S_B^i\right\}\right) - \chi\left(\left\{\pi_i^{(n)}\right\}, \left\{S_{E^{(n)}}^i\right\}\right)\right] = \max_{S^{(n)}} I_c\left(S^{(n)}, \Phi_B^{\otimes n}\right)$$

which is equal to $nQ_1\left(\Phi_B\right)$ due to (10.56). Substituting this into (10.61) we obtain (10.63). □

10.10.16 10.4.2 Proof of the Private Capacity Theorem

We first prove inequality $\leq$ i. e., the weak converse. Let R be an achievable rate. In this case, by (5.32) and the information bound (5.16),

$$\begin{aligned}
\bar{P}_e\left(\Sigma^{(n)}, M^{(n)}\right) &\geq 1 - \frac{\chi\left(\left\{1/N\right\}, \left\{S_{B^{(n)}}^i\right\}\right)}{nR} - \frac{1}{nR} \\
&= 1 - \frac{\chi\left(\left\{1/N\right\}, \left\{S_{B^{(n)}}^i\right\}\right) - \chi\left(\left\{1/N\right\}, \left\{S_{E^{(n)}}^i\right\}\right)}{nR} \\
&\quad - \frac{1 + \chi\left(\left\{1/N\right\}, \left\{S_{E^{(n)}}^i\right\}\right)}{nR}.
\end{aligned} \tag{10.64}$$

According to (10.59),

$$\chi\left(\left\{1/N\right\}, \left\{S_{E^{(n)}}^i\right\}\right) \leq v_E\left(\Sigma^{(n)}\right)\left[n \log d_E - \log v_E\left(\Sigma^{(n)}\right)\right]$$

where $d_E = \dim \mathcal{H}_E$. Therefore, the last term in the right-hand side of (10.64) tends to zero as $n \to \infty$, along with the left-hand side. From this follows $0 \geq 1 - \bar{C}_p/R$, where $\bar{C}_p$ is the right-hand side of (10.61), and hence $C_p\left(\Phi_{BE}\right) \leq \bar{C}_p$.

To prove the direct statement it is sufficient to show that for an arbitrary ensemble $\{\pi_\chi, S_A^\chi\}$ and $\delta > 0$ the rate $\chi\left(\{\pi_\chi\}, \{S_B^\chi\}\right) - \chi\left(\{\pi_\chi\}, \{S_E^\chi\}\right) - \delta$ is achievable. Achievability of the rate $\bar{C}_p - \delta$ then follows by additional blocking. Consider the c-q channel $x \to S_B^x$ and the random codebook $W^{(n)}$ of size $N = 2^{n\left[\chi\left(\{\pi_\chi\},\left\{S_B^X\right\}\right)-c\delta\right]}$, with independent words having the probability distribution

$$\mathrm{P}\left\{w = (x_1, \ldots, x_n)\right\} = \pi_{x_1} \cdots \pi_{x_n}. \tag{10.65}$$

The constant c in the definition of N will be fixed later. To simplify the notation, we will denote all constants that appear below by the same letter c. In fact, we can always take the maximum of them. By the remark that follows the proof of the direct quantum coding theorem at the end of Section 5.6, for sufficiently large n, there exist decision rules $M^{(n)}$ for the system B such that

$$E\bar{P}_e\left(W^{(n)}, M^{(n)}\right) \le 2^{-n\beta}, \quad \beta > 0.$$

Now, consider the new random code with independent words having the uniform distribution on the set $\hat{T}^{n,\delta}$ of δ-strongly typical words,

$$\tilde{\mathrm{P}}(w) = \begin{cases} \frac{1}{\left|\hat{T}^{n,\delta}\right|}, & w \in \hat{T}^{n,\delta} \\ 0, & w \notin \hat{T}^{n,\delta} \end{cases}$$

By Exercise 9.10, $\left|\hat{T}^{n,\delta}\right| \ge 2^{n[H(\pi)-\Delta_n(\delta)]}$, where $\lim_{\delta\to 0}\lim_{n\to\infty}\Delta_n(\delta) = 0$. Since $\mathrm{P}(w) \ge 2^{-n[H(\pi)+c\delta]}$ for $w \in \hat{T}^{n,\delta}$, where c is a constant (depending on $\{\pi_x\}$), we have $\tilde{\mathrm{P}}(w) \le 2^{n[c\delta+\Delta_n(\delta)]}\mathrm{P}(w)$ for all w, and hence

$$\tilde{\mathrm{E}}\bar{P}_e\left(W^{(n)}, M^{(n)}\right) \le 4^{n[c\delta+\Delta_n(\delta)]}2^{-n\beta} \le \varepsilon$$

for n large enough, because the estimate (5.51) for $\bar{P}_e\left(W^{(n)}, M^{(n)}\right)$ involves at most two independent words. Hence, by the Markov inequality,

$$\tilde{\mathrm{P}}\left\{\bar{P}_e\left(W^{(n)}, M^{(n)}\right) \ge \sqrt{\varepsilon}\right\} \le \sqrt{\varepsilon}. \tag{10.66}$$

So far, this was just a slight modification of the random code for the classical information transmission from A to B. To make it secure against eavesdropping, A has to sacrifice $n\left[\chi\left(\{\pi_\chi\}, \left\{S_E^X\right\}\right) + c\delta/2\right]$ bits of information, by additional randomization of the input. Assuming $\chi\left(\{\pi_\chi\}, \left\{S_B^X\right\}\right) - \chi\left(\{\pi_\chi\}, \left\{S_E^X\right\}\right) > 0$, set

$$N_E = 2^{n\left[\chi\left(\{\pi_x\},\left\{S_E^x\right\}\right)+c\delta/2\right]}, \quad N_B = 2^{n\left[\chi\left(\{\pi_x\},\left\{S_B^x\right\}\right)-\chi\left(\{\pi_x\},\left\{S_E^x\right\}\right)-3c\delta/2\right]},$$

so that $N_E N_B = N$, and arrange the codebook $W^{(n)}$ in a rectangular array with N_B rows and N_E columns. Then

$$W^{(n)} = \left\{w^{mj}; m = 1, \ldots, N_B; j = 1, \ldots, N_E\right\},$$
$$M^{(n)} = \left\{M_{mj}; m = 1, \ldots, N_B; j = 1, \ldots, N_E\right\}.$$

(For brevity of notation we omit the zero component of $M^{(n)}$ which corresponds to "no decision.")

For each m, A will take the value j at random, with equal probabilities, which results in the input states

$$m \to S_{A^{(n)}}^m = \frac{1}{N_E}\sum_{j=1}^{N_E} S_{A^{(n)}}^{w^{mj}}$$

with the corresponding outputs $S^m_{B^{(n)}}$ for B and $S^m_{E^{(n)}}$ for E. (Let us recall here that $S^W_{A^{(n)}} = S^{x_1}_A \otimes \cdots \otimes S^{x_n}_A$ for a word $w = (x_1, \ldots, x_n)$.) Such a randomization will make the transmitted information almost secret to E, because from the viewpoint of the eavesdropper, for every m the codebook

$$\left\{w^{mj}; j = 1, \ldots, N_E\right\}$$

with a high probability is a "good" codebook, that carries almost the maximum possible information from A to E, provided an optimal strategy is applied by E. Therefore, the mutual information between the codebooks with different m must be close to zero. Hence, randomizing inside each of these codebooks discards almost all information carried from A to E.

The crucial step in the rigorous justification of this scenario is the application of the following estimate, based on a quantum version of the Bernstein inequality to be established in the next section.

Proposition 10.32. Let $S^{w^{mj}}_{E^{(n)}}, m = 1, \ldots, N_B, j = 1, \ldots, N_E$, be the random i.i.d. density operators, with N_B, N_E chosen as above. There exists a $\beta_1 > 0$ such that, for n large enough,

$$\tilde{\mathrm{P}}\left\{\left\|\frac{1}{N_E}\sum_{j=1}^{N_E} S^{w^{mj}}_{E^{(n)}} - \theta\right\|_1 \geq \varepsilon\right\} \leq 2^{-2^{n\beta_1}}, \tag{10.67}$$

for each $m = 1, \ldots, N_B$, where θ is a nonrandom operator (in fact, one can take $\theta = \tilde{\mathrm{E}} S^{w^{mj}}_{E^{(n)}}$, but we do not need this).

This estimate implies that the probability

$$\begin{aligned}\tilde{\mathrm{P}}\left\{\left\|S^m_{E^{(n)}} - \theta\right\|_1 < \varepsilon; m = 1, \ldots, N_B\right\} &\geq 1 - N_B 2^{-2^{n\beta_1}} \\ &= 1 - 2^{n\left[X\left(\{\pi_x\},\left\{S^x_B\right\}\right) - \chi\left(\{\pi_x\},\left\{S^x_E\right\}\right) - 3c\delta/2\right] - 2^{n\beta_1}}\end{aligned}$$

can be made arbitrarily close to 1 for n large enough. Together with (10.66) this implies that there exists a realization of the codebook $W^{(n)} = \{W^{mj}\}$, for which

$$\bar{P}_e\left(W^{(n)}, M^{(n)}\right) < \sqrt{\varepsilon},$$

and

$$\left\|S^m_{E^{(n)}} - S^l_{E^{(n)}}\right\|_1 < 2\varepsilon, \quad m, l = 1, \ldots, N_B. \tag{10.68}$$

Defining $\Sigma^{(n)} = \left\{S^m_{A^{(n)}}; m = 1, \ldots, N_B\right\}, \tilde{M}^{(n)} = \left\{\tilde{M}_m; m = 0, 1, \ldots, N_B\right\}$, where $\tilde{M}_m = \sum_{j=1}^{N_E} M_{mj}$, we have $\bar{P}_e\left(\Sigma^{(n)}, \tilde{M}^{(n)}\right) \leq \bar{P}_e\left(W^{(n)}, M^{(n)}\right) < \sqrt{\varepsilon}$. An argument similar to Lemma 4.11 shows that we can choose a subcode for which the maximal error $P_e\left(W^{(n)},\ M^{(n)}\right) < 2\sqrt{\varepsilon}$ while $v_E\left(\Sigma^{(n)}\right) < \varepsilon'$, where $\varepsilon' \to 0$ if $\varepsilon \to 0$, which proves the theorem. □

Proof of Proposition 10.32. As in Section 5.6, we introduce the density operator

$$\bar{S}_\pi = \sum_x \pi_x S^X_E,$$

and we write for brevity

$$H\left(\bar{S}_\pi\right) = H(E), \quad \sum_x \pi_x H\left(S^x_E\right) = H(E \mid A),$$

with $\chi\left(\{\pi_\chi\},\{S_E^\chi\}\right) = H(E) - H(E \mid A)$.
Denote by λ_j the eigenvalues of $\bar{S}_\pi$. Let us fix a small positive δ, and let $P = P^{n,\delta}$ be the strongly typical projector of the density operator $\bar{S}_\pi^{\otimes n}$, corresponding to the eigenvalues $\lambda_J = \lambda_{j_1}\cdots\lambda_{j_n}$ for which the sequence $J = (j_1,\ldots,j_n)$ is strongly typical, i.e., the numbers $N(j \mid J)$ of times the symbol j appears in J satisfy the condition

$$\left|\frac{N(j \mid J)}{n} - \lambda_j\right| < \delta, \quad j = 1,\ldots,d_E,$$

and $N(j \mid J) = 0$ if $\lambda_j = 0$ (see Definition 9.9). Denote by $\lambda_j(x)$ the eigenvalues of the density operator S_E^X. For a codeword $w = (x_1,\ldots,x_n)$ of length n, let $S_w = S_E^{x_1} \otimes \cdots \otimes S_E^{x_n}$ and denote by P_w the typical projector of S_w, corresponding to the eigenvalues $\lambda_J(w) = \lambda_{j_1}(x_1)\cdots\lambda_{j_n}(x_n)$, for which

$$\left|\frac{N(j,x \mid J,w)}{n} - \frac{N(x \mid w)}{n}\lambda_j(x)\right| < \delta, \quad j = 1,\ldots,d_E,$$

and $N(j,x \mid J,w) = 0$ if $\lambda_j(x) = 0$. We shall need the following properties, which are just a reformulation of the corresponding properties for strongly typical sequences in the classical information theory (see [50]):
i. For $w \in \hat{T}^{n,\delta}$, the eigenvalues of the operator $P_w S_w P_w$ lie in the interval $\left(2^{-n[H(E|A)+c\delta]}, 2^{-n[H(E|A)-c\delta]}\right)$, where c is another constant, depending on $\{\lambda_j(x)\}$ (to simplify the notation we use the same c as before; in fact, we can choose the maximum of the two constants). In particular, $P_w S_w P_w \le 2^{-n[H(E|A)-c\delta]} P_w$.
ii. For $\varepsilon_1 > 0$ and sufficiently large n, $\operatorname{Tr} P_w S_w \ge 1 - \varepsilon_1$ (this is a corollary of the law of large numbers for the probability distribution given by the eigenvalues of S_w).

The following property is less straightforward.
iii. For given $\varepsilon_1, \delta > 0$, there is a $\delta_1 > 0$ such that for $w \in \hat{T}^{n,\delta_1}$ and sufficiently large n, $\operatorname{Tr} P S_w \ge 1 - \varepsilon_1$, where $P = P^{n,\delta}$ is the strongly typical projector of $\bar{S}_\pi^{\otimes n}$.

Proof. Denote by $p^{(k)}(j) = \langle e_j| S_E^{x_k} |e_j\rangle$, where $|e_j\rangle$ are the eigenvectors of $\bar{S}_\pi$, and note that $p^{(k)}(j) = 0$ if $\lambda_j = 0$, because $\operatorname{supp} S_E^{x_k} \subset \operatorname{supp} \bar{S}_\pi$. Then

$$\begin{aligned}\operatorname{Tr} P^{n,\delta} S_w &= \sum_{J \in B^{n,\delta}} p^{(1)}(j_1)\cdots p^{(n)}(j_n) \\ &= \mathrm{P}\left\{\left|\frac{N(j \mid J)}{n} - \lambda_j\right| < \delta, \text{ if } \lambda_j > 0\right\}, \end{aligned} \tag{10.69}$$

where P is the probability distribution, ascribing the probability $p^{(1)}(j_1)\cdots p^{(n)}(j_n)$ to the sequence $J = (j_1,\ldots,j_n)$, and $B^{n,\delta}$ is the set of strongly typical sequences. The fact that $w \in \hat{T}^{n,\delta_1}$ is expressed by similar inequalities

$$\left|\frac{N(x \mid w)}{n} - \pi_x\right| < \delta_1, \quad \text{if } \pi_x > 0,$$

and $N(x \mid w) = 0$ if $\pi_x = 0$, which implies for $\bar{\lambda}_j = \frac{1}{n}\sum_{k=1}^n p^{(k)}(j)$,

$$\begin{aligned}\left|\bar{\lambda}_j - \lambda_j\right| &= \left|\langle e_j| \left[\frac{1}{n}\sum_{k=1}^n S_E^{x_k} - \bar{S}_\pi\right] \middle| e_j\right\rangle| \\ &= \left|\sum_x \left[\frac{N(x \mid w)}{n} - \pi_x\right] \langle e_j| S_E^x \middle| e_j\right\rangle| < \delta_1 K, \end{aligned}$$

where K is the number of symbols x. Therefore, by choosing $\delta_1 = \delta/2K$, we have

$$\begin{aligned}
&\mathrm{P}\left\{\left|\frac{N(j\mid J)}{n}-\lambda_j\right|<\delta;\ \text{for all } j:\lambda_j>0\right\}\\
&\quad\geq \mathrm{P}\left\{\left|\frac{N(j\mid J)}{n}-\bar{\lambda}_j\right|<\delta/2;\ \text{for all } j:\lambda_j>0\right\}\\
&\quad\geq 1-\sum_{j:\lambda_j>0}\mathrm{P}\left\{\left|\frac{N(j\mid J)}{n}-\bar{\lambda}_j\right|\geq\delta/2\right\}
\end{aligned}$$

But under the probability distribution P , the random variable $N(j \mid J)$ has mean value $\sum_{k=1}^{n} p^{(k)}(j) = n\bar{\lambda}_j$ and variance $\sum_{k=1}^{n} p^{(k)}(j)\left(1-p^{(k)}(j)\right) \leq n/4$. Applying the Chebyshev inequality and taking into account (10.69), we obtain iii. □

We proceed with the proof of Proposition 10.32, for which we also need the following lemma.

Lemma 10.33. For a positive operator X and a projector P

$$\|X-PXP\|_1 \leq 3\sqrt{\operatorname{Tr} X \operatorname{Tr}(I-P)X}$$

Proof. By the triangle inequality and the properties of the trace norm

$$\|X-PXP\|_1 \leq \|(I-P)X(I-P)\|_1 + 2\|PX(I-P)\|_1 \leq 3\|X(I-P)\|_1.$$

There is a unitary U such that $\|X(I-P)\|_1 = \operatorname{Tr} X(I-P)U$. By the Cauchy-Schwarz inequality for the trace (take $S = I/d$ in (2.24))

$$[\operatorname{Tr}\sqrt{X}\sqrt{X}(I-P)U]^2 \leq \operatorname{Tr} X \operatorname{Tr} U^*(I-P)X(I-P)U = \operatorname{Tr} X \operatorname{Tr}(I-P)X.$$

Hence, the result follows. □

To simplify notation in (10.67), we shall denote $S_{E^{(n)}}^{W^{mj}} = S_{w^j}$, where the codewords $w^j, j = 1,\ldots,N_E$, are i. i. d. uniformly on the set T^{n,δ_1}. We shall obtain (10.67) by applying the operator Bernstein inequality (10.76), to be established in the next section, to the random operators

$$X_j = 2^{n[H(E|A)-\delta]}\Pi P P_{w^i} S_{w^i} P_{w^i} P \Pi,$$

where Π is the projector onto the eigenspace of the operator

$$\theta' = \tilde{\mathrm{E}} P P_{w^j} S_{w^j} P_{w^j} P$$

corresponding to eigenvalues $\geq 2^{-n[H(E)+3c\delta/2]}$. By construction, $0 \leq X_j \leq I$,

$$M = \tilde{\mathrm{E}} X_j = 2^{n[H(E|A)-c\delta]}\tilde{\mathrm{E}}\left(\Pi P P_{w^j} S_{w^j} P_{w^j} P \Pi\right) = 2^{n[H(E|A)-c\delta]}\Pi\theta'\Pi$$

and $\mu = 2^{n[H(E|A)-H(E)-5c\delta/2]} = 2^{-n\left[x\left(\{\pi_x\},\left\{S_E^x\right\}\right)+5c\delta/2\right]}$, so that $N_E\mu = 2^{-2nc\delta}$ and (10.76) imply

$$\begin{aligned}
\tilde{\mathrm{P}}\left\{\omega : \left\|\frac{1}{N_E}\sum_{j=1}^{N_E} X_j(\omega) - M\right\|_1 \geq \varepsilon_2 2^{n[H(E|A)-c\delta]}\right\} &\leq 2d_E^n \exp\left(-2^{-2nc\delta}\varepsilon_2^2/4\right)\\
&\leq 2^{-2^{-n\beta_1}} \qquad (10.70)
\end{aligned}$$

for some $\beta_1 > 0$ and n large enough. Here, we used the fact that $\operatorname{Tr} M \leq 2^{n[H(E|A)-c\delta]}$. It remains for us to derive (10.67) from (10.70).

Denoting $\theta = \Pi\theta'\Pi$, we have

$$\left\| \frac{1}{N_E} \sum_{j=1}^{N_E} S_{w^j} - \theta \right\|_1 \leq \frac{1}{N_E} \sum_{j=1}^{N_E} \| S_{w^j} - P S'_{w^j} P \|_1 \tag{10.71}$$

$$+ \left\| \frac{1}{N_E} \sum_{j=1}^{N_E} P S'_{w^j} P - \frac{1}{N_E} \sum_{j=1}^{N_E} \Pi P S'_{w^j} P \Pi \right\|_1 \tag{10.72}$$

$$+ \left\| \frac{1}{N_E} \sum_{j=1}^{N_E} \Pi P S'_{w^j} P \Pi - \theta \right\|_1 . \tag{10.73}$$

The estimate (10.70) implies

$$\tilde{\mathrm{P}} \left\{ \left\| \frac{1}{N_E} \sum_{j=1}^{N_E} \Pi P S'_{w^j} P \Pi - \theta \right\|_1 \leq \varepsilon_2 \right\} > 1 - 2^{-2^{-n\beta_1}} .$$

The inequality

$$\left\| \frac{1}{N_E} \sum_{j=1}^{N_E} \Pi P S'_{w^j} P \Pi - \theta \right\|_1 \leq \varepsilon_2 \tag{10.74}$$

gives the estimate for the term (10.73).

For the term (10.71), we use the triangle inequality

$$\| S_{w^j} - P S'_{w^j} P \|_1 \leq \| S_{w^j} - P_{w^j} S'_{w^j} P_{w^j} \|_1 + \| S'_{w^j} - P S'_{w^j} P \|_1 .$$

The first term on the right can be made small for sufficiently large n by property ii and Lemma 10.33. Further, note that for $w^j \in \hat{T}^{n,\delta_1}$

$$\operatorname{Tr} P S'_{w^j} = \operatorname{Tr} S'_{w^j} - \operatorname{Tr}(I - P) S'_{w^j} \geq \operatorname{Tr} P_{w^j} S_{w^j} - \operatorname{Tr}(I - P) S_{w^j} \geq 1 - 2\varepsilon_1 \tag{10.75}$$

by ii and iii. Applying the lemma, we can also make the second term on the right small for sufficiently large n.

The term (10.72) has the form $\| S - \Pi S \Pi \|_1$. Therefore, to show that it is close to zero, by Lemma 10.33 it is sufficient to show that

$$\operatorname{Tr} \Pi S = \operatorname{Tr} \frac{1}{N_E} \sum_{j=1}^{N_E} \Pi P S'_{w^j} P \Pi$$

is close to 1 . But, according to (10.74), this is not less than $\operatorname{Tr} \theta - \varepsilon_2 = \operatorname{Tr} \Pi \theta' - \varepsilon_2$. Now, $\operatorname{Tr} \Pi \theta' = \operatorname{Tr} \theta' - \operatorname{Tr}(I - \Pi) \theta' \geq \operatorname{Tr} \theta' - 2^{-nc\delta/2}$, because $\operatorname{Tr}(I - \Pi)\theta'$ is the sum of eigenvalues of θ' that are less than $2^{-n[H(E)+3c\delta/2]}$, while the total number of positive eigenvalues is less than or equal to $\dim\operatorname{supp} \theta' \leq \dim\operatorname{supp} P = 2^{n[H(E)+c\delta]}$. It remains for us to prove that $\operatorname{Tr} \theta'$ is close to 1 . However, $\theta' = \tilde{\mathrm{E}} P S'_{w^j} P$ and $\operatorname{Tr} \theta' = \tilde{\mathrm{E}} \operatorname{Tr} P S'_{w^j} \geq 1 - 2\varepsilon_1$ by (10.75). This implies that, given ε, we can choose $\varepsilon_1, \varepsilon_2$ such that (10.67) holds for n large enough. □

10.10.17 10.4.3 Large Deviations for Random Operators

Theorem 10.34 (Ahlswede and Winter [5]). Let $X_1(\omega), \ldots, X_N(\omega)$ be i.i.d. operatorvalued random variables in $\mathcal{H}, \dim \mathcal{H} = d$, such that $0 \leq X_i(\omega) \leq I, M = \mathrm{E} X_i \geq \mu I$. Then, for $0 \leq \varepsilon \leq 1$,

$$\mathrm{P}\left\{\omega : \left\| \frac{1}{N}\sum_{j=1}^{N} X_j(\omega) - M \right\|_1 \geq \varepsilon \operatorname{Tr} M \right\} \leq 2d \exp\left(-\frac{N\mu\varepsilon^2}{4}\right). \tag{10.76}$$

Proof. The proof consists of several steps. First, we prove the operator Markov inequality. Let X be a Hermitian operator-valued random variable, $t > 0$. In this case,

$$\mathrm{P}\{\omega : X(\omega) \not\leq 0\} \leq \operatorname{Tr} E \exp tX,$$

where $\{\omega : X(\omega) \not\leq 0\} = \overline{\{\omega : X(\omega) \leq 0\}}$. Indeed,

$$\begin{aligned}\mathrm{P}\{\omega : X(\omega) \not\leq 0\} &= \mathrm{P}\{\omega : \exp tX(\omega) \not\leq I\} \\ &\leq \mathrm{E}1_{\{\exp tX \not\leq I\}} \operatorname{Tr} \exp tX \\ &\leq \operatorname{Tr} \mathrm{E} \exp tX,\end{aligned}$$

where the first inequality follows from the fact that $0 \leq Y \not\leq I$ implies $1 \leq \operatorname{Tr} Y$.

Second, by letting $X(\omega) = \sum_{i=1}^{N} X_i(\omega)$, where X_i are i.i.d. Hermitian operatorvalued random variables, we obtain

$$\begin{aligned}\mathrm{P}\left\{\omega : \sum_{i=1}^{N} X_i(\omega) \not\leq 0\right\} &\leq \operatorname{Tr} \mathrm{E} \exp\left(t \sum_{i=1}^{N} X_i\right) \\ &\leq \mathrm{E} \operatorname{Tr} \exp\left(t \sum_{i=1}^{N-1} X_i\right) \exp tX_N \\ &= \operatorname{Tr} \mathrm{E} \exp\left(t \sum_{i=1}^{N-1} X_i\right) \mathrm{E} \exp tX_N\end{aligned}$$

where the Golden-Thompson inequality ([31], Theorem IX.3.7) was used, i.e.,

$$\operatorname{Tr} \exp(A + B) \leq \operatorname{Tr} \exp A \exp B.$$

By inequality (1.18) this is less than or equal to

$$\operatorname{Tr} E \exp\left(t \sum_{i=1}^{N-1} X_i\right) \|E \exp tX_N\|.$$

Applying the estimate iteratively, we get

$$\mathrm{P}\left\{\omega : \sum_{i=1}^{N} X_i(\omega) \not\leq 0\right\} \leq d \left\|\mathrm{E} \exp tX_i\right\|^N. \tag{10.77}$$

Third, let $X_1(\omega), \ldots, X_N(\omega)$ be i. i. d. operator-valued random variables, such that $0 \leq X_i(\omega) \leq I, \mathrm{E}X_i = \mu I$, and $0 \leq \mu \leq a \leq 1$. Then

$$\mathrm{P}\left\{\omega : \frac{1}{N}\sum_{i=1}^{N} X_i(\omega) \not\leq aI\right\} \leq d \exp(-Nh(a;\mu)), \tag{10.78}$$

where $h(a;\mu) = a \ln \frac{a}{\mu} + (1-a) \ln \frac{1-a}{1-\mu}$. Indeed, by using (10.77) for $X_i(\omega) - aI$, we obtain

$$\mathrm{P}\left\{\omega : \frac{1}{N}\sum_{i=1}^{N} X_i(\omega) \not\leq aI\right\} \leq d \left\|\mathrm{E} \exp tX_i\right\|^N \exp(-atN).$$

But $\exp tx \leq 1 + x(\exp t - 1)$ for $x \in [0,1]$; hence

$$\exp tX_i \le I + X_i(\exp t - 1),$$

and the right-hand side is less than or equal to

$$d[1 + \mu(\exp t - 1)]^N \exp(-atN).$$

Taking $\exp t = \frac{a}{\mu}\frac{1-\mu}{1-a} \ge 1$ provides the right-hand side of (10.78). Similarly, for $0 \le a \le \mu \le 1$,

$$\mathrm{P}\left\{\omega : \frac{1}{N}\sum_{i=1}^{N} X_i(\omega) \not\ge aI\right\} \le d\exp(-Nh(a;\mu)). \tag{10.79}$$

Note that $h(\mu;\mu) = 0$, $\frac{\partial}{\partial a}h(a;\mu)\big|_{\mu=a} = 0$, $\frac{\partial^2}{\partial^2 a}h(a;\mu) = \frac{1}{a(1-a)}$. It follows that

$$\frac{\partial^2}{\partial^2 \varepsilon}h(\mu(1\pm\varepsilon);\mu) = \frac{\mu}{(1\pm\varepsilon)(1-\mu(1\pm\varepsilon))} \ge \frac{\mu}{2},$$

if $\mu \le \frac{1}{2}, |\varepsilon| \le 1$. Hence,

$$h(\mu(1\pm\varepsilon);\mu) \ge \frac{\mu\varepsilon^2}{4}. \tag{10.80}$$

Finally, let $X_i(\omega)$ satisfy the conditions of Theorem 10.34. Consider the operator random variables $Y_i(\omega) = \mu M^{-1/2} X_i(\omega) M^{-1/2}$, such that $0 \le Y_i(\omega) \le I$ and $EY_i = \mu I$. We have

$$\begin{aligned}
&\left\{\omega : \left\|\frac{1}{N}\sum_{i=1}^{N} X_i(\omega) - M\right\|_1 < \varepsilon \operatorname{Tr} M\right\} \\
&\quad\supseteq \left\{\omega : (1-\varepsilon)M \le \frac{1}{N}\sum_{i=1}^{N} X_i(\omega) \le (1+\varepsilon)M\right\} \\
&\quad= \left\{\omega : (1-\varepsilon)\mu \le \frac{1}{N}\sum_{i=1}^{N} Y_i(\omega) \le (1+\varepsilon)\mu\right\} \\
&\quad= \left\{\omega : (1-\varepsilon)\mu \le \frac{1}{N}\sum_{i=1}^{N} Y_i(\omega)\right\} \\
&\quad\cap \left\{\omega : \frac{1}{N}\sum_{i=1}^{N} Y_i(\omega) \le (1+\varepsilon)\mu\right\}
\end{aligned}$$

By taking the complements and applying the estimates (10.78) and (10.79), together with (10.80), we get (10.76). □

10.10.18 10.4.4 The Direct Coding Theorem for the Quantum Capacity

The proof of inequality $Q(\Phi) \ge \bar{Q}(\Phi)$ will be based on a "coherent" version of the proof for the private classical capacity, i.e., a version that uses the same random coding, but where the mixtures of states are replaced with superpositions. It is sufficient to prove that for a given input state S the quantity $R = I_c(S,\Phi) - \delta$ is an achievable rate. Achievability of $\bar{Q}(\Phi) - \delta$ is then shown by applying the argument to $\Phi^{\otimes n}$ and taking the
limit $n \to \infty$. In this section, we will show how to construct an encoding and decoding such that

$$F_e\left(\bar{S}^{(n)}, \mathcal{D}^{(n)} \circ \Phi^{\otimes n} \circ \mathcal{E}^{(n)}\right) \to 1, \tag{10.81}$$

where $\bar{S}^{(n)}$ is the chaotic state in $\mathcal{H}^{(n)}, d_n = \dim \mathcal{H}^{(n)} = 2^{nR}$. By the argument following Definition 10.19 this means that the rate R is achievable for asymptotically perfect transmission of quantum information.

For channel Φ, we consider representation (6.7) (Theorem 6.9), namely,

$$\Phi[S] = \mathrm{Tr}_E\, VSV^*,$$

where V is an isometric map from the input space $\mathcal{H}_A$ to the tensor product $\mathcal{H}_B \otimes \mathcal{H}_E$ of the output and the environment spaces.

Consider a spectral decomposition $S = \sum_x \pi_x S_A^x$, where $S_A^x = |\phi_x\rangle_A \langle\phi_x|$, and $\{|\phi_x\rangle_A\}$ form an orthonormal basis. Denote by $|\phi'_x\rangle_{BE} = V|\phi_x\rangle_A$ the joint output states of BE. In this case, the states of B and E, correspondingly, will be $S_B^X = \mathrm{Tr}_E |\phi'_x\rangle_{BE} \langle\phi'_x|$ and $S_E^X = \mathrm{Tr}_B |\phi'_x\rangle_{BE} \langle\phi'_x|$. Let us recall that, according to (10.58),

$$I_c(S, \Phi) = \chi\left(\{\pi_\chi\}, \left\{S_B^X\right\}\right) - \chi\left(\{\pi_\chi\}, \left\{S_E^X\right\}\right). \tag{10.82}$$

Our aim is to construct a sequence of subspaces $\mathcal{H}^{(n)}$ such that $\dim \mathcal{H}^{(n)} = 2^{nR}, R = I_c(S, \Phi) - \delta$, and corresponding encodings and decodings for which (10.81) holds.

Now, consider the block channel $\Phi^{\otimes n}$ and the codebook

$$W^{(n)} = \left\{w^{mj}; m = 1, \ldots, N_B; j = 1, \ldots, N_E\right\},$$

used in the construction of the privacy code, with the corresponding resolution of the identity $M^{(n)} = \{M_{mj}\}$ in $\mathcal{H}_B^{\otimes n}$, such that

$$P_e\left(W^{(n)}, M^{(n)}\right) \equiv \max_{mj}\left(1 - \mathrm{Tr}\, S_{B^{(n)}}^{mj} M_{mj}\right) < \varepsilon, \tag{10.83}$$

where $S_{B^{(n)}}^{mj} = S_B^{x_1} \otimes \cdots \otimes S_B^{x_n}$ if $w^{mj} = (x_1, \ldots, x_n)$,

$$\left\| \frac{1}{N_E} \sum_{j=1}^{N_E} S_{E^{(n)}}^{mj} - \theta \right\|_1 < \sqrt{\varepsilon}, \quad m = 1, \ldots, N_B. \tag{10.84}$$

Consider the space $\mathcal{H}^{(n)}$ with the orthonormal basis $\{|m\rangle; m = 1, \ldots, N_B\}$, where

$$N_B = 2^{n\left[\chi\left(\{\pi_x\}, \left\{S_B^x\right\}\right) - \chi\left(\{\pi_x\}, \left\{S_E^x\right\}\right) - \delta\right]} = 2^{n[I_c(S,\Phi) - \delta]},$$

and the encoding $\mathcal{E}^{(n)}$ given by the following isometric map from $\mathcal{H}^{(n)}$ to $\mathcal{H}_A^{\otimes n}$:

$$|m\rangle \to \frac{1}{\sqrt{N_E}} \sum_{j=1}^{N_E} e^{i\alpha_{mj}} |\phi_{mj}\rangle_A$$

where $|\phi_{mj}\rangle_A = |\phi_{x_1}\rangle_A \otimes \cdots \otimes |\phi_{x_n}\rangle_A$ if $w^{mj} = (x_1, \ldots, x_n)$, and $\{\alpha_{mj}\} = \alpha$ is a collection of phases to be chosen later. Isometry of this map follows from the fact that $\left\{|\phi_{mj}\rangle_A\right\}$ is an orthonormal system, because it is built from the orthonormal vectors $|\phi_x\rangle_A$.

This is what was called the coherent version of the private code for the classical information. The action of the encoding on the maximally entangled vector (10.38) produces the vector

$$\frac{1}{\sqrt{N_B}} \sum_{m=1}^{N_B} |m\rangle \otimes \left[\frac{1}{\sqrt{N_E}} \sum_{j=1}^{N_E} e^{i\alpha_{mj}} |\phi_{mj}\rangle_A\right]$$

The encoding followed by the channel $\Phi^{\otimes n}$ gives

$$\frac{1}{\sqrt{N_B}}\sum_{m=1}^{N_B}|m\rangle\otimes\left[\frac{1}{\sqrt{N_E}}\sum_{j=1}^{N_E}e^{i\alpha_{mj}}\left|\phi'_{mj}\right\rangle_{BE}\right] \tag{10.85}$$

where the vectors $\left|\phi'_{mj}\right\rangle_{BE} = V\left|\phi_{mj}\right\rangle_A$ are again orthonormal. Note that $S^{mj}_{B^{(n)}} = \mathrm{Tr}_E\left|\phi'_{mj}\right\rangle_{BE}\left\langle\phi'_{mj}\right|, S^{mj}_{E^{(n)}} = \mathrm{Tr}_B\left|\phi'_{mj}\right\rangle_{BE}\left\langle\phi'_{mj}\right|$, where, in order to simplify notations, we denote by Tr_E the partial trace with respect to $\mathcal{H}_E^{\otimes n}$, etc.

To construct the decoding $\mathcal{D}^{(n)}$, we first use the observable $M^{(n)} = \{M_{mj}\}$, which provides a measurement of mj with asymptotically vanishing error. By the discussion of the measurement process leading to relation (6.37), there are an auxiliary system $\mathcal{H}_0^{(n)} = \mathcal{H}^{(n)}\otimes\mathcal{H}_1^{(n)}$ with the basis $\{|m\rangle\otimes|j\rangle_1\}$, a unit vector $|\psi_0\rangle\in\mathcal{H}_0^{(n)}$, and a unitary operator U in $\mathcal{H}_B^{\otimes n}\otimes\mathcal{H}_0^{(n)}$, such that

$$M_{mj} = \mathrm{Tr}_0\left(I_{B^{(n)}}\otimes|\psi_0\rangle\langle\psi_0|\right)U^*\left(I_{B^{(n)}}\otimes|mj\rangle_0\langle mj|\right)U,$$

where we denoted $|mj\rangle_0 = |m\rangle\otimes|j\rangle_1$. Defining

$$|\psi_{mj}\rangle_{BE0} = \left(I_{E^{(n)}}\otimes U\right)\left(\left|\phi'_{mj}\right\rangle_{BE}\otimes|\psi_0\rangle\right),$$

we have the following state vector of the system $\mathcal{H}^{(n)}\otimes\mathcal{H}_B^{\otimes n}\otimes\mathcal{H}_E^{\otimes n}\otimes\mathcal{H}_0^{(n)}$:

$$|Y(\alpha)\rangle = \frac{1}{\sqrt{N_B}}\sum_{m=1}^{N_B}|m\rangle\otimes\left[\frac{1}{\sqrt{N_E}}\sum_{j=1}^{N_E}e^{i\alpha_{mj}}\left|\psi_{mj}\right\rangle_{BE0}\right]$$

as the result of the action of the encoding, followed by the channel, and further followed by the measurement, on the maximally entangled vector. Here, $\left\{\left|\psi_{mj}\right\rangle_{BE0}\right\}$ is again an orthonormal system. Relation (10.83) means that the "projection" of this system onto $\mathcal{H}_0^{(n)}$ is close to $\{|mj\rangle_0\}$. More precisely,

$${}_0\langle mj|\left(\mathrm{Tr}_{BE}\left|\psi_{mj}\right\rangle_{BE0}\left\langle\psi_{mj}\right|\right)|mj\rangle_0 > 1-\varepsilon \quad \text{for all } mj$$

The following lemma implies that there exist unit vectors $\left|\chi_{mj}\right\rangle_{BE}\in\mathcal{H}_B^{\otimes n}\otimes\mathcal{H}_E^{\otimes n}$ such that, for $\left|\tilde{\psi}_{mj}\right\rangle_{BE0} = \left|\chi_{mj}\right\rangle_{BE}\otimes|mj\rangle_0$, one has

$$\left|{}_{BE0}\left\langle\psi_{mj}\mid\tilde{\psi}_{mj}\right\rangle_{BE0}\right|^2 > 1-\varepsilon. \tag{10.86}$$

Lemma 10.35. Let $|\varphi\rangle_0\in\mathcal{H}_0, |\psi\rangle\in\mathcal{H}_0\otimes\mathcal{H}$ be two unit vectors. In this case,

$${}_0\langle\varphi|\left(\mathrm{Tr}_{\mathcal{H}}\left|\psi\right\rangle\langle\psi|\right)|\varphi\rangle_0 = \max_{\chi}\mid\langle\psi|\left(|\varphi\rangle_0\otimes|\chi\rangle\right)|^2, \tag{10.87}$$

where the maximum is taken over all unit vectors $|\chi\rangle\in\mathcal{H}$.

Proof. By fixing an orthonormal basis $\{|e_j\rangle\}$ in $\mathcal{H}$, we have $|\chi\rangle = \sum_j c_j|e_j\rangle$, with $\sum_j|c_j|^2 = 1$ and

$$\mid\langle\psi|\left(|\varphi\rangle_0\otimes|\chi\rangle\right)|^2 = \mid\sum_j c_j\langle\psi|\left(|\varphi\rangle_0\otimes|e_j\rangle\right)\Bigg|^2.$$

Maximizing with respect to c_j we obtain (10.87). □

Note that $\left\{\left|\tilde{\psi}_{mj}\right\rangle_{BE0}\right\}$ is again an orthonormal system, approximating $\left\{\left|\psi_{mj}\right\rangle_{BE0}\right\}$ in the sense (10.86). Defining

$$|\Gamma(\alpha)\rangle = \frac{1}{\sqrt{N_B}} \sum_{m=1}^{N_B} |m\rangle \otimes \left[\frac{1}{\sqrt{N_E}} \sum_{j=1}^{N_E} e^{i\alpha_{mj}} \left| \tilde{\psi}_{mj} \right\rangle_{BE0} \right]$$

we have

$$\int \cdots \int \langle \Upsilon(\alpha) \mid \Gamma(\alpha + \alpha') \rangle \, d\mu(\alpha) = \frac{1}{N_B N_E} \sum_{m=1}^{N_B} \sum_{j=1}^{N_E} e^{i\alpha'_{mj}} {}_{BE0} \left\langle \psi_{mj} \mid \tilde{\psi}_{mj} \right\rangle_{BE0}$$

where $d\mu(\alpha)$ is the uniform distribution. Here, the integration eliminates the inner products with $j \neq j'$. One can always pick $\alpha' = \left\{ \alpha'_{mj} \right\}$ such that the right-hand side will be

$$\frac{1}{N_B N_E} \sum_{m=1}^{N_B} \sum_{j=1}^{N_E} \left| {}_{BE0} \left\langle \psi_{mj} \mid \tilde{\psi}_{mj} \right\rangle_{BE0} \right| > \sqrt{1-\varepsilon}$$

by (10.86). Hence, there is an α such that $\operatorname{Re} \langle Y(\alpha) \mid \Gamma(\alpha + \alpha') \rangle > \sqrt{1-\varepsilon}$. By introducing an additional common phase to α'_{mj} we can always make the inner product positive. Hence,

$$\langle \Upsilon(\alpha) \mid \Gamma(\alpha + \alpha') \rangle > \sqrt{1-\varepsilon}. \tag{10.88}$$

There is one more transformation to incorporate into the decoding $\mathcal{D}^{(n)}$, which will leave the system E in the state almost independent of m. To achieve this, note that combining (10.86) with (10.17) gives

$$\| \, |\psi_{mj}\rangle_{BE0} \langle \psi_{mj}| - \left| \tilde{\psi}_{mj} \right\rangle_{BE0} \left\langle \tilde{\psi}_{mj} \right| \, \|_1 < 2\sqrt{\varepsilon} \tag{10.89}$$

Now note that $S^{mj}_{E^{(n)}} = \operatorname{Tr}_{B0} |\psi_{mj}\rangle_{BE0} \langle \psi_{mj}|$ and denote

$$\tilde{S}^{mj}_{E^{(n)}} = \operatorname{Tr}_{B0} \left| \tilde{\psi}_{mj} \right\rangle_{BE0} \left\langle \tilde{\psi}_{mj} \right| = \operatorname{Tr}_B |\chi_{mj}\rangle_{BE} \langle \chi_{mj}| \, .$$

Then (10.89) and Exercise 10.25 imply

$$\left\| S^{mj}_{E^{(n)}} - \tilde{S}^{mj}_{E^{(n)}} \right\|_1 < 2\sqrt{\varepsilon}, \tag{10.90}$$

which, combined with (10.84), implies

$$\left\| \frac{1}{N_E} \sum_{j=1}^{N_E} \tilde{S}^{mj}_{E^{(n)}} - \theta \right\|_1 < O(\sqrt{\varepsilon}), \quad m = 1, \ldots, N_B. \tag{10.91}$$

Consider the vectors

$$|\varphi_m\rangle_{BE1} = \frac{1}{\sqrt{N_E}} \sum_{j=1}^{N_E} e^{i\left(\alpha_{mj} + \alpha'_{mj}\right)} |\chi_{mj}\rangle_{BE} \otimes |j\rangle_1,$$

which are purifications of $\frac{1}{N_E} \sum_{j=1}^{N_E} \tilde{S}^{mj}_{E^{(n)}}$. Let $|\phi_\theta\rangle \in \mathcal{H}_B^{\otimes n} \otimes \mathcal{H}_E^{\otimes n} \otimes \mathcal{H}_1^{(n)}$ be a purification of θ. Then (10.91) implies that there are unitary operators W_m in $\mathcal{H}_B^{\otimes n} \otimes \mathcal{H}_1^{(n)}$ such that

$$\left| {}_{BE1} \left\langle \phi_\theta \mid \left(I_{\mathcal{H}_E^{\otimes n}} \otimes W_m \right) \varphi_m \right\rangle_{BE1} \right| > 1 - O(\sqrt{\varepsilon}) \quad \text{for all } m. \tag{10.92}$$

This follows from inequality (10.33), which says that if two states are close in trace norm, there exist purifications of these states with fidelity close to 1 .

Defining a "controlled unitary" operator $W = \sum_{m=1}^{N_B} e^{i\beta_m} W_m \otimes |m\rangle\langle m|$ in $\mathcal{H}_B^{\otimes n} \otimes \mathcal{H}_0^{(n)}$, where β_m are phases to be adjusted later, we have

$$\left(I_{\mathcal{H}_E^{\otimes n}} \otimes W\right) \left(|\varphi_m\rangle_{BE1} \otimes |m\rangle\right) = e^{i\beta_m} \left(I_{\mathcal{H}_E^{\otimes n}} \otimes W_m\right) |\varphi_m\rangle_{BE1} \otimes |m\rangle.$$

Hence,

$$\begin{aligned} &\left(I_{\mathcal{H}^{(n)}} \otimes I_{\mathcal{H}_E^{\otimes n}} \otimes W\right) |\Gamma\left(\alpha + \alpha'\right)\rangle \\ &\quad = \frac{1}{\sqrt{N_B}} \sum_{m=1}^{N_B} |m\rangle \otimes |m\rangle \otimes e^{i\beta_m} \left(I_{\mathcal{H}_E^{\otimes n}} \otimes W_m\right) |\varphi_m\rangle_{BE1}. \end{aligned}$$

Denoting $\left|\Omega^{(n)}\right\rangle = \frac{1}{\sqrt{N_B}} \sum_{m=1}^{N_B} |m\rangle \otimes |m\rangle$ the maximally entangled vector in $\mathcal{H}^{(n)} \otimes \mathcal{H}^{(n)}$, we have

$$\begin{aligned} &\left(\left\langle\Omega^{(n)}\right| \otimes \langle\phi_\theta|\right) \left(I_{\mathcal{H}^{(n)}} \otimes I_{\mathcal{H}_E^{\otimes n}} \otimes W\right) |\Gamma\left(\alpha + \alpha'\right)\rangle \\ &\quad = \frac{1}{N_B} \sum_{m=1}^{N_B} e^{i\beta_m} \langle\phi_\theta| \left(I_{\mathcal{H}_E^{\otimes}} \otimes W_m\right) |\varphi_m\rangle_{BE1}. \end{aligned}$$

This can be made equal to

$$\frac{1}{N_B} \sum_{m=1}^{N_B} \left| \langle\phi_\theta| \left(I_{\mathcal{H}_E^{\otimes n}} \otimes W_m\right) \right| \varphi_m \Bigg\rangle_{BE1} |$$

by an appropriate choice of phases β_m, which is greater than $1 - O(\sqrt{\varepsilon})$ by the estimate (10.92). Comparing this with (10.88), we have

$$\left(\left\langle\Omega^{(n)}\right| \otimes \langle\phi_\theta|\right) \left(I_{\mathcal{H}^{(n)}} \otimes I_{\mathcal{H}_E^{\otimes n}} \otimes W\right) |\Upsilon(\alpha)\rangle > 1 - O(\sqrt{\varepsilon}),$$

as follows from the triangle inequality (10.31).
Introducing the density operator

$$S' = \mathrm{Tr}_{BE1} \left(I_{\mathcal{H}^{(n)}} \otimes I_{\mathcal{H}_E^{\otimes n}} \otimes W\right) |\mathrm{Y}(\alpha)\rangle\langle\Upsilon(\alpha)| \left(I_{\mathcal{H}^{(n)}} \otimes I_{\mathcal{H}_E^{\otimes n}} \otimes W\right)$$

in $\mathcal{H}^{(n)} \otimes \mathcal{H}^{(n)}$, we have

$$\begin{aligned} F\left(\left|\Omega^{(n)}\right\rangle \left\langle\Omega^{(n)}\right|, S'\right) &\equiv \left\langle\Omega^{(n)}\right| S' \left|\Omega^{(n)}\right\rangle \\ &\geq \left| \left(\left\langle\Omega^{(n)}\right| \otimes \langle\phi_\theta|\right) \left(I_{\mathcal{H}^{(n)}} \otimes I_{\mathcal{H}_E^{\otimes n}} \otimes W\right) |Y(\alpha)\rangle \right|^2 \\ &> 1 - O(\sqrt{\varepsilon}) \end{aligned} \tag{10.93}$$

On the other hand,

$$S' = \left(\mathrm{Id}_{\mathcal{H}^{(n)}} \otimes \mathcal{D}^{(n)} \circ \Phi^{\otimes n} \circ \mathcal{E}^{(n)}\right) \left[\left|\Omega^{(n)}\right\rangle \left\langle\Omega^{(n)}\right|\right]$$

where the decoding $\mathcal{D}^{(n)}$ is defined as

$$\mathcal{D}^{(n)}\left[S_{B^{(n)}}\right] = \mathrm{Tr}_{B1}\, WU \left(S_{B^{(n)}} \otimes |\psi_0\rangle\langle\psi_0|\right) U^* W^*$$

(remember that $|\psi_0\rangle \in \mathcal{H}_0^{(n)} = \mathcal{H}^{(n)} \otimes \mathcal{H}_1^{(n)}$). Then (10.93) is the same as

$$F_e\left(\bar{S}^{(n)}, \mathcal{D}^{(n)} \circ \Phi^{\otimes n} \circ \mathcal{E}^{(n)}\right) > 1 - O(\sqrt{\varepsilon})$$

and (10.81) is established.

10.10.19 10.5 Notes and References

1. The first examples of quantum error-correcting codes were constructed by Shor [39] and by Steane [225]. Many authors contributed to the subsequent development of the subject, sketched in this chapter (see a survey in Nielsen and Chuang [179] and Gottesman [87]). Necessary and sufficient conditions for error correction of Theorem 10.3 were proposed by Knill and Laflamme [153]. For the solution of Exercise 10.4, see [179], n. 10.2. The possibility of error correction is of basic importance to the problem of
the realization of a quantum computer; see, e. g., Nielsen and Chuang [179] and Valiev [235]. An architecture of a fault-tolerant quantum computer was proposed, correcting errors not only in the quantum register, but also in the error-correcting modules; see Kitaev [154] and Steane [225].

The importance of coherent information to perfect error correction was pointed out by Barnum, Nielsen, and Schumacher [18].

2. The relations between the fidelity measures were studied by Fuchs [74], Barnum, Nielsen, and Schumacher [18] and Werner and Kretschmann [158]. Fidelity for mixed states was investigated by Uhlmann [233]. Lemma 10.17 goes back to Powers and Størmer [191]; see also [109].

3. The coding theorem for the quantum capacity was first conjectured by Lloyd [168] as $Q(\Phi) = \max_\rho I_c(\rho, \Phi)$, but it was soon recognized by Di Vincenzo, Shor, and Smolin [65] that $\bar{Q}_n$ is strictly superadditive; see also Smith and Yard [224]. Hence, taking the limit in (10.43) is indeed required. Additional evidence in favor of a heuristic random subspace coding argument was given by Shor [216]. See also the discussion in Horodeckis' paper [138]. The proof based on this approach was given later by Hayden [98].

The inequality $Q(\Phi) \leq \bar{Q}(\Phi)$ (the converse coding theorem), as well as lemmas in Section 10.3.1, were established by Barnum, Nielsen, and Schumacher [18] and Barnum, Knill, and Nielsen [17]. Corollary 10.22 is inspired by an observation of Smith and Smolin [222].

Relation (10.58) was obtained by Schumacher and Westmoreland [201], who used the ideas of classical information theory [3] to relate the "privacy" of information transmission via quantum channel Φ to the quantity

$$\chi\left(\{\pi_\chi\}, \{S_B^X\}\right) - \chi\left(\{\pi_\chi\}, \{S_E^X\}\right).$$

The notion of a degradable channel was introduced by Devetak and Shor [63], who showed that the quantum capacity of a degradable channel is given by the oneletter expression (10.53). This resembles the notion of a "stochastically degraded" channel [47] for classical broadcast channels, with the role of second receiver played by the environment. For such channels, there is a one-letter expression for the capacity region. Antidegradable channels were considered by Caruso, Giovannetti, and Holevo [41]. Corollary 10.28 is obtained in the work of Cubitt, Ruskai, and Smith [49].

Smith and Yard [224] provided an explicit example of a remarkable phenomenon named superactivation. There exist cases in which, given two quantum channels Φ_1, Φ_2 with zero quantum capacity, it is possible to have $Q(\Phi_1 \otimes \Phi_2) > 0$. The example in [224] is built by joining an antidegradable channel Φ_1 with an entanglementbinding channel Φ_2. Further results in this direction were obtained by Cubitt et al. [48]. Shirokov and Shulman [213], Shirokov [214] demonstrated superactivation phenomena for zero-error quantum capacity.

4. A complete proof of the direct coding theorem ($Q(\Phi) \geq \bar{Q}(\Phi)$) was given by Devetak [62]. It is based on an idea that reveals a profound relation between the quantum and the private classical capacities; see(10.58). It is this proof (as well as a simpler proof of the converse) which we follow here. The large deviation estimates for random operators of the Bernstein type using the operator version (10.78) of Hoeffding's inequality ([105], Theorem 1) are due to Ahlswede and Winter [5]. Another proof, based on random subspaces, which is closer to the

initial argument of Lloyd, was given by Hayden, Shor, and Winter [101]. Proposition 10.31 is due to Smith [221]. For more recent results concerning tail bounds for sums of i. i. d. Hermitian matrices, including an improvement of the Ahlswede-Winter inequality using Lieb's theorem on convex trace functions in place of the Golden-Thompson inequality, see Tropp [232].

It was already stressed that a quantum channel is characterized by a whole spectrum of capacities. Apart from the capacities $C, C_\chi, C_{ea}, C_p, Q$, treated in detail in this book, there are classical and quantum feedback capacities (denoted by C_b, Q_b correspondingly) and the classical and quantum capacities with a classical two-side communication (correspondingly C_2, Q_2). In classical information theory, it is well known that feedback does not increase the Shannon capacity of a memoryless channel. In the quantum case, a similar property is established [33] for the entanglement-assisted capacity $C_{ea}(\Phi)$. Regarding the quantum capacity $Q(\Phi)$, it is known that it cannot be increased by an additional unlimited forward classical communication [28, 18]. However, $Q(\Phi)$ can be increased if there is a possibility of transmitting the classical information in the backward direction. Such a protocol would allow one to create the maximum entanglement between the input and output, which can be used for quantum state teleportation. By this trick, even channels with zero quantum capacity supplemented with classical feedback can be used for the reliable transmission of quantum information [179, 33]. For a quantum channel, there is a hierarchy

$$\begin{array}{ccccccc} C_\chi & \leq & C_b & \leq & C_2 & \leq & C_{ea} \\ \text{VI} & & \text{VI} & & \text{VI} & & \\ Q & \leq & Q_b & \leq & Q_2 & \leq & Q_{ea} \end{array}$$

where $\leq$ should be understood as "less than or equal to for all channels and strictly less for some channels" (see Bennett, Devetak, Shor, and Smolin [24]). Also, $C_{ea} = 2Q_{ea}$ and for some other pairs of capacities both inequalities are possible. Furthermore, there exists a so-called "mother" protocol for information transmission that realizes all the protocols, by using additional resources (such as, e. g., feedback or entanglement) [1]. For a very detailed and thoroughly systematized survey of the modern state of the art in the quantum Shannon theory, see the treatises of Watrous [240] and Wilde [248].

10.11 11 Channels with Constrained Inputs

The importance of quantum channels with constrained inputs was clear from the beginning of quantum communication. A main question motivating the emergence of quantum information theory was the capacity of an optical channel with constrained energy of the input signal. From a mathematical point of view, the necessity for constraints appears when the system describing the information carrier is infinite, which in the quantum case means using infinite-dimensional Hilbert space. One such class of systems, called "continuous-variable" quantum systems, whose states are in a natural sense "Gaussian," will be considered in the next chapter. One of the main goals of the present chapter is to obtain general expressions for the capacities of infinitedimensional channels with constrained inputs, suitable for applications to quantum Gaussian channels with the energy constraint.

A new feature of the infinite-dimensional case is the discontinuity and unboundedness of the entropy of quantum states, which requires us to pay serious attention to the continuity of the entropic quantities. Another important feature of channels in infinite dimensions is the natural emergence of generalized "continuous" ensembles, understood as probability measures on the set of all quantum states. Various capacitylike quantities for a quantum channel involve optimization with respect to state ensembles that satisfy the appropriate constraint. The supremums in question turn out to be achievable under certain conditions, namely, continuity of the entropic quantity and the compactness of the constrained set. These two mathematical

problems will be studied in the present chapter. Another subject of this chapter is the structure of entanglement-breaking channels in infinite dimensions.

10.11.1 11.1 Convergence of Density Operators

In what follows, $\mathcal{H}$ is a separable Hilbert space. A linear operator A, defined on $\mathcal{H}$, is called bounded if it maps the unit ball into a norm-bounded subset of $\mathcal{H}$. Most of the definitions in Chapter 2 carry over to bounded operators, and we shall explicitly mention when a modification should be made (see also [193], Chapter VI). In particular, the operator norm $\|A\|$ is defined as in (1.16) with the maximum replaced by the supremum. The operator A is bounded if and only if $\|A\| < \infty$. All bounded operators form the Banach algebra $\mathfrak{B}(\mathcal{H})$. The trace norm $\|\cdot\|_1$ is defined as in (1.14), and the collection of all bounded operators with $\|T\|_1 < \infty$ forms the Banach space $\mathfrak{T}(\mathcal{H})$ of trace-class operators. The inequality

$$|\operatorname{Tr} TA| \leq \|T\|_1 \|A\| \tag{11.1}$$

holds for all $T \in \mathfrak{T}(\mathcal{H}), A \in \mathfrak{B}(\mathcal{H})$. The dual space of $\mathfrak{T}(\mathcal{H})$ is $\mathfrak{T}(\mathcal{H})^* = \mathfrak{B}(\mathcal{H})$, which means that every continuous linear functional on $\mathfrak{T}(\mathcal{H})$ has the form $T \to \operatorname{Tr} TA$ for some $A \in \mathfrak{B}(\mathcal{H})$, with the norm equal to $\|A\|$. Note also that

$$\|A\| \leq \|A\|_1 \tag{11.2}$$

and $\mathfrak{T}(\mathcal{H})$ is a proper subspace of $\mathfrak{B}(\mathcal{H})$ in the infinite-dimensional case.

A density operator (we also use the term state) is a positive trace-class operator with unit trace (cf. Definition 2.2). The state space $\mathfrak{S}(\mathcal{H})$ is the closed convex subset of $\mathfrak{T}(\mathcal{H})$ consisting of all density operators in $\mathcal{H}$. It is a complete separable metric space with the metric defined by the trace norm, i. e., $\rho(S_1, S_2) = \|S_1 - S_2\|_1$.

A sequence of bounded operators $\{A_n\}$ in $\mathcal{H}$ weakly converges to an operator A if $\lim_{n\to\infty}\langle\psi|A_n|\phi\rangle \to \langle\psi|A|\phi\rangle$ for all $\phi, \psi \in \mathcal{H}$. It turns out that the weak convergence, which is in general weaker than the trace norm convergence, coincides with it on $\mathfrak{S}(\mathcal{H})$.

Lemma 11.1. Let $\{S_n\}$ be a sequence of density operators in $\mathcal{H}$ weakly converging to a density operator S. Then it converges to S in the trace norm.

Proof. For any finite-dimensional projector P,

$$\begin{aligned}\|S_n - S\|_1 \leq \|P(S_n - S)P\|_1 + 2\|PS_n(I-P)\|_1 + 2\|PS(I-P)\|_1 \\ + \|(I-P)S_n(I-P)\|_1 + \|(I-P)S(I-P)\|_1.\end{aligned}$$

The first term on the right tends to zero for any choice of P, since $PS_nP \to PSP$ due to the weak convergence, and due to the equivalence of all kinds of convergence in the finite-dimensional case. For the last two terms we have

$$\|(I-P)S(I-P)\|_1 = \operatorname{Tr}(I-P)S(I-P) = \operatorname{Tr}(I-P)S = 1 - \operatorname{Tr} PS,$$

which can be made arbitrarily small by the choice of P, and

$$\|(I-P)S_n(I-P)\|_1 = 1 - \operatorname{Tr} PS_n \to 1 - \operatorname{Tr} PS$$

by the weak convergence. Finally, the intermediate terms can be evaluated as follows:

$$\|PS_n(I-P)\|_1 = \operatorname{Tr} U^* PS_n(I-P) = \operatorname{Tr} U^* P\sqrt{S_n}\sqrt{S_n}(I-P)$$

where U is the unitary operator from the polar decomposition of $PS_n(I-P)$. Now, by the operator Cauchy-Schwarz inequality for the trace,

$$\operatorname{Tr} U^* P\sqrt{S_n}\sqrt{S_n}(I-P) \le \sqrt{\operatorname{Tr} PS_n}\sqrt{1-\operatorname{Tr} PS_n} \to \sqrt{\operatorname{Tr} PS}\sqrt{1-\operatorname{Tr} PS},$$

which can again be made small by the choice of P.

In what follows, when speaking of convergence of density operators or states, we will have in mind the convergence in the sense of this lemma. A subset $K \subseteq \mathfrak{S}(\mathcal{H})$ is compact if any sequence $\{S_n\} \subset \mathfrak{S}(\mathcal{H})$ contains a subsequence that converges to a state $S \in K$.

Theorem 11.2. A trace norm closed subset K of $\mathfrak{S}(\mathcal{H})$ is compact if and only if for arbitrary $\varepsilon > 0$ there exists a finite-rank projector P_ε such that $\operatorname{Tr} P_\varepsilon S > 1-\varepsilon$ for all $S \in K$.

Proof. Let K be a trace norm compact subset of $\mathfrak{S}(\mathcal{H})$. Suppose that there exists $\varepsilon > 0$ such that for an arbitrary finite-rank projector P there exists a state $S \in K$ such that $\operatorname{Tr} PS \le 1-\varepsilon$. Let P_n be a sequence of finite-rank projectors in $\mathcal{H}$ converging monotonously to the identity operator $I_\mathcal{H}$ in the weak operator topology and let S_n be the corresponding sequence of states in K. By the compactness of K, there exists a subsequence S_{n_k} that converges to a state $S_0 \in K$. By construction $\operatorname{Tr} P_{n_l} S_{n_k} \le \operatorname{Tr} P_{n_k} S_{n_k} \le 1-\varepsilon$ for $k > l$. Hence,

$$\operatorname{Tr} S_0 = \lim_{l\to+\infty} \operatorname{Tr} P_{n_l} S_0 = \lim_{l\to+\infty} \lim_{k\to+\infty} \operatorname{Tr} P_{n_l} S_{n_k} \le 1-\varepsilon,$$

which contradicts the fact that $S_0 \in K \subseteq \mathfrak{S}(\mathcal{H})$.

Conversely, let K be a closed subset of $\mathfrak{S}(\mathcal{H})$ that satisfies the criterion, and let S_n be an arbitrary sequence in K. Since the unit ball in $\mathfrak{B}(\mathcal{H})$ is compact in the weak operator topology (this follows from the Banach-Alaoglu theorem, see, e. g., [193], Theorem VI.21), there exists a subsequence S_{n_k} that converges weakly to a positive operator S_0. We have

$$\operatorname{Tr} S_0 \le \liminf_{k\to\infty} \operatorname{Tr} S_{n_k} = 1.$$

Therefore, to prove that S_0 is a state, it is sufficient to show that $\operatorname{Tr} S_0 \ge 1$. Let $\varepsilon > 0$ and P_ε be the corresponding projector. We have

$$\operatorname{Tr} S_0 \ge \operatorname{Tr} P_\varepsilon S_0 = \lim_{k\to\infty} \operatorname{Tr} P_\varepsilon S_{n_k} > 1-\varepsilon,$$

where the equality follows from the fact that P_ε has finite rank. Thus, S_0 is a state. Lemma 11.1 implies that the subsequence S_{n_k} converges to the state S_0 in the trace norm. Thus, the set K is compact. □

In the sequel we will need the following partial infinite-dimensional analog of the spectral decomposition (1.5). Let $\{|e_j\rangle\}$ be an orthonormal basis in $\mathcal{H}$ and $\{f_j\}$ a sequence of real numbers bounded from below. In this case, the formula

$$F|\psi\rangle = \sum_j f_j\, |e_j\rangle\, \langle e_j \mid \psi\rangle \tag{11.3}$$

defines a self-adjoint operator F (see Section 12.1.1) on the dense domain

$$\mathcal{D}(F) = \left\{ \psi : \sum_j |f_j|^2\, |\langle e_j \mid \psi\rangle|^2 < \infty \right\}, \tag{11.4}$$

for which $|e_j\rangle$ are the eigenvectors and f_j are the corresponding eigenvalues.

Definition 11.3. An operator defined on the domain (11.4) by formula (11.3) will be called an operator of the type $\mathfrak{F}$.

In applications, F is the operator of energy (of an oscillator system). In connection with this, an important role will be played by the operator $\exp(-\theta F), \theta > 0$, defined by the relation

$$\exp(-\theta F)|\psi\rangle = \sum_j \exp\left(-\theta f_j\right)|e_j\rangle\langle e_j \mid \psi\rangle \tag{11.5}$$

which is a bounded positive operator of the type $\mathfrak{F}$.

Let F be an operator of the type $\mathfrak{F}$. For an arbitrary density operator S, we define the expectation

$$\operatorname{Tr} SF = \sum_{j=1}^{\infty} f_j \langle e_j| S |e_j\rangle \leq +\infty, \tag{11.6}$$

which is correctly defined, with values in $(-\infty, +\infty]$.

Lemma 11.4. The functional $S \to \operatorname{Tr} SF$ is affine lower semicontinuous on the set $\mathfrak{S}(\mathcal{H})$.

Proof. Affinity is obvious. Next, we will use the fact that the least upper bound of a family of continuous functions is lower semicontinuous. We have

$$\operatorname{Tr} SF = \sup_N \sum_{j=1}^{N} f_j \langle e_j| S |e_j\rangle$$

where all the finite sums are continuous. Hence, $S_n \to S$ implies

$$\liminf_{n\to\infty} \operatorname{Tr} S_n F \geq \operatorname{Tr} SF,$$

which means the lower semicontinuity. □

Lemma 11.5. Let the spectrum of the operator F consist of the eigenvalues f_n of finite multiplicity and $\lim_{n\to\infty} f_n = +\infty$. In this case, the set

$$\mathfrak{S}_E = \{S : \operatorname{Tr} SF \leq E\} \tag{11.7}$$

is compact.

Proof. Without loss of generality, we assume that f_n is monotonously nondecreasing, and we denote by P_n the finite-dimensional projector onto the eigenspace corresponding to the first n eigenvalues, so that $P_n \uparrow I$. The set $\mathfrak{S}_E$ is closed, due to Lemma 11.4. Since $f_{n+1}(I - P_n) \leq F$, we have $\operatorname{Tr} S(I - P_n) \leq f_{n+1}^{-1} \operatorname{Tr} SF \leq f_{n+1}^{-1} E < \varepsilon$ for large enough n and for all $S \in \mathfrak{S}_E$. By the criterion of compactness of Theorem 11.2, $\mathfrak{S}_E$ is compact. □

In applications this result implies the compactness of the set of quantum states with mean energy bounded by a certain constant.

10.11.2 11.2 Quantum Entropy and Relative Entropy

In the infinite-dimensional case, the von Neumann entropy $H(S)$ of a density operator S can be defined as in formula (5.7), although now it can take the value $+\infty$ if the corresponding series diverges. The relative entropy can be correctly defined by using formula (7.2). Most of the properties in Chapter 7 can be extended to this case, except for the continuity, which is weakened to the lower semicontinuity.

Theorem 11.6. The quantum entropy and relative entropy are lower semicontinuous on $\mathfrak{S}(\mathcal{H})$. Let $\{S_n\}$ (resp. $\{S'_n\}$) be a sequence of density operators in $\mathcal{H}$, converging to a density operator S (resp. S'). Then

$$H(S) \leq \liminf_{n\to\infty} H(S_n),$$
$$H(S; S') \leq \liminf_{n\to\infty} H(S_n; S'_n).$$

Proof. By inequality (11.2), we have $\|S_n - S\| \to 0$. The function $\eta(x) = -x \log x$ is continuous on the interval $[0, 1]$. Hence, $\|\eta(S_n) - \eta(S)\| \to 0$. Indeed, $\eta(x)$ can be uniformly approximated by a polynomial on $[0, 1]$, and then we can use the following estimate.

Exercise 11.7 For a polynomial f and arbitrary operators A, B of norm less than or equal to one,

$$\|f(A) - f(B)\| \leq C_f \|A - B\|$$

where the constant depends only on f. Hint: use the decomposition

$$A^k - B^k = \sum_{l=0}^{k-1} A^{k-l-1}(A - B)B^l$$

Therefore, for any finite-dimensional projector P, due to inequality (11.1) we have

$$|\operatorname{Tr} P(\eta(S_n) - \eta(S))| \leq \operatorname{Tr} P \|\eta(S_n) - \eta(S)\| \to 0. \tag{11.8}$$

On the other hand, by the same inequality, for a Hermitian positive operator A,

$$\operatorname{Tr} PA \leq \|P\| \operatorname{Tr} A,$$

and hence $\operatorname{Tr} A = \sup_P \operatorname{Tr} PA$, where P runs over all finite-dimensional projectors. Thus,

$$H(S) = \sup_P \operatorname{Tr} P\eta(S) \leq \liminf_{n\to\infty} \sup_P \operatorname{Tr} P\eta(S_n) = \liminf_{n\to\infty} H(S_n).$$

Similarly, by using representation (7.23) for the relative entropy, we get

$$H(S; S') = \sup_{\lambda>0} \frac{1}{\lambda} [H(\lambda S + (1-\lambda)S') - \lambda H(S) - (1-\lambda)H(S')]$$

hence

$$\begin{aligned} H(S; S') &= \sup_{P,\lambda>0} \frac{1}{\lambda} \operatorname{Tr} P [\eta(\lambda S + (1-\lambda)S') - \lambda\eta(S) - (1-\lambda)\eta(S')] \\ &\leq \liminf_{n\to\infty} \sup_{P,\lambda>0} \frac{1}{\lambda} \operatorname{Tr} P [\eta(\lambda S_n + (1-\lambda)S_n') - \lambda\eta(S_n) - (1-\lambda)\eta(S_n')] \\ &= \liminf_{n\to\infty} H(S_n; S_n') \end{aligned}$$

□

Lemma 11.8. Let F be an operator of type $\mathfrak{F}$, satisfying the condition

$$\operatorname{Tr} \exp(-\theta F) < \infty \quad \text{for all } \theta > 0. \tag{11.9}$$

In this case, the quantum entropy $H(S)$ is bounded and continuous on the set $\mathfrak{S}_E$ defined in (11.7).

Note that relation (11.9) implies that the operator F satisfies the conditions of Lemma 11.5, and hence the set $\mathfrak{S}_E$ is compact.

Proof. By introducing the density operator $S_\theta = \exp(-\theta F - c(\theta))$, where $c(\theta) = \ln \operatorname{Tr} \exp(-\theta F)$, we have

$$H(S) = -H(S; S_\theta) + \theta \operatorname{Tr} SF + c(\theta), \tag{11.10}$$

where $H(S; S_\theta)$ is the relative entropy. Hence,

$$H(S) \leq -H(S; S_\theta) + \theta E + c(\theta), \tag{11.11}$$

if $S \in \mathfrak{S}_E$. Therefore, the entropy $H(S)$ is bounded on $\mathfrak{S}_E$. Since $H(S)$, by Theorem 11.6, is lower semicontinuous, it is sufficient to show that it is also upper semicontinuous, and hence continuous, on the compact set $\mathfrak{S}_E$. Let $\{S_n\} \subset \mathfrak{S}_E$ be a sequence of states weakly converging to S. From inequality (11.11) applied to S_n, by the lower semicontinuity of the relative entropy,

$$\begin{aligned} \limsup_{n\to\infty} H(S_n) &\le -H(S;S_\theta) + \theta E + c(\theta) \\ &= H(S) + \theta(E - \operatorname{Tr} SF), \end{aligned} \tag{11.12}$$

where in the last equality we used (11.10). Letting $\theta \to 0$, we obtain the upper semicontinuity of $H(S)$. $\square$

Note that when F is the operator of the energy, S_θ is the density operator of the Gibbs equilibrium state at the inverse temperature θ, and the function $-\theta^{-1}c(\theta)$ is the free energy. The relation (11.10) and the nonnegativity of the relative entropy imply

$$H(S) \le \theta \operatorname{Tr} SF + c(\theta), \tag{11.13}$$

which is equivalent to the Gibbs variational principle.

10.11.3 11.3 Constrained c-q Channel

Let $\mathcal{X} = \{x\}$ be an infinite alphabet. For every x, let S_x be a density operator in $\mathcal{H}$ with finite von Neumann entropy $H(S_x)$. The map $x \to S_x$ will be called a c - q channel with input alphabet $\mathcal{X}$. Let $f(x)$ be a function defined on $\mathcal{X}$, taking values in $[0, +\infty]$. We shall consider the class $\mathcal{P}_E$ of finitely supported probability distributions $\pi = \{\pi_x\}$ on $\mathcal{X}$ satisfying the condition

$$\sum_x f(x)\pi_x \le E \tag{11.14}$$

where E is a positive real number. We assume that $\mathcal{P}_E$ is nonempty and impose the following condition onto the channel:

$$\sup_{\pi\in\mathcal{P}_E} H\left(\sum_x \pi_x S_x\right) < \infty \tag{11.15}$$

Definition 11.9. We define a code $(\ W, M\ )$ of size N and length n as in Definition 5.1, with the additional requirement that all codewords $w = (x_1, \dots, x_n) \in W$ satisfy the additive constraint

$$f(x_1) + \cdots + f(x_n) \le nE. \tag{11.16}$$

The average error $\bar{P}_e(W, M)$ and the minimal error $\bar{p}_e(n, N)$ of the code are given by formulas (5.5) and (5.6), respectively. The constrained classical capacity of channel $x \to S_x$ is defined as in Definition 5.2, i.e., as the supremum of achievable rates R such that $\lim_{n\to\infty} \bar{p}_e\left(n, 2^{nR}\right) = 0$.

Theorem 11.10. The constrained classical capacity C of a $c-q$ channel $x \to S_x$ that satisfies condition (11.15), with input constraint (11.16), is equal to the quantity

$$C_\chi = \sup_{\pi\in\mathcal{P}_E} \left[H\left(\sum_x \pi_x S_x\right) - \sum_x \pi_x H(S_x) \right]. \tag{11.17}$$

Proof. We denote by $\mathcal{P}_E^{(n)}$ the class of probability distributions on $\mathcal{X}^n$ satisfying the condition

$$\sum_{x_1,\dots,x_n} [f(x_1)+\cdots+f(x_n)]\,\pi_{x_1,\dots,x_n} \le nE \tag{11.18}$$

and define the quantity $C_\chi^{(n)}$ as in (5.29), with the modification that the supremum with respect to π is taken over $\mathcal{P}_E^{(n)}$, i.e.,

$$C_\chi^{(n)} = \sup_{\pi\in\mathcal{P}_E^{(n)}} \chi(\{\pi_w\};\{S_w\})$$

Lemma 11.11. The sequence $\left\{C_\chi^{(n)}\right\}$ is additive, i.e., $C_\chi^{(n)} = nC_\chi$.

Proof. By (5.30), we have

$$\chi_n(\pi) \le \sum_{k=1}^n \chi\left(\pi^{(k)}\right),$$

where $\pi^{(k)}$ is the k th marginal distribution of π on $\mathcal{X}$. Also,

$$\sum_{k=1}^n \chi\left(\pi^{(k)}\right) \le n\chi(\bar\pi), \tag{11.19}$$

where $\bar\pi = \frac{1}{n}\sum_{k=1}^n \pi^{(k)}$, since $\chi(\pi)$ is a concave function of π (as follows from concavity of the von Neumann entropy). Inequality (11.18) can be rewritten as

$$\frac{1}{n}\sum_{k=1}^n \sum_x f(x)\pi^{(k)}(x) \le E$$

which implies that $\bar\pi \in \mathcal{P}_E$ if $\pi \in \mathcal{P}_E^{(n)}$. Taking the supremum in relation (11.19) with respect to $\pi \in \mathcal{P}_E^{(n)}$, we obtain $C_\chi^{(n)} \le nC_\chi$. The converse inequality is obvious. □

The proof of the converse coding theorem can be based on the following corollary of the Fano inequality (cf. (5.32)):

$$\bar P_e(W,M) \ge 1 - \frac{\sup_{\pi\in\mathcal{P}_E^{(n)}} \sup_M \mathcal{I}_n(\pi,M)}{nR} - \frac{1}{nR}, \tag{11.20}$$

which is obtained as follows. Let again the words in the code (W, M) be taken with the input distribution $\pi^{(N)}$ assigning equal probability $1/N$ to each word. Consider inequality (4.37). Since the words in the code satisfy (11.16), we have $\pi^{(N)} \in \mathcal{P}_E^{(n)}$, and hence (11.20) follows.

Using inequality (11.20) and Theorem 5.9, we obtain

$$\bar p_e\left(n, 2^{nR}\right) \ge 1 - \frac{C_\chi}{R} - \frac{1}{nR},$$

where C_χ is defined by (11.17), which implies $p_e\left(n, 2^{nR}\right) \nrightarrow 0$ for $R > C_\chi$.

In the classical information theory, the direct coding theorem for channels with additive constraints can be proved by using random coding with a probability distribution (5.46) modified by a factor concentrated on words, for which the constraint holds close to the equality. The same tool can be applied to a c − q channel. Let π be a distribution on $\mathcal{X}$ satisfying (11.14), and let P be a distribution on the set of N words, under which the words are independent and have the probability distribution (5.46). Let $v_n = \mathrm{P}\left(\frac{1}{n}\sum_{k=1}^n f(x_k) \le E\right)$ and define the modified distribution $\tilde{\mathrm{P}}$ under which the words are still independent, but

$$\tilde{\mathrm{P}}\left(w=(x_1,\ldots,x_n)\right)=\begin{cases} v_n^{-1}\pi_{x_1}\cdots\pi_{x_n}, & \text{if } \sum_{k=1}^n f\left(x_k\right)\le nE,\\ 0, & \text{otherwise .}\end{cases} \tag{11.21}$$

Let us remark that since $\pi\in\mathcal{P}_E$, we have $Ef\le E$ (where E is the expectation corresponding to P) and hence, by the central limit theorem,

$$\lim_{n\to\infty} v_n\ge 1/2.$$

Therefore, $\tilde{\mathrm{E}}\xi\le 2^m\mathrm{E}\xi$ (where $\tilde{\mathrm{E}}$ is the expectation corresponding to $\tilde{\mathrm{P}}$) for any nonnegative random variable ξ depending on m different words.

For the error probability $\bar{P}_e(W,M)$, we have the basic upper bound (5.51). Now, take the expectation of this bound with respect to $\tilde{P}$. Since every term in the right-hand side of (5.51) depends on no more than two different words, we have

$$\tilde{\mathrm{E}}\inf_M \bar{P}_e(W,M)\le 4\mathrm{E}\inf_M \bar{P}_e(W,M),$$

and the expectation with respect to P can be made arbitrarily small for $N=2^{nR}, n\to\infty$, with $R<C_\chi-3\delta$. Thus, $\tilde{E}\bar{P}_e(W,M)$ can also be made arbitrarily small under the same circumstances. Since the distribution $\tilde{\mathrm{P}}$ is concentrated on words that satisfy (11.16), we can choose a code for which $\bar{P}_e(W,M)$ can be made arbitrarily small for sufficiently large n. □

10.11.4 11.4 Classical-Quantum Channel with Continuous Alphabet

Let the input alphabet $\mathcal{X}$ be a complete, separable metric space with the σ-algebra of Borel subsets. In applications, $\mathcal{X}$ is typically a domain in $\mathbb{R}^k$ that is locally compact. However, we need the more general case for the treatment of infinite-dimensional quantum channels in the next section. We consider the c − q channel given by a continuous mapping $x\to S_x$ from the alphabet $\mathcal{X}$ to the set of quantum states $\mathfrak{S}(\mathcal{H})$ (by Lemma 11.1, for continuity it is necessary and sufficient that all matrix elements $\langle\psi|S_x|\phi\rangle;\psi,\phi\in\mathcal{H}$ are continuous with respect to the metric in $\mathcal{X}$). We will obtain a convenient integral expression for the classical capacity C of the channel $x\to S_x$ under the constraint (11.16).

We assume that f is a nonnegative Borel function on $\mathcal{X}$. Consider the set $\mathcal{P}_E^B$ of Borel probability measures π on $\mathcal{X}$ satisfying

$$\int_{\mathcal{X}} f(x)\pi(dx)\le E. \tag{11.22}$$

Recall that a sequence of Borel probability measures $\{\pi_n\}$ converges weakly to π if

$$\int_{\mathcal{X}}\varphi(x)\pi_n(dx)\to\int_{\mathcal{X}}\varphi(x)\pi(dx)$$

for arbitrary $\varphi\in C(\mathcal{X})$, the Banach space of bounded continuous functions on $\mathcal{X}$ (see, e. g., Parthasarathy's book [186]).

Exercise 11.12 Let f be lower semicontinuous. In this case, the functional $\pi\to\int_{\mathcal{X}} f(x)\pi(dx)$ is lower semicontinuous with respect to the weak convergence of probability measures.

Hint: use the fact that f is the least upper bound of the family of all bounded continuous functions $\varphi\le f$.

We will need the following auxiliary result, the proof of which can be found in [186].
Lemma 11.13. Let f be lower semicontinuous. In this case, the set $\mathcal{P}_E$ of all finitely supported probability measures that satisfy (11.22) is weakly dense in $\mathcal{P}_E^B$.

Let us also give a convenient sufficient condition of weak compactness of the set $\mathcal{P}_E^B$.

Lemma 11.14. Assume that f is lower semicontinuous and for any positive k the set $\{x : f(x) \leq k\} \subset \mathcal{X}$ is compact. Then the subset of probability measures

$$\mathcal{P}_E^B = \left\{\pi : \int_{\mathcal{X}} f(x)\pi(dx) \leq E\right\}$$

is weakly compact.

Proof. The lower semicontinuity of f implies that the functional $\pi \to \int_{\mathcal{X}} f(x)\pi(dx)$ is lower semicontinuous with respect to the weak convergence of probability measures (Exercise 11.12). Hence, the set $\mathcal{P}_E^B$ is weakly closed. It is known that a weakly closed subset $\mathcal{P}$ of Borel probability measures on $\mathcal{X}$ is weakly compact if and only if for any $\varepsilon > 0$ there is a compact $K \subset \mathcal{X}$, such that $\pi(\bar{K}) \leq \varepsilon$ for all $\pi \in \mathcal{P}$ (see, e. g., [186]). For a given $\varepsilon > 0$, consider the compact set $K = \{x : f(x) \leq E/\varepsilon\}$. Then,

$$\pi(\bar{K}) \leq \frac{\varepsilon}{E} \int_{\bar{K}} f(x)\pi(dx) \leq \varepsilon$$

for $\pi \in \mathcal{P}_E^B$. Hence, the set $\mathcal{P}_E^B$ is weakly compact.

For an arbitrary Borel probability measure π on $\mathcal{X}$, we introduce the average state

$$\bar{S}_\pi = \int_{\mathcal{X}} S_x \pi(dx) \tag{11.23}$$

where, by assumption, the function S_x is continuous, the integral is well-defined, and it represents a density operator in $\mathcal{H}$.

Assuming $H\left(\bar{S}_\pi\right) < \infty$, consider the functional

$$\chi(\pi) = H\left(\bar{S}_\pi\right) - \int_{\mathcal{X}} H\left(S_x\right) \pi(dx) \tag{11.24}$$

where, by Theorem 11.6, the function $H\left(S_x\right)$ is nonnegative and lower semicontinuous and hence the integral is well-defined.

Theorem 11.15. Let there exist a self-adjoint operator F of the type $\mathfrak{F}$, satisfying condition (11.9), such that

$$f(x) \geq \operatorname{Tr} S_x F, \quad x \in \mathcal{X}. \tag{11.25}$$

Then the condition (11.15) holds and the classical capacity C of the channel $x \to S_x$ with the constraint (11.16) is finite and is given by the relation (11.17).

If, moreover, the function f satisfies the conditions of Lemma 11.14, then

$$C = \max_{\pi \in \mathcal{P}_E^B} \chi(\pi) \tag{11.26}$$

Proof. By integrating (11.25), we obtain

$$\operatorname{Tr} \bar{S}_\pi F \leq E \tag{11.27}$$

for $\pi \in \mathcal{P}_E$. Hence, by (11.13),

$$H\left(\bar{S}_\pi\right) \leq \theta \operatorname{Tr} \bar{S}_\pi F + c(\theta) \leq \theta E + c(\theta)$$

Therefore, condition (11.15) is fulfilled, C is finite and equal to (11.17).

If the function f satisfies the conditions of Lemma 11.14, the set $\mathcal{P}_E^B$ is weakly compact. Let us show that the functional $\pi \to \chi(\pi)$ is upper semicontinuous. From expression (11.17) and Lemma 11.13 it now follows that

$$C = \sup_{\pi \in \mathcal{P}_E} \chi(\pi) = \sup_{\pi \in \mathcal{P}_E^B} \chi(\pi).$$

Moreover, the last supremum is achieved by upper semicontinuity of $\chi(\pi)$ and compactness of $\mathcal{P}_E^B$.

Consider the first term in expression (11.24) for $\chi(\pi)$. Since the matrix elements of the family $\{S_x\}$ depend continuously on x, the mapping $\pi \to \bar{S}_\pi$ into the set $\mathfrak{S}_E$, equipped with the weak operator topology, is continuous with respect to the weak convergence of probability measures. By Lemma 11.1, the weak operator topology on $\mathfrak{S}(\mathcal{H})$ is equivalent to the trace norm topology. By Lemma 11.8, the entropy is continuous on $\mathfrak{S}_E$. Therefore, the functional $\pi \to H\left(\bar{S}_\pi\right)$ is continuous on the set $\mathcal{P}_E^B$.

The function $x \to H(S_x)$ is lower semicontinuous. Hence, by Exercise 11.12, the second term in (11.24) is upper semicontinuous in π. Thus, the functional (11.24) is also upper semicontinuous.

10.11.5 11.5 Constrained Quantum Channel

Let $\mathcal{H}_A, \mathcal{H}_B$ be separable Hilbert spaces called the input and output spaces, respectively.

Definition 11.16. By channel we call a linear, bounded, trace-preserving, completely positive map $\Phi : \mathfrak{T}(\mathcal{H}_A) \to \mathfrak{T}(\mathcal{H}_B)$. As in the finite-dimensional case, complete positivity means that, for any $n = 1, 2 \ldots$, the map $\Phi \otimes \mathrm{Id}_n$ is positive.

Exercise 11.17 Sow that any affine map $\Phi_s : \mathfrak{S}(\mathcal{H}_A) \to \mathfrak{S}(\mathcal{H}_B)$ extends uniquely to a linear, bounded, positive map $\Phi : \mathfrak{T}(\mathcal{H}_A) \to \mathfrak{T}(\mathcal{H}_B)$. Hint: to define the linear extension, use the construction of Exercise 2.7. To prove boundedness, use the argument from the proof of Lemma 10.12 (estimates of the type (10.22), (10.23) for $\|\Phi[T]\|_1$).

Example 11.18. Let $x \to S_x$ be a c-q channel with the input alphabet $\mathcal{X}$, which is a complete separable metric space. Then it can be extended to a quantum channel in the sense of Definition 11.16 as follows. Consider the Hilbert space $\mathcal{H}_A = L^2(\mathcal{X}, m)$, where m is a σ-finite measure on $\mathcal{X}$. Assume that S_X is an m-measurable family of density operators in $\mathcal{H}_B$. Any operator $S \in \mathfrak{T}(\mathcal{H}_A)$ is given by a kernel with a correctly defined diagonal value $\langle x|S|x\rangle$. Then the relation

$$\Phi[S] = \int_{\mathcal{X}} \langle x|S|x\rangle S_x m(dx)$$

defines a channel $\Phi : \mathfrak{T}(\mathcal{H}_A) \to \mathfrak{T}(\mathcal{H}_B)$.

In this section, we study the classical capacity of a channel under the additive constraint at its input. Let F be an operator of type $\mathfrak{F}$ in $\mathcal{H}_A$, representing an observable, the mean value of which is to be constrained. We assume that the input states $S^{(n)}$ of the composite channel $\Phi^{\otimes n}$ are subject to the additive constraint

$$\mathrm{Tr}\, S^{(n)} F^{(n)} \leq nE, \tag{11.28}$$

where

$$F^{(n)} = F \otimes \cdots \otimes I + \cdots + I \otimes \cdots \otimes F,$$

and E is a positive constant. Adapting Definition 8.1 and the proof of Proposition 8.2 to the case of the input states constrained by (11.28), one can prove the following.

Proposition 11.19. Let the channel Φ satisfy the condition

$$\sup_{S : \mathrm{Tr}\, SF \leq E} H(\Phi[S]) < \infty. \tag{11.29}$$

Then the classical capacity of this channel, under the constraint (11.28), is finite and is equal to

$$C(\Phi, F, E) = \lim_{n\to\infty} \frac{1}{n} C_\chi \left(\Phi^{\otimes n}, F^{(n)}, nE\right), \tag{11.30}$$

where

$$C_\chi(\Phi, F, E) = \sup_{\pi:\mathrm{Tr}\,\bar{S}_\pi F\le E} \left[H\left(\Phi\left[\bar{S}_\pi\right]\right) - \sum_i \pi_i H\left(\Phi\left[S_i\right]\right)\right] \tag{11.31}$$

Here, $\bar{S}_\pi = \sum_i \pi_i S_i$ is the average state of the ensemble $\pi = \{\pi_i, S_i\}$.
The finiteness of the capacity follows from the following.
Lemma 11.20. Condition (11.29) for the channel Φ implies a similar condition for the channel $\Phi^{\otimes n}$, namely,

$$\sup_{S^{(n)}:\mathrm{Tr}\,S^{(n)}F^{(n)}\le nE} H\left(\Phi^{\otimes n}\left[S^{(n)}\right]\right) \le n \sup_{S:\mathrm{Tr}\,SF\le E} H(\Phi[S]) \tag{11.32}$$

Proof. Denoting by S_j the partial state of $S^{(n)}$ in the j th tensor factor of $\mathcal{H}^{\otimes n}$, and letting $\bar{S} = \frac{1}{n}\sum_{j=1}^n S_j$, we have

$$H\left(\Phi^{\otimes n}\left[S^{(n)}\right]\right) \le \sum_{j=1}^n H\left(\Phi\left[S_j\right]\right) \le nH(\Phi[\bar{S}])$$

where in the first inequality we use subadditivity of the quantum entropy, while in the second we use its concavity. Moreover, $\mathrm{Tr}\,\bar{S}F = \frac{1}{n}\mathrm{Tr}\,S^{(n)}F^{(n)} \le E$ and hence (11.32) follows.

If the channel Φ satisfies the additivity property

$$C_\chi\left(\Phi^{\otimes n}, F^{(n)}, nE\right) = nC_\chi(\Phi, F, E) \tag{11.33}$$

then

$$C(\Phi, F, E) = C_\chi(\Phi, F, E)$$

This is closely related to the property of superadditivity of the convex hull of the output entropy (8.36), which implies the additivity of χ-capacity under the linear constraints (8.39) (see Section 8.3.2).

Exercise 11.21 Prove the following inequality:

$$C_X\left(\Phi^{\otimes n}, F^{(n)}, nE\right) \ge nC_X(\Phi, F, E) \tag{11.34}$$

In any case, the quantity (11.31) provides a lower bound for the classical capacity $C(\Phi, F, E)$. We shall obtain a more convenient expression for $C_\chi(\Phi, F, E)$, by using the results of the previous section. Consider a c-q channel with the alphabet $\mathcal{X} = \mathfrak{S}(\mathcal{H}_A)$, defined by the mapping $S \to \Phi[S]$. The constraint is given by the function $f(S) = \mathrm{Tr}\,SF$, which is affine and lower semicontinuous by Lemma 11.4, whereas the condition (11.15) turns into (11.29).

Definition 11.22. We call generalized ensemble an arbitrary Borel probability measure π on $\mathfrak{S}(\mathcal{H}_A)$. The average state of the generalized ensemble π is defined as the barycenter of the probability measure

$$\bar{S}_\pi = \int_{\mathfrak{S}(\mathcal{H}_A)} S\pi(dS).$$

The conventional ensembles correspond to finitely supported measures.
Theorem 11.6 implies, in particular, that the nonnegative function $S \to H(\Phi[S])$ is measurable. Hence, under condition $H\left(\Phi\left(\bar{S}_\pi\right)\right) < \infty$, the functional

$$\chi_\Phi(\pi) = H\left(\Phi\left(\bar{S}_\pi\right)\right) - \int_{\mathfrak{S}(\mathcal{H}_A)} H(\Phi(S))\pi(dS) \tag{11.35}$$

is well-defined.

Exercise 11.23 Show that the quantity $X_\Phi(\pi)$ is a concave functional of π. Hint: the second term is affine, the concavity of the first term follows from the concavity of the entropy.

Corollary 11.24. Let there exist a positive operator F' in $\mathcal{H}_B$, such that

$$\operatorname{Tr} \exp\left(-\theta F'\right) < +\infty, \quad \text{for all } \theta > 0 \tag{11.36}$$

and

$$\operatorname{Tr} \Phi[S]F' \leq \operatorname{Tr} SF, \quad S \in \mathfrak{S}(\mathcal{H}). \tag{11.37}$$

In this case, condition (11.29) is fulfilled and

$$C_\chi(\Phi, F, E) = \sup_{\pi:\operatorname{Tr}\bar{S}_\pi F \leq E} \chi_\Phi(\pi).$$

Moreover, the output entropy $H(\Phi[S])$ is continuous on the compact set $\mathfrak{S}_E = \{S : \operatorname{Tr} SF \leq E\}$.

If, additionally, F satisfies the conditions of Lemma 11.5, then there exists an optimal generalized ensemble, i.e.,

$$C_\chi(\Phi, F, E) = \max_{\pi:\operatorname{Tr}\bar{S}_\pi F \leq E} \chi_\Phi(\pi). \tag{11.38}$$

Proof. The statement is obtained by applying Theorem 11.15 to the c-q channel $S \to \Phi[S]$, with the constraint function $f(S) = \operatorname{Tr} SF$, the role of condition (11.25) is played by (11.37), and the operator F' plays the role of F. The function $f(S) = \operatorname{Tr} SF$ satisfies the conditions of Lemma 11.14, due to Lemmas 11.4, 11.5.

The continuity of the entropy $H(\Phi[S])$ follows from the continuity of the map $S \to S' = \Phi[S]$ and Lemma 11.8, which guarantees continuity of $H(S')$ on the compact set $\{S' : \operatorname{Tr} S'F' \leq E\}$. □

10.11.6 11.6 Entanglement-Assisted Capacity of Constrained Channels

Let systems A and B share an entangled (pure) state S_{AB}. We assume that the amount of entanglement is unlimited but finite, i.e., $H(S_A) = H(S_B) < \infty$. By generalizing the result of Section 9, one can prove the following.

Proposition 11.25. Let Φ be a channel that satisfies the condition (11.29) with the operator F satisfying (11.9). In this case, its entanglement-assisted classical capacity under the constraint (11.28) is finite and equals

$$C_{ea}(\Phi) = \sup_{S:\operatorname{Tr} SF \leq E} I(S, \Phi), \tag{11.39}$$

where

$$I(S, \Phi) = H(S) + H(\Phi[S]) - H(S; \Phi), \tag{11.40}$$

and $H(S;\Phi)$ is the entropy exchange.
Now, we investigate the problem when the supremum in the right-hand side of (11.39) is achieved. Note that condition (11.9) implies that F satisfies the condition of the Lemma 11.5 and, hence, the set $\mathfrak{S}_E = \{S : \operatorname{Tr} SF \le E\}$ is compact.

Proposition 11.26. Let the constraint operator F satisfy the condition (11.9), and let there exist a self-adjoint operator F' of the type $\mathfrak{F}$, satisfying (11.9) and (11.37). In this case,

$$C_{ea}(\Phi) = \max_{S:\operatorname{Tr} SF\le E} I(S,\Phi). \tag{11.41}$$

Moreover, if the channel Φ is such that

$$\sup_S I(S,\Phi) = \infty, \tag{11.42}$$

the maximum in (11.41) is achieved on a density operator S, that satisfies the constraint with the equality $\operatorname{Tr} SF = E$.

Proof. We will consider each term in formula (11.40) separately. Note that, by Theorem 11.6, the quantum entropy is lower semicontinuous. Since the entropy exchange can be represented as $H(S;\Phi) = H(\tilde{\Phi}[S])$, where $\tilde{\Phi}$ is the complementary channel from the system space $\mathcal{H}_A$ to the environment space $\mathcal{H}_E$, it is also lower semicontinuous and thus the last term in (11.40) is upper semicontinuous. Concerning the first term, by Lemma 11.8, it is continuous on the set $\mathfrak{S}_E = \{S : \operatorname{Tr} SF \le E\}$ if the constraint operator F satisfies (11.9). By using the proof of Corollary 11.24, we can apply a similar argument to the second term in (11.40), namely, $H(\Phi[S])$. Moreover, this corollary also implies that condition (11.29) and hence (11.39) hold. As follows from the above,
the mutual information (11.40) is upper semicontinuous on the compact set $\mathfrak{S}_E$, and hence attains its maximum.

To prove the second statement, we consider

$$f_0(E) = \max_{\operatorname{Tr} SF=E} I(S,\Phi),$$

and we assume that there exists a state S_1 such that

$$\operatorname{Tr} S_1F < E, \quad I(S_1,\Phi) > f_0(E).$$

Condition (11.42) implies that there exists a state S_2 such that

$$\operatorname{Tr} S_2F > E, \quad I(S_2,\Phi) > f_0(E).$$

Now, putting

$$\lambda = \frac{\operatorname{Tr} S_2F - E}{\operatorname{Tr} S_2F - \operatorname{Tr} S_1F},$$

we have $0 < \lambda < 1$ and $\operatorname{Tr}(\lambda S_1 + (1-\lambda)S_2)F = E$, so that

$$I(\lambda S_1 + (1-\lambda)S_2,\Phi) \le f_0(E) < \lambda I(S_1,\Phi) + (1-\lambda) I(S_2,\Phi),$$

which contradicts the concavity of $I(S,\Phi)$. $\square$

10.11.7 11.7 Entanglement-Breaking Channels in Infinite Dimensions

A state $S \in \mathfrak{S}(\mathcal{H}_1 \otimes \mathcal{H}_2)$ is called separable (unentangled) if it belongs to the convex closure (i. e., closure of the convex hull) of the set of all product states $S_1 \otimes S_2 \in \mathfrak{S}(\mathcal{H}_1 \otimes \mathcal{H}_2)$.

Proposition 11.27. State S is separable if and only if it admits a representation

$$S = \int_{\mathcal{X}} S_1(x) \otimes S_2(x) \pi(dx), \tag{11.43}$$

where $\pi(dx)$ is the Borel probability measure and $S_j(x), j = 1, 2$, are Borel $\mathfrak{S}(\mathcal{H}_j)$-valued functions on some complete, separable metric space $\mathcal{X}$.

Proof. According to the definition, the state S is separable if and only if $S = \lim_{n\to\infty} S_n$, where

$$S_n = \int_{\mathfrak{S}(\mathcal{H}_1)} \int_{\mathfrak{S}(\mathcal{H}_2)} S_1 \otimes S_2 \pi_n (dS_1 dS_2), \tag{11.44}$$

and $\{\pi_n\}$ is a sequence of Borel probability measures with finite supports.

Let S be representable in the form (11.43). In this case, by making a change of variable $x \to S_1(x) \otimes S_2(x)$, we can reduce the integral representation (11.43) to

$$S = \int_{\mathfrak{S}(\mathcal{H}_1)} \int_{\mathfrak{S}(\mathcal{H}_2)} S_1 \otimes S_2 \pi (dS_1 dS_2), \tag{11.45}$$

where we use the same notation π for the image of the initial measure under the change of variable. The mapping $\pi \to S$ is continuous under weak convergence of probability measures. This is clear if the set of density operators is equipped with the weak operator topology and, by Lemma 11.1, this topology coincides with the trace norm topology on this set. By Lemma 11.13, there is a sequence $\{\pi_n\}$ of Borel probability measures with finite supports, which converges weakly to π. By using the continuity of the mapping $\pi \to S$, we obtain $S = \lim_{n\to\infty} S_n$, where S_n is given by relation (11.44). Hence, S is separable.

Conversely, let S be a separable state. In this case, $S = \lim_{n\to\infty} S_n$, where S_n is given by (11.44). If we can prove that the sequence of measures $\{\pi_n\}$ is weakly relatively compact, this will imply representation (11.45), where π is a partial limit of this sequence. The converging sequence $\{S_n\}$ is relatively compact. Therefore, by Theorem 11.2, for any $\varepsilon > 0$ there is a finite-dimensional projection P such that $\operatorname{Tr} S_n(I - P) \le \varepsilon$ for all n. For $m = 1, 2, \ldots$ we denote by P_m the projection such that $\operatorname{Tr} S_n (I - P_m) \le 4^{-m}$, and hence

$$\int \operatorname{Tr} (S_1 \otimes S_2)(I - P_m) \pi_n (dS_1 dS_2) \le 4^{-m} \tag{11.46}$$

We introduce the following subsets in the direct product $\mathfrak{S}(\mathcal{H}_1) \times \mathfrak{S}(\mathcal{H}_2)$:

$$K_m = \left\{(S_1, S_2) : \operatorname{Tr} (S_1 \otimes S_2)(I - P_m) \le \delta^{-1} 2^{-m}\right\}, \quad \mathcal{K}_\delta = \cap_{m\ge 1} K_m,$$

where $\delta > 0$. By the same Theorem 11.2, the set $\mathcal{K}_\delta$ is compact by construction. Its complement satisfies

$$\pi_n\left(\overline{\mathcal{K}}_\delta\right) \le \sum_m \pi_n\left(\bar{K}_m\right) \le \delta \sum_m 2^m \int \operatorname{Tr} (S_1 \otimes S_2)(I - P_m) \pi_n (dS_1 dS_2) \le \delta$$

according to (11.46). Thus, the sequence of measures $\{\pi_n\}$ satisfies the criterion of weak relative compactness (see [186]), which completes the proof of the theorem.

Definition 11.28. Channel $\Phi : \mathfrak{T}(\mathcal{H}_A) \to \mathfrak{T}(\mathcal{H}_B)$ is called entanglement-breaking if for an arbitrary Hilbert space $\mathcal{H}_R$ and an arbitrary state $S \in \mathfrak{S}(\mathcal{H}_A \otimes \mathcal{H}_R)$, the state $(\Phi \otimes \mathrm{Id}_R)[S] \in \mathfrak{S}(\mathcal{H}_B \otimes \mathcal{H}_R)$, where Id_R is the identity map in $\mathfrak{T}(\mathcal{H}_R)$, is separable.

To describe the structure of such channels, we will need a generalization of the notion of an observable (Definition 2.9) to the case of an arbitrary set of outcomes.

Definition 11.29. Let $\mathcal{X}$ be a measurable space with a σ-algebra of measurable subsets $\mathcal{B}$. An observable with values in $\mathcal{X}$ is a probability operator-valued measure (POVM) on $\mathcal{X}$, i. e., a family $M = \{M(B), B \in \mathcal{B}\}$ of Hermitian operators in $\mathcal{H}$ satisfying the following conditions:
i. $M(B) \geq 0, B \in \mathcal{B}$;
ii. $M(\mathcal{X}) = I$;
iii. for any countable decomposition $B = \cup B_j$ $(B_i \cap B_j = \emptyset, i \neq j)$ one has $M(B) = \sum_j M(B_j)$ in the sense of weak operator convergence.

A probability operator-valued measure E is called orthogonal (or a spectral measure) if

$$E(B_1 \cap B_2) = E(B_1) E(B_2), \quad B_1, B_2 \in \mathcal{B}.$$

In this case, all operators $E(B)$ are projectors, and the projectors that correspond to disjoint subsets are orthogonal. The corresponding observable is called sharp.

The probability distribution of the observable M in the state S is given by the probability measure

$$\mu_S^M(B) = \mathrm{Tr}\, SM(B), \quad B \in \mathcal{B} \tag{11.47}$$

Note that the linear extension of the affine map $S \to \mu_S^M$ can be regarded as a generalization of the notion of a quantum-classical (q − c) channel (see Section 6.4).

Exercise 11.30 Prove that formula (11.47) defines a probability measure on $\mathcal{B}$.

Theorem 11.31. The channel Φ is entanglement-breaking if and only if there is a complete, separable metric space $\mathcal{X}$, a Borel $\mathfrak{S}(\mathcal{H}_B)$-valued function $S_B(x)$, and an observable M in $\mathcal{H}_A$ with values in $\mathcal{X}$ given by POVM $M(dx)$ such that

$$\Phi[S] = \int_{\mathcal{X}} S_B(x) \mu_S^M(dx) \tag{11.48}$$

Relation (11.48) is a continual version of representation (6.28), and to some extent the statement can be regarded as an infinite-dimensional generalization of Proposition 6.22, saying that an entanglement-breaking channel is a concatenation of a q − c channel (measurement of observable M) and a c-q channel (preparation of states $S_B(x)$ depending on the measurement outcome). In the infinite-dimensional case, the difference is that an observable with a nondiscrete set of outcomes cannot define a quantum channel in the sense of Definition 11.16. Indeed, in the finite-dimensional case, q − c channels are characterized by the property that all output states commute. Let Φ
be an infinite-dimensional channel with this property. This can then always be represented in the form (11.48), with a discrete set $\mathcal{X}$. There exists a basis $\{|k\rangle\}$ such that all commuting density operators $\Phi[S]$ are diagonal. Then

$$\Phi[S] = \sum_k |k\rangle\langle k|\Phi[S]|k\rangle\langle k| = \sum_k |k\rangle\langle k| \,\mathrm{Tr}\, SM_k,$$

where $M_k = \Phi^*[|k\rangle\langle k|]$ are the components of an observable with a discrete set of outcomes $\mathcal{X} = \{k\}$.

Sketch of the proof of Theorem 11.31. Let the channel have the form (11.48). Consider a state $\omega \in \mathfrak{S}(\mathcal{H}_A \otimes \mathcal{H}_R)$. Then

$$(\Phi \otimes \mathrm{Id}_R)(\omega) = \int_{\mathcal{X}} S_B(x) \otimes m_\omega(dx) \tag{11.49}$$

where

$$m_\omega(B) = \mathrm{Tr}_A\, \omega\left(M(B) \otimes I_R\right), \quad B \subseteq \mathcal{X}.$$

Any matrix element of the operator-valued measure m_ω (in a particular basis) is a complex-valued measure on $\mathcal{X}$, absolutely continuous with respect to the probability measure $\mu_\omega(B) = \mathrm{Tr}\, m_\omega(B), B \subseteq \mathcal{X}$. The Radon-Nikodym theorem implies the representation

$$m_\omega(B) = \int_B \sigma_\omega(x)\mu_\omega(dx)$$

where $\sigma_\omega(x)$ is a function on $\mathcal{X}$ that takes values in $\mathfrak{S}(\mathcal{H}_R)$. By using this representation, we can rewrite (11.49) as

$$(\Phi \otimes \mathrm{Id}_R)(\omega) = \int_{\mathcal{X}} S'(x) \otimes \sigma_\omega(x)\mu_\omega(dx) \tag{11.50}$$

which, by Proposition 11.27, is a separable state.
Conversely, let Φ be an entanglement-breaking channel. Fix a nondegenerate state σ_A in $\mathfrak{S}(\mathcal{H}_A)$ and let $\{|e_j\rangle, j = 1, \ldots\}$, be the basis of the eigenvectors of σ_A with corresponding (positive) eigenvalues $\{\lambda_j\}$. Consider the unit vector

$$|\Omega\rangle = \sum_{j=1}^{+\infty} \sqrt{\lambda_j}\, |e_j\rangle \otimes |e_j\rangle$$

in the space $\mathcal{H}_A \otimes \mathcal{H}_A$. Then $|\Omega\rangle\langle\Omega|$ is a purification of the state σ_A. Since Φ is entanglement-breaking, the state

$$\sigma_{AB} = (\mathrm{Id}_A \otimes \Phi)\left[|\Omega\rangle\langle\Omega|\right] \tag{11.51}$$

in $\mathfrak{S}(\mathcal{H}_A \otimes \mathcal{H}_B)$ is separable. By (11.43), there exists a probability measure π on $\mathfrak{S}(\mathcal{H}_A) \times \mathfrak{S}(\mathcal{H}_B)$ such that

$$\sigma_{AB} = \int_{\mathfrak{S}(\mathcal{H}_A)} \int_{\mathfrak{S}(\mathcal{H}_B)} S_A \otimes S_B \pi\left(dS_A dS_B\right). \tag{11.52}$$

This implies

$$\begin{aligned} \sigma_A &= \mathrm{Tr}_B\left(\mathrm{Id}_A \otimes \Phi\right)\left(|\Omega\rangle\langle\Omega|\right) \\ &= \int_{\mathfrak{S}(\mathcal{H}_A)} \int_{\mathfrak{S}(\mathcal{H}_B)} S_A \pi\left(dS_A dS_B\right) \\ &= \int_{\mathfrak{S}(\mathcal{H}_A)} \int_{\mathfrak{S}(\mathcal{H}_B)} \bar{S}_A \pi\left(dS_A dS_B\right), \end{aligned} \tag{11.53}$$

where the bar denotes complex conjugation in the basis $\{|e_i\rangle\}$. By this equality, for an arbitrary Borel set $B \subseteq \mathfrak{S}(\mathcal{H}_B)$, the operator

$$M(B) = \sigma_A^{-1/2} \left[\int_{\mathfrak{S}(\mathcal{H}_A)} \int_B \bar{S}_A \pi\left(dS_A dS_B\right)\right] \sigma_A^{-1/2} \tag{11.54}$$

can be correctly defined as a bounded positive operator on $\mathcal{H}_A$ such that $M(B) \leq M(\mathcal{X}) = I_A$. It is easy to check that M is an observable with values in $\mathcal{X} = \mathfrak{S}(\mathcal{H}_B)$.

Now, consider the entanglement-breaking channel

$$\hat{\Phi}(S) = \int_{\mathfrak{S}(\mathcal{H}_B)} S_B \mu_S^M (dS_B),$$

and let us show that $\Phi(S) = \hat{\Phi}(S)$. For this it is sufficient to prove that

$$\hat{\Phi}(|e_i\rangle\langle e_j|) = \Phi(|e_i\rangle\langle e_j|)$$

for all i, j. However,

$$\begin{aligned}\hat{\Phi}(|e_i\rangle\langle e_j|) &= \int_{\mathfrak{S}(\mathcal{H}_B)} S_B \langle e_j| M(dS_B) |e_i\rangle \\ &= \lambda_i^{-1/2}\lambda_j^{-1/2} \int_{\mathfrak{S}(\mathcal{H}_A)} \int_{\mathfrak{S}(\mathcal{H}_B)} \langle e_i| S_A |e_j\rangle S_B \pi(dS_A dS_B) \\ &= \lambda_i^{-1/2}\lambda_j^{-1/2} \operatorname{Tr}_A (|e_j\rangle\langle e_i| \otimes I_B)\sigma_{AB} = \Phi(|e_i\rangle\langle e_j|),\end{aligned}$$

where in the last equality relation (11.51) was used. □

As was shown in Section 8.3.3, in finite dimensions, entanglement-breaking channels form a large class, in which the additivity conjecture for the classical capacity holds. This fact can be generalized to the infinite-dimensional case.

Proposition 11.32. Let there be two channels Φ_1, Φ_2 with the corresponding input constraints F_1, F_2, satisfying the conditions of Corollary 11.24, and let Φ_1 be an entanglementbreaking channel. Then all additivity properties (8.36), (8.33), and (8.39) hold. In particular, the classical capacity of an entanglement-breaking channel Φ is equal to

$$C(\Phi, F, E) = C_\chi(\Phi, F, E)$$

The proof of this statement is obtained by generalizing the argument in the finitedimensional case (Proposition 8.19), with the replacement of sums with integrals and ensembles with generalized ensembles, taking into account that the conditions of Corollary 11.24 guarantee finiteness of all involved entropies.

10.11.8 11.8 Notes and References

1. The first attempt at a mathematically rigorous treatment of the basic notions of quantum mechanics in a separable Hilbert space was made in the classical treatise of von Neumann [237]. In particular, the difference between Hermitian (symmetric) and self-adjoint operators and the key role self-adjointness plays in the spectral decomposition were stressed, in contrast to the preceding works by physicists. The other important circle of ideas is related to the notions of trace and trace-class operators. A modern treatment of these concepts, in connection with applications in quantum theory, is given in the books [193], [56], and [122].

Lemma 11.1 is due to Dell'Antonio [58]; see also the Appendix to the book of Davies [56]. The compactness criterion for subsets of quantum states is a modification of a result of Sarymsakov [198], called by him the "noncommutative Prokhorov theorem." The latter provides a criterion for weak compactness of families of probability measures on a metric space; see [186]. It is used in Section 11.4.

2. It is well known that the topological properties of entropy in the infinite-dimensional case differ sharply from those in finite dimensions. In the last case, the entropy is a bounded, continuous function on $\mathfrak{S}(\mathcal{H})$, while in infinite dimensions it is discontinuous everywhere and

infinite "almost everywhere" in the sense that the set of states with finite entropy is a first-category subset of $\mathfrak{S}(\mathcal{H})$. See the survey of Wehrl [242], where a number of useful properties of the entropy, including Theorem 11.6 and Lemma 11.8, are discussed. For recent results concerning the topological properties of the entropy in infinite dimensions, see Shirokov [208].
3. The importance of considering input constraints for quantum channels was clear from the beginnings of quantum communication. For a detailed physical discussion of the problem of the determination of the capacity of an optical channel with constrained energy of the input signal, see the survey [43]. The present study of the classical capacity of a constrained c-q channel is based on the works [114] and [117], taking advantage of the random encoding (11.21), which is used in a similar classical problem.
4. Channels with a continuous alphabet were considered in the works of Holevo [117] and Holevo and Shirokov [130], where the notion of a generalized ensemble was systematically applied. Proofs of the used facts from the theory of probability measures on metric spaces, such as Exercise 11.12 and Lemma 11.13, can be found in the monograph of Parthasarathy [186].
5. For the proof of the boundedness of the map Φ in Exercise 11.17, see the book [56], Lemma 2.2.1. Our consideration of the χ-capacity of constrained quantum channels is based on the works [117] and [130]. A detailed investigation of the properties of the χ-capacity and other entropic characteristics of infinite-dimensional channels, without assuming finiteness of the output entropy, was made by Shirokov [210], [209].
6. This section is based on the results of the work [117]. In the paper of Shirokov and Holevo [131] one can find an extension of Proposition 11.25 to a natural degree of generality, free of any finiteness assumptions. In this paper, the question of coincidence of the classical entanglement-assisted and unassisted capacities was also studied. The energy-constrained quantum and private classical capacities of infinitedimensional channels were studied by Wilde and Qi [250], Davis, Shirokov and Wilde [57].
7. The concept of a quantum observable as POVM is presented in detail in the books [122], [115]. Theorem 11.31 is proved in the paper of Holevo, Shirokov, and Werner [132]. Concerning the proof of Proposition 11.32, see [121].

10.12 12 Gaussian Systems

The fundamental physical information carrier is electromagnetic waves, such as light or radio waves. Mathematically the radiation field is known to be equivalent to an ensemble of oscillators. In quantum optics one considers quantized fields and hence quantum oscillators. This is a typical "continuous-variable" bosonic quantum system, whose basic observables (oscillator amplitudes) satisfy the canonical commutation relations (CCRs). Many of the current experimental realizations of quantum information processing are carried out in such systems.

There is a class of particularly important states of bosonic systems which naturally correspond to classical multidimensional Gaussian distributions. From a physical viewpoint, this class comprises thermal equilibrium states of light as well as coherent and squeezed states produced by lasers and some "nonlinear" quantum optics devices. Mathematically, they are completely characterized by the mean and the covariance matrix, in a close parallel to the classical case. Restricting to a finite number of oscillator modes, which is an usual approximation in quantum optics, makes it possible to handle them with techniques from finite-dimensional linear algebra.

Our central problems will be unraveling the structure of quantum Gaussian channels and finding their capacities. Both problems appear rather involved mathematically and, up to now, have only been solved partially. Along with the established results, we give formulations of the basic conjectures, which, we hope, will stimulate attempts to their solutions.

A number of analytical complications related to infinite dimensionality and unboundedness of operators unavoidably arises in connection with bosonic systems and Gaussian states. In our treatment of CCRs we focus on the aspects essential for applications while a detailed presentation of related mathematical tools can be found in the literature. For the sake of convenience for nonspecialist readers, some mathematical and physical preliminaries, as well as motivation, are given in the introductory section.

10.12.1 12.1 Preliminary Material

10.12.2 12.1.1 Spectral Decomposition and Stone's Theorem

Let $\mathcal{H}$ be a separable Hilbert space and let $\{E(B); B \in \mathcal{B}(\mathbb{R})\}$ be a spectral measure on $\mathbb{R}$ where $\mathcal{B}(\mathbb{R})$ is the σ-algebra of Borel subsets. According to Definition 11.29, the spectral measure E defines a sharp real observable. As explained below, such observables are in one-to-one correspondence with self-adjoint operators in $\mathcal{H}$.

For the arbitrary unit vector $\psi \in \mathcal{H}$ the relation

$$\mu_\psi(B) = \langle\psi|E(B)|\psi\rangle$$

defines the Borel probability measure on $\mathbb{R}$. If $f(x)$ is a Borel measurable function on $\mathbb{R}$, then the integral

$$X_f = \int_{-\infty}^{\infty} f(x)E(dx) \tag{12.1}$$

converges strongly on the dense domain

$$\mathcal{D}\left(X_f\right) = \left\{\psi : \int_{-\infty}^{\infty} |f(x)|^2 \mu_\psi(dx) < \infty\right\}$$

and thus uniquely defines a linear operator on the domain $\mathcal{D}\left(X_f\right)$. (Strong convergence of operators $\{X_n\}$ to the operator X on the domain $\mathcal{D}$ means that $\lim_{n\to\infty} \|X_n\psi - X\psi\| = 0$ for $\psi \in \mathcal{D}$. In the case $\mathcal{D} = \mathcal{H}$ it is just the strong operator convergence.)

Indeed, if $f(x) = \sum_{i=1}^{\infty} f_i 1_{B_i}(x)$ is a countably-valued function (here $\{B_i\}$ is a measurable decomposition of $\mathbb{R}$), then

$$X_f = \sum_{i=1}^{\infty} f_i E\left(B_i\right),$$

and due to the orthogonality of the vectors $E\left(B_i\right)|\psi\rangle$,

$$\left\|X_f\psi\right\|^2 = \sum_{i=1}^{\infty} \left|f_i\right|^2 \langle\psi|E\left(B_i\right)|\psi\rangle = \sum_{i=1}^{\infty} \left|f_i\right|^2 \mu_\psi\left(B_i\right), \tag{12.2}$$

so that $\mathcal{D}\left(X_f\right)$ is just the set of all vectors $|\psi\rangle$ for which this series converges. This definition can be extended to an arbitrary Borel function $f(x)$, by approximating it uniformly with countably-valued functions and using (12.2). In particular, for the function $f(x) = x$ we obtain the operator

$$X = \int_{-\infty}^{\infty} xE(dx) \tag{12.3}$$

with the domain

$$\mathcal{D}(X) = \left\{ \psi : \int_{-\infty}^{\infty} |x|^2 \mu_\psi(dx) < \infty \right\},$$

for which

$$\langle \psi | X | \psi \rangle = \int_{-\infty}^{\infty} x \mu_\psi(dx), \quad \|X\psi\|^2 = \int_{-\infty}^{\infty} |x|^2 \mu_\psi(dx), \quad \psi \in \mathcal{D}(X) \tag{12.4}$$

The operators obtained in this way are self-adjoint in the following sense. For any densely defined operator X there is a unique adjoint X^* satisfying

$$\langle X^* \varphi \mid \psi \rangle = \langle \varphi \mid X\psi \rangle, \quad \psi \in \mathcal{D}(X), \varphi \in \mathcal{D}\left(X^*\right), \tag{12.5}$$

where $\mathcal{D}\left(X^*\right)$ is the (dense) subspace of all vectors φ such that the right-hand side is a bounded linear functional of ψ. The operator X is called Hermitian (symmetric) if

$$\langle X\varphi \mid \psi \rangle = \langle \varphi \mid X\psi \rangle, \tag{12.6}$$

for all $\varphi, \psi \in \mathcal{D}(X)$ and self-adjoint if $X = X^*$ in the sense that $\mathcal{D}\left(X^*\right) = \mathcal{D}(X)$ and (12.6) holds. Often one has to deal with essentially self-adjoint operators defined on some nonmaximal domain, which however extend uniquely to self-adjoint operators.

The spectral theorem (see, e. g., [193], Section VIII.3) says that for any self-adjoint operator X there exists a unique spectral measure E on $\mathbb{R}$ for which the relations (12.3), (12.4) hold. Thus, self-adjoint operators are those which have the spectral decomposition (12.3) over the real line. Such operators are naturally associated with (sharp) real observables in quantum mechanics. Then the measure μ_ψ gives the probability distribution of the observable X in the pure state $|\psi\rangle\langle\psi|$, and (12.4) gives the first and the second moments of this distribution.

In a certain sense which we will not comment here the relation $X_f = f(X)$ holds. By taking $f(x) = \exp(itx)$ in (12.1) we obtain the operators

$$V_t = \int_{-\infty}^{\infty} \exp(itx) E(dx) = \exp itX$$

Then the family $\{V_t; t \in \mathbb{R}\}$ is a strongly continuous group of unitary operators with the infinitesimal generator X, i.e.,

$$\lim_{t \to 0} (it)^{-1} \left(V_t - I\right) |\psi\rangle = X|\psi\rangle, \quad \psi \in \mathcal{D}(X) \tag{12.7}$$

Conversely, any strongly continuous group of unitary operators $\{V_t; t \in \mathbb{R}\}$ has the form $V_t = \exp itX$, where X is a uniquely defined self-adjoint operator. These statements are the content of Stone's theorem.

Exercise 12.1 1. Let $\mathcal{H} = L^2(\mathbb{R})$ be the Hilbert space of square integrable functions $\psi(\xi)$, $\xi \in \mathbb{R}$, and let $E = \{E(B); B \in \mathcal{B}(\mathbb{R})\}$ be defined by the expression

$$(E(B)\psi)(\xi) = 1_B(\xi)\psi(\xi), \quad \psi \in \mathcal{H}.$$

Prove that E is the spectral measure of the operator q of multiplication by ξ while V_t is the operator of multiplication by $\exp it\xi$, and in general X_f is the operator of multiplication by $f(\xi)$.

2. Consider the unitary operator in $\mathcal{H}$ defined by the Fourier transform

$$(\tilde{F}\psi)(\lambda) = \frac{1}{\sqrt{2\pi}} \int \exp(-i\lambda\xi)\psi(\xi) d\xi$$

Then $\tilde{E}(B) = \tilde{F}^* E(B)\tilde{F}$ is a spectral measure on $\mathbb{R}$, corresponding to the self-adjoint operator $p \equiv \tilde{q} = \frac{1}{i}\frac{d}{d\xi}$, which generates the group of unitary operators

$$(U_t\psi)(\xi) = \psi(\xi + t)$$

Self-adjoint operators $X_j, j = 1, \ldots, s$, commute if their spectral measures commute. The following is a multidimensional generalization of Stone's theorem.

Theorem 12.2. Let $V_x, x = [x_1, \ldots, x_s] \in \mathbb{R}^s$, be a strongly continuous group of unitary operators in a separable Hilbert space $\mathcal{H}$. Then there exists a family $X_j, j = 1, \ldots, s$, of commuting self-adjoint operators in $\mathcal{H}$ such that

$$V_x = \exp\left(i\sum_{j=1}^{s} x_j X_j\right). \tag{12.8}$$

Conversely, for any family $X_j, j = 1, \ldots, s$, of commuting self-adjoint operators in $\mathcal{H}$ the relation (12.8) defines strongly continuous unitary groups in $\mathcal{H}$.

10.12.3 12.1.2 Operators Associated with the Heisenberg Commutation Relation

In the Hilbert space $\mathcal{H} = L^2(\mathbb{R})$ we consider the operators

$$(q\psi)(\xi) = \xi\psi(\xi), \quad (p\psi)(\xi) = \frac{\hbar}{i}\frac{d}{d\xi}\psi(\xi),$$

defined on a common dense domain $\mathcal{D} \subseteq \mathcal{H}$. For example, $\mathcal{D}$ can be the subspace $\mathcal{S}(\mathbb{R})$ of infinitely differentiable rapidly decreasing functions, with all the derivatives tending to zero quicker than any degree of $|\xi|$ when $|\xi| \to \infty$. These operators are essentially self-adjoint, and hence they represent (sharp) real observables (see Section 12.1.1). Here $\hbar$ is a positive constant equal to Planck's constant in physical applications where it relates different systems of units (later we will choose the system in which $\hbar = 1$).

On this domain, q and p satisfy the Heisenberg commutation relation

$$[q, p] = i\hbar I. \tag{12.9}$$

For a unit vector ψ from the common domain of q, p consider a pure state $|\psi\rangle\langle\psi|$ and introduce the notation

$$x = \langle\psi|q|\psi\rangle, \quad y = \langle\psi|p|\psi\rangle,$$
$$\mathrm{D}_\psi(q) = \|(q - x)\psi\|^2, \quad \mathrm{D}_\psi(p) = \|(p - y)\psi\|^2$$

for the mean values and the variances of observables q, p. Then for any real ω

$$\begin{aligned}\omega^2\mathrm{D}_\psi(q) - \omega\hbar + \mathrm{D}_\psi(p) &= \omega^2\mathrm{D}_\psi(q) + i\omega\langle\psi|[q, p]|\psi\rangle + \mathrm{D}_\psi(p)\\ &= \|[\omega(q - x) + i(p - y)]\psi\|^2 \geq 0\end{aligned}$$

whence

$$\mathrm{D}_\psi(q)\mathrm{D}_\psi(p) \geq \frac{\hbar^2}{4}, \tag{12.10}$$

with equality attained if and only if there exists a positive ω such that

$$[\omega(q - x) + i(p - y)]\psi = 0.$$

This amounts to the differential equation

$$\left[\omega(\xi - x) + \left(\hbar\frac{d}{d\xi} - iy\right)\right]\psi(\xi) = 0, \tag{12.11}$$

the normalized solution of which, up to a constant factor of modulus one, is

$$\psi(\xi) = \sqrt[4]{\frac{\omega}{\pi\hbar}}\exp\left[\frac{iy}{\hbar}\left(\xi - \frac{x}{2}\right) - \frac{\omega(\xi - x)^2}{2\hbar}\right]. \tag{12.12}$$

Inequality (12.10) is the Heisenberg uncertainty relation and (12.12) are the minimal uncertainty state vectors with $\mathrm{D}_\psi(q) = \frac{\hbar}{2\omega}, \mathrm{D}_\psi(p) = \frac{\omega\hbar}{2}$.

By introducing the complex combinations

$$a = \frac{1}{\sqrt{2\hbar\omega}}(\omega q + ip), \quad \zeta = \frac{1}{\sqrt{2\hbar\omega}}(\omega x + iy)$$

and denoting the corresponding state vector (12.12) by $|\zeta\rangle$, we can rewrite the defining equation (12.11) as

$$a|\zeta\rangle = \zeta|\zeta\rangle, \quad \zeta \in \mathbb{C}. \tag{12.13}$$

In particular,

$$a|0\rangle = 0, \tag{12.14}$$

where $|0\rangle$ is the vector described by the function

$$\psi(\xi) = \sqrt[4]{\frac{\omega}{\pi\hbar}}\exp\left[-\frac{\omega\xi^2}{2\hbar}\right].$$

Operator $a = \frac{1}{\sqrt{2\hbar\omega}}(\omega q + ip)$ has the adjoint $a^\dagger = \frac{1}{\sqrt{2\hbar\omega}}(\omega q - ip)$. The commutation relation (12.9) can be rewritten as

$$\left[a, a^\dagger\right] = I. \tag{12.15}$$

Consider the operator

$$\mathcal{N} = a^\dagger a = aa^\dagger - I, \tag{12.16}$$

which is essentially self-adjoint. By (12.14) it satisfies

$$\mathcal{N}|0\rangle = 0.$$

Exercise 12.3 Applying successively the relation (12.16), show that the vectors

$$|n\rangle = \frac{\left(a^\dagger\right)^n}{\sqrt{n!}}|0\rangle \tag{12.17}$$

form an orthonormal system of eigenvectors of the operator $\mathcal{N}$, i. e.,

$$\mathcal{N}|n\rangle = n|n\rangle, \quad n = 0, 1, \ldots$$

The corresponding functions in $L^2(\mathbb{R})$ up to normalizing factors are

$$\left[\omega\xi - \hbar\frac{d}{d\xi}\right]^n \exp\left[-\frac{\omega\xi^2}{2\hbar}\right] \simeq H_n\left(\sqrt{\frac{\omega}{\hbar}}\xi\right)\exp\left[-\frac{\omega\xi^2}{2\hbar}\right],$$

where $H_n(\cdot), n = 0, 1, \ldots$, are the Hermite polynomials which form a complete orthogonal system in $L^2(\mathbb{R})$. Hence $\{|n\rangle; n = 0, 1, \ldots\}$ is an orthonormal basis in $\mathcal{H}$,

$$\sum_{n=0}^{\infty} |n\rangle\langle n| = I$$

and $\mathcal{N}$ has the spectral decomposition

$$\mathcal{N} = \sum_{n=0}^{\infty} n|n\rangle\langle n|. \tag{12.18}$$

Exercise 12.4 Operator $\mathcal{N}$ is self-adjoint of the type $\mathfrak{F}$ (Definition 11.3) with the domain

$$\mathcal{D}(\mathcal{N}) = \left\{ \psi : \sum_{n=0}^{\infty} n^2 |\langle n \mid \psi\rangle|^2 < \infty \right\}$$

and (12.18) holds in the sense of strong convergence on $\mathcal{D}(\mathcal{N})$.
Further, the relations

$$a|n\rangle = \sqrt{n}|n-1\rangle, \quad a^\dagger|n\rangle = \sqrt{n+1}|n+1\rangle$$

hold. By introducing the group of unitary operators $\left\{e^{i\mathcal{N}\omega t}; t \in \mathbb{R}\right\}$, one has

$$e^{i\mathcal{N}\omega t} a e^{-i\mathcal{N}\omega t} = a e^{-i\omega t}, \quad e^{i\mathcal{N}\omega t} a^\dagger e^{-i\mathcal{N}\omega t} = a^\dagger e^{i\omega t}. \tag{12.19}$$

Coming back to the operators q, p, one sees that

$$\hbar\omega \left(a^\dagger a + \frac{I}{2} \right) = \frac{1}{2} \left(\omega^2 q^2 + p^2 \right) \equiv \hbar H \tag{12.20}$$

is the energy operator for the quantum harmonic oscillator with frequency ω. Then $\mathcal{N} = a^\dagger a$ is the number (of quanta) operator, $|n\rangle$ are the number state vectors, $|0\rangle$ is the vacuum state vector, and a (resp. $a^\dagger$) is the annihilation (resp. creation) operator. In quantum optics the operators $a, a^\dagger$ describe a mode of electromagnetic field corresponding to a definite frequency (and a definite polarization).

10.12.4 12.1.3 Classical Signal Plus Quantum Noise

The states $|\zeta\rangle\langle\zeta|, \zeta \in \mathbb{C}$, are called coherent. From (12.17), (12.13) we obtain

$$\langle n \mid \zeta\rangle = \frac{1}{\sqrt{n!}} \langle 0 \mid a^n \zeta\rangle = \frac{\zeta^n}{\sqrt{n!}} \langle 0 \mid \zeta\rangle = \frac{\zeta^n}{\sqrt{n!}} \exp\left(-\frac{|\zeta|^2}{2} \right),$$

where we also used the formula

$$\langle \zeta_1 \mid \zeta_2\rangle = \exp\left[-\frac{1}{2} \left(|\zeta_1|^2 + |\zeta_2|^2 - 2\bar{\zeta}_1 \zeta_2 \right) \right]. \tag{12.21}$$

Exercise 12.5 Prove (12.21) by using the real parametrization (12.12) of the vectors $|\zeta\rangle$.
Exercise 12.6 The system of vectors $\{|\zeta\rangle; \zeta \in \mathbb{C}\}$ is overcomplete in the sense

$$\frac{1}{\pi} \int |\zeta\rangle\langle\zeta| d^2\zeta = I$$

where $d^2\zeta = \frac{1}{2\hbar} dxdy$. Hint: the matrix elements of the integral in the basis $\{|n\rangle\}$ have the form

$$\frac{1}{\pi}\int \frac{\zeta^n}{\sqrt{n!}}\frac{\bar{\zeta}^m}{\sqrt{m!}}\exp\left(-|\zeta|^2\right)d^2\zeta = \delta_{nm}.$$

Let $p(\zeta)$ be a probability density on $\mathbb{C}$. Then

$$S = \int |\zeta\rangle\langle\zeta| p(\zeta) d^2\zeta \tag{12.22}$$

is a density operator of a state called (quasi-)classical in quantum optics. In particular, taking the complex Gaussian density with zero mean and the variance $N > 0$ we obtain the density operator

$$S_0 = \frac{1}{\pi N}\int |\zeta\rangle\langle\zeta| \exp\left(-\frac{|\zeta|^2}{N}\right) d^2\zeta \tag{12.23}$$

with the matrix elements

$$\langle n|S_0|m\rangle = \frac{1}{\pi N}\int \frac{\zeta^n}{\sqrt{n!}}\frac{\bar{\zeta}^m}{\sqrt{m!}}\exp\left(-\frac{(N+1)|\zeta|^2}{N}\right) d^2\zeta = \delta_{nm}\frac{1}{N+1}\left(\frac{N}{N+1}\right)^n.$$

Therefore the operator S_0 has the spectral decomposition

$$S_0 = \frac{1}{N+1}\sum_{n=0}^{\infty}\left(\frac{N}{N+1}\right)^n |n\rangle\langle n|. \tag{12.24}$$

This relation makes sense also for $N = 0$ when $S_0 = |0\rangle\langle 0|$ is defined by the Gaussian distribution degenerate at the point $\zeta = 0$.

Taking into account the spectral decomposition (12.18) and the relation (12.20), this can be written as

$$S_0 = \frac{\exp[-\theta H]}{\operatorname{Tr}\exp[-\theta H]}, \tag{12.25}$$

which is the Gibbs equilibrium (thermal) state of the quantum harmonic oscillator at the inverse temperature $\theta/\hbar = \frac{1}{\hbar\omega}\ln\frac{N+1}{N}$. The parameter $N = \operatorname{Tr} S_0 a^\dagger a$ is interpreted as the mean number of the oscillator energy quanta. The von Neumann entropy of the state (12.24)

$$H(S_0) = \frac{1}{N+1}\sum_{n=0}^{\infty}\left(\frac{N}{N+1}\right)^n [(n+1)\log(N+1) - n\log N] = g(N), \tag{12.26}$$

where we introduced the Gordon function

$$\begin{aligned} &g(x) = (x+1)\log(x+1) - x\log x, \quad x > 0, \\ &g(0) = 0. \end{aligned} \tag{12.27}$$

Another important density operator is obtained from the shifted probability density

$$S_\mu = \frac{1}{\pi N}\int |\zeta\rangle\langle\zeta| \exp\left(-\frac{|\zeta-\mu|^2}{N}\right) d^2\zeta, \tag{12.28}$$

where $\mu = \frac{1}{\sqrt{2\hbar\omega}}(\omega m_q + i m_p)$. Introducing the unitary operators

$$D(\zeta)\psi(\xi) = \exp\left[\frac{iy}{\hbar}\left(\xi - \frac{x}{2}\right)\right]\psi(\xi - x) \tag{12.29}$$

we see that

$$|\zeta\rangle = D(\zeta)|0\rangle$$
$$D\left(\zeta_2\right)|\zeta_1\rangle = \exp\left(i\,\mathrm{Im}\,\bar{\zeta}_1\zeta_2\right)|\zeta_1+\zeta_2\rangle$$

that is, the action of this operator is to make a displacement in mean values of q, p. Physically such a displacement is realized by action of an external source, such as an idealized laser producing coherent state $|\zeta\rangle\langle\zeta|$ from the vacuum state $|0\rangle\langle 0|$. The quasi-classical state (12.22) is a chaotic mixture of coherent states, while

$$S_\mu = D(\mu)S_0D(\mu)^* \tag{12.30}$$

represents transformation of the equilibrium state under the action of an external source characterized by complex amplitude μ. Note that the state S_μ is pure if and only if $N = 0$, in which case it coincides with the coherent state $|\mu\rangle\langle\mu|$. In information theoretic applications μ is the classical signal to be transmitted via the noisy quantum mode q, p. The state S_μ is thus a model for a classical signal plus quantum Gaussian noise (see the next section).

Exercise 12.7 Prove that the displacement operators satisfy the commutation relation

$$D\left(\zeta_2\right)D\left(\zeta_1\right) = \exp\left(i\,\mathrm{Im}\,\bar{\zeta}_1\zeta_2\right)D\left(\zeta_1+\zeta_2\right), \tag{12.31}$$

which implies

$$D(\mu)^*D(\zeta)D(\mu) = \exp(2i\,\mathrm{Im}\,\bar{\mu}\zeta)D(\zeta). \tag{12.32}$$

In what follows we need the noncommutative analog of the characteristic function for the state S_μ, i.e.,

$$\mathrm{Tr}\,S_\mu D(\zeta) = \exp\left[2i\,\mathrm{Im}\,\bar{\mu}\zeta - \left(N+\frac{1}{2}\right)|\zeta|^2\right]. \tag{12.33}$$

Proof of formula (12.33). By (12.30), (12.32) we have

$$\mathrm{Tr}\,S_\mu D(\zeta) = \exp\Big(2i\widetilde{J}\widetilde{\mu}\zeta\Big)\,\mathrm{Tr}\,S_0D(\zeta)$$

and it is sufficient to prove (12.33) for $\mu = 0$. Then

$$\begin{aligned}\mathrm{Tr}\,S_0D(\zeta) &= \int\langle\zeta_1|\,D(\zeta)\,|\zeta_1\rangle\,\frac{1}{\pi N}\exp\left(-\frac{|\zeta_1|^2}{N}\right)d^2\zeta_1 \\ &= \int\langle 0|D\left(\zeta_1\right)^*D(\zeta)D\left(\zeta_1\right)|0\rangle\frac{1}{\pi N}\exp\left(-\frac{|\zeta_1|^2}{N}\right)d^2\zeta_1 \\ &= \int\exp\left(2i\,\mathrm{Im}\,\bar{\zeta}_1\zeta\right)\langle 0|D(\zeta)|0\rangle\frac{1}{\pi N}\exp\left(-\frac{|\zeta_1|^2}{N}\right)d^2\zeta_1\end{aligned} \tag{12.34}$$

By using (12.21) we obtain

$$\langle 0|D(\zeta)|0\rangle = \langle 0\mid\zeta\rangle = \exp\left(-\frac{1}{2}|\zeta|^2\right).$$

Substituting this expression into (12.34) and using the expression for the characteristic function of Gaussian probability distribution, we obtain

$$\operatorname{Tr} S_0 D(\zeta) = \exp\left(-\left(N+\frac{1}{2}\right)|\zeta|^2\right).$$

□

10.12.5 12.1.4 The Classical-Quantum Gaussian Channel

The mapping $\mu \to S_\mu$ can be considered as a classical-quantum (c-q) channel in the sense of Section 11.4 realizing transmission of the classical signal $\mu \in \mathbb{C}$ with the additive quantum Gaussian noise of the power N. For the first two moments we have

$$\operatorname{Tr}_\mu a = \mu, \quad \operatorname{Tr}_\mu a^\dagger a = N + |\mu|^2 \tag{12.35}$$

To compute its classical capacity we can use the general approach of Section 11.4.

Assuming that the words $w = (\mu_1, \ldots, \mu_n)$ are transmitted by independent uses of this channel (memoryless channel), we impose the additive energy constraint on the signal μ of the type (11.16), i. e.,

$$|\mu_1|^2 + \cdots + |\mu_n|^2 \leq nE \tag{12.36}$$

which corresponds to the constraint function $f(\mu) = |\mu|^2$. Then the conditions of Theorem 11.15 are fulfilled with the choice $F = a^\dagger a \equiv \mathcal{N}$, and the classical capacity of the channel $\mu \to S_\mu$ with the energy input constraint (12.36) is equal to

$$C = \max_{\pi \in \mathcal{P}_E} \left[H\left(\bar{S}_\pi\right) - \int H\left(S_\mu\right) \pi\left(d^2\mu\right) \right] \tag{12.37}$$

where $\mathcal{P}_E$ is the set of the input distributions $\pi\left(d^2\mu\right)$ satisfying

$$\int |\mu|^2 \pi\left(d^2\mu\right) \leq E \tag{12.38}$$

and

$$\bar{S}_\pi = \int S_\mu \pi\left(d^2\mu\right)$$

is the average state.

Note that the states S_μ are unitarily equivalent by (12.30) and hence have the same entropy $H\left(S_\mu\right) = H\left(S_0\right) = g(N)$; see (12.26). Therefore for any input distribution $\pi\left(d^2\mu\right)$ the χ-quantity (11.24) is equal to

$$\chi(\pi) = H\left(\bar{S}_\pi\right) - H\left(S_0\right)$$

and the problem reduces to maximization of the entropy $H\left(\bar{S}_\pi\right)$ under the constraint (12.38). Due to (12.35), relation (12.38) implies

$$\operatorname{Tr} \bar{S}_\pi a^\dagger a \leq N + E \tag{12.39}$$

This is a restriction onto second moments of the state $\bar{S}_\pi$; according to the maximal entropy principle (see Lemma 12.26), the maximal value of the entropy

$$H\left(\bar{S}_\pi\right) = g(N+E) \tag{12.40}$$

is attained by the Gaussian density operator

$$\bar{S}_\pi = \frac{1}{N+E+1} \sum_{n=0}^{\infty} \left(\frac{N+E}{N+E+1} \right)^n |n\rangle\langle n|, \tag{12.41}$$

which turns (12.39) into equality. It corresponds to the optimal distribution

$$\pi\left(d^2\mu\right) = \frac{1}{\pi E} \exp\left(-\frac{|\mu|^2}{E} \right) d^2\mu \tag{12.42}$$

Finally, the capacity of the memoryless c-q Gaussian channel is given by the expression

$$\begin{aligned} C = C_\chi &= g(N+E) - g(N) \\ &= \log\left(1 + \frac{E}{N+1}\right) + (N+E)\log\left(1 + \frac{1}{N+E}\right) - N\log\left(1 + \frac{1}{N}\right) \end{aligned} \tag{12.43}$$

which behaves as $\log\left(1+\frac{E}{N+1}\right)$ asymptotically in the classical limit $N \to \infty, E/N \to \text{const}$. Thus the relation (12.43) can be regarded as quantum generalization of Shannon's formula (4.51) with Gaussian white noise of power N. The factor $1/2$ is absent in (12.43) because one oscillator mode amounts to the two independent identically distributed real amplitudes m_q, m_p.

In what follows we will develop a general theory of quantum Gaussian channels and their capacities.

10.12.6 12.2 Canonical Commutation Relations

10.12.7 12.2.1 Weyl-Segal Canonical Commutation Relation

In quantum mechanics the CCRs arise in quantization of a mechanical system with finite number of degrees of freedom or a classical field represented as an infinite collection of oscillators. In quantum optics one usually deals only with a finite number of relevant oscillator frequencies, thus again reducing to the case of mechanical system with a finite number s of degrees of freedom.

Consider the Hilbert space $\mathcal{H} = L^2\left(\mathbb{R}^S\right)$ of complex square integrable functions of the real variables $\xi_j, j = 1, \ldots, s$, where $\mathbb{R}^s$ is the coordinate space of the underlying classical system. In the space $\mathcal{H}$ we consider the two groups of unitary operators (cf. Exercise 12.1)

$$V_x\psi(\xi) = \exp\left(i\xi^\top x\right)\psi(\xi), \quad U_y\psi(\xi) = \psi(\xi+y) \tag{12.44}$$

where $\xi, x, y \in \mathbb{R}^s$ are understood as column vectors and $^\top$ denotes transposition. These groups satisfy the Weyl CCR

$$U_y V_x = \exp\left(iy^\top x\right) V_x U_y \tag{12.45}$$

Note analogy with the discrete groups arising from (6.51). The groups U_y, V_x describe the change of a quantum state under the displacements in position (resp. momentum) space, and the Weyl CCR is an expression for the kinematics of a nonrelativistic quantum mechanical system, which in fact can be derived from the Galilei covariance; see, e.g., [122].

Computing the generators of the groups V_x, U_y by a multidimensional analog of formula (12.7), we obtain a particular instance of Stone's theorem, Theorem 12.2, i. e.,

$$V_x = \exp\left(i\sum_{j=1}^{s} x_j q_j \right), \quad U_y = \exp\left(i\sum_{j=1}^{s} y_j p_j \right),$$

where $x = [x_1 \dots x_s]^\top, y = [y_1 \dots y_s]^\top$, and the self-adjoint operators

$$q_j = \xi_j, \quad p_j = \frac{1}{i}\frac{\partial}{\partial \xi_j}$$

are the canonical observables satisfying the Heisenberg CCRs

$$[q_j, p_k] = i\delta_{jk} I, \quad [q_j, q_k] = 0, \quad [p_j, p_k] = 0 \tag{12.46}$$

Here and in what follows we choose the units in which $\hbar = 1$. The operators q_j, p_j are unbounded, hence the relations (12.46) should be considered only on a common dense domain, such as the subspace $\mathcal{S}(\mathbb{R})$ of infinitely differentiable rapidly decreasing functions.

To make use of apparent symmetry between x, y, we introduce the $2s$-vector $z = [x_1, y_1, \dots, x_s, y_s]^\top$ and the unitary Weyl operators

$$W(z) = \exp\left(\frac{i}{2} y^\top x\right) V_x U_y \tag{12.47}$$

From (12.47) and (12.45) it follows that the operators $W(z)$ satisfy the Weyl-Segal CCR

$$W(z)W(z') = \exp\left[-\frac{i}{2}\Delta(z, z')\right] W(z + z') \tag{12.48}$$

where

$$\Delta(z, z') = \sum_{j=1}^{s} \left(x_j y'_j - x'_j y_j\right) = z^\top \Delta z' \tag{12.49}$$

is the canonical symplectic form. Here we denote by the same letter Δ the matrix of the form

$$\Delta = \begin{bmatrix} 0 & 1 & & & \\ -1 & 0 & & & \\ & & \ddots & & \\ & & & 0 & 1 \\ & & & -1 & 0 \end{bmatrix} \equiv \operatorname{diag}\begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix} \tag{12.50}$$

From (12.48) and unitarity of the operators $W(z)$ it follows that $W(-z) = W(z)^*$. The relation (12.48) implies

$$W(z')^* W(z) W(z') = \exp\left[-i\Delta(z, z')\right] W(z). \tag{12.51}$$

Similarity between the commutation relations (12.31) and (12.48) is not accidental: in fact the operators $W(-\Delta^{-1} z)$ are the multimode generalization of the unitary displacement operators.

Exercise 12.8 Show that in the case of one degree of freedom

$$D(\mu) = W(m_p/\hbar, -m_q/\hbar), \tag{12.52}$$

where $\mu = \frac{1}{\sqrt{2\hbar\omega}}(\omega m_q + i m_p)$, so that

$$D(\mu)^* W(z) D(\mu) = \exp i\left(m_q x + m_p y\right) W(z). \tag{12.53}$$

Since $\Delta(z, z) \equiv 0$, the relation (12.48) implies that for any fixed z the one-parameter family $\{W(tz); t \in \mathbf{R}\}$ is a unitary group. The generator of this group computed according to formula (12.7) is the self-adjoint operator

$$Rz = \sum_{j=1}^{s} (x_j q_j + y_j p_j)$$

where

$$R = \left[\begin{array}{cccccc} q_1 & p_1 & \dots & q_s & p_s \end{array} \right]$$

is the row vector of the canonical observables. According to Stone's theorem,

$$W(z) = \exp iRz \tag{12.54}$$

Exercise 12.9 Use (12.51) to prove the relation

$$W\left(-\Delta^{-1}z\right)^* RW\left(-\Delta^{-1}z\right) = R + z^\top I \tag{12.55}$$

Exercise 12.10 Show that the Heisenberg commutation relations (12.46) can be written in the form

$$[Rz, Rz'] = i\Delta(z, z')\, I \tag{12.56}$$

10.12.8 12.2.2 The Symplectic Space

The space $Z = \mathbb{R}^{2s}$ equipped with the nondegenerate skew-symmetric form $\Delta(z, z')$ defined in (12.49) is a symplectic vector space. [1] It represents the phase space of the

classical system, the quantum version of which is described by the family of unitary operators $W(z)$ in the Hilbert space $\mathcal{H}$. This quantization is essentially unique: any irreducible family of unitary operators $W(z)$ in a Hilbert space satisfying the Weyl-Segal CCR is unitarily equivalent to the representation in $L^2(\mathbb{R}^s)$ described above, which is called the Schrödinger representation (Stone-von Neumann's uniqueness theorem; see, e. g., [193], [122]). In what follows $W(z), z \in Z$, can be any irreducible representation of the CCR.

A basis $\{e_j, h_j; j = 1, \dots, s\}$ in Z is called symplectic if

$$\Delta(e_j, h_k) = \delta_{jk}, \quad \Delta(e_j, e_k) = \Delta(h_j, h_k) = 0, \quad j, k = 1, \dots, s. \tag{12.57}$$

In any such basis the symplectic form $\Delta(z, z')$ has the standard expression (12.49). The transition matrix T from the initial symplectic basis in Z to the new symplectic basis is a matrix of symplectic transformation in (Z, Δ), which is characterized by the property

$$\Delta(Tz, Tz') = \Delta(z, z'), \quad z, z' \in Z.$$

Operator J in (Z, Δ) is called operator of complex structure if

$$J^2 = -I, \tag{12.58}$$

where I is the identity operator in Z, and it is Δ-positive in the sense that the bilinear form

$$j(z, z') = \Delta(z, Jz') \tag{12.59}$$

is an inner product in Z. Note that Δ-positivity is equivalent to the conditions

$$\Delta J = -J^\top \Delta, \quad \Delta J \geq 0. \tag{12.60}$$

[1] 1 Most of the content of this chapter can be adapted to the case of an abstract symplectic vector space equipped with an arbitrary nondegenerate skew-symmetric form.

Exercise 12.11 Operator / defines the structure of complex unitary space in Z (of dimensionality s) in which $iz = Jz$ and the inner product is

$$\frac{1}{2}\left[j\left(z,z'\right)+i\Delta\left(z,z'\right)\right]=\frac{1}{2}\left[\Delta\left(z,Jz'\right)+i\Delta\left(z,z'\right)\right]. \tag{12.61}$$

This structure will be studied in detail later in this Chapter.
In what follows we will consider various bilinear forms $\alpha,\ldots$ in the space $Z=\mathbb{R}^{2s}$, and the matrices of such forms will be denoted by the same letters, e. g., $\alpha\left(z,z'\right)=z^{\top}\alpha z'$, etc.

Lemma 12.12. Let $\alpha\left(z,z'\right)=z^{\top}\alpha z'$ be an inner product in the symplectic space (Z,Δ). Then there is a symplectic basis $\{e_j,h_j;j=1,\ldots,s\}$ in Z such that the form α is diagonal with the matrix

$$\tilde{\alpha}=\operatorname{diag}\left[\begin{array}{cc}\alpha_j & 0\\ 0 & \alpha_j\end{array}\right] \tag{12.62}$$

where $\alpha_j>0$.

Proof. Consider the operator $A=\Delta^{-1}\alpha$ satisfying

$$\alpha\left(z,z'\right)=\Delta\left(z,Az'\right)$$

The operator A is skew-symmetric in the Euclidean space (Z,α) : $A^{*}=-A$. According to a theorem from linear algebra, there is an orthogonal basis $\{e_j,h_j\}$ in (Z,α) and positive numbers $\{\alpha_j\}$ such that

$$Ae_j=\alpha_j h_j,\quad Ah_j=-\alpha_j e_j$$

Choosing the normalization $\alpha\left(e_j,e_j\right)=\alpha\left(h_j,h_j\right)=\alpha_j$ gives the symplectic basis in (Z,Δ) with the required properties.

For an arbitrary inner product α in Z there is at least one operator of complex structure J, commuting with the operator $A=\Delta^{-1}\alpha$, namely, the orthogonal operator J from the polar decomposition

$$A=|A|J=J|A| \tag{12.63}$$

in the Euclidean space (Z,α). Applying Lemma 12.12, we obtain that there is a symplectic basis $\{e_j,h_j;j=1,\ldots,s\}$ in which the form α is diagonal with the matrix (12.62) while J has the matrix

$$\tilde{J}=\operatorname{diag}\left[\begin{array}{cc}0 & -1\\ 1 & 0\end{array}\right], \tag{12.64}$$

so that

$$Je_j=h_j,\quad Jh_j=-e_j \tag{12.65}$$

Denoting by T the transition matrix from the initial symplectic basis in Z to the new symplectic basis, i. e., the matrix with the columns $\{e_j,h_j;j=1,\ldots,s\}$, we have

$$\Delta=T^{\top}\Delta T,\quad \tilde{\alpha}=T^{\top}\alpha T,\quad \tilde{J}=T^{-1}JT.$$

The canonical observables in the new basis are given by the relations

$$\tilde{q}_j=Re_j,\quad \tilde{p}_j=Rh_j,\quad j=1,\ldots,s, \tag{12.66}$$

so that $RT=\tilde{R}$, where $\tilde{R}=[\tilde{q}_1\tilde{p}_1\ldots\tilde{q}_s\tilde{p}_s]$.

10.12.9 12.2.3 Dynamics, Quadratic Operators, and Gauge Transformations

For any symplectic transformation T in Z there is a unitary operator U_T in $\mathcal{H}$ such that

$$U_T^* W(z) U_T = W(Tz) \tag{12.67}$$

This follows from the Stone-von Neumann uniqueness theorem because the operators $W(Tz), z \in Z$, again form an (irreducible) representation of the CCR (12.48) in $\mathcal{H}$. In view of relation (12.54) this is equivalently expressed in terms of canonical observables

$$U_T^* R U_T = RT \tag{12.68}$$

Let us consider one-parameter semigroup of symplectic transformations in Z

$$T_t = \mathrm{e}^{tD}, \quad t \in \mathbb{R}$$

describing linear dynamics in the classical phase space. We assume that the generator D is Δ-positive, i. e., $\Delta(z, Dz')$ is an inner product in Z. In matrix notations

$$\Delta D = -D^\top \Delta \geq 0 \tag{12.69}$$

Quantization of the linear dynamics T_t is given by the following theorem.
Theorem 12.13. Consider the operator $H = R\epsilon R^\top$ in $\mathcal{H}$ which is quadratic in the canonical variables R, where

$$\epsilon = -\frac{1}{2} D\Delta^{-1} \tag{12.70}$$

Then H is a positive self-adjoint operator in $\mathcal{H}$ generating the unitary group $\left\{\mathrm{e}^{itH}\right\}$ such that

$$W(T_t z) = \mathrm{e}^{itH} W(z) \mathrm{e}^{-itH} \tag{12.71}$$

Proof (sketch). In terms of generators of the Weyl unitaries, the relation (12.71) we wish to establish is equivalent to

$$R\mathrm{e}^{tD} = \mathrm{e}^{itR\epsilon R^\top} R \mathrm{e}^{-itR\epsilon R^\top} \tag{12.72}$$

with $D = -2\epsilon\Delta$.
Consider the bilinear form

$$\frac{1}{2}\Delta(z, Dz') = -z^\top \Delta\epsilon\Delta z'$$

which is an inner product by our assumption on the operator D. According to Lemma 12.12 there is a symplectic basis $\{e_j, h_j\}$ such that the matrix of this form is diagonal, i. e.,

$$-\Delta\tilde{\epsilon}\Delta = \mathrm{diag} \begin{bmatrix} \omega_j/2 & 0 \\ 0 & \omega_j/2 \end{bmatrix}$$

where $\omega_j > 0$, hence

$$\tilde{\epsilon} = \mathrm{diag} \begin{bmatrix} \omega_j/2 & 0 \\ 0 & \omega_j/2 \end{bmatrix}$$

By introducing the new canonical observables $\tilde{q}_j = Re_j, \tilde{p}_j = Rh_j, j = 1, \ldots, s$, we have

$$H = \sum_{j=1}^{s} \frac{\omega_j}{2} \left(\tilde{q}_j^2 + \tilde{p}_j^2 \right), \tag{12.73}$$

implying that H is a positive self-adjoint operator as a sum of operators of the type (12.20) referring to different modes. It is called the energy operator or Hamiltonian of the oscillator system. In terms of the creation-annihilation operators

$$\tilde{a}_j^\dagger = \frac{1}{\sqrt{2}} \left(\tilde{q}_j - i\tilde{p}_j \right), \quad \tilde{a}_j = \frac{1}{\sqrt{2}} \left(\tilde{q}_j + i\tilde{p}_j \right),$$

the energy operator is

$$H = \sum_{j=1}^{s} \omega_j \left(\tilde{a}_j^\dagger \tilde{a}_j + I/2 \right) \tag{12.74}$$

In the new basis $\{e_j, h_j\}$ the matrix of operator $D = -2\epsilon\Delta$ has the form

$$\tilde{D} = \operatorname{diag} \left[\begin{array}{cc} 0 & -\omega_j \\ \omega_j & 0 \end{array} \right] = \tilde{J} \left[\begin{array}{cc} \omega_j & 0 \\ 0 & \omega_j \end{array} \right]$$

where the last expression is just the polar decomposition of $\tilde{D}$, so that the complex structure $J = T\tilde{J}T^{-1}$ arises from the similar decomposition

$$D = J|D| = |D|J. \tag{12.75}$$

Consider formula (12.72), which we wish to establish in the new basis. Taking into account that the right action of J on R is equivalent to multiplication of the annihilation operators by $-i$, this formula reduces just to the equations of the type (12.19), i.e.,

$$\tilde{a}_j \mathrm{e}^{-i\omega_j t} = \mathrm{e}^{i\omega_j t \tilde{a}_j^\dagger \tilde{a}_j} \tilde{a}_j \mathrm{e}^{-i\omega_j t \tilde{a}_j^\dagger \tilde{a}_j}, \quad j = 1, \ldots, S \tag{12.76}$$

describing dynamics of quantum harmonic oscillators with frequencies ω_j.
The components of the quantum system described by the operators $\tilde{a}_j, \tilde{a}_j^\dagger$ or $\tilde{q}_j, \tilde{p}_j$, corresponding to the frequencies ω_j, are called normal modes and the approach based on the representation of the energy matrix ϵ in the diagonal form is just the normal mode decomposition.

With an operator of complex structure J we can associate the cyclic one-parameter group $\left\{ \mathrm{e}^{\varphi J}; \varphi \in [0, 2\pi] \right\}$ of symplectic transformations which we call the gauge group. According to the Theorem 12.13 above (with $D = J$), the gauge group in Z induces the unitary group of the gauge transformations $\{U_\varphi\}$ in $\mathcal{H}$ by the formula

$$W\left(\mathrm{e}^{\varphi J} z \right) = U_\varphi^* W(z) U_\varphi \tag{12.77}$$

where $U_\varphi = \mathrm{e}^{-i\varphi G}$, and $G = -\frac{1}{2} R J \Delta^{-1} R^\top$ is a positive self-adjoint operator in $\mathcal{H}$. In terms of generators, (12.77) reduces to the canonical transformation

$$R\mathrm{e}^{\varphi J} = \mathrm{e}^{i\varphi G} R \mathrm{e}^{-i\varphi G} \tag{12.78}$$

which is a particular case of (12.72).

Applying the previous argument to the case $D = J$ and using (12.58), (12.65), we obtain that there exists a symplectic basis $\{e_j, h_j; j = 1, \ldots, s\}$ such that $Je_j = h_j, Jh_j = -e_j$, in which

$$G = \sum_{j=1}^{s} \frac{1}{2} \left(\tilde{q}_j^2 + \tilde{p}_j^2 \right) = \mathcal{N} + \frac{s}{2} I \tag{12.79}$$

where

$$\mathcal{N} = \sum_{j=1}^{s} \tilde{a}_j^\dagger \tilde{a}_j$$

is the total number operator.
An operator X in $\mathcal{H}$ is called gauge invariant if

$$U_\varphi^* X U_\varphi = X$$

for all $\varphi \in [0, 2\pi]$. By using (12.78) and (12.60) we find that a quadratic operator $X = R\epsilon R^\top$, where ϵ is a symmetric positive matrix, is gauge invariant if

$$[J, \epsilon\Delta] = 0,$$

i. e., J is the operator of complex structure from the polar decomposition (12.75) of $D = -2\epsilon\Delta$. During the proof of Theorem 12.13 we established that such a complex structure exists for every energy matrix ϵ.

Exercise 12.14 Let $\omega_j, j = 1, \ldots, s$, be positive numbers, and let

$$H = \sum_{j=1}^{S} \frac{1}{2} \left(\omega_j^2 q_j^2 + p_j^2\right)$$

be the energy operator of ensemble of oscillators with the frequencies ω_j. Then $\tilde{q}_j = \sqrt{\omega_j} q_j, \tilde{p}_j = \sqrt{\omega_j}^{-1} p_j$, so that

$$\tilde{a}_j^\dagger = \frac{1}{\sqrt{2\omega_j}} \left(\omega_j q_j - i p_j\right), \quad \tilde{a}_j = \frac{1}{\sqrt{2\omega_j}} \left(\omega_j q_j + i p_j\right)$$

and

$$H = \sum_{j=1}^{S} \frac{\omega_j}{2} \left(\tilde{q}_j^2 + \tilde{p}_j^2\right) = \sum_{j=1}^{S} \omega_j \left(\tilde{a}_j^\dagger \tilde{a}_j + I/2\right).$$

The corresponding operator of complex structure is

$$J = \operatorname{diag} \begin{bmatrix} 0 & -\omega_j \\ \omega_j^{-1} & 0 \end{bmatrix},$$

while the gauge operator G in $\mathcal{H}$ is given by (12.79).

10.12.10 12.3 Gaussian States

10.12.11 12.3.1 Characteristic Function

The characteristic function of a quantum state S is defined as

$$\phi_S(z) = \operatorname{Tr} SW(z), \quad z \in Z.$$

This is a kind of noncommutative Fourier transform, uniquely defining the operator S. The corresponding inversion formula is

$$S = \frac{1}{(2\pi)^s} \int \phi_S(z) W(-z) d^{2s} z$$

where $d^{2s}z = dx_1 \dots dy_s$ is the element of symplectic volume in Z. Similar relations hold for arbitrary trace class operator S; see [122].

Positivity of the operator S implies (and is in fact equivalent to) the nonnegative definiteness of $n \times n$-matrices, i.e.,

$$\left[\phi_S\left(z_r - z_S\right) \exp\left(\frac{i}{2}\Delta\left(z_r, z_S\right)\right)\right]_{r,S=1,\dots,n} \geq 0. \tag{12.80}$$

for all $n = 1, 2, \dots$ and arbitrary collections $\{z_1, \dots, z_n\} \in Z$. To see the necessity of this condition, note that the matrix element is nothing but $\operatorname{Tr} W\left(z_s\right)^* SW\left(z_r\right)$ so that for arbitrary $c_1, \dots, c_n \in \mathbb{C}$

$$\sum_{r,S} c_r \bar{c}_S \phi_S\left(z_r - z_S\right) \exp\left(\frac{i}{2}\Delta\left(z_r, z_S\right)\right) = \operatorname{Tr} SAA^* \geq 0$$

where $A = \sum_r c_r W\left(z_r\right)$.

A density operator S has finite second moments if $\operatorname{Tr} S\left(q_j^2 + p_j^2\right) < \infty$ for all j, where the trace is defined as in (11.6). In this case one can define the mean vector $\operatorname{Tr} SR = m$ and the covariance matrix $\mathrm{B}_S(R) = \alpha$ (cf. Section 2.3.3 for the case of bounded observables). By CCR (12.56) the commutation matrix $\mathrm{C}_S(R) = -\Delta$, so that

$$\alpha + \frac{i}{2}\Delta = \operatorname{Tr}(R - m)^\top S(R - m) \tag{12.81}$$

This relation (and its transpose) implies the inequality

$$\alpha \geq \pm\frac{i}{2}\Delta \tag{12.82}$$

which is nothing but the uncertainty relation (2.20) for the canonical observables R. Below in Theorem 12.17 we show that the condition (12.82) is not only necessary but also sufficient for α to be the covariance matrix of a quantum state. We denote by $\Sigma(m, \alpha)$ the set of all states with the mean vector m and the covariance matrix α.

As in probability theory, the components of m, α (as well as higher moments) can be expressed via the derivatives of the characteristic function.

Exercise 12.15 Assuming existence of the corresponding moments, show that

$$\operatorname{Tr} S(Rz)^n = i^{-n} \frac{d^n}{dt^n} \phi(tz)\bigg|_{t=0}.$$

10.12.12 12.3.2 Definition and Properties of Gaussian States

The characteristic function (12.33) of the one-mode density operator (12.28), expressed in the real variables using (12.52), is

$$\operatorname{Tr} SW(z) = \exp\left[i\left(m_q x + m_p y\right) - \frac{\alpha}{2}\left(x^2 + y^2\right)\right] \tag{12.83}$$

where $\alpha = N + \frac{1}{2} \geq \frac{1}{2}$. We call such S elementary Gaussian state. Let us now elaborate the general definition of a multimode Gaussian state.

The state S is called Gaussian, if its characteristic function $\phi(z) = \operatorname{Tr} SW(z)$ has the form

$$\phi(z) = \exp\left(\mathrm{im}(z) - \frac{1}{2}\alpha(z, z)\right) \tag{12.84}$$

where $m(z) = mz$ is a linear form and $\alpha(z,z) = z^\top \alpha z$ is a bilinear form on $(\ Z, \Delta\ )$. Here m is a row $2s$-vector and α is a real symmetric $(\ 2s\ ) \times (2s)$-matrix.

Exercise 12.16 Considering the derivatives of (12.84) at $z = 0$, show that m is indeed the mean vector, and α is the covariance matrix determined from (12.81).

Usually $(\ m, \alpha\ )$ are called the parameters of the Gaussian state. In the case $m = 0$ we call the Gaussian state centered. If S_m is the Gaussian state with parameters $(\ m, \alpha\ )$, then

$$S_m = W\left(-\Delta^{-1} m^\top\right) S_0 W\left(-\Delta^{-1} m^\top\right)^* \tag{12.85}$$

as follows from (12.55). By this unitary equivalence many questions reduce to consideration of centered states.

Theorem 12.17. For relation (12.84) to define a quantum state, it is necessary and sufficient that the matrix α satisfies the condition (12.82). Under this condition formula (12.84) defines the unique Gaussian state in $\Sigma(m, \alpha)$.

Proof. It was already mentioned that the necessity follows from the relation (12.81). An alternative proof follows from the following lemma, which will be also needed in the sequel.

Lemma 12.18. Let α be an inner product and Δ a skew-symmetric form in Z, such that for all $n = 1, 2, \ldots$ and arbitrary collection $\{z_1, \ldots, z_n\} \subset Z$,

$$\left[\exp\left(\alpha\left(z_r, z_s\right) + \frac{i}{2}\Delta\left(z_r, z_s\right)\right)\right]_{r,s=1,\ldots n} \geq 0. \tag{12.86}$$

Then the matrices of forms α, Δ satisfy the condition (12.82).

Proof. Let $t > 0$. By writing the condition of nonnegative definiteness for the collection $\left\{0, \sqrt{t} z_1, \ldots, \sqrt{t} z_n\right\}$ with the variables $\{c_0, c_1, \ldots, c_n\} \in \mathbb{C}$ such that $c_0 = -\sum_{j=1}^n c_j$, we have

$$\sum_{r,S=1}^n \bar{c}_r c_S \left(\exp t\left[\alpha\left(z_r, z_S\right) + \frac{i}{2}\Delta\left(z_r, z_S\right)\right] - 1\right) \geq 0$$

Dividing by t and letting $t \to 0$ we obtain that the matrices with elements $\alpha\left(z_r, z_s\right) + \frac{i}{2}\Delta\left(z_r, z_S\right)$ are nonnegative definite for arbitrary collection $z_1, \ldots, z_n$, which is equivalent to the condition (12.82). This proves the lemma.

Substituting the Gaussian expression (12.84) into (12.80), one can see that

$$\phi\left(z_r - z_s\right) \exp\left[\frac{i}{2}\Delta\left(z_r, z_s\right)\right] = \phi\left(z_r\right) \overline{\phi\left(z_s\right)} \exp\left\{\alpha\left(z_r, z_s\right) + \frac{i}{2}\Delta\left(z_r, z_s\right)\right\}$$

thus the condition of Lemma 12.18 is fulfilled, implying inequality (12.82).

To prove sufficiency assume that the matrix α satisfies inequality (12.82). Lemma 12.12 then implies that there exists a symplectic transformation T such that

$$\tilde{\alpha} = T^\top \alpha T = \operatorname{diag}\begin{bmatrix} \alpha_j & 0 \\ 0 & \alpha_j \end{bmatrix} \tag{12.87}$$

where $\alpha_j > 0$, while inequality (12.82) is easily seen to be equivalent to

$$\alpha_j \geq \frac{1}{2}, \quad j = 1, \ldots, s \tag{12.88}$$

The relation (12.87) implies

$$\begin{aligned} \phi(Tz) &= \exp\left(i\tilde{m}z - \frac{1}{2} z^\top \tilde{\alpha} z\right) \\ &= \exp \sum_{j=1}^s \left[i\left(\tilde{m}_{jq} x_j + \tilde{m}_{jp} y_j\right) - \frac{1}{2}\alpha_j\left(x_j^2 + y_j^2\right)\right] \end{aligned}$$

where $\tilde{m} = mT$.
Denoting by $S^{(j)}$ the corresponding elementary one-mode Gaussian states (12.83) and putting

$$S = \bigotimes_{j=1}^{s} S^{(j)} \tag{12.89}$$

we obtain

$$\phi(Tz) = \operatorname{Tr} S \exp i\tilde{R}z = \operatorname{Tr} SW(Tz),$$

where $\tilde{R} = RT$ are the new canonical observables. It follows that the state S has the characteristic function $\phi(z)$. □

In quantum optics the representation of a Gaussian state in the form (12.89) is usually related to the normal mode decomposition.

Let J be an operator of complex structure in Z and $\{U_\varphi\}$ be the corresponding unitary group of gauge transformations in $\mathcal{H}$. A state S is gauge invariant if

$$S = U_\varphi S U_\varphi^* \tag{12.90}$$

for all φ, which by (12.77) is equivalent to the property $\phi(z) = \phi\left(\mathrm{e}^{\varphi J} z\right)$ of the characteristic function. From this it follows that the Gaussian density operator S is gauge invariant if $m(z) \equiv 0$ and $\alpha(z, z') = \alpha(Jz, Jz')$, which is equivalent to

$$m = 0, \quad J^\top \alpha + \alpha J = 0. \tag{12.91}$$

By using (12.60), the last equality can be written as

$$[J, A] = 0, \tag{12.92}$$

where $A = \Delta^{-1}\alpha$, which means that J is the complex structure from the polar decomposition (12.63), i. e., $J = T\tilde{J}T^{-1}$, where $\tilde{J}$ is defined by the relation (12.64).

Note that the elementary Gaussian state (12.83) is pure if and only if $N = 0$, i.e., $\alpha = 1/2$. Using the decomposition (12.89) this implies several equivalent conditions for purity of a general Gaussian state.

Exercise 12.19 Show that the Gaussian state S is pure if and only if one of the following equivalent conditions holds:
i. $\alpha_j = 1/2, j = 1, \ldots, s$;
ii. $|\det(2A)| = 1$;
iii. the operator $A = \Delta^{-1}\alpha$ satisfies

$$A^2 = -\frac{1}{4} l; \tag{12.93}$$

iv. $\alpha = \frac{1}{2}\Delta J$, where J is an operator of complex structure;
v. α is a minimal solution of inequality (12.82).

Hint: it is sufficient to check conditions ii-iv in the symplectic basis from Lemma 12.12.

Under these conditions the set $\Sigma(m, \alpha)$ consists of one pure Gaussian state.

Let S be a centered Gaussian state with the covariance matrix α, let J be an operator of complex structure from the polar decomposition (12.63), and let S_0 be the pure centered Gaussian state with the covariance matrix $\frac{1}{2}\Delta J$. Then both these states are gauge invariant under the unitary group $\{\exp(i\varphi G)\}$ corresponding to this complex structure.

Exercise 12.20 By using the normal mode decomposition (12.89) prove the following multi-mode generalization of formula (12.23):

$$S = \int W(z) S_0 W(z)^* P\left(d^{2s}z\right) \tag{12.94}$$

where P is the Gaussian probability distribution with the characteristic function

$$\int \mathrm{e}^{i\Delta(w,z)} P\left(d^{2s}z\right) = \exp\left[-w^\top\left(\alpha - \frac{1}{2}\Delta J\right)w\right]$$

This distribution is invariant under the complex structure J in Z.

The gauge invariant pure state S_0 plays the role of the vacuum state while $W\left(-\Delta^{-1}z\right) S_0 W\left(-\Delta^{-1}z\right)^*$ are the coherent states with respect to the complex structure J (usually one uses the complex parametrization, see below). Note that a state that is "squeezed" relative to a given complex structure can be always made "coherent" by using the complex structure associated with its covariance matrix. In physics the distinguished complex structure is one with which the oscillator Hamiltonian has the canonical form (12.73) and coherent/squeezed states are defined relative to that complex structure.

Let us come back to the coordinate picture of the symplectic space $Z = \mathbb{R}^{2s}$. Putting $z_j = \frac{1}{\sqrt{2}}\left(x_j + iy_j\right)$, we consider the complex linear space $\mathbf{Z} = \mathbb{C}^{\mathcal{S}}$ of s-dimensional complex column vectors $\mathbf{z} = \left[z_1, \ldots, z_s\right]^\top$. The symplectic form (12.49) is expressed as

$$\Delta\left(z, z'\right) = 2\,\mathrm{Im}\,\mathbf{z}^*\mathbf{z}'$$

where * denotes Hermitian conjugation of the vectors. The operator J acts as multiplication by i and the corresponding Hermitian inner product (12.61) in $\mathbf{Z}$ is just $\mathbf{z}^*\mathbf{z}'$. A symplectic basis $e_1, h_1, \ldots, e_s, h_s$ gives rise to the orthonormal basis $\sqrt{2}e_1, \ldots, \sqrt{2}e_s$ with respect to this inner product.

The canonical observables $R = \left[q_1, \ldots, q_s, p_1, \ldots, p_s\right]$ (note the rearrangement of the order of components) are replaced by the creation-annihilation operators $\mathbf{a}^\dagger = \left[a_1^\dagger, \ldots, a_s^\dagger\right], \mathbf{a} = \left[a_1, \ldots, a_s\right]^\top$, where

$$a_j^\dagger = \frac{1}{\sqrt{2}}\left(q_j - ip_j\right), \quad a_j = \frac{1}{\sqrt{2}}\left(q_j + ip_j\right)$$

satisfy the commutation relations

$$\left[a_j, a_k^\dagger\right] = \delta_{jk} I, \quad \left[a_j, a_k\right] = \left[a_j^\dagger, a_k^\dagger\right] = 0. \tag{12.95}$$

The complex parametrization of the Weyl operators is given by the displacement operators

$$D(\mathbf{z}) = W(-Jz), \quad \mathbf{z} \in \mathbf{Z}. \tag{12.96}$$

The relation (12.54) can be rewritten as $D(\mathbf{z}) = \exp\left(\mathbf{a}^\dagger\mathbf{z} - \mathbf{z}^*\mathbf{a}\right)$.
The linear operators in Z commuting with J are represented by complex $s \times s$-matrices. The gauge group acts in $\mathbf{Z}$ as multiplication by $e^{i\phi}$.

Consider the Gaussian state (12.84) with the correlation matrix

$$\alpha = \begin{bmatrix} \alpha_{qq} & \alpha_{qp} \\ \alpha_{pq} & \alpha_{pp} \end{bmatrix},$$

where $\alpha_{qq}, \alpha_{qp}, \alpha_{pp}$ are real $s \times s$-matrices satisfying

$$\alpha_{qq}^\top = \alpha_{qq} = \left[\mathrm{Tr}\, S\left(q_j \circ q_k\right)\right], \quad \alpha_{pp}^\top = \alpha_{pp} = \left[\mathrm{Tr}\, S\left(p_j \circ p_k\right)\right], \quad \alpha_{qp}^\top = \alpha_{pq} = \left[\mathrm{Tr}\, S\left(q_j \circ p_k\right)\right].$$

It is gauge invariant if its mean m is zero while the correlation matrix satisfies (12.91). With

$$J = \begin{bmatrix} 0 & -I_s \\ I_s & 0 \end{bmatrix}$$

this implies $\alpha_{qq} = \alpha_{pp}, \alpha_{qp} = -\alpha_{pq}$, hence (12.84) can be rewritten as

$$\phi(\mathbf{z}) = \operatorname{Tr} SD(\mathbf{z}) = \exp\left(-\mathbf{z}^* \boldsymbol{\alpha} \boldsymbol{z}\right), \tag{12.97}$$

where

$$\boldsymbol{\alpha} = \alpha_{qq} - i\alpha_{qp}.$$

Exercise 12.21 Show that the (nonvanishing identically) second moments of the gauge invariant state S satisfy the relation

$$\operatorname{Tr} \mathbf{a} S \mathbf{a}^\dagger = \left[\operatorname{Tr} a_j S a_k^\dagger\right] = \boldsymbol{\alpha} - \frac{1}{2}\mathbf{I}. \tag{12.98}$$

Note that

$$U^* \alpha U = \begin{bmatrix} \alpha_{qq} - i\alpha_{qp} & 0 \\ 0 & \alpha_{qq} + i\alpha_{qp} \end{bmatrix},$$

where

$$U = \frac{1}{\sqrt{2}} \begin{bmatrix} I_s & I_s \\ -iI_s & iI_s \end{bmatrix} \tag{12.99}$$

is a unitary $2s \times 2s$-matrix. It follows for real λ that

$$\det\left(\alpha - \lambda I_{2s}\right) = \left|\det\left(\alpha - \lambda I_s\right)\right|^2,$$

hence the Hermitian matrix $\boldsymbol{\alpha}$ has the eigenvalues α_j (see (12.88)), so that $\boldsymbol{\alpha} \geq \mathbf{I}/2$. The unique minimal solution of the last inequality is $\frac{1}{2}\mathbf{I}$, to which correspond the vacuum state S_0 and the family of coherent states $\{S_{\mathbf{z}}; \mathbf{z} \in \mathbf{Z}\}$, such that

$$S_{\mathbf{z}} = D(\mathbf{z}) S_0 D(\mathbf{z})^*$$

One has

$$\operatorname{Tr} S_{\mathbf{w}} D(\mathbf{z}) = \exp\left(2i \operatorname{Im} \mathbf{w}^* \mathbf{z} - \frac{1}{2}|\mathbf{z}|^2\right)$$

The relation (12.94) thus takes the form

$$S = \int S_{\mathbf{z}} P\left(d^{2s} z\right) \tag{12.100}$$

where P is the Gaussian probability distribution with the characteristic function

$$\int \mathrm{e}^{2i \operatorname{Im} \mathbf{w}^* \mathbf{z}} P\left(d^{2s} z\right) = \exp\left[-\mathbf{z}^* \left(\boldsymbol{\alpha} - \frac{1}{2}\mathbf{I}\right) \mathbf{z}\right]$$

10.12.13 12.3.3 The Density Operator of Gaussian State

The spectral decomposition of an arbitrary Gaussian state (12.89) can be obtained by tensor multiplication of the spectral decompositions of the one-mode states $S^{(j)}$ from the normal mode decomposition. We are going to prove the theorem which generalizes the relation (12.25) to arbitrary Gaussian states without a pure component.

Lemma 12.22. The Gaussian density operator S is nondegenerate if and only if

$$\det\left(\alpha+\frac{i}{2}\Delta\right)\neq 0.$$

Proof. The Gaussian density operator S is nondegenerate if and only if it has no pure component, i.e., $\alpha_j>\frac{1}{2}, j=1,\dots,s$. We will prove the lemma by establishing the identities

$$\det\left(\alpha+\frac{i}{2}\Delta\right)=\left[\det\left(-A^2-\frac{1}{4}I\right)\right]^{\frac{1}{2}}=\prod_{j=1}^{s}\left(\alpha_j^2-\frac{1}{4}\right), \tag{12.101}$$

where $A=\Delta^{-1}\alpha$. Choosing the symplectic basis as in Lemma 12.12, we have $A=T\left(\Delta^{-1}\tilde{\alpha}\right)T^{-1}$, where

$$\Delta^{-1}\tilde{\alpha}=\operatorname{diag}\begin{bmatrix}0 & -\alpha_j\\ \alpha_j & 0\end{bmatrix} \tag{12.102}$$

Hence the numbers $\pm i\alpha_j, j=1,\dots,s$, are the eigenvalues of the operator A. It follows that the symmetric operator $-A^2-\frac{1}{4}I$ in the Euclidean space (Z,α) is positive since its eigenvalues are $\alpha_j^2-1/4\geq 0$ (note that this operator is equal to 0 if and only if the state S is pure by (12.93)). Each of these eigenvalues appears twice, hence the second identity in (12.101) follows.

To prove the first identity note that

$$-\left(\Delta^{-1}\alpha\right)^2-\frac{1}{4}I=-\Delta^{-1}\left(\alpha+\frac{i}{2}\Delta\right)\Delta^{-1}\left(\alpha-\frac{i}{2}\Delta\right).$$

Taking into account that $\det\left(\pm\Delta^{-1}\right)=1$ and $\det\left(\alpha+\frac{i}{2}\Delta\right)=\det\left(\alpha-\frac{i}{2}\Delta\right)\geq 0$ we obtain the result.

Theorem 12.23. Let the matrix $\alpha+\frac{i}{2}\Delta$ be nondegenerate. Then the centered Gaussian density operator with covariance matrix α has the form

$$S_0=c\exp\left(-R\epsilon R^{\top}\right), \tag{12.103}$$

where

$$c=\left[\det\left(\alpha+\frac{i}{2}\Delta\right)\right]^{-\frac{1}{2}}=\left[\det\left(-4\sin^2\epsilon\Delta\right)\right]^{\frac{1}{4}} \tag{12.104}$$

and ϵ is found from the relation

$$2\Delta^{-1}\alpha=\cot\epsilon\Delta. \tag{12.105}$$

Proof. Rewriting the relation (12.25) (for $\omega=1$) in the form

$$\left(\mathrm{e}^{\theta/2}-\mathrm{e}^{-\theta/2}\right)\exp\left(-\frac{\theta}{2}\left(q^2+p^2\right)\right),$$

using the normal modes decomposition (12.87) diagonalizing α, and using (12.89) we have

$$S_0=c\exp\left(-\tilde{R}\tilde{\epsilon}\tilde{R}^{\top}\right),$$

where

$$c = \prod_{j=1}^{s} \left(\mathrm{e}^{\theta_j/2} - \mathrm{e}^{-\theta_j/2} \right), \quad \tilde{\epsilon} = \operatorname{diag} \begin{bmatrix} \theta_j/2 & 0 \\ 0 & \theta_j/2 \end{bmatrix},$$

and $\theta_j = \ln\left(\frac{\alpha_j+\frac{1}{2}}{\alpha_j-\frac{1}{2}}\right)$, so that

$$\mathrm{e}^{\theta_j/2} - \mathrm{e}^{-\theta_j/2} = \left(\alpha_j^2 - \frac{1}{4}\right)^{-\frac{1}{2}}. \tag{12.106}$$

Taking into account (12.101), the first of the expressions in (12.104) follows. Returning to the initial canonical observables R, we obtain (12.103) where $\epsilon = T\tilde{\epsilon}T^{\top}$.

Inverting formula (12.106) gives

$$\alpha_j = \frac{1}{2} \coth \frac{\theta_j}{2} \tag{12.107}$$

Further

$$\tilde{\epsilon}\Delta = \operatorname{diag} \begin{bmatrix} 0 & \theta_j/2 \\ -\theta_j/2 & 0 \end{bmatrix}.$$

Note that $\epsilon\Delta = T\tilde{\epsilon}\Delta T^{-1}$ and $\Delta^{-1}\alpha = T\Delta^{-1}\tilde{\alpha}T^{-1}$ are the matrices of operators, with $\Delta^{-1}\tilde{\alpha}$ given by the relation (12.102). The operators $-\tilde{\epsilon}\Delta$ and $\tilde{\Delta}^{-1}\tilde{\alpha}$ have the same eigenvectors with the eigenvalues $\pm i\theta_j/2$ and $\pm i\alpha_j$, therefore via the relation $\cot(i\lambda) = -i\coth\lambda$, (12.107) implies (12.105).

10.12.14 12.3.4 Entropy of a Gaussian State

To compute the von Neumann entropy of a general Gaussian state one can use the normal mode decomposition (12.89). By (12.85) the entropy is the same for all Gaussian states with arbitrary mean and covariance matrix α, reducing the problem to the case of centered state. For a single mode ($s = 1$), the density operator $S^{(j)}$ is unitarily equivalent to the state (12.24) with the entropy equal to $g(N)$; see (12.27). For a general Gaussian state we obtain by summing over normal modes

$$H(S) = \sum_{j=1}^{S} g\left(N_j\right) \tag{12.108}$$

where $N_j = \alpha_j - 1/2 \geq 0$. In particular, the entropy of the gauge invariant Gaussian state with characteristic function (12.97) is

$$H(S) = \operatorname{Spg}\left(\boldsymbol{\alpha} - \frac{1}{2}\mathbf{I}\right) \tag{12.109}$$

where Sp is used to denote the trace of a matrix as distinct from the trace Tr of operators in the underlying Hilbert space.

To write the relation (12.108) in the coordinate-free form, recall that the operator $A = \Delta^{-1}\alpha$ has the eigenvalues $\pm i\alpha_j$. Hence its matrix is diagonalizable (in the complex domain). For any diagonalizable matrix $M = U \operatorname{diag}(m_j) U^{-1}$, we put $\operatorname{abs}(M) = U \operatorname{diag}(|m_j|) U^{-1}$, similarly to other continuous functions on the complex plane. Then equation (12.108) can be written as

$$H(S) = \frac{1}{2} \operatorname{Spg}\left(\operatorname{abs}\left(\Delta^{-1}\alpha\right) - \frac{I}{2}\right) \tag{12.110}$$

An alternative expression for the entropy of a Gaussian state can be obtained from the representation (12.103). By definition, we have

$$H(S) = -\log c + \mathrm{Sp}\epsilon\alpha$$

which by (12.104) and (12.105) is equal to

$$\begin{aligned} &\frac{1}{4}\,\mathrm{Sp}\log\left[-\left(\Delta^{-1}\alpha\right)^2 - \frac{1}{4}I\right] + \mathrm{Sp}\left(\Delta^{-1}\alpha\right)\mathrm{arccot}\left(2\Delta^{-1}\alpha\right) \\ &\quad = -\frac{1}{4}\,\mathrm{Sp}\log\left(-\sin^2\epsilon\Delta\right) + \frac{1}{2}\,\mathrm{Sp}(\epsilon\Delta\cot\epsilon\Delta) \end{aligned} \tag{12.111}$$

Exercise 12.24 Use the relation

$$g\left(x-\frac{1}{2}\right) = \frac{1}{2}\log\left(x^2-\frac{1}{4}\right) + x\log\frac{x+\frac{1}{2}}{x-\frac{1}{2}}$$

to show that (12.110) and (12.111) are the same.

Example 12.25. In the case of a one-mode Gaussian density operator we have $\alpha = \begin{bmatrix} \alpha^{qq}\alpha^{qp} \\ \alpha^{qp}\alpha^{pp} \end{bmatrix}$ with $\alpha^{qq}\alpha^{pp} - (\alpha^{qp})^2 \geq \frac{1}{4}$ (this inequality is equivalent to the condition (12.82)). Then

$$-\left(\Delta^{-1}\alpha\right)^2 = \left[\alpha^{qq}\alpha^{pp} - (\alpha^{qp})^2\right]\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix},$$

hence

$$\left|\Delta^{-1}\alpha\right| = \sqrt{\alpha^{qq}\alpha^{pp} - (\alpha^{qp})^2}\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$$

and

$$H(S) = g\left(\sqrt{\alpha^{qq}\alpha^{pp} - (\alpha^{qp})^2} - \frac{1}{2}\right).$$

Geometrically, the quantity $\pi\sqrt{\alpha^{qq}\alpha^{pp} - (\alpha^{qp})^2}$ is equal to the area of the deviation ellipsoid

$$z^\top\alpha^{-1}z = 1, \quad z = [x,y]^\top$$

for the two-dimensional Gaussian distribution with the covariance matrix α.
Note that in accordance with (12.93) the Gaussian state is pure if and only if it has the minimal uncertainty $\alpha^{qq}\alpha^{pp} - (\alpha^{qp})^2 = \frac{1}{4}$. This comprises both coherent states for which

$$\alpha^{qq} = \alpha^{pp} = \frac{1}{2}, \quad \alpha^{qp} = 0$$

and squeezed states for which this condition is violated (as distinct from quantum optics we use here real rather than complex parametrization). The case of many modes can be treated by using the normal mode decomposition.

While pure Gaussian states are the minimal uncertainty states for the canonical observables, a general Gaussian state is characterized by the following property of maximal entropic uncertainty under fixed moments of the canonical observables.

Lemma 12.26. The Gaussian state has the largest entropy among all states with the given mean m and the correlation matrix α. Therefore, for any set of states defined by restrictions

on the first and second moments, the maximum of the entropy always can be sought among the Gaussian states.

Proof. Let $S \in \Sigma(m,\alpha)$ and let $\tilde{S}$ be the unique Gaussian state in $\Sigma(m,\alpha)$. Without loss of generality we may assume that $\tilde{S}$ is nondegenerate. The general case can be reduced to this by separating the pure component in the tensor product decomposition of $\tilde{S}$. Indeed by making the normal modes decomposition, we can assume that $Z = Z_1 \oplus Z_2$ with $\Delta = \Delta_1 \oplus \Delta_2, \alpha = \alpha_1 \oplus \alpha_2$ (see the next section for the direct sum decompositions), where α_1 corresponds to the unique, necessarily pure Gaussian state in Z_1, while α_2 corresponds to a nondegenerate density operator. We have

$$H(\tilde{S}) - H(S) = H(S;\tilde{S}) + \mathrm{Tr}(S-\tilde{S})\log\tilde{S},$$

where the last term is equal to zero, because for a nondegenerate Gaussian $\tilde{S}$ the operator $\log\tilde{S}$ is a second-order polynomial in canonical variables by (12.103), while the first and second moments of $S, \tilde{S}$ coincide. Thus $H(\tilde{S}) - H(S) = H(S;\tilde{S}) \geq 0$. □

A similar result is obtained for the conditional quantum entropy [66]. In its formulation and proof we use the description of composite bosonic systems introduced in the next section 12.3.5.

Lemma 12.27. The Gaussian state has the largest conditional entropy among all states of a composite bosonic system AB with a given mean m and a correlation matrix α.

Proof. Let $S_{AB} \in \Sigma(m_{AB},\alpha_{AB})$ and let $\tilde{S}_{AB}$ be the unique Gaussian state in $\Sigma(m_{AB},\alpha_{AB})$. Then $S_A \in \Sigma(m_A,\alpha_A)$ and $\tilde{S}_A$ is the Gaussian state in $\Sigma(m_A,\alpha_A)$. Again we may assume that $\tilde{S}_{AB}$ is nondegenerate. Denoting

$$H(A \mid B) = H(S_{AB}) - H(S_B), \quad H(\tilde{A} \mid \tilde{B}) = H\left(\tilde{S}_{AB}\right) - H\left(\tilde{S}_B\right),$$

we have

$$\begin{aligned} H(\tilde{A} \mid \tilde{B}) - H(A \mid B) =& H\left(S_{AB};\tilde{S}_{AB}\right) - H\left(S_A;\tilde{S}_A\right) \\ &+ \mathrm{Tr}\left(S_{AB}-\tilde{S}_{AB}\right)\log\tilde{S}_{AB} - \mathrm{Tr}\left(S_A-\tilde{S}_A\right)\log\tilde{S}_A \\ =& H\left(S_{AB};\tilde{S}_{AB}\right) - H\left(S_A;\tilde{S}_A\right) \end{aligned}$$

because $\log\tilde{S}_{AB}, \log\tilde{S}_A$ are the second-order polynomials in canonical variables by (12.103). By monotonicity of the relative entropy, $H\left(S_{AB};\tilde{S}_{AB}\right) - H\left(S_A;\tilde{S}_A\right) \geq 0$. □

10.12.15 12.3.5 Separability and Purification

Consider two bosonic systems described by CCRs with the symplectic spaces (Z_1,Δ_1), (Z_2,Δ_2). The symplectic space of the composite system is the direct sum $Z = Z_1 \oplus Z_2$, the elements of which are conveniently represented by the column vectors $z = [z_1, z_2]^\top$ while the symplectic matrix Δ_{12} is block diagonal, i.e.,

$$\Delta_{12} = \begin{bmatrix} \Delta_1 & 0 \\ 0 & \Delta_2 \end{bmatrix}.$$

The Weyl operators of the composite system are defined as $W_{12}(z_1,z_2) = W_1(z_1) \otimes W_2(z_2)$. Let S_{12} be a Gaussian state of the composite system with the mean m_{12} and the covariance matrix α_{12}. The restriction of the Gaussian state S_{12} to the first factor is determined by the expectations of the Weyl operators $W_1(z_1) \otimes I_2 = W_{12}(z_1,0)$, hence according to (12.84), it has the mean m_1 which is just the first component of $m_{12} = [m_1 m_2]$, and the covariance matrix α_1 which is the first diagonal block in the block matrix decomposition

$$\alpha_{12} = \begin{bmatrix} \alpha_1 & \beta \\ \beta^\top & \alpha_2 \end{bmatrix}. \tag{12.112}$$

The covariance matrix α_{12} of a state S_{12} of the composite system is block diagonal ($\beta = 0$) if and only if the state is a product $S_{12} = S_1 \otimes S_2$.

Proposition 12.28. [244] The Gaussian state is separable if and only if there exist real symmetric matrices $\check{\alpha}_j$ satisfying

$$\check{\alpha}_j \geq \pm\frac{i}{2}\Delta_j, \quad j = 1, 2, \tag{12.113}$$

such that

$$\alpha_{12} \geq \begin{bmatrix} \check{\alpha}_1 & 0 \\ 0 & \check{\alpha}_2 \end{bmatrix}. \tag{12.114}$$

Proof. By using formula (12.85) and the fact that the action of the displacement operators is "local" and has no effect on (non)separability, we can assume without loss of generality that S_{12} is centered. Let S_{12} be separable. Then it has a representation (11.43). Since S_{12} has finite second moments, this representation implies that the states $S_1(x), S_2(x)$ have finite second moments for π-almost all x, hence their mean vectors $m_j(x)$ and covariance matrices $\alpha_j(x) \geq \pm\frac{i}{2}\Delta_j, j = 1, 2$, are defined for π-almost all x. In
view of (12.81) the representation (11.43) implies that α_{12} has the block decomposition (12.112) with

$$\alpha_j = \int_{\mathcal{X}} \left[\alpha_j(x) + m_j(x)^\top m_j(x)\right] \pi(dx), \quad j = 1, 2$$
$$\beta = \int_{\mathcal{X}} m_1(x)^\top m_2(x) \pi(dx)$$

Denoting $\check{\alpha}_j = \int_{\mathcal{X}} \alpha_j(x)\pi(dx)$, we have (12.113) and

$$\alpha_{12} - \begin{bmatrix} \check{\alpha}_1 & 0 \\ 0 & \check{\alpha}_2 \end{bmatrix} = \begin{bmatrix} \alpha_1 - \check{\alpha}_1 & \beta \\ \beta^\top & \alpha_2 - \check{\alpha}_2 \end{bmatrix}$$
$$= \int_{\mathcal{X}} \begin{bmatrix} m_1(x)^\top m_1(x) & m_1(x)^\top m_2(x) \\ m_2(x)^\top m_1(x) & m_2(x)^\top m_2(x) \end{bmatrix} \pi(dx) \geq 0$$

Conversely, if (12.114) holds, then let

$$\gamma_{12} = \alpha_{12} - \begin{bmatrix} \check{\alpha}_1 & 0 \\ 0 & \check{\alpha}_2 \end{bmatrix} \geq 0$$

and define π to be the Gaussian probability distribution on $Z = Z_1 \oplus Z_2$ with the characteristic function

$$\int_Z \mathrm{e}^{-i\Delta(w,z)} \pi\left(d^{2s}w\right) = \exp\left(-\frac{1}{2} z^\top \gamma_{12} z\right)$$

Then the comparison of the quantum characteristic functions shows that

$$S_{12} = \int_Z W_1(z_1) S_1 W_1(z_1)^* \otimes W_2(z_2) S_2 W_2(z_2)^* \pi\left(d^{2s}z\right) \tag{12.115}$$

where S_j is the centered Gaussian state with the covariance matrix $\check{\alpha}_j$, hence S_{12} is separable.

This proof shows in fact that a separable Gaussian state can be represented as a Gaussian mixture of Gaussian states.

From (12.114) and (12.82) it follows that the covariance matrix of a separable state, in addition to the usual condition $\alpha_{12} \geq \pm\frac{i}{2}\Delta_{12}$, satisfies

$$\alpha_{12} \geq \pm\frac{i}{2}\begin{bmatrix} \Delta_1 & 0 \\ 0 & -\Delta_2 \end{bmatrix} \tag{12.116}$$

This condition expresses the property that the state S_{12} has positive partial transpose (PPT) with respect to the second system. In fact, changing sign of the symplectic form Δ_2 corresponds to taking the transpose of the Weyl operators $W_2(z_2)$, as it follows from the CCR (12.48). As shown in [244], the PPT condition is in general weaker than the separability condition (12.114), which means that there exist bound entangled Gaussian states.

When considering purification, it is also sufficient to restrict to centered Gaussian states. Purification of one-mode Gaussian states can be performed by using the spectral decomposition (12.24) and the general purification recipe of Theorem 3.11; then for many-mode states one can use the decomposition (12.89). This leads to rather lengthy computations [106]; therefore we will just give the final result and check that it satisfies all the necessary requirements.

Now let S_1 be a Gaussian state with the covariance matrix α_1 on the symplectic space Z_1 with the form $\Delta_1 = \Delta$. It appears convenient to take $Z_2 = \bar{Z}_1$ with $\Delta_2 = -\Delta$, so that

$$\Delta_{12} = \begin{bmatrix} \Delta & 0 \\ 0 & -\Delta \end{bmatrix}. \tag{12.117}$$

Theorem 12.29. Consider the symplectic space $Z = Z_1 \oplus \bar{Z}_1$ and the Gaussian state S_{12} with the covariance matrix

$$\alpha_{12} = \begin{bmatrix} \alpha_1 & \alpha_1^{1/2}B^{-1}\sqrt{-B^2 - I/4}\alpha_1^{1/2} \\ -\alpha_1^{1/2}B^{-1}\sqrt{-B^2 - I/4}\alpha_1^{1/2} & \alpha_1 \end{bmatrix}, \tag{12.118}$$

where $B = \alpha_1^{1/2}\Delta^{-1}\alpha_1^{1/2}$. Then S_{12} is a purification of S_1.

Proof. We have seen in the proof of Lemma 12.22 that the operator $A = \Delta^{-1}\alpha_1$ is skewsymmetric in the Euclidean space (Z, α); moreover, $-A^2 - I/4 \geq 0$ with equality if and only if the Gaussian state is pure. Consider the block operator

$$A_{12} = \begin{bmatrix} A & \sqrt{-A^2 - I/4} \\ \sqrt{-A^2 - I/4} & -A \end{bmatrix} \tag{12.119}$$

in $Z = Z_1 \oplus \bar{Z}_1$, where the square root is the operator square root in the space (Z, α). It is easy to check that $-A_{12}^2 - I_{12}/4 = 0$ and hence the form $\alpha_{12} = \Delta_{12}A_{12}$ corresponds to the covariance matrix of a pure Gaussian state. Moreover, its restriction to Z_1 coincides with α_1. Formula (12.118) then gives the matrix expression for α_{12}. Note that the matrix (12.118) is symmetric nonnegative definite, which follows from the fact that $-B^2 - I/4 \geq 0$ while B is skew-symmetric. □

In the case of elementary Gaussian state (12.83) in one mode with

$$\alpha_1 = \begin{bmatrix} N + 1/2 & 0 \\ 0 & N + 1/2 \end{bmatrix},$$

formulas (12.117), (12.118) amount to

$$\Delta_{12} = \begin{bmatrix} 0 & 1 & 0 & 0 \\ -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 \end{bmatrix},$$

$$\alpha_{12} = \begin{bmatrix} N+1/2 & 0 & 0 & \sqrt{N^2+N} \\ 0 & N+1/2 & -\sqrt{N^2+N} & 0 \\ 0 & -\sqrt{N^2+N} & N+1/2 & 0 \\ \sqrt{N^2+N} & 0 & 0 & N+1/2 \end{bmatrix}$$

so that

$$\Delta_{12}^{-1}\alpha_{12} = \begin{bmatrix} 0 & -(N+1/2) & \sqrt{N^2+N} & 0 \\ N+1/2 & 0 & 0 & \sqrt{N^2+N} \\ \sqrt{N^2+N} & 0 & 0 & N+1/2 \\ 0 & \sqrt{N^2+N} & -(N+1/2) & 0 \end{bmatrix} \tag{12.120}$$

10.12.16 12.4 Gaussian Channels

10.12.17 12.4.1 Open Bosonic Systems

In this subsection we consider a class of quantum channels which arise naturally from the interaction of a bosonic system with a bosonic environment. Let Z_A, Z_B be symplectic spaces describing the input and the output of the channel and Z_D, Z_E their corresponding environments so that

$$Z_A \oplus Z_D = Z_B \oplus Z_E = Z \tag{12.121}$$

and let $W_A(z_A), \ldots$ be the Weyl operators on the Hilbert spaces $\mathcal{H}_A, \ldots$ of the corresponding bosonic systems. We may assume that in each subspace $Z_A, \ldots$ a symplectic basis is chosen, which allows to apply the coordinate representation.

Assume that the composite system in the Hilbert space

$$\mathcal{H}_A \otimes \mathcal{H}_D = \mathcal{H}_B \otimes \mathcal{H}_E = \mathcal{H} \tag{12.122}$$

is prepared in the initial state $S_A \otimes S_D$ and evolves according to the unitary operator U_T, which corresponds to a symplectic transformation T in Z by (12.67). In accordance with the direct sum decompositions (12.121), T can be written in the block matrix form

$$T = \begin{bmatrix} K & L \\ K_D & L_D \end{bmatrix} \tag{12.123}$$

where $K : Z_B \to Z_A, L : Z_E \to Z_A, K_D : Z_B \to Z_D, L_D : Z_E \to Z_D$.

The characteristic function of the system state after the interaction described by this unitary transformation U_T is

$$\begin{aligned} \varphi_B(z_B) &= \operatorname{Tr} U_T (S_A \otimes S_D) U_T^* (W_B(z_B) \otimes I_E) \\ &= \operatorname{Tr} (S_A \otimes S_D) U_T^* (W_B(z_B) \otimes W_E(0)) U_T \\ &= \operatorname{Tr} (S_A \otimes S_D) (W_A(Kz_B) \otimes W_D(K_D z_B)) \\ &= \varphi_A(Kz_B) \cdot \varphi_D(K_D z_B), \end{aligned}$$

where $\varphi_D(z_D) = \operatorname{Tr} S_D W_D(z_D)$ is the characteristic function of the initial state of the environment. This transformation can be written in the form

$$\varphi_B(z_B) = \varphi_A(Kz_B) \cdot f(z_B), \tag{12.124}$$

where

$$f(z_B) = \varphi_D(K_D z_B) \tag{12.125}$$

If the initial state of the environment is Gaussian with parameters (m_D, α_D), then f has the form of the Gaussian characteristic function

$$f(z_B) = \exp\left[il(z_B) - \frac{1}{2}\mu(z_B, z_B)\right], \tag{12.126}$$

where $l(z_B) = m_D(K_D z_B)$ and

$$\mu(z_B, z'_B) = \alpha_D(K_D z_B, K_D z'_B). \tag{12.127}$$

Transformation of states according to formula (12.124) is a concatenation of the unitary evolution and partial trace which are channels in the sense of Definition 11.16 and hence defines a quantum channel $\Phi : \mathfrak{T}(\mathcal{H}_A) \to \mathfrak{T}(\mathcal{H}_B)$. In what follows we will also use the abbreviation $\Phi : A \to B$.

Definition 12.30. A channel transforming states according to the rule (12.124) is called linear bosonic. If, additionally, f is a Gaussian characteristic function (12.126), where l is a linear form and μ is a pre-inner product on Z_B, the channel is called Gaussian with parameters (K, l, μ).

Let $R_A, \ldots$ be the vectors of canonical observables in $\mathcal{H}_A, \ldots$ with the commutation matrices $\Delta_A, \ldots$. From the tensor product decomposition (12.122) we have two different splits of the set of canonical observables of the composite system, i.e.,

$$[R_B R_E] = [R_A R_D].$$

According to (12.68), the action of the operator U_T is described by linear transformation

$$[R'_B R'_E] \equiv U_T^* [R_B R_E] U_T = [R_A R_D] T, \tag{12.128}$$

where T is the block matrix (12.123), and for simplicity of notations we write $R_A, \ldots$ instead of $R_A \otimes I_D, \ldots$ In particular,

$$R'_B = R_A K + R_D K_D. \tag{12.129}$$

The commutation and the covariance matrices of the canonical observables R'_B at the output of the channel are given by the expression

$$\alpha_B + \frac{i}{2}\Delta_B = \mathrm{Tr}\,(R'_B)^\top S R'_B$$

where $S = S_A \otimes S_D$ and S_A, S_D are density operators in $\mathcal{H}_A$ and $\mathcal{H}_D$ with the covariance matrices α_A and α_D, respectively. By using (12.129), we obtain

$$\Delta_B = K^\top \Delta_A K + K_D^\top \Delta_D K_D, \tag{12.130}$$

$$\alpha_B = K^\top \alpha_A K + K_D^\top \alpha_D K_D. \tag{12.131}$$

Note that in the Gaussian case $\mu = K_D^\top \alpha_D K_D$ is the matrix of the corresponding form that enters the expression for the function (12.126) defining the channel. Since $\alpha_D \geq \pm\frac{i}{2}\Delta_D$, the relation (12.130) implies the inequality

$$\mu \geq \pm \frac{i}{2} \left[\Delta_B - K^\top \Delta_A K \right] \tag{12.132}$$

which will play a key role in what follows.

Equation (12.129) is the "input-output relation" describing the channel in the way closest to the classical description "signal plus Gaussian noise." Here R_A is the quantum signal and $N_D = R_D K_D$ is the Gaussian noise with the covariance matrix $\mu = K_D^\top \alpha_D K_D$. Note that the noise can be partially quantum, partially classical because of possible degeneracy of the commutator matrix $\Delta_B - K^\top \Delta_A K$.

The final state of the environment is defined by a similar equation for the canonical observables R_E after the interaction, i.e.,

$$R'_E = R_A L + R_D L_D$$

Remark 12.31. The weakly complementary channel $\Phi_E : A \to E$ (see Section 6.6) is defined by the relation

$$\varphi_E(z_E) = \varphi_A(L z_E) \cdot \varphi_D(L_D z_E)$$

and hence it is also linear bosonic and it is Gaussian if the state S_D is Gaussian. If the initial state of the environment is pure, $S_D = |\psi_D\rangle \langle \psi_D|$, then the channel Φ_E is complementary to Φ, with the Stinespring isometry given by the formula $V = U_T |\psi_D\rangle$.

Theorem 12.32. Inequality (12.132) is necessary and sufficient condition for a set of parameters (K, l, μ) to define Gaussian channel.

Proof. The necessity of the condition (12.132) was established before. Let us show now that under this condition one can construct the symplectic transformation T defining the dynamics of the open bosonic system which gives rise to the required Gaussian channel. In doing this we can always restrict ourselves to the centered case ($l = 0$) by performing a displacement operation (12.85).

First of all, note that for the given operators K, K_D satisfying (12.130) one can always extend the transformation (12.129) to a symplectic transformation T. Indeed, the relation (12.130) means that the transformation $z_B \to [K z_B, K_D z_B]^\top$ is a symplectic embedding of Z_B into $Z_A \oplus Z_D = Z$, i.e., the columns of the matrix $[K, K_D]^\top$ form a system which can be complemented to a symplectic basis in Z, which forms the matrix T. Thus the problem reduces to the following: for given K, μ, satisfying inequality (12.132), find a symplectic space (Z_D, Δ_D), an operator $K_D : Z_B \to Z_D$, and an inner product in Z_D, defined by symmetric matrix $\alpha_D \geq \pm \frac{i}{2} \Delta_D$, such that

$$K_D^\top \Delta_D K_D = \Delta_B - K^\top \Delta_A K \equiv \tilde{\Delta}_D \tag{12.133}$$

$$K_D^\top \alpha_D K_D = \mu \tag{12.134}$$

Assume first that μ is nondegenerate. Consider the Euclidean space (Z_B, μ) with the skew-symmetric form $\tilde{\Delta}_D$. Let $2n = \dim Z_B$. By the assumption, $\mu \geq \pm \frac{i}{2} \tilde{\Delta}_D$. Consider the skew-symmetric operator S, defined by the relation

$$\tilde{\Delta}_D(z_B, z'_B) = \alpha_D(z_B, S z'_B), \quad z_B, z'_B \in Z_B.$$

According to a theorem from linear algebra, there is an orthonormal basis $\tilde{e}_j, j = 1, \ldots, 2n - l, \tilde{h}_j, j = 1, \ldots, l$, in (Z_B, μ) such that

$$S\tilde{e}_j = s_j \tilde{h}_j, S\tilde{h}_j = -s_j \tilde{e}_j, \quad j = 1, \ldots, l, \quad S\tilde{e}_j = 0, \quad j = l+1, \ldots, 2n-l$$

The condition $\mu \geq \pm\frac{i}{2}\tilde{\Delta}_D$ implies $I - \frac{i}{2}S \geq 0$, hence $0 < s_j \leq 2$.
Let (Z_D, Δ_D) be the standard symplectic space of dimensionality $2l + 2(2n-2l) = 2(2n-l)$ with the basis $e_j, h_j, j = 1, \ldots, 2n-l$. Define α_D as a form with the diagonal matrix

$$\alpha_D e_j = s_j^{-1} e_j, \quad \alpha_D h_j = s_j^{-1} h_j, \quad j = 1, \ldots, l,$$
$$\alpha_D e_j = e_j, \quad \alpha_D h_j = \frac{1}{4} h_j, \quad j = l+1, \ldots, 2n-l.$$

Then $\alpha_D \geq \pm\frac{i}{2}\Delta_D$. Define the operator $K_D : Z_B \to Z_D$ by the formula

$$K_D \tilde{e}_j = \sqrt{s_j} e_j, \quad K_D \tilde{h}_j = \sqrt{s_j} h_j, \quad j = 1, \ldots, l,$$
$$K_D \tilde{e}_j = e_j, \quad j = l+1, \ldots, 2n-l. \tag{12.135}$$

Then the relations (12.133), (12.134) follow from the consideration of the values of the corresponding quadratic forms on the basis vectors $\tilde{e}_j, j = 1, \ldots, 2n-l, \tilde{h}_j, j = 1, \ldots, l$, in Z_B. Note that by construction, α_D is the covariance matrix of a pure state if and only if $s_j = 2, j = 1, \ldots, l$.

If, on the other hand, μ vanishes on a nontrivial subspace of $Z_0 \subset Z_B$, then $\tilde{\Delta}_D$ also vanishes on Z_0 due to the condition $\mu \geq \pm\frac{i}{2}\tilde{\Delta}_D$. Therefore the vectors $\tilde{e}_j, j = l+1, \ldots, 2n-l$, can be chosen in such a way that part of them will form a basis in Z_0. Then the definition (12.135) can be modified by requiring $K_D \tilde{e}_j = 0$ for $\tilde{e}_j \in Z_0$, and the relations (12.133), (12.134) will be fulfilled. □

10.12.18 12.4.2 Gaussian Channels: Basic Properties

Formula (12.124) is equivalent to the following equation for the dual channel:

$$\Phi^* \left[W_B \left(z_B \right) \right] = W_A \left(K z_B \right) f \left(z_B \right), \tag{12.136}$$

which shows that the Weyl operators are mapped into Weyl operators, up to a factor. In the case of Gaussian channels

$$\Phi^* \left[W_B \left(z_B \right) \right] = W_A \left(K z_B \right) \exp \left[il \left(z_B \right) - \frac{1}{2} \mu \left(z_B, z_B \right) \right]. \tag{12.137}$$

From the point of view of information theory, the Gaussian channels can be defined abstractly by the relation (12.137) without reference to the picture of interaction with the environment considered in the previous section. According to Theorem 12.32 the parameters (K, l, μ) satisfy the necessary and sufficient condition (12.132) ensuring the complete positivity of Φ.

We will make use of the following properties of Gaussian channels:
i. A Gaussian channel transforms Gaussian states into Gaussian states. The parameters of the input state are transformed according to the relations

$$m_B = m_A K + l$$
$$\alpha_B = K^\top \alpha_A K + \mu. \tag{12.138}$$

Compare these with the relation (12.131).
This property is a characteristic one, i. e., any channel, which transforms Gaussian states into Gaussian states, is Gaussian [60].
ii. The dual of a linear bosonic channel transforms any polynomial in the canonical observables

R_B into a polynomial in R_A of the same order, provided the function f has derivatives of sufficiently high order. This property follows by differentiating the relation (12.136) at the point $z_B = 0$.

iii. A concatenation of Gaussian channels is a Gaussian channel. Indeed, let $\Phi_j, j = 1{,}2$, be two Gaussian channels with parameters K_j, l_j, μ_j. Then applying the definition (12.137) we get the Gaussian channel $\Phi_2 \circ \Phi_1$ with parameters

$$\begin{aligned} K &= K_1 K_2 \\ l &= K_2^\top l_1 + l_2 \\ \mu &= K_2^\top \mu_1 K_2 + \mu_2 \end{aligned} \tag{12.139}$$

iv. Any linear bosonic, in particular Gaussian, channel is covariant in the sense that

$$\Phi\left[W_A(z)^* S W_A(z)\right] = W_B\left(K'z\right)^* \Phi[S] W_B\left(K'z\right), \tag{12.140}$$

where $K' = \Delta^{-1} K^\top \Delta$ is the symplectic adjoint of K.

10.12.19 12.4.3 Gaussian Observables

Assume we have two symplectic spaces Z_A, Z_B with the corresponding Weyl systems in Hilbert spaces $\mathcal{H}_A, \mathcal{H}_B$. Let M be an observable in $\mathcal{H}_A$ with the outcome set Z_B, given by the probability operator-valued measure $M\left(d^{2n}z\right)$. In what follows we occasionally skip the index $_B$ so that $Z = Z_B$, etc. The observable is completely determined by the operator characteristic function

$$\phi_M(w) = \int \mathrm{e}^{-i\Delta(w,z)} M\left(d^{2n}z\right).$$

Note the following apparent property of the operator characteristic function: for any choice of a finite subset $\{w_j\} \subset Z_B$ the block matrix with operator entries $\phi_M\left(w_j - w_k\right)$ is nonnegative definite.

The observable M will be called Gaussian if its operator characteristic function has the form

$$\phi_M(w) = W_A(Kw) \exp\left(-\frac{1}{2}\alpha(w,w)\right) = \exp\left(iR_A K w - \frac{1}{2}\alpha(w,w)\right), \tag{12.141}$$

where $K : Z_B \to Z_A$ is a linear operator and α is a pre-inner product on Z_B. The pair (K, α) defines parameters of the Gaussian observable.

Theorem 12.33. A necessary and sufficient condition for relation (12.141) to define an observable is the matrix inequality

$$\alpha \geq \pm\frac{i}{2} K^\top \Delta_A K. \tag{12.142}$$

Proof. For an operator function given by (12.141),

$$\phi_M\left(w_j - w_k\right) = C_k^* C_j \exp\left[\alpha\left(w_j, w_k\right) - \frac{i}{2}\Delta\left(Kw_j, Kw_k\right)\right]$$

where $C_j = W_A\left(Kw_j\right) \exp\left[-\frac{1}{2}\alpha\left(w_j, w_j\right)\right]$, and nonnegative definiteness of matrices with scalar entries $\exp\left[\alpha\left(w_j, w_k\right) - \frac{i}{2}\Delta\left(Kw_j, Kw_k\right)\right]$ implies inequality (12.142) according to Lemma 12.18.

Sufficiency of the condition (12.142) will be established by a direct construction of the Naimark extension of observable M in the spirit of Corollary 3.8.

Proposition 12.34. Assume the condition (12.142). Then one can find bosonic systems in the space $\mathcal{H}_C$ with the canonical observables R_C, for which $\mathcal{H}_B \subseteq \mathcal{H}_A \otimes \mathcal{H}_C$, and the Gaussian state $S_C \in \mathfrak{S}(\mathcal{H}_C)$, such that

$$M(U) = \mathrm{Tr}_C (I_A \otimes S_C) E_{AC}(U), \quad U \subseteq Z_B \tag{12.143}$$

where E_{AC} is the sharp observable in the space $\mathcal{H}_A \otimes \mathcal{H}_C$, given by the spectral measure of commuting self-adjoint operators

$$X_B = (R_A K + R_C K_C) \Delta_B^{-1} \tag{12.144}$$

(here we again abbreviate the notations as R_A instead of $R_A \otimes I_C$, etc.), where $K_C : Z_B \to Z_C$ is operator such that

$$K_C^\top \Delta_C K_C = -K^\top \Delta_A K \tag{12.145}$$

Proof. The condition (12.145) means that $K_C^\top \Delta_C K_C + K^\top \Delta_A K = 0$, that is, commutativity of operators (12.144). By adapting the proof of Theorem 12.32, we obtain a symplectic space $(\ Z_C, \Delta_C\ )$, an operator $K_C : Z_B \to Z_C$, and an inner product in Z_C, given by the symmetric matrix $\alpha_C \geq \pm \frac{i}{2} \Delta_C$ such that (12.145) holds along with

$$K_C^\top \alpha_C K_C = \alpha$$

Then the characteristic function of the observable E_{AC} is

$$\begin{aligned} \phi_{E_{AC}}(w) &= \int \mathrm{e}^{-i\Delta(w,z)} E_{AC}\left(d^{2n} z\right) \\ &= \exp\left(i X_B \Delta_B w\right) = \exp i \left(R_A K + R_C K_C\right) w \\ &= W_A(Kw) W_C\left(K_C w\right) \end{aligned}$$

whence, denoting by S_C the centered Gaussian state with the correlation matrix α,

$$\begin{aligned} \mathrm{Tr}_C (I_A \otimes S_C) \phi_{E_{AC}}(w) &= W_A(Kw) \exp\left(-\frac{1}{2} \alpha_C\left(K_C w, K_C w\right)\right) \\ &= W_A(Kw) \exp\left(-\frac{1}{2} \alpha(w, w)\right) = \phi_M(w) \end{aligned}$$

and (12.143) follows.
The observable M is sharp if and only if $\alpha = 0$, in which case it is related to the spectral measure of the commuting self-adjoint operators $R_A K$.

Example 12.35. If $R = [qp]$ are the canonical observables of one mode A and $R_C = [q_C p_C]$ those of another mode C, then the operators $X_B = \left[\begin{array}{cc} q' & p' \end{array}\right]$ defined as

$$q' = q - q_C, \quad p' = p + p_C$$

are commuting essentially self-adjoint. If S_C is the elementary Gaussian state (12.83) with parameters $(\ 0, \alpha\ )$, then we have an extension, in the sense of Proposition 12.34, of a Gaussian observable M with parameters $(\ \Delta, \alpha\ )$. In quantum optics the observable M describes statistics of optical heterodyning.

On the other hand, a single self-adjoint operator $X = k_q q + k_p p$, where k_q, k_p are real, describes the sharp Gaussian observable with parameters $\left(\ \left[\begin{array}{cc} k_q & k_p \end{array}\right]^\top, 0\ \right)$ corresponding to optical homodyning. See, e. g., [43], [122] for more detail.

10.12.20 12.4.4 Gaussian Entanglement-Breaking Channels

Theorem 12.36. A Gaussian channel Φ with parameters $(K, 0, \mu)$ is entanglementbreaking if and only if μ admits the decomposition

$$\mu = \alpha_A + \alpha_B, \quad \text{where } \alpha_A \geq \pm\frac{i}{2}K^\top \Delta_A K, \alpha_B \geq \pm\frac{i}{2}\Delta_B. \tag{12.146}$$

In this case Φ has the representation

$$\Phi[S] = \int_{Z_B} W_B(z) S_B W_B(z)^* \mu_S\left(d^{2n}z\right) \tag{12.147}$$

where S_B is the Gaussian state with parameters $(0, \alpha_B)$ and $\mu_S(U) = \operatorname{Tr} S M_A(U), U \subseteq Z_B$, is the probability distribution of the Gaussian observable M_A with the characteristic function

$$\phi_{M_A}(w) = W_A(Kw)\exp\left(-\frac{1}{2}\alpha_A(w,w)\right). \tag{12.148}$$

Proof. First, assume that μ admits the decomposition (12.146) and consider the channel defined by (12.147); we have to show that

$$\Phi^*\left[W_B(w)\right] = W_A(Kw)\exp\left[-\frac{1}{2}\mu(w,w)\right]. \tag{12.149}$$

Indeed, for arbitrary state S

$$\begin{aligned}
\operatorname{Tr} S\Phi^*\left[W_B(w)\right] &= \operatorname{Tr}\Phi[S]W_B(w) = \int_{Z_B} \operatorname{Tr} W_B(z) S_B W_B(z)^* W_B(w) \mu_S\left(d^{2n}z\right) \\
&= \int_{Z_B} \operatorname{Tr} S_B W_B(z)^* W_B(w) W_B(z) \mu_S\left(d^{2n}z\right) \\
&= \operatorname{Tr} S_B W_B(w) \int_{Z_B} \exp[-i\Delta(w,z)]\mu_S\left(d^{2n}z\right) \\
&= \exp\left[-\frac{1}{2}\alpha_B(w,w)\right]\operatorname{Tr} S\phi_{M_A}(w) \\
&= \operatorname{Tr} S W_A(Kw)\exp\left[-\frac{1}{2}\alpha_B(w,w) - \frac{1}{2}\alpha_A(w,w)\right],
\end{aligned} \tag{12.150}$$

whence (12.149) follows.

Conversely, let the channel Φ be Gaussian and entanglement-breaking. We will use a Gaussian version of the proof of Theorem 11.31. Fix a nondegenerate Gaussian state σ_A in $\mathfrak{S}(\mathcal{H}_A)$ and let $\{|e_j\rangle\}_{j=1}^{+\infty}$ be the basis of eigenvectors of σ_A with the corresponding (positive) eigenvalues $\{\lambda_j\}_{j=1}^{+\infty}$. Consider the unit vector

$$|\Omega\rangle = \sum_{j=1}^{+\infty} \sqrt{\lambda_j}\,|e_j\rangle \otimes |e_j\rangle$$

in the space $\mathcal{H}_A \otimes \mathcal{H}_A$. Then $|\Omega\rangle\langle\Omega|$ is Gaussian purification of σ_A. Since Φ is entanglement-breaking, the Gaussian state

$$\sigma_{AB} = (\mathrm{Id}_A \otimes \Phi)\left[|\Omega\rangle\langle\Omega|\right] \tag{12.151}$$

in $\mathfrak{S}(\mathcal{H}_A \otimes \mathcal{H}_B)$ is separable. This implies representation (12.115), i.e.,

$$\sigma_{AB} = \int_{Z_A}\int_{Z_B} W_A(z_A)\, S_A W_A(z_A)^* \otimes W_B(z_B)\, S_B W_B(z_B)^*\, P\left(d^{2m}z_A d^{2n}z_B\right), \qquad (12.152)$$

where S_A, S_B are Gaussian states with covariance matrices α_A, α_B and P is a Gaussian probability distribution.

Taking partial trace with respect to B, this gives

$$\begin{aligned}\sigma_A &= \mathrm{Tr}_B\left(\mathrm{Id}_A \otimes \Phi\right)\left[|\Omega\rangle\langle\Omega|\right] \\ &= \int_{Z_A}\int_{Z_B} W_A(z_A)\, S_A W_A(z_A)^*\, P\left(d^{2m}z_A d^{2n}z_B\right) \\ &= \int_{Z_A}\int_{Z_B} \overline{W_A(z_A)\, S_A W_A(z_A)^*} P\left(d^{2m}z_A d^{2n}z_B\right),\end{aligned}$$

where the bar means complex conjugation in the basis of eigenvectors of σ_A. Then similarly to (11.54), we conclude that the relation

$$M_A(U) = \sigma_A^{-1/2}\left[\int_{Z_A}\int_U \overline{W_A(z_A)\, S_A W_A(z_A)^*} P\left(d^{2m}z_A d^{2n}z_B\right)\right]\sigma_A^{-1/2}$$

defines a bounded positive operator such that $M_A(U) \leq M_A(Z_B) = I_A$. It is easy to see that $M_A(U)$ is a POVM on Borel subsets $U \subseteq Z_B$.

Let us show that the representation (12.147) holds for the channel Φ with these M_A and S_B. Consider an entanglement-breaking channel

$$\hat{\Phi}[S] = \int_{Z_B} W_B(z) S_B W_B(z)^* \mu_S\left(d^{2n}z\right),$$

where $\mu_S(U) = \mathrm{Tr}\, S M_A(U), U \subseteq Z_B$. To prove $\Phi = \hat{\Phi}$, it is sufficient to show that $\hat{\Phi}\left[|e_j\rangle\langle e_k|\right] = \Phi\left[|e_j\rangle\langle e_k|\right]$ for all j, k. But

$$\begin{aligned}\hat{\Phi}\left[|e_j\rangle\langle e_k|\right] &= \int_{Z_B} W_B(z) S_B W_B(z)^* \langle e_k|\, M_A\left(d^{2n}z\right)|e_j\rangle \\ &= \lambda_j^{-1/2}\lambda_k^{-1/2}\iint_{Z_A}\langle e_j|\, W_A(z_A)\, S_A W_A(z_A)^*\, |e_k\rangle\, W_B(z_B)\, S_B W_B(z_B)^*\, P\left(d^{2m}z_A d^{2n}z_B\right) \\ &= \lambda_j^{-1/2}\lambda_k^{-1/2}\,\mathrm{Tr}_A\left(|e_k\rangle\langle e_j| \otimes I_B\right)\sigma_{AB} = \Phi\left[|e_j\rangle\langle e_k|\right]\end{aligned}$$

according to (12.151), (12.152).

It remains to show that M_A is Gaussian observable with the characteristic function (12.148) where $\alpha_A = \mu - \alpha_B$, and α_B is the covariance matrix of the state S_B; without loss of generality we can assume its mean is zero. Indeed, the density operator S_B can be modified with the help of the Weyl operators to have zero mean, resulting only in a change in the probability distribution (12.152), which however will remain Gaussian. But from (12.150),

$$\Phi^*\left[W_B(w)\right] = \exp\left[-\frac{1}{2}\alpha_B(w,w)\right]\phi_{M_A}(w)$$

for any channel Φ with the representation (12.147), whence taking into account (12.149), we indeed get (12.148) with $\alpha_A = \mu - \alpha_B$. $\square$

A necessary condition for the decomposability (12.146) and hence for the channel to be entanglement-breaking is

$$\mu \geq \frac{i}{2}\left(\Delta_B \pm K^\top \Delta_A K\right). \tag{12.153}$$

In general this condition means that for any input Gaussian state of the channel $\mathrm{Id}_A \otimes \Phi$, the output has PPT. Indeed, this channel transforms the covariance matrix of the input state according to the rule

$$\begin{bmatrix} \alpha_{11} & \alpha_{12} \\ \alpha_{21} & \alpha_{22} \end{bmatrix} \to \begin{bmatrix} I & 0 \\ 0 & K^\top \end{bmatrix} \begin{bmatrix} \alpha_{11} & \alpha_{12} \\ \alpha_{21} & \alpha_{22} \end{bmatrix} \begin{bmatrix} I & 0 \\ 0 & K \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ 0 & \alpha \end{bmatrix} \equiv \alpha_{AB}.$$

The right-hand side representing the covariance matrix of the output state satisfies

$$\begin{aligned} \alpha_{AB} &\geq \frac{i}{2}\begin{bmatrix} I & 0 \\ 0 & K^\top \end{bmatrix} \begin{bmatrix} \Delta_A & 0 \\ 0 & \Delta_A \end{bmatrix} \begin{bmatrix} I & 0 \\ 0 & K \end{bmatrix} + \frac{i}{2}\begin{bmatrix} 0 & 0 \\ 0 & \pm\Delta_B - K^\top \Delta_A K \end{bmatrix} \\ &= \frac{i}{2}\begin{bmatrix} \Delta_A & 0 \\ 0 & \pm\Delta_B \end{bmatrix}, \end{aligned}$$

where in the estimate of the second term we used (12.153) with its transpose. However, this is equivalent to the condition (12.116), which is necessary and sufficient for the output state to have PPT. Thus the condition (12.153) characterizes the class of Gaussian PPT channels which in general is larger than the class of entanglement-breaking channels.

The condition of the theorem is automatically fulfilled in the special case where

$$K^\top \Delta_A K = 0.$$

In this case the operators $R_A K$ commute, hence M_A is a sharp observable given by their spectral measure and the probability distribution $\mu_S\left(d^{2n}z\right)$ can be arbitrarily sharply peaked around any point z by appropriate choice of the state S. Hence in this case it is natural to identify Φ as $\mathrm{c}-\mathrm{q}$ channel determined by the family of states $z \to W(z) S_B W(z)^*$.

10.12.21 12.5 The Capacities of Gaussian Channels

10.12.22 12.5.1 Maximization of the Mutual Information

We start with the classical entanglement-assisted capacity which can be computed most effectively in the Gaussian case. When the state S and the channel Φ are Gaussian, the quantities $H(S), H(\Phi[S]), H(S,\Phi)$, and $I(S,\Phi)$ can be found by using formulas (12.110), (12.131), (12.118). Namely, $H(\Phi[S])$ is given by formula (12.110) with α replaced by $\alpha' = \alpha_B$ computed via (12.131). By purifying the input state and using formula (7.49), we obtain

$$H(S,\Phi) = \frac{1}{2}\,\mathrm{Spg}\left(\mathrm{abs}\left(\Delta_{12}^{-1}\alpha'_{12}\right) - \frac{I}{2}\right),$$

where the matrix

$$\alpha'_{12} = \begin{bmatrix} \alpha' & K\beta \\ \beta^\top K^\top & \alpha \end{bmatrix} \tag{12.154}$$

is computed by inserting R'_B given by (12.129) into

$$\alpha'_{12} - \frac{i}{2}\Delta'_{12} = \mathrm{Tr}\left[R'_B R_2\right]^\top S\left[R'_B R_2\right],$$

where R_2 are the (unchanged) canonical observables of the reference system. Alternatively, if an explicit description of the complementary channel $\tilde{\Phi}$ is available, the entropy exchange can be calculated as its output entropy $H(\tilde{\Phi}[S])$.

The following result greatly simplifies computation of the entanglement-assisted capacity of Gaussian channels, by reducing to the case of Gaussian input states.

Proposition 12.37. Let Φ be a Gaussian channel and S be a state with finite first and second moments. Let $\tilde{S}$ be the Gaussian channel with the same first and second moments as S. Then

$$I(S,\Phi) \leq I(\tilde{S},\Phi).$$

Proof. By using the representation (7.53) for the quantum mutual information, we can write

$$I(S,\Phi) = H(B \mid E) + H(B),$$

where B is the output of the channel and E is the environment. For a Gaussian channel first and second moments are transformed in the same way for all states in $\Sigma(m,\alpha)$. By using Lemma 12.26 we have

$$H(B) = H(\Phi[S]) \leq H(\widetilde{\Phi[S]}) = H(\Phi[\tilde{S}]) = H(\tilde{B}),$$

where $\widetilde{\Phi[S]}$ (resp. $\tilde{S}$) is the Gaussian state with the same first and second moments as $\Phi[S]$ (resp. S). The channel $S \to S_{BE} = VSV^*$, where V is the Stinespring isometry for Φ, is also Gaussian, since it is implemented by a unitary operator U_T with Gaussian state of environment, namely,

$$\operatorname{Tr} S_{BE} W(z_B) \otimes W(z_E) = \phi_A(Kz_B + Lz_E)\,\phi_D(K_D z_B + L_D z_E). \tag{12.155}$$

Therefore a similar argument based on Lemma 12.27 implies that $H(B \mid E) \leq H(\tilde{B} \mid \tilde{E})$. Thus $I(S,\Phi) \leq I(\tilde{S},\Phi)$. $\square$

This result implies that if the maximum of $I(S,\Phi)$ over a set of density operators defined by an arbitrary constraint on the first and second moments is achieved, then it is achieved on a Gaussian density operator. Now consider the energy constraint

$$\operatorname{Tr} SF \leq E, \tag{12.156}$$

where $F = R\epsilon R^\top$ is the quadratic operator with positive nondegenerate energy matrix ϵ. Note that

$$\operatorname{Tr} SF = \operatorname{Sp}(\epsilon\alpha_A) + m_A \epsilon m_A^\top,$$

where m_A is the mean vector and α_A is the covariance matrix of the state S. The expression for the entanglement-assisted classical capacity $C_{ea}(\Phi)$ given by Proposition 11.26 is the maximum of the quantum mutual information $I(S,\Phi)$ over all states S satisfying the constraint (12.156).

Corollary 12.38. The maximum of the quantum mutual information over all states S satisfying the constraint (12.156) is attained on a Gaussian state.

Proof. The set of conditions for Proposition 11.26 is fulfilled for the operator $F = R\epsilon R^\top$. Indeed, by Theorem 12.23, the operator F satisfies the condition (11.9). Taking

$$\tilde{F} = c\left[R_A R_A^\top - \left(\operatorname{Sp} K_D \alpha_D K_D^\top\right) I\right],$$

and using the input-output relation (12.129), we have $\Phi^*[\tilde{F}] = cR_B K^\top K R_B^\top$ and we can always choose positive c such that $\Phi^*[\tilde{F}] \leq F$. Moreover, $\tilde{F}$ satisfies the condition (11.9). Therefore the maximum of the quantity $I(S,\Phi)$ is achieved and formula (11.41) holds. Since the energy constraint can be expressed in terms of m_A, α_A, the maximal value $C_{ea}(\Phi,F,E)$ is achieved on the Gaussian state.

Further reduction of the maximization problem can be obtained by invoking gauge covariance.

10.12.23 12.5.2 Gauge Covariant Channels I

Consider a channel $\Phi : A \to B$. Assume that in the spaces Z_A, Z_B some operators of complex structure J_A, J_B are fixed, and let U_ϕ^A, U_ϕ^B be the unitary groups of gauge transformations in $\mathcal{H}_A, \mathcal{H}_B$ according to formula (12.77). The channel is called gauge covariant, if

$$\Phi\left[U_\phi^A S \left(U_\phi^A\right)^*\right] = U_\phi^B \Phi[S] \left(U_\phi^B\right)^* \tag{12.157}$$

for all input states S and all $\phi \in [0, 2\pi]$. In the case of a linear bosonic channel Φ, due to (12.77), (12.124), this is equivalent to the following:

$$\phi\left(\mathrm{e}^{-\varphi J_A} K z_B\right) f\left(z_B\right) = \phi\left(K \mathrm{e}^{-\varphi J_B} z_B\right) f\left(\mathrm{e}^{-\varphi J_B} z_B\right),$$

where $\phi\left(z_A\right)$ is the characteristic function of the state S. For the Gaussian channel (12.137) with parameters $(\ K, l, \mu\ )$ this reduces (cf. (12.91)) to

$$l = 0, \quad K J_B - J_A K = 0, \quad J_B^\top \mu + \mu J_B = 0 \tag{12.158}$$

By using (12.60), the last equation can be written as

$$\left[J_B, \Delta^{-1} \mu\right] = 0 \tag{12.159}$$

Channel Φ is called gauge contravariant if

$$\Phi\left[U_\phi^A S \left(U_\phi^A\right)^*\right] = \left(U_\phi^B\right)^* \Phi[S] U_\phi^B \tag{12.160}$$

for all input states S and all $\phi \in [0, 2\pi]$. For the Gaussian channel (12.137) with parameters $(\ K, l, \mu\ )$ this amounts to

$$l = 0, \quad K J_B + J_A K = 0, \quad J_B^\top \mu + \mu J_B = 0. \tag{12.161}$$

Thus, for a gauge covariant or contravariant channel, a natural choice of the complex structure in Z_B is given by any J_B, commuting with the operator $\Delta_B^{-1} \mu$. Existence of such a complex structure is proved similarly to (12.92) with the difference that the matrix μ can be degenerate.

In optimization problems with bounded mean energy a natural complex structure in Z_A is determined by the energy operator $F = R \epsilon R^\top$, namely, J_A is the operator of complex structure in Z_A, commuting with the operator $\epsilon \Delta_A$, so that

$$J_A \epsilon + \epsilon J_A^\top = 0 \tag{12.162}$$

In the case where F is the usual Hamiltonian of the oscillator system, the action of J_A reduces to multiplication by i in the complexification associated with creationannihilation operators.

Let now the Gaussian channel Φ be gauge covariant or contravariant with respect to these natural complex structures. Then

$$I\left(U_\phi^A S \left(U_\phi^A\right)^*, \Phi\right) \equiv I(S, \Phi),$$

which follows from the similar property of the three terms comprising $I(S, \Phi)$. For $H(S)$ this is simply a consequence of the unitary invariance of the entropy, for $H(\Phi[S])$ the covariance of the channel Φ is additionally used, and for $H(S, \Phi) = H(\tilde{\Phi}[S])$ this follows from covariance of the complementary channel $\tilde{\Phi}$ (Exercise 6.38). Defining the average gauge invariant state

$$S_{av} = \frac{1}{2\pi} \int_0^{2\pi} U_\phi^A S \left(U_\phi^A\right)^* d\phi$$

we have

$$\operatorname{Tr} SF = \operatorname{Sp}(\epsilon\alpha_A) + m_A\epsilon m_A^\top \geq \operatorname{Sp}(\epsilon\alpha_A) = \operatorname{Tr} S_{av}F,$$

where m_A, α_A are the first and the second moments of the state S and the last equality follows because of (12.162), i. e.,

$$\begin{aligned}\operatorname{Tr} S_{av}F &= \frac{1}{2\pi}\int_0^{2\pi} \operatorname{Tr} U_\phi^A S \left(U_\phi^A\right)^* \left(R\epsilon R^\top\right) d\phi \\ &= \frac{1}{2\pi}\int_0^{2\pi} \operatorname{Sp}\left(\mathrm{e}^{\phi J_A}\epsilon \mathrm{e}^{\phi J_A^\top}\alpha_A\right) d\phi = \operatorname{Sp}(\epsilon\alpha_A)\end{aligned}$$

Now using the concavity of the mutual information $I(S,\Phi)$, we conclude that $I(S,\Phi) \leq I(\bar{S},\Phi)$. Thus the maximum of the quantum mutual information over the set of states with bounded mean energy $\operatorname{Tr} SF \leq E$ is attained on a gauge invariant (G_A-invariant) Gaussian state. The first and the second moments of such a state necessarily satisfy the relations $m_A = 0, [J_A, \Delta^{-1}\alpha_A] = 0$. Considering the Gaussian state with these first and second moments, we finally obtain the following.

Corollary 12.39. Let Φ be a Gaussian channel which is gauge covariant or contravariant with respect to the natural complex structures J_A, J_B (where J_A is associated with the energy operator). Then the maximum of the quantum mutual information over the set of states with bounded mean energy is attained on a gauge invariant (G_A-invariant) Gaussian state.

10.12.24 12.5.3 Maximization of the Coherent Information

Consider the coherent information

$$I_c(S,\Phi) = H(\Phi[S]) - H(S,\Phi).$$

Proposition 12.40. Let Φ be a Gaussian channel which is degradable,

$$\tilde{\Phi} = \Gamma \circ \Phi, \tag{12.163}$$

such that Γ is a Gaussian channel. Then the quantum capacity

$$Q(\Phi) = \sup_{\tilde{S}} I_c(\tilde{S},\Phi),$$

where the supremum is taken over Gaussian states $\tilde{S}$. If in addition the channel is gauge covariant or contravariant, then the supremum can be taken only over gauge invariant (G_A-invariant) Gaussian states.

Proof. Assuming that the channel is degradable, i. e., (12.163) holds, where $\tilde{\Phi}$ is the complementary channel and Γ is some channel, we have (see Section 10.3.3)

$$I_c(S,\Phi) = H(E' \mid E) = H(S_{E'E}) - H(S_E), \tag{12.164}$$

where $S_{E'E} = V'S_BV'^*$ and $V' : \mathcal{H}_B \to \mathcal{H}_E \otimes \mathcal{H}_{E'}$ is the minimal Stinespring isometry for the channel Γ. Now if the channel Γ can be chosen Gaussian, then the channel $S_B \to S_{E'E}$ is also Gaussian and the argument invoking Lemma 12.27 applies. Therefore $I_c(S,\Phi) = H(E' \mid E) \leq H\left(\tilde{E}' \mid \tilde{E}\right) = I_c(\tilde{S},\Phi)$. By using Proposition 10.27 it follows that the quantum capacity of the degradable channel is given by

$$Q(\Phi) = \sup_S I_c(S,\Phi) = \sup_{\tilde{S}} I_c(\tilde{S},\Phi),$$

where the supremum is taken over Gaussian states $\tilde{S}$.

If in addition Φ is gauge covariant, then concavity of the conditional quantum entropy (12.164) implies that the supremum can be taken only over gauge invariant Gaussian states.

10.12.25 12.5.4 The Classical Capacity

The Conjectures

It is natural to consider the classical capacity of a quantum Gaussian channel Φ under the additive input constraint (11.28) with

$$F^{(n)} = F \otimes I \otimes \cdots \otimes I + \cdots + I \otimes \cdots \otimes I \otimes F,$$

where $F = R\epsilon R^\top$ is the quadratic energy operator with positive definite matrix ϵ. However finding the classical capacity $C(\Phi, F, E)$ in general depends on the solution of the problem of additivity of the constrained χ-capacity (11.33) which is still open for the Gaussian channels with quadratic input constraints. In any case, the χ-capacity $C_\chi(\Phi, F, E)$, defined by the relation (11.31), is a lower estimate for $C(\Phi, F, E)$ which coincides with $C(\Phi, F, E)$ in the case of additivity, e. g., for entanglement-breaking channels. A related open problem is additivity of the minimal output entropy (8.33) in the class of all Gaussian channels.

However even the computation of $C_\chi(\Phi, F, E)$ for Gaussian channels remains in general an open problem (except for the case of c − q channels and the channels with gauge symmetry considered in the rest of this section). At least in this situation an optimal generalized ensemble always exists, because the conditions of Corollary 11.24 for $F = R\epsilon R^\top$ are fulfilled, as was shown in Section 12.5.1. Thus the maximum of the quantity $\chi_\Phi(\pi)$ defined in (11.35) is achieved and $C_\chi(\Phi, F, E)$ is given by the relation (11.38).

Consider the following.

Hypothesis of Gaussian optimal ensembles. For a Gaussian channel Φ with the quadratic input energy constraint the maximum of the quantity $\chi_\Phi(\pi)$ in the expression (11.38) for $C_\chi(\Phi, F, E)$ is attained on the Gaussian generalized ensemble π, consisting of generalized coherent states $W(z)S_0W(z)^*$, where S_0 is a pure Gaussian state, with a Gaussian probability distribution $P\,(d^{2n}z)$.

For such an ensemble the covariance property (12.140) implies

$$H\left(\Phi\left[W(z)S_0W(z)^*\right]\right) = H\left(\Phi\left[S_0\right]\right)$$

hence

$$\chi_\Phi(\pi) = H\left(\Phi\left[\bar{S}_\pi\right]\right) - H\left(\Phi\left[S_0\right]\right) \tag{12.165}$$

where $\bar{S}_\pi$ is the average state of the ensemble, which leads us to the following.

Hypothesis of Gaussian minimizers for the output entropy. For a Gaussian channel Φ the minimum of the output entropy is attained on a (pure) Gaussian state S_0.

These two hypotheses turn out to be closely related. In what follows we describe positive solutions for both of them in an important class of Gaussian channels with the gauge symmetry. However both conjectures remain open for general quantum Gaussian channels.

Gauge Covariant Channels II

In what follows we restrict to channels that are gauge covariant or contravariant with respect to fixed complex structures. Similar to the end of Section 12.3.2, we realize a symplectic space $Z = \mathbb{R}^{2s}$ as the complex space $\mathbf{Z} = \mathbb{C}^s$ with the symplectic form

$$\Delta\left(z, z'\right) = 2\,\mathrm{Im}\,\mathbf{z}^*\mathbf{z}'.$$

An operator in Z commuting with $J = \begin{bmatrix} 0 & -I_s \\ I_s & 0 \end{bmatrix}$ is represented by a $2s \times 2s$-matrix of the form

$$M = \begin{bmatrix} X & Y \\ -Y & X \end{bmatrix}, \tag{12.166}$$

where X, Y are real $s \times s$-matrices. In the complex space $\mathbf{Z}$ the action of M is described by the action of the complex $2s \times 2s$-matrix

$$\mathbf{M} = X - iY.$$

The correspondence $M \to \mathbf{M}$ preserves algebraic operations and involution, i.e., $M^\top \to \mathbf{M}^*$. This follows from the relation

$$U^* M U = \begin{bmatrix} X - iY & 0 \\ 0 & X + iY \end{bmatrix}, \tag{12.167}$$

where U is the unitary matrix (12.99). This relation holds also for complex matrices of the form (12.166); in particular, for $i\Delta = \begin{bmatrix} 0 & iI_s \\ -iI_s & 0 \end{bmatrix}$ one obtains

$$U^*(i\Delta)U = \begin{bmatrix} I_s & 0 \\ 0 & -I_s \end{bmatrix}. \tag{12.168}$$

An important consequence of (12.167) is that for a complex matrix M of the form (12.166), nonnegative definiteness $M \geq 0$ is equivalent to $X \pm iY \geq 0$.

With these facts at hand, we pass to the consideration of Gaussian gauge co(contra)variant channels.

Let $\mathbf{Z}_A, \mathbf{Z}_B$ be the input and the output symplectic spaces. We denote by $s_A = \dim \mathbf{Z}_A, s_B = \dim \mathbf{Z}_B$ the numbers of modes of the input and the output of the channel.

The description obtained above for matrices commuting with complex structures extends with obvious changes to the case $s_A \neq s_B$ by including consideration of rectangular matrices M of the form (12.166). The action of a Gaussian gauge covariant channel is described by (12.137) where $l = 0$, and the matrices K, μ satisfy (12.158), hence they have the form (12.166). The relation (12.137) then can be rewritten as

$$\Phi^* \left[D_B(\mathbf{z}) \right] = D_A(\mathbf{K}\mathbf{z}) \exp\left(-\mathbf{z}^* \boldsymbol{\mu} \mathbf{z} \right), \quad \mathbf{z} \in \mathbf{Z}_B, \tag{12.169}$$

where $K \to \mathbf{K}$ is a complex $s_B \times s_A$-matrix, and $\mu \to \boldsymbol{\mu}$ is a Hermitian $s_B \times s_B$-matrix. The condition (12.132) turns into

$$\boldsymbol{\mu} \geq \pm \frac{1}{2} \left(\mathbf{I}_B - \mathbf{K}^* \mathbf{K} \right), \tag{12.170}$$

by the properties of the correspondence $M \to \mathbf{M}$. Here $\mathbf{I}_B$ is the unit $s_B \times s_B$-matrix which appears since $i\Delta \to \mathbf{I}$ due to the relation (12.168).

Later we will need the following.

Lemma 12.41. The channel Φ defined via (12.169) is injective if and only if ${}^2\mathbf{K}\mathbf{K}^* > \mathbf{0}$ (in which case necessarily $s_B \geq s_A$).

Proof. Injectivity means that $\Phi\left[S_1\right] = \Phi\left[S_2\right]$ implies $S_1 = S_2$. But $\Phi\left[S_1\right] = \Phi\left[S_2\right]$ is equivalent to $\operatorname{Tr} S_1 \Phi^* \left[D_B(\mathbf{z})\right] = \operatorname{Tr} S_2 \Phi^* \left[D_B(\mathbf{z})\right]$, i. e., $\operatorname{Tr} S_1 D_A(\mathbf{K}\mathbf{z}) = \operatorname{Tr} S_2 D_A(\mathbf{K}\mathbf{z})$ for all $\mathbf{z} \in \mathbf{Z}_B$. By irreducibility of the Weyl system, this property is equivalent to $\operatorname{Ran} \mathbf{K} = \mathbf{Z}_A$, i. e., $\operatorname{Ker} \mathbf{K}^* = \{\mathbf{0}\}$ or $\mathbf{K}\mathbf{K}^* > 0$. $\square$

The channel (12.169) is extreme [3] if μ is a minimal solution of inequality (12.170). Special cases of the maps (12.169) are provided by the attenuator and amplifier channels, characterized

by matrix $\mathbf{K}$ fulfilling the inequalities $\mathbf{K}^*\mathbf{K} \leq \mathbf{I}$ and $\mathbf{K}^*\mathbf{K} \geq \mathbf{I}$, respectively. We are particularly interested in the extreme attenuator which corresponds to

$$\mathbf{K}^*\mathbf{K} \leq \mathbf{I}_B, \quad \boldsymbol{\mu} = \frac{1}{2}\left(\mathbf{I}_B - \mathbf{K}^*\mathbf{K}\right) \tag{12.171}$$

and the extreme amplifier

$$\mathbf{K}^*\mathbf{K} \geq \mathbf{I}_B, \quad \boldsymbol{\mu} = \frac{1}{2}\left(\mathbf{K}^*\mathbf{K} - \mathbf{I}_B\right). \tag{12.172}$$

In the case of a contravariant channel the parameters satisfy (12.161), in particular, K anticommutes with J. Let $\Lambda = \begin{bmatrix} I_s & 0 \\ 0 & -I_s \end{bmatrix}$, so that Λz corresponds to $\overline{\mathbf{z}}$ - the column vector obtained by taking the complex conjugates of the elements of $\mathbf{z}$. One has $\Lambda^2 = I_{2s}$,

$\Lambda J + J\Lambda = 0$. Then $K = \Lambda K_1$, where $K_1 = \Lambda K$ commutes with J. The action of the Gaussian gauge contravariant channel (12.137) is then described as

$$\Phi^*\left[D_B(\mathbf{z})\right] = D_A\left(-\overline{\mathbf{K}_1\mathbf{z}}\right)\exp\left(-\mathbf{z}^*\boldsymbol{\mu}\mathbf{z}\right). \tag{12.173}$$

The condition (12.132) takes the form

$$\mu \geq \pm\frac{i}{2}\left(\Delta_B + K_1^\top \Delta_A K_1\right),$$

which reduces to

$$\boldsymbol{\mu} \geq \frac{1}{2}\left(\mathbf{I}_B + \mathbf{K}_1^*\mathbf{K}_1\right). \tag{12.174}$$

These maps are extreme if

$$\boldsymbol{\mu} = \frac{1}{2}\left(\mathbf{I}_B + \mathbf{K}_1^*\mathbf{K}_1\right). \tag{12.175}$$

In what follows, we will use the notation $\mathbf{K}$ instead of $\mathbf{K}_1$.

The Structure of Gauge Covariant Channels

Proposition 12.42. Any Gaussian gauge covariant channel $\Phi : A \to B$ is a concatenation $\Phi = \Phi_2 \circ \Phi_1$ of an extreme attenuator $\Phi_1 : A \to B$ and an extreme amplifier $\Phi_2 : B \to B$.

Any Gaussian gauge contravariant channel $\Phi : A \to B$ is a concatenation of an extreme attenuator $\Phi_1 : A \to B$ and an extreme gauge contravariant channel $\Phi_2 : B \to B$.

Proof. The concatenation $\Phi = \Phi_2 \circ \Phi_1$ of Gaussian gauge covariant channels Φ_1 and Φ_2 obeys the following rule:

$$\mathbf{K} = \mathbf{K}_1\mathbf{K}_2, \tag{12.176}$$
$$\boldsymbol{\mu} = \mathbf{K}_2^*\boldsymbol{\mu}_1\mathbf{K}_2 + \boldsymbol{\mu}_2. \tag{12.177}$$

By inserting relations

$$\boldsymbol{\mu}_1 = \frac{1}{2}\left(\mathbf{I}_B - \mathbf{K}_1^*\mathbf{K}_1\right) = \frac{1}{2}\left(\mathbf{I}_B - |\mathbf{K}|_1^2\right), \quad \boldsymbol{\mu}_2 = \frac{1}{2}\left(\mathbf{K}_2^*\mathbf{K}_2 - \mathbf{I}_B\right) = \frac{1}{2}\left(|\mathbf{K}_2|^2 - \mathbf{I}_B\right)$$

[0]2 For Hermitian matrices M, N, the strict inequality $M > N$ means that $M - N$ is positive definite.
3 In physical literature such channels are called quantum-limited.

into (12.177) and using (12.176) we obtain

$$|\mathbf{K}_2|^2 = \mathbf{K}_2^*\mathbf{K}_2 = \boldsymbol{\mu} + \frac{1}{2}\left(\mathbf{K}^*\mathbf{K} + \mathbf{I}_B\right) \geq \left\{ \begin{array}{l} \mathbf{I}_B \\ \mathbf{K}^*\mathbf{K} \end{array} \right. \tag{12.178}$$

from inequality (12.170). By using operator monotonicity of the square root (see, e. g., [31], Section V.1), we have

$$|\mathbf{K}_2| \geq \mathbf{I}_B, \quad |\mathbf{K}_2| \geq |\mathbf{K}|.$$

The first inequality (12.178) implies that choosing

$$\mathbf{K}_2 = |\mathbf{K}_2| = \sqrt{\boldsymbol{\mu} + \frac{1}{2}\left(\mathbf{K}^*\mathbf{K} + \mathbf{I}_B\right)} \tag{12.179}$$

and the corresponding $\boldsymbol{\mu}_2 = \frac{1}{2}\left(|\mathbf{K}_2|^2 - \mathbf{I}_B\right)$, we obtain the extreme amplifier $\Phi_2 : B \to B$. Then with

$$\mathbf{K}_1 = \mathbf{K}\,|\mathbf{K}_2|^{-1} \tag{12.180}$$

we obtain, taking into account the second inequality in (12.178) and Lemma 12.43,

$$\mathbf{K}_1\mathbf{K}_1^* = \mathbf{K}\,|\mathbf{K}_2|^{-2}\,\mathbf{K}^* = \mathbf{K}\left[\boldsymbol{\mu} + \frac{1}{2}\left(\mathbf{K}^*\mathbf{K} + \mathbf{I}_B\right)\right]^{-1}\mathbf{K}^* \leq \mathbf{I}_A \tag{12.181}$$

which implies $\mathbf{K}_1^*\mathbf{K}_1 \leq \mathbf{I}_B$, hence $\mathbf{K}_1$ with the corresponding $\boldsymbol{\mu}_1 = \frac{1}{2}\left(\mathbf{I}_B - \mathbf{K}_1^*\mathbf{K}_1\right)$ give the extreme attenuator.

Lemma 12.43. Let $\mathbf{M} \geq \mathbf{K}^*\mathbf{K}$. Then $\mathbf{K}\mathbf{M}^{-}\mathbf{K}^* \leq \mathbf{I}_A$, where $^-$means (generalized) inverse.
Proof. By the definition of the generalized inverse,

$$u^*\mathbf{M}^{-}u = \sup_{v \in \operatorname{Ran}\mathbf{M}, v \neq 0} \frac{|u^*v|^2}{v^*\mathbf{M}v}$$

By inserting $\mathbf{K}^*u$ in place of u and using the Cauchy-Schwarz inequality in the numerator of the fraction, we obtain

$$u^*\mathbf{K}\mathbf{M}^{-}\mathbf{K}^*u \leq u^*u \sup_{v \in \operatorname{Ran}\mathbf{M}, v \neq 0} \frac{v^*\mathbf{K}^*\mathbf{K}v}{v^*\mathbf{M}v} \leq u^*u$$

In the case of a contravariant channel the relations (12.176), (12.177) are replaced with

$$\overline{\mathbf{K}} = \mathbf{K}_1\overline{\mathbf{K}}_2, \tag{12.182}$$

$$\boldsymbol{\mu} = \mathbf{K}_2^*\overline{\boldsymbol{\mu}}_1\mathbf{K}_2 + \boldsymbol{\mu}_2. \tag{12.183}$$

By substituting

$$\boldsymbol{\mu}_1 = \frac{1}{2}\left(\mathbf{I} - \mathbf{K}_1^*\mathbf{K}_1\right), \quad \mu_2 = \frac{1}{2}\left(\mathbf{K}_2^*\mathbf{K}_2 + \mathbf{I}_B\right)$$

into (12.183) and using (12.174) we obtain

$$|\mathbf{K}_2|^2 = \mathbf{K}_2^*\mathbf{K}_2 = \boldsymbol{\mu} + \frac{1}{2}\left(\mathbf{K}^*\mathbf{K} - \mathbf{I}_B\right) \geq \mathbf{K}^*\mathbf{K} \tag{12.184}$$

Taking $\mathbf{K}_2 = |\mathbf{K}_2|, \boldsymbol{\mu}_2 = \frac{1}{2}\left(|\mathbf{K}_2|^2 + \mathbf{I}_B\right)$ gives the extreme gauge contravariant channel $\Phi_2 : B \to B$. With

$$\overline{\mathbf{K}}_1 = \mathbf{K}\,|\mathbf{K}_2|^- \tag{12.185}$$

we obtain, by using Lemma 12.43,

$$\begin{aligned}\overline{\mathbf{K}}_1\overline{\mathbf{K}}_1^* &= \mathbf{K}\left(|\mathbf{K}_2|^-\right)^2\mathbf{K}^* \\ &= \mathbf{K}\left[\boldsymbol{\mu} + \frac{1}{2}\left(\mathbf{K}^*\mathbf{K} - \mathbf{I}_B\right)\right]^-\mathbf{K}^* \leq \mathbf{I}_A,\end{aligned} \tag{12.186}$$

which implies $\mathbf{K}_1\mathbf{K}_1^* \leq \mathbf{I}_A$, so $\mathbf{K}_1$ and the corresponding $\boldsymbol{\mu}_1$ define the extreme attenuator $\Phi_1 : A \to B$. $\square$

Remark 12.44. In the case of a gauge covariant channel, the equality in (12.181) shows that $\mathbf{K}\mathbf{K}^* > 0$ implies $\mathbf{K}_1\mathbf{K}_1^* > 0$, while the inequality $\boldsymbol{\mu} > \frac{1}{2}\left(\mathbf{K}^*\mathbf{K} - \mathbf{I}_B\right)$ implies $\mathbf{K}_1\mathbf{K}_1^* < \mathbf{I}_A$. In the case of a gauge contravariant channel, the inequality $\boldsymbol{\mu} > \frac{1}{2}\left(\mathbf{I}_B + \mathbf{K}^*\mathbf{K}\right)$ implies $0 < \mathbf{K}_1\mathbf{K}_1^* < \mathbf{I}_A$ via (12.186).

Special Properties of Attenuators and Amplifiers

In this subsection we will establish several properties which will be used in the proof of the main theorem, Theorem 12.52.

Proposition 12.45. The extreme attenuator with matrix $\mathbf{K}$ and the extreme attenuator with matrix $\widetilde{\mathbf{K}} = \sqrt{\mathbf{I}_A - \mathbf{K}\mathbf{K}^*}$ are mutually complementary.

The extreme amplifier with matrix $\mathbf{K}$ and the extreme gauge contravariant channel with matrix $\widetilde{\mathbf{K}} = \sqrt{\overline{\mathbf{K}\mathbf{K}}^* - \mathbf{I}_A}$ are mutually complementary.

Proof. For the simple case of one mode, see Section 12.6.1. Below we sketch the proof for several modes, based on Remark 12.31. Namely, assume that there is a composite quantum system $AD = BE$ in the Hilbert space

$$\mathcal{H} = \mathcal{H}_A \otimes \mathcal{H}_D \simeq \mathcal{H}_B \otimes \mathcal{H}_E,$$

which is initially prepared in the state $S_A \otimes S_D$ and then evolves according to the unitary operator U. Then the output state S_B depending on the input state $S_A = S$ is

$$\Phi_B[S] = \mathrm{Tr}_E\, U\left(S \otimes S_D\right)U^*, \tag{12.187}$$

while the output state of the "environment" E is the output of the channel

$$\Phi_E[S] = \mathrm{Tr}_B\, U\left(S \otimes S_D\right)U^*. \tag{12.188}$$

We will occasionally use the notation $P_\psi = |\psi\rangle\langle\psi|$ for a density operator of pure state ($|\psi\rangle$ is a unit vector). If the initial state of D is pure, i. e., $S_D = P_{\psi_D}$, then by introducing the isometry $V : \mathcal{H}_A \to \mathcal{H}_B \otimes \mathcal{H}_D$, which acts as

$$V\psi = U\left(\psi \otimes \psi_D\right), \quad \psi \in \mathcal{H}_A,$$

we see that the relations (12.187), (12.188) convert into (6.38), and Φ_E is just the complementary of Φ_B.

Now, define $\mathbf{Z}_E \simeq \mathbf{Z}_A, \mathbf{Z}_D \simeq \mathbf{Z}_B$, so that $\mathbf{Z} = \mathbf{Z}_A \oplus \mathbf{Z}_D \simeq \mathbf{Z}_B \oplus \mathbf{Z}_E$.
In the case of an attenuator, consider the block unitary matrix in $\mathbf{Z}$,

$$\mathbf{V} = \begin{bmatrix} \mathbf{K} & \sqrt{\mathbf{I}_A - \mathbf{K}\mathbf{K}^*} \\ \sqrt{\mathbf{I}_B - \mathbf{K}^*\mathbf{K}} & -\mathbf{K}^* \end{bmatrix}, \tag{12.189}$$

which defines unitary dynamics U in $\mathcal{H} = \mathcal{H}_A \otimes \mathcal{H}_D \simeq \mathcal{H}_B \otimes \mathcal{H}_E$ by the relation $U^* D_{BE}(\mathbf{z}_{BE}) U = D_{AD}(\mathbf{V}\mathbf{z}_{BE})$. Here $\mathbf{z}_{BE} = [\mathbf{z}_B \mathbf{z}_E]^\top$, $D_{BE}(\mathbf{z}_{BE}) = D_B(\mathbf{z}_B) \otimes D_E(\mathbf{z}_E)$, and unitarity follows from the relation

$$\mathbf{K}\sqrt{\mathbf{I}_B - \mathbf{K}^*\mathbf{K}} = \sqrt{\mathbf{I}_A - \mathbf{K}\mathbf{K}^*}\mathbf{K} \tag{12.190}$$

(In general, $\mathbf{K} f(\mathbf{K}^*\mathbf{K}) = f(\mathbf{K}\mathbf{K}^*)\mathbf{K}$ for any polynomial f, and this can be extended to a continuous function f via standard approximation.)

Let $S_D = S_0$ be the vacuum state, and let $S_A = S$ an arbitrary state. Then formulas (12.187), (12.188) define the mutually complementary extreme attenuators as described in the first statement. The proof is obtained by computing the characteristic function of the output states for the channels. For the state of the composite system $S_{BE} = U(S \otimes S_D)U^*$ we have

$$\begin{aligned}
\phi_{BE}(\mathbf{z}_{BE}) &= \operatorname{Tr} U(S \otimes S_D) U^* [D_B(\mathbf{z}_B) \otimes D_E(\mathbf{z}_E)] \\
&= \operatorname{Tr} (S \otimes S_D) U^* [D_B(\mathbf{z}_B) \otimes D_E(\mathbf{z}_E)] U \\
&= \operatorname{Tr} (S \otimes S_D) \left[D_A\left(\mathbf{K}\mathbf{z}_B + \widetilde{\mathbf{K}}\mathbf{z}_E\right) \otimes D_D\left(\sqrt{\mathbf{I}_B - \mathbf{K}^*\mathbf{K}}\mathbf{z}_B - \mathbf{K}^*\mathbf{z}_E\right)\right] \\
&= \phi_A\left(\mathbf{K}\mathbf{z}_B + \widetilde{\mathbf{K}}\mathbf{z}_E\right) \exp\left[-\frac{1}{2}\left|\sqrt{\mathbf{I}_B - \mathbf{K}^*\mathbf{K}}\mathbf{z}_B - \mathbf{K}^*\mathbf{z}_E\right|^2\right].
\end{aligned} \tag{12.191}$$

By setting $\mathbf{z}_E = 0$ or $\mathbf{z}_B = 0$ we obtain

$$\begin{aligned}
\phi_B(\mathbf{z}_B) &= \phi_A(\mathbf{K}\mathbf{z}_B) \exp\left[-\frac{1}{2}\mathbf{z}_B^*(\mathbf{I}_B - \mathbf{K}^*\mathbf{K})\mathbf{z}_B\right] \\
\phi_E(\mathbf{z}_E) &= \phi_A\left(\widetilde{\mathbf{K}}\mathbf{z}_E\right) \exp\left[-\frac{1}{2}\mathbf{z}_E^*\mathbf{K}\mathbf{K}^*\mathbf{z}_E\right]
\end{aligned}$$

as required.

In the case of an amplifier, set

$$\mathbf{V} = \begin{bmatrix} \mathbf{K} & -\sqrt{\mathbf{K}\mathbf{K}^* - \mathbf{I}_A}\Lambda_A \\ -\Lambda_B\sqrt{\mathbf{K}^*\mathbf{K} - \mathbf{I}_B} & \Lambda_B\mathbf{K}^*\Lambda_A \end{bmatrix}$$

where Λ is the operator of complex conjugation in the corresponding complex subspace, anticommuting with multiplication by i. By using the property $\Delta(\Lambda z, \Lambda z') = -\Delta(z, z')$, we obtain that $\mathbf{V}$ corresponds to a symplectic transformation in $\mathbf{Z}$ generating unitary dynamics U in $\mathcal{H}$.

Exercise 12.46 Check the identity

$$\Delta_{BE}(\mathbf{V}\mathbf{z}_{BE}, \mathbf{V}\mathbf{z}'_{BE}) = \Delta_{BE}(\mathbf{z}_{BE}, \mathbf{z}'_{BE}),$$

where

$$\Delta_{BE}(\mathbf{z}_{BE}, \mathbf{z}'_{BE}) \equiv \Delta_B(z_B, z'_B) + \Delta_E(z_E, z'_E).$$

Let again $S_D = S_0$ be the vacuum state of the environment. Then formulas (12.187), (12.188) define the mutually complementary channels as described in the second statement of the proposition, and the proof is similar. □

In general, we will say that two density operators S and $\widetilde{S}$ (possibly acting in different Hilbert spaces) are isometrically equivalent if there is a partial isometry W such that $S = W\widetilde{S}W^*, \widetilde{S} = W^*SW$. Apparently, this is the case if and only if nonzero spectra (counting multiplicity) of the density operators S and $\widetilde{S}$ coincide. We denote this fact with the notation $S \sim \widetilde{S}$.

Lemma 12.47. Let $\Phi, \widetilde{\Phi}$ be mutually complementary channels. Then $\Phi[P_\psi] \sim \widetilde{\Phi}[P_\psi]$ for all $\psi \in \mathcal{H}_A$.

Proof. Let $V : \mathcal{H}_A \to \mathcal{H}_B \otimes \mathcal{H}_E$ be the isometry from the representations of complementary channels (6.38). Then $S_{BE} = VP_\psi V^*$ is a pure state in $\mathcal{H}_B \otimes \mathcal{H}_E$, and the statement follows from Theorem 3.10 (the "Schmidt decomposition"): if S_{BE} is a pure state in $\mathcal{H}_B \otimes \mathcal{H}_E$ and $S_B = \operatorname{Tr}_E S_{BE}, S_E = \operatorname{Tr}_B S_{BE}$ are its partial states, then S_B, S_E have identical nonzero eigenvalues, i. e., $S_B \sim S_E$. $\square$

Lemma 12.48. Let $\Phi_1 : A \to B$ be an extreme attenuator with $\mathbf{0} < \mathbf{K}_1\mathbf{K}_1^* < \mathbf{I}_A$. Then $\Phi_1[P_\psi] = P_{\psi'}$ (a pure state) if and only if P_ψ is a coherent state.

Proof. According to Proposition 12.45, the complementary channel $\widetilde{\Phi}_1$ is an extreme attenuator with the matrix $\widetilde{\mathbf{K}} = \sqrt{\mathbf{I}_A - \mathbf{K}_1\mathbf{K}_1^*}$, such that $\mathbf{0} < \widetilde{\mathbf{K}} < \mathbf{I}_A$. Its output is also pure, $\widetilde{\Phi}_1[P_\psi] = P_{\psi'_E}$, as the outputs of complementary channels have identical nonzero spectra by Lemma 12.47. Thus

$$U(\psi \otimes \psi_0) = \psi' \otimes \psi'_E,$$

where $\psi_0 \in \mathcal{H}_D$ is the vacuum vector and U is the unitary operator in $\mathcal{H}$ implementing the symplectic transformation corresponding to the unitary (12.189) in $\mathbf{Z}_A \oplus \mathbf{Z}_D \simeq \mathbf{Z}_B \oplus \mathbf{Z}_E$, with $\mathbf{Z}_D \simeq \mathbf{Z}_B, \mathbf{Z}_E \simeq \mathbf{Z}_A$. Denoting by

$$\phi(\mathbf{z}) = \operatorname{Tr} P_\psi D_A(\mathbf{z}), \quad \phi'(\mathbf{z}_B) = \operatorname{Tr} P_{\psi'} D_B(\mathbf{z}_B), \quad \phi_E(\mathbf{z}_E) = \operatorname{Tr} P_{\psi'_E} D_E(\mathbf{z}_E)$$

the quantum characteristic functions and using the relation (12.191), we have the functional equation

$$\phi'(\mathbf{z}_B)\,\phi_E(\mathbf{z}_E) = \phi\left(\mathbf{K}_1\mathbf{z}_B + \widetilde{\mathbf{K}}\mathbf{z}_E\right) \exp\left[-\frac{1}{2}\left|\sqrt{\mathbf{I}_B - \mathbf{K}_1^*\mathbf{K}_1}\mathbf{z}_B - \mathbf{K}_1^*\mathbf{z}_E\right|^2\right]. \tag{12.192}$$

By letting $\mathbf{z}_E = 0$ or $\mathbf{z}_B = 0$, we obtain, respectively,

$$\phi'(\mathbf{z}_B) = \phi(\mathbf{K}_1\mathbf{z}_B) \exp\left[-\frac{1}{2}\left|\sqrt{\mathbf{I}_B - \mathbf{K}_1^*\mathbf{K}_1}\mathbf{z}_B\right|^2\right],$$
$$\phi_E(\mathbf{z}_E) = \phi\left(\widetilde{\mathbf{K}}\mathbf{z}_E\right) \exp\left[-\frac{1}{2}\left|\mathbf{K}_1^*\mathbf{z}_E\right|^2\right],$$

thus, after the change of variables $\mathbf{z} = \mathbf{K}_1\mathbf{z}_B, \mathbf{z}' = \widetilde{\mathbf{K}}\mathbf{z}_E$, and using (12.190), equation (12.192) reduces to

$$\phi(\mathbf{z})\phi(\mathbf{z}') = \phi(\mathbf{z} + \mathbf{z}') \exp[\operatorname{Re} \mathbf{z}^*\mathbf{z}']$$

The condition of the lemma ensures that $\operatorname{Ran} \mathbf{K}_1 = \operatorname{Ran} \widetilde{\mathbf{K}} = \mathbf{Z}_A$. Substituting $\omega(\mathbf{z}) = \phi(\mathbf{z}) \exp\left[\frac{1}{2}|\mathbf{z}|^2\right]$, the last equation becomes

$$\omega(\mathbf{z})\omega(\mathbf{z}') = \omega(\mathbf{z} + \mathbf{z}') \tag{12.193}$$

for all $\mathbf{z}, \mathbf{z}' \in \mathbf{Z}_A$. The function $\omega(\mathbf{z})$, as well as the characteristic function $\phi(\mathbf{z})$, is continuous and satisfies $\omega(-\mathbf{z}) = \overline{\omega(\mathbf{z})}$. The only solution of (12.193) satisfying these conditions is the exponent $\omega(\mathbf{z}) = \exp[i \operatorname{Im} \mathbf{w}^*\mathbf{z}]$ for some complex $\mathbf{w}$. Thus

$$\phi(\mathbf{z}) = \exp\left[i \operatorname{Im} \mathbf{w}^*\mathbf{z} - \frac{1}{2}|\mathbf{z}|^2\right]$$

is the characteristic function of the coherent state $S_{\mathbf{w}/2}$.
For a natural number n we denote by $\mathfrak{L}_n$ the finite-dimensional subspace spanned by the eigenvectors of the total number operator

$$\mathcal{N} = \sum_{j=1}^{s} a_j^\dagger a_j$$

corresponding to all its eigenvalues $\leq n$. We also denote by $\mathfrak{P}_n$ the subspace of finiterank Hermitian operators supported by $\mathfrak{L}_n$.

Lemma 12.49. An extreme attenuator $\Phi : A \to A$ leaves the subspace $\mathfrak{P}_n$ invariant.
Proof. (sketch) We will consider the case $s = 1$, which clearly demonstrates the idea of the proof avoiding somewhat cumbersome multiindex notations. The operators $S \in \mathfrak{P}_n$ can be characterized by the equation $a^{n+1}S = 0$, where a is the annihilation operator of the mode. By using Lemma 5.4.3 in [122] we obtain the characteristic function of the operator aS, i.e.,

$$\phi_{aS}(z) = \mathrm{e}^{-|z|^2/2} \left(\frac{d}{dz}\right) \mathrm{e}^{|z|^2/2} \phi_S(z)$$

where $\frac{d}{dz} = \frac{1}{\sqrt{2}} \left(\frac{d}{dx} - i\frac{d}{dy}\right)$. Thus $S \in \mathfrak{P}_n$ is equivalent to the fact that $\mathrm{e}^{|z|^2/2}\phi_S(z)$ is a polynomial in z of the degree $\leq n$. By using the equation of the extreme attenuator

$$\Phi^*[D(z)] = D(kz) \exp\left(-\frac{1-k^2}{2}|z|^2\right), \quad 0 < k < 1,$$

we obtain

$$\mathrm{e}^{|z|^2/2}\phi_{\Phi[S]}(z) = \mathrm{e}^{|kz|^2/2}\phi_S(kz).$$

Thus, if $S \in \mathfrak{P}_n$, then $\mathrm{e}^{|z|^2/2}\phi_S(z)$ is a polynomial in z of the degree $\leq n$, and the righthand side of this equality and hence also the left-hand side are as well. □

Gaussian Optimizers

Denote by $\mathfrak{F}$ the class of real concave functions f on $[0, 1]$, such that $f(0) = 0$. For any $f \in \mathfrak{F}$ and for any density operator S we can consider the quantity

$$\operatorname{Tr} f(S) = \sum_j f(\lambda_j),$$

where λ_j are the (nonzero) eigenvalues of the density operator S, counting multiplicity. Note that this quantity is defined unambiguously with values in $(-\infty, \infty]$. This follows from the fact that $f(x) \geq cx$, where $c = f(1)$, hence $\operatorname{Tr} f(S) \geq c \operatorname{Tr} S = c$. We also will use the fact that the functional $S \to \operatorname{Tr} f(S)$ is (strictly) concave on $\mathfrak{S}(\mathcal{H})$ if f is (strictly) concave (see, e. g., [40]).

Denote by $\lambda_j^\downarrow(S)$ the eigenvalues of a density operator S, counting multiplicity, arranged in nonincreasing order. One says that the density operator S majorizes the density operator S' if

$$\sum_{j=1}^{k} \lambda_j^\downarrow(S) \geq \sum_{j=1}^{k} \lambda_j^\downarrow(S'), \quad k = 1, 2, \ldots$$

A consequence of a well-known result (see, e. g., [40]) is that this is the case if and only if $\operatorname{Tr} f(S) \leq \operatorname{Tr} f(S')$ for all $f \in \mathfrak{F}$.

Moreover, the functional $\operatorname{Tr} f(S)$ is lower semicontinuous in the trace norm distance. In fact, for arbitrary concave f on $[0, 1]$ there is a monotonously nondecreasing sequence of

concave polygonal functions f_m converging to f pointwise. Any such function is Lipschitz, $|f_m(x) - f_m(y)| \le x_m|x-y|$, hence the corresponding functional $\operatorname{Tr} f_m(S)$ is continuous.

Lemma 12.50. Let $|f(x) - f(y)| \le x|x-y|$ for $x, y \in [0,1]$. Then for any density operators S, S'

$$|\operatorname{Tr} f(S') - \operatorname{Tr} f(S)| \le \varkappa \|S' - S\|_1 .$$

Proof. Let $\lambda_1 \ge \lambda_2 \ge \cdots (\mu_1 \ge \mu_2 \ge \cdots)$ be the eigenvalues of S' (correspondingly, S). By Mirsky's theorem (Lemma IV.3.2 in [31])

$$\sum_i |\lambda_i - \mu_i| \le \|S' - S\|_1 .$$

Therefore

$$|\operatorname{Tr} f(S') - \operatorname{Tr} f(S)| \le \sum_i |f(\lambda_i) - f(\mu_i)| \le \varkappa \sum_i |\lambda_i - \mu_i| \le \varkappa \|S' - S\|_1 .$$

□

Then $\operatorname{Tr} f(S)$ is a pointwise limit of monotonously nondecreasing sequence of continuous functionals $\operatorname{Tr} f_m(S)$ and hence is lower semicontinuous. Thus the Jensen inequality

$$\operatorname{Tr} f\left(\sum_j p_j S_j\right) \ge \sum_j p_j \operatorname{Tr} f(S_j) \tag{12.194}$$

holds not only for finite but also for countable convex decompositions.

For a quantum channel Φ we introduce the quantity

$$\check{f}(\Phi) = \inf_{S \in \mathfrak{S}(\mathcal{H})} \operatorname{Tr} f(\Phi[S]) = \inf_{P_\psi \in \mathfrak{P}(\mathcal{H})} \operatorname{Tr} f(\Phi[P_\psi]) , \tag{12.195}$$

where the second equality follows from the concavity of the functional $S \to \operatorname{Tr} f(\Phi[S])$ on the convex set $\mathfrak{S}(\mathcal{H})$. Moreover, for strictly concave f, any minimizer is of the form P_ψ for some vector $\psi \in \mathcal{H}$.

In particular, taking $f(x) = -x \log x$ we obtain $\check{f}(\Phi) = \check{H}(\Phi)$.

Lemma 12.51. If $\Phi, \widetilde{\Phi}$ are complementary channels, then $\check{f}(\Phi) = \check{f}(\widetilde{\Phi})$.

Proof. From Lemma 12.47, $\Phi[P_\psi]$ and $\widetilde{\Phi}[P_\psi]$ have identical nonzero spectra ($\Phi[P_\psi] \sim \widetilde{\Phi}[P_\psi]$). Then

$$\operatorname{Tr} f(\Phi[P_\psi]) = \operatorname{Tr} f\left(\widetilde{\Phi}[P_\psi]\right) \tag{12.196}$$

since $f(0) = 0$. The second equality in (12.195) implies $\check{f}(\Phi) = \check{f}(\widetilde{\Phi})$. □

Theorem 12.52. (i) Let Φ be a gauge covariant or contravariant channel and let f be a real concave function on $[0,1]$, such that $f(0) = 0$. Then

$$\operatorname{Tr} f(\Phi[S]) \ge \operatorname{Tr} f(\Phi[S_{\mathbf{w}}]) = \operatorname{Tr} f(\Phi[S_0]) \tag{12.197}$$

for all states S and any coherent state $S_{\mathbf{w}}$ (the value on the right is the same for all coherent states by the unitary covariance property of a Gaussian channel (12.140)).

(ii) Let f be strictly concave. Then equality in (12.197) is attained only if S is a coherent state in the following cases:

(a) $s_B = s_A$ and Φ is an extreme amplifier with $\boldsymbol{\mu} = \frac{1}{2}(\mathbf{K}^*\mathbf{K} - \mathbf{I}_B) > 0$;

(b) $s_B \ge s_A$, the channel Φ is gauge covariant with $\mathbf{K}\mathbf{K}^* > 0$, and

$$\boldsymbol{\mu} > \frac{1}{2}(\mathbf{K}^*\mathbf{K} - \mathbf{I}_B) ; \tag{12.198}$$

(c) $s_B \geq s_A$, the channel Φ is gauge contravariant with $\mathbf{K}\mathbf{K}^* > 0$, and $\boldsymbol{\mu} > \frac{1}{2}(\mathbf{I}_B + \mathbf{K}^*\mathbf{K})$.

Proof. (i) We first prove inequality (12.197) for strictly concave f. Then the inequality for arbitrary concave f follows by the monotone approximation $f(x) = \lim_{\varepsilon \downarrow 0} f_\varepsilon(x)$, since $f_\varepsilon(x) = f(x) - \varepsilon x^2$ are strictly concave. Also, by concavity, it is sufficient to prove (12.197) only for $S = P_\psi$.

By Proposition 12.42, $\Phi = \Phi_2 \circ \Phi_1$, where $\Phi_1 : A \to B$ is an extreme attenuator and $\Phi_2 : B \to B$ is either an extreme amplifier or an extreme gauge contravariant channel. Any extreme attenuator maps a vacuum state into vacuum. Indeed,

$$\begin{aligned}\operatorname{Tr}\Phi_1[S_0]\, D_B(\mathbf{z}) &= \operatorname{Tr} S_0 \Phi_1^*[D_B(\mathbf{z})] \\ &= \operatorname{Tr} S_0 D_A(\mathbf{K}\mathbf{z}) \exp\left(-\frac{1}{2}\mathbf{z}^*(\mathbf{I}_B - \mathbf{K}^*\mathbf{K})\,\mathbf{z}\right) \\ &= \exp\left(-\frac{1}{2}|\mathbf{z}|^2\right) = \operatorname{Tr} S_0 D_B(\mathbf{z})\end{aligned}$$

and therefore, $\operatorname{Tr} f(\Phi[S_0]) = \operatorname{Tr} f(\Phi_2[S_0])$. Then it is sufficient to prove (12.197) for all extreme amplifiers and all extreme gauge contravariant channels Φ_2. Indeed, assume that we have proved

$$\operatorname{Tr} f(\Phi_2[P_\psi]) \geq \operatorname{Tr} f(\Phi_2[S_0]) \tag{12.199}$$

for any state vector ψ. Consider the spectral decomposition $\Phi_1[P_\psi] = \sum_j p_j P_{\phi_j}$, where $p_j > 0$. Then

$$\begin{aligned}\operatorname{Tr} f(\Phi[P_\psi]) &= \operatorname{Tr} f(\Phi_2[\Phi_1[P_\psi]]) && (12.200)\\ &\geq \sum_j p_j \operatorname{Tr} f\left(\Phi_2\left[P_{\phi_j}\right]\right) && (12.201)\\ &\geq \operatorname{Tr} f(\Phi_2[S_0]) && (12.202)\\ &= \operatorname{Tr} f(\Phi_2[\Phi_1[S_0]]) = \operatorname{Tr} f(\Phi[S_0]) && (12.203)\end{aligned}$$

Then, according to the second statement of Proposition 12.45 and Lemma 12.47,

$$\operatorname{Tr} f(\Phi_2[P_\psi]) = \operatorname{Tr} f\left(\widetilde{\Phi}_2[P_\psi]\right),$$

where Φ_2 is an extreme amplifier and $\widetilde{\Phi}_2$ is an extreme gauge contravariant channel. Thus it is sufficient to prove (12.199) only for an extreme amplifier $\Phi_2 : B \to B$, with Hermitian matrix $\mathbf{K}_2 \geq \mathbf{I}_B$.

Lemma 12.53. For an extreme amplifier $\Phi_2 : B \to B$, with matrix $\mathbf{K}_2 \geq \mathbf{I}_B$, there is an extreme attenuator Φ_1' such that for all $\psi \in \mathcal{H}_B$

$$\Phi_2(P_\psi) \sim (\Phi_2 \circ \Phi_1')(P_\psi). \tag{12.204}$$

If $\mathbf{K}_2 > \mathbf{I}_B$, then the attenuator satisfies the conditions of Lemma 12.48.

Proof. By Proposition 12.45 and Lemma 12.47, $\Phi_2(P_\psi) \sim \widetilde{\Phi}_2(P_\psi)$ for all $\psi \in \mathcal{H}_B$, where $\widetilde{\Phi}_2$ is an extreme gauge contravariant channel with the matrix $\widetilde{\mathbf{K}} = \sqrt{\overline{\mathbf{K}}_2^2 - \mathbf{I}_B}$.

Define the transposition map $\mathcal{T} : B \to B$ by the relation $\mathcal{T}[D(\mathbf{z})] = D(-\overline{\mathbf{z}})$. The concatenation $\Phi = \mathcal{T} \circ \widetilde{\Phi}_2$ is a gauge covariant Gaussian channel, i. e.,

$$\Phi^*[D(\mathbf{z})] = \widetilde{\Phi}_2^* \circ \mathcal{T}[D(\mathbf{z})] = D\left(\sqrt{\mathbf{K}_2^2 - \mathbf{I}_B}\mathbf{z}\right) \exp\left(-\frac{1}{2}\mathbf{z}^*\mathbf{K}_2^2\mathbf{z}\right),$$

and $\Phi(P_\psi) \sim \widetilde{\Phi}_2(P_\psi)$ since transposition preserves the spectrum. Applying decomposition from Proposition 12.42, namely, the relation (12.178), gives $\Phi = \Phi_2 \circ \Phi_1'$, where Φ_2 is the original amplifier, and $\Phi_1' : B \to B$ is another extreme attenuator with matrix $\mathbf{K}_1 = \sqrt{\mathbf{I}_B - \mathbf{K}_2^{-2}}$. This implies the relation (12.204). Also $\mathbf{K}_2 > \mathbf{I}_B$ implies $0 < \mathbf{K}_1\mathbf{K}_1^* < \mathbf{I}_B$. $\square$

Lemma 12.53 and Lemma 12.51 imply

$$\operatorname{Tr} f(\Phi_2(P_\psi)) = \operatorname{Tr} f((\Phi_2 \circ \Phi_1')(P_\psi)) \tag{12.205}$$

At this point we fix a natural number n and restrict to $\psi \in \mathfrak{L}_n$, the finite-dimensional subspace spanned by the eigenvectors of the total number operator $\mathcal{N}$ corresponding to eigenvalues $\leq n$. According to Lemma 12.49, the attenuator Φ_1' maps P_ψ into a density operator supported by $\mathfrak{L}_n$. Therefore, in its spectral decomposition

$$\Phi_1'(P_\psi) = \sum_j p_j' P_{\psi_j}, \quad p_j' > 0$$

we must have $\psi_j \in \mathfrak{L}_n$. By concavity,

$$\operatorname{Tr} f((\Phi_2 \circ \Phi_1')[P_\psi]) \geq \sum_j p_j' \operatorname{Tr} f\left(\Phi_2\left[P_{\psi_j}\right]\right) \tag{12.206}$$

Since f is assumed strictly concave, $S \to \operatorname{Tr} f(\Phi_2[S])$ is strictly concave [40] (the amplifier Φ_2 is injective by Lemma 12.41). Also, this functional is lower semicontinuous and therefore attains the minimum on the finite-dimensional set of density operators supported by $\mathfrak{L}_n$. Assuming that P_ψ is such a minimizer for the functional (12.205), we conclude that $\Phi_2\left[P_{\psi_j}\right]$ must all coincide, otherwise the above inequality would be strict, contradicting the assumption. From Lemma 12.41 it follows that $P_{\psi_j} = P_{\psi'}$ for all j and for some $\psi' \in \mathcal{H}_B$, and hence, assuming that P_ψ is a minimizer, the output $\Phi_1[P_\psi] = P_{\psi'}$ is a pure state.

Since $\mathbf{K}_1 = \sqrt{\mathbf{I}_B - \mathbf{K}_2^{-2}}$, the condition of Lemma 12.48 is fulfilled when $\mathbf{K}_2 > \mathbf{I}_B$. In this case, if P_ψ is a minimizer, the lemma implies that P_ψ is a coherent state. In fact, since $\psi \in \mathfrak{L}_n$, it has to be the vacuum state S_0. Thus we obtain inequality (12.199) for the amplifier Φ_2 with $\mathbf{K}_2 > \mathbf{I}_B$ and strictly concave f, provided $\psi \in \mathfrak{L}_n$. By standard approximation, this fact is extended to concave f, including all concave polygonal functions. For such functions Lemma 12.50 implies continuity of the functional in question. Then arbitrary $\psi \in \mathcal{H}$ can be approximated in the norm by a sequence $\psi_n \in \mathfrak{L}_n, n \to \infty$, and using this continuity, we arrive at (12.199) for polygonal functions and all $\psi \in \mathcal{H}$. By using the monotone approximation by polygonal functions, we finally obtain (12.199) for all concave functions f satisfying $f(0) = 0$.

In the case of an amplifier Φ_2 with $\mathbf{K}_2 \geq \mathbf{I}_B$, we can take any sequence $\mathbf{K}_2^{(n)} > \mathbf{I}_B$, $\mathbf{K}_2^{(n)} \to \mathbf{K}_2$, and the corresponding amplifiers $\Phi_2^{(n)}$. Then $\operatorname{Tr} f\left(\Phi_2^{(n)}[S]\right) \to \operatorname{Tr} f(\Phi_2[S])$ for any concave polygonal function f on $[0,1]$, such that $f(0) = 0$, and any $S \in \mathfrak{S}(\mathcal{H}_B)$ by Lemma 12.50. This follows from the fact that any such function is Lipschitz, $|f(x) - f(y)| \leq \varkappa |x - y|$, and $\left\|\Phi_2^{(n)}[S] - \Phi_2[S]\right\|_1 \to 0$. It follows that (12.199) holds for all extreme amplifiers Φ_2 in the case of polygonal concave functions f. For arbitrary concave f on $[0,1]$ there is a monotonously nondecreasing sequence of concave polygonal functions f_m converging to f pointwise. Passing to the limit $m \to \infty$ gives inequality (12.199) for an arbitrary extreme amplifier, and hence, (12.197) holds for arbitrary Gaussian gauge covariant or contravariant channels.

(ii) Let f be strictly concave. Repeating the argument after equation (12.206) for the case $\mathbf{K}_2 > \mathbf{I}_B$ and $\psi \in \mathcal{H}_A$, we obtain case (a).

The "only if" statement in cases (b) and (c) are obtained from the decomposition $\Phi = \Phi_2 \circ \Phi_1$ and the relations (12.200)-(12.202). Note that the conditions on the channel Φ imply that in the decomposition $\Phi = \Phi_2 \circ \Phi_1$ the attenuator Φ_1 is defined by the matrix $\mathbf{K}_1$ such that

$0 < \mathbf{K}_1\mathbf{K}_1^* < \mathbf{I}_A$ (see Remark 12.44). Applying the argument involving (12.205) with strictly concave f to the relations (12.200)-(12.203), we obtain that for any pure minimizer P_ψ of $\operatorname{Tr} f(\Phi[P_\psi])$ the output of the extremal attenuator $\Phi_1[P_\psi]$ is necessarily a pure state. Applying Lemma 12.48 to the attenuator Φ_1 we conclude that P_ψ is necessarily a coherent state. □

Explicit Formulas and Additivity

As an immediate corollary of Theorem 12.52 we obtain the following.

Corollary 12.54. For any Gaussian gauge covariant or contravariant channel Φ,

$$\check{H}(\Phi) = H(\Phi[S_0]) = \operatorname{Sp} g(\boldsymbol{\mu} + (\mathbf{K}^*\mathbf{K} - \mathbf{I}_B)/2), \tag{12.207}$$

where S_0 is the vacuum state.

For any two Gaussian gauge covariant (contravariant) channels Φ_1 and Φ_2 the additivity (8.33) of the minimal von Neumann entropy holds.

Proof. The first equality in (12.207) follows from Theorem 12.52 by taking $f(x) = -x\log x$.

From the definitions of gauge covariant/contravariant channels (12.169), (12.173), it follows that the state $\Phi[S_0]$ is gauge invariant Gaussian with the correlation matrix $\boldsymbol{\mu} + \mathbf{K}^*\mathbf{K}/2$, and hence, by using formula (12.109) for the entropy, we obtain

$$\check{H}(\Phi) = \operatorname{Sp} g(\boldsymbol{\mu} + (\mathbf{K}^*\mathbf{K} - \mathbf{I}_B)/2). \tag{12.208}$$

If Φ_1 and Φ_2 are both gauge covariant (contravariant), then their tensor product $\Phi_1 \otimes \Phi_2$ shares this property. The second statement then follows from the expressions (12.207) and the product property of the vacuum state $S_0 = S_0^{(1)} \otimes S_0^{(2)}$, which follows from the definition. □

We now turn to the classical capacity of the channel Φ. We refer to Section 11.5 for all relevant general definitions and results in infinite dimensions. The constrained classical capacity is given by the expression

$$C(\Phi, F, E) = \lim_{n\to\infty} \frac{1}{n} C_\chi\left(\Phi^{\otimes n}, F^{(n)}, nE\right), \tag{12.209}$$

where $C_\chi\left(\Phi^{\otimes n}, F^{(n)}, nE\right)$ is the constrained χ-capacity, F is the constraint operator, and $F^{(n)} = F \otimes I \cdots \otimes I + \cdots + I \otimes \cdots \otimes I \otimes F$.

Let Φ be a Gaussian gauge covariant channel, and consider a gauge invariant oscillator energy operator

$$F = \sum_{j,k=1}^{s_A} \epsilon_{jk} a_j^\dagger a_k, \tag{12.210}$$

where $\boldsymbol{\epsilon} = [\epsilon_{jk}]$ is a Hermitian positive definite matrix, $a_j = \frac{1}{\sqrt{2}}(q_j + ip_j)$ - the annihilation operator for the j th mode. For any state S satisfying $\operatorname{Tr} SF < \infty$, the first moments $\operatorname{Tr} Sa_j$ and the second moments $\operatorname{Tr} Sa_j^\dagger a_k, \operatorname{Tr} Sa_j a_k$ are well-defined. For a Gaussian gauge invariant state (12.97) we have $\operatorname{Tr} Sa_j = 0$ and $\operatorname{Tr} Sa_j a_k = 0$, while (see (12.98))

$$\boldsymbol{\alpha} - \mathbf{I}/2 = \left[\operatorname{Tr} a_j S a_k^\dagger\right]_{j,k=1,\ldots,s}.$$

For this choice of the channel and the constraint, the conditions of Corollary 11.24 are fulfilled, and the χ-capacity is in general given by the relation (11.38).

Theorem 12.55. The constrained classical capacity of the Gaussian gauge covariant channel Φ is

$$
\begin{aligned}
C(\Phi;F,E) =& C_\chi(\Phi;F,E)\\
=& \max_{\boldsymbol{v}:\mathrm{Sp}\,\boldsymbol{v}\boldsymbol{\epsilon}\le E} \mathrm{Spg}\left(\mathbf{K}^*\boldsymbol{v}\mathbf{K}+\boldsymbol{\mu}+\left(\mathbf{K}^*\mathbf{K}-\mathbf{I}_B\right)/2\right)\\
&-\mathrm{Spg}\left(\boldsymbol{\mu}+\left(\mathbf{K}^*\mathbf{K}-\mathbf{I}_B\right)/2\right). \qquad (12.211)
\end{aligned}
$$

The optimal ensemble π which attains the maximum in (11.38) consists of coherent states $S_{\mathbf{z}}=D_A(\mathbf{z})S_0D_A(\mathbf{z})^*, \mathbf{z}\in\mathbf{Z}_A$, distributed with gauge invariant Gaussian probability distribution $Q_{\boldsymbol{v}}\left(d^{2s}z\right)$ on $\mathbf{Z}_A$ having zero mean and the correlation matrix $\boldsymbol{v}$ which solves the maximization problem in (12.211).

Proof. Consider a Gaussian ensemble $\pi_{\boldsymbol{v}}$ consisting of coherent states $S_{\mathbf{z}}=D_A(\mathbf{z})\times S_0D_A(\mathbf{z})^*, \mathbf{z}\in\mathbf{Z}_A$, with gauge invariant Gaussian probability distribution $Q_{\boldsymbol{v}}\left(d^{2s}z\right)$ on $\mathbf{Z}_A$ having zero mean and some correlation matrix $\boldsymbol{v}$. It is defined by the classical characteristic function

$$
\int_{\mathbf{Z}_A}\exp\left(2i\,\mathrm{Im}\,\mathbf{w}^*\mathbf{z}\right)Q_{\boldsymbol{v}}\left(d^{2s}w\right)=\exp\left(-\mathbf{z}^*\mathbf{v}\mathbf{z}\right).
$$

By using the covariance property (12.140) of Gaussian channels, we have

$$
H\left(\Phi\left[S_{\mathbf{z}}\right]\right)=H\left(\Phi\left[D_A(\mathbf{z})S_{\mathbf{0}}D_A(\mathbf{z})^*\right]\right)=H\left(\Phi\left[S_0\right]\right)=\mathrm{Spg}\left(\boldsymbol{\mu}+\left(\mathbf{K}^*\mathbf{K}-\mathbf{I}_B\right)/2\right),
$$

which does not depend on $\mathbf{z}$, and hence it gives the value of the integral term in (11.35). Integration of the characteristic functions of the coherent states gives for the average state of the ensemble (cf. (12.100))

$$
\mathrm{Tr}\,\bar{S}_{\pi_v}D_A(\mathbf{z})=\exp\left(-\mathbf{z}^*\left(\boldsymbol{v}+\mathbf{I}_A/2\right)\mathbf{z}\right).
$$

Then $\boldsymbol{v}=\left[\mathrm{Tr}\,a_j\bar{S}_{\pi_v}a_k^\dagger\right]_{j,k=1,\ldots,S_A}$ (see (12.98)), and

$$
\mathrm{Tr}\,\bar{S}_{\pi_v}F=\sum_{j,k=1}^{s_A}\epsilon_{jk}\,\mathrm{Tr}\,\bar{S}_{\pi_v}a_j^\dagger a_k=\mathrm{Sp}\,\boldsymbol{\epsilon}\boldsymbol{v}^\top=\mathrm{Sp}\,\boldsymbol{v}\boldsymbol{\epsilon},
$$

where we used $\boldsymbol{\epsilon}^\top=\boldsymbol{\epsilon}$. The state $\Phi\left[\bar{S}_{\pi_v}\right]$ is gauge invariant Gaussian with the correlation matrix

$$
\mathbf{K}^*\left(\boldsymbol{v}+\mathbf{I}_A/2\right)\mathbf{K}+\boldsymbol{\mu},
$$

hence it has the entropy

$$
\mathrm{Sp}\,g\left(\mathbf{K}^*\boldsymbol{v}\mathbf{K}+\boldsymbol{\mu}+\left(\mathbf{K}^*\mathbf{K}-\mathbf{I}_B\right)/2\right).
$$

Thus for the Gaussian ensemble π_v

$$
\chi\left(\pi_{\boldsymbol{v}}\right)=\mathrm{Sp}\,g\left(\mathbf{K}^*\boldsymbol{v}\mathbf{K}+\boldsymbol{\mu}+\left(\mathbf{K}^*\mathbf{K}-\mathbf{I}_B\right)/2\right)-\mathrm{Spg}\left(\boldsymbol{\mu}+\left(\mathbf{K}^*\mathbf{K}-\mathbf{I}_B\right)/2\right). \qquad (12.212)
$$

Summarizing, we need to show

$$
C(\Phi;F,E)=C_\chi(\Phi;F,E)=\sup_{v:\mathrm{Sp}\,v\in\le E}\chi\left(\pi_v\right). \qquad (12.213)
$$

Let us denote by $\mathcal{G}$ the set of Gaussian gauge invariant states in $\mathcal{H}_A$.

Lemma 12.56. Let Φ be a Gaussian gauge covariant channel and the constraint operator F is given by (12.210). Then

$$\max_{S^{(n)}:\mathrm{Tr}\, S^{(n)}F^{(n)}\le nE} H\left(\Phi^{\otimes n}\left[S^{(n)}\right]\right) \le n \max_{S:S\in\mathcal{G},\mathrm{Tr}\, SF\le E} H(\Phi[S]). \tag{12.214}$$

Proof. We first note that Lemma 11.20 implies

$$\sup_{S^{(n)}:\mathrm{Tr}\, S^{(n)}F^{(n)}\le nE} H\left(\Phi^{\otimes n}\left[S^{(n)}\right]\right) \le n \sup_{S:\mathrm{Tr}\, SF\le E} H(\Phi[S]). \tag{12.215}$$

By using gauge covariance of the channel Φ, we can then reduce maximization in the right-hand side of (12.215) to gauge invariant states. Indeed, for a given state S, satisfying the constraint $\mathrm{Tr}\, SF \le E$, the averaging

$$S_{av} = \frac{1}{2\pi}\int_0^{2\pi} U_\phi S U_\phi^* d\phi$$

also satisfies the constraint, while $H(\Phi[S]) \le H\left(\Phi\left[S_{av}\right]\right)$ by concavity of the entropy. Finally, we use the maximum entropy principle which says that among states with fixed second moments the Gaussian state has maximal entropy (see Lemma 12.26). This proves (12.214). □

We have

$$\max_{S:S\in\mathcal{G},\mathrm{Tr}\, SF\le E} H(\Phi[S]) = \max_{\boldsymbol{v}:\mathrm{Sp}\,\boldsymbol{v}\boldsymbol{\epsilon}\le E} \mathrm{Spg}\left(\mathbf{K}^*\boldsymbol{v}\mathbf{K} + \boldsymbol{\mu} + \left(\mathbf{K}^*\mathbf{K} - \mathbf{I}_B\right)/2\right)\Big]. \tag{12.216}$$

Now let $\boldsymbol{v}$ be the solution of the maximization problem in the right-hand side. To prove (12.211) observe that

$$\begin{aligned} n\chi\left(\pi_\nu\right) &\le nC_\chi(\Phi, F, E) \le C_\chi\left(\Phi^{\otimes n}, F^{(n)}, nE\right) \\ &\le \max_{S^{(n)}:\mathrm{Tr}\, S^{(n)}F^{(n)}\le nE} H\left(\Phi^{\otimes n}\left[S^{(n)}\right]\right) - \min_{S^{(n)}} H\left(\Phi^{\otimes n}\left[S^{(n)}\right]\right) \end{aligned}$$

By using Lemma 12.56 and Corollary 12.54 we see that this is less than or equal to

$$n\left[\max_{S:S\in\mathcal{G},\mathrm{Tr}\, SF\le E} H(\Phi[S]) - H\left(\Phi\left[S_0\right]\right)\right] = n\chi\left(\pi_v\right),$$

where the equality follows from (12.216) and (12.212).
Thus the additivity $C_\chi\left(\Phi^{\otimes n}, F^{(n)}, nE\right) = nC_\chi(\Phi, F, E)$ holds, and hence the constrained classical capacity (12.209) of the Gaussian gauge covariant channel is given by the expression (12.211). □

A similar argument applies to the Gaussian gauge contravariant channel (12.173), giving the expression (12.211) with $\boldsymbol{\epsilon}$ replaced by $\overline{\boldsymbol{\epsilon}}$. Indeed, in this case the state $\Phi\left[\bar{S}_{\pi_v}\right]$ is gauge invariant Gaussian with the characteristic function

$$\begin{aligned} \mathrm{Tr}\,\Phi\left[\bar{S}_{\pi_v}\right] D(\mathbf{z}) &= \exp\left(-\left(\overline{\mathbf{K}\mathbf{z}}\right)^*\left(\boldsymbol{v} + \mathbf{I}_A/2\right)\overline{\mathbf{K}\mathbf{z}} - \mathbf{z}^*\boldsymbol{\mu}\boldsymbol{z}\right) \\ &= \exp\left(-\left(\mathbf{K}\mathbf{z}\right)^*\left(\overline{\boldsymbol{v}} + \mathbf{I}_A/2\right)\mathbf{K}\mathbf{z} - \mathbf{z}^*\boldsymbol{\mu}\boldsymbol{z}\right), \end{aligned}$$

with the correlation matrix $\mathbf{K}^*\left(\overline{\boldsymbol{v}} + \mathbf{I}_A/2\right)\mathbf{K} + \boldsymbol{\mu}$. Redefining $\overline{\boldsymbol{v}}$ as $\boldsymbol{v}$ and noting that $\mathrm{Sp}\,\overline{\boldsymbol{v}}\boldsymbol{\epsilon} = \mathrm{Sp}\,\boldsymbol{v}\overline{\boldsymbol{\epsilon}}$ since $\boldsymbol{v}, \boldsymbol{\epsilon}$ are Hermitian, we get the statement.

The maximization in (12.211) is a finite-dimensional optimization problem which is a quantum analog of the "water-filling" problem in classical information theory; see, e. g., [47]. Apart from the case of a single mode considered in the next section, it can be solved explicitly only in some special cases, e.g., when $\mathbf{K}, \boldsymbol{\mu}, \boldsymbol{\epsilon}$ commute, and it is a subject of separate study.

10.12.26 12.6 The Case of Single Mode

10.12.27 12.6.1 Classification of Gaussian Channels

In this section we will be interested in the problem of reducing an arbitrary quantum Gaussian channel to the simplest "normal" form which can be obtained by applying suitable unitary operators, corresponding to symplectic transformations T_1, T_2 via formula (12.67), to the input and the output of the channel, i.e.,

$$\Phi^{*\prime}[W(z)] = U_{T_1}^* \Phi^* \left[U_{T_2}^* W(z) U_{T_2}\right] U_{T_1},$$

that is,

$$\Phi^{*\prime}[W(z)] = W\left(T_1 K T_2 z\right) f\left(T_2 z\right). \tag{12.217}$$

Here we give a complete solution of this problem in one mode, $s = 1$.
Let Z be the two-dimensional symplectic space, i. e., the real linear space of vectors $z = \left[\begin{array}{cc} x & y \end{array}\right]^\top$ with the symplectic form

$$\Delta\left(z, z'\right) = xy' - x'y. \tag{12.218}$$

A basis e, h in Z is symplectic if $\Delta(e, h) = 1$, i. e., if the area of the oriented parallelogram based on e, h is equal to 1 . Recall that a linear transformation T in Z is symplectic if it maps a symplectic basis into a symplectic basis.

According to formula (12.137), a Gaussian channel is characterized by the parameters (K, l, μ) satisfying

$$\mu \geq \pm \frac{i}{2}\left[\Delta - K^\top \Delta K\right]. \tag{12.219}$$

By way of a displacement transformation (12.53) we can always make $l = 0$, which we assume. Thus

$$\Phi^*[W(z)] = W(Kz) \exp\left[-\frac{1}{2} z^\top \mu z\right]. \tag{12.220}$$

The transformation (12.217) amounts to $K \to T_1 K T_2, \mu \to T_2^\top \mu T_2$ which leaves invariant the quantities

$$\det K = \Delta(Ke, Kh), \quad \det \mu, \tag{12.221}$$

as well as the rank of the matrices K and μ. It is therefore not surprising that these quantities play a special role in the classification.

In the following theorem we use the notation

$$I_2 = \left[\begin{array}{cc} 1 & 0 \\ 0 & 1 \end{array}\right].$$

Theorem 12.57. Let $\{e, h\}$ be a symplectic basis. Then, depending on the value
(A) $\Delta(Ke, Kh) = 0$;
(B) $\Delta(Ke, Kh) = 1$;
(C) $\Delta(Ke, Kh) = k^2 > 0, k \neq 1$;
(D) $\Delta(Ke, Kh) = -k^2 < 0$,
there are symplectic transformations T_1, T_2, such that the channel $\Phi^{*\prime}$ has the form (12.220) with

$$
\begin{aligned}
&(\mathrm{A}_1)\quad K=0,\\
&\mu=\left(N_0+\frac{1}{2}\right)I_2,\quad N_0\geq 0;\\
&(\mathrm{A}_2)\quad K=\begin{bmatrix}1&0\\0&0\end{bmatrix},\\
&\mu=\left(N_0+\frac{1}{2}\right)I_2;\\
&(\mathrm{B}_1)\quad K=I_2,\\
&\mu=\frac{1}{2}\begin{bmatrix}1&0\\0&0\end{bmatrix};\\
&\qquad\qquad K=I_2,\\
&\qquad\qquad \mu=N_cI_2,\quad N_c\geq 0;\\
&\qquad(\mathrm{C}_1)\quad K=kI_2,\quad 0<k<1,\\
&(\mathrm{B}_2)\qquad\quad \mu=\left(N_c+\frac{1-k^2}{2}\right)I_2;\\
&\qquad(\mathrm{C}_2)\quad K=kI_2,\quad k>1,\\
&\qquad\qquad \mu=\left(N_c+\frac{k^2-1}{2}\right)I_2;\\
&\qquad\qquad K=k\begin{bmatrix}1&0\\0&-1\end{bmatrix},\quad k>0,\\
&(\mathrm{D})\\
&\qquad\qquad \mu=\left(N_c+\frac{k^2+1}{2}\right)I_2.
\end{aligned}
$$

Apparently, in the cases $(\mathrm{A}_1), (\mathrm{B}_2), (\mathrm{C})$ the channel is gauge covariant with respect to the natural complex structure associated with multiplication by i in the complex plane x, y. In case (D) the channel is gauge contravariant. It is convenient to describe the variety of all channels with gauge symmetry by two parameters expressed in terms of the invariants (12.221), i.e.,

$$
\varkappa=\det K,\quad N_c=\sqrt{\det\mu}-\frac{1}{2}|\det K-1|. \tag{12.222}
$$

One has $-\infty<x<\infty$ ($x=k^2$ for $(\mathrm{A}_1), (\mathrm{B}_2), (\mathrm{C})$, $x=-k^2$ for (D)), and $N_c\geq 0$, so that the variety is just the upper half-plane of the variables x, N_c (Figure 12.3).

Proof. (A) $\Delta(Ke,Kh)=0$. In this case $\Delta(Kz,Kz')\equiv 0$ and either $K=0$ or K has rank one. Then inequality (12.219) is just the condition on the covariance matrix of a quantum Gaussian state. As follows from Lemma 12.12, there is a symplectic transformation T_2 such that

$$
\mu(T_2z,T_2z)=\left(N_0+\frac{1}{2}\right)\left(x^2+y^2\right). \tag{12.223}
$$

In the case $K=0$ we just have (A_1).

Let K have rank one. Then KT_2 has rank one and there is a vector e' such that $KT_2\begin{bmatrix}x&y\end{bmatrix}^\top=(k_1x+k_2y)\,e'$. Then there is a symplectic transformation T_1 such that $T_1e'=\begin{bmatrix}1&0\end{bmatrix}$ and hence $T_1KT_2\begin{bmatrix}x&y\end{bmatrix}^\top=\begin{bmatrix}k_1x+k_2y&0\end{bmatrix}^\top$. By making a rotation T_2' which leaves μ unchanged, we can transform this vector to $[k_1'x\quad 0]^\top$ with $k_1'\neq 0$, and then by a symplectic scaling (squeezing) T_1' we arrive to case (A_2).

(B), (C) $\Delta(Ke,Kh)=k^2>0$. Then $T=k^{-1}K$ is a symplectic transformation and

$\Delta(Kz, Kz') = k^2\Delta(z, z')$. Let $T_1 = (TT_2)^{-1}$, where T_2 will be chosen later, so that $T_1 K T_2 = kI$.

In case (B)$k = 1$ and the condition (12.219) is just positive definiteness of μ. Then we have the following subcases:

(B_2) If μ is nondegenerate, then by Lemma 12.12 there is a symplectic transformation T_2 such that

$$\mu(T_2 z, T_2 z) = N_c\left(x^2 + y^2\right),$$

where $N_c > 0$. Also if $\mu = 0$, we have a similar formula with $N_c = 0$.

(B_1) On the other hand, if μ is degenerate of rank one, then $\mu(z, z) = (k_1 x + k_2 y)^2$ for some k_1, k_2 simultaneously not equal to zero, and then for arbitrary $N_c > 0$ there is a symplectic transformation T_2 such that

$$\mu(T_2 z, T_2 z) = N_c x^2,$$

in particular, we can take $N_c = \frac{1}{2}$.

In case (C) $k \neq 1$, and the condition (12.219) implies that $\mu/|k^2 - 1|$ is a covariance matrix of a quantum Gaussian state, hence there exists a symplectic transformation T_2 such that

$$\mu(T_2 z, T_2 z) = \left|k^2 - 1\right|\left(N_0 + \frac{1}{2}\right)\left(x^2 + y^2\right) = \left(N_c + \frac{|k^2 - 1|}{2}\right)\left(x^2 + y^2\right),$$

where $N_0 \geq 0, N_c = |k^2 - 1| N_0$.

(D) $\Delta(Ke, Kh) = -k^2 < 0$. Then $T = k^{-1}K$ is an antisymplectic transformation, which means that $\Delta(Tz, Tz') = -\Delta(z, z')$ and $\Delta(Kz, Kz') = -k^2\Delta(z, z')$. Similar to cases (B) and (C), we obtain

$$\mu(T_2 z, T_2 z) = \left(k^2 + 1\right)\left(N_0 + \frac{1}{2}\right)\left(x^2 + y^2\right) = \left(N_c + \frac{(k^2 + 1)}{2}\right)\left(x^2 + y^2\right)$$

with $N_0 \geq 0, N_c = (k^2 + 1) N_0$. Letting $T_1 = \Lambda(TT_2)^{-1}$, where $\Lambda \begin{bmatrix} x & y \end{bmatrix}^\top = \begin{bmatrix} x & -y \end{bmatrix}^\top$, we obtain the first equation in (D). Note that T_1 is symplectic since both T and Λ are antisymplectic.

As explained in Section 12.4.1, a Gaussian channel Φ can be dilated to a linear dynamics of open bosonic system described by symplectic transformation of canonical variables q, p and ancillary canonical variables $q_E, p_E, \ldots$ in a Gaussian state S_E; moreover this linear dynamics provides also a description of the weak complementary channel Φ_E mapping initial state of the system q, p into the final state of the environment $q'_E, p'_E, \ldots$; in the case where the state S_E is pure, Φ_E is just the complementary channel $\widetilde{\Phi}$, which is determined by Φ up to isometric equivalence. Note that the environment may have more than one mode (which is reflected by introducing ... in the environment variables).

Let us give such a description in terms of an input-output relation in each of the cases of Theorem 12.57.

(A_1) This is the completely depolarizing channel

$$q' = q_E,$$
$$p' = p_E,$$

where q_E, p_E describe the environment in the quantum thermal state S_E with mean number of quanta N_0. Its weak complementary is the ideal channel Id.

(A_2) The input-output relation is

$$q' = q + q_E \tag{12.224}$$
$$p' = p_E$$

where q_E, p_E are again in the quantum thermal state S_E with mean number of quanta N_0. The equation describes the degenerate classical signal q with additive quantum Gaussian noise. The weak complementary to this channel is described by the transformation

$$q'_E = q \tag{12.225}$$
$$p'_E = p - p_E$$

where p_E can be regarded as a classical real Gaussian variable with variance $N_0 + \frac{1}{2}$.
(B_1) The equation of the channel has the form (12.225), where p_E has variance $\frac{1}{2}$, so that the mode q_E, p_E is in pure (vacuum) state, and the complementary channel is given by (12.224). This is quantum signal plus degenerate (two-dimensional) classical Gaussian noise.
(B_2) For a channel with (nondegenerate) additive classical Gaussian noise,

$$q' = q + \xi$$
$$p' = p + \eta$$

where ξ, η are i. i. d. Gaussian random variables with zero mean and variance N_c.

Exercise 12.58 Check that the Stinespring dilation for this channel can be obtained by adding environment with two bosonic modes $q_j, p_j, j = 1, 2$, in pure Gaussian state having zero means, zero covariances, and the variances

$$\mathrm{D}q_1 = \mathrm{D}q_2 = N_c, \quad \mathrm{D}p_1 = \mathrm{D}p_2 = \frac{1}{4N_c},$$

so that $\xi = q_1, \eta = q_2$ and with the following dynamics for the canonical observables

$$q' = q + q_1,$$
$$p' = p + q_2,$$
$$q'_1 = q_1,$$
$$p'_1 = p_1 - p - q_2/2,$$
$$q'_2 = q_2,$$
$$p'_2 = p_2 + q + q_1/2.$$

(C) Attenuation/amplification channel with coefficient k and quantum noise with mean number of quanta N_0. In the attenuation case ($k < 1$) the input-output relation is

$$q' = kq + \sqrt{1 - k^2} q_E,$$
$$p' = kp + \sqrt{1 - k^2} p_E,$$

where q_E, p_E are in the quantum thermal state S_E with mean number of quanta N_0. The weak complementary is given by the equations

$$q'_E = \sqrt{1 - k^2} q - k q_E \tag{12.226}$$
$$p'_E = \sqrt{1 - k^2 p} - k p_E \tag{12.227}$$

and is again an attenuation channel (with coefficient $k' = \sqrt{1-k^2}$).

In the amplification case ($k > 1$) we have

$$q' = kq + \sqrt{k^2-1}q_E$$
$$p' = kp - \sqrt{k^2-1}p_E$$

with the weak complementary

$$q'_E = \sqrt{k^2-1}q + kq_E$$
$$p'_E = -\sqrt{k^2-1}p + kp_E$$

(see case (D)).

D) The input-output relation is

$$q' = kq + \sqrt{k^2+1}q_E$$
$$p' = -kp + \sqrt{k^2+1}p_E$$

which is the same as the weak complementary to an amplification channel with coefficient $k' = \sqrt{k^2+1}$ and quantum noise with mean number of quanta N_0. This channel describes attenuation/amplification with phase conjugation, i.e., $q, p \to q, -p$.

Finally, let us show how the c-q channel considered in Section 12.1.4 fits into the general description of quantum Gaussian channels. Since the input is twodimensional classical, one has to use two bosonic input modes q_1, p_1, q_2, p_2 to describe it quantum mechanically, so that, e.g., $m_q = q_1, m_p = q_2$. The environment is one mode q, p in the Gaussian state S_0 so the output is given by the equations

$$q' = q_1 + q = q + m_q,$$
$$p' = q_2 + p = p + m_p,$$

and the channel parameters are

$$K = \begin{bmatrix} 1 & 0 \\ 0 & 0 \\ 0 & 1 \\ 0 & 0 \end{bmatrix}, \quad \mu = \left(N_0 + \frac{1}{2}\right) I_2. \tag{12.228}$$

In this case the full set of the Heisenberg equations is the same as in case (B_2), with the roles of input modes and environmental modes interchanged.

10.12.28 12.6.2 Entanglement-Breaking Channels

Let us apply Theorem 12.36 to the case of one bosonic mode $A = B$, where $\Delta_A(z, z') = \Delta_B(z, z')$ is given by the relation (12.218). As shown above, any one-mode Gaussian channel can be transformed to one of the normal forms.

We only have to find the form $K^\top \Delta_A K$ and check the decomposability (12.146) in each of these cases. We rely upon the following fact.

Exercise 12.59 Show that

$$\left(N + \frac{1}{2}\right) I_2 \geq \pm \frac{i}{2}\Delta$$

if and only if $N \geq 0$.

With this we proceed to a consideration of each class:

(A) $K^\top \Delta K = 0$, hence Φ is a c-q (in fact essentially classical) channel;

(B) $K^\top \Delta K = \Delta$, hence the necessary condition of decomposability (12.146) requires $\mu \geq i\Delta$; this is never fulfilled in case (B_1) due to the degeneracy of μ. Thus the channel is not entanglement-breaking (in fact it has infinite quantum capacity as shown in [120]); on the other hand, in case (B_2) the condition (12.146) is fulfilled with $\alpha_B = \alpha_A = \mu/2$ if and only if $N_c \geq 1$, hence Φ is entanglement-breaking in this case;
(C) $K^\top \Delta K = k^2 \Delta$; it is clear that in this case the decomposability condition holds if and only if $\mu \geq \pm\frac{i}{2}(1+k^2)\Delta$, which is equivalent to $N_c + \frac{|1-k^2|}{2} \geq \frac{(1+k^2)}{2}$ or

$$N_c \geq \min\left(1, k^2\right) \tag{12.229}$$

this gives the condition for the entanglement breaking (which also formally includes case (B_2);
(D) $K^\top \Delta K = -k^2 \Delta$; again the decomposability condition holds if and only if $\mu \geq \pm\frac{i}{2}(1+k^2)\Delta$, which is always the case, hence the channel is entanglement-breaking for all $N_c \geq 0$.

Thus the additivity property (11.33) holds for one-mode Gaussian channels of the form (A), (D) with arbitrary parameters, and (B_2), (C) with parameters satisfying (12.229). In general, entanglement-breaking channels have zero quantum capacity, $Q(\Phi) = 0$ (see Corollary 10.28). However, in Section 12.6.4 a broader domain of zero quantum capacity will be demonstrated basing on degradability analysis.

Exercise 12.60 Use Exercise 12.59 to show that in the case of one mode the condition (12.153) implies (12.146), hence every PPT channel is entanglement-breaking.

10.12.29 12.6.3 Attenuation/Amplification/Classical Noise Channel

From the point of view of applications the gauge covariant cases (C), (B_2) are the most interesting. The action of the channel Φ in these cases can be described by a single formula, i. e.,

$$\Phi^*[D(\mathbf{z})] = D(k\mathbf{z}) \cdot \exp\left[-\left(N_c + \left|k^2 - 1\right|/2\right)|\mathbf{z}|^2\right], \tag{12.230}$$

where the parameter $N_c \geq 0$ is the power of the environment noise and $k > 0$ is the coefficient of attenuation/amplification in case (C). Then $N_c = |k^2 - 1|\, N_0$, where N_0 is the mean photon number of the environment. Case (B_2) of additive classical Gaussian noise channel corresponds to the value $k = 1$. The channel is gauge covariant with respect to the natural complex structure associated with the multiplication by i of the complex variable $\mathbf{z} = (x + iy)/\sqrt{2} \in \mathbb{C}$. Therefore, in what follows, basing on the results of Section 12.5, we can restrict ourselves to the gauge invariant input states.

In the case of one mode the only such states are the elementary Gaussian states $S = S(N)$ with the characteristic function

$$\operatorname{Tr} S(N) D(\mathbf{z}) = \exp\left[-(N + 1/2)|\mathbf{z}|^2\right],$$

the parameter N representing the power (mean number of quanta) of the signal

$$\operatorname{Tr} S(N) a^\dagger a = N. \tag{12.231}$$

The entropy of $S(N)$ is

$$H(S(N)) = g(N). \tag{12.232}$$

From (12.230) we find that the output state $\Phi[S]$ is the Gaussian state $S(N')$ where

$$N' = k^2 N + N'_0, \tag{12.233}$$

and the total noise

$$N'_0 = \max\left\{0, \left(k^2 - 1\right)\right\} + N_c \tag{12.234}$$

is the output mean photon number corresponding to the vacuum input state $S(0)$. The first term is nonzero only in the case $k > 1$ when it represents the amplifier noise. The output entropy is equal to

$$H(\Phi[S(N)]) = g\left(N'\right). \tag{12.235}$$

Now we compute the entropy exchange $H(S(N), \Phi)$. The (pure) input state S_{12} of the extended system $\mathcal{H} \otimes \mathcal{H}_0$ is characterized by the 2×2-matrix (12.120). According to (12.154), the action of the extended channel $\Phi \otimes \mathrm{Id}$ transforms this matrix into

$$\Delta_{12}^{-1}\mu'_{12} = \begin{bmatrix} 0 & -\left(N' + 1/2\right) & k\sqrt{N^2+N} & 0 \\ N' + 1/2 & 0 & 0 & k\sqrt{N^2+N} \\ k\sqrt{N^2+N} & 0 & 0 & N + 1/2 \\ 0 & k\sqrt{N^2+N} & -(N+1/2) & 0 \end{bmatrix},$$

where N' is given by (12.233). From formula (12.110) we deduce $H(S(N), \Phi) = g\left(|\lambda_1| - \frac{1}{2}\right) + g\left(|\lambda_2| - \frac{1}{2}\right)$, where $\pm\lambda_1, \pm\lambda_2$ are the eigenvalues of the matrix on the right-hand side. Solving the characteristic equation we obtain

$$\lambda_{1,2} = \frac{i}{2}\left(\left(N' - N\right) \pm D\right), \tag{12.236}$$

where

$$D = \sqrt{\left(N + N' + 1\right)^2 - 4k^2 N(N+1)}.$$

Hence

$$H(S(N), \Phi) = g\left(\frac{D + N' - N - 1}{2}\right) + g\left(\frac{D - N' + N - 1}{2}\right). \tag{12.237}$$

Let us consider the classical capacities of the channel Φ under the additive input energy constraint (11.28) corresponding to the operator $F = a^\dagger a$. According to Corollary 12.38, the entanglement-assisted classical capacity

$$C_{ea}(\Phi, F, E) = \max_{S:\mathrm{Tr}\, Sa^+a \le E} I(S, \Phi)$$

is attained on a gauge invariant Gaussian state. Since the condition (11.42) is obviously fulfilled for our channel, $\mathrm{Tr}\, \mathrm{S}a^\dagger a = E$ for this state, which is thus the elementary Gaussian state $S(E)$. Hence the maximum is equal to

$$C_{ea}(\Phi, F, E) = I(S(E), \Phi) = H(S(E)) + H(\Phi[S(E)]) - H(S(E), \Phi), \tag{12.238}$$

where the entropies are given by the relations (12.232), (12.235), and (12.237) with N replaced by E.

Considering $C_{ea}(\Phi, F, E)$ as a function of the parameters E, k, N_c, it is interesting to compare it with the classical capacity $C(\Phi, F, E)$ computed in Theorem 12.55. In the case of one mode the maximum in formula (12.211) with $\boldsymbol{\epsilon} = 1$ is attained for $\boldsymbol{v} = E$. Hence the optimal

ensemble consists of coherent states $S_\zeta = |\zeta\rangle\langle\zeta|; \zeta \in \mathbb{C}$, with the Gaussian probability density $p(\zeta) = (\pi E)^{-1} \exp(-|\zeta|^2/E)$, giving the value

$$C(\Phi, F, E) = g\left(k^2 E + N_0'\right) - g\left(N_0'\right), \tag{12.239}$$

where N_0' is given by (12.234), so that

$$C(\Phi, F, E) = g\left(k^2 E + N_c + \max\left\{0, \left(k^2 - 1\right)\right\}\right) - g\left(N_c + \max\left\{0, \left(k^2 - 1\right)\right)\right.\right.\right.

The entanglement-assisted classical capacity can be computed via formula (12.238) in which the entropies are calculated with $N' = k^2 E + N_0'$, but N_0' is given by (12.243). We leave the detail to the interested reader.

10.12.30 12.6.4 Estimating the Quantum Capacity

In this section the quantum capacity of the one-mode channel will be computed in several cases, basing on the (anti)degradability property (see Sections 10.3.3, 12.5.3). We use the fact that composition of one-mode Gaussian channels is again a one-mode Gaussian channel. In particular, the general rule (12.139) implies the following relations.

Denote by $\Phi_{C,k}$ (resp. $\Phi_{D,k}$) a channel of class C (resp. D) with coefficient k and a fixed value of parameter N_c. Then

$$\begin{array}{ll} \Phi_{C,k_2} \circ \Phi_{C,k_1} = \Phi_{C,k_1 k_2}, & \text{if } k_1, k_2 < 1, \\ \Phi_{D,k_2} \circ \Phi_{C,k_1} = \Phi_{D,k_1 k_2}, & \text{if } k_1 > 1. \end{array} \tag{12.246}$$

Proposition 12.62. For attenuators with $k \leq \frac{1}{\sqrt{2}}$ the quantum capacity $Q(\Phi_{C,k}) = 0$. For attenuation/amplification channels with $k \geq \frac{1}{\sqrt{2}}$ and $N_c = 0$

$$Q(\Phi_{C,k}) = Q_G(\Phi_{C,k}) = \log \frac{k^2}{|k^2 - 1|}. \tag{12.247}$$

Here

$$Q_G(\Phi) = \sup_{N \geq 0} I_c(S(N), \Phi),$$

where the supremum of the coherent information $I_c(S, \Phi) = H(\Phi[S]) - H(S, \Phi)$ is taken over all gauge invariant Gaussian input states $S(N)$.

Proof. The proof will follow from Proposition 12.40 if we show that attenuators with $k < \frac{1}{\sqrt{2}}$ are antidegradable while attenuation/amplification channels with $k \geq \frac{1}{\sqrt{2}}$ and $N_c = 0$ are degradable.

Let $k < \frac{1}{\sqrt{2}}$. Then $k_1 = \frac{k}{\sqrt{1-k^2}} < 1$ and taking into account that the weak complementary of $\Phi_{C,k}$ is

$$\widetilde{\Phi}^W_{C,k} = \Phi_{C,\sqrt{1-k^2}} \tag{12.248}$$

(see (12.226)), the relation (12.245) takes the form

$$\Phi_{C,k} = \Phi_{C,\frac{k}{\sqrt{1-k^2}}} \circ \widetilde{\Phi}^W_{C,k}, \tag{12.249}$$

which implies that $\Phi_{C,k}$ is antidegradable, since the weak complementary can be dilated to complementary by purifying the environment state. Hence its quantum capacity is equal to zero by Proposition 10.27.

In the case $N_c = 0$, when the environment state is pure, the complementary channel coincides with the weakly complementary, i. e., $\widetilde{\Phi}_{C,k} = \widetilde{\Phi}^w_{C,k} = \Phi_{C,k'}$, where $k' = \sqrt{1-k^2} > \frac{1}{\sqrt{2}}$, and the relation (12.249) is the same as

$$\widetilde{\Phi}_{C,k'} = \Phi_{C,\frac{k}{\sqrt{1-k^2}}} \circ \Phi_{C,k'},$$

which means that $\Phi_{C,k'}$ is degradable for $\frac{1}{\sqrt{2}} < k' < 1$. Therefore Proposition 12.40 applies implying

$$Q(\Phi_{C,k}) = Q_G(\Phi_{C,k}). \tag{12.250}$$

Similarly in the amplifier case ($k > 1, N_c = 0$) the relation (12.246) implies

$$\widetilde{\Phi}_{C,k} = \Phi_{D,\frac{\sqrt{k^2-1}}{k}} \circ \Phi_{C,k},$$

whence $\Phi_{C,k}$ is degradable, and (12.250) continues to hold. It remains to compute $Q_G(\Phi_{C,k})$.

Since the channels are gauge covariant, Proposition 12.40 implies that in looking for the maximum of the coherent information over Gaussian input states it is sufficient to restrict to the one-mode gauge invariant states $S(N)$.

In the general case where $N_c \geq 0$, the coherent information

$$I_c(S(N), \Phi) = g(N') - g\left(\frac{D + N' - N - 1}{2}\right) - g\left(\frac{D - N' + N - 1}{2}\right) \tag{12.251}$$

is a complicated function of the input power N. We have $I_c(S(0), \Phi) = 0$ and

$$\lim_{N\to\infty} I_c(S(N), \Phi) = \log k^2 - \log\left|k^2 - 1\right| - g\left(N_c/\left|k^2 - 1\right|\right), \quad k \neq 1.$$

Whenever positive, this gives a lower bound $\underline{Q}(\varkappa, N_c), \varkappa = k^2$, for the quantum capacity $Q(\Phi_{C,k})$.

Let us now consider the case $N_c = 0$. The behavior of the entropies $H(\Phi[S(N)])$, $H(S(N), \Phi)$ as functions of k for $N_c = 0$ is shown in Figure 12.1. Note that for all N the coherent information $H(\Phi[S(N)]) - H(S(N), \Phi)$ turns out to be positive for $k^2 > \frac{1}{2}$ and negative otherwise. It tends to $-H(S(N))$ for $k \to 0$, is equal to $H(S(N))$ for $k = 1$, and quickly tends to zero as $k \to \infty$.

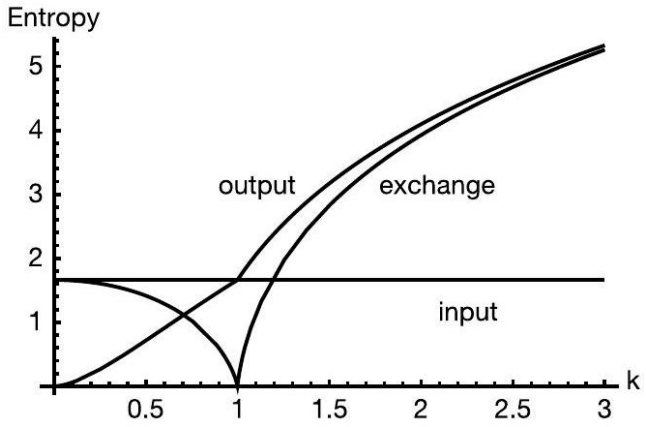

Figure 12.1: Entropies: the output entropy (12.235), the entropy exchange (12.237) in the case $N_{c} =0$.

If $k < 1$ (ideal attenuator), then $N' = k^2 N, D = (1 - k^2) N + 1$ and

$$I_c(S(N), \Phi) = g\left(k^2 N\right) - g\left(\left(1 - k^2\right) N\right).$$

Exercise 12.63 Show that $I_c(S(N), \Phi)$ is a convex decreasing function of N for $k^2 < \frac{1}{2}$ (correspondingly, a concave increasing function for $k^2 > \frac{1}{2}$), hence

$$\sup_N I_c(S(N), \Phi) = \begin{cases} I_c(S(N), \Phi)|_{N=0} = 0, & k^2 < \frac{1}{2}, \\ \lim_{N\to\infty} I_c(S(N), \Phi) = \log \frac{k^2}{1-k^2}, & k^2 > \frac{1}{2}. \end{cases}$$

In the case $k > 1$ (ideal amplifier), using (12.233), we have $N' = k^2(N + 1) - 1, D = k^2(N + 1) - N$, and

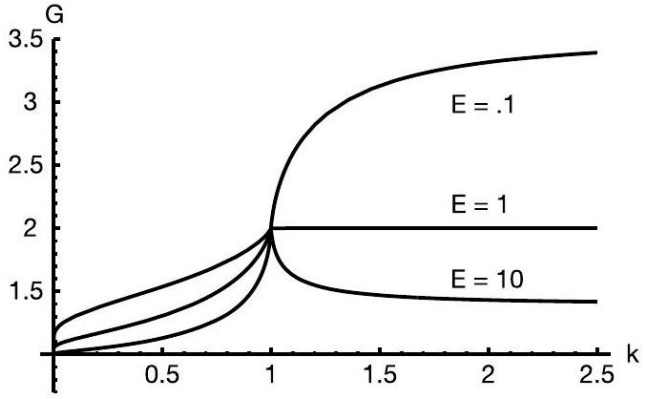

Figure 12.2: The entanglement-assistance gain (12.240) as a function of k for $N_{c =0$. Parameter = the input energy E.}

$$I_c(S(N),\Phi) = g\left(k^2(N+1)-1\right) - g\left(\left(k^2-1\right)(N+1)\right).$$

Exercise 12.64 Show that $I_c(S(N),\Phi)$ is a concave increasing function of N and therefore

$$\sup_N I_c(S(N),\Phi) = \lim_{N\to\infty} I_c(S(N),\Phi) = \log\frac{k^2}{k^2-1}.$$

Summarizing we get the general expression (12.247) for the quantum capacity of the attenuator/amplifier with $N_c = 0$. □

In view of an appropriate infinite-dimensional generalization of Proposition 10.31, a similar expression is obtained for the properly defined private classical capacity C_p of extreme attenuator/amplifier channels.

A vast area of zero quantum capacity, containing the domain (12.229) of the entanglement-breaking channels, is given by the following proposition.

Proposition 12.65. Let $k \geq \frac{1}{\sqrt{2}}$. Then $Q\left(\Phi_{C,k}\right) = 0$ for

$$N_c \geq \frac{1}{2}\left(k^2 - \left|k^2-1\right|\right) = \min\left\{k^2, 1\right\} - \frac{1}{2}. \tag{12.252}$$

Proof. Consider the concatenation $\Phi = \Phi_2 \circ \Phi_1$, where

$$\Phi_1^*[D(\mathbf{z})] = D(\sqrt{2}k\mathbf{z}) \exp\left[-\left(2k^2-1\right)\left(N_1+\frac{1}{2}\right)|\mathbf{z}|^2\right],$$
$$\Phi_2^*[D(\mathbf{z})] = D\left(\frac{\mathbf{z}}{\sqrt{2}}\right) \exp\left[-\frac{1}{2}\left(N_2+\frac{1}{2}\right)|\mathbf{z}|^2\right],$$

so that $Q\left(\Phi_2\right) = 0$ by Proposition 12.62 and hence $Q\left(\Phi_2 \circ \Phi_1\right) = 0$ by (10.35). Then

$$\Phi_1^* \circ \Phi_2^*[D(\mathbf{z})] = D(k\mathbf{z}) \exp\left[-\left(\frac{|k^2-1|}{2} + N_c\right)|\mathbf{z}|^2\right],$$

where

$$\frac{|k^2-1|}{2} + N_c = \frac{1}{2}\left(N_2+\frac{1}{2}\right) + \frac{(2k^2-1)}{2}\left(N_1+\frac{1}{2}\right).$$

By varying $N_1, N_2 \geq 0$ one gets all the values N_C satisfying (12.252). □

In cases (A) and (D) the channel Φ is antidegradable [120] and hence also $Q(\Phi) = 0$ (see Figure 12.3).

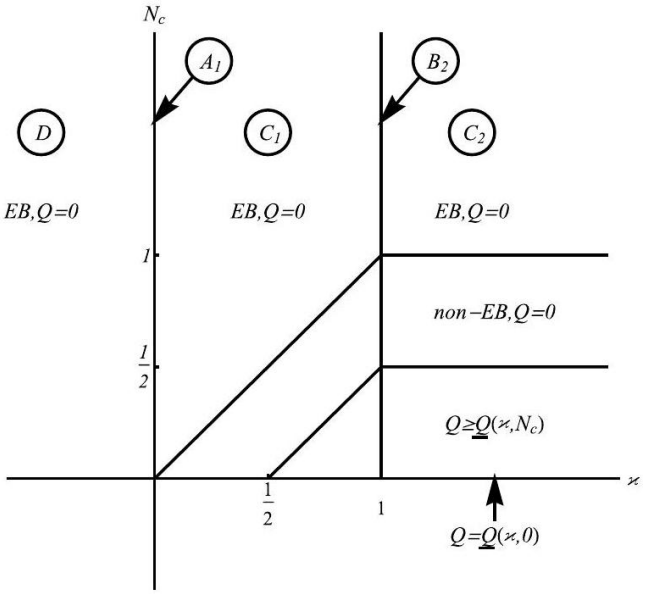

Figure 12.3: The chart of the variety of one-mode gauge-symmetric channels in the invariant coordinates (12.222). EB = entanglement-breaking channel.

The behavior of the capacities $C, C_{ea}, Q = C_p$ of extreme ($N_c = 0$) attenuation/amplification channel as functions of $x = k^2$ is shown in Figure 12.4.

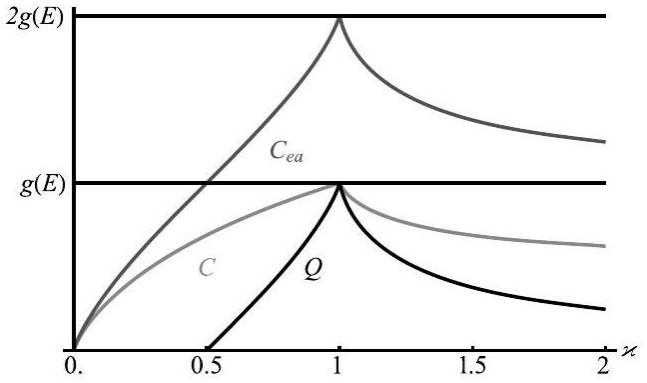

Figure 12.4: Capacities of extreme (quantum-limited, $N_{c =0$) attenuation/amplification channel (signal power $E = 1$)).}

10.12.31 12.7 Notes and References

1. The spectral theorem for self-adjoint operators, Stone's theorem, and related questions are considered in detail in the book of Reed and Simon [193].

The quantum harmonic oscillator, first studied by Dirac [64], underlies many mathematical models in quantum optics and quantum electronics. In particular, useful symbolic calculus leading to algebraic identities following from CCRs such as (12.15) was developed in the book of Louisell [169]. Analysis based on coherent states was developed in the classical work of Glauber [84]. The relation (12.22) is the famous P-representation widely used in quantum optics. Representation of the radiation field as an ensemble of quantum oscillators introduced by Dirac is discussed in the books of Klauder and Sudarshan [155] and Helstrom [103] in the

form suitable for use in quantum optics. For applications of results of the present chapter in lightwave communication see the comprehensive monograph of Papen and Blahut [185].

By using overcompleteness of the system of coherent vectors (Exercise 12.6), one can define the unsharp observable with values in $\mathbb{C} \simeq \mathbb{R}^2$

$$M(B) = \frac{1}{\pi} \int_B |\zeta\rangle\langle\zeta| d^2\zeta, \tag{12.253}$$

which plays a key role in the description of "approximate joint measurement" of observables q and p. A detailed discussion and further references can be found in the books of Davies [56] and Holevo [122].

The formula for the capacity of c-q Gaussian channels was conjectured by Gordon [86]. In our proof we follow [114], where one can also find a consideration of the multimode Gaussian c-q channel including a realistic stochastic process model of classical signals against a background of colored quantum noise. The capacity of channels with squeezed Gaussian noise was computed by Holevo, Sohma, and Hirota in [133]. Much more detailed information concerning the rate of convergence of the error probability for pure state Gaussian channels can be obtained by modifying the estimates from Section 5.7 to channels with infinite alphabets and constrained input [134].

2. The usefulness of the symmetric description (12.48) of CCRs was stressed by Segal [204]. For the proof of the following theorem see, e. g., [122].

Stone-von Neumann uniqueness theorem. Let $V_x, U_y, x, y \in \mathbf{R}^s$ be two strongly continuous families of unitary operators in a separable Hilbert space $\mathcal{H}$ satisfying the Weyl CCR (12.45). Then V_x, U_y are unitarily equivalent to a direct sum of an at most countable number of copies of the Schrödinger representation arising from (12.44). In particular, any irreducible representation is unitarily equivalent to the Schrödinger representation.

The paper of Williamson [252] contains general results concerning normal forms of classical not necessarily positive quadratic Hamiltonians. For the proof of Lemma 12.12 see also Chapter V of the book [122].

Many physical applications of linear dynamics of systems with quadratic Hamiltonians are considered in the book of Malkin and Man'ko [173]. A detailed review of the group of real symplectic transformations with applications to quantum optics and mechanics is given by Arvind, Dutta, Mukunda, and Simon [11].

3. In our exposition of quantum Gaussian states we follow Chapter V of the book [122], where the proofs of Exercises 12.15, 12.16, 12.19 and of sufficiency of the condition (12.80) can be found. In [122] one can find also an accurate treatment of expectations of unbounded operators and moments of a quantum state. The approach to quantum Gaussian states via characteristic functions is based on apparent analogies with probability theory and is perhaps the most direct and transparent. An alternative way used in physical papers is via the Wigner distribution function; see, e.g., [220].

The formulas for entropy of general quantum states were obtained in [133]. The maximum entropy characterization of the Gaussian states (Lemma 12.26) is a particular case of the maximum entropy principle in statistical mechanics (see, e. g., [169], Section 6.6); a similar property with respect to the conditional quantum entropy (Lemma 12.27) was observed by Eisert and Wolf [66].

The separability criterion for Gaussian states was obtained in the paper of Werner and Wolf [244]. This paper also contains important results concerning Gaussian PPT states, in particular, proof that in $1 \times N$ bosonic modes PPT is sufficient for separability of Gaussians and the construction of a family of Gaussian PPT nonseparable (bound entangled) states in a 2×2 system. Purification of Gaussian states was computed in [106].

4. The general description of bosonic linear and Gaussian channels was given in Holevo and

Werner [135] (see also the survey [66]) following [108]. By making a canonical decomposition for a general bosonic Gaussian channel studied in this section, it is possible to show that an arbitrary quantum optical communication circuit can be seen as composed of basic building blocks, comprising linear multiport interferometers and a few basic single-mode "nonlinear" (mathematically - non-gauge covariant) operations, such as parametric down-converters or squeezers [35].

On the other hand, the Gaussian channels are a special case of quasi-free maps of the CCR-algebra considered by Demoen, Vanheuverzwijn, and Verbeure [59]. In [59] the problem of unitary dilation of a quasi-free map was considered under rather special restriction on the operator K. The proof of Theorem 12.32 contains the construction of the unitary dilation for arbitrary Gaussian channels; see Caruso, Eisert, Giovannetti, and Holevo [42] for more detail. Maps which leave globally invariant the set of Gaussian states were studied in [60], in particular, it is shown that a channel having this property is necessarily Gaussian. In [124] it is shown that a Gaussian channel is an extreme point of the convex set of all channels if and only if its correlation matrix is a minimal solution of inequality (12.132).

Gaussian observables are essentially Gaussian q-c channels; they are considered in Chapter VI of the book [122]. In particular, it is shown that the Naimark dilation for the unsharp observable (12.253) is given by the joint spectral measure of commuting operators $q+q_C, p-p_C$, where the mode C is in the vacuum state.

Gaussian entanglement-breaking channels were studied in the work of Holevo [121].

5. The principle "Gaussian channels have Gaussian optimizers" is well known in classical information theory. Theorem 12.38, proved in Holevo and Werner [135], extrapolates this principle to quantum Gaussian states and channels for the mutual quantum information. Proposition 12.40, expressing this principle for the quantum capacity of degradable Gaussian channels, is based on the observation of Wolf, PérezGarcía, and Giedke [258].

There are indications that confirmation of the hypothesis of optimal Gaussian ensembles should depend on the solution of the additivity problem for quantum Gaussian channels. In the paper of Wolf, Giedke, and Cirac [256] it is shown that if the additivity holds, then the average state $\bar{S}_\pi$ of the optimal ensemble should be Gaussian. A closely related conjecture of Gaussian minimizers for entanglement of formation by Wolf et al. was shown to have positive solutions for symmetric Gaussian states in 1×1 composite bosonic systems [257]. Later the condition of symmetry was relaxed; see [4] for a survey of progress in this problem.

In the paper of Giovannetti, Guha, Lloyd, Maccone, Shapiro, and Yuen [80] it was shown that the vacuum state minimizes the output entropy of the single-mode pure loss channel. In this case the minimum is zero implying the additivity. Basing on this, the constrained classical capacity of this channel is easily computed. A breakthrough in the general problem was made in the paper of Giovannetti, Holevo, and GarciaPatron [81], where both hypotheses were proved to hold for a broad class of multimode gauge covariant or contravariant channels. Such channels are of main interest in quantum optics, where they are called phase-insensitive channels.

In our exposition of the solution we follow the survey [125]. Proposition 12.42 generalizes to many modes the decomposition of single-mode channels, the usefulness of which was emphasized and exploited in the paper [79] (see also [41] on concatenations of single-mode channels). Lemma 12.53 is based on a key observation by Giovannetti.

The basic Theorem 12.52 for one mode was obtained in [174]. Here we present a complete proof in the multimode case, a sketch of which was given in [82].

A mathematical model of quantum communication channels with time-continuous additive stationary Gaussian noise was considered in [128]. The multimode capacity formula (12.211) was applied to compute the classical capacity of quantum Gaussian "broadband" gauge covariant channels in spectral terms.

By taking $f(x) = -x^p, p > 1$, Theorem 12.52 implies the multiplicativity property of the (

$1 \to p$)-norms of the Gaussian channels, defined as

$$\|\Phi\|_{1\to p} = \sup_{X\neq 0} \|\Phi[X]\|_p / \|X\|_1 = \sup_{\|X\|_1\leq 1} \|\Phi[X]\|_p,$$

where $\|\cdot\|_p$ is the Schatten p-norm, and hence the additivity of the output Rényi entropies of arbitrary order $p > 1$. The problem of Gaussian maximizers for similarly defined ($q \to p$)-norms, $q < p$, remains in general open, while for $q = p$ the norm is attained asymptotically on a sequence of Gaussian states for arbitrary (not necessarily gauge covariant) Gaussian channels [71], [127]. For a survey of partial results in these directions as well as other related hypotheses, see [61].

6. The classification of one-mode Gaussian channels was obtained by Holevo [121]; see also [41]. A detailed study of their structure based on explicitly described Kraus decompositions is given in the paper of Ivan, Sabapathy, and Simon [143]. On the other hand, in the case of more than one mode the structure of nongauge covariant Gaussian channels is far from clear; see, e. g., [126].

The capacities of the attenuation/amplification channel were considered by Holevo and Werner [135], where formula (12.239) for the classical capacity was conjectured. The fact that the quantum capacity is given by the Gaussian expression obtained in [135] was proved by Wolf, Pérez-García, and Giedke [258]. The regions of zero quantum capacity were described in Caruso, Giovannetti, and Holevo [41]. Solutions of the exercises from Section 12.6.4 and additional information on the channel with additive classical Gaussian noise are given in the paper [120]. In the case $N_c > 0$ (thermal noise in the environment) bounds on the quantum capacity of attenuation/amplification channels were developed in [250], [207], [195]; see also references therein. Smith, Smolin, and Yard [223] demonstrated superactivation of quantum capacity for the couple of zero-capacity Gaussian channels: one-mode attenuators with $k^2 = 1/2$ and an explicitly constructed two-mode PPT channel.

Numerous physical applications of continuous-variable (in particular bosonic Gaussian) information processing systems, including experimental realizations, are discussed in the surveys [36], [241].

11 Quantum supremacy using a programmable superconducting processor by Google AI Quantum

11.1 Device design and architecture

The Sycamore device was designed with both the quantum supremacy experiment [1] and small noisy intermediate scale quantum (NISQ) applications in mind. The architecture is also suitable for initial experiments with quantum error correction based on the surface code. While we are targeting 0.1% error two-qubit gates for error correction, a quantum supremacy demonstration can be achieved with 0.3-0.6% error rates.

For decoherence-dominated errors, a 0.1% error means a factor of about 1000 between coherence and gate times. For example, a 25 μs coherence time implies a 25 ns gate. A key design objective in our architecture is achieving short two-qubit gate time, leading to the choice of tunable transmon qubits with direct, tunable coupling.

A difficult challenge for achieving a high-performance two-qubit gate is designing a sufficiently strong coupling when the gate is active, which is needed for fast gates, while minimizing the coupling otherwise for low residual control errors. These two competing requirements are difficult to satisfy with a fixed-coupling architecture: our prior processors [2] used large qubit-qubit detuning ($\sim$1 GHz) to turn off the effective interaction, requiring relatively high-amplitude precise flux pulses to tune the qubit frequencies to implement a CZ gate. In the Sycamore device, we use adjustable couplers [3] as a natural solution to this control problem, albeit at the cost of more wiring and control signals. This means that the qubits can idle at much smaller relative detuning. We chose a capacitor-coupled design [3, 4], which is simpler to layout and scale, over the inductor-based coupler of previous gmon devices [5, 6]. In Sycamore,

the coupling g is tunable from 5 MHz to -40 MHz. The experiment uses 'on' coupling of about -20 MHz.

By needing only small frequency excursions to perform a two-qubit gate, the tunable qubit can be operated much closer to its maximum frequency, thus greatly reducing flux sensitivity and dephasing from $1/f$ flux noise. Additionally, the coupling can be turned off during measurement, reducing the effect of measurement crosstalk, a phenomenon that has shown to be somewhat difficult to understand and minimize [7].

The interaction Hamiltonian of a system of on-resonance transmons with adjustable coupling (truncated to the qubit levels) has the following approximate form,

$$H_{\text{int}}(t) \approx \sum_{\langle i,j \rangle} g_{ij}(t) \left(\sigma_i^+ \sigma_j^- + \sigma_i^- \sigma_j^+\right) + \frac{g_{ij}^2(t)}{|\eta|} \sigma_i^z \sigma_j^z \,, \tag{11.1}$$

where g_{ij} is the nearest neighbor coupling, η is the non-linearity of the qubits (roughly constant), i and j index nearest-neighbor qubit pairs, and $\sigma^\pm = (\sigma^x \pm i\sigma^y)/2$. We pulse the coupling in time to create coupling gates.

Our two-qubit gate can be understood using Cartan decomposition [8], which enables an arbitrary two-qubit gate to be decomposed into four single-qubit gates around a central two-qubit gate that can be described by a unitary matrix describing only XX, YY and ZZ interactions, with 3 parameters indicating their strengths. For the physical interaction describing our hardware, we see a swapping interaction between the $|01\rangle$ and $|10\rangle$ qubits states, corresponding to an XX+YY interaction. Interaction of the qubit $|11\rangle$ state with the $|2\rangle$ states of the data transmons produce a phase shift of that state, corresponding to a ZZ interaction. By changing the qubit frequencies and coupling strength we can vary the magnitude of these interactions, giving net control of 2 out of the 3 possible parameters for an arbitrary gate.

11.2 Fabrication and layout

Our Sycamore quantum processor is configured as a diagonal array of qubits as seen in the schematic of Fig. 1 in the main text. The processor contains 142 transmon qubits, of which 54 qubits have individual microwave and frequency controls and are individually read out (referred to as qubits). The remaining 88 transmons are operated as adjustable couplers remaining in their ground state during the algorithms (referred to as couplers).

The qubits consist of a DC SQUID sandwiched between two metal islands, operating in the transmon regime. An on-chip bias line is inductively coupled to the DC SQUID, which allows us to tune qubit frequency by applying control fluxes into the SQUID loop. For regular operations, we tune qubits through a small frequency range (< 100 MHz). This corresponds to a relatively small control signal and makes qubit operation less sensitive to flux crosstalk.

Each pair of nearest-neighbor qubits are coupled through two parallel channels: direct capacitive coupling and indirect coupling mediated by coupler [3, 9, 4]. Both channels result in qubit-qubit coupling in the form of $\sigma_i^x \sigma_j^x + \sigma_i^y \sigma_j^y$ in the rotating frame, although with different signs. The indirect coupling is negative, given it is a second-order virtual process. The strength of the indirect coupling is adjusted by changing the coupler frequency with an additional on-chip bias line, giving a net zero qubit-qubit coupling at a specific flux bias.

The Sycamore processor consists of two die that we fabricated on separate high resistivity silicon wafers. The fabrication process, using aluminum on silicon, requires a total of 14 lithography layers utilizing both optical and electron beam lithography. Crosstalk and dissipation are mitigated through ground plane shielding [10]. After fabrication and die singulation, we use indium bump bonding [11, 12] of the two separate dies to form the Sycamore processor.

The Sycamore processor is connected to a 3-layer Al-plated circuit board with Al wirebonds [13]. Each line is routed through a microwave connector to an individual coax cable. We shield

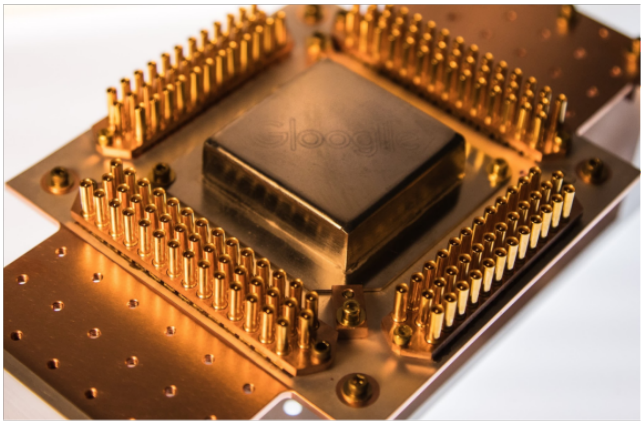

Figure S1: **A photograph of a packaged Sycamore processor.** The processor is shielded from the electromagnetic environment by a mu-metal shield (middle) and a superconducting aluminum cap, inside the mu-metal shield. The processor control wires are routed, through PCB circuit board, to coaxial connectors shown around the edge.

the processor from stray light using a superconducting Al lid with black coating, and from magnetic fields using a mu-metal shield as shown in Fig. S1.

11.3 Qubit control and readout

11.3.1 Control

Operating the device requires simultaneous synchronized control waveforms for each of the qubits and couplers. We use 54 coherent microwave control signals for qubit XY rotations, 54 fast flux bias lines for qubit frequency tuning, and 88 fast flux biases for the adjustable couplers. Dispersive readout requires an additional 9 microwave signals and phase sensitive receivers. A schematic of the room temperature electronics is shown in Fig. S2, and the cryogenic wiring is shown in Fig. S3.

Waveform generation is based on a custom-built multi-channel digital to analog converter (DAC) module. Each DAC module provides 8 DACs with 14-bit resolution and 1 GS/s sample rate. Each DAC sample clock is synchronized to a global 10 MHz reference oscillator, and their trigger is connected by a daisy chain to synchronize all modules used in the experiment. This set of DAC modules forms a >250-channel, phase-synchronous waveform generator. We have measured 20 ps of jitter between channels. The modules are mounted in 14-slot 6U rackmount chassis. A single chassis, shown in FIG. S4, can control approximately 15 qubits including their associated couplers and readout signals. A total of 4 chassis are used to control the entire Sycamore chip.

The DAC outputs are used directly for fast flux biasing the qubits and couplers required for two-qubit gates. Microwave control for single-qubit XY rotations and dispersive readout combine two DAC channels and a mixer module to form a microwave arbitrary waveform generator (Microwave AWG) via single-sideband upconversion in an IQ mixer as shown in Figure S2 a. The microwave AWG provides signals with arbitrary spectral content within ±350 MHz of the local oscillator (LO). A single LO signal is distributed to all IQ mixers so that all qubits' XY controls are phase coherent. The mixer modules are mounted in the same chassis as the DAC modules. Each mixer's I and Q port DC offsets are calibrated for minimum carrier leakage and the I and Q amplitudes and phases are calibrated to maximize image rejection.

Each DAC module contains an FPGA that provides a gigabit ethernet interface, SRAM to store waveform patterns, and sends the waveform data to the DAC module's 8 DACs. To

optimize the use of SRAM, the FPGA implements a simple jump table to allow reusing or repeating waveform segments. A computer loads the desired waveforms and jump table onto each FPGA using a UDP-based protocol and then requests the first (master) FPGA to start. The start pulse is passed down the daisy chain causing the remainder (slave) DACs and ADCs to start.

11.3.2 Readout

Qubit state measurement and readout (hereafter "readout") are done via the dispersive interaction between the qubit and a far-detuned harmonic resonator [14, 15, 16]. A change in the qubit state from $|0\rangle$ to $|1\rangle$ causes a frequency shift of the resonator from $\omega_{|0\rangle}$ to $\omega_{|1\rangle}$. A readout probe signal applied to the resonator at a frequency in between $\omega_{|0\rangle}$ and $\omega_{|1\rangle}$ reflects with a phase shift $\phi_{|0\rangle}$ or $\phi_{|1\rangle}$ that depends on the resonator frequency and therefore on the qubit state. By detecting the phase of the reflected probe signal we infer the qubit state. The readout probe signal is generated with the same microwave AWG as the XY control signals, but with a separate local oscillator, and is received and demodulated by the circuit shown in Figure S2 c.

The readout probe intensity is typically set to populate the readout resonator with only a few photons to avoid readout-induced transitions in the qubit [17]. Detecting this weak signal at room temperature with conventional electronics requires 100 dB of amplification. To limit the integration time to a small fraction of the qubit coherence time, the amplification chain must operate near the quantum noise limit [18, 19].

Inside the cryostat the signal is amplified by an impedance matched lumped element Josephson parametric amplifier (IMPA) [20] on the mixing chamber stage followed by a Low Noise Factory cryogenic HEMT amplifier at 3 K. At room temperature the signal is further amplified before it is mixed down with an IQ mixer producing a pair of intermediate frequency (IF) signals $I(t)$ and $Q(t)$. The IF signals are amplified by a pair of variable gain amplifiers to fine-tune their level, and then digitized by a pair of custom 1 GS/s, 8-bit analog to digital converters (ADC). The digitized samples I_n and Q_n are processed in an FPGA which combines them into a complex phasor

$$z_n = I_n + iQ_n = E_n \exp(i(\omega n dt + \phi))$$

where dt is the sample spacing, ω is the IF frequency, ϕ is the phase that depends on the qubit state, and E_n is the envelope of the reflected readout signal. The envelope is measured experimentally once and then used by the FPGA in subsequent experiments as the optimal demodulation window w_n to extract the phase of the reflected readout signal [21, 22]. The FPGA multiplies z_n by $w_n \exp(-i\omega n dt)$, and then sums over time to produce a final complex value $\exp(i\phi)$

$$\sum_{n=0}^{N-1} z_n w_n \exp(-i\omega n dt) \propto \exp(i\phi)$$

In the absence of noise, the final complex value would always be one of two possible values corresponding to the qubit states $|0\rangle$ and $|1\rangle$. However, the noise leads to Gaussian distributions centered at those two points. The size of the clouds is determined mostly by the noise of the IMPA and cryogenic HEMT amplifier, while the separation between the clouds' centers is determined by the resonator probe power and duration. The signal to noise ratio of the measurement is determined by the clouds' separation and width [22, 23].

The 54 qubits are divided into nine frequency multiplexed readout groups of six qubits each. Within a group, each qubit is coupled to its own readout resonator, but all six resonators are coupled to a shared bandpass Purcell filter [24, 25, 22]. All qubits in a group can be readout simultaneously by frequency-domain multiplexing [26, 2] in which the total probe signal

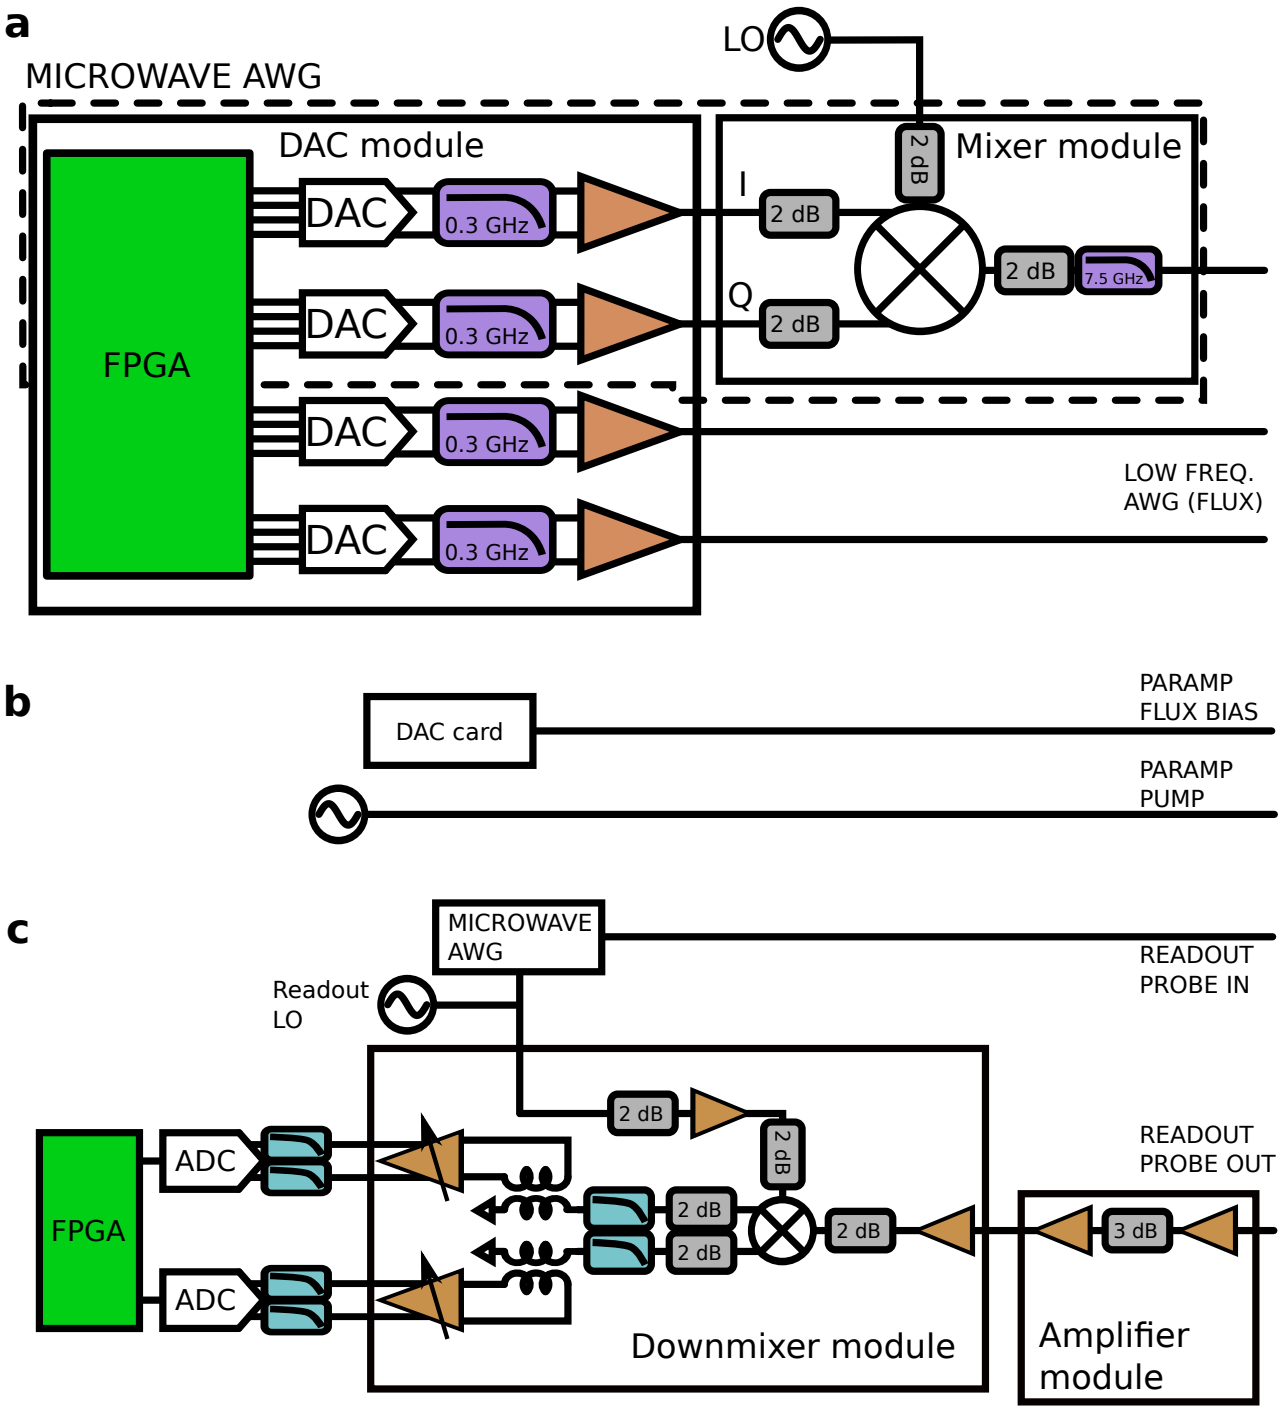

Figure S2: **Control electronics. a,** The custom DAC module provides 8 DAC channels (4 shown). DACs are used individually for flux pulses or in pairs combined with a mixer module to comprise a microwave AWG channel (dashed box). **b,** A single DAC channel and a microwave source are used to bias and pump the parametric amplifier for readout. **c,** Readout pulses are generated by a microwave AWG. The reflected signal is amplified, mixed down to IF, and then digitized in a pair of ADCs. The digital samples are analyzed in the FPGA.

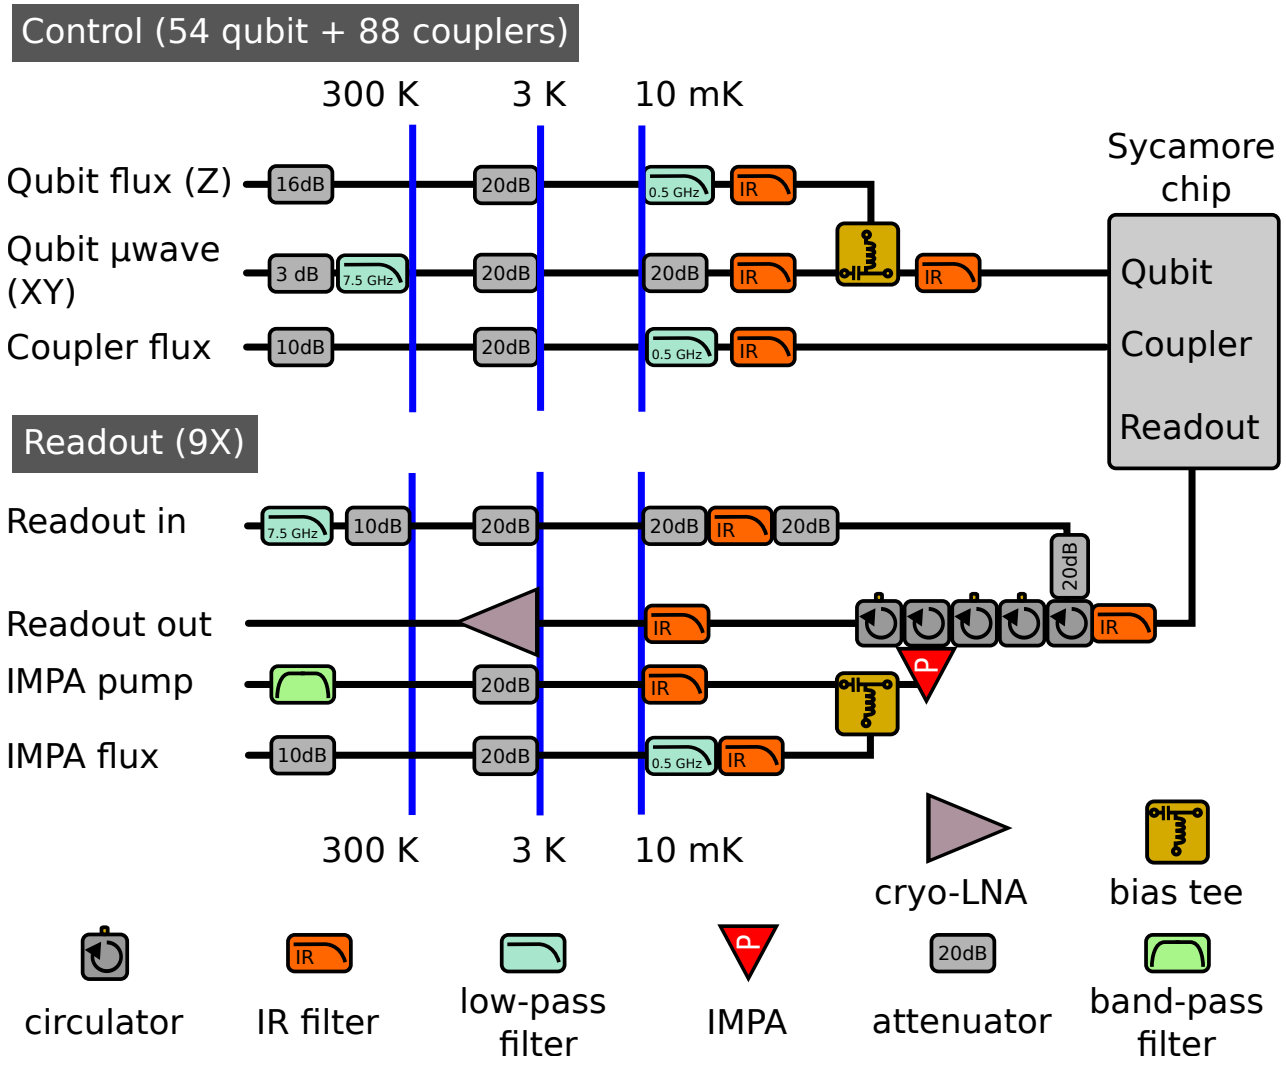

Figure S3: **Cryogenic wiring.** Control and readout signals are carried to and from the Sycamore chip with a set of cables, filters, attenuators, and amplifiers.

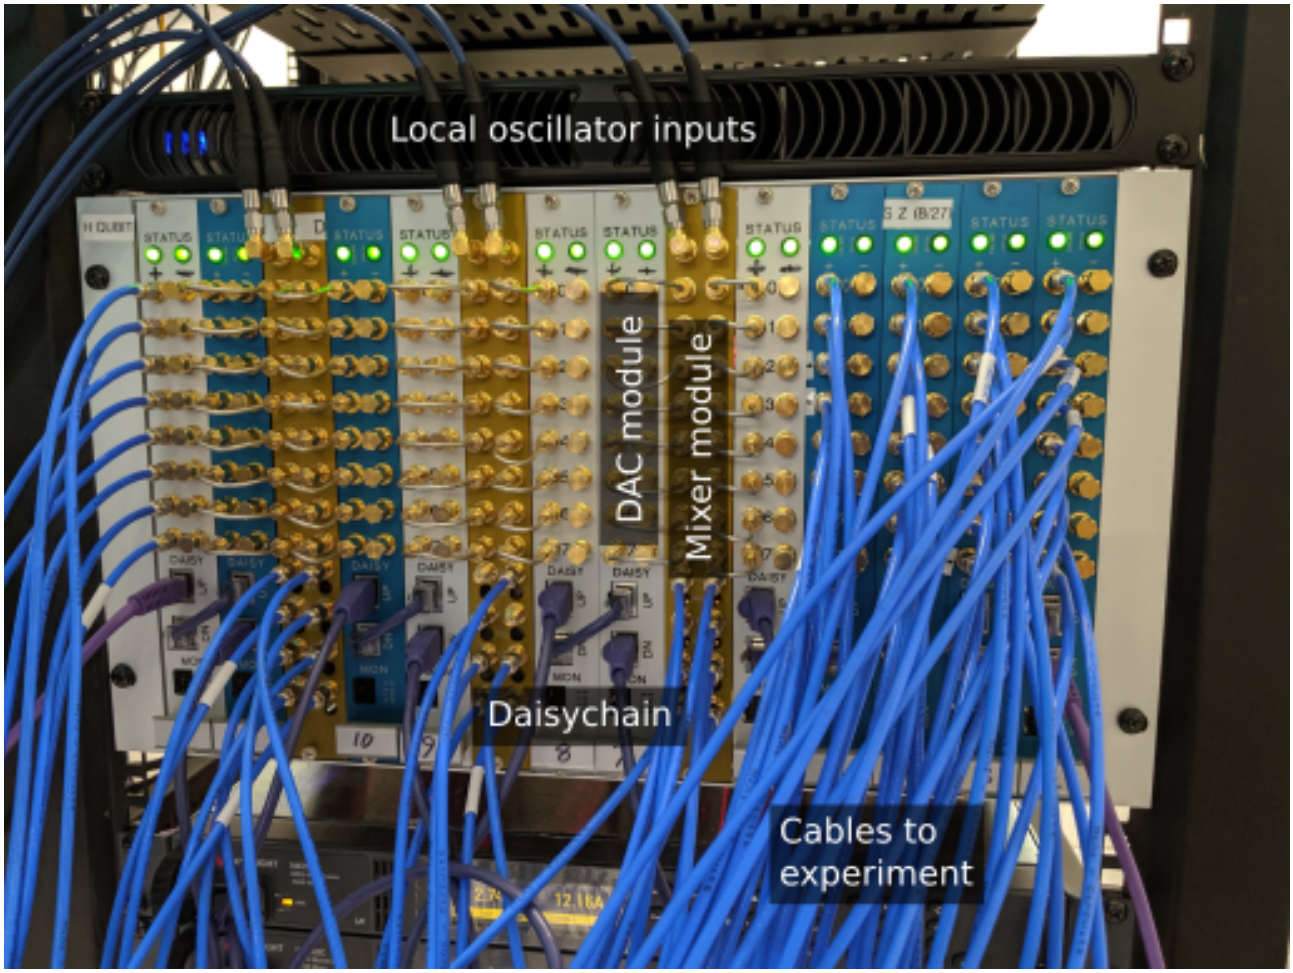

Figure S4: **Electronics chassis.** Each chassis supports 14 DAC and/or mixer modules. Local oscillators are connected at the top of each mixer module. A set of daisychain cables connects from each ADC module to the next. Control signals exit the chassis through coaxial cables.

is a superposition of probe signals at each of the readout resonators' frequencies. The phase shifts of these superposed signals are independently recovered in the FPGA by demodulating the complex IQ phasor with each intermediate frequency. In other words, we know what frequencies are in the superposed readout signal and we compute the Fourier coefficients at those frequencies to find the phase of each reflected frequency component.

11.4 XEB theory

We use cross entropy benchmarking (XEB) [27, 6] to calibrate general single- and two-qubit gates, and also to estimate the fidelity of random quantum circuits with a large number of qubits. XEB is based on the observation that the measurement probabilities of a random quantum state have a similar pattern to laser "speckles", with some bitstrings more probable than others [28, 29]. The same holds for the output state of random quantum circuits. As errors destroy the speckle pattern, this is enough to estimate the rate of errors and fidelity in an experiment. Crucially, XEB does not require the reconstruction of experimental output probabilities, which would need an exponential number of measurements for increasing number of qubits. Rather, we use numerical simulations to calculate the likelihood of a set of bitstrings obtained in an experiment according to the ideal expected probabilities. Below we describe the theory behind this technique in more detail.

11.4.1 XEB of a small number of qubits

We first consider the use of XEB to obtain the error rate for single- and two-qubit gates. As explained above, for a two-qubit XEB estimation we use sequences of cycles, each cycle consisting of two sufficiently random single-qubit gates followed by the same two-qubit gate.

The density operator of the system after application of a random circuit U with m cycles can be written as a sum of two parts

$$\rho_U = \varepsilon_m \left|\psi_U\right\rangle \left\langle\psi_U\right| + (1-\varepsilon_m)\chi_U \ , \quad D = 2^n \ . \tag{11.2}$$

Here $\left|\psi_U\right\rangle = U\left|\psi_0\right\rangle$ is the ideal output state and χ_U is an operator with unit trace that along with ε_m describes the effect of errors. For a depolarizing channel model $\chi_U = I/D$ and ε_m has the meaning of the depolarization fidelity after m cycles. Nevertheless, in the case of small number of qubits, the part of the operator χ_U has nonzero matrix elements between the states with no error and the states with the error. However, if we undo the evolution of each random circuit and average over an ensemble of circuits such cross-terms are averaged out and we expect

$$\overline{U^\dagger \chi_U U} = \frac{I}{D} \ . \tag{11.3}$$

Here and below we use the horizontal bar on the top to denote averaging over the ensemble of random circuits. Because of this property it is possible to establish the connection between the quantity ε_m and the depolarization fidelity after m cycles.

From Eqs. (11.2) and (11.3) we get

$$\overline{U^\dagger \rho_U U} = \overline{\varepsilon_m} \left|\psi_0\right\rangle \left\langle\psi_0\right| + (1-\overline{\varepsilon_m})\frac{I}{D} \ . \tag{11.4}$$

This is a depolarizing channel. From this and the exponential decay of fidelity we get

$$\overline{\varepsilon_m} = p_c^m \ , \tag{11.5}$$

connecting $\overline{\varepsilon_m}$ to the depolarization fidelity p_c per cycle.

The noise model (11.2) is very general in the context of random circuits. To provide some insight about the origin of this model we consider a specific case with pure systematic error in the two-qubit gate. In this case the resulting pure state after the application of the random circuit $\tilde{U}$ with the error can be expanded into the direction of the ideal state vector and the orthogonal direction

$$\tilde{U}\,|\psi_0\rangle = \xi_m\;|\psi_U\rangle + \sqrt{1-|\xi_m|^2}\,|\varphi_{\tilde{U}}\rangle\;\;, \tag{11.6}$$

where

$$\langle\psi_U|\varphi_{\tilde{U}}\rangle = 0, \quad \langle\varphi_{\tilde{U}}|\varphi_{\tilde{U}}\rangle = 1\;. \tag{11.7}$$

For the ensemble of random circuits U the error vector is distributed completely randomly in the plane orthogonal to the ideal vector $U\,|\psi_0\rangle$ (see Fig. S5). This condition of orthogonality is the only constraint on the vector $|\varphi_{\tilde{U}}\rangle$ that involves $|\psi_U\rangle$. Therefore we expect

$$\overline{U^\dagger\,|\varphi_{\tilde{U}}\rangle\,\langle\varphi_{\tilde{U}}|\,U} = \frac{1}{D-1}(I - |\psi_0\rangle\,\langle\psi_0|)\;. \tag{11.8}$$

Also

$$\overline{U^\dagger\left(\xi_m\sqrt{1-|\xi_m|^2}\;|\psi_U\rangle\,\langle\varphi_{\tilde{U}}| + h.c\right)U} = 0\;. \tag{11.9}$$

This gives the connection between the error vector $|\varphi_{\tilde{U}}\rangle$ and the operator χ_U

$$(1-\varepsilon_m)\chi_U - \frac{1-\varepsilon_m}{D}\,|\psi_U\rangle\,\langle\psi_U| = (1-|\xi_m|^2)\,|\varphi_{\tilde{U}}\rangle\,\langle\varphi_{\tilde{U}}| + \left(\xi_m\sqrt{1-|\xi_m|^2}\;|\psi_U\rangle\,\langle\varphi_{\tilde{U}}| + h.c\right)\;. \tag{11.10}$$

The resulting equation

$$\overline{|\xi_m|^2} = \overline{\varepsilon_m} + \frac{1-\overline{\varepsilon_m}}{D} \tag{11.11}$$

is to be expected, because $|\xi_m|^2$ is the average state fidelity while $\overline{\varepsilon_m}$ is the depolarization fidelity (see Sec. 11.5). Note that Eqs. (11.8)–(11.11) lead to Eq. (11.4). This result can also be derived assuming that single qubit gates form a 2-design in the Hilbert space of each qubit.

We demonstrate the above findings by numerically simulating the random circuits for 2 qubits that contains single qubit gates randomly sampled from Haar measure and ISWAP-like gate

$$V(\theta) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos\theta & -i\sin\theta & 0 \\ 0 & -i\sin\theta & \cos\theta & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}\;. \tag{11.12}$$

The systematic error $\Delta\theta = \theta - \pi/2$ corresponds to the deviation of the swap angle from $\pi/2$. Then assuming that the single qubit gates are error free the depolarizing channel model gives the prediction for the depolarizing fidelity per cycle

$$\begin{aligned} p_c &= \frac{|\mathrm{tr}(V(\theta)V^\dagger(\pi/2))|^2 - 1}{D^2-1} \\ &= \frac{1}{15}(8\cos(\Delta\theta) + 2\cos(2\Delta\theta) + 5)\;. \end{aligned} \tag{11.13}$$

As shown in Fig. S6 the depolarizing fidelity p_c^m for the circuit of depth m based on Eq. (11.13) closely matches the corresponding quantity obtained by the averaging of the squared overlap over the ensemble of random circuits (cf. (11.11)

$$\overline{\varepsilon_m} = \frac{D\,\overline{|\xi_m|^2} - 1}{D-1}\;. \tag{11.14}$$

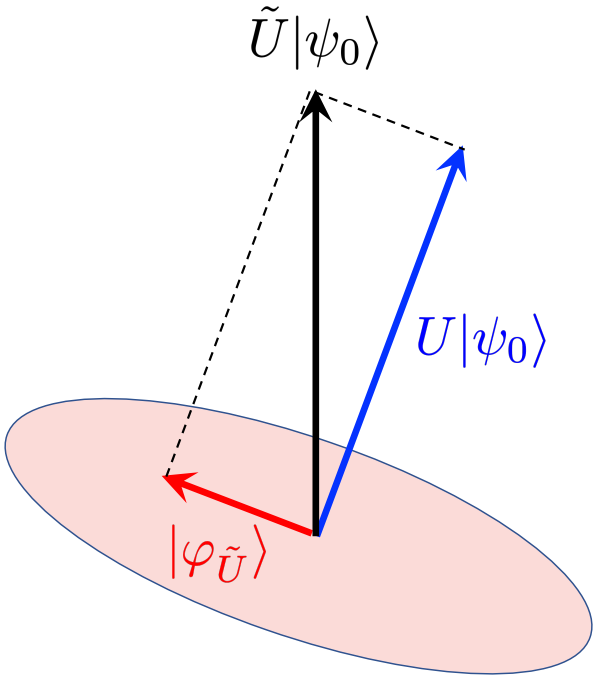

Figure S5: **Cartoon: decomposition of the quantum state into the vector aligned with the ideal quantum state and its orthogonal complement**

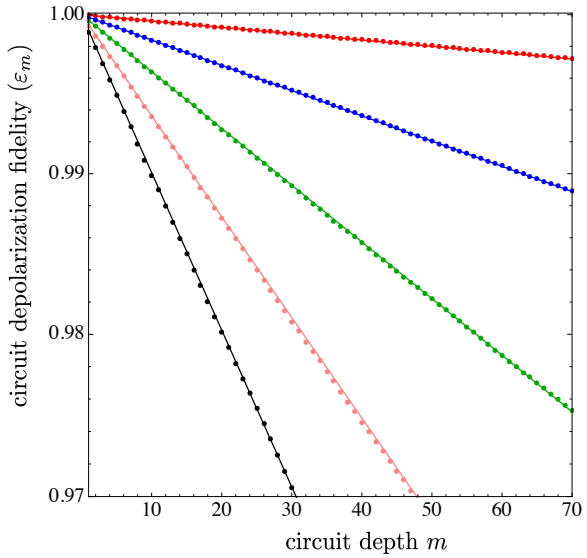

Figure S6: **Plots of the circuit depolarizing fidelity** *vs* **the circuit depth.** Solid lines corresponds to the predictions from the depolarizing channel model (11.13) and points correspond to $\overline{\varepsilon_m}$ (11.14) obtained by the averaging of the squared overlap over the ensemble of random circuits. Different colored pots correspond to different values of the swap error $\Delta\theta =$ 0.01(red), 0.02(blue), 0.03 (green), 0.04 (pink), 0.05 (black).

Returning to the generic case, property (11.3) can be extended so that for any smooth function $f(u)$ the following relation holds

$$\overline{\sum_{q\in\{0,1\}^n} f(p_s(q))\,\langle q|\,\chi_U\,|q\rangle} = \sum_{q\in\{0,1\}^n} \frac{\overline{f(p_s(q))}}{D} + \epsilon\ , \tag{11.15}$$

where $|q\rangle$ is a computational basis state corresponding to bitstring q, and $p_s(q) = \langle q|\,U\rho_0 U^\dagger\,|q\rangle$ is the simulated (computed) ideal probability of q. If the average is performed over a sample of random circuits of size S then the correction is $\epsilon \in O(1/\sqrt{S})$. We tested numerically for the case of $n = 2$ that relation (17.6) holds even for purely systematic errors in the case of a sufficiently random set of single qubit gates.

We now make the critical step of estimating the parameter p_c^m from a set of experimental realizations of random circuits with m cycles. We map each measured bitstring q with a function $f(p_s(q))$ and then average this function over the measured bitstrings. The standard XEB [27, 6] uses the natural logarithm, $f(p_s(q)) = \log(p_s(q))$. In the main text we use the linear version of XEB, for which $f(p_s(q)) = Dp_s(q)-1$. Both these functions give higher values to bitstrings with higher simulated probabilities. Another closely related choice is the Heavy Output Generation test [30], for which f is a step-function.

Under the model (11.2), in an experiment with ideal state preparation and measurement, we obtain the bitstring q with probability

$$p_c^m\ p_s(q) + (1 - p_c^m)\,\langle q|\,\chi_U\,|q\rangle\ , \tag{11.16}$$

For the linear XEB, the average value of $Dp_s(q) - 1$ when sampling with probabilities given by Eq. (11.16) is

$$\overline{\langle Dp_s(q) - 1\rangle} = p_c^m \left(D \sum_q \overline{p_s(q)^2} - 1 \right)\ . \tag{11.17}$$

Similarly to Eq. (17.6), the horizontal bar denotes averaging over the random circuits.

The sum on the right hand side of (11.17) goes over all bitstrings in the computational basis, and can be obtained with numerical simulations. It can also be found analytically assuming that the random circuit ensemble approximates the Haar measure where for a given q the quantity $p_s(q)$ is distributed with the beta distribution function $(D-1)(1-p_s)^{D-2}$. In this case the right hand side in (11.17) equals $p_c^m(2D/(D+1) - 1)$.

The experimental average on the left hand side of (11.17) can be estimated with accuracy $1/\sqrt{SN_s}$ using S random circuit realizations with N_s samples each

$$\frac{1}{SN_s} \sum_{j=1}^{S} \sum_{i=1}^{N_s} \left(Dp_s^j(q_{i,j}) - 1\right) = \overline{\langle Dp_s(q) - 1\rangle} + O\left(\frac{1}{\sqrt{SN_s}}\right)\ . \tag{11.18}$$

This gives an estimate of p_c^m.

This estimate can be justified using Bayes rule. The log-likelihood for a set of experimental measurements $\{q_{i,j}\}$ assuming that the experimental probabilities are given by Eq. (11.16) is proportional to

$$\sum_{j=1}^{S} \sum_{i=1}^{N_s} \log\left(1 + p_c^m(Dp_s^j(q_{i,j}) - 1)\right)\ , \tag{11.19}$$

where $p_s^j(q)$ is a simulated probability corresponding to the j-th circuit realization. We want to maximize the log-likelihood as a function of p_c^m. Taking the derivative with respect to p_c^m and equating to 0 we obtain

$$\sum_{j=1}^{S}\sum_{i=1}^{N_s}\frac{Dp_s^j(q_{i,j})-1}{1+p_c^m(Dp_s^j(q_{i,j})-1)}=0\ , \tag{11.20}$$

For $p_c^m \ll 1$ it is easy to solve this equation and obtain the estimate

$$p_c^m \simeq \frac{\sum_{j=1}^{S}\sum_{i=1}^{N_s}\left(Dp_s^j(q_{i,j})-1\right)}{\sum_{j=1}^{S}\sum_{i=1}^{N_s}\left(Dp_s^j(q_{i,j})-1\right)^2} \simeq \frac{\overline{\langle Dp_s(q)-1\rangle}}{D\sum_q \overline{p_s(q)^2}-1}\ . \tag{11.21}$$

In the spirit of the XEB method, we can use other functions $f(p_s(q))$ to estimate p_c^m. One alternative is derived from the log-likelihood of a sample $\{q_{i,j}\}$ with respect to the simulated (computed) ideal probabilities

$$\log \Pi_{j=1}^{S}\Pi_{i=1}^{N_s}p_s^j(q_{i,j})=\sum_{j=1}^{S}\sum_{i=1}^{N_s}\log p_s^j(q_{i,j})\ , \tag{11.22}$$

which converges to the cross entropy between experimental probabilities and simulated probabilities. The experimental average of the function $f(p_s(q))=\log p_s(q)$ under the probabilities from Eq. (11.16) with additional averaging over random circuits is

$$\begin{aligned}\overline{\langle \log p_s(q)\rangle} \simeq p_c^m&\left(\sum_q \overline{(p_s(q)-1/D)\log p_s(q)}\right)\\ &+\frac{1}{D}\sum_q \overline{\log p_s(q)}\ .\end{aligned} \tag{11.23}$$

As before, the sums on the right hand side can be obtained with numerical simulations and the average value on the left hand side can be estimated experimentally. This also gives an estimate of p_c^m.

Both Eq. (11.17) and Eq. (11.23) give a linear equation, from which we can obtain an estimate of the total polarization p_c^m for an experimental implementation of one quantum circuit with m cycles. We normally use mutiple circuits with the same number of cycles m to estimate p_c^m, which we can do using the least squares method. Finally, we obtain an estimate of p_c from a fit of the estimates p_c^m as an exponential decay in m. This is standard in randomized benchmarking [31, 32]. One advantage of this method is that it allows us to estimate the cycle polarization p_c independently of the state preparation and measurement errors (SPAM). See also below.

11.4.2 XEB of a large number of qubits

We now consider the case of a large number of qubits $n \gg 1$. We are typically interested in estimating the fidelity F of each of a set of circuits with a given number of qubits and depth. As above, we write the output of an approximate implementation of the random quantum circuit U as

$$\rho_U = F\left|\psi_U\right\rangle\left\langle\psi_U\right| + (1-F)\chi_U\ , \tag{11.24}$$

where $|\psi_U\rangle$ is the ideal output and $F=\langle\psi_U|\,\rho_U\,|\psi_U\rangle$ is the fidelity. We do not necessarily assume $\chi_U = I/D$, and we will ignore the small difference, of order 2^{-n}, $n \gg 1$, between the fidelity F and the depolarization fidelity p.

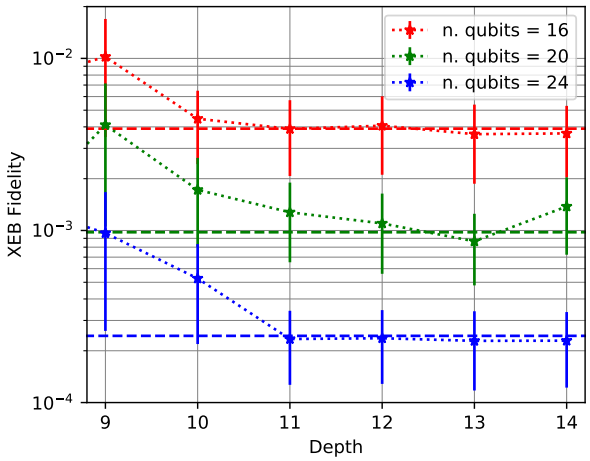

Figure S7: Absolute value of the XEB fidelity between a random quantum circuit and the same circuit with a single Pauli error. Markers show the median over all possible positions in the circuit for both bit-flip and phase-flip errors. Error bars correspond to the first and third quartile. The dashed lines are the $1/\sqrt{D}$ theory prediction.

As for the case of small number of qubits n, we map each output bitstring q with a function $f(p_s(q))$. Given that the values $\langle q|\,\chi_U\,|q\rangle$ resulting from errors are typically uncorrelated with the chaotic "speckles" of $p_s(q)$, we make our main assumption

$$\sum_q \langle q|\,\chi_U\,|q\rangle\, f(p_s(q)) = \frac{1}{D}\sum_q f(p_s(q)) + \epsilon\ . \tag{11.25}$$

This equation is trivial if we assume a depolarizing model, $\chi_U = I/D$. More generally, it can be understood in the geometric context of concentration of measure [33, 34, 35, 36] for high dimensional spaces, and from Levy's lemma [37] we expect a typical statistical fluctuation $\epsilon \in O(1/\sqrt{D})$ with $D = 2^n$. We will only require $\epsilon \ll F$. We check Eq. (11.25) numerically for the output $\rho_e = |\psi_e\rangle\langle\psi_e|$ where $|\psi_e\rangle$ is the wave function obtained after a single phase-flip or bit-flip error is added somewhere in the circuit, see Fig. S7 and Ref. [27]. We have also tested this assumption numerically comparing the fidelity with the XEB estimate for a pure state $\sqrt{F}\,|\psi_U\rangle + \sqrt{1-F}\,|\psi_\perp\rangle$, see also Ref. [38] and Section 11.10.

From Eqs. (11.24) and (11.25) we obtain Eq. (11.17) for linear XEB, $f(p_s(q)) = Dp_s(q) - 1$ ($\mathcal{F}_{\rm XEB}$ in the main text). We also obtain Eq. (11.23) for XEB, $f(p_s(q)) = \log p_s(q)$, with p_c^m replaced by fidelity F. As before, the sums on the right hand side can be obtained with numerical simulations and the average value on the left hand side can be estimated experimentally with accuracy $1/\sqrt{N_s}$ using N_s samples. This gives an estimate of F.

In practice, circuits of enough depth (as in the experiments reported here) exhibit the Porter-Thomas distribution for the measurement probabilities $p = \{p_s(q)\}$, that is

$$\Pr(p) = De^{-Dp}\ . \tag{11.26}$$

In this case the linear cross entropy Eq. (11.17) gives

$$F = \langle Dp_s(q) - 1\rangle\ . \tag{11.27}$$

The standard deviation of the estimate of F with N_s samples from the central limit theorem is $\sqrt{(1+2F-F^2)/N_s}$. The cross entropy Eq. (11.23) gives

$$F = \langle \log Dp_s(q)\rangle + \gamma\ , \tag{11.28}$$

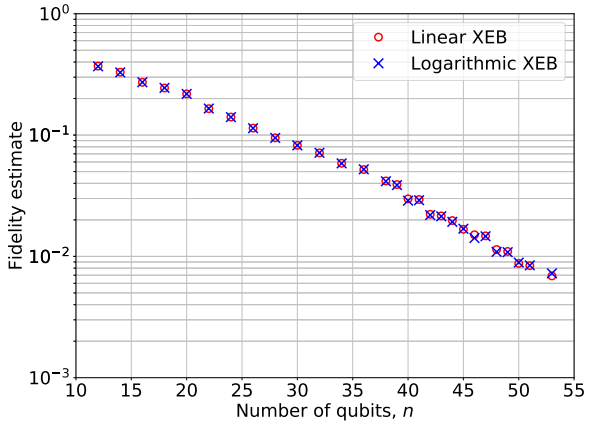

Figure S8: Comparison of fidelity estimates obtained using linear XEB, Eq. (11.27) and logarithmic XEB, Eq. (11.28) from bitstrings observed in our experiment using elided circuits (see Section 11.7.7). Standard deviation smaller than markers.

where γ is the Euler-Mascheroni constant ≈ 0.577. The standard deviation of the estimate of F with N_s samples is $\sqrt{(\pi^2/6 - F^2)/N_s}$. The logarithmic XEB has a smaller standard deviation for $F > 0.32$ (it is the best estimate when $F \approx 1$), while for $F < 0.32$ the linear XEB has a smaller standard deviation (it is the best estimate for $F \ll 1$, where it relates to the maximum likelihood estimator). See Fig. S8 for comparison of the fidelity estimates produced by the linear and logarithmic XEB.

We note in passing another example for an estimator of F related to the HOG test [30] which counts the number of measured bitstrings with probabilities $p_s(q)$ greater than the median of the probabilities. The function $f(p_s(q))$ in this case returns 1 for $Dp_s(q) \geq \log(2)$, and 0 in the other case. The fidelity estimator uses the following normalization

$$F = \frac{1}{\log(2)} \langle 2n_s(q) - 1 \rangle \ , \tag{11.29}$$

where $n_s(q)$ is defined to be 1 if $Dp_s(q) \geq \log(2)$, and 0 otherwise. The standard deviation of this estimator is $\sqrt{[\log^{-2}(2) - F^2]/N_s}$, which is always larger than for the XEB. See Fig. S9 for comparison of the fidelity estimates produced by linear XEB and the HOG-based fidelity estimator. HOG test is also related to a definition of quantum volume [39].

11.4.3 Two limiting cases

Here, we consider two special cases of Eq. (11.27) and the formula (1) in the main paper [1]. First, suppose bitstrings q_i are sampled from the uniform distribution. In this case the sampling probability is $1/D$ for every bitstring and $\mathcal{F}_{\text{XEB}} = 0$. Therefore, if the qubits are in the maximally mixed state, the estimator yields zero fidelity, as expected.

Second, suppose that bitstrings are sampled from the theoretical output distribution of a random quantum circuit. Assume that the distribution has Porter-Thomas shape. By Eq. (11.26), the fraction of bitstrings with theoretical probability in $[p, p + dp]$ is

$$\Pr(p)\, dp = De^{-Dp} dp \tag{11.30}$$

and the total number of such bitstrings is

$$N(p)\, dp = D^2 e^{-Dp}\, dp. \tag{11.31}$$

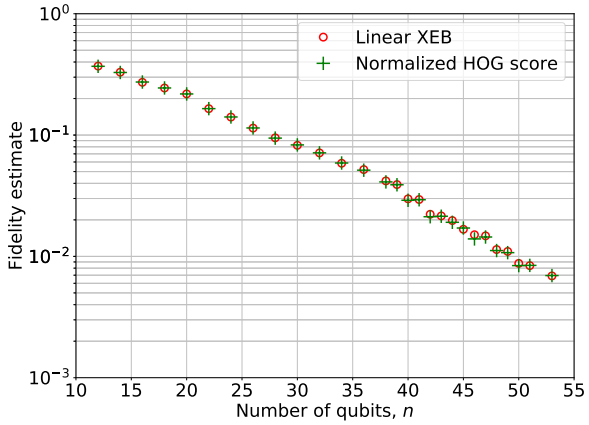

Figure S9: Comparison of fidelity estimates obtained using linear XEB, Eq. (11.27) and normalized HOG score, Eq. (11.29) from bitstrings observed in our experiment using elided circuits (see Section 11.7.7). Standard deviation smaller than markers.

Therefore, the probability that a bitstring with probability in $[p, p+dp]$ is sampled equals

$$p \cdot N(p)\, dp = pD^2 e^{-Dp}\, dp = f(p)\, dp \tag{11.32}$$

where $f(p)$ is the probability density function of the random variable defined as the ideal probability of a sampled bitstring, i.e. the random variable which is being averaged in the formula (1) of the main paper. Thus, the average probability of a sampled bitstring is

$$\begin{aligned} \langle p_s(q) \rangle &= \int_0^1 p f(p)\, dp = \int_0^1 p^2 D^2 e^{-Dp}\, dp \\ &= \frac{2}{D}\left(1 - e^{-D}\left(\frac{D^2}{2} + D + 1\right)\right) \approx \frac{2}{D}. \end{aligned} \tag{11.33}$$

Substituting into equation (1) in the main paper yields $\mathcal{F}_{\text{XEB}} = 1$. The general case of a depolarizing error can be obtained from the two limiting cases by convex combination.

11.4.4 Measurement errors

We now consider how measurement errors affect the estimation of fidelity. Let us assume uncorrelated classical measurement errors, so that if the "actual" measurement result of a qubit is 0, we can get 1 with probability e_{m0}, and similarly with probability e_{m1} we get 0 for actual result 1, i.e., $p(1|0) = e_{m0}$, $p(0|0) = 1 - e_{m0}$, $p(0|1) = e_{m1}$, $p(1|1) = 1 - e_{m1}$. In this case the probability to get measurement result $q = k_1 k_2 .. k_n$ for actual result $q' = k'_1 k'_2 .. k'_n$ is the product of the corresponding factors. The probability of correct measurement result is then

$$\begin{aligned} p_{\text{m}}(q') &= (1 - e_{m0})^{n - |q'|} (1 - e_{m1})^{|q'|} \\ &\approx (1 - e_{m0})^{n/2} (1 - e_{m1})^{n/2}, \end{aligned} \tag{11.34}$$

where $|q'|$ is the number of 1s (Hamming distance from 00..0) in the initial bitstring q', and in the second expression we approximated $|q'|$ with $n/2$ for large n.

Now let us make a natural assumption that if there was one or more measurement errors, $q' \to q$, then the resulting ideal probability $p_s(q)$ is uncorrelated with the actual ideal probability $p_s(q')$. Using this assumption we can write

$$F = F_U p_{\text{m}} \tag{11.35}$$

where F_U is the circuit fidelity and F is the complete (effective) fidelity. The complete fidelity F is estimated as before. The measurement fidelity $p_{\rm m}$ can be obtained independently. For instance, we can prepare a bistring q and measure immediately to obtain the probability of a correct measurement result for q. We obtain $p_{\rm m}$ by repeating this for a set of random bitstrings. We can therefore obtain F_U from Eq. (11.35). As explained above, fitting the depolarization fidelity per cycle p_c for different circuit depths m is also a method to separate measurement errors.

The state preparation errors can be treated similarly, assuming that a single error leads to uncorrelated resulting distribution $p_s(q)$, so that the measurement fidelity $p_{\rm m}$ in Eq. (11.35) is combined with a similar factor describing the state preparation fidelity.

11.5 Quantifying errors

An important test for this experiment is predicting XEB fidelity $\mathcal{F}_{\rm XEB}$ based on simpler measurements of single- and two-qubit errors. Here we review how this is calculated, illustrating important principles with the example of a single qubit. The general theory is described at the end of this section.

First, we assume Pauli errors describe decoherence using a depolarizing model. This model is used, for example, to compute thresholds and logical error rates for error correction. The parameter describing decoherence in a single qubit is the Pauli error e_P, giving a probability $e_P/3$ for applying an erroneous X, Y, or Z gate to the qubit after the gate, corresponding to a bit and/or phase flip.

Second, the depolarization model is assumed to describe the system state using simple classical probability. The probability of no error for many qubits and many operations, corresponding to no change to the system state, is then found by simply multiplying the probability of no error for each qubit gate. This is a good assumption for RB and XEB since a bit- or phase-flip error effectively decorrelates the state. The depolarization model assumes that when there is an error with probability e_d, the system state randomly splits to all qubits states, which has Hilbert space dimension $D = 2^n$. This is described by a change in density matrix $\rho \to (1 - e_d)\rho + e_d \times \mathbb{1}/D$. Note the depolarization term has a small possibility of the state resetting back to its original state. For a single qubit where $D = 2$, this can be described using a Pauli-error type model as a probability $e_d/4$ applying a I, X, Y, or Z gate. Comparing to the Pauli model, the error probability thus needs to be rescaled by $e_d = e_P/(1 - 1/D^2)$. This gives a net polarization p of the qubit state due to many Pauli errors as

$$p = \prod_i \left[1 - e_P(i)/\left(1 - 1/D^2\right)\right]. \tag{11.36}$$

Third, the effect of this depolarization has to be accounted for considering the measured signal. The measured signal for randomized benchmarking is given by $RB = p(1-1/D)+1/D$, which can be understood in a physical argument that a complete randomization of the state has a 1/D chance to give the correct final state. A cross-entropy benchmarking measurement gives $\mathcal{F}_{\rm XEB} = p$. A measurement of p, which can have offsets and prefactors in these formulas, also includes other scaling factors coming from state preparation and measurement errors. All of these scaling issues are circumvented by applying gates in a repeated number of cycles m such that $p = p_c^m$. A measurement of the signal versus m can then directly pull out the fractional polarization change per cycle, p_c, independent of these scale factors.

Fourth, from this polarization change we can then compute the Pauli error, which is the metric that should be reported since it is the fundamental error rate that is independent of D. Unfortunately, a fidelity $1 - e_P/(1 + 1/D)$ for RB is commonly reported, which has a D-dependent correction. We recommend this practice be changed, but note that removing the

Table 11: A "Rosetta stone" translation between error metrics. In single- and two-qubit RB or XEB experiments, we measure the per-gate (or per-cycle) depolarization decay constant p. The second column shows conversions from this rate to the various error metrics. The last two columns are representative comparisons for 0.1% Pauli error.

Error metric	Relation to depolarization decay constant p	n=1 (D=2)	n=2 (D=4)
Pauli error (e_p, r_P) [1]	$(1-p)(1-1/D^2)$	0.1%	0.1%
Average error (e_a, r)	$(1-p)(1-1/D)$	0.067%	0.08%
Depolarization error (e_d)	$1-p$	0.133%	0.107%

$1/(1+1/D)$ factor decreases the reported fidelity value. We also recommend reporting Pauli error, e_P instead of entanglement fidelity $(1-e_P)$, since it is more intuitive to understand how close some quantity is to 0 than to 1. Table 11 summarizes the different error metrics and their relations.

This general model can also account for non-depolarizing errors such as energy decay, since quantum states in an algorithm typically average over the entire Bloch sphere (as in XEB), or for example when the algorithm purposely inserts spin-echoes. Thus the average effect of energy decay effectively randomizes the state in a way compatible with Pauli errors. For a gate of length t_g with a qubit decay time T_1, averaging over the Bloch sphere (2 poles and 4 equator positions) gives (to first order) an average error probability $e_a = t_g/3T_1$. Using Table 11, this converts to a Pauli error $e_P = t_g/2T_1$.

A detailed theory of the D scaling factor is as follows. In order to arrive at a first order estimate on how error rates accumulate on random quantum circuits, the errors can be modeled via the set of Kraus operators. The density matrix of the system ρ after application of a gate is connected to the density matrix ρ_0 before the gate as follows:

$$\rho = \Lambda(\rho_0) = \sum_{k=0}^{K} A_k \rho_0 A_k^\dagger, \quad \sum_k A_k^\dagger A_k = \mathbb{1}. \tag{11.37}$$

For the closed-system quantum evolution with unitary U (no dephasing nor decay) the sum on the right hand side contains only one term with k=0 and $A_0 = U$. In general, Kraus operators describe the physical effects of many types of errors (control error, decoherence, etc.) that can explicitly depend on the gate. Knowing the Kraus operators allows us to calculate the total error budget as well as its individual components.

Conventionally, circuit fidelities are reported as a metric of its quality. To make a connection to physically observable quantities, the average fidelity can be expressed in terms of Kraus operators. In the absence of leakage errors and cross-talk the average fidelity equals

$$F = 1 - \frac{e_P}{1+1/D}, \quad e_P = 1 - \frac{1}{D^2}\sum_{k=0}^{K} |\operatorname{tr}\left(U A_k^\dagger\right)|^2 \tag{11.38}$$

where $D = 2^n$ is the dimension of the Hilbert space and the quantity e_P plays a role of a Pauli error probability in the depolarizing channel model (see below).

For random circuits the effects of errors can be described by a depolarizing channel model, with Kraus operators of the form

$$\begin{aligned} A_{\mathbf{k}} &= \sqrt{\frac{e_P}{D^2-1}}\, P_{\mathbf{k}} U, \quad \mathbf{k} \neq \mathbf{0}, \\ A_{\mathbf{0}} &= \sqrt{1-e_P}\, P_{\mathbf{0}} U, \\ P_{\mathbf{k}} &= \sigma_{k_1} \otimes \sigma_{k_2} \ldots \otimes \sigma_{k_n} \end{aligned} \tag{11.39}$$

where $P_{\mathbf{k}}$ are strings of Pauli operators σ_{k_j} for individual qubits for $k_j = 1, 2, 3$ and also identity matrices σ_0 in the qubit subspace for $k_j = 0$. This form assumes that individual Pauli errors all happen with the same probability e_P.

To make a connection to experimental measurements of the cross-entropy we substitute (11.39) into (11.37) and obtain

$$\Lambda(\rho_0) = (1 - e_P)U\rho_0 U^{-1} + \frac{e_P}{D - 1/D}\left(\mathbb{1} - \frac{U\rho_0 U^{-1}}{D}\right). \quad (11.40)$$

We compare this expression with the standard form of the depolarizing channel model

$$\Lambda(\rho_0) = pU\rho_0 U^{-1} + (1 - p)\frac{\mathbb{1}}{D}, \quad (11.41)$$

expressed in terms of the depolarization fidelity parameter p. Note the difference between the expressions. On the one hand, in (11.41) the second term corresponds to full depolarization in all directions. On the other hand, in (11.40) the second term describes full depolarization in all directions except for the direction corresponding to the ideal quantum state.

From (11.40), (11.41) one can establish the connection between the Pauli error rate and depolarizing fidelity parameter p

$$e_P = (1 - p)(1 - 1/D^2) \quad (11.42)$$

We note that the explicit assumption of connecting Pauli errors to depolarization is needed for the small D case, typically for single- and two-qubit error measurements. Once we have measured the Pauli errors, then only a simple probabilistic calculation is needed to compute $\mathcal{F}_{\text{XEB}}$ in the large D case.

11.6 Metrology and calibration

11.6.1 Calibration overview

Quantum computations are physically realized through the time-evolution of quantum systems steered by analog control signals. As quantum information is stored in continuous amplitudes and phases, these control signals must be carefully chosen to achieve the desired result. Calibration is the process of performing a series of experiments on the quantum system to learn optimal control parameters.

Calibration is challenging for a number of reasons. Analog control requires careful control-pulse shaping as any deviation from the ideal will introduce error. Qubits require individual calibration as variations in the control system and qubits necessitate different control parameters to hit target fidelities. Optimal control parameters can also drift in time, requiring calibrations to be revisited to maintain performance. Additionally, the full calibration procedure requires bootstrapping: using a series of control sequences with increasing complexity to determine circuit and control parameters to increasingly higher degrees of precision. Lastly, each qubit needs to perform a number of independent operations which are independently calibrated: single-qubit gates, two-qubit gates, and readout.

Our Sycamore processor offers a high degree of programmability: we can dynamically change the frequency of each qubit, as well as the effective qubit-qubit coupling between nearest neighbor qubits. This tunability gives us the freedom to enact many different control strategies, as well as account for non-uniformities in the processor's parameters. However, these extra degrees of freedom are a double-edged sword. Additional control knobs always introduce a source of decoherence and control errors as well as an added burden on calibration.

Our approach is to systematize and automate our calibration procedure as much as possible, thus abstracting complexity away. This automation allows us to turn calibration into a science, where we can compare calibration procedures to determine optimal strategies for time, performance, and reliability. By employing calibration science to study full-system performance with different control strategies, we have been able to improve full-system fidelities by over an order of magnitude from initial attempts while decreasing the calibration time and improving reliability. Lastly, we design our calibration to be done almost entirely at the single- or two-qubit level, rather than at the system level, in order to be as scalable as possible.

Device registry

The device registry is a database of control variables and configuration information we use to control our quantum processors. The registry stores information such as operating frequencies, control biases, gate parameters such as duration, amplitude, parameterization of circuit models, etc. The goal of calibration is to experimentally determine and populate the registry with optimal control parameters. We typically store >100 parameters per qubit to achieve high fidelity across all of the various qubit operations. The large number of parameters and subtle interdependencies between them highlights the need for automated calibration.

Scheduling calibrations: “Optimus"

We seek a strategy for identifying and maintaining optimal control parameters for a system of physical qubits given incomplete system information. To perform these tasks, we use the “Optimus" formulation as in Ref [40], where each calibration is a node in a directed acyclic graph that updates one or more registry parameters, and the bootstrapping nature of calibration sequences is represented as directed edges between nodes. Now, calibrating a system of physical qubits becomes a well-defined graph traversal problem. The calibration graph used for the Sycamore device can be see in Figure S10. This strategy is particularly useful for maintaining calibrations in the presence of drift, where we want to do the minimal amount of work to bring the system back in spec, and when extending the calibration procedure, as interdependencies are explicit. Typical timescales for bringup of a new Sycamore processor are approximately 36 hours upon first cooldown, and 4 hours per day thereafter for maintaining calibrations. These times are specific to current available technology, and can be significantly improved.

11.6.2 Calibration procedure

Device configuration

Throughout the calibration procedure, the device registry may be configured in different states in order to calibrate certain parameters. We call these different states “device configurations", and different kinds of configurations reflect our knowledge of the system at different points in the full calibration procedure. As illustrated in Figure S11, the primary difference between the different configurations is the set of “active" qubits, where active qubits are biased to an operating frequency between 5-7 GHz, and “inactive" qubits are biased near zero frequency. Following the outline above, we have three device configurations of interest:

Root config.

The root configuration is the starting state of the system immediately after cool down and basic system verification. In this configuration, we calibrate coarse frequency vs bias curves for each readout resonator, qubit, and coupler.

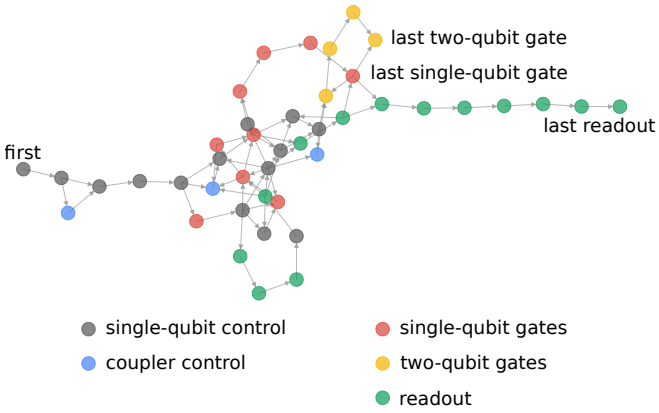

Figure S10: **Optimus calibration graph for Sycamore.** Calibration of physical qubits is a bootstrapping procedure between different pulse sequences or "experiments" to extract control and system parameters. Initial experiments are coarse and have interplay between fundamental operations and elements such as single-qubit gates, readout, and the coupler. Final experiments involve precise metrology for each of the qubit operations: single-qubit gates, two-qubit gates, and readout.

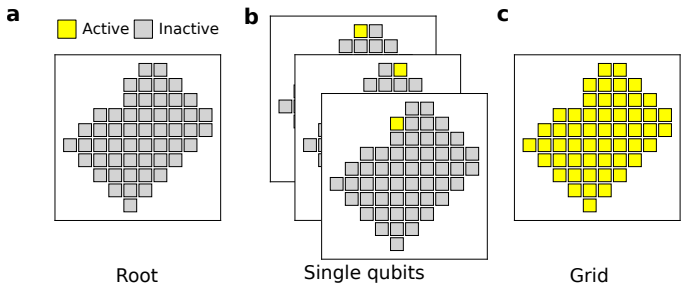

Figure S11: **Configurations of the device over the course of calibration. a,** In the root configuration, we start with no knowledge of the system and measure basic device parameters. **b,** We create a single qubit configuration for each qubit, where all qubits except the qubit of interest are biased to near zero frequency. **c,** Using knowledge learned in the single qubit configurations, we build a grid of qubits.

Single qubit config.

After completing root calibrations, we now know how to bias each qubit to its minimum and maximum frequencies. We create one configuration of the device registry for each qubit, where the qubit of interest is biased in a useful region (5-7 GHz) and the remaining qubits are biased to their minimum frequencies in order to isolate the qubit of interest. In each of these configurations, we fine tune the bias vs frequency curves for the qubit and its associated couplers and resonators, and also measure T_1 as a function of frequency, necessary due to background TLS defects and modes.

Grid config.

After completing calibrations in each isolated qubit configuration, we feed the information we learned into a frequency optimization procedure. The optimizer places the biases for each qubit and coupler in a user defined grid of any desired size up to the entire chip. We then proceed to calibrate high fidelity single qubit gates, two qubit gates, and readout.

Root config: procedure

We begin calibration with simple frequency-domain experiments to understand how each qubit and coupler responds to its flux bias line.

- Calibrate each parametric amplifier (flux bias, pump frequency, pump power).
- For each qubit, identify its readout resonator and measure the readout signal versus qubit bias ("Resonator Spectroscopy") [41]. Estimate the resonator and qubit frequency as a function of qubit bias.
- For each coupler, place one of its qubits near maximum frequency and the other near minimum frequency, then measure the readout signal of the first qubit as a function of coupler bias. The readout signal changes significantly as the coupler frequency passes near the qubit frequency. Identify where the coupler is near its maximum frequency, so the qubit-qubit coupling is small (a few MHz) and relatively insensitive to coupler bias.

Single-qubit config: procedure

After setting the biases to isolate a single qubit, we follow the procedure outlined in [42] which we will summarize here:

- Perform fixed microwave drive qubit spectroscopy while sweeping the qubit bias and detecting shifts in the resonator response, to find the bias that places the qubit at the desired resonant frequency.
- Using the avoided level crossing identified in the root config, determine the operating bias to bring the qubit on resonance with its readout resonator to perform active ground state preparation. We use a 10 μs pulse consistent with the readout resonator ringdown time.
- Perform power Rabi oscillations to find the drive power that gives a π pulse to populate the $|1\rangle$ state.
- Optimize the readout frequency and power to maximize readout fidelity.
- Fine tune parameters (qubit resonant frequency, drive power, drive detuning [43]) for π and $\pi/2$ pulses.

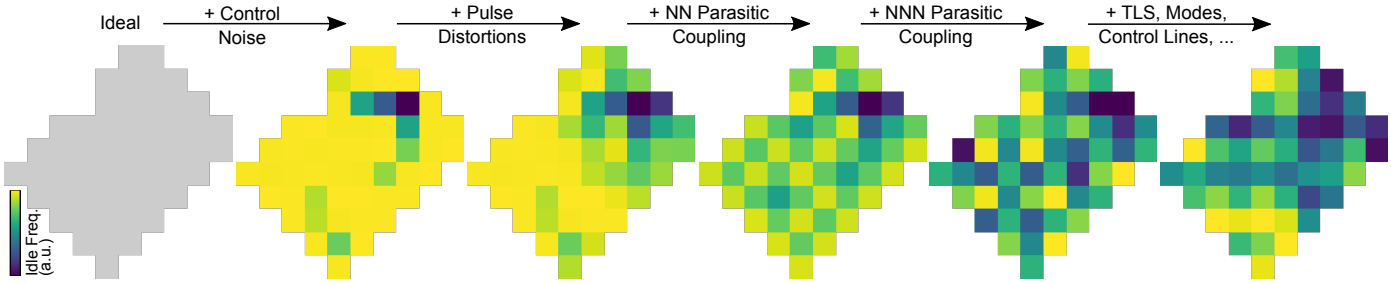

Figure S12: **Idle frequency solutions found by our Snake optimizer with different error mechanisms enabled.** The optimizer makes increasingly complex tradeoffs as more error mechanisms are enabled. These tradeoffs manifest as a transition from a structured frequency configuration into an unstructured one. Similar tradeoffs are simultaneously made in optimizing interaction and readout frequencies. Optimized idle and interaction operating frequencies are shown in Figure S13 and optimized readout frequencies are shown in Figure S20. Color scales are chosen to maximize contrast. Grey indicates that there is no preference for any frequency.

- Calibrate the timing between the qubit microwave drive, qubit bias, and coupler bias.
- Perform qubit spectroscopy as a function of qubit bias to fine tune the qubit bias vs frequency curves.
- Measure T_1 vs. frequency by preparing the qubit in $|1\rangle$ then biasing the qubit to a variable frequency for a variable amount of time, and measuring the final population [44].
- Measure the response of a qubit to a detuning pulse to calibrate the frequency-control transfer function [45, 6, 42].

With the single-qubits calibrated in isolation, we have a wealth of information on circuits parameters and coherence information for each qubit. We use this information as input to a frequency placement algorithm to identify optimal operating frequencies for when the full processor is in operation.

Optimizing qubit operating frequencies

In our quantum processor architecture, we can independently tune each qubit's operating frequency. Since qubit performance varies strongly with frequency, selecting good operating frequencies is necessary to achieve high fidelity gates. In arbitrary quantum algorithms, each qubit operates at three distinct types of frequencies: idle, interaction, and readout frequencies. Qubits idle and execute single-qubit gates at their respective idle frequencies. Qubit pairs execute two-qubit gates near their respective interaction frequencies. Finally, qubits are measured at their respective readout frequencies. In selecting operating frequencies, it is necessary to mitigate and make nontrivial tradeoffs between energy-relaxation, dephasing, leakage, and control imperfections. We solve and automate the frequency selection problem by abstracting it into an optimization problem.

We construct a quantum-algorithm-dependent and gate-dependent optimization objective that maps operating frequencies onto a metric correlated with system error. The error mechanisms embedded within the objective function are parasitic coupling between nearest-neighbor and next-nearest-neighbor qubits, spectrally-diffusing two-level-system (TLS) defects [44], spurious microwave modes, coupling to control lines and the readout resonator, frequency-control electronics noise, frequency-control pulse distortions, microwave-control pulse distortions, and microwave-carrier bleedthrough. Additional considerations in selecting readout frequencies are

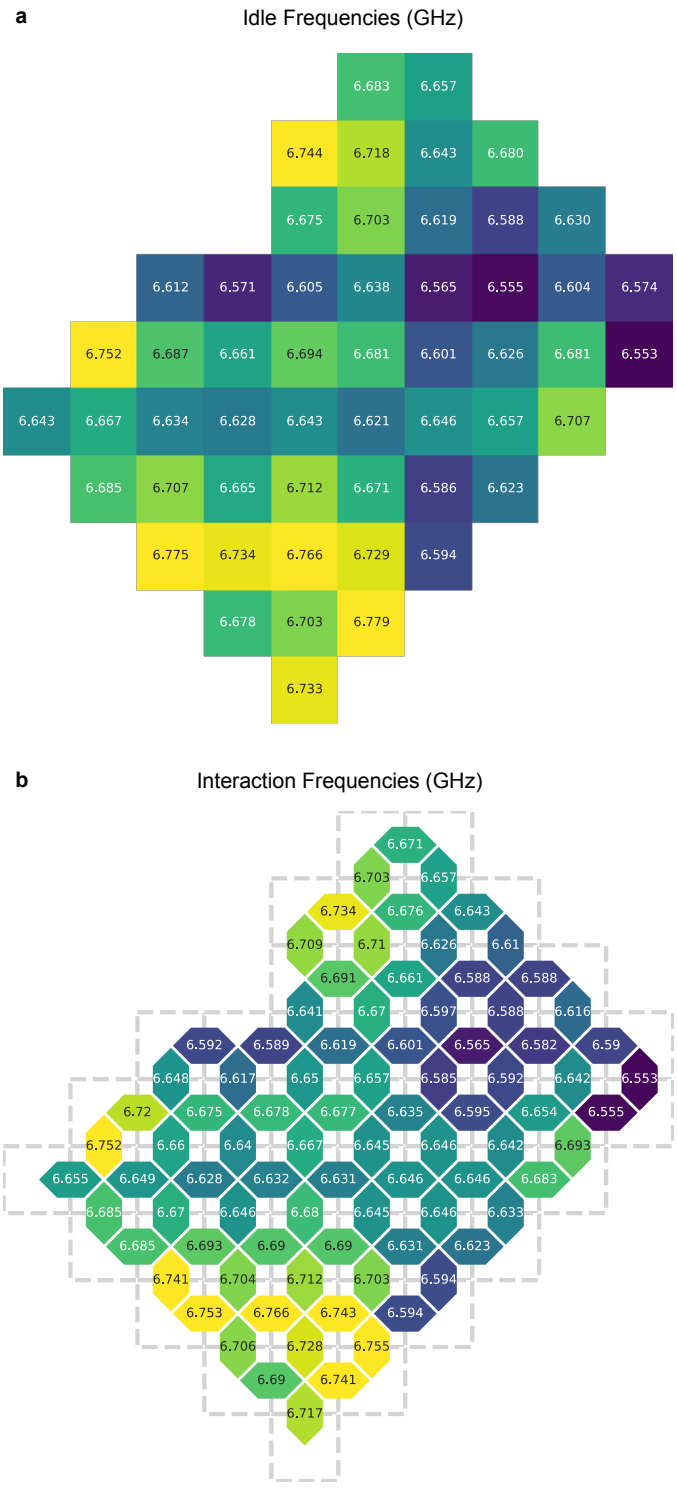

Figure S13: **Optimized idle and interaction frequencies found by our Snake optimizer. a,** Idle frequencies, **b,** interaction frequencies. Readout frequencies are shown in Figure S20. These solutions are sufficient for state-of-the-art system performance. See Figure S12 to understand some of the tradeoffs that are made during optimization. Color scales are chosen to maximize contrast.

covered in Section 11.6.4. The objective is constructed from experimental data and numerics, and the individual error mechanisms are weighted by coefficients determined either heuristically or through statistical learning.

Minimizing the objective function is a complex combinatorial optimization problem. We characterize the complexity of the problem by the optimization dimension and search space. For a processor with N qubits on a square lattice with nearest-neighbor coupling, there are N idle, N readout, and $\sim 2N$ interaction frequencies to optimize. In an arbitrary quantum algorithm, all frequencies are potentially intertwined due to coupling between qubits. Therefore, the optimization dimension is $\sim 4N$. The optimization search-space is constrained by qubits' circuit parameters and control-hardware specifications. Discretizing each qubit's operational range to 100 frequencies results in an optimization search space of $\sim 100^{4N}$. This is much larger than the dimension of the Hilbert space of an N qubit processor, which is 2^N.

Given the problem complexity, it is assumed that finding globally optimal operating frequencies is intractable. However, we have empirically verified that locally optimal solutions are sufficient for state-of-the-art system performance. To find local optima, we developed the "Snake" homebrew optimizer that combines quantum algorithm structure with physics intuition to exponentially reduce optimization complexity and take intelligent optimization steps. For the circuits used here, the optimizer exploits the time-interleaved structure of single-qubit gates, two-qubit gates, and readout. For our 53 qubit processor, it returns local optima in ~ 10 seconds on a desktop. Because of its favorable scaling in runtime versus number of qubits, we believe the Snake optimizer is a viable long-term solution to the frequency selection problem.

To illustrate how the Snake optimizer makes tradeoffs between error mechanisms, we plot idle frequency solutions with different error mechanisms enabled (Figure S12). Starting with an ideal processor with no error mechanisms enabled, there is no preference for any frequency configuration. Enabling frequency-control electronics noise, the optimizer pushes qubits towards their respective maximum frequencies, to minimize flux-noise susceptibility. Note that each qubit has a different maximum frequency due to fabrication variability. Enabling frequency-control pulse distortions forces a gradual transition between qubit frequencies to minimize two-qubit-gate frequency-sweep amplitudes. Enabling nearest-neighbor (NN) and next-nearest neighbor (NNN) parasitic coupling further lowers the degeneracy between qubit frequencies into a structure that resembles a multi-tiered checkerboard. Finally, enabling errors from TLS defects, spurious microwave modes, and all other known error mechanisms removes any obvious structure. A set of optimized idle and interaction frequencies is shown in Figure S13, and readout frequencies are shown in Figure S20.

Grid config: procedure

Calibrating a grid of qubits follows the same procedure as calibrating an isolated qubit with additional calibrations to turn off the qubit-qubit coupling.

- Achieve basic state discrimination for each qubit at its desired frequency.
- For each coupler, minimize the qubit-qubit coupling (note changing coupler biases affects qubit frequencies). For each case below, we choose the coupler bias minimizing the interaction.
  - For qubit pairs idling within 60 MHz of each other, use a resonant swapping experiment. We excite one qubit and apply flux pulses to nominally put the qubits on resonance and let the qubits interact over time [9].
  - For qubit pair idling further apart, use a conditional phase experiment. We perform two Ramsey experiments on one qubit, where the other qubit is in the ground state

and the excited state, to identify the state-dependent frequency shift of the first qubit.

- Adjust the qubit biases to restore the desired qubit frequencies and proceed with qubit calibration as in the single-qubit configurations.
- Calibrate the entangling gate.
  - Estimate the qubit pulse amplitudes to reach the desired interaction frequency with their frequency versus bias calibration.
  - Fine-tune the qubit pulse amplitudes to reach resonance, compensating for pulse undershoot.
  - Tune the coupler pulse amplitude to achieve a complete photon exchange.

In the next two sections, we describe in more detail the fine tuning required to achieve high fidelity two qubit gates and multiqubit readout.

11.6.3 Two-qubit gate metrology

High-fidelity two-qubit gates are very hard to achieve. In an effort to make this easier, we design qubits with tunable frequencies and tunable interactions. This added control allows for immense flexibility when implementing gates. In the following subsections, we discuss a simple high-fidelity control and metrology strategy for two-qubit gates in our system.

The natural two-qubit gate for transmon qubits

Consider two transmon qubits at different frequencies (say 6.0 and 6.1 GHz). Here are two potential ways of generating a multi-qubit gate in this system. If the qubits are tuned into resonance, then excitations swap back-and-forth and this interaction can be modeled as a partial-iSWAP gate [46]. If the qubits are detuned by an amount close to their nonlinearity, then the 11-state undergoes an evolution that can be modeled as a controlled-phase gate (assuming the population does not leak) [47, 48]. In fact, any two-qubit control sequence that does not leak can be modeled as a partial-iSWAP followed by a controlled-phase gate.

A typical control sequence is shown Fig. S14a. Gate times of 12 ns are chosen to trade off decoherence (too slow) and leakage to higher states of the qubit (too fast). Figure S14b depicts how this operation can be decomposed as a quantum circuit. This circuit contains Z-rotations that result from the frequency excursions of the qubits, and can be expressed by the unitary:

$$\begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & e^{i(\Delta_+ + \Delta_-)}\cos\theta & -ie^{i(\Delta_+ - \Delta_{-,\mathrm{off}})}\sin\theta & 0 \\ 0 & -ie^{i(\Delta_+ + \Delta_{-,\mathrm{off}})}\sin\theta & e^{i(\Delta_+ - \Delta_-)}\cos\theta & 0 \\ 0 & 0 & 0 & e^{i(2\Delta_+ - \phi)} \end{bmatrix}. \tag{11.43}$$

These gates have an efficient mapping to interacting fermions and have been coined 'fSim' gates, short for fermionic simulation [49]. The long-term goal is to implement the entire space of gates (shown in Fig. S14c).

For quantum supremacy, the two-qubit gate of choice is the iSWAP gate. For example, CZ is less computationally expensive to simulate on a classical computer by a factor of two [38, 50]. A dominant error-mechanism when trying to implement an iSWAP is a small conditional-phase that is generated by an interaction of the $|11\rangle$-state with higher states of the transmons ($|02\rangle$ and $|20\rangle$). For this reason, the fSim gate with swap-angle $\theta \approxeq 90°$ and conditional phase $\phi \approxeq 30°$ has become the gate of choice in our supremacy experiment. Note that small deviations from

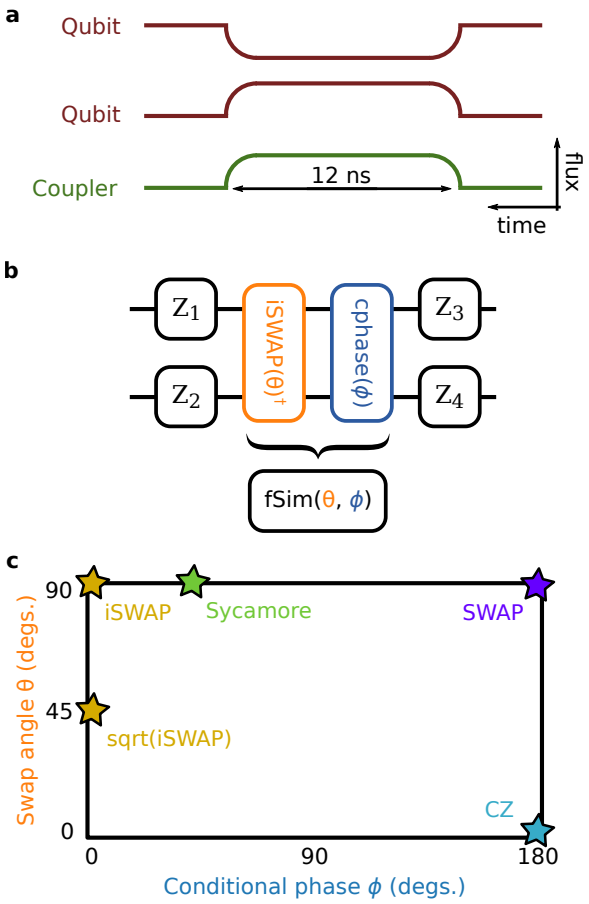

Figure S14: **Two-qubit gate strategy. a,** Control waveforms for two qubits and a coupler. Each curve represents the control flux applied to the qubit's and coupler's SQUID loops as a function of time. **b,** Generic circuit representation for an arbitrary two-qubit gate using flux pulses. This family of gates have been named "fSim" gates, short for fermionic-simulation gates. Our definition of the fSim gate uses θ with the sign opposite to the common convention for the iSWAP gate. **c,** Control landscape for fSim gates as a function of the swap angle and conditional phase, up to single qubit rotations. The coordinates of common entangling gates are marked along with the Sycamore gate fSim($\theta = 90°, \phi = 30°$).

these angles are also viable quantum supremacy gates. These gates result from the natural evolution of two qubits making them easy to calibrate, high intrinsic fidelity gates for quantum supremacy.

Using cross entropy to learn a unitary model

We have recently introduced cross-entropy as a fidelity metric for quantum supremacy experiments. Cross-entropy benchmarking (XEB) was introduced as an analog to randomized benchmarking (RB) that can be used with any number of qubits and is independent of state-preparation and measurement errors [6, 27].

A distinct advantage of XEB is that the resulting data can be analyzed to find an optimal representation of a unitary; this process is outlined in Fig. S15. The gate sequence for a two-qubit XEB experiment is shown in Fig. S15a. The sequence alternates between single-qubit gates on both qubits and a two-qubit gate between them. At the end of the sequence, both qubits are measured and the probabilities of bitstrings (00, 01, 10, 11) are estimated. This procedure is repeated for ~10-20 instances of randomly selected single-qubit gates. The measured probabilities can then be compared to the ideal probabilities using the expression for

fidelity Eq. (3) in Ref. [6].

The data from a two-qubit XEB experiment is shown in Fig. S15b (green dots). By performing additional sequences with tomography rotations prior to measurement, we can infer the decay of purity with increasing circuit depth (blue dots). For two qubits, the decay of fidelity tells us the total error of our gates while the purity decay tells us the contribution from decoherence —the difference is control error. Based on the data in green and blue, it appears that the total error is about half control and half decoherence.

So far, we have established a generic unitary model (Fig. S14b), a training dataset (Fig. S15a), and a cost-function (Fig. S15b). These three ingredients form the foundation for using optimization techniques to improve fidelity. Using a simple Nelder-Mead optimization protocol, we can maximize the XEB fidelity by varying the parameters of the unitary model. The fidelity decay curve for the optimal unitary model are shown in Fig. S15b (orange dots). The optimized results are nearly coherence limited.

The optimal control-model parameters for all pairs are shown as integrated histograms in Fig. S16a,b. Panel (a) shows the histograms for partial-iSWAP angles (∼90 degrees) and conditional phases (∼30 degrees). Panel (b) shows histograms for the various flavors of Z-rotations. While conceptually there are four possible Z-rotations (see Fig. S14b), only three of these rotations are needed to uniquely define the operation. These three rotations can be thought of as the detuning of the qubits before the iSWAP, the detuning after the iSWAP, and an overall frequency shift of both qubits which commutes with the iSWAP.

Comparison with randomized benchmarking

In Fig. S17 we show that two-qubit gate fidelity extracted using XEB agrees well with the fidelity as measured with RB, an important sanity check in validating XEB as a gate metrology tool. In two-qubit XEB, we extract the error per cycle which consists of a single-qubit gate on each qubit and a two-qubit gate between them. In Fig. S17a we show the individual RB decay curves for single-qubit gates. In panel b, we show the RB decay curve for benchmarking a CZ gate. Adding up the three errors from RB, we would expect an XEB cycle error of 0.57%. In panel c, we show the measured XEB decay curve which indicates a cycle error of 0.59% —nearly identical to the value predicted by RB.

For single-qubit gate benchmarking on the Sycamore device used in this work (see Table 12), we find that π pulse fidelities are somewhat worse than $\pi/2$ pulse fidelities, which we attribute to reflections from the imperfect microwave environment. Because the XEB gateset we have used consists only of $\pi/2$ pulses, we find that the single-qubit gate errors extracted from conventional RB, which contains π pulses, are somewhat higher than those extracted from single-qubit XEB. Using only $\pi/2$ pulses instead of π pulses in single-qubit RB brings the extracted error close to that measured via XEB.

Speckle purity benchmarking (SPB)

It is experimentally useful to be able to extract state purity from XEB experiments in order to error-budget the contribution of decoherence. Conventionally, purity estimation can be done with state tomography, where the full density matrix ρ is reconstructed and used to quantify the state purity. This involves expanding a single sequence into a collection of sequences each appended with single-qubit gates. Unfortunately, full tomographic reconstruction scales exponentially in the number of qubits, both for the number of sequences needed as well as the number of measurements needed per sequence. Here, we introduce an exponentially more efficient method to extract the state purity without additional sequences.

We use a re-scaled purity definition such that a fully-decohered state has a purity of 0, and

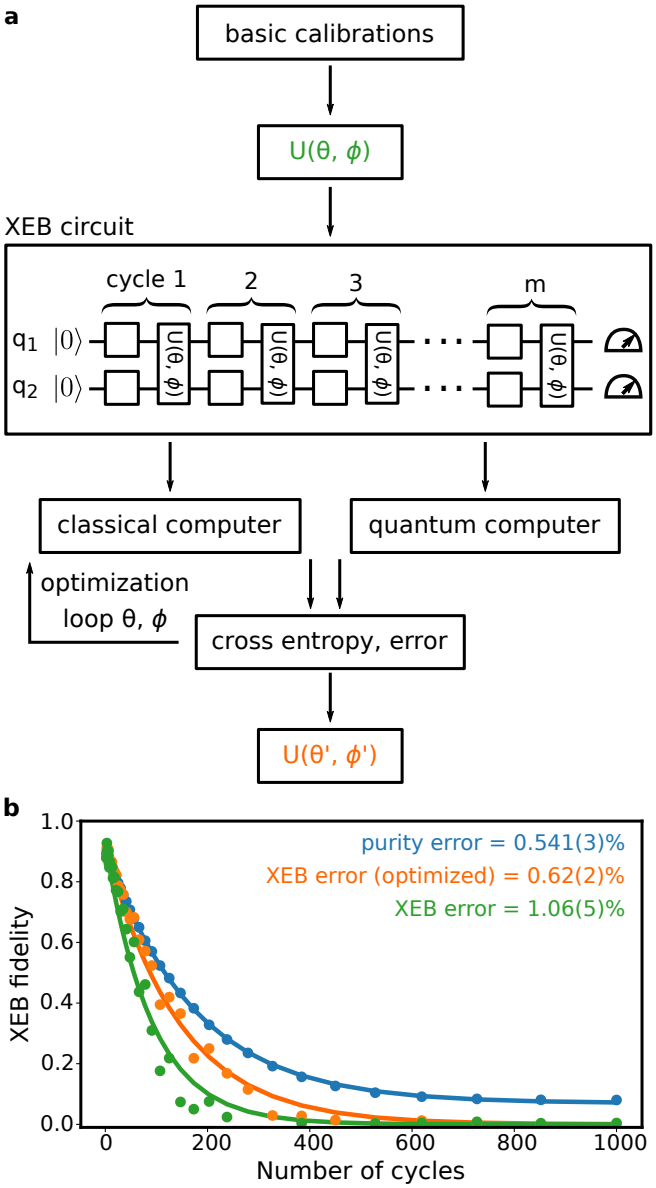

Figure S15: **Using XEB to learn a unitary model. a,** Process flow diagram for using XEB to learn a unitary model. After running basic calibrations, we have an approximate model for our two-qubit gate. Using this gate, we construct a random circuit that is fed into both the quantum computer and a classical computer. The results of both outputs can be compared using cross-entropy. Optimizing over the parameters in the two qubit model provide a high-fidelity representation of the two-qubit unitary. **b,** Data from a two-qubit XEB experiment. The two-qubit purity (blue) was measured tomographically and provides the coherence-limit of the operations. The decay of the XEB fidelity is shown in green and orange. In orange, the parameters of a generic unitary model were optimized to determine a higher-fidelity representation of the unitary. All errors are quoted as Pauli errors.

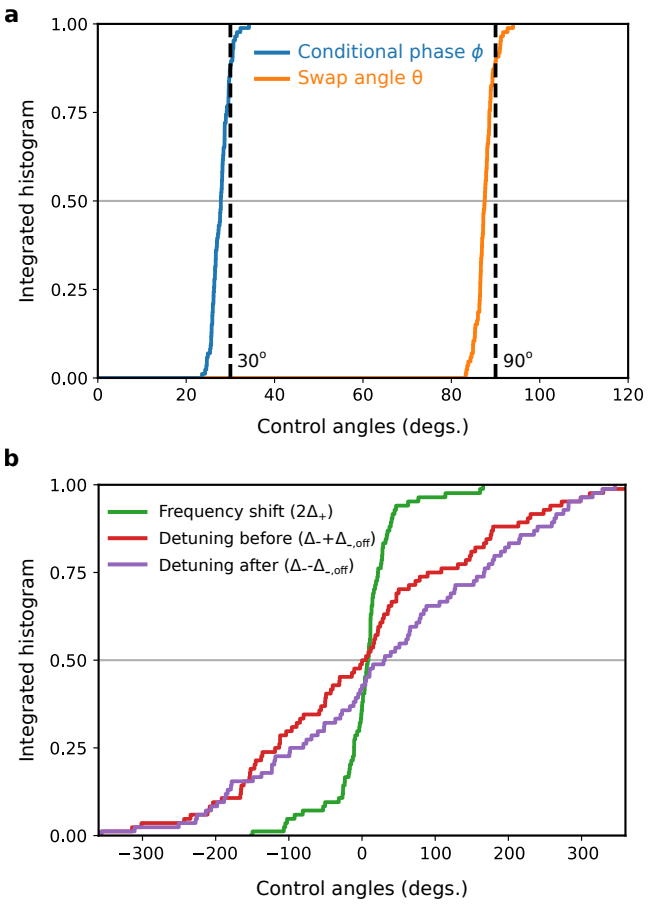

Figure S16: **Parameters of the control model.** A generic model for two-qubit gates using flux-control has five free parameters. Using XEB we can measure these parameters with high fidelity. **a,** Integrated histogram (cumulative distribution) of the control parameters that determine the interaction between the qubits. **b,** An integrated histogram of the remaining three parameters that represent different flavors of single-qubit Z-rotations. While the first two parameters (panel a) define the entangling gate, the final three parameters (panel b) are simply measured and then kept track of during an algorithm. Intuitively, these three angles correspond to a detuning before the swap, a detuning after the swap, and an overall frequency shift which commutes through the swap; these correspond to $\Delta_- + \Delta_{-,\mathrm{off}}$, $\Delta_- - \Delta_{-,\mathrm{off}}$, and $2\Delta_+$ respectively in Eq. (11.43). Note that θ and ϕ angles are 360 degrees periodic and Z-rotation angles are 720 degree periodic.

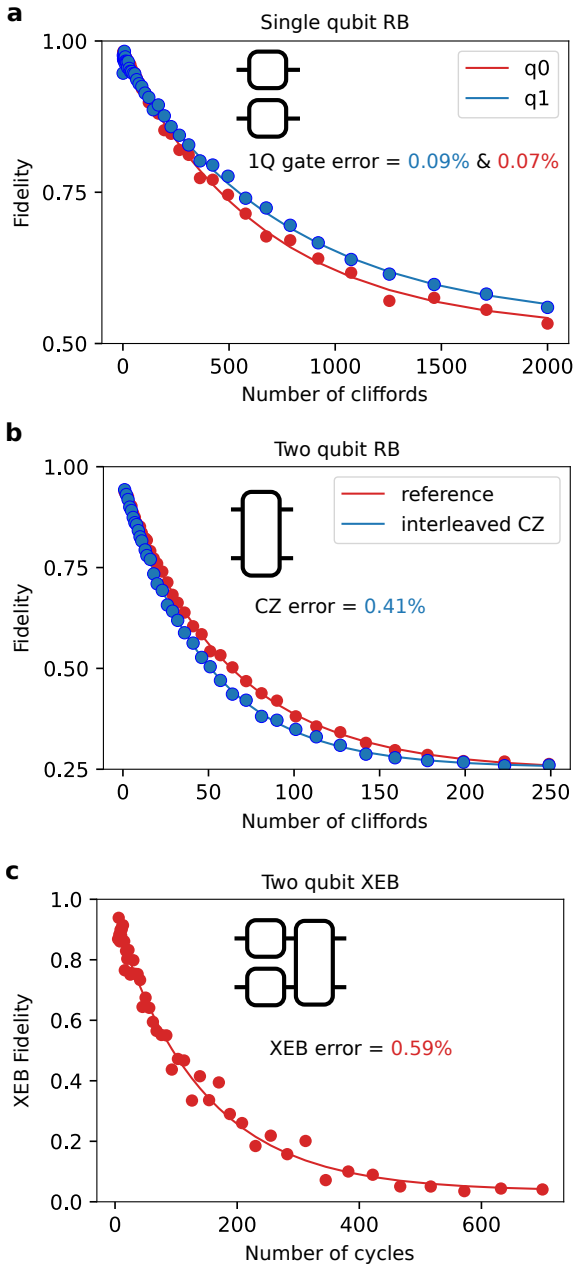

Figure S17: **Sanity check: XEB agrees with RB. a,** Single-qubit randomized benchmarking (RB) data taken separately on two qubits. **b,** Two-qubit randomized benchmarking data for a CZ on the same pair of qubits. **c,** Two-qubit cross-entropy benchmarking (XEB) on the same pair of qubits. The measured XEB error (0.59% / cycle) agrees well with the prediction from single- and two-qubit RB (0.57%). All errors are quoted as Pauli errors.

a pure state has a purity of 1. We define

$$\text{Purity} = \frac{D}{D-1}\left(\text{Tr}(\rho^2) - \frac{1}{D}\right), \tag{11.44}$$

which is consistent with what is defined in Ref. [51]. This can be understood as the squared length of the generalized Bloch vector in D dimensions (for a qubit, $D = 2$, this definition gives $\langle X\rangle^2 + \langle Y\rangle^2 + \langle Z\rangle^2$).

"Speckle" Purity Benchmarking (SPB) is the method of measuring the state purity from raw XEB data. Assuming the depolarizing-channel model with polarization parameter p, we can model the quantum state as

$$\rho = p\ |\psi\rangle\langle\psi| + (1-p)\,\frac{\mathbb{1}}{D}. \tag{11.45}$$

Here, p is the probability of a pure state $|\psi\rangle$ (which in this case is not necessarily known to us), while $1-p$ is the probability of being in the fully-decohered state ($\mathbb{1}$ is the identity operator). For the state (11.45), from the definition (11.44) it is easy to find the relation

$$\text{Purity} = p^2. \tag{11.46}$$

We will now work out how to obtain p^2 from a distribution of measured probabilities P_m of various bitstrings for a sequence, collected over many XEB sequences (Figs. S18a and S18b).

First, we note that for $p = 0$ the probabilities of all bitstrings are $1/D$, and the distribution is the δ-function located at $1/D$ (the integrated histogram is then the step-function – see Fig. S18b). In contrast, if $p = 1$, then the measured probabilities P_m follow the D-dimensional Porter-Thomas distribution [27]

$$\mathcal{P}_{\text{PT}}(P_m) = (D-1)(1-P_m)^{D-2}, \tag{11.47}$$

which has the same average $1/D$ and variance

$$\text{Var}_{\text{PT}}(P_m) = \frac{D-1}{D^2(D+1)}. \tag{11.48}$$

For the fully-decohered state all bitstrings have the same probability $1/D$, so in this case the variance of the distribution of probabilities is zero. For the state (11.45) with an arbitrary p, the histogram of probabilities P_m will be described by the distribution (11.47) shrunk towards the average $1/D$ by the factor p. Consequently, the variance of the experimental probabilities will be p^2 times the Porter-Thomas variance (11.48).

Thus, we can find p^2 by dividing the variance of experimentally measured probabilities P_m by the Porter-Thomas variance (11.48). Finally, using the relation (11.46) for the depolarization model (11.45), we can relate the variance of the experimental probabilities P_m to the average state purity

$$\text{Purity} = \text{Var}(P_m)\,\frac{D^2(D+1)}{D-1}. \tag{11.49}$$

With these convenient relations, we can directly compare the XEB fidelity $\mathcal{F}_{\text{XEB}} = p$ to $\sqrt{\text{Purity}}$ from SPB on the same scale, and check their dependence $p = p_c^m$ on the number of cycles m. Without systematic control errors, the XEB and SPB results should coincide. Experimentally, we always have control errors which lead us to incorrectly predict $|\psi\rangle$, so control errors give XEB a higher error than SPB. Thus, with a single XEB dataset we can extract the XEB error per-cycle, and the purity loss per-cycle with SPB. By subtracting these,

we are left with the control error per-cycle. Thus, with a single experiment we can error budget total error into control error and decoherence error.

These relationships can be seen experimentally in Figure S18. Amazingly, computing the speckle purity can be done with no knowledge of the specific gate sequence performed; as long as the experiment introduces sufficient randomization of the Hilbert Space, Porter-Thomas statistics apply. Practically, SPB allows us to measure the state purity from raw XEB data with exponentially fewer number of pulse sequences as compared to full state tomography. This favorable scaling allows one to extend purity measurements to larger numbers of qubits. It is important to note that an exponential number of measurements are still required to fully characterize the probability distribution for a given sequence, as in tomography, so purity measurements of the full processor are impractical.

"Per-layer" parallel XEB

To execute quantum circuits efficiently, it is helpful to run as many gates as possible in parallel. We wish to benchmark our entangling gates operating simultaneously. Resulting fidelities and optimized unitaries may differ from the isolated case, where we benchmark each pair individually, due to imperfections such as control crosstalk and stray qubit-qubit interactions. In the quantum supremacy algorithm, we partition the set of two-qubit gates into four layers, each of which can be executed in parallel. We then cycle through these layers interleaved with randomly chosen single-qubit gates (see Fig. 3a). However, it is intractable to directly use full-system XEB to benchmark our entangling gates for two reasons: we would simultaneously optimize over the unitary model parameters of every entangling gate, and the classical simulation would be exponentially expensive in system size.

We solve this problem with "per-layer" parallel XEB (see Ref. [52] for a related technique in the context of RB). Instead of alternating among the four layers of entanglers, where each qubit becomes entangled with each of its neighbors, we perform four separate experiments, one for each layer. The experiment sequences are illustrated in Fig. S19a. For each layer, we construct parallel sequences where the layer is repeated with interleaved single-qubit gates; nominally, each qubit only interacts with one other. Following each parallel XEB sequence, we measure all the qubits and extract the equivalent XEB data for each pair. Every two-qubit gate can be characterized in these four experiments, regardless of system size. The optimization and classical simulation are also efficient, as each pair can be analyzed individually.

We present experimental results of "per-layer" parallel XEB in Fig. S19b-c. In Fig. S19b, we compare the performance in the isolated and simultaneous (parallel) experiments. In both cases, the optimized XEB error is close to purity-limited. Simultaneous operation modestly increases the error, by roughly 0.003. This increase is primarily from purity error, which would arise from unintended interactions with other qubits, where coherent errors at the system scale manifest as incoherent errors when we focus on individual pairs. The unitaries we obtain in the simultaneous case differ slightly from the isolated case, which would arise from control crosstalk and unintended interactions. To quantify how these differences affect the gate error, we recalculate the error with the unitaries from the isolated optimization and the data from the simultaneous experiment, which increases the error. We also plot the distributions of the differences in unitary model parameters in Fig. S19c. The dominant change is in Δ_+, a single-qubit phase.

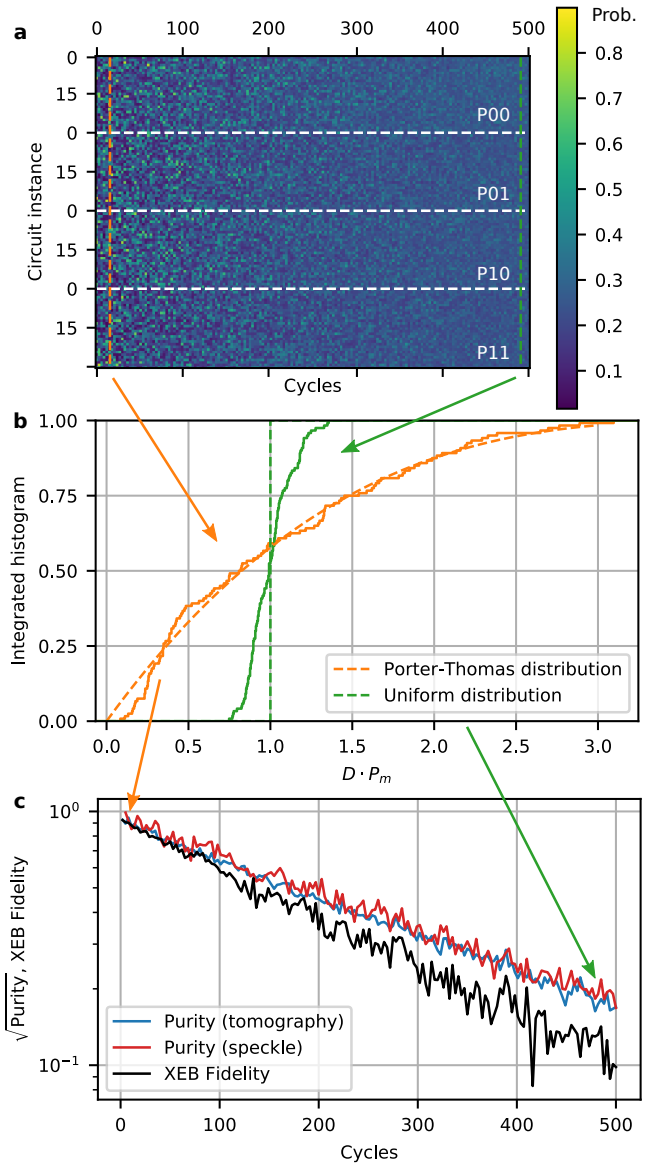

Figure S18: **"Speckle" purity extracted from XEB. a,** Measured probabilities from XEB for a two-qubit system and 30 random circuits. Raw probabilities show a speckle pattern at low cycles (orange dashed) over circuit instance and probabilities ($|00\rangle$, $|01\rangle$, $|10\rangle$, $|11\rangle$). The speckle contrast decreases with cycles and thus decoherence (green dashed). **b,** Integrated histogram (cumulative distribution) of probabilities. The x-axis is scaled by the dimension $D = 2^2$, so the uniform distribution is a step function at 1.0. At low cycles, the distribution is well-described by Porter-Thomas, and at high cycles, the distribution approaches the uniform distribution. **c,** We can directly relate the variance of the distribution to the average state purity. We fit an exponential to the square root of Purity. We compare this purity-derived number per-cycle= 0.00276 to a similar number per-cycle=0.00282 derived from tomographic measure of purity, and see good agreement. The error of XEB, which also includes control errors, is slightly higher at error per-cycle=0.00349.

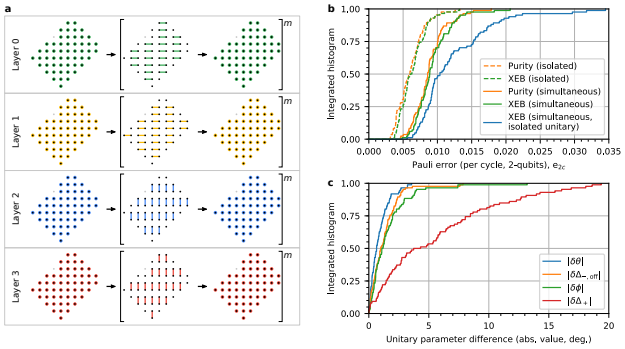

Figure S19: **Parallel XEB. a,** Schematics of four device-wide sequences, one for each entangler layer. Black points are active qubits, colored circles are single-qubit gates, and colored lines are two-qubit gates. We cycle between single- and two-qubit gates m times. Compare to Fig. 3a, main text, where the layers are interleaved. **b,** Integrated histograms of Pauli error e_{2c} (see Fig. 2a, main text). These include isolated results, where each entangler is measured in its own experiment, and simultaneous (parallel) results. Purity is "speckle" purity. **c,** Difference, δ, in unitary model parameters (Eq. 11.43) between the unitaries obtained in the isolated and simultaneous experiments. $\delta\Delta_-$ is not plotted because it has a negligible effect on the unitary when $\theta \approx 90$ degrees.

11.6.4 Grid readout calibration

Choosing qubit frequencies for readout

The algorithm described in Section 11.6.2 generally chooses qubit idling frequencies which are far detuned from the resonator to optimize for dephasing. However, these idling frequencies are not optimal for performing readout. To address this problem, we dynamically bias each qubit to a different frequency during the readout phase of the experiment. The qubit frequencies during readout are shown in Fig. S20 (compare to Fig. S13).

To choose the qubit frequencies for readout, we first measure readout fidelity as a function of qubit frequency and resonator drive frequency at a fixed resonator drive power, in each of the isolated single qubit configurations. This scan captures errors due to both non-optimal detuning between the qubit and resonator, as well as regions with low T_1 values due to TLSs. We then use the data for each qubit and a few constraints to optimize the placement of the qubit frequencies during readout, using the same optimization technique that was described in Section 11.6.2. We describe two of the important constraints and related error reduction techniques below.

First, because the coupling between qubits relies on a dispersive interaction with the coupler, the coupling would no longer be off when the qubits were detuned by a significant amount from their idling positions. Thus, we impose a constraint that qubits should not be placed near resonance during readout. Nevertheless, we found that for some pairs of qubits, we had to dynamically bias the coupler during readout to avoid any swapping transitions between the qubits during readout. This readout coupler bias is found by sweeping the coupler bias and maximizing the two-qubit readout fidelity.

Second, the pattern of the bare resonator frequencies on the chip as shown in Fig. S20 led to an unexpected problem. Pairs of readout resonators which were coupled to neighboring qubits and were also within a few MHz in frequency space were found to have non-negligible coupling. This coupling was strong enough to mediate swapping of photons from one resonator to the other. The pairs of qubits with similar resonator frequencies were all located in a diagonal chain bisecting the qubit grid, as shown by the red outline in Fig. S20. To mitigate this problem, we arrange the qubit frequencies for these qubits so that the resonator eigenfrequencies are as

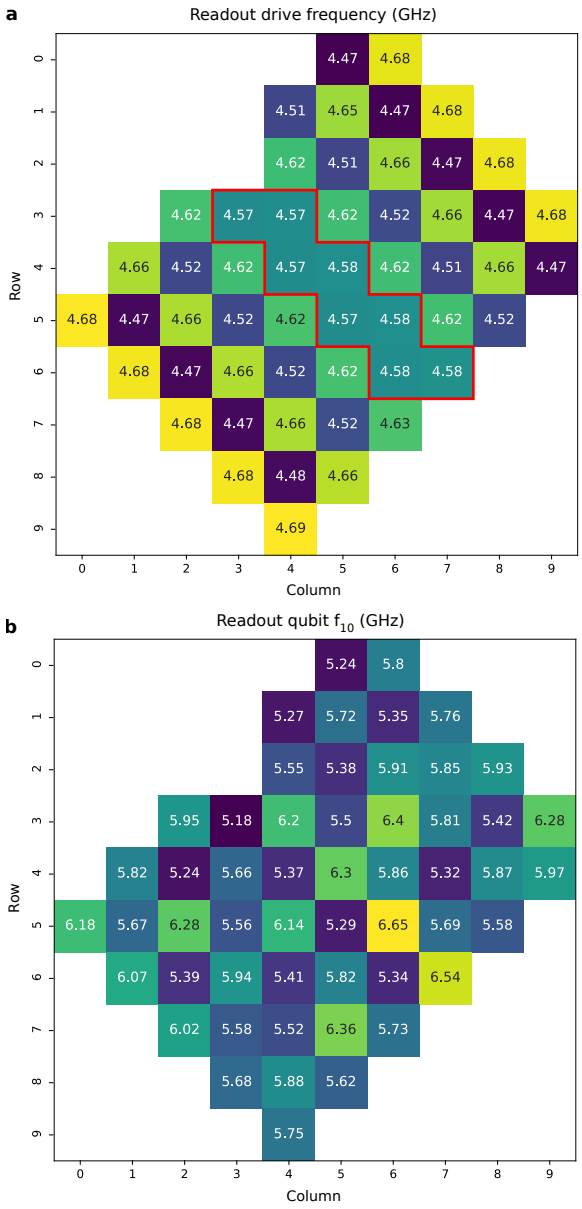

Figure S20: **a,** Drive frequencies for the readout resonators for each qubit. The red outline shows the area where we had to perform correlated discrimination because of unwanted cross-couplings between the resonators. **b,** Qubit frequencies during readout, found using a frequency optimization procedure.

far apart as possible. The resulting spectral separation is not quite enough to eliminate all deleterious effects, so in addition, we use correlated discrimination on the eight of the qubits in this chain. In other words, we use the results of all eight detector values to determine which one of $2^8 = 256$ states the eight qubits were in. All other qubits in the grid are discriminated as isolated qubits.

Single qubit calibration

After placing the qubit frequencies for readout, we calibrate and fine tune the readout parameters for each qubit. For each qubit, we use a 1 μs drive pulse and a 1 μs demodulation window. We summarize the procedure for choosing the remaining parameters as follows:

- Choose the resonator drive frequency to maximize the separation between measurements performed with the qubit in either $|0\rangle$ and $|1\rangle$ [16].
- Choose the resonator drive power to hit a target separation between $|0\rangle$ and $|1\rangle$, so that the error due to this separation is below a 0.3% threshold. We do not choose the readout power to maximize the separation as doing so would saturate our amplifiers, and cause unwanted transitions of the qubit state [53, 22, 54, 17].
- Find the optimal demodulation weight function by measuring the average detector voltage as a function of time during the course of the readout pulse [16, 21].
- Finally, choose the discrimination line between the measurement results for $|0\rangle$ and $|1\rangle$, except as noted in the previous section where we need to apply correlated discrimination.

After completing these calibrations, we check each qubit's readout fidelity by preparing either $|0\rangle$ or $|1\rangle$ and reading the qubit out. We define the identification error to be the probability that the qubit was not measured in the state we intended to prepare. We achieve 0.97% median identification error for the $|0\rangle$ state, and 4.5% for $|1\rangle$, when each qubit is measured in isolation. The full distribution is shown in dashed lines in Fig. S21a. We conjecture that the error in $|0\rangle$ is due to thermal excitation during preparation or measurement, and that the error in $|1\rangle$ is due to energy relaxation during readout.

Characterizing multi-qubit readout

To assess the fidelity of multi-qubit readout, we prepare and measure 150 random classical bitstring states with 53 qubits, with 3000 trials per state. We find that 13.6% of all trials successfully identified the prepared state. We can decompose this overall fidelity in two ways. First, we plot in solid lines in Fig. S21 the errors for each qubit during simultaneous readout, averaged over the 150 random bitstrings. We find that the median errors increase from 0.97% for $|0\rangle$ and 4.5% for $|1\rangle$ in isolation, to 1.8% and 5.1% for simultaneous readout. We do not yet understand the root causes of this increase in error. In addition, we show in Fig. S21 the distribution of errors among the multiqubit results. We see that the most likely error is one lost excitation in the measured state.

11.6.5 Summary of system parameters

Table 12 reports aggregate values for qubit and pair parameters in our processor. A complete table of single-qubit parameter values by qubit is available in supporting online materials, Ref. [55], and illustrated in Figs. S22 through S24. Single-qubit metrics represent a sample size of 53. Two-qubit metrics represent 86 pairs.

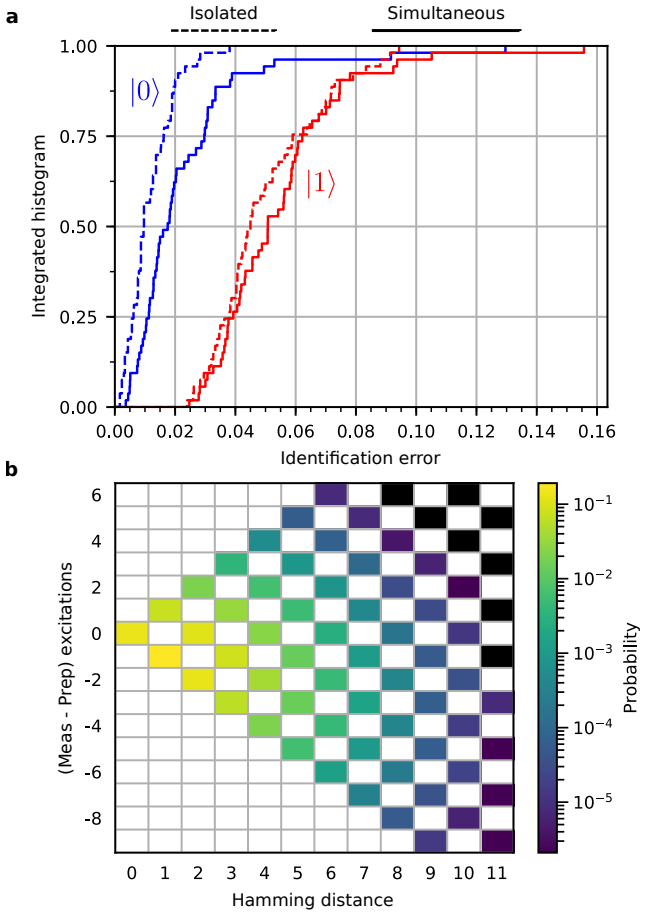

Figure S21: **Readout errors. a,** Histogram of readout errors for each qubit when prepared in $|0\rangle$ or $|1\rangle$, and readout in isolation or simultaneously. **b,** Distribution of errors in multi-qubit readout. The x-axis Hamming distance is the number of bits that are different between measured and prepared states, while the y-axis is the difference in the number of 1's in the states. For example, if we prepare $|011\rangle$ and measure $|101\rangle$, the Hamming distance is 2 and the difference in the number of excitations is 0.

11.7 Quantum circuits

11.7.1 Background

We sample the output of random quantum circuits (RQCs) with two use cases in mind: performing a computational task beyond the reach of state-of-the-art supercomputers (quantum supremacy); and estimating the experimental fidelity (performance evaluation).

In order for the RQCs to cover both use cases, we define a circuit family with a varying number of qubits n and cycles m. Our quantum supremacy demonstration uses RQCs with a large number of qubits $n = 53$ and high depth $m = 20$. Large number of qubits hinders wave function (Schrödinger) simulation and high depth impedes tensor network (Feynman) simulation (see Sec. 11.10.2). We find that the most competitive classical simulator for our hardest RQCs is the Schrödinger-Feynman algorithm (SFA, see Sec. 11.10.1) which copes well with high depth circuits on many qubits.

SFA takes as input an n-qubit quantum circuit and a *cut* which divides $n = n_1 + n_2$ qubits into two contiguous partitions with n_1 and n_2 qubits. The algorithm computes the output state as the sum over simulation paths formed as the product of the terms of the Schmidt decomposition of all cross-partition gates. By the distributive law there are r^g such simulation paths for a circuit with g cross-partition gates of Schmidt rank r. Consequently, the algorithm achieves runtime proportional to $(2^{n_1} + 2^{n_2})r^g$. Circuit cuts with n_1, n_2 and g that make the simulation task tractable are called *promising cuts*. The most promising cut for our largest RQCs runs parallel to the shorter axis of the device starting in the vicinity of the broken qubit. The sum over the simulation paths can be interpreted as tensor contraction. In this view, the r^g factor can be thought of as the *bond dimension* associated with the circuit partitioning, i.e. the cardinality of the index set ranged over in the contraction corresponding to all cross-partition gates. SFA is described in more detail in [38] and section 11.10.

11.7.2 Overview and technical requirements

The two use cases for our RQCs give rise to a tension in technical requirements at the heart of quantum supremacy. On the one hand, supremacy RQC sampling should by definition be prohibitively hard to simulate classically. On the other hand, performance evaluation entails classical simulation of the RQCs. To resolve the conflict, we note that the fidelity of a RQC experiment depends primarily on the number and quality of the gates. By contrast, the simulation cost is highly sensitive to minor perturbations in the circuit. Consequently, experiment fidelity for RQCs that cannot be simulated directly may be approximated from the experiment fidelity of similar RQCs obtained as the result of transformations that reduce simulation cost without significantly affecting experiment fidelity (see Section 11.7.7).

Performance evaluation using XEB provides another design consideration. The procedure requires knowledge of the cross-entropy of the theoretical output distribution of the circuit. An analytical expression for this quantity has been derived in [27] for circuits whose measurement probabilities approach the Porter-Thomas distribution. We find that our RQCs satisfy this assumption when the circuit depth is larger than 12, see Fig. **??**a. Note that high circuit depth also increases the cost of classical simulation.

11.7.3 Circuit structure

A RQC with n qubits generally utilizes qubits 1 through n in the qubit order shown in Fig. S27 with small deviations from this default qubit ordering in some circuits. The qubit order has been chosen to ensure that for most RQCs with fewer than 51 qubits, there is a partitioning of the qubits into two similarly sized blocks connected by only five couplers. The

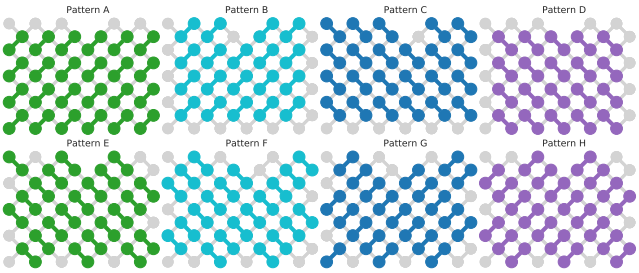

Figure S25: **Coupler activation patterns.** Coupler activation pattern determines which qubits are allowed to interact simultaneously in a cycle. Quantum supremacy RQCs utilize the staggered patterns shown in the top row in the sequence ABCDCDAB, repeated in subsequent cycles. Performance evaluation RQCs employ the patterns shown in the bottom row in the sequence EFGH, likewise repeated in subsequent cycles. The former sequence makes SFA simulation harder by facilitating prompt transfer of entanglement created at promising circuit cuts into the bulk of each circuit partition.

next larger RQC, with 51 qubits, has seven couplers along the most promising circuit cut. Since the cost of SFA grows exponentially in the number of gates across the partitions our circuit geometry leads to a steep increase in the simulation cost of 51-qubit RQCs relative to the circuits with fewer qubits. This creates a sizeable gap in the computational hardness between most of our evaluation circuits and the quantum supremacy circuits ($n = 53$).

In the time dimension, each RQC is a series of m full cycles and one half cycle followed by measurement of all qubits. Every full cycle consists of two steps. In the first step, a single-qubit gate is applied to every qubit. In the second step, two-qubit gates are applied to pairs of qubits. Different qubit pairs are allowed to interact in different cycles. Specifically, in the supremacy RQCs we loop through the direct neighbors of every qubit over the eight-cycle sequence ABCDCDAB and in the evaluation RQCs we use the four-cycle sequence EFGH where A, B, ..., H are coupler activation patterns shown in Fig. S25. The sequence is repeated in subsequent cycles. The cost of SFA simulation is highly sensitive to the specific sequence employed in a circuit, see 11.7.7. Border qubits have fewer than four neighbors and no gate is applied to them in some cycles. The half cycle preceding the measurement consists of the single-qubit gates only. The overall structure of our RQCs is shown in Fig. 3 of the main paper [1].

11.7.4 Randomness

Single-qubit gates in every cycle are chosen randomly using a pseudo-random number generator (PRNG). The generator is initialized with a seed s which is the third parameter for our family of RQCs. The single-qubit gate applied to a particular qubit in a given cycle depends only on s. Consequently, two RQCs with the same s apply the same single-qubit gate to a given qubit in a given cycle as long as the qubit and the cycle belong in both RQCs as determined by their size n and depth m parameters.

Conversely, the choice of single-qubit gates is the sole property of our RQCs that depends on s. In particular, the same two-qubit gate is applied to a given qubit pair in a given cycle by all RQCs that contain the pair and the cycle.

11.7.5 Quantum gates

In our experiment, we configure three single-qubit gates. Each one is a $\pi/2$-rotation around an axis lying on the equator of the Bloch sphere. Up to global phase, the gates are

$$X^{1/2} \equiv R_X(\pi/2) = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & -i \\ -i & 1 \end{bmatrix}, \tag{11.50}$$

$$Y^{1/2} \equiv R_Y(\pi/2) = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & -1 \\ 1 & 1 \end{bmatrix}, \tag{11.51}$$

$$W^{1/2} \equiv R_{X+Y}(\pi/2) = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & -\sqrt{i} \\ \sqrt{-i} & 1 \end{bmatrix} \tag{11.52}$$

where $W = (X + Y)/\sqrt{2}$ and $\sqrt{\pm i}$ denotes the principal value of the square root. The first two belong to the single-qubit Clifford group, while $W^{1/2}$ is a non-Clifford gate. Single-qubit gates in the first cycle are chosen independently and uniformly at random from the set of the three gates above. In subsequent cycles, each single-qubit gate is chosen independently and uniformly at random from among the gates above except the gate applied to the qubit in the preceding cycle. This prevents simplifications of some simulation paths in SFA. Consequently, there are $3^n 2^{nm}$ possible random choices for a RQC with n qubits and m cycles.

Two-qubit gates in our RQCs are not randomized, but are determined by qubit pair and cycle number. The gates preserve the number of ground and excited states of the qubits which gives their matrices block diagonal structure with 1×1, 2×2 and 1×1 blocks. Therefore, up to global phase they belong to $U(1) \oplus U(2) \oplus U(1)/U(1)$ and thus can be described by five real parameters (see Fig. S16, and Eq. 11.43). Each gate in this family can be decomposed into four Z-rotations described by three free parameters and the two-parameter fermionic simulation gate

$$\mathrm{fSim}(\theta, \phi) = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos(\theta) & -i\sin(\theta) & 0 \\ 0 & -i\sin(\theta) & \cos(\theta) & 0 \\ 0 & 0 & 0 & e^{-i\phi} \end{bmatrix} \tag{11.53}$$

which is the product of a fractional iSWAP and controlled phase gate (see Fig. S14b).

In our experiment, we tune up the two-qubit gates close to $\theta \approx \pi/2$ and $\phi \approx \pi/6$ radians and then infer more accurate values of all five parameters for each qubit pair using XEB. Consequently, all five parameters of the two-qubit gate depend on the qubit pair. While inferred unitaries are suitable for RQC sampling, future applications of the Sycamore processor, for example, in quantum chemistry, will require precise targeting of the entangling parameters [49, 56]. The three parameters which control the Z-rotations implicit in the two-qubit gates can be canceled out with active Z-rotations turning an arbitrary five-parameter gate into pure $\mathrm{fSim}(\theta, \phi)$. In our RQCs, we have decided not to apply such correction gates. This choice affords us greater number of interactions within the available circuit depth budget and introduces additional implicit non-Clifford single-qubit gates into the RQCs.

The Z-rotations have two origins. First, they capture the phase shifts due to qubit frequency excursions during the two-qubit gate. Second, they account for phase changes due to different idle frequencies of the interacting qubits. The latter introduces dependency of the three parameters defining the Z-rotations on the time at which the gate is applied. By contrast, for a given qubit pair θ and ϕ do not depend on the cycle.

The $\mathrm{fSim}(\pi/2, \pi/6)$ gate is the product of a non-Clifford controlled phase gate and an iSWAP which is a two-qubit Clifford gate.

11.7.6 Programmability and universality

Programmability of Sycamore rests on our ability to tune up a variety of gate sets including sets that are universal for quantum computation. For example, the set of gates employed in our quantum supremacy demonstration is universal, as we show in this section.

The proof consists of two parts. First, we show that the CZ gate can be obtained as a composition of two fSim gates and single-qubit rotations. Second, we outline how the well-known proof that the H and T gates are universal for SU(2) [57] can be adapted for $X^{1/2}$ and $W^{1/2}$. The conclusion follows from the fact that the gate set consisting of the CZ gate and SU(2) is universal [58].

Decomposition of CZ into fSim gates

Here, we show how to decompose a controlled-phase gate into two fSim gates and several single-qubit gates. The fSim gate is native to our hardware and can be decomposed into

$$\mathrm{fSim}(\theta,\phi) = e^{-i\theta(X\otimes X+Y\otimes Y)/2}\, e^{-i\phi(I-Z)\otimes(I-Z)/4}\,, \tag{11.54}$$

where the iSWAP angle $\theta \simeq \pi/2$ and the controlled-phase angle $\phi \simeq \pi/6$. The controlled-phase part can be further decomposed into

$$\begin{aligned} &e^{-i\phi(I-Z)\otimes(I-Z)/4} \\ &\quad = e^{-i\phi/4}\, e^{i\phi(Z\otimes I+I\otimes Z)/4}\, e^{-i\phi Z\otimes Z/4}\,. \end{aligned} \tag{11.55}$$

To simplify notations, we introduce the two-qubit gate

$$\begin{aligned} \Upsilon(\theta,\phi) &= e^{-i\theta(X\otimes X+Y\otimes Y)/2}\, e^{-i\phi Z\otimes Z/4} \\ &= e^{i\phi/4}\, e^{-i\phi(Z\otimes I+I\otimes Z)/4}\, \mathrm{fSim}(\theta,\phi)\,, \end{aligned} \tag{11.56}$$

which is equivalent to the fSim gate up to single-qubit Z rotations. The sign of θ in $\Upsilon(\theta,\phi)$ can be changed by the single-qubit transformation,

$$Z_1\, \Upsilon(\theta,\phi)\, Z_1 = \Upsilon(-\theta,\phi)\,, \tag{11.57}$$

where $Z_1 = Z\otimes I$ ($Z_2 = I\otimes Z$ works equally well).

Multiplying two Υ gates with opposite values of θ on both sides the operator $X_1 = X\otimes I$, we have

$$\begin{aligned} \Upsilon(-\theta,\phi)\, X_1\, \Upsilon(\theta,\phi) &= e^{i\theta Y\otimes Y/2}\, X_1\, e^{-i\theta Y\otimes Y/2} \\ &= \cos\theta\, X_1 + \sin\theta\, Z\otimes Y\,. \end{aligned} \tag{11.58}$$

With the identity (11.58), we have

$$\begin{aligned} \Upsilon(-\theta,\phi)\, e^{i\alpha X_1}\, \Upsilon(\theta,\phi) &= \cos\alpha\left(\cos\frac{\phi}{2}\, I\otimes I - i\sin\frac{\phi}{2}\, Z\otimes Z\right) + i\sin\alpha\left(\cos\theta\, X\otimes I + \sin\theta\, Z\otimes Y\right) \\ &= \left(\cos\alpha\cos\frac{\phi}{2}\, I + i\sin\alpha\cos\theta\, X\right)\otimes I - iZ\otimes\left(\cos\alpha\sin\frac{\phi}{2}\, Z - \sin\alpha\sin\theta\, Y\right), \end{aligned} \tag{11.59}$$

where $0 \le \alpha \le \pi/2$ is to be determined. We introduce the Schmidt operators

$$\Gamma_1(\alpha) = \cos\alpha\cos(\phi/2)\, I + i\sin\alpha\cos\theta\, X\,, \tag{11.60}$$

$$\Gamma_2(\alpha) = \cos\alpha\sin(\phi/2)\, Z - \sin\alpha\sin\theta\, Y\,, \tag{11.61}$$

and the unitary (11.59) takes the simple form

$$\Upsilon(-\theta,\phi)\, e^{i\alpha X_1}\, \Upsilon(\theta,\phi) = \Gamma_1\otimes I - iZ\otimes\Gamma_2\,. \tag{11.62}$$

The Schmidt rank of this unitary is two. Therefore, it is equivalent to a controlled-phase gate (also with Schmidt rank two) up to some single-qubit unitaries. The two non-zero Schmidt coefficients of the unitary (11.59) are equal to the operator norms of $\Gamma_{1,2}$.

The target controlled-phase gate that we want to decompose into the fSim gate is

$$\mathrm{diag}\big(1,\, 1,\, 1,\, e^{-i\delta}\big) = e^{-i\delta(I-Z)\otimes(I-Z)/4}\,, \tag{11.63}$$

where $0 \le \delta \le 2\pi$. It has two non-zero Schmidt coefficients $\cos(\delta/4)$ and $\sin(\delta/4)$. For example, we set the operator norm of Γ_2 to be equal to the second Schmidt coefficient of the target unitary

$$\begin{aligned} \big|\Gamma_2(\alpha)\big| &= \sqrt{\big(\cos\alpha\sin(\phi/2)\big)^2 + \big(\sin\alpha\sin\theta\big)^2} \\ &= \sin(\delta/4)\,, \end{aligned} \tag{11.64}$$

and the parameter α can be determined

$$\sin\alpha = \sqrt{\frac{\sin(\delta/4)^2 - \sin(\phi/2)^2}{\sin(\theta)^2 - \sin(\phi/2)^2}}\,. \tag{11.65}$$

This equation has a solution if and only if one of the following two conditions is satisfied

$$|\sin\theta| \le \sin(\delta/4) \le |\sin(\phi/2)|\,, \tag{11.66}$$

$$|\sin(\phi/2)| \le \sin(\delta/4) \le |\sin\theta|\,. \tag{11.67}$$

A large set of controlled-phase gates can be implemented with the typical values of θ and ϕ of the fSim gate, except for those that are very close to the identity.

To fix the local basis of the first qubit in Eq. (11.59), we introduce two X rotations of the same angle

$$e^{-i\xi X/2}\,\Gamma_1(\alpha)\,e^{-i\xi X/2} = \cos(\delta/4)\,I\,, \tag{11.68}$$

$$e^{-i\xi X/2}\,Z\,e^{-i\xi X/2} = Z\,, \tag{11.69}$$

where the angle ξ is

$$\xi = \arctan\left(\frac{\tan\alpha\cos\theta}{\cos(\phi/2)}\right) + \frac{\pi}{2}\Big(1 - \mathrm{sgn}\big(\cos(\phi/2)\big)\Big)\,. \tag{11.70}$$

To fix the local basis of the second qubit in Eq. (11.59), we introduce two X rotations of opposite angles

$$e^{i\eta X/2}\,\Gamma_2(\alpha)\,e^{-i\eta X/2} = \sin(\delta/4)\,Z\,, \tag{11.71}$$

where the angle η is

$$\eta = \arctan\left(\frac{\tan\alpha\sin\theta}{\sin(\phi/2)}\right) + \frac{\pi}{2}\Big(1 - \mathrm{sgn}\big(\sin(\phi/2)\big)\Big)\,. \tag{11.72}$$

Applying these local X rotations before and after the gate sequence in Eq. (11.59), we have

$$\begin{aligned} &e^{-i(\xi X_1 - \eta X_2)/2}\,\Upsilon(-\theta,\phi)\,e^{i\alpha X_1}\,\Upsilon(\theta,\phi)\,e^{-i(\xi X_1+\eta X_2)/2} \\ &\quad = \cos(\delta/4)\,I\otimes I - i\sin(\delta/4)\,Z\otimes Z\,, \end{aligned} \tag{11.73}$$

which is the desired controlled-phase gate up to some single-qubit Z rotations.

The target controlled-phase gate equals to the CZ gate for $\delta = \pi$. We numerically checked that the decomposition (11.73) yields the CZ gate for all 86 fSim gates (with different values of θ and ϕ) in our device.

Universality for SU(2)

Here, we show how the argument for the well-known result that the H and T gates are universal for SU(2) [57] can be adapted for the $X^{1/2}$ and $W^{1/2}$ gates. At the core of the argument lies the observation that $T \equiv R_Z(\pi/4)$ followed by $HTH \equiv R_X(\pi/4)$ is a single-qubit rotation by angle α which is an irrational multiple of π. Specifically, α is such that

$$\cos\frac{\alpha}{2} = \cos^2\frac{\pi}{8} = \frac{1}{2}\left(1 + \frac{1}{\sqrt{2}}\right). \tag{11.74}$$

By Theorem B.1 in Appendix B of [57], α/π is irrational because the monic minimal polynomial with rational coefficients of $e^{i\alpha}$

$$x^4 + x^3 + \frac{1}{4}x^2 + x + 1 \tag{11.75}$$

is not cyclotomic (since not all its coefficients are integers).

Similarly, $W^{1/2} \equiv R_{X+Y}(\pi/2)$ followed by $X^{1/2} \equiv R_X(\pi/2)$ is a single-qubit rotation by angle β such that

$$\cos\frac{\beta}{2} = \cos^2\frac{\pi}{4} - \frac{1}{\sqrt{2}}\sin^2\frac{\pi}{4} = \frac{1}{2}\left(1 - \frac{1}{\sqrt{2}}\right). \tag{11.76}$$

The monic minimal polynomial with rational coefficients of $e^{i\beta}$ is (11.75), the same as that of $e^{i\alpha}$. Therefore, β is also an irrational multiple of π. The rest of the universality argument for H and T also applies in the case of $X^{1/2}$ and $W^{1/2}$.

11.7.7 Circuit variants

Since XEB entails classical simulation, it is hard or impossible to use it to estimate experimental fidelity of circuits which are hard or impossible to simulate classically. As described above, we designed our RQCs to ensure that an effective partitioning for SFA exists for circuits with fewer than 51 qubits. This gives rise to a significant gap in the cost of classical simulation between quantum supremacy circuits and most of our performance evaluation circuits. This gap facilitates performance evaluation of the Sycamore processor near the quantum supremacy frontier. In practice, however, we would like greater control over the simulation hardness, for two reasons. First, performance evaluation is still very costly for large n approaching the supremacy frontier. Second, we would like to be able to estimate the fidelity of supremacy RQCs more directly, even though classical simulation of this case is unfeasible by definition.

In order to achieve more fine-grained control over the cost of classical simulation of our RQCs, we exploit the fact that the experimental fidelity depends primarily on the number and quality of the gates while the simulation cost is highly sensitive to the structure of the quantum circuit. Therefore, we approximate the experimental fidelity of RQCs which are hard or impossible to simulate from the fidelity of similar RQCs obtained as the result of transformations that reduce simulation cost without significantly affecting experimental fidelity.

We employ two such transformations. Each decreases simulation cost by reducing the bond dimension of promising circuit cuts. The first one removes some or all cross-partition gates. We say that the removed gates have been *elided* and term the transformation *gate elision*. The second transformation changes the sequence of coupler activation patterns shown in Fig. S25 to enable the formation of *wedges* which reduce the bond dimension by slowing the spread of entanglement generated at the circuit cut.

The two transformations complete the description of RQCs used in our experiment. Consequently, each RQC is uniquely determined by five parameters: number of qubits n, number of cycles m, PRNG seed s, number of elided gates and the sequence of coupler activation patterns.

Circuit variant	Gates elided	Sequence of patterns
non-simplifiable full	none	ABCDCDAB
non-simplifiable elided	some	ABCDCDAB
non-simplifiable patch	all	ABCDCDAB
simplifiable full	none	EFGH
simplifiable elided	some	EFGH
simplifiable patch	all	EFGH

Table 13: **Circuit variants.** Six variants of RQCs employed in quantum supremacy demonstration (non-simplifiable full) and performance evaluation (remaining five variants) classified by transformations applied in order to control the cost of classical simulation. The eight coupler activation patterns A, B, ..., H are shown in Fig. S25.

Circuit variant	n	m	Single-qubit gates	All two-qubit gates	Cross-partition two
non-simplifiable full	53	20	1113	430	35
non-simplifiable elided	53	20	1113	408	13
non-simplifiable patch	53	20	1113	395	0
simplifiable full	38	14	570	210	18
simplifiable elided	38	14	570	204	12
simplifiable patch	38	14	570	192	0

Table 14: **Gate counts.** Number of gates in selected random quantum circuits employed for quantum supremacy demonstration and performance evaluation of the Sycamore processor.

Gate elision

The most straightforward way to reduce the cost of classical simulation of a RQC is to remove a number of cross-partition gates across the most promising circuit cut. In order to enable independent propagation by the SFA of the wave function of each circuit partition for the first few cycles, the gates are elided beginning with the initial cycle. Each elided gate reduces the bond dimension of the partitioning by a factor of two or four, see Section 11.10.

We refer to RQCs with a small number of elided gates as *elided circuits*. A particularly dramatic speedup is possible when all two-qubit gates across the partitions are elided leading to two disconnected circuits running in parallel. We refer to such disconnected RQCs as *patch circuits*. Base RQCs in which no gates have been elided are referred to as *full circuits*.

If the error probability of the elided two-qubit gate is similar to the error probability of the two-qubit identity gate which it is replaced with, the circuit resulting from gate elision exhibits fidelity that is similar to the fidelity of the original circuit. This assumption holds when the two-qubit gate errors are dominated by the same decoherence processes that govern the single-qubit gate errors such as finite T_1 and T_2. Indeed, for circuit sizes where XEB on full circuits is possible, we have observed good agreement between fidelity estimates produced for patch, elided and full circuits. For harder circuits, we have observed good agreement between fidelity estimates for patch and elided circuits. See Section 11.8 for detailed discussion of these results.

Wedge formation

The most competitive algorithm for our hardest circuits, SFA (see Sec. 11.10.1) scales proportionally to the bond dimension of the circuit partitioning which is equal to the product of Schmidt rank of all cross-partition gates (see Sec. 11.10.4). The Schmidt decomposition of most two-qubit gates in our RQCs consists of four terms (a few gates can be replaced with

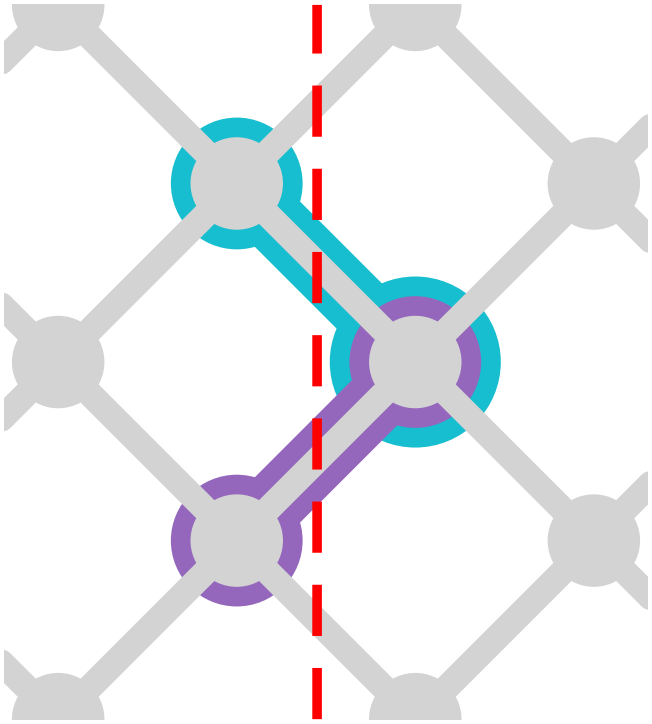

Figure S26: **Cross-partition wedge.** Two consecutive cross-partition gates which share a qubit form a *wedge*, as illustrated here with gates highlighted in turquoise and magenta. Schmidt rank of a single two-qubit gate is at most four. Schmidt rank of a wedge is also at most four. Therefore, generally wedges are not efficient at increasing entanglement across partitions and can be simulated efficiently by the SFA.

simpler gates with Schmidt rank of two, see Section 11.10). Therefore most cross-partition gates contribute a factor of four to the bond dimension of the partitioning. However, when two consecutive cross-partition gates share a qubit forming a *wedge* as shown in Fig. S26, the Schmidt decomposition of the resulting three-qubit unitary also has only four terms. In other words, the second cross-partition gate does not generally produce substantial new entanglement (as quantified by the Schmidt rank) among the partitions in excess of the entanglement produced by the first gate. Consequently, every wedge reduces the bond dimension of the partitioning by a factor of four.

The eight-cycle sequence ABCDCDAB and the four constituent coupler activation patterns A, B, C and D shown in Fig. S25 have been designed to prevent formation of wedges across promising circuit cuts. In other words, the sequence ensures that entanglement created in a given cycle by cross-partition gates is transferred into the bulk of each partition in the following cycle.

On the other hand, the four-cycle sequence EFGH enables formation of wedges and thus efficient simulation of RQCs using SFA. We employ the latter sequence in most evaluation circuits and use the former eight-cycle sequence for the quantum supremacy circuits and largest evaluation circuits, see Table 13.

11.8 Large scale XEB results

In Section 11.6, we have detailed the device calibration processes used for individual components such as qubits, couplers, and coupled pairs of qubits. We have also introduced cross-entropy benchmarking (XEB) as a method that allows us to evaluate the performance of a quantum system. In this section, we describe how we use a few circuit variations to benchmark

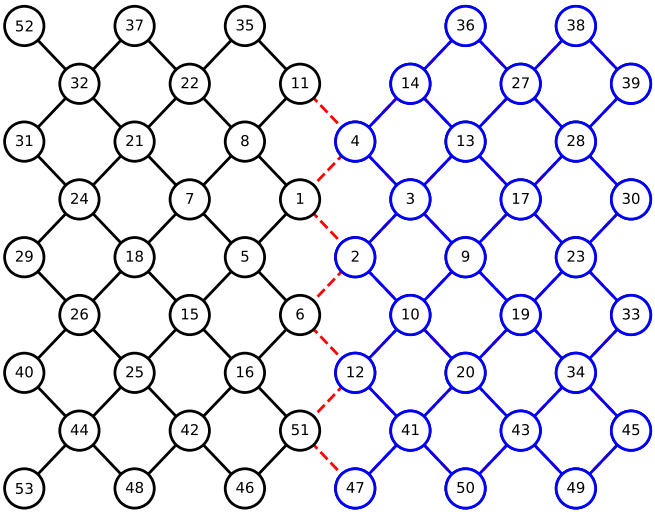

Figure S27: **Qubit ordering for large-scale XEB experiments.** Illustration of the order in which qubits are added for large-scale experiments. The partition between left (black) and right (blue) qubits along the boundary (dashed red lines) is used in patch and elided circuits, as explained below.

our Sycamore processor at a larger scale. In particular, we present a modular version of XEB with "patch circuits" that does not require exponential classical computation resources for estimating XEB fidelities $\mathcal{F}_{\text{XEB}}$ of larger systems. We also describe the effect of choice of unitary model on large-scale $\mathcal{F}_{\text{XEB}}$, as well as how we use patch circuits to monitor the stability of the full system.

11.8.1 Limitations of full circuits

We first discuss what we refer to as "full circuits", where for a given set of qubits, all possible two-qubit gates participate in the circuit. With full circuits, we benchmarked the system as a function of size, where as discussed below the classical resources and techniques used to compute the $\mathcal{F}_{\text{XEB}}$ is a function of the number of qubits. The order in which each qubit was added is labeled in Fig. S27. The rationale behind this ordering is explained in Section 11.7. At each system size, we executed 10 randomly generated circuit instances on the processor and sampled output bitstrings 500k times for each circuit (unless otherwise specified). To minimize potential instance-to-instance fluctuations, we chose the gate sequences in a persistent, "stable" manner: using a known seed for a random number generator, for each circuit, each time a new qubit is added, we maintain the same gateset for all the "existing" qubits and new gates are only introduced to qubits and pairs associated with the added qubit (see Section 11.7 for details).

Once a sufficient number of bitstrings are collected, $\mathcal{F}_{\text{XEB}}$ can be calculated for each system size, following the method described in Section 11.4. As the system size increases, the computational complexity of XEB analysis grows exponentially, which can be qualitatively divided into three regimes. For system size from 12 to 37 qubits, XEB analysis was carried out by evolving the full quantum state (Schrödinger method) on a high-performance server (88 hyper-threads, 1.5TB memory in our case) using the "qsim" program. At 38 qubits we used a n1-ultramem-160 VM in Google's cloud (160 hyperthreads, 3.8TB memory). Above 38 qubits, Google's large-scale cluster computing became necessary, and in addition a hybrid Schrödinger-Feynman approach, the "qsimh" program, was used to improve the efficiency: in this case, we break the system up into two patches, where each patch can be efficiently computed via the Schrödinger method and then connected by a Feynman path-integral approach (see Section

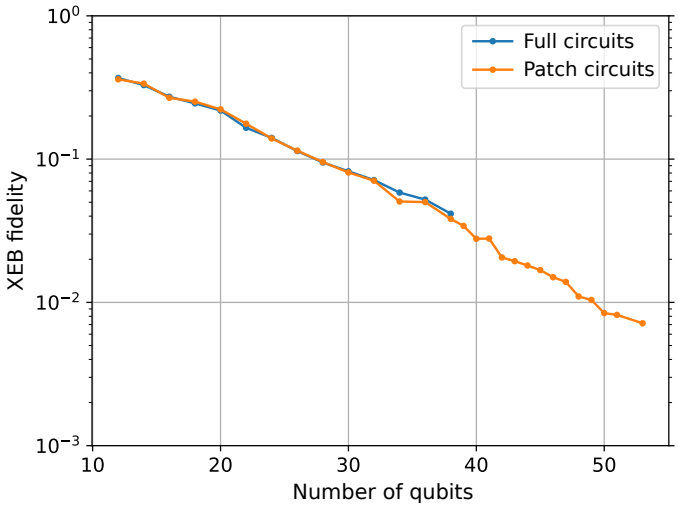

Figure S28: **Comparison between XEB with patch circuits and full circuits.** Full vs. patch circuit benchmarking up to 38 qubits with 14 cycles, showing close agreement to within the intrinsic fluctuations of the system. We plot the results for patch circuits out to 53 qubits.

11.10 for more details). Finally we used a Schrödinger algorithm in the Jülich supercomputer for some circuits up to 43 qubits.

In order to reduce the computational cost, we introduce two modified circuit types in the following sections. By using slightly simplified gate sequences, these two methods can provide good approximate predictions of system performance all the way out to the "quantum supremacy" regime.

11.8.2 Patch circuits: a quick performance indicator for large systems

The simplest approach to large-scale performance estimation is referred to as "patch circuits," which predicts the performance of the full system by multiplying together the fidelities of non-interacting subsystems, or "patches". In this work, we use two such subsystems, where each patch is roughly half the size of the full system. The two subsystems are run simultaneously, so that effects such as gate and measurement crosstalk between patches are included, but the two patches are analyzed separately when computing the fidelity. The two patches are defined by the gates removed along their boundary, as illustrated in Fig. S27. For sufficiently large systems, these removed two-qubit gates represent a small portion of the whole circuit. As a consequence, $\mathcal{F}_{\text{XEB}}$ of the full system can be estimated as the product of the fidelities of the two subsystems; compared with full circuits, the main missing factor is the absence of entanglement between the two patches.

We evaluate the efficacy of using patch circuits by comparing it against full circuits with the same set of qubits. The experimental results can be seen in Fig. 4a (main text), where we show fidelities measured by these two methods for systems from 12 qubits to 53 qubits, in an interleaved fashion. We re-plot this data here in Fig. S28 as well. As expected, the fidelities obtained via patch XEB show a consistent exponential decay (up to fluctuations arising from qubit-dependent gate fidelities and a small amount of system fluctuations) as a function of system size. For every system size investigated, we found that patch and full XEB provide fidelities that are in good agreement with each other, with a typical deviation of $\sim$5% of the fidelity itself (we attribute the worst-case disagreement of 10% at 34 qubits due to a temporary system fluctuation in between the two datasets, which was also seen in interleaved measurement

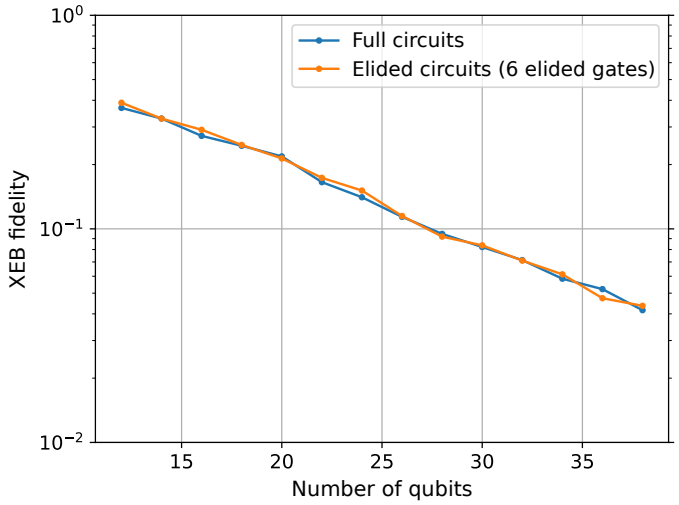

Figure S29: **Comparison between XEB with elided circuits and full circuits.** Full vs. elided circuit benchmarking up to 38 qubits at 14 cycles, showing close agreement to within the intrinsic fluctuations of the system.

fidelity data). Theoretically, one would expect patch circuits to result in $\sim 10\%$ higher fidelity than full circuits due to the slightly reduced gate count. We find that patch circuits perform slightly worse than expected, which we believe is due to the fact that the two-qubit gate unitaries are optimized for full operation and not patch operation. In any case, agreement between patch and full circuits shows that patch circuits can be a good estimator for full circuits, which is quite remarkable given the drastic difference in entanglement generated by the two methods. These results give us a good preview of the system performance in all three regimes discussed earlier.

The advantage of using patch circuits lies in its exponentially reduced computational cost, as it only requires calculating $\mathcal{F}_{\text{XEB}}$ of subsystems at half the full size (or less if a larger number of smaller patches is used). This allows for quick estimates of large-scale system performance on a day-to-day basis, including for system and circuit sizes in the "quantum supremacy" regime. As a consequence, we typically use patch circuits as a quick system performance indicator, which we use for rapid turnarounds between system calibration and performance evaluation, as well as for monitoring full system stability (see Section 11.8.8). We also note that patch circuits can be used well beyond 50 qubits, and in fact can be extended to arbitrary numbers of qubits while keeping the analysis time at most linear in the number of qubits (or even constant if the patches can be analyzed in parallel), assuming that the patch size stays roughly constant and more non-interacting patches are added as the number of qubits grows.

11.8.3 Elided circuits: a more rigorous performance estimator for large systems

For a more rigorous prediction of full $\mathcal{F}_{\text{XEB}}$, we introduce a more sophisticated approach referred to as "elided circuits". Similar to patch circuits, we partition a given set of qubits into two subsets separated by a boundary, but elide (remove) only a fraction of the two-qubit gates along this boundary during a few early cycles of the sequence (more specifically, we elide the earliest gates in time, meaning early layers will have none of their gates along the boundary while later layers will have all of their usual gates across the boundary). Accordingly, the two subsets of qubits are no longer isolated from each other and we cannot simply compute their fidelities separately and multiply. Rather, we must still compute the evolution of the full system. Given that a sufficient number of gates are elided, we can take advantage of the "weak link"

between patches with a hybrid analysis technique: we compute each patch via the Schrödinger method and then connect them with a Feynman path-integral approach (see Section 11.10 for more details on this “qsimh" program).

Compared with patch circuits, elided circuits more closely approach a description of the full system performance under a full circuit: in addition to capturing issues such as control and readout crosstalk, elided circuits allow entanglement to form between the two weakly connected subsystems. It covers essentially all the possible processes that occur in the full circuit, and therefore can be used to predict system performance at a dramatically reduced computational cost, albeit significantly costlier than patch circuits.

In order to validate the use of elided circuits as a system performance estimator, we evaluated its accuracy via a direct comparison with full circuits. In Fig. S29 we show two sets of fidelities from interleaved full and elided circuit experiments. For every system size investigated, using elided circuits yields a fidelity value that is in good agreement with the one obtained with the corresponding full circuits. The average ratio of elided circuit fidelity to full circuit fidelity over all verification circuits was found to be 1.01, with a standard deviation of 5%, dominated by system fluctuations. It is this agreement that certifies elided circuits as a precise predictor for full circuits (within a systematic relative uncertainty of 5%), which we rely on to extrapolate the system performance in the regimes where full circuit analysis is too expensive to perform (i.e., Fig. 4b of the main text).

Compared with full circuits, elided circuits can result in a reduced amount of quantum entanglement in the system. The amount of reduced entanglement can be bounded from above by counting the number of iSWAP gates across the boundary: one iSWAP gate generates at most two units of bipartite entanglements (ebits). This upper bound translates directly into the exponential cost of a Schrödinger-Feynman simulation. For elided circuits with 50 qubits and 14 cycles, the full circuit has approximately 25 ebits of entanglement, while with 6 elisions the elided circuit has at most 12 ebits entanglement between the two patches. For the 53-qubit elided circuits used in the main paper [1], there were enough iSWAPs across the boundary that the amount of entanglement between patches for full vs. elided circuits should be close, giving us even more confidence in using elided circuits to predict the fidelity of the circuit used to claim quantum supremacy.

11.8.4 Choice of unitary model for two-qubit entangling gates

In Section 11.6, we discussed how the two-qubit gate unitaries can be measured by two different approaches: isolated two-qubit XEB and per-layer simultaneous two-qubit XEB. These two methods resulted in two different unitary models when deducing the best-fit unitary. Since we must specify the two-qubit gate unitary matrices in order to compute $\mathcal{F}_{\mathrm{XEB}}$ of the larger system, a natural question is which unitary model should be used. To address this question, we point out that full XEB on the large system occurs in repeated cycles, where during each two-qubit gate layer, all the two-qubit gates in the same orientation take place at the same time (see Fig. 3 in the main text). As a consequence, the two-qubit gate layers during simultaneous pair XEB in Fig. S19 emulate the corresponding layer when running full XEB on a large system. Accordingly, learning the unitaries in parallel operation captures any small coherent modifications induced by the simultaneous application of the other two-qubit gates, such as flux control crosstalk and dispersive shifts from stray interactions. This is evident from the fact that by re-learning the two-qubit unitary parameters, the errors extracted from simultaneous pair XEB become purity-limited (see Fig. S19). This correspondence assures us that unitary parameters extracted from simultaneous pair XEB provides a more accurate description of the full system when full XEB is performed.

In Fig. S30, we show patch circuit fidelities at different system sizes, where the fidelity is

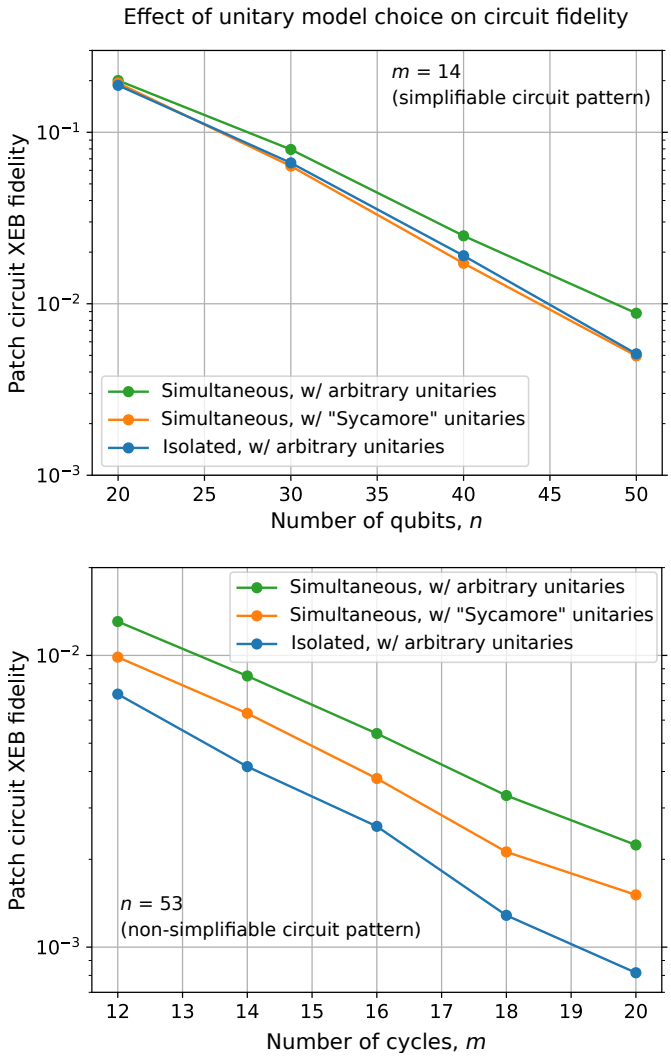

Figure S30: **Effect of unitary model on full system fidelity. a,** Patch circuit fidelity versus number of qubits and choice of unitary model. **b,** Same but versus number of cycles and for the non-simplifiable supremacy circuits. Blue: patch XEB fidelities using the unitaries deduced from the best-fit fSim unitary from isolated pair XEB. Green: patch XEB fidelities using the unitaries deduced from the best-fit fSim unitary from per-layer simultaneous pair XEB. Orange: patch XEB fidelities using the unitaries deduced from the best-fit "Sycamore unitary" ($\theta = \pi/2$, $\phi = \pi/6$) from per-layer simultaneous pair XEB. As expected, the best fidelities arise from fitting to the most general unitary in parallel operation, although the fidelities are high enough to achieve quantum supremacy with the Sycamore unitary model as well.

evaluated using three different unitary models: the best-fit unitaries from isolated pair XEB, the best-fit unitaries from simultaneous pair XEB, and the best-fit "Sycamore" unitaries from simultaneous pair XEB. The Sycamore unitaries are the unitaries obtained when keeping the swap angle fixed at $\theta = \pi/2$ and conditional phase fixed at $\phi = \pi/6$ for all qubits, and then fitting only for two single-qubit phase terms. For the purpose of benchmarking the system fidelity for the operations we performed, we have focused on using unitaries learned from simultaneous pair XEB, which provide the most accurate description of the system. The validity of this approach is experimentally verified—for the same gate sequences, using the simultaneous pair XEB unitaries leads to the best full-system fidelity values at every system size. This is direct evidence that the unitaries learned from simultaneous pair XEB form a more accurate description of the system than those from isolated pair XEB.

On the other hand, in order to be useful for generic quantum algorithms, it will be desirable to use calibrated gatesets that are independent of the specific gate sequences used. For this purpose, it is important to check the circuit fidelity under the other two unitary models, where the two-qubit gate unitaries were calibrated in more generic settings. One can see that fidelities calculated from these two unitary models still demonstrate nearly as good performance despite the addition of small coherent control errors. They differ from the fidelities using the simultaneous pair XEB unitaries by less than a factor of 2 at 50 qubits (fidelity goes from 9×10^{-3} to 5×10^{-3} at 50 qubits). This is remarkable since it suggests going from a 2-qubit setting to 50-qubit setting, our full system calibration precision degrades only by a factor of < 2 despite the system size increasing by a factor of 25. This high precision in gate calibration gives us confidence to use our processors in NISQ algorithms.

11.8.5 Understanding system performance: error model prediction

In this section, we perform additional analysis to compare the measured fidelities to that predicted from the constituent gate and measurement errors.

The most commonly used error model in quantum computing theory is the digital error model. Analogous to the independent noise model in classical information theory, the digital error model is based on the assumption that there are no space and time correlations between errors of quantum gates [59, 60, 27]. If this assumption is valid, it should be possible to construct the fidelity of a large quantum system from the fidelities of its constituent parts: single- and two-qubit gates, and measurement. It is important to point out that the gate fidelity metric that should be used here is the entanglement fidelity, $1 - e_P$ (see Section 11.5 for more details). This is the correct quantity to describe the fidelity of quantum operations since, in contrast to other metrics such as the commonly used average fidelity, it is independent of the dimension of the Hilbert space.

In Fig. S31, we show fidelities as a function of both system size and number of cycles (circuit depth), measured with patch circuits. In each plot, we compare the measured fidelities to the predicted fidelities, which are calculated from a simple multiplication of individual gate entanglement fidelities as measured during simultaneous operation, along with the measurement fidelities obtained during simultaneous measurement. We note that the measured readout fidelities actually also automatically include the effect of state preparation errors as well. More explicitly, if a circuit contains the set of single-qubit gates G_1, the set of two-qubit gates G_2, and the set of qubits Q, then we approximate the fidelity F as

$$F = \prod_{g \in G_1} (1 - e_g) \prod_{g \in G_2} (1 - e_g) \prod_{q \in Q} (1 - e_q), \tag{11.77}$$

where e_g are the individual gate Pauli errors and e_q are the state preparation and measurement errors of individual qubits. It is evident that there is a good agreement between the measured

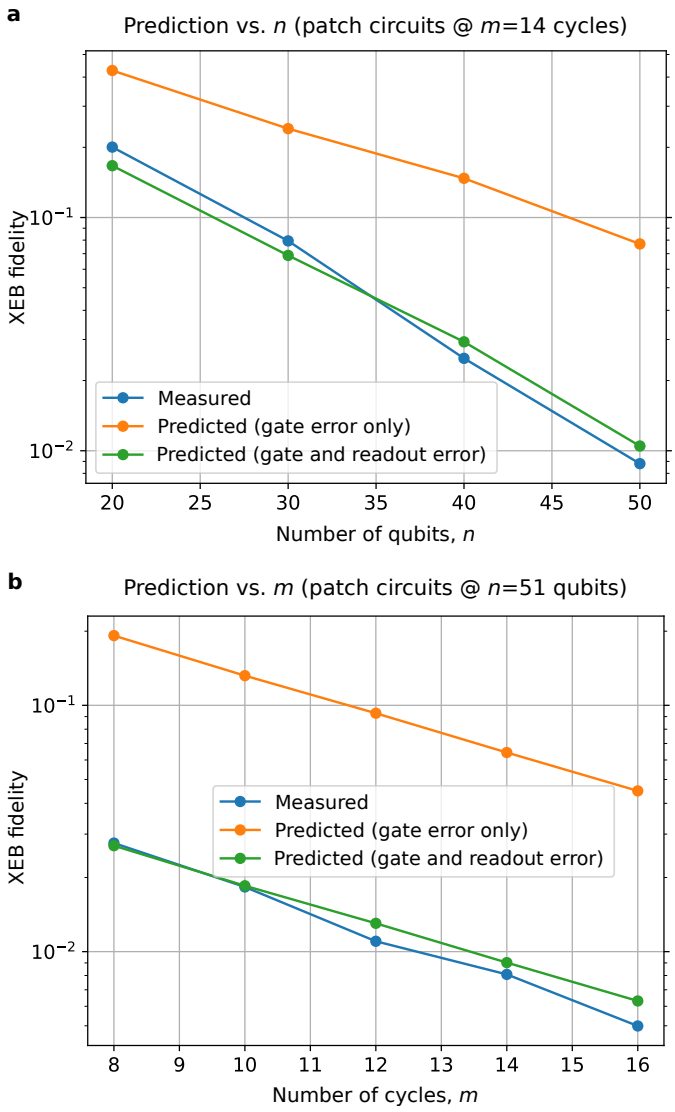

Figure S31: **Predicted vs. measured large-scale XEB fidelity. a,** Data and two predictions for 14-cycle patch circuits vs. number of qubits. Predictions are based on the product of single- and two-qubit gate entanglement fidelities under simultaneous operation. Blue curve contains measured fidelities. Orange is the prediction based only on gate errors during parallel operation, but without taking measurement error into account. Green is the same but multiplied by the measured readout fidelities. **b,** Same as the first panel, but vs. number of cycles at a fixed number of qubits $n = 51$. Again, the prediction from simultaneous gate fidelities and measurement fidelity is a good prediction of the actual system performance.

and predicted fidelities, with deviations of up to only 10-20%. Given that the sequence here involves tens of qubits and $\sim$ 1000 quantum gates, this level of agreement provides strong evidence to the validity of the digital error model.

This conclusion can be further strengthened by the close agreement between the fidelities of full circuits, patch circuits, and elided circuits. Even though these three methods differ only slightly in the gate sequence, they can result in systems with drastically different levels of computational complexity and entanglement between subsystems. The agreement between the fidelities measured by these different methods, as well as the agreement with the predicted fidelity from individual gates, gives compelling evidence confirming the assumptions made by the digital error model. Moreover, these assumptions remain valid even in the presence of quantum entanglement.

The validation of the digital error model has crucial consequences, in particular for quantum error correction. The absence of space or time correlations in quantum noise has been a commonly assumed property in quantum error correction since the very first paper on the topic [59]. Our data is evidence that such a property is achievable with existing quantum processors.

11.8.6 Distribution of bitstring probabilities

In Section 11.4, we motivate two different estimates for fidelity F, one based on the cross entropy, Eq. (11.28), and the other based on linear cross entropy, Eq. (11.27). In this section, we examine the probabilities of sampled bitstrings and compare them against theoretical distributions. We use bitstring samples from non-supremacy region to demonstrate the analysis methodology, then apply it to the sample in the supremacy region.

The theoretical PDF for the bitstring probability p with linear XEB is

$$P_l(x|F) = (Fx + (1-F))e^{-x}$$

where $x \equiv Dp$ is the probability p scaled by the Hilbert space dimension D, and F is the linear cross entropy fidelity. The PDF for $\log p$ is

$$P_c(x|F) = (1 + F(e^x - 1))e^{x-e^x}$$

where $x \equiv \log(Dp)$ and F is the cross entropy fidelity.

From a set of bitstrings $\{q_i\}$, the fidelity is estimated from the ideal probabilities $\{p_i = p_s(q_i)\}$ as

$$\hat{F}_l = \langle Dp \rangle - 1, \tag{11.78}$$
$$\hat{F}_c = \langle \log(Dp) \rangle + \gamma, \tag{11.79}$$

where γ is the Euler-Mascheroni constant, see Sec. 11.4.2.

Figure **??** shows the distribution of $\{p_i\}$ from 0.5 million bitstrings obtained in an experiment with a 20-qubit 14-cycle random quantum circuit. For comparison, we produce 0.5 million bitstrings sampled uniformly at random and 0.5 million bitstrings sampled from the output distribution of the ideal circuit and show them in the same figure. The theoretical distribution curves are also shown, where the fidelity estimated from data is fed into the curve $P_l(x|\hat{F})$ and $P_c(x|\hat{F})$.

We see good agreements between experiment and theory. To quantify the agreements, we use the Kolmogorov-Smirnov test [61] to characterize the goodness of fit of data $\{p_i\}$ to theoretical PDFs. First we compute the Kolmogorov-Smirnov statistics D_{KS}, that is, the distance between data and theory as the supremum of point-wise distances between the empirical cumulative distribution function of data ECDF(p) and the theoretical cumulative distribution function CDF(p):

$$D_{KS} = \sup_i |\text{ECDF}(p_i) - \text{CDF}(p_i)|.$$

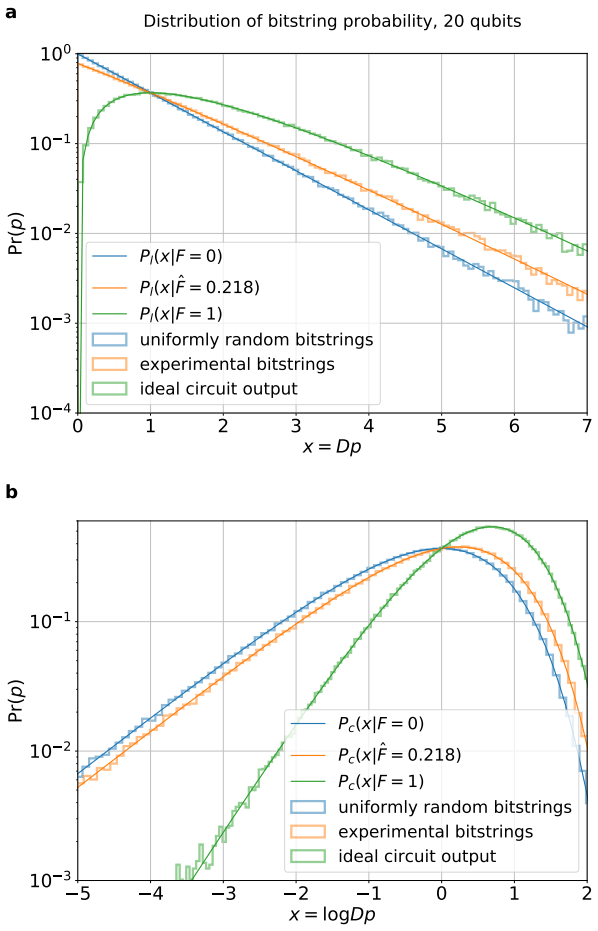

Figure S32: **Histograms of ideal probabilities.** The ideal probability p is calculated from the final state amplitudes of a (20-qubit 14-cycle) random circuit. The blue, orange, and green histogram is the ideal probabilities of bitstrings sampled uniformly at random, from the experiment, and ideal output, respectively. **a,** The distribution of Dp and theoretical curves $P_l(x|F_l)$ normalized to histogram counts for $F_l = 0, \hat{F}_l, 1$, respectively. **b,** The distribution of $\log(Dp)$ and theoretical curves $P_c(x|F_c)$ for $F_c = 0, \hat{F}_c, 1$, respectively.

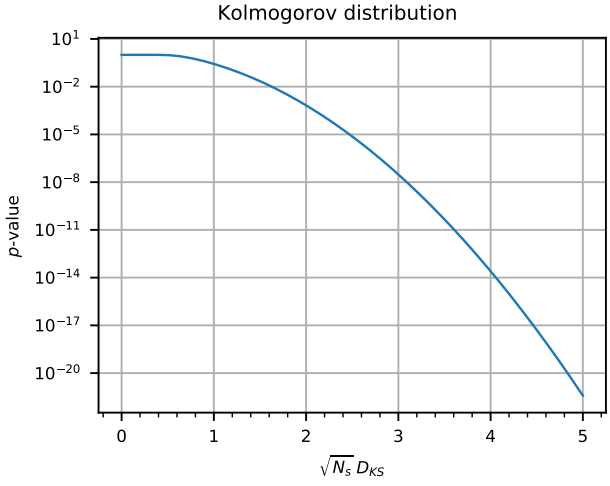

Figure S33: **The Kolmogorov distribution function.** This function is used to compute p-value from a given D_{KS} and number of samples N_s.

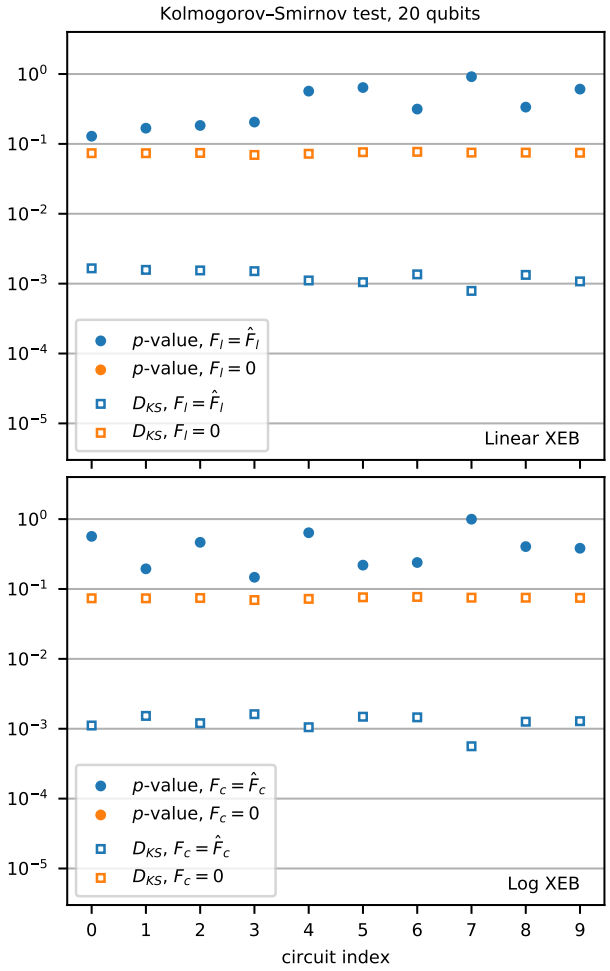

Figure S34: **The Kolmogorov-Smirnov test results for each of 10 circuits for a (20-qubit 14-cycle) random circuit.** See text for the definition of D_{KS} and p-value. The upper plot is for linear XEB, and the lower one is for log XEB.

	D_{KS}		p-value	
	$F = \hat{F}$	$F = 0$	$F = \hat{F}$	$F = 0$
Linear XEB	1.3×10^{-4}	9.6×10^{-4}	0.66	$< 2.2 \times 10^{-16}$
Log XEB	9.5×10^{-5}	9.6×10^{-4}	0.95	$< 2.2 \times 10^{-16}$

Table 15: **The Kolmogorov-Smirnov test results on combined samples**.

We then convert the distance D_{KS} to a p-value using the Kolmogorov distribution shown in Fig. ??. The p-value is used for rejecting the null hypothesis that the data $\{p_i\}$ is consistent with the theoretical distribution. The whole Kolmogorov-Smirnov test is done using the scipy package [62] and checked against R package ks.test [63]. Both packages produce consistent results.

We test the ideal probabilities of bitstrings observed in the experiment $\{p_i\}$ against 2 theoretical distributions, one with estimated fidelity $F = \hat{F}$ and one with fidelity $F = 0$. The Kolmogorov-Smirnov statistics D_{KS} and the p-value of every circuit are shown in figure ??. Note that the p-values for $F = 0$ are not shown because they are $\ll 10^{-20}$ due to the large $D_{KS} \approx 0.07$ with $N_s = 5 \times 10^5$ points in the sample. That is evident from reading off Fig. ??.

We reject the null hypothesis that the experimental bitstrings are consistent with the uniform random distribution with very high confidence for this (20-qubit 14-cycle) random circuit.

Now we turn our attention to the supremacy circuits.

We use random circuits with gate elisions for checking the distributions because it is exponentially expensive to calculate the ideal theoretical probability of a bitstring without gate elisions. The effect on fidelity from gate elisions is well understood, see Sec. 11.8.3. The gate elisions are chosen to minimize the effect while making the classical estimation feasible, see Sec. 11.7.7. We sample $N_s = 3 \times 10^6$ bitstrings $\{q_i | i = 1...N_s\}$ from each of 10 (53-qubit 20-cycle) random circuits, and compute the theoretical ideal probabilities of each bitstring $\{p_i | i = 1...N_s\}$.

The distributions of Dp and $\log(Dp)$ from one such circuit along with the corresponding theoretical curves are shown in Fig. ??.

We again use the Kolmogorov-Smirnov test to characterize the goodness of fit of data $\{p_i\}$ to theoretical PDFs with estimated fidelity $F = \hat{F}$ and zero fidelity $F = 0$. The Kolmogorov-Smirnov statistics D_{KS} and the p-value of every circuit are shown in figure ??.

The p-value for the null hypothesis of zero fidelity is generally small for every circuit, with a maximum of 0.045 for circuit number 1. We say that the null hypothesis of zero fidelity is rejected better than a 95% confidence level for each circuit. On the other hand, the p-value of null hypothesis of estimated fidelity $\hat{F}$ is generally large. The p-value is between 0.18 and 0.98 for linear XEB, and between 0.33 and 0.98 for log XEB. That indicates that the empirical cumulative distribution functions $\mathrm{ECDF}(p_i)$ from data is quite consistent with the theoretical $\mathrm{CDF}(p_i|\hat{F})$.

As will be seen in Fig. S38 in section 11.8.7 below, the fidelity of individual circuits are consistent with each other within the statistical uncertainties. Therefore it makes sense to do a Kolmogorov-Smirnov test on all samples combined, containing 30 million bitstrings. The estimated fidelities from the combined sample are $\hat{F}_l = 2.24 \times 10^{-3}$ and $\hat{F}_c = 2.34 \times 10^{-3}$, respectively. The D_{KS} and p-values are listed in table ??. The p-value for the null hypothesis of $F = 0$ is very small: p-value $= 3 \times 10^{-24}$ from scipy, and p-value $< 2.2 \times 10^{-16}$ from R. We note the more conservative value in the table. The null hypothesis of $F = 0$ is rejected with much higher confidence levels than individual circuits.

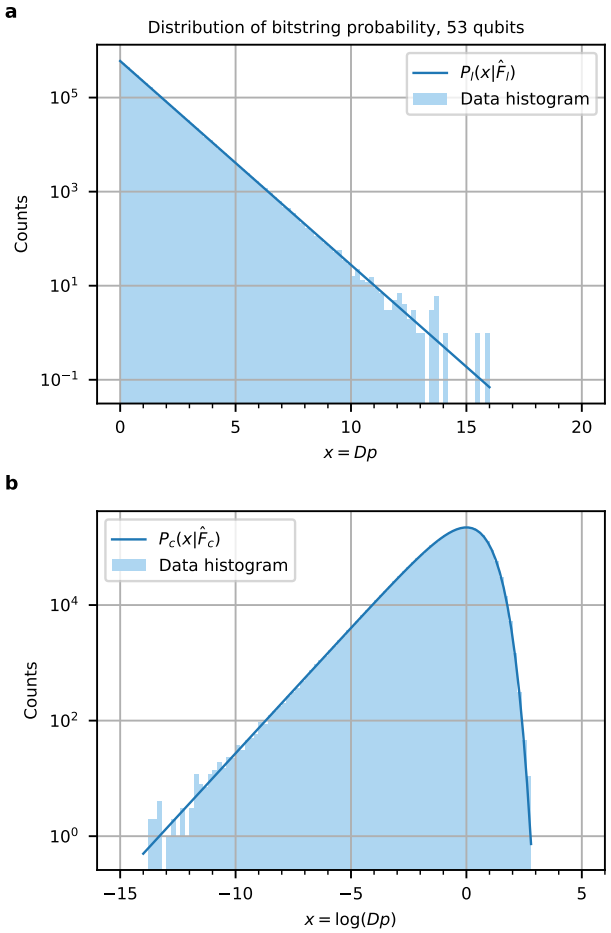

Figure S35: **Distribution of bitstring probabilities from a 53-qubit 20-cycle circuit.** We calculate the theoretical probabilities of experimentally-observed bitstrings. **a,** The distribution of Dp and the theoretical curve $P_l(x|\hat{F}_l)$ normalized to histogram counts. **b,** The distribution of $\log(Dp)$ with theoretical curve $P_c(x|\hat{F}_c)$.

11.8.7 Statistical uncertainties of XEB measurements

In this section we check the statistical uncertainties of our fidelity estimates against theoretical predictions.

The statistical uncertainties of $\hat{F}_l$ and $\hat{F}_c$ are estimated from data using the standard error-on-mean formula as

$$\begin{aligned} \hat{\sigma}_{F_l} &= D\sqrt{\mathrm{Var}(p)/N_s}, \\ \hat{\sigma}_{F_c} &= \sqrt{\mathrm{Var}(\log p)/N_s}, \end{aligned}$$

where $\mathrm{Var}(x)$ is the variance estimator of sample $\{x_i\}$. Because the distribution of p and $\log p$ have finite variances both experimentally and theoretically, we can use the bootstrap procedure [64] to verify the estimate of statistical uncertainties.

The fidelity distribution from 4000 bootstrap samples are shown in Fig. ??. The distribution of $\hat{F}_l$ and $\hat{F}_c$ are each fit to a Gaussian distribution function using maximum likelihood.

The Kolmogorov-Smirnov test on the Gaussian fit produces p-values of 0.99 and 0.41 for $\hat{F}_l$ and $\hat{F}_c$ bootstrap distributions, respectively. It indicates that the central limit theorem is at work and the distributions are consistent with Gaussian distributions.

The estimated statistical uncertainty, the standard deviation of the bootstrap distribution, and the σ parameter of the Gaussian fit are compared against each other to verify that the

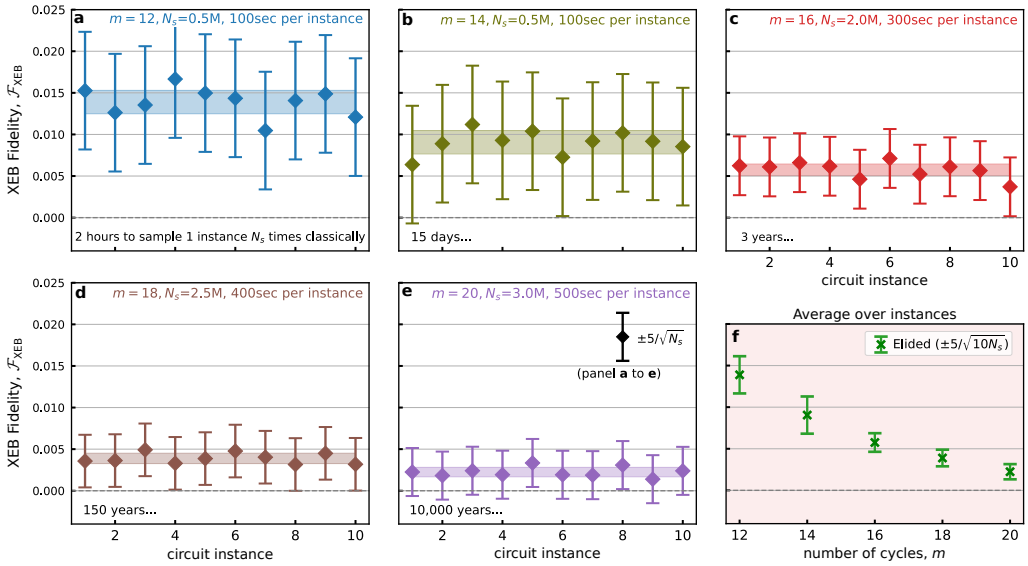

Figure S38: Per-instance elided circuit fidelities and statistical uncertainties. XEB fidelities of all 10 elided circuit instances for each circuit depth from Fig. 4b of the main text. **a** to **e**, Here, each panel corresponds to a single circuit depth m. In these panels, $\pm 5\sigma$ statistical error bars, where $\sigma = 1/\sqrt{N_s}$, are shown for each of the individual circuit instance fidelities. Also shown is a band corresponding to $\pm\sigma$ for a single instance, but about the mean fidelity of the 10 instances, showing that the variations between circuits can be explained by statistical fluctuations from the finite number of samples. **f**, Fidelity averaged over all 10 circuits along with $\pm 5\sigma$ error bars are shown (the same quantity is plotted in Fig. 4b of the main text but on a log scale), where in this case $\sigma = 1/\sqrt{10N_s}$. Here, for all circuit depths, the mean fidelity is more than 5σ above 0.001.

statistical uncertainty estimate is minimally biased. For the example circuit used in the figures, the three parameters are 5.78, 5.78, 5.78 ($\times 10^{-3}$) for $\hat{\sigma}_{F_l}$, respectively. The same parameters for $\hat{\sigma}_{F_c}$ are 7.40, 7.46, 7.46 ($\times 10^{-3}$). The relative differences are less than 1%, consistent with the expected agreement of parameters for 4000 bootstrap samples.

We repeat the bootstrap procedure on all ten 53-qubit 20-cycle circuits with 2500 bootstrap resamples. The statistical uncertainty estimates are all within 3.1% of the bootstrap standard deviation.

The combined linear cross entropy fidelity and statistical uncertainty of 10 random circuits is calculated using inverse-variance weighting to be $\hat{F}_l = (2.24 \pm 0.18) \times 10^{-3}$. The theoretical prediction of the statistical uncertainty, $\sqrt{(1 + 2F - F^2)/N_s}$, is 1.8×10^{-4}, which agrees with the experimental estimate. As a comparison, the combined cross entropy fidelity is $\hat{F}_c = (2.34 \pm 0.23) \times 10^{-3}$. The theoretical prediction of statistical uncertainty, $\sqrt{(\pi^2/6 - F^2)/N_s}$, is 2.3×10^{-4}, which agrees with the experimental estimate as well. Thus, the cross entropy fidelity and linear cross entropy fidelity estimators produce consistent results. Furthermore, the statistical uncertainty of the linear cross entropy estimator is smaller, as expected from its theoretical formula.

In Fig. S38, we also show the linear XEB fidelities and 5σ statistical uncertainties of all 10 elided circuit instances for each circuit depth from Fig. 4b of the main text. Variations between the fidelities of different circuit instances are consistent with the expected statistical noise due to the finite number of samples. In the last panel, we also show the smaller statistical uncertainties of the fidelity averaged over the 10 circuit instances for each depth.

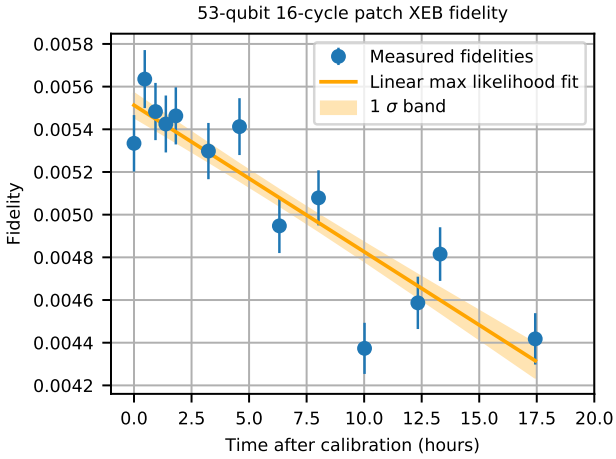

Figure S39: Stability of repeated 53-qubit 16-cycle patch circuit benchmarking over 17.4 hours, without any system recalibration. Statistical error bars from the finite bitstring sample number are included. The intrinsic system fluctuations are likely dominated by a small number of TLSs moderately coupled to a few qubits at their idling and/or readout biases.

11.8.8 System stability and systematic uncertainties

In addition to statistical errors, XEB fidelity is also subject to systematic drift as the system performance may fluctuate and/or degrade over time. To quantify these mechanisms, we performed a patch circuits time stability measurement on 53 qubits using a circuit of 16 cycles and 1 million bitstrings for 17.4 hours after calibration. In between these measurements, we measured the fidelity of other 53-qubit circuits with 16 to 20 cycles. The analyzed results are shown in Fig. S39. The statistical uncertainties of the fidelities are estimated to be 1.29×10^{-4}, as indicated by the error bars.

We repeated the stability measurements twice, with different circuits and on different days. Fig. S39 shows the one that exhibits greater degradation as a conservative estimate of the effect. The measurement indicates a degradation of fidelity within the range of time. A linear fit with $F = p_0 + p_1 t$ results in estimated parameters $\hat{p}_0 = (5.51 \pm 0.055) \times 10^{-3}$, $\hat{p}_1 = (-6.87 \pm 0.64) \times 10^{-5}$, and a correlation coefficient of $\hat{p}_0$ and $\hat{p}_1$, ρ, to be -0.76. The χ^2 per degree of freedom is 26.3/11.

The p-value for the χ^2 for 11 degrees of freedom is 0.0058, indicating that it is not a very good fit. Because the correctness of the estimates of statistical uncertainties has been verified in Section 11.8.7, this is attributed to systematic fluctuation in addition to degradation. It is supported by the larger variance of fidelity than the 1σ band in Fig. S39.

The 1σ band depends on the statistical uncertainties of fidelities and the variance of time on the x-axis, but is independent of the variance of fidelity. To take the variance of fidelity into account, we use the variance of the residuals of the linear fit as an estimator of the variance of fidelity. The standard deviation of residuals is estimated to be 1.84×10^{-4}, which is added to σ_{p_0} in quadrature to be the total σ_{p_0}. The estimate is total $\sigma_{p_0} = 1.92 \times 10^{-4}$, 3.5 times larger than the statistical-only σ_{p_0} of 5.5×10^{-5}.

The uncertainty on a fidelity measured at time t can be estimated by the standard error propagation, assuming that t is uncorrelated with either p_0 or p_1.

$$\sigma_F = \left[\sigma_{p_0}^2 + 2t\sigma_{p_0}\sigma_{p_1}\rho + \sigma_{p_1}^2 t^2\right]^{1/2} \tag{11.80}$$

The value of σ_F as well as the ratio σ_F/F in the range of measured fidelities monotonically decreases. We take $\max(\sigma_F/F)$ as the estimate of relative systematic uncertainty for fidelities measured in the same run. The value is found to be 4.4% and is used in subsequent analysis.

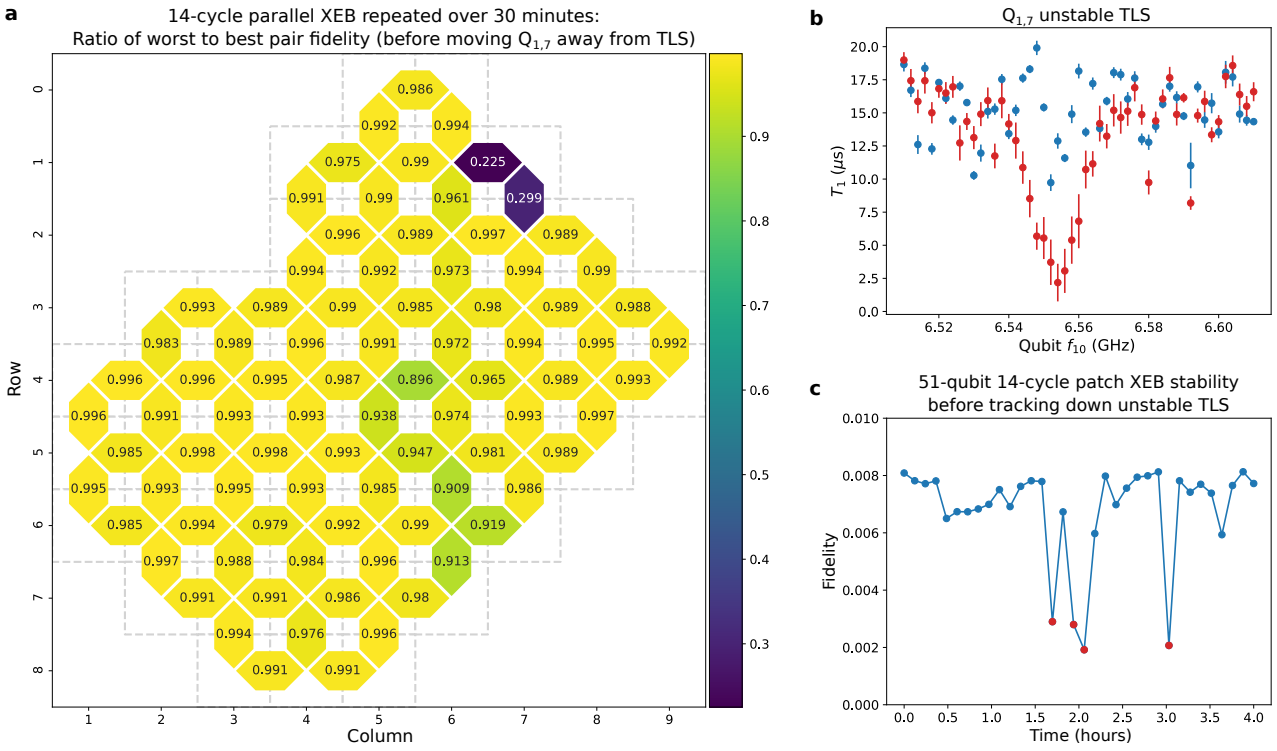

Figure S40: **Identifying sources of fluctuations with repetitive per-layer simultaneous pair XEB. a,** Per-pair ratio of worst fidelity to best fidelity measured via per-layer simultaneous pair XEB at a depth of 14 cycles over the course of 30 minutes. During this time, fluctuations were dominated by a single TLS. **b,** Measured qubit T_1 vs. f_{10} for $Q_{1,7}$ at two different times a few minutes apart (red vs. blue points), showing an unstable TLS that was dominating the fluctuations in full system fidelity seen in **c,**. Moving $Q_{1,7}$ far from this TLS led to the stability seen in Fig. S39.

The physical origin of the observed system fluctuations can be attributed to many possible channels: $1/f$ flux noise, qubit T_1 fluctuations, control signal drift, etc. We speculate that the dominant mechanism is the moderate interaction between a small number of TLS's and a few qubits at their idling and/or readout biases. In Fig. S40a, we show the result of measuring per-layer simultaneous pair XEB at a fixed depth of 14 cycles repeatedly over time. The quantity plotted is the ratio of the worst pair fidelity to best fidelity observed over the course of 30 minutes. This type of repetitive measurement allows us to pinpoint which pairs dominate the fluctuations in full system fidelity. Note that because we used fidelity at a fixed cycle depth rather than the one extracted from the exponential decay, these numbers contain the effect of fluctuating measurement fidelity as well.

As shown in Fig. S40a, the depth-14 fidelity of most pairs fluctuates downward by only $\sim$1% at depth 14, which translates to either a $\sim$1% fluctuation in measurement fidelity for a pair, or a $\sim$0.08% fluctuation in the two-qubit gate fidelity for a pair. Before finding the unstable TLS defect in Fig. S40b, a single qubit dominated the fluctuations in full system fidelity seen in Fig. S40c. After we moved this problematic qubit far from the fluctuating TLS, the fluctuations in fidelity during the actual quantum supremacy experiment (Fig. S39) were dominated by a handful of pairs containing qubits in the "degenerate" readout region (described in section 11.6). For these qubits, due to constraints from readout crosstalk we had little freedom in what readout detunings we could choose, and so the best we could do was to put some qubits near defects or transmon-resonator transition modes during readout. We speculate that this is where the remaining dominant fluctuations originate.

11.8.9 The fidelity result and the null hypothesis on quantum supremacy

We use the mean fidelity of ten 53-qubit 20-cycle circuits as the final benchmark of the system. In section 11.8.7 we estimated the fidelity and statistical uncertainty to be $(2.24 \pm 0.18) \times 10^{-3}$ using the linear cross entropy. In section 11.8.8 we estimated the relative systematic uncertainty due to drift to be 4.4%. Combining these 2 estimations we arrive at the final fidelity as $(2.24 \pm 0.10(\text{syst.}) \pm 0.18(\text{stat.})) \times 10^{-3}$. Fidelity estimates with statistical and systematic uncertainty for other quantum circuits are shown in Figure S41.

As we show in section 11.10, a noisy sampling of a random quantum circuit at fidelity $F = 10^{-3}$ requires 5000 years with a classical computer with CPU power equivalent to 1 million cores, and it scales linearly with fidelity F. It takes a quantum computer less than an hour to complete the same noisy sampling. Therefore we form the null hypothesis that the fidelity of the quantum computer is $F \leq 10^{-3}$, and the alternative hypothesis that $F > 10^{-3}$. If the alternative hypothesis is true, we can say that a classical computer can not perform the same noisy sampling task as the quantum computer.

The total uncertainty on fidelity is estimated with addition in quadrature of systematic uncertainty and statistical uncertainty. The mean fidelity of 10 random circuits with 53 qubits and 20 cycles is $(2.24 \pm 0.21) \times 10^{-3}$. The null hypothesis is therefore rejected with a significance of 6σ.

While our analysis of the uncertainty in $\mathcal{F}_{\text{XEB}}$ was computed from both statistical and systematic errors, some care should be taken in the consideration of systematic errors as they pertain to the claim of quantum supremacy. Systematic errors should be included if we wish to use the XEB fidelity value, for example comparing fidelities of patch, elided and full circuits. However for quantum supremacy, a false claim would arise if $\mathcal{F}_{\text{XEB}}$ was zero, but we obtained a non-zero value because of a fluctuation. Systematic fluctuations produce a change in magnitude of XEB, as seen in the data in this section, which is thus a multiplicative-type error that does not change the XEB fidelity value when it is zero. A false positive is only produced by a additive-

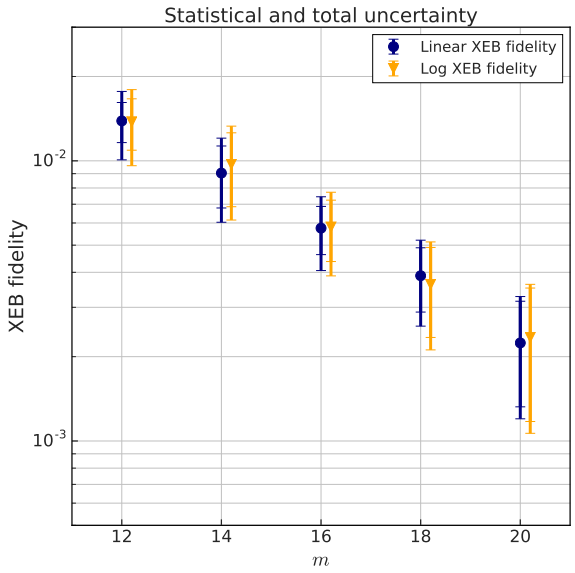

Figure S41: Statistical and total uncertainty of fidelity estimates produced by the linear XEB and logarithmic XEB from ten random quantum circuits with 53 qubits and m cycles. The inner error bars represent the statistical uncertainty discussed in section 11.8.7. The outer error bars represent the total uncertainty discussed in section 11.8.8.

type statistical fluctuations and thus it is the only mechanism that should be considered when computing the uncertainty. Therefore, the 6σ significance of our claim should be considered as conservative.

Some skeptics have warned that a quantum computer may not be possible [65, 66], for example due to the fragility of quantum information at large qubit number and exponentially large Hilbert space. The demonstration here of quantum behavior at 10^{16} Hilbert space is strong confirmation that nothing unusual or unexpected happens to our current understanding of quantum mechanics at this scale.

11.9 Sensitivity of XEB to errors

An important requirement for a procedure used to evaluate quantum processors, such as XEB, is sensitivity to errors. Qubit amplitudes are complex variables and therefore quantum errors are inherently continuous. Nevertheless, they can be given a discrete description, for example in the form of a finite set of Pauli operators. The digital error model is used for instance in quantum error correction where errors are discretized by syndrome extraction. In this section we examine the impact of both discrete and continuous errors on the fidelity estimate obtained from the XEB algorithm.

The XEB procedure uses a set of random quantum circuits $\mathcal{U} = \{U_1, \ldots, U_S\}$ with n qubits and m cycles. Every circuit is executed N_s times on the quantum processor under test. Each execution of the circuit U_j applies the quantum operation Λ_j, which is an imperfect realization of U_j, to the input state $|0\rangle\langle 0|$. The result of the experiment is a set $\mathcal{B}$ of SN_s bitstrings $q_{i,j}$ sampled from the distributions $p_e(q_{i,j}) = \langle q_{i,j}| \rho_j |q_{i,j}\rangle$ where $\rho_j = \Lambda_j(|0\rangle\langle 0|)$ is the output state in the experiments with circuit U_j. For each bitstring $q_{i,j}$, a simulator computes the ideal probability $p_s(q_{i,j}) = |\langle q_{i,j}|\psi_j\rangle|^2$ where $|\psi_j\rangle = U_j|0\rangle$ is the ideal output state of the circuit U_j. Finally, XEB uses Eq. (11.27) or (11.28) to compute an estimate $\mathcal{F}_{\text{XEB}}(\mathcal{B},\mathcal{U})$ of fidelity $F(|\psi_j\rangle\langle\psi_j|, \rho_j) = \langle\psi_j|\rho_j|\psi_j\rangle$ averaged over circuits $\mathcal{U}$. The result quantifies how well the

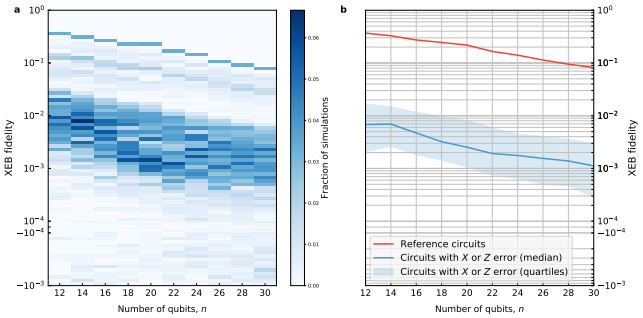

Figure S42: **Impact of one single-qubit Pauli error on fidelity estimate from XEB. a,** Distributions of fidelity estimates from XEB using measured bitstrings and quantum circuits with one bit-flip or one phase-flip error. For each n, shades of blue represent the normalized histogram of the estimates obtained for the error gate placed at different circuit locations. The highest fidelity estimates correspond to phase-flip errors immediately preceding measurement and are equal to the fidelity estimates from XEB using error-free circuits. **b,** Quartiles of the distributions shown in **a** (blue) compared to the fidelity estimates from XEB using measured bitstrings and unmodified quantum circuits (red). Both plots use linear scale between 10^{-4} and -10^{-4} and logarithmic scale everywhere else.

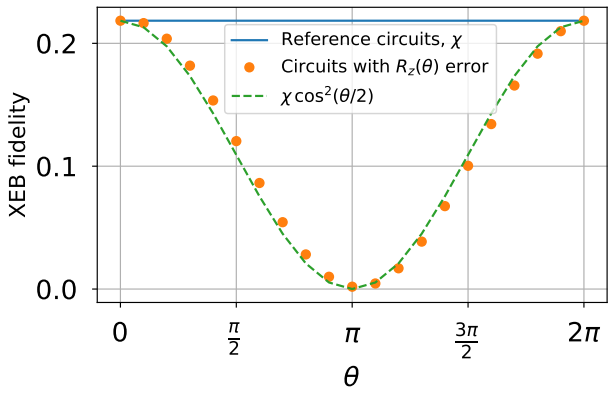

Figure S43: **Impact of the $R_z(\theta)$ error on XEB.** Fidelity estimates computed by XEB from measured bitstrings and circuits with $n = 20$ qubits and $m = 14$ cycles modified to include $R_z(\theta)$ error applied in 10th cycle to one of the qubits as a function of θ (orange dots). Also shown is XEB fidelity computed using the same bitstrings and unmodified circuits (blue solid line) and a simple model which predicts the effect of the error (green dashed line).

quantum processor is able to realize quantum circuits of size n and depth m. See section 11.4 for more details on XEB.

The estimate $\mathcal{F}_{\rm XEB}(\mathcal{B},\mathcal{U})$ is a function of bistrings $\mathcal{B}$ obtained in experiment and of the set of quantum circuits $\mathcal{U}$ used to compute ideal probabilities. This enables a test of the sensitivity of the method to errors by replacing the error-free reference circuits $\mathcal{U} = \{U_1, \ldots, U_S\}$ with circuits $\mathcal{U}_E = \{U_{1,E}, \ldots, U_{S,E}\}$ where $U_{j,E}$ is the quantum circuit obtained from U_j by the insertion at a particular location in the circuit of a gate E representing the error. We identify errors inserted at different circuit locations that lead to the same output distribution since XEB cannot differentiate between them.

We first consider the impact of a discrete single-qubit Pauli error E placed in a random location in the circuit. In Fig. S42 we plot $\mathcal{F}_{\rm XEB}(\mathcal{B},\mathcal{U}_E)$ where $\mathcal{B}$ are bitstrings observed in our experiment and $\mathcal{U}_E$ are quantum circuits modified by the insertion of an additional X or Z gate following an existing single-qubit gate. Each fidelity estimate corresponds to a different circuit location where the error gate has been inserted. For every n, the highest fidelity values correspond to the insertion of the Z gate in the final cycle of the circuit. They have no impact on measurements and thus are equivalent to absence of error. The corresponding fidelity estimates match the estimates for the unmodified circuits.

The probability of only seeing the error E is approximately $q = ep$ where e is the probability of E arising at the particular circuit location and p is the probability that no other error occurs. The fraction q of executions realize circuit $U_{j,E} \in \mathcal{U}_E$ yielding bitstrings $\mathcal{B}_E$ while the remaining fraction $1-q$ yield bitstrings $\mathcal{B}_*$. XEB averages over circuit executions, so

$$\mathcal{F}_{\rm XEB}(\mathcal{B},\mathcal{U}_E) = q\,\mathcal{F}_{\rm XEB}(\mathcal{B}_E,\mathcal{U}_E) + (1-q)\,\mathcal{F}_{\rm XEB}(\mathcal{B}_*,\mathcal{U}_E). \quad (11.81)$$

Since bitstrings $\mathcal{B}_E$ originated in a perfect realization of $\mathcal{U}_E$ we have $\mathcal{F}_{\rm XEB}(\mathcal{B}_E,\mathcal{U}_E) \simeq 1$ with high probability. Also, assuming the circuits randomize the output quantum state sufficiently, we have $\mathcal{F}_{\rm XEB}(\mathcal{B}_*,\mathcal{U}_E) \simeq 1/\sqrt{D}$, where $D = 2^n$, see Eq. (11.25) and Fig. S7. Therefore, for large n

$$\mathcal{F}_{\rm XEB}(\mathcal{B},\mathcal{U}_E) \simeq q + \frac{1-q}{\sqrt{D}} \simeq q \quad (11.82)$$

with high probability.

Now, the probability p that no error other than E occurs is approximately equal to the experimental fidelity F which is approximated by $\mathcal{F}_{\rm XEB}(\mathcal{B},\mathcal{U})$, so

$$\mathcal{F}_{\rm XEB}(\mathcal{B},\mathcal{U}_E) \simeq e\,\mathcal{F}_{\rm XEB}(\mathcal{B},\mathcal{U}) \quad (11.83)$$

which means that XEB result obtained using circuits modified to include E is approximately proportional to the XEB result obtained using the error-free reference circuits. Moreover, the ratio of the two XEB results is approximately equal to the probability of E.

The data in Fig. S42 agrees with the approximate proportionality in Eq. (11.83) and allows us to estimate the median probability of a Pauli error. Based on the drop in XEB fidelity estimate by a factor of almost 100 due to the insertion of one single-qubit Pauli error into the circuit, the probability is on the order of 1%. While more work on the gate failure model needs to be done to correctly relate Sycamore gate error rates to the probability of specific Pauli errors, we already see that e has the same order of magnitude as our per cycle and per qubit error given by $e_{2c}/2 \simeq 0.5\%$, see Table 12. A possible resolution of the factor of two discrepancy may lie in the fact that more than one gate failure can manifest itself as a particular Pauli error E in a particular circuit location.

Lastly, we consider the impact of continuous errors on XEB result. Fig. S43 shows the fidelity estimate obtained from XEB using bitstrings observed in our experiment and quantum circuits modified to include a single rotation $R_Z(\theta)$. The middle point of the plot is equal to the fidelity estimate obtained for one of the discrete errors in Fig. S42 whereas the leftmost and rightmost points correspond to the fidelity estimate obtained from XEB using the error-free reference circuit.

The analysis above illustrates how questions about the behavior and performance of quantum processors can be formulated in terms of modifications to the reference quantum circuits and how XEB can help investigate these questions. While XEB has proven itself a powerful tool for calibration and performance evaluation (see sections 11.6 and 11.8), more work is required to assess its efficacy as a diagnostic tool for quantum processors.

11.10 Classical simulations

11.10.1 Local Schrödinger and Schrödinger-Feynman simulators

We have developed two quantum circuit simulators: qsim and qsimh. The first simulator, qsim, is a Schrödinger full state vector simulator. It computes all 2^n amplitudes, where n is the number of qubits. Essentially, the simulator performs matrix-vector multiplications repeatedly. One matrix-vector multiplication corresponds to applying one gate. For a 2-qubit gate acting on qubits `q1` and `q2` (`q1` < `q2`), it can be depicted schematically by the following pseudocode.

```
#iterate over all values of qubits q > q2
for (int i = 0; i < 2^n; i += 2 * 2^q2) {
  #iterate values for q1 < q < q2
  for (int j = 0; j < 2^q2; j += 2 * 2^q1) {
    #iterate values for q < q1
    for (int k = 0; k < 2^q1; k += 1) {
      #apply gate for fixed values
      #for all q not in [q1,q2]
      int l = i + j + k;

      float v0[4]; #gate input
      float v1[4]; #gate output

      #copy input
      v0[0] = v[l];
      v0[1] = v[l + 2^q1];
      v0[2] = v[l + 2^q2];
      v0[3] = v[l + 2^q1 + 2^q2];

      #apply gate
      for (r = 0; r < 4; r += 1) {
        v1[r] = 0;
        for (s = 0; s < 4; s += 1) {
          v1[r] += U[r][s] * v0[s];
        }
      }

      #copy output
      v[l] = v1[0];
```

qubits, n	run time in seconds
32	111
34	473
36	1954
38	8213

Table 16: Circuit simulation run times using qsim on a single Google cloud node (n1-ultramem-160).

```
      v[l + 2^q1] = v1[1];
      v[l + 2^q2] = v1[2];
      v[l + 2^q1 + 2^q2] = v1[3];
    }
  }
}
```

Here `U` is a 4x4 gate matrix and `v` is the full state vector. To make the simulator faster, we use gate fusion [67], single precision arithmetic, AVX/FMA instructions for vectorization, and OpenMP for multi-threading. We are able to simulate 38-qubit circuits on a single Google cloud node that has 3844 GB memory and four CPUs with 20 cores each (n1-ultramem-160). The run times for different circuit sizes at depth 14 are listed in Table **??**.

The second simulator, qsimh, is a hybrid Schrödinger-Feynman algorithm (SFA) simulator [38]. We cut the lattice into two parts and use the Schmidt decomposition for the 2-qubit gates on the cut. If the Schmidt rank of each gate is r and the number of gates on the cut is g then there are r^g paths, corresponding to all the possible choices of Schmidt terms for each 2-qubit gate across the cut. To obtain fidelity equal to unity, we need to simulate all the r^g paths and sum the results. The total run time is proportional to $(2^{n_1} + 2^{n_2})r^g$, where n_1 and n_2 are the qubit numbers in the first and second parts. Each part is simulated by qsim using the Schrödinger algorithm. Path simulations are independent of each other and can be trivially parallelized to run on supercomputers or in data centers. Note that one can run simulations with fidelity $F < 1$ just by summing over a fraction F of all the paths (see Ref. [38] and Sec. 11.10.4). In order to speed up the computation, we save a copy of the state after the first p 2-qubit gates across the cut, so the remaining r^{g-p} paths can be computed without re-starting the simulation from the beginning. We call the specific choice of Schmidt terms for the first p gates in the cut a *prefix*.

11.10.2 Feynman simulator

qFlex was introduced in Ref. [50] and later adapted to GPU architectures in Ref. [68] to allow efficient computation on Summit, currently the world's Top-1 supercomputer. qFlex is open source and available at https://github.com/ngnrsaa/qflex. Given a random quantum circuit, qFlex computes output bitstring amplitudes by adding all the Feynman path contributions via tensor network (TN) contractions [69, 70], and so it follows what we call a Feynman approach (FA) to circuit sampling. TN simulators are known to outperform all other methods for circuits with low depth or a large number of qubits (*e.g.*, Ref. [68] successfully simulates 121 qubits at low depth using this technique), as well as for small sample sizes (N_s), since simulation cost scales linearly with N_s.

TN simulators compute one amplitude (or a few amplitudes; see below) per contraction of the entire network. In order to sample bitstrings for a given circuit, a set of random output bitstrings is chosen before the computation starts. Then, the amplitudes for these bitstrings are

						PFlop/s*		efficiency (%)		
qubits	**cycles**	$\mathcal{F}_{\mathbf{XEB}}$ (%)	N_s	**nodes**	**runtime**	**peak**	**sust.**	**peak**	**sust.**	**power**
53	12	0.5	1M	4550	1.29 hours	235.2	111.7	57.4	27.3	5
		1.4	0.5M		1.81 hours**					
		1.4	3M		10.8 hours**					
	14	2.22×10^{-6}	1M		0.72 hours	347.5	252.3	84.8	61.6	7
		0.5	1M		67.7 days**					
		1.0	0.5M		67.7 days**					
		1.0	3M		1.11 years**					

Table 17: **Runtimes, efficiency and energy consumption for the simulation of random circuit sampling of N_s bitstrings from Sycamore with fidelity $\mathcal{F}$ using qFlex on Summit**. Simulations used 4550 nodes out of 4608, which represents about 99% of Summit. Single batches of 64 amplitudes were computed on each MPI task using a socket with three GPUs (two sockets per node); given that one of the 9100 MPI tasks acts as master, 9099 batches of amplitudes were computed. For the circuit with 12 cycles, 144/256 paths for these batches were computed in 1.29 hours, which leads to the sampling of about 1M bitstrings with fidelity $\mathcal{F} \approx 0.5\%$ (see Ref. [50] for details on the sampling procedure); runtimes and energy consumption for other sample sizes and fidelities are extrapolated linearly in N_s and $\mathcal{F}$ from this run. At 14 cycles, 128/524288 paths were computed in 0.72 hours, which leads to the sampling of about 1M bitstrings with fidelity 2.22×10^{-6}. In this case, one would need to consider 288101 paths on all 9099 batches in order to sample about 1M (0.5M) bitstrings with fidelity $\mathcal{F} \approx 0.5\%$ (1.0%). By extrapolation, we estimate that such computations would take 1625 hours (68 days). For N_s =3M bitstrings and $\mathcal{F} \approx 1.0\%$, extrapolation gives us an estimated runtime of 1.1 years. Performance is higher for the simulation with 14 cycles, due to higher arithmetic intensity tensor contractions. Power consumption is also larger in this case. Job, MPI, and TAL-SH library initialization and shutdown times, as well as initial and final IO times are not considered in the runtime, but they are in the total energy consumption. *Single precision. **Extrapolated from the simulation with a fractional fidelity.

computed and either accepted or rejected using *frugal rejection sampling* [38]. This ensures that the selected subset of bitstrings is indistinguishable from bitstrings sampled from a quantum computer. The cost of the TN simulation is therefore linear in the number of output bitstrings. This makes TN methods more competitive for small sets of output bitstrings.

The optimization of qFlex considers a large number of factors to achieve the best time-to-solution on current supercomputers, an approach that often diverges from purely theoretical considerations on the complexity of TN contractions. More precisely, qFlex implements several features such as:

- **Avoidance of distributed tensor contractions:** by "cutting" the TN (slicing some indexes), the contraction of the TN is decomposed into many *paths* that can be contracted locally and independently, therefore avoiding internode communication, which is the main cause for the slowdown of distributed tensor contractions.
- **Contraction orderings for high arithmetic intensity:** TN contraction orderings are chosen so that the expensive part of the computation consists of a small number of tensor contractions with high arithmetic intensity. This lowers the time-to-solution.
- **Highly efficient tensor contractions on GPU:** the back-end TAL-SH library [71] provides fully asynchronous execution of tensor operations on GPU and fast tensor transposition, allowing out-of-core tensor contractions for instances that exceed GPU memory. This achieves very high efficiency (see Table 17) on high arithmetic intensity contractions.

In addition, qFlex implements two techniques in order to lower the cost of the simulation:

- **Noisy simulation:** the cost of a simulation of fidelity $\mathcal{F} < 1$ ($\mathcal{F} \approx 5 \times 10^{-3}$ in practice) is lowered by a factor $1/\mathcal{F}$, *i.e.*, is linear in $\mathcal{F}$ [38, 50].
- **Fast sampling technique:** the overhead in applying the frugal rejection sampling mentioned above is removed by this technique, giving an order of magnitude speedup [50]. This involves the computation of the amplitudes of a few correlated bitstrings (*batch*) per circuit TN contraction.

As shown in Table 17, qFlex is successful in simulating Sycamore with 12 cycles on Summit, sampling 1M bitstrings with fidelity close to 0.5% in 1.29 hours. At 14 cycles, we perform a partial simulation and extrapolate the simulation time for the sampling of 1M bitstrings with fidelity close to 0.5% using Summit, giving an estimated 68 days to complete the task. Sampling 3M bitstrings at 14 cycles with fidelity close to 1.0% (average experimentally realized fidelity) would take an estimated 1.1 years to complete. Other estimates for different sample sizes and fidelities can be found in Table 17. At 16 cycles and beyond, however, the enormous amount of Feynman paths required so that the computation does not exceed the 512 GB of RAM of each Summit node makes the computation impractical.

The contraction of the TNs involved in the computation of amplitudes from Sycamore using qFlex is preceded by a simplification of the circuits, which allows us to decrease the bond (index) dimension of some of the indexes of the TN. This comes from the realization that $\mathrm{fSim}(\theta = \pi/2, \phi) = -i \cdot [\mathrm{R_z}(-\pi/2) \otimes \mathrm{R_z}(-\pi/2)] \cdot \mathrm{cphase}(\pi + \phi) \cdot \mathrm{SWAP}$ (see Sections 11.6 and 11.7.5); note that the SWAP gate can be applied either at the beginning or at the end of the sequence. We apply this transformation to all fSim gates at the beginning (end) of the circuit that affect qubits that are not affected by any other two-qubit gate before (after) in the circuit. The SWAP is then applied to the input (output) qubits and their respective one-qubit gates trivially, and the bond dimension remaining from this gate is 2, corresponding

to the cphase gate, as opposed to the bond dimension 4 of the original fSim gate. Note that in practice this identity is only approximate, since $\theta \approx \pi/2$; we find that transforming all gates described above causes a drop in fidelity to about 95%.

After the above simplification is applied, we proceed to cut (slice) some of the indexes of the TN (see Ref. [50] for details). The size of the slice of the index involved in each cut (the effective bond dimension of the index) is variable, and is chosen differently for different number of cycles on the circuit. Cutting indexes decomposes the contraction of the TN into several simpler contractions, whose results are summed after computing them independently on different nodes of the supercomputer.

Fig. S44 shows the bond dimensions of the TN corresponding to the circuits with 12 and 14 cycles simulated. We can see the decrease in bond dimension after the fSim simplification is applied, as well as the remaining bond dimension on the indexes cut for each case.

Finally, we contract the tensor network corresponding to the computation of a set of amplitudes (for fast sampling) for a particular batch of output bitstrings. The contraction ordering, which is chosen (together with the size and position of the cuts) in order to minimize the time-to-solution of the computation (which involves a careful consideration of the memory resources used and the efficiency achieved on the GPUs) is shown in Fig. S45. The computation can be summarized in the following pseudo-code, where α, β, and γ are variables that denote the different instances of the cuts:

```
# Qubits on C are used for fast sampling.
# size_of_batch amps. per circuit contraction.
size_of_batch = 2^num_qubits(C)

# Placeholder for all amplitudes in the batch.
batch_of_amplitudes = zeros(size_of_batch)

# Start contracting...
contract(A)  # Panel 2
contract(B)  # Panel 2
contract(C)  # Panel 2

# alpha labels instances of 1st cut
for each alpha {

    # beta labels instances of 2nd cut
    for each beta {
        contract(D)  # Panels 3 & 4
        contract(E)  # Panels 5 & 6

        # gamma labels instances of 3rd cut
        for each gamma {
            contract(F)  # Panels 7 & 8

            # Add contribution from this
            # path (alpha, beta, gamma).
            batch_of_amplitudes += F
        }
    }
}
```

Dotted qubits on Fig. S45 denote the region used for fast sampling, where output indexes are

left open. The circuit TN contraction leads to the computation of 64 amplitudes of correlated bitstrings (tensor F). Note that computing only a fraction $\mathcal{F}$ of the paths results in amplitudes with a fidelity roughly equal to $\mathcal{F}$. Computing a set of perfect fidelity batches of amplitudes, where the number of batches is smaller than the number of bitstrings to sample also provides a similar fidelity $\mathcal{F}$ in the sampling task, where $\mathcal{F}$ is equal to the ratio of the number of batches to the number of bitstrings in the sample. A hybrid approach (fraction of batches, each only with a fraction of paths), which we use in practice, also provides a similar sampling fidelity. See Refs. [38, 50] and Section 11.10.1 for more details.

A new feature of qFlex, implemented for this work, is the possibility to perform out-of-core tensor contractions (of tensors that exceed GPU memory) over more than one GPU on the same node. Although the arithmetic intensity requirements to achieve high efficiency are now higher (about an arithmetic intensity of 3000 for an efficiency close to 90% over three GPUs, as opposed to 1000 for a similar efficiency using a single GPU), the fact that a large part of a node is performing a single TN contraction lets us work with larger tensors, which implies reducing the number of cuts, as well as increasing the bond dimension of each cut; this, in turn, achieves better overall time-to-solution for sampling than simulations based on TNs with smaller tensors and with a lower memory footprint during their contraction (which could perhaps show a higher GPU efficiency due to the simultaneous use of each GPU for independent TNs). It is worth noting that the TN contraction ordering presented in Fig. S45 provides us with the best time-to-solution after considering several possibilities for the simulation of sampling from Sycamore using qFlex for both 12 and 14 cycles. This is generally not the case, since different numbers of cycles generate different TNs, which generally have different contraction schemes for best simulation time-to-solution.

Sampling of random circuits on Sycamore is difficult to simulate with TN simulators at 16 cycles and beyond. Indeed, FA simulators suffer from an exponential scaling of runtime with circuit depth. For qFlex, this is manifested in the large size of the tensors involved in the circuit TN contraction (this size grows exponentially with the number of cycles of the circuit), which require a large number of cuts in order not to exceed the RAM of a computation node, and which in turn generates an impractical number of Feynman paths. For other simulators, such as the one presented in Ref. [72], the number of projected variables is expected to be so large that the computation time (which increases exponentially with the number of projected variables) on a state-of-the-art supercomputer makes the computation impractical; see Section 11.10.5 for a detailed analysis. For TN-based simulators that attempt the circuit contraction distributed over several nodes (without cuts) [73], we expect the size of the largest tensor encountered during the TN contraction (which grows exponentially with depth) to exceed the RAM available on any current supercomputer. Not having enough memory for a simulation is the problem that led to developing FA simulators in the first place, for circuits of close to 50 qubits and beyond, for which the Schrödinger simulator (see Section 11.10.3) requires more memory to store the wave function than available. FA simulators give best performance as compared to other methods in situations with a large number of qubits and low depth. For circuits where both the number of qubits and the number of cycles are considered large enough to make the computation expensive, and contribute equally in doing so (formally, each linear dimension of the qubit grid is comparable to the time dimension), like the supremacy circuits considered in this work, we expect SFA of Section 11.10.1 to be the leading approach for sampling from a random circuit, given a large enough sample size ($\sim$ 1M in this work); note the linear dependence of the runtime of FA with sample size, which is absent for SFA.

11.10.3 Supercomputer Schrödinger simulator

We also performed supercomputer Schrödinger simulations in the Jülich Supercomputing Centre. For a comprehensive description of the universal quantum computer simulators JUQCS-E and JUQCS-A, see Refs. [74] and [75].

For a given quantum circuit U designed to generate a random state, JUQCS-E [75] executes U and computes (in double precision floating point) the probability distribution $p_U(j)$ for each output or bitstring $j \in \{0, \ldots, D-1\}$, where $D = 2^n$, n denoting the number of qubits. JUQCS-E can also compute (in double precision floating point) the corresponding distribution function $P_U(k) = \sum_{j=0}^{k} p_U(j)$ and sample bitstrings from it. We denote by $\mathcal{U}$ the set of m states generated by executing the circuit U. A new feature of JUQCS-E, not documented in Ref. [75], allows the user to specify a set $\mathcal{Q}$ of M bitstrings for which JUQCS-E calculates $p_U(j)$ for all $j \in \mathcal{Q}$ and saves them in a file.

Similarly, for the same circuit U, JUQCS-A [75] computes (with adaptive two-byte encoding) the probability distribution $p_A(j)$ for each bitstring $j \in \{0, \ldots, D-1\}$. Although numerical experiments with Shor's algorithm for up to 48 qubits indicate that the results produced by JUQCS-A are sufficiently accurate, there is, in general, no guarantee that $p_A(j) \approx p_U(j)$. In this sense, JUQCS-A can be viewed as an approximate simulator of a quantum computing device.

In principle, sampling states with probabilities $p_A(j)$ requires the knowledge of the distribution function $P_A(k) = \sum_{j=0}^{k} p_A(j)$. If D is large, and $p_A(j) \approx O(1/D)$, as in the case of random states, computing $P_A(k)$ requires the sum over j to be performed with sufficiently high precision. For instance, if $D = 2^{39}$, $p_A(j) \approx O(10^{-12})$ and even with double precision arithmetic (≈ 16 digits), adding $D = 2^{39}$ small numbers requires some care. Note that in practice, each MPI process only calculates a partial sum, which helps to reduce the loss of significant digits. JUQCS-A can compute $P_A(k)$ in double precision and sample bitstrings from it. We denote by $\mathcal{A}$ the set of M bitstrings generated by JUQCS-A after executing the circuit U. Activating this feature requires additional memory, effectively reducing the maximum number of qubits that can be simulated by three. This reduction of the maximum number of qubits might be avoided as follows. In the case at hand, we know that all $p_A(j) \approx O(1/D)$. Then, since $p_A(j)$ is known, one might as well sample the states from a uniform distribution, list the weight $w_A(j) = Np_A(j)$ for each generated state j and use these weights to compute averages. We do not pursue this possibility here because for the present purpose, it is essential to be able to compute $p_U(j)$ and therefore, the maximum number of qubits that can be studied is limited by the amount of memory that JUQCS-E, not JUQCS-A, needs to perform the simulation.

For an XEB comparison, the quantities of interest are

$$\alpha_{U,U} \equiv \log D + \gamma + \sum_{j=0}^{D-1} p_U(j) \log p_U(j), \tag{11.84}$$

$$\alpha_{A,U} \equiv \log D + \gamma + \sum_{j=0}^{D-1} p_A(j) \log p_U(j), \tag{11.85}$$

$$\alpha_{A,A} \equiv \log D + \gamma + \sum_{j=0}^{D-1} p_A(j) \log p_A(j), \tag{11.86}$$

$$\alpha_{\mathcal{X},U} \equiv \log D + \gamma + \frac{1}{M} \sum_{j \in \mathcal{X}} \log p_U(j), \tag{11.87}$$

where $\mathcal{X}$ is one of the four sets $\mathcal{U}$, $\mathcal{A}$, $\mathcal{M}$ (a collection of bitstrings generated by the experiment), or $\mathcal{C}$ (obtained by generating bistrings distributed uniformly). If M is sufficiently large ($M = 500000$ in the case at hand), we may expect that $\alpha_{\mathcal{U},U} \approx \alpha_{U,U}$ and $\alpha_{\mathcal{A},U} \approx \alpha_{A,U}$.

In addition to the cross entropies Eqs. (11.84)–(11.87), we also compute the linear cross entropies

$$\widehat{\alpha}_{U,U} \equiv \sum_{j=0}^{D-1} p_U(j)(Dp_U(j)-1), \tag{11.88}$$

$$\widehat{\alpha}_{A,U} \equiv \sum_{j=0}^{D-1} p_A(j)(Dp_U(j)-1), \tag{11.89}$$

$$\widehat{\alpha}_{A,A} \equiv \sum_{j=0}^{D-1} p_A(j)(Dp_A(j)-1), \tag{11.90}$$

$$\widehat{\alpha}_{\mathcal{X},U} \equiv \frac{1}{M}\sum_{j\in\mathcal{X}}(Dp_U(j)-1). \tag{11.91}$$

Table 18 presents simulation results for the α's defined by Eqs. (11.84)–(11.87) and for the $\widehat{\alpha}$'s defined by Eqs. (11.88)–(11.91), obtained by running JUQCS-E and JUQCS-A on the supercomputers at the Jülich Supercomputer Centre. For testing quantum supremacy using these machines, the maximum number of qubits that a universal quantum computer simulator can handle is 43 (45 on the Sunway TaihuLight at Wuxi China [75]).

The fact that in all cases, $\alpha_{U,U} \approx \alpha_{A,A} \approx 1$ supports the hypothesis that the circuit U, executed by either JUQCS-E or JUQCS-A, produces a Porter-Thomas distribution. The fact that in all cases, $\alpha_{\mathcal{U},U} \approx 1$ supports the theoretical result that replacing the sum over all states by the sum over $M = 500000$ states yields an accurate estimate of the former (see Section 11.4). Although $\alpha_{A,A} \approx 1$ in all cases, using the sample $\mathcal{A}$ generated by JUQCS-A to compute $\alpha_{\mathcal{A},U}$ shows an increasing deviation from one, the deviation becoming larger as the number of qubits increases. In combination with the observation that $\alpha_{A,A} \approx 1$, this suggests that JUQCS-A produces a random state, albeit not the same state as JUQCS-E. Taking into account that JUQCS-A stores the coefficients of each of the basis states as two single-byte numbers and not as two double precision floating point numbers (as JUQCS-E does), this is hardly a surprise.

From Table 18 it is clear that the simulation results for $\alpha_{\mathcal{X},U}$ and $\widehat{\alpha}_{\mathcal{X},U}$ where $\mathcal{X} = \mathcal{A}, \mathcal{M}, \mathcal{C}$ are consistent. The full XEB fidelity estimates $\alpha_{\mathcal{M},U}$ and $\widehat{\alpha}_{\mathcal{M},U}$, that is the values computed with the bitstrings produced by the experiment, are close to the fidelity estimates of the probabilistic model, patch XEB, and elided XEB, as seen in Fig. 4(a) of the main text.

For reference, in Tables 19 and 20 we present some technical information about the supercomputer systems used to perform the simulations reported in this appendix and give some indication of the computer resources used.

11.10.4 Simulation of random circuit sampling with a target fidelity

A classical simulator can leverage the fact that experimental sampling from random circuits occurs at low fidelity $\mathcal{F}_{\text{XEB}}$ by considering only a small fraction of the Feynman paths (see Secs. 11.10.1 and 11.10.2) involved in the simulation [38], which provides speedups of at least a factor of $1/\mathcal{F}_{\text{XEB}}$. This is done by Schmidt decomposing a few two-qubit gates in the circuit and counting only a fraction of their contributing terms (*paths*). A key assumption here is that the different paths result in orthogonal output states, as was studied in Ref. [38] and later in Ref. [50]. In what follows, we argue that, provided the generation of paths through decomposing gates, the Schmidt decomposition is indeed the optimal approach to achieving the largest speedup, *i.e.*, that the fidelity kept by considering only a fraction of paths is largest when keeping the paths with the largest Schmidt coefficient. This is different from proving the optimality of the Schmidt decomposition of a single gate, since here we refer to the fidelity

Table 18: Simulation results for various α's as defined by Eqs. (11.84)–(11.87), obtained by JUQCS-E and JUQCS-A. The results for the $\widehat{\alpha}$'s defined by Eqs. (11.88)–(11.91) are given in parenthesis. The set of bitstrings $\mathcal{M}$ has been obtained from experiments. In the first column, the number in parenthesis is the circuit identification number. Horizontal lines indicate that data is not available (and would require additional simulation runs to obtain it).

of the entire output state, and decomposed gates are embedded in a much larger circuit. In addition, we show that, for the two-qubit gates used in this work, the speedup is very close to linear in $\mathcal{F}_{\rm XEB}$ (and not much larger), since their Schmidt spectrum is close to flat. We close this section by relating the present discussion to Section 11.7.7, where the formation of simplifiable gate patterns in some two-qubit gate tilings of the circuit is introduced.

In summary, this section provides a method to simulate approximate sampling with a classical computational cost proportional to $\mathcal{F}_{\rm XEB}$. Sec. 11.11 argues, based on complexity theory, that this scaling is optimal. We note that Refs [78, 79, 80] propose an alternative method to approximately sample the output distribution at low fidelity. In essence, this method relies on the observation that, for some noise models, the high weight Fourier components of the noisy output distribution decay exponentially to 0. Then this method proposes to estimate low weight Fourier components with an additive error which is polynomial in the computational cost. Nevertheless, Ref. [81] shows that all Fourier components of the output distribution of random circuits are exponentially small, and therefore they can not be estimated in polynomial time with this method. The conclusion is then that the noisy output distribution can be approximated by sampling bitstrings uniformly at random, the distribution for which all Fourier components are 0. This is consistent with Ref. [27] and Secs. 11.4 and 11.8.5, but it will produce a sample with $\mathcal{F}_{\rm XEB} = 0$, while the output of the experimental samples at 53 qubits and $m = 20$ still has $\mathcal{F}_{\rm XEB} \geq 0.1\%$

Optimality of the Schmidt decomposition for gates embedded in a random circuit

Consider a two-qubit gate V_{ab} acting on qubits a and b. We would like to replace it by a tensor product operator $M_a \otimes N_b$. The final state of the ideal circuit is

$$|\psi\rangle := U_2 V_{ab} U_1 |0^n\rangle \tag{11.92}$$

where $U_1(U_2)$ is a unitary composed by all the gates applied before (after) V_{ab}. The final normalized state of the circuit with the replacement by $M_a \otimes N_b$ is

$$|\phi_{M,N}\rangle := U_2(M_a \otimes N_b)U_1|0^n\rangle / \|U_2(M_a \otimes N_b)U_1|0^n\rangle\|. \tag{11.93}$$

We would like to find M, N which maximize the fidelity of the two states, given by

$$\langle\psi|\phi_{M,N}\rangle = \langle 0^n|U_1^\dagger V_{ab}^\dagger|\beta\rangle / \sqrt{\langle\beta|\beta\rangle}, \tag{11.94}$$

where

$$|\beta\rangle \equiv (M_a \otimes N_b)U_1|0^n\rangle \tag{11.95}$$

As the overlap is invariant if we multiply $(M_a \otimes N_b)$ by a constant, we fix the normalization $\mathrm{tr}[(M_a \otimes N_b)^\dagger (M_a \otimes N_b)] = 1$.

We now make the assumption that the circuit is random (or sufficiently scrambling) and that the V_{ab} is a gate placed sufficiently in the middle of the computation that the reduced density matrix of qubits a and b of $U_1|0^n\rangle$ shows maximal mixing between the two. In more detail, let

$$\varepsilon := \left\| \mathrm{tr}_{\setminus(a,b)}(U_1|0^n\rangle\langle 0^n|U_1^\dagger) - \frac{I}{4} \right\|_2, \tag{11.96}$$

with $\|X\|_2 := \mathrm{tr}(X^\dagger X)^{1/2}$ the Hilbert-Schmidt norm and $\mathrm{tr}_{\setminus(a,b)}$ the partial trace of all qubits except a and b.

Using Eq. (11.96) and Eq. (11.94), we find

$$\begin{aligned} \langle\psi|\phi_{M,N}\rangle &= \mathrm{tr}(\mathrm{tr}_{\setminus(a,b)}(U_1|0^n\rangle\langle 0^n|U_1^\dagger)V_{ab}^\dagger(M_a \otimes N_b)) \\ &= \frac{1}{4}\mathrm{tr}[V_{ab}^\dagger(M_a \otimes N_b)] \pm \|(M_a \otimes N_b)\|_2 \|V_{ab}\|_2 \varepsilon. \end{aligned} \tag{11.97}$$

As $\|(M_a \otimes N_b)\|_2 = 1$ and $\|V_{ab}\|_2 = 2$, we find

$$\langle\psi|\phi_{M,N}\rangle = \frac{1}{4}\mathrm{tr}[V_{ab}^\dagger (M_a \otimes N_b)] \pm 2\varepsilon. \tag{11.98}$$

Refs. [82, 83] proved that for a random circuit U_1 of depth D in one dimension, $\varepsilon \leq (4/5)^D$. In two dimensions we expect ε to go to zero even faster with depth, so we can ignore the second term of Eq. (11.98) for sufficiently large depth.

We now want to find M_a, N_b which are optimal for

$$\max_{M_a, N_b : \|M_a\|_2 = \|N_b\|_2} \mathrm{tr}[V_{ab}^\dagger (M_a \otimes N_b)]. \tag{11.99}$$

At this point, we have reduced the problem to finding the optimal decomposition of the gate as a standalone operator.

Consider the operator Schmidt decomposition of V_{ab}:

$$V_{ab} = \sum_i \lambda_i R_{a,i} \otimes S_{b,i}, \tag{11.100}$$

where $R_{a,i}$ ($S_{b,i}$) are orthonormal set of operators in the Hilbert-Schmidt inner product, i.e. $\mathrm{tr}(R_{a,i}^\dagger R_{a,j}) = \mathrm{tr}(S_{a,i}^\dagger S_{b,j}) = \delta_{ij}$. The Schmidt singular values $\lambda_1 \geq \lambda_2 \geq \ldots$ are in decreasing order. Then it follows that the solution of Eq. (11.99) is λ_1, with optimal solution $M_a = R_{a,1}$ and $N_b = S_{b,1}$. Indeed we can write Eq. (11.99) as

$$\max_{|x\rangle, |y\rangle} \langle x|\overline{V}|y\rangle \tag{11.101}$$

where the maximum is over all unit vectors $|x\rangle, |y\rangle$ in $(\mathbb{C}^2)^{\otimes 2}$ and $\overline{V}$ is the matrix

$$\overline{V} := \sum_i \lambda_i (R_{a,i} \otimes I)|\Phi\rangle\langle\Phi|(S_{b,i}^\dagger \otimes I) \tag{11.102}$$

with $|\Phi\rangle = \sum_i |i\rangle \otimes |i\rangle$. This can be verified using the fact that any unit vector $|x\rangle$ in $(\mathbb{C}^d)^{\otimes 2}$ can be written as $|x\rangle = (L \otimes I)|\Phi\rangle$ for a matrix L acting on $(\mathbb{C}^d)$ s.t. $\|L\|_2 = 1$. The result follows by noting that λ_i are the singular values of $\overline{V}$.

The argument above easily generalizes to the problem of finding the optimal operator of Schmidt rank k for replacing the unitary gate. In that case the optimal choice is $\sum_{i=1}^k \lambda_i R_{a,i} \otimes S_{b,i}$.

Classical speedup for imbalanced gates

We now want to analyze the Schmidt spectrum of the two-qubit gates used in this work. The $\mathrm{fSim}(\theta, \phi)$ gate is introduced in Section 11.7.5. This gate, which is presented in matrix form in Eq. (11.53), has the following Schmidt singular values:

$$\lambda_1 = \sqrt{1 + 2 \cdot |\cos(\phi/2)\cos\theta| + \cos^2\theta} \tag{11.103}$$

$$\lambda_2 = \lambda_3 = \sin\theta \tag{11.104}$$

$$\lambda_4 = \sqrt{1 - 2 \cdot |\cos(\phi/2)\cos\theta| + \cos^2\theta}\,, \tag{11.105}$$

where normalization is chosen so that $\sum_i^4 \lambda_i^2 = 4$. In practice, we have $\theta \approx \pi/2$ and $\phi \approx \pi/6$, and so we obtain $\lambda_i \approx 1$, $\forall i \in \{1, 2, 3, 4\}$, which gives a flat spectrum.

In the case that $\theta = \pi/2 \pm \delta_\theta$, the spectrum becomes imbalanced, as expected. When considering the decomposition of a number g of $\mathrm{fSim}(\pi/2 \pm \delta_\theta, \phi \approx \pi/6)$ gates, the set of

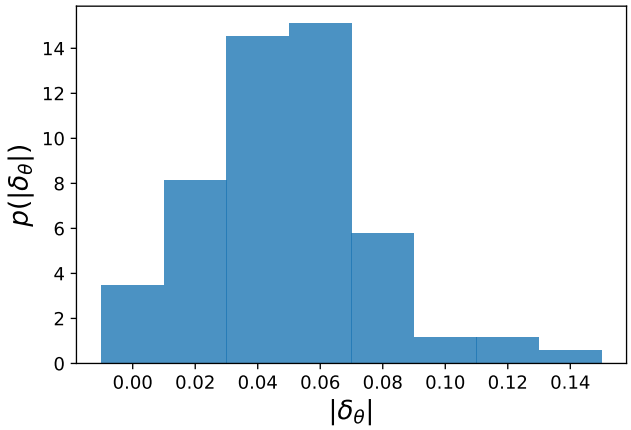

Figure S46: **Probability distribution of the deviations $|\delta_\theta|$ from $\theta \approx \pi/2$ for** fSim **gates.** The magnitude of δ_θ is directly related to the runtime speedup low fidelity classical sampling can take from exploiting the existence of paths with large Schmidt coefficients. In practice, $|\delta_\theta| \approx 0.05$ radians on average, which imposes a bound of less than an order of magnitude on this potential speedup for the circuits, gates, and simulation techniques considered in this work.

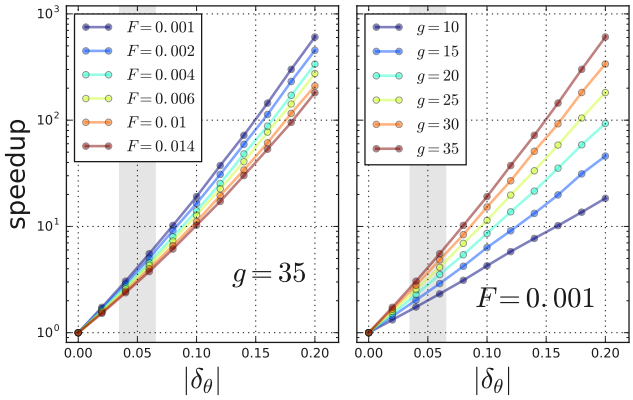

Figure S47: **Classical speedup given by the imbalance in the Schmidt coefficients of the gates decomposed.** The speedup is computed by comparison with the case where $\theta = \pi/2$ exactly. The classical simulation has a target fidelity $\mathcal{F}$, and g fSim gates are decomposed. For simplicity, we assume $\theta = \pi/2 + \delta_\theta$ is the same for all gates, as well as $\phi = \pi/6$. *Left:* speedup at different target fidelities for fixed $g = 35$. Note that the speedup decreases with $\mathcal{F}$; this is due to the fact that at very low fidelity, considering a few paths with very high weight might be enough to achieve the target fidelity, while for larger values of $\mathcal{F}$, paths with a smaller weight have to be considered, and so a larger number of them is needed per fractional fidelity increase. *Right:* speedup for fixed fidelity $\mathcal{F} = 0.001$ for different values of g. As expected, the speedup is greater as g increases, since the weight of the highest contributing paths increases exponentially with g. The largest speedup is achieved at large g and small $\mathcal{F}$. For $g = 35$ and $\mathcal{F} \gtrapprox 0.001$, we find speedups well below an order of magnitude, given that $|\delta_\theta| \approx 0.05$ radians in practice (shaded area); this case is representative of our simulation of Sycamore with $m = 20$ (see Section 11.10.1) targeting the fidelity measured experimentally.

weights of all paths is equal to the outer product of all sets of Schmidt coefficients (one per gate). Achieving a fidelity $\mathcal{F}_{\text{XEB}} > 0$ implies (in the optimal case) including the largest contributing paths, and so the advantage one can get from this is upper bounded by the magnitude of the largest weight, which is equal to $\prod_{\alpha=1}^{g} \lambda_{\alpha,max}^2$, where α labels the gates decomposed and $\lambda_{\alpha,max}$ is the largest Schmidt coefficient for gate α. In practice, $|\delta_\theta|$ has values of around 0.05 radians (see Fig. S46). The geometric mean of λ_{max} is about 1.047, which gives an upper bound of 1.047^{2g} to the speedup discussed here. For the largest value of g considered in this work, *i.e.*, the decomposition of $g = 35$ gates using the SFA simulator (Section 11.10.1) on a circuit of $m = 20$ cycles, we obtain a value of $1.047^{2\times 35} = 25.4$. Note that the speedup obtained in practice (as compared to runtimes over circuits with perfectly flat gate Schmidt decompositions) for fidelities of the order of 0.1% and larger is expected to be far smaller than this value, given that one has to consider a large number of paths, from which only an exponentially small number will have a weight close to 25.4.

We can get a better estimate for the speedup achieved in practice, beyond the upper bound of about a factor of 25 that decomposing $g = 35$ gates with typical parameters would give. For simplicity, let us assume that all g gates have the same values of θ and ϕ. Then the weight of each path arising from this decomposition can be written as $W_i = W_{(a,b,c)} = \lambda_1^{2a}\lambda_2^{2b}\lambda_3^{2c}$, where $a + b + c = g$, and that the number of paths for each choice of (a, b, c) is equal to $\#(a, b, c) = \sum_{k=0}^{b} \text{multinomial}(a, b - k, k, c) = 2^b \times \text{multinomial}(a, b, c)$. After sorting all 4^g weights (and paths) by decreasing value, given a target fidelity, $\mathcal{F}$, one now has to consider the first S paths (*i.e.*, those with the largest weight), up to the point where the sum of their weights $\sum_{i=1}^{S} \frac{W_i}{4^g}$ matches the target fidelity. The normalization factor 4^g guarantees that if one were to consider all paths, the fidelity would be unity, as expected. Compared to the case where we consider a number $\mathcal{F} \times 4^g$ of paths, as for a flat Schmidt spectrum, this provides a speedup equal to $\frac{S}{\mathcal{F}\times 4^g}$. We show the speedup achieved this way in Fig. S47. For the case where we would achieve the largest speedup in the simulations considered in this work, namely the simulation of Sycamore at $m = 20$ cycles and a fidelity $\mathcal{F} \approx 0.2\%$ with $g = 35$ gates decomposed (see Section 11.10.6), we estimate that the speedup obtained this way would be well below an order of magnitude, since $|\delta_\theta|$ typically takes values of about 0.05 radians.

Verifiable and supremacy circuits

So far we have considered the decomposition of gates one by one, *i.e.*, where the total number of paths is equal to the product of the Schmidt rank of all gates decomposed. However, by fusing gates together in a larger unitary, one can provide some speedup to the classical simulation of the sampling task.

The rationale here comes from the realization that a unitary that involves a number of qubits q cannot have a rank larger than $4^{\min(q_l,q_r)}$ when Schmidt decomposed over two subsets of qubits of size q_l and q_r, with $q_l + q_r = q$. Therefore one might reduce exponentially the number of paths by fusing gates such that the resulting unitary reaches on either side (l or r) a number of qubits that is smaller than the product of the ranks of the fused gates to be decomposed. This is at the heart of the formation of *wedges* of Section 11.7.7. These wedges denote particular sequences of consecutive two-qubit gates that only act upon three qubits. Fusing these two-qubit gates together generates 4 paths, as opposed to a naive count of 4^2 paths if one decomposes each gate separately. Each wedge identified across a circuit cut provides a speedup by a factor of 4.

In this work, we define two classes of circuits: *verifiable* and *supremacy* circuits. Verifiable circuits present a large number of wedges across the partition used with the SFA simulator (Section 11.10.1) and are therefore classically simulatable in a reasonable amount of time. These circuits were used to perform full XEB over the entire device up to depth $m = 14$ (see Fig. 4a of the main article and Sections 11.7 and 11.8), which involves perfect fidelity computations. On the other hand, supremacy circuits are designed so that the presence of

wedges and similar sequences is mitigated, therefore avoiding the possibility of exploiting this classical speedup.

It is natural to apply the ideas presented here beyond *wedges*. It is also easy to look for similar structures in the circuits algorithmically. This way, we find that for the supremacy circuits there is a small number of such sequences. On the sequence of cycles DCD (see Fig. S25), three two-qubit gates are applied on qubits 16, 47, and 51 (see Fig. S27 for numbering). These three gates can be fused in one. Then, if the two gates between qubits 47 and 51 are decomposed (as is done with the SFA simulations of Section 11.10.1 used in Fig. 4 of the main article), this technique provides a speedup of a factor of 4. The sequence of layouts DCD appears twice for circuits of $m = 20$, which provides a total speedup of $4^2 = 16$ in the simulation of the supremacy circuits. This particular decomposition is currently not implemented, and the estimated timings of Section 11.10.1 and Fig. 4 of the main article do not take it into account.

Beyond this, one has to go to groups of several cycles of the circuit (more than two) in order to identify regions where the fusion of several gates provides any advantage of this kind. In our circuits, the resulting unitaries act upon a large number of qubits, which makes explicitly building the unitary impractical.

11.10.5 Treewidth upper bounds and variable elimination algorithms

We explained in Section 11.10.2 that the Feynman method to compute individual amplitudes of the output of a quantum circuit can be implemented as a tensor network when quantum gates are interpreted as tensors. All indexes of the tensor network have dimension two because indexes correspond to qubits. Similarly, Ref. [70] showed that a quantum circuit can be mapped directly to an undirected graphical model. In the undirected graphical model, vertices or variables correspond to tensor indexes, and cliques correspond to tensors. Individual amplitudes can be computed using a variable elimination algorithm on the undirected graphical model, which is similar to a tensor contraction on a tensor network. The variable elimination algorithm depends on the ordering in which variables are eliminated or contracted. If we define the *contraction width* of an ordering to be the rank of the largest tensor formed along the contraction, the *treewidth* of the undirected graph is equal to the minimum contraction width over all orderings. Therefore, the complexity of a tensor network contraction grows in the optimal case exponentially with the treewidth, and the treewdith can be used to study the complexity of Feynman methods for simulating quantum circuits [69]. Ref. [70] showed that for diagonal gates the undirected graphical model is simpler, potentially lowering its treewidth, and hence improving the complexity. This simplification is not achievable in the tensor network view without including hyperedges, *i.e.*, edges attached to more than two tensors. Ref. [70] also introduced the use of `QuickBB` to find a heuristic contraction ordering [84]. If allowed to run for long enough, `QuickBB` finds the optimal ordering, together with the treewidth of the graph. However, note that obtaining the treewidth of a graph is an NP-hard problem, and so in practice a suboptimal solution is considered for the simulations described here.

Once the width of a contraction is large enough, the largest tensor it generates is beyond the memory resources available. This constraint was overcome in Ref. [72] by *projecting* a subset of p variables or vertices in the undirected graphical model into each possible bistring of 0 and 1 values. This generates 2^p similar subgraphs, each of which can be contracted with lower complexity and independently from each other, making the computation embarrassingly parallelizable. Choosing the subset of variables that, after projection, optimally decreases the treewidth of the resulting subgraph is also NP-hard. However, Ref. [72] developed a heuristic

approach that works well in practice. The algorithm proceeds as follows:

1. Run `QuickBB` for S seconds on the initial graph. This gives a heuristic contraction ordering, as well as an upper bound for the treewidth.

2. For each variable, estimate the cost of contracting the subgraph after projection. The estimate is done with the ordering inherited from the previous step.

3. Choose to project the variable which results in the minimum contraction cost.

4. Repeat steps 2 and 3 until the cost is within reasonable resources.

5. Once all variables have been chosen and projected, run `QuickBB` for S seconds on the resulting subgraph to try to improve the contraction ordering inherited from step 1 and lower the contraction cost.

In the top panel of Fig. S48 we show the contraction width as a function of the number of variables that are projected for the supremacy circuits used in this paper. In order to decrease the contraction width to 28 or below (a tensor with 28 binary indexes consumes 2 GB of memory using single precision complex numbers), we need to project between 8 and 63 variables, depending on the depth of the circuits. In addition, we report the result of the projection procedure on the Bristlecone circuits considered in Refs. [50, 85] and available at https://github.com/sboixo/GRCS for depths (1+32+1) and (1+40+1), since these cases were benchmarked in Ref. [85]. We obtain a contraction width equal to 28 after 10 projections for Bristlecone at depth (1+32+1), and width 26 after 22 projections for Bristlecone at depth (1+40+1), consistent with the results in Ref. [85]. Even though Ref. [72] uses $S = 60$, we run `QuickBB` for 1800 seconds (30 minutes) every time, in order to decrease the contraction width of the Bristlecone simulations to values that match the memory requirements reported in Ref. [85]. Note that Ref. [85] neither reports the value of S used nor the contraction widths found; however, with $S = 1800$ we are able to match the scaling of time complexity reported, as is explained below.

To estimate the runtime of the computation of a single amplitude using this algorithm on the circuits presented in this work, we use the following scaling formula:

$$T_{\mathrm{VE}} = C_{\mathrm{VE}}^{-1} \cdot 2^{p} \cdot (\text{cost after } p \text{ projections})/n_{\mathrm{cores}}, \tag{11.106}$$

where VE refers to the variable elimination algorithm with projections described in this section, C_{VE} is a constant factor, p is the number of variables projected, and n_{cores} is the number of cores used in the computation. The cost of the full contraction of each subgraph is estimated as the sum of 2^{rank}, where the rank refers to the number of variables involved in each individual contraction along the full contraction of the subgraph. We obtain the value of C_{VE} from the runtimes reported in Ref. [72], which shows that a single amplitude of Bristlecone at depth (1+32+1) takes 0.43 seconds to compute on 127,512 CPU cores with 10 projected variables, and at depth (1+40+1) it takes 580.7 seconds with 22 projected variables using the same number of cores. We use the benchmark at depth (1+32+1) because it provides the largest value for C_{VE} (lowest time estimates), which is equal to 52.7 MHz; the benchmark at depth (1+40+1) gives $C_{\mathrm{VE}} = 51.6$ MHz. In order to sample 1M bitstrings from a random circuit with fidelity 0.5%, we need to compute 5000 amplitudes.

We present our estimates for Sycamore supremacy circuits in the bottom panel of Fig. S48. Note that depth (1+40+1) in Refs. [72, 85] is equivalent to m=20 cycles here because of the denser layout of two-qubit gates. Furthermore, computation times reported previously are for circuit variations less complex than for Sycamore, arising from changes in complexity such as

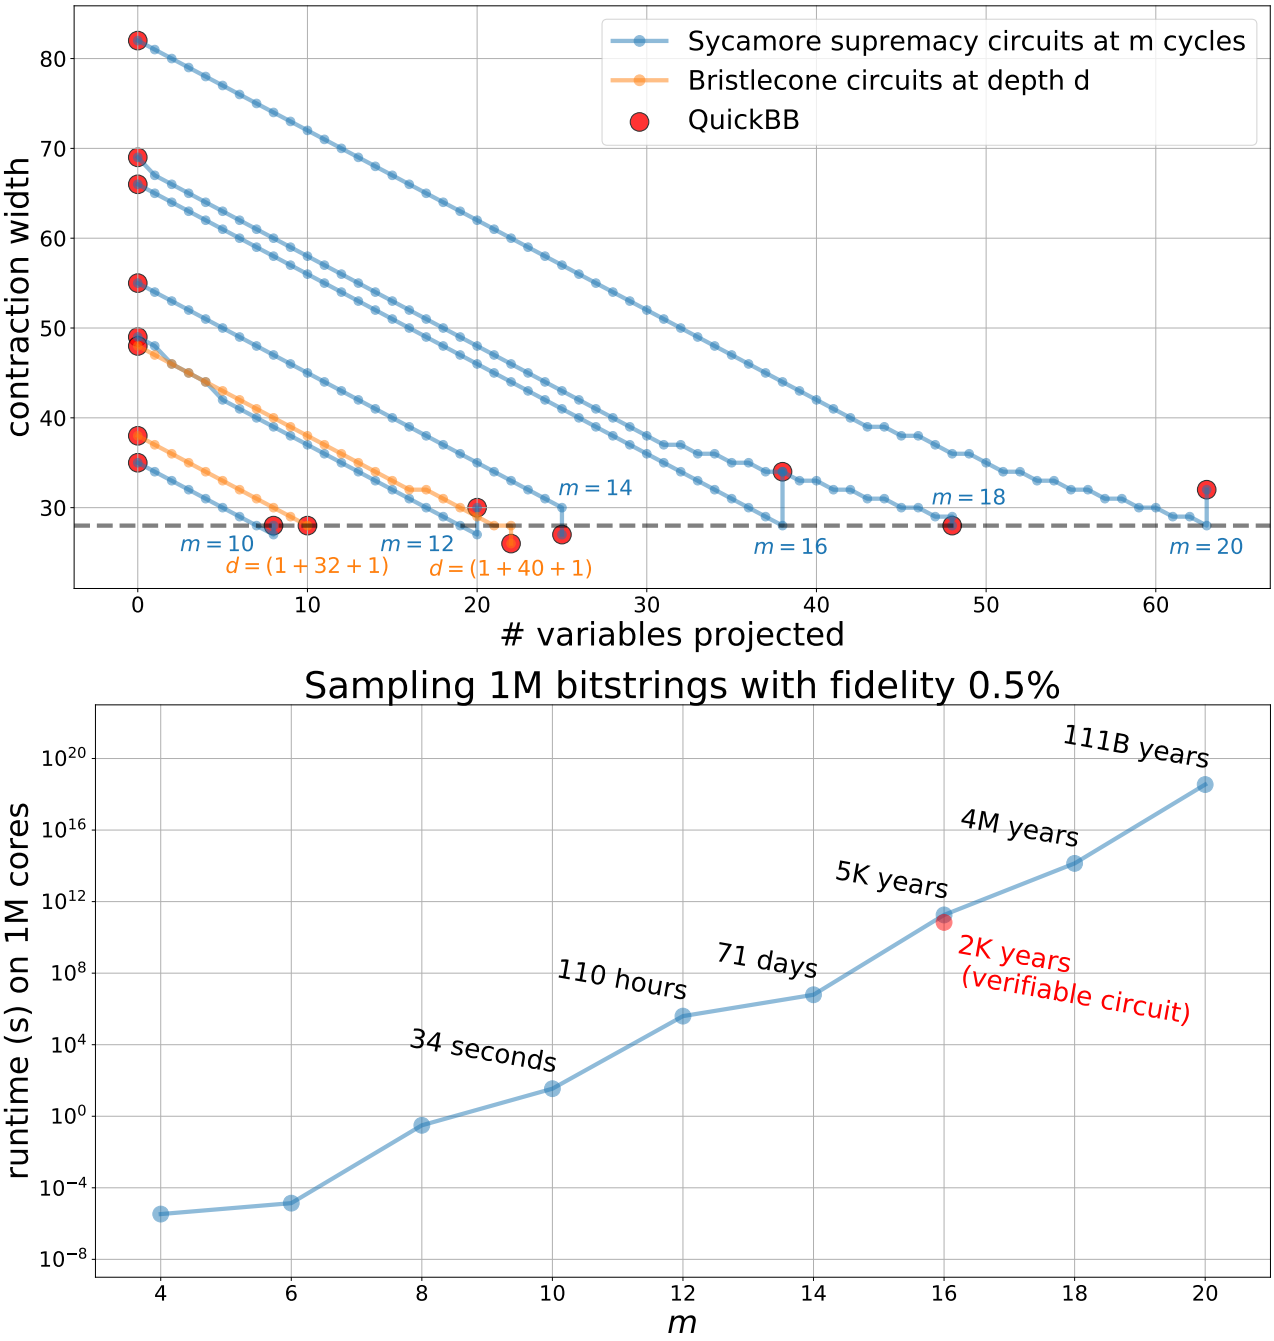

Figure S48: **Contraction widths and estimated runtimes for classical sampling using the variable elimination algorithm with projected variables of Ref. [72] for Sycamore supremacy circuits.** *Top:* contraction width as a function of the number of variables projected using the algorithm of Ref. [72]. We project enough variables in order to decrease the width to 28 or lower. Note that often the second `QuickBB` run does not decrease the treewidth (and might even increase it), in which case the resulting contraction ordering it is ignored. *Bottom:* estimated runtimes for the classical sampling of 1M bitstrings from the supremacy circuits with fidelity 0.5% using the contraction ordering found by `QuickBB` at the end of the projection procedure shown in the top panel. The red data point shows the estimated runtime for a verifiable circuit; note that the heuristic algorithm analyzed here provides some speedup in this case. Our time estimates assume the use of fast sampling, although it is so far unclear whether this technique can be adapted to the algorithm described here. Failure to do so would result in a slowdown of about an order of magnitude.

CZ vs. fSim gates and differing patterns; with this change of gates, depth (1+40+1) in Refs. [72, 85] is actually equivalent to m=10 cycles here. Finally, note that we present optimistic estimates, since we are assuming that the fast sampling technique discussed in Section 11.10.2 is applicable here. To the best of our knowledge, it is not known how to apply this technique for the heuristic variable elimination algorithm discussed here; in the absence of an implementation of this technique, in order to successfully apply rejection sampling we would instead need to compute a few independent amplitudes per sampled bitstring, which would increase the estimated times by about an order of magnitude (see Section 11.10.2 and Refs. [38, 86] for more details). According to our estimates, sampling from supremacy circuits at $m = 16$ and beyond is out of reach for this algorithm. Interestingly, we find some speedup for the simulation of verifiable circuits, as is shown in Fig. S48 for $m = 16$ (red data point).

Finally, note that the undirected graphical model derived from the supremacy circuits can take advantage of the structure of the Sycamore gates (fSim plus single-qubit R_z rotations). Due to the fact that $\text{fSim}(\theta \approx \pi/2, \phi) \approx -i \cdot [R_z(-\pi/2) \otimes R_z(-\pi/2)] \cdot \text{cphase}(\pi + \phi) \cdot \text{SWAP}$, the Sycamore gate corresponds to a subgraph of only two variables, which explicitly represents the diagonal cphase and the logical SWAP. This simplification, used in our estimates, results in an undirected graphical model that is simpler than that one generated by arbitrary two-qubit gates. See Fig. S49 for an example.

11.10.6 Computational cost estimation for the sampling task

We find that the most efficient simulator for our hardest circuits is the SFA simulator (see Sec. 11.10.1). In order to estimate the computational cost associated with simulating a 53 qubit circuit with 20 cycles, where no gates are elided on the cut, we use a Google cloud cluster composed of 1000 machines with 2 vCPUs and 7.5 GB of RAM each (n1-standard-2). We use n1-standard-2 because this is the smallest non-custom machine with sufficient RAM for simulating the two halves of the circuit. In 20 cycles, the circuit contains 35 gates across the cut. All cross gates have a Schmidt rank of 4 except for the last four gates which can be simplified to cphase with a Schmidt rank of 2. To obtain a perfect fidelity simulation we would need to simulate all $4^{31} \times 2^4$ paths. We configure qsimh according to Ref. [38] to have a prefix of 30 cross gates, thus requiring 4^{30} separate qsimh runs. The first 1000 paths of the required 4^{30} were used for timing purposes. In Figure S50 we plot the distribution of simulation times with qsimh consuming two hyperthreads. The average job time is 246 seconds resulting in a calculated 1.6×10^{14} core hours for a simulation of the circuit with 0.002 fidelity [87]. Extrapolated run times for other circuits with 53 qubits are shown in Table **??**. To calculate a total cost for the largest circuit we multiply the Google Cloud preemptible n1-standard-2 price in zone us-central-1 of $0.02 per hour, 246 seconds average run time, 0.002 target fidelity, and 4^{30} qsimh runs. This results in an estimated cost of 3.1 trillion USD. For perfect fidelity simulations (necessary for XEB), an extrapolation to a fidelity value of 100% gives a good estimate of the run time. We believe these estimates are a lower bound on costs and simulation time due to the fact that these calculations are likely to compete with each other if they are run on the same nodes.

As a final remark, note that a hypothetical implementation of the decomposition discussed at the end of Section 11.10.4 could decrease the computation time presented here by a factor of 16.

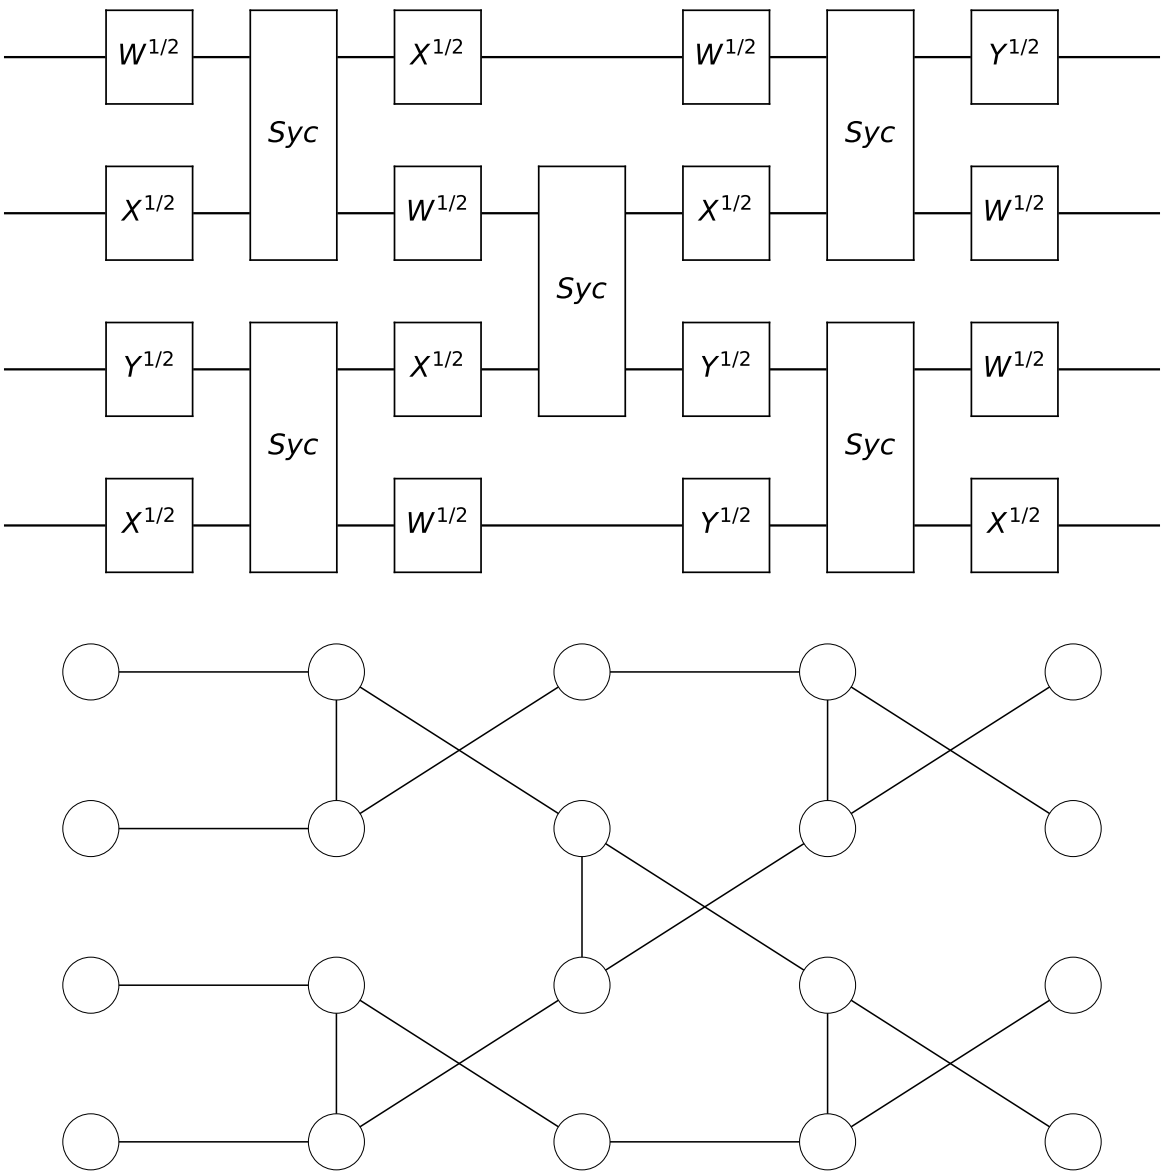

Figure S49: **Circuit with Sycamore gates (top) and its corresponding undirected graphical model (bottom).** Each non-diagonal single-qubit gate introduces a new vertex or variable. Note that, even though two-qubit gates are generally represented by a clique with four vertices or variables, Sycamore gates can be simplified as a cphase followed by a SWAP. The cphase is represented as an edge between two existing variables. The SWAP, however, provides more complexity to the graph as it swaps the corresponding variables.

qubits, n	cycles, m	total #paths	fidelity	run time
53	12	$4^{17}2^4$	1.4%	2 hours
53	14	$4^{21}2^4$	0.9%	2 weeks
53	16	$4^{25}2^3$	0.6%	4 years
53	18	$4^{28}2^3$	0.4%	175 years
53	20	$4^{31}2^4$	0.2%	10000 years

Table 21: Approximate qsimh run times using one million CPU cores extrapolated from the average simulation run time for 1000 simulation paths on one CPU core.

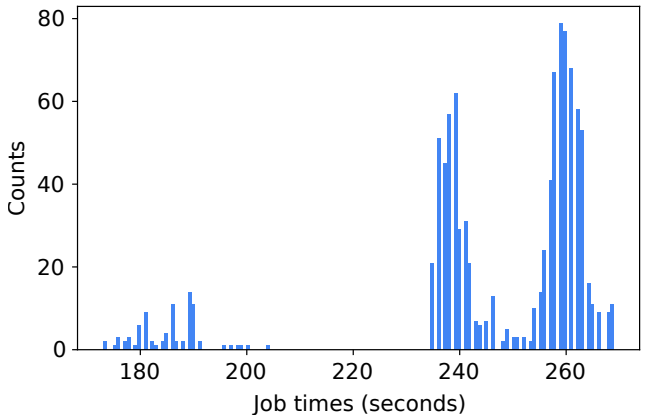

Figure S50: Qsimh execution time for a 53 qubit circuit with 20 cycles for the first 1000 prefix values. The average job time $\langle t_{\text{prefix}} \rangle$ is calculated to be 246 seconds.

11.10.7 Understanding the scaling with width and depth of the computational cost of verification

Runtime scaling formulas

Here we study the scaling of the runtime of the classical computation of exact amplitudes from the output wave function of a circuit with m cycles and n qubits on Sycamore, assuming a supercomputer with 1M cores. This computation is needed in order to perform XEB on the circuits run. We consider two algorithms: a distributed Schrödinger algorithm (SA) [74, 75] (see Section 11.10.3) and a hybrid Schrödinger-Feynman algorithm (SFA) [38] that splits the circuit in two patches and time evolves each of them for all Feynman paths connecting both patches (see Section 11.10.1). The latter is embarrassingly parallelizable. Note that these scaling formulas provide rough estimates presented with the intent of building intuition on the scaling of runtimes with the width and depth of the circuits, and that the finite size effects of the circuits can give discrepancies of an order of magnitude or more for the circuit sizes considered in this work.

For SA, the runtime is directly proportional to the size of the wave function on n qubits. This is equal to 2^n. In addition, the runtime is proportional to the number of gates applied, which scales linearly with n and m. For this reason, we propose the scaling:

$$T_{\text{SA}} = C_{\text{SA}}^{-1} \cdot mn \cdot 2^n, \tag{11.107}$$

where the constant C_{SA} is fit to runtimes observed experimentally when running on a supercomputer, and scaled to 1M cores.

For SFA the runtime is proportional to the number of paths connecting both patches, as well as to the time taken to simulate each pair of patches. When using the *supremacy* two-qubit gate layouts (ABCDCDAB...), each fSim gate bridging between the two patches (cross-gates) generates a factor of 4 in the number of paths. The number of cross-gates scales with $\sqrt{n}$ (we assume a two-dimensional grid) and with m. The time taken to simulate each patch is proportional to $2^{n/2}$, where $n/2$ estimates the number of qubits per patch, and the exponential dependence comes from a linear scaling of the runtime with the size of the wave function over that patch. The runtime therefore scales as:

$$T_{\text{SFA, supremacy}} = C_{\text{SFA}}^{-1} \cdot 2 \cdot 2^{\frac{n}{2}} \cdot 4^{B \cdot m\sqrt{n}}, \tag{11.108}$$

where the extra factor of two accounts for the fact that, for every path, two patches have to be simulated. The constant C_{SFA}, with units of frequency, is the effective frequency with which 1M cores simulate paths and is fit from experimentally observed runtime. The constant B accounts for the average number of cross-gates observed per cycle, which depends on the two-dimensional grid considered and on the two-qubit gate layouts used. For Sycamore, with the supremacy layouts, we find 35 cross-gates for $n = 53$ and $m = 20$, which gives $B = 0.24 \approx 1/4$.

For SFA, using the *verifiable* two-qubit gate layouts (EFGHEFGH...), the main difference with the supremacy circuits case is the fact that most of the cross-gates can be fused in pairs, forming three-qubit gates we refer to as *wedges* (see Sec. 11.7.7 and 11.10.4). Each cross-wedge generates only 4 paths, as opposed to the 4^2 paths the two independent fSim gates would have generated. Since every 4 cycles provide 7 cross-gates, and from those 7 gates, 6 are converted into 3 wedges, we count only 4^4 paths, as opposed to a naive count of 4^7 for those 4 cycles. In turn, the exponent in the last factor of Eq. 11.108 is corrected by the fraction $\frac{4}{7}$. This results in:

$$T_{\text{SFA, verifiable}} = C_{\text{SFA}}^{-1} \cdot 2 \cdot 2^{\frac{n}{2}} \cdot 4^{\frac{4}{7} B \cdot m\sqrt{n}}. \tag{11.109}$$

Assumptions and corrections

There are several assumptions considered in Section 11.10.7 and other details that can either (1) contribute to a somewhat large discrepancy between the runtimes predicted by the scaling formulas and the actual runtimes potentially measured experimentally, or (2) be ignored with no significant impact on the accuracy of the predictions. Here we discuss the ones we consider most relevant.

Concerning SA, the algorithm is benchmarked in practice on up to 100K cores. Since this is a distributed algorithm, the scaling with number of cores is not ideal and therefore the constant C_{SA} can only be estimated roughly. We assume perfect scaling in our estimates for runtime on 1M cores, *i.e.*, the runtime on 1M cores is the one on 100K cores divided by 10; this is of course an optimistic estimate, and runtimes should be expected to be larger.

For memory requirement estimates, we assume a 2 byte encoding of complex numbers. Beyond about 49 qubits there is not enough RAM on any existing supercomputer to store the wave function. In those cases, runtimes are given for the unrealistic, hypothetical case that one *can* store the wave function.

SFA is embarrassingly parallelizable, and so it does not suffer from non-ideal scaling. However, there are other factors to take into account. First, we have written no explicit dependence of the time to simulate patches of the circuit with m; the number of cycles m only plays a role when counting the number of paths to be considered. SFA stores several copies of the state of a patch after its evolution at different depths, iterating over paths over several nested loops. For this reason, most of the time is spent iterating over the inner-most loop, which accounts for the last few gates of the circuit and is similar in cost for all depths. This implies that the amortized time per path is considered approximately equal for all depths and the direct m dependence was correctly ignored.

A factor contributing to the discrepancy between the predicted runtimes of the scaling formulas of Section 11.10.7 and those expected in practice is due to finite size effects. While these scaling formulas consider the average number of cross-gates encountered per cycle, different cycles have layouts that contribute a few more (or less) gates than others. Since the runtime dependency is exponential in the number of gates, this might cause discrepancies of around an order of magnitude. Furthermore, for verifiable circuits, wedges form over groups of two cycles; this coarse graining exacerbates finite size effects. For the sake of simplicity in the scaling

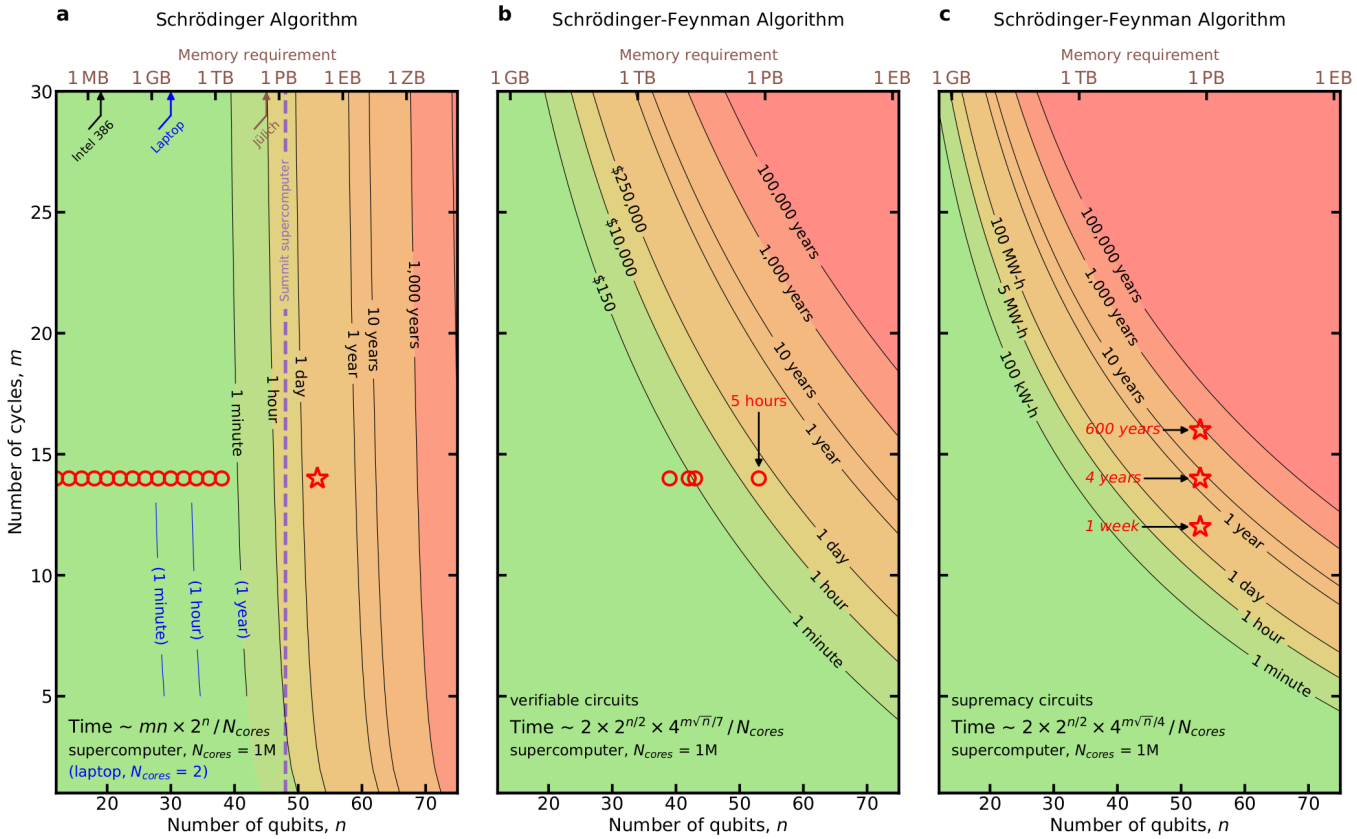

Figure S51: **Scaling of the computational cost of XEB using SA and SFA. a,** For a Schrödinger algorithm, the limitation is RAM size, shown as vertical dashed line for the Summit supercomputer. Circles indicate full circuits with $n = 12$ to 43 qubits that are benchmarked in Fig. 4a of the main paper [1]. 53 qubits would exceed the RAM of any current supercomputer, and is shown as a star. **b,** For the hybrid Schrödinger-Feynman algorithm, which is more memory efficient, the computation time scales exponentially in depth. XEB on full verifiable circuits was done at depth $m = 14$ (circle). **c,** XEB on full supremacy circuits is out of reach within reasonable time resources for $m = 12$, 14, 16 (stars), and beyond. XEB on patch and elided supremacy circuits was done at $m = 14$, 16, 18, and 20.

formulas, we do not perform any corrections to include these factors. However, in order to mitigate the propagation of finite size effect errors, we consider different constants $C_{\text{SFA, supremacy}}$ and $C_{\text{SFA, verifiable}}$, that we fit independently.

Finally, we refer to runtimes of our simulations on a hypothetical supercomputer with 1M cores. While this is a realistic size for a Top-5 supercomputer currently, a core-hour can vary significantly between different CPU types. Again, we only intend to provide rough estimates in order to build intuition on the dependence of runtimes with circuit width and depth.

Fitting constants

In the case of SA, we fit the constant C_{SA} with a runtime of 0.1 hours for the simulation with $n = 43$ and $m = 14$. This runtime is obtained by assuming ideal scaling when extrapolating a runtime of 1 hour on nearly 100K nodes (2^{15} MPI processes, 3 cores per process), as reported in Sec. 11.10.3. This gives a value of

$$C_{\text{SA}} = 0.015 \times 10^6 \text{ GHz}. \tag{11.110}$$

For SFA, we consider $B = 1/4$ for simplicity. In order to fit C_{SFA}, we consider a runtime of 5 hours and 4 years for the case with $n = 53$ and $m = 14$ for verifiable and supremacy circuits, respectively (see Fig. 4 of the main text). This gives:

$$\begin{aligned} C_{\text{SFA, verifiable}} &= 0.0062 \times 10^6 \text{ GHz} \\ C_{\text{SFA, supremacy}} &= 3.3 \times 10^6 \text{ GHz}. \end{aligned} \tag{11.111}$$

As discussed above, these fits provide times estimated for a supercomputer with 1M cores. Contour plots showing the dependency of runtime with n and m are presented in Fig. S51.

Memory usage scaling

Let us conclude with a discussion of the memory footprint of both algorithms. For these estimates, we assume a 2-byte encoding of complex numbers, as opposed to 8 bytes (single precision) or 16 bytes (double precision). This results in a lower bound for the memory usage of these two algorithms. These estimates need an extra factor of 4 (8) when using single (double) precision. SA stores the wave function of the state on all qubits. For this reason, it needs $2^n \times 2 = 2^{n+1}$ bytes. SFA simulates the wave function of both halves of the system ($n/2$ qubits) per path, one at a time. This requires $2^{\frac{n}{2}} \cdot 2$ bytes per path. In practice, the use of checkpoints implies the need to store more than one wave function per path; for simplicity, and in the same optimistic spirit of other assumptions, we ignore this fact. If 1M cores are used and each path is simulated using a single core, the total memory footprint is estimated to be $10^6 \times 2^{\frac{n}{2}+1}$ bytes. State-of-the-art supercomputers have less than 3 PB of memory.

11.10.8 Energy advantage for quantum computing

With the end of Dennard scaling for CMOS circuits, gains in computing energy efficiency have slowed significantly [88]. As a result, today's high performance computing centers are usually constrained by available energy supplies rather than hardware costs. For example, the Summit supercomputer at Oak Ridge National Laboratory has a total power capacity of 14 MW available to achieve a design specification of 200 Pflop/s double-precision performance. We took detailed energy measurements with qFlex running on Summit. The energy consumption grows exponentially with the circuit depth, as illustrated in Table 17.

For a superconducting quantum computer, the two primary sources of energy consumption are:

1. **A dilution refrigerator:** our refrigerator has a direct power consumption of ∼10 kW, dominated by the mechanical compressor driving the 3 K cooling stage. The power required to provide chilled water cooling for the compressor and pumps associated with the refrigerator can be an additional 10 kW or more.

2. **Supporting electronics:** these include microwave electronics, ADCs, DACs, clocks, classical computers, and oscilloscopes that are directly associated with a quantum processor in the refrigerator. The average power consumption of supporting electronics was nearly 3 kW for the experiments in this paper.

We estimate the total average power consumption of our apparatus under worst-case conditions for chilled water production to be 26 kW. This power does not change appreciably between idle and running states of the quantum processor, and it is also independent of the circuit depth. This means that the energy consumed during the 200 s required to acquire 1M samples in our experiment is $\sim 5 \times 10^6$ J ($\sim$ 1 kWh). As compared to the qFlex classical simulation on Summit, we require roughly 7 orders of magnitude less energy to perform the same computation (see Table 17). Furthermore, the data acquisition time is currently dominated by control hardware communications, leading to a quantum processor duty cycle as low as 2%. This means there is significant potential to increase our energy efficiency further.

11.11 Complexity-theoretic foundation of the experiment

The notion of quantum supremacy was originally introduced by John Preskill [89]. He conceived of it as "the day when well controlled quantum systems can perform tasks surpassing what can be done in the classical world". For the purpose of an experimental demonstration we would like to refine the definition.

Demonstrating quantum supremacy requires:

1. A well defined computational task, i.e. a mathematical specification of a computational problem with a well defined solution.

   Comment: This requirement, standard in computer science, excludes tasks such as "simulate a glass of water". However, it would include finding the ground state energy of an H_2O molecule to a given precision governed by a specific Hamiltonian. Note that a mathematical specification of a computational problem calls for highly accurate control resulting in measurable system fidelity.

2. Programmable computational device

   Comment: Many physics experiments estimate the values of observables to a precision which can not be obtained numerically. But those do not involve a freely programmable computational device and the computational task is often not well defined as required above. Ideally, we would even restrict ourselves to devices that are computationally universal. However, this would exclude proposals to demonstrate quantum supremacy with BosonSampling [90] or IQP circuits [91].

3. A scaling runtime difference between the quantum and classical computational processes that can be made large enough as a function of problem size so that it becomes impractical for a supercomputer to solve the task using any known classical algorithm.

Comment: What is impractical for classical computers today may become tractable in ten years. So the quantum supremacy frontier will be moving towards larger and larger problems. But if a task is chosen such that the scaling for the quantum processors is polynomial while for the classical computer it is exponential then this shift will be small. Establishing an exponential separation requires substantial efforts designing and benchmarking classical algorithms [74, 67, 27, 70, 50, 75, 68, 72, 69, 85], and support from complexity theory arguments [27, 30, 92]. Sampling the output of random quantum circuits is likely to exhibit this scaling separation as a function of the number of qubits for large enough depth. In this context, we note that quantum analog simulations that estimate an observable in the thermodynamic limit typically do not define a problem size parameter.

The requirements above are satisfied by proposals of quantum supremacy emerging from computer science, such as BosonSampling [90], IQP circuits [91], and random circuit sampling [27, 6, 30, 92, 93]. They are also implicit in the "Extended Church-Turing Thesis": any "reasonable" model of computation can be efficiently simulated, as a function of problem size, by a Turing machine.

We note that formal complexity proofs are asymptotic, and therefore assume an arbitrarily large number of qubits. This is only possible with a fault tolerant quantum computer and therefore near term practical demonstrations of quantum supremacy must rely on a careful comparison with highly optimized classical algorithms on state-of-the-art supercomputers.

So far we have argued for quantum supremacy by comparing the running time of the quantum experiment with the time required for the same task using the best known classical algorithms, running on the most powerful supercomputers currently available. The fastest known algorithm for exact sampling (or for computing transition probabilities) runs in time exponential in the treewidth of the quantum circuit [69, 70]; for a depth D circuit on a rectangular lattice of sizes l_x and l_y, the treewidth is given by $\min(\min(l_x, l_y)D, l_x l_y)$. For approximate simulation in which one only requires a given global fidelity F, the classical cost is reduced linearly in F [38]. As classical algorithms and compute power can be improved in the future, the classical cost benchmark is a moving target.

A complementary approach to back up supremacy claims consists of giving complexity-theoretic arguments for the classical hardness of the problem solved (in our case sampling from the output distribution of a random circuit of a given number of qubits, depth and output fidelity). Previous work gave hardness results for sampling *exactly* from the output distribution of different classes of circuits [90, 94, 95, 27, 96]. Most relevant to us are Refs. [92, 97, 93], which proved that it is classically intractable (unless the polynomial hierarchy collapses to its third level, which is considered extremely unlikely [98]) to sample from the exact probability distribution of outcomes of measurements in random circuits. We note the distribution of circuits considered in [92, 97, 93] is different from ours.

An important clarification is that such results are asymptotic, i.e. they show that, unless the polynomial hierarchy collapses, there are no polynomial-time classical algorithms for sampling from output measurements of certain quantum circuits. But they cannot be used directly to give concrete lower bounds for quantum computations of a fixed number of qubits and depth. Refs. [99, 100, 101] tackled this question using tools from fine-grained complexity, giving several finite size bounds.

There are also results arguing for the hardness of *approximate* sampling (see e.g. [90, 91, 27, 95]), where the task is only to sample from a distribution which is close to the ideal one. As the quantum experiment will never be perfect, this is an important consideration. However those results are weaker than the ones for exact sampling, as the hardness assumptions required have been much less studied (and in fact were introduced with the exact purpose of arguing for quantum supremacy). Another drawback is that the results only apply to the situation where

the samples come from a distribution very close to the ideal one (i.e. with high fidelity with the ideal one). This is not the regime in which our experiment operates.

With these challenges in mind, we consider an alternative hardness argument in this section, which will allow us to lower bound the classical simulation cost of noisy quantum circuits by the cost of the ideal one. On one hand, our argument will be more restrictive than previous results in that we will assume a particular noise model for the quantum computer (one, however, which models well the experiment). On the other hand, it will be stronger in two ways: (1) it will apply even to the setting in which the output fidelity of the experimental state with the ideal one can be very small, but still the product of total fidelity with exact computational cost is large; and (2) it will be based on more mainstream complexity assumptions in contrast to the tailor-made conjectures required in e.g. [90, 91, 95] to handle the case of small adversarial noise.

11.11.1 Error model

Our error model is the following. We assume that the quantum computer samples from the following output distribution:

$$r_{U,F}(x) := F|\langle x|U|0\rangle|^2 + (1-F)/2^n, \tag{11.112}$$

with U the circuit implemented. In words, we assume global depolarizing noise. Ref. [27] argues that Eq. (11.112) is a good approximation for the output state of random circuits (see Sec. 11.4 and Section III of [27]); this form has also been verified experimentally on a small number of qubits. In the experiment, F is in the range $10^{-2} - 10^{-3}$.

We note that while we assume a global white noise model in this section, we do not assume it in the rest of the paper, neither for validating the cross entropy test nor in the comparison with state-of-the-art classical algorithms (and indeed the algorithm considered in Section 11.10 samples from an approximate distribution different from the one in Eq. (11.112)).

11.11.2 Definition of computational problem

Before stating our result, let us define precisely the computational problem we consider. We start with the ideal version of the problem with no noise:

Circuit Sampling: The input is a description of a n qubit quantum circuit U, described by a sequence of one- and two-qubit gates. The task of the problem is to sample from the probability distribution of outcomes $p_U(x) := |\langle x|U|0\rangle|^2$.

Circuit sampling is an example of a *sampling problem* [102]. A classical algorithm for circuit sampling can be thought of, without loss of generality, as a function A mapping $m \in \text{poly(n)}$ bits $r = (r_1, \ldots r_m)$ to n bits such that

$$\frac{1}{2^m}|\{(r_1, \ldots, r_m) \text{ s.t. } A(r_1, \ldots, r_m) = x\}| = \tilde{p}_U(x), \tag{11.113}$$

with $\tilde{p}(x)$ an approximation of $p_U(x)$ to $l \in \text{poly(n)}$ bits of precision. So when r is chosen uniformly at random, the output of A are samples from p (up to rounding errors which can be made super-exponentially small).

Assuming the polynomial hierarchy does not collapse, it is known that Circuit Sampling cannot be solved classically efficiently in n, meaning any algorithm A satisfying Eq. (11.113) must have superpolynomial circuit complexity, for several classes of circuits (such as short depth circuits [96], IQP [94] and Boson Sampling [90]). We might also be interested in the average case of circuit sampling (for a restricted class of circuits).

Random Circuit Sampling: The input is a set of quantum circuits $\mathcal{U}$ on n qubits. The task is to sample from $p_U(x) := |\langle x|U|0\rangle|^2$ for most circuits $U \in \mathcal{U}$.

Ref. [92] proved that an efficient (in terms of n) classical algorithm for this task for random circuits would also collapse the polynomial hierarchy. As every realistic quantum experiment will be somewhat noisy, it is relevant to consider a variant of this task allowing for small deviations from ideal. One possible formulation is the following:

ε-Approximate Random Circuit Sampling: The input is a set of quantum circuits $\mathcal{U}$ on n qubits. The task is to sample for most circuits $U \in \mathcal{U}$, from any distribution q_U s.t. $d_{\mathrm{VD}}(q_U, p_U) \leq \varepsilon$, where $d_{\mathrm{VD}}(p, q)$ is the variational-distance between the distributions p, q [103] and $p_U(x) := |\langle x|U|0\rangle|^2$.

Refs. [90, 91, 27] put forward new complexity-theoretic assumptions about the #P-hardness of certain problems and proved they imply that several restricted classes of circuits are hard to approximately sample for ε sufficiently close to zero. However, we cannot use these results here as the ε we achieve is far from zero. We will resort to the following different variant of approximate circuit sampling.

Unbiased-Noise F-Approximate Random Circuit Sampling: The input is a set of quantum circuits $\mathcal{U}$ on n qubits. The task is to sample from the distribution $r_{U,F}$ given by Eq. (11.112), for most circuits $U \in \mathcal{U}$.

We note that there are alternatives for defining the computational problem for which supremacy is achieved without having to use sampling problems. These have the advantage that it is possible to verify, for each problem instance, that the task was achieved (whereas while it is in principle possible to verify that one is sampling from the correct distribution by estimating the frequencies of outcomes, this is unfeasible in practice for high entropy distributions with $> 2^{50}$ outcomes as the one we consider here).

One such problem (considered on Refs. [30, 27]) is the following:

b-Heavy Output Generation: Given as input a number $b > 1$ and a random circuit U on n qubits (drawn at random from a set of circuits $\mathcal{U}$), generate output strings $x_1, \ldots, x_k$ s.t.

$$\frac{1}{k}\sum_{j=1}^{k} |\langle x_j|U|0\rangle|^2 \geq \frac{b}{2^n} \tag{11.114}$$

Ref. [30] argues for the hardness of this task for every $b > 1$, although here again one has to resort to rather bold complexity-theoretic conjectures. Cross entropy benchmarking allows us to estimate b for a reasonable value of k (though the classical time needed to compute $|\langle x_j|U|0\rangle|^2$ still grows very fast), see Sec. 11.4. In terms of known algorithms, the complexity of solving Heavy Output Generation is equivalent to the complexity of sampling k samples from a noisy distribution corresponding to the same b value.

The experiment we report in this paper can be interpreted as showing quantum supremacy in solving the b-Heavy Output Generation with $b = 1 + F$ and F the fidelity of the output quantum state.

11.11.3 Computational hardness of unbiased-noise sampling

To state our result, we use the complexity class Arthur-Merlin, which is a variant of the class NP and is denoted by AM[T]. It is defined as the class of problems for which there is an Arthur-Merlin one-round protocol of the following form: given an instance of a problem in $AM[T]$ (which Arthur would like to decide if it is a YES or NO instance), Arthur first sends random bits to Merlin. Merlin (which is computationally unbounded) then sends back a proof

to Arthur. Finally Arthur uses the proof and decides in time T if he accepts. In the YES case, Arthur accepts with probability larger than 2/3. In the NO case, he accepts with probability no larger than 1/3.

Теорема 1. *Assume there is a classical algorithm running in time T and using m bits of randomness that samples from the distribution $r_{U,F}(x)$ given by Eq. (11.112), for a given quantum circuit U on n qubits and $F \geq 0$. Then for every integer L, there is an $AM[LT+2Lm]$ protocol for deciding, given $\lambda > 0$, whether*

$$|\langle 0|U|0\rangle|^2 \geq \lambda\left(1+\frac{2}{L}\right)+\frac{2(1-F)}{FL2^n} \tag{11.115}$$

or

$$|\langle 0|U|0\rangle|^2 \leq \lambda\left(1-\frac{2}{L}\right)-\frac{2(1-F)}{FL2^n} \tag{11.116}$$

Before giving the proof, let us discuss the significance of the result. We are interested in the theorem mostly when $L = c/F$ with c a small constant (say 10). Noting that for a random circuit, with high probability, $|\langle 0|U|0\rangle|^2 \geq 2^{-n}/5$ [97], the theorem states that if we can sample classically in time T from the distribution given in Eq. (11.112), then we can calculate a good estimate for $|\langle 0|U|0\rangle|^2$ in time $10T/F$ (with the help from an all-powerful but untrustworthy Merlin). It is unlikely that Merlin can be of any help for this task for random circuits, as estimating $|\langle 0|U|0\rangle|^2$ for random circuits is a #P-hard problem [92], and it is believed #P is vastly more complex than AM (which is contained on the third level of the polynomial hierarchy [98]). Therefore we conclude that global white noise leads to no more than a linear decrease in fidelity in classical simulation time (which is in fact optimal as it is achieved by the method presented in Ref. [38]).

Ref. [104] proposed a similar, but more demanding, conjecture about the non-existence of certain AM protocols for estimating transition probabilities of random circuits. This conjecture was applied to show that the output bits of our supremacy experiment can be used to produce certifiable random bits.

We note Theorem 1 does not establish a lower bound on the classical computation cost of calculating a transition amplitude with additive error $\delta/2^n$, for small constant $\delta > 0$. What it does is to show that the sampling problem with unbiased noise is as hard as this task, up to a linear reduction in F in complexity.

Concerning the hardness of computing $|\langle 0|U|0\rangle|^2$ it is known that this problem is #P hard for random circuits to additive error $2^{-poly(n)}$ [92]. This implies that there is no subexponential-time algorithms for this task (unless #P collapses to P). For finite size bounds, which are more relevant to our experiment, the result of Ref. [99] is the most relevant. It shows that under the Strong Exponential Time Hypothesis (SETH) [105], there are quantum circuits on n qubits which require $2^{(1-o(1))n}$ time for estimating $|\langle 0|U|0\rangle|^2$ to additive error $2^{-(n+1)}$ [106]. Together with Theorem 1, we find there is a quantum circuit U on n qubits for which the distribution $r_{U,F}$ (given by Eq. (11.112)) cannot be sampled in time $F2^{(1-o(1)n)}$, unless SETH is false.

It is an open question to show a similar lower bound to the one proved in Ref. [99] for estimating the transition probability of random circuits. Even more relevant for this work, it would be interesting to study if one can show a lower bound of the form $2^{(1-o(1))\text{treewidth}}$ for a random quantum circuit, under a suitable complexity-theoretic assumption, as the depth of the construction in [99] is relatively high.

11.11.4 Proof of Theorem 1

The proof will follow along similar lines to previous work [90, 91, 95]. We will use approximate counting (which can be done in AM) to show that a sampling algorithm for $r_{U,F}$ running

in time T implies an AM protocol to compute $r_{U,F}(0)(1 \pm 1/L)$, with classical verification of order LT. Since the noise is unbiased, i.e. $r_{U,F}(0) = F\langle 0|U|0\rangle|^2 + (1-F)/2^n$, we can subtract it and find an AM protocol for estimating $|\langle 0|U|0\rangle|^2$ as stated in the theorem.

In more detail, suppose there is a classical algorithm for sampling from $r_{U,F}$ given by a function A mapping $m \in$ poly(n) bits $r = (r_1, \dots r_m)$ to n bits such that

$$\frac{1}{2^m}|\{(r_1, \dots, r_m) \text{ s.t. } A(r_1, \dots, r_m) = x\}| = r_{U,F}(x). \quad (11.117)$$

Let $a(r_1, \dots, r_m)$ be a function which is 1 if $A(r_1, \dots, r_m) = 0^n$ and zero otherwise.

We start with the following lemma, showing the existence of A implies an $AM[LT + 2Lm]$ protocol for estimating $r_{U,F}(0)$:

Lemma. Assume there is an algorithm A given by Eq. (11.117). Then for every θ and L there is an $AM[LT+2Lm]$ protocol which determines if (i) $r_{U,F}(0) \geq \theta(1+2/L)$ (YES instance) or (ii) $r_{U,F}(0) \leq \theta(1-2/L)$ (NO instance).

Proof: The protocol is the following:

1. For every $t \in [Lm]$, Arthur chooses a function at random $h_t \in H_{Lm,t}$ from a family $H_{Lm,t}$ of 2-universal linear hash functions from $\{0,1\}^{Lm}$ to $\{0,1\}^t$ [98]. Then he communicates his choice of $(h_1, \dots, h_{Lm})$ to Merlin.

2. Merlin sends an Lm-bitstring w to Arthur and an integer $s \in [Lm]$.

3. Arthur verifies that $h_s(w) = 0$ and

$$a(w_{1,1}, \dots w_{1,m}) \wedge \dots \wedge a(w_{L,1}, \dots w_{L,m}) = 0.$$

He rejects if any of the three equations is not satisfied. Then he checks if $\theta \leq 2^{-m} 20^{1/L} 2^{s/L} (1 + 2/L)^{-1}$, accepting if it is the case and rejecting otherwise.

The cost to compute $a(w_{1,1}, \dots w_{1,m})$ is T, and the cost to compute is $h_s(w)$ is less than $2Lm$, so the total verification time of the AM protocol is $LT + 2Lm$.

Let us analyze the completeness and soundness of the protocol.

Completeness: Suppose we have a YES instance, $r_{U,F}(0) \geq \theta(1+2/L)$. Let us show that Merlin can send w and s which makes Arthur accept with high probability.

Let M be the number of solutions of $a(r_1, \dots, r_m) = 0$ (i.e. $M = 2^m r_{U,F}(0)$). Then $a(r_{1,1}, \dots r_{1,m}) \wedge \dots \wedge a(r_{L,1}, \dots r_{L,m})$ has M^L solutions, M for each copy of the function a. As part of the proof Merlin sends s satisfying $20 \geq M^L/2^s \geq 10$ (such a value always exists as s can be an arbitrary integer less than or equal to Lm).

Let us apply Lemma 11.11.4 (stated below) with $q = Lm$, $t = s$, $\delta = 1/2$, and S the set of solutions, so $|S| = M^L$. Then indeed $|S|/2^s > 10 > 1/\delta^3$. Therefore, with high probability, the number of solutions of

$$a(x_{1,1}, \dots x_{1,m}) \wedge \dots \wedge a(x_{L,1}, \dots x_{L,m}) \wedge h_s(x) \quad (11.118)$$

is in the interval $[(1/2)M^L/2^s, 2M^L/2^s]$. Since $(1/2)M^L/2^s \geq 1$, there is a string w s.t. $a(w_{1,1}, \dots w_{1,m}) \wedge \dots \wedge a(w_{L,1}, \dots w_{L,m}) \wedge h_s(w) = 0$, which Merlin also sends to Arthur as part of the proof.

Since $M = 2^m r_{U,F}(0) \geq 2^m \theta(1 + 2/L)$ and $M^L/2^s \leq 20$,

$$20 \geq \frac{M^L}{2^s} \geq \frac{2^{Lm}}{2^s} \theta^L \left(1 + \frac{2}{L}\right)^L, \quad (11.119)$$

so indeed $\theta \leq 2^{-m}20^{1/L}2^{s/L}(1+2/L)^{-1}$ and Arthur will accept with high probability.

Soundness: Suppose we have a NO instance, $r_{U,F}(0) \leq \theta(1-2/L)$. Let us show that no matter which witnesses w, s Merlin sends, Arthur will only accept with a small probability. Merlin must send s such that

$$\theta^L \leq (20)2^{-Lm}2^s(1+2/L)^{-L}, \tag{11.120}$$

otherwise Arthur rejects. By Lemma 11.11.4 (stated below), the number of solutions of

$$a(x_{1,1},\ldots x_{1,m}) \wedge \ldots \wedge a(x_{L,1},\ldots x_{L,m}) \wedge h_s(x) \tag{11.121}$$

will be in the interval $[(1/2)M^L/2^s, 2M^L/2^s]$, with $M = 2^m r_{U,F}(0) \leq 2^m\theta(1-2/L)$. Since

$$\begin{aligned} & 2M^L/2^s \leq 2(2^{-s})2^{Lm}\theta^L(1-2/L)^L \\ \leq\ & 40(1-2/L)^L(1+2/L)^{-L} \leq 40e^{-4} < 1, \end{aligned} \tag{11.122}$$

there is no solution to Eq. (11.121) and thus there is no w which will make Arthur accept. This finishes the proof of Lemma 11.11.4.

Reduction to AM protocol for $|\langle 0|U|0\rangle|^2$: Finally let us show how to use Lemma 11.11.4 to build the AM protocol stated in Theorem 1. Since $r_{U,F}(0) = F|\langle 0|U|0\rangle|^2 + (1-F)/2^n$, on one hand:

$$|\langle 0|U|0\rangle|^2 \geq \lambda\left(1+\frac{2}{L}\right) + \frac{2(1-F)}{FL2^n} \tag{11.123}$$

implies that

$$r_{U,F}(0) \geq (F\lambda + (1-F)/2^n)\left(1+\frac{2}{L}\right). \tag{11.124}$$

On the other hand:

$$|\langle 0|U|0\rangle|^2 \leq \lambda\left(1-\frac{2}{L}\right) - \frac{2(1-F)}{FL2^n} \tag{11.125}$$

implies that

$$r_{U,F}(0) \leq (F\lambda + (1-F)/2^n)\left(1-\frac{2}{L}\right). \tag{11.126}$$

Setting $\theta = F\lambda + (1-F)/2^n$ we see that the AM protocol from before can also be used to decide if Eq. (11.123) or Eq. (11.125) hold true. This ends the proof of the theorem.

Lemma. [98] For $t \leq q$, let $H_{q,t}$ be a family of pairwise-independent linear hash functions mapping $\{0,1\}^q$ to $\{0,1\}^t$, and let $\delta > 0$. Let $S \subseteq \{0,1\}^n$ be arbitrary with $|S| \geq \delta^{-3}2^t$. Then with probability larger than 9/10 over the choice of $h \in H_{n,t}$,

$$(1-\delta)\frac{|S|}{2^t} \leq |\{x \in S | h(x) = 0^t\}| \leq (1+\delta)\frac{|S|}{2^t} \tag{11.127}$$

Moreover $h(x)$ can be evaluated in time $2n$, for every $h \in H_{n,t}$.

12 Quantum Probability and Quantum Statistics by Holevo

12.0.1 Introduction

0.1. Конечномерные системы.

Изложение теории вероятностей принято начинать с конечной схемы. Следуя этой традиции, рассмотрим конечное вероятностное пространство Ω. Имеют место три тесно связанных между собой факта, которые по-разному выражают классичность вероятностной схемы:

1. множество событий $A \subset \Omega$ образует булеву алгебру;

2. множество распределений вероятностей $[p_1, \ldots, p_N]$ на Ω является симплексом, т. е. выпуклым множеством, в котором каждая точка однозначно представляется в виде смеси (выпуклой комбинации) крайних точек;

3. множество случайных величин $[\lambda_1, \ldots, \lambda_N]$ на Ω образует коммутативную алгебру (относительно поточечного умножения).

Квантовым аналогом этой схемы является модель N-уровневой системы. Аналог распределения вероятностей- состоя ни е такой системы описывается м а трице й плотностиэрмитовой $N \times N$-матрицей S, удовлетворяющей условиям положительной определенности и единичности следа

$$S \geqslant 0, \operatorname{Tr} S = 1;$$

аналог случайной величины - на блюд а ем а я описывается произвольной эрмитовой $N \times N$-матрицей X. Пусть

$$X = \sum_{j=1}^{n} x_j E_j$$

- спектральное разложение эрмитовой матрицы X, где $x_1 < x_2 < \ldots$ - собственные числа, $E_1, E_2, \ldots$ - проекторы на соответствующие собственные подпространства. Набор $\mathbf{E} = \{E_j\}$ образует ортогональное разложение еди н и ц ы:

$$E_j E_k = \delta_{jk} E_j; \quad \sum_{j=1}^{n} E_j = \mathrm{I}$$

где I - единичная матрица. Из свойств (0.1), (0.3) следует, что соотношение

$$\mu_S^X(x_j) = \operatorname{Tr} S E_j; \quad j = 1, \ldots, n$$

задает распределение вероятностей на спектре $\mathrm{Sp}X = \{x_1, x_2, \ldots\}$ наблюдаемой X; в квантовой механике постулируется, что это есть распределение вероятностей наблюдаемой X в состоянии S.

В частности, среднее значение X в состоянии S есть

$$\mathrm{E}_S(X) = \operatorname{Tr} SX$$

Если в этой модели ограничиться рассмотрением только диагональных матриц

$$S = \begin{bmatrix} p_1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & p_N \end{bmatrix}, \quad X = \begin{bmatrix} \lambda_1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & \lambda_N \end{bmatrix},$$

то мы возвращаемся к классической схеме с N элементарными событиями, где, в частности, (0.5) сводится к $\mathbf{E}_S(X) = \sum_{j=1}^{N} p_j \lambda_j$. То же самое мы получили бы, рассматривая только одновременно диагонализуемые, т. е. коммутирующие (перестановочные между собой) матрицы. Поскольку имеются наблюдаемые, описываемые некоммутирующими матрицами, модель N-уровневой системы не сводится к классической схеме.

Роль индикаторов событий в квантовом случае играют наблюдаемые, принимающие значения 0 или 1, т. е. эрмитовы идемпотентные матрицы: $E^2 = E$. Вводя унитарное координатное пространство $\mathscr{H} = \mathbf{C}^N$, в котором действуют $N \times N$-матрицы, такую матрицу E можно рассматривать как ортогональный проектор на подпространство $\mathscr{E}$ в $\mathscr{H}$. Таким образом, кв ан тов ы е собы тия можно отождествить с подпространствами унитарного пространства . Множество квантовых событий, называемое кв а нтовой логикой, частично упорядочено (по включению) и наделено операциями $\mathscr{E}_1 \bigvee \mathscr{E}_2$ (линейная оболочка подпространств $\mathscr{E}_1, \mathscr{E}_2$), $\mathscr{E}_1 \wedge \mathscr{E}_2$ (пересечение подпространств $\mathscr{E}_1, \mathscr{E}_2$), $\mathscr{E}'$ (ортогональное дополнение) с известными свойствами. Неклассичность модели N-уровневой системы можно выразить тремя различными утверждениями:

1. квантовая логика событий не является булевой алгеброй, поскольку в ней не выполнено тождество дистрибутивности

$$\mathscr{E}_1 \wedge (\mathscr{E}_2 \backslash \mathscr{E}_3) = (\mathscr{E}_1 \wedge \mathscr{E}_2) \vee (\mathscr{E}_1 \wedge \mathscr{E}_3)$$

Вследствие этого, нет «элементарных событий», на которые однозначно распадалось бы любое квантовое событие;

2. выпуклое множество состояний не является симплексом, т. е. представление матрицы плотности в виде смеси крайних точек неоднозначно;

3. комплексная оболочка множества наблюдаемых является некоммутативной (ассоциативной) алгеброй.

В бесконечномерном случае вместо матриц приходится расчатривать операторы, действующие в некотором гильбертовом пространстве $\mathscr{C}$. Математически корректное изложение основных понятий квантовой механики в гильбертовом пространстве было впервые дано Дж. фон Нейманом [26]. Он, в частности, подчеркнул существенное различие между эрмитовыми (симметричными) и самосопряженными операторами, которое, ко- нечно, не проводилось в предшествовавших физических работах и указал, что именно условие самосопряженности обеспечивает в случае $\dim \mathscr{H} = \infty$ аналог спектрального разложения (0.2). Другой круг вопросов в случае $\dim \mathscr{H} = \infty$ связан с уточнением понятия следа и соответствующего класса операторов с конечным следом. Математическая схема, называемая ст андарт но й формулировкой квантовой механики в гильбертовом пространстве, рассматривается в гл. 1.

0.2. Общие постулаты статистического описания. Каждая из математических структур - квантовая логика событий, выпуклое множество состояний и алгебра квантовых наблюдаемых -может быть охарактеризована определенной системой аксиом, но возникающие при этом характеризационные проблемы оказываются совсем не тривиальными и по существу составляют отдельные направления исследований, обзор которых выходит за рамки настоящей статьи (см., в частности, Сигал [32], Макки [23], Варадарайан [160], Людвиг [125], Гаддер [95]). Имея дело с конкретным объектом - квантовой теорией вероятностей в гильбертовом пространстве, не приходится прибегать к тем или иным системам аксиом; более того, именно знание структурных особенностей этого объекта и дает основание для мотивировки той или иной аксиомы. Одним из полезных уроков аксиоматического подхода является, однако, указание на плодотворный параллелизм в описании классических и квантовых систем. Формулируемые ниже положения являются модификацией первых четырех аксиом Макки, одинаково применимых как к классическим, так и квантовым системам.

(I) Заданы множество (5, элементы которого называются состояниями и множество D, элементы которого называются (вещественными) наблюдаемыми. Для любой пары S, XS задано распределение вероятностей $\mu_{SX}(\,\mathrm{d}x)$ на σ-алгебре $\mathscr{B}(\mathbf{R})$ борелевских подмножеств вещественной прямой $\mathbf{R}$, называемое распределением вероятностей наблюдаемой X в состоянии S.

Состояние S интерпретируется как более или менее детальное описание приготовления ст а ти сти че ск ого а н с а м бля независимых индивидуальных представителей рассматриваемой системы, а наблюдаемая X - как величина, измеряемая определенным прибором для каждого представителя в данном ансамбле. Аксиома (1), таким образом, предполагает воспрои з в о д и мость индивидуальных экспериментов и устой ч и в о с т ь ч а с т о т при их независимых повторениях. Следующая аксиома выражает возможность с м е ш и в ан и я ансамблей.

(II) Для любых $S_1, S_2 \in$ и любого числа $p, 0 < p < 1$, существует $S \in$, takoe, что

$$\mu_S^X = p\mu_{s_1}^X + (1-p)\mu_{s_2}^X.$$

для всех $X \in \mathcal{N}$; S называется смесью состояний S_1, S_2 в пропорции $p : (1-p)$.

Следующая аксиома говорит о возможности преобразования информации, полученной при измерении наблюдаемой. Пусть f борелевская функция из $\mathbf{R}$ в $\mathbf{R}$. Если $X_1, X_2 \in \supset$ таковы, что для ВСеХ $S \in S$

$$\mu_S^{X_2}(B) = \mu_S^{X_1}\left(f^{-1}(B)\right); \quad B \in \mathscr{B}(\mathbb{R})$$

где $f^{-1}(B) = \{x : f(x) \in B\}$, то наблюдаемая X_2 функционально подинена наблюдаемой X_1. В этом случае будем писать $X_2 = f \circ X_1$.

(III) Для любой $X_1 \in S'$ и любой борелевской функции f существует $X_2 \in \mathcal{N}$, такая что $X_2 = f \circ X_1$.

Пару непустых множеств (,), удовлетворяющих аксиомам (I)-(III), назовем статистической моделью. Статистическая модель называется отделимой, если

(IV) Из того, что $\mu_S^{X_1} = \mu_S^{X_2}$ для всех $X \in \mathrm{Im}$ следует $S_1 = S_2$; из того, что $\mu_S^{X_1} = \mu_S^{X_2}$ для всех $S \in \subseteq$ следует $X_1 = X_2$.

Для отделимой модели операция смешивания в и отношение функциональной подчиненности в $\supseteq$ определены однозначно. Тем самым множество состояний $\subseteq$ наделяется выпуклой структурой, а множество наблюдаемых $\subseteq$ получает частичную упорядоченность.

Наблюдаемые $X_1, \ldots, X_m$ называются совместимьми, если они функционально подчинены некоторой наблюдаемой X, т. е. $X_j = f_j \circ X; j = 1, \ldots, m$. Совместимые наблюдаемые могут быть измерены в одном эксперименте. Наблюдаемые, совместимые со

всеми наблюдаемыми $X \in D$, образуют *центр* статистической мо-

дели. Запас элементов в центре определяет степень классичности модели.

0.3. Классические и квантовые системы. Пусть $(\Omega, (\Omega))$ - измеримое пространство, $\mathrm{Re}(\Omega)$ - выпуклое множество всех вероятностных мер на Ω, а $\Omega(\Omega)$ совокупность всех вещественных случайных величин с естественным отношением функциональной подчиненности. Пусть

$$\mu_P^X(B) = P\left(X^{-1}(B)\right) : B \in \mathscr{B}(\mathbf{R})$$

- распределение вероятностей $X \in D(\Omega)$ относительно $P \notin \mathrm{Re}(\Omega)$. Пара $(\mathfrak{P}(\Omega), \mathscr{D}^-(\Omega))$ образует отделимую статистическую модель, которую можно назвать колмогоров с кой. В этой модели все наблюдаемые совместимы и центр совпадает с $\Omega(\Omega)$. Для

простоты продемонстрируем совместимость наблюдаемых с конечным множеством значений. Всякая такая наблюдаемая имеет представление, аналогичное (0.2)

$$\therefore (\omega) = \sum_{j=1}^{n} x_j E_j(\omega)$$

где $E_j(\omega)$ есть индикатор множества $B_j = \{\omega_1 : X(\omega) = x_j\}$. Множества B_j образуют разбиение пространства Ω, а $\{E_j(\omega)\}$ яв- ляются аналогом ортогонального разложения единицы (0.3). Если $X_1, \ldots, X_m$ - произвольный набор таких наблюдаемых, то достаточно взять разбиение $\{B_j\}$ более мелкое, чем все разбиения, соответствующие наблюдаемым X_i, чтобы было возможно представить все X_i как функции наблюдаемой X, соответствующей такому разбиению $\{B_j\}$.

Статистическая модель N-уровневой квантовой системы фактически была описана в п. 1. Если наблюдаемая X имеет спектральное разложение (0.2), то наблюдаемая $f \circ X$ определяется как

$$f \circ X = \sum_{j=1}^{n} f(x_j) E_j$$

Квантовые наблюдаемые $X_1, \ldots, X_m$ совместимы тогда и только тогда, когда соответствующие матрицы перестановочны, т. е.

$$X_i X_j = X_j X_i; i, j = 1, \ldots, m$$

Центр такой модели тривиален: он состоит из матриц, кратных единичной, т. е. только из постоянных наблюдаемых.

Для совместимых наблюдаемых естественно вводится совместное распределение вероятностей относительно любого состояния S. Если же $X_1, \ldots, X_m$ несовместимы, то совместное распределение относительно произвольного состояния не существует. Это обстоятельство отражает квантовый п р инци п до пол н и те льности. Физические измерения над микрообъектами осуществляются макроскопическими экспериментальными установками, каждая из которых предполагает (ложную и специфичную организацию пространственно-временной среды. Разные способы такой организации, отвечающие разным наблюдаемым, могут быть взаимно исключающими (хотя и относятся к одному и тому же микрообъекту), т. е. дополнительными. Наличие обширного запаса несовместимых наблюдаемых - первое из основных отличий квантовой статистики от классической.

Один из наиболее спорных вопросов квантовой теории проблема скрытых параметров, т. е. вопрос о принципиальной возможности описания квантовой статистики в терминах классического вероятностного пространства. Первая попытка доказательства невозможности введения скрытых параметров была предпринята Дж. фон Нейманом в [26] и долгое время его аргументы рассматривались как решающие. В 1966 г. Дж. Белл обратил внимание на их неполноту и указал на другое фундаментальное свойство квантовомеханического описания, которое можно обозначить как свойство ц елостностй [11]. Математически оно связано с принципом суперпозиции и с тем обстоятель-

1. Английский термин - поп-separability. ством, что составные квантовые системы описываются с помощью тензорного, а не декартова произведения, как в классической теории вероятностей. Свойства дополнительности и целостности лежат в основе негативных результатов в проблеме скрытых параметров, которые обсуждаются в конце гл. 1.

0.4. Рандомизация в классической и квантовой статистике. Вернемся к колмогоровой модели и рассмотрим случайную величину (0.6). В каждой точке $\omega \in \Omega$ она с вероятностью 1 принимает одно из значений x_j. В математической статистике, в частности в теории статистических решений полезно рассмотрение «рандомизованных» случайных величин, которые определяются указанием вероятностей $M_j(\omega), (0 \leqslant M_j(\omega) \leqslant 1)$ принятия значения x_j для любого элементарного события ω. Набор функций $\mathbf{M} = \{M_j(\omega))$ характеризуется условиями

$$M_j(\omega) \geqslant 0; \quad \sum_{j=1}^{n} M_j(\omega) = 1; \quad \omega \in \Omega$$

и описывает неточное измерение случайной величины X, т. е. измерение со случайными ошибками. Распределение вероятностей такого измерения относительно вероятностной меры P дается формулой

$$\mu_P^M(x_j) = \int_\Omega P(d\omega) M_j(\omega)$$

В частности, измерение является точным (безошибочным), если $M_j(\omega) = E_j(\omega)$. Таким образом возникает другая классическая статистическая модель, которую по имени создателя теории статистических решений можно назвать моделью В альда.

Естественно рассмотреть квантовый аналог модели Вальда, в которой наблюдаемая с конечным множеством значений описывается конечным разложение м единицы, т. е. семейством матриц (операторов) $\mathbf{M} = \{M_j\}$, удовлетворяющим условням

$$M_j \geqslant 0; \quad \sum_{j=1}^{n} M_j == \mathrm{I}$$

Вероятность j-го исхода в состоянии S определяется формулой, аналогичной (0.9)

$$\mu_S^M(x_j) = \operatorname{Tr} S M_j$$

Эти определения естественно переносятся и на наблюдаемые с произвольным множеством значений. Так возникает обобщен ная с т а ти с тическая модель квантовой механики (см. §2.1).

Общие разложения единицы в квантовой теории появляются на рубеже 70 -х годов. К этому независимо приводят исследова- ния по квантовой аксиоматике (Г. Людвиг), по проблеме воспроизводимости, связанной с повторными измерениями (Э. Б. Дэвис и Дж. Льюис); по квантовой теории статистических решений (А. С. Холево) и другие работы. Обобщенная статистическая модель квантовой механики является логическим следствием ее вероятностной структуры и дает основу для рассмотрения ряда вопросов, не находящих удовлетворительного решения в рамках стандартной формулировки.

0.5. Выпуклая геометрия разложений единицы и фундаментальные пределы точности. Хотя описанное выше расширение понятия наблюдаемой формально аналогично введению рандovизованных величин в классической статистике, неортогональные разложения единицы имеют в квантовой теории принципиально более важное значение, нежели просто средство описания неточных измерений. Дело в том, что и с математической, и с физической точек зрения наибольший интерес представляют крайние точки выпуклого множества разложений единицы (0.10), описывающие статистику предельно точных и максимально информативных измерений. В классическом случае крайние точки множества (0.8) совпадают с нерандомизованными процедурами $\{E_j(\omega)\}$, соответствующими обычным случайным величннам. Однако в

квантовом случае крайние точки множества (0.10) при $n > 2$ уже не исчерпываются ортогональными разложениями единицы. Следовательно, для описания предельно точных квантовых измерений требуются, в общем случае, неортогональные разложения единицы.

С другой стороны, как показал М. А. Наймарк (1940), произвольное разложение единицы расширяется до ортогонального в некотором объемлющем гильбертовом пространстве. Это позволяет истолковать неортогональное разложение единицы как обычную наблюдаемую в расширении исходной квантовой системы, содержащем независимую дополнительную систему. Таким образом, измерение над расширением может быть более точным и информативным, чем любое прямое квантовое измерение. Этот парадоксальный с точки зрения классической статистики факт связан с затронутым в п. 3 квантовым свойством целостности.

В 1940 -50 годы в работах Д. Габора и Л. Бриллюэна было высказано предположение, что квантово-механическая природа канала связи должна налагать фундаментальные ограничения на скорость передачи и точность воспроизведения информации. Этот вопрос приобрел актуальность в 60-е годы с появлением квантовых каналов связи - систем передачи информации, основанных на свойствах когерентного лазерного излучения. В 70-е годы была создана последовательная квантовая теория статистических решений, которая дает принципиальную основу для рассмотрения вопросов предельной точности и информативности измерений (см. К. Хелстром [37], А. С Холево [43]).

В этой теории решающие процедуры - измерения описываются разложениями единицы в гильбертовом пространстве системы и решаются задачи об отыскании экстремума некоторого функционала (меры точности, шенноновской информации) в классе квантовых решающих процедур, обычно подчиненных дополнительным ограничениям (несмещенности, ковариантности и т. п.) (см. гл. 2).

0.6. Проблема соответствия. Одна из трудностей в стандартной формулировке квантовой механики состоит в невозможности сопоставления некоторым величинам, таким как время, угол, фаза и т. п. самосопряженного оператора в гильбертовом пространстве системы. Причина кроется в теореме единственности Стоуна-фон Неймана, которая налагает жесткие ограничения на спектры канонически сопряженных наблюдаемых.

К этому же кругу вопросов можно отнести и трудности с локализуемостью (т. е. введением ковариантных наблюдаемых положения) для релятивистских квантовых частиц с нулевой массой. Рассмотрение в качестве наблюдаемых неортогональных разложений единицы, подчиненных условиям ковариантности, аналогичных коммутационным соотношениям Вейля в теореме Стоуна-фон Неймана, позволяет в значительной степени избежать этих трудностей (см. гл. 2). В спектральной теории неортогональные разложения единицы возникают как обобщенные спектральные меры несамосопряженных операторов. В соответствии с этим, например, оператор, отвечающий наблюдаемой времени, оказывается максимальным эрмитовым (но не самосопряженным). Можно сказать, что обобщенная статистическая модель квантовой механики на новом математическом уровне оправдывает «наивное» представление о вещественной наблюдаемой, как об эрмитовом, но не обязательно самосопря. женным, операторе.

0.7. Повторные и непрерывные измерения. В колмогоровской модели преобразования состояний системы могут быть описаны с помощью условных вероятностей. Пусть в результате измерения случайной величины (0.6) получено значение x_j. При этом классическое состояние, т. е. вероятностная мера $P(d_\omega)$ на Ω преобразуется по формуле

$$P(A) \to P\left(A|B_j\right) = \frac{\int\limits_A P(d\omega)E_j(\omega)}{\int\limits_\Omega P(d\omega)E_j(\omega)}; \quad A \in \mathscr{B}(\Omega)$$

Очевидно, что если результат измерения не принимается во внимание, то состояние P вообще не изменяется:

$$P(A) \to \sum_{j=1}^{n} P\left(A|B_j\right) P\left(B_j\right) = P(A)$$

В квантовой статистике ситуация качественно более сложна. Аналогом преобразования (0.12) является знаменитый п роекц и он н ый п о с т у л а т Дж. фон Неймана

$$S \to S_j = \frac{E_j S E_{ij}}{\operatorname{Tr} S E_j}$$

где S оператор плотности состояния перед измерением, а S_j после измерения наблюдаемой (0.2), в результате которого получено значение x_j. Основанием для этого постулата служит феноменологическая гипотеза воспроизводимости, подразумевающая предельную точность и минимальность возмущения, вносимого измерением наблюдаемой X. Если результат измерения не принимается во внимание, то состояние S преобразуется по формуле, аналогичной (0.13):

$$S \to \sum_{j=1}^{n} S_j \mu_S^X\left(x_j\right) = \sum_{j=1}^{n} E_j S E_j$$

Однако в общем случае $\sum\limits_j E_j S E_j \neq S$; это означает, что изменение состояния в ходе квантового измерения не сводится только к преобразованию информации и отражает также принципиально неустранимое и необратимое физическое воздействие измерительного прибора на наблюдаемую систему. С проекционным постулатом связан целый ряд проблем; не затрагивая вопросов философского характера, которые выходят за пределы вероятностной интерпретации, остановимся на конкретных проблемах, которые успешно решаются в рамках обобщенной статистической модели квантовой механики.

Принципиальную трудность представляет формулировка проекционного постулата для наблюдаемых с непрерывным спектром. Для описания изменения состояния при произвольном квантовом измерении Э. Б. Дэвис и Дж. Льюис (1970) ввели понятие инструмента - меры со значениями в множестве преобразований квантовых состояний. Этим понятием охватываются и неточные измерения, не удовлетворяющие условию воспроизводимости, что позволяет включить и случай непрерывного спектра. С каждым инструментом связано разложение единицы, причем инструментам, возникающим из проекционного постулата, отвечают ортогональные разложения единицы. Понятие инструмента открывает возможность описания статистики любой последовательности квантовых измерений.

Новое освещение получает вопрос о траекториях, восходящий к фейнмановской формулировке квантовой механики. Процесс непрерывного (во времени) измерения квантовой наблюдаемой можно представить как предел «серий» последовательных неточных измерений. Математическое описание такого предела обнаруживает замечательные аналогии с классической схемой суммирования случайных величин, .

функциональными предельными теоремами в теории вероятностей и представлением Леви-Хинчина для процессов с независимыми приращениями (см. гл. 4).

0.8. Необратимая динамика. Обратимая динамика изолированной квантовой системы описывается уравнением

$$S \to U_t S U_t^{-1}; \quad -\infty < t < \infty,$$

где $\{U_t\}$-группа унитарных операторов. Если система является отк ры то й, т. е. взаимодействует с окружением, то ее эволюция является, как правило, необратимой. Пример такого необратимого изменения состояния, обусловленного взаимодействием с измерительным прибором, дается соотношением (0.15). Наиболее общий вид динамического отображения, задающего конечную эволюцию открытой системы, включает как (0.16), так и (0.15):

$$S \to \sum_j V_j S V_j^*$$

где $\sum\limits_j V_j^* V_j = \mathrm{I}$. Среди всевозможных аффинных преобразований выпуклого множества состояний, отображения (0.17) выделяются специфически некоммутативным свойством полно й по ложительности, возникшим и играющим важную роль в современной теории операторных алгебр.

Непрерывная марковская эволюция открытой системы описывается дин а ми че ской полугр у ппо й, т. е. полугруппой динамических отображений, удовлетворяющей определенным условиям непрерывности (см. Э. Б. Дэвис [78]). Динамические полугруппы являются некоммутативным аналогом марковских полугрупп в теории вероятностей. В 1976 г. Г. Линдблад и независимо, в конечномерном случае, В. Горини, А. Коссаковский и Э. Сударшан получили полное описание инфинитезимального оператора непрерывной по норме динамической полугруппы. Этот результат, лежащий в основе многих фактов теории квантовых случайных процессов, рассматривается в гл. 3.

0.9. Квантовые случайные процессы. Одним из стимулов возникновения теории квантовых случайных процессов послужила проблема р а сши рен и я динамической полугруппы до обратимой динамики «большой системы», включающей открытую систему и окружение. Возможность такого расширения означает, в частности, согласованность понятия динамической полугруппы с основным динамическим принципом квантовой механики, выраженным соотношением (0.16).

В теории вероятностей подобное расширение марковской полугруппы до группы временных сдвигов в пространстве траекторий, соответствующих марковскому случайному процессу, осуществляется известной конструкцией Колмогорова-Даниэля. Понятие квантового случайного процесса, играющее важнуюроль в проблеме расширения динамической полугруппы, было сформулировано Л. Аккарди, А. Фриджерио и Дж. Льюнсом (1980). Роль марковского свойства особенно подчеркивалась Л. Аккарди. В 80-е годы теория квантовых случайных процессов превратилась в обширное самостоятельное поле исследований (см., в частности, сборники [141]-[145]).

Аналитический аппарат кв антового стохастического и с ч и с ле н и я, позволяющий, в частности, строить нетривиальные классы квантовых случайных процессов и конкретные расширения динамических полугрупп, был предложен Р. Л. Хадсоном и К. Р. Партасарати (1982). Квантовое стохастическое исчисление возникает на пересечении двух концепций - временной фильтрации в смысле теории случайных процессов и вторичного квантования в пространстве Фока. В конце 60-х годов Р. Стритер и Х. Араки указали на структуру непрерывного тензорного произведения, которая лежит в основе связи между безграничной делимостью, процессами с независимыми приращениями и

пространством Фока. Благодаря этому, пространство Фока оказывается носителем процессов «квантового шума», которые дают универсальную модель окружения открытой квантовой системы. Квантовое стохастическое исчисление представляет интерес и с точки зрения классической теории случайных процессов. Оно перебрасывает мост между исчислением Ито и вторичным квантованием, открывает неожиданные связи между непрерывными и скачкообразными процессами, позволяет по-новому взглянуть на понятие стохастического интеграла. Наконец, на этой основе развиваются потенциально важные приложения, относяшиеся к теории управления и фильтрации для квантовых случайных процессов (см. гл. 5).

12.1 Standard Statistical Model of Quantum Mechanics

12.1.1 1. Basic Concepts

1.1. Операторы в гильбертовом пространстве.

Изложению теории операторов в гильбертовом пространстве, в значительной мере стимулированной проблемами квантовой механики, посвящено много прекрасных книг (см., в частности, [2], [30]). Ниже мы лишь напоминаем некоторые факты и фиксируем обозначения.

Далее $\mathscr{C}$ обозначает сепарабельное комплексное гильбертово пространство. Для скалярного произведения в $\mathscr{C}$ используется дираковское обозначение $\langle\varphi|\psi\rangle$, причем считается, что форма $\langle\varphi|\psi\rangle$ линейна по ψ и антилинейна по φ. Символ $|\psi\rangle\langle\varphi|$ обозначает оператор, действующий на вектор $\chi \in \mathscr{H}$ по формуле

$$|\psi\rangle\langle\varphi|\chi = \psi\langle\varphi|\chi\rangle.$$

В частности, если $\langle\psi|\psi\rangle = 1$, то $|\psi\rangle\langle\psi|$ есть проектор на вектор $\psi \in \mathscr{H}$. Линейная оболочка множества операторов вида $|\psi\rangle\langle\varphi|$ совпадает с множеством операторов конечного ранга в $\mathscr{H}$.

Если X-ограниченный оператор в $\mathscr{H}$, то X^* обозначает $c0$ пряженный оператор, определяемый соотношением

$\langle\varphi|X^*\psi\rangle = \langle X\varphi|\psi\rangle; \varphi, \psi \in \mathscr{H}$.

$$\langle\varphi|X^*\psi\rangle = \langle X\varphi|\psi\rangle; \quad \varphi, \psi \in \mathscr{H}$$

вал огех огиченных операторов в $\mathscr{C}$ является банаховой алгеброй с инволюцией *. Оператор $X \in \mathscr{B}(\mathscr{B})$ эрмитов, если $X = X^*$. Унитарныц оператором называется оператор U, такой что $U^*U = UU^* = \mathrm{I}$, где I- единичный оператор. Проектором называется эрмитов оператор E, такой что $E^2 = E$. Эрмитов оператор X положителен ($X \geqslant 0$), если $\langle\psi|X\psi\rangle \geqslant 0$ для всех $\psi \in \mathscr{H}$. Для положительного оператора однозначно определен положительный квадратный корень.

Для всякого ограниченного положительного оператора T однозначно определен след

$$\operatorname{Tr} T = \sum_{i=1}^{\infty} \langle e_i|Te_i\rangle \leqslant +\infty$$

где $\{e_i\}$ произвольный ортонормированный базис. Оператор T называется ядерныц (оператором со следом), если он является линейной комбинацией положительных операторов с конечным следом. Для такого оператора след определяется однозначно, как сумма абсолютно сходящегося ряда вида (1.1). Множество ядерных операторов $\mathfrak{T}(\mathscr{H})$ является банаховым пространством относительно нормы $\|T\|_1 = \operatorname{Tr}\sqrt{T^*T}$, причем множество операторов конечного ранга плотно в $\mathfrak{I}(\mathscr{H})$.

Множество $\mathfrak{I}(\mathscr{C})$ образует двусторонний идеал в алгебре $\mathfrak{B}(\mathscr{H})$. Сопряженное к банахову пространству $\mathfrak{T}(\mathscr{C})$ изоморфно $\mathfrak{B}(\mathscr{G})$, причем двойственность определяется билинейной формой

$$\langle T, X\rangle = \operatorname{Tr} TX; \quad T \in \mathfrak{T}(\mathscr{H}), \quad X \in \mathscr{B}(\mathscr{H}).$$

Нижний индекс h в обозначении множества операторов означает, что рассматривается соответствуюшее подмножество эрмитовых операторов, например, $\mathfrak{B}_h(\mathscr{H})$ есть вещественное банахово пространство ограниченных эрмитовых операторов в $\mathscr{C}$. Отметим, что $\mathfrak{T}_h(\mathscr{H})* = \mathfrak{V}_h(\mathscr{C})$, причем двойственность по-прежнему задается формой (1.2).

Кроме сходимости по операторной норме в $\mathscr{O}(\mathscr{H})$, часто используются более слабые понятия сходимости. Последовательность $\{X_n\}$ сходится к X сильно, если $\lim \|X_n\psi - X\psi\| = 0$ для всех $\psi \in \mathscr{H}$, слабо, если $\lim_{n\to\infty} \langle\varphi|X_n\psi\rangle = \langle\varphi|X\psi\rangle$ для всех $\varphi, \psi \in \mathscr{C}$, и w^*-слабо (ультраслабо), если $\lim \operatorname{Tr} TX_n = \operatorname{Tr} TX$ для, всех $T \in \mathfrak{Z}(\mathscr{Z})$. Если $\{X_n\}$ ограниченная по норме последовательность операторов, такая что $X_n \leqslant X_{n+1}$, то X_n сходится сильно, слабо и w* - слабо к ограниченному оператору X (обозначается $X_n \uparrow X$).

1.2 Оператор плотности.

Так называется всякий положительный оператор S с единичным следом:

$$S \geqslant 0; \operatorname{Tr} S = 1.$$

Множество операторов плотности $\subseteq$ $(\mathscr{H})$ является выпуклым подмножеством вещественного линейного пространства $\mathfrak{T}_h(\mathscr{C})$; более, того, оно является основанием конуса положительных элементов, порождающего $\mathfrak{T}_h()$. Точка S выпуклого множества $\odot$ называется крайней, если из того, что $S = pS_1 + (1-p)S_2$, где $S_1, S_2 \in \mathcal{G}, 0 < p < 1$, следует $S_1 = S_2 = S$. Крайними точками множества $\odot(\mathscr{H})$ являются одномерные проекторы

$$S_\psi = |\psi\rangle\langle\psi|,$$

где $\psi \in \mathscr{H}, \langle\psi|\psi\rangle = 1$. Всякий оператор плотности представим в виде счетной выпуклой комбинации

$$S = \sum_{j=1}^{\infty} p_j \,|\psi_j\rangle\,\langle\psi_j|$$

где $\langle\psi_j|\psi_j\rangle = 1, p_j \geqslant 0, \sum\limits_{j=1}^{\infty} p_j = 1$. Одно из таких представлений дается спектральным разложением оператора S, когда ψ_j явля ются его собственными векторами, а p_j соответствующими собственными числами.

Рассмотрим множество $\mathscr{E}(\mathscr{H})$ проекторов в $\mathscr{H}$, изоморфное квантовой логике событий (замкнутых линейных подпространств $\mathscr{H}$). *Вероятностной мерой* на $\mathfrak{E}(\mathscr{H})$ называется вещественная функция μ со свойствами: 1)$0 \leqslant \mu(E) \leqslant 1, E \in (\mathscr{H})$; 2) если $\{E_j\} \subset\Subset (\mathscr{H})$, причем $E_jE_k = 0$ при $j \neq k$ и $\sum\limits_j E_j = \mathrm{I}$, то

$$\sum_j \mu\,(E_j) = \mathrm{I}$$

Отвечая на вопрос Макки, Глисон (1957) доказал следуюшую теорему.

Т е о ре ма. Пусть $\dim \mathscr{H} \geqslant 3$. Тогда всякая вероятностная мера на $\leftleftarrows$ () имеет вид

$$\mu(E) = \operatorname{Tr} SE$$

где S - однозначно определяемый оператор плотности.

Случай $\dim \mathscr{H} = 2$ является особым - для него легко указать меры, не представимые в виде (1.4), однако они не используются в квантовой теории. Доказательство теоремы Глисона совершенно нетривиально и породило целое направление в некоммутативной теории меры, посвященное всевозможным обобщениям и упрощениям этой теоремы (см. обзор Кручиньского в [141]).

По поводу некоммутативной теории меры и интегрирования см. обзоры Ш. А. Аюпова и А. Н. Шерстнева и другие статьи в сборниках [18], [34].

1.3 Спектральная мера.

Пусть $\mathscr{X}$ множество с б-алгеброй измеримых подмножеств $\mathscr{B}(\mathscr{L})$. Ортогональжым разложением единиц в $\mathscr{H}$ называется проекторно-значная мера на $\mathscr{B}(\mathscr{X})$,

т. е. функция множеств $\mathbf{E} : \mathscr{B}(\mathscr{X}) \to \mathfrak{C}(\mathscr{H})$, удовлетворяющая

условиям:

1. если $B_1, B_\varepsilon \in \mathscr{B}(\mathscr{H})$ и $B_1 \cap B_2 = \varnothing$, то $E(B_1)\, E(\mathrm{B}_2) = 0$;

2) если $\{B_j\}$ - конечное или счетное разбиение $\mathscr{X}$ на попарно-непересекающиеся измеримые подмножества, то

где ряд сходится сильно.

$$\sum_j E(B_j) = \mathrm{I}$$

Пусть X-оператор с плотной областью определения $\mathscr{D}(X) \subset \mathscr{O}$. Обозначим $\mathscr{D}(X^*)$ множество векторов φ таких, что существует $\chi \in \mathscr{C}$, для которого

$$\langle \varphi | X\psi \rangle = \langle \chi | \psi \rangle; \psi \in \mathscr{D}(X)$$

Определим оператор X^* с областью определения $\mathscr{D}(X^*)$, полагая $X^*\varphi = \chi$. Оператор X называется эрмитовым (симметрическим), если $X \subseteq X^*$, и самосопрянженным, если $X = X^*$.

Спектральная те орем а (фон Нейман, Стоун, Рисс, 1929-1932) устанавливает взаимно однозначное соответствие между ортогональными разложениями единицы $\mathbf{E}$ на σ-алгебре $\mathscr{B}(\mathbf{R})$ борелевских подмножеств вещественной прямой $\mathbf{R}$ и самосопряженными операторами в $\mathscr{H}$ по формуле

$$X = \int_{-\infty}^{\infty} xE(dx)$$

где интеграл понимается в подходящем смысле (см. [30]). Разложение единицы E называется спектральной мерой оператора X. Для любой борелевской функции f определен самосопряженный оператор

$$f \circ X = \int_{-\infty}^{\infty} xE(dx)$$

спектральная мера $\mathbf{F}$ которого связана со спектральной мерой оператора X соотношением

$$F(B) = E\left(f^{-1}(B)\right), B \in \mathscr{B}(\mathbf{R})$$

Совокупность всех самосопряженных операторов в $\mathscr{H}$ обозначим $D(\mathscr{H})$.

1.4. Статистический постулат. С каждой квантовомеханической системой связывается сепарабельное комплексное гильбертово пространство $\mathscr{H}$. Состояния системы описываются операторами плотности в $\mathscr{H}$. Вещественной наблюдаемой называется лю- бой самосопряженный оператор в $\mathscr{C}$. Распределение вероятностей наблюдаемой X в состоянии S задается соотношением

$$\mu_S^X(B) = \operatorname{Tr} SE(B), \quad B \in \mathscr{B}(\mathbf{R})$$

где $\mathbf{E}$ - спектральная мера X. Определенную таким образом отделимую статистическую модель $((\mathscr{H}), \mathscr{D}(\mathscr{C}))$ будем называть стандартной статистической моделью квантовой механики.

Из (1.5), (1.6) вытекает, что среднее значение наблюдаемой X в состоянии S,

$$\mathrm{E}_s(X) = \int_{-\infty}^{\infty} x\mu_S^X(dx)$$

равно

$$\mathbf{E}_s(X) = \operatorname{Tr} SX$$

(по крайней мере, для ограниченных наблюдаемых).

Крайние точки множества $\subseteq (\mathscr{C})$, описываемые операторами плотности (1.3), называются чистыми состояниями, а вектор ψ называется вектором состояния. Среднее значение наблюдаемой X в таком состоянии равно

$$\mathbf{E}_{s_\psi}(X) = \langle\psi|X\psi\rangle.$$

Допуская вольность речи, ограниченной наблюдаемой иногда называют произвольный $X \in \mathscr{B}(\mathscr{C})$. Соотношение (1.7) определяет линейный положительный нормированный $(\mathrm{E}_s(\mathrm{I}) = 1)$ функционал на алгебре $\mathscr{O}(\mathscr{C})$, т. е. состоян и е в смысле теории алгебр (предыдущие рассуждения поясняют происхождение этого математического термина). Состояние на $\mathscr{B}(\mathscr{C})$, определяемое оператором плотности по формуле (1.7), является нормальным в том смысле, что если $X_n \uparrow X$, то $\mathbf{E}_s(X_n) \to \mathbf{E}_s(X)$.

Алгеброй фон Неймана называется всякая алгебра огранченных операторов в $\mathscr{C}$, содержащая единичный оператор, замкнутая относительно инволюции и предельного перехода в сильной (слабой) операторной топологии. С любой алгеброй фон Неймана $\mathscr{P}$, как и с $\mathfrak{B}(\mathscr{H})$, ассоциируется статистическая модель, в которой состояниями являются нормальные состояния на $\mathscr{P}$, а наблюдаемыми - самосопряженные операторы, присоединенные к $\mathscr{B}$. Такие модели занимают промежуточное положение между квантовой и классическими (соответствующими коммутативным алгебрам $\mathfrak{B}$), и играют важную роль в теории квантовых систем с бесконечно большим числом степеней свободы - полей и сред (см. [7], [9], [51]).

1.5. Совместимые наблюдаемые. Коммутатором ограниченных операторов X, Y называется оператор

$$[X, Y] = XY - YX$$

Операторы $X, Y \in \mathscr{B}(\mathscr{H})$ - перестановочны (коммутируют), если $[X, Y] = 0$. Самосопряженные операторы X, Y называются пере- становочными, если перестановочны их спектральные меры. Следующие утверждения эквивалентны:

1. Наблюдаемые $X_1, \ldots, X_n$ совместимь, т. е. существует наблюдаемая X и борелевские функции $f_1, \ldots, f_n$ такие, что $X_j = f_j \circ X; j = 1, \ldots; n$.

2. Операторы $X_1, \ldots, X_n$ перестановочны.

Если $E_1, \ldots, E_n$ - спектральные меры совместимых наблюдаемых $X_1, \ldots, X_n$, то соотношение

$$E\left(B_1 \times \ldots \times B_n\right) = E_1\left(B_1\right) \cdot \ldots \cdot E_n\left(B_n\right); B_j \in \mathscr{B}$$

однозначно определяет ортогональное разложение единицы $\boldsymbol{E}$ на $\mathscr{B}\left(\mathbf{R}^n\right)$, называемое совместной спектральной мерой операторов $X_1, \ldots, X_n$. Для любого оператора плотности S определено совместное распределение вероятностей наблюдаемых $X_1, \ldots, X_n$

$$\mu \mathrm{iS}_1^{X_1, \ldots, X_n(B)} = \operatorname{Tr} SE(B), B \in \mathscr{B}\left(\mathbb{R}^n\right)$$

Для любой борелевской функции $f\left(x_1, \ldots, x_n\right)$ определена наблюдаемая

$$f\left(x_1, \ldots, \ddot{X}_n\right) = \int_{-\infty}^{\infty} \ldots \int_{-\infty}^{\infty} f\left(x_1, \ldots, x_n\right) E\left(dx_1 \ldots dx_n\right)$$

причем

$$\mathbf{E}_S\left(f\left(\dot{x}_1, \ldots, x_n\right)\right) = \int_{-\infty}^{\infty} \ldots \int_{-\infty}^{\infty} f\left(x_1, \ldots, x_n\right) \times$$
$$\times \mu_{is}^{X_1 \ldots, X_n\left(dx_1 \ldots dx_n\right).}$$

Сушествование несовместимых наблюдаемых отражает квантовый принцип дополнительности. Количественное выражение этого принципа дает соотношение неопределенностей. Для наблюдаемых X, Y, имеющих конечный второй момент относительно состояния S, корректно определяются билинейные формы

$$\langle X, Y\rangle_S = \operatorname{Re} \operatorname{Tr} YSX, [X, Y]_S = 2 \operatorname{Im} \operatorname{Tr} YSX$$

(см. [43, гл. II]). Пусть $\mathbf{X} = [X_1, \ldots, X_n]$ - набор произвольных наблюдаемых с конечным вторым моментом. Введем вещественные матрицы

$$\mathbf{D}_S(\mathbf{X}) = \left[\left\langle X_i - \mathrm{I} \cdot \mathbf{E}_S\left(X_i\right), X_j - \mathrm{I} \cdot \mathbf{E}_S\left(X_j\right)\right\rangle_S\right]_{i,j=1}, \ldots, n$$
$$\mathbf{C}_S(\mathbf{X}) = \left[\left[X_i, X_j\right]_S\right]_{i,j=1}, \ldots, n$$

Из положительной определенности полуторалинейных форм $X, Y \rightarrow \operatorname{Tr} Y^* SX, \operatorname{Tr} XSY^*$ вытекает неравенство [1)]

$$\mathrm{D}_s(\mathrm{X}) \geqslant \pm \frac{i}{2} \mathrm{C}_s(\mathrm{X})$$

1. Впервые такое неравенство было указано Робертсоном (1934); впоследствни оно неоднократно переоткрывалось (см. [17]). где левая и правая части рассматриваются как комплексные эрмитовы матрицы. Для двух наблюдаемых $X = X_1, Y = X_2$ неравенство (1.8) равносильно соотношению неопределенностей Шрёдингера-Робертсона

$$\mathbf{D}_s(X)\cdot\mathbf{D}_s(Y)\geqslant\langle\langle X-\mathrm{I}\cdot\mathbf{E}_s(X),Y-\mathrm{I}\cdot\mathbf{E}_s(Y)\rangle^2+$$
$$+\frac{1}{4}[X,Y]_s^2,$$

где

$$\mathbf{D}_s(\dot{X})=\int\limits_{-\infty}^{\infty}(x-\mathbf{E}_s(X))^2\,\mu_s^X(dx)$$

- дисперсия наблюдаемой X в состоянии S. Если X,Y-совместимые наблюдаемые, то величина

$$\langle X-\mathrm{I}\cdot\mathbf{E}_S(X),Y-\mathrm{I}\cdot\mathbf{E}_s(Y)\rangle_s=$$
$$=\int\limits_{-\infty}^{\infty}\int\limits_{-\infty}^{\infty}(x-\mathbf{E}_S(X))\,(y-\mathbf{E}_s(Y))\,\mu_S^{X,Y}(dxdy)$$

представляет собой ковариацию X,Y в состоянии S; при этом $[X,Y]_S=0$ и (1.9) превращается в неравенство Коши-Шварца для ковариации случайных величин.

Детальный обзор многообразных вариантов и обобщений соотношения неопределенностей см. в [17].

Заметим, что если X,Y - произвольные (ограниченные) операторы, то

$$\langle X,Y\rangle_S=\operatorname{Tr}SX\circ Y$$

где

$$X\circ Y=\frac{1}{2}(XY+YX)$$

- йорданово (симметризованное) произведение операторов X,Y. Величина вида (1.10) в квантовой статистической механике называется корреляцией, хотя если наблюдаемые X,Y не совместимы, она не связана каким-либо простым образом с измерениями X,Y.

1.6. Простейший пример. Пусть $\dim\mathscr{H}=2$. Базис в $\mathscr{D}(\mathscr{C})$ образован матрицами

$$\mathrm{I}=\begin{bmatrix}1&0\\0&1\end{bmatrix},\sigma_1=\begin{bmatrix}0&1\\1&0\end{bmatrix},\quad\sigma_2=\begin{bmatrix}0&-i\\i&0\end{bmatrix},\quad\sigma_3=\begin{bmatrix}1&0\\0&-1\end{bmatrix}$$

где σ_i-матрищь Паули. Полагая $X(\mathbf{a})=\sum\limits_{i=1}^{3}a_i\boldsymbol{\sigma}_i$, где $\mathbf{a}=(a_1,a_2,a_3)\in R^3$, имеем

$$X(\mathbf{a})\cdot X(\mathbf{b})=(\mathbf{a}\cdot\mathbf{b})\mathrm{I}+iX(\mathbf{a}\times\mathbf{b})$$

a, b. Отсюда

$$\operatorname{Tr}X(\mathbf{a})X(\mathbf{b})=2\mathbf{a}\cdot\mathbf{b}$$

Всякая матрица плотности однозначно записывается в виде

$$S(\mathrm{a})=\frac{1}{2}(\mathrm{I}+X(\mathrm{a}))$$

где $|a| \leqslant 1$. Таким образом, $\mathfrak{S}(\mathscr{H})$ как выпуклое множество изоморфно единичному шару в $\mathbf{R}^3$, причем чистые состояния соответствуют точкам сферы $|\mathbf{a}| = 1$. В этом случае

$$S(\mathrm{a}) = |\psi(\mathrm{a})\rangle\langle\psi(\mathrm{a})|$$

где $\psi(a)$-единичный вектор состояния. Поскольку $\langle\psi(a)|\psi(-a)\rangle = 0$, то соотношение

$$X(a) = |\psi(a)\rangle\langle\psi(a)| - |\psi(-a)\rangle\langle\psi(-a)|, (|a| = 1)$$

дает спектральное разложение наблюдаемой $X(\mathbf{a})$. Итак, наблюдаемая $X(\ \mathrm{a})$ принимает значения \pm 1, причем вероятность значения \pm 1 в состоянии $S(\mathbf{b})(|\mathbf{b}| \leqslant 1)$ есть

$$\operatorname{Tr} S(\mathbf{b})S(\pm\mathbf{a}) = \frac{1}{2}(1 \pm \mathbf{a}\cdot\mathbf{b})$$

так что $X(a)$ имеет распределение Бернулли.

В физике конечномерное гильбертово пространство обычно описывает внутренние (спиновые) степени свободы квантовой системы. Случай $\dim\mathscr{H} = 2$ отвечает минимальному спину 1/2. Матрица $\frac{1}{2}X(\mathbf{a})$ описывает наблюдаемую спина в направлении a, а оператор плотности $S(\mathbf{a})(|\mathbf{a}| = 1)$ - «полностью поляризованное состояние», в котором спин в направлении a имеет точное значение $\frac{1}{2}$. Операторы плотности с $|\mathbf{a}| < 1$, представляющие собой смеси полностью поляризованных состояний, описывают «частично поляризованные» состояния, в частности, $\mathrm{a} = 0$ соответствует хаотическому состоянию $S(0) = \frac{1}{2}\mathrm{I}$.

Из соотношения (1.11) следует, что наблюдаемые $X(a)$, X (b) совместимы тогда и только тогда, когда a и $\mathbf{b}$ коллинеарны. С другой стороны, для всех $\mathbf{a}, \mathbf{b} \in \mathbf{R}^3$

$$X(\mathbf{a})X(\mathbf{b}) + X(\mathbf{b})X(\mathbf{a}) = 2(\mathbf{a}\cdot\mathbf{b})\mathrm{I}$$

Фиксируем некоторое состояние и рассмотрим соотношение

$$X(\mathrm{a}) + X(\ \mathrm{b}) = X(\mathrm{a} + \mathrm{b}).$$

Оно показывает, что распределение Бернулли устойчиво по отношению к сложению наблюдаемых, подчиненных соотношению антикоммутации (1.14), и что в квантовой теории вероятностей существует векторное пространство бернуллиевских случайных величин размерности, большей единицы (в обычной теории вероятностей таким свойством обладают только гауссовские случайные величины).

На самом деле такое пространство существует для любой конечной размерности n. Пусть $\mathscr{C}(n)$ - конкретная алгебра Клиффорда, т. е. комплексная алгебра матриц, порождаемая эрмитовыми образующими $X_1, \ldots, X_n$, удовлетворяющими соотношениям

$$X_j^2 = \mathrm{I}, \lambda_j\bar{\Lambda}_k + X_kX_j = 0; k \neq j; k, j = 1, \ldots, n$$

Более точное определение и дальнейшие сведения об алгебрах Клиффорда см., например, в [160]. Полагая $X(\mathrm{a}) = \sum_{j=1}^{n} a_jX_j$ для $\mathbf{a} = (a_1, \ldots, a_n) \in \mathbf{R}^n$, соотношения (1.16) можно записать в форме (1.14). При этом, конечно, выполняется (1.15). Наблюдаемые $X(\mathbf{a}), \mathbf{a} \in \mathbf{R}^n$, принимают только значения $\pm|\mathbf{a}|$ и поэтому имеют распределение Бернулли относительно любого состояния на алгебре $\mathscr{C}(n)$.

На алгебре Клиффорда естественно определяется «бернуллиевское состояние», подобное многомерному гауссовскому распределению в обычной теории вероятностей (т. н. квазисвободное состояние канонических антикоммутационных соотношений [58], [150]).

12.1.2 2. Symmetries, Kinematics, Dynamics

2.1. Группы симметрий.

Рассмотрим отделимую статистическую модель $(\mathfrak{S}, \mathfrak{D})$. Пусть задана пара взаимно однозначных преобразований: Ψ, отображающее ς на $\mathcal{S}$ и Φ, отображающее D на $\mathfrak{D}$, причем

$$\mu_{\Psi(S)}^{\Phi(X)}(B) = \mu_S^X(B); B \in \mathscr{B}(\mathbf{R})$$

для всех $S \in \subseteq, X \in \mathfrak{D}$. Отсюда следует, что Ψ является аффинным отображением, т. е.

$$\Psi\left(\sum_{i=1}^n p_i S_i\right) = \sum_{i=1}^n p_i \Psi\left(S_i\right)$$

если $p_i \geqslant 0, \sum_{i=1}^n p_i = 1$. Преобразование Ψ назовем симметрией в пространстве состояний.

Т е орем а (Вигнер, 1931). Всякая симметрия пространства квантовых состояний имеет вид

$$\Psi(S) = USU^*$$

где U унитарный или антиунитарный оператор в $\mathscr{G}$.

Для средних значений наблюдаемых имеем

$$\operatorname{Tr} \Psi(S)X = \operatorname{Tr} S\Psi^*(X)$$

где

$$\Psi^*(X) = U^*XU$$

С точки зрения наблюдаемой статистики преобразование (2.1) состояний эквивалентно преобразованию (2.2) наблюдаемых. В первом случае говорят о картине Шрёдингера, а во второмо картине Гейзенберга.

Пусть G - группа и $g \to \Psi_g$ - представление G в группу симметрий $\odot(\mathscr{H})$, так что

$$\Psi_{g_1 \cdot g_2} = \Psi_{g_1} \cdot \Psi_{g_2}; g_1, g_2 \in G$$

Если G-связная топологическая группа, а представление $g \to \Psi_g$ непрерывно, то Ψ_g представляется в виде

$$\overset{\Psi}{g}_g(S) = U_g S U_g{}^*$$

где $g \to U_g$ - проективное унит арное представление группы G в пространстве $\mathscr{C}$, т. е. операторы U_g унитарны и удовлетворяют уравнению

$$U_{g_1} U_{g_2} = \omega\left(g_1, g_2\right) U_{g_1 \cdot g_2}$$

где $\omega\left(g_1, g_2\right)$ - множитель представления - комплексная функция, удовлетворяющая определенным алгебраическим соотношениям (см., например, Варадарайан [160]).

2.2. Однопараметрические группы. В случае $G = \mathbf{R}$, как показали Вигнер и Баргманн, всегда можно выбрать $\omega\left(g_1, g_2\right) = 1$, так что однопараметрическая группа симметрий определяется унитарным представлением R в $\mathscr{C}$.

Т е о р е м а (Стоун, 1932). Пусть $t \to U_t, t \in \mathbf{R}$ - сильно непрерывная группа унитарных операторов в $\mathscr{H}$, так что

$$U_{t_1} U_{t_2} = U_{t_1+t_2}; t_1, t_2 \in \mathbf{R}.$$

Тогда существует самосопряженный оператор A в $\mathscr{H}$, такой что $U_t = e^{itA}$. Обратно, для любого самосопряженного оператора A семейство $e^{itA}, t \in \mathbf{R}$, образует сильно непрерывную однопараметрическую группу.

Итак, предположив, например, что статистическое описание изолированной квантовой системы инвариантно относительно выбора начала отсчета времени, мы приходим к выводу, что в $\mathscr{H}$ существует самосопряженный оператор H такой, что состояние системы в момент времени t описывается формулой

$$S_t = e^{-iHt} S_0 e^{iHt}$$

Оператор H называется гамильтонианом (или наблюдаемой энергии) системы. Из (2.4) следует уравнение эволюции (в картине Шрёдингера)

$$i\frac{dS_t}{dt} = [H, S_t]$$

Если $S_0 = |\psi_0\rangle \langle\psi_0|$ - чистое состояние, то $S_t = |\psi_t\rangle \langle\psi_t|$, где $\{\psi_t\}$ - семейство векторов в $\mathscr{H}$, удовлетворяющее уравнению шрёдингера

$$i\frac{d\psi_t}{dt} = H\psi_t$$

Как правило, H - неограниченный оператор (полуограниченный снизу), так что в соотношениях (2.5), (2.6) следует позаботиться об областях определения.

Уравнение эволюции в картине Гейзенберга имеет вид

$$X_t = e^{iHt} \check{\Lambda}_0 e^{-iHt}; i\frac{dX_t}{dt} = [X_t, H]$$

Аналогично, из предположения о пространственной однородности вытекает существование самосопряженного оператора P, такого что состояние квантовой системы в системе отсчета, сдвинутой на расстояние x вдоль данной координатной оси, определяется уравнением

$$S_x = e^{-iPx} S_0 e^{iPx}$$

Оператор P называется оператором импульса вдоль этой оси. Вообще, всякой однопараметрической группе симметрий геометрического или кинематического характера отвечает самосопряженный оператор, порождающий по формулам типа (2.4), (2.7) преобразования квантовых состояний.

2.3. Соотношения Г. Вейля. инематика нерелятивистских систем как классических, так и квантовых, основана на прин. ципе относительности Галилея, согласно которому описание изолированной системы одинаково во всех инерциальных системах отсчета. Пусть $W_{\alpha,\nu}$ - унитарный оператор, порождающий преобразование состояний при переходе в систему отсчета, сдвинутую на расстояние x и движушуюся относительно исходной со скоростью v вдоль выделенной координатной оси. Тогда $(x, v) \to W_x, v$ есть проективное представление группы $G = \mathbf{R}^2$ в гильбертовом пространстве $\mathscr{H}$. Можно доказать, что соотношение (2.3) приводится к виду

$$W_{x_1,v_1} W_{x_2,v_2} = \exp\left[-\frac{im}{2}(x_1 v_2 - x_2 v_1)\right] W_{x_1+x_2, v_1+v_2}$$

где m - вещественный параметр (связанный с массой частицы) и далее строго положительный. Выделяя однопараметрические подгруппы - группу пространственных сдвигов $V_x = W_{x,0}$ и группу «галилеевых бустов» $U_v = W_{0,v}$, соотношение (2.8) можно переписать в виде

$$U_v V_x = e^{imxv} V_x U_v; \quad x, v \in \mathbf{R},$$

причем $W_{x,v} = e^{imxv/2} V_x U_v$. Соотношение (2.9) называется жанониеским коммутационным соотношением (ККС) Г. Вейла [10].

Согласно теореме Стоуна,

$$U_v = e^{imvQ}, \quad V_x = e^{-ixP},$$

где Q, P - самосопряженные операторы в $\mathscr{H}$. Рассматривая Q как вещественную наблюдаемую, заметим, что соотношение

$$V_x^* E(B + x) V_x = E(B); B \in \mathscr{B}(\mathbf{R})$$

для спектральной меры $\mathbf{E}$ оператора Q. Это же равносильно тому, что распределение вероятностей наблюдаемой преобразуется ковариантно при пространственных сдвигах (2.7):

$$\mu^Q_{s_x}(B + x) = \mu^Q_{S_0}(B); \quad B \in \mathscr{B}(\mathbf{R})$$

для любого состояния S_0. Это дает основание назвать Q наблюдаемой координаты вдоль выделенной оси. Симметричное рассуждение показывает, что P/m есть наблюдаемая скорости изолированной квантовой системы.

Представлением ККС считается любая конкретная пара (V, U), удовлетворяющая соотношениям (2.9). Представление называется неприводимым, если в $\mathscr{C}$ нет замкнутого подпространства, инвариантного относительно V_x, U_v. Неприводимым является представление Шрёдингера в $\mathscr{C} = L^2(\mathrm{R})$

$$V_x \psi(\xi) = \psi(\xi - x), U_v \psi(\xi) = e^{imv\xi} \psi(\xi)$$

В этом представлении Q задается оператором умножения на ξ, а P - оператором $i^{-1} \frac{d}{d\zeta^\circ}$.

Операторы P, Q имеют общую плотную инвариантную область определения и удовлетворяют на ней KKC Гейзенберга [1)]:

$$[P, Q] = i\mathrm{I}$$

Операторы P, Q называются каноническими наблюдаемыми. Обратный переход от соотношения Гейзенберга к соотношению Вейля (экспоненциирование) имеет ряд аналитических тонкостей, связанных с неограниченностью операторов P, Q и породил обширную математическую литературу (см. Иоргенсен, Мур [112]).

Принципиальное значение для квантовой механики имеет тот факт, что ККС определяют канонические наблюдаемые P, Q практически однозначно.

Теорем а (Стоун-фон Нейман, 1931). Всякое сильно непрерывное представление ККС− водимых представлений, каждое из которых унитарно эквивалентно представлению Шрёдингера.

В частности, в любом представлении ККСP, Q, как и в представлении Шрёдингера, неограничены и имеют лебегов спектр, простирающийся на всю вещественную прямую. С этим связана известная трудность с установлением разумного принципа соответствия в квантовой механике. Вопрос состоит в определении канонически сопряженных квантовых наблюдаемых, аналогичным обобщенным координатам и импульсам в

1. Соотношение (2.111) впервые было рассмотрено в 50-х годах прошлого века ирландским математиком Грейвсом, который развил соответствующее символическое исчисление. гамильтоновом формализме квантовой механики, и связан с: проблемой квантования классических систем. Так, в классической механике время и энергия, подобно координате и импульсу, являются канонически сопряженными величинами. Однако наблюдаемая энергии H имеет ограниченный снизу спектр, поэтому из теоремы Стоуна-фон Неймана вытекает, что не существует самосопряженного оператора времени T, которым был бы связан с H каноническим коммутационным соотношением. Эти трудности, возникающие и для других канонических пар, разрешаются в рамках обобщенной статистической модели квантовой механики (см. гл. 2, §3).

Аналогично формулируются ККС для систем с пронзвольным числом степеней свободы. Пусть $\{Z, \Delta\}$-симплектическое пространство, т. е. вещественное линейное пространство с билинейной кососимметричной формой $\Delta(z, z'); z, z' \in Z$. Представлением ККС называется семейство $z \to W(z)$ унитарных операторов в гильбертовом пространстве $\mathscr{H}$, удовлетворяющее KKC ВейляСигала

$$W(z)W(z') = \exp \frac{i}{2}\Delta(z, z')\, W(z + z')$$

Если форма Δ невырождена, а Z конечномерно, то оно имеет четную размерность d, и существует базис, в котором

$$\Delta(z, z') = \sum_{j=1}^{d} \left(x_j y'_j - x'_j y_j\right)$$

При этом операторы сильно непрерывного представления Вейля записываются в виде

$$W(z) = \exp i \sum_{j=1}^{d} (x_j P_j + y_j Q_j)$$

где самосопряженные операторы P_j, Q_j удовлетворяют многмерному аналогу ККС Гейзенберга (2.11)

$$[P_j, Q_k] = i\delta_{jk}\mathrm{I}; [P_j, P_k] = 0, [Q_j, Q_k] = 0$$

В этом случае теорема единственности Стоуна-фон Неймана сохраняет силу.

Для систем с бесконечным числом степеней свободы единственность нарушается и сушествует континуальное множество неэквивалентных представлений, что является причиной «инфракрасных расходимостей» в квантовой теории поля (см. [7], [32], [51]).

Неединственность представлений ККС тесно связана с неэквивалентностью вероятностных мер в бесконечномерных пространствах и послужила одним из первоначальных стимулов для изучения этого вопроса, занимающего большое место в классической теории случайных процессов.

2.4. Гауссовские состояния. Неравенство (1.9) и ККС (2.11) влекут соотношение неопределенностей Гейзенберга

$$\mathbf{D}_s(P)\mathbf{D}_{\boldsymbol{s}}(Q) \geqslant 1/4$$

из которого видно, что не существует состояния S, в котором P и Q одновременно принимали бы некоторые точные значения c вероятностью 1. Состояния, для которых

в (2.14) достигается равенство, называются состояниями минимальной неопределенности. Это чистые состояния $S_{x,v}$, определяемые векторами

$$\psi_{x,v} = W_{x,v}\psi_{0,0}; (x,v) \in \mathbf{R}^2$$

где $\psi_{0,0}$ - вектор основного состояния, в представлении Шрёдингера имеющий вид

$$\psi_{0,0}(\xi) = \left(2\pi\sigma^2\right)^{-1/4} \exp\left(-\xi^2/4\sigma^2\right)$$

Состояния $S_{x,v}$ характеризуются тремя параметрами

$$x = \mathbf{E}_{s_{x,v}}(Q), \quad v = \mathbf{E}_{s_{x,v}}(P),$$
$$\sigma^2 = \mathbf{D}_{s_{x,v}}(Q) = \left[4\mathbf{D}_{s_{x,v}}(P)\right]^{-1}.$$

При фиксированном σ^2 векторы $\psi_{x,v}$ образуют семейство, известное в квантовой оптике как семейство когерентных состояний [12], [21]. Для этих состояний

$$\left\langle Q - \mathbf{E}_{s_{x,v}}(Q)\cdot \mathrm{I}, \quad P - \mathrm{E}_{s_{x,v}}(P)\cdot \mathrm{I}\right\rangle_{s_{x,v}} = 0.$$

Более широкий класс образуют чистые состояния, для оторых достигается равенство в соотношении неопределенностей (1.9) (для P и Q), но условие (2.16) не обязано выполняться. Эти состояния широко обсуждались в физической литературе под именем сжатых (squeezed) состояний (см., например, [140]). С математической точки зрения все эти состояния входят в класс состояний, являющихся естественным квантовым аналогом гауссовских распределений в теории вероятностей.

Пусть $\{Z, \Delta\}$ - конечномерное симплектическое пространство с невырожденной кососимметричной формой Δ и $z \to W(z)$ - неприводимое представление ККС в гильбертовом пространстве $\mathscr{H}$. Характеристическая функция оператора плотности S в $\mathscr{H}$ определяется соотношением

$$\varphi(z) = \operatorname{Tr} SW(z); \quad z \in Z$$

и обладает рядом свойств, аналогичных свойствам характеристических функций в теории вероятностей [43, гл. V]. В частности, аналог условия положительной определенности имеет вид

$$\sum_{j,k} \bar{c}_j c_k \varphi\left(z_j - z_k\right) \exp\frac{i}{2}\Delta\left(z_j, z_k\right) \geqslant 0$$

для всех конечных наборов $\{c_j\} \subset \mathbf{C}, \{z_j\} \subset Z$. Состояние S называется гауссовским, если его характеристическая функция име32 ет вид

$$\varphi(z) = \exp\left[im(z) - \frac{1}{2}\alpha(z,z)\right]$$

где $m(z)$ - линейная, а $\alpha\left(z, z'\right)$ - билинейная формы на Z. Эго соотношение задает характеристическую функцию тогда и только тогда, когда выполнено условие

$$\alpha(z,z)\alpha\left(z',z'\right) \geqslant \frac{1}{4}\Delta\left(z,z'\right)^2; \quad z, z' \in Z$$

непосредственно связанное с (2.18). Общее определение для бесконечномерного Z было дано в [127]. В квантовой теории поля такие состояния описывают квазнсвободные (обобщенносвободные) поля и носят такое же название. В статистической механике они возникают как равновесные состояния бозе-систем с квадратичным гамильтонианом (см., например, [70], [51]).

12.1.3 3. Composite Systems

3.1. Тензорное произведение гильбертовых пространств.

Пусть $\mathscr{C}_1, \mathscr{H}_2$ - гильбертовые пространства со скалярными пронзведениями $\langle\cdot|\cdot\rangle_1$ и $\langle\cdot|\cdot\rangle_2$. В множестве $\mathscr{L}$ формальных линейных комбинаций элементов $\psi_1 \times \psi_2 \epsilon_2 \mathscr{C}_1 \times \mathscr{H}_2$ введем положительно определенную эрмитову форму, полагая

$$\langle\varphi_1 \backslash \langle\varphi_2|\psi_1 \backslash \psi_2\rangle = \langle\varphi_1|\psi_1\rangle_1 \langle\varphi_2|\psi_2\rangle_2$$

и продолжая ее на $\mathscr{L}$ по линейности. Пополнение (факторизованного по нулевому подпространству формы) пространства $\mathscr{L}$ является гильбертовым пространством, которое называется тензорным произведением $\mathscr{H}_1, \mathscr{C}_2$ и обозначается $\mathscr{H}_1 \otimes \mathscr{H}_2$. Вектор пространства $\mathscr{C}_1 \otimes \mathscr{H}_2$, соответствующий классу эквивалентности векторов $\psi_1 \backslash \psi_2 \in \mathscr{L}$, обозначается $\psi_1 \otimes \psi_2$.

Если $\mathscr{H}_j = L^2(\Omega_j, \mu_j); j = 1, 2$, то пространство $\mathscr{H}_1 \otimes \mathscr{H}_2 = L^2(\Omega_1 \times \Omega_2, \mu_1 \times \mu_2)$ состоит из всех функций $\psi(\omega_1, \omega_2)$, квадратично интегрируемых по мере $\mu_1 \times \mu_2$, причем вектор $\psi_1 \otimes \psi_2$ определяется функцией $\psi_1(\omega_1)\psi_2(\omega_2)$.

Тензорное произведение операторов $X_1 \otimes X_2$, где X_j - оператор в $\mathscr{H}_j$, определяется формулой

$$(X_1 \otimes X_2)(\psi_1 \otimes \psi_2) = X_1\psi_1 \otimes X_2\psi_2$$

Если $\mathscr{C}_j$ - конечномерные (комплексные) гильбертовы пространства, то

$$\dim \circlearrowleft (\mathscr{H}_1 \otimes \mathscr{H}_2) = \dim \curvearrowleft (\mathscr{H}_1) \dim \circlearrowleft (\mathscr{H}_2).$$

Если же $\mathscr{C}_j$ - вещественные гильбертовы пространства, то здесь имеет место знак $>$, а для кватернионных гильбертовых пространств (при некотором разумном определении $\mathscr{H}_1 \otimes \mathscr{H}_2$), знак $<$. Это обстоятельство рассматривается как косвенный аргумент в пользу поля комплексных чисел в аксиоматической квантовой механике.

Аналогично определяется тензорное произведение любого конечного числа гильбертовых пространств $\mathscr{C}_1 \otimes \ldots \otimes \mathscr{H}_n$. В квантовой механике $\mathscr{H}_1 \otimes \ldots \otimes \mathscr{H}_n$ описывает систему из n различимых частиц. В статистической механике приходится рассматривать системы неразличимых частиц - бозонов нли фермионов. В n-кратном тензорном пронзведении $\mathscr{H}^{\otimes n}$ выделяются два подпространства: симметричное тензорное произведение $\mathscr{H}^{sn}$, описывающее бозоны, и антисимметричное тензорное произведение $\mathscr{H}^{an}$, описывающее фермноны (в случае $\mathscr{H} = L^2(\Omega, \mu)$ первое состоит из симметричных, а второе - из антисимметричных функций $\psi(\omega_1, \ldots, \omega_n)$ аргументов $\omega_1, \ldots, \omega_n \in \Omega$). Системы из переменного (неограниченного) числа частиц описываются пространствами Фока: симметричным пространством $\Gamma_a(\mathscr{C}) = \sum_{n=0}^{\infty} \bigoplus \oplus \mathscr{H}^{\mathrm{sn}}$ в случае бозонов и антисимметричным пространством $\Gamma_a(\mathscr{G}) = \sum_{n=0} \oplus \mathscr{H}^{an}$ в случае фермнонов. В этих пространствах действует специальное представление канонических коммутационных (соответственно, антикоммутационных) соотношений, связанное с процедурой вторичного квантования (см. [6], [51], [70]).

3.2. Произведение квантовых состояний. Если S_j - операторы плотности в $\mathscr{C}_j$, то $S_1 \otimes S_2$ - оператор плотности в $\mathscr{C}_1 \otimes \mathscr{H}_2$, причем

$$\operatorname{Tr}(S_1 \otimes S_2)(X_1 \otimes X_2) = \operatorname{Tr} S_1X_1 \cdot \operatorname{Tr} S_2X_2; X_j \in \mathscr{P}(\mathscr{H}_j)$$

Операторы вида $X \otimes \mathrm{I}_2$, где $X \in \mathscr{P}(\mathscr{H}_1)$, а I_2 - единичный оператор в $\mathscr{C}_2$, образуют подалгебру $\mathfrak{P}_1 \subset \mathfrak{P}(\mathscr{C}_1 \otimes \mathscr{H}_2)$, нзоморфную $\mathfrak{B}(\mathscr{C}_1)$. Формула

$$\mathscr{E}\left(X_1 \otimes X_2\right) = X_1 \otimes \left(\operatorname{Tr} S_2 X X_2\right) I_2$$

определяет отображение $\mathscr{E}$ из $\mathscr{P}\left(\mathscr{C}_1 \otimes \mathscr{H}_2\right)$ на $\mathscr{P}\left(\mathscr{H}\mathscr{C}_1\right)$, обладающее свойством у словного о жид ан ия

$$\mathbf{E}_{\boldsymbol{s}}(XY) = \mathbf{E}_{\boldsymbol{B}}(\mathscr{E}(X)Y); X \in \mathscr{B}\left(\mathscr{H}_1 \otimes \mathscr{H}_2\right), Y \in \mathscr{B}_1,$$

относительно состояния $S = S_1 \otimes S_2$. В квантовой теории вероятностей условные ожидания играют меньшую роль, чем в классnческой, поскольку в общем случае условное ожидание на данную подалгебру $\mathscr{B}$ относительно данного состояния S существует лишь при весьма ограничительном соотношении между и S, в определенной мере, сводящем ситуацию к классической; точнее см. п. 3.1.3.

Если S - произвольный оператор плотности в $\mathscr{C}_1 \otimes \mathscr{H}_2$, то в $\mathscr{G}_1$ найдется единственный оператор плотности S_1, такой что

$$\operatorname{Tr} S_1 X = \operatorname{Tr} S\left(X \otimes \mathrm{I}_2\right); X \in \mathscr{B}\left(\mathscr{H}_1\right).$$

Это же верно для любой линейной комбинации операторов плотности, т. е. для любого ядерного оператора T в $\mathscr{H}_1 \otimes \mathscr{H}_2$. Отображение $T \to T_1$ называется частичным следом оператора T (обозначается $T_1 = \operatorname{Tr} \mathscr{H}_2 T$). Операция частичного следа аналогична нахождению маргинального распределения в теории вероятностей.

3.3. Независимасть и предельные теоремы. Рассмотрим сначала ситуацию, соответствующую одномерной центральной предельной теореме в теории вероятностей. Пусть S - фиксированное состояние. Вещественные наблюдаемые $X_1, \ldots, X_n, \ldots$ называются независимыми, если

$$\begin{aligned}&\mathbf{E}_s\left(\varphi_1\left(X_{i_1}\right)^* \ldots \varphi_m\left(X_{j_m}\right)\right) = \\ =&\mathbf{E}_{\boldsymbol{s}}\left(\varphi_1\left(X_{j_1}\right)\right)^{\cdot} \ldots \mathbf{E}_{\boldsymbol{s}}\left(\varphi_m\left(X_{i_m}\right)\right)\end{aligned}$$

для любых $m = 1, 2, \ldots$, любых ограниченных борелевских функщий $\varphi_1, \ldots, \varphi_m$ и любых номеров $j_1, \ldots, j_m$, таких что $j_k \neq \dot{j}_l$ при $k \neq l$. Предполагается, что X_j одинаково распределены и имеют второй момент, причем $\mathbf{E}_s\left(X_j\right) = 0, \mathbf{D}_s\left(X_j\right) = 1$. Что можно сказать о предельном распределении нормированных сумм

$$S_n = \frac{1}{\sqrt{n}} \sum_{j=1}^{n} x_j^{\times}$$

Если $X_1, \ldots, X_n, \ldots$-попарно перестановочны, то

$$\exp it\left(X_1 + \ldots + X_n\right) = \exp \text{ it } X_1 \ldots \exp itX_n; t \in \mathbb{R}$$

и применение характеристических функций сводит вопрос k классической центральной предельной теореме, со стандартным нормальным распределением в качестве предельного. В общем случае (3.3) не выполняется и предельное поведение сумм существенно зависит от алгебраических свойств последовательности слагаемых. Пусть, например, $X_1, \ldots, X_n, \ldots$ - а н т и п е р е с т ан о в о ны в том смысле, что

$$X_j X_k = -X_k X_j \text{ при } j \neq k.$$

Тогда прямой подсчет (в предположении конечности 4-го момента X_j) показывает, что

$$\mathbf{E}_{\mathcal{B}}\left(S_n^4\right) - \left(\mathbf{E}_{\mathbf{B}}\left(S_n^2\right)\right)^2 \to 0$$

откуда следует, что ${S_n}^2 \to 1$ по вероятности. Поскольку $\mathbf{E}_{\boldsymbol{s}}(S_n) = 0$, то распределение S_n стремится к симметричному распределению Бернулли, сосредоточенному в точках ± 1[11]. Это согласуется с наблюдением, что распределение Бернулли устойчиво относительно сложения антиперестановочных наблюдаемых (n. 1.6).

Богатство новых возможностей, открывающихся в некоммутативной теории, демонстрируют понятие свободной независимо-

1. Это рассуждение сообщено автору В. фон Вальденфельсом. .сти и соответствующая предельная теорема, открытые Войкулеску [162] (см. также Шпайхер [151]). Вещественные наблюдаемые $X_1, \ldots, X_n, \ldots$ называются свободно независимыми, если соотношения (3.2) выполняются для всех номеров $j_1, \ldots, j_m$, та. ких что $j_k \neq j_{k+1}, k = 1, \ldots, m-1$.

Те орема. Пусть X_j - свободно независимые наблюдаемые, $\|X_j\| \leqslant c; j = 1, \ldots, n, \ldots$ Пусть X_j одинаково распределены и $\mathbf{E}_{\boldsymbol{s}}(X_j) = 0, \mathbf{D}_{\boldsymbol{s}}(X_j) = 1/4$. Тогда распределение нормированных сумм S_n сходится при $n \to \infty$ к полукруговому закону Вигнера с. Плотностью

$$p(x) = \begin{cases} \frac{2}{\pi}\sqrt{1-x^2}, & |x| \leqslant 1 \\ 0, & |x| > 1 \end{cases}$$

Доказательство этой теоремы методом моментов требует довольно сложных комбинаторных подсчетов. Другой метод доказательства - использование преобразования Коши, которое играет роль логарифма характеристической функции для сво'бодно независимых' величин [163].

При переходе к многомерной предельной теореме возникает принципиально новая ситуация, обусловленная возможностью различных алгебраических соотношений между компонентами каждого из слагаемых. В работе Кашена, Хадсона [77] (соответственно, Хадсона [106]) предполагается, что компоненты слагаемых подчинены каноническим коммутационным (антикоммутационным) соотношениям и доказывается; что состояния, описы:вающие нормированную сумму, сходятся к квазисвободному состоянию канонических коммутационных (антикоммутационных) соотношений, т. е. к квантовому гауссовскому (бернуллиевскому) состоянию. При этом в случае антикоммутационных соотношений вместо обычного тензорного произведения алгебр, порожденных компонентами каждого слагаемого, необходимо использовать так называемое градуированное тензорное произведение, обобщающее понятие антиперестановочности. Более интересны результаты работ Гири, фон Вальденфельса [90] и Вальденфельса [164], в которых показано, что квазисвободное состояние на алгебре канонических коммутационных (соответственно, антикоммутационных) соотношений возникает в квантовой центральной предельной теореме без априорных предположений об алгебраической природе слагаемых, а лишь в зависимости от выбора обычного (или градуированного) тензорного произведения. Однако метод доказательства в этих работах, основанный на вычислении моментов, предполагает ограничительное в аналитическом плане условие существование моментов всех порядков.

В ряде работ рассматривался случай слабо зависимых наблюдаемых. М. Ш. Гольдштейн доказал сходимость к нормальному распределению в случае последовательности вещественных наблюдаемых $X_1, \ldots, X_n, \ldots$, удовлетворяющей условиям сла- бой зависимости и асимптотической перестановочности типа условия Розенблатта (см. обзор В. В. Аншелевича и М. Ш. Гольдштейна в сборнике [34] и книгу Т. А. Сарымсакова [31]). Обобщение результатов фон Вальденфельса об асимптотической квазисвободности на случай слабо зависимых слагаемых даны в работе

Аккарди и Баха [53] (алгебру $\mathscr{B}$ в этой работе следует считать коммутативной). Наиболее полный результат для слабо зависимых (перестановочных) слагаемых получен Годерисом, Вербером, Ветсом [92]. Следует отметить, что истоком работ [90], [92] послужили известные работы Хеппа и Либа о флуктуациях в мазере Дикке, которые дают некоторую физическую мотивацию квантовой центральной предельной теоремы для перестановочных слагаемых.

Различные алгебраические обобщения центральной предельной теоремы (связанные, в частности, с понятием безграничной, делимости) рассматривались также Хегерфельдтом [97], Партасарати и Шмидтом [138], Фаннесом и Куагебером (статья в сборнике [142]).

12.1.4 4. The Problem of Hidden Parameters

Проблема скрытых параметров - это вопрос о принципиальной возможности описания квантовой механики в терминах классического фазового пространства. Несмотря на устоявшееся среди физнков мнение о невозможности такого описания, конструирование теорий со скрытыми параметрами не прекращается (одной из недавних и наиболее интересных попыток является стохастическая механика [132]). Этой проблеме посвящена обширная литература (см., например, [14]). Здесь мы ограничимся обсуждением наиболее существенных логических аргументов против «скрытых параметров».

4.1. Скрытые параметры и квантовая дополнительность. С математической точки зрения в проблеме скрытых параметров речь ндет о возможности установления соответствий $S(d\omega) \to \hat{S}, X(\omega) \to \hat{X}$ между классическими состояниями, т. е. распределениями вероятностей $S(d\omega)$ на измеримом «фазовом пространстве» $(\Omega, \mathscr{B}(\Omega))$ и операторами плотности $\hat{S}$ в гильбертовом пространстве $\mathscr{H}$ квантовой системы, и между случайными величинами $X(\omega)$ и наблюдаемыми $\hat{X}$ в $\mathscr{H}$, которые воспроизводили бы статистические предсказания квантовой теории и удо-: влетворяли некоторым физически мотивированным. условиям. Такими условиями, естественно возникающими из общего понятия статистической модели (п. 0.2), в первую очередь являются сохранение функциональной подчиненности в пространстве наблюдаемых, а также выпуклой структуры в множестве состояний. Обзор с этой точки зрения основных «доказательств невозможности» скрытых параметров дан в [45]. Так, результаты

Белла [66] и Кошена, Шпеккера [115] равносильны следующему утверждению.

Пр едложение. Пусть $\dim \mathscr{H} \geqslant 3$. Не существует однозначного отображения $X \to X(\omega)$ множества наблюдаемы X $\mathcal{D}(\mathscr{H})$ в множество случайных величин на каком-либо измеримом пространстве Ω, удовлетворяющего условню:

1. если $X \to X(\omega)$, то $f \circ X \to f(X(\omega))$ для любой борелевской функции f.

Дока зательство. Можно считать, что $\dim \mathscr{H} < \infty$. Пусть такое отображение существует, тогда из 1) выводятся следующие свойства

2. $X(\omega) \in \operatorname{Sp} X$ для любого $\omega \in \Omega$;

3. Если $\hat{X}_j$ - совместимые наблюдаемые и $\hat{X}_j \to X_j(\omega)$, то $\sum\limits_j \hat{X}_j \to \sum\limits_j X_j(\omega)$.

Фиксируем $\omega \in \Omega$ и рассмотрим функцию проекторов $\mu(E) = E(\omega)$, где $E \to E(\omega)$. Из 2), 3) вытекает, что μ является вероятностной мерой на $\mathbb{E}(\mathscr{H})$, принимающей только значения 0,1. По теореме Глисона $\mu(E) = \operatorname{Tr} \hat{S}E$, где $\hat{S}$ - оператор плотности, но такая функция не может быть двузначной мерой.

Недостаток аргументации фон Неймана [26] состоит в том, что он требовал выполнения свойства 3) для п роизвольны **x**, а не только совместимых наблюдаемых $\boldsymbol{X}_j$. Рассуждение

с аддитивностью средних значений, которое он привел для обоснования этого требования, по существу, заранее исключает теории со скрытыми параметрами [45], [14].

Приведенное выше доказательство означает невозможность введения скрытых параметров по схеме частичной наблюдаемости, реализуемой, например, в классической статистической механике, где имеется взаимно однозначное соответствие между «макроскопическими» наблюдаемыми и некоторыми функциями на фазовом пространстве. Однако оно не исключает более сложных конструкций, в которых одна и та же квантовая наблюдаемая $\boldsymbol{X}$ может быть измерена множеством разных способов и соответствие $X(\omega) \to X$, таким образом, не взаимно однозначно. На самом деле в квантовой механике имеется по крайней мере столько различных способов измерения наблюдаемой $\bar{X}$, сколько есть представлений $\bar{X} = f \circ \bar{Y}$ в виде функций от других наблюдаемых $\vec{P}$. Если $\mathbb{X}$ имеет кратное собственное значение, то заведомо найдутся несовместимые наблюдаемые $\vec{P}_1$ и $\vec{P}_2$ такие, что $\mathbb{X} = f_1 \circ \widehat{P}_1 = f_2 \circ \hat{Y}_2$. Требование взаимной однозначности входит тогда в прямое противоречие с квантовым свойством дополнительности [1)]. Отсюда вытекает, что в теориях

1). Если $\dim \mathscr{H} = 2$, то наблюдаемые с кратным спектром - это постоянные величины; тогда такого противоречия не возникает, и теория со скрытыми параметрами, удовлетворяющая условиям доказанного предложенння, строится явным образом [66]. со скрытыми параметрами следует оставить возможность для различных классических представлений одной и той же квантовой наблюдаемой (такого рода теории Дж. Белл назвал ко н текстуальным и). Аналогичное замечание можно отнести и представление квантовых состояний. А. С. Холево дал явное описание такой формальной конструкции, сохраняющей структуры статистической модели [45], [101].

Предложение. Пусть $\mathscr{H}$ - гильбертово пространство. Существует измеримое пространство Ω и отображения $X(\omega) \to \dot{X}$ некоторого множества случайных величин на $\mathfrak{O}(\mathscr{C})$ и $S(d\omega) \to S$ некоторого множества вероятностных мер на $\mathfrak{S}(\mathscr{C})$ такие, что

1. Если $S_j(d\omega) \to \hat{S}_j$ и $\{p_j\}$-конечное распределение вероят. ностей, то $\sum\limits_j p_j S_j(d\omega) \to \sum\limits_j p_j \hat{S}_j$;
2. Если $\dot{X}(\omega) \to \hat{\lambda}^*$ и f-борелевская функция, то $f(X(\omega)) \to \to f \circ \hat{X}$
3. Если $\ddot{\dot{X}}(\omega) \to \hat{\lambda}$ и $S(d\omega) \to \hat{S}$, то

$$\int\limits_{\Omega} X(\omega) S(d\omega) = \operatorname{Tr} \hat{S}\hat{X}$$

В случае $\dim \mathscr{H} \geqslant 3$ отображения $X(\omega) \to X, S(d\omega) \to \hat{S}$ с необходимостью не являются взаимно однозначными. Этот результат показывает, что принцип дополнительности препятствует классическому описанию квантовой статистики лишь при дополнительном требовании взаимной однозначности (неконтекстуальности).

4.2. Скрытые параметры и квантовая целостность. Рассмотрим квантовую систему, состоящую из двух компонент $\mathscr{H}_1, \mathscr{H}_2$. Чистые состояния такой системы задаются единичными векторами $\psi \in \mathscr{C}_1 \otimes \mathscr{H}_2$, которые являются линейными комбинациями (суперпозициями) факторизуемых векторов $\psi_1 \otimes \psi_2$. Если $\psi = \psi_1 \otimes \psi_2$, то обе компоненты системы находятся в однозначно определенных чистых состояниях; если же ψ нефакторизуемо, то между компонентами обнаруживаются специфические корреляции, которые невозможно смоделировать никаким класснческим механизмом случайности. На это обратил внимание Белл, показавший, что даже в контекстуальной

теории со скрытыми параметрами нельзя удовлетворить естественному требованию, названному им «эйнштейновской локальностью» [66][11]. Обсудим близкое, но более общее условие р азделимости [45].

1. В этой связи см. также статью Э. Вигнера «Скрытые параметры и квантовомеханические вероятности» в сб. [11].

Рассмотрим наблюдаемые

$$\hat{X}_j = \hat{X}_j^{(1)} \otimes \hat{I}^{(2)}, j_k = 1 \ldots, n$$
$$\hat{Y}_k = \hat{I}^{(1)} \otimes \hat{Y}_j^{(2)}, k = 1, \ldots, m$$

где $\hat{\mathrm{I}}^{(j)}$-единичный оператор в $\mathscr{H}_j$, так что

$$\left[\hat{X}_j, \hat{Y}_k\right] = 0$$

т. е. каждая наблюдаемая $\hat{X}_j$ совместима с каждой $\hat{Y}_k$. Поэтому для любого состояния $\hat{S}$ в $\mathscr{C}_1 \otimes \mathscr{H}_2$ определены квантовые корреляции $\left\langle \hat{X}_j, \hat{Y}_k \right\rangle_{\hat{s}}$. Матрица $\mathbf{C} = \left[\left\langle \hat{X}_j, \hat{Y}_k \right\rangle_{\hat{s}}\right]_{j=1,\ldots,n,k=1,\ldots,m}$ описывает статистические результаты nm различных экспериментов, вообще говоря, несовместимых между собой.

П р едложе ние. Пусть $n, m \geqslant 2$. Не существует измеримого пространства Ω и отображений $S(d\omega) \to \hat{S}, X(\omega) \to \hat{X}$ таких, что:

1. если $X(\omega) \to \hat{X}$, то $X(\omega) \in \mathrm{Cp}\, \hat{X}$;
2. для любого $\hat{S}$ и любых $\hat{X}_1, \ldots, \hat{X}_n; \hat{Y}_1, \ldots, \hat{Y}_m$ вида найдутся $X_j(\omega), Y_k(\omega)$ такие, что $X_j(\omega) \to \hat{X}_j, Y_k(\omega) \to \hat{Y}_k$ и $\left\langle \hat{X}_j, \hat{Y}_k \right\rangle_{\hat{s}} = \int\limits_{\Omega} X_j(\omega) Y_j(\omega) S(d\omega)$; $j = 1, \ldots, n$, $k = 1, \ldots, m$, для какого-либо $S(d\omega) \to \hat{S}$.

Доказательств о. Достаточно ограничиться случаем $n = m = 2$. Рассмотрим наблюдаемые $\hat{X}_1, \hat{X}_2, \hat{Y}_1, \hat{Y}_2$ вида (4.1) и такие, что

$$\left\|\hat{X}_j\right\| \leqslant 1, \left\|\hat{Y}_k\right\| \leqslant 1$$

Предположим, что указанные отображения существуют и пусть. X_j, Y_k - соответствующие случайные величины на вероятностном пространстве $(\Omega, \mathscr{B}(\Omega), \quad S(d\omega))$. В силу условия 1), $|X_i(\omega)| \leqslant 1, |Y_n(\omega)| \leqslant 1$, откуда

$$X_1(\omega)Y_1(\omega) + X_1(\omega)Y_2(\omega) + X_2(\omega)Y_1(\omega) - X_2(\omega)Y_2(\omega) \leqslant 2, \quad \omega \in \Omega$$

Усредняя по $S(d\omega)$ и используя условие 2), получаем неравенство Белла-Клаузера-Хорна-Шимони (БКХШ)

$$\left\langle \hat{\lambda}_1, \hat{Y}_1 \right\rangle_{\hat{s}} + \left\langle \hat{X}_1, \hat{Y}_2 \right\rangle_{\hat{s}} + \left\langle \hat{X}_2, \hat{Y}_1 \right\rangle_{\hat{s}} - \left\langle \hat{\Lambda}_2, \hat{Y}_2 \right\rangle_{\hat{s}} \leqslant 2.$$

Остается указать квантовле наблюдаемые $\hat{X}_j, \hat{Y}_k$ и состояние $\hat{S}$, для которых неравенство (4.4) нарушается. Рассмотрим систему из двух частиц со спином 1/2, так что $\dim \mathscr{H}_1 = \dim \mathscr{H}_2 = 2$. (см. п. 1.6). Пусть $\hat{S}$-чистое состояние состав- ной системы с вектором

$$\psi = \frac{1}{\sqrt{2}} [\psi_1(\mathrm{e}) \otimes \psi_2(-\mathrm{e}) - \psi_1(-\mathrm{e}) \otimes \psi_2(\mathrm{e})]$$

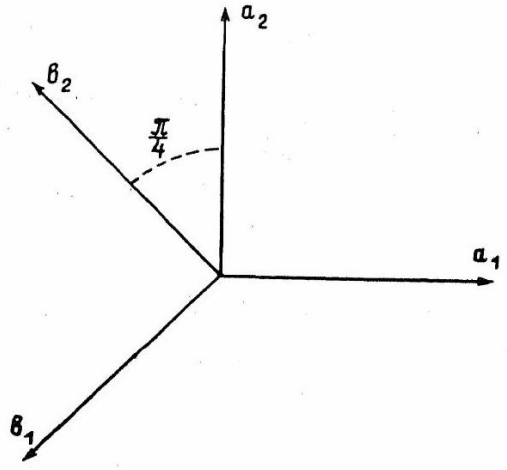
где $\psi_j(\mathrm{e})$-единичный вектор j-й компоненты, описывающй полностью поля ризованное состояние с направлением спина e. Положнм

$$\hat{\lambda}'(\mathrm{a}) = \hat{X}^{(1)}(\mathrm{a}) \otimes \hat{\mathrm{I}}^{(2)}, \quad \hat{Y}(\ \mathrm{b}) = \hat{\mathrm{I}}^{(1)} \otimes \hat{\lambda}^{*(2)}(\mathrm{b})$$

где $\hat{\mathbf{\Lambda}}^{(j)}(\mathrm{a})$ - наблюдаемые спина в $\mathscr{H}_j$ (см. П. 1.6). Корреляции между компонентами имеют вид

$$\langle \hat{X}(\mathbf{a}), \hat{Y}(\mathbf{b}) \rangle_{\hat{s}} = \left\langle \psi | \hat{\Lambda}^{(1)}(\mathbf{a}) \otimes \hat{X}^{(2)}(\mathbf{b}) \psi \right\rangle = -\mathbf{a} \cdot \mathbf{b}.$$

Пусть векторы $\mathbf{a}_j, \mathbf{b}_k$ образуют конфигурацию, обозначенную на рисунке, тогда значение левой части неравенства (4.4) для наблюдаемых $\hat{X}_j = \hat{X}\,(\mathrm{a}_j)\,, \hat{Y}_k = \hat{Y}\,(\ \mathrm{b}_k)$ равно $2\sqrt{2}$, что противоречит неравенству и доказывает предложение [1].



В [114] указано общее неравенство

$$\left(\hat{X}_1\hat{Y}_1 + \hat{X}_1\hat{Y}_2 + \hat{X}_2\hat{Y}_1 - \hat{A}_2\hat{Y}_2\right)^2 \leqslant 4\hat{I} - \left[\hat{X}_1, \hat{\lambda}_2\right] \cdot \left[\hat{Y}_1, \hat{Y}_2\right]$$

справедливое лля любэх операторов, удовлетворяющих условиям (4.2), (4.3). Из него вытекает как неравенство БКХШ (при $\left[\hat{X}_1, \hat{X}_2\right] = \left[\hat{Y}_1, \hat{Y}_2\right] = 0$), так и граница

$$\left\| \hat{X}_1\hat{Y}_1 + \hat{X}_1\hat{Y}_2 + \hat{X}_2\hat{Y}_1 - \hat{\hat{X}}_2\hat{Y}_2 \right\| \leqslant 2\sqrt{2}$$

из которой видно, что в построенном примере неравенство БКХШ нарушается максимальным образом.

1. Работы Дж. Белла стимулировали ряд экспериментов, в которых нарушение неравенства БКХШ получило подтверждение (см., например, [14]).

Поскольку компоненты составной системы могут представлять собой частицы, пространственно отделенные друг от друга макроскопическим расстоянием, то описывающая их теория со скрытыми параметрами должна быть существенно нелокальной [1)]. В работе Саммерса и Вернера [156] показано, что положение не спасает и переход к локальной квантовой теории поля, где неравенство БКХШ также нарушается максимальным образом.

4.3. Структура множества квантовых корреляций. В работе Б. С. Цирельсона [48] было изучено выпуклое множество $\mathrm{Cor}(n,m)$ квантовопредставимых матриц $\mathbf{C} = [c_{jk}]_{k=1,\ldots,n,m}^{j=1,\ldots,n}$, элементы которых представимы как корреляции $c_{jk} = \left\langle \hat{X}_j, \hat{Y}_k \right\rangle_{\hat{s}}$ каких-либо квантовых наблюдаемых $\mathcal{X}_j, P_k$, удовлетворяющих условиям (4.2), (4.3). Оказывается, что формально более сильное, чем (4.2). (и физически содержательное), условие (4.1) приводит к тому же множеству корреляционных матриц C. Это видно из доказательства следующей теоремы, которая дает прозрачное геометрическое описание множества $\mathrm{Cor}(n,m)$.

Т е о рема. Матрица C принадлежит множеству Cor (n,m) тогда и только тогда, когда в евклидовом пространстве размерности $\min(n,m)$ сушествуют векторы $\mathbf{a}_1,\ldots,\mathbf{a}_n;\mathbf{b}_1,\ldots,\mathbf{b}_m$ такие, что $\|\mathbf{a}_j\| \leqslant 1, \|\mathbf{b}_k\| \leqslant 1$ и $\mathbf{a}_j \cdot \mathbf{b}_k = c_{jk}$ для всех j,k.

Дадим набросок конструкции, существенной для доказательства. Пусть $\mathscr{C}(n)$ - комплексная алгебра Клиффорда с n эрмитовыми образующими $X_1,\ldots,X_n$, удовлетворяющими соотношениям

$$X_j^2 = 1, \quad X_jX_k + X_kX_j = 0; \quad j,k = 1,\ldots,n, \quad j \neq k$$

Поскольку элементы $X_j \otimes X_j$ алгебры $\mathscr{B}(n) \otimes \mathscr{B}(n)$ перестановочны и их спектр состоит из \pm 1, то 1 является точкой спектра элемента

$$A = \frac{1}{n}\left(X_1 \otimes X_1 + \ldots + X_n \otimes X_n\right)$$

(кратности 1). Пусть π - неприводимое представление алгебры $\mathscr{C}(n) \otimes \mathscr{C}(n)$, тогда в пространстве представления сушествует единственный с ' точностью до множителя вектор ψ, такой что $\pi(A)\psi = \psi$. Доказывается, что

$$\langle \psi | \pi(X(a) \otimes X(b))\psi \rangle = \mathbf{a} \cdot \mathbf{b}; \mathbf{a}, \mathbf{b} \in \mathbf{R}^n.$$

Вектор ψ определяет состояние $\hat{S}$ в точном представлении алгебры $\mathscr{B}(n) \otimes \mathscr{B}(n)$ такое, что

$$\left\langle \hat{\lambda}_j, \hat{Y}_k \right\rangle_{\hat{s}} = \mathbf{a}_j \cdot \mathbf{b}_k$$

1. По поводу нелокальности в стохастической, механике см. статью Э. Нельсона [132].
тде $\hat{X}_j = X\left(\mathbf{a}_j\right) \otimes \mathrm{I}, \hat{Y}_k = \mathrm{I} \otimes X\left(\mathbf{b}_k\right)$ удовлетворяіот условию (4.1) а значит, и (4.2).

Из этой теоремы в [48] получено описание крайних точек множества $\mathrm{Cor}(n,m)$, а также указаны неравенства, задающие множество Cor $(2,2)$.

Обозначая $\mathrm{Cor}_1(n,m)$ множество классически-представимых матриц C, таких что

$$c_{jk} = \int X_j(\omega)Y_k(\omega)S(d\omega),$$

где X_j, Y_k - случайные величины, такие что $|X_j(\omega)| \leqslant 1$, $|Y_k(\omega)| \leqslant 1$, имеем, очевидно,

$$\mathrm{Cor}_1(n,m) \subsetneq \mathrm{Cor}(n,m).$$

Несовпадение этих множеств математически выражает свойство квантовой целостности. Неравенство БХШ задает граничную гиперплоскость, отделяющую многогранник $\mathrm{Cor}_1(2,2)$ от квантово-реализуемой матрицы $\frac{1}{\sqrt{2}}\begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix} \in \mathrm{Cor}(2,2)$. Естественно поставить вопрос, насколько Cor (n,m) превосходит $\mathrm{Cor}_1(n,m)$. Пусть $K(n,m)$ - наименьшее число, обладающее свойством

$$\mathrm{Cor}(n,m) \subset K(n,m)\,\mathrm{Cor}_1(n,m)$$

Последовательность $K(n,m)$ возрастает с ростом n,m. Как отмечается в [48], из геометрического описания множества Cor (n,m) вытекает, что $K = \lim K(n,m)$ совпадает с известной в теории нормированных пространств константой Гротендика $K_G \leqslant \frac{\pi}{2\ln\left(1+\sqrt{2}\right)} \approx 1,782$.

12.2 Statistics of Quantum Measurements

12.2.1 1. Generalized Observables

1.1. Разложения единицы.

Пусть $(\mathscr{L}, \mathscr{B}(\mathscr{X}))$ - измеримое пространство. В дальнейшем часто $\mathscr{L}$ с танд артно е измеримое пространство, т. е. борелевское подмножество полного сепарабельного метрического пространства. Стандартные измеримые пространства одинаковой мощности изоморфны (см., например, [160, гл. V]), поэгому с точки зрения теории меры они эквивалентны борелевским подмножествам вещественной прямой $\mathbf{R}$.

Разложением единицы в гильбертовом пространстве $\mathscr{H}$ называется нормированная положительная операторнозначная ме- ра на $\mathscr{B}(\mathscr{X})$, т. е. функция множеств $\mathbf{M} : \mathscr{B}(\mathscr{X}) \to \mathscr{B}(\mathscr{C})$, удовлетворяющая условиям:

1. $M(B)$ - положительный оператор в $\mathscr{H}$ для любого $B \in \mathscr{B}(\mathscr{H})$;
2. Если $\{B_j\}$ - конечное или счетное разбиение $\mathscr{Z}$ на попарно-непересекающиеся измеримые подмножества, то

$$\sum_j M\left(B_j\right) = \mathrm{I}$$

где ряд сходится сильно.

Если $M(B)^2 = M(B)$ для всех $B \in \mathscr{B}(\mathscr{D})$, то $\mathbf{M}$ - ортогональное разложение единицы (см. п. 1.1.3). Неортогональные разложения единицы (на R) появились в работе арлемана (1923), в связи с проблемой спектрального разложения несамосопряженных операторов и были детально изучены в 1940-60-е годы (см., например, [2], [30], [68]).

Т е о ре м а (М. А. Наймарк, 1940). Всякое разложение единицы в $\mathscr{C}$ может быть расширено до ортогонального разложения единицы, т. е. существует гильбертово пространство $\tilde{\mathscr{H}} \supset \mathscr{H}$ и ортогональное разложение единицы $\mathrm{E} : \mathscr{B}(\mathscr{X}) \to (E)(\widetilde{\mathscr{C}})$ в $\widetilde{\mathscr{H}}$ такое, что

$$M(B) = PE(B)P; \quad B \in \mathscr{B}(\mathscr{R})$$

где P-проектор из $\tilde{\mathscr{H}}$ на $\mathscr{H}$. Если $\mathscr{H}$ - сепарабельно, а $\mathscr{X}$ - стандартно, то $\tilde{\mathscr{H}}$ можно выбрать сепарабельным. Существует единственное с точностью до унитарной эквивалентности минимальное расширение, характеризующееся тем свойством, что множество $\{E(B)P\psi; B \in \mathscr{B}(\mathscr{X}), \psi \in \mathscr{C}\}$ плотно в $\widetilde{\mathscr{H}}$.

Если существует σ-конечная мера μ, такая что $\|M(B)\| \leqslant \leqslant C\mu(B)$, то

$$M(B) = \int\limits_B P(x)\mu(dx); \quad B \in \mathscr{B}(\mathscr{X})$$

где $P(x)$ - измеримая ограниченная функция со значениями в $\mathscr{P}(\mathscr{C})$, называемая плотностью $\mathbf{M}$ относительно меры μ (интеграл сходится в сильной операторной топологии). Если $\dim \mathscr{H} = \infty$, то ортогональное разложение единицы не может иметь. плотности относительно какой-либо б-конечной меры.

Пр им ер. Переполненной системой [21], [6] в $\mathscr{C}$ называется семейство $\{e_x; x \in \mathscr{Q}\} \subset \mathscr{H}$, удовлетворяющее условию

$$\|\psi\|^2 = \int\limits_{\mathscr{Q}} |\langle e_x|\psi\rangle|^2 \, \mu(dx); \quad \psi \in \mathscr{E}$$

где μ - некоторая σ-конечная мера на $\mathscr{B}(\mathscr{L})$, т. е.

$$\int\limits_{\mathscr{X}} |e_x\rangle \langle e_x| \, \mu(dx) = 1$$

Частным случаем переполненной системы является полная ортогональная система в $\mathscr{C}$, однако в обшем случае векторы $e_{\boldsymbol{x}}$ могут быть не ортогональны и линейно зависимы. Всякий вектор $\psi \in \mathscr{H}$ имеет разложение

$$\psi = \int\limits_{\mathscr{Q}} \langle e_x|\psi\rangle \, e_{x\mu}(dx)$$

по векторам переполненной системы. Соотношение

$$M(B) = \int\limits_{B} |e_x\rangle \langle e_x| \, \mu(dx)$$

.орределяет разложение единицы с плотностью $P(x) = |e_x\rangle \langle e_x|$. Дадим для него явную конструкцию минимального расширения Наймарка (см. [78, гл. 8]). Определим ортогональное разложение единицы $\mathbf{E}$ в $\tilde{\mathscr{H}} = L^2(\mathscr{X}, \mu)$ соотношением

$$E(B)f(x) = 1_B(x)f(x); x \in \mathscr{B},$$

где $1_B(\cdot)$ - индикатор множества $B \in \mathscr{B}(\mathscr{X})$. В (1.2), (1.3) следует, что соотношение

$$(V\psi)(x) = \langle e_x|\psi\rangle$$

задает изометрическое вложение $\mathscr{H}$ в $\mathscr{C}$, причем

$$M(B) = V^* E(B) V$$

Образ $V\mathscr{H}$ пространства $\mathscr{H}$ в $L^2(\mathscr{L}, \mu)$ является гильбертовым пространством с воспроизводящим ядром $\mathscr{K}(x, y) = \langle e_x|e_y\rangle$, т. е. проектор P из $L^2(\mathscr{Q}, \mu)$ на $V\mathscr{H}$ является интегральным оператором с ядром $\mathscr{K}(x, y)$.

1.2

Обобщенная статистическая модель квантовой механики. Это отделимая статистическая модель (см. п. 0.2), в которой состояния описываются операторами плотности, а вещественные наблюдаемые - разложениями единицы на $\mathscr{B}(\mathbf{R})$ в гильбертовом пространстве $\mathscr{C}$. Функциональная подчнненность наблюдаемых определяется соотношением $(f \circ M)(B) = M\,(f^{-1}(B))$. Если $\mathscr{X}$ - измеримое пространство, то обобщенной наблюдаемой (наблюдаемой) со значениями в $\mathscr{X}$ называется произвольное (ортогональное) разложение единицы $\boldsymbol{M}$ на $\mathscr{B}(\mathscr{X})$.

Распределение вероятностей обобщенной наблюдаемой $\mathbf{M}$ в состоянии S определяется формулой

$$\mu_S^M(B) = \operatorname{Tr} SM(B); \quad B \in \mathscr{B}(\mathscr{X}).$$

Основанием для этих определений служит

П редлож ен и е ([143, гл. 2]). Соответствие $S \to \mu_S^M$ является аффинным отображением выпуклого множества квантовых состояний $\subseteq (\mathscr{C})$ в множество вероятностных мер $\mathfrak{B}(\mathscr{L})$. Обратно, всякое аффинное отображение из $(\mathscr{H})$ в $\mathfrak{B}(\mathscr{X})$ имеет вид $S \to \mu_S^M$, где $\mathbf{M}$ - однозначно определенное разложение единицы на $\mathscr{B}(\mathscr{X})$.

Аффинность означает, что смесь состояний переходит в соответствующую смесь распределений

$$\mu^M_{\sum p_j s_j} = \sum_j p_j \mu^M_{s_j}$$

для любых $S_j \in \operatorname{Im}(\mathscr{H}); p_j \geqslant 0, \Sigma_j p_j = 1$, и имеет прямое истолкование в терминах статистических ансамблей. Можно сказать, что разложение единицы дает наиболее общее описание статистики исходов квантового измерения, совместимое с вероятностной интерпретацией квантовой механики.

Опираясь на теорему Наймарка, можно доказать, что для любого разложения единицы $\mathbf{M}$ в $\mathscr{C}$ найдутся гильбертово пространство $\mathscr{C}_0$, оператор плотности S_0 в $\mathscr{C}_0$ и ортогональное разложение единицы E в $\mathscr{H} \otimes \mathscr{H}$, такие что

$$\mu_S^M(B_3) = \operatorname{Tr}(S \otimes S_0) E(B); \quad B \in \mathscr{B}(\mathscr{Q})$$

для всех $S \in ((\mathscr{H})$ или $M(B) = \mathscr{E}_0(E(B))$, где $\mathscr{E}_0$ - условное ожндание относительно состояния S_0, определяемое аналогично формуле (1.3.1). Таким образом, разложение единицы описывает статистику измерения обычной наблюдаемой в некотором расширении исходной системы, содержащем вспомогательную независимую систему в состоянии S_0, что говорит о согласованности понятия обобщенной наблюдаемой со стандартной формулировкой квантовой механики.

Пр и м е р. Векторы состояний минимальной определенности (1.2.15) образуют переполненную систему в $\mathscr{H} = L^2(\mathbf{R})$,

$$\frac{m}{2\pi} \int\limits_{R^2} \int\limits_{x,v} |\psi_x\rangle \langle\psi_{x,v}| \, dxdv = \mathrm{I}$$

([12], [21]), что позволяет определить обобщенную наблюдаемую. со значениями в $\mathbf{R}^2$

$$M(B) = \frac{m}{2\pi} \iint_B |\psi_{x,v}\rangle \langle\psi_{x,v}| \, dxdv$$

Укажем конструкцию, которая связывает M с приближенным совместным измерением координаты и скорости квантовой частицы. Пусть $\mathscr{C}_0 = L^2(\mathbf{R}), P_0, Q_0$ - канонические наблюдаемые в $\mathscr{C}_0$ и $S_0 = |\psi_{0,0}\rangle \langle\psi_{0,0}|$ - основное состояние в $\mathscr{C}_0$. Самосопряженные операторы

$$\tilde{Q} = Q \otimes \mathrm{I}_0 - \mathrm{I} \otimes Q_0, \quad \frac{1}{m}\widetilde{P} = \frac{1}{m}\left[P \otimes \mathrm{I}_0 + \mathrm{I} \otimes P_0\right]$$

в $\mathscr{H} \otimes \mathscr{H}_0$ перестановочны [1)], а значит, имеют совместную спектральную меру $E(dxdv)$. Используя аппарат характеристических

1. На эо указал Н. Бор в статье «О понятиях причинности и дополнительности» (1948) (см. Избранные научные труды.- М.: Наука, 1971.- 2.С. 391 – 398). функций из п. 1.2.4, можно доказать, что для любого состояния: распределение вероятностей обобщенной наблюдаемой (1.6)

$$\mu_S^M(B) = \frac{m}{2\pi} \int\limits_B \int\limits_{x,v} \langle \psi_x \psi_{x,v} \rangle \, dxdv$$

удовлетворяет соотношению (1.5), т. е. совпадает с совместным распределением вероятностей наблюдаемых $\widetilde{Q}, \widetilde{P}/m$ в состоянии $S \otimes S_0$ (см. [43, гл. 3]). Относительно приближенных измерений Q, P см. также [78], [37], [159] и цитированные там работы.

1.3

Геометрия множества обобщенных наблюдаемых. Аналогом обобщенной наблюдаемой в классической статистике является рандомизованная случайная величина, т. е. переходная вероятность $\Pi(B|\omega)$ из пространства элементарных событий Ω в пространстве значений X. Будем далее предполагать, что $\mathscr{X}$ - стандартное пространство. Тогда соотношение

$$\Pi(B|\omega) = 1_B(f(\omega)); \quad \omega \in \Omega$$

устанавливает взаимно однозначное соответствне между случайными величинами f со значениями в $\mathscr{X}$ и де те р мини ров анными переходными вероятностями, такими что $\Pi(B|\omega) = 0$ или 1, т. е. $\Pi(B|\omega)^2 = \Pi(B|\omega)$. Переходные вероятности из Ω в $\mathscr{L}$ образуют выпуклое множество, крайними точками которого являются детерминированные переходные вероятности и только они (см., например, [41, гл. II]).

Соотношение между наблюдаемыми и обобщенными наблюдаемыми в квантовом случае значительно сложнее и интереснее. Обозначим $\mathfrak{M}(\mathscr{Q})$ выпуклое множество обобщенных наблюдаемых со значениями в $\mathscr{Q}$, $\operatorname{Extr}\mathfrak{M}(\mathscr{X})$ множество его крайних точек, $\operatorname{Conv}\mathfrak{M}$ выпуклую оболочку подмножества $\mathfrak{R} \subset \mathfrak{M}(\mathscr{Q})$. В $\mathfrak{M}(\mathscr{Q})$ вводится естественная топология: последовательность $\left\{\mathbf{M}^{(n)}\right\} \subset \mathfrak{M}(\mathscr{Z})$ сходится к $\boldsymbol{M}$, если для любого состояния S последовательность вероятностных мер $\mu_s^{(n)}(B) = \operatorname{Tr} SM^{(n)}(B)$ сходится по вариацин к $\mu_{\mathcal{S}}(B) = \operatorname{Tr} SM(B); \overline{\mathfrak{M}}$ означает замыкание подмножества $\mathfrak{M}$ в этой топологии. Пусть $\mathfrak{M}_0(\mathscr{Q})$ - подмножество обычных наблюдаемых и $\mathfrak{R}_1(\mathscr{Q})$ - подмножество обобщенных наблюдаемых $\mathbf{M}$, таких что $[M(B_1), M(B_2)] = 0$ для всех $B_1, B_2 \in \mathscr{B}(\mathscr{X})$. В работе А. С. Холево [38] показано, что $\boldsymbol{M} \in \mathbb{R}_1(\mathscr{X})$ тогда и только тогда, когда

$$M(B) = \int\limits_{\mathscr{X}_1} \Pi(B|x_1) \, E(dx_1)$$

где $\mathbf{E}$ - наблюдаемая со значениями в некотором пространстве $\mathscr{Q}_1, \Pi(B|x_1)$ - переходная вероятность из $\mathscr{X}_1$ в $\mathscr{X}$. По аналогии с классической статистикой, наблюдаемые, описываемые ортогональными разложениями единицы $\mathbf{E}\,(E(B)^2 = E(B))$, можно рассматривать как де терминированны е (более точное обсуждение см. в [101]). Наблюдаемые из $\mathfrak{R}_1(\mathscr{Q})$, кото- рые задаются перестановочными разложениями единицы, являются классически-рандомизованными в том смысле, что $M \in \mathbb{R}_1(\mathscr{Q})$ получается из обычной наблюдаемой путем преобразования (1.8), содержащего внешний классический источник неопределенности. Всякую обобщенную наблюдаемую $\boldsymbol{M} \in \mathfrak{M}(\mathscr{Z})$ можно рассматривать как квантово-рандомизованжую в смысле представления (1.5): она

эквивалентна обычной наблюдаемой в расширении исходной системы, включающем независимую квантовую систему. Наконец, точки из $\operatorname{Extr}\mathfrak{R}(\mathscr{Q})$ представляют собой обобщенные наблюдаемые, в которых неопределенность, обусловленная процедурой измерения, сведена к минимуму.

Обозначим m мощность множества значений $\mathscr{X}$.

Т е о рема. Если $m=2$, то $\mathfrak{R}_0(\mathscr{Q})=\operatorname{Extr}\mathfrak{M}(\mathscr{D})$ и $\mathfrak{M}_1(\mathscr{Q})=\overline{\operatorname{Conv}\mathfrak{R}_0(\mathscr{L})}=\mathfrak{R}(\mathscr{L})$. Если $m>2$, то $\mathfrak{R}_0(\mathscr{L})\subsetneq\operatorname{Extr}\quad\mathfrak{R}(\mathscr{X})$ и

$$\mathfrak{M}_1(\mathscr{B})\subsetneq\overline{\operatorname{Conv}\mathfrak{M}_0(\mathscr{B})}\subset\mathfrak{M}(\mathscr{B}),\quad\text{причем}\quad\text{если}\quad\dim\mathscr{H}<\infty,\quad\text{то}$$

последнее включение точн. Если же $\dim\mathscr{H}=\infty$, то $\overline{\mathfrak{M}_0(\mathscr{B})}=\mathfrak{M}(\mathscr{Q})$.

Таким образом, ситуация аналогична классической лишь в случае обобщенных наблюдаемых с двумя значениям [1)]. В этом случае $\boldsymbol{M}=\{M_0,M_1\}$, где $M_1=\mathrm{I}-M_0$ и $\mathfrak{R}(\mathscr{Q})$ как выпуклое подмножество изоморфно порядковому интервалу $\{M_0: M_0\mathfrak{L}_h(\mathscr{H}),\ 0\leqslant M_0\leqslant\mathrm{I}\}$, крайние точки которого совпадают с проекторами в $\mathscr{H}$ (см., например, [78, гл. 2]).

Чтобы доказать, что $\mathfrak{D}_0(\mathscr{P})\neq\operatorname{Extr}\mathfrak{M}(\mathscr{L})$ при $m>2$, достаточно сделать это в случае $m=3$ и $\dim\mathscr{H}=2$ (см. [43, §1.6]). Рассмотрим неортогональное разложение единицы

$$M_k=\frac{1}{3}\left|\psi\left(\mathrm{e}_k\right)\right\rangle\left\langle\psi\left(\mathrm{e}_k\right)\right|;k=1,2,3$$

где $\psi\left(\mathrm{e}_k\right)$ - векторы состояний системы со спином $1/2$ (см. п. 1.1.6), причем $\mathrm{e}_k, k=1,2,3$, образуют правильный треугольник. Тот факт, что (1.9) является крайней точкой, можно установить непосредственно, либо воспользовавшись критерием из статьи Штермера.в [85]: конечное разложение единицы $\mathbf{M}=\{M_1,\ldots,M_m\}$ является крайней точкой тогда и только тогда, когда для любых $X_1,\ldots,X_m\in\mathscr{B}(\mathscr{H})$ из $\sum\limits_{i=1}^{m}E_iX_iE_i=0$ следует $E_iX_iE_i=0$, где E_i - носитель M_i, т. е. проектор на ортогональное дополнение к нулевому подпространству M_i. Если $\dim\mathscr{H}<\infty$, то из наличия крайних точек, не попадающих в $\mathfrak{D}_0(\mathscr{Q})$, следует, что $\overline{\operatorname{Conv}\mathfrak{M}_0(\mathscr{X})}\neq\mathfrak{M}(\mathscr{X})$.

Интересный пример крайней точки дает неортогональное разложение единицы (1.6).

1. Такие наблюдаемые, называемые «эффектами», играют центральную роль в аксноматическом подходе Людвнга [125], [118].

Доказательство того, что $\overline{\mathfrak{R}_0(\mathscr{X})}=\mathfrak{M}(\mathscr{Q})$ в случае $\dim\mathscr{H}=\infty$, основывается на теореме M. А. Наймарка. Пусть $\mathrm{M}\in\mathrm{M}(\mathscr{R})$ и $\left\{P^{(n)}\right\}$ - последовательность конечномерных проекторов в $\mathscr{H}$, снльно сходящаяся к I. Тогда $M^{(n)}(B)=P^{(n)}M(B)P^{(n)}$ - разложение единицы в конечномерном пространстве $\mathscr{C}^{(n)}=P^{(n)}\mathscr{H}$, которое можно расширить до ортогонального разложения единицы $\mathbf{E}^{(n)}$ в сепарабельном гильбертовом пространстве $\tilde{\mathscr{G}}^{(n)}\supset\supset\mathscr{H}^{(n)}$. Поскольку $\dim\mathscr{H}=\infty$, можно считать, что $\tilde{\mathscr{H}}^{(n)}=\mathscr{H}$. Имеет место оценка

$$\operatorname{var}\left(\mu_B^{(n)}-\mu_B\right)\leqslant 6\left\|\left(I-P^{(n)}\right)S\right\|_1,$$

где $\mu_s^{(n)}(B)=\operatorname{Tr}SE^{(n)}(B)$, $\mu_s(B)=\operatorname{Tr}SM(B)$ [44], доказывающая утверждение. Итак, в случае $\dim\mathscr{H}=\infty$, все обобщенные наблюдаемые являются предельными точками множества наблюдаемых.

12.2.2 2. The Quantum Theory of Statistical Solutions

2.1. Проверка гипотез.

В гильбертовом пространстве $\mathscr{H}$ наблюдаемой квантовой системы заданы операторы плотности S_θ; $\theta=1,\ldots,m$, описывающие одно из возможных состояний снстемы. Выбор

одной из гипотез $\theta = 1, \ldots, m$ осуществляется на основе решающего правила, задаваемого разложением единицы $\mathbf{M} = \{M_1, \ldots, M_m\}$. При этом вероятность принятия гипотезы $u = 1, \ldots, m$, если система находится в состоянии S_θ, равна

$$\xi_{\theta\theta}^M(u) = \operatorname{Tr} S_A M_u.$$

Как и в классической статистике, задается некоторый функционал от вероятностей (2.1) и вопрос состоит в нахождении экстремума этого функционала в том или ином классе решающих правил. В физических задачах квантовая система является носителем информации, состояния которого S_θ зависят от «передаваемого сигнала» θ. «Приемник» осуществляет квантовое измерение, статистика которого описывается разложением единнцы M в $\mathscr{C}$. Речь идет об отыскании квантовых ограничений на качество измерения и о его оптимизации.

При байесовском подходе задаются априорные вероятности гипотез π_θ и функция отклонения $W_\theta(u); \theta, u = 1, \ldots, m$. Байесовский риск определяется обычной формулой

$$\mathscr{R}\{M\} = \sum_{\theta=1}^m \pi_\theta \sum_{u=1}^m W_\theta(u) \mu_\theta^M(u)$$

Решающее правило, минимизирующее $\mathscr{R}\{\mathbf{M}\}$, называется байесовским. Часто рассматривают случай $W_\theta(u) = 1 - \delta_{\theta u}$ и $\pi_\theta = 1/\mathrm{m}$. Тогда речь идет о максимизации средней вероятности правильного решения

$$\mathscr{P}\{\boldsymbol{M}\} = \frac{1}{m} \sum_{\theta=1}^m \mu_\theta^{\boldsymbol{M}}(\theta)$$

что является дискретным аналогом метода максимального правдоподобия. Наконец, важной мерой качества решающего правила является шенноновская информация

$$\mathscr{I}\{M\} = \sum_{\theta=1}^m \pi_\theta \sum_{u=1}^m \mu_\theta^M(u) \ln \frac{\mu_\theta^M(u)}{\sum\limits_{\lambda=1}^m \pi_\lambda \mu_\lambda^M(u)}.$$

Первоначальная постановка квантовой задачи различения гипотез (Хелстром, 1967) основывалась на стандартном квантово-механическом формализме, в соответствии с которым решающие правила описывались ортогональными разложениями единицы. Формулировка квантовой теории статистических решений, основанная на обобщенных наблюдаемых, была предложена А. С. Холево (1972). Обозначим $\mathfrak{P}$ класс всех решающих правил $\boldsymbol{M} = \{M_1, \ldots, M_m\}, \mathfrak{D}_1$ - класс классически-рандомизированных правил (т. е. таких, что $M_j M_k = M_k M_j$) и $\mathfrak{D}_0$ - класс детерминированных решающих правил ($M_j M_k = \delta_{jk} M_j$).

П р и м е р ([38]). Рассмотрим задачу различения равновероятных гипотез

$$S_\theta = |\psi(\mathrm{e}_\theta)\rangle \langle \psi(\mathrm{e}_\theta)|; \quad \theta = 1, 2, 3$$

где $\psi(\mathrm{e}_\theta)$ - векторы состояний системы со спином $1/2$, возникающие в (1.9). Тогда

$$\max_{\mathbb{N}_0} \mathscr{P}\{\boldsymbol{M}\} = \max_{\mathfrak{N}_1} \mathscr{P}\{\boldsymbol{M}\} = \frac{1}{6}(2 + \sqrt{3}) < \frac{2}{3} = \max_{\mathscr{N}} \mathscr{P}\{\boldsymbol{M}\}$$

причем максимум достигается на решающем правиле (1.9). Более того,

$$\max_{\mathfrak{M}_0} \mathscr{F}\{\mathbf{M}\} = \max_{\mathfrak{M}_1} \mathscr{F}\{\mathbf{M}\} < \max_{\mathscr{N}} \mathscr{F}\{\mathbf{M}\}$$

Этот и другие подобные примеры (см. [80]) демонстрируют неожиданный с классической точки зрения факт: квантовая рандомизация может увеличивать информацию о состоянии системы. Хотя этот эффект проявляется только в конечномерных гильбертовых пространствах (см. предыдущий пункт), он ясно указывает на необходимость использования обобщенных наблюдаемых.

2.2. Байесовская задача. Байесовский риск (2.2) представляется в виде

$$\mathscr{R}\{\mathbf{M}\} = \operatorname{Tr} \sum_{u=1}^{m} \hat{W}_u M_u$$

где $\hat{W}_u = \sum\limits_{\theta=1}^{m} \pi_\theta W_\theta(u) S_\theta$-операторная апостериорная функция отклонения. Поскольку $\mathscr{R}\{\boldsymbol{M}\}$ - аффинный функционал на выпуклом множестве $\mathfrak{M}$, задача о его минимизации может быть рассмотрена с помощью методов линейного программирования.

Т е о рем а (А. С. Холево, Юн). Имеет место соотношение двойственности

$$\min_{\mathfrak{M}} \mathscr{R}\{M\} = \max \left\{ \operatorname{Tr} \Lambda : \Lambda \in \mathfrak{T}(\mathscr{C}), \Lambda \leqslant \hat{W}_u; u = 1, \ldots, m \right\}$$

Следующие утверждения эквивалентны:

0. $\mathbf{M}^0 = \{{M_u}^0\}$ - байесовское решающее правило;

1. существует $\Lambda^0 \in \mathfrak{E}(\mathscr{H})$, такой что

$$\Lambda^0 \leqslant \hat{W}_u; \quad \left(\hat{W}_u - \Lambda^0\right) M_u^0 = 0; \quad u = 1, \ldots, m$$

2. оператор $\Lambda^0 = \sum\limits_{u=1}^{m} \hat{W}_u {M_u}^0$ эрмитов и $\Lambda^0 \leqslant \hat{W}_u; u = 1, \ldots, m$.

Задача в правой части (2.5) имеет единственное решение, которым является оператор Λ^0, входящий в условия 1), 2).

Наиболее часто используется достаточность условня 1), которая доказывается элементарно: для любого $\mathbf{M} = \{M_u\}$

$$\mathscr{R}\{\mathbf{M}\} = \operatorname{Tr} \sum_{u=1}^{m} \hat{W}_u M_u \geqslant \operatorname{Tr} \Lambda \sum_{u=1}^{m} M_u^0 = \operatorname{Tr} \sum_{u=1}^{m} \hat{W}_u M_u^0 = \mathscr{R}\left\{\mathbf{M}^0\right\}$$

С помощью этого условия легко проверяется оптимальность решающего правила (1.9) в примере предыдущего пункта,

П риме р 1. Пусть операторы $\hat{W}_u - \hat{W}_v; u, v = 1, \ldots, m$, перестановочны, т. е. $\hat{W}_u = C + {\hat{W}_u}^0$, где $\hat{W}_u^0$ - перестановочные операторы. Тогда существует самосопряженный оператор. $\ddot{\wedge}$ и функции $\hat{W}_u^0(x)$ на R, такие что

$$\hat{W}_u^0 = \hat{W}_k^0()$$

Пусть $\{\mathscr{X}_k\}$-разбиение R, такое что $\hat{W}_k^0(x) \leqslant {\hat{W}_j}^0(x)$ при $x \in \mathscr{X}_k, \quad j \neq k$, и положим $\Lambda^0 = C + \min_k {\hat{W}_k}^0(X), {M_k}^0 = 1\mathscr{X}_k(X)$. Тогда условия 1) выполнены. Если $C^k = 0$, то это соответствует вычислению байесовского решающего правила в классической статистике: правило является детерминированным и для каждого x предписывает выбирать решение u, для которого апостериорное отклонение $\hat{W}_u(x)$ минимально [37, гл. IV].

П р и м е р 2. Условия предыдущего примера автоматически выполняются в случае двух гипотез S_0, S_1. Для простоты рассмотрим функцию потерь $W_\theta(u) = 1 - \delta_{\theta u}$, так что речь идет минимизации средней ошибки. Байесовское решающее правило имеет 'вид

$$M_0^0 = 1_{(0,\infty)}\left(\pi_0 S_0 - \pi_1 S_1\right), \quad M_1^0 = 1_{(-\infty,0]}\left(\pi_0 S_0 - \pi_1 S_1\right)$$

и минимальная ошибка

$$\mathscr{R}\left\{\mathbb{M}^0\right\} = \frac{1}{2}\left(1 - \left\|\pi_0 S_0 - \pi_1 S_1\right\|_1\right)$$

Если S_0, S_1-чистые состоя ния с векторами ψ_0, ψ_1, то

$$\mathscr{R}\left\{\mathbf{M}^0\right\} = \frac{1}{2}\left(1 - \sqrt{1 - 4\pi_0\pi_1\left|\langle\psi_0|\psi_1\rangle\right|^2}\right).$$

В общем случае уравнения оптимальности сводятся к сложной нелинейной задаче, часто геометрического характера. Много интересных явно решаемых случаев, в которых условия примера 1 не выполняются, рассмотрено Хелстромом [37], Р. Л. Стратоновичем [155] и В. П. Белавкиным [63]. Остано.вимся на задаче различения m чистых состояний с линейно независимыми векторами ψ_θ и априорными вероятностями $\pi_\theta > 0$. Можно считать, что $\mathscr{H}$ порождается векторами $\psi_\theta; \theta = 1, \ldots, m$. Кеннеди показал, что в этом случае байесовское решающее.правило имеет вид

$$M_u = |e_u\rangle\langle e_u|; u = 1, \ldots, m$$

где $\{e_u\}$ - некоторый ортонормированный базис в $\mathscr{H}$ (см. [37, гл. IV]). Таким образом, задача сводится к нахождению ортонормированного базиса, наилучшим образом приближающего систему $\{\psi_u\}$ в смысле критерия

$$\mathscr{R}\{\mathbf{M}\} = \sum_{\theta=1}^{in} \pi_\theta\left(1 - \left|\langle\psi_\theta|e_\theta\rangle\right|^2\right)$$

В [63] из общих условий оптимальности 1), 2) получено нелинейное уравнение для базиса $\{e_u\}$ и указан случай, когда оно решается явно. Пусть диагональные элементы матрицы $Q^{1/2}$, где $Q = \left[\sqrt{\pi_j\pi_k}\langle\psi_j|\psi_k\rangle\right]_{j,k=1}, \ldots, m$, совпадают и равны $\sqrt{q}$. Тогда оптимальный базис

$$e_k = \sum_{j=1}^{m} \sqrt{\pi_j}\lambda_{jk}\psi_j$$

где $[\lambda_{jk}] = Q^{1/2}$, причем минимальная ошибка

$$\min \mathscr{R}\{\boldsymbol{M}\} = 1 - mq$$

В частности, в «равноугольном» случае, когда $\langle\psi_j|\psi_k\rangle \equiv \gamma$ при $j \neq k$, а $\pi_\theta = 1/m$, получается формула Юна-Лэкса

$$\min \mathscr{R}\{\mathbf{M}\} = \frac{m-1}{m^2}(\sqrt{1 + (m-1)\gamma} - \sqrt{1-\gamma})^2$$

А. С. Холево заметил [42], что в случае р а в н о в е роятны Х чистых состояний имеет место оценка

$$\mathscr{R}\{M\} \leqslant \frac{1}{m}\sum_{\theta=1}^{m} \left\|\psi_\theta - e_\theta\right\|^2$$

Базис, минимизирующий правую часть, имеет вид

$$e_k = \sum_{j=1}^{m} a_{kj}\psi_j$$

где $[a_{yk}] = \Gamma^{-1/2}$ и $\Gamma = [\langle\psi_j|\psi_k\rangle]$, причем

$$\min_{\{e_\theta\}} \sum_{\theta=1}^{m} \|\psi_\theta - e_\theta\|^2 = \operatorname{Tr}\left(I - \Gamma^{1/2}\right)^2 = 2\operatorname{Tr}\left(I - \Gamma^{1/2}\right)$$

(теорема М. Г. Крейна). Отсюда.

$$\min \mathscr{R}\{M\} \leqslant \frac{1}{m}\operatorname{Tr}\left(I - \Gamma^{1/2}\right)^2$$

Решающее правило, отвечающее базису (2.8), асимптотическі оптимально в пределе почти ортогональных состояний, $\Gamma \to \mathrm{I}_3$ причем правая часть в (2.9) дает первый член асимптотики. В «равноугольном» случае (2.9) обращается в равенство.

2.3. Пропускная способность квантового канала связи. Набор операторов плотности $\{S_\theta\}$ определяет простейшую модель квантового канала связи (см. [39], [98]), для которого θ играет роль «сигнала», пробегающего входной алфавит $1, \ldots, \mathrm{m}$. Ко^2 дирование задается распределением вероятностей $\pi = \{\pi_\theta\}$: на входном алфавите, а декодирование-разложением единицы $\mathbf{M} = \{M_u\}$, где u пробегает выходной алфавит $1, \ldots, p$. Вероятность получить на выходе символ u при условии, что на входе сигнал θ, дается формулой (2.1). Таким образом, квантовый канал связи можно рассматривать как обычный канал со специфическими ограничениями на переходные вероятности, неявно выраженными формулой (2.1). Чему равна пропускная способность такого канала связи?

Рассмотрим информационное количество $\mathscr{I}_1(\pi, \mathbf{M})$, определяемое формулой типа (2.4) (где $\boldsymbol{u}$ пробегает от 1 до p) и величину $C_1 = \sup \mathscr{I}_1(\pi, M)$, где супремум берется по всевозможным кодированиям и декодированиям. В раниих работах для оценки пропускной способности использовалась величина

$$\bar{C} = \sup_{\pi}\left[H\left(\sum_{\theta=1}^{m}\pi_\theta S_\theta\right) - \sum_{\theta=1}^{m}\pi_\theta H\left(S_\theta\right)\right]$$

где $H(S) = -\operatorname{Tr} S\ln S$-энтропия фон Неймана квантового состояния S. В [40], [121] показано, что для любого кодиро- вания π и декодирования M

$$\mathscr{I}_1(\pi, \mathrm{M}) \leqslant H\left(\sum_{\theta=1}^{m}\pi_\theta S_\theta\right) - \sum_{\theta=1}^{m}\pi_\theta H\left(S_\theta\right)$$

причем если операторы S_θ неперестановочны, то неравенство строгое [1)]. По-видимому, при том же условии $C_1 \overline{< C}$, хотя в полной общности это не было установлено. Однако как показывают следующие рассуждения, величина C_1 также не может рассматриваться как пропускная способность.

Правильное определение пропускной способности должно быть связано с предельной скоростью асимптотически безошибочной передачи информации. Рассмотрим n-ю степень канала в пространстве $\mathscr{H}_n = \mathscr{C}^{\otimes^n}$, определя емую состояниями $S_v = S_{\theta_1} \otimes \ldots \otimes S_{\theta_n}$, где $v = (\theta_1, \ldots, \theta_n)$ - всевозможные слова входного алфавита длины n. Пусть $\mathscr{I}_n(\pi, \mathbf{M})$ и $C_n = \sup_{\pi;\mathrm{M}} \mathscr{I}_n(\pi, \mathbf{M})$ -

величины, определяемые для n-й степени канала аналогично $\mathscr{I}_1(\pi,\ \mathrm{M})$ и C_1. Информационное количество $\mathscr{I}_n(\pi,\ \mathrm{M})$ о бладает свойством аддитивности [40]

$$\sup_{M^{(n)},M^{(m)}} \mathscr{I}_{n+m}\left(\pi^{(n)}\times\pi^{(m)}, M^{(n)}\otimes M^{(m)}\right) =$$
$$= \sup_{M^{(n)}} \mathscr{I}_n\left(\pi^{(n)}, M^{(n)}\right) + \sup_{M^{(m)}} \mathscr{I}_m\left(\pi^{(m)}, M^{(m)}\right),$$

откуда следует, что последовательность $\{C_n\}$ субаддитивна, $C_n + C_m \leqslant C_{n+m}$, а следовательно, существует

$$C = \lim_{n\to\infty} C_n/n = \sup_n C_n/n.$$

Основываяссь на классической теореме кодирования, можно доказать, что при $R < C$ сушествугт такие кодирования и декодирования объема $N = \left[2^{nR}\right]$, что средняя ошибка

$$\bar{\lambda}(n,N) = \frac{1}{N}\sum_{j=1}^{N}\left(1 - \operatorname{Tr} S_{v_j} M_j\right)$$

стремится к нулю при $n\to\infty$, тогда как при $R > C$ она не стремится к нулю при любом выборе кодирования и декодирования [42]. Это дает основание назвать величину C пропускной способностью данного квантового канала связи.

Следует отметить, что для соответствующего классического канала «без памяти» последовательность $\{C_n\}$ аддитивна и поэтому $C \equiv C_n/_n = C_1$. Оказывается, что в квантовом случае возможно строгое неравенство

$$C_1 < C$$

1. Это утверждение было высказано Л. Б. Левитиным в 1969 г. что соответствует парадоксальному с классической точки зрения наличию «памяти» в произведении независимых каналов. Измерение в таком произведении может нести больше информации, чем сумма информаций, получаемых в каждой компоненте. Этот факт, разумеется, обусловлен необычными статистическими свойствами составных квантовых систем и является еще одним проявлением квантовой целостности.

Доказательство этого факта, данное в работе А. С. Холево [42], использует следующую оценку пропускной способности C для канала с чистыми состояниями $S_\theta = |\psi_\theta\rangle\langle\psi_\theta|$:

$$C \geqslant \tilde{C} \equiv -\ln\min_{\pi}\left[\sum_{j,k=1}^{m}\pi_j\pi_k\left|\langle\psi_j|\psi_k\rangle\right|^2\right]$$

в основе которой лежит неравенство (2.9) для средней ошибки и модифнкация метода случайных кодов, предложенная Р. Л. Стратоновичем и А. Г. Ванцян в [36]. Для двоичного канала ($m = 2$)

$$\widetilde{C} = 1 - \ln\left(1+\varepsilon^2\right) > 1 - \varepsilon^2/\ln 2,$$

где $\varepsilon = |\langle\psi_1|\psi_2\rangle|$. В случае «почти ортогональных состояний»

$$C_1 \leqslant 1 + \frac{1}{8}\varepsilon^2\ln\varepsilon^2 + o\left(\varepsilon^2\ln\varepsilon^2\right), \varepsilon\to 0$$

откуда следует (2.13) для достаточно малых ε.

В этой области остается ряд трудных нерешенных вопросов [98]. Определенная формулой (2.12) пропускная способность не вычислена в точном виде даже для двоичного канала. Ввиду серьезных аналитических трудностей, представляют большой

интерес всевозможные оценки и приближенные результаты (см. Бенджбаллах и Чарбит [67], В. П. Белавкин [63], Ингарден [110], Линдблад [121], Чемберс [74]). В общем случае $C \leqslant \bar{C}$, однако неизвестно, достигается ли здесь равенство для неперестановочных операторов плотности S_θ.

2.4. Общая формулировка. Как и в классической теории статистических решений [50], задается множество значений Θ неизвестного параметра θ, множество $\mathscr{X}$ решений x (часто $\mathscr{X} = \Theta$) и функция отклонения $W_\theta(x)$, определяющая качество решения x при данном значении параметра θ. Множество $\mathscr{X}$ измеримое (обычно стандартное) пространство и $W_\theta(x)$ ограничена снизу и измерима по x при фиксированном $\theta \in \Theta$.

Каждому значению θ соответствует оператор плотности S_θ в гильбертовом пространстве рассматриваемой квантовой системы, а решающее правило задается разложением единицы $\boldsymbol{M} : \mathscr{B}(\mathscr{X}) \to \mathscr{P}(\mathscr{C})$ в $\mathscr{H}$. Ортогональные разложения единицы описывают детерминированные решающие правила. При данном значении параметра θ и данном решающем правиле $\mathbf{M}$ решение выбирается в соответствии с распределением вероятно- стей

$$\mu_\theta^M(B) = \operatorname{Tr} S_\theta M(B); B \in \mathscr{B}(\mathscr{Q}).$$

Среднее отклонение, определяемое формулой

$$\mathscr{R}_\theta\{\mathbf{M}\} = \int\limits_{\mathscr{Q}} W_\theta(x)\mu_\theta^M(dx)$$

является для каждого $\theta \in \Theta$ аффинным функционалом на выпуклом множестве решающих правил $\mathfrak{R}(\mathscr{Q})$.

Решающее правило называется байесовским, если оно минимизирует байесовский риск

$$\mathscr{R}_\pi\{\mathbf{M}\} = \int\limits_{\Theta} \mathscr{R}_\theta\{\mathbf{M}\}\pi(d\theta)$$

для данного априорного распределения π на Θ, и минимаксньц, если оно минимизирует максимальное среднее отклонение $\max_\theta \mathscr{R}_\theta\{\mathbf{M}\}$. Как классическая, так и квантовая теории статистических решений включаются в общую схему, в которой состояния описываются точками произвольного выпуклого множества $\mathcal{S}$, причем значительная часть результатов классической теории Вальда переносится на эту схему, достигая естественных границ общности (А. С. Холево [41]). При минимальных требованиях на функцию отклонений установлены общие условия существования байесовского (Озава [133]) и минимаксного решающих правил, полнота класса байесовских решающих правил (Н. А. Богомолов [8]), аналог теоремы Ханта-Стейна [43], [8]. Обобщения понятия достаточности изучали Умегаки [158], А. С. Холево [41], Петц [139]. В силу ограниченности понятия условного ожидания, в квантовой теории статистических решений достаточность играет гораздо меньшую роль, чем в классической, зато на первый план выходят свойства инвариантности относительно подходящих групп симметрий (см. 3).

На основе соответствующего аппарата интегрирования в [41] получены необходимые и достаточные условия оптимальности и соотношение двойственности в байесовской задаче с произвольными $\Theta, \mathscr{X}$, обобщающие теорему из п. 2.2. Эти условия позволяют, в частности; дать исчерпывающее решение многомерной байесовской задачи оценивания среднего значения гауссовских состояний (В. П. Белавкин, Б. А. Гришанин [5], А. С. Холево [41]), которое иллюстрируется здесь одним при- мером.

В задаче оценивания $\Theta = \mathscr{Q}$ является конечномерным многообразием, в частности, областью в $\mathbf{R}^n$. В этом случае детерминированное решающее правило может быть

задано набором совместимых вещественных наблюдаемых $X_1, \ldots, X_n$ в $\mathscr{H}$. Согласно п. 1.2, произвольное решающее правило задается на56 бором совместимых наблюдаемых $X_1, \ldots, X_n$ в расширении $\mathscr{H}$ вида $\mathscr{H} \otimes \mathscr{H}_0$, где $\mathscr{H}_0$ - вспомогательное гильбертово пространство с оператором плотности S_0. При таком способе задания решающее правило называется оценкой многомерного параметра $\theta = (\theta_1, \ldots, \theta_n)$. В квантовой задаче оценивания, в отличие от классической, байесовские оценки могут оказаться существенно недетерминированными.

Пр и м е р. Пусть $\{S_{\alpha,\beta}; (\alpha, \beta) \in \mathbb{R}^2\}$ - семейство гауссовских состояний (см. п. 1.2.4) с характеристической функцией

где P, Q - канонические наблюдаемые, $\sigma^2 \geqslant \frac{1}{2}$. Рассмотрим байесовскую задачу оценивания параметра $\theta = (\alpha, \beta)$ с функцией отклонения

$$W_{\alpha,\beta}(\alpha', \beta') = g_1 (\alpha - \alpha')^2 + g_2 (\beta - \beta')^2$$

и гауссовским априорным распределением вероятностей с плот ностью $(2\pi)^{-1} \exp\left(-\frac{\sigma_0^2}{2}(\alpha^2 + \beta^2)\right)$. Решение этой задачи качественно зависит от величины g_1/g_2. Если $g_1/g_2 \leqslant (2s^2)^{-2}$ или $g_1/g_2 \geqslant\geqslant (2s^2)^2$, где $s^2 = \sigma^2 + \sigma_0^2$, то байесовские оценки детерминированы, т. е. задаются парой перестановочных самосопряженных операторов A, B в $\mathscr{C}$. В первом случае $A = \left(\frac{\sigma_0}{s}\right)^2 P, B = 0$, а во втором $A = 0, B = \left(\frac{\sigma_0}{s}\right)^2 Q$. Если же $(2s^2)^{-2} \leqslant g_1/g_2 \leqslant (2s^2)^2$, то оценки задаются перестановочными операторами

$$A = k_1 (P \otimes \mathrm{I}_0) + k_2 (\mathrm{I} \otimes P_0), B = k_2 (Q \otimes \mathrm{I}) - k_1 (\mathrm{I} \otimes Q_0)$$

в $\mathscr{H} \otimes \mathscr{H}_0$ (ср. (1.7)), где k_1, k_2-коэффициенты, нелинейно зависящие от s^2, g_1, g_2, а оператор плотности S_0 в $\mathscr{H}_0$ гауссовский и имеет характеристическую функцию

$$\operatorname{Tr} S_0 \exp[i (P_0 x + Q_0 y)] =$$
$$= \exp\left[-\frac{1}{4}\left(\sqrt{\frac{g_2}{g_1}}\frac{k_1}{k_2} x^2 + \sqrt{\frac{g_1}{g_2}}\frac{k_2}{k_1} y^2\right)\right]$$

Соответствующее разложение единицы в $\mathscr{H}$ отличается от (1.7) линейной заменой переменных. В отличие от аналогичной классической задачи, зависимость байесовского риска от весов g_1, g_2 также имеет существенно нелинейный характер.

2.5. Квантовые неравенства Рао-Крамера. Рассмотрим задачу оценивания в семействе состояний $\{S_\theta\}$, где $\theta = (\theta_1, \ldots \ldots, \theta_k) \in \mathbf{R}^k$. Решающее правило $\mathbf{M}$ назовем несмещенным, если для всех $\theta \in \Theta$

$$\int \ldots \int x_j \mu_\theta^M (dx_1 \ldots dx_k) = \theta_j; \quad j = 1, \ldots, k.$$

В предположении конечности вторых моментов определена матрица ковариации
$\mathbf{D}_\theta\{\boldsymbol{M}\} = \left[\int \ldots \int (x_i - \theta_i)(x_j - \theta_j) \mu_\theta^M (dx_1 \ldots dx_{*k})\right]; i, j = 1, \ldots, k.$

В классической статистике хорошо известно неравенство РаоКрамера, ограничивающее снизу матрицу ковариации несмещенных оценок. Входящая в эту границу информационная матрица Фишера однозначно определяется метрической геометрией симплекса «классических состояний», т. е. распределений вероятностей на пространстве элементарных событий Ω [50]. В квантовой статистике имеется много неэквивалентных неравенств типа Рао-Крамера, что связано с существенно более сложной геометрией множества состояний.

Поскольку неравенство Рао-Крамера имеет локальный характер, достаточно предполагать, что семейство состояний определено в окрестности фиксированной точки θ. Введем вещественное гильбертово пространство $L^2(S_\theta)$, определяемое как пополнение

множества $\mathfrak{P}_h(\mathscr{C})$ ограниченных вещественных наблюдаемых относительно скалярного произведения

$$\langle X, Y\rangle_\theta = \operatorname{Re}\operatorname{Tr} Y S_\theta X \equiv \operatorname{Tr} S_\theta X \circ Y,$$

где $X \circ Y = \frac{1}{2}(XY + YX)$ - йорданово произведение X, Y. Предположим, что

1. семейство $\{S_\theta\}$ сильно дифференцируемо в точке θ как функция со значениями в $\mathfrak{T}(\mathscr{C})$;
2. линейные функционалы $X \to \operatorname{Tr}\frac{dS_\theta}{d\theta}X$ непрерывны относительно скалярного произведения (2.15).

При этих условиях по теореме Ф. Рисса существуют симметризованнье логарифмические производные $L_\theta{}^j \in L^2(S_\theta)$, определяемые из условий

$$\operatorname{Tr}\frac{\partial S_\theta}{\partial \theta_j}X = \left\langle L_\theta^j, X\right\rangle, \quad \overline{X \in \mathfrak{B}_h}(\mathscr{H})$$

Формально,

$$\frac{\partial S_\theta}{\partial \theta_j} = S_{\theta^\circ L_\theta^j}$$

Тогда для любого решающего правила $\mathbf{M}$, имеющего конечные вторые моменты и удовлетворяющего условию лок а льной нес мещен но с ти

$$\int \ldots \int x_i \frac{\partial \mu_\theta^M}{\partial \theta_j}(dx_1 \ldots dx_k) = \delta_{ij}; \quad i, j = 1, \ldots, k$$

где $\frac{\partial \mu_\theta^M}{\partial \theta_j}(B) = \operatorname{Tr}\frac{\partial S_\theta}{\partial \theta_j}M(B)$, имеет место неравенство

$$\mathbf{D}_{\mathrm{e}}\{\mathbf{M}\} \geqslant \mathbf{J}_\theta^{-1}.$$

Здесь $\mathbf{J}_\theta = \left[\langle L_\theta{}^i, L_\theta{}^j\rangle_\theta\right]_{i,j=1,\ldots,k}$ - вещественная симметричная матрица - аналог информационной матрицы Фишера для симметризованной логарифмической производной.

С другой стороны, введем комплексные гильбертовы пространства $L_\pm{}^2(S_\theta)$ как пополнения $\mathscr{B}(\mathscr{H})$ относительно скалярных произведений

$$\langle X, Y\rangle_\theta^+ = \operatorname{Tr} X^* S_\theta Y, \langle X, Y\rangle_\theta^- = \operatorname{Tr} Y S_\theta X^*$$

и определим правую и левую логарифмические производнье $L_\theta{}^{\pm j}$ как решения уравнений

$$\operatorname{Tr}\frac{\partial S_\theta}{\partial \theta_j}X = \left\langle L_\theta^{\pm j}, X\right\rangle_\theta^\pm, \quad X \in \mathfrak{B}(\mathscr{H})$$

(существующие при тех же условиях 1), 2)). Формально

$$\frac{\partial S_\theta}{\partial \theta_j} = S_\theta L_\theta^{+j} = L_\theta^{-j} S_\theta$$

Тогда, при условии (2.18)

$$\mathbf{D}_\theta\{\mathbf{M}\} \geqslant \left(\mathbf{J}_\theta^\pm\right)^{-1}$$

где $\mathbf{J}_\theta^\pm = \left[\left\langle L_\theta^{\pm i}, L_\theta^{\pm j}\right\rangle_\theta^\pm\right]_{i,j=1,\ldots,k}$-комплексные эрмитовы матрицы, и (2.20) рассматривается как неравенство для эрмитовых матриц.

Формальное определение (2.17), симметризованной логарифмической пронзводной и неравенство (2.19) принадлежит Хелстрому, а неравенство (2.20) - Юну и Лэксу (см. [37, гл. VIII]). Другие неравенства были получены Р. Л. Стратоновичем [155]. Математически корректные определения логарифмических производных и вывод соответствующих неравенств дан в книге [43, гл. VI]. Пространства L^2, ассоциированные с квантовым состоянием, полезны и в других вопросах. Элементы этих пространств могут быть интерпретированы как (классы эквивалентности) неограниченных операторов в $\mathscr{C}$ ([43, гл. II]).

Неравенства (2.19), (2.20) дают существенно разлнчные, несравнимые границы для $\mathbf{D}_\theta\{\mathbf{M}\}$. В случае одномерного параметра ($k = 1$) всегда $J_\theta \leqslant J_\theta^\pm$, причем равенство имеет место тогда и только тогда, когда $\left[S_\theta, \frac{dS_\theta}{d\theta}\right] = 0$. В этом случае неравенство, основанное на симметризованной логарифмической произ- водной, оказывается наилучшим [37, гл. VIII]. С другой стороны; для двупараметрического семейства гауссовских состояний (2.14) неравенство (2.19) дает $\operatorname{Tr}\mathbf{D}_\theta\{\boldsymbol{M}\} \geqslant 2\sigma^2$, тогда как из. (2.20) вытекает $\operatorname{Tr}\mathbf{D}_\theta\{\mathbf{M}\} \geqslant 2\sigma^2 + 1$. Последняя граница достигается для несмещенных оценок, определяемых операторами типа (1.7). Неравенство (2.20), основанное на правой (или левой) логарифмической производной, вообще лучше приспособлено к задачам оценивания, в которых параметр допускает естественную комплексификацию (в последнем примере $\theta = \alpha + i\beta$).

Выражение

$$d\left(S_1, S_2\right) = \sqrt{2\left(1 - \left\|\sqrt{S_1}\sqrt{S_2}\right\|_1\right)}$$

определяет метрику в множестве операторов плотности $\subseteq (\mathscr{H})$. В более широком контексте алгебр фон Неймана эта метрика, известная как расстояние Бюреса, подробно изучалась Араки, Ульманом и др. (см. обзор Раджио в [141]). Если $\{S_\theta\}$-семейство, удовлетворяющее условиям 1), 2), то при $\Delta\theta \to 0$

$$d\left(S_\theta, S_{\theta+\Delta\theta}\right)^2 \approx \frac{1}{4}\sum_{i,j=1}^{k}\left\langle L_\theta^i, L_\theta^j\right\rangle_\theta \Delta\theta_i\Delta\theta_j$$

Таким образом, расстояние Бюреса эквивалентно в малом римановой метрике, определяемой квантовым аналогом информационной матрицы Фишера. Е. А. Морозова и И. Н. Ченцов в [35] описали всевозможные римановы метрики в $\subseteq (\mathscr{G})$ ($\dim\mathscr{H} < \infty$), монотонно инвариантные в категории марков-

ских морфизмов (аффинных отображений $\mathscr{C}(\mathscr{H})$ в себя). Ми-

нимальной в этом классе является риманова метрика в правой части (2.21).

12.2.3 3. Covariant Observables

3.1. Формулировка проблемы.

Пусть G - локально компактная группа, действующая непрерывно на транзитивном G-пространстве $\mathscr{X}$ и $\mathbf{V} : g \to V_g, g \in G$, - непрерывное (проективное) унитарное представление группы G в гильбертовом пространстве $\mathscr{H}$. Разложение единицы M: $B \to M(B), B \in \mathscr{B}(\mathscr{X})$ в $\mathscr{H}$ ковариантно по отношению k$\mathbf{V}$, если

$$V_g * M(B)V_g = M\left(g^{-1}B\right); g \in G, B \in \mathscr{B}(\mathscr{X})$$

В квантовой механике $\mathscr{L}$ является пространством значений физического параметра (обобщенной координаты) x, обладающего группой симметрий (движений) G. Фиксируем $x_0 \in \mathscr{X}$ и оператор плотности S_0. Соотношение

$$S_x = V_g S_0 V_g^*, \quad \text{где} \quad x = gx_0$$

описывает преобразование квантового состояния, отвечающее движению g. Рассмотрим обобщенную наблюдаемую M, удовлетворяющую условию ковариантности (3.1), и пусть $\mu_{:x}^M(B) = \operatorname{Tr} S_x M(B)$ - ее распределение вероятностей в состоянии S_x. Тогда условие (3.1) равносильно следующему:

$$\mu_{gx_0}^{\mathrm{M}}(gB) = \mu_{x_0}^{\mathrm{M}}(B); \quad B \in \mathscr{B}(\mathscr{X}), g \in G$$

для любого состояния S_0. Это означает, что статистика наблюдаемой M преобразуется согласно движениям g в пространстве обобщенной координаты $\mathscr{X}$ (см. пример в п. 1.2.3). Условие ковариантности, таким образом, дает правило для установления соответствия между классическими параметрами и квантовыми наблюдаемыми.

Такое соответствие является, конечно, далеко не однозначным. Среди множества ковариантных обобщенных наблюдаемых основной интерес представляют те, которые описывают предельно точные измерения соответствующего параметра. Рассмотрим задачу оценивания параметра $x \in \mathscr{X}$ в семействе состояний (3.2). Пусть на множестве $\mathscr{Z} = \Theta$ задана функция отклонения $W_\theta(x)$, такая что $W_{g\theta}(gx) = W_\theta(x)$. Среднее отклонение

$$\mathscr{R}_\theta\{M\} = \int_{\mathscr{X}} W_\theta(x) \mu_\theta^M(dx)$$

при условии (3.1) не зависит от θ. Минимум аффинного функционала (3.4) достигается в крайней точке выпуклого множества $\mathfrak{M}^{G,V}(\mathscr{P})$ ковариантных обобщенных наблюдаемых. Обозначим $\mathfrak{R}_0{}^{G,V}(\mathscr{Q})$ подмножество ковариантных наблюдаемых, задаваемых ортогональными разложениями единицы. Проглема соответствия в математическом плане сводится к изучению запаса элементов и структуры множеств $\mathfrak{M}_0^{G,V}(\mathscr{L}), \mathfrak{R}^{G,V}(\mathscr{X})$. В общем случае

$$\mathfrak{M}_0^{G,\mathrm{v}}(\mathscr{X}) \subsetneqq \operatorname{Extr} \mathfrak{M}^{G,\mathrm{v}}(\mathscr{X})$$

Целый ряд парадоксов в стандартной формулировке квантовой механики обусловлен тем, что множество $\mathfrak{M}_0{}^{G.V}(\mathscr{X})$ оказывается пустым. С другой стороны, Extr $\mathfrak{R}^G, V'(\mathscr{X})$ имеет значительно более обширный запас элементов, среди которых и находится обобщенная квантовая наблюдаемая, отвечающая данному классическому параметру.

3.2. Структура ковариантного разложения единицы. При специальных предположениях относительно $G, \mathscr{X}, \mathrm{V}$ можно дать прямое решение уравнения ковариантности (3.1), проливающее свет и на общий случай.

Пусть G - унимодулярна, а $G_0 = G/\mathscr{X}$ компактна, тогда на G существует σ-конечная инвариантная мера μ, а на $\mathscr{X}$ конечная инвариантная мера v, такая что $v(B) = \mu\left(\lambda^{-1}(B)\right)$, где $\lambda : g \to gx_0$.

Т е о рем а ([78], [43]). Пусть $\mathbf{V}$ - конечномерное представление группы G. Для любого ковариантного разложения единицы M найдется положительный оператор P_0, такой что $[P_0, V_g] = 0, g \in G_0$ и

$$M(B) = \int_B P(x) v(dx)$$

где плотность $P(x)$ определяется соотношением

$$P(gx_0) = V_g P_0 V_g^*$$

Дока з а тел и ство. Из тождества

$$\int_G \operatorname{Tr} V_g S V_g^* M(B)\mu(dg) = v(B), \quad S \in \Subset (\mathscr{H})$$

(см. [43, гл. IV]), полагая $S = (\dim \mathscr{H})^{-1}$ I, получаем $\operatorname{Tr} M(B) = (\dim \mathscr{H})^{-1} v(B)$. Поэтому существует плотность $P(x)$ со значениями в $\mathfrak{I}(\mathscr{H})$. Соотношение (3.5) вытекает из условия ковариантности.

Ограничение на P_0, вытекающее из условия нормировки $M(\mathscr{X}) = \mathrm{I}$, иногда удается выразить явно. Очень просто устроено множество $\mathfrak{R}^{G,V}(\mathscr{X})$ в случае, когда V есть неприводимое квадратично-интегрируемое представление ($\dim \mathscr{H} \leqslant +\infty$) унимодулярной группы $G = \mathscr{Q}$. Из соотношений ортогональности для V (см. [126]) следует, что при надлежащей нормировке μ

$$\int_G V_g S_0 V_{g\mu}^* (dg) = I$$

для любого оператора плотности S_0. Таким образом, формула

$$M(B) = \int_B V_g S_0 V_{g\mu}^* (dg)$$

устанавливает взаимно однозначное аффинное соответствие между $\mathfrak{R}^G$, $\mathrm{V}(G)$ и $\mathcal{S}(\mathscr{C})$. В частности, крайние точки множества $\mathfrak{R}^{G,V}(G)$ описываются формулой

$$M(B) = \int_B |\psi(g)\rangle\langle\psi(g)|\mu(dg)$$

где $\psi(g) = V_g\psi_0$, а ψ_0 - произвольный единичный вектор в $\mathscr{H}$. Семейство $\{\psi(g); g \in G\}$ образует переполненную систему, называемую в физике обобщенными когерентными состоямиями (обычные когерентные состояния отвечают неприводимому представлению ККС и специальному выбору вектора ψ_0, см. п. 1.2.4).

3.3. Обобщенные системы импримитивности. Если M в соотношении (3.1) ортогональное разложение единицы, то пара (V, M) называется системой импримитивности. Это понятие, введенное Дж. Макки (см. [126]), играет важную роль в теории представлений групп: представление V продолжается до системы импримитивности тогда и только тогда, когда оно индуцировано с подгруппы $G/\mathscr{X}$. Если же $\mathbf{M}$ - произвольное ковариантное разложение единицы, то (V, M) называется обобщенной системой импримитивности. Имеет место следующее обобщение теоремы М. А. Наймарка о расширении.

Те оре м а ([72], [148]). Пусть G - локально компактная группа, удовлетворяющая второй аксиоме счетности, $(\mathscr{X}, \mathscr{R}(\mathscr{D}))$ - стандартное измеримое пространство. Пусть $(\mathbf{V}, \mathbf{M})$ - обобщенная система импримитивности в $\mathscr{H}$, тогда существуют изометрическое вложение W пространства $\mathscr{C}$ в некоторое гильбертово пространство $\widetilde{\mathscr{H}}$ и система импримитивности $(\tilde{\mathbf{V}}, \mathrm{E})$ в $\widetilde{\mathscr{H}}$, такие что

$$V_g = W^* \tilde{V}_g W; \quad M(B) = W^* E(B) W$$

Если множество $\{E(B)W\psi|B \in \mathscr{B}(\mathscr{X}), \psi \in \mathscr{H}\}$ плотно в $\widetilde{\mathscr{H}}$, то $(\widetilde{V}, \mathrm{E})$ унитарно эквивалентно системе импримитивности, продолжающей представление в $\widetilde{\mathscr{H}} = L^2_{\mathscr{F}}(\mathscr{X},$ щ), индуцированное с подгруппы $\boldsymbol{G}/\mathscr{Q}^{1)}$.

Для иллюстрации рассмотрим пару $(\mathbf{V}, \mathbf{M})$, где $\mathbf{V}$ - неприводимое квадратично интегрируемое представление, $\boldsymbol{M}$ дается формулой (3.6). Искомое расширение в $\mathscr{C} = L^2(G, \mu)$ является модификацией конструкции для произвольной переполненной системы (см. п. 2.1.1), именно

$$\tilde{V}_g f(x) = f(gx); \quad E(B)f(x) = 1_B(x)f(x),$$

причем вложение W действует по формуле $W\psi(g) = \langle\psi(g)|\psi\rangle$. Подпространство $W\mathscr{H} \subset L^2(G, \mu)$ связано с воспроизводящим ядром $\mathscr{K}(g, g') = \langle\psi(g)|\psi(g')\rangle = \langle\psi_0|V(g^{-1}g')\psi_0\rangle$. Связь между обобщенными когерентными состояниями и индуцированными представлениями подробно исследовал Скутару [148]. В общем случае Каттанео [73] показал, что $\mathbf{M}$ имеет ограниченную плотность $P(x)$ относительно квазнинвариантной меры μ на $\mathscr{X}$ тогда и только тогда, когда подпространство $W\mathscr{H} \subset L^{\overset{\mathscr{K}}{2}}(\mathscr{X}, \mu)$ является гильбертовым пространством с воспроизводящим ядром (со значениями в $\mathscr{Y}(\mathscr{K})$).

3.4. Случай абелевой группы. Случай, когда $G = \mathscr{X}$ - абелева локально компактная группа, представляет интерес, в частности, в связи с проблемой канонической сопряженности в квантовой механике. Полное описание ковариантных разложений единицы для произвольного (непрерывного) представления V дается в терминах преобразования Фурье; при этом значения «плотности» $P(x)$ оказываются, вообще говоря, неограниченны-

1. $L^2\mathscr{K}(\mathscr{L}, \mu)$ обозначает гильбертово пространство функций на $\mathscr{L}$ со значениями в некотором гильбертовом пространстве $\mathscr{K}$, квадратично интегрируемых по мере μ. ми положительно-определенными формами. Излагаемые далее результаты могут быть получены как прямыми методами гармонического анализа, так и с помощью теоремы о расширении из предыдущего пункта (см. статью А. С. Холево в [141]). Обобщение на неабелевы группы типа I дано в работе [46].

Пусть $\hat{G}$-двойственная группа, $d\hat{g}$ - мера Хадра в $\hat{G}$.

Предложение 1. $\mathfrak{M}^{G,V}(G) \neq \varnothing$ тогда и только тогда,

когда спектр $\mathbf{V}$ абсолютно непрерывен относительно $d\hat{g}$.

Если это выполнено, то $\mathbf{V}$ разлагается в прямой интеграл факторных представлений, именно

$$\mathscr{H} = \int\limits_{\Lambda} \oplus \mathscr{H}(\lambda) d\lambda$$

где Λ-измеримое подмножество $\hat{G}, \{\mathscr{G}(\lambda); \lambda \in \Lambda\}$-измеримое семейство гильбертовых пространств с $\dim \mathscr{H}(\lambda) > 0$ для п. в. $\lambda \in \Lambda$, причем

$$V_g\psi = \int\limits_{\Lambda} \oplus \overline{\lambda(g)}\psi(\lambda)d\lambda, \text{ если } \psi = \int\limits_{\Lambda} \oplus \psi(-\lambda)d\lambda.$$

Здесь $\lambda(g)$−-начение характера $\lambda \in \hat{G}$ на элементе $g \in G$. Следующее утверждение вытекает из теоремы импримитивности Макки, которая обобщает теорему единственности Стоуна фон Неймана (п. 1.2.3).

Предложение 2. $\mathfrak{m}_0^{G,V}(G) \neq \varnothing$ тогда и только тогда, когда $\Lambda = \hat{O}$ с точностью до множества нулевой меры и $\dim \mathscr{H}(\lambda) = \text{const}$ для п. в. $\lambda \in \hat{G}$.

Ядром будем называть семейство $\{P(\lambda,\lambda');\lambda,\lambda'\in\Lambda\}$, где $P(\lambda,\lambda')$ - сжимающие операторы из $\mathscr{H}(\lambda')$ в $\mathscr{H}(\lambda)$, причем комплексная функция $\langle\varphi(\lambda)|P(\lambda,\lambda')\psi(\lambda')\rangle_\lambda$ измерима по мере $d\lambda\times d\lambda'$ для любjx $\varphi=\int\oplus\varphi(\lambda)d\lambda,\psi=\int\oplus\psi(\lambda)d\lambda\in\mathscr{H}$ ($\langle\cdot|\cdot\rangle_\lambda$ обозначает скалярное произведение в $\mathscr{H}(\lambda)$). Ядро положительно определено, если

$$\int\limits_\Lambda\int\limits_\Lambda\langle\varphi(\lambda)|P(\lambda,\lambda')\varphi(\lambda')\rangle_\lambda d\lambda d\lambda'\geqslant 0$$

для всех $\varphi\in\mathscr{C}_1=\left\{\varphi:\int\limits_\Lambda\|\varphi(\lambda)\|_\lambda d\lambda<\infty\right\}$. Для таких ядер однозначно с точностью до эквивалентности определяется диагональное значение $P(\lambda,\lambda)$ (см. [141]). Обозначим $1_B(\lambda)=\int\limits_B\lambda(g)dg$, где dg-мера Хаара в G.

Т е о р ема. Соотношение

$$\langle\varphi|M(B)\psi\rangle=\int\limits_\lambda\int\limits_\Lambda\langle\varphi(\lambda)|P(\lambda,\lambda')\varphi(\lambda')\rangle_\lambda\hat{1}_B(\lambda-\lambda')d\lambda d\lambda',$$

где B пробегает компактные подмножества в $G,\varphi,\psi\in\mathscr{H}_1$, устанавливает взаимно однозначное соответствие между ковариантными разложениями едниицы в $\mathscr{H}$ и кллассами эквивалентности положительно определенных ядер $\{P(\lambda,\lambda')\}$, таких что $P(\lambda,\lambda)=\mathrm{I}_\lambda$ (единичный оператор в $\mathscr{H}(\lambda)$).

Эта теорема сводит вопрос об описании множества $\operatorname{Extr}\mathfrak{R}^{G,V}(G)$ к нахождению крайних точек выпуклого множества положительно определенных ядер $\{P(\lambda,\lambda')\}$, удовлетворяющих условию $P(\lambda,\lambda)=\mathrm{I}_\lambda$. В полном объеме эта задача не решена даже для конечного Λ. Можно, однако, выделить подкласс множества $\operatorname{Extr}\mathfrak{R}^{G,V}(G)$, существенный для квантовомеханических приложений.

Для простоты ограничимся далее случаем, когда $\dim\mathscr{H}(\lambda)=\mathrm{const}$, $\lambda\in\Lambda$. Обозначим $\mathfrak{R}_c^{G,v}(G)$ класс ковариантных разложений единицы, ядра которых удовлетворяют соотношению

$$P(\lambda,\lambda')P(\lambda',\lambda'')=P(\lambda,\lambda'');\lambda,\lambda',\lambda''\in\Lambda$$

Если $\Lambda=G$, то этот класс совпадает с $\mathfrak{M}_0^{G,\mathrm{v}}(G)$, с другой стороны, $\mathfrak{M}_c^{G,\mathrm{v}}(G)\subset\operatorname{Extr}\mathfrak{M}^{G,\mathrm{v}}(G)$, причем совпадение имеет место только, если Λ состоит из двух точек. Все элементы $\mathfrak{M}_c^{G,\mathrm{v}}(G)$ получаются друг из друга калибровочными преобразованиями

$$M'(B)=U^*M(B)U$$

где $U=\int\limits_\Lambda\oplus U(\lambda)d\lambda$ - разложимый унитарный оператор в $\mathscr{H}=\int\limits_\Lambda\oplus\mathscr{H}(\lambda)d\lambda$.

Если реализовать $\mathscr{H}$ как $L^2_{\mathscr{K}}(\Lambda,d\lambda)$, где $\mathscr{H}(\lambda)\equiv\mathscr{K},\lambda\in\Lambda$, то в классе $\mathfrak{R}_c^{G,v}(G)$ выделяется разложение единицы M_c, определя емое ядром $P(\lambda,\lambda')\equiv\mathrm{I}_{\mathscr{K}}$ (единичный оператор в $\mathscr{K}^2$), для которого

$$\langle\psi|M_c(B)\varphi\rangle=\int\limits_\Lambda\int\limits_\Lambda\langle\psi(\lambda)|\varphi(\lambda')\rangle\hat{\mathscr{K}^{1_B}}(\lambda-\lambda')d\lambda d\lambda'$$

Всякое $M\in\mathfrak{R}_c^{G,v}(G)$ имеет ядро вида $U(\lambda)^*U(\lambda')$, где $\{U(\lambda)\}$-измеримое семейство унитарных операторов в $\mathscr{K}$.

3.5. Каноническая сопряженность в квантовой механике. Пусть x-одномерный параметр, так что $G=\mathscr{D}$ является ве- щественной прямой $\mathbf{R}$ (случай параметра сдвига),

или единичной окружностью T (случай параметра поворота), и пусть $x \to \to V_\alpha = e^{-ixA}$ - унитарное представление группы G в $\mathscr{H}$. Спектр Λ оператора A содержится в двойственной группе $\hat{G}$, которая совпадает с $\mathbf{R}$ в случае $G = \mathbf{R}$ и с множеством целых чнсел $\mathbf{Z}$ в случае $G = \mathbf{T}$.

Условие ковариантности обобщенной наблюдаемой $\mathbf{M}$ имеет вид

$$V_x^* M(B) V_x = M(B - x); \quad B \in \mathscr{B}(G), x \in G$$

где $B - x = \{y : y + x \in B\}$, причем в случае $G = \mathbf{T}$ имеется в виду сложение по модулю 2π. Вводя операторы

$$U_y = \int\limits_G e^{iyx} M(dx), \quad y \in \hat{G}$$

получаем, что (3.9) равносильно соотношению Вейля (см. п. 1.2.3)

$$U_y V_x = e^{ixy} V_x U_y; \quad x \in G, y \in \hat{G}$$

в котором, однако, операторы U_v, вообще говоря, неунитарны. В этом смысле обобщенная наблюдаемая $\boldsymbol{M}$ является канонически сопряженной к наблюдаемой A.

Для обобщенной канонической пары $(A, \mathbf{M})$ имеет место соотношение неопределенностей [100]

$$\Delta_S^M(y) \cdot \mathbf{D}_S(A) \geqslant 1/4; \quad y \in \hat{G}$$

где $\Delta_S^M(y) = y^{-2} \left\{ |\operatorname{Tr} S U_y|^{-2} - 1 \right\}, \quad y \neq 0$, есть некоторая функциональная мера неопределенности ковариантной обобшенной наблюдаемой M в состоянии S-(см. [43, & IV.7]). Если $G = \mathbf{R}$ и $\mathbf{M}$ имеет конечнуго дисперсию $\mathbf{D}_S(\mathbf{M})$, то $\lim_{y \to 0} \Delta_S^{\mathbf{M}}(y) = \mathbf{D}_S(\mathbf{M})$, так что из (3.11) следует обобщение соотношения неопределенностей Гейзенберга

$$\mathbf{D}_S(\mathbf{M}) \mathbf{D}_S(A) \geqslant 1/4$$

Для параметра поворота ($G = \mathrm{T}$) дисперсия не является адекватной мерой неопределенности, и неравенство (3.11) следует рассматривать как окончательное. Различные формы соотношения неопределенностей для угловых переменных обсуждались в обзорах [19], [17]. Следует отметить, что обобщенная наблюдаемая угла поворота существует всегда, поскольку условня предложения 1 из предыдущего пункта выполняются автоматически ($\hat{G} = \mathbf{Z}$). С другой стороны, условия предложения 2 не могут быть выполнены, если $\dim \mathscr{H} < \infty$ (как для систем с конеqным спином), и в этих случаях обычной наблюдаемой угла поворота не существует.

Нанбольший интерес представляют ковариантные обобщенные наблюдаемые, имеющие минимальную неопределенность.

Те орем а ([100]). Пусть $S = |\psi\rangle\langle\psi|$ - чистое состояние, тогда

$$\min_{M \in \mathbb{M}^{G,\ \mathrm{V}(G)}} \Delta_S^M(y) = y^{-2} \left[\left(\int\limits_{\hat{\sigma}} \|\psi(y')\| \, \|\psi(y' + y)\| \, dy' \right)^{-2} - 1 \right]$$

В частности, для $G := \mathbf{R}$

$$\min_{\mathbf{M} \in \mathbb{N}^{\mathbf{R},\mathbf{V}}(\mathbf{R})} \mathbf{D}_s(\mathbf{M}) = \int\limits_{\mathbf{R}} \left(\frac{d}{dy} \|\psi(y)\| \right)^2 dy$$

где $\psi(y)$ - компоненты вектора ψ в представлении, диагонализующем оператор A. Минимум достигается на ковариантной наблюдаемой $\boldsymbol{M}^*$ класса $\mathfrak{R}_c^{G,v}$, которая задается ядром $P^*(y,y')$ таким, что $P^*(y,y')\,\psi(y') / \|\psi(y')\| = \psi(y)/\|\psi(y)\|; \quad y, \quad y' \in \Lambda$.

Величины (3.12), (3.13) дают внутреннюю меру неопределенности параметра x в состоянии S.

Таким образом, требования ковариантности и минимальной неопределенности (относительно чистых состояний) определяют канонически сопряженную обобщенную наблюдаемую однозначно с точностью до калибровочного преобразования (3.7). Следует отметить, что аналогичная степень произвола остается и в стандартной формулировке квантовой механики, поскольку в случае $\Lambda = \hat{G}$ класс ${\mathfrak{P}_c}^{G,V}(G)$ совпадает с классом ковариантных наблюдаемых $\mathfrak{R}_0^{G,v}(G)$.

П р и м ер. Рассмотрим квантовую систему с положительным гамильтонианом H. Представление $t \to V_t = e^{-iHt}$ группы временных сдвигов не удовлетворяет условиям предложения 2 предыдущего пункта, поскольку $\Lambda \subset \mathrm{R}_+$. Поэтому ковариантной наблюдаемой временного сдвига не существует [1)]. Предположим для простоты, что $\Lambda = \mathbb{R}_+$и что спектр H однороден (т. е. имеет постоянную кратность для п. в. $\lambda \in \Lambda$). Тогда H унитарно эквивалентен оператору умножения на λ в гильбертовом пространстве $\mathscr{C} = L^2_{\mathscr{K}}(\mathbf{R}_+)$квадратично-интегрируемых функций $\psi = [\psi(\lambda)]$ на $\mathbb{R}_+$со значениями в некотором гильбертовом пространстве $\mathscr{K}$. Ковариантные обобщенные наблюдаемые класса $\mathfrak{M}_c^{\mathbf{R},V}(\mathbb{R})$ с точностью до калибровочного преобразования (3.7) эквивалентны наблюдаемой $\mathbf{M}_c$, определяемой соотношением (3.8), т. е.

$$\langle\psi|M_c(B)\varphi\rangle = \int\limits_{R_+}\int\limits_{R_+} \langle\psi(\lambda)|\varphi(\lambda')\rangle\, \mathscr{F}\int\limits_B e^{i(\lambda'-\lambda)\tau}\frac{d\tau}{2\pi}.$$

Разложение единицы $\mathbf{M}_c$ является обобщенной спектральной мерой в смысле [2] максимального симметричного (но не самосо-

1. На трудности с определением наблюдаемой времени в квантовой механике указывал Паули (см. Handbuch der Physik.-1958.-5/1.-C. 60-63). пряженного) оператора

$$T = i\frac{d}{d\lambda}, \quad \mathscr{D}(T) = \{\psi : \psi \text{ абсолют но непрерывна, } \psi(0) = 0,$$
$$\int\limits_{\mathbf{R}_+} \left\| \frac{d}{d\lambda}\psi(\lambda) \right\|^2_{\mathscr{K}} d\lambda < \infty \Bigg\}.$$

Минимальное расширение Наймарка разложения единицы $\mathbf{M}_c$ в пространстве $\widetilde{\mathscr{H}} = L^2_{\mathscr{K}}(\mathbf{R})$ дается формулой, аналогичной (3.14), с заменой $\mathbf{R}_+$на $\mathbf{R}$, и является спектральной мерой самосопряженного оператора $i\frac{d}{d\lambda^3}L^2_{\mathscr{K}}(\mathbf{R})$.

3.6. Локализуемость. Пусть $\mathbf{W}$—-унитарное представление группы, описывающей кинематику данной квантовой системы (универсальной накрывающей группы Галилея в нерелятивистском или группы Пуанкаре в релятивистском случае), в гильбертовом пространстве $\mathscr{C}$ и пусть $\mathbf{U}$ - ограничение $\mathbf{W}$ на универсальную накрывающую G группы евклидовых преобразований $g : x \to Ax + b, x \in \mathbf{R}^3$. Система называется локализуемой по Вайтману, если в $\mathscr{K}$ существует ортогональное разложение единицы $\mathbf{E}$ на σ-алгебре $\mathscr{B}(\mathbf{R}^3)$ борелевских подмножеств координатного пространства $\mathbf{R}^3$, удовлетворяющее условию евклидовой ковариантности

$$U_g^* E(B) U_g = E\left(g^{-1}B\right); g \in G, B \in \mathscr{B}\left(\mathbb{R}^3\right)$$

При этом условии для любой области $B \subset \mathbf{R}^3$ найдется вектор состояния ψ такой, что $\langle\psi|E(B)\psi\rangle = 1$, т. е. вероятность обнаружения системы в области B равна 1. Для локализуемой системы определены совместимые наблюдаемые координат

$$Q_j = \iiint x_j E\left(dx_1 dx_2 dx_3\right); j = 1, 2, 3$$

ковариантные относительно евклидовых преобразований.

Используя то обстоятельство, что (U, E) - система импримитивности, можно доказать, что локализуемыми по Вайтману являются все массивные частицы и релятивистские безмассовые частицы с нулевой спиральностью. Безмассовые частицы с ненулевой спиральностью (фотон, нейтрино) оказываются нелокализуемыми (Ньютон, Вигнер, 1949, Вайтман, 1962). Такой вывод не согласуется с экспериментальной локализуемостью фотона; более того, как показал Хегерфельдт, такое понятие локализуемости приводит к противоречию с требованием причинности в релятивистской динамике (см., например, [55]). Эти трудности снимаются, если в определении локализуемости допускаются произвольные разложения единицы. Неортогональное разложение единицы M, описывающее локализацию фотона, было -указано, в частности, в работах Крауса (в сб. [159]), А. С. Холево [99]. Полная классификация соответствующих обобщенных систем импримитивности, при дополнительном условии кова' риантности относительно преобразований подобия, включающая характеризацию крайних точек, дана Кастрижьяно [71]. Релятивистские безмассовые частицы оказываются п и бл л ж е н но локализуемыми в том смысле, что $\sup_{\|\psi\|=1}\langle\psi|M(B)\psi\rangle = 1$ для любой области $B \subset \mathbf{R}^3$. Наблюдаемые координаты, определенные соотношением (3.15), являются самосопряженными, но неперестановочными операторами и поэтому не имеют совместной спектральной меры.

В ряде работ, обзор которых имеется в статьях Али, Пруговечки [55], развивалась идея стохастической локализуемости в фазовом пространстве. Результаты этих работ также указывают на то, что обобщенная статистическая модель квантовой механики дает возможность, по крайней мере, смягчить известные противоречия между релятивистской инвариантностью и нелокальностью квантовомеханического описания.

12.3 Evolution of an Open System

12.3.1 1. Transformations of Quantum States and Observables

Динамика изолированной квантовой системы, описываемая однопараметрической группой унитарных операторов, обратима во времени. Эволюция открытой системы, подверженной внешним воздействиям, будь то процесс установления равновесия с окружением или взаимодействие с измерительным прибором, обнаруживает черты необратимости. В математическом плане такие необратимые изменения описываются вполне положительными отображениями.

1.1. Вполне положительные отображения.

Пусть $\mathscr{A} \subset \mathfrak{B}(\mathscr{H})$ - некоторая C^*-алгебра операторов, т. е. подпространство $\mathfrak{B}(\mathscr{H})$, замкнутое относительно алгебраических операций, инволюции и перехода к пределу по операторной норме (см., например, [32], [9]). Обозначим $\mathfrak{P}_n$ алгебру комплексных $n \times n$-матриц. Линейное отображение Φ из $\mathscr{A}$ в $\mathscr{P}(\mathscr{K})$ (где $\mathscr{K}$ гильбертово пространство) называется положительным, если из $X \in \mathfrak{A}, X \geqslant 0$ следует $\Phi[X] \geqslant 0$, и вполне положительным, если для любого $n \geqslant 1$ отображение $\Phi_n C^*$-алгебры $\mathscr{A} \otimes \mathfrak{M}_n$ в C^*-алгебру $\mathfrak{B}(\mathscr{K}) \otimes \mathfrak{M}_n$, определяемое формулой $\Phi_n(X \otimes Y) = \Phi_n(X) \otimes Y$, является

положительным. Другими словами, для любой матрицы $[X_{jk}]_{j,k=1,\ldots,n}$ с элементами $X_{jh} \in \mathscr{A}$, положительно определенной в том смысле, что $\sum_{k=1}^{n} \langle \varphi_j | X_{jk} \varphi_k \rangle \geqslant 0$ для любого набора $\{\varphi_j\} \subset \mathscr{H}$, матрица

$[\Phi(X_{jk})]_{j,k=1,\ldots,n}$ также является положительно определенной.

Еще одно эквивалентное определение: для любых конечных на- боров $\{X_i\} \subset \mathscr{A}$ и $\{\psi_j\} \subset \mathscr{H}$

$$\sum_{j,k} \left\langle \psi_j | \Phi \left[x_j^* X_k \right] \psi_k \right\rangle \geqslant 0$$

Для положительного отображения имеет место неравенство Кэдисона-Шварца

$$\Phi[X]^* \Phi[X] \leqslant \|\Phi\| \Phi\left[X^* X\right]$$

для всех X Я таких, что $X^*X = XX^*$. Если Φ вполне положительно, то это неравенство выполняется для всех X я. Пример положительного, но не вполне положительного отображениятранспонирование в $\mathfrak{D}_n$. Если Φ положительно и $\mathfrak{A}$, либо $\Phi(\mathrm{Re})$ коммутативны, то Φ вполне положительно. Таким образом, свойство полной положительности проявляется лишь в некоммутативной ситуацин.

Отображение $\pi : \mathfrak{A} \to \mathfrak{B}(\tilde{\mathscr{K}})$. называется *-гомоморбизмом (представлением), если оно сохраняет алгебраические операции и инволюциіо.

Т е о р ем а (Стайнспринг, 1955). Пусть $\mathscr{A} \subset \mathfrak{B}(\mathscr{H})$ – C^*-алгебра с единицей и $\Phi : \mathfrak{A} \to \mathfrak{B}(\mathscr{K})$-линейное отображение. Φ вполне положительно тогда и только тогда, когда оно допускает представление

$$\Phi[\lambda] = V^* \pi[X] V$$

где V-ограниченное линейное отображение из $\mathscr{K}$ в некоторое гильбертово пространство $\breve{\mathscr{K}}, \pi$ - -гомоморфизм $\mathfrak{A}$ В $\mathfrak{F}(\widetilde{\mathscr{K}})$.

Существует единственное с точностью до унитарной эквивалентности минимальное представление (1.3), характеризующееся свойством: по дпространство $\{\pi[\curvearrowright] V\psi : X \in \mathscr{A}, \psi \in \mathcal{K}\}$ плотно в $\tilde{\mathcal{K}}$.

Доказательство прямого утверждения представляет собой обобщение конструкции Гельфанда-Наймарка-Сигала (ГНС), которая соответствует случаю положительного линейного функционала на $\mathscr{A}(\dim \mathscr{K} = 1)$ [32], [9]. На алгебраическом тензорном произведении $\mathfrak{A} \otimes \mathscr{K}$ определяется (псевдо-) скалярное произведение, такое что

$$\langle X \otimes \varphi | Y \otimes \psi \rangle = \langle \varphi | \Phi\left[X^* Y\right] \psi \rangle_{\mathscr{K}}; \quad X, Y \in \mathscr{A}; \varphi, \psi \in \mathscr{K}.$$

Неотрицательность скалярного квадрата следует из (1.1). Пусть $\widetilde{\mathscr{K}}$ гильбертово пространство, получающееся в результате факторизации и пополнения $\mathscr{A} \otimes \mathscr{G}$ по этому скалярному произведению. Соотношения

$$\pi[X](Y \otimes \psi) = XY \otimes \psi$$
$$V_\varphi = I \otimes \varphi$$

определяют переходом в $\tilde{\mathscr{K}}$ объекты V, л, удовлетворяющие соотношению (1.3).

З а м е ч а н и е. Если $\mathscr{X}$ - метризуемый компакт и $\mathbf{M}$ - разложение единицы в $\mathscr{K}$ на σ-алгебре борелевских подмножеств $\mathscr{B}(\mathscr{X})$, то отображение

$$f \to \int_{\mathscr{X}} f(x) M(dx); \quad f \in C(\mathscr{Q})$$

C^*-алгебры $C(\mathscr{X})$ непрерывных комплексных функций на $\mathscr{Z}$ в $\mathscr{Y}(\mathscr{K})$ является (вполне) положительным. Теорема Стайнспринга в этом случае дает расширение Наймарка для $\mathbf{M}$, поскольку *-гомоморфизм $C(\mathscr{X})$ задается ортогональным разложением единицы.

Всякая алгебра фон Неймана $\mathscr{B}$ является C^*-алгеброй с единицей. Положительное отображение Φ алгебры $\mathscr{B}$ называется нормальныц, если из $X_\alpha \uparrow X$ в $\mathscr{B}$ следует $\Phi[X_\alpha] \uparrow \Phi[X]$.

С лед ств и е ([117]). Всякое нормальное вполне положительное отображение $\Phi : \mathfrak{B}(\mathscr{H}) \to \mathscr{P}(\mathscr{C})$ имеет вид

$$\Phi[\ddot{\Lambda}] = \sum_{n=1}^{\infty} V_n^* \bar{\Lambda}_n$$

тде ряд $\sum\limits_{n=1}^{\infty} V_n^* V_n$ сходится сильно в $\mathfrak{B}(\mathscr{H})$.

Доказат ельство. Если Φ нормально, то представление π в формуле (1.3) также можно считать нормальным. Известно, qто всякое нормальное представление алгебры $\mathfrak{B}(\mathscr{H})$ в пространстве $\tilde{\mathscr{K}}$ кратно единичному, т. е. $\tilde{\mathscr{K}} = \mathscr{H} \otimes \mathscr{H}_0$ и $\pi[\lambda] = X \otimes \mathrm{I}_0$, где $\mathscr{C}_0$-некоторое гильбертово пространство, I_0-единичный оператор в $\mathscr{C}_0$ (см., например, [78, гл. 9]). Пусть $\{e_j\}$-ортонормированный базис в $\mathscr{C}_0$, тог да $V\psi = \sum\limits_{n=1}^{\infty} V_n \psi \otimes e_n$, а соотношение (1.3) переходит в (1.4).

Обзор свойств вполне положительных отображений имеется в статье Штермера в сборнике [85]. Андо и Чой [57] рассмотрели н е ли н е й н ы е вполне положительные отображения и установили для них обобщение теоремы Стайнспринга.

1.2 Операции, динамические отображения.

Алгебра $\mathscr{B}(\mathscr{C})$ как банахово пространство является сопряженным к пространству ядерных операторов $\mathfrak{T}(\mathscr{C})$ (см. П. 1.1.1). Если Ψ - линейное отображение в $\mathfrak{T}(\mathscr{G})$, положительное в том смысле, что $\Psi[T] \geqslant 0$, если $T \geqslant 0$, то Ψ ограничено (см., например, [78, гл. 2]) и поэтому имеет сопряженное отображение $\Phi = \Psi^* : \mathscr{B}(\mathscr{H}) \to \to \mathscr{P}(\mathscr{G})$, которое является линейным положительным нормальным отображением; более того, всякое Φ с такими свойствами является сопряженным к некоторому Ψ. Если Ψ положительно и, кроме того, $\operatorname{Tr}\Psi[T] \leqslant \operatorname{Tr} T$ для всех $T \in \mathfrak{T}(\mathscr{C}), T \geqslant 0$, то Ψ на- зывается операцией (в пространстве состояний). Это равноснльно тому, что $\Phi[\mathrm{I}] \leqslant \mathrm{I}$. Отображение Φ также называется операцией (в алгебре наблюдаемых).

В квантовой статистике операции описывают изменения состояний (наблюдаемых) открытой системы в результате эволюции или макроскопического воздействия, включая отбор по какому-либо признаку (например, по результату измерения) в соответствующем статистическом ансамбле. Если S-оператор плотности исходного состояния, то число $\operatorname{Tr}\Psi[S]$ интерпретируется как доля отобранных представителей ансамбля, а $\Psi[S]/\operatorname{Tr}\Psi[S]$ как оператор плотности, описывающей новое состояние отобранного ансамбля. Термин «операция» был введен в известной работе Хаага и Кастлера (1964), посвященной обоснованию квантовой теории поля. Базирующийся на понятии операции аксиоматический подход к квантовой механике был развит Дэвисом и Льюисом, Людвигом и другими авторами (см., например, [78], [125], [116], [85]).

В динамической теории особенно важны операции, переводящие состояние в состояние. Это равносильно тому, что $\operatorname{Tr}\Psi[T] = \operatorname{Tr} T$ для всех $T \in \mathfrak{T}(\mathscr{C})$ или же $\Phi[\mathrm{I}] = \mathrm{I}$, где $\Phi = \Psi^*$. Если, кроме того, Φ - вполне положительно, то Ψ (или Φ) называется динамическим

отображением [1)]. Из теоремы Вигнера (п. 1.2.1) следует, что обратимые динамические отображения описываются формулами

$$\Psi[T] = UTU^*, \quad \Phi[X] = U^*XU$$

где U - унитарный оператор в $\mathscr{C}$ (если U антиунитарный, то Φ не может быть линейным отображением). В общем случае динамические отображения описывают необратимые эволюции и являются некоммутативным аналогом марковских отображений в теории вероятностей. Мерой необратимости может служить относительная энтропия квантовых состояний

$$H(S_2|S_1) = \operatorname{Tr} S_1 (\ln S_1 - \ln S_2)$$

О свойствах относительной энтропии см. Линдблад [122], Верль. [166], Петц [139]). Важнейшим является о бо бш е н н а я H - те орем а: для любого динамического отображения Ψ:

$$H(\Psi[S_2]|\Psi[S_1]) \geqslant H(S_2|S_1)$$

Согласно следствию из п. 1.1, динамическое отображение допускает представление

$$\Psi[T] = \sum_{n=0}^{\infty} V_n T V_n^*, \Phi[X] = \sum_{n=0}^{\infty} V_n^* \tilde{\lambda} V_n$$

где $\sum\limits_{n=0}^{\infty} V_n^* V_n = \mathrm{I}$. Отсюда нетрудно получить

1. На свойство полной положительности эволюции открытой системы. было указано, в частности в работах [117], [39].

С ле д с т в и е ([123]). Отображение $\Psi : \mathfrak{T}(\mathscr{H}) \to \mathfrak{T}(\mathscr{H})$ является динамическим тогда и только тогда, когда существуют гильбертово пространство $\mathscr{H}_0$, состояние S_0 в $\mathscr{H}_0$ и унитарный оператор U в $\widetilde{\mathscr{B}} = \mathscr{H} \otimes \mathscr{H}\mathscr{C}_0$, такие что

$$\Psi[S] = \operatorname{Tr}_{\mathscr{H}_0} U (S_{\otimes} S_0) U^*$$

где $\operatorname{Tr}\mathscr{G}_0$ - частичный след в $\mathscr{H}_0$.

Таким образом, динамическое отображение расширяется до обратимой эволюции составной системы, включающей исходную открытую систему и «окружение», причем возможность такого расширения обусловлена свойством полной положительности.

1.3 Условные ожидания.

Так называются отображения $\mathscr{E} : \mathscr{B}(\mathscr{C}) \to \mathscr{D}(\mathscr{C})$, являющиеся идемпотентами ($\mathscr{E}^2 = \mathscr{E}$) с единичной нормой. $\mathscr{E}$ отображает $\mathscr{B}(\mathscr{H})$ на C^*-подалгебру $\mathscr{A} = \{X : X \in \mathscr{B}(\mathscr{H}), \mathscr{E}[X] = X\}$. Если $\mathscr{E}$ нормально, то $\mathscr{A}$-алгебра фон Неймана. Условное ожидание согласовано с состоянием S, если $\operatorname{Tr} S\mathscr{E}[X] = \operatorname{Tr} SX; X \in \mathscr{B}(\mathscr{H})$. Томияма показал, что условное ожидание является положительным отображением и обладает свойством

$$\mathscr{E}(XYZ) = X\mathscr{E}(Y)Z; \quad Y \in \mathscr{B}(\mathscr{H}); \quad X, Z \in \mathscr{A},$$

которое включалось в первоначальное определение, данное Умегаки [158]. На самом деле всякое условное ожидание вполне положительно.

Общий критерий существования нормального условного ожидания в алгебрах фон Неймана дал Такесаки [157]. В случае $\mathscr{B}(\mathscr{C})$ этот критерий имеет следующую формулировку. Пусть S - невырожденный оператор плотности, тогда с ним связана модулярная групп а автоморфизмов $\mathscr{B}(\mathscr{H})$

$$\alpha_t[X] = S^{it} X S^{-it}; \quad X \in \mathscr{B}(\mathscr{H}), \quad t \in \mathbf{R}.$$

Условное ожидание $\mathscr{E}$ на подалгебру $\mathscr{A} \subset \mathscr{P}(\mathscr{H})$, согласованное с состоянием S, существует тогда и только тогда, когда $\mathscr{A}$ инвариантна относительно α_t. В частности, это выполняется, если $[S, X] = 0$ для всех $X \in (?)$

Пример нормального условного ожидания (усреднение по подсистеме составной системы) был дан в п. 1.3.1. Приведем другой важный пример. Пусть $\{E_n\}$ - ортогональное разложение единицы в $\mathscr{H}$. Тогда

$$\mathscr{E}[X] = \sum_{n=1}^{\infty} E_n X E_n$$

является нормальным условным ожиданием на подалгебру $\mathfrak{A}$ операторов вида (1.5), согласованным с любым состоянием, оператор плотности которого принадлежит $\mathscr{A}$. Алгебру $\mathfrak{A}$ можно описать также соотношением $\mathscr{V} = \{E_n; n = 1, 2, \ldots\}'$, где $\mathfrak{M}'$ обозначает ко м м у т а н т подмножества $\mathfrak{R} \subset \mathfrak{F}(\mathscr{H})$, т. е. совокупность всех ограниченных операторов, коммутирующих с операторами из $\mathfrak{M}$.

Обзор результатов об условных ожиданиях в алгебрах фон Неймана имеется в статьях Чеккини в сб. [141] и Петца в сб. [143]. В них же излагается некоторое обобщение понятия условного ожидания, принадлежащее Аккарди и Чеккини.

12.3.2 2. Quantum Dynamical Semigroups

2.1. Определение и примеры.

Динамнческая полугруппа является некоммутативным обобщением полугруппы переходных - операторов в теории марковских случайных процессов. Возможны два эквивалентных способа задания динамической полу. группы-в пространстве состояний и в алгебре наблюдаемых системы. Квантовой дижамической полугруппой в пространстве состояний называется семейство динамических отображений $\{\Psi_t; t \in \mathrm{R}_+\}$банахова пространства ядерных операторов $\mathfrak{T}(\mathscr{H})$, такое что

1. $\Psi_t \cdot \Psi_s = \Psi_{t+s}; t, s \in \mathbf{R}_+$;
2. $\Psi_0 = \mathrm{Id}$ (тождественное отображение);
3. $\{\Psi_t\}$ сильно непрерывна, т. е. $\lim_{t\to 0} \|\Psi_t[T] - T\|_1 = 0$ для ліобого $T \in \mathfrak{E}(\mathscr{H})$.

Из общей теории полугрупп в банаховом пространстве (см., например, [9, гл. 3]) вытекает, что существует плотно определенный инфинитезимальный оператор

$$\mathscr{K}[T] = \lim_{t\to 0} \frac{\Psi_t[T] - T}{t}$$

Если Ψ_t непрерывна по норже, т. е. $\lim_{t\to 0} \|\Psi_t - \mathrm{Id}\| = 0$, то $\mathscr{K}$ - всюду определенное, ограниченное отображение $\mathfrak{T}(\mathscr{H})$. Если S_0 начальное состояние, то функция $S_t = \Psi_t[S_0]$ удовлетворяет квантовому марковскому управляющему уравнению [1)]

$$\frac{dS_t}{dt} = \mathscr{K}[S_t]$$

которое является некоммутативным аналогом уравнения Колмогорова-Чепмена. В физических приложениях динамические полугруппы и возникают как решения марковских управляющих уравнений.

Динамическая полугруппа в алгебре наблюдаемых - это полугруппа динамических отображений $\{\Phi_t; t \in \mathbf{R}_+\}$алгебры $\mathfrak{B}(\mathscr{H})$,

такая что $\Phi_0 = \mathrm{Id}$ и $w^* - \lim_{t\to 0} \Phi_t[X] = X$ для любого $X \in \mathfrak{B}(\mathscr{H})$.

1. Английский термин - master equation.

Мы будем в основном рассматривать полугруппы, непрерывные по норме, т. е. такие, что $\lim_{t\to 0} \|\Phi_t - \mathrm{Id}\| = 0$.

П р и ме р ([116]). Пусть $^{t\to 0}G$ - сепарабельная локально компактная группа, $g \to V_g$ - непрерывное унитарное представление G в $\mathscr{G}$ и $\{\mu_t; t \in \mathbf{R}_+\}$ −непрерывная сверточная полугруппа вероятностных мер на G (см., например, [13]). Соотношения

$$\Psi_t[S] = \int\limits_G V_g S V_g^* \mu_t(dg); \Phi_t[X] = \int\limits_G V_g^* X V_g \mu_t(dg)$$

задают квантовые динамические полугруппы, соответственно, в $\mathfrak{E}(\mathscr{H})$ и в $\mathfrak{B}(\mathscr{H})$.

В частности, пусть A-эрмитов оператор в $\mathscr{H}$, тогда выражение

$$\Psi_t[S] = \frac{1}{\sqrt{2\pi t}} \int\limits_{-\infty}^{\infty} e^{-\frac{x^2}{2t}} e^{-iAx} S e^{iAx}$$

соответствующее гауссовской сверточной полугруппе на $\mathbf{R}$, определяет динамическую полугруппу с инфинитезимальным оператором

$$\mathscr{K}[S] = ASA - A^2 \circ S.$$

Если U-унитарный оператор, $\lambda > 0$, то

$$\Psi_t[S] = \sum_{n=0}^{\infty} \frac{(\lambda t)^n}{n!} e^{-\lambda t} U^n S U^{*n}$$

является динамической полугруппой, отвечающей пуассоновской сверточной полугруппе на $\mathbf{Z}$, с инфинитезимальным оператором

$$\mathscr{K}[S] = \lambda [USU^* - S]$$

Понятие динамической полугруппы было предложено Коссаковским [116] (см. также Дэвис [78]), однако без условия полной положительности, которое позднее было введено Линдбладом [123]. Многие физические примеры укладываются в общую схему квазисвободных динамических полугрупп, которые являются квантовым аналогом гауссовских марковских полугрупп. В случае ККС такие полугруппы характеризуются условием, что они переводят гауссовские состояния в гауссовские (см. п. 1.2.4). В статистической механике они описывают необратимую динамику открытых Бозе- или Ферми-систем с квадратичным взаимодействием (см. обзоры [27], [56]).

2.2. Инфинитезимальный оператор.

Требование полной положительности налагает нетривиальные ограничения на инфинитезимальный оператор полугруппы. Описание инфинитезимального оператора непрерывной по норме квантовой динамической полугруппы было получено Линдбладом и, независимо в случае $\dim \mathscr{C} < \infty$, Горини, Коссаковским и Сударшаном.

Т еорема ([123]). Для того чтобы ограниченное отображение $\mathscr{K}$ пространства $\mathfrak{T}(\mathscr{H})$ было инфинитезимальным оператором непрерывной по норме квантовой динамической полугруппы, необходимо и достаточно, чтобы

$$\mathscr{K}[S] = -i[H, S] + \sum_{j=1}^{\infty} \left(L_j S L_j^* - L_j^* L_j \circ S \right)$$

где $H, L_j \in \mathfrak{B}(\mathscr{H}), H = H^*$ и ряд $\sum\limits_{j=1}^{\infty} L_j^* L_j$ сходится сильно.

Первое слагаемое в (2.4) отвечает обратимой эволюции с гамильтонианом H, а второе задает диссипативные члены. Оператор $\sum\limits_{j=1}^{\infty} L_j^* L_j$ связан со скоростью диссипации. Переходя к формулировке в алгебре наблюдаемых, имеем для инфинитезимального оператора $\mathscr{L} = \mathscr{K}^*$ полугруппы $\Phi_t = \Psi_t^*$

$$\mathscr{L}[X] = i[H, X] + \sum_{j=1}^{\infty} \left(L_j^* \dot{\Lambda} L_j - L_j^* L_j \circ X \right)$$

В основе доказательства теоремы лежат следующие два факта [123], [84].

Предложени е. Пусть $\mathscr{L}$ - ограниченное отображение $\mathfrak{B}(\mathscr{H})$ в себя, такое что $\mathscr{L}[\mathrm{I}] = 0$. Следующие утверждения эквивалентны:

1. $\exp t\mathscr{L}$ вполне положительно для всех $t \in \mathbf{R}_+$;

2. $\mathscr{L}$ вполне диссипативно, т. е. $\mathscr{L}[X^*] = \mathscr{L}[X]^*$ и

$$\sum_{j,k} \left\langle \psi_j \mid \left(\mathscr{L}\left[X_j^* X_k\right] - X_j^{**} \mathscr{L}[X_k] - \mathscr{L}[X_j]^* X_k \right) \psi_k \right\rangle \geqslant 0$$

для любых конечных наборов $\{\psi_j\} \subset \mathscr{H}, \{X_j\} \subset \mathscr{B}(\mathscr{H})$;

3. $\mathscr{L}[X^*] = \mathscr{L}[X]^*$ и $\mathscr{L}$ условно вполне положительно т. е. из $\sum\limits_j X_j \psi_j = 0$ следует

$$\sum_{j,k} \left\langle \psi_j | \mathscr{L}\left[X_j^* \ddot{X}_k\right] \psi_k \right\rangle \geqslant 0$$

Это утверждение родственно теореме Шенберга в теории условно положительно определенных функций (см., например, [138], а также п. 4.2.4).

Те орем а. Пусть $\mathscr{L}$ - ограниченное отображение $\mathscr{B}(\mathscr{H})$ в себя, такое что $\mathscr{L}[\mathrm{I}] = 0$. Для того чтобы $\mathscr{L}$ было вполне диссипативным, необходимо и достаточно, чтобы

$$\mathscr{L}[X] = \Phi[X] + K^* X + XK$$

где Ф-вполне положительное отображение, $\mathscr{Y}(\mathscr{H})$.

Соотношение (2.5) получается тогда из формулы (1.3) для нормального вполне положительного отображения.

Доказательство формулы (2.6) может быть связано с когомологиями алгебры $\mathscr{B}(\mathscr{H})$. Конструкция типа ГНС сопоставляет вполне диссипативному отображению $\mathscr{L}$ линейное отображение B алгебры $\mathscr{B}(\mathscr{G})$ в пространство ограниченных операторов из $\mathscr{H}$ в $\mathscr{K}$ (другое гильбертово пространство), так что

$$\mathscr{L}[X^*Y] - X^*\mathscr{L}[Y] - \mathscr{L}[X]^*Y = B[X]^*B[Y]$$

Более того, отображение B оказывается к о и к лом некоторого представления (*-гомоморфизма) π алгебры $\mathscr{B}(\mathscr{H})$ в $\mathfrak{B}(\mathscr{K})$, т. е. удовлетворяет уравнению

$$B[XY] = \pi[X]B[Y] + B[X]Y; X, Y \in \mathscr{B}(\mathscr{H}).$$

Основную трудность представляет доказательство того, что всякий коцикл тривиален, т. е. имеет вид $B[X] = \pi[X]R - RX$, где R-ограниченный оператор из $\mathscr{H}$ в $\mathscr{K}$. Кристенсен и Эванс [76] обобщили этот подход и получили аналог представления (2.6) для произвольной C^*-алгебры операторов.

2.3. Свойство консервативности.

Проблема характеризации инфинитезимального оператора динамической полугруппы без требования непрерывности по норме трудна и остается открытой. Нетривиальной является и задача построения динамической полугруппы по формальному выражению типа (2.5), где H, L_j - неограниченные операторы. Дэвис [79] указал довольно общие условия, при которых с формальным выражением (2.4) ассоциируется сильно непрерывная полугруппа вполне положительных отображений $\{\Phi_t; t \in \mathbf{R}_+\}$, такая что

$$\Phi_t[\mathrm{I}] \leqslant \mathrm{I}$$

и являюшаяся аналогом феллеровского минимального решения в классической теории марковских процессов. Если минимальная полугруппа консервативна в том смысле, что $\Phi_t[\mathrm{I}] = \mathrm{I}$, то она является единственной динамической полугруппой, инфинитезимальный оператор которой является замыканием оператора (2.5). Неконсервативность, как и в классической теории, связана с возможностью «ухода на бесконечность» за конечное время.

Прим е р 1 ([79]). Пусть $\mathscr{H} = l^2$ - гильбертово пространство последовательностей $\{\psi_n; n \geqslant 0\}$ и «операторы рожденияуничтожения» a^*, a определены соотношениями $(a^*\psi)_n = \sqrt{n}\psi_{n-1}, \quad (a\psi)_n = \sqrt{n+1}\psi_{n+1}$. Рассмотрим управляющее уравнение

$$\frac{dS_t}{dt} = LS_tL^* - L^*L_0S_t$$

где $L = a^{*2}, L^* = a^2$, а S_t - диагональный оператор плотности в l^2. Диагональные элементы $p_n(t); n = 0, 1, \ldots$, оператора S_t удовлетворяют уравнению чистого рождения

$$\frac{dp_n(t)}{dt} = -(n+2)(n+1)p_n(t) \pm n(n-1)p_{n-2}(t)$$

минимальное решение которого неконсервативно, $\sum\limits_{n=0}^{\infty} p_n(t) < 1$ при $t > 0$.

Дэвис дал достаточные условия консервативности, пригодные для класса моделей квантовой диффузии. Оригинальные общие условия консервативности, основанные на аналогиях с классической теорией марковских процессов, предложил А. М. Чеботарев в [49], [35]. Рассмотрим для простоты случай формального инфинитезимального оператора

$$\mathscr{L}[X] = L^*XL + K^*X + XK$$

где L, L^*, K, K^* - операторы, имеющие плотную общую инвариантную, область определения $\mathscr{D}$. Предполагается, что $\mathscr{D}$ - существенная область определения для операторов K, K^*, которые являются инфинитезимальными операторами сильно непрерывных сжимающих полугрупп в $\mathscr{H}$, и что $K = -\frac{1}{2}L^*L + iH$, где H - самосопряженный оператор. Условия консерва- тивности имеют вид

$$[L, L^*] \geqslant -cI, i\,[L^*L, H] \geqslant -cL^*L,$$

где $c > 0$ и неравенства понимаются как неравенства для соответствующих форм, определенных на $\mathscr{D}$. Представление о диапазоне применимости этих условий дают два примера.

Пример 2. Пусть $\mathscr{H} = L^2(\mathbf{R}), Q$-оператор умножения на $x; P = i^{-1}\frac{d}{dx}$, $a(x)$ - дважды непрерывно дифференцируемая функция. Рассмотрим формальное выражение

$$\mathscr{L}[\tilde{X}] = Pa(Q)Xa(Q)P - Pa(Q)^2P \circ X$$

Если X-оператор уможения на дважды непрерывно дифференцируемую функцию $f(x)$, то $\mathscr{L}[X]$ есть оператор умно жения на $\frac{1}{2}\frac{d}{dx}\left(a(x)^2\frac{df}{dx}\right)$, т. е. совпадает с инфинитезимальным оператором симметричной диффузии на коммутативной подалгебре $L^\infty(\mathbf{R}) \subset \mathfrak{B}\,(L^2(\mathbf{R}))$.

Условия А. М. Чеботарева выполняются, если $\sup_x a(x)a''(x) < \infty$.

П риме р 3. В обозначениях предыдущего примера рассмотрим выражение

$$\mathscr{L}[X] = \int_{-\infty}^{\infty} m(d\xi)c(Q,\xi)^*V_\xi^*X^*V_\xi c(Q,\xi) -$$

$$- \int_{-\infty}^{\infty} m(d\xi)|c(Q,\xi)|^{2\circ}\tilde{K},$$

где $V_x = \exp(-ixP), m$ - вероятностная мера на $\mathbf{R}, c$-комплексная измеримая функция, такая что $x(x) \equiv \int m(d\xi)|c(x,\ \xi)\,|^2 < \infty$ для всех x. На коммутативной подалгебре $L^\infty(\mathbf{R})(2.8)$ совпадает с инфинитезимальным оператором скачкообразного марковского процесса в R с интенсивностью скачков $x(x)$. Достаточные условия консервативности выполняются, если

$$\sup_x \int m(x|d\xi)\,[\varkappa_1(x+\xi) - \varkappa_i(x)] < \infty,$$

где $m(x|d\xi) = m(d\xi)|c(x,\xi)|^2/x(x)$ - условные вероятности скачков.

Полученные в [49] условия консервативности позволяют рас. смотреть также суммы выражений типа (2.7), (2.8) и гамильтоновых членов вида $i[H, X]$ с неограниченным H.

2.4. Ковариантные эволюции.

Пусть $g \to V_g$ - представление в $\mathscr{C}$ группы G, описывающей симметрии окружения открытой квантовой системы. Динамическая полугруппа $\{\Psi_t; t \in \mathbb{R}_+\}$называется ковариантной, если

$$\Psi_t\left[V_gSV_g^*\right] = V_g\Psi_t[S]V_g^*$$

для всех $S \in \mathcal{S}(\mathscr{G}), g \in G, t \in \mathbb{R}_+$. Структура ковариантных вполне положительных отображений рассмотрена в [149]. В конечномерном случае получена достаточно полная

классификация инфинитезимальных операторов динамических полугрупп, ковариантных относительно групп простр анственных симметрий [93], [1].

П р и м е р. Рассмотрим эволюцию (2.1) открытой системы со спином $1/2(\dim \mathscr{H} = 2$; см. п. 1.1.6), ковариантную относительно действия группы SO(2), соответствующей аксиально симметричному окружению. Представление имеет вид $\varphi \to e^{iq\sigma_3}$, где $\varphi \in [0, 2\pi)$. Общий вид инфинитезимального оператора ковариантной динамической полугруппы

$$\mathscr{L}[S] = -i[H, S] + \sum_{j=-1}^{1} c_j \left(L_j S L_j^* - L_j^* L_j \mathrm{O} S \right)$$

где $c_j \geqslant 0, \quad H = \frac{1}{2}\omega_0\sigma_3, L_{-1} = \frac{1}{\sqrt{2}}(\sigma_1 - i\sigma_2), \quad L_0 = \sigma_3, \quad L_1 = \frac{1}{\sqrt{2}}(\sigma_1 + i\sigma_2)$. Полагая $S_t = S(\mathrm{a}_t)$, для вектора a_t имеем. уравнение Блоха

$$\frac{d\mathrm{a}_t}{dt} = \begin{bmatrix} -T_\perp^{-1} & \omega_0 & 0 \\ -\omega_0 & -T_\perp^{-1} & 0 \\ 0 & 0 & T_\parallel^{-1} \end{bmatrix} \mathrm{a}_{t.} + \begin{bmatrix} 0 \\ 0 \\ c_\infty/T_\parallel \end{bmatrix}$$

где $T_\perp^{-1} = 2c_0 + (c_1 + c_{-1}), T_\parallel^{-1} = 2(c_1 + c_{-1}), \quad c_\infty = 2T_\parallel (c_1 - c_{-1})$. Уравнение (2.10) описывает релаксацию спина в аксиальносимметричном магнитном поле. Параметр $T_\parallel (T_\perp)$ имеет смысл времени продольной (поперечной) релаксации. При $t \to +\infty$ $\mathbf{a}_t \to \begin{bmatrix} 0 \\ 0 \\ c_\infty \end{bmatrix}$, так что S_t стремится к предельному состоянию

$$S_\infty = \frac{1}{2}(\mathrm{I} + c_\infty \sigma_3)$$

Инфинитезимальный оператор (2.9) вполне диссипативен, что налагает нетривиальные ограничения на физические параметры эволюции. Именно, $2T_\perp^{-1} - T_\parallel^{-1} = 2c_0 \geqslant 0$, откуда $2T_\parallel \geqslant \geqslant T_\perp$[93].

$\bar{B}$ серии работ, обзор которых имеется в [83], описаны инфинитезимальные операторы инвариантных динамических полугрупп (не обязательно непрерывных по норме), действующих тождественно на алгебре инвариантных элементов.

2.5. Эргодические свойства.

Если Ф-динамическое отображение, то семейство $\left\{\Phi^k; k = 0, 1, \ldots\right\}$ можно рассматривать как динамическую полугруппу с дискретным временем. Асимптотические свойства таких полугрупп при $k \to \infty$ являются нетривиальным обобщением эргодической теории для классических цепей Маркова. Свойство полной положительности используется при этом лишь постольку, поскольку оно влечет неравенство Кэдисона-Шварца (1.2), а эргодические теоремы для средних верны для положительных отображений.

В большинстве работ в той или иной форме присутствует предположение, что Ф имеет точное нормальное инвариантное состояние, т. е. состояние с невырожденным оператором плотности S_∞, такое, что $\mathrm{Tr}\, S_\infty \Phi[X] = \mathrm{Tr}\, S_\infty X$ для всех $X \in \mathscr{F}(\mathscr{H})$. Имеет место эргодическая теорема для средних

$$w^* - \lim_{k\to\infty} \frac{1}{k} \sum_{j=0}^{k} \Phi^k[\bar{X}] = \mathscr{E}_\infty[X]$$

где $\mathscr{E}_\infty$ - условное ожидание на подалгебру $\mathscr{N}_\infty$ инвариантных элементов Ф. В разной степени общности этот результат был получен Я. Г. Синаем, Е. А. Морозовой и Н. Н.

Ченцовым, Кюммерером и другими авторами (см. обзор [27]). Соотношение (2.11) можно рассматривать как обобщение закона больших чисел. Много внимания было уделено распространению теорем типа (2.11) на неограниченные операторы и изучению некомму- тативноо. аналога сходймости почти наверное в алгебрах фон Неймана. Подробный обзор этих результатов дан В. В. Аншелевичем и M. Ш. Гольдштейном в [34], Петцем в [141], Яйте [111]. Отображение Φ неприводимо (Дэвис, Эванс), если не существует проектора $P \neq 0$, I, такого что $\Phi[P] = P$. Последнее равенство равносильно тому, что подалгебра операторов внда $PXP; P \in \mathscr{B}(\mathscr{H})$ инвариантна относительно Φ. Неприводимость эквивалентна адинственности инвариантного состоянйя S_∞ и одномерности подалгебры $\varkappa_\infty$. При этом в формуле (2.11)$\mathscr{E}_\infty[X] = (\operatorname{Tr} S_\infty X) \cdot \mathrm{I}$. Для неприводимости отображения Φ, записанного в виде (1.4), необходимо и достаточно, чтобы $\{V_n; n = 1, 2, \ldots \ldots\}'' = \mathfrak{B}(\mathscr{H})$, где $\mathfrak{A}'' = (\mathfrak{A}')'$. Для неприводимого отображения имеет место аналог теоремы Перрона-Фробениуса, отвечающй разложению замкнутого класса состояний цепи Маркова на подклассы (Эванс, Хег-Крон, Альбеверио; см. обзор [27]). Случай $\dim \mathscr{H} < \infty$ детально рассмотрен также в книге Т. А. Сарымсакова [31].

Пусть теперь $\{\Phi_t; t \in \mathbf{R}_+\}$-квантовая динамическая полугруппа, имеющая точное нормальное инвариантное состояние S_∞. Для нее также имеет место эргодическая теорема для средних (см. обзоры [27], [94]). Неприводимые полугруппы изучалн Дэвис, Эванс, Шпон, Фриджерио (см. [78], [152]). Необходимое и достаточное условие неприводимости динамической полугруппы с инфинитезимальным оператором (2.5) состоит в том, что

$$\left\{H, L_j, L_j^*; j = 1, 2, \ldots\right\}' = \mathfrak{B}(\mathscr{H})$$

Для неприводимых квантовых динамических полугрупп с непрерывным временем имеет место существенное усиление эргодической теоремы (см. [94])

$$w^* - \lim_{t \to +\infty} \Phi_t[X] = (\operatorname{Tr} S_\infty X) \cdot \mathrm{I}$$

Этот факт не переносится на динамические полугруппы в произвольных алгебрах фон Неймана. Обобщения на этот случай других асимптотических свойств, спектральной теории и теоремы Перрона-Фробениуса подробно рассмотрены в обзоре Гроха [94].

Основные физические примеры эргодических динамических полугрупп относятся к классу квазисвободных полугрупп, для которых эргодичность устанавливается непосредственно (см. обзор [27]).

2.6. Расширения динамических полугрупп.

С точки зрения статистической механики закономерен вопрос- насколько по-

нятие динамической полугруппы согласуется с более фундамен-

тальным законом обратимой эволюции для изолированной системы. В физических приложениях управляющее уравнение (2.1) получается при рассмотрении взаимодействия квантовой системы с окружением в марковском приближении (пределы слабого или сингулярного взаимодействия). Строгое обоснова- ние такого приближения требует достаточно громоздких оценок даже для простых моделей. Имеется ряд обзоров [152], [56], [93], [27], [52], в которых эта проблема квантовой статистической механики получила всестороннее освещение, и лучшее, что здесь. можно предложить - это обратиться к одному из этих обзоров.

В принципиальном плане представляет интерес также постановка обратной задачи о расширении динамической полугруппы до группы автоморфизмов, т. е. представление марковской динамики через обратимую динамику открытой системы,

взанмодействующей с окружением. Возможность такого расширения обусловлена, главным образом, свойством полной положительности (Дэвис; Эванс, Льюис; см. [84]).

Т е о р е м а. Пусть $\{\Psi_t; t \in \mathbf{R}_+\}$- непрерывная по норме динамическая полугруппа в пространстве состояний $\mathfrak{S}(\mathscr{H})$. Найдутся гильбертово пространство $\mathscr{H}_0$, состояние S_0 в $\mathscr{H}_0$ и сильно непрерывная группа унитарных операторов $\{U_t; t \in \mathbf{R}\}$ в $\mathscr{H} \otimes \mathscr{H}_0$. такие что

для всех $t \in \mathbf{R}_+$.

$$\Psi_t[S] = \operatorname{Tr}_{\mathscr{H}_0} U_t (S \otimes S_0) U_t^*; S \in S(\mathscr{H})$$

В п. 5.2.2 будет приведена явная конструкция расширения, допускающая прозрачное динамико-статистическое истолкование. Следует отметить, что одна и та же динамическая полугруппа может иметь много неэквивалентных расширений (даже если требовать минимальность расширения). Дополнительный свет на структуру возможных расширений проливает понятие квантового случайного процесса. Согласно определению Аккарди, Фриджерио и Льюиса (1980), квантовый случайный процесс задается тройкой $(\mathrm{Re}, (j_t), \varphi)$, где $\mathfrak{A}$ – C^*-алгебра, $(j_t)_{t\in\mathbf{R}}$ - семейство *-гомоморфизмов некоторой фиксированной C^*-алгебры в в $\mathfrak{A}, \varphi$ - состояние на $\mathfrak{A}$. При определенных условиях регулярности квантовый случайный процесс однозначно с точностью до эквивалентности восстанавливается по корреляционным ядрам

$$w_1^t, \ldots, t_n (X_1, \ldots, X_n; Y_1, \ldots, Y_n) =$$
$$= \varphi \left(j_{t_1} (X_1)^* \ldots j_{t_n} (X_n)^* j_{t_n} (Y_n) \ldots j_{t_1} (Y_1)_) \right)$$

(некоммутативный аналог теоремы А. Н. Колмогорова о продолжении системы конечномерных распределений) (см. сборник [20]). В классическом случае $\mathscr{A}$ и $\mathfrak{B}$ коммутатнвные алгебры измеримых ограниченных функций, соответственно, на пространстве элементарных исходов Ω и на фазовом пространстве системы $E, (j_t)$ определяется семейством случайных величин на Ω со значениями в E, а φ - функционал математического ожидания, соответствующий вероятностной мере на Ω.

С квантовым случайным процессом связываются семейства подалгебр «прошлого», «настоящего» н «будущего»

$$\mathfrak{A}_{t]} = \bigvee_{s\leqslant t} j_s(\mathfrak{B}), \quad \mathfrak{A}_t = j_t(\mathfrak{B}), \quad \mathfrak{A}_{[t} = \bigvee_{s\geqslant t} j_s(\mathfrak{B})$$

Процесс называется жарковскик, если существует согласованное с φ семейство условных ожиданий $(\mathscr{E}_{t]})_{t\in\mathbf{R}}$ из $\mathfrak{A}$ на $\mathfrak{A}_{t]}$, такое что

$$\mathscr{E}_{t]} \left(\mathfrak{A}_{[t} \right) \subseteq \mathscr{A}_t$$

ковариантным марковския, если дополнительно существует группа *-автоморфизмо в $(\alpha_t)_{t\in R}$ алгебры $\mathscr{A}$, такая что $\alpha_t \left(\mathrm{Re}_{s]} \right) = \mathfrak{R}_{t+s]}; t, s \in \mathbb{R}$, и $\alpha_t \cdot \mathscr{E}_{s]} \cdot \alpha_{-t} = \mathscr{E}_{t+s]}$, и стационарныцм марковским, если φ инвариантно относительно (α_t). Для ковариантного марковского процесса соотношение

$$\Phi_t[X] = j_t^{-1} \mathscr{E}_{t]} \dot{j}_t[X]$$

при выполнении некоторых условнй непрерывности определяет динамическую полугруппу в Я. Обратно, всякая непрерывная по норме квантовая динамическая полугруппа $\{\Phi_t\}$ расширяется до. ковариантного марковского процесса, удовлетворяющего соотношению (2.12). Если же динамическая полугруппа

удовлетворяет условню детального равновесия, то она расширяется до стационарного марковского квантового случайного процесса (Горини, Фриджерио). Условие детального равновесия относи· тельно состояния S для полугруппы $\{\Phi_t\}$ в $\mathscr{B}(\mathscr{Z})$ означает, что существует другая динамическая полугруппа $\left\{\Phi_t^+\right\}$в $\mathscr{B}(\mathscr{H})$, такая что

$$\operatorname{Tr} S\Phi_t + [X]Y = \operatorname{Tr} SX\Phi_t[Y]; \quad X, Y \in \mathscr{B}(\mathscr{H})$$

с инфинитезимальным оператором $\mathscr{L}^+$, удовлетворяющим соотношению

$$\mathscr{L}[X] - \mathscr{L} + [X] = 2i[H, X]$$

где $H \in \mathscr{P}_h(\mathscr{H})$ (состояние S с необходимостью оказывается стационарным для Φ_t и Φ_t^+). До сих пор отсутствует полное описание динамических полугрупп, допускающих стационарные марковские расширения.

Фриджерио и Маассен [87] указали широкий класс полугрупп, не удовлетворяющих условию детального равновесия, но допускающих расширение с помощью «квантового пуассоновского процесса». Систематическое исследование стационарных марковских расширений предпринял Кюммерер [119]. Он установил прямую связь между эргодическими свойствами динамического отображения (неприводимость, слабое, сильное перемешивание) и его минимального стационарного марковского расширения. Кюммерер и Маассен [120] показали, что квантовая динамическая полугруппа в конечномерном гильбертовом пространстве допускает стационарное марковское расширение с помощью классического случайного процесса тогда и только тогда, когда ее

. инфинитезимальный оператор имеет вид

$$\mathscr{L}[\mathrm{X}] = i[H, X] + \sum_{s=1}^{k} \left(A_s X A_s - A_s^2 \circ X\right) + \\ + \sum_{r=1}^{l} \lambda_r \left(U_r^* X U_r - X\right)$$

тде A_s - эрмитовы, U_r - унитарные операторы, $\lambda_r > 0$. Оператор (2.13) является суммой выражений $(2.2), (2.3)$, соответствующих гауссовским и пуассоновским полугруппам, а расширение получается с помощью случайного блуждания на группе автоморфизмов алгебры $\mathfrak{M}_n$.

Неоднозначность расширения динамической полугруппы до случайного процесса связана с тем, что знание полугруппы $\{\Phi_t\}$ позволяет восстановить лишь хронологически-упорядоченные корреляционные ядра

$$w_{t_1,\ldots,t_n}(X_1, \ldots, X_n; Y_1, \ldots, Y_n) = \\ = \varphi_0\left(\Phi_{t_1}\left[X_1^* \Phi_{t_2 - t_1}\left[\ldots \Phi_{t_n - t_{n-1}}\left[X_n^* Y_n\right]\ldots\right] Y_1\right]\right),$$

-для которых $0 < t_1 < \ldots < t_n$ (здесь $\varphi_0 = \varphi|\mathscr{A}_0$ - начальное состояние). В классической теории вероятностей корреляционные ядра зависят от времен $t_1, \ldots, t_n$ симметричным образом; известная конструкция Колмогорова-Даниэля однозначно сопоставляет полугруппе переходных вероятностей марковский процесс, являющийся ее минимальным расширением до группы временных сдвигов в пространстве траекторий. Определение квантового случайного процесса, основанное только на хронологически-упорядоченных ядрах, было предложено Линдбладом [124], некоммутативные обобщения конструкции КолмогороваДаниэля рассматривались Винсент-Смитом [161], В. П. Белавкиным [3], Соважо [146].

Алицки и Мессер установили существование и единственность решения класса н елине й ных кинетических уравнений, в частности, квантового уравнения Больцмана:

$$\frac{dSt}{dt} = \mathrm{Tr}_{(2)}\, W\,(S_t \otimes S_t)\, W^* - (\mathrm{Tr}\, S_t)\cdot S_t$$

где W - унитарный «оператор парных столкновений» в $\mathscr{C}\otimes\mathscr{H}$, $\mathrm{Tr}_{(2)}$ - частичный след по второму множителю в $\mathscr{H}\otimes\mathscr{H}$. Отвечая на вопрос, поставленный Стритером в [143], Фриджерио и - Аратари построили расширение «нелинейной квантовой динами'ческой полугруппы», определенной уравнением (2.14) по уни"тарной эволюции в квантовой системе, состоящей из бесконечно'го числа частиц с парными взаимодействиями (квантовое обобщение «карикатуры Мак-Кина» классического уравнения Боль- цмана). В. П. Белавкин [4] дал конструкцию квантового ветвящегося процесса, в котором одночастичная динамика описывается полугруппой нелинейных вполне положительных отображений общего вида.

12.4 Consistent and Continuous Measurement Processes

12.4.1 1. Statistics of Successive Measurements

1.1. Понятие инструмента.

Рассмотрим последовательное измерение двух величин X, Y, принимающих значения, соответственно, в множествах $\mathscr{X}$ и $\mathscr{Y}$, которое осуществляется над системой в состоянии S. Совместная вероятность того, что исход первого измерения x попадает в множество A, а исход второго y попадает в B (где $A\subset\mathscr{X}, B\subset\mathscr{Y}$) есть

$$\mu_s(A;B) = \mu_s(A)\mu_s(B|A)$$

где $\mu_{\mathcal{S}}(A) = \mu_{\mathcal{B}}(A;\dagger)$ - вероятность того, что $x\in A$, а $\mu_{\mathcal{S}}(B|A)$ - соответствуюшая условная вероятность. Обозначим S_A состояние системы после первого измерения (оно зависит также от S, но не зависит от B). Тогда, согласно (2.1.4),

$$\mu_S(B|A) = \mathrm{Tr}\, S_A M(B)$$

где $\boldsymbol{M}$ - разложение единицы, отвечающее величине Y. Из (1.1), (1.2) видно, что функция множеств

$$\mathscr{M}(A)[S] = \mu_S(A)S_A$$

должна быть σ-аддитивна по A. Это мотивирует следующее определение (Дэвис и Льюис, 1970).

Пусть $\mathscr{X}$ - множество с σ-алгеброй измеримых подмножеств $\mathscr{B}(\mathscr{Q})$. Инструментом (в пространстве состояний) со значениями в $\mathscr{X}$ называется функция множеств $\mathscr{M}$, заданная на $\mathscr{B}(\mathscr{L})$ и удовлетворяющая условиям:

1. $\mathscr{M}(B)$ - операция для любого $B\in\mathscr{B}(\mathscr{X})$;
2. $\mathscr{M}(\mathscr{X})$ - динамическое отображение, т. е. $\mathrm{Tr}\,\mathscr{M}(\mathscr{X})[T] = \mathrm{Tr}\, T$ для всех $T\in\mathfrak{T}(\mathscr{C})$;
3. если $\{B_j\}\subset\mathscr{B}(\mathscr{X})$ - конечное или счетное разбиение множества $B\in\mathscr{B}(\mathscr{C})$ на попарно непересекающиеся подмножест-; ва, то

$$\mathscr{M}(B)[T] = \sum_j \mathscr{M}(B_j)[T]; T \in \mathfrak{T}(\mathscr{H})$$

где ряд сходится по норме $\mathfrak{T}(\mathscr{H})$.

Постулируется, что если S - оператор плотности, описываю: щий состояние системы перед измерением, то вероятность собы: тия, что исход измерения попадает в множество $B \in \mathscr{B}(\mathscr{X})$, равна

$$\mu_{\boldsymbol{s}}(B) = \operatorname{Tr} \mathscr{A}(B)[S]$$

а состояние доли статистического ансамбля, в которой зарегистрировано это событие, дается оператором плотности

$$S_B = \mathscr{M}(B)[S] / \operatorname{Tr} \mathscr{M}(B)[S]$$

(при условии, что $\mu_8(B) > 0$). В частности, изменение состояния всего статистического ансамбля задается динамическим отображением $S \to \mathscr{M}(\mathscr{X})[S]$.

Переходя к сопряженным отображениям $\mathscr{P}(B) = \mathscr{M}(B)^*$, получаем формулировку в алгебре наблюдаемых: инструмент это функция множеств $\mathscr{P}$ на $\mathscr{B}(\mathscr{D})$, такая что

1. $\mathscr{P}(B)$ - положительное нормальное отображение $\mathscr{B}(\mathscr{H})$ в себя для любого $B \in \mathscr{B}(\mathscr{Q})$;
2. $\mathscr{P}(\mathscr{X})[\mathrm{I}] = \mathrm{I}$;
3. если $\{B_i\} \subset \mathscr{B}(\mathscr{X})$ - разбиение множества B, то

$$\mathscr{P}(B)[X] = \sum_j \mathcal{P}(B_j)[X]; X \in \mathscr{B}(\mathscr{H})$$

где ряд сходится *-слабо.

Каждому инструменту отвечает обобщенная наблюдаемая

$$M(B) = \mathscr{P}(B)[\mathrm{I}]; \quad B \in \mathscr{B}(\mathscr{X})$$

такая, что

$$\mu_B(B) = \operatorname{Tr} SM(B)$$

Озава [135] показал, что для любого инструмента $\mathscr{M}$ и любого состояния S существует семейство апостериорных состояний $\{S_x; x \in \mathscr{Q}\}$, т. е. операторов плотности S_x, таких что:

1. функция $x \to \operatorname{Tr} S_x Y \mu_s$-измерима для любого $Y \in \mathscr{F}(\mathscr{C})$;
2. $\operatorname{Tr} \mathscr{M}(B)[S]Y = \int\limits_B (\operatorname{Tr} S_x Y)\, \mu_s(dx)$.

Оператор плотности S_x описывает состояние доли статистического ансамбля, в которой исход измерения равен x, а величина $\operatorname{Tr} S_x Y = \mathbf{E}_s(Y|x)$ есть апостериорное среднее наблюдаемой Y при условни, что исход предыдущего измерения равен x.

Инструмент $\mathscr{M}$ (или $\mathscr{P}$) называется вполне положительным, если отображения $\mathscr{P}(B); B \in \mathscr{B}(\mathscr{X})$, вполне положительны.

П р и м е р 1. Пусть $A = \sum_i x_i E_i$ - вещественная наблюдаемая с чисто точечным спектром. Соотношение

$$\mathscr{M}(B)[S] = \sum_{i:x_i \in B} E_i S E_i$$

определяет вполне положительный инструмент со значениями в $\mathbf{R}$, соответствующий проекционному постулату фон Неймана, который описывает предельно точное измерение наблюдаемой A.

Распределение вероятностей в состоянии S есть

$$\mu_S(B) = \sum_{i:x_i \mathrm{G}^B} \operatorname{Tr} S E_i$$

а апостериорные состояния даются формулой

$$S_i = E_i S E_i / \operatorname{Tr} S E_i$$

Прим е р 2. Пусть A - вещественная наблюдаемая и $p(x)$ - плотность распределения вероятностей на $\mathbf{R}$, такая что

$$\int_{-\infty}^{\infty} x p(x) dx = 0, \quad \int_{-\infty}^{\infty} x^2 p(x) dx = \sigma^2 < \infty$$

Вполне положительный инструмент

$$\mathscr{M}(B)[S] = \int_B \sqrt{p(xI - A)} S \sqrt{p(xI - A)} dx$$

описывает неточное измерение наблюдаемой A со случайной ошибкой, распределенной с плотностью $p(x)$. В самом деле

$$\mu_S(B) = \int_B \operatorname{Tr} S p(x\mathrm{I} - A) dx =$$
$$= \int_B \int_B p(x - y) \mu_S^A(dy) dx,$$

где ${\mu_s}^A$ - распределение вероятностей наблюдаемой A в состоянии S. Апостериорные состояния суть

$$S_x = \frac{\sqrt{p(x\mathrm{I} - A)} S \sqrt{p(x\mathrm{I} - A)}}{\operatorname{Tr} S p(x\mathrm{I} - A)}$$

Чем меньше σ^2, т. е. чем ближе $p(x)$ к δ-функции, тем точнее измерение наблюдаемой A. Для наблюдаемой A с чисто точечным спектром случай $\sigma^2 = 0$ соответствует примеру 1 ; для наблюдаемой с непрерывным спектром возникают принципиальные трудности, не позволяющие непосредственно обобщить проекционный постулат на этот случай (см. далее п. 1.3).

1.2 Представление вполне положительного инструмента.

Многие реальные процессы укладываются в следующую схему косвенного измерения: рассматриваемая система взаимодействует с «пробной» системой, после чего над пробной системой производится прямое измерение некоторой квантовой наблюдаемой. Пусть $\mathscr{C}_0$ - гильбертово пространство пробной системы, S_0 - оператор плотности, описывающий ее исходное состояние, U - унитарный оператор в $\mathscr{C} \otimes \mathscr{H}_0$, задающий взаимодействие и E_0 - ортогональное разложение единицы в $\mathscr{C}_0$, соответствующее измеряемой величине. Распределение вероятностей такого измерения дается формулой

$$\mu_{\mathcal{S}}(B) = \operatorname{Tr} U\,(S \otimes S_0)\,U^*\,(\mathrm{I} \otimes E_0(B))\,;\, B \in \mathscr{B}(\mathscr{X})$$

где S - оператор плотности системы перед измерением. Оно может быть записано в виде (1.3), где

$$\mathscr{M}(B)[S] = \operatorname{Tr}_{\mathscr{C}_0} U\,(S \otimes S_0)\,U^*\,(\mathrm{I}_{\otimes} E_0(B))$$

- вполне положительный инструмент в пространстве состояний системы $\mathscr{H}$ (здесь $\operatorname{Tr}\mathscr{H}_0$ - частичный след по $\mathscr{H}0$). Верно и обратное.

Т е оре м а (Озава, [134]). Пусть $\mathscr{M}$ - вполне положительный инструмент со значениями в $\mathscr{X}$. Найдется гильбертово пространство $\mathscr{C}_0$, оператор плотности S_0 в $\mathscr{C}_0$, унитарный оператор $U_{\text{в}}\,\mathscr{C} \otimes \mathscr{C}_0$ и ортогональное разложение единицы $\mathbf{E}_0$ в $\mathscr{C}$, такие что для любого оператора плотности S в $\mathscr{H}$ имеет место формула (1.10).

В основе этой теоремы лежит следующая комбинация теоремы Наймарка и теоремы Стайнспринга: если $\mathscr{P}$ - вполне положительный инструмент (в алгебре наблюдаемых), то существует гильбертово пространство $\mathscr{K}$, изометрический оператор V из $\mathscr{H}$ в $\mathscr{K}$, ортогональное разложение единицы E в $\mathscr{K}$ и нормальный *-гомоморфизм π из $\mathscr{B}(\mathscr{H})$ в $\mathfrak{F}(\mathscr{K})$, такие что $[E(B), \pi[X]] = 0$ для всех $B \in \mathscr{B}(\mathscr{C}), X \in \mathscr{B}(\mathscr{C})$ и

$$\mathscr{P}(B)[X] = V^* E(B)\pi[X]V$$

Пространство $\mathscr{K}$ превращается в $\mathscr{H} \otimes \mathscr{H}_0$ с помощью рассуждений, которые были использованы при доказательстве формулы (3.1.4).

Из (1.11) выводится аналог представления (3.1.4) для вполне положительного инструмента

$$\mathscr{P}(B)[X] = \int\limits_B \sum_{n=1}^{\infty} V_n(x)^* X V_n(x)\mu(dx)$$

где $\mu - \sigma$-конечная мера на $\mathscr{R}$, а $V_n(x) - \mu$-измеримые функции на $\mathscr{X}$ со значениями в $\mathscr{O}(\mathscr{H})$, такие что

$$\int\limits_{\mathscr{Q}}^{\infty} \sum_{k=1}^{\infty} V_n(x)^* V_n(x)\mu(dx) = \mathrm{I}$$

Соответствующий инструмент в пространстве состояний имеет вид

$$\mathscr{K}(B)[S] = \int\limits_B \sum_{n=1}^{\infty} V_n(x) S V_n(x)^* \mu(dx)$$

При этом распределение вероятностей в состоянии S дается формулой

$$\mu_S(B) = \int\limits_B \sum_{n=1}^{\infty} \operatorname{Tr} SV_n(x)^* V_n(x) \mu(dx)$$

$$S_x = \sum_{n=1}^{\infty} V_n(x) S V_n(x)^* | \sum_{n=1}^{\infty} \operatorname{Tr} SV_n(x)^* V_n(x)$$

1.3 Три уровня описания квантовых измерений.

Теорема Озава имеет принципиальное значение, поскольку демонстрирует согласованность понятия (вполне положительного) инструмента со стандартным формализмом квантовой механики. Описание измерения в обобщенной статистической модели квантовой механики может быть осуществлено с различной степенью подробности. Имеется три основных уровня описания, каждому из которых отвечает определенный математический объект в гильбертовом пространстве системы:

1. Задана только статистика исходов измерения. Как показано в п. 2.1.2, это эквивалентно заданию обобщенной наблюдаемой, т. е. некоторого разложения единицы в $\mathscr{H}$.

2. Кроме статистики, задан закон преобразования состояний в зависимости от исхода измерения. На этом уровне адекватное описание измерения дается понятием инструмента. Каждому инструменту по формуле (1.5) отвечает обобщенная наблюдаемая, однако это соответствие не взаимно однозначно, поскольку инструмент дает более подробное описание измерения, нежели наблюдаемая.

3. Задано динамическое описание взаимодействия системы с пробной системой. Этот уровень является еще более подробным: каждому инструменту по формуле (1.10) может соответствовать. множество различных процедур косвенного измерения. Детальность схемы косвенного измерения зависит от того, где в измерительном приборе проводится черта между «пробной системой» и «детектором», осушествляющим прямое измерение.

С точки зрения физических приложений представляет большой интерес вопрос о реализуемости той или иной теоретической схемы квантового измерения. Высказывалась мысль (см., например, статью «Проблема измерения» в сборнике [11]), что хотя квантовая механика правильно отражает некоторые черты микромира, далеко не все, что содержится в ее математической модели, может иметь свой прототип в реальности. Известны обшие ограничения типа правил суперотбора (см., например, [23]), которые постулируют измеримость только наблюдаемых, совместимых с некоторой выделенной величиной типа заряда. В связи со схемой косвенного измерения возникают следующие вопросы:

1. Соответствует ли данному унитарному оператору U реальное квантовомеханическое взаимодействие?

2. Соответствует ли данной наблюдаемой A реально измеримая физнческая величина?

Подробное обсуждение таких вопросов выходит за рамки настоящего обзора, но некоторые комментарии здесь все же необходимы. В работах Ваневского [165] и Мельника [129] показано, что всякий унитарный оператор может быть получен из шрёдингеровской эволюции с некоторым потенциалом, зависящим от времени. Таким

образом, первый вопрос сводится к реализуемости потенциалов в квантовой механике. С другой стороны, в п. 1.5 будет показано, что второй вопрос сводится к первому для взаимодействий специальног) вида. Практически, конечно, эти вопросы могут быть совсем не просты и требуют отдельного рассмотрения в каждой конкретной задаче измерения (см. в этой связи поучительное обсуждение «приемника Долинара» в [37, гл. VI] и в [18]).

1.4. Воспроизводимость. Пусть S-оператор плотности, $\mathscr{M}_1, \ldots, \mathscr{M}_n$ - последовательность инструментов со значениями в измеримых пространствах $\mathscr{X}_1, \ldots, \mathscr{X}_n$. Из постулатов (1.3), (1.4) следует, что величина

$$\mu_S^{\mathscr{M}_1,\ldots,\mathscr{M}_n}(B_1 \times \ldots \times B_n) = \\ = \operatorname{Tr} \mathscr{M}_n(B_n)[\ldots \mathscr{M}_1(B_1)[S]\ldots]$$

где $B_j \in \mathscr{B}(\mathscr{X})$ есть вероятность того, что в последовательности измерений, задаваемых инструментами $\mathscr{M}_1, \ldots, \mathscr{M}_n$, над системой, первоначально находившейся в состоянии S, будут получены исходы $x_j \in B_j; j = 1, \ldots, n$. Если $\mathscr{X}_1, \ldots, \mathscr{X}_n$ - стандартные измеримые пространства, то функция множеств (1.12), заданная на параллелепипедах $B_1 \times \ldots \times B_n$, однозначно продолжается до вероятностной меры на б-алгебре $\mathscr{B}(\mathscr{R}\mathscr{R}_1) \times \ldots \ldots \times \mathscr{B}(\mathscr{X}_n)$ (см. [78,4.2]). Соотношение (1.15) можно записать также в виде

$$\mu_S^{\mathscr{M}_1}, \ldots, \mathscr{M}_n(B_1 \times \ldots \times B_n) = \\ = \operatorname{Tr} S\mathscr{P}_1(B_1)[\ldots \mathscr{P}_n(B_n)[1]\ldots]$$

В случае инструментов, сооответствующих проекционному постулату (1.6), соотношение (1.15) переходит в формулу Вигнера (см. статью «Проблема измерения» в сборнике [11]).

Рассмотрим повторное измерение, описываемое инструментом $\mathscr{M}$. Инструмент $\mathscr{M}$ называется воспроизводимьм, если

$$\mathscr{M}(B_1)[\mathscr{M}(B_2)[S]] = \mathscr{M}(B_1 \cap B_2)[\mathrm{S}]; B_1, B_2 \in \mathscr{B}(\mathscr{X})$$

для любого оператора плотности S. Это свойство является математическим выражением гипотезы воспроизводи мо с ти, гласящей, что «если физическая величина дважды измеряется на системе $\mathscr{P}$, причем измерения следуют непосредственно одно за другим, то в обоих случаях получается одно и.то же значение» (см. [26, гл. IV, п. 3]).

Рассмотрим инструмент со счетным множеством исходов $\mathscr{Z} = \{x_1, x_2, \ldots\}$ и положим $\mathscr{M}_i = \mathscr{M}(\{x_i\})$.

П р едложение ([134], [78]). Всякий инструмент вида (1.6) обладает свойствами:

1. $\mathscr{M}_i[\mathscr{M}_j[S]] = \delta_{ij}\mathscr{M}_i[S]$ (воспроизводимость); ния);
2. если $\operatorname{Tr} \mathscr{M}_i[S] = 1$, то $\mathscr{M}_i[S] = S$ (минимальность возмуще-
3. если $X \geqslant 0$ и $\mathscr{M}_i^*[X] = 0$ для $i = 1, 2, \ldots$, то $X = 0$ (невырожденность). (1.6).

Обратно, всякий инструмент с этими свойствами имеет вид

Таким образом, проекционный постулат (1.6) можно рассматривать как следствие ряда физически содержательных свойств соответствующего инструмента, включающих воспроизводимость. Как уже отмечалось, в случае непрерывного спектра возникают принципиальные трудности, которые в наиболее ясной форме выражаются следующей теоремой

Т е о ре м а (Озава [134]). Пусть $\mathscr{X}$ - стандартное измеримое пространство. Всякий инструмент со значениями в $\mathscr{X}$, обладающий свойством воспроизводимости (1.17), с необходимостью является дискретным, т. е. существует счетное подмножество $\mathscr{E}_0 \subset \mathscr{X}$, такое что $\mathscr{M}(\mathscr{X}\setminus\mathscr{X}_0)[S] = 0$ для всех S.

Доказ ательство. Рассмотрим точное состояние, задаваемое невырожденным оператором плотности S. Согласно п. 1.1, существует семейство апостериорных состояний $\{S_x\}$. Пусть $\{B_n\}$ - счетная подалгебра, порождающая $\mathscr{B}(\mathscr{X})$. Обозначая $M(B) = \mathscr{M}(B) * [\mathrm{I}]$ й используя воспроизводимость, имеем

$$\int_B \operatorname{Tr} S_x M(B_n)\,\mu_S(dx) = \operatorname{Tr}\mathscr{M}(B)[S]M(B_n) =$$

$$= \operatorname{Tr}\mathscr{N}(B\cap B_n)[S] = \int_B 1_{B_n}(x)\mu_S(dx),$$

откуда $\operatorname{Tr} S_x M(B_n) = 1_{B_n}(x)$ для μ_S-почти всех $x \in \mathscr{X}$. Поэтому найдется подмножество $\mathscr{X}_0 \subset \mathscr{X}$, такое что $\mathscr{M}(\mathscr{X}\setminus\mathscr{X}_0)[S] = 0$ и

$$\operatorname{Tr} S_x M(B) = 1_B(x); x \in \mathscr{X}_0, B \in \mathscr{B}(\mathscr{X})$$

Но тогда $\operatorname{Tr} S_x M(\{x\}) = 1, x \in \mathscr{X}_0$, т. е. $M(\{x\}) \neq 0$ и $\mu_S(\{x\}) \neq 0$, откуда следует, что $\mathscr{Q}_0$ счетно.

В примере 1 апостериорные состояния (1.7) таковы, что в этих состояниях (дискретная) наблюдаемая A с вероятностью 1 имеет определенное значение x_j. Причина трудностей с непрерывным спектром связана с тем, что (алгебраическое) состояние, в котором непрерывная наблюдаемая A имеет определенное значение, не может быть нормальным (т. е. задаваться каким-либо оператором плотности).

1.5. Измерения непрерывных наблюдаемых. В работах Шриниваза [153] и Озавы [136] указана возможность описания воспроизводимых измерений непрерывных наблюдаемых, использующая состояния и инструменты, не удовлетворяющие ус- ловию нормальности. Пусть $A = \int_{-\infty}^{\infty} xE_A(dx)$ - вещественная наблюдаемая и пусть η-какое-либо инвариантное среднее [1)] на пространстве $C(\mathrm{R})$ ограниченных непрерывных функций на R. Следуя [153], рассмотрим отображение ${\mathscr{E}_\eta}^A$ алгебры $\mathscr{B}(\mathscr{H})$ в себя, определяемое формулой

$$\operatorname{Tr} S{\mathscr{E}_\eta}^A[X] = \eta_y\left(\operatorname{Tr} Se^{iyA}Xe^{-iyA}\right)$$

где индекс y означает, что усреднение происходит по переменной y, и функцию множеств

$$\mathscr{S}_A(B)[X] = E_A(B){\mathscr{E}_\eta}^A[X]; \quad B \in \mathscr{B}(\mathbf{R})$$

Отображение ${\mathscr{E}_\eta}^A$ является условным ожиданием на коммутативную подалгебру $\{E_A(B); B \in \mathscr{B}(\mathbf{R})\}' = \mathscr{P}_A$, порожденную; наблюдаемой A. Если A имеет чисто точечный спектр, то ${\mathscr{E}_\eta}^A$ есть нормальное условное ожидание, задаваемое формулой (3.1.5), а соотношение (1.18) совпадает с проекционным посту. латом (1.6). В общем случае отображение ${\mathscr{E}_\eta}^A$ не нормальное, а функция множеств (1.18) обладает всеми свойствами воспроизводимого инструмента, кроме нормальности.

Вероятности последовательного измерения наблюдаемых $A_1, \ldots, A_n$ даются обобщением формулы (1.16)

$$\mu_S^{A_1,\ldots,A_n}(B_1\times\ldots\times B_n) =$$
$$= \operatorname{Tr} S\mathscr{P}_{A_1}(B_1)[\ldots\mathscr{P}_{A_n}(B_n)[\mathrm{I}]\ldots].$$

Если $A_1, \ldots, A_n$ совместимы, то $\mathscr{E}_\eta^{A_j}[E_{A_k}(B)] = E_{A_k}(B)$, откуда

$$\mu_S^{A_1,\ldots,A_n}(B_1 \times \ldots \times B_n) = \operatorname{Tr} S E_{A_1}(B_1) \ldots E_{A_n}(B_n)$$

т. е. распределение вероятностей последовательных точных измерений совместимых наблюдаемых совпадает с распределением точного совместного измерения этих наблюдаемых (см. п. 1.1.5) - результат, который подтверждает правомерность «обобщенного проекционного постулата» (1.18).

С другой стороны, если A_j несовместимы, то из-за не нормальности отображений $\mathscr{E}_\eta^{A_j}$, функция множеств (1.18) может оказаться лишь конечно аддитивной на (R). Для того чтобы восстановить σ-аддитивность, необходимо рассматривать распределение на компактификации вещественной прямой $\overline{\mathbf{R}} = \mathbf{R} \cup \{-\infty\} \cup \{\infty\}$. Например, после точного измерения наблюдаемой координаты Q система переходит в не нормальное состояние, в котором импульс P с положительными вероятностями принимает значения $\pm\infty$[153].

1. См. Ф. Гринлиф. Инвариантные средние на топологических группах и их приложения.- М.: Мир, 1973.

Озава [136] построил процесс косвенного измерения, отвечающий обобщенному проекционному постулату (1.18) и разъяснил роль инвариантного среднего η. Рассмотрим наблюдаемые Q, P во вспомогательном гильбертовом пространстве $\mathscr{H}_0 = L^2(\mathbf{R})$, которое будет описывать «пробную систему». Пользуясь теоремой Банаха о продолжении, можно показать, что для любого η на алгебре $\mathfrak{B}(\mathscr{C}_0)$ сушествует (не нормальное) состояние E_n, такое, что

$$E_\eta(f(Q)) = f(Q), E_\eta(f(P)) = \eta(f)$$

для любой $f \in C(\mathbb{R})$. Пусть $U_t = \exp(-itH_{\text{lnt}})$ - унитарная эволюция в $\mathscr{H} \otimes \mathscr{H}_0$, где

$$H_{\text{lnt}} = \lambda(A \otimes P)$$

причем λ может быть выбрано произвольно большим, чтобы пренебречь свободной динамикой системы и прибора. В [136] показано, что для любого (нормального) состояния S и любого $X \in \mathscr{B}(\mathscr{H})$

$$\operatorname{Tr} S \mathscr{P}_A(B)[X] = (E_S \otimes E_\eta)\left(U_{1/\lambda}^*(X \otimes E_Q(B))\, U_{1/\lambda}\right); \quad B \in \mathscr{B}(\mathbf{R})$$

Таким образом, пробная система, находящаяся в состоянии E_η с точно определенной координатой, в течение времени $1/\lambda$ взаимодействует с наблюдаемой системой согласно (1.21), после чего производится точное измерение координаты пробной системы.

Такая схема является обобщением процедуры косвенного измерения, рассмотренной фон Нейманом в случае чисто точечного спектра ([26, гл. VI, п. 3]). В принципиальном плане она сводит измерение произвольной квантовой наблюдаемой к измерению координаты пробной системы, при условии реализуемости гамильтониана взаимодействия (1.21).

12.4.2 2. Continuous Measurement Processes

2.1. Неразрушающие измерения.

Рассмотрим изолированную квантовую систему, эволюция которой описывается группой унитарных операторов $\{U_t; t \in \mathbf{R}\}$ в гильбертовом пространстве $\mathscr{H}$. Пусть $\{A_{jt}; j = 1, \ldots, m; t \in T\}$, где $T \subset \mathbf{R}$ - семейство вещественных наблюдаемых. Обозначим

$$A_j(t) = U_t^* A_{jt} U_t; \quad t \in T$$

и предположим, что для любых моментов времени $t_1 < \ldots < t_n$ и любых $j_1, \ldots, j_n$ наблюдаемые $A_{j_1}(t_1), \ldots, A_{j_n}(t_n)$ со в м стимы. Согласно формуле (1.20), последовательное точное измерение наблюдаемых $A_{j_1}(t_1), \ldots, A_{f_n}(t_n)\,(j_k = 1, \ldots, m)$ имеет распределение вероятностей

$$\mu_S\left(B_1 \times \ldots \times \bar{D}_n\right) = \operatorname{Tr} S E_{(t_1)}(B_1) \ldots E_{(t_n)}(B_n)$$

где $B_k \in \mathscr{R}(\mathbf{R}^m)$ и $E_{(t_k)}$-совместная спектральная мера наблю* даемых $A_j(t_k); j = 1, \ldots, m$.

Семейство вероятностных мер (2.2) при всевозможных $n = 1, 2, \ldots; t_1, \ldots, t_n$ является согласованным. Используя теорему А. Н. Колмогорова о продолжении, можно доказать, что существует единственное ортогональное разложение единицы $\mathbf{E}$ на $\mathscr{B}\left(\mathbb{R}^T\right)$, где $\mathscr{B}\left(\mathbf{R}^T\right)$ – σ-алгебра цилиндрических множеств на пространстве траекторий $\mathbf{R}^T$ такое, что

$$E\left(x(\cdot) : x(t_1) \in B_1, \ldots, x(t_n) \in B_n\right) = E_{(t_1)}(B_1) \ldots E_{(t_n)}(B_n)$$

Оно описывает статистику непрерывного (во времени) точного измерения семейства совместимых наблюдаемых (2.1), в том смысле, что вероятность подмножества B в пространстве траекторнй есть

$$\mu_S(x(\cdot) \in B) = \operatorname{Tr} S E(B)$$

В физике подобные измерения получили название неразрушающих и привлекли внимание, в связи с задачей обнаружения слабой силы (гравитационной волны), действующей на пробную систему [69], [140].

П р и м ер. Квантовомеханический осциллятор массы m и с частотой ω, возбуждаемый скалярной силой $\varphi(t)$, описывается уравнениями

$$\dot{Q}(t) = m^{-1} P(t), \quad \dot{P}(t) = -m\omega^2 Q(t) + \varphi(t)\mathrm{I},$$

где $Q(0) = Q$, $P(0) = P$-канонические наблюдаемые, т. е. $[P, Q] = i$. Положим $A_{1t} = Q\cos\omega t - (P/m\omega)\sin\omega t$, так ч то

$$A_1(t) = Q(t)\cos\omega t - (P(t)/m\omega)\sin\omega t.$$

Из уравнений (2.3)

$$\dot{A}_1(t) = -(\varphi(t)/m\omega)\sin\omega t\mathrm{I}$$

поэтому наблюдаемые $A_1(t)$ совместимы при разных t и возможно непрерывное неразрушающее измерение семейства $\{A_1(t)\}$. Сила $\varphi(t)$ может быть определена по любой траектории из соотношения (2.4).

Аналогично, для $A_{2t} = P\cos\omega t + m\omega Q\sin\omega t$ получаем семейство совместимых наблюдаемых

$$A_2(t) = P(t)\cos\omega t + m\omega Q(t)\sin\omega t$$

для которого $\dot{A}_2(t) = \varphi(t)\cos\omega t$ I. Заметим, что $A_1(t)$ и $A_2(t)$ несовместимы, поскольку $[A_2(t), A_1(t)] = i\mathrm{I}$. Действуя в духе п. 2.1.3, рассмотрим семейство совместимых наблодаемых

$$\tilde{A}_1(t) = A_1(t) \otimes \mathrm{I}_0 - \mathrm{I} \otimes Q_0; \quad \widetilde{A}_2(t) = A_2(t) \otimes \mathrm{I}_0 + \mathrm{I} \otimes P_0$$

в пространстве $\mathscr{H} \otimes \mathscr{H}_0$ (см. [103]). Сила $\varphi(t)$ определяется тогда из соотношения

$$\varphi(t) = \cos \omega t \dot{\tilde{A}}_2(t) - m\omega \sin \omega t \dot{\tilde{A}}_1(t).$$

2.2. «Квантовый парадокс Зенона». Попытки рассмотрения непрерывных измерений н е с о ме ст и мых наблюдаемых, опирающиеся на проекционный постулат, приводят к парадоксальным выводам, в основе которых лежит следующий математический факт. Пусть H - самосопряженный оператор из $\mathscr{B}(\mathscr{H}), E$ - проектор, тогда

$$\lim_{n\to\infty} (E \exp(itH/n)E)^n = E \exp(itEHE)$$

Это следует из того, что $\| \exp(itH/n) - \mathrm{I} - itH/n\| = o(1/n)$ и $E^2 = E$. Обобщение этого результата на случай неограниченного H является непростой задачей; некоторые условия были получены Фридманом [86]. Его результаты включают случай, когда $\mathscr{H} = L^2(\mathbf{R}^n), \quad H = -\Delta/2m$ - гамильтониан свободной частицы в $\mathbf{R}^n$, а $E = 1_{\mathscr{D}}(\cdot)$ - индикатор ограниченной области $\mathscr{D} \subset \mathbb{R}^n$ с гладкой границей.

Рассмотрим свободную частицу, эволюционирующую на временном интервале $[0, t]$, и предположим, что в каждый момент времени $tk/n, k = 0, 1, \ldots, n$, производится точное измерение наблюдаемой E, описываемое проекционным постулатом (1.6). Если исход измерения равен 1, то это означает, что частица находится в области $\mathscr{D}$. Вероятность того, что во всех $n + 1$ измерениях получен исход 1, есть

$$\mu_B(1, \ldots, 1) = \mathrm{Tr}(E \exp(itH/n)E)^n S (E \exp(itH/n)E)^n$$

и при $n \to \infty$ в силу (2.6) стремится к

$$\mathrm{Tr}\, E \exp(itEHE) S_0 \exp(-itEHE)E = \mathrm{Tr}\, S_0 E$$

где S_0 - начальное состояние. Если в начальный момент частица находится в области $\mathscr{D}$, то вероятность (2.7) равна 1 независимо от эволюции, т. е. при непрерывном точном измерении местоположения частица никогда не покидает область $\mathscr{D}$ (см. также Дэвис [78, п. 7.4]). Необычные физические следствия соотношения (2.6) были подробно рассмотрены в работе Мисры и Сударшана [130], где для них было предложено общее название «квантовый парадокс Зенона».

Причина парадокса состоит в том, что измерение, описываемое проекционным постулатом, переводя состояние системы в состояние, отвечающее точно определенному значению наблюдаемой, производит конечное изменение, на фоне которого эффект эволюции за время t/n является пренебрежимо малым при $n \to \infty$. Чтобы избежать этого и получить нетривиальный предельный процесс непрерывного измерения, включающий эволюцию, Баркиелли, Ланц и Проспери [59], [60], предложили рассматривать последовательность неточных измерений, точность которых убывает пропорционально числу измерений n. Первоначально описание предельного процесса в частных случаях связывалось с фейнмановским интегралом по траекториям (ср. в этой связи также Менский [25]), однако общая картина прямо основывается на идеях, изложенных в §1, в частности на понятии инструмента. В работах А. С. Холево [47], [102] было указано на параллель такого подхода с классическими предельными теоремами в схеме серий, причем предельный процесс непрерывного измерения оказывается некоммутативным аналогом процесса с независимыми приращениями. Подобно классическому случаю, все такие процессы описываются некоторой формулой типа Леви-Хинчина [102], [35]. Квантовые случайные процессы в смысле Дэвиса [78] с

этой точки зрения соответствуют сложному пуассоновскому процессу. Дальше кратко излагаются результаты этих работ.

2.3. Предельная теорема для сверток инструментов. Для простоты ограничимся измерениями со значениями в $\mathbf{R}$ (сушественно лишь, что пространство значений является абелевой локально компактной группой; см. [102], [35]). Пусть $\mathfrak{N}_1, \ldots, \mathfrak{N}_n$ - инструменты (в алгебре наблюдаемых) со значениями в $\mathbb{R}$. Существует единственный инструмент $\mathcal{P}$ со значениями в $\mathbf{R}^n$, таКоЙ что

$$\mathscr{P}\left(B_1 \times \ldots \times B_n\right)[X] = \mathscr{P}_1\left(B_1\right)[\ldots \mathscr{P}_n\left(B_n\right)[X]\ldots]\,; B_j \in \mathscr{B}(\mathbf{R})$$

Свертка инструментов $\mathscr{P}_1, \ldots, \mathscr{N}_n$ определяется соотношением $\mathscr{N}_1 * \ldots * \mathscr{N}_n(B)[X] = \mathscr{P}\left((x^1, \ldots, x_n) : x_1 + \ldots + x_n \in B\right); B \in \mathscr{B}(\mathbf{R})$

и, согласно формуле (1.13), описывает статистику суммы исходов n последовательнх изме рений, отвечающих инструментам $\mathscr{P}_1, \ldots, \mathscr{N}_n$. Инструмент $\mathscr{N}$ со значениями в $\mathbf{R}$ называется безгранично-делимыцж, если для любого $n = 1, 2, \ldots$ найдется инструмент $\mathscr{N}_{(n)}$ такой, что $\mathscr{S} = \mathscr{N}_{(n)} * \ldots * \mathscr{N}_{(n)} \equiv \mathscr{S}_{(n)}^{*n}$. Проблема непрерывного измерения оказывается тесно связанной с пределами n-кратных сверток вида $\mathscr{P}_{(n)}^{*n}$ при $n \to \infty$ и структурой безгранично-делимых инструментов. Решение этих вопросов опирается на некоторое обобщение метода характеристичесих функций в теории вероятностей.

Обозначим $\mathfrak{F}_\sigma$ банахову алгебру w^*-непрерывных линейных отображений $\mathfrak{B}(\mathscr{H})$ в себя с произведением $\Phi \cdot \Psi[X] = \Phi[\Psi[X]]$. Единицей в этой алгебре является тождественное отображение, обозначаемое Id. В алгебре $\mathscr{F}_\sigma$ вводится топология τ, определяемая семейством полунорм

$$\|\Phi\|_S = \sup_{\|X\|<1} |\operatorname{Tr} S\Phi[X]|, \quad S \in \subseteq (\mathscr{C})$$

Характеристическая функция инструмента определяется соотношением

$$\Phi(\lambda)[\ddot{\Lambda}] = \int\limits_{\mathbf{R}} e^{i\lambda x}\mathscr{P}(d\lambda)[\tilde{X}]$$

где интеграл сходится в топологии τ. Функция $\Phi(\lambda)$ со значениями в $\mathfrak{F}_\sigma$ является характеристической функцией вполне положительного инструмента тогда и только тогда, когда

1. $\Phi(0)[I] = I$;
2. $\Phi(\lambda)\tau$-непрерывна в точке $\lambda = 0$;
3. $\Phi(\lambda)$ положительно определенна в следуюшем смысле: для любых конечных наборов $\{\psi_j\} \subset \mathscr{H}, \{\lambda_j\} \subset \mathbb{R}, \{X_j\} \subset \mathscr{B}(\mathscr{B})$

$$\sum_{j,k} \left\langle \psi_j | \Phi\left(\lambda_k - \lambda_j\right)\left[\lambda_j^* X_k^*\right]\psi_k \right\rangle \geqslant 0$$

(аналог теоремы Бохнера-Хинчина, сводящийся к ней в случае $\dim \mathscr{H} = 1$).

Характеристическая функция свертки $\mathscr{P}_1 \ldots\ldots \mathscr{P}_n$ есть поточечное произведение соответствующих характеристических функций $\Phi_1(\lambda) \cdot \ldots \Phi_n(\lambda)$, поэтому n-кратная свертка $\mathscr{P}_{(n)}^{*n}$ имеет характеристическую функцию $\Phi_{(n)}(\lambda)^n$, где $\Phi_{(n)}(\lambda)$ - характеристическая фунция инструмента $\mathscr{P}_{(n)}$. Распределение вероятностей $\mu_s^{(n)}$ суммы n повторных измерений, описываемых инструментом $\mathscr{P}_{(n)}$, определяется формулой

$$\int\limits_{\mathbf{R}} e^{i\lambda x_\mu^{(n)}}(dx) = \operatorname{Tr} S\Phi_{(n)}(\lambda)^n[1]$$

Следующее утверждение является аналогом центральной предельной теоремы в схеме серий.

П ред лож ение. Пусть $\{\mathcal{P}_{(n)}\}$ - последовательность вполне положительных инструментов и пусть существует τ - непрерывный предел

$$\tau - \lim_{n\to\infty} n\left(\Phi_{(n)}(\lambda) - \mathrm{Id}\right) = \mathscr{L}(\lambda)$$

Тогда свертки ${\mathscr{P}_{(n)}}^{*n}$ слабо сходятся к безгранично делимому инструменту $\mathscr{P}$ с характеристической функцией $\exp \mathscr{L}(\lambda)$[11] в том смысле, что

$$\tau - \lim_{n\to\infty} \int\limits_{\mathbf{R}} f(x)\mathscr{P}_{(n)}(dx) = \int\limits_{\mathbf{R}} f(x)\mathscr{N}^P(dx)$$

для всех непрерывных ограниченных функций $f(x)$.

Заметим, что аналог классического условия асимптотической пренебрегаемости

$$\lim_{n\to\infty} \left\|\Phi_{(n)}(\lambda) - \mathrm{Id}\right\| = 0$$

1. Имеется в виду экспонента в банаховой алгебре σ. в общем случае не влечет (2.9). Вопрос об описании возможных пределов $\tau - \lim_{n\to\infty} \Phi_{(n)}(\lambda)$ при одном этом условии остается открытым.

П р и м е р. Пусть A, H - (ограниченные) вещественные наблюдаемые, $p(x)$ - плотность распределения вероятностей на $\mathbf{R}$, удовлетворяющая условиям (1.8). Рассмотрим вполне положительный инструмент

$$\mathscr{P}_{(n)}(B)[X] = e^{itH/n}\sqrt{n} \int\limits_B \sqrt{p\left(\sqrt{n}x\mathrm{I} - \frac{1}{\sqrt{n}}A\right)}\times$$
$$\times x\sqrt{p\left(\sqrt{n}\times \mathrm{I} - \frac{1}{\sqrt{n}}A\right)}dx e^{-itH/n}$$

Свертка $\mathscr{P}_{(n)}^{*n}$ имеет следующую статистическую интерпретацию. Рассмотрим квантовую систему, динамика которой на интервале $[0,t]$ описывается гамильтонианом H. В моменты времени $t_j = jt/n; j = 0,1,\ldots,n-1$, производится приближенное измерение наблюдаемой A с дисперсией $n\sigma^2 = n\int x^2 p(x)dx$, а затем берется среднее $\frac{1}{n}\sum\limits_{j=0}^{n-1} \alpha\left(t_j^{(n)}\right)$ полученных результатов $\alpha\left(t_j^{(n)}\right)$ (которое имеет дисперсию σ^2). Предел при $n\to\infty$ соответствует среднему $\frac{1}{t}\int\limits_0^t \alpha(\tau)d\tau$ результатов $\alpha(\tau)$ некоторого «непрерывного измерения» наблюдаемой A. Вычисления показывают, что для достаточно гладкой плотности $p(x)$ предел (2.9) равен

$$\mathscr{L}(\lambda)[X] = it[H,X]+$$
$$+\frac{1}{4}J\left(AXA - A^2\circ X\right) + i\lambda A\circ X - \frac{1}{2}\sigma^2\lambda 2X$$

где $J = \int p'(x)^2 p(x)^{-1}dx$ - информационное количество Фишера для семейства плотностей $\{p(x+\theta)\}$ с параметром сдвига $\theta\in\mathbb{R}$, так что $\sigma^2 J \geqslant 1$.

2.4. Сверточные полугруппы инструментов. Следующий результат типа теоремы Шенберга (см., например, [96], [138]) перебрасывает мост между скалярными условно положительно определенными функциями и вполне диссипативными отображениямн (п. 3.2.2). В F_σ.

Предложение. Пусть $\mathscr{L}(\lambda)$ - функция со значениями Следующие условня эквивалентны:

1. $\exp t\mathscr{L}(\lambda)$ положительно определенна для всех $t \geqslant 0$;
2. функция $\mathscr{L}(\lambda)$ эрмитова, т. е. $\mathscr{L}(-\lambda)[X^*] = \mathscr{L}(\lambda)[X]^*$ и условно положительно определенная, т. е. для любых конечных наборов $\{\psi_j\} \subset \mathscr{H}, \{\lambda_j\} \subset \mathbb{R}, \{X_j\} \subset \mathscr{B}(\mathscr{C})$ таких, что $\sum\limits_j X_j\psi_j = 0$ выполняется

$$\sum_{j,k} \left\langle \psi_j | \mathscr{L}\left(\lambda_k - \lambda_j\right)\left[\lambda_j^* X_k\right]\psi_k \right\rangle \geqslant 0$$

Для того чтобы функция $\mathscr{L}(\lambda)$ представлялась в виде предела (2.9), необходимо и достаточно, чтобы она удовлетворяла одному из условий этого предложения, была τ-непрерывна и $\mathscr{L}(0)[1] = 0$. Такие функции будем называть квазихарактеристическими.

Семейство инструментов $\{\mathscr{S}_t; t \in \mathbf{R}_+\}$образует свертоиную полугруппу, если $\mathscr{P}_t * \mathscr{P}_s = \mathscr{P}_{t+s}; t, s \in \mathbb{R}_+$. Очевидно, что все инструменты $\mathscr{P}_t$ безгранично делимы. Пусть $\Phi_t(\lambda)$ - характеристическая функция инструмента $\mathscr{P}_t$. Соотношение

$$\Phi_t(\lambda) = \exp t\mathscr{L}(\lambda); t \in \mathbb{R}_+$$

устанавливает взаимно однозначное соответствие между квазихарактеристическими функциями $\mathscr{L}(\lambda)$ и сверточными полугруппами вполне положительных инструментов, удовлетворяющими условию непрерывности

$$\lim_{t\to 0} \|\mathscr{P}_t(U_0) - \mathrm{Id}\| = 0$$

для любой окрестности нуля U_0.

Следующий результат можно рассматривать как обобщение представления Леви-Хинчина для логарифма характеристической функции безгранично делимого распределения.

Т е о р е м а. Для того чтобы функция $\mathscr{L}(\lambda)$ со значениямн в $F_\triangleleft$ была квазнхарактеристической, необходимо и достаточно, чтобы она допускала представление

$$\mathscr{L}(\lambda) = \mathscr{L}_0 + \mathscr{L}_1(\lambda) + \mathscr{L}_2(\lambda),$$

где $\mathscr{L}_0$ - вполне диссипативное отображение вида (3.2.5), $\mathscr{L}_1(\lambda)[\lambda^*] = \sigma^2\left[(L^*XL - L^*L_0X) + i\lambda\left(L^*X + XL\right) - \frac{1}{2}\lambda_2 X\right]$, (2.15) причем $\sigma^2 \geqslant 0, L \in \mathscr{B}(\mathscr{H})$; т. е. функция типа (2.11);

$$\mathscr{L}_2(\lambda)[X] = \sum_{r,s=1}^{\infty} \int\limits_{\mathbf{R}\setminus 0} \left(V_s^* X V_r e^{i\lambda x} - V_s^* V_{r^\circ} X\right) \mu_{rs}(dx) +$$
$$+ \sum_{s=1}^{\infty} V_s^* X \int\limits_{\mathbf{R}\setminus 0} \left(e^{i\lambda\lambda x} - 1\right) \mu_{0s}(dx) +$$
$$+ \sum_{r=1}^{\infty} X V_r \int\limits_{\mathbf{R}\setminus 0} \left(e^{i\lambda x} - 1\right) \mu_{r0}(dx) +$$
$$+ \left[\int\limits_{R} \left(e^{i\lambda\lambda x} - 1 - \frac{i\lambda x}{1+x^2}\right) \mu_{00}(dx) + i\alpha\lambda\right] \pi$$

где $\alpha \in \mathbb{R}, V_s \in \mathscr{B}(\mathscr{H})$, а $[\mu_r, s]_{r,s=1,2,\ldots}$-положительно определенная матрица комплексных мер на $\mathbf{R}\setminus 0$, такая, что ряд

$$\sum_{r,s=1}^{\infty} \mu_{rs}(\mathbf{R}\setminus 0) V_s^* V_r \text{ сходится } w^*\text{-слабо, и}$$

$$\int\limits_{R\setminus 0} \frac{x^2}{1+x^2} \mu_{00}(dx) < \infty.$$

Доказательство формулы (2.14) использует разновидность конструкции ГНС, которая сопоставляет условно положительно определенной функции $\mathscr{L}(\lambda)$ пару коммутирующих кощиклов алгебры $\mathscr{B}(\mathscr{H})$ и группы $\mathbf{R}$, а также сведения о структуре этих коциклов [96], [84], [76] (доказательство проходит для любой алгебры фон Неймана и абелевой локально-компактной группы). Перенесение вероятностного метода, основанного на понятии сопровождающего закона, представляется в некоммутативной снтуации затруднительным.

Вероятностный смысл каждого из слагаемых в формуле (2.12) выясняется в связи с процессами непрерывного измерения.

2.5. Инструментальные процессы. Пусть - пространство всех вещественных функций на $\mathbf{R}, \mathscr{B}_{a,b}$ – σ-алгебра, порождаемая приращениями $y(s) - y(t); a \leqslant t < s \leqslant b$. Ннструментальным процессом с независимьми приращениями (и. -процессом) называется семейство $\{\mathscr{P}_{a,b}; a, b \in \mathbf{R}, a \leqslant b\}$, где $\mathscr{P}_{a,b}$ - инструмент (в алгебре наблюдаемых) со значениями в $(\mathscr{Y}, \mathscr{B}_{a,b})$, причем

$$\mathscr{P}_{a,b}(E) \cdot \mathscr{P}_{b,c}(F) = \mathscr{P}_{a,c}(E \cap F)$$

если $a \leqslant b \leqslant c$ и $E \in \mathscr{B}_{a,b}, F \in \mathscr{B}_{b,c}$. Если все инструменты $\mathscr{P}_{a,b}$ вполне положительны, то и.-процесс называется вполне положительным. Для любого оператора плотности S и временного промежутка $[a, b]$ и.-процесс определяет распределение вероятностей

$$\mu_s(E) = \operatorname{Tr} S \mathscr{P}_{a,b}(E)[I]; E \in \mathscr{B}_{a,b}$$

на пространстве траекторий $y(t); t \in [a, b]$. С физической точки зрения, исходом непрерывного измерения является производная $\dot{y}(t)$, однако оказывается, что распределение (2.18) сосредоточено на недифференцируемых функциях. Это определение, данное в [102], является модификацией определения Дэвиса [78], использовавшего лишь пространство скачкообразных функций и более общего

определения Баркиелли, Ланца, Проспери [59], основанного на пространстве обобщенных функций. В случае $\dim \mathscr{H} = 1$ и.-процессы - это обычные вещественные процессы с независимыми приращениями. Всякий и.-процесс однозначно определяется набором своих конечномерных распределений, ко- торые в силу (2.17) имеют следующую структуру

$$\begin{gathered}\mathscr{P}_{\tau_0,\tau_p}\left(y(\cdot) : y\left(\tau_1\right) - y\left(\tau_0\right) \in B_1, \ldots, y\left(\tau_p\right) - y\left(\tau_{p-1}\right) \in B_p\right) = \\ = \mathscr{P}_{\tau_0,\tau_1}\left(y(\cdot) : y\left(\tau_1\right) - y\left(\tau_0\right) \in B_1\right) \ldots \\ \ldots \cdot \mathscr{P}_{\tau_{p-1}}, \tau_p\left(y(\cdot) : y\left(\tau_p\right) - y\left(\tau_{p-1}\right) \in B_p\right),\end{gathered}$$

где $\tau_0 \leqslant \tau_1 \leqslant \ldots \leqslant \tau_p; B_1, \ldots, B_p \in \mathscr{B}(\mathbf{R})$.

И.-процесс называется однородным, если для любых a, b, $\tau \in \mathbf{R}$ выполняется

$$\mathscr{P}_{a+\tau,b+\tau}\left(T_\tau(E)\right) = \mathscr{P}_{a,b}(E), \quad E \in \mathscr{B}_{a,b},$$

где $\left(T_\tau y\right)(t) = y(t+\tau)$. Соотношение

$$\mathscr{N}_t(B) = \mathscr{N}_{a,a+t}(y(\cdot) : y(a+t) - y(a) \in B); \quad B \in \mathscr{B}(\mathbf{R})$$

определяет тогда сверточную полугруппу инструментов, через которую конечномерные распределения выражаются по формуле

$$\begin{gathered}\mathscr{P}_{\tau_\bullet,\tau_p}\left(y(\cdot) : y\left(\tau_1\right) - y\left(\tau_0\right) \in B_1, \ldots, y\left(\tau_p\right) - y\left(\tau_{p-1}\right) \in B_p\right) = \\ = \mathscr{P}_{\tau_1-\tau_0}\left(B_1\right) \cdot \ldots \cdot \mathscr{P}_{\tau_p-\tau_{p-1}}\left(B_p\right).\end{gathered}$$

Если и.-процесс непрерывен в том смысле, что

$$\lim_{t\to 0} \left\| \mathscr{P}_{a,a+t}(y(\cdot) : |y(a+t) - y(a)| \geqslant \varepsilon) - \mathrm{Id} \right\| = 0$$

для любого $\varepsilon > 0$, то соответствующая сверточная полугруппа непрерывна в смысле (2.13), и, следовательно, ее характеристи: ческие функцин имеют вид (2.12), где $\mathscr{L}(\lambda)$ - некоторая квази: характеристическая функция. Обратно пусть $\mathscr{L}(\lambda)$ - квазихарактеристическая функция, $\{\mathscr{P}_t\}$ - соответствующая сверточная полугруппа, тогда соотношение (2.20) определяет конечномерные распределения, продолжающиеся до однородного, непрерывного, вполне положительного и.-процесса $\{\mathscr{P}_{a,b}\}$. Более того, модифицируя технику продолжения теории случайных процессов [11], можно доказать, что и.-процесс $\{\mathscr{P}_{a,b}\}$ сосредоточен на подпространстве $\mathscr{D} \subset \mathscr{Y}$, состоящем из функций без разрывов второго рода. Функция $\mathscr{L}(\lambda)$ называется генератором н.-процесса $\{\mathscr{N}_{a,b}\}$.

Слагаемое $\mathscr{L}_0$ в формуле (2.14) описывает эволюцию (в общем случае необратимую) рассматриваемой квантовой системы, происходящую независимо от процесса измерения. В класснческом случае ($\dim \mathscr{H} = 1$) это слагаемое вообще отсутствует. Второе слагаемое $\mathscr{L}_1(\lambda)$ описывает процесс непрерывного приближенного измерения наблюдаемой $A = \sigma^2\left(L + L^*\right)$. Соответствующий и.-процесс сосредоточен на непрерывных траекториях и отвечает классическому вннеровскому процессу. Многомерное обобщение - сумма слагаемых вида (2.11) с разными операторами $L_1, \ldots, L_m$ - задает процесс непрерывного приближенного

1. См. И. И. Гихман, А. В. Скороход. Теория случайных процессов.- М.: Наука, 1973.- 2. измерения нескольких (вообще говоря, несовместимых) наблюдаемых [60]. Наконец, слагаемое $\mathscr{L}_2(\lambda)$ описывает скачкообразную компоненту процесса измерения.

Пр и м е р (ср. [78, гл. 5]). Пусть $B \to \mathscr{P}(B)$; $B \in \mathscr{B}(\mathbf{R}\backslash 0)$ - функция множеств, удовлетворяющая определению (вполне положительного) инструмента (см. п. 1.1), за исключением условия нормировки 2). Таким образом, $C = \mathscr{P}(\mathbf{R}\backslash 0)[\mathrm{I}]$ - некоторый положительный оператор. Соотношение

$$\mathscr{L}(\lambda)[X] = \int\limits_{\mathbf{R}\backslash 0} e^{i\lambda x\mathscr{P}}(dx)[X] - C \circ X + i[H, X]$$

определяет квазихарактеристическую функцию, представляющую собой первое слагаемое в формуле (2.16). Однородный н.-процесс $\{\mathcal{P}_{a,b}\}$ с генератором (2.22) имеет кусочно-постоянные траектории; пусть, например, $F \subset \mathscr{D}$ - подмножество траекторий, имеющих ровно m скачков на отрезке $[a, b]$, причем j-й скачок происходит на интервале $\Delta_j \subset [a, b]$ и имеет величину $h_j \in B_j$, где $B_j \in \mathscr{B}(\mathbf{R}\backslash 0)$. Если интервалы $\Delta_1, \ldots, \Delta_m$ следуют друг за другом без пересечений, то

$$\mathcal{P}_{a,b}(F) = \int\limits_{\Delta_1} \ldots \int\limits_{\Delta_m} e^{(t_1-a)\mathscr{L}_0 \cdot \mathscr{P}}(B_1) \cdot \ldots \mathscr{P}(B_m) \times$$
$$\times\, e^{(b-t_m)\mathscr{L}_0} dt_1 \ldots dt_m,$$

где $\mathscr{L}_0[X] = -C \cdot X + i[H, X]$. Особенно просто устроен аналог пуассоновского процесса с генератором

$$\mathscr{L}(\lambda)[X] = \mu\left(e^{i\lambda h} U^* X U - X\right) + i[H, X]$$

где U - изометрический оператор. Это считающий процесс [154], для которого скачки траектории фиксированной величины h происходят в случайные моменты времени, имеющие экспоненциальное распределение с параметром $\mu > 0$. В момент скачка состояние преобразуется по формуле $S \to USU^*$, а между скачками эволюционирует согласно закону

$$S \to e^{-\mu t} e^{-iHt} S e^{i\#t}.$$

Рассмотрим вкратце вотрос о сходимости повторных измерений к процессу непрерывного измерения. Пусть временная ось $\mathbf{R}$ разбита на промежутки $\left[t_i^{(n)}, t_{l+1}^{(n)}\right]$ длины $1/n$, и каждому моменту времени отвечает измерение, описываемое вполне положительным инструментом $\mathscr{P}_{(n)}$ с характеристической функцией $\Phi_{(n)}(\lambda)$. Серия таких повторных измерений естественным образом определяет и.-процесс $\{\mathscr{P}_{a,b}\}$, траекториями которого являются кусочно-постоянные функции (см. [102]). Обозначим

$$\mu_{S,X}^{(n)}(B) = \operatorname{Tr} S \mathscr{P}_{a,b}^{(n)}(E)[X]; \quad E \in \mathscr{B}_{a,b}$$

где $X \geqslant 0$.

Т е о р е м а. Пусть существует τ-непрерывный предел

$$\tau - \lim_{n\to\infty} n\left(\Phi_{(n)}(\lambda) - \mathrm{Id}\right) = \mathscr{L}(\lambda)$$

причем $\sup_n \sup_{|\lambda|\leqslant 1} n\|\Phi_{(n)}(\lambda) - \mathrm{Id}\| < \infty$. Тогда последовательность мер $\left\{\mu_{S,x}^{(n)}\right\}^n$ сходится в топологии Скорохода к мерам

$$\mu_{S,X}(E) = \operatorname{Tr} S \mathscr{P}_{a,b}(E)\left[X^-\right]$$

где $\{\mathcal{P}_{a,b}\}$-однородный вполне положительный и.-процесс с генератором $\mathscr{L}(\lambda)$.

В частности, последовательность повторных приближенных измерений наблюдаемой A из примера п. 2.3 сходится к процессу непрерывного измерения с генератором (2.11).

В случае $\dim \mathscr{H} = 1$ этот результат переходит в теорему А. В. Скорохода о сходимости сумм незавнсимых случайных величин к процессу с независимыми приращениями.

Знание генератора и.-процесса позволяет в принципе определить основные вероятностные характеристики распределения (2.18) в пространстве траекторий, в частности, произвольные смешанные моменты [60]. На этом основаны квантово-статистические приложения рассматриваемой теории. В работе [103] проведено сравнение оценок неизвестной силы, действующей на открытую квантовую систему, построенных на основе различных процессов непрерывного измерения. Статистика сцитающих процессов рассматривалась в работах [154], [18].

12.5 Processes in the Fock Space

12.5.1 1. Quantum Stochastic Calculus

1.1. Extensions in the Fock Space

Пусть $\mathfrak{b}$-гильбертово пространство. Симметричное пространство Фока, ассоциированное с $\mathfrak{h}$, -определяется как

$$\Gamma(\mathfrak{h}) = \sum_{n=0}^{\infty} \oplus \Gamma_n(\mathfrak{h})$$

где $\Gamma_0(\mathfrak{h}) = \mathbf{C}, \Gamma_n(\mathfrak{h}) = \mathfrak{h}^{sn}$ - симметризованная n-я тензорная степень пространства h) (см. п. 1.3.1). $\Gamma_n(\mathfrak{h})$ называется n-частичным подпространством, $\Gamma_0(\mathfrak{h})$ - вакуумным подпространством. В квантовой физике $\Gamma(\mathfrak{h})$ описывает систему из переменного (неограниченного) числа частиц (бозонов [6], [7]).

В интересуюшем нас случае, когда $\mathfrak{h} = L^2(\mathbf{R}_+)$, пространство Фока $\Gamma(\mathfrak{b})$ состоит из бесконечных последовательностей

$$\psi = [f_0, f_1(t), \ldots, f_n(t_1, \ldots, t_n), \ldots]$$

где $f_0 \mathrm{EC}, f_n(t_1, \ldots, t_n)$-комплексная симметричная квадратично-интегрируемая функция от $t_1, \ldots, t_n \in \mathbf{R}_+$, причем

$$\langle \psi | \psi \rangle \equiv \sum_{n=0}^{\infty} \frac{1}{n!} \int_0^{\infty} \ldots \int_0^{\infty} |f_n(t_1, \ldots, t_n)|^2 \, dt_1 \ldots dt_n < \infty.$$

Удобная модификация этого представления была предложена Маассеном в [142]. Пусть $\tau = \{t_1, \ldots, t_n\}$-цепь в $\mathbf{R}_+$, т. е. подмножество $\mathbf{R}_+$конечной мощности $|\tau| = n$, упорядоченное так, что $t_1 < \ldots < t_n$. Обозначая $\mathfrak{P}$ множество всех цепей, $\mathfrak{P}_n$ - множество цепей мощности n, имеем $\mathfrak{P} = \bigcup_{n=0}^{\infty} \mathfrak{P}_n$, где $\mathfrak{P}_0 = \{\varnothing\}$. Определим на $\mathfrak{p}\sigma$-конечную меру $\mu(d\tau)$, которая совпадает с мерой $dt_1 \ldots dt_n$ на $\mathfrak{P}_n, n > 0$, и $\mu(\varnothing) = 1$. Для $\psi \in \Gamma$ () положим $\psi(\tau) = f_n(t_1, \ldots, t_n)$, если $|\tau| = n > 0$ и $\psi(\varnothing) = f_0$. Симметричная функция f_n однозначно определяется своим ограничением на $\mathfrak{P}_n$, причем $\frac{1}{n!} \int_0^{\infty} \ldots \int_0^{\infty} |f_n(t_1, \ldots, t_n)|^2 \, dt_1 \ldots dt_n = \int_{\mathfrak{P}_n} |\psi(\tau)|^2 \mu(d\tau)$, так что

$$\langle \psi | \psi \rangle = \sum_{n=0}^{\infty} \int_{\mathfrak{P}_n} |\psi(\tau)|^2 \mu(d\tau) = \int_{\mathfrak{P}} |\psi(\tau)|^2 \mu(d\tau).$$

Для любого $t \geqslant 0$ определим операторы $A(t), A^+(t), \Lambda(t)$ соотношениями

$$(A(t)\psi)(\tau) = \int\limits_0^t \psi(\tau \cup \{s\})ds$$

$$\left(A^+(t)\psi\right)(\tau) = \sum_{s\in\tau} 1_{[0,t]}(s)\psi(\tau\backslash\{s\})$$

$$(\Lambda(t)\psi)(\tau) = \sum_{s\in\tau} 1_{[0,t]}(s)\psi(\tau)$$

Оператор $A(t)$ переводит $\Gamma_n \equiv \Gamma_n\left(L^2\left(\mathbf{R}_+\right)\right)$в $\Gamma_{n-1}, A^+(t)$ переводит Γ_n в Γ_{n+1}, и $\Lambda(t)$ переводит Γ_n в Γ_n. В квантовой физике $A(t)$ является оператором уничтожения (бозона на временном отрезке $[0,t]), A^+(t)$ - оператором рождения, $\Lambda(t)$ - оператором числа частиц (бозонов). Общей инвариантной областью определения является подпространство Γ_∞, состоящее из векта- ров $\psi \in \Gamma(\mathfrak{h})$ таких, что

$$\int\limits_{\mathfrak{P}} \lambda^{|\tau|}|\psi(\tau)|^2\mu(d\tau) < \infty$$

для всех $\lambda > 0$. Операторы $A(t), A^+(t)$ однозначно продолжаются до замкнутых взаимно сопряженных операторов (для которых сохраняются прежние обозначения). Операторы $\Lambda(t)$, а также

$$Q(t) = A(t) + A^+(t), P(t) = i\left(A^+(t) - A(t)\right)$$

являются существенно самосопряженными на Γ_∞ (см., например, [6], [29]).

Из определений (1.2) вытекают следующие коммутационные соотношения на Γ_∞

$$[A(t), A(s)] = 0, \quad \left[A^+(t), A^+(s)\right] = 0$$
$$\left[A(t), A^+(s)\right] = (t \wedge s)\mathrm{I}$$
$$[\Lambda(t), \Lambda(s)] = 0$$
$$[\Lambda(t), A(s)] = -A(t \wedge s), \quad \left[\Lambda(t), A^+(s)\right] = A^+(t \wedge s)$$

где $t \wedge s = \min(t, s)$. Отсюда следует, что

$$[Q(t), Q(s)] = 0, \quad [P(t), P(s)] = 0$$
$$[Q(t), P(s)] = 2i(t \wedge s)\mathrm{I}$$

$$[\Lambda(t), Q(s)] = -iP(t \wedge s), \quad [\Lambda(t), P(s)] = iQ(t \wedge s)$$

Пусть $f \in L^2\left(\mathbf{R}_+\right)$. Экспоненциальныц вектором называется вектор $\psi_f \in \Gamma(\mathfrak{h})$ такой, что $\psi_f(\varnothing) = 1, \psi_f(\tau) = \prod_{t\in\tau} f(t)$. Скаля рное произведение двух экспоненциальных векторов

$$\langle\psi_f|\psi_g\rangle = \exp\int\limits_0^\infty \overline{f(t)}g(t)dt$$

Из (1.2) следует, что $A(t)\psi_f = \left(\int\limits_0^t f(s)ds\right)\cdot\psi_f$.

Вектор ψ_0, соответствующий $f \equiv 0$, называется вакуумным вектором. Для него

$$A(t)\psi_0 = 0, \Lambda(t)\psi_0 = 0$$

Линейную оболочку семейства экспоненциальных векторов обозначим Γ_e. Она плотна в $\Gamma(\mathfrak{h})$ (см., например, [96]).

1.2 Стохастический интеграл.

Одно из основных свойств пространства Фока - Функтори а льное св ой ство

$$\Gamma(\mathfrak{h}_1 \oplus \mathfrak{h}_2) = \Gamma(\mathfrak{h}_1) \otimes \Gamma(\mathfrak{h}_2),$$

в частности, для любого $t \in \mathbf{R}_+$

$$\Gamma\left(L^2(\mathbf{R}_+)\right) = \Gamma\left(L^2(0,t)\right) \otimes \Gamma\left(L^2(t,\infty)\right)$$

При этом экспоненциальные векторы, включая вакуумный, также факторизуются

$$\psi_f = \psi_f^{(0,t)} \otimes \psi_f^{(t,\infty)}$$

Поскольку $L^2(\mathbf{R}_+)$можно рассматривать как непрерывную прямую сумму (прямой интеграл) одномерных гильбертовых пространств, пространство $\Gamma(L^2(R_+))$является, в определенном смысле, непрерывным тензорным произведением. Эта структура лежит в основе связи между пространством Фока, безграничной делимостью и процессами с независимыми приращениями (см., например, [96], [138]).

Далее $\mathfrak{G} = \mathscr{H} \otimes \Gamma(L^2(\mathbf{R}_+))$, где $\mathscr{H}$-некоторое «начальное» пространство. Элементы 5 можно рассматривать как функции $\downarrow(\tau), \tau \in \mathrm{Re}$, со значениями в $\mathscr{H}$. Будет удобно не различать в написании операторы, действующие в $\mathscr{H}$, или в $\Gamma(L^2(\mathbf{R}_+))$, и их поднятия в \$; например, $A(t)$ обозначает как оператор в $\Gamma(L^2(\mathbf{R}_+))$, так и оператор $I \otimes A(t)$ в ратор в $\mathscr{H}$). Обозначим $\mathscr{H} \otimes \Gamma_e$ алгебраическое тензорное произведение $\mathscr{H}$ и Γ_e. Семейство (вообще говоря, неограниченных) операторов $\{M(t); t \in \mathbf{R}_+\}$, определенных на $\mathscr{C} \otimes \Gamma_e$, будет называться процессом в 5.

Соотношения (1.8), (1.9) задают естественную фильтрацию в пространстве $\mathfrak{g}$. Процесс $\{M(t); t \in \mathbf{R}_+\}$в $\mathfrak{g}$ называется согласованжбц (с данной фильтрацией), если для любого $t \in \mathbf{R}_+$

$$M(t) = M_{t]} \otimes I_{[t}$$

где $M_{t]}$-оператор, действующий в $\mathscr{C} \otimes \Gamma(L^2(0,t))$, а $\mathrm{I}_{[t}$ - единичный оператор в $\Gamma(L^2(t,\infty))$. Благодаря (1.8), (1.9), определено отображение условного ожидания $\mathscr{E}_{t]}$ в алгебру операторов вида (1.10), согласованное с вакуумным состоянием $|\psi_0\rangle\langle\psi_0| \cdot$ Согласованный процесс называется жартингалож, если $\mathscr{E}_{t]}[M(s)] = M(t)$ при $s > t$. Основные процессы $\{A(t)\}$, $\{A^+(t)\}, \{\Lambda(t)\}$ я вляются мартингалами.

Партасарати и Хадсон [108], [20] построили стохастический интеграл от согласованных процессов по основным мартингалам $A(t), A^+(t), \Lambda(t)$. Дальше излагается модификация этой конструкции (см. статью А. С. Холево в [145]). Процесс $\{M(t); t \in [0,T]\}$ называется простыск, если существует разбиение $0 = t_0 < t_1 < \ldots < t_N = T$, такое что $M(t) = M(t_{j-1})$ для $t \in [t_{j-1},\ t_j)$. Для четверки простых согласованных процессов $\{M_\alpha(t)\}$, $\alpha = 0,1,2,3$, стохастический интеграл определяется соотно ;шением

$$I(T) \equiv \int_0^T \left(M_0 d\Lambda + M_1 dA + M_2 dA^+ + M_3 dt\right) =$$

$$= \sum_{j=1}^N \{M_0(t_{j-1})[\Lambda(t_j) - \Lambda(t_{j-1})] +$$

$$+ M_1(t_{j-1})[A(t_j) - A(t_{j-1})] + M_2(t_{j-1})\left[A^+(t_j) - A^+(t_{j-1})\right] +$$

$$+ M_3(t_{j-1})(t_j - t_{j-1})\}$$

Из неравенств Журне (см. [128, п. V.1.4]) вытекает оценка

$$\sup_{0<t\leqslant T}\left\|I(t)\psi\otimes\bar{\psi}_f\right\|_-^2\leqslant C(\|f\|)\cdot\left\{\int_0^T|f(t)|^2\times\right.$$

$$\times\left\|M_0(t)\psi\otimes\psi_f\right\|^2dt+\int_0^T\left[\left\|M_1(t)\psi\otimes\psi_f\right\|^2+\right.$$

$$\left.\left.+\left\|M_2(t)\psi\otimes\psi_f\right\|^2\right]dt+\left[\int_0^T\left\|M_3(t)\psi\otimes\psi_f\right\|dt\right]^2\right\},$$

тде $\psi\in\mathscr{H}, f\in L^2(\mathbf{R}_+)$. Назовем $\{M_\alpha(t)\}$ допустимой четверкой, если для любого $\varepsilon>0$ найдется четверка $\left\{\tilde{M}_\alpha(t)\right\}$ простых согласованных процессов, такая что

$$\operatorname*{ess\,sup}_{0\leqslant t\leqslant T}\left\|\left[M_0(t)-\tilde{M}_0(t)\right]\psi\otimes\psi_f\right\|<\varepsilon$$

$$\int_0^T\left\|\left[M_{1,2}(t)-\tilde{M}_{1,2}(t)\right]\psi\otimes\psi_f\right\|^2dt<\varepsilon$$

$$\int_0^T\left\|\left[M_3(t)-\tilde{M}_3(t)\right]\psi\otimes\psi_f\right\|dt<\varepsilon$$

и сильно допустимой четверкой, если для любого $\varepsilon>0$ найдется четверка $\left\{\widetilde{M}_\alpha\right\}$ простых согласованных процессов со значениями в $\mathfrak{B}(()$, такая что

$$\operatorname*{ess\,sup}_{0<t\leqslant T}\left\|M_0(t)-\tilde{M}_0(t)\right\|<\varepsilon,$$

$$\int_0^T\left\|M_{1,2}(t)-\tilde{M}_{1,2}(t)\right\|^2dt<\varepsilon,$$

$$\int_0^T\left\|M_3(t)-\tilde{M}_3(t)\right\|dt<\varepsilon.$$

Из неравенства (1.12) вытекает, что для любой допустимо четверки стохастический интеграл

$$I(T)=\int_0^T\left(M_0d\Lambda+M_1dA+M_2dA^+M_3dt\right)$$

определен на $\mathscr{C}\otimes\Gamma_e$ как сильный предел стохастических интегралов вида (1.11) от простых процесов $\left\{\tilde{M}_\alpha\right\}$ и является согласованным процессом. Если $M_3\equiv0$, то $I(t)$ является мартингалом; доказано, что достаточно произвольный ограниченный мартингал в пространстве Фока является стохастическим интегралом (Партасарати и Синха). Пример неограниченного мартингала, не представимого в виде стохастического интеграла по основным процессам, содержится в работе Журне [113].

Из определений (1.2) основных мартингалов вытекает явная формула (В. П. Белавкин [35])

$$(I(t)\psi)(\tau) = \int_0^t \left[M_3(s)\psi + M_1(s)\psi^{(s)}\right](\tau)ds +$$
$$+ \sum_{\substack{s\in\tau \\ s\leqslant t}} \left[M_2(s)\psi + M_0(s)\psi^{(s)}\right](\tau\backslash\{s\}),$$

где $\psi^{(s)}(\tau) = \psi(\tau\bigcup\{s\})$, которая может служить для альтернативного определения стохастического интеграла, имеющего смысл для более широких классов процессов (включая несогласованные процессы).

Стохастический интеграл по процессам в антисимметричном пространстве Фока рассматривался Барнетом, Стритером, Уайлдом [62], [141], Хадсоном и Эпплбаумом [107].

1.3 Квантовая формула Ито.

Соотношение (1.14) принято записывать в дифференциальной форме

$$dI = M_0 d\Lambda + M_1 dA + M_2 dA^+ + M_3 dt$$

Пусть $J(t)$ - другой стохастический интеграл, так что $dJ = N_0 d\Lambda + N_1 dA + N_2 dA^+ + N_3 dt$.

Т е о р ем а. Если четверки $\{M_\alpha\}, \{N_\alpha\}$ сильно допустимы, то произведение $I(t)J(t)$ является стохастическим интегралом, причем

$$d(IJ) = I(dJ) + (dI)J + (dI)(dJ)$$

где произведение вычисляется по следующим формальным правилам: значения любого согласованного процесса в момент t коммутируют со стохастическими дифференциалами основных процессов $d\Lambda(t), dA(t), dA^+(t), dt$, а в слагаемом $(dI)(dJ)$ произведения стохастических дифференциалов основных процессов находятся согласно таблице умножения

	dA^+	$d\Lambda$	dA	dt
dA	dt	dA	0	0
$d\Lambda$	dA^+	$d\Lambda$	0	0
dA^+	0	0	0	0
dt	0	0	0	0

Алгебра стохастических дифференциалов (1.15) с таблицей умножения (1.16) изоморфна некоторой алгебре 3×3-матриц. Особенно удобна реализация, предложенная В. П. Белавкиным в [35]: соответствие

$$dI = M_0 d\Lambda + M_1 dA + M_2 dA^+ + M_3 dt \leftrightarrow$$
$$\mathbf{M} = \begin{bmatrix} 0 & M_1 & M_3 \\ 0 & M_0 & M_2 \\ 0 & 0 & 0 \end{bmatrix}$$

оказывается инволютивным алгебраическим изоморфизмом, переводящим инволюцию $(dI)^* = M_0{}^* d\Lambda + M_2{}^* dA + M_1{}^* dA^+ + M_3^* dt$ в инволюцию

$$\begin{bmatrix} 0 & M_1 & M_3 \\ 0 & M_0 & M_2 \\ 0 & 0 & 0 \end{bmatrix}^\star = \begin{bmatrix} 0 & M_2^* & M_3^* \\ 0 & M_0^* & M_1^* \\ 0 & 0 & 0 \end{bmatrix}$$

П р и м е р. Рассмотрим стохастические интегралы

$$B(t) = \int_0^t J(s)dA(s), B^+(t) = \int_0^t J(s)dA^+(s)$$

где $J(t) = (-1)^{\Lambda(t)}$ - сильн допустимый процесс. Из формулы (1.24) следующего пункта вытекает, что $J(t)$ удовлетворяет уравнению

$$dJ = -2Jd\Lambda$$

Пользуясь таблицей (1.16), находим

$$d(BJ + JB) = -2(BJ + JB)d\Lambda$$

Поскольку $B(0) = 0$, то из теоремы следующего пункта вытекает, что $B(t)J(t) + J(t)B(t) \equiv 0$. Снова пользуясь таблицей (1.16), находим $d\left(BB^+ + B^+B\right) = dt$, откуда

$$B(t)B^+(t) + B^+(t)B(t) = t,$$

т. е. операторы $B(t), B^+(t)$ удовлетворяют каноническому антикоммутационному соотношению для фермионных операторов рождения-уничтожения. Этот факт лежит в основе изоморфизма между симметричным (бозонным) и антисимметричным (фермионным) пространствами Фока, установленного Хадсоном и Партасарати [109].

Квантовый стохастический интеграл и формула Ито имеют естественное обобщение на случай многих степеней свободы, когда основные процессы $A_j(t), A_k{}^+(t), \Lambda_{jk}(t)$ многомерны и действуют в пространстве Фока $\Gamma\left(L_{\mathscr{K}}{}^2(\mathbf{R}_+)\right)$, где $\mathscr{K}$ - гильбертово пространство, размерность которого равна числу степеней свободы (Хадсон, М. П. Эванс [143], В. П. Белавкин [35]), а также в нефоковских пространствах, связанных с гауссовскими состояниями канонических коммутационных соотношений (Хадсон, Линдсей [142]).

1.4. Квантовые стохастические дифференциальные уравнения. Рассмотрим линейное однородное квантовое стохастическое дифференциальное уравнение

$$dV = \left[L_0d\Lambda + L_1dA + L_2dA^+ + L_3dt\right]V, t \geqslant 0$$

с начальным условием $V(0) = \mathrm{I}$, которое является краткой записью интегрального уравнения

$$V(t) = I + \int_0^t \left[L_0(s)d\Lambda(s) + L_1(s)dA(s) + L_2(s)dA^+(s) + \right.$$
$$\left. + L_3(s)ds\right]V(s).$$

Модифицируя рассуждение Хадсона и Партасарати [108], основанные на методе последовательных приближений, можно доказать следующую теорему.

Т е ор ем а. Если $\{L_\alpha\}$ - сильно допустимая четверка, то решение $\{V(t); t \in \mathbf{R}_+\}$уравнения (1.18) существует, единственно и является сильно непрерывным согласованным процессом.

Обозначим $\mathscr{P}_t$ оператор временного сдвига в : $\mathscr{P}_t\psi(\tau) = \psi(\tau_t)$, где $\tau_t = \{t_1 + t, \ldots, t_n + t\}$, если $\tau = \{t_1, \ldots, t_n\}$. Решение $V(t)$ удовлетворяет уравнению ко ц и к л а

$$V(t + u) = \left(\mathscr{S}_u^*V(t)\mathscr{S}_u\right)V(u); t, u \in \mathbf{R}_+$$

Особый интерес представляет случай, когда $V(t), t \in \mathbf{R}_+$, являются унитарными операторами. Для этого необходимо и достаточно, чтобы уравнение (1.18) имело вид

$$dV = \Big[(W-I)d\Lambda + LdA^+ - L^*WdA - \left(iH + \frac{1}{2}L^*L\right)dt\Big]V,$$

где W-унитарный, а H-самосопряженный операторы из $\mathscr{B}(\mathscr{C})$.

Весьма важной является задача обобщения теоремы существования и единственности решения уравнения (1.18) на случай неограниченных коэффициентов $L_\alpha(t)$. Некоторые результаты в этом направлении имеются в работах Хадсона и Партасарати [108], Журне [113], Фриджерио, Фаньолы, А. М. Чеботарева [75]. В работе [113] частично решена задача описания силь- но непрерывных унитарных решений уравнения (1.19). Этот вопрос тесно связан с проблемой консервативности, обсуждавшейся в п. 3.2.3.

Уравнения типа (1.18) связаны с линейными стохастическими дифференциальными уравнениями в гильбертовом пространстве (см., в частности, А. В. Скороход [33]), и можно надеяться, что эти два направления взаимно обогатят друг друга. Решения уравнения (1.20) являются некоммутативным аналогом мультипликативного процесса с независимыми стационарными приращениями в группе унитарных операторов. Общая теория таких процессов развита Аккарди, фон Вальденфельсом и Шурманом [54]. Последний показал [144], [147], что всякий такой процесс, удовлетворяющий условию равномерной непрерывности, является решением уравнения типа (1.20). Используя аналогию с квантовыми процессами, А. С. Холево указал стохастическое дифференциальное уравнение, которому удовлетворяет произвольный классический мультипликативный процесс с независимыми стационарными приращениями в группе Ли (мультипликативный аналог разложения Ито) [104].

Наглядное представление решений уравнения (1.18) дают хронологически упорядоченные экспоненты, родственные мультипликативному стохастическому интегралу в классической теории случайных процессов (по поводу последнего см. Эмери [82]). Пусть $\left\{\widetilde{M}_\alpha(t)\right\}$ - четверка простых согласованных процессов на $[0,T]$ со значениями в $\mathscr{B}(\mathscr{C})$. Положим

$$V_j = \exp\Big[\tilde{M}_0(t_{j-1})(\Lambda(t_j) - \Lambda(t_{j-1})) + \\ + \tilde{M}_1(t_{j-1})(A(t_j) - A(t_{j-1})) + \tilde{M}_2(t_{j-1})\left(A^+(t_j) - A^{+^-}(t_{j-1})\right) + \\ + \tilde{M}_3(t_{j-1})(t_j - t_{j-1})\Big]$$

и обозначим

$$\leftarrow \overleftarrow{\exp} \int_0^T \left(\tilde{M}_0 d\Lambda + \tilde{M}_1 dA + \tilde{M}_2 dA^+ + \tilde{M}_3 dt\right) = \\ = V_N \cdot \ldots \cdot V_1.$$

Оператор (1.21) определен на $\mathscr{H} \otimes \Gamma_e$. В работе А. С. Холево (см. [145]) доказано, что если $\{M_\alpha\}$-сильно допустимая четверка согласованных процессов со значениями в $\mathscr{B}(\mathscr{H})$ и $\left\{\tilde{M}_\alpha^{(N)}\right\}$ - последовательность четверок простых процессов, аппроксимирующая $\{M_\alpha\}$ в смысле (1.13), то существует сильный предел на $\mathscr{C} \otimes \Gamma_e$ выражений вида (1.21), который называется хронологически упорядоченной экспонентой. При этом семейство хронологически упорядоченных экспонент

$$V(t) = \leftarrow \exp_0^T \left(M_0 d\Lambda + M_1 dA + M_2 dA^+ + M_3 dt \right), \quad t \in \mathrm{R}_+$$

является сильно непрерывным на $\mathscr{C} \otimes \Gamma_e$, согласованным процессом, который удовлетворяет стохастическому дифференциальному уравнению (1.18), где $\{L_\alpha\}$ и $\{M_\alpha\}$ связаны соотношениями

$$L_0 = a(M_0), L_1 = M_1 b(M_0), L_2 = b(M_0) M_2$$
$$L_3 = M_3 + M_1 c(M_0) M_2$$

Здесь a, b, c-целые функции

$$a(z) = e^z - 1, \quad b(z) = \frac{e^z - 1}{z}, \quad c(z) = \frac{e^z - 1 - z}{z^2}, \quad z \neq 0$$

Используя изоморфизм (1.17), эти соотношения можно объединить в одно матричное равенство

$$\mathbf{L} = e^{\boldsymbol{M}} - \mathrm{I}$$

Если коэффициенты $M_\alpha(t)$ коммутируют между собой при всевозможных значениях временных аргументов, то хронологически упорядоченная экспонента превращается в обычную

$$V(t) = \exp \int_0^t \left(M_0 d\Lambda + M_1 dA + M_2 dA^+ + M_3 dt \right)$$

и дает, таким образом, явное решение уравнения (1.18).

П р и м е р. Решение уравнения

$$dJ_z = z J_z d\Lambda; \quad J_z(0) = \mathrm{I}$$

при $z \neq -1$ записывается в виде

$$J_z(t) = (z+1)^{\Lambda(t)}, t \in \mathrm{R}_+$$

Если $z = -1$, то решение уравнения (1.24) имеет вид

$$J_{-1}(t) = \delta_{0,\Lambda(t)}$$

где $\delta_{i,j}$-символ Кронекера. Поскольку $J_{-1}(t)$ обращается в нуль, оно не может быть записано в виде экспоненты.

Хронологически упорядоченные экспоненты

$$V(t) = \underset{\exp}{\leftarrow} \int_0^t \left(L dA^+ - L^* dA - iH dt \right)$$

рассматривались фон Вандельфельсом, а также Хадсоном и Партасарати в [141], [20]. Эти экспоненты я вляются унитарными операторами, удовлетворяющими уравнению

$$dV = \left[L dA^+ - L^* dA - \left(iH + \frac{1}{2} L^* L \right) dt \right] V; V(0) = \mathrm{I}$$

П риме р. Пусть $\dim \mathscr{H} = 1$ и $f \in L^2(\mathbf{R}_+)$. Экспонента

$$V_f(t) = \exp \int_0^t \left(f(s) dA^+(s) - \overline{f(s)} dA(s) \right)$$

является унитарным решением уравнения

$$dV_f(t) = \left[f(t) dA^+(t) - \overline{f(t)} dA(t) - \frac{1}{2} |f(t)|^2 dt \right] V_f(t)$$

в $\Gamma\left(L^2\left(\mathbf{R}_+\right)\right)$. Из этого уравнения и квантовой формулы Ито вытекает, что процессы $V_f(t)V_g(\dot{t})$ и $V_{f+\dot{g}}(t) \exp i \operatorname{Im} \int_0^t f(s) \times \quad \times \overline{g(s)} ds$, где g-другая функция из $L^2\left(\mathbf{R}_\mathrm{t}\right)$, удовлетворяют одному и тому же уравнению; кроме того, они совпадают при $t = 0$ и, следовательно, тождественно равны, Т. е.

$$V_f(t) V_g(\boldsymbol{t}) = V_{f+g}(t) \exp \left[i \operatorname{Im} \int_0^t f(s) \overline{\mathrm{g}(s)} ds \right]$$

Рассмотрим $L^2\left(\mathbf{R}_+\right)$как вещественное линейное пространство Z с кососимметричной формой

$$\Delta(f, g) = 2 \operatorname{Im} \int_0^\infty f(s) \overline{g(s)} ds$$

Из (1.28) тогда следует, что операторы $W(f) = V_f(\infty)$ образуют (неприводимое) представление канонического коммутационного соотношения Вейля (1.2.12) в симметричном (бозонном) про. странстве Фока $\Gamma\left(L^2\left(\mathbf{R}_+\right)\right)$, а формулы (1.4), (1.5) дают ннфннтезимальную форму канонического коммутационного соотношения. При этом экспоненциальные векторы играют ту же роль, что и когерентные состояния в случае конечного числа степеней свободы, а отображение дуальности (см. п. 2.1) соответствует переходу к представлению Шрёдингера, диагонализирующему операторы $Q(t)$.

Дальнейшие сведения о квантовом стохастическом исчислении можно найти в обзоре Мейера [128], а также в сборниках [142]-[145], охватывающих такие темы, как связи с некоммутативной геометрией (Хадсон, Эпплбаум, Робинсон), применение в теории кратного стохастического интеграла (Маассен, Мейер, Партасарати, Линдсей), некоммутативные случайные блуждания в «игрушенном пространстве Фока» и их сходимость к основным процессам (Партасарати, Линдсей, Аккарди) и другие.

12.5.2 2. Расширения в пространстве Фока

Благодаря структуре непрерывного тензорного пронзведения, пространство Фока является естественным вместилишем различных «безгранично делимых» объектов. В конце 60-х годов Араки и Стритер рассматривали безгранично делимые представления групп и показали, что такие представления вкладываются в пространство Фока. Поскольку представление группы определяется некоторой положительно определенной функцией, то этот результат дает запись безгранично делимой положительно определенной функции через фоковское вакуумное среднее (см. [96], [138]). Отсюда также следует, что всякое безгранично-делимое распределение вероятностей может быть реализовано как распределение некоторой квантовой наблюдаемой относительно вакуумного состояния в пространстве Фока. Таким образом r $_r$ пространство Фока вмещает в себя все процессы с независимыми приращениями, а также процессы

«квантового шума», которые дают универсальную модель окружения открытой квантовой системы. Это обстоятельство лежит в основе конструкций расширення, использующих фоковское пространство.

2.1. Винеровский и пуассоновский процессы в пространстве Фока. Если $\{X(t); t \in \mathbf{R}\}$ - коммутирующее семейство самосопряженных операторов в гильбертовом пространстве $\mathfrak{g}$, то оно ∂a - гомализуемо: существует пространство с мерой $(\Omega, \mathscr{B}(\Omega), \mu)$ и унитарный оператор J из $\mathfrak{g}$ на $L^2(\Omega, \mu)$, такие что

$$\left(JX(t)J^{-1}\varphi\right)(\omega) = X_t(\omega)\varphi(\omega)$$

для $\varphi \in L^2(\Omega, \mu)$, где $X_t(\omega)$ - вещественные измеримые функция. При этом для любого $\psi \in \xi$ и ограниченной борелевской функции $f(x_1, \ldots, x_n)$

$$\langle \psi | f(X(t_1), \ldots, X(t_n))\, \psi \rangle = \int f(X_{t_1}(\omega), \ldots, X_{t_n}(\omega))\, P(d\omega)$$

где $P(d\omega) = |(J\psi)(\omega)|^2 \mu(d\omega)$ - вероятностная мера на Ω. В этом смысле семейство $\{X(t)\}$ в гильбертовом пространстве 5 с выделенным вектором ψ стохастически квивалентно случайному процессу $\{X_t(\omega)\}$ в вероятностном пространстве $(\Omega, \mathscr{B}(\Omega), P)$.

Рассмотрим коммутирующее (в силу (1.5)) семейство самосопряженных операторов $\{Q(t)\}$ в $\Gamma(L^2(\mathbf{R}_+))$. Пусть $\{W_t;\ t \in \mathbf{R}_+\}$- стандартный винеровский процесс, $L^2(W)$ - гильбертово пространство комплексных квадратично интегрируемых функционалов от винеровского процесса. Отображение дуальности (Сигал)

$$J\psi = f_0 + \sum_{n=1}^{\infty} \int_{\mathfrak{P}_n} \ldots \int f_n(t_1, \ldots, t_n)\, dW_{t_1} \ldots dW_{t_n}$$

где в правой части формулы - кратные стохастические интегралы в смысле Ито, является изоморфизмом пространства Фока $\mathfrak{G} = \Gamma(L^2(\mathbf{R}_+))$и $L^2(W)$, причем

$$J\Psi_0 = 1; \quad JQ(t)^{J-1} = W_t$$

Поэтому семейство $\{Q(t)\}$ в $\Gamma(L^2(\mathbf{R}_+))$с вакуумным вектором ψ_0 стохастически эквивалентно винеровскому процессу W_t. Аналогичное утверждение справедливо и для коммутирующего се- мейства $\{P(t)\}$. Заметим, что в силу (1.5) операторы $Q(t)$ и $P(s)$ не коммутируют между собой и поэтому семейство $\{Q(t),\ P(t)\}$ не эквивалентно двумерному винеровскому процессу. Унитарный оператор $U\psi(\tau) = i^{|\tau|}\psi(\tau)$ переводит ψ_0 в ψ_0 и

$$P(t) = UQ(t)U^{-1}.$$

Оператору U в $L^2(W)$ отвечает преобразование Фурье-Винера [1)].

Рассмотрим теперь коммутирующее семейство самосопряженных операторов $\{\Lambda(t)\}$. Пусть $\{N_t; t \in \mathbf{R}_+\}$- пуассоновский процесс интенсивности λ на вероятностном пространстве $(\Omega, \mathscr{B}(\Omega), P_\lambda)$ и $L^2(N) \equiv L^2(\Omega, P_\lambda)$. Отображение

$$J^{(\lambda)}\psi = f_0 + \sum_{n=1}^{\infty} \int_{\mathfrak{P}_n} \ldots \int f_n(t_1, \ldots, t_n)\, dX_{t_1} \ldots dX_{t_n}$$

где $X_t = \lambda^{-1/2}(N_t - \lambda t)$ - компенсированный пуассоновский процесс, является изоморфизмом пространства Фока $\Gamma(L^2(\mathbf{R}_+))$и $L^2(N)$, причем

$$J^{(\lambda)}\psi_0 = 1, \quad J^{(\lambda)}\Pi^{(\lambda)}(t)J^{(\lambda)-1} = N_t$$

где

$$\Pi^{(\lambda)}(t) = \Lambda(t) + \sqrt{\lambda}Q(t) + \lambda t.$$

Таким образом, семейство $\left\{\Pi^{(\lambda)}(t)\right\}$ в $\Gamma\left(L^2\left(\mathbf{R}_+\right)\right)$с вакуумным вектором ψ_0 стохастически эквивалентно пуассоновскому процессу [108].

С точки зрения классической теории вероятностей соотношение (2.1) не может не вызвать удивления - пуассоновский процесс представлен как сумма винеровского процесса с постоянным сносом и процесса $\Lambda(t)$, равного нулю почти наверное (относительно вакуумного состояния). Дело, конечно, в том, что слагаемые не коммутируют и поэтому не могут рассматриваться как классические случайные процессы на одном вероятностном пространстве. Заметим, что подобная связь между пуассоновским и нормальным распределением хорошо известна в: квантовой оптике [21].

В подходящее пространство Фока $\Gamma\left(L^2_{\mathscr{K}}\left(\mathbf{R}_+\right)\right)$, где $L^2_{\mathscr{K}}\left(\mathbf{R}_+\right)$ - пространство квадратично-интегрируемых функций со значениями в некотором гильбертовом пространстве $\mathscr{K}$, может быть. вложен произвольный стохастически непрерывный процесс с независимыми приращениями (Партасарати, см. [128]). Представление такого процесса требует, вообще говоря, бесконечного числа независимых процессов рождения-уничтожения-числа частиц.

Среди процессов с независимыми приращениями только ви-

1. См. Т. Хида. Броуновское движение.- М.: Наука, 1987. :неровский и пуассоновский обладают следующим свойством хаотической представимости: гильбертово пространство квадра.тично интегрируемых функционалов от процесса является прямой суммой подпространств, порождаемых n-кратными стохастическими интегралами (Винер, Ито). Вопрос-какие другие мартингалы обладают этим свойством - привлек внимание спе-циалистов по теории случайных процессов. В частности, Эмери показал, что этим свойством обладает мартингал Аземы

$$X_t = \operatorname{sgn} W_t \sqrt{2\left(t - g_t\right)}$$

,где g_t - последний нуль винеровского процесса W_t перед моментом t. Партасарати [137] рассмотрел квантовое стохастическое дифференциальное уравнение

$$dX_\cdot(t) = (c-1)X(t)d\Lambda(t) + dQ_\cdot(t), \quad X(0) = 0$$

и показал, что при любом $c \in [-1, 1]$ оно имеет решение, являю- щееся коммутирующим семейством самосопряженных операто: ров и стохастически эквивалентное (относительно вакуумного вектора) мартингалу со свойством хаотической представимости. Как заметил Мейер, при $c = 0$ решение $X(t)$ стохастически эквнвалентно мартингалу Аземы. Таким образом, в высшей степени нелинейное преобразование (2.2) винеровского процесса оказывается тесно связанным с линейным стохастическим дифференциальным уравнением для некоммутирующих процессов.

2.2 Стохастические эволюции и расширения динамических полугрупп. Интересный класс безгранично делимых объектов возникает в связи с динамическими полугруппами. Пусть $\mathscr{C}$ - гильбертово пространство, Ф-динамическое отображение в алгебре $\mathfrak{B}(\mathscr{H})$, т. е. нормальное вполне положительное отображение, такое что $\Phi[\mathrm{I}] = \mathrm{I}$. Назовем Φ безгранично делимым, если для любого $n = 1, 2, \ldots \Phi = (\Phi_n)^n$, где Φ_n - динамическое отображение. Если $\{\Phi_t; t \in \mathbf{R}_+\}$- динамическая полугруппа, то все отображения Φ_t безгранично делимы, поскольку $\Phi_t = \left(\Phi_{t/n}\right)^n$. С другой стороны, если $\dim \mathscr{H} < \infty$, то всякое безгранично де-лимое динамическое отображение имеет вид $\Phi = \mathscr{E} \cdot e^{\mathscr{L}}$, где $\mathscr{E}$ -

условное ожидание на некоторую подалгебру $\mathscr{B} \subset \mathfrak{P}(\mathscr{H})$, а $\mathscr{L}$ - вполне диссипативное отображение, оставляющее подалгебру инвариантной [15]. Отображение $\mathscr{E}$ играет роль, аналогичную идемпотентному делителю в теории безгранично делимых положйтельно определенных функций на группах [138]. Если $\mathscr{E} = \mathrm{Id}$, то через Φ можно провести квантовую динамическую полугруппу.

В работе Хадсона и Партасарати [108] было построено вложение непрерывной по норме квантовой динамической полугруппы в пространство Фока, которое может быть истолковано как расширение до марковского квантового случайного процесса в смысле п. 3.2.6 (см. статью Фриджерио в [142]). Для простоты ограничимся описанием конструкции работы [108] для по- лугруппы с инфинитезимальным оператором вида

$$\mathscr{L}[X] = i[H, X] + L^* X L - L^* L_\circ X$$

где $H, L \in \mathcal{B}(\mathscr{H}), H^* = H$.

П р е д лож ен и е. Пусть $\{\Phi_t; t \in \mathbb{R}_+\}$-квантовая динамичес-: кая полугруппа в $\mathscr{B}(\mathscr{H})$ с инфинитезимальным оператором (2.3). тогда

$$\Phi_t[X] = \mathscr{E}_0 \left[V(t)^*(X \otimes I)V(t)\right], X \in \mathscr{B}(\mathscr{H})$$

где $\{V(t); t \in \mathbf{R}_+\}$-семейство унитарных операторов в $\mathscr{G} = \mathscr{H} \otimes \Gamma\left(L^2\left(\mathbf{R}_+\right)\right)$, удовлетворяющее уравнению (1.26), а отображение $\mathscr{E}0 : \mathscr{V}(\mathfrak{G}) \to \mathscr{O}(\mathscr{C})$ - усреднение по вакуумному состоянию, определяемое формулой

$$\mathrm{Tr}\, S\mathscr{E}_0[Y] = \mathrm{Tr}\left(S \otimes |\psi_0\rangle \langle\psi_0|\right) Y$$

для любого оператора плотности S в $\mathscr{H}$ и любого $Y \in \mathscr{Z}(\natural)$.

Док а за тельство. Из уравнения (1.26) и квантовой формулы Ито вытекает квантовое уравнение Ланжевена для; $X(t)$:

$$dX(t) = [L(t)*, X(t)]dA(t) + [X(t), L(t)]dA^+(t) +$$
$$+ \left\{i[H(t), X(t)] + (L(t)^* X(t) L(t) - L(t)^* L(t) \circ X(t))\right\} dt$$

Усредняя по вакуумному состоянию и учитывая первое из соотношений

$$dA(t)\psi_0 = 0, \quad d\Lambda(t)\psi_0 = 0$$

вытекающих из (1.6), получаем, что семейство наблюдаемых $\tilde{\Phi}_t[X] = \mathscr{E}_0\left[V(t)^*(X \otimes \mathrm{I})V(t)\right]$ в алгебре системы $\mathscr{B}(\mathscr{H})$ удов; летворяет уравнению

$$d\widetilde{\Phi}_t[X] = \widetilde{\Phi}_t[\mathscr{L}[X]]dt; \quad \tilde{\Phi}_0[X] = X$$

Отсюда следует, что $\tilde{\Phi}_t[X] = \exp t\mathscr{L}[X] = \Phi_t[X]$.

Пусть теперь $\{\Psi_t; t \in \mathbf{R}_+\}$-соответствуюшая динамическая полугруппа в пространстве состояний. Из представления (2.4) вытекает конструктивное доказательство теоремы о расширении, сформулированной в п. 3.2.6. Обозначим $\mathscr{C}_0 = \Gamma\left(L^2(\mathbf{R})\right)$ пространство Фока, ассоциированное с $L^2(\mathbf{R})$, и пусть $S_0 = |\psi_0\rangle \langle\psi_0|$, где ψ_0 - вакуумный вектор в $L^2(\mathbf{R})$. В пространстве $\mathscr{C} \otimes \mathscr{C}_0$ действует группа унитарных операторов временного. сдвига $\{\mathscr{P}_t; t \in \mathbf{R}\}$, определяемых как в п. 1.4. Поскольку $\mathscr{H}_0 = \Gamma\left(L^2\left(\mathbf{R}_-\right)\right) \otimes \Gamma\left(L^2\left(\mathbf{R}_+\right)\right)$, где $\mathbf{R}_- = (-\infty, 0)$, действие основных процессов $A(t), A^+(t), \Lambda(t); t \in \mathrm{R}_+$;естественно переносится в $\mathscr{C} \otimes \mathscr{H}_{\circ}$. Решение уравнения (1.26) является тогда семейством унитарных операторов $\{V(t); t \in \mathbf{R}_+\}$в $\mathscr{H} \otimes \mathscr{H}_0$, удовлетворяющим соотношению коцикла (1.19). Из этого соотношения вытекает qt0

$$U_t = \begin{cases} \mathscr{S}_t V(t), & t \in \mathrm{R}_+ \\ V(-t)^* \mathscr{S}_t, & t \in \mathrm{R}_- \end{cases}$$

является группой унитарных операторов в $\mathscr{H} \otimes \mathscr{H}_0$. Поскольку $\mathscr{P}_t^* (X \otimes \mathrm{I}) \mathscr{P}_t = X \otimes \mathrm{I}$, из (2.4) следует, что

$$\Psi_t[S] = \mathrm{Tr}_{?\mathscr{H}_0} U_t \, (S \otimes S_0) \, U_t^*, \quad t \in \mathbf{R}_+.$$

Построенное расширение имеет прозрачную физическую интерпретацию. Группа операторов временного сдвига $\{\mathscr{I}_t\}$ описывает динамику квантового шума, который играет роль окружения рассматриваемой системы. Записывая операторы $V(t)$ в виде хронологически упорядоченной экспоненты (1.25), можно видеть, что они задают эволюцию системы с гамильтонианом H, взаимодействующей с окружением посредством сингулярного гамильтониана

$$H_{\mathrm{Int}} \ = i \left(L\dot{A} + (t) - L^* \dot{A}(t) \right).$$

Усреднение унитарной эволюции $\{U_t\}$ по вакуумному состоянию шума и дает динамическую полугруппу в $\mathscr{B}(\mathscr{C})$.

Аналогичное унитарное расширение имеет место для пронзвольной квантовой динамической полугруппы с инфинитезкмальным оператором (3.2.4) - надо только использовать квантовое стохастическое исчисление с бесконечным набором операторов рождения-уничтожения.

С точки зрения статистической механики представляет интерес выяснение точных условий, при которых такая в высшей степени идеалиэированная динамическая система, как квантовый шум, возникает из более реалистичных физических моделей открытых систем (см. в этой связи работу [52], где обсуждаются приближения слабого взаимодействия и малой плотности).

Из формулы (2.4) можно получить представления квантовой динамической полугруппы через решения классических стохастических дифференциальных уравнений в гильбертовом пространстве $\mathscr{H}$ (см. статью А. С. Холево в [35]). Пусть W_t - стандартный винеровский процесс и $\left\{ V_t^{(1)}(W); t \in \mathbf{R}_+ \right\}$- случайный процесс со значениями в $\mathscr{B}(\mathscr{H})$, удовлетворяющий стохастическому дифференциальному уравнению

$$dV_t^{(1)}(W) = \left[L dW_t - \left(iH + \frac{1}{2} L^* L \right) dt \right] V_t^{(1)}(W)$$
$$V_0^{(1)}(W) = 1$$

Тогда

$$\Phi_t[X] = \mathbf{M}_{(1)} V_t^{(1)}(W)^* \lambda V_t^{(1)}(W),$$

где $\mathbf{M}_{(1)}$-математическое ожидание, отвечающее распределению винеровского процесса. С другой стороны, пусть N_t - пуассоновский процесс. с единичной интенсивностью и $\left\{ V_t^{(2)}(N) ; \right.$

Тогда

$$dV_t^{(2)}(N) = \left[(L - \mathrm{I}) dN_t - \left(iH + \frac{1}{2} \left(L^* L - \mathrm{I} \right) \right) dt \right] V_t^{(2)}(N)$$
$$V_0^{(2)}(N) = \mathrm{I}$$

$$\Phi_t[X] = M_{(2)} V_t^{(2)}(N)^* \lambda V_t^{(2)}(N)$$

где $\mathbf{M}_{(2)}$ - математическое ожидание, отвечающее распределению пуассоновского процесса.

Заметим, что решения уравнений $(2.7), (2.9)$ могут быть заэисаны в виде хронологически-упорядоченных экспонент (мультипликативных стохастических интегралов)

$$V_t^{(1)}(W) = \underset{\exp}{\leftarrow} \int_0^t \left\{ L dW_s - \left[iH + \frac{1}{2}(L^* + L) L \right] ds \right\}$$

$$V_t^{(2)}(N) = \underset{\exp}{\leftarrow} \int_0^t \left\{ (\ln L) dN_s - \left[iH + \frac{1}{2}(L^* L - \mathrm{I}) \right] ds \right\}.$$

Ограничимся выводом представления (2.8). Введем семейство изометрических операторов $V_t^{(1)}$ из $\mathscr{H}$ в $\mathfrak{H}_\ell = \mathscr{H}, \otimes \Gamma(L^2(\mathbf{R}_+))$, определя емых соотношением

$$V_t^{(1)} \varphi = V(t)(\varphi \otimes \psi_0); \quad \varphi \in \mathscr{H}\mathscr{C}.$$

Из уравнения (1.26) следует

$$dV_t^{(1)} = \left[L dQ(t) - \left(iH + \frac{1}{2} L^* L \right) dt \right] V_t^{(1)}$$

поскольку в силу (2.5) коэффициент при $dA(t)$ может быть произвольным. Если воспользоваться теперь преобразованнем дуальности, то формула (2.4) перейдет в (2.8), а уравнение (1.26) - в уравнение (2.7). Аналогично, вывод представления (2.10) из формулы (2.4) основан на преобразовании $J^{(\lambda)}$ из п. 2.1 (при $\lambda = 1$) (см. п. 2.4).

2.3. Расширения инструментальных процессов. При рассмотрении процессов непрерывного измерения естественно возникает понятие безграничной делимости инструмента, которое объединяет безграничную делимость распределений вероятностей и динамических отображений. В работе Баркиелли и Лупиери (см. [61], [142]) указано соответствующее расширение в пространстве Фока, которое можно рассматривать как конкретизацию общего результата Озава (п. 4.1.2) для процессов нзмерения, протекающих во времени. Ограничимся здесь двумя наяболее важными примерами.

Приме р 1. Рассмотрим и.-процесс $\left\{ \mathcal{N}_{a,b}^{(1)} \right\}$ с генератором

$$\mathscr{L}^{(1)}(\lambda)[X] = \mathscr{L}[\lambda] + i\lambda (L^* X + X L) - \frac{1}{2} \lambda^2 X,$$

где $L, H = H^*$-ограниченные операторы в гильбертовом пространстве $\mathscr{H}$, а $\mathscr{L}[X]$ дается формулой (2.3). Согласно п. 4.2.3, это есть процесс непрерывного измерения наблюдаемой $A = (L + L^*)$ в системе, эволюционирующей с гамильтонианом H. Из результата Баркиелли и Лупиери следует, что

$$\mathscr{P}_{0,t}^{(1)}(E)[X] = \mathscr{E}_0 \left[V(t)^* \left(X \otimes P_{0,t}^{(1)}(E) \right) V(t) \right]; \quad E \in \mathscr{B}_{0,t}$$

где $\{V(t)\}$-семейство унитарных операторов в гильбертовом пространстве $= \mathscr{H}, \otimes \Gamma(L^2(\mathbf{R}_+))$, удовлетворяющее квантовому стохастическому дифференциальному уравнению (1.26), а $P_{0,t}^{(1)}(E)$; $E \in \mathscr{B}_{0,t}$, спектральная мера семейства совместимых наблюдаемых $Q(s); 0 \leqslant s \leqslant t$, в $\Gamma(L^2(\mathbf{R}_+))$(см. п. 4.2.1) (в силу однородности аналогичное представление имеет место и для $\mathscr{P}_{a,b}^{(1)}$, где $a \leqslant b$).

Пусть $\left\{\mathscr{N}_{a,b}^{(1)}\right\}$-соответствующий и.-процесс в пространстве состояний. Тогда соотношение (2.16) приобретает вид формулы (4.1.10)

$$\mathscr{K}_{0,t}^{(1)}(E)[S] = \mathrm{Tr}_{\Gamma(L^2(\mathrm{R}_+)}\, V(t)\left(S\otimes|\psi_0\rangle\langle\psi_0|\right)\times \\ \times V(t)^*\left(\mathrm{I}\otimes P_{0,t}^{(1)}(E)\right),$$

которая имеет ясную физическую интерпретацию: наблюдаемая система, первоначально находившаяся в состоянии S и эволюционирующая с гамильтонианом H, взаимодействует с квантовым шумом посредством сингулярного гамильтониана (2.6). При этом над квантовым шумом, который играет роль пробной системы, производится непрерывное неразрушающее измерение семейства совместимых наблюдаемых $Q(s); 0\leqslant s\leqslant t$.

Прим ер 2. И.-процесс $\left\{\mathcal{P}_{a,b}^{(2)}\right\}$ с генератором

$$\mathscr{L}^{(2)}(\lambda)[X] = i[H,\ddot{\Lambda}] + \left(L^*XLe^{i\lambda} - L^*L\circ\dddot{\Lambda}\right),$$

где $H, L\in\mathfrak{B}(\mathscr{H})$, является естественным обобщением считающего процесса из п. 4.2.5. Для этого процесса расширение имеет вид

$$\mathscr{S}_{0,t}^{(2)}(E) = \mathscr{E}_0\left[V(t)^*\left(\mathrm{I}\otimes P_{0,t}^{(2)}(E)\right)V(t)\right];\quad E\in\mathscr{B}_{0,t}$$

где $P_{0,t}^{(2)}(E); E\in\mathscr{B}_{0,t}$, спектральная мера семейства совместимых наблюдаемiх $\Lambda(s);\ 0\leqslant s\leqslant t$, в $\Gamma\left(L^2\left(\mathbf{R}_+\right)\right)$. Соответствуюшее представление в пространстве состояний

$$\mathscr{K}_{0,t}^{(2)}(E) = \mathrm{Tr}_{\Gamma(L^2(R_+))}\, V(t)\left(S\otimes|\psi_0\rangle\langle\psi_0|\right)V(t)^*\left(\mathrm{I}\otimes P_{0,t}^{(2)}(E)\right) \quad (2.20)$$

имеет интерпретацию, аналогичную соотошению (2.17).

Несколько слов о методе доказательства соотношения (2.16), (2.19). Обозначим

$$\tilde{\mathscr{P}}_t^{(j)}(B) = \mathscr{E}_0\left[V(t)^*\left(I\otimes P_{0,t}^{(j)}(y(\cdot): y(t)-y(0)\in B)\right)V(t)\right],$$

где $B\in\mathscr{B}(\mathbf{R})$, и введем характеристические функции
Тогда

$$\tilde{\Phi}_t^{(j)}(\lambda) = \int_{\mathbf{R}} e^{i\lambda x}\tilde{\mathcal{P}}_t^{(j)}(dx)$$

$$\tilde{\Phi}_t^{(j)}(\lambda)[K] = \mathscr{E}_0\left[V(t)^*\cdot\left(\lambda^n\otimes e^{i\lambda Y^{(j)}(t)}\right)V(t)\right],$$

где $Y^{(1)}(t) = Q(t)$ и $Y^{(2)}(t) = \Lambda(t)$. Используя Квантовую формулу Ито, можно доказать, что функции (2.21) удовлетворяют уравнениям

$$d\widetilde{\Phi}_t^{(j)}(\lambda) = \mathscr{L}^{(j)}(\lambda)\cdot\widetilde{\Phi}_t^{(j)}(\lambda)dt,$$

r. e.

$$\tilde{\Phi}_t^{(j)}(\lambda) = \exp t\mathscr{L}^{(f)}(\lambda).$$

Отсюда вытекает, что $\left\{\tilde{\mathcal{P}}_t^{(j)}\right\}$ есть сверточная полугруппа, отвечающая и.-процессу $\left\{\mathcal{P}_{a,b}^{(j)}\right\}$. В силу взаимной однозначности соответствия между и.-процессами и сверточными полугруппами (п. 4.2.5) отсюда следуют соотношения (2.16), (2.19).

2.4. Стохастические представления процессов непрерывного измерения. Используя прием, который позволил получить в п. 2.2 стохастические представления квантовой динамической полугруппы, найдем соответствующие стохастические представ, ления для процессов непрерывного измерения [105]. Из этих представлений вытекает явное описаник распределений вероятностей в пространстве траекторий - исходов непрерывного измерения и апостериорных состояний наблюдаемой квантовой системы.

Рассмотрим сначала и.-процесс с генератором (2.15). ак отмечалось в п. 4.2.5, он сосредоточен на непрерывных траекториях. Пусть $\mu_{(1)}$-мера Винера в пространстве непрерывных функций $\mathscr{B}$, отвечающая стандартному винеровскому процессу W_t.

Предложение 1. И.-процесс $\left\{\boldsymbol{N}_{a,b}^{(1)}\right\}$ абсолютно непрерывен по мере, $\mu_{(1)}$ в том смысле, что

$$\mathscr{K}_{0,t}^{(1)}(E)[S]=\int\limits_E V_{(t)}^{1;}(W)SV_t^{(1)}(W)^*d_{\mu_{(1)}}(W);E\in\mathscr{B}_{0,t}\cap\mathscr{C},$$

где $\left\{V_t^{(1)}(W)\right\}$-семейство ограниченных операторов в $\mathscr{C}$, удовлетворяющее стохастическому дифференциальному уравнению (2.7) относительно меры $\mu_{(1)}$.

Доказательство основано на применении преобразования дуальности к представлению (2.17). При этом, как в п. 2.2, поя вляются операторы $V_t^{(1)}(W)$, а спектральная мера $P_{0,t}^{(1)}$ семеАсства $Q(s);0\leqslant s\leqslant t$, так что проектор $P_{0,i}^{(1)}(E)$ переходит в индикатор множества $E\in\mathscr{B}_{0,t}\cap\mathscr{C}$.

Соотношение (2.17) дает конкретное представление вполне положительного инструмента $\boldsymbol{x}_{0,t}^{(1)}$ в виде (4.1.12). Отсюда получается распределение вероятностей в пространстве наблюдаемых траекторий

$$\mu_S(E)=\int\limits_E \operatorname{Tr} SV_t^{(1)}(W)^*V_t^{(1)}(W)d_{\mu_{(1)}}(W);\quad E\in\mathscr{B}_{0,t}\cap\mathscr{C}$$

Оно абсолютно непрерывно по мере Винера $\mu_{(1)}$, причем плотность дается формулой

$$p_t^{(1)}(W)=\operatorname{Tr} SV_t^{(1)}(W)V_t^{(1)}(W)^*$$

и почти наверное положительна. Апостериорное состояние, отвечающее наблюдаемой траектории $W_s;0\leqslant s\leqslant t$, есть

$$S_t^{(1)}(W)=p_t^{(1)}(W)^{-1}V_t^{(1)}(W)SV_t^{(1)}(W)^*$$

Отметим, что если начальное состояние чистое, $S=|\psi\rangle\langle\psi|$, то апостериорные состояния являются чистыми $S_t^{(1)}(W)=\left|\psi_i^{(1)}(W)\right\rangle\left\langle\psi_t^{(1)}(W)\right|$, где

$$\psi_t^{(1)}(W)=V_t^{(1)}(W)\psi/\left\|V_t^{(1)}(W)\psi\right\|$$

Переидем к случаю гчитающего процесса с генератором (2.18). Пусть $\mu_{(2)}$-мера в пространстве $\mathscr{D}$, отвечающая пуассоновскому процессу единичной интенсивности.

П редложен и е 2. И.-процесс $\left\{\mathscr{M}_{a,b}^{(2)}\right\}$ абсолютно непрерывен по мере $\mu_{(2)}$, а именно

$$\mathscr{A}_{0.t}^{(2)}(E)[S]=\int\limits_E V_t^{(2)}(N)SV_t^{(2)}(N)^*d_{\mu_{(2)}}(N);E\in\mathscr{B}_{0,t}\cap\mathscr{D},$$

где $\left\{V_t^{(2)}(N)\right\}$-семейство ог раниченных операторов в $\mathscr{B}$, удовлетворяющее стохастическому дифференциальному уравнению (2.9) относительно меры $\mu_{(2)}$.

Доказательство соотношения (2.25) требует некоторого преобразования представления (2.20). Рассмотрим унитарные операторы Вейля $V_{\mathbf{s}}(t) = \exp[zA^+(t) - zA(t)]$, где $z \in \mathbf{C}$. При $s \leqslant t$ имеет место соотношение

$$V_{\mathrm{x}}(t)^*\Lambda(s)V_{\mathrm{z}}(t) = \Lambda(s) + \bar{z}A(s) + zA^+(s) + |z|^2 s \equiv \Pi(s)$$

которое проверяется с использованием уравнения (1.27) и квантовой формулы Ито. Положим $\bar{z} = 1$, тогда $\Pi(\mathrm{s})$ является пуассоновским процессом единичной интенсивности в пространстве

Фока. Обозначая $\widetilde{U}_t = V_1(t) * V(t)$, перепишем (2.20) в виде

$$\boldsymbol{x}^{(2)}_{0,t}(E) = \mathrm{Tr}_{\Gamma(L^2(R_+))}\, \tilde{U}_t \left(S \otimes |\psi_0\rangle \langle\psi_0|\right) \tilde{U}_t^* \left(\mathrm{I} \otimes \tilde{P}^{(2)}_{0,t}(E)\right),$$

где $\widetilde{P}^{(2)}_{0,t}$-спектральная мера семейства совместимых наблюдаемых $\Pi(s)$; $\quad 0 \leqslant s \leqslant t$. Из квантовой формулы Ито вытекает уравнение для $\tilde{U}_t$:

$$\begin{aligned} d\widetilde{U}_t = \big\{&(L - \mathrm{I})dA^+(t) - (L - \mathrm{I})^* dA(t) - \\ &- \left[iH + \frac{1}{2}\left(L^*L - 2L + \mathrm{I}\right)\right] dt \Big\} \tilde{U}_t \end{aligned}$$

Вводя изометрические операторы $V_t^{(2)}$ из $\mathscr{C}$ в $\mathfrak{F}$ по формуле

$$V_t^{(2)}\varphi = \tilde{U}_t\left(\varphi \otimes \psi_0\right); \quad \varphi \in \mathscr{B}$$

и учитывая соотношения (2.5), получаем уравнение

$$dV_t^{(2)} = \left\{(L - \mathrm{I})d\Pi(t) - \left[iH + \frac{1}{2}\left(L^*L - \mathrm{I}\right)\right] dt\right\} V_t^{(2)}$$

Унитарный оператор $J^{(1)}$ из п. 2.1 переводит пространство Фока $\Gamma\left(L^2\left(\mathbf{R}_+\right)\right)$в $L^2(N)$, где N_t - классический пуассоновский процесс единичной интенсивности, при этом уравнение (2.27) переходит в (2.9), проектор $\widetilde{P}^{(2)}_{0,t}(E)$ - в индикатор множества E, а формула (2.26) - в представление (2.25).

Для распределения вероятностей в пространстве наблюдаемых траекторий и апостериорных состояний получаются формулы, аналогичные (2.23) – (2.25).

2.5. Нелинейные стохастические уравнения апостериорной динамики. Получим стохастические дифференциальные уравнения, которым удовлетворяют наблюдаемые траектории и апостериорные состояния в процессе непрерывного квантового измерения. Рассмотрим сначала процесс измерения наблюдаемой $A = L + L^*$ с. генератором (2.15). Из уравнения (2.7) для семейства $V_t^{(1)}(W)$ и формулы (2.23) вытекает, что плотность $P_t^{(1)}(W)$ распределения вероятностей наблюдаемых траекторий μ_s относительно меры Винера $\mu_{(1)}$ удовлетворяет стохастическому дифференциальному уравнению

$$dp_t^{(1)}(W) = m_t(W)p_t^{(1)}(W)dWW_t$$

где

$$m_t(W) = \mathrm{Tr}\, S_t^{(1)}(W)A$$

- апостериорное среднее наблюдаемой A. Отсюда следует [1)], что наблюдаемый процесс $Y(t)$ является процессом диффузнонного типа, удовлетворяющим стохастическому дифференциальному уравнению

$$dY(t) = m_t(Y)dt + dW_t$$

1. См. Р. Ш. Липцер, А. Н. Ширяев. Статистика случайных процессов.М.: Наука, 1974, 7.2.

Применяя стохастическое исчисление Ито, получаем уравнение для апостернорного состояния (2.24)

$$dS_t^{(1)}(Y) - \mathscr{K}\left[S_t^{(1)}(Y)\right] = \Big[(L - m_t(Y))\, S_t^{(1)}(Y) + \\ + S_t^{(1)}(Y)\,(L - m_t(Y))^*\Big]\,[dY(t) - m_t(Y)dt]$$

где

$$\mathscr{K}[S] = -i[H, S] + LSL^* - L^*L \circ S$$

Это уравнение было получено В. П. Белавкиным из рассмотрения квантового аналога задачи фильтрации случайных процессов [64]. В случае чистых состояний уравнение для вектора апостериорного состояния имеет вид

$$d\psi_t^{(1)}(Y) = [L - m_t(Y)]\,\psi_t^{(1)}(Y)\,[dY(t) - m_t(Y)dt] - \\ - \left[iH + \frac{1}{2}\left(L^*L - 2Lm_t(Y) + m_t(Y)^2\right)\right]\psi_t^{(1)}(Y)dt$$

Нелинейность уравнений $(2.30), (2.31)$ обусловлена нормировкой апостериорных состояний (2.24), в основе же лежит линейное стохастическое уравнение (2.7) типа уравнения Закаи в классической теории фильтрации.

Большой интерес представляет задача вывода и исследования уравнений (2.30), (2.31) в случае, когда L, H - неограниченные операторы. В работе В. П. Белавкина и Сташевского [65] рассмотрено уравнение

$$d\psi_t^{(1)}(Y') = (Q - m_t(Y))\,\psi_t^{(1)}(Y)\,[dY(t) - m_t(Y)dt] - \\ - \left[iP^2/2m + \frac{1}{2}\,(Q - m_t(Y))^2\right]\psi_t^{(1)}(Y)dt$$

которое получается из (2.31) формальной заменой $H = P^2/2m$, $L = Q$, где P, Q - канонические наблюдаемые нерелятивистской частицы массы m. Это соответствует непрерывному приближенному измерению координаты свободной частицы. Найдено явное решение в случае гауссовского начального состояния и показано, что оно является гауссовским с дисперсией, стремящейся к конечному пределу при $t \to +\infty$. Таким образом, уравнение (2.32) снимает известный квантовомеханический парадокс с расплыванием волнового пакета свободной частицы.

Интересно, что сходные нелинейные уравнения, однако с совершенно иной мотивировкой и интерпретацией, возникли практически одновременно в работах ряда авторов, занимающихся поисками альтернативного концептуального обоснования теории квантового измерения. В работе, опубликованной в сборнике [142], Гирарди, Римини и Вебер поставили вопрос о нахождении уравнений, дающих единое описание микро-и макросистем, из которых, в частности, вытекали бы как обратимая квантовая динамика, так и необратимые изменения типа проекционного постулата. Предлагались различные решения этого вопроса; в работах Джизена [91], Гирарди, Пирла и Римини [89] введено уравнение типа (2.31), где, однако, вместо $dY(t)$ - $m_t(Y)dt$ фигурирует стохастический дифференциал некоторого априорно данного винеровского процесса (уравнение в [91]

отличается за счет выбора фазового множителя у $\psi_t^{(1)}\Big)$. Пусть $H = 0, L = \Sigma x_i E_i$ - самосопряженный оператор с чисто точечным спектром. В [91], [89] отмечается, что получающееся уравнение

$$d\psi_t = (L - \langle L\rangle_t)\,\psi_t dW_t - \frac{1}{2}\,(L - \langle L\rangle_t)^2\,\psi_t dt$$

где $\langle L\rangle_t = \langle\psi_t|L\psi_t\rangle$, дает динамическое описание проекционного постулата $\psi \to \psi_i = E_i\psi/\,\|E_i\psi\|$, в том смысле, что при $t \to +\infty$ решение ψ_t стремится к одному из состояний ψ_i. В работе Гатарека и Джизена [88] дано математическое исследование уравнения (2.33) для неог раниче н ного оператора L, а также уравнения типа (2.32). Для доказательства существования слабого решения эти авторы использовали формальный прием преобразования вероятностной меры (теорему Гирсанова), который в схеме непрерывного измерения имеет содержательный смысл перехода от процесса $Y(t)$ к винеровскому процессу W_t, определяемого формулой (2.29).

В случае считающего процесса с генератором (2.18) стохастическое уравнение для плотности в пространстве траекторий имеет вид

$$dp_t^{(2)}(N) = [\lambda_t(N) - 1]\,p_t^{(2)}(N)(dN - dt)$$

где

$$\lambda_t(N) = \mathrm{Tr}\,S_t^{(2)}(N)L^*L$$

- апостериорнай интенсивность скачков. Уравнение для апостерио рного состояния

$$dS_t^{(2)}(Y) - \mathscr{K}\left[S_t^{(2)}(Y)\right]dt =$$
$$= \left[\frac{LS_t^{(2)}(Y)L^*}{\lambda_t(Y)} - \mathrm{I}\right][dY(t) - \lambda_t(Y)dt]$$

В статье В. П. Белавина в сборнике [35] приведено общее нелинейное уравнение квантовой фильтрации, включающее в себя как уравнение (2.30), так и (2.34).

Ф-вв-л2.1 Параметры Стокса

Найдите параметры Стокса для поляризационного состояния фотона

$$|\psi\rangle = \frac{\sqrt{2}-i}{2}|H\rangle + \frac{e^{i\pi/6}}{2}|V\rangle$$

Solution

Представляем состояние в виде столбца, находим матричный элемент (??? Почему такие формулы???)

$$|\psi\rangle = \frac{1}{2}\begin{pmatrix} \sqrt{2}-i \\ e^{i\pi/6} \end{pmatrix} \qquad \langle\psi| = \frac{1}{2}\begin{pmatrix} \sqrt{2}+i & e^{-i\pi/6} \end{pmatrix}$$

$$\langle X\rangle = \langle\psi|X|\psi\rangle = \frac{1}{4}\begin{pmatrix} \sqrt{2}+i & e^{-i\pi/6} \end{pmatrix}\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} \sqrt{2}-i \\ e^{i\pi/6} \end{pmatrix} = \frac{\sqrt{6}-1}{4}$$

$$\langle Y\rangle = \langle\psi|Y|\psi\rangle = \frac{1}{4}\begin{pmatrix} \sqrt{2}+i & e^{-i\pi/6} \end{pmatrix}\begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}\begin{pmatrix} \sqrt{2}-i \\ e^{i\pi/6} \end{pmatrix} = \frac{\sqrt{2}+\sqrt{3}}{4}$$

$$\langle Z\rangle = \langle\psi|Z|\psi\rangle = \frac{1}{4}\begin{pmatrix} \sqrt{2}+i & e^{-i\pi/6} \end{pmatrix}\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}\begin{pmatrix} \sqrt{2}-i \\ e^{i\pi/6} \end{pmatrix} = \frac{1}{2}$$

Ф-вв-л2.2 Измерение

Физическая величина задаётся оператором $F = 2|H\rangle\langle H| + (1-i)|H\rangle\langle V| + (1+i)|V\rangle\langle H|$. Какие результаты можно получить при измерении этой физической величины?

Solution

Пишем состояние в виде матрицы и находим собственные значения:

$$F = \begin{pmatrix} 2 & 1-i \\ 1+i & 0 \end{pmatrix}$$

$$\det\begin{pmatrix} 2-\lambda & 1-i \\ 1+i & -\lambda \end{pmatrix} = \lambda^2 - 2\lambda - 2 = 0$$

$$\lambda_\pm = 1 \pm \sqrt{3}$$

Ф-вв-л2.3 Коллапс

В какие состояния может перейти (коллапсировать) квантовая система при измерении физической величины $F = 2|H\rangle\langle H| + (1-i)|H\rangle\langle V| + (1+i)|V\rangle\langle H|$?

Solution

$$F\,|f_\pm\rangle = \lambda_\pm\,|f_\pm\rangle$$
$$|f_+\rangle = \frac{1}{\sqrt{6+2\sqrt{3}}}\begin{pmatrix} 1+\sqrt{3} \\ 1+i \end{pmatrix}, \quad |f_-\rangle = \frac{1}{\sqrt{6-2\sqrt{3}}}\begin{pmatrix} 1-\sqrt{3} \\ 1+i \end{pmatrix}$$

Ф-вв-л2.4 Перепутанность

При каких значениях действительного параметра φ квантовое состояние двух фотонов

$$|\psi\rangle = \frac{1}{2}\left(|H\rangle\otimes|H\rangle + |H\rangle\otimes|V\rangle + |V\rangle\otimes|H\rangle + e^{i\varphi}|V\rangle\otimes|V\rangle\right)$$

является перепутанным?

Solution

Задача сводится к проверке определения:

$$\frac{1}{2}\begin{pmatrix} 1 \\ 1 \\ 1 \\ e^{i\varphi} \end{pmatrix} \stackrel{?}{=} \begin{pmatrix} ac \\ ad \\ bc \\ bd \end{pmatrix} = \begin{pmatrix} a \\ b \end{pmatrix} \otimes \begin{pmatrix} c \\ d \end{pmatrix}$$

Ответ: при всех $\varphi \neq 2\pi n, n \in \mathbb{Z}$

Ф-вв-л3.2 Измерение

Двухкубитная система находится в квантовом состоянии $|\psi\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$, где $\{|0\rangle, |1\rangle\}$ - стандартный базис для каждого кубита. В некоторый момент времени происходит измерение физической величины $X = |0\rangle\langle 1| + |1\rangle\langle 0|$ пад первым кубитом. В какие состояния может перейти (коллапсировать) вся система после измерения?

Solution

(думать нужно, там его рукой написан ответ)

Ф-вв-л3.3 Спектр

Какие значения может принимать при измерении физическая величина $F \otimes G$ если $F = (\mathbf{a}\cdot\sigma)$ и $G = (\mathbf{b}\cdot\sigma), \mathbf{a}, \mathbf{b} \in \mathbb{R}^3$?

Solution

(думать нужно, там его рукой написан ответ)

1.

Для d-уровневой системы, где d - простое число, экспериментатор равновероятно выбирает взаимно несмещенные базисы $\{|a\alpha\rangle\}_\alpha, a = 1, \ldots, d+1$ (из полного набора таких базисов) и проводит проективные измерения в этих базисах. Выразите матрицу плотности ϱ через вероятности исходов измерений.

2. О

Известно, что чистые кубитные состояния $|\psi_1\rangle = |0\rangle$ и $|\psi_2\rangle = \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)$ генерируются квантовым источником с вероятностями $p_1 = \frac{4}{5}$ и $p_2 = \frac{1}{5}$ соответственно. Какова максимально возможная вероятность успеха в задаче безошибочного различения этих состояний?

3. О

Найдите физически реализуемое приближение для транспонирования d-уровневой квантовой системы. Для этого рассмотрите деполяризующее отображение $\Phi_q[\varrho] = q\varrho + (1-q)\,\mathrm{tr}[\varrho]\frac{I}{d}$ и укажите диапазон для действительного параметра q, при котором отображение Φ_q о T является квантовым каналом.)T - транспонирование в фиксированном ортонормированном базисе).

5. Кубитный инструмент

Рассмотрите кубитный инструмент $\{i \to \mathcal{I}_i\}$ с двумя элементарными исходами ($i = 1, 2$) вида $\mathcal{I}_1[\varrho] = \frac{1}{2}U_1\sqrt{1+p\sigma_z}\varrho\sqrt{1+p\sigma_z}U_1^\dagger, \mathcal{I}_2[\varrho] = \frac{1}{2}U_2\sqrt{1-p\sigma_z}\varrho\sqrt{1-p\sigma_z}U_2^\dagger$, где U_1 и U_2 - унитарные операторы, $-1 < p < 1$. Постройте физическую реализацию этого квантового инструмента.

7.

Классический источник производит биты " 0 " и " 1 " с вероятностями p_0 и p_1 соответственно. Бит " 1 " физически кодируется в оптический импульс интенсивности $I_1 = I$, а биту " 0 " соответствует отсутствие сигнала $(I_0 = 0)$. Информация передается по длинному оптоволокну и детектируется "оп-off" детектором. В результате ослабления оптического импульса в волокне и конечной квантовой эффективности детектора вероятность зарегистрировать исход "оп" при пересылке бита "1" равна $1/2$. Темновых отсчетов у детектора нет. Найячте пропускную способность классического канала связи. Каким должно быть соотношение битов "0" и "1" в словах, используемых для достижения максимальной скорости надежной передачи данных?

8. Дефазировка

В линии квантовой коммуникации происходит дефазировка квантовых состояний и присутствуют потери частиц, что приводит к квантовому каналу

$$\Phi[\varrho] = \left(\begin{array}{c|c} p\,(q\varrho + (1-q)\sigma_x\varrho\sigma_x) & 0 \\ \hline 0 & (1-p)\,\mathrm{tr}[\varrho] \end{array}\right), \quad 0 \leqslant p, q \leqslant 1$$

где ϱ - матрица плотности кубита. Используя однобуквенные кодирования, при которых среднее состояние ансамбля ϱ_A является максимально смешанным,

а) оцените классическую пропускную способность этого канала;

б) найдите комплементарньй канал;

в) оцените классическую пропускную способность линии связи с использованием ресурса перепутанности;

г) оцените квантовую пропускную способность линии связи.

9.

При каком условии на параметр q кубитный деполяризующий канал $\Phi_q[\varrho] = q\varrho + (1-q)\,\mathrm{tr}[\varrho]\frac{I}{2}$ является дважды самосовместимым? Т.е., при каких значениях шумового параметра q возможно приближенное клонирование произвольных кубитных состояний?

10. О кинетическом уравнении Накажимы-Цванщига для кубита

Решите кинетическое уравнение Накажимы-Цванщига для кубита:

$$\frac{d}{dt}\varrho(t) = \int\limits_0^t \left(\gamma\delta\left(t-t'\right) - \gamma^2 \sin\left[\gamma\left(t-t'\right)\right]\right)\left[\sigma_z\varrho\left(t'\right)\sigma_z - \varrho\left(t'\right)\right]dt'$$

Part V
Other Basic Topics

16 Topological phases and quantum computation Kitaev, Laumann

16.1 Introduction: The quest for protected qubits

The basic building block of quantum computation is the qubit, a system with two (nearly) degenerate states that can be used to encode quantum information. Real systems typically have a full spectrum of excitations that are considered illegal from the point of view of a computation, and lead to decoherence if they couple too strongly into the qubit states during some process. See Fig. 16.1. The essential problem then is to preserve the quantum state of the qubit as long as possible to allow time for computations to take place.

Assuming the gap Δ to the illegal states is reasonable, we can quite generally describe the dynamics of the qubit state by an effective Schödinger equation

$$\frac{d}{dt}|\Psi\rangle = -iH_{\text{eff}}|\Psi\rangle \tag{16.1}$$

where H_{eff} is the effective qubit Hamiltonian. In quantum optics, H_{eff} is often known with high precision. This is not so in condensed matter systems such as quantum dots. Even worse, H_{eff} may fluctuate or include interaction with the environment. This causes decoherence of the qubit state.

Ideally, we would like to arrange for H_{eff} to be zero (or $H_{\text{eff}} = \epsilon I$) for some good reason. Usually, we use a symmetry to protect degeneracies in quantum systems. For example, a quantum spin $\frac{1}{2}$ has a two-fold degeneracy protected by the $SU(2)$ symmetry, as do the $2s+1$ degeneracies of higher spins s. Indeed, any *non-Abelian* symmetry would work. Unfortunately, the $SU(2)$ symmetry of a spin is lifted by magnetic fields and it's generally difficult to get rid of stray fields.

Rather than symmetry, in what follows we will look to topology to provide us with physically protected degeneracies in quantum systems. In particular, we will examine a number of

exactly solvable models in one and two dimensions which exhibit topologically phases – that is, gapped phases with a protected ground state degeneracy dependent on the topology of the manifold in which the quantum model is embedded. In Sec. 16.2 we warm up with the study of several quantum chains that exhibit Majorana edge modes and thus a two-fold degeneracy on open chains. The topological phenomena available in two dimensional models are much richer and will be the focus of the remaining three sections. We introduce and solve the toric code on the square lattice in Sec. 16.3, exhibiting its topolological degeneracy and excitation spectrum explicitly. The following section steps back to examine the general phenomenology of quasiparticle statistics braiding in two dimensional models. Finally, in Sec. 16.5 we introduce the honeycomb lattice model which exhibits several kinds of topological phases, including that of the simple toric code and, in the presence of time reversal symmetry breaking, a gapped phase with chiral edge modes protected by the topology of the Fermi surface.

16.2 Topological phenomena in 1D: boundary modes in the Majorana chain

We will consider two examples of 1D models with $\mathbb{Z}_2$ symmetry and topological degeneracy: the *transverse field Ising model* (TFIM) and the *spin-polarized superconductor* (SPSC). Although these models look rather different physically, we will find that they are mathematically equivalent and that they both exhibit a topological phase in which the ground state degeneracy is dependent on the boundary conditions of the chain. That is, the ground state on an open chain is 2-fold degenerate due to the presence of boundary zero modes, whereas the ground state is unique on a closed loop. This topological degeneracy will be stable to small *local* perturbations that respect the $\mathbb{Z}_2$ symmetry. More details on these models may be found in [4].

1. The *transverse field Ising model* is a spin-1/2 model with Hamiltonian:

$$H_S = -J\sum_{j=1}^{N-1}\sigma_j^x\sigma_{j+1}^x - h_z\sum_{j=1}^{N}\sigma_j^z. \tag{16.2}$$

   Here J is the ferromagnetic exchange coupling in the x direction and h_z is a uniform transverse (z) field. This model has a $\mathbb{Z}_2$ symmetry given by a global spin flip in the σ_x basis:

$$P_S = \prod_{j=1}^{N}\sigma_j^z \tag{16.3}$$

2. The *spin-polarized 1-D superconductor* is a fermionic system with Hamiltonian:

$$\begin{aligned} H_F &= \sum_{j=1}^{N-1}\left(-w(a_j^\dagger a_{j+1} + a_{j+1}^\dagger a_j) + \Delta a_j a_{j+1} + \Delta^* a_{j+1}^\dagger a_j^\dagger\right) \\ &\quad -\mu\sum_{j=1}^{N}\left(a_j^\dagger a_j - \frac{1}{2}\right) \end{aligned} \tag{16.4}$$

   where a_j and $a_j^\dagger$ are fermionic annihilation and creation operators, w is the hopping amplitude, Δ is the superconducting gap and μ is the chemical potential. For simplicity, we will assume that $\Delta = \Delta^* = w$, so that

$$H_F = w\sum_{j=1}^{N-1}(a_j - a_j^\dagger)(a_{j+1} + a_{j+1}^\dagger) - \mu\sum_{j=1}^{N}\left(a_j^\dagger a_j - 1/2\right). \tag{16.5}$$

This model has a $\mathbb{Z}_2$ symmetry given by the fermionic parity operator:

$$P_F = (-1)^{\sum_j a_j^\dagger a_j} \tag{16.6}$$

Although the two models are mathematically equivalent, as we will see in Sec. 16.2.2, they are clearly physically different. In particular, for the superconductor, the $\mathbb{Z}_2$ symmetry of fermionic parity cannot be lifted by any local physical operator, as such operators must contain an even number of fermion operators. Unfortunately, for the spin system the degeneracy is lifted by a simple longitudinal magnetic field $h_x \sum_j \sigma_j^x$ and thus the topological phase of the TFIM would be much harder to find in nature.

16.2.1 Nature of topological degeneracy (spin language)

Consider the transverse field Ising model of Eq. (16.2). With no applied field, there are a pair of Ising ground states ($h_z = 0$):

$$|\psi_\rightarrow\rangle \;=\; |\rightarrow\rightarrow\rightarrow\cdots\rightarrow\rangle\,,\; |\psi_\leftarrow\rangle = |\leftarrow\leftarrow\leftarrow\cdots\leftarrow\rangle\,. \tag{16.7}$$

The introduction of a small field h_z allows the spins to flip in the σ^x basis. In particular, tunneling between the two classical ground states arises via a soliton (domain-wall) propagating from one side of the system to the other:

$$|\rightarrow\rightarrow\rightarrow\cdots\rightarrow\rangle \;\longrightarrow\; |\leftarrow:\rightarrow\rightarrow\cdots\rightarrow\rangle \longrightarrow |\leftarrow\leftarrow:\rightarrow\cdots\rightarrow\rangle \tag{16.8}$$

$$\longrightarrow\; |\leftarrow\leftarrow\leftarrow:\cdots\rightarrow\rangle \longrightarrow \cdots \longrightarrow |\leftarrow\leftarrow\leftarrow\cdots\leftarrow\rangle\,. \tag{16.9}$$

As usual, the tunneling amplitude t associated with this transition falls off exponentially in the distance the soliton must propagate

$$t \sim e^{-N/\xi} \tag{16.10}$$

where ξ is the correlation length of the model. The two-fold degeneracy is therefore lifted by the effective Hamiltonian:

$$H_{\text{eff}} = \begin{pmatrix} 0 & -t \\ -t & 0 \end{pmatrix}. \tag{16.11}$$

The splitting is exponentially small in the system size and the two-fold degeneracy is recovered in the thermodynamic limit as expected. Moreover, it is clear why introduction of a longitudinal field h_x will fully split the degeneracy.

16.2.2 Reduction of TFIM to SPSC by the Jordan-Wigner transformation

To show the equivalence of the one dimensional models introduced above, we will use a standard Jordan-Wigner transformation to convert the spins of the Ising model into fermions. It is perhaps not surprising that a fermionic description exists for spin 1/2 systems – we simplify identify the up and down state of each spin with the presence or absence of a fermion. The only difficulty arises in arranging the transformation so that the appropriate (anti)-commutation relations hold in each description. The Jordan-Wigner transformation does this by introducing string-like fermion operators that work out quite nicely in 1-D nearest neighbor models.

To reduce H_S to H_F, we

1. Associate the projection onto the z-axis of the spin with the fermionic occupation number:

$$|\uparrow\rangle \leftrightarrow n = 0, \quad |\downarrow\rangle \leftrightarrow n = 1. \tag{16.12}$$

That is,

$$\sigma_j^z = (-1)^{a_j^\dagger a_j}. \tag{16.13}$$

2. Introduce the string-like annihilation and creation operators

$$\begin{aligned} a_j &= \left(\prod_{k=1}^{j-1} \sigma_k^z\right) \sigma_j^+ \\ a_j^\dagger &= \left(\prod_{k=1}^{j-1} \sigma_k^z\right) \sigma_j^- \end{aligned} \tag{16.14}$$

where σ^+ and σ^- are the usual spin raising and lower operators. At this stage, we can check that the usual fermionic anticommutation relations hold for the $a_j, a_j^\dagger$:

$$\left\{a_i, a_j^\dagger\right\} = \delta_{ij} \tag{16.15}$$

3. Observe that

$$\sigma_j^x \sigma_{j+1}^x = -(a_j - a_j^\dagger)(a_{j+1} + a_{j+1}^\dagger), \tag{16.16}$$

so H_S (Eq. (16.2)) reduces to H_F (Eq. (16.5)) with

$$w = J, \quad \mu = -2h_z \tag{16.17}$$

16.2.3 Majorana operators

Majorana operators provide a convenient alternative representation of Fermi systems when the number of particles is only conserved modulo 2, as in a superconductor. Given a set of N Dirac fermions with annihilation/creation operators $a_j, a_j^\dagger$, we can define a set of $2N$ real Majorana fermion operators as follows:

$$\begin{aligned} c_{2j-1} &= a_j + a_j^\dagger \\ c_{2j} &= \frac{a_j - a_j^\dagger}{i}. \end{aligned} \tag{16.18}$$

These operators are Hermitian and satisfy a fermionic anticommutation relation:

$$\begin{aligned} c_k^\dagger &= c_k \\ c_k^2 &= 1, \quad c_k c_l = -c_l c_k (k \neq l). \end{aligned} \tag{16.19}$$

Or, more compactly,

$$\{c_k, c_l\} = 2\delta_{kl}. \tag{16.20}$$

From any pair of Majorana operators, we can construct an annihilation and creation operator for a standard Dirac fermion ($a = (c_1 + ic_2)/2$ and h.c.), and thus the unique irreducible representation for the pair is a 2-dimensional Hilbert space which is either occupied or unoccupied by the a fermion.

Both models H_S and H_F can be written as

$$H_{\text{maj}} = \frac{i}{2}\left(v \sum_{j=1}^{N} c_{2j-1} c_{2j} + w \sum_{j=1}^{N-1} c_{2j} c_{2j+1}\right) \tag{16.21}$$

where $v = h_z = -\mu/2$ and $w = J$. The $\mathbb{Z}_2$ symmetry of fermionic parity is given in the Majorana language by

$$P_{\text{maj}} = \prod_{k=1}^{N} (-ic_{2k-1} c_{2k}). \tag{16.22}$$

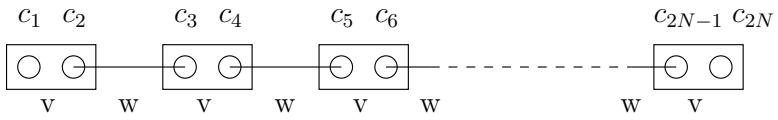

Figure 16.2: Majorana chain representation of 1-d superconductor. Each boxed pair of Majoranas corresponds to one site of the original fermionic chain.

We can view this model graphically as a chain of coupled Majorona modes, two to each of the N sites of the original problem as in Fig. 16.2. If $v = 0$, then the Majorana modes at the ends of the chain are not coupled to anything. This immediately allows us to identify the 2-fold ground state degeneracy in H_{maj} as the tensor factor given by the 2-dimensional representation of the boundary pair c_1, c_{2N}.

We will see in Sec. 16.2.4 that if $v \neq 0$ but $|v| < w$, the operators c_1 and c_{2N} are replaced by some *boundary mode operators* b_l, b_r. The effective Hamiltonian for this piece of the system is then

$$H_{\text{eff}} = \frac{i}{2}\epsilon b_l b_r = \epsilon(a^\dagger a - \frac{1}{2}) \tag{16.23}$$

where $\epsilon \sim e^{-N/\xi}$ and a, $a^\dagger$ are the Dirac fermion operators constructed from the boundary pair. Thus, the ground state degeneracy is lifted by only an exponentially small splitting in system size.

16.2.4 General properties of quadratic fermionic Hamiltonians

We now step back and consider a generic quadratic fermionic Hamiltonian:

$$H(A) = \frac{i}{4}\sum_{j,k} A_{jk} c_j c_k \tag{16.24}$$

where A is a real, skew-symmetric matrix and the c_j are Majorana fermion operators. The normalization $\frac{i}{4}$ is convenient because it has the property that

$$[-iH(A), -iH(B)] = -iH\left([A, B]\right) \tag{16.25}$$

where $A, B \in \mathfrak{so}(2N)$, and $H(A), H(B)$ act on the Fock space $\mathfrak{F}_N = \mathbb{C}^{2^N}$. Thus $H(\cdot)$ provides a natural representation of $\mathfrak{so}(2N)$.

We now bring $H(A)$ to a canonical form:

$$H_{\text{canonical}} = \frac{i}{2}\sum_{k=1}^{m} \epsilon_k b'_k b''_k = \sum_{k=1}^{m} \epsilon_k(\tilde{a}_k^\dagger \tilde{a}_k - \frac{1}{2}) \tag{16.26}$$

where b'_k, b''_k are appropriate real linear combinations of the original c_j satisfying the same Majorana fermion commutation relations and the $\tilde{a}_k, \tilde{a}_k^\dagger$ are the annihilation and creation operators associated to the b'_k, b''_k pair of Majoranas. This form for H follows immediately from the standard block diagonalization of real skew symmetric matrices

$$A = Q \begin{pmatrix} 0 & \epsilon_1 & & & \\ -\epsilon_1 & 0 & & & \\ & & 0 & \epsilon_2 & \\ & & -\epsilon_2 & 0 & \\ & & & & \cdots \end{pmatrix} Q^T, \quad Q \in O(2N), \epsilon_k \geq 0 \tag{16.27}$$

From this form it is easy to check that the eigenvalues of A are $\pm i\epsilon_k$ and that the eigenvectors are the coefficients of c in $\tilde{a}_k$, $\tilde{a}_k^\dagger$.

If some of the ϵ_k vanish, then we refer to the associated fermions as *zero modes*. In particular, these will lead to ground state degeneracies, since occupation or nonoccupation of such modes does not affect the energy. For the Majorana chain of Eq. (16.21), we have

$$A = \begin{pmatrix} 0 & v & & & & \\ -v & 0 & w & & & \\ & -w & 0 & v & & \\ & & -v & 0 & w & \\ & & & -w & 0 & \\ & & & & & \cdots \end{pmatrix} \tag{16.28}$$

We can find a vector u such that $uA = 0$ by inspection:

$$u = (1, 0, \frac{v}{w}, 0, \left(\frac{v}{w}\right)^2, 0, \cdots) \tag{16.29}$$

This vector leads to a left boundary mode

$$b_l = \sum u_k c_k \tag{16.30}$$

while an analogous calculation starting at the right end will find a right boundary mode b_r. These modes form a Majorana canonical pair, leading to a two-fold degeneracy of the ground state of the chain. Clearly, $u_k \sim e^{-k/\xi}$ falls off exponentially from the edges of the chain with correlation length $\xi^{-1} = \ln\left|\frac{w}{v}\right|$, as expected in section 16.2.3.

16.2.5 Why are the boundary modes robust?

In the simple case of a quadratic fermion Hamiltonian, we know that the modes correspond to eigenvalues of a skew-symmetric real matrix. These come in pairs $\pm i\epsilon$, in general, and the case $\epsilon = 0$ is special. In particular, if the pair of Majoranas corresponding to a zero mode are physically well separated, we expect perturbations to have trouble lifting the boundary degeneracy.

More generally, for interacting fermions, we can extend the symmetry group $\mathbb{Z}_2$, generated by $P = P_{\text{maj}}$, to a *non-commuting* algebra acting on the the ground state space $\mathfrak{L}$. First, in the noninteracting limit, at $v = 0$, we define

$$X = Y \prod_{k=1}^{j} (-ic_{2k-1}c_{2k}) \tag{16.31}$$

where $Y = c_{2j+1}$ is a local Majorana operator at site $2j + 1$. A straightforward calculation shows that

$$XP = -PX \tag{16.32}$$

and that $[H, X] = 0$ so that the algebra generated by X, P acts on $\mathfrak{L}$ nontrivially. We now allow Y to vary as we adiabatically turn on interactions and, so long as an energy gap is maintained, we expect Y to remain a local operator near $2j$, which we can separate from the boundary by suitably large choice of j. That is, to find Y, one needs to know the ground state or at least the structure of the ground state near $2j$. This is a nontrivial operation but see [3] for more details.

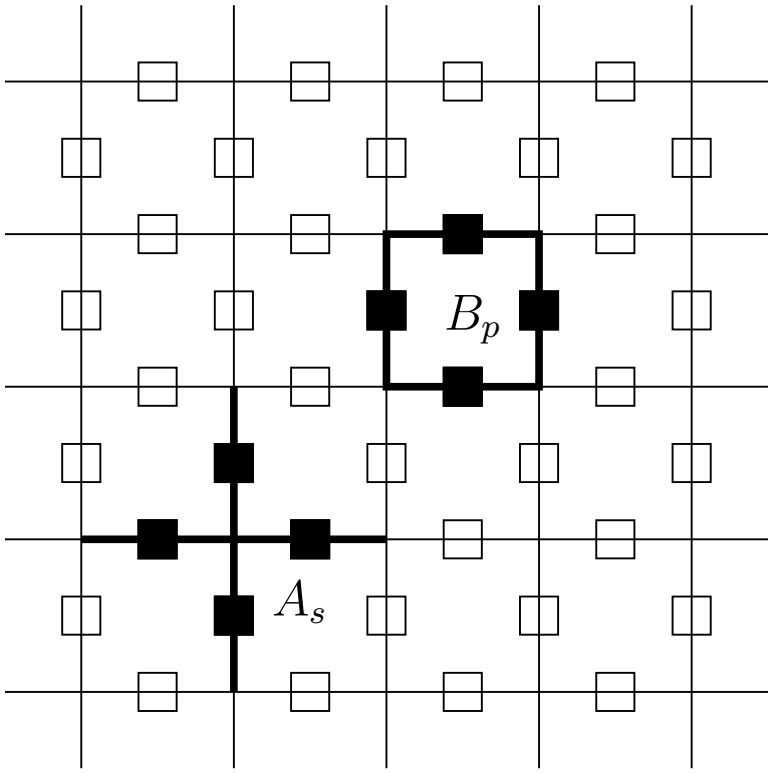

Figure 16.3: A piece of the toric code. The spins live on the edges of the square lattice. The spins adjacent to a star operator A_s and a plaquette operator B_p are shown.

16.3 The two-dimensional toric code

The toric code is an exactly solvable spin 1/2 model on the square lattice. It exhibits a ground state degeneracy of 4^g when embedded on a surface of genus g and a quasiparticle spectrum with both bosonic and fermionic sectors. Although we will not introduce it as such, the model can be viewed as an Ising gauge theory at a particularly simple point in parameter space (see Sec. 16.4.5). Many of the topological features of the toric code model were essentially understood by [8], but they did not propose an exactly solved model. A more detailed exposition of the toric code may be found in [5].

We consider a square lattice, possibly embedded into a nontrivial surface such as a torus, and place spins on the edges, as in Fig. 16.3. The Hamiltonian is given by

$$H_T = -J_e \sum_s A_s - J_m \sum_p B_p \tag{16.33}$$

where s runs over the vertices (stars) of the lattice and p runs over the plaquettes. The star operator acts on the four spins surrounding a vertex s,

$$A_s = \prod_{j \in \mathrm{star}(s)} \sigma_j^x \tag{16.34}$$

while the plaquette operator acts on the four spins surrounding a plaquette,

$$B_p = \prod_{j \in \partial p} \sigma_j^z. \tag{16.35}$$

Clearly, the A_s all commute with one another, as do the B_p. Slightly less trivially,

$$A_s B_p = B_p A_s \tag{16.36}$$

because any given star and plaquette share an even number of edges (either none or two) and therefore the minus signs arising from the commutation of σ^x and σ^z on those edges cancel. Since all of the terms of H_T commute, we expect to be able to solve it term by term.

In particular, we will solve H_T working in the σ^z basis. Define classical variables $s_j = \pm 1$ to label the σ^z basis states. For each classical spin configuration $\{s\}$, we can define the plaquette flux

$$w_p(s) = \prod_{j \in \partial p} s_j. \tag{16.37}$$

If $w_p = -1$, we say that there is a *vortex* on plaquette p.

16.3.1 Ground states

To find the ground states $|\Psi\rangle$ of H_T, we need to minimize the energy, which means maximize the energy of each of the A_s and B_p terms. The plaquette terms provide the condition

$$B_p |\Psi\rangle = |\Psi\rangle \tag{16.38}$$

which holds if and only if

$$|\Psi\rangle = \sum_{\{s: w_p(s)=1 \ \forall p\}} c_s |s\rangle \tag{16.39}$$

. That is, the ground state contains no vortices. The group of star operators act on the configurations s by flipping spins. Thus, the star conditions

$$A_s |\Psi\rangle = |\Psi\rangle \tag{16.40}$$

hold if and only if *all of the c_s are equal for each orbit of the action of star operators*. In particular, if the spin flips of A_s are ergodic, as they are on the plane, all c_s must be equal and the ground state is uniquely determined.

On the torus, the star operators preserve the *cohomology class* of a vortex-free spin configuration. In more physical terms, we can define conserved numbers given by the Wilson loop like functions

$$w_l(s) = \prod_{j \in l} s_j, \quad l = l_1, l_2 \tag{16.41}$$

where l_1 and l_2 are two independent non-trivial cycles on the square lattice wrapping the torus (Fig. 16.4). Any given star will overlap with a loop l in either zero or two edges and therefore A_s preserves w_l. Since there are two independent loops on the torus, each of which can have $w_l = \pm 1$, there is a four-fold degenerate ground state:

$$|\Psi\rangle = \sum_{\{s: w_p(s)=1 \ \forall p\}} c_{w_{l_1} w_{l_2}} |s\rangle . \tag{16.42}$$

16.3.2 Excitations

The excitations of the toric code come in two varieties: the *electric charges* and *magnetic vortices* of a $\mathbb{Z}_2$ gauge theory. We will see this connection more explicitly later. In the following, we restrict attention to the planar system for simplicity.

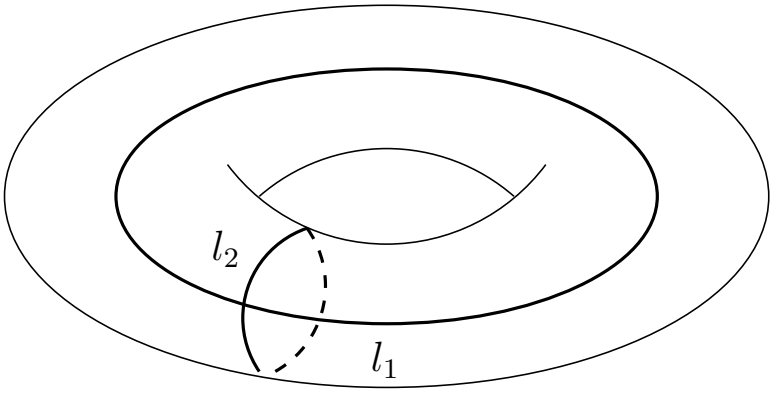

Figure 16.4: Large cycles on the torus.

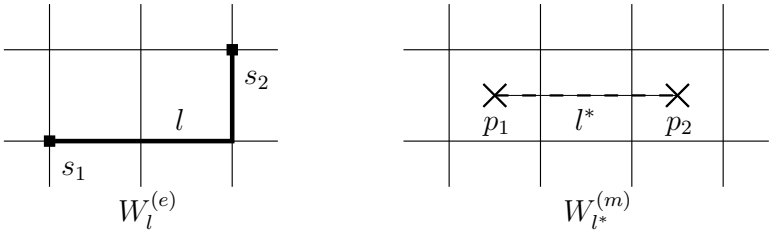

Figure 16.5: Electric and magnetic path operators.

To find the electric charges, let us define the electric path operator

$$W_l^{(e)} = \prod_{j \in l} \sigma_j^z \tag{16.43}$$

where l is a path in the lattice going from s_1 to s_2 (see Fig. 16.5). This operator clearly commutes with the plaquette operators B_p and with all of the star operators A_s except for at the end points s_1 and s_2, where only one edge overlaps between the star and the path and we have

$$W_l^{(e)} A_{s_1} = -A_{s_1} W_l^{(e)}. \tag{16.44}$$

Therefore, the state

$$|\Psi_{s_1,s_2}\rangle = W_l^{(e)} |\Psi_0\rangle , \tag{16.45}$$

where $|\Psi_0\rangle$ is the planar ground state, is an eigenstate of the Hamiltonian with excitations (charges) at s_1 and s_2 that each cost energy $2J_e$ to create relative to the ground state.

An analogous construction will find the magnetic vortices: we can define a dual path operator

$$W_{l^*}^{(m)} = \prod_{j \in l^*} \sigma_j^x \tag{16.46}$$

where the path l^* lies in the dual lattice (see Fig. 16.5) and goes from p_1 to p_2. In this case, the stars A_s all commute with $W_{l^*}^{(m)}$, as do all of the plaquette operators B_p except the two at the end points of l^*, which anticommute. Thus, the $W_{l^*}^{(m)}$ operator creates a pair of magnetic vortices on the plaquettes p_1 and p_2 at an energy of $2J_m$ each.

16.4 Abelian anyons and quasiparticle statistics

Let us discuss what can possibly happen if we exchange two particles in two dimensions. To ensure that particle statistics is well-defined, we assume that there is no long-range interaction

and that the phase is gapped. If we drag two particles around one another adiabatically,

then we expect both dynamical phase accumulation and a statistical effect due to the exchange. We are well acquainted with this effect for everyday bosons and fermions, for which:

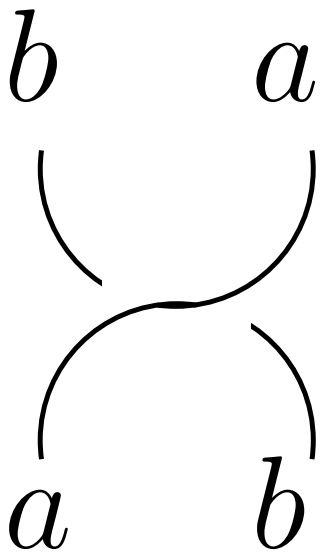
$$\begin{array}{lrcl} \text{Bosons:} & |\Psi\rangle & \mapsto & |\Psi\rangle \\ \text{Fermions:} & |\Psi\rangle & \mapsto & -|\Psi\rangle \end{array} \tag{16.47}$$

where we have dropped the dynamical phase so as to focus on the statistics. In both of these standard cases, a full rotation (two exchanges),

leaves $|\Psi\rangle$ unchanged.

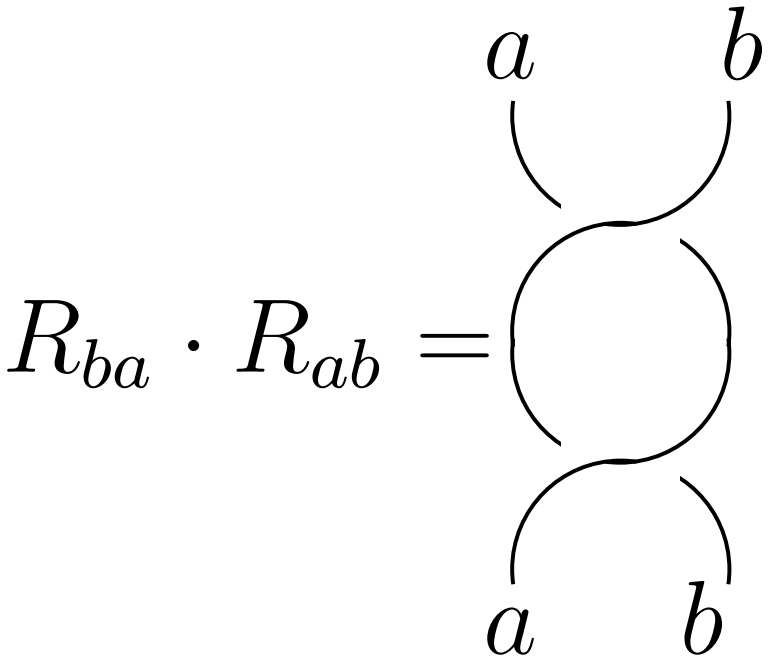
In principle,

$$R_{ab} = \tag{16.48}$$



is an arbitrary phase factor or even an operator (*braiding operator*). If the two particles are

distinguishable ($a \neq b$), then R_{ab} does not have an invariant meaning, but the *mutual statistics*

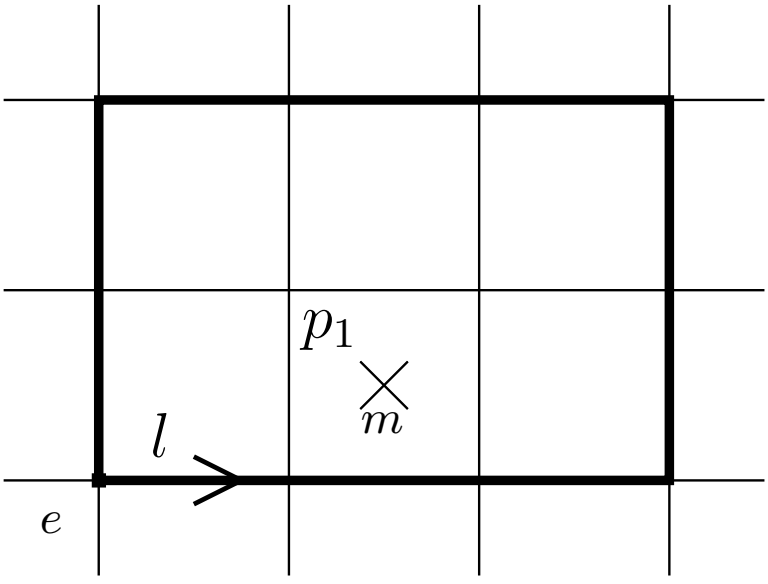


(16.49)

does.

Let us illustrate this in the toric code model. In section 16.3.2 we found two kinds of quasiparticle excitations in the toric code: electric charges (e) and magnetic vortices (m). Since path operators of the same type commute with one another, it is easy to show that each of these are bosons. However, they have nontrivial mutual statistics.

To calculate the mutual statistics, consider taking a charge e around a vortex m.



Let $|\xi\rangle$ be some state containing a magnetic vortex at p_1. Under the full braiding operation,

$$\begin{aligned} |\xi\rangle &\mapsto \left(\prod_{j\in l} \sigma_j^z\right) |\xi\rangle \\ &= \left(\prod_{p \text{ inside } l} B_p\right) |\xi\rangle \end{aligned} \tag{16.50}$$

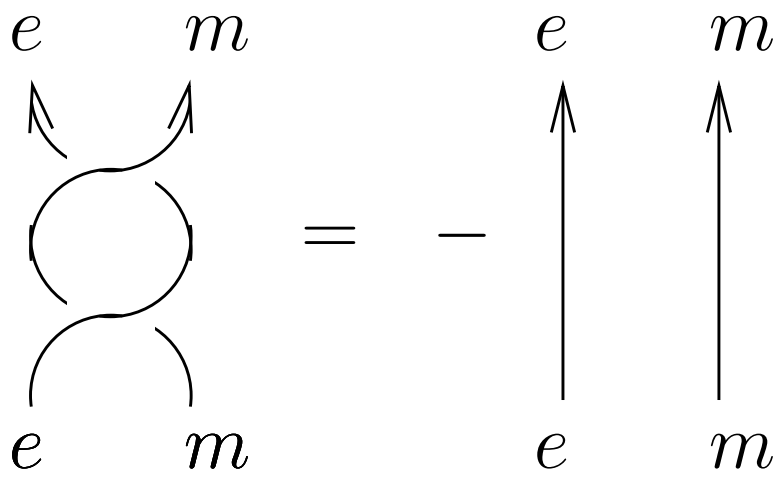
where the second line is a Stokes' theorem like result relating the product around a loop to the products of internal loops. Since

$$B_{p_1} |\xi\rangle = - |\xi\rangle \tag{16.51}$$

for the plaquette p_1 containing the vortex, we have that

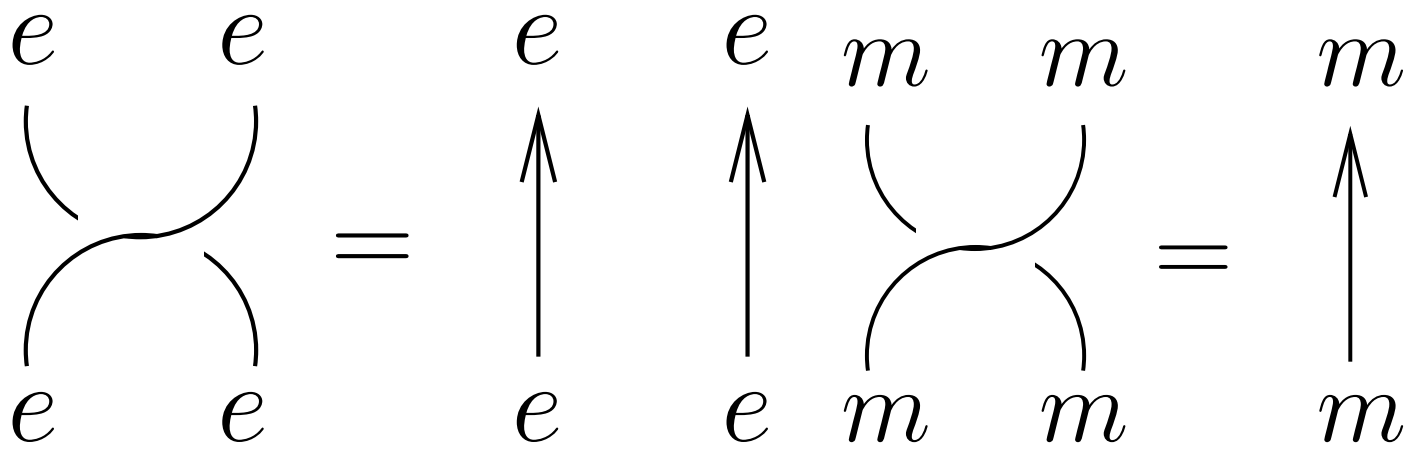
$$|\xi\rangle \mapsto - |\xi\rangle \,, \tag{16.52}$$

or



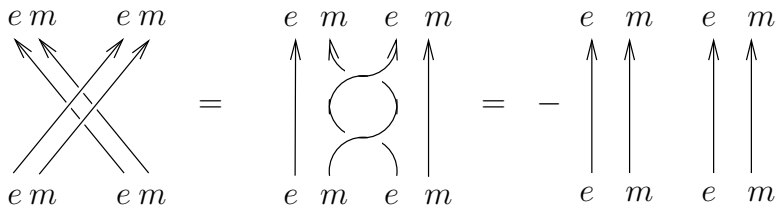
(16.53)

Using the bosonic self-statistics equations,



(16.54)

we can derive the nontrivial corollary that composite $e - m$ particles are fermions:



(16.55)

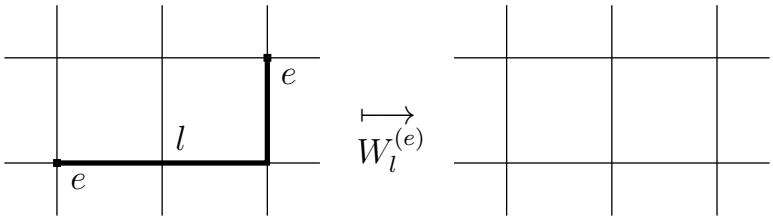
16.4.1 Superselection sectors and fusion rules

Initially, we exhibited two kinds of bosonic excitations in the toric code model (charges e and vortices m) in the solution of the Hamiltonian. After a bit of work, we discovered that a composite $e - m$ object has a meaningful characterization within the model as well, at least in that it has fermionic statistics. This begs the question, how many particle types exist in the toric code model and how can we identify them?

We take an algebraic definition of a particle type: each type corresponds to a *superselection sector*, which is a representation of the local operator algebra. In particular, we say that two particles (or composite objects) are *of the same type*

$$a \sim b \tag{16.56}$$

if a can be transformed to b by some operator acting in a finite region. For example, in the toric code, two e-particles are equivalent to having no particles at all,



(16.57)

by acting with an appropriate, geometrically bounded electric path operator $W_l^{(e)}$.

We introduce the notation

$$e \times e = 1 \tag{16.58}$$

to represent the *fusion rule* that two e-particles are equivalent to the vacuum sector 1. In the toric code, there are 4 superselection sectors:

$$1,\ e,\ m,\ \text{and}\ \epsilon = e \times m \tag{16.59}$$

with the fusion rules:

$$\begin{array}{ll} e \times e = 1 & e \times m = \epsilon \\ m \times m = 1 & e \times \epsilon = m \\ \epsilon \times \epsilon = 1 & m \times \epsilon = e \end{array} \tag{16.60}$$

16.4.2 Mutual statistics implies degeneracy on the torus

This is an argument due to [1]. Suppose that there are at least two particle types, e and m with -1 mutual statistics. Let us define an operator Z acting on the ground state in an abstract fashion (not refering to the actual model) which creates an e pair, wraps one particle around the torus and annihilates the pair. In the toric code, this will be the path operator $W_l^{(e)} = \prod_{j \in l} \sigma_j^z$ for a loop l winding one of the nontrivial cycles on the torus, but we need not know that specifically.

We can define another operator X that creates a pair of the other type m and winds around the other nontrivial cycle on the torus. But now a bit of geometric introspection reveals that the combination,

$$Z^{-1}X^{-1}ZX = \quad \textcircled{m} \quad \textcircled{e} \quad = -1 \tag{16.61}$$

Thus, there are two non-commuting operators acting on the ground state space $\mathfrak{L}$, and we conclude dim $\mathfrak{L} > 1$. In fact, there are four such operators, each of the two particle types can be moved around each of the two nontrivial cycles. Working out the commutation relations of these operators implies that dim $\mathfrak{L} = 4$.

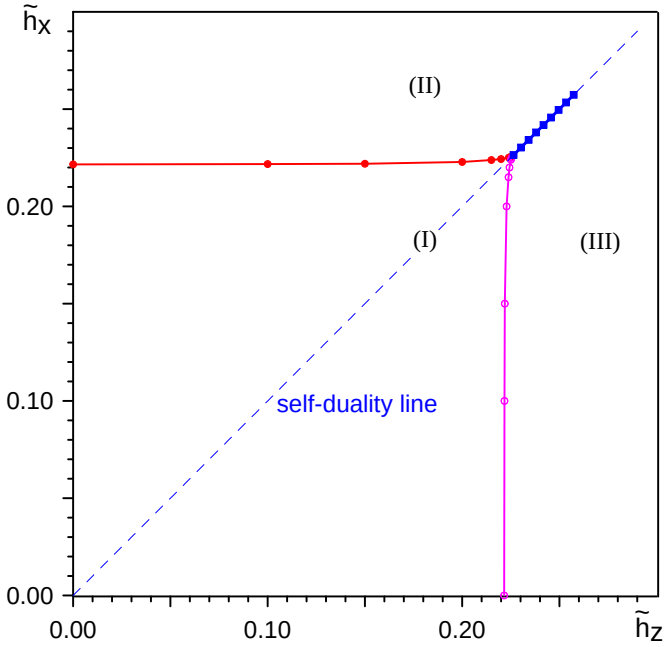


Figure 16.6: Numerically determined phase diagram of the toric code in a field from [9]. (I) labels the topological phase, (II) and (III) the vortex and charge condensates (*i.e.* the paramagnetic phase). The numerics were done using discrete imaginary time with a rather large quantization step.

16.4.3 The toric code in a field: perturbation analysis

We now apply a magnetic field to the toric code that will realistically allow the quasiparticles to hop and, unfortunately, destroy its exact solvability (see [9]). To wit:

$$H = -J_e \sum_s A_s - J_m \sum_p B_p - \sum_j \left(h_x \sigma_j^x + h_z \sigma_j^z \right) \tag{16.62}$$

For example, with $h_x = 0$ but $h_z \neq 0$, we can view the perturbation as an electric path operator of length 1 on each edge. Hence, it can cause charge pair creation and annihilation (at an energy cost $\sim 4J_e$) or hop existing charges by one lattice displacement, at no cost. For small h_z this provides a nontrivial tight-binding dispersion to the charges,

$$\epsilon(q) \approx 2J_e - 2h_z(\cos q_x + \cos q_y) \tag{16.63}$$

but does not close the gap or lead to a change in the topological degeneracy of the ground state in the thermodynamic limit.

At large $h_z \gg J_e, J_m$, the model should simply align with the applied field as a paramagnet. Clearly, in this limit the topological degeneracy has been destroyed and we have a unique spin-polarized ground state. The phase transition can be understood from the topological side as a bose condensation of the charges, which proliferate as h_z increases.

The same argument is applicable if $h_x \gg J_e, J_m$. If h_x increases while $h_z = 0$, then vortices condense. However, the high-field phase is just a paramagnet, so one can continuously rotate the field between the x- and z-direction without inducing a phase transition. Thus, the charge and vortex condensates are actually the same phase! This property was first discovered by [2] for a 3D classical $\mathbb{Z}_2$ gauge Higgs model, where it appears rather mysterious.

16.4.4 Robustness of the topological degeneracy

The splitting of the ground state levels due to virtual quasiparticle tunneling is given by

$$\delta E \sim \Delta e^{-L/\xi} \tag{16.64}$$

This follows from the effective Hamiltonian

$$H_{\text{eff}} = -(t_{1Z}Z_1 + t_{2Z}Z_2 + t_{1X}X_1 + t_{2X}X_2) \tag{16.65}$$

where the Z_i, X_i operators are the winding loop operators of Sec. 16.4.2. Physically, this is simply a statement of the fact that the only way to act upon the ground state is to wind quasiparticles around the torus. This is a process exponentially suppressed in system size.

16.4.5 Emergent symmetry: gauge formulation

There are two ways to introduce symmetry operators in the perturbed toric code model.

1. One can define *loop operators* (e.g. Z_1, Z_2, X_1, X_2), the definition of which depends on the actual ground state of the perturbed Hamiltonian. This is similar to the definition of the operator Y in the 1D case of Sec. 16.2.5, which also requires detailed knowledge of the ground state.

2. One can exploit *gauge invariance* by rewriting the model in a gauge invariant form. This can be done for any spin model by introducing redundancy. In this case, the symmetry does not depend on the model but is only manifest in the topological phase.

We will take the second approach in order to avoid the difficulty of defining the appropriate loop operators and also to introduce the important gauge formulation of the model. To gauge the model we proceed in steps:

1. Introduce one extra spin μ_v per vertex that always remains in the state

$$\frac{1}{\sqrt{2}}\left(|\uparrow\rangle + |\downarrow\rangle\right). \tag{16.66}$$

   This state is characterized by the condition

$$\mu_v^x |\Psi\rangle = |\Psi\rangle, \tag{16.67}$$

   where μ_v^x is the Pauli spin matrix for the spin μ at vertex v.

2. Change spin operators from σ_{uv}, μ_v to $\tilde{\sigma}_{uv}, \tilde{\mu}_v$ where we represent the classical value of each old spin s_{uv} as $\tilde{m}_u \tilde{s}_{uv} \tilde{m}_v$. Here s_{uv} is the spin on the edge connecting u and v and m_u, m_v are the classical values of the new spins (*i.e.* the labels in the μ^z basis).

Thus the complete transformation is given by

$$\begin{aligned}
\sigma_{uv}^z &= \tilde{\mu}_u^z \tilde{\sigma}_{uv}^z \tilde{\mu}_v^z \\
\sigma_{uv}^x &= \tilde{\sigma}_{uv}^x \\
\mu_u^z &= \tilde{\mu}_u^z \\
\mu_u^x &= \tilde{\mu}_u^x \prod_{j \in \text{star}(u)} \tilde{\sigma}_j^x = \tilde{\mu}_u^x \tilde{A}_u
\end{aligned} \tag{16.68}$$

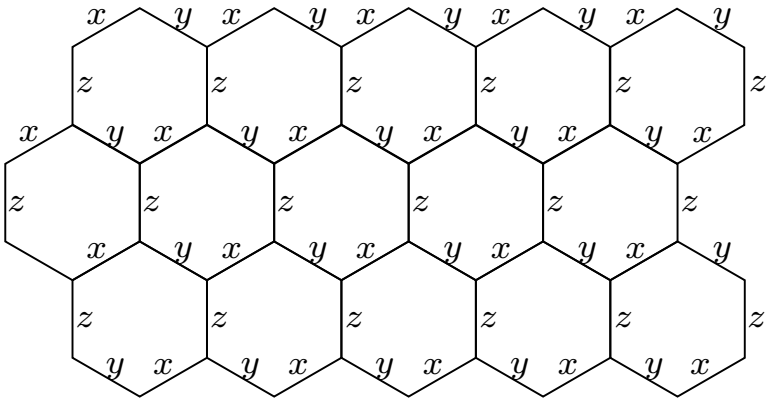

Figure 16.7: The honeycomb model has spins living on the vertices of a honeycomb lattice with nearest neighbor interactions that are link-orientation dependent. x-links have $\sigma^x\sigma^x$ interactions, y-links have $\sigma^y\sigma^y$ interactions and z-links have $\sigma^z\sigma^z$ interactions.

and the constraint Eq. (16.67) becomes the standard $\mathbb{Z}_2$ gauge constraint:

$$\tilde{\mu}_u^x \tilde{A}_u \left|\Psi\right\rangle = \left|\Psi\right\rangle . \tag{16.69}$$

On states satisfying the gauge constraint Eq. (16.69), $A_u = \tilde{A}_u = \tilde{\mu}_u^x$. Therefore,

$$A_u \left|\Psi\right\rangle = \tilde{\mu}_u^x \left|\Psi\right\rangle \tag{16.70}$$

and we can rewrite the Hamiltonian as

$$H = -J_e \sum_v \tilde{\mu}_v^x - J_m \sum_p \tilde{B}_p - \sum_{\langle u,v\rangle} (h_x \tilde{\sigma}_{uv}^x + h_z \tilde{\mu}_u \tilde{\sigma}_{uv}^z \tilde{\mu}_v) \tag{16.71}$$

subject to the gauge constraint.

Viewed as a standard $\mathbb{Z}_2$ gauge theory, the protected topological degeneracy of the ground state is physically familiar as the protected degeneracy associated with the choice of flux threading the $2g$ holes of the genus g surface.

16.5 The honeycomb lattice model

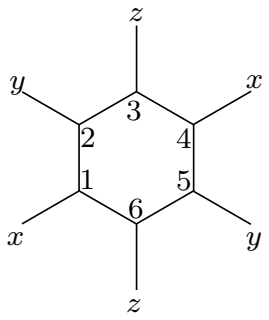
We now investigate the properties of another exactly solvable spin model in two dimensions, the *honeycomb lattice model*. This model exhibits a number of gapped phases that are perturbatively related to the toric code of the previous sections. Moreover, in the presence of time-reversal symmetry breaking terms, a new topological phase arises with different topological properties, including nontrivial *spectral Chern number*. An extended treatment of the properties of this model with much greater detail can be found in [6].

In the honeycomb lattice model, the degrees of freedom are spins living on the vertices of a honeycomb lattice with nearest neighbor interactions. The unusual feature of this model is that the interactions are link orientation dependent (see Fig. 16.7). The Hamiltonian is

$$H = -J_x \sum_{x \text{ links}} \sigma_j^x \sigma_k^x - J_y \sum_{y \text{ links}} \sigma_j^y \sigma_k^y - J_z \sum_{z \text{ links}} \sigma_j^z \sigma_k^z \tag{16.72}$$

We might expect this model to be integrable because $[H, W_p] = 0$ for an extensive collection of

plaquette operators



$$W_p = \sigma_1^x \sigma_2^y \sigma_3^z \sigma_4^x \sigma_5^y \sigma_6^z \tag{16.73}$$

where the spins and labels follow from the figure for each plaquette. Unfortunately, this is not quite enough: there are two spins but only one constraint per hexagon so that half of each spin remains unconstrained. In fact, the remaining degrees of freedom are Majorana operators!

16.5.1 A (redundant) representation of a spin by 4 Majorana operators

We consider a collection of four Majorana operators c, b^x, b^y and b^z that act on the 4-dimensional Fock space $\mathfrak{F}$. We define the following three operators

$$\begin{aligned} \tilde{\sigma}^x &= ib^x c \\ \tilde{\sigma}^y &= ib^y c \\ \tilde{\sigma}^y &= ib^y c. \end{aligned} \tag{16.74}$$

These operators do not obey the spin algebra relations on the full Fock space, but we clearly have two extra dimensions of wiggle room. In fact, the physical state space is identified with a two-dimensional subspace $\mathfrak{L} \subset \mathfrak{F}$ given by the constraint

$$D\,|\Psi\rangle = |\Psi\rangle\,, \qquad \text{where } D = b^x b^y b^z c \tag{16.75}$$

Within $\mathfrak{L}$, the $\tilde{\sigma}^\alpha$ act as σ^α act on the actual spin. Of course, $\tilde{\sigma}^\alpha$ also act on $\mathfrak{L}^\perp$, but we can ignore these states by enforcing the constraint.

To be careful, we need to check two consistency conditions:

1. $\tilde{\sigma}^\alpha$ preserves the subspace $\mathfrak{L}$, which follows from $[\tilde{\sigma}^\alpha, D] = 0$.

2. The $\tilde{\sigma}^\alpha$ satisfy the correct algebraic relations when restricted to $\mathfrak{L}$. For example,

$$\tilde{\sigma}^x \tilde{\sigma}^y \tilde{\sigma}^z = (ib^x c)(ib^y c)(ib^z c) = i^3(-1) b^x b^y b^z c^3 = iD = i \tag{16.76}$$

   where the last equality only holds in the physical subspace $\mathfrak{L}$.

16.5.2 Solving the Honeycomb Model using Majoranas

We now use the Majorana representation of spins just introduced to rewrite each spin of the entire honeycomb model as in Fig. 16.8. This will greatly expand the 2^N-dimensional Hilbert space to the Fock space $\mathfrak{F}$ of dimension 2^{2N}, but the physical space $\mathfrak{L} \subset \mathfrak{F}$ is fixed by the gauge condition

$$D_j\,|\Psi\rangle = |\Psi\rangle \quad \text{for all } j \tag{16.77}$$

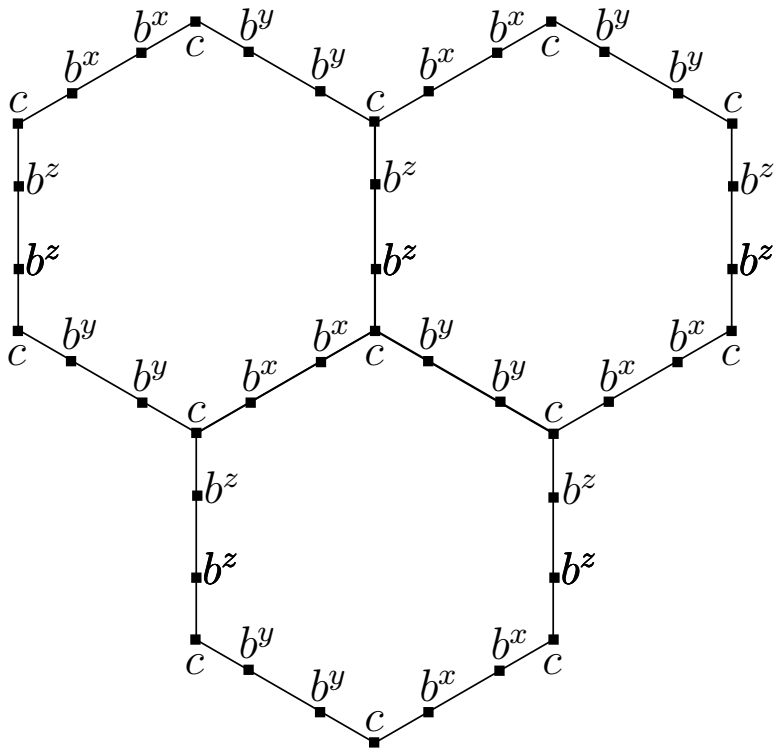


Figure 16.8: Majorana representation of honeycomb model.

where $D_j = b_j^x b_j^y b_j^z c$. We define a projector onto $\mathfrak{L}$ by

$$\Pi_{\mathfrak{L}} = \prod_j \left(\frac{1 + D_j}{2} \right) \tag{16.78}$$

In the Majorana representation, the Hamiltonian (16.72) becomes

$$\begin{aligned} \tilde{H} &= \frac{i}{4} \sum_{\langle j,k \rangle} \hat{A}_{jk} c_j c_k \\ \hat{A}_{jk} &= 2 J_{\alpha(j,k)} \hat{u}_{jk} \\ \hat{u}_{jk} &= i b_j^{\alpha(j,k)} b_k^{\alpha(j,k)} \end{aligned} \tag{16.79}$$

where $\alpha(j,k) = x, y, z$ is the direction of the link between j and k.

We have suggestively written the Hamiltonian $\tilde{H}$ as if it were a simple quadratic fermion Hamiltonian as in Sec. 16.2.4, but of course $\hat{A}_{jk}$ is secretly an operator rather than a real skew-symmetric matrix. However, each operator b_j^α enters only one term of the Hamiltonian and therefore $\hat{u}_{jk}$ commute with each other and with $\tilde{H}$! Thus, we can fix $u_{jk} = \pm 1$, defining an orthogonal decomposition of the full Fock space:

$$\mathfrak{F} = \bigoplus_u \mathfrak{F}_u, \quad \text{where } |\Psi\rangle \in \mathfrak{F}_u \text{ iff } \hat{u}_{jk} |\Psi\rangle = u_{jk} |\Psi\rangle \quad \forall\ j,k \tag{16.80}$$

Within each subspace $\mathfrak{F}_u$, we need to solve the quadratic Hamiltonian

$$\begin{aligned} \tilde{H}_u &= \frac{i}{4} \sum_{\langle j,k \rangle} A_{jk} c_j c_k \\ A_{jk} &= 2 J_{\alpha(j,k)} u_{jk} \end{aligned} \tag{16.81}$$

which we know how to do in principle. On the other hand, the integrals of motion W_p (the hexagon operators) define a decomposition of the physical subspace $\mathfrak{L}$ labeled by the eigenvalues $w_p = \pm 1$:

$$\mathfrak{L} = \bigoplus_w \mathfrak{L}_w, \quad \text{where } |\Psi\rangle \in \mathfrak{L}_w \text{ iff } W_p |\Psi\rangle = w_p |\Psi\rangle \quad \forall\ p \tag{16.82}$$

We can relate these two decompositions by expressing W_p in the Majorana representation and noting that within the physical subspace

$$\tilde{W}_p = \prod_{\langle j,k\rangle \in \partial p} \hat{u}_{jk} \tag{16.83}$$

Thus, we find

$$\mathfrak{L}_w = \Pi_{\mathfrak{L}} \mathfrak{F}_u \tag{16.84}$$

where $w_p = \prod_{(j,k)\in\partial p} u_{jk}$.

So we have a procedure for finding the ground state of the honeycomb model:

1. Fix $w_p = \pm 1$ for all p.
2. Find u_{jk} satisfying
$$w_p = \prod_{(j,k)\in\partial p} u_{jk}. \tag{16.85}$$
There is a small subtletly here in that $u_{jk} = -u_{kj}$ so we must be careful about ordering. We can consistently take j in the even sublattice of the honeycomb and k in the odd sublattice in equation (16.85).
3. Solve for the ground state of the quadratic Hamiltonian (16.81), finding the energy $E(w)$.
4. Project the found state onto the physical subspace (*i.e.* symmetrize over gauge transformations).
5. Repeat for all w; pick the w that minimizes the energy.

If there were no further structure to $E(w)$, this would be an intractable search problem in the space of w_p. Fortunately, due to a theorem by Lieb 1994, the ground state has no vortices. That is,

$$E(w) = \min \text{ if } w_p = 1\ \forall\ p \tag{16.86}$$

Using this choice of w_p, it is easy to solve the model and produce the phase diagram of Fig. 16.9. The gapless phase has two Dirac points in the fermionic spectrum.

16.5.3 Fermionic spectrum in the honeycomb lattice model

We just need to diagonalize the Hamiltonian

$$\begin{aligned} \tilde{H}_u &= \frac{i}{4} \sum_{\langle j,k\rangle} A_{jk} c_j c_k \\ A_{jk} &= 2 J_{\alpha(j,k)} u_{jk} \\ u_{jk} &= \begin{cases} +1 & \text{if } j \in \text{even sublattice} \\ -1 & \text{otherwise} \end{cases} \end{aligned} \tag{16.87}$$

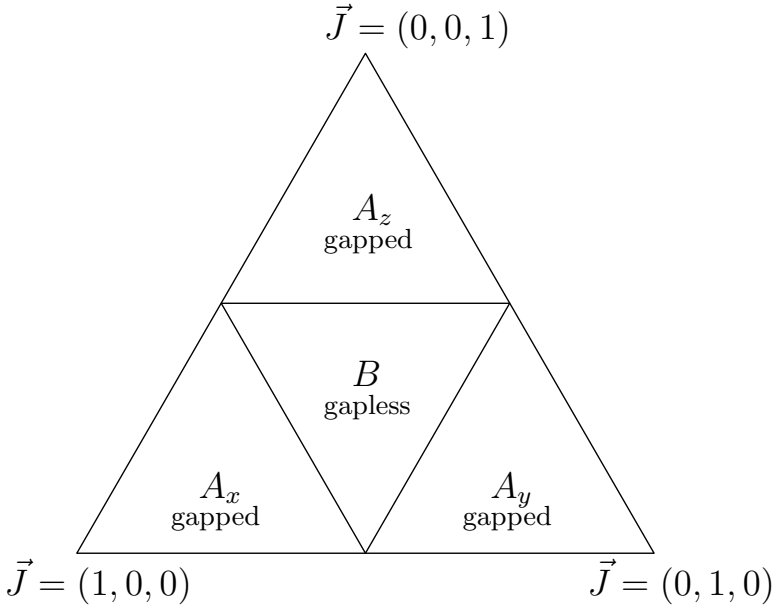

Figure 16.9: Phase diagram of honeycomb model. This is a slice through the positive octant in $\vec{J}$ coupling space along the $J_x + J_y + J_z = 1$ plane. The other octants are analogous.

Figure 16.10: Direct and reciprocal lattices of the honeycomb. The points $\pm\vec{q}_*$ are the two Dirac points of the gapless phase B.

This is equivalent to finding the eigenvalues and eigenvectors of the matrix iA. Since the honeycomb lattice has two sites per unit cell, by applying the Fourier transform we get a 2×2 matrix $A(\vec{q})$:

$$\begin{aligned} iA(\vec{q}) &= \begin{pmatrix} 0 & if(\vec{q}) \\ -if(\vec{q}) & 0 \end{pmatrix} \\ \epsilon(\vec{q}) &= \pm|f(\vec{q})| \end{aligned} \tag{16.88}$$

where $f(\vec{q})$ is some complex function that depends on the couplings J_x, J_y, J_z. In the gapless phase (phase B in Fig. 16.9), $f(\vec{q})$ has two zeros which correspond to Dirac points (see Fig. 16.10). At the transition to phase A, the Dirac points merge and disappear.

16.5.4 Quasiparticle statistics in the gapped phase

It appears that there are two particle types: fermions and vortices (hexagons with $w_p = -1$). The vortices are associated with a $\mathbb{Z}_2$ gauge field, where u_{jk} plays the role of vector potential. Taking a fermion around a vortex results in the multiplication of the state by -1 (compared to the no-vortex case). However, the details such as the fusion rules are not obvious.

Let us look at the model from a different perspective. If $J_x = J_y = 0, J_z > 0$, the system is just a set of dimers (see Fig. 16.11). Each dimer can be in two states: $\uparrow\uparrow$ and $\downarrow\downarrow$. The other two states have $2J_z$ higher energy. Thus, the ground state is highly degenerate.

If $J_x, J_y \ll J_z$, we can use perturbation theory relative to the noninteracting dimer point.

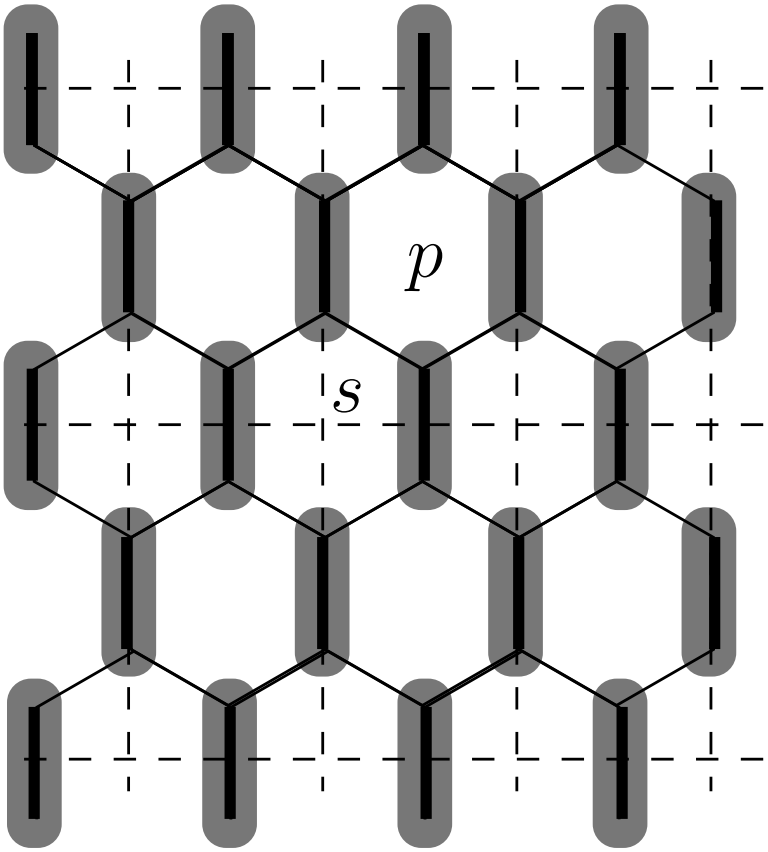

Figure 16.11: The vertical dimers on the honeycomb lattice themselves form the edges of a (dashed) square lattice. The plaquettes of alternate rows of the hexagonal lattice correspond to the stars and plaquettes of the square lattice. This is *weak breaking of translational symmetry.*

Let us characterize each dimer by an effective spin:

$$|\Uparrow\rangle = |\uparrow\uparrow\rangle\,; \qquad |\Downarrow\rangle = |\downarrow\downarrow\rangle\,. \tag{16.89}$$

At 4th order of perturbation theory, we get:

$$H_{\text{eff}}^{(4)} = \text{const} - \frac{J_x^2 J_y^2}{16 J_z^3} \sum_p Q_p \tag{16.90}$$

where p runs over the square plaquettes of the dimer lattice (see Fig. 16.11) and

$$Q_p = \sigma_{p_1}^y \sigma_{p_2}^x \sigma_{p_3}^y \sigma_{p_4}^x \tag{16.91}$$

is a plaquette operator on the effective spin space $|\Uparrow\rangle$, $|\Downarrow\rangle$. By adjusting the unit cell and rotating the spins, we can reduce this Hamiltonian to the toric code!

The vertices and plaquettes of the new lattice correspond to alternating rows of hexagons. Thus, vortices on even rows belong to one superselection sector and vortices on odd rows to the other. It is impossible to move a vortex from an even row to an odd row by a local operator without producing other particles (*e.g.* fermions). The fermions and $e-m$ pairs belong to the same superselection sector, ϵ, though these are different physical states.

16.5.5 Nonabelian phase

In the gapless phase B, vortex statistics are not well-defined. However, a gap can be opened by applying a perturbation that breaks the time-reversal symmetry, such as a magnetic field. Unfortunately the honeycomb model in a field is not exactly solvable. [10] studied an exactly solvable spin model where the time-reversal symmetry is spontaneously broken, but we will satisfy ourselves by introducing a T-breaking next nearest neighbor interaction on the fermionic level (which can be represented by a 3-spin interaction in the original spin language).

Written in terms of Majorana fermions, we consider the Hamiltonian

$$H = \frac{i}{4} \sum_{\langle j,k \rangle} A_{jk} c_j c_k \tag{16.92}$$

where A_{jk} now has chiral terms connecting Majoranas beyond nearest neighbor in the honeycomb lattice (see Fig. 16.12). After Fourier transforming, we find

$$iA(\vec{q}) = \begin{pmatrix} \Delta(\vec{q}) & if(\vec{q}) \\ -if(\vec{q}) & -\Delta(\vec{q}) \end{pmatrix} \tag{16.93}$$

with the massive dispersion relation

$$\epsilon(\vec{q}) = \pm\sqrt{f(\vec{q})^2 + \Delta(\vec{q})^2}. \tag{16.94}$$

Within this massive phase, we will find nontrivial topological invariants of the quasiparticle spectrum. Let $iA(\vec{q})$ be a nondegenerate Hermitian matrix that continously depends on $\vec{q}$. In our case, A acts in $\mathbb{C}^2$, but in general it can be $\mathbb{C}^n$ for any n. Let us keep track of the "negative eigenspace" of $iA(\vec{q})$: the subspace $\mathfrak{L}(\vec{q}) \subseteq \mathbb{C}^n$ spanned by eigenvectors corresponding to negative eigenvalues. For matrix (16.93), $\dim\ \mathfrak{L}(\vec{q}) = 1$. This defines a map F from momentum space (the torus) to the set of m-dimensional subspaces in $\mathbb{C}^n$. More formally:

$$F:\ \mathbb{T}^2 \longrightarrow U(n)/U(m) \times U(n-m) \tag{16.95}$$

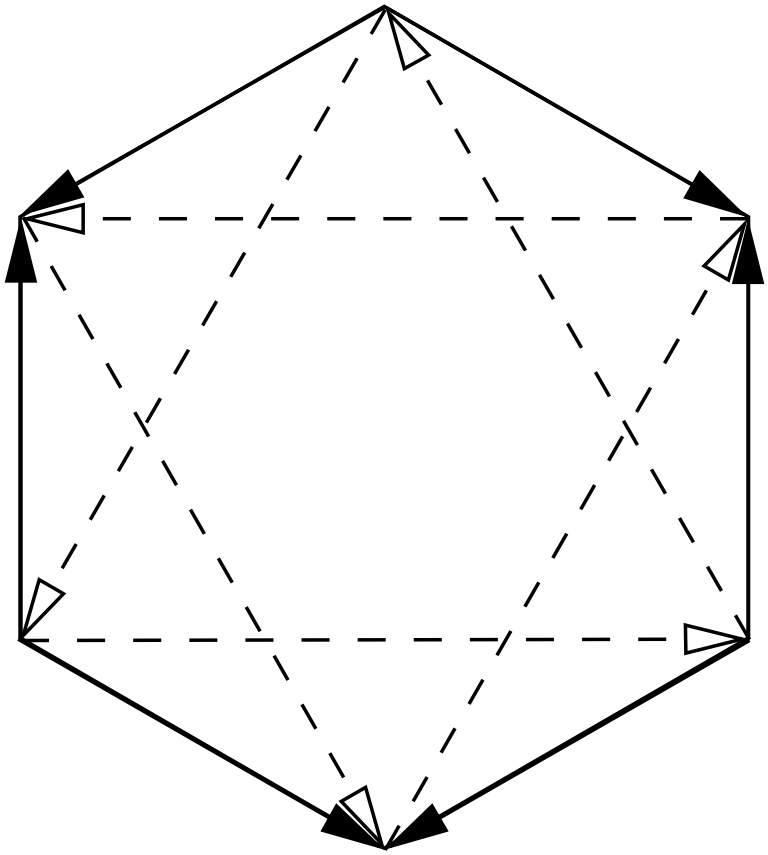

Figure 16.12: Picture of chiral interaction matrix A_{jk}. Forward arrows correspond to positive entries in the skew-symmetric real matrix A_{jk}. Solid arrows are the interactions of the original honeycomb model; dashed arrows give the time-reversal symmetry breaking perturbation.

This map F may have nontrivial topology.

In the honeycomb model with T-breaking, we have $n = 2$, $m = 1$ and $U(2)/U(1) \times U(1) = \mathbb{C}P^1 = S^2$ is the unit sphere. Thus, $F : \mathbb{T}^2 \longrightarrow S^2$ and for the matrix $iA(\vec{q})$ of Eq. (16.93), F has degree 1. That is, the torus wraps around the sphere once. More abstractly, $\mathfrak{L}(\vec{q})$ defines a complex vector bundle over the momentum space $\mathbb{T}^2$. This has an invariant Chern number ν, which in this case is $\nu = 1$.

What is the significance of the spectral Chern number? It is known to characterize the integer quantum Hall effect, where it is known as the "TKNN invariant". For a Majorana system, there is no Hall effect since particles are not conserved. Rather, the spectral Chern number determines the number of chiral modes at the edge:

$$\nu = (\#\text{ of left-movers}) - (\#\text{ of right-movers}). \tag{16.96}$$

16.5.6 Robustness of chiral modes

A chiral edge mode may be described by its Hamiltonian:

$$H_{\text{edge}} = \frac{iv}{4} \int \hat{\eta}(x) \partial_x \hat{\eta}(x) dx \tag{16.97}$$

where $\hat{\eta}(x)$ is a real fermionic field. That is,

$$\hat{\eta}(x)\hat{\eta}(y) + \hat{\eta}(y)\hat{\eta}(x) = 2\delta(x - y). \tag{16.98}$$

At temperature T, each mode carries energy current

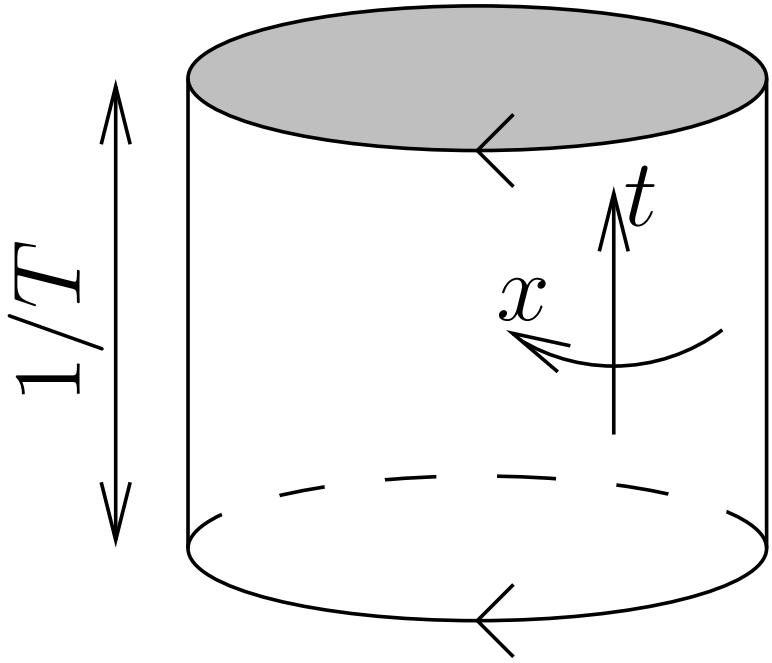
$$I_1 = \frac{\pi}{24} T^2. \tag{16.99}$$

The easiest explanation of this is a straightforward 1-D fermi gas calculation:

$$\begin{aligned} I_1 &= v \int_0^\infty n(q)\epsilon(q) \frac{dq}{4\pi} \\ &= \frac{1}{2\pi} \int_0^\infty \frac{\epsilon d\epsilon}{1 + e^{\epsilon/T}} \\ &= \frac{\pi}{24} T^2 \end{aligned} \tag{16.100}$$

However, it is useful to reexamine this current using conformal field theory (CFT), in order to understand better why the chiral modes are robust. We consider a disc of B phase extended into imaginary time at temperature T. That is, we have a solid cylinder with top and bottom

identified:



We have obtained a solid torus whose surface is a usual torus. The partition function is mostly determined by the surface.

Let the spatial dimensions be much greater than $\frac{1}{T}$. From this point of view, the cylinder looks more like:

According to the usual CFT arguments, we have

$$\begin{aligned} Z &\sim q^{\frac{c}{24}}\bar{q}^{\frac{\bar{c}}{24}} \\ q &= e^{2\pi i\tau} \\ \tau &= i\frac{LT}{v} + \text{twist} \end{aligned} \tag{16.101}$$

Twisting the torus changes the partition function by:

$$\begin{aligned} \tau &\mapsto \tau + 1 \\ Z &\mapsto Ze^{2\pi i\frac{c-\bar{c}}{24}}. \end{aligned} \tag{16.102}$$

On the other hand, the twist parameter ($\operatorname{Re}\tau$) couples to the some component of the energy-momentum tensor, namely, T_{xt}, which corresponds to the energy flow. This relation implies that

$$I = \frac{\pi}{12}(c-\bar{c})T^2. \tag{16.103}$$

The chiral central charge, $c - \bar{c}$, does not depend on the boundary conditions. Indeed, the energy current on the edge cannot change because the energy cannot go into the bulk.

17 Entanglement in quantum critical phenomena by Vidal, Latorre, Rico, Kitaev

Abstract

Quantum phase transitions occur at zero temperature and involve the appearance of long-range correlations. These correlations are not due to thermal fluctuations but to the intricate structure of a strongly entangled ground state of the system. We present a microscopic computation of the scaling properties of the ground-state entanglement in several 1D spin chain models both near and at the quantum critical regimes. We quantify entanglement by using the entropy of the ground state when the system is traced down to L spins. This entropy is seen to scale logarithmically with L, with a coefficient that corresponds to the central charge associated to the conformal theory that describes the universal properties of the quantum phase transition. Thus we show that entanglement, a key concept of quantum information science, obeys universal scaling laws as dictated by the representations of the conformal group and its classification motivated by string theory. This connection unveils a monotonicity law for ground-state entanglement along the renormalization group flow. We also identify a majorization rule possibly associated to conformal invariance and apply the present results to interpret the breakdown of density matrix renormalization group techniques near a critical point.

The study of entanglement in composite systems is one of the major goals of quantum information science [1, 2], where entangled states are regarded as a valuable resource for processing information in novel ways. For instance, the entanglement between systems A and B in a joint pure state $|\Psi_{AB}\rangle$ can be used, together with a classical channel, to *teleport* or send quantum information [3]. From this resource-oriented perspective, the *entropy of entanglement* $E(\Psi_{AB})$ measures the entanglement contained in $|\Psi_{AB}\rangle$ [4]. It is defined as the von Neumann entropy of the reduced density matrix ρ_A (equivalently ρ_B),

$$E(\Psi_{AB}) = -\mathrm{tr}\,(\rho_A \log_2 \rho_A)\,, \tag{17.1}$$

and directly determines, among other aspects, how much quantum information can be teleported by using $|\Psi_{AB}\rangle$.

On the other hand, entanglement is appointed to play a central role in the study of strongly correlated quantum systems [5, 6, 7], since a highly entangled ground state is at the heart of a large variety of collective quantum phenomena. Milestone examples are the entangled ground states used to explain superconductivity and the fractional quantum Hall effect, namely the BCS ansatz [8] and the Laughlin ansatz [9]. Ground-state entanglement is, most promisingly, also a key factor to understand quantum phase transitions [10, 11], where it is directly responsible for the appearance of long-range correlations. Consequently, a gain of insight into phenomena including, among others, Mott insulator-superfluid transitions, quantum magnet-paramagnet transitions and phase transitions in a Fermi liquid is expected by studying the structure of entanglement in the corresponding underlying ground states.

In the following we analyze the ground-state entanglement near and at a quantum critical point in a series of 1D spin-1/2 chain models. In particular, we consider the hamiltonians

$$H_{XY} = -\sum_{l=0}^{N-1} \left(\frac{a}{2}[(1+\gamma)\sigma_l^x \sigma_{l+1}^x + (1-\gamma)\sigma_l^y \sigma_{l+1}^y] + \sigma_l^z \right) \tag{17.2}$$

and

$$H_{XXZ} = -\sum_{l=0}^{N-1} \left(\sigma_l^x \sigma_{l+1}^x + \sigma_l^y \sigma_{l+1}^y + \Delta \sigma_l^z \sigma_{l+1}^z + \lambda \sigma_l^z \right), \tag{17.3}$$

which contain both first-neighbor interactions and an external magnetic field, and are used to describe a range of $1D$ quantum systems [10]. Notice that $H_{XY}(\gamma = 1)$ corresponds to the Ising chain, whereas $H_{XXZ}(\Delta = 1)$ describes spins with isotropic Heisenberg interaction. Both Hamiltonians coincide for $\gamma = \Delta = 0$, where they become the XX model.

Osterloh *et al* [12] and Osborne and Nielsen [11] have recently considered the entanglement in the XY spin model, Eq. (17.2), in the neighborhood of a quantum phase transition. Their analysis, focused on *single-spin* entropies [11] and on *two-spin* quantum correlations [12, 11], suggestively shows that these one- and two-spin entanglement measures are picked either near or at the critical point. Here, alternatively, we undertake the study of the *entanglement between a block of L contiguous spins and the rest of the chain*, when the spin chain is in its ground state $|\Psi_g\rangle$. Thus, the aim in the following is to compute the entropy of entanglement, Eq. (17.1), for the state $|\Psi_g\rangle$ according to bipartite partitions parameterized by L,

$$S_L \equiv -\mathrm{tr}\,(\rho_L \log_2 \rho_L)\,, \tag{17.4}$$

where $\rho_L \equiv \mathrm{tr}_{\bar{\mathcal{B}}_L} |\Psi_g\rangle\langle\Psi_g|$ is the reduced density matrix for $\mathcal{B}_L$, a block of L spins.

The XY model, Eq. (17.2), is an *exactly solvable* model, in that H_{XY} can be diagonalized by first using a Jordan-Wigner transformation into fermionic modes and by subsequently concatenating a Fourier transformation and a Bogoliubov transformation (see for instance [10]). The calculation of S_L, as sketched below, also uses the fact that the ground state $|\Psi_g\rangle$ of H_{XY} and the corresponding density matrices ρ_L are all *gaussian* states that can be completely characterized by means of certain correlation matrix of second moments.

More specifically, let us introduce two Majorana operators, c_{2l} and c_{2l+1}, on each site $l = 0, \cdots, N-1$ of the spin chain,

$$c_{2l} \equiv \left(\prod_{m=0}^{l-1} \sigma_m^z\right) \sigma_l^x; \quad c_{2l+1} \equiv \left(\prod_{m=0}^{l-1} \sigma_m^z\right) \sigma_l^y. \tag{17.5}$$

Operators c_m are hermitian and obey the anti-commutation relations $\{c_m, c_n\} = 2\delta_{mn}$. Hamiltonian H_{XY} can be rewritten as

$$H_{XY} = i \sum_{l=0}^{N-1} \Big(\frac{a}{2} \left[(1+\gamma)\, c_{2l+1} c_{2l+2} - (1-\gamma)\, c_{2l} c_{2l+3} \right] + c_{2l} c_{2l+1} \Big)\,,$$

and can be subsequently diagonalized by canonically transforming the operators c_m. The expectation value of c_m when the system is in the ground state, i.e. $\langle c_m \rangle \equiv \langle \Psi_g | c_m | \Psi_g \rangle$, vanishes for all m due to the $\mathcal{Z}_2$ symmetry $(\sigma_l^x, \sigma_l^y, \sigma_l^z) \to (-\sigma_l^x, -\sigma_l^y, \sigma_l^z)$ $\forall l$ of H_{XY}. In turn, the expectation values

$$\langle c_m c_n \rangle = \delta_{mn} + i B_{mn}, \tag{17.6}$$

completely characterize $|\Psi_g\rangle$, for any other expectation value can be expressed, by using Wick's theorem, in terms of $\langle c_m c_n \rangle$. Matrix B reads [13]

$$B = \begin{bmatrix} \Pi_0 & \Pi_1 & \cdots & \Pi_{N-1} \\ \Pi_{-1} & \Pi_0 & & \vdots \\ \vdots & & \ddots & \vdots \\ \Pi_{1-N} & \cdots & \cdots & \Pi_0 \end{bmatrix}, \quad \Pi_l = \begin{bmatrix} 0 & g_l \\ -g_{-l} & 0 \end{bmatrix}, \tag{17.7}$$

with real coefficients g_l given, when $N \to \infty$, by

$$g_l = \frac{1}{2\pi} \int_0^{2\pi} d\phi e^{-il\phi} \frac{a\cos\phi - 1 - ia\gamma\sin\phi}{|a\cos\phi - 1 - ia\gamma\sin\phi|}. \tag{17.8}$$

From Eqs. (17.7)-(17.8) we can extract the entropy S_L of Eq. (17.4) as follows. First we compute the correlation matrix of the state ρ_L for block $\mathcal{B}_L$, namely $\delta_{mn} + i(B_L)_{mn}$, where

$$B_L = \begin{bmatrix} \Pi_0 & \Pi_1 & \cdots & \Pi_{L-1} \\ \Pi_{-1} & \Pi_0 & & \vdots \\ \vdots & & \ddots & \vdots \\ \Pi_{1-L} & \cdots & \cdots & \Pi_0 \end{bmatrix} \tag{17.9}$$

is constructed by eliminating $2(N-L)$ contiguous columns and rows from B, those corresponding to the $N-L$ traced-out spins. Let $V \in SO(2L)$ denote an orthogonal matrix that brings B_L into a block-diagonal form, that is

$$\tilde{B}_L = V B_L V^T = \oplus_{m=0}^{L-1} \nu_m \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix}, \quad \nu_m \geq 0. \tag{17.10}$$

Then the set of $2L$ Majorana operators $d_m \equiv \sum_{n=0}^{2L-1} V_{mn} c_n$, obeying $\{d_m, d_n\} = 2\delta_{mn}$, have a block-diagonal correlation matrix $\langle d_m d_n \rangle = \delta_{mn} + i(\tilde{B}_L)_{mn}$. Therefore, the L fermionic operators $b_l \equiv (d_{2l} + i d_{2l+1})/2$, obeying $\{b_m, b_n\} = 0$ and $\{b_m^\dagger b_n\} = \delta_{mn}$, have expectation values

$$\langle b_m \rangle = 0, \quad \langle b_m b_n \rangle = 0, \quad \langle b_m^\dagger b_n \rangle = \delta_{mn} \frac{1+\nu_m}{2}. \tag{17.11}$$

Eq. (17.11) indicates that the above fermionic modes are in a *product* or *uncorrelated* state, that is

$$\rho_L = \varrho_0 \otimes \cdots \otimes \varrho_{L-1}, \tag{17.12}$$

where ϱ_m denotes the mixed state of mode m. The entropy of ρ_L is a sum over the entropy $H_2((1+\nu_m)/2)$ of each mode [$H_2(x) = -x \log_2 x - (1-x)\log_2(1-x)$ is the binary entropy] and thus reads

$$S_L = \sum_{m=0}^{L-1} H_2\left(\frac{1+\nu_m}{2}\right). \tag{17.13}$$

For arbitrary values of (a, γ) in H_{XY} and in the thermodynamic limit, $N \to \infty$, one can evaluate Eq. (17.8) numerically, diagonalize B_L in Eq. (17.9) to obtain ν_m and then evaluate Eq. (17.13). The computational effort grows only polynomically with L and produces reliable values of S_L for blocks with up to several tens of spins. However, further analytical characterization is possible in some cases, which speeds the computation significantly. For instance, for the XX model with magnetic field, $\gamma = 0$ and $1/a \in [-1, 1]$, one obtains $g_0 = \phi_a/\pi - 2$ and $g_l = 2\sin(l\phi_a)/l\pi$ for $l \neq 0$, where $\phi_a = \arccos(1/a)$, from which S_L can be numerically determined. We obtain, up to $L = 100$ spins,

$$S_L^{XX} \approx \frac{1}{3}\log_2(L) + k_1(a), \tag{17.14}$$

where $k_1(a)$ depends only on a. For the Ising model with critical magnetic field, $\gamma = 1, a = 1$, one finds $g_l = -2/l$ for odd l and $g_l = 0$ for even l and, for up to $L = 100$ spins,

$$S_L^{Ising} \approx \frac{1}{6}\log_2(L) + k_2, \qquad k_2 \approx \pi/3. \tag{17.15}$$

Finally, for the Ising model with magnetic field, $\gamma = 1$, and for a close to 1, Kitaev has obtained an analytical expression for the entropy of half of an infinite chain [15]. To use this result in our setting we need to double its value because the entropy resides near the boundary. Thus we get

$$S_{N/2}^{Ising} \approx \frac{1}{6}\log_2 \frac{1}{|1-a|}. \tag{17.16}$$

The XXZ model, Eq. (17.3), cannot be analyzed using the previous method. Instead we have used the Bethe ansatz [16] to exactly determine, through a numerical procedure, the ground state $\left|\Psi_g^{(20)}\right\rangle$ of H_{XXZ} for a chain of up to $N = 20$ spins, from which $S_L^{(20)}$ can be computed. Recall that in the XXZ model the non-analyticity of the ground-state energy characterizing a phase transition occurs already for a finite number N of spins in the chain, since it is due to level-crossing. It turns out that, correspondingly, already for $N = 20$ spins one can observe a distinct, characteristic behavior of $S_L^{(20)}$ depending on whether the values (Δ, λ) in Eq. (17.3) belong to a critical regime.

The results of the computation of S_L for the spin chains (17.2) and (17.3) can be summarized as follows.

Non-critical regime. For those values (a, γ) or (Δ, λ) for which the models are non-critical, the entropy of entanglement S_L either vanishes for all L [*e.g.* when a sufficiently strong magnetic field aligns all spins into a product, unentangled state] or grows monotonically as a function of L until it reaches a *saturation* value S_{max}. For instance, in the infinite Ising chain the saturation entropy S_{max} is given by Eq. (17.16). As shown in Fig. (**??**), S_L often approaches S_{max} already for a small number L of spins.

Critical regime. Instead, critical ground-states are characterized by an entropy S_L that diverges logarithmically with L,

$$S_L \approx \frac{c + \bar{c}}{6} \log_2(L) + k, \tag{17.17}$$

with a coefficient given by the holomorphic and antiholomorphic *central charges* c and $\bar{c}$ of the conformal field theory that describes the universal properties of the phase transition [17], see Fig. (17.1). This expression was derived by Holzhey, Larsen and Wilczek [18] for the *geometric entropy* (analogous of Eq. (17.4) for a conformal field theory), and our calculation confirms it for several critical spin chains. Thus, the critical Ising model corresponds to a free fermionic field theory, with central charges $c_f = \bar{c}_f = 1/2$, whereas the rest of critical regimes in (17.2) and (17.3) are described by a free bosonic field theory, $c_b = \bar{c}_b = 1$ (cf. Eqs. (17.14) and (17.15)). In particular, the marginal deformation $0 < \gamma \leq 1$ for $a = 1$ shows scaling for every γ with universal coefficient $c = \bar{c} = 1/2$. It is possible to compare the subleading correction between two different values of γ. The behavior we obtain is described by

$$\lim_{L\to\infty} [S_L(\gamma = 1) - S_L(\gamma)] = -\frac{c + \bar{c}}{6} \log_2 \gamma \ . \tag{17.18}$$

The singular behavior at $\gamma = 0$ is the signature of the fact that that point belongs to the abrupt change of universality class for the XX model.

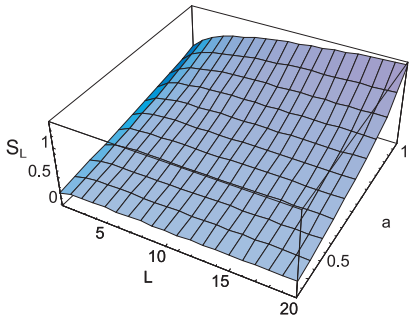


Figure 17.1: Numerical calculation of critical entanglement S_L for 1D spin chains. Points (+) come from an infinite Ising chain with critical magnetic field, $H_{XY}(a = 1, \gamma = 1)$ in Eq. (17.2), and corresponds to $S_L^{Ising} \approx \log_2(L)/6 + k_2$. Curve (×) comes from an infinite XX spin chain without magnetic field, $H_{XY}(a = \infty, \gamma = 0)$ in Eq. (17.2), and corresponds to $S_L^{XX} \approx \log_2(L)/3 + k_1$. Thus the growth in L of entanglement in the XX model, asymptotically described by a free boson, is twice that in the Ising model, corresponding to a free fermion, $S_{L+1}^{XX} - S_L^{XX} \approx 2(S_{L+1}^{Ising} - S_L^{Ising})$. Finally, curve (∗) comes from a XXX chain of 20 spins without magnetic field, $H_{XXZ}(\Delta = 1, \lambda = 0)$ in Eq. (17.3). These finite-chain results, obtained using the Bethe ansatz, combine the logarithmic behavior ($L = 1, \cdots, 5$) of a free boson field theory with a finite-size saturation effect ($L = 6, \cdots, 10$). We have added the lines $\frac{c+\bar{c}}{6}[\log_2(L) + \pi]$ both for bosons and fermions to highlight their remarkable agreement with the numerical diagonalization.

The above characterizations motivate a number of observations, that we move to discuss.

Critical and non-critical ground states contain structurally different forms of quantum correlations. Non-critical ground-state entanglement corresponds to a weak, *semi-local* form of entanglement driven by the appearance of a length scale, *e.g.* a mass gap. Indeed, for any L, the reduced density matrix ρ_L is supported on a small, bounded subspace of the Hilbert space of the L spins, and can be obtained by diagonalizing the hamiltonian corresponding to the block $\mathcal{B}_L$ and only a few extra *neighboring* spins, as skillfully exploited in White's density matrix renormalization group (DMRG) techniques [19]. We note here that a bounded rank for ρ_L (relatedly, a saturation value for S_L) is instrumental for the success of DMRG schemes, where only of a finite number of eigenvectors of ρ_L can be kept. Critical bound-state entanglement corresponds, on the contrary, to a stronger form of entanglement, one that embraces the system at all length scales simultaneously. DMRG techniques have reportedly failed to reproduce quantum critical behavior [20] and we may, in view of Eq. (17.17), be in a position to understand why. Indeed, the divergent character of S_L is just one particular manifestation of the fact that the number of relevant eigenvectors of ρ_L unboundedly grows with L. If, as is the case in DMRG schemes, only a finite number of levels can be considered, then a sufficiently large L will always make the computation of ρ_L impossible (arguably, even in an approximate sense) by using such schemes. This strongly suggests that overcoming the above difficulties necessarily requires techniques that do not attempt to reproduce the critical behavior of the ground state through a local, real space construction.

Another remarkable, far-reaching fact is that, as mentioned below Eq. (17.17), our results coincides with entropy computations performed in conformal field theory. There, a *geometric* or *fine-grained* entropy analogous to Eq. (17.4) but for a continuous field theory has been considered by several authors, including Srednicki [21], Callan and Wilczek [22], Holzhey et al [18] and Fiola et al [23]. Thus, starting from non-relativistic spin chain models, and by performing a microscopic analysis of a relevant quantity in quantum information, we have obtained a universal scaling law for entanglement that is in full agreement with previous findings

in the context of, say, black-hole thermodynamics in 1+1 dimensions [18, 23].

The above connection has a number of implications to be exploited. For instance, Srednicki [21] has obtained the behavior of entropy in 2+1 and 3+1 dimensional conformal field theories. For a region $\mathcal{R}$ in 2 or 3 spatial dimensions, the entropy of $\mathcal{R}$ is proportional to the size $\sigma(\mathcal{R})$ of its boundary,

$$S_{\mathcal{R}} \approx \kappa\sigma(\mathcal{R}). \tag{17.19}$$

That is, the entropy per unit of boundary area, κ, is independent of the size of $\mathcal{R}$. [This is in sharp contrast with the same quantity in 1D, where the boundary consists of two points and $S_{\mathcal{R}}/\sigma(\mathcal{R})$ diverges logarithmically with the length L of $\mathcal{R}$]. Accordingly, Eq. (17.19) also describes the critical ground-state entanglement of 2D and 3D spin lattices.

Also the fact that the entropy of entanglement for $1D$ critical spin chains, Eq. (17.17), matches well-known conformal field theory parameters carries an extra bonus. The coefficient in control of the divergent behavior of S_L at critical points is the central charge, which is subject to Zamolodchikov's c-theorem [24]. The c-theorem states that the central charges associated to the ultraviolet and infrared end points of renormalization group flows, labeled by C_{UV} and C_{IR}, obey the inequality $C_{UV} > C_{IR}$ for unitary theories. This powerful result establishes an irreversible arrow as renormalization group transformations are performed. The translation of this idea to the quantum information setting is that entanglement decreases along renormalization group flows. An infrared theory carries less global entanglement than the ultraviolet theory where it flowed from. The c-theorem seems natural as renormalization group transformations integrate out short distance degrees of freedom, accompanied with their quantum correlations. Yet, it is not at all trivial due to, first, the infinite degrees of freedom (needing regularization) existing in a quantum field theory and, second, the rescaling step in the renormalization group transformation. It is noteworthy, then, that entanglement decreases both (*i*) under the *local operations and classical communication* and (*ii*) along *renormalization group trajectories*. The former case corresponds to *local manipulation* of an entangled system while the second is made out of a block-spin transformation followed by a *rescaling* of the system. Both actions do reduce quantum correlations and become irreversible [24, 25].

One more remark. From Eqs. (17.8)-(17.9) the complete spectrum of ρ_L can be extracted. The 2^L eigenvalues are given by

$$\lambda_{x_1 x_2 \cdots x_L} = \prod_{m=0}^{L-1} \frac{1 + (-1)^{x_m}\nu_m}{2}, \quad x_m = 0, 1 \ \forall m. \tag{17.20}$$

This allows us to look in more detail to the reshuffling of the ground state as more sites are incorporated in the block $\mathcal{B}_L$. Every time a new spin is added, the amount of local surprise due to quantum correlations with the rest of the chain increases, and so does the entropy. But critical quantum correlations entangle every single subset of the system, and the way they are reordered is far more subtle than the relation hinted by entropy arguments. We have numerically verified that also a majorization relation [26] holds for the ground-state reduced density matrices of the infinite XY spin chain, namely

$$\vec{\lambda}_{L+2} \prec \vec{\lambda}_L \quad \forall L, \tag{17.21}$$

where the jump in steps of two is forced by the subtleties of the microscopic model. Thus, a critical ground state orderly redistributes weights, so as to accommodate for the new correlations, according to a detailed, exponentially large set of inequalities as contained in Eq. (17.21). In this sense, majorization may be a signature –admittedly a very refined one– of conformal invariance.

But the majorization counterpart in the continuum conformal field theory is not yet known. Perhaps, then, the correspondence between concepts of quantum information science and conformal field theory, between critical ground-state entanglement and geometrical entropy, can also be exploited in the reverse direction.

18 What limits the simulation of quantum computers? by Zhou, Stoudenmire, Waintal

Abstract

An ultimate goal of quantum computing is to perform calculations beyond the reach of any classical computer. It is therefore imperative that useful quantum computers be very difficult to simulate classically; otherwise classical computers could be used for the applications envisioned for the quantum ones. *Perfect* quantum computers are unarguably exponentially difficult to simulate: the classical resources required grow exponentially with the number of qubits N or the depth D of the circuit. This difficulty has triggered recent experiments on deep, random circuits that aim to demonstrate that quantum devices may already perform tasks beyond the reach of classical computing. These *real* quantum computing devices, however, suffer from many sources of decoherence and imprecision which limit the degree of entanglement that can actually be reached to a fraction of its theoretical maximum. They are characterized by an exponentially decaying fidelity $\mathcal{F} \sim (1-\epsilon)^{ND}$ with an error rate ϵ per operation as small as $\approx 1\%$ for current devices with several dozen qubits or even smaller for smaller devices.

In this work, we provide new insights on the computing capabilities of real quantum computers by demonstrating that they can be simulated at a tiny fraction of the cost that would be needed for a perfect quantum computer. Our algorithms compress the representations of quantum wavefunctions using matrix product states (MPS), which are able to capture states with low to moderate entanglement very accurately. This compression introduces a finite error rate ϵ so that the algorithms closely mimic the behavior of real quantum computing devices. The computing time of our algorithm increases only linearly with N and D in sharp contrast with exact simulation algorithms. We illustrate our algorithms with simulations of random circuits for qubits connected in both one and two dimensional lattices. We find that ϵ can be decreased at a polynomial cost in computing power down to a minimum error ϵ_∞. Getting below ϵ_∞ requires computing resources that increase exponentially with ϵ_∞/ϵ. For a two dimensional array of $N = 54$ qubits and a circuit with Control-Z gates, error rates better than state-of-the-art devices can be obtained on a laptop in a few hours. For more complex gates such as a swap gate followed by a controlled rotation, the error rate increases by a factor three for similar computing time. Our results suggest that, despite the high fidelity reached by quantum devices, only a tiny fraction ($\sim 10^{-8}$) of the system Hilbert space is actually being exploited.

18.1 Introduction

Operating a quantum computer is a race against the clock. The same phenomenon enabling the potential computing power of quantum computers—entanglement—is also responsible for decoherence when it occurs with unmonitored degrees of freedom. The main challenge of quantum computing is to quickly build entanglement between the qubits before imperfections or decoherence overly corrupt the quantum state. This decoherence is an intrinsic characteristic of any quantum computer and its origin and consequences must be understood thoughtfully. But in all hardware realizations, it means each operation incurs a loss of fidelity relative to the ideal target quantum state.

As different experimental platforms for quantum manipulation make rapid, impressive advances, there has been a justifiable interest in the computational capability of near-term quantum computers [1]. One of the key questions is when and how to achieve the goal of "quantum supremacy" [2], which is the crossover point where a quantum system ceases to be within reach of simulation on a classical computer. Precise circuits and fidelity metrics have been designed to meet this goal [3]. Recently, an experiment using $N = 53$ qubits and a circuit of depth $D = 20$ has reached a multi-qubit fidelity $\mathcal{F} = 0.002$ [4]. According to the authors, such an experiment would take thousands of years to be simulated on the largest existing supercomputers. This statement was then challenged by another estimate which claims that only two days would be needed [5]. Such a disparity between estimates raises the question of the difficulty of simulating a quantum computer and consequently of the true computing power realized in a quantum computer.

The implicit assumption behind quantum supremacy as well as the most appealing applications of quantum computing is that a quantum computer is exponentially hard to simulate. Indeed, in recent years many techniques have been developed to simulate quantum computers, and they all have an exponential cost in some parameter. A brute force approach where one holds the full quantum state in memory as a large vector of size 2^N (N: number of qubits) requires a computing time and memory that scales exponentially with N but linearly with the depth D of the circuit. Other approaches require a computing time that scale exponentially with the number of two-qubit gates [6, 7, 8, 9], with the number of non-Clifford gates [10] and/or with the number of gates that are non-diagonal in a chosen basis [11, 12]. All these techniques can simulate *perfect* quantum computers. In all cases, the required computing resources are exponential so that getting beyond $N = 50$ and a depth $D = 20$ for an arbitrary circuit is extremely difficult.

In this article, we show that *real* quantum computers can be simulated at a tiny fraction of the cost that would be needed for a *perfect* quantum computer. To do so, we take advantage of the fact that in real quantum computers, decoherence limits the amount of entanglement that can be built into the quantum state to a fraction of what the exponentially large Hilbert space would suggest. Our algorithms use a compressed wavefunction representation that achieves very high accuracy for states with low to moderate entanglement. This compression introduces a finite error rate ϵ per two-qubit gate. Hence, in this class of algorithms the limiting factor is the fidelity with which the calculation is performed while the computing time is linear in both the number of qubits N and the depth D. These algorithms "mimic" actual quantum computers both in the sense of how they scale with N and D, and in the sense that the main difficulty lies in increasing the fidelity of the calculation: a small finite error ϵ is made each time a two-qubit gate is applied to the state. Therefore, they offer a better reference point than exact simulation algorithms for assessing the computing power harvested by actual quantum chips.

Our algorithms are based on tensor networks and more precisely on matrix product states (MPS) [13]. MPS have been recognized very early as an interesting parameterization of many-qubit quantum states for quantum simulations [6] and its generalizations are used in some of

the most advanced quantum simulation approaches [14]. However, so far, the focus of classical simulations of quantum hardware has been building essentially exact simulations techniques and little attention has been devoted to approximate techniques. Interestingly these exact techniques can require one to go well beyond double precision calculations [15] which already hints at the link between error rate and underlying computing difficulty.

The historical success of MPS has *not* been for exact calculations but, in contrast, for the development of controlled, approximate techniques to address quantum many-body physics problems. This includes the celebrated density matrix renormalization group (DMRG) algorithm [16] which has provided precise solutions to a number of one-dimensional and quasi-one-dimensional problems, as well as time-dependent extensions [17] and generalizations to higher dimensions through projected entangled pair states (PEPS) [18] or multi-scale entanglement renormalization ansatz (MERA) [19] tensor networks. At the root of these successes is the fact that MPS naturally organizes states according to the amount of entanglement entropy between different parts of the system. Hence, slightly entangled systems can be easily represented with MPS. As entanglement entropy grows, one eventually truncates the basis. The associated error can be made arbitrarily small by keeping a larger set of basis states.

In this article, we construct such an approximate technique in the context of quantum computing. Our chief result is that, for fidelities comparable to those reached experimentally, the computational requirement for simulating an imperfect quantum computer is only a tiny fraction of the requirements for a perfect one.

18.2 Possible strategies for approximate simulations of quantum circuits

Let us start by discussing possible strategies for simulating quantum circuits in an approximate manner. Suppose that we have partitioned the qubits into two different sets A and B with respectively N_A and N_B qubits ($N_A + N_B = N$). Let us consider the two-qubit gates that connect A and B and ignore gates internal to A or B. Performing a singular value decomposition (SVD) of such a gate, it can be written as a sum of terms that act separately on A and B. This sum contains two terms for the case of usual gates (Control-NOT and Control-Z) and at most four terms for an arbitrary two-qubit gate. It follows that computing the state after n of these gates amounts to keeping track of 2^n (up to 4^n) different amplitudes. These amplitudes are the discrete analogue of Feynman paths and are referred to as such in the literature. For the random circuits that will be considered in this article, these 2^n amplitudes have essentially random phases. It follows that if one keep track of just a *single* path, one reaches an overall multi-qubit fidelity $\mathcal{F} = (1/2)^n$ (or $\mathcal{F} = (1/4)^n$ in the worst situation). This very simple strategy could be used to simulate an arbitrary large number of qubits with low fidelity per gate in a computing time $\sim n$. However, if one wants to keep a fixed fidelity per gate f defined as $\mathcal{F} = f^n$, in analogy with real quantum computers, the number of paths $N_{\rm path}$ that must be tracked during the simulation is $N_{\rm path} = (2f)^n$, and hence increases exponentially with n. Such a strategy has been used in Ref. [4] to validate the experimental results reported there.

We now seek algorithms where a constant fidelity f can be obtained at a constant computing cost per gate, independent of the total number of gates n. One starts by writing a general state for the bipartite system as

$$|\Psi\rangle = \sum_{a,b} \Psi_{ab} |a\rangle_A |b\rangle_B \tag{18.1}$$

where the states $|a\rangle$ ($|b\rangle$) form an orthonormal basis of A (B). Performing a singular value decomposition (SVD)

$$\Psi_{ab} = \sum_{\mu} U_{a\mu} S_\mu V_{\mu b}, \tag{18.2}$$

one can define an orthonormal basis

$$|\mu\rangle_A = \sum_a U_{\mu a}|a\rangle_A \tag{18.3}$$

(with similar notation for the B subsystem) and arrive at the usual Schmidt decomposition of $|\Psi\rangle$:

$$|\Psi\rangle = \sum_\mu S_\mu |\mu\rangle_A |\mu\rangle_B \tag{18.4}$$

in terms of a finite number of singular values S_μ. States with only one non-zero singular value $S_0 = 1$ are simple, unentangled product states. A measure of the number of significant singular values needed to describe the state to high accuracy is given by the entanglement entropy

$$S = -\text{Tr } \rho_A \log \rho_A = -\text{Tr } \rho_B \log \rho_B = -\sum_\mu S_\mu^2 \log S_\mu^2 \tag{18.5}$$

where ρ_A (ρ_B) is the reduced density matrix for the subsystem A (B). The general strategy of DMRG-like algorithms is to keep only a finite number χ of the singular values. After a two-qubit gate that connects A and B, one performs a SVD decomposition of Ψ_{ab} and truncate the state by keeping only the χ largest singular values. When $\chi \gg e^S$ this procedure is essentially exact. As the entanglement increases, this procedure lead to a certain fidelity per gate $f < 1$ that can be controlled by increasing the parameter χ. Of interest to the present article is the typical value of f that can be reached in a reasonable computing time.

18.3 Noisy algorithm in one dimension

Above we motivated the truncated SVD of a two-qubit wavefunction as an approximation strategy that works well for wavefunctions with only a moderate amount of entanglement. A natural generalization of this strategy to the N-qubit case is to use matrix product states (MPS), which can be viewed as a simultaneous Schmidt decomposition of the wavefunction across N different partitions [6] or equivalently a sequence of compatible SVD factorizations of the wavefunction, grouping qubits $1, 2, \ldots, j$ and $j+1, \ldots, N$ and performing an approximate SVD of the resulting matrix [13].

18.3.1 MPS representation of the state

We first consider a one dimensional network of N qubits where two-qubit gates can be only applied directly between nearest neighbors. (Within this connectivity, gates acting on other non-neighboring qubits are still possible at the cost of using $\sim N$ SWAP operations to bring the qubits onto neighboring sites.) We define our MPS state in terms of N tensors $M(n)$ as

$$|\Psi\rangle = \sum_x \Psi_x |x\rangle = \sum_{i_1 \ldots i_N} \sum_{\mu_1 \ldots \mu_{N-1}} M(1)^{i_1}_{\mu_1} M(2)^{i_2}_{\mu_1 \mu_2} M(3)^{i_3}_{\mu_2 \mu_3} \ldots M(N)^{i_N}_{\mu_{N-1}} |i_1 i_2 i_3 \ldots i_N\rangle \tag{18.6}$$

where the "physical" indices $i_n \in \{0, 1\}$ span the 2^N dimensional Hilbert space while the bond (or virtual) indices $\mu_n \in \{1, ..., \chi_n\}$ control the maximum degree of entanglement allowed by the MPS. $|x\rangle$ is a shorthand for $|i_1 i_2 ... i_N\rangle$. If the χ_n are allowed to grow exponentially large as a function of N, then the MPS form of the wavefunction becomes exact and can represent any wavefunction [13]. In contrast, we will enforce $\chi_n \leq \chi$ in what follows so that the resulting MPS represents an approximation of the true wavefunction. The parameter χ controls the error rate made by our algorithm as well as the computational and memory costs required to run it.

As we will see below, applying a two-qubit gate takes $\sim \chi^3$ operations and the overall memory footprint is $N\chi^2$. A sketch of the MPS structure is shown in Fig. 18.1b.

To be acceptable, our algorithm must provide the same features that a real quantum computer would provide. Applying a one-qubit gate U on qubit n can be done exactly and without increasing any of the χ_n: it simply amounts to updating the corresponding tensor $M(n) \to M'(n)$:

$$M'(n)^{i'_n}_{\mu_{n-1}\mu_n}(n) = \sum_{i_n} U_{i'_n i_n} M(n)^{i_n}_{\mu_{n-1}\mu_n}. \tag{18.7}$$

as shown in Fig. 18.2(a). Calculating the overlap between different MPS states or calculating individual wavefunction amplitudes $\langle i_1 i_2 ... i_{N-1} i_N | \Psi \rangle$ can be done with contraction algorithms which, for MPS, can be done exactly in $\sim N\chi^3$ operations (see e.g. [13] for a detailed description of standard MPS algorithms). It follows that one can also sample from the distribution $|\langle i_1 i_2 ... i_{N-1} i_N | \Psi \rangle|^2$ within the same complexity. Quantum measurements (sampling of a given qubit followed by its projection) can also be done efficiently in a straightforward manner [20].

To perform a two-qubit gate U between qubit n and qubit $n+1$, one first transforms the MPS into the so-called "canonical form" centered around the qubits of interest, through a series of QR factorizations [13]. This step is crucial for the accuracy of truncations of the MPS. The steps to apply the gate are then shown in Fig. 18.2(b). One first forms the two-qubit tensor

$$T^{i_n i_{n+1}}_{\mu_{n-1}\mu_{n+1}} = \sum_{\mu_n} M(n)^{i_n}_{\mu_{n-1}\mu_n} M(n+1)^{i_{n+1}}_{\mu_n \mu_{n+1}}. \tag{18.8}$$

Then one applies the two-qubit gate U and obtains

$$(T')^{i'_n i'_{n+1}}_{\mu_{n-1}\mu_{n+1}} = \sum_{i_n i_{n+1}} U_{i'_n i'_{n+1}, i_n i_{n+1}} T^{i_n i_{n+1}}_{\mu_{n-1}\mu_{n+1}}. \tag{18.9}$$

In a last stage, considering the tensor T' as a matrix with indices spanned by (i'_n, μ_{n-1}) and (i'_{n+1}, μ_{n+1}), one performs a singular value decomposition and writes

$$(T')^{i'_n i'_{n+1}}_{\mu_{n-1}\mu_{n+1}} = \sum_{\mu_n} X^{i'_n}_{\mu_{n-1}\mu_n} S_{\mu_n} Y^{i'_{n+1}}_{\mu_n \mu_{n+1}} \tag{18.10}$$

where the tensors X and Y are formed of orthogonal vectors while the vector S_μ contains the singular values of T'. Here S_μ has up to 2χ components (irrespective of the nature of the two-qubit gate) so that exact algorithms imply a doubling of χ after each application of a two-qubit gate. In the spirit of DMRG like algorithms, we truncate S_μ and keep only its χ largest components to obtain S'_μ. The new MPS tensors are then simply given by

$$M'(n)^{i_n}_{\mu_{n-1}\mu_n} = X^{i_n}_{\mu_{n-1}\mu_n} S'_{\mu_n} \tag{18.11}$$

$$M'(n+1)^{i_{n+1}}_{\mu_n \mu_{n+1}} = Y^{i_{n+1}}_{\mu_n \mu_{n+1}} \tag{18.12}$$

which completes the algorithm. Overall, the cost of applying a two-qubit gate is dominated by the SVD step which scales as χ^3. We emphasize that such an algorithm can do anything that a quantum computer does but the reverse statement is not true: in the MPS approach, one holds the full wavefunction in memory which provides much more information than can be obtained from samples of the wavefunction. For instance, one can compute bipartite entanglement entropy of an MPS, and it is straightforward to calculate quantities such as observables or correlation functions without any statistical errors. The MPS format also satisfies the sample and query access criteria needed for quantum inspired de-quantizing algorithms [21].

18.3.2 Random Quantum Circuit

Fig. 18.1a shows the quantum circuit used in our numerical experiments. It consists of alternating layers of one-qubit and two-qubit gates. This circuit has been designed following the proposal of [3] in order to create strongly entangled states in as few operations as possible. It it believed to be one of the most difficult circuit to simulate on a classical computer since its many-qubit quantum state is extremely sensitive to modification of any of the gates. The one-qubit gates U_n represented as colored squares in Fig. 18.1a are chosen randomly such as to remove any structure or symmetry from the many qubit state. A gate U_n is a rotation $U_n = \exp(-i\theta_n \vec{\sigma}.\vec{m}_n)$ of angle θ_n around a unit vector $\vec{m}_n = (\sin\alpha_n \cos\phi_n, \sin\alpha_n \sin\phi_n, \cos\alpha_n)$ ($\vec{\sigma}$ is the vector of Pauli matrices). We take the angles θ_n, α_n, and ϕ_n to be uniformly distributed (note that the resulting matrix U_n is *n*ot distributed according to the Haar distribution of $U(2)$). While the U_n are random, the actual sequence used is carefully recorded for comparison with e.g. exact calculations. We call the number of two-qubit gate layers applied the depth D of the circuit, focusing on the number of two-qubit gate layers because those are the only source of imperfection in our calculations. In real quantum computers, two-qubit gates also dominate the errors over one-qubit gates in terms of fidelity. However real quantum computers also have other sources of error (decoherence, unknown couplings between qubits, leakage to non-computational states...) not present in the algorithm. After a depth $D \sim N$, the state obtained with the circuit of Fig. 18.1a is totally scrambled and well described by a Porter-Thomas distribution. This is illustrated in Fig. 18.3 where the cumulative distribution of $p_x = |\langle x|\Psi\rangle|^2$ is compared to the Porter-Thomas form for various maximum MPS bond dimensions (main panel) and for various depths using exact calculations (inset). One indeed observes that the distribution quickly approaches the chaotic Porter-Thomas distribution as one increases the bond dimension χ.

18.3.3 Effective two-qubit gate fidelity

Let us introduce the main quantity of interest for this study, the effective two-qubit fidelity f_n. The effective two-qubit fidelity f_n is the computational analogue to the fidelity reported experimentally for two-qubit gates. $f_n = 1$ for a perfect calculation, but the truncation of the MPS will induce $0 < f_n < 1$.

Let us call $|\Psi_T(n)\rangle$ the MPS state after a sequence of n individual two-qubit gates ($n \approx (N-1)D/2$ for the circuit of Fig. 18.1a). Up to irrelevant one-qubit gates, $|\Psi_T(n)\rangle$ is obtained by applying one Control-Z gate C_Z onto $|\Psi_T(n-1)\rangle$ followed by the truncation operation which introduces a finite error. We define the effective fidelity f_n as,

$$f_n = |\langle \Psi_T(n)|C_Z|\Psi_T(n-1)\rangle|^2 \tag{18.13}$$

and the corresponding error rate ϵ_n as,

$$\epsilon_n = 1 - f_n. \tag{18.14}$$

f_n can be calculated using the contraction algorithm in $N\chi^3$ operations. However, when the MPS is in canonical form, f_n is simply obtained without any additional calculations as,

$$f_n = \left(\sum_{\mu=1}^{\chi} S_\mu^2\right) / \left(\sum_{\mu=1}^{2\chi} S_\mu^2\right) \tag{18.15}$$

where recall that 2χ is the maximum possible number of non-zero singular values of the tensor T' in Eq. (18.10). The denominator above is always equal to one for a state which is normalized before it is acted on by a two-qubit gate. We have explicitly checked the equivalence between the two algorithms.

A typical simulation is shown in Fig. 18.4 for the circuit with the Control-Z gate. At small depth $D < 2\log_2\chi$, the simulation is exact and $f_n = 1$. Above this threshold, one starts to truncate the MPS after each two-qubit gate. We observe a transient regime where f_n decreases after which f_n quickly saturates at a constant value, here around 0.988. The first thing to notice in Fig. 18.4 is that these simulations are many orders of magnitude easier than an equivalent *perfect* calculation: simulating the exact state for $N = 60$ and $D = 200$ would be out of reach even with thousand of years of computing time on the largest existing supercomputer. Yet here, these simulations of a *noisy* quantum computer have been performed on a laptop. The averaged fidelity for a modest $\chi = 64$ is better than 99% which already corresponds to qubits of very good quality. This is rather remarkable since the percentage of the Hilbert space spanned by the MPS ansatz is only a very tiny fraction $\sim 10^{-13}$ percent of the whole Hilbert space. After the transient regime, f_n is, up to some fluctuations, independent of both D and N. The second statement is true up to small $1/N$ corrections. These corrections arise from the fact that the fidelity associated with gates applied on the edge of the system (i.e. associated to matrices $M(i)$ with $i < 2\log_2\chi$ or $N - i < 2\log_2\chi$) is always equal to unity since the entanglement entropy associated to the subsystem of qubits $i < a$ is bounded by $S \leq a\log 2$.

Our main goal is to understand how the residual error $\epsilon_n = 1 - f_n$ decreases as one increases the bond dimension χ. As χ approaches $\chi = 2^{N/2}$, one must have $\epsilon_n \to 0$. This is because reshaping the wavefunction as a $2^{N/2} \times 2^{N/2}$ matrix implies a maximum rank of $2^{N/2}$ for any factorization of the wavefunction, thus an MPS with $\chi = 2^{N/2}$ remains exact. However, here we are interested in the regime $\chi \ll 2^{N/2}$ which remains accessible to simulations. Fig. 18.5 shows how the residual error $\epsilon_n = 1 - f_n$ decreases with increasing the bond dimension. The main finding of Fig. 18.5 is that the residual error per gate at large depth D and number of particle N eventually saturates at a finite value, in this case around $\epsilon_\infty \approx 10^{-2}$. In other words, this algorithm can simulate any 1D quantum computer that has a two-qubit gate fidelity smaller than $f_\infty = 99\%$ *at a linear cost in both* N *and* D. As the depth or number of qubits is reduced, the average fidelity increases. The black cross in Fig. 18.5 corresponds to a calculation where only the last part of the circuit has been taken into account in the calculation of the average fidelity, i.e. the average is performed for $D > 100$ where the system has already entered its stationary regime. Note that in that regime, there remains a small logarithmic decrease of the error: as χ increases a number $\propto \log_2\chi$ of gates close to the edges of the system become exact, as discussed above. The black line in Fig. 18.5 corresponds to calculation made in a larger system of $N = 240$ qubits where we have restricted the calculation of the fidelity to the gates for qubits in the center of the system (i.e. away from the edges where the fidelity is perfect) as well as removed the small depth regime (only gates for $100 \leq D \leq 200$ are taken into account). For this case, we observe a clear saturation of the error rate to a finite value ϵ_∞. As we shall see, decreasing the error rate beyond ϵ_∞ requires an exponential effort.

18.4 Links between two-qubit and multi-qubit fidelity

Before investigating the origin of ϵ_∞, we make a short detour to discuss how the effective two-qubit fidelity f_n is related to the actual N-qubit fidelity $\mathcal{F}$ of the state and is related to practical estimates of the fidelity that can be measured experimentally.

18.4.1 Multi-qubit fidelity

Let us call $|\Psi_P(n)\rangle$ the exact perfect state after n two-qubit gates—meaning it is never truncated or otherwise approximated at any stage of its evolution by the circuit—while $|\Psi_T(n)\rangle$

is the truncated MPS state (P stands for Perfect and T for Truncated). The N-qubit fidelity $\mathcal{F}$ is defined as,

$$\mathcal{F}(n) = |\langle \Psi_P(n) | \Psi_T(n) \rangle|^2 \tag{18.16}$$

The fidelity $\mathcal{F}$ is a direct measure of how reliable is our truncated state. As the errors accumulate, it is natural to expect that the fidelities f_n are multiplicative,

$$\mathcal{F}(n) \approx \prod_{i=1}^{n} f_i. \tag{18.17}$$

Eq. (18.17) is indeed a very accurate approximation. An analytical argument will be given below. The validity of Eq. (18.17) can also been shown by numerical simulations. Fig. 18.6 shows the fidelity versus D for $N = 20$ particles obtained in two independent ways. The symbols corresponds to a direct calculation of $\mathcal{F}$ while the lines correspond to the the right hand side of Eq. (18.17). We find an almost perfect match in all the regimes that we have studied. Eq. (18.17) is a very useful result: it relates a property of the perfect state (left hand side) to a property solely defined in terms of the MPS (right hand side). It allows us to easily estimate the fidelity in regimes where we do not have access to the exact state anymore. When f_n has reached its stationary value f_∞, Eq. (18.17) simplifies into

$$\mathcal{F}(n) \approx (f_\infty)^n \sim (f_\infty)^{\frac{ND}{2}}. \tag{18.18}$$

In an actual experiment, one cannot measure the f_n but rather one has access to an estimate of $\mathcal{F}(n)$ (see the subsection below). To compare the accuracy of the simulations with the capabilities of actual quantum chips, we therefore define the average two-qubit fidelity f_{av} after n two-qubit gates,

$$f_{\text{av}} = \left(\prod_{i=1}^{n} f_i \right)^{1/n} \approx \mathcal{F}(D)^{\frac{2}{ND}} \tag{18.19}$$

where the second equality is specific to the quantum circuit studied here.

Derivation of Eq. (18.17). Let us define a full basis of orthogonal states $|\alpha\rangle$ such that state $|1\rangle \equiv |\Psi_T(n-1)\rangle$ is our truncated state and we complement state $|1\rangle$ with an arbitrary basis. Writing $|\Psi_P(n-1)\rangle$ in that basis as $|\Psi_P(n-1)\rangle = \sum_{\alpha=1}^{2^N} p_\alpha |\alpha\rangle$, we have $p_1 = \sqrt{\mathcal{F}(n-1)}$. Similarly, we write $|\Psi_T(n)\rangle = \sum_{i=1}^{2^N} t_\alpha C_Z |\alpha\rangle$ with $t_1 = \sqrt{f_n}$. From these definitions, the fact that C_Z is unitary and that $|\Psi_P(n)\rangle = C_Z |\Psi_P(n-1)\rangle$, we have,

$$\mathcal{F}(n) = \left[\sum_{\alpha=1}^{2^N} p_\alpha t_\alpha \right]^2 = \left[\sqrt{\mathcal{F}(n-1) f_n} + \sum_{\alpha=2}^{2^N} p_\alpha t_\alpha \right]^2 \tag{18.20}$$

As the fidelity goes down, the p_α and t_α become increasingly decorrelated, in particular in sign. Assuming random signs between the p_α and the t_α and using that $p_\alpha \sim 1/\sqrt{2^N}$, we find that the second term in the above equation is at most of order $1/\sqrt{2^N}$ and is therefore negligible. Eq. (18.17) follows directly.

We end this subsection by proving a weaker but exact bound for shallow circuits without the above assumption.

The Schwartz inequality implies that,

$$\left(\sum_{\alpha=2}^{2^N} p_\alpha t_\alpha \right)^2 \leq \sum_{\alpha=2}^{2^N} p_\alpha^2 \sum_{\alpha=2}^{2^N} t_\alpha^2 \leq \epsilon_n \tag{18.21}$$

from which we obtain,

$$|\sqrt{\mathcal{F}(n)} - \sqrt{f_n \mathcal{F}(n-1)}| \leq \sqrt{\epsilon_n} \tag{18.22}$$

The Eq. (18.22) bound is exact, but saturating this bound in practice implies that all the terms $p_\alpha t_\alpha$ interfere constructively which is not realized in actual circuits. Eq. (18.22) implies that,

$$\begin{aligned} \mathcal{F}(n) &\geq \left(\sqrt{f_n \mathcal{F}(n-1)} - \sqrt{\epsilon_n}\right)^2 \\ &\geq \mathcal{F}(n-1) - 2\sqrt{\epsilon_n} \end{aligned} \tag{18.23}$$

from which one can prove that,

$$\mathcal{F}(n) \geq 1 - 2\sum_{i=1}^{n} \sqrt{\epsilon_i} \tag{18.24}$$

The exact statement Eq. (18.24) can be useful for small depth circuits where the actual decrease of the fidelity $\mathcal{F}(n)$ is indeed linear with n, before one enters into the true exponential regime.

18.4.2 Other fidelity metrics

So far we have used the overlap $\mathcal{F}$ between the exact state $|\Psi_P\rangle$ and our approximate state $|\Psi_T\rangle$ as our metric for the fidelity of the calculation. It is a natural metric as it measures the probability for the approximate state to be in the exact state one. It is bounded $0 \leq \mathcal{F} \leq 1$ and is nicely related to the probabilities per gate f_n through the formulas of the preceding subsection.

However $\mathcal{F}$ cannot be directly measured experimentally, so that other fidelity metrics must be designed. Indeed, in an actual quantum computer, the only existing output are samples of bitstrings $x = i_1 i_2 ... i_N$ distributed according to $|\langle x|\Psi_T\rangle|^2$. A natural metric is the cross entropy defined as

$$\mathcal{C} = -\sum_x |\langle x|\Psi_T\rangle|^2 \log |\langle x|\Psi_P\rangle|^2 \tag{18.25}$$

Cross entropy is a standard tool of machine learning and has several interesting properties. First it is measurable through sampling as

$$\mathcal{C} = -\lim_{M\to\infty} \frac{1}{M} \sum_{m=1}^{M} \log |\langle x_m|\Psi_P\rangle|^2 \tag{18.26}$$

where the x_m are the output of the quantum computer when the experiment is repeated M times. Second, the cross entropy between two distributions $|\langle x|\Psi_T\rangle|^2$ and $|\langle x|\Psi_P\rangle|^2$ is maximum when the two distribution are identical. Hence it is a genuine measure of the likelihood of the two distributions. Cross entropy was proposed in [3] as a fidelity metric. Note however that the cross entropy is not a symmetric function of the two distributions. In particular it is strongly affected by particular configurations x where $|\langle x|\Psi_P\rangle|^2$ is very low but $|\langle x|\Psi_T\rangle|^2$ is not.

Cross entropy was eventually abandoned by the Google team and replaced [4] by the cross entropy benchmarking (XEB) defined as

$$\mathcal{B} = -1 + 2^N \sum_x |\langle x|\Psi_T\rangle|^2 |\langle x|\Psi_P\rangle|^2 \tag{18.27}$$

XEB is also sampleable and is symmetric with respect to the two distributions. When the approximate state is the uniform distribution, the XEB metric vanishes, $\mathcal{B} = 0$ indicating a total lack of fidelity. However, when the approximate state is actually exact, the value of the XEB metric can be arbitrary. When the approximate state is exact *and* distributed according

to the Porter Thomas distribution (which happens in our circuits after a few cycles), then the XEB metric gets a well defined $\mathcal{B} = 1$ value. The XEB metric is not in general a good measure of the likelihood between two distributions: for a given perfect state, it is maximum when the approximate state is sharply peaked around the values of x where the perfect state is maximum. In our circuit the initial value of XEB is exponentially high $\mathcal{B} = 2^N - 1$ and quickly decreases as the distribution approaches the Porter-Thomas one. Calling D^* the depth after which XEB has reached unity (ideally D^* would the depth after which $|\langle x|\Psi_P\rangle|^2$ corresponds to Porter-Thomas), we find empirically that

$$\mathcal{F}_n \approx \mathcal{F}(D^*)\mathcal{B}_n \tag{18.28}$$

Equation (18.28) could be used to estimate the actual fidelity $\mathcal{F}$ from XEB measurements.

Figure 18.7 show an example of calculations contrasting the fidelity $\mathcal{F}$ with the XEB metric. Here we have used no truncation but added some noise on the two qubit gate so as to induce a finite fidelity per gate f. We find that both $\mathcal{F}$ and XEB decay exponentially with consistent decay rates. However, the large difference of the initial values at $D = 0$ leads to a shift of the fidelity which is significantly lower than the XEB curve. This shift increases as the fidelity is lowered and corresponds typically to one order of magnitude for a typical experimental value $f = 99\%$.

18.5 Random Tensor Theory of ϵ_∞

We now turn back to the discussion of the asymptotic value f_∞ reached by the two-qubit gate fidelity in our calculations. The first remark of importance is that f_∞ is a property associated with a single tensor of the full MPS state: if we apply a gate between qubit i and qubit $i+1$, only the associated T' tensor defined in Eq. (18.10) comes into play. Since the whole goal of our quantum circuit is to scramble the wavefunction as efficiently as possible, a natural hypothesis is that the tensors $M(i)$ and $M(i+1)$ become eventually well described by totally random tensors. In this section we explore this possibility and calculate the properties of the associated tensor T' as well as the corresponding two-qubit gate fidelity $f_{\rm GTE}$. We find that the distribution of singular values of T' obtained from the random ensemble closely matches what we observe in the MPS state.

In the spirit of random matrix theory [22, 23], we introduce the Gaussian tensor ensemble (GTE) where a tensor $M^i_{\mu\nu}$ is supposed to be totally random. The GTE can be thought of as a "worse case scenario" where the quantum circuit is so chaotic that the tensors are left with no structure. In the GTE, the tensor M are distributed according to

$$P\left[M^i_{\mu\nu}\right] \propto \exp\left[-\frac{1}{2}\sum_{\mu\nu i}|M^i_{\mu\nu}|^2\right] \tag{18.29}$$

where the sum over ν spans $1\dots\chi$, the sum over i spans $0, 1$ and the sum over μ span $1\dots\beta\chi$. In the remaining of this section, we restrict ourselves to $\beta = 1$ which corresponds to the tensors of Eq.(18.6). We shall have an example of $\beta = 2$ for the grouped-qubit algorithm we will discuss in section 18.6. From two such tensors, we apply a two-qubit gate following Eq.(18.8)-(18.12) constructing the associated tensor T and T' and the SVD of T'. From the $2\beta\chi$ singular values S_μ of T', we can obtain the associated fidelity $f_{\rm GTE}$ through Eq. (18.15).

Fig. 18.8 studies the distribution of the singular values S_μ for tensor T' obtained from the GTE. The singular values are sorted in order of decreasing magnitude and plotted as a function of the index $\mu = 1, \dots, 2\chi$. Plotting χS^2_μ as a function of μ/χ, we observe that all the different values of χ collapse onto a single curve. In other words, we find that there is some function

$g(x)$ such that

$$S_\mu^2 = \frac{1}{\chi} g\left(\frac{\mu}{\chi}\right). \tag{18.30}$$

This scaling is already valid for rather small values of χ. This observation can probably be put on firm mathematical grounds - it is consistent with the usual scaling of the semi-circular law of the so-called Gaussian unitary ensemble - but for the moment it is merely an empirical statement made from numerical evidence. It follows from this scaling that f_{GTE} very quickly converges to

$$f_{\mathrm{GTE}} = \frac{\int_0^1 dx\ g(x)}{\int_0^{2\beta} dx\ g(x)}. \tag{18.31}$$

In other word, one finds a finite value of the fidelity that is independent of χ. The resulting f_{GTE} depends on the other hand on the two-qubit gate used. Control-Z (C_Z) and control-NOT (C_X) are equivalent (they are related to each other through a change of basis of the second qubit) and corresponds to $f_{\mathrm{GTE}} = 96.2\%$. Gates like the iSWAP gate (iS) or iSWAP followed by a $\pi/6$ rotation over the z-axis ($iS_{\pi/6}$, close to what is used in [4]) have 4 different singular values which roughly doubles the error with respect to C_Z ($f_{\mathrm{GTE}} = 93.2\%$).

Fig. 18.9 shows how the distribution of the singular values in the GTE compares to the one obtained in the MPS simulation. We find a close agreement between GTE and the MPS simulations when looking at the T' tensor for a gate in the center of the system and at large depth. The agreement is not perfect however, and we observe that the asymptotic fidelity of MPS simulations is always better than the one found in GTE,

$$f_\infty \geq f_{\mathrm{GTE}}. \tag{18.32}$$

To try and understand why the inequality in Eq. (18.32) is not saturated, we plot in Fig. 18.9 the distribution of the singular value of the initial tensor M (dotted line). After truncation, the distribution of the singular values of M' are given by the dashed line restricted to $0 \leq \mu/\chi \leq 1$ (up to a small shift due to the normalization of the state). These two distributions differ very significantly. In order to saturate the bound of Eq. (18.32) we would need extra steps to scramble the distribution of M' back to the distribution of M (i.e. go from the dashed line to the dotted line). However, since in our protocol only a single one-qubit gate separates one truncation from the next one, we find that it is not sufficiently chaotic and therefore we never reach the "worse case scenario" of the GTE.

To summarize, f_{GTE} can be thought as a lower bound for the fidelity found in the simulations for large enough χ (typically $\chi \geq 300$ in practice) and large enough depth. Getting beyond the asymptotic value requires algorithms that have an exponential cost. In the following section we describe possible strategies.

18.6 Algorithms for getting beyond ϵ_∞

The algorithm discussed above can also be used for 2D arrays, since any two qubit gates between distant qubits can always be written as a combination of gates on neighboring qubits using SWAP gates. However, this is inefficient and leads to a decrease of the effective f as the transverse dimension of the 2D array increases. Another limitation of the above algorithm is that one cannot efficiently simulate systems that have a fidelity above f_∞.

There are multiple strategies that could be used to go beyond the above algorithm. In particular, recent progress in the algorithms for contracting tensor networks, such as [9] could be interesting candidates in 2D. Below, we follow a very simple strategy where we keep using MPS states, but group the qubits so that each tensor now represents several qubits.

18.6.1 Grouped MPS State and Extraction Algorithm

We now consider the MPS structure sketched in Fig. 18.1c where each tensor addresses several qubits. We now have $P \leq N$ tensors $M(n)$ each addressing N_n qubits with $\sum_{n=1}^{P} N_n = N$. The tensors $M(1)$ and $M(P)$ possess $N_n + 1$ indices while the others possess $N_n + 2$ indices,

$$M(n)_{\mu\nu}^{i_1 i_2 \ldots i_{N_n}} \tag{18.33}$$

The number of elements of these tensors is $\chi^2 2^{N_n}$ so that the computing time now increases exponentially with the number of qubits per tensor. On the other hand, the two qubit gates that are performed inside a given tensor $M(n)$ are now handled exactly, so that the average fidelity of a circuit increases.

To perform a two-qubit gate between neighboring tensors $M(n)$ and $M(n+1)$, one proceeds in three steps. The first two are shown diagrammatically in Fig. 18.10. In the first step, one performs a QR decomposition of the two tensors to "extract" smaller tensors corresponding to the involved qubits. Assuming (without loss of generality) that the two qubit gate involves qubit N_n of tensor $M(n)$ and qubit 1 of tensor $M(n+1)$, one decomposes $M(n)$ as

$$M(n)_{\mu\nu}^{i_1 i_2 \ldots i_{N_n}} = \sum_{\sigma=1}^{2\chi} Q(n)_{\mu,\sigma}^{i_1 i_2 \ldots i_{N_n - 1}} R(n)_{\sigma,\nu}^{i_{N_n}} \tag{18.34}$$

where the "vectors" of $Q(n)$ indexed by σ are orthonormal. The important point here is that the index σ takes only 2χ values. Similarly, we write:

$$M(n+1)_{\nu\rho}^{i'_1 i'_2 \ldots i'_{N_{n+1}}} = \sum_{\sigma=1}^{2\chi} R(n+1)_{\nu,\sigma'}^{i'_1} Q(n+1)_{\sigma',\rho}^{i'_2 \ldots i'_{N_{n+1}}} \tag{18.35}$$

The second step follows Eqs. (18.8)-(18.12) of the algorithm of Section 18.3 with the replacement $M(n) \to R(n)$ and $M(n+1) \to R(n+1)$, and is shown for the present case in Fig. 18.10(b). In the last step the new tensors $M'(n)$ and $M'(n+1)$ are obtained by contracting $Q(n)$ with $R'(n)$ and $R'(n+1)$ with $Q(n+1)$.

The main difference between the algorithm of Section 18.3 and the grouped MPS algorithm is that the resulting tensor T' of Eq. (18.10) now has 4χ singular values instead of 2χ. As a result, upon truncation to keep only χ singular values, we anticipate that the fidelity per gate will be smaller than in the 1D case. However, as we shall see, this decrease will be more than compensated by the gain of having perfect gates within one tensor. In the terminology of random tensors, the grouped MPS algorithm corresponds to $\beta = 2$. For the C_Z gate, the GTE fidelity drops from $f_{\rm GTE}(\beta = 1) = 96.2\%$ down to $f_{\rm GTE}(\beta = 2) = 87.4\%$.

18.6.2 Application to a two dimensional circuit

We now show the results of simulations performed on a 2D circuit. To put the results into the perspective of what can be achieved experimentally, we choose a circuit very close to the one used by the Google team in their "supremacy" experiment [4]. We consider a 2D grid of 54 qubits as shown in Fig. 18.11a. The circuit is shown in Fig. 18.11b and alternates one-qubit gates applied to each qubit (same distribution as in the 1D case) with two-qubits gates (Control-Z) applied on different pairs of qubits according to the color shown. Except for the choices of one- and two-qubit gates, and the number of qubits (53 versus 54), the setup is identical to the "supremacy sequence" of the Google experiment [4]. In Ref.[4] a XEB fidelity $\mathcal{B} = 0.002$ was reached after a depth $D = 20$ corresponding to a total of 430 two-qubit gates. Ignoring the difference between XEB and the fidelity $\mathcal{F}$, this translates into $\epsilon_{\rm av} = 1.4\%$ which we shall use as our reference value to evaluate the performance of the grouped MPS algorithm.

Fig. 18.11c shows various strategies for grouping the qubits. The $[1^{12}]$ grouping corresponds to 12 tensors that contains one column of qubit each (i.e. alternatively 5 and 4 qubits). The $[6, 6]$ grouping is the most expensive computationally with two tensors of 27 qubit each. Note that the tensors on the edges are less computationally costly than the middle ones, since they only have one bond index. The results of the simulations are shown in Fig. 18.12 for a depth of $D = 20$. While the error rate is significantly larger than in the 1D case, we find that it can be brought down to less than 1.4% (which corresponds to a global fidelity of $\mathcal{F} = 0.002$) on a single core computer. The computing times of the data points of Fig. 18.12 range from a few seconds to less than 48 hours for the most expensive points on a non-parallel code (single core calculation). We find that the grouping strategy is effective, but not as efficient as the maximum gain that one could expect: even though some of the gates become perfect upon grouping, we observe a decrease of the fidelity for the noisy gates which reduces the overall gain. For $\chi = 320$ and the $[4, 2, 2, 4]$ partition where the final fidelity is slightly better than $\mathcal{F} = 0.002$ (see Fig. 18.12), the memory footprint of the calculation is 4.5 GB of memory which represents only 1.5×10^{-6} percent of the size of the total Hilbert space spanned by the 2^{54} qubits.

18.6.3 Split-and-Merge algorithm for more complex gates

We end this article with results in a configuration that closely matches the one of Ref. [4]. The one-qubit gates are chosen at random between $\sqrt{X}$, $\sqrt{Y}$ and $\sqrt{W}$ while the two-qubit gate iS_θ is a combination of iSWAP followed by a controlled rotation along the z axis

$$iS_\theta = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & -i & 0 \\ 0 & -i & 0 & 0 \\ 0 & 0 & 0 & e^{-i\theta} \end{pmatrix} \tag{18.36}$$

This gate has four different singular values and is therefore expected to produce more entanglement than the C_Z gate. The link between number of singular values and the actual growth of entanglement is not totally straightforward, however. Indeed, the pure iSWAP gate has four different singular values ± 1 and $\pm i$; yet as it preserves the structure of product states, it is trivial to simulate with perfect fidelity. In what follows, we use $\theta = 1$ which is non-trivial to simulate.

The algorithm of the previous subsection behaves rather poorly for the iS_θ gate. For instance, for $\chi = 128$, and the $[4, 2, 2, 4]$ grouping, the two-qubit gate fidelity drops from $f \approx 98\%$ (C_Z) to $f \approx 92\%$ (iS_θ). However, a simple modification of the algorithm allows one to recover a much higher fidelity $f \approx 95\%$.

To study iS_θ, we therefore switch to a "Split-and-Merge" strategy: instead of "extracting" qubits one-by-one to perform two-qubit gates as in Section 18.6.1, we extract one full column of qubits at a time. In the Split-and-Merge strategy, we use two different groupings of the qubits, for instance switching between the $[4, 2, 2, 4]$ grouping and the $[5, 2, 5]$ grouping (hereafter referred to as the $[4, 2, 2, 4] \leftrightarrow [5, 2, 5]$ grouping strategy). Switching from one grouping to another induces truncation errors. However, once the switching has been done, many two-qubit gates can be performed exactly. A schematic of the Split and Merge strategy is shown in Fig. 18.13 for the $[4, 2, 2, 4] \leftrightarrow [5, 2, 5]$ case.

Fig. 18.14 shows our numerical results for ϵ_{av} versus χ. The curves are very similar to those obtained for C_Z at similar computational cost, but with an error rate roughly three times larger than with C_Z.

To conclude this section, we have shown that for the Control-Z gate a simple grouping strategy allows one to reach the same fidelity as the Google experiment [4] in a matter of hours on a single core computer (i.e. $f_{\rm av} \geq 98.6\%$). For the more challenging iS_θ gate, this fidelity drops down to 95% for similar computing time.

A natural question that arises is whether these algorithms may be used to defeat the claim of quantum supremacy put forward in [4], i.e. raise the fidelity from 95% to $> 98\%$. We have not be able to do so on a single core implementation. However, the Split-and-Merge is to a large extent trivially parallelizable since most tensor operations contain "spectator" indices whose different values can be fixed, and the resulting tensor "slices" dispatched to different computing cores or nodes. Extrapolations from our results suggest that such a parallel implementation should be able to reach fidelities in the $98 - 99\%$ range with a few hundred cores and a few terabytes of memory. However, such a calculation has not be attempted at the moment. Let us note, in any case, that not too much emphasis should be put on quantum supremacy by itself. It is not because a task is difficult to simulate that it provides a useful output. Also, there is no question that quantum many-body problems are extremely difficult to simulate. The insight that we get from the present work is an estimate of the relation between the accuracy reached in the quantum state and the underlying amount of entanglement that could potentially be exploited.

18.7 Discussion

In this work, we have discussed a practical algorithm that allows to simulate a quantum computer in a time which grows linearly with the number of qubits N and the depth D at the cost of having a finite fidelity f per two-qubit operation. The fidelity f can be increased at a polynomial cost up to a finite value f_∞; increasing it further has an exponential cost in the fidelity. Our main observation is that fidelities of the order of 99%, which are typical fidelities found in state of the art experiments, can be reproduced at a moderate computational cost.

Is a fidelity of 99% large or small? From an experimental physics perspective, it is certainly quite an achievement to keep several dozen qubits at this level of fidelity. From a quantum information and classical algorithms point of view, a question is what is the level of entanglement—hence the actual fraction of the Hilbert space that can truly been accessed—associated with this level of fidelity. Our MPS ansatz can provide an estimate (or at least an upper bound for one may come up with better algorithms) for this fraction. Since the MPS ansatz only spans a very tiny fraction of the overall Hilbert space, it follows that the computational power associated with fidelities in the 99% range is much more limited than the full size 2^N of the Hilbert space would suggest. We conclude that increasing the computational power of a quantum computer will primarily require increasing the fidelity/precision with which the different operations are performed [24]. Secondarily, one could try to improve its connectivity with e.g. quantum buses [25] as we have seen that 1D simulations are far easier than 2D ones. However, increasing the number of qubits will remain ineffective until better fidelities have been reached.

As a side comment, our approach could also be used to get lower bounds for quantum error correction (QEC) schemes [26]. Suppose that for a certain connectivity, one has an algorithm that can reach a fidelity f in polynomial time in N and D. Then, it is reasonable to expect that any QEC code has a threshold $p > f$. If it were not the case, one could build a logical quantum computer with a classical one at a polynomial cost by simply simulating the QEC protocols on the classical computer. In this respect, extending our approach to a truly 2D algorithm (beyond the quasi-1D one discussed in this article) would be particularly interesting. Indeed, 2D surface codes have a particularly low threshold $p \approx 99\%$. How close to $f = 99\%$ can one get at a polynomial cost in 2D is currently an open question.

Finally, it would be interesting to perform a similar study, but of how well MPS of practical sizes can approximate circuits designed for *useful* tasks. Goals could include estimating minimum fidelities needed to perform these tasks with a high success probability and understanding crossovers where useful quantum algorithms begin to offer advantages over classical approaches.

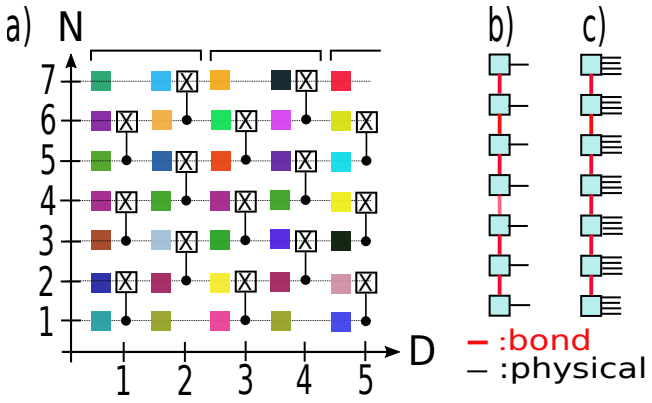

Figure 18.1: a) Sketch of the quantum circuit with N qubits. The colored squares indicate arbitrary one-qubit gates while the dots connected to a cross indicate a two qubit gate such as Control-NOT or Control-Z. The depth D counts the number of two-qubit gates performed in the sequence. b) structure of the Matrix Product States (MPS) for 1D circuits. Red lines indicate bond (or virtual) indices while thin black lines correspond to physical indices. c) MPS structure for quasi-one dimensional structures.

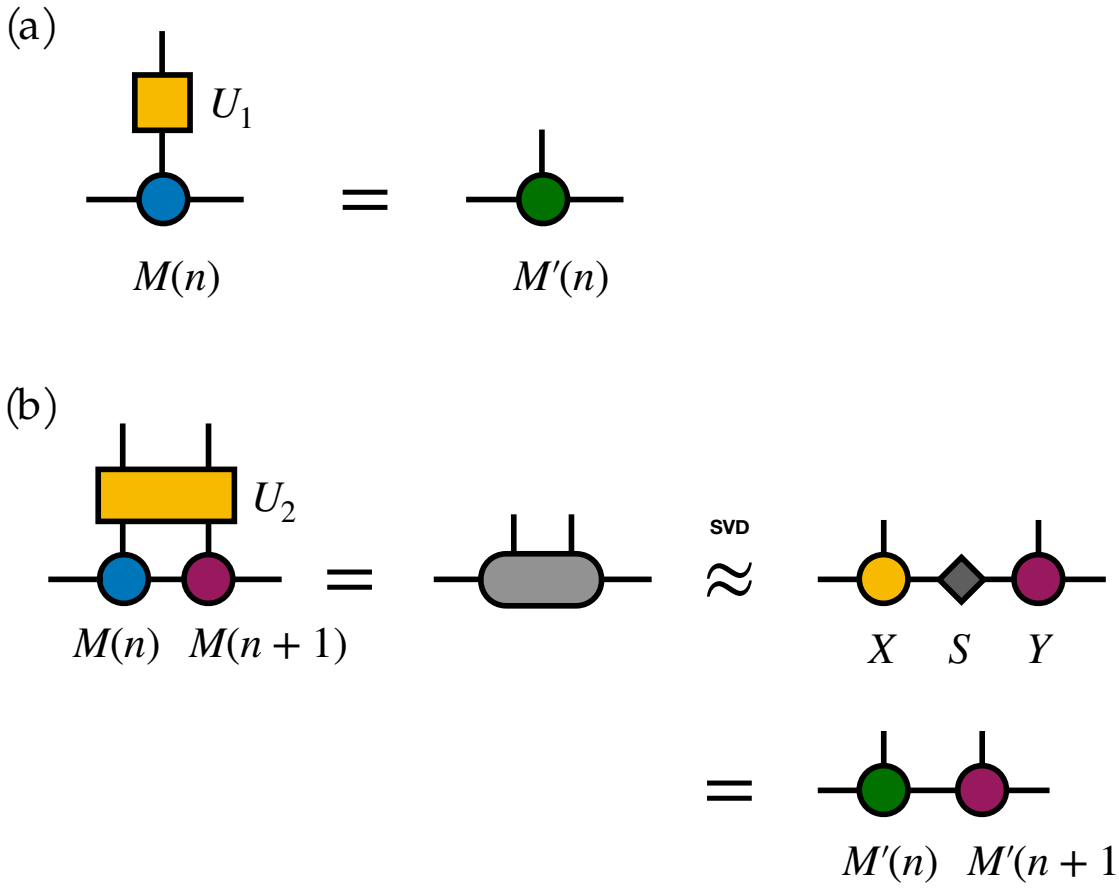

Figure 18.2: (a) Applying a single qubit gate to an MPS can be done without approximation by multiplying the gate by a single MPS tensor. (b) To apply a two-qubit gate to qubits n and $n+1$, one contracts the corresponding tensors together, then applies the gate. To restore the MPS form, the resulting tensor is decomposed with an SVD truncated to keep the largest χ singular values, and the matrix of singular values is multiplied into one of the unitary factors X or Y.

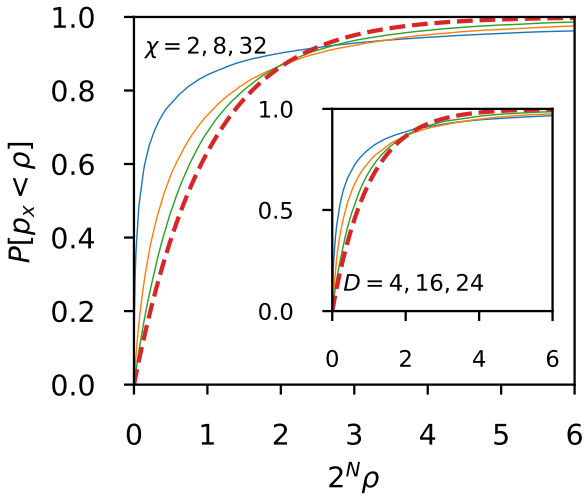

Figure 18.3: Cumulative distribution $P(p_x < \rho)$ where $p_x = |\langle x|\Psi\rangle|^2$ for $N = 15$. The dashed line corresponds to the Porter-Thomas distribution $P_{PT}(\rho) = 1 - (1-\rho)^{2^N-1}$. Main panel: $D = 24$ and various MPS truncation levels $\chi = 2$ (blue), 8 (orange), and 32 (green). Inset: exact results for $D = 2$ (blue), 16 (orange), and 24 (green)

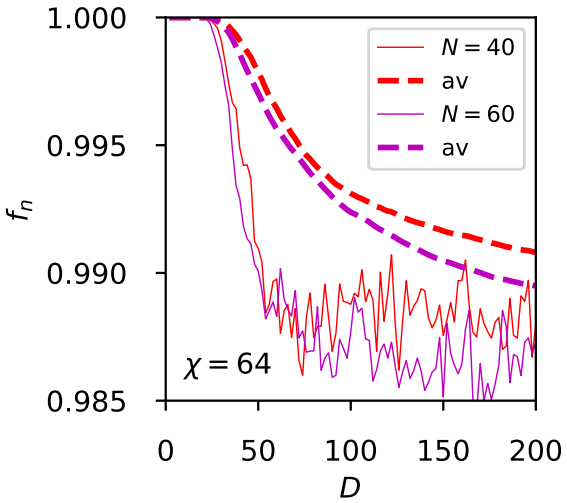

Figure 18.4: Effective two-qubit gate fidelity f_n as a function of the depth D of the circuit for $\chi = 64$ and the Control-Z gate for $N = 40$ (red) and $N = 60$ (magenta). The thin lines correspond to the geometric average of f_n over one full sequence, i.e. all the two-qubits gates performed between depth $D-2$ and depth D ($N-1$ two-qubits gates). The thick dashed lines correspond to f_{av}, the geometric average of f_n over all two-qubit gates since the beginning of the circuit up to depth D.

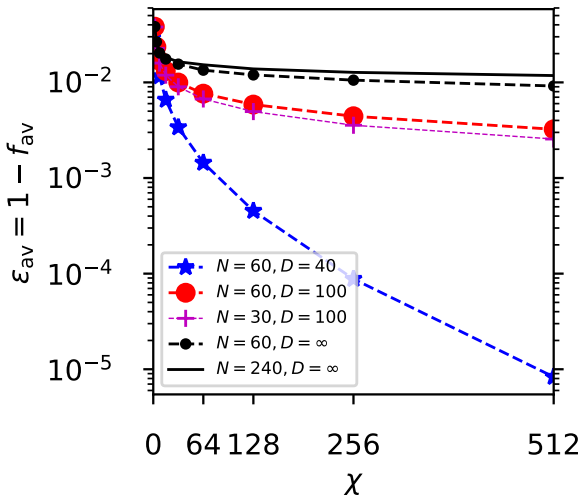

Figure 18.5: Geometric average of the residual error per gate $\epsilon_{\rm av} = 1 - f_{\rm av}$ as a function of the bond dimension χ. The average is performed over the entire circuit except for the black curves ($D = \infty$) where it is restricted to the regime where the fidelity has reached its asymptotic value ($100 \leq D \leq 200$). For the largest system $N = 240$, we have also excluded the gates on the edges of the system in our calculation as they have by construction perfect fidelity.

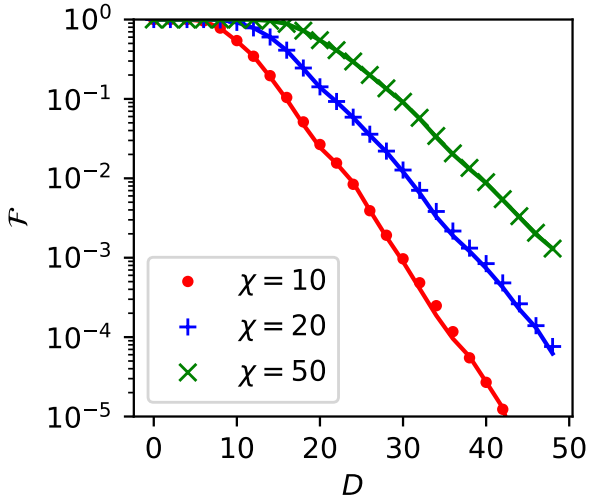

Figure 18.6: Fidelity $\mathcal{F}$ versus depth D for $N = 20$ and various values of $\chi = 10, 20, 50$. The symbols correspond to a direct calculation of $\mathcal{F}$ obtained by comparing with an exact calculation. The lines corresponds to the right hand side of Eq. (18.17).

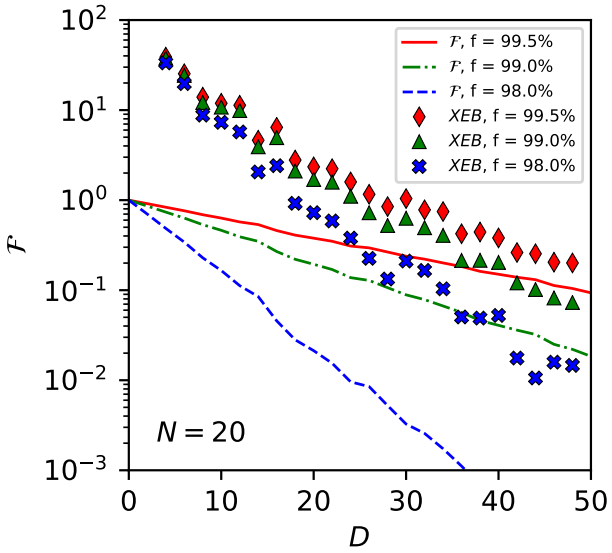

Figure 18.7: Comparison between the fidelity $\mathcal{F}$ (lines) and the XEB metric $\mathcal{B}$ (markers) as a function of depth D. Different colors label different levels of noise on the two-qubit gates, respectively $f = 99.5\%$ (red), $f = 99\%$ (green) and $f = 98\%$ (blue). The calculations were performed for the 1D random circuit with $N = 20$ qubits.

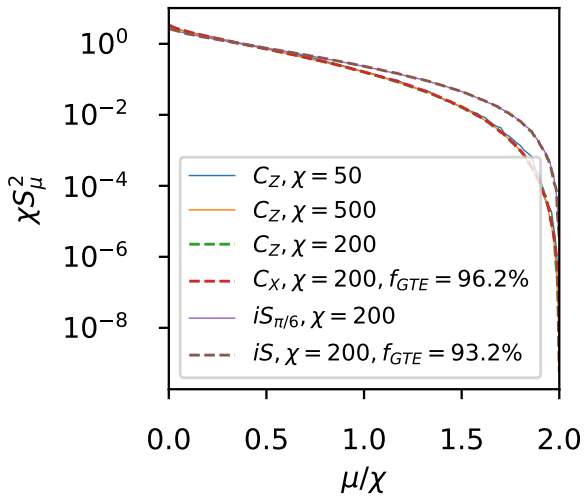

Figure 18.8: Squared singular values S_μ^2 of the matrix T' obtained from the GTE ensemble. We find a perfect scaling of the form $S_\mu^2 = g(\mu/\chi)/\chi$ where μ is the index of the μ^{th} singular value. The two bundles of curves correspond respectively to the C_X,C_Z gates (two non-zero eigenvalues) and the $iS_{\pi/6}/iS$ gates (four non-zero eigenvalues). Within one bundle, the different curves are indistinguishable.

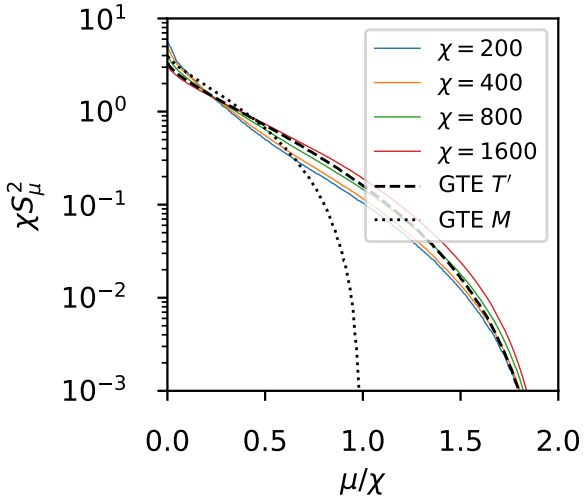

Figure 18.9: Squared singular values S_μ^2 of the matrix T' obtained from the MPS simulations of $N = 30$ qubits and a depth of $D = 60$ for various values of χ. The singular values correspond to a gate C_X performed in the middle of the system. Dotted line: Squared singular values of the M matrix in in the GTE. Dashed line: Squared singular values of T' in the GTE.

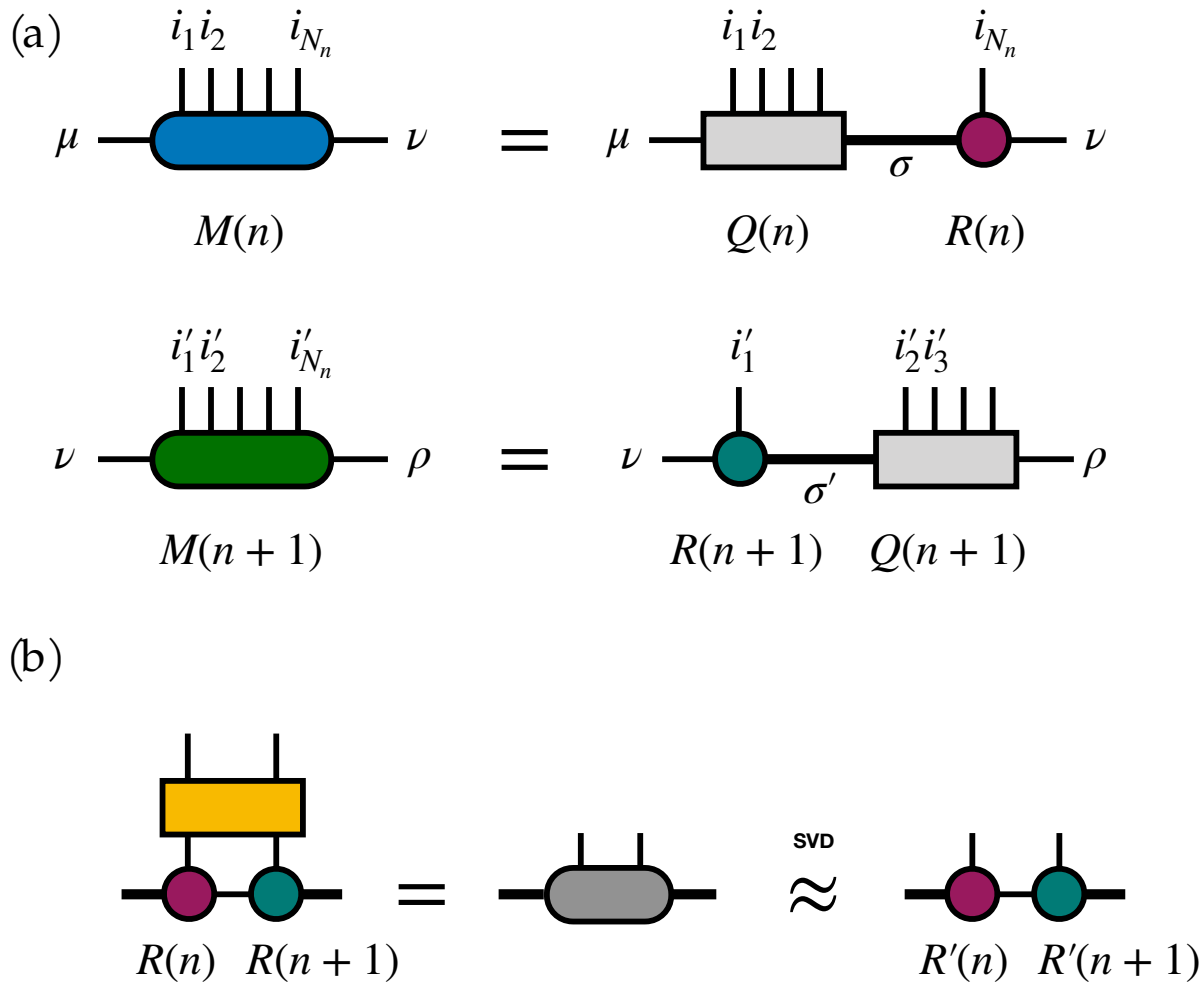

Figure 18.10: Main steps for applying a gate which acts across two grouped MPS tensors, as described in Eqs. (18.34)–(18.35). In (a) the grouped MPS tensors $M(n)$ and $M(n+1)$ are exactly factorized using QR decompositions, such that the $R(n)$ and $R(n+1)$ tensors carry the qubit indices acted on by the gate and the newly introduced indices σ and σ' range over 2χ values. In (b) the gate acts on the product of $R(n)$ and $R(n+1)$, and the resulting tensor is factorized using an SVD truncated to χ singular values. Finally, to update the MPS (not shown), one computes the new tensors $M'(n) = Q(n)R'(n)$ and $M'(n+1) = R'(n+1)Q(n+1)$ which diagrammatically looks like step (a) but in reverse.

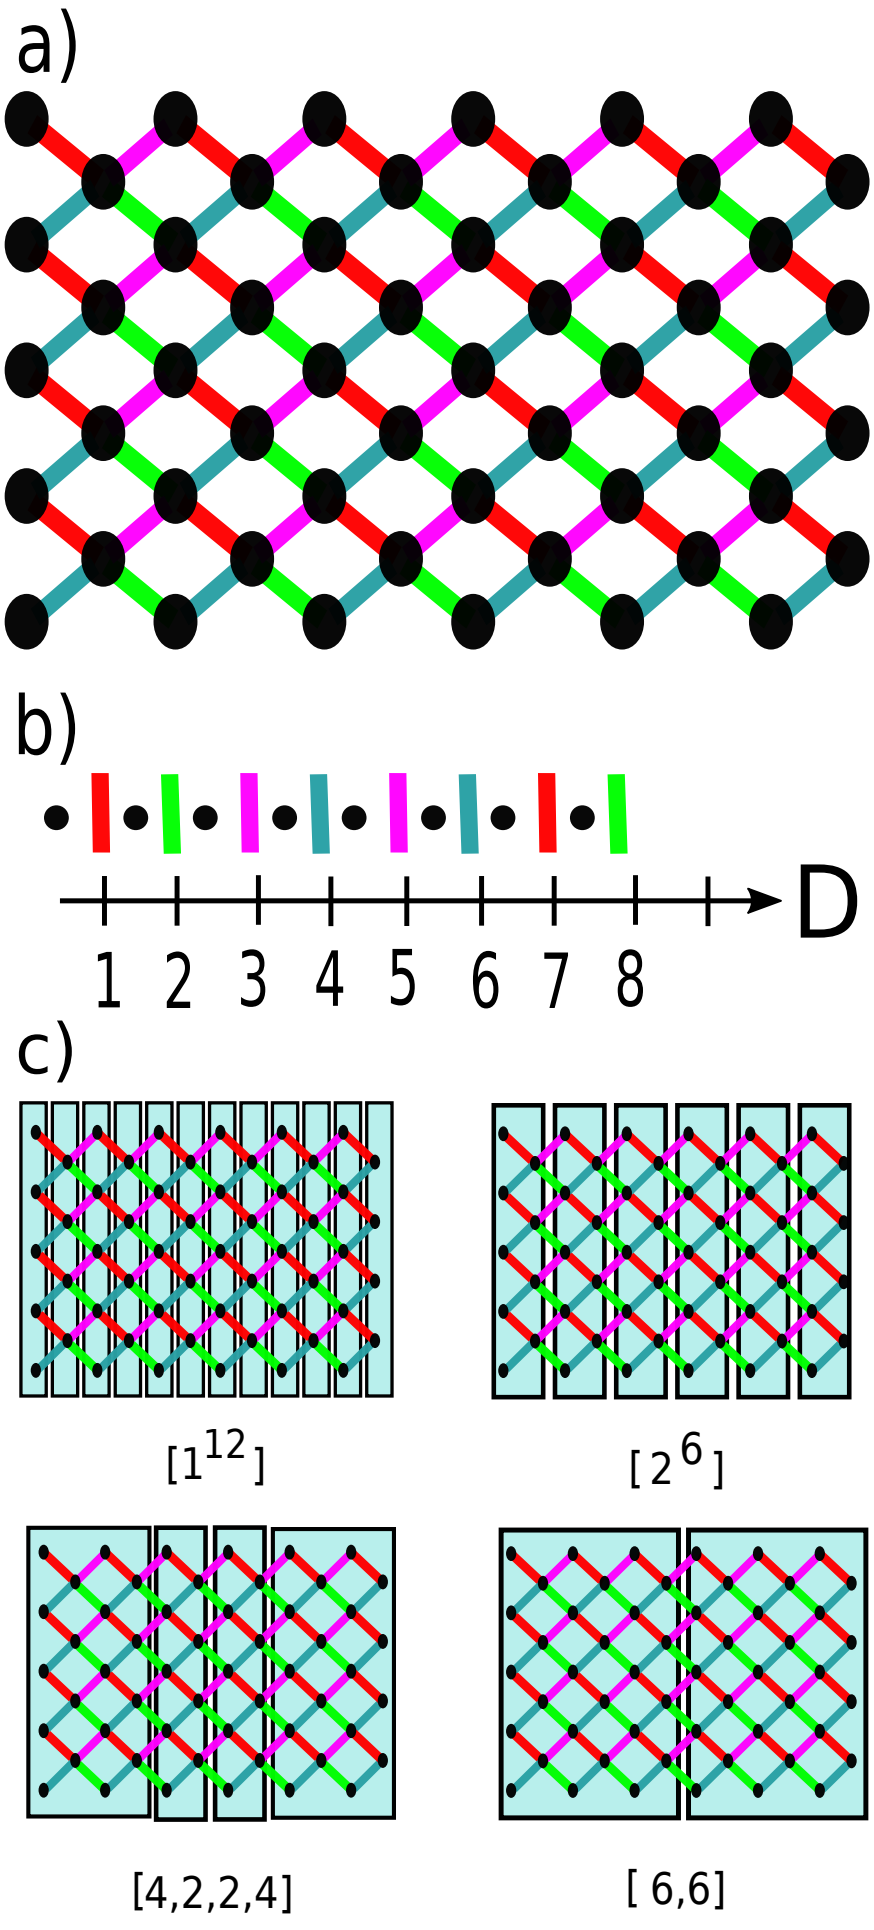

Figure 18.11: a) Sketch of the quantum circuit with 54 qubits in a 2D grid. The qubits are represented by the black dots while the two-qubit gates by the color links. b) The circuit alternates one-qubit gates (black dots) with two-qubit gates (here the Control-Z gate). The

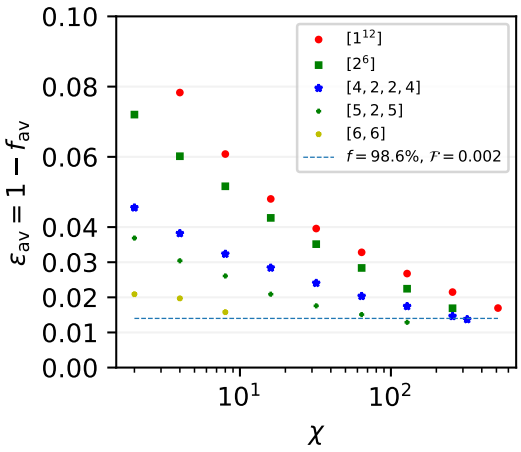

Figure 18.12: Residual error per gate $\epsilon_{\text{av}} = 1 - f_{\text{av}}$ as a function of the bond dimension χ for the $2D$ circuit of Fig. 18.11 for a depth $D = 20$. The different curves correspond to different groupings. The horizontal dashed line corresponds to the error rate associated with a global fidelity $\mathcal{F} = 0.002$.

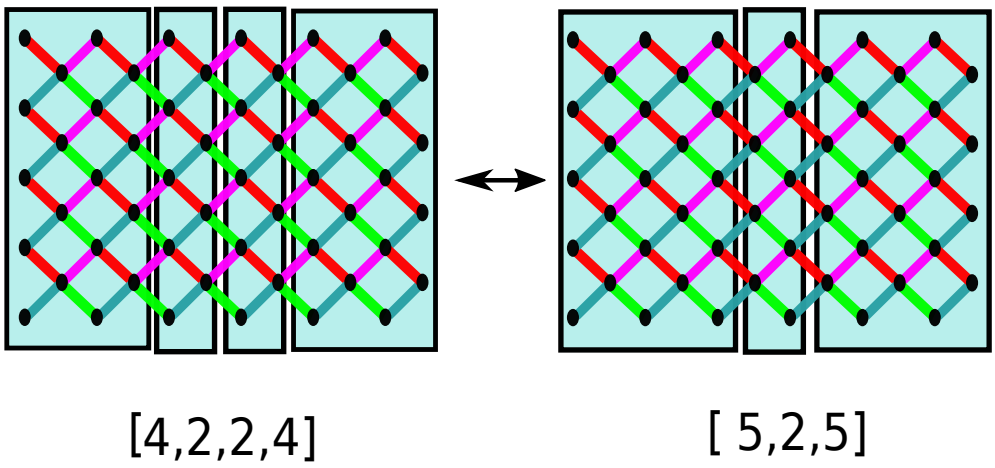

Figure 18.13: Schematic of the Split-and-Merge algorithm for the $[4, 2, 2, 4] \leftrightarrow [5, 2, 5]$. The two-qubit gates shown in red and dark green are performed in the $[4, 2, 2, 4]$ configuration and one switches to the $[5, 2, 5]$ to perform the light green and purple gates.

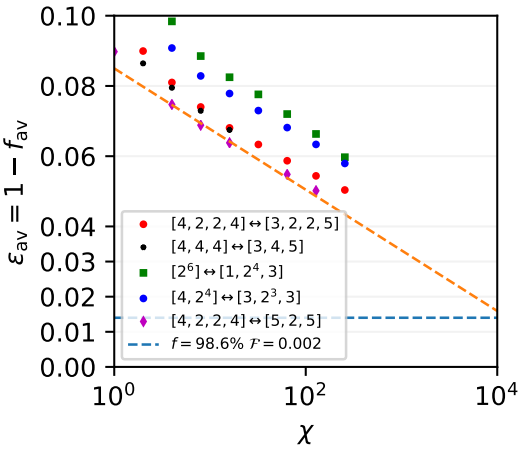

Figure 18.14: Residual error per gate $\epsilon_{\text{av}} = 1 - f_{\text{av}}$ as a function of the bond dimension χ for the iS_θ gate for a 2D circuit with $N = 54$ qubits and a depth $D = 20$. The different curves correspond to different groupings. The horizontal dashed line corresponds to the error rate associated with a global fidelity $\mathcal{F} = 0.002$. The orange line is just a guide to the eye.

19 How the Result of a Measurement of a Component of the Spin of a Spin-$\frac{1}{2}$ Particle Can Turn Out to be 100 by Aharonov, Albert, and Vaidman (1987)

Abstract

We have found that the usual measuring procedure for preselected and postselected ensembles of quantum systems gives unusual results. Under some natural conditions of weakness of the measurement, its result consistently defines a new kind of value for a quantum variable, which we call the weak value. A description of the measurement of the weak value of a component of a spin for an ensemble of preselected and postselected spin-$\frac{1}{2}$ particles is presented.

This paper will describe an experiment which measures a spin component of a spin $-\frac{1}{2}$ particle and yields a result which is far from the range of "allowed" values. We shall start with a brief description of the standard measuring procedure. Considering measurements on an ensemble of preselected and postselected systems, we shall define a new concept: a weak value of a quantum variable. And, finally, we shall describe the measurement of the weak value on the example of a spin $-\frac{1}{2}$ particle.

In quantum theory, the result of a measurement of a variable A which has discrete eigenvalues a_i must necessarily be one of those values. The Hamiltonian of the standard measurement procedure [1,2] is

$$H = -g(t)qA, \tag{1}$$

where $g(t)$ is a normalized function with a compact support near the time of measurement, and q is a canonical variable of the measuring device with a conjugate momentum π. The initial state of the measuring device in the ideal case has to be such that π is well defined. After the interaction (1) we can ascertain the value of A from the final value of π: $A = \delta\pi$.

As a reasonable approximation for a real situation, we may take the initial state of the measuring device as a Gaussian in the q (and consequently also in the π) representation. For this case, the Hamiltonian (1) leads to the transformation

$$\begin{aligned} & e^{-i\int H dt} e^{-\pi^2/4(\Delta\pi)^2} \sum_i \alpha_i \left| A = a_i \right\rangle \\ & = \sum_i a_i e^{-(\pi - a_i)^2/4(\Delta\pi)^2} \left| A = a_i \right\rangle , \end{aligned} \tag{2}$$

where $\sum_i \alpha_i \left| A = a_i \right\rangle$ is the initial state of our system. If the spread of the π distribution $\Delta\pi$ is much smaller than the differences between the a_i, then, after the interaction, we shall be left with the mixture of Gaussians located around a_i correlated with different eigenstates of A. A measurement of π will then indicate the value of A.

In the opposite limit, where $\Delta\pi$ is much bigger than all
a_i, the final probability distribution will be again close to a Gaussian with the spread $\Delta\pi$. The center of the Gaussian will be at the mean value of A : $\langle A \rangle = \Sigma_i \left|\alpha_i\right|^2 a_i$. One measurement like this will give no information because $\Delta\pi \gg \langle A \rangle$; but we can make this same measurement on each member of an ensemble of N particles prepared in the same state, and that will reduce the relevant uncertainty by the factor $1/\sqrt{N}$, while the mean value of the average will remain $\langle A \rangle$. By enlarging the number N of particles in the ensemble, we can make the measurement of $\langle A \rangle$ with any desired precision.

The outcome of the measurement is the average of the obtained values π of the measuring devices. As we explained earlier, it will yield, for a sufficiently large ensemble, the value $\langle A \rangle$. We now raise the question: Can we change the above outcome by taking into account the values of π of only a part of the original ensemble, performing a particular postselection? We may, of course, achieve this rather trivially, by selecting only measuring devices with large values of π which we can always find, since the original distribution of π has nonvanishing tails. But suppose we allow only postselection performed on the particles themselves; how then can we maximize the outcome for the average of π? It might appear at first that the best method for this will be to select all particles for which the final state corresponds to the eigenvalue $a_{\max}$. But this is not the case. Surprisingly, we found that by making other postselections we can obtain much bigger outcomes.

Indeed, we shall now show that the above measurements (with large $\Delta\pi$), when applied to preselected and postselected ensembles, may yield new values which lie outside the "allowed" range, i.e., outside the interval $[\min(a_i), \max(a_i)]$. The procedure of the measurement is as follows. We start with a large ensemble of particles prepared in the same initial state. Every particle interacts with a separate measuring device, and then the measurement which selects the final state is performed. Finally, we take into account only the "readings" of the measuring devices corresponding to the postselected particles.

Let us consider an ensemble of particles with an initial state $|\psi_{\text{in}}\rangle$ and a final state $|\psi_f\rangle$. At a time in between we switch on the interaction (1) where the initial state of each of the measuring devices is $\left[1/\sqrt{\Delta}(2\pi)^{1/4}\right] \times \exp(-q^2/4\Delta^2)$. After the postselection the state of the measuring device (up to a normalization factor) is

$$\begin{aligned} &\langle\psi_f| e^{-i\int H dt} |\psi_{\text{in}}\rangle e^{-q^2/4\Delta^2} \\ &\quad \cong \langle\psi_f|\psi_{\text{in}}\rangle \exp\left(iq\frac{\langle\psi_f| A |\psi_{\text{in}}\rangle}{\langle\psi_f|\psi_{\text{in}}\rangle}\right) e^{-q^2/4\Delta^2} \end{aligned} \tag{3}$$

This formula is valid if the spread Δ is sufficiently small [3]:

$$\Delta \ll \max_n \frac{|\langle\psi_f|\psi_{\text{in}}\rangle|}{\left(|\langle\psi_f| A^n |\psi_{\text{in}}\rangle|^{1/n}\right)} \tag{4}$$

In the π representation, the state of the measuring device is approximately

$$\exp\left[-\Delta^2 (\pi - \langle\psi_f| A |\psi_{\text{in}}\rangle / \langle\psi_f|\psi_{\text{in}}\rangle)^2\right] \tag{5}$$

The standard interpretation of this outcome of the measuring device is that the measured value of A is $\langle\psi_f| A |\psi_{\text{in}}\rangle / \langle\psi_f|\psi_{\text{in}}\rangle$. This is the weak value of A for this preselected and postselected ensemble:

$$A_w \equiv \langle\psi_f| A |\psi_{\text{in}}\rangle / \langle\psi_f|\psi_{\text{in}}\rangle \tag{6}$$

The uncertainty of π for each of the measuring devices is much bigger than the measured value; i.e., $\Delta\pi = 1/2\Delta \gg A_w$ [see Eq. (4)]. However, for an ensemble of N such devices, the uncertainty of the average of π is decreased by the factor of $1/\sqrt{N}$. Therefore, if N is sufficiently large, then $(1/\sqrt{N})\Delta\pi \ll A_w$ and the value of A_w can be ascertained with arbitrary accuracy. As we see from the definition (6). A_w is not bounded by the minimal and the maximal eigenvalues of A.[4]

One may wonder how a superposition of shifts, all smaller than $a_{\max}$, leads to a shift which is much larger than $a_{\max}$. We shall demonstrate this by proving a mathematical identity which

corresponds to the type of experiment considered in the present note (see also Aharonov et al. [5]).

For all functions $f(q)$ which tend to zero faster than exponential, $f(q) < \exp(-\ln \alpha^2 |q|)$, the following equality can be made valid with any precision by our taking N large enough [6]:

$$\sum_{n=-N}^{N} c_n e^{iqn/N} f(q) \cong e^{iaq} f(q) \tag{7}$$

where

$$c_n = \frac{N!}{n!(N-n)!} \left(\frac{1-\alpha^2}{4}\right)^N \left(\frac{1+\alpha}{1-\alpha}\right)^{n/2}$$

The Fourier transform of this equation exhibits the property described above: For function $\tilde{f}(\pi)$ [the Fourier transform of $f(q)$] the superposition of shifts, which are all smaller than 1 , is equivalent to a shift by the arbitrarily large value α, i.e.,

$$\sum_{n=-N}^{N} c_n \tilde{f}(\pi - n/N) \cong \tilde{f}(\pi - \alpha) \tag{8}$$

We shall now describe an experiment that measures the weak value of the z component of a spin- $\frac{1}{2}$ particle and yields an arbitrarily large result for it. A version of this experiment can, we believe, be performed in the laboratory.

We start with a beam of particles moving in the y direction with a well-defined velocity. The particles are initially well localized in the xz plane and have their spins pointed in a direction $\hat{\xi}$. We choose $\hat{\xi}$ in the xz plane with an angle α between $\hat{\xi}$ and $\hat{\mathbf{x}}$ (Fig. 1). The prepared beam comes through a Sterm-Gerlach device which measures the spin weakly in the z direction. The requirement of weakness is fulfilled by our making the gradient of the magnetic field sufficiently small. The motion of the beam changes, therefore, only slightly. This weak measurement causes the spatial part of the wave function to change into a mixture of two slightly shifted functions in the p_z representation, correlated to the two values of σ_z. We then pass the particles through another, normal, Stern-Gerlach device which splits them into two beams corresponding to the two values of σ_x. We keep only the beam with $\sigma_x = 1$, which continues to move freely towards a screen placed in front of it. The screen is placed sufficiently far so that the displacement in the $\hat{\mathbf{z}}$ direction due to the average momentum p_z ac-

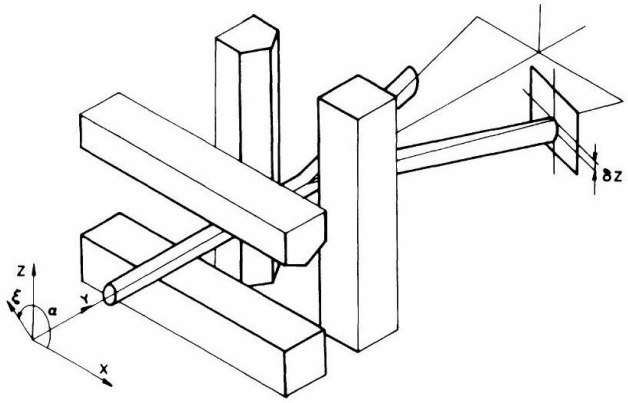

FIG. 1. The experimental device for measurement of the weak value of σ_z. The beam of particles with the spin pointed in the direction $\hat{\boldsymbol{\xi}}$ passes through an inhomogeneous (in the z direction) weak magnetic field and is split by the strong magnet with an inhomogeneous field in the x direction. The beam of particles with $\sigma_x = 1$ comes toward the screen and the deflection of the spot on the screen in the z direction is proportional to the weak value of $\sigma_z : \sigma_{z_w} = (\delta z p_0 \mu / l)\,(\partial B_z/\partial z)^{-1}$.

quired during the above weak interaction will be larger than the initial uncertainty Δz. On the screen we shall obtain a wide spot whose displacement in the direction $\hat{\mathbf{z}}$ is measured. This displacement will yield the weak value of σ_z:

$$\sigma_{z,w} = \langle\uparrow_x| \sigma_z |\uparrow_\xi\rangle / \langle\uparrow_x | \uparrow_\xi\rangle = \tan\frac{1}{2}\alpha \tag{9}$$

A brief mathematical description of this experiment follows. The particles have mass m, magnetic moment μ, and average momentum p_0 in the y direction. Their initial state is

$$|\psi_{\text{in}}\rangle = \Delta^{-3/2}(2\pi)^{-3/4} e^{-x^2/4\Delta^2} e^{-z^2/4\Delta^2} e^{-y^2/4\Delta^2} e^{-ip_0 y} \left(\cos(\alpha/2)\,|\uparrow_x\rangle + \sin(\alpha/2)\,|\downarrow_x\rangle\right) \tag{10}$$

The Hamiltonian of the weak interaction is

$$H_1 = -\mu\,(\partial B_z/\partial z)\, z\sigma_z g\,(y - y_1) \tag{1I}$$

where $g\,(y - y_i)$ has a compact support at the location of the weak Stern-Gerlach device, which is arranged such that $\left(m/p_0 \int g(y)dy = 1\right.$. It is, indeed, essentially a Hamiltonian of the von Neumann type [see Eq. (1)]. Since $y \cong (p_0/m)\,t$, $g\,(y - y_1)$ is effectively a function of time (we arrange the momentum in the y direction such that $p_0 \gg \Delta p_y = 1/2\Delta$); the canonical variable q of Eq. (1) is, here, $\mu\,(\partial B_z/\partial z)\, z$. The change in the momentum in the z direction during the interaction is $\delta p_z = \mu\,(\partial B_z/\ \partial z)\sigma_z$. For our ensemble of preselected and postselected particles, we shall see that $\delta p_z = \mu\,(\partial B_z/\partial z)\tan(\alpha/2)$. The necessary requirement of the weakness of the interaction [see Eq. (4)] is

$$\mu \left|\frac{\partial B_z}{\partial z}\right| \max\left[\left|\tan\frac{\alpha}{2}\right|, 1\right] \ll \Delta p_z = \frac{1}{2\Delta} \tag{12}$$

The Hamiltonian of the second Stern-Gerlach device, which selects the particles with $\sigma_x = 1$, is

$$H_2 = -\mu\,(\partial B_x/\partial x)\, x\sigma_x g\,(y - y_2) \tag{13}$$

The requirement for the splitting of the beam is $\mu\,|\partial B_x/\partial x| \gg \Delta p_x = 1/2\Delta$. If the angle α between the directions of spin in the initial and the final states is close to π, then the requirement has to be stronger, i.e.,

$$\exp\left(-2\Delta^2\mu^2\,|\partial B_x/\partial x|^2 \ll \cot^2(\alpha/2)\right.$$

The direction of the beam with $\sigma_x = 1$ is $\mu\,(\partial B_x/\partial x)\,\hat{\mathbf{x}} + p_0\hat{\mathbf{y}}$. The screen is placed at the distance l such that

$$\frac{l\mu}{p_0}\left|\frac{\partial B_z}{\partial z}\tan\frac{\alpha}{2}\right| \gg \Delta.$$

The wave function of the particle in the z representation, before the collapse on the screen, is approximately

$$\exp\left[-\Delta^2\left(\frac{p_0}{l}\right)^2\left(z - \frac{l\mu}{p_0}\frac{\partial B_z}{\partial z}\tan\frac{\alpha}{2}\right)^2\right] \tag{14}$$

The measured value of the spin component corresponding to this wave function is $\tan(\alpha/2)$. A rough estimation for the number N of particles in the initial beam necessary for our obtaining accuracy of $1/M$ is $N \cong M^3/\cos^2(\alpha/2)$.

In the above description we have not, so far, taken into account the influence of $\partial B_x/\partial x$ and $\partial B_y/\partial y$ which cannot both vanish since $\operatorname{div}\mathbf{B} = 0$. In a standard SternGerlach experiment, one takes care of this problem by adding a large constant magnetic field in the direction of the measured component of the spin. It is interesting to note that the same method can be used in our weak measurement. The strong magnetic field in the z direction will, of course, rotate the direction of the spin and, therefore, during the interaction (11) we have to calculate the weak value sandwiched not between the states $|\uparrow_\xi\rangle$ and $|\uparrow_x\rangle$ [see Eq. (6)], but between the rotated states. It turns out, however, that if we arrange the magnetic field in the z direction, such that it rotates the spin during the interaction by $2n\pi$, then the weak value of σ_z during the whole period of the interaction does not change.

Another striking aspect of this experiment becomes evident when we consider it as a device for measuring a small gradient of the magnetic field $\partial B_z/\partial z$. Our choosing α close to π yields a tremendous amplification. Indeed, any weak coupling with the spin of the particles from our preselected and postselected ensemble will be amplified by the factor $[\cos(\alpha/2)]^{-1}$.

This research was supported in part by the National Science Foundation under Grant No. PHY 8408265.

[3] If condition (4) is valid, then

$$
\begin{aligned}
&\langle\psi_f|\, e^{-i\int H dt}|\,\psi_{\rm in}\,\rangle\, e^{-q^2/4\Delta^2} \\
&\qquad = \sum_{n=0}^{\infty} \frac{(iq)^n}{n!}\,\langle\psi_f|\,A^n\,|\psi_{\rm in}\,\rangle\, e^{-q^2/4\Delta^2} \\
&\qquad \cong \langle\psi_f|\psi_{\rm in}\,\rangle \left(1 + \frac{iq\,(\langle\psi_f|\,A\,|\psi_{\rm in}\,\rangle)}{\langle\psi_f|\psi_{\rm in}\,\rangle}\right) e^{-q^2/4\Delta^2} \\
&\qquad \cong \langle\psi_f|\psi_{\rm in}\,\rangle \exp\left(iq\frac{\langle\psi_f|\,A\,|\psi_{\rm in}\,\rangle}{\langle\psi_f|\psi_{\rm in}\,\rangle}\right) e^{-q^2/4\Delta^2}
\end{aligned}
$$

[4] A_w may even be a complex number. The measurement of π gives only the real part $\operatorname{Re} A_w$. In our case, in which the initial state of the measuring device is a Gaussian, we can also find the imaginary part $\operatorname{Im} A_w$ by measuring the canonical variable q itself. Indeed, in the q representation the state of the measuring device is

[5] Y. Aharonov, D. Albert, A. Casher, and L. Vaidman, Phys. Lett. A 124, 199 (1987). [6] The coefficients c_n are derived from the binomial expansion. We can rewrite the left-hand side of (7), the part which multiplies $f(q)$ as

$$
\begin{aligned}
&\sum_{n=N}^{N} \frac{N!}{n!(N-n)!}\left(\frac{1-\alpha^2}{4}\right)^N \left(\frac{1+\alpha}{1-\alpha}\right)^{n/2} e^{iqn/N} \\
&= \left(\frac{1+\alpha}{2}e^{iq/2N} + \frac{1-\alpha}{2}e^{-iq/2N}\right)^{2N} \\
&= [\cos(q/2N) + i\alpha\sin(q/2N)]^{2N} \\
&= \left[1 - \left(1-\alpha^2\right)\sin^2(q/2N)\right]^N e^{i2N\phi}
\end{aligned}
$$

where $\tan\phi = \alpha\tan(q/2N)$. For $f(q) < \exp\left(-\ln\alpha^2|q|\right)$, we obtain

[11] J. von Neumann, Mathematische Gründlagen der Quantemechanik (Springer-Verlag, Berlin, 1932) [English translation: Mathematical Foundations of Quantum Mechanics (Princeton Univ. Press, Princeton, NJ, 1955)].

[2] This Hamiltonian (1) is the effective Hamiltonian of a Stern-Gerlach measuring device as will be explained later [see Eq. (11)].

$$\lim_{N\to\infty} \sum_{n=-N}^{N} c_n e^{iq/2N} f(q)$$
$$= \lim_{N\to\infty} \left[1 - \left(1-\alpha^2\right)\sin^2(q/2N)\right]^N e^{i2N\phi} f(q)$$
$$= e^{iaq} f(q)$$

This proves the statement in the text (7).

20 The Physical Implementation of Quantum Computation by DiVincenzo

Abstract

After a brief introduction to the principles and promise of quantum information processing, the requirements for the physical implementation of quantum computation are discussed. These five requirements, plus two relating to the communication of quantum information, are extensively explored and related to the many schemes in atomic physics, quantum optics, nuclear and electron magnetic resonance spectroscopy, superconducting electronics, and quantum-dot physics, for achieving quantum computing.

20.1 Introduction

[2] The advent of quantum information processing, as an abstract concept, has given birth to a great deal of new thinking, of a very concrete form, about how to create physical computing devices that operate in the hitherto unexplored quantum mechanical regime. The efforts now underway to produce working laboratory devices that perform this profoundly new form of information processing are the subject of this book.

In this chapter I provide an overview of the common objectives of the investigations reported in the remainder of this special issue. The scope of the approaches, proposed and underway, to the implementation of quantum hardware is remarkable, emerging from specialties in atomic physics[1], in quantum optics[2], in nuclear[3] and electron[4] magnetic resonance spectroscopy, in superconducting device physics[5], in electron physics[6], and in mesoscopic and quantum dot research[7]. This amazing variety of approaches has arisen because, as we will see, the principles of quantum computing are posed using the most fundamental ideas of quantum mechanics, ones whose embodiment can be contemplated in virtually every branch of quantum physics.

The interdisciplinary spirit which has been fostered as a result is one of the most pleasant and remarkable features of this field. The excitement and freshness that has been produced bodes well for the prospect for discovery, invention, and innovation in this endeavor.

20.2 Why *quantum* information processing?

The shortest of answers to this question would be, why not? The manipulation and transmission of information is today carried out by physical machines (computers, routers, scanners, etc.), in which the embodiment and transformations of this information can be described using the language of classical mechanics. But the final physical theory of the world is not Newtonian mechanics, and there is no reason to suppose that machines following the laws of quantum

[2]Prepared for Fortschritte der Physik special issue, *Experimental Proposals for Quantum Computation*, eds. H.-K. Lo and S. Braunstein.

mechanics should have the same computational power as classical machines; indeed, since Newtonian mechanics emerges as a special limit of quantum mechanics, quantum machines can only have greater computational power than classical ones. The great pioneers and visionaries who pointed the way towards quantum computers, Deutsch[8], Feynman[9], and others, were stimulated by such thoughts. Of course, by a similar line of reasoning, it may well be asked whether machines embodying the principles of other refined descriptions of nature (perhaps general relativity or string theory) may have even more information processing capabilities; speculations exist about these more exotic possibilities, but they are beyond the scope of the present discussion.

But computing with quantum mechanics really deserves a lot more attention than wormhole computing or quantum-gravity computing; quantum computing, while far in the future from the perspective of CMOS roadmaps and projections of chip fab advances, can certainly be seen as a real prospect from the perspective of research studies in quantum physics. It does not require science fiction to envision a quantum computer; the proposals discussed later in this issue paint a rather definite picture of what a real quantum computer will look like.

So, how much is gained by computing with quantum physics over computing with classical physics? We do not seem to be near to a final answer to this question, which is natural since even the ultimate computing power of classical machines remains unknown. But the answer as we know it today has an unexpected structure; it is not that quantum tools simply speed up all information processing tasks by a uniform amount. By a standard complexity measure (i.e., the way in which the number of computational steps required to complete a task grows with the "size" n of the task), some tasks are not sped up at all[10] by using quantum tools (e.g., obtaining the nth iterate of a function $f(f(...f(x)...))$[11]), some are sped up moderately (locating an entry in a database of n entries[12]), and some are apparently sped up exponentially (Shor's algorithm for factoring an n-digit number[13]).

In other types of information processing tasks, particularly those involving communication[14], both quantitative and qualitative improvements are seen[15]: for certain tasks (choosing a free day for an appointment between two parties from out of n days) there is a quadratic reduction of the amount of communicated data required, if quantum states rather than classical states are transmitted[16]. For some tasks (the "set disjointness problem", related to allocating non-overlapping segments of a shared memory in a distributed computation) the reduction of required communication is exponential[17]. Finally, there are tasks that are doable in the quantum world that have no counterpart classically: quantum cryptography provides an absolute secrecy of communication between parties that is impossible classically[18]. And for some games, winning strategies become possible with the use of quantum resources that are not available otherwise[19, 20].

This issue, and this chapter, are primarily concerned with the "hows" of quantum computing rather than the "whys," so we will leave behind the computer science after this extremely brief mention. There is no shortage of other places to obtain more information about these things; I recommend the recent articles by Aharonov[21] and by Cleve[22]; other general introductions[23] will give the reader pointers to the already vast specialized literature on this subject.

20.3 Realizing quantum computation

Let me proceed with the main topic: the physical realization of quantum information processing. As a guide to the remainder of the special issue, and as a means of reviewing the basic steps required to make quantum computation work, I can think of no better plan than to review a set of basic criteria that my coworkers and I have been discussing over the last few years[24] for the realization of quantum computation (and communication), and to discuss the application of these criteria to the multitude of physical implementations that are found below.

So, without further ado, here are the

Five (plus two) requirements for the implementation of quantum computation

1. A scalable physical system with well characterized qubits

For a start, a physical system containing a collection of qubits is needed. A qubit (or, more precisely, the embodiment of a qubit) is[25] simply a quantum two-level system like the two spin states of a spin 1/2 particle, like the ground and excited states of an atom, or like the vertical and horizontal polarization of a single photon. The generic notation for a qubit state denotes one state as $|0\rangle$ and the other as $|1\rangle$. The essential feature that distinguishes a qubit from a bit is that, according to the laws of quantum mechanics, the permitted states of a single qubit fills up a two-dimensional complex vector space; the general state is written $a|0\rangle + b|1\rangle$, where a and b are complex numbers, and a normalization convention $|a|^2+|b|^2 = 1$ is normally adopted. The general state of two qubits, $a|00\rangle + b|01\rangle + c|10\rangle + d|11\rangle$, is a four-dimensional vector, one dimension for each distinguishable state of the two systems. These states are generically *entangled*, meaning that they cannot be written as a product of the states of two individual qubits. The general state of n qubits is specified by a 2^n-dimensional complex vector.

A qubit being "well characterized" means several different things. Its physical parameters should be accurately known, including the internal Hamiltonian of the qubit (which determines the energy eigenstates of the qubit, which are often, although not always, taken as the $|0\rangle$ and $|1\rangle$ states), the presence of and couplings to other states of the qubit, the interactions with other qubits, and the couplings to external fields that might be used to manipulate the state of the qubit. If the qubit has third, fourth, etc., levels, the computer's control apparatus should be designed so that the probability of the system ever going into these states is small. The smallness of this and other parameters will be determined by the capabilities of quantum error correction, which will be discussed under requirement 3.

Recognizing a qubit can be trickier than one might think. For example, we might consider a pair of one-electron quantum dots that share a single electron between them as a two-qubit system. It is certainly true that we can denote the presence or absence of an electron on each dot by $|0\rangle$ and $|1\rangle$, and it is well known experimentally how to put this system into the "entangled" state $1/\sqrt{2}(|01\rangle + |10\rangle)$ in which the electron is in a superposition of being on the left dot and the right dot. But it is fallacious to consider this as a two-qubit system; while the states $|00\rangle$ and $|11\rangle$ are other allowed physical states of the dots, superselection principles forbid the creation of entangled states involving different particle numbers such as $1/\sqrt{2}(|00\rangle + |11\rangle)$.

It is therefore false to consider this as a two-qubit system, and, since there are not two qubits, it is nonsense to say that there is entanglement in this system. It is correct to say that the electron is in a superposition of different quantum states living on the two different dots. It is also perfectly correct to consider this system to be the embodiment of a *single* qubit, spanned by the states (in the misleading notation above) $|01\rangle$ ("electron on the right dot") and $|10\rangle$ ("electron on the left dot"). Indeed, several of the viable proposals, including the ones by Schön, Averin, and Tanamoto in this special issue, use exactly this system as a qubit. However, false lines of reasoning like the one outlined here have sunk various proposals before they were properly launched (no such abortive proposals are represented in this book, but they can be found occasionally in the literature).

An amazing variety of realizations of the qubit are represented in this volume. There is a very well developed line of work that began with the proposal of Cirac and Zoller[1] for an ion-trap quantum computer, in which, in its quiescent state, the computer holds the qubits in pairs of energy levels of ions held in a linear electromagnetic trap. Various pairs of energy levels (e.g., Zeeman-degenerate ground states, as are also used in the NMR approach[3] discussed by Cory) have been proposed and investigated experimentally. The many neutral-atom proposals (see chapters by Kimble[2], Deutsch[26], and Briegel[27]) use similar atomic energy levels of

neutral species. These atomic-physics based proposals use other auxiliary qubits such as the position of atoms in a trap or lattice, the presence or absence of a photon in an optical cavity, or the vibrational quanta of trapped electrons, ions or atoms (in the Platzman proposal below[6] this is the primary qubit). Many of the solid-state proposals exploit the fact that impurities or quantum dots have well characterized discrete energy level spectra; these include the spin states of quantum dots (see chapters by Loss[7] and Imamoglu[2]), the spin states of donor impurities (see Kane[4]), and the orbital or charge states of quantum dots (see Tanamoto[7]). Finally, there are a variety of interesting proposals which use the quantized states of superconducting devices, either ones involving the (Cooper-pair) charge (see Schön, Averin), or the flux (see Mooij)[5].

2. The ability to initialize the state of the qubits to a simple fiducial state, such as $|000...\rangle$

This arises first from the straightforward computing requirement that registers should be initialized to a known value before the start of computation. There is a second reason for this initialization requirement: quantum error correction (see requirement 3 below) requires a continuous, fresh supply of qubits in a low-entropy state (like the $|0\rangle$ state). The need for a continuous supply of 0s, rather than just an initial supply, is a real headache for many proposed implementations. But since it is likely that a demonstration of a substantial degree of quantum error correction is still quite some time off, the problem of continuous initialization does not have to be solved very soon; still, experimentalists should be aware that the speed with which a qubit can be zeroed will eventually be a very important issue. If the time it takes to do this initialization is relatively long compared with gate-operation times (see requirement 4), then the quantum computer will have to equipped with some kind of "qubit conveyor belt", on which qubits in need of initialization are carried away from the region in which active computation is taking place, initialized while on the "belt", then brought back to the active place after the initialization is finished. (A similar parade of qubits will be envisioned in requirement 5 for the case of low quantum-efficiency measurements[28].)

There are two main approaches to setting qubits to a standard state: the system can either be "naturally" cooled when the ground state of its Hamiltonian is the state of interest, or the standard state can be achieved by a measurement which projects the system either into the state desired or another state which can be rotated into it. These approaches are not fundamentally different from one another, since the projection procedure is a form of cooling; for instance, the laser cooling techniques used routinely now for the cooling of ion states to near their ground state in a trap[1] are closely connected to the fluorescence techniques used to measure the state of these ions. A more "natural" kind of cooling is advocated in many of the electron spin resonance based techniques (using quantum dots or impurities)[7, 4] in which the spins are placed in a strong magnetic field and allowed to align with it via interaction with their heat bath. In this kind of approach the time scale will be a problem. Since the natural thermalization times are never shorter than the decoherence time of the system, this procedure will be too slow for the needs of error correction and a "conveyor belt" scheme would be required. Cooling by projection, in which the Hamiltonian of the system and its environment are necessarily perturbed strongly, will have a time scale dependent on the details of the setup, but potentially much shorter than the natural relaxation times. One cannot say too much more at this point, as the schemes for measurement have in many cases not been fully implemented (see requirement 5). In the NMR quantum computer implementations to date (see Cory below), cooling of the initial state has been foregone altogether; it is acknowledged[3] that until some of the proposed cooling schemes are implemented (a nontrivial thing to do), NMR can never be a scalable scheme for quantum computing.

3. Long relevant decoherence times, much longer than the gate operation time

Decoherence times characterize the dynamics of a qubit (or any quantum system) in contact with its environment. The (somewhat overly) simplified definition of this time is that it is the

characteristic time for a generic qubit state $|\psi\rangle = a\,|0\rangle + b\,|1\rangle$ to be transformed into the mixture $\rho = |a|^2\,|0\rangle\,\langle 0| + |b|^2\,|1\rangle\,\langle 1|$. A more proper characterization of decoherence, in which the decay can depend on the form of the initial state, in which the state amplitudes may change as well, and in which other quantum states of the qubit can play a role (in a special form of state decay called "leakage" in quantum computing[29, 30]), is rather more technical than I want to get here; but see Refs. [31] and [32] for a good general discussion of all these. Even the simplest discussion of decoherence that I have given here should also be extended to include the possibility that the decoherence of neighboring qubits is correlated. It seems safest to assume that they will be neither completely correlated nor completely uncorrelated, and the thinking about error correction has taken this into account.

Decoherence is very important for the fundamentals of quantum physics, as it is identified as the principal mechanism for the emergence of classical behavior. For the same reason, decoherence is very dangerous for quantum computing, since if it acts for very long, the capability of the quantum computer will not be so different from that of a classical machine. The decoherence time must be long enough that the uniquely quantum features of this style of computation have a chance to come into play. How long is "long enough" is also indicated by the results of quantum error correction, which I will summarize shortly.

I have indicated that the "relevant" decoherence times should be long enough. This emphasizes that a quantum particle can have many decoherence times pertaining to different degrees of freedom of that particle. But many of these can be irrelevant to the functioning of this particle as a qubit. For example, the rapid decoherence of an electron's position state in a solid state environment does not preclude its having a very long spin coherence time, and it can be arranged that this is the only time relevant for quantum computation. Which time is relevant is determined by the choice of the qubit basis states $|0\rangle$ and $|1\rangle$; for example, if these two states correspond to different spin states but identical orbital states, then orbital decoherence will be irrelevant.

One might worry that the decoherence time necessary to do a successful quantum computation will scale with the duration of the computation. This would place incredibly stringent requirements on the physical system implementing the computation. Fortunately, in one of the great discoveries of quantum information theory (in 1995-6), it was found that error correction of quantum states is possible[33] and that this correction procedure can be successfully applied in quantum computation[34], putting much more reasonable (although still daunting) requirements on the needed decoherence times.

In brief, quantum error correction starts with coding; as in binary error correction codes, in which only a subset of all boolean strings are "legal" states, quantum error correction codes consist of legal states confined to a subspace of the vector space of a collection of qubits. Departure from this subspace is caused by decoherence. Codes can be chosen such that, with a suitable sequence of quantum computations and measurements of some ancillary qubits, the error caused by decoherence can be detected and corrected. As noted above, these ancillary qubits have to be continuously refreshed for use. I will not go much farther into the subject here, see [31] for more. It is known that quantum error correction can be made fully fault tolerant, meaning that error correction operations can be successfully intermingled with quantum computation operations, that errors occurring during the act of error correction, if they occur at a sufficiently small rate, do no harm, and that the act of quantum computation does not itself cause an unreasonable proliferation of errors.

These detailed analyses have indicated the magnitude of decoherence time scales that are acceptable for fault-tolerant quantum computation. The result is that, if the decoherence time is $10^4 - 10^5$ times the "clock time" of the quantum computer, that is, the time for the execution of an individual quantum gate (see requirement 4), then error correction can be successful. This is, to tell the truth, a rather stringent condition, quantum systems frequently do not have

such long decoherence times. But sometimes they do, and our search for a successful physical implementation must turn towards these. At least this result says that the required decoherence rate does not become ever smaller as the size and duration of the quantum computation grows. So, once the desired threshold is attainable, decoherence will not be an obstacle to scalable quantum computation.

Having said this, it must be admitted that it will be some time before it is even possible to subject quantum error correction to a reasonable test. Nearly all parts of requirements 1-5 must be in place before such a test is possible. And even the most limited application of quantum error correction has quite a large overhead: roughly 10 ancillary qubits must be added for each individual qubit of the computation. Fortunately, this overhead ratio grows only logarithmically as the the size of the quantum computation is increased.

In the short run, it is at least possible to design and perform experiments which measure the decoherence times and other relevant properties (such as the correlation of decoherence of neighboring qubits) of candidate implementations of qubits. With such initial test experiments, caution must be exercised in interpreting the results, because decoherence is a very system-specific phenomenon, depending on the details of all the qubits' couplings to various environmental degrees of freedom. For example, the decoherence time of the spin of an impurity in the bulk of a perfect semiconductor may not be the same as its decoherence time when it is near the surface of the solid, in the immediate neighborhood of device structures designed to manipulate its quantum state. Test experiments should probe decoherence in as realistic a structure as is possible.

4. A "universal" set of quantum gates

This requirement is of course at the heart of quantum computing. A quantum algorithm is typically specified[8] as a sequence of unitary transformations U_1, U_2, U_3,..., each acting on a small number of qubits, typically no more than three. The most straightforward transcription of this into a physical specification is to identify Hamiltonians which generate these unitary transformations, viz., $U_1 = e^{iH_1 t/\hbar}$, $U_2 = e^{iH_2 t/\hbar}$, $U_3 = e^{iH_3 t/\hbar}$, etc.; then, the physical apparatus should be designed so that H_1 can be turned on from time 0 to time t, then turned off and H_2 turned on from time t to time $2t$, etc.

Would that life were so simple! In reality what can be done is much less, but much less can be sufficient. Understanding exactly how much less is still enough, is the main complication of this requirement. In all the physical implementations discussed in this volume, only particular sorts of Hamiltonians can be turned on and off; in most cases, for example, only two-body (two-qubit) interactions are considered. This immediately poses a problem for a quantum computation specified with three-qubit unitary transformations; fortunately, of course, these can always be re-expressed in terms of sequences of one- and two-body interactions[35], and the two-body interactions can be of just one type[36], the "quantum XOR" or "cNOT". There are some implementations in which multi-qubit gates can be implemented directly[37].

However, this still leaves a lot of work to do. In some systems, notably in NMR (see Cory), there are two-body interactions present which cannot be turned *off*, as well as others which are switchable. This would in general be fatal for quantum computation, but the particular form of the fixed interactions permit their effects to be annulled by particular "refocusing" sequences of the controllable interactions, and it has recently been discovered[38] that these refocusing sequences can be designed and implemented efficiently.

For many other systems, the two-body Hamiltonian needed to generate directly the cNOT unitary transformation is not available. For example, in the quantum-dot proposal described by Loss below[7], the only two-body interaction which should be easily achievable is the exchange interaction between neighboring spins, $H \propto \vec{S}_i \cdot \vec{S}_{i+1}$; in the Imamoglu chapter[2], the attainable interaction is of the XY type, i.e., $H \propto S_{ix}S_{jx} + S_{iy}S_{jy}$. An important observation is that with the appropriate sequence of exchange or XY interactions, in conjunction with particular one-

body interactions (which are assumed to be more easily doable), the cNOT transformation can be synthesized[39]. It is incumbent on each implementation proposal to exhibit such a sequence for producing the cNOT using the interactions that are naturally realizable.

Often there is also some sophisticated thinking required about the time profile of the two-qubit interaction. The naive description above uses a "square pulse" time profile, but often this is completely inappropriate; for instance, if the Hamiltonian can also couple the qubit to other, higher-lying levels of the quantum system, often the only way to get the desired transformation is to turn on and off the interaction smoothly and slowly enough that an adiabatic approximation is accurate[29, 30] (in a solid-state context, see also [40]). The actual duration of the pulse will have to be sufficiently long that any such adiabatic requirement is satisfied; then typically only the time integral $\int dt H(t)$ is relevant for the quantum gate action. The overall time scale of the interaction pulse is also controlled by the attainable maximum size of the matrix elements of $H(t)$, which will be determined by various fundamental considerations, like the requirement that the system remains in the regime of validity of a linear approximation, and practical considerations, like the laser power that can be concentrated on a particular ion. Given these various constraints, the "clock time" of the quantum computer will be determined by the time interval needed such that two consecutive pulses have negligible overlap.

Another consideration, which does not seem to present a problem with any current implementation schemes, but which may be an issue in the future, is the classicality of the control apparatus. We say that the interaction Hamiltonian $H(t)$ has a time profile which is controlled externally by some "classical" means, that is, by the intensity of a laser beam, the value of a gate voltage, or the current level in a wire. But each of these control devices is made up themselves of quantum mechanical parts. When we require that these behave classically, it means that their action should proceed without any entanglement developing between these control devices and the quantum computer. Estimates indicate that this entanglement can indeed be negligible, but this effect needs to be assessed for each individual case.

In many cases it is impossible to turn on the desired interaction between a pair of qubits; for instance, in the ion-trap scheme, no direct interaction is available between the ion-level qubits[1]. In this and in other cases, a special quantum subsystem (sometimes referred to as a "bus qubit") is used which can interact with each of the qubits in turn and mediate the desired interaction: for the ion trap, this is envisioned to be the vibrational state of the ion chain in the trap; in other cases it is a cavity photon whose wavefunction overlaps all the qubits. Unfortunately, this auxiliary quantum system introduces new channels for the environment to couple to the system and cause decoherence, and indeed the decoherence occurring during gate operation is of concern in the ion-trap and cavity-quantum electrodynamics schemes.

Some points about requirement 4 are important to note in relation to the implementation of error correction. Successful error correction requires fully parallel operation, meaning that gate operations involving a finite fraction of all the qubits must be doable simultaneously. This can present a problem with some of the proposals in which the single "bus qubit" is needed to mediate each interaction. On the other hand, the constraint that interactions are only among nearest neighbors in a lattice, as in many of the solid-state proposals, does allow for sufficient parallelism[41].

Quantum gates cannot be implemented perfectly; we must expect both systematic and random errors in the implementation of the necessary Hamiltonians. Both types of errors can be viewed as another source of decoherence and thus error correction techniques are effective for producing reliable computations from unreliable gates, if the unreliability is small enough. The tolerable unreliability due to random errors is in the same vicinity as the decoherence threshold, that is, the magnitude of random errors should be $10^{-4} - 10^{-5}$ per gate operation or so. It might be hoped that systematic errors could be virtually eliminated by careful calibration; but this will surely not always be the case. It seems harder to give a good rule for how much

systematic error is tolerable, the conservative estimates give a very, very small number (the square of the above)[31], but on the other hand there seems to be some evidence that certain important quantum computations (e.g., the quantum Fourier transform) can tolerate a very high level of systematic error (over- or under-rotation). Some types of very large errors may be tolerable if their presence can be detected and accounted for on the fly (we are thinking, for example, about charge switching in semiconductors or superconductors).

Error correction requires that gate operations be done on coded qubits, and one might worry that such operations would require a new repertoire of elementary gate operations for the base-level qubits which make up the code. For the most important error correction techniques, using the so called "stabilizer" codes, this is not the case. The base-level toolkit is exactly the same as for the unencoded case: one-bit gates and cNOTs, or any gate repertoire that can produce these, are adequate. Sometimes the use of coding can actually *reduce* the gate repertoire required: in the work on decoherence free subspaces and subsystems, codes are introduced using blocks of three and four qubits for which two-qubit exchange interactions alone are enough to implement general quantum computation[42, 43]. This simplification could be very useful in the quantum-dot[7] or semiconductor-impurity[4] implementations.

5. A qubit-specific measurement capability

Finally, the result of a computation must be read out, and this requires the ability to measure specific qubits. In an ideal measurement, if a qubit's density matrix is $\rho = p\,|0\rangle\langle 0| + (1-p)\,|1\rangle\langle 1| + \alpha\,|0\rangle\langle 1| + \alpha^*\,|1\rangle\langle 0|$, the measurement should give outcome "0" with probability p and "1" with probability $1-p$ independent of α and of any other parameters of the system, including the state of nearby qubits, and without changing the state of the rest of the quantum computer. If the measurement is "non-demolition", that is, if in addition to reporting outcome "0" the measurement leaves the qubit in state $|0\rangle\langle 0|$, then it can also be used for the state preparation of requirement 2; but requirement 2 can be fulfilled in other ways.

Such an ideal measurement as I have described is said to have 100% quantum efficiency; real measurements always have less. While the fidelity of a quantum measurement is not captured by a single number, the single quantum-efficiency parameter is often a very useful way to summarize it, just as the decoherence time is a useful if incomplete summary of the damage caused to a quantum state by the environment.

While quantum efficiency of 100% is desirable, much less is needed for quantum computation; there is, in fact, a tradeoff possible between quantum efficiency and other resources which results in reliable computation. As a simple example, if the quantum efficiency is 90%, then, in the absence of any other imperfections, a computation with a single-bit output (a so-called "decision problem", common in computer science) will have 90% reliability. If 97% reliability is needed, this can just be achieved by rerunning the calculation three times. Much better, actually, is to "copy" the single output qubit to three, by applying two cNOT gates involving the output qubit and two other qubits set to $|0\rangle$, and measuring those three. (Of course, qubits cannot be "copied", but their value in a particular basis can.) In general, if quantum efficiency q is available, then copying to somewhat more than $1/q$ qubits and measuring all of these will result in a reliable outcome. So, a quantum efficiency of 1% would be usable for quantum computation, at the expense of hundreds of copies/remeasures of the same output qubit. (This assumes that the measurement does not otherwise disturb the quantum computer. If it does, the possibilities are much more limited.)

Even quantum efficiencies much, much lower than 1% can be and are used for successful quantum computation: this is the "bulk" model of NMR (see Cory and [3]), where macroscopic numbers of copies of the same quantum computer (different molecules in solution) run simultaneously, with the final measurement done as an ensemble average over the whole sample. These kinds of weak measurements, in which each individual qubit is hardly disturbed, are quite common and well understood in condensed-matter physics.

If a measurement can be completed quickly, on the timescale of 10^{-4} of the decoherence time, say, then its repeated application during the course of quantum computation is valuable for simplifying the process of quantum error correction. On the other hand, if this fast measurement capability is not available, quantum error correction is still possible, but it then requires a greater number of quantum gates to implement.

Other tradeoffs between the complexity and reliability of quantum measurement vs. those of quantum computation have recently been explored. It has been shown that if qubits can be initialized into pairs of maximally entangled states, and two-qubit measurements in the so-called Bell basis ($\Psi^{\pm} = |01\rangle \pm |10\rangle$, $\Phi^{\pm} = |00\rangle \pm |11\rangle$) are possible, then no two-qubit quantum gates are needed, one-bit gates alone suffice[44]. Now, often this tradeoff will not be useful, as in many schemes a Bell measurement would require two-bit quantum gates.

But the overall message, seen in many of our requirements, is that more and more, the theoretical study of quantum computation has offered a great variety of tradeoffs for the potential implementations: if X is very hard, it can be substituted with more of Y. Of course, in many cases both X and Y are beyond the present experimental state of the art; but a thorough knowledge of these tradeoffs should be very useful for devising a rational plan for the pursuit of future experiments.

20.4 Desiderata for quantum communication

For computation alone, the five requirements above suffice. But the advantages of quantum information processing are not manifest solely, or perhaps even principally, for straightforward computation only. There are many kinds of information-processing tasks, reviewed briefly at the beginning, that involve more than just computation, and for which quantum tools provide a unique advantage.

The tasks we have in mind here all involve not only computation but also communication. The list of these tasks that have been considered in the light of quantum capabilities, and for which some advantage has been found in using quantum tools, is fairly long and diverse: it includes secret key distribution, multiparty function evaluation as in appointment scheduling, secret sharing, and game playing[14].

When we say communication we mean quantum communication: the transmission of intact qubits from place to place. This obviously adds more features that the physical apparatus must have to carry out this information processing. We formalize these by adding two more items to the list of requirements:

6. The ability to interconvert stationary and flying qubits

7. The ability faithfully to transmit flying qubits between specified locations

These two requirements are obviously closely related, but it is worthwhile to consider them separately, because some tasks need one but not the other. For instance, quantum cryptography[18] involves only requirement 7; it is sufficient to create and detect flying qubits directly.

I have used the jargon "flying qubits"[2], which has become current in the discussions of quantum communication. Using this term emphasizes that the optimal embodiment of qubits that are readily transmitted from place to place is likely to be very different from the optimal qubits for reliable local computation. Indeed, almost all proposals assume that photon states, with the qubit encoded either in the polarization or in the spatial wavefunction of the photon, will be the flying qubit of choice, and indeed, the well developed technology of light transmission through optical fibers provides a very promising system for the transmission of qubits. I would note, though, that my colleagues and I have raised the possibility that electrons traveling though solids could provide another realization of the flying qubit[14, 45].

Only a few completely developed proposals exist which incorporate requirements 6 and 7. Of course, there are a number of quite detailed studies of 7, in the sense that experiments on quantum cryptography have been very concerned with the preservation of the photon quantum state during transmission through optical fibers or through the atmosphere. However, these studies are rather disconnected from the other concerns of quantum computing. Requirement 6 is the really hard one; to date the only theoretical proposal sufficiently concrete that experiments addressing it have been planned is the scheme produced by Kimble and coworkers[46] for unloading a cavity photon into a traveling mode via atomic spectroscopy, and loading it by the time-reversed process. Other promising concepts, like the launching of electrons from quantum dots into quantum wires such that the spin coherence of the electrons is preserved, need to be worked out more fully.

20.5 Summary

So, what is the "winning" technology going to be? I don't think that any living mortal has an answer to this question, and at this point it may be counterproductive even to ask it. Even though we have lived with quantum mechanics for a century, our study of quantum effects in complex artificial systems like those we have in mind for quantum computing is in its infancy. No one can see how or whether all the requirements above can be fulfilled, or whether there are new tradeoffs, not envisioned in our present theoretical discussions but suggested by further experiments, that might take our investigations in an entirely new path.

Indeed, the above discussion, and the other chapters of this special issue, really do not cover all the foreseeable approaches. I will mention two of which I am aware: first, another computational paradigm, that of the cellular automaton, is potentially available for exploitation. This is distinguished from the above "general purpose" approach in that it assumes that every bit pattern throughout the computer will be subjected to the same evolution rule. It is known that general-purpose computation is performable, although with considerable overhead, by a cellular automaton. This is true as well for the quantum version of the cellular automaton, as Lloyd[47] indicated in his original work. New theoretical work by Benjamin[48] shows very explicitly how relatively simple local rules would permit the implementation of some quantum computations. This could point us perhaps towards some sort of polymer with a string of qubits on its backbone that can be addressed globally in a spectroscopic fashion. Experiments are not oriented towards this at the moment, but the tradeoffs are very different, and I don't believe it should be excluded in the future.

Second, even more speculative, but very elegant, is the proposal of Kitaev[49] to use quantum systems with particular kinds of topological excitations, for example nonabelian anyons, for quantum computing. It is hard to see at the moment how to turn this exciting proposal into an experimental program, as no known physical system is agreed to have the appropriate topological excitations. But further research in, for example, the quantum Hall effect might reveal such a system; more likely, perhaps, is that further understanding of this approach, and that of Freedman and his colleagues[50], will shed more light on doing quantum computing using the "standard" approach being considered in this book.

I am convinced of one thing: the ideas of quantum information theory will continue to exert a decisive influence on the further investigation of the fundamental quantum properties of complex quantum systems, and will stimulate many creative and exciting developments for many years to come.

21 Decoherence, Einselection, and the Quantum Origins of the Classical by Zurek

Decoherence is caused by the interaction with the environment which in effect monitors certain observables of the system, destroying coherence between the *pointer states* corresponding to their eigenvalues. This leads to *environment-induced superselection* or *einselection*, a quantum process associated with selective loss of information. Einselected pointer states are stable. They can retain correlations with the rest of the Universe in spite of the environment. Einselection enforces classicality by imposing an effective ban on the vast majority of the Hilbert space, eliminating especially the flagrantly non-local "Schrödinger cat" states. Classical structure of phase space emerges from the quantum Hilbert space in the appropriate macroscopic limit: Combination of einselection with dynamics leads to the idealizations of a point and of a classical trajectory. In measurements, einselection replaces quantum entanglement between the apparatus and the measured system with the classical correlation. Only the preferred pointer observable of the apparatus can store information that has predictive power. When the measured quantum system is microscopic and isolated, this restriction on the predictive utility of its correlations with the macroscopic apparatus results in the effective "collapse of the wavepacket". *Existential interpretation* implied by einselection regards observers as open quantum systems, distinguished only by their ability to acquire, store, and process information. Spreading of the correlations with the effectively classical pointer states throughout the environment allows one to understand 'classical reality' as a property based on the *relatively objective existence* of the einselected states: They can be "found out" without being re-prepared, e.g, by intercepting the information already present in the environment. The redundancy of the records of pointer states in the environment (which can be thought of as their 'fitness' in the Darwinian sense) is a measure of their classicality. A new symmetry appears in this setting: Environment - assisted invariance or *envariance* sheds a new light on the nature of ignorance of the state of the system due to quantum correlations with the environment, and leads to Born's rules and to the reduced density matrices, ultimately justifying basic principles of the program of decoherence and einselection.

21.1 Introduction

The issue of interpretation is as old as quantum theory. It dates back to the discussions of Niels Bohr, Werner Heisenberg, Erwin Schrödinger, (Bohr, 1928; 1949; Heisenberg, 1927; Schrödinger, 1926; 1935a,b; see also Jammer, 1974; Wheeler and Zurek, 1983). Perhaps the most incisive critique of the (then new) theory was due to Albert Einstein, who, searching for inconsistencies, distilled the essence of the conceptual difficulties of quantum mechanics through ingenious "gedankenexperiments". We owe him and Bohr clarification of the significance of the quantum indeterminacy in course of the Solvay congress debates (see Bohr, 1949) and elucidation of the nature of quantum entanglement (Einstein, Podolsky, and Rosen, 1935; Bohr, 1935, Schrödinger, 1935a,b). Issues identified then are still a part of the subject.

Within the past two decades the focus of the research on the fundamental aspects of quantum theory has shifted from esoteric and philosophical to more "down to earth" as a result of three developments. To begin with, many of the old *gedankenexperiments* (such as the EPR "paradox") became compelling demonstrations of quantum physics. More or less simultaneously the role of decoherence begun to be appreciated and einselection was recognized as key in the emergence of classicality. Last not least, various developments have led to a new view of the role of information in physics. This paper reviews progress with a focus on decoherence, einselection and the emergence of classicality, but also attempts a "preview" of the future of this exciting and fundamental area.

21.1.1 The problem: Hilbert space is big

The interpretation problem stems from the vastness of the Hilbert space, which, by the principle of superposition, admits arbitrary linear combinations of any states as a possible quantum state. This law, thoroughly tested in the microscopic domain, bears consequences that defy classical intuition: It appears to imply that the familiar classical states should be an exceedingly rare exception. And, naively, one may guess that superposition principle should always apply literally: Everything is ultimately made out of quantum "stuff". Therefore, there is no *a priori* reason for macroscopic objects to have definite position or momentum. As Einstein noted[3] localization with respect to macrocoordinates is not just *independent*, but *incompatible* with quantum theory. How can one then establish correspondence between the quantum and the familiar classical reality?

Copenhagen Interpretation

Bohr's solution was to draw a border between the quantum and the classical and to keep certain objects – especially measuring devices and observers – on the classical side (Bohr, 1928; 1949). The principle of superposition was suspended "by decree" in the classical domain. The exact location of this border was difficult to pinpoint, but measurements "brought to a close" quantum events. Indeed, in Bohr's view the classical domain was more fundamental: Its laws were self-contained (they could be confirmed from within) and established the framework necessary to define the quantum.

The first breach in the quantum-classical border appeared early: In the famous Bohr – Einstein double-slit debate, quantum Heisenberg uncertainty was invoked by Bohr at the macroscopic level to preserve wave-particle duality. Indeed, as the ultimate components of classical objects are quantum, Bohr emphasized that the boundary must be moveable, so that even the human nervous system could be regarded as quantum provided that suitable classical devices to detect its quantum features were available. In the words of John Archibald Wheeler (1978; 1983) who has elucidated Bohr's position and decisively contributed to the revival of interest in these matters, "No [quantum] phenomenon is a phenomenon until it is a recorded (observed) phenomenon".

This is a pithy summary of a point of view – known as the Copenhagen Interpretation (CI) – that has kept many a physicist out of despair. On the other hand, as long as a compelling reason for the quantum-classical border could not be found, the CI Universe would be governed by two sets of laws, with poorly defined domains of jurisdiction. This fact has kept many a student, not to mention their teachers, in despair (Mermin 1990a; b; 1994).

Many Worlds Interpretation

The approach proposed by Hugh Everett (1957a, b) and elucidated by Wheeler (1957), Bryce DeWitt (1970) and others (see DeWitt and Graham, 1973; Zeh, 1970; 1973; Geroch, 1984; Deutsch, 1985, 1997, 2001) was to enlarge the quantum domain. Everything is now represented by a unitarily evolving state vector, a gigantic superposition splitting to accommodate all the alternatives consistent with the initial conditions. This is the essence of the Many Worlds Interpretation (MWI). It does not suffer from the dual nature of CI. However, it also does not explain the emergence of classical reality.

[3] In a letter dated 1954, Albert Einstein wrote to Max Born "Let ψ_1 and ψ_2 be solutions of the same Schrödinger equation.... When the system is a macrosystem and when ψ_1 and ψ_2 are 'narrow' with respect to the macrocoordinates, then in by far the greater number of cases this is no longer true for $\psi = \psi_1 + \psi_2$. Narrowness with respect to macrocoordinates is not only independent of the principles of quantum mechanics, but, moreover, incompatible with them." (The translation from Born (1969) quoted here is due to Joos (1986).)

The difficulty many have in accepting MWI stems from its violation of the intuitively obvious "conservation law" – that there is just one Universe, the one we perceive. But even after this question is dealt with, , many a convert from CI (which claims allegiance of a majority of physicists) to MWI (which has steadily gained popularity; see Tegmark and Wheeler, 2001, for an assessment) eventually realizes that the original MWI does not address the "preferred basis question" posed by Einstein[1] (see Wheeler, 1983; Stein, 1984; Bell 1981, 1987; Kent, 1990; for critical assessments of MWI). And as long as it is unclear what singles out preferred states, perception of a unique outcome of a measurement and, hence, of a single Universe cannot be explained either[4].

In essence, Many Worlds Interpretation does not address but only postpones the key question. The quantum - classical boundary is pushed all the way towards the observer, right against the border between the material Universe and the "consciousness", leaving it at a very uncomfortable place to do physics. MWI is incomplete: It does not explain what is effectively classical and why. Nevertheless, it was a crucial conceptual breakthrough: Everett reinstated quantum mechanics as a basic tool in the search for its interpretation.

21.1.2 Decoherence and einselection

Decoherence and einselection are two complementary views of the consequences of the same process of environmental monitoring. Decoherence is the destruction of quantum coherence between preferred states associated with the observables monitored by the environment. Einselection is its consequence – the *de facto* exclusion of all but a small set, a *classical domain* consisting of pointer states – from within a much larger Hilbert space. Einselected states are distinguished by their resilience – stability in spite of the monitoring environment.

The idea that "openness" of quantum systems may have anything to do with the transition from quantum to classical was resolutely ignored for a very long time, probably because in classical physics problems of fundamental importance were always settled in isolated systems. In the context of measurements Gottfried (1967) anticipated some of the latter developments. The fragility of energy levels of quantum systems was emphasized by seminal papers of Dieter Zeh (1970; 1973), who argued (inspired by remarks relevant to what would be called today "deterministic chaos" (Borel, 1914)) that macroscopic quantum systems are in effect impossible to isolate.

The understanding of how the environment distills the classical essence from quantum systems is more recent (Zurek, 1981; 1982; 1993a). It combines two observations: (1) In quantum physics "reality" can be attributed to the measured states. (2) Information transfer usually associated with measurements is a common result of almost any interaction with the environment of a system.

Some quantum states are resilient to decoherence. This is the basis of einselection. Using Darwinian analogy, one might say that pointer states are most 'fit'. They survive monitoring by the environment to leave 'descendants' that inherit their properties. Classical domain of pointer states offers a static summary of the result of quantum decoherence. Save for classical dynamics, (almost) nothing happens to these einselected states, even though they are immersed in the environment.

[4]DeWitt, in the Many Worlds re-analysis of quantum measurements makes this clear: in DeWitt and Graham (1973), last paragraph of p. 189 he writes about the key 'remaining problem': "Why is it so easy to find apparata in states [with a well defined value of the pointer observable]? In the case of macroscopic apparata it is well known that a small value for the mean square deviation of a macroscopic observable is a fairly stable property of the apparatus. But how does the mean square deviation become so small in the first place? Why is a large value of the mean square deviation of a macroscopic observable virtually never, in fact, encountered in practice? ... a proof of this does not yet exist. It remains a program for the future."

It is difficult to catch einselection "in action": Environment has little effect on the pointer states, as they are already classical. Therefore, it was easy to miss decoherence - driven dynamics of einselection by taking for granted its result – existence of the classical domain, and a ban on arbitrary quantum superpositions. Macroscopic superpositions of einselected states disappear rapidly. Einselection creates effective superselection rules (Wick, Wightman and Wigner, 1952; 1970; Wightman, 1995). However, in the microscopic, decoherence can be slow in comparison with the dynamics.

Einselection is a quantum phenomenon. Its essence cannot be even motivated classically: In classical physics arbitrarily accurate measurements (also by the environment) can be in principle carried out without disturbing the system. Only in quantum mechanics acquisition of information inevitably alters the state of the system – the fact that becomes apparent in double-slit and related experiments (Wootters and Zurek, 1979; Zurek, 1983).

Quantum nature of decoherence and the absence of classical analogues are a source of misconceptions. For instance, decoherence is sometimes equated with relaxation or classical noise that can be also introduced by the environment. Indeed, *all* of these effects often appear together and as a consequence of the "openness". The distinction between them can be briefly summed up: *Relaxation and noise are caused by the environment perturbing the system*, while *decoherence and einselection are caused by the system perturbing the environment.*

Within the past few years decoherence and einselection became familiar to many. This does not mean that their implications are universally accepted (see comments in the April 1993 issue of *Physics Today*; d'Espagnat, 1989 and 1995; Bub, 1997; Leggett, 1998 and 2002; Stapp, 2001; exchange of views between Anderson, 2001, and Adler, 2001). In a field where controversy reigned for so long this resistance to a new paradigm is no surprise.

21.1.3 The nature of the resolution and the role of envariance

Our aim is to explain why does the quantum Universe appear classical. This question can be motivated only in the context of the Universe divided into systems, and must be phrased in the language of the correlations between them. In the absence of systems Schrödinger equation dictates deterministic evolution;

$$|\Psi(t)\rangle \;=\; \exp(-iHt/\hbar)\;|\Psi(0)\rangle\;, \tag{1.1}$$

and the problem of interpretation seems to disappear.

There is no need for "collapse" in a Universe with no systems. Yet, the division into systems is imperfect. As a consequence, the Universe is a collection of open (interacting) quantum systems. As the interpretation problem does not arise in quantum theory unless interacting systems exist, we shall also feel free to assume that an environment exists when looking for a resolution.

Decoherence and einselection fit comfortably in the context of the Many Worlds Interpretation where they define the "branches" of the universal state vector. Decoherence makes MWI complete: It allows one to analyze the Universe as it is seen by an observer, who is also subject to decoherence. Einselection justifies elements of Bohr's CI by drawing the border between the quantum and the classical. This natural boundary can be sometimes shifted: Its effectiveness depends on the degree of isolation and on the manner in which the system is probed, but it is a very effective quantum - classical border nevertheless.

Einselection fits either MWI or CI framework: It supplies a statute of limitations, putting an end to the quantum jurisdiction. . It delineates how much of the Universe will appear classical to observers who monitor it from within, using their limited capacity to acquire, store, and process information. It allows one to understand classicality as an idealization that holds in the limit of macroscopic open quantum systems.

Environment imposes superselection rules by preserving part of the information that resides in the correlations between the system and the measuring apparatus (Zurek, 1981, 1982). The observer and the environment compete for the information about the system. Environment – because of its size and its incessant interaction with the system – wins that competition, acquiring information faster and more completely than the observer. Thus, a record useful for the purpose of prediction must be restricted to the observables that are already monitored by the environment. In that case, the observer and the environment no longer compete and decoherence becomes unnoticeable. Indeed, typically *observers use environment as a "communication channel", and monitor it to find out about the system.*

Spreading of the information about the system through the environment is ultimately responsible for the emergence of the "objective reality". Objectivity of a state can be quantified by the redundancy with which it is recorded throughout Universe. Intercepting fragments of the environment allows observers to find out (pointer) state of the system without perturbing it (Zurek, 1993a, 1998a, and 2000; see especially section VII of this paper for a preview of this new "environment as a witness" approach to the interpretation of quantum theory).

When an effect of a transformation acting on a system can be undone by a suitable transformation acting on the environment, so that the joint state of the two remains unchanged, the transformed property of the system is said to exhibit "environment assisted invariance" or *envariance* (Zurek, 2002b). Observer must be obviously ignorant of the envariant properties of the system. Pure entangled states exhibit envariance. Thus, in quantum physics perfect information about the joint state of the system-environment pair can be used to prove ignorance of the state of the system.

Envariance offers a new fundamental view of what is information and what is ignorance in the quantum world. It leads to Born's rule for the probabilities and justifies the use of reduced density matrices as a description of a part of a larger combined system. Decoherence and einselection rely on reduced density matrices. Envariance provides a fundamental resolution of many of the interpretational issues. It will be discussed in section VI D.

21.1.4 Existential Interpretation and 'Quantum Darwinism'

What the observer knows is inseparable from what the observer is: The physical state of his memory implies his information about the Universe. Its reliability depends on the stability of the correlations with the external observables. In this very immediate sense decoherence enforces the apparent "collapse of the wavepacket": After a decoherence timescale, only the einselected memory states will exist and retain useful correlations (Zurek, 1991; 1998a,b; Tegmark, 2000). The observer described by some specific einselected state (including a configuration of memory bits) will be able to access ("recall") only that state. The collapse is a consequence of einselection and of the one-to-one correspondence between the state of his memory and of the information encoded in it. Memory is simultaneously a description of the recorded information and a part of the "identity tag", defining observer as a physical system. It is as inconsistent to imagine observer perceiving something else than what is implied by the stable (einselected) records in his possession as it is impossible to imagine the same person with a different DNA: Both cases involve information encoded in a state of a system inextricably linked with the physical identity of an individual.

Distinct memory/identity states of the observer (that are also his "states of knowledge") cannot be superposed: This censorship is strictly enforced by decoherence and the resulting einselection. Distinct memory states label and "inhabit" different branches of the Everett's "Many Worlds" Universe. Persistence of *correlations* is all that is needed to recover "familiar reality". In this manner, the distinction between epistemology and ontology is washed away: To put it succinctly (Zurek, 1994) there can be *no information without representation* in physical

states.

There is usually no need to trace the collapse all the way to observer's memory. It suffices that the states of a decohering system quickly evolve into mixtures of the preferred (pointer) states. All that can be known in principle about a system (or about an observer, also introspectively, e.g., by the observer himself) is its decoherence-resistant 'identity tag' – a description of its einselected state.

Apart from this essentially negative function of a censor the environment plays also a very different role of a "broadcasting agent", relentlessly cloning the information about the einselected pointer states. This role of the environment as a witness in determining what exists was not appreciated until now: Throughout the past two decades, study of decoherence focused on the effect of the environment on the system. This has led to a multitude of technical advances we shall review, but it has also missed one crucial point of paramount conceptual importance: Observers monitor systems indirectly, by intercepting small fractions of their environments (e.g., a fraction of the photons that have been reflected or emitted by the object of interest). Thus, if the understanding of why we perceive quantum Universe as classical is the principal aim, study of the nature of accessibility of information spread throughout the environment should be the focus of attention. This leads one away from the models of measurement inspired by the "von Neumann chain" (1932) to studies of information transfer involving branching out conditional dynamics and the resulting "fan-out" of the information throughout environment (Zurek, 1983, 1998a, 2000). This new 'quantum Darwinism' view of environment selectively amplifying einselected pointer observables of the systems of interest is complementary to the usual image of the environment as the source of perturbations that destroy quantum coherence of the system. It suggests the redundancy of the imprint of the system in the environment may be a quantitative measure of relative *objectivity* and hence of classicality of quantum states. It is introduced in Sections VI and VII of this review.

Benefits of recognition of the role of environment include not just operational definition of the objective existence of the einselected states, but – as is also detailed in Section VI – a clarification of the connection between the quantum amplitudes and probabilities. Einselection converts arbitrary states into mixtures of well defined possibilities. Phases are envariant: Appreciation of envariance as a symmetry tied to the ignorance about the state of the system was the missing ingredient in the attempts of 'no collapse' derivations of Born's rule and in the probability interpretation. While both envariance and the "environment as a witness" point of view are only beginning to be investigated, the extension of the program of einselection they offer allowes one to understand emergence of "classical reality" form the quantum substrate as a consequence of quantum laws.

21.2 Quantum Measurements

The need for a transition from quantum determinism of the global state vector to classical definiteness of states of individual systems is traditionally illustrated by the example of quantum measurements. An outcome of a "generic" measurement of the state of a quantum system is *not* deterministic. In the textbook discussions this random element is blamed on the "collapse of the wavepacket", invoked whenever a quantum system comes into contact with a classical apparatus. In a fully quantum discussion this issue still arises, in spite (or rather because) of the overall deterministic quantum evolution of the state vector of the Universe: As pointed out by von Neumann (1932), there is no room for a 'real collapse' in the purely unitary models of measurements.

21.2.1 Quantum conditional dynamics

To illustrate the ensuing difficulties, consider a quantum system $\mathcal{S}$ initially in a state $|\psi\rangle$ interacting with a quantum apparatus $\mathcal{A}$ initially in a state $|A_0\rangle$:

$$|\Psi_0\rangle = |\psi\rangle|A_0\rangle = \big(\sum_i a_i|s_i\rangle\big)|A_0\rangle$$
$$\longrightarrow \sum_i a_i|s_i\rangle|A_i\rangle = |\Psi_t\rangle \ . \qquad 2.1 \tag{21.1}$$

Above, $\{|A_i\rangle\}$ and $\{|s_i\rangle\}$ are states in the Hilbert spaces of the apparatus and of the system, respectively, and a_i are complex coefficients. Conditional dynamics of such premeasurement (as the step achieved by Eq. (2.1) is often called) can be accomplished by means of a unitary Schrödinger evolution. Yet it is not enough to claim that a measurement has been achieved: Equation (2.1) leads to an uncomfortable conclusion: $|\Psi_t\rangle$ is an EPR-like *entangled state*. Operationally, this EPR nature of the state emerging from the premeasurement can be made more explicit by re-writing the sum in a different basis:

$$|\Psi_t\rangle \ = \sum_i a_i|s_i\rangle|A_i\rangle = \sum_i b_i|r_i\rangle|B_i\rangle \ . \qquad 2.2 \tag{21.2}$$

This freedom of basis choice – basis ambiguity – is guaranteed by the principle of superposition. Therefore, if one were to associate states of the apparatus (or the observer) with decompositions of $|\Psi_t\rangle$, then even before enquiring about the specific outcome of the measurement one would have to decide on the decomposition of $|\Psi_t\rangle$; the change of the basis redefines the measured quantity.

Controlled not and a bit-by-bit measurement

The interaction required to entangle the measured system and the apparatus, Eq. (2.1), is a generalization of the basic logical operation known as a "controlled not" or a `c-not`. Classical, `c-not` changes the state a_t of the target when the control is 1, and does nothing otherwise:

$$0_{\mathtt{c}}\ a_{\mathtt{t}} \ \longrightarrow \ 0_{\mathtt{c}}\ a_{\mathtt{t}} \ ; \quad 1_{\mathtt{c}}\ a_{\mathtt{t}} \ \longrightarrow \ 1_{\mathtt{c}}\ \neg a_{\mathtt{t}} \tag{2.3}$$

Quantum `c-not` is a straightforward quantum version of Eq. (2.3). It was known as a "bit by bit measurement" (Zurek, 1981; 1983) and used to elucidate the connection between entanglement and premeasurement already before it acquired its present name and significance in the context of quantum computation (see e.g. Nielsen and Chuang, 2000). Arbitrary superpositions of the control bit and of the target bit states are allowed:

$$(\alpha|0_{\mathtt{c}}\rangle \ + \ \beta|1_{\mathtt{c}}\rangle)|a_{\mathtt{t}}\rangle$$
$$\longrightarrow \ \alpha|0_{\mathtt{c}}\rangle|a_{\mathtt{t}}\rangle \ + \ \beta|1_{\mathtt{c}}\rangle|\neg a_{\mathtt{t}}\rangle \qquad 2.4 \tag{21.3}$$

Above "negation" $|\neg a_{\mathtt{t}}\rangle$ of a state is basis dependent;

$$\neg(\gamma|0_{\mathtt{t}}\rangle + \delta|1_{\mathtt{t}}\rangle) = \gamma|1_{\mathtt{t}}\rangle + \delta|0_{\mathtt{t}}\rangle \tag{2.5}$$

With $|A_0\rangle = |0_{\mathtt{t}}\rangle$, $|A_1\rangle = |1_{\mathtt{t}}\rangle$ we have an obvious analogy between the `c-not` and a premeasurement.

In the classical controlled not the direction of information transfer is consistent with the designations of the two bits: The state of the control remains unchanged while it influences the target, Eq. (2.3). Classical measurement need not influence the system. Written in the logical

basis $\{|0\rangle, |1\rangle\}$, the truth table of the quantum `c-not` is essentially – that is, save for the possibility of superpositions – the same as Eq. (2.3). One might have anticipated that the direction of information transfer and the designations ("control/system" and "target/apparatus") of the two qubits will be also unambiguous, as in the classical case. This expectation is incorrect. In the conjugate basis $\{|+\rangle, |-\rangle\}$ defined by:

$$|\pm\rangle = (|0\rangle \pm |1\rangle)/\sqrt{2} \ , \tag{2.6}$$

the truth table of Eq. (2.3) along with Eq. (2.6) lead to a new complementary truth table:

$$|\pm\rangle|+\rangle \longrightarrow |\pm\rangle|+\rangle; \quad |\pm\rangle|-\rangle \longrightarrow |\mp\rangle|-\rangle \ . \qquad 2.7,\ 2.8 \tag{21.4}$$

In the complementary basis $\{|+\rangle, |-\rangle\}$ roles of the control and of the target are reversed: The former (basis $\{|0\rangle, |1\rangle\}$) target – represented by the second ket above – remains unaffected, while the state of the former control (the first ket) is conditionally "flipped".

In the bit-by-bit case the measurement interaction is:

$$\begin{aligned} H_{int} \ &= \ g|1\rangle\langle 1|_{\mathcal{S}}|-\rangle\langle -|_{\mathcal{A}} \ = \\ \frac{g}{2}|1\rangle\langle 1|_{\mathcal{S}} \otimes (\mathbf{1} - (|0\rangle\langle 1| + |1\rangle\langle 0|))_{\mathcal{A}} \qquad & 2.9 \end{aligned} \tag{21.5}$$

Above, g is a coupling constant, and the two operators refer to the system (i.e., to the former control), and to the apparatus pointer (the former target), respectively. It is easy to see that the states $\{|0\rangle, |1\rangle\}_{\mathcal{S}}$ of the system are unaffected by H_{int}, since;

$$[H_{int}, e_0|0\rangle\langle 0|_{\mathcal{S}} + e_1|1\rangle\langle 1|_{\mathcal{S}}] = 0 \tag{2.10}$$

The measured (control) observable $\hat{\epsilon} = e_0|0\rangle\langle 0| + e_1|1\rangle\langle 1|$ is a constant of motion under H_{int}. `c-not` requires interaction time t such that $gt = \pi/2$.

The states $\{|+\rangle, |-\rangle\}_{\mathcal{A}}$ of the apparatus encode the information about phase between the logical states. They have exactly the same "immunity":

$$[H_{int}, f_+|+\rangle\langle +|_{\mathcal{A}} + f_-|-\rangle\langle -|_{\mathcal{A}}] = 0 \tag{2.11}$$

Hence, when the apparatus is prepared in a definite phase state (rather than in a definite pointer/logical state), it will pass on its phase onto the system, as Eqs. (2.7) - (2.8), show. Indeed, H_{int} can be written as:

$$\begin{aligned} H_{int} \ &= \ g|1\rangle\langle 1|_{\mathcal{S}}|-\rangle\langle -|_{\mathcal{A}} \\ = \tfrac{g}{2}(\mathbf{1} - (|-\rangle\langle +| + |+\rangle\langle -|))_{\mathcal{S}} \otimes |-\rangle\langle -|_{\mathcal{A}} \qquad & 2.12 \end{aligned} \tag{21.6}$$

making this "immunity" obvious.

This basis-dependent direction of information flow in a quantum `c-not` (or in a premeasurement) is a consequence of complementarity. While the information about the observable with the eigenstates $\{|0\rangle, |1\rangle\}$ travels from the system to the apparatus, in the complementary $\{|+\rangle, |-\rangle\}$ basis it seems that the apparatus is measured by the system. This remark (Zurek 1998a, b; see also Beckman, Gottesman, and Nielsen, 2001) clarifies the sense in which phases are inevitably "disturbed" in measurements. They are not really destroyed, but, rather, as the apparatus measures a certain observable of the system, the system simultaneously "measures" phases between the possible outcome states of the apparatus. This leads to loss of phase coherence: Phases become "shared property" as we shall see in more detail in the discussion of envariance.

The question "what measures what?" (decided by the direction of the information flow) depends on the initial states. In "the classical practice" this ambiguity does not arise. Einselection limits the set of possible states of the apparatus to a small subset.

Measurements and controlled shifts.

The truth table of a whole class of `c-not` like transformations that includes general premeasurement, Eq. (2.1), can be written as:

$$|s_j\rangle|A_k\rangle \longrightarrow |s_j\rangle|A_{k+j}\rangle \tag{2.13}$$

Equation (2.1) follows when $k = 0$. One can therefore model measurements as controlled shifts – `c-shifts` – generalizations of the `c-not`. In the bases $\{|s_j\rangle\}$ and $\{|A_k\rangle\}$, the direction of the information flow appears to be unambiguous – from the system $\mathcal{S}$ to the apparatus $\mathcal{A}$. However, a complementary basis can be readily defined (Ivanovic, 1981; Wootters and Fields, 1989);

$$|B_k\rangle \;=\; N^{-\frac{1}{2}} \sum_{l=0}^{N-1} \exp\left(\frac{2\pi i}{N} kl\right) |A_l\rangle \ . \tag{2.14a}$$

Above N is the dimensionality of the Hilbert space. Analogous transformation can be carried out on the basis $\{|s_i\rangle\}$ of the system, yielding states $\{|r_j\rangle\}$.

Orthogonality of $\{|A_k\rangle\}$ implies:

$$\langle B_l|B_m\rangle = \delta_{lm} \ . \tag{2.15}$$

$$|A_k\rangle \;=\; N^{-\frac{1}{2}} \sum_{l=0}^{N-1} \exp\left(-\frac{2\pi i}{N} kl\right) |B_l\rangle \tag{2.14b}$$

inverts of the transformtion of Eq. (2.14a). Hence:

$$|\psi\rangle = \sum_l \alpha_l |A_l\rangle = \sum_k \beta_k |B_k\rangle \ , \tag{2.16}$$

where the coefficients β_k are:

$$\beta_k = N^{-\frac{1}{2}} \sum_{l=0}^{N-1} \exp\left(-\frac{2\pi i}{N} kl\right) \alpha_l \ . \tag{2.17}$$

Hadamard transform of Eq. (2.6) is a special case of the more general transformation considered here.

To implement the truth tables involved in premeasurements we define observable $\hat{A}$ and its conjugate:

$$\hat{A} = \sum_{k=0}^{N-1} k|A_k\rangle\langle A_k|; \ \ \hat{B} = \sum_{l=0}^{N-1} l|B_l\rangle\langle B_l| \ . \tag{2.18a, b}$$

The interaction Hamiltonian:

$$H_{int} = g\hat{s}\hat{B} \tag{2.19}$$

is an obvious generalization of Eqs. (2.9) and (2.12), with g the coupling strength and $\hat{s}$:

$$\hat{s} = \sum_{l=0}^{N-1} l|s_l\rangle\langle s_l| \tag{2.20}$$

In the $\{|A_k\rangle\}$ basis $\hat{B}$ is a shift operator,

$$\hat{B} = \frac{iN}{2\pi} \frac{\partial}{\partial \hat{A}} \ . \tag{2.21}$$

To show how H_{int} works, we compute:

$$\exp(-iH_{int}t/\hbar)|s_j\rangle|A_k\rangle = |s_j\rangle N^{-\frac{1}{2}} \sum_{l=0}^{N-1} \exp[-i(jgt/\hbar + 2\pi k/N)l]|B_l\rangle \qquad 2.22 \tag{21.7}$$

We now adjust the coupling g and the duration of the interaction t so that the action ι expressed in Planck units $2\pi\hbar$ is a multiple of $1/N$;

$$\iota = gt/\hbar = G * 2\pi/N \ . \tag{2.23a}$$

For an integer G, Eq. (2.22) can be readily evaluated:

$$\exp(-iH_{int}t/\hbar)|s_j\rangle|A_k\rangle = |s_j\rangle|A_{\{k+G*j\}_N}\rangle. \qquad 2.24 \tag{21.8}$$

This is a shift of the apparatus state by an amount $G * j$ proportional to the eigenvalue j of the state of the system. G plays the role of gain. The index $\{k + G * j\}_N$ is evaluated modulo N, where N is the number of the possible outcomes, that is, the dimensionality of the Hilbert space of the apparatus pointer $\mathcal{A}$: When $G * j > N$, the pointer will just rotate through the initial "zero". The truth table for $G = 1$ defines a `c-shift`, Eq. (2.13), and with $k = 0$ leads to a premeasurement, Eq. (2.1).

The form of the interaction, Eq. (2.19), in conjunction with the initial state decide the direction of information transfer. Note that – as was the case with the `c-not`s – the observable that commutes with the interaction Hamiltonian will not be perturbed:

$$[H_{int}, \hat{s}] = 0 \tag{2.25}$$

$\hat{s}$ commutes with H_{int}, and is therefore a non-demolition observable (Braginsky, Vorontsov and Thorne, 1980; Caves et al, 1980; Bocko and Onofrio, 1996).

Amplification

Amplification was often regarded as the process forcing quantum potentialities to become classical reality. Its example is an extension of the model of measurement described above.

Assume the Hilbert space of the apparatus pointer is large compared with the space spanned by the eigenstates of the measured observable $\hat{s}$:

$$N = Dim(\mathcal{H}_\mathcal{A}) \gg Dim(\mathcal{H}_\mathcal{S}) = n \tag{2.26}$$

Then one can increase ι to an integer multiple G of $2\pi/N$. This was implicit in Eqs. (2.23a) and (2.24). However, larger ι will lead to redundancy only when the apparatus the Hilbert space has many more dimensions in then there are possible outcomes. Otherwise, only "wrapping" of the same record will ensue. The simplest example of such wrapping: $(\texttt{c-not})^2$ is the identity. For $N \gg n$, however, one can attain gain:

$$G = Ngt/2\pi\hbar \ . \tag{2.23b}$$

The outcomes are now separated by $G-1$ "empty" eigenstates of the record observable. In this sense $G \gg 1$ achieves redundancy, providing that wrapping of the record is avoided, which is guaranteed when:

$$nG < N \ . \tag{2.27}$$

Amplification is useful in presence of noise. For example, it may be difficult to initiate the apparatus in $|A_0\rangle$, so the initial state may be a superposition;

$$|a_l\rangle = \sum_k \alpha_l(k)|A_k\rangle \ . \tag{2.28a}$$

Indeed, typically a mixture of such superpositions;

$$\rho^0_{\mathcal{A}} = \sum_i w_i |a_i\rangle\langle a_i| \tag{2.28b}$$

may be the starting point for a premeasurement. Then:

$$|s_k\rangle\langle s_{k'}|\rho_{\mathcal{A}} = |s_k\rangle\langle s_{k'}| \sum_l w_l |a_l\rangle\langle a_l|$$

$$\longrightarrow |s_k\rangle\langle s_{k'}| \sum_l w_l |a_{l+Gk}\rangle\langle a_{l+Gk'}| \qquad 2.29 \tag{21.9}$$

where $|a_{l+Gk}\rangle$ obtains from $|a_l\rangle$, Eq. (2.28a), through:

$$|a_{l+Gk}\rangle \;=\; \sum_j \alpha_l(j) |A_{j+Gk}\rangle \;, \tag{2.30}$$

and the simplifying assumption about the coefficients;

$$\alpha_l(j) = \alpha(j-l) \tag{2.31}$$

has been made. Its aim to focus on the case when the apparatus states are peaked around a certain value l (e.g., $\alpha_l(j) \sim \exp(-(j-l)^2/2\Delta^2)$, and where the form of their distribution over $\{|A_k\rangle\}$ does not depend on l.

A good measurement allows one to distinguish states of the system. Hence, it must satisfy:

$$|\langle a_{l+Gk}|a_{l+Gk'}\rangle|^2$$

$$= |\textstyle\sum_j \alpha(j+G(k-k'))\alpha^*(j)|^2 \approx \delta_{k',k} \;. \qquad 2.32 \tag{21.10}$$

States of the system that need to be distinguished should rotate the pointer of the apparatus to the correlated outcome states that are approximately orthogonal. When the coefficients $\alpha(k)$ are peaked around $k=0$ with dispersion Δ, this implies:

$$\Delta \ll G \;. \tag{2.33}$$

In the general case of an initial mixture, Eq. (2.29), one can evaluate the dispersion of the expectation value of the record observable $\hat{A}$ as:

$$\langle \hat{A}^2\rangle - \langle \hat{A}\rangle^2 \;=\; Tr\rho^0_{\mathcal{A}}\hat{A}^2 \;-\; (Tr\rho^0_{\mathcal{A}}\hat{A})^2 \tag{2.34}$$

The outcomes are distinguishable when:

$$\langle \hat{A}^2\rangle - \langle \hat{A}\rangle^2 \ll G \tag{2.35}$$

Interaction with the environment yields a mixture of the form of Eq. (2.29). Amplification can protect measurement outcomes from noise through redundancy.[5]

[5]The above model of amplification is unitary. Yet, it contains seeds of irreversibility. Reversibility of `c-shift` is evident: As the interaction continues, the two systems will eventually disentangle. For instance, it takes $t_e = 2\pi\hbar/(gN)$ (see Eq. (2.23b) with $G=1$) to entangle $\mathcal{S}$ ($Dim(\mathcal{H}_{\mathcal{S}}) = n$) with an $\mathcal{A}$ with $Dim(\mathcal{H}_{\mathcal{A}}) = N \geq n$ pointer states. However, as the interaction continues, $\mathcal{A}$ and $\mathcal{S}$ disentangle. For a `c-shift` this recurrence timescale is: $t_{Rec} = Nt_e = 2\pi\hbar/g$. It corresponds to gain $G = N$. Thus, for an instant of less than t_e at $t = t_{Rec}$ the apparatus disentangles from the system, as $\{k + N * j\}_N = k$. Reversibility results in recurrences of the initial state, but for $N \gg 1$, they are rare.
For less regular interactions (e.g, involving environment) recurrence time is much longer. In that case, t_{Rec} is,

21.2.2 Information transfer in measurements

Information transfer is the objective of the measurement process. Yet, quantum measurements were only rarely analyzed from that point of view. As a result of the interaction of the system $\mathcal{S}$ with the apparatus $\mathcal{A}$, their joint state is still pure $|\Psi_t\rangle$, Eq. (2.1), but each of the subsystems is in a mixture:

$$\rho_{\mathcal{S}} \;=\; Tr_{\mathcal{A}}|\Psi_t\rangle\langle\Psi_t| \;=\; \sum_{i=0}^{N-1} |a_i|^2 |s_i\rangle\langle s_i| \;; \qquad \text{2.36a} \tag{21.11}$$

$$\rho_{\mathcal{A}} \;=\; Tr_{\mathcal{S}}|\Psi_t\rangle\langle\Psi_t| \;=\; \sum_{i=0}^{N-1} |a_i|^2 |A_i\rangle\langle A_i| \;. \qquad \text{2.36b} \tag{21.12}$$

Partial trace leads to *reduced density matrices*, here $\rho_{\mathcal{S}}$ and $\rho_{\mathcal{A}}$, important for what follows. They describe subsystems to the observer who, before the premeasurement, knew pure states of the system and of the apparatus, but who has access to only one of them afterwards.

Reduced density matrix is a technical tool of paramount importance. It was introduced by Landau (1927) as the only density matrix that gives rise to the correct measurement statistics given the usual formalism that includes Born's rule for calculating probabilities (see e.g. p. 107 of Nielsen and Chuang, 2000, for an insightful discussion). This remark will come to haunt us later when in Section VI we shall consider the relation between decoherence and probabilities: In order to derive Born's rule it will be important not to assume it in some guise!

Following premeasurement, the information about the subsystems available to the observer locally decreases. This is quantified by the increase of the entropies:

$$\begin{aligned} H_{\mathcal{S}} \;&=\; -Tr\rho_{\mathcal{S}} \log \rho_{\mathcal{S}} = -\sum_{i=0}^{N-1} |a_i|^2 \log |a_i|^2 \\ &=\; -Tr\rho_{\mathcal{A}} \log \rho_{\mathcal{A}} = H_{\mathcal{A}} \qquad \text{2.37} \end{aligned} \tag{21.13}$$

As the evolution of the whole $\mathcal{SA}$ is unitary, the increase of entropies in the subsystems is

---

in effect, a Poincaré time: $t_{Rec} \sim t_{Poincaré} \approx N! t_e$. In any case $t_{Rec} \gg t_e$ for large N. Undoing entanglement in this manner would be exceedingly difficult because one would need to know precisely when to look, and because one would need to isolate the apparatus or the immediate environment from other degrees of freedom – their environments.

The price of letting the entanglement undo itself by waiting for an appropriate time interval is at the very least given by the cost of storing the information on how long is it necessary to wait. In the special `c-shift` case this is $\sim \log N$ memory bits. In situations when eigenvalues of the interaction Hamiltonian are not commensurate, it will be more like $\sim \log N! \approx N \log N$, as the entanglement will get undone only after a Poincaré time. Both classical and quantum case can be analyzed using algorithmic information . For related discussions see Zurek, (1989), Caves, (1994); Schack and Caves (1996) and Zurek (1998b).

Amplified correlations are hard to contain. The return to purity after t_{Rec} in the manner described above can be hoped for only when either the apparatus or the immediate environment $\mathcal{E}$ (i.e., the environment directly interacting with the system) cannot "pass on" the information to their more remote environments $\mathcal{E}'$. The degree of isolation required puts a stringent limit on the coupling $g_{\mathcal{E}\mathcal{E}'}$ between the two environments: Return to purity can be accomplished in this manner only if $t_{Rec} < t_{e'} = 2\pi\hbar/(N' g_{\mathcal{E}\mathcal{E}'})$, where N' is the dimension of the Hilbert space of the environment $\mathcal{E}'$. Hence, the two estimates of t_{Rec} translate into: $g_{\mathcal{E}\mathcal{E}'} < g/N'$ for the regular spectrum, and the much tighter; $g_{\mathcal{E}\mathcal{E}'} < g/N!N'$ for the random case more relevant for decoherence.

In short, once information "leaks" into the correlations between the system and the apparatus or the environment, keeping it from spreading further ranges between very hard and next to impossible. With the exception of very special cases (small N, regular spectrum), the strategy of "enlarging the system, so that it includes the environment" – occasionally mentioned as an argument against decoherence – is doomed to fail, unless the Universe as a whole is included. This is a questionable setting (as the observers are *inside* this "isolated" system) and in any case makes the relevant Poincaré time absurdly long!

compensated by the increase of the mutual information:

$$\mathcal{I}(\mathcal{S}:\mathcal{A}) = H_{\mathcal{S}} + H_{\mathcal{A}} - H_{\mathcal{SA}} = -2\sum_{i=0}^{N-1} |a_i|^2 \log |a_i|^2 \qquad 2.38 \tag{21.14}$$

It was used in quantum theory as a measure of entanglement (Zurek, 1983; Barnett and Phoenix, 1989).

Action per bit

An often raised question concerns the price of information in units of some other "physical currency", (Brillouin, 1962; 1964; Landauer, 1991). Here we shall establish that the least action necessary to transfer one bit is of the order of a fraction of $\hbar$ for quantum systems with two-dimensional Hilbert spaces. Information transfer can be made cheaper on the "wholesale" level, when the systems involved have large Hilbert spaces.

Consider Eq. (2.1). It evolves initial product state of the two subsystems into a superposition of product states, $(\sum_j \alpha_j|s_j\rangle)|A_0\rangle \longrightarrow \sum_j \alpha_j|s_j\rangle|A_j\rangle$. The expectation value of the action involved is no less than:

$$I = \sum_{j=0}^{N-1} |\alpha_j|^2 \arccos |\langle A_0|A_j\rangle| \tag{2.39}$$

When $\{|A_j\rangle\}$ are mutually orthogonal, the action is:

$$I = \pi/2 \tag{2.40}$$

in Planck ($\hbar$) units. This estimate can be lowered by using the initial $|A_0\rangle$, a superposition of the outcomes $|A_j\rangle$. In general, interaction of the form:

$$H_{\mathcal{SA}} = ig \sum_{k=0}^{N-1} |s_k\rangle\langle s_k| \sum_{l=0}^{N-1} (|A_k\rangle\langle A_l| - h.c.) \qquad 2.41 \tag{21.15}$$

saturates the lower bound given by:

$$I = \arcsin \sqrt{1 - 1/N}\ , \tag{2.42}$$

For a two-dimensional Hilbert space the average action can be thus brought down to $\pi\hbar/4$ (Zurek, 1981; 1983).

As the size of the Hilbert space increases, action involved approaches the asymptotic estimate of Eq. (2.40). The entropy of entanglement can be as large as $\log N$ where N is the dimension of the Hilbert space of the smaller of the two systems. Thus, the least action per bit of information decreases with the increase of N:

$$\iota = \frac{I}{\log_2 N} \approx \frac{\pi}{2\log_2 N} \tag{2.43}$$

This may be one reason why information appears "free" in the macroscopic domain, but expensive (close to $\hbar$/bit) in the quantum case of small Hilbert spaces.

21.2.3 "Collapse" analogue in a classical measurement

Definite outcomes we perceive appear to be at odds with the principle of superposition. They can nevertheless occur also in quantum physics when the initial state of the measured system is – already before the measurement – in one of the eigenstates of the measured observable. Then

Eq. (2.1) will deterministically rotate the pointer of the apparatus to the appropriate record state. The result of such a measurement can be predicted by an *insider* – an observer aware of the initial state of the system. This *a priori* knowledge can be represented by the preexisting record $|A_i\rangle$, which is only corroborated by an additional measurement:

$$|A_i\rangle|A_0\rangle|\sigma_i\rangle \longrightarrow |A_i\rangle|A_i\rangle|\sigma_i\rangle \ . \qquad (2.44a)$$

In classical physics complete information about the initial state of an isolated system always allows for an exact prediction of its future state: A well-informed observer will be even able to predict future of the classical Universe as a whole ("Laplace's demon").

Any element of surprise (any use of probabilities) must be therefore blamed on partial ignorance. Thus, when the information available initially does not include the exact initial state of the system, observer can use an ensemble described by $\rho_{\mathcal{S}}$ – by a list of possible initial states $\{|\sigma_i\rangle\}$ and their probabilities p_i. This is the *ignorance interpretation* of probabilities. We shall see in section VI that – using quantum envariance – one can justify ignorance about a part of the system by relying on perfect knowledge of the whole.

Through measurement observer finds out which of the potential outcomes consistent with his prior (lack of) information actually happens. This act of acquisition of information changes physical state of the observer – the state of his memory: The initial memory state containing description A_{ρ_S} of an ensemble and a "blank" A_0, $|A_{\rho_S}\rangle\langle A_{\rho_S}| \ |A_0\rangle\langle A_0|$, is transformed into record of a specific outcome: $|A_{\rho_S}\rangle\langle A_{\rho_S}| \ |A_i\rangle\langle A_i|$. In quantum notation this process will be described by such a *discoverer* as a random "collapse":

$$|A_{\rho_S}\rangle\langle A_{\rho_S}| \ |A_0\rangle\langle A_0| \ \sum_i p_i|\sigma_i\rangle\langle\sigma_i|$$
$$\longrightarrow |A_{\rho_S}\rangle\langle A_{\rho_S}| \ |A_i\rangle\langle A_i| \ |\sigma_i\rangle\langle\sigma_i| \ . \qquad 2.44\text{b} \qquad (21.16)$$

This is only the description of what happens "as reported by the discoverer". Deterministic representation of this very same process by Eq. (2.44a) is still possible. In other words, in classical physics discoverer can be always convinced that the system was in a state $|\sigma_i\rangle$ already before the record is made in accord with Eq. (2.44b).

This sequence of events as seen by the discoverer looks like a "collapse" (see also Zurek, 1998a,b): For instance, insider who knew the state of the system before discoverer carried out his measurement need not notice any change of that state when he makes further "confirmatory" measurements. This property is the cornerstone of the "reality" of classical states – they need not ever change as a consequence of measurements. We emphasize, however, that while the state of the system may remain unchanged, the state of the observer must change to reflect the acquired information.

Last not least, an *outsider* – someone who knows about the measurement, but (in contrast to the insider) not about the initial state of the system nor (in contrast to the discoverer) about the measurement outcome, will describe the same process still differently:

$$|A_{\rho_S}\rangle\langle A_{\rho_S}| \ |A_0\rangle\langle A_0| \ \sum_i p_i|\sigma_i\rangle\langle\sigma_i| \longrightarrow$$
$$\longrightarrow |A_{\rho_S}\rangle\langle A_{\rho_S}|(\sum_i p_i|A_i\rangle\langle A_i| \ |\sigma_i\rangle\langle\sigma_i|) \ . \qquad 2.44\text{c} \qquad (21.17)$$

This view of the outsider, Eq. (2.44c), combines one-to-one classical correlation of the states of the system and the records with the indefiniteness of the outcome.

We have just seen three distinct quantum-looking descriptions of the very same *classical* process (see Zurek, 1989, and Caves, 1994 for previous studies of the insider - outsider theme). They differ only in the information available *ab initio* to the observer. The information in

possession of the observer prior to the measurement determines in turn whether – to the observer – the evolution appears to be (a) a confirmation of the preexisting data, Eq. (2.44a), (b) a "collapse" associated with the information gain, Eq. (2.44b) – and with the entropy decrease translated into algorithmic randomness of the acquired data (Zurek, 1989; 1998b) – or (c) an entropy-preserving establishment of a correlation, Eq. (2.44c). All three descriptions are classically compatible, and can be implemented by the same (deterministic and reversible) dynamics.

In classical physics the insider view always exists in principle. In quantum physics it does not. Every observer in a classical Universe could in principle aspire to be an ultimate insider. The fundamental contradiction between every observer knowing precisely the state of the rest of the Universe (including the other observers) can be swept under the rug (if not really resolved) in the Universe where the states are infinitely precisely determined and the observer's records (as a consequence of the $\hbar \to 0$ limit) may have an infinite capacity for information storage. However – given a set value of $\hbar$ – information storage resources of any finite physical system are finite. Hence, in quantum physics observers remain largely ignorant of the detailed state of the Universe as there can be *no information without representation* (Zurek, 1994).

Classical "collapse" is described by Eq. (2.44b): The observer discovers the state of the system. From then on, the state of the system will remain correlated with his record, so that all the future outcomes can be predicted, in effect by iterating Eq. (2.44a). This disappearance of all the potential alternatives save for one that becomes a "reality" is the essence of the collapse. There need not be anything quantum about it.

Einselection in observers memory provides many of the ingredients of the "classical collapse" in the quantum context. In presence of einselection, one-to-one correspondence between the state of the observer and his knowledge about the rest of the Universe can be firmly established, and (at least in principle) operationally verified: One could measure bits in observers memory and determine what he knows without altering his records – without altering his state. After all, one can do so with a classical computer. Existential interpretation recognizes that the information possessed by the observer is reflected in his einselected state, explaining his perception of a single "branch" – "his" classical Universe.

21.3 Chaos and Loss of Coherence

The study of the relationship between the quantum and the classical has been – for a long time – focused almost entirely on measurements. However, the problem of measurement is difficult to discuss without observers. And once observer enters, it is often hard to avoid its ill-understood anthropic attributes such as consciousness, awareness, and the ability to perceive.

We shall sidestep these presently "metaphysical" problems and focus on the information-processing underpinnings of the "observership". It is nevertheless fortunate that there is another problem with the quantum - classical correspondence that leads to interesting questions not motivated by measurements. As was anticipated by Einstein (1917) before the advent of modern quantum theory, chaotic motion presents such a challenge. Full implications of classical dynamical chaos were understood much later. The concern about the quantum-classical correspondence in this modern context dates to Berman and Zaslavsky (1978) and Berry and Balazs (1979) (see Haake, 1991 and Casati and Chirikov, 1995a, for references). It has even led some to question validity of quantum theory (Ford and Mantica, 1992).

21.3.1 Loss of the quantum-classical correspondence

The interplay between quantum interference and chaotic exponential instability leads to the rapid loss of the quantum-classical correspondence. Chaos in dynamics is characterized by the

exponential divergence of the classical trajectories. As a consequence, a small patch representing the probability density in phase space is exponentially stretching in unstable directions and to exponentially compressing in the stable directions. The rates of stretching and compression are given by positive and negative Lyapunov exponents Λ_i. Hamiltonian evolution demands that the sum of all the Lyapunov exponents be zero. In fact, they appear in $\pm\Lambda_i$ pairs.

Loss of the correspondence in chaotic systems is a consequence of the exponential stretching of the effective support of the probability distribution in the unstable direction (say, x) and its exponential narrowing in the complementary direction (Zurek and Paz, 1994; Zurek, 1998b). As a consequence, classical probability distribution will develop structures on the scale:

$$\Delta p \sim \Delta p_0 \ \exp(-\Lambda t) \ . \tag{3.1}$$

Above, Δp_0 is the measure of the initial momentum spread. Λ is the net rate of contraction in the direction of momentum given by the Lyapunov exponents (but see Boccaletti, Farini, and Arecchi, 1997). In the real chaotic system stretching and narrowing of the probability distribution in both x and p occur simultaneously, as the initial patch is rotated and folded. Eventually, the envelope of its effective support will swell to fill in the available phase space, resulting in the wavepacket coherently spread over the spatial region of no less than;

$$\Delta x \sim (\hbar/\Delta p_0) \ \exp(\Lambda t) \tag{3.2}$$

until it becomes confined by the potential, while the small-scale structure will continue to descend to ever smaller scales (Fig. 1). Breakdown of the quantum-classical correspondence can be understood in two complementary ways, either as a consequence of small Δp (see the discussion of Moyal bracket below), or as a result of large Δx.

Coherent exponential spreading of the wavepacket – large Δx – must cause problems with correspondence. This is inevitable, as classical evolution appeals to the idealization of a point in phase space acted upon by a force given by the gradient $\partial_x V$ of the potential $V(x)$ evaluated at that point. But quantum wavefunction can be coherent over a region larger than the nonlinearity scale χ over which the gradient of the potential changes significantly. χ can be usually estimated by:

$$\chi \simeq \sqrt{\partial_x V/\partial_{xxx} V} \ , \tag{3.3}$$

and is typically of the order of the size L of the system:

$$L \sim \chi \ . \tag{3.4}$$

An initially localized state evolving in accord with Eqs. (3.1) and (3.2) will spread over such scales after:

$$t_\hbar \simeq \Lambda^{-1} \ln \frac{\Delta p_0 \chi}{\hbar} \ . \tag{3.5}$$

It is then impossible to tell what is the force acting on the system, as it is not located in any specific x. This estimate of what can be thought of as Ehrenfest time – the time over which a quantum system that has started in a localized state will continue to be sufficiently localized for the quantum corrections to the equations of motion obeyed by its expectation values to be negligible (Gottfried, 1966) – is valid for chaotic systems. Logarithmic dependence is the result of inverting of the exponential sensitivity. In the absence of the exponential instability ($\Lambda = 0$) divergence of trajectories is typically polynomial, and leads to a power law dependence, $t_\hbar \sim (I/\hbar)^\alpha$, where I is the classical action. Thus, macroscopic (large I) integrable systems can follow classical dynamics for a very long time, providing they were initiated in a localized state. For chaotic systems $t_\hbar$ also becomes infinite in the limit $\hbar \to 0$, but that happens only logarithmically slowly. As we shall see below, in the context of quantum-classical correspondence this is too slow for comfort.

Another way of describing the "root cause" of the correspondence breakdown is to note that after the timescale of the order of $t_\hbar$ quantum wave function of the system would have spread over all of the available space, and is being forced to "fold" onto itself. Fragments of the wavepacket arrive at the same location (although with different momenta, and having followed different paths). The ensuing evolution critically depends on whether they have retained phase coherence. When coherence persists, a complicated interference event decides the subsequent evolution. And – as can be anticipated from the double slit experiment – there is a big difference between coherent and incoherent folding in the configuration space. This translates into the loss of correspondence, which sets in surprisingly quickly, at $t_\hbar$.

To find out how quickly, we estimate $t_\hbar$ for an obviously macroscopic Hyperion, chaotically tumbling moon of Saturn (Wisdom, 1985). Hyperion has a prolate shape of a potato and moves on an eccentric orbit with a period t_O =21 days. Interaction between its gravitational quadrupole and the tidal field of Saturn leads to chaotic tumbling with Lyapunov time $\Lambda^{-1} \simeq$42 days.

To estimate the time over which orientation of Hyperion becomes delocalized, we use a formula (Berman and Zaslavsky, 1978, Berry and Balazs, 1979):

$$t_r = \Lambda^{-1} \ln \frac{LP}{\hbar} = \Lambda^{-1} \ln \frac{I}{\hbar} \tag{3.6}$$

Above L and P give the range of values of the coordinate and momentum in phase space of the system. Since $L \simeq \chi$ and $P > \Delta p_0$, it follows that $t_r \geq t_\hbar$. On the other hand, $LP \simeq I$, the action of the system.

The advantage of Eq. (3.6) is its insensitivity to initial conditions, and the ease with which the estimate can be obtained. For Hyperion, a generous overestimate of the classical action I can be obtained from its binding energy E_B and its orbital time t_O:

$$I/\hbar \simeq E_B t_O/\hbar \simeq 10^{77} \tag{3.7}$$

The above estimate (Zurek, 1998b) is "astronomically" large. However, in the calculation of the loss of correspondence, Eq. (3.6), only its logarithm enters. Thus,

$$t_r^{Hyperion} \simeq 42[\text{days}] \ln 10^{77} \simeq 20[\text{yrs}] \tag{3.8}$$

After approximately 20 years Hyperion would be in a coherent superposition of orientations that differ by 2π!

We conclude that after a relatively short time an obviously macroscopic chaotic system becomes forced into a flagrantly non-local "Schrödinger cat" state. In the original discussion (Schrödinger, 1935a,b) an intermediate step in which decay products of the nucleus were *measured* to determine the fate of the cat was essential. Thus, it was possible to maintain that the preposterous superposition of the dead and alive cat could be avoided providing that quantum measurement (with the "collapse" it presumably induces) was properly understood.

This cannot be the resolution for chaotic quantum systems. They can evolve – as the example of Hyperion demonstrates – into states that are non-local, and, therefore, extravagantly quantum, simply as a result of the exponentially unstable dynamics. Moreover, this happens surprisingly quickly, even for very macroscopic examples. Hyperion is not the only chaotic system. There are asteroids that have chaotically unstable orbits (e.g., Chiron), and even indications that the solar system as a whole is chaotic (Laskar, 1989; Sussman and Wisdom, 1992). In all of these cases straightforward estimates of $t_\hbar$ yield answers much smaller than the age of the solar system. Thus, if unitary evolution of closed subsystems was a complete description of planetary dynamics, planets would be delocalized along their orbits.

21.3.2 Moyal bracket and Liouville flow

Heuristic argument about breakdown of the quantum-classical correspondence can be made more rigorous with the help of the Wigner function. We start with the von Neumann equation:

$$i\hbar\dot{\rho} = [H, \rho] \ . \tag{3.9}$$

It can be transformed into the equation for Wigner function W, which is defined in phase space:

$$W(x,p) = \frac{1}{2\pi\hbar}\int \exp\left(\frac{ipy}{\hbar}\right)\rho(x-\frac{y}{2}, x+\frac{y}{2})dy \ . \tag{3.10}$$

The result is:

$$\dot{W} = \{H, W\}_{MB} \ . \tag{3.11}$$

Here $\{...,...\}_{MB}$ stands for Moyal bracket, the Wigner transform of the von Neumann bracket (Moyal, 1949).

Moyal bracket can be expressed in terms of the Poisson bracket $\{...,...\}$, which generates Liouville flow in the classical phase space, by the formula:

$$i\hbar\{...,...\}_{MB} = \sin(i\hbar\{...,...\}) \ . \tag{3.12}$$

When the potential $V(x)$ is analytic, Moyal bracket can be expanded (Hillery et al, 1984) in powers of $\hbar$:

$$\dot{W} = \{H, W\} + \sum_{n\geq 1} \frac{\hbar^{2n}(-)^n}{2^{2n}(2n+1)!}\partial_x^{2n+1}V\partial_p^{2n+1}W \ . \qquad 3.13 \tag{21.18}$$

The first term is just the Poisson bracket. Alone, it would generate classical motion in phase space. However, when the evolution is chaotic, quantum corrections (proportional to the odd order momentum derivatives of the Wigner function) will eventually dominate the right hand side of Eq. (3.10). This is because the exponential squeezing of the initially regular patch in phase space (which begins its evolution in the classical regime, where the Poisson bracket dominates) leads to an exponential explosion of the momentum derivatives. Consequently, after a time logarithmic in $\hbar$, (Eqs. (3.5), (3.6)) the Poisson bracket will cease to be a good estimate of the right hand side of Eq. (3.13).

The physical reason for the ensuing breakdown of the quantum-classical correspondence was already explained before: Exponential instability of the chaotic evolution delocalizes the wavepacket. As a result, the force acting on the system is no longer given by the gradient of the potential evaluated at the location of the system: It is not even possible to say where the system is, since it is in a superposition of many distinct locations. Consequently, phase space distribution and even the typical observables of the system noticeably differ when evaluated classically and quantum mechanically (Haake, Kuś and Sharf, 1987; Habib, Shizume and Zurek, 1998; Karkuszewski, Zakrzewski, and Zurek, 2002). Moreover, this will happen after an uncomfortably short time $t_\hbar$.

21.3.3 Symptoms of correspondence loss

Wavepacket becomes rapidly delocalized in a chaotic system, and the correspondence between classical and quantum is quickly lost. Schrödinger cat states appear after $t_\hbar$ and this is the overarching interpretational as well as physical problem: In the familiar real world we never seem to encounter such smearing of the wavefunction even in the examples of chaotic dynamics it is predicted by quantum theory.

Expectation values

Measurements often average out fine phase space structures, which may be striking, but experimentally inaccessible symptom of breakdown of the correspondence. Thus, one might hope that when interference patterns in the Wigner function are ignored by looking at the coarse-grained distribution, the quantum results should be in accord with the classical. This would not exorcise the 'chaotic cat' problem. Moreover, breakdown of correspondence can be also seen in the expectation values of quantities that are smooth in phase space.

Trajectories diverge exponentially in a chaotic system. A comparison between expectation values for a single trajectory and for a delocalized quantum state (which is how the Ehrenfest theorem mentioned above is usually stated) would clearly lead to a rapid loss of correspondence. One may object to the use of a single trajectory and argue that both quantum and classical state be prepared and accessed only through measurements that are subject to the Heisenberg indeterminacy. Thus, it should be fair to compare averages over an evolving Wigner function with an initially identical classical probability distribution (Ballentine, Yang, and Zibin, 1994; Haake, Kuś & Sharf, 1987; Fox and Elston, 1994; Miller, Sarkar and Zarum, 1998). These are shown in Fig. 2 for an example of a driven chaotic system. Clearly, there is reason for concern: Fig. 2 (corroborated by other studies, see e.g. Karkuszewski, Zakrzewski, and Zurek, 2002, for references) demonstrates that not just phase space portrait but also averages diverge at a time $\sim t_\hbar$.

In integrable systems rapid breakdown of correspondence may still occur, but only for very special initial conditions. It is due to the local instability in phase space. Indeed, a double - slit experiment is an example of a regular system in which a local instability (splitting of the paths) leads to correspondence loss, but only for judiciously selected initial conditions. Thus, one may dismiss it as a consequence of a rare pathological starting point, and argue that the conditions that lead to discrepancies between classical and quantum behavior exist, but are of measure zero in the classical limit.

In the chaotic case the loss of correspondence is typical. As shown in Fig. 2, it happens after a disturbingly short $t_\hbar$ for generic initial conditions. The time at which the quantum and classical expectation values diverge in the example studied here is consistent with the estimates of $t_\hbar$, Eq. (3.5), but exhibits a significant scatter. This is not too surprising – exponents characterizing local instability vary noticeably with the location in phase space. Hence, stretching and contraction in phase space will occur at a rate that depends on the specific trajectory. Dependence of its typical magnitude as a function of $\hbar$ is still not clear. Emerson and Ballentine (2001a&b) study coupled spins and argue that it is of order of $\hbar$, but Fig. 2 suggests it decreases more slowly than that, and that it may be only logarithmic in $\hbar$ (Karkuszewski et al. 2002).

Structure saturation

Evolution of the Wigner function exhibits rapid buildup of interference fringes. These fringes become progressively smaller, until saturation when the wavepacket is spread over the available phase space. At that time their scales in momentum and position are typically:

$$dp = \hbar/L \quad ; \quad dx = \hbar/P \tag{3.14, 3.15}$$

where L (P) defines the range of positions (momenta) of the effective support of W in phase space.

Hence, smallest structures in the Wigner function occur (Zurek, 2001) on scales corresponding to action:

$$a \;=\; dx\; dp \;=\; \hbar \times \hbar/LP \;=\; \hbar^2/I \;, \tag{3.16}$$

where $I \simeq LP$ is the classical action of the system. Action $a \ll \hbar$ for macroscopic I.

Sub-Planck structure is a kinematic property of quantum states. It limits their sensitivity to perturbations, and has applications outside quantum chaos or decoherene. For instance, Schrödinger cat state can be used as a weak force detector (Zurek, 2001), and its sensitivity is determined by Eqs. (3.14)-(3.16).

Structure saturation on scale a is an important distinction between quantum and classical. In chaotic systems smallest structures in the classical probability density exponentially shrink with time, in accord with Eq. (3.1) (see Fig. 1). Equation (3.16) has implications for decoherence, as a controls sensitivity of the systems as well as environments (Zurek, 2001; Karkuszewski, Jarzynski, and Zurek, 2002): As a result of smallness of a, Eq. (3.16), and as anticipated by Peres (1993), quantum systems are more sensitive to perturbations when their classical counterparts are chaotic (see also Jalabert and Pastawski, 2001). But – in contrast to classical chaotic systems – they are not exponentially sensitive to infinitesimally small perturbations: Rather, the smallest perturbations that can effective are set by Eq. (3.16).

Emergence of Schrödinger cats through dynamics is a challenge to quantum - classical correspondence. It is not yet clear to what extent one should be concerned about the discrepancies between quantum and classical averages: The size of this discrepancy may or may not be negligible. But in the original Schrödinger cat problem quantum and classical expectation values (for the survival of the cat) were also in accord. In both cases it is ultimately the state of the cat which is most worrisome.

Note that we have not dealt with dynamical localization (Casati and Chirikov, 1995a). This is because it appears after too long a time ($\sim \hbar^{-1}$) to be a primary concern in the macroscopic limit, and is quite sensitive to small perturbations of the potential (Karkuszewski, Zakrzewski, and Zurek, 2002).

21.4 Environment-Induced Superselection

The principle of superposition applies only when the quantum system is closed. When the system is open, interaction with the environment results in an incessant monitoring of some of its observables. As a result, pure states turn into mixtures that rapidly diagonalize in the einselected states. These pointer states are chosen with the help of the interaction Hamiltonian and are independent of the initial state of the system. Their predictability is key to the effective classicality (Zurek, 1993a; Zurek, Habib, and Paz, 1993).

Environments can be external (such as particles of the air or photons that scatter off, say, the apparatus pointer) or internal (collections of phonons or other internal excitations). Often, environmental degrees of freedom emerge from the split of the original set of degrees of freedom into the "system of interest" which may be a collective observable (e.g., an order parameter in a phase transition), and the "microscopic remainder".

The set of einselected states is called *the pointer basis* (Zurek, 1981) in recognition of its role in measurements. The criterion for the einselection of states goes well beyond the often repeated characterizations based on the instantaneous eigenstates of the density matrix. What is of the essence is the ability of the einselected states to survive monitoring by the environment. This heuristic criterion can be made rigorous by quantifying predictability of the evolution of the candidate states, or of the associated observables. Einselected states provide optimal initial conditions: They can be employed for the purpose of prediction better than other Hilbert space alternatives – they retain correlations in spite of their immersion in the environment.

Three quantum systems – the measured system $\mathcal{S}$, the apparatus $\mathcal{A}$, and the environment $\mathcal{E}$ – and correlations between them are the subject of our study. In pre-measurements $\mathcal{S}$ and $\mathcal{A}$ interact. Their resulting entanglement transforms into an effectively classical correlation as a result of the interaction between $\mathcal{A}$ and $\mathcal{E}$.

This $\mathcal{SAE}$ triangle helps analyze decoherence and study its consequences. By keeping all

three corners of this triangle in mind, one can avoid confusion, and maintain focus on the *correlations* between, e.g., the memory of the observer and the state of the measured system. The evolution from a quantum entanglement to the classical correlation may be the easiest relevant theme to define operationally. In the language of the last part of Section II, we are about to justify the "outsider" point of view, Eq. (2.44c), before considering the "discoverer", Eq. (2.44b) and the issue of the "collapse". In spite of this focus on correlations, we shall often suppress one of the corners of the $\mathcal{SAE}$ triangle to simplify notation. All three parts will however play a role in formulating questions and in motivating criteria for classicality.

21.4.1 Models of einselection

The simplest case of a single act of decoherence involves just three one-bit systems (Zurek, 1981; 1983). They are denoted by $\mathcal{S}$, $\mathcal{A}$, and $\mathcal{E}$ in an obvious reference to their roles. The measurement starts with the interaction of the measured system with the apparatus:

$$|\uparrow\rangle|A_0\rangle \longrightarrow |\uparrow\rangle|A_1\rangle,\ |\downarrow\rangle|A_0\rangle \longrightarrow |\downarrow\rangle|A_0\rangle; \qquad (4.1a,\ b)$$

where $\langle A_0|A_1\rangle = 0$. For a general state:

$$(\alpha|\uparrow\rangle + \beta|\downarrow\rangle)|A_0\rangle \longrightarrow \alpha|\uparrow\rangle|A_1\rangle + \beta|\downarrow\rangle|A_0\rangle = |\Phi\rangle. \qquad (4.2)$$

These formulae are an example of a `c-not` like the premeasurement discussed in section 2.

The basis ambiguity – the ability to re-write $|\Phi\rangle$, Eq. (4.2), in any basis of, say, the system, with the superposition principle guaranteeing existence of the corresponding pure states of the apparatus – disappears when an additional system, $\mathcal{E}$, performs a premeasurement on $\mathcal{A}$:

$$\begin{aligned}&(\alpha|\uparrow\rangle|A_1\rangle + \beta|\downarrow\rangle|A_0\rangle)|\varepsilon_0\rangle \\ &\longrightarrow \alpha|\uparrow\rangle|A_1\rangle|\varepsilon_1\rangle + \beta|\downarrow\rangle|A_0\rangle|\varepsilon_0\rangle = |\Psi\rangle. \qquad 4.3\end{aligned} \qquad (21.19)$$

A collection of three correlated quantum systems is no longer subject to the basis ambiguity we have pointed out in connection with the EPR-like state $|\Phi\rangle$, Eq. (4.2). This is especially true when states of the environment are correlated with the simple products of the states of the apparatus - system combination (Zurek, 1981; Elby and Bub, 1994). In Eq. (4.3) this can be guaranteed (irrespective of the value of α and β) providing that:

$$\langle\varepsilon_0|\varepsilon_1\rangle = 0\ . \qquad (4.4)$$

When this orthogonality condition is satisfied, the state of the $\mathcal{A}-\mathcal{S}$ pair is given by a reduced density matrix:

$$\begin{aligned}\rho_{\mathcal{AS}} \ &= \ Tr_{\mathcal{E}}|\Psi\rangle\langle\Psi| = \\ |\alpha|^2|\uparrow\rangle\langle\uparrow||A_1\rangle\langle A_1| + |\beta|^2|\downarrow\rangle\langle\downarrow||A_0\rangle\langle A_0| \qquad 4.5a\end{aligned} \qquad (21.20)$$

containing only classical correlations.

If the condition of Eq. (4.4) did not hold – that is, if the orthogonal states of the environment were not correlated with the apparatus in the basis in which the original premeasurement was carried out – then the eigenstates of the reduced density matrix $\rho_{\mathcal{AS}}$ would be sums of products rather than simply products of states of $\mathcal{S}$ and $\mathcal{A}$. Extreme example of this situation is the pre-decoherence density matrix of the pure state:

$$\begin{aligned}|\Phi\rangle\langle\Phi| \quad &= |\alpha|^2|\uparrow\rangle\langle\uparrow||A_1\rangle\langle A_1| \ + \alpha\beta^*|\uparrow\rangle\langle\downarrow||A_1\rangle\langle A_0| \\ &+\alpha^*\beta|\downarrow\rangle\langle\uparrow||A_0\rangle\langle A_1| + |\beta|^2|\downarrow\rangle\langle\downarrow||A_0\rangle\langle A_0| \qquad 4.5b\end{aligned} \qquad (21.21)$$

Its eigenstate is $|\Phi\rangle$. When expanded, $|\Phi\rangle\langle\Phi|$ contains terms that are off-diagonal when expressed in any of the natural bases consisting of the tensor products of states in the two systems. Their disappearance as a result of tracing over the environment removes the basis ambiguity. Thus, for example, the reduced density matrix $\rho_{\mathcal{AS}}$, Eq. (4.5a), has the same form as the outsider description of the classical measurement, Eq. (2.44c).

In our simple model pointer states are easy to characterize: To leave pointer states untouched, the Hamiltonian of interaction $H_{\mathcal{AE}}$ should have the same structure as for the `c-not`, Eqs. (2.9) - (2.10): It should be a function of the pointer observable; $\hat{A} = a_0|A_0\rangle\langle A_0| + a_1|A_1\rangle\langle A_1|$ of the apparatus. Then the states of the environment will bear an imprint of the pointer states $\{|A_0\rangle, |A_1\rangle\}$. As noted in section II:

$$[H_{\mathcal{AE}}, \hat{A}] = 0 \tag{4.6}$$

immediately implies that $\hat{A}$ is a control, and its eigenstates will be preserved.

Decoherence of a single qubit

An example of continuous decoherence is afforded by a two-state apparatus $\mathcal{A}$ interacting with an environment of N other spins (Zurek, 1982). The two apparatus states are $\{|\Uparrow\rangle, |\Downarrow\rangle\}$. For the simplest, yet already interesting example the self-Hamiltonian of the apparatus disappears, $H_{\mathcal{A}} = 0$, and the interaction has the form:

$$\begin{aligned} H_{\mathcal{AE}} &= (|\Uparrow\rangle\langle\Uparrow| - |\Downarrow\rangle\langle\Downarrow|) \\ &\quad \otimes \sum_k g_k(|\uparrow\rangle\langle\uparrow| - |\downarrow\rangle\langle\downarrow|)_k \ , \qquad 4.7 \end{aligned} \tag{21.22}$$

Under the influence of this Hamiltonian the initial state:

$$|\Phi(0)\rangle = (a|\Uparrow\rangle + b|\Downarrow\rangle) \prod_{k=1}^{N}(\alpha_k|\uparrow\rangle_k + \beta_k|\downarrow\rangle_k) \qquad 4.8 \tag{21.23}$$

evolves into:

$$|\Phi(t)\rangle = a|\Uparrow\rangle|\mathcal{E}_{\Uparrow}(t)\rangle + b|\Downarrow\rangle|\mathcal{E}_{\Downarrow}(t)\rangle \ ; \tag{4.9}$$

$$|\mathcal{E}_{\Uparrow}(t)\rangle = \prod_{k=1}^{N}(\alpha_k e^{ig_k t}|\uparrow\rangle_k + \beta_k e^{-ig_k t}|\downarrow\rangle_k) = |\mathcal{E}_{\Downarrow}(-t)\rangle. \qquad 4.10 \tag{21.24}$$

The reduced density matrix is:

$$\begin{aligned} \rho_{\mathcal{A}} &= |a|^2|\Uparrow\rangle\langle\Uparrow| + ab^* r(t)|\Uparrow\rangle\langle\Downarrow| \\ &+ a^* b r^*(t)|\Downarrow\rangle\langle\Uparrow| + |b|^2|\Downarrow\rangle\langle\Downarrow| \ . \qquad 4.11 \end{aligned} \tag{21.25}$$

The coefficient $r(t) = \langle\mathcal{E}_{\Uparrow}|\mathcal{E}_{\Downarrow}\rangle$ determines the relative size of the off-diagonal terms. It is given by:

$$r(t) = \prod_{k=1}^{N}[\cos 2g_k t + i(|\alpha_k|^2 - |\beta_k|^2)\sin 2g_k t] \ . \qquad 4.12 \tag{21.26}$$

For large environments consisting of many (N) spins at large times the off-diagonal terms are typically small:

$$|r(t)|^2 \simeq 2^{-N}\prod_{k=1}^{N}[1 + (|\alpha_k|^2 - |\beta_k|^2)^2] \tag{4.13}$$

The density matrix of any two-state system can be represented by a point in the 3-D space. In terms of the coefficients a, b, and $r(t)$ coordinates of the point representing it are; $z = (|a|^2 - |b|^2)$, $x = \mathrm{Re}(ab^* r)$, $y = \mathrm{Im}(ab^* r)$. When the state is pure, $x^2 + y^2 + z^2 = 1$: Pure states lie on the surface of the Bloch sphere (Fig. 3).

Any conceivable (unitary or non-unitary) quantum evolution can be thought of as a transformation of the surface of the pure states into the ellipsoid contained inside the Bloch sphere. Deformation of the Bloch sphere surface caused by decoherence is a special case of such general evolutions (Zurek, 1982, 1983; Berry, 1995). Decoherence does not affect $|a|$ or $|b|$. Hence, evolution due to decoherence alone occurs in plane z=const. Such a "slice" through the Bloch sphere would show the point representing the state at a fraction $|r(t)|$ of its maximum distance. The complex $r(t)$ can be expressed as the sum of complex phase factors rotating with the frequencies given by differences $\Delta\omega_j$ between the energy eigenvalues of the interaction Hamiltonian, weighted with the probabilities of finding them in the initial state:

$$r(t) = \sum_{j=1}^{2^N} p_j \exp(-i\Delta\omega_j t) \ . \tag{4.14}$$

The index j denotes the environment part of the energy eigenstates of the interaction Hamiltonian, Eq. (4.7): $|j\rangle = |\uparrow\rangle_1 \otimes |\downarrow\rangle_2 \otimes \cdots \otimes |\uparrow\rangle_N$. The corresponding differences between the energies of the eigenstates $|\Uparrow\rangle|j\rangle$ and $|\Downarrow\rangle|j\rangle$ are; $\Delta\omega_j = \langle\Uparrow|\langle j|H_{\mathcal{AE}}|j\rangle|\Downarrow\rangle$. There are 2^N distinct $|j\rangle$'s, and, barring degeneracies, the same number of different $\Delta\omega_j$'s. Probabilities p_j are:

$$p_j = |\langle j|\mathcal{E}(t=0)\rangle|^2 \ , \tag{4.15}$$

which is in turn easily expressed in terms of the appropriate squares of α_k and β_k.

The evolution of $r(t)$, Eq. (4.14), is a consequence of the rotations of the complex vectors $p_k \exp(-i\Delta\omega_j t)$ with different frequencies. The resultant $r(t)$ will then start with the amplitude 1, and quickly "crumble"to

$$\langle |r(t)|^2 \rangle \sim \sum_{j=1}^{2^N} p_j^2 \sim 2^{-N} \ . \tag{4.16}$$

In this sense, decoherence is exponentially effective – the magnitude of the off-diagonal terms decreases exponentially fast with the physical size N of the environment effectively coupled to the state of the system.

We note that the effectiveness of einselection depends on the initial state of the environment: When $\mathcal{E}$ is in the k'th eigenstate of $H_{\mathcal{AE}}$, $p_j = \delta_{jk}$, the coherence in the system will be retained. This special environment state is, however, unlikely in realistic circumstances.

The classical domain and a quantum halo

Geometry of flows induced by decoherence in the Bloch sphere exhibits characteristics encountered in general:

(i) The classical set of the einselected pointer states ($\{|\Uparrow\rangle, |\Downarrow\rangle\}$ in our case). Pointer states are the pure states least affected by decoherence.

(ii) Classical domain consisting of all the pointer states and their mixtures. In Fig. 3 it corresponds to the section [-1,+1] of z-axis.

(iii) The quantum domain – the rest of the volume of the Bloch sphere – consisting of more general density matrices.

Visualizing decoherence-induced decomposition of the Hilbert space may be possible only in the simple case studied here, but whenever decoherence leads to classicality, emergence of generalized and often approximate version of the elements (i) – (iii) is an expected feature.

As a result of decoherence the part of the Hilbert space outside of the classical domain is "ruled out" by einselection. The severity of the prohibition on its states varies. One may measure "non-classicality" of (pure or mixed) states by quantifying their distance from this classical state with the rate of entropy production and comparing it with the much lower rate in the classical domain. Classical pointer states would be then enveloped by a "quantum halo" (Anglin and Zurek, 1996) of nearby, relatively decoherence - resistant but still somewhat quantum states, with a more flagrantly quantum (and more fragile) Schrödinger cat states further away.

By the same token, one can define einselection - induced metric in the classical domain, with the distance between two pointer states given by the rate of entropy production of their superposition. This is not the only way to define a distance: As we shall see in Section VII, redundancy of the record of a state imprinted on the environment is a very natural measure of its classicality. In course of decoherence, pointer states tend to be recorded redundantly and can be deduced by intercepting a very small fraction of the environment (Zurek, 2000; Dalvit, Dziarmaga and Zurek, 2001). One can then define distance using the fraction of the environment that needs to be intercepted to distinguish between two pointer states of the system (Ollivier, Poulin, and Zurek, 2002).

Einselection and controlled shifts

Discussion of decoherence can be generalized to the situation where the system, the apparatus, and the environment have many states, and their interactions are more complicated. Here we assume that the system is isolated, and that it interacts with the apparatus in a `c-shift` manner discussed in Section II. As a result of that interaction the state of the apparatus becomes entangled with the state of the system: $(\sum_i \alpha_i|s_i\rangle)|A_0\rangle \longrightarrow \sum_i \alpha_i|s_i\rangle|A_i\rangle$. This state suffers from the basis ambiguity: The $\mathcal{S}-\mathcal{A}$ entanglement implies that for any state of either there exists a corresponding pure state of its partner. Indeed, when the initial state of $\mathcal{S}$ is chosen to be one of the eigenstates of the conjugate basis:

$$|r_l\rangle = N^{-\frac{1}{2}} \sum_{k=0}^{N-1} \exp(2\pi ikl/N)|s_k\rangle \ , \tag{4.17}$$

`c-shift` could equally well represent a measurement of the apparatus (in the basis conjugate to $\{|A_k\rangle\}$) by the system. Thus, it is not just the basis which is ambiguous: Also the roles of the control (system) and of the target (apparatus) can be reversed when the conjugate basis is selected. These ambiguities can be removed by recognizing the role of the environment.

Figure 4 captures the essence of the idealized decoherence process, that allows the apparatus to be – in spite of the interaction with the environment – a noiseless classical communication channel (Schumacher, 1996; Lloyd, 1997). This is possible because the $\mathcal{A}-\mathcal{E}$ `c-shift`s do not disturb pointer states.

The advantage of this caricature of the decoherence process as a sequence of `c-shift`s lies in its simplicity. However, the actual process of decoherence is usually continuous (so that it can be only approximately broken up into discrete `c-shift`s). Moreover, in contrast to the `c-not`s used in quantum logic circuits, the record inscribed in the environment is usually distributed over many degrees of freedom. Last not least, the observable of the apparatus (or any other open system) may be subject to noise (and not just decoherence) or its self-Hamiltonian may rotate instantaneous pointer states into their superpositions. These very likely complications will be investigated in specific models below.

Decoherence is caused by a premeasurement - like process carried out by the environment

$\mathcal{E}$:

$$|\Psi_{\mathcal{SA}}\rangle|\varepsilon_0\rangle = (\sum_j \alpha_j|s_j\rangle|A_j\rangle)|\varepsilon_0\rangle$$
$$\longrightarrow \sum_j \alpha_j|s_j\rangle|A_j\rangle|\varepsilon_j\rangle \;=\; |\Phi_{\mathcal{SAE}}\rangle \qquad 4.18 \tag{21.27}$$

Decoherence leads to einselection when the states of the environment $|\varepsilon_j\rangle$ corresponding to different pointer states become orthogonal:

$$\langle\varepsilon_i|\varepsilon_j\rangle = \delta_{ij} \tag{4.19}$$

Then the Schmidt decomposition of the state vector $|\Phi_{\mathcal{SAE}}\rangle$ into a composite subsystem $\mathcal{SA}$ and $\mathcal{E}$ yields product states $|s_j\rangle|A_j\rangle$ as partners of the orthogonal environment states. The decohered density matrix describing $\mathcal{SA}$ pair is then diagonal in product states: For simplicity we shall often discard reference to the object that

$$\rho^D_{\mathcal{SA}} \;=\; \sum_j |\alpha_j|^2|s_j\rangle\langle s_j||A_j\rangle\langle A_j|$$
$$\;=\; Tr_{\mathcal{E}}|\Phi_{\mathcal{SAE}}\rangle\langle\Phi_{\mathcal{SAE}}| \; . \qquad 4.20 \tag{21.28}$$

does not interact with the environment (here – the system $\mathcal{S}$). Nevertheless, *preservation of the $\mathcal{SA}$ correlations is the criterion defining the pointer basis.* Invoking it would get rid of many a confusion (see, e.g, discussions in Halliwell, Perez-Mercader, and Zurek, 1994; Venugopalan, 1994). The density matrix of a single object in contact with the environment will be always diagonal in an (instantaneous) Schmidt basis. This instantaneous diagonality should not be used the *sole* criterion for classicality (although see Zeh, 1973, 1990; Albrecht, 1992&1993). Rather, ability of certain states to retain correlations in spite of the coupling to the environment is decisive.

When the interaction with the apparatus has the form:

$$H_{\mathcal{AE}} = \sum_{k,l,m} g^{\mathcal{AE}}_{klm}|A_k\rangle\langle A_k||\varepsilon_l\rangle\langle\varepsilon_m| + h.c. \; , \tag{4.21}$$

the basis $\{|A_k\rangle\}$ is left unperturbed and any correlation with the states $\{|A_k\rangle\}$ is preserved. But, by definition, pointer states preserve correlations in spite of decoherence, so that any observable A co-diagonal with the interaction Hamiltonian will be pointer observable. For, when the interaction is a function of A, it can be expanded in A as a power series, so it commutes with A:

$$[H_{\mathcal{AE}}(A), A] = 0 \tag{4.22}$$

The dependence of the interaction Hamiltonian on the observable is an obvious precondition for the monitoring of that observable by the environment. This admits existence of degenerate pointer eigenspaces of A.

21.4.2 Einselection as the selective loss of information

Establishment of the measurement-like correlation between the apparatus and the environment changes the density matrix from the premeasurement $\rho^P_{\mathcal{SA}}$ to the decohered $\rho^D_{\mathcal{SA}}$, Eq. (4.20). For the initially pure $|\Psi_{\mathcal{SA}}\rangle$, Eq. (4.18), this transition is represented by:

$$\rho^P_{\mathcal{SA}} = \sum_{i,j} \alpha_i\alpha^*_j|s_i\rangle\langle s_j||A_i\rangle\langle A_j| \longrightarrow$$
$$\longrightarrow \sum_i |\alpha_i|^2|s_i\rangle\langle s_i||A_i\rangle\langle A_i| = \rho^D_{\mathcal{SA}} \qquad 4.23 \tag{21.29}$$

Einselection is accompanied by the increase of entropy:

$$\Delta H(\rho_{\mathcal{SA}}) = H(\rho^D_{\mathcal{SA}}) - H(\rho^P_{\mathcal{SA}}) \geq 0 \tag{4.24}$$

and by the disappearance of the ambiguity in what was measured (Zurek, 1981, 1993a). Thus, before decoherence the conditional density matrices of the system $\rho_{\mathcal{S}|C_j\rangle}$ are pure for any state $|C_j\rangle$ of the apparatus pointer. They are defined using the unnormalized:

$$\tilde{\rho}_{\mathcal{S}|\Pi_j} = Tr_{\mathcal{A}}\Pi_j\rho_{\mathcal{SA}} \tag{4.25}$$

where in the simplest case $\Pi_j = |C_j\rangle\langle C_j|$ projects onto a pure state of the apparatus.[6]

Normalized $\rho_{\mathcal{S}|\Pi_j}$ can be obtained by using the probability of the outcome:

$$\rho_{\mathcal{S}|\Pi_j} = p_j^{-1}\tilde{\rho}_{\mathcal{S}|\Pi_j} \ ; \quad p_j = Tr\tilde{\rho}_{\mathcal{S}|\Pi_j} \ . \qquad 4.26 \tag{21.30}$$

Conditional density matrix represents the description of the system $\mathcal{S}$ available to the observer who knows that the apparatus $\mathcal{A}$ is in a subspace defined by Π_j.

Before decoherence, $\rho^P_{\mathcal{S}|C_j\rangle}$ is pure for any state $|C_j\rangle$:

$$(\rho^P_{\mathcal{S}|\Pi_j})^2 \ = \ \rho^P_{\mathcal{S}|\Pi_j} \quad \forall|C_j\rangle \tag{4.27a}$$

providing the initial premeasurement state, Eq. (4.23), was pure as well. It follows that:

$$H(\rho^P_{\mathcal{SA}|C_j\rangle}) = 0 \quad \forall|C_j\rangle \ . \tag{4.28a}$$

For this same case given by the initially pure $\rho^P_{\mathcal{SA}}$ of Eq. (4.23), conditional density matrices obtained from the decohered $\rho^D_{\mathcal{SA}}$ will be pure if and only if they are conditioned upon the pointer states $\{|A_k\rangle\}$;

$$(\rho^D_{\mathcal{S}|C_j\rangle})^2 = \rho^P_{\mathcal{S}|C_j\rangle} = |s_k\rangle\langle s_k| \iff |C_j\rangle = |A_j\rangle; \qquad 4.27\text{b} \tag{21.31}$$

$$H(\rho^D_{\mathcal{S}|A_j\rangle}) = H(\rho^P_{\mathcal{S}|A_j\rangle}) \ . \tag{4.28b}$$

This last equation is valid even when the initial states of the system and of the apparatus are not pure. Thus, only in the pointer basis the pre-decoherence strength of the $\mathcal{SA}$ correlation will be maintained. In all other bases:

$$Tr(\rho^D_{\mathcal{S}|C_j\rangle})^2 \ < \ Tr\rho^D_{\mathcal{S}|C_j\rangle}; \quad |C_j\rangle \notin \{|A_j\rangle\} \tag{4.27c}$$

$$H(\rho^P_{\mathcal{S}|C_j\rangle}) \ < \ H(\rho^D_{\mathcal{S}|C_j\rangle}); \quad |C_j\rangle \notin \{|A_j\rangle\} \tag{4.28c}$$

In particular, in the basis $\{|B_j\rangle\}$ conjugate to the pointer states $\{|A_j\rangle\}$, Eq. (2.14), there is no correlation left with the state of the system, that is:

$$\rho^D_{\mathcal{S}|B_j\rangle} = N^{-1}\sum_k |s_k\rangle\langle s_k| = \mathbf{1}/N \tag{4.29}$$

where $\mathbf{1}$ is a unit density matrix. Consequently;

$$(\rho^D_{\mathcal{S}|B_j\rangle})^2 = \rho_{\mathcal{S}|B_j\rangle}/N, \tag{4.27d}$$

$$H(\rho^D_{\mathcal{S}|B_j\rangle}) = H(\rho^P_{\mathcal{S}|B_j\rangle}) - \lg N = -\lg N \ . \tag{4.28d}$$

Note that, initially, conditional density matrices were pure also in the conjugate (and any other) basis, provided that the initial state was the pure entangled projection operator $\rho^P_{\mathcal{SA}} = |\Psi_{\mathcal{SA}}\rangle\langle\Psi_{\mathcal{SA}}|$, Eq. (4.23).

[6] This can be generalized to projections onto multidimensional subspaces of the apparatus. In that case, purity of the conditional density matrix will be usually lost during the trace over the states of the pointer. This is not surprising: When the observer reads off the pointer of the apparatus only in a coarse-grained manner, he will forgo part of the information about the system. Amplification we have considered before can prevent some of such loss of resolution due to coarse graining in the apparatus. Generalizations to density matrices conditioned upon projection operator valued measures (POVM's) (Kraus, 1983) are also possible.

Mutual information and discord

Selective loss of information everywhere except in the pointer states is the essence of einselection. It is reflected in the change of the mutual information which starts from:

$$\begin{aligned} \mathcal{I}^P(\mathcal{S}:\mathcal{A}) &= H(\rho^P_{\mathcal{S}}) + H(\rho^P_{\mathcal{A}}) - H(\rho^P_{\mathcal{S},\mathcal{A}}) \\ &= -2\sum_i |\alpha_i|^2 \lg |\alpha_i|^2 \qquad 4.30\text{a} \end{aligned} \tag{21.32}$$

As a result of einselection, for initially pure cases, it decreases to at most half its initial value:

$$\begin{aligned} \mathcal{I}^D(\mathcal{S}:\mathcal{A}) &= H(\rho^D_{\mathcal{S}}) + H(\rho^D_{\mathcal{A}}) - H(\rho^D_{\mathcal{S},\mathcal{A}}) \\ &= -\sum_i |\alpha_i|^2 \lg |\alpha_i|^2 \qquad 4.30\text{b} \end{aligned} \tag{21.33}$$

This level is reached when the pointer basis coincides with the Schmidt basis of $|\Psi_{\mathcal{SA}}\rangle$. The decrease in the mutual information is due to the increase of the joint entropy $H(\rho_{\mathcal{S},\mathcal{A}})$:

$$\begin{aligned} \Delta\mathcal{I}(\mathcal{S}:\mathcal{A}) &= \mathcal{I}^P(\mathcal{S}:\mathcal{A}) - \mathcal{I}^D(\mathcal{S}:\mathcal{A}) \\ &= H(\rho^D_{\mathcal{S},\mathcal{A}}) - H(\rho^P_{\mathcal{S},\mathcal{A}}) = \Delta H(\rho_{\mathcal{S},\mathcal{A}}) \qquad 4.31 \end{aligned} \tag{21.34}$$

Classically, equivalent definition of the mutual information obtains from the asymmetric formula:

$$\mathcal{J}_{\mathcal{A}}(\mathcal{S}:\mathcal{A}) = H(\rho_{\mathcal{S}}) - H(\rho_{\mathcal{S}|\mathcal{A}}) \tag{4.32}$$

with the help of the conditional entropy $H(\rho_{\mathcal{S}|\mathcal{A}})$. Above, subscript $\mathcal{A}$ indicates the member of the correlated pair that will be the source of the information about its partner. A symmetric counterpart of the above equation, $\mathcal{J}_{\mathcal{S}}(\mathcal{S}:\mathcal{A}) = H(\rho_{\mathcal{A}}) - H(\rho_{\mathcal{A}|\mathcal{S}})$, can be also written.

In the quantum case, definition of Eq. (4.32) is so far incomplete, as a quantum analogue of the classical conditional information has not been yet specified. Indeed, Eqs. (4.30a) and (4.32) jointly imply that in the case of entanglement a quantum conditional entropy $H(\rho_{\mathcal{S}|\mathcal{A}})$ would have to be negative! For, in this case;

$$H(\rho_{\mathcal{S}|\mathcal{A}}) = \sum_i |\alpha_i|^2 \lg |\alpha_i|^2 < 0 \tag{4.33}$$

would be required to allow for $\mathcal{I}(\mathcal{S}:\mathcal{A}) = \mathcal{J}_{\mathcal{A}}(\mathcal{S}:\mathcal{A})$. Various quantum redefinitions of $\mathcal{I}(\mathcal{S}:\mathcal{A})$ or $H(\rho_{\mathcal{S}|\mathcal{A}})$ have been proposed to address this (Lieb, 1975; Schumacher and Nielsen, 1996; Lloyd, 1997; Cerf and Adami, 1997). We shall simply regard this fact as an illustration of the strength of quantum correlations (i. e., entanglement), which allow $\mathcal{I}(\mathcal{S}:\mathcal{A})$ to violate the inequality:

$$\mathcal{I}(\mathcal{S}:\mathcal{A}) \leq min(H_{\mathcal{S}}, H_{\mathcal{A}}) \tag{4.34}$$

This inequality follows directly from Eq. (4.32) and the non-negativity of classical conditional entropy (see e.g. Cover and Thomas, 1991).

Decoherence decreases $\mathcal{I}(\mathcal{S}:\mathcal{A})$ to this allowed level (Zurek, 1983). Moreover, now the conditional entropy can be defined in the classical pointer basis as the average of partial entropies computed from the conditional $\rho^D_{\mathcal{S}|A_i\rangle}$ over the probabilities of different outcomes:

$$H(\rho_{\mathcal{S}|\mathcal{A}}) = \sum_i p_{|A_i\rangle} H(\rho^D_{\mathcal{S}|A_i\rangle}) \tag{4.35}$$

Prior to decoherence, the use of probabilities would not have been legal.

For the case considered here, Eq. (4.18), the conditional entropy $H(\rho_{\mathcal{S}|\mathcal{A}}) = 0$: In the pointer basis there is a perfect correlation between the system and the apparatus, providing that the premeasurement Schmidt basis and the pointer basis coincide. Indeed, it is tempting to define a good apparatus or a *classical* correlation by insisting on such a coincidence.

The difficulties with conditional entropy and mutual information are highly symptomatic. The trouble with $H(\rho_{\mathcal{S}|\mathcal{A}})$ arises for states that exhibit quantum correlations – entanglement of $|\Psi_{\mathcal{SA}}\rangle$ being an extreme example – and, thus, do not admit an interpretation based on probabilities. A useful sufficient condition for the classicality of correlations is then the existence of an apparatus basis that allows quantum versions of the two classically identical expressions for the mutual information to coincide, $\mathcal{I}(\mathcal{S}:\mathcal{A}) = \mathcal{J}_{\mathcal{A}}(\mathcal{S}:\mathcal{A})$, (Zurek, 2000b; 2002a; Ollivier and Zurek, 2002): Equivalently, the *discord*

$$\delta\mathcal{I}_{\mathcal{A}}(\mathcal{S}|\mathcal{A}) \;=\; \mathcal{I}(\mathcal{S}:\mathcal{A}) - \mathcal{J}_{\mathcal{A}}(\mathcal{S}:\mathcal{A}) \tag{4.36}$$

must vanish: Unless $\delta\mathcal{I}_{\mathcal{A}}(\mathcal{S}|\mathcal{A}) = 0$, probabilities of the distinct apparatus pointer states cannot exist.

We end this subsection with a part summary, part anticipatory remarks: Pointer states retain undiminished correlations with the measured system $\mathcal{S}$, or with any other system, including observers. The loss of information caused by decoherence is given by Eq. (4.31). It was precisely such as to lift conditional information from the paradoxical (negative) values to the classically allowed level, Eq. (4.33). This is equal to the information gained by the observer when he consults the apparatus pointer. This is no coincidence – the environment has 'measured' (became correlated with) the apparatus in the very same pointer basis in which observers have to access $\mathcal{A}$ to take advantage of the remaining (classical) correlation between the pointer and the system. Only when observers and the environment monitor co-diagonal observables they do not get in each others way.

In the idealized case, preferred basis was distinguished by its ability to retain perfect correlations with the system in spite of decoherence. This remark shall serve as a guide in other situations: It will lead to a criterion – predictability sieve – used to identify preferred states in less idealized circumstances. For example, when the self-Hamiltonian of the system is nontrivial, or when the commutation relation, Eq. (4.22), does not hold exactly for any observable, we shall seek states that are best in retaining correlations with the other systems.

21.4.3 Decoherence, entanglement, dephasing, and noise

In the symbolic representation of Fig. 4, noise is the process in which environment acts as a control, inscribing information about its state in the state of the system, that assumes the role of the target. However, the direction of the information flow in `c-nots` and `c-shifts` depends on the choice of initial states. Control and target switch roles when, for a given Hamiltonian of interaction, one prepares input of the `c-not` in the basis conjugate to the logical "pointer" states. Einselected states correspond to the set which – when used in `c-nots` or `c-shifts` – minimizes the effect of interactions directed from the environment to the system.

Einselection is caused by the premeasurement carried out by the environment on the pointer states. Decoherence follows from the Heisenberg's indeterminacy: Pointer observable is measured by the environment. Therefore, the complementary observable must become at least as indeterminate as is demanded by the Heisenberg's principle. As the environment and the systems entangle through an interaction that favors a set of pointer states, their phases become indeterminate (see Eq. (4.29) and discussion of envariance in section VI). Decoherence can be thought of as the resulting loss of phase relations.

Observers can be ignorant of phases for reasons that do not lead to an imprint of the state of the system on the environment. Classical noise can cause such *dephasing* when the observer does

not know the time-dependent classical perturbation Hamiltonian responsible for this unitary, but unknown evolution. For example, in the pre-decoherence state vector, Eq. (4.18), random phase noise will cause a transition:

$$|\Psi_{\mathcal{SA}}\rangle = (\sum_j \alpha_j |s_j\rangle|A_j\rangle)$$
$$\longrightarrow \sum_j \alpha_j \exp\Big(i\phi_j^{(n)}\Big)|s_j\rangle|A_j\rangle \;=\; |\Psi_{\mathcal{SA}}^{(n)}\rangle \;. \qquad 4.37 \tag{21.35}$$

A dephasing Hamiltonian acting either on the system or on the apparatus can lead to such an effect. In this second case its form could be:

$$H_D^{(n)} = \sum_j \dot{\phi}_j^{(n)}(t)|A_j\rangle\langle A_j| \;. \tag{4.38}$$

In contrast to interactions causing premeasurements, entanglement, and decoherence, H_D cannot influence the nature or the degree of the $\mathcal{SA}$ correlations: H_D does not imprint the state of $\mathcal{S}$ or $\mathcal{A}$ anywhere else in the Universe: For each individual realization n of the phase noise (each selection of $\{\phi_j^{(n)}(t)\}$ in Eq. (4.37)) the state $|\Phi_{\mathcal{SA}}^{(n)}\rangle$ remains pure. Given only $\{\phi_j^{(n)}\}$ one could restore pre-dephasing state on a case - by - case basis. However, in absence of such detailed information, one is often forced to represent $\mathcal{SA}$ by the density matrix averaged over the ensemble of noise realizations:

$$\overline{\rho}_{\mathcal{SA}} = \langle|\Psi_{\mathcal{SA}}\rangle\langle\Psi_{\mathcal{SA}}|\rangle = \sum_j |\alpha_j|^2 |s_j\rangle\langle s_j||A_j\rangle\langle A_j|$$
$$+\sum_{j,k}\sum_n e^{i(\phi_j^{(n)}-\phi_k^{(n)})}\alpha_j\alpha_k|s_j\rangle\langle s_k||A_j\rangle\langle A_k| \qquad 4.39 \tag{21.36}$$

In this phase - averaged density matrix off-diagonal terms may disappear. Nevertheless, each member of the ensemble may exist in a state as pure as it was before dephasing. NMR offers examples of dephasing (which can be reversed using spin echo). Dephasing is a loss of phase coherence due to noise in phases. It does not result in an information transfer to the environment.

Dephasing cannot be used to justify existence of preferred basis in individual quantum systems. Nevertheless, the ensemble as a whole may obey the same master equation as individual systems entangling with the environment. Indeed, many of the symptoms of decoherence arise in this setting. Thus, in spite of the light shed on this issue by the discussion of simple cases (Wootters and Zurek, 1979; Stern, Aharonov, and Imry, 1989) more remains to be understood, perhaps by considering implications of envariance (see Section VI).

Noise is an even more familiar and less subtle effect represented by transitions that break one-to-one correspondence in Eq. (4.39). Noise in the apparatus would cause a random rotation of states $|A_j\rangle$. It could be modelled by a collection of Hamiltonians similar to $H_D^{(n)}$ but not co-diagonal with the observable of interest. Then, after an ensemble average similar to Eq. (4.39), one-to-one correspondence between $\mathcal{S}$ and $\mathcal{A}$ would be lost. However – as before – the evolution is unitary for each n, and the unperturbed state could be reconstructed from the information observer could have in advance.

Hence, in case of dephasing or noise information about their cause obtained either in advance, or afterwards, suffices to undo their effect. Decoherence relies on entangling interactions (although, strictly speaking, it need not invlove entanglement (Eisert and Plenio, 2002). Thus, neither prior nor posterior knowledge of the state of environment is enough. Transfer of information about the decohering system to the environment is essential, and plays key role in the interpretation.

We note that, while nomenclature used here seems most sensible to this author and is widely used, it is unfortunately not universal. For example, in the context of quantum computation "decoherence" is sometimes used to describe any process that can cause errors (but see related discussion in Nielsen and Chuang, 2000).

21.4.4 Predictability sieve and einselection

Evolution of a quantum system prepared in a classical state should emulate classical evolution that can be idealized as a "trajectory" – a predictable sequence of objectively existing states. For a purely unitary evolution, all of the states in the Hilbert space retain their purity and are therefore equally predictable. However, in the presence of an interaction with the environment, a generic superposition representing correlated states of the system and of the apparatus will decay into a mixture diagonal in pointer states, Eq. (4.23). Only when the pre-decoherence state of $\mathcal{SA}$ is a product of a single apparatus pointer state $|A_i\rangle$ with the corresponding outcome state of the system (or a mixture of such product states), decoherence has no effect:

$$\rho^P_{\mathcal{SA}} = |s_i\rangle\langle s_i||A_i\rangle\langle A_i| = \rho^D_{\mathcal{SA}} \tag{4.40}$$

A correlation of a pointer state with any state of an isolated system is untouched by the environment. By the same token, when the observer prepares $\mathcal{A}$ in the pointer state $|A_i\rangle$, he can count on it remaining pure. One can even think of $|s_i\rangle$ as the record of the pointer state of $\mathcal{A}$. Einselected states are predictable: they preserve correlations, and hence are effectively classical.

In the above idealized cases predictability of some states follows directly from the structure of the relevant Hamiltonians (Zurek, 1981). Correlation with a subspace associated with a projection operator P_A will be immune to decoherence providing that:

$$[H_{\mathcal{A}} + H_{\mathcal{AE}}, P_A] = 0 \ . \tag{4.41}$$

In more realistic cases it is difficult to demand exact conservation guaranteed by such a commutation condition. Looking for approximate conservation may still be a good strategy. Various densities used in hydrodynamics are one obvious choice (Gell-Mann and Hartle, 1990, 1994).

In general, it is useful to invoke a more fundamental predictability criterion (Zurek, 1993a). One can measure the loss of predictability caused by the evolution for every pure state $|\Psi\rangle$ by von Neumann entropy or some other measure of predictability such as the purity:

$$\varsigma_\Psi(t) = Tr\rho^2_\Psi(t) \ . \tag{4.42}$$

In either case, predictability is a function of time and a functional of the initial state as $\rho_\Psi(0) = |\Psi\rangle\langle\Psi|$. Pointer states are obtained by maximizing predictability functional over $|\Psi\rangle$. When decoherence leads to classicality, good pointer states exist, and the answer is robust.

Predictability sieve sifts all of the Hilbert space, ordering states according to their predictability. The top of the list will be the most classical. This point of view allows for unification of the simple definition of the pointer states in terms of the commutation relation Eq. (4.41), with the more general criteria required to discuss classicality in other situations. The eigenstates of the exact pointer observable are selected by the sieve: Eq. (4.41) guarantees that they will retain their purity in spite of the environment, and are (somewhat trivially) predictable.

Predictability sieve can be generalized to situations where the initial states are mixed (Paraoanu, 2002). Often whole subspaces emerge from the predictability sieve, naturally leading to "decoherence-free subspaces" (see e. g. Lidar et al., 1999) and can be adapted to yield "noiseless subsystems" (which are a non-Abelian generalization of pointer states; see e.g. Zanardi, 2000;

Knill, Laflamme, and Viola, 2000). However, calculations are in general quite difficult even for the initial pure state cases.

The idea of the "sieve" selecting preferred to-be-classical states is novel and only partly explored. We shall see it "in action" below. We have outlined two criteria for sifting through the Hilbert space in search for classicality: von Neumann entropy and purity define, after all, two distinct functionals. Entropy is arguably an obvious information-theoretic measure of predictability loss. Purity is much easier to compute and is often used as a "cheap substitute", and has a physical significance of its own. It seems unlikely that pointer states selected by the predictability and purity sieves could substantially differ. After all, $-Tr\rho\ln\rho = Tr\rho\{(\mathbf{1}-\rho) - (\mathbf{1}-\rho)^2/2 + ...$ so that one can expect the most predictable states to also remain purest (Zurek, 1993a). However, the expansion, Eq. (4.43), is very slowly convergent. Therefore, a more mathematically satisfying treatment of the differences between the states selected by these two criteria would be desirable, especially in cases where (as we shall see in the next section for the harmonic oscillator) preferred states are coherent, and hence the classical domain forms relatively broad "mesa" in the Hilbert space.

The possible discrepancy between the states selected by the sieves based on the predictability and on the purity raises a more general question: Will all the sensible criteria yield identical answer? After all, one can imagine other reasonable criteria for classicality, such as the yet-to-be-explored "distinguishability sieve" of Schumacher (1999) which picks out states whose descendants are most distinguishable in spite of decoherence. Moreover, as we shall see in Section VII (also, Zurek 2000) one can ascribe classicality to states that are most redundantly recorded by the environment. The menu of various classicality criteria already contains several positions, and more may be added in the future. There is no *a priori* reason to expect that *all* of these criteria will lead to *identical* sets of preferred states. It is nevertheless reasonable to hope that, in the macroscopic limit in which classicality is indeed expected, differences between various sieves should be negligible. The same stability in the selection of the classical domain is expected with respect to the changes of, say, the time of the evolution from the initial pure state: Reasonable changes of such details within the time interval where einselection is expected to be effective should lead to more or less similar preferred states, and certainly to preferred states contained within each others "quantum halo" (Anglin and Zurek, 1996). As noted above, this seems to be the case in the examples explored to date. It remains to be seen whether all criteria will agree in other situations of interest.

21.5 Einselection in phase space

Einselection in phase space is a special, yet very important topic. It should lead to phase space points, trajectories, and to classical (Newtonian) dynamics. Special role of position in classical physics can be traced to the nature of interactions (Zurek, 1981; 1982; 1991) that depend on distance, and, therefore, commute with position (see Eq. (4.22)). Evolution of open systems includes, however, the flow in phase space induced by the self-Hamiltonian. Consequently, the set of preferred states turns out to be a compromise, localized in both position and momentum – localized in phase space.

Einselection is responsible for the classical structure of phase space. States selected by the predictability sieve become phase space "points", and their time-ordered sequences are "trajectories". In the underdamped, classically regular systems one can recover this phase space structure along with the (almost) reversible evolution. In chaotic systems there is a price to be paid for classicality: Combination of decoherence with the exponential divergence of classical trajectories (which is the defining feature of chaos) leads to entropy production at a rate given – in the classical limit – by the sum of positive Lyapunov exponents. Thus, the dynamical second law can emerge from the interplay of classical dynamics and quantum decoherence, with

the entropy production caused by the information "leaking" into the environment (Zurek and Paz 1994 & 1995a; Zurek, 1998b; Paz and Zurek 2001).

21.5.1 Quantum Brownian motion

Quantum Brownian motion model consists of an environment $\mathcal{E}$ – a collection of harmonic oscillators (coordinates q_n, masses m_n, frequencies ω_n, and coupling constants c_n) interacting with the system $\mathcal{S}$ (coordinate x), with a mass M and a potential $V(x)$. We shall often consider harmonic $V(x) = M\Omega_0^2 x^2/2$, so that the whole $\mathcal{SE}$ is linear and one can obtain an exact solution. This assumption will be relaxed later.

The Lagrangian of the system-environment entity is:

$$L(x, q_n) = L_{\mathcal{S}}(x) + L_{\mathcal{SE}}(x, \{q_n\}) \; ; \tag{5.1}$$

The system alone has the Lagrangian:

$$L_{\mathcal{S}}(x) = \frac{M}{2}\dot{x}^2 - V(x) \;\; = \;\; \frac{M}{2}(\dot{x}^2 - \Omega_0^2 x^2) \; . \tag{5.2}$$

The effect of the environment is modelled by the sum of the Lagrangians of individual oscillators and of the system-environment interaction terms:

$$L_{\mathcal{SE}} = \sum_n \frac{m_n}{2}\left(\dot{q}_n^2 - \omega_n^2\big(q_n - \frac{c_n x}{m_n\omega_n^2}\big)^2\right) \; . \tag{5.3}$$

This Lagrangian takes into account renormalization of potential energy of the Brownian particle. The interaction depends (linearly) on the position x of the harmonic oscillator. Hence, we expect x to be an instantaneous pointer observable. In combination with the harmonic evolution this leads Gaussian pointer states – well-localized in both x and p. An important characteristic of the model is the spectral density of the environment:

$$C(\omega) \;\; = \;\; \sum_n \frac{c_n^2}{2m_n\omega_n}\delta(\omega - \omega_n) \; . \tag{5.4}$$

The effect of the environment can be expressed through the propagator acting on the reduced $\rho_{\mathcal{S}}$:

$$\rho_{\mathcal{S}}(x, x', t) = \int dx_0 dx_0' J(x, x', t|x_0, x_0', t_0)\rho_{\mathcal{S}}(x_0, x_0', t_0). \tag{5.5}$$

We focus on the case when the system and the environment are initially statistically independent, so that their density matrices in a product state:

$$\rho_{\mathcal{SE}} \;\; = \;\; \rho_{\mathcal{S}}\rho_{\mathcal{E}} \; . \tag{5.6}$$

This is a restrictive assumption. One can try to justify it as an idealization of a measurement that correlates $\mathcal{S}$ with the observer and destroys correlations of $\mathcal{S}$ with $\mathcal{E}$, but that is only an approximation, as realistic measurements leave partial correlations with the environment intact. Fortunately, pre-existing post-measurement correlations lead only to minor differences in the salient features of the subsequent evolution of the system (Romero and Paz, 1997; Anglin, Paz and Zurek, 1997).

Evolution of the whole $\rho_{\mathcal{SE}}$ can be represented as:

$$\rho_{\mathcal{SE}}(x, q, x', q', t) = \int dx_0 dx_0' dq_0 dq_0' \; \rho_{\mathcal{SE}}(x_0, q_0, x_0', q_0', t_0)$$
$$K(x, q, t, x_0, q_0)K^*(x', q', t, x_0', q_0') \qquad 5.7 \tag{21.37}$$

Above, we suppress the sum over the indices of the individual environment oscillators. The evolution operator $K(x,q,t,x_0,q_0)$ can be expressed as a path integral:

$$K(x,q,t,x_0,q_0) = \int DxDq \exp\left(\frac{i}{\hbar} I[x,q]\right) \tag{5.8}$$

where $I[x,q]$ is the action functional that depends on the trajectories $x,\ q$. The integration must satisfy boundary conditions:

$$x(0) = x_0;\ x(t) = x;\ q(0) = q_0;\ q(t) = q\ . \tag{5.9}$$

The expression for the propagator of the density matrix can be now written in terms of actions corresponding to the two Lagrangians, Eqs. (5.1-3):

$$\begin{aligned} J(x,x',t|x_0,x_0',t_0) = \int\ Dx\ Dx' \exp\left\{\frac{i}{\hbar}\right\}(I_{\mathcal{S}}[x] - I_{\mathcal{S}}[x']) \\ \times \int\ dq\ dq_0\ dq_0'\ \rho_{\mathcal{E}}(q_0,q_0') \\ \int\ Dq\ Dq' \exp\left\{\frac{i}{\hbar}\right\}(I_{\mathcal{SE}}[x,q] - I_{\mathcal{SE}}[x',q'])\ . \qquad 5.10 \end{aligned} \tag{21.38}$$

The separability of the initial conditions, Eq. (5.6), was used to make propagator depend only on the initial conditions of the environment. Collecting all terms containing integrals over $\mathcal{E}$ in the above expression leads to the influence functional (Feynman and Vernon, 1963):

$$\begin{aligned} F(x,x') \quad = \int\ dq\ dq_0\ dq_0'\ \rho_{\mathcal{E}}(q_0,q_0') \\ \int\ Dq\ Dq' \exp\left\{\frac{i}{\hbar}\right\}(I_{\mathcal{SE}}[x,q] - I_{\mathcal{SE}}[x',q'])\ . \qquad 5.11 \end{aligned} \tag{21.39}$$

It can be evaluated explicitly for specific models of the initial density matrix of the environment.

Environment in thermal equilibrium provides a useful and tractable model for the initial state. The density matrix of the n'th mode of the thermal environment is:

$$\begin{aligned} \rho_{\mathcal{E}_n}(q,q') \ = \ \frac{m_n\omega_n}{2\pi\hbar\sinh\left(\frac{\hbar\omega_n}{k_BT}\right)} \times \exp -\Big\{\frac{m_n\omega_n}{2\pi\hbar\sinh\left(\frac{\hbar\omega_n}{k_BT}\right)} \\ \times\Big[(q_n^2+q_n'^2)\cosh\left(\frac{\hbar\omega_n}{k_BT}\right) - 2q_nq_n'\Big]\Big\}\ . \qquad 5.12 \end{aligned} \tag{21.40}$$

The influence functional can be written as (Grabert, Schramm, and Ingold, 1988):

$$\begin{aligned} i\ln F(x,x') = \int_0^t ds\ (x-x')(s)\ \int_0^s du \\ \Big(\eta(s-s')(x+x')(s') - i\nu(s-s')(x-x')(s')\Big)\ , \qquad 5.13 \end{aligned} \tag{21.41}$$

where $\nu(s)$ and $\eta(s)$ are dissipation and noise kernels, respectively, defined in terms of the spectral density:

$$\nu(s) = \int_0^\infty d\omega\ C(\omega)\coth(\hbar\omega\beta/2)\cos(\omega s); \tag{5.14}$$

$$\eta(s) = \int_0^\infty d\omega\ C(\omega)\sin(\omega s)\ . \tag{5.15}$$

With the assumption of thermal equilibrium at $k_BT = 1/\beta$, and in the harmonic oscillator case $V(x) = M\Omega_0^2 x^2/2$, the integrand of Eq. (5.10) for the propagator is Gaussian: The integral can be computed exactly, and should also have a Gaussian form. The result can be conveniently written in terms of the diagonal and off-diagonal coordinates of the density matrix in the position representation, $X = x + x'$, $Y = x - x'$:

$$\begin{aligned} J(X,Y,t|X_0,Y_0,t_0) \;&= \\ \frac{b_3}{2\pi}\frac{\exp i(b_1XY + b_2X_0Y - b_3XY_0 - b_4X_0Y_0)}{\exp(a_{11}Y^2 + 2a_{12}YY_0 + a_{22}Y_0^2)}\;. \qquad 5.16 \end{aligned} \tag{21.42}$$

The time-dependent coefficients b_k and a_{ij} are computed from the noise and dissipation kernels, that reflect the properties of the environment. They obtain from the solutions of the equation:

$$\ddot{u}(s) + \Omega_0^2 u(s) + 2\int_0^s ds\eta(s-s')u(s') = 0\;. \tag{5.17}$$

Two such solutions that satisfy boundary conditions $u_1(0) = u_2(t) = 1$ and $u_1(t) = u_2(0) = 0$ can be used for this purpose. They yield the coefficients of the Gaussian propagator through;

$$b_{1(2)}(t) = \dot{u}_{2(1)}(t)/2\;, \quad b_{3(4)}(t) = \dot{u}_{2(1)}(0)/2\;, \tag{5.18a}$$

$$a_{ij}(t) = \frac{1}{1+\delta_{ij}}\int_0^t ds\int_0^t ds' u_i(s)u_j(s')\nu(s-s'). \qquad 5.18\text{b} \tag{21.43}$$

The master equation can be now obtained by taking the time derivative of the Eq. (5.5), which in effect reduces to the computation of the derivative of the propagator, Eq. (5.16) above:

$$\begin{aligned} \dot{J} \;=\; & \{\dot{b}_3/b_3 + i\dot{b}_1XY + i\dot{b}_2X_0Y - i\dot{b}_3XY_0 \\ & -i\dot{b}_4X_0Y_0 - \dot{a}_{11}Y^2 - \dot{a}_{12}YY_0 - \dot{a}_{22}Y_0^2\}J\;. \qquad 5.19 \end{aligned} \tag{21.44}$$

The time derivative of $\rho_{\mathcal{S}}$ can be obtained by multiplying the operator on the right hand side by an initial density matrix and integrating over the initial coordinates X_0, Y_0. Given the form of Eq. (5.19), one may expect that this procedure will yield an integro-differential (non-local in time) evolution operator for $\rho_{\mathcal{S}}$. However, time dependence of the evolution operator disappears as a result of two identities satisfied by the propagator:

$$Y_0J = \Big(\frac{b_1}{b_3}Y + \frac{i}{b_3}\partial_X\Big)J\;, \tag{5.20a}$$

$$\begin{aligned} X_0J = \; & \Big(-\frac{b_1}{b_2}X - \frac{i}{b_2}\partial_Y \\ & -i\big(\frac{2a_{11}}{b_2} + \frac{a_{12}b_1}{b_2b_3}\big)Y + \frac{a_{12}}{b_2b_3}\partial_X\Big)J\;. \qquad 5.20b \end{aligned} \tag{21.45}$$

After the appropriate substitutions, the resulting equation with renormalized Hamiltonian has a form:

$$\begin{aligned} \dot{\rho}_{\mathcal{S}}(x,x',t) \;&=\; -\frac{i}{\hbar}\langle x|[H_{ren}(t),\rho_{\mathcal{S}}]|x'\rangle \\ &-\big(\gamma(t)(x-x')(\partial_x+\partial_{x'}) - D(t)(x-x')^2\big)\rho_{\mathcal{S}}(x,x',t) \\ &-if(t)(x-x')(\partial_x+\partial_{x'})\rho_{\mathcal{S}}(x,x',t). \qquad 5.21 \end{aligned} \tag{21.46}$$

The calculations leading to this master equation are non-trivial. They involve use of relations between the coefficients b_k and a_{ij}. The final result leads to explicit formulae for its coefficients:

$$\Omega_{ren}(t)/2 = b_1\dot{b}_2/b_2 - \dot{b}_1 \ , \tag{5.22a}$$

$$\gamma(t) = -b_1 - \dot{b}_2/2b_2 \ , \tag{5.23a}$$

$$\begin{aligned} D(t) = \quad & \dot{a}_{11} - 4a_{11}b_1 \\ & +\dot{a}_{12}b_1/b_3 - \dot{b}_2(2a_{11} + a_{12}b_1/b_3)/b_2 \ , \qquad 5.24a \end{aligned} \tag{21.47}$$

$$2f(t) = \dot{a}_{12}/b_3 - \dot{b}_2 a_{12}/(b_2 b_3) - 4a_{11} \ . \tag{5.25a}$$

The fact that the exact master equation (5.21) is local in time for an arbitrary spectrum of the environment is remarkable. It was demonstrated by Hu, Paz, and Zhang (1992) following discussions carried out under more restrictive assumptions by Caldeira and Leggett (1983), Haake and Reibold (1985), Grabert, Schramm, and Ingold (1988), and Unruh and Zurek (1989). It depends on the linearity of the problem, that allows one to anticipate (Gaussian) form of the propagator.

The above derivation of the exact master equation used the method of Paz (1994) (see also Paz and Zurek, 2001). Explicit formulae for the time-dependent coefficients can be obtained when one focuses on the perturbative master equation. It can be derived *ab initio* (see Paz and Zurek, 2001) but can be also obtained from the above results by finding a perturbative solution to Eq. (5.17), and then substituting it in Eqs. (5.22*a* - 5.25*a*). The resulting master equation in the operator form is:

$$\begin{aligned} \dot{\rho}_{\mathcal{S}} \ = \quad & -\frac{i}{\hbar}[H_{\mathcal{S}} + M\tilde{\Omega}(t)^2 x^2/2, \rho_{\mathcal{S}}] - \frac{i\gamma(t)}{\hbar}[x, \{p, \rho_{\mathcal{S}}\}] \\ & -D(t)[x,[x,\rho_{\mathcal{S}}]] - \frac{f(t)}{\hbar}[x,[p,\rho_{\mathcal{S}}]] \ . \qquad 5.26 \end{aligned} \tag{21.48}$$

Coefficients such as the frequency renormalization $\tilde{\Omega}$, the relaxation coefficient $\gamma(t)$, and the normal and anomalous diffusion coefficients $D(t)$ and $f(t)$ are given by:

$$\tilde{\Omega}^2(t) = -\frac{2}{M}\int_0^t ds \cos(\Omega s)\eta(s) \tag{5.22b}$$

$$\gamma(t) = \frac{2}{M\Omega}\int_0^t ds \sin(\Omega s)\eta(s) \tag{5.23b}$$

$$D(t) = \frac{1}{\hbar}\int_0^t ds \cos(\Omega s)\nu(s) \tag{5.24b}$$

$$f(t) = -\frac{1}{M\Omega}\int_0^t ds \sin(\Omega s)\eta(s) \tag{5.25b}$$

These coefficient can be made even more explicit when a convenient specific model for the spectral density:

$$C(\omega) = 2M\gamma_0\frac{\omega}{\pi}\frac{\Gamma^2}{\Gamma^2+\omega^2} \tag{5.27}$$

is adopted. Above, γ_0 characterizes the strength of the interaction, and Γ is the high-frequency cutoff. Then:

$$\tilde{\Omega}^2 = -\frac{2\gamma_0\Gamma^3}{\Gamma^2+\Omega^2}\left(1 - \left(\cos\Omega t - \frac{\Omega}{\Gamma}\sin\Omega t\right)e^{-\Gamma t}\right) \ ; \tag{5.22c}$$

$$\gamma(t) = \frac{\gamma_0 \Gamma^2}{\Gamma^2 + \Omega^2}\left(1 - \left(\cos\Omega t - \frac{\Gamma}{\Omega}\sin\Omega t\right)e^{-\Gamma t}\right) . \qquad (5.23c)$$

Note that both of these coefficients are initially zero. They grow to their asymptotic values on a timescale set by the inverse of the cutoff frequency Γ.

The two diffusion coefficients can be also studied, but it is more convenient to evaluate them numerically. In Fig. 5 we show their behavior. The normal diffusion coefficient quickly settles to its long-time asymptotic value:

$$D_\infty = M\gamma_0 \Omega \hbar^{-1} \coth(\hbar\Omega\beta/2)\Gamma^2/(\Gamma^2 + \Omega^2) . \qquad (5.28)$$

The anomalous diffusion coefficient $f(t)$ also approaches asymptotic value. For high temperature it is suppressed by a cutoff Γ with respect to D_∞, but the approach to f_∞ is more gradual, algebraic rather than exponential. Environments with different spectral content exhibit different behavior (Hu, Paz, and Zhang, 1992; Paz, Habib, and Zurek, 1993; Paz, 1994; Anglin, Paz and Zurek, 1997).

21.5.2 Decoherence in quantum Brownian motion

The coefficients of the master equation we have just derived can be computed under a variety of different assumptions. The two obvious characteristics of the environment one can change are its temperature T and its spectral density $C(\omega)$. One general conclusion: In case of high temperatures, $D(t)$ tends to a temperature-dependent constant, and dominates over $f(t)$. Indeed, in this case all of the coefficients settle to asymptotic values after an initial transient. Thus:

$$\begin{aligned} \dot\rho_{\mathcal S} = \quad & -\frac{i}{\hbar}[H_{ren}, \rho_{\mathcal S}] - \gamma(x-x')(\partial_x - \partial_{x'})\rho_{\mathcal S} \\ & -\frac{2M\gamma k_B T}{\hbar^2}(x-x')^2\rho_{\mathcal S} . \qquad 5.29 \end{aligned} \qquad (21.49)$$

This master equation for $\rho(x,x')$ obtains in the unrealistic but convenient limit known as the *high temperature approximation* valid when k_BT is much higher than all the other relevant energy scales, including the energy content of the initial state and the frequency cutoff in $C(\omega)$ (see, e.g, Caldeira and Leggett, 1983). However, when these restrictive conditions hold, Eq. (5.29) can be written for an arbitrary $V(x)$. To see why, we give a derivation patterned on Hu, Paz, and Zhang (1993).

We start with the propagator, Eq. (5.5), $\rho_{\mathcal S}(x,x',t) = J(x,x',t|x_0,x_0',t_0)\rho_{\mathcal S}(x_0,x_0',t_0)$, which we shall treat as if it were an equation for *state vector* of the *two dimensional* system with coordinates x, x'. The propagator is then given by the high-temperature version of Eq. (5.10);

$$\begin{aligned} J(x,x',t|x_0,x_0',t_0) = \int \; & DxDx' \exp\left\{\frac{i}{\hbar}\right\}\Big\{I_R(x) - I_R(x')\Big\} \\ & e^{-M\gamma\left(\int_0^t ds[x\dot x - x'\dot x' + x\dot x' - x'\dot x] + \frac{2k_BT}{\hbar^2}[x-x']^2\right)} . \qquad 5.30 \end{aligned} \qquad (21.50)$$

The term in the exponent can be interpreted as an effective Lagrangian of a two-dimensional system:

$$\begin{aligned} L_{eff}(x,x') = & M\dot x^2/2 - V_R(x) - M\dot x'^2/2 + V_R(x') \\ & +\gamma(x-x')(\dot x + \dot x') + i\frac{2M\gamma k_BT}{\hbar^2}(x-x')^2 . \qquad 5.31 \end{aligned} \qquad (21.51)$$

One can readily obtain the corresponding Hamiltonian;

$$H_{eff} \;=\; \dot{x}\partial L_{eff}/\partial\dot{x} + \;\dot{x}'\partial L_{eff}/\partial\dot{x}' - L_{eff}\;. \tag{5.32}$$

Conjugate momenta $p = p_x = M\dot{x} + \gamma(x - x')$ and $p' = p_{x'} = -M\dot{x}' + \gamma(x - x')$ are used to express the kinetic term of H_{eff}. After evaluating $\dot{x}$ and $\dot{x}'$ in terms of p and p' in the expression for H_{eff} one obtains:

$$\begin{aligned} H_{eff} = \quad & \big(p - \gamma(x - x')\big)^2/2M - \big(p' - \gamma(x - x')\big)^2/2M \\ & + V(x) - V(x') - i2M\gamma k_B T(x' - x)^2/\hbar^2\;. \qquad 5.33 \end{aligned} \tag{21.52}$$

This expression yields the operator that generates the evolution of the density matrix, Eq. (5.29).

The coefficients of Eq. (5.21) approach their high-temperature values quickly (see Fig. 5). Already for T well below what the rigorous derivation would demand high-temperature limit appears to be an excellent approximation. The discrepancy – manifested by symptoms such as some of the diagonal terms of $\rho_{\mathcal{S}}(x', x)$ assuming negative values when the evolutions starts from an initial state that is so sharply localized in position to have kinetic energy in excess of the values allowed by the high-temperature approximation – is limited to the initial instant of order $1/\Gamma$, and is known to be essentially unphysical for other reasons (Unruh and Zurek, 1989; Ambegoakar, 1991; Romero and Paz, 1997; Anglin, Paz, and Zurek, 1997). This short - time anomaly is closely tied to the fact that Eq. (5.33) (and, indeed, many of the exact or approximate master equations derived to date) does not have the Lindblad form (Lindblad, 1976; see also Gorini, Kossakowski and Sudarshan, 1976, Alicki and Lendi, 1987) of a dynamical semigroup.

High temperature master equation (5.29) is a good approximation in a wider range of circumstances than the one for which it was derived (Feynman and Vernon, 1963; Dekker, 1977; Caldeira and Leggett, 1983). Moreover, our key qualitative conclusion – rapid decoherence in the macroscopic limit – does not crucially depend on the approximations leading to Eq. (5.29). We shall therefore use it in our further studies.

Decoherence timescale

In the macroscopic limit (that is, when $\hbar$ is small compared to other quantities with dimensions of action, such as $\sqrt{2Mk_BT\langle(x - x')^2\rangle}$ in the last term) the high-temperature master equation is dominated by:

$$\partial_t\rho_{\mathcal{S}}(x, x', t) = -\gamma\Big\{\frac{(x - x')}{\lambda_T}\Big\}^2\rho_{\mathcal{S}}(x, x', t)\;. \tag{5.34}$$

Above;

$$\lambda_T \;=\; \frac{\hbar}{\sqrt{2Mk_BT}} \tag{5.35}$$

is thermal de Broglie wavelength. Thus, the density matrix looses off-diagonal terms in position representation:

$$\rho_{\mathcal{S}}(x, x', t) \;=\; \rho_{\mathcal{S}}(x, x', 0)e^{-\gamma t(\frac{x-x'}{\lambda_T})^2}\;. \tag{5.36}$$

while the diagonal ($x = x'$) remains untouched.

Quantum coherence decays exponentially at the rate given by the relaxation rate times the square of the distance measured in units of thermal de Broglie wavelength (Zurek, 1984a). Position is the "instantaneous pointer observable": If Eq. (5.36) was always valid, eigenstates of position would attain the classical status.

The importance of position can be traced to the nature of the interaction Hamiltonian between the system and the environment. According to Eq. (5.3):

$$H_{\mathcal{SE}} \ = \ x \sum_n c_n q_n \ . \tag{5.37}$$

This form of $H_{\mathcal{SE}}$ is motivated by physics (Zurek, 1982; 1991): Interactions depend on the distance. However, had we endeavored to find a situation where a different form of the interaction Hamiltonian – say, a momentum-dependent interaction – was justified, the form and consequently predictions of the master equation would have been analogous to Eq. (5.36), but with a substitution of the relevant observable "monitored" by the environment for x. Such situations may be experimentally accessible (Poyatos, Cirac, and Zoller, 1996) providing a test of one of the key ideas of einselection: the relation between the form of interaction and the preferred basis.

The effect of the evolution, Eqs. (5.34) - (5.36), on the density matrix in the position representation is easy to envisage. Consider a superposition of two minimum uncertainty Gaussians. Off-diagonal peaks represent coherence. They decay on a *decoherence timescale* τ_D, or with a *decoherence rate* (Zurek, 1984a, 1991);

$${\tau_D}^{-1} \ = \ \gamma(\frac{x-x'}{\lambda_T})^2 \ . \tag{5.38}$$

Thermal de Broglie wavelength, λ_T, is microscopic for massive bodies and for the environments at reasonable temperatures. For a mass 1g at room temperature and for the separation $x' - x$ =1cm, Eq. (5.38) predicts decoherence approximately 10^{40} times faster than relaxation! Even cosmic microwave background suffices to cause rapid loss of quantum coherence in objects as small as dust grains (Joos and Zeh, 1985). These estimates for the rates of decoherence and relaxation should be taken with a grain of salt: Often the assumptions that have led to the simple high temperature master equation (5.29) are not valid (Gallis & Fleming, 1990; Gallis, 1992; Anglin, Paz & Zurek, 1997). For example, the decoherence rate cannot be faster than inverse of the spectral cutoff in Eq. (5.27), or than the rate with which the superposition is created. Moreover, for large separations quadratic dependence of decoherence rate may saturate (Gallis and Fleming, 1990; Anglin, Paz, and Zurek, 1997) as seen in the "simulated decoherence" experiments of Cheng and Raymer (1999). Nevertheless, in the macroscopic domain decoherence of widely delocalized "Schrödinger cat" states will occur very much faster than relaxation, which proceeds at the rate given by γ.

Phase space view of decoherence

A useful alternative way of illustrating decoherence is afforded by the Wigner function representation:

$$W(x,p) = \frac{1}{2\pi\hbar}\int_{-\infty}^{+\infty} dy \ e^{(ipy/\hbar)}\rho(x+\frac{y}{2}, x-\frac{y}{2}) \ . \qquad 5.39 \tag{21.53}$$

Evolution equation followed by the Wigner function obtains through the Wigner transform of the corresponding master equation. In the high temperature limit, Eq. (5.29) (valid for general potentials) this yields:

$$\partial_t W = \{H_{ren}, W\}_{MB} + 2\gamma\partial_p(pW) + D\partial_{pp}W \ . \tag{5.40}$$

The first term – Moyal bracket – is the Wigner transform of the von Neumann equation (see Section III). In the linear case it reduces to the Poisson bracket. The second term is responsible for relaxation. The last diffusive term is responsible for decoherence.

Diffusion in momentum occurs at the rate set by $D = 2M\gamma k_B T$. Its origin can be traced to the continuous "measurement" of the position of the system by the environment: In accord with the Heisenberg indeterminacy, measurement of position results in the increase of the uncertainty in momentum (see Section IV).

Decoherence in phase space can be explained on the example of a superposition of two Gaussian wavepackets. Wigner function in this case is given by:

$$W(x,p) = G(x+x_0,p) \ + \ G(x-x_0,p)$$
$$+(\pi\hbar)^{-1}\exp\bigl(-p^2\xi^2/\hbar^2 - x^2/\xi^2\bigr)\cos(\Delta x p/\hbar) \ , \qquad 5.41 \tag{21.54}$$

where;

$$G(x\pm x_0, p-p_0) = \frac{e^{-(x\mp x_0)^2/\xi^2-(p-p_0)^2\xi^2/\hbar^2}}{\pi\hbar} \ . \qquad 5.42 \tag{21.55}$$

We have assumed the Gaussians are not moving ($p_0 = 0$).

The oscillatory term in Eq. (5.41) is the signature of superposition. The frequency of the oscillations is proportional to the distance between the peaks. When the separation is only in position x, this frequency is:

$$f = \Delta x/\hbar = 2x_0/\hbar \ . \tag{5.43}$$

Ridges and valleys of the interference pattern are parallel to the separation between the two peaks. This, and the fact that $\hbar$ appears in the interference term in W is important for phase space derivation of the decoherence time. We focus on the dominant effect and direct our attention on the last term of Eq. (5.40). Its effect on the rapidly oscillating interference term will be very different from its effect on the two Gaussians: The interference term is dominated by the cosine:

$$W_{int} \sim \cos\left(\frac{\Delta x}{\hbar}p\right) \ . \tag{5.44}$$

This is an eigenfunction of the diffusion operator. Decoherence timescale emerges (Zurek, 1991) from the corresponding eigenvalue;

$$\dot{W}_{int} \approx -\{D\Delta x^2/\hbar^2\} \times W_{int} \ . \tag{5.45}$$

We have recovered the formula for τ_D, Eq. (5.38), from a different looking argument: Eq. (5.40) has no explicit dependence on $\hbar$ for linear potentials (in the nonlinear case $\hbar$ enters through the Moyal bracket). Yet, the decoherence timescale contains $\hbar$ explicitly – $\hbar$ enters through Eq. (5.43), that is through its role in determining the frequency of the interference pattern W_{int}.

The evolution of the pure initial state of the type considered here is shown in Fig. 6. There we illustrate evolution of the Wigner function for two initial pure states: Superposition of two positions and superposition of two momenta. There is a noticeable difference in the rate at which the interference term disappears between these two cases. This was anticipated. The interaction in Eq. (5.3) is a function of x. Therefore, x is monitored by the environment directly, and the superposition of positions decoheres almost instantly. By contrast, the superposition of momenta is initially insensitive to the monitoring by the environment – the corresponding initial state is already well localized in the observable singled out by the interaction. However, a superposition of momenta leads to a superposition of positions, and hence to decoherence, albeit on a dynamical (rather than τ_D) timescale.

An intriguing example of a long-lived superposition of two seemingly distant Gaussians was pointed out by Braun, Braun and Haake (2000) in the context of superradiance. As they note, the relevant decohering interaction cannot distinguish between some such superpositions, leading to a 'Schrödinger cat' pointer subspace.

21.5.3 Predictability sieve in phase space

Decoherence rapidly destroys non-local superpositions. Obviously, states that survive must be localized. However, they cannot be localized to a point in x, as this would imply – by Heisenberg's indeterminacy – an infinite range in momenta, and, hence, of velocities. As a result, a wave function localized too well at one instant would become very non-local a moment later.

Einselected pointer states minimize the damage done by decoherence over the "timescale of interest" (usually associated with predictability or with dynamics). They can be found through the application of the predictability sieve outlined at the end of Section IV. To implement it, we compute entropy increase or purity loss for all initially pure states in the Hilbert space of the system under the cumulative evolution caused by the self-Hamiltonian and by the interaction with the environment. It would be a tall order to carry out the requisite calculations for an arbitrary quantum system interacting with a general environment. We focus on the exactly solvable case.

In the high temperature limit the master equations (5.26) and (5.29) can be expressed in the operator form:

$$\dot{\rho} = \frac{1}{i\hbar}[H_{ren},\rho] + \frac{\gamma}{i\hbar}[\{p,x\},\rho] - \frac{\eta k_B T}{\hbar^2}[x,[x,\rho]] - \frac{i\gamma}{\hbar}\big([x,\rho p]-[p,\rho x]\big) \qquad 5.46 \tag{21.56}$$

Above, $\eta = 2M\gamma$ is the viscosity. Only the last two terms can change entropy. Terms of the form:

$$\dot{\rho} = [\hat{O},\rho] \tag{5.47}$$

where $\hat{O}$ is Hermitean leave the purity $\varsigma = Tr\rho^2$ and the von Neumann entropy $H = -Tr\rho\lg\rho$ unaffected. This follows from the cyclic property of the trace:

$$\frac{d}{dt}Tr\rho^N = \sum_{k=1}^{N}(Tr\rho^{k-1}[\hat{O}\rho]\rho^{N-k}) = 0 \tag{5.48}$$

Constancy of $Tr\rho^2$ is obvious, while for $Tr\rho\lg\rho$ it follows when the logarithm is expanded in powers of ρ.

Equation (5.46) leads to the loss of purity at the rate (Zurek, 1993a):

$$\frac{d}{dt}Tr\rho^2 = -\frac{4\eta k_B T}{\hbar^2}Tr\big(\rho^2x^2-(\rho x)^2\big) + 2\gamma Tr\rho^2 \tag{5.49}$$

The second term increases purity – decreases entropy – as the system is damped from an initial highly mixed state. For predictability sieve this term is usually unimportant, as for a vast majority of the initially pure states its effect will be negligible when compared to the first, decoherence - related term. Thus, in the case of pure initial states:

$$\frac{d}{dt}Tr\rho^2 = -\frac{4\eta k_B T}{\hbar^2}(\langle x^2\rangle - \langle x\rangle^2), \tag{5.50}$$

Therefore, the instantaneous loss of purity is minimized for perfectly localized states (Zurek, 1993a). The second term of Eq. (5.49) allows for the equilibrium. (Nevertheless, early on, and for very localized states, its presence causes an (unphysical) *increase* of purity to *above* unity. This is a well-known artifact of the high-temperature approximation (see discussion following Eq. (5.33)).

To find most predictable states relevant for dynamics consider entropy increase over a period of the oscillator. For a harmonic oscillator with mass M and frequency Ω, one can compute purity loss averaged over $\tau = 2\pi/\Omega$:

$$\Delta\varsigma|_0^{2\pi/\Omega} = -2D\big(\Delta x^2 + \Delta p^2/(M\Omega)^2\big) \ . \tag{5.51}$$

Above, Δx and Δp are dispersions of the state at the initial time. By the Heisenberg indeterminacy, $\Delta x \Delta p \geq \hbar/2$. The loss of purity will be smallest when:

$$\Delta x^2 = \hbar/2M\Omega, \ \Delta p^2 = \hbar M\Omega/2 \ . \tag{5.52}$$

Coherent quantum states are selected by the predictability sieve in an underdamped harmonic oscillator (Zurek, 1993a; Zurek, Habib and Paz, 1993; Gallis, 1996; Tegmark and Shapiro, 1994; Wiseman and Vaccaro, 1998; Paraoanu, 2002). Rotation induced by the self-Hamiltonian turns preference for states localized in position into preference for localization in phase space. This is illustrated in Fig. 7.

We conclude that for an underdamped harmonic oscillator coherent Gaussians are the best quantum theory has to offer as an approximation to a classical point. Similar localization in phase space should obtain in the reversible classical limit in which the familiar symptoms of the "openness" of the system – such as the finite relaxation rate $\gamma = \eta/2M$ – become vanishingly small. This limit can be attained for large mass $M \longrightarrow \infty$, while the viscosity η remains fixed and sufficiently large to assure localization (Zurek, 1991; 1993a). This is, of course, not the only possible situation. Haake and Walls (1987) discussed the overdamped case, where pointer states are still localized, but relatively more narrow in position. On the other hand, "adiabatic" environment enforces einselection in energy eigenstates (Paz and Zurek, 1999).

21.5.4 Classical limit in phase space

There are three strategies that allow one to simultaneously recover both the classical phase space structure and the classical equations of motion.

Mathematical approach ($\hbar \to 0$)

This "mathematical" classical limit could not be implemented without decoherence, since the oscillatory terms associated with interference do not have an analytic $\hbar \to 0$ limit (see, e.g, Peres, 1993). However, in the presence of the environment, the relevant terms in the master equations increase as $\mathcal{O}(\hbar^{-2})$, and make the non-analytic manifestations of interference disappear. Thus, phase space distributions can be always represented by localized coherent state "points", or by the distributions over the basis consisting of such points.

This strategy is easiest to implement starting from the phase-space formulation. It follows from Eq. (5.45) that the interference term in Eq. (5.41) will decay (Paz, Habib, and Zurek, 1993) over the time interval Δt as:

$$W_{int} \sim \exp\big(-\Delta t \frac{D\Delta x^2}{\hbar^2}\big) \cos\big(\frac{\Delta x}{\hbar} p\big) \ . \tag{5.53}$$

As long as Δt is large compared to decoherence timescale $\tau_D \simeq \hbar^2/D\Delta x^2$, the oscillatory contributions to the Wigner function $W(x,p)$ shall disappear with $\hbar \to 0$. Simultaneously, Gaussians representing likely locations of the system become narrower, approaching δ-functions in phase space. For instance, in Eq. (5.42);

$$\lim_{\hbar\to 0} G(x - x_0, p - p_0) \ = \ \delta(x - x_0, p - p_0) \ , \tag{5.54}$$

providing half-widths of the coherent states in x and p decrease to zero as $\hbar \to 0$. This would be assured when, for instance, in Eqs. (5.41)-(5.42):

$$\xi^2 \sim \hbar \ . \tag{5.55}$$

Thus, individual coherent-state Gaussians approach phase space points. This behavior indicates that in a macroscopic open system nothing but probability distributions over localized phase space points can survive in the $\hbar \to 0$ limit for any time of dynamical or predictive significance. (Coherence between immediately adjacent points separated only by $\sim \xi$, Eq. (5.55), can last longer. This is no threat to the classical limit. Small scale coherence is a part of a "quantum halo" of the classical pointer states (Anglin and Zurek, 1996).)

The *mathematical classical limit* implemented by letting $\hbar \to 0$ becomes possible in presence of decoherence. It is tempting to take this strategy to its logical conclusion, and represent every probability density in phase space in the point(er) basis of narrowing coherent states. Such a program is beyond the scope of this review, but the reader should be by now convinced that it is possible. Indeed, Perelomov (1986) shows that a general quantum state can be represented in a sparse basis of coherent states that occupy sites of a regular lattice, providing that the volume per coherent state "point" is no more than $(2\pi\hbar)^d$ in the $d-$dimensional configuration space. In presence of decoherence arising from the coordinate-dependent interaction, evolution of a general quantum superposition should be – after a few decoherence times – well approximated by the probability distribution over such Gaussian "points".

Physical approach: The macroscopic limit

The possibility of the $\hbar \to 0$ classical limit in presence of decoherence is of interest. But $\hbar = 1.05459 \times 10^{-27}$erg s. Therefore, a physically more reasonable approach increases the size of the object, and, hence, its susceptibility to decoherence. This strategy can be implemented starting with Eq. (5.40). Reversible dynamics obtains as $\gamma \to 0$ while $D = 2M\gamma k_B T = \eta k_B T$ increases.

The decrease of γ and the simultaneous increase of $\eta k_B T$ can be anticipated with the increase of the size and mass. Assume that density of the object is independent of its size R, and that the environment quanta scatter from its surface (as would photons or air molecules). Then $M \sim R^3$ and $\eta \sim R^2$. Hence:

$$\eta \sim \mathcal{O}(R^2) \longrightarrow \infty \ , \tag{5.56}$$

$$\gamma = \eta/2M \sim \mathcal{O}(1/R) \longrightarrow 0 \ , \tag{5.57}$$

as $R \to \infty$: Localization in phase space and reversibility can be simultaneously achieved in a macroscopic limit.

Existence of macroscopic classical limit in simple cases has been pointed out some time ago (Zurek 1984a, 1991; Gell-Mann and Hartle, 1993). We shall analyze it in the next section in a more complicated chaotic setting, where reversibility can no longer be taken for granted. In the harmonic oscillator case approximate reversibility is effectively guaranteed, as the action associated with the 1-σ contour of the Gaussian state increases with time at the rate (Zurek, Habib, and Paz, 1993):

$$\dot{I} = \gamma \frac{k_B T}{\hbar \Omega} \tag{5.58}$$

Action I is a measure of the lack of information about phase space location. Hence, its rate of increase is a measure of the rate of predictability loss. Trajectory is a limit of the "tube" swept in phase space by the moving volume representing instantaneous uncertainty of the observer about the state of the system. Evolution is approximately deterministic when the area of this

contour is nearly constant. In accord with Eqs. (5.56)-(5.57) $\dot{I}$ tends to zero in the reversible macroscopic limit:

$$\dot{I} \sim \mathcal{O}(1/R) \tag{5.59}$$

The existence of an approximately reversible trajectory-like thin tubes provides an assurance that, having localized the system within a regular phase space volume at $t = 0$, we can expect that it can be found later inside the Liouville - transported contour of nearly the same measure. Similar conclusions follow for integrable systems.

Ignorance inspires confidence in classicality

Dynamical reversibility can be achieved with einselection in the macroscopic limit. Moreover, $\dot{I}/I$ or other measures of predictability loss decrease with the increase of I. This is especially dramatic when quantified in terms of the von Neumann entropy, that, for Gaussian states, increases at the rate (Zurek, Habib and Paz, 1993):

$$\dot{H} = \dot{I} \lg \frac{I+1}{I-1} \tag{5.60a}$$

The resulting $\dot{H}$ is infinite for pure coherent states ($I = 1$), but quickly decreases with increasing I. Similarly, the rate of purity loss for Gaussians is:

$$\dot{\varsigma} = \dot{I}/I^2 \ . \tag{5.60b}$$

Again, it tapers off for more mixed states.

This behavior is reassuring. It leads us to conclude that irreversibility quantified through, say, von Neumann entropy production, Eq. (5.60a), will approach $\dot{H} \approx 2\dot{I}/I$, vanishing in the limit of large I. When in the spirit of the macroscopic limit we do not insist on the maximal resolution allowed by the quantum indeterminacy, the subsequent predictability losses measured by the increase of entropy or through the loss of purity will diminish. Illusions of reversibility, determinism, and exact classical predictability become easier to maintain in presence of ignorance about the initial state!

To think about phase space points one may not even need to invoke a specific quantum state. Rather, a point can be regarded as a limit of an abstract recursive procedure, in which phase space coordinates of the system are determined better and better in a succession of increasingly accurate measurements. One may be tempted to extrapolate this limiting process *ad infintessimum* which would lead beyond Heisenberg's indeterminacy principle and to a false conclusion that idealized points and trajectories "exist objectively", and that the insider view of Section II can be always justified. While in our quantum Universe this conclusion is wrong, and the extrapolation described above illegal, the presence, within the Hilbert space, of localized wavepackets near the minimum uncertainty end of such imagined sequences of measurements is reassuring. Ultimately, the ability to represent motion in terms of points and their time - ordered sequences (trajectories) is the essence of classical mechanics.

21.5.5 Decoherence, chaos, and the Second Law

Breakdown of correspondence in this chaotic setting was described in section III. It is anticipated to occur in all non-linear systems, as the stretching of the wavepacket by the dynamics is a generic feature, absent only in a harmonic oscillator. However, exponential instability of chaotic dynamics implies rapid loss of quantum - classical correspondence after the Ehrenfest time, $t_\hbar = \Lambda^{-1} \ln \chi \Delta p/\hbar$. Here Λ is the Lyapunov exponent, $\chi = \sqrt{V_x/V_{xxx}}$ typically characterizes the dominant scale of nonlinearities in the potential $V(x)$, and Δp gives the coherence scale in the initial wavepacket. The above estimate, Eq. (3.5) depends on the initial conditions.

It is smaller than, but typically close to, $t_r = \Lambda^{-1} \ln I/\hbar$, Eq. (3.6), where I is the characteristic action of the system. By contrast, phase space patches of regular systems undergo stretching with a power of time. Consequently, loss of correspondence occurs only over a much longer $t_r \sim (I/\hbar)^\alpha$, that depends polynomially on $\hbar$.

Restoration of correspondence

Exponential instability spreads the wavepacket to a "paradoxical" extent at the rate given by the positive Lyapunov exponents $\Lambda_+^{(i)}$. Einselection attempts to enforce localization in phase space by tapering off interference terms at the rate given by the inverse of the decoherence timescale $\tau_D = \gamma^{-1}(\lambda_T/\Delta x)^2$. The two processes reach *status quo* when the coherence length ℓ_c of the wavepacket makes their rates comparable, that is:

$$\tau_D \Lambda_+ \simeq 1 \tag{5.61}$$

This yields an equation for the steady-state coherence length and for the corresponding momentum dispersion:

$$\ell_c \simeq \lambda_T \sqrt{\Lambda_+/2\gamma}\ ; \tag{5.62}$$

$$\sigma_c = \hbar/\ell_c = \sqrt{2D/\Lambda_+}\ . \tag{5.63}$$

Above, we have quoted results (Zurek and Paz, 1994) that follow from a more rigorous derivation of the coherence length ℓ_c than the "rough and ready" approach that led to Eq. (5.61). They embody the same physical argument, but seek asymptotic behavior of the Wigner function that evolves according to the equation:

$$\begin{aligned} \dot{W} = \quad & \{H, W\} + \sum_{n\geq 1} \frac{\hbar^{2n}(-)^n}{2^{2n}(2n+1)!} \partial_x^{2n+1} V \partial_p^{2n+1} W \\ & + D\partial_p^2 W\ . \qquad 5.64 \end{aligned} \tag{21.57}$$

The classical Liouville evolution generated by Poisson bracket ceases to be a good approximation of the decohering quantum evolution when the leading quantum correction becomes comparable to the classical force:

$$\frac{\hbar^2}{24} V_{xxx} W_{ppp} \approx \frac{\hbar^2}{24} \frac{V_x}{\chi^2} \frac{W_p}{\sigma_c^2} \tag{5.65}$$

The term $\partial_x V \partial_p W$ represents the classical force in Poisson bracket. Quantum corrections are small when;

$$\sigma_c \chi \gg \hbar \tag{5.66}$$

Equivalently, Moyal bracket generates approximately Liouville flow when the coherence length satisfies:

$$\ell_c \ll \chi \tag{5.67}$$

This last inequality has an obvious interpretation: It is a demand for the localization to within a region ℓ_c small compared to the scale χ of the nonlinearities of the potential. When this condition holds, classical force will dominate over quantum corrections.

Restoration of correspondence is illustrated in Fig. 8 where Wigner functions are compared with classical probability distributions in a chaotic system. The difference between the classical and quantum expectation values in same chaotic system is shown in Fig. 9. Even relatively weak decoherence suppresses the discrepancy, helping reestablish the correspondence: $D = 0.025$ translates through Eq. (5.62) into coherence over $\ell_c \simeq 0.3$, not much smaller than the nonlinearity scale $\chi \simeq 1$ for the investigated Hamiltonian of Fig. 8.

Entropy production

Irreversibility is the price for the restoration of quantum-classical correspondence in chaotic dynamics. It can be quantified through the entropy production rate. The simplest argument recognizes that decoherence restricts spatial coherence to ℓ_c. Consequently, as the exponential instability stretches the size $L^{(i)}$ of the distribution in directions corresponding to the positive Lyapunov exponents $\Lambda_+^{(i)}$, $L^{(i)} \sim \exp\left(\Lambda_+^{(i)} t\right)$ the squeezing mandated by the Liouville theorem in the complementary directions corresponding to $\Lambda_-^{(i)}$ will halt at $\sigma_c^{(i)}$, Eq. (5.63). In this limit, the number of pure states needed to represent resulting mixture increases exponentially

$$N^{(i)} \simeq L^{(i)}/\ell_c^{(i)} \tag{5.68}$$

in each dimension. The least number of pure states overlapped by W will be then $\mathcal{N} = \Pi_i N^{(i)}$. This implies:

$$\dot{H} \simeq \partial_t \ln \mathcal{N} \simeq \sum_i \Lambda_+^{(i)} \ . \tag{5.69}$$

This estimate for entropy production rate becomes accurate as the width of the Wigner function reaches saturation at $\sigma_c^{(i)}$. When a patch in phase space corresponding to the initial W is regular and smooth on scales large compared to $\sigma_c^{(i)}$, evolution will start nearly reversibly (Zurek and Paz, 1994). However, as squeezing brings the extent of the effective support of W close to $\sigma_c^{(i)}$, diffusion bounds from below the size of the smallest features of W. Stretching in the unstable directions continues unabated. As a consequence, the volume of the support of W will grow exponentially, resulting in an entropy production rate set by Eq. (5.69), the sum of the classical Lyapunov exponents. Yet, it has an obviously quantum origin in decoherence. This quantum origin may be apparent initially, as the rate of Eq. (5.69) will be approached from above when the initial state is a non-local. On the other hand, in a multidimensional system different Lyapunov exponents may begin to contribute to entropy production at different instants (as the saturation condition, Eq. (5.61), may not be met simultaneously for all $\Lambda_+^{(i)}$). Then the entropy production rate can accelerate (before subsiding as a consequence of approaching equilibrium).

The timescales on which this estimates of entropy production apply are still subject to investigation (Zurek and Paz, 1995a; Zurek, 1998b; Monteoliva and Paz 2000 & 2001) and even controversy (Casati and Chirikov, 1995b; Zurek and Paz, 1995b). The instant when Eq. (5.69) becomes a good approximation corresponds to the moment when the exponentially unstable evolution forces the Wigner function to develop small phase space structures on the scale of the effective decoherence - imposed "coarse graining", Eq. (5.63). This will be a good approximation until the time t_{EQ} at which equilibrium sets in. Both $t_\hbar$ have a logarithmic dependence on the corresponding (initial and equilibrium) phase space volumes I_0 and I_{EQ}, so the validity of Eq. (5.69) will be limited to $t_{EQ} - t_\hbar \simeq \Lambda^{-1} \ln I_{EQ}/I_0$.

There is a simple and conceptually appealing way to extend the interval over which entropy is produced at the rate given by Eq. (5.69): Imagine an observer monitoring a decohering chaotic system, finding out its state at time intervals small compared to Λ^{-1}, but large compared to the decoherence timescale. One can show (Zurek, 1998b) that the average increase of the size of the algorithmically compressed records of measurement of a decohering chaotic system (that is, the algorithmic randomness of the acquired data, see e.g. Cover and Thomas, 1991) is given – after conversion into bits from "nats" – by Eq. (5.69). This conclusion holds providing that the effect of the "collapses of the wavepacket" caused by the repeated measurements is negligible – i.e., the observer is "skillful". A possible strategy a skillful observer may adopt is that of indirect measurements, of monitoring a fraction of the environment responsible for decoherence to find out the state of the system. As we shall see in more detail in the following sections of the paper, this is a very natural strategy, often employed by the observers.

A classical analogue of Eq. (5.69) has been obtained by Kolmogorov (1960) and Sinai (1960) starting from very different, mathematical arguments that in effect relied on an arbitrary but fixed coarse graining imposed on phase space (see Wehrl, 1978). Decoherence leads to a similar looking *quantum* result in a very different fashion: Coarse graining is imposed by the coupling to the environment, but only in the sense implied by the einselection. Its "graininess" (resolution) is set by the accuracy of the monitoring environment. This is especially obvious when the indirect monitoring strategy mentioned immediately above is adopted by the observers. Preferred states will be partly localized in x and p, but (in contrast to the harmonic oscillator case with its coherent states) details of this environment - imposed coarse graining will likely depend on phase space location, precise nature of the coupling to the environment, etc. Yet, in the appropriate limit, Eqs. (5.66)-(5.67), the asymptotic entropy production rate defined with the help of the algorithmic contribution discussed above (i.e., in a manner of the *physical entropy*, Zurek (1989)) does not depend on the strength or nature of the coupling, but is instead given by the sum of the positive Lyapunov exponents.

Von Neumann entropy production consistent with the above discussion has been now seen in numerical studies of decohering chaotic systems (Shiokawa and Hu, 1995; Furuya, Nemes, and Pellegrino, 1998; Miller and Sarkar, 1999; Schack, 1998; Monteoliva and Paz, 2000 & 2001). Extensions to situations where relaxation matters, as well as in the opposite direction – to where decoherence is relatively gentle – have been also discussed (Brun, Percival, and Schack, 1995; Miller, Sarkar, and Zarum, 1998; Pattanyak, 2000). An exciting development is the experimental study of the Loschmidt echo using NMR techiques (Levstein, Usaj, and Pastawski, 1998; Levstein et al, 2000, Jalabert and Pastawski, 2001) which sheds a new light on the irreversibility in decohering complex dynamical systems. We shall briefly return to this subject in Section VIII, while discussing experimental investigations relevant for decoherence and quantum chaos.

Quantum predictability horizon

The cross section I of the trajectory-like tube containing the state of the harmonic oscillator in phase space increases only slowly, Eq. (5.58), at a rate which – once the limiting Gaussian is reached – does not depend on I. By contrast, in chaotic quantum systems this rate is:

$$\dot{I} \simeq I \sum_i \Lambda_+^{(i)} . \tag{5.70}$$

A fixed rate of entropy production implies an exponential increase of the cross-section of the tube of, say, the 1-σ contour containing points consistent with the initial conditions: Phase space support expands exponentially.

This quantum view of chaotic evolution can be compared with the classical "deterministic chaos". In both cases, in the appropriate classical limit – which may involve either mathematical $\hbar \to 0$, or a macroscopic limit – the future state of the system can be in principle predicted to a set accuracy for an arbitrarily long time. However, such predictability can be accomplished only when the initial conditions are given with the resolution that increases exponentially with the time interval over which the predictions are to be valid. Given the fixed value of $\hbar$, there is therefore a *quantum predictability horizon* after which the Wigner function of the system starting from an initial minimum uncertainty Gaussian becomes stretched to the size of the order of the characteristic dimension of the system (Zurek, 1998b). The ability to predict the location of the system in the phase space is then lost after $t \sim t_\hbar$, Eq. (3.5), regardless of whether evolution is generated by the Poisson or Moyal bracket, or, indeed, whether the system is closed or open.

The case of regular systems is closer to the harmonic oscillator. The rate of increase of the cross-section of phase space "trajectory tube" consistent with the initial patch in the phase

space will asymptote to $\dot{I} \simeq const$:

$$\dot{H} = \dot{I}/I \sim 1/t \ . \tag{5.71}$$

Thus, initial conditions allow one to predict future of a regular system for time intervals that are exponentially longer than in the chaotic case. The rate of entropy production of an open quantum system is therefore a very good indicator of the nature of its dynamics, as was conjectured some time ago (Zurek and Paz, 1995a), and as seems born out in the numerical simulations (Shiokawa and Hu, 1995; Miller, Sarkar and Zarum, 1998; Miller and Sarkar, 1999; Monteoliva and Paz, 2000 & 2001).

21.6 Einselection and Measurements

It is often said that quantum states play only an *epistemological* role in describing observers knowledge about the past measurement outcomes that have prepared the system (Jammer, 1974; d'Espagnat, 1976, 1995; Fuchs and Peres, 2000). In particular – and this is a key argument against their objective existence (against their *ontological* status) – it is impossible to find out what the state of an isolated quantum system *is* without prior information about the observables used to prepare it: Measurement of observables that do not commute with this original set will inevitably create a *different* state.

The incessant monitoring of the einselected observables by the environment allows pointer states to *exist* in much the same way classical states do. This ontological role of the einselected quantum states can be justified operationally, by showing that *in presence of einselection one can find out what the quantum state is, without inevitably re-preparing it by the measurement.* Thus, einselected quantum states are no longer just epistemological. In a system monitored by the environment *what is* – the einselected states – coincides with *what is known to be* – what is recorded by the environment (Zurek, 1993a,b; 1998a).

The conflict between the quantum and the classical was originally noted and discussed almost exclusively in the context of quantum measurements (Bohr, 1928; Mott, 1929; von Neumann, 1932; Dirac, 1947; Zeh, 1971, 1973, 1993; d'Espagnat, 1976, 1995; Zurek 1981, 1982, 1983, 1991, 1993a&b, 1998a; Omnès 1992, 1994; Elby, 1993, 1998; Butterfield, 1996; Donald, 1995; Giulini et al., 1996; Bub, 1997; Saunders, 1998; Healey, 1998; Bacciagaluppi and Hemmo, 1998; Healey and Hellman, 1998). Here I shall consider quantum measurements, and, more to the point, acquisition of information in quantum theory from the point of view of decoherence and einselection.

21.6.1 Objective existence of einselected states

To demonstrate *objective existence* of *einselected* states we now develop an operational definition of existence and show how, in the open system, one can find out what the state *was and is*, rather than just "prepare" it. This point was made before (Zurek, 1993a; 1998a), but this is first time I discuss it in more detail.

Objective existence of states can be defined operationally by considering two observers. The first of them is the *record keeper* **R**. He prepares the states with the original measurement and will use his records to find out if they were disturbed by the measurements carried out by other observers, e.g. the *spy* **S**. The goal of **S** is to discover the state of the system without perturbing it. When an observer can consistently find out the state of the system without changing it, that state – by our operational definition – will be said to *exist objectively.*

In absence of einselection the situation of the spy **S** is hopeless: **R** prepares states by measuring sets of commuting observables. Unless **S** picks, by sheer luck, the same observables *in case of each state*, his measurements will re-prepare states of the systems. Thus, when **R**

re-measures using the original observables, he will likely find answers different from his records. The spy **S** will "get caught", because it is impossible to find out an initially unknown state of an isolated quantum system.

In presence of environmental monitoring the nature of the "game" between **R** and **S** is dramatically altered. Now it is no longer possible for **R** to prepare an arbitrary pure state that will persist or predictably evolve without losing purity. Only the einselected states that are already monitored by the environment – that are selected by the predictability sieve – will survive. By the same token, **S** is no longer clueless about the observables he can measure without leaving incriminating evidence. For example, he can independently prepare and test survival of various states in the same environment to establish which states are einselected, and then measure appropriate pointer observables. Better yet, **S** can forgo direct measurements of the system, and gather information indirectly, by monitoring the environment.

This last strategy may seem contrived, but indirect measurements – acquisition of information about the system by examining fragments of the environment that have interacted with it – is in fact more or less the only strategy employed by the observers. Our eyes, for example, intercept only a small fraction of the photons that scatter from various objects. The rest of the photons constitute the environment, which retains at least as complete a record of the same einselected observables as we can obtain (Zurek, 1993; 1998a).

The environment $\mathcal{E}$ acts as a persistent observer, dominating the game with frequent questions, always about the same observables, compelling both **R** and **S** to focus on the einselected states. Moreover, $\mathcal{E}$ can be persuaded to share its records of the system. This accessibility of the einselected states is not a violation of the basic tenets of quantum physics. Rather, it is a consequence of the fact that the data required to turn quantum state into an ontological entity – an einselected pointer state – are abundantly supplied by the environment.

We emphasize the *operational* nature of this criterion for existence: There may be in principle a pure state of the Universe including the environment, the observer, and the measured system. While this may matter to some (Zeh, 2000), real observers are forced to perceive the Universe the way we do: We are a part of the Universe, observing it from within. Hence, for us, *environment-induced superselection specifies what exists.*

Predictability emerges as a key criterion of *existence*. The only states **R** can rely on to store the information are the pointer states. They are also the obvious choice for **S** to measure. Such measurements can be accomplished without danger of re-preparation. Einselected states are insensitive to measurement of the pointer observables – they have already been "measured" by the environment. Therefore, additional projections P_i onto the einselected basis will not perturb the density matrix (Zurek, 1993a) – it will be the same before and after the measurement:

$$\rho^D_{after} = \sum_i P_i \rho^D_{before} P_i \ . \tag{6.1}$$

Correlations with the einselected states will be left intact (Zurek 1981; 1982).

Superselection for the observable $\hat{A} = \sum_i \lambda_i P_i$ with essentially arbitrary non-degenerate eigenvalues λ_i and eigenspaces P_i can be expressed (Bogolubov et al., 1990) through Eq. (6.1). Einselection attains this, guaranteeing diagonality of density matrices in the projectors P_i corresponding to pointer states. These are sometimes called *decoherence - free subspaces* when they are degenerate; compare also nonabelian case of *noiseless subsystems* discussed in quantum computation; see Zanardi and Rasetti, 1997; Zanardi 1998; Duan and Guo 1998; Lidar, Bacon, and Whaley, 1999; Knill, Laflamme, and Viola, 2000; Blanchard and Olkiewicz, 2000; Zanardi 2000).

21.6.2 Measurements and memories

The memory of an apparatus or of an observer can be modelled as an open quantum $\mathcal{A}$, interacting with $\mathcal{S}$ through a Hamiltonian explicitly proportional to the measured observable $\hat{s}$ [7]

$$H_{int} = -g\hat{s}\hat{B} \sim \hat{s}\frac{\partial}{\partial \hat{A}} \ . \tag{6.2}$$

Von Neumann (1932) considered an apparatus isolated from the environment. At the instant of the interaction between the apparatus and the measured system this is a convenient assumption. For us it suffices to assume that, at that instant, the interaction Hamiltonian between the system and the apparatus dominates. This can be accomplished by taking the coupling g in Eq. (6.2) to be $g(t) \sim \delta(t - t_0)$. Premeasurement happens at t_0:

$$(\sum_i \alpha_i |s_i\rangle)|A_0\rangle \ \longrightarrow \ \sum_i \alpha_i |s_i\rangle|A_i\rangle \ . \tag{6.3}$$

In practice the action is usually large enough to accomplish amplification. As we have seen in section II, all this can be done without an appeal to the environment.

For a real apparatus interaction with the environment is inevitable. Idealized effectively classical memory will retain correlations, but will be subject to einselection: Only the einselected memory states (rather than their superpositions) will be useful for (or, for that matter, accessible to) the observer: Decoherence timescale is very short compared to the time after which memory states are typically consulted (i. e., copied or used in information processing), which is in turn much shorter than the relaxation timescale, on which memory "forgets".

Decoherence leads to *classical* correlation:

$$\begin{aligned} \rho^P_{\mathcal{SA}} &= \sum_{i,j} \alpha_i \alpha_j^* |s_i\rangle\langle s_j||A_i\rangle\langle A_j| \longrightarrow \\ &\longrightarrow \sum_i |\alpha_i|^2 |s_i\rangle\langle s_i||A_i\rangle\langle A_i| = \rho^D_{\mathcal{SA}} \qquad 6.4 \end{aligned} \tag{21.58}$$

following an entangling premeasurement. Left hand side of Eq. (6.4) coincides with Eq. (2.44c), the "outsiders" view of the classical measurement. We shall see how and to what extent its other aspects – including the insiders Eq. (2.44a) and the discoverers Eq. (2.44b) – can be understood through einselection.

21.6.3 Axioms of quantum measurement theory

Our goal is to establish whether the above model can fulfill requirements expected from measurement in textbooks (that are, essentially without exception, written in the spirit of the Copenhagen Interpretation). There are several equivalent 'textbook' formulations of axioms of quantum theory. We shall (approximately) follow Farhi, Goldstone, and Gutmann (1989) and posit:

(i) The states of a quantum system $\mathcal{S}$ are associated with the vectors $|\psi\rangle$ which are the elements of the Hilbert space $\mathcal{H}_\mathcal{S}$ that describes $\mathcal{S}$.

[7] The observable $\hat{s}$ of the system and $\hat{B}$ of the apparatus memory need not be discrete with a simple spectrum as was previously assumed. Even when $\hat{s}$ has a complicated spectrum, the outcome of the measurement can be recorded in the eigenstates of the memory observable $\hat{A}$, conjugate of $\hat{B}$, Eq. (2.21). For the case of discrete $\hat{s}$ the necessary calculations that attain premeasurement – the quantum correlation that is the first step in the creation of the record – were already carried out in section II. For the other situations they are quite similar. In either case, they follow the general outline of the von Neumann's (1932) discussion.

(ii) The states evolve according to $i\hbar|\dot{\psi}\rangle = H|\psi\rangle$ where H is Hermitean.

(iii a) Every observable O is associated with a Hermitian operator $\hat{O}$.

(iii b) The only possible outcome of a measurement of O is an eigenvalue o_i of $\hat{O}$.

(iv) Immediately after a measurement that yields the value o_i the system is in the eigenstate $|o_i\rangle$ of $\hat{O}$.

(v) If the system is in a normalized state $|\psi\rangle$, then a measurement of $\hat{O}$ will yield the value o_i with the probability $p_i = |\langle o_i|\psi\rangle|^2$.

The first two axioms make no reference to measurements. They state the formalism of the theory. Axioms (iii) - (v) are, on the other hand, at the heart of the present discussion. In the spirit, they go back to Bohr and Born. In the letter, they follow von Neumann (1932) and Dirac (1947). The two key issues are the *projection postulate*, implied by a combination of (iv) with (iiib), and the (Born's) *probability interpretation*, axiom (v).

To establish (iiib), (iv) and (v) we shall interpret – in operational terms – statements such as "the system *is* in the eigenstate" and "measurement will yield value ... with *the probability* ..." by specifying what these statements mean for the sequences of *records* made and maintained by an idealized, but physical *memory*.

We note that the above Copenhagen-like axioms presume existence of quantum systems and of classical measuring devices. This (unstated) "axiom (o)" complements axioms (i) - (v). Our version of axiom (o) demands that the Universe consists of systems, and asserts that a composite system can be described by a tensor product of the Hilbert spaces of the constituent systems. Some quantum systems can be measured, others can be used as measuring devices and/or memories, and as quantum environments that interact with either or both.

Axioms (iii) - (v) contain many idealizations. For instance, in real life or in laboratory practice measurements have errors (and hence can yield outcomes other than the eigenvalues o_i). Moreover, only rarely do they "prepare" the system in the eigenstate of the observable they are designed to measure. Furthermore, coherent states – often an outcome of measurements, e. g., in quantum optics – form an overcomplete basis. Thus, their detection does not correspond to a measurement of a Hermitean observable. Last not least, the measured quantity may be inferred from some other quantity (e.g. deflection of a beam in the Stern-Gerlach experiment). Yet, we shall not go beyond the idealizations of (i) - (v) above. Our goal is to describe measurements in a quantum theory "without collapse", to use axioms (o), (i) and (ii) to understand the origin of the other axioms. Non-ideal measurements are a fact of life incidental to this goal.

Observables are Hermitean – axiom (iiia)

In the model of measurement considered here the observables are Hermitean as a consequence of the assumed premeasurement interaction, e.g. Eq. (2.24). In particular, H_{int} is a product of the to-be-measured observable of the system and of the "shift operator" in the pointer of the apparatus or in the record state of the memory. Interactions involving non-Hermitean operators (e.g., $H_{int} \sim a^\dagger b + ab^\dagger$) may be, however, also considered.

It is tempting to speculate that one could dispose of the observables (and, hence, of the postulate (iiia)) altogether in the formulation of the axioms of quantum theory. The only ingredients necessary to describe measurements are then the effectively classical, but ultimately quantum apparatus, and the measured system. Observables emerge as a derived concept, as a useful idealization, ultimately based on the structure of the Hamiltonians. Their utility relies on the conservation laws that relate outcomes of several measurements. Most basic of these laws states that the system that did not (have time to) evolve will be found in the same state

when it is re-measured: This is the content of axiom (iv). Other conservation laws are also reflected in the patterns of correlation in the measurement records, that must in turn arise from the underlying symmetries of the Hamiltonians.

Einselection should be included in this program, as it decides which of the observables are accessible and useful – which are effectively classical. It is conceivable that also the "fundamental" superselection may emerge in this manner (see Zeh, 1970; Zurek, 1982; for early speculations; Giulini, Kiefer, and Zeh, 1995; and Kiefer, 1996; Giulini, 2000, for the present status of this idea).

Eigenvalues as outcomes – axiom (iiib)

This statement is the first part of the "collapse" postulate. Given einselection, (iiib) is easy to justify: We need to show that only the records inscribed in the einselected states of the apparatus pointer can be read off, and that – in a well-designed measurement – they correlate with the eigenstates (and, therefore, eigenvalues) of the measured observable $\hat{s}$.

With Dirac (1947) and von Neumann (1932) we assume that the apparatus is built so that it satisfies the obvious "truth table" when the eigenstates of the measured observable are at the input:

$$|s_i\rangle|A_0\rangle \longrightarrow |s_i\rangle|A_i\rangle \tag{6.5}$$

To assure this one can implement the interaction in accord with Eq. (6.2) and the relevant discussion in section II. This is not to say that there are no other ways: Braginski and Khalili (1996), Aharonov, Anandan and Vaidman (1993), and Unruh (1994) have all considered "adiabatic measurements", that correlate the apparatus with the discrete energy eigenstates of the measured system, nearly independently of the structure of H_{int}.

Truth table of Eq. (6.5) does not require collapse – for any initial $|s_i\rangle$ it represents a "classical measurement in quantum notation" in the sense of Section II. However, Eq. (6.5) typically leads to a superposition of outcomes. This is the "measurement problem". To address it, we assume that the record states $\{|A_i\rangle\}$ are einselected. This has two related consequences: (i) Following the measurement, the joint density matrix of the system and the apparatus decoheres, Eq. (6.3), so that it satisfies the superselection condition, Eq. (6.1), for $P_i = |A_i\rangle\langle A_i|$. (ii) Einselection restricts states that can be read of "as if they were classical" to pointer states.

Indeed, following decoherence only pointer states $\{|A_i\rangle\}$ of the memory can be measured without diminishing the correlation with the states of the system. Without decoherence, as we have seen in section II, one could use entanglement between $\mathcal{S}$ and $\mathcal{A}$ to end up with an almost arbitrary superposition states of either, and, hence, to violate the letter and the spirit of (iiib).

Outcomes are restricted to the eigenvalues of measured observables because of einselection. Axiom (iiib) is then a consequence of the effective classicality of pointer states, the only ones that can be "found out" without being disturbed. They can be consulted repeatedly and remain unaffected under the joint scrutiny of the observers and of the environment (Zurek, 1981; 1993a; 1998a).

Immediate repeatability, axiom (iv)

This axiom supplies the second half of the "collapse" postulate. It asserts that in the absence of (the time for) evolution quantum system will remain in the same state, and its re-measurement will lead to the same outcome. Hence, once the system is found out to be in a certain state, it really is there. As in Eq. (2.44b) observer perceives potential options "collapse" to a single actual outcome. (The association of the axiom (iv) with the collapse advocated here seems obvious, but it is not common: Rather, some form of our axiom (iiib) is usually regarded as the sole "collapse postulate".)

Immediate repeatability for Hermitean observables with discrete spectra is straightforward to justify on the basis of Schrödinger evolution generated by H_{int} of Eq. (6.2) alone, although its implications depend on whether the premeasurement is followed by einselection. Everett (1957) used the "no decoherence" version as a foundation of his relative state interpretation. On the other hand, without decoherence and einselection one could postpone the choice of what was actually recorded by taking advantage of the entanglement between the system and the apparatus, evident on the left hand side of Eq. (6.3). For instance, a measurement carried out on the apparatus in a basis different from $\{|A_i\rangle\}$ would also exhibit a one-to-one correlation with the system: $\sum_i \alpha_i|s_i\rangle|A_i\rangle = \sum_k \beta_k|r_k\rangle|B_k\rangle$. This flexibility to re-write wavefunctions in different bases comes at a price of relaxing the demand that the outcome states $\{|r_k\rangle\}$ be orthogonal (so that there would be no associated Hermitean observable). However, as was already noted, coherent states associated with a non-Hermitean annihilation operator can also be an outcome of a measurement. Therefore (and in spite of the strict interpretation of axiom (iiia)) this is not a very serious restriction.

In presence of einselection the basis ambiguity disappears. Immediate repeatability would apply only to the records made in the einselected states. Other apparatus observables lose correlation with the state of the system on decoherence timescale. In the effectively classical limit it is natural to demand repeatability extending beyond that very short time interval. This demand makes the role of einselection in establishing axiom (iv) evident. Indeed, such repeatability is – albeit in a more general context – the motivation for the predictability sieve.

Probabilities, einselection and records

Density matrix alone – without the preferred set of states – does not suffice as a foundation for a probability interpretation. For, any mixed state density matrix $\rho_{\mathcal{S}}$ can be decomposed into sums of density matrices that add up to the same resultant $\rho_{\mathcal{S}}$, but need not share the same eigenstates. For example, consider $\rho^a_{\mathcal{S}}$ and $\rho^b_{\mathcal{S}}$, representing two different preparations (i.e., involving measurement of two distinct, non-commuting observables) of two ensembles, each with multiple copies of a system $\mathcal{S}$. When they are randomly mixed in proportions p^a and p^b, the resulting density matrix:

$$\rho^{a\vee b}_{\mathcal{S}} = p^a\rho^a_{\mathcal{S}} + p^b\rho^b_{\mathcal{S}}$$

is the complete description of the unified ensemble (see Schrödinger (1936); Jaynes (1957)).

Unless $[\rho^a_{\mathcal{S}}, \rho^b_{\mathcal{S}}] = 0$, the eigenstates of $\rho^{a\vee b}_{\mathcal{S}}$ do not coincide with the eigenstates of the components. This feature makes it difficult to regard any density matrix in terms of probabilities and ignorance. Such ambiguity would be especially troubling if it arose in the description of an observer (or, for that matter, of any classical system). Ignorance interpretation – i.e., the idea that probabilities are observer's way of dealing with uncertainty about the outcome we have briefly explored in the discussion of the insider-outsider dichotomy, Eqs. (2.44), – requires at the very least that the set of events ("the sample space") exists independently of the information at hand – i.e, independently of p^a and p^b in the example above. Eigenstates of the density matrix do not supply such events, since the additional loss of information associated with mixing of the ensembles alters the candidate events.

Basis ambiguity would be disastrous for record states. Density matrices describing a joint state of the memory $\mathcal{A}$ and of the system $\mathcal{S}$:

$$\rho^{a\vee b}_{\mathcal{AS}} = p_a\rho^a_{\mathcal{AS}} + p_b\rho^b_{\mathcal{AS}}$$

would have to be considered. In absence of einselection the eigenstates of such $\rho^{a\vee b}_{\mathcal{AS}}$ need not be even associated with a fixed set of record states of the presumably classical $\mathcal{A}$. Indeed, in general

$\rho^{a\vee b}_{\mathcal{AS}}$ has a non-zero discord,[8] and its eigenstates are entangled (even when the above $\rho^{a\vee b}_{\mathcal{AS}}$ is separable, and can be expressed as mixture of matrices that have no entangled eigenstates). This would imply an ambiguity of what are the record states, precluding probability interpretation of measurement outcomes.

Observer may nevertheless have records of a system that is in an ambiguous situation described above. Thus;

$$\rho^{a\vee b}_{\mathcal{AS}} \;=\; \sum_k w_k |A_k\rangle\langle A_k| (p^a_k \rho^a_{\mathcal{S}_k} + p^b_k \rho^b_{\mathcal{S}_k})$$

are admissible for an effectively classical $\mathcal{A}$ correlated with a quantum $\mathcal{S}$. Now the discord $\delta_{\mathcal{A}}\mathcal{I}(\mathcal{S}|\mathcal{A}) = 0$.

Mixing of ensembles of pairs of correlated systems one of which is subject to einselection does not lead to ambiguities discussed above. Discord $\delta_{\mathcal{A}}(\mathcal{S}|\mathcal{A})$ disappears in the einselected basis of $\mathcal{A}$, and the eigenvalues of the density matrices can behave as classical probabilities associated with 'events' – with the records. The "menu" of possible events in the sample space – e.g., records in memory – is fixed by einselection. Whether one can really justify this interpretation of the eigenvalues of the reducued density matrix is a separate question we are about to address.

21.6.4 Probabilities from Envariance

The view of 'the emergence of the classical' based on the environment – induced superselection has been occassionally described as "for practical purposes only" (see, e.g., Bell, 1990), to be contrasted with more fundamental (if nonexistent) solutions of the problem one could imagine (i.e., by modifying quantum theory; see Bell, 1987, 1990). This attitude can be in part traced to the reliance of einselection on reduced density matrices: For, even when explanations of all aspects of the effectively classical behavior are accepted in the framework of, say, Everett's MWI, and after the operational approach to objectivity and perception of unique outcomes based on the existential interpretation explained earlier is adopted, one major gap remains: Born's rule – axiom (v) connecting probabilities with the amplitudes, $p_k = |\psi_k|^2$ – has to be postulated in addition to axioms (o) - (ii). True, one can show that within the framework of einselection Born's rule emerges naturally (Zurek, 1998a). Decoherence is, however, based on on reduced density matrices. Now, since they were introduced by Landau (1927), it is known that "partial trace" leading to reduced density matrices is predicated on Born's rule (see Nielsen and Chuang, 2000, for discussion). Thus, derivations of Born's rule that employ reduced density matrices are open to charge of circularity (Zeh, 1997). Moreover, repeated attempts to justify $p_k = |\psi_k|^2$

[8] As we have seen in section IV, Eqs. (4.30) – (4.36), *discord* $\delta\mathcal{I}_{\mathcal{A}}(\mathcal{S}|\mathcal{A}) = \mathcal{I}(\mathcal{S}:\mathcal{A}) - \mathcal{J}_{\mathcal{A}}(\mathcal{S}:\mathcal{A})$ is a measure of the"quantumness" of correlations. It should disappear as a result of the classical equivalence of two definitions of the mutual information, but is in general positive for quantum correlations, including, in particular, predecoherence $\rho_{\mathcal{SA}}$. Discord is asymmetric, $\delta\mathcal{I}_{\mathcal{A}}(\mathcal{S}|\mathcal{A}) \neq \delta\mathcal{I}_{\mathcal{S}}(\mathcal{A}|\mathcal{S})$. Vanishing of $\delta\mathcal{I}_{\mathcal{A}}(\mathcal{S}|\mathcal{A})$ (i.e., of the discord in the direction exploring the classicality of the states of $\mathcal{A}$, on which $H(\rho_{\mathcal{S}|\mathcal{A}})$ in the asymmetric $J_{\mathcal{A}}(S:A)$, Eq. (4.32), is conditioned) is necessary for the classicality of the measurement outcome (Zurek, 2000; Ollivier and Zurek, 2002, Zurek, 2002a). $\delta\mathcal{I}_{\mathcal{A}}(\mathcal{S}|\mathcal{A})$ can disappear as a result of decoherence in the einselected basis of the apparatus. Following einselection it is then possible to ascribe probabilities to the pointer states.
In perfect measurements of Hermitean observables discord vanishes "both ways": $\delta\mathcal{I}_{\mathcal{A}}(\mathcal{S}|\mathcal{A}) = \delta\mathcal{I}_{\mathcal{S}}(\mathcal{A}|\mathcal{S}) = 0$ for the pointer basis and for the eigenbasis of the measured observable correlated with it. Nevertheless, it is possible to encounter situations when vanishing of the discord in one direction is *not* accompanied by its vanishing "in reverse". Such correlations are "classical one way" (Zurek, 2002a) and could arise, for instance, in measurements of non-hermitean observables (which – as we have already noted – happen, in spite of the axiom (iii)).
This asymmetry between classical $\mathcal{A}$ and quantum $\mathcal{S}$ arises from the einselection. Classical record states are not arbitrary superpositions. Observer accesses his memory in the basis in which it is monitored by the environment. The information stored is effectively classical because it is being widely disseminated. States of the observers memory exist objectively – they can be found out through their imprints in the environment.

within the no - collapse MWI (Everett, 1957 a&b; DeWitt, 1970; DeWitt and Graham, 1973; Geroch, 1984) have failed (see e.g., Stein, 1984; Kent, 1990; Squires, 1990): The problem is their circularity: An appeal to the connection (especially in certain limiting procedures) between the smallnes of the amplitude and the vanishing of probabilities has to be made to establish that relative frequencies of events averaged over branches of the universal state vector are consitent with Born's rule. In particular, one must a claim that "maverick" branches of the MWI state vector that have "wrong" relative frequencies are of measure zero because their Hilbert space measures are small. This is circular, as noted even by the proponents (DeWitt, 1970).

My aim here is to look at the origin of ignorance, information, and, therefore, probabilities from a very quantum and fundamental perspective: Rather than focus on probabilities for an individual isolated system I shall – in the spirit of einselection, but without employing its usual tools such as trace or reduced density matrices – consider what the observer can (and cannot) know about a system entangled with its environment. Within this context I shall demonstrate that Born's rule follows from the very quantum fact that one can know precisely the state of the composite system and yet be provably ignorant of the state of its components. This is due to *environment - assited invariance* or *envariance*, a hitherto unrecognised symmetry I am about to describe. Envariance of pure states is conspicuously missing from classical physics. It allows one to define ignorance as aconsequence of invariance, and thus to understand the origin of Born's rule, probabilities, and ultimately the origin of information through arguments based on assumptions different from Gleason's (1957) famous theorem. Rather, it is based on the Machian idea of 'relativity of quantum states' entertained by this author two decades ago (see p. 772 of Wheeler and Zurek, 1983), but not developed untill now. Envariance (Zurek, 2002b) addresses the question of meaning of these probabilities by defining "ignorance", and justifies a relative frequency argument, although in a manner different from the previous attempts.

Envariance

Environment - assisted invariance is a symmetry exhibited by the system $\mathcal{S}$ correlated with the other system (usually 'the environment' $\mathcal{E}$). When a state of the composite $\mathcal{SE}$ can be transformed by $u_{\mathcal{S}}$ acting solely on the Hilbert space $\mathcal{H}_{\mathcal{S}}$, but the effect of this transformation can be undone with an appropriate $u_{\mathcal{E}}$ acting only on $\mathcal{H}_{\mathcal{E}}$, so that the joint state $|\psi_{\mathcal{SE}}\rangle$ remains unaltered;

$$u_{\mathcal{S}} u_{\mathcal{E}} |\psi_{\mathcal{SE}}\rangle \ = \ |\psi_{\mathcal{SE}}\rangle \tag{6.6}$$

such $|\psi_{\mathcal{SE}}\rangle$ is envariant under $u_{\mathcal{S}}$. Generalization to mixed $\rho_{\mathcal{SE}}$ is obvious, but we shall find it easier to assume that $\mathcal{SE}$ has been purified in the usual fashion – i.e., by enlarging the environment.

Envariance is best elucidated by considering an example – an entangled state of $\mathcal{S}$ and $\mathcal{E}$. It can be expressed in the Schmidt basis as:

$$|\psi_{\mathcal{SE}}\rangle \ = \ \sum_k \alpha_k |s_k\rangle |\varepsilon_k\rangle \ , \tag{6.7}$$

where α_k are complex, while $\{|s_k\rangle\}$ and $\{|\varepsilon_k\rangle\}$ are orthonormal. For $|\psi_{\mathcal{SE}}\rangle$ (and, hence – given our above remark about purification – for any system correlated with the environment) it is easy to demonstrate:

Lemma 6.1: Unitary transformations co-diagonal with the Schmidt basis of $|\psi_{\mathcal{SE}}\rangle$ leave it envariant.

The *proof* relies on the form of such transformations:

$$u_{\mathcal{S}}^{\{|s_k\rangle\}} = \sum_k e^{i\sigma_k} |s_k\rangle\langle s_k| \ , \tag{6.8}$$

where σ_k is a phase. Hence;

$$u_{\mathcal{S}}^{\{|s_k\rangle\}}|\psi_{\mathcal{SE}}\rangle \; = \; \sum_k \alpha_k e^{i\sigma_k}|s_k\rangle|\varepsilon_k\rangle \; , \tag{6.9}$$

can be undone by:

$$u_{\mathcal{E}}^{\{|\varepsilon_k\rangle\}} = \sum_k e^{i\epsilon_k} \; |\varepsilon_k\rangle\langle\varepsilon_k| \tag{6.10}$$

providing that $\epsilon_k = 2\pi l_k - \sigma_k$ for some integer l_k. QED.

Thus, phases associated with the Schmidt basis are envariant. We shall see below that they are the only envariant property of entangled states. The transformations defined by Eq. (6.8) are rather specific – they share (Schmidt) eigenstates. Still, their existence leads us to:

Theorem 6.1: Local description of the system $\mathcal{S}$ entangled with a causally disconnected environment $\mathcal{E}$ must not depend on the phases of the coefficients α_k in the Schmidt decomposition of $|\psi_{\mathcal{SE}}\rangle$.

It follows that *all the measurable properties of the $\mathcal{S}$ are completely specified by the list of pairs* $\{|\alpha_k|; |s_k\rangle\}$. An equivalent way of establishing this phase envariance theorem appeals even more directly to causality: Phases of $|\psi_{\mathcal{SE}}\rangle$ can be arbitrarily changed by acting on $\mathcal{E}$ alone (e.g, by the local Hamiltonian with eigenstates $|\varepsilon_k\rangle$, generating evolution of the from of Eq. (6.9)). But causality prevents faster than light communication. Hence, no measurable property of $\mathcal{S}$ can be effected. QED.

Phase envariance theorem will turn out to be the crux of our argument. It relies on an input – entanglement and causality – which has not been employed to date in discussions of the origin of probabilities. In particular, this input is different and more "physical" than that of the succesfull derivation of Born's rules by Gleason (1957).

We also note that information contained in the "data base" $\{|\alpha_k|; |s_k\rangle\}$ implied by the Theorem 6.1 is the same as in the reduced density matrix of the system $\rho_{\mathcal{S}}$: Although we do not yet know probabilities of various $|s_k\rangle$, preferred basis of $\mathcal{S}$ has been singled out – Schmidt states (sometimes regarded as instantaneous pointer states; see e.g. Albrecht, (1992; 1993)) play a special role as the eigenstates of envariant transformations. Moreover, probabilities can depend on $|\alpha_k|$ (but not on the phases). We still do not know that $p_k = |\alpha_k|^2$.

The causality argument we could have used to establis Theorem 6.1 applies of course to arbitrary transformations one could perform on $\mathcal{E}$. However, such transformations would not be in general envariant (i.e., could not be undone by acting on $\mathcal{S}$ alone). Indeed – by the same token – all envariant transformations must be diagonal in Schmidt basis:

Lemma 6.2: All of the unitary envariant transformations of $|\psi_{\mathcal{SE}}\rangle$ have Schmidt eigenstates.

The proof relies on the fact that other unitary transformations would rotate Schmidt basis, $|s_k\rangle \rightarrow |\tilde{s}_k\rangle$. The rotated basis becomes a new 'Schmidt', and this fact cannot be affected by unitary transformations of $\mathcal{E}$ – by state rotations in the environment. But a state that has a different Schmidt decomposition from the original $|\psi_{\mathcal{SE}}\rangle$ is different. Hence, unitary transformation must be co-diagonal with Schmidt states to leave it envariant. QED.

Born's rule from envariance

When absolute values of some of the coefficients in Eq. (6.7) are equal, any orthonormal basis is 'Schmidt' in the corresponding subspace of $\mathcal{H}_{\mathcal{S}}$. This implies envariance of more general nature, e.g. under a *swap*;

$$u_{\mathcal{S}}(k \leftrightarrow j) = e^{i\phi_{kj}}|s_k\rangle\langle s_j| + h.c. \tag{6.11}$$

Swap can be generated by a phase rotation, Eq. (6.8), but in a basis complementary to the one swapped. Its envariance does not contradict Lemma 6.2, as any orthonormal basis in this case

is also 'Schmidt'). So, when $|\alpha_k| = |\alpha_j|$, the effect of a swap on the system can be undone by an obvious *counterswap* in the environment:

$$u_{\mathcal{S}}(k \leftrightarrow j) = e^{-i(\phi_{kj}+\phi_k-\phi_j+2\pi l_{kj})}|\varepsilon_k\rangle\langle\varepsilon_j| + h.c. \tag{6.12}$$

Swap can be applied to states that do not have equal absolute values of the coefficients, but in that case it is no longer envariant. Partial swaps can be also generated e.g., by underrotating or by a $u_{\mathcal{S}}^{\{|r_i\rangle\}}$, Eq. (6.8), but with the eigenstates $\{|r_i\rangle\}$ intermediate between these of the swapped and the complementary (Hadamard) basis. Swap followed by a counterswap exchanges coefficients of the swapped states in the Schmidt expansion, Eq. (6.7).

Classical correlated states can also exhibit something akin to envariance under a classical version of "swaps". For instance, a correlated state of system and an apparatus described by: $\rho_{\mathcal{SA}} \sim |s_k\rangle\langle s_k||A_k\rangle\langle A_k| + |s_j\rangle\langle s_j||A_j\rangle\langle A_j|$ can be swapped and counterswapped. The corresponding transformations would be still given by, in effect, Eqs. (6.11) - (6.12), but without phases, and swaps could no longer be generated by the rotations around the complementary basis. This situation corresponds to the "outsiders view" of the measurement process, Eq. (2.44c): Outsider can be aware of the correlation between the system and of the apparatus, but ignorant of their individual states. This connection between ignorance and envariance shall be exploited below.

Envariance based on ignorance may be found in the classical setting, but envariance of pure states is purely quantum: Observers can know perfectly the quantum joint state of $\mathcal{SE}$, yet be provably ignorant of $\mathcal{S}$. Consider a measurement carried out on the state vector of $\mathcal{SE}$ from the point of view of envariance:

$$|A_0\rangle\sum_{k=1}^{N}|s_k\rangle|\varepsilon_k\rangle \rightarrow \sum_{k=1}^{N}|A_k\rangle|s_k\rangle|\varepsilon_k\rangle \sim |\Phi_{\mathcal{SAE}}\rangle \tag{6.13}$$

Above, we have assumed that the absolute values of the coefficients are equal (and omitted them for notational simplicity). We also have ignored phases (which need not be equal) since – by the phase envariance theorem – they will not influence the state (and, hence, the probabilities) associated with $\mathcal{S}$.

Before the measurement observer with access to $\mathcal{S}$ cannot notice swaps in the state (such as Eq. (6.13)) with equal absolute values of the Schmidt coefficients. This follows from envariance of the pre-measurement $|\psi_{\mathcal{SE}}\rangle$ under swaps, Eq. (6.11).

One could argue this point in more detail by comparing what happens for two very different input states; an entangled $|\psi_{\mathcal{SE}}\rangle$ with equal absolute values of Schmidt coefficients and a product state:

$$|\varphi_{\mathcal{SE}}\rangle = |s_J\rangle|\varepsilon_J\rangle \ .$$

When observer knows he is dealing with $\varphi_{\mathcal{SE}}$, he knows the state and can predict outcome of the corresonding measurement on $\mathcal{S}$: Schrödinger equation or just the resulting truth table, Eq. (6.5), imply with certainty that his state – the future state of his memory – will be $|A_J\rangle$. Moreover, swaps involving $|s_J\rangle$ are *not* envariant for $\varphi_{\mathcal{SE}}$. They just swap the outcomes (i.e. when $u_{\mathcal{S}}(J \leftrightarrow L)$ precedes the measurement, memory will end up in $|A_L\rangle$).

By contrast,

$$|\psi_{\mathcal{SE}}\rangle \sim \sum_{k=1}^{N} e^{i\phi_k}|s_k\rangle|\varepsilon_k\rangle$$

is envariant under swaps. This allows the observer (who knows the joint state of $\mathcal{SE}$ exactly) to conclude that the probabilities of all the envariantly swappable outcomes must be the same. *Observer cannot predict his memory state after the measurement of $\mathcal{S}$ because he knows too much; the exact combined state of $\mathcal{SE}$.*

For completeness, we note that when there are system states that are absent from the above sum – i.e., states that 'appear with zero amplitude' – they cannot be envariantly swapped with the states present in the sum. Of course, observer can predict with certainty he will not detect any of the corresponding zero - amplitude outcomes.

This argument about *the ignorance of the observer concerning his future state – concerning the outcome of the measurement he is about to perform – is based on his perfect knowledge of a joint state of* $\mathcal{SE}$.

Probabilities refer to the guess observer makes on the basis of his information *before the measurement* about the state of his memory – "the future outcome" – after the measurement. As the left hand side of Eq. (6.13) is envariant under swaps of the system states, probabilities of all the states must be equal. Thus, by normalisation;

$$p_k = 1/N \ . \tag{6.14}$$

Moreover, probability of n mutually exclusive events that all appear in Eq. (6.13) with equal coefficients must be:

$$p_{k_1 \vee k_2 \vee ... \vee \ k_n} = n/N \ . \tag{6.15}$$

This concludes discussion of the equal probability case. Our case rests on the independence of the state of $\mathcal{S}$ entangled with $\mathcal{E}$ from the phases of the coefficients in the Schmidt representation – the Theorem 6.1 – which in the case of equal coefficients Eq. (6.13), allows envariant swapping, and yields Eqs. (6.14)-(6.15).

After a measurement situation changes. In accord with our preceding discussion we interpret presence of the term $|A_k\rangle$ in Eq. (6.13) as evidence that an outcome $|s_k\rangle$ can be (or indeed has been – the language here is somewhat dependent on the interpretation) recorded. Conversely, absence of some $|A_{k'}\rangle$ in the sum above implies that the outcome $|s_{k'}\rangle$ cannot occur. After a measurement memory of the observer who has detected $|s_k\rangle$ will contain the record $|A_k\rangle$. Futher measurements of the same observable on the same system will confirm that $\mathcal{S}$ is in indeed in the state $|s_k\rangle$.

This post-measurement state is still envariant, but only under swaps that involve *jointly* the state of the system and the correlated state of the memory:

$$u_{\mathcal{AS}}(k \leftrightarrow j) = e^{i\phi_{kj}} |s_k, A_k\rangle\langle s_j, A_j| + h.c. \tag{6.16}$$

Thus, if another observer ('Wigner's friend') was getting ready to find out – either by direct measurement of $\mathcal{S}$ or by communicating with observer $\mathcal{A}$ – the outcome of his measurement, he would be (on the basis of envariance) provably ignorant of the outcome $\mathcal{A}$ has detected, but could be certain of the $\mathcal{AS}$ correlation. We shall employ this joint envariance in the discussion of the case of unequal probabilities immediately below.

Note that our reasoning does not really appeal to the "information lost in the environment" in a sense in which this phrase is often used. Perfect knowledge of the combined state of the system and the environment is the basis of the argument for the ignorance od $\mathcal{S}$ alone: For entangled $\mathcal{SE}$, perfect knowlegde of $\mathcal{SE}$ is incompatible with perfect knowledge of $\mathcal{S}$. This is really a consequence of indeterminacy – joint observables with entangled eigenstates such as $\psi_{\mathcal{SE}}$ simply do not commute (as the reader is invited to verify) with the observables of the system alone. Hence, ignorance associated with envariance is ultimately mandated by Heisenberg indeterminacy.

The case of unequal coefficients can be reduced to the case of equal coefficients. This can be done in several ways, of which we choose one that makes use of the preceding discussion of envariance of the post-measurement state. We start with:

$$|\Phi_{\mathcal{SAE}}\rangle \sim \sum_{k=1}^{N} \alpha_k |A_k\rangle|s_k\rangle|\varepsilon_k\rangle \tag{6.17}$$

where $\alpha_k \sim \sqrt{m}_k$ and m_k is a natural number (and, by phase envariance theorem, we drop the phases). To get an envariant state we "increase the resolution" of $\mathcal{A}$ by assuming that;

$$|A_k\rangle = \sum_{j_k=1}^{m_k} |a_{j_k}\rangle/\sqrt{m}_k \tag{6.18}$$

An increase of resolution is a standard trick, used in classical probability theory "to even the odds". Note that we assume that basis states such as $|A_k\rangle$ are normalised (as they must be in a Hilbert space). This leads to:

$$|\Phi_{\mathcal{SAE}}\rangle \sim \sum_{k=1}^{N} \sqrt{m}_k \frac{\sum_{j_k=1}^{m_k} |a_{j_k}\rangle}{\sqrt{m}_k} |s_k\rangle|\varepsilon_k\rangle \tag{6.19}$$

We now assume that $\mathcal{A}$ and $\mathcal{E}$ interact (e.g., through a `c-shift` of section 2, with a truth table $|a_{j_k}\rangle|\varepsilon_k\rangle \rightarrow |a_{j_k}\rangle|e_{j_k}\rangle$ where $\{|e_{j_k}\rangle\}$ are all orthonormal), so that after simplifying and re-arranging terms we get a sum, over a new 'fine-grained' index, with the states of $\mathcal{S}$ that remain the same within 'coarse - grained cells', i.e., intervals measured by m_k:

$$|\tilde{\Phi}_{\mathcal{SAE}}\rangle \sim \sum_{k=1}^{N} |s_k\rangle(\sum_{j_k=1}^{m_k} |a_{j_k}\rangle|e_{j_k}\rangle) = \sum_{j=1}^{M} |s_{k(j)}\rangle|a_j\rangle|e_j\rangle \tag{6.20}$$

Above, $M = \sum_{k=1}^{N} m_k$, and $k(j) = 1$ for $j \leq m_1$, $k(j) = 2$ for $j \leq m_1 + m_2$, etc. The above state is envariant under combined swaps;

$$u_{\mathcal{SA}}(j \leftrightarrow j') = \exp(i\phi_{jj'})|s_{k(j)}, a_j\rangle\langle a_{j'}, s_{k(j')}| + h.c.$$

Suppose that an additional observer measures $\mathcal{SA}$ in the obviously swappable joint basis. By our equal coefficients argument, Eq. (6.14), we get $p(s_{k(j)}, a_j) = 1/M$. But the observer can ignore states a_j. Then the probability of different Schmidt states of $\mathcal{S}$ is, by Eq. (6.15);

$$p(s_k) = m_k/M = |\alpha_k|^2 \ . \tag{6.21}$$

This is Born's rule.

The case with coefficients that do not lead to commensurate probabilities can be treated by assuming continuity of probabilities as a function of the amplitudes and taking appropriate (and obvious) limits. This can be physically motivated: One would not expect probabilities to change drastically depending on the infinitesimal changes of the state. One can also extend the strategy outlined above to deal with probabilities (and probability densities) in cases such as $|s(x)\rangle$, i.e. when the index of the state vector changes continuously. This can be accomplished by discretising it (so that the measurement of Eq. (6.17) correlates different apparatus states with small intervals of x) and then repeating the strategy of Eqs. (6.17) - (6.21). The wavefuction $s(x)$ should be sufficiently smooth for this strategy to succeed.

We note that the "increase of resolution" we have exploited, Eqs. (6.18)-(6.21), need not be physically implemented for the argument to go through: The very possibility of carrying out these steps within the quantum formalism forces one to adopt Born's rule. For example, if the apparatus did not have the requisite extra resolution, Eq. (6.18), interaction of the environment with a still different 'counterweight' system $\mathcal{C}$ that yields

$$|\Psi_{\mathcal{SAEC}}\rangle = \sum_{k=1}^{N} \sqrt{m}_k |s_k\rangle|A_k\rangle|\varepsilon_k\rangle|C_k\rangle \tag{6.22}$$

would lead one to the Born's rule through steps similar to these we have invoked before, providing that $|C_k\rangle\}$ has the requisite resolution, $|C_k\rangle = \sum_{j_k=1}^{m_k} |c_{j_k}\rangle/\sqrt{m}_k$. Interaction resulting in a correlation, Eq. (6.22), can occur between $\mathcal{E}$ and $\mathcal{C}$, and happen far from the system of interest or from the apparatus. Thus, it will not influence probabilities of the outcomes of measurements carried out on $\mathcal{S}$ or of the records made by $\mathcal{A}$. Yet, the fact that it can happen leads us to the desired conclusion.

Relative frequencies from envariance

Relative frequency is a common theme studied with the aim of elucidating the physical meaning of probabilities in quantum theory (Everett, 1957; Hartle, 1968; DeWitt, 1970; Graham, 1970; Farhi, Goldstone, and Gutmann, 1989; Aharonov and Resnik, 2002). In particular, in the context of the "no collapse" MWI relative frequency seem to offer the best hope of arriving at the Born's rule and elucidating its physical significance. Yet, it is generally acknowledged that the MWI derivations offered to date have failed to attain this goal (Kent, 1990).

We postpone brief discussion of these efforts to the next section, and describe an approach to relative frequencies based on envariance. Consider an ensemble of many ($\mathcal{N}$) distinguishable systems prepared in the same initial state:

$$|\sigma_{\mathcal{S}}\rangle = \alpha|0\rangle + \beta|1\rangle \tag{6.23}$$

We focus on the two state case to simplify the notation. We also assume that $|\alpha|^2$ and $|\beta|^2$ are commensurate, so that the state vector of the whole ensemble of correlated triplets $\mathcal{SAE}$ after the requisite increases of resolution (see Eqs. (6.18)-(6.20) above) is given by:

$$|\Phi^{\mathcal{N}}_{\mathcal{SAE}}\rangle \sim \big(\sum_{j=1}^{m} |0\rangle|a_j\rangle|e_j\rangle + \sum_{j=m+1}^{M} |1\rangle|a_j\rangle|e_j\rangle\big)^{\otimes\mathcal{N}} \tag{6.24}$$

save for the obvious normalisation. This state is envariant under swaps of the joint states $|s, a_j\rangle$, as they appear with the same (absolute value) of the amplitude in Eq. (6.24). (By Theorem 6.1 we can omitt phases.)

After the exponentiation is carried out, and the resulting product states are sorted by the number of 0's and 1's in the records, we can calculate the number of terms with exactly n 0's, $\nu_{\mathcal{N}}(n) = \binom{\mathcal{N}}{n} m^n (M-m)^{\mathcal{N}-n}$. To get probability, we normalise:

$$p_{\mathcal{N}}(n) = \binom{\mathcal{N}}{n} \frac{m^n (M-m)^{\mathcal{N}-n}}{M^{\mathcal{N}}} = \binom{\mathcal{N}}{n} |\alpha|^{2n} |\beta|^{2(\mathcal{N}-n)} \ . \tag{6.25}$$

This is the distribution one would expect from Born's rule. To establish the connection with relative frequencies we appeal to the de Moivre - Laplace theorem (Gnedenko, 1982) which allows one to approximate above $p_{\mathcal{N}}(n)$ with a Gaussian:

$$p_{\mathcal{N}}(n) \simeq \frac{1}{\sqrt{2\pi\mathcal{N}}|\alpha\beta|} e^{-\frac{1}{2}\left(\frac{n-\mathcal{N}|\alpha|^2}{\sqrt{\mathcal{N}}|\alpha\beta|}\right)^2} \tag{6.26}$$

This last step requires large $\mathcal{N}$, but our previous discussion including Eq. (6.25) is valid for arbitrary $\mathcal{N}$. Indeed, equation (6.21) can be regarded as the $\mathcal{N} = 1$ case.

Nevertheless, for large $\mathcal{N}$ relative frequency is sharply peaked around the expected $\langle n\rangle = \mathcal{N}|\alpha|^2$. Indeed, in the limit $\mathcal{N} \to \infty$ appropriately rescaled $p_{\mathcal{N}}(n)$ tends to a Dirac $\delta(\upsilon - |\alpha|^2)$ in relative frequency $\upsilon = n/\mathcal{N}$. This justifies the relative frequency interpretation of the squares of amplitudes as probabilities in the MWI context. 'Maverick universes' with different

relative frequencies exist, but have a vanishing *probability* (and not just vanishing Hilbert space measure) for large $\mathcal{N}$.

Our derivation of the physical significance of probabilities – while it led to the relative frequency argument – was based on a very different set of assumptions than previous derivations. The key idea behind it is the connection between a symmetry (envariance) and ignorance (impossibility of knowing something). The unusual feature of our argument is that this ignorance (for an individual system $\mathcal{S}$) is demonstrated by appealing to the perfect knowledge of the larger joint system that includes $\mathcal{S}$ as a subsystem.

We emphasize that one could not carry out the basic step of our argument – the proof of the independence of the likelihoods from the phases of the Schmidt expansion coefficients – for an equal amplitude pure state of a single, isolated system. The problem with: $|\psi\rangle = N^{-\frac{1}{2}} \sum_k^N \exp(i\phi_k)|k\rangle$ is the accessibility of the phases. Consider, for instance; $|\psi\rangle \sim |0\rangle+|1\rangle-|2\rangle$ and $|\psi'\rangle \sim |2\rangle + |1\rangle - |0\rangle$. *In absence of decoherence* swapping of k's is detectable: Interference measurements (i.e., measurements of the observables with phase-dependent eigenstates $|1\rangle + |2\rangle$; $|1\rangle - |2\rangle$, etc.) would have revealed the difference between $|\psi\rangle$ and $|\psi'\rangle$. Indeed, given an ensemble of identical *pure* states an observer will simply find out what they are. Loss of phase coherence is essential to allow for the shuffling of the states and coefficients.

Note that in our derivation environment and einselection play an additional, more subtle role: Once a measurement has taken place – i.e., a correlation with the apparatus or with the memory of the observer was established – one would hope that records will retain validity over a long time, well beyond the decoherence timescale. This is a pre-condition for the axiom (iv). Thus, a "collapse" from a multitude of possibilities to a single reality can be confirmed by subsequent measurements only in the einselected pointer basis.

Other approaches to probabilities

Gnedenko (1982), in his classic textbook, lists three classical approaches to probability:

a. Definitions that appeal to *relative frequency* of occurrence of events in a large number of trials.

b. Definitions of probability as a *measure of certainty* of the observer.

c. Definitions that reduce probability to the more primitive notion of *equal likelihood*.

In the quantum setting, the relative frequency approach has been to date the most popular, especially in the context of the "no collapse" MWI ' (Everett, 1957a&b; Graham, 1970; DeWitt, 1970). Counting the number of the "clicks" seems most directly tied to the experimental manifestations of probability. Yet, Everett interpretation versions were generally found lacking (Kent, 1990; Squires, 1990), as they relied on circular reasoning, invoking *without physical justification* an abstract measure of Hilbert space to obtain a physical measure (frequency). Some of the criticisms seem relevant also for the versions of this approach that allow for the measurement postulates (iii) and (iv) (Hartle, 1968; Farhi, Goldstone and Guttmann, 1989). Nevertheless, for the infinite ensembles considered in the above references, (where, in effect, the Hilbert space measure of the MWI branches that violate relative frequency predictions is zero) that the eigenvalues of the *frequency operator* acting on a large or infinite ensemble of identical states will be consistent with the (Born formula) prescription for probabilities.

However, the infinite size of the ensemble necessary to prove this point is troubling (and unphysical) and taking the limit starting from a finite case is difficult to justify (Stein, 1984; Kent, 1990; Squires, 1990). Moreover, the frequency operator is a collective observable of the whole ensemble. It may be possible to relate observables defined for such an infinite ensemble supersystem to the states of individual subsystems, but the frequency operator does not do

it. This is well illustrated by the gedankenexperiment envisaged by Farhi et al. (1989). To provide a physical implementation of the frequency operator they consider a version of the Stern-Gerlach experiment where all the spins are attached to a common lattice, so that – during the passage through the inhomogeneity of the magnetic field – the center of mass of the whole lattice is deflected by an angle proportional to the projection of the net magnetic moment associated with the spins on the direction defined by the field gradient. The deflection is proportional to the eigenvalue of the frequency operator that is then a *collective* observable – states of individual spins remain in superpositions, uncorrelated with anything outside. This difficulty can be addressed with the help of decoherence (Zurek, 1998a), but using decoherence without justifying Born's formula first is fraught with danger of circularity.

Measure of certainty seems to be a rather vague concept. Yet, Cox (1946) has demonstrated that Boolean logic leads – after addition of a few reasonable assumptions – to the definition of probabilities that, in a sense, appear as an extension of the logical truth values. However, the rules of symbolic logic that underlie Cox's theorems are *classical*. One can adopt this approach (Zurek, 1998a) to probabilities in quantum physics only after decoherence "intervenes" restoring the validity of the distributive law, which is not valid in quantum physics (Birkhoff and von Neumann, 1936).

One can carry out equal likelihood approach in the context of decoherence (Zurek, 1998a). The problem is – as pointed out before – the use of trace, and the dangers of circularity. An attempt to pursue a strategy akin to equal likelihood in the quantum setting at the level of pure states of individual systems has been also made by Deutsch in his (unpublished) "signalling" approach to probabilities. The key idea is to consider a source of pure states, and to find out when the permutations of a set of basis states can be detected, and, therefore, used for communication. When permutations are undetectable, probabilities of the permuted set of states are declared equal. The problem with this idea (or with its more formal version described by DeWitt, 1998) is that it works only for superposition that have all the coefficients identical, *including their phases*. Thus, as we have already noted, for closed systems phases matter and there is no invariance under swapping. In a recent paper Deutsch (1999) has adopted a different approach based on decision theory. The basic argument focuses again on individual states of quantum systems, but – as noted in the critical comment by Barnum et al. (2000) – seems to make appeal to some of the aspects of decision theory that do depend on probabilities. In my view, it also leaves the problem of the phase dependence of the coefficients unaddressed.

Among other approaches, recent work of Gottfried (2000) shows that in a discrete quantum system coupled with a continuous quantum system Born's formula follows from the demand that the continuous system should follow classical mechanics in the appropriate limit. A somewhat different strategy, with a focus on the coincidences of the expected magnitude of fluctuations was proposed by Aharonov and Resnik (2002).

In comparison with all of the above strategies, 'probabilities from envariance' is the most radically quantum, in that it ultimately relies on entanglement (which is still sometimes regarded as 'a paradox', and 'to be explained': I have used it as an explanation). This may be the reason why it has not been discovered untill now. The insight offered by envariance into the nature ignorance and information sheds a new light on probabilities in physics. The (very quantum) ability to prove ignorance of a part of a system by appealing to perfect knowledge of the whole may resolve some of the difficulties of the classical approaches.

21.7 Environment as a Witness

Emergence of classicality can be viewed either as a consequence of the widespread dissemination of the information about the pointer states through the environment, or as a result of the censorship imposed by decoherence. So far I have focused on this second view, defining

existence as persistence – predictability in spite of the environmental monitoring. Predictability sieve is a way of discovering states that are classical in this sense (Zurek, 1993a&b; Zurek, Habib and Paz, 1993; Gallis, 1996).

A complementary approach focusses *not* on the system, but on the records of its state spread throughout the environment. Instead of "the least perturbed states" one can ask "what states of the system are easiest to discover by looking at the environment". Thus, environment is no longer just a source of decoherence, but acquires a role of a communication channel with a basis - dependent noise that is minimised by the preferred pointer states.

This approach can be motivated by the old dilemma: On the one hand, quantum states of isolated systems are purely "epistemic" (see e.g., Peres, (1993); Fuchs and Peres (2000)). Quantum cryptography (Bennett and DiVincenzo, 2000; Nielsen and Chuang, 2000, and references therein) uses this impossibility of finding out what is an unknown state of an isolated quantum system. On the other hand classical reality seems to be made up of quantum building blocks: States of macroscopic systems exist objectively – they can be found out by many observers independently without being destroyed or re-prepared. So – the question arises – how can objective existence — the "reality" of the classical states – emerge from "purely epistemic" wavefunctions?

There is not much one can do about this in case of a single state of an isolated quantum system. But open systems are subject to einselection and can bridge the chasm dividing their epistemic and ontic roles. The most direct way to see this arises from the recognition of the fact that we never *directly* observe any system. Rather, we discover states of macroscopic systems from the imprints they make on the environment: A small fraction of the photon environment intercepted by our eyes is often all that is needed. States that are recorded most redundantly in the rest of the Universe (Zurek, 1983; 1998a; 2000) are also easiest to discover. They can be found out indirectly, from multiple copies of the evidence imprinted in the environment, without a threat to their existence. Such states exist and are real – they can be found out without being destroyed as if they were really classical.

Environmental monitoring creates an ensemble of "witness states" in the subsystems of the environment, that allow one to invoke some of the methods of the statistical interpretation (Ballentine, 1970) while subverting its ideology – to work with an *ensemble* of objective evidence of a state of a *single* system. From this ensemble of witness states one can infer the state of the quantum system that has led to such "advertising". This can be done without disrupting the einselected states.

Predictability sieve selects states that entangle least with the environment. Question about predictability simultaneously lead to states that are most redundantly recorded in the environment. Indeed, this idea touches on the "quantum Darwinism" we have alluded to in the introduction: The einselected pointer states are not only best in surviving the environment, but, also, they broadcast the information about themselves – spread out their "copies" – throughout the rest of the Universe: Amplified information is easiest to amplify. This leads to analogies with "fitness" in the Darwinian sense, and suggests looking at einselection as a sort of natural selection.

21.7.1 Quantum Darwinism

Consider the "bit by byte" example of Section IV. Spin - system $\mathcal{S}$ is correlated with the environment:

$$\begin{aligned} |\psi_{\mathcal{SE}}\rangle &= a|\uparrow\rangle|00\ldots0\rangle + b|\downarrow\rangle|11\ldots1\rangle \\ &= a|\uparrow\rangle|\mathcal{E}_\uparrow\rangle + b|\downarrow\rangle|\mathcal{E}_\downarrow\rangle \qquad 7.1 \end{aligned} \tag{21.59}$$

The basis $\{|\uparrow\rangle, |\downarrow\rangle\}$ of $\mathcal{S}$ is singled out by the redundancy of the record. By comparison, the same $|\psi_{\mathcal{SE}}\rangle$ is:

$$\begin{aligned} |\psi_{\mathcal{SE}}\rangle &= |\odot\rangle(a|00\ldots0\rangle + b|11\ldots1\rangle)\sqrt{2} \\ &+ |\otimes\rangle(a|00\ldots0\rangle - b|11\ldots1\rangle)/\sqrt{2} \\ &= (|\odot\rangle|\mathcal{E}_{\odot}\rangle + |\otimes\rangle|\mathcal{E}_{\otimes}\rangle)/\sqrt{2} \qquad 7.2 \end{aligned} \tag{21.60}$$

in terms of the Hadamard-transformed $\{|\odot\rangle, |\otimes\rangle\}$.

One can find out whether $\mathcal{S}$ is $|\uparrow\rangle$ or $|\downarrow\rangle$ from a small subset of the environment bits. By contrast, states $\{|\odot\rangle, |\otimes\rangle\}$ cannot be easily inferred from the environment. States $\{|\mathcal{E}_{\odot}\rangle, |\mathcal{E}_{\otimes}\rangle\}$ are typically not even orthogonal, $\langle\mathcal{E}_{\odot}|\mathcal{E}_{\otimes}\rangle = |a|^2 - |b|^2$. And even when $|a|^2 - |b|^2 = 0$, the record in the environment is fragile: Only one relative phase distinguishes $|\mathcal{E}_{\odot}\rangle$ from $|\mathcal{E}_{\otimes}\rangle$ in that case, in contrast with multiple records of the pointer states in $|\mathcal{E}_{\uparrow}\rangle$ and $|\mathcal{E}_{\downarrow}\rangle$. Remarks that elaborate this observation follow. They correspond to several distinct measures of 'fitness' of states.

Consensus and algorithmic simplicity

>From the state vector $|\psi_{\mathcal{SE}}\rangle$, Eqs. (7.1) and (7.2), observer can find the state of the quantum system just by looking at the environment. To accomplish this, the total N of the environment bits can be divided into samples of n bits each, with $1 \ll n \ll N$. These samples can be then measured using observables that are the same within each sample, but differ between samples. They may correspond, for example, to different antipodal points in the Bloch spheres of the environment bits. In the basis $\{|0\rangle, |1\rangle\}$ (or bases closely aligned with it) the record inferred from the bits of information scattered in the environment will be easiest to come by. Thus, starting from the environment part of $|\psi_{\mathcal{SE}}\rangle$, Eq. (7.1), *the observer can find out, with no prior knowledge, the state of the system*: Redundancy of the record in the environment allows for a trial-and-error 'indirect' approach while leaving the system untouched.

In particular, measurement of n environment bits in a Hadamard transform of the basis $\{|0\rangle, |1\rangle\}$ yields a random-looking sequence of outcomes (i.e., $\{|+\rangle_1, |-\rangle_2, \ldots |-\rangle_n\}$). This record is algorithmically random: Its algorithmic complexity is of the order of its length (Li and Vitànyi, 1994):

$$K(\langle\mathcal{E}_n|+,-\rangle) \simeq n \tag{7.3}$$

By contrast, algorithmic complexity of the measurement outcomes in the $\{|0\rangle, |1\rangle\}$ basis will be small:

$$K(\langle\mathcal{E}_n|0,1\rangle) \ll n \ , \tag{7.4}$$

since the outcomes will be either $00\ldots0$ or $11\ldots1$. Observer seeking preferred states of the system by looking at the environment should then search for the minimal record size and, thus, for the maximum redundancy in the environmental record. States of the system that are recorded redundantly in the environment must have survived repeated instances of the environment monitoring, and are obviously robust and predictable.

Predictability we have utilized before to devise a "sieve" to select preferred states is used here again, but in a different guise: Rather than search for predictable sets of states of the system we are now looking for the records of the states of the system in the environment. Sequences of states of environment subsystems correlated with pointer states are mutually predictable and, hence, collectively algorithmically simple. States that are predictable in spite of the interactions with the environment are also easiest to predict from their impact on its state.

The state of the form of Eq. (7.1) can serve as an example of amplification. Generation of redundancy through amplification brings about objective existence of the otherwise subjective quantum states. States $|\uparrow\rangle$ and $|\downarrow\rangle$ of the system can be found out reliably from a small

fraction of the environment. By contrast, to find out whether the system was in a state $|\odot\rangle$ or $|\otimes\rangle$ one would need to detect *all* of the environment. Objectivity can be defined as the ability of many observers to reach consensus independently. Such consensus concerning states $|\uparrow\rangle$ and $|\downarrow\rangle$ is easily established – many ($\sim N/n$) can independently measure fragments of the environment.

Action distance

One measure of robustness of the environmental records is the action distance (Zurek, 1998a). It is given by the total *action* necessary to undo the distinction between the states of the environment corresponding to different states of the system, subject to the constraints arising from the fact that the environment consists of subsystems. Thus, to obliterate the difference between $|\mathcal{E}_\uparrow\rangle$ and $|\mathcal{E}_\downarrow\rangle$ in Eq. (7.1), one needs to "flip" one-by-one N subsystems of the environment. That implies an action – i.e., the least total angle by which a states must be rotated, see Section IIB – of:

$$\Delta(|\mathcal{E}_\uparrow\rangle, |\mathcal{E}_\downarrow\rangle) = N \left[\frac{\pi}{2} \cdot \hbar\right] \ . \tag{7.5}$$

By contrast a "flip" of phase of just one bit will reverse the correspondence between the states of the system and of the environment superpositions that make up $|\mathcal{E}_\odot\rangle$ and $|\mathcal{E}_\otimes\rangle$ in Eq (7.2). Hence:

$$\Delta(|\mathcal{E}_\odot\rangle, |\mathcal{E}_\otimes\rangle) = 1 \left[\frac{\pi}{2} \cdot \hbar\right] \ . \tag{7.6}$$

Given a fixed division of the environment into subsystems the action distance is a metric on the Hilbert space (Zurek, 1998a). That is;

$$\Delta(|\psi\rangle, |\psi\rangle) = 0 \ , \tag{7.7}$$

$$\Delta(|\psi\rangle, |\varphi\rangle) = \Delta(|\varphi\rangle, |\psi\rangle) \geq 0, \tag{7.8}$$

and the triangle inequality:

$$\Delta(|\psi\rangle, |\varphi\rangle) + \Delta(|\varphi\rangle, |\gamma\rangle) \geq \Delta(|\psi\rangle, |\gamma\rangle) \tag{7.9}$$

are all satisfied.

In defining Δ it is essential to restrict rotations to the subspaces of the subsystems of the whole Hilbert space, and to insist that the unitary operations used in defining distance act on these subspaces. It is possible to relax constraints on such unitary operations by allowing, for example, pairwise or even more complex interactions between subsystems. Clearly, in absence of any restrictions the action required to rotate any $|\psi\rangle$ into any $|\varphi\rangle$ would be no more than $\frac{\pi}{2}\hbar$. Thus, constraints imposed by the natural division of the Hilbert space of the environment into subsystems play an essential role. Preferred states of the system can be sought by extremizing action distance between the corresponding record states of the environment. In simple cases (e.g., see "bit-by-byte", Eq. (4.7) and below) the action distance criterion for preferred states coincides with the predictability sieve definition (Zurek, 1998a).

Redundancy and mutual information

The most direct measure of reliability of the environment as a witness is the information-theoretic redundancy of einselection itself. When environment monitors the system (see Fig. 4), the information about its state will spread to more and more subsystems of the environment. This can be represented by the state vector $|\psi_{\mathcal{SE}}\rangle$, Eq. (7.1), with increasingly long sequences of 0's and 1's in the record states. The record size – the number N of the subsystems of the environment involved – does not affect the density matrix of the system $\mathcal{S}$. Yet, it obviously

changes accessibility abd robustness of the information analogues of the Darwinian "fitness". As an illustration, let us consider `c-shift`'s. One subsystem of the environment (say, $\mathcal{E}_1$) with the dimension of the Hilbert space no less than that of the system

$$Dim\mathcal{H}_{\mathcal{E}1} \geq Dim\mathcal{H}_{\mathcal{S}}$$

suffices to eradicate off-diagonal elements of $\rho_{\mathcal{S}}$ in the control basis. On the other hand, when N subsystems of the environment correlate with the same set of states of $\mathcal{S}$, the information about these states is simultaneously accessible more widely. While $\rho_{\mathcal{S}}$ is no longer changing, spreading of the information makes the existence of the pointer states of $\mathcal{S}$ more objective – they are easier to discover without being perturbed.

Information theoretic *redundancy* is defined as the difference between the least number of bits needed to uniquely specify the message and the actual size of the encoded message. Extra bits allow for detection and correction of errors (Cover and Thomas, 1991). In our case, the message is the state of the system, and the channel is the environment. The information about the system will often spread over all of the Hilbert space $\mathcal{H}_{\mathcal{E}}$ that is enormous compared to $\mathcal{H}_{\mathcal{S}}$. Redundancy of the record of the pointer observables of selected systems can be also huge. Moreover, typical environments consist of obvious subsystems (i.e., photons, atoms, etc.). It is then useful to define redundancy of the record by the number of times the information about the system has been copied, or by how many times it can be independently extracted from the environment.

In the simple example of Eq. (7.1) such *redundancy ratio* $\mathcal{R}$ for the $\{|\uparrow\rangle, |\downarrow\rangle\}$ basis will be given by N, the number of environment bits perfectly correlated with the obviously preferred basis of the system. More generally, but in the same case of perfect correlation we obtain:

$$\mathcal{R} = \frac{\lg(Dim\mathcal{H}_{\mathcal{E}})}{\lg(Dim\mathcal{H}_{\mathcal{S}})} = \log_{Dim\mathcal{H}_{\mathcal{S}}}(Dim\mathcal{H}_{\mathcal{E}}) = N \tag{7.10}$$

where $\mathcal{H}_{\mathcal{E}}$ is the Hilbert space of the environment perfectly correlated with the pointer states of the system.

On the other hand, with respect to the $\{|\odot\rangle, |\otimes\rangle\}$ basis, the redundancy ratio for $|\psi_{\mathcal{SE}}\rangle$ of Eq. (7.2) is only $\sim$1 (see also Zurek, 1983; 2000): Redundancy measures the number of errors that can obliterate the difference between two records, and in this basis one phase flip is clearly enough. This basis dependence of redundancy suggests an alternative strategy to seek preferred states.

To define $\mathcal{R}$ in general we can start with mutual information between the subsystems of the environment $\mathcal{E}_k$ and the system $\mathcal{S}$. As we have already seen in section IV, definition of mutual information in quantum mechanics is not straightforward. The basis-independent formula:

$$\mathcal{I}_k = \mathcal{I}(\mathcal{S} : \mathcal{E}_k) = H(\mathcal{S}) + H(\mathcal{E}_k) - H(\mathcal{S}, \mathcal{E}_k) \tag{7.11}$$

is simple to evaluate (although it does have some strange features; see Eqs. (4.30) - (4.36)). In the present context it involves joint density matrix:

$$\rho_{\mathcal{SE}_k} = Tr_{\mathcal{E}/\mathcal{E}_k}\rho_{\mathcal{SE}} \tag{7.12}$$

where the trace is carried out over all of the environment except for its singled out fragment $\mathcal{E}_k$. In the example of Eq. (7.1) for any of the environment bits

$$\rho_{\mathcal{SE}_k} = |a|^2|\uparrow\rangle\langle\uparrow| \otimes |0\rangle\langle 0| + |b|^2|\downarrow\rangle\langle\downarrow| \otimes |1\rangle\langle 1| \quad .$$

Given the partitioning of the environment into subsystems, the redundancy ratio can be defined as:

$$\mathcal{R}_{\mathcal{I}(\{\otimes\mathcal{H}_{\mathcal{E}_k}\})} = \sum_k \mathcal{I}(\mathcal{S} : \mathcal{E}_k)/H(\mathcal{S}) \quad . \tag{7.13}$$

When $\mathcal{R}$ is maximized over all of the possible partitions,

$$\mathcal{R}_{\mathcal{I}max} = R_{\{\otimes \mathcal{H}_{\mathcal{E}k}\}} \tag{7.14}$$

obtains. Roughly speaking, and in the case when the number of the environment subsystems is large, $\mathcal{R}_{\mathcal{I}max}$ is the total number of copies of the information about (the optimal basis of) $\mathcal{S}$ that exist in $\mathcal{E}$. Maximal redundancy ratio $\mathcal{R}_{\mathcal{I}max}$ is of course basis - independent.

The information defined through the symmetric $\mathcal{I}_k$, Eq. (7.11), is in general inaccessible to observers who interrogate environment one subsystem at a time (Zurek, 2002a). It makes therefore a lot of sense to consider the basis-dependent locally accessible information and define the corresponding redundancy ratio $\mathcal{R}_{\mathcal{J}}$ using:

$$\mathcal{J}_k = \mathcal{J}(\mathcal{S} : \mathcal{E}_k) = H(\mathcal{S}) + H(\mathcal{E}_k) - (H(\mathcal{S}) + H(\mathcal{E}_k|\mathcal{S})). \tag{7.15}$$

Conditional entropy must be computed in a specific basis of the system (see Eq. (4.32)). All of the other steps that have led to the definition of $\mathcal{R}_{\mathcal{I}max}$ can be now repeated using $\mathcal{J}_k$. In the end, a basis - dependent:

$$\mathcal{R}_{\mathcal{J}}(\{|s\rangle\}) = \mathcal{R}_{\mathcal{J}}(\otimes \mathcal{H}_{\mathcal{E}k}) \tag{7.16}$$

obtains. $\mathcal{R}_{\mathcal{J}}(\{|s\rangle\})$ quantifies the mutual information between the collection of subsystems $\mathcal{H}_{\mathcal{E}k}$ of the environment and the basis $\{|s\rangle\}$ of the system. We note that the condition of non-overlapping partitions guarantees that all of the corresponding measurements commute, and that the information can be indeed extracted independently from each environment fragment $\mathcal{E}_k$.
