Superconductivity

Yury Holubeu *

October 31, 2025

The note is not intended for distribution. Superconductivity and its applications is discussed in detail. The note has solved problems and summary of special topics. Readers who have opened this note for the first time are highly recommended to read the preface.

Contents

Preface and main motivation **18**

I —— Superconductivity in a Nutshell —— **20**

1 Main Models and Properties of Superconductors **20**
1.1 Main Theories for Superconductors . . . 20
1.1.1 Main properties of SC and overview of theoretical methods . . . 20
1.1.2 GL theory . . . 25
1.1.3 BCS theory . . . 29
1.1.4 Electrodynamics of superconductors . . . 33
1.1.5 BdG equations, BTK formalism, Andreev states . . . 33
1.1.6 Currents, Thermodynamics, Susceptibilities . . . 36
1.1.7 General important features of superconductors and theories . . . 38
1.2 Typical SC Effects . . . 38
1.2.1 Josephson equations, SNS, SQUID, RCSJ . . . 38
1.2.2 NS, NIS, SIS, other typical junctions . . . 48
1.2.3 Skin effect, inductance, impedance . . . 50
1.2.4 Thin films, plates . . . 52
1.2.5 Vortices: basic models . . . 54
1.3 Basic concepts of condensed matter for SC . . . 56
1.4 Mathematics . . . 56
1.5 Materials, experimental facts . . . 57

2 Most Useful Special Methods **58**
2.1 Very useful special methods for special applications . . . 58
2.1.1 Functional integral for SC . . . 58
2.1.2 Scattering Matrix, Beenkker method for SC Junctions . . . 59

II Fundamentals of Superconductivity **60**

3 Framework for understanding superconductivity **60**
3.1 General ideas about fundamental nature of superconductivity . . . 60
3.1.1 How to predict existence of SC from literally nothing? . . . 60
3.1.2 How to predict existence of SC from high-T properties? . . . 60
3.1.3 Taking into account shape of the Fermi surface (????) . . . 60
3.1.4 Intuitive understanding of GL theory . . . 60
3.1.5 How to guess about GL theory? . . . 60
3.1.6 Intuitive understanding of BCS theory . . . 60
3.1.7 How to guess about BCS theory? . . . 60
3.2 Basic Experimental Facts about Typical SC . . . 61
3.2.1 Overview of Basic Experimental Facts about Typical SC . . . 61
3.2.2 The Isotope Effect . . . 64
3.2.3 The Anisotropy Effect. . . . 67

*https://yuriholubeu.github.io/, yuri.holubev@gmail.com

3.2.4 Meissner effect . . . 67
3.2.5 Advanced Experimental Facts about Typical SC . . . 67
3.3 Other Ideas for Introduction to Superconductivity . . . 72
3.3.1 General Introduction to Superconductivity . . . 72
3.3.2 I-I A new condensed state by de Gennes . . . 76
3.4 Professional Choice of Model for SC . . . 77
3.5 Linear Electrodynamics of Superconductors: Basics . . . 77
3.5.1 The London Equations: Basics . . . 77
3.5.2 The London Equations: Another Theories . . . 79
3.5.3 2.2 Magnetic Field Penetration Depth . . . 85
3.5.4 2.3 Nonlocal Electrodynamics of Superconductors . . . 86
3.5.5 Propagation of a electric field inside the SC . . . 87
3.5.6 2.4 Quantum Generalization of the London Equations. . . . 87
3.5.7 Magnetic Flux Quantization . . . 88
3.6 Ginzburg Landau Theory: Basics . . . 90
3.6.1 General GL philosophy of phase transitions . . . 90
3.6.2 3.2 Equations of the Ginzburg-Landau Theory . . . 93
3.6.3 Characteristic Lengths, Proximity Effect, Thermodynamic Critical Field . . . 101
3.6.4 Characteristic Lengths of the Ginzburg-Landau Theory . . . 106
3.6.5 Energy of a Normal Metal-Superconductor Interface . . . 111
3.6.6 Limits of Applicability of GL Theory . . . 115
3.6.7 1-4 Two kinds of superconductors by de Gennes . . . 115
3.6.8 The Wall Energy, derivation of $\varkappa_c = 1/2$ . . . 117
3.7 Ginzburg Landau theory: advanced general features and details . . . 123
3.7.1 Anderson-Higgs mechanics and Goldstone Theorem in SC . . . 123
3.7.2 Typical Subtle Features of GL theory . . . 125
3.7.3 Fluctuation effects near SC phase transitions: basic concepts . . . 126
3.7.4 Intuitive understanding of GL theory . . . 133
3.7.5 Short Examples of Applications of GL theory . . . 133
3.8 Background for Real Understanding of BCS Theory . . . 134
3.8.1 Speedrun of Condensed Matter for Superconductivity . . . 134
3.8.2 Superfluid Fermi Gas: Energy Spectrum . . . 134
3.8.3 Superfluid Fermi Gas: Thermodynamic Properties . . . 134
3.8.4 Green's Functions of Superfluid Fermi Gas . . . 134
3.8.5 Temperature Green's Functions of Superfluid Fermi Gas . . . 134
3.8.6 QFT formalism for bound states of two particles . . . 135
3.9 BCS Theory: Basic General Properties . . . 135
3.9.1 Cooper Pairs: General Idea and Physical Picture . . . 135
3.9.2 Cooper Pairs: Basic Calculations . . . 144
3.9.3 Cooper Pairs: QFT framework . . . 147
3.9.4 BCS Hamiltonian: Derivation and Features . . . 153
3.9.5 Mean-field Approximation of BCS Hamiltonian, Diagonalization . . . 165
3.9.6 Meaning of the gap Δ, gap equation . . . 175
3.9.7 Tight-binding 1D BCS model . . . 184
3.9.8 Ground State Energy and Wavefunction in BCS . . . 188
3.9.9 What exactly happens at a ground state of a SC (at $T = 0$)? . . . 192
3.9.10 System of QFT GF Equations for a Superconductor . . . 197
3.9.11 The Superconductivity QFT Equations: Derivation . . . 205
3.9.12 Δ_0 and T_c, The Universal BCS Relation . . . 208
3.9.13 Gap Δ as a function of T . . . 212
3.9.14 The gap Δ: 1001 questions and statements about details . . . 216
3.9.15 The gap Δ: Measurement and Effects from It . . . 218
3.9.16 Chemical Potential of a Superconductor . . . 221

3.9.17 The Coupling Constant of BCS Model . . . 221
3.10 BCS: Advanced Features and Details of a Typical Setups . . . 222
3.10.1 Overview of general important features of BCS . . . 222
3.10.2 How Good and Useful Is BCS Theory? . . . 224
3.10.3 Cooper Pairs: Deeper Understanding . . . 224
3.10.4 Cooper Pairs: Spatial Structure, Life Time, Speed . . . 227
3.10.5 BCS theory in 1D, 2D: General Features . . . 232
3.10.6 Original 1957 BCS Paper 1: Conclusion, Introduction, General Questions . . . 232
3.10.7 Original 1957 BCS Paper 1: Ground State . . . 239
3.10.8 Original 1957 BCS Paper: Excited States . . . 247
3.10.9 Original 1957 BCS Paper: Calculation of Matrix Elements . . . 257
3.10.10 Original 1957 BCS Paper: Electrodynamic Properties . . . 264
3.10.11 Original 1957 BCS Paper: Appendices . . . 274
3.10.12 Phase and Particle Number Operators in SC . . . 284
3.10.13 BCS model with net motion of electrons . . . 285
3.11 BCS: Formalisms for Special Setups . . . 286
3.11.1 BCS in a Framework of Path Integral . . . 286
3.11.2 Nambu Notation, Hole Interpretation . . . 286
3.11.3 Gap in Unconventional Superconductors: Basics . . . 287
3.11.4 Anderson's Random-Phase Approximation in SC . . . 290
3.11.5 Impurities in BCS: General Idea How to Take Them into Account . . . 290
3.11.6 Impact of Lattice Configuration in BCS . . . 290
3.11.7 BCS theory in the Density Matrix Framework . . . 291
3.11.8 Time-Dependent BCS . . . 294
3.12 General Formalisms for Typical Effects . . . 294
3.12.1 Currents and Tunneling Effects: Basic Concepts 1 . . . 294
3.12.2 Currents and Tunneling Effects: Basic Concepts 2 . . . 304
3.12.3 6.5 Persistent Current and the Meissner-Ochsenfeld Effect . . . 311
3.12.4 Formalism for Thermodynamic Effects of the Meissner State . . . 314
3.12.5 Introduction to Thermodynamics of Superconductors . . . 322
3.12.6 Which Equilibrium Properties will Be Not Present in Nonequilibrium? . . . 325
3.13 General Ideas of Other Effects . . . 325
3.13.1 Dissipative and open BCS: General Concepts . . . 325
3.13.2 Magnetic Field, Created by Cooper Pairs (???) . . . 326

4 Basic Effects of Superconductors 326
4.1 General Effects . . . 326
4.1.1 Critical supercurrent: basics . . . 326
4.1.2 Critical supercurrent: advanced features 1 . . . 331
4.1.3 Critical supercurrent: advanced features 2 . . . 339
4.1.4 Description of Isotope effect . . . 356
4.1.5 Description of Meissner effect . . . 356
4.1.6 Flux quantization . . . 357
4.1.7 Flux quantization: Experimental confirmation . . . 358
4.1.8 Levitation over Superconductor: Basic understanding . . . 358
4.1.9 1-2 Diamagnetism by de Gennes . . . 359
4.1.10 1-3 Absence of low energy excitations by de Gennes . . . 362
4.2 Thermodynamic Effects . . . 364
4.2.1 Specific heat, Free Energy, Entropy 1 . . . 364
4.2.2 Specific heat, Free Energy, Entropy 2 . . . 369
4.2.3 Specific Heat: Experimental confirmation . . . 372
4.2.4 Thermal Conductivity . . . 374
4.2.5 Vortices: General Properties . . . 376
4.2.6 Critical field of superconductors 1 . . . 378

4.2.7 Critical field of superconductors 2 . . . 381
4.2.8 Critical Magnetic Field of Thin Films in a Field Parallel to the Surface . . . 386
4.2.9 The Intermediate State . . . 387
4.2.10 Critical Magnetic Fields for Type-II SC . . . 390
4.2.11 38. Superconductors Close to the T_c in an Arbitrary Magnetic Field . . . 412

5 Details of Fundamental Effects and Other Basic Properties 416
5.1 Basics of Determination of Physical Parameters . . . 416
5.1.1 Determination of the value of T_c . . . 416
5.2 Important general features of theories of superconductivity . . . 416
5.2.1 Connection of the Ginzburg-landau and BCS theory . . . 416
5.2.2 What is Different in Equilibrium and Non-Equilibrium Superconductors? . . . 424
5.2.3 Derivation of phenomena of GL theory in the framework of BCS theory . . . 424
5.2.4 Derivation of phenomena of BCS theory in the framework of GL theory . . . 424
5.2.5 Existence of 1D superconductors . . . 425
5.2.6 General idea of dissipation in superconductors . . . 425
5.2.7 Other General Fundamental Concepts . . . 425
5.2.8 How can we theoretically prove that other low-energy effects do not destroy SC? 426
5.3 Other Typical Properties . . . 426
5.3.1 Velocity of superconductive electrons . . . 426
5.3.2 Parity Effect in SC by Shmidt 48* . . . 426
5.3.3 Unconventional superconductivity: Relation to the Basic Theory . . . 429

III Bulk Properties of Superconductors 434

6 Methods from De Gennes 434
6.0.1 3-3 Nonequilibrium Properties . . . 434
6.1 Description of the Condensed State . . . 441
6.1.1 4-1 Instability of the Normal State in the Presence of an Attractive Interaction 441
6.1.2 4-2 Origin of the Attractive Interaction . . . 444
6.1.3 4-3 Ground State and Elementary Excitations . . . 450
6.1.4 4-4 Calculations at Finite Temperature . . . 462
6.2 The Self-Consistent Field Method . . . 473
6.2.1 5-1 The Bogoliubov Equations . . . 473
6.2.2 5-2 Theorems on the Pair Potential and the Excitation Spectrum . . . 480
6.2.3 5-3 The Meissner Effect in Metals and Alloys . . . 491
6.3 Phenomenological Landau-Ginsburg Equations . . . 499
6.3.1 6-1 Introduction . . . 499
6.3.2 6-2 Construction of the Free Energy . . . 499
6.3.3 6-3 Equilibrium Equations . . . 502
6.3.4 6-4 The Two Characteristic Lengths . . . 503
6.3.5 6-5 Situations Where $|\psi|$ Is Constant . . . 507
6.3.6 6-6 Situations Where $|\psi|$ Varies Spatially . . . 517
6.3.7 6-7 Structure of the Vortex Phase in Strong Fields ($H \sim H_{C2}$) . . . 521
6.4 Microscopic Analysis of the Landau-Ginsburg Equations . . . 527
6.4.1 7-1 Linearized Self-Consistency Equation . . . 527
6.4.2 7-2 Landau-Ginsburg Equations . . . 534
6.4.3 7-3 Surface Problems in the Landau-Ginsburg Region . . . 540
6.5 Effects of Strong Magnetic Fields and of Magnetic Impurities . . . 555
6.5.1 8-1 Relation Between Transition Temperature and Time-Reversal Properties . . . 556
6.5.2 8-2 Ergodic Versus Nonergodic Behavior - Gapless Superconductivity . . . 561
6.5.3 8-3 Dirty Superconductors in High Magnectic Fields . . . 570

7 Well-known phenomena of superconductors **574**
7.1 Magnetic properties of first kind superconductors by de Gennes . . . 574
7.1.1 2-1 Critical field of a long cylinder . . . 574
7.1.2 2-2 Penetration depths . . . 577
7.1.3 2-3 Magnetic properties of a sample of arbitrary shape: intermediate state . . . 582
7.2 Magnetic properties of second kind superconductors by de Gennes . . . 596
7.2.1 3-1 Magnetization curves of a long cylinder . . . 596
7.2.2 3-2 Vortex state: microscopic description . . . 600
7.3 Thin films . . . 620
7.3.1 3.5 Critical Field of a Thin Film . . . 620
7.3.2 3.6 Critical Current of a Thin Film . . . 623
7.4 2. Some Effects in Scope of Linear Electrodynamics of Superconductors . . . 627
7.4.1 2.5 Magnetic Field and Current Distributions in Simple Configurations . . . 627
7.4.2 2.6 Kinetic Inductance . . . 633
7.4.3 2.7 Complex Conductivity of a Superconductor . . . 635
7.4.4 2.8 Skin Effect and Surface Impedance . . . 636
7.5 Other Bulk Effects in Electromagnetic Field . . . 638
7.5.1 Superconductors in a Weak Electromagnetic Field by AGD . . . 638
7.6 5. Type-II Superconductors . . . 649
7.6.1 5.1 Introduction . . . 649
7.6.2 5.2 Field of an Isolated Vortex . . . 651
7.6.3 5.3 The Lower Critical Field . . . 653
7.6.4 5.4 Interaction Between Vortices . . . 655
7.6.5 5.5 The Upper Critical Field . . . 657
7.6.6 5.6 Reversible Magnetization of a Type-II Superconductor . . . 657
7.6.7 5.7 Surface Superconductivity. The Third Critical Field . . . 659
7.6.8 5.8 Surface Barrier. Superheating of the Meissner State . . . 662
7.6.9 5.9 Some Remarks About High-Temperature Superconductors . . . 666
7.6.10 5.10 Critical Current of a Type-II Superconductor. Critical State . . . 668
7.6.11 5.11 Interaction of Vortices with Pinning Centers . . . 670
7.6.12 5.12 Resistive State . . . 675
7.7 Type II Superconductors: Advanced Properties . . . 679
7.7.1 35*. Anisotropic Type-II Superconductors . . . 679
7.7.2 36*. Разрушение сверхпроводимости в тонкой пленке тепловыми вихрями . . . 681
7.7.3 37*. Melting of the Vortex Lattice . . . 687
7.7.4 38. Critical current in type-II SC . . . 689
7.7.5 41*. Collective Pinning of Vortices by Weak Defects . . . 691
7.7.6 42*. Magnetic Flux Creep and Nonlinear Conductivity in HTSC . . . 696

8 Superconductivity by Abrikosov **701**
8.1 15 Macroscopic theory of superconductivity . . . 701
8.1.1 15.1. General properties of superconductors . . . 701
8.1.2 15.2. Thermodynamics of the superconducting transition . . . 704
8.1.3 15.2. Thermodynamics of the superconducting transition . . . 705
8.1.4 15.3. The intermediate state . . . 706
8.1.5 15.4. Destruction of superconductivity by a current . . . 711
8.1.6 15.4. Destruction of superconductivity by a current . . . 712
8.1.7 15.4. Destruction of superconductivity by a current . . . 713
8.1.8 15.5. The London equations . . . 717
8.2 16 Basic ideas of the microscopic theory . . . 721
8.2.1 16.1. The superfluidity condition . . . 721
8.2.2 16.2. Phonon attraction . . . 722
8.2.3 16.3. Cooper pairs . . . 724
8.2.4 16.3. Cooper pairs . . . 725

8.2.5 16.4. The energy spectrum . . . 727
8.2.6 16.5. Temperature dependence of the energy gap . . . 734
8.2.7 16.6. Thermodynamics of superconductors . . . 736
8.2.8 16.7. London and Pippard superconductors (qualitative theory) . . . 742
8.2.9 16.8. The Meissner effect at $T = 0$ . . . 743
8.2.10 16.9. The relationship between current and field at finite temperatures. The London limit . . . 749
8.2.11 16.10. The superconducting correlation and surface energy. Two types of superconductors. The role of impurities . . . 751
8.2.12 16.11. High-temperature superconductivity . . . 755
8.3 17 The Ginzburg-Landau theory . . . 765
8.3.1 17.1. Derivation of the Ginzburg-Landau equations . . . 765
8.3.2 17.2. Surface energy at the interface between the normal and superconducting phases . . . 775
8.3.3 17.2. Surface energy at the interface between the normal and superconducting phases . . . 776
8.3.4 17.3. The critical field and magnetization of a thin film. Supercooling and superheating . . . 777
8.3.5 17.4. The critical current of a thin wire with $x \ll 1$ . . . 782
8.3.6 17.4. The critical current of a thin wire with $x \ll 1$ . . . 783
8.3.7 17.5. Quantization of the magnetic flux . . . 787
8.4 18 Type II superconductivity . . . 791
8.4.1 18.1. Magnetic properties of type II superconductors. The qualitative picture . 791
8.4.2 18.2. Magnetic properties of type II superconductors. Quantitative theory for the vicinity of H_{c2} . . . 795
8.4.3 18.3. Magnetic properties of type II superconductors. Metals with $x > 1$ . . . 803
8.4.4 18.3. Magnetic properties of type II superconductors. Metals with $x \gg 1$ . . . 804
8.4.5 18.4. Surface superconductivity . . . 814
8.4.6 18.5. Type II superconductors at low temperatures . . . 820
8.4.7 18.6. A thin film of a type II superconductor in a magnetic field . . . 827
8.4.8 18.7 Anisotropic type II superconductor in a magnetic field . . . 833
8.4.9 18.8. Superconducting magnets. Pinning . . . 838
8.5 19 Kinetics of superconductors . . . 843
8.5.1 19.1. Electronic thermal conductivity . . . 843
8.5.2 19.2. Thermoelectric phenomena . . . 846
8.5.3 19.3. The behavior of superconductors in a weak high-frequency field . . . 851
8.5.4 19.3. The behavior of superconductors in a weak high-frequency field . . . 852
8.5.5 19.4. Absorption of ultrasound . . . 854
8.5.6 19.5. Stimulation of superconductivity by high-frequency, high-intensity field and sound . . . 856
8.5.7 19.5. Stimulation of superconductivity by high-frequency, high-intensity field and sound . . . 857
8.5.8 19.6. Paraconductivity . . . 860
8.6 20 The interface between a superconductor and a normal metal . . . 866
8.6.1 20.1. The proximity effect . . . 866
8.6.2 20.2. Superconductivity of twinning planes . . . 873
8.6.3 20.3. Andreev reflection . . . 892

8.7 21 Superconductivity and magnetism . . . 896
8.7.1 21.1. Superconductors containing magnetic impurities. Gapless superconductivity 896
8.7.2 21.2. The inhomogeneous superconducting state . . . 902
8.7.3 21.3. Ferromagnetic superconductors . . . 908
8.7.4 21.4. The Knight shift . . . 916

8.8 22 Tunnel junctions. The Josephson effect . . . 920
8.8.1 22.1. Single-particle tunnel current . . . 920
8.8.2 22.2. The Josephson effect . . . 928
8.8.3 22.3. Microscopic derivation of the Josephson current . . . 935
8.8.4 22.3. Microscopic derivation of the Josephson current . . . 936
8.8.5 22.3. Microscopic derivation of the Josephson current . . . 936
8.8.6 22.4. The Josephson effect in a magnetic field . . . 942
8.8.7 22.5. The ac Josephson effect . . . 947
8.8.8 22.5. The ac Josephson effect . . . 947
8.8.9 22.6. Waves in the Josephson junction . . . 951
8.8.10 22.7. Josephson junctions with a normal metal or a semiconductor layer . . . 955
8.8.11 22.7. Josephson junctions with a normal metal or a semiconductor layer . . . 956
8.8.12 22.8. Practical applications of the Josephson effect . . . 959
8.8.13 22.9. The dynamical resistive state of a thin superconductor at supercritical currents . . . 962

IV Junctions, tunneling 972

9 Typical Methods for Junctions with Examples 972
9.1 Reminder of Tunneling in Mesoscopic Physics and in Semiconductors . . . 972
9.2 Josephson Junction: Basic Models and Effects . . . 972
9.2.1 4.1 Phase Coherence and Types of Weak Links . . . 972
9.2.2 4.2 The DC Josephson Effect . . . 974
9.2.3 4.3 The AC Josephson Effect . . . 979
9.2.4 1001 Questions about what exactly happens in JJ? . . . 981
9.2.5 Experimental Confirmation of CPR in JJ . . . 981
9.2.6 Shapiro Steps . . . 981
9.2.7 Josephson Junction in an External Magnetic Field . . . 981
9.2.8 SQUIDs (Superconducting Quantum Interferometers): Basic Concepts . . . 988
9.2.9 SQUIDs: Typical Modifications . . . 995
9.2.10 46. Tunneling Effects by Shmidt . . . 996
9.2.11 7.4 Andreev Reflection . . . 1003
9.2.12 Andreev Reflection: Experimental Consequences . . . 1004
9.3 Overview and Comparison of Methods for different JJ . . . 1004
9.4 Special properties and Deeper Understanding of SC Contacts . . . 1005
9.4.1 22. Nonstationary Josephson Effect, Resistive Characteristics . . . 1005
9.4.2 23*. Fluctuations of Critical Current, Macroscopic Tunneling . . . 1012
9.4.3 Ambegoakar-Baratoff formula . . . 1018
9.4.4 Superconducting weak links by Likharev: Main Statements . . . 1018
9.4.5 Current-phase relation in JJ by Golubov et al.: Main Statements . . . 1018
9.4.6 Other basic features of Josephson junctions . . . 1018
9.4.7 Inelastic tunneling: Main Concepts . . . 1019
9.4.8 Josephson radiation . . . 1019
9.4.9 Junctions by de Gennes book . . . 1019
9.5 Bogliubov-de Gennes Equations for Superconductors in the Continuum Model . . . 1019
9.5.1 1.2 Hopping in a Quantum Many-Body Hamiltonian . . . 1019
9.5.2 1.3 Second Quantization of Hopping Hamiltonians . . . 1023
9.5.3 1.5 Derivation of the BdG Equations in the Continuum Model . . . 1026
9.5.4 1.7 Solution to the BdG Equations in Homogeneous Systems . . . 1032
9.5.5 1.8 Relation of BdG Method to the Abrikosov-Gor'kov Equations . . . 1037
9.6 Transport Across Normal-Metal/Superconductor Junctions . . . 1040
9.6.1 6.1 Blonder-Tinkham-Klapwijk Scattering Formalism . . . 1040
9.6.2 6.2 Tunneling Conductance Through a NS Junction . . . 1045

9.6.3 6.3 Suppression of Andreev Reflection in a FS Junction . . . 1052
9.6.4 Transport Properties Through a TI-S Junction . . . 1054
9.7 BdG Equations in Tight-Binding Model . . . 1060
9.7.1 2.1 Derivation of BdG Equations in a Tight-Bind Model . . . 1060
9.7.2 Local Density of States and Bond Current in the Lattice Model . . . 1066
9.7.3 Nambu Notation for SC Junctions . . . 1067
9.7.4 Optical Conductivity and Superfluid Density in the Lattice Model . . . 1067
9.7.5 2.2 Solution to the Lattice BdG Equations for a Uniform Superconductor . . . 1076
9.7.6 2.3 Lattice Abrikosov-Gorkov Equations . . . 1078
9.8 Junctions in Microscopic Framework: Basics . . . 1082
9.9 Junctions in Microscopic Framework: Other Features . . . 1082
9.10 GF method for JJ . . . 1082
9.10.1 Caroli's GF Method . . . 1082
9.10.2 GF method for JJ: Examples . . . 1082
9.11 Beeankker's Determinant Framework: Basics . . . 1083
9.12 Beeankker's Determinant Framework: Other Features . . . 1083
9.13 Green's function for SC Junctions: Other Working Methods . . . 1083
9.14 "Classic" theoretical results of Josephson Junctions: An Overview . . . 1083

10 Well-Known Models of Junctions 1083
10.1 Very Famous Models . . . 1083
10.1.1 Blonder Tinkham Klapwijk Original Model 1: Basics . . . 1083
10.1.2 Blonder Tinkham Klapwijk Original Model 1: Advanced Sratements . . . 1093
10.1.3 Josephson Junction with impurity by Bagwell . . . 1106
10.1.4 Josephson Junction with impurity by Bagwell: Calculations . . . 1118
10.1.5 Ballistic JC through an asymmetric SNS by Chang, Bagwell . . . 1127
10.1.6 Josephson and Andreev transport through quantum dots . . . 1127
10.1.7 JJ through a Semiconductor Nanowire . . . 1127

11 Specific Junctions, Applications 1128
11.1 SFS Junction (Junction Through a Ferromagnet) . . . 1128
11.1.1 47*. SFS junction by Shmidt . . . 1128
11.2 Multiterminal junctions . . . 1133
11.3 Very exotic models and properties of junctions . . . 1133
11.3.1 Casimir froce in Josephson Junctions . . . 1133
11.4 Application of Junctions: Main Ideas . . . 1133
11.4.1 4.6 Applications of Weak Superconductivity . . . 1133

V Very Useful Methods 1136

12 Methods for BCS SC 1136
12.1 Transformations . . . 1136
12.1.1 Selected GF methods for superconductivity . . . 1136
12.1.2 Matrix transformations for BCS . . . 1137
12.2 Numerical methods . . . 1137
12.2.1 Typical examples of numerical methods . . . 1137

13 Bogliubov-de Gennes Equations: Methods and Applications by Jian-Xin Zhu 1139
13.1 3 Local Electronic Structure Around a Single Impurity in Superconductors . . . 1139
13.1.1 3.1 Introduction . . . 1139
13.1.2 3.2 Yu-Shiba-Rusinov Impurity States in an s-Wave Superconductor . . . 1140
13.1.3 3.3 Majorana Fermion in an s-Wave SC with a Chain of Localized Spins . . . 1145
13.1.4 3.4 Impurity Resonance State in a d-Wave Superconductor . . . 1149

13.2 4 Disorder Effects on Electronic and Transport Properties in Superconductors 1153
13.2.1 4.1 Anderson Theorem for Disordered *s*-Wave Superconductor 1153
13.2.2 4.2 Suppression of Superconductivity in a Disordered *d*-Wave Superconductor . 1157
13.2.3 4.3 Quasiparticle Localization in a Disordered *d*-Wave Superconductor 1162
13.3 5 Local Electronic Structure in Superconductors Under a Magnetic Field 1169
13.3.1 5.1 Effect of the Magnetic Field 1169
13.3.2 5.2 Vortex Core State in an *s*-Wave Superconductor 1171
13.3.3 5.2.1 Single Isolated Vortex 1171
13.3.4 5.2.2 High Field Limit 1178
13.3.5 5.3 Vortex Core States in a *d*-Wave Superconductor 1179
13.3.6 5.3.1 Single Isolated Vortex 1179
13.3.7 5.3.2 Quasiparticle States in a Mixed-State of d-Wave Superconductors 1181
13.3.8 5.4 Fulde-Ferrell-Larkin-Ovchinikov State due to a Zeeman Magnetic Field . . . 1187
13.4 7 Topological and Quantum Size Effects in SC at Reduced Length Scale 1190
13.4.1 7.1 Persistent Current in a Mesoscopic *s*-Wave SC Ring 1190
13.4.2 7.2 Current in Multiply Connected Mesoscopic *d*-Wave SC Geometries 1196
13.4.3 7.2.1 Cylindrical Geometry 1196
13.4.4 7.2.2 Square Loop Geometry 1198
13.4.5 7.3 Quantum Size Effects in Nanoscale Superconductors 1199

VI Problems and Questions 1203

14 Typical problems 1203
14.1 Simplified problems about SC phenomena 1203
14.1.1 Problems about superconductors in magnetic field 1203
14.1.2 Qualitative, basic problems about SC 1 1203
14.1.3 Qualitative, basic problems about SC 2 1212
14.2 Problems about Typical Methods, Effects 1216
14.2.1 Framework of BCS: Problems about Basic Transformations 1216
14.2.2 Framework of BCS: Basic, General Properties 1225
14.2.3 Problems about the Gap Equation 1229
14.2.4 Problems about Exotic Transformations in BCS Model 1237
14.2.5 Problems about Numerical Computations in BCS Model 1239
14.2.6 Questions about Applicability of Formulas 1242
14.2.7 Problems about phenomena in the theoretical BCS 1 1242
14.2.8 Dirty Superconductors: Basic Problems 1 1252
14.2.9 Dirty Superconductors: Basic Problems 2 1257
14.2.10 Problems about tunneling, junctions 1: Basic Models 1264
14.2.11 Problems about tunneling, junctions 2: Basic Models 1271
14.2.12 Problems about tunneling, junctions 3: Basic Models 1273
14.2.13 Ginzburg-Landau Formalism: Problems about phenomena [SEE COND MATT] 1278
14.2.14 Type II superconductors: Basic Problems 1 1282
14.2.15 Other Problems by Shmidt's book 1283
14.3 Questions about Checking Basic Knowledge 1283
14.3.1 Questions about Understanding Basics 1 1283
14.3.2 Questions about Understanding Basics 2 1286
14.3.3 Questions about Understanding Basics 3 1288
14.3.4 Questions about Understanding Typical Phenomena 1 1289
14.3.5 Questions about Understanding Typical Phenomena 2 1290
14.3.6 Questions about Understanding Special Models 1290
14.3.7 Problems about Understanding Special Effects 1290
14.3.8 Hypothetical questions about сверхпроводниках 1290
14.4 Other Questions about Superconductivity 1290

14.4.1 Questions about what is exactly going on in BCS? . . . 1290

15 Problems about specific phenomena and properties 1291
15.1 Problems about Special Useful Methods . . . 1291
15.1.1 Problems about GF Special Methods for SC 1 . . . 1291
15.1.2 Problems about GF Special Methods for SC 1 . . . 1294
15.2 Problems about Special Effects . . . 1296
15.2.1 Problems about Nambu Notation for Applications . . . 1296
15.2.2 Problems Transformations of SC Green's functions . . . 1301
15.2.3 Problems about флуктуационные эффекты в слабых контактах . . . 1302
15.2.4 Problems about GF Special Methods for SC . . . 1303
15.2.5 Problems about Majorana states in SC-s . . . 1306
15.2.6 Problems about vortices . . . 1306
15.2.7 Problems about fluctuation effects . . . 1307
15.2.8 Problems about properties of unconventional superconductors . . . 1308
15.2.9 Problems about models with unconventional superconductors . . . 1309
15.3 Creation of Special Models . . . 1309
15.3.1 Problems about Creation of a Model for Special Superconductors 1 . . . 1309
15.3.2 Problems about Creation of a Model for Special Superconductors 2 . . . 1310
15.4 Problems about Special Methods . . . 1311
15.4.1 Problems about numerical evaluation . . . 1311
15.5 Problems about Special Devices, Junctions . . . 1311
15.5.1 Problems about Creation of a Model for SC Devices 1 . . . 1311
15.5.2 Problems about Creation of a Model for SC Devices 2 . . . 1312
15.5.3 Problems about special junctions with SC . . . 1312
15.5.4 Problems about Creation of a Model of Special MTJJ . . . 1313
15.5.5 Problems about Special Junctions 1 . . . 1313
15.5.6 Problems about Special Junctions 2 . . . 1314
15.5.7 Problems about Special Junctions 3 . . . 1315
15.5.8 Problems about MTJJ . . . 1315

VII —— Specific Superconductivity in a Nutshell —— 1316

16 Special also useful theories and properties 1316
16.1 Details of general properties of superconductors . . . 1316
16.2 Details of basic theories . . . 1318
16.2.1 Details of GL theory . . . 1318
16.2.2 Details of BCS theory . . . 1320
16.2.3 BCS: examples of diagrammatic methods . . . 1322
16.2.4 Gorkov formalism . . . 1331
16.2.5 General details of theories of SC . . . 1336
16.3 Details of well-known SC models . . . 1336
16.3.1 Josephson junctions: other methods and properties . . . 1336
16.3.2 RCSJ, SQUID: other methods and properties . . . 1337
16.3.3 Superconductors of II kind: other well-known properties . . . 1340
16.4 Other well-known methods for SC junctions . . . 1341
16.4.1 Tight-binding SC models . . . 1341
16.4.2 Overview of other tunneling properties . . . 1341
16.4.3 BTK Method . . . 1342
16.4.4 Beenakker's Determinant Method . . . 1346
16.4.5 Majorana wires and junctions . . . 1347
16.4.6 Fluctuation effects in weak contacts . . . 1349
16.5 Other well-known theories and formalisms for typical SC . . . 1349

16.5.1 Superconductors with dissipation . . . 1349
16.5.2 Theory of Superconducting Alloys by Abrikosov–Gorkov . . . 1350
16.5.3 Other experimental hints for a true SC theory . . . 1350
16.5.4 Effects of Temperature and Magnetic Field . . . 1350
16.5.5 Eliashberg Theory of Electron–Phonon Interaction (???) . . . 1350
16.6 Unconventional Superconductivity in a Nutshell . . . 1350
16.6.1 Overview of UC SC . . . 1351
16.6.2 Fundamentals of UC SC . . . 1351
16.6.3 Advanced properties of basic UC SC . . . 1354
16.6.4 9 Paramagnetic Susceptibility and Knight Shift . . . 1356
16.6.5 11 Superconducting States with Multicomponent Order Parameters . . . 1356
16.6.6 12 Ginzburg-Landau Equations and Upper Critical Field . . . 1356
16.6.7 13 Boundary Conditions and Surface Superconductivity . . . 1356
16.6.8 14 Meissner and Mixed States in Unconventional Superconductors . . . 1356
16.6.9 15 Magnetic Superconductors . . . 1356
16.6.10 18 Ginzburg-Landau Functional for UC SC . . . 1356
16.6.11 19 Upper Critical Field in a p-wave Superconductor . . . 1356
16.6.12 20 Boundary Conditions for the Order Parameter . . . 1356
16.6.13 21 Effect of Impurities on Unconventional Superconductivity . . . 1356
16.6.14 22 Electronic Thermal Conductivity of Unconventional Superconductors . . . 1356
16.7 Special effects . . . 1356
16.7.1 Thermoelectric effects . . . 1356
16.7.2 Heat Capacity from Fluctuation, Diamagnetism of SC II kind . . . 1356
16.7.3 Functional integral for Gor'kov and GL theories . . . 1359

17 Very special theories and models 1360
17.1 Very special SC junctions . . . 1360
17.1.1 Tight-biding models of SC junctions . . . 1360
17.1.2 Special Voltage States of JJ . . . 1360
17.1.3 Fluctuation Effects in Weak Junctions . . . 1361
17.1.4 SFS junctions . . . 1361
17.1.5 MTJJ methods and models . . . 1361
17.1.6 Overview of other not so used methods for SC contacts . . . 1363
17.2 Disorder in Superconductors in a Nutshell . . . 1364
17.2.1 Disorder of superconductors: Basic Models . . . 1364
17.2.2 Superconductor-insulator Phase Transition . . . 1370
17.2.3 2D Superconductors . . . 1370
17.2.4 Materials with Localization and SC . . . 1370
17.2.5 Superconductivity of a Graph . . . 1370
17.3 Less currently applicable, but potentially useful theories . . . 1371
17.3.1 Kitaev's 1D chain . . . 1371
17.3.2 Majorana Fermions in a Superconductors . . . 1371
17.3.3 London's theory . . . 1371
17.3.4 London equations, consequences . . . 1373
17.3.5 On 1D superconductors . . . 1373
17.3.6 BCS-BEC Crossover . . . 1373
17.4 High-T SC . . . 1373

18 Overview of special phenomena and applications 1375
18.1 Other Phenomena In a Nutshell . . . 1375
18.1.1 Thermoelectric Effects in Superconductors . . . 1375
18.1.2 Vortex Lattice Melting and Pinning in a Nutshell . . . 1375
18.1.3 Fluctuation Effects by Varlamov, Larkin in a Nutshell (????) . . . 1375
18.1.4 Other Magnetic Phenomena . . . 1375

18.1.5 On induced superconductivity of 2D materials (???) . . . 1376
18.2 Superconductivity for quantum computation (???) . . . 1376
18.3 Applications of superconductivity . . . 1376
18.3.1 On superconductivity for qubits and quantum computers . . . 1376
18.3.2 Overview of typical applications of superconductivity . . . 1379
18.3.3 Digital Electronics . . . 1379
18.3.4 Superconducting Photon and Particle Detectors . . . 1379
18.3.5 Microwave Applications . . . 1379
18.3.6 Applications of SC junctions and SQUIDS . . . 1380

VIII Other Properties, Theories and Effects 1381

19 Other Known Phenomena and Models 1381
19.1 Unconventional Superconductivity by Mineev, V.P. Samokhin, K., part 1 . . . 1381
19.1.1 1. Cooper Pairing in General . . . 1381
19.1.2 2. Spin Structure of Paired States . . . 1384
19.1.3 3. Phases of Superfluid Helium-3 . . . 1386
19.1.4 4. Superconducting States in Crystals . . . 1389
19.1.5 5. Energy of Elementary Excitations of a Superconductor . . . 1398
19.1.6 6. Gap in the Excitation Spectrum and Critical Temperature . . . 1405
19.1.7 7. Temperature Behavior of Thermodynamic Quantities as $T \to 0$ . . . 1408
19.1.8 8. Parity Effects of the Number of Electrons in Superconductors . . . 1410
19.1.9 9. Paramagnetic Susceptibility and Knight Shift . . . 1417
19.1.10 10. Landau Expansion of the Free Energy of Superconductors . . . 1421
19.1.11 11. Superconducting States with Multicomponent Order Parameters . . . 1424
19.1.12 12. Ginzburg–Landau Equations and the Upper Critical Field . . . 1428
19.1.13 13. Boundary Conditions and Surface Superconductivity . . . 1436
19.1.14 14. Meissner and Mixed States in Unconventional Superconductors . . . 1444
19.1.15 15. Magnetic Superconductors . . . 1452
19.1.16 16. Эффект Джозефсона . . . 1457
19.2 Unconventional Superconductivity by Mineev, V.P. Samokhin, K., part 2 . . . 1461
19.2.1 17. Gor'kov Equations . . . 1461
19.2.2 18. Ginzburg–Landau Functional . . . 1468
19.2.3 19. Upper Critical Field in p-wave Superconductors . . . 1474
19.2.4 20. Boundary Conditions for the Order Parameter . . . 1481
19.2.5 21. Influence of Impurities on Unconventional Superconductivity . . . 1489
19.2.6 22. Electronic Thermal Conductivity of Unconventional Superconductors . . . 1498
19.3 Eliashberg Theory: a short review by F. Marsiglio . . . 1508
19.3.1 Introduction . . . 1508
19.3.2 The Eliashberg Equations . . . 1510
19.3.3 Results on the imaginary axis: T_c . . . 1514
19.3.4 Validity of the Theory . . . 1516
19.3.5 Results on the imaginary axis: in the superconducting state . . . 1519
19.3.6 Results on the real axis . . . 1519
19.3.7 Summary and Outlook . . . 1525
19.4 Open superconductive systems . . . 1530
19.4.1 Choice of the Dissipator and the Model . . . 1530
19.4.2 Models of Open Superconductors . . . 1530
19.4.3 Experimental Results of Open Superconductors . . . 1530
19.5 Some phenomena by Abrikosov, Gor'kov, Dzyaloshinsky . . . 1530
19.5.1 Superconductor in an Arbitrary Magnetic Field Near the T_c . . . 1530
19.5.2 Theory Of Superconducting Alloys by AGD [see cond matter about it] . . . 1535

20 Fluctuation Phenomena in Superconductors by Larkin, Varlamov **1535**
20.1 Introduction . . . 1535
20.2 Ginzburg-Landau formalism. Thermodynamics . . . 1539
20.2.1 Fluctuation contribution to heat capacity . . . 1539
20.2.2 Ginzburg-Levanyuk criterion . . . 1544
20.2.3 Scaling and renormalization group . . . 1545
20.2.4 Fluctuation diamagnetism . . . 1550
20.3 Ginzburg-Landau formalism. Transport . . . 1559
20.3.1 Time dependent GL equation . . . 1559
20.3.2 Paraconductivity . . . 1561
20.3.3 General expression for paraconductivity . . . 1563
20.3.4 Fluctuation conductivity of layered superconductor . . . 1565
20.3.5 Magnetic field angular dependence of paraconductivity . . . 1568
20.4 Fluctuations near S-I transition . . . 1570
20.4.1 Quantum phase transition . . . 1570
20.4.2 3D superconductors . . . 1571
20.4.3 2D superconductors . . . 1575
20.5 Microscopic derivation of the TDGL equation . . . 1577
20.5.1 Preliminaries . . . 1577
20.5.2 The Cooper channel of electron-electron interaction . . . 1578
20.5.3 Superconductor with impurities . . . 1581
20.5.4 Microscopic theory of fluctuation conductivity of layered superconductor . . . 1585
20.6 Manifestation of fluctuations in various properties . . . 1599
20.6.1 The effects of fluctuations on magnetoconductivity [97, 127, 154, 155] . . . 1600
20.6.2 Fluctuations far from T_c or in strong magnetic fields . . . 1604
20.6.3 The effect of fluctuations on the Hall conductivity[174] . . . 1607
20.6.4 Fluctuations in the ultra-clean case [175] . . . 1609
20.6.5 The effect of fluctuations on the one-electron density of states and on tunneling measurements . . . 1611
20.6.6 Nonlinear fluctuation effects [14] . . . 1616
20.6.7 The effect of fluctuation on the optical conductivity [199] . . . 1618
20.6.8 Thermoelectric power above the superconducting transition [203, 201] . . . 1620
20.6.9 The effect of fluctuations on NMR characteristics [176] . . . 1622
20.7 Conclusions . . . 1626

21 Nonequilibrium SC **1627**
21.1 General Properties of Nonequilibrium Superconductors . . . 1627
21.1.1 General Understanding of Physics in Nonequilibrium SC . . . 1627
21.1.2 Choosing a Framework for Nonequilibrium SC . . . 1628
21.2 Typical Experiments with Nonequilibrium Superconductors . . . 1630
21.3 7. Some Nonequilibrium Effects in Superconductors by Shmidt . . . 1630
21.3.1 7.1 Quasiparticles: Electrons and Holes . . . 1631
21.3.2 7.2 Charge of a Quasiparticle in the Superconductor . . . 1632
21.3.3 7.3 Relaxation Time for the Quasiparticle Charge . . . 1634
21.3.4 7.5 Branch Imbalance of the Elementary Excitation Spectrum and Electric Field in the Superconductor . . . 1635
21.3.5 7.6 Experimental Study of a Nonequilibrium State at a Normal Metal-Superconductor Interface . . . 1639
21.3.6 7.7 Phase-Slip Centers . . . 1642
21.3.7 7.8 Nonequilibrium Enhancement of Superconductivity . . . 1643
21.3.8 7.9 Thermoelectric Effect in Superconductors . . . 1644
21.3.9 7.10 Superconducting 'Thermocouple' and the Magnetic Flux Induced by a Heat Flow . . . 1645
21.3.10 7.11 Thermoelectric Effects in Josephson Junctions . . . 1647

21.3.11 Solutions . . . 1651
21.4 Nonequlibrim Superconductors: Other Models, Features, Approaches . . . 1657

22 Disorder SC **1657**
22.1 Usadel theory . . . 1657

23 Other theoretical models **1657**
23.0.1 Strange, useless statements about typical theories of SC . . . 1657
23.1 Possibility of superconductivity type phenomena in a one-dimensional system . . . 1657
23.2 Very exotic models and properties of superconductors . . . 1658
23.3 Interesting Ideas, which are proven to be unphysical . . . 1658
23.3.1 On proposal by W. Heisenberg: Z. Naturforsch. 2a, 185 (1947) . . . 1658
23.3.2 On proposal by H. Welker: Z. Phys. 114, 525 (1939) . . . 1658
23.3.3 On proposal by M. Born, K. C. Cheng: Nature (London) . . . 1658

24 BCS-BEC Crossover by Chen et al. **1658**
24.1 Conclusions . . . 1658
24.2 Introduction to Qualitative Crossover Picture . . . 1659
24.2.1 Fermionic Pseudogaps and Meta-stable Pairs: Two Sides of the Same Coin . . . 1660
24.2.2 Introduction to high T_c Superconductivity: Pseudogap Effects . . . 1664
24.2.3 Introduction to High T_c SC: Mott Physics and Possible Ordered States . . . 1670
24.2.4 Overview of the BCS-BEC Picture of High T_c SC in the Underdoped Regime . . . 1672
24.2.5 Many Body Hamiltonian and Two Body Scattering Theory: Mostly Cold Atoms 1674
24.2.6 Cold Atom Experiments: Crossover in the Presence of Feshbach Resonances . . . 1679
24.2.7 T-Matrix-Based Approaches to BCS-BEC Crossover in the Absence of Feshbach Effects . . . 1681

Preface and main motivation

The key sections are:

Fundamentals of superconductivity

Basics of Ginzburg-Landau theory

Basics of BCS theory

Junctions with superconductors.

This note also includes theory of superconductive fluctuations by Varlamov, Larkin, Mineev's and Samokhin's unconventional superconductivity. I used the following literature.

Let's discuss some minimum knowledge and motivation that would be good to understand for studying the subject.

Сверхпроводимость - раздел, позволяющий соприкоснуться с результатами чело- веческого гения

(все-таки это одно из наиболее сильно мотивирующих! потом раскрою эту мысль.)

Best fundamental questions

(потом добавлю из ЛШ пару задач тут, пока в другом месте тренируюсь.)

I-motiv-1. Nature of Superconductivity

(вопрос про то, почему вообще есть сверхпро- водимость? по сути для этого во многом мы и изучаем сверхпроводники.)

I-motiv-2. Dielectric properties of superconductor (???)

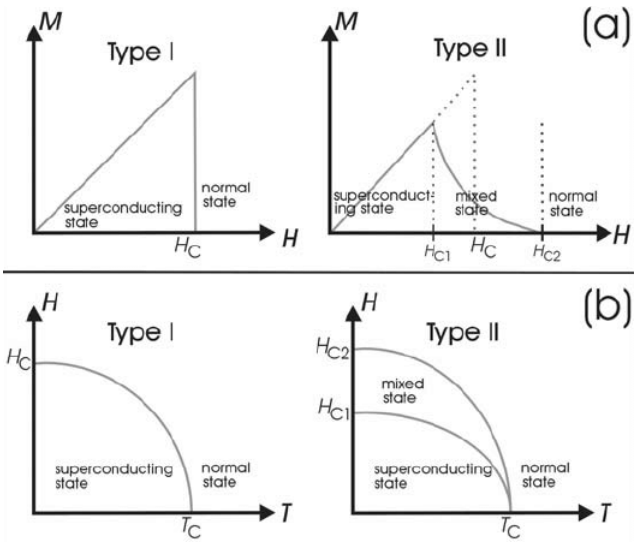
Why do we have a Meissner effect?
(потом напишу подробнее вопрос и ответ, почему такое вообще??? совсем не тривиально, что такое происходит.)

I-motiv.3 Levitation of superconductor

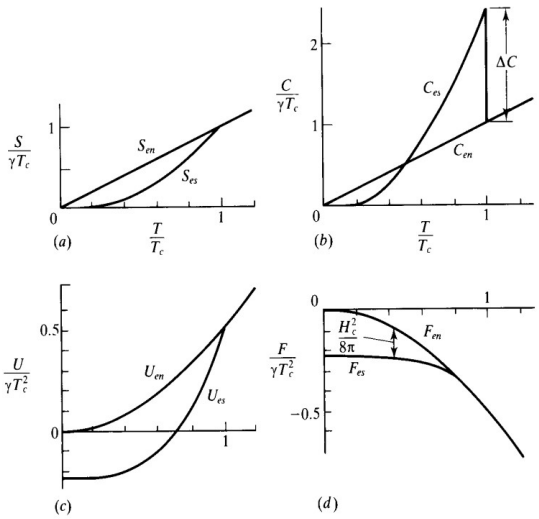
(??? почему такое явление есть????)

Best technical questions

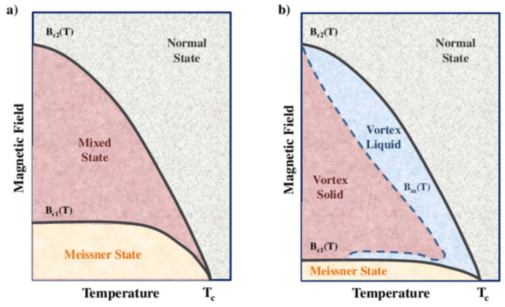
(потом добавлю из ЛШ пару задач тут, пока в другом месте тренируюсь.)



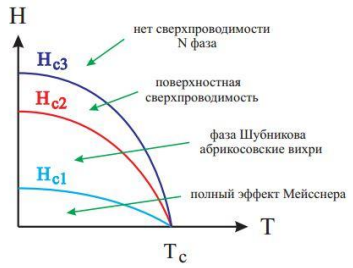
Part I
Superconductivity in a Nutshell



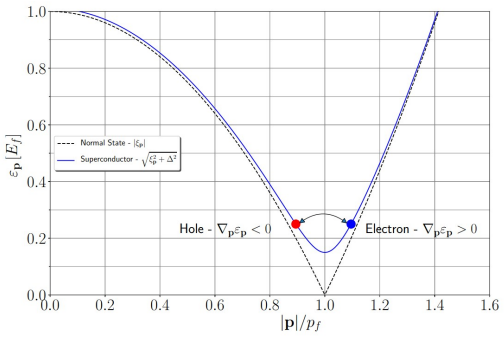
1 Main Models and Properties of Superconductors



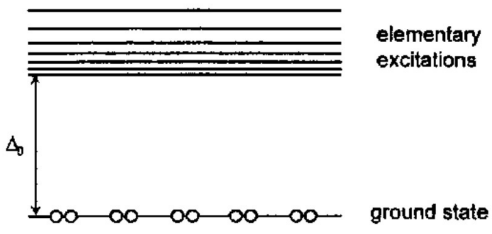
1.1 Main Theories for Superconductors

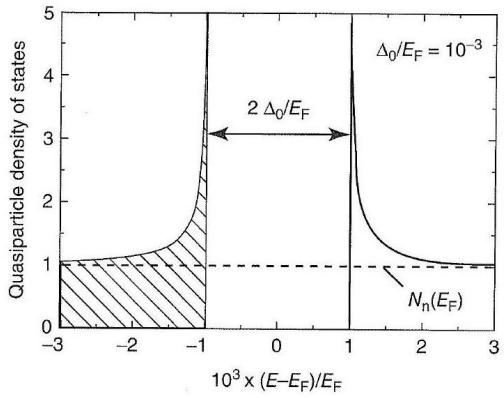


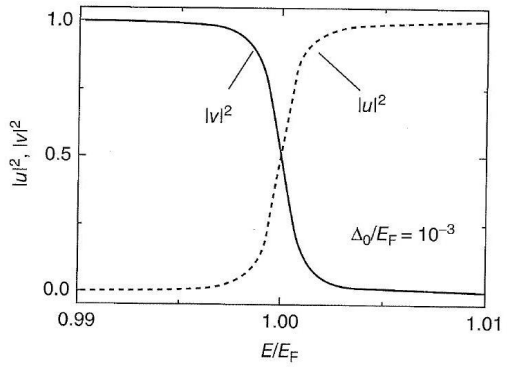
1.1.1 Main properties of SC and overview of theoretical methods

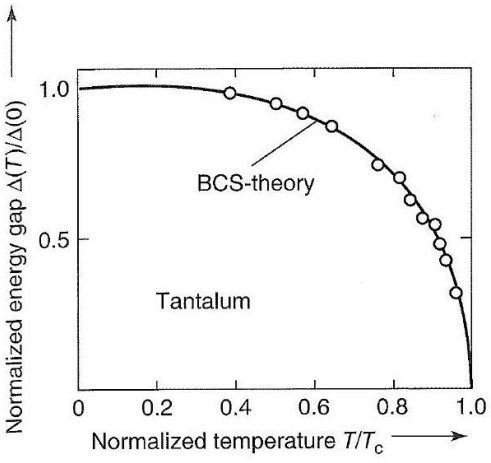


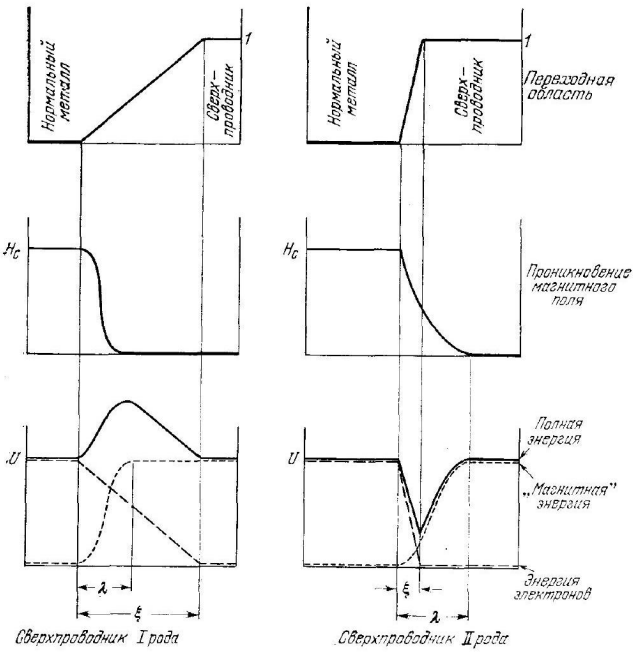
Main physical properties of superconductors

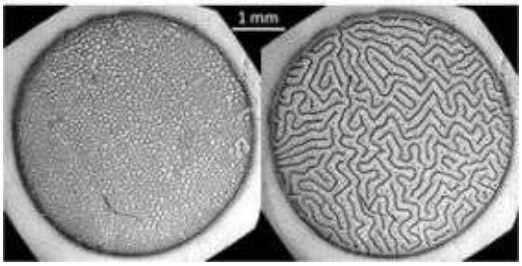












This is a spectrum of an unpaired electrons, that are excited above the superconductive paired ones. The superconductive ones are located below the Fermi surface.

Quasiparticle density of states
$\Delta_0/E_F = 10^{-3}$
$2\,\Delta_0/E_F$
$N_n(E_F)$
$10^3 \times (E-E_F)/E_F$

$|u|^2, |v|^2$
$|v|^2$
$|u|^2$
$\Delta_0/E_F = 10^{-3}$
E/E_F

Normalized energy gap $\Delta(T)/\Delta(0)$
BCS-theory
Tantalum
Normalized temperature T/T_c

Нормальный металл
Сверх-проводник
Переходная область
H_c
Проникновение магнитного поля
U
Полная энергия
„Магнитная" энергия
Энергия электронов
λ
ξ
Сверхпроводник I рода
Сверхпроводник II рода

Fundamental relations and concepts of superconductors

$$\Psi(r) \sim |\Delta| \sim \sqrt{n_s}.$$

$$\Psi(\mathbf{r}) = \sqrt{\frac{n_s}{2}} e^{i\phi}.$$

$$T_c \propto \omega_D \propto \frac{1}{\sqrt{M}} \qquad \text{Isotope effect}$$

$$T_c = 1,13 \frac{\hbar \omega_D}{k_B} \exp\left(-\frac{1}{N_n\left(E_F\right) V}\right)$$

$$\varepsilon(p) = \sqrt{\Delta^2 + v_F^2 (p - p_F)^2}$$

Основные экспериментальные факты

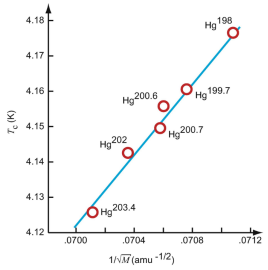
1. Идеальные проводники ниже критической температуры T_c. Температура перехода $T_c \sim 10$ K (Камерлинг-Оннес, 1911).

2. Разрушение сверхпроводимости магнитным полем $H_c \sim 300$ Э или транспортным током $j_c \sim 10^6$ A $\cdot$ cm^{-2} (Камерлинг-Оннес, 1914).
(??? в итоге, почему это, словами????)

3. Эффект Мейсснера (Мейсснер, Оксенфельд, 1933). Сверхпроводник - идеальный диамагнетик. Ниже критической температуры магнитное поле полностью выталкивается из сверхпроводника. Это важное обстоятельство. Поскольку $B = 0$ при $T < T_c$ независимо от предыстории возникновения сверхпроводимости, сверхпроводимость - это новая термодинамическая фаза металла.
(??? в итоге, почему это, словами????)

4. Экспоненциальная зависимость теплоемкости от температуры

$$C_e \sim \exp(-\Delta/T)$$



(W. S. Corak, et. al., 1954). Это означает, что возбуждённые состояния сверхпроводника отделены от основного «энергетической щелью» Δ как в полупроводнике. Поскольку при $T = T_c$ происходит фазовый переход II рода со скачком теплоемкости, то $\Delta(T) = 0$ в точке перехода. Далее электронная теплоемкость имеет нормальное поведение $C_e \sim T$.
(???)

5. Изотопический эффект (Максвелл, Рейнольдс, 1950):

$$T_c \propto (\text{Atomic mass of the metal})^{-1/2}.$$

Это значит, что ключевую роль при возникновении сверхпроводимости играет решётка металла. Электроны могут взаимодействовать между собой посредством обмена фононов, типичная энергия которых $\hbar\omega_D \approx 300$ K. Это могут быть виртуальные фононы, которые возбуждает в решётке движущийся в кристалле электрон. Испущенный одним электроном фонон может поглотиться другим электроном, и между ними возникает эффективное притяжение. Энергия связи такой пары $\Delta \sim T_c$. Поэтому

$$T_c \propto \hbar\omega_D.$$

(????)

Lengths of superconductors

$$\kappa = \lambda_L/\xi_{GL}$$

$\kappa = \frac{\lambda_L}{\xi_{GL}} < 1/\sqrt{2}$ Type-I superconductors, positive wall energy.
$\kappa = \frac{\lambda_L}{\xi_{GL}} > 1/\sqrt{2}$ Type-II superconductors, negative wall energy.
Characteristic lengths:

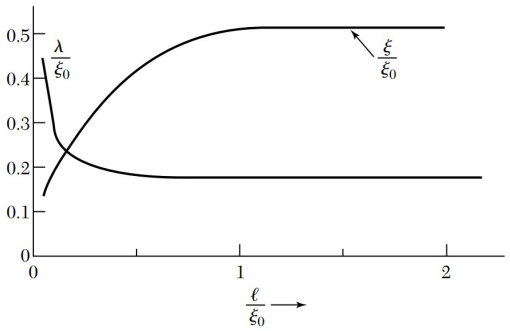
$$\lambda_L := \sqrt{m/\left(\mu_0 q^2 n_s\right)} \quad \xi_{GL} := \sqrt{-\hbar^2/2m\alpha} \quad \xi_0 := 0,18\frac{\pi\hbar v_F}{2k_B T_c}$$

$$\xi^2 = \frac{\hbar^2}{4ma\left(T_c - T\right)},$$
$$\lambda^2 = \frac{mc^2 b}{8\pi e^2 a\left(T_c - T\right)}.$$

London penetration depth $\lambda_{\mathrm{L}}(T)$ - typical distance it takes to screen the magnetic field inside a superconductor

Coherence length ξ_0 (BCS, Pippard) characterizes the length scale over which the correlation between the electrons in a Cooper pair is active. It is the typical size of a Cooper pair.

GL-coherence length $\xi_{\mathrm{GL}}(T)$ Gives the typical distance over which the superconducting order parameter can vary.



Dependence of$\lambda_{\mathrm{L}}, \xi_{\mathrm{GL}}$ and ξ_0 on impurities:

$$\lambda_L(T) = 0,71\frac{\lambda_L(0)}{\sqrt{1 - T/T_c}} \quad \xi_{GL}(T) = 0,74\frac{\xi_0}{\sqrt{1 - T/T_c}} \qquad \text{(clean limit)}$$

$$\lambda_L(T) = 0,64\lambda_L(0)\sqrt{\frac{\xi_0}{l^*\left(1 - T/T_c\right)}} \quad \xi_{GL}(T) = 0,855\sqrt{\frac{\xi_0 l^*}{1 - T/T_c}} \quad \xi_0 \approx l^* \qquad \text{(dirty limit)}$$

(?????!!!)

$$\xi_0 = 0,18\frac{\pi\hbar v_F}{2k_B T_c} \quad \xi_0 \approx l^*$$

(???)
$\lambda_L(T) \sim \frac{1}{\sqrt{1-T/T_c}}, \qquad \xi_{GL}(T) \sim \frac{1}{\sqrt{1-T/T_c}}$
$\xi = \frac{1}{\sqrt{2m\Delta}}$ (???)

$$\nu = mp_F/2\pi^2\hbar^3$$

- плотность состояний электрона на уровне Ферми в нормальном состоянии (без учета спина)

$$\hbar\boldsymbol{\nabla}\varphi = m_\mathrm{s}\boldsymbol{v}_\mathrm{s} + q_\mathrm{s}\boldsymbol{A}$$

(????? откуда такая формула??)

$$\boldsymbol{j}_\mathrm{s} = q_\mathrm{s}n_\mathrm{s}\boldsymbol{v}_\mathrm{s} = \frac{q_\mathrm{s}n_\mathrm{s}}{m_\mathrm{s}}\left(\hbar\boldsymbol{\nabla}\varphi - q_\mathrm{s}\boldsymbol{A}\right)$$

$$\boldsymbol{\nabla}\varphi = \frac{2\pi}{\Phi_0}\left(\mu_0\lambda_\mathrm{L}^2\boldsymbol{j}_\mathrm{s} + \boldsymbol{A}\right)$$

$$a \approx T_c/\varepsilon_F \qquad b \approx T_c^2/n\varepsilon_F$$

Wall energy per unit area:
(type-I) $\alpha_w \approx (\xi_{GL} - \lambda_\mathrm{pen})\frac{B_{ch}^2}{2\mu_0}$
(type-II) $\alpha_w \approx \xi_{GL}\frac{B_{ch}^2}{2\mu_0} - \lambda_L\frac{B^2}{2\mu_0}$

Magnetic fields

Effective field $B_\mathrm{eff} = \frac{1}{1-N_M}B_a$

$$B_{c1} = \frac{1}{\sqrt{2}\kappa}(\ln\kappa + 0.08)B_{clh} = \frac{\Phi_0}{4\pi\lambda_L^2}(\ln\kappa + 0.08)$$
$$B_{c2} = \sqrt{2}\kappa B_{cth} = \frac{\Phi_0}{2\pi\xi_{GL}^2}$$

$$g_n - g_s = \frac{B_{cth}^2}{2\mu_0}$$

Overview of methods for taking into account different effects

Taking into account Coulomb repulsion of electrons is done in Abricosov-Gorkov formalism. I don't know, how to do it in other way.

(?? add some formulas)

For fluctuation effects the functional integral approach works, but it is a special part of superconductivity.

(?? add some formulas)

(??? how to take into account structure of a lattice??)

1.1.2 GL theory

Idea and main properties of GL theory

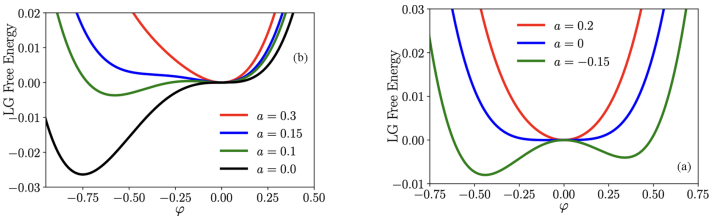
There is an order parameter that is non-zero in ordered state and zero in the disordered state. (??)

$$\text{(order parameter)} \qquad \Psi(r) \sim |\Delta| \sim \sqrt{n_s}.$$

$$\Psi(\mathbf{r}) = \sqrt{\frac{n_s}{2}} e^{i\phi}.$$

$$\Omega_s[\Psi(\mathbf{r}), \mathcal{A}(\mathbf{r})] \overset{\text{(series)}}{\approx} \Omega_n + \int \left[\alpha |\Psi|^2 + \frac{b}{2}|\Psi|^4 + \frac{1}{2 \cdot 2m^*} \left| -i\hbar\nabla\Psi - \frac{2e}{c}\mathcal{A}\Psi \right|^2 + \frac{(\nabla \times \mathcal{A})^2}{8\pi} \right] dV.$$

$$\alpha = a\,(T - T_c)\,, \qquad a \geq 0 \qquad b \geq 0 \qquad e := -|e|$$



(??? слова про отсутствие нечетных членов!)

$$a \approx T_c/\varepsilon_F; \qquad b \approx T_c^2/n\varepsilon_F; \qquad c = \frac{\hbar^2}{4m}.$$

$$a^2/b = 4\Delta_0^2 n/\varepsilon_F T_c^2 \approx n/\varepsilon_F.$$

(add proof!)

$$a^2/b = 4\Delta_0^2 n/\varepsilon_F T_c^2 \approx n/\varepsilon_F \qquad (T = 0)$$

$$\alpha\Psi + b\Psi|\Psi|^2 + \frac{1}{4m}\left(i\hbar\nabla + \frac{2e}{c}\mathcal{A}\right)^2 \Psi = 0, \qquad \text{(1 GL eq.)}$$

$$\left(i\hbar\nabla\Psi + \frac{2e}{c}\mathcal{A}\Psi\right)_S \bar{n} = 0.$$

$$\nabla \times \nabla \times \mathcal{A} = \frac{4\pi}{c}\mathbf{j}_\mathrm{s}, \qquad \mathbf{j}_\mathrm{s} = -\frac{ie\hbar}{2m^*}\left(\Psi^*\nabla\Psi - \Psi\nabla\Psi^*\right) - \frac{2e^2}{m^*c}|\Psi|^2\mathcal{A}. \qquad \text{(2 GL eq.)}$$

$\psi = \dfrac{\Psi}{\Psi_0} \equiv |\psi|e^{i\phi}$

$$\xi^2\left(i\nabla + \frac{2\pi}{\Phi_0}\mathcal{A}\right)^2\psi - \psi + \psi|\psi|^2 = 0, \qquad \xi^2 := \frac{\hbar^2}{4ma\left(T_c - T\right)},$$
$$\lambda^2\nabla\times\nabla\times\mathcal{A} + |\psi|^2\mathcal{A} = \frac{-\Phi_0}{2\pi}|\psi|^2\nabla\phi, \qquad \lambda^2 := \frac{mc^2b}{8\pi e^2 a\left(T_c - T\right)}.$$

$\Phi_0 := \frac{\pi\hbar c}{e} = 2\cdot 10^{-7}\frac{\mathrm{Gs}}{\mathrm{cm}^2}$

$$\Psi(r) = \mathrm{const},\ B = 0 \ \Rightarrow\ (\min) \ \Rightarrow\ \frac{n_s}{2} \equiv |\Psi_0|^2 = \begin{cases} -\frac{a(T-T_c)}{b}, & T < T_c, \\ 0, & T > T_c. \end{cases}$$
$$n_s(T)|_{T=0} = 2aT_c/b.$$

Без внешнего поля $\Omega_n - \Omega_s(\mathcal{H}=0) \equiv V\alpha^2/2b$ может быть скомпенсирован проигрышем в энергии из-за магнитного поля $\Omega_s(\mathcal{H}) - \Omega_s(\mathcal{H}=0) = V\mathcal{H}^2/8\pi$ (ибо $\mathcal{M} = -\mathcal{H}/4\pi$ и $-V\int\limits_0^{\mathcal{H}}\mathcal{M}d\mathcal{H} = \mathcal{H}^2/8\pi$). Отсюда

$$\mathcal{H}_c^2 = \frac{4\pi a^2\left(T - T_c\right)^2}{b}.$$

$$\lambda_L = \sqrt{m/\left(\mu_0 q^2 n_s\right)} \qquad \lambda_L(T) = \frac{1}{\sqrt{1 - T/T_c}}$$
$$\xi_{GL} = \sqrt{\hbar^2/(2m|\alpha|)} \qquad \xi_{GL}(T) \sim \frac{1}{\sqrt{1 - T/T_c}}$$

(discuss what it means?)

$$\kappa = \lambda/\xi = \frac{mc}{\hbar e}\left(\frac{\beta}{2\pi}\right)^{1/2}$$

Критерий применимости теории Гинзбурга–Ландау

GL theory is applicable everywhere, except the little region near the critical temperature. (def?)
(here are Pukhov arguments)

$$\mathrm{Gi} = T_c b^2/ac^3 \approx \left(\frac{T_c}{\varepsilon_F}\right)^4 \ll 1.$$

so GL theory is applied well. Fluctuation effects are also big, if Gi number is little (???)

Proof 2:

$$\mathrm{Gi} = \Delta_\mathrm{fl}C_\phi/\Delta_\mathrm{gap}C = \left(\frac{T_c}{\varepsilon_F}\right)^4 \ll 1$$

since $\qquad \Delta_\mathrm{fl}C_\phi = \dfrac{T_c^2 V a^{3/2}}{16c^{3/2}\pi\sqrt{T - T_c}} \qquad \Delta_\mathrm{gap}C \sim C\left(T_c\right) \approx g_F T_c/\varepsilon_F,$

$c := \hbar^2/4m$, $a = T_c m\pi^2/p_F^2$ (?).

Second option to view it is by:
(???)

$$\left\| 1 - \frac{T}{T_c} \right\| \geq \left(\frac{kT_c}{H^2_{\mathrm{cm}(0)}\xi_0^3} \right) \equiv \mathrm{Gi}$$

(add some formulas for disorder and D=2, D=1)
(а в нетипичном - см ниже от Варламова Ларкина особые темы, потом добавлю что-то сюда тоже)

Типичные эффекты в рамках уравнений Гинзбурга-Ландау (???)

(чисто с точки зрения УМФ допишу уравнения и указания про решения потом)

Энергия границы раздела между сверхпроводящей и нормальной фазами и два рода сверхпроводников по ГЛ (!!!!!!!)

(!!!????)

$$\mathcal{H}_c = \frac{\Phi_0}{2\sqrt{2}\pi\lambda\xi} \qquad \text{(therm crit f)}$$

(add here words about proofing that $\varkappa = \sqrt{2}$!)
Wall energy per unit area
(type-I) $\alpha_w \approx (\xi_{GL} - \lambda_{\mathrm{pen}}) \frac{B^2_{ch}}{2\mu_0}$
(type-II) $\alpha_w \approx \xi_{GL} \frac{B^2_{ch}}{2\mu_0} - \lambda_L \frac{B^2}{2\mu_0}$

$$B_{c1} = \frac{1}{\sqrt{2}\kappa}(\ln\kappa + 0.08) B_{clh} = \frac{\Phi_0}{4\pi\lambda_L^2}(\ln\kappa + 0.08)$$
$$B_{c2} = \sqrt{2}\kappa B_{cth} = \frac{\Phi_0}{2\pi\xi_{GL}^2}$$
$$g_n - g_s = \frac{B^2_{cth}}{2\mu_0}$$

Верхнее и нижнее критические магнитные поля

(сперва подумаю про рассуждения, потом уже напишу их!)

Эффект Мейсснера по ГЛ

$\lambda^2 \nabla \times \nabla \times \mathcal{A} + |\psi|^2 \mathcal{A} = \frac{-\Phi_0}{2\pi} |\psi|^2 \nabla\phi$ rot $\nabla \times \mathcal{A} = \mathcal{B}$, $\nabla \cdot \mathcal{B} = 0$, $|\psi|^2 \overset{\text{d ins}}{=} 1$,

$$\lambda^2 \cdot \nabla^2 \mathcal{B} - \mathcal{B} = 0. \qquad \text{(London's eq)}$$

$$\mathcal{B} = \mathcal{B}_0 \exp(-z/\lambda)$$

(?? ниже - додумаю теорпол - пойму это??) Возникновение эффекта Мейсснера связано со спонтанным нарушением симметрии при $T < T_c$ и калибровочной инвариантности Ω-потенциала сверхпроводника. Он совершенно аналогичен эффекту Хиггса возникновения массы m у частицы при спонтанном нарушении симметрии

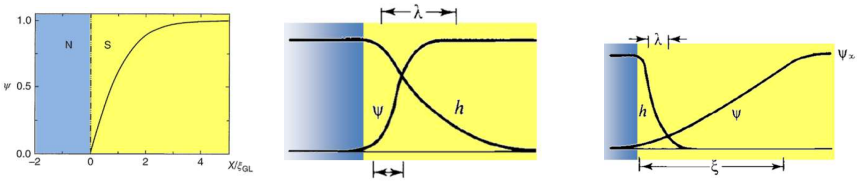
теории. Подобно тому, как кулоновский потенциал безмассовых частиц заменяется юкавским потенциалом массивных частиц с конечным радиусом действия $\lambda \sim m^{-1}$, в сверхпроводнике ниже точки перехода магнитное поле экспоненциально «зарезается» мейсснеровскими токами на масштабе лондоновской глубины проникновения λ.

Квантование потока по ГЛ

$$\Phi = n\Phi_0 \qquad \Phi_0 = \pi\hbar c/e = 2 \cdot 10^{-7}\text{Гс} \cdot \text{см}^{-2}$$

Proof. $j_S = \frac{-c|\psi|^2}{4\pi\lambda^2}\left(\frac{\Phi_0}{2\pi}\nabla\phi + \mathcal{A}\right)$, в топологически неодносвязном образце (СП торе), в котором «заморожен» некоторый магнитный поток, этот поток создаётся текущими по внутренней поверхности полости сверхпроводящими токами. Проинтегрируем ток по контуру, охватывающий дырку и проходящий глубоко ($\ll \lambda$) в сверхпроводник, $|\psi|^2 = 1$ и $\mathbf{j}_\text{s} = 0$:

$$\frac{\Phi_0}{2\pi}\oint \nabla\phi \cdot d\mathbf{l} = \oint \mathcal{A} \cdot d\mathbf{l}$$



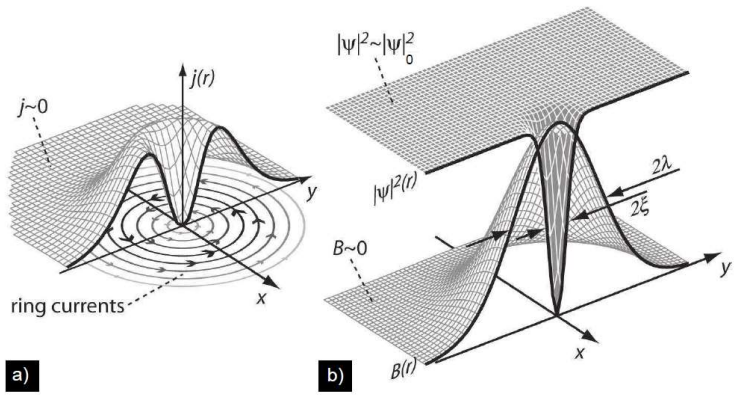
Тут интеграл от фазы не ноль, потому что у нас топологически не связный образец, а $\oint \nabla\phi \cdot d\mathbf{l} = 2\pi n$.

(?? так вот ловко обошли теорему Гаусса)

□

(?!?!?!? пара слов про флюксоид, что это за понятие. не супер важное. и что же там в итоге квантуется то? и в теорию про это допишу)

Глубина проникновения поля в сверхпроводник 1го и 2го родов по ГЛ



Уравнение Лондонов справедливо если $\lambda_L \gg \xi_0$, потому что при его выводе неявно предполагалось, что волновой пакет сверхпроводящих частиц целиком повержен магнитному полю, мы получили, что магнитное поле изменяется на масштабе λ_L. Если $\xi_0 \gg \lambda_L$, то лишь малая часть волнового пакета подвержена влиянию магнитного поля (СП 2го рода). Для оценки глубины проникновения считаем, что концентрация будет теперь $n = n_s\lambda/\xi_0$, в остальном вывод такой же, получаем:

$$\lambda = \left(\frac{mc^2\xi_0}{4\pi n_s e^2 \lambda}\right)^{1/2} \qquad \Rightarrow \qquad \lambda = \lambda_L\left(\frac{\xi_0}{\lambda_L}\right)^{1/3} \gg \lambda_L.$$

Solution ур ГЛ для абрикосовского вихря

$$\mathcal{B}(0) = \frac{\Phi_0}{2\pi\lambda^2}\ln\frac{\lambda}{\xi}.$$

(тут коротко про вывод!)

Другие типичные свойства и методы для ГЛ

Overview of methods for effective usage of GL theory

(??? мб это численно решается, пока не знаю, и не важно это)

Derivation of GL equations from GL functional

(I'll write key formulas of that boring variations)

Functional integral methods for GL theory

(if it is very useful, I'll add it to the top)

Broken symmetry and Goldstone mode in GL theory

(??? still don't understand what is meant by this?)

1.1.3 BCS theory

Idea and main properties of BCS theory

$$\hat{H}-\mu\hat{N}=\sum_{\mathbf{p}\sigma}\xi_{\mathbf{p}}\hat{a}^{\dagger}_{\mathbf{p}\sigma}\hat{a}_{\mathbf{p}\sigma}-\lambda\sum_{\mathbf{p}\mathbf{p}'}{}'\hat{a}^{\dagger}_{\mathbf{p}'+}\hat{a}^{\dagger}_{-\mathbf{p}'-}\hat{a}_{\mathbf{p}+}\hat{a}_{-\mathbf{p}-},$$

prime - region n. F. surf.

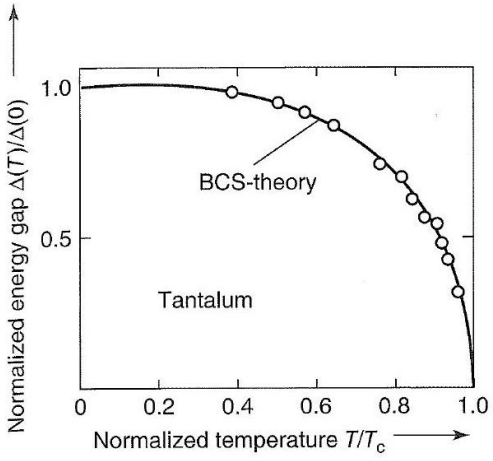
$\left\{\hat{a}_{\mathbf{p}\sigma},\hat{a}^{+}_{\mathbf{p}'\sigma'}\right\}=\delta_{\mathbf{p}\mathbf{p}}\delta_{\sigma\sigma'}$

$\hat{a}^{\dagger}_{\mathbf{p}'+}\hat{a}^{\dagger}_{-\mathbf{p}'-}$ – cr mode of Coop p

$$\Delta^{*}=\lambda\cdot\sum_{\mathbf{p}'}{}'\langle\hat{a}^{\dagger}_{\mathbf{p}',+}\hat{a}^{\dagger}_{-\mathbf{p}',-}\rangle,\qquad \Delta=\lambda\cdot\sum_{\mathbf{p}'}{}'\langle\hat{a}_{-\mathbf{p}',-}\hat{a}_{\mathbf{p}',+}\rangle\,.$$

$$\Delta_0=2\hbar\omega_D e^{-\frac{2}{\lambda g_F}}.\qquad g_F:=p_F m/\pi^2\hbar^3,$$

$$E_{\text{condens-n}}=-N\left(E_F\right)\Delta_0^2/2$$



$$E_{\text{paired el.}}=2E_F-2\hbar\omega_D e^{-2/N(E_F)V}$$

$$T_c = 1,13\frac{\hbar\omega_D}{k_B}\exp\left(-\frac{1}{N_n\left(E_F\right)V}\right) \qquad T \sim \omega_D \sim M_{\text{isotope}}^{-1/2}$$

(write what are the parameters)

$$\frac{\Delta_0}{k_B T_c} \approx 1.76$$

It is proven by comparison two solutions of the Gap equation (at $T = T_c$ and $T = 0$).

Typical derivations in scope of BCS theory

Approximation and diagonalization of BCS Hamiltonian

$$\hat{H} - \mu\hat{N} = \sum_{\mathbf{p}\sigma}\xi_{\mathbf{p}}\hat{a}^{\dagger}_{\mathbf{p}\sigma}\hat{a}_{\mathbf{p}\sigma} - \lambda\sum_{\mathbf{p}\mathbf{p}'}{}'\underbrace{\hat{a}^{\dagger}_{\mathbf{p}'+}\hat{a}^{\dagger}_{-\mathbf{p}'-}}_{\text{crate C. pair}}\hat{a}_{\mathbf{p}+}\hat{a}_{-\mathbf{p}-}, \qquad \begin{matrix}\text{prime - region n. F. surf.}\\ \left\{\hat{a}_{\mathbf{p}\sigma}, \hat{a}^{+}_{\mathbf{p}'\sigma'}\right\} = \delta_{\mathbf{p}\mathbf{p}}\delta_{\sigma\sigma'}\end{matrix}$$

$$\Delta^* = \lambda\cdot\sum_{\mathbf{p}'}{}'\langle\hat{a}^{\dagger}_{\mathbf{p}',+}\hat{a}^{\dagger}_{-\mathbf{p}',-}\rangle, \qquad \Delta = \lambda\cdot\sum_{\mathbf{p}'}{}'\left\langle\hat{a}_{-\mathbf{p}',-}\hat{a}_{\mathbf{p}',+}\right\rangle.$$

(??????)

$$\hat{H} - \mu\hat{N} = \sum_{\mathbf{p}\sigma}\xi_{\mathbf{p}}\hat{a}^{\dagger}_{\mathbf{p}\sigma}\hat{a}_{\mathbf{p}\sigma} + \frac{1}{\lambda}|\Delta|^2 + \sum_{\mathbf{p}}\left[\Delta^*\hat{a}_{\mathbf{p}+}\hat{a}_{-\mathbf{p}-} + \Delta\hat{a}^{\dagger}_{-\mathbf{p}-}\hat{a}^{\dagger}_{\mathbf{p}+}\right]$$

$$\widehat{b}_{\mathbf{p}-} = u_p\widehat{a}_{\mathbf{p}-} + v_p\widehat{a}^{+}_{-\mathbf{p},+} \qquad \widehat{a}_{\mathbf{p}-} = u_p\widehat{b}_{\mathbf{p}-} - v_p\widehat{b}^{+}_{-\mathbf{p},+}$$
$$\widehat{b}_{\mathbf{p}+} = u_p\widehat{a}_{\mathbf{p}+} - v_p\widehat{a}^{+}_{-\mathbf{p},-} \qquad \widehat{a}_{\mathbf{p}+} = u_p\widehat{b}_{\mathbf{p}+} + v_p\widehat{b}^{+}_{-\mathbf{p},-}$$

$$\left\{\hat{b}_{\mathbf{p}\sigma}, \hat{b}^{\dagger}_{\mathbf{p}'\sigma'}\right\} = \delta_{\mathbf{p}\mathbf{p}}\delta_{\sigma\sigma'}$$

$$\hat{H} - \mu\hat{N} = \Omega_0 + \sum_{\mathbf{p}}{}'\varepsilon(p)\left(\hat{b}^{\dagger}_{\mathbf{p}+}\hat{b}_{\mathbf{p}+} + \hat{b}^{\dagger}_{\mathbf{p}-}\hat{b}_{\mathbf{p}-}\right)$$

$$\varepsilon(p) := \sqrt{\xi^2_{\mathbf{p}} + \Delta^2} \qquad \Omega_0 := 2\sum_{\mathbf{p}}{}'\left[\xi_{\mathbf{p}}v^2_{\mathbf{p}} - \Delta u_{\mathbf{p}}v_{\mathbf{p}}\right] + \frac{1}{\lambda}\Delta^2,$$

$$u^2_{\mathbf{k}} = \frac{1}{2}\left(1 + \frac{\xi_{\mathbf{k}}}{\sqrt{\xi^2_{\mathbf{k}} + \Delta^2}}\right), \qquad v^2_{\mathbf{k}} = \frac{1}{2}\left(1 - \frac{\xi_{\mathbf{k}}}{\sqrt{\xi^2_{\mathbf{k}} + \Delta^2}}\right)$$

Ground state and excitations

Ground state energy: $E_0 := \Omega_0(\Delta_0) - \Omega_0(0)$

$$E_0 = \frac{1}{2} g_F (\hbar\omega_D)^2 - \frac{1}{2} g_F \hbar\omega_D \Delta_0 \sqrt{1 + \left(\frac{\hbar\omega_D}{\Delta_0}\right)^2} \overset{\Delta_0 \ll \hbar\omega_D}{\approx} -g_F \Delta_0^2/4 \quad \text{(negative)}$$

$$E_{\text{Coop p}} = 2\sqrt{\Delta_0^2 + \xi_{\text{p}}^2}$$

(????)

$$|\text{BCS}\rangle = \prod_{\mathbf{k}} \left(u_{\mathbf{k}} + v_{\mathbf{k}} \hat{c}^\dagger_{\mathbf{k},\uparrow} \hat{c}^\dagger_{-\mathbf{k},\downarrow}\right) |\text{vac}\rangle.$$

Gap equation: obtaining $\Delta(T=0)$ and T_c

$$\Delta_0 = 2\hbar\omega_D e^{-\frac{2}{\lambda g_F}}; \qquad T_c = \frac{\gamma}{\pi}\Delta_0 \approx 0,57\Delta_0, \qquad \gamma = 1,78; \quad g_F := p_F m/\pi^2\hbar^3$$

Proof:

$$\Delta := \lambda \sum_{\mathbf{p}'}{}' \langle \hat{a}^\dagger_{\mathbf{p}',+} \hat{a}^\dagger_{-\mathbf{p}',-} \rangle \qquad \Rightarrow \qquad \begin{aligned} \widehat{a}_{\mathbf{p}+} &= u_p \widehat{b}_{\mathbf{p}+} + v_p \widehat{b}^+_{-\mathbf{p},-} \\ \widehat{a}_{\mathbf{p}-} &= u_p \widehat{b}_{\mathbf{p}-} - v_p \widehat{b}^+_{-\mathbf{p},+} \end{aligned}$$

$\left\langle \hat{b}^\dagger_{\text{p}+} \hat{b}_{\text{p}+} \right\rangle = \bar{n}_{\text{p}} = \left\langle \hat{b}^\dagger_{\text{p}-} \hat{b}_{\text{p}-} \right\rangle = [\exp(\varepsilon(p)/T) + 1]^{-1},$

$$\frac{1}{\lambda} = \frac{1}{2} \sum_{\mathbf{p}}{}' \frac{1 - 2\bar{n}_{\mathbf{p}}}{\sqrt{\xi^2_{\mathbf{p}} + \Delta^2}}. \qquad \text{(gap eq.)}$$

For Δ_0, we set $\bar{n}_{\text{p}}(T=0) \equiv 0$,
(???)

$$1 = \frac{\lambda}{2} \frac{4\pi}{(2\pi\hbar)^3} \frac{p_F^2}{v_F} \int_{-\hbar\omega_D}^{+\hbar\omega_D} \frac{d\xi_{\text{p}}}{\sqrt{\xi_{\text{p}}^2 + \Delta_0^2}} = \frac{\lambda}{2} \frac{4\pi}{(2\pi\hbar)^3} \frac{p_F^2}{v_F} 2 \int_0^{\hbar\omega_D/\Delta_0} \frac{dx}{\sqrt{1+x^2}},$$

$\int dx/\sqrt{1+x^2} = \ln\left|x + \sqrt{1+x^2}\right| \qquad \Rightarrow \qquad \Delta_0 \approx 2\hbar\omega_D e^{-\frac{2}{\lambda g_F}}.$

For T_c, we set $\Delta(T = T_c) = 0$:

$$1 = \frac{\lambda}{2} \int{}' \frac{d^3\mathbf{p}}{(2\pi\hbar)^3} \frac{1 - 2\bar{n}_{\mathbf{p}}}{|\xi_{\mathbf{p}}|} = \frac{\lambda g_F}{2} \int_{-\hbar\omega_D}^{+\hbar\omega_D} \frac{d\xi_{\mathbf{p}}}{2\xi_{\mathbf{p}}} \text{ th } \frac{|\xi_{\mathbf{p}}|}{2T_c} = \frac{\lambda g_F}{2} \int_0^{\hbar\omega_D/2T_c} \frac{\text{th}x}{x} dx.$$

$$\varepsilon(p) = |\xi_{\text{p}}|, \qquad 1 - 2\bar{n}_{\text{p}} = \text{th}\left(|\xi_{\text{p}}|/2T_c\right).$$

$\int_0^x (\text{th}x/x)dx \overset{x \gg 1}{\approx} \int_1^x dx/x = \ln|x|.$

$$2T_c \approx \hbar\omega_D \exp\left(-2/\lambda g_F\right) = 0,5\Delta_0.$$

Finding gap as a function of T

(??? it is done only numerically, I'll summarize it here later)
It was obtained numerically and from it we see that $\sqrt{1-T/T_c}$ is a nice approximation.

Green's function derivation, transformation for BCS

(??? I'll write it later)

Other Typical BCS ideas

Nambu spinors for BCS superconductors

(I'll write about it from my master's thesis later)
Often the hole interpretation is used, then we associate one real excitation with one non-real excitation with the negative energy:

$$h_k = c^\dagger_{-k,\bar{s}}$$

So, creating an electron is the same as destroying a hole.

Tight-binding BCS model

(I'll write about it from my master's thesis)

BCS for the case, when net momenta of pair not equal to zero

(see AGD about it later! maybe it is written there)

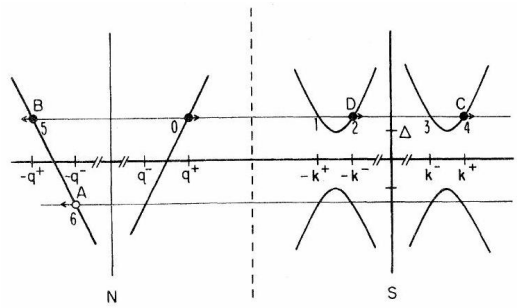
1.1.4 Electrodynamics of superconductors

Equations of electrodynamics of SC

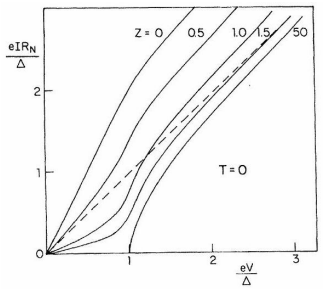
(write Londons eq)

Examples

(write some comments which results can they give??)

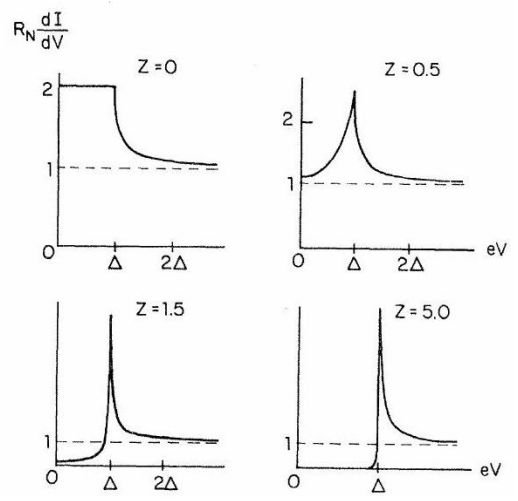


1.1.5 BdG equations, BTK formalism, Andreev states



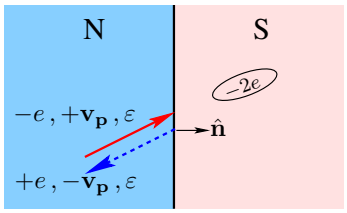
BdG equations

(see note on cond matter for now)

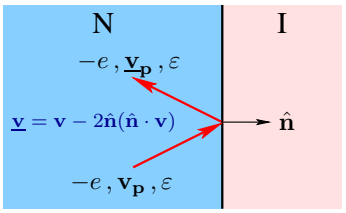


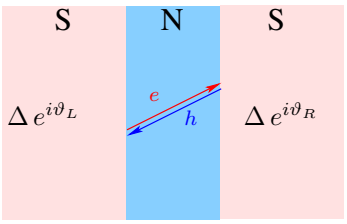
BTK method

(here are main formulas!!!)



These curves attain their asympototic limits only for very high voltages. For example, the tunnel junction ($Z = 50$) curve will be within 1% of the normal-state curve (dotted line) only when $eV \geq 7\Delta$.

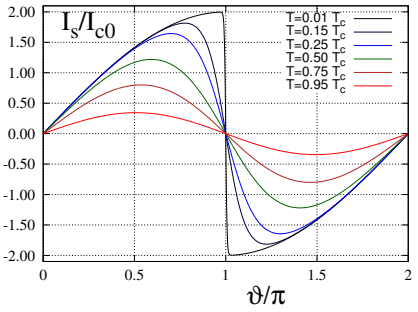


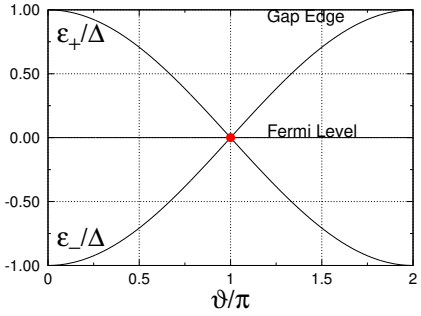


Differential conductance vs voltage for various barrier strengths Z at $T = 0$. This quantity is proportional to the transmission coefficient for electric current for particles at $E = eV$.

	A	B	C	D
Normal state	0	$\frac{Z^2}{1+Z^2}$	$\frac{1}{1+Z^2}$	0
General form				
$E<\Delta$	$\frac{\Delta^2}{E^2+(\Delta^2-E^2)(1+2Z^2)^2}$	$1-A$	0	0
$E>\Delta$	$\frac{u_0^2v_0^2}{\gamma^2}$	$\frac{(u_0^2-v_0^2)^2Z^2(1+Z^2)}{\gamma^2}$	$\frac{u_0^2(u_0^2-v_0^2)(1+Z^2)}{\gamma^2}$	$\frac{v_0^2(u_0^2-v_0^2)Z^2}{\gamma^2}$
No barrier ($Z=0$)				
$E<\Delta$	1	0	0	0
$E>\Delta$	v_0^2/u_0^2	0	$1-A$	0
Strong barrier $[Z^2(u^2-v^2)>>1]$				
$E<\Delta$	$\frac{\Delta^2}{4Z^2(\Delta^2-E^2)}$	$1-A$	0	0
$E>\Delta$	$\frac{u_0^2v_0^2}{Z^4(u_0^2-v_0^2)^2}$	$1-\frac{1}{Z^2(u_0^2-v_0^2)}$	$\frac{u_0^2}{Z^2(u_0^2-v_0^2)}$	$\frac{v_0^2}{Z^2(u_0^2-v_0^2)}$

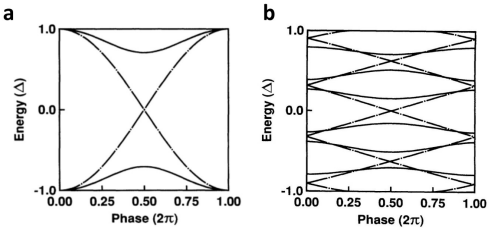
The Andreev Reflection and States





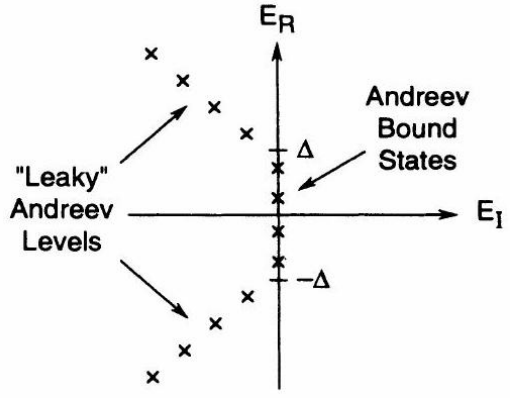
$$|r_{\mathrm{A}}|^2 = \begin{cases} 1 & \varepsilon \le |\Delta|, \\ \dfrac{|\Delta|^2}{(\varepsilon + \sqrt{\varepsilon^2 - |\Delta|^2})^2} & \varepsilon > |\Delta|\ . \end{cases} \tag{1.1}$$

$$\varphi - 2\arccos\left[\frac{E(\varphi)}{\Delta}\right] - 2\frac{E(\varphi)}{\Delta}\frac{L_N}{\xi} = 2\pi n, \qquad n \in \mathbb{Z}, \tag{1.2}$$



(for general length of a junction L_N)

$$E_i(\varphi) = \pm\Delta\sqrt{1 - T_N^i \sin^2\frac{\varphi}{2}}. \tag{1.3}$$



$$I_{c0} = \frac{\pi\Delta(0)}{2e\,R_{\mathrm{N}}}.$$

Spectrum of Andreev bound state. a) Short ballistic junction with (solid) and without (dotted) the presence of impurity b) Long ballistic junction. The discrete Andreev levels are shown with (solid) and without (dashed) the presence of an impurity. In both (a) and (b), an energy gap is opened in this quasi-particle spectrum.

Тепловая длина когерентности, введение в метод квазиклассических функций Грина.

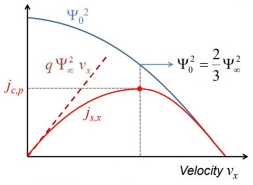
Контакт сверхпроводников через ферромагнетик (S-F-S) и инверсия фазы (π–контакт).

1.1.6 Currents, Thermodynamics, Susceptibilities

Critical currents in SC from GL

$\Delta(T) \sim (T_c - T)^{1/2}$ from numerical solution of gap eq.

$$\Delta := \lambda \cdot \sum_{\mathbf{p}'} \langle \hat{a}_{-\mathbf{p}',-} \hat{a}_{\mathbf{p}',+} \rangle \qquad \Rightarrow \qquad \Delta^2 \sim n_s.$$



$$v_c = \min \frac{\varepsilon(p)}{p} = \min \frac{\sqrt{\xi_{\mathrm{p}}^2 + \Delta^2}}{p} \approx \frac{\Delta}{p_F}. \qquad \text{(superfluid crit)}$$

$$j_c = e n_s v_c \sim \Delta^3 \sim (T_c - T)^{3/2}$$

$n_s \approx 10^{22}\ \mathrm{cm}^{-3}, \Delta \approx 5\ \mathrm{K}, \varepsilon_F \approx 5\mathrm{eV} \qquad \Rightarrow \qquad j_s \approx 10^7\ \mathrm{A/cm}^2.$

Critical currents from current maximum by GL theory:

$$j_{s,x} = q\Psi_0^2(v_x)\, v_x \qquad \Psi_0^2(v_x) = \Psi_\infty^2 \left(1 - \frac{m v_x^2}{2|\alpha|}\right)$$

$$v_{\max,p} = \sqrt{\frac{2|\alpha|}{3m}}; \qquad j_{c,p} = q\frac{2}{3}\sqrt{\frac{2|\alpha|}{3m}}\Psi_\infty^2 = \frac{2}{3}\sqrt{\frac{2}{3}} B_{\mathrm{cth}} \frac{1}{\mu_0 \lambda_L}$$

(???)

(There is also another derivation from looking at Cooper pair (see par. 50 in Shmidt), I'll add it later)

Энергия и теплоемкость сверхпроводника

$$C_s \sim \exp(-\Delta/T) \qquad \text{(gapped)}$$

Proof 1: $\varepsilon(p) := \sqrt{\Delta^2 + v_F^2 \left(p - p_F\right)^2}, \quad g_s := 2s + 1 = 2$

$$E(T) = \int\limits_0^\infty \frac{g_s V 4\pi p^2 dp \varepsilon(p)}{(2\pi\hbar)^3 \left(e^{\frac{\varepsilon(p)}{T}} + 1\right)} \approx \frac{8V\pi p_F^2}{(2\pi\hbar)^3} e^{-\frac{\Delta}{T}} \int\limits_0^\infty \left(\Delta + \frac{v_F^2 \left(p - p_F\right)^2}{2\Delta}\right) e^{-\frac{v_F^2 (p-p_F)^2}{2T\Delta}} dp \approx$$
$$\approx \frac{8V\pi p_F^2}{(2\pi\hbar)^3} \frac{\sqrt{\pi T\Delta}}{v_F} e^{-\frac{\Delta}{T}} \sim e^{-\frac{\Delta}{T}}$$

Proof 2:

$$S = -\sum_k \left\{(1 - f_k)\ln(1 - f_k) + f_k \ln f_k\right\}$$

$$C_\mathrm{s} = \sum_{\mathrm{k}\alpha} E_\mathrm{k} \frac{\partial f_\mathrm{k}}{\partial T}$$

$$C_\mathrm{s} = 2N_0 \int\limits_{-\infty}^{+\infty} d\xi \sqrt{\xi^2 + \Delta^2} \frac{\partial}{\partial T} \left(\frac{1}{\exp\left(\sqrt{\xi^2 + \Delta^2}/T^1\right) + 1}\right) \overset{T\to 0}{\approx}$$
$$\approx \frac{2N_0\Delta^2}{T^2} e^{-\Delta/T} \int\limits_{-\infty}^{+\infty} d\xi e^{-\xi^2/(2\Delta T)} \approx N_0 \left(\frac{\Delta_0}{T}\right)^2 \sqrt{2\pi T\Delta_0} e^{-\Delta_c/T}.$$

Also, the total number of electrons:

$$N(T) = \int\limits_0^\infty \frac{g_s V 4\pi p^2 dp}{(2\pi\hbar)^3 \left(e^{\frac{\varepsilon(p)}{T}} + 1\right)} \approx \frac{8V\pi p_F^2}{(2\pi\hbar)^3} e^{-\frac{\Delta}{T}} \int\limits_{-\infty}^{+\infty} dp' e^{\frac{-v_F^2 p'^2}{2T\Delta}} = \frac{8V\pi p_F^2 \sqrt{2\Delta}}{(2\pi\hbar)^3 v_F} T^{1/2} e^{-\frac{\Delta}{T}} \propto e^{-\frac{\Delta}{T}} \ll 1.$$

Jump of heat capacity

$$\left(C_s - C_n\right)/C_s = 1.43. \qquad \text{BCS}$$

$$C = T\frac{\partial S}{\partial T} \qquad S_s - S_n = \frac{H_{cm}}{4\pi}\left(\frac{\partial H_{cm}}{\partial T}\right)_R$$
$$C_s - C_n = \frac{T}{4\pi}\left[\left(\frac{\partial H_{cm}}{\partial T}\right)^2 + H_{cm}\frac{\partial^2 H_{cm}}{\partial T^2}\right] = \frac{T_c}{4\pi}\left(\frac{\partial H_{cm}}{\partial T}\right)^2_{T_c} \qquad \text{(Rutgers),}$$

ибо при $T = T_c$ критическое поле $H_{cm} = 0$.

(??maybe the derivation is done in Levitos Shitov, I'll check later)

Entropy of a superconductor

(see Shmidt for now, sec. 3)

Diamagnetic susceptibility of a SC

(add ideas from Shmidt)

(maybe here I'll show some plots from calculations or from experiments)

(here there will be formulas from LS)

(maybe I'll write some important formulas from Varlamov Larkin)

1.1.7 General important features of superconductors and theories

General questions about measurements

Как измеряют нулевое сопротивление?

Как измеряют ток при нулевом сопротивлении?

Как измеряют такие малые температуры?

General questions about all theories

Connection of BCS and GL theory

(a short basic answer to this question is here)

Why SC doesn't work at low dimensions and what is meant by this?

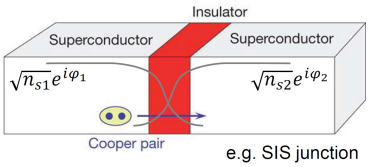
(I'll write formulas, how fluctuations destroy it and why?)

1.2 Typical SC Effects

1.2.1 Josephson equations, SNS, SQUID, RCSJ

Finally, what is going on with tunneling?

Consider just NS border. Помимо термоактивационного вклада в ток, описываемого $I_{N-S}(V,T) = \frac{\sqrt{2\pi\Delta T}}{eR} e^{-\Delta/T} \operatorname{sh} \frac{eV}{T}$, под порогом $eV = \Delta$ существует еще один весьма интересный вклад, не исчезающий при $T \to 0$. Он связан с когерентным туннелированием пары электронов с противоположными импульсами и спинами.



(??? add before that we don't consider two paericle tunnelings. why???)

Оказавшись в сверхпроводнике, такие два электрона могут образовать куперовскую пару. Туннелирование пары, в отличие от одночастичного туннелирования, не требует затраты энергии Δ на каждую частицу, и поэтому такой вклад не «вымерзает» при низких температурах. Когерентное туннелирование пар электронов часто называют андреевским отражением, поскольку описанный процесс перехода двух электронов из нормального металла в сверхпроводник можно рассматривать как превращение электрона в дырку при отражении от поверхности сверхпроводника. Вероятность двухчастичного туннелирования пропорциональна $|T_0|^4$, а не $|T_0|^2$, как для одночастичного туннелирования. Поэтому при $|T_0| \ll 1$ и не слишком низкой температуре двухчастичные процессы очень редки по сравнению с одночастичными. Вследствие этого андреевское отражение вносит существенный вклад в туннельный ток лишь при достаточно низких температурах.

Finally, what ideas are used in the most useful methods for tunneling?

(for now, see theoretical section with discussion of it)

Josephson effect and equations

$$I_s = I_c \sin(\varphi_2 - \varphi_1) \qquad (1^{\text{st}} \text{ Joseph. eq./current-phase})$$

$$\frac{\partial(\varphi_2 - \varphi_1)}{\partial t} = \frac{2e}{\hbar}U \equiv \frac{2\pi}{\Phi_o}U \qquad (2^{\text{nd}} \text{ Joseph. eq./voltage-phase})$$

$I_c := \frac{4eK\sqrt{N_1 N_2}}{\hbar}$, K - model const.

Particular cases are as follows:

DC Josephson effect: At zero applied voltage we have a finite supercurrent, upto a maximum 'critical' current.

AC Josephson effect: A DC voltage causes variation over time of the gauge invariant phase difference and thus produces an AC current. The frequency of the current is proportional to the voltage.

In formulas: from $\frac{\partial\gamma}{\partial t} = \frac{2\pi}{\Phi_0}U = \frac{2e}{\hbar}U$ we get $\gamma(t) = \gamma(0) + \frac{2\pi}{\Phi_0}Ut$, thus $I(t) = I_c \sin\left(\frac{2\pi}{\Phi_0}Ut + \gamma(0)\right)$, here

$$f_J := \frac{1}{\Phi_0}U \equiv \frac{2e}{h}U$$

Josephson constant

$$K_J := 2e/h = 483,5979\text{GHz/mV} \qquad (\text{material independent})$$

The inverse AC Josephson effect: Microwave radiation of a single frequency can induce quantized DC voltages across the Josephson junction, in which case the Josephson phase takes the form $\varphi(t) = \varphi_0 + n\omega t + a\sin(\omega t)$,

$$V(t) = \frac{\hbar}{2e}\omega(n + a\cos(\omega t)), \qquad I(t) = I_c \sum_{m=-\infty}^{\infty} J_m(a)\sin(\varphi_0 + (n+m)\omega t)$$

$$V_{\text{DC}} = n\frac{\hbar}{2e}\omega, \qquad I_{\text{DC}} = I_c J_{-n}(a)\sin\varphi_0.$$

A Josephson junction can act like a perfect frequency-to-voltage converter, which is the theoretical basis for the Josephson voltage standard (???? see wiki).

$$I_{\text{max, JJ}} = \frac{\pi\Delta}{2eR}\,\text{th}\,\frac{\Delta}{2T} \qquad (\text{Ambegaokar–Baratoff})$$

(add idea of the proof. It is done in Levitov Sitov, for example, and it is a long ones.)

Proof of Josephson relations

Proof from Schrödinger eq.:

$$\psi_A = \sqrt{n_A}e^{i\phi_A} \qquad \psi_B = \sqrt{n_B}e^{i\phi_B}$$

$$\frac{\partial}{\partial t}\begin{pmatrix}\sqrt{n_{s1}}e^{i\varphi_1}\\ \sqrt{n_{s2}}e^{i\varphi_2}\end{pmatrix} = \frac{-i}{\hbar}\begin{pmatrix}E_1 & K\\ K & E_2\end{pmatrix}\begin{pmatrix}\sqrt{n_{s1}}e^{i\varphi_1}\\ \sqrt{n_{s2}}e^{i\varphi_2}\end{pmatrix} \qquad \text{(Schrödinger)}$$

$$E_1 - E_2 = 2eV \qquad \sqrt{n_A} + i\sqrt{n_A}\dot{\phi}_A = \frac{1}{i\hbar}\left(eV\sqrt{n_A} + K\sqrt{n_B}e^{i\varphi}\right)$$

$$\varphi := \phi_B - \phi_A. \qquad \sqrt{n_B} + i\sqrt{n_B}\dot{\phi}_B = \frac{1}{i\hbar}\left(-eV\sqrt{n_B} + K\sqrt{n_A}e^{i\varphi}\right)$$

$$\dot{n}_A = \frac{2K\sqrt{n_A n_B}}{\hbar}\sin\varphi \qquad \dot{\phi}_A = -\frac{1}{\hbar}\left(eV + K\sqrt{\frac{n_B}{n_A}}\cos\varphi\right).$$

$$\dot{n}_B = -\frac{2K\sqrt{n_A n_B}}{\hbar}\sin\varphi, \qquad \dot{\phi}_B = \frac{1}{\hbar}\left(eV - K\sqrt{\frac{n_A}{n_B}}\cos\varphi\right).$$

Adding, using $I_s := 2eV\frac{\partial n_s}{\partial t}$ we get 1-st; subtracting, we get 2-nd Josephson equation.

Josephson inductance, energy, (etc...)

$$\text{J inductance} \qquad L(\varphi) = \frac{\Phi_0}{2\pi I_c\cos\varphi} = \frac{L_J}{\cos\varphi} \qquad L_J := L(0) = \frac{\Phi_0}{2\pi I_c}$$

Which is from $\frac{\partial I}{\partial t} = \frac{\partial I}{\partial\varphi}\frac{\partial\varphi}{\partial t} = I_c\cos\varphi\cdot\frac{2\pi}{\Phi_0}V$, so $V = \frac{\Phi_0}{2\pi I_c\cos\varphi}\frac{\partial I}{\partial t} \equiv L(\varphi)\frac{\partial I}{\partial t}$. Note that although the kinetic behavior of the Josephson junction is similar to that of an inductor, there is no associated magnetic field. This behavior is derived from the kinetic energy of the charge carriers, instead of the energy in a magnetic field.

Energy storage in JJ → Nonlinear reactance

$$\frac{dI_s}{dt} = I_c\cos\varphi\frac{d\varphi}{dt} \quad \Rightarrow \frac{dI_s}{dt} = I_c\cos\varphi\frac{2\pi}{\Phi_0}V$$

$$I_s(t) = I_c\sin\varphi(t)$$

$$\frac{d\varphi}{dt} = \frac{2\pi}{\Phi_0}V$$

For small variations near $I_s = I_c\sin\varphi \rightarrow$ JJ equivalent to inductance

$$L_s = \frac{\Phi_0}{2\pi I_c\cos\varphi} = L_c\frac{1}{\cos\varphi}$$

with $L_c = \frac{\hbar}{2el_c}$ Josephson inductance

Properties of the Josephson inductance: Negative for $\pi/2+2\pi n < \varphi < 3\pi/2+2\pi n$ (V > 0 → Oscillating Josephson current)

$\cos\varphi = \pm\sqrt{1-\left(\frac{I_s}{I_c}\right)^2}$

Josephson energy:

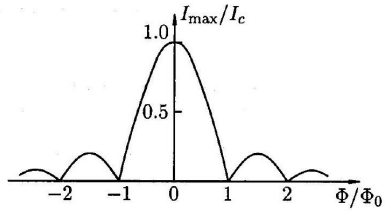
$$U_J(\delta) = E_J(1-\cos\delta)$$

Because the superconducting phase evolution equation is analogous to Faraday's law: $V = \mathrm{d}\Phi/\mathrm{d}t$. Assume that at time t_1, the Josephson phase is φ_1; At a later time t_2, the Josephson phase evolved to φ_2.

$$\Delta E = \int_1^2 IV\ \mathrm{d}t = \int_1^2 I\ \mathrm{d}\Phi = \int_{\varphi_1}^{\varphi_2} I_c\sin\varphi\mathrm{d}\left(\Phi_0\frac{\varphi}{2\pi}\right) = -\frac{\Phi_0 I_c}{2\pi}\Delta\cos\varphi.$$

This shows that the change of energy in the Josephson junction depends only on the initial and final state of the junction and not the path. Therefore, the energy stored in a Josephson junction is a state function, which can be defined as:

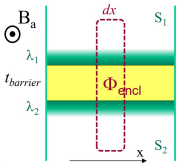
$$E(\varphi) = -\frac{\Phi_0 I_c}{2\pi}\cos\varphi = -E_J\cos\varphi$$



Here $E_J = |E(0)| = \frac{\Phi_0 I_c}{2\pi}$ is a characteristic parameter of the Josephson junction, named the Josephson Energy. It is related to the Josephson Inductance by $E_J = L_J I_c^2$.

$$E_s = \int_0^t I_s V dt \qquad \Rightarrow \qquad I_s V = \frac{\partial E_s}{\partial t} = \frac{\partial E_s}{\partial \varphi}\frac{\partial \varphi}{\partial t} = \frac{2eV}{\hbar}\frac{\partial E_s}{\partial \varphi} \qquad \Rightarrow$$

$$I_s = \frac{2e}{\hbar}\frac{\partial E_s}{\partial \varphi}$$



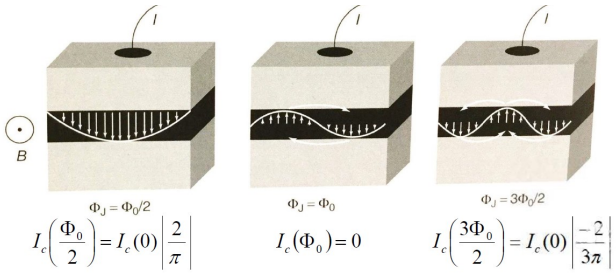
Magnetic field in single JJ

Fraughofer pattern:

$$I_c(\Phi_J) = I_c(0)\left|\frac{\sin[\pi\Phi_J/\Phi_0]}{\pi\Phi_J/\Phi_0}\right|$$

$\Phi_J = B_a t_{\text{eff}} a$ - flux through the junction, $t_{\text{eff}} = t_{\text{barrier}} + \lambda_{L,1} + \lambda_{L,2}$, $I_c(0) = j_c ab$ - critical current at zero magnetic field.

We consider a little contour, in which $\gamma_2 - \gamma_1 = \frac{2\pi}{\Phi_0}\Phi$. Then, we move along side of a junction $\gamma(x+dx) - \gamma(x) = \frac{2\pi}{\Phi_0}\Phi_{\text{encl}} = \frac{2\pi}{\Phi_0}B_a t_{\text{eff}} dx$, from here:



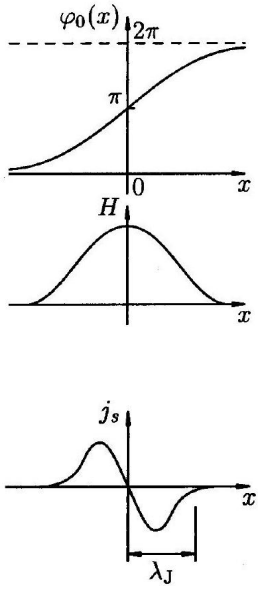
$$\frac{d\gamma}{dx} = \frac{2\pi}{\Phi_0}B_a t_{\text{eff}}$$

$$\gamma(x) = \gamma(0) + \frac{2\pi}{\Phi_0}B_a t_{\text{eff}} x$$

$$j_s(x) = j_c \sin\left[\gamma(0) + \frac{2\pi}{\Phi_0}B_a t_{\text{eff}} x\right]$$

$$I_c(\Phi_J) = I_c(0)\left|\frac{\sin[\pi\Phi_J/\Phi_0]}{\pi\Phi_J/\Phi_0}\right|$$

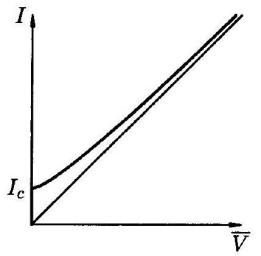
If we fix total flux, spatial distribution of current can be:



another theory, by Shmiedt:

$$\hbar\nabla\theta = 2m\mathbf{v}_s + \frac{2e}{c}\mathbf{A} \qquad \theta - \text{phase}$$

$j_{s,y} = \frac{c}{4\pi}\frac{dH}{dx}$



$$\frac{d^2\varphi}{dx^2} = \frac{1}{\lambda_J^2}\sin\varphi \qquad \lambda_J := \left(\frac{c\Phi_0}{8\pi^2 j_c d}\right)^{1/2}$$

On RCSJ, RSJL Josephson Junctions

RSJ

If we have just a JJ with resistance:

$$I = \frac{V}{R} + I_c\sin(\phi) = \frac{\hbar}{2eR}\frac{\partial\phi}{\partial t} + I_c\sin(\phi)$$

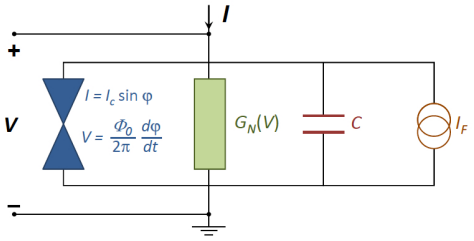
(???)

$$I_c > I \qquad \phi = \arcsin\left(I/I_c\right)$$

$$I_c < I \qquad \frac{\hbar}{2eR}\frac{d\phi}{I - I_c\sin(\phi)} = dt \quad \Rightarrow \quad \int_0^{t_0}, \int_0^{2\pi} \quad \Rightarrow$$

$$t_0 = \frac{\hbar}{2eR}\frac{2\pi}{\sqrt{I^2 - I_c^2}}$$

$$\langle V\rangle = \frac{1}{t_0}\int_0^{t_0} V dt = \frac{\hbar}{2e}\frac{1}{t_0}\int_0^{t_0}\frac{d\phi}{dt}dt = \frac{2\pi\hbar}{2e}\frac{1}{t_0}$$



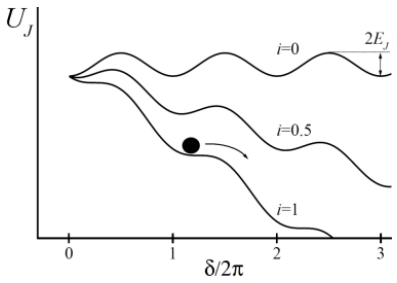
If we average $V(t) = R\frac{I^2 - I_c^2}{I + I_c\cos\omega t}$, where $\omega = \frac{2e}{\hbar}R\sqrt{I^2 - I_c^2}$, we get

$$2e\bar{V} = \hbar\omega.$$

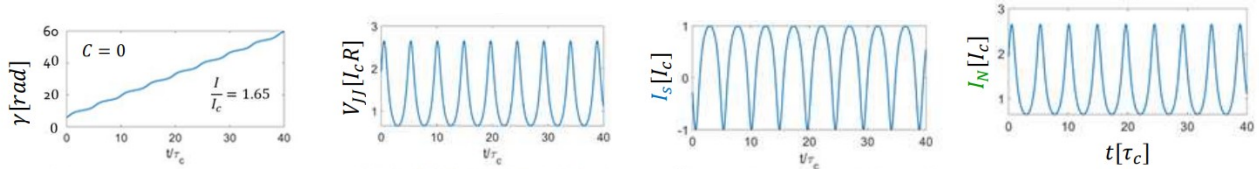
Если среднее расстояние по энергиям между уровнями куперовских пар в двух половинках перехода равно $2e\bar{V}$, то при переходе одной пары через область слабой связи такая энергия выделяется в виде кванта электромагнитного излучения. (????)

Resistively and Capacitively Shunted Junction (RCSJ)

Junction $\Leftrightarrow$

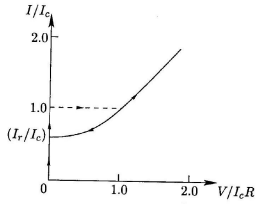


$$\frac{\hbar}{2e}C\frac{d^2\gamma}{dt^2} + \frac{1}{R}\frac{\hbar}{2e}\frac{d\gamma}{dt} + [I_c\sin\gamma - I] = 0$$



$$\beta_C\frac{d^2\gamma}{d\tau^2} + \frac{d\gamma}{d\tau} + \sin\gamma - i = 0$$

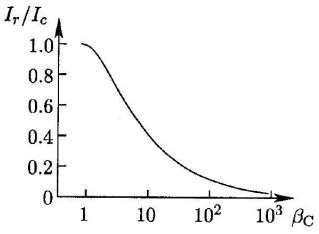
$$\left(\frac{\hbar}{2e}\right)^2 C\frac{d^2\gamma}{dt^2} + \frac{1}{R}\left(\frac{\hbar}{2e}\right)^2\frac{d\gamma}{dt} + \frac{d}{d\gamma}\{E_0[1 - cos\gamma - i\gamma]\} = 0$$

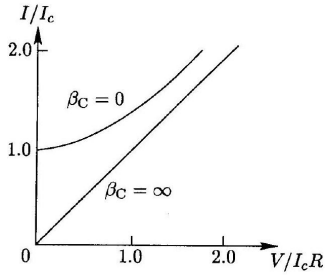


$$\left(\frac{\hbar}{2e}\right)^2 C\frac{d^2\gamma}{dt^2} + \frac{1}{R}\left(\frac{\hbar}{2e}\right)^2\frac{d\gamma}{dt} + \frac{d}{d\gamma}\{E_{J0}[1 - \cos\gamma - i\gamma]\} = 0 \qquad M\frac{d^2x}{dt^2} + \eta\frac{dx}{dt} + \nabla U = 0$$

$$x(t) \leftrightarrow \gamma(t) \qquad M \leftrightarrow \left(\frac{\hbar}{2e}\right)^2 C \qquad \eta \leftrightarrow \frac{1}{R}\left(\frac{\hbar}{2e}\right)^2 \qquad U \leftrightarrow E_{J0}[1 - \cos\gamma - i\gamma]$$

For $\beta_c = 4$





With inductance:

$$\beta_C := (2e/\hbar) I_c C R^2.$$

$$\omega_c := (2e/\hbar) I_c R$$

$$I/I_c = \beta_C \omega_c^{-2} \ddot{\varphi} + \omega_c^{-1} \dot{\varphi} + \sin\varphi.$$

Shapiro spikes (AC voltage circuits)

$$I_s(t) = I_c \sum_{-\infty}^{+\infty} (-1)^n \mathcal{J}_n\left(\frac{2\pi V_1}{\Phi_0 \omega_1}\right) \sin[(\boldsymbol{\omega_{DC}} - n\omega_1)t + \gamma_0]$$

$\mathcal{J}_n$ is the nth order Bessel function of the first kind

$$\boldsymbol{\omega_{DC}} \equiv \frac{2\pi}{\Phi_0} \boldsymbol{V_{DC}}$$

The Josephson frequency associated with the V_{DC} bias

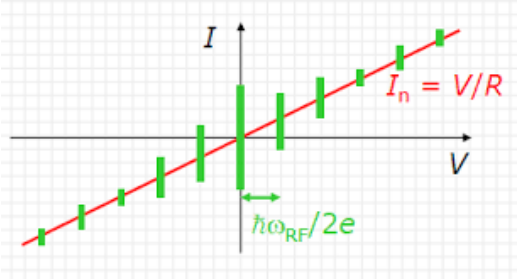
$$V = V_0 + V_1 \cos(\omega t)$$

$$\phi = \int \frac{2eV}{\hbar} dt = \frac{2e}{\hbar} \int \left[V_0 + V_1 \cos(\omega t)\right] dt = \phi_0 + \frac{2e}{\hbar} V_0 t + \frac{2e}{\hbar\omega} V_1 \sin(\omega t)$$

$$I_s = I_c \sin(\phi) = I_c \,\mathrm{Im}\left[\exp\left(i\left(\phi_0 + \frac{2e}{\hbar} V_0 t + \frac{2eV_1}{\hbar\omega}\sin(\omega t)\right)\right)\right]$$

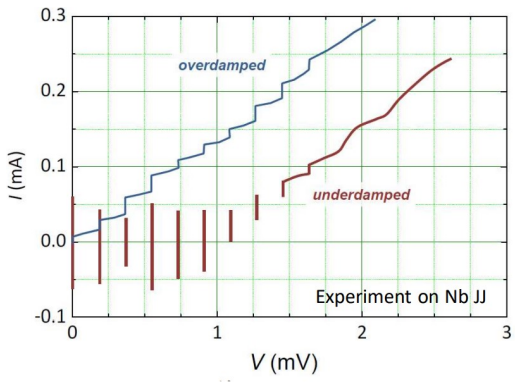
Inverse AC Josephson effect:

$$I = I_s + \frac{V_0}{R} = I_c \sum_{k=-\infty}^{\infty} (-1)^k J_k\left(\frac{2eV_1}{\hbar\omega}\right) \sin\left(\phi_0 + \frac{2e}{\hbar} V_0 t - k\omega t\right) + \frac{V_0}{R}$$



The DC part of the current is V_0/R unless

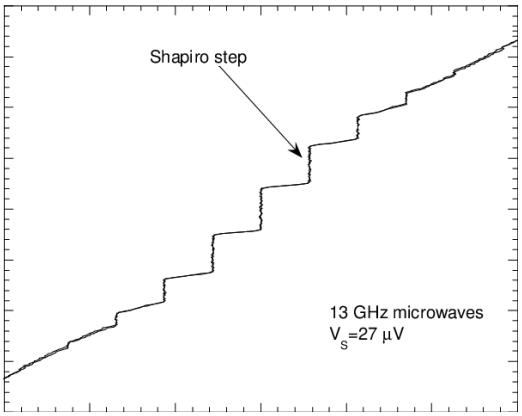
$$V_0 = \frac{k\hbar\omega}{2e}, \quad k = 0, \pm 1, \pm 2, \ldots$$



Then the supercurrent has the DC component

$$I_s = I_c (-1)^k J_k\left(\frac{2eV_1}{\hbar\omega}\right) \sin\left(\phi_0\right)$$

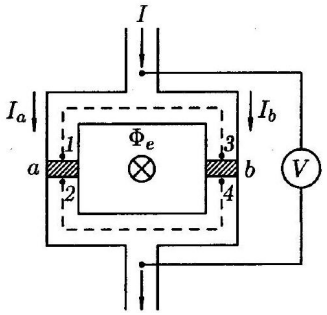
If the potential is not precisely given by Eq. (46) the supercurrent will oscillate slowly with an amplitude given by Eq. (47) with $\phi_0 = \pi/2$, i.e. given by the Bessel function value.



(???)

Shapiro steps (AC current circuits)

We don't know how to solve analytically equations, but we know numerical results:



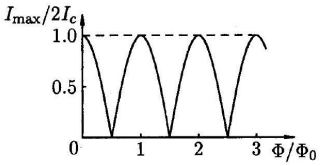
We have some hysteresis effect here (???)

The currents jump at the Shapiro step by an amount given by the Bessel function expression above.

The plateau appears and a Shapiro step occurs when the voltage match an integer value of $\hbar\omega/(2e)$

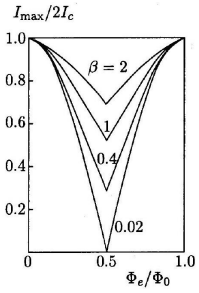
Typical SQUID in a nutshell

Typical SQUID



$$I_{s,\max} = 2I_c \left|\cos \pi \frac{\Phi_a}{\Phi_0}\right| \qquad \begin{matrix} I_{c,1} = I_{c,2} = I_c, \\ \beta_L \equiv \dfrac{2LI_c}{\Phi_0} \ll 1 \end{matrix}$$

$$I = I_1 + I_2, \qquad \begin{matrix} I_1 = \dfrac{I}{2} + J = I_c \sin \gamma_1, \\ I_2 = \dfrac{I}{2} - J = I_c \sin \gamma_2 \end{matrix} \qquad I_{c,1} = I_{c,2}$$



$$\gamma_2 - \gamma_1 = \frac{2\pi}{\Phi_0} \underbrace{(\Phi_a + LJ)}_{\text{tot flux}} \overset{\beta_L := \frac{2LI_c}{\Phi_0} \ll 1}{\approx} \frac{2\pi\Phi_a}{\Phi_0}$$

(????)

$$I_{s,\max} = 2I_c \left\|\cos \pi \frac{\Phi_a}{\Phi_0}\right\|$$

(???)

Другие типичные свойства и типичные джозефсоновы контакты

Overview other theoretical general properties of JJ

Free energy of a JJ at temperature T:

$$\Omega = -gT \int_0^\infty d\varepsilon \rho(\varepsilon) \ln[2\cosh(\varepsilon/2T)].$$

The spectrum of H_{BdG} consists of bound states (Andreev levels) for $\varepsilon < \Delta_0$ and a continuous spectrum for $\varepsilon > \Delta_0$.

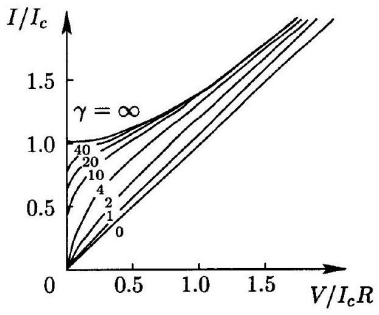
$$\rho(\varepsilon) = -\frac{1}{\pi}\mathrm{Im}\frac{d}{d\varepsilon}\ln\det\left[1 - R_{\mathrm{A}}\left(\varepsilon + i0^+\right) S_{\mathrm{N}}\left(\varepsilon + i0^+\right)\right],$$

where R_{A} is an Andreev reflection matrix and S_{N} is the scattering matrix of the junction in the normal state.

Энергия связи в S-I-S контакте и критический ток.

(see Feigelman's lectures about it later, I am not sure what is meant here)

Температурная зависимость тока, формула Амбегаокара-Баратова для симметричного S-I-S.



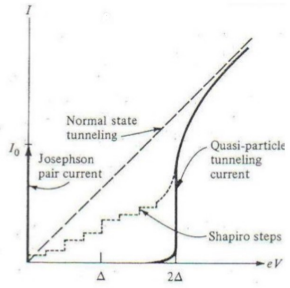
(maybe I'll write from LS main ideas)

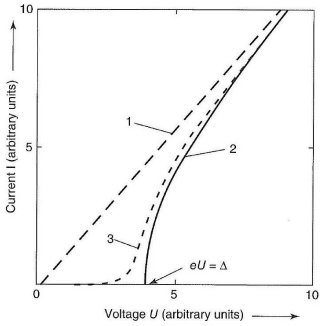
Влияние тепловых флуктуаций на эффект Джохефсона (????7)

Shmidt cites some literature and states:

$$U_0(I) = \frac{4\sqrt{2}}{3} E_{\mathrm{J}} \left(1 - I/I_c\right)^{3/2}.$$

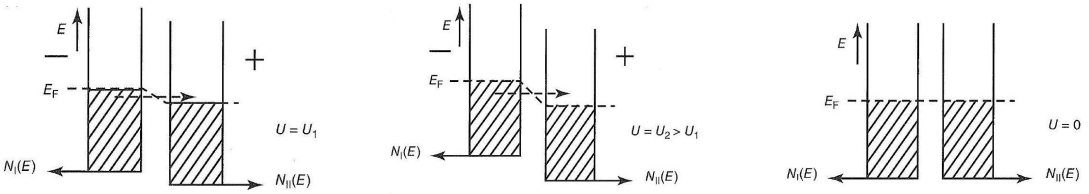
$$\omega(I) = \omega_p \left[1 - (I/I_c)^2\right]^{1/4},$$





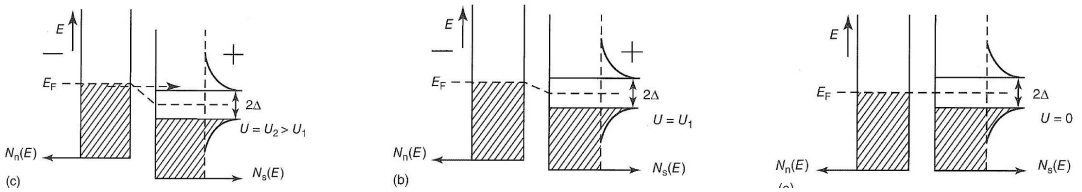
(I'll add later some conclusions from Varlamov, Larkin)

1.2.2 NS, NIS, SIS, other typical junctions

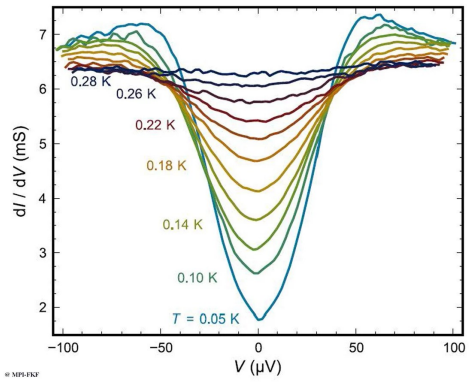


Свойства типичных сверхпроводящих контактов

Основные свойства NS контактов



$N - N$ junction



$N - S$ junction

At low temperatures the tunneling provides direct information on the superconducting state. Figure 2 shows d//dV(V) tunneling characteristics at temperatures below the superconducting transition. The characteristics reveal a clear superconducting gap and allow the gap of the 2DEL to be measured for the first time: it equals $\Delta(50\text{mK}) \approx 40\mu\text{V}$. This value is derived

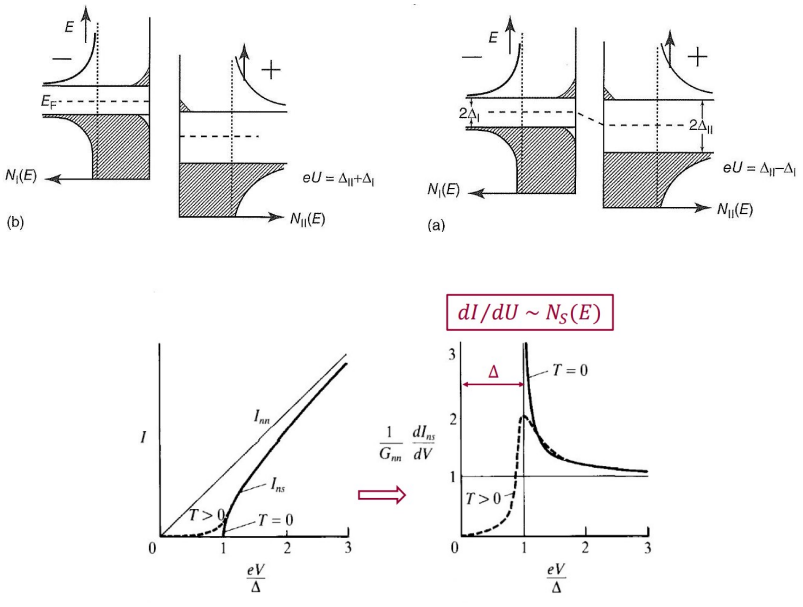
from fitting the data with a quasiparticle lifetimebroadened BCS s-wave quasiparticle density of states. The gap vanishes at 280mK and the temperature dependence is well described by that expected from the BCS theory. (????)

(?????? how to get a gap from it????)

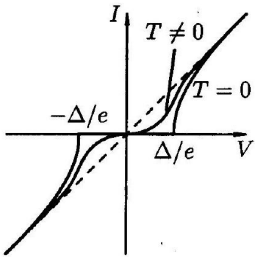
Типичное явление - эффект близости: проникновение ψ в нормальный металл. Это же и для двух разных сверхпроводников.

Из ГЛ:

$$-\xi^2(d\psi/dx)^2 - \psi^2 + \frac{1}{2}\psi^4 = C,$$

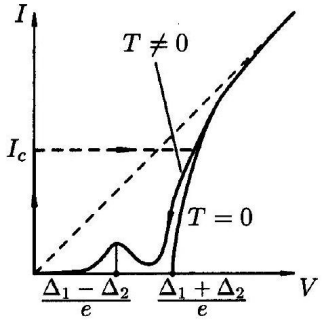


$(d\psi/dx) \overset{x\to\infty}{\to} 0, \psi \to 1 \;\Rightarrow\; C = -1/2,$



$$\psi = \text{th}\left[(x - x_0)/\sqrt{2}\xi\right]. \qquad x_0 = \text{const}$$

$$\frac{1}{\psi}\frac{d\psi}{dx} = \frac{1}{b}$$



(снова тут картинка!)

Superconductor-Insulator-Superconductor (SIS) контакт

Normal–Insulator-Superconductor (NIS) junctions

(??????)

(есть также Эффект близости в SIN-контакте, см. Шелкочева, за минут 20 додумаю, если будет нужно)

SINIS junction

(см Щелкочева, просто, интересно, но пока не до этого)

1.2.3 Skin effect, inductance, impedance

(просто саммари 1й части Шмидта, хорошие темы там)

Принцип замыкания по Шмидту

(есть такой принцип, Шмидт говорит, что он хороший, я пока не читал, не нужно это было.)

Кинетическая индуктивность

(!!?? нужно додумать еще смысл этого!)

$$\mathcal{F}^{\mathrm{M}} = \frac{1}{8\pi}\int H^2 dV = \frac{1}{2c^2} L^{\mathrm{M}} I^2;$$

$$L^K := c^2 \Lambda \int j_s^2 dV / I^2$$

Примеры кинетической индуктивности

(см Шмидт пар 10.)

Комплексная проводимость сверхпроводника

$$\mathbf{E} = \Lambda d\mathbf{j}_s/dt.$$

$$e\mathbf{E} - \frac{m}{n_n e}\frac{\mathrm{j}_n}{\tau} = \frac{m}{n_n e}\frac{d\mathrm{j}_n}{dt}. \qquad \Rightarrow \qquad \mathbf{E} = \frac{n_s}{n_n}\Lambda\frac{d\mathrm{j}_n}{dt} + \frac{n_s}{n_n}\Lambda\frac{\mathrm{j}_n}{\tau}.$$

$$\mathbf{j}_n \propto e^{i\omega t},$$

$$\mathbf{j} = \mathrm{j}_s + \mathrm{j}_n, \qquad \mathbf{j}_s = -i\frac{1}{\Lambda\omega}\mathbf{E}, \qquad \mathrm{j}_n = \frac{n_n}{n_s}\frac{\tau}{\Lambda}\frac{1-i\omega\tau}{1+(\omega\tau)^2}\mathbf{E}$$

$$\mathbf{j} = \sigma\mathbf{E}, \qquad \sigma = \sigma_1 - i\sigma_2, \qquad \sigma_1 := \frac{n_n}{n_s}\frac{\tau}{\Lambda}\frac{1}{1+(\omega\tau)^2} \qquad \sigma_2 := \frac{1}{\Lambda\omega}\left[1 + \frac{n_n}{n_s}\frac{(\omega\tau)^2}{1+(\omega\tau)^2}\right].$$

Скин эффект

Нормальный скин-эффект

$$\mathrm{rot}\mathbf{H} = \frac{4\pi}{c}\sigma\mathbf{E}, \qquad \mathrm{rot}\mathbf{E} = -\frac{1}{c}\frac{\partial\mathbf{H}}{\partial t}.$$

$$-\nabla^2\mathbf{H} = -\frac{4\pi}{c}\sigma\frac{\partial\mathbf{H}}{\partial t}.$$

$$k^2 = -i\frac{4\pi}{c^2}\sigma\omega,$$

$$k = (1-i)/\delta$$

$$\delta = \left(\frac{c^2}{2\pi\sigma\omega}\right)^{1/2}.$$

$$\sigma = \frac{n_n}{n_s}\frac{\tau}{\Lambda} - i\frac{1}{\Lambda\omega}.$$

$$\delta = \frac{\sqrt{2}\lambda}{\left(\frac{n_n}{n_s}\omega\tau - i\right)^{1/2}}.$$

Поверхностный импеданс

$$Z := \frac{4\pi}{c}\frac{E}{H}$$

$$ikH = \frac{4\pi}{c}\sigma E.$$

$$Z = \frac{ik}{\sigma} = \frac{1+i}{\sigma\delta}.$$

$$Z = R_\square + iX_{L\square},$$
$$R_\square = \frac{2\pi\omega^2\lambda}{c^2}\frac{n_n}{n_s}\tau$$
$$X_{L_\square} = 4\pi\lambda\omega/c^2 = \omega L_\square/c^2$$

$\lambda \propto (1-t^4)^{-1/2}$, $t = T/T_c$. Поскольку $\lambda \propto n_s^{-1/2}$, то $n_s \propto (1-t^4)$, или $n_s = n\,(1-t^4)$, n-плотность свободных электронов металла. Тогда $n_n = nt^4$, таким образом,

$$R_\square \propto t^4/\left(1-t^4\right)^{3/2}, \quad X_{L_\square} \propto \left(1-t^4\right)^{-1/2}.$$

$$Z = \frac{2\pi}{c^2}\left(2\omega\tau\frac{n_s}{n_n}\right)^{1/2}\frac{\lambda}{\tau}(1+i) = \frac{1+i}{\sigma_n\delta_n}$$

(картинку добавлю)

1.2.4 Thin films, plates

(выпишу Шмидта и ЛЛ9, добавлю задачи в каталог. не так акутально просто, но тут много нетривиального)

Critical field of a thin film ($d \ll \xi, \lambda$)

$$-\left(1-(2\pi\xi A/\Phi_0)^2\right)\psi + \psi^3 = 0$$
$$d^2A/dx^2 = \left(\psi^2/\lambda^2\right)A$$
$$H(\pm d/2) = H_0$$

(words)

$$H = A_1(\psi/\lambda)\,\mathrm{sh}(\psi x/\lambda) + A_2(\psi/\lambda)\,\mathrm{ch}(\psi x/\lambda)$$

(words)

$$\psi^2 = 1 - \frac{1}{24}\frac{H_0^2 d^2}{H_{cm}^2\lambda^2}$$

Finally,

$$H_\mathrm{K} = 2\sqrt{6}H_{cm}\frac{\lambda}{d}$$

Если толщина пленки на порядок меньше ее глубины проникновения, $\lambda/d \sim 10$, а $H_{cm} \sim 10^3$, то $H_\mathrm{K} \sim 40000$. Физически это вполне понятно. Поскольку магнитное поле проникает в пленку, она имеет существенно меньший диамагнитный момент на единицу объема, чем массивный образец. Но малый диамагнитный момент во внешнем поле - это маленькая магнитная стрелка, ориентированная навстречу полю. Такая ситуация энергетически более выгодна, чем в случае большого диамагнитного момента. Поэтому пленка оказывается во внешнем поле гораздо более устойчивой, чем массивный образец, и может сохранить сверхпроводимость в существенно больших полях.

Критический ток тонкой пленки

(words, somehting very similar to the previous par)

$$2\lambda^2 H_I^2 / \left(d^2 H_{cm}^2\right) = \psi^4 - \psi^6$$

$$\frac{d}{d\psi}\left(2\lambda^2 H_I^2 / d^2 H_{cm}^2\right) = 4\psi_c^3 - 6\psi_c^5 = 0,$$

отсюда $\psi_c^2 = 2/3$

$$H_{I_c} = \frac{\sqrt{2}}{3\sqrt{3}} H_{cm} \frac{d}{\lambda}.$$

$2H_{I_c} = (4\pi/c) I_c$

$$j_c = \frac{\sqrt{2}}{6\pi\sqrt{3}} \frac{cH_{cm}}{\lambda}.$$

1. Поле, созданное критическим током на поверхности пленки, оказывается пропорциональным ее толщине: $H_{I_c} \propto d$, т.е. падает с уменьшением толщины пленки, в то время как критическое поле пленки $H_к \propto 1/d$, т.е. растет с уменьшением толщины. Так, если $d/\lambda \sim 0.1$, а $H_{cm} = 1000$ Э, то $H_\kappa \sim 4 \cdot 10^4$, а $H_{I_c} \sim 30$. Это значит, что для тонкой пленки разрушение сверхпроводимости током никак нельзя сводить к разрушению сверхпроводимости магнитным полем этого тока.

2. Критическая плотность тока j_c, согласно (18.5), не зависит от толщины пленки. Из этой формулы следует, что j_c просто является характеристикой токонесущей способности данного материала.

3. Отметим, наконец, еще один очень важный момент. Разрушение сверхпроводимости током не сопровождается каким-либо фазовым переходом. При этом мы, конечно, имеем в виду, что пленка с током хорошо омывается жидким гелием и все выделяющееся в ней тепло сразу отводится, т. е. ее температура остается равной температуре гелиевой ванны. В этом случае даже при токе I_c свободная энергия сверхпроводящего состояния все еще остается меньше свободной энергии нормального состояния.

(by the way, it is similar to considerations about critical current. (??? how??))

Проникновение потока

(тут основное указание про то, как по итогу это вообще получается!!!)

Глубина проникновения по Ландау 9 (????)

(??? там много соображений, потом подумаю про них еще раз)

Пластина толщиной d в однородном параллельном магнитном поле B_0

$$\vec{h} + \lambda^2 \text{ rot rot } \vec{h} = 0$$

$$h - \lambda^2 \frac{d^2 h}{dx^2} = 0$$

$$h(x) = h_1 \text{ch}(x/\lambda) + h_2 \text{sh}(x/\lambda)$$

$$h(\pm d/2) = B_0$$
$$h(x) = B_0 \frac{\mathrm{ch}(x/\lambda)}{\mathrm{ch}(d/(2\lambda))}$$
$$j_s(x) = -\frac{c}{4\pi}\frac{dh}{dx} = -\frac{cB_0}{4\pi\lambda}\frac{\mathrm{sh}(x/\lambda)}{\mathrm{ch}(d/(2\lambda))}$$

(?? там ур Максвелла в конце??)

Пластна с током

В единичной полосе вдоль оси z течет ток I. На поверхностях пластины ($x = \pm d/2$) он создает магнитное поле $H(\pm d/2) = \mp H_I$. Подставляя эти граничные условия в общее решение (9.2), найдем поле в пластине:

$$H(x) = -H_I \frac{\mathrm{sh}(x/\lambda)}{\mathrm{sh}(d/2\lambda)}, \qquad H_I := 2\pi I/c$$

$$j_s(x) = \frac{cH_I}{4\pi\lambda}\frac{\mathrm{ch}(x/\lambda)}{\mathrm{sh}(d/2\lambda)}$$

$$H = -H_I \cdot 2x/d, \quad j_s = \frac{cH_I}{2\pi d} = \frac{I}{d}.$$

(картинку из Шмидта добавлю)

Пленка над экраном.

(тоже картинки у него есть)

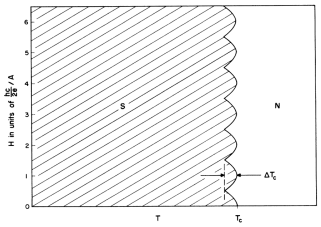
Квантование потока

Little–Parks oscillations

Суть эффекта заключается в незначительном подавлении сверхпроводимости незатухающим током.

Результаты схематически показаны на рис. где наблюдаются периодические осцилляции критической температуры (Tc) на параболическом фоне.

(поизучаю мб потом, не самый важный эффект, если усвою основы, по идее быстро и решу его сам)



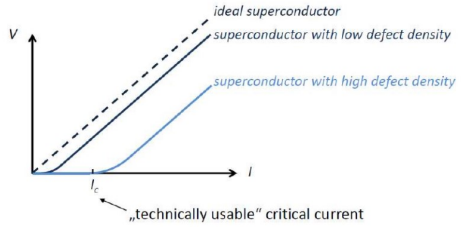


FIG. 1. Phase diagram for a thin cylindrical superconductor in an axial magnetic field. The scalloped edge of the superconducting phase results from the periodicity in the free energy of the bound pairs, in the magnetic flux through the cylinder.

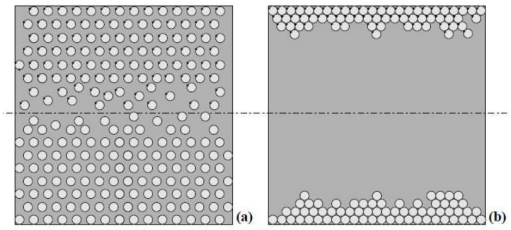
1.2.5 Vortices: basic models

Основные свойства вихрей



Мы рассматриваем сверхпроводники 2го рода при магнитном поле между 1м и 2м критическом, потому что это наиболее типичный случай.

"Lorentz"-like force $\boldsymbol{F}_L$ between current and magnetic flux lines.
→ force ⊥ current and ⊥ magnetic field
→ Flux lines move ⊥ current and ⊥ magnetic field
→ Moving flux lines create dissipation (electrical resistance!):
→ $j_c << j_{c,p}$ 'Ideal' superconductors have zero critical current density

Silsbee's hypothesis for the critical current:
"The threshold value of the current is that at which the magnetic field due to the current itself is equal to the critical magnetic field."
For type-II superconductors: $I_c = B_{c1} 2\pi R/\mu_0$
(????? как оценить размер вихря???? они супер мелкие, но я пока не умею их оценивать)

Вихри проникают именно через границу, потому что так им выгоднее (? когда-то мб пойму, почему?). Внутри они так вот просто не возникают. Если пининг сильный, то они особо и не двигаются, если же малый, то особо и не двигаются.

2 Most Useful Special Methods

2.1 Very useful special methods for special applications

2.1.1 Functional integral for SC

(I'll write soon)

Main formulas for Path integral for BCS

$$Z = \int \mathcal{D}[\bar{c}, c] e^{-S}, \qquad S = \int_0^\beta \sum_{\mathbf{k}\sigma} \bar{c}_{\mathbf{k}\sigma} \left(\partial_\tau + \epsilon_{\mathbf{k}}\right) c_{\mathbf{k}\sigma} - \frac{g_0}{V} \bar{A} A$$

$$-g\bar{A}A \to \bar{\Delta}A + A\bar{\Delta} + \frac{V}{g_0}\bar{\Delta}\Delta$$

$$Z = \int \mathcal{D}[\bar{\Delta}, \Delta, \bar{c}, c] e^{-S}$$
$$S = \int_0^\beta d\tau \left\{ \sum_{\mathbf{k}\sigma} \bar{c}_{\mathbf{k}\sigma} \left(\partial_\tau + \epsilon_{\mathbf{k}}\right) c_{\mathbf{k}\sigma} + \bar{\Delta} A + A\bar{\Delta} + \frac{V}{g_0}\bar{\Delta}\Delta \right\}$$

$$Z = \int \mathcal{D}[\bar{\Delta}, \Delta, \bar{\psi}, \psi] e^{-S}$$
$$S = \int_0^\beta d\tau \left\{ \sum_{\mathbf{k}} \bar{\psi}_{\mathbf{k}} \left(\partial_\tau + \underline{h}_{\mathbf{k}}\right) \psi_{\mathbf{k}} + \frac{V}{g_0}\bar{\Delta}\Delta \right\},$$

$$Z = \int \mathcal{D}[\bar{\Delta}, \Delta] e^{-S_E[\bar{\Delta},\Delta]}$$
$$e^{-S_E[\bar{\Delta},\Delta]} = \prod_{\mathbf{k}} \det\left[\partial_\tau + \underline{h}_{\mathbf{k}}(\tau)\right] e^{-V\int_0^\beta d\tau \frac{\bar{\Delta}\Delta}{g_0}}$$

$$S_E[\bar{\Delta}, \Delta] = V\int_0^\beta d\tau \frac{\bar{\Delta}\Delta}{g_0} + \sum_{\mathbf{k}} \mathrm{Tr}\ln\left(\partial_\tau + \underline{h}_{\mathbf{k}}\right)$$

Mean-field theory as a saddle point of the path integral:

$$Z_{BCS} = \int \prod_{\mathbf{k}n} d\bar{\psi}_{\mathbf{k}n} d\psi_{\mathbf{k}n} e^{-S_{MFT}\left[\bar{\psi}_{\mathbf{k}n}, \psi_{\mathbf{k}n}\right]} \qquad S_{MFT}\left[\bar{\psi}_{\mathbf{k}n}, \psi_{\mathbf{k}n}\right] = \sum_{\mathbf{k}n} \bar{\psi}_{\mathbf{k}n}\left(-i\omega_n + h_{\mathbf{k}}\right)\psi_{\mathbf{k}n} + \beta V \frac{\bar{\Delta}\Delta}{g_0}.$$

Proof.

$$Z = \int \mathcal{D}[\bar{\Delta}, \Delta] e^{-S_E[\bar{\Delta},\Delta]}.$$

$S_E = VS_0$,
$\delta S_E/\delta\Delta = 0$,

□

free energy: BCS pair condensate

$$\mathcal{F}[\Delta, T] = \frac{S_E}{\beta} = -T\sum_{\mathbf{k}n} \ln\left[\omega_n^2 + \epsilon_{\mathbf{k}}^2 + |\Delta|^2\right] + V\frac{|\Delta|^2}{g_0}$$

Proof.

$$\det\left[\partial_\tau + \underline{h}_{\mathbf{k}}\right] = \prod_n \det\left[-i\omega_n + \underline{h}_{\mathbf{k}}\right] = \prod_n \left[\omega_n^2 + \epsilon_{\mathbf{k}}^2 + |\Delta|^2\right]$$

$$Z_{BCS} = \prod_n \left[\omega_n^2 + \epsilon_{\mathbf{k}}^2 + |\Delta|^2\right] \times e^{-\frac{\beta V|\Delta|^2}{g_0}} = e^{-S_E}$$

Fundamentals of Superconductivity

3 Framework for understanding superconductivity

3.1 General ideas about fundamental nature of superconductivity

3.1.1 How to predict existence of SC without knowing anything about low-temperature physics?

(good question, I'll think later about it when I'll have nothing important to do)

3.1.2 How to predict properties of SC if one knows everything about a material at normal state?

(good question, I'll think later about it when I'll have nothing important to do)

3.1.3 Taking into account shape of the Fermi surface (????)

(good question, I'll think later about it when I'll have nothing important to do. we always have $N(E_F)$, so there is a way to calculate it somehow for a different metals??? what is the dependence on the metal of it??? are there are articles about such examples, that for some concrete Fermi surface there are some concrete features of SC?)

3.1.4 Intuitive understanding of GL theory

Analogies of GL theory in life

(??? I had some ideas, but they are not strong now and it is not important)

3.1.5 How to guess about GL theory?

(how to get this idea? I don't know a good answer now)

But anyway, GL theory is not the only one way how one can see superconductivity. Sometimes it is useless to see it this way. There is a BCS and other theories (?? which??) and frameworks that are also useful.

3.1.6 Intuitive understanding of BCS theory

Analogies of BCS theory in life

(??? I had some ideas, but they are not strong now and it is not important)

3.1.7 How to guess about BCS theory?

(how to get this idea? I don't know a good answer now)

But anyway, BCS theory is not the only one way how one can see superconductivity. Sometimes it is useless to see it this way. There is a GL and other theories (?? which??) and frameworks that are also useful.

3.2 Basic Experimental Facts about Typical SC

3.2.1 Overview of Basic Experimental Facts about Typical SC

1.1.1 The Discovery of Superconductivity

Superconductivity was discovered in 1911 at the Leiden Laboratory. While studying the temperature dependence of the electrical resistivity of mercury, H. Kamerlingh-Onnes discovered that at a temperature T^* in the vicinity of 4 K the resistance of the sample dropped suddenly to zero and remained unmeasurable at all attainable temperatures below T^* [6]. Importantly, as the temperature decreased, the resistance disappeared instantly rather than gradually. It was obvious that the sample had undergone a transformation into a novel, as yet unknown, state characterized by zero electrical resistance. This phenomenon was named 'superconductivity'.

All attempts to find at least traces of resistance in bulk superconductors were to no avail. On the basis of the sensitivity of modern equipment, we can argue that the resistivity of superconductors is zero, at least at the level of $10^{-24}\Omega$ cm. For comparison, we note that the resistivity of high-purity copper is of the order $10^{-9}\Omega$ cm at 4.2 K.

Soon after the discovery of superconductivity in mercury, the same property was found in several other metals: tin, lead, indium, aluminum, niobium, and others. Many alloys and intermetallic compounds also turned out to be superconductors.

The temperature of the transition from the normal to the superconducting state is called the critical temperature T_c. Shortly after the discovery, it was found that superconductivity can be destroyed not only by heating the sample, but also by placing it in a relatively weak magnetic field. This field is called the critical field of bulk material, $H_{\rm cm}$. In most of the English-language literature, $H_{\rm cm1}$ is called the thermodynamic critical field, $H_{\rm ct/h}$.

Table 1.1 gives values of $T_{\rm c}$ and $H_{\rm crn}$ for a number of superconducting elements. Here $H_{\rm cm}(0)$ is the critical field extrapolated to absolute zero. The temperature dependence of $H_{\rm cm}$ is well described by the empirical formula

$$H_{\rm cm}(T) = H_{\rm cm}(0)\left[1 - (T/T_{\rm c})^2\right]. \tag{1.1}$$

Table 1.1. Critical temperatures and critical magnetic fields of superconducting elements [7]

Element	T_c/K	$H_{\rm cm}$ (0)/Oe	Element	$T_{\rm c}$/K	$H_{\rm cm}(0)$/Oe
Al	1.175 ± 0.002	104.9 ± 0.03	Pa	1.4	
Be	0.026		Pb	7.196 ± 0.006	803 ± 1
Cd	0.517 ± 0.002	28 ± 1	Re	1.697 ± 0.006	200 ± 5
Ga	1.083 ± 0.001	59.2 ± 0.3	Ru	0.49 ± 0.015	69 ± 2
Hf	0.128		Sn	3.722 ± 0.001	305 ± 2
Hg(α)	4.154 ± 0.001	411 ± 2	Ta	4.47 ± 0.04	829 ± 6
Hg (β)	3.949	339	Tc	7.8 ± 0.01	1410
In	3.408 ± 0.001	281.5 ± 2	Th	1.38 ± 0.02	160 ± 3
Ir	0.1125 ± 0.001	16 ± 0.05	Ti	0.40 ± 0.04	56
La (α)	4.88 ± 0.02	800 ± 10	Tl	2.38 ± 0.04	178 ± 5
La (β)	6.0 ± 0.1	1096, 1600	V	5.40 ± 0.05	1408
Lu	0.1	< 400	W	0.0154 ± 0.0005	1.15 ± 0.03
Mo	0.915 ± 0.005	96 ± 3	Zn	0.850 ± 0.01	54 ± 0.3
Nb	9.25 ± 0.02	2060 ± 50	Zr	0.61 ± 0.15	47
Os	0.66 ± 0.03	70			

This dependence is shown in Fig. 1.1 which essentially represents the $H-T$ phase diagram of the superconducting state. Within the dashed area, any point in the $H-T$ plane corresponds to the superconducting state.

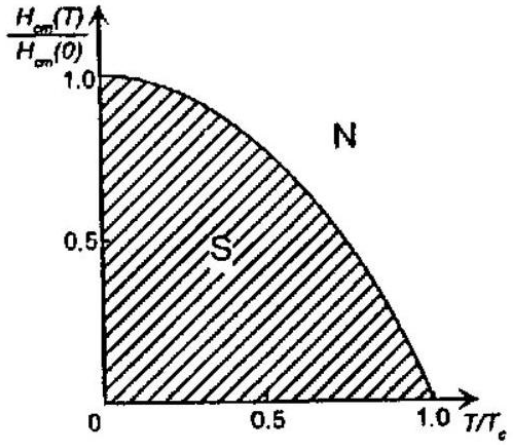

Fig. 1.1. Temperature dependence of the critical field $H_{\rm cm}$

Isotope Effect: Basics

(I'll add here about it from Shmidt's book, it is written below)

Isotope Effect: Experiments

(write articles about it shortly)

Magnetic Flux Quantization: Basics

An electric current in a superconducting ring can persist for an infinitely long time. Naturally, this does not require a power supply, since the resistance of the ring is zero. Such a persistent current can be produced as follows. Let us place the ring at $T > T_c$ in an external magnetic field so that the magnetic
external magnetic field is switched off. At the first moment after switch off the field, the magnetic flux through the ring decreases and, accordi to Faraday's law of electromagnetic induction, induces a current in the ri which will be persistent from this moment on. This current prevents a furtl decrease of the magnetic flux through the ring, i.e., now that the extern field is zero, the current itself supports the flux through the ring at the init level. Indeed, if the ring had a finite resistance R, the flux through the ri would decay during the time of the order of L/R, where L is the inductance the ring. In a superconducting ring, since $R = 0$, it takes the flux infinite ti to decay. This means that the magnetic flux becomes 'frozen' while the ri carries a persistent current usually referred to as a superconducting curr or a supercurrent.

At first sight it may seem that the 'frozen' magnetic flux can take on arbitrary value. However, a number of experiments [8, 9] intended to clar this situation established a very important experimental fact: The magne flux through a hollow superconducting cylinder may only assume values th are integral multiples of $\Phi_0 = 2.07 \times 10^{-7}\mathrm{Gcm}^2$. The latter is called t magnetic flux quantum and can be written as a combination of fundamen constants: $\Phi_0 = \pi\hbar c/e$, where $\hbar$ is Planck's constant, c is the speed of lig and e is the electron charge. In MKSA units $\Phi_0 = h/2e$.

It is surprising that these studies (1961) were not attempted earlier, sir by the mid-1930s superconductivity had already been generally perceived a quantum phenomenon.

Magnetic Flux Quantization: Experiments

(write articles about it shortly)

1.1.3 Josephson Effects

Another manifestation of the quantum nature of superconductivity was pl vided by the so-called weak superconductivity, or Josephson, effects [1 They were predicted in 1962 and soon verified experimentally. The ter 'weak superconductivity' refers to a situation in which two superconduct are coupled together by a weak link. The weak link can be provided by a tu nel junction or a short constriction in the cross-section of a thin film. Mc generally, this can simply be a weak contact between two superconductc over a small area or other arrangements where the superconducting conta between two superconductors is somehow 'weakened'.

There are two Josephson effects to distinguish: stationary (the dc Josep son effect) and nonstationary (the ac Josephson effect).

Consider first the dc effect. Let us apply a current through a weak lis (or, in other words, through a Josephson junction). Then, if the current sufficiently small, it passes through the weak link without resistance, ev if the material of the weak link itself is not superconducting (for examp) if it is an insulator in a tunnel junction). Here we directly come across tl most important property of a superconductor: the coherent behavior of s
in a different way. Having penetrated via the weak link into the second superconductor, the wavefunction of electrons from the first superconductor interferes with the 'local' electron wavefunction. As a result, all superconducting electrons on both sides of the weak link are described by the same wavefunction. The presence of the weak link should not change significantly the wavefunctions on the two sides, compared to what they had been before the link was established.

The ac Josephson effect is even more remarkable. Let us increase the dc current through the weak link until a finite voltage appears across the junction. Then, in addition to a dc component V, the voltage will also have an ac component of angular frequency ω, so that

$$\hbar\omega = 2\mathrm{eV}. \tag{1.2}$$

A fundamental experiment intended to record this so-called Josephson radiation (i.e., the electromagnetic radiation emitted by a Josephson junction) was successfully carried out by I.K. Yanson, V.M. Svistunov, and I.M. Dmitrenko [11].

1.1.4 The Meissner-Ochsenfeld Effect

For as long as 22 years after the discovery of superconductivity, scientists believed that a superconductor was simply an ideal conductor, that is, a piece of metal with zero resistance.

Let us work out how such an ideal conductor should behave in an external magnetic field that is weak enough so as not to destroy the specimen's ideal conductivity.

Suppose that initially the ideal conductor is cooled down below the critical temperature in zero external magnetic field. After that an external field is applied. From general considerations, it is easy to show that the field does not penetrate the interior of our sample, as shown schematically in Fig. 1.2. Indeed, immediately after the field penetrates the surface layer of the ideal conductor, an induced current is set up which, according to Lenz's law, generates a magnetic field in the direction opposite to that of the external field. Therefore, the total field in the interior of the specimen is zero.

Let us prove this with the help of Maxwell's equations. As the induction B changes, an electric field E must be induced in the specimen with

$$\operatorname{curl} \boldsymbol{E} = -\frac{1}{c}\frac{\partial \boldsymbol{B}}{\partial t},$$

where c is the speed of light in vacuum. In the ideal conductor $E = 0$, since $E = j\rho$, where ρ is the resistivity (which in our case is zero) and j is the density of the induced current. It follows that $\boldsymbol{B} = \text{const}$ and, taking into account that $\boldsymbol{B} = 0$ before applying the external field, we arrive at $\boldsymbol{B} = 0$ also after the field is applied. This phenomenon can also be interpreted in a

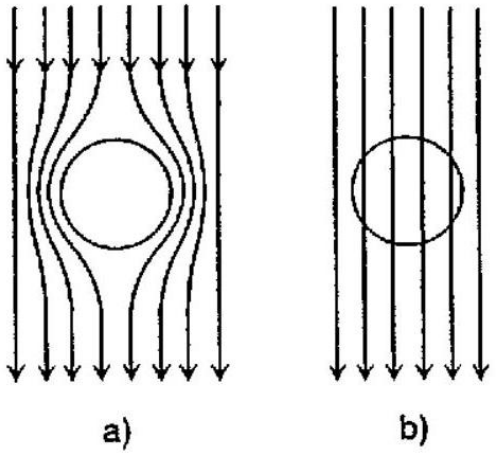

Fig. 1.2. For an ideal conductor, its magnetic state at $T < T_c, H > 0$ depends on its history: (a) magnetic field applied to an ideal conductor at $T < T_c$; (b) field applied at $T > T_c$

Thus, we have established that $\boldsymbol{B} = 0$ at any point of an ideal conductor placed in an external magnetic field. However, the same situation (an ideal conductor at $T < T_c$ in an external magnetic field) can be reached through a different sequence of events, that is, by first applying the external field to a 'warm' specimen and then cooling it down to $T < T_c$.

In that case, for the ideal conductor, electrodynamics predicts an entirely different result. At $T > T_c$, the resistivity of the specimen is finite and, therefore, the magnetic field penetrates into it. After cooling the specimen down through the superconducting transition, the field remains in it, as illustrated in Fig. 1.2 (b).

Note that in the above reasoning we always referred to the specimen characterized by $\rho = 0$ as an ideal conductor and not a superconductor.

It was generally believed before 1933 that the superconductor was indeed simply an ideal conductor. But the experiment by W. Meissner and R. Ochsenfeld [12] revealed that this was not true! They found that at $T < T_c$ the field inside a superconducting specimen was always zero ($B = 0$) in the presence of an external field, independent of which procedure had been chosen to cool the superconductor through T_c.

This discovery was immensely important. Indeed, if $B = 0$ independent of the specimen's history, the zero induction can be treated as an intrinsic property of the superconducting state at $H < H_{cm}$. Furthermore, it implies that we can treat a transition to the superconducting state as a phase transition and, consequently, apply all the might of the thermodynamic approach to examine the superconducting phase.

Thus, the superconducting state obeys the equations

$$\rho = 0, \tag{1.3}$$

$$\boldsymbol{B} = 0. \tag{1.4}$$

3.2.2 The Isotope Effect

The Isotope Effect

Already in 1922, Kamerlingh-Onnes [10] studied the question of whether the nuclear mass of the lattice atoms has an influence on superconductivity, that is, if superconductivity depends on

the lattice of the atomic ions, or whether it is restricted only to the system of the electrons. At the time, only the kinds of lead naturally occurring at different locations ($M = 206$ "uranium lead" and $M = 207.2$ "natural lead") were at his disposal. Within his experimental accuracy, he could not detect any difference in the transition temperature. Also subsequent experiments with lead samples by Justi in 1941 [11] did not show an influence of atomic mass on T_c .

With the advent of modern nuclear physics, it was possible to produce isotopes with a larger mass difference in sufficient concentration within nuclear reactors. In 1950 in mercury a dependence of the transition temperature on nuclear mass was observed [12, 13]. Some results are listed in Table 3.1.

We have already mentioned that these results were highly important for the development of superconductivity, since they appeared just in time to confirm perfectly the idea of the electron-phonon interaction. Already the initial rather qualitative discussions of Fröhlich or Bardeen suggested that the transition temperature T_c should be inversely proportional to the square root of the atomic mass M

$$T_c \propto M^{-1/2}$$

This dependence also remained valid in the BCS theory appearing only 7 years later, as we have discussed in Section 3.1.2.

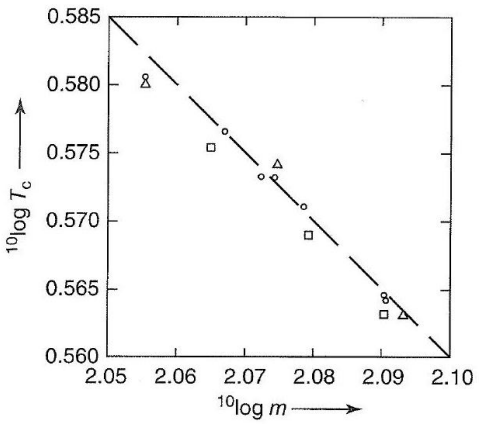

Figure 3.8 Isotope effect in tin: O Maxwell; □ Lock, Pippard, and Shoenberg; and Δ Serin, Reynolds, and Lohman. (From [14]])

Table 3.2 Isotope effect.

Element	Hg	Sn	Pb	Cd	TI	Mo	Os	Ru
Isotope exponent $\rho^{a)}$	0.50	0.47	0.48	0.5	0.5	0.33	0.2	0.0

a) The exponent β is obtained from experiment by fitting to the relation $T_c \propto M^{-\beta}$. The values shown are taken from Ref. [15].

The relation (3.8) is well satisfied for a series of superconductors. In Figure 3.8 we show the results for tin. Tin is a favorable substance, since its possible variations of the nuclear mass are relatively large, namely from $M = 113$ up to $M = 123$ In Figure 3.8 the results from different laboratories are shown [14]. The dashed line corresponds to the exponent $-1/2$ in relation (3.8). The agreement between experiment and the theoretical expectation is excellent.

From our current point of view this agreement is surprising, since the theory leading to relation (3.8) is strongly simplified. However, the agreement shows that apparently these simplifications are justified for a large number of superconductors. On the other hand, we see from Table 3.2, which lists measurements of the isotope effect in different superconductors, that this is not always the case.

The nontransition metals display well the exponent $\beta = 1/2$, the transition metal show strong deviations from this value. In spite of the great difficulties of these experiments, [8] the deviations are well reproduced. Measurements for uranium even indicate a value of $\beta = -2.2$, that is, an isotope effect with opposite sign [16].

For small changes of T_c sufficient accuracy of the experiments cannot be achieved easily. The measurements of T_c must be performed for different samples. Hence, all oher pdedesty The mea-

Because of the great success of the BCS theory, one is tempted to find an explanation of the isotope exponent deviating from 1/2 within the framework of this theory. This is quite possible, if we closely analyze the parameter V in Eq. (3.6) characterizing the interaction. Essentially, this interaction parameter results from the difference between the attractive electron - phonon interaction and the repulsive Coulomb interaction between the electrons. If both interactions are explicitly introduced into the theory, which became possible during further development of the theory, one obtains an improved and also more complicated formula for T_c[17]:

$$T_\mathrm{c} \propto \omega_\mathrm{D} \exp\left(\frac{\lambda^* + 1}{\lambda^* - \mu^* \left(1 + \lambda^* \langle\omega\rangle / \omega_\mathrm{D}\right)}\right)$$

Here, the electron-phonon interaction is characterized by λ^*, the Coulomb interaction by μ'', and $\langle\omega\rangle$ denotes a certain average value taken over all frequencies of the crystal lattice."

We do not want to discuss this formula in more detail. As the essential point, we note that in such a more detailed analysis the lattice frequencies also appear explicitly in the exponent, as expected. Hence, depending on the magnitude of λ^* and μ^*, the influence of the factor ω_D upon T_c (see Eq. (3.9)) is changed to a greater or lesser degree. Therefore, deviations of the quantity β in the relation $T_\mathrm{c} \propto M^{-\beta}$ from the value 1/2 cannot be taken as evidence against the importance of the electron-phonon interaction in these superconductors. The same applies even to the complete absence of any dependence of T_c upon M.

An important advance was achieved by tunneling experiments with superconductors, which we will discuss in the following section. The electron-phonon interaction shows up in the voltage - current characteristic of tunnel junctions, if the interaction is sufficiently strong. A careful analysis of such curves allows one to determine the quantities λ'' and μ''.

The isotope effect demonstrates most directly the influence of lattice vibrations. Because of its quantitative agreement with the theory, at least for many superconductors, it confirms the crucial role of the electron-phonon interaction. Here, the progress of nuclear physics, allowing the production of new isotopes in nuclear reactors, has strongly affected the development of superconductivity. This is one of the many examples in the field of superconductivity where different areas of physics have influenced each other during the progress that has been accomplished.

Also newly discovered superconductors have been investigated regarding the isotope effect, if possible. The results for the high-temperature superconductor will be discussed in Section 3.2.2. Here, as further examples, we mention the fullerides K_3C_{60} and Rb_3C_{60} [18] as well as magnesium diboride MgB_2 [19].

The order of magnitude of these parameters can be indicated as follows: λ° varies between 0 and 0.1 and 0.2 ; and $< \omega > |\omega_D$ is about 0.6. In the fullerides, the carbon isotope ^{12}C was partly or completely replaced by the isotope ^{13}C. Since carbon is a relatively light element, in this case a relatively large shift of T_c in the percent range could be observed. An isotope exponent of about 0.3 was found with a large scattering of the data. This value agrees well with the electron-phonon coupling, if we assume that the intramolecular vibrations of the C_{60} molecules provide the dominant contribution to the Cooper pairing. For MgB_2 the isotope effect was studied regarding both Mg and B. For the variation of the boron isotopes (^{10} B $\leftrightarrow$ ^{11} B) an exponent of about 0.3 was found, and the variation of the magnesium isotopes (^{26}Mg $\leftrightarrow$ ^{27}Mg)

only yielded an exponent of 0.02. This indicates that the vibrations of the boron ions apparently play an important role for the Cooper pairing in MgB_2.

3.2.3 The Anisotropy Effect.

(??? I forgot, where did I take it)

The correlation of the electrons, leading to the formation of Cooper pairs, is due to the elastic vibrations of the lattice, that is, the phonons. This interaction may depend on the direction within the crystal. In the presence of such anisotropy, in a simplified way we can say that certain crystal directions are more favorable for superconductivity than others.

For example, the energy gap Δ_0 can have different values along different directions. The strength of this anisotropy is quantified in terms of the averaged square of a parameter α[16] A value $\langle\alpha^2\rangle = 0.02$, as observed, say, for tin, means that in the different crystal directions the energy gap deviates from the average value by about $14\% \approx 0.02^{1/2}$. Such differences in the energy gap have been detected, for example, by means of tunneling experiments or by measurements of the absorption of ultrasound (see Section 3.1.3.2).

The transition temperature T_c is essentially determined by the more favorable spatial directions, since the transition into the superconducting state takes place when the first Cooper pairs are formed under equilibrium. [17] If lattice defects exist in the crystal, the electrons will be scattered at these imperfections. However, this means that the momentum of an electron quickly covers all spatial directions because of the scattering. Therefore, the interaction leading to superconductivity will be averaged. The most favorable directions will not become fully active anymore, since electrons with momentum along these directions are scattered quickly into other less favorable directions. This leads to an overall reduction of the transition temperature with an increasing concentration of the scattering centers.

The microscopic theory of superconductivity allows one to calculate this influence of the lattice defects on T_c. In Figure 3.22 we show some results for tin [42]. The scattering centers are formed by impurity atoms. Since the impurity atoms have different scattering properties, for convenience we take the residual resistance ratio $\rho'' = R_n/(R_{273} - R_n)$ as a measure of the electron mean free path. Here, R_n is the resistance extrapolated to low temperatures, and R_{273} is the resistance at 273 K. In Figure 3.22 the transition temperature is plotted versus ρ ". The anisotropy effect is dominated by the universal, linear decrease in T_c at small impurity concentrations (see Figure 3.22b), in good agreement with the theory. For large impurity concentrations, that is, for small values of the electron mean free path, complete averaging over all spatial directions is accomplished. For the anisotropy effect alone, T_c should then approach a limiting value a small percentage below the value of the defect-free superconductor.

Figure 3.22 indicates that this behavior is not observed anymore for large defect concentrations. Apparently, in this case, specific properties of the impurities become important, leading to various dependences of the transition temperature on the different impurity atoms. Presently we are still unable to understand

The averaging must be performed over all the electrons on the Fermi surface. the direction.

3.2.4 Meissner effect

(???? TODO: read about Experimental confirmation)

3.2.5 Advanced Experimental Facts about Typical SC

According to their magnetic properties, superconductors are divided into type-I superconductors and type-II superconductors. Type-I superconductors include all superconducting elements except niobium. Niobium, superconducting alloys and chemical compounds make up

the second group, type-II superconductors. The so-called high- T_c superconductors also belong to this group.

The chief difference between the two groups lies in their different response to an external magnetic field. The Meissner-Ochsenfeld effect (Sect. 1.1.4) is observed in type-I superconductors only.

1.2.1 Magnetic Properties of Type-I Superconductors

Let us consider the magnetization curve of a superconductor. Suppose that the specimen is a long cylinder in a longitudinal external magnetic field $\boldsymbol{H}_0$. As the field $\boldsymbol{H}_0$ increases, the induction inside the specimen does not change at first; it remains $B = 0$. As soon as H_0 reaches the value of H_{cm}, the superconductivity is destroyed, the field penetrates into the superconductor, and $\boldsymbol{B} = \boldsymbol{H}_0$. Therefore, the magnetization curve $B = B(H_0)$ appears as shown in Fig. 1.3 (a). The magnetic induction $\boldsymbol{B}$ and the magnetic field $\boldsymbol{H}_0$ are related to each other by the well-known expression

$$B = H_0 + 4\pi M \tag{1.5}$$

where M is the magnetic moment per unit volume. The magnetization curve is often plotted as $-4\pi M$ versus H_0, as illustrated in Fig. 1.3 (b). We shall now derive the basic magnetic properties of type-I superconductors proceeding from equations (1.3) and (1.4) [13].

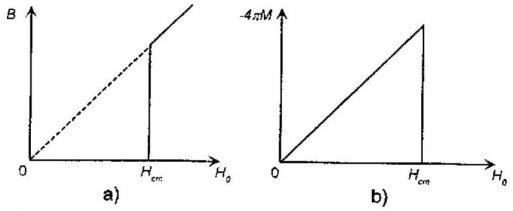

Fig. 1.3. (a) Magnetization curve of a superconductor: (b) magnetic moment per unit volume, M, versus H_0

(1) Magnetic field lines outside a superconductor are always tangential to its surface. Indeed, we know from electrodynamics that magnetic field lines,
be written as the equation

$$\operatorname{div} B = 0$$

from which it follows that the components of B normal to the surface must be equal on both sides of the surface, that is, inside and outside a piece of material. However, the field in the interior of a superconductor is $\boldsymbol{B}^{(i)} = 0$ and, consequently, $\boldsymbol{B}_{\mathrm{n}}^{(\mathrm{i})} = 0$. It follows that the normal component $\boldsymbol{B}_{\mathrm{n}}^{(\mathrm{e})}$ at the outside of the superconductor's surface is zero, too: $\boldsymbol{B}_{11}^{(\mathrm{e})} = 0$. And the meaning of the last equation is exactly that the magnetic field lines are tangential to the surface of the superconductor.

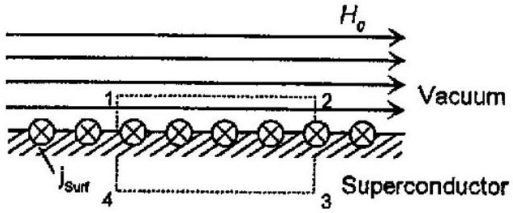

Fig. 1.4. A superconductor placed in an external magnetic field carries a surface current j_{surf}

(2) One of the consequences of the previous property is that a superconductor in an external magnetic field always carries an electric current near its surface. This statement is illustrated in Fig. 1.4. Let $\boldsymbol{H}_0$ be the field at a certain point of the surface of a superconductor. Then

it follows from Maxwell's equation curl $B = (4\pi/c)j$ and the requirement $B = 0$ that the volume current in the interior of the superconductor is zero ($j = 0$) and only a surface current is possible. To elucidate this statement, let us consider the contour $1-2-3-4-1$ in Fig. 1.4. First we find the circulation of B about this contour: $\oint \boldsymbol{B}\mathrm{d}l$. Along the section $1-2$, which is parallel to the surface, we have $\int_1^2 B\ \mathrm{d}l = H_0 l_{12}$, where l_{12} is the length of the section $1-2$. The contributions from the sections $2-3$ and $1-4$ are both zero because, from symmetry arguments, the vector $\boldsymbol{B}$ in these two sections is orthogonal to the integration path. The contribution from the section $3-4$ is zero, too, because $\boldsymbol{B} = 0$ in the interior of the superconduction. The result is $\oint \boldsymbol{B}\mathrm{d}l = H_0 l_{12}$. On the other hand, we find from Maxwell's equation

$$\oint B\ \mathrm{d}l = \frac{4\pi}{c} I$$

where I is the total current through the surface bounded by the contour 1-2-3-4-1. It follows that there must be a surface current at the surface of the superconductor, flowing 'into the page' (as shown in Fig. 1.4) and of linear density j_{surf} defined by

$$H_0 l_{12} = \frac{4\pi}{c} j_{\mathrm{s1rff}} l_{12}$$

The relation between the surface current and th

$$j_{\mathrm{surf}} = \frac{c}{4\pi}\,[n \times H_0] \tag{1.6}$$

where n is the unit vector along the normal to the surface.
Thus, the surface current $\boldsymbol{j}_{\mathrm{surf}}$ is completely defined by the magnetic field H_0 at the surface of a superconductor. In other words, the surface current automatically assumes a value such that the magnetic field generated by it inside a superconductor is exactly equal in value and opposite in direction to the external field. This assures zero total field in the interior: $\boldsymbol{B} = 0$.
(3) Let us point out one more, almost obvious, property: In a simply connected superconductor [1] surface currents can exist only when the superconductor is placed in an external magnetic field. Indeed, if the surface current remained after switching off the external field, it would create its own field in the superconductor which is impossible.

1.2.2 The Intermediate State

We already know that for a type-I superconductor in the shape of a long cylinder placed in a uniform magnetic field parallel to its surface, the superconductivity is destroyed when the field reaches the critical value H_{cm} . It is much harder, however, to destroy the superconductivity of the same cylinder if it is placed in a transverse magnetic field. The same is true for an ellipsoid, a sphere, or other bodies of more complicated geometries.

Consider, for example, the behavior of a superconducting sphere placed in an external magnetic field (Fig. 1.5). Since the magnetic field lines are always tangential to the surface of a superconductor, for our sphere it is obvious that the field lines have a higher density at the 'equator' thereby producing a local increase of the magnetic field. At the same time, the field at the 'poles' is zero. Far away from the sphere, where any perturbations caused by it average out, the uniform external field H_0 is lower than that at the 'equator'.

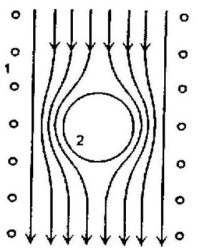

Fig. 1.5. Superconducting sphere in the homogeneous field of a solenoid; 1 - the winding of the solenoid, 2 - the superconducting sphere

A natural question now arises: what happens when the equatorial field reaches the critical value, $H_{\rm cm}$? Clearly, H_0 at that moment is below $H_{\rm cm}$ i A simply
and, therefore, it is not permitted for the whole sphere to revert to the normal state. On the other hand, it is not permitted for the whole sphere to be superconducting either, because the field at the 'equator' has already reached the critical value.

This contradiction is reconciled by a coexistence of alternating superconducting and normal regions within the sphere which is called the intermediate state. The interfaces between these regions are always parallel to the external field, while in the cross-section perpendicular to the field they may assume various intricate configurations.

Assume that before a superconducting body goes into the intermediate state, the maximum field at its surface (in the case of a sphere, at the 'equator') is $H_{\rm m}$ and the external field far away from the body is H_0. It is clear then that, on the one hand, $H_{\rm m} > H_0$ and, on the other hand, $H_{\rm m}$ is proportional to H_0, with the proportionality coefficient dependent on the exact shape of the body. This can be written in the form

$$H_{\rm m} = \frac{H_0}{1-n} \tag{1.7}$$

The values of n for various geometries [2] are given in Table 1.2.

Table 1.2. The demagnetizing factor n for various geometries

Sample geometry	n
Cylinder in parallel field	0
Cylinder in transverse field	1/2
Sphere	1/3
Thin plate in perpendicular field	1

With the help of Table 1.2 we can readily calculate the field H_0 corresponding to the transition into the intermediate state for a body of a certain shape. The transition occurs when the field $H_{\rm m}$ reaches the value of $H_{\rm cm}$. Therefore, for a sphere it takes place when, from (1.7), the external field H_0 reaches the value of

$$H_0 = H_{\rm cm}(1 - 1/3) = 2/3 H_{\rm cm}$$

A thin slab in a perpendicular magnetic field shows the intermediate state starting from an infinitesimal magnetic field H_0. This follows both from (1.7) ($n = 1$) and from general physical arguments, as we shall now demonstrate. Consider a thin disk in a perpendicular magnetic field. Since the magnetic field lines must go around the disk, their density increases substantially at the disk edges. The larger the radius of the disk, the larger the increase of
the field line density, i.e., of the field H_m, will be. For a disk of infinite radius, the transition to the intermediate state occurs in an infinitesimal field H_0.

A thin slab in the intermediate state is shown in Fig. 1.6,

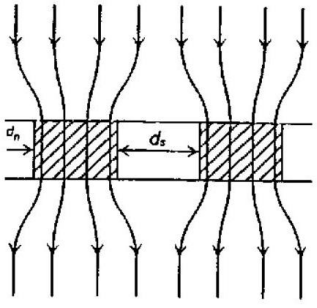

Fig. 1.6. Intermediate state of a thin superconducting plate in a perpendicular field; d_β is the width of a superconducting region, d_n is the width of a normal region

Let us now consider the conditions for thermodynamic equilibrium in the intermediate state.

We shall show that the field in the normal regions always equals the critical field $H_{\rm cm}$, and these regions automatically adjust their size $d_{\rm n}$ so as to provide the correct value of the field (see Fig. 1.6). Assume that the field in one of the normal regions exceeds $H_{\rm cm}$. Then it must destroy the superconductivity of the adjacent superconducting regions. Conversely, if the field in a normal region is less than $H_{\rm cm}$, this region must be superconducting. Therefore, a stable coexistence of the normal and superconducting regions is only possible if the field in the normal regions equals $H_{\rm rm}$.

In the cross-section perpendicular to the magnetic field, the domain patterms of the intermediate state can be very irregular. Classic experiments intended to clarify their configurations were performed by A.I. Shalnikov and A.G. Meshkovskii [14, 15]. They used a thin bismuth wire to study the magnetic field distribution in the equatorial cross-section of a tin sphere. In order to do this, they cut the sphere along the equatorial plane and then placed the two half-spheres slightly apart, with a very narrow gap between them, so that the external field was perpendicular to the surfaces of the cut. Then a bismuth wire was inserted into the gap. At low temperatures, the resistivity of the wire depends strongly on the external magnetic field and can be used as a probe of the field. By moving this probe inside the gap it was possible to examine the magnetic flux pattern. The result is shown in Fig. 1.7. The intermediate state was also studied by other methods, for example, by sputtering tiny ferromagnetic particles onto the superconducting surface and thereby producing a replica of the magnetic flux pattern (Fig.1.8).

The intermediate state assumes an interesting and unusual pattern in a cylindrical wire carrying an electric current. As soon as the current reaches a
distribution of normal (blank) and superconducting (shaded) regions in such a wire is shown in Fig. 1.9, for a current exceeding the critical value.

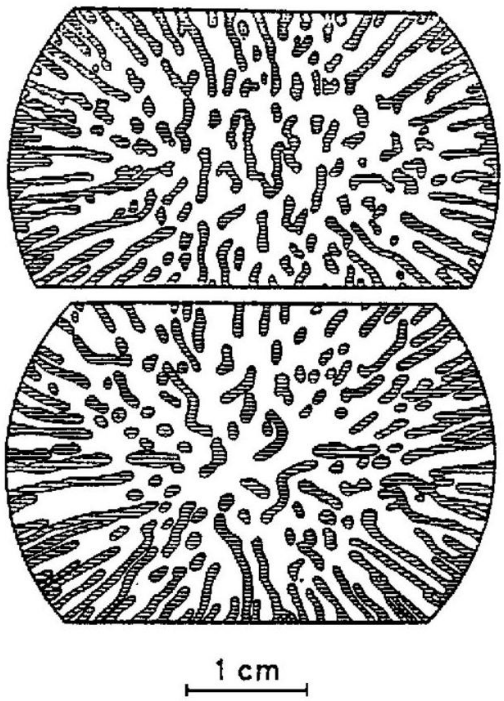

Fig. 1.7. Superconducting and normal regions in a tin sphere [15]. Shaded regions are superconducting

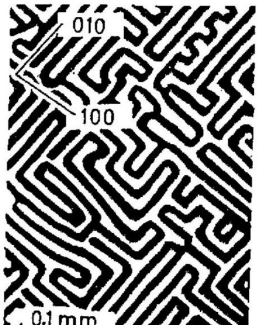

Fig. 1.8. Intermediate state of a single-

As one can see, a normal layer of thickness $(R-a)$ forms at the surface of the wire, and its thickness grows in proportion to the excess current, above the critical value.

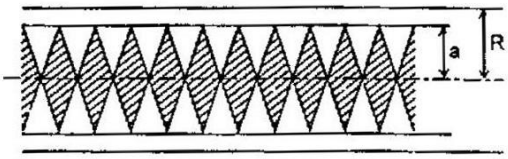

Fig. 1.9. Intermediate state of a wire carrying a supercritical electric current

1.2.3 Magnetic Properties of Type-II Superconductors

In contrast to type-I superconductors, type-II superconductors do not show the Meissner-Ochsenfeld effect. A magnetic field penetrates into these materials in a quite extraordinary way.

Let us take a type-II superconductor in the form of a long cylinder and place it in a longitudinal magnetic field. The field is increased from zero. At first the cylinder pushes all the field out, i.e., the magnetic induction in the interior of the cylinder is zero. This means that we initially observe the Meissner-Ochsenfeld effect. However, beginning from a certain value of the field we shall start to register a finite induction in the cylinder. This field is called the lower critical field and denoted by H_{c1}. With further increase of the external field H_0, the induction will build up until the average field in the cylinder becomes equal to the external field H_0 and the cylinder goes to the normal state. This will happen at the so-called upper critical field H_{c2}. However, in a thin surface layer the superconductivity will remain even at $H_0 > H_{c2}$, until $H_0 = 1.69H_{c2}$. This field is strong enough to destroy the superconductivity in the surface layer as well. It is called the third critical field and denoted by H_{c3}.

The physics of type-II superconductors will be discussed in more detail in Chap. 5.

3.3 Other Ideas for Introduction to Superconductivity

3.3.1 General Introduction to Superconductivity

Basic estimations

Сделаем предварительные оценки. Энергия конденсации куперовских пар на 1см^3, равна $H_c^2/8\pi \sim 10^5{}_{9\text{pr}}/\text{cm}^3$, если принять $H_c \sim 10^3$. Число электронов в 1 cm^3 по порядку величины равно 10^{22}. Таким образом, за сверхпроводимость отвечает энергия примерно равная $10^5/10^{22} = 10^{-17}$ эрг / электрон $= 10^{-5}$ эВ электрон. Заметим, что современная квантовая теория металлов прекрасно описывает многие их свойства даже в пренебрежении кулоновской энергией, имеющей порядок 1эВ электрон. Таким образом, предстояло объяснить природу явления, которой соответствует энергия на много порядков меньше энергии других взаимодействий, которыми обычно пренебрегают.

Abstract introduction for people who se superconductivity first time in their life

In daily life, one is frequently encountered with the states of classical matter, and transformation among these states or so called phases. For example, water can exist in the forms of ice, liquid, and vapor. The transition between these forms can be realized by varying temperature and pressure. These classical phenomena are the outcomes of the collective motion of atoms and molecules, the understanding of which constitutes the main subject of classical statistical physics.

In solid-state electronic materials, electrons are the major players. Since each of them possesses charge $-e(e > 0)$ and spin (an intrinsic degree of freedom), the electronic states exhibit insulating, metallic, and even superconducting and magnetic behaviors. The Mott-Hubbard-type insulating state occurs when the Coulomb repulsion among valence electrons are too large as compared with their kinetic energy (i.e., narrow electron energy band) in a pristine crystal [1, 2]. Therefore, these electrons have no nearby empty sites for them to hop to and they are trapped around ions. In an Anderson insulator, the electrons are localized due to the random distributed impurities in an impure metal, in which one can think of these electrons as waves and these waves cannot propagate beyond the localization length due to the wave-like interference effect [3-5]. Ideally, no conductivity exists in both types of insulators. In the metallic state, they can sneak by all ions in the presence of an electric field and conduct electricity. The difference between metallic and insulating states is striking in real materials. For example, the resistivity in copper is about $1.7 \times 10^{-8}\Omega$ m while the resistivity in undoped Sm_2CuO_{4+y} is as large as $\sim 1\Omega$ m at low temperatures [6]. In the magnetic state, electronic spins can be aligned into parallel, antiparallel, or other patterns.

More interestingly, in the superconducting state, electrons move throughout the whole system with zero resistance. These unique properties have formed the basis for operating electronic devices. Some of them have already been used in nowadays power plants, computers, and wind turbines, to list a few. Therefore, a microscopic understanding of the origin of these electronic states as well as how to control them has significant implications to technological applications. For superconductivity, it is now well accepted that the superconducting current arises from the formation of Cooper pairs [7] mediated by some kind of bosons such as phonons, which is originally proposed by Bardeen, Cooper, and Schrieffer (BCS) [8]. The singleparticle excitations in the superconducting state can not only provide insight into the fundamental properties of superconductivity itself such as pairing nature but also serve as new entities of significant technology implications as a response to defects or magnetic field etc. The Bogoliubov-de Gennes (BdG) [9] approach, which is the main focus of this text, is now a very powerful method to describe these singleparticle approximations in inhomogeneous superconductors. Before we proceed to bring out the BdG mathematical formalism, it should be helpful for the readers to be exposed with a quantum many-body framework in a more broad area of strongly correlated electronic systems.

1. Superconductivity

The problem of superconductivity is one of the most important and difficult presented to quantum statistics. It is well known that many metals undergo a phase change to a new "superconducting" state at sufficiently low temperatures. In this state the metal has thermodynamic and electromagnetic properties that are quite different from those in the normal state. Perhaps the most striking way in which the transition manifests itself experimentally is that the metal, on cooling to a critical temperature, suddenly ceases to present a resistance to electric current. In other words, there is no dissipation of energy when a current flows in a superconductor.

Experimental investigations have shown that the properties of a superconductor in a magnetic field are very different from the relatively simple properties of the normal metal. The

magnetic field does not penetrate into the body of the superconductor (the Meissner-Ochsenfeld effect). The effective depth, measured from the surface of a superconductor located in a constant magnetic field, at which the field is still different from zero (the so-called penetration depth) is extremely small, of the order of 10^{-5} to 10^{-6} cm. The thermodynamic transition from the normal to the superconducting state is a phase transition of the second kind and is characterized by a discontinuity in the specific heat at the transition temperature.

A substantial advance in the understanding of this phenomenon has been achieved in recent years. It has been found that the development of a theory of superconductivity requires a wide use of the methods of quantum field theory. These methods will be treated in subsequent sections; in the present section, we shall dwell mainly on the physical side of the subject.

It has been clear for a long time that superconductivity is somewhat akin to superfluidity. This is evident, first of all, from the fact that the maintainance of an electric current in a superconductor does not require an external potential difference, i.e. does not require work from external
sources. The current carriers in a metal are electrons; we are therefore concerned with none other than superfluidity of the electron liquid.

In Chap. I, in reference to the superfluidity of helium, we dwelt in detail on the properties of the energy spectrum of the excitations required for producing superfluidity. It must be remarked right away, however, that, at small momenta, the spectrum for a superconductor cannot be of the same type as that which we have to associate with liquid helium. For helium has a phonon acoustic branch as the initial part of its spectrum. As is well known, the propagation of sound is connected with long-wavelength density oscillations. But, for an electron liquid in a metal, a change in density involves a fairly substantial amount of energy, since it is hindered by the Coulomb forces acting between the electrons and the lattice, and between the electrons themselves. A change in the density of the electron liquid destroys the condition of electric neutrality, so that the corresponding spectrum of the long-wavelength oscillations starts at some finite frequency, just as in the case of a plasma. This frequency is in fact extremely high in a metal ($\sim$ 1eV $\simeq 10^{4}$°K). Our remarks naturally do not apply to the short-wavelength excitations, with a wave vector of the order of the reciprocal of an inter-atomic distance. We know that it is precisely these electron excitations that play the main role in a normal metal. In accordance with the results of Chap. I, a sufficient condition for the existence of superfluidity is that such excitations be separated by a gap from the ground state, i.e. that the spec-

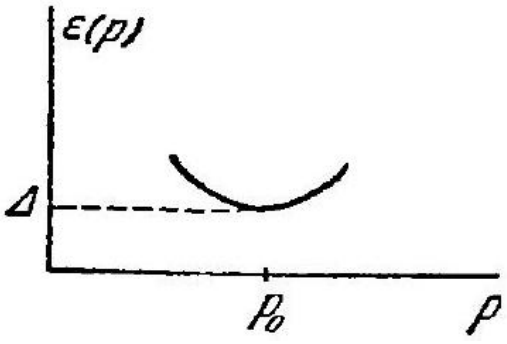

Fig. 88 trum has the shape illustrated in Fig. 88. It may be remarked that, apart from the arguments adduced above, the presence of a spectrum of this type in superconductors has been indicated by experimental data on the electronic specific heat at low temperatures; these data lead to a temperature dependence of the spccific heat of the form $e^{-\Delta/T}$.
We shall not dwell here on a treatment of various phenomenological theories; though they often give an adequate description of experimental data. they cannot provide an explanation of the microscopic mechanism involved.

The isotopic effect discovered in 1950 [5] provided a key to an understanding of the relative roles of the different interactions in a metal when it becomes superconducting. The critical tem-

perature T_c (the temperature at which the transition from the normal to the superconducting state occurs) was found to be a function of the mass of an isotope, of the form $T_c \sim (MI)^{-1/2}$. Frhlich [56] proposed independently that the main interaction corresponding to superconductivity must be of electrons with phonons. This interaction involves a strong dependence on the mass of the ions.

Short introduction with review of materials

Superconductivity was discovered by H. Kamerlingh Onnes in 1911 on mercury. Thereafter, it has also been discovered in other elemental solids like lead and niobium, and other simple compounds. The highest temperature superconductor has been Nb_3Sn until the year of 1986, when the high temperature superconductivity was discovered in copper-based oxides. In the copper-family of superconductors, the highest temperature superconductor is the ceramic $HgBa_2Cu_2Cu_3O_{8+8}$ with a transition temperature $T_c \sim 130$ degrees of Kelvin. In 2008, the iron-based superconductors was discovered with a highest transition temperature of 55 K obtained in SmO_{1-x} F_xFeAs. A chronicle for the discovery of superconductors is shown in Fig. 1.3.

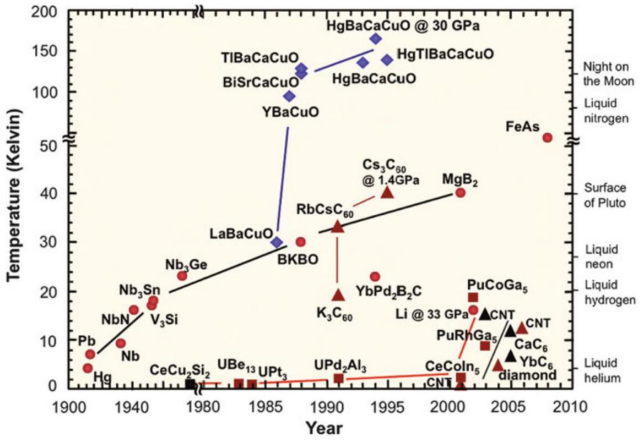

Fig. 1.3 Timeline of the superconductor discovery. Image courtesy of U.S. DOE Office of Basic Energy Sciences

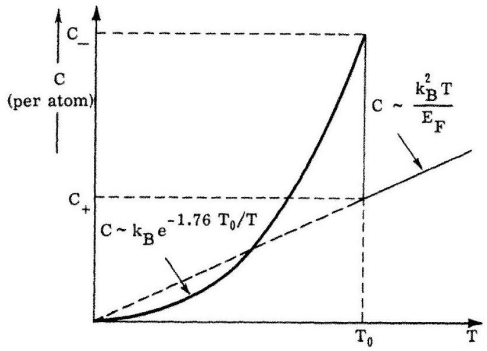
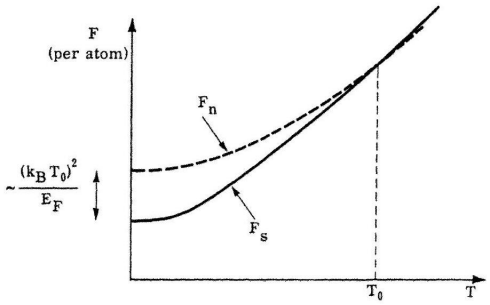
The hallmarks of the superconductors are the zero resistivity and perfect diamagnetism as they are cooled below a critical temperature T_c. For all the superconductors discovered so far, the flux quantization experiments have provided strong evidence that the superconductivity arises from the formation of Cooper pairs [7] by electrons. However, the mechanism for glueing the electrons can be very different from materials to materials. The Cooper pairs are mediated by phonons, that is, lattice vibrational modes, in conventional superconductors while they are via a more exotic process (e.g., the fluctuations of the electron spins) in unconventional superconductors. Accordingly, the pairing symmetry that describes the relative orbital motion of the paired electrons can be different. An s-wave pairing symmetry is commonly observed in conventional superconductors, while other unconventional pairing symmetry like $p-, d-, f$ - and $s_{\pm}$-wave can occur in unconventional superconductors. The latter includes Sr_2RuO_4, ^{3}He, high-temperature cuprates, heavy fermion inter-metallic compounds, and recently discovered ironbased superconductors. On the one hand, the unconventional superconductors are accompanied with multiple electronic phases, a typical feature of strongly correlated electronic materials. On the other hand, although the BCS [8] theory, invoking the electron-phonon coupling as a pairing mechanism, is originally developed for the conventional superconductors, it seems that the quasiparticle properties in the superconducting state can be described by the BCS theory for the unconventional superconductors. This is the underlying basic assumption for the BdG [9] approach.

3.3.2 I-I A new condensed state by de Gennes



We take a piece of tin and cool it down; at a temperature $T_0 = 3.7°K$ we find a specific heat anomaly (Fig. 1-1a). Below T_0 the tin is in a new thermodynamical state. What has happened?

It is not a change in the crystallographic structure, as far as x rays can tell. It is not a ferromagnetic, or antiferromagnetic, transition. (It can be seen by magnetic scattering of neutrons, that tin carries no magnetic moment on an atomic scale.) The striking new property is that the tin has zero electrical resistance. (For instance, a current induced in a tin ring has been observed to persist over times > 1 year.) We say that tin, in this particular phase, is a superconductor, and we call the permanent current a supercurrent.



A large number of metals and alloys are superconductors, with critical temperatures T_0 ranging from less than 1°K to 18°K. Even some heavily doped semiconductors have been found to be superconductors.

Historically, the first superconductor (mercury) was discovered by Kammerling Onnes in 1911.

The free energy F_S in the superconducting phase can be derived from the specific heat data and is represented on Fig. 1-1b (solid line). The dotted line gives the corresponding curve F_n for the normal metal. The difference $(F_S - F_n)_{T=0}$ is called the condensation energy. It is not of order $k_B T_0$ per electron; it is, in fact, much smaller, of order $(k_B T_0)^2 / E_F$ (where E_F is the Fermi energy of the conduction electrons in the normal metal). Typically $E_F \sim 1$eV and $k_B T_0 \sim 10^{-3}$eV. Only a fraction $k_B T_0 / E_F$ $(\sim 10^{-3})$ of the metallic electrons have their energy significantly modified by the condensation process.

(a)

(b)

Figure 1-1

(a) The electronic specific heat C of a superconductor (in zero magnetic field) as a function of temperature (qualitative plot). Above T_0 (in the normal phase) $C_{(\text{per atom})} \sim k_B^2 \, T/E_F$ where E_F is the Fermi energy. At the transition point T_0, C has a discontinuity. At $T \ll T_0, C$ is roughly exponential $C \sim \exp(-1.76 \, T_0/T)$.

(b) Free energy of the superconducting phase (F_S) and of the normal phase (F_n) versus temperature. The two curves meet (with the same slope) at the transition point $T = T_0$. At $T = 0$ the difference $F_n - F_S$ is of order $(k_B T_0)^2 / E_F$ per atom.

3.4 Professional Choice of Model for SC

(an answer about which model to take???)

How accurate the predictions of the gap in scope of an operator approach compared to Gor'kov's approach are? Is it good idea to use it?

(????????????/)

(if all results are obtained by Gor'kov's formalism, then should we use at all in research such methods?)

Why to choose operator BCS model?

Why to choose Dorkov's QFT BCS model?

Why to choose GL model?

3.5 Linear Electrodynamics of Superconductors: Basics

3.5.1 The London Equations: Basics

In order to understand the behavior of a superconductor in an external electromagnetic field, let us use the so-called two-fluid model. We assume that all free electrons of the superconductor are divided into two groups: superconducting electrons of density n_8 and normal electrons of density n_n. The total density of free electrons is $n = n_\mathrm{s} + n_\mathrm{n}$. As the temperature increases from 0 to T_c, the density n_s decreases from n to 0.

Let us start our systematic study of the superconductor in an electromagnetic field with the simplest case. Assume that both the electric and magnetic fields are so weak that they do not have any appreciable influence on the superconducting electron density. Assume, in addition, that the density n_8 is the same everywhere, i.e., spatial variations of n_s are disregarded. The relation between the current, electric field, and magnetic field in this case is linear and described by the London equations [17].

2.1.1 The First London Equation

The equation of motion for superconducting electrons in an electric field is

$$n_\mathrm{s} m \frac{\mathrm{d}\boldsymbol{v}_\mathrm{s}}{\mathrm{d}t} = n_\mathrm{s} e E \tag{2.1}$$

where m is the electron mass, e is the electron charge, v_s is the superfluid velocity, and n_s is the number density of the superfluid. Taking into account that the supercurrent density is $j_\mathrm{s} = n_\mathrm{s} e v_\mathrm{s}$, we have

$$\boldsymbol{E} = \frac{\mathrm{d}}{\mathrm{d}t} (\Delta \boldsymbol{j}_\mathrm{s}) \tag{2.2}$$

with

$$A = m / n_\mathrm{s} e^2 \tag{2.3}$$

Equation (2.2) is simply Newton's second law for the superconducting electrons. It follows from this equation that in the stationary state, that is, when
superconducting electrons. Such variations become important, for example, when one considers the interface between a superconducting and a normal region, with a non-zero current passing through the interface. More details about this situation can be found in Chap. 7.

2.1.2 The Second London Equation

Let us now work out the relation between the supercurrent and the magnetic field in a superconductor. We denote the true microscopic magnetic field at a given point of a superconductor by $\boldsymbol{H}(\boldsymbol{r})$. Here an additional explanation is needed. We remember from Chap. 1 that magnetic field does not penetrate the interior of a type-I superconductor. Now we shall find that this is true only to a certain extent. Magnetic field does in fact penetrate to a shallow depth (of the order of $500 - 1000$Å) at the surface of a body. Our task at the moment is to work out how this field, $\boldsymbol{H}(\boldsymbol{r})$, varies in space.

Assume that the free energy of a superconductor in zero magnetic field is $\mathcal{F}_{50}$. The kinetic energy density of the supercurrent is

$$W_{\rm kin} = \frac{n_{\rm s} m v_{\rm s}^2}{2} = \frac{m j_{\rm s}^2}{2 n_{\rm s} e^2} \tag{2.4}$$

Taking into account Maxwell's equation

$$\operatorname{curl} H = \frac{4\pi}{c} j_{\rm s} \tag{2.5}$$

expression (2.4) for $W_{\rm kin}$ becomes

$$W_{\rm kin} = \frac{\lambda^2}{8\pi} (\operatorname{curl} \boldsymbol{H})^2 \tag{2.6}$$

where we have defined

$$\lambda^2 = \frac{mc^2}{4\pi n_{\rm s} e^2} \tag{2.7}$$

As we already know, the magnetic energy density at some point of the superconductor is $H^2/8\pi$. Therefore, the free energy of the superconductor as a whole, including both the kinetic energy of the supercurrent and the magnetic field energy, is

$$\mathcal{F}_{{\rm s}H} = \mathcal{F}_{\rm s0} + \frac{1}{8\pi} \int \left[\boldsymbol{H}^2 + \lambda^2 (\operatorname{curl} \boldsymbol{H})^2 \right] {\rm d}V \tag{2.8}$$

The integration is carried out over the entire volume of the superconductor.
Let us now solve a variational problem, namely, let us find the identity of the function $\boldsymbol{H}(\boldsymbol{r})$ corresponding to the minimum value of $\mathcal{F}_{{\rm s}H}$. We note that a more accurate approach would be to minimize the Gibbs free energy. We shall indeed do that when deriving the Ginzburg-Landau equations (see Sect. 3.2). However, the result is independent of which particular function is examined for a minimum, $\mathcal{F}_{{\rm B}H}$ or $\mathcal{G}_{{\rm B}H}$. Therefore, we examine $\mathcal{F}_{{\rm B}H}$ as it is easier to do.

Let us ascribe a small variation $\delta\boldsymbol{H}(\boldsymbol{r})$ to the function $\boldsymbol{H}(\boldsymbol{r})$. The resulting change in $\mathcal{F}_{{\rm B}H}$ will be $\delta\mathcal{F}_{{\rm s}H}$:

$$\delta\mathcal{F}_{{\rm s}H} = \frac{1}{8\pi} \int \left(2\boldsymbol{H} \cdot \delta\boldsymbol{H} + 2\lambda^2 \operatorname{curl} \boldsymbol{H} \cdot \operatorname{curl} \delta\boldsymbol{H} \right) {\rm d}V \tag{2.9}$$

The function $\boldsymbol{H}(\boldsymbol{r})$ to be found is the function that makes $\mathcal{F}_{{\rm B}H}$ a minimum, that is,

$$\delta \mathcal{F}_{BH} = 0. \tag{2.10}$$

Using the identity

$$\boldsymbol{a} \cdot \operatorname{curl} \boldsymbol{b} = \boldsymbol{b} \cdot \operatorname{curl} \boldsymbol{a} - \operatorname{div}[\boldsymbol{a} \times \boldsymbol{b}] \tag{2.11}$$

and combining (2.9) and (2.10), we obtain

$$\int \left[\boldsymbol{H} + \lambda^2 (\operatorname{curl} \operatorname{curl} \boldsymbol{H})\right] \cdot \delta \boldsymbol{H} \mathrm{d}V - \int \operatorname{div}[\operatorname{curl} \boldsymbol{H} \times \delta \boldsymbol{H}] \mathrm{d}V = 0 \tag{2.12}$$

The second integral in (2.12) is zero, as one can see from the following. By Gauss's theorem, the second term in (2.12) can be written in the form $\oint [\operatorname{curl} \boldsymbol{H} \times \delta \boldsymbol{H}] \cdot \mathrm{d}\boldsymbol{S}$, where the integration is carried out over the surface of the superconductor. But the field at the surface is fixed, it is the external field; therefore $\delta \boldsymbol{H}(\boldsymbol{r}) = 0$ there.

We have arrived at the equation $\int (\boldsymbol{H} + \lambda^2 \operatorname{curl} \operatorname{curl} \boldsymbol{H}) \cdot \delta \boldsymbol{H} \mathrm{d}V = 0$. For an arbitrary variation $\delta \boldsymbol{H}(r)$, this equation can be satisfied only if the sum in parentheses is zero. Thus we have obtained the equation for the magnetic field in a superconductor:

$$\boldsymbol{H} + \lambda^2 \operatorname{curl} \operatorname{curl} \boldsymbol{H} = 0 \tag{2.13}$$

This is the second Iondon equation. It can also be written in a different form. Using Maxwell's equation (2.5) and the equality $\boldsymbol{H} = \operatorname{curl} \boldsymbol{A}$, we obtain from (2.13)

$$j_{\mathrm{s}} = -\frac{c}{4\pi\lambda^2} \boldsymbol{A} \tag{2.14}$$

One can go from (2.13) to (2.14) only on the condition that the so-called London gauge is chosen for the vector potential:

$$\operatorname{div} \boldsymbol{A} = 0, \tag{2.15}$$

$$\boldsymbol{A} \cdot \boldsymbol{n} = 0, \tag{2.16}$$

where n is the unit vector normal to the superconductor's surface.
Equation (2.15), together with (2.14), specifies the conditions of continuity of the current and absence of a supercurrent source, while (2.16) assures that

It is assumed, of course, that there are no external circuits or contacts to current leads.

Using (2.3) and (2.7), we can write (2.14) in the form

$$j_{\mathrm{s}} = -\frac{1}{cA} \boldsymbol{A} \tag{2.17}$$

$$A = 4\pi\lambda^2/c^2 \tag{2.18}$$

In the rest of the book, we shall often use the second London equation in the form (2.17).

3.5.2 The London Equations: Another Theories

вывод уравнения Лондонов из минимума свободной энергии

просто посчитаем свободную энергию и найдем ее минимум.

Запишем полную свободную энергию сверхпроводника в виде

$$\mathcal{F} = \int F_s dV + E_{kin} + E_{mag}$$

здесь F_s - плотность свободной энергии сверхпроводящих электронов в отсутствие тока, E_{kin} - кинетическая энергия электронов, ответственных за сверхпроводящий ток:

$$E_{kin} = \frac{1}{2}\int n_s m v^2 dV$$

В рамках макроскопической электродинамики имеем

$$\operatorname{rot}\mathbf{B} = \frac{4\pi}{c}\mathbf{j}_s$$
$$\operatorname{divB} = 0$$

Запишем $\mathbf{j}_s$ по определению и через магнитное поле:

$$\mathbf{j}_s(\mathbf{r}) = n_s e\mathbf{v}(\mathbf{r}) = \frac{c}{4\pi}\operatorname{rot}\mathbf{B}$$

Тогда

$$E_{kin} = \frac{1}{2}\int n_s m\left(\frac{c}{4\pi n_s e}\operatorname{rot}\mathbf{B}\right)^2 dV$$

Магнитная энергия

$$E_{mag} = \int \frac{\mathbf{B}^2}{8\pi} dV$$

связана с энергией магнитного поля, индуцированного сверхпроводящими токами.

Здесь m, e - соответственно масса и заряд электрона, n_s - концентрация сверхпроводящих электронов.

Из (17),(18),(19) следует, что

$$\mathcal{F} = \int dV\left[\mathcal{F}_s + \frac{1}{8\pi}\left(\mathbf{B}^2 + \lambda_L^2(\operatorname{rot}\mathbf{B})^2\right)\right]$$

где

$$\lambda_L = \left(\frac{mc^2}{4\pi n_s e^2}\right)^{1/2}$$

Проварьируем свободную энергию по магнитному поло h:

$$\delta\mathcal{F} = \frac{1}{4\pi}\int\left(\mathrm{B}\delta\mathrm{B} + \lambda_L^2\mathrm{rotB}\cdot\mathrm{rot}\delta\mathrm{B}\right)dr$$

Попробуем вытащить δB.

Второе слагаемое преобразуется:

$$\operatorname{rot}\mathbf{B}\cdot\operatorname{rot}\delta\mathbf{B} = \delta\mathbf{B}\operatorname{rot}\mathbf{B}\cdot\operatorname{rot}\operatorname{rot}\mathbf{B} - \operatorname{div}[\operatorname{rot}\mathbf{B}\times\delta\mathbf{B}]$$

потому что

$$\operatorname{arot}\mathbf{b} = \operatorname{brot}\mathbf{a} - \operatorname{div}[\mathbf{a}\times\mathbf{b}] \qquad \mathbf{a} = \operatorname{rot}\mathbf{B},\ \mathbf{b} = \delta\mathbf{B}$$

Учтем, что член с дивергенцией преобразуется в поверхностный интеграл, равный нулю (так как на поверхности равна нулю вариация δB). (????)

Тогда оставшийся объемный интеграл должен равняться нулю при произвольном δB внутри тела.

Поэтому

$$\mathbf{B} + \lambda_L^2\operatorname{rot}\operatorname{rot}\mathbf{B} = 0$$

Это уравнение называется уравнением Лондонов и является следствием существования незатухающих токов.

границы применимости уравнения Лодонов

При выводе уравнения Лондонов мы неявно использовали тот факт, что размер сверхпроводящих электронов много меньше глубины проникновения λ.

Если это не так, и размер электрона $\xi > \lambda$, то в зоне действия магнитного поля находится только "часть электрона" и поэтому уравнение Лондонов несправедливо.

Приведем простейшие физические соображения, как можно прийти к рассмотрению задачи на этом уровне.

Очевидно, что при температуре T_c за сверхпроводимость должны отвечать электроны с энергией порядка T_c.

В соответствии с основными положениями теории ферми-жидкости характерный импульс сверхпроводящих электронов таков, что (????)

$$E_F - T_c < \frac{p^2}{2m} < E_F + T_c$$
$$T_c \ll E_F$$

где E_F - энергия Ферми.

Элементарные возбуждения в такой системе представляют собой волновые пакеты шириной $\delta p \sim T_c/v_F$, где $v_F = p_F/m$. Тогда характерная протяженность волнового пакета равна

$$\xi_0 \sim \frac{\hbar v_F}{T_c}$$

При вы воде уравнения Лондонов неявно предполагалось, что этот волновой пакет целиком повержен влиянию внешнего магнитного поля.

При этом мы получили, что магнитное поле изменяется на масштабе лондоновской глубины проникновения λ_L.

Если $\xi_0 \gg \lambda_L$, то лишь малая часть волнового пакета подвержена влиянию магнитного поля. Таким образом, уравнение Лондонов справедливо если $\lambda_L \gg \xi_0$. Такие сверхпроводники называются сверхпроводниками второго рода.

Парадоксально, но после открытия эффекта Мейсснера, главным образом, исследовались сверхпроводники первого рода, когда $\lambda_L \ll \xi_0$, для которых уравнение Лондонов не работает.

Оценим глубину проникновения магнитного поля λ в другом предельном случае, когда $\lambda \ll \xi_0$.

В этом случае, только λ/ξ_0 часть волнового пакета подвержена влиянию магнитного поля, то есть участвует в формировании незатухающего тока. Для оценки можно считать, что это эквивалентно уменьшению концентрации n. Тогда вычислениеλ можно провести тем же способом, каким получалась лонлоновская глубина проникновения, но с концентрацией $n_s\lambda/\xi_0$. В результате получаем самосогласованное уравнение

$$\lambda = \left(\frac{mc^2\xi_0}{4\pi n_s e^2 \lambda}\right)^{1/2}$$

Отсюда слелует, что

$$\lambda = \lambda_L \left(\frac{\xi_0}{\lambda_L}\right)^{1/3} \gg \lambda_L$$

Мы видим, что квантовомеханические соображения позволяют чисто феноменологически ввести парметр ξ_0.

Пойдем немного дальше.

Пусть сверхпроводяшщие электроны описы ватотся некоторой эффективной волновой функцией Ψ. Квалрат модуля этой функции определяет плотность сверхпроводяшщих

электронов. Это плотность обранцается в нуль в нормальном металле и увеличиваясь на NS гра- нице достигает своего максимального значения в толше сверхпроводника. Таким образом на границе $|\nabla\Psi|^2 \neq 0$.

Из квантовой механики известно, что эта величина пропорционалына плотности кинетической энергии.

Кинетическая энергия - положительна и дает положительный вклад в поверхностную энергию.

Таким образом, можно ожидать, что последовательный учет неоднородности позволит изменить знак результирующего поверхностного натяжения на $\sigma > 0$ и расслоение станет невыгодным.

эффект Мейсснера из уравнения Лондонов

Покажем, как из уравнения Лондонов следует эффект Мейсснера.

простейший случай уравнения лондонов - это когда два ротора становятся тупо второй производной. (Как???)

ну и в таком случае понятно, что решение - это затухающая экспонента, то есть простейшее явление проникновения поля в тело можно описать.

поэтому оно и сойдет для эффекта Мейсснера.

Ограничившись рассмотрением цилиндра большого радиуса, его границу можно считать полоской. Пусть продольное внешнее магнитное поле B_0 направлено по оси z, а нормаль к поверхности сверхпроводника направлена по осиx.

Тогда уравнение Лондонов (???) перепишется в виде:

$$B_z - \lambda_L^2 \frac{\partial^2}{\partial x^2} B_z = 0$$

Магнитная инлукция, конечная внутри сверхроводиика, имеет вид

$$B_x = B(0) e^{-\frac{x}{\lambda_L}} = B_0 e^{-\frac{x}{\lambda_L}}$$

что описывает эффект Мейсснера.

Во избежание недоразумений напомним, что в макроскопической электродинамике непрерывными являются тангенциальная составляющая напряженности магнитного поля и нормальная составляющая магнитной индукции.

При этом тангенциальная составляющая магнитной индукции может, вообще говоря иметь скачок, связанный с существованием поверхностных токов.

Если интересоваться масштабами, много большими глубины проникновения, масштаб λ следует считать бесконечно малым.

Это приводит к тому, что плотность сверхпроводящих токов обращается в бесконечность и их следует рассматривать как поверхностные.

Наличие поверхностных токов приводит к скачку тангенциальной составляющей магнитной индукции.

Заметим попутно, что при таком рассмотрении не определена напряженность магнитного поля внутри сверхпроводника.

В самом деле, магнитное поле определяется как вариация энергии по магнитной индукции. В сверхпроводнике $B \equiv 0$. (??)

Поэтому вариационная производная не определена.

Из уравнений (24),(21) и (15) имеем

$$\operatorname{rot} \mathbf{j}_s = -\frac{ne^2}{mc}\mathbf{B}$$

Введем потенциал A

$$\mathbf{B} = \mathrm{rot}\,\mathbf{A}$$

Этот потенциал определен неоднозначно, с точностью до градиента некоторой функции $\nabla\phi$. Тогда

$$\mathbf{j}_s = -\frac{ne^2}{mc}\left(\mathbf{A}' - \nabla\phi\right)$$

A′ - один из возможных потенциалов.

Если потребовать, чтобы $\mathrm{div j}_s = 0$, то $\mathrm{div}\left(\mathbf{A}' - \nabla\phi\right) = 0$.

Поэтому можно вектор-потенциал выбрать так, чтобы

$$\mathrm{div}\,\mathbf{A} = 0$$

Такой выбор потенциала A называется лондоновской калибровкой.

В этой калибровке получаем

$$\mathrm{j}_s = -\frac{ne^2}{mc}\,\mathrm{A}$$

Из уравнения Максвелла следует, что

$$\mathrm{j} = \frac{c}{4\pi}\mathrm{rotrotA}$$

Подставляя это выражение в уравнение Лондонов получим еще одну форму уравнения Лондонов

$$\mathrm{rotrot}\,\mathbf{A} = -\frac{1}{\lambda_L^2}\mathbf{A}, \quad \lambda_L = \frac{4\pi}{c}\frac{ne^2}{mc}$$

Итак, характерный масштаб затухания магнитного поля и токов в глубь сверхпроводника определяется параметром λ_L, называемым лондоновской глубиной проникновения.

(по факту тупое преобразование уравнения и все, и что тут такого? перепишу наверное с позиции, что это очевидно)

недостатки теории Лондонов

Обсудим теперь основные недостатки теории Лондонов.

В первую очередь, обратим внимание, что оно не является калибровочно инвариантным.

Это основной, так сказать, "фунламентальный" недостаток теории Лондонов.

Но из теории Лондонов следует, что во внешнем магнитном поле сверхпроводнику всегда термодинамически выгодно расслоиться на максимально мелкую сеть чередующихся нормальных и сверхпроводящих областей, так называемое промежуточное состояние.

Это означает, что на границе поверхностное натяжение $\sigma_{ns} < 0$.

Докажем это, используя уравнение Лондонов.

Пусть образец находится во внешнем магнитном поле.

Для простоты рассмотрим плоскую NS -границу между нормальной и сверхпроводящей частями образца.

Граница расположена перпендикулярно оси x. В левом полупространстве $x < 0$ имеем сверхпроводник, справа при$x > 0$ - нормальный металл.

Металл считаем немагнитным.

Поэтому в нем магнитная индукция равна магнитному полю.

Из условия сосуществования нормальной и сверхпроводящей фаз следует, что в нормальной фазе автоматически устанавливается магнитное поле $H = H_c$.

Поэтому можно считать, что мы имеем дело с образцом находящимся в заданном внешнем поле напряженностью H_c.

Тогда минимум должен иметь термо динамический потенциал G:

$$G = F - \frac{\mathrm{BH}_c}{4\pi}$$

Вдали от границы (где B = 0!) в сверхпроводящей части имеем

$$G_s = F_s(\mathbf{B}) - \left.\frac{\mathbf{BH}_c}{4\pi}\right|_{\mathbf{B}=0} = F_{s0}$$

Вдали от границы в нормальной фазе $H = B = H_c$.

Поэтому

$$G_n = F_n + \frac{\mathrm{B}^2}{8\pi} - \frac{\mathrm{BH}_c}{4\pi} = F_n - \frac{\mathrm{H}_c^2}{8\pi}$$

Учитывая (6), получаем, что, как и следовало ожидать в равновесии

$$G_s = G_n$$

Магнитное поле проникает в сверхпроводник на глубину λ и изменяет свободную энергию сверхпроводящей области.

Для анализа рассмотрим плоскую границу между нормальной и сверхпроводящей фазами.

Напомним, что если нормальная и сверхпроводящая фазы сосуществуют только если магнитное поле в нормальной фазе равно H_c.

Термодинамический потенциал Гиббса сверхпроводящего полупространства ($x > 0$) имеет вид

$$\mathcal{G} = \int\limits_{x>0} dV \left[F_{s0} + \frac{B^2}{8\pi} - \frac{H_c B}{4\pi} + \frac{\lambda^2}{8\pi}\left(\frac{dB}{dx}\right)^2 \right]$$

Здесь первый член - плотность свободной энергии Гиббса$G_s = F_{s0}$ в отсутствие магнитного поля, второй - энергия магнитного поля в сверпроводнике, третий - аналог члена HB в (14), последний - кинетическая энергия сверхпроводящих токов.

Если бы магнитное поле не проникало в сверхпроводник, то последние три члена обращались бы в нуль.

Из решения уравнения Лондонов следует, что $B = H_c \exp(-x/\lambda)$(cm.(25)).

Подставляя это выражение в потенциал Гиббса, вычислим поправку к свободной энергии за счет частичного проникновения магнитного поля в сверхпроводник:

$$\Delta\mathcal{G} = \gamma S$$

где S - площадь поверхности, σ - поверхностное натяжение

$$\sigma = \int\limits_{x>0} dx \left[\frac{B^2}{8\pi} - \frac{H_c B}{4\pi} + \frac{\lambda^2}{8\pi}\left(\frac{dB}{dx}\right)^2 \right] = -\frac{H_c^2}{8\pi}\lambda$$

Отсюда следует, что образование поверхности энергетически выгодно и упомянутое расслоение должно происходить всегда!

(????)

Такое расслоение действительно наблюдается, но далеко не для всех сверхпроводников и скорее является исключением, чем правилом.

Если с отсутствием калибровочной инвариантности в теории Лондонов экспериментаторы еще могли смириться, то с необходимостью расслоения - нет.

Пришлось теоретикам искать причину, по которой в большинстве сверхпроводников образование поверхности между сверхпроводящим и нормальным состоянием невыгодно.

Во введении мы определили сверхпроводники первого рода как вещества, в которых имеет место полный эффект Мейсснера - магнитное поле в них не проникает.

Как будет показано ниже для них $\sigma > 0$ и уравнение Лондонов несправедливо.

В противоположном случае $\sigma < 0$ мы имеем дело со сверхпроводниками второго рода, для которых имеет место смешанное (вихревое) состояние.

3.5.3 2.2 Magnetic Field Penetration Depth

Let us apply the London equations to examine how a magnetic field penetrates a superconductor. Consider a superconducting semispace $x > 0$. The surface of the superconductor coincides with the plane $x = 0$. An external magnetic field H_0 is oriented along the z axis. To solve this problem, we shall use (2.13). Taking into account the symmetry of the problem and that curl curl $\boldsymbol{H} = -\nabla^2 \boldsymbol{H}$, we can rewrite (2.13) in the form

$$\mathrm{d}^2 H/\mathrm{d}x^2 - \lambda^{-2} H = 0 \tag{2.19}$$

The boundary conditions are: $H(0) = H_0, H(\infty) = 0$. The second boundary condition takes account of the Meissner-Ochsenfeld effect. The solution of (2.19) is

$$H = H_0 \mathrm{e}^{-x/\lambda} \tag{2.20}$$

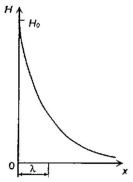


Fig. 2.1. Magnetic field penetration into a bulk superconductor. The field at the surface is H_0

It means that the magnetic field falls off with increasing distance from the surface of the superconductor. The characteristic deca len th is λ (see

Fig. 2.1). This length clarifies the physical significance of the quantity λ formally defined by (2.7) and is called the London magnetic field penetration depth:

$$\lambda = \left(\frac{mc^2}{4\pi n_8 e^2} \right)^{1/2} \tag{2.21}$$

It follows that the screening (Meissner) supercurrent at the surface falls off over the same length. Indeed, the supercurrent is $\boldsymbol{j}_\mathrm{s} = (c/4\pi)$ curl $\boldsymbol{H}$, which in our simple geometry reduces to $j_\mathrm{s} = (c/4\pi)\mathrm{d}H/\mathrm{d}x$. Substituting (2.20) in the last expression, we get

$$j_\mathrm{s} = \frac{cH_0}{4\pi\lambda} \mathrm{e}^{-x/\lambda} \tag{2.22}$$

One can see from (2.21) that λ is temperature-dependent because it depends on n_s. A good approximation for the temperature dependence of λ is given by the empirical formula

$$\lambda(T) = -\frac{\lambda(0)}{\left[1 - (T/T_\mathrm{c})^4\right]^{1/2}} \tag{2.23}$$

Let us now evaluate $\lambda(0)$. At $T = 0$ all electrons are superconducting, that is, $n_s = n \approx 10^{22}$ cm^{-3} (??? this is not true, right??? not all). Substituting this in (2.21), together with $m \sim 10^{-27}$ g, $c \sim 3 \times 10^{-10}$ cm s^{-1}, $e = 4.8 \times 10^{-10}$ esu, we obtain $\lambda(0) \sim 600$Å.

The values of $\lambda(0)$ for some superconductors are given in Table 2.1.

Table 2.1. London penetration depths for some superconductors [2]

Element	Al	Cd	Hg	In	Nb	Pb	Sn	Tl	$YBa_2Cu_3O_7$
$\lambda(0)$/A	500	1300	380 − 450 (anisotropy)	640	470	390	510	920	1700

3.5.4 2.3 Nonlocal Electrodynamics of Superconductors

Equations of Nonlocal Electrodynamics of Superconductors

Everything said so far about the electrodynamics of superconductors falls into the category of the so-called local electrodynamics. For instance, London's equation (2.17) relates the supercurrent density j_s (that is, the velocity of the supercurrent carriers, $\boldsymbol{v}_s$) to the vector potential $\boldsymbol{A}$ at the same point. Therefore, strictly speaking, (2.17) is applicable only if the size of the current carriers is much smaller than the characteristic length over which the vector potential changes, that is, smaller than the penetration deoth λ. We know
the size of a pair by ξ_0. For pure metals, ξ_0 is of the order $\xi_0 \sim 10^{-4}$ cm, as we shall find out later on, in Chap. 6. On the other hand, the penetration depth is $\lambda \sim 10^{-5} - 10^{-6}$ cm. Therefore, the local London electrodynamics is not applicable to pure superconductors, because the magnetic field changes appreciably over the length ξ_0.

Hence, the local equation (2.17) must be replaced by a nonlocal one relating the velocity of a particle to the magnetic field which is allowed to change substantially over the size of the particle, ξ_0. Such a nonlocal relation was proposed by A.B. Pippard [18] several years before the microscopic theory of superconductivity appeared.

In its general form, the nonlocal relation between $\boldsymbol{j}_5$ and $\boldsymbol{A}$ can be written as

$$j_\varepsilon(r) = \int \hat{Q}\,(r - r')\,A\,(r') \cdot \mathrm{d}r' \tag{2.24}$$

where $\hat{Q}$ is an operator which, operating on the vector $\boldsymbol{A}$, converts it into the vector $\hat{Q}A$. The operation range of the operator $\hat{Q}\,(\boldsymbol{r} - \boldsymbol{r}')$ is taken to be ξ_0, that is, $\hat{Q}\,(\boldsymbol{r} - \boldsymbol{r}')$ is nonzero only for $|\boldsymbol{r} - \boldsymbol{r}'| \leq \xi_0$. This is how the effect of the vector $\boldsymbol{A}$ on a large particle (a supercurrent carrier) is averaged out. If we now let the operation range go asymptotically to zero, $\hat{Q}$ turns into the δ-function, and we come back to local electrodynamics.

Pippard's proposal was to choose $\hat{Q}A$ in the form

$$\hat{Q}\,(\boldsymbol{r} - \boldsymbol{r}')\,\boldsymbol{A}\,(\boldsymbol{r}') = -\frac{3n_e e^2}{4\pi mc\xi_0}\frac{(\boldsymbol{r} - \boldsymbol{r}')}{(\boldsymbol{r} - \boldsymbol{r}')^{\frac{4}{4}}}\left[\boldsymbol{A}\,(\boldsymbol{r}') \cdot (\boldsymbol{r} - \boldsymbol{r}')\right] \mathrm{e}^{-|\boldsymbol{r} - \boldsymbol{r}'|/\xi_0} \tag{2.25}$$

The exact form of the magnetic field penetration into a superconductor in the nonlocal case differs from the exponential dependence. However, in this case one can also speak of a magnetic field penetration depth defined as

$$\lambda = \frac{1}{\bar{H}_0}\int_0^\infty H\ \mathrm{d}x \tag{2.26}$$

Here H_0 is the field at the surface of a semi-infinite superconductor. If the field near the surface falls off exponentially, all three definitions of λ[(2.26), (2.19), and (2.20)] coincide.

We shall not attempt here to solve the nonlocal problem explicitly. Rather, we shall show how to find an estimate of the correct answer [4]. Assume that the true dependence $H(x)$

is approximated by an exponential dependence with a new penetration depth denoted by λ_P (Pippard's penetration depth). Then, the vector potential $\boldsymbol{A}$ acts on a particle of size ξ_0 only within the depth $\lambda_P \ll \xi_0$ near the surface of the particle. The result is that, although the particle still participates in creating the current density j_5, the effect of A on it is reduced, because only the part of it λ_P/ξ_0 'feels' the presence of the vector potential. Accordingly, the current density is reduced by a factor

$$j_\mathrm{s} = -\frac{c}{4\pi\lambda^2}\frac{\lambda_\mathrm{P}}{\xi_0}\boldsymbol{A} \tag{2.27}$$

Rewriting (2.27) in the form

$$j_s = -\frac{c}{4\pi\lambda_P^2}A \tag{2.28}$$

we obtain, just as we wished, the exponential penetration of the magnetic field to the depth λ_P. Comparing (2.27) and (2.28), we get $\lambda_\mathrm{P}^2 = \lambda^2\xi_0/\lambda_\mathrm{P}$, which leads to the following estimate for λ_P:

$$\lambda_\mathbf{P} \approx \left(\lambda^2\xi_0\right)^{1/3} \tag{2.29}$$

The quantity λ in (2.29) is defined by (2.7). Then it follows from (2.29) that, in the case $\lambda \ll \xi_0$, we have $\lambda_\mathrm{P} \gg \lambda$, i.e., the nonlocal electrodynamics predicts deeper penetration of the magnetic field than would be expected from the London equations. This statement assumes, of course, that λ_p also satisfies the inequality $\lambda_\mathrm{P} \ll \xi_0$, which is not always the case even for pure metals.

A typical representative of superconductors which are well-described by the nonlocal relations (the so-called Pippard superconductors) is Al. In contrast, Pb, even of high purity, is a London superconductor. When the temperature T approaches T_c, all superconductors become local (London superconductors) because λ diverges at $T \to T_\mathrm{c}$ while ξ_0 is independent of temperature.

Everything said so far applies to pure metals, that is, those characterized by a mean free path $l \gg \xi_0$. If a metal contains a large number of impurities, $l \ll \xi_0$ can occur. We shall refer to such metals as dirty superconductors. Alloys also fall into this category. In very dirty metals, the role of the coherence length is played by the mean free path l. With the help of the microscopic theory, one can show that the magnetic field penetration depth for dirty superconductors is $\lambda_\mathrm{d} \approx \lambda\left(\xi_0/l\right)^{1/2}$ at $l \ll \xi_0$. Thus, superconducting alloys are described well by the local London equations. In the rest of the book we shall use local equations only.

Examples of Nonlocal Electrodynamics of Superconductors

(??? I'll write later)

3.5.5 Propagation of a electric field inside the SC

(this may be done in scope of linear electrodynamics of SC, I'll later write, how it works. See note on ED also about it)

3.5.6 2.4 Quantum Generalization of the London Equations.

2.4.1 Generalized London Equation

It was already mentioned in Chap. I that the elementary carrier of the supercurrent is a pair of electrons called the Cooper pair. All pairs occupy the same energy level, or the same

quantum state, i.e., they form a condensate. The wavefunction of a particle in the condensate can be written in the form
$\Psi(r) = (n_8/2)^{1/2}\, \mathrm{e}^{\mathrm{j}\theta(r)}$, where θ is the phase of the wavefunction. The normalization of $\Psi(r)$ has taken into account that the density of electron pairs is $n_5/2$, where n_5 is the density of the superconducting electrons.

Consider a particle of mass $2m$ and charge $2e$ moving in a magnetic field. Let us show that its momentum can be written as

$$\hbar\nabla\theta = 2mv_\mathrm{s} + \frac{2e}{c}A \tag{2.30}$$

where $\hbar$ is Planck's constant. In the absence of magnetic field, the particle flow density $n_5 v_5/2$ can be written in the form $(\mathrm{i}\,\hbar/4m)\,(\Psi\nabla\Psi^* - \Psi^*\nabla\Psi)$. Substituting here the expression $\Psi(\boldsymbol{r}) = (n_s/2)^{1/2}\,\mathrm{e}^{\mathrm{i}\theta}$, we get $\hbar\nabla\theta = 2mv_s$. Thus the total momentum of a particle moving in a magnetic field, $\hbar\nabla\theta$, is a sum of the momentum $2mv$ and the momentum $(2e/c)A$ due to the magnetic field.

Taking the expression for the supercurrent density in the form

$$j_\mathrm{s} = n_\mathrm{s} e v_\mathrm{s} \tag{2.31}$$

and using (2.7) and (2.18); it is easy to obtain from (2.30) the generalized second London equation:

$$j_\mathrm{s} = \frac{1}{cA}\left(\frac{\Phi_0}{2\pi}\nabla\theta - A\right) \tag{2.32}$$

Here we use the notation $\Phi_0 = \pi\hbar c/e$. The quantity Φ_0 has the dimensions of magnetic flux. Its physical significance will become clear in the following section.

3.5.7 Magnetic Flux Quantization

2.4.2 Magnetic Flux Quantization

We now proceed to a remarkably interesting phenomenon: magnetic flux quantization in superconductors.

Consider a hole through a bulk superconductor, such as shown in Fig. 2.2. At first, the temperature is $T > T_\mathrm{c}$ and the superconductor is in the normal state. Then we apply an external field H_0 parallel to the axis of the cylinder, and lower the temperature so that the specimen goes into the superconducting state. The field is now pushed out of the interior of the superconductor; while in the hole some frozen magnetic flux remains. This flux is produced by the supercurrent generated at the internal surface of the hole. Let us find this frozen magnetic flux.

Consider the contour C inside the superconductor, as in Fig. 2.2, enclosing the hole so that the distance between the contour and the internal surface of the hole is everywhere well in excess of λ. Then at any point of the contour, the supercurrent is $\boldsymbol{j}_\mathrm{s} = 0$ and the path integral of (2.32) along the contour reduces to

$$\frac{\Phi_0}{2\pi}\oint \nabla\theta \cdot \mathrm{d}\boldsymbol{l} = \oint \boldsymbol{A}\cdot\mathrm{d}\boldsymbol{l} \tag{2.33}$$

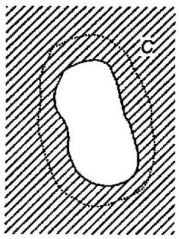

Fig. 2.2. Solid superconductor (dashed area) contains a hole. The contour C goes around the hole through the interior of the superconductor

Taking into account that

$$\oint_C \boldsymbol{A} \cdot \mathrm{d}\boldsymbol{l} = \Phi \tag{2.34}$$

we have

$$\Phi = \frac{\Phi_0}{2\pi} \oint_C \nabla\theta \cdot \mathrm{d}l \tag{2.35}$$

Here Φ is the total magnetic flux through the contour C. From (2.35), one can see immediately that θ is a multiple-valued function; it changes by a certain value after every full circle around the hole. But the wavefunction Ψ must be single-valued. Therefore, we have to stipulate that the change in θ after a full circle around the hole containing the magnetic flux must be an integral multiple of $2\pi n$, where $n = 0, 1, 2 \ldots$. Indeed, the addition of $2\pi n$ to $\theta(\boldsymbol{r})$ does not change the function $\Psi(\boldsymbol{r}) = (n_\mathrm{s}/2)^{1/2}\,\mathrm{e}^{\mathrm{i}\theta}$, because $\mathrm{e}^{\mathrm{i}2\pi n} = 1$. Therefore, $\oint_C \nabla\theta \cdot \mathrm{d}l = 2\pi n$ and (2.35) can finally be written as

$$\Phi = n\Phi_0 \tag{2.36}$$

where

$$\Phi_0 = \frac{\pi\hbar c}{e} = \frac{hc}{2e} \tag{2.37}$$

It follows from (2.36) that the magnetic flux enclosed in the hole (or, more accurately, the magnetic flux through the contour C) can only assume values that are integral multiples of the minimum possible value of magnetic flux, the magnetic flux quanturn Φ_0. The value of Φ_0 is defined by (2.37):

$$\Phi_0 = 2.07 \times 10^{-7}\mathrm{Gcm}^2$$

Physically, the origin of the magnetic flux quantization is the same as the quantization of electron orbits in atom. The wavefunction of electrons moving along a closed orbit must contain an integral number of wavelengths over the

Experimentally, magnetic flux quantization was discovered in 1961 almost simultaneously in the USA (B. Deaver and W. Fairbank) [8] and in Germany (R. Doll and M. Nbauer) [9]. It is interesting to note that F. London, who predicted the flux quantization, believed that the flux quantum should be hc/e, that is, he predicted a value twice as large as Φ_0. But that is not surprising because he believed that the charge of an elementary supercurrent carrier was equal to the electron charge e. Experiment confirmed the validity of (2.37). Thus the experiments that detected the quantization of magnetic flux also provided direct evidence that the supercurrent is carried by pairs of electrons.

3.6 Ginzburg Landau Theory: Basics

3.6.1 General GL philosophy of phase transitions

(discuss why in general we can view phase transitions this way? and how it is exactly?)

3.1 Introduction to GL by Shmidt

The London theory (Chap. 2) did not take into account quantum effects. The first quantum (phenomenological) theory of superconductivity was the Ginzburg-Landau (GL) theory [23].

A quantum theory should take into account, firstly, that the superconducting state is more ordered than the normal one and, secondly, that the transition from one state to the other (without magnetic field) is a secondorder phase transition. This implies the existence of an order parameter for a superconductor, which is nonzero at $T < T_c$ and vanishes at $T \geq T_c$. At the same time, in order to develop a quantum theory, it is necessary to introduce an effective wavefunction of the superconducting electrons, $\Psi(r)$.

Ginzburg and Landau decided to combine the two prerequisites: they decided to consider $\Psi(r)$ as an order parameter. This step required great scientific courage and deep physical intuition.

The GL theory is based on the theory of second-order phase transitions developed by Landau [24]. According to this theory, a phase transition of second order occurs when the state of a body changes gradually while its symmetry changes discontinuously at the transition temperature. Furthermore, the low-temperature phase is the one of reduced symmetry, i.e., it is more ordered. Such phenomena as the ferromagnetic transition at the Curie point, the transition of helium to the superfluid state, a number of orderdisorder transitions in alloys, and the superconducting transition all fall into the category of second-order phase transitions.

Let us explain how a gradual change of the state of a body can be accompanied by a discontinuous change of its symmetry. It becomes apparent from the following example of a structural transition leading to a more ordered state. Consider a linear chain of atoms of two different types: A and B. Assume that at a sufficiently high temperature the probabilities that the atoms of type A and type B occupy one of the sites in the chain are equal (this state corresponds to complete disorder, as in Fig. 3.1 (a)). At lower temperatures, $T < T_c$, the probability that the atoms of type A occupy the various sites in the chain is sketched in Fig. 3.1 (b). Now the arrangement of the atoms is
η appeared and gradually started to increase, while the period of the structure, which was a above T_c, underwent a discontinuous change at $T = T_c$ and became $2a$.

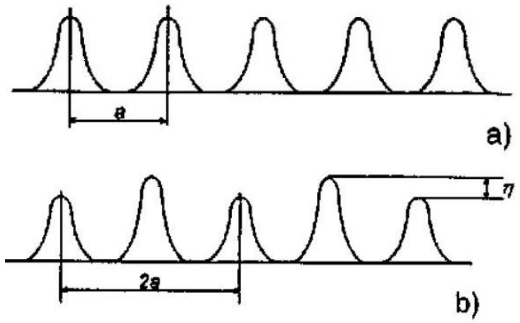

Fig. 3.1. Illustration of the discontinuous symmetry change in a structural phase transition of second order; (a) probability of finding an atom of type A at a given point of the crystal at $T > T_c$; (b) the same at $T < T_c$

Let us now go back to superconductivity. The Landau theory of second order phase transitions is based on an expansion of the free energy in powers of the order parameter, which is

small near the transition temperature. Such a starting point for the theory implies that it is valid only at temperatures close to the critical temperature, $T_c - T \ll T_c$. The range of validity of the GL theory will be discussed in more detail in Sect.6.6.

Let us assume that the wavefunction of superconducting electrons $\Psi(r)$ is the order parameter. In addition, let us choose normalization of this wavefunction such that $|\Psi(r)|^2$ gives the density of Cooper pairs:

$$|\Psi(r)|^2 = n_3/2 \tag{3.1}$$

Consider first the simplest case: a homogeneous superconductor without external magnetic field. In this case Ψ does not depend on r and the expansion of the free energy in powers of $|\Psi|^2$ near T_c becomes

$$F_{50} = F_n + \alpha|\Psi|^2 + \frac{\beta}{2}|\Psi|^4. \tag{3.2}$$

Here F_{s0} is the free energy density of the superconductor in the absence of magnetic field, F_n is its free energy density in the normal state and α and β are some phenomenological expansion coefficients which are characteristics of the material.

Let us find the value of $|\Psi|^2$ for which the free energy of a homogeneous superconductor, F_{s0}, is a minimum. This value, $|\Psi_0|^2$, is the solution of the equation

$$\frac{dF_{50}}{d|\Psi|^2} = 0$$

Substituting here (3.2) and carrying out elementary calculations we obtain

$$|\Psi_0|^2 = -\alpha/\beta. \tag{3.3}$$

$$F_n - F_{B0} = \alpha^2/2\beta \tag{3.4}$$

Recalling that, from (1.12), this difference equals $H_{cm}^2/8\pi$, we have

$$H_{cm}^2 = 4\pi\alpha^2/\beta \tag{3.5}$$

Let us discuss the temperature dependence of the coefficients α and β. Since the order parameter must be zero at $T = T_c$ and finite at $T < T_c$, it follows from (3.3) that $\alpha = 0$ at $T = T_c$ and $\alpha < 0$ at $T < T_c$. Therefore we can write, to first order in $(T_c - T)$,

$$\alpha \propto (T - T_c)\,. \tag{3.6}$$

This temperature dependence of α correlates (3.5) with the empirical formula (1.1) near T_c.

The coefficient β is positive and independent of temperature. Indeed, as follows from (3.3), at $T < T_c$ and $\alpha < 0, |\Psi_0|^2$ can be positive only if $\beta > 0$. On the other hand, if $T > T_c$ (and consequently, from (3.6), $\alpha > 0$) and $\beta > 0$, the energy F_{50} reaches its minimum at $|\Psi_0|^2 = 0$. This means that there is no superconducting state at $T > T_c$ as indeed ought to be the case. Thus we have $\beta > 0$ both at $T < T_c$ and at $T > T_c$. Therefore, to a first approximation in $(T_c - T)$, we may assume $\beta = \text{const}$.

Discussion of possible terms in the GL functional

(discuss why there are also exotic models with φ^3 and so on)

Seeing the Phase Transitions in the GL functional

Применим теорию среднего поля к сверхпроводящему переходу в присутствии магнитного поля. Вблизи температуры перехода Ψ и $\nabla\Psi$ малы, и Ω - потенциал, как обычно, может быть разложен в ряд. Нужно только учесть два обстоятельства. Во-первых, следует добавить кинетическую энергию сверхпроводящих электронов; плотность кинетической энергии в квантовой механике может быть представлена как $|(-i\hbar\nabla - e\mathcal{A}/c)\Psi|^2/2m$. Во-вторых, следует добавить энергию магнитного поля; ее плотность равна $\mathcal{B}^2/8\pi$. В общем случае $\Psi(\mathbf{r})$ и $\mathcal{A}(\mathbf{r})$ распределения по образцу неоднородны, и Ω-потенциал становится функционалом $\Omega_s = \Omega_s[\Psi(\mathbf{r}), \mathcal{A}(\mathbf{r})]$. Итак,

$$\Omega_s[\Psi(\mathbf{r}), \mathcal{A}(\mathbf{r})] = \Omega_n + \int \left[\alpha|\Psi|^2 + \frac{b}{2}|\Psi|^4 + \frac{1}{4m}\left| -i\hbar\nabla\Psi - \frac{2e}{c}\mathcal{A}\Psi \right|^2 + \frac{(\nabla\times\mathcal{A})^2}{8\pi} \right] dV.$$

Здесь, как обычно, $\alpha = a\,(T - T_c)\,, a$ и b положительны и мы заранее учли, что носителями заряда являются куперовские пары с $m \to 2m, e \to 2e$. Здесь и далее мы полагаем $e = -|e|$.

В однородном случае $\Psi(\mathbf{r}) = \text{const}$ в отсутствии поля внутри образца ($\mathcal{B} = 0$) функционал (12.2) превращается в обычную функцию. Минимизация этой функции, Ω-потенциала, как и ранее (см. лекцию 10), даёт

$$|\Psi_0|^2 = \begin{cases} -\frac{a(T-T_c)}{b}, & T < T_c \\ 0, & T > T_c \end{cases}$$

Это позволяет найти концентрацию сверхпроводящих электронов $|\Psi_0|^2 = n_s/2$. Например, при нулевой температуре $n_s = n$ получаем оценку

$$n_s = 2aT_c/b$$

Далее, «выигрыш» в энергии сверхпроводящей фазы в отсутствии внешнего поля $\Omega_n - \Omega_s(\mathcal{H} = 0) = V\alpha^2/2b$ может быть скомпенсирован «проигрышем» энергии из-за помещения образца во внешнее магнитное поле $\Omega_s(\mathcal{H}) - \Omega_s(\mathcal{H} = 0) = V\mathcal{H}^2/8\pi$. Действительно, поскольку в силу эффекта Мейсснера $\mathcal{B} = 0$ сверхпроводник - идеальный диамагнетик $\mathcal{M} = -\mathcal{H}/4\pi$, то плотность его дополнительной энергияи из-за поля равна $-V\int_0^{\mathcal{H}} \mathcal{M}d\mathcal{H} = \mathcal{H}^2/8\pi$. Это дает величину термодинамического критического поля:

$$\mathcal{H}_c^2 = \frac{4\pi a^2\,(T - T_c)^2}{b}.$$

И, наконец, выигрыш энергии сверхпроводящей фазы (например, в отсутствии поля) мы можем рассматривать как энергию конденсации куперовских пар. Поскольку энергия пары 2Δ, а образуются они из электронов, расположенных в слое толщиной $\Delta \ll \varepsilon_F$ вблизи энергии Ферми ε_F, то $\alpha^2/2b = 2\Delta^2 n/\varepsilon_F$. Здесь явно предполагается, что при $T = 0$ все электроны сверхпроводящие $n_s = n$ (см. лекцию 12). Это позволяет при нулевой температуре получить еще одно соотношение между коэффициентами функционала (13.2) a и b:

$$a^2/b = 4\Delta_0^2 n/\varepsilon_F T_c^2 \approx n/\varepsilon_F$$

Таким образом, из (13.4) и (13.6) получаем выражения для коэффициентов разложения (13.2) $a \approx T_c/\varepsilon_F$ и $b \approx T_c^2/n\varepsilon_F$ через микроскопические параметры сверхпроводника.

How to chose an order parameter of a superconductor?

(??? here, discuss how it is related to wave function of a condensate)

(write that this idea is also telling us that there exist a some gap, which will be introduced later. this is a non-trivial statement that it exist.)

3.6.2 3.2 Equations of the Ginzburg-Landau Theory

3.2.1 Free Energy Density

Let us now go over to the general case of an inhomogeneous superconductor in a uniform external magnetic field.

Near T_c, the Gibbs free energy can be expanded in powers of Ψ as

$$G_{sH} = G_n + \alpha|\Psi|^2 + \frac{\beta}{2}|\Psi|^4 + \frac{1}{2m^*}\left|-i\hbar\nabla\Psi - \frac{2e}{c}A\Psi\right|^2 + \frac{H^2}{8\pi} - \frac{\boldsymbol{H}\cdot\boldsymbol{H}_0}{4\pi} \tag{3.7}$$

where G_n is the free energy density of a superconductor in the normal state and $\boldsymbol{H}_0$ is the external magnetic field. The last but one term in (3.7) simply represents the magnetic energy density, where H is the exact microscopic field at a given point of the superconductor. The term before that is the kinetic energy density of the superconducting electrons. Let us analyze the latter in more detail.

In quantum mechanics, the kinetic energy density of a particle of mass m is

$$\frac{1}{2m}|-i\hbar\nabla\Psi|^2$$

operator $-i\hbar\nabla$ in the expression for the kinetic energy density has to be modified:

$$-i\hbar\nabla \to -i\hbar\nabla - \tfrac{e}{c}\boldsymbol{A} = mv$$

Therefore, the velocity operator is

$$v = -(i\hbar/m)\nabla - (e/cm)\boldsymbol{A}$$

Since it is the velocity v that enters the expression for the kinetic energy density, we can now understand why the corresponding term in (3.7) looks as it does. It should only be added that a substitution $e \to 2e$ has been made in (3.7) which takes into account that the elementary charge carrier of the supercurrent is $2e$. Accordingly, m^* in (3.7) is twice the electron mass.

Parameters of GL functional

(?? maybe I'll add several other derivations)

Let's discuss the coefficients in

$$\Omega_s[\Psi(\mathbf{r}), \mathcal{A}(\mathbf{r})] = \Omega_n + \int\left[\alpha|\Psi|^2 + \frac{b}{2}|\Psi|^4 + \frac{1}{4m}\left|-i\hbar\nabla\Psi - \frac{2e}{c}\mathcal{A}\Psi\right|^2 + \frac{(\nabla\times\mathcal{A})^2}{8\pi}\right]dV.$$

Derivation 1

И, наконец, выигрыш энергии сверхпроводящей фазы (например, в отсутствии поля) мы можем рассматривать как энергию конденсации куперовских пар. Поскольку энергия пары 2Δ, а образуются они из электронов, расположенных в слое толщиной $\Delta \ll \varepsilon_F$ вблизи энергии Ферми ε_F, то $\alpha^2/2b = 2\Delta^2 n/\varepsilon_F$. Здесь явно предполагается, что при $T = 0$ все электроны сверхпроводящие $n_s = n$ (см. лекцию 12). Это позволяет при нулевой температуре получить еще одно соотношение между коэффициентами функционала (13.2) a и b:

$$a^2/b = 4\Delta_0^2 n/\varepsilon_F T_c^2 \approx n/\varepsilon_F$$

Таким образом, из (13.4) и (13.6) получаем выражения для коэффициентов разложения (13.2) $a \approx T_c/\varepsilon_F$ и $b \approx T_c^2/n\varepsilon_F$ через микроскопические параметры сверхпроводника.

Derivation 2

Коэффициенты a и b уже оценивались в параграфе 3. Проделаем это еще раз, другим способом. Соотношения $a \approx T_c/\varepsilon_F$ и $b \approx T_c^2/n\varepsilon_F$ получаются, если воспользоваться формулами (13.4) и (13.15) при $T = 0$. В последнюю нужно подставить размер куперовской пары ξ_0, полученный из соотношения неопределенностей $\xi_0 \cdot \delta p \sim \hbar$, связывающего его с неопределенностью импульса $v_F \cdot \delta p \sim \Delta_0$. При этом следует учесть, что $\Delta_0 \approx T_c$ и $\varepsilon_F \sim m v_F^2 \sim \hbar^2 n_s^{2/3}/m$. Соотношение $c = \hbar^2/4m$ следует из сравнения функционалов (10.31) и (13.2).

3.2.2 Derivation of Ginzburg-Landau (GL) Equations from free energy

Derivation of the first equation

By (3.7), the Gibbs free energy of a superconductor as a whole is

$$\mathcal{G}_{sH} = \mathcal{G}_n + \int \left[\alpha|\Psi|^2 + \frac{\beta}{2}|\Psi|^4 + \frac{1}{4m}\left| -i\hbar\nabla\Psi - \frac{2e}{c}\boldsymbol{A}\Psi \right|^2 + \frac{(\operatorname{curl}\boldsymbol{A})^2}{8\pi} - \frac{(\operatorname{curl}\boldsymbol{A})\cdot\boldsymbol{H}_0}{4\pi} \right] \mathrm{d}V \tag{3.8}$$

where the integration is carried out over the entire volume of the superconductor. Our task now is to find equations for the functions $\Psi(r)$ and $A(r)$ such that their solutions, when substituted in (3.8), give the minimum value of $\mathcal{G}_{sH}$.

In order to do that we shall first assume that $\Psi(\boldsymbol{r})$ and $\boldsymbol{A}(\boldsymbol{r})$ are invariant and then solve the variational problem with respect to $\Psi^*(r)$:

$$\delta_{\Psi^*}\mathcal{G}_{\delta H} = 0 \tag{3.9}$$

$$\delta_{\Psi^*}\mathcal{G}_{sH} = \int \mathrm{d}V \left[\alpha\Psi\delta\Psi^* + \beta\Psi|\Psi|^2\delta\Psi^* + \frac{1}{4m}\left(i\hbar\nabla\delta\Psi^* - \frac{2e}{c}\boldsymbol{A}\delta\Psi^* \right)\cdot\left(-i\hbar\nabla\Psi - \frac{2e}{c}\boldsymbol{A}\Psi \right) \right] \tag{3.10}$$

The term $\delta\Psi^*$ could be taken out of the square brackets but for the term $i\hbar\nabla\delta\Psi^*$. Let us make some modifications. We write

$$\varphi = \left(-\mathrm{i}\hbar\nabla\Psi - \frac{2e}{c}A\Psi\right)$$

Using the identity

$$\nabla\left(\delta\Psi^*\varphi\right) = \varphi\nabla\delta\Psi^* + \delta\Psi^*\nabla\varphi$$

$$\int \mathrm{d}V\nabla\delta\Psi^*\varphi = -\int \delta\Psi^*\nabla\varphi\ \mathrm{d}V + \int \nabla\left(\delta\Psi^*\varphi\right)\mathrm{d}V \tag{3.11}$$

By Gauss's theorem, the last integral in (3.11) can be converted into a surface integral:

$$\int \nabla\left(\delta\Psi^*\varphi\right)\mathrm{d}V = \oint_S \delta\Psi^*\varphi\ \mathrm{d}S$$

Substituting (3.11) into (3.10) and (3.10) into (3.9), we obtain

$$\delta_{\Psi^*}\mathcal{G}_{\mathrm{s}H} = \int \mathrm{d}V\left[\alpha\Psi + \beta\Psi|\Psi|^2 + \frac{1}{4m}\left(-\mathrm{i}\hbar\nabla - \frac{2e}{c}\boldsymbol{A}\right)^2\Psi\right]\delta\Psi^* + \oint_S\left[-\mathrm{i}\hbar\nabla\Psi - \frac{2e}{c}A\Psi\right]\delta\Psi^*\ \mathrm{d}S = 0$$

For an arbitrary function $\delta\Psi^*$, this expression can be zero only if both expressions in square brackets are zero. From this requirement we obtain the first equation of the GL theory and its boundary condition:

$$\alpha\Psi + \beta\Psi|\Psi|^2 + \frac{1}{4m}\left(\mathrm{i}\hbar\nabla + \frac{2e}{c}\boldsymbol{A}\right)^2\Psi = 0 \tag{3.12}$$

$$\left(\mathrm{i}\hbar\nabla\Psi + \frac{2e}{c}A\Psi\right)\cdot n = 0$$

where n is the unit vector normal to the surface of the superconductor. One can easily verify that minimization of $\mathcal{G}_{\mathrm{B}H}$ with respect to Ψ leads to the complex-conjugate of (3.12). Thus, we have obtained the equation for the order parameter Ψ.

Derivation of the second equation

One variable still remains: $\boldsymbol{A}$. In order to obtain the equation for A, we shall minimize the expression for $\mathcal{G}_{sH}$ (3.8) with respect to A:

$$\begin{aligned}\delta_A\mathcal{G}_{sH} = \int \mathrm{d}V\Bigg\{\frac{1}{4m}\delta_{\boldsymbol{A}}\left[\left(\mathrm{i}\hbar\nabla\Psi^* - \frac{2e}{c}\boldsymbol{A}\Psi^*\right)\cdot\left(-\mathrm{i}\hbar\nabla\Psi - {}^{2e}_{c}\boldsymbol{A}\Psi\right)\right] + \\ + \frac{1}{4\pi}\operatorname{curl}\boldsymbol{A}\cdot\operatorname{curl}\delta\boldsymbol{A} - \frac{\boldsymbol{H}_0}{4\pi}\cdot\operatorname{curl}\delta\boldsymbol{A}\Bigg\} = \\ = \int\Bigg\{\frac{1}{4m}\left(-\frac{2e}{c}\Psi^*\delta\boldsymbol{A}\right)\cdot\left(-\mathrm{i}\hbar\nabla\Psi - \frac{2e}{c}\boldsymbol{A}\Psi\right) + \\ + \frac{1}{4m}\left(\mathrm{i}\hbar\nabla\Psi^* - \frac{2e}{c}\boldsymbol{A}\Psi^*\right)\cdot\left(-\frac{2e}{c}\Psi\delta\boldsymbol{A}\right) + \frac{1}{4\pi}\left(\operatorname{curl}\boldsymbol{A} - \boldsymbol{H}_0\right)\cdot\operatorname{curl}\delta\boldsymbol{A}\Bigg\}\mathrm{d}V\end{aligned} \tag{3.13}$$

One notices that δA in (3.13) could be taken out of the brackets but for the term $(1/4\pi)\left(\operatorname{curl}\boldsymbol{A} - \boldsymbol{H}_0\right)\cdot\operatorname{curl}\delta\boldsymbol{A}$. Using the identity

(??? restore it from rus version)
we can carry out the integration in the last term of (3.13):

$$\frac{1}{4\pi}\int \mathrm{d}V\,(\operatorname{curl}\boldsymbol{A}-\boldsymbol{H}_0)\cdot\operatorname{curl}\delta\boldsymbol{A}=\frac{1}{4\pi}\int \mathrm{d}V\delta\boldsymbol{A}\cdot\operatorname{curl}\operatorname{curl}\boldsymbol{A}-\frac{1}{4\pi}\oint \mathrm{d}\boldsymbol{S}\cdot[\delta\boldsymbol{A}\times(\operatorname{curl}\boldsymbol{A}-\boldsymbol{H}_0)] \tag{3.15}$$

When doing so we have used Gauss's theorem to convert the volume integral into a surface integral:

$$\int \mathrm{d}V\,\operatorname{div}[\delta\boldsymbol{A}\times(\operatorname{curl}\boldsymbol{A}-\boldsymbol{H}_0)]=\oint \mathrm{d}\boldsymbol{S}\cdot[\delta\boldsymbol{A}\times(\operatorname{curl}\boldsymbol{A}-\boldsymbol{H}_0)]\,.$$

The surface integral is zero because the magnetic field at the surface of the superconductor is fixed; hence $\delta\boldsymbol{A}|_S=0$.

Substituting now (3.15), without the last term, into (3.13) and equating the free energy variation to zero, we get, after elementary modifications,

$$\delta_A\mathcal{G}_{\mathrm{s}H}=\int\left[\frac{i\hbar e}{2mc}\left(\Psi^*\nabla\Psi-\Psi\nabla\Psi^*\right)+\frac{2e^2}{mc^2}\boldsymbol{A}|\Psi|^2+\frac{1}{4\pi}\operatorname{curlcurl}\boldsymbol{A}\right]\cdot\delta\boldsymbol{A}\mathrm{d}V=0 \tag{3.16}$$

For arbitrary δA, the integral in (3.16) can be zero only if the expression in square brackets is zero. This condition determines the second equation of the GL theory, for the vector potential $\boldsymbol{A}$:

$$j_{\mathrm{s}}=-\frac{i\hbar e}{2m}\left(\Psi^*\nabla\Psi-\Psi\nabla\Psi^*\right)-\frac{2e^2}{mc}|\Psi|^2A \tag{3.17}$$

where, by Maxwell's equation, the current density $\boldsymbol{j}_{\mathrm{s}}$ in the superconductor is

$$j_{\mathrm{s}}=\frac{c}{4\pi}\operatorname{curlcurl}A,\quad H=\operatorname{curl}A \tag{3.18}$$

Let us go over to a dimensionless wavefunction $\psi(r)$ by setting

$$\psi(\boldsymbol{r})=\Psi(\boldsymbol{r})/\Psi_0 \tag{3.19}$$

where ${\Psi_0}^2=n_{\mathrm{s}}/2=|\alpha|/\beta$. In addition, we introduce two more definitions:

$$\xi^2=\frac{\hbar^2}{4m|\alpha|} \tag{3.20}$$

$$\lambda^2=\frac{mc^2}{4\pi n_s e^2}=\frac{mc^2\beta}{8\pi e^2|\alpha|} \tag{3.21}$$

Now the GL equations can be written in a more concise and convenient form:

$$\xi^2\left(\mathrm{i}\nabla+\frac{2\pi}{\Phi_0}\boldsymbol{A}\right)^2\psi-\psi+\psi|\psi|^2=0 \tag{3.22}$$

$$\operatorname{curl}\operatorname{curl}\boldsymbol{A}=-\mathrm{i}\frac{\Phi_0}{4\pi\lambda^2}\left(\psi^*\nabla\psi-\psi\nabla\psi^*\right)-\frac{|\psi|^2}{\lambda^2}\boldsymbol{A} \tag{3.23}$$

Furthermore, if ψ is written as $\psi=|\psi|\mathrm{e}^{i\theta}$, the second GL equation becomes

$$\operatorname{curl}\operatorname{curl}\boldsymbol{A} = \frac{|\psi|^2}{\lambda^2}\left(\frac{\Phi_0}{2\pi}\nabla\theta - \boldsymbol{A}\right) \tag{3.24}$$

From (3.12) we obtain a boundary condition for ψ. If the superconductor has an interface with vacuum or an insulator, the condition will be

$$\left(\mathrm{i}\nabla + \frac{2\pi}{\Phi_0}\boldsymbol{A}\right)\cdot n\psi = 0 \tag{3.25}$$

where n in the unit vector normal to the surface of the superconductor. It is easy with the help of (3.17) to verify that (3.25) satisfies a very natural physical requirement, that is, it assures that no supercurrent passes through the superconductor-dielectric interface. However, the same requirement (that the normal component of the supercurrent through the interface is zero) will also be satisfied if a more general condition is imposed:

$$\left(\mathrm{i}\nabla + \frac{2\pi}{\Phi_0}A\right)\cdot n\psi = \mathrm{i}a\psi \tag{3.26}$$

where a is an arbitrary real number. With the help of the microscopic theory of superconductivity one can show that (3.26) is appropriate for the interface between a superconductor and a normal metal.

3.2.3 Gauge Invariance of the GL Theory

The GL equations contain the vector potential $\boldsymbol{A}$. But it is well-known that the choice of $\boldsymbol{A}$ is not unique. Indeed, the transformation

$$A = A' + \nabla\varphi, \tag{3.27}$$

where $\varphi(\boldsymbol{r})$ is a single-valued scalar function, does not change the magnetic field:

$$\boldsymbol{H} = \operatorname{curl}\boldsymbol{A} = \operatorname{curl}\boldsymbol{A'}$$

because

$$\operatorname{curl}\nabla\varphi = 0$$

To ensure that the theoretical results are independent of the choice of the vector potential, or, in other words, that they are gauge invariant, one has to impose the condition that the GL equations themselves are gauge invariant.

It is easy to verify that this condition is satisfied if we use the following transformations to go from the variables $\boldsymbol{A}$ and ψ to variables $\boldsymbol{A'}$ and ψ':

$$A = A' + \nabla\varphi \tag{3.28}$$

$$\psi = \psi' \exp\left[\mathrm{i}\frac{2\pi}{\Phi_0}\varphi(r)\right] \tag{3.29}$$

Let us verify this for (3.24). We proceed from $\boldsymbol{A}$ and ψ to $\boldsymbol{A'}$ and ψ' following (3.28) and (3.29). Then we see immediately that the second GL equation remains unaffected:

$$\operatorname{curl}\operatorname{curl}\boldsymbol{A'} = \frac{|\psi'|^2}{\lambda^2}\left(\frac{\Phi_0}{2\pi}\nabla\theta' - \boldsymbol{A'}\right)$$

Similarly, one can verify the gauge invariance of the first GL equation (3.22).
The gauge invariance of the GL equations implies a conclusion which is very important for our future discussions: For a simply connected superconductor, it is always possible to choose a gauge for the vector potential $\boldsymbol{A}$ such that the function $\psi(\boldsymbol{r})$ is real. (Recall that a simply connected body is a body in the interior of which an arbitrary closed contour can be reduced to a point without having to cross the boundaries of the body. In other words, there are no unbroken holes in a simply connected body. A toroid is an example of a doubly connected body.)

The requirement that a superconductor be simply connected is essential because, in a multiply connected superconductor, the phase of the order parameter, θ, is no longer a single-valued function. On going around a cavity in a multiply connected superconductor, the phase can vary by an integral multiple of 2π. Therefore, $\theta(r)$ becomes unsuitable as the corresponding gauge for $\boldsymbol{A}$.

Ginzburg-Landau Theory

So far in our thermodynamic discussions we have treated the Gibbs function of the system in an integrated way, such that spatial variations of the superconducting state did not appear explicitly. Furthermore, we have not yet utilized the fact that the superconducting state can be described in terms of a macroscopic wave function with a well-defined phase.

Both aspects were incorporated by Ginzburg and Landau into their theory published in 1950. This theory represents an important extension of the London theory [20], in which a spatially constant density of the superconducting charge carriers was assumed. Surprisingly, for a long time, the Ginzburg-Landau theory did not receive the proper attention. It was only after the development of a microscopic theory that the importance of this extended phenomenological theory was generally recognized. Only gradually it has become clear that the theory accounts for important physical properties of the superconducting state. It was shown by Gor'kov that for temperatures near T_c the theory can be derived from the BCS theory [21]. One of the great successes of the theory was the prediction of the vortex state by Abrikosov [22]. Often the theory is now referred to as GLAG theory after the four scientists Ginzburg, Landau, Abrikosov, and Gor'kov. In 2003, A. A. Abrikosov and V. L. Ginzburg together with A. J. Leggett received the Nobel Prize in physics for the development of the theory of superconductivity and superfluidity.

The GLAG theory starts from the argument that in the normal superconducting transition in the absence of a magnetic field, we are dealing with a secondorder phase transition (see Section 4.1). Landau had developed a theory exactly for such phase transitions. In the theory a parameter, the so-called order parameter, was defined, which in the new phase (here the superconducting phase) should increase continuously from zero at T_c up to the value 1 at $T = 0$. To describe the superconducting state, Ginzburg and Landau introduced a function $\Psi(\mathbf{r})$ as the order parameter. The quantity $|\Psi(\mathbf{r})|^2$ can be interpreted as the density of the superconducting charge carriers. Since in the superconducting state $|\Psi(\mathbf{r})|^2$ must approach zero continuously for $T \to T_\mathrm{c}$, near T_c we can expand the Gibbs function g_s of the superconducting phase in a Taylor series of the density $|\Psi(\mathbf{r})|^2$. Then we obtain

$$g_\mathrm{s} = g_\mathrm{n} + \alpha|\Psi|^2 + \frac{1}{2}\beta|\Psi|^4 + \cdots$$

Here, the Gibbs function g_n of the normal conducting phase appears, since for $\Psi = 0$ the Gibbs function g_s must be equal to g_n. Since for $T < T_\mathrm{c}$ we also have $g_\mathrm{s} < g_\mathrm{n}$ (stability criterion), we find $\alpha < 0$.

Sufficiently close to T_c an approximation that includes only the first two terms of the series is satisfactory, that is, one that cuts off the series after the $|\Psi|^4$ term. For temperatures close to the transition temperature, very general statements about the sign of the coefficients α and β are possible:

The coefficient β must be positive, otherwise a very large value of $|\Psi|$ would always lead to a value of g_s that is smaller than g_n. The "minimum" of g_s would only be reached for $|\Psi| \to \infty$.

For $T < T_c$, the coefficient α must be negative, otherwise g_s would always be larger than g_n, since β is positive.

For $T > T_c, \alpha$ must be positive. In this regime the normal state should have the smaller value of the Gibbs function, leading to $|\Psi| = 0$ as the most favorable solution.

Therefore, for temperatures close to T_c, the coefficients α and β can also be expanded in Taylor series of the temperature. Here, we include only the first nonvanishing coefficient. For α, we can write

$$\alpha(T) = \alpha(0)\left(\frac{T}{T_c} - 1\right)$$

However, the coefficient β can be taken as constant:

$$\beta(T) = \beta = \text{ const.}$$

The rather abstract expansion coefficients α and β can now be connected in a simple way with the so-called "thermodynamic critical field" B_{cth} and with the equilibrium density n_s in zero field. In the following, we will deal with B_{cth} many times. If we denote the equilibrium value of Ψ sufficiently far away from any interface by Ψ_∞, then we have the relation $n_s = |\Psi_\infty|^2$. We introduce the magnetic field B_{cth} based on the difference $g_n - g_s$:

$$g_n - g_s = -\alpha |\Psi_\infty|^2 - \frac{1}{2}\beta |\Psi_\infty|^4 = \frac{1}{2\mu_0} B_{cth}^2$$

In Section 4.6.1 we will see that for a type-I superconductor under certain conditions B_{cth} exactly corresponds to the critical field B_c.

We denote the Gibbs function by the letter g to indicate that it is an energy density. Since the equiminimum, one should use the terminology of energy functional. However, for simplicity in the following we continue to denote g as Gibbs function.

One obtains an additional equation for α and β from the fact that at equilibrium $g_s\left(|\Psi_\infty|^2\right)$ reaches a minimum. For the equilibrium value $|\Psi_\infty|^2$, we must have also $dg_s/\mathrm{d}|\Psi|^2 = 0$. Tis yields

$$\alpha + \beta |\Psi_\infty|^2 = 0$$

From this we obtain

$$n_s = |\Psi_\infty|^2 = -\frac{\alpha}{\beta}$$

and from Eq. (4.21) we find

$$B_{cth}^2 = \mu_0 \frac{\alpha^2}{\beta}$$

From the temperature dependences of Eqs. (4.20a) and (4.20b) for α and β, we see immediately that, near T_c, n_s and B_{cth} are proportional to $(1 - T/T_c)$, that is, for $T \to T_c$ they linearly approach zero. So we have [144]

$$n_\mathrm{s}(T) = n_\mathrm{s}(0)\,(1 - T/T_\mathrm{c}) \qquad \text{and} \qquad B_\mathrm{cth}(T) = B_\mathrm{cth}(0)\,(1 - T/T_\mathrm{c})$$

By solving for α and β, we find

$$\alpha = -\frac{1}{\mu_0}\frac{\beta_\mathrm{cth}^2}{n_\mathrm{s}}$$
$$\beta = -\frac{1}{\mu_0}\frac{\beta_\mathrm{cth}^2}{n_\mathrm{s}^2}$$

Now we can see directly that a second-order phase transition is described by Eq. (4.19) or (4.21):

For $T = T_\mathrm{c}$ we have $g_\mathrm{s} = g_\mathrm{n}$, since $|\Psi| = 0$.

The derivative $\partial g_\mathrm{s}/\partial T$ is

$$\frac{\partial g_\mathrm{s}}{\partial T} = \frac{\partial g_\mathrm{n}}{\partial T} - \frac{B_\mathrm{cth}}{\mu_0}\frac{\partial B_\mathrm{cth}}{\partial T} = \frac{\partial g_\mathrm{n}}{\partial T} + \frac{B_\mathrm{cth}^2(0)}{\mu_0}\left(1 - \frac{T}{T_\mathrm{c}}\right)\frac{1}{T_\mathrm{c}}$$

At T_c the second-term vanishes, that is, $\partial g/\partial T$ passes through T_c continuously - For the second derivative $\partial^2 g_\mathrm{s}/\partial T^2$, one finds

$$\frac{\partial^2 g_\mathrm{s}}{\partial T^2} = \frac{\partial^2 g_\mathrm{n}}{\partial T^2} - \frac{B_\mathrm{cth}^2(0)}{\mu_0}\frac{1}{T_\mathrm{c}^2}$$

We see that $\partial^2 g/\partial T^2$ jumps by the amount $B_\mathrm{cth}^2(0)/\left(\mu_0 T_\mathrm{c}^2\right)$, as it must for a second-order phase transition.

We note that we can also describe a first-order phase transition in a similar way. In this case we must supplement the series expansion in Eq. (4.19) by a term $|\Psi|^6$, and a negative sign of β must be allowed.

Note that these expressions are valid only near T_c. The crucial extension of the phenomenological description is achieved by the ansatz of the Gibbs function of the superconductor in a magnetic field under the assumption of a possible spatial variation of Ψ. Hence, one uses the ansatz

$$g_s(B) = g_\mathrm{n} + \alpha|\Psi|^2 + \frac{1}{2}\beta|\Psi|^4 + \frac{1}{2\mu_0}\left|\mathbf{B}_\mathrm{a} - \mathbf{B}_\mathrm{i}\right|^2 + \frac{1}{2m}\left|\left(\frac{\hbar}{i}\nabla - q\mathbf{A}\right)\Psi\right|^2$$

where m and q are the mass and charge, respectively, of the particles described by Ψ, that is, $m = 2m_\mathrm{e}$ and $|q| = 2e$ for Cooper pairs, and ∇ is a differential operator namely the gradient

$$\nabla\Psi = \mathrm{grad}\,\Psi = \frac{\partial\Psi}{\partial x}\mathbf{e}_x + \frac{\partial\Psi}{\partial y}\mathbf{e}_y + \frac{\partial\Psi}{\partial z}\mathbf{e}_z$$

operating on the function Ψ

We see that two additional terms appear. The first term refers to the energy needed to change the magnetic field from $\mathbf{B_a}$, the external field in the absence of the superconductor, to the value $\mathbf{B}_\mathrm{i}$. For the Meissner phase with $\mathbf{B}_i = 0$, this term yields the total energy to be supplied for the magnetic field expulsion. The second term takes into account a possible spatial variation of $\mathbf{B}_\mathrm{i}$ and Ψ within the superconductor. It includes the supercurrents leading to a variation of the magnetic field. Furthermore, it contains the energy needed to establish a spatial variation of the Cooper pair density. This contribution introduces a "stiffness" of the wave function, which gains importance at the phase boundary between the superconducting and normal conducting phases. We note that this second term is constructed quite analogously to the expression in the Schrödinger equation of the kinetic energy of a particle with mass m and charge q.

One obtains the Gibbs function for the total superconducting sample from an integration of Eq. (4.26) over the volume V of the sample:

$$\int_V \left\{ g_\mathrm{n} + \alpha|\Psi|^2 + \frac{1}{2}\beta|\Psi|^4 + \frac{1}{2\mu_0}\left|\mathbf{B}_\mathrm{a} - \mathbf{B}_\mathrm{i}\right|^2 + \frac{1}{2m}\left|\left(\frac{\hbar}{i}\nabla - q\mathbf{A}\right)\Psi\right|^2 \right\} \cdot \mathrm{d}V \quad (4.27)$$

This function G_s must be minimized by the variation of Ψ and A. The variation then yields the two equations of the Ginzburg-Landau theory:

$$\frac{1}{2m}\left(\frac{\hbar}{i}\nabla - q\mathbf{A}\right)^2 \Psi + \alpha\Psi + \beta|\Psi|^2\Psi = 0$$

$$\mathbf{j}_\mathrm{s} = \frac{q\hbar}{2mi}\left(\Psi^*\nabla\Psi - \Psi\nabla\Psi^*\right) - \frac{q^2}{m}|\Psi|^2\mathbf{A}$$

Here, Ψ " is the complex conjugate function to Ψ.

This system of differential equations must still be supplemented by a proper boundary condition. Frequently, in this case, one applies the obvious condition that the supercurrent cannot flow out of the superconductor, that is, that the current (Eq. (4.29)) perpendicular to the surface of the superconductor must vanish.

Next we will look in detail at the Ginzburg-Landau equations (4.28) and (4.29) or at the Gibbs function (4.27) in various limiting cases and compare the theoretical predictions with the experimental results.

3.6.3 Characteristic Lengths, Proximity Effect, Thermodynamic Critical Field

3.3.1 The Coherence Length and the Penetration Depth

In the preceding section, we formally introduced a quantity ξ in (3.20). Now we shall find its physical significance.

Let us consider a simple example. A thin film of a normal metal is deposited onto a clean flat surface of a superconductor. This will cause a local reduction in the superconducting electron density near the surface of the superconductor. In other words, the order parameter $|\psi|$ at the surface will be somewhat different from its equilibrium value deep inside the superconductor, where $|\psi| = 1$. What then is the characteristic length over which the order parameter returns to unity?

Let us take the x axis perpendicular to the surface of the superconductor ($x = 0$ at the surface). Then it is obvious that ψ can vary only along the x axis, i.e., $\psi = \psi(x)$. In addition, ψ can be presumed real because we are dealing with a simply connected superconductor (see Sect.3.2). Then the first GL equation (3.22) reduces to a simple form:

$$-\xi^2 \frac{\mathrm{d}^2}{-\frac{1}{r} - \frac{\psi}{2}} - \psi + \psi^3 = 0 \quad (3.30)$$

Suppose that the normal layer at the surface is so thin that the magnitude of ψ at the surface is not very different from 1, that is,

$$\psi = 1 - \varepsilon(x), \quad \varepsilon(x) \ll 1$$

Substituting this into (3.30) and keeping only linear terms in $\varepsilon(x)$, we obtain

$$\xi^2 \frac{\mathrm{d}^2\varepsilon(x)}{\mathrm{d}x^2} - 2\varepsilon(x) = 0 \quad (3.31)$$

Allowing for the fact that as $x \to \infty$ the order parameter $\psi \to 1$, we have $\varepsilon(\infty) = 0$. Then the obvious solution of (3.31) is

$$\varepsilon = \varepsilon(0)\mathrm{e}^{-\sqrt{2}x/\xi}$$

It follows that ξ is indeed the characteristic scale over which variations of the order parameter ψ occur. This length is called the coherence length.

Another quantity, λ, introduced in (3.21), is already known to us (Sect.2.2). This is the penetration depth for a weak magnetic field. Both ξ and λ are temperature dependent:

$$\lambda^2 = \frac{mc^2\beta}{8\pi|\alpha|e^2} \tag{3.32}$$

$$\xi^2 = \frac{\hbar^2}{4m|\alpha|} \tag{3.33}$$

In the vicinity of T_c, we have $|\alpha| \propto (T_\mathrm{c} - T)$. Therefore, in the temperature interval close to T_c

$$\lambda \propto (T_\mathrm{c} - T)^{-1/2}\,, \quad \xi \propto (T_\mathrm{c} - T)^{-1/2}\,. \tag{3.34}$$

In the entire temperature interval, a good approximation for $\lambda(T)$ is given by the empirical formula

$$\lambda(T) = \lambda(0)\,(1 - T/T_\mathrm{c})^{-1/4} \tag{3.35}$$

The values of $\lambda(0)$ for a number of superconducting materials are given in Table 2.1. Using (3.3) and (3.1), one can verify that the penetration depth (3.32) is the same as that introduced earlier in (2.7).

Now we can introduce another important quantity, the GL parameter κ:

$$\kappa = \lambda/\xi \tag{3.36}$$

Another expression for κ can be obtained from (3.32), (3.33) and (3.36):

$$\kappa = 2\sqrt{2}\frac{e}{\hbar c}\lambda^2 H_\mathrm{cm} \tag{3.37}$$

An additional, very useful, formula follows from (3.37) and the expression for the flux quantum $\Phi_0 = \pi\hbar c/e$:

$$\sqrt{2}H_\mathrm{cm} = \frac{\Phi_0}{2\pi\lambda\xi} \tag{3.38}$$

Before concluding this section, let us discuss the effect of magnetic field on the order parameter and the penetration depth.

Suppose that a superconducting specimen characterised by $\kappa \ll 1$ (or $\lambda \ll \xi$) occupies the semispace $x > 0$, with an external magnetic field along the z axis. Since by assumption $\lambda \ll \xi$, the magnetic field penetrates the specimen only to a small depth, $d \ll \xi$. This implies that the order parameter Ψ is affected by the magnetic field only over a small depth λ, while it can be expected to vary in a substantial way over a much larger length, ξ. Therefore, over the major part of the coherence length, the order parameter is 'not aware' of the existence of the magnetic field and is close to $\Psi_0 = (|\alpha|/\beta)^{1/2}$. Hence we can conclude that, for $\kappa \ll 1$, the effect of the magnetic field on the order parameter is insignificant.

It follows immediately that the magnetic field penetration depth, which depends on $|\Psi|^2$, is also only slightly affected by the magnetic field. Rigorous calculations show that, in the

presence of an external magnetic field H_0, the amplitude of the order parameter ψ is reduced near the surface of the superconductor by [23]

$$\frac{1}{4\sqrt{2}}\kappa\frac{H_0^2}{H_{\rm cm}^2}$$

For $\lambda \gg \xi$, the effect of an external magnetic field on the order parameter is much greater and brings about a number of qualitatively new and interesting effects. We shall discuss these in detail in the following sections.

Thermodynamic Critical Field

«Выигрыш» в энергии сверхпроводящей фазы в отсутствии внешнего поля $\Omega_n - \Omega_s(\mathcal{H} = 0) = V\alpha^2/2b$ может быть скомпенсирован «проигрышем» энергии из-за помещения образца во внешнее магнитное поле $\Omega_s(\mathcal{H}) - \Omega_s(\mathcal{H} = 0) = V\mathcal{H}^2/8\pi$. Действительно, поскольку в силу эффекта Мейсснера $\mathcal{B} = 0$ сверхпроводник - идеальный диамагнетик $\mathcal{M} = -\mathcal{H}/4\pi$, то плотность его дополнительной энергияи из-за поля равна $-V\int_0^{\mathcal{H}} \mathcal{M}d\mathcal{H} = \mathcal{H}^2/8\pi$. Это дает величину термодинамического критического поля:

$$\mathcal{H}_c^2 = \frac{4\pi a^2 \left(T - T_c\right)^2}{b}$$

This is it!

3.3.2 The Proximity Effect

The role of the coherence length becomes particularly evident when we consider a normal metal N and a superconductor S in good contact with each other. The Cooper pairs can penetrate from S into N and 'live' there for some time. As a result, a thin layer near the NS interface becomes superconducting. On the other hand, the penetration of the Cooper pairs from S into N results in their density being reduced in S. That is, in the vicinity of the interface, the order parameter ψ in the superconductor becomes less than 1, even without magnetic field.

This is the so-called proximity effect.

Consider the simplest case. Suppose that two superconductors, with slightly different critical temperatures ($T_{\rm cn}$ and $T_{\rm cs}$), are in good contact: $T_{\rm cs} > T_{\rm cn}, T_{\rm cs} - T_{\rm cn} \ll T_{\rm cn}$. The temperature of the specimen T is chosen to satisfy the inequality $T_{\rm cn} < T < T_{\rm cs}$, hence the material with the critical temperature $T_{\rm cn}$ is in the normal state. The interface between the two materials is flat and coincides with the plane $x = 0$. The superconductor occupies the semispace $x > 0$, and the normal metal $x < 0$.

The behavior of the order parameter in the S region ($x > 0$) can be determined by solving the first GL equation (3.12) of the form (3.30). The

$$-\xi^2\left(\frac{{\rm d}\psi}{{\rm d}x}\right)^2 - \psi^2 + \frac{1}{2}\psi^4 = C \tag{3.39}$$

where C is the integration constant. Since at $x \to \infty$ we have $({\rm d}\psi/{\rm d}x) \to 0$ and $\psi \to 1$, the integration constant is $C = -1/2$. Substituting this into (3.39) and carrying out the integration, we obtain

$$\psi = \tanh\left[\left(x - x_0\right)/\sqrt{2}\xi\right] \tag{3.40}$$

Here x_0 is the integration constant to be determined from the boundary condition at $x = 0$. In our case this condition is

$$\frac{1}{\psi}\frac{\mathrm{d}\psi}{\mathrm{d}x} = \frac{1}{b} \tag{3.41}$$

The value of b, in general, should be calculated using the microscopic theory. Its geometrical significance becomes evident from Fig.3.2.

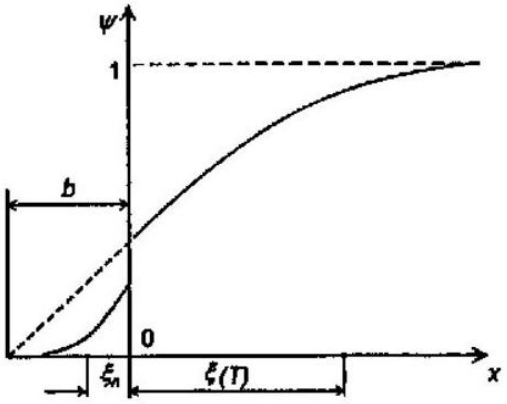

Fig. 3.2. Order parameter $\psi(x)$ near the interface between a superconductor ($x > 0$) and a normal metal ($x < 0$)

On substitution of (3.40) into (3.41), we find how the integration constant x_0 relates to b:

$$-\sinh\left(\sqrt{2}\frac{x_0}{\xi}\right) = \sqrt{2}\frac{b}{\xi}$$

Consider now the behavior of the order parameter ψ in the normal region ($x < 0$). The first GL equation is also applicable in this case (see, for example, [25]). Indeed, by (3.6), we have $\alpha_\mathrm{n} \propto (T - T_\mathrm{cn})$ so that $\alpha_\mathrm{n} < 0$ at $T < T_\mathrm{cn}$ and $\alpha_\mathrm{n} > 0$ at $T > T_\mathrm{cn}$. Hence, for the N region, the first GL equation (3.12) subject to the condition $T - T_\mathrm{cn} \ll T_\mathrm{cr}$ becomes

$$-\xi_\mathrm{n}^2\frac{\mathrm{d}^2\psi}{\mathrm{d}x^2} + \psi + \psi^3 = 0$$

where ${\xi_\mathrm{n}}^2 = \hbar^2/4m\alpha_\mathrm{n}$.

The order parameter in the normal region is small ($\psi \ll 1$), therefore the cubic term can be neglected. Then

$$-{\xi_\mathrm{n}}^2\frac{\mathrm{d}^2\psi}{1\ldots} + \psi = 0$$

Subject to the condition $\psi \to 0$ at $x \to \infty$, the solution is

$$\psi = \psi_0 \exp\left(-|x|/\xi_\mathbf{n}\right) \tag{3.42}$$

From (3.42) we see that the order parameter penetrates the N region to the depth ξ_n while decaying exponentially over this distance. Since T_cn and T_cs are close to each other, ψ and $\mathrm{d}\psi/\mathrm{d}x$ can be assumed continuous at the NS interface. Then, from (3.42), we have $b = \xi_\mathrm{n}$.

In the general case of a superconductor in contact with a true normal metal ($T_\mathrm{cn} = 0$), the GL equations are not applicable to the normal region, Nevertheless, qualitatively, the phenomenon remains, that is, the order parameter penetrates the normal region to a certain depth ξ_n. Rigorous calculations based on the microscopic theory give the following results [26].

In a pure N metal, that is, when the electron mean free path is $l_\mathrm{n} \gg \xi_\mathrm{n}$, the coherence length is

$$\xi_\mathrm{n} = \frac{\hbar v_\mathrm{Fn}}{2\pi k_\mathrm{B} T} \tag{3.43}$$

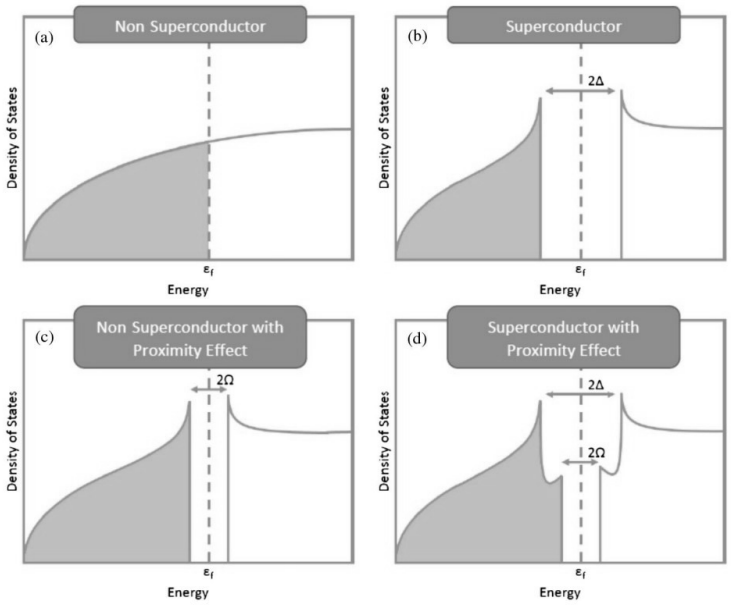
where v_{Fn} is the Fermi velocity and k_{B} is the Boltzmann constant. One should bear in mind, however, that at $T \to 0$ the decay of the order parameter in the N region is much slower than exponential.

In a 'dirty' N metal ($l_{\mathrm{n}} \ll \xi_{\mathrm{n}}$) the coherence length is

$$\xi_{\mathrm{n}} = \left(\frac{\hbar v_{\mathrm{Fn}} l_{\mathrm{n}}}{6\pi k_{\mathrm{B}} T} \right)^{1/2} \tag{3.44}$$

Evaluations by (3.43, 44) give values for ξ_{n} in the range $10^{-5} - 10^{-4}$ cm.
The behavior of the order parameter in the general case is sketched in Fig. 3.2. According to [27], the value of b in the 'dirty' case is

$$b = \frac{\sigma_{\mathrm{s}}}{\alpha \sigma_{\mathrm{n}}} \xi_{\mathrm{n}}, \tag{3.45}$$



where σ_{s} and σ_{n} are the conductivities in the S and N regions, respectively, ξ_{n} is defined by (3.44), and the coefficient α is of the order 1. The exact values of α for a number of situations can be found in [27].

The existence of the proximity effect has been reliably established by experiment. If a superconducting film is deposited onto the surface of a normal metal, the critical temperature of the film decreases. Such a system was studied, for instance, in [28], namely a Pb film deposited on top of an Al film of thickness 4400Å and $T_{\mathrm{c}} = 1.2$ K. When the thickness of the Pb film was $d($ Pb$) = 900$Å, the critical temperature of the whole system, T_{c}, was close to the critical temperature of bulk lead (7.2 K). However, as the Pb film was made thinner, $d($ Pb$) = 600$Å$, T_{\mathrm{c}}$ fell to approximately 5.6 K, and at $d($ Pb$) = 200$Å it became $T_c = 1.6$ K, that is, close to the critical temperature of Al.

The proximity effect is utilized in SNS Josephson junctions where the phase coherence between the superconducting electrodes is established via a

Other about coherence lengths

What else coherence length is?

The coherence length is a size, on which the order parameter is changed. By an "order parameter" I mean some complex variable Δ, that characterizes a condensate. This order parameter somehow is related to the concentration of superconducting electrons (??? how exactly??), which are determined by a Cooper pairs. Thus, GL coherence length is the size of a Cooper pair in the BCS model.

(????? this is a strange statement, I'll write theoretical sections, then return to it again.)

Are there several coherence lengths?

(??? I am not sure, maybe no, there is only one, the GL one. I'll think later. if there are many, I'll list them here)

3.6.4 Characteristic Lengths of the Ginzburg-Landau Theory

In the following, we will show that the Ginzburg-Landau equations contain two characteristic lengths, namely the London penetration depth λ_L and the Ginzburg-Landau coherence length ξ_GL. At this stage we cannot avoid a number of derivations and formulas. However, they are not very difficult.

We start by looking at Eq. (4.29). We want to rewrite this equation by normalizing Ψ to the value Ψ_∞. With the notation $\psi = \Psi/\Psi_\infty$, we find

$$\mathbf{j}_\mathrm{s} = \frac{q\hbar\left|\Psi_\infty\right|^2}{2mi}\left(\psi^*\nabla\psi - \psi\nabla\psi^*\right) - \frac{q^2\left|\Psi_\infty\right|^2}{m}|\psi|^2\mathbf{A}$$

With the definition (1.10) of the London penetration depth, $\lambda_\mathrm{L} = \sqrt{m/\left(\mu_0 q^2 n_\mathrm{s}\right)}$, and the relation $n_\mathrm{s} = \left|\Psi_\infty\right|^2$, we find

$$\mathbf{j}_\mathrm{s} = \frac{\hbar}{2iq}\frac{1}{\mu_0\lambda_\mathrm{L}^2}\left(\psi^*\nabla\psi - \psi\nabla\psi^*\right) - \frac{1}{\mu_0\lambda_\mathrm{L}^2}|\psi|^2\mathbf{A}$$

Using $\psi = \psi_0 \mathrm{e}^{i\varphi}$ for calculating the gradient in the brackets ($\nabla\psi = \mathrm{e}^{i\varphi}\nabla\psi_0 + \psi_0\mathrm{e}^{i\varphi}i\nabla\varphi$), we obtain

$$\mathbf{j}_\mathrm{s} = \psi_0^2\frac{\hbar}{q}\frac{1}{\mu_0\lambda_\mathrm{L}^2}\nabla\varphi - \frac{1}{\mu_0\lambda_\mathrm{L}^2}\psi_0^2\mathbf{A}$$

If the function Ψ is spatially constant, $\nabla\varphi$ vanishes, and $|\psi| = 1.0$. Then we have

$$\mathbf{j}_\mathrm{s} = -\frac{1}{\mu_0\lambda_\mathrm{L}^2}\mathbf{A}$$

Taking the curl on both sides and using curl $\mathbf{A} = \mathbf{B}$, we obtain the second London equation (1.14):

$$\mathbf{B} = -\mu_0\lambda_\mathrm{L}^2\,\mathrm{curl}\,\mathbf{j}_\mathrm{s}$$

We see that we recover the London theory in the case of a spatially constant Cooper pair density $n_{\mathrm{s}'}$. However, going beyond this case, the second Ginzburg-Landau equation apparently can take into account the supercurrents for a spatially varying wave function.

Let us turn to the first Ginzburg-Landau equation (4.28). Again we normalize Ψ to the value Ψ_∞. After a short calculation we find

$$\frac{1}{2m}\left(\frac{\hbar}{i}\nabla - q\mathbf{A}\right)^2\psi + \alpha\psi - \alpha|\psi|^2\psi = 0$$

Here, we must use the relation (4.23) to change the term $\beta\,|\Psi_\infty|^2$, appearing on the left-hand side, into $-\alpha$. We divide both sides by α and obtain

$$\frac{\hbar^2}{2m\alpha}\left(\frac{1}{i}\nabla - \frac{q}{\hbar}\mathbf{A}\right)^2\psi + \psi - |\psi|^2\psi = 0$$

Here, we have taken Planck's constant $\hbar$ in front of the bracket on the left-hand side. The quantity $-\hbar^2/(2m\alpha)$ has the dimension of [length] ^{2}. Obviously, it yields a second characteristic length of the Ginzburg-Landau theory, the Ginzburg-Landau coherence length ξ_{GL}, given by

$$\xi_{\mathrm{GL}} = \sqrt{\frac{-\hbar^2}{2m\alpha}}$$

Then the second Ginzburg-Landau equation can be written as

$$-\xi_{\mathrm{GL}}^2\left(\frac{\nabla}{i} - \frac{q}{\hbar}\mathbf{A}\right)^2\psi + \psi - |\psi|^2\psi = 0$$

With the temperature dependence of α (Eq. (4.20a)), we find immediately also the temperature dependences of λ_{L} and ξ_{GL}:

$$\lambda_{\mathrm{L}}(T) = \frac{\lambda_{\mathrm{L}}(0)}{\sqrt{1 - T/T_{\mathrm{c}}}}$$
$$\xi_{\mathrm{GL}}(T) = \frac{\xi_{\mathrm{L}}(0)}{\sqrt{1 - T/T_{\mathrm{c}}}}$$

For $T \to T_{\mathrm{c}}$ both quantities approach infinity. We note that Eqs. (4.35) and (4.36) are valid only close to T_{c}, although $\lambda_{\mathrm{L}}(0)$ and $\xi_{\mathrm{GL}}(0)$ appear in the equations. The Ginzburg-Landau theory is valid only in this limit.

Now we can introduce the ratio

$$\kappa = \frac{\lambda_{\mathrm{L}}}{\xi_{\mathrm{GL}}}$$

referred to as the Ginzburg-Landau parameter. Within the Ginzburg-Landau equations presented earlier, it is independent of the temperature and of the magnetic field.

In Eqs. (4.30b) and (4.34) we could also have normalized the other quantities having a dimension. Then we would find that the dimensionless Ginzburg-Landau equations would depend only on the Ginzburg-Landau parameter κ. Hence, this parameter is crucial for the behavior of these equations. Which length is indicated by ξ_{GL}? This is illustrated by a simple situation, in which the superconductor extends in the x-direction from $x = 0$ up to $x \to \infty$. In the y and z directions, the superconductor is assumed to be extended infinitely. For $x = 0$ we assume $|\psi| = 0$. Furthermore, we assume $\mathbf{A} = 0$. Then we can find a real solution for ψ from the equation

$$\xi_{\mathrm{GL}}^2\frac{\mathrm{d}^2\psi}{\mathrm{d}x^2} + \psi - \psi^3 = 0$$

which depends only on x. For $x \geq 0$, this equation has the solution

$$\psi(x) = \tanh\left(x/\sqrt{2}\xi_{\mathrm{GL}}\right)$$

shown in Figure 4.6. According to Eq. (4.39), $\psi(x)$ first increases linearly from 0 and then it approaches the limiting value 1 in the interior of the superconductor. We see that, at least in the situation we have discussed, ξ_{GL} can be interpreted as the characteristic length within which the order parameter ψ can change.

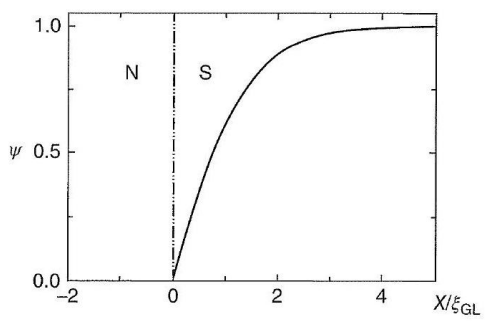

Figure 4.6 Variation of the function $\psi(x)$ according to Eq. (4.39) at the edge of a superconducting half-space.

Now we know the two length scales of the Ginzburg-Landau theory. The fact that the Ginzburg-Landau theory is valid only close to T_{c} should not diminish the importance of λ_{L} and ξ_{GL} as the characteristic length scales within which the supercurrents (or the magnetic field) and the Cooper pair density (or Ψ) can change. Both lengths are fundamental to the superconducting state. They can be analyzed further within the microscopic theory.

At very low temperatures, in the case of conventional superconductors, one finds that λ_{L} is approximately constant. The deviation from this constant value $\lambda_{\mathrm{L}}(0)$ decreases exponentially with decreasing temperature. On the other hand, in the case of unconventional superconductors, for which the energy gap has locations with value zero along certain crystal directions, the difference $\Delta\lambda = \lambda_L\ (T) - \lambda_L(0)$ increases from zero following a power law. In the case of the $d_{x^2-y^2}$ symmetry, $\Delta\lambda$ is proportional to T, if the samples are sufficiently pure. For impure samples, one observes a T^2 law. In Chapter 2 we listed the values of $\lambda_{\mathrm{L}}(0)$ for many conventional and unconventional superconductors.

Figure 4.7 shows experimental results for the temperature dependence of the penetration depth in mercury. Here, λ_{L} was determined from the magnetization of mercury colloid, that is, from small Hg balls [23]. For this material, as well as for many other conventional superconductors, the observed temperature dependence can be approximated over a wide temperature range by the empirical expression

$$\frac{\lambda_{\mathrm{L}}(T)}{\lambda_{\mathrm{L}}(0)} \propto \left[1 - \left(\frac{T}{T_{\mathrm{c}}}\right)^4\right]^{-1/2}$$

For $T \to T_{\mathrm{c}}$ this relation yields Eq. (4.35), in agreement with the Ginzburg-Landau theory. [15)] The plot in Figure 4.7 allows the comparison with Eq. (4.40). The solid straight line corresponds to this equation. The agreement between the analytic expression and the experimental data is excellent.

To see this we write $\left[1 - (T/T_c)^4\right] = \left[1 - (T/T_{\mathrm{c}})^2\right]\left[1 + (T/T_{\mathrm{c}})^2\right]$ and for $T \to T_{\mathrm{c}}$ replace the second factor by the factor 2. We apply the same procedure to $\left[1 - (T/T_{\mathrm{c}})^2\right]$ and finally obtain Eq. (4.35). 4.5 Characteristic Lengths of the Ginzburg-Landau Theory |219

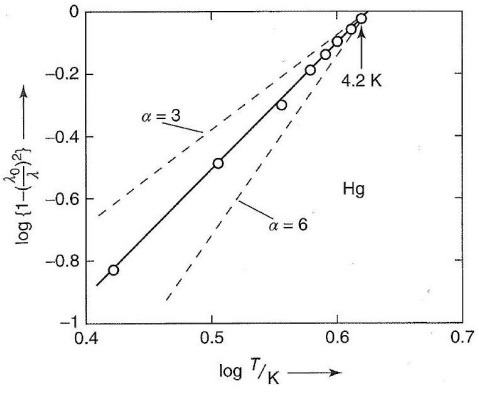

Figure 4.7 Temperature dependence of the penetration depth of Hg [23]. The solid line corresponds to the exponent $a = 4$ in the bracket of Eq. (4.40). For comparison, the cases $a = 3$ and $a = 6$ are also shown by the dashed curves.

For comparison we show in Figure 4.8 the experimental results obtained for a highly pure $YBa_2Cu_3O_7$ single crystal. The penetration depth was determined from the surface impedance of the crystal (see also Section 7.5.1). The latter was found from the frequency shift of a resonating cavity into which the crystal had been inserted. The data referring to the left vertical axis show the ratio $\lambda_L(0)^2/\lambda_L(T)^2$, which is proportional to the density of Cooper pairs according

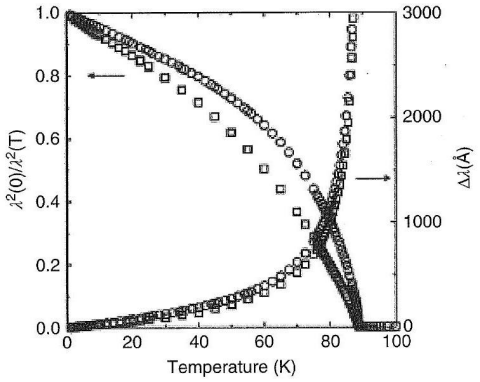

Figure 4.8 Temperature dependence of the crystal, and the squares indicate the penemagnetic penetration depth in highly pure tration depth along the b-direction. At low values $\lambda_g(0) = 160$ nm and $\lambda_b(0) = 80$ nm[24].

to Eq. (1.10). The data referring to the right vertical axis show the difference $\Delta\lambda = \lambda_L(T) - \lambda_L(0)$. For each axis there are two curves, which correspond to the penetration depth along the a and b directions of the crystal, respectively. We clearly see the linear increase in $\Delta\lambda$ over a wide temperature range.

The Ginzburg-Landau coherence length ξ_{GL} is much more difficult to determine experimentally than the penetration depth λ_L. (Numerical values of ξ_{GL} are listed in Chapter 2 for a number of superconductors.) Usually one employs indirect methods. The value of ξ_{GL} is closely connected with the upper critical field of type-II superconductors, from which it can be determined (see Section 4.7.1). Another indirect method uses the analysis of the electrical conductivity above the transition temperature. Because of thermal fluctuations, superconducting small regions always appear temporarily closely above T_c, contributing to an enhanced electrical conductivity. We will return to this subject in Section 4.8.

Within the Ginzburg-Landau theory, λ_L and ξ_G represent material properties, which depend on the Cooper pair density and on the thermodynamic critical field B_{ot} because of the parameters α and β. The microscopic theory provides us with another important relation: the

dependence of λ_L and ξ_{GL} on the electron mean free path l^*.[16] For conventional superconductors in the limit $T \to 0$, one finds

$$\lambda_L(T=0,l^*) = \lambda_L(T=0,l^* \to \infty)\left\{1 + \frac{\xi_{GL}(T=0,l^* \to \infty}{l^*}\right\}^{1/2}$$

and for $l^* \ll \xi_{GL}(T=0,l^* \to \infty)$ one has

$$\xi_{GL}(T=0,l^*) = \{\xi_{GL}(T=0,l^* \to \infty)\, l^*\}^{1/2}$$

This dependence is not yet taken into account by the expressions (4.35), (4.36), and (4.40), which are valid only in the limit of very large mean free paths, $l^* \to \infty$. From Eqs. (4.41) and (4.42) we see that, with decreasing l^*, the length λ_L increases and the length ξ_{GL} decreases. Hence, the Ginzburg-Landau parameter κ strongly depends on l^*. It increases with decreasing l^*.

The length l^* depends on the purity of the samples and can be controlled by the admixture of impurities. In Section 4.7 we will see that by varying the degree of purity, one can change a type-I superconductor into a type-II superconductor.

Together with the BCS coherence length presented in Section 3.1.1, we have introduced three different characteristic lengths of a superconductor:

penetration depth λ_L measuring the decay of the magnetic field in the interior of the superconductor

average extension ξ_0 of a Cooper pair as a measure of the distance within which the correlation forming Cooper pairs is active;

coherence length ξ_{GL} as the smallest length within which the Cooper pair density can vary - it is always larger than ξ_0, since the number density of Cooper pairs cannot vary within a distance smaller than the average extension of a Cooper pair.

The electron mean free path l indicates the average distance that a conduction electron can propagate between two collisions.

The coherence length ξ_0 is nearly temperature-independent, and in the limit $l^* \to 0$ it is about equal to l^*. In different limiting cases, we can also find simple relations for this length. For example, in the BCS theory:

$$\xi_0(T=0,l^* \to \infty) = 0.18\frac{\pi\hbar v_F}{2k_B T_c}$$

$$\xi_{GL} \approx \xi_0 \frac{\lambda_L(T,l^*)}{\lambda_L(T=0,l^* \to \infty)}$$

where v_F is the Fermi velocity and k_B is Boltzmann's constant. Such relations represent good approximations mostly only within specific regimes of T and l^*. In general, their mathematical derivation from the microscopic theory requires appreciable effort.

It is interesting to note that in 1951 Pippard postulated a coherence length for the interpretation of high-frequency measurements [25]. Based on this coherence length, which is closely related to ξ_0, Pippard could extend the London theory y claiming that the supercurrent density $j_s(x,y,z)$ should depend not only on the magnetic field $B(x,y,z)$ at the location (x,y,z) but also on the average field in a region with an extension of about the coherence length.

In the following, we return again to the thermodynamic properties of the superconducting state, and we start with type-I superconductors.

3.6.5 Energy of a Normal Metal-Superconductor Interface

Theory by Shmidt

Type-I and type-II superconductors, as we already know, can show entirely different responses to an external magnetic field. The reason is that the surface energy of the interface between a normal and a superconducting region, $\sigma_{\rm ns}$, is positive for type-I superconductors and negative for those of type-II. We are now in a position to understand the origin of this difference. It turned out that for type-I superconductors $\lambda < \xi$, and for those of type-II $\lambda > \xi$. The dividing line between the superconductors of type-I and type-II will be determined more precisely later. Let us start with a type-I superconductor.

Consider a flat NS interface within a superconductor in the intermediate state. Assume that far away to the left of the interface, the material is superconducting, and far away to the right of the interface, it is normal. The interface is perpendicular to the x axis and the magnetic field is parallel to the z axis. Since we consider a superconducting semispace, i.e., a simply connected superconductor, we can always choose an appropriate gauge so that the wavefunction of the GL theory is real. In addition, due to the simple geometry of the problem, all variables depend only on x, and the vector potential A may be assumed parallel to the y axis. The origin $x = 0$ is chosen at the interface.

Thus the initial data are:
(1) $\boldsymbol{H} = (0, 0, H(x))$,
(2) $\psi = \psi(x)$ is a real function,
(3) $\boldsymbol{A} = (0, A(x), 0)$.

Then the GL equations (3.22) and (3.24) can be rewritten in the form

$$-\xi^2 \frac{\mathrm{d}^2\psi}{\mathrm{d}x^2} + \left(\frac{2\pi\xi}{\Phi_0}\right)^2 A^2\psi - \psi + \psi^3 = 0$$
$$\frac{\mathrm{d}^2 A}{\mathrm{d}x^2} = \left(\frac{\psi^2}{\lambda^2}\right) A \tag{3.46}$$

One can easily verify that the first integral of these equations is

$$\left[1 - \left(\frac{2\pi\xi A}{-\Phi_0}\right)^2\right]\psi^2 - \frac{1}{2}\psi^4 + \left(\frac{2\pi\lambda\xi}{\Phi_0}\right)^2 \left(\frac{\mathrm{d}A}{\mathrm{d}x}\right)^2 + \xi^2 \left(\frac{\mathrm{d}\psi}{\mathrm{d}x}\right)^2 = C, \tag{3.47}$$

where C is the integration constant which can be found from the boundary conditions: at $x \to -\infty, \psi \to 1,\ \mathrm{d}\psi/\mathrm{d}x \to 0$, and $A \to 0$.

Indeed, at the far left, that is, as $x \to -\infty$, there is no magnetic field and the wavefunction of the GL theory tends to 1. On substitution of these boundary conditions into (3.47), we obtain $C = 1/2$ and, using (3.38), we finally have

$$\left[\left(\frac{2\pi\xi A}{\pi}\right)^2 - 1\right]\psi^2 + \frac{1}{n}\psi^4 = \xi^2 \left(\frac{\mathrm{d}\psi}{1\ldots}\right)^2 + \frac{H^2}{\pi\pi^7\bar{n}} - \frac{1}{n}. \tag{3.48}$$

Now, after these preliminary preparations, let us turn to calculation of the surface energy per unit area of the interface between a normal and a superconducting region. But first a little bit of physics. When inspecting a superconducting domain, we shall need to know the exact value of the external magnetic field surrounding it. As this domain is a part of the specimen in the intermediate state, there must be a normal domain next to it, which is penetrated by a magnetic field of strength $H_{\rm cm}$. (Recall that this is the field strength established automatically in the normal regions of a superconductor in the intermediate state.)

Thus, with respect to the superconducting domain, the external field is always $H_{\rm cm}$. Let us now write down the density of the Gibbs free energy deep in the interior of the superconducting domain, that is, far away to the left of the interface. From (1.22) we have

$$G_{\rm s} = F_{\rm s0} - HH_{\rm cm}/4\pi$$

Since at the far left $H = 0$, we get $G_{\rm s} = F_{\rm s0}$, where $F_{\rm s0}$ is the free energy density of the superconductor without magnetic field. Far to the right of the NS interface, i.e., in the normal metal where the magnetic field is $H_{\rm cm}$, the free energy density is

$$F = F_{\rm n} + H_{\rm cm}^2/8\pi$$

where the second term is simply the energy density of the magnetic field.

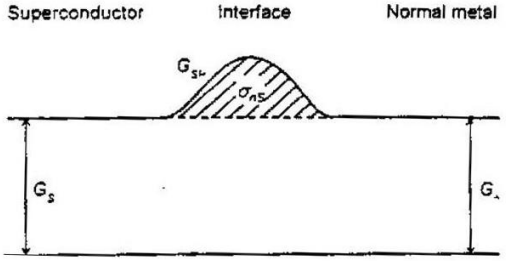

Fig. 3.3. Density of the Gibbs free energy G_{sH} in the vicinity of a normal metal-superconductor interface

In the normal domain, the Gibbs free energy density is

$$\begin{aligned} G_{\rm n} &= F - HH_{\rm cm}/4\pi = F_{\rm n} + H_{\rm cm}^2/8\pi - H_{\rm cm}^2/4\pi \\ &= F_{\rm n} - H_{\rm cm}^2/8\pi = F_{\rm s0} \end{aligned} \tag{3.49}$$

Here we have used the well-known relation between $F_{\rm n}$ and $F_{\rm s0}$ (1.12):

$$F_{\rm n} - F_{\rm s0} = H_{\rm cm}^2/8\pi$$

and the condition that in the normal domain $H = H_{\rm cm}$.

Thus we have arrived at a result which is precisely what one should have expected: In equilibrium, the density of the Gibbs free energy far to the left of the interface equals the energy density far to the right.

But what should be happening at the interface? The answer is given by

At the interface, the Gibbs free energy density may differ from G_n. Then it is natural to define the surface energy of the interface, $\sigma_{\rm ns}$, as

$$\sigma_{\rm ns} = \int_{-\infty}^{\infty} (G_{{\rm s}H} - G_{\rm n})\,{\rm d}x \tag{3.50}$$

where

$$G_{{\rm s}H} = F_{{\rm s}H} - HH_{\rm cm}/4\pi \tag{3.51}$$

$$F_{{\rm s}H} = F_{\rm n} + \frac{H^2}{8\pi} + \frac{H_{\rm cm}^2}{4\pi}\left[-|\psi|^2 + \frac{1}{2}|\psi|^4 + \xi^2\left|{\rm i}\nabla\psi + \frac{2\pi}{\Phi_0}A\psi\right|^2\right] \tag{3.52}$$

$$G_{\rm n} = F_{\rm n} - H_{\rm cm}^2/8\pi \tag{3.53}$$

Formula (3.51) follows from the general expression for the Gibbs free energy (where H is the magnetic field in the superconductor), formula (3.52), which forms the basis of the GL theory, can be easily derived from (3.7), and (3.53) was obtained earlier (see (3.49)).

On substitution of (3.51-53) into (3.50), we have

$$\sigma_{\rm ns} = \int_{-\infty}^{\infty} \left\{ \frac{H_{\rm cm}^2}{4\pi} \left[-|\psi|^2 + \frac{1}{2}|\psi|^4 + \xi^2 \left| {\rm i}\nabla\psi + \frac{2\pi}{\Phi_0}\boldsymbol{A}\psi \right|^2 \right] + \frac{H^2}{8\pi} - \frac{H H_{\rm cm}}{4\pi} + \frac{H_{\rm cm}^2}{8\pi} \right\} {\rm d}x$$

After recalling that $\boldsymbol{A} = (0, A, 0)$ and ψ is real, this becomes

$$\sigma_{\rm ns} = \int_{-\infty}^{\infty} \left\{ \frac{H_{\rm cm}^2}{4\pi} \left[-\psi^2 + \frac{1}{2}\psi^4 + \xi^2 \left(\frac{{\rm d}\psi}{{\rm d}x} \right)^2 + \left(\frac{2\pi\xi A}{\Phi_0} \right)^2 \psi^2 \right] + \frac{H^2}{8\pi} - \frac{H H_{\rm cm}}{4\pi} + \frac{H_{\rm cm}^2}{8\pi} \right\} {\rm d}x$$

Finally, using (3.48), we obtain

$$\sigma_{\rm ns} = \frac{H_{\rm cm}^2}{2\pi} \int_{-\infty}^{\infty} \left[\xi^2 \left(\frac{{\rm d}\psi}{{\rm d}x} \right)^2 + \frac{H\left(H - H_{\rm cm}\right)}{2H_{\rm cm}^2} \right] {\rm d}x \tag{3.54}$$

Let us analyze the result. First of all, the field penetrating the superconducting region is always less than the field at the interface, that is, less than $H_{\rm cm}$. Therefore, the second term in square brackets is always negative.

Now we understand why $\sigma_{\rm ns} < 0$ in the London theory: because quantum effects are not taken into account and, consequently, there is no term $\xi^2(\,{\rm d}\psi/{\rm d}x)^2$. One can see from (3.54) that this inadequacy of the London theory is removed by the GL theory. By taking into account quantum effects, a positive term $\xi^2(\,{\rm d}\psi/{\rm d}x)^2$ has appeared that leads to the energy $\sigma_{\rm ns}$ being positive.

Let us now make some evaluations. On going from N to S, the order parameter changes from 0 to 1 in the vicinity of the interface. This change takes place over a distance of the order of the coherence length ξ. Therefore, ${\rm d}\psi/{\rm d}x \sim 1/\xi$ and $\xi^2(\,{\rm d}\psi/{\rm d}x)^2 \sim 1$. This term is nonzero over a distance $x \sim \xi$ near the interface. Therefore,

$$\int_{-\infty}^{\infty} \xi^2(\,{\rm d}\psi/{\rm d}x)^2\,{\rm d}x \sim \xi \tag{3.55}$$

The term $H\left(H - H_{\rm cm}\right)/2H_{\rm cm}^2$ reaches approximately -1 at the interface and becomes zero deep in the interior of both S and N domains. The area where it is nonzero extends over a distance of the order of the penetration depth λ. Hence the contribution of this term to the integral in (3.54) is roughly $-\lambda$.

Consider two limiting cases.

(1) $\kappa \ll 1$, i.e., $\lambda \ll \xi$. Then, by (3.55), the dominant contribution to the integral in (3.54) comes from the gradient term and

$$\sigma_{ns} \sim H_{\rm cm}^2 \xi > 0.$$

Exact integration of (3.54) using the GL theory yields

$$\sigma_{\rm ns} = 1.89 \frac{H_{\rm cm}^2}{8\pi} \xi \tag{3.56}$$

(2) $\kappa \gg 1$, i.e., $\lambda \gg \xi$. In this case, the dominant contribution to the integral in (3.54) comes from the term $H\left(H - H_{\rm cm}\right)/2H_{\rm cm}^2$ and the surface energy of the interface is

$$\sigma_{\rm ns} \sim -H_{\rm cm}^2 \lambda$$

Exact calculations yield

$$\sigma_{\rm ns} = -\frac{H_{\rm cm}^2}{8\pi}\lambda. \tag{3.57}$$

Let us now interpret the results physically.
(1) The case $\kappa \ll 1, \lambda \ll \xi$. Figure 3.4 shows how the order parameter ψ and the magnetic field H vary in the vicinity of the interface. The former falls off over a distance ξ and the latter over a distance λ. As a result, there is a region of thickness $\sim \xi$ where the order parameter is already sufficiently small and the magnetic field is kept out. This region enjoys 'the privilege' of the superconductor: it is free of magnetic field; but the order parameter is still very small there compared to the superconducting regions. This ought to area at the far left. In other words, the energy of this region exceeds that of the superconducting region by the additional energy required to break the electron (Cooper) pairs within the region and thus to reduce the order parameter ψ. The density of the additional energy is $H_{\rm cm}^2/8\pi$, hence the energy of the region is $\sim H_{\rm cm}^2\xi/8\pi$, in accord with (3.56).

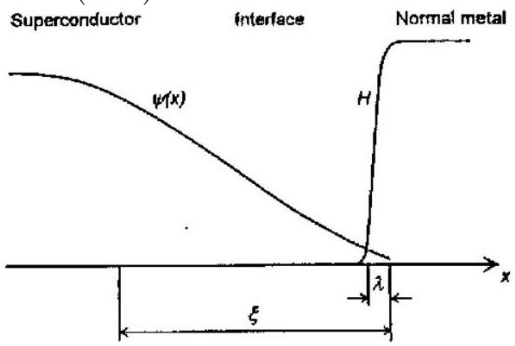

Fig. 3.4. Spatial variations of the order parameter ψ and the magnetic field H in the vicinity of the NS interface for $\kappa \ll 1$

This situation can be looked at from a different perspective. To keep the magnetic field out of the region with a reduced value of ψ (i.e., with the energy close to the energy of the normal metal), work must be done on the magnetic field to expel it from this region. This means that one must overcome a 'pressure' from the magnetic field $H_{\rm cm}^2/8\pi$ and shift its boundary by the distance ξ to the right. For this, the work $(H_{\rm cm}^2/8\pi)\,\xi$ must be done.

Fig. 3.5. Spatial variations of the order parameter ψ and the magnetic field H in the vicinity of the NS interface for $\kappa \gg 1$

(2) The case $\kappa \gg 1, \lambda \gg \xi$. The variations of $\psi(x)$ and $H(x)$ in this case are sketched in Fig. 3.5. This time, ψ varies much more rapidly than the magnetic field so that there is a region of thickness $\sim \lambda$ where the order parameter is $\psi \sim 1$ but a relatively strong magnetic field still remains. The presence of the magnetic field compels us to compare this region with the normal metal. Unlike the latter, the electrons in the region are coupled in Cooper pairs ($\psi \sim 1$). Hence its energy is less than the energy of the normal region to the right by the value of the condensation energy. As the thickness of the region is $\sim \lambda$ and the condensation energy density is $H_{\rm cm}^2/8\pi$, it is mordnotthnt - - tri2 to-il

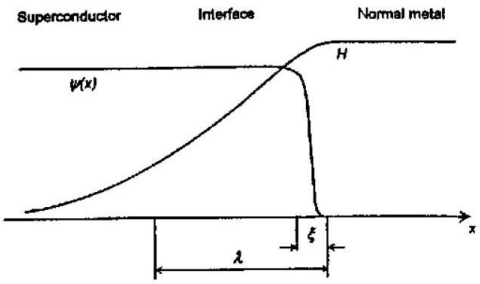

Fig. 3.5. Spatial variations of the order parameter ψ and the magnetic field H in the vicinity of the NS interface for $\kappa \gg 1$ field H in the vicinity of the NS in-(??)

From a different perspective, one can say that, in the case $\kappa \gg 1$, there is a region of thickness $\sim \lambda$ with $\psi \sim 1$ near the interface which is penetrated by the magnetic field. It implies that the energy of the system as a whole has decreased by the value of the work done to shift the field $H_{\rm cm}$ by the distance λ. We come to the following conclusions.

If $\kappa \ll 1$, then $\sigma_{\rm ns} > 0$. Such materials are called type-I superconductors.
If $\kappa \gg 1$, then $\sigma_{\rm ns} < 0$. Such materials are called type-II superconductors.
Evidently, at some value $\kappa \sim 1$, the energy $\sigma_{\rm ns}$ must be zero. Exact calculations show that this occurs at $\kappa = 1/\sqrt{2}$. Our conclusions are summarized in Table 3.1:

Table 3.1.

Type I	Type II
$\kappa < 1/\sqrt{2}$	$\kappa > 1/\sqrt{2}$
$\sigma_{\rm ne} > 0$	$\sigma_{\rm ns} < 0$

3.6.6 Limits of Applicability of GL Theory

Short Estimation

(write the background here!)

Теория Гинзбурга-Ландау является типичной теорией среднего поля. Учет флуктуаций ограничивает пределы применимости таких теорий. Критерием применимости является малость числа Гинзбурга-Леванюка $\mathrm{Gi} = T_c b^2/ac^3$.

(?? comment, why it is so??)

Подставляя полученные выше a, b и c, для числа Гинзбурга-Леванюка получаем оценку $\mathrm{Gi} \approx (T_c/\varepsilon_F)^4$. Таким образом, область применимости теории среднего поля в сверхпроводниках определяется критерием

$$\mathrm{Gi} = \left(\frac{T_c}{\varepsilon_F}\right)^4 \ll 1$$

Для реальных сверхпроводников число, стоящее в (13.33), как минимум на десять порядков меньше единицы. Это значит, что флуктуационная область на много порядков меньше тех вариаций температуры, которые можно контролировать в эксперименте. Таким образом, теория Гинзбурга-Ландау для сверхпроводников применима с огромной точностью.

3.6.7 1-4 Two kinds of superconductors by de Gennes

Our derivation of the London equation (1-9) assumes a slow variation in space of $v(r)$ or of the supercurrent $f_s(r)$. What do we mean by the word "slow"? In the condensed state, the

velocities of two electrons (1) and (2) are correlated if the distance between them R_{12} is smaller than a certain range. For pure metals, the correlation length is called ξ_0. Our derivation applies when $v(r)$ has a negligible variation over distances $\sim \xi_0$. To estimate ξ_0 we notice that the important domain in momentum space is defined by

$$\mathrm{E_F} - \Delta < \frac{\mathrm{p}^2}{2\ \mathrm{m}} < \mathrm{E_F} + \Delta \tag{1-18}$$

where $\mathrm{E_F}$ is the Fermi level. The thickness of the shell in p space defined by Eq. $(1-18)$ is $\delta \mathrm{p} \cong (2\Delta/\mathrm{v_F})$ (where $\mathrm{v_F} = \mathrm{p_F}/\mathrm{m}$ is the velocity at the Fermi level; we have made use of the fact that $\Delta \ll \mathrm{E_F}$ in all cases). A wave packet formed of plane waves whose momentum has an uncertainty $\delta \mathrm{p}$ has a minimum spatial extent $\delta \mathrm{x} \sim (\hbar/\delta \mathrm{p})$. This leads us to take

$$\xi_0 = \frac{\hbar v_F}{\pi \Delta} \tag{1-19}$$

(The factor $1/\pi$ is arbitrary but will become convenient later.) The length ξ_0 defined by Eq. $(1-19)$ is called the coherence length of the superconductor.

Equations (1-15) and (1-13) show that h, j_s, or v vary on a scale λ_L. Thus our derivation of the London equation holds only if $\lambda_L \gg \xi_0$.

(1) In simple (nontransition) metals as we have seen, λ_L is small (~ 300Å). The Fermi velocity v_F is large ($v_F > 10^8$ cm/sec) and according to Eq. (1-19) ξ_0 is also large ($\xi_0 \cong 10^4$ A for aluminum). Thus for these metals the London equation does not apply. In fact, they do exhibit the Meissner effect, but in order to calculate the penetration depth it is necessary to replace Eq. (1-9) by a somewhat more complicated relation, the form of which has been suggested by Pippard. We call these first kind (Type I) or Pippard superconductors and discuss them in Chapter 2.

(2) For transition metals and intermetallic compounds of the type $\mathrm{Nb_3Sn}, \mathrm{V_3Ga}$, the effective mass is very large, λ_L is large (~ 2000Å) and the Fermi velocity is small ($\sim 10^6$ cm/sec). Also, in these
compounds the transition temperature T_0 above which superconductivity disappears is found to be high (18°K in $\mathrm{Nb_3Sn}$). As we will see later, Δ is roughly proportional to T_0 and is therefore larger. For all these reasons ξ_0 is very small (~ 50Å). Therefore for this class of materials Eq. $(1-9)$ is well applicable in weak fields. We call these second kind (Type II) or London superconductors.

In order to complete this discussion, it is necessary to mention the case of superconducting alloys, for which the coherence length and penetration depth are modified by mean free path effects, which we will discuss later. Qualitatively, if the mean free path due to disorder in the structure is short, the coherence length becomes smaller than $\hbar v_F/\pi\Delta$ and λ_L is increased with respect to Eq. (1-7). Therefore it frequently occurs that the addition of impurities into a Pippard superconductor transforms it into a London superconductor.

The distinction here between the two classes is crucial for all experiments made in the presence of external fields. Historically, during a period of 20 years after the discovery of the Meissner effect, experiments were mainly carried out in first kind superconductors. The detailed study of second kind superconductors is much more recent. Paradoxically, the theory has followed the inverse order. Equation (1-9) was introduced by the London brothers in 1935, but the necessary modifications for first type superconductors was only proposed by Pippard in 1953. We now study in detail the magnetic properties of the two types.

3.6.8 The Wall Energy, derivation of $\varkappa_c = 1/2$

$$\kappa = \lambda/\xi = \frac{mc}{\hbar e}\left(\frac{\beta}{2\pi}\right)^{1/2}$$

Next we want to look more closely at the wall energy associated with an interface between a normal conducting domain and a superconducting domain. This positive [23] wall energy has been crucial for our understanding of the intermediate state. We will find that under certain conditions the generation of an interface does not require an expense of energy. This has to do with the type-II superconductors, the properties of which will be described in Section 4.7.

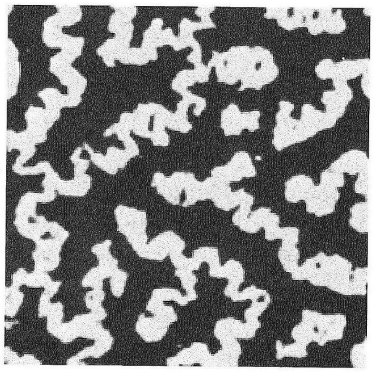

Figure 4.16 Intermediate state structure of an indium plate. The dark regions represent the superconducting domains. In purity: 99.999 at%; thickness: 11.7 mm; diameter: 38 mm; $B_\mathrm{a}/B_\mathrm{cth} = 0.1; T = 1.98$ K; T_c of indium: 3.24 K.

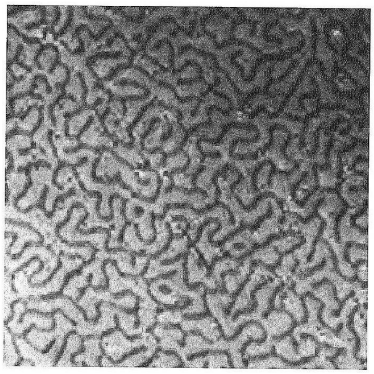

Figure 4.17 Intermediate state structure imaged by means of the Faraday effect. Pb layer with $7\mu m$ thickness; thickness of about 100 nm; magnetic fieds and EuF B_2:

In Chapter 1 we discussed other techniques in conjunction with the imaging of vortices perpendicular to the layer. The dark regions represent the superconducting domains. The imaged area is about 0.5 mm $\times$ 0.5 mm [34]. (By courtesy of Dr Kirchner, Siemens, the superconductor much larger than λ_L, and a constant assumptions, at an interface the magnetic fied must be ju equa to the cicica field B_cth . In the normal conductor we have $B > B_c$, vanishes within a layer thickness of about λ_L

The difference between a normal conducting domain and a superconducting domain within the same material comes from the fact that in the normal state doma cooper pair density n is zero, whereas in the superconductor it has a definite value $n_\mathrm{s}(T)$ depending on the material and the temperature. We recall that it is the condensation into Cooper pairs that effects the lowering of the free enthalpy and that below T_c results in the thermodynamic stability of the superconductor instead of the normal conductor

For our further discussion, it is crucial that at the interface the number density $n_s(T)$ cannot drop discontinuously from $n_{\rm s}(T)$ to zero. Because of the strong correlation between the Cooper pairs, a spatial variation of $n_{\rm s}(T)$ is stossible only within a distance larger than the Ginzburg-Landau coherence length $\xi_{\rm GL}$.

Figure 4.18 schematically indicates the situation at such an interface. In the normal domain on the left ($x < 0$), the magnetic field is just $B_{\rm cth}$ or larger. Therefore, within this domain the normal conducting state is stabilized, since the expulsion of the magnetic field would require more free enthalpy than can be supplied by he tanstion into the superconducting state [24)] In the superconducting domain

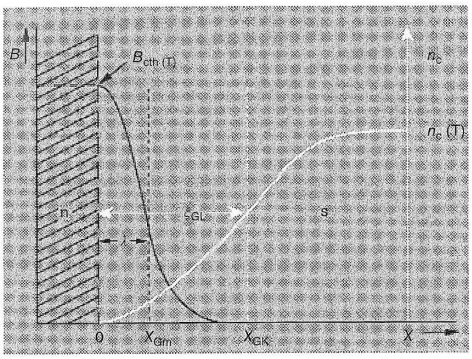

Figure 4.18 Spatial variation of B and n_s at an interface between a normal conducting (Here, x_{Gm} = "magnetic boundary" and x_{GK} = "condensate boundary.")

The boundy is only table if d diphcement to the left or to the right would lead to an increase or a decrease in the magnetic field, respectively.

($x > 0$), the Cooper pair density increases up to the equilibrium value $n_{\rm s}(T)$ within about the coherence length. Here, we have assumed that for the superconductor we have

$$\xi_{\rm GL} > \lambda_{\rm L}$$

At the boundary layer we must compare two contributions to the energy, namely the energy $E_{\rm B}$ associated with the expulsion of the magnetic field, and the energy $E_{\rm C}$ gained because of the condensation into Cooper pairs. In the normal conductor we have $E_{\rm B} = E_{\rm C} = 0$. The magnetic field is not expelled, and no Cooper pairs exist. Deep within the interior of the superconducting domain, for the application of the critical field $B_{\rm cth}$, we have at the boundary $E_{\rm B} = E_{\rm C} = (1/2\mu_0)\, B_{\rm cth}^2\, V$ (see Eq. (4.50)). The magnitude of the full condensation energy is just equal to the expulsion energy.

Within the boundary layer, the two energies do not have their full value. The magnetic field is not completely screened. Instead, it penetrates up to a depth $\lambda_{\rm L}$. The expulsion energy is reduced by the amount

$$\Delta E_{\rm B} = F\lambda_{\rm L}\frac{1}{2\mu_0}B_{\rm cth}^2$$

(where F is the area of the discussed boundary layer) compared to the case of complete expulsion up to the boundary line $x = 0$ in Figure 4.18. However, within the boundary layer the condensation energy is also reduced, since the number density of Cooper pairs is smaller than the equilibrium value $n_s(T)$. This reduction of the condensation energy is given by

$$\Delta E_{\rm C} = -F\xi_{\rm GL}\frac{1}{2\mu_0}B_{\rm cth}^2$$

where F is the area of the discussed boundary layer and ξ_{GLI} is the Ginzburg-Landau coherence length

For simplicity, we have defined λ_{L} and ξ_{GL} in such a way that the energy values ΔE_{B} and ΔE_{C} are equivalent to the case in which the magnetic field penetrates ΔE_{B} and ΔE_{C} are equivalent to the case in which the magnetic field penetrates completely up to the depth λ_{L} and then abruptly drops to zero and, on the other hand, the Cooper pair density abruptly jumps up to its full value $n_s(T)$ at ξ_{GL}. In this way, we have defined a "magnetic boundary" and a "condensate boundary." For the present case $\xi_{\mathrm{GL}} > \lambda_{\mathrm{L}}$, we find

$$\Delta E_{\mathrm{C}} - \Delta E_{\mathrm{B}} = (\xi_{\mathrm{GL}} - \lambda_{\mathrm{L}})\, F \frac{1}{2\mu_0} B^2_{\mathrm{cth}} > 0$$

Because of relation (4.67), the loss in condensation energy is larger than the gain in expulsion energy. In order to generate such a boundary, we must deliver the following wall energy α_{w} per unit area to the system:

$$\alpha_{\mathrm{w}} = (\xi_{\mathrm{GL}} - \lambda_{\mathrm{L}})\, F \frac{1}{2\mu_0} B^2_{\mathrm{cth}}$$

In Figure 4.19 we show the spatial variation of the energy densities ε_{B} and ε_{C} and their difference, which passes through a maximum.

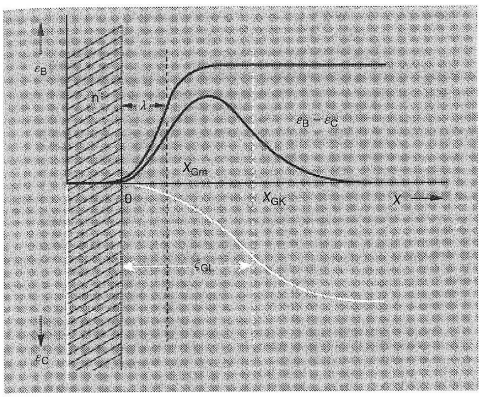

Figure 4.19 Spatial variation of the expulsion energy ε_B and of the condensation energy ε_C per unit volume at the boundary. We have $\int_0^{x \to x_{\mathrm{GK}}} (\varepsilon_{\mathrm{B}} - \varepsilon_{\mathrm{C}})\, F \mathrm{d}x = (\xi_{\mathrm{GL}} - \lambda_{\mathrm{L}})\, F \frac{1}{2\mu_0} B^2_{\mathrm{cth}}$.

Here we see very clearly that the generation of a boundary layer between a normal conducting domain and a superconducting domain in a homogeneous material requires energy if ξ_{GL} is larger than λ_{L}[2525] In the case where $\xi_{\mathrm{GL}} = \lambda_{\mathrm{L}}$, that is, if the magnetic boundary and the condensate boundary coincide, we have $\alpha_{\mathrm{w}} = 0$. In the case where $\xi_{\mathrm{GL}} < \lambda_{\mathrm{L}}$ formally we would obtain a negative wall energy. Now a new state, the so-called mixed state, is established. However, we must emphasize that these arguments based on the Ginzburg-Landau theory are valid only close to T_{c}

We will return to our discussion of the boundary between a normal conducting domain and a superconducting domain in conjunction with type-II superconductors. Next we want to discuss the pressure dependence of the superconducting state. Again we can apply the rules of thermodynamics. This section will conclude our treatment of type-I superconductors.

Influence of Pressure on the Superconducting State

In Sections 4.6.1 and 4.6.2 we discussed the difference between the free enthalpies of the normal and the superconducting states at constant pressure as a function of

We must note that the magnetic penetration depth at the boundary area in a metal can be slightly Cooper pair density. Here, we have ignored this difference.

the temperature. In order to simplify the formulas, for the quantitative discussion we have made three assumptions:

In the superconducting state, an external magnetic field should be completely expelled from the superconducting material, that is, there should be an ideal Meissner-Ochsenfeld effect. This assumption is well satisfied for macroscopic type-I superconductors over the whole stability range. It yielded the connection between the external field and the magnetization.

In order to find the magnetic moment m from the magnetization M, we must know the sample volume. In this context, we have used an approximation by ignoring the dependence of the volume upon the magnetic field B. Experience indicates that this dependence is very small.

Finally, we have taken the temperature dependence of the critical field B_c from experiment, and we have used the parabolic dependence $B_\mathrm{c}(T) = B_\mathrm{c}(0)\left[1 - (T/T_\mathrm{c})^2\right]$ as an analytic, satisfactory approximation.

All our discussions have been restricted to constant pressure. In this section, we take up the influence of pressure on superconductivity,

Already by 1925, Sizoo and Kamerlingh-Onnes had observed such an influence on the transition temperature T_c [35]. In Figure 4.20 we show the change of the transition temperature with increasing pressure for tin in the absence of an external magnetic field [36]. The transition temperature decreases with increasing pressure. The effect is not very large. In order to change T_c in tin by 0.1 K, we must apply pressures of about 2000bar[26)]

The behavior shown in Figure 4.20 is typical for many superconductors. However, there are also some materials (e.g., Ti, Zr, V, La, U) whose transition temperature increases with increasing pressure [37, 38].

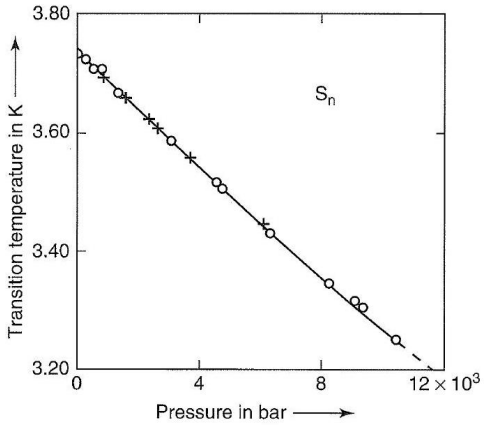

Figure 4.20 Pressure dependence of the transition temperature of tin [36]. 26) Pressure conversions: $1\mathrm{bar} = 10^5\ \mathrm{Pa} = 10^5\ \mathrm{N/m^2} = 1\mathrm{kp/cm^2}$.

The change of T_c under pressure in zero magnetic field must be connected with The of the critical field B_c with pressure. This influence of pressure on B a change of the chosen the results for cadis shown in Fgure 4.21 for cadmium [39]. We have cho sene resis cad mium, since they repres lemperatures combined with the application of high techniques. The very low temperatures combined

The pressure was generated in a so-called "ice bomb" [40]. A steel vessel is completely filled with water. During cooling below the freezing point a pressure of about 1800 bar develops, since the volume is kept constant. At constant pressure, the freezing of water is accompanied by a volume expansion of about 10%. If the liquid-solid phase transition takes place at constant volume, the resulting ice must develop under a pressure that is sufficiently high to effect a 10% volume reduction of the ice. This ice bomb method has served for performing many experiments on the behavior under pressure.

For the studies of Cd, the ice bomb was cooled down to about 6×10^{-2} K by means of so-called adiabatic demagnetization (a magnetic cooling technique), and the critical field B_c was measured down to these temperatures. In the case of C, the critical field B_c decreases with increasing pressure, as expected from the pressure dependence of T at zero magnetic field.

The reduction of the critical field under pressure means that the difference $G_n - G_0$ decreases with increasing pressure at constant B and T. If we know the $G_n - G_s$ decreases with increasing pressure at constant B and T. If we know the volumes of the normal conductor V_n and of the superconductor V_s as a function of our independent variables T, p, and B, we can calculate the p dependence of $G_1 - G$. However, the volume changes $\Delta V/V$ are very small, namely only a few 10^{-8}. Therefore, it represents an experimental challenge to demonstrate these

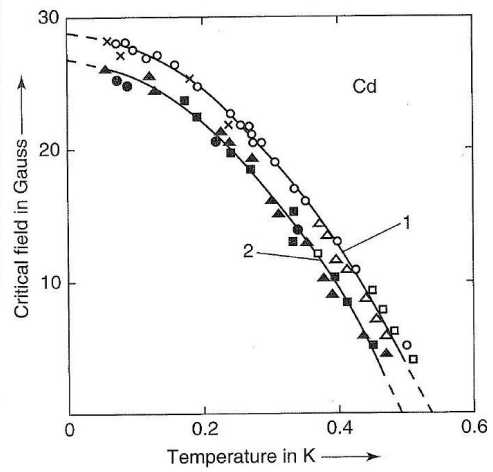

Figure 4.21 Temperature dependence of the critical field ($1\text{G} = 10^{-4}$ T) of cadmium at atmospheric pressure (curve 1) and at 1550 bar (curve 2). (From [39].) The original curves have many more data points than this reproduction.

changes convincingly. The measurements of B_c under pressure are somewhat simpler, and Figure 4.21 gives an example. From these measurements, we can determine the volume change during the phase transition by means of the Gibbs function G.

In general, we have the expression given in Eq. (4.11):

$$(\mathrm{d}G/\mathrm{d}p)_{T,B} = V$$

At the phase transition, we obtain [27]

$$(V_n - V_s)_{B=B_c} = V_s(B_c)\,\frac{\partial}{\partial p}\left(\frac{B_c^2}{2\mu_0}\right) = V_s(B_c)\,\frac{B_c}{\mu_0}\frac{\partial B_c}{\partial p}$$

This is analogous to the expression we have indicated in Section 4.2 for the entropy difference. From this expression we see that $V_n - V_s$ vanishes at T_c, because B_c is zero. Furthermore, we see that for $T < T_c$ we have $V_s > V_d$ if B_c decreases with p, that is, if $\partial B_c/\partial p < 0$, which is generally the case. The additional derivative with respect to p or T yields the difference of the compressibilities κ_s and κ_n or the difference of the thermal expansion coefficients α_s and α_n in the superconducting state and the normal state, respectively.

During the transition from the superconducting to the normal state, the volume changes have been measured directly using highly sensitive methods. Primarily, the length change of a sample in the form of a rod or a strip was determined. In Figure 4.22 we show the results for tin [41]. We see that $l_s > l_n$ for all temperatures $T > T_c$, as expected, where T_c denotes the transition temperature in zero magnetic field.

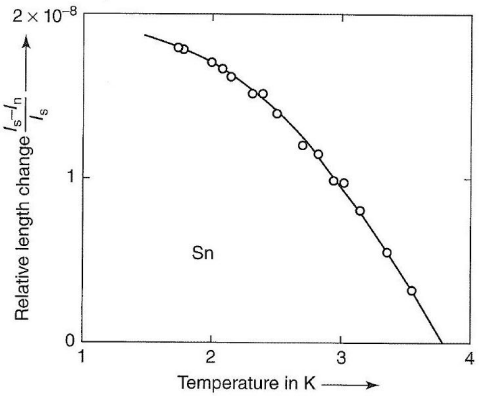

Figure 4.22 Relative length change $(I_s - I_n)\, I_s$ of a tin rod at the transition into the superconducting state. (From [41].)

At the transition from the superconducting to the normal conducting state, the volume change possible dependenced V_s/dp has been ignored

At the transition into the superconducting state, the sample expands. This is At tistent with the indications of our Gibbs function, for which we had assumed consise whe a perfect expusint of this length change near T_c requires a sensitivity of the length measurement of about 10^{-8} cm

Since the development of a microscopic theory, the BCS theory, studies of the pressure dependence of the transition temperature have gained much in importance. The application of hydrostatic pressure allows the continuous variation o the lattice constant of a substance. However, the lattice constant represents an important parameter for the quantum states of the electrons as well as of the lattice vibrations, the phonons. Since both quantities are highly important for superconductivity, new information for quantitative improvements of the microscopic conductivity, new information for quantits ive deressure. In Section 1.2 we have theory can be extracted from experiments under pressure. In Section 1.2 we have seen that our knowledge about the quantitative connections between the parameters of metals and superconductivity is still highly incomplete. For the transition the relation [28] (see Section 3.1.2, Eq. (3.6)):

$$T_c \propto \Theta_D \exp\left(-\frac{1}{N_n\left(E_F\right) V^*}\right)$$

We take the derivative with respect to p and obtain

$$\frac{\partial T_c}{\partial p} \propto \frac{\partial \Theta_D}{\partial p} \exp\left(-\frac{1}{N\left(E_F\right) V^*}\right) + \Theta_D \exp\left(-\frac{1}{N\left(E_F\right) V^*}\right)\left(\frac{1}{N\left(E_F\right) V^*}\right)^2 \frac{\partial\left(N\left(E_F\right) V^*\right)}{\partial p}$$

For determining the relative change of T_c, we divide by T_c

$$\frac{1}{T_c}\frac{\partial T_c}{\partial p} = \frac{1}{\Theta_D}\frac{\partial \Theta_D}{\partial p} + \left(\frac{1}{N\left(E_F\right) V^*}\right)^2 \frac{\partial\left(N\left(E_F\right) V^*\right)}{\partial p}$$

From the determination of the pressure dependence of T_c and from the Deby temperature Θ_D, we obtain information on the pressure dependence of the quantity $N\left(E_F\right) V^*$[38]

The change of the transition temperature under hydrostatic pressure can also serve for the construction of a superconducting manometer. Lead is particularly suitable, since it does not have any phase transition up to about 160kbar, and it is insensitive to lattice defects. Therefore, one can place a small lead wire into the pressure cell and determine the pressure within the cell at low temperatures from the transition temperature T_c of the wire. A calibration of this Pb manometer up to about 160 kbar has been carried out by Eichler and Wittig [42]. The insensitivity

Here, we denote the interaction potential between the electrons by V°, in order to distinguish it from the volume of the superconductor.

of T_c to lattice defects is important, since at the high pressures there is always a certain amount of plastic deformation, leading to the generation of lattice defects. This is even more pronounced at low temperatures.

So far we have discussed the influence of pressure within a single-crystalline phase. For many substances, under pressure one can obtain new crystalline phases, new modifications. Then we expect that during such a phase transition the superconducting properties are also changed. The high-pressure modification simply represents a new material.

Substances that do not show superconductivity at room pressure, but have superconducting phases at high pressure, are very interesting. In recent years, a number of such superconducting high-pressure phases have been found in semiconductors and in the transition range between metals and semiconductors (see also Table 2.1 and Figure 2.1).

Frequently, newly discovered superconductors are also studied early under high pressure. So in the case of the lanthanum-barium cuprate, one found a surprisingly large increase in T_c under hydrostatic pressure [43]. Since hydrostatic pressure reduces the lattice constant, also a "chemical" reduction of the lattice constant by inserting particularly small ions into the lattice could lead to T_c enhancement. C. W. Chu and coworkers utilized this argument and replaced the lanthanum by the smaller yttrium ion. In this way, they discovered the system $Y - Ba - Cu - O$ and prepared samples with values of T_c above 80 K[44][29]

Careful studies of the thermal expansion and of the effect of pressure were performed with single crystals without twin boundaries. The thermal expansion of $YBa_2Cu_3O_{7-x}$ was measured with a resolution of 10^{-9} cm. It shows a strong anisotropy also within the $Cu - O$ layers [45]. For a uniaxial pressure along the a-axis (Section 2.8.1), the experiments indicated a reduction of T_c, but along the b-axis an increase in T_c was found [46]. Similar results were obtained for other cuprates [47]. These observations were interpreted in terms of a change of concentration of the charge carriers in the Cu-O layers.

In the case of MgB_2, with increasing pressure a linear decrease in T_c was observed, in good agreement with the behavior expected from the BCS theory [48]. In the case of the iron pnictides, depending on the doping, one finds an increase or decrease in T_c[49].

3.7 Ginzburg Landau theory: advanced general features and details

3.7.1 Anderson-Higgs mechanics and Goldstone Theorem in SC

This Section is related to the Chapter on symmetry breaking. The idea is to put the Meissner effect into a wider perspective. Therefore, we will also use somewhat simpler notation in this Section and we will assume a relativistically invariant model, so that the expressions are more familiar. Apart from this, the Lagrangian that we write below is very much related to the functional $\mathcal{F}$ above.

Matter field

Asssume a matter field $\psi : \mathbb{R}^4 \to \mathbb{C}$ with Lagrangian

$$\mathcal{L}_M = \partial^\mu \psi^* \partial_\mu \psi - r_0 \psi^* \psi - \frac{u_0}{2} (\psi^* \psi)^2$$

where we use the signature $(1, -1, -1, -1)$ for the metric, so that the first term corresponds to $|\partial_t \psi|^2 - |\nabla \psi|^2$.

This is of course (apart from the temporal dependence) exactly the Gross-Pitaevskii functional. The extremal points of this Lagrangian (with uniform ψ) are

$$\begin{aligned} r_0 > 0 \Rightarrow &\text{ symmetric phase } \psi = 0 \\ r_0 < 0 \Rightarrow &\text{ symmetry broken phase } |\psi|^2 = -r_0/u_0 \end{aligned}$$

In the symmetry broken phase, it is instructive to choose new coordinates

$$\begin{aligned} \psi &= \mathrm{e}^{\mathrm{i}\phi}\left(\psi_0 + \eta\right) \\ \psi^* &= \mathrm{e}^{-\mathrm{i}\phi}\left(\psi_0 + \eta\right) \end{aligned}$$

Expanding the Lagrangian to second order gives

$$\mathcal{L} = -\frac{r_0}{u_0}\partial^\mu\phi\partial_\mu\phi + \partial^\mu\eta\partial_\mu\eta + 2r_0\eta^2$$

and ones sees that ϕ is massless whereas η has mass $-2r_0$. Again, this calculation was already done in the section on superfluids. We recall that the appearance of a massless field ϕ is a consequence of the Goldstone theorem.

EM field

Consider now also the EM Lagrangian, with gauge field $A : \mathbb{R}^d \to \mathbb{R}^4$

$$\mathcal{L}_{EM} = \mathcal{L}(A) = -\frac{1}{4}F^{\mu,\nu}F_{\mu,\nu}, \quad F^{\mu,\nu} = \partial^\mu A^\nu - \partial^\nu A^\mu$$

As one knows very well, this theory is free (quadratic) and has two massless modes (two physical polarizations)

Let us know couple the two fields

$$\mathcal{L} = \mathcal{L}_{EM} + \left(D^\mu\psi\right)^* D_\mu\psi - \left(u_0/2\right)\left(\psi^*\psi\right)^2, \quad D_\mu = \partial_\mu - \mathrm{i}qA_\mu$$

note the gauge invariance

$$\begin{aligned} \psi &\to \psi\mathrm{e}^{\mathrm{i}\chi(\boldsymbol{r})} \\ \psi^* &\to \psi^*\mathrm{e}^{-\mathrm{i}\chi(\boldsymbol{r})} \\ A^\mu &\to A^\mu + \frac{1}{q}\partial^\mu\chi \end{aligned}$$

(we chose units here such that $\hbar, c$ do not appear)

Symmetry broken phase

We start by again expanding around the solution $\psi = \psi_0$. We assume that the phase ϕ is small and in particular a univalued function (winding number 0). For the moment we do not yet expand the A field (anticipating the fact that instead of expanding around $A = 0$, we might as well expand around a pure gauge $A = \nabla\chi$). By performing the expansion in η, we get

$$\mathcal{L} = \left(D^\mu\eta\right)^* D_\mu\eta + \left|\psi_0\right|^2\left(D^\mu\mathrm{e}^{\mathrm{i}\phi}\right)^*\left(D_\mu\mathrm{e}^{\mathrm{i}\phi}\right) + 2r_0\eta^2 + \mathcal{L}_{EM}$$

Now we do the crucial step by choosing a gauge: Perform the gauge transformation with $\chi := \phi$ (gauge away the field ϕ, which is possible because of the assumption that it has vanishing winding number), then

$$\left|\psi_0\right|^2\left(D^\mu\mathrm{e}^{\mathrm{i}\phi}\right)^*\left(D_\mu\mathrm{e}^{\mathrm{i}\phi}\right) \to \left|\psi_0\right|^2 A^\mu A_\mu$$

Moreover, we will now also drop terms higher than of second order in the fields, including the field A (which can still be assumed small because χ was small as well.) This allows to simplify

$$(D^\mu \eta)^* D_\mu \eta \to \partial^\mu \eta \partial_\mu \eta$$

Finally, we use that $\mathcal{L}_{EM}$ is gauge invariant, so that $\mathcal{L}_{EM}(A - (\mathrm{i}/q)\phi) = \mathcal{L}_{EM}(A)$. Then we end up with the Lagrangian

$$\mathcal{L} = \partial^\mu \eta \partial_\mu \eta + |\psi_0|^2 A^\mu A_\mu + 2r_0 \eta^2 + \mathcal{L}_{EM}(A)$$

The big deal about this Lagrangian is that there is now a mass term for the A-field, whereas the Goldstone mode ϕ has dissappeared. As one says, the gauge particle (photon) has eaten the Goldstone boson (ϕ) and it has become massive. The symmetry breaking of ϕ has been traded for a breaking of gauge invariance. Indeed, if you interpret the resulting Lagrangian, with variables η, A as given, it does not have gauge-invariance. This should of course not be taken seriously, the gauge invariance is not really a symmetry but a redundancy in the description, so it cannot be broken. It is just that in the gauge where $\phi = 0$, the result is most transparent.

How did the 'Goldstone Theorem' get violated?

The Goldstone theorem, as stated in Section 3.2, relied on the intuition that, if one has continuous symmetry breaking, than one can form spin waves as excitations. The energy of such a spin wave then vanishes when the momentum goes to 0. However, this intuition relies crucially on the fact that the interaction is local, i.e. merely a function of the difference between nearby spins. If we allow long-range interactions, than the calculation of the energy of a smooth domain wall (and hence of a spin wave) would break down. In fact, this was explicitly demonstrated for the case of a discrete domain wall in Section??.

Hence, the Goldstone theorem should not be expected to hold for long-range interactions. This is why the Higgs-Anderson mechanism is possible, because electromagnetism is a long-range interaction.

3.7.2 Typical Subtle Features of GL theory

В уравнениях ГЛ m - это масса электрона или эффективная масса электрона? (???)

This is an effective mass.
(?? proof from comparison to some experiment???)

What is the order parameter?

(maybe I'll write it in the beginning of GL theory)

Why GL theory is written not in terms of Hamiltonian?

(I'll answer later, maybe we can do it by Hamiltonian as well??)

How to take into account field from moving electrons and what is exactly B in the functional?

(I'll think later about it)

When do we need F, or G, or Ω functionals for GL theory?

(I'll think later about it)

3.7.3 Fluctuation effects near SC phase transitions: basic concepts

19.1. Оценка ширины флуктуационной области.

Теория Гинзбурга - Ландау оперирует с распределением параметра порядка $\Psi(\mathbf{r})$, предполагая, что оно реализует минимум свободной энергии $G(\Psi)$ (при заданных температуре и магнитном поле), т.е. при его определении уже проведено усреднение по всем термодинамическим флуктуациям. Как представить себе такие флуктуации? Самый наглядный пример - критическая точка жидкость-пар: вблизи критической точки плотность пара флуктуирует во времени и пространстве, $n(\mathbf{r},t) = \bar{n} + \delta n(\mathbf{r},t)$. Явления вблизи критической точки тоже можно, до известной степени, представлять себе как аналогичные фазовому переходу II рода; здесь роль параметра порядка играет отклонение Δn средней плотности $\bar{n}$ от ее значения в критической точке n_0. Таким образом, флуктуации плотности $\delta n(\mathbf{r},t)$ приводят к появлению "флуктуационных зародышей" жидкости в паре (когда $\Delta n + \delta n(\mathbf{r},t) > 0$) и наоборот. Чем ближе система к критической точке, тем больше оказывается амплитуда характерных флуктуаций плотности и характерное время t_c существования таких зародышей. Аналогичным образом, выше точки сверхпроводящего перехода возникают и исчезают зародыши сверхпроводящего состояния, т.е. на большое (в микроскопическом масштабе - по сравнению с $\hbar/k_{\mathrm{B}}T_c$) время возникают локально сверхпроводящие области. Параметр порядка, описываемый теорией Гинзбурга - Ландау, возникает после усреднения по всем таким флуктуациям. При этом считается, что можно усреднять по различным флуктуациям независимо, т.е. пренебрегая корреляциями между ними. Такое предположение в любом случае оправдано, пока пространственный размер L рассматриваемых флуктуаций мал по сравнению с корреляционной длиной параметра порядка $\xi(T)$, однако при $L \sim \xi(T)$ оно справедливо лишь при условии $|\delta\Psi(\mathbf{r},t)| \equiv |\Psi(\mathbf{r},t) - \Psi| \ll |\Psi|$. Более точно это же условие записывается как

$$\langle \delta\Psi^*(\mathbf{r})\delta\Psi(0)\rangle|_{r\sim\xi(T)} \ll \left|\Psi^2(T)\right| \tag{19.1}$$

В теории Гинзбурга-Ландау предполагается, что условие (19.1) выполнено. Из общей теории фазовых переходов II рода [28], [34] известно, что это предположение становится неверным достаточно близко к точке фазового перехода. Окрестность температуры перехода $(\Delta T)_{\text{флукт}} = T - T_c$, где флуктуации оказываются сильными, называется флуктуационной областью. Поскольку теория Гинзбурга - Ландау строилась для окрестности точки перехода, $|\Delta T| \ll T_c$, область ее применимости существует лишь при условии $(\Delta T)_{\text{флукт}} \ll T_c$, или, иначе говоря, при условии малости так называемого параметра Гинзбурга $\mathrm{Gi} \equiv (\Delta T)_{\text{флукт}}/T_c$. Величина параметра Гинзбурга определяется микроскопической природой взаимодействия, приводящего к фазовому переходу II рода.

В некоторых случаях, как, например, при фазовом переходе ^{4}He в сверхтекучее состояние (который с точки зрения феноменологической теории фазовых переходов очень похож на сверхпроводящий фазовый переход), $\mathrm{Gi} \sim 1$, и область применимости теории Гинзбурга - Ландау вообще отсутствует. В большинстве сверхпроводников, напротив, флуктуационные эффекты очень слабы в объемных образцах. Исключение составляют ВТСП и некоторые другие сильно анизотропные сверхпроводники, например, $NbSe_2$ [35]. Кроме того, даже в «обычных» сверхпроводниках величина флуктуаций сильно возрастает при переходе от объемных образцов к тонким пленкам или проволокам. Ниже мы найдем связь между относительной шириной

флуктуационной области Gi и микроскопическими параметрами сверхпроводника для различных размерностей $d = 1, 2, 3$ образца.

Начнем с простой качественной оценки: изменение свободной энергии $F_{sn} = F_{s0} - F_n$ вследствие перехода в сверхпроводящее состояние в области размером с длину корреляции $\xi(T)$ имеет порядок $F_{sn}(T) \sim H_{cm}^2(T)\xi^3(T) \sim H_{cm}^2(0)\xi_0^3 \cdot (1 - T/T_c)^{1/2} = F_{sn}(0)(1 - -T/T_c)^{1/2}$. Это изменение свободной энергии положительно при $T > T_c$, т.е. сверхпроводящие области возникают лишь флуктуационно; напротив, при $T < T_c$ устойчиво сверхпроводящее состояние, а флуктуации приводят к его временному разрушению, т.е. появлению зародышей нормальной фазы. Вероятность флуктуационного образования зародышей с пространственным масштабом $L \sim \xi(T)$ определяется соотношением $F_{sn}(T)$ и тепловой энергии $k_{\mathrm{B}}T$: если $k_{\mathrm{B}}T \ll F_{sn}(T)$, то зародыши размера порядка $\xi(T)$ образуются экспоненциально редко, и условие (19.1) выполнено. Таким образом, получаем условие

$$\left|1 - \frac{T}{T_c}\right| \geqslant \left(\frac{k_{\mathrm{B}}T_c}{H_{cm}^2(0)\xi_0^3}\right)^2 \equiv \mathrm{Gi} \tag{19.2}$$

Убедимся, что величина Gi, определяемая правой частью (19.2), действительно очень мала. Для этого воспользуемся формулой (15.8) для H_{cm} и оценкой $\xi_0 \simeq \hbar v_{\mathrm{F}}/2\pi k_{\mathrm{B}}T_c$, которая будет обсуждаться ниже. Используя также выражение (6.3) для глубины проникновения $\lambda(0)$ и считая, что плотность сверхпроводящих
электронов n_s порядка полной их плотности $n \sim k_{\mathrm{F}}^3$, окончательно получим

$$\mathrm{Gi} \sim (k_{\mathrm{F}}\xi_0)^{-4} \ll 1. \tag{19.3}$$

Во всех известных сверхпроводниках длина когерентности ξ_0 велика по сравнению с межэлектронным расстоянием k_{F}^{-1}, что связано со слабостью куперовского притяжения; напротив, межатомное взаимодействие в жидком ^{4}He очень сильное, и аналогичная длина когерентности $\xi_{\mathrm{ст}}(0)$ для сверхтекучего состояния близка к межатомному расстоянию. Для сверхпроводников наименьшее известное значение параметра $k_{\mathrm{F}}\xi_0 \simeq 10$ относится к ВТСП и некоторым органическим сверхпроводникам [36]. Здесь надо заметить, что формулы (19.2), (19.3) неприменимы непосредственно к упомянутым сильно анизотропным материалам, т.к. были получены для изотропных трехмерных сверхпроводников. [1)] В большинстве «классических» сверхпроводников $k_F\xi_0 \geqslant \geqslant 100$, так что ширина флуктуационной области Gi пренебрежимо мала. Надо, однако, заметить, что сделанное при выводе оценки (19.3) предположение, что $n_s \sim k_{\mathrm{F}}^3$, применимо (по порядку величины) лишь для чистых сверхпроводников с длиной свободного пробега на примесях $l \gg \xi_0$. В «грязном» пределе $l \ll \ll \xi_0$ (что иначе может быть выражено как условие $k_{\mathrm{B}}T_c\tau/\hbar \ll 1$, где $\tau = l/v_{\mathrm{F}}$ - время свободного пробега) длина когерентности существенно уменьшается: $\xi_{0d} \simeq \sqrt{\xi_0 l} \simeq \sqrt{\hbar D/2\pi k_{\mathrm{B}}T_c}$, где $D = \frac{1}{3}v_{\mathrm{F}}l$-коэффициент диффузии в металле с примесями. В то же время термодинамическое критическое поле H_{cm} и температура перехода T_c не зависят (в главном приближении) от концентрации примесей (доказательство этого утверждения, называемого иногда "теоремой Андерсона», мы обсудим в 45). Приведенные выше оценки для ξ_0 и ξ_{0d} можно понять следующим образом: масштаб времени, соответствующий по соотношению неопределенности энергии связи пары $\Delta \sim k_{\mathrm{B}}T_c$ (см. §§44, 45), есть $\tau_p \sim \hbar/\Delta \sim \hbar/k_{\mathrm{B}}T_c$ и по порядку величины определяет время прохождения электроном области размером в

• Формулу (19.2) можно обобщить с учетом анизотропии, если заменить ξ_0^3 на произведение длин когерентности $(\xi_{0x}\xi_{0y}\xi_{0z})$ по всем трем направлениям.

длину когерентности. Учитывая независимость Δ от беспорядка, получаем в чистом случае $\xi_0 \sim v_{\rm F}\tau_p \sim \hbar v_{\rm F}/k_{\rm B}T_c$, а в грязном $-\xi_{0d} \sim \sim (D\tau_p)^{1/2} \sim (\hbar D/k_{\rm B}T_c)^{1/2}$, т. е. $\xi_{0d}^2 \sim \xi_0 l$.

Влияние примесей на ширину флуктуационной области ${\rm Gi}_d$ в грязном пределе проще всего усмотреть тогда из уравнения (19.2):

$$ {\rm Gi}_d \simeq {\rm Gi}\left(\frac{\hbar}{k_{\rm B}T_c\tau}\right)^3 \sim \frac{1}{\left(k_{\rm F}^2\xi_{0d}l\right)^2} \tag{19.4} $$

Перейдем теперь к оценке параметра Gi для низкоразмерных сверхпроводников - тонких пленок толщиной d и проволок поперечным сечением S. Теперь в качестве объема характерного «зародыша» следует брать либо $\xi^2(T)d$, либо $\xi(T)S$; будем также считать, что T_c и ξ_0 не меняются при уменьшении d или S. В результате для чистого сверхпроводника вместо (19.2) получим

$$ {\rm Gi}^{(2D)} = \frac{k_{\rm B}T_c}{H_{cm}^2(0)\xi_0^2 d} \sim \frac{1}{k_{\rm F}^2\xi_0 d} \tag{19.5} $$

$$ {\rm Gi}^{(1D)} = \left(\frac{k_{\rm B}T_c}{H_{cm}^2(0)\xi_0 S}\right)^{2/3} \sim \left(k_{\rm F}^2 S\right)^{-2/3}. \tag{19.6} $$

Разумеется, формулы (19.5) и (19.6) имеют смысл постольку, поскольку получающиеся из них значения ${\rm Gi}^{(2D)}, {\rm Gi}^{(1D)} \gg {\rm Gi}$. При выводе этих оценок мы предполагали, что толщина пленки d или поперечный размер проволоки $S^{1/2}$ малы по сравнению с длиной корреляции $\xi(T)$ в интересующей нас окрестности вблизи точки перехода - чем и вызвано эффективное уменьшение размерности образца. При этом низкотемпературная длина когерентности ξ_0 может быть и меньше $d, S^{1/2}$, и тогда при низких температурах сверхпроводник эффективно трехмерен. Как правило, низкоразмерные сверхпроводники имеют (по технологии их приготовления) довольно малую длину пробега $l \ll \xi_0$, т. е. реализуется грязный предел. Для оценки ширины флуктуационной области можно
в этом случае использовать первые из равенств (19.5), (19.6), заменяя ξ_0 на ξ_{0d} и учитывая независимость H_{cm} от беспорядка. В результате получим

$$ {\rm Gi}_d^{(2D)} \sim \left(k_{\rm F}^2 l d\right)^{-1} \sim g^{-1} \tag{19.7} $$

$$ {\rm Gi}_d^{(1D)} \sim \left(\frac{\xi_{0d}}{k_{\rm F}^2 S l}\right)^{2/3} \tag{19.8} $$

где $g = \frac{\hbar}{e^2}\sigma_{2d}$-безразмерная проводимость пленки на квадрат, а σ_{2d} - проводимость пленки на квадрат в нормальном состоянии. Интересно, что оценки (19.6) и (19.7) для Gi в одномерном чистом и двумерном грязном случаях оказались не зависящими от ξ или других собственно сверхпроводящих параметров, они определяются чисто металлическими свойствами - числом каналов проводимости $N_{\rm кан} \sim S/\lambda_{\rm F}^2 \sim k_{\rm F}^2 S$ в проволоке, либо безразмерной проводимостью g пленки, соответственно. Для совсем тонких пленок и проволок оценки (19.7), (19.8) должны быть уточнены, т. к. рассеяние электронов на поверхности образца может в этом случае оказаться наиболее сильным источником беспорядка, уменьшающим длину когерентности ξ_0 и тем самым увеличивающим Gi. Наконец, необходимо заметить, что формулы (19.3), (19.5) - (19.8) были получены лишь как порядковые оценки, указывающие на зависимость Gi от параметров, но не содержащие правильных численных коэффициентов; более аккуратное вычисление показывает, например, что ${\rm Gi}_d^{(2D)} \simeq 0.1g^{-1}$ (см. (19.17)).

19.2. Флуктуационные эффекты в окрестности T_c. Обсудим теперь, к каким наблюдаемым физическим эффектам приводят флуктуации параметра порядка, причем начнем со

[2)] Дело в том, что при решении задач по электропереносу вдоль тонких пленок удобно пользоваться величинами сопротивления на квадрат R^{2D} и проводимости на квадрат σ^{2D}, т.е. величинами для пленки с толщиной d и одинаковыми планарными размерами $L \times L$. Легко видеть, что эти величины от размера квадрата L не зависят и связаны с удельными сопротивлением и проводимостью соотношениями $R^{2D} = \rho/d, \sigma^{2D} = \sigma d$.

случая трехмерного сверхпроводника. Самый универсальный из таких эффектов, присутствующий при всех фазовых переходах II рода - изменение поведения теплоемкости $C(T)$ при $T \simeq T_c$ по сравнению с предсказанием теории Ландау. Например, при сверхтекучем фазовом переходе в ^{4}He (где Gi $\sim$ 1) теплоемкость логарифмически расходится в точке перехода, $C(T) \propto -\ln|1 - -T/T_c|$, вместо того чтобы испытывать конечный скачок при $T = T_c$. Общая теория фазовых переходов II рода [34] предсказывает, что в непосредственной окрестности T_c поведение системы описывается лишь симметрией параметра порядка и пространственной размерностью. Сверхтекучий фазовый переход в ^{4}He, как и обычный сверхпроводящий, описывается комплексным однокомпонентным параметром порядка, поэтому такая же логарифмическая аномалия теплоемкости должна наблюдаться и в сверхпроводниках в узкой окрестности точки перехода $|1 - T/T_c| \leqslant$ Gi Однако, из-за крайней малости Gi в объемных сверхпроводниках это явление почти никогда не наблюдается. Исключение представляют высокотемпературные сверхпроводники; в частности, на рис. 19.1 приведен график теплоемкости, измеренной вблизи сверхпроводящего перехода в YBaCuO в работе [37]. Вне флуктуационной области (т. е. при $|1 - T/T_c| \geqslant$ Gi) поправки к теплоемкости, обусловленные флуктуациями, малы:

$$\frac{\delta C(T)}{C_0} \sim \begin{cases} \left(\frac{\text{Gi}}{|1-T/T_c|}\right)^{1/2} & \text{при } d = 3, \\ \frac{\text{Gi}^{(2D)}}{|1-T/T_c|} & \text{при } d = 2, \end{cases} \tag{19.9}$$

где $C_0 \equiv C_s - C_n = T_c\widetilde{\alpha}^2/\beta$ - скачок теплоемкости при сверхпроводящем переходе (см. (3.12), (13.5) и (13.6)). Как видно из (19.9), в случае $d = 2$ поправки к теплоемкости растут заметно быстрее с приближением к T_c, однако измерять теплоемкость тонких пленок очень сложно из-за их малого объема. Интересный компромисс обнаруживается, если рассмотреть квазидвумерный (слоистый) объемный сверхпроводник с очень слабой связью между слоями (например, ВТСП семейства BiSrCaCuO): с понижением температуры в довольно широкой окрестности T_c взаимодей ствие между слоями несущественно и применима вторая из формул (19.9), описывающая "двумерные" флуктуации параметра порядка.

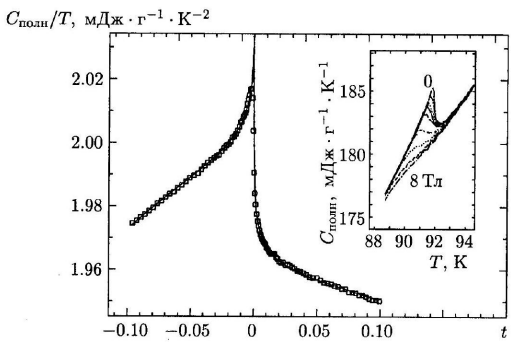

Рис. 19.1. Критическая аномалия теплоемкости монокристалла YBaCuO[37], близкая по форме к «-особенности» при сверхтекучем переходе в ^{4}He.

Взаимодействие критических флуктуаций меняет в области $\left(\frac{T}{T_c}-1\right) \leqslant \mathrm{Gi}$ вид температурных зависимостей и других величин, помимо теплоемкости. Так, длина корреляции $\xi(T) \propto (T - -T_c)^{-\nu}$, а глубина проникновения $\lambda \propto (T-T_c)^{-\nu/2}$, где критический показатель ν близок к 2/3 для трехмерной системы с комплексным параметром порядка [34].

Другая интересная для наблюдения флуктуационных поправок величина - диамагнитная восприимчивость $\chi(T)$. Действительно, в нормальном металле χ очень мала (обычно $\chi \leqslant 10^{-5}$); в то же время в сверхпроводнике имеется полный диамагнетизм, $\chi = -(4\pi)^{-1}$, т.е. в узкой окрестности перехода происходит скачок диамагнитной восприимчивости на несколько порядков. Поэтому следует ожидать, что сверхпроводящие флук туации будут давать относительно заметный вклад в χ и при $(1-T/T_c) \gg \mathrm{Gi}$. Магнитный момент сверхпроводника $M = -\partial G/\partial H_0$, где G - свободная энергия во внешнем поле H_0, определяемая согласно общим правилам статистической физики как

$$\exp\left(-G/k_{\mathrm{B}}T\right) = \int \mathcal{D}\Psi(\mathbf{r}) \exp\left(-G[\Psi(\mathbf{r})]/k_{\mathrm{B}}T\right) \tag{19.10}$$

где значок $\mathcal{D}$ обозначает интегрирование по всем возможным конфигурациям параметра порядка $\Psi(\mathbf{r})$ с весом, определяемым свободной энергией Гинзбурга-Ландау $G[\Psi(\mathbf{r})]$ (см. уравнение (14.1)). При $\left(\frac{T}{T_c}-1\right) > \mathrm{Gi}$ членом $|\Psi|^4$ в (14.1) можно пренебречь, и функциональный интеграл (19.10) сводится к произведению независимых интегралов

$$\exp\left(-G/k_{\mathrm{B}}T\right) = \prod_{\mu} da_\mu d\bar{a}_\mu \exp\left(-E_\mu \left|a_\mu\right|^2\right) \tag{19.11}$$

где использовано разложение $\Psi(\mathbf{r}) = \sum\limits_{\mu} a_\mu \psi_\mu(\mathbf{r})$ поля параметра порядка по собственным функциям оператора

$$\mathcal{H}_2 = \frac{1}{4m}\left(-i\hbar\nabla - \frac{2e}{c}\mathbf{A}\right)^2 + \alpha$$

соответствующего квадратичной части функционала Гинзбурга-Ландау (здесь $\alpha = \widetilde{\alpha}\,(T-T_c)$, где $\widetilde{\alpha} = \mathrm{const}$); величины E_μ - соответствующие собственные значения. Интеграл по каждой паре переменных $a_\mu, \bar{a}_\mu$ дает множитель $\pi k_{\mathrm{B}}T/E_\mu$. В результате диамагнитный момент равен

$$M = -\frac{\partial G}{\partial H_0} = -k_{\mathrm{B}}T \sum_{\mu} \frac{\partial \ln E_\mu}{\partial H_0} \tag{19.12}$$

Вычислим флуктуационную диамагнитную восприимчивость для самого простого случая [38] - шарика радиуса $R \ll \xi(T)$, когда в сумме (19.12) достаточно оставить лишь член с наименьшим собственным значением E_0, соответствующим постоянной по объему шарика собственной функции $\psi_0 = (4\pi R^3/3)^{-1/2}$ с нормировкой $\int d^3r \psi_0^2(\mathbf{r}) = 1$. Величину E_0 найдем просто как среднее значение оператора $\mathcal{H}_2$:

$$E_0 = \alpha + \psi_0^2 \int\limits_{r<R} d^3r \frac{e^2}{mc^2} A^2(\mathbf{r}) = \alpha + \frac{e^2 H_0^2 R^2}{10mc^2} \tag{19.13}$$

При вычислении интеграла в (19.13) мы выбрали векторный потенциал в виде $\mathbf{A} = \frac{1}{2}\left[\mathbf{H}_0\mathbf{r}\right]$; при этом $\mathbf{A}$ везде перпендикулярен нормали к поверхности шара, что необходимо

для удовлетворения граничного условия $\left(-i\nabla\psi - \frac{2e}{\hbar c}\mathbf{A}\right)_{r=R} = 0$ при $\psi_0 = \text{const}$ внутри шара. Комбинируя уравнения (19.12) и (19.13), получаем

$$M(H_0) = -\frac{e^2 T_c R^2 H_0}{5m^2c^2\left(\widetilde{\alpha}(T - T_c) + \frac{e^2 H_0^2 R^2}{10mc^2}\right)} \tag{19.14}$$

Таким образом, линейная часть флуктуационной диамагнитной восприимчивости шарика на единицу его объема равна

$$\chi_{\text{флукт}}(T) = \frac{3e^2 T_c}{20\pi mc^2 R\widetilde{\alpha}(T - T_c)} \tag{19.15}$$

Магнитная восприимчивость металла имеет порядок $\chi_0 \sim \frac{e^2 k_\text{F}}{mc^2}$; выражая по порядку величины $\tilde{\alpha}$ через ξ_0 и T_c с помощью (14.14), находим отношение флуктуационного вклада в восприимчивость к нормальному:

$$\frac{\chi_{\text{флукт}}(T)}{\chi_0} \sim \frac{\min(\xi_0, l)}{R}\frac{T_c}{T - T_c} \tag{19.16}$$

Как видно из (19.16), флуктуационный вклад в восприимчивость не выражается через число Gi, более того, он падает при уменьшении длины когерентности ξ_0 либо (в грязном пределе) примесной длины пробега l, несмотря на то, что число Gi при этом растет. В случае объемного сверхпроводника отношение $\chi_{\text{флукт}}/\chi_0 \sim \left(\frac{T_c}{T - T_c}\right)^{1/2}$ (вычисление см. в [39]) вообще не зависит от параметров материала. Такое отличие флуктуационных поправок к магнитной восприимчивости (по сравнению с поправками к теплоемкости и проводимости - см. ниже) происходит из-за того, что диамагнитный отклик сверхпроводника нелокален в пространстве; иначе говоря, он определяется экранирующими токами, текущими по его поверхности. Именно поэтому, в частности, в выражение (19.16) входит радиус шарика R.

Флуктуации сверхпроводящего параметра порядка приводят также к росту проводимости металла с понижением температуры к T_c. Этот эффект был предсказан Асламазовым и Ларкиным [40] и надежно подтвержден экспериментально. Мы качественно обсудим происхождение эффекта Асламазова - Ларкина в следующем разделе, а здесь приведем лишь результаты вычислений отношения флуктуационных поправок к нормальной проводимости грязных сверхпроводников различных размерностей d вблизи T_c:

$$\begin{gathered}
\left(\frac{\Delta\sigma_{AL}}{\sigma}\right)^{(1D)} = \frac{3\sqrt{\pi}}{4\sqrt{2}}\frac{1}{k_\text{F}^2 l}\sqrt{\frac{T_c}{D}}\left(\frac{T_c}{T - T_c}\right)^{1/2} = \\
= \left(\frac{\text{Gi}_d}{T/T_c - 1}\right)^{1/2}, \\
\left(\frac{\Delta\sigma_{AL}}{\sigma}\right)^{(2D)} = \frac{1}{16g}\frac{T_c}{T - T_c} = \frac{\text{Gi}_d^{(2D)}}{T/T_c - 1}, \\
\left(\frac{\Delta\sigma_{AL}}{\sigma}\right) = \left(\frac{\Delta\sigma_{AL}}{\sigma}\right)^{(3D)} = \frac{5.4}{(T_c\tau)^{1/2}}\frac{1}{k_\text{F}^2 S}\left(\frac{T_c}{T - T_c}\right)^{3/2} = \\
= \left(\frac{\text{Gi}_d^{(1D)}}{T/T_c - 1}\right)^{3/2}.
\end{gathered} \tag{19.17}$$

Iараметры $\mathrm{Gi}_d, \mathrm{Gi}_d^{(2D)}$ и $\mathrm{Gi}_d^{(1D)}$, введенные в формулах (19.17), сошпадают по порядку величины с оценками (19.4), (19.7) и (19.8);
мы выбрали флуктуационные поправки именно к проводимости, чтобы дать точное определение параметров Gi, поскольку проводимость удобнее всего измерять экспериментально. Микроскопическое вычисление поправок к теплоемкости [40] показывает, что численные коэффициенты в формулах (19.9) порядка единицы, т.е. ширина флуктуационной области, определенная по критическому поведению теплоемкости, такая же, как и при ее определении по проводимости.

19.3. Парапроводимость (эффект Асламазова-Ларкина). Флуктуационный вклад в проводимость металла вблизи сверхпроводящего перехода называют также парапроводимостью. Мы приведем сейчас качественное объяснение этого эффекта (см. также [41]), предсказанного Асламазовым и Ларкиным при помощи микроскопической теории [40]. Начнем с известной формулы Друде для остаточной (низкотемпературной) проводимости металла с примесями:

$$\sigma = \frac{e^2 n_e \tau_{tr}}{m} \tag{19.18}$$

В этой формуле n_e - плотность электронов проводимости, τ_{tr} транспортное время свободного пробега электронов на примесях (т. е. время за которое электрон заметно меняет направление своего импульса), m - масса электрона. В окрестности сверхпроводящего перехода в металле имеются флуктуационно возникшие куперовские пары. Их дополнительный вклад в проводимость мы и оценим с помощью формулы типа (19.18). Для этого необходимо понять, чем следует заменить параметры n_e и τ_{tr} в случае переноса заряда флуктуационными парами.

Мы уже знаем, что при $T < T_c$ величина $\langle\Psi\rangle^2$ играет роль плотности куперовских пар. Выше точки перехода эта величина равна нулю, в соответствии с тем, что настоящих пар с бесконечным временем жизни здесь нет. Однако можно рассмотреть величину $n(p) = \langle\psi_{\mathbf{p}}\psi_{-\mathbf{p}}\rangle$, которая представляет собой плотность флуктуационных пар, имеющих импульс $\mathbf{p}$. Величине $n_e\tau_{tr}$ в формуле (19.18) будет соответствовать теперь $\int d\mathbf{p} n(\mathbf{p})\tau(\mathbf{p})$.

Здесь $\tau(\mathbf{p})$ - время жизни флуктуационной пары с импульсом p, которое, как мы покажем ниже, сильно зависит от величины импульса $|\mathbf{p}|$. Начнем с оценки зависимости $n(\mathbf{p})$. Для этого надо лишь представить квадратичную часть функционала Гинзбурга-Ландау в виде (19.11), где теперь собственными функциями $\psi_\mu(\mathbf{r})$ являются просто плоские волны $e^{i\mathrm{p}r}$, а собственные значения $E_p = \hbar^2 p^2/4m + \alpha$. Соответственно, для $n(\mathbf{p}) = \langle\psi_{\mathbf{p}}\psi_{-\mathbf{p}}\rangle$ получаем

$$n(\mathbf{p}) = \frac{k_\mathrm{B}T}{\alpha + \hbar^2 p^2/4m} \tag{19.19}$$

Займемся теперь оценкой времени $\tau(\mathbf{p})$. В отличие от времени жизни τ_{tr} электрона с заданным импульсом, время жизни флуктуационной пары определяется не рассеянием на примесях, а распадом на отдельные электроны. Это время можно оценить без использования микроскопической теории, если произвести простейшее обобщение уравнений ГинзбургаЛандау для слабонеравновесной ситуации, когда параметр порядка $\Psi(\mathbf{r})$ не совпадает со своим равновесным значением Ψ_0. В этом случае вариация функционала ГЛ не равна нулю и (пределяет скорость возвращения величины параметра порядка к равновесному значению (в данном случае к нулю, т.к. $T >> T_c$:

$$\gamma\frac{\partial\Psi(\mathbf{r})}{\partial t} = -\frac{\delta F[\Psi]}{\delta\Psi(\mathbf{r})} \equiv \frac{\hbar^2}{4m}\nabla^2\Psi(\mathbf{r}) - \alpha\Psi(\mathbf{r}) - \beta|\Psi(\mathbf{r})|^2\Psi(\mathbf{r}) \tag{19.20}$$

'де γ имеет смысл кинетического коэффициента; порядок вели'ины этого параметра мы определим чуть ниже. Считая флукгуации малыми, пренебрегаем последним членом

в (19.20), после 'іго это уравнение становится линейным. Теперь можно перейти к переменным $\psi(\mathbf{p}) = \int d\mathbf{r}\Psi(\mathbf{r})e^{i\mathbf{p}r}$, в которых уравнение (19.20) чринимает простой вид:

$$\gamma\partial\psi(\mathbf{p})/\partial t = -\left(\alpha + \hbar^2 p^2/4m\right)\psi(\mathbf{p}) \tag{19.21}$$

Из уравнения (19.21) видно, что время релаксации флуктуаций параметра порядка с импульсом p равно

$$\tau(\mathbf{p}) = \frac{\gamma}{\alpha + \hbar^2 p^2/4m} \tag{19.22}$$

В результате, собирая вместе (19.19) и (19.22), получим

$$\sigma_{\mathrm{AL}} \sim \frac{e^2}{m}\sum_{\mathbf{p}} \frac{k_{\mathrm{B}}T\gamma}{\left(\alpha + \hbar^2 p^2/4m\right)^2} \tag{19.23}$$

Рассмотрим случай тонкой сверхпроводящей пленки (толщина $d \ll \xi$), когда выражение для парапроводимости имеет особенно простой и универсальный вид. Заменяя $\sum_{\mathbf{p}}$ на интеграл $(1/d)\int d^2p/(2\pi)^2$, получаем для проводимости на квадрат пленки

$$\sigma_{\mathrm{AL}}^{2D} = \sigma_{\mathrm{AL}} \cdot d \sim \frac{e^2 k_{\mathrm{B}} T_c \gamma}{\alpha\hbar^2} \sim \frac{e^2}{\hbar}\frac{T_c}{T - T_c} \tag{19.24}$$

Чтобы получить последнее выражение в правой части (19.24), мы учли, что при $(T - T_c) \sim T_c$ время релаксации сверхпроводящего параметра порядка $\tau_0 \sim \gamma/\widetilde{\alpha}T_c$ должно быть порядка $\hbar/k_{\mathrm{B}}T_c$, поэтому $\gamma \sim \hbar\widetilde{\alpha}$. Таким образом, в двумерном случае вклад в проводимость от флуктуационньг пар определяется только относительной близостью к точке перехода, и вообще не зависит от параметров сверхпроводника. Микроскопическое вычисление [40] подтверждает качественную оценку (19.24) и определяет численный коэффициент в правой части, равный 1/16.

Для тонких проволок и массивных сверхпроводников (размерность $d = 1, 3$) оценка, аналогичная (19.24), дает вклад в проводимость

$$\sigma_{\mathrm{AL}}^{(d)} \sim \left(\frac{T_c}{T - T_c}\right)^{(4-d)/2} \tag{19.25}$$

Коэффициент перед этой зависимостью уже не является универсальным; используя выражения из 51 для параметра $\alpha(T)$
и оценку для γ, можно получить (по порядку величины) формулы (19.17). В заключение заметим, что в отличие от обычного стационарного уравнения Гинзбурга-Ландау, неравновесное его обобщение применимо, строго говоря, только при $T > T_c$. Дело в том, что наличие конечной щели Δ в спектре нормальных возбуждений сверхпроводника при $T < T_c$ (см. 45) делает неверным предположение о простой релаксационной динамике параметра порядка, использованное в (19.20). Мы обсудим неравновесные процессы в сверхпроводящем состоянии в главе VII.

3.9 BCS Theory: Basic General Properties

3.9.1 Cooper Pairs: General Idea and Physical Picture

6.1 Introduction. Electron-Phonon Interaction by Shmidt

The physical mechanism of superconductivity became clear only 46 years after the phenomenon had been discovered, when Bardeen, Cooper and Schrieffer published their theory (the BCS theory).

The following estimates will help us to understand how serious were the difficulties facing theoreticians at the time. The difference in free energy between the normal metal and the superconductor is, as we already know, $H_{\rm cm}^2/8\pi \sim 10^5$ erg cm^{-3}, for $H_{\rm cm} \sim 10^3$ Oe.

(??? why it is so???)

The number of conduction electrons in 1 cm^3 is approximately 10^{22}. Then the energy responsible for superconductivity (??? what is meant by it???) is approximately $10^5/10^{22} = 10^{-17}$ erg/electron $\sim 10^{-5}$eV/ electron.

This energy should be compared with the Coulomb interaction energy $\sim$ 1eV which is sufficiently small to be neglected in many applications of the modern quantum theory of metals, without affecting the results.

The comparison implies that it was necessary to explain the coherent behavior of electrons coupled by an interaction of energy many orders of magnitude smaller than that of other interactions, which are often neglected exactly because of their small energies.

The first hint at the origin of superconductivity came with the discovery of the isotope effect. It was found that different isotopes of the same superconducting metal have different critical temperatures, $T_{\rm c}$, for the superconducting transition and that they obey the relation

$$T_{\rm c} M^a = \text{const}$$

where M is the mass of the isotope. For the majority of superconducting elements, a is close to 0.5.

Thus it became clear that the lattice of ions in a metal is an active participant in creating the superconducting state. Further theoretical analysis has demonstrated that the interaction between electrons and quantized excitations of the crystal lattice, phonons, can bring about an additional interaction between the electrons. Under certain circumstances, this interaction takes the form of electron-electron attraction. Furthermore, if the attraction proves to be stronger than the Coulomb repulsion, the electrons become effectively coupled which gives rise to the superconducting state.

Let us first try to understand how electrons can interact with each other via phonons (the latter are characterized by the energy $\hbar\omega_q$ and the wave vector q).

Consider a metal at $T = 0$. Evidently, at absolute zero, there are no phonons. How is it possible then that the electrons interact via them?

There is exactly zero phonons at $T = 0$ (???? why????) The default answer is as follows. In a perfect crystal treated harmonically, the $T = 0$ state is the phonon vacuum: every mode has occupation $n_{{\rm q},s} = 0$. The lattice still has zero-point energy $E_0 = \frac{1}{2}\sum_{{\rm q},s} \hbar\omega_{{\rm q},s}$ but that

doesn't correspond to real phonons being present. (Phonon number isn't conserved and, with anharmonicity/e-ph coupling, it's not even a sharply defined observable, but the ground state still has no thermally excited phonons.)

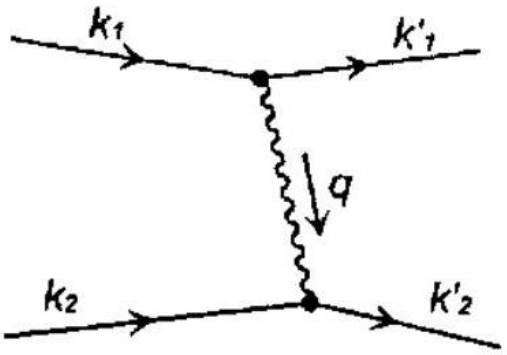

Fig. 6.1. Diagram illustrating electron-electron interaction via emission and subsequent absorption of a phonon of momentum $\hbar \boldsymbol{q}$

Consider a free electron of wave vector k_1 moving in a crystal. At some moment of time it excites a lattice vibration. In other words, the electron creates a phonon (which did not exist before) and goes to a new state k_1'.

(??? so the speed of phonon is much bigger than speed of moving out of each other electrons???)

Let the wavevector of the created phonon be $\boldsymbol{q}$. Then, by the law of momentum conservation,

$$k_1 = k_1' + q$$

The phonon q is almost immediately absorbed by another electron $\boldsymbol{k}_2$ which goes to the state k_2' as a result. Now, what has happened? Two electrons which at first occupied the states k_1 and k_2, ended up in the states k_1' and k_2'. This means that they were scattered by one another so that

$$k_1 + k_2 = k_1' + k_2'$$

But two particles can be mutually scattered only if they interact with each other. Therefore, we conclude that the above process, which is illustrated in Fig. 6.1, describes an effective electron-electron interaction. Let us consider the sign of this interaction. At the moment when one of the electrons goes from the state k_1 to the state k_1', it causes local oscillations of electron density at the frequency $\omega = \left(\bar{\varepsilon}_{k1} - \bar{\varepsilon}_{k1'}\right)/\hbar$, where $\bar{\varepsilon}_{k1}$ and $\bar{\varepsilon}_{k1'}$ are the electron energies in the states $\boldsymbol{k}_1$ and $\boldsymbol{k}_1'$, respectively. Suppose, more specifically, that at a given moment a local electron density (negative charge) has increased. The surrounding ions will then be attracted to this location and will start moving towards it, gradually compensating the electron density increase. However, due to their large mass, the ions will continue their motion even after the density increase has been compensated and will thereby create an excess positive charge. As a result, the second electron with momentum k_2 will be immediately attracted to it, that is, the particles k_1 and k_2 will be effectively attracted to each other. Such an attraction arises only if the lattice vibrations are in phase with the external force (its role in our case is played by the electron density oscillations of frequency $\omega = \left(\bar{\varepsilon}_{k1} - \bar{\varepsilon}_{k1'}\right)/\hbar$). Furthermore this ran only happen if the frequency of the external force, ω.

This will be only in case when the driving frequency ω is less than the characteristic frequency of the ion system, that is, the Debye frequency (which is also the maximum possible frequency [1]). Therefore, the condition for the attraction can be formulated as $\omega < \omega_{\mathrm{D}}$.

To elucidate the above statement, let us consider a simple oscillator of mass m and eigenfrequency ω_0 subjected to an external force $fe^{\mathrm{i}\omega t}$. The equation of motion for such a system reads

$$\ddot{x} + \omega_0^2 x = \frac{f}{m} e^{\mathrm{i}\omega t} \tag{6.1}$$

We seek the solution of the form $x = x_0 \mathrm{e}^{\mathrm{i}\omega t}$. Substituting it into (6.1), we have

$$x_0 = \frac{f}{\omega_0^2 - \omega^2}$$

that is, as long as $\omega^2 < \omega_0^2$, the oscillations $x = x_0 \mathrm{e}^{\mathrm{i}\omega t}$ are in phase with the external force f. At $\omega^2 > \omega_0^2$, the oscillations are out of phase with f.

Let us go back to our clectrons. To enable an electron to go from the state k_1 to the state k_1', the latter must be free (due to the Pauli exclusion principle) which is possible only in the vicinity of the Fermi surface. (Recall that the latter is represented by a sphere of radius k_F in momentum space.)

Now we are ready to formulate the law of phonon-mediated interaction between electrons which forms the foundation of the BCS theory: Electrons with energies that differ from the Fermi energy by no more than $\hbar\omega_\mathrm{D}$ are attracted to each other. We shall denote the energy of their interaction by $-V$. The rest of the electrons do not interact.

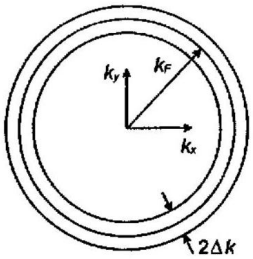

Fig. 6.2. In the BCS picture, only the electrons within the $2\Delta k$ layer near the Fermi surface interact via phonons

Let us write the matrix element of the electron interaction in the form

$$V_{kk'} = \begin{cases} -V, |\bar{\varepsilon}_k - \varepsilon_F| \le \hbar\omega_D, & |\bar{\varepsilon}_{k'} - \varepsilon_F| \le \hbar\omega_D \\ 0, |\bar{\varepsilon}_k - \varepsilon_F| > \hbar\omega_D, & |\bar{\varepsilon}_{k'} - \varepsilon_F| > \hbar\omega_D \end{cases} \tag{6.2}$$

Thus, in the BCS model, only those electrons that occupy the states within a narrow spherical layer near the Fermi surface experience mutual attraction. The thickness of the layer, $2\Delta k$, is determined by the Debye energy (see Fig. 6.2):

$$\frac{\Delta k}{k_\mathrm{F}} \sim \frac{\hbar\omega_\mathrm{D}}{\varepsilon_\mathrm{F}}, \quad \varepsilon_\mathrm{F} = \frac{\hbar^2 k_\mathrm{F}^2}{2m}.$$

Cooper Pairing by Means of Electron-Phonon Interaction by a book for experimenters

Following our discussion in Chapter 1, it appears relatively easy to arrive at a theory of superconductivity based on the microscopic interaction between the electrons themselves and between electrons and the surrounding crystal lattice. (?????)

[1] The existence of a maximum possible frequency for atom vibrations in crystals is easy to understand: a sound wave in a crystal is meaningless if its wavelength is less than the crystal lattice period. The existence of a minimum possible wavelength, which implies the existence of a maximum possible frequency, is then evident.

However, historically such a theory was confronted with extreme difficulties Because of the striking change of the electrical conductivity and the magnetic effects during the onset of superconductivity, one could presume that essentially one is dealing with an ordering process within the system of conduction electrons As we saw in Section 1.1, because of the Pauli principle the conduction electrons have fairly large energies up to a few electronvolts (1eV corresponds to thermal energy $k_{\mathrm{B}}T$ at a temperature of about 11000 K). However, the transition into the superconducting state occurs at only a few kelvins. Hence, one had to find an interaction that could lead to ordering within the electron system in spite of the high electron energies.

There exists a multitude of possible interactions between the conduction electrons in a metal. It had been imagined [W. Heisenberg: Z. Naturforsch. 2a, 185 (1947)] that Coulomb repulsion between the electrons could lead to a spatial ordering of the electrons in the form of a lattice. (??? what is there????)

Also [H. Welker: Z. Phys. 114, 525 (1939)] a magnetic interaction seemed possible. (I'll read later) The electrons propagating through the metal lattice with impressive velocities (electrons having energies near the Fermi energy can reach velocities near 1% of the velocity of light) generate a magnetic field because of the associated currents and can then interact with each other due to this magnetic field.

Other interactions can result from the structure of the electron states (allowed energy bands, see Section 1.1) [M. Born, K. C. Cheng: Nature (London) 161, 968 and 1017 (1948).]

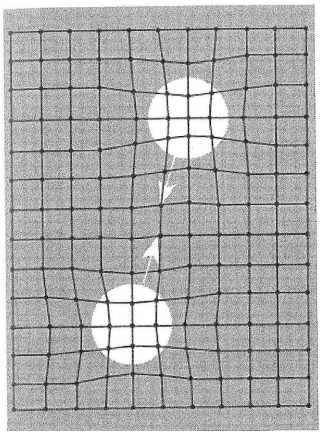
All these attempts did not lead to a satisfactory microscopic theory of superconductivity. Only in 1950/1951 was an interaction between the electrons mediated by the vibrations of the lattice discussed simultaneously and independently by Fröhlich [H. Fröhlich: Phys. Rev. 79, 845 (1950)] and Bardeen [J. Bardeen: Phys. Rev. 80, 567 (1950)]. As it turned out later, these ideas would lead to a fundamental understanding of superconductivity in terms of established concepts about the behavior of metals. Starting from this interaction, in 1957 Bardeen (Bardeen-Cooper-Schrieffer) theory, which was able to explain quantitatively many known experimental facts, and which turned out to be extremely stimulating. Motivated by this theory, after 1957 a large number of completely new experiments were performed, which strongly expanded our ideas about superconductivity and which basically changed our underlying concepts.

Still the road from the suggestion of a new interaction (1950) to the formulation of a satisfactory theory (1957) was a very difficult one. It was thus highly favorable when, nearly simultaneously with the theoretical discussion of this new interaction and of its possible importance for superconductivity, a surprisingly clear experimental confirmation of the basic correctness of the theory reached the scene. During the study of the different isotopes of the same superconductor, it had been found that the transition temperature T_{c} of superconductivity depends on the mass of the lattice atoms. Furthermore, the experimentally observed dependence exactly corresponded to that expected from the theoretical concepts of Fröhlich. This has shown that apparently the theory had hit the correct point, independent of all formal difficulties. This confirmation of the basic concepts had an important influence on the subsequent development.

How can we understand the interaction between the electrons that is mediated through the lattice vibrations? In the following, we will discuss some model ideas regarding this interaction. However, we must keep in mind that these model ideas are of little value if we try to extract further conclusions.

We start with a static model. The lattice of the atomic ions, in which the conduction electrons propagate as a Fermi gas, has elastic properties. The atomic ions are not stiffly

bound to their lattice sites at rest. Instead, they can be deflected from their sites. At finite temperatures, they oscillate in an irregular way around these sites, as we have discussed. If we consider just two negative charges within this lattice of atomic ions, and in an oversimplified way ignore all other electrons, the negative charge of both electrons will slightly distort the lattice by attracting the surrounding positive charges. In other words, the lattice is polarized because of the negative charge. This situation is shown schematically in Figure 3.1.



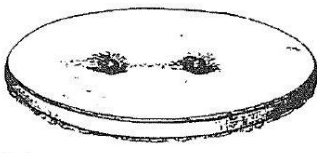


Figure 3.1 Polarization of the lattice of atomic ions due to the electrons. Within a static model, this polarization cannot overcompensate the repulsion between the electrons because of their equal charge. It can only strongly reduce the repulsion.

Compared to the uniform distribution of the positive charges, the polarization leads to an accumulation of positive charge near the polarizing negative charge. The second electron with its polarization then feels the polarization of the first electron It experiences an attraction to the location of the polarization and, hence, to the first electron. In this way, we have described an attractive interaction between two electrons due to the polarization of the lattice.

(??? does the analogy below makes sense at all??? maybe it is just a nonsense)

We can present a mechanical analogy for this static, attractive interaction. We represent the elastically deformed lattice of atomic ions by an elastic membrane, say, by a thin, stretched rubber sheet or by the surface of a liquid. Due to the surface tension it costs energy to deform the equilibrium configuration of the surface of a liquid. Next, we place two small balls onto this membrane. In the case of the liquid, the balls must remain non-wetted. If the distance between the balls is sufficiently large because of its weight, each ball will locally deform the membrane independent of the other (Figure 3.2a).

This corresponds to the deformation of the lattice. We recognize intuitively that the energy of the total system (membrane with the two balls) can be lowered if the the energy of the total system (membrane with the two balls) can be lowered if the two small balls lie in the same hollow. They will sink in more deeply (Figure 3.2b), which corresponds to a decrease of the potential energy in the gravitational field. Hence, also the total energy of the system decreases, and the difference between the mechanical energy at the beginning and at the end is changed into heat due to frictional effects. We see that we obtain an interaction between the small balls because of the elastic membrane, resulting in a bound state, that is, in a state where the two small balls are spatially located very close to each other.

(a)

Figure 3.2 Attraction between two small balls on an elastic membrane. The configuration (a) is unstable and changes into configuration (b).

The model illustrates that an attractive interaction can be realized by means of elastic deformations, no more than that. In a metal, the electrons have impressive velocities. They do not polarize the lattice statically. One could presume that rather, during this motion through the lattice, the polarization takes place along the way, which sensitively depends on how quickly the lattice can follow the polarizing action of the electron. The time during which the lattice of atomic ions can respond to any displacements should be crucial.

(??? I don't know what is below, I propose to delete it)

However, for an elastic system, this means that the characteristic internal frequencies are important (????). Because of this overall incorporation of a dynamical aspect, we have achieved an essential advance. Now we understand at least qualitatively that the strength of the polarization (????????), and hence of the interaction for the same other conditions, can depend on the characteristic frequency of the lattice and, therefore, also on the mass of the atomic ions. Heavy isotopes oscillate somewhat slower, that is, they have smaller frequencies of the lattice. They can follow the polarizing action only more slowly compared to lighter isotopes. Hence, the polarization remains smaller. From this, we expect that the interaction becomes weaker and that the superconducting transition temperature is smaller. With increasing isotope mass the transition temperature decreases, in agreement with the experimental results. However, we must keep in mind that these last discussions are meaningful only in a heuristic sense and do not allow any quantitative conclusions. (??? so that is why I'll later just delete these nonsense)

Only a quantum mechanical treatment can yield the frequencies of the lattice, which are essential for this interaction.

At this stage, we have introduced dynamic aspects into the interaction throug the polarization of the lattice. However, we have kept the concepts of a static discussion, which yielded the energy gain of an electron due to the polarization achieved by another electron (????). In order to extend our dynamic model a little further, we can imagine that the second electron propagates within the polarization trail of the first electron and thereby lowers its energy, since it experiences the lattice already in a polarized state.

(??? I don't know, how polarization is connected to the SC.... I mean, in terms of formulas. virtual phonon - one thing, polarization - another thing)

There are two possibilities. The first is that both electrons can propagate with the same momentum $\mathbf{p} = hbar\mathbf{k}$. Then we can justifiably treat this object a particle, namely an electron pair. However, the total momentum of this particle would be twice the momentum of a single electron. The other possibility would be that the electrons have opposite momentum. Again, one electron can propagate within the polarization trail of the other. However, in this case, the idea of a new particle, an electron pair, is more difficult. By a little abstraction, we note that in the first case the individual electrons are correlated due to the requirement that they have the same momentum, that is, $\mathbf{p}_1 = \mathbf{p}_2$ or $\mathbf{k}_1 = \mathbf{k}_2$.

(????????? so what is wrong physically with this model, when they are moving to the same direction???)

An equally definite correlation is obtained by the requirement that $\mathbf{p}_1 = -\mathbf{p}_2$ or $\mathbf{k}_1 = -\mathbf{k}_2$. We are justified to treat these strongly correlated electrons also as a pair. The latter electron pair has total momentum zero. Such pairs are referred to as Cooper pairs, since Cooper was the first to show that such a correlation leads to a decrease in the total energy [7]. If we take into account also the intrinsic angular momentum (spin) of the electrons, which is important for the statistical behavior of the new particles, a Cooper pair consists of two electrons with

opposite momentum of equal magnitude and with opposite spins:

Cooper pair: $\{\mathbf{k}\uparrow, -\mathbf{k}\downarrow\}$

The center of mass of the following Cooper pair is at rest, with a total momentum $\mathbf{P} = \hbar\mathbf{K} = 0$. However if we want to describe a state in which a supercurrent flows, the Cooper pairing must be performed for $\mathbf{K} \neq 0$, that is, for a state $\{\mathbf{k}+\mathbf{K}\uparrow, -\mathbf{k}+\mathbf{K}\downarrow\}\}$.

(???? why when I consider current, I haven't consider such pairs and just stationary pairs????)

The correlation leading to Cooper pairs is energetically favored because of the lattice of positive atomic ions.

Exchange interaction

Since the possibility of a pair correlation represents the crucial key of the microscopic theory of superconductivity and, hence, for an understanding of the superconducting state, we also want to present another more general consideration We can also understand the formation of electron pairs in a lattice from the very general formalism of the so-called exchange interaction.

Systems that exchange some physical quantities among themselves must experience an interaction for trivial reasons. This statement is very general. The exchange interaction of quantum mechanics deals with the fact that the exchange can lead to an attraction between two physical systems. For instance, two particles can experience an attraction because of the exchange of a third particle, leading to a state in which both particles are bound to each other.

A repulsion because of cally. Two people, throwing a ball back and forth between themselves, experience ach a repulsion. This seems obvious and can be checked easily by placing the people on two mobile platforms, which can move along the line connecting the two people. Because the ball is thrown back and forth, the two cars move away from each other. Here, it is only the exchange of the ball and the corresponding exchange of momentum that causes the repulsive interaction. action. Instead, we want to discuss an example of modern physics.

It is well known that two hydrogen atoms form a hydrogen molecule, and that the chemical bond in this molecule is very strong. In order to break this bond, one needs an energy of 26×10^4 W s/mol(62.5kcal/mol), that is, for dissociating 2 g of H_2. How can we understand such a strong bond between neutral H atoms in an H_2 molecule? To explain the principle, we look at a slightly simpler system, namely H_2^+, that is, a positively charged H_2 molecule. This ion consists of two hydrogen nuclei (two protons) and one electron. The two possible states of this system are shown in Figure 3.3a,b for a large distance between the two protons.

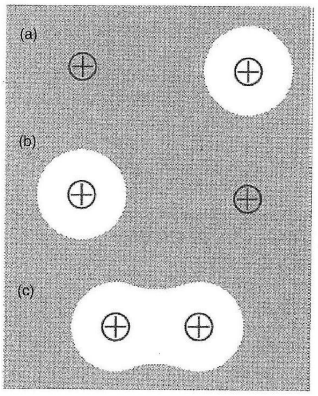

Figure 3.3 Binding of the H_2^+molecule. The scales are arbitrary. (a), (b): Two possible electron distributions for a large distance between the protons. (c) electron distribution for a small distance between the protons.

The electron resides near one of the two protons. If we bring the protons closer together, the electron will hop from one proton to the other, with a certain probability, as we know from

quantum mechanics. In our terminology, the electrons are exchanged. The probability for the exchange increases with decreasing distance. Then the electron belongs equally to both protons, as indicated in Figure 3.3c. As an important result of quantum mechanics, for this problem one finds that the total energy of the system can be lowered because of the exchange. However, this means that smaller distances R are energetically more favorable. A bond between the two protons appears because of the common electron. The equilibrium distance results from the condition that the attractive force of the electron exchange is exactly balanced by the repulsive force between the two protons.

We can understand the energy gain due to the exchange of electrons in a particularly simple way, if we apply a highly fundamental principle of modern physics, namely the uncertainty principle. This principle says that both the spatial location and the momentum of a particle cannot simultaneously be determined exactly. The accuracy of the observation of both quantities is limited by the famous relation

$\Delta p_x \Delta x = \hbar$

For our system this means that the smearing of the momentum Δp_x can be reduced if the electron is allowed to exist near both protons, since the smearing of its location Δx is enhanced in this case. As a result the energy smearing is reduced, and the energy of the electron is lowered [8].

If this energy gain is larger than the energy increase due to the Coulomb repulsion between the two protons, a net attraction is obtained. We see that the chemical bond of the H_2 molecule represents a typical quantum mechanical effect. These arguments briefly outlined provide the key for the understanding of the chemical bond.

Using similar arguments, we can also understand the attractive interaction between the conduction electrons in a metal. In the metal, a new kind of particle can be exchanged, namely the phonons. The phonons are the quantized elementary vibrations of the crystal lattice. Any complex vibrational state of the lattice can be separated into normal modes, that is, into harmonic waves. This corresponds to the description in terms of a Fourier series. For a macroscopic body, the normal modes have well-defined energies. They also have definite wavelengths and, because of the relation $p = h/\lambda$, definite momenta. Hence, they represent particles and are referred to as phonons or as quanta of sound.

So an electron in a lattice can interact with another electron by the exchange of phonons. One speaks of the electron-electron interaction via phonons. The exchanged phonons only exist virtually during their transfer from one electron to another, since they cannot escape from the electrons into the lattice as real phonons.3) Here, we note an important difference compared to the interaction within the H_2 molecule. In the latter case, the exchanged electrons are real particles. This interaction via phonons is shown schematically in Figure 3.4. In certain cases, namely in superconductors, it can be so strong that it becomes larger than the repulsion between the electrons due to the electrostatic forces.) [4] Then we obtain the pair correlation we have discussed.

For pure superconductors, the average distance within which this pair correlation is active ranges between 100 and 1000 nm.[5]) This length is referred to as the *BCS* coherence length ξ_0 of the Cooper pair. This length must not be mixed up with the Ginzburg-Landau coherence length ξ_{GL}, which indicates the length scale within which the total system of Cooper pairs can change.

The BCS coherence length ξ_0 can also be interpreted as the average size of a Cooper pair. In a highly simplified way we can say that in a pure superconductor a Cooper pair has an average size between 10^2 and 10^3 nm. This size is large compared to the average distance between two conduction electrons, which amounts

3) If real phonons are generated by an electron, we are dealing with a process causing

electrical resistance, since energy is transferred from the electrons to the lattice in this case.

4) We note that the electrostatic repulsion is highly screened by the positive charges of the atomic ions.

5) The interaction via the exchange of phonons is so weak that it cannot localize the electrons of a Cooper pair more sharply than within about ξ_0. Because of the uncertainty principle, a sharper localization would result in a kinetic energy of the electrons larger than the binding energy of the pair. However, these intuitive arguments quickly run into difficulties. For instance one can ask if the whole pair correlation is not destroyed by the high Fermi velocity. The answer is "no", but we do not attempt to justify this. Here, we would overextend the simple particle picture.

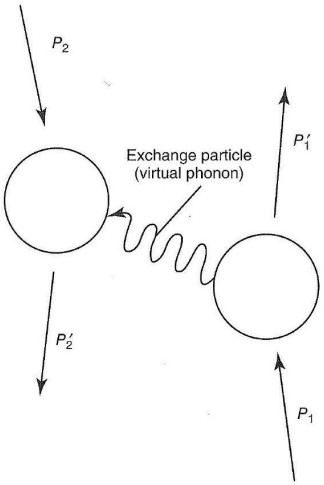

Figure 3.4 Electron-electron interaction via phonons.

to a few times 10^{-1} nm. The Cooper pairs strongly overlap. Within the space of a single pair there exist $10^6 - 10^7$ other electrons, each being correlated in pairs. Intuitively we expect that a system of such strongly overlapping particles must have unusual properties. This will be discussed in the next section.

Two pictures of BCS excitations

(write what Kabanov told me, this is very useful for understanding)

Despite Fermions are repulsive by Pauli's principle, they still can form a bound states

This is the main statement of Cooper pairs. This is because two electrons on top of a Fermi sea are effectively in 2D.

(?? I'll write more about it)

What is the virtual phonon?

It is not a real phonon.

In a perfect crystal treated harmonically, the $T = 0$ state is the phonon vacuum: every mode has occupation $n_{\mathrm{q},s} = 0$. The lattice still has zero-point energy $E_0 = \frac{1}{2}\sum_{\mathrm{q},s} \hbar\omega_{\mathrm{q},s}$ but that doesn't correspond to real phonons being present. (Phonon number isn't conserved and, with anharmonicity/e-ph coupling, it's not even a sharply defined observable, but the ground state still has no thermally excited phonons.)

(??? I'll answer here, what is it???)

Density of states near the Fermi surface

In many formulas below we will use the fact that

$$g_F := p_F m/\pi^2\hbar^3.$$

This is an important formula to keep in mind, because many quantities are deduced from it.

(write formulas for gap at 0, Tc, and maybe something else, I'll check later)

So let us derive it here.

(I'll do this trivial derivation later)

Other questions about BCS pairing

What happens with other excitations, higher than the cutoff of the BCS interaction?

Like, the electrons in the Debye's window are coupled, but what about those who are even higher in energies? Why they can't exchange a phonon? Yes, there are a very little number of them.

So, why phonons can make electrons attract each other?

(I'll write again an answer, but with formulas and precise!!! I don't have a good answer now, since all this story about lattice deformation is not enough to write the well-known formulas)

3.9.2 Cooper Pairs: Basic Calculations

Introduction about calculations of Cooper instability

(I'll add comments about this feature of theory)

This is not needed for anything (at least, now I haven't found any application of it).

And there are slightly different approaches to this derivation, though it is the same idea and same equations.

Cooper instability by Coleman

(write his derivation here)

The Cooper problem by Chalker

This is an attractive interaction for pairs of electrons with $|\epsilon(\mathbf{k}) - \epsilon(\mathbf{k}-\mathbf{q})| < \hbar\omega$: that is, for pairs within the Debye energy $\hbar\omega_{\mathrm{D}}$ of the Fermi surface. It is, however, typically very weak. This leads us to a puzzle: for two particles moving in free space in three dimensions, an attractive interaction must exceed a critical strength to produce a bound state. So how can a weak attraction generate superconductivity? The Cooper problem takes us one step towards answering this question: we consider a pair of particles moving not in free space, but above a filled Fermi sea, and will find that Pauli exclusion facilitates binding.

Consider the wavefunction for this pair of particles. We want to write a low-energy state, and so we set the centre-of-mass momentum to zero. To take advantage of a local attractive interaction, we choose the pair to be in a spin-singlet state so that the spatial wavefunction is symmetric. And to respect Pauli exclusion from a filled Fermi sea, we require the wavefunction to be built from orbitals outside the Fermi surface. The general form is then

$$\psi\left(\mathbf{r}_1\sigma_1, \mathbf{r}_2\sigma_2\right) = \left(\uparrow_1\downarrow_2 - \downarrow_1\uparrow_2\right) \cdot \sum_{|\mathbf{k}|>k_\mathrm{F}} g_\mathbf{k} \mathrm{e}^{\mathrm{i}\mathbf{k}\cdot\left(\mathbf{r}_1-\mathbf{r}_2\right)}$$

with $g_\mathbf{k}$ determined by requiring this to be a solution to the two-particle Schrödinger equation. Writing the pair energy as E and the pair potential as $U\left(\mathbf{r}_1 - \mathbf{r}_2\right)$, we have

$$\sum_{|\mathbf{k}|>k_\mathrm{F}} g_\mathbf{k} \mathrm{e}^{\mathrm{i}\mathbf{k}\cdot\left(\mathbf{r}_1-\mathbf{r}_2\right)} U\left(\mathbf{r}_1 - \mathbf{r}_2\right) = \sum_{|\mathbf{k}|>k_\mathrm{F}} \left(E - 2\epsilon(\mathbf{k})\right) g_\mathbf{k} \mathrm{e}^{\mathrm{i}\mathbf{k}\cdot\left(\mathbf{r}_1-\mathbf{r}_2\right)}.$$

To solve this Schrödinger equation, we operate on both sides with

$$\frac{1}{V}\int \mathrm{d}^d\left(\mathbf{r}_1 - \mathbf{r}_2\right) \ldots \mathrm{e}^{-\mathrm{i}\mathbf{q}\cdot\left(\mathbf{r}_1-\mathbf{r}_2\right)}$$

(where V is the system volume) and introduce the notation $\int \mathrm{d}^d\mathbf{r} U(\mathbf{r}) \mathrm{e}^{\mathrm{i}(\mathbf{k}-\mathbf{q})\cdot\mathbf{r}} = U_{\mathbf{kq}}$. Then Eq. (43) becomes

$$\frac{1}{V}\sum_{|\mathbf{k}|>k_\mathrm{F}} g_\mathbf{k} U_{\mathbf{kq}} = \left(E - 2\epsilon(\mathbf{q})\right) g_\mathbf{q}$$

We can understand the essentials in a simple way by taking

$$U_{\mathbf{kq}} = \begin{cases} -U & \text{if } \epsilon(\mathbf{k}) \text{ and } \epsilon(\mathbf{q}) \text{ are within } \hbar\omega_\mathrm{D} \text{ of } E_\mathrm{F} \\ 0 & \text{otherwise} \end{cases}$$

Then

$$\frac{U}{V}\sum_{\mathbf{k}}{}' g_\mathbf{k} = \left(2\epsilon(\mathbf{q}) - E\right) g_\mathbf{q}$$

where $\sum\limits_{\mathbf{k}}{}'$ is a sum over states within $\hbar\omega_\mathrm{D}$ of E_F.

$$\frac{1}{V}\sum_{\epsilon=E_\mathrm{F}}^{\epsilon=E_\mathrm{F}+\hbar\omega_\mathrm{D}} \frac{1}{2\epsilon - E} = \frac{1}{U}.$$

With a constant density of states ρ per unit volume, this yields

$$\int_{E_\mathrm{F}}^{E_\mathrm{F}+\hbar\omega_\mathrm{D}} \mathrm{d}\epsilon \frac{\rho}{2\epsilon - E} = \frac{\rho}{2} \ln\left[\frac{2\left(E_\mathrm{F} + \hbar\omega_\mathrm{D}\right) - E}{2E_\mathrm{F} - E}\right] = \frac{1}{U}.$$

There is a bound state for any positive U, and at weak coupling the binding energy is

$$2E_\mathrm{F} - E = 2\hbar\omega_\mathrm{D} \mathrm{e}^{-2/\rho U}.$$

Strikingly, this form is non-perturbative in ρU.

феномен Купера by Micheenkov

Прежде, чем заниматься многочастичной проблемой,

рассмотрим поведение двух выделенных электронов с локальным взаимодействием, которые двигаются на фоне остальных электронов, заполняющих сферу Ферми.

Это движение описывается стационарным уравнение Шредингера:

$$\left[\left(\frac{\hat{p}_1^2}{2m} - \mu\right) + \left(\frac{\hat{p}_2^2}{2m} - \mu\right) + U_0\delta\left(\mathbf{r}_1 - \mathbf{r}_2\right)\right]\psi\left(r_1, r_2\right) = E\psi\left(r_1, r_2\right)$$

Роль заполненной ферми-сферы сводится к тому, что из фазового пространства, доступного этим электронам, в силу принципа Паули исключены состояния, находяпциеся внутри этой сферы. Тогда волновая функция основного состояния есть функция покоюшейся пары электронов. Эта функция зависит только от расстояния межлу электронами $\mathbf{r} = (\mathbf{r}_1 - \mathbf{r}_2)$ и может быть представлена в форме

$$\psi(\mathbf{r}_1, \mathbf{r}_2) = \sum_{k>k_F} \psi_k e^{i\mathbf{kr}}$$

При суммировании по импульсам учтено, что все состояния внутри поверхности Ферми заняты. Для краткости здесь и далее мы полагаем$\hbar = 1$. Подставляя в(12), получим

$$\sum_{k'>k_F} \left[2\left(\frac{k'^2}{2m} - \mu\right) - E\right] \psi_{k'} e^{i\mathbf{k'r}} + U_0 \sum_{k'>k_F} \psi_{k'} \delta(\mathbf{r}) = 0$$

Умножая это уравнение на $e^{-i\mathrm{kr}}$ и интегрируя по объему V, находим

$$V\left[2\left(\frac{k^2}{2m} - \mu\right) - E\right] \psi_k + U_0 \sum_{k'>k_F} \psi_{k'} = 0$$

отсюда

$$\psi_k = -\frac{U_0/V}{2\left(\frac{k^2}{2m} - \mu\right)) - E} \sum_{k'>k_F} \psi_{k'}$$

Суммируя по импульсам и сокращая на $\sum\limits_{k'>k_F} \psi_{k'}$, получаем интегральное уравнение

$$1 = -\sum_{k>k_F} \frac{U_0/V}{2\left(\frac{k^2}{2m} - \mu\right) - E}$$

которое сводится к интегралу по $\xi = \frac{k^2}{2m} - \mu$.

Напомним, что

$$\sum_{k>k_F} = \frac{1}{2} V \int_0^{\omega_D} d\xi \nu(\xi), \nu(\xi) - \text{плотность состояний.}$$

Tor/a

$$-\frac{1}{2} g \int_0^{\omega_D} d\xi \frac{\nu(\xi)}{2\xi - E} = 1$$

Верхний предел интегрирования мы формально обозначили через ω_D, имея в виду, что впоследствии будет установлено $(***)$, что в металле притягиваготся электроны вблизи энергии Ферми в корочке толшиной порядка энергии Дебая ω_D При $g < 0$ сушествует решение этого уравнения с отрицательным собственное значением $E = -|E|$. Пренебрегая зависимостыо плотности $\nu(\xi)$ электронных состояний от энергии возбужления, получаем

$$\frac{1}{2} |U_0| \nu(0) \ln \frac{2\omega_D}{|E|} = 1$$

Откуда следует, что

$$|E| = \omega_D \exp\left[-\frac{2}{|U_0| \nu(0)}\right]$$

Cooper instability by Pukhov

(write his derivation here)

3.9.3 Cooper Pairs: QFT framework

Instability Of The Ground State Of A System Of Non-interacting Fermions With Respect To Arbitrarily Weak Attractions Between The Particles

1. Equation for the vertex part

We consider the properties of the system with the interaction (32.3). For this, we return to a study of the vertex part $\Gamma_{\alpha\beta,\gamma\delta}(p_1,p_2;p_3,p_4)$ at absolute zero. Let us write down the perturbation theory series for this quantity. The vertex part is, to a first approximation:

$$\lambda\left(\delta_{\alpha\gamma}\delta_{\beta\delta}-\delta_{\alpha\delta}\delta_{\gamma\beta}\right) \tag{33.1}$$

The diagrams corresponding to the first terms of the perturbation theory scries are illustrated in Fig. 90.

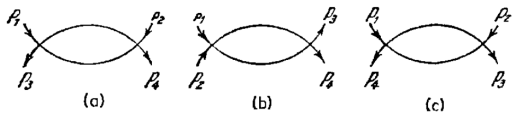

Fig. 90

As we know, singularities in the vertex part of "zero sound" type are connected with diagrams (a) and (c), i.e. these singularities are important for small momentum transfer. The diagrams of type (b) are connected with singularities in $\Gamma_{\alpha\beta,\gamma\delta}(p_1,p_2;p_3,p_4)$ at small values of the total 4 -momentum $q=p_1+p_2$. Let us investigate the last case in more detail. By using the concrete properties of the model in question, we can obtain more detailed information on the vertex part in the region of small q in comparison with the general results of (20.8).

The matrix element for the diagram of Fig. 90*b* is equal to

$$\lambda^2\frac{i}{(2\pi)^4}\left(\delta_{\alpha\gamma}\delta_{\beta\delta}-\delta_{\alpha\delta}\delta_{\gamma\beta}\right)\int \mathrm{d}^4k G(k)G(q-k)$$

where $q=\{\omega_0,q\}=\{\omega_1+\omega_2,p_1+p_2\}$. On substituting in this the expressions for the Green functions and integrating over the frequencies, we gct

$$\begin{gathered}\frac{\lambda^2}{(2\pi)^3}\left(\delta_{\alpha\gamma}\delta_{\beta\delta}-\delta_{\alpha\delta}\delta_{\beta\gamma}\right)\int\frac{\mathrm{d}^3k}{\omega_0-\varepsilon_0(k)-\varepsilon_0(q-k)+2\mu+i\delta}\\ (\varepsilon_0(k)>\mu,\varepsilon_0(q-k)>\mu)\\ -\frac{\lambda^2}{(2\pi)^3}\left(\delta_{\alpha\gamma}\delta_{\beta\delta}-\delta_{\alpha\delta}\delta_{\beta\gamma}\right)\int\frac{\mathrm{d}^3k}{\omega_0-\varepsilon_0(k)-\varepsilon_0(q-k)+2\mu-i\dot{\delta}}\\ (\varepsilon_0(k)<\mu,\varepsilon_0(q-k)<\mu)\end{gathered} \tag{33.2}$$

In the model which we are discussing, the only electrons that interact are those in a narrow region of energies close to the Fermi cnergy $\varepsilon_F\simeq\mu$. The integration over k in integrals (33.2) is therefore limited by the conditions $|\varepsilon_0(k)-\mu|,|\varepsilon_0(q-k)-\mu|<\omega_D$. On putting $\omega_0,|q|v\ll\omega_D$, we change in the ordinary way to an integration over $\xi=v(|k|-p_0)$. If we also neglect in the integrals a change in the upper limit of the order ω_0, or $|q|v$, we can transform (33.2) as follows:

$$-\frac{\lambda^2 m p_0}{2\pi^2}\left(\delta_{\alpha\gamma}\delta_{\beta\delta}-\delta_{\alpha\delta}\delta_{\beta\gamma}\right)\int_0^{\omega_D}\mathrm{d}\xi\int_0^1\left[\frac{1}{\omega_0+2\xi+2v|q|x-i\delta}+\frac{1}{2\xi+v|q|x-\omega_0-i\delta}\right]\mathrm{d}x$$

(where $x=\cos\theta,\theta$ is the angle between the directions of the vectors q and k). The remaining integrations are performed by elementary methods. Having chosen the branches of the logarithms from the condition that the integral of the first term in the square brackets be positive for $\omega_0>0$, and of the second, for $\omega_0<0$, we get the following expression for the diagram:

$$-\frac{\lambda^2 m p_0}{2\pi^2}\left(\delta_{\alpha\gamma}\delta_{\beta\delta}-\delta_{\alpha\delta}\delta_{\beta\gamma}\right)\left[1+\frac{1}{2}\ln\frac{2\omega_D-i\delta}{\omega_0+v|q|-i\delta}\right.$$
$$\left.+\frac{1}{2}\ln\frac{2\omega_D-i\delta}{-\omega_0+v|q|-i\delta}+\frac{\omega_0}{2v|q|}\left(\ln\frac{\omega_0-i\delta}{\omega_0+v|q|-i\delta}+\ln\frac{v|q|-\omega_0-i\delta}{-\omega_0-i\delta}\right)\right]. \qquad (33.3)$$

The principal term in this expression becomes, for small ω_0 and $v|q|$:

$$-\lambda^2\frac{mp_0}{2\pi^2}\left(\delta_{\alpha\gamma}\delta_{\beta\delta}-\delta_{\alpha\delta}\delta_{\beta\gamma}\right)\ln\frac{\omega_D}{\max\{\omega_0,v|q|\}}$$

Thus, when $\omega_D\gg\omega_0,v|q|$, the smallness of the interaction constant λ can be compensated by the large value of the logarithm, as a result of which this term becomes of the same order as the first term of the perturbation theory (33.1). In order to find the vertex part in the neighborhood of small ω_0 and $v|\boldsymbol{q}|$, when $\lambda\ln\omega_D/\max\{\omega_0,v|\boldsymbol{q}|\}\sim 1$, we must therefore sum the set of principal terms of the perturbation theory series, as in Chap. IV.

For this purpose, we write the equation for the vertex part in a form in which the terms leading to singularities of $\Gamma_{\alpha\beta,\gamma\delta}(p_1,p_2;p_3,p_4)$ for small $q=p_1+p_2$ are distinguished:

$$\Gamma_{\alpha\beta,\gamma\delta}(p_1,p_2;p_3,p_4)=\widetilde{\Gamma}_{\alpha\beta,\gamma\delta}(p_1,p_2;p_3,p_4) \qquad (33.4)$$
$$+\frac{i}{2(2\pi)^4}\int\tilde{\Gamma}_{\alpha\beta,\xi\eta}(p_1,p_2;k,q-k)\,G(k)G(q-k)\Gamma_{\xi\eta,\gamma\delta}(k,q-k;p_3,p_4)\,\mathrm{d}^4k$$

In this equation $\tilde{\Gamma}_{\alpha\beta,\gamma\delta}(p_1,p_2;p_3,p_4)$ is the sum of all the matrix elements whose diagrams are irreducible in the sense that interests us, i.e. cannot be split into two parts, one containing only incoming and the other only outgoing exterior ends and connected by two electron lines. The kernel of integral equation (33.4) contains a large logarithmic term from the integration of the two Green functions. In view of the smallness of the interaction constant, it is sufficient for us to take for $\tilde{\Gamma}$ its expression in terms of the first terms of the perturbation theory, since the corresponding expressions for $\tilde{\Gamma}$ do not contain large quantities. We have made it our aim, however, to calculate the kernel of equation (33.4) without confining ourselves to terms of order $\lambda\ln\omega_D/\omega_0\sim 1$; we try to find an expression for it up to and including terms of order λ. It would therefore seem at first sight that we need to know $\tilde{\Gamma}$ up to terms of order λ^2 in the perturbation theory, since the logarithmic integration in (33.4) can compensate one of the orders of λ. Let us consider terms of the second order of perturbation theory for $\tilde{\Gamma}$. The relevant diagrams are illustrated in Fig. 91.

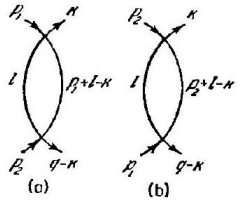

Fig. 91

Let us find the order of the matrix element corresponding to, say, diagram (a). Omitting numerical coefficients, we get

$$\lambda^2 \int G(l) G\left(l-k+p_1\right) \mathrm{d}^4 l.$$

On substituting the expressions for the Green functions, we can integrate over the frequency: (???? how to get these equations???)

$$\begin{aligned} &\lambda^2 \int \frac{\mathrm{d}^3 l}{\omega_k - \omega_\lambda + \varepsilon_0\left(l-k+p_1\right) - \varepsilon_0(l)} \left(\varepsilon_0(l) > \mu; \varepsilon_0\left(l-k+p_1\right) < \mu\right), \\ &-\lambda^2 \int \frac{\mathrm{d}^3 l}{\omega_k - \omega_1 + \varepsilon_0\left(l-k+p_1\right) - \varepsilon_0(l)} \left(\varepsilon_0(l) < \mu; \varepsilon_0\left(l-k+p_1\right) > \mu\right). \end{aligned} \tag{33.5}$$

The domain of integration over l is in fact much narrower than if it were determined only by the last conditions. This is connected with the properties of the model, in which only electrons with momenta in the neighbourhood of the Fermi momentum $|v\left(|\boldsymbol{p}| - p_0\right)| < \omega_D$ can interact. The actual domain of integration is shaded in Fig. 92 for the first condition in (33.5) and shown in black for the second In both cases the expression $\varepsilon\left(\boldsymbol{l}-\boldsymbol{k}+\boldsymbol{p}_1\right) - \varepsilon(\boldsymbol{l})$ in the denominator of the integrand is equal to ω_D in order of magnitude in the domain in question, whereas the volume of the domain over which the integration is carried out is $\sim m^2\omega_D^2/p_0$.

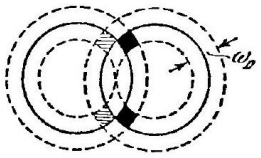

Fig. 92

The matrix element for the diagrams of Fig. 91 is therefore of order $\lambda^2 m^2 \omega_D/p_0$, i.e. their relative order compared with the simple vertex is $(\lambda m p_0)\, \omega_D/\varepsilon_T$. (As is clear from (33.3), the quantity $\lambda m p_0 \ll 1$ is a small dimensionless parameter in our model.) Since, by its physical meaning, $\omega_D \ll \varepsilon_F$, this extra order of smallness cannot be compensated in the domain considered by the large value of the logarithm. In view of this, we can confine ourselves in equation (33.4) for $\tilde{\Gamma}$ to the simple first order vertex of perturbation theory (33.1).

The equation obtained for the vertex part can now be solved easily. We notice that, as is clear from (33.3), $\Gamma_{\alpha\beta,\gamma\delta}\left(p_1, p_2; p_3, p_4\right)$ depends only on the sum of the variables $q = p_1 + p_2$. Hence the integral on the righthand side of (33.4) reduces to the integral already calculated by us for the matrix element of the second order of perturbation theory (33.3). We obtain as a result ($\omega_0 > v|\boldsymbol{q}|$):

$$\Gamma_{\alpha\beta,\gamma\delta}\left(p_1, p_2; p_3, p_4\right) \equiv \Gamma(q)\left(\delta_{\alpha\gamma}\delta_{\beta\delta} - \delta_{\alpha\delta}\delta_{\beta\gamma}\right)$$

$$\Gamma(q) = \lambda\left\{1 + \left(\frac{\lambda m p_0}{2\pi^2}\right)\left[1 + \ln\left|\frac{2\omega_D}{\omega_0}\right| + \frac{\pi i}{2} + \frac{1}{2}\ln\left|\frac{\omega_0^2}{\omega_0^2 - v^2|q|^2}\right| + \frac{\omega_0}{2v|q|}\ln\left|\frac{\omega_0 - v|q|}{\omega_0 + v|q|}\right|\right]\right\}^{-1} \tag{33.6}$$

2. Properties of the vertex part

Let us first consider for simplicity (33.6) with $q = 0$. We have for real and positive ω_0:

$$\Gamma\left(\omega_0\right) = \frac{\lambda}{1 + \left(\frac{\lambda m p_0}{2\pi^2}\right)\left[\ln\left|\frac{2\omega_D}{\omega_0}\right| + \frac{\pi i}{2}\right]} \tag{33.7}$$

We shall now regard $\Gamma(\omega_0)$ as a function of the complex variable ω_0, defining it as the analytic continuation of (33.7) in the upper half-plane $\operatorname{Im}\omega_0 > 0$. We now get

$$\Gamma(\omega_0) = \frac{\lambda}{1 + \left(\frac{\lambda m p_0}{2\pi^2}\right)\left[\ln\left|\frac{2\omega_D}{\omega_0}\right| + \frac{\pi i}{2} - i\varphi\right]}$$

Hence, if the interaction is an attraction $(\lambda < 0), \Gamma(\omega_0)$ has a pole at the point $\omega_0 = i\Omega$, where

$$\Omega = 2\omega_D \exp\left[-2\pi^2/|\lambda| m p_0\right] \tag{33.8}$$

In the neighbourhood of the pole $\Gamma(\omega_0)$ has the form

$$\Gamma(\omega_0) = -\frac{2\pi^2}{m p_0}\frac{i\Omega}{\omega_0 - i\Omega}$$

This result has to be connected with the above-mentioned idea of Cooper about the formation of bound-electron pairs. The vertex part $\Gamma_{\alpha\beta,\gamma\delta}(p_1, p_2; p_3, p_4)$ is defined in terms of the Fourier components of the two-particle Green function by the relation (10.17). Thus the fact that Γ has a pole means that the two-particle Green function has the same pole. The formation of bound pairs implies the instability of the ground state of the gas of interacting fermions from which we started out. The imposition of arbitrarily weak forces of attraction between the particles implies a readjustment of the entire system. The existence of an instability finds its reflexion in the appearance of poles in the vertex function with respect to the variable $\omega_0 = \omega_1 + \omega_2$ in the upper halfplane. This pole, being pure imaginary, determines the relaxation time of the unstable ground state. By the principle of indeterminacy, this time corresponds to the binding energy of the actual pair. In the new ground state the pairs behave as Bose formations and, as is the case for bosons, are capable of any degree of accumulation at the level of least energy. In the superconducting state these pairs are at the zero momentum level of the motion of the pair as a whole, in complete analogy with what occurs on the "Bose condensation" of ordinary bosons.

When $v|\boldsymbol{q}|$ is non-zero, (33.6) can be written as $(\omega_0 > v|\boldsymbol{q}|)$:

$$\Gamma(q, \omega_0) = \lambda\left\{1 + \frac{\lambda m p_0}{2\pi^2}\left[1 + \ln\left|\frac{2\omega_D}{\omega_0}\right| + \frac{i\pi}{2} - \frac{1}{2}\ln\left(1 - \frac{v^2|q|^2}{\omega_0^2}\right) + \frac{\omega_0}{2v|q|}\ln\left(\frac{\omega_0 - v|q|}{\omega_0 + v|q|}\right)\right]\right\}^{-1}.$$

After continuation into the half-plane $\operatorname{Im}\omega_0 > 0$ and use of definition (33.8) for Ω, we get

$$\Gamma(q, \omega_0) = -\frac{2\pi^2}{m p_0}\left\{\ln\frac{\omega_0}{i\Omega} - 1 + \frac{1}{2}\ln\left(1 - \frac{v^2|q|^2}{\omega_0^2}\right) - \frac{\omega_0}{2v|q|}\ln\left(\frac{\omega_0 - v|q|}{\omega_0 + v|q|}\right)\right\}^{-1}. \tag{33.9}$$

With small $v|\boldsymbol{q}| \ll \Omega$,

$$\Gamma(q, \omega_0) = -\frac{2\pi^2}{m p_0}\frac{i\Omega}{\omega_0 - i\Omega + i\left(v^2|q|^2/6\Omega\right)}$$

Equating to zero the denominator of (33.9) determines the pole of $\Gamma(\boldsymbol{q}, \omega_0)$ as a functions of $|\boldsymbol{q}|$. At small $|\boldsymbol{q}|$,

$$\omega_0 = i\Omega\left(1 - \frac{v^2|\boldsymbol{q}|^2}{6\Omega^2}\right)$$

i.e. the absolute value of ω_0 has decreased. At some value, $v|\boldsymbol{q}|_{\max}$, the pole ω_0 becomes zero, after which for greater $v|q|$ there is no pole of Γ. We can easily find the value of $v|q|_{\max}$ for which $\omega_0 = 0$:

$$v|q|_{\max} = e\Omega. \tag{33.10}$$

Since q is the momentum of the system of two particles as a whole, this result means that only those electrons which are moving almost towards one another reveal a tendency to the formation of bound pairs.

3. Determination of the transition temperature

Let us remark once more that the arguments adduced throw light on the instability of the ordinary ground state of a system of "attracting" particles at low temperatures. This instability amounts to an ability of two particles whose centre of mass is almost at rest to form bound pairs, i.e. a type of bosons, which "condense" in the lowest level.

The temperature at which such an instability first appears will be the transition temperature of the metal from the normal to the superconducting state.

To determine this, we can make use of the above-mentioned analogy with a boson gas. In the approximation in which we neglect the scattering of particles by one another (the weak interaction model), the bound pairs form an ideal gas. We know that the temperature-dependent Green function of an ideal boson gas is

$$\mathfrak{G}(\boldsymbol{q}, i\omega_n) = \left[i\omega_n - \frac{\boldsymbol{q}^2}{2m} + \mu\right]^{-1}$$

and represents the values at the points $\omega = i\omega_n = i2n\pi T$ of a function $G^R(q, \infty)$, analytic in the upper half-plane of ω. This function is equal to $[\mu - (q^2/2m)]^{-1}$ at $\omega_n = 0$. The latter first becomes infinite at the point $q = 0$ at some temperature $T = T_0$, called the temperature of the "Bose condensation". The temperature T_0 is determined by the condition $\mu = 0$.

The analogue of the boson Green function is, for a bound pair, the twoparticle fermion Green function (16.5). At the transition point, this latter must have analogous properties in the sense of its dependence on the variables $\omega_{0n} = (\omega_1 + \omega_2)_n$ and $\boldsymbol{q} = \boldsymbol{p}_1 + \boldsymbol{p}_2$, corresponding to the centre of mass of the pair. The fermion Green functions in (16.5) have no singularities with respect to these variables. We therefore consider the vertex part $\Gamma_R(q, \omega_0)$ (we shall omit the spin indices everywhere; the meaning of q and ω_0 is indicated above) and define it as an analytic function in the upper half-plane of ω_0, coinciding at the points $\omega_0 = i(\omega_1 + \omega_2)_n$ with the vertex part in the thermodynamic method. In other words, the function $\Gamma_R(\boldsymbol{q}, \omega_0)$ is the analytic continuation of the thermodynamic vertex part $\mathscr{T}_{\alpha\beta,\gamma\delta}(p_1\omega_1, p_2\omega_2; p_3\omega_3, p_4\omega_4) \equiv \mathcal{T}(q, \omega_0)(\delta_{\alpha\gamma}\delta_{\beta\delta} - \delta_{\alpha\delta}\delta_{\beta\gamma})$ (we shall show below that, in the approximation of interest to us, this function, like (33.9), actually depends only on the variables $\boldsymbol{q}$ and ω_0). We assume at the basis of the above that, at temperatures below the transition temperature, $\Gamma_R(\boldsymbol{q}, \omega_0)$ has poles $\operatorname{Im}\omega_0 > 0$. At the transition temperature, a pole $\omega_0 = 0$ first makes its appearance in the function $\Gamma_R(q, \omega_0)$.

The necessary equation for the thermodynamic vertex part has the same structure as (33.4):

$$\begin{aligned}\mathscr{T}_{\alpha\beta,\gamma\delta}(\boldsymbol{p}_1\omega_1, \boldsymbol{p}_2\omega_2; \boldsymbol{p}_3\omega_3, \boldsymbol{p}_4\omega_4) &= \tilde{\mathscr{T}}_{\alpha\beta,\gamma\delta}(\boldsymbol{p}_1\omega_1, \boldsymbol{p}_2\omega_2; \boldsymbol{p}_3\omega_3, \boldsymbol{p}_4\omega_4) \\ &- \frac{T}{2(2\pi)^3}\sum_{\omega'}\int \tilde{\mathscr{T}}_{\alpha\beta,\xi\eta}(\boldsymbol{p}_1\omega_1, \boldsymbol{p}_2\omega_2; \boldsymbol{k}\omega'; \boldsymbol{q} - \boldsymbol{k}, \omega_0 - \omega')\,\mathfrak{G}(k)\mathfrak{G}(q - k)\cdot \\ &\cdot \mathscr{T}_{\xi\eta,\gamma\delta}(\boldsymbol{k}\omega', \boldsymbol{q} - \boldsymbol{k}, \omega_0 - \omega'; \boldsymbol{p}_3\omega_3, \boldsymbol{p}_4\omega_4)\,\mathrm{d}^3\boldsymbol{k}, \end{aligned} \tag{33.11}$$

where $\tilde{\mathscr{T}}$ again is the sum of the matrix elements for all the diagrams which cannot be split by a vertical line into two parts, joined by two lines in the same direction. For the same reasons as above, we can confine ourselves to the first approximation of perturbation theory for $\tilde{\mathscr{T}}_{\alpha\beta,\gamma\delta}(\boldsymbol{p}_1\omega_1, \boldsymbol{p}_2\omega_2; \boldsymbol{p}_3\omega_3, \boldsymbol{p}_4\omega_4)$. The problem of finding the vertex part now reduces to finding the sum and the integral in the matrix element:

$$-\frac{\lambda^2}{(2\pi)^3} T \sum_{\omega'} \int \mathfrak{G}(k)\mathfrak{G}(q-k)\mathrm{d}^3k \tag{33.12}$$

On substituting (14.6) for the Green functions in this, we can easily perform the elementary summation over the frequencies.

We shall not evaluate (33.12) for arbitrary values of ω_0 and $|\boldsymbol{q}|$. It is clear from uniformity considerations that, as in a Bose gas, a pole first makes an appearance in $\Gamma_R(\boldsymbol{q}, \omega_0)$ for values $\omega_0 = |\boldsymbol{q}| = 0$. It is therefore sufficient to find the solution of equation (33.11) for $|\boldsymbol{q}| = \omega_0 = 0$. The instant at which this quantity becomes infinite determines the transition temperature from the normal to the superconducting state. When $|q| = \omega_0 = 0$, integral (33.12) can be transformed to

$$-\frac{\lambda}{2\pi}^2 mp_0 \int_0^{\omega_D} \tanh\left(\frac{\xi}{2T}\right)\frac{\mathrm{d}\xi}{\xi} = -\lambda^2 \frac{mp_0}{2\pi^2}\left(\ln\frac{\omega_D}{2T} - \int_0^\infty \frac{\ln x\ \mathrm{d}x}{\cosh^2 x}\right) \tag{33.13}$$

(after integration by parts, since the remaining integral is convergent, the limit $x = \omega_D/2T$ can be replaced by infinity. The integral is equal to $-\ln(2\gamma/\pi)$, where $\ln\gamma = C = 0.577$). Hence

$$\Gamma_R(0,0) = \mathscr{T}(0,0) = \frac{\lambda}{1 + \frac{\lambda mp_0}{2\pi^2}\ln\left(\frac{2\omega_D\gamma}{\pi T}\right)}$$

Close to the transition temperature, this expression can be written as

$$\mathscr{T}(0,0) = -\frac{2\pi^2}{mp_0}\frac{T_c}{T - T_c} \tag{33.14}$$

where the transition temperature T_c is equal to

$$T_c = \frac{\gamma}{\pi} 2\omega_D \exp\left[-\left(2\pi^2/|\lambda| mp_0\right)\right]. \tag{33.15}$$

The value of the frequency Ω, introduced above and characterising the instability of the system at absolute zero, is equal to

$$\Omega = \frac{\pi}{\gamma} T_{c*} \tag{33.16}$$

Cooper Pairs in QFT framework: The most important general questions

Why in general a two particle Green's function for BCS model is useful?

(????? can some one tell me??? where does it come from in the course of QFT? why in general when one looks at the BCS Hamiltonian, one says "Aha, I need to use the two-particle Green's function")

How to guess that such an approach exists?

(this is the deeper version of the previous question. Suppose we don't know that it exist. How to guess that this framework exists? I have no idea now....)

3.9.4 BCS Hamiltonian: Derivation and Features

BCS Hamiltonian

(here we will discuss why do we write it this way???)
(write that well-known expression)
(discuss here what it the momenta that corresponds to Debye frequency??)

Different way of writing original BCS Hamiltonians

Here, I'll summarize the different way of writing original BCS Hamiltonians without mean-field approximation.
(??? which are general version of which??)
from LS:

$$\widehat{\mathcal{H}}_{\text{ВКШ}} = \sum_p \xi_p a_p^+ a_p - \frac{1}{2} \sum_{p+p'=q+q'} V_{pp'qq'} a_{p\alpha}^+ a_{p'\beta}^+ a_{q\beta} a_{q'\alpha}$$

Как и раньше, будем считать, что взаимодействие отлично от нуля только вблизи ферми-поверхности:

$$V_{pp'qq'} = \begin{cases} \lambda & \text{при } \xi_{\max} < \omega_D, \\ 0 & \text{при } \xi_{\max} > \omega_D, \end{cases}$$

где $\xi_{\max} = \max\{|\xi_p|, |\xi_{p'}|, |\xi_q|, |\xi_{q'}|\}$. Выражение (10.10) называется гамильтонианом теории Бардина-Купера-Шриффера (БКШ).

$$\hat{H} - \mu\hat{N} = \sum_{\mathbf{p}\sigma} \xi_{\mathbf{p}} \hat{a}_{\mathbf{p}\sigma}^\dagger \hat{a}_{\mathbf{p}\sigma} - \lambda \sum_{\mathbf{pp}'}{}' \hat{a}_{\mathbf{p}'+}^\dagger \hat{a}_{-\mathbf{p}'-}^\dagger \hat{a}_{\mathbf{p}+} \hat{a}_{-\mathbf{p}-},$$

(??? here we have just all q-s, so which is more right?)

(discuss some notations with some minuses in some places)

(discuss here the order of operators. we have first two dagger, then two non-dagger in the coupling term. why is it so? answer! currently, I am not sure, but there is a derivation before, so the answer is already before)

Choice of model for AGD method

The interaction Hamiltonian has can be written as

$$H_{int}(x) = g\psi^+(x)\psi(x)\varphi(x) \tag{32.1}$$

Let us find the matrix clement of the scattering of two electrons by one another, in the process of which the electrons exchange one phonon. This process is illustrated schematically in Fig. 89. The dotted line represents the exchange of a phonon, which corresponds in the matrix element to the phonon D-function,

$$g^2 D(\varepsilon_3 - \varepsilon_1; p_3 - p_1) = g^2 \frac{u^2 (p_3 - p_1)^2}{(\varepsilon_3 - \varepsilon_1)^2 - u^2 (p_3 - p_1)^2}$$

where $\varepsilon_3 - \varepsilon_1, p_3 - p_1$ are respectively the changes in the cnergy and momentum of one of the electrons on collision. Close to the Fermi surface the momentum change on collision is in general of the order p_0 (i.e. $u\,|p_3 - p_1|$ is of the order of the Dcbye frequency ω_D, since $p_0 \sim a^{-1}$), so that the change in the cnergy of the electrons may be fairly small. In this region, i.e. when $|\varepsilon_3 - \varepsilon_1| \ll \omega_D$, the effective interaction, which is determined by the foregoing expression, simply reduces to

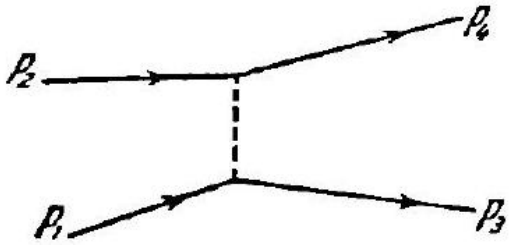

Fig. 89 the constant $-g^2$, i.e. there is an attraction.

L. Cooper [57] discovered in 1957 that the effective attraction between electrons close to the Fermi surface, resulting from an arbitrarily weak electron-phonon interaction, necessarily leads to the formation of bound electron pairs. Since binding involves an increase in energy, a readjustment of the ground state of the system must result when interaction takes place. Excitation of such a system requires the expenditure of a finite energy, cqual to the binding cnergy of the pair, which will in fact play the role of a gap in the excitation spectrum. It proved possible, on the basis of this idea, to construct a complete theory of superconductivity, explaining the vast mass of facts accumulated in several decades of intensive study of the phenomenon.

The basis chosen for our statement of the theory is not the same as in the original statements (Bardeen, Cooper and Schrieffer [58], Bogolyubov [59](†)), since it secms to us that the methods of quantum field theory offer substantial advantages. Apart from its simplicity and harmony, the approach described below enables a number of important new results to be obtained.

Before procecding further, let us remark that the electron-phonon interaction is not the only one for electrons in a metal. Repulsive Coulomb forces also operate between the electrons. The effective interaction between them will therefore be either an attraction or a repulsion, depending on

(†) See also [60].

the ratio of the magnitudes of the electron-phonon attraction and the Coulomb repulsion of the electrons. In general, the problem of taking into account both interactions for actual metals is extremely difficult. In addition to this, actual superconductors are anisotropic. A proviso must therefore be made regarding the present-day theory of superconductivity, that in essence it considers a simple model with a quadratic dispersion law for the clectrons, in which it is postulated in advance that the interaction of the electrons has the nature of an attraction in a narrow band of their energies close to the Fermi surface. This energy region is obviously of the order of the maximum energy of the emitted phonons, i.e. $\sim \omega_D$, where ω_D is the Debye frequency. In addition, we shall assume below, for simplicity, that the interaction is constant in this region and is fairly small.

To date, no theory of superconductivity has been developed on the basis of the Fermi liquid concept and which also takes the anisotropic properties into account. Nevertheless, it is interesting to note that, in spite of the crudity of the model, the theory not only explains the phenomena qualitatively, but also lcads to good quantitative agreement with the available experimental data.

We write down the effective interaction Hamiltonian of the electrons with one another in the second quantization representation as follows:

where $\lambda < 0$, and θ_p are the cut-off factors:

$$\theta_p = \begin{cases} 1, |\varepsilon(p) - \varepsilon_F| < \omega_D, \\ 0, |\varepsilon(p) - \varepsilon_F| > \omega_D. \end{cases}$$

The presence of these factors denotes that the only electrons taking part in the interaction are those with energies in a narrow band of width $2\omega_D$ close to the Fermi surface ($\omega_D \ll \varepsilon_F$). This Hamiltonian will often be written below in terms of the operators $\psi_\alpha(r)$ and $\psi_\beta^+(r)$ in the coordinate representation

$$H_{inl} = \frac{\lambda}{2} \int \psi_\alpha^+(r)\psi_\beta^+(r)\psi_\beta(r)\psi_\alpha(r)\mathrm{d}^3r. \tag{32.3}$$

It should be understood, of course, that the values of the four arguments of the ψ-operators in (32.3) are in fact somewhat different. This last is connected with the presence of the factors θ_p in expression (32.2) for the Hamiltonian. It would be more exact to write, instead of (32.3):

$$\begin{aligned} H_{\text{int}} = \frac{\lambda}{2} \iiint \iint \theta\left(r-\xi_1\right)\theta\left(r-\xi_2\right)\theta\left(r-\xi_3\right)\theta\left(r-\xi_4\right) \\ \times \psi_\alpha^+\left(\xi_1\right)\psi_\beta^+\left(\xi_2\right)\psi_\beta\left(\xi_3\right)\psi_\alpha\left(\xi_4\right)\mathrm{d}^3r\ \mathrm{d}^3\xi_1 \cdots\ \mathrm{d}^3\xi_4 \end{aligned} \tag{32.4}$$

where $\theta(x)$ is the Fourier transform of θ_p:

$$\theta(x) = \frac{1}{(2\pi)^3} \int e^{i(p\cdot x)}\theta_p\ \mathrm{d}^3p \tag{32.5}$$

It is easily verified by Fourier transforming that the functions $\theta(x)$ have δ-function characteristics:

$$\int \theta(x-y)f(y)\mathrm{d}^3y = f(x)$$

if the function $f(x)$ has noll-zero Fourier components f_p only for momenta p close to the Fermi surface. It is precisely with these functions that we shall be concerned in the theory described below. Expression (32.3) is to be understood in this sense.

Derivation of BCS Hamiltonian from electron-phonon interactions by Chalker

Experiments on the isotope effect showed that phonons are central to superconductivity. In the ideal case, for different isotopes of the same superconductor the energy scales represented by the critical temperature T_c and the critical field H_c vary with isotope mass like phonon frequencies, as (ionic mass) $^{-1/2}$. For a pair of electrons that are close in energy, phonon exchange generates an attractive interaction that beats the obvious screened Coulomb repulsion.

To derive this effective interaction we start from the Hamiltonian $\mathcal{H} = \mathcal{H}_0 + \mathcal{H}_1$ written in terms of electron operators $c_\mathbf{k}^\dagger$ and $c_\mathbf{k}$, and phonon operators $a_\mathbf{q}^\dagger$ and $a_\mathbf{q}$ as

$$\mathcal{H}_0 = \sum_\mathbf{k} \epsilon(\mathbf{k}) c_\mathbf{k}^\dagger c_\mathbf{k} + \hbar\omega \sum_\mathbf{q} a_\mathbf{q}^\dagger a_\mathbf{q} \quad \text{and} \quad \mathcal{H}_1 = \sum_\mathbf{kq} \left(M c_{\mathbf{k}+\mathbf{q}}^\dagger c_\mathbf{k} a_\mathbf{q} + \text{ h.c. } \right).$$

Here $\epsilon(\mathbf{k})$ is the electron dispersion relation and the phonons are represented as Einstein oscillators, all with frequency ω; the electron-phonon coupling is represented by the matrix element M; and we have omitted spin labels, though they will be crucial later.

We wish to focus on the electron system. To this end we eliminate the electron-phonon coupling by means of a canonical transformation, which we determine perturbatively. We write

$$\tilde{\mathcal{H}} = \mathrm{e}^{-S}\mathcal{H}\mathrm{e}^S = \mathcal{H} + [\mathcal{H}, S] + \frac{1}{2}[[\mathcal{H}, S], S] + \ldots$$

and at leading order we fix S simply by setting

$$\mathcal{H}_1 + [\mathcal{H}_0, S] = 0,$$

yielding

$$\tilde{\mathcal{H}} = \mathcal{H}_0 + \frac{1}{2}[\mathcal{H}_1, S] \equiv \mathcal{H}_0 + \mathcal{H}_{\text{int}}$$

To find S explicitly, we take matrix elements of Eq. (41) in eigenstates of $\mathcal{H}_0$, which satisfy $\mathcal{H}_0|n\rangle = E_n|n\rangle$. In this way we obtain

$$\langle n|S|m\rangle = \frac{\langle n\,|\mathcal{H}_1|\,m\rangle}{E_m - E_n} \quad \text{and} \quad \langle f\,|\mathcal{H}_{\text{int}}\,|\,i\rangle = \frac{1}{2}\sum_v \langle f\,|\mathcal{H}_1|\,v\rangle\,\langle v\,|\mathcal{H}_1|\,i\rangle \left(\frac{1}{E_i - E_v} + \frac{1}{E_f - E_v}\right).$$

From its matrix elements we can read off $\mathcal{H}_{\text{int}}$ in operator form, as

$$\mathcal{H}_{\text{int}} = \frac{1}{2}\sum_{\mathbf{pkq}} c^\dagger_{\mathbf{p}+\mathbf{q}} c_{\mathbf{p}} c^\dagger_{\mathbf{k}-\mathbf{q}} c_{\mathbf{k}} |M|^2 \left(\frac{1}{\epsilon(\mathbf{k}) - \epsilon(\mathbf{k}-\mathbf{q}) - \hbar\omega} + \frac{1}{\epsilon(\mathbf{p}+\mathbf{q}) - \epsilon(\mathbf{p}) - \hbar\omega}\right).$$

Derivation from электрон-фононное взаимодействие 2

Покажем, каким образом электрон-фононное взаимодействие может привести к эффективному притяжению электронов.

В отсутствие взаимодействия между электронами и решеткой гамильтониан системы имеет вид

$$H_0 = \sum_q \hbar\omega_q c_q^+ c_q + \sum_k \varepsilon_k a_k^+ a_k$$

Когда атомы решетки колеблотся возникает локальная леформация решетки и возникает локальная поляризация, описываемая дипольным моментом $\mathbf{P}(\mathrm{r})$.

Возникаюшее при этом изменение плотности связанного заряда выражается чepes диполыны й момент соотношением $\rho(\mathrm{r}) = -\operatorname{div}\mathrm{P}(\mathrm{r})$. Взаимолействие электрона, находящегося в точке $\mathbf{r}$, с этой поляризалией лается выражением

$$e\int Q\left(\mathbf{r} - \mathbf{r}'\right) \operatorname{div}\mathbf{P}$$

Если бы не было дебаевской экранировки (см. наши Лекиии по физической ки- экранировки, кулоновское взаимодействие обрезается на межатомном расстоянии $a \sim \hbar/p_F$. Поэтому можно считать, что

$$Q\left(\mathbf{r} - \mathbf{r}'\right) = a^2\delta\left(\mathbf{r} - \mathbf{r}'\right)$$

Дипольный момент $P \sim$ neu, где n - концентрания этомов, по поря дку величины равная концентрании электронов, u - смепение узла решетки из положения равновесия. Рассмотрим вклад в divP от некоторой фурье-компоненты флуктуацией $\operatorname{div}\mathbf{P}_k \sim V^{-1/2} iku_k$. Поэтому

$$V_k \sim V^{-1/2} ie^2a^2n(\omega/s)u_k$$

Оператор смещения есть линейная комбинация операторов рождения и уничтожения фононов c^+ и это разложение операторы рождения и уничтожения входят в комбинации

$i\sqrt{\frac{\hbar}{2nM\omega_k}}\left(c_k + c_k^+\right)$. Поэтому процесс, при котором происходит поглощение или испускание фонона описывается оператором

$$V_k \sim V^{-1/2} i e^2 a^2 n \left(\omega_k/s\right)^{1/2} \sqrt{\frac{\hbar}{2nM\omega_k}} \left(c_k + c_k^+\right) \sim$$

$$iV^{-1/2}\frac{ne^2a^2}{s}\sqrt{\frac{\omega_k\hbar}{2nM}} = iV^{-1/2}\left(na^3\right)\frac{e^2}{as}\sqrt{\frac{\omega_k\hbar}{2nM}}\left(c_k + c_k^+\right)$$

Типичный масштаб энергий в металле есть $e^2/$ a. Приравнивая эту величину кинетической части энергии колебаний $Ms^2/2$, получим для скорость звука оценку $s \sim a\omega_D \sim \sqrt{e^2/aM} \sim \sqrt{p_F^2/mM}$. Кроме того $na^3 \sim 1$. Подставляя эти оценки в (94), получим

$$V_k \sim iV^{-1/2} p_F \sqrt{\frac{\hbar\omega_k}{2nm}} \left(c_k + c_k^+\right)$$

Поглошение или испускание фонона, происходит при рассеянии электрона. Полный гамильтониан системы электронов и фононов с учетом взаимолействия между ними может, таким образом, быть представлен в виде

$$H = H_0 + V$$
$$H_0 = \sum_q \hbar\omega_q c_q^+ c_q + \sum_k \varepsilon_k a_k^+ a_k; V = D\sum_{kq}\sqrt{\hbar\omega_q}a_{k+q}^+ a_k\left(c_q + c_{-q}^+\right)$$

Здесьc_q^+, c_q - операторы рождения и уничтожения фононов с импульсом и энергией q и ω_q соответственно; a_k^+, a_k - операторы рожления и уничтожения электронов с импульсомk и энергией ε_k, соответственно. Последний член в (95) описывает рассеяние электронов на колебаниях решетки с испусканием (поглошением)

фонона, причем D - матричный элемент перехода. Гамильтониан V описы вает рассеяние электрона с испусканием или поглошением электрона. Гамильтониан рассеяния (БКII) возникает как процесс второго порядка теории возмущений. Вместо станлартной теории возмущений удобно применить каноническое преобразовние, предложенное Фрелихом,

$$\tilde{H} \equiv e^{-S} H e^S = H + [H, S] + \frac{1}{2}[[H, S], S]\ldots$$

Переход от H к $\tilde{H}$ с помонцьо унитарного канонического преобразования означает просто переход к другому базису, в котором гамильтониан может выглядеть проше.

Будем считать V малым возмупением по параметру D. Тогда S также мало по этому параметру. Выберем S из условия обращения в нуль в $\tilde{H}$ линейных по D членов:

$$V + [H_0, S] = 0$$

Во втором порялке теории возмунцений

$$\tilde{H} \equiv e^{-S} H e^S = H_0 + [V, S] + \frac{1}{2}\left[\left[H_0, S\right], S\right] + O\left(D^3\right) =$$
$$= H_0 + \frac{1}{2}[V, S] + O\left(D^3\right)$$

Перепишем (97) в базисе собственных функцций гамильтонтана H_0 с собственными значениями E_m. Тогда

$$S_{mn} = \frac{V_{mn}}{E_n - E_m}$$

и эффективный гамильтониан рассеяния электронов через обмен виртуальным фононом равен

$$H_2 = \frac{1}{2}[V, S]$$

Для простоты ограничимся случаем нулевых температур (когда фононы возникают лишь виртуальным образом). Для вычисления энергии $\tilde{H}$ нас интересует матричный элемент$\langle 0|\tilde{H}|0\rangle$ (являющийся оператором по отношению к электронному гильбертову пространству). Здесь $|0\rangle$ - фононная компонента полной волновой функции электрон-фононной системы при отсутствии фононов. При вычислении энергии во втором порядке теории возмущений нас интересуют матричные элементы

$$\langle 1_q|S|0\rangle = D\sum_k \frac{\sqrt{\hbar\omega_q}a^+_{k-q}a_k}{\varepsilon_k - \varepsilon_{k-q} - \hbar\omega_q}$$

$$\langle 0|S|1_q\rangle = D\sum_k \frac{\sqrt{\hbar\omega_q}a^+_{k+q}a_k}{\varepsilon_k + \hbar\omega_q - \varepsilon_{k+q}}$$

здесь $|1\rangle$ - фононная компонента волновой функции электрон-фононной системы с одним фононом в состоянии q. Очевидно, что

$$\langle 0|V|1_q\rangle = D\sqrt{\hbar\omega_q}\sum_k a^+_{k+q}a_k$$

$$\langle 1_q|V|0\rangle = D\sqrt{\hbar\omega_q}\sum_k a^+_{k-q}a_k$$

Используя (100) – (102), получим

$$\frac{1}{2}[V, S] = \frac{1}{2}D^2\sum_{kqk'} a^+_{k'+q}a_{k'}\frac{\hbar\omega_q a^+_{k-q}a_k}{\varepsilon_k - \varepsilon_{k-q} - \hbar\omega_q} - \frac{\hbar\omega_q a^+_{k+q}a_k}{\varepsilon_k + \hbar\omega_q - \varepsilon_{k+q}}a^+_{k'-q}a_{k'}$$

Учитывая, что$\omega_q = \omega_{-q}$, во втором слагаемом делаем замену $q \to -q$ и переставим пары операторов $a^+_{k+q}a_k$ и $a^+_{k'-q}a_{k'}$. (Коммутатор этих операторов есть квацратичная форма по операторам и может быть включен в перенормировку ε_k.)

$$\frac{1}{2}D^2\sum_{kqk'}\hbar\omega_q a^+_{k'+q}a_{k'}a^+_{k-q}a_k\left(\frac{1}{\varepsilon_k - \varepsilon_{k-q} - \hbar\omega_q} - \frac{1}{\varepsilon_k + \hbar\omega_q - \varepsilon_{k-q}}\right) =$$

$$= D^2\sum_{kqk'} a^+_{k'+q}a_{k'}a^+_{k-q}a_k\frac{(\hbar\omega_q)^2}{(\varepsilon_k - \varepsilon_{k-q})^2 - (\hbar\omega_q)^2} =$$

$$= D^2\sum_{kqk'} a^+_{k-q}a^+_{k'+q}a_{k'}a_k\frac{(\hbar\omega_q)^2}{(\varepsilon_k - \varepsilon_{k-q})^2 - (\hbar\omega_q)^2}$$

Отсюда следует, что если

$$|\varepsilon_k - \varepsilon_{k-q}| < \hbar\omega_q$$

то амплитуда рассеяния двух электронов имеет отрицательный знак. Итак, после канонического преобразовния гамильтоноан электрон-фононной системы имеет вид

$$H = H_0 + D^2\sum_{kqk'}\frac{(\hbar\omega_q)^2}{(\varepsilon_k - \varepsilon_{k-q})^2 - (\hbar\omega_q)^2}a^+_{k-q}a^+_{k'+q}a_{k'}a_k$$

Наиболыпий фазовый объем $\sim q^2$ отвечает процессам, в которых импульс q достигает своего максимального значения $q \sim \hbar/a$. Этому имульсу отвечает дебаевская энергия $\hbar\omega_D$. Поэтому в (106) можно заменить $\hbar\omega_q$ на $\hbar\omega_D$. Рассмотрим теперь только состояния, дуя которых $|\varepsilon_k - \varepsilon_{k-q}| \ll \hbar\omega_D$. Тогда

$$H = H_0 - D^2 \sum_{kqk'} a^+_{k-q} a^+_{k'+q} a_{k'} a_k$$

Если перейти в этом выражении в координатное представление то мы получим для взаимодействия выражение типа (11). Это означает, обмен фононами во втором порядке теории возмунений, эквивалнетен точечному притяжению. В силу принципа Паули это может иметь место, только если взаимодействуют элекроны с противоположными спинами.

Очевидно, что если рассеиваются электроны с противоположными импульсами $\mathrm{k} = -\mathrm{k}'$, то в результате рассеяния должны получиться два электрона также с противоположными импульсами, причем это может быть любой импульс из этой корочки корочки. Если же рассеивалтся электроны с одинаковыми импульсами (близкими к импульсу Ферми) то фазовый объем, доступный рассеянным электронам исчезагоше мал. Поэтому основной вклал в рассеяние датт процессы в которых электроны имегот практически противоположные импульсы.

мы рассматриваем модель, в которой только такое рассеяние и учитывается. Соображения, описанные выше обосновывают модель БКШ, описываемую гамильтонианом

$$H = H_0 - g \sum_{kq} a^+_{k+q,\sigma} a^+_{-k+q,-\sigma} a_{-k,-\sigma} a_{k,\sigma}, \quad g > 0$$

Why in the BCS Hamiltonian is what is there?

Why there is a plus sign in front of the part with Δ?

(I'll write that some initial Hamiltonians have different order of operators, in that nonation in a mean field approximation, there is a minus sign)

(??? I believe that it does not matter, but later maybe I'll explicetely write why it does not matter. It is not obvious)

What if one writes operators in a different position in the interaction term?

(??? I'll write later)

What exactly the meaning of $\mu\hat{N}$ in the BCS Hamiltonian?

The basic answer is that we have a chemical potential, which is the Fermi energy, so this term is just a subtraction of all the states below the Fermi energy.

(????? right???)

(???? see my thesis for deeper discussion.)

BCS model is nonlocal $\hat{V}(\mathbf{r}_1, \mathbf{r}_2) \neq V(\mathbf{r}_1 - \mathbf{r}_2)$

(??? I'll explain in details, why it is so???)

(???? why local theory would not work??)

Overview of other derivations of BCS coupling

Idea of derivation from functional integral

(??? maybe integration out phonon field will also give it. I'll derive it in the section on BCS in functional integral and explain this idea here. It is a very nontrivial idea!)

BCS Hamiltonian in the real space

This is an old scary notation, which is still a good thing to learn to understand it in a different way.

(translate it!)

Полный гамильтониан подсистемы электронов в представлении вторичного квантования для большого канонического ансамбля запишем в форме суммы кинетической энергии электронов и эффективного парного взаимодействия

$$\hat{H} = \int d^3 r \hat{\Psi}_\sigma^+(t,\mathbf{r}) \left(\frac{\left(\hat{\mathbf{p}} - \frac{e}{c}\mathbf{A}\right)^2}{2m} + e\varphi - \mu \right) \hat{\Psi}_\sigma(t,\mathbf{r}) + \\ + \frac{1}{2} \int d^3 r_1 d^3 r_2 \hat{\Psi}_\sigma^+(t,\mathbf{r}_1)\, \hat{\Psi}_{\sigma'}^+(t,\mathbf{r}_2)\, U(\mathbf{r}_1 - \mathbf{r}_2)\, \hat{\Psi}_{\sigma'}(t,\mathbf{r}_2)\, \hat{\Psi}_\sigma(t,\mathbf{r}_1)$$

где $\hat{\Psi}_\sigma(t,\mathbf{r})$ - оператор уничтожения электрона в (r,t)-представлении, $\hat{\mathbf{p}}$ - operagor импульса электрона, A, φ - потенциалы электромагнитного поля. В (2) мы пренебрегаем кристаллической структурой тела, $\sigma = \pm 1$ есть удвоенная проекция спина на одну из осей, постоянная μ есть химический потенциал электронов. Вы пишем также оператор полного числа частиI

$$\hat{N} = \int d^3 r \hat{\Psi}_\sigma^+(t,\mathbf{r}) \hat{\Psi}_\sigma(t,\mathbf{r})$$

Квантовое поле ферми-частиц удовлетворяет коммутащионным соотношениям:

$$\left\{ \hat{\Psi}_\sigma(t,\mathbf{r}_1), \hat{\Psi}_{\sigma'}^+(t,\mathbf{r}_2) \right\} = \delta_{\sigma\sigma'} \delta(\mathbf{r}_1 - \mathbf{r}_2) \\ \left\{ \hat{\Psi}_\sigma(t,\mathbf{r}_1), \hat{\Psi}_{\sigma'}(t,\mathbf{r}_2) \right\} = 0$$

где $\{\ldots\}$ - антикоммутатор. Обратим внимание, что в (2) операторы ферми-поля стоят в иормалъиом порядке - слева операторы рожления фермионов, справа операторы поглопения.

Потенциал $U(\mathrm{r}_1 - \mathrm{r}_2)$ равен сумме кулоновского отталкивания электронов и притяжения, которое возникает как результат взаимодействия летяшцх навстречу друг другу электронов благодаря обмену фононом или магноном. Обмен фононами - процесс второго порялка, и, согласно теории возмунений, приводит к понижению энергии, т. е. к притяжению (см. раздел$* * **$). В металлах кулоновское взаимодействие заэкранировано и сильно ослаблено. Если притяжение превалирует, то металл при достаточно низких температурах переходит в сверхпроводянее состояние. В таких металлах какCu преоблалает отталкивание, и перехола в сверхпроводящее состояния нет. Интересно, что в соединениях, которые называлотся купратами, причиной сверхпроводимости является сильное взаимодействие электронов проводимости с подсистемой спинов ионов меди во внутрикристаллических плоскостях CuO_2.

Короткодействующий парны й потенциал эффективного притяжения электронов можно заменить на локальны й

$$U(\mathbf{r}_1 - \mathbf{r}_2) = U_0 \delta(\mathbf{r}_1 - \mathbf{r}_2)$$

Параметр U_0 имеет размерность энергия хобъем и записы вается в виле

$$U_0 = \frac{4\pi\hbar^2 a}{m}$$

Величина a назы вается длиной рассеяния. В случае притяжения величины U_0 и a отрицательны. Итак, гамильтониан (2) принимает вид

$$\hat{H} = \int d^3r \left[\hat{\Psi}^+_\sigma(t,\mathbf{r}) \left(\frac{\left(\hat{p} - \frac{e}{c}\mathbf{A}\right)^2}{2m} + e\varphi - \mu \right) \hat{\Psi}_\sigma(t,\mathbf{r}) + \frac{1}{2} U_0 \hat{\Psi}^+_\sigma(t,\mathbf{r}) \hat{\Psi}^+_{-\sigma}(t,\mathbf{r}) \hat{\Psi}_{-\sigma}(t,\mathbf{r}) \hat{\Psi}_\sigma(t,\mathbf{r}) \right]$$

Потенциал (6) подразумевает, что взаимодействуют электроны находяпиеся в одном месте. В силу принципа Паули, для этого они должны иметь разные проекции спина, что и отражено в (8). Производная по времени от гайзенберговских операторов равна

$$i\hbar \frac{\partial}{\partial t} \hat{\Psi}_\sigma(t,\mathbf{r}) = \left[\hat{\Psi}_\sigma(t,\mathbf{r}), \hat{H} \right]$$

Вычисляя коммутатор с помощью (4), (5), приходим к "нелинейному уравнению Шредингера":

$$i\hbar \frac{\partial}{\partial t} \hat{\Psi}_\sigma(t,\mathbf{r}) = \left(\frac{\left(\hat{p} - \frac{e}{c}\mathbf{A}\right)^2}{2m} + e\varphi - \mu \right) \hat{\Psi}_\sigma(t,\mathbf{r}) + U_0 \hat{\Psi}^+_{-\sigma}(t,\mathbf{r}) \hat{\Psi}_{-\sigma}(t,\mathbf{r}) \hat{\Psi}_\sigma(t,\mathbf{r})$$

В отсутствие внешнего электромагнитного поле имеем

$$i\hbar \frac{\partial}{\partial t} \hat{\Psi}_\sigma(t,\mathbf{r}) = \left(\frac{\hat{p}^2}{2m} - \mu \right) \hat{\Psi}_\sigma(t,\mathbf{r}) + U_0 \hat{\Psi}^+_{-\sigma}(t,\mathbf{r}) \hat{\Psi}_{-\sigma}(t,\mathbf{r}) \hat{\Psi}_\sigma(t,\mathbf{r})$$

Современная наука не может решить это уравнение точно. Но в случае слабого взаимодействия ($nU_0 \ll \mu$), чтобы найти элементарные возбуждения достаточно нелинейный член учесть приближенно. Рассмотрение его в рамках теории возмущений дает только перенормировку массы электрона и слабое затухание возбужлений. Чтобы увидеть в (10) сверхпроводимость, неоходимо в решение задачи ввести илего, которая бы отражала физическую причину качественной перестройки электронной подсистемы, аналогичную той, которая привела к микроскопическому объяснению сверхтекучести бозе-газа. В бозе-газе - это конленсация Бозе-Эйнштейна. Явления конденсации в ферми-газе не может супествовать из-за принципа Паули. Но на уровне коллективных бозе-возбуждений конденсация становится возможной. Такими коллективными возбуждениями в ферми-газе являются куперовские пары.

Diagonalization of BCS Hamiltonian in the Real space

Двухчастичная задача Купера поучительна в том смысле, что она демонстрирует, что при $U_0 < 0$ электроны вблизи поверхности Ферми связываются в покоящиеся пары - бозе-частицы с нулевым суммарным импульсом.

Этот результат подсказывает, в каком направлении нужно двигаться.

Если таких пар много, то, по аналогии с бозе-газом, можно говорить о конденсате покоящихся пар.

Основной недостаток задачи Купера заключается в том, что она не учитывает тождественности электронов внутри сферы Ферми и двух выделенных электронов.

Из теории атома водорода и теории позитрония (связанного состояния электрон-позитрон) мы знаем, что волновая функция связанного состояния двух частиц есть произведение волновых функций этих частиц.

Поэтому произведение $\hat{\Psi}_\sigma(t,\mathbf{r})\hat{\Psi}_{-\sigma}(t,\mathbf{r})$ в (11) можно интерпретировать как оператор уничволновой функции куперовской пары.

Поскольку число куперовских пар есть макроскопическое число, то это произведение можно заменить на с-число.

$$\hat{\Psi}_{-\sigma}(t,\mathbf{r})\hat{\Psi}_\sigma(t,\mathbf{r}) \to \left\langle \hat{\Psi}_{-\sigma}(t,\mathbf{r})\hat{\Psi}_\sigma(t,\mathbf{r}) \right\rangle = \lim_{N\to\infty} \left(\mathrm{Sp}\,\rho_N \left\langle N \left| \hat{\Psi}_{-\sigma}(t,\mathbf{r})\hat{\Psi}_\sigma(t,\mathbf{r}) \right| N+2 \right\rangle \right)$$

В отличие от сверхтекучести, здесь мы хотим рассмотреть свойства сверхпроводника при всех температурах вплоть до критической температуры перехода в нормальное состояние.

Поэтому в (16) справа символ усреднения $\langle \ldots \rangle$ означает двойное усреднение по когерентному состоянию конденсата куперовских пар и по распределению Гиббса сN -частичной матрицей плотности ρ_N.

В однородном случае среднее (16) не зависит ни от времени, ни от координаты, но,как следует из (5), меняет знак при изменении знака σ. В приближении (16) уравнение (11) формально становится линейным

$$i\hbar\frac{\partial}{\partial t}\hat{\Psi}_\sigma(t,\mathbf{r}) = \left(\frac{\hat{p}^2}{2m} - \mu\right)\hat{\Psi}_\sigma(t,\mathbf{r}) + U_0\hat{\Psi}^+_{-\sigma}(t,\mathbf{r})\left\langle \hat{\Psi}_{-\sigma}(t,\mathbf{r})\hat{\Psi}_\sigma(t,\mathbf{r}) \right\rangle$$

Введем обозначения

$$\xi_k = \frac{k^2}{2m} - \mu, \sigma\Delta = U_0\left\langle \hat{\Psi}_{-\sigma}(t,\mathbf{r})\hat{\Psi}_\sigma(t,\mathbf{r}) \right\rangle$$

Аномалыное среднее Δ, вообне говоря, есть комплексная величина. Разложим поле $\hat{\Psi}_\sigma(t,\mathbf{r})$ по плоским волнам $|\mathbf{k}\sigma\rangle = |\mathbf{k}\rangle|\sigma\rangle$ $\left(|\mathbf{k}\rangle = \frac{1}{\sqrt{V}}e^{ikr}, |\sigma\rangle -\right.$ спиновая волновая функция):

$$\hat{\Psi}_\sigma(t,\mathbf{r}) = \sum_{k\sigma'}\langle \mathbf{k}\sigma'|r\sigma\rangle\,\hat{a}_{k\sigma'} = \sum_{k\sigma'}\langle\sigma'|\sigma\rangle\,\langle k|r\rangle\hat{a}_{k\sigma'} = \sum_k \frac{1}{\sqrt{V}}e^{ikr}\hat{a}_{k\sigma}$$

Тогда из (17) имеем уравнение для $\hat{a}_{k\sigma}$:

$$i\hbar\frac{\partial}{\partial t}\hat{a}_{k\sigma} = \xi_k\hat{a}_{k\sigma} + \sigma\Delta\hat{a}^+_{-k-\sigma}$$

Диагонализуем это уравнение с помоп,ью преобразования Боголобова

$$\hat{a}_{k\sigma} = u_k\hat{b}_{k\sigma} - \sigma v^*_k\hat{b}^+_{-k-\sigma}$$

Операторы поглошщения и рожления квазичастиI$\hat{b}_{k\sigma}, \hat{b}^+_{-k-\sigma}$ должны быть собственными функциями оператора энергии $i\hbar\frac{\partial}{\partial t}$:

$$i\hbar\frac{\partial}{\partial t}\hat{b}_{k\sigma} = \varepsilon_k\hat{b}_{k\sigma}, i\hbar\frac{\partial}{\partial t}\hat{b}^+_{-k-\sigma} = -\varepsilon_k\hat{b}^+_{-k-\sigma}$$

Кроме того,.операторы частиц и квазичастиц должны удовлетворять одинаковым правилам антикоммутации

$$\left\{\hat{a}_{k\sigma}, \hat{a}^+_{k'\sigma'}\right\} = u_k^2\left\{\hat{b}_{k\sigma}, \hat{b}^+_{k'\sigma'}\right\} + v_k^2\left\{\hat{b}^+_{-k-\sigma}, \hat{b}_{-k'-\sigma'}\right\} = \delta_{kk'}\delta_{\sigma\sigma'}$$

и, следовательно:

$$u_k^2 + v_k^2 = 1$$

Подстановка (21) в (20) дает

$$(\varepsilon_k - \xi_k)\, u_k \hat{b}_{k\sigma} + (\varepsilon_k + \xi_k)\, \sigma v_k^* \hat{b}^+_{-k-\sigma} = \sigma\Delta \left(u_k^* \hat{b}^+_{-k-\sigma} + \sigma v_k \hat{b}_{k\sigma} \right)$$

Orciola

$$\begin{gathered}(\varepsilon_k - \xi_k)\, u_k = \Delta v_k \\ (\varepsilon_k + \xi_k)\, v_k = \Delta^* u_k\end{gathered}$$

Репая эту систему уравнений находим энергию квазичастиц

$$\varepsilon_k = \sqrt{\xi_k^2 + |\Delta|^2}$$

и коэффициенты преобразования [9]

$$u_k = \sqrt{\frac{1}{2}\left(1 + \frac{\xi_k}{\varepsilon_k}\right)}, v_k = \frac{\Delta^*}{|\Delta|}\sqrt{\frac{1}{2}\left(1 - \frac{\xi_k}{\varepsilon_k}\right)}, 2u_k v_k^* = \frac{\Delta}{\varepsilon_k}, |u_k|^2 - |v_k|^2 = \frac{\xi_k}{\varepsilon_k}$$

Преобразование от операторов поглошения и рожления электронов к операторам квазичастиц диагонализует гамильтониан (8), и он равен сумме энергии основного состояния и энергии квазичастиц

$$H_s = E_0 + \sum \varepsilon_k \hat{b}^+_{k\sigma} \hat{b}_{k\sigma}$$

Filling factor, chemical potential, N-operator

(how does it exactly work??? why we define N as we define it??)

The constant in BCS Hamiltonians

(here will be a detailed discussion about what is its value???)

Connection of BCS model and weakly interacting Bose gas

The BCS model is basically

$$\hat{H} - \mu\hat{N} = \frac{1}{\lambda}|\Delta|^2 + \sum_{\mathbf{p}\sigma} \xi_{\mathbf{p}} \hat{a}^\dagger_{\mathbf{p}\sigma} \hat{a}_{\mathbf{p}\sigma} + \sum_{\mathbf{p}}{}' \left[\Delta^* \hat{a}_{\mathbf{p}+} \hat{a}_{-\mathbf{p}-} + \Delta \hat{a}^\dagger_{-\mathbf{p}-} \hat{a}^\dagger_{\mathbf{p}+} \right]$$

(write meaning of indices and that we have fermions here)

and Bose gas is described by

$$\hat{H} - \mu\hat{N} = \sum_{\mathbf{p}} \left(\frac{\mathbf{p}^2}{2m} - \mu \right) \hat{a}^+_{\mathbf{p}} \hat{a}_{\mathbf{p}} + \frac{U_0}{2V} \sum_{\mathbf{p}_1 + \mathbf{p}_2 = \mathbf{p}_1' + \mathbf{p}_2'} \hat{a}^+_{\mathbf{p}_1'} \hat{a}^+_{\mathbf{p}_2'} \hat{a}_{\mathbf{p}_1} \hat{a}_{\mathbf{p}_2}.$$

(??? explain this formula)

(write that even in the model, the model is basically the same, just a different constant and different type of operators.)

(write also that summation in bose gas is over much more momenta than just p, -p like in BCS, this is why constant is different(???))

(point out that Δ has its meaning)

then the $\hat{a}_0^+ = \hat{a}_0 = \sqrt{N_0}$ was introduced.

(??? write that finally we see that Δ is the same as a_0. Pukhov wrote that it is so. I'll study Bose gas, than I'll return to this statement.)

In Bose liquid, only excitations are temperature dependent (higher temperature - higher levels are excited). Here, also the spectrum is temperature dependent (not only higher levels are are excited, but also all excitation levels will change)

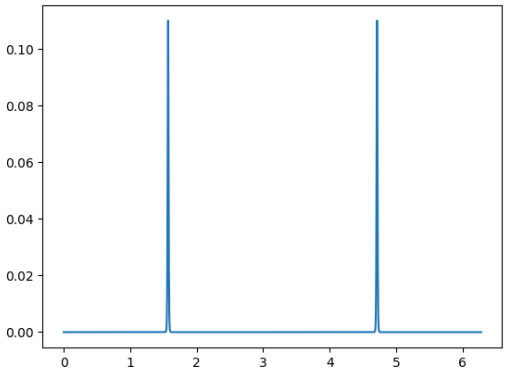
(??? maybe I'll write more explicit how is it? but maybe it is already very clear)

How from BCS Hamiltonian one can get some superconductivity?

(write question that one has the Hamiltonian, so what, we can approximate it, then diagonalize it, so where is the SC?)

(currently, the answer is that there are no excitations, so it will be still in the ground state thus no resistance. But I'll write the better answer!!!!)

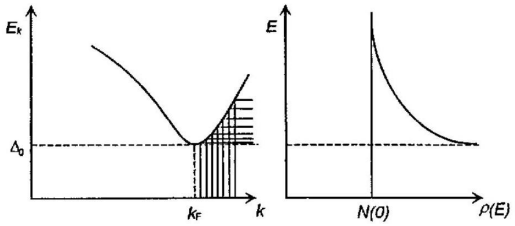
(another argument is that superfluidity criterion is satisfied, so there is a superfluid....)



Still, there is a question, where is the current in the Hamiltonian? I don't see it.

What is exactly the excited state of a superconductor?

Plot of excitations



Here we will show, how typical excitations in a superconductor look like?

They look as follows:

(make this plot better, add axes, titles)

In this plot we just show how many excitations there are over the gap. Another plot which shows their energy values is:

(explain why they are about the same, it is rather obvious)

This is the case for BCS TB model and can be obtained by the code:

```
import numpy as np
import matplotlib.pyplot as plt
from scipy.optimize import brentq

EXP_MAX = 700.0
TINY    = 1e-12

init_tempr_fraction = 0.7
```

```
L      = 2000

p_vals = np.linspace(0, 2*np.pi, L, endpoint=False)

t_hop  = 1.0

mu     = 0.0
xi_vec = - 2*t_hop * np.cos(p_vals) - mu

cutoff = 0.4
mask   = (np.abs(xi_vec) <= cutoff)

lambd = 1.7

def gap_eq_thermal(Delta, T):
    E = np.sqrt(xi_vec**2 + Delta**2)
    f = np.exp(-E/T) / (1.0 + np.exp(-E/T))
    val = np.sum((1.0 - 2.0 * f[mask]) / E[mask])
    return 0.5 * val / L - 1.0 / lambd

Tc     = brentq(lambda T: gap_eq_thermal(1e-8, T), 1e-4, 1.0, maxiter=200)
Delta0 = brentq(lambda D: gap_eq_thermal(D, 1e-4), 1e-6, 2.0, maxiter=200)

Delta_init = brentq(lambda D: gap_eq_thermal(D, T_init), 1e-8, 2.0, maxiter=200)
T_init = init_tempr_fraction * Tc

E_init = np.sqrt(xi_vec**2 + Delta_init**2)
n_init = np.exp(-(E_init/T_init)) / (1.0 + np.exp(-E_init/T_init))

plt.plot(p_vals, n_init,   label='Initial')
plt.show()
```

What is the positive and what is the negative excitation?

(does an excited electron give the positive energy? if it has a negative charge, is still his energy positive? I think, yes, I'll explain why here.)

(now, there are excitation below Fermi surface. what are these holes exactly? are they an absence of electron with the positive energy? so totally what happens, do we have twice energy of the only excitations near Fermi surface?)
(how does it relate to having two branches n_+ and n_-? both of them have holes?)

(why there is no gap in the excitation spectrum (we don't see any gap on the plot)? well, because there are just excitations with the new spectrum (that square root), that it all)

(how can we see that energy is indeed bigger that the Fermi energy? well, we just plug the ξ_p into $E = \sqrt{\xi^2 + \Delta^2}$. in the plot, we assume that these are excitations, so we everything else is already assumed)

3.9.5 Mean-field Approximation of BCS Hamiltonian, Diagonalization

Mean-field approximation of BCS Hamiltonian by introduction of condensate by a common sense

We know that there is a sense of the model with

$$\hat{H} - \mu\hat{N} = \sum_{\mathbf{p}\sigma} \xi_{\mathbf{p}} \hat{a}^\dagger_{\mathbf{p}\sigma} \hat{a}_{\mathbf{p}\sigma} - \lambda \sum_{\mathbf{p}\mathbf{p}'} \hat{a}^\dagger_{\mathbf{p}'+} \hat{a}^\dagger_{-\mathbf{p}'-} \hat{a}_{\mathbf{p}+} \hat{a}_{-\mathbf{p}-},$$

(??? somehow) We know that there is a condensate, so we need to introduce it. We have seen that if there is an attraction between two electrons on the Fermi surface, then they form a bound state. Thus we understand that condensate will be formed by these paired electrons. There are a lot of them, so we need to average over all those who are near the Fermi surface.

(??? is it a good reasoning???)

Thus, we introduce an operator of creation of a Cooper pair $\hat{a}^\dagger_{\mathbf{p},+}\hat{a}^\dagger_{-\mathbf{p},-}$ and its annihilation $\hat{a}_{-\mathbf{p}-}\hat{a}_{\mathbf{p}+}$.

Why does operators in exactly this order and not vice versa? (????????? this I don't know, but one can see that exactly this order is in the interaction term in the BCS Hamiltonian, so it makes more sense then to do it than to do it vice versa)

Thus we can just write

$$\Delta^* = \lambda \cdot \sum_{\mathbf{p}'} \left\langle \hat{a}^\dagger_{\mathbf{p}',+}\hat{a}^\dagger_{-\mathbf{p}',-} \right\rangle,$$

$$\Delta = \lambda \cdot \sum_{\mathbf{p}'} \left\langle \hat{a}_{-\mathbf{p}',-}\hat{a}_{\mathbf{p}',+} \right\rangle.$$

Note that operators in Δ^* are exactly ordered as first two operators in the interaction term in the BCS Hamiltonian. This is not the case for Δ, its operators are changed compared to the two latter operators in the interaction term in the BCS Hamiltonian. This is important to understand, because otherwise some minus signs will appear (because we work with fermions).

This is how we get

$$\hat{H} - \mu\hat{N} = \frac{1}{\lambda}|\Delta|^2 + \sum_{\mathbf{p}\sigma} \xi_{\mathbf{p}}\hat{a}^\dagger_{\mathbf{p}\sigma}\hat{a}_{\mathbf{p}\sigma} + \sum_{\mathbf{p}}{}' \left[\Delta^*\hat{a}_{\mathbf{p}+}\hat{a}_{-\mathbf{p}-} + \Delta\hat{a}^\dagger_{-\mathbf{p}-}\hat{a}^\dagger_{\mathbf{p}+}\right]$$

Proof. (add a little derivation here. I forgot it....)

□

And here we have all terms with positive sign. Initially the interaction term was with negative sign.

(??? I can't explain it right now...)

Mean-field approximation of BCS Hamiltonian by path integral

(write several ways how to get there and what it the meaning of the new Hamiltonian?)

Mean-field approximation of BCS Hamiltonian by (another way)

(write several ways how to get there and what it the meaning of the new Hamiltonian?)

How exact is the mean-field approximation of BCS Hamiltonian?

(discussion of it. Yusbashyan said that it is very exact. I'll write it later)

Features of mean-field approximation of BCS Hamiltonian

Position of operators in the coupling term

The coupling term looks like this:

$$\sum_{kk'} V_{kk'} c^\dagger_{k\uparrow} c^\dagger_{-k\downarrow} c_{-k'\downarrow} c_{k'\uparrow}.$$

But how exactly it should be? What should be the proper position of the operators? Or it does not matter?

(answer here, currently I am not sure)

Which averages are zero, and which are nonzero?

(write what I understood after discussion with Zala that there are actually nonzero avearages because the Hamiltonian in general are not diagonal. or how???)

Does mean-field approximation of BCS Hamiltonian work in nonequilibrium?

I think that yes, it works. However, it is a complicated topic, so I don't have some good arguments.

(one can say that it does not work, because everything is more complicated there, but it is also not an argument that it does not works. Even I can't estimate, how much does it not work? So, answer on this question requires a month of studying nonequilibrium superconductivity)

In the mean-field Hamiltonian we neglect collisions, so all nonequilibrium effects are neglected

This is important to understand if one wants to look at some dynamical

Different forms of the mean-field BCS Hamiltonian

The H_{BCS} can be written in the matrix form as:

$$\sum_k \left(\xi_{\mathbf{k}} \sum_\sigma c^\dagger_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma} + \left[\bar{\Delta} c_{-\mathbf{k}\downarrow} c_{\mathbf{k}\uparrow} + c^\dagger_{\mathbf{k}\uparrow} c^\dagger_{-\mathbf{k}\downarrow} \Delta \right] \right) = \sum_k \left(c^\dagger_{\mathbf{k}\uparrow}, c_{-\mathbf{k}\downarrow} \right) \begin{bmatrix} \xi_{\mathbf{k}} & \Delta \\ \bar{\Delta} & -\xi_{\mathbf{k}} \end{bmatrix} \begin{pmatrix} c_{\mathbf{k}\uparrow} \\ c^\dagger_{-\mathbf{k}\downarrow} \end{pmatrix} + \sum_k \xi_{\mathbf{k}}.$$

Note that in the raw and the column, †-s are at different positions. The constant term $\xi_{\mathbf{k}}$ originates from the term $-\xi_{\mathbf{k}} c_{-\mathbf{k}\downarrow} c^\dagger_{-\mathbf{k}\downarrow}$ and it is not a matrix. Note that the conjugation of gap $\bar{\Delta}$ is exactly at the upper right position (not lower left).

There is a one very similar form:

$$\sum_k \left(\xi_{\mathbf{k}} \sum_\sigma c^\dagger_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma} + \left[\bar{\Delta} c_{-\mathbf{k}\downarrow} c_{\mathbf{k}\uparrow} + c^\dagger_{\mathbf{k}\uparrow} c^\dagger_{-\mathbf{k}\downarrow} \Delta \right] \right) = \sum_k \left(c^\dagger_{\mathbf{k}\uparrow}, c_{-\mathbf{k}\downarrow} \right) \begin{bmatrix} \xi_{\mathbf{k}} & \Delta \\ \bar{\Delta} & -\xi_{\mathbf{k}} \end{bmatrix} \begin{pmatrix} c_{\mathbf{k}\uparrow} \\ c^\dagger_{-\mathbf{k}\downarrow} \end{pmatrix}.$$

Now, there is no term $\xi_{\mathbf{k}}$ if one compares it to the previous version. This is because this sum is symmetric (runs from $-k$ to k), so it is zero.

(???? is there indeed no mistakes if one leaves this constant or neglects it??? Currently, I think that it is so.)

(write this in the Nambu notation)
The Nambu notation will be discussed below.

The Hamiltonian can be written in a diagonal basis:

$$\sum_k \left(\xi_{\mathbf{k}} \sum_\sigma c^\dagger_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma} + \left[\bar{\Delta} c_{-\mathbf{k}\downarrow} c_{\mathbf{k}\uparrow} + c^\dagger_{\mathbf{k}\uparrow} c^\dagger_{-\mathbf{k}\downarrow} \Delta \right] \right) = \\ = 2 \sum_{\mathbf{p}} \left[\xi_{\mathbf{p}} v_p^2 - u_p v_p \Delta \right] + \sum_{\mathbf{p}} \sqrt{\Delta^2 + \varepsilon^2} \left[\hat{b}^\dagger_{\mathbf{p}-} \hat{b}_{\mathbf{p},-} + \hat{b}^\dagger_{\mathbf{p}+} \hat{b}_{\mathbf{p},+} \right].$$

This is the Bogoliubov transformation, which is discussed below. This "constant term" in front can be transformed since $u_p^2 = \frac{1}{2}\left(1 + \frac{\xi_p}{\varepsilon_p}\right),\ v_p^2 = \frac{1}{2}\left(1 - \frac{\xi_p}{\varepsilon_p}\right)$ as

$$2(\xi_p v_p^2 - u_p v_p \Delta) = \xi_p \left(1 - \frac{\xi_p}{\varepsilon_p}\right) - \sqrt{\left(1 - \frac{\xi_p^2}{\varepsilon_p^2}\right)}\Delta = \xi_p - \frac{\xi_p^2}{\varepsilon_p} - \frac{\sqrt{\xi_p^2 + \Delta^2 - \xi_p^2}}{\varepsilon_p}\Delta =$$
$$= \xi_p - \frac{\xi_p^2 + \Delta^2}{\varepsilon_p} = \xi_p - \varepsilon_p$$

so, this means that we can also write:

$$\sum_k \left(\xi_{\mathbf{k}} \sum_\sigma c^\dagger_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma} + \left[\bar{\Delta} c_{-\mathbf{k}\downarrow} c_{\mathbf{k}\uparrow} + c^\dagger_{\mathbf{k}\uparrow} c^\dagger_{-\mathbf{k}\downarrow} \Delta\right]\right) =$$
$$= \sum_{\mathbf{p}} \left[\xi_p - \varepsilon_p\right] + \sum_{\mathbf{p}} \sqrt{\Delta^2 + \varepsilon^2} \left[\hat{b}^\dagger_{\mathbf{p}-} \hat{b}_{\mathbf{p},-} + \hat{b}^\dagger_{\mathbf{p}+} \hat{b}_{\mathbf{p},+}\right] =$$
$$= \sum_{\mathbf{p}} (-\varepsilon_p) + \sum_{\mathbf{p}} \varepsilon_p \left[\hat{b}^\dagger_{\mathbf{p}-} \hat{b}_{\mathbf{p},-} + \hat{b}^\dagger_{\mathbf{p}+} \hat{b}_{\mathbf{p},+}\right] =$$
$$= \sum_{\mathbf{p}} (-\varepsilon_p) + \sum_{\mathbf{p}} \varepsilon_p + \sum_{\mathbf{p}} \begin{pmatrix} \hat{b}^\dagger_{\mathbf{p}+} & \hat{b}_{\mathbf{p},-} \end{pmatrix} \begin{pmatrix} \varepsilon_p & 0 \\ 0 & -\varepsilon_p \end{pmatrix} \begin{pmatrix} \hat{b}_{\mathbf{p},+} \\ \hat{b}^\dagger_{\mathbf{p}-} \end{pmatrix} =$$
$$= \sum_{\mathbf{p}} \begin{pmatrix} \hat{b}^\dagger_{\mathbf{p}+} & \hat{b}_{\mathbf{p},-} \end{pmatrix} \begin{pmatrix} \varepsilon_p & 0 \\ 0 & -\varepsilon_p \end{pmatrix} \begin{pmatrix} \hat{b}_{\mathbf{p},+} \\ \hat{b}^\dagger_{\mathbf{p}-} \end{pmatrix}.$$

I don't have $\hat{b}^\dagger_{-\mathbf{p}-}$ instead of $\hat{b}^\dagger_{\mathbf{p}-}$ (like in the Nambu notation), because anyway the sum over p is symmetric, so both options will give the same result.

Different forms of the mean-field BCS Hamiltonian: Features

What role the constant term plays in the diagonalized BCS Hamiltonian?

(point out, when the constant term is important, when it is non-zero and when is it zero?)

Are there effects beyond mean-field approximation to the BCS Hamiltonian?

(I don't know, but some papers maybe consider it. I'll think later)

Diagonalization by Bogoliubov transformations: Matrix notation

The matrix notation is the most convenient approach for the derivation of a diagonal form.

(here, it will be written for an abstract fermionic Hamiltonian for now, later I'll change it to exacctly BCS notation)

We start with

$$\mathcal{H} = \epsilon \left(c_1^\dagger c_1 + c_2^\dagger c_2\right) + \lambda \left(c_1^\dagger c_2^\dagger + c_2 c_1\right),$$

and we rewrite it in the matrix form

$$\mathcal{H} = \frac{1}{2} \begin{pmatrix} c_1^\dagger & c_2 & c_2^\dagger & c_1 \end{pmatrix} \begin{pmatrix} \epsilon & \lambda & 0 & 0 \\ \lambda & -\epsilon & 0 & 0 \\ 0 & 0 & \epsilon & -\lambda \\ 0 & 0 & -\lambda & -\epsilon \end{pmatrix} \begin{pmatrix} c_1 \\ c_2^\dagger \\ c_2 \\ c_1^\dagger \end{pmatrix} + \epsilon$$

For conciseness, consider just the upper block

$$\begin{pmatrix} c_1^\dagger & c_2 \end{pmatrix} \begin{pmatrix} \epsilon & \lambda \\ \lambda & -\epsilon \end{pmatrix} \begin{pmatrix} c_1 \\ c_2^\dagger \end{pmatrix}$$

and write the Bogoliubov transformation also in matrix form as

$$\begin{pmatrix} c_1 \\ c_2^\dagger \end{pmatrix} \begin{pmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{pmatrix} \begin{pmatrix} d_1 \\ d_2^\dagger \end{pmatrix}.$$

We pick θ so that

$$\begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix} \begin{pmatrix} \epsilon & \lambda \\ \lambda & -\epsilon \end{pmatrix} \begin{pmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{pmatrix} = \begin{pmatrix} \tilde{\epsilon} & 0 \\ 0 & -\tilde{\epsilon} \end{pmatrix},$$

where $\tilde{\epsilon} = \sqrt{\epsilon^2 + \lambda^2}$. Including the other 2×2 block of $\mathcal{H}$, we conclude that

$$\mathcal{H} = \tilde{\epsilon}\left(d_1^\dagger d_1 + d_2^\dagger d_2\right) + \epsilon - \tilde{\epsilon}$$

Diagonalization by Bogoliubov transformations: Explicit substitution

The BCS Hamiltonian

$$\hat{H} = \sum_{\mathbf{p}\sigma} \varepsilon_{\mathbf{p}} \hat{a}^\dagger_{\mathbf{p}\sigma} \hat{a}_{\mathbf{p}\sigma} + \sum_{\mathbf{p}} \left[\Delta^* \hat{a}_{\mathbf{p}+} \hat{a}_{-\mathbf{p}-} + \Delta \hat{a}^\dagger_{-\mathbf{p}-} \hat{a}^\dagger_{\mathbf{p}+}\right]$$

is diagonalized by introduction of new operators b

$$\begin{aligned} \hat{b}_{\mathbf{p}-} &= u_p \hat{a}_{\mathbf{p}-} + v_p \hat{a}^\dagger_{-\mathbf{p},+}, \\ \hat{b}_{\mathbf{p}+} &= u_p \hat{a}_{\mathbf{p}+} - v_p \hat{a}^\dagger_{-\mathbf{p},-}; \end{aligned} \qquad u^2 + v^2 = 1.$$

This is rather a direct calculation.

It is not hard to remember them: first operators are the same as at the l.h.s., the second is purely opposite: opposite spin, momenta, it is daggered.

Note that we have a minus here in one of the terms.

(???? will it work if I change a minus to another similar place??? I'll discuss it below, here I'll just write the statement)

Now, here is the main part of this paragraph, that if we plug them, we will get

$$\hat{H} - \mu\hat{N} = \Omega_0 + \sum_{\mathbf{p}}{}' \varepsilon(p) \left(\hat{b}^\dagger_{\mathbf{p}+} \hat{b}_{\mathbf{p}+} + \hat{b}^\dagger_{\mathbf{p}-} \hat{b}_{\mathbf{p}-}\right)$$

$$\Omega_0 = 2\sum_{\mathbf{p}} \cdot \left[\xi_{\mathbf{p}} v_{\mathbf{p}}^2 - \Delta u_{\mathbf{p}} v_{\mathbf{p}}\right] + \frac{1}{\lambda}\Delta^2$$

$$\varepsilon(p) = \sqrt{\xi_{\mathbf{p}}^2 + \Delta^2}$$

Diagonalization by Bogoliubov transformations: Matrix eigenvalues

There is an easy way of obtaining spectrum of BCS Hamiltonian without knowing much about Bogoliubov transformation: One can just write the Hamiltonian in a matrix form, and then just find its eigenvalues.

(write that matrix!!!s)

To do this, we define the Bogoliubov transformation:

$$\begin{pmatrix} \gamma_{\mathbf{k}\uparrow} \\ \gamma^\dagger_{-\mathbf{k}\downarrow} \end{pmatrix} = \begin{pmatrix} u_{\mathbf{k}} & -v_{\mathbf{k}} \\ v^*_{\mathbf{k}} & u^*_{\mathbf{k}} \end{pmatrix} \begin{pmatrix} c_{\mathbf{k}\uparrow} \\ c^\dagger_{-\mathbf{k}\downarrow} \end{pmatrix}.$$

For this transformation to diagonalize $H_{\mathbf{k}}$, the eigenvalues of $H_{\mathbf{k}}$ must satisfy:

$$\det \begin{pmatrix} \xi_{\mathbf{k}} - E_{\mathrm{k}} & -\Delta \\ -\Delta^* & -\xi_{\mathrm{k}} - E_{\mathrm{k}} \end{pmatrix} = 0$$

And by solving for $E_{\mathbf{k}}$

$$E^2_{\mathrm{k}} = \xi^2_{\mathrm{k}} + |\Delta|^2,$$

we get the spectrum:

$$E_{\mathrm{k}} = \pm\sqrt{\xi^2_{\mathrm{k}} + |\Delta|^2}$$

(??? comment, do we need to know Bogoliubov transformations at all if this approach works?)

Diagonalization by Bogoliubov transformations: Using angle of rotation

We know that Bogoliubov transformations are mixing electrons and holes

$$c^\dagger_{\mathbf{k}\uparrow} = u_{\mathbf{k}}\gamma^\dagger_{\mathbf{k}0} + v^*_{\mathbf{k}}\gamma_{\mathbf{k}1} \quad \text{and} \quad c^\dagger_{-\mathbf{k}\downarrow} = u_{\mathbf{k}}\gamma^\dagger_{\mathbf{k}1} - v^*_{\mathbf{k}}\gamma_{\mathbf{k}0},$$

where we require $|u_{\mathbf{k}}|^2 + |v_{\mathbf{k}}|^2 = 1$ to preserve anticommutation relations, and $2\xi_{\mathbf{k}}u_{\mathbf{k}}v_{\mathbf{k}} + \Delta v^2_{\mathbf{k}} - \Delta^* u^2_{\mathbf{k}} = 0$ to eliminate number-changing terms from the transformed Hamiltonian. Writing $\Delta = \mathrm{e}^{\mathrm{i}\phi}|\Delta|$ these conditions are met by

$$u_{\mathbf{k}} = \mathrm{e}^{\mathrm{i}\phi/2}\cos\theta_{\mathbf{k}}, \quad v_{\mathbf{k}} = \mathrm{e}^{-\mathrm{i}\phi/2}\sin\theta_{\mathbf{k}} \quad \text{and} \quad \cot 2\theta_{\mathbf{k}} = \frac{\xi_{\mathbf{k}}}{|\Delta|}.$$

(??? I'll just write this formalism)

Diagonalization by exact diagonalization

(???????????)

I just think that in statistical physics there are methods of diagonalization that can be used here without any problem.

(??? I'll write it in stat phys and then try to apply them here. I can't do it now)

The spectrum of BCS model when particles are moving

(??? that statement from de Gennes book. (????))

Bogoliubov transformations: Features

Formula for averaging of electron and hole operators in superconductor

Using the Bogoliubov transform and $\langle b^\dagger b\rangle = n$, one gets

$$\begin{aligned}\langle c^\dagger c\rangle &= v^2 + \frac{\xi}{\varepsilon}n,\\ \langle cc^\dagger\rangle &= u^2 - \frac{\xi}{\varepsilon}n, \quad u^2 = \frac{1}{2}\left(1+\frac{\xi}{\varepsilon}\right), v^2 = \frac{1}{2}\left(1-\frac{\xi}{\varepsilon}\right), uv = \frac{\Delta}{2\varepsilon}.\\ \langle c^\dagger c^\dagger\rangle &= \langle cc\rangle = uv(1-2n),\end{aligned}$$

(add some other later.)

This formulas might be very helpful for doing similar Bogoliubov transformations in some special cases.

How to understand physically Bogoliubov transformations?

What is physically a superposition of electron and a hole?
(it was discussed some time ago, I'll study it later)

Physical meaning of coefficients of Bogoliubov transformations?

(it is already written in Schmidt... I'll write it later)

In general u was near annihilation operator, so u^2 is the probability that this state is free. Also, v was in front of a creation operator, so v^2 is the probability that this state is occupied.

(????? why???? and why we have square???? I don't understand it now)

Diagonalization of BCS by matrix notation from Coleman book

Here, I'll write the same Bogoliubov's transformations, but in different notation.

(??? I don't understand it, it uses that (u, v) vector diagonalizes the h, but I didn't find the proof of it)

$$\begin{aligned}a^\dagger_{\mathbf{k}\uparrow} &= \psi^\dagger_{\mathbf{k}}\cdot\begin{pmatrix}u_{\mathbf{k}}\\ v_{\mathbf{k}}\end{pmatrix} = c^\dagger_{\mathbf{k}\uparrow}u_{\mathbf{k}} + c_{-\mathbf{k}\downarrow}v_{\mathbf{k}}\\ a_{-\mathbf{k}\downarrow} &= \psi^\dagger_{\mathbf{k}}\cdot\begin{pmatrix}-\mathrm{v}^*_{\mathbf{k}}\\ u^*_{\mathbf{k}}\end{pmatrix} = c_{-\mathbf{k}\downarrow}u^*_{\mathbf{k}} - c^\dagger_{\mathbf{k}\uparrow}\mathrm{v}^*_{\mathbf{k}}.\end{aligned}$$

Bogoliubov transformation

This transformation, mixing particles and holes, is named after its inventor, Nikolai Bogoliubov. If one takes the complex conjugate of the quasihole operator and reverses the momentum, one obtains $a^\dagger_{\mathbf{k}\downarrow} = c^\dagger_{\mathbf{k}\downarrow}u_{\mathbf{k}} - c_{-\mathbf{k}\uparrow}v_{\mathbf{k}}$, which defines the spin-down quasiparticle. The general expression for the spin-up and spin-down quasiparticles can be written

$$a^\dagger_{\mathbf{k}\sigma} = c^\dagger_{\mathbf{k}\sigma}u_{\mathbf{k}} + \mathrm{sgn}(\sigma)c_{-\mathbf{k}-\sigma}\mathbf{v}_{\mathbf{k}}.$$

Let us combine the two expressions (14.96) into a single Nambu spinor $a^\dagger_{\mathbf{k}}$:

$$a_{\mathbf{k}}^\dagger = \left(a_{\mathbf{k}\uparrow}^\dagger, a_{-\mathbf{k}\downarrow}\right) = \psi_{\mathbf{k}}^\dagger \overbrace{\begin{pmatrix} u_{\mathbf{k}} & -\mathrm{v}_{\mathbf{k}}^* \\ \mathrm{v}_{\mathbf{k}} & u_{\mathbf{k}}^* \end{pmatrix}}^{U_{\mathbf{k}}} = \psi_{\mathbf{k}}^\dagger U_{\mathbf{k}}.$$

Taking the Hermitian conjugate $a_{\mathbf{k}} = U_{\mathbf{k}}^\dagger \psi_{\mathbf{k}}$, then $\psi_{\mathbf{k}} = U_{\mathbf{k}} a_{\mathbf{k}}$, since $UU^\dagger = 1$. Using (14.94),

$$\psi_{\mathbf{k}}^\dagger h_{\mathbf{k}} \psi_{\mathbf{k}} = a_{\mathbf{k}}^\dagger U_{\mathbf{k}}^\dagger \overbrace{U_{\mathbf{k}}^\dagger h_{\mathbf{k}} U_{\mathbf{k}}}^{U_{\mathbf{k}} E_{\mathbf{k}} \tau_{\mathbf{k}}} a_{\mathbf{k}} = a_{\mathbf{k}}^\dagger E_{\mathbf{k}} \tau_3 a_{\mathbf{k}},$$

so that, as expected,

$$H = \sum_{\mathbf{k}} a_{\mathbf{k}}^\dagger E_{\mathbf{k}} \tau_3 a_{\mathbf{k}} + V \frac{\bar{\Delta}\Delta}{g_0}$$

Bogoliubov Transformations as a change of basis

Indeed, c operators were one basis, b operators are the basis where the Hamiltonian is diagonal.

(????????????? here, I'll write what exactly is meant by this????? how is it related to the basis of the vector space in linear algebra?)

Why Bogoliubov transformations are called "canonical transformations"?

(??? connect them to the can. tr-s from mechanics??? write this from Levitov Shitov)

Position of a minus in fermionic Bogoliubov transformations

(??? here, I'll discuss, does it matter or not, in front of what)

Bogoliubov transformations for abstract fermionic model Hamiltonian

One can use the Bogoliubov Transformations to diagonalize more abstract Hamiltonians:

(this is exactly the SC Hamiltonian, but with different indices, so it is kind of very stupid statement, but okay)

Bogoliubov coefficients interpolate between electrons and holes

We know that Bogoliubov transformations are mixing electrons and holes

$$c_{\mathbf{k}\uparrow}^\dagger = u_{\mathbf{k}} \gamma_{\mathbf{k}0}^\dagger + v_{\mathbf{k}}^* \gamma_{\mathbf{k}1} \quad \text{and} \quad c_{-\mathbf{k}\downarrow}^\dagger = u_{\mathbf{k}} \gamma_{\mathbf{k}1}^\dagger - v_{\mathbf{k}}^* \gamma_{\mathbf{k}0},$$

Main statement: Note that for $\xi_{\mathbf{k}} \gg |\Delta|, \theta_{\mathbf{k}} \to 0$ and so $c_{\mathbf{k}\uparrow}^\dagger \sim \gamma_{\mathbf{k}0}^\dagger$ and $c_{-\mathbf{k}\downarrow}^\dagger \sim \gamma_{\mathbf{k}1}^\dagger$. Conversely, for $\xi_{\mathbf{k}} \ll -|\Delta|, \theta_{\mathbf{k}} \to \pi/2$ and so $c_{\mathbf{k}\uparrow}^\dagger \sim \gamma_{\mathbf{k}1}$ and $c_{-\mathbf{k}\downarrow}^\dagger \sim \gamma_{\mathbf{k}0}$. The Bogoliubov coefficients thus interpolate between electrons and holes, and at the Fermi energy, where $\xi_{\mathbf{k}} = 0$ and $\theta_{\mathbf{k}} = \pi/4$, have equal electron and hole content.

Spectrum of the BCS Hamiltonian in the presence of current

(I'll point out, why in general, the spectrum should change if there is a passing current?)

Connection of mean field approximation and conservation of particle number (???)

https://physics.stackexchange.com/questions/306515/mean-field-equations-in-the-bcs-theory-of-superconductivity?noredirect=1&lq=1

In BCS theory, one takes the model Hamiltonian

$$\sum_{k\sigma}(E_k-\mu)c^\dagger_{k\sigma}c_{k\sigma}+\sum_{kk'}V_{kk'}c^\dagger_{k\uparrow}c^\dagger_{-k\downarrow}c_{-k'\downarrow}c_{k'\uparrow}$$

This Hamiltonian clearly conserves particle number. Thus, we expect the ground state to have a definite particle number. It's possible the ground state is degenerate, but that could be lifted by perturbing μ.

Then, one makes a mean field approximation. One replaces

$$c^\dagger_{k\uparrow}c^\dagger_{-k\downarrow}c_{-k'\downarrow}c_{k'\uparrow}$$

with

$$\langle c^\dagger_{k\uparrow}c^\dagger_{-k\downarrow}\rangle c_{-k'\downarrow}c_{k'\uparrow}+c^\dagger_{k\uparrow}c^\dagger_{-k\downarrow}\langle c_{-k'\downarrow}c_{k'\uparrow}\rangle-\langle c^\dagger_{k\uparrow}c^\dagger_{-k\downarrow}\rangle\langle c_{-k'\downarrow}c_{k'\uparrow}\rangle$$

This doesn't make any sense to me. This seems to be saying that we know the terms $c^\dagger_{k\uparrow}c^\dagger_{-k\downarrow}$ and $c_{-k'\downarrow}c_{k'\uparrow}$ don't fluctuate much around their mean values. But we also know that in the actual ground state, the mean values are given by $\langle c_{-k'\downarrow}c_{k'\uparrow}\rangle=\langle c^\dagger_{k\uparrow}c^\dagger_{-k\downarrow}\rangle=0$ since the ground state will have definite particle number. Thus the fluctuations about the mean value aren't small compared to the mean value.

How can this mean field treatment be justified?

Answer

> First, why do we choose those terms to put the brakets around? Do we > somehow know that these are the terms that won't fluctuate much?

The heuristic motivation is that the superconductivity phenomenon can be understood as the non-relativistic analog of the Higgs mechanism for the EM $U_{\rm EM}(1)$ (this idea explains the main properties of the superconductor, such as absence of resistivity, magnetic field expulsion and other). For the Higgs mechanism one need a condensate of some particles. In the solid body, the only candidates are electrons. The simplest choice of the condensate is the scalar condensate (very-very heuristically, we require the Galilei invariance into the superconductor). Therefore the only allowed simplest scalar bounded state $|\psi\rangle$ is constructed from the electron pair with zero total spin, which can be imagine as two fermions moving in opposite directions:

$$|\psi\rangle=c^\dagger_{\mathbf{k},\uparrow}c^\dagger_{-\mathbf{k},\downarrow}|0\rangle$$

This is indeed realized when we calculate the four-fermion vertex in the microscopic theory of electron-phonon interactions. Indeed, we start from the interaction Hamiltonian

$$H_{\rm int}=g\psi^\dagger\psi\varphi,$$

where ψ is electron field, while φ is phonon field, and assume the second order in g diagrams of electron-electron scattering; let's denote their momenta as $\mathbf{p}_i$. After tedious calculations of the corresponding diagram one finds that the vertex $\Gamma^{(4)}(\mathbf{p}_1,\mathbf{p}_2,\mathbf{p}_3,\mathbf{p}_4)$ (with $\mathbf{q}=\mathbf{p}_1+\mathbf{p}_2$) has the pole at zero momentum $\mathbf{q}$ and zero total spin of fermions $1,2$ and $3,4$ or ($1,4$ and $2,3$). The pole quickly disappears once one enlarges $|\mathbf{q}|$.

Finally, since 4-fermion vertex is expressed through two-particles Green $G^{(2)}$ function, then the presence of the pole in $\Gamma^{(4)}$ means the presence of the pole in $G^{(2)}$. This means that bounded states of electrons appear.

> Second, why can't we just immediately say $\langle c_{-k'\downarrow}c_{k'\uparrow}\rangle = \langle c^\dagger_{k\uparrow}c^\dagger_{-k\downarrow}\rangle = 0$ since we know the ground state will > have definite particle number, and $c_{-k'\downarrow}c_{k'\uparrow}$ > and $c^\dagger_{k\uparrow}c^\dagger_{-k\downarrow}$ don't conserve > particle number?

(Added) Let's again use the idea of Higgs mechanism. It is clearly that the number of particles isn't strictly conserved in superconducting state. Really, because of the SSB of $U_{\text{EM}}(1)$ group the system loses the definition of the conserved particle number (being associated to the global phase invariance current) in the ground state.

Microscopically the formation of the condensate is argued in a following way: the presence of the two-fermions bounded states leads to instability of the electron gas inside the superconductor, and fermions are converted in Cooper pairs. Really, for bosons the lowest energy state can be filled by infinitely many number of particles, while for fermions this is not true due to Pauli principle. This (under some assumptions, see below) leads to formation of new vacuum state on which the operator $\hat{c}^\dagger_{\mathbf{k},\uparrow}\hat{c}^\dagger_{-\mathbf{k},\downarrow}$ has non-zero VEV:

$$\langle \text{vac}|\hat{c}^\dagger_{\mathbf{p},\uparrow}\hat{c}^\dagger_{-\mathbf{p},\downarrow}|\text{vac}\rangle = \Psi \neq 0$$

It's not hard to construct this state:

$$|\text{vac}\rangle = \prod_{\mathbf{k}=\mathbf{k}_1\ldots k_{\frac{N}{2}}} (u_{\mathbf{k}} + v_{\mathbf{k}}\hat{c}^\dagger_{\mathbf{k},\uparrow}\hat{c}^\dagger_{-\mathbf{k},\downarrow})|0\rangle, \quad |v_{\mathbf{k}}|^2 + |u_{\mathbf{k}}|^2 = 1$$

This state called **the coherent state** really doesn't have definite number of particles.

For the particles number operator $\hat{N} = \sum_{\mathbf{k}} \hat{c}^\dagger_{\mathbf{k},\uparrow}\hat{c}^\dagger_{-\mathbf{k},\downarrow}$ the VEV $\langle \text{vac}|\hat{N}|\text{vac}\rangle$ is

$$1N = \langle \text{vac}|\hat{N}|\text{vac}\rangle \sim \sum_{\mathbf{k}} |v_{\mathbf{k}}|^2,$$

Why the number of particles is not so indefinite

However, the root $\sqrt{\Delta N^2}$ of quadratic deviation from while the quadratic deviation $\langle \text{vac}|(\hat{N} - N)^2|\text{vac}\rangle$ is

$$2\Delta N^2 = \langle \text{vac}|(\hat{N} - N)^2|\text{vac}\rangle = \sum_{\mathbf{k}} |u_{\mathbf{k}}|^2|v_{\mathbf{k}}|^2$$

is negligible in the limit of large particle number (and volume). Really, both of (1) and (2) are proportional to the volume V (note only one summation over wave-numbers $\mathbf{k}$ in (2)), and hence $\sqrt{\Delta N^2} \sim \sqrt{V}$ which is negligible in the large volume limit. This argument is seemed to be first published in the BCS article.

(Added) This means that the state of superconductor with good accuracy can be projected on the state with definite particle number N. Precisely, define the phase dependent ground state

$$|\text{vac}(\theta)\rangle = |\text{vac}[c^\dagger_{\mathbf{k},\uparrow/\downarrow} \to c^\dagger_{\mathbf{k},\uparrow/\downarrow}e^{-i\theta}]\rangle$$

The state with definite particle number N is defined as

$$|N\rangle = \int_0^{2\pi} d\theta e^{i\hat{N}\theta}|\text{vac}(\theta)\rangle$$

Why there can be excitations below Fermi energy?

(write that because we have holes)

3.9.6 Meaning of the gap Δ, gap equation

The Meaning of Energy Gap and Addition of an Electron

Let us focus on an arbitrary pair of states $(\boldsymbol{q}, -\boldsymbol{q})$ in a superconductor, in momentum space. First we find the contribution of this pair, w_q, to the total energy of the superconductor. One can see from $E_s = \sum_k 2\varepsilon_k v_k^2 + \sum_{k.k'} V_{kk'} v_{k'} u_k v_k u_{k'}$ that

$$w_q = 2\varepsilon_q v_q^2 - 2V v_q u_q \sum_k{}' v_k u_k \tag{6.21}$$

(???? why???)

Here the first term is the kinetic energy of the pair $(\boldsymbol{q}, -\boldsymbol{q})$ and the second term is the pair's contribution to the negative part of the ground-state energy. The latter arises from various interactions in which our pair participates. As a result of these interactions, the pair can go to any other state $(k, -k)$ or, conversely, any other pair $(\boldsymbol{k}, -\boldsymbol{k})$ can go to the state $(\boldsymbol{q}, -\boldsymbol{q})$ which we have earmarked for our analysis.

The coefficient 2 in the second term takes into account that the pair $(\boldsymbol{q}, -\boldsymbol{q})$ is encountered twice as the summation in $E_s = \sum_k 2\varepsilon_k v_k^2 + \sum_{k.k'} V_{kk'} v_{k'} u_k v_k u_{k'}$ is carried out: first time when the sum runs over k, and the second time when it runs over $\boldsymbol{k'}$. Using the expression $\Delta_0 = V \sum_k{}' v_k u_k$, as well as $E_k = \sqrt{\varepsilon_k^2 + \Delta_0^2}$ and $v_k^2 = \frac{1}{2}\left(1 - \frac{\varepsilon_k}{E_k}\right)$, we obtain

$$w_q = 2\varepsilon_q \frac{1}{2}\left(1 - \frac{\varepsilon_q}{E_q}\right) - 2\left[\frac{1}{4}\left(1 - \frac{\varepsilon_q^2}{E_q^2}\right)\right]^{1/2} \Delta_0 = \varepsilon_q - \frac{\varepsilon_q^2}{E_q} - \frac{\Delta_0^2}{E_q} = \varepsilon_q - E_q \tag{6.22}$$

Let us now make use of (6.22). Suppose that the pair state $(\boldsymbol{q}, -\boldsymbol{q})$ in the ground state of a superconductor is empty. How will the energy of the system change if we add one more electron to it from outside and place it in the state $\boldsymbol{q}$? Since we then have a single electron in the state $\boldsymbol{q}$, the pair state $(\boldsymbol{q}, -\boldsymbol{q})$ is not allowed to take part in the scattering events, that is, it cannot contribute to the ground-state energy of the superconductor. Its potential contribution is known to us, it equals w_q. Hence the energy of the superconductor with one 'extra' electron in the state q will be

$$W_q = W - w_q + \varepsilon_q \tag{6.23}$$

We shall refer to this 'extra' uncoupled electron as an elementary excitation of our system, or quasiparticle. The quantity W in (6.23) is the ground-state energy of the superconductor and the third term accounts for the kinetic anarer of nur 'extra' plectron. Substituting (6.22) into (6.23) vields

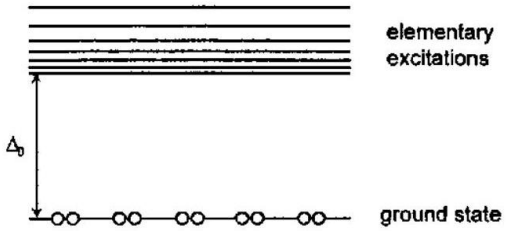
$$W_q = W + E_q \tag{6.24}$$

This relation is very important. Since, according to $E_k = \sqrt{\varepsilon_k^2 + \Delta_0^2}$,

$$E_q = \sqrt{\varepsilon_q^2 + \Delta_0^2},$$

it is evident that, by adding one extra electron to a superconductor in the ground state, we increase the energy of the system by at least the value of Δ_0 (the minimum increase corresponds to $\varepsilon_q = 0$, that is, to the state q being on the Fermi surface). This means that the spectrum of elementary excitations of the superconductor is separated from the ground-state energy level by an energy gap.

To elucidate this statement, let us go back to the superconductor in the ground state. Suppose that, as a result of an external effect, one of the electrons from the pair $(q, -q)$ is moved to a neighboring state in momentum space. Recall that initially all states were either occupied in pairs or empty in pairs. Then the transfer of one electron from the pair $(\boldsymbol{q}, -\boldsymbol{q})$ to the neighboring state implies that two uncoupled (excited) electrons have appeared. One of them stays in one of the states $(q, -q)$ while the other turns up in the neighboring k state and, naturally, does not have a partner in the $-k$ state. But we have just found out that, in order to break a pair, one needs at least the energy $2\Delta_0$, as illustrated by the diagram in Fig. 6.6.



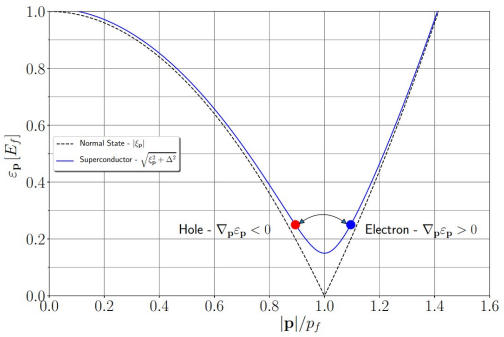


Fig. 6.6. The energy gap Δ_0 separates the energy levels of elementary excitations from the groundstate level (the energy level of electron pairs in the condensate)

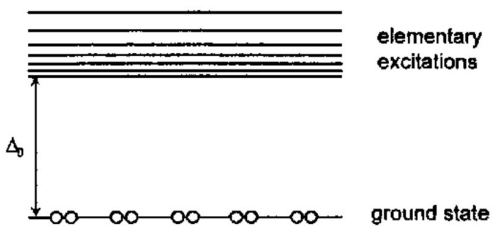
(??? what is meant by this picture? that literally all electrons, even the one which are far below Fermi surface are in the ground state? then why?)

All pair states belong to the condensate occupying the ground-state energy level. A single extra electron is not allowed to be at this level and must therefore occupy the first empty level available in the elementary excitation spectrum. If a pair is broken, both electrons must go up to the elementary excitation levels which requires an energy larger than $2\Delta_0$.



The existence of this energy gap is a very important property of the superconductor and explains many aspects of its behavior.

Picture of the dispersion of electrons and holes in a superconductor

(write here how to understand this plot! and also how one should not understand it!!! it is not obvious what is meat here!)

Simple picture of the dispersion of a superconductor and a ground state

(write here how to understand this plot! and also how one should not understand it!!! it is not obvious what is meat here!)

What happens physically with the Fermi sphere, when the gap opens?

(we had a ball, now what? I imagine that there are particles still up to Fermi level, but a lot of them are shifted down. and very few are excited.)
(??? what if Fermi surface goes out of the Brillouin zone???)

At $T = 0$, there are no particles above the filled Fermi surface.

Basically, we have renormalization of the Fermi surface at $T = 0$, it becomes suddenly lower than we would expect.

In BCS model, we assumed that the Fermi surface is nearly filled, but now there is a gap near Fermi surface, so is our assumption is still valid?

(?????????? maybe yes, but I have never seen answer to this question)

What physically happens with the system, when the gap decreases?

(!!!! this is a very important question, since we don't measure the gap. maybe we measure the current. So, what happens physically with the system?????)

What physically means by the excitation above the gap?

(these are electron-hole pares, so electron and the absence of electron)
(I'll discuss more how exactly is it?)

Density of States of Elementary Excitations in the Superconductor and the Coherence Length

The lower part of the elementary excitation spectrum is illustrated in Fig. 6.6. An expression for the density of states in this spectrum can be easily derived from $E_k = \sqrt{\varepsilon_k^2 + \Delta_0^2}$. Indeed. E_k is the energy of an elementary excitation (see (6.24)), it tells us how much the energy of the system increases when an extra electron with momentum k is added to the superconductor:

$$E_k = \sqrt{\varepsilon_k^2 + \Delta_0^2} = \sqrt{\left(\frac{\hbar^2 k^2}{2m} - \frac{\hbar^2 k_F^2}{2m}\right)^2 + \Delta_0^2}.$$

The dependence of E_k on k given by this expression is shown in Fig. 6.7.

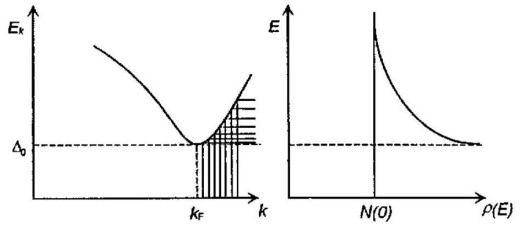


Fig. 6.7. Spectrum of elementary excitations, E_k, of the superconductor and the density of states $\rho(E)$

It is easy to see from the plot that the energy levels of elementary excitations become denser at $E_k \to \Delta_0$. The density of states or, in other words, the number of the energy levels per unit energy interval and unit volume (1 cm^3) of the material, is

$$\rho(E) = \mathrm{d}\nu/\mathrm{d}E,$$

where $\mathrm{d}\nu$ is the number of energy levels in the energy interval $\mathrm{d}E$, in the vicinity of the level E. We recall that $\mathrm{d}\nu/\mathrm{d}\varepsilon$ gives the density of states near the Fermi level (??? why near it?? is it an approximation???) for the normal metal, i.e.,

$$\mathrm{d}\nu/\mathrm{d}\varepsilon = N(0)$$

Therefore

$$\rho(E) = \frac{\mathrm{d}\nu}{\mathrm{d}\varepsilon}\frac{\mathrm{d}\varepsilon}{\mathrm{d}E} = N(0)\frac{E}{\sqrt{E^2-\Delta_0^2}}. \tag{6.25}$$

It follows from (6.25) that, at $E \to \Delta_0$, the density of states of elementary excitations in the superconductor is indeed $\rho(E) \to \infty$, as illustrated in Fig. 6.7.

Overview of different forms of the gap equation

Different forms of a trivial gap equation

$$\Delta_0 = V \sum_k{}' v_k u_k$$

$$\Delta = \lambda \sum_p{}' \langle c_{-p,-} c_{p,+} \rangle .$$

$$\Delta = V \sum_k{}' v_k u_k \left(1 - 2f_k\right)$$

$$\Delta = V \sum_k{}' \frac{\Delta}{2E_k}\left(1 - \frac{2}{\exp\left(E_k/k_\mathrm{B}T\right)+1}\right)$$

$$\frac{1}{N(0)V} = \int_0^{\hbar\omega_\mathrm{D}} \frac{\mathrm{d}\varepsilon}{\sqrt{\varepsilon^2+\Delta^2(T)}} \tanh\frac{\sqrt{\varepsilon^2+\Delta^2(T)}}{2k_\mathrm{B}T}.$$

The most typical form of the gap equation is:

$$\frac{1}{\lambda} = \frac{1}{2}\sum_{\mathbf{p}} \frac{1+2\bar{n}_{\mathbf{p}}}{\sqrt{\xi_{\mathbf{p}}^2+\Delta^2}}$$

where $\bar{n}_{\mathbf{p}} = \left\langle \hat{b}^\dagger_{\mathbf{p}+}\hat{b}_{\mathbf{p}+}\right\rangle = \left\langle \hat{b}^\dagger_{\mathbf{p}-}\hat{b}_{\mathbf{p}-}\right\rangle = [\exp(\varepsilon(p)/T)+1]^{-1}$

$$\Delta = V \sum_k{}' v_k u_k \left(1 - 2f_k\right)$$

After plugging $v_q^2 = \frac{1}{2}\left(1 - \frac{\varepsilon_q}{E_q}\right)$ where $E_q = \sqrt{\varepsilon_q^2+\Delta^2(T)}$, it becomes equivalent to

$$\Delta = V \sum_k{}' \frac{\Delta}{2E_k}\left(1 - \frac{2}{\exp\left(E_k/k_\mathrm{B}T\right)+1}\right)$$

Replacing summation with integration yields, after simple algebra,

$$\frac{1}{N(0)V} = \int_0^{\hbar\omega_\mathrm{D}} \frac{\mathrm{d}\varepsilon}{\sqrt{\varepsilon^2+\Delta^2(T)}} \tanh\frac{\sqrt{\varepsilon^2+\Delta^2(T)}}{2k_\mathrm{B}T}. \tag{6.35}$$

Here, again, we approximated the integral by extracting $N(0)$ out.

Basically the same equation, but with

$$1 = \frac{|\lambda| m p_0}{2\pi^2} \int_0^{\omega_D} \mathrm{d}\xi \frac{\tanh \frac{\sqrt{\xi^2+\Delta^2(T)}}{2T}}{\sqrt{\xi^2+\Delta^2(T)}}. \tag{34.37}$$

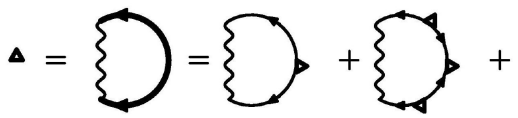
One can write the gap equation as integral with parameter in the integration range and inside of the integral:

$$\Delta = \lambda\Delta \int_{|\Delta|}^{\omega_\mathrm{D}} \mathrm{d}\epsilon \frac{\tanh \epsilon/2T}{\sqrt{\epsilon^2-|\Delta|^2}}$$

To bring it to well-known form, one changes variables as $\xi = \sqrt{\epsilon^2-|\Delta|^2}$ to write $\epsilon = \sqrt{|\Delta|^2+\xi^2}$, and finds $1 = \lambda \int_0^{\omega_\mathrm{D}} \left(\mathrm{d}\xi/\sqrt{|\Delta|^2+\xi^2}\right) \tanh \sqrt{|\Delta|^2+\xi^2}/2T$.

(??? do it! I haven't checked it, I believe Kamenev)

(this a general summary of what will be written above)
(add a very brief discussions of all the forms)



In the GF formalism, it is:

$$\Delta_{\alpha\beta} = \lambda \int F_{\alpha\beta}(\varepsilon, \mathbf{p}) \frac{d\varepsilon d^3p}{(2\pi)^4},$$

$$\Delta = \lambda T \sum_{\omega_n} \int F\left(i\omega_n, \mathbf{p}\right) \frac{d^3p}{(2\pi)^3} = \lambda T \sum_{\omega_n} \int \frac{\Delta}{\omega_n^2 + \xi_\mathbf{p}^2 + \Delta^2} \frac{d^3p}{(2\pi)^3},$$

(write def of F)

In diagrammatic representation it is

(describe what is here)

(??? explain the below formula)

$$\tilde{\Delta}(i\varepsilon) = T \sum_{\varepsilon'} \Gamma^0\left(i\varepsilon, i\varepsilon'\right) F\left(i\varepsilon', \mathbf{r}=\mathbf{r}'\right),$$

$$F\left(i\varepsilon, \mathbf{r}=\mathbf{r}'\right) := \int \frac{\tilde{\Delta}(i\varepsilon)}{\varepsilon^2 + \xi_p^2 + \tilde{\Delta}^2(i\varepsilon)} \frac{d^3p}{(2\pi)^3}. \qquad \Gamma^0\left(i\varepsilon, i\varepsilon'\right) = \lambda v(i\varepsilon) v\left(i\varepsilon'\right), \qquad \tilde{\Delta}(i\varepsilon) \equiv \Delta(T) v(i\varepsilon),$$

$$\Delta(T) = \lambda T \sum_{\varepsilon} \int \frac{v^2(i\varepsilon)\Delta(T)}{\varepsilon^2 + \xi_\mathbf{p}^2 + v^2(i\varepsilon)\Delta^2(T)} \frac{d^3p}{(2\pi)^3}.$$

Вычисляя интеграл по ξ (?????)

$$\frac{1}{\lambda\nu_0} = \pi T \sum_{\varepsilon} \frac{v^2(i\varepsilon)}{\sqrt{\varepsilon^2 + \Delta^2(T) v^2(i\varepsilon)}}.$$

$v(i\varepsilon) = \frac{\omega_D}{\sqrt{\varepsilon^2+\omega_D^2}}$

Some trivial transformation:

$$\frac{\Delta}{\lambda}=\frac{\Delta}{2}\sum_{\mathbf{p}}{}'\frac{1-2\bar{n}_{\mathbf{p}}}{\sqrt{\xi_{\mathbf{p}}^2+\Delta^2}}=\frac{\Delta}{2}\sum_{\mathbf{p}}{}'\frac{1-2\frac{1}{e^{\beta\varepsilon_p}+1}}{\sqrt{\xi_{\mathbf{p}}^2+\Delta^2}}=\frac{\Delta}{2}\sum_{\mathbf{p}}{}'\frac{1}{\sqrt{\xi_{\mathbf{p}}^2+\Delta^2}}\frac{(e^{\beta\varepsilon_p}-1)}{(e^{\beta\varepsilon_p}+1)}=\frac{\Delta}{2}\sum_{\mathbf{p}}{}'\operatorname{th}\frac{\varepsilon_p}{2T}$$

with $\varepsilon_p=\sqrt{\xi_p^2+\Delta^2}$

$$\frac{1}{\lambda\nu_0}=\pi T\sum_{\varepsilon}\frac{v^2(i\varepsilon)}{\sqrt{\varepsilon^2+\Delta^2(T)v^2(i\varepsilon)}};\qquad v(i\varepsilon)=\omega_D/\left(\omega_D^2+\varepsilon^2\right)^{1/2}$$

(write comments that here we have a different cutoffs! explain that it it the same equation, it is not obvious!)

$$2\sum_{n=0}^{\infty}\frac{\omega_D^2}{\left(\omega_D^2+\pi^2T_c^2(2n+1)^2\right)(2n+1)}=\frac{1}{\lambda\nu_0}$$

$$\frac{1}{\lambda\nu_0}=\sum_{k}\frac{\tanh\frac{\sqrt{\varepsilon^2+|\Delta|^2}}{2T}}{2\sqrt{\varepsilon^2+|\Delta|^2}}$$

Different forms of a gap equation for specific superconductors

Now, I'll collect some gap equations for some non-trivial models.
For a dirty superconductors:

$$\Delta=\lambda T\sum_{\omega_n}\int_{-\infty}^{\infty}\frac{\nu_0 d\xi\tilde{\Delta}}{\tilde{\omega}_n^2+\tilde{\Delta}^2+\xi^2}\qquad\begin{aligned}\tilde{\omega}_n&:=\omega_n\left(1+\frac{1}{2\tau\sqrt{\omega_n^2+\Delta^2}}\right),\\ \tilde{\Delta}&:=\Delta\left(1+\frac{1}{2\tau\sqrt{\omega_n^2+\Delta^2}}\right)\end{aligned}$$

$$\Delta=\pi\lambda\nu_0T\sum_{\omega_n}\frac{\tilde{\Delta}}{\sqrt{\tilde{\omega}_n^2+\tilde{\Delta}^2}}=\pi\lambda\nu_0T\sum_{\omega_n}\frac{\Delta}{\sqrt{\omega_n^2+\Delta^2}}$$

(I'll collect others later!)

Overview of working approaches for derivation of the gap equation

Обычные богол трансф

U v подстановка как в Шмидте, по сути тот же Боголюбов, только в другом формализме

(something similar is in original BCS article about it, it is very interesting, how did they do it, without any Bogoliubov transformations?)

Метод Дениса через матричное преобр

Метод Лункина через эксп и перестановку так, чтобы потом получить щель и ещё что-то

Derivation of the gap equation from plugging Bogoliubov operators in the definition

We know that $\Delta = \lambda \cdot \sum'_{\mathbf{p}'} \langle \hat{a}_{-\mathbf{p}',-} \hat{a}_{\mathbf{p}',+} \rangle$ and that $\begin{matrix} \hat{b}_{\mathbf{p}^-} = u_{\mathbf{p}} \hat{a}_{\mathbf{p}_-} + v_{\mathbf{p}_-} \hat{a}^\dagger_{-\mathbf{p}_+}, \\ \hat{b}_{\mathbf{p}^+} = u_{\mathbf{p}_-} \hat{a}_{\mathbf{p}_+} - v_{\mathbf{p}_-} \hat{a}^\dagger_{-\mathbf{p}_-}. \end{matrix}$, if one plugs them, one will get

$$\frac{1}{\lambda} = \frac{1}{2} \sum_{\mathbf{p}} \frac{1 + 2\bar{n}_{\mathbf{p}}}{\sqrt{\xi^2_{\mathbf{p}} + \Delta^2}}$$

where $\bar{n}_{\mathbf{p}} = \left\langle \hat{b}^\dagger_{\mathbf{p}+} \hat{b}_{\mathbf{p}+} \right\rangle = \left\langle \hat{b}^\dagger_{\mathbf{p}-} \hat{b}_{\mathbf{p}-} \right\rangle = [\exp(\varepsilon(p)/T) + 1]^{-1}$

(write more explanation)

Derivation of the gap equation using equations of motion for Nambu operators and interchanging them

(write Lunkin's method!)

Derivation of the gap equation from free energy

(??? not sure about this method)

As the temperature increases, the energy gap Δ decreases (the notation Δ_0 will be kept for $T = 0$). This is easy to understand. As we already know, in order to break a Cooper pair and create two elementary excitations, the energy 2Δ is needed. If the temperature T is such that

$$k_{\mathrm{B}} T \approx 2\Delta,$$

it is evident that many Cooper pairs will be broken through thermal processes. Accordingly, a large number of states in momentum space will be filled by elementary excitations (single electrons). But this implies that these states can no longer participate in the pair transitions and, therefore, cannot contribute to the net reduction of the superconductor's energy. (the energy of the superconductor has to increase). These states will likewise be unable to participate in forming the energy gap ($\Delta_0 = V \sum'_k v_k u_k$).

(??? by the way, why finally we have $4k_{\mathrm{B}}T \approx 2\Delta$, approximately, 4 times bigger??)

Since the elementary excitations obey the Fermi-Dirac statistics, the probability that the state k is occupied by a single electron is

$$f_k = \frac{1}{\exp\left(\frac{E_{\mathrm{k}}}{k_{\mathrm{B}}T}\right) + 1} \tag{6.29}$$

where E_k is the energy of an elementary excitation. One can see that $f_k \ll 1$ at $k_{\mathrm{B}}T \ll E_k$, and $f_k \simeq 0.5$ at $k_{\mathrm{B}}T \gg E_k$. This is how Fermi distribution function works for the case of zero chemical potential.

If at least one of the states, (k) or $(-k)$, is occupied, the pair state $(k, -k)$ cannot take part in creating the superconducting state. The probability of this is $2f_k$. Hence, the probability that the pair state $(k, -k)$ can participate in the scattering processes, i.e., can take part in creating the superconducting state, is $1 - 2f_k$.

The expression for the total energy of the superconductor at $T \neq 0$ can then be written in the form (see Sect.6.2) (??? why it is so????)

$$W = \sum_k 2\left|\varepsilon_k\right| f_k + 2\sum_k \varepsilon_k \left(1 - 2f_k\right) v_k^2 - V \sum_{kk'}{}' v_k u_k v'_k u'_k \left(1 - 2f_k\right)\left(1 - 2f_{k'}\right). \tag{6.30}$$

Here the first term is the kinetic energy of the elementary excitations, the second term is the kinetic energy of the superconducting electrons and the last term is the energy of the phonon-mediated electron interaction which is the prime cause of the superconducting state. The two last factors account for the probability of this interaction.

The free energy density of the superconductor is

$$F = W - TS \tag{6.31}$$

where S is the entropy of the material. The functions v_k^2, describing the distribution of the supeconducting electrons in momentum space at thermodynamic equilibrium, can be found from the condition that the free energy density F is a minimum:

$$\frac{\partial F}{\partial \left(v_q^2\right)} = 0 \tag{6.32}$$

Substituting F in terms of W and W in terms of u, v in this equation yields (??? what to do with entropy???? or derivative of it is zero?? I'll check later)

$$\frac{v_q u_q}{1 - 2v_q^2} = \frac{\Delta}{2\varepsilon_q} \tag{6.33}$$

where

$$\Delta = V \sum_k{}' v_k u_k \left(1 - 2f_k\right) \tag{6.34}$$

This last expression gives the temperature dependence of the energy gap. As $T \to 0$, the gap is $\Delta \to \Delta(0)$, where $\Delta(0) = \Delta_0$ is the gap at $T = 0$ defined earlier. The only thing that is left, is to simplify it. First, we write $v_q^2 = \frac{1}{2}\left(1 - \frac{\varepsilon_q}{E_q}\right)$ where $E_q = \sqrt{\varepsilon_q^2 + \Delta^2(T)}$.

Then $\Delta = V \sum_k{}' v_k u_k \left(1 - 2f_k\right)$ reduces to (??? I'll check later)

$$\Delta = V \sum_k{}' \frac{\Delta}{2E_k}\left(1 - \frac{2}{\exp\left(E_k/k_{\mathrm{B}}T\right) + 1}\right)$$

Replacing summation with integration yields, after simple algebra,

$$\frac{1}{N(0)V} = \int_0^{\hbar\omega_{\mathrm{D}}} \frac{\mathrm{d}\varepsilon}{\sqrt{\varepsilon^2 + \Delta^2(T)}} \tanh \frac{\sqrt{\varepsilon^2 + \Delta^2(T)}}{2k_{\mathrm{B}}T}. \tag{6.35}$$

Here, again, we approximated the integral by extracting $N(0)$ out.

Thus we have obtained an implicit temperature dependence of the energy gap.

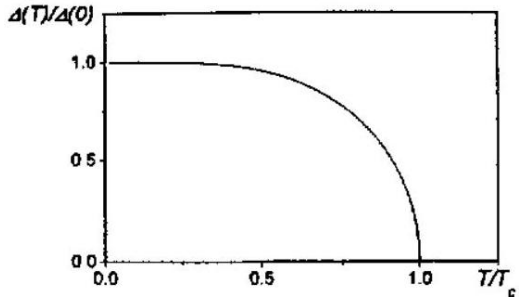


Fig. 6.8. Temperature dependence of the energy gap in the BCS theory

This dependence is sketched in Fig. 6.8: Near T_c, the variation of the gap with temperature obeys $\Delta \propto (T_c - T)^{1/2}$. The discussion of numerical obtaining this results are below.

How one should not derive of the gap equation

To get the gap equation, we need to calculate basically

$$\langle c_{-k,-} c_{k,+} \rangle = \mathrm{Tr}\left(\frac{\exp\Big[-\beta H \Big]}{\mathrm{Tr}[e^{-\beta H}]} c_{k,+} c_{-k,-} \right); \qquad H_{\mathrm{BCS}} = \sum_{p,\sigma} \Big(\xi_p c^\dagger_{p\sigma} c_{p\sigma} + \Delta \big(c_{p\uparrow} c_{-p\downarrow} + c^\dagger_{-k\downarrow} c^\dagger_{k\uparrow} \big) \Big), \quad \xi_p = v_F(p - p_F).$$

To do it, we need to plug the eigenstates under trace. They are obtain from the diagonalized Hamiltonian. These states are the excitations, not the Cooper pairs that are inside the condensate! Thus, one can't just plug states to the trace, because one needs to understand, what are these states? To understand, what are they, one needs to diagonalize the Hamiltonian. So, approaches by some clever transformation of just c operators inside the trace (without diagonalization of Hamiltonian) is, maybe, just impossible, since then anyway we need to plug states, which are known only when we know how to diagonalize the Hamiltonian. Nor matrix exponent of the Hamiltonian, nor expansion the exponent in series will not work, since evaluation of the trace by plugging states with some number of electrons or holes there is just a wrong approach. A real eigenstate under the trace is a superposition of electron and a hole.

Another, also maybe impossible approach is that suppose we have diagonalized the Hamiltonian and we know that the excitation is the Bogoliubov particles, then one might again try to massage the electron and hole operators, such that they will combine to some expression which will be evaluatable. I don't think that is also possible. Writing all in c operators is still a terrible idea, the only solution is to rotate the basis to b operators.

(??? okay, maybe there is a way how to do it using only c operators and evaluating trace explicitly, but I don't know this. Maybe one needs to plug two states there, with $b^\dagger b = 1$ and $b^\dagger b = 0$ in terms of c operators in the trace and see what is left? Sounds still complicated, because we have an exponent there. So, my conclusion is as was before: don't use this method unless you read some good article which tells you how to do it)

Mathematical properties of the gap equation

(??? about this sum)

Properties of the gap equation for numerical evaluation

(write that methods of finding a middle point)

If numerical function in Python says that it sees no root, increase the number of lattice sites!

```
L      = 300
p_vals = np.linspace(0, 2*np.pi, L, endpoint=False)
```

this is the good lattice cites, for a L=30 it was giving an error.

Other properties of the gap equation

(they will be discussed in detail below, in the special sections about special methods, here I'll just write main ideas and formulas)

What is more fundamental, the form of summation or the integral form of the gap equation?

This question can be important because the integral form can be approximated differently and there could be different cutoffs. Thus, to understand, what is the most exact solution, we need to understand, what is the most exact equation?

Idea of derivation of the gap equation using the density matrix

(??? I'll just write why it can be done so?? and key things about it)
(it is written in detail in the section of BCS in density matrix framework)

3.9.7 Tight-binding 1D BCS model

The 1D BCS tight-binding is a basic model of a simplest superconductor. It is very useful for research, so it is a basic model.

Reminder: The idea of tight-binding models

Derivation of the tight-binding BCS model

(write here the search of the spectrum $-2tcos\phi$)

Limit of applicability of 1D TB BCS models

(???? write it after learning that fluctuations)

Features of TB BCS models

Division by number of lattice sites N when sums are computed

(write that these sums should be understood as they were with division by N)
(??? explain, why??? I don't know, why?)

Remember that the division by N is also assumed sometimes if there is no sum, but it was originally there.
(write example of the dissipator that we used)

Parameters of tight-binding BCS model

At this stage we understand that there is a TB BCS model that explains superconductivity in 1D, but it is not clear which parameters to put into it? Here, we will answer this question.

Comparison of BCS relation at different parameters

We have a criterion that we need such parameters of the tight-binding model that the universal BCS relation is fulfilled.
(??? why??? the conclusion is that analytic derivation is very important)

```
import numpy as np
import matplotlib.pyplot as plt

plt.legend()
plt.show()
```

And now we can compare parameters graphically:

Which values should have a hopping parameter?

(??? discuss of it!!)

Значения t зависят от конкретного материала и выбора единиц:

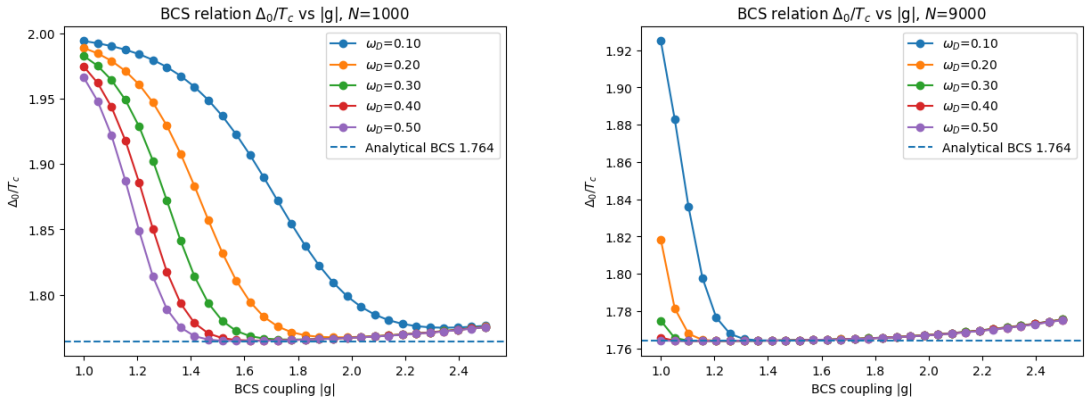
1. В модельных расчётах t обычно просто выбирают равным 1 . Тогда все энергии (включая щель Δ, температуру T, дебаевский срез ω_D) выражаются в единицах t.

Это упрощает численные вычисления, так как остаётся лишь безразмерный набор параметров: $|g|, \omega_D/t, \mu/t$, и т.д.

2. В реальных материалах t лежит в диапазоне порядка десятков - сотен мэВ:
- В органических проводниках и оптических решётках холодных атомов t может быть $\sim 0.01 - 0.1$eV.
- В медь-оксидных высокотемпературных сверхпроводниках $t \approx 0.3 - 0.5$eV.
- В простых металлах или модельных tight-binding системах часто берут $t \sim 1$ eV .
3. Отношение t и щели: у обычных сверхпроводников щель Δ и дебаевская частота ω_D существенно меньше t. Обычно

$$\Delta, k_B T_c, \omega_D \ll t,$$

чтобы зона была «широкой» и условие приближения БКШ выполнялось.
Причина в том, что в tight-binding BCS модели t играет роль масштабного параметра энергии, а сама модель безразмерна.



(how Tc and the gap Delta depend on the hopping parameter???? I can check numerically, but I don't understand it analytically)

Which values should have a Debye cutoff?

(??? discuss of it!!)

Which values should have a grid of the Brillouin zone (N)?

If we increase N, we'll get closer and closer to the real BCS relation.

(write that we have an increase of the BCS relation with increase of the coupling constant because it becomes not little compared to the kinetic energy. but why??? I'll answer here)

Which values should have a BCS coupling constant?

(??? discuss of it!!)
It can be lower and bigger than the hopping parameter t, but not too little and not too big. (????)

Which values should have a chemical potential?

We take it always to zero.
(why??? discuss of it!!)

Overview of different notations of tight-binding BCS model

(detalis of it will be later, here is just an intro to it)

Other general questions about TB BCS models

Relation of TB BCS model to the Ising and other spin models from statistical physics?

(??? there was an article about it by Zurek, so I'll point it out here)

How to take into account another orthogonal dimensions in 1D TB BCS models?

(???? good general question, I don't know. there is a discussion of degeneration of quantization, but I don't unerstand it)

How the basic TB BCS model can be generalized?

(??? there may be next nearest neighbor hopping and maybe something else? why? Ask Rock Zitko maybe about it later)

3.9.8 Ground State Energy and Wavefunction in BCS

Short calculation of BCS ground state energy

(?? add from Pukhov)

Long calculation of BCS ground state energy by Mexeenkov

Энергия основного состояния есть значение E при нулевой температуре. (??? почему??? у нас же разное число электронов будет в граунд стейте???)

Температуре $T = 0$ отвечают числа заполнения $n_p = 0$. Поэтому в основном состоянии для перестроенного спектра энергия равна:

(????? remind the formulas here?!!!)

$$E_g(\Delta) = \sum_p \xi_p \left(1 - \frac{\xi_p}{\sqrt{\xi_p^2 + \Delta^2}}\right) - \Delta^2 \sum_p \frac{1}{2\sqrt{\xi_p^2 + \Delta^2}} =$$
$$= \sum_p \left[\left(\xi_p - \sqrt{\xi_p^2 + \Delta^2}\right) + \frac{\Delta^2}{2\sqrt{\xi_p^2 + \Delta^2}}\right]$$

Если бы взаимодействия не было, то энергия основного нормального состояния равнялась бы энергии ферми-сферы

$$E_g = 2 \sum_{p<p_F} \xi_p$$

Запишем изменение энергии основного состояния:

$$E_g(\Delta) - E_g = \sum_{p>p_f}\left[\left(\xi_p - \sqrt{\xi_p^2+\Delta^2}\right) + \frac{\Delta^2}{2\sqrt{\xi_p^2+\Delta^2}}\right] + \sum_{p<p_f}\left[\left(-\xi_p - \sqrt{\xi_p^2+\Delta^2}\right) + \frac{\Delta^2}{2\sqrt{\xi_p^2+\Delta^2}}\right] =$$
$$= \sum_{p}\left[\left(|\xi_p| - \sqrt{\xi_p^2+\Delta^2}\right) + \frac{\Delta^2}{2\sqrt{\xi_p^2+\Delta^2}}\right] =$$
$$= 2\sum_{p>p_f}\left[\left(\xi_p - \sqrt{\xi_p^2+\Delta^2}\right) + \frac{1}{2}\frac{\Delta^2}{\sqrt{\xi_p^2+\Delta^2}}\right]$$

Докажем, что для перестроенного состояния $E_g(\Delta) < E_g$. We have:

$$I_1 = 2\sum_{p>p_f}\xi_p = 2\frac{\nu_F}{2}\int\limits_0^{\hbar\omega_D}\xi_p d\xi_p = \frac{\nu_F}{2}\left(\hbar\omega_D\right)^2$$

$$I_2 = 2\sum_{p>p_F}\sqrt{\xi_p+\Delta^2} = 2\frac{\nu_F}{2}\int\limits_0^{\hbar\omega_D}\sqrt{\xi^2+\Delta^2}d\xi = \Delta^2\nu_F\int\limits_0^{\hbar\omega_D/\Delta}\sqrt{x^2+1}dx$$

After $x = \sinh y$, we have

$$\int\sqrt{x^2+1}dx = \int dy\cosh^2 y = \frac{1}{4}\sinh(2y) + \frac{y}{2} = \frac{1}{2}\left(x\sqrt{x^2+1} + \operatorname{Arsh} x\right)$$

thus

$$I_2 = \Delta^2\frac{\nu_F}{2}\left(\hbar\omega_D/\Delta\right)\left[1+\left(\hbar\omega_D/\Delta\right)^2\right]^{1/2} + \Delta^2\frac{\nu_F}{2}\operatorname{Arsh}\left(\hbar\omega_D/\Delta\right)$$

From (??) следует, что

$$\sum_{p>p_f}\frac{\Delta^2}{\sqrt{\xi_p^2+\Delta^2}} = \frac{\Delta^2}{g}$$

Итак,

$$E_g(\Delta) - E_g = \frac{\nu_F}{2}\left(\hbar\omega_D\right)^2 - \Delta^2\frac{\nu_F}{2}\left(\hbar\omega_D/\Delta\right)\left[1+\left(\hbar\omega_D/\Delta\right)^2\right]^{1/2} - \Delta^2\frac{\nu_F}{2}\operatorname{Arsh}\left(\hbar\omega_D/\Delta\right) + \frac{\Delta^2}{g}$$

В силу (??) последняя строка в (58) обращается в нуль. Из выражения (58) немелленно слелует, что $E_g(\Delta) - E_g < 0$. При $\hbar\omega_D/\Delta \gg 1$

$$E_g(\Delta) - E_g = \frac{\nu_F}{2}\left(\hbar\omega_D\right)^2 - \Delta^2\frac{\nu_F}{2}\left(\hbar\omega_D/\Delta\right)\left[1+\left(\hbar\omega_D/\Delta\right)^2\right]^{1/2} \approx -\frac{\nu_F\Delta^2}{4}$$

Таким образом, энергия основного состояния сверхпроводящего состояния ($\Delta \neq 0$) ниже энергии нормального состояния.

Calculation of the ground state energy

Reminder: (write shortly what we have and where did we take it?) we know that $\Delta_0 = ...$
(statement about Δ_0, from which it follows? I moved it lower, the derivation was here)

The general expression for E_s is given by $E_s = \sum_k 2\varepsilon_k v_k^2 + \sum_{k.k'} V_{kk'}v_{k'}u_k v_k u_{k'}$. In the normal state, when the interaction between the electrons is switched off and all states below the Fermi level are full, the ground-state energy is given by

$$E_{\mathrm{n}} = \sum_{k<k_{\mathrm{F}}} 2\varepsilon_k \tag{6.17}$$

Here the coefficient 2 appears because the sum is taken over pairs of states $(k, -k)$.

The ground-state energy of the superconductor is measured from the ground-state energy of the normal metal, i.e., we seek the quantity

$$W = E_{\mathrm{s}} - E_{\mathrm{n}}$$

Using $E_s = \sum_k 2\varepsilon_k v_k^2 + \sum_{k.k'} V_{kk'} v_{k'} u_k v_k u_{k'}$ and (6.17), we obtain

$$W = \sum_{k<k_{\mathrm{F}}} 2\varepsilon_k \left(v_k^2 - 1\right) + \sum_{k>k_{\mathrm{F}}} 2\varepsilon_k v_k^2 - V \sum_{kk'}{}' v_k u_k v_{k'} u_{k'} \tag{6.18}$$

The prime on the last summation sign indicates that the sum is taken over the layer $\pm\hbar\omega_D$ near the Fermi surface. Substituting here $v_k^2 = \frac{1}{2}\left(1 - \frac{\varepsilon_k}{E_k}\right)$ yields, after elementary transformations,

$$W = \sum_{k<k_F} |\varepsilon_k| \left(1 - \frac{|\varepsilon_k|}{E_k}\right) + \sum_{k>k_F} \varepsilon_k \left(1 - \frac{\varepsilon_k}{E_k}\right) - V \sum_{kk'}{}' v_k u_k v_{k'} u_{k'} =$$

$$= 2 \sum_{k>k_F} \varepsilon_k \left(1 - \frac{\varepsilon_k}{E_k}\right) - V \sum_{kk'}{}' v_k u_k v_{k'} u_{k'}.$$

Taking into account the definition of $\Delta_0 = V \sum_k' v_k u_k$, we find

$$\sum_{kk'}{}' v_k u_k v_{k'} u_{k'} = \frac{\Delta_0^2}{V^2}$$

Then

$$W = 2 \sum_{k>k_{\mathrm{F}}} \varepsilon_k \left(1 - \frac{\varepsilon_k}{E_k}\right) - \frac{\Delta_0^2}{V}.$$

Going over from summation to integration, we have

$$W = 2N(0) \int_0^{\hbar\omega_{\mathrm{D}}} \varepsilon \left(1 - \frac{\varepsilon}{\sqrt{\varepsilon^2 + \Delta_0^2}}\right) \mathrm{d}\varepsilon - \frac{\Delta_0^2}{V}$$

Integrating yields

$$W = N(0)\Delta_0^2 \left\{ \left(\frac{\hbar\omega_{\mathrm{D}}}{\Delta_0}\right)^2 - \frac{\hbar\omega_{\mathrm{D}}}{\Delta_0} \left[1 + \left(\frac{\hbar\omega_{\mathrm{D}}}{\Delta_0}\right)^2\right]^{1/2} + \operatorname{arcsinh} \frac{\hbar\omega_{\mathrm{D}}}{\Delta_0} \right\} - \frac{\Delta_0^2}{V}.$$

Using (6.15), we obtain for $\hbar\omega_{\mathrm{D}} \gg \Delta_0$ the final result:

$$W = -\frac{1}{2} N(0) \Delta_0^2 \tag{6.19}$$

Thus, at $T = 0$, the difference in energy between the superconducting and the normal state is negative, that is, the superconducting state is more favorable energetically. And, of course, it is the state of lower energy that will be preferred by Nature.

The BCS wavefunction by Chalker

Given a wavefunction for a pair of electrons of the form we have been considering

$$\phi\left(\mathbf{r}_1, \mathbf{r}_2\right) = \left(\uparrow_1\downarrow_2 - \downarrow_1\uparrow_2\right) g\left(\mathbf{r}_1 - \mathbf{r}_2\right)$$

we can attempt to write a wavefunction for $2N$ electrons in which pairs are Bose condensed, of the form

$$\psi\left(\mathbf{r}_1 \ldots \mathbf{r}_{2N}\right) = \mathcal{A} \prod_{n=1}^{n=N} \phi\left(\mathbf{r}_{2n}, \mathbf{r}_{2n+1}\right)$$

where $\mathcal{A}$ denotes antisymmetrisation. It is initially unclear whether Pauli exclusion allows this - whether a nonzero wavefunction survives after the operation of $\mathcal{A}$ when N is large. That it does is clearer when we write both these states in k-space and using operator notation, as

$$|\phi\rangle = \sum_{\mathbf{k}} g_{\mathbf{k}} c^\dagger_{\mathbf{k}\uparrow} c^\dagger_{-\mathbf{k}\downarrow} |0\rangle$$

and

$$|\psi\rangle = \prod_{n=1}^{N} \left(\sum_{\mathbf{k}_n} g_{\mathbf{k}_n} c^\dagger_{\mathbf{k}_n\uparrow} c^\dagger_{-\mathbf{k}_n\downarrow} \right) |0\rangle$$

since when we expand the product, terms with all $\mathbf{k}_n$'s different will survive. The form of the wavefunction in Eq. (45) is not very convenient, because the occupation of different orbitals is correlated through the constraint that exactly $2N$ electrons are present. The BCS wavefunction relaxes this condition (passing to it is analogous to going from the cannonical to the grand canonical distributions in statistical mechanics). It has the form

$$|\mathrm{BCS}\rangle = \prod_{\mathbf{k}} \left(u_{\mathbf{k}} + v_{\mathbf{k}} c^\dagger_{\mathbf{k}\uparrow} c^\dagger_{-\mathbf{k}\downarrow} \right) |0\rangle.$$

Here $u_{\mathbf{k}}$ is the amplitude for a pair of orbitals to be empty, and $v_{\mathbf{k}}$ is the amplitude for them to contain a Cooper pair, so we require $|u_{\mathbf{k}}|^2 + |v_{\mathbf{k}}|^2 = 1$ for normalisation, and $\sum_{\mathbf{k}} |v_{\mathbf{k}}|^2 = N$ in a system containing $2N$ electrons on average.

In fact, a wavefunction of the form of Eq. (46) can represent a variety of states, depending on the choice of coefficients $v_{\mathbf{k}}$. A filled Fermi sea simply has $v_{\mathbf{k}} = 1$ for $\mathbf{k}$ inside the Fermi surface and $v_{\mathbf{k}} = 0$ outside. By contrast, in a state containing many Cooper pairs, we expect $v_{\mathbf{k}}$ to vary smoothly between 1 and 0 across a window of width $\hbar\omega_{\mathrm{D}}$ around the Fermi energy. One approach to finding $v_{\mathbf{k}}$ is variational, and the subject of Question 2 on Problem Sheet 2. An alternative is a mean field treatment of the Hamiltonian, as described next.

BCS ground state by Coleman

(??)

After Cooper's discovery, it took a further six months of intense exploration of candidate wavefunctions before Bardeen, Cooper and Schrieffer succeeded in formulating the theory of superconductivity in terms of a pair condensate [15]. It was the graduate student in the team, J. Robert Schrieffer, who took the next leap. Schrieffer's insight was to identify the superconducting ground state as a coherent state of the Cooper pair operator:

$$|\psi_{BCS}\rangle = \exp\left[\Lambda^\dagger\right] |0\rangle$$

where $|0\rangle$ is the electron vacuum and $\Lambda^\dagger = \sum_{\mathbf{k}} \phi_{\mathbf{k}} c^\dagger_{\mathbf{k}\uparrow} c^\dagger_{-\mathbf{k}\downarrow}$ is the Cooper pair creation operator (14.13). If we expand the exponential as a product in momentum space,

$$|\psi_{BCS}\rangle = \prod_{\mathbf{k}} \exp\left[\phi_{\mathbf{k}} c^\dagger_{\mathbf{k}\uparrow} c^\dagger_{-\mathbf{k}\downarrow}\right] |0\rangle = \prod_{\mathbf{k}} \left(1 + \phi_{\mathbf{k}} c^\dagger_{\mathbf{k}\uparrow} c^\dagger_{-\mathbf{k}\downarrow}\right) |0\rangle$$

BCS wavefunction

3.9.9 What exactly happens at a ground state of a SC (at $T = 0$)?

6.2.1 Electron Distribution in the Ground State

In this section, our objective is to investigate the state of a superconductor at $T = 0$, i.e., when its energy is a minimum.

First it is appropriate to recall the basic postulates of quantum mechanics which we shall need for what comes later. Suppose that $\psi_n(\boldsymbol{r}_1, \boldsymbol{r}_2, \ldots, \boldsymbol{r}_N)$ is a complete system of functions, where n runs over a set of values which we use to assign numbers to these functions. Then an arbitrary wavefunction $\Psi(r_1, r_2, \ldots, r_N)$ can be expanded in a series

$$\Psi = \sum_n a_n \psi_n \tag{6.3}$$

where a_n stands for the amplitude of the state ψ_n and $|a_n|^2$ defines the probability of finding the system in the state ψ_n.

Suppose that the Hamilton operator $\hat{H}$ is

$$\dot{H} = \hat{H}_{\text{kin}} + \hat{V} \tag{6.4}$$

where $\hat{H}_{\text{kin}}$ is the kinetic energy operator and $\hat{V}$ is the interaction energy operator. Then the mean value of energy $\bar{E}$ in the state Ψ can be written as

$$\vec{E} = \int \Psi^* \hat{H} \Psi \, \mathrm{d}\tau \tag{6.5}$$

the integration is carried out over all N variables. Substituting (6.3) and (6.4) into (6.5) yields

$$\bar{E} = \bar{E}_{\text{kin}} + \bar{V},$$

where

$$\bar{V} = \int \Psi^* \hat{V} \Psi \, \mathrm{d}\tau = \int \sum_n a_n^* \psi_n^* \hat{V} \sum_m a_m \psi_m \, \mathrm{d}\tau = \sum_{n,m} a_n^* a_m V_{nm} \tag{6.6}$$

Here V_{nm} is the matrix element for the transition from the state ψ_m to the state ψ_n:

$$V_{nm} = \int \psi_n^* \hat{V} \psi_m \, \mathrm{d}\tau \tag{6.7}$$

Let us go back to the ground state of the superconductor. The ground state of the normal metal in well known. At $T = 0$, the lowest energy belongs to the state, in momentum space (k space), in which all electron states inside the Fermi surface are occupied while all those outside it are empty. The kinetic energy of such a state is obviously a minimum while the potential energy is simply absent, i.e., it is zero.

Let us now switch on the interaction energy between electrons near the Fermi level, as discussed in the foregoing section. Since this energy is associated with the effective attraction between the electrons, its contribution will be negative and the total energy of the system will be reduced. But this can happen only if the electrons are allowed to scatter from the state $(\boldsymbol{k_1}, \boldsymbol{k_2})$ to the state (k_1', k_2'), that is, if, just before the event of scattering, the state (k_1, k_2) is full while the state (k_1', k_2') is empty.

Therefore, the Fermi sphere with all states below the Fermi level occupied and all states above it empty no longer corresponds to the state of minimum energy at $T = 0$.

What happens is that Nature risks a certain loss in kinetic energy in the hope of winning it back in potential energy. The total energy is now a minimum when the Fermi surface is 'smeared out', i.e., when some of the states in k space above the Fermi level are occupied while some of those below the Fermi level are empty. Moreover, when the states are being filled up, it happens in pairs: if the state $\boldsymbol{k} \uparrow$ becomes occupied, the state $-\boldsymbol{k} \downarrow$ must also be occupied (the arrows indicate the directions of electron spins). This process is illustrated in Fig. 6.3. The same applies to the empty states.

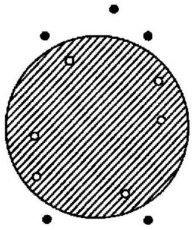


Fig. 6.3. Schematic diagram of an electron state, the energy of which can be lower than the energy of the main state (characterized by all k states below the Fermi level occupied and those above it empty)

Let us now explain why the most favorable way of coupling the electrons is such that the pairs - which are called Cooper pairs - are made of electrons with opposite momenta. A transition of an electron pair from the state (k_1, k_2) to the state (k_1', k_2') must obey the law of momentum conservation: $k_1 + k_2 = k_1' + k_2'$. The sum in (6.6) includes all possible transitions of this kind. The larger the number of allowed transitions, the larger the отрицательный вклад $\bar{V}$ в среднюю энергию $\bar{E}$ сверхпроводника.

If coupled electrons have a total momentum q, the interaction involves only the electrons occupying k states within the dashed areas

Consider, for example, $\boldsymbol{k}_1 + \boldsymbol{k}_2 = \boldsymbol{q}$ as illustrated in Fig. 6.4.

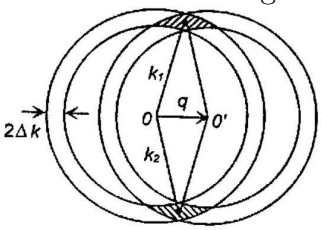

Fig. 6.4.

Here only the electrons occupying the k states in the dashed areas of momentum space are allowed to participate in the transitions. If we now reduce $\boldsymbol{q}$, the dashed areas will grow larger. Finally, at $q = 0$, all states within a band of width $\sim 2\hbar\omega_{\mathrm{D}}$ near the Fermi surface will contribute to the reduction of the average energy.

Let us identify all possible states similar to those shown in Fig. 6.3. Let us assign an index n to them. Then they form a complete system of functions which can be used as a basis for a series expansion of the ground state wavefunction Ψ. The mutual scattering of two coupled electrons $(k, -k)$ to the new state $(\boldsymbol{k}', -\boldsymbol{k}')$ can then be described as a transition from the state ψ_n to another state ψ_m. The state ψ_n corresponds to all states $(\boldsymbol{k}, -\boldsymbol{k})$ full and all states

$(\boldsymbol{k}', -\boldsymbol{k}')$ empty, while the state ψ_m is analogous to the state ψ_n with a single exception: here all states $(k, -k)$ are empty and all states $(\boldsymbol{k}', -\boldsymbol{k}')$ are full (the spin indices have been omitted).

Let us introduce a new function of k, v_k^2. Suppose that it gives the probability that the pair state $(k, -k)$ is occupied. Then the amplitude of the state corresponding to all states $(\boldsymbol{k}, -\boldsymbol{k})$ occupied and all states $(\boldsymbol{k}', -\boldsymbol{k}')$ empty reads

$$a_n = \left[v_k^2 \left(1 - v_{k'}^2\right)\right]^{1/2} = v_k u_{k'}, \quad \text{where} \quad u_k^2 = 1 - v_k^2.$$

By analogy, the amplitude of the state ψ_m corresponding to all states $(k, -k)$ empty and all states $(\boldsymbol{k}', -\boldsymbol{k}')$ occupied is

$$a_m = v_{k'} u_k$$

Using (6.6) we can write the total energy of a superconductor in the state described by the distribution v_k^2 as

$$E_s = \sum_k 2\varepsilon_k v_k^2 + \sum_{k,k'} V_{kk'} v_{k'} u_k v_k u_{k'} \tag{6.8}$$

The first term here gives the total kinetic energy of the system, where ε_k is the energy of an electron in the state k measured from the Fermi level, that is,

$$\varepsilon_k = \frac{\hbar^2 k^2}{2m} - \frac{\hbar^2 k_F^2}{2m} = \bar{\varepsilon}_k - \varepsilon_F.$$

The second term is, according to (6.6), the mean potential energy of electron interaction, where the matrix element $V_{kk'}$ is defined by (6.2).

Now we should find the identity of the function v_k^2 such that the total energy E_s is a minimum. This requires that v_k^2 satisfies the equation

$$\frac{\partial E_{\mathrm{B}}}{\partial v_k^2} = 0.$$

Substituting here $E_s = \sum_k 2\varepsilon_k v_k^2 + \sum_{k.k'} V_{kk'} v_{k'} u_k v_k u_{k'}$ and (6.2), we obtain

$$2\varepsilon_k - V \frac{1 - 2v_k^2}{v_k u_k} \sum_{k'}{}' v_{k'} u_{k'} = 0$$

It follows that

$$\frac{v_k u_k}{1 - 2v_k^2} = \frac{\Delta_0}{2\varepsilon_k} \tag{6.9}$$

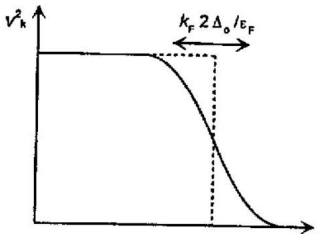
where

$$\Delta_0 = V \sum_k{}' v_k u_k \tag{6.10}$$

The prime on the summation sign indicates that the summation is carried out only over the states k within the spherical layer near the Fermi surface, where the matrix element $V_{kk'}$ is nonzero (see (6.2)).

Expressing v_k^2 from (6.9) yields a quadratic equation for v_k^2:

$$v_k^4 - v_k^2 + \frac{\Delta_0^2}{4\bar{E}_k^2} = 0,$$



where

$$E_k = \sqrt{\varepsilon_k^2 + \Delta_0^2} \tag{6.11}$$

Then

$$v_k^2 = \frac{1}{2}\left(1 - \frac{\varepsilon_k}{E_k}\right). \tag{6.12}$$

The minus sign in (6.12) stems from a general argument that, as $k \to 0$, we ought to have $v_k^2 \to 1$ while $\varepsilon_k \to -\varepsilon_{\mathrm{F}}$.

The dependence of v_k^2 on k is plotted in Fig. 6.5. As one can see, the total energy of the system reaches its minimum when the electron distribution in the vicinity of the Fermi level is 'smeared out' over the energy interval $\sim 2\Delta_0$. Let us emphasize once more that this occurs at absolute zero! This is the identity of the ground state of the superconductor.

At $T = 0$ not all electrons are superconducting

This is because BCS model assumes the filled Fermi surface, which is field by typical electrons, not paired. Pairing comes into the game only near the Fermi surface, which is already created by some other electrons.

(??? need to discuss this with someone)

At $T = 0$ not all electrons are superconducting: Answers to some questions

(??????? don't know yet, how does it work????)

Proof that all they are in SC state

Газ электронов в сверхпроводнике характеризуется разделением его плотности n на нормальную n_n и сверхтекучую n_s части. Величину нормальной плотности, переносящей импульс, мы уже вычислили в прошлой лекции. Заменяя в (11.23) бозевскую функцию распределения квазичастиц на фермиевскую и умножая на 2 с учетом спина электронов, получаем

$$\rho_n = -\frac{8\pi}{3(2\pi\hbar)^3}\int_0^\infty \frac{dn_F}{dp} p^4 dp$$

Поскольку интеграл (12.29) «набирается» в окрестности импульса Ферми $p \approx p_F$, его можно представить приближенно в виде

$$\rho_n = -\frac{p_F^4}{3\pi^2\hbar^3 v_F}\int_{-\infty}^{+\infty} \frac{dn_F}{d\varepsilon} d\xi$$

Полная же плотность электронного газа $\rho = \rho_n + \rho_s$ равна $\rho = mN/V = = p_F^3 m/3\pi^2\hbar^3$. Таким образом, плотность нормальной компоненты равна

$$\frac{\rho_n}{\rho} = -2\int_0^{+\infty} \frac{dn_F}{d\varepsilon} d\xi$$

Интеграл в правой части (12.31) определяется температурной зависимостью щели $\Delta(T)$. Дифференцируя (12.23) по T и подставляя в (12.31), получаем

$$\frac{\rho}{\rho_n} = 1 - \frac{d\ln T}{d\ln \Delta}$$

Из (12.32) следует важный вывод. При $T \to 0$ плотность нормальной компоненты обращается в ноль $\rho_n \to 0$.

Это значит, что с точки зрения переноса массы и заряда при нулевой температуре все электроны становятся сверхпроводящими. Действительно, поскольку $\rho_{n,s} = mn_{n,s}$ и $n = n_s + n_n$, то $n_s(0) = n$. Тот же вывод можно получить из (12.32), представленный в форме

$$\frac{\rho_s}{\rho} = -\frac{d\ln T}{d\ln(\Delta/T)}$$

(???? so, what to say about it??? is it wrong???)

Other conceptually important statements about the ground state

At $T = 0$ real electrons are distributed according to "tilted Fermi distribution", not the Fermi distribution

(here I'll write that one expects for all fermions at ground state to have step distribution because of from of Fermi distribution)

(but for SC (and for interacting fermions) this is not the case)

(discuss it, add plot)

Critical field from the ground state energy

At the beginning of this book we established that (??? why it is so??) the difference in free energy between the normal and the superconducting state equals $H_{\rm cm}^2/8\pi$, where $H_{\rm cm}$ is the thermodynamic critical field. It then follows that at $T = 0$

$$\frac{H_{\rm cm}^2(0)}{8\pi} = \frac{1}{2}N(0)\Delta_0^2$$

or

$$H_{\rm cm}(0) = \Delta_0\sqrt{4\pi N(0)} \tag{6.20}$$

Thus we have expressed the thermodynamic critical field in terms of characteristic parameters of the superconductor, i.e., parameters describing its electron spectrum and electron-phonon interaction.

Let us check whether (6.20) gives reasonable orders of magnitude for relevant physical quantities. 1 cm^3 of metal contains $\sim 10^{22}$ electrons and the width of the conduction band is $\sim 10\text{eV} = 10 \times 1.6 \times 10^{-12}$erg. Then the density of states is $N(0) \sim 10^{22}/\left(10 \times 1.6 \times 10^{-12}\right) \sim 10^{33}\text{erg}^{-1}\ \text{cm}^{-3}$. According to our previous estimates, $\Delta_0 \sim 10$ K $\sim 10^{-15}$erg. This leads to $H_{\rm cm} \sim 10^{-15} \times \sqrt{10^{34}} = 100$Oe, which is a reasonable value for the thermodynamic critical field.

Argument that distribution of electrons $n_{\mathbf{FD}}(T=0)$ is a step regardless spectra doesn't work.

(!!! I'll write, why it is so. because the Hamiltonian is non-diagoanal in terms of operators of real electron. I'll elaborate, why)

3.9.10 System of QFT GF Equations for a Superconductor

Why do we need any QFT superconductivity equations

(?????? write, why???)

Why can we work with GF for superconductors?

(I need a really good answer to it!!! I'll think later)

1. Superconductor at absolute zero

We now proceed to the derivation of a system of equations for the Green functions describing the properties of a metal in the superconducting state (Gor'kov [61]). We shall confine ourselves for a start to the case of absolute zero. In our model, the complete Hamiltonian of the system of electrons in the second quantisation representation has the form

$$\hat{H} = \int \left\{ -\left(\psi^{+} \frac{\nabla^2}{2m} \psi \right) + \frac{\lambda}{2} \left(\psi^{+} \left(\psi^{+} \psi \right) \psi \right) \right\} \mathrm{d}^3 r$$

where $(\psi^{+}\psi) \equiv \psi_{\alpha}^{+}\psi_{\alpha}$ and the operators $\psi(\boldsymbol{r}), \psi^{+}(\boldsymbol{r})$ in the Schrdinger representation satisfy the usual commutation relations

$$\begin{aligned} \left\{ \psi_{\alpha}(\boldsymbol{r}), \psi_{\beta}^{+}\left(\boldsymbol{r}'\right) \right\} &= \delta_{\alpha\beta} \delta\left(\boldsymbol{r} - \boldsymbol{r}'\right) \\ \left\{ \psi_{\alpha}(\boldsymbol{r}), \psi_{\beta}\left(\boldsymbol{r}'\right) \right\} &= \left\{ \psi_{\alpha}^{+}(\boldsymbol{r}), \psi_{\beta}^{+}\left(\boldsymbol{r}'\right) \right\} = 0 \end{aligned} \tag{34.1}$$

We change to the Heisenberg representation, in which the operators $\tilde{\psi}, \tilde{\psi}^{+}$depend on the time and obey the following operator equations:

$$\begin{aligned} \left\{ i\frac{\partial}{\partial t} + \frac{\nabla^2}{2m} \right\} \tilde{\psi}_{\alpha}(x) - \lambda \left(\tilde{\psi}^{+}(x) \tilde{\psi}(x) \right) \tilde{\psi}_{\alpha}(x) = 0 \\ \left\{ i\frac{\partial}{\partial t} - \frac{\nabla^2}{2m} \right\} \tilde{\psi}_{\alpha}^{+}(x) + \lambda \tilde{\psi}_{\alpha}^{+}(x) \left(\tilde{\psi}^{+}(x) \tilde{\psi}(x) \right) = 0 \end{aligned} \tag{34.2}$$

The equation for the Green function of the system

$$G_{\alpha\beta}\left(x, x'\right) = -i \left\langle T \left(\tilde{\psi}_{\alpha}(x) \tilde{\psi}_{\beta}^{+}\left(x'\right) \right) \right\rangle$$

can be obtained in an obvious way from equations (34.2):

$$\left\{ i\frac{\partial}{\partial t} + \frac{\nabla^2}{2m} \right\} G_{\alpha\beta}\left(x, x'\right) + i\lambda \left\langle T \left(\left[\tilde{\psi}^{+}(x) \tilde{\psi}(x) \right] \tilde{\psi}_{\alpha}(x), \tilde{\psi}_{\beta}^{+}\left(x'\right) \right) \right\rangle = \delta\left(x - x'\right).$$

(???? I am not sure, how????)

This equation contains the mean of the product of four $\tilde{\psi}$-operators for a system of non-interacting electrons, which can be expanded by Wick's theorem into averages of pairs of operators $\tilde{\psi}, \tilde{\psi}^{+}$. The product of four $\tilde{\psi}$-operators for interacting particles is already expressible

in terms of the vertex part, i.e. includes the contribution of the different scattering processes. In our weak interaction model, the scattering of different particles by one another can be neglected. At the same time we have to take into account that the ground state of the system differs from the ordinary state with a filled Fermi sphere by the presence of bound electron pairs. As already mentioned in the previous section, such pairs are Bose formations and therefore possess the ability to accumulate in any amount at the level with the lowest energy. In the absence of an external field, and neglecting scattering processes, the pairs obviously "condense" in the state in which they are at rest as a whole.

Let us consider the product of operators $\tilde{\psi}\tilde{\psi}$ or $\tilde{\psi}^+\tilde{\psi}^+$. The first annihilates, whilst the second creates, two electrons. In particular, these two electrons may find themselves in a bound state, in other words, the operators $\tilde{\psi}\tilde{\psi}$ and $\tilde{\psi}^+\tilde{\psi}^+$contain terms corresponding to the annihilation and creation of bound pairs, including pairs at the lowest level. Since there are many such pairs (the number of them is proportional to the total number of particles), the corresponding contribution to the operators $\tilde{\psi}\tilde{\psi}$ and $\tilde{\psi}^+\tilde{\psi}^+$can be regarded as a c-number, just as in the case of a system of bosons.

Notice that there are special reasons, in a metal, why we do not consider pairs which are not at the lowest level: a bound pair of electrons, when the motion as a whole has finite momentum, is a Bose excitation with zero spin.

(??????)

As we have already remarked, the condition for electric neutrality in a metal actually implies that a substantial energy ($\sim$ 1eV) is required for the excitation of such a "Bose condensate" pair, this being much greater than the characteristic energies which we encounter when developing the theory of superconductivity.

Returning to equation (34.3) for the Green function, in the light of what has been said, the average of the product of four ψ-operators can be written as follows, e.g.

$$\begin{aligned}\left\langle \mathrm{T}\left(\tilde{\psi}_\alpha(x_1)\,\tilde{\psi}_\beta(x_2)\,\tilde{\psi}^+_\gamma(x_3)\,\tilde{\psi}^+_\delta(x_4)\right)\right\rangle = \\ = -\left\langle T\left(\tilde{\psi}_\alpha(x_1)\,\tilde{\psi}^+_\gamma(x_3)\right)\right\rangle\left\langle T\left(\tilde{\psi}_\beta(x_2)\,\tilde{\psi}^+_\delta(x_4)\right)\right\rangle + \\ + \left\langle T\left(\tilde{\psi}_\alpha(x_1)\,\tilde{\psi}^+_\delta(x_4)\right)\right\rangle\left\langle T\left(\tilde{\psi}_\beta(x_2)\,\tilde{\psi}^+_\gamma(x_3)\right)\right\rangle + \\ + \langle N|T\left(\tilde{\psi}_\alpha(x_1)\,\tilde{\psi}_\beta(x_2)\right)|N+2\rangle\langle N+2|T\left(\tilde{\psi}^+_\gamma(x_3)\,\tilde{\psi}^+_\delta(x_4)\right)|N\rangle \quad (34.4)\end{aligned}$$

where $|N\rangle$ and $|N+2\rangle$ are the ground states of the systems with N and $N+2$ particles.

(????? why there is the last term here???)

This way of writing the average implies that we have neglected all the effects of scattering of particles by one another. The existence of interactions is only taken into account in so far as it leads to the formation of bound pairs. The third term on the right-hand side of (34.4) is written in complete analogy with the case of a Bose gas, in accordance with the fact that a large number of bound pairs has "condensed" into the lowest level. The quantity

$$\langle N|T(\tilde{\psi}\tilde{\psi})|N+2\rangle\langle N+2|T\left(\tilde{\psi}^+\tilde{\psi}^+\right)|N\rangle$$

is obviously of the order of the density of the number of pairs.

It is easily verified that the functions thus introduced can be written as

$$\begin{aligned}\langle N|T\left(\tilde{\psi}_\alpha(x)\tilde{\psi}_\beta(x')\right)|N+2\rangle = e^{-2i\mu t}F_{\alpha\beta}(x-x') \\ \langle N+2|T\left(\tilde{\psi}^+_\alpha(x)\tilde{\psi}^+_\beta(x')\right)|N\rangle = e^{2i\mu t}F^+_{\alpha\beta}(x-x') \quad (34.5)\end{aligned}$$

(??????????????????????)

For the uniform problem (in the absence of an external field), the Green function $G(x-x')$ depends only on the coordinate difference $x-x'$. The source of the extra dependence on t in expressions (34.5) is clear from the general formulae of quantum mechanics for the time derivative of an arbitrary operator $\tilde{A}(t)$:

$$\frac{\partial}{\partial t}\langle N|\tilde{A}(t)|N+2\rangle = i\left(E_N - E_{N+2}\right)\langle N|\tilde{A}(t)|N+2\rangle.$$

By definition, the chemical potential $\mu = \partial E/\partial N$, so that the energy difference $E_{N+2} - E_N$ is equal to 2μ.

When substituting expression (34.4) into equation (34.3) for the Green function, we shall always omit the first two terms on the right-hand side of (34.4), since they may easily be shown to lcad, in the equations for functions G, F, F^+, to an additive correction to the chemical potential, and are of no interest. As a result, we get the following equation connecting G and F^+:

$$\left\{i\frac{\partial}{\partial t} + \frac{\nabla^2}{2m}\right\}\hat{G}(x-x') - i\lambda\hat{F}(0+)\hat{F}^+(x-x') = \delta(x-x') \tag{34.6}$$

(Here, $\hat{G}, \hat{F}, \hat{F}^+$denote the matrix forms of the functions $G_{\alpha\beta}, F_{\alpha\beta}, F^+_{\alpha\beta}$ in the spin indices, their products being the matrix products.)

The function $\hat{F}(0+)$ is defined as follows:

$$F_{\alpha\beta}(0+) := e^{2i\mu t}\langle N|\tilde{\psi}_\alpha(x)\tilde{\psi}_\beta(x)|N+2\rangle \equiv \lim_{r\to r', t\to t'+0} F_{\alpha\beta}(x-x'). \tag{34.7}$$

The equation for $\hat{F}^+(x-x')$ can be obtained in the same way by using the second of equations (34.2):

$$\left\{i\frac{\partial}{\partial t} - \frac{\nabla^2}{2m} - 2\mu\right\}\hat{F}^+(x-x') + i\lambda\hat{F}^+(0+)\hat{G}(x-x') = 0. \tag{34.8}$$

In accordance with (34.7),

$$F^+_{\alpha\beta}(0+) = e^{-2i\mu t}\langle N+2|\tilde{\psi}^+_\alpha(x)\tilde{\psi}^+_\beta(x)|N\rangle. \tag{34.9}$$

In the absence of spin-dependent interactions, the Green function $\hat{G}(x-x')$ is proportional to the unit matrix $\delta_{\alpha\beta}$ in the spin variables:

$$\hat{G}_{\alpha\beta}(x-x') = \delta_{\alpha\beta}G(x-x')$$

The functions $\hat{F}, \hat{F}^+$are proportional to the matrix $\hat{I}$, anti-symmetric with respect to its indices. Since the operators $\tilde{\psi}_\alpha(x)$ and $\tilde{\psi}_\beta(x')$ anticommute at the same instant, $F_{\alpha\beta}(r-r', 0) = -F_{\beta\alpha}(r'-r, 0)$. It follows from this that

$$\left\{F^+_{\alpha\beta}(\boldsymbol{r}-\boldsymbol{r}', 0)\right\}^* = -\boldsymbol{F}_{\alpha\beta}(\boldsymbol{r}-\boldsymbol{r}', 0) \tag{34.10}$$

In particular,

$$\left\{F^+_{\alpha\beta}(0+)\right\}^* = -F(0+) \tag{34.11}$$

It is convenient to write $\hat{F}, \hat{F}^+$as

$$\hat{F}^{+}(x-x') = \hat{I}F^{+}(x-x') \qquad (34.12)$$
$$\hat{F}(x-x') = -\hat{I}F'(x-x')$$

where $\left(\hat{I}^2\right)_{\alpha\beta} = -\delta_{\alpha\beta}$.

It is clear from (34.10) that $F^{+}(x-x')$ and $F(x-x')$ satisfy the relationship

$$\left\{F^{+}(r-r',0)\right\}^{*} = F(r-r',0)$$

The anti-symmetry of $\hat{F}, \hat{F}^{+}$with respect to the spin indices corresponds to the fact that the bound pairs are at a displaced level. The function $F_{\alpha\beta}(r-r',0)$ can obviously, apart from a factor, be regarded as the wave function of a pair of particles in a bound state (the centre of mass of the pair is at rest).

Let us write down the system of equations for these functions, omitting everywhere the dependence on the spin variables:

$$\left\{i\frac{\partial}{\partial t} + \frac{\nabla}{2m}\right\} G(x-x') - i\lambda F'(0+)F^{+}(x-x') = \delta(x-x') \qquad (34.13)$$
$$\left\{i\frac{\partial}{\partial t} - \frac{\nabla^2}{2m} - 2\mu\right\} F^{+}(x-x') + i\lambda F^{+}(0+)G(x-x') = 0$$

where $(F(0+))^{*} = F^{+}(0+)$.

Fourier transforming everywhere (†) we obtain:

$$\left(\omega - \frac{p^2}{2m}\right) G(p) - i\lambda F(0+)F^{+}(p) = 1 \qquad (34.14)$$
$$\left(\omega + \frac{p^2}{2m} - 2\mu\right) F^{+}(p) + i\lambda F^{+}(0+)G(p) = 0$$

(†) This system of equations has a great similarity to the system for the functions G' and $\hat{G}$ in the Bose system. It must be borue in mind, however, that the analogues of the functions F and $F^{+}$are in this case the operators $\xi_0, \xi_0^{+}$of the condensate particles. We therefore use the notations G and F^{+}as distinct from Q' and $\hat{G}$ for bosons.

The foregoing discussion has been carried through in the thermodynamic variables, where the number of particles is given. It is much more convenient to use the chemical potential μ as the independent variable. As usual, the transformation to this variable can be accomplished formally by substituting $\omega = \omega' + \mu$.

(???? why????)

Omitting the primes from the frequency, (34.14) can be rewritten as

$$(\omega - \xi)G(p) - i\lambda F(0+)F^{+}(p) = 1$$
$$(\omega + \xi)F^{+}(p) + i\lambda F^{+}(0+)G(p) = 0 \qquad (34.15)$$

where $\xi = v(|\boldsymbol{p}| - p_0), p_0 \simeq \sqrt{2m\mu}$ is the Fermi limiting momentum, and $v = p_0/m$.

The solution is

$$G(p) = \frac{\omega + \xi}{\omega^2 + \xi^2 - \Delta^2}, \qquad F^+(p) = -i\lambda \frac{F^+(0+)}{\omega^2 - \xi^2 - \Delta^2}$$

where

$$\Delta^2 = \lambda^2 \left| F^+(0+) \right|^2 \tag{34.16}$$

The determinant of the left-hand side of system (34.15) vanishes at the points $\omega = \pm\varepsilon(p)$, where $\varepsilon(p) = \sqrt{\xi^2 + A^2}$. The solution of (34.15) is therefore obtained up to arbitrary terms of the form

$$A_1(p)\delta(\omega - \varepsilon(p)) + A_2(p)\delta(\omega + \varepsilon(p)).$$

The boundary condition, determining the choice of the arbitrary A_1 and A_2 in the functions G and F^+, is supplied by Landau's theorem (Chap. II), in accordance with which the sign of the imaginary part of the Green function G is opposite to the sign of ω, whilst the function

$$G_R(\omega, p) = \operatorname{Re} G(\omega, p) + i \operatorname{sign}(\omega) \operatorname{Im} G(\omega, p)$$

must be analytic and cannot have singularities in the upper half-plane. It may easily be verified that the solution satisfying these requirements is (†)

$$G(p) = \frac{u_p^2}{\omega - \varepsilon(p) + i\delta} + \frac{v_p^2}{\omega + \varepsilon(p) - i\delta}, \tag{34.17}$$

$$F^+(p) = -i\lambda \frac{F^+(0+)}{(\omega - \varepsilon(p) + i\delta)(\omega + \varepsilon(p) - i\delta)}, \tag{34.18}$$

where the functions u_p^2 and v_p^2 are equal to

$$u_p^2 = \frac{1}{2}\left(1 + \frac{\xi}{\varepsilon(p)}\right); \quad v_p^2 = \frac{1}{2}\left(1 - \frac{\xi}{\varepsilon(p)}\right) \tag{34.19}$$

(†) We have chosen $F^+(0+)$ to be real. This is always possible in the absence of an external field, since equations (34.13) admit of the transformations $\{F(x - x'), F(0+)\} \to \{F(x - x')\, e^{2i\varphi}, F(0+)e^{2i\varphi}\}$ and $\{F^+(x - x'), F + (0+)\} \to \{F^+(x - x')\, e^{-2i\varphi}, F^+(0+)e^{-2i\varphi}\}$ with constant phase. For more details about this, see subsection 2 below.

The positive pole $\omega = \varepsilon(p)$ in Green function (34.17) determines the excitation spectrum $\varepsilon(p) = \sqrt{\xi^2 + \Delta^2}$. This spectrum has a gap Δ, which we find by starting from the relation

$$F^+(0) = (2\pi)^{-4} \int F^+(p) \mathrm{d}\omega \ \mathrm{d}^3 p \tag{34.20}$$

On substituting (34.18) in this, we get the equation
(??? I'll think later about this derivation and writ it here!!!!)

$$1 = -\frac{\lambda}{2(2\pi)^3} \int \frac{\mathrm{d}^3 p}{\sqrt{\xi^2 + \Delta^2}} \tag{34.21}$$

The divergence is cut out of this integral due to the condition that, in our model, the only electrons taking part in the interaction are those with energies in a layer of width $2\omega_D$ about the Fermi surface. We find on performing the integration that

$$1 = -\frac{\lambda}{2\pi^2} m p_0 \ln \frac{2\omega_D}{\Delta}.$$

We get as a result:

$$\Delta = 2\omega_D e^{-1/\eta}, \tag{34.22}$$

where $\eta = |\lambda| m p_0 / 2\pi^2$. On comparing this expression with the result of the previous subsection, we find that the size of the gap in the energy spectrum at absolute zero has the following relation with the transition temperature:

$$\Delta = \frac{\pi}{\gamma} T_c \tag{34.23}$$

2. The equations in the presence of an external electromagnetic field. Gauge-invariance

If a superconductor is located in an external field, say in an electromagnetic field, system (34.13) becomes rather more complicated. Notice, first of all, that in an external field the functions are no longer functions of the coordinate difference only. The electromagnetic field can be brought into (34.13) in the usual way by the following substitution:

$$\nabla \to \nabla - ieA \text{ or } \nabla \to \nabla + ieA, \tag{34.24}$$

depending on whether the differentiation refers to the operator $\tilde{\psi}$ or $\tilde{\psi}^+$. (It is generally convenient to use the gauge in which the scalar potential φ is zero.) The equations for G and F^+in the case of a field are

$$\begin{aligned} &\left\{ i\frac{\partial}{\partial t} + \frac{1}{2m}\left(\frac{\partial}{\partial r} - ieA(r)\right)^2 + \mu \right\} G(x,x') - i\lambda F(x,x) F^+(x,x') = \delta(x-x'), \\ &\left\{ i\frac{\partial}{\partial t} - \frac{1}{2m}\left(\frac{\partial}{\partial r} + ieA(r)\right)^2 - \mu \right\} F^+(x,x') + i\lambda F^+(x,x) G(x,x') = 0. \end{aligned} \tag{34.25}$$

Notice the obvious gauge-invariance of these equations. A gauge transformation of the vector potential,

$$A \to A + \frac{\partial \varphi}{\partial r} \tag{34.26}$$

leads to different transformations of the functions G, F' and F^+:

$$\begin{aligned} G(x,x') &\to G(x,x')\, e^{ie[\varphi(r)-\varphi(r')]} \\ F(x,x') &\to F(x,x')\, e^{ie[\varphi(r)+\varphi(r')]} \\ F^+(x,x') &\to F^+(x,x')\, e^{-ie[\varphi(r)+\varphi(r')]} \end{aligned} \tag{34.27}$$

whilst the "gap" $|\lambda| F(x,x)$ or $|\lambda| F^+(x,x)$, which, in an external field, is generally speaking a function of x, transforms in accordance with

$$F(x,x) \to F(x,x) e^{2ie\varphi(r)}, \quad F^+(x,x) \to F^+(x,x) e^{-2ie\varphi(r)}. \tag{34.28}$$

The gauge-invariance of the equations enables us to study now the properties of a superconductor in a magnetic field. It must be emphasized, as regards the gauge-invariance of (34.25), that it is connected with the use of the form (32.3) for writing the interaction Hamiltonian. Strictly speaking, Hamiltonian (32.2) is not gauge-invariant, this being, of course, a property

of the model. It may easily be shown that, in this model, equation (34.13) contains, instead of $F(0+)$ and $F^+(0+)$ - the values of the functions F and F^+at coincident points - the functions

$$\overline{F'(x,x)} = \int \theta(r-y)\theta(r-z)F(y,z)\mathrm{d}^3z\ \mathrm{d}^3y$$

and $\overline{F^+(x,x)}$ respectively. As the wave function of a pair, $F(y,z;t=t')$ has a correlation radius of the order of the pair dimensions $\xi_0 \sim hv/T_c$, and falls off rapidly when $|y-z| \gg \xi_0$. The functions θ are of the δ function type, as mentioned in par. 32, with a half-width of the order v/ω_D. Hence replacing of $\overline{F(x,x)}$ by $F(x,x)$ involves an error of the order T_c/ω_D, which is always small in real superconductors.

(??? write, where these equations are used???)

3. GF Equations for Superconductor at finite temperatures

We shall end the present section by considering the question of extending the above approach to the case of non-zero temperatures. This extension is obviously possible on the basis of the method described in Chap. III for $T \neq 0$. A system is characterised in the superconducting state by the non-zero averages

$$\mathfrak{F}(x,x') = \frac{\langle T_\tau(\psi(x)\psi(x')\mathfrak{S})\rangle}{\langle\mathfrak{S}\rangle}, \quad \mathfrak{F}^+(x,x') = \frac{\left\langle T_\tau\left(\psi(x)\bar{\psi}(x')\mathfrak{S}\right)\right\rangle}{\langle\mathfrak{S}\rangle}$$

(the meaning of the averaging and the definition of operators $\psi(x)$, $\bar{\psi}(x)$ being the same as in Chap. III. Remember that the chemical potential is chosen as the independent thermodynamic variable). If we regard the ensemble averages in the definitions of $\mathfrak{F}(x,x')$ and $\mathfrak{F}^+(x,x')$ as quantum mechanical averages over the state with energy equal to the mean energy $\bar{E}$, and with a number of particles equal to the average number of particles, this means that the creation or annihilation of a pair of electrons leaves the state virtually unchanged. It is necessary for this that the pair of electrons in question belong to those bound pairs that find themselves in the "Bose condensate" state. Since the number of these pairs is very large (proportional to the total number of particles in the total volume of the system), the addition or annihilation of one such pair makes no difference to the total state of the system.

(????)

In other words, as in the case of absolute zero, in the system the superconducting state possesses terms in the operator products $\psi\psi$ and $\psi^+\psi^+$that can be regarded as c-numbers. We assume that the (thermodynamic) average of the product of four ψ-operators can be written in terms of the Green function $\mathfrak{G}(x,x') = -\left\langle T_\tau\left(\psi(x)\bar{\psi}(x')\mathfrak{S}\right)\right\rangle/\langle\mathfrak{S}\rangle$ and the functions $\mathfrak{F}(x,x')$, $\mathfrak{F}^+(x,x')$, just as was done in expression (34.4) at absolute zero. As above, this implies neglecting the effects of scattering of particles by one another. We have:

$$\frac{\left\langle T_\tau\left(\psi_\alpha(x_1)\psi_\beta(x_2)\bar{\psi}_\gamma(x_3)\bar{\psi}_\delta(x_4)\mathfrak{S}\right)\right\rangle}{\langle\mathfrak{S}\rangle} = -\mathfrak{G}_{\alpha\gamma}(x_1,x_3)\mathfrak{G}_{\beta\delta}(x_2,x_4) + \\ + \mathfrak{G}_{\alpha\delta}(x_1,x_4)\mathfrak{G}_{\beta\gamma}(x_2,x_3) + \mathfrak{F}_{\alpha\beta}(x_1,x_2)\mathfrak{F}^+_{\gamma\delta}(x_3,x_4). \quad (34.29)$$

We shall not repeat here the derivation of the equations for the functions () and $\mathfrak{F}^+$. It is very similar to the derivation of (34.13); we shall just quote the final form of these equations:

$$\left\{-\frac{\partial}{\partial\tau}+\frac{\nabla^2}{2m}+\mu\right\}\mathfrak{G}\left(x-x'\right)+\Delta\mathfrak{F}^{+}\left(x-x'\right)=\delta\left(x-x'\right),$$
$$\left\{\frac{\partial}{\partial\tau}+\frac{\nabla^2}{2m}+\mu\right\}\mathfrak{F}^{+}\left(x-x'\right)-\Delta^{*}\mathfrak{G}\left(x-x'\right)=0 \tag{34.30}$$

where

$$\Delta=|\lambda|\mathfrak{F}\left(0^{+}\right),\quad \Delta^{*}=|\lambda|\mathfrak{F}^{+}\left(0^{+}\right). \tag{34.31}$$

It sometimes proves necessary to determine the function $\mathfrak{F}\left(x-x'\right)$. The corresponding equation is easily obtained:

$$\left\{-\frac{\partial}{\partial\tau}+\frac{\nabla^2}{2m}+\mu\right\}\mathfrak{F}\left(x-x'\right)-\Delta\mathfrak{G}\left(x'-x\right)=0.$$

This contains the function $\mathfrak{G}$ with arguments interchanged.

It is easy to show that the set of four equations for $\mathfrak{G}\left(x-x'\right),\mathfrak{F}^{+}\left(x-x'\right)$, $\mathfrak{F}\left(x-x'\right)$ and $\mathfrak{G}\left(x'-x\right)$ can be written symbolically in the matrix form

$$\begin{pmatrix}\left\{-\frac{\partial}{\partial\tau}+\frac{\nabla^2}{2m}+\mu\right\} & \Delta\\ -\Delta^{*} & \left\{\frac{\partial}{\partial\tau}+\frac{\nabla^2}{2m}+\mu\right\}\end{pmatrix}\times\begin{pmatrix}\mathfrak{G}\left(x-x'\right) & \mathfrak{F}\left(x-x'\right)\\ \mathfrak{F}^{+}\left(x-x'\right) & -\mathfrak{G}\left(x'-x\right)\end{pmatrix}=\hat{\mathbf{1}}. \tag{34.32}$$

In other words, the four functions form one Green function matrix for the operator on the left-hand side of (34.30).

In the temperature-dependent method, as we know, all the functions are expanded into Fourier series, rather than into a Fourier integral over the frequency. It is clear from these equations that. if we Fourier transform the functions $\mathfrak{F}$ and $\mathfrak{F}^{+}$, in the same way as we Fourier transformed the Green function in Chap. III:

$$\mathfrak{F}^{+}\left(x-x'\right)=(2\pi)^{-3}T\sum_{n}e^{-i\omega_n\tau}\int\mathrm{d}^3pe^{i(p\cdot r)}\mathfrak{F}_{\omega}^{+}(p)$$
$$\mathfrak{F}\left(x-x'\right)=(2\pi)^{-3}T\sum_{n}e^{-i\omega_n\tau}\int\mathrm{d}^3pe^{i(p\cdot r)}\mathfrak{F}_{\omega}(p) \tag{34.33}$$

where $\omega=(2n+1)\pi T$, equations (34.15) now correspond to the set

$$(i\omega-\xi)\mathfrak{G}_{\omega}(p)+\Delta\mathfrak{F}_{\omega}^{+}(p)=1$$
$$(i\omega+\xi)\mathfrak{F}_{\omega}^{+}(p)+\Delta^{*}\mathfrak{G}_{\omega}(p)=0 \tag{34.34}$$

which is satisfied by

$$\mathfrak{G}_{\omega}(\boldsymbol{p})=-\frac{i\omega+\xi}{\omega^2+\xi^2+\Delta^2},\qquad \mathfrak{F}_{\omega}^{+}(\boldsymbol{p})=\frac{\Delta^{*}}{\omega^2+\xi^2+\Delta^2}. \tag{34.35}$$

Notice also that, in the absence of a field, $\mathfrak{F}$ and $\mathfrak{F}^{+}$are equal to one another, and Δ is real. This solution is single-valued, as distinct from the situation holding for the system (34.15).

This is connected with the fact that the analytic properties of the thermodynamic functions are uniquely defined. The size of the gap is determined from the condition

$$1 = \frac{|\lambda| T}{(2\pi)^3} \sum_n \int \frac{\mathrm{d}^3 p}{\omega + \xi^2 + \Delta^2} \tag{34.36}$$

The series over the frequencies is easily summed. Instead of condition (34.21) at $T = 0$, a new relation is obtained, from which we can find the size of the gap at finite temperatures:

$$1 = \frac{|\lambda| m p_0}{2\pi^2} \int_0^{\omega_D} \mathrm{d}\xi \frac{\tanh \frac{\sqrt{\xi^2+\Delta^2(T)}}{2T}}{\sqrt{\xi^2+\Delta^2(T)}}. \tag{34.37}$$

At the point of the phase transition, i.e. at the temperature $T = T_c$, the gap $\Delta(T)$ vanishes and, as must be the case, condition $1 = \frac{|\lambda| m p_0}{2\pi^2} \int_0^{\omega_D} \mathrm{d}\xi \frac{\tanh \frac{\sqrt{\xi^2+\Delta^2(T)}}{2T}}{\sqrt{\xi^2+\Delta^2(T)}}$ turns into (33.15), from which the transition temperature T_c can be determined.

3.9.11 The Superconductivity QFT Equations: Derivation

Theory

Let us dwell on the derivation of the superconductivity equations in the model in which the electrons interact with one another through the electron-phonon interaction. Of course, such a model suffers from the same defect as the approach described above, inasmuch as no account is taken in it of the Coulomb forces acting in the metal. Nevertheless it evidently has a more direct physical significance than the model with a four-fermion interaction, even though the latter is more useful when it comes to obtaining practical results. The basic advantage of the phonon model lies, first of all, in the electron-phonon interaction Hamiltonian (32.1) being gauge-invariant right from the start, as distinct from the method with the four-fermion interaction Hamiltonian (32.2), which is only approximately gauge-invariant, by virtue of the relation $T_c \ll \omega_D$. As regards this relation, it is in general fulfilled only in the weak binding approximation(†). We shall show below that the restriction to weak binding is not essential in the theory of superconductors and that only the ratio $\omega_D/\varepsilon_F \ll 1$ is actually a small parameter of the theory ($\omega_D/\varepsilon_F \sim u/v \sim 10^{-2} - 10^{-3}$, where u is the sound velocity in the body, and v is the electron velocity on the Fermi surface ($\overset{(+)}{*}$)). We shall confine ourselves to deriving the equations at absolute zero.

Suppose, then, that the interaction Hamiltonian of the system of electrons and phonons is

$$H_{int}(x) = g\left(\tilde{\psi}^+(x)\tilde{\psi}(x)\right)\tilde{\varphi}(x)$$

If the system is in the superconducting state, its properties are characterised by two functions F, F^+, in addition to the Green function G. Hence, instead of the usual Dyson equation (21), it is generally necessary to investigate three equations, connecting the three functions

$$\begin{aligned}
\hat{G}_{\alpha\beta}(x,x') &= -i\left\langle T\left(\tilde{\psi}_\alpha(x), \tilde{\psi}^+_\beta(x')\right)\right\rangle \equiv \delta_{\alpha\beta} G(x-x'), \\
\hat{F}^+_{\alpha\beta}(x,x') &= \left\langle T\left(\tilde{\psi}^+_\alpha(x), \tilde{\psi}^+_\beta(x')\right)\right\rangle = I_{\alpha\beta} F^+(x-x'), \\
\hat{F}_{\alpha\beta}(x,x') &= \left\langle T\left(\tilde{\psi}_\alpha(x), \tilde{\psi}_\beta(x')\right)\right\rangle = -I_{\alpha\beta} F(x-x').
\end{aligned} \tag{35.1}$$

As regards the equation for the phonon Green function

$$D(x_1 - x_2) = -i \langle T(\varphi(x_1), \varphi(x_2)) \rangle ,$$

it remains almost unchanged, as we shall see.

The equation for the Green function can be obtained from the diagram technique of perturbation theory. Just as in the case of a boson system below the "Bose condensation" point, the set of possible diagrams of perturbation theory is widened due to the appearance in them of lines corresponding to the functions F and F^+. Let us agree to represent on the diagram the functions $G, F^+$and F by heavy lines with two arrows, the directions of which at the points x, x' are chosen in accordance with (35.1) in such a way that the operator $\tilde{\psi}$ at the point in question corresponds to an arrow directed away from the point, whereas $\tilde{\psi}^+$corresponds to an arrow directed towards the point. All three lines are illustrated in Fig. 93.

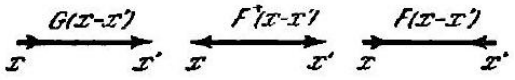


Fig. 93

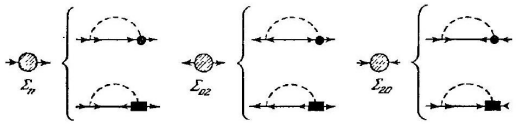

Fig. 94

(†) We always have, however, $T_c \ll \omega_D$ for actual superconductors.

(‡) Electron-phonon interactions in the theory of superconductors were investigated in [59], [60].

It may easily be seen now that, in complete analogy with a boson gas, there are three types of irreducible self-energy parts, which we denote by $\Sigma_{11}(x, x')$, $\Sigma_{20}(x, x')$ and $\Sigma_{02}(x, x')$. In Fig. 94, illustrating the $\sum_{ik}$ diagrams, the dotted line corresponds to the phonon D-functions, the point to a simple vertex, or factor g, and the heavy point or rectangle denotes the modification to the simple vertex as a result of the different elec-tron-phonon interactions.

Let us Fourier transform all the functions and consider one of the selfenergy diagrams, say $\Sigma_{11}(p)$. It will easily be seen that, up to terms of order ω_D/ε_F, we can neglect all the phonon corrections to the electron-phonon vertex part in the simplest diagram for $\Sigma_{11}(p)$ of Fig. 95.

Fig. 95

In fact, as we proved in 21, the values of the D-function (and phonon vertex) of importance in the relevant integrand are those for phonons with momenta of the order of the Fermi momentum of the electrons. For this reason, the estimate obtained in 21 for the corrections to the phonon vertex resulting from the electron-phonon interaction still remains valid in the present case. since the size of these corrections is determined by the values of the Green functions in the energy and momentum region remote from the Fermi surface. It is quite rlear that the Fourier components of the electron Green function for a metal in the superconducting state differ from their values in the normal metal only in a narrow region close to the Fermi surface, with excitation energies not greater than the order of the maximum phonon energies, i.c. of order ω_D. To the same degree, the functions $F^+(p), F(p)$, which are characteristic of the superconducting state, also differ from zcro only in the region mentioned. Fig. 94 illustrates the two possible types of self-energy diagram, for each of the parts Σ_{11}, Σ_{20} and Σ_{02}, depending on the choice of the modification to the phonon vertex. On the basis of what has just been said, we can immediately onit the diagrams of the sccond type. where the phonon vertex is marked by a

heavy rectangle, since the diagrams of this kind can be formed only by using the superconductor Green functions F and F^+.

We can therefore confine ourselves to the zero order approximation of perturbation theory for the phonon vertex in the irreducible parts of Σ_{11}, Σ_{20} and Σ_{02}.

For the same reasons, the phonon Green function $D(x_1 - x_2)$ will remain unchanged, and we can use (21.14) directly for its Fourier component. The structure of the equations for G and $F^+$is illustrated in Fig. 96 and is clear without further explanation.

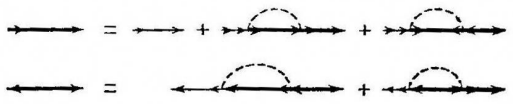

Fig. 96

Let us write these equations in analytic form. In the coordinate representation.

$$\begin{aligned}
\left\{i\frac{\partial}{\partial t}+\frac{\nabla^2}{2m}+\mu\right\}G(x-x') &= \delta(x-x') + g^2 i\int G(x-z)D(x-z)G(z-x')\,\mathrm{d}^4z \\
&\quad + g^2 i\int F(x-z)D(x-z)F^+(z-x')\,\mathrm{d}^4z \\
\left\{-i\frac{\partial}{\partial t}+\frac{\nabla^2}{2m}+\mu\right\}F^+(x-x') &= g^2 i\int G(z-x)D(z-x)F^+(z-x')\,\mathrm{d}^4z \\
&\quad + g^2 i\int F^+(x-z)D(x-z)G(z-x')\,\mathrm{d}^4z
\end{aligned} \tag{35.2}$$

(!!!! write here, what it the meaning of this equations????)

An electromagnetic field can be included in these equations in the usual way, precisely as was done above in 34. Let us emphasise that the resulting system is completely gauge-invariant, as distinct from system (34.13), in which the gauge-invariance was only approximate, up to terms T_c/ω_D. Unfortunately, as is clear from (35.2), this system has a much more complicated form, with a non-linear integral term, which makes it less suitable for solution in the coordinate representation, as is required in a number of problems in which a non-uniform magnetic field exists. On the other hand, the practical results obtained are as a rule equivalent for the two models.

In the absence of a magnetic field, on transforming to the momentum representation in equations (35.2), we easily get equations for the Fourier components of all the functions:

$$\begin{aligned}
\left(\omega-\xi-g^2 i\bar{G}_\omega\right)G(p) - g^2 i\bar{F}_\omega F^+(p) &= 1, \\
\left(-\omega-\xi-g^2 i\bar{G}_{-\omega}\right)F^+(p) - g^2 i\bar{F}^+_\omega G(p) &= 0.
\end{aligned} \tag{35.3}$$

Here, we have written

$$\begin{aligned}
\bar{G}_\omega &= \frac{1}{(2\pi)^4}\int G(p-k)D(k)\mathrm{d}^4k, \qquad \bar{F}_\omega = \frac{1}{(2\pi)^4}\int F(p-k)D(k)\mathrm{d}^4k, \\
\overline{F^+_\omega} &= \frac{1}{(2\pi)^4}\int F^+(p-k)D(k)\mathrm{d}^4k, \qquad G_{-\omega} = \bar{G}_\omega(-p).
\end{aligned} \tag{35.4}$$

This system is completely analogous to the system (34.15) obtained above. The only difference is this: whereas, in equations (34.15), $\bar{G}_\omega, \bar{F}_\omega$ and $\bar{F}^\top_\omega$ are constant in the region $|v(|p|-p_0)| < \omega_D$ about the Fermi surface and vanish outside this region, the functions (35.4) are in general functions of ω and p, smoothly decreasing to zero when ω, $|v(|p|-p_0)| \gg \omega_D$.

Let us express G and F^+in terms of $\bar{G}_\omega, \bar{F}_\omega$ and $\overline{F^+_\omega}$:

$$G(p) = \frac{\omega - g^2 i\bar{G}_\omega + \xi}{\left[\omega - \xi - g^2 iG_\omega\right]\left[\omega + \xi + g^2 i\bar{G}_{-\omega}\right] - g^4\left|\bar{F}^+_\omega\right|^2}$$
$$F^+(p) = \frac{-ig^2\bar{F}^+_\omega}{\left[\left(\omega - \xi - g^2 i\bar{G}_\omega\right)\left[\omega + \xi + g^2 i\bar{G}_{-\omega}\right] - g^4\left|\overline{F^+_\omega}\right|^2}$$

After substituting these expressions into the definitions (35.4) of $\bar{Q}_\omega$ and $\overline{F^+_\omega}$, we get two integral equations for these functions instead of the one equation (21.16) of 21. The solution of these equations was obtained by Eliashberg [62]. We shall give the final result, without dwelling on the details. It turns out that, at small energies, the excitation spectrum has the form

$$\varepsilon(p) = \sqrt{\xi^2 + \Delta^2},$$

where, however, $\xi = v_1\,(p - p_0)$ contains, in accordance with §21, the renormalised velocity on the Fermi surface v_1. The gap at absolute zero is connected with $\overline{F^+_\omega} = 0$ by the relation

$$\Delta = g^2\frac{v_1}{v_0}\left|\overline{F^+_{\omega=0}}\right|.$$

In the weak interaction limit, $g^2 \ll 1$, these formulae are the same as the results of the previous section.

3.9.12 Δ_0 and T_c, The Universal BCS Relation

Overview of approaches for establishing the gap at $T = 0$, Δ_0

(write later, not that important)

Calculations of the Δ_0

Calculation of Δ_0 from substitution of u, v into the gap equation and integration

(write what do we have to start doing it??)

We know that $\Delta_0 = V\sum'_k v_k u_k$, and that $v_k^2 = \frac{1}{2}\left(1 - \frac{\varepsilon_k}{E_k}\right)$ and $v_k^2 = \frac{1}{2}\left(1 + \frac{\varepsilon_k}{E_k}\right)$. So, we just transform the gap:

$$\Delta_0 = V\sum_k{}' \left[\frac{1}{2}\left(1 - \frac{\varepsilon_k}{E_k}\right)\frac{1}{2}\left(1 + \frac{\varepsilon_k}{E_k}\right)\right]^{1/2} = \frac{V}{2}\sum_k{}' \left(\frac{E_k^2 - \varepsilon_k^2}{E_k^2}\right)^{1/2} = \frac{V\Delta_0}{2}\sum_k{}' \left(\varepsilon_k^2 + \Delta_0^2\right)^{-1/2}$$

Here we have used the definition $E_k := \sqrt{\varepsilon_k^2 + \Delta_0^2}$.

Thus the equation for Δ_0 has the form:

$$1 = \frac{V}{2}\sum_k{}' \left(\varepsilon_k^2 + \Delta_0^2\right)^{-1/2} \tag{6.13}$$

Let us use the formula

$$\sum_k{}' \cdots = \int_{-\hbar\omega_D}^{\hbar\omega_D} \ldots N(\varepsilon)\mathrm{d}\varepsilon$$

to go from the summation over k to an integration over ε, where $N(\varepsilon)$ is the density of states at the energy ε. Then (6.13) reduces to

$$1 \approx \frac{N(0)V}{2} \int_{-\hbar\omega_{\rm D}}^{\hbar\omega_{\rm D}} \left(\varepsilon^2 + \Delta_0^2\right)^{-1/2} \, {\rm d}\varepsilon \tag{6.14}$$

Here $N(0)$ is the density of states at the Fermi level (recall that the energy ε is measured from the Fermi level) and we have taken into account that the integration is carried out over the energy interval $(2\hbar\omega_D)$ which is small compared to the Fermi energy ε_F. Therefore, any variations of the density of states $N(\varepsilon)$ over this are neglected. Since the function under the integral sign in (6.14) is even and the integration limits are symmetric, it can be written as

$$1 = N(0)V \int_{0}^{\hbar\omega_D} \left(\varepsilon^2 + \Delta_0^2\right)^{-1/2} \, {\rm d}\varepsilon$$

Since $\frac{d}{dx}\operatorname{arsinh} x = \frac{1}{\sqrt{x^2+1}}$, we get $\frac{1}{N(0)V} = \operatorname{arcsinh}\left(\frac{\hbar\omega_{\rm D}}{\Delta_0}\right)$, or

$$\frac{\hbar\omega_{\rm D}}{\Delta_0} = \sinh\left(\frac{1}{N(0)V}\right) \tag{6.15}$$

Recalling that for the majority of superconductors $N(0)V \leq 0.3$, we obtain Δ_0 in the form

$$\Delta_0 \simeq 2\hbar\omega_{\rm D} \exp\left(-\frac{1}{N(0)V}\right) \tag{6.16}$$

Let us estimate Δ_0: Taking the Debye temperature $\hbar\omega_{\rm D} \sim 100$ K and $N(0)V \sim 0.3$, we obtain $\Delta_0 \sim 4$ K.

Calculation of Δ_0 from the gap equation

One can use the gap equation in the form $\frac{1}{\lambda} = \frac{1}{2}\sum_{\mathbf{p}} \frac{1+2\bar{n}_{\mathbf{p}}}{\sqrt{\xi_{\mathbf{p}}^2+\Delta^2}}$.

При $T = 0$ квазичастиц нет $\bar{n}_{\rm p} = 0$. Заменяя в (12.23) сумму на интеграл с плотностью состояний $v_F g_F/2$ (??? this is the change to ξ, write about it!), we get

$$1 = \frac{\lambda}{2}\frac{4\pi}{(2\pi\hbar)^3}\frac{p_F^2}{v_F}\int_{-\hbar\omega_D}^{+\hbar\omega_D} \frac{d\xi_{\rm p}}{\sqrt{\xi_{\rm p}^2+\Delta_0^2}} = \frac{\lambda}{2}\frac{4\pi}{(2\pi\hbar)^3}\frac{p_F^2}{v_F} 2\int_{0}^{\hbar\omega_D/\Delta_0} \frac{dx}{\sqrt{1+x^2}}$$

Безразмерный интеграл в (12.24), как известно, равен «длинному логарифму» $\int dx/\sqrt{1+x^2} = \ln\left|x+\sqrt{1+x^2}\right|$. Если Вам это неизвестно, то его недолго и оценить асимптотически. Действительно, поскольку верхний предел интегрирования в (12.24) велик $\hbar\omega_D/\Delta_0 \gg 1$, то $\int_0^x dx/\sqrt{1+x^2} \propto \propto \int_1^x dx/x \propto \ln|x|$. Точность этой оценки обусловлена соотношениями $\Delta_0 \sim T_c \ll \hbar\omega_D \ll \varepsilon_F$. Отсюда получаем

$$\Delta_0 = 2\hbar\omega_D e^{-\frac{2}{\lambda g_F}}$$

Stability of numerical calculations of the gap equation

(discuss, for which parameters it is stable and fro which it will break. I have no idea, this question is in scope of computational mathematics)

Overview of approaches for establishing the T_c

Calculations of the T_c

Calculation of the T_c by known integral gap equation

(add comments, where does this formula come from?)

From $\frac{1}{N(0)V} = \int_0^{\hbar\omega_{\rm D}} \frac{{\rm d}\varepsilon}{\sqrt{\varepsilon^2+\Delta^2(T)}} \tanh \frac{\sqrt{\varepsilon^2+\Delta^2(T)}}{2k_{\rm B}T}$, an explicit expression for the critical temperature $T_{\rm c}$ can be derived as follows. At $T = T_{\rm c}$, the gap is $\Delta = 0$. Hence, replacing T in this equation with $T_{\rm c}$ and setting $\Delta = 0$ yields an equation for $T_{\rm c}$:

$$\frac{1}{N(0)V} = \int_0^{\hbar\omega_{\rm D}} \frac{{\rm d}\varepsilon}{\varepsilon} \tanh \frac{\varepsilon}{2k_{\rm B}T_{\rm c}} \tag{6.36}$$

Carrying out the integration (???? do it!!!), we get

$$k_{\rm B}T_{\rm c} = 1.14\hbar\omega_{\rm D} \exp\left(-\frac{1}{N(0)V}\right) \tag{6.37}$$

(??? what is exactly constant there???)

On the other hand, we already know from setting $T = 0$ in the gap equation that $\Delta_0 = 2\hbar\omega_{\rm n} \exp\left(-\frac{1}{N(0)V}\right)$. Then

$$2\Delta_0 = 3.52k_{\rm B}T_{\rm c} \tag{6.38}$$

Calculation of the T_c by transforming the gap equation to integral form and approximating

This derivation is basically the same as before, but in a different notation.

При конечных температурах величина щели уменьшается и в точке перехода $T = T_c$ обращается в ноль $\Delta = 0$:

$$1 = \frac{\lambda}{2} \int \frac{d^3\mathbf{p}}{(2\pi\hbar)^3} \frac{1-2\bar{n}_{\mathbf{p}}}{|\xi_{\mathbf{p}}|} = \frac{\lambda g_F}{2} \int_{-h\omega_D}^{+h\omega_D} \frac{d\xi_{\mathbf{p}}}{2\xi_{\mathbf{p}}} \ {\rm th} \ \frac{|\xi_{\mathbf{p}}|}{2T_c}$$

Здесь мы учли, что при $T = T_c$ и $\Delta = 0$ спектр квазичастиц имеет вид $\varepsilon(p) = |\xi_{\rm p}|$, а также $1 - 2\bar{n}_{\rm p} = {\rm th}\left(|\xi_{\rm p}|/2T_c\right)$. Таким образом,

$$1 = \frac{\lambda g_F}{2} \int_0^{\hbar\omega_D/2T_c} \frac{{\rm th}\, x}{x} dx$$

Безразмерный интеграл в (12.27) легко оценить, его главная асимптотика при больших $x \gg 1$ есть $\int_0^x ({\rm th}\, x/x)dx \approx \int_1^x dx/x = \ln|x|$. Отсюда получаем для критической температуры $2T_c \approx \hbar\omega_D \exp(-2/\lambda g_F) = 0,5\Delta_0$. Это лишь численным множителем отличается от точного расчета, который дает

$$T_c = \frac{e^\gamma}{\pi}\Delta_0 \approx 0,57\Delta_0$$

где $e^\gamma = 1,78$ - постоянная Эйлера.

The physical picture is as follows. Due to thermal processes, some of the Cooper pairs become broken and turn into uncoupled single electrons which can also be classified as normal electrons (aka elementary excitations). The single electrons occupy certain k states in momentum space thereby excluding these states (and their partner states) from the sum in $\Delta_0 = V \sum_k' v_k u_k$ which defines the gap Δ. As a result, the gap shrinks. When it finally becomes zero, the superconductor goes to the normal state, so all excitations above Fermi surface will be possible.

Calculation of the T_c by numerical summation

We could just sum the terms in the gap equation and get T_c numerically, and not think about any integrals at all.

General preparation:

```
import numpy as np
import matplotlib.pyplot as plt
from scipy.optimize import bisect

# Parameters
tttt = 0.3        # hopping parameter
lambd = 1.0       # coupling strength
cutoff = 0.3      # energy window near Fermi surface
N = 500          # number of momentum points
p_vals = np.linspace(-np.pi, np.pi, N)

def disp(p):
    return -2 * tttt * np.cos(p)

def fermi(E, beta):
    x = beta * E
    x = np.clip(x, -700, 700)  # safe range to avoid overflow
    return 1 / (np.exp(x) + 1)
```

And the function is:

```
def linearized_gap_eq(T):
    beta = 1 / T
    sum_val = 0.0
    for p in p_vals:
        xi = disp(p)
        if abs(xi) > cutoff:
            continue
        Ep = abs(xi)
        f = fermi(Ep, beta)
        sum_val += (1 - 2 * f) / Ep
    return 0.5 * sum_val / N - 1 / lambd

from scipy.optimize import brentq
Tc = brentq(linearized_gap_eq, 0.001, 0.1)
```

(??? finish writing it!)

The universal BCS relation $T_c = \frac{e^\gamma}{\pi}\Delta_0$

Derivation of $T_c = \frac{e^\gamma}{\pi}\Delta_0$ by comparison of Δ_0 and T_c

(write exactly about it)

And we see that this relation does not depend on the material (on the Debye's frequency and Fermi energy).

How accurate the universal BCS relation for continuous (not tight binding) model? (???)

(??? I don't know, I tested it only for TB model now)

Is it okay that in some model the universal BCS relation is not fulfilled by 10% or by 40%?

One can say "it is also just approximation", so it is fine. But is it really fine?

Other basic questions about T_c and Δ_0

Are there some divergences in the gap equation?

(???? I don't know them. My answer is that no, there are no them. But I'll think more about it. Is it because we have a cut-off of the integral?)

3.9.13 Gap Δ as a function of T

Overview of approaches for solving the gap equation (for general temperature)

(numerical approach)

Numerical Calculation of $\Delta(T)$ by `fsolve` in Python

(??? write the background better!!!!)
We know that

$$\Delta_0 \approx 1.76 k_B T_c; \qquad \frac{\hbar\omega_D}{\Delta_0} = \sinh\eta;$$

(?? explain!!)
We start from the gap equation and some introduced variables:

$$\eta := \frac{1}{N(0)V}; \quad \eta = \int_0^{\hbar\omega_D} \tanh\frac{\sqrt{\Delta^2+\xi^2}}{2k_BT}\frac{d\xi}{\sqrt{\Delta^2+\xi^2}};$$

We introduce

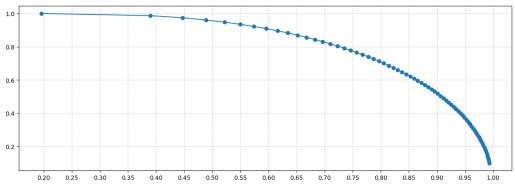
$$\delta := \Delta(T)/\Delta_0, \qquad \tau := T/T_c$$

and transform it as follows:

$$\begin{aligned}\eta &= \int_0^{\hbar\omega_D} \tanh\left(\frac{\Delta_0}{2k_BT_c}\frac{1}{T/T_c}\frac{\Delta}{\Delta_0}\sqrt{1+\xi^2/\Delta^2}\right)\frac{d\xi/\Delta}{\sqrt{1+\xi^2/\Delta^2}} \\ &\approx \int_0^{\delta^{-1}\sinh\eta} \tanh\left(0.882\frac{\delta}{\tau}\sqrt{1+z^2}\right)\frac{dz}{\sqrt{1+z^2}}\end{aligned}$$

here $\hbar\omega_D/\Delta = \Delta_0\hbar\omega_D/(\Delta_0\Delta) = \sinh\eta/\delta$. The number 0.882 is more precise than 1.76/2 for the computer.

The numerical strategy is as follows. We fix δ and find τ, change δ and solve for $\tau, \ldots$ up to obtain $\delta(\tau)$.



(discuss just these lines blow more!!!)

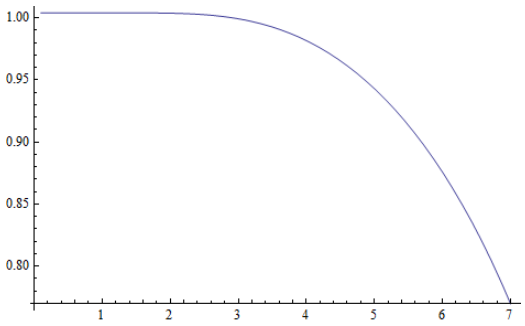
```
def bcs_gap_equation(d, t):
    integral, _ = quad(lambda z: np.tanh(0.882 * d * np.sqrt(1 + z**2) / t) / np.sqrt(1 +
    z**2), 0, np.sinh(eta) / d)
    return eta - integral

d_vals = np.linspace(0.1, 0.9999, 70)  # don't set zero here, since we are deviding by d.

t0 = 0.1
t_vals = [fsolve(lambda t: bcs_gap_equation(d, t), t0)[0] for d in d_vals]
```

We get what we expected:

The disadvantage of this approach is that there are no homogeneous points on temperature axes, only on gap axes. But still, it is fine.



(????) This is simpler than first fixing τ to solve for δ, because of the $1/\delta$ in the boundary, but maybe Im wrong on this point. (??? I'll maybe try later it and write here code for this way)

Numerical Calculation of $\Delta(T)$ by `FindRoot` in Wolfram

(discuss just these lines blow more!!!)

```
Delta[T_]:=
  Block[{a = Log[1.13*hbar*omegad/kb/Tc], b = hbar *omegad/2/kb},
   Return[     FindRoot[     NIntegrate[
         Tanh[b/T*Sqrt[\[Epsilon]^2 + x^2]]/
          Sqrt[\[Epsilon]^2 + x^2], {\[Epsilon], 0, 1},  AccuracyGoal -> 2] - a, {x, 0.01,
    0.1}][[1, 2]]*hbar* omegad]];
Plot[Delta[x]/Delta0, {x, 0.1, 7}]
```

We get what we expected:

(??? there are warnings and the T axes is not normalized. so maybe it is a bad code, but still, it can teach us about using wolfram for superconductivity, so I'll keep it for now.)

Gap at $T \approx 0$

Analytical approximation of the gap at $T \sim 0$ by Bessel functions

Let us investigate in greater detail the temperature-dependence of the gap. We first take the case of low temperatures $T \ll T_0$ and carry out a suitable expansion of condition $1 = \frac{|\lambda| m p_0}{2\pi^2} \int_0^{\omega_D} \mathrm{d}\xi \frac{\tanh \frac{\sqrt{\xi^2+\Delta^2(T)}}{2T}}{\sqrt{\xi^2+\Delta^2(T)}}$. We have identically:

$$\frac{1}{\eta} = \int_0^{\omega_D} \frac{\mathrm{d}\xi}{\sqrt{\xi^2+\Delta^2}} - 2\int_0^{\infty} \frac{\mathrm{d}\xi}{\sqrt{\xi^2+\Delta^2}} \frac{1}{\exp\left(\sqrt{\xi^2+\Delta^2}/T\right)+1}, \tag{36.1}$$

where

$$\eta := |\lambda| m p_0 / 2\pi^2$$

(the second integral is convergent, so that its upper limit can be put equal to infinity). This is the gap equation.

By expanding with respect to the exponent in the second integrand, changing to an integration over ε, and using the definitions of the corresponding Bessel functions, we can write the gap equation as a series in zero order Bessel functions:

(!!!! do the derivations here!!!)

$$\ln \frac{\Delta_0}{\Delta} = 2 \sum_{n=1}^{\infty} (-1)^{n+1} K_0 \left(\frac{n\Delta}{T} \right) \tag{36.2}$$

(here $\Delta_0 \equiv \Delta(T=0)$).

At low temperatures $\Delta \gg T$, we obtain on using the asymptotic expansions of the Bessel functions:

(!!!! do the derivations here!!!)

$$\Delta = \Delta_0 - \sqrt{2\pi T \Delta_0} \left(1 - \frac{T}{8\Delta_0} \right) e^{-\Delta_0/T}. \tag{36.3}$$

The behavior of the gap at temperatures close to the transition temperature T_c is most conveniently determined by starting from $1 = \frac{|\lambda| T}{(2\pi)^3} \sum_n \int \frac{\mathrm{d}^3 p}{\omega + \xi^2 + \Delta^2}$.

Gap at $T \approx T_c$

Analytical approximation of the gap at $T \sim T_c$ by decomposing into series

The gap is small close to T_c, so that we can expand in powers of A^2/T^2 in it:
(!!!! do the derivations here!!!)

$$\frac{1}{\eta} = T \sum_n \int_{-\omega_D}^{\omega_D} \mathrm{d}\xi \left\{ \frac{1}{\omega^2 + \xi^2} - \frac{\Delta^2}{\left(\omega^2 + \bar{\xi}^2\right)^2} + \frac{\Delta^4}{\left(\omega^2 + \xi^2\right)^3} + \cdots \right\}.$$

On interchanging the order of summation over the frequency and integration over ξ in the convergent terms on the right-hand side we get

$$\frac{1}{\eta} = \int_0^{\omega_D} \frac{\mathrm{d}\xi}{\xi} \tanh \frac{\xi}{2T} - \frac{\Delta^2}{(\pi T)^2} \sum_0^{\infty} \frac{1}{(2n+1)^3} + \frac{3}{4} \frac{\Delta^4}{(\pi T)^4} \sum_0^{\infty} \frac{1}{(2n+1)^5} + \cdots \tag{36.4}$$

The series that appear here can be expressed in terms of the Riemann ζ-functions:

$$\sum_0^{\infty} \frac{1}{(2n+1)^z} = \frac{2^z - 1}{2^z} \zeta(z). \tag{36.5}$$

We find on substituting this into the previous expression:

$$\ln \frac{T}{T_c} = -\frac{7\zeta(3)}{8} \frac{\Delta^2}{(\pi T)^2} + \frac{93\zeta(5)}{128} \frac{\Delta^4}{(\pi T)^4} + \cdots$$

We obtain to a first approximation for the size of the gap close to T_c:

$$\Delta = \pi T_c \sqrt{\frac{8}{7\zeta(3)}} \sqrt{1 - \frac{T}{T_c}} \simeq 3.06 T_c \sqrt{1 - \frac{T}{T_c}}. \tag{36.6}$$

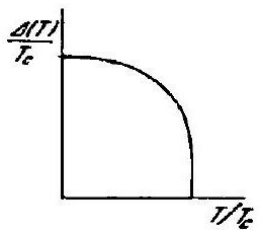


Fig. 97

Fig. 97 illustrates the graph of the temperature-dependence of the gap throughout the temperature interval.

Analytical approximation of the gap at $T \sim T_c$ by strange change the limit of integration

(???? need to think about it again, forgot the method)

Установим закон, по которому вблизи T_c шель обрашается в нуль. Из (51) и (??) имеем

$$1 = \frac{g\nu_F}{2} \int\limits_0^{\hbar\omega_D} d\xi \frac{\tanh \frac{\sqrt{\xi^2+\Delta^2}}{2T}}{\sqrt{\xi^2+\Delta^2}}$$

Из подынтегрального выражения (68) вылелим его значение с нулевой шелью

$$1 = \frac{g\nu_F}{2} \int\limits_0^{\hbar\omega_D} d\xi \frac{\tanh \frac{\xi}{2T}}{\xi} + \frac{g\nu_F}{2} \int\limits_0^{\hbar\omega_D} d\xi \left[\frac{\tanh \frac{\sqrt{\xi^2+\Delta^2}}{2T}}{\sqrt{\xi^2+\Delta^2}} - \frac{\tanh\left(\frac{\xi}{2T}\right)}{\xi} \right]$$

Первый член справа определяется (65), а второй член на верхнем прелеле сходится, и этот прелел можно заменить на бесконечность:

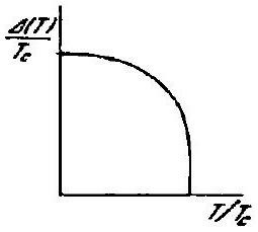
$$J = \int\limits_0^{\infty} d\xi \left[\frac{\tanh \frac{\sqrt{\xi^2+\Delta^2}}{2T}}{\sqrt{\xi^2+\Delta^2}} - \frac{\tanh\left(\frac{\xi}{2T}\right)}{\xi} \right] = \int\limits_0^{\infty} dx \left[\frac{\tanh \frac{\sqrt{x^2+(\Delta/T)^2}}{2}}{\sqrt{x^2+(\Delta/T)^2}} - \frac{\tanh \frac{x}{2}}{x} \right] \simeq -A(\Delta/T)^2$$

где $A \simeq 0.1$. Уравнение (69) принимает вид

$$1 \equiv \frac{g\nu_F}{2} \ln \frac{2\hbar\omega_D\gamma}{\pi T_c} = \frac{g\nu_F}{2} \ln \frac{2\hbar\omega_D\gamma}{\pi T} - A(\Delta/T)^2$$

Тогда

$$0 = \left(\ln \frac{T_c}{T} - A(\Delta/T)^2 \right)$$



Поэтому вблизи T_c

$$\Delta = \sqrt{T_c \frac{T_c - T}{A}}$$

Analytical properties of the gap equation: Other questions

Do we need to know, how the gap looks in its asymptotics analytically?

No. One can just solve numerically the gap eq. and stop on it. But still, this purely mathematical question can be asked, and there are beautiful answers to it. And also, one can see the main features of the plot

just by analytical methods, which is also a powerful physical statement. However, still, in experiment we have just a plot, so to make a prediction of the behavior of the gap, it is very irrelevant to think about its analytical asymptotics, if one can just obtain it numerically.

(????? this is maybe a bad answer, since maybe I saw in one place that someone used the form of the gap as function of T at T≈0. I don't remember, but I am not sure that we don't need it 100%)

What do we need to know, to do these derivations analytically?

(I'll just select some not obvious mathematical statements that were used and write it here. also a good, but useless question.)

3.9.14 The gap Δ: 1001 questions and statements about details

The cutoff for the gap equation

The dependence of physical quantities on a cutoff in the interaction potential

(write how it is dependent!)

What if we sum over all little and not near a little region near Fermi surface?

Seems that if we have sum over

(write an argument, why is it so??? someone might say that it will be fine to sum over all the lattice, how to explain him that he is wrong?)

Range of summation near Fermi surface matters for the value of the gap

(I'll just explicitly write that)

(we know that there are expressions for Δ and T_c, and they depend on Debye's frequency, which determines exactly the range of integration.)

Thus, if we have an input $T_c = 1$ (we'll calculate temperature in units of critical temperature), then there will be only a fixed range of summation. If we increase the range of summation, there will be extra terms that will be added to the T_c and it will never be 1 again.

We can never sum over all the range of moments.

(?? what LS wrote about it, why did they sum over all the momenta?)

(??? how much is the rest contribution??? Is it little (change by 10% the results), or it will makes the results x20 times different?)

The cutoff of the AGD method versus cutoff of the typical method

(???? how are they related??)

The meaning of energy gap and the gap equation: Extra statements

The Gap is the wave-function of the superconductor (?????)

(??? or it is not???)
(add formulas about it)
(??? why there are such statements??? there is also a BCS wavefunction, which is not the gap!)
(??? what with a wave function of a two-particles which make a Cooper pair, this is not the w.f. of SC??? Currently, I think so.)

Δ sets the energy scale on which the occupation numbers change

This is obvious from the formula

$$\langle n_{k,\sigma} \rangle = \left\langle c^{\dagger}_{k,\sigma} c_{k,\sigma} \right\rangle = \sin^2 \theta_{\boldsymbol{k}} = \frac{1}{2}\left(1 - \frac{\xi_{\boldsymbol{k}}}{\xi^2_{\boldsymbol{k}} + \Delta^2}\right)$$

(!!! check it, there is most likely a typo. De Roeck's notation)
For $\Delta \to 0$, this converges to the function $\theta(-\xi_k)$, as it should, and that Δ sets the energy scale on which the occupation numbers change.

What is meant by self-consistency of the gap equation?

The default answer is that Hamiltonian depends on the gap and gap depends on the Hamiltonian.
How can we see that it is indeed self-consistent?
(????? I don't understand it that deep. why for example a gap which is x2 bigger is not self-consistent???)

(I'll add a comment that some people might say that by self-consistency something different is meant. Can it be?)

(comment about self-consistency for the case of current. Why at that situation, there is a change of a spectrum???)

How can there be a pseudogap?

(??? some strange gap??? I'll think some time later)

How can there be a two gaped superconductors?

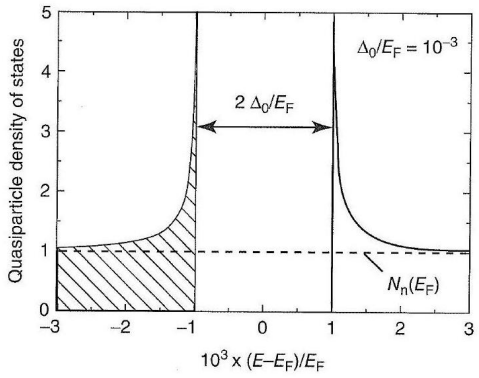
(??? some strange gap??? I'll think some time later)

The isotope effect from the gap equation

Remarkably, $k_{\mathrm{B}}T_{\mathrm{c}} = 1.14\hbar\omega_{\mathrm{D}} \exp\left(-\frac{1}{N(0)V}\right)$ also provides an explanation for the isotope effect: For different isotopes of the same superconducting element, the critical temperatures are different and follow the rule

$$T_{\mathrm{c}} M^{1/2} = \text{ const}$$

where M is the mass of the isotope. Recalling that the Debye frequency varies as



$$\omega_{\mathrm{D}} \propto M^{-1/2}$$

we immediately obtain the isotope effect from (6.37).

(??? why do we change the sum to integral? what is going on with dimensions???)

3.9.15 The gap Δ: Measurement and Effects from It

In figure below:

we have shown the normalized density of states of unpaired electrons in the superconducting state for $T = 0$. The existence of a forbidden energy range ("energy gap") has given us a simple means to understand the fact that, below a critical kinetic excitation energy, Cooper pairs cannot interact with the crystal lattice. We can use different methods for the measurement of this energy gap, which we will discuss in the following.

How in general a gap can be measured?

(I'll have below big discussions of each method, here I'll just write shortly later an answer. It is a hard question, if one was reading just a textbook on statistical physics)

Getting gap by Absorption of Electromagnetic Radiation

The energy gap can be determined by measuring the absorption of electromagnetic radiation. The first experiment proving the existence of a gap in the energy spectrum of the unpaired electrons for $T < T_c$ was reported in 1957 by Glover and Tinkham [20]. They observed the infrared transmission of thin superconducting films. (??? what was there?)

Already by the early 1930 s, it had been pointed out that electromagnetic waves of suitable frequency should serve well to break up the ordered state of a superconductor below its transition temperature. This should show up as an anomaly in the absorption. In the 1930s, such experiments could not be carried out, since the required range of electromagnetic wavelengths was not yet experimentally available. Assuming a binding energy E_{B} of about 10^{-3}eV, for this energy we need radiation quanta with a frequency $f = E_{\mathrm{B}}/h = 2.4 \times 10^{11}$ Hz(240GHz). These are waves with about 1 mm wavelength, for which no generation or detection methods were available in the 1930s. Only 20 years later, however, this method was applied successfully for measuring the energy gap, [20]. Today, for the range of wavelengths between about 500μm and 3 cm, we have sufficient, well-functioning experimental techniques for performing such measurements for quantitative determination of the energy gap.

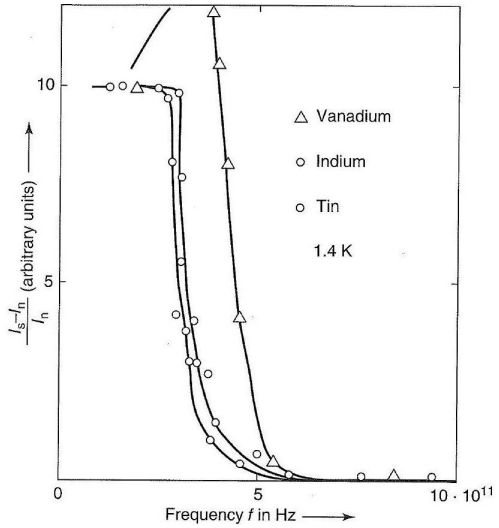


Figure 3.9 Absorption of electromagnetic waves with frequency f in superconductors. Transition temperatures Measurement temperature is 1.4 K. In vanadium for $f < 2\Delta_0/h$, a frequency dependence is observed, the possible origin of which can- not be discussed here. (From [22].) are V, 5.3 K; In, 3.42 K; and Sn, 3.72 K

The quantitative data analysis for this method is somewhat complicated, and we do not want to discuss it in more detail. In Figure 3.9 we just show an example of such a measurement [22]. Here, the radiation was guided into a small cavity, made from the material to be studied. Within the cavity the radiation is reflected many times before it is detected. The stronger the absorption of the radiation in the cavity wall, the smaller is the detected power. For the measurement, at a fixed temperature (here about 1.4 K), the power in the superconducting and in the norma states, I_s and I_n, respectively, is determined for each wavelength. In this experiment, the superconductivity can be eliminated by a sufficiently high magnetic field. The difference between the two power values yields the difference between the reflection for both states.

In Figure 3.9 this difference, normalized by the power in the normal conducting state, is plotted versus the frequency. At small frequencies, we see a distinct difference between the reflection in the superconducting and in the normal conducting states. In the superconducting state the reflection is larger. At a certain frequency the difference drops abruptly, and at higher frequencies it reaches zero. Apparently, the abrupt drop sets in as soon as the quantum energy of the radiation is large enough to break up the Cooper pairs. This results in an additional absorption. For energies $hf > 2\Delta_0$ the energy gap practically does not influence the absorption, since the electrons can be excited far beyond the energy gap by the radiation quanta. In Table 3.3 we list the values of the energy gap at $T = 0$ obtained from such measurements for different superconductors. Table 3.4 presents values of the energy gap for some selected superconducting compounds and alloys.

Table 3.3 Energy gap $2\Delta_0$ in units of $k_B T_C$ for some superconducting elements.

Element		Method		
	T_c(K)	Tunnel junctions	Ultrasound	Light absorption
Sn	3.72	$3.5 \pm 0.1(1.15)$	-	3.5
In	3.4	$3.5 \pm 0.1(1.05)$	3.5 ± 0.2	3.9 ± 0.3
Tl	2.39	$3.6 \pm 0.1(0.75)$	-	-
Ta	4.29	$3.5 \pm 0.1(1.30)$	3.5 ± 0.1	3.0
Nb	9.2	3.6 (2.90)	4.0 ± 0.1	2.8 ± 0.3
Hg	4.15	$4.6 \pm 0.1(1.65)$	-	4.6 ± 0.2
Pb	7.2	$4.3 \pm 0.05(2.70)$		4.4 ± 0.1

The numbers in brackets indicate the energy gap in megaelectronvolts. The values are taken from Ref. [23]. For special details see Superconductivity Data, no. 19-1 (1982), Fachinformationszentrum Karlsruhe GmbH.

Experimental methods tunneling effect, optical methods, nuclear spin resonance, specific heat, and so on. Much data can also be found in the monograph [M14].

Getting gap by Ultrasound Absorption

(??? what is it????)

Sound waves also interact with the system of conduction electrons in a metal. We can look at a sound wave as a current of coherent phonons. Until recently, only sound waves with frequencies up to about 30GHz were available. Most measurements were carried out using frequencies from a few megahertzs up to 10MHz. The energies of these frequencies are much smaller than the width of the energy gap. Only very close to T_c, where the energy gap $2\Delta_0(T)$ approaches zero, it is possible that the sound energy of these frequencies becomes comparable to $2\Delta_0(T)$. Hence, in addition to other mechanisms, absorption essentially depends on the number of unpaired electrons. Below T_c this number decreases rapidly with decreasing temperature. Correspondingly, the damping of sound also decreases rapidly below T_c. In Figure 3.10 we present an example of such a measurement [32]. Since for a given temperature the number

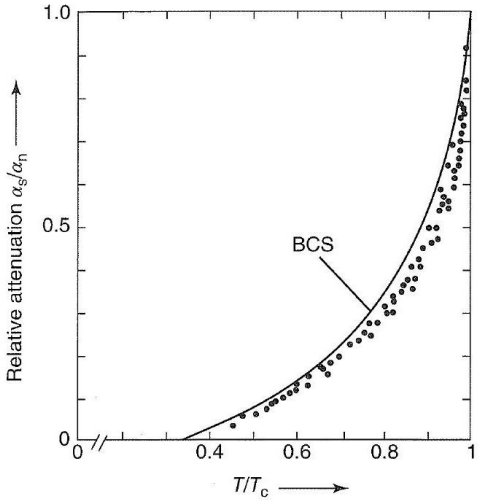

Figure 3.10 Ultrasound absorption in superconducting tin and indium. The solid line indicates the behavior expected from the BCS theory for the energy gap $2\Delta_0 = 3.5k_BT_C$. (From [32].)

of unpaired electrons depends on the width of the energy gap, the latter can be determined from such absorption measurements by means of a comparison with the theoretically expected behavior. In Figure 3.10 the curve expected from the BCS theory for $2\Delta_0(T = 0) = 3.5k_BT_c$ (Eq. (3.7)) is shown.

Here, we cannot discuss in detail the analysis of such measurements, which is not quite simple. We just want to point out that, compared to electromagnetic waves, sound waves have the great advantage of penetrating more deeply into the metal, whereas high-frequency electromagnetic waves only reach a thin layer at the surface, namely within the skin depth.

3.9.16 Chemical Potential of a Superconductor

(just all what I think about it, that it is zero because of quasiparticles.... or not zero, because it is a Fermi energy. I don't understand it fully yet, that is why there is a section about it here)

3.9.17 The Coupling Constant of BCS Model

Typical values of the coupling constant

This is also important for any numerical calculation.

Can the coupling constant be determined experimentally?

(????? I am not sure, since the measured quantities have many parameters, so currently, i don't know, is it possible at all to do it????)

Theoretical derivation of the coupling constant

(????? maybe no one knows how to do it, so it is an unsolved question)

Determining the Coupling BCS Constant for a Given Material

(???? TODO: write clear, how to do it?)

Determining using McMillan's formula (???)

McMillan's formula can help $T_c = \frac{\Theta_D}{1.45} \exp\left(-\frac{1.04(1+\lambda)}{\lambda-\mu^*(1+0.62\lambda)}\right)$, assuming $\mu^* \approx 0.1$.

From Tunneling Experiments or Spectroscopy

(??? maybe it is also possible)

Can the coupling constant change?

(??? there are articles about quenches, so maybe in some effective superconductors it can. I don't know yet, how)

3.10 BCS: Advanced Features and Details of a Typical Setups

3.10.1 Overview of general important features of BCS

Coherence length from BCS

Рассмотрим теперь, как микроскопическая теория сверхпроводимости позволяет оценить длину когерентности сверхпроводника. Волновая функция основного состояния сверхпроводника нами уже рассматривалась в п.44.1. Основное состояние может быть изображено распределением спаренных электронов в $\mathbf{k}$-пространстве, что дается функцией $v_{\mathbf{k}}^2$. График зависимости $v_{\mathbf{k}}^2$ от k представлен на рис. 44.3. Видно, что область k-пространства, где функция $v_{\mathbf{k}}^2$ испытывает сильные изменения, имеет размер порядка

$$\Delta k \sim 2\Delta_0 \frac{k_{\mathrm{F}}}{\varepsilon_{\mathrm{F}}}$$

Отсюда следует, что область Δx в x-пространстве, где волновая функция основного состояния сверхпроводника будет существенно изменяться, должна определяться соотношением

$$\Delta x \Delta k \sim 1$$

Отсюда следует, что

$$\Delta x \sim \frac{\varepsilon_F}{2\Delta_0 k_F} = \frac{1}{2\Delta_0 k_F}\frac{\hbar^2 k_F^2}{2m} = \frac{\hbar p_F}{4\Delta_0 m} = \frac{\hbar v_F}{4\Delta_0}. \tag{45.6}$$

Здесь p_{F} - импульс электрона на поверхности Ферми, v_{F} - фермиевская скорость электрона. Но по самому смыслу Δx-это как раз та величина, которую при изучении теории Гинзбурга-Ландау мы называли длиной когерентности ξ. Поэтому мы теперь можем говорить, что из (45.6) следует оценка для длины когерентности ξ_0 при $T = 0$:

$$\xi_0 \sim \hbar v_{\mathrm{F}}/4\Delta_0 \tag{45.7}$$

Скоро будет показано, что $\Delta_0 \sim k_{\mathrm{B}} T_c$, где k_{B} - постоянная Больцмана, T_c-критическая температура. Точный расчет дает

$$\xi_0 = 0.18\hbar v_{\mathrm{F}}/k_{\mathrm{B}} T_c \tag{45.8}$$

Эту величину ξ_0 можно также рассматривать как размер электронной пары, для оценки которого можно принять, что $v_F \sim \sim 10^8$ cm/c, $T_c \sim 1$ K, тогда

$$\xi_0 \simeq 0.18 \frac{10^{-27} \cdot 10^8}{1.38 \cdot 10^{-16} \cdot 1} \sim 10^{-4} \text{ cm}$$

Это очень большое, вполне макроскопическое расстояние.

Averaging of operators in BCS model

(remind the formalism, that ψ is the initial operator, in which the Hamiltonian is non-diagonal)

$$F_{\alpha\beta}(x, x') := -i \langle \mathrm{T}\psi_\alpha(x)\psi_\beta(x') \rangle .$$

It is nonzero for superconductor.

Proof. (???? I'll open the bra-kets and write explicitly...)

(but the idea is that the interacting term in Hamiltonian has also non-diag terms in ψ, that is why it is not zero)

□

(remind the formalism, that b below are those, in which the Hamiltonian is non-diagonal)

Statement:

$$-i \langle \mathrm{T}b_\alpha(x)b_\beta(x') \rangle = 0$$

Proof. (???? I'll open the bra-kets and write explicitly... and since the Hamiltonian is diagonal, we have zero)

□

Can perturbation theory be applicable to the BCS Hamiltonian?

When we see the BCS Hamiltonian, we can think: "Oh, another correction to a free Hamiltonian, let's use the perturbation theory for it!" Here we will discuss what would be if we do so?

(I'll try and report here what happens???)

(??? Pukhov said that no, PT is not applicable, but why?)

(?????)

How to work with BCS without Bogoliubov transformations?

(This is what Gor'kov's formalism is doing, so I'll write exactly, how it works?)

BCS model without Bogoliubov transformations

(here I'll show, what we can do with BCS model if we don't use Bogoliubov transformations at all. a good question.)

Proof that indeed in BCS theory the resistance of the current is zero

(here I'll show just that it is so. not so obvious)

(maybe we use the Landau criteria for superfluids, but I want to write here more explicitly that it is so? maybe I'll repeat the proof of Landau's criterion in the context of superconductors)

3.10.2 How Good and Useful Is BCS Theory?

Is it fine that one can't reproduce any effects in scope of electrodynamics of SC?

(I have no idea how to reproduce it. maybe it means the BCS theory is not that useful and rather specific? I don't know, I'll discuss here)

The problem with a Debye model

Debye model is an approximate model. So from the beginning we start from a simplified abstraction.

In which cases of metals at low temperatures the BCS model is not applicable?

(experimental intro to generalization of bcs)

3.10.3 Cooper Pairs: Deeper Understanding

Physical picture of Cooper pairs

(?? all about interpretation)

Механизм притяжения электронов в решётке по Вайскопфу (1981 г.).

Пусть электрон движется через ионную решётку металла. Интерес представляют только электроны, импульс которых лежит вблизи поверхности Ферми. Действительно, электроны вдали от этой поверхности ($\varepsilon < \varepsilon_F$) не могут менять своё состояние, поскольку отсутствуют близлежащие свободные состояния, в которые они могли бы переходить в результате взаимодействия с фононами. Тогда

$$\varepsilon \approx \varepsilon_F, v \approx v_F$$

«Пролетая» мимо иона, электрон взаимодействует с ним с силой $f \sim e^2/a^2$, где a - постоянная решётки. Длительность взаимодействия $\tau \sim a/v_F$. Полагая для оценки $a \sim 10^{-8}$ cm, $v_F \sim 10^8$ cm/c, получаем $\tau \sim 10^{-16}$ c. Это время много меньше характерного периода колебаний атома в решётке $\omega_D^{-1} \sim (10^{-12} - 10^{-13})$ c. Однако за это время ион приобретает импульс $p_\perp \sim f\tau \sim \frac{e^2}{a^2} \cdot \frac{a}{v_F} = \frac{e^2}{av_F}$. Поскольку $e^2/a \sim \varepsilon_\text{B} \sim \varepsilon_F$, то $p_\perp \sim \varepsilon_F/v_F \sim p_F$. Таким образом, ион приобретает импульс $p_\perp$ порядка фермиевского импульса электрона, направленный к траектории электрона. Максимальное смещение иона массой M можно оценить из соотношения

$$\frac{p_\perp^2}{2M} \sim \frac{\kappa x^2}{2} \Rightarrow x \sim \frac{p_F}{\sqrt{M\kappa}}$$

Эффективная жёсткость связи к иона в решётке оценивается из тех соображений, что смещение иона на величину порядка межатомного расстояния существенно меняет энергию электронной конфигурации, т.е.

$$\frac{\kappa a^2}{2} \sim \varepsilon_B \sim \varepsilon_F \Rightarrow \kappa \sim \frac{\varepsilon_F}{a^2}$$

С учётом этого получаем оценку результирующего смещения иона:

$$x \sim \frac{p_\perp}{\sqrt{M\kappa}} \sim \frac{p_F}{\sqrt{M\varepsilon_F/a^2}} \sim a\sqrt{\frac{m}{M}}$$

где $\varepsilon_F = p_F^2/2m, m$ - масса электрона. Следовательно, смещение иона мало: $x \sim 10^{-2}a \ll a$. В процессе своего движения электрон вызывает смещение ионов, мимо которых он пролетает, возникает «хвост». Длина этого «хвоста» L определяется тем, что смещение ионов существует в течение конечного промежутка времени $\sim T/2 = \pi/\omega_D$. Учитывая, что $\omega_D \sim \sqrt{\kappa/M} \sim \sqrt{\varepsilon_F/Ma^2}$, находим длину «хвоста»:

$$L \sim \frac{v_F}{\omega_D} \sim v_F\sqrt{\frac{Ma^2}{\varepsilon_F}} \sim a\sqrt{\frac{Mv_F^2}{\varepsilon_F}} \sim a\sqrt{\frac{M}{m}} \sim 10^2 a \gg a.$$

Заметим, что оценке величины L можно придать иной вид:

$$L \sim \frac{v_F T}{2} = \frac{\pi v_F}{\omega_D} = \frac{\pi v_F}{(\pi s/a)} \approx \frac{\pi v_F}{s\,(p_F/\hbar)} = \frac{\pi\hbar}{ms}$$

Полагая $m = m_e, s \sim 3 \cdot 10^5$ cm/c, получим $L \sim 10^3$Å. Смещение ионов приводит к повышению плотности положительных зарядов вдоль траектории электрона на нейтральном фоне, присутствующем «в среднем» в металле. Оценим полный заряд «хвоста». На участке длиной a прирост заряда, обусловленный смещением одного иона, составляет

$$\Delta q \sim |e|\frac{x}{a} \sim |e|\sqrt{\frac{m}{M}}$$

а на участке длиной L полный заряд составляет

$$q \sim \Delta q\frac{L}{a} \sim |e|\sqrt{\frac{m}{M}}\sqrt{\frac{M}{m}} = |e|$$

Таким образом, этот заряд приблизительно равен заряду электрона, но имеет положительный знак. К сформировавшемуся «хвосту» уже может притягиваться второй электрон. При этом электроны сильно разнесены в пространстве, и вследствие дебаевского экранирования их прямое кулоновское отталкивание уже практически отсутствует.

Interpretation, why superconductivity is destroyed when some parameters are increased?

Беспорядок не разрушает куперовские пары, хоть импульс и становится плохим квантовым числом. Качественно это можно пояснить так. В присутствии примесей электроны двигаются по ломаным, от одной примеси к другой. За каждым электроном вдоль линии его движения остается деформация решетки, представляющая собой шлейф из виртуальных фононов, рассасывающийся за время порядка ω_D^{-1}. Этот «ароматический след» притягивает другие электроны, причем эффект притяжения максимален для электрона, движущегося в точности по той же траектории, но в обратном направлении.

Такие состояния есть при любой степени беспорядка, поскольку увеличение концентрации примесей лишь делает траектории более изломанными, но не выделяет определенного направления движения на каждой из них (в отличие, скажем, от траекторий в магнитном поле). Из этого рассуждения видно, что чисто потенциальное рассеяние на примесях, оставляющее систему инвариантной по отношению к обращению времени, не подавляет сверхпроводимость. А магнитное поле, например, подавляет.

Two-particle density matrix

(????)

Why do we need two-particle density matrix?

(answer to this question, I don't know)

Construction of two-particle density matrix

As in the case of BEC, it is instructive to consider the (in this case) two-particle density matrix $\rho^{(2)}$, whose kernel in momentum space is

$$\hat{\rho}^{(2)}\left(\boldsymbol{k}_1', \sigma_1', \boldsymbol{k}_2', \sigma_2'; \boldsymbol{k}_1, \sigma_1, \boldsymbol{k}_2, \sigma_2\right) := \left\langle c^\dagger_{\boldsymbol{k}_2'} c^\dagger_{\boldsymbol{k}_1'} c_{\boldsymbol{k}_1} c_{\boldsymbol{k}_2} \right\rangle$$

Note that $\hat{\rho}^{(2)}$ is a self-adjoint operator on $P_a(\mathcal{H} \otimes \mathcal{H})$, where $\mathcal{H} = L^2(\Lambda) \otimes \mathbb{C}^2$ is the one-particle Hilbert space and P_a projects to antisymmetric functions. Just as in BEC, BCS is marked by the appearance of a macroscopic eigenvalue of this operator. We are interested only in the case $\boldsymbol{k}_1 = -\boldsymbol{k}_2, \sigma_1 = -\sigma_2$ and analogously for the primes, so in the kernel

$$\hat{\rho}^{(\text{pair})}\left(\boldsymbol{k}', \sigma', \boldsymbol{k}, \sigma\right) = \hat{\rho}^{(2)}\left(\boldsymbol{k}', \sigma', -\boldsymbol{k}', -\sigma'; \boldsymbol{k}, \sigma, -\boldsymbol{k}, -\sigma\right) = \left\langle c^\dagger_{\boldsymbol{k}', \sigma'} c^\dagger_{-\boldsymbol{k}', -\sigma'} c_{\boldsymbol{k}, \sigma} c_{-\boldsymbol{k}, -\sigma} \right\rangle$$

The reason that it is legitimate to make the reduction form $\hat{\rho}^{(2)}$ to $\hat{\rho}^{(\text{pair})}$ is that the system is assumed to be translation and rotation invariant and does not contain spin-orbit coupling. Therefore, the operator $\rho^{(2)}$ commutes with the total momentum (of two particles) and with the total spin, therefore, the space spanned by the base states $|\boldsymbol{k}, \sigma, -\boldsymbol{k}, -\sigma\rangle$ is mapped into itself. It follows that any eigenvalue of the restriction of $\rho^{(\text{pair})}$ to this space is also an eigenvalue of $\rho^{(2)}$.

(Reminder: in this notation $\hat{F}_k := \langle c_{k,\downarrow} c_{-k,\uparrow} \rangle$)

If we neglect fluctuations (in the spirit of BCS), then $\hat{\rho}^{(\text{pair})}$ equals $\hat{F}^*_{\boldsymbol{k}'} \hat{F}_{\boldsymbol{k}}$, up to signs that are irrelevent since all different choices for σ, σ' are related by antisymmetry and the symmetry under $\boldsymbol{k} \to -\boldsymbol{k}$. Fourier-transforming $\boldsymbol{k} \leftrightarrow \boldsymbol{r}, \boldsymbol{k}' \leftrightarrow \boldsymbol{r}'$, we get

$$\rho^{(\text{pair})}\left(\boldsymbol{r}', \uparrow, \boldsymbol{r}, \uparrow\right) \approx F^*\left(\boldsymbol{r}'\right) F(\boldsymbol{r})$$

Hence $F(\boldsymbol{r})$ is an eigenfunction with eigenvalue $N_0 = \int \mathrm{d}\boldsymbol{r} |F(\boldsymbol{r})|^2$. However, note that $\boldsymbol{r}$ is a relative coordinate! The condensate is uniform in space, corresponding to the fact that we assumed pairing with center of mass momentum 0.

Influence of Lattice Defects on Conventional Cooper Pairing

We use the term defects to denote all deviations from perfect periodicity of the crystal lattice, independent of whether they are due to the presence of foreign atoms or due to only structural perturbations, that is, displacements of the atoms from their regular sites. Primarily, such lattice defects act as scattering centers for the system of conduction electrons, reducing the electron mean free path.

However, in general, the lattice defects influence all the properties of a superconductor. In this section, we will discuss some of these effects.

Size of cooper pair and unsetainty relation for it (???)

(a special section about the question: why can we use unsetainty relation to find size of a cooper pair? Can we show some similar examples of usage of this method? Now I just belive that we just can do so.)

Introduction and overview: The Superconducting State, Quasiparticles, and BCS Theory

At least qualitatively we have seen that two electrons attract each other momentarily because of the electron-phonon interaction, and in this way they form a Cooper pair $\{\mathbf{k}\uparrow, -\mathbf{k}\downarrow\}$. Next we deal with the question of how these pairs collectively can occupy the same quantum state. Here, BCS found an ingenious answer, which we want to outline for the case of zero temperature.

Let us recall first the situation of the unpaired electrons. At $T = 0$ they occupy the lowest possible energy states. If we treat the electrons as free particles, their energy is given by

$$\varepsilon_k = \frac{1}{2m}\left(p_x^2 + p_y^2 + p_z^2\right)$$

or, with $\mathbf{p} = \hbar\mathbf{k}$,

$\varepsilon_k = \frac{\hbar^2}{2m}\left(k_x^2 + k_y^2 + k_z^2\right)$

The possible values of $\mathbf{k}$ are discrete (see Section 1.2), and in the simplest case in k-space the electrons occupy the Fermi sphere (see Figure 1.18). All states within the Fermi sphere must be occupied by an electron, and all states outside the Fermi sphere must remain unoccupied.

The electrons near the Fermi energy will interact attractively with each other. The attractive interaction energy is taken as a negative constant $-V$ for the electrons, with its energy range distributed over the interval $\pm\hbar\omega_c$ near the Fermi energy.6) Everywhere else the interaction is assumed to be zero. It is not necessary that the interaction energy V results from the electron-phonon interaction. However, if this is the case, it is likely that the energy $\hbar\omega_\mathrm{c}$ is associated with a characteristic phonon energy, or the frequency ω_c with a characteristic phonon frequency, namely the Debye frequency.

Around the surface of the Fermi sphere, the Cooper pairs constitute a highly peculiar state, in which, within a certain interval around the Fermi energy E_F, the pair states $\{\mathbf{k}\uparrow, -\mathbf{k}\downarrow\}$ are simultaneously unoccupied with probability $|u_k|^2$ and occupied with probability $|v_k|^2$. In general, the probability amplitudes u_k and v_k are complex numbers, which depend on the wave vector k. The condition $|u_k|^2 + |v_k|^2 = 1$ must be valid, since the two probabilities must add up to 1. Classically, such a state cannot be imagined. However, in quantum mechanics such superpositions are quite possible.

Next we must determine the parameters u and v. This can be done by inserting the ansatz of the wave function of the Cooper pairs given above into the Schrödinger equation of the system. Then one calculates the energy of the system as a function of u and v, and finally one chooses u and v such that the energy reaches a minimum [M3, M4]. Then we have found the energetically optimum state consistent with the assumed wave function.

Using this procedure, for $|v_k|^2$ one finds the expression

$$|v_k|^2 = \frac{1}{2}\left[1 - \frac{\varepsilon_k - E_\mathrm{F}}{\sqrt{|\Delta|^2 + (\varepsilon_k - E_\mathrm{F})^2}}\right]$$

Here, the energy of the individual electrons in the absence of the interaction V is denoted by ε_k as in Eqs. (3.2a) and (3.2b), and E_F is the Fermi energy. The quantity Δ will become highly important in the following. It is given by the sum $\Delta = -V\sum u_k v_k$. Hence, it is different from zero only for values of ε_k within the interval $\pm\hbar\omega_c$, similar to the interaction V. In general, Δ is a complex number, which we write in the following as $\Delta = \Delta_0 \mathrm{e}^{i\varphi}$ with real amplitude Δ_0. Then we have $|\Delta|^2 = \Delta_0^2$. For $|u_k|^2 = 1 - |v_k|^2$, one finds

$$|u_k|^2 = \frac{1}{2}\left[1 + \frac{\varepsilon_k - E_\mathrm{F}}{\sqrt{|\Delta|^2 + (\varepsilon_k - E_\mathrm{F})^2}}\right] = \frac{1}{2}\left[1 + \frac{\varepsilon_k - E_\mathrm{F}}{\sqrt{\Delta_0^2 + (\varepsilon_k - E_\mathrm{F})^2}}\right] \quad (3.3b)$$

In a more general way, we can also allow the interaction between the electrons to depend on the momentum or the wave vector of the electrons.

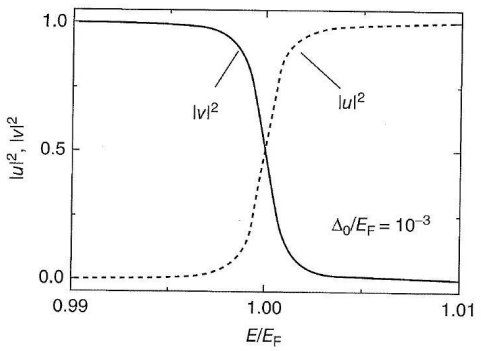

Figure 3.5 The functions $|u_k|^2$ and $|v_k|^2$, indicating the probability that a pair state $\{\mathbf{k}\uparrow, -k\downarrow\}$ is occupied $\left(|v_k||^2\right)$ or unoccupied $\left(|u_k|^2\right)$. For the figure, the values $E_F = 1\text{eV}$ and

The two functions $|u_k|^2$ and $|v_k|^2$ are shown in Figure 3.5. Here, we have assumed for E_F a value of 1eV and for Δ_0 a value of 1meV, which are typical for metallic superconductors. Deep within the Fermi sphere (i.e., for $\varepsilon_k \ll E_\mathrm{F}$), the probability $|v_k|^2$ of finding an electron pair in the state $\mathbf{k}$ (or $|\mathbf{k}|$) is practically equal to one, as would also be in the case for noninteracting electrons. Analogously, for energies $e_k \gg E_\mathrm{F}$, the probability $|u_k|^2$ that this state is unoccupied is nearly equal to one. However, within an interval of about $\pm\Delta_0$ around the Fermi energy, both functions $|u_k|^2$ and $|v_k|^2$ strongly deviate from the value one. For independent, unpaired electrons, exactly this would not be the case. We see that the Cooper pair system shows nontrivial behavior in this energy interval. In Figure 3.5, the ratio $\Delta_0/E_\mathrm{F} = 10^{-3}$. Hence, we can say that only about 0.1% of all electrons, namely hose near the Fermi energy, participate in the superconductivity.

The quantity Δ depends on all states k because of the product $u_k v_k$ This shows that all Cooper pairs are collectively connected with each other. Contrary to this, for independent electrons, Δ would always be zero, since either u_k or v_k always vanishes.

In the state described by the BCS theory, all pairs show the same values of all physical quantities. In particular, the motion of the center of mass is the same for all pairs. So we have arrived at the macroscopic matter wave, the properties of which we have described in detail in Chapter 1. What further information is provided by the microscopic theory?

First one can calculate the energy gain because of the Cooper pairing, that is, the condensation energy. One finds that this is given by $-N\left(E_\mathrm{F}\right)\Delta_0^2/2$, where $N\left(E_\mathrm{F}\right)$ is the density of states at the Fermi energy (see Section 1.1). In addition to $N\left(E_\mathrm{F}\right)$, the condensation energy also depends on the pair interaction V because of Δ_0^2. Apparently, it is favorable for superconductivity if both quantities become very large.

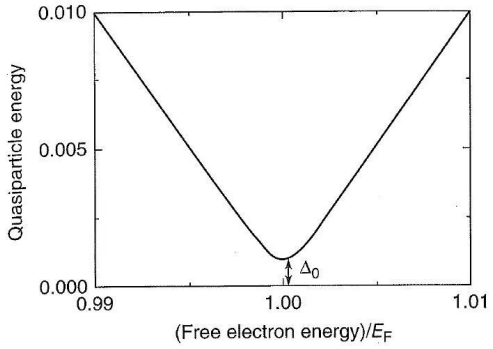

Figure 3.6 Energy of an unpaired electron (quasiparticle) in a superconductor, plotted versus the energy the electron would have without the pair interaction.

The next important question concerns the possible excitations of the supercon ducting ground state. As a very simple excitation we can imagine that a Cooper pair is broken, yielding two independent electrons. Here, we can look at a single unpaired electron as an "elementary process," and we can ask how its (excitation) energy compares with the energy ε_k of the same electron in the normal state. The resulting electron is referred to as quasiparticle. Due to the pair interaction in the superconductor, this quasiparticle does not satisfy any longer the energy-momentum relation (3.2 b).

Instead, one finds that the energy of this unpaired electron is given by [M3, M4]

$$E_k = \sqrt{\left(\varepsilon_k - E_\mathrm{F}\right)^2 + \Delta_0^2}$$

This function is shown in Figure 3.6. If Δ_0 were zero, we would have $E_k = \pm\left(\varepsilon_k - E_\mathrm{F}\right)$, and we would recover the energy of the noninteracting electrons. However, for $\Delta_0 \neq 0, E_k$ attains a

minimum value Δ_0. This also means that at least twice this amount must be supplied, in order to break a Cooper pair and to generate two quasiparticles.

At this stage, we can already see the influence of the Cooper pair interaction on the density of states of unpaired electrons. Even without this interaction, the density of states is in general a very complicated function depending on the crystal structure. We denote this function by $N_n(E)$. However, here we are concerned only with a small interval $\pm\Delta_0$ near the Fermi energy. In this interval, we can treat the density of states of the noninteracting electrons as constant: $N_{\mathrm{n}}(E) \approx N_{\mathrm{n}}(E_{\mathrm{F}})$. In this case there are states already very close to the Fermi energy, into which the electrons can be excited. However, this is by no means possible for the quasiparticles. According to Eq. (3.4), for this the minimum energy Δ_0 is needed.

For the density of states of the quasiparticles, this means that a gap appears in an interval $\pm\Delta_0$ at the Fermi energy. Within this gap, no states exist anymore. The exact expression for the density of states of the quasiparticles, which we want to denote by $N_s(E)$, is given from the BCS theory by

$$N_{\mathrm{s}}(E) = N_{\mathrm{n}}(E_{\mathrm{F}}) \frac{|E - E_{\mathrm{F}}|}{\sqrt{(E - E_{\mathrm{F}})^2 - \Delta_0^2}}$$

for energies $|E - E_{\mathrm{F}}| \geq \Delta_0$. For $|E - E_{\mathrm{F}}| < \Delta_0$, the function $N_{\mathrm{s}}(E)$ is zero. This density of states is shown in Figure 3.7.

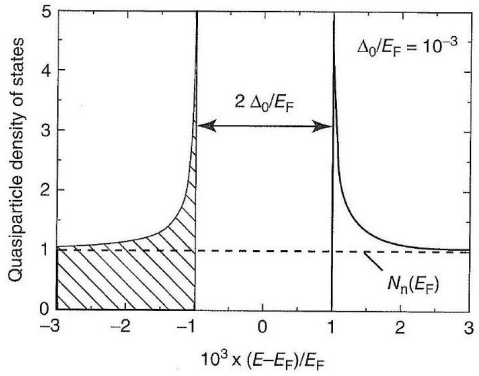

Figure 3.7 Normalized density of states $N_{\mathrm{s}}(E)/N_n(E_{\mathrm{F}})$ of the quasiparticles in a superconductor according to the BCS theory. The ratio Δ_0/E_F was taken as 10^{-3}. At the temperature $T = 0$, all states below the Fermi energy are occupied (hatched region).

At energies $E = E_{\mathrm{F}} \pm \Delta_0$ it reaches infinity, and for large values of $|E|$ it rapidly approaches the density of states $N_{\mathrm{n}}(E_{\mathrm{F}})$. Within the energy interval $E_{\mathrm{F}} \pm \Delta_0$, there are no states." Therefore, $2\Delta_0$ is also referred to as the energy gap of the superconductor.

At this point we note that the energy states of the unpaired electrons are energetically redistributed because of the Cooper pair interaction, but they are not annihilated. If we integrate $N_{\mathrm{s}}(E)$ over all energies, we obtain the same number of states as in the normal state. Most of the states between E_{F} and $E_{\mathrm{F}} + \Delta_0$ in the normal conductor appear at energies slightly above $E_{\mathrm{F}} + \Delta_0$ in a superconductor. As we will see in Section 3.1.3, the energy gap in a superconductor can be observed very nicely in infrared absorption experiments and also by means of superconducting tunnel junctions. These experiments perfectly confirm our ideas about the superconducting state.

Next we turn to the properties of superconductors at finite temperatures. At $T > 0$ some Cooper pairs are broken because of thermal fluctuations, and thermally excited quasiparticles are generated. These quasiparticles are fermions, exactly like the electrons in a normal conductor. Hence, the probability of finding a quasiparticle in a given energy state is indicated by the Fermi distribution function (1.3).

In Section 3.2 we will see that this property changes if the.Cooper pairs do not form an $L = 0$ state (see Section 21) In this case, quasiparticles exist for all energies.

We note that a quasiparticle in the quantum state $\mathbf{k}$ is blocking this state for the condensation of Cooper pairs, thereby affecting a reduction of the total number of Cooper pairs and also a reduction of their binding energy. One obtains a decrease in Δ_0 with increasing temperature. For $T \to T_c, \Delta_0$ approaches zero.

How does the density n_s of Cooper pairs depend on Δ_0? One finds that n is proportional to Δ_0^2. We see that, on the one hand, the quantity Δ_0 appears as (half) the "energy gap" of the superconductor. On the other hand, it also determines the number of Cooper pairs. In Chapter 1, we described the Cooper pair density in terms of the absolute square of the macroscopic wave function $\Psi = \Psi_0 e^{i\varphi}$. One can show that $\Delta \propto \Psi$[9]. Hence, pair amplitude Ψ_0 and Δ_0 are often used synonymously.

Finally, from the BCS theory one can derive a very simple connection between T_c and the quantities $N_n(E_F), \hbar\omega_c$, and the Cooper pair interaction V: it is [M3, M4]

$$T_c = 1.13 \frac{\hbar\omega_c}{k_B} \exp\left(-\frac{1}{N_n(E_F)V}\right)$$

If we identify ω_c with the Debye frequency ω_D, we also obtain immediately a connection between the transition temperature and the mass M of the elements building the lattice, since the frequency of the lattice vibrations is inversely proportional to the square root of M. If we substitute an isotope on a lattice site by another one, the interaction between these elements building the lattice remain unchanged. This results in the isotope effect, which we expect for Cooper pairing because of the electron-phonon interaction

Furthermore, from the BCS theory, we can derive the following important relation between Δ_0 at zero temperature and T_c:

$$2\Delta_0(T = 0) = 3.5 k_B T_c$$

In the following section, we turn to the experimental results dealing with the microscopic concepts of the superconducting state.

3.1.3

Experimental Confirmation of Fundamental Concepts about the Superconducting Stat

In the previous section we have outlined a picture of the superconducting state based on the BCS theory, which represents a most successful microscopic theory of superconductivity. In principle, it is the total sum of all experimental observations explained quantitatively or at least qualitatively by the theory, which completely justifies the essential concepts. There are a few experimental results that particularly strongly illuminate certain characteristic properties of the superconducting state.

In Chapter 1 we discussed results showing directly that superconductivity manifests itself in terms of a macroscopic quantum state with a well-defined phase. In the following section, we will present additional results that should strengthen our confidence in the somewhat complicated ideas about the

Table 3.1 Isotope effect in mercury [13].

Average atomic mass	199.7	200.7	202.0	203.4
Tran				

superconducting state, and which should deepen our understanding by means of concrete experiments. Except for the isotope effect, these characteristic properties are independent of the special interaction leading to the pair correlation.

Some of the experimental facts, such as, say, the behavior of the specific heat or the isotope effect, were already known before the development of the BCS theory. Other experiments, such as, say, measurements of the tunneling effect and of the Josephson effects (discussed already in

Chapter 1), were stimulated only by the microscopic theory. However, the flux quantization, also discussed in Chapter 1, is a special case, since it was already predicted by F. London long before the BCS theory arrived. On the other hand, it was experimentally observed only after the development of this theory and represents an impressive quantitative confirmation of the concept of Cooper pairing.

Time of Cooper Pair coherence

(what with BCS in d=1 or d=2?)

Main ideas

3.10.6 Original 1957 BCS Paper 1: Conclusion, Introduction, General Questions

Abstract

A theory of superconductivity is presented, based on the fact that the interaction between electrons resulting from virtual exchange of phonons is attractive when the energy difference between the electrons states involved is less than the phonon energy, $\hbar\omega$. It is favorable to form a superconducting phase when this attractive interaction dominates the repulsive screened Coulomb interaction. The normal phase is described by the Bloch individual-particle model. The ground state of a superconductor, formed from a linear combination of normal state configurations in which electrons are virtually excited in pairs of opposite spin and momentum, is lower in energy than the normal state by amount proportional to an average $(\hbar\omega)^2$, consistent with the isotope effect. A mutually orthogonal set of excited states in one-to-one correspondence with those of the normal phase is obtained by specifying occupation of certain Bloch states and by using the rest to form a linear combination of virtual pair configurations. The theory yields a second-order phase transition and a Meissner effect in the form suggested by Pippard. Calculated values of specific heats and penetration depths and their temperature variation are in good agreement with experiment. There is an energy gap for individual-particle excitations which decreases from about $3.5kT_c$ at $T = 0°\mathrm{K}$ to zero at T_c. Tables of matrix elements of single-particle operators between the excited-state superconducting wave functions, useful for perturbation expansions and calculations of transition probabilities, are given.

VI. CONCLUSION

Although our calculations are based on a rather idealized model, they give a reasonably good account of the equilibrium properties of superconductors. When the parameters of the theory are determined empirically, we find that we get agreement with observed specific heats and penetration depths to within the order of 10%. Only the critical temperature involves the superconducting phase; the other two parameters required (density of states and average velocity at the Fermi surface) are determined from the normal phase. This quantitative agreement, as well as the fact that we can account for the main features of superconductivity is convincing evidence that our model is essentially correct.

The basis for the theory is a net attractive interaction between electrons for transitions in which the energy difference between the electron states involved is less than the phonon energy, $\hbar\omega$. For simplicity we have assumed a constant matrix element, $-V$, for transitions within an

average energy $\hbar\omega$ of the Fermi surface and have neglected the repulsive interaction outside this region. In more accurate calculations one should take an interaction region dependent on the initial states of the electron and the transition involved, and also take into account any anisotropy in the Fermi surface and in the matrix elements. The fact that there is a law of corresponding states is empirical evidence that such effects are not of great importance. Neglect of the repulsive part of the interaction is in the spirit of the Bloch approximation for normal metals, and appears to be well justified in first approximation. Our theory may be regarded as an extension of the Bloch theory to superconductors in which we introduce only those interactions responsible for the transition.

An improvement in the general formulation of the theory is desirable. We have used that of Bardeen and Pines in which screening of the Coulomb field is taken into account by the Bohm-Pines collective model, and the phonon interaction between electrons is determined only to second order. Diagonal or self-energy terms in the net interaction have been omitted with the assumption that they are included in the Bloch energies of the normal state. When the phonon interaction is so large as to give superconductivity, higher order terms than the second may well be important. One should really have used a renormalized interaction in which such higher order terms are taken into account as well as possible. Very likely the assumption of two-particle interactions is a reasonably good one, so that the only effect would be a redefinition of the interaction constant V in terms of microscopic quantities.

The discussion of the matrix elements in Sec. IV should be a good starting point for calculation of transport properties in the superconducting phase. Our excited state many-particle wave functions are not
much more difficult to use in such calculations than the determinantal wave functions of the Bloch theory.

For calculation of boundary energies and related problems, one would like to introduce an order parameter which can decrease continuously from an equilibrium value for the superconducting phase to zero in the normal phase as the boundary is crossed. The Ginsburg-Landau theory and its extensions [7] appear to give a good phenomenological description of such effects. Perhaps the energy gap, $2\epsilon_0$, or, what is equivalent, the coherence distance, ξ_0, could be used for such a parameter.

Another problem, not yet solved, is the calculation of the paramagnetic susceptibility of the electrons in a superconductor, such as is required to account for Reif's data [38] on the Knight shift in the nuclear paramagnetic resonance of colloidal mercury. Our ground state is for total spin $S = 0$. It is possible that there is no energy gap between this state and those for $S \neq 0$. While a finite energy is required to turn over an individual spin, it might be possible to construct states analogous to those used in spin-wave theory in which each virtual pair has a small net spin, and for which the energy varies continuously with S. The explanation of the observed electronic paramagnetism (about twothirds that of the normal metal) would then be similar to that suggested by Reif himself.

In view of its success with equilibrium properties, it may be hoped that our theory will be able to account for these and for other so far unsolved problems.

The authors are indebted to many of their associates for discussions which have helped to clarify the problems involved. We should like to mention particularly discussions with C. P. Slichter and L. C. Hebel on calculation of matrix elements, with D. Pines on the criterion for superconductivity, and with K . A. Brueckner on the exactness of the solution for the ground state.

I. INTRODUCTION

The main facts which a theory of superconductivity must explain are (1) a second-order phase transition at the critical temperature, T_c, (2) an electronic specific heat varying as

$\exp(-T_0/T)$ near $T = 0°\mathrm{K}$ and other evidence for an energy gap for individual particle-like excitations, (3) the MeissnerOchsenfeld effect ($\mathbf{B} = 0$), (4) effects associated with infinite conductivity ($\mathbf{E} = 0$), and (5) the dependence of T_c on isotopic mass, $T_c\sqrt{M} = \text{const}$. We present here a theory which accounts for all of these, and in addition gives good quantitative agreement for specific heats and penetration depths and their variation with temperature when evaluated from experimentally determined parameters of the theory.

When superconductivity was discovered by Onnes [1] (1911), and for many years afterwards, it was thought to consist simply of a vanishing of all electrical resistance below the transition temperature. A major advance was the discovery of the Meissner effect [2] (1933), which showed that a superconductor is a perfect diamagnet; magnetic flux is excluded from all but a thin penetration region near the surface. Not very long afterwards (1935), London and London [3] proposed a phenomenological theory of the electromagnetic properties in which the diamagnetic aspects were assumed

basic. F. London [4] suggested a quantum-theoretic approach to a theory in which it was assumed that there is somehow a coherence or rigidity in the superconducting state such that the wave functions are not modified very much when a magnetic field is applied. The concept of coherence has been emphasized by Pippard, [5] who, on the basis of experiments on penetration phenomena, proposed a nonlocal modification of the London equations in which a coherence distance, ξ_0, is introduced. One of the authors [6,7] pointed out that an energy-gap model would most likely lead to the Pippard version, and we have found this to be true of the present theory. Our theory of the diamagnetic aspects thus follows along the general lines suggested by London and by Pippard. [7]

The Sommerfeld-Bloch individual-particle model (1928) gives a fairly good description of normal metals, but fails to account for superconductivity. In this theory, it is assumed that in first approximation one may neglect correlations between the positions of the electrons and assume that each electron moves independently in some sort of self-consistent field determined by the other conduction electrons and the ions. Wave functions of the metal as a whole are designated by occupation of Bloch individual-particle states of energy $\epsilon(\mathbf{k})$ defined by wave vector $\mathbf{k}$ and spin σ; in the ground state all levels with energies below the Fermi energy, $\mathcal{E}_F$, are occupied; those above are unoccupied. Left out of the Bloch model are correlations between electrons brought about by Coulomb forces and interactions between electrons and lattice vibrations (or phonons).

Most of the relatively large energy associated with correlation effects occurs in both normal and superconducting phases and cancels out in the difference. One of the problems in constructing a satisfactory microscopic theory of superconductivity has been to isolate that part of the interaction which is responsible for the transition. Heisenberg [8] and Koppe [9] proposed a theory based on long-wavelength components of the Coulomb interaction, which were presumed to give fluctuations in electron density described roughly by wave packets localizing a small fraction of the electrons on lattices moving in different directions. A great break-through occurred with the discovery of the isotope effect, [10] which strongly indicated, as had been suggested independently by Fröhlich, [11] that electronphonon interactions are primarily responsible for superconductivity.

Early theories based on electron-phonon interactions have not been successful. Fröhlich's theory, which makes use of a perturbation-theoretic approach, does give the correct isotopic mass dependence for H_0, the critical field at $T = 0°\mathrm{K}$, but does not yield a phase with superconducting properties and further, the energy difference between what is supposed to correspond to normal and superconducting phases is far too large. A variational approach by one of the authors [12] ran into similar difficulties. Both theories are based primarily on the self-energy of the electrons in the phonon field rather than on the true interaction between electrons, although it was recognized that the latter might be important. [13]

The electron-phonon interaction gives a scattering from a Bloch state defined by the wave vector $\mathbf{k}$ to $\mathbf{k}' = \mathbf{k} \pm \boldsymbol{k}$ by absorption or emission of a phonon of wave vector $\boldsymbol{k}$. It is this interaction which is responsible for thermal scattering. Its contribution to the energy can be estimated by making a canonical transformation which eliminates the linear electron-phonon interaction terms from the Hamiltonian. In second order, there is one term which gives a renormalization of the phonon frequencies, and another, H_2, which gives a true interaction between electrons, independent of the vibrational amplitudes. A transformation of this sort was given first by Fröhlich [14] in a formulation in which Coulomb interactions between electrons were disregarded. In a later treatment, Nakajima [15] showed how such interactions could be included. Particularly for the longwavelength part of the interaction, it is important to take into account the screening of the Coulomb field of any one electron by other conduction electrons. Such effects are included in a more complete analysis by Bardeen and Pines, [16] based on the Bohm-Pines collective model, in which plasma modes are introduced for long wavelengths.

We shall call the interaction, H_2, between electrons resulting from the electron-phonon interaction the "phonon interaction." This interaction is attractive when the energy difference, $\Delta\epsilon$, between the electron states involved is less than $\hbar\omega$. Diagonal or self-energy terms of H_2 give an energy of order of $-N(\mathcal{E}_F)(\hbar\omega)^2$, where $N(\mathcal{E}_F)$ is the density of states per unit energy at the Fermi surface. The theories of Fröhlich and Bardeen mentioned above were based largely on this part of the energy. The observed energy differences between superconducting and normal states at $T = 0°\mathrm{K}$ are much smaller, of the order of $-N(\mathcal{E}_F)(kT_c)^2$ or about 10^{-8} ev/ atom. The present theory, based on the off-diagonal elements of H_2 and the screened Coulomb interaction, gives energies of the correct order of magnitude. While the self-energy terms do depend to some extent on the distribution of electrons in $\mathbf{k}$ space, it is now believed that this part of the energy is substantially the same in the normal and superconducting phases. The self-energy terms are also nearly the same for all of the various excited normal state configurations which make up the superconducting wave functions.

In a preliminary communication, [17] we gave as a criterion for the occurrence of a superconducting phase that for transitions such that $\Delta\epsilon < \hbar\omega$, the attractive H_2 dominate the repulsive short-range screened Coulomb interaction between electrons, so as to give a net attraction. We showed how an attractive interaction of this sort can give rise to a cooperative many-particle state which is lower in energy than the normal state by an amount proportional to $(\hbar\omega)^2$, consistent with the isotope effect. We have since extended the theory to higher temperatures, have shown that it gives both a second-order transition and a Meissner effect, and have calculated

specific heats and penetration depths.

In the theory, the normal state is described by the Bloch individual-particle model. The ground-state wave function of a superconductor is formed by taking a linear combination of many low-lying normal state configurations in which the Bloch states are virtually occupied in pairs of opposite spin and momentum. If the state $\mathbf{k}\uparrow$ is occupied in any configuration, $-\mathbf{k}\downarrow$ is also occupied. The average excitation energy of the virtual pairs above the Fermi sea is of the order of kT_c. Excited states of the superconductor are formed by specifying occupation of certain Bloch states and by using all of the rest to form a linear combination of virtual pair configurations. There is thus a one-to-one correspondence between excited states of the normal and superconducting phases. The theory yields an energy gap for excitation of individual electrons from the superconducting ground state of about the observed order of magnitude.

The most important concribution to the interaction energy is given by short- rather than long-wavelength phonons. Our wave functions for the suerconducting phase give a coherence of short-wavelength components of the density matrix which extend over large distances in real space, so as to take maximum advantage of the attractive part of the interaction. The coherence distance, of the order of Pippard's ξ_0, can be estimated from uncertainty principle arguments. [5,7] If intervals of the order of $\Delta k \sim (kT_c/\mathcal{E}_F)\, k_F \sim 10^4$ cm^{-1} are important in $\mathbf{k}$ space, wave functions in real space must extend over distances of at least $\Delta x \sim 1/\Delta k \sim 10^{-4}$ cm. The fraction of the total number of electrons which have energies within kT_c of the Fermi surface, so that they can interact effectively, is approximately $kT_c/\mathcal{E}_F \sim 10^{-4}$. The number of these in an interaction region of volume $(\Delta x)^3$ is of the order of $10^{22} \times (10^{-4})^3 \times 10^{-4} = 10^6$. Thus our wave functions must describe coherence of large numbers of electrons. [18]

In the absence of a satisfactory microscopic theory, there has been considerable development of phenomenological theories for both thermal and electromagnetic properties. Of the various two-fluid models used to describe the thermal properties, the first and best known is that of Gorter and Casimir, [19] which yields a parabolic critical field curve and an electronic specific heat varying as T^3. In this, as well as in subsequent theories of thermal properties, it is assumed that all of the entropy of the electrons comes from excitations of individual particles from the ground state. In recent years, there has been considerable experimental evidence [20] for an energy gap for such excitations, decreasing from $\sim 3kT_c$ at $T = 0°$K to zero at $T = T_c$. Two-fluid models which yield an energy gap and an exponential specific heat curve at low temperatures have been discussed by Ginsburg [21] and by Bernardes. [22] Koppe's

theory may also be interpreted in terms of an energygap model. [7] Our theory yields an energy gap and specific heat curve consistent with the experimental observations.

The best known of the phenomenological theories for the electromagnetic properties is that of F . and H . London. [23] With an appropriate choice of gauge for the vector potential, A, the

17 Bardeen, Cooper, and Schrieffer, Phys. Rev. 106, 162 (1957).

[18] Our picture differs from that of Schafroth, Butler, and Blatt, Helv. Phys. Acta 30, 93 (1957), who suggest that pseudomolecules of pairs of electrons of opposite spin are formed. They show if the size of the pseudomolecules is less than the average distance between them, and if other conditions are fulfilled, the system has properties similar to that of a charged Bose-Einstein gas, including a Meissner effect and a critical temperature of condensation. Our pairs are not localized in this sense, and our transition is not analogous to a Bose-Einstein condensation.

London equation for the superconducting current density, $\mathbf{j}$, may be written

$$-c\Lambda\mathbf{j} = \mathbf{A} \tag{1.1}$$

The London penetration depth is given by:

$$\lambda_L^2 = \Lambda c^2/4\pi \tag{1.2}$$

F. London has pointed out that (1.1) would follow from quantum theory if the superconducting wave functions are so rigid that they are not modified at all by the application of a magnetic field. For an electron density n/cm^3, this approach gives $\Lambda = m/ne^2$.

On the basis of empirical evidence, Pippard [5] has proposed a modification of the London equation in which the current density at a point is given by an integral of the vector potential over a region surrounding the point:

$$\mathbf{j}(\mathbf{r}) = -\frac{3}{4\pi c\Lambda\xi_0}\int \frac{\mathbf{R}\left[\mathbf{R}\cdot\mathbf{A}\left(\mathbf{r}'\right)\right]e^{-R/\xi_0}}{R^4}d\tau' \tag{1.3}$$

where $\mathbf{R} = \mathbf{r} - \mathbf{r}'$. The "coherence distance," ξ_0, is of the order of 10^{-4} cm in a pure metal. For a very slowly varying $\mathbf{A}$, the Pippard expression reduces to the London form (1.1).

The present theory indicates that the Meissner effect is intimately related to the existence of an energy gap, and we are led to a theory similar to, although not quite the same as, that proposed by Pippard. Our theoretical values for ξ_0 are close to those derived empirically by Pippard. We find that while the integrand is relatively independent of temperature, the coefficient in front of the integral (in effect Λ) varies with T in such a way as to account for the temperature variation of penetration depth.

Our theory also accounts in a qualitative way for those aspects of superconductivity associated with infinite conductivity and a persistent current flowing in a ring. When there is a net current flow, the paired states $(\mathbf{k}_1\uparrow, \mathbf{k}_2\downarrow)$ have a net momentum $\mathbf{k}_1 + \mathbf{k}_2 = \mathbf{q}$, where $\mathbf{q}$ is the same for all virtual pairs. For each value of $\mathbf{q}$, there is a metastable state with a minimum in free energy and a unique current density. Scattering of individual electrons will not change the value of $\mathbf{q}$ common to virtual pair states, and so can only produce fluctuations about the current determined by $\mathbf{q}$. Nearly all fluctuations will increase the free energy; only those which involve a majority of the electrons so as to change

the common $\mathbf{q}$ can decrease the free energy. These latter are presumably extremely rare, so that the metastable current carrying state can persist indefinitely. [24]

It has long been recognized that there is a law of corresponding states for superconductors. The various properties can be expressed approximatly in terms of a small number of parameters. If the ratio of the electronic specific heat at T to that of the normal state at $T_c, C_s(T)/C_n\left(T_c\right)$, is plotted on a reduced temperature scale, $t = T/T_c$, most superconductors fall on nearly the same curve. There are two parameters involved: (1) the density of states in energy at the Fermi surface, $N\left(\mathcal{E}_F\right)$, determined from $C_n(T) = \gamma T$ and (2) one which depends on the phonon interaction, which can be estimated from T_c. A consequence of the similarity law is that $\gamma {T_c}^2/V_m {H_0}^2$ (where V_m is the molar volume and H_0 the critical field at $T = 0°\mathrm{K}$) is approximately the same for most superconductors.

A third parameter, the average velocity, v_0, of electrons at the Fermi surface,

$$v_0 = \hbar^{-1}|\partial\mathcal{E}/\partial\mathbf{k}|_F \tag{1.4}$$

is required for penetration phenomena. As pointed out by Faber and Pippard, [25] this parameter is most conveniently determined from measurements of the anomalous skin effect in

[23] An excellent account may be found in F. London, Superfluids (John Wiley and Sons, Inc., New York, 1954), Vol. 1.

normal metals in the high-frequency limit. The expression, as given by Chambers [26] for the current density when the electric field varies over a mean free path, l, may be written in the form:

$$\mathbf{j}_n(r) = \frac{e^2 N(\mathcal{E}_F) v_0}{2\pi} \int \frac{\mathbf{R}[\mathbf{R}\cdot\mathbf{A}(\mathbf{r}')] e^{-R/l}}{R^4} d\tau'. \tag{1.5}$$

The coefficient $N(\mathcal{E}_F) v_0$ has been determined empirically for tin and aluminum.

Pippard based his Eq. (1.3) on Chambers' expression. London's coefficient, Λ, for $T = 0°\mathrm{K}$ may be expressed in the form:

$$\Lambda^{-1} = \frac{2}{3} e^2 N(\mathcal{E}_F) v_0^2. \tag{1.6}$$

Faber and Pippard suggest that if ξ_0 is written:

$$\xi_0 = a\hbar v_0/kT_c, \tag{1.7}$$

the dimensionless constant a has approximately the
same value for all superconductors and they find it equal to about 0.15 for Sn and Al.[27]

Our theory is based on a rather idealized model in which anisotropic effects are neglected. It contains three parameters, two corresponding to $N(\mathcal{E}_F)$ and v_0, and one dependent on the electron-phonon interaction which determines T_c. The model appears to fit the law of corresponding states about as well as real metals do ($\sim 10\%$ for most properties). We find a relation corresponding to (1.7) with $a = 0.18$. It thus appears that superconducting properties are not dependent on the details of the band structure but only upon the gross features.

Section II is concerned with the nature of the ground state and the energy of excited states near $T = 0°\mathrm{K}$, Sec. III with excited states and thermal properties, Sec. IV with calculation of matrix elements for application to perturbation theory expansions and transition probabilities and Sec. V with electrodynamic and penetration phenomenon. Some of the computational details are given in Appendices.

We give a fairly complete account of the equilibrium properties of our model, but nothing on transport or boundary effects. Starting from matrix elements of single-particle scattering operators as given in Sec. IV, it should not be difficult to determine transport properties in the superconducting state from the corresponding properties of the normal state.

How did they derive the gap as function of temperature without Bogoliubov transformations?

(??? this was always in my mind... I'll read later)

[24] Blatt, Butler, and Schafroth, Phys. Rev. 100, 481 (1955) have introduced the concept of a "correlation length," roughly the distance over which the momenta of a pair of particles are correlated. M. R. Schafroth, Phys. Rev. 100, 502 (1955), has argued that there is a true Meissner effect only if the correlation length is effectively infinite. In our theory, the correlation length (not to be confused with Pippard's coherence distance, ξ_0) is most reasonably interpreted as the distance over which the momentum of virtual pairs is the same. We believe that in this sense, the correlation length is effectively infinite. The value of $\mathbf{q}$ is exactly zero everywhere in a simply connected body in an external field. When there is current flow, as in a torus, there is a unique distribution of $\mathbf{q}$ values for minimum free energy.

3.10.7 Original 1957 BCS Paper 1: Ground State

II. THE GROUND STATE

The interaction which produces the energy difference between the normal and superconducting phases in our theory arises from the virtual exchange of phonons and the screened Coulomb repulsion between electrons. Other interactions, such as those giving rise to the single-particle self-energies, are thought to be essentially the same in both states, their effects thus cancelling in the energy difference. The problem is therefore one of calculating the ground state and excited states of a dense system of fermions interacting via two-body potentials.

The Hamiltonian for the fermion system is most conveniently expressed in terms of creation and annihilation operators, based on the renormalized Bloch states specified by wave vector $\mathbf{k}$ and spin σ, which satisfy the usual Fermi commutation relations:

$$\left[c_{\mathrm{k}\sigma}, c_{\mathrm{k}'\sigma'}\right]_+\Big]_+ = \delta_{\mathrm{k}\mathrm{k}'}\delta_{\sigma\sigma'}, \tag{2.1}$$

$$\left[c_{\mathrm{k}\sigma}, c_{\mathrm{k}'\sigma'}\right]_+ = 0. \tag{2.2}$$

The single-particle number operator $n_{\mathrm{k}\sigma}$ is defined as

$$n_{\mathrm{k}\sigma} = {c_{\mathrm{k}\sigma}}^* c_{\mathrm{k}\sigma} \tag{2.3}$$

The Hamiltonian for the electrons may be expressed in the form

$$H = \sum_{k>k_F} \epsilon_{\mathrm{k}} n_{\mathrm{k}\sigma} + \sum_{k<k_F} |\epsilon_{\mathrm{k}}| \left(1 - n_{\mathrm{k}\sigma}\right) + H_{\mathrm{Coul}} + \\ + \frac{1}{2} \sum_{\mathbf{k},\mathbf{k}',\sigma,\sigma',\mathbf{k}} \frac{2\hbar\omega_k \left|M_{\mathbf{k}}\right|^2 c^*\left(\mathbf{k}'-\mathbf{k},\sigma'\right) c\left(\mathbf{k}',\sigma'\right) c^*(\mathbf{k}+\mathbf{k},\sigma) c(\mathbf{k},\sigma)}{\left(\epsilon_{\mathrm{k}} - \epsilon_{\mathrm{k}+\alpha}\right)^2 - \left(\hbar\omega_k\right)^2} \\ = H_0 + H_I, \tag{2.4}$$

where ϵ_{k} is the Bloch energy measured relative to the Fermi energy, $\mathcal{E}_F$. We denote by $k > k_F$ states above the Fermi surface, by $k < k_F$ those below. The fourth term on the right of (2.4) is H_2, the phonon interaction, which comes from virtual exchange of phonons between the electrons. The matrix element for phonon-electron interaction, M_κ, calculated for the zero-point amplitude of the lattice vibrations, is related to the v_κ introduced by Bardeen and Pines [16] by

$$\left|M_\kappa\right|^2 = \left|v_\kappa\right|^2 \left\langle q_\kappa^2 \right\rangle_{\mathrm{Av}} = \left|v_\kappa\right|^2 \left(\hbar/2\omega_\kappa\right). \tag{2.5}$$

Since $\left|M_\kappa\right|^2$ varies with isotopic mass in the same way that ω_κ does, the ratio $\left|M_\kappa\right|^2/\hbar\omega_\kappa$ is independent of isotopic mass. We consider only the off-diagonal interaction terms of H_2, assuming that the diagonal terms are taken into account by appropriate renormalization of the Bloch energies, ϵ_{k}. The third term is the screened Coulomb interaction.

Following Bardeen and Pines, [16] the phonons are assumed to be decoupled from the electrons by a renormalization procedure and their frequencies are taken to be unaltered by the transition to the superconducting state. While this assumption is not strictly valid, the shift in self-energy can be taken into account after we have solved for the electronic part of the wave function. This

[27] From analysis of data on transmission of microwave and far infrared radiation through superconducting films of tin and lead, Glover and Tinkham (reference 20) find $a = 0.27$.

separation is possible because the phonons depend only upon the average electron distribution in momentum space and the wave function for electrons at any temperature is formed from configurations with essentially the same distribution of particles. The Bloch energies are also assumed to be constant; however, their shift with temperature could be treated as in the phonon case.

The form of the phonon interaction shows that it is attractive (negative) for excitation energies $|\epsilon_{\mathrm{k}} - \epsilon_{\mathrm{k+k}}| < \hbar\omega_\kappa$. Opposed to this is the repulsive Coulomb interaction, which may be expressed in a form similar to H_2. For free electrons in a system of unit volume the interaction in momentum space is $4\pi e^2/\kappa^2$. In the BohmPines theory, the long-wavelength components are expressed in the form of plasma oscillations, so that κ can be no smaller than minimum value κ_c, usually slightly less than the radius of the Fermi surface, k_F. One could also take screening into account by a FermiThomas method, in which case κ^2 would be replaced by $\kappa^2 + {\kappa_s}^2$, where κ_s depends on the electron density. Our criterion for superconductivity is that the attractive phonon interaction dominate the Coulomb interaction
for those matrix elements which are of importance in the superconducting wave function:

$$-V \equiv \left\langle -\frac{2\left|M_\kappa\right|^2}{\hbar\omega_\kappa} + \frac{4\pi e^2}{\kappa^2} \right\rangle_{\mathrm{Av}} < 0 \tag{2.6}$$

The most important transitions are those for which $|\epsilon_{\mathrm{k}} - \epsilon_{\mathrm{k+k}}| \sim kT_c \ll \hbar\omega_{\mathrm{k}}$. A detailed discussion of the criterion (2.6) has been given by Pines, [28] who shows that it accounts in a reasonable way for the empirical rules of Matthias [29] for the occurrence of superconductivity. Numerically, the criterion is not much different from one given earlier by Fröhlich, [11] based on a different principle.

To obtain the ground state function, we observe that the interaction Hamiltonian connects a large number of nearly degenerate occupation number configurations with each other via nonzero matrix elements. If the matrix elements were all negative in sign, one could obtain a state with low energy by forming a linear combination of the basis functions with expansion coefficients of the same sign. The magnitude of the interaction energy obtained in this manner would be approximately given by the number of configurations which connect to a given typical configuration times an average matrix element. This was demonstrated by one of the authors [30] by solving a problem in which two electrons with zero total momentum interact via constant negative matrix elements in a small shell above the Fermi surface. It was shown that the ground state of this system is separated from the continuum by a volume independent energy. This type of coherent mixing of Bloch states produces a state with qualitatively different properties from the original states.

In the actual problem, the interaction which takes a pair from ($\mathbf{k}_1\sigma_1, \mathbf{k}_2\sigma_2$) to ($\mathbf{k}_1'\sigma_1, \mathbf{k}_2'\sigma_2$) contains the operators,

$$c^*\left(\mathbf{k}_2', \sigma_2\right) c\left(\mathbf{k}_2, \sigma_2\right) c^*\left(\mathbf{k}_1', \sigma_1\right) c\left(\mathbf{k}_1, \sigma_1\right). \tag{2.7}$$

Conservation of momentum requires that

$$\mathbf{k}_1 + \mathbf{k}_2 = \mathbf{k}_1' + \mathbf{k}_2' \tag{2.8}$$

Because of Fermi-Dirac statistics, matrix elements of (2.7) between arbitrary many electron configurations alternate in sign so that if the configurations occur in the ground state with roughly equal weight, the net interaction energy would be small. We can, however, produce a coherent low state by choosing a subset of configurations between which the matrix elements are negative. Such a subset can be formed by those configurations in which the Bloch states are occupied in pairs, ($\mathbf{k}_1\sigma_1, \mathbf{k}_2\sigma_2$); that is, if one member of the pair is occupied in any configuration in the subset, the other is also. Since the interaction conserves momentum, a

maximum number of matrix elements will be obtained if all pairs have the same net momentum, $\mathbf{k}_1 + \mathbf{k}_2 = \mathbf{q}$. It is further desirable to take pairs of opposite spin, because exchange terms reduce the interaction for parallel spins. The best choice for q for the ground state pairing is $q = 0$, ($k \uparrow, -k \downarrow$).

We start then by considering a reduced problem in which we include only configurations in which the states are occupied in pairs such that if $\mathbf{k} \uparrow$ is occupied so is $-\mathbf{k} \downarrow$. A pair is designated by the wave vector $\mathbf{k}$, independent of spin. Creation and annihilation operators for pairs may be defined in terms of the singleparticle operators as follows:

$$b_{\mathrm{k}} = c_{-\mathrm{k}\downarrow} c_{\mathrm{k}} \uparrow \tag{2.9}$$

$$b_{\mathrm{k}}{}^{*} = c_{\mathrm{k}} \uparrow^{*} \, c_{-\mathrm{k}\downarrow}{}^{*} \tag{2.10}$$

These operators satisfy the commutation relations

$$[b_{\mathrm{k}}, b_{\mathrm{k}'} *]_{-} = (1 - n_{\mathrm{k}} \uparrow - n_{-\mathrm{k}\downarrow}) \, \delta_{\mathrm{k}\mathrm{k}'} \tag{2.11}$$

$$[b_{\mathrm{k}}, b_{\mathrm{k}'}]_{-} = 0 \tag{2.12}$$

$$[b_{\mathrm{k}}, b_{\mathrm{k}'}]_{+} = 2 b_{\mathrm{k}} b_{\mathrm{k}'} \, (1 - \delta_{\mathrm{k}\mathrm{k}'}) \tag{2.13}$$

where $n_{\mathrm{k}\sigma}$ is given by (2.3). While the commutation relation (2.12) is the same as for bosons, the commutators (2.11) and (2.13) are distinctly different from those for Bose particles. The factors ($1 - n_{\mathrm{k}} \uparrow - n_{-\mathrm{k}\downarrow}$) and ($1 - \delta_{\mathrm{k}\mathrm{k}'}$) arise from the effect of the exclusion principle on the single particles.

That part of the Hamiltonian which connects pairs with zero net momentum may be derived from the Hamiltonian (2.4) and expressed in terms of the b 's. Measuring the energy relative to the Fermi sea, we obtain:

$$H_{\mathrm{red}} = 2 \sum_{k > k_F} \epsilon_{\mathrm{k}} b_{\mathrm{k}} * b_{\mathrm{k}} + 2 \sum_{k < k_F} |\epsilon_{\mathrm{k}}| b_{\mathrm{k}} b_{\mathrm{k}}^{*} - \sum_{\mathrm{k}\mathrm{k}'} V_{\mathrm{k}\mathrm{k}'} b_{\mathrm{k}'}^{*} b_{\mathrm{k}} \tag{2.14}$$

We have defined the interaction terms with a negative sign so that $V_{kk'}$ will be predominantly positive for a superconductor. There are many other terms in the complete interaction which connect pairs with total momentum $\boldsymbol{q} \neq 0$. These have little effect on the energy, and can be treated as a perturbation. Although the interaction terms kept in H_{red} may appear to have a negligible weight, it is this part which contributes overwhelmingly to the interaction energy.

We have used a Hartree-like method to determine the expansion coefficients, which appears to give an excellent approximation, and may, indeed, even be correct in the limit of a large number of particles. [31] (See Appendix A.)

Excited states are treated in much the same way as the ground state. One must distinguish between singly excited particles, in which one and only one of a pair ($\mathbf{k} \uparrow, -\mathbf{k} \downarrow$) is occupied, and excited or "real" pair states. We treat singly excited particles in the Bloch scheme, as in the normal metal. They contribute a negligible amount to the interaction energy directly, but reduce the amount of phase space available for real and virtual pairs. Thus the interaction

28 D. Pines (to be published).

[29] B. Matthias, Progress in Low Temperature Physics (NorthHolland Publishing Company, Amsterdam, 1957), Vol. 2.

[30] L. N. Cooper, Phys. Rev. 104, 1189 (1956).

[31] Since (2.14) is quadratic in the b 's, one might hope to get an exact solution for the ground state by an appropriate redefinition of the single-particle states, as can be done for either Fermi-Dirac or Einstein-Bose statistics. Our pairs obey neither of these, and no such simple solution appears possible.

portion of H_{red} is modified by deleting from the sums over $\mathbf{k}$ and $\mathbf{k}'$ all singly occupied states, and the remainder is used to determine the interaction energy associated with the pairs.

One might expect to get some interaction energy from singly occupied states by associating them in various pairs with $\boldsymbol{q} \neq 0$. However, an appreciable energy is obtained only if a finite fraction of the pairs have the same $\mathbf{q}$, and this will not be true for randomly excited particles. States with a net current flow can be obtained by taking a pairing ($\mathbf{k}_1 \uparrow, \mathbf{k}_2 \downarrow$), with $\mathbf{k}_1 + \mathbf{k}_2 = \mathbf{q}$, and $\boldsymbol{q}$ the same for all virtual pairs.

The most general wave function satisfying the pairing condition ($\mathbf{k} \uparrow, -\mathbf{k} \downarrow$) is of the form

$$\sum_{\mathbf{k}_1 \cdots \mathbf{k}_n} \left[h\left(\mathbf{k}_1 \cdots \mathbf{k}_n\right)\right]^{\frac{1}{2}} f\left(\cdots 1\left(k_1\right) \cdots 1\left(k_n\right) \cdots\right) \tag{2.15}$$

where the sum extends over all distinct pair configurations. To construct our ground state function we make a Hartree-like approximation in which the probability that a specific configuration of pairs occurs in the wave function is given by a product of occupancy probabilities for the individual pair states. If for the moment we relax the requirement that the wave function describes a system with a fixed number of particles, then a function having this Hartree-like property is

$$\Psi = \prod_{\mathrm{k}} \left[(1 - h_{\mathrm{k}})^{\frac{1}{2}} + h_{\mathrm{k}}^{\frac{1}{2}} b_{\mathrm{k}}^*\right] \Phi_0 \tag{2.16}$$

where Φ_0 is the vacuum. It follows from (2.16) that the probability of the n states $\mathbf{k}_1 \cdots \mathbf{k}_n$ being occupied is $h\left(\mathbf{k}_1\right) \cdots h\left(\mathbf{k}_n\right)$, and since n is unrestricted we see that Ψ is closely related to the intermediate coupling approximation.

For any specified wave vector $\mathbf{k}'$, it is convenient to decompose Ψ into two components, in one of which, φ_1, the pair state designated by $\mathbf{k}'$ is certainly occupied and the other, φ_0, for which it is empty:

$$\Psi = h_{\mathbf{k}'}^{\frac{1}{2}} \varphi_1 + (1 - h_{\mathbf{k}'})^{\frac{1}{2}} \varphi_0 \tag{2.17}$$

The coefficient $h_{\mathrm{k}'}$ is the probability that state $\mathbf{k}'$ is occupied and the φ 's are the normalized functions:

$$\varphi_1 = b_{\mathrm{k}'} * \varphi_0 = b_{\mathrm{k}'} * \prod_{\mathrm{k}(\neq \mathrm{k}')} \left[(1 - h_{\mathrm{k}})^{\frac{1}{2}} + h_{\mathrm{k}^2}^{\frac{1}{2}} b_{\mathrm{k}} *\right] \Phi_0 \tag{2.18}$$

In the limit of a large system, the weights of states with different total numbers of pairs in Ψ will be sharply peaked about the average number, N, which will be dependent on the choice of the h 's. We take for our
ground state function, Ψ_N, the projection of Ψ onto the space of exactly N pairs. [32] This function may also be decomposed as in (2.17), but since φ_{N1} and φ_{N0} now have the same number of pairs, φ_{N1} is not equal to ${b_{\mathrm{k}'}}^* \varphi_{N0}$. To decompose Ψ_N, we suppose that $\mathbf{k}$ space is divided into elements, $\Delta\mathbf{k}$, with $\mathfrak{U}_{\mathbf{k}}$ available states of which in a typical configuration m_{k} are occupied by pairs. The m_{k} 's are restricted so that the total number of pairs is specified:

$$\sum_{\text{all } \Delta\mathrm{k}} m_{\mathrm{k}} = N = \sum_{\text{all } \Delta\mathrm{k}} \left\langle m_{\mathrm{k}} \right\rangle_{\mathrm{Av}} \tag{2.19}$$

The total weight of a given distribution of m_{k} 's in Ψ is

$$W\left(m_{\mathrm{k}}\right) = \prod_{\text{all } \Delta\mathrm{k}} \frac{\mathfrak{N}_k!}{m_{\mathrm{k}}!\left(\mathfrak{V}_{\mathrm{k}} - m_k\right)!} h_{\mathrm{k}}^{m_k} \left(1 - h_{\mathrm{k}}\right)^{\mathfrak{N}_{\mathrm{k}} - m_{\mathrm{k}}} \tag{2.20}$$

and the total weight of functions with specified N is

$$W_N = \sum_{(\Sigma m_{\mathrm{k}}=N)} W\left(m_{\mathrm{k}}\right) \tag{2.21}$$

where the sum is over-all distributions of the m_{k} 's subject to the conditions (2.19).

The decomposition of Ψ_N into a part in which a specified pair state $\mathbf{k}'$ is occupied and one where it is not can be carried out by calculating from Ψ_N the total weight, $W_{N,\mathrm{k}'}$, corresponding to $\mathbf{k}'$ occupied with the restriction $\sum m_{\mathrm{k}} = N$. When $\mathbf{k}'$ is occupied, there are $\mathscr{C}_{k'} - 1$ other states in the cell over which the remaining $m_{\mathrm{k}'} - 1$ particles can be distributed and this cell will contribute a factor

$$\frac{(\mathfrak{C}_{\mathfrak{k}'} - 1)! h_{\mathfrak{k}'}, m_{\mathfrak{k}'} \left(1 - h_{\mathfrak{k}'}\right)^{\mathfrak{C}_{\mathfrak{k}'} - m_{\mathfrak{k}'}}}{\left(m_{\mathfrak{k}'} - 1\right)! \left(\mathfrak{l}_{\mathfrak{k}'} - m_{\mathfrak{k}'}\right)!} \tag{2.22}$$

to the weight for a given distribution of m_{k} 's. It follows that

$$W_{N,\mathrm{k}'} = \sum_{(\Sigma m_{\mathrm{k}}=N)} \frac{m_{\mathrm{k}'}}{\mathfrak{T}_{\mathrm{k}'}} W\left(m_{\mathrm{k}}\right) = h_{\mathrm{k}'} W_N. \tag{2.23}$$

The last equality holds except for terms which vanish in the limit of a large system because the state vector Ψ gives a probability $\left\langle m_{\mathrm{k}'} / \mathscr{T}_{\mathrm{k}'} \right\rangle_{\mathrm{Av}} = h_{\mathrm{k}'}$ that a given state in $\Delta\mathbf{k}'$ is occupied. Now the weights for different numbers of pairs in Ψ are strongly peaked about the most probable number N and therefore the average over distributions with exactly N pairs is essentially equal to the average over all distributions. Since all terms in the wave function come in with a positive sign, it follows that the normalized Ψ_N may be decomposed in the form

$$\Psi_N = {h_{\mathrm{k}'}}^{\frac{1}{2}} \varphi_{N1} + \left(1 - h_{\mathrm{k}'}\right)^{\frac{1}{2}} \varphi_{N0} \tag{2.24}$$

where φ_{N1} and φ_{N0} are normalized functions.
For purposes of calculating matrix elements and

interaction energies, a further decomposition into states in which occupancy of two pair states, $\mathbf{k}$ and $\mathbf{k}'$, is specified is often convenient. Thus we may write:

$$\begin{aligned} \Psi_N = (hh')^{\frac{1}{2}} \varphi_{N11} + \left[h\left(1 - h'\right)\right]^{\frac{1}{2}} \varphi_{N10} + \left[(1 - h)h'\right]^{\frac{1}{2}} \varphi_{N01} \\ + \left[(1 - h)\left(1 - h'\right)\right]^{\frac{1}{2}} \varphi_{N00} \end{aligned} \tag{2.25}$$

where the first index gives the occupancy of $\mathbf{k}$ and the second of $\mathbf{k}'$. It follows from the definition of the functions that

$$b_{\mathrm{k}'}, {}^*b_{\mathrm{k}} \varphi_{N10} = \varphi_{N01} \tag{2.26}$$

Thus the diagonal matrix element of $b_{\mathrm{k}'} * b_{\mathrm{k}}$ is

$$\left(\Psi_N \left| {b_{\mathrm{k}'}}^* b_{\mathrm{k}} \right| \Psi_N\right) = \left[h_{\mathrm{k}}\left(1 - h_{\mathrm{k}}\right) h_{\mathrm{k}'}\left(1 - h_{\mathrm{k}'}\right)\right]^{\frac{1}{2}} \tag{2.27}$$

Ground-State Energy

If the wave function (2.24) is used as a variational approximation to the true ground-state function, the ground-state energy relative to the energy of the Fermi sea is given by

$$W_0 = \left(\Psi_0, H_{\mathrm{red}} \Psi_0\right) \tag{2.28}$$

[32] It is easily seen that Ψ_N has zero total spin, corresponding to a singlet state.

where Ψ_0 is the N-pair function Ψ_N, for the ground state. The Bloch energies, ϵ_{k}, are measured with respect to the Fermi energy and

$$-V_{\mathbf{k}\mathbf{k}'} = (-\mathbf{k}'\downarrow, \mathbf{k}'\uparrow|\ H_I\ |-\mathbf{k}\downarrow, \mathbf{k}\uparrow) + (\mathbf{k}'\uparrow, -\mathbf{k}'\downarrow|H_I|\,\mathbf{k}\uparrow, -\mathbf{k}\downarrow)\,. \tag{2.29}$$

The decomposition (2.23) leads to the Bloch energy contribution to W_0 of the form

$$W_{\mathrm{KE}} = 2\sum_{k>k_F} \epsilon_{\mathrm{k}} h_{\mathrm{k}} + 2\sum_{k<k_F} |\epsilon_{\mathrm{k}}|\,(1-h_{\mathrm{k}}) \tag{2.30}$$

where "KE" stands for kinetic energy. The matrix elements of the interaction term in H_{red} are given by (2.27) and the interaction energy is

$$W_I = -\sum_{\mathbf{k},\mathbf{k}'} V_{\mathbf{k}\mathbf{k}'} \left[h_{\mathbf{k}}\,(1-h_{\mathbf{k}})\,h_{\mathrm{k}'}\,(1-h_{\mathrm{k}'})\right]^{\frac{1}{2}} \tag{2.31}$$

and therefore

$$W_0 = W_{\mathrm{KE}} + W_I = 2\sum_{k>k_F} \epsilon_{\mathrm{k}} h_{\mathrm{k}} + 2\sum_{k<k_F} |\epsilon_{\mathrm{k}}|\,(1-h_{\mathrm{k}}) - \sum_{\mathbf{k},\mathbf{k}'} V_{\mathrm{k}\mathbf{k}'} \left[h_{\mathrm{k}}\,(1-h_{\mathrm{k}})\,h_{\mathrm{k}'}\,(1-h_{\mathrm{k}'})\right]^{\frac{1}{2}}. \tag{2.32}$$

By minimizing W_0 with respect to h_{k}, we are led to an integral equation determining the distribution function:

$$\frac{\left[h_{\mathrm{k}}\,(1-h_{\mathrm{k}})\right]^{\frac{1}{2}}}{1-2h_{\mathrm{k}}} = \frac{\sum_{\mathrm{k}'} V_{\mathrm{k}\mathrm{k}'} \left[h_{\mathrm{k}'}\,(1-h_{\mathrm{k}'})\right]^{\frac{1}{2}}}{2\epsilon_{\mathrm{k}}}. \tag{2.33}$$

We shall neglect anisotropic effects and assume for simplicity that the matrix element $V_{\mathbf{k}\mathbf{k}}$, can be replaced by a constant average matrix element,

$$V = \langle V_{\mathrm{k}\mathrm{k}\mathbf{k}'}\rangle_{\mathrm{Av}}\,, \tag{2.34}$$

for pairs making transitions in the region $-\hbar\omega < \epsilon < \hbar\omega$
and by zero outside this region, where ω is the average phonon frequency. This cutoff corresponds to forming our wave function from states in the region where the interaction is expected to be attractive and not mixing in states outside this region. The average is primarily one over directions of $\mathbf{k}$ and $\mathbf{k}'$ since the interaction is insensitive to the excitation energy for those transitions of importance in describing the superconducing phase. The average may also be viewed as choosing h to be a function of energy alone, thus neglecting the details of band structure. The laws of similarity indicate this to be a reasonable assumption and the good agreement of our theory with a wide class of superconductors supports this view.

Introduction of the average matrix element into (2.33) leads to

$$h_{\mathrm{k}} = \frac{1}{2}\left[1 - \frac{\epsilon_{\mathrm{k}}}{(\epsilon_{\mathrm{k}}^2 + \epsilon_0^2)^{\frac{1}{2}}}\right], \tag{2.35}$$

and

$$\left[h_{\mathrm{k}}\,(1-h_{\mathrm{k}})\right]^{\frac{1}{2}} = \frac{\epsilon_0}{2\,(\epsilon_{\mathrm{k}}^2 + \epsilon_0^2)^{\frac{1}{2}}}, \tag{2.36}$$

where

$$\epsilon_0 = V \sum_{\mathrm{k}'} \left[h_{\mathrm{k}'} \left(1 - h_{\mathrm{k}'}\right)\right]^{\frac{1}{2}}, \tag{2.37}$$

the sum extending over states within the range $|\epsilon_{\mathrm{k}}| < \hbar\omega$. If (2.36) and (2.37) are combined, one obtains a condition on ϵ_0 :

$$\frac{1}{V} = \sum_{\mathbf{k}} \frac{1}{2\left(\epsilon_{\mathbf{k}}^2 + \epsilon_0^2\right)^{\frac{1}{2}}} \tag{2.38}$$

Replacing the sum by an integral and recalling that $V = 0$ for $|\epsilon_{\mathrm{k}}| > \hbar\omega$, we may replace this condition by

$$\frac{1}{N(0)V} = \int_0^{\hbar\omega} \frac{d\epsilon}{\left(\epsilon^2 + \epsilon_0^2\right)^{\frac{1}{2}}} \tag{2.39}$$

Solving for ϵ_0, we obtain

$$\epsilon_0 = \hbar\omega / \sinh\left[\frac{1}{N(0)V}\right] \tag{2.40}$$

where $N(0)$ is the density of Bloch states of one spin per unit energy at the Fermi surface.

The ground state energy is obtained by combining the expressions for h_{k} and ϵ_0, (2.35), (2.36), and (2.37), with (2.32). We find

$$\begin{aligned} W_0 &= 4N(0) \int_0^{\hbar\omega} \epsilon h(\epsilon) d\epsilon - \frac{\epsilon_0^2}{V} \\ &= 2N(0) \int_0^{\hbar\omega} \left[\epsilon - \frac{\epsilon^2}{\left(\epsilon^2 + \epsilon_0^2\right)^{\frac{1}{2}}}\right] d\epsilon - \frac{\epsilon_0^2}{V} \end{aligned} \tag{2.41}$$

where we have used the fact that $[1 - h(-\epsilon)] = h(\epsilon)$, that is, the distribution function is symmetric in electrons and holes with respect to the Fermi surface.

Using the relations (2.40), we find that the difference in energy between the superconducting and normal states at the absolute zero becomes
$W_0 = N(0)(\hbar\omega)^2 \left\{1 - \left[1 + \left(\frac{\epsilon_0}{\hbar\omega}\right)^2\right]^{\frac{1}{2}}\right\} = \frac{-2N(0)(\hbar\omega)^2}{e^{[2/N(0)V]} - 1}$.

If there is a net negative interaction on the average, no matter how weak, there exists a coherent state which is lower in energy than the normal state. Thus our criterion for superconductivity is that $V > 0$, as given in (2.6).

For excitations which are small compared to $\hbar\omega$, the phonon interaction is essentially independent of isotopic mass and therefore the total mass dependence of W_0 comes from $(\hbar\omega)^2$, in agreement with the isotope effect. Empirically, W_0 is of the order of $N(0)\left(kT_c\right)^2$ and in general kT_c is much less than $\hbar\omega$. According to (2.42), this will occur if $N(0)V < 1$, that is, the weak coupling limit.

It should be noted that the ground state energy cannot be obtained in any finite-order perturbation theory. In the strong-coupling limit, (2.42) gives the correct result, $-N(0)(\hbar\omega)^2 V$, for the average interaction approximation and it is possible that our solution is accurate in the statistical limit over the entire range of coupling. (See Appendix A.)

In the weak-coupling limit, the energy becomes

$$W_0 = -2N(0)(\hbar\omega)^2 \exp\left[-\frac{2}{N(0)V}\right] \tag{2.43}$$

which may be expressed in terms of the number of electrons, n_c, in pairs virtually excited above the Fermi surface as

$$W_0 = -\frac{1}{2} n_c^2 / N(0), \tag{2.44}$$

where

$$n_c = 2N(0)\hbar\omega \exp\left[-\frac{1}{N(0)V}\right] \tag{2.45}$$

In this form, the cooperative nature of the ground state is evident. Using the empirical order of magnitude relation between W_0 and kT_c, we might estimate

$$kT_c \sim \hbar\omega \exp\left[-\frac{1}{N(0)V}\right]. \tag{2.46}$$

In the next chapter we shall see that the explicit calculation of kT_c from the free energy as a function of temperature leads to nearly this result.

Energy gap at $T = 0°\mathrm{K}$

An important feature of the reduced Hamiltonian is that there are no excitations from the ground state, analogous to single-particle excitations of the Bloch theory, with vanishing excitation energy. This is easily
seen by considering a function

$$\Psi_{\mathrm{exc}} = \left\{ \prod_{\mathrm{k} \neq \mathrm{k}', \mathrm{k}''} \left[(1 - h_{\mathrm{k}})^{\frac{1}{2}} + h_{\mathrm{k}^2}^{\frac{1}{2}} b_{\mathrm{k}} * \right] \right\} c_{-\mathrm{k}'\downarrow} * c_{\mathrm{k}'\prime\uparrow} * \Phi_0 \tag{2.47}$$

which is orthogonal to the ground state function and corresponds to breaking up a pair in $\mathbf{k}'$, the spin-up member going to $\mathbf{k}'' \uparrow$. The projection of Ψ_{exc} onto the space with N pairs is also orthogonal to Ψ_0. The decomposition of $\Psi_{N\,\mathrm{exc}}$ is the same as that of Ψ_0, except that $-\mathbf{k}' \downarrow$ and $\mathbf{k}'' \uparrow$ are definitely known to be occupied and $\mathbf{k}' \uparrow$ and $-\mathbf{k}'' \downarrow$ are unoccupied. This leads to the excitation energy

$$\begin{aligned} W_{\mathbf{k}',\mathbf{k}''} - W_0 = {} & \epsilon_{\mathrm{k}'} (1 - 2h_{\mathrm{k}'}) + \epsilon_{\mathrm{k}''} (1 - 2h_{\mathrm{k}''}) \\ & + 2V \sum_{\mathbf{k}} \left[h_{\mathrm{k}} (1 - h_{\mathrm{k}}) \right]^{\frac{1}{2}} \left\{ \left[h_{\mathrm{k}'} (1 - h_{\mathrm{k}'}) \right]^{\frac{1}{2}} \right. \\ & \left. + \left[h_{\mathrm{k}''} (1 - h_{\mathrm{k}''}) \right]^{\frac{1}{2}} \right\} \end{aligned} \tag{2.48}$$

the decrease in interaction energy arising from the fact that pairs cannot make transitions into or out of pair states $\mathbf{k}'$ and $\mathbf{k}''$ in the excited function because these states are occupied by single particles. Combining (2.35), (2.36), and (2.37) with (2.48), we find

$$\begin{aligned} W_{\mathrm{k}',\mathrm{k}''} - W_0 = {} & \frac{{\epsilon_{\mathrm{k}'}}^2}{E_{\mathrm{k}'}} + \frac{{\epsilon_{\mathrm{k}''}}^2}{E_{\mathrm{k}''}} + \epsilon_0^2 \left(\frac{1}{E_{\mathrm{k}'}} + \frac{1}{E_{\mathrm{k}''}} \right) \\ & = E_{\mathrm{k}'} + E_{\mathrm{k}''} \end{aligned} \tag{2.49}$$

where

$$E_{\mathrm{k}} = \left(\epsilon_{\mathrm{k}}^2 + \epsilon_0^2 \right)^{\frac{1}{2}} \tag{2.50}$$

When $\epsilon_k \to 0$, then $E_k \to \epsilon_0$ and (2.49) shows that the minimum excitation energy is $2\epsilon_0$. These single-particlelike excitations have the new dispersion law (2.50) which goes over to the normal law when $\epsilon_k \gg \epsilon_0$.

To obtain a complete set of excitations, we must include excited state pair functions generated by

$$\left[(1-h_k)^{\frac{1}{2}} b_k^* - h_k^{\frac{1}{2}}\right], \tag{2.51}$$

which by construction are orthogonal to the ground state pair functions generated by

$$\left[(1-h_k)^{\frac{1}{2}} + h_k^{\frac{1}{2}} b_k^*\right]. \tag{2.52}$$

The decomposition of an excited state with an excited pair in $\mathbf{k}'$ and a ground pair in $\mathbf{k}$ would be

$$\begin{aligned}\Psi_{k'} = {} & [h_k (1-h_{k'})]^{\frac{1}{2}} \varphi_{11} - [h_k h_{k'}]^{\frac{1}{2}} \varphi_{10} \\ & + [(1-h_k)(1-h_{k'})]^{\frac{1}{2}} \varphi_{01} - [(1-h_k) h_{k'}]^{\frac{1}{2}} \varphi_{00}\end{aligned} \tag{2.53}$$

where the functions φ are normalized and the second script denotes the occupancy of $\mathbf{k}'$. Taking the expectation value of H_{red} with respect to (2.53), we find the energy to form an excited pair in state $\mathbf{k}'$ is:

$$\begin{aligned}W_{k'} - W_0 = {} & 2\epsilon_{k'}(1-2h_{k'}) \\ & + 4V \sum_k [h_k (1-h_k) h_{k'} (1-h_{k'})]^{\frac{1}{2}} = 2E_{k'}\end{aligned} \tag{2.54}$$

Again the minimum energy required to form an excitation is $2\epsilon_0$ and an energy gap of width $2\epsilon_0$ appears in
the excitation spectrum in a natural way. It follows that in general the energy difference between two states, 1 and 2, is given by the difference in the sums of the excited-particle energies,

$$W_1 - W_2 = \sum_1 E_k - \sum_2 E_k \tag{2.55}$$

and it is unnecessary to distinguish between single particles and two members of an excited pair in calculating the sums.

Collective excitations corresponding to long-range density fluctuations are suppressed by the subsidiary condition on the wave function resulting from the collective description of the electron-ion interaction. [16] The effect of the terms neglected in the Hamiltonian, $H - H_{\text{red}} = H'$, can be estimated by a perturbation expansion of H' in eigenfunctions of H_{red}. This expansion is carried out to second order in Appendix A and it is concluded that H' will contribute little to the condensation energy. The shift in the zero-point energy of the lattice associated with the transition at the absolute zero is estimated in Appendix B and it is shown that this effect contributes a small correction to W_0. The electron self-energy shift has not been calculated at the present time; however, it is also believed that the correction is small.

3.10.8 Original 1957 BCS Paper: Excited States

III. EXCITED STATES

An excited state of the system will be formed by specifying the set of states, $\mathcal{S}$, which are occupied by single particles and the set of states, $\mathcal{P}$, occupied by excited pairs. The rest

of the states, $\mathcal{G}$, will be available for occupation by ground pairs. The term "singleparticle" occupation means that either $\mathbf{k}\uparrow$ or $-\mathbf{k}\downarrow$ is occupied by an electron, but not both. "Excited pair" and "ground pair" occupation refers to pairs which are in functions generated by operators of the form (2.51) and (2.52) respectively. Wave functions with different distributions of single particles and excited pairs are orthogonal to each other and the totality of such functions constitutes a complete set of excited states which are in one-to-one correspondence with the Bloch-type excitations in the normal metal.

The energy of the excited states will be evaluated by using the reduced Hamiltonian plus the Bloch energy for single particles:

$$H_e = \sum_{k>k_F,\sigma} \epsilon_{\mathrm{k}} n_{\mathrm{k}\sigma} + \sum_{k<k_F,\sigma} |\epsilon_{\mathrm{k}}| \left(1 - n_{\mathrm{k}\sigma}\right) - \sum_{\mathbf{k},\mathbf{k}'} V_{\mathbf{k}\mathbf{k}'} b_{\mathbf{k}'} * b_{\mathbf{k}} \tag{3.1}$$

where the second term gives the Bloch energy of the holes and the energies ϵ_{k} are measured relative to the Fermi energy. Since H_I contains only terms for transitions by ground pairs and excited pairs, the single particles contribute only to the Bloch energy and hence they are treated as in the Bloch scheme.

The equilibrium condition of the system at a specified temperature will be determined by minimizing the free
energy with respect to the distribution function for excited particles, f, and ground pairs, h.

It turns out that h_{k} is a function of temperature and therefore excited and ground pairs are not necessarily orthogonal to each other at different temperatures, although the excited states form a complete orthonormal set at each temperature. The most probable distribution of single particles also varies with temperature and thus the great majority of states contributing to the free energy at different temperatures will be orthogonal in any event. The situation is similar to taking the lattice constant temperature dependent as a result of thermal expansion. This freedom in choosing h_{k} allows us to work in that representation which minimizes the free energy at the specified temperature.

A typical excited state wave function can be written as the projection of

$$\Psi_{\mathrm{exc}} = \prod_{\mathbf{k}(\mathcal{G})} \left[(1-h_{\mathrm{k}})^{\frac{1}{2}} + h_{\mathrm{k}^2}^{\frac{1}{2}} b_{\mathrm{k}^2}^*\right] \prod_{\mathbf{k}'(\mathcal{P})} \left[(1-h_{\mathrm{k}'})^{\frac{1}{2}} b_{\mathrm{k}'}{}^* - h_{\mathrm{k}'}^{\frac{3}{2}}\right] \prod_{\mathbf{k}''(\mathcal{S})} c_{(\mathrm{k}'')^*\Phi_0} \tag{3.2}$$

onto the space with N pairs, where $\mathcal{G}, \mathcal{P}$, and $\mathcal{S}$ specify the states occupied by ground pairs, excited pairs, and single particles respectively and $c_{(\mathrm{k}'')}{}^*$ denotes either $\mathbf{k}''\uparrow$ or $-\mathbf{k}''\downarrow$ is included in the product. For any specified $\mathbf{k}$, this function can be decomposed into a portion with $\mathbf{k}$ occupied and a portion with $\mathbf{k}$ unoccupied. The decompositions for the three cases in which $\mathbf{k}$ is in the sets $\mathcal{G}, \mathcal{P}$, and $\mathcal{S}$ are
Ground:

$$\Psi = h_{\mathrm{k}}^{\frac{1}{2}} \varphi_1 \left(\cdots 1_{\mathrm{k}} \cdots\right) + (1-h_{\mathrm{k}})^{\frac{1}{2}} \varphi_0 \left(\cdots 0_{\mathrm{k}} \cdots\right), \tag{3.3}$$

Excited:

$$\Psi = (1-h_{\mathrm{k}})^{\frac{1}{2}} \varphi_1 \left(\cdots 1_{\mathrm{k}} \cdots\right) - h_{\mathrm{k}^2}^{\frac{1}{2}} \varphi_0 \left(\cdots 0_{\mathrm{k}} \cdots\right), \tag{3.4}$$

Single in $\mathbf{k}\uparrow$:

$$\Psi = c_{\mathrm{k}}\uparrow^{*}\varphi_0\left(\cdots 0_{\mathrm{k}}\cdots\right), \tag{3.5}$$

where the φ 's are normalized functions with 1_{k} representing pair state k being occupied and 0_{k} unoccupied.

To determine the distribution functions, we need the free energy

$$F = W - TS \tag{3.6}$$

where W is the energy calculated by an ensemble average over the wave functions of the form (3.2) and S is the entropy.

To enumerate the systems in the ensemble we divide k-space into cells $\Delta\mathbf{k}$ containing $\mathfrak{I}_k$ pair states as before. Let there be S_{k} single particles and P_{k} excited pairs in $\Delta\mathbf{k}$, with the rest of the $\mathfrak{N}_{\mathbf{k}}$ states being occupied by ground pairs. The probability that either $\mathbf{k}\uparrow$ or $-\mathbf{k}\downarrow$ is occupied by a single particle is $s_{\mathrm{k}} = S_{\mathrm{k}}/\mathfrak{V}_{\mathrm{k}}$, while the probability for an excited pair in state $\mathbf{k}$ is $p_{\mathrm{k}} = P_{\mathrm{k}}/\mathscr{C}_{\mathrm{k}}$ and therefore the probability for a ground pair is $(1 - s_k - p_k)$. Above the Fermi surface, $h < \frac{1}{2}$ and s
and p refer to excited electrons; below the Fermi surface, $h > \frac{1}{2}$ and s and p refer to holes.

The diagonal element of $n_{\mathrm{k}\sigma}$ follows immediately from (3.3), (3.4), and (3.5). Including the factor giving fractional number of configurations for which each decomposition applies, we have

$$\begin{aligned}
(\psi\,|n_{\mathrm{k}\sigma}|\,\psi) &= (1/2)s_{\mathrm{k}} + p_{\mathrm{k}}\,(1-h_{\mathrm{k}}) \\
&\quad + (1 - s_{\mathrm{k}} - p_{\mathrm{k}})\,h_{\mathrm{k}}, \quad \epsilon > 0; \\
(\psi\,|1-n_{\mathrm{k}\sigma}|\,\psi) &= (1/2)s_{\mathrm{k}} + p_{\mathrm{k}}h_{\mathrm{k}} \\
&\quad + (1 - s_{\mathrm{k}} - p_{\mathrm{k}})\,(1-h_{\mathrm{k}}), \quad \epsilon < 0.
\end{aligned} \tag{3.7}$$

Upon using (3.7) and the fact that $1 - h_{\mathrm{k}}(-\epsilon) = h_{\mathrm{k}}(\epsilon)$, the Bloch energy contribution to W,

$$\left(\psi\left|\sum_{\mathrm{k}>k_F\sigma}\epsilon_{\mathrm{k}}n_{\mathrm{k}\sigma} + \sum_{\mathrm{k}<k_F\sigma}\right|\epsilon_{\mathrm{k}}\,|(1-n_{\mathrm{k}\sigma})|\,\psi\right), \tag{3.8}$$

becomes
$W_{\mathrm{KE}} = \sum_{\mathrm{k}}|\epsilon_{\mathrm{k}}|\,[s_{\mathrm{k}} + 2p_{\mathrm{k}} + 2\,(1 - s_{\mathrm{k}} - 2p_{\mathrm{k}})\,h_{\mathrm{k}}\,(|\epsilon_{\mathrm{k}}|)]$,
where we have carried out the spin sum.

To calculate the matrix elements of the pair interaction operator $\sum V_{\mathrm{kk}'}b_{\mathrm{k}'}{}^{*}b_{\mathrm{k}}$, we assume that $V_{\mathrm{kk}'}$ varies continuously with $\mathbf{k}$ and $\mathbf{k}'$ so that $V_{\mathbf{kk}'}$ may be considered to be the same for all transitions from states in $\Delta\mathbf{k}$ to states in $\Delta\mathbf{k}'$. Let $\mathbf{k}$ and $\mathbf{k}'$ represent two specified wave vectors in $\Delta\mathbf{k}$ and $\Delta\mathbf{k}'$. To obtain nonvanishing matrix elements for $b_{\mathrm{k}'}{}^{*}b_{\mathrm{k}}$, these states must be occupied by either excited (-) or ground (+) pairs, giving the four possibilities,,,+−+−+− for $\mathbf{k}$ and $\mathbf{k}'$, respectively. For any one of these cases, a typical wave function may be decomposed into components in which the pair occupancy of $\mathbf{k}$ and $\mathbf{k}'$ is specified:

$$\begin{aligned}
\Psi_{\mathrm{k},\mathrm{k}'} = \alpha_{11}\varphi_{11}(&\cdots 1_{\mathrm{k}}\cdots 1_{\mathrm{k}'}\cdots) \\
&+ \alpha_{10}\varphi_{10}\,(\cdots 1_{\mathrm{k}}\cdots 0_{\mathrm{k}'}\cdots) \\
&+ \alpha_{01}\varphi_{01}\,(\cdots 0_{\mathrm{k}}\cdots 1_{\mathrm{k}'}\cdots) \\
&+ \alpha_{00}\varphi_{00}\,(\cdots 0_{\mathrm{k}}\cdots 0_{\mathrm{k}'}\cdots)
\end{aligned} \tag{3.10}$$

where the φ 's are normalized functions. Table I gives the values of the α 's for the different cases along with the fractional number of configurations for which they apply.

The diagonal elements of $b_{\mathrm{k}'}, {}^{*}b_{\mathrm{k}}$ are given by $\alpha_{10}\alpha_{01}$ in each case. If we sum these, weighted according to the probability they occur in the ensemble, we obtain

$$\begin{aligned}
&[h(1-h)h'(1-h')]^{\frac{1}{2}}\{(1-s-p)(1-s'-p') \\
&+pp'-(1-s-p)p'-p(1-s'-p')\} \\
&\quad=[h(1-h)h'(1-h')]^{\frac{1}{2}} \\
&\quad\times\{(1-s-2p)(1-s'-2p')\} \qquad (3.11)
\end{aligned}$$

Introducing these matrix elements into the ensemble average of the interaction Hamiltonian, we find

$$\begin{aligned}
W_I=-\sum_{\mathrm{k},\mathrm{k}'}V_{\mathrm{k}\mathrm{k}'}&[h_{\mathrm{k}}(1-h_{\mathrm{k}})h_{\mathrm{k}'}(1-h_{\mathrm{k}'})]^{\frac{1}{2}} \\
&\times\{(1-s_{\mathrm{k}}-2p_{\mathrm{k}})(1-s_{\mathrm{k}'}-2p_{\mathrm{k}'})\}. \qquad (3.12)
\end{aligned}$$

Table I. Coefficients for the decomposition of Ψ according to Eq. (3.10).

Wave function						
k	$\mathbf{k'}$	Fractional No. of cases	α_{11}	$\boldsymbol{\alpha_{10}}$	α_{01}	α_{00}
+	+	$(1-s-p)(1-s'-p')$	$[hh']^{\frac{1}{2}}$	$[h(1-h')]^{\frac{1}{2}}$	$[(1-h)h']^{\frac{1}{2}}$	$[(1-h)($
-	-	pp'	$[(1-h)(1-h')]^{\frac{1}{2}}$	$-[(1-h)h']^{\frac{1}{2}}$	$-[h(1-h')]^{\frac{1}{2}}$	$[hh']^{\frac{1}{2}}$
+	-	$(1-s-p)p'$	$[h(1-h')]^{\frac{1}{2}}$	$-[hh']^{\frac{1}{2}}$	$[(1-h)(1-h')]^{\frac{1}{2}}$	$-[(1-h$
-	+	$p(1-s'-p')$	$[(1-h)h']^{\frac{1}{2}}$	$[(1-h)(1-h')]^{\frac{1}{2}}$	$-[hh']^{\frac{1}{2}}$	$-[h(1-$

It should be noted that the Bloch energy (3.9) and the interaction energy (3.12) depend on ($s+2p$) or the total occupancy probability. The energy does not depend upon the relative probability for single-particle and excited-pair occupation. Thus one may use a distribution function f which gives the over-all probability of occupancy, where

$$s_{\mathrm{k}}=2f_{\mathrm{k}}(1-f_{\mathrm{k}}), \qquad (3.13)$$

and

$$p_{\mathrm{k}}=f_{\mathrm{k}}^2, \qquad (3.14)$$

which follows from the fact that s_{k} is the probability that either $\mathbf{k}\uparrow$ is occupied and $-\mathbf{k}\downarrow$ is empty or the reverse and $p_{\mathbf{k}}$ is the probability that both $\mathbf{k}\uparrow$ and $-\mathbf{k}\downarrow$ are occupied. The free energy can be minimized directly with respect to $h_{\mathrm{k}}, p_{\mathrm{k}}$, and s_{k} without introducing f_{k} and one indeed finds that (3.13) and (3.14) hold.

Since the excited particles are specified independently for each system in the ensemble, the usual expression for the entropy in terms of f may be used:
$-TS=2kT\sum_{\mathrm{k}'}\{f_{\mathrm{k}'}\ln f_{\mathrm{k}'}+(1-f_{\mathrm{k}'})\ln(1-f_{\mathrm{k}'})\}$.

Minimization of the Free Energy

If the expressions (3.13) and (3.14) are introduced into (3.9) and (3.12), the free energy becomes

$$F = 2\sum_{\mathbf{k}} |\epsilon_{\mathbf{k}}| \left[f_{\mathbf{k}} + (1-2f_{\mathbf{k}})\, h_{\mathbf{k}}\left(|\epsilon_{\mathbf{k}}|\right)\right]$$
$$- \sum_{\mathbf{k},\mathbf{k}'} V_{\mathbf{k}\mathbf{k}'} \left[h_{\mathbf{k}}\left(1-h_{\mathbf{k}}\right) h_{\mathbf{k}'}\left(1-h_{\mathbf{k}'}\right)\right]^{\frac{1}{3}}$$
$$\times \left\{\left(1-2f_{\mathbf{k}}\right)\left(1-2f_{\mathbf{k}'}\right)\right\} - TS \tag{3.16}$$

When we minimize F with respect to h_{k}, we find that

$$2\epsilon_{\mathrm{k}} - \sum_{\mathrm{k}'} V_{\mathrm{k}\mathrm{k}'} \left[h_{\mathrm{k}'}\left(1-h_{\mathrm{k}'}\right)\right]^{\frac{1}{2}} \left(1-2f_{\mathrm{k}'}\right)$$
$$\times \frac{\left(1-2h_{\mathrm{k}}\right)}{\left[h_{\mathrm{k}}\left(1-h_{\mathrm{k}}\right)\right]^{\frac{1}{2}}} = 0, \tag{3.17}$$

or

$$\frac{\left[h_{\mathrm{k}}\left(1-h_{\mathrm{k}}\right)\right]^{\frac{1}{2}}}{1-2h_{\mathrm{k}}} = \sum_{\mathrm{k}'} \frac{V_{\mathrm{k}\mathrm{k}'}\left[h_{\mathrm{k}'}\left(1-h_{\mathrm{k}'}\right)\right]^{\frac{1}{2}}\left(1-2f_{\mathrm{k}'}\right)}{2\epsilon_{\mathrm{k}}}, \tag{3.18}$$

where the energy ϵ_{k} is measured relative to the Fermi energy and $\epsilon_{\mathrm{k}} < 0$ for $k = k_F$. Assuming as before that the interaction can be replaced by a constant average matrix element $-V$, defined by (2.34) for $|\epsilon_{\mathrm{k}}| < \hbar\omega$ and by zero outside this region, it follows that h_{k} is again of the form

$$h_{\mathrm{k}} = \frac{1}{2}\left[1 - \left(\epsilon_{\mathrm{k}}/E_{\mathrm{k}}\right)\right], \tag{3.19}$$

and

$$\left[h_{\mathrm{k}}\left(1-h_{\mathrm{k}}\right)\right]^{\frac{1}{2}} = \frac{1}{2}\epsilon_0/E_{\mathrm{k}}. \tag{3.20}$$

The energy E_{k}, a positive definite quantity, is defined as

$$E_{\mathrm{k}} = +\left(\epsilon_{\mathrm{k}}^2 + \epsilon_0^2\right)^{\frac{1}{2}}, \tag{3.21}$$

where

$$\epsilon_0 = V\sum_{\mathrm{k}'} \left[h_{\mathrm{k}'}\left(1-h_{\mathrm{k}'}\right)\right]^{\frac{1}{2}}\left(1-2f_{\mathrm{k}'}\right) \tag{3.22}$$

It will turn out that $2\epsilon_0$ is the magnitude of the energy gap in the single-particle density of states and therefore the distribution of ground pairs is determined by the magnitude of the gap at that temperature.

When we minimize F with respect to f_{k}, we find that

$$2\epsilon_{\mathrm{k}}\left(1-2h_{\mathrm{k}}\right) + 4\sum_{\mathrm{k}'} V_{\mathrm{k}\mathrm{k}'}\left[h_{\mathrm{k}'}\left(1-h_{\mathrm{k}'}\right) h_{\mathrm{k}}\left(1-h_{\mathrm{k}}\right)\right]^{\frac{1}{2}}$$
$$\times\left(1-2f_{\mathrm{k}'}\right) + 2kT\ln\left(f_{\mathrm{k}}/\left(1-f_{\mathrm{k}}\right)\right) = 0 \tag{3.23}$$

and using (3.19) through (3.22), we find that

$$-\ln\left(f_{\mathrm{k}}/\left(1-f_{\mathrm{k}}\right)\right)=\beta\left[\frac{\epsilon_{\mathrm{k}}^{2}}{E_{\mathrm{k}}}+\frac{\epsilon_{0}^{2}}{E_{\mathrm{k}}}\right]=\beta E_{\mathrm{k}} \tag{3.24}$$

where $\beta = 1/kT$ and E_{k} is a positive quantity. The solution for f_k is

$$f_{\mathrm{k}}=\frac{1}{e^{\beta E_{\mathrm{k}}}+1}=f\left(E_{\mathrm{k}}\right). \tag{3.25}$$

Thus the single particles and excited pairs describe a set of independent fermions with the modified dispersion law (3.21). For $k > k_F$, f_{k} specifies electron occupation while for $k < k_F$, f_{k} specifies hole occupation. These electrons and holes are identified with the normal component of the two-fluid model.

When $\epsilon_{\mathrm{k}} \to 0^{+}$, then $E_{\mathrm{k}} \to \epsilon_0$ for the electron and when $\epsilon_{\mathrm{k}} \to 0^{-}$, then $E_{\mathrm{k}} \to \epsilon_0$ for the hole or the corresponding electron energy $\to -\epsilon_0$. Thus the new density of states has an energy gap of magnitude $2\epsilon_0$ centered about the Fermi energy. The modified density of states is given by

$$\frac{dN(E)}{dE}=\frac{dN(\epsilon)}{d\epsilon}\frac{d\epsilon}{dE}=N(0)\frac{E}{\left(E^{2}-\epsilon_{0}^{2}\right)^{\frac{1}{2}}}, \tag{3.26}$$

which is singular at the edges of the gap, $E = \epsilon_0$. The total number of states is of course unaltered by the interaction.

If the distribution functions (3.19) and (3.25) are introduced, the condition determining the energy gap

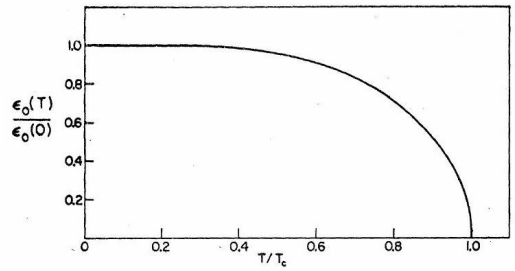

Fig. 1. Ratio of the energy gap for single-particle-like excitations to the gap at $T = 0°\mathrm{K}$ vs temperature.

(3.22) becomes (dividing by ϵ_0)

$$\frac{1}{N(0)V}=\int_{0}^{\hbar\omega}\frac{d\epsilon}{\left(\epsilon^{2}+\epsilon_{0}^{2}\right)^{\frac{1}{2}}}\tanh\left[\frac{1}{2}\beta\left(\epsilon^{2}+\epsilon_{0}^{2}\right)^{\frac{1}{2}}\right] \tag{3.27}$$

where we have replaced the sum by an integral and used the fact that the distribution functions are symmetric in holes and electrons with respect to the Fermi energy. The transition temperature, T_c, is defined as the boundary of the region beyond which there is no real, positive ϵ_0 which satisfies (3.27). Above T_c therefore, $\epsilon_0 = 0$ and $f\left(E_{\mathrm{k}}\right)$ becomes $f\left(\epsilon_{\mathrm{k}}\right)$, so that the metal returns to the normal state. Below T_c the solution of (3.27), $\epsilon_0 \neq 0$, minimizes the free energy and we have the superconducting phase. Thus (3.26) can be used to determine the critical temperature and we find

$$\frac{1}{N(0)V}=\int_{0}^{\hbar\omega}\frac{d\epsilon}{\epsilon}\tanh\left(\frac{1}{2}\beta_{c}\epsilon\right) \tag{3.28}$$

or

$$kT_{c}=1.14\hbar\omega\exp\left[-\frac{1}{N(0)V}\right] \tag{3.29}$$

as long as $kT_c \ll \hbar\omega$, which corresponds to the weakcoupling case discussed in Sec. II. The transition temperature is proportional to $\hbar\omega$, which is consistent with the isotope effect. The small magnitude of T_c compared to the Debye temperature is presumably due to the cancellation of the phonon interaction and the screened Coulomb interaction for transitions of importance in describing the superconducting state, and the resulting effect of the exponential.

The transition temperature is a strong function of the electron concentration since the density of states enters exponentially. It should be possible to make estimates of the change in transition temperature with pressure, alloying, etc., from (3.29).

A plot of the energy gap as a function of temperature is given in Fig. 1. The ratio of the energy gap at $T = 0°\mathrm{K}$ to kT_c is given by combining (2.36) and (3.28):

$$2\epsilon_0/kT_c = 3.50 \tag{3.30}$$

From the law of corresponding states, this ratio is predicted to be the same for all superconductors. Near
T_c, the gap may be expressed as

$$\epsilon_0 = 3.2kT_c\,[1 - (T/T_c)]^{\frac{1}{2}} \tag{3.31}$$

which has the form suggested by Buckingham. [33]
It can be seen from the distribution functions that our theory goes over into the Bloch scheme above the transition temperature. As $T \to T_c, E_\mathrm{k} \to |\epsilon_\mathrm{k}|$, and h_k vanishes for $k > k_F$ and is unity for $k < k_F$. According to (3.4) the excited-pair function specifies complete electron occupancy for $k > k_F$ and complete hole occupancy for $k < k_F$ in this case. Thus, in the normal state, the ground pairs vanish above the Fermi surface and form the Fermi sea below, while the single particles and excited pairs combine to describe excited electrons for $k > k_F$ and excited holes for $k < k_F$.

Critical Field and Specific Heat

The critical field for a bulk specimen of unit volume is given by

$$H_c^2/8\pi = F_n - F_s \tag{3.32}$$

where F_n is the free energy of the normal state:

$$\begin{aligned} F_n &= -4N(0)kT\int_0^\infty d\epsilon \log(1 + e^{-\beta\epsilon}) \\ &= -\frac{1}{3}\pi^2 N(0)(kT)^2 \end{aligned} \tag{3.33}$$

With the aid of (3.25) the entropy in the superconducting state, (3.15) may be expressed as

$$TS = 4kT\sum_{k>k_F}\left[\ln\left(1 + e^{-\beta E_\mathrm{k}}\right) + \beta E_\mathrm{k} f_\mathrm{k}\right] \tag{3.34}$$

Replacing the sum by an integral and performing a partial integration, we find

$$TS = 4N(0)\int_0^\infty d\epsilon \left[\frac{\epsilon^2}{E} + E\right] f(\beta E) \tag{3.35}$$

where the upper limit has been extended to infinity because $f(\beta E)$ decreases rapidly for $\beta\epsilon > 1$. If (3.34) and (3.16) are combined with the distribution functions (3.19) and (3.25), the free energy becomes

$$F_s = -4N(0)\int_0^\infty d\epsilon E f(\beta E) + 2N(0)\int_0^{\hbar\omega} d\epsilon \left[\epsilon - \frac{\epsilon^2}{E}\right] - \frac{\epsilon_0^2}{V} \tag{3.36}$$

which with the aid of (3.27) may be expressed as

$$F_s = -2N(0)\int_0^\infty d\epsilon \left[\frac{2\epsilon^2+\epsilon_0^2}{E}\right] f(\beta E) - N(0)(\hbar\omega)^2 \left\{\left[1+\left(\frac{\epsilon_0}{\hbar\omega}\right)^2\right]^{\frac{1}{2}} - 1\right\} \tag{3.37}$$

The critical field is given by combining (3.31), (3.32), and (3.37):

$$\frac{H_c^2}{8\pi} = N(0)(\hbar\omega)^2 \left\{\left[1+\left(\frac{\epsilon_0}{\hbar\omega}\right)^2\right]^{\frac{1}{2}} - 1\right\} - \frac{\pi^2}{3}N(0)(kT)^2 \times \left\{1 - \beta^2\int_0^\infty d\epsilon \left[\frac{2\epsilon^2+\epsilon_0^2}{E}\right] f(\beta E)\right\} \tag{3.38}$$

A plot of the critical field as a function of $(T/T_c)^2$ is given in Fig. 2. The curve agrees fairly well with the $1-(T/T_c)^2$ law of the Gorter-Casimir two-fluid model, [19] the maximum deviation being about four percent. There is good experimental support for a similar deviation in vanadium, thallium, indium, and tin; however, our deviation appears to be somewhat too large to fit the experimental results.

The critical field at $T = 0$ is

$$H_0 = [4\pi N(0)]^{\frac{1}{2}}\epsilon_0(0) = 1.75[4\pi N(0)]^{\frac{1}{2}}kT_c \tag{3.39}$$

where $2\epsilon_0(0)$ is the energy gap at $T = 0$ and the density of Bloch states $N(0)$ is taken for a system of unit volume.

A law of corresponding states follows from (3.39) and may be expressed as

$$\gamma T_c^2/H_0^2 = \frac{1}{6}\pi\left[kT_c/\epsilon_0(0)\right]^2 = 0.170 \tag{3.40}$$

where the electronic specific heat in the normal state is given by

$$C_{en} = \gamma T\left(\text{ergs}/^\circ\text{C cm}^3\right), \tag{3.41}$$

and

$$\gamma = \frac{2}{3}\pi^2 N(0)k^2. \tag{3.42}$$

The Gorter-Casimir model gives the value of 0.159 for the ratio (3.40). The scatter of experimental data is too great to choose one value over the other at the present time.

[33] M. J. Buckingham, Phys. Rev. 101, 1431 (1956).

Near $T = 0$, the gap is practically independent of temperature and large compared to kT, and hence for

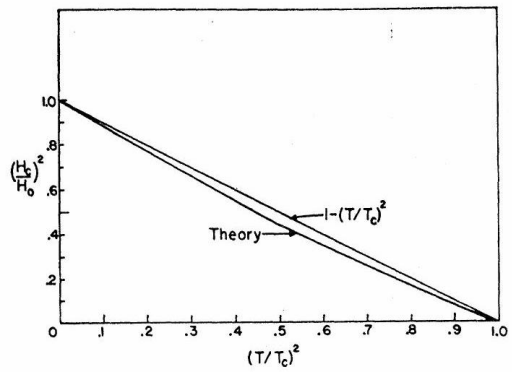

Fig. 2. Ratio of the critical field to its value at $T = 0°$K vs $(T/T_c)^2$. The upper curve is the $1 - (T/T_c)^2$ law of the GorterCasimir theory and the lower curve is the law predicted by the theory in the weak-coupling limit. Experimental values generally lie between the two curves.
$T/T_c \ll 1$ we have the relation
or

$$H_c^2 = H_0^2 \left[1 - \frac{2}{3}\pi^2 \left(kT/\epsilon_0\right)^2\right], \tag{3.43}$$

$$H_c \cong H_0 \left[1 - 1.07 \left(T/T_c\right)^2\right]. \tag{3.44}$$

This approximation corresponds to neglecting the freeenergy change of the superconducting state, the total effect coming from F_n.

The electronic specific heat is most readily obtained from the entropy, (3.34):

$$C_{es} = T\frac{dS}{dT} = -\beta\frac{dS}{d\beta} = -4k\beta \sum_{k>kF} \beta E_{\mathrm{k}} \frac{df_{\mathrm{k}}}{d\beta}, \tag{3.45}$$

or

$$C_{es} = 4k\beta^2 \sum_{k>k_F} f_{\mathrm{k}} \left(1 - f_{\mathrm{k}}\right) \left[E_{\mathrm{k}}^2 + \frac{\beta}{2}\frac{d\epsilon_0^2}{d\beta}\right] \tag{3.46}$$

The expression for C_{es} is simply interpreted as the specific heat due to electrons and holes with the modified spectrum (3.21) plus the change in condensation energy with temperature.

At the transition temperature, the energy gap vanishes and the jump in specific heat associated with the second order transition is given by

$$\begin{aligned}\left(C_{es} - C_{en}\right) \mid T_c &= 2k\beta^3 \sum_{k>kF} f_{\mathrm{k}n} \left(1 - f_{\mathrm{k}n}\right) \left[\frac{d\epsilon_0^2}{d\beta}\right]_{T_c} \\ &= kN(0)\beta_c^2 \left[\frac{d\epsilon_0^2}{d\beta}\right]_{T_c}\end{aligned} \tag{3.47}$$

where

$$f_{\mathrm{k}n} = 1/\left(e^{\beta\epsilon_{\mathrm{k}}} + 1\right) \tag{3.48}$$

The derivative $d{\epsilon_0}^2/d\beta$ can be obtained from the relation between ϵ_0 and T, (3.27). After some calculation we find

$$\left.\frac{d\epsilon_0^2}{d\beta}\right|_{T_c} = \frac{10.2}{\beta_c^3} \tag{3.49}$$

and the jump in specific heat becomes

$$\left.\frac{C_{es} - \gamma T_c}{\gamma T_c}\right|_{T_c} = 1.52 \tag{3.50}$$

The Gorter-Casimir model gives 2.00 and the Koppe theory [9] gives 1.71 for this ratio. The experimental data in general range between our value and 2.00 .

The initial slope of the critical-field curve at the transition temperature is given by the thermodynamic relation

$$\left.\frac{T_c}{4\pi}\left(\frac{dH_c}{dT}\right)^2\right|_{T_c} = (C_s - C_n)|_{T_c} \tag{3.51}$$

With use of (3.47) this becomes

$$\left.\frac{1}{\gamma}\left(\frac{dH_c}{dT}\right)^2\right|_{T_c} = 19.4 \tag{3.52}$$

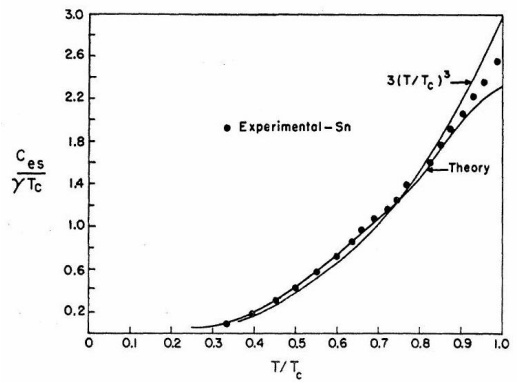

Fig. 3. Ratio of the electronic specific heat to its value in the normal state at T_c vs T/T_c for the Gorter-Casimir theory and for the present theory. Experimental values for tin are shown for comparison. Note added in proof.-The plotted theoretical curve is incorrect very near T_c; the intercept at T_c should be 2.52 .

or with (3.39),

$$\left.\frac{dH_c}{dT}\right|_{T_c} = -\frac{1.82 H_0}{T_c}. \tag{3.53}$$

When $\beta\epsilon_0 \gg 1$, the specific heat can be expressed in the form

$$\begin{aligned}\frac{C_{es}}{\gamma T_c} = \frac{3}{2\pi^2}\left(\frac{\epsilon_0}{kT_c}\right)^3\left(\frac{T_c}{T}\right)^2\left[3K_1(\beta\epsilon_0) + K_3(\beta\epsilon_0)\right] \\ \cong 8.5 e^{-1.44 T_c/T}\end{aligned} \tag{3.54}$$

where K_n is the modified Bessel function of the second kind.

The ratio $C_{es}/(\gamma T_c)$ is plotted in Fig. 3 from (3.46) and compared with the T^3 law and the experimental values for tin. The agreement is rather good except near T_c where our specific heat is somewhat too small. The logarithm of the same ratio is plotted in Fig. 4 to bring out the experimental deviation from the T^3 law. The recent work of Goodman et al. [20] shows that the data for tin and vanadium fit the law:

$$C_{es}/\left(\gamma T_c\right) = ae^{-bT_c/T} \tag{3.55}$$

with high accuracy for $T_c/T > 1.4$, where $a = 9.10$ and $b = 1.50$. These values are in good agreement with our results in this region, (3.54).

Thus we see that our theory predicts the thermodynamic properties of a superconductor quite accurately and in particular gives an exponential specific heat for $T/T_c \ll 1$ and explicitly exhibits a second-order phase transition in the absence of a magnetic field.

3.10.9 Original 1957 BCS Paper: Calculation of Matrix Elements

IV. CALCULATION OF MATRIX ELEMENTS

There are many problems for which one would like to determine matrix elements of a single-particle scattering operator of the form $U = \sum_j H_j$, where H_j involves only the coordinates of particle j. In terms of creation and destruction operators,

$$U = \sum_j H_j = \sum_{\mathbf{k},\mathbf{k}',\sigma,\sigma'} B_{\mathbf{k}\sigma\mathbf{k}'\sigma'} C_{\mathbf{k}'\sigma'} * C_{\mathbf{k}\sigma} \tag{4.1}$$

where

$$B_{\mathrm{k}\sigma\mathrm{k}'\sigma'} = \int \psi_{\mathrm{k}'\sigma'} * H_j \psi_{\mathrm{k}\sigma} d\tau_j \tag{4.2}$$

is the matrix element for scattering of a single electron from $\mathbf{k}\sigma$ to $\mathbf{k}'\sigma'$. In this section we shall determine matrix elements of U between two of our many-particle excited-state wave functions for a superconductor and give tables which should be useful for application to perturbation theory and transport problems. We first give a brief review of the corresponding problems for the normal state.

The matrix element of ${c_{\mathrm{k}'\sigma'}}^* c_{\mathrm{k}\sigma}$ between two normal state configurations is zero unless the occupation numbers differ only in transfer of an electron from $\mathbf{k}\sigma$ in the initial to $\mathbf{k}'\sigma'$ in the final configuration, in which case it is unity. If one wishes to calculate the probability that at temperature T an electron be scattered from a state of spin σ in an element $\Delta\mathbf{k}$ to one of spin σ' in $\Delta\mathbf{k}'$, one must multiply the usual single-particle expression by $f\left(1-f'\right)$, the probability that $\mathbf{k}\sigma$ be occupied and $\mathbf{k}'\sigma'$ unoccupied in a typical initial configuration. A similar factor occurs in the second-order perturbation theory expansion of U :

$$\sum_{\mathrm{k},\sigma,\mathrm{k}',\sigma'} \frac{\left|B_{\mathrm{k}\sigma\mathrm{k}'\sigma'}\right|^2 f\left(1-f'\right)}{\epsilon-\epsilon'}. \tag{4.3}$$

If H_j is independent of spin, $\sigma' = \sigma$ and the sum reduces to

$$2\sum_{\mathbf{k},\mathbf{k}'} \frac{\left|B_{\mathrm{k}\mathrm{k}'}\right|^2 f\left(1-f'\right)}{\epsilon-\epsilon'} = -\sum_{\mathbf{k},\mathbf{k}'} \left|B_{\mathbf{k}\mathbf{k}'}\right|^2 \left(\frac{f'-f}{\epsilon-\epsilon'}\right) \tag{4.4}$$

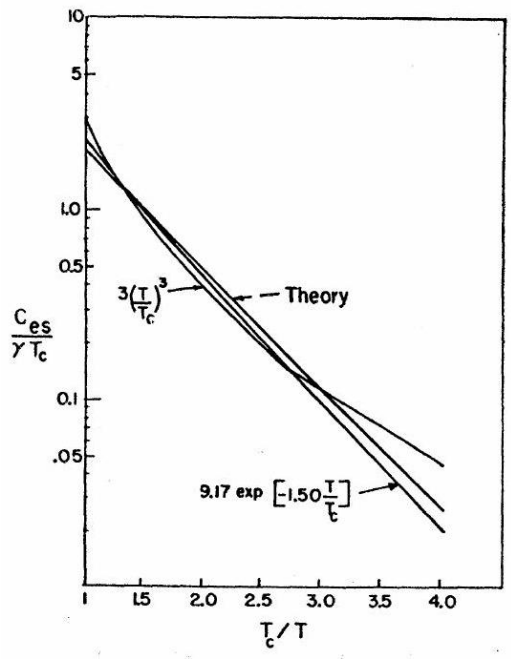

Fig. 4. A logarithmic plot of the ratio of the electronic specific heat to its value in the normal state at T_c vs T_c/T. The simple exponential fits the experimental data for tin and vanadium well for $T_c/T > 1.4$.

				-	+	$E - E'$	$p\,(1 - s' - p')$

[a] For transitions which change spin, reverse designations of ($\mathbf{k}' \uparrow, -\mathbf{k}' \downarrow$) in the initial and in the final states.

The factor of two comes from the sum over spins in the initial configuration and the second form from the fact that $|B_{\mathbf{k}\mathbf{k}'}|^2$ is symmetric in $\mathbf{k}$ and $\mathbf{k}'$.

The calculation of the corresponding factors for the superconducting case is complicated by the fact that any given state $\mathbf{k}\sigma$ may be occupied singly or by either ground or excited pairs, and these possibilities must be weighted by the probability that they occur in a typical initial wave function. First consider matrix elements of an operator which does not give a spin change:

$$\left(\Psi_f \left| \sum_{\mathrm{k},\mathrm{k}',\sigma} B_{\mathrm{k}\mathrm{k}'} {c_{\mathrm{k}'\sigma}}^* c_{\mathrm{k}\sigma} \right| \Psi_i \right) \tag{4.5}$$

Nonvanishing matrix elements of ${c_{\mathrm{k}'\uparrow}}^* c_{\mathrm{k}\uparrow}$ are obtained only when the single and excited-pair occupancy of Ψ_i and Ψ_f is the same except for those designated by wave vectors $\mathbf{k}$ and $\mathbf{k}'$. Further, Ψ_i must contain a configuration in which $\mathbf{k}\uparrow$ is occupied and $\mathbf{k}'\uparrow$ unoccupied and Ψ_f one in which $\mathbf{k}'\uparrow$ is occupied and $\mathbf{k}\uparrow$ unoccupied. The various possible transitions along with the matrix elements are listed in Table II. While the individual matrix elements are complicated, fairly simple results are obtained when a sum is made over all transitions in which $\mathbf{k}$ is in a volume element $\Delta\mathbf{k}$ and $\mathbf{k}'$ in $\Delta\mathbf{k}'$, it being assumed that $B_{\mathbf{k}\mathbf{k}'}$ is a continuous function of $\mathbf{k}$ and $\mathbf{k}'$.

The first type of transition, (a), listed in Table II corresponds to single occupancy of $\mathbf{k}\uparrow$ in the initial and of $\mathbf{k}'\uparrow$ in the final state. Pair occupancy of $\mathbf{k}'$ (i.e., the pair $\mathbf{k}'\uparrow, -\mathbf{k}'\downarrow$) in Ψ_i and of $\mathbf{k}$ in Ψ_f may be either excited or ground, giving the four possible combinations listed in the second column. These have components in
which the pair states $\mathbf{k}'$ in Ψ_i and $\mathbf{k}$ in Ψ_f are unoccupied, designated by $X000$ for Ψ_i and $00X0$ for Ψ_f. There is a nonvanishing matrix element of ${c_{\mathrm{k}'\uparrow}}^* c_{\mathrm{k}\uparrow}$ between these components. Other components of the same wave functions have the pair states $\mathbf{k}'$ in Ψ_i and $\mathbf{k}$ in Ψ_f occupied, as is indicated by the designations $X0XX$ and $XXX0$, respectively. While the matrix element of ${c_{k'}}^* c_k \uparrow$ between these latter vanishes, that of ${c_{-k\downarrow}}^* c_{-k'\downarrow}$ does not. Since both ${c_{\mathrm{k}'}}^* c_{\mathrm{k}} \uparrow$ and ${c_{-\mathrm{k}\downarrow}}^* c_{-\mathrm{k}'\downarrow}$ are included in the sum in (4.5), they will give coherent contributions and must be considered together. Matrix elements between these states of all other terms in the sum are zero.

Matrix elements of type (b) are for single-particle occupancy of $-\mathbf{k}'\downarrow$ in Ψ_i and of $-\mathbf{k}\downarrow$ in Ψ_f, while $\mathbf{k}$ in Ψ_i and $\mathbf{k}'$ in Ψ_f may be occupied by either excited or ground pairs. With interchange of spin and of $\mathbf{k}$ and $\mathbf{k}'$, they are similar to type (a). Type (c) represents single occupancy of $\mathbf{k}\uparrow$ and $-\mathbf{k}'\downarrow$ in Ψ_i and either excited or ground pair occupancy of both $\mathbf{k}$ and $\mathbf{k}'$ in Ψ_f. Transitions of ${c_{\mathrm{k}'\uparrow}}^* c_{\mathrm{k}} \uparrow$ are allowed for the component $00XX$ of Ψ_f and of ${c_{-\mathrm{k}\downarrow}}^* c_{-\mathrm{k}'\downarrow}$ for the component $XX00$. Again, these are coherent. Finally, type (d) represents excited or ground pair occupancy of Ψ_i and single particle occupancy of $-\mathbf{k}\downarrow, \mathbf{k}'\uparrow$ in Ψ_f.

The energy differences $W_i - W_f$ listed in the third column are obtained by taking an energy $2E$ for an excited pair, E for single occupancy, and zero for a ground pair. We have used the notation $E = E(\mathbf{k})$; $E' = E(\mathbf{k}')$, etc.

In column 4 are given the probabilities of the initial state designations, based on taking $\frac{1}{2}s$ for a specified
single occupancy, p for an excited pair, and ($1-s-p$) for a ground pair. For example, Ψ_i in the top row corresponds to $\mathbf{k}\uparrow$ occupied and a ground pair in $\mathbf{k}'$, and the fraction of the states $\mathbf{k}$ in the volume element $\Delta\mathbf{k}$ and $\mathbf{k}'$ in $\Delta\mathbf{k}'$ which have this designation is $\frac{1}{2}s(\mathbf{k})\left[1 - s(\mathbf{k}') - p(\mathbf{k}')\right]$.

To calculate the matrix elements, it is convenient to decompose the wave functions into components corresponding to definite occupancy of excited and ground pairs as in (3.10). Thus, for the top row in which $\mathbf{k}'$ in Ψ_i and $\mathbf{k}$ in Ψ_f are both ground pairs,

$$\Psi_i = c_{\mathrm{k}} \uparrow^* \left[h'^{\frac{1}{2}} \varphi_{01}(0_{\mathrm{k}}, 1_{\mathrm{k}'}) + (1-h')^{\frac{1}{2}} \varphi_{00}(0_{\mathrm{k}}, 0_{\mathrm{k}'})\right] \tag{4.6a}$$

$$\Psi_f = c_{\mathrm{k}'} \uparrow^* \left[h^{\frac{1}{2}} \varphi_{10}(1_{\mathrm{k}}, 0_{\mathrm{k}'}) + (1-h)^{\frac{1}{2}} \varphi_{00}(0_{\mathrm{k}}, 0_{\mathrm{k}'})\right] \tag{4.6b}$$

where

$$\varphi_{10} = b_{\mathrm{k}}^{*} b_{\mathrm{k}'} \varphi_{01}$$

The matrix element of $c_{\mathrm{k}'}{}^{*} c_{\mathrm{k}} \uparrow$ is

$$\begin{aligned}(\Psi_f \left| c_{\mathrm{k}'\uparrow} * c_{\mathrm{k}} \uparrow \right| \Psi_i) &= \left[(1-h)\left(1-h'\right)\right]^{\frac{1}{2}} \left(c_{\mathrm{k}'\uparrow} * \varphi_{00} \mid c_{\mathrm{k}'\uparrow}{}^{*} \varphi_{00}\right) \\ &= \left[(1-h)\left(1-h'\right)\right]^{\frac{1}{2}} \end{aligned} \tag{4.7}$$

The matrix element of $c_{-\mathrm{k}\downarrow}{}^{*} c_{-\mathrm{k}'\downarrow}$ is given by

$$\begin{aligned}&(\Psi_f \left| c_{-\mathrm{k}\downarrow} * c_{-\mathrm{k}'\downarrow} \right| \Psi_i) \\ &\quad = \left(hh'\right)^{\frac{1}{2}} \left(c_{\mathrm{k}'\uparrow} * b_{\mathrm{k}} * b_{\mathrm{k}'} \varphi_{01} \mid c_{-\mathrm{k}\downarrow} * c_{-\mathrm{k}'\downarrow} c_{\mathrm{k}} \uparrow * \varphi_{01}\right)\end{aligned} \tag{4.8}$$

Since

$$c_{\mathrm{k}'\uparrow}{}^{*} b_{\mathrm{k}} * b_{\mathrm{k}'} \varphi_{01} = -c_{-\mathrm{k}'\downarrow} b_{\mathrm{k}}{}^{*} \varphi_{01} \tag{4.9}$$

$$c_{-\mathrm{k}\downarrow}{}^{*} c_{-\mathrm{k}'\downarrow} c_{\mathrm{k}} \uparrow^{*} \varphi_{01} = c_{-\mathrm{k}'\downarrow} b_{\mathrm{k}}{}^{*} \varphi_{01} \tag{4.10}$$

the matrix element is $-\left(hh'\right)^{\frac{1}{2}}$. The other matrix elements of types (a) and (b) may be calculated in a similar manner.

For types (c) and (d) we make use of the decomposition (3.10). For example, for type (d),

$$\begin{aligned}\Psi_i = \alpha_{11}\varphi_{11}\left(1_{\mathrm{k}}, 1_{\mathrm{k}'}\right) + \alpha_{10}\varphi_{10}\left(1_{\mathrm{k}}, 0_{\mathrm{k}'}\right) \\ + \alpha_{01}\varphi_{01}\left(0_{\mathrm{k}}, 1_{\mathrm{k}'}\right) + \alpha_{00}\varphi_{00}\left(0_{\mathrm{k}}, 0_{\mathrm{k}'}\right)\end{aligned} \tag{4.11}$$

where the α 's are as listed in Table I. The final wave function is

$$\Psi_f = c_{\mathrm{k}'\uparrow} * c_{\mathrm{k}\uparrow} \uparrow \varphi_{10} \tag{4.12}$$

Thus the matrix element of $c_{\mathrm{k}'}|^{*} c_{\mathrm{k}} \uparrow$ is just α_{10}. The matrix element of $c_{-\mathrm{k}\downarrow}{}^{*} c_{-\mathrm{k}'\downarrow}$ is found from

$$\begin{aligned}c_{-\mathrm{k}\downarrow} * c_{-\mathrm{k}'\downarrow} \varphi_{01} &= c_{-\mathrm{k}\downarrow} * c_{-\mathrm{k}'\downarrow} b_{\mathrm{k}'} * b_{\mathrm{k}} \varphi_{10} \\ &= c_{\mathrm{k}'\uparrow} * c_{\mathrm{k}} \uparrow \varphi_{10},\end{aligned} \tag{4.13}$$

so that we find

$$(\Psi_f \left| c_{-\mathrm{k}\downarrow}{}^{*} c_{-\mathrm{k}'\downarrow} \right| \Psi_i) = \alpha_{01} \tag{4.14}$$

Those for type (c) can be obtained by interchanging initial and final states and spin up and spin down.

We have so far assumed a spin-independent interaction. One involving a spin flip may be treated by exactly similar methods. Initial and final states differ from the parallel spin case by interchange of spin designation of $\mathbf{k}'$ in the initial and in the final state. There is a coherence between the matrix elements for $c_{-k'} \downarrow^{*} c_{k} \uparrow$ and
$c_{-\mathrm{k}}{}^{*} c_{\mathrm{k}'} \uparrow$. They are the same as the corresponding matrix elements for parallel spin, except for

a reversal of sign of the reverse spin transitions. For example, for the type (a) transition of the top row, the final state is now

$$\Psi_f = c_{-\mathrm{k}'\downarrow^*}\left[h^{\frac{1}{2}}\varphi_{10}\left(1_\mathrm{k}, 0_{\mathrm{k}'}\right) + (1-h)^{\frac{1}{2}}\varphi_{00}\left(0_\mathrm{k}, 0_{\mathrm{k}'}\right)\right] \tag{4.15}$$

The matrix element of $c_{-\mathrm{k}'\downarrow}{}^* c_\mathrm{k} \uparrow$ is $\left[(1-h)(1-h')\right]^{\frac{1}{2}}$ as before. To obtain matrix element of $c_{-k} \downarrow^* c_{k'} \uparrow$, we now have, corresponding to (4.9) and (4.10),

$$c^*_{-\mathrm{k}'\downarrow^*} b_{\mathrm{k}'} b^*_\mathrm{k} \varphi_{01} = c_{\mathrm{k}'\uparrow} \uparrow b^*_\mathrm{k}\varphi_{01}$$
$$c_{-\mathrm{k}\downarrow}{}^* c_{\mathrm{k}'} \uparrow c_\mathrm{k} \uparrow^* \varphi_{01} = c_{\mathrm{k}'\uparrow} b^*_\mathrm{k}\varphi_{01}$$

giving $+(hh')^{\frac{1}{2}}$. We have indicated the change in sign in the table by listing $-c_{-\mathrm{k}\downarrow}{}^* c_{\mathrm{k}'} \uparrow$ at the top of column 6.
In a second-order perturbation theory calculation, one is interested in determining

$$\sum_f \frac{\left|\left(\Psi_f \left| \sum_{\mathbf{k},\mathbf{k}',\sigma} B_{\mathrm{k}\mathrm{k}'} c_{\mathrm{k}'\sigma}{}^* c_{\mathrm{k}\sigma} \right| \Psi_i\right)\right|^2}{W_i - W_f} \tag{4.16}$$

where the sum is over all intermediate states, f. The initial state should be a typical one for a given temperature T. In general, one might have either

$$B_{\mathrm{k}\mathrm{k}'} = +B_{-\mathrm{k}',-\mathrm{k}}, \quad (\text{ case I}) \tag{4.17}$$

or

$$B_{\mathrm{k}\mathrm{k}'} = -B_{-\mathrm{k}',-\mathrm{k}}. \quad (\text{ case II }) \tag{4.18}$$

The latter applies to the magnetic interaction. To take the coherence into account, one may take the spinindependent sum over $\mathbf{k}$ and $\mathbf{k}'$, which designate initial and intermediate states: $+\sum_{\mathrm{k},\mathrm{k}'} \frac{|B_{\mathrm{k}\mathrm{k}'}|^2 \langle |\left(\Psi_f \left| c_{\mathrm{k}'\uparrow}{}^* c_{\mathrm{k}\uparrow} \pm c_{-\mathrm{k}\downarrow}{}^* c_{-\mathrm{k}'\downarrow} \right| \Psi_i\right)|^2 \rangle_{\mathrm{Av}}}{W_i - W_f}$,
where the average is taken over volume elements $\Delta\mathbf{k}$ and $\Delta\mathbf{k}'$ for the initial state.

For terms with an energy denominator $W_i - W_f = E - E'$, we have

$$\begin{aligned}\left\{\left[(1-h)(1-h')\right]^{\frac{1}{2}} \mp (hh')^{\frac{1}{2}}\right\}^2 &\left[\frac{1}{2}s(1-s'-p')\right. \\ &\left. + \frac{1}{2}ps' + \frac{1}{4}ss' + p(1-s'-p')\right] \\ &= \frac{1}{2}\left\{1 + \frac{\epsilon\epsilon' \mp \epsilon_0^2}{EE'}\right\} f(1-f')\end{aligned} \tag{4.20}$$

Table III lists the average matrix elements for the various values of $W_i - W_f$.
The second-order perturbation theory sum may be written

$$-\sum_{\mathbf{k},\mathbf{k}'} |B_{\mathbf{k}\mathbf{k}'}|^2 L(\epsilon, \epsilon') \tag{4.21}$$

Table III. Mean square matrix elements for possible values of $W_i - W_f$.

$W_i - W_f$	$\left\langle \left\vert \left(\Psi_f \left\vert {c_{\mathrm{k}'\uparrow}}^* c_{\mathrm{k}\uparrow} \pm {c_{-\mathrm{k}\downarrow}}^* c_{-\mathrm{k}'\downarrow}\right\vert \Psi_i\right)\right\vert^2 \right\rangle_{\mathrm{Av}}$
$E - E'$	$\frac{1}{2}\left(1 + \frac{\epsilon\epsilon' \mp {\epsilon_0}^2}{EE'}\right) f\left(1 - f'\right)$
$E' - E$	$\frac{1}{2}\left(1 + \frac{\epsilon\epsilon' \mp {\epsilon_0}^2}{EE'}\right) f'(1 - f)$
$-\left(E + E'\right)$	$\frac{1}{2}\left(1 - \frac{\epsilon\epsilon' \mp {\epsilon_0}^2}{EE'}\right) (1 - f)\left(1 - f'\right)$
$E + E'$	$\frac{1}{2}\left(1 - \frac{\epsilon\epsilon' \mp {\epsilon_0}^2}{EE'}\right) f f'$

where

$$\begin{aligned} L\left(\epsilon, \epsilon'\right) =& \frac{1}{2}\left(1 + \frac{\epsilon\epsilon' \mp \epsilon_0^2}{EE'}\right)\left(\frac{f' - f}{E - E'}\right) \\ &+ \frac{1}{2}\left(1 - \frac{\epsilon\epsilon' \mp \epsilon_0^2}{EE'}\right)\left(\frac{1 - f - f'}{E + E'}\right) \\ =& \frac{1}{2}\left(\frac{(1 - 2f)E - \left(1 - 2f'\right)E'}{\epsilon^2 - \epsilon'^2}\right) \\ &+ \frac{1}{2}\left(\frac{\epsilon\epsilon' \mp \epsilon_0^2}{EE'}\right)\left(\frac{(1 - 2f)E' - \left(1 - 2f'\right)E}{\epsilon^2 - \epsilon'^2}\right) \end{aligned} \tag{4.22}$$

The upper signs correspond to case I, the lower to case II.

To determine the probability of a transition in which an energy quantum $h\nu$ is absorbed, we have a sum of the form

$$\begin{aligned} \tfrac{2\pi}{\hbar} \textstyle\sum_{\mathbf{k},\mathbf{k}'} \left|B_{\mathrm{kk}'}\right|^2 \left\langle \left\vert \left(\Psi_f \left\vert {c_{\mathrm{k}'\uparrow}}^* c_{\mathrm{k}} \uparrow \pm c_{-\mathrm{k}\downarrow} c_{-\mathrm{k}'\downarrow}\right\vert \Psi_i\right)\right\vert^2 \right\rangle_{\mathrm{Av}} \\ \times \delta\left(W_f - W_i - h\nu\right) \end{aligned} \tag{4.23}$$

For the matrix elements for which $W_f - W_i = E - E'$, we may interchange $\mathbf{k}$ and $\mathbf{k}'$ in the sum and combine them with those for which $W_f - W_i = E' - E$. This just gives either one multiplied by a factor of two:

$$\begin{aligned} \frac{2\pi}{\hbar} \sum_{\mathbf{k},\mathbf{k}'} 2\left|B_{\mathbf{kk}'}\right|^2 \frac{1}{2}(1 + \frac{\epsilon\epsilon' \mp \epsilon_0^2}{EE'}\Big) \\ \times f\left(1 - f'\right)\delta\left(W_f - W_i - h\nu\right) \end{aligned} \tag{4.24}$$

One may interpret the factor of two as accounting for the sum over the two spin possibilities of the initial state. If $\left|B_{\mathrm{kk}'}\right|^2$ is symmetric with respect to the Fermi surface, so that we may sum over + and - values of ϵ and ϵ', terms odd in ϵ and ϵ' drop out, and we find

$$\begin{aligned} \frac{2\pi}{\hbar} \sum_{k,k' > kF} 4\left|B_{\mathrm{kk}'}\right|^2 (1 \mp \frac{\epsilon_0^2}{EE'}\Big) \\ \times f\left(1 - f'\right)\delta\left(E' - E - h\nu\right) \end{aligned} \tag{4.25}$$

The corresponding expressions for $W_f - W_i = E + E'$ and $-\left(E + E'\right)$ are:

$$\begin{aligned} \frac{2\pi}{\hbar} \sum_{k,k' > k_F} 2\left|B_{\mathrm{kk}'}\right|^2 \left(1 \pm \frac{\epsilon_0^2}{EE'}\right) \\ \times (1 - f)\left(1 - f'\right)\delta\left(E + E' - h\nu\right) \end{aligned} \tag{4.26}$$

$$\frac{2\pi}{\hbar} \sum_{k,k' > k_F} 2\left|B_{\mathrm{kk}'}\right|^2 \left(1 \pm \frac{\epsilon_0^2}{EE'}\right) f f'\delta\left(E + E' + h\nu\right) \tag{4.27}$$

respectively, where again we have dropped terms odd in ϵ and ϵ'.

Hebel and Slichter [34] have used (4.25) to estimate the temperature dependence of the relaxation time for nuclear spin resonance in the superconducting state from the corresponding value in the normal state. They are able to account for an observed initial decrease in relaxation time in Al as the temperature is lowered below T_c. The increased density of states in energy in the superconducting phase more than makes up for the decrease in number of excited electrons at temperatures not too far below T_c. For this problem, the lower sign (+) is appropriate.

These expressions may also be used to determine transport properties, such as electrical conductivity in the microwave region and thermal conductivity.

Note added in proof.-The marked effect of coherence on the matrix elements is verified experimentally by comparing absorption of ultrasonic waves, which follows case I, with nuclear spin relaxation or electromagnetic absorption, both of which follow case II. For frequencies such that $h\nu \ll kT_c$, one expects for case II an initial increase in absorption just below T_c, followed by a decrease to values below that of the normal state as the temperature is lowered, as is observed experimentally. On the other hand, for case I one expects the absorption to drop with an infinite slope at T_c, such as is found for ultrasonic waves.

The expressions for the transition probabilities are simplified if we change our convention for the moment to give E the same sign as ϵ, so that $E = -\left(\epsilon^2 + \epsilon_0^2\right)^{\frac{1}{2}}$ below the Fermi surface. One may then write (4.26) and (4.27) in the same form as (4.25), with E and E' now taking on both positive and negative values. Considering both direct absorption and induced emission, the net rate of absorption of energy in the superconducting state is proportional to

$$\alpha_s \propto \int \left(1 \mp \frac{\epsilon_0^2}{EE'}\right) \left[f\left(1 - f'\right) - f'(1 - f)\right] \rho(E)\rho\left(E'\right) dE \tag{4.28}$$

where $E' = E + h\nu$ and $\rho(E) = N(0)E/\left(E^2 - \epsilon_0^2\right)^{\frac{1}{2}}$ is the density of states in energy.

With the upper sign (case I) and with $h\nu \ll kT$, the density of states terms are cancelled by the first factor, and the expression reduces to

$$\alpha_s \propto 2[N(0)]^2 \int_{\epsilon_0}^{\infty} \left(f - f'\right) dE \cong 2[N(0)]^2 h\nu f\left(\epsilon_0\right)$$

The factor 2 comes from adding contributions above and below the Fermi surface. The corresponding expression for the normal

state is similar, except that $\epsilon_0 = 0$. We thus find

$$\alpha_s/\alpha_n = 2f\left(\epsilon_0\right) \tag{4.29}$$

R. W. Morse and H. V. Bohm (to be published) have used (4.29) for analysis of data on ultrasonic attenuation in an indium specimen for which the electronic mean free path is large compared with the wavelength of the ultrasonic wave, so that one might expect the theory to apply. Values of $\epsilon_0(T)$ estimated from the data by use of (4.29) are in excellent agreement with our theoretical values (Fig. 1).

For case II, the integral may be expressed in the form:

$$\frac{\alpha_s}{\alpha_n} = \frac{1}{h\nu} \int \frac{\left(EE' + \epsilon_0^2\right)\left(f - f'\right) dE}{\left\{\left(E^2 - \epsilon_0^2\right)\left[(E + h\nu)^2 - \epsilon_0^2\right]\right\}^{\frac{1}{2}}} \tag{4.30}$$

The integral diverges at $E = \epsilon_0$ if $h\nu$ is set equal to zero in the denominator. Numerical evaluation of the integral indicates that for $h\nu \sim \frac{1}{2}kT_c$ or less, (4.30) gives an increase in

[34] L. C. Hebel and C. P. Slichter, Phys. Rev. 107, 901 (1957). We are indebted to these authors for considerable help in working out the details of the calculation of matrix elements, particularly in regard to taking into account the coherence of matrix elements of opposite spin.

absorption just below T_c as observed by Hebel and Slichter in nuclear magnetic resonance and by Tinkham and co-workers (private communication) for microwave absorption in thin superconducting films.

In order to have absorption at $T = 0, h\nu$ must be greater than the energy gap, $2\epsilon_0$. We take E negative and E' positive, and find for this case:

$$\frac{\alpha_s}{\alpha_n} = \frac{1}{h\nu} \int_{\epsilon_0 - h\nu}^{-\epsilon_0} \frac{[E(E + h\nu) + \epsilon_0^2]\, dE}{\{(E^2 - \epsilon_0^2)\,[(E + h\nu)^2 - \epsilon_0^2]\}^{\frac{1}{2}}} \tag{4.31}$$

The integral may be evaluated in terms of the complete elliptic integrals, $E(\gamma)$ and $K(\gamma)$ as follows:

$$\frac{\alpha_s}{\alpha_n} = \left(1 + \frac{2\epsilon_0}{h\nu}\right) E(\gamma) - 2\left(\frac{2\epsilon_0}{h\nu}\right) K(\gamma) \tag{4.32}$$

where

$$\gamma = (h\nu - 2\epsilon_0) \,/\, (h\nu + 2\epsilon_0)\,. \tag{4.33}$$

This expression is in excellent agreement with data of Glover and Tinkham (reference 20, Fig. 6) on infrared absorption in thin films.

3.10.10 Original 1957 BCS Paper: Electrodynamic Properties

V. ELECTRODYNAMIC PROPERTIES

The electrodynamic properties of our model are determined using a perturbation treatment in which the first order change in the wave function is used to calculate the current as a functional of the field. For such properties as the Meissner effect this approach is quite rigorous since we are interested in the limit as $\mathbf{A}(\mathbf{r})$ approaches zero. It is assumed that the medium is infinite and that the sources of the field may be introduced by inserting current sheets in the interior. This method has been applied previously to the calculation of the diamagnetic properties of an electron gas. [35]

We first derive an expression, valid for arbitrary temperatures, relating the current density to the total field (the field due to the sources and to the induced currents). The fact that the system displays a Meissner effect is established by investigating the Fourier transform of the current density in the limit that $q \to 0$. In this limit we obtain the equation,

$$\lim_{\mathbf{q}\to 0} \mathbf{j}(\mathbf{q}) = -\frac{1}{c\Lambda_T} \mathfrak{a}(\mathbf{q}) \tag{5.1}$$

where Λ_T is a function of temperature, increasing, in the free-electron approximation, from the London value $\Lambda = m/ne^2$ at $T = 0$ to infinity at the transition temperature.

The limiting expression (5.1) is valid only for values of q smaller than those important for most penetration phenomena. In general we find the current density is a functional of the vector potential A which, with $\operatorname{div} \mathbf{A} = 0$, may be expressed in a form similar to that proposed by Pippard (1.3):

$$\mathbf{j}(\mathbf{r}) = -\frac{3}{4\pi c\Lambda_T \xi_0} \int \frac{\mathbf{R}\,[\mathbf{R} \cdot \mathbf{A}\,(\mathbf{r}')]\, J(R,T) d\mathbf{r}'}{R^4} \tag{5.2}$$

[35] This method was first applied to the calculation of the diamagnetic properties of an electron gas by O. Klein, Arkiv Mat. Astron Fysik, A31, No. 12 (1944). Our treatment follows that of one of the authors as given in reference 7, pp. 303-321, where further references to the literature may be found.

The kernel, $J(R,T)$, is a relatively slowly varying function of temperature, and at $T = 0°\mathrm{K}$ is not far different from Pippard's $\exp(-R/\xi_0)$.

To calculate penetration depths, it is more convenient to use the Fourier transform of (5.2), which may be expressed in the form

$$\mathbf{j}(\mathbf{q}) = -(c/4\pi)K(q)\mathfrak{a}(\mathbf{q}), \tag{5.3}$$

where $K(q)$ is a scalar which approaches the constant value $4\pi/(\Lambda_T c^2)$ in the limit $q \to 0$. One may determine $K(q)$ directly from the perturbation expansion of the wave function, or one may first calculate $J(R,T)$ and then find the transform of (5.2). The latter procedure is followed in Appendix C, where an explicit expression for $K(q)$ valid for q not too small is derived. In this section we shall give a direct derivation of the transform which can be used to investigate the limit $q \to 0$, and then give the derivation of (5.2). A comparison of calculated and observed values of penetration depths is given at the end of the section.

In the absence of the electromagnetic field, the system at a given temperature is characterized by the complete orthonormal set of wave functions which we denote by

$$\Psi_0(T), \Psi_1(T), \cdots \Psi_n(T), \cdots$$

with corresponding energies

$$W_0(T), W_1(T) \cdots W_n(T) \cdots \tag{5.4}$$

We choose for $\Psi_0(T)$ a typical wave function of the type described in the previous sections, where the occupation of "single particles" and "excited pairs" is given by the s and p distributions, respectively, appropriate to the temperature T; the rest of the phase space is available for "ground pairs" whose distribution is specified by h which is also a function of T. The set of orthogonal states is obtained by varying s and p (in analogy with the normal metal) and not changing h. We thus are choosing a representative configuration of the most probable distribution and taking system averages with respect to this representative configuration.

The electromagnetic interaction term for an electron of charge $q = -e, e > 0$, is, in second quantized form,

$$H_I = \int d\mathbf{r}\psi^*(\mathbf{r}) \left[\frac{-ie\hbar}{2mc}(\mathbf{A}\cdot\nabla + \nabla\cdot\mathbf{A}) + \frac{e^2}{2mc^2}\mathbf{A}^2(\mathbf{r}) \right] \psi(\mathbf{r}) \tag{5.5}$$

We choose a gauge in which $\boldsymbol{\nabla}\cdot\mathbf{A} = 0$ and in which $\mathbf{A} = 0$ if the magnetic field is zero.

We expand ψ and ψ^* in creation and annihilation operators [36] :

$$\psi(\mathbf{r}) = \frac{1}{\Omega^{\frac{1}{2}}} \sum_{\mathbf{k},\sigma} c_{\mathrm{k},\sigma} u_\sigma e^{i\mathbf{k}\cdot\mathbf{r}}$$
$$\psi^*(\mathbf{r}) = \frac{1}{\Omega^{\frac{1}{2}}} \sum_{\mathbf{k}',\sigma'} c_{\mathbf{k}',\sigma'}{}^* u_{\sigma'}{}^* e^{-i\mathbf{k}'\cdot\mathbf{r}} \tag{5.6}$$

where the c 's satisfy the usual fermion anticommutation relations, (2.1) and (2.2), u_σ is a two-component spinor, and Ω is the volume of the container. The interaction Hamiltonian becomes, when one neglects the term of higher order in A,

$$H_I = \frac{e\hbar}{mc}\frac{(2\pi)^{\frac{3}{2}}}{\Omega}\sum_{\mathbf{k},\mathbf{q},\sigma} {c_{\mathbf{k}+\mathbf{q},\sigma}}^* c_{\mathbf{k},\sigma}\mathfrak{a}(\mathbf{q})\cdot\mathbf{k} \tag{5.7}$$

where

$$\mathfrak{a}(\mathbf{q}) = \left(\frac{1}{2\pi}\right)^{\frac{3}{2}}\int d\mathbf{r}\mathbf{A}(\mathbf{r})e^{-i\mathbf{q}\cdot\mathbf{r}}$$

The current operator $\mathfrak{I}(\mathbf{r})$ is

$$\begin{aligned}\mathfrak{J}(\mathbf{r}) = \frac{ie\hbar}{2m}(\psi^*\nabla\psi - \text{ Herm. conj. }) - \frac{e^2}{mc}\psi^*\mathbf{A}\psi \\ = \mathfrak{J}_P(\mathbf{r}) + \mathfrak{J}_D(\mathbf{r})\end{aligned} \tag{5.8}$$

Expanding ψ and ψ^* as in (5.6), we get

$$\begin{aligned}\mathfrak{J}_P(\mathbf{r}) &= \frac{e\hbar}{2m\Omega}\sum_{\mathbf{k},\mathbf{q},\sigma} {c_{\mathbf{k}+\mathbf{q},\sigma}}^* c_{\mathbf{k},\sigma}e^{-i\mathbf{q}\cdot\mathbf{r}}(2\mathbf{k}+\mathbf{q}), \\ \mathfrak{J}_D(\mathbf{r}) &= -\frac{e^2}{mc}\frac{1}{\Omega}\sum_{\mathbf{k},\mathbf{q},\sigma} {c_{\mathbf{k}+\mathbf{q},\sigma}}^* c_{\mathbf{k},\sigma}e^{-i\mathbf{q}\cdot\mathbf{r}}\mathbf{A}(\mathbf{r}).\end{aligned} \tag{5.9}$$

In the presence of the electromagnetic field the wave function for the system may be written

$$\Phi(\mathbf{A}) = \Phi_0 + \Phi_1 + \left(\text{ terms of order } \mathbf{A}^2\cdots\right), \tag{5.10}$$

where the usual perturbation expression for Φ_1 is

$$\Phi_1 = \sum_{i\neq 0}\frac{(\Psi_i\,|H_I|\,\Psi_0)}{W_0 - W_i}\Bigg|\ \Psi_i\Bigg) \tag{5.11}$$

To the lowest order in $\mathbf{A}(\mathbf{r})$, the expectation value of the current operator is then

$$\begin{aligned}\mathbf{j}(\mathbf{r}) = (\Phi|\text{Im}\,(\mathbf{r})|\Phi) = (\Phi_1\,|\text{Im}_{\,P}(\mathbf{r})|\,\Phi_0) \\ + (\Phi_0\,|\text{Im}_{\,P}(\mathbf{r})|\,\Phi_1) + (\Phi_0\,|\text{Im}_{\,D}(\mathbf{r})|\,\Phi_0)\end{aligned} \tag{5.12}$$

where the last equality follows if the current in the field free state, $\mathbf{j}_0(\mathbf{r}) = (\Phi_0|\mathfrak{J}(\mathbf{r})|\Phi_0)$, vanishes. [36a]

If (5.7), (5.9), and (5.11) are combined with (5.12) and the condition $\mathbf{q}\cdot\mathfrak{a}(\mathbf{q}) = 0$ is used, we obtain for the paramagnetic part of the current density,

$$\begin{aligned}\mathbf{j}_P(\mathbf{r}) = -\frac{e^2\hbar^2(2\pi)^{\frac{3}{2}}}{2m^2c\Omega^2}\sum_{i\neq 0}\sum_{\mathbf{k},\mathbf{q},\sigma}\sum_{\mathbf{k}',\mathbf{q}',\sigma'}(2\mathbf{k}+\mathbf{q})\mathbf{k}' \\ \cdot\left[\mathfrak{a}(\mathbf{q}')\,e^{-i\mathbf{q}'\cdot\mathbf{r}}\,(\Psi_0(T)\,|c_{\mathbf{k}'+\mathbf{q}',\sigma'}c_{\mathbf{k}'\sigma'}|\,\Psi_i(T))\right. \\ \times(\Psi_i(T)\,|c_{\mathbf{k}+\mathbf{q},\sigma^*}c_{\mathbf{k},\sigma}|\,\Psi_0(T))\,\frac{1}{W_0 - W_i} \\ \left.+\text{ complex conjugate }\right]\end{aligned} \tag{5.13}$$

[36] At this point we insert plane waves for the Bloch functions. It would be possible to carry through an analogous procedure formally with Bloch functions. The average matrix elements which enter cannot be evaluated explicitly, but can be expressed in terms of empirically determined parameters. The appropriate modifications of the free-electron expressions are as indicated in the introduction.

while for the diamagnetic part we have

$$\mathbf{j}_D(\mathbf{r}) = -\left(ne^2/mc\right)\mathbf{A}(\mathbf{r}) \tag{5.14}$$

where n is the number of conduction electrons, of both spin directions, per unit volume.

The spin sums and the calculation of the average matrix elements can be carried out as indicated in Sec. IV, (4.16) to (4.22). We then obtain

$$\mathbf{j}_P(\mathbf{r}) = \frac{e^2\hbar^2}{2m^2c}\frac{(2\pi)^{\frac{3}{2}}}{\Omega^2}\sum_{\mathbf{k},\mathbf{q}}(2\mathbf{k}+\mathbf{q})\mathbf{k} \cdot\mathfrak{a}(-\mathbf{q})e^{-i\mathbf{q}\cdot\mathbf{r}}L\left(\epsilon_{\mathbf{k}},\epsilon_{\mathbf{k}+\mathbf{q}}\right) \tag{5.15}$$

where $L\left(\epsilon_{\mathrm{k}},\epsilon_{\mathrm{k+q}}\right)$ is given by (4.22) with the lower signs, corresponding to case II. Setting $\epsilon_{\mathrm{k}} = \epsilon$ and $\epsilon_{\mathrm{k+q}} = \epsilon'$, the explicit expression for L is

$$\begin{aligned} L\left(\epsilon,\epsilon'\right) = \frac{1}{2}\left(\frac{1-f-f'}{E+E'}\right)\left(1-\frac{\epsilon\epsilon'+\epsilon_0^2}{EE'}\right) \\ +\frac{1}{2}\left(\frac{f'-f}{E-E'}\right)\left(1+\frac{\epsilon\epsilon'+\epsilon_0^2}{EE'}\right) \end{aligned} \tag{5.16}$$

To show how (5.16) reduces to the usual expression for a free-electron gas in the limit $\epsilon_0 \to 0$, we note that E is defined so that it is intrinsically positive, while the Bloch energy ϵ may be either positive or negative. As $\epsilon_0 \to 0, E \to |\epsilon|$. If ϵ is negative,

$$f(\epsilon) = f(-|\epsilon|) = 1 - f(|\epsilon|) = 1 - f(E), \tag{5.17}$$

To get a nonvanishing contribution from the first line, ϵ and ϵ' must have opposite signs, while for the second line they must have the same signs. We thus find that $L\left(\epsilon,\epsilon'\right) \to \left(f'-f\right)/\left(\epsilon-\epsilon'\right)$, as it should [see (4.4)].

The Meissner Effect

To establish the existence of the Meissner effect, we investigate the Fourier transform of $\mathbf{j}(\mathbf{r})$ in the limit $\mathbf{q} \to 0$. If $\mathbf{j}(\mathbf{q})$ does not go to zero in this limit, and is opposite in sign to $\mathfrak{a}(\mathbf{q})$, then the system will expel the field from its interior and behave like a perfect diamagnet.

The Fourier transform of the paramagnetic part of the current density, $\mathbf{j}_P(\mathbf{r})$, is given by

$$\mathbf{j}_P(\mathbf{q}) = \left(\frac{1}{2\pi}\right)^{\frac{3}{2}}\int d\mathbf{r}\mathbf{j}_P(\mathbf{r})e^{-i\mathbf{q}\cdot\mathbf{r}} \tag{5.18}$$

Referring to (5.15), this can be written as
$\mathbf{j}_P(\mathbf{q}) = \frac{e^2\hbar^2}{m^2c}\left(\frac{1}{2\pi}\right)^3\int d\mathbf{k}(2\mathbf{k}+\mathbf{q})\mathbf{k}\cdot\mathfrak{a}(\mathbf{q})L\left(\epsilon_{\mathbf{k}},\epsilon_{\mathbf{k}+\mathbf{q}}\right)$,
where in the limit that $\mathbf{q} \to 0, \epsilon_{\mathrm{k}} = \epsilon_{\mathrm{k+q}}$ and $L\left(\epsilon_{\mathrm{k}},\epsilon_{\mathrm{k+q}}\right)$ becomes

36a Note added in proof.-We neglect the effects of the momentum dependent cutoff on the expression for the current density; as shown explicitly by P. W. Anderson (private communication) errors introduced are negligible in the weak coupling limit. In a general gauge, $\mathrm{A} = \mathrm{A}_0 + \mathrm{grad}\,\varphi$, with $\mathrm{div}\ \mathrm{A}_0 = 0$, it would be necessary to include in the perturbation expansion collective excitations of the electrons, the simplest of which corresponds to a uniform displacement of all of the electrons in momentum space. Energies and matrix elements of collective excitations are nearly the same in normal and superconducting phases. We assume the collective excitations make a negligible contribution to the current form $\mathbf{A}_0$ (see J. Bardeen, Nuovo Cimento 5, 1766 (1957)).

$$\lim_{\mathrm{q}\to 0} L\left(\epsilon_{\mathrm{k}}, \epsilon_{\mathrm{k+q}}\right) = \frac{\beta e^{\beta E}}{\left(1+e^{\beta E}\right)^2}. \tag{5.20}$$

Thus we want to evaluate

$$\lim_{\mathbf{q}\to 0} \mathbf{j}_P(\mathbf{q}) = \frac{e^2\hbar^2}{m^2 c}\left(\frac{1}{2\pi}\right)^3 2\beta \int d\mathbf{kkk}\cdot\mathfrak{a}(\mathbf{q})\frac{e^{\beta E}}{\left(1+e^{\beta E}\right)^2}. \tag{5.21}$$

Choosing $\mathfrak{a}(\mathbf{q})$ as the polar axis, the angular integration can be done; then, using the relations $n = {k_F}^3/3\pi^2$ and $\mathcal{E}_F = \hbar^2 {k_F}^2/2m$, we get

$$\lim_{\mathbf{q}\to 0} \mathbf{j}_P(\mathbf{q}) = \frac{ne^2}{mc}\left(1-\frac{\Lambda}{\Lambda_T}\right)\mathfrak{a}(\mathbf{q}), \tag{5.22}$$

where

$$1-\frac{\Lambda}{\Lambda_T} \equiv \frac{2\beta\mathcal{E}_F}{{k_F}^5}\int_0^\infty k^4 dk e^{\beta E}\left(1+e^{\beta E}\right)^{-2} \tag{5.23}$$

Letting $y = \epsilon/kT$, and using the sharp maximum of the integrand at $\epsilon = 0$, we find

$$1-\frac{\Lambda}{\Lambda_T} = 2\int_0^\infty dy \frac{\exp\left(y^2+\beta^2\epsilon_0^2\right)^{\frac{1}{2}}}{\left[1+\exp\left(y^2+\beta^2\epsilon_0^2\right)^{\frac{1}{2}}\right]^2}. \tag{5.24}$$

The London constant Λ_T can also be expressed in terms of derivatives of ϵ_0, as is done in Appendix C where the following result is derived

$$\Lambda_T = \Lambda\left(1+\frac{\beta}{\epsilon_0}\frac{d\epsilon_0}{d\beta}\right). \tag{5.25}$$

The total induced current thus becomes:

$$\lim_{\mathbf{q}\to 0}\mathbf{j}(\mathbf{q}) = \mathbf{j}_P + \mathbf{j}_D = -\frac{\Lambda}{\Lambda_T}\frac{ne^2}{mc}, \quad \mathfrak{a}(\mathbf{q}) = -\frac{1}{\Lambda_T c}\mathfrak{a}(\mathbf{q}). \tag{5.26}$$

In the two limiting situations $T\to 0$ and $T\to T_c, \Lambda/\Lambda_T$ can very easily be evaluated. As $T\to 0, \beta$ becomes infinite, so that Λ_T becomes equal to Λ, the London value

$$\lim_{T\to 0}\left(\Lambda/\Lambda_T\right) = 1-2\int_0^\infty dy \exp\left[-\left(y^2+\beta^2\epsilon_0^2\right)^{\frac{1}{2}}\right] = 1 \tag{5.27a}$$

This could have been seen immediately from (5.19) since in the $T\to 0$ limit $L\left(\epsilon_{\mathrm{k}}, \epsilon_{\mathrm{k+q}}\right) = 0$ and the paramagnetic part of the current density is zero. This limit just gives the equation obtained by London assuming complete rigidity of the unperturbed system wave function in the presence of an electromagnetic field. When $T\to T_c, \epsilon_0\beta$ goes to zero and Λ/Λ_T also goes to zero, since

$$\lim_{T\to T_c}\left(\frac{\Lambda}{\Lambda_T}\right) = 1-2\int_0^\infty \frac{e^y dy}{\left(1+e^y\right)^2} = 0 \tag{5.27b}$$

The small Landau diamagnetism would appear only in a higher order. We thus find that when the system is in the superconducting phase, the current density in the London limit has the form (5.1), with Λ_T varying from Λ to ∞ as T goes from 0 to T_c.

It is interesting to note that the Meissner effect occurs for any value of $\epsilon_0 \neq 0$. If $\epsilon_0 = 0$ (for example if we let $V = 0$), then, for $T > 0, \beta\epsilon_0 = 0$ and from (5.27b) we see that $\Lambda/\Lambda_T = 0$. The paramagnetic part of the current density is then

$$\lim_{\mathbf{q}\to 0}\mathbf{j}_P(\mathbf{q}) = \frac{ne^2}{mc}\mathfrak{a}(\mathbf{q}), \tag{5.28}$$

and the total current in the $\mathbf{q}\to 0$ limit becomes

$$\lim_{\mathbf{q}\to \mathbf{0}}\mathbf{j}(\mathbf{q}) = 0. \tag{5.29}$$

This is also true when $T = 0$, though in this case one must be careful of the order in which the various limits are taken.

Current Density

We now evaluate the spacial distribution of the current density and exhibit it in a form similar to that proposed by Pippard. The method we use follows that of one of the authors [7] who carried out a similar calculation for an energy-gap model.

Beginning with (5.15), setting $\mathbf{q} = \mathbf{k}' - \mathbf{k}$, and using the fact that $\mathbf{q}\cdot\mathfrak{a}(\mathbf{q}) = 0$ and that we can write terms like $\mathbf{k}e^{i\mathbf{k}\cdot\mathbf{r}}$ as

$$\mathbf{k}e^{i\mathbf{k}\cdot\mathbf{r}} = -i\nabla e^{i\mathbf{k}\cdot\mathbf{r}}, \tag{5.30}$$

we can reduce all of the angular integrations to integrals of the form

$$\int_0^\pi \sin\theta d\theta e^{\pm ik\cdot(r-r')} = \frac{2}{kR}\sin kR \tag{5.31}$$

where $R = |\mathbf{r}-\mathbf{r}'|$. Then, using the relation

$$\nabla\left(\frac{\sin kR}{kR}\right) = \frac{kR\cos kR - \sin kR}{kR^2}\nabla R, \tag{5.32}$$

we finally obtain

$$\mathbf{j}_P(\mathbf{r}) = \frac{e^2\hbar^2}{2m^2c\pi^4}\int d\mathbf{r}'\frac{(\mathbf{A}(\mathbf{r}')\cdot\nabla' R)\,\nabla R G_s(R)}{R^4} \tag{5.33}$$

where

$$G_s(R) = \int_0^\infty dk\int_0^\infty dk' kk' f(k,R) f(k',R)\, L(\epsilon,\epsilon') \tag{5.34}$$

and

$$f(k,R) = kR\cos kR - \sin kR. \tag{5.35}$$

These equations correspond to (21.4)-(21.6) of reference 7. The entire current density $\mathbf{j}(\mathbf{r})$ can now be written

$$\mathbf{j}(\mathbf{r}) = \mathbf{j}_P(\mathbf{r}) - \frac{ne^2}{mc}\mathbf{A}(\mathbf{r}). \tag{5.36}$$

It is convenient to subtract and add $G_n(R)$ inside the integral (5.33), where $G_n(R)$ is $G_s(R)$ evaluated at $\epsilon_0 = 0$. The integral evaluated with $G_n(R)$ gives the paramagnetic current contribution of a free electron gas and just cancels the term $-(ne^2/mc)\,\mathbf{A}(\mathbf{r})$, leaving the small Landau diamagnetic term in which we are not interested. We have left the interesting part of the current density:
$\mathbf{j}(\mathbf{r}) = \frac{e^2\hbar^2}{2m^2c\pi^4}\int d\mathbf{r}'\frac{[G_s(R)-G_n(R)]\mathbf{R}[\mathbf{A}(\mathbf{r}')\cdot\mathbf{R}]}{R^6}$.
An inspection of $G_s(R)$, (5.34), reveals that the major contribution to the integral comes

from the region $k, k' \simeq k_F$ (i.e., very close to the Fermi surface). Since we are interested in values of $R \gtrsim$ penetration depth which is $\simeq 10^{-5}$ cm, in the region of the major contribution, $kR \simeq k'R \gg 1$. With this in mind, the product $f(k,R)f(k'R)$ becomes

$$\begin{aligned} f(k,R)f(k',R) &\simeq kk'R^2 \cos kR \cos k'R \\ &= \frac{1}{2}kk'R^2 \left[\cos(k+k')R + \cos(k-k')R\right] \\ &\simeq \frac{1}{2}kk'R^2 \cos(k-k')R \end{aligned} \tag{5.38}$$

as $\cos(k+k')R$ is very rapidly oscillating in the region of interest.

Now, making the change of variable $dk = (dk/d\mathcal{E})d\epsilon$, approximating the slowly varying terms $k + k' \simeq 2k_F$ and $dk/d\mathscr{E} \simeq 1/\hbar v_0$, where v_0 is the velocity of an electron at the Fermi surface, and using the rapid convergence of the integral to extend large finite limits to infinite ones, we obtain

$$\begin{aligned} &G_s(R) - G_n(R) \\ &\quad = -\frac{1}{2}k_{F^4}R^2 \left(\frac{dk}{d\mathcal{E}}\right)_F^2 \pi^2 \epsilon_0(0) \frac{\Lambda}{\Lambda_T} J(R,T) \end{aligned} \tag{5.39}$$

where

$$J(R,T) = I(R,0) - I(R,\epsilon_0) \tag{5.40}$$

and

$$\begin{aligned} I(R,\epsilon_0) = \frac{\Lambda_T}{\Lambda\pi^2\epsilon_0(0)} \iint_{-\infty}^{+\infty} d\epsilon d\epsilon' L(\epsilon,\epsilon') \\ \times \cos\left[(\epsilon-\epsilon')\frac{R}{\hbar v_0}\right]. \end{aligned} \tag{5.41}$$

The current density then becomes

$$\mathbf{j}(\mathbf{r}) = \frac{-3}{4\pi c\Lambda_T} \frac{\pi\epsilon_0(0)}{\hbar v_0} \int d\mathbf{r}' \frac{J(R,T)\mathbf{R}\left[\mathbf{A}(\mathbf{r}')\cdot\mathbf{R}\right]}{R^4} \tag{5.42}$$

where Λ_T has been given by (5.25).

The current density has now been written in a form in which it is easily comparable to Eq. (1.3), proposed by Pippard for a pure superconductor, where we identify $1/\xi_0$ with the microscopic quantities:

$$\frac{1}{\xi_0} = \frac{\pi\epsilon_0(0)}{\hbar v_0} \tag{5.43}$$

and where $J(R,T)$ is to be compared with the exponential function, $\exp[-R/\xi_0]$. We have defined $J(R,T)$ so that it has the same integral as $\exp[-R/\xi_0]$:

$$\int_0^\infty J(R,T)dR = \xi_0 \tag{5.44}$$

As evaluated in Appendix C, $J(R,T)$ is given by

$$J(R,T) = \frac{\Lambda_T}{\Lambda}\frac{\epsilon_0(T)}{\epsilon_0(0)}\left[\tanh\frac{\epsilon_0(T)}{2kT} - \frac{2\epsilon_0(T)}{\pi}\int_0^\infty d\epsilon' \sin\left(\frac{2R}{\hbar v_0}\epsilon'\right)\frac{1-2f(E')}{\epsilon' E'}\right] \tag{5.45}$$

from which (5.44) can be established. In the London limit, where $\mathbf{A}(\mathbf{r})$ varies so slowly compared to the coherence distance ξ_0 that it may be taken out of the integral sign, we obtain

$$\mathbf{j}(\mathbf{r}) = -\frac{1}{c\Lambda_T}\mathbf{A}(\mathbf{r}), \tag{5.46}$$

as has been shown previously.

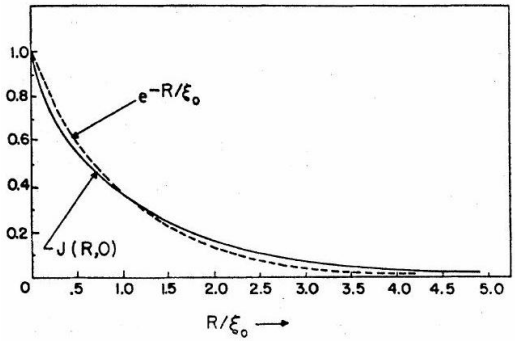

Fig. 5. The kernel $J(R,0)$ for the current density at $T = 0°\mathrm{K}$ vs R/ξ_0, compared with the Pippard kernel, $\exp(-R/\xi_0)$.

With this normalization of $J(R,T)$ it turns out that most of the temperature variation of the current density is contained in Λ_T, and that the integral does not produce effects that vary very much with the temperature. This will be made clear later in the calculation of the penetration depth as a function of the temperature.

At $T = 0, J(R,0)$ has the simple form

$$J(R,0) = \frac{2}{\pi}\int_{2\epsilon_0(0)R/\hbar v_0}^\infty K_0(y)dy \tag{5.47}$$

and when $R = 0$

$$J(0,0) = 1 \tag{5.48}$$

Thus $J(R,0)$ not only has the same integral as the exponential but also the same value at $R = 0$. A comparison of the two given in Fig. 5 shows that they are quite similar.

We may express ξ_0 in a form similar to that suggested by Faber and Pippard [25] :

$$\xi_0 = a\,(\hbar v_0/kT_c) \tag{5.49}$$

where a was adjusted empirically from observed penetration depths. From (5.43), we find

$$\xi_0 = \frac{\hbar v_0}{\pi\epsilon_0(0)} = \frac{1}{\pi\epsilon_0(0)}\frac{kT_c}{kT_c} = 0.18\frac{\hbar v_0}{kT_c} \tag{5.50}$$

Our theoretical value of 0.18 is between the empirical estimates of 0.15 by Faber and Pippard [25] and of 0.27 by Glover and Tinkham. [27] Thus at the absolute zero our theory gives a current density very much like that proposed by Pippard. Since $J(R,T)$ varies slowly with T, most of the temperature variation is contained in the constant Λ_T.

Penetration Depths

A most important application of the equations we have derived for the current density is to the calculation of field penetration at a plane surface. The results depend to some extent on the boundary conditions for scattering of electrons at the surface. Pippard [26] has given general solutions for the limiting cases for specular
reflection and for random scattering, based on corresponding expressions derived by Reuter and Sondheimer [37] for the anomalous skin effect. The penetration depth, defined by

$$\lambda = \frac{1}{H(0)} \int_0^\infty H(x)dx \tag{5.51}$$

is given by

$$\lambda = \frac{2}{\pi} \int_0^\infty \frac{dq}{q^2 + K(q)} \tag{5.52}$$

for specular reflection and by

$$\lambda = \frac{\pi}{\int_0^\infty \ln\left[1 + q^{-2}K(q)\right]} \tag{5.53}$$

for random scattering, where $K(q)$ is defined by (5.3).
Limiting expressions have been given for ξ_0/λ large or small compared with unity. The London limit corresponds to $\xi_0 \ll \lambda$, in which case $K(q)$ is a constant $= 4\pi/\Lambda_T c^2$ over the important range of integration. The penetration depth is then

$$\lambda_L(T) = \left(4\pi/\Lambda_T c^2\right)^{\frac{1}{2}}. \tag{5.54}$$

For a free-electron gas, this reduces to the London value ($mc^2/4\pi ne^2$) at $T = 0°\mathrm{K}$. Since, for most metals, $\xi_0 \simeq 10^{-4}$ cm and $\lambda \simeq 5 \times 10^{-6}$ cm, it is the opposite limit, $\xi_0 \gg \lambda$, which is more applicable (except possibly near T_c). In this limit $J(R,T)$ does not vary much over the penetration depth, so that it is only the value at $R = 0, J(0,T)$, which enters. Pippard [25] has given expressions for λ in this limit, called λ_∞. For random scattering,

$$\lambda_\infty = \frac{3^{1/6}}{(2\pi)^{\frac{1}{3}}} \left(\frac{\xi_0 \lambda_L^2}{J(0,T)}\right)^{\frac{1}{3}}, \tag{5.55}$$

while the value for specular reflection is smaller by a factor 8/9.

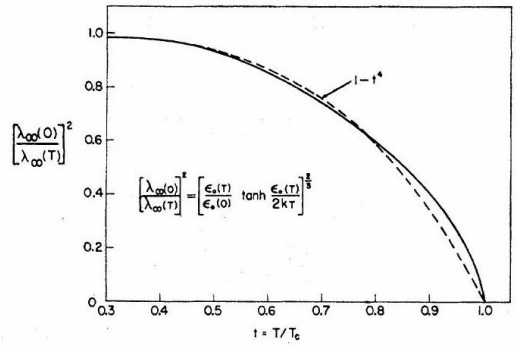

Fig. 6. The temperature variation of the penetration depth, λ_∞, in the infinite coherence distance limit, $(\xi_0/\lambda) \to \infty$, compared with the empirical law, $[\lambda(0)/\lambda(T)]^2 = 1 - t^4$.

Table IV. Penetration depth, λ, at $T = 0°\mathrm{K}$.[a]

					Specular reflection		Random scattering	
Metal	$10^6\lambda_L$ cm	$10^4\hbar v_0/kT_c$ cm	$10^4\xi_0$ cm	ξ_0/λ_L	$\lambda/\lambda L$	$10^6\lambda$	λ/λ_L	$10^6\lambda$
Tin	3.5	1.4	0.25	7.3	1.4	4.8	1.6	5.7
Aluminum	1.6	8.2	1.5	93.			3.2	5.2

[a] Values of λ_L and v_0 are those estimated by Faber and Pippard [25] from high-frequency skin resistance and normal electronic specific heat. The value of ξ_0 is $0.18hv_0/kT_c$, as in (5.43). Ratios in columns 5 and 7 are taken from Fig. 6. Observed values are from reference 25.

The temperature dependence of λ_∞ can be obtained directly from (5.45). The second term vanishes when $R = 0$, so that we have

$$\frac{\lambda_\infty^2(0)}{\lambda_\infty^2(T)} = \left[\frac{\epsilon_0(T)\tanh\left[\frac{1}{2}\beta\epsilon_0(T)\right]}{\epsilon_0(0)}\right]^{\frac{2}{3}} \tag{5.56}$$

A plot of this quantity on a reduced temperature scale is given in Fig. 6. It is plotted in this way so that a comparison can be made with the empirical law:

$$\lambda^2(0)/\lambda^2(t) = 1 - t^4 \tag{5.57}$$

based on the Gorter-Casimir two-fluid model. It is seen that our theory is very close to the empirical law except for temperatures very close to T_c. It is in this region that the approximation $\xi_0 \gg \lambda$ becomes invalid as a result of λ increasing with T. The corrections are such as to reduce the theoretical values so as to bring them closer to the experimental values.

To determine $\lambda(T)$ for intermediate cases, we plot in Fig. 7 the quantity $\lambda(T)/\lambda_L(T)$ as a function of $\xi_0/\ \lambda_L(T)$. The calculations are based on use of the asymtotic forms for $K(q)$ near $T = 0°$ and $T = T_c$ given in Appendix C, and numerical integrations of (5.52) and (5.53). The curves for the two limiting temperatures are quite close together, indicating that the effect of the variation of $J(R, T)$ with temperature is rather small. This procedure is analogous to that of Pippard [5] who gave a plot by means of which one can determine λ from known values of ξ_0 and λ_L for the case $J(R, 0) = \exp(-R/\xi_0)$.

Using our theoretical expression (5.50) for ξ_0 and empirically estimated values of v_0 and $\lambda_L(0)$ for tin and aluminum, [25] we have obtained $\xi_0/\lambda_L(0)$, and, using Fig. 7, have determined $\lambda(0)/\lambda_L(0)$ for these two metals (Table IV). The agreement between theory and experiment is reasonably good, the experimental values falling between the theoretical values calculated for random scattering and specular reflection.

The theory we have presented applies to a pure metal. Pippard [5] has shown experimentally that the existence of a finite mean free path, l, due to impurity scattering, has the effect of increasing the penetration depth, and has suggested that it may be taken into account by introducing an extra factor, $\exp(-R/l)$, into the kernel for the current density. One of the authors [7] has shown why such a factor may be expected from a theory of the diamagnetic properties based on
an energy-gap model. Similar considerations apply to the theory developed in this section; however, effects of coherence on the scattering matrix elements introduce complications and the proper correction factor has not yet been worked out.

To complete the electrodynamics we should give a relation corresponding to the second London equation, the one which gives the time-rate of change of current when an electric field is present. Such a theory would require a calculation, not yet completed, of transport properties with our excited-state wave functions. We expect to find something similar to a two-fluid model, in which thermally excited electrons correspond to the normal component of

the fluid. For frequencies such that $h\nu \ll \epsilon_0$, one may determine $\partial \mathbf{j}/\partial t$ for the superconducting component by taking the time derivative of the integral relation (5.2) and then setting $\partial \mathbf{A}/\partial t = -c\mathbf{E}$ in the result (see reference 7).

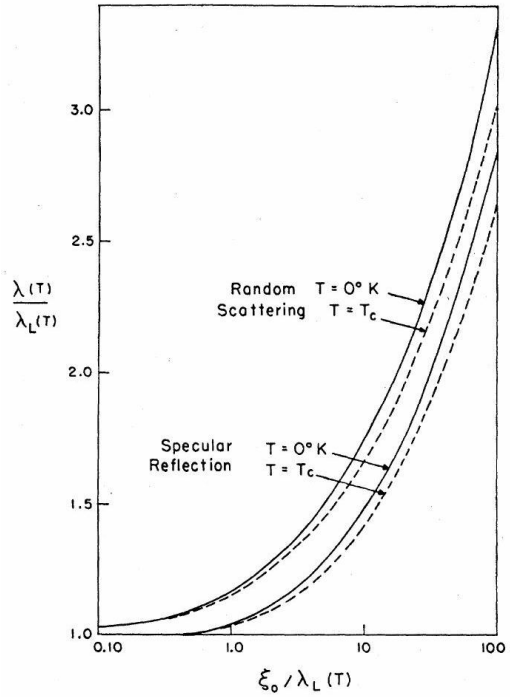

Fig. 7. The ratio $\lambda(T)/\lambda_L(T)$ vs $\xi_0/\lambda_L(T)$ for the boundary conditions of random scattering and specular reflection and for temperatures near $T = 0°\mathrm{K}$ and near $T = T_c$. The temperature variation of $\lambda_L(T)$ is given by $\lambda_L(T) = (\Lambda_T c^2/4\pi)^{\frac{1}{2}}$.

3.10.11 Original 1957 BCS Paper: Appendices

APPENDIX A. CORRECTIONS TO GROUND STATE ENERGY

We may estimate the accuracy of our superconducting ground state energy, W_0, measured relative to that of the normal state, by making a perturbation theory expansion, using the complete set of excited state superconducting wave functions as the basis functions of the expansion. We first consider the reduced, H_{red} , which includes only pair transitions for pair momentum $q = 0$, and then the effect of the neglected portion of the Hamiltonian, $H' = H - H_{\mathrm{red}}$.

To the second order, the ground state energy of H_{red} is:

$$\begin{aligned} \mathscr{W}_0 &= (\Psi_0 \left|H_{\mathrm{red}}\right| \Psi_0) + \sum_{i\neq 0} \frac{\left|(\Psi_i \left|H_{\mathrm{red}}\right| \Psi_0)\right|^2}{W_0 - W_i} + \cdots \\ &= W_0 + W_0^{(2)} + \cdots \end{aligned} \tag{A1}$$

[38] F. Reif, Phys. Rev. 106, 208 (1957).

Since the smallest excitation energy is $2\epsilon_0$, the second order energy is overestimated by setting $|W_0 - W_i| = 2\epsilon_0$ and performing a closure sum. We obtain the inequality

$$\begin{aligned} W_0^{(2)} &\leq \left[\left(\Psi_0 \left|H_{\mathrm{red}}^2\right| \Psi_0\right) - (\Psi_0 \left|H_{\mathrm{red}}\right| \Psi_0)^2\right] / (-2\varepsilon_0) \\ &= \frac{w_a + w_b + w_c}{-2\epsilon_0}, \end{aligned} \tag{A2}$$

where

$$w_a = \left(\Psi_0 \left| H_0^2 \right| \Psi_0\right) - \left(\Psi_0 \left| H_0 \right| \Psi_0\right)^2 \tag{A3}$$

$$w_b = \left(\Psi_0 \left| H_0 H_v + H_v H_0 \right| \Psi_0\right) - 2\left(\Psi_0 \left| H_0 \right| \Psi_0\right)\left(\Psi_0 \left| H_v \right| \Psi_0\right) \tag{A4}$$

$$w_c = \left(\Psi_0 \left| H_v^2 \right| \Psi_0\right) - \left(\Psi_0 \left| H_v \right| \Psi_0\right)^2 \tag{A5}$$

and

$$H_0 = \sum_{k>k_F} \epsilon_{\mathrm{k}} b_{\mathrm{k}}^* b_{\mathrm{k}} + \sum_{k<k_F} \left|\epsilon_{\mathrm{k}}\right| b_{\mathrm{k}} b_{\mathrm{k}}^* \tag{A6}$$

$$H_v = -V \sum_{\mathrm{k},\mathrm{k}'} b_{\mathrm{k}'}^* b_{\mathrm{k}} \tag{A7}$$

the sum in (A7) being carried out over the region $|\epsilon_k|$ and $|\epsilon_{k'}| < \hbar\omega$. If terms in ${W_0}^{(2)}$ linear in the volume of the system are evaluated, the following expressions may be derived with the aid of the decomposition (2.25) :

$$w_a = 8N(0)\int_0^{\hbar\omega} d\epsilon h(\epsilon)[1-h(\epsilon)]\epsilon^2 \tag{A8}$$

$$\begin{aligned} w_b = &-16N(0)V\int_0^{\hbar\omega} d\epsilon_1 \int_0^{\hbar\omega} d\epsilon_2 \left\{h\left(\epsilon_1\right)\left[1-h\left(\epsilon_1\right)\right]\right. \\ &\left.\times h\left(\epsilon_2\right)\left[1-h\left(\epsilon_2\right)\right]\right\}^{\frac{1}{2}}\left[1-2h\left(\epsilon_1\right)\right]\epsilon_1 \\ w_c = &\, 8[N(0)V]^2\left[\int_0^{\hbar\omega} d\epsilon_1 h\left(\epsilon_1\right)\left[1-h\left(\epsilon_1\right)\right]\right]^2 \\ &\times \int_0^{\hbar\omega} d\epsilon_2\left[1-2h\left(\epsilon_2\right)\right]^2 \end{aligned} \tag{A9}$$

With the use of the relations (2.35), (2.36), and (2.37), terms linear in the volume in (A2) become

$$\begin{aligned} -2\varepsilon_0 W_0^{(2)} \leq 8N(0)\int_0^{\hbar\omega} d\epsilon\epsilon^2\{h(\epsilon)[1-h(\epsilon)] \\ -\frac{\epsilon_0^2}{2E^2}+\frac{\epsilon_0^2}{4E^2}\Bigg\} = 0 \end{aligned} \tag{A11}$$

and therefore ${W_0}^{(2)}/W_0$ vanishes in the limit of a large system.

It is likely that $\left(\Psi_0 \left| {H_{\mathrm{red}}}^n \right| \Psi_0\right) - \left(\Psi_0 \left| H_{\mathrm{red}} \right| \Psi_0\right)^n$ also vanishes in this limit for n small compared with the total number of valance electrons in the system. For Ψ_0 to be an exact eigenfunction of H_{red} , in the statistical limit, it is required that the above condition hold for all n. Since this requirement can be shown to hold in
the strong coupling limit, it is possible that Ψ_0 is exact in the statistical limit for all values of the coupling constant, although no proof has been found at this time.

We may estimate the effect of the neglected portion of the Hamiltonian, $H' = H - H_{\mathrm{red}}$ by a similar perturbation calculation. To second order in H' the correction to the superconducting ground state energy W_0 (measured relative to the normal ground state) is

$$W' = \sum_i \frac{|(i\,|H'|\,0)|^2}{W_0 - W_i}, \tag{A12}$$

where

$$\begin{aligned}(i\,|H'|\,0) = -V \Big\{ &[h(\mathbf{k}_0)\,(1-h(\mathbf{k}_0{}'))\,h(\mathbf{k})\,(1-h(\mathbf{k}'))]^{\frac{1}{2}} \\ &- [h(\mathbf{k}_0{}')\,(1-h(\mathbf{k}_0))\,h(\mathbf{k}')\,(1-h(\mathbf{k}))]^{\frac{1}{2}} \Big\}\end{aligned} \tag{A13}$$

The first term in ($i\,|H'|\,0$) may be identified with breaking up a pair in $\mathbf{k}_0$, the spin-down member going to $-\mathbf{k}_0{}' \downarrow$ and breaking up a pair in $\mathbf{k}$, the spin-up member going into $\mathbf{k}' \uparrow$. The second term arises from $\mathbf{k}_0{}'$ and $\mathbf{k}'$ being occupied in the ground state and arriving at the same intermediate state by $\mathbf{k}_0{}' \uparrow \rightarrow \mathbf{k}_0 \uparrow$ and $-\mathbf{k}' \downarrow \rightarrow -\mathbf{k} \downarrow$. The transitions involving particles with parallel spin have been neglected since their contribution is reduced by exchange.

Since the distribution of particle changes differs only over an energy region several ϵ_0 wide, it is to be expected that most of W' will cancel between the normal and superconducting phases. To estimate the energy difference, we shall carry out the sums over a region $6\epsilon_0$ wide. Inserting typical values in (A12), we find

$$W' \sim -\frac{V^2\,[3N(0)\epsilon_0]^3}{2\epsilon_0}\left(\frac{3\epsilon_0}{E_F}\right) \sim 10^{-3} W_0 \tag{A14}$$

where the factor ($3\epsilon_0/E_F$) comes from the average reduction in phase space as a result of conservation of momentum of the pairs making transitions.

These estimates indicate that although the total energy associated with H' may be significant, the effect of H' on the condensation energy is very small. It should be possible to obtain any required quantitative corrections to W_0 by use of perturbation theory.

APPENDIX B. CHANGE IN ZERO-POINT ENERGY OF LATTICE VIBRATIONS

The contribution to the condensation energy from the change in zero-point energy of the lattice can be estimated on the basis of the Bardeen and Pines collective ion-electron treatment. [16] Their theory gives

$$\begin{aligned}&W_{ZP}{}^{(s)} - W_{ZP}{}^{(n)} \\ &\quad = \sum_{\mathbf{k},\boldsymbol{k}} \frac{|M_{\mathbf{k}}|^2 \left\{ \left(n_{\mathbf{k}}^{(s)} - n_{\mathbf{k}}^{(n)}\right) - \left(n_{\mathrm{k}+\kappa}^{(s)} - n_{\mathrm{k}+\kappa}^{(n)}\right) \right\}}{\epsilon_{\mathrm{k}} - \epsilon_{\mathrm{k}+\kappa} - \hbar\omega}\end{aligned} \tag{B1}$$

where $n_{\mathrm{k}}{}^{(s)}$ is the average occupation number in the superconducting state and $n_{\mathrm{k}}{}^{(n)}$ that for the normal
state. The sum over $\boldsymbol{\kappa}$ ranges over the first zone and $\mathbf{k} + \boldsymbol{k}$ is to be interpreted as the corresponding reduced wave vector so that Umklapp processes may be taken into account. If $\mathbf{k} + \boldsymbol{\kappa}$ is replaced by $\mathbf{k}$ and $\boldsymbol{\kappa}$ by $-\boldsymbol{\kappa}$ in the terms containing $n_{\mathrm{k}+\kappa}$, (B1) reduces to

$$\begin{aligned}&W_{ZP^{(s)} - W_{ZP^{(n)}}} \\ &\quad = \sum_{\mathrm{k,k}} \frac{2\,|M_{\mathrm{k}}|^2\,(\epsilon_{\mathrm{k}} - \epsilon_{\mathrm{k+k}})\left(n_{\mathrm{k}}^{(s)} - n_{\mathrm{k}}^{(n)}\right)}{(\epsilon_{\mathrm{k}} - \epsilon_{\mathrm{k}+\kappa})^2 - (\hbar\omega_\kappa)^2}\end{aligned} \tag{B2}$$

If the sum over $\boldsymbol{\kappa}$ is carried out, it is seen that the quantity multiplying the difference in occupation numbers is almost independent of $\mathbf{k}$. Since ${n_{\mathrm{k}}}^{(s)} - {n_{\mathrm{k}}}^{(n)}$ is antisymmetric with respect to the Fermi surface and differs from zero only in a range of the order of several ϵ_0, it follows that the change in zero-point energy will be small compared to W_0.

A rough estimate of the sum gives

$$\begin{aligned} W_{ZP^{(s)}-W_{ZP^{(n)}}=-2\langle|M_\kappa|^2\rangle\int_0^{\hbar\omega}N(0)h(\epsilon)d\epsilon} & \\ \times\int_{\mathcal{E}_F}^{\mathcal{E}_Z}N(\epsilon')\left\{\frac{\epsilon-\epsilon'}{(\epsilon-\epsilon')^2-(\hbar\omega)^2}+\frac{\epsilon+\epsilon'}{(\epsilon+\epsilon')^2-(\hbar\omega)^2}\right\}d\epsilon' & \\ \simeq -2\langle|M_\kappa|^2\rangle\int_0^{\hbar\omega}N(0)h(\epsilon)d\epsilon\cdot 2\epsilon\left[N(\mathcal{E}_Z)/\mathcal{E}_Z\right] & \\ \simeq -2\frac{\langle|M_\kappa|^2\rangle}{\mathcal{E}_Z}[N(0)]^2\epsilon_0^2\simeq(\hbar\omega/\mathcal{E}_Z)W_0\simeq 10^{-3}W_0, \quad \text{(B} & \end{aligned} \tag{B3}$$

where $\mathcal{E}_Z$ is the energy at the zone boundary and typical values have been inserted for the parameters. Thus, it appears that the lattice zero-point energy should have little effect on the condensation energy.

APPENDIX C. EVALUATION OF THE KERNEL IN THE PIPPARD INTEGRAL

According to (5.41), the kernel of the Pippard integral expression for the current density at any temperature T may be written

$$\begin{aligned} J(R,T) &= I(R,0)-I(R,\epsilon_0) \\ &= \frac{\Lambda_T}{\pi^2\epsilon_0(0)\Lambda}\iint_{-\infty}^{+\infty}\left\{\frac{f(\epsilon')-f(\epsilon)}{\epsilon-\epsilon'}-L(\epsilon,\epsilon')\right\}\cos\alpha(\epsilon-\epsilon')\,d\epsilon d\epsilon' \end{aligned} \tag{C1}$$

where $\alpha = R/\hbar v_0$. The limits should really be $\pm\hbar\omega$, but the convergence is sufficiently rapid in the weak coupling limit so that we may replace $\hbar\omega$ by ∞ without appreciable error. One integration can be performed if use is made of the symmetry of the integrand in ϵ and ϵ'. We shall use the second form given for $L(\epsilon,\epsilon')$ in (4.22), with the lower (+) signs. From the symmetry
for positive and negative values of ϵ and ϵ', the integral may be written as the sum of two integrals with limits 0 and ∞ :

$$J(R,T) = \left[\Lambda_T/\pi^2\epsilon_0(0)\Lambda\right](I_1+I_2) \tag{C2}$$

where

$$I_1 = 2\int_0^\infty\int_0^\infty\frac{[F(\epsilon)-F(\epsilon')]\cos\alpha\epsilon\cos\alpha\epsilon'}{\epsilon^2-\epsilon'^2}d\epsilon d\epsilon' \tag{C3}$$

$$I_2 = 2\int_0^\infty\int_0^\infty\frac{[G(\epsilon)-G(\epsilon')]\,\epsilon\epsilon'\sin\alpha\epsilon\sin\alpha\epsilon' d\epsilon d\epsilon'}{\epsilon^2-\epsilon'^2} \tag{C4}$$

and

$$F(\epsilon) = [1-2f(\epsilon)]\epsilon-[1-2f(E)]\left(E+\epsilon_0^2E^{-1}\right) \tag{C5}$$

$$G(\epsilon) = [1-2f(\epsilon)]\epsilon^{-1}-[1-2f(E)]E^{-1} \tag{C6}$$

Unless the argument is given explicitly, $\epsilon_0 \equiv \epsilon_0(T)$.
If integration over the region about $\epsilon' = \epsilon$ is made by principal parts, each of the two terms in I_1 (and each of the two terms in I_2) will give equal contributions. Care must be taken to take the same limits for ϵ and ϵ'. Thus we may write

$$I_1 = 4 \odot' \lim_{a\to 0, b\to\infty} \int_a^b \int_a^b \frac{F(\epsilon)\cos\alpha\epsilon\cos\alpha\epsilon' d\epsilon d\epsilon'}{\epsilon^2 - \epsilon'^2} \tag{C7}$$

Here $\mathscr{P}'$ indicates the principal part of the integral of ϵ' past $\epsilon' = \epsilon$ is to be taken. Since $F(\epsilon) \to 0$ as $\epsilon \to \infty$, the value of the integral does not depend on how the upper limits of the integrals over ϵ and ϵ' are approached. Thus we may set $b = \infty$ for both, and integrate over ϵ' first. This would not have been true if we had not included $I(R, 0)$, the normal state contribution, which is equivalent to the term proportional to $\mathbf{A}$ in the expression for the current density. The lower limit is more critical; we must take a the same for both ϵ and ϵ' and approach the limit $a = 0$ only in the final result. The integral over ϵ' may be obtained from

$$\int_a^\infty \frac{\cos\alpha\epsilon' d\epsilon'}{\epsilon^2 - \epsilon'^2} = \int_0^\infty \frac{\cos\alpha\epsilon' d\epsilon'}{\epsilon^2 - \epsilon'^2} - \int_0^a \frac{d\epsilon'}{\epsilon^2 - \epsilon'^2} \tag{C8}$$

In the second integral on the right we have assumed that a is sufficiently small so that $\cos\alpha\epsilon'$ may be replaced by unity. The first integral on the right may be evaluated by contour integration and the second directly to give

$$\mathscr{O}' \int_a^\infty \frac{\cos\alpha\epsilon' d\epsilon'}{\epsilon^2 - \epsilon'^2} = \frac{1}{2}\pi\frac{\sin\alpha\epsilon}{\epsilon} - \frac{1}{2\epsilon}\ln\left(\frac{\epsilon + a}{\epsilon - a}\right) \tag{C9}$$

Similarly, to evaluate I_2, we have

$$\mathscr{P}' \int_0^\infty \frac{\epsilon' \sin\alpha\epsilon' d\epsilon'}{\epsilon^2 - \epsilon'^2} = -\frac{1}{2}\pi\cos\alpha\epsilon \tag{C10}$$

In this integral we may take $a = 0$, since the integrand is not singular at the origin. Combining I_1 and I_2, we find

$$\begin{aligned} I_1 + I_2 = -2\int_a^\infty F(\epsilon)\ln\left(\frac{\epsilon + a}{\epsilon - a}\right)\frac{d\epsilon}{\epsilon} \\ + \pi\int_0^\infty \left[F(\epsilon) - \epsilon^2 G(\epsilon)\right]\frac{\sin 2\alpha\epsilon}{\epsilon} d\epsilon \end{aligned} \tag{C11}$$

In the limit $a \to 0$, the first integral gives a contribution only near $\epsilon = 0$. We may therefore replace $F(\epsilon)$ by $F(0)$. The logarithmic integral may then be evaluated, and we find

$$\begin{aligned} I_1 + I_2 = \pi^2\epsilon_0\left[1 - 2f\left(\epsilon_0\right)\right] \\ - 2\pi\epsilon_0^2\int_0^\infty \frac{1 - 2f(E)}{E}\sin 2\alpha\epsilon d\epsilon \end{aligned} \tag{C12}$$

Note that this expression vanishes in the two limits $\epsilon_0 \to 0$ and α (or R) $\to \infty$, as it should. The second term vanishes as $R \to 0$.

From (C2) and (C12), we may write

$$\begin{aligned} J(R,T) = \frac{2\Lambda_T\epsilon_0^2}{\pi\epsilon_0(0)\Lambda}\int_0^\infty \left\{\frac{1 - 2f\left(\epsilon_0\right)}{\epsilon_0}\right. \\ \left. - \frac{1 - 2f(E)}{E}\right\}\frac{\sin 2\alpha\epsilon}{\epsilon} d\epsilon \end{aligned} \tag{C13}$$

which is equivalent to (5.45) of the text.
Since $f = 0$ when $T = 0$, we can write

$$J(R,O) = \frac{2\epsilon_0(0)}{\pi}\left(\frac{\pi}{2\epsilon_0(0)} - \int_0^\infty \frac{\sin 2\alpha\epsilon}{\epsilon E}d\epsilon\right) \tag{C14}$$

This can be put into a form convenient for evaluation by using

$$\begin{aligned}\frac{\partial}{\partial\alpha}\int_0^\infty \frac{\sin 2\alpha\epsilon}{\epsilon E}d\epsilon &= 2\int_0^\infty \frac{\cos 2\alpha\epsilon}{E}d\epsilon \\ &= 2K_0\left(2\alpha\epsilon_0\right)\end{aligned} \tag{C15}$$

where K_0 is a modified Bessel function [39] which falls off exponentially for large values of its argument. If we now observe that $\int_0^\infty K_0(y)dy = \pi/2$, we obtain

$$J(R,O) = \frac{2}{\pi}\int_{2R/\pi\xi_0}^\infty K_0(y)dy \tag{C16}$$

We next consider the integral of $J(R,T)$ with respect to R. If we introduce a convergence factor, we may
integrate under the sign in (C13):

$$\lim_{\gamma\to 0}\int_0^\infty e^{-\gamma R}\sin\left(2\epsilon R/\hbar v_0\right)dR = \frac{1}{2}\hbar v_0/\epsilon \tag{C17}$$

Thus, remembering that $\xi_0 = hv_0/\left[\pi\epsilon_0(0)\right]$, we find

$$\begin{aligned}&\frac{1}{\xi_0}\int_0^\infty J(R,T)dR \\ &\quad = \frac{\epsilon_0^2\Lambda_T}{\Lambda}\int_0^\infty\left\{\frac{1-2f\left(\epsilon_0\right)}{\epsilon_0} - \frac{1-2f(E)}{E}\right\}\frac{d\epsilon}{\epsilon^2}\end{aligned} \tag{C18}$$

According to (5.44) of the text, Λ_T is defined so that the expression on the left is equal to unity. If we integrate the right hand side by parts, we find that

$$\frac{\Lambda}{\Lambda_T} = -\epsilon_0^2\int_0^\infty \frac{d}{dE}\left(\frac{1-2f(E)}{E}\right)\frac{d\epsilon}{E} \tag{C19}$$

This integral may be expressed in terms of ϵ_0 and its temperature derivative by differentiating the defining integral for ϵ_0 with respect to $\beta = 1/kT$. By a change of variable, $\beta\epsilon = x, \beta\epsilon_0 = y$, we may write

$$\begin{aligned}\frac{1}{N(0)V} &= \int_0^{\hbar\omega}\frac{1-2f(E)}{E}d\epsilon \\ &= \int_0^{\beta\hbar\omega}\frac{1-2f\left(\left(x^2+y^2\right)^{\frac{1}{2}}\right)}{\left(x^2+y^2\right)^{\frac{1}{2}}}dx\end{aligned} \tag{C20}$$

We now differentiate with respect to β, remembering that y depends on β. In the weak-coupling limit $[\epsilon_0 \ll \hbar\omega, f(\beta\hbar\omega) \simeq 0]$, we find:

[39] See Erdelyi, Magnus, Oberhettinger, and Tricomi, Higher Transcendental Functions (McGraw Hill Book Company, Inc., New York, 1953), Vol. 2, pp. 5 and 19.

$$0 = \frac{1}{\beta} + \frac{d(\beta\epsilon_0)}{d\beta} \cdot \frac{\epsilon_0}{\beta} \int_0^{\hbar\omega} \frac{d}{dE}\left(\frac{1-2f(E)}{E}\right) \frac{d\epsilon}{E} \tag{C21}$$

The integral converges sufficiently rapidly so that we may replace the upper limit by ∞. Comparing (C19) and (C21), we find that

$$\frac{\Lambda_T}{\Lambda} = \frac{1}{\epsilon_0} \frac{d(\beta\epsilon_0)}{d\beta} \tag{C22}$$

as stated in (5.25).

Finally, we shall derive an approximate expression for the transform $K(q)$ valid when $qhv_0 > \epsilon_0(0)$. First we express $K(q)$ as an integral of $J(R,T)$. The transform of $\mathbf{j}(\mathbf{r})$ may be written

$$\begin{aligned} \mathbf{j}(\mathbf{q}) &= -\frac{c}{4\pi} K(q) \mathfrak{a}(\mathbf{q}) \\ &= -\frac{3}{4\pi c \Lambda_T \xi_0} \int \frac{\mathbf{R}[\mathbf{R}\cdot\mathfrak{a}(\mathbf{q})] e^{i\mathbf{q}\cdot\mathbf{R}}}{R^4} J(R,T) d\tau \end{aligned} \tag{C23}$$

To carry out the integration over angles, we take the polar axis in the direction of $\mathbf{q}$ and set $u = \cos\theta$. This gives

$$K(q) = \frac{3\pi}{c^2 \Lambda_T \xi_0} \int_0^\infty \int_{-1}^{+1} \left(1-u^2\right) e^{iRqu} J(R,T) du dR.$$

When (C13) is substituted for $J(R,T)$, we require the following integral:

$$g(b) = \int_0^\infty \int_{-1}^{+1} e^{iRqu} \left(1-u^2\right) \sin\left(\epsilon Rq/\epsilon_1\right) du dR = \left(1-b^2\right) \ln\left(\frac{1+b}{1-b}\right) + 2b \tag{C25}$$

where $\epsilon_1 = \frac{1}{2} q\hbar v_0$ and $b = \epsilon/\epsilon_1$. We thus find

$$K(q) = \frac{6\pi\epsilon_0^2}{qc^2\Lambda\hbar v_0} \int_0^\infty \left\{ \frac{1-2f(\epsilon_0)}{\epsilon_0} - \frac{1-2f(E)}{E} \right\} g(b) \frac{d\epsilon}{\epsilon}.$$

Expansions of $g(b)$ for b small and b large are

$$b < 1 : g(b) = 4\left(b - \frac{1}{3}b^3 - \frac{1}{15}b^5 \cdots\right) \tag{C27}$$

$$b > 1 : g(b) = 4\left(\frac{1}{3b} + \frac{1}{15b^3} + \cdots\right) \tag{C28}$$

Further,

$$\int_0^\infty g(b) \frac{db}{b} = \frac{1}{2}\pi^2 \tag{C29}$$

We may change the variable of integration in (C26) from ϵ to b, and then use different expansions for $b < 1$ and $b > 1$. One of the integrals required is

$$\begin{aligned} &4\int_0^1 \frac{1-2f(E)}{E} \left\{ b - \frac{1}{3}b^3 - \frac{1}{15}b^5 - \cdots \right\} \frac{db}{b} \\ &+ 4\int_1^\infty \frac{1-2f(E)}{E} \left\{ \frac{1}{3b} + \frac{1}{15b^3} + \cdots \right\}_{\frac{db}{b}} \end{aligned} \tag{C30}$$

In terms of b,

$$E = \epsilon_1 \left(b^2 + b_0^2\right)^{\frac{1}{2}} \tag{C31}$$

where

$$b_0 = \epsilon_0/\epsilon_1. \tag{C32}$$

An approximate expression valid in the limit $b_0 \ll 1$ may be obtained by neglecting b_0 in the integral for $b > 1$, and also in terms in b^3 and higher in the integral for $b < 1$. The only integral in which ${b_0}^2$ is not neglected in comparison with b^2 is the first term,

$$4\int_0^1 \frac{1-2f(E)}{E} db = \frac{4}{\epsilon_1}\int_0^{\epsilon_1} \frac{1-2f(E)}{E} d\epsilon \tag{C33}$$

which can be determined from (C20), the defining integral for ϵ_0. For $\epsilon > \epsilon_1$ we may take $f(E) = 0$. Thus we find

$$\frac{4}{\epsilon_1}\int_0^{\epsilon_1} \frac{1-2f(E)}{E} d\epsilon \simeq \frac{4}{\epsilon_1}\left(\frac{1}{N(0)V} - \ln\frac{\hbar\omega}{\epsilon_1}\right) = \frac{4}{\epsilon_1}\ln\frac{q\hbar v_0}{\epsilon_0(0)} \tag{C34}$$

The latter form follows from the expression for $\epsilon_0(0)$ in the weak-coupling limit. The remaining terms cancel when ${b_0}^2$ is neglected:

$$\int_0^1 \left\{\frac{b^3}{3} - \frac{b^5}{15} - \cdots\right\}\frac{db}{b^2} + \int_1^\infty \left\{\frac{1}{3b} + \frac{1}{15b^3} + \cdots\right\}\frac{db}{b^2} = 0 \tag{C35}$$

Thus we find that for $q\hbar v_0/\epsilon_0(0) = \pi q\xi_0 \gg 1$,

$$K(q) = \frac{3\pi^2\epsilon_0}{qc^2\Lambda\hbar v_0}\left\{1 - 2f\left(\epsilon_0\right) - \frac{16\epsilon_0}{\pi^2 q\hbar v_0}\ln\left(\pi q\xi_0\right)\right\}. \tag{C36}$$

For q very small, $K(q)$ approaches the constant value,

$$K(q) = \lambda_L^{-2}(T) = 4\pi/\left(\Lambda_T c^2\right), \quad (q \to 0) \tag{C37}$$

where Λ_T is the temperature-dependent London constant defined by (C22). For intermediate values of q, one may interpolate between this constant value for $\pi q\xi_0 < 1$ and the asymptotic form (C36) for large q.

The two limiting cases are $T = 0°\mathrm{K}$ and T close to T_c. At $T = 0°\mathrm{K}, \epsilon_0 \to \epsilon_0(0)$ and $f\left(\epsilon_0\right) \to 0$, and we find

$$K(q) = 4\pi/\left(\Lambda c^2\right) = 1/{\lambda_L}^2(0), \quad (q \to 0); \tag{C38}$$

$K(q) = \frac{3\pi}{4q{\lambda_L}^2(0)\xi_0}\left\{1 - \frac{16}{\pi^3 q\xi_0}\ln\left(\pi q\xi_0\right)\right\}$, (large q).

Near T_c, one may determine Λ_T from (C22) and (3.49):

$$\Lambda/\Lambda_T = 0.23\beta_c^2\epsilon_0^2(T) = 2(1-t) \tag{C40}$$

where $\beta_c = 1/kT_c$ and $t = T/T_c$. When $\epsilon_0(T)$ is small,

$$1 - 2f\left(\epsilon_0\right) = \tanh\left(\frac{1}{2}\beta\epsilon_0\right) \to \frac{1}{2}\beta_c\epsilon_0(T) \tag{C41}$$

Thus the limiting expressions for $K(q)$ as $T \to T_c$ are

$$K(q) = \frac{1}{{\lambda_L}^2(T)} = \frac{2(1-t)}{{\lambda_L}^2(0)}, \quad (q \to 0); \tag{C42}$$

$K(q) = \frac{3.75\pi}{4q{\lambda_L}^2(T)\xi_0}\left\{1 - \frac{18.3}{\pi^3 q\xi_0}\ln(\pi q\xi_0)\right\}, \quad (\text{ large } q).$

The close similarity of the expressions for the two limiting cases is evident. The reason for the similarity is that $J(R,T)$ varies slowly with T.

At temperatures very close to T_c, λ becomes larger than ξ_0, so that $\lambda(T)$ approaches $\lambda_L(T)$. A comparison of penetration depths measured near T_c to those measured at low temperatures would then be expected to give

$$\frac{\lambda(0)}{\lambda(T)} = \frac{\lambda(0)}{\lambda_L(0)}\frac{\lambda_L(0)}{\lambda(T)} = \frac{\lambda(0)}{\lambda_L(0)}\sqrt{2}(1-t)^{\frac{1}{2}} \tag{C44}$$

This is to be compared with the ratio $2(1-t)^{\frac{1}{2}}$ which the empirical law, $(1-t^4)^{\frac{1}{2}}$, gives as $t \to 1$.

APPENDIX D. CORRELATION OF ELECTRONS OF OPPOSITE SPIN

Insight into the coherent structure of our ground state wave function may be obtained by an investigation of the correlation function for electrons of opposite spin. For the normal metal (in the Bloch approximation), electrons of antiparallel spin are entirely uncorrelated while for electrons of parallel spin there is the exchange correlation.

The correlation function $\rho_{\sigma'\sigma''}(\mathbf{r}', \mathbf{r}'')$ for an n-electron system is defined as

$$\begin{aligned}\rho_{\sigma'\sigma''}(\mathbf{r}', \mathbf{r}'') = \sum_{i,j=1}^{2n} \int \cdots \int d\tau_1 \cdots d\tau_n \Psi^*(\mathbf{r}_1 \cdots r_n) \\ \times \Psi(\mathbf{r}_1 \cdots r_n)\, \delta_{\sigma'}(\mathbf{r}_i - \mathbf{r}')\, \delta_{\sigma''}(\mathbf{r}_j - \mathbf{r}'')\end{aligned} \tag{D1}$$

This can be written in second quantized form, following the notation of Sec. V, as

$$\begin{aligned}\rho_{\sigma'\sigma''}(\mathbf{r}', \mathbf{r}'') = (\Psi_0 \left|\psi_{\sigma''} * (\mathbf{r}'')\, \psi_{\sigma'} * (\mathbf{r}')\, \psi_{\sigma'}(\mathbf{r}')\, \psi_{\sigma''}(\mathbf{r}'')\right| \Psi_0) \\ = \sum_{\mathbf{k}_1,\mathbf{k}_2,\mathbf{k}_3,\mathbf{k}_4} (\Psi_0 \left|c^*(\mathbf{k}_1, \sigma'')\, c^*(\mathbf{k}_2, \sigma')\, c(\mathbf{k}_3, \sigma')\, c(\mathbf{k}_4, \sigma'')\right| \Psi_0) \\ \times e^{i(\mathbf{k}_4 - \mathbf{k}_1)\cdot\mathbf{r}'' + i(\mathbf{k}_3 - \mathbf{k}_2)\cdot\mathbf{r}'},\end{aligned} \tag{D2}$$

where Ψ_0 is our ground-state wave function.

Of particular interest is the correlation function for electrons of opposite spin. If we define

$$\rho_A = \rho_{\uparrow\downarrow} + \rho_{\downarrow\uparrow} \tag{D3}$$

use the matrix elements obtained in Sec. IV, and set $\mathbf{r} = \mathbf{r}' - \mathbf{r}''$, we get at the absolute zero of temperature

$$\rho_A(r) = n\left[\frac{1}{2}n + P_A(r)\right]$$

where

$$P_A(r) = \frac{1}{2n}\left(\frac{1}{2\pi}\right)^6 \iint_{\mathcal{R}} d\mathbf{k} d\mathbf{k}' \left\{e^{i(\mathbf{k}' - \mathbf{k})\cdot\mathbf{r}} \frac{\epsilon_0^2(0)}{EE'}\right\} \tag{D4}$$

The integration is over $\mathcal{R}$, the region of interaction ($|\epsilon| < \hbar\omega$), and n is the number of electrons of both spin directions per unit volume. The terms in the bracket give the number of

electrons of opposite spin per unit volume one would find a distance r away from an electron of given spin direction. The first term is just the average density, while the second gives the effects of correlation.

The integral of $P_A(r)$ gives the number of electrons of opposite spin correlated with a given electron. This is

$$\begin{aligned}\int P_A(r)d\tau &= \frac{\epsilon_0^2(0)}{2n}\left(\frac{1}{2\pi}\right)^3\int_{\mathscr{R}} dk\frac{1}{\epsilon^2+\epsilon_0^2(0)} \\ &\simeq \frac{\epsilon_0^2(0)}{2n}\frac{1}{\pi^2}\frac{dk}{d\mathscr{E}}\Big]_F k_{F^2}\int_0^{\hbar\omega}\frac{d\epsilon}{\epsilon^2+\epsilon_0^2(0)} \\ &\simeq \frac{3}{4}\frac{1}{k_F\xi_0} = \frac{\pi n_c}{2}\end{aligned} \tag{D5}$$

where we have given slowly varying functions their value at the Fermi surface, and have used (5.43) and $n_c = N(0)\epsilon_0(0)$. Thus the number of electrons of given spin correlated to one of opposite spin is of the order of the ratio of the number of electrons in coherent pairs to the total number of electrons in the system.

The range of the spacial correlation may be determined by investigating $P_A(r)$. We must then evaluate

$$I = \left(\frac{1}{2\pi}\right)^3\int_{\mathcal{R}} d\mathbf{k}\frac{e^{i\mathbf{k}\cdot\mathbf{r}}}{E} = \frac{1}{2\pi^2 r}\int_{k_F-\delta}^{k_F+\delta}\frac{k\sin krdk}{\left[\epsilon^2+\epsilon_0^2(0)\right]^{\frac{1}{2}}} \tag{D6}$$

To evaluate this, we make use of the sharp maximum of the integral near $\epsilon = 0$ and the fact that the sine function is rapidly oscillating in this region for values of r of interest, $k_F r \gg 1$. We set (as in Sec. V)

$$k \simeq k_F + \frac{dk}{d\mathscr{E}}\Big]_F \epsilon = k_F + \epsilon/\left(hv_0\right) \tag{D7}$$

and

$$\sin\left(k_F+\frac{\epsilon}{hv_0}\right)r \simeq \sin k_F r\cos\left(\frac{\epsilon}{hv_0}r\right) \tag{D8}$$

give slowly varying functions their value at the Fermi surface, and drop terms antisymmetric in ϵ. Then, setting $x = \epsilon/\epsilon_0$, we get

$$I = \frac{k_F}{\pi^2 r}\frac{1}{hv_0}\sin k_F r\int_0^a\frac{\cos\left(rx/\pi\xi_0\right)dx}{\left(x^2+1\right)^{\frac{1}{2}}} \tag{D9}$$

where $a = \hbar\omega/\epsilon_0 \gg 1$. The integral may be expressed as

$$\int_0^a\frac{\cos\left(r/\pi\xi_0\right)x}{\left(x^2+1\right)^{\frac{1}{2}}}dx = K_0\left(\frac{r}{\pi\xi_0}\right) - \int_a^\infty\frac{\cos\left(rx/\pi\xi_0\right)}{\left(x^2+1\right)^{\frac{1}{2}}}dx \tag{D10}$$

where K_0 is a modified Bessel function. [39] Since $a \gg 1$ except for very small values of $r, \left(x^2+1\right)^{\frac{1}{2}} \simeq x$ in the last integral. Then, setting $t = rx/\left(\pi\xi_0\right)$, we have

$$I = \frac{k_F}{\pi^2 r}\frac{1}{hv_0}\sin k_F r\left[K_0\left(\frac{r}{\pi\xi_0}\right) - \int_{ar/\pi\xi_0}^\infty\frac{\cos t}{t}dt\right].$$

Asymptotically

$$-\int_x^\infty \frac{\cos t}{t} dt \sim \frac{\sin x}{x}, \quad x \gg 1$$

while $K_0(x)$ falls off exponentially. Thus the asymptotic behavior of $P_A(r)$ is given by

$$P_A(r) \sim \frac{9n\epsilon_0^2(0)}{2(\hbar\omega)^2} \frac{\sin^2 k_F r \sin^2\left(\frac{\epsilon_0}{\hbar\omega}\frac{r}{\pi\xi_0}\right)}{(k_F r)^4}.$$

Since $a = h\omega/\epsilon_0 \gg 1$, the range of correlation is determined by the K_0 function which drops off rapidly when $r/(\pi\xi_0) \gtrsim 1$. Thus correlation distance is the order of $\pi\xi_0 \simeq 10^{-4}$ cm.

3.10.12 Phase and Particle Number Operators in SC

Calculation of the Number of Particles

One gets the number of particles from $F_{\boldsymbol{k}}$, which has the meaning of a 'condensate wave-function' (apart from normalization)

$$\frac{N_0}{|\Lambda|} := \frac{1}{|\Lambda|}\sum_{\text{band}} |F_{\boldsymbol{k}}|^2 = \frac{1}{|\Lambda|}\sum_{\text{band}} \Delta^2/(2E_{\boldsymbol{k}})^2 = \frac{N(0)}{4}\int_{\text{band}} \mathrm{d}\xi \frac{\Delta^2}{\xi^2+\Delta^2}$$

For obvious reasons, N_0 is identified with the number of particles in the condensate. In the limit $\Delta \ll \omega_c$, the integral can be extended to the full line and this yields

$$\frac{N_0}{|\Lambda|} = \frac{\pi}{4}\Delta N(0)$$

In the free-electron approximation, we have

$$N(0) \sim (3\epsilon_F)^{-1} N/\Lambda$$

where N/Λ is the total density, then

$$N_0/N = \pi\Delta/(12\epsilon_F)$$

what is in particular clear from this relation, is that the condensate density vanishes with Δ. This is logical because only the electrons near the FS participate in the condensate.

Particle number is not conserved in superconductors

(here I'll explain, why it is so?)

Particle number and phases have uncertainty

It's common knowledge (and has been discussed in other questions on this site) that the standard BCS ground state $|\Psi_{BCS}\rangle = \prod_k \left(u_k + v_k c^\dagger_{k\uparrow} c^\dagger_{-k\downarrow}\right)|0\rangle$ does not have a well-defined particle number and that this doesn't matter in bulk superconductors because the standard deviation is $\Delta N \propto \sqrt{N}$ and hence irrelevant for $N \to \infty$.

But I also read that you can arrive at a BCS state with well-defined particle number by first defining

$$|\Psi_{BCS}(\phi)\rangle = \left(|u_k| + e^{i\phi}|v_k|c^\dagger_{k\uparrow}c^\dagger_{-k\downarrow}\right)|0\rangle$$

and then "integrating out" the phase according to

$$|\Psi_{BCS}(N)\rangle = \int_0^{2\pi} \mathrm{d}\phi\, e^{-iN\phi/2}\,|\Psi_{BCS}(\phi)\rangle \ ,$$

which gives you a BCS state with precisely N particles **at the cost of having a completely ill-defined phase**.

If that is true, then surely this is the actual "physical" state of a superconductor and the original BCS state is merely used for convenience.

But that, in turn, *would make the well-defined phase of the superconducting state a mere mathematical artifact*, when every other textbook highlights it as something very fundamental (and if I remember correctly, it's very important for things like the Josephson effect as well).

So, can anyone point to the error in the logic above?

The important point is that $[N, \phi] = i$, with N the number of electron et ϕ the phase. So you can apply the Heisenberg uncertainty principle, of which you gave the two extremum situations of 1) either perfectly defined N and completely unknown ϕ or 2) perfectly defined ϕ and completely unknown N. In general varying a bit the phase ϕ let a bit of electron N flowing, which is the basic situation in mesoscopic systems (e.g. Josephson junctions).

Conceptually, isolate a part of a superconductor (or any macroscopic system behaving as quantum mechanics), if you can count the number of electrons precisely, there is no current and so no phase difference, so ϕ is not a good quantum number. If you can define a current (and so fix a phase *difference*) you can not count the electrons in your control volume of superconductor.

Note that it is not that obvious to demonstrate the commutation relation $[N, \phi] = i$ in the general case, and discussions using this relation are usually subtle.

3.10.13 BCS model with net motion of electrons

(??? write it later here! it is already written before in Shmid's theory and in Gor'kov's theory)

Net motion of Cooper pairs in BCS

(оставил этот вопрос, внятного ответа не читал, самому думать про это нет времени)

Электроны в паре Купера все-таки куда-то в общей массе двигаются, пусть и имеют противоположные импульсы, потому что их импульсы противоположны только в их СО, а не в нашей. (???? никак это не соотношу с формулой?????????????77)

BCS model with net motion of Cooper pairs

(write solution to it here)

How can each electron move in the Cooper pair to the different directions?

(подробно отвечу на этот вопрос, потому что давно он весит. не знаю пока удовлетворяющего меня ответа! потом пропишу. ну да, говорим, что это в СО электронов, а эта СО и движется. но где конкретно это в формулах?)

3.11 BCS: Formalisms for Special Setups

3.11.1 BCS in a Framework of Path Integral

(write this later here! also, before there will be paragraphs with it)

Why path integral is applicable for the BCS model?

(because this is a general framework of the cond matter. but I'll write a really good answer here)

What do we mean by path integral for the BCS model?

(now, there is no that interpretation of paths, so what do we mean by these formulas?)

Formulation of BCS using Path Integral

(see Coleman and others, add it here)

Advantages of path integral approach?

(discuss advantages)

Should we really use path integral approach?

(??? currently, I think that no, without it all works fine. but maybe later I'll see that it is better to formulate all in it...)

3.11.2 Nambu Notation, Hole Interpretation

(I'll write about it from my master's thesis)

Formulation of the Nambu formalism

(??? write a good theory)
There are several ways of introduction of the Nambu notation.

The typical Nambu spinor is defined as

$$\psi_{\mathbf{k}} = \begin{pmatrix} c_{\mathbf{k}\uparrow} \\ c^{\dagger}_{-\mathbf{k}\downarrow} \end{pmatrix} \quad \text{electron}$$

with the corresponding Hermitian conjugate

$$\psi^{\dagger}_{\mathbf{k}} = \left(c^{\dagger}_{\mathbf{k}\uparrow}, c_{-\mathbf{k}\downarrow} \right)$$

Nambu spinors behave like conventional electron fields, with an algebra

$$\left\{ \psi_{\mathbf{k}\alpha}, \psi^{\dagger}_{\mathbf{k}'\beta} \right\} = \delta_{\alpha\beta}\delta_{\mathbf{k},\mathbf{k}'}$$

but instead of up and down electrons, they describe electrons and holes. These spinors enable us to unify the kinetic and pairing energy terms into a single vector field, analogous to a magnetic field, that acts in isospin space.

The kinetic energy can be written as

$$\sum_{\mathbf{k}} \epsilon_{\mathbf{k}} \left(c^{\dagger}_{\mathbf{k}\uparrow} c_{\mathbf{k}\uparrow} - c_{-\mathbf{k}\downarrow} c^{\dagger}_{-\mathbf{k}\downarrow} + 1 \right) = \left(c^{\dagger}_{\mathbf{k}\uparrow}, c_{-\mathbf{k}\downarrow} \right) \begin{bmatrix} \epsilon_{\mathbf{k}} & 0 \\ 0 & -\epsilon_{\mathbf{k}} \end{bmatrix} \begin{pmatrix} c_{\mathbf{k}\uparrow} \\ \bar{c}^{\dagger}_{-\mathbf{k}\downarrow} \end{pmatrix} + \sum_{\mathbf{k}} \epsilon_{\mathbf{k}},$$

where the sign reversal in the lower component derives from anticommuting the downspin electron operators. The energy $-\epsilon_{\mathbf{k}}$ is the energy to create a hole. We will drop the constant remainder term $\sum_{\mathbf{k}} \epsilon_{\mathbf{k}}$. We can now combine the kinetic and pairing terms into a single matrix:

$$\epsilon_{\mathbf{k}} \sum_{\sigma} c^{\dagger}_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma} + \left[\bar{\Delta} c_{-\mathbf{k}\downarrow} c_{\mathbf{k}\uparrow} + c^{\dagger}_{\mathbf{k}\uparrow} c^{\dagger}_{-\mathbf{k}\downarrow} \Delta \right] = \left(c^{\dagger}_{\mathbf{k}\uparrow}, c_{-\mathbf{k}\downarrow} \right) \begin{bmatrix} \epsilon_{\mathbf{k}} & \Delta \\ \bar{\Delta} & -\epsilon_{\mathbf{k}} \end{bmatrix} \begin{pmatrix} c_{\mathbf{k}\uparrow} \\ c^{\dagger}_{-\mathbf{k}\downarrow} \end{pmatrix}$$

And in this notation one can work with BCS Hamiltonian further.

Another way of introducing another Nambu notation, more in matrix from is as follows:

$$\begin{aligned} \mathcal{H} &= \epsilon \left(c^{\dagger}_1 c_1 + c^{\dagger}_2 c_2 \right) + \lambda \left(c^{\dagger}_1 c^{\dagger}_2 + c_2 c_1 \right) = \\ &= \frac{1}{2} \begin{pmatrix} c^{\dagger}_1 & c_2 & c^{\dagger}_2 & c_1 \end{pmatrix} \begin{pmatrix} \epsilon & \lambda & 0 & 0 \\ \lambda & -\epsilon & 0 & 0 \\ 0 & 0 & \epsilon & -\lambda \\ 0 & 0 & -\lambda & -\epsilon \end{pmatrix} \begin{pmatrix} c_1 \\ c^{\dagger}_2 \\ c_2 \\ c^{\dagger}_1 \end{pmatrix} + \epsilon \end{aligned}$$

(??? by the way, how to derive it???)
Maybe it is not exactly a Nambu notation, just it also works. And we can find spectrum by just computing eigenvalues of the obtained squared matrix.

(here, about extended Nambu notation, see my thesis or articles)
(discuss that actually there are two ways of introducing it)
(and that there is an important minus in the last component)

(and there are other notations from articles, which I'll list here)

Hole interpretation of excitation of SC

(it is an easy idea, I'll write later)

Nambu Notation: Other features

Nambu Notation for MTJJ

(a good example, I'll write from my thesis that we have such SC Hamiltonian, so let's write it in Nambu notation. A good illustration)

What was Nambu originally doing when he introduced his notation?

(I don't know, since his article is a very complicated one, but the question is very interesting)

3.11.3 Gap in Unconventional Superconductors: Basics

(this is not needed, just to connect it with NC SC section)

Theory

The spin wavefunction of a singlet state is antisymmetric upon an interchange of the particles (spin indices). It enables us to write the order parameter as

$$\hat{\Delta}(\mathbf{k}) = d_0(\mathbf{k}) \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} = d_0(\mathbf{k}) i\hat{\sigma}_2 = d_0(\mathbf{k})\hat{\chi}_0 \tag{1.81}$$

In terms of the spin up ($\uparrow$) and spin down ($\downarrow$) wavefunctions of individual electrons, the quantity

$$\hat{\chi}_0 = i\hat{\sigma}_2 = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \tag{1.82}$$

corresponds to the singlet wave function $\frac{1}{\sqrt{2}}[|\uparrow\rangle|\downarrow\rangle - |\downarrow\rangle|\uparrow\rangle]$. The factor $\hat{\chi}_0$ is antisymmetric upon interchanging spin variables of the order parameter while $d_0(\mathbf{k})$ is symmetric upon interchanging orbital variables of the order parameter, that is, $d_0(-\mathbf{k}) = d_0(\mathbf{k})$. The singlet pairing symmetry has been discovered in most of the conventional superconductors [28], high-temperature cuprates [29], ironbased superconductors [30], and $\mathrm{Ce}-115$ [31] and $\mathrm{Pu}-115$ [32, 33] heavy fermion superconductors.

For the triplet pairing state, the total spin is $S = 1$ for the two paired electrons and accordingly there are three spin wavefunctions. Therefore, the pairing amplitude for each of these spin states can be different and $\mathbf{k}$-dependent. The order parameter may then be written in the form:

$$\hat{\Delta}(\mathbf{k}) = \mathbf{d}(\mathbf{k}) \cdot \hat{\boldsymbol{\sigma}} i\hat{\sigma}_2 = \mathbf{d}(\mathbf{k}) \cdot \hat{\chi}, \tag{1.83}$$

where the vector $\mathbf{d}$ measures the amplitude of the order parameter and the matrices

$$\hat{\chi}_1 = i\hat{\sigma}_1\hat{\sigma}_2 = \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}, \tag{1.84}$$

$$\hat{\chi}_2 = i\hat{\sigma}_2\hat{\sigma}_2 = \begin{pmatrix} i & 0 \\ 0 & i \end{pmatrix}, \tag{1.85}$$

and

$$\hat{\chi}_3 = i\hat{\sigma}_3\hat{\sigma}_2 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}. \tag{1.86}$$

They correspond to the spin wavefunctions

$$\hat{\chi}_1 \to \frac{-1}{\sqrt{2}}[|\uparrow\rangle|\uparrow\rangle - |\downarrow\rangle|\downarrow\rangle] \tag{1.87}$$

$$\hat{\chi}_2 \to \frac{i}{\sqrt{2}}[|\uparrow\rangle|\uparrow\rangle + |\downarrow\rangle|\downarrow\rangle] \tag{1.88}$$

and

$$\hat{\chi}_3 \to \frac{1}{\sqrt{2}}[|\uparrow\rangle|\downarrow\rangle + |\downarrow\rangle|\uparrow\rangle]. \tag{1.89}$$

Now all three of these wavefunctions are symmetric upon interchanging the spin indices. In an expanded form, the triplet order parameter is written as:

$$\hat{\Delta}(\mathbf{k}) = \begin{pmatrix} -d_x(\mathbf{k}) + id_y(\mathbf{k}) & d_z(\mathbf{k}) \\ d_z(\mathbf{k}) & d_x(\mathbf{k}) + id_y(\mathbf{k}) \end{pmatrix}. \tag{1.90}$$

Recall that $\hat{\Delta}$ must satisfy the Pauli antisymmetric property $\hat{\Delta}_{\beta\alpha}(-\mathbf{k}) = -\hat{\Delta}_{\alpha\beta}(\mathbf{k})$, so we have $\mathbf{d}(-\mathbf{k}) = -\mathbf{d}(\mathbf{k})$. Also notice that the parity of spherical harmonics is $(-1)^{-l}$, the above behavior is in accord with our intuition for p-wave ($l = 1$) (or more generally, odd angular momentum) pairing.

If the vector $\mathbf{d}(\mathbf{k})$ has the form $\mathbf{d}(\mathbf{k}) = a(\mathbf{k})\hat{\mathbf{n}}(\mathbf{k})$, where $a(\mathbf{k})$ is a complex number and $\hat{\mathbf{n}}(\mathbf{k})$ is a real unit vector, we then have the property

$$\mathbf{d}(\mathbf{k}) \times \mathbf{d}^*(\mathbf{k}) = 0 \tag{1.91}$$

This property leads to the constraint

$$\hat{\Delta}^\dagger(\mathbf{k})\hat{\Delta}(\mathbf{k}) = |\mathbf{d}|^2\hat{\mathbf{1}} + i\hat{\boldsymbol{\sigma}} \cdot [\mathbf{d}(\mathbf{k}) \times \mathbf{d}^*(\mathbf{k})] \;=\; |\mathbf{d}|^2\hat{\mathbf{1}} \tag{1.92}$$

We refer to a state where $\mathbf{d}$ has the property as given by Eq.(1.91) as the unitary state because $\hat{\Delta}^\dagger\hat{\Delta}$ is then proportional to the unit matrix. A rigorous classification of the symmetry properties of triplet superconductors was given by Blount [34], and Ueda and Rice [35] based on the group theory.

For the p-wave pairing state, the most general gap structure would involve a sum over all possible spin-orbital wavefunction products, each with its own complex amplitude, which we may write as

$$\hat{\Delta} = \sum_{i,\alpha} D_{\alpha i}\hat{\chi}_\alpha \hat{k}_i \tag{1.93}$$

Here the indices α and i denotes the three component in spin and orbitals spaces with $\hat{k}_x = \sin\theta\cos\phi, \hat{k}_y = \sin\theta\sin\phi$, and $\hat{k}_z = \cos\theta$ while χ_α already given above. The matrix $D_{\alpha i}$ allows nine complex (equivalently, 18 real) coefficients and suggests the possibility of 18 types of pairing states.

So far, the spin triplet pairing states has been discovered in ^{3}He superfluid [36] and possibly in Sr_2RuO_4 [37] and heavy-fermion UPt_3 and UBe_{13} [38-40] superconductors. In superfluid ^{3}He, two phases are stabilized at zero magnetic field and very low temperatures, depending on pressure [41]. They can be represented by the $D_{\alpha i}$ matrices:

$$\text{(B phase): } \hat{D} = \Delta_0 \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \tag{1.94}$$

$$\text{(A phase): } \hat{D} = \Delta_0 \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 1 & i & 0 \end{pmatrix}. \tag{1.95}$$

The corresponding gap matrices are:

$$\begin{aligned} \text{(B phase): } \hat{\Delta} &= \Delta_0 \begin{pmatrix} -\hat{k}_x + i\hat{k}_y & \hat{k}_z \\ \hat{k}_z & \hat{k}_x + i\hat{k}_y \end{pmatrix}, \\ (\text{ A phase for } \mathbf{d}\|\hat{\mathbf{z}}): \quad \hat{\Delta} &= \Delta_0 \begin{pmatrix} 0 & \hat{k}_x + i\hat{k}_y \\ \hat{k}_x + i\hat{k}_y & 0 \end{pmatrix}. \end{aligned} \tag{1.97}$$

The B-phase is also called the BW phase proposed by Balian and Werthamer [42]. In this phase, the single particle spectrum and the energy gap are isotropic; the total spin and orbital angular momenta are each equal to 1 ; the spin susceptibility is finite at zero temperature. The A-phase is also called the ABM-phase proposed by Anderson, Brinkman, and Morel [43]. In this phase, the S_z channel is completely suppressed and the spin susceptibility is very similar to that in the normal state.

3.11.4 Anderson's Random-Phase Approximation in SC

(add it later here)

Main ideas

3.11.5 Impurities in BCS: General Idea How to Take Them into Account

Остановимся теперь кратко на вопросе о влиянии примесей на спаривание электронов. В присутствии примесей направление импульса электрона не сохраняется, поэтому строить пары из электронов с противоположными импульсами $\hbar\mathbf{k}$ и $-\hbar\mathbf{k}$, как мы это делали выше, затруднительно. Однако ничто не мешает использовать вместо электронных плоских волн $e^{i\mathbf{kr}}$ точные волновые функции $\chi_n(\mathbf{r})$ электронов с учетом потенциала примесей $U(\mathbf{r})$, описывающие диффузионное распространение электронных волн. Точный вид этих функций нам неизвестен, но он и не войдет в окончательные уравнения типа (44.11) и (45.15) на величину щели Δ. Единственное, но важное условие состоит в том, чтобы для всякого электронного состояния n с волновой функцией $\chi_n(\mathbf{r})$ имелось «парное» состояние $\bar{n}$ с волновой функцией $\chi_{\bar{n}}(\mathbf{r}) = \chi_n^*(\mathbf{r})$, отвечающее движению электрона "вспять" но диффузионной траектории, соответствующей состоянию n. Комплексное сопряжение волновых функций в квантовой механике эквивалентно операции обращения времени, поэтому в одном и том же случайном потенциале $U(\mathbf{r})$ существуют одновременно точные состояния $\chi_n(\mathbf{r})$ и $\chi_n^*(\mathbf{r})$, если $U(\mathbf{r})$ не меняется при:амене $t \to -t$. Это условие выполнено для обычных примесей, которые поэтому очень слабо влияют на Δ_0 и другие термодинамические свойства сверхпроводника даже в "грязном" пределе, когда длина свободного пробега $l \ll \xi_0$ (т. наз. "теорема Андерсона», подробнее см. [7]).

Совсем иначе обстоит дело, если в сверхпроводнике имеются магнитные примеси, непосредственно взаимодействующие со спинами электронов (или если к грязному сверхпроводнику приложено магнитное поле). В этом случае 'имметрия электронных состояний по отношению к обращению «ремени нарушается, и температура сверхпроводящего перехода резко падает с концентрацией таких примесей.

3.11.6 Impact of Lattice Configuration in BCS

(here we will discuss in details, how to take into account lattice structure. (????))
(??? I don't know it at all now)

General Idea How to Take Lattice Configuration into Account

(???? still, have no idea, I need to read papers about it)

3.11.7 BCS theory in the Density Matrix Framework

Do we need the density matrix for superconductivity?

(I don't know, actually, distribution of particles are fine. but maybe I'll write later, when it is useful?zx)

Formulation of BCS theory in the density matrix framework

(no, currently I don't understand how to write it)

(write here how the density matrix of a SC look like!!!)

Conceptual details of formulation of BCS theory in the density matrix framework

What is a density matrix for BCS in general?

(write, how to understand it????)

Evolution of BCS theory in the density matrix framework

(write how we deal with BCS in it????)
(no, currently I don't understand how to write it)
(??? how to answer it???? Read Brower Petrucione, this is the only way I know)

Gap in the density matrix framework

(???? I don't know, how is it related to the density matrix, but okay, I'll learn it later)
Here, we will present the evaluation of a gap in a notation of diagonalization of Hamiltonian. First, we write the Hamiltonian in the Nambu notation:

$$\epsilon_{\mathbf{k}} \sum_{\sigma} c^{\dagger}_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma} + \left[\bar{\Delta} c_{-\mathbf{k}\downarrow} c_{\mathbf{k}\uparrow} + c^{\dagger}_{\mathbf{k}\uparrow} c^{\dagger}_{-\mathbf{k}\downarrow} \Delta \right] = \left(c^{\dagger}_{\mathbf{k}\uparrow}, c_{-\mathbf{k}\downarrow} \right) \begin{bmatrix} \epsilon_{\mathbf{k}} & \Delta \\ \bar{\Delta} & -\epsilon_{\mathbf{k}} \end{bmatrix} \begin{pmatrix} c_{\mathbf{k}\uparrow} \\ c^{\dagger}_{-\mathbf{k}\downarrow} \end{pmatrix}$$

we will introduce a matrix and an index notation

$$H = \psi^{\dagger} h \psi = \sum_{jl} h_{jl} \psi^{\dagger}_{j} \psi_{l}$$

Our goal is to obtain the gap, which is the average of two hole operators. For this, we need to go to a basis where the Hamiltonian is diagonal.

The Hamiltonian matrix is diagonalized by a unitary matrix U:

$$h = U^{\dagger} D U$$

or in index notation,

$$h_{jl} = \sum_{kk'} \left(U_{kj} \right)^{\dagger} D_{kk'} U_{k'l} = \sum_{k} U^{*}_{jk} D_{kk} U_{kl},$$

where we used that $D_{kk'}$ is diagonal and that $\left(U_{kj} \right)^{\dagger} = U^{*}_{jk^{*}}$. By the algorithm of diagonalization, the U_{kl} and U_{kj} are constructed by the right eigenvector matrices, i.e., matrices where the columns are the right eigenvectors of h.

The full Hamiltonian is rewritten in terms of the diagonal basis

$$H = \sum_{jl,k} U^*_{jk} D_{kk} U_{kl} c^\dagger_j \psi_l = \sum_{jl,k} D_{kk} (U^*_{jk} \psi^\dagger_j)(U_{kl}\psi_l) = \sum_k D_{kk} \eta^\dagger_k \eta_k,$$

where we introduced a new basis

$$\eta_k = \sum_l U_{kl}\psi_l \qquad \eta^\dagger_k = \sum_j (U_{kj})^\dagger \psi^\dagger_j = \sum_j U^*_{jk}\psi^\dagger_j$$

and the back transformation is

$$\psi_l = \sum_k U^*_{lk}\eta_k, \qquad \psi^\dagger_j = \sum_k \left(U^*_{jk}\right)^\dagger \eta^\dagger_k = \sum_k U_{kj}\eta^\dagger_k$$

This is obvious from looking at the previous transformations as a multiplication of a matrix to a column.

Now, we can notice that all the combination of daggered and non-daggered operators in general can be expressed as

$$\begin{aligned}
A_{jl} &= \left\langle \psi^\dagger_j \psi_l \right\rangle \\
&= \frac{1}{Z} \operatorname{Tr}\left[e^{-\beta H} \psi^\dagger_j \psi_l \right] \\
&= \frac{1}{Z} \operatorname{Tr}\left[e^{-\beta \sum_k D_{kk}\eta^\dagger_k \eta_k} \sum_{k'} U_{k'j}\eta^\dagger_{k'} \sum_{k''} U^*_{lk''}\eta_{k''} \right] \\
&= \sum_{k'k''} U_{k'j} U^*_{lk''} \underbrace{\frac{1}{Z} \operatorname{Tr}\left[e^{-\beta \sum_k D_{kk}\eta^\dagger_k\eta_k} \eta^\dagger_{k'}\eta_{k''} \right]}_{F_{kk'} = \delta_{k,k'} \operatorname{diag}(f(D_{kk},\beta))} \\
&= \sum_k U^*_{lk} F_{kk} U_{kj}
\end{aligned}$$

Here, the f is the Fermi function. This is because we now can easily compute the trace, because we have just two states with $\eta^\dagger_k\eta_k = 0$ and $\eta^\dagger_k\eta_k = 1$.

(??? don't understand the density matrix!!! what about other states??? or it is just a matrix from our common sense, but not a density matrix of thermal superconductor???)

In matrix notation, this corresponds to

$$A = U^\dagger F U$$

Thus, we can just take the 10-component to get the conjugated gap (this component corresponds to $\psi^\dagger_1\psi_0 = c_{-k\downarrow}c_{k\uparrow}$). This is the exactly its definition. Note that the 01-component will give us also exactly the definition of the conjugated gap (this component corresponds to $\psi^\dagger_0\psi_1 = c^\dagger_{k\uparrow}c^\dagger_{-k\downarrow}$). There are no problems with minus sign which could arise from the order of Fermi operators under the averaging.

Other (00 and 11) components have no meaning. This is not a Fermi function, since $c\,\dagger\,c$ is not an excitation (the excitations are Bogoliubov operators). (????? yes?)

Now, we need to find the U matrix. For this, we find normalized eigenvalues and just plug them into the columns.

(??? write it analytically)

This is realized in Wolfram as follows:

```
ham = {{\[Xi],
    Conjugate[\[CapitalDelta]]}, {\[CapitalDelta], -\[Xi]}};

Eigenvectors[ham]

norm1 = Sqrt[(\[Xi] +
       Sqrt[\[Xi]^2 + \[CapitalDelta] ^2])^2/\[CapitalDelta]^2 + 1];
norm2 = Sqrt[(\[Xi] -
       Sqrt[\[Xi]^2 + \[CapitalDelta] ^2])^2/\[CapitalDelta]^2 + 1];

Uinv = {{-((-\[Xi] -
       Sqrt[\[CapitalDelta]^2 + \[Xi]^2])/\[CapitalDelta]) 1/
     norm1, -((-\[Xi] +
       Sqrt[\[CapitalDelta]^2 + \[Xi]^2])/\[CapitalDelta]) 1/
     norm2}, {1/norm1, 1/norm2}} // MatrixForm
```

we get

$$U = \begin{pmatrix} -\frac{-\xi-\sqrt{\Delta^2+\xi^2}}{\Delta\sqrt{\frac{\left(\xi+\sqrt{\Delta^2+\xi^2}\right)^2}{\Delta^2}+1}} & -\frac{\sqrt{\Delta^2+\xi^2}-\xi}{\Delta\sqrt{\frac{\left(\xi-\sqrt{\Delta^2+\xi^2}\right)^2}{\Delta^2}+1}} \\ \frac{1}{\sqrt{\frac{\left(\xi+\sqrt{\Delta^2+\xi^2}\right)^2}{\Delta^2}+1}} & \frac{1}{\sqrt{\frac{\left(\xi-\sqrt{\Delta^2+\xi^2}\right)^2}{\Delta^2}+1}} \end{pmatrix}$$

And then we get the stated expression:

```
FullSimplify[ConjugateTranspose[Uinv].ham.Uinv,
 Assumptions -> {\[CapitalDelta] > 0, \[Xi] > 0}]

fermi[\[Epsilon]_, \[Beta]_] := 1/(1 + Exp[\[Beta] \[Epsilon]]);

rhodiag =
  DiagonalMatrix[{fermi[Sqrt[\[Xi]^2 + \[CapitalDelta]^2], \[Beta]],
    fermi[- Sqrt[\[Xi]^2 + \[CapitalDelta]^2], \[Beta]]}];

FullSimplify[ConjugateTranspose[Uinv].rhodiag.Uinv,
  Assumptions -> {\[CapitalDelta] > 0, \[Xi] > 0}] // MatrixForm
```

after taking the 01- component we get the gap equation:
(copy it from wolrfam!)
This is how by knowing the density matrix, we can obtain the gap.

3.12 General Formalisms for Typical Effects

3.12.1 Currents and Tunneling Effects: Basic Concepts 1

Experimental Introduction to Tunneling

In 1961, Giaever pointed out the possibility of determining the energy gap by means of tunneling experiments [33, 34]. We will treat this method in some detail, since it yielded much new information far beyond just the measurement of the energy gap. The method is based on the observation of the tunneling current across a thin insulating layer between a reference sample and the superconductor to be studied. In contrast to the Josephson current we treated in Chapter 1, now we are concerned with the tunneling of the unpaired electrons.

The arrangement is shown schematically in Figure 3.11a. Two metallic conductors, for instance, two aluminum layers, are separated from each other by mean of a thin insulating layer, for instance, Al_2O_3. The Al_2O_3 is an excellent electrical insulator, which can be fabricated nearly perfectly also with a thickness of only a few nanometers.

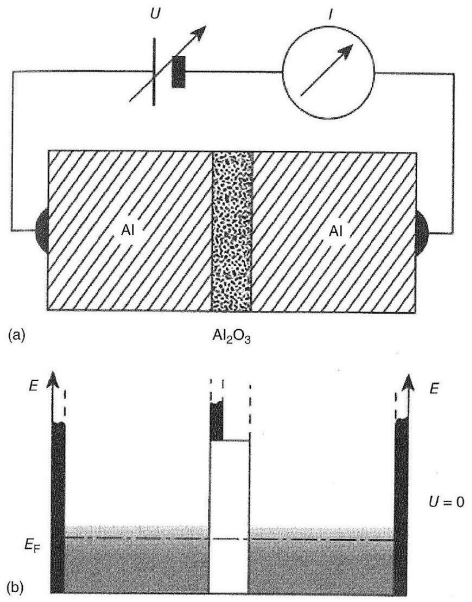

Figure 3.11 (a) The arrangement for measuring a tunneling current. (b) The allowed energy values (black areas) and their occupation (gray shaded areas).

Because of the great importance of this tunneling effect, for instance, also in semiconductor physics, we want to look at it in more detail. Therefore, in Figure 3.11b we have indicated schematically the allowed and forbidden energy ranges near the Fermi energy for the three parts of the tunneling arrangement. The black vertical areas indicate the allowed energy bands. The gray shaded areas show the occupation of the bands. The thermal smearing of the occupation is also indicated. In the electrical insulator the nearest allowed and unoccupied energy values are much higher.

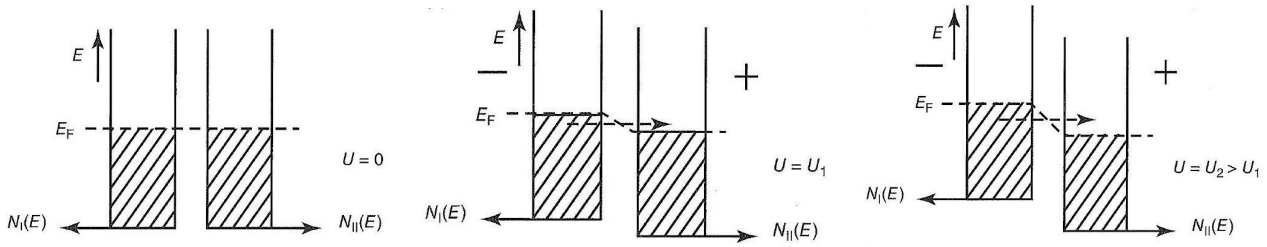
We can also understand the tunneling effect without a detailed calculation, if we recall the wave character of our particles. If a wave encounters the surface of a medium into which it cannot enter, the wave must be totally reflected. Here, we recognize intuitively that the wave must penetrate a small distance into the forbidden portion. In some sense, the wave tests the possibility of whether it can exist in this medium. At the same time, its amplitude decreases exponentially, this decrease being faster, the larger the difference between the energy of the wave and

an allowed energy value, that is, the higher the barrier. From this highly qualitative argument, we see immediately that for a sufficiently thin barrier there is a finite probability that the wave can extend beyond the barrier. This is always the case if the thickness of the barrier is comparable with the decay length of the wave amplitude in the forbidden regime. In this case, a finite amplitude arrives at the back side where it can exit again into the allowed regime. However, there the amplitude is very small, that is, the probability for the passage of a particle decreases rapidly with increasing barrier thickness along with the wave amplitude. We see that the tunneling probability depends on the energetic height and on the thickness of the barrier. Here, the energetic height of the barrier must be taken from the particle energy, that is, in our case of Figure 3.11b practically from E_F.

In our present discussion we are dealing with electrons, that is, with Fermi particles. They must satisfy the Pauli principle (see Section 1.1). In order to traverse the barrier, the electron must find an unoccupied state on the other side. If all states are already occupied on the other side, the passage of the electron is impossible, even for a sufficiently thin barrier. Therefore, the number of particles passing across the barrier depends on the following three quantities:

number of electrons reaching the barrier;

tunneling probability across the barrier;



number of unoccupied energy levels on the other side.

In a quantitative treatment of the tunneling current of electrons, all three quantities must be taken into account

In Figure 3.11b we have shown the tunneling arrangement without an external voltage. If electrons can be exchanged between two systems, the equilibrium state is fixed by the fact that the Fermi energy is located at the same height, that is, the Fermi energy is displayed by a horizontal line in our schematic diagram. For this state the net exchange of particles is exactly zero. The same number of electrons tunnel to the right as to the left.

Next we apply a voltage $U \neq 0$ to the arrangement. Practically, the voltage drop is completely restricted to the barrier layer. This means that the Fermi energies on the right and on the left of the barrier differ by the amount eU. Now the tunneling currents in both directions no longer compensate each other, and a net current I flows.

To illustrate the magnitude of the current and its dependence on the voltage U, in Figure 3.12 we present a schematic diagram that also includes the density of states. Close to the Fermi energy, within the model of free electrons, the density of states can be taken approximately as constant. In Figure 3.12 the tunneling arrangement is shown for the voltages $U = 0, U_1$, and $U_2 > U_1$. The occupation of the states is indicated by the hatched areas. For simplicity we have taken the case $T = 0$. On the positive side of the voltage, the energy of the electrons with their negative charge is lowered compared to the negative side. In this case, more electrons can tunnel from left to right than in the opposite direction, that is, an electron current is flowing, as shown by the horizontal arrow in Figure 3.12b,c. Since we have assumed a constant density of states, the number of electrons that can

a) b) c)

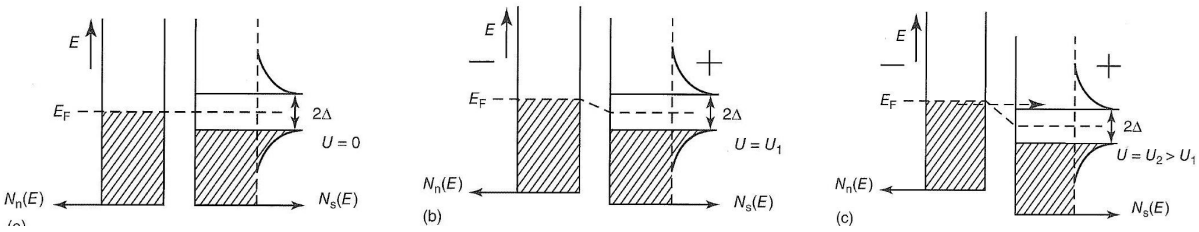
Figure 3.12 Tunneling current between normal metals for three values of applied voltage, (a) $U = 0$, (b) $U = U_1$ and (c) $U = U_2 > U_1$. For simplicity, the distribution for $T = 0$ is shown. Near the energy E_F there are no states in the insulating barrier.

tunnel from left to right increases proportional to the voltage U. Therefore, the net tunneling current I is also proportional to the applied voltage U (see Figure 3.14, dashed curve. Here, we neglect the influence of the applied voltage on the energetic height of the barrier. At this point we emphasize again that we are only considering tunneling processes at constant energy, that is, transitions indicated horizontally in our scheme. During the tunneling process, for instance, within the barrier, an electron can absorb or emit a phonon. Such processes are referred to as "phonon-assisted tunneling". They are relatively rare and will be neglected initially.

The current-voltage characteristic of such a tunneling arrangement changes if one or both sides are in the superconducting state. This is immediately obvious, if we recall that in the superconducting state an energy gap appears in the energy spectrum of the unpaired electrons, which strongly changes the density of states near the Fermi energy.

In Figure 3.13 we show the first case, a normal conductor against a superconductor, following the scheme of Figure 3.12. Again, for simplicity we take the case $T = 0$. The corresponding current-voltage characteristic is shown in Figure 3.14 as curve 2. No tunneling current can flow

up to the voltage $U = \Delta_0/e$, since the electrons from the normal conductor do not find any states in the superconductor. At $U = \Delta_0/e$ the tunneling current sets in with a vertical slope. This steep rise is caused by the high density of unoccupied states in the superconductor. At higher voltages, the curve approaches the tunneling characteristic between two normal conductors (curve 1). At finite temperatures, in the normal conductor the distribution is thermally smeared, and also a few unpaired electrons exist in the superconductor above the energy gap. Furthermore, the energy gap is slightly reduced, as we have discussed in Section 3.1.2. The resulting characteristic is shown schematically in Figure 3.14 as curve 3.



From such characteristics the energy gap can be determined easily. From the function $I(U)$, for a given density of states of the normal conductor, we can also extract quantitative information on the energy-dependent density of states of the unpaired electrons in the superconductor. For $T = 0$ and $N_{\mathrm{n}}(E) =$ constant, the derivative $\mathrm{d}//\mathrm{d}U$ directly yields the density of states of the unpaired electrons $N_{\mathrm{S}}(E)$.

We note that the tunneling characteristic is independent of the direction of the voltage. During reversal of the voltage, only the role of the unoccupied and occupied states is changed. If the superconductor is connected to the negative side, at $U = \Delta_0/e$ the unpaired electrons can tunnel into the free states of the normal conductor. We must recall that because of the Pauli principle during the tunneling process of single electrons, in addition to the electrons of the state at the starting point (for instance, on the left side in Figure 3.13), the free energy sites at the terminal point (on the right side in Figure 3.13) must also exist.

Before we turn to case 2, namely the tunnel junction between two superconductors, we want to look at the quantitative relation between the important quantities. As we have seen, the tunneling probability depends on the height and width of the barrier. Within the small energy range near the Fermi energy with which we are concerned, we can treat this probability as a constant (independent of the energy). We denote it by D. The number of electrons tunneling per unit time at energy E from left to right is proportional to the number of occupied states $^{13}N_{\mathrm{I}}(E)f(E)$ on the left side and to the number of unoccupied states on the right side. The probability of finding an unoccupied state at energy E is 1 minus the probability that this state is occupied, that is, $1 - f(E)$. In the case of a voltage drop U across the barrier, the electrons tunnel from a state with energy E on the left side into a state with energy $E + eU$ on the right side. Hence, at the voltage U, their number is

$N_{\mathrm{II}}(E + eU)[1 - f(E + eU)]$

We denote the density of states in the electrodes by the indices I or II.

a) b) c)

Figure 3.13 Tunneling current between a normal conductor and a superconductor for $T = 0$ and three values of applied voltage, (a) $U = 0$, (b) $U = U_1$ and (c) $U = U_2 > U_1$.

Basic Intuitive Formulas for Tunneling

In the following we measure the electron energy from the Fermi energy: $\varepsilon = E - E_\mathrm{F}$. So in a small energy interval $\mathrm{d}\varepsilon$ at the energy ε, we have the following small contribution to the tunneling current from left to right:

$$\mathrm{d}I_{\mathrm{I}\to\mathrm{II}} \propto DN_\mathrm{I}(\varepsilon)f(\varepsilon)N_\mathrm{II}(\varepsilon + eU)[1 - f(\varepsilon + eU)]\mathrm{d}\varepsilon$$

The total tunneling current $I_{\mathrm{I}\to\mathrm{II}}$ is obtained by integration over all energies. One finds

$$I_{\mathrm{I}\to\mathrm{II}} \propto D \int_{-\infty}^{\infty} N_\mathrm{I}(\varepsilon)f(\varepsilon)N_\mathrm{II}(\varepsilon + eU)[1 - f(\varepsilon + eU)]\mathrm{d}\varepsilon$$

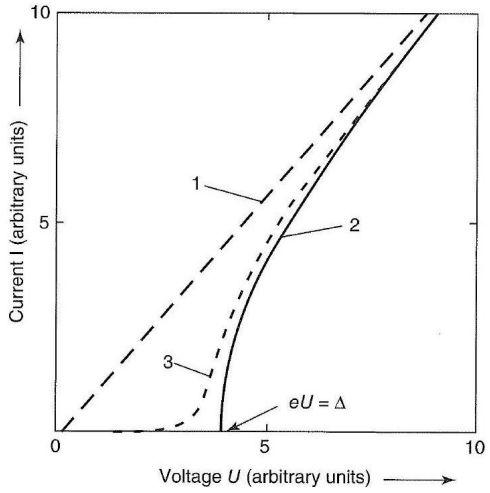


Figure 3.14 Current-voltage characteristic of tunnel junctions: curve 1, normal conductor/normal conductor (Figure 3.12); curve 2, normal conductor/superconductor, $T = 0$ K (Figure 3.13); and curve 3, normal conductor/superconductor, $0 < T < T_c$.

Since we measure the energy from E_F, we must integrate from $-\infty$ to $+\infty$. Similarly we obtain the tunneling current $I_{\mathrm{II}\to 1}$ from right to left:

$$I_{\mathrm{II}\to\mathrm{I}} \propto D \int_{-\infty}^{\infty} N_\mathrm{II}(\varepsilon + eU)f(\varepsilon + eU)N_\mathrm{I}(\varepsilon)[1 - f(\varepsilon)]\mathrm{d}\varepsilon$$

The difference between the two yields the net tunneling current:

$$I = I_{\mathrm{I}\to\mathrm{II}} - I_{\mathrm{II}\to\mathrm{I}} \propto D \int_{-\infty}^{\infty} N_\mathrm{I}(\varepsilon)N_\mathrm{II}(\varepsilon + eU)[f(\varepsilon) - f(\varepsilon + eU)]\mathrm{d}\varepsilon$$

Here, according to Eq. (1.3), we have

$$f(\varepsilon) = \frac{1}{\mathrm{e}^{\varepsilon/k_\mathrm{B}T} + 1} \quad \text{with } \varepsilon = E - E_\mathrm{F}$$

We have indicated this brief derivation, since it yields in a simple way the quantitative connection in the form of a balance equation. For the situation in Figure 3.13, for example, we can assume $N_\mathrm{n}(\varepsilon) = \text{constant}$, and for $N_\mathrm{s}(\varepsilon)$ we can use relation (3.5) from Section 3.1.2 after changing it from E to ε:

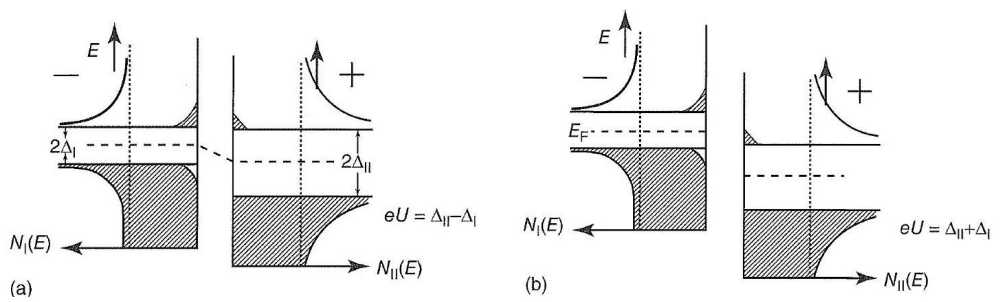
$$N_\mathrm{s}(\varepsilon) = N_\mathrm{n}(0)\frac{|\varepsilon|}{\sqrt{\varepsilon^2 - \Delta_0^2}} \text{ for } |\varepsilon| \geq \Delta_0$$

Now we can calculate the tunneling characteristic. The case of a tunnel junction between two normal conductors shown in Figure 3.12 represents a very simple example for further exercise. [14])

Next we turn to the case of a tunnel junction between two superconductors. Such a junction is shown in Figure 3.15a,b in the usual way. However, the case $U = 0$ is omitted. In Figure 3.15c the current-voltage characteristic is presented schematically.

In this case the characteristic for finite temperatures differs strongly from that for $T = 0$. Therefore, we have assumed a distribution for $T \neq 0$. The dashed line in Figure 3.15c would be obtained for $T = 0$. At $eU = \Delta_{\mathrm{II}} - \Delta_{\mathrm{I}}$ a maximum of the tunneling current is reached, since now all single electrons of superconductor I can tunnel to the right, where they encounter a particularly high density of unoccupied states. Then the current decreases with a further increase in the voltage, since the density of the unoccupied states in II decreases. Finally, at $eU = \Delta_{\mathrm{I}} + \Delta_{\mathrm{II}}$ one observes a particularly steep increase in the current because of the high density of the occupied as well as the unoccupied states. It is this extremely steep slope that provides the important advantage of measurement using two superconductors.

Tunneling experiments have provided much important information about the energy gap. In most cases, two thin evaporated layers with an oxide layer as the barrier are used. However, also compact bulk samples can be used for studying substances that are difficult to evaporate. In the latter case, the barrier can consist also of a natural oxide layer, or it can be fabricated by the evaporation of an insulator. The study of compact bulk samples is necessary if the energy gap is to be determined in a specific crystallographic direction by using single crystals.



In Figure 3.16 we present an arrangement of evaporated layers. It is advantageous to keep the tunneling area small, in order to avoid large tunneling currents and to reduce the chances for the appearance of holes in the oxide layer.

Figure 3.17 shows the results obtained for an $\mathrm{Al} - \mathrm{Al_2O_3} - \mathrm{Pb}$ tunnel junction at four different temperatures [35]. For the curves $1 - 3$, the Al is normal conducting. Only for curve 4 do we deal with a junction of two superconductors. However, although in the latter case the measuring temperature of 1.05 K is only slightly below the transition temperature of Al(1.2 K), the different shape of the characteristic is clearly visible

Figure 3.18 shows the characteristic of a typical junction between two superconductors, namely Nb-niobium oxide- Sn at 3.4 K [36]. At this temperature Nb ($T_{\mathrm{c}} = 9.3$ K) and Sn ($T_{\mathrm{c}} = 3.7$ K) are both superconducting. The solid line is

In the case of Figure 3.12, for all $\varepsilon > 0$, the term in brackets $[f(\varepsilon) - f(\varepsilon - eU)]$ is equa to zero, since both Fermi functions are zero. Independent of the sign of the electron charge, we have assumed $ell > 0$. For $\varepsilon < -ell$ the term in brackets is zero again, since both Fermi functions have the value 1. Only in the (??? text is missing) antain the value 1. The density of states, of the integral. 'Then we obtain (see curve 1 in Figure 3.14):

$$I \propto DN_{\mathrm{I}}N_{\mathrm{n}} \int_{-eU}^{0} 1 \, \mathrm{d}\varepsilon \propto U$$

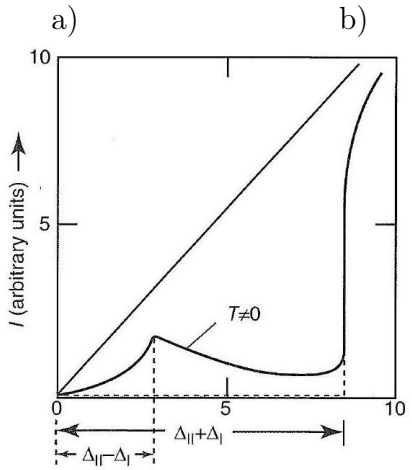


Figure 3.15 Tunneling current between two superconductors; $0 < T < T_c$. (a) and (b) show the density of states and (c) displays the current voltage characteristic.

the experimentally recorded result. The dots are calculated from Eq. (3.13) using proper values of the energy gaps ($2\Delta_{\mathrm{Sn}} = 0.74\mathrm{meV}; 2\Delta_{\mathrm{Nb}} = 2.98\mathrm{meV}$).

How one should see BCS to deal with tunneling problems

(write the question that we have a Hamiltonian and so what? okay, there is a gap. but how to approach a current?)

Continuing Experimental Discussions

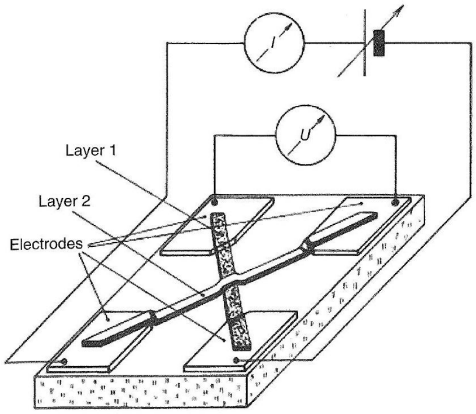

Figure 3.16 Tunnel junction between two layers. Layer 1 was oxidized before the depobelow 1μm. Usually, the oxide barriers are about 3 nm thick.

We see from Tables 3.3 and 3.4, which only contain a small part of the many possible results, that in a series of metals the ratio $2\Delta_0/k_{\mathrm{B}}T_{\mathrm{c}}$ for $T = 0$ is close to the value 3.5 predicted by the BCS theory (Eq. (3.7)). Deviations from this value in metals such as Nb can be caused easily by impurities near the surface. For such tors Pb and Hg show strong deviations from the values of the BCS theory. These deviations can be understood in terms of a particularly strong electron-phonon interaction in these metals.

From tunneling experiments, we can find out if the interaction leading to Cooper pairing is indeed the exchange of phonons. If the coupling between the lattice vibrations and the electron system is sufficiently strong, the density of states of the quasiparticles will be changed due to this coupling. These changes manifest themselves in the tunneling characteristic and can be measured using equipment with sufficiently high sensitivity. With some numerical work it is then possible to determine the coupling constant λ^* of the attractive electron-phonon

interaction and the constant μ' of the repulsive Coulomb interaction (see Eq. (3.9)). In this way, one obtains the so-called Eliashberg function $\alpha^2 F(\omega)$, which is closely connected with λ°. Here, $F(\omega)$ is the density of states of the phonons. In order to avoid any confusion with the density of states of the electrons, here we denote the energy by ω.

The tunneling measurements only deal with the phonons coupling to the electron system. On the other hand, neutron diffraction experiments can measure the

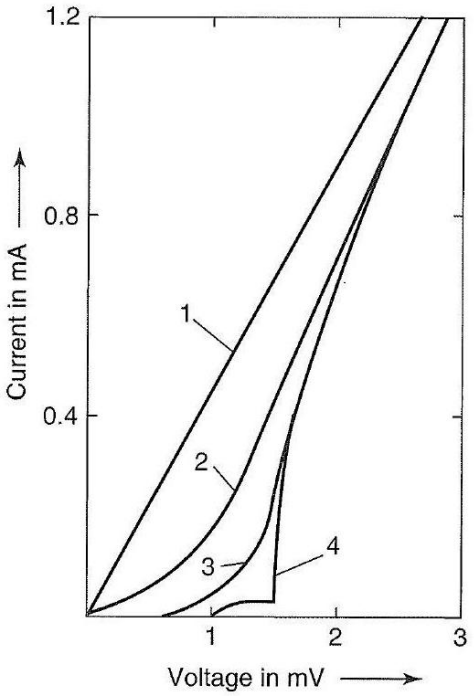

Figure 3.17 Voltage-current characterMeasuring temperature: curvel junction. curve $2, T = 4.2$ K; curve $3, T = 1,64$ K; curve 4 $T = 1.05$ K. At 1.05 K the Al is also superconclearly be seen. Transition temperatures are

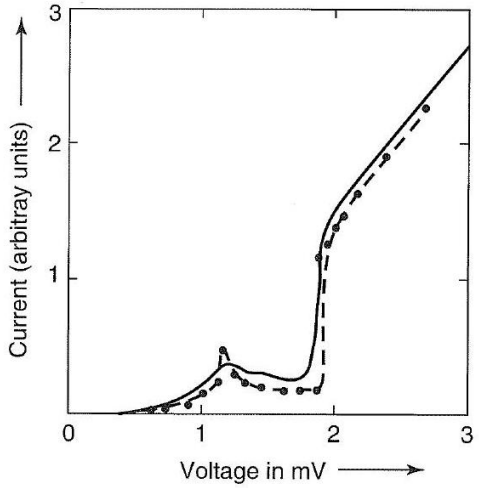

Figure 3.18 Current-voltage characteristic of a Nb-insulator-Sn tunnel junction at $T = 3.38$ K. The solid line is the experimentally recorded curve. The dots are calculated from Eq. (3.13) using the values $2\Delta_{\mathrm{sn}} = 0.74$meV and $2\Delta_{\mathrm{Nb}} = 2.98$meV. (From [36].)

density of states of the phonons independent of whether or not the latter couple to the electrons. Hence, from the comparison of both measurements, one obtains information about the coupling. Figure 3.20 shows such a comparison for Pd-D samples, the properties of which we

discussed in Section 2.3.3 [38, 39]. In spite of the strongly different deuterium concentration, we clearly see that prominent structures appear in both measurements. In particular, the phonons with high energies, resulting from the implanted deuterium, are also visible in the tunneling measurements, indicating that these vibrations couple well to the

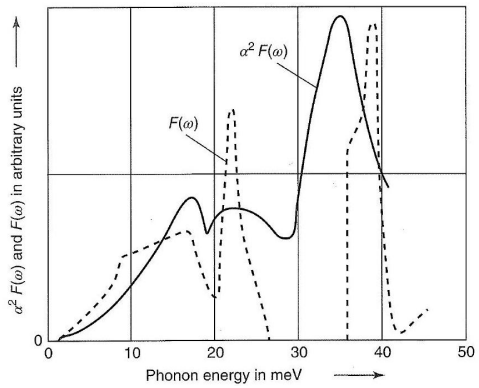

Figure 3.20 Plot showing $\alpha^2 F(\omega)$ obtained from tunneling measurements and $F(\omega)$ from neutron diffraction experiments as functions of the phonon energy ω for Pd − D samples (see Section 2.3.3). (From [38, 39].

electrons. These results explain the relatively high transition temperatures of the palladium-hydrogen system.

The determination of the function $\alpha^2 F(\omega)$ from the detailed structure of the tunneling conductivity and the comparison with the phonon spectrum $F(\omega)$ obtained, say, from neutron diffraction, represented the key experiment demonstrating that in conventional superconductors Cooper pairing is due to the electron-phonon interaction.

In a similar way, for each newly discovered superconductor one can try tò measure accurately the quasiparticle density of states by means of tunneling spectroscopy, if a tunnel junction with high quality can be fabricated. In the following (Section 3.2), we will see that, for high-temperature superconductors, not only tunneling spectroscopy but also other methods yield highly peculiar results, which are not yet completely understood. However, they clearly indicate that in this case the Cooper pairing is unconventional.

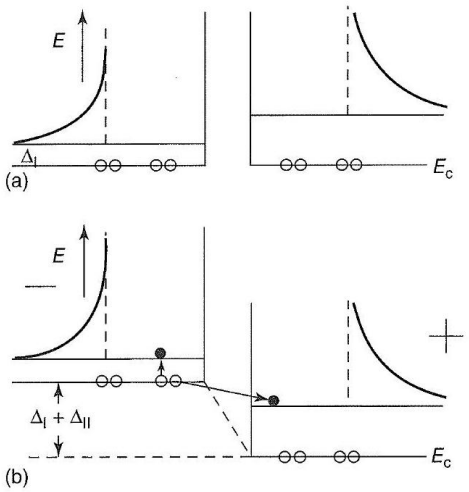
At this stage, we want to mention three additional aspects in context with the energy gap, which will be discussed in more detail in Section 3.1.4.

The energy gap can have different magnitudes along different crystallographic directions. Such superconductors are referred to as anisotropic. This anisotropy can lead to different results in various experiments. Depending on the evaporation conditions, special crystal directions can also be distinguished in experiments performed with thin layers. Measurements with single crystals along different directions yield information about the magnitude of the anisotropy.

It appears that in some compounds at least two energy gaps exist. As an example we mention $SrTiO_3$ doped with niobium, which becomes superconducting below 0.7 K [40]. Another example is MgB_2 [41]. In these materials, two or more different Fermi surfaces or energy bands contribute to the superconductivity, each forming its own energy gap, respectively ("two-band superconductivity". So in the case of MgB_2 one finds one energy gap around 2meV and another one around 7meV).

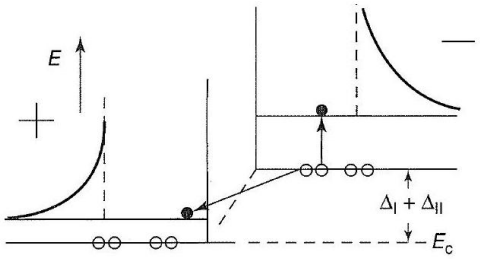
In principle, the energy gap can be changed even by very small concentrations of impurities, having an atomic angular momentum and, hence, a magnetic moment (paramagnetic impurities). In this way, superconductors can be generated without an energy gap ("gapless superconductor"). However, they are still superconducting, since they display pair correlation.

So far in our discussion of the tunneling experiments with superconductors, we have only been concerned with the unpaired electrons. For the interpretation of the experimental observations, we have taken into account only the density of states of the unpaired electrons in the



superconducting state. The Cooper pairs and their binding energy have never been mentioned. This also could not be expected, since within our picture of the individual electrons the total interaction was expressed in terms of the change of the density of states of the unpaired electrons.

On the other hand, since the superconducting state is based entirely on the concept of Cooper pairs, we are also interested in a picture where the Cooper pairs become distinctly visible. In the following, we will briefly discuss such a picture. However, there is a certain difficulty within this picture, since states of pairs, that is, collective states, and states of single electrons are shown in a single scheme. For our discussion we take the case of a tunnel junction between two different superconductors (Figure 3.15), and for simplicity we assume $T = 0$. Now superconductors are characterized by showing the Cooper pairs in one state and indicating the states that are occupied by the single electrons after breaking a pair (Figure 3.21). In equilibrium without an external voltage, the Cooper pair states are shown at the same energy level. This configuration is established if we allow the exchange of particles. At an applied voltage, in the case $T = 0$, according to Figure 3.15 we do not expect a tunneling current I in the range $\mathrm{e}U < \Delta_\mathrm{I} + \Delta_\mathrm{II}$. At $eU = \Delta_\mathrm{I} + \Delta_\mathrm{II}$, we expect a steep rise of I. In Figure 3.21 b, c, we show the situation for the two possible polarities of the voltage $U = (\Delta_\mathrm{I} + \Delta_\mathrm{II})/e$. In our present picture, we must explain the appearance of a tunneling current at this voltage in terms of the breaking of Cooper pairs. The applied voltage must be at least large enough that a pair can decay into an electron in superconductor I and an electron in superconductor II. This is exactly the process we want to describe, namely the transfer of a particle across the insulating layer. With increasing voltage U, the possibility for such a process first appears at $U = (\Delta_\mathrm{I} + \Delta_\mathrm{II})/e$. If the energy of superconductor II is lowered compared to that of superconductor I by means of the voltage, at $U = (\Delta_\mathrm{I} + \Delta_\mathrm{II})/e$, a pair in I can be broken up. As a result, a single electron appears in the lowest state of I, whereas the other single electron tunnels into the lowest state of II. During this process the energy remains conserved. The excitation energy of the one electron can be supplied by the transfer of the other electron in the electric field of the external voltage. The final states occupied by the two electrons are crucial for the necessary value of the voltage. At voltages $U < (\Delta_\mathrm{I} + \Delta_\mathrm{II})/e$, the electrons of a pair cannot be transferred into two single-electron states in I and II, respectively, at constant energy. If the superconductor II is connected to the negative side, again at $|U| = (\Delta_\mathrm{I} + \Delta_\mathrm{II})/e$ a pair can break up, however, this time in superconductor II, and the single electrons occupy states in I and II, respectively. [15] Because of the extremely large density of states for single electrons at $E = \Delta_\mathrm{I}$, the tunneling current sets in very steeply at $|U| = (\Delta_\mathrm{I} + \Delta_\mathrm{II})/e$. The argument is now similar as in the other picture. The number of processes is proportional to the number of possible final states.



If we want to keep this picture also for finite temperatures and to derive from it at least the qualitative form of the current-voltage characteristic, for single electrons existing in thermal equilibrium we must use the first picture discussed earlier.

In Section 4.2 we will discuss another possibility for determining the energy gap in conjunction with the specific heat in the superconducting state. Furthermore, we will see in Chapter 4 that, for example, the temperature dependence of the London penetration depth, being a property of the Cooper pairs, depends on the energy gap. In principle, each physical property depending on the density of states of the single electrons can be used for determining Δ_0. We have discussed three of these possibilities, namely the absorption of light, the damping of ultrasound, and the tunneling of single electrons. These techniques yielded many results, and the underlying physics is particularly clear.

The condition $I(U) = -I(-U)$, which must always be valid for tunnel junctions, is satisfied.

3.12.2 Currents and Tunneling Effects: Basic Concepts 2

Another theory, by Shmidt

The most direct way of examining the energy gap is by tunneling experiments. This technique was developed by Giaever in 1960 [63]. Its principle is very simple (see Fig. 6.9). A narrow film of the first metal is deposited onto a glass substrate with contact pads made in advance. Then the film is oxidized, so that it is covered with an insulating oxide layer of several nanometers thickness (the barrier layer). After that, a narrow film of the second metal is deposited in the transverse direction. The intersection of the two films (of area ~ 1 mm^2) forms a tunnel junction. The experiment consists in examining the current-voltage characteristic of this junction. Physically, the experiment employs the special quantum-mechanical ability of electrons to pass through thin potential barriers (in our case, through the insulating layer) by means of tunneling.

Let us discuss the current-voltage characteristics expected for different types of tunnel junctions.

The simplest case is when both the first and the second metal are normal. As soon as the two metals are in contact, their Fermi levels become equal.

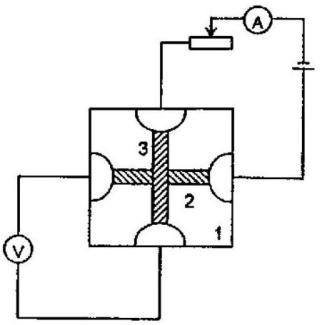

Fig. 6.9. Scheme of an electron tunneling experiment: 1 - glass substrate; 2 - thin film of the first metal; 3-thin film of the second metal

V is then applied to the junction (see Fig. 6.10 (b)), the Fermi levels will shift apart by the amount of eV and a tunneling current will begin to flow. If the density of states in the energy interval of interest is assumed to be constant, the current will be directly proportional to eV, as is evident from Fig. 6.10 (b). In other words, the current will obey Ohm's law.

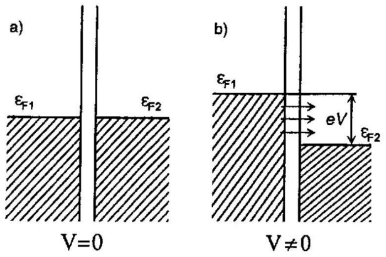

Fig. 6.10. Energy-level diagram for two normal metals brought into contact: (a) $V = 0$; (b) $V \neq 0$, a tunneling current proportional to eV passes through the junction

Let us now consider the case when one of the metals is normal and the other superconducting. The elementary excitation spectrum of the superconductor is already known to us (see Figs. 6.6 and 6.7). The energy of elementary excitations is measured from the ground-state level of the superconductor. In the normal metal, the energy of elementary excitations is measured from the Fermi level. Hence, when a tunnel junction is established between a normal metal and a superconductor, the energy levels to be equalized (due to the voltage drop) are the Fermi level of the normal metal and the ground-state level of the superconductor, as illustrated in Fig. 6.11 (a).

Let us apply a voltage V to the junction. Suppose that, as a result, the Fermi level of the normal metal has moved up by the value of eV above the ground-state level of the superconductor. A current from N to S can flow

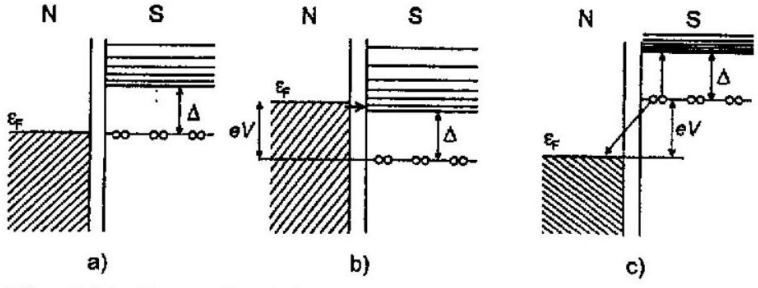

Fig. 6.11. Energy-level diagram for an NS tunnel junction: (a) $V = 0, \epsilon_{\mathrm{F}}$ coincides with the ground-state level of the superconductor; (b) $V \neq 0, |eV| > \Delta$, a finite tunneling current passes from N to S ; (c) $V \neq 0, |eV| > \Delta$, a finite tunneling current passes from S to N

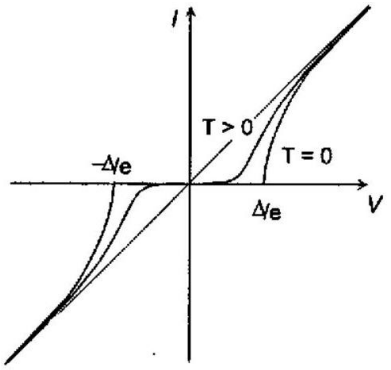
gap of the superconductor. The result will be the same if the polarity of the applied voltage is reversed. In that case, electrons will tunnel from S to N and a current will start to flow when the break-up of Cooper pairs in S becomes possible. That is, the energy released as a result of the tunneling of one electron from the pair has to be sufficient for the second electron to be excited into the energy band allowed for single electrons, i.e., above the energy gap (see Fig.

6.11 (c)).



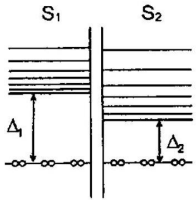


Fig. 6.12. Current-voltage characteristic of an NS tunnel junction

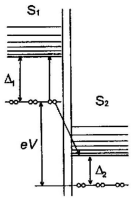

Thus the current-voltage characteristic of such a junction must be an odd function of V, as illustrated in Fig. 6.12. In the case $T \neq 0$, the currentvoltage characteristic will be somewhat smeared out, as one would expect.

Let us turn to the tunneling effects which occur when both metals (S_1 and S_2) are superconducting. Then the cases $T = 0$ and $T \neq 0$ are essentially different.

Consider the case $T = 0$ first. It follows from Fig. 6.13 that a tunneling current can start to flow only when the voltage across the junction is $V > (\Delta_1 + \Delta_2)/e$. Indeed, it is only on this condition that the tunneling process shown in Fig. 6.13 becomes possible? Cooper pair in S? break up and one of the electrons of the pair tunnels to S_2 thereby releasing an energy equal to, or greater than, Δ_1. The released energy is absorbed by the second electron of the broken pair, which is subsequently excited to the quasiparticle energy band of S_1.

$V = 0, I = 0$

$eV > \Delta_1 + \Delta_2, I \neq 0$

Fig. 6.13. Energy-level diagrams for an S_1 S_2 tunnel junction at $T = 0$

In a real experiment, when $T \neq 0$, the pattern is somewhat more complicated. At finite temperatures, there is always a certain number of excited single (unpaired) electrons in both superconductors; their equilibrium number is determined by the temperature.

The energy-level diagrams for this case are shown in Fig. 6.14. The number of dots at a given energy level roughly corresponds to the number of excited states at this energy. One can see that, at $V = 0$ (Fig. 6.14 (a)), the number of excited states at the levels of the same energy in S_1 and S_2 are equal despite the fact that the energy gaps in S_1 and S_2 are different. Therefore, the number of particles tunneling from S_1 to S_2 is exactly the same as the number of particles tunneling in the opposite direction, from S_2 to S_1. That is, at equilibrium, the net tunneling current is $I = 0$, as one would expect.

If we now apply a voltage V, the equilibrium will be immediately lifted and a flow of

quasiparticles will start from one superconductor to the other, even if the voltage is very small. One should bear in mind, however, that the quasiparticle density of states in the superconductor has a singularity at $E = \Delta$ (see (6.25) and Fig. 6.7). Hence, if the applied voltage is precisely $eV = \Delta_1 - \Delta_2$ (see Fig. 6.14 (b)), the equalized energy levels in S_1 and S_2 will be those having a density of states $\rho = \infty$. This will result in a sharp rise of the tunneling current. As the voltage V is increased further, the energy levels with $\rho = \infty$ will move apart again and the tunneling current will decrease. This implies that the current-voltage characteristic exhibits a maximum at

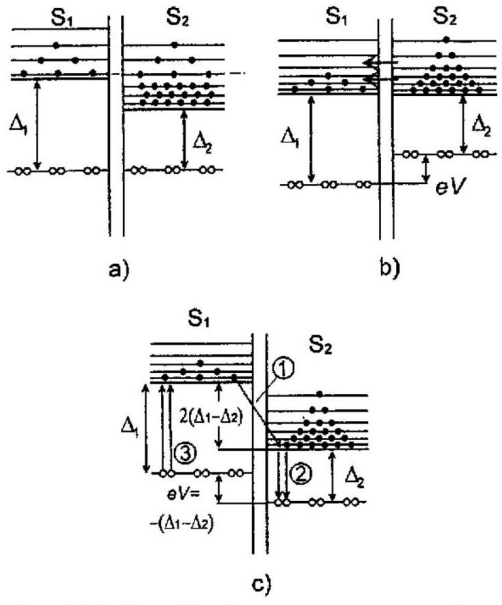

Fig. 6.14. Tunneling between two superconductors at $T \neq 0$: (a) $V = 0$, the numbers of excitations of the same energy are identical in S_1 and S_2 and the current is zero; (b) $eV = \Delta_1 - \Delta_2$, the finite current is due to the transfer of excited particles from S_1 to S_2; (c) $eV = -(\Delta_1 - \Delta_2)$, an excited particle passes from S_2 to S_1 (process 1); in S_2, it couples with one of the electrons there and relaxes back to the ground level (process 2); the energy $2\ \Delta_1$ released during process 2 is sufficient to break a Cooper pair in S_1 (process 3)

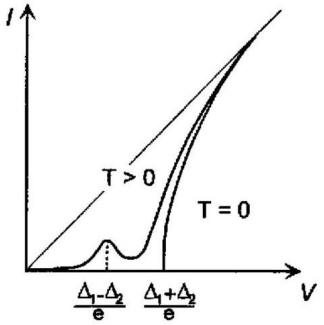

Fig. 6.15. Current-voltage characteristic of an S_1 S_2 tunnel junction

the corresponding energy-level diagram will be that shown in Fig. 6.14 (c). A sharp rise of current will be observed at $|V| = (\Delta_1 - \Delta_2)/e$ in this case, too. Hence the current-voltage characteristic of the tunnel junction formed by two superconductors is an odd function of the voltage V.

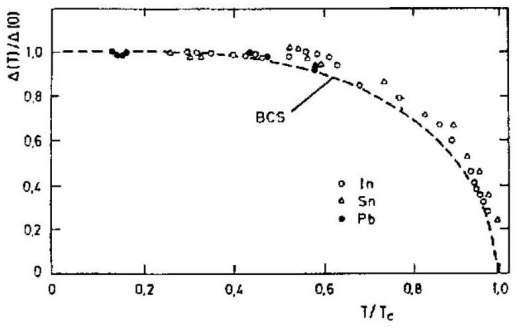

Fig. 6.16. Experimental temperature dependences of the energy gap in indium (open circles), tin (triangles), and lead (solid circles). The dashed line is $\Delta(T)$ given by the BCS theory

To conclude this section, we show the results of the tunneling experiment by Giaever and Megerle [64] who studied the details of the energy gap and its temperature dependence for different superconductors (see Fig. 6.16). The dashed line shows the variation of the gap given by the BCS theory.

Теория (?)

Уравнение Шредингера для одного электрона в ЭМ поле имеет вид

$$i\hbar\frac{\partial\psi}{\partial t} = \left(\frac{1}{2m}\left(-i\hbar\nabla - \frac{e}{c}\mathbf{A}\right)^2 + e\varphi\right)\psi$$

Введем фазовое преобразование $\chi = \chi(r,t)$

$$\psi = \psi_0 e^{i\chi}$$

Тогда

$$i\hbar\frac{\partial\psi}{\partial t} = e^{i\chi}\left(i\hbar\frac{\partial\psi_0}{\partial t} - \hbar\frac{\partial\chi}{\partial t}\psi_0\right)$$

$$\left(-i\hbar\nabla - \frac{e}{c}\mathbf{A}\right)\psi = e^{i\chi}\left(-i\hbar\nabla - \frac{e}{c}A + (\hbar\nabla\chi)\right)\psi_0$$

$$\left(-i\hbar\nabla - \frac{e}{c}A\right)^2\psi = e^{i\chi}\left(-i\hbar\nabla - \frac{e}{c}A + (\hbar\nabla\chi)\right)^2\psi_0$$

Одновременно рассмотрим градиентное преобразование

$$-\frac{e}{c}A_0 = -\frac{e}{c}A + (\hbar\nabla\chi), e\varphi_0 = e\varphi + \hbar\frac{\partial\chi}{\partial t}$$

Выбираем фазу преобразования, так, чтобы в представлении с индексом нуль отсутствовал электрический потенциал

$$\frac{\partial\chi}{\partial t} = -\frac{e}{\hbar}\varphi$$

Уравнение (73) преобразуется к виду

$$i\hbar\frac{\partial\psi_0}{\partial t} = \left[\frac{1}{2m}\left(-i\hbar\nabla - \frac{e}{c}\mathbf{A}_0\right)^2\right]\psi_0$$

Переход от (73) к (76) называется калибровочным преобразованием. При этом преобразовании меняются и потенциалы поля, и фаза волновой функции. Это формальное преобразование, и оба уравнения описывают одно и то же движение электрона.

В такой калибровке во вторичном квантовании гамильтониан системы электронов (8) имеет вид:

$$\hat{H} = \int d^3r \left[\hat{\Psi}^+_{0\sigma}(t,\mathbf{r}) \left(\frac{\left(\hat{\mathbf{p}} - \frac{e}{c}\mathbf{A}_0\right)^2}{2m} - \mu \right) \hat{\Psi}_{0\sigma}(t,\mathbf{r}) + \frac{1}{2} g \hat{\Psi}^+_{0\sigma}(t,\mathbf{r}) \hat{\Psi}^+_{0-\sigma}(t,\mathbf{r}) \hat{\Psi}_{0-\sigma}(t,\mathbf{r}) \hat{\Psi}_{0\sigma}(t,\mathbf{r}) \right]$$

Введем обозначение $-\frac{e}{c}\mathbf{A}_0 = \mathbf{v}_s m$, и ограничимся линейным приближением по магнитному поло (квалратичный член содержит скорость света c в знаменателе). Тогда

$$\hat{H} = \hat{H}_1 + \hat{H}_2$$

$$\hat{H}_1 = \int d^3r \left[\hat{\Psi}^+_{0\sigma}(t,\mathbf{r}) \left(\frac{\hat{\mathbf{p}}^2}{2m} - \mu \right) \hat{\Psi}_{0\sigma}(t,\mathbf{r}) + \frac{1}{2} g \hat{\Psi}^+_{0\sigma}(t,\mathbf{r}) \hat{\Psi}^+_{0-\sigma}(t,\mathbf{r}) \hat{\Psi}_{0-\sigma}(t,\mathbf{r}) \hat{\Psi}_{0\sigma}(t,\mathbf{r}) \right]$$

$$\hat{H}_2 = \int d^3r \hat{\Psi}^+_{0\sigma}(t,\mathbf{r}) \left(\hat{\mathbf{p}}\mathbf{v}_s\right) \hat{\Psi}_{0\sigma}(t,\mathbf{r})$$

(Здесь мы воспользовались тем, что, если дополнительно потребовать, чтобы $\operatorname{div} \mathbf{A} = 0$, то операторы $\hat{\mathbf{p}}$ и $\mathbf{A}$ коммутируют) Первый член H_1 - гамильтониан сверхпроводника без поля, который в импульсном представлении имеет вид (39), а второй член равен

$$\hat{H}_2 = \int d^3r \hat{\Psi}^+_{0\sigma}(t,\mathbf{r}) \left(\hat{\mathbf{p}}\mathbf{v}_s\right) \hat{\Psi}_{0\sigma}(t,\mathbf{r}) = \int d^3r \sum_{\mathbf{k}\sigma} \frac{1}{\sqrt{V}} e^{-i\mathbf{k}\mathbf{r}} \hat{a}^+_{\mathbf{k}} \left(\hat{\mathbf{p}}\mathbf{v}_s\right) \sum_{\mathbf{k}'\sigma} \frac{1}{\sqrt{V}} e^{i\mathbf{k}'\mathbf{r}} \hat{a}_{\mathbf{k}'} = \mathbf{v}_s \sum_{\mathbf{k}\sigma} \mathbf{k} \hat{a}^+_{\mathbf{k}} \hat{a}$$

В основном состоянии без поля система электронов находится в состоянии покоя. Поэтому импульс системы в поле равен импульсу квазичастиц. Это легко доказать с помоїью преобразования Боголюбова, оставив только диагональные члены

$$\mathbf{P} = \sum_{\mathbf{k}\sigma} \mathbf{k} \hat{a}^+_{\mathbf{k}} \hat{a}_{\mathbf{k}} = \sum_{\mathbf{k}\sigma} \mathbf{k} \hat{b}^+_{\mathbf{k}\sigma} \hat{b}_{\mathbf{k}\sigma}$$

В результате гамильтониан сверхпроводника в поле принимает вид

$$H = E_0 + \sum \varepsilon_{\mathbf{k}} \hat{b}^+_{\mathbf{k}\sigma} \hat{b}_{\mathbf{k}\sigma} + \mathbf{v}_s \sum \mathbf{k} \hat{b}^+_{\mathbf{k}\sigma} \hat{b}_{\mathbf{k}\sigma} = E_0 + \sum \tilde{\varepsilon}_{\mathbf{k}} \hat{b}^+_{\mathbf{k}\sigma} \hat{b}_{\mathbf{k}\sigma}$$

Мы видим, что энергия квазичастицы в поле деформируется

$$H = E_0 + \sum \tilde{\varepsilon}_{\mathbf{k}} \hat{b}^+_{\mathbf{k}\sigma} \hat{b}_{\mathbf{k}\sigma}, \tilde{\varepsilon}_{\mathbf{k}} = \varepsilon_{\mathbf{k}} + \mathbf{v}_s \mathbf{k}, \mathbf{v}_s = -\frac{e}{mc}\mathbf{A}_0$$

Поскольку для спаренных электронов характерное значение импульса есть p_F то минимальная энергия возбуждения

$$\min \tilde{\varepsilon}_{\mathbf{k}} = |\Delta| - v_s p_F$$

В соответствии с критерием Ландау (27) сверхпроводянее состояние разрупается если $\min \tilde{\varepsilon}_{\mathbf{k}} \leq 0$. Значит, сильное магнитное поле разрушает сверхпроводник, если

$$v_s = \frac{e}{mc}\mathbf{A}_0 > v_c = \frac{|\Delta|}{p_F}$$

Свяжем величину v_s с электрическим током, который в сверхпроводнике генерируется не электрическим, а магнитным полем. Согласно квантовой механике, плотность электрического тока, создаваемого электронами в присутствии магнитного потенциала,

равна (вспомним, что скорость заряженной частицы есть отношение кинематического импульса $\left(\mathrm{p}-\frac{e}{c}\,\mathrm{A}_0\right)$ к массе)

$$\mathbf{j}=e\mathbf{v}n=e\left\langle \mathrm{Re}\,\hat{\Psi}_0^+\frac{\left(\hat{\mathbf{p}}-\frac{e}{c}\mathbf{A}_0\right)}{m}\hat{\Psi}_0\right\rangle=e\sum\left(\frac{\mathrm{k}}{m}+\mathbf{v}_s\right)\left\langle \hat{a}_k^+\hat{a}_k\right\rangle$$

Внесем знак суммы под знак статистического усреднения

$$\mathbf{j}=e\mathbf{v}_s\left\langle\sum\hat{a}_k^+\hat{a}_k\right\rangle+\frac{e}{m}\left\langle\sum\mathbf{k}\hat{a}_k^+\hat{a}_k\right\rangle$$

Тогда в первом члене получаем полное число электронов N_e, а во втором - с учетом (79) - ток квазичастиц

$$\mathbf{j}=e\mathbf{v}_sN_e+\frac{e}{m}\left\langle\sum\mathbf{k}\hat{b}_{\mathbf{k}\sigma}^+\hat{b}_{\mathbf{k}\sigma}\right\rangle$$

(Заметим, что в силу (83) ток обрандается в нуль, когда $P=\left\langle\sum\mathrm{k}\hat{b}_{\mathrm{k}\sigma}^+\hat{b}_{\mathrm{k}\sigma}\right\rangle=-m\mathbf{v}_sN_e$ т.е. когда импульс квазичастиц полностью компенсирует суммарный импульс электронов, двигагопихся как целое со скоростью v_s)

При нулевой температуре квазичастиц нет, и в системе сунествует незатухающий ток

$$\mathbf{j}=e\mathbf{v}_sN_e$$

Из этой формулы следует, что в образовании сверхтекучего электрического тока приниматот участие все электроны. Это удивительно, поскольку при переходе в сверхпроводяпее состояние по Боголобову перестраиватотся только электроны в узкой корочке около поверхности Ферми.

(????????????????????????????????????)

При $T\neq 0$ в термодинамическом равновесии число квазичастиц в заданном состоянии равно

$$n_{bk}=\left\langle\hat{b}_{k\sigma}^+\hat{b}_{k\sigma}\right\rangle=\frac{1}{e^{\beta\tilde{\varepsilon}_k}+1}$$

Энергия квазичастиц зависит от направления. Если скорость мала, то $\tilde{\varepsilon}_k\approx\varepsilon_k+\mathrm{v}_s\mathrm{k}$ и

$$n_{bk}\left(\tilde{\varepsilon}_k\right)\approx n_{bk}\left(\varepsilon_k\right)+\left(\mathbf{v}_s\mathbf{k}\right)\frac{\partial n_{bk}}{\partial\varepsilon_k}$$

Только поправка в (85) дает вклал квазичастиц в электрический ток при подстановке (85) в (84):

$$\tilde{\mathbf{j}}=\frac{e}{m}\sum\mathbf{k}\left(\mathbf{v}_s\mathbf{k}\right)\frac{\partial n_{bk}}{\partial\varepsilon_k}=-\frac{e}{3m}\mathbf{v}_s\sum k^2\left|\frac{\partial n_{bk}}{\partial\varepsilon_k}\right|$$

Здесь мы воспользовались тем, что, если перейти от суммирования к интегрированиго по k, то

$$\sum_{\mathbf{k}}\mathbf{k}\left(\mathbf{v}_s\mathbf{k}\right)\frac{\partial n_{bk}}{\partial\varepsilon_k}=\frac{V}{(2\pi)^3}\int dk\frac{\partial n_{bk}}{\partial\varepsilon_k}\int\mathbf{k}\left(\mathbf{v}_s\mathbf{k}\right)d\Omega_k=$$

$$\frac{V}{(2\pi)^3}\int dk\frac{\partial n_{bk}}{\partial\varepsilon_k}(4\pi/3)\mathbf{v}_sk^2=\mathbf{v}_s/3\frac{V}{(2\pi)^3}\int dk\frac{\partial n_{bk}}{\partial\varepsilon_k}(4\pi/3)k^2=\mathbf{v}_s/3\sum_{\mathbf{k}}k^2\frac{\partial n_{bk}}{\partial\varepsilon_k}$$

Возникающий(87) здесь интеграл по углам считается так:

$$\int d\Omega\mathbf{k}\left(\mathbf{v}_s\mathbf{k}\right)=a\mathbf{v}_s$$

Домножив обе части скалярно на $\mathbf{v}_s$, получим

$$av_s^2 = \int d\Omega \left(\mathbf{v}_s\mathbf{k}\right)^2 = 2\pi v_s^2 \int\limits_0^\pi d(-\cos\theta)\cos^2(\theta) = v_s^2 4\pi/3$$

То есть $a = 4\pi/3$. Обратим внимание, что квазичастицы создагот электрический ток (86), противоположный скорости $\mathbf{v}_s$, в направлении которой течет элекрический ток электронов в основном состоянии. Таким образом, при фиксировантом значении v_s с увеличением температуры сверхтекучий ток падает

$$\mathbf{j} = e\mathbf{v}_s N_s(T)$$

где плотность сверхтекучих электронов равна

$$N_s(T) = N_e + \frac{1}{3}\sum_{\mathbf{k}} k^2 \frac{\partial n_{bk}}{\partial \varepsilon_k}$$

Когда

$$N_s(T) = 0$$

сверхтекучесть пропалает. Это происходит при $T = T_c$

$$\frac{1}{3}\sum_{\mathbf{k}} k^2 \left(\frac{\partial n_{bk}}{\partial \varepsilon_k}\right)_{T_c} = \frac{1}{3}\sum_{\mathbf{k}} k^2 \left(\frac{\partial n_{bk}}{\partial \left|\xi_k\right|}\right)_{\Delta=0} = -N_e$$

Используя (82), напишем максимальный (критический) ток

$$\mathbf{j} = e\frac{\Delta}{p_F} N_s$$

С помошыо формул (74) вернемся в исходное представление

$$\mathbf{j} = \frac{e}{m} N_s \left(-\frac{e}{c}\mathbf{A} + (\hbar\nabla\chi)\right)$$

Это есть калибровочно-инвариантная формула для плотности тока сверхпроводящик электронов в электромагнитном поле. При калибровочном преобразовании меняется векторный потенциал и фаза волновой функции, но вил выражения в скобках остается неизменным. Этот ток супествует в состоянии термодинамического равновесия, в отличие от тока электронов в нормальном состоянии, который есть проявление необратимого процесса с вылелением тепла.

Features of tunneling density of states

Smoothness of the dI/dV over E plot

(??? does it often smoothed? I think so. But Kiselev told me that it is only if there is a pseudogap. so how does it work???)

3.12.3 6.5 Persistent Current and the Meissner-Ochsenfeld Effect

Earlier in this chapter, we discussed the basic ideas of the superconducting state. We gave a description of the ground state of the superconductor, examined the elementary excitation spectrum, and proved the existence of the energy gap. However, the reader may have wanted

to ask whether there is any proof that everything said so far has anything to do with superconductivity. After all, at this moment, all we know about superconductivity from the microscopic theory is only the following.

The existence of electron-phonon interaction in some metals can result in an effective attraction between the electrons. This, in turn, reduces the energy of the ground state which is then represented by an electron distribution smeared out in momentum space about the Fermi surface. The elementary excitation spectrum of such a metal has an energy gap, that is, the lowest energy level allowed for elementary excitations is separated from the ground state by the energy gap. However, we have not found any indication so far that a material having all these properties is a superconductor.

In this section, we shall demonstrate that the possibility of a persistent current - a fundamental property of the superconductor - follows directly examine the normal metal. In particular, we are interested in the electron distribution in momentum space in the presence of a constant current passing through a normal metal. At $T = 0$ and zero current, all electrons of the metal occupy the states within the Fermi surface while all states outside it are empty. If we then apply an electric field to the metal (for example, in the direction of the x axis), the electrons will start accelerating in this direction. But accelerated motion of electrons in real space is equivalent to their steady motion in momentum space, with constant velocity. This means that the Fermi sphere as a whole will start to move at a steady rate in the direction of the k_x axis in momentum space. This steady motion can be considered uninterrupted as long as electron collisions with crystal defects or impurity atoms can be neglected. When this is no longer possible, there arises a dynamic equilibrium: As a resultof scattering, the electrons having the maximum value of momentum component k_x are carried to the empty states in momentum space until an equilibrium is attained. This implies that, despite the electric field and the steady motion of electrons in momentum space in the direction of k_x, their scattering results in an electron distribution in momentum space which is on average stationary. The Fermi surface shifts somewhat with respect to the origin and the electron scattering results in a transfer of energy to the crystal lattice, that is, in heating up the conductor.

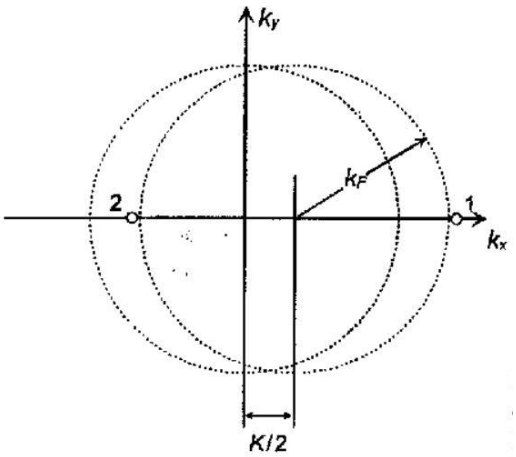

Fig. 6.17. Electron states in a superconductor carrying a current. The 'smeared' Fermi sphere shifts as a whole by $K/2$

Consider now the superconductor. In this case, a current can start to flow (in the absence of an electric field!) if all Cooper pairs have the same momentum K. Suppose that the direction of the current coincides with the x axis, that is, $K = (K, 0, 0)$. This is equivalent to a shift of the 'smeared' Fermi sphere in momentum space by the value of $K/2$ in the direction of the k_x axis, as illustrated in Fig. 6.17. Let us follow the transformations of a Cooper pair (1,2) of momentum $(k_\mathrm{F} + K/2, 0, 0)$ indicated in the figure. Electron 1 having the maximum kinetic energy $(\hbar^2/2m)\,(k_F + K/2)^2$ would have benefited from a transition to an empty state

somewhere near electron 2. Such a process would have been accompanied by an energy decrease by the value of

$$\frac{\hbar^2}{2m}\left(k_F+\frac{K}{2}\right)^2-\frac{\hbar^2}{2m}\left(k_F-\frac{K}{2}\right)^2=\frac{\hbar^2}{m}k_FK$$

where m is the electron mass and k_F is the radius of the Fermi sphere. But then the pair (1, 2) must be broken, which would cause an increase of the total energy of the system by 2Δ, where Δ is the energy gap.

It is now evident that, at sufficiently small currents (or sufficiently small K), the energy gain $\hbar^2k_\mathrm{F}K/m$ cannot compensate for the energy loss 2Δ and the pair will not break up. Of course, on the whole, such a state is less favored energetically than the state without a current ($K=0$), but it can happen to be metastable and exist for an infinitely long time. An example of such a state is provided by a closed superconducting ring carrying a current: A break-down of the current state begins when it becomes energetically favorable to break Cooper pairs, that is, when

$$\frac{\hbar^2k_FK_c}{m}\approx 2\Delta$$

where $\hbar K_\mathrm{c}=P_\mathrm{c}$ is the critical momentum of a pair. Hence

$$P_\mathrm{c}=\hbar K_\mathrm{c}\approx\frac{2m\Delta}{p_\mathrm{F}}=\frac{2\Delta}{v_\mathrm{F}} \tag{6.39}$$

where v_F is the electron velocity on the Fermi surface.
Let us evaluate the current density corresponding to the critical momentum. Since the critical velocity of a pair is

$$v_\mathrm{c}=\frac{P_\mathrm{c}}{2m} \tag{6.40}$$

the critical current density will be, according to (6.39) and (6.40),

$$j_\mathrm{c}=n_\mathrm{s}ev_\mathrm{c}=n_\mathrm{s}e\frac{\Delta}{mv_\mathrm{F}} \tag{6.41}$$

where n_s is the density of the superconducting electrons, which, at $T=0$, is equivalent to the total density of electrons in the metal. Expressing n_s in terms of the London magnetic penetration depth λ, according to (2.7), and Δ_0 in terms of the coherence length ξ, according to (6.27), we obtain the critical current density at $T=0$ in the form

$$j_\mathrm{c}=\frac{\hbar c^2}{16\pi e}\frac{1}{\bar{\lambda}^2\dot{\xi}_0} \tag{6.42}$$

To estimate the order of magnitude of j_c, we assume $\lambda\sim10^{-5}$ cm and $\xi_0\sim10^{-4}$ cm. Then

$$j_\mathrm{c}\sim\frac{10^{-27}\left(3\times10^{10}\right)^2}{16\pi\times4.8\times10^{-10}}\frac{1}{\left(10^{-5}\right)^2\,10^{-4}}\sim4\times10^{15}\ \text{CGS units}$$

$$j_\mathrm{c}=\frac{4\times10^{15}}{3\times10^9}\approx1.3\times10^6\ \text{A cm}^{-2}$$

The critical current density j_c in (6.41) can be expressed in terms of $H_\mathrm{cm}(0)$ and λ. Using the expressions for the density of states near the Fermi surface, $N(0)=k_\mathrm{F}m/\left(\pi^2\hbar^2\right)$, and the electron density $n_\mathrm{s}=k_\mathrm{F}^3/3\pi^2$, together with (6.20) and (6.27), we obtain

$$j_c = \frac{1}{\sqrt{3}4\pi}\frac{cH_{cm}(0)}{\lambda} \tag{6.43}$$

It is interesting to compare the result (6.43) with the critical current density (3.67) given by the Ginzburg-Landau theory. One can easily verify that the two results are equivalent except for a numerical factor (if, of course, (6.43) is extrapolated to temperatures close to T_c). The discrepancy in the numerical factor is not surprising because (6.43) is only intended as an estimate.

Thus we can draw a very important conclusion: the critical current (3.67) given by the Ginzburg-Landau theory has the physical significance of a pairbreaking current, that is, of a current that causes electron pairs in the condensate to become unstable.

Let us now turn to a discussion of how the existence of the energy gap in the elementary excitation spectrum of the superconductor explains the Meissner-Ochsenfeld effect, i.e., the exclusion of weak magnetic fields from the interior of the superconductor. Rigorous calculations which prove that the existence of the energy gap is a sufficient condition for the Meissner effect are beyond the scope of this book. Nevertheless, we shall attempt an interpretation of the Meissner effect using the language of microscopic theory.

Following London [65], one can introduce the so-called 'rigidity' of the electron wavefunction of the superconductor. This means that, owing to the energy gap and the coherent behavior of the whole body of electrons, a weak magnetic field is unable to change the wavefunction in any significant way. From this the Meissner effect follows immediately.

Indeed, assume that $\Psi(\boldsymbol{r}_1, \boldsymbol{r}_2, \ldots, \boldsymbol{r}_N)$ is the wavefunction of N electrons in the superconductor. Note that here Ψ is not an effective wavefunction of the superconducting electrons, as in the Ginzburg-Landau theory (which depends on only one coordinate r), but a true wavefunction. Then the following expression for a current in the presence of a magnetic field can be derived using general relations of quantum mechanics:

$$j(r) = \sum_{n=1}^{N} \int \ldots \int \left\{ \frac{e\hbar}{2im} \left[\Psi^* \nabla_n \Psi - \Psi \nabla_n \Psi^*\right] - \frac{e^2}{mc} \boldsymbol{A}(r_n) |\Psi|^2 \right\} \delta(\boldsymbol{r} - \boldsymbol{r}_n) \, \mathrm{d}^3\boldsymbol{r}_1 \ldots \, \mathrm{d}^3\boldsymbol{r}_N \tag{6.44}$$

Here $\boldsymbol{A}$ is the vector potential of the magnetic field. If the magnetic field is zero ($A = 0$), the current and the integral of the first term are zero, too:

$$\sum_{n=1}^{N} \int \ldots \int \left[\Psi^* \nabla_n \Psi - \Psi \nabla_n \Psi^*\right] \delta(r - r_n) \, \mathrm{d}^3 r_1 \ldots \, \mathrm{d}^3 r_N = 0 \tag{6.45}$$

But we have assumed that the wavefunction is 'rigid', that is, it is not affected by the magnetic field. Hence, formula (6.45) must hold in a nonzero magnetic field. Then, omitting the first term of (6.44), we obtain, after elementary integration

$$\boldsymbol{j}(r) = -\text{ const } \times \boldsymbol{A}(r) \tag{6.46}$$

This last formula is equivalent to the well-known London equation (2.17) and, therefore, is indeed a mathematical expression of the Meissner effect.

3.12.4 Formalism for Thermodynamic Effects of the Meissner State

Formalism 1

In the following, we discuss the consequences for other properties of a superconductor resulting from the temperature dependence of the critical field according to Eq. (4.51). Here, we

will use the strong advantage of the thermodynamic treatment, namely that all the important quantities can be obtained from the Gibbs function by means of simple differential operations.

We recall that the entropy S is found from G according to Eq. (4.10): $S = -\left(\frac{\partial G}{\partial T}\right)_{B,p}$

In the absence of a magnetic field, we have

$$S_{\mathrm{n}} - S_{\mathrm{s}} = -V \frac{B_{\mathrm{cth}}}{\mu_0} \frac{\partial B_{\mathrm{cth}}}{\partial T}$$

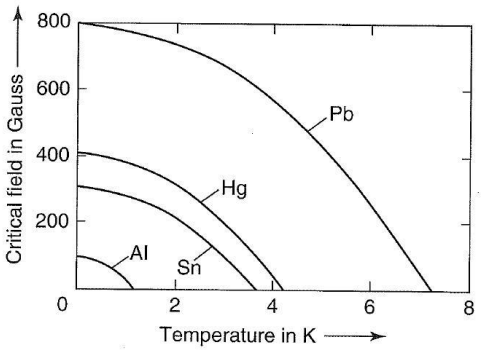

Figure 4.12 Critical magnetic field plotted versus the temperature for different typesuperconductors (1G = 10^{-4} T).

Again we have neglected the T dependence of V, since it is very small. In Section 4.6.6 we will return to this change of V, making the justification of our approximation more clear.

By looking at the temperature dependence of the critical field B_{cth} , as seen in Figure 4.12 and as approximated by Eq. (4.51), we can immediately find the general behavior of $S_{\mathrm{n}} - S_{\mathrm{s}}$. For $T \to T_{\mathrm{c}}$ we have $B_{\mathrm{cth}} \to 0$. Hence, we conclude that $S_{\mathrm{n}} - S_{\mathrm{s}} \to 0$ for $T \to T_{\mathrm{c}}$. At T_{c} (in the absence of a magnetic field) the entropies of the normal conducting and of the superconducting phases are equal, and no heat of transition appears at T_{c} . Hence, we are dealing with a second-order or higherorder phase transition. In our discussion of the specific heat (see Section 4.2), we have derived this result already in a different way.

At temperatures $T < T_{\mathrm{c}}$ the entropy difference $S_{\mathrm{n}} - S_{\mathrm{s}}$ takes a positive value, since in the total range $0 < T < T_{\mathrm{c}}$ we have $\mathrm{d}B_{\mathrm{cth}}/\mathrm{d}T < 0$. According to the third law of thermodynamics, for $T \to 0$ also $S_{\mathrm{n}} - S_{\mathrm{s}}$ must approach zero (the approximation (Eq. (4.51)) satisfies this condition). However, this means that $S_{\mathrm{n}} - S_{\mathrm{s}}$ passes through a maximum. This fact has important consequences for the specific heat. Further we note that at all temperatures $0 < T < T_{\mathrm{c}}$, there exists a finite entropy difference $S_{\mathrm{n}} - S_{\mathrm{s}}$, that is, in this temperature range we have a first-order phase transition with a finite heat of transition.

Figure 4.13 shows the temperature dependences of $G_{\mathrm{n}}, G_{\mathrm{s}}$, and $S_{\mathrm{n}} - S_{\mathrm{s}}$ plotted in arbitrary units on the vertical axis. At $T = T_{\mathrm{c}}$ the two curves $G_{\mathrm{n}}(T)$ and $G_{\mathrm{s}}(T)$ must not only take the same value but also have the same slope, as we have seen. This is the signature of a first-order phase transition. The transition to superconductivity is a second-order phase transition (as we will see explicitly in a moment), since at T_{c} the second derivatives of the Gibbs functions G_{n} and G_{s} are different.

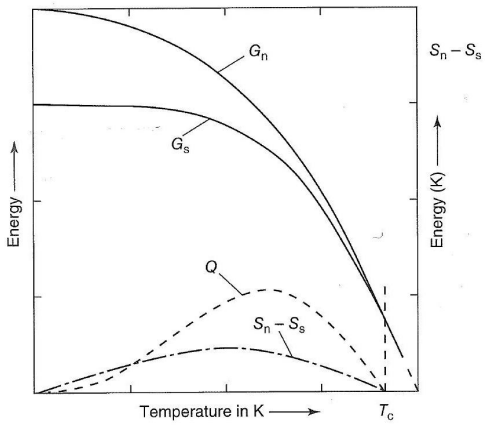

Figure 4.13 Gibbs functions G_n and $G_{s'}$ entropy difference $S_\mathrm{n} - S_{s'}$ and heat of transition Q plotted versus the temperature. Numerical example for 1 molSn : $T_C = 3.72$ K $(G_\mathrm{n} - G_\mathrm{s})_{T=0} = 5 \times 10^{-3}$ Ws; $(S_\mathrm{n} - S_\mathrm{s})_\mathrm{max} = 2.28 \times 10^{-3}$ W s/K; and $Q_\mathrm{max} = 5 \times 10^{-3}$Ws.

These results that we have derived from thermodynamics fit very well into our microscopic picture, as they should. From $S_\mathrm{n} - S_\mathrm{s} > 0$, we conclude that the superconducting phase has a smaller entropy than the normal conducting phase. Without going into details, we recall that the entropy is a measure of the disorder of a physical system. Hence, from $S_\mathrm{n} > S_\mathrm{s}$, we conclude that the degree of order in the superconducting phase is larger than in the normal conducting phase. This higher degree of order can immediately be associated with the correlation between single electrons forming Cooper pairs and between the Cooper pairs themselves. This correlation amounts to an additional order in our system.

For $T \to T_\mathrm{c}$, the Cooper pair density and the energy gap continuously approach zero. Hence, at T_c we cannot expect a heat of transition. Instead, our microscopic picture indicates that we deal with a transition of higher than first order. However, below T_c there exists a finite density of Cooper pairs. In an applied magnetic field permanent currents are generated. However, in type-I superconductors the Cooper pair density practically remains constant until the critical field is reached. At the critical field, the superconductivity breaks down, and all the Cooper pairs are broken up. This requires a finite heat of transition. At the transition from the superconducting to the normal conducting state, heat energy is consumed, namely $(S_\mathrm{n} - S_\mathrm{s})\,T$. In an isothermal process this energy must be delivered to the system. However, if the transition from normal conducting to superconducting state is performed adiabatically, that is, thermally insulated with $\mathrm{d}Q = 0$, the sample becomes colder, since the heat energy is extracted from the other degrees of freedom. Superconductors represent a substance that can be cooled by means of adiabatic demagnetization [26]. However, since much more effective cooling techniques have been developed, this particular method has not become an important application.

Formulas

The second derivative of the Gibbs function with respect to the temperature yields the specific heat, here at constant pressure and constant B (see Eq. (4.13)). From Eq. (4.50),

$$G_\mathrm{n} - G_\mathrm{s} = V \frac{B_\mathrm{cth}^2}{2\mu_0}$$

for the difference $c_\mathrm{n} - c_\mathrm{s}$ of the specific heat in the normal state and in the superconducting state, we obtain

$$c_\mathrm{n} - c_\mathrm{s} = -\frac{VT}{\mu_0} \left\{ \left(\frac{\partial B_\mathrm{cth}}{\partial T} \right)^2 + B_\mathrm{cth} \frac{\partial^2 B_\mathrm{cth}}{\partial T^2} \right\}$$

$$c_\mathrm{s} - c_\mathrm{n} = \frac{VT}{\mu_0}\left\{\left(\frac{\partial B_\mathrm{cth}}{\partial T}\right)^2 + B_\mathrm{cth}\frac{\partial^2 B_\mathrm{cth}}{\partial T^2}\right\}$$

Again we have taken the volume V as constant. Further we note that we insert here the specific volume, that is, the volume per unit mass. In this way we obtain specific quantities, here the specific heat, which refers to the amount of 1 g of the substance. The result of Eq. (4.54) was derived by Keesom [2] in 1924, but without a solid justification of the existence of a superconducting phase in the thermodynamic sense.

From Eq. (4.54) we see that at $T = T_\mathrm{c}$, we have $c_\mathrm{s} > c_\mathrm{n}$. At T_c the critical field vanishes, $B_\mathrm{cth} = 0$, and, hence, $c_\mathrm{s} - c_\mathrm{n} > 0$. At T_c the specific heat displays a jump, which is given by

$$(c_\mathrm{s} - c_\mathrm{n})_{T=T_\mathrm{c}} = \frac{VT_\mathrm{c}}{\mu_0}\left(\frac{\partial B_\mathrm{cth}}{\partial T}\right)^2_{T=T_c}$$

In the literature this important relation is referred to as the Rutgers formula [27]. It connects a thermal quantity, namely the jump of the specific heat, with the critical magnetic field. For a number of superconductors this relation is well satisfied. In Table 4.1 we list some values of $(c_\mathrm{s} - c_\mathrm{n})_{T=T\mathrm{c}}$, as obtained from thermal data and from measurements of the critical field.

Since we found $\mathrm{d}^2 B_\mathrm{cth}/\mathrm{d}T^2 < 0$ and since $\mathrm{d}B_\mathrm{cth}/\mathrm{d}T$ becomes smaller and smaller with decreasing temperature, we find a temperature $0 < T < T_\mathrm{c}$ at which $c_\mathrm{s} = c_\mathrm{n}$. Below this temperature we have $c_\mathrm{s} < c_\mathrm{n}$. The intersection of $c_\mathrm{s}(T)$ and $c_\mathrm{n}(T)$ must appear at the temperature at which $S_\mathrm{n} - S_\mathrm{s}$ reaches a maximum (see Figure 4.13). Since the density of states represents an important quantity for superconductivity, we discuss the possibility for its determination from $B_{cth}(T)$. We start from Eq. (4.54). In many cases, the contribution of the lattice to the specific heat practically does not change at the onset of superconductivity. Hence, we can attribute the difference $c_\mathrm{s} - c_\mathrm{n}$ completely to the electron system. So we obtain

$$c_\mathrm{sE} - c_\mathrm{nE} = \frac{VT}{\mu_0}\left\{\left(\frac{\partial B_\mathrm{cth}}{\partial T}\right)^2 + B_\mathrm{cth}\frac{\partial^2 B_\mathrm{cth}}{\partial T^2}\right\}$$

According to Figures 4.2 and 4.3 and due to the higher degree of order of the superconducting state, we can assume that in the superconducting state the specific heat of the electrons for $T \to 0$ approaches zero faster than in the normal conducting state. We can express this as follows: $c_\mathrm{sE} \propto T^{1+a}$ with $a > 0$. This means that c_sE/T

Table 4.1 Values of $(c_s - c_n)_{T=T_c}$ obtained from thermal and magnetic data.

b) Ref. [29].

approaches zero for $T \to 0$. Then for sufficiently small temperatures, if c_sE/T is

$$-\frac{c_\mathrm{nE}}{T} = \frac{V}{\mu_0}\left\{\left(\frac{\partial B_\mathrm{cth}}{\partial T}\right)^2 + B_\mathrm{cth}\frac{\partial^2 B_\mathrm{cth}}{\partial T^2}\right\}$$

According to Eq. (4.14), the quantity c_nE/T is equal to the Sommerfeld coefficient γ, which is proportional to $N(E_\mathrm{F})$ due to Eq. (4.16). If we also assume that

$$\left(\frac{\partial B_{\mathrm{cth}}}{\partial T}\right)^2 \ll B_{\mathrm{cth}}\frac{\partial^2 B_{\mathrm{cth}}}{\partial T^2}$$

which is always valid for sufficiently small temperatures, we find

$$\gamma = -\frac{V}{\mu_0}B_{\mathrm{cth}}\frac{\partial^2 B_{\mathrm{cth}}}{\partial T^2}$$

and finally with Eq. (4.51) we get

$$\gamma = -\frac{V}{\mu_0}2B_{\mathrm{cth}}\frac{B^2_{\mathrm{cth}}(0)}{T_{\mathrm{c}}^2}$$

We see that at sufficiently low temperatures, the observation of B_{cth} is independent of the special temperature dependence of the critical field and can serve for determining γ and thereby yield information about $N(E_{\mathrm{F}})$.

Связь между B и H в промежуточном состоянии

Рассмотрим сверхпроводник первого рода.

Казалось бы, поскольку в нем, $\sigma > 0$, то он должен находится в одиородиом состоянии. Несложный анализ показывает, что в этом случае форма образца существенно опрелеляет распрелеление магнитного поля внутри сверхпроводника.

В сверхпроводниках первого рода глубина проникновения $\lambda = 0$, если он находится во внешнем магнитном поле $H < H_c$. Рассмотрим сверхпроводянций шар, помешенный в изначально однородное магнитное поле.

Применим уравнение Максвелла divB = 0 к области, вблизи одного из полюсов. В силу симметрии залачи, в этом месте магнитное поле может быть направлено только по нормали к поверхности. Но поскольку в сверхпроводнике B = 0 то и снаружи вблизи полюса магнитное поле H = 0.

Рассмотрим теперь область вблизи экватора. В силу симметрии залачи магнитная индукция как внутри, так и вне шара по-прежнему может быть направлена параллельно оси, соединяюшей полюса. Внутри пара B = 0. А вне шара может сунествоать ненулевая тангенциальная сосавляюшдая магнитного поля. В этом случае условие divB = 0 не наклалывает на внешнее тангенциальное поле никаких ограничений. Поэтому экваториальный участок находится в ненулевом магнитном поле. Итак, при движении вдоль меридиана, магнитное поле вблизи поверхности шара. изменяется от нуля до некоторого максимального, пропорционального исходному внепнему полю.

Будем постепенно увеличивать внешнее поле. Тогда в тот момент, когда на экваторе поле достигло значение H_c в оствльных точках поверхности шара поле меньше H_c. Это означает, что экваториальная часть шара должна перейти в нормальное состояние (магнитное поле разрушило сверхпроводимость), в то время как часть шара ближе к полюсам может сохраняет сверхпроводимость. То есть мы имеем сосуществование двух фаз - нормальной и сверхпроводяней. Из теории фазовых переходов следует, что это в этом случае имеет место фазовый переход первого рода.

Можно поставить залачу, какая часть образца находится в сверхпроводяней фазе в магнитном поле. Рассмотрим, для простоты плоскую пластинку в нормальном внешнем поле. В этом случае, сколь угодно слабое магнитное поле переводит пластину в промежуточное состояние. В самом деле, если пластина находится в однородном сверхпроводяпем состоянии, то в ней $B = 0$.

Очевидно, что, поскольку вне пластины $B \neq 0$, то это несовместимо с условием divB = 0.

В то же время пластина не может находиться полностью в нормальном состоянии, так как проникшее в нее поле слабо, чтобы разрушить сверхпроводимость.

Таким образом пластина находится в промежуточном состоянии.

Очевидно, что в нормальной фазе в равновесии напряженность магнитного поля есть H_c и совпадает в ней с магнитной индукцией.

В сверхпроводящей фазе магнитная индукция равна нуло.

Пусть вне образца магнитное поле, равное магнитной индукции, есть H.

Тогда, в силу сохранения магнитного потока через поверхность ($\operatorname{div} \mathrm{B} = 0$!) имеем

$$H = H_c(1 - \rho)$$

гдеρ - доля пластинки, находяпейся в сверхпроводящем состоянии. Переход из промежуточного в нормальное состояние имеет место, если $\rho = 0$, что происходит при $H = H_c$ Несложно показать, что д,линный цилиндр из сверхпроводника первого рода в продольном магнитном поле в промежуточное состояние не переходит никогда. То есть магнитное поле в него не проникает.

(????)

Критическое поле для сверхпроводника первого рода

Рассмотрим металлический цилиндр в однородном продольном магнитном поле. Свободная энергия системы есть свободная энергия иилиндра в отсутствие магнитного поля + энергия поля (в отсутствие цилиндра) +энергия взаимодействия цилиндра с полем. Свободную энергию системы будем отсчитывать от состояния в котором имеется только поле. Тогда плотность энергии нормального цилиндра есть F_n. Будем охлаждать систему до тех пор, пока цилиндр не перейдет в сверхпроводяпее состояние. Тогда его магнитный момент станет равным $\mathrm{M} = -\mathrm{H}/4\pi$.

Для энергии этого цилиндра в магнитном поле

$$dE_m = -\mathrm{M}d\mathrm{H} = \frac{HdH}{4\pi}$$

поэтому

$$E_m = H^2/8\pi = \frac{MH}{2}$$

Пусть F_{s0} - своболная энергия сверхпроводника в нулевом магнитном поле. Тогда $F_{sH} = F_{s0} + H^2/8\pi$ - свободная энергия сверхпроводника в магнитном поле. Очевилно, что в равновесии

$$F_n = F_{sH}$$

Это имеет место при критическом поле H_c :

$$F_n - F_{s0} = H_c^2/8\pi$$

Итак, в иулевом внешнем магнитном поле внутренняя энергия сверхпроводника меньше энергии нормального состояния (при той же температуре и объеме) на величину $H_c^2/8\pi$. При включении внешего магнитного поля, появление магнитного момента у сверхпроводящего металла приводит к увеличению его энергии на величину (5). Ло тех пор, пока $H_0 < H_c$, сверхпроводнику выгодно оставаться в сверхпроводяпем состоянии. Поле H_c назы вагот критическим термодинамическим магитным полем. Обратим внимание, что конечно же, это поле есть свойство только материала.

13.3.2 Энтропия и теплоемкость сверхпроводника

Из термодинамики известно, что энтропия

$$S = -(\partial F/\partial T)_V$$

Из (6) и (7) следует, что

$$S_s - S_n = \frac{H_c}{4\pi}\left(\frac{\partial H_c}{\partial T}\right)_V$$

состояние является чем-то более упорядоченным, чем нормальное. Это наталкивает на мысль описы вать переход в сверхпроводящее состояние как фазовый переход в духе теории Ландау. (см. соответствующую главу).

При $T = T_c$ магнитное поле $H_c = 0$. Тогда $S_s - S_n = 0$. Следовательно, переход в сверхпроводящее состояние в этом случае является фазовым переходом второго рода. При $T < T_c$, имеет место скачок энтропии, то есть при переходе в сверхпроводящее состояние из нормального скрытая теплота выделяется, и наоборот, при переходе из сверхпроводящего в нормальное - поглощается. Это переход первого рода. Удельная теплоемкость $C = T(\partial S/\partial T)$. Из выражения (8) следует, что

$$C_s - C_n = \frac{T}{4\pi}\left[\left(\frac{\partial H_c}{\partial T}\right)^2 + H_c\frac{\partial^2 H_c}{\partial T^2}\right]$$

$$S_s - S_n = \frac{H_c}{4\pi}\left(\frac{\partial H_c}{\partial T}\right)_V$$

состояние является чем-то более упорядоченным, чем нормальное. Это наталкивает на мысль описы вать переход в сверхпроводящее состояние как фазовый переход в духе теории Ландау. (см. соответствующую главу).

Термодинамические потенциалы

Макроскопическая электродинамика описывает электромагнитные поля в веществе, усредненные по временам, много большим времени изменения молекулярных полей τ_a и по расстояниям, много большим межатомных расстояний a. то есть макроскопическая электродинамика описывает низкочастотные и длинноволновые поля, удовлетворяющие условиям

$$\omega \ll \frac{1}{\tau_a}, a \ll \lambda$$

Магнитной индукцией в веществе называется усредненная по достаточно большим временам и размерам полная напряженность магнитного поля - сумма внешнего магнитного поля и молекулярного поля. При изменении внешнего магнитного поля происходит изменение магнитной индукции внутри тела δB. При этом изменение энергии системы "магнитное поле + тело":

$$\delta R = \frac{1}{4\pi}\int dV \mathbf{H}\delta\mathbf{B}$$

Входящий в это выражение параметр **H** назвается напряженностью магнитного поля в веществе. Он не обязательно совпадает с внешним магнитным полем.

Совпадение, например, имеет место в случае длинного цилиндра в продолыном внешнем магнитном поле. В соответствии с теоремой о малых добавках, в равновесии для свободной энергии $\mathcal{F}$ имеем внешнем магнитном поле. В соответствии с теоремой о малых добавках, в равновесии для своболной энергии $\mathcal{F}$ имеем

$$\delta\mathcal{F} = -S\delta T - pdV + \frac{1}{4\pi}\int dV \mathrm{H}\delta\mathrm{B}$$

мъи поле+тело. Определенный таким образом термодинамический потенциал $\mathcal{F}$ $(T, V, \mathbf{B})$ в равновесии имеет минимум. Предположим, что мы хотим измерять теплоемкость при заданных значениях T, V, B. На эксперименте контролировать значение магнитной инлукции B внутри тела неудобно, а в случае тел с нецилиндрической геометрией попросту невозможно. Фактически эксперимент проводится в заланном виеинем магнитном поле.

Для исследования термодинамики сверхпроводника в таких условиях введем термодинамический потенциал

$$\mathcal{G} = \mathcal{F} - \int dV \frac{\mathrm{HB}}{4\pi}$$

Этот прием в теоретической механике назывался преобразованием. Лежандра.

Тогда

$$\delta\mathcal{G} = -S\delta T - \frac{1}{4\pi}\int dV\ \mathrm{B}\delta\mathrm{H}$$

В соответствии с обнцми принципами термодинамики именно этот потенциал имеет минимум при заданных температуре T, объеме и магнитном поле H. Напомним лишний раз, что в формуле (13) H - магнитное поле виутри образиа. В случае цилиндрической геометрии в продолыном магнитном поле напряженность магнитного поля в веществе совпалает с напряженностыо внешнего магнитного поля. Полезно также ввести плотность потенциала $\mathcal{G}$:

$$G = F - \frac{\mathrm{HB}}{4\pi}$$

В случае других геометрий для описания термодинамики вешества во внешнем магнитном поле вводят другие термодинамические потенциалы. Например

$$\tilde{\mathcal{G}} = \mathcal{F} - \frac{\mathrm{H_0M}}{2}$$

где $\mathrm{H_0}$ - внешнее магнитное поле, а M - полный магнитный момент образца. Для простоты считаем тело однородным. Рассмотрим некоторый термодинамический потенциал, например свободную энергию F. Она является функцией объема, энтропии, и магнитной индукции внутри телаB. Если поле B постоянно, то свободная энергия F имеет минимум.

В равновесии, при малом изменении B для изменения свободной энергии имеем

$$dF = SdT - pdV + HdB/4\pi$$

Если равновесия нет, то

$$\delta F \leq S\delta T - p\delta V + H\delta B/4\pi$$

Пусть процессы в теле происходят таким образом, что постоянны H, T и V. Из последнего соотношения следует, что

$$d(F - HB/4\pi) \leq .0$$

Поэтому в теле могут происходить только такие процессы, что потенциал $F - HB$ может только уменьшаться и в состоянии равновесия он имеет минимум

Как правило теоретики выводят (либо постулируют) вид свободной энергии F, как функции магнитной индукции B. В тоже время, экспериментаторы работают с системами, помешенными во внешнем поле, которым они и управляют. Если образец - длинный цилиндр, то магнитное поле внутри образца численно равно внешнему магнитному полю. Тогда в условиях эксперимента минимум имеет потенциал $\mathcal{G}$.

3.12.5 Introduction to Thermodynamics of Superconductors

Just Intro

In the last chapter we saw that a well-established theory exists for conventional superconductors. The theory explains how a coherent matter wave is constructed by means of the formation of Cooper pairs. However, we also saw that, in particular for unconventional superconductors, the microscopic details often remain unclear. On the other hand, based on only a few basic symmetry arguments, we were able to account for many properties of the pair wave function.

Next we want to treat superconductivity on a macroscopic scale. We will se that by means of a rigorous application of the general laws of thermodynamics we can reach a deep understanding of the properties of the superconducting state. This will lead us to the Ginzburg-Landau theory [1], which was developed in the early 1950s, and which turned out to be highly powerful for the solution of many practical problems. It serves for the description of conventional as well as unconventional superconductors

Already in 1924 Keesom [2] had tried to apply thermodynamics to superconductivity. At the time there was the difficulty that the superconducting state could not be interpreted in terms of a single new thermodynamic phase. Then in 1933 the discovery of the Meissner-Ochsenfeld effect brought crucial progress. At the onset of superconductivity, a magnetic field is expelled from the interior of a type-I superconductor, independent of the experimental details. This represented a clear experimental confirmation of the existence of a single superconducting phase. The thermodynamic equilibrium state is unequivocally determined by the specification of T and B also in the case of a type-II superconductor, where the magnetic field penetrates into the superconductor

Before we turn to the details, we make some general remarks on the thermodynamic treatment of physical systems.

Reminder: General Aspects of Thermodynamics

A crucial quality of the thermodynamic treatment of a macroscopic physical system arises from the fact that the immense number of independent coordinates of the individual particles is reduced to only a few macroscopic variables of the system. For instance, for the thermodynamic treatment of an ideal gas, one does not start from the $3N$ spatial coordinates and the $3N$ momentum coordinates of the N gas atoms. Instead, one describes the behavior by such variables as the temperature T, the volume V, the particle number N, and so on

One is interested in the macroscopic behavior of the system, say, in the stability of the different phases, such as the solid, liquid, and gaseous phases, during the variation of one variable while the other variables are kept constant. The thermodynamic equilibrium states of a system under specified conditions play an important role. Here, we deal with the following question. A system, say, a liquid-vapor mixture, is specified by fixing the temperature T, the volume V, and the total particle number N. We want to know the number N of atoms in the vapor in thermodynamic equilibrium, that is, in the state that is established if all other quantities can be freely adjusted under the given conditions. The system then exists in a definite state, where the particles can be freely exchanged between the vapor and the liquid, and where a definite heat exchange with a thermal bath must be possible.

At this point we mention that frequently the thermodynamic equilibrium state is not established at all or only very slowly, because the free exchange of some quantity is not possible in the particular experiment. The thermodynamic prediction on the equilibrium state is completely independent of the question of the chances for it to become realized.

All such questions are dealt with by specifying suitable thermodynamic functions, the Gibbs

functions, or thermodynamic potentials. These Gibbs functions are constructed from the variables in such a way that a certain Gibbs function is associated with a definite set of independent variables. The system is completely accounted for by means of this Gibbs function.

To find the correct Gibbs function of a system is not easy. First, we must find a set of independent variables, which is sometimes difficult. Standard sets of variables are temperature T, volume V, and particle number N; or temperature T, pressure p, and particle number N. Other variables must be added if a system is also affected, for example, by electric or magnetic fields. The behavior in a magnetic field will be highly important for superconductors

If we have found the Gibbs function associated with a set of variables, the equilibrium states are determined by the extrema of the Gibbs function.") Two phases of a system are in equilibrium if their Gibbs functions have the same value. In principle, from this we can already answer the question of the stability of a phase. If the equilibrium state is determined by the minimum of the Gibbs function, then 1) A well-known case is the condition for the extremum of the entropy S as the Gibbs observed macroscopic state of the wyst the realized. Systems having the entropy as the Gibbs function move in the direction of

increasing entropy. The equilibrium state corresponds to a state wh maximum entropy, of course, always under the given cibbs functions, the rium states with other extremum can always be related to the second law of thermodynamics. function which, in the end, is a measure of

phase I will be unstable relative to phase II if the Gibbs function of phase I is larger than that of phase II..2)

The Gibbs functions are distinguished by the fact that, for a differential variation, just the differentials of the independent variables appear. For illustration, we present a few known examples.

For the internal energy U, we have

$$\mathrm{d}U = T\ \mathrm{d}S + \delta A$$

If we include only the compressional work $\delta A^V = -p\ \mathrm{d}V$, we obtain

$$\mathrm{d}U = T\ \mathrm{d}S - p\ \mathrm{d}V$$

U is the Gibbs function for the variables S and V. We note that these two variable change with the size of the system ("extensive state variables"), whereas this is not so in the case of the variables T and p (intensive state variables"). In the Gibbs functions there always appear products of extensive and intensive quantities. The negative sign of the term $p\ \mathrm{d}V$ is needed, since we define that all energies added to a system are counted as positive. For a reduction of the volume, that is, $\mathrm{d}V < 0$ work is added to the system.3. Of course, other variables, for example, the particle number N, may also appear. In the following, we always keep the particle number constant. Hence, we can ignore this variable.

The free energy F is given as

$$F = U - TS$$

leading to

$$\mathrm{d}F = \mathrm{d}U - T\ \mathrm{d}S - S\ \mathrm{d}T = -S\ \mathrm{d}T - p\ \mathrm{d}V$$

We see that F is the Gibbs function for the variables T and V.

Frequently, the arbitrary variation of the pressure p is much easier than that of V and, hence, p is introduced as the independent variable. The Gibbs function for the variables T and p is the enthalpy G with

$$G = U - TS + pV$$

and

$$\mathrm{d}G = -S\ \mathrm{d}T + V\ \mathrm{d}p$$

In our above-mentioned discussion, we have considered only the variables pressure and temperature. For the thermodynamic treatment of the superconducting phase,") we must include an additional variable, which accounts for the behavior in a magnetic field. As the additional independent variable, we choose the magnetic

At this stage we should mention that phase transitions also exist at $T = 0$. They originate from quantum mechanics. The transition point is referred to as quantum-critical point. of this kind are discussed in connection with he cuprate superconductors, and also in the case of materials such as the heary fermions Superconductivity can appear near a and many other substances [3]

In technical thermodynamics mostly one proceeds differently. There the work that is done by the 4) system is counted as positive (representing the interesticin palt for tecchnologs)

field $\mathbf{B}$. The Gibbs function associated with the variables T, p, and $\mathbf{B}$ for constant particle number is

$$G = U - TS + pV - \mathbf{m} \cdot \mathbf{b}$$

are always parallel or antiparallel, and since we indicate this in the sign of m, we can ignore the vector property in this discussion. For the variation of the internal energy, we obtain [6]

$\mathrm{d}U = T\ \mathrm{d}S - p\ \mathrm{d}V + B\ \mathrm{d}m$

as is shown in standard textbooks on the theory of heat. Hence, one finds?

$\mathrm{d}G = -S\ \mathrm{d}T + V\ \mathrm{d}p - m\ \mathrm{d}B$

For our choice of the Gibbs function $G(T, p, B)$, the independent variables T, p, and B appear in the differentials, as expected.

If we know the Gibbs function of a system, we can calculate from it very easily many thermodynamic quantities by means of suitable derivatives with respect to the variables. In this way, we find the entropy S from G:

$$S = -\left(\frac{\partial G}{\partial T}\right)_{p,B}$$

Here, the symbol $\partial/\partial T$ indicates the partial derivative with respect to temperture. At the same time, the pressure p and the magnetic field B must be kept constant. This is indicated by the subscript index p, B. In this way the dependence of the entropy on the temperature, on the magnetic field, and on the pressure is obtained: $S = S(T, B, p)$. If G depends on additional variables, these must also be kept constant. In this case these variables also appear in the subscript index after the bracket

Analogously, we can also derive other thermodynamic quantities from G. From the partial derivative with respect to the pressure at constant temperature, we find the sample volume V (as a function of T, B, and p):

$$V = \left(\frac{\partial G}{\partial p}\right)_{T,B}$$

The specific heat c is another important quantity that we will need in the following It is defined by the relation

$$\Delta Q = cm'\Delta T$$

where ΔQ is the amount of heat we must introduce into a substance of mass m' in order to raise its temperature by ΔT. We distinguish between different kinds

magnetic moment m always appears together with B, confusion with the mass is unlikely.

The differential work $\delta A^m = B\ \mathrm{d}m$ exactly corresponds to the compressional work $\delta A^V = -p\ \mathrm{d}V$ where B and the magnetic moment m appear in place of the pressure p and the negative vol ume $-V$, respectively. We take paramagnetic materials as an example. Then **m** is paralifel to B. During an increase in m, that is, dm>0, work is added to the system, which appears as heat of 7) See, for example, [4] f secific heat, depending on the conditions under which the addition of heat fres example, if the pressure is kept constant, we speak of the energy taks place. For exant pressure.

From the function G the specific heat is obtained directly by means of the expression

$$-T\left(\partial^2 G/\partial T^2\right)_{p,B} = T(\partial S/\partial T)_{p,B} = c_{\mathrm{p}}$$

Relations such as Eq. (4.13) are highly important for calculating the entropy from he measured temperature dependence of the specific heat. There exist specific characteristic relations between the different thermodynamic quantities. In this chapter, we will deal with several examples.

As the last general aspect we will discuss the order of the transition between two thermodynamic phases. We have mentioned already that at a phase transition the relevant Gibbs functions have the same value. If the first derivative of the Gibbs function with respect to the temperature is discontinuous at the phase transibs one speaks of a first-order phase transition. In this case, the entropy iumps by a finite value. Analogously, if the entropy is continuous at the phase transition, but if the second derivative of the Gibbs function, which is proportional to the specific heat, shows a jump, one speaks of a second-order phase transition For such higher-order phase transitions, L. D. Landau has developed a powerful theory [5].

Also the superconducting phase transition in the absence of a magnetic field of second order. The application of the concepts of the Landau theory to the superconducting phase transition will lead us to the Ginzburg-Landau theory. However, before we turn to this theory, we want to show by means of specific-heat measurements that the superconducting phase transition is, indeed, of second order. Also we want to discuss the thermal conductivity of superconductors.

4 Basic Effects of Superconductors

4.1 General Effects

(отсюда многое, возможно, в главы дальше перенесу)

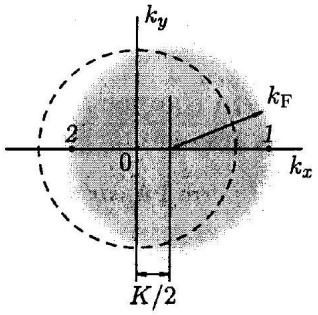
4.1.1 Critical supercurrent: basics

Gap from spectrum leads to supercurrent by Shmidt

Наличие электрон-фононного взаимодействия в некоторых металлах может привести к эффективному притяжению электронов металла друг к другу. Это приводит к понижению энергии основного состояния, которое теперь представляет собой размазанное около поверхности Ферми распределение электронов в k-пространстве. Спектр элементарных возбуждении такого материала имеет энергетическую щель, т.е. первые разрешенные уровни спектра элементарных возбуждений отделены от уровня основного состояния энергетической щелью. Но мы до сих пор никак не показали, что материал, обладающий этими свойствами, - сверхпроводник.

Сейчас мы покажем, как из существования энергетической щели следует возможность незатухающего тока - основного свойства сверхпроводника. Для того чтобы это лучше понять, обратимся сперва к нормальному металлу. Нас будет интересовать распределение электронов нормального металла в **k**-пространстве, когда по металлу идет постоянный ток. Если тока нет, то при $T = 0$ все электроны заполняют состояния внутри сферы Ферми, и все состояния вне этой сферы пусты. Создадим в металле электрическое поле (пусть в направлении оси x), тогда электроны начнут ускоряться в этом направлении, а ускоренному движению электронов в x-пространстве будет отвечать равномерное движение с постоянной скоростью электронов в k-пространстве. В результате вся сфера Ферми начнет с постоянной скоростью перемещаться в **k**-пространстве в направлении оси k_x. Так будет происходить до тех пор, пока мы можем пренебрегать процессами соударений электронов с примесями и дефектами кристаллической решетки. Если эти процессы учесть, то окажется, что в результате рассеяния электроны, имеющие максимальное значение компоненты импульса k_x, будут переки дываться в свободные ячейки k-пространства и, в конце концов, возникнет динамическое равновесие. Это значит, что, несмотря на электрическое поле и равномерное движение электронов в **k**-пространстве в направлении оси k_x, рассеяние на дефектах приводит к тому, что в целом распределение электронов в **k**-пространстве становится стационарным. Сфера Ферми оказывается несколько сдвинутой относительно начала координат, что естественно для токового состояния. Рассеяние электронов приводит к передаче энергии решетке, к разогреву проводника.

Теперь рассмотрим сверхпроводник. Ток в сверхпроводнике (в отсутствие электрического поля!) может возникнуть, если все электронные пары будут иметь один и тот же импульс $\hbar$ K. Пусть ток течет вдоль оси x сверхпроводника, т.е. $\mathbf{K} = (K, 0, 0)$. Это значит, что "размазаннал» сфера Ферми будет сдвинута в k-пространстве на



величину $K/2$ в направлении оси k_x. Это схематически изображено на рис. 50.1. Проследим за поведением показанной там электронной пары $(1,2)$, имеющей состояние $(\pm k_{\mathrm{F}} + K/2, 0, 0)$. Электрону 1, имеющему наибольшую кинетическую энергию $(\hbar^2/2m)\,(k_{\mathrm{F}} + K/2)^2$, конечно, было бы выгодно перейти в свободную ячейку где-нибудь около электрона 2. При этом энергия системы понизится на величину

$$\frac{\hbar^2}{2m}\left(k_{\mathrm{F}} + \frac{K}{2}\right)^2 - \frac{\hbar^2}{2m}\left(k_{\mathrm{F}} - \frac{K}{2}\right)^2 = \frac{\hbar^2}{m} k_{\mathrm{F}} K$$

Но тогда пара $(1,2)$ будет разрушена и, как мы уже знаем, энергия системы повысится на 2Δ, где Δ-энергетическая щель, m-масса электрона, k_{F} - радиус сферы Ферми.

Отсюда ясно, что при достаточно маленъких токах (достаточно малых K) выигрыш в энергии $\hbar^2 k_F K/m$ не может скомпенсировать проигрыш 2Δ, и пара разрываться не будет. Конечно, в целом такое состояние энергетически менее выгодно, чем состояние без тока ($K = 0$), но оно может оказаться метастабильным и существовать бесконечно долго. Примером тому служит замкнутое сверхпроводящее кольцо с током. Разрушение такого состояния начнется тогда, когда разрыв пар станет энергетически оправданным. Правильную оценку мы получим, если

Рис. 50.1. Токовое состояние в сверхпроводнике. Вся "размазаннал» сфера Ферми сдвинута на $K/2$.

напишем

$$\hbar^2 k_{\mathrm{F}} K_c/m \simeq 2\Delta,$$

где $\hbar K_c$ - критический импульс пары. Следовательно, критический импульс пары равен

$$P_c = \hbar K_c \simeq 2m\Delta/p_{\mathrm{F}} = 2\Delta/v_{\mathrm{F}} \tag{50.1}$$

здесь v_F - скорость электрона на поверхности Ферми.

Оценим, какой плотности тока соответствует такой критический импульс. Поскольку критическая скорость пары

$$v_c = P_c/2m \tag{50.2}$$

то критическая плотность тока, согласно (50.1) и (50.2), будет

$$j_c = n_s e v_c = n_s e \frac{\Delta}{m v_{\mathrm{F}}} \tag{50.3}$$

где n_s-плотность сверхпроводящих электронов, которая при $T = 0$ просто равна электронной плотности металла. Выражая n_s через лондоновскую глубину проникновения магнитного поля λ, согласно (5.7), и Δ_0 через длину когерентности ξ_0, согласно (45.7), получим окончательно плотность критического тока при $T = 0$ в виде

$$j_c = \frac{\hbar c^2}{16\pi e}\frac{1}{\lambda^2 \xi_0} \tag{50.4}$$

Оценим порядок получившейся величины. Пусть $\lambda \sim 10^{-5}$см, $\xi_0 \sim 10^{-4}$см, тогда

$$j_c \sim \frac{10^{-27}\left(3\cdot 10^{10}\right)^2}{16\pi \cdot 4.8 \cdot 10^{-10}}\frac{1}{\left(10^{-5}\right)^2 10^{-4}} \text{ абс. ед. } \sim 4\cdot 10^{15} \text{ абс. ед.}$$

Учитывая, что 1 А содержит $3\cdot 10^9$ абс. ед. силы тока, имеем

$$j_c = \frac{4\cdot 10^{15}}{3\cdot 10^9} \text{ A/cm}^2 \simeq 1.3\cdot 10^6 \text{ A/cm}^2.$$

Выразим критическую плотность тока j_c в формуле (50.3) через $H_{cm}(0)$ и λ. Воспользовавшись выражением для плотности состояний у поверхности Ферми $N(0) = k_F m/\left(\pi^2\hbar^2\right)$, формулой (44.18), выражением для электронной плотности $n_s = k_{\mathrm{F}}^3/3\pi^2$ и формулой (45.7), получим

$$j_c = \frac{1}{\sqrt{3}4\pi}\frac{cH_{cm}(0)}{\lambda}. \tag{50.5}$$

Интересно сравнить результат (50.5) с плотностью критического тока, полученной в теории Гинзбурга-Ландау (18.5). С точностью до численного коэффициента эти результаты совпадают (если, конечно, формулу (50.5) проэкстраполировать в область температур, близких к T_c). Расхождение в численном коэффициенте вполне естественно, так как формула (50.5) носит оценочный характер.

Следовательно, мы можем сформулировать теперь важный физический вывод: критический ток (18.5), даваемый теорией Гинзбурга-Ландау, имеет смысл критического тока распаривания, т. е. такого тока, при котором теряется устойчивость электронных пар, образующих сверхпроводящий конденсат.

Intro: Currents in Type-I and Type-ll Superconductors

We have already seen several times that a superconductor can carry only a limited electric current. As the first example, in Section 1.5.1 we discussed the critical current in a Josephson junction. However, also in the case of homogeneous superconductors the strong correlation of the Cooper pairs leads to the existence of a critical velocity and, hence, of a critical current density j_c. If this critical value is exceeded, Cooper pairs will be broken up.

Next we want to discuss some relations resulting from the existence of a critical current density, for the maximum possible current in a superconductor. We will restrict ourselves to simple geometric situations.

Our discussions of the critical current are highly important for the technical applications of superconductivity. In type-II superconductors we have materials that can still remain superconducting also for technically interesting magnetic fields. However, for applications it is also important that these superconductors can still transport high electric currents sufficiently without resistance in high magnetic fields. As we will see, here we are confronted with another problem, which has been solved only with the so-called hard superconductors.

Before we turn in detail to the special features in type-I and type-II superconductors, we want to investigate the magnitude of the critical supercurrent density in the ideal case of a thin and homogeneous superconducting wire.

Limit of the Supercurrent from Superfluidity Criterion

Более точное разложение $E_0 = \frac{1}{2} g_F (\hbar\omega_D)^2 - \frac{1}{2} g_F \hbar\omega_D \Delta_0 \sqrt{1 + \left(\frac{\hbar\omega_D}{\Delta_0}\right)^2}$ вблизи точки перехода $T = T_c$ позволяет получить зависимость $\Delta(T) \sim (T_c - T)^{1/2}$. Из $\Delta = \lambda \cdot \sum'_{\mathbf{p}'} \langle \hat{a}_{-\mathbf{p}',-} \hat{a}_{\mathbf{p}',+} \rangle$. видно, что щель Δ пропорциональна оператору уничтожения куперовских пар, что означает $\Delta^2 \sim n_s$. Это позволяет оценить температурную зависимость критического j_c тока от температуры T. В соответствии с критерием сверхтекучести для куперовских пар со спектром $\varepsilon(p) = \sqrt{\xi_{\mathrm{p}}^2 + \Delta^2}$, их критическая скорость $v_c = \Delta / p_F$. Это значит, что при скоростях, больших v_c, пары утрачивают свойство сверхтекучести и разваливаются. Поэтому плотность критического тока $j_c = e n_s v_c \sim \Delta^3 \sim (T_c - T)^{3/2}$ еще называют током распаривания.

(!!! elaborate!!!)

Limit of the Supercurrent Due to Pair Breaking in scope of GL formalism

In order to determine the maximum supercurrent density that can be reached under the most favorable conditions, we consider a homogeneous superconducting wire extending along the x-direction. The diameter of the wire is assumed to be smaller than the London penetration depth λ_{L} and the Ginzburg-Landau coherence length ξ_{GI}. In this case, the Cooper pair density can be taken as constant over the cross-section of the wire, and the Ginzburg-Landau equations (4.28) and (4.29) can be solved for this problem.

In order to keep our calculation no more complicated than necessary and to uncover the underlying physics, resulting in the maximum supercurrent of our wire, we use a few simplifications. For the wave function Ψ of the superconductor, we use the ansatz

$$\Psi = \Psi_0 \mathrm{e}^{ikx}$$

Here, the amplitude Ψ_0 is independent of location. This means that the Cooper pair density $n_s = |\Psi|^2$ is spatially homogeneous. The exponential function is taken such that the wave with wavenumber k is running along the wire.

In order to see how Ψ is connected with the supercurrent or the supercurrent density along the wire, we insert Eq. (5.1) into the second Ginzburg-Landau equation (4.29):

$$j_{\mathrm{s}} = \frac{q\hbar}{2mi} (\Psi^* \nabla\Psi - \Psi \nabla\Psi^*) - \frac{q^2}{m} |\Psi|^2 \mathbf{A}$$

Then we obtain for the x component of the current density

$$j_{\mathrm{s},x} = \frac{q\hbar k}{m} \Psi_0^2 - \frac{q^2}{m} \Psi_0^2 A_x = q\Psi_0^2 \frac{\hbar k - q A_x}{m}$$

According to Eqs. (1.5) and (1.6), the ratio on the right-hand side is just the Cooper pair velocity. Hence, we have

$$j_{\mathrm{s},x} = q\Psi_0^2 v_x$$

This corresponds exactly to the relation $j = qnv$ for the current density of electrically charged particles.

Next, we turn to the first Ginzburg - Landau equation (4.28):

$$\frac{1}{2m} \left(\frac{\hbar}{i} \nabla - q\mathbf{A} \right)^2 \Psi + \alpha\Psi + \beta |\Psi|^2 \Psi = 0$$

By inserting Eq. (5.1) and by assuming the vector potential to be also independent of x,[1)] we obtain

$$\frac{(\hbar k - qA_x)^2}{2m}\Psi + \alpha\Psi + \beta\Psi_0^2\Psi = 0$$

or by introducing the velocity v_x and after dividing by Ψ

$$\frac{1}{2}mv_x^2 + \alpha + \beta\Psi_0^2 = 0$$

With $\alpha < 0$, this yields

$$\Psi_0^2 = -\frac{\alpha}{\beta}\left(1 - \frac{mv_x^2}{2|\alpha|}\right) = \Psi_\infty^2\left(1 - \frac{mv_x^2}{2|\alpha|}\right)$$

Here, we have used the relation $-\alpha/\beta = \Psi_\infty^2$ (Eq. (4.23)), and we have introduced the wave function Ψ_∞ of the homogeneous system in the absence of a supercurrent. We see that the Cooper pair density Ψ_0^2 decreases with increasing kinetic energy $^1/2mv_x^2$. It vanishes if this energy is equal to $|\alpha|$.

The calculation can also be performed using a spatially varying A_{x_x}, resulting in a more complicated calculatio This dependence of the Cooper pair density on the velocity must also be taken into account in the expression (5.2b) for the supercurrent density. If the Cooper pair density were constant, $j_{s,x}$ would simply increase linearly with the velocity of the charge carriers. This is exactly what happens at small velocities. However the larger v_x, the more pronounced is the decrease of the Cooper pair density. A the larger v_x, the more pronounced is the decrease of the Cooper pair density. As soon as Ψ_0^2 reaches zero, j_x vanishes. Between $v_x = 0$ and this limiting value, j_x has a maximum as a function of v_x, which we want to determine next.

For this, we must calculate the derivative $\mathrm{d}j_s/\mathrm{d}v_w$, set it equal to zero, and find v_x. For the velocity yielding the maximum supercurrent density, we obtain

$$v_{x,p} = \sqrt{\frac{2|\alpha|}{3m}}$$

According to Eq. (5.5), at this velocity the Cooper pair density attains the value $2/3\Psi_\infty^2$, and Eq. (5.2b) yields

$$j_{\mathrm{c,p}} = q\frac{2}{3}\sqrt{\frac{2|\alpha|}{3m}}\Psi_\infty^2$$

This current density is also referred to as the critical pair-breaking current density. Using expression (4.25a), connecting α with B_{cth}, and with expression (1.10) for the London penetration depth, we can write it also in the form [2)]

$$j_{\mathrm{c,p}} = \frac{2}{3}\sqrt{\frac{2}{3}}B_{\mathrm{cth}}\frac{1}{\mu_0\lambda_{\mathrm{L}}}$$

This critical current density can become very large. If for B_{cth} we take a value of 1 T and for λ_{L} a value of 100 nm, we obtain for $j_{c,p}$ a value of about 4.3×10^8 A/cm^2. In the following sections, we will see to what extent this high critical current density can be achieved in real superconductors.

4.1.2 Critical supercurrent: advanced features 1

Experimental Overview of Type-I Superconductors (??)

As the simplest geometric example, we consider a wire with circular cross-section carrying a current I. The wire is assumed to be much thicker than the London penetration depth

At sufficiently small currents, the superconducting wire resides in the Meissner phase. In this phase, the interior of the superconductor must remain free of magnetic flux. However, this also means that the interior cannot carry an electric current, since otherwise the magnetic field due to the current would exist. From this we also conclude that the current passing through a superconductor is restricted to the thin surface layer, into which the magnetic field can penetrate in the Meissner phase. The external currents applied to a superconductor are

Since Eq. (5.7b) has been obtained from an analysis of the Ginzburg-Landau equations, this expression is valid only near T_c. From the microscopic bCS theory, one finds that $j_{c,p}$ is proportional to obtain again $j_{c,p} = B_{cth}/\mu_0\lambda_L$ 286 Fritical Currents in Type-l and Type-ll Superconductors

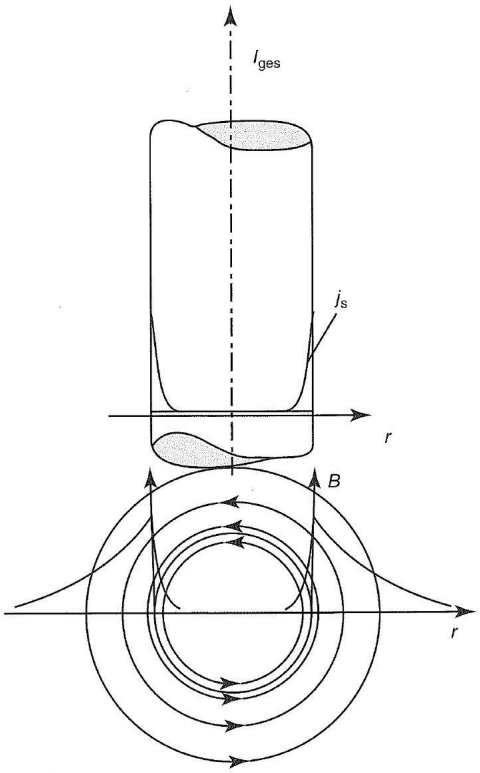


Figure 5.1 Distribution of the current density and of the magnetic field in a currentcarrying superconducling wire. The surface layer has the thickness of only the penetration depth λ_L.

referred to as transport currents, in contrast to the shielding currents appearing in the superconductor as circulating currents.

In Figure 5.1 we show schematically the spatial distribution of a transport current in a wire with circular cross-section in a plot of the current density versus the wire radius. The total current is given by the integral of the current density over the cross-sectional area

$$I = \int_F j_s df$$

The magnetic field of this current is also shown in Figure 5.1

Silsbee hypothesis

Already by 1916, Silsbee [1] had proposed the hypothesis that in the case of "thick" superconductors, that is, for superconductors with a fully developed shielding layer, the critical current is reached exactly when the magnetic field of the current at the surface attains the value B_{cth} . This hypothesis has been confirmed perfectly. In other words, it means that the magnetic field and the current density at a surface with a well-developed shielding layer are strongly correlated (Eq. (4.60)). The critical value of the current density is associated with a certain critical field, namely B_{cth}, where it is completely irrelevant whether the current density is due to shielding currents or a transport current.

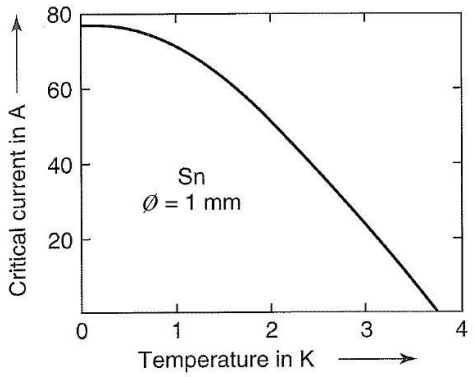

Figure 5.2 Critical current of a tin wire with 1 mm diameter plotted versus the temperature.

Because of the validity of the Silsbee hypothesis, it is very simple to calculate the critical currents of wires with circular cross-section from the critical fields, for example, from those of Figure 4.12. The magnetic field at the surface of such a wire carrying the current I is given by

$$B_0 = \mu_0 \frac{1}{2\pi R}$$

where B_0 is the field at the surface, I is the transport current, R is the wire radius, and $\mu_0 = 4\pi \times 10^{-7}$ V s/Am. The only requirement is cylindrical symmetry of the current distribution. The radial dependence of the current density is arbitrary.

It follows from Eq. (5.9) that the critical current shows the same temperature dependence as the critical magnetic field (at I_{c} the field B_{c} is reached). As an example, in Figure 5.2 we show the temperature dependence of the critical current for a tin wire with 1 mm diameter. According to Eq. (5.9), the critical field of about 300G at 0 K corresponds to a critical current $I_{\mathrm{c0}} = 75$ A. This critical current increases proportional to the wire radius, since the total current only flows within the thin shielding layer

We can also find an average critical current density at the surface. In this case we replace the exponentially decaying current density (Figure 5.1) by a distribution in which the full current density at the surface remains constant to a depth λ_{L}, the penetration depth, and then abruptly drops to zero.3) Based on this argument, for the tin wire, for example, at 0 K we obtain a critical current density

Since the penetration depth is only a few times 10^{-6} cm, for macroscopic wires we always have plane

$$j_{\mathrm{c0}} = \frac{I_{\mathrm{c0}}}{2\pi R \lambda_{\mathrm{L}}(0)} = 7.9 \times 10^7 \ \mathrm{A/cm^2}$$

with $R = 0.5$ mm, $\lambda_{\mathrm{L}}(0) = 3 \times 10^{-6}$ cm, and $I_{00} = 75$ A. This critical current density is similar to the critical pair-breaking current density of a thin wire treated in Section 5.1. It would allow very high transport currents if the shielding effect, leading to the restriction of the current to

a thin surface layer, could be avoided. Such substances have been developed in the form of the hard superconductors.

Using Silsbee's hypothesis, we can also calculate the critical currents of a superconductor in an external magnetic field. For this purpose, we only have to add the vectors of the external field and of the field of the transport current at the surface. The critical current density is reached when this resulting field attains the critical value. We consider a wire of radius R and a magnetic field B_a applied perpendicula to the wire axis. At first, no transport current is passing through the wire. Due to the Meißner effect, the field B_a is expelled from the wire, as shown in Figure 5.3a.

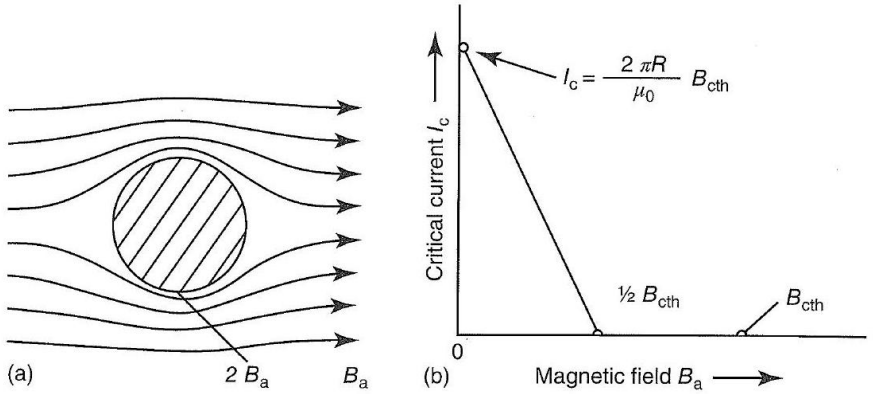

Figure 5.3 (a) Field distribution around a superconducting wire in the Meissner phase without a transport current. (b) Critical current of a wire with circular cross-section in external field B_a oriented perpendicular to the wire axis.

In the case of a wire in a perpendicular magnetic field, the demagnetization factor is 1/2. Therefore, at the top and the bottom side of the wire, the effective field is $B_\mathrm{eff} = 2B_\mathrm{a}$. A transport current I passing through the wire generates a magnetic field as indicated in Figure 5.1. At the top side of the wire, this field is directed opposite to the applied field. At the bottom side of the wire both fields add to each other. Hence, here one observes the highest total field, $B_\mathrm{ges} = 2B_2 + \mu_0 I/2\pi R$. The critical current is reached in the case $B_\mathrm{ges} = B_\mathrm{cth}$, that is,

$$I_\mathrm{c} = \frac{2\pi R}{\mu_\mathrm{o}} (B_\mathrm{cth} - 2B_\mathrm{a})$$

This dependence is plotted in Figure 5.3b

Next we turn to the question of how the superconductor enters the normal state upon reaching the critical current. For this, we again consider a wire with cir cular cross-section. If the critical current is exceeded, the Meissner phase with its complete flux expulsion must become unstable. One would expect that the superconductor becomes completely normal conducting. However, in this case

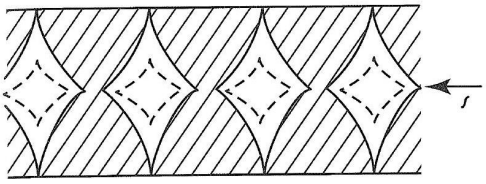

Figure 5.4 Intermediate-state structure of symmetry around the cylinder axis. For a (????) ical current. Hatched domains are normal conducting. The structure shows rotationa

the transport current would be distributed over the total cross-section. The magnetic field at the surface would remain unaffected by this redistribution. However then everywhere in the superconductor the current density would be smaller than its critical value. Since the critical

current density represents the crucial quantity for the stability of the superconducting state, we expect that the transition cannot take place in such a way that the current density is everywhere smaller than the critical value.

'This assumption is confirmed by experiment. If the critical current is exceeded, the superconductor enters the intermediate state, that is, there appear normal conducting domains. Several models have been proposed to describe this intermediate state. In this case, configurations of the normal conducting or superconducting domains are sought that yield the critical field B_{cth} at all interfaces as much as possible. For the macroscopic structure of the intermediate state, this critical field value also yields the critical current density because of the fully developed shielding. A model of this kind is shown in Figure 5.4 [2]. Since the magnetic field of the transport current consists of circular field lines, the phase boundaries must also run perpendicularly to the wire axis. Because of the requirement that for each radius the field must be equal to B_{cth}, the current density must increase toward the wire axis. This is accomplished also by an increase in the thickness of the superconducting domains toward the wire axis.

The geometrical details can only be found from a calculation. In this case certain additional assumptions are necessary. The various models of this current-induced intermediate state are different because of these additional assumptions.

The domain structure of this intermediate state has been demonstrated beautifully by means of the powder decoration method (see Section 4.6.4). An example of this structure is shown in Figure 5.5 [3]. Upon exceeding the critical current density, the superconducting wire jumps into a state where the superconducting domains still extend to the sample surface. Upon a further increase in the current, a normal conducting ring-shaped domain appears, which surrounds a core region resing in the intermediate state, the thickness of which increases with increasing current.

In Figure 5.6 we show the electrical resistance of the wire plotted versus the transport current [2]. At I_{c} the resistance jumps; however, the full normal resistance is not yet established. The latter is obtained only upon a further 290 5 Critical Currents in Type-l and Type-ll Superconductors

increase in I. Such measurements are quite difficult, since in the current-induced intermediate state at finite resistance the dissipated joule heat can easily lead to an increase in temperature and, hence, to instabilities."

Regarding the stability of the intermediate state, a "thick" wire carrying a transport current corresponds to a sample with a demagnetization coefficient different from zero in the external field (see Section 4.6.4). In both cases, by means of the transition into the intermediate state, the superconductor can respond to the constraint of the external variables (current or magnetic field) by splitting up into normal conducting and superconducting domains. In this way, the critical value can be kept constant over a range of external variables.

So far we have treated static models of the intermediate state. For a given state, the superconducting or normal conducting domains remain fixed within the sample, except for thermal fluctuations. Gorter [7] has proposed a dynamic model, according to which domain motion appears in the presence of a transport current, leading to a resistance. In this case, within this model, the interfaces are oriented

For sufficiently small resistance in the external circuit, the voltage-current characteristic can be traversed completely. However, the dissipated joule heat results in an increase in the average temperature. 5.3 Type-ll Superconductors 291

parallel to the direction of the transport current. In the static model discussed earlier (Figure 5.4), they were oriented perpendicular to the current direction. Decoration experiments using Nb powder have shown that for sufficiently large transport current the domains, indeed, move across the superconductor perpendicular to the current [8].

Very complicated intermediate state structures are obtained in wires that carry large transport currents in the presence of a longitudinal magnetic field. In this case, the longitudinal external field and the circular field of the current are superimposed such that the phase boundaries, which must always be oriented parallel to the field, display a screw pattern. Therefore, the transport current is also wound in a screw pattern. In this case, unexpected effects occur. For example, field enhancement is observed in the interior of the sample, which can be understood from the structure of the intermediate state, and which demonstrates impressively the general rule (see Section 4.6.4) that the phase boundaries must always be oriented parallel to the magnetic field [9].

5.3 Type-II Superconductors

Next we turn to type-II superconductors, which differ in an important fundamental way from type-I superconductors. For small magnetic fields and, hence, also for small transport currents, type-II superconductors reside in the Meissner phase. In this phase they behave like type-I superconductors, that is, they expel the magnetic field and the current into a thin surface layer.

A difference from type-I superconductors first appears when the magnetic field at the surface exceeds the value B_{c1}. Then a type-II superconductor must enter the Shubnikov phase, that is, flux lines must penetrate into the superconductor One finds that in the Shubnikov phase the ideal [5] type-II superconductor has a finite electrical resistance even at very small transport currents [10]. In the next section, we will treat this in detail. On the other hand, in type-II superconductors containing a large amount of defects, we can observe very large supercurrents. These "hard superconductors" will be discussed in Section 5.3.2.

5.3.1

Ideal Type-II Superconductor

We consider a rectangular plate carrying a current parallel to the plane of the plate and kept in the Shubnikov phase due to a magnetic field $B_{\mathrm{a}} > B_{\mathrm{c1}}$ oriented perpendicular to the plate (Figure 5.7).

In Section 4.7.1, an ideal type-II superconductor was defined by the fact that reversibly for increasing and decreasing evernal magnetic field In this case the corresponding equilibrium flux-line

configuration must be established arbitrarily easily, that is, arbitrarily easy flux-line motion must be possible. Hence, an ideal homogeneous with respect to the locations of the flux lines. 2925 Critical Currents in Type-l and Type-ll Superconductors

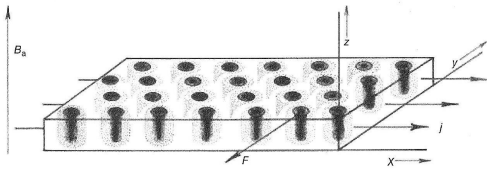

Figure 5.7 Shubnikov phase in the presence of a transport current density j. The flux line experience a force F driving them along the y-direction. The magnetic field distribution around the flux lines is indicated by the shading.

As the first important result of such an experiment, one finds that under these conditions the transport current I is distributed over the total cross-section of the plate, that is, it is no longer completely restricted to a thin surface layer. After the penetration of the magnetic flux into the superconducting sample, the transport current can also flow within the interior of the superconductor

In this case there exists an important interaction between the transport current and the vortices. The transport current, say, along the x-direction, also passes through the vortices, that is, through regions where a magnetic field exists.) Between an electric current and a magnetic field, there exists the Lorentz force. In the case of a current I along a wire of length L in a perpendicular magnetic field B_2, the absolute magnitude of this force is

$F = ILB$

This force is oriented perpendicular to B and to the current (here given by the wire axis). It is also this Lorentz force that drives our electric motors.

the Shubnikov phase carrying a transport current, the Lorentz force acts between the vortices and the current. Since the transport current is spatially fixed by the boundaries of the plate, under the influence of the Lorentz force the vortices must move perpendicular to the current direction and to the magnetic field, that is, perpendicular to their own axis [11]. For ideal type-II superconductors, in which free motion of the vortices is possible, this vortex motion should appear already at arbitrarily small forces and, hence, at arbitrarily small transport currents.

However, the vortex motion across the superconductor causes dissipation, that is, electrical energy is changed into heat. This energy can only be taken from the

In the illustration of the Shubnikov phase, for simplicity cylindrical vortices are presented (see, e.g., Figures 1.8 and 5.7). This picture could lead to the wrong conclusion that the by flowing around them, and thereby also avoids the magnetic field regions. However in this case, because of the vortex motion, we are dealing with a complicated nonequilibrium phenomenon, and a more detailed discussion can be found in monograph [M17].

transport current by means of an electrical voltage appearing along the sample. Hence, the sample shows electrical resistance.

The dissipation of electrical energy into heat during vortex motion may be due to two fundamentally different processes. The first loss mechanism is associated with the appearance of local electric fields generated by the moving vortices. This electric field also accelerates the unpaired electrons. They can deliver their energy taken up from the electric field to the lattice and thereby generate heat.

In addition to this process for energy dissipation, associated with the spatial variation of the magnetic field in a vortex, there exists another process caused by the spatial variation of

the Cooper pair density in a vortex. If a vortex moves across the location P a temporal change of the Cooper pair density n_s also appears at this location, since n_s increases from its value zero in the vortex center toward the outside. In this case we must take into account that, following a deviation from equilibrium, this equilibrium value of n_n is re-established only after a finite time τ (the relaxation time, see Section 4.9). If n_s changes very slowly, that is, within times much larger than τ, the system only passes through equilibrium states. In his case the energy consumed at the front side of the vortex during breaking up of Cooper pairs will be delivered back at the back side during pair formation. Therefore, practically no net heat is generated in this process. However, if the vortex moves sufficiently fast, such that the Cooper pair density cannot pass only through equilibrium states anymore, energy will be dissipated during the temporal change of n_s, and heat will be generated.

We can understand this in the following way. The high magnetic field within the vortex core moves sufficiently fast that the equilibrium concentration of Cooper vortex core moves sufficiently fast that the equilibrium concentration of Cooper pairs corresponding to each field value cannot be established anymore. In this case, at the front side of the vortex, the Cooper pairs are broken up in a magnetic field that is too high. On the other hand, at the back side the Cooper pairs recombine in a field that is already too small for the corresponding concentration. Since the heat of reaction of the breaking of a Cooper pair decreases with increasing magnetic field," during the break-up process less heat energy is consumed than is delivered back during the recombination. Therefore, heat will be generated, if the temporal variation of n_s is made fast enough such that deviations from equilibrium appear between all parameters.

What we just have described for the example of the Cooper pair density is exactly the mechanism of all relaxation processes for changes of external parameters during times comparable to the relaxation time. Other well-known examples are the polarization losses of a dielectric substance in an alternating electric field or the magnetization losses of a ferromagnetic material in an alternating magnetic field.

So we summarize: As soon as the vortices in the Shubnikov phase start to move due to a transport current, we have losses and, hence, electrical resistance.

In the Shubnikoy phase, with increasing magnetic field, the Cooper pair density and, hence, the binding energy decrease. 2945 Critical Currents in Type-I and Type-ll Superconductors

Since in an ideal type-II superconductor arbitrarily small transport currents already lead to vortex motion, the critical current of such a superconductor in the Shubnikov phase is zero [10]. Therefore, such superconductors are useless for technical applications, say, for building magnets, in spite of their high critical field B_{c2}. Finite critical currents in the Shubnikov phase can only be obtained if the vortices in some way are bound to their locations. Such pinning of the vortices can, indeed, be achieved. Type-II superconductors containing such pinning centers are referred to as hard superconductors. Their properties will be discussed in the next section.

So far in our discussions of the critical current in type-II superconductors, we have stabilized the Shubnikov phase by means of an external magnetic field. Now we return to the question of the critical current in the absence of an external magnetic field, with which we had started. Again, we assume a wire with circular cross-section carrying the transport current I. Upon exceeding the value $I_c = B_{c1} 2\pi R/\mu_0$, which generates just the field B_{c1} at the surface, the superconductor enters the Shubnikov phase. Since the magnetic field of the transport current circulates around the wire axis, in this geometry circular closed vortices are also generated. Under the influence of the Lorentz force they move toward the wire axis by shrinking and vanish at the axis. So for an ideal type-II superconductor with this geometry, we expect a critical current I_c determined from B_{c1} in the same way as for a type-I superconductor from B_{cth} (see Section 5.2). Since B_{c1} is smaller than B_{cth}, in ideal type-II superconductors this critical current will always be smaller than in the corresponding type-I superconductors.

For a long time, there has been an animated discussion on the role of vortex motion in the

generation of electrical voltage. Within this context many experiments were contemplated and carried out. Here, we want to treat only one example.

In 1996 Giaever [12] performed an experiment, the idea of which is illustrated with the configuration shown in Figure 5.8. A thin film of a superconductor (A) is driven into the Shubnikov phase by means of an external magnetic field, and a transport current is applied. In this case, motion of the flux lines should occur. In order to detect this flux motion, on top of film A Giaever deposited a second superconducting film B, which was electrically insulated from film A by means of a thin insulating layer. In this configuration the magnetic flux lines in both films are coupled to each other.9) If the vortices move across the superconductor A under the influence of the transport current, the vortices in B are dragged along because of the coupling. If, as felt by Giaever, an electrical voltage appears between the ends of the superconductor because of the vortex motion, this voltage must also be observed along the film B, which is completely separated from the primary circuit. Therefore, the arrangement represents some kind of "flux transformer,"

Here, "corresponding" means that the superconductors have the same geometry and the same $B_{\text{cht.}}$.

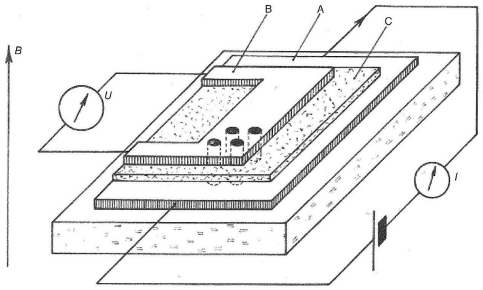

Figure 5.8 Generation of an electrical voltage U during vortex motion. A and B are superconductors, C is an insulating layer. All layer thicknesses are strongly exaggerated. (From [12].)

Giaever performed the experiment in the absence of an external magnetic field. Also in this case, the magnetic field of the transport current applied to film A penetrates into both films in the form of flux lines. These flux lines have opposite sign at the left and the right sides of the film, respectively, and they move from both sides of the film A to the center, where they annihilate each other. This vortex motion resulted in the expected voltage also along the electrically completely separated film B. If both films were normal conducting, no electrical voltage was observed along film B for the same conditions otherwise. This experiment clearly demonstrated the importance of vortex motion for the appearance of an electrical voltage in the Shubnikov phase.

Recently, the geometry of the flux transformer has been taken up again in order to investigate if in high-temperature superconductors the vortices can move independently of each other in the form of pancakes (see Section 4.7.2) [13]. For this purpose, at one side, for example, of a $Bi_2Sr_2CaCu_2O_8$ single crystal a transport current is injected parallel to the layer structure, and the voltage drop is measured resulting from the vortex motion. If the vortices represent compact, continuous flux lines across the crystal, at the opposite crystal surface a voltage of equal magnitude will be induced. However, if the pancakes move independently of each other, this secondary voltage will be smaller than the primary voltage. In this way, the existence of pancake vortices in $Bi_2Sr_2CaCu_2O_8$ could be beautifully demonstrated. On the other hand, it turned out that the vortices in $YBa_2Cu_3O_7$ behave more like compact, continuous flux lines. 296 F critical Currents in Type-I and Type-ll Superconductors

5.3.2

Hard Superconductors

In Section 4.7.1 we have discussed the magnetization curves of type-II superconductors (Figure 4.23). We started with ideal, homogeneous substances, that is, substances in which the vortices of the Shubnikov phase are freely mobile, having no energetically favorable locations. This discussion only represents a limiting case, which is approximated only more or less poorly by real samples.

In this section we will discuss the case in which the vortices of the Shubnikov phase are energetically strongly bound to favorable locations. These superconductors are referred to as hard superconductors and represent technically useful materials.

4.1.3 Critical supercurrent: advanced features 2

Pinning of Flux Lines

First we want to discuss how vortices in type-II superconductors can be pinned. We will deal with a series of different types of pinning centers.

In the simplest way we can understand the effect of pinning centers by means of an energy consideration. The formation of a vortex requires a certain amount of energy. This energy is contained, say, in the circulating currents flowing around the vortex core. We see that for the given conditions a vortex is associated with a the vortex core. We see that for the given conditions a vortex is associated with a certain amount of energy per unit length, that is, the longer the flux line, the larger the energy needed for its generation.

We denote this energy by ε^*. It can be estimated from the lower critical field B_{c1} above which magnetic flux starts to penetrate into a type-II superconductor. The resulting gain in expulsion energy suffices to generate vortices in the interior. For simplicity, we consider again a long cylinder in a magnetic field parallel to its axis, that is, a geometry with zero demagnetization coefficient. At B_{c1} the penetration of the magnetic flux results in n flux lines per unit area. Each flux line carries just one flux quantum Φ_0. This requires the energy

$$\Delta E_F = n\varepsilon^* LF$$

where n = number of flux lines per unit area, ε^* = energy per unit length of vortex, L = sample length, and F = sample cross-section. The gain in magnetic expulsion energy is

$$\Delta E_M = B_{c1}\Delta MV$$

where $\triangle M$ = change of the magnetization of the sample and $V = LF$ = sample volume. ΔM can be expressed in terms of the penetrated flux quanta. We have

$$\Delta M = n\Phi_0/\mu_0$$

This yields for the gain in expulsion energy

$$\Delta E_M = \frac{1}{\mu_0} B_{c1} n\Phi_0 LF$$

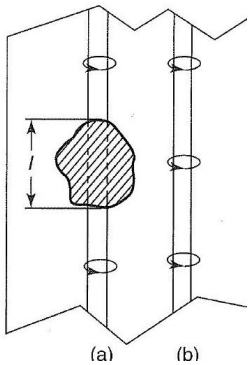

Figure 5.9 Pinning effect of normal conducting precipshorter compared to that in location " b," since there are no circulating currents in the normal conducting region.

If the two energy changes are being set equal ($\Delta E_{\mathrm{F}} = \Delta E_{\mathrm{M}}$), from the definition of B_{c1} we obtain

$n\varepsilon^* LF = \frac{1}{\mu_0} B_{\mathrm{c1}} n \Phi_0 LF$

and hence [10)]

$$\varepsilon^* = \frac{1}{\mu_0} B_{c1} \Phi_0$$

In the case of the estimate given above, we have considered only the fieldexpulsion energy. However, the loss of condensation energy on the scale of the coherence length also affects the value of ε^*. From our knowledge of the vortex energy ε^*, we can easily understand the pinning effect of normal precipitates. If a vortex can pass through a normal conducting inclusion, its length within the superconducting phase and thereby its energy are reduced. This is schematically indicated in Figure 5.9. The hatched region indicates the normal inclusion. A vortex in location "a" has an energy smaller by the amount $\varepsilon^* l$ compared to one in location "b." This means that we must supply the energy $\varepsilon^* l$ to the vortex in order to move it from "a" to "b." Hence, a force is needed to effect this change in location.

If there are many pinning centers, the vortices will attempt to occupy the energetically most favorable locations. As shown in Figure 5.10, they will also bend in order to reach the minimum value of the total energy. The length increment caused by the bending must be overcompensated by the effective shortening within the

The energy per unit length, $\varepsilon^{\|\prime}$, can also be currents (see, e.g, [M8], Chapter 3, p. 57). One obtains the expression

$\varepsilon^* = \frac{1}{\mu_0} \left(\Phi/\lambda_{\mathrm{L}}\right)^2 \ln\left(\lambda_{\mathrm{L}}/\xi_{\mathrm{GL}}\right)$

We see that the energy $\varepsilon^\star$ increases proportional to the square of the magnetic flux Φ in a vortex. Therefore, vortices containing more than one flux quantum Φ_0 are energetically unfavorable In a type-II superconductor or in hard superconductors, such vortices can only exist if they are strongly promoted by other conditions such as inhomogeneities in the material.
298 5 Critical Currents in Type-l and Type-ll superconductors

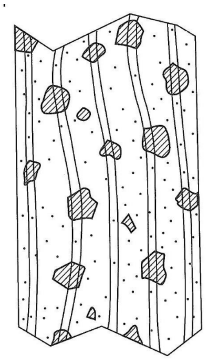

Figure 5.10 Vortex configuration in a hard superconductor. The hatched regions represent pinning centers. The dots indicate atomic defects.

normal conducting regions. In a vortex lattice as it is generated in the Shubnikov phase, we must take into account in the total energy balance also the repulsive forces acting between the flux lines.

(We must note, however, that often the details are difficult, and that a complete account of the effects of all pinning centers is impossible)

In principle, other pinning centers, say, lattice defects, can also be understood in the same way..1) Every inhomogeneity of the material that is less favorable for superconductivity acts as a pinning center, with the completely normal state representing the limiting case. For example, superconducting precipitates, however, with a lower transition temperature, in general act as pinning centers.

If for a certain material the superconductivity is associated with an expansion of If for a certain material the superconductivity is associated with an expansion of less favorable for superconductivity and, hence, will act as pinning centers. This may be the case within grain boundaries and dislocation configurations, as they are generated during plastic deformation.

Atomic defects within the crystal lattice represent a particular issue with respect Atomic defects within the crystal lattice represent a particular issue with respect to the coherence length ξ_{GL}, which amounts to many lattice constants in many superconductors. Hence, one could expect that atomic defects are not effective pinning centers. However, it could be shown that the scattering of electrons at atomic defects leads to an appreciable pinning effect [14]. On the other hand, since each flux line usually covers many atomic defects, in the case of a homogeneous distribution of the atomic defects the effective pinning force vanishes, since no particular location within the material is distinguished. Such distinction only appears if the density of the atomic defects varies spatially.

In the case of superconductors with an extremely small value of the coherence length as, for example, the cuprates, the situation is completely different. Here, spatially very small defects can act as pinning centers in different ways.22)

In the extreme case, even the crystal structure itself can have an effect. In Section 4.7.2 we have already discussed that, in the case of the cuprates, in magnetic fields oriented parallel to the superconducting CuO_2 planes, there develop Josephson vortices with their axis being located in the nonsuperconducting or only weakly superconducting intermediate layers. These intermediate layers represent highly effective pinning centers against vortex motion perpendicular to the planes. One speaks of “intrinsic pinning” [15] On the other hand, the vortices can still move easily parallel to the layer structure.

In a similar way grain boundaries or twin boundaries between single-crystalline regions act as defects, preventing vortex motion perpendicular to these defects. [13] Line defects and point defects are also important. Dislocation lines represent a example. Line defects and point defects were also artificially generated by irradiating high-temperature superconductors with high-energy heavy ions or also with protons [16]. During irradiation with heavy ions, along the path of the beam particles there appears a straight, highly perturbed region across the crystal, which is referred to as a columnar defect. On the other hand, irradiation with protons results in accumulations of point defects.

For the generation of well-controlled pinning centers, the continuously improved techniques of nanotechnology are applied. A summary can be found in [17]. During the deposition of thin films one can incorporate nanoparticles into the superconducting matrix. Equally distributed "round" nanoparticles consisting, for example, of Y_2O_3, result in a nearly isotropic pinning of flux lines. On the other hand, in the case of rod-like structures, a preferential direction is obtained. As an example we mention $BaZrO_3$ nanorods, which grow on the film during its deposition by means of pulsed laser ablation [18]. In the case of pulsed laser deposition by means of pulsed $YBa_2Cu_3O_7$ thin film, in an oxygen atmosphere of about 0.3mbar, highly intensive laser pulses are directed onto a "target" made of massive $YBa_2Cu_3O_7$. The ablated

material condenses on a single-crystalline $SrTiO_3$ substrate such that the CuO_2 planes of the cuprate are oriented parallel to the surface of the substrate. In order to incorporate $BaZrO_3$ nanorods in addition, one uses a target containing some $BaZrO_3$ in addition to

Furthermore, the vortices can form not only more or less crystalline lattices, but also liquid and even gaseous phases (see Section 4.7.2). In the later phases the

13) However, we do not want to suggest that centers. In high-temperature superconductors, for not too small tilting angles between two grains, the grain pinning forces, and, hence, the critical current I_c are small, Frequently, above I_c the electric resistance increases grad boundaries act as Josephson junctions, even in the absence of an external magnetic field. In a magnetic field this supercurrent is strongly reduced further. 300 5 Critical Currents in Type-l and Type-ll Superconductors

$YBa_2Cu_3O_7$. If this mixture is deposited, in addition to the $YBa_2Cu_3O_7$ matrix, also $BaZrO_3$ rods of about 10 nm diameter grow on the substrate, which penetrate the total thickness of the film and act as rod-shaped pinning centers.

In thin films of metallic superconductors and also in the cuprates, one can fabricate "defects" in a well-controlled way in the form of microholes within the material. In this case one often speaks of "antidots" [19]. Also the opposite of the antidots, magnetic particles placed on the film surface ("magnetic dots"), have been studied [20]

Another "defect" we want to mention is the surface of the superconductor itself. If the external magnetic field is increased (decreased), vortices enter (exit) the sample at the edge. This process is already prevented by the flow of the shielding currents, and the vortices must traverse a surface barrier. This is also referred to as the Bean-Livingston barrier [21]

The effect of the pinning centers can also be described in terms of an energy landscape. Now the pinning center represents a potential well of depth E_p. The vortex is located at its most favorable position, similar to a ball at the lowest point of a bowl. If the ball is to be displaced from this location, one needs a force in order to supply the increase of the potential energy. To remove the ball from its most favorable location, we must supply the energy needed to lift the ball out of the bowl. Usually, in a material there are many pinning centers, which are irregularly distributed and have different energy depths E_p. If the superconductor is cooled below T_c in a magnetic field, the vortices will quickly occupy the potential wells, instead of generating a regular triangular lattice. At best, we have a distorted lattice, or in the extreme case even a glassy state [22].

The deviation of an individual vortex from its ideal location within the triangular vortex lattice depends on the depth of the potential wells, and also on the configuration of all other vortices, because of the repulsive interaction between them. An energetically highly unfavorable arrangement of the vortices will be changed quickly because of the thermal fluctuations. These fluctuations can provide the energy difference ΔE needed to leave the potential well, with a probability $w = \exp(-\Delta E/k_B T)$. In this case, the thermodynamic fluctuations can reduce the depth of the potential well, or they can supply the missing energy to the vortex. At low temperatures and for large values of ΔE, this probability can become very small, such that the state with the lowest energy cannot be occupied any more. Furthermore, because of the interaction between the vortices, ΔE can approach infinity. In this case we are dealing with the state of a vortex glass, which experiences no changes anymore within finite times.

A special effect occurs if two pinning centers are located very close to each other. In this case a vortex can jump very easily back and forth between the two potential wells because of thermal fluctuations. This effect is highly important in the context of superconducting quantum interferometers (SQUIDs) made from high-temperature superconductors. The magnetic field of a flux quantum located within the superconducting material of the SQUID is recorded as a measuring signal by the SQUID. If this flux quantum moves, then this (unwanted) signal changes

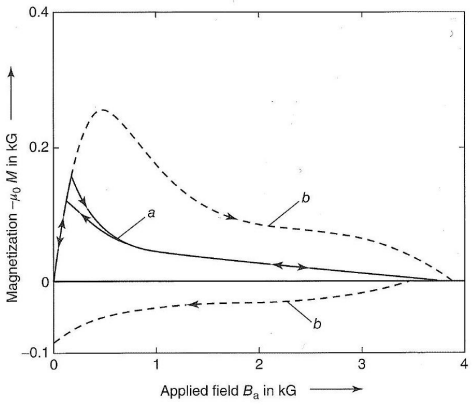

Figure 5.11 Magnetization curves of a Nb_{55} T_{45} alloy: curve a, well annealed; curve b, with many lattice defects (1kG = 0.1 T),from [23])

and causes a reduction of the SQUID sensitivity for real measuring signals..[14)] Therefore, the investigation of such pinning centers and the development of most effective and strong pinning centers are highly important.

What is the effect of the pinning centers if in the superconducting state the magnetic field is changed or a transport current is applied to the superconductor? These questions will be discussed in the next two sections. We start with the magnetization curves of hard superconductors.

Magnetization Curve of Hard Superconductors

If in the Shubnikov phase the vortices are attached to certain locations within the material, then in an external field the magnetization corresponding to thermodynamic equilibrium cannot establish itself. The prerequisite for this is the free mobility of the vortices. Hence, we have to expect quite different magnetization curves. Furthermore, it represents an important difference, whether the superconductor is cooled in a field B_a, or this field is applied only after the superconducting state is established. First, we treat the properties of massive metallic superconductors, and then we turn to the high-temperature superconductors and to special thin-film structures, in which pinning centers were artificially generated.

In Figure 5.11 as an example we show the behavior of a Nb-Ta alloy [23]. Niobium and tantalum can be mixed in any ratio. After careful annealing one obtains 14) This effect is to be compared with Figure 1.10e. In this case, the displacement of flux quanta by means of an electron beam was specifically utilized for the imaging of vortices. 302 5 Critical Currents in Type-I and Type-II Superconductors

highly homogeneous mixed crystals. They yield a nearly reversible magnetization curve (curve a). After deformation of such a mixed crystal, say, by pulling for the fabrication of wires, many lattice defects exist within the crystal, acting as pinning centers for vortices. In this case the magnetization curve is completely different (curve b). First we note that a much higher magnetization is reached. This also means that in external fields much higher than B the deformed sample can still display nearly perfect diamagnetic shielding. Furthermore, any trace of reversibility has disappeared. For decreasing field, magnetic flux remains trapped in the sample also at $B_2 = 0$. In this case the trapped flux is oriented parallel to the previously applied external field.

Only the upper critical field B_{c_2} remains unchanged. This can be understood from the fact that a mixed crystal of the alloy $Nb_{55}Ta_{45}$ already has a very small mean free path l^*. Hence, the additional defects can hardly change κ and also B_{c2} (see Section 4.7.1) any more. If we assume that the vortices are more or less strongly pinned within the deformed material, we can easily understand this magnetization curve qualitatively. We look at the curve starting at field

zero. Up to the external field B_{c1} there is no difference. The sample resides in the Meissner phase, which is hardly influenced by perturbations..[15)]

If B_{c1} is exceeded, vortices enter the sample at the surface. At first, these vortices are attached to their locations immediately below the surface, and they cannot distribute themselves equally over the volume as in a homogeneous material. However, within the surface layer, where the pinned vortices are, shielding current can also flow. As a result, the total shielding current, determining the diamagnetic behavior, extends further into the superconductor than in the Meissner phase where it is restricted only to a layer with the thickness of the penetration depth. As a result, the shielding current and, hence, the diamagnetic signal in the vortex state can exceed those in the Meissner phase.

At B_{c2} the Cooper pair density is zero, and the superconductivity disappears. [10] The magnetic field homogeneously penetrates the superconductor. If the externa field is decreased below B_{c2}, the sample again enters the Shubnikov phase. Again the magnetic flux is divided into multiples of the flux quantum Φ_0, and the vortices are more or less strongly pinned to the perturbations in the crystal lattice. Hence, with decreasing external field they can leave the material only with difficulty. The field within the sample then becomes larger than the external field, and the magnetization of the sample becomes positive. Even at $B_a = 0$ there remains a finite magnetic flux along the field direction trapped within the sample. 15) Here, we ignore the small influence of the perturbation on the penetration depth λ_1. 16) Here, we do not include the surface superconductivity in a thin layer near the surface, which can exist in parallel fields up to $B_a = 1.7B_{c2}$

We note that this irreversible behavior was observed already in very early experimen isistercefic alloys [24]. At the nerise Therefore, a frest attempt at explaining tie hysteretic magnetization curves was based on the assumption of a sponge-like

As a second example, in Figure 5.12 we show the magnetization curve of a lead-bismuth alloy containing 53at%Bi [26]. At low fields-we see abrupt changes of the magnetization, which are due to so-called flux jumps. In this case large flux-line bundles or regions of the vortex lattice tear off the pinning sites and thereby result in a jump of the magnetization toward thermodynamic equilibrium. In superconducting magnets such flux jumps are very dangerous, since, because of the generated heat energy, the superconductor can become normal conducting over its whole cross-section (see Section 7.1.2) and the magnetic field can break down

Flux jumps can look spectacular and can develop into avalanches. In Figure 5.13 we show an example in the case of an MgB_2 thin film [27]. The image was obtained by magneto-optics (see Figure 1.10b). The branching bright regions represent the locations where magnetic flux has penetrated into the sample. This is also referred to as dendritic flux avalanches.

In high-temperature superconductors the situation is still more complicated, since a number of different vortex phases can exist even in the absence of pinning centers, as we have discussed in Section 4.7.2 (see Figures 4.33-4.38). The pinning centers act differently in the different phases. Different glassy states can develop, like the amorphous vortex glass [28] or the "Bragg glass" [29]. In the latter case, at small distances the vortices are somewhat disordered. However, at large distances the vortices again approach a vortex lattice because of the interactions between them. Another example is the "Bose glass" appearing in the presence of columna defects along a certain direction [30]. This is illustrated in Figure 5.14 based on a phase diagram calculated for cuprates in magnetic fields oriented perpendicular to the layer structure [31]. Here the vortices were treated as continuous lines, that is, additional degrees of freedom due to the pancake vortices were ignored

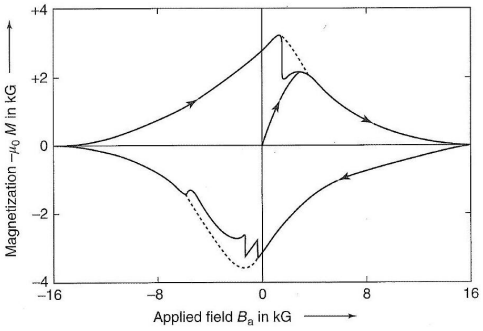

Figure 5.12 Complete magnetization cycle of a Pb-Bi alloy (53at% Bi). The dashed curve is expected if there are no flux jumps (1kG = 0.1 T).(from [26]

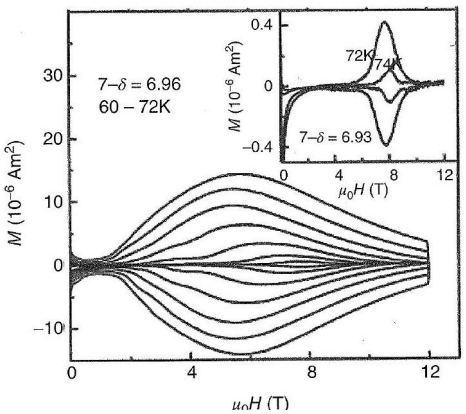
In the magnetization curve, the transition between two vortex phases sometimes shows up as a maximum, which is also referred to as a second peak or as a fishtail. This is shown in Figure 5.15 based on a measurement for a $YBa_2Cu_3O_{7-\delta}$ 5.3 Type-ll Superconductors | 305



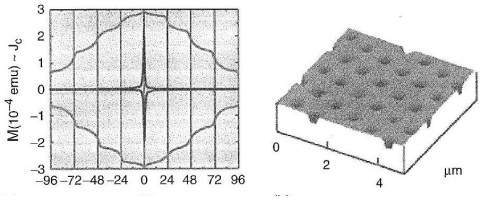


Figure 5.15 Magnetization curve of a $YBa_2Cu_3O_{7-\delta}$ single crystal at temperatures between 60 and 72 K. At fields above 4 T, we note a second peak [32].

single crystal [32]. This effect can also be well observed in $Bi_2Sr_2CaCu_2O_8$ [33]. During the transition between the Bragg glass and the vortex glass observed here, the elastic constants of the vortex ensemble decrease, so that the vortices can adjust themselves better to the pinning centers in the material.

As a last example of the interaction between vortices and pinning centers, in Figure 5.16 we show the magnetization curve of a PbGe film, in which microholes (antidots) with a separation of 1μm were fabricated [34]. If a magnetic field is applied to this film, there are certain field values at which the number of vortices

(a)

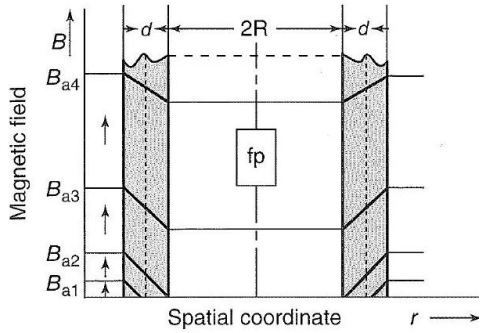
vortices is an integer multiple of the number 306 5 critical Currents in Type-I and Type-ll Superconductors

in the film is an integer multiple of the number of antidots. At these matching fields the vortices are distributed regularly onto the antidots. It is also possible that more than one vortex can be trapped within one antidot. In Figure 5.15 in the diagram on the left the matching-field values are indicated by vertical lines. At the matching fields the vortex lattice is particularly strongly pinned. [18] For comparison, Figure 5.15 also shows the magnetization curve of a PbGe film without antidots. In this case the magnetization curve strongly decreases already at small fields



The possibility of fabricating pinning centers in thin films allows the investigation of specific models of the interaction between vortices and pinning centers. This is interesting for both the fundamental physics and technical applications. For example, in SQUID magnetometers, antidots can be placed strategically in such a way that the perturbing signals due to the vortex motion are minimized [35].

Next we want to discuss the origin of the hysteresis in the magnetization curve more quantitatively and look at the connection between the magnetization and the maximum possible supercurrent in the sample. Frequently, the direct measurement of the maximum supercurrent is difficult, since currents of 100 A or higher must be measured. Hence, it is advantageous to have a procedure for measuring the critical current without electrical contacts. This method turns out to be particularly important for the study of sintered materials, which mostly are not available in the form of wires or sheets and, hence, cannot be investigated with the standard methods.

In this context Bean [36] has proposed a model, which we want to discuss in the following in a slightly simplified version. We consider a simple geometry, namely a long, hollow cylinder (length L, diameter $2R$, wall thickness $d \ll 2R$). If a circulating current I flows within this cylinder, it generates a magnetic field $B_\mathrm{i} = \mu_0 I/L$, which can also be written in terms of the average current density $j = I/(Ld)$ as $B_\mathrm{i} = \mu_j j$ j

The cylinder is assumed to be cooled in zero applied magnetic field. Upon the application of the field B_a parallel to the cylinder axis, at the outside of the superconducting cylinder a circulating current is generated shielding the interior of the cylinder (Figure 5.17). As long as the hard superconductor resides in the Meissne phase, the shielding current only flows within the penetration depth near the surface of the cylinder. If B_2 exceeds the value B_{c1}, which we can assume to be ver small, magnetic flux can penetrate into the superconductor in the form of vortices. Initially, the vortices are trapped by the pinning centers below the surface. In this case, the Bean model simply assumes that the critical transport current within the region of the superconductor penetrated by the vortices just has the homogeneous critical current density j_c. For simplicity, this current density is taken as constant, that is, it is assumed to be independent of the magnetic field in the superconductor. This state carrying the critical current density is referred to as the critical state.

A similar but weaker effect also appears for rational values of the ratio: (number of antidots)/(number of vortices). 5.3 Type-ll Superconductors | 307

(a)

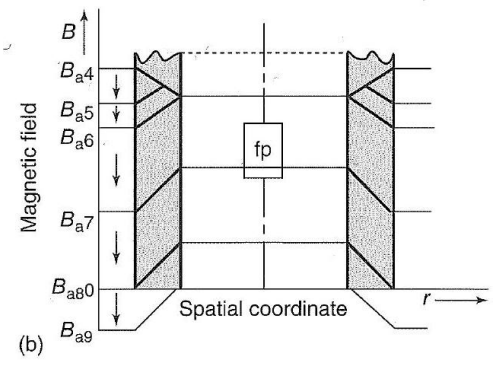


Figure 5.17 Magnetic field distribution in a hollow cylinder of a hard superconductor for increasing B is indicated by a less steep field slope [36]. f = field probe.

If the field B_a is increased further beyond the value B_{c1}, a thicker and thicker layer below the cylinder surface is filled with vortices. The total shielding current increases proportional to the thickness of this layer which, according to our assumption, carries the constant current density j_i[19] The critical state grows into the superconductor. Because of the shielding current, the magnetic field within the superconductor decreases toward the cylinder axis. If the radius R is large compared to the thickness d of the cylinder wall, we can well approximate the latter in terms of a planar layer. In this case, the magnetic field decreases linearly toward the axis. [20)] In Figure 5.17a this field variation is indicated for different values of the external field. At B_{21} only part of the cylinder wall is filled with vortices (dashed lines, part a). At B_{22} the shielding current has reached its maximum value, since now the current density j_c flows homogeneously in the whole cylinder wall. However, in the interior of the cylinder, the field B_i still remains zero. Only during a further increase in B_a does a magnetic field also appear in the interior. In our simple model this field is equal to $B_a - B_{22}$ (with $B_a > B_{22}$)

Of course, for large fields our assumption j_C = constant cannot be valid anymore, since j_c must approach zero for $B_a \to B_{c2}$. So we must improve our model by requiring that j_c decreases with increasing B_2. In this case with increasing field B_a, the difference $B_2 - B_i$ gradually approaches zero.

In Figure 5.18 the field B_i in the interior of the cylinder is plotted versus the external field B_a for a $V_3(Ga_{0.54}Al_{0.46})$ sample (high-field superconductor). Up to the value B_{22} the field B_i remains zero. In this case, with j_c = constant, we would always have $B_i = B_a - B_{a2}$ (dashed line). However, since j_c decreases with increasing field, the curve $B_i(B_2)$ more and more approaches the straight line $B_i = B_a$. From the behavior of $B_i(B_a)$, or from the magnetization curve 19) If the thickness of the cylinder wall is very small compared to the radius R, we can ignore the vari20) Wion of r within the wall thickness. Within the superconductor, because

netic field In our discussion of the model, the field in the, we have a spatial varia tion

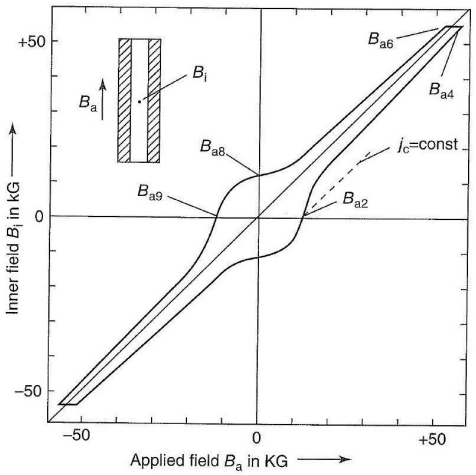

Figure 5.18 Magnetic shielding of a hollow cylinder made from $V_3(Ga_{0.54}Al_{0.46})$. Inner field B_i plotted versus the external field B_a(1kG = 0.1 T). Measuring temperature: 4.2 K; transition temperature: 12.2 K. (By courtesy of DrH. Voigt, Siemens.)

$M(B_2) = (B_i - B_a)/\mu_0$, within our model (which assumes the existence of a critical state) we can determine the critical current density of the material investigated Frequently, this elegant method is applied in the study of novel superconductors. In the case of a long hollow cylinder, one obtains

$$|M(B_a)| = j_c(B_a)\, d$$

where d is the wall thickness of the hollow cylinder. Analogously, for a solid cylinder with diameter $2R$ one finds the magnetization $|M| = j_c R/3$ (from, e.g., [M4]).

We want to also discuss the case where the external field is lowered starting say, from B_{24}. Now, because of the negative field change ($\Delta B < 0$), an induction process takes place, which slows down the shielding current flowing at the outer part of the cylinder and generates a critical current in the opposite direction. In igure 5.17 b the magnetic field variation is indicated for a few sequential values B_{a5} up to B_{a7}. Again a critical state exists in the whole cylinder. However, now the ortex density increases toward the interior. In this case the vortices appear to exit om the outer cylinder wall. Up to the value B_{26} the field B_1 remains constant. Then B_i decreases. At $B_a = 0$ a certain magnetic flux and, hence, a field B_i is trapped. The corresponding points are indicated in Figure 5.18.

If in the next step we increase the external field in the opposite direction, then at $-B_{29} = B_{a2}$ we just obtain the field $B_i = 0$. This can clearly be seen from Figure 5.17b. In Figure 5.18 we show the corresponding variation of B_i together with the complete hysteresis loop traversed in such an experiment. In many hard superconductors, this dependence is well described by the expression [37]

$$j_c = \frac{\alpha_c}{B + B_0}$$

Here, the constants α_c and B_0 are characteristic for the particular material. In samples with a more complicated shape, for example, in thin films or irreguarly shaped crystals, and also in materials with an inhomogeneous structure, the enetration of magnetic flux can occur in a highly complicated way. However, in this case techniques such as magneto-optics provide the possibility to measure the spatially resolved magnetization and to derive from this the supercurrent density in the material. Here, we do not want to discuss the details and, instead, refer to the review articles [38, 39].

If, like during the measurement of the magnetization curve, the magnetic field B_2 is changed, within a hard superconductor an inhomogeneous distribution of vortices develops, which by no means corresponds to thermodynamic equilibrium. Now we want to investigate what happens if the magnetic field is raised to a certain value and then is kept constant at this value. In this case we will deal with the phenomenon of flux creep.

In the critical state all locations at which magnetic flux has penetrated into the sample carry the critical current density j_c, which in turn acts with the Lorentz force on the vortices. If the applied field is kept at the value B, the Lorentz force is exactly compensated by the force originating from the pinning centers. Therefore, without thermal fluctuations, the vortex distribution would remain unchanged. However, because of thermal fluctuations, the energy needed to leave a pinning site can be supplied to a vortex. In this case, under the influence of the Lorentz force, the vortex will move a short distance until it is trapped again at another pinning center. Eventually, all vortices will move in this way, such that the magnetization gradually decreases and a state with lower energy is established. During this process the supercurrent density quickly falls below its critical value. This thermally activated vortex motion is referred to as flux creep.

If the supercurrent density is not too close to the critical current density, the velocity of the vortex motion will be proportional to $\exp(-\Delta E/k_B T)$. In general, one can show that the temporal change is then given by $\mathrm{d}j/\mathrm{d}t = -j_c \exp(-\Delta E/k_B T)/t_0$. Here, t_0 denotes a characteristic time constant that depends on the material parameters. However, the height ΔE of the energy barrier in turn depends on the supercurrent density. It must vanish when the critical current is reached, since in this case the vortices are torn off from the pinning centers. Near the critical state this behavior can be expressed by the relation

$$\Delta E\,(j \to j_c) \approx E_c\,(1 - j/j_c)^{\alpha}$$

with a certain exponent α. In the case $\alpha = 1$, this just leads to a reduction of the supercurrent density or of the magnetization, which is logarithmic initially:

$$|M(t)| \propto j(t) \approx j_c \left[1 - \frac{k_B T}{E_c} \ln(1 + t/t_0)\right]$$

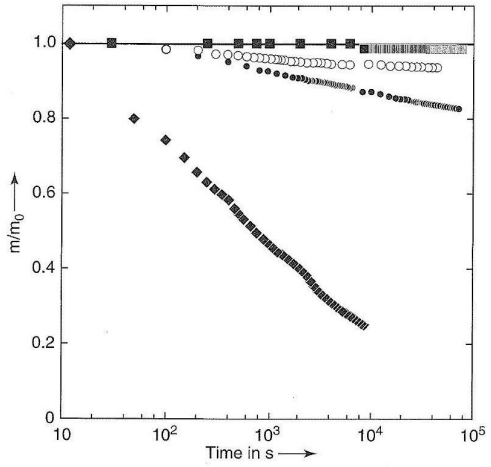

Figure 5.19 Temporal decay of the mag- were turned on [40]. □NbTi at 4.2 K; O, netization of different superconductors. The $YBa_2Cu_3O_7$ with oriented grains at 77 K; magnetization is normalized to its value

In Figure 5.19 we show the temporal decay of the magnetization of some superconductors [40]. This decay occurs by means of flux creep. In NbTi, a classical superconductor, at about 4.2 K, that is, at about $T_c/2$, within more than 10^5 s (slightly more than 1 day) hardly any change is observed. On the other hand, in $YBa_2Cu_3O_7$ the supercurrents clearly decrease, particularly in the single-crystalline sample. The data shown here are from the year 1990, that is, from the early period of high-temperature superconductivity. In the meantime, also $YBa_2Cu_3O_7$ samples have been prepared in such a way that well above 15 T they can trap magnetic fields for a long time. We will discuss this subject in more detail in Section 7.2.

In the high-temperature superconductors, we must note that the different vortex phases can behave much differently. In particular, in the region of the vortex liquid one observes no or at most only a weak pinning force. In this case the magnetization curves are reversible. Therefore, the phase boundary line at the transition between the vortex liquid and the crystalline or glass-like vortex phases is referred to as the irreversibility line.

Critical Currents and Current-Voltage Characteristics

Next we want to discuss the effect of the pinning centers during current transport in superconducting wires or thin films. In Section 5.3.1 we saw that an ideal type-II superconductor in the Shubnikov phase cannot carry a current perpendicular to

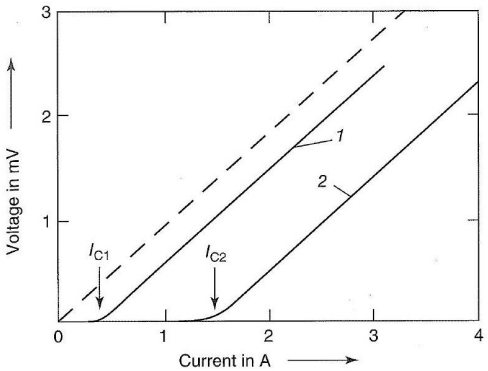

Figure 5.20 Current-voltage characteristics of an $Nb_{55}Ta_{50}$ alloy in the Shubnikov phase. $T = 3.0$ K; external field $B_a = 0.2$ T; T_c in zero field: 6.25 K. (From [41].)

the direction of the magnetic field without dissipation, since due to the influence of the Lorentz force the vortices start moving, resulting in dissipative processes. However, in a real superconductor, the vortices are never completely freely mobile. There is always a perhaps very small force necessary in order to tear the vortices off the pinning centers that are practically always present. The strength of the pinning forces acting on the individual vortices will have a certain distribution about an average value F_H. Also the whole vortex lattice will affect the pinning forces due to collective effects. However, for simplicity we will only speak of a single pinning force F_H.

As long as the Lorentz force F_L is smaller than the pinning force F_H, the vortices cannot move. Therefore, also in every real type-II superconductor in the Shubnikov phase, we will be able to observe current flow without dissipation. If the transport current exceeds its critical value at which $F_L = F_H$, the vortex motion sets in, and electrical resistance appears. [21)] We see that the critical current is a measure of the force F_H with which the vortices are pinned at energetically favored locations.

In Figure 5.20 we show the current-voltage characteristics of two samples of an $Nb_{50}Ta_{50}$ alloy with a different amount of internal disorder [41]. Both samples were cooled in the magnetic field and were measured in the Shubnikov phase. For the more strongly disordered sample 2, no electrical voltage is observed up to a transport current I_{c2} of about 1.2 A.22 On the other hand, the less perturbed

If the pinning forces acting on the individual vortices are different, initially the most weakly pinned vortices will start moving, resulting in only a relatively small resistance. With increasing current 22) Of of course, the terminology "no voltage" represents a strong simplification. Since for currents $I < I_c$ usually a finite and also very weak dissipation is possible, we will also observe small voltages in this case. The curves in Figure 5.19 indicate this by gradually approaching the linear part.

sample 1 shows a voltage and, hence, resistance already at about 0.2 A. The currents I_{c1} and I_{c2}, respectively, are referred to as the critical currents of both samples. An ideal sample of the same material, that is, a completely homogeneous sample, for the same conditions would display a current-voltage characteristic indicated by the dashed line.

In hard superconductors, the pinning forces must be made particularly high in order to allow the highest possible transport currents to flow without resistance. Before we discuss a few examples of hard superconductors, we want to look at the linear part of the characteristics in Figure 5.20. Also in this part of the characteristic, the voltage along the superconductor is generated by vortex motion. The resulting differential resistance $\mathrm{d}U/\mathrm{d}I = R_f$, the flux-flow resistance, clearly has the same value in both samples, that is, it is independent of the pinning centers acting on the vortices.

This observation can be understood in the following way: If the vortices are removed from the pinning centers, they move through the material under the influence of the force difference $F^* = \mathrm{F_L} - \mathrm{F_H}$. Because of the dissipative processes during the motion, resulting in a kind of "friction" for the vortex in the superconductor, a flux-flow velocity v develops, which is proportional to F^*. We have

$$v \propto F^* \propto (I - I_c)$$

On the other hand, the electrical voltage U is proportional to v, that is, one finds

$$U \propto v \propto I - I_c$$

and hence

$\mathrm{d}U/\mathrm{d}I = \text{const.}$

The equal values of $\mathrm{d}U/\mathrm{d}I$ for samples with different amounts of imperfections (Figure 5.20) indicate clearly that the pinning centers do not affect the relation between F^* and v. Independent of the nature of the pinning centers, the same value of F^* yields the same velocity v and, hence, the same voltage U. The characteristics are only shifted parallel to each other along the current axis.

According to these arguments, we have two components of the energy dissipation UI, namely UI_c and $U\,(I - I_c)$. We start with the component UI_c. The vortices move through the material under the influence of the Lorentz force due to a transport current. This means that they must pass through a number of potential wells. To raise a vortex out of a well costs energy. One could imagine that this energy is recovered when the vortex falls into the next (equally deep) well. In this case, there would be no net energy dissipation during vortex motion across the potential wells. However, there is the crucial fact that during their motion across the pinning centers the vortices are always elastically deformed [42, M17]. These deformations lead to the energy losses described by the component UI_{c}.

Next we turn to the component $U\,(I - I_{\mathrm{c}})$ of the dissipated power determining the vortex velocity according to Eq. (5.23). The most important energy losses during the vortex motion are caused by the appearance of local electric fields acting on the unpaired electrons. This means that the flux-flow resistance depends on

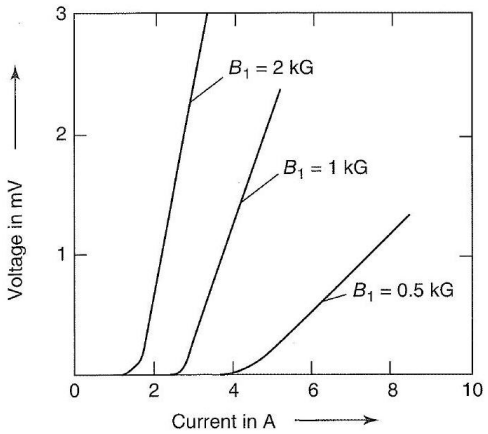

Figure 5.21 Current-voltage characteristics of a Pb-In alloy in the Shubnikov phase. Material: Pb + 17at%In; T = 2.0 K; transition temperature in zero field: about 7.1 K. (From [41].)

the normal resistance of the material. One finds that R_{f} is proportional to R_{n}[23)] Furthermore, the same dissipative effects appear at each vortex. Therefore, the dynamic (flux-flow) resistance is proportional to the vortex density. This density increases with increasing external field B_{a}. With increasing magnetic field, the $U - I$ characteristics become steeper. This dependence of the flux-flow resistance on the external field is shown in Figure 5.21 for a lead-indium alloy (Pb + 17 at% In) [41].

With increasing magnetic field, the critical current I_{c} decreases. This decrease can be caused in different ways. For increasing vortex density, not all vortices can experience the same pinning force. Hence, the average pinning force becomes smaller. On the other hand, for one and the same pinning center, with increasing external field, the pinning force decreases and approaches zero for $B_{\mathrm{a}} \to B_{\mathrm{c2}}$. The behavior of the critical current for increasing external field will be seen particularly clearly in a plot of the field dependence of I_c (see Figures 5.22 and 5.23). [24]

In our discussion of Figure 5.20 we have already seen that the critical current I_{c} depends on the degree of disorder within the sample. This internal disorder

Under otherwise the same conditions, with increasing R_{n} the vortex velocity v due to the given force $F^2 = \mathrm{F}_L - \mathrm{F}_{\mathrm{H}}$ (i.e., for a given current $I = I_c + F_1$) increases. $_{\mathrm{H}}$ (ilis can be seen

from a simple but instructive discussion of velocity v through the material dwe to the force F^v, the force F^s generates the power $P^*_= = F^*\nu$. This power must be turned into

heat because of the local electric fields E_1 thus $P^*_F = P_{el}$. For the resistivity ρ_n of the aterial in the normal state, the electrical power P_{el} is proportional to $L^2\rho_n$. n the ther hand, w, he serise $E^2/\rho, \propto F^* v\alpha\gamma^2/\rho^2$ and hence, $F^{*\prime}\alpha\nu$ For a given F^* the velocity v increases with

$P^*_F = F^*\nu$. This power must be turned into increasing ρ_n.

24) We mention that the shape of the current–voltage characteristic in an external magnetic field als

depends on the sample geometry. For example, for the same material, different characteristics are observed in a tape than in a circular disk with the current running fiom the center to the outer edge (“Corbino disk")

(!!!!!!!!!!)

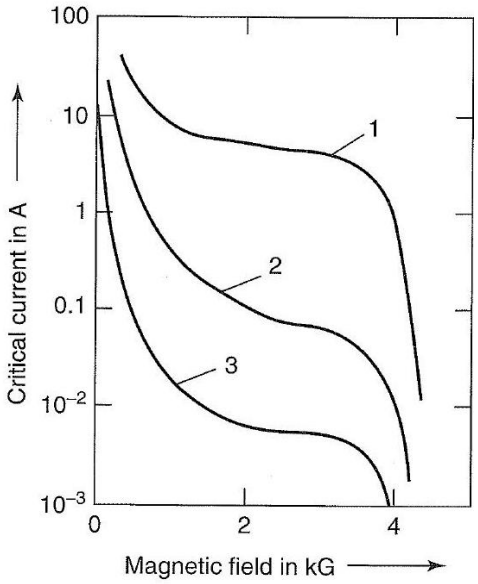

Figure 5.22 Critical current of an Nb_{55} T_{45} alloy in an external magnetic field (1kG = 0.1 W) oriented perpendicular to the current. Wire diameter: 0.38 mm; measuring temperature: 4.2K. Curve 1, immediately 1800 K; curve 3, after 48 h at 1800 K. (From [23].)

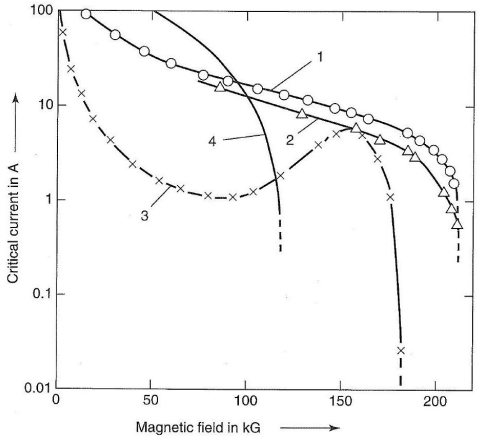

Figure 5.23 Critical currents of thin wires In each case the compound exists only of metallic high-field superconductors within a surface layer obtained by diffu(1kG = 0.17). Measuring temperature: 4.2 K. sion of the second component into the base Wire diameter of all three samples: 0.5 mm. eter 0.15 mm. (From [43, 44].) can be caused, for example, by plastic deformation. If a metal wire (such as Cu) is pulled through a die at room temperature to

reduce the cross-section, many imperfections, that is, regions in which the periodic structure of the metallic lattice is strongly perturbed, are generated within the wire. Grain boundaries (i.e., transition regions between individual grains), for example, are such regions. If subsequently the metal is heated, these disordered regions gradually can be annealed out and can be transformed more and more into well-ordered regions.

If the disordered regions act as pinning sites for the vortices, a plastically deformed superconductor is expected to display a particularly high value of the critical current immediately after deformation. During heating, along with the gradual removal of the disordered regions, the critical current should also decrease

In Figure 5.22 we clearly see this effect [23]. For an $Nb_{55}Ta_{45}$ alloy the critical current is plotted versus the external magnetic field oriented perpendicular to the current for different degrees of disorder. Immediately after the mechanical pulling process, that is, in a state with a high degree of disorder, the critical current in the Shubnikov phase is large.. [25]) During the removal of the perturbations by means of annealing, the pinning centers disappear more and more. The critical current strongly decreases as expected. In Figure 5.11 the corresponding magnetization curves are shown for the same alloy. In this case, the pinning centers lead to strong irreversibilities of the magnetization curve.

In Figure 5.23 we show the values of the critical current of wires of a few metallic high-field superconductors. Since the critical current is strongly influenced by the previous treatment of the sample because of its dependence on the degree of disorder, as we have discussed, the data of Figure 5.23 can serve only as a rough indication. The curves are chosen arbitrarily from a large number of examples. However, they show that suitably prepared hard superconductors, with a wire diameter of only 0.5 mm and for external fields above 10 T, can carry supercurrents of more than 10 up to 100 A without dissipation. Wires containing many thin filaments, so-called multifilamentary wires, can even carry still much higher currents. Of course, such superconductors are highly important for the construction of superconducting magnets (see Section 7.1).

In Figure 5.23 we show a curve (V_3Ga) having a maximum of the critical current near B_2 (the so-called peak effect, see also Figure 5.15). Apparently, with increasing external field, conditions can develop leading to a more effective pinning of the vortices. In this case the elastic properties of the vortex lattice are essential [M17]. The lattice becomes more elastic, and the vortices can adjust themselves better to the configuration of the pinning sites. Furthermore, near B_{c2} also normal conducting regions can appear, which act as additional pinning centers and cause an increase in the critical current.

By means of a systematic study of hard superconductors, it has been possible empirically to develop quite useful materials. However, the detailed dependence

The steep drop of the critical current at very small magnetic fields occurs in the Meissner phase of the superconductor at fields $B_2 < B_{cc}$ (see Figure 5.3b).

of the critical current on the defect structures is still by no means completely clarified.

This is even more valid for the high-temperature superconductors [45]. In thi case the initial measurements of the critical currents in polycrystalline, sintered samples yielded disappointingly small values of the critical current density. At 77 K, the boiling point of liquid nitrogen, even in zero applied magnetic field, frequently the critical current density was found to be less than 10^3 A/cm^2. However it soon became clear that to a large extent the critical current was limited by grain boundaries. In this case, the critical current of a grain boundary strongly decreases with increasing relative tilt angle between the crystal axes in the two grains. This could be demonstrated by transport measurements in thin films of $YBa_2Cu_3O_7$ deposited onto $SrTiO_3$ bicrystal substrates [26][47].

In 2010 the details of current limitation by means of grain boundaries could be explained theoretically [48]. Apparently, the dominating mechanism of the critical-current reduction is

due to the fact that near the dislocation lines the grain boundary is electrically charged. Many additional properties of curren transport across grain boundaries are summarized in the review articles [49, 50] An additional limitation of the critical current results from the layered structure of the cuprates. Along the CuO_2 planes a high value of the critical current is observed, whereas perpendicular to the planes the value is very small, and in some cases it is limited by the Josephson effect (see Figure 1.22f). Also in the case of current flow parallel to the CuO_2 planes it is important, how the external magnetic field is oriented relative to the crystal structure. This effect is shown in Figure 5.24 for the example of a $YBa_2Cu_3O_7$ thin film [51]. The film was prepared by mean of laser ablation. In the figure the critical current density in the case of current flow along the CuO_2 planes is plotted versus the applied magnetic field for different temperatures. The field was oriented either perpendicular to the CuO_2 planes (i.e., along the crystallographic c-direction) or perpendicular to the c-axis. We see hat at 4.2 K critical current densities of several 10^7 A/cm^2 are reached, and at 77 K still values of several 10^6 A/cm^2. As long as the magnetic field is applied parallel to the planes, these values remain also in high fields (in fact, in fields up to far above 20 T) at least at 4.2 K [52]. However, the critical current density decrease rapidly, if the magnetic field is oriented perpendicular to the lavered structure. O the other hand, in the meantime (the measurements in Figure 5.24 are from 1990) appreciable improvements could be achieved. Now, for example, $YBa_2Cu_3O_7$ thin films in a field of 5 T perpendicular to the layers can carry supercurrents of several 0^5 A/cm^2 also at 77 K[17]

If $YBa_2Cu_3O_7$ is condensed on a single-crystalline $SrTiO_3$ substrate under low oxygen pressure (about 0.1mbar), the thin se show the crystal orientation mostly fabrica. In this case the substrates are CuO_2 pabicas in such a way that the to the surface of the substrate. This technique served in the early days for preparing $YBa_2Cu_3O_7$ thin fins with redaively high

quality [46]. In a bicrystal substrate, two single-crystalline parts are rotated relative to each other. In this case the grain boundary Im on top and, transmitted into the thin can be studied systematically. Such grrain boundaries have been discussed already in Section 1.5 in the context of Josephson junctions (see Figure 1.22e),

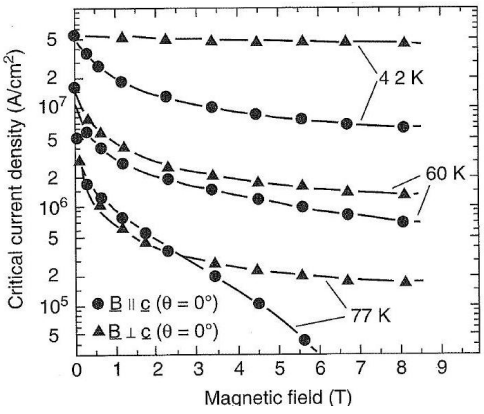

Figure 5.24 Critical current density of $YBa_2Cu_3O_7$ thin film for three temperatures plotted versus the applied magnetic field. The field was oriented either perpendicular to the layered structure (i.e., parallel to the crystallographic c-axis) or parallel to it. (From [51].)

In general, to achieve a high supercurrent density, in the case of the cuprates it is necessary to avoid grain boundaries, and the transport currents must flow parallel to the layered structure as much as possible. By means of thin-film technology, the corresponding epitaxial film growth can be achieved relatively easily, long as the substrate size is not too large [53]. However, if one is interested in high-current-carrying wires or tapes fabricated from the cuprates, obviously the material must have a high critical-current value over long lengths. Furthermore, the fabrication technique should be relatively simple and not too expensive. In recent years a number of procedures have been developed, which we will discuss in Section 7.1.2. Enormous progress

has also been achieved in the field of massive materials, which are needed, for example, for magnetic levitation or for magnetic energy storage (see Section 7.2). These developments are by no means finished. In addition, MgB_2 and the iron pnictides can become important for the conductor development. On the one hand, the upper critical field can reach very high values. On the other hand, at least in the case of MgB_2 grain boundaries practically do not suppress the supercurrent density [54]

We want to conclude our discussion of the critical currents in superconductors with a few general remarks. We have seen that the mechanism of pair breaking results in an intrinsic maximum supercurrent density. However, in cases that are technically relevant, the critical current of a superconductor is determined by extrinsic properties. On the one hand, the latter properties in the form of pinning centers in the Shubnikov phase only allow a finite supercurrent, and on the other hand, for example, in the form of grain boundaries in high-temperature superconductors, they represent weak regions in the material, strongly reducing the maximum supercurrent. Whether a new material, say, MgB_2, finds interesting technical applications depends on the concrete problems, and often can be answered only after a long development period. In Chapter 7, we will discuss some examples in more detail.

Change of the state if current approaches the Critical supercurrent

4.1.5 Description of Meissner effect

Gap from spectrum leads to Meissner effect by Shmidt

Обсудим теперь, как существование щели в спектре элементарных возбуждений сверхпроводника объясняет выталкивание слабого магнитного поля, т. е. эффект Мейсснера - Оксенфельда. Существуют строгие расчеты, выходящие за рамки настоящего курса, из которых следует, что существование энергетической щели является достаточным условием для эффекта Мейсснера.

Тем не менее, мы попытаемся все же проинтерпретировать эффект Мейсснера на языке микротеории. Следуя Лондону [154], можно предположить так называемую "жесткость" волновой функции электронов сверхпроводника. Это значит, что наличие энергетической щели, когерентное поведение всего коллектива электронов приводят к тому, что слабое магнитное поле не может сколь-нибудь существенно иэменить эту волновую функцию. Но отсюда эффект Мейсснера следует мгновенно.

Действительно, пусть $\Psi(\mathbf{r}_1, \ldots, \mathbf{r}_N)$ - волновая функция N электронов сверхпроводника. Заметим, что здесь Ψ-это не эффективная волновая функция сверхпроводящих электронов теории Гинзбурга - Ландау (которая, кстати, зависит только от одной переменной $\mathbf{r}$), а истинная волновая функция. Тогда из общих соотношений квантовой механики следует такое выражение для тока при наличии магнитного поля:

$$\mathbf{j}(r) = \sum_{n=1}^{N} \int \dots \int \left\{ \frac{e\hbar}{2im} \left[\Psi^* \nabla_n \Psi - \Psi \nabla_n \Psi^* \right] - \right.$$
$$\left. - \frac{e^2}{mc} \mathbf{A}\left(r_n\right) \left|\Psi\right|^2 \right\} \delta\left(\mathbf{r} - \mathbf{r}_n\right) d^3\mathbf{r}_1 \dots d^3\mathbf{r}_N \tag{50.6}$$

здесь $\mathbf{A}$ - векторный потенциал магнитного поля. Если магнитного поля нет ($\mathbf{A} = 0$), то, конечно, и тока в сверхпроводнике нет, и тогда интеграл от первого слагаемого должен равняться нулю:

$$\sum_{n=1}^{N} \int \dots \int \left[\Psi^* \nabla_n \Psi - \Psi \nabla_n \Psi^* \right] \delta\left(\mathbf{r} - \mathbf{r}_n\right) d^3\mathbf{r}_1 \dots d^3\mathbf{r}_N = 0 \tag{50.7}$$

Но мы предполагаем "жесткосты" волновой функции, т. е. ее неизменность под действием магнитного поля. Это значит, что и при наличии магнитного поля равенство (50.7) сохраняется. Опуская поэтому первое слагаемое в (50.6), получим после элементарного интегрирования

$$\mathbf{j}(r) = -\text{const} \cdot \mathbf{A}(r) \tag{50.8}$$

А это равенство есть математическое выражение эффекта Мейсснера, поскольку оно является известным уравнением Лондонов (5.17).

4.1.6 Flux quantization

Description of flux quantization

(theory is here)

Во многих квантово-механических задачах (квантование потока в полости сверхпроводника, эффект Ааронова-Бома, монополь Дирака) возникает необходимость вычислить изменение фазы ϕ волновой функции $\exp(i\phi)$ вдоль некоторого контура. По определению для контура, связывающего начальную 1 и конечную 2 точки имеем

$$\int_1^2 \nabla\phi(\mathbf{r}) \cdot |d\mathbf{r} = \phi_2 - \phi_1$$

Для замкнутого контура $\mathbf{r}_1 = \mathbf{r}_2$ из (25.1) казалось бы получаем ноль.

Этот же вывод дает применение теоремы Стокса:

$$\oint \nabla\phi(\mathbf{r}) \cdot d\mathbf{r} = \int \nabla \times \nabla\phi \cdot d\mathbf{S} = 0$$

Однако это верно не для всех функций $\phi(\mathbf{r})$.

Если речь идет о фазе волновой функции $\exp(i\phi(\mathbf{r}))$, то величина (25.1) определяется топологией области, охватываемой замкнутым контуром.

Это связано с требованиями однозначности и гладкости волновой функции $\exp(i\phi(\mathbf{r}))$, которые вытекают из экспериментов по интерференции волновой функции.

Если область односвязна, то контур можно стянуть в точку.

В процессе такого стягивания волновая функция на контуре должна оставаться однозначной и гладкой.

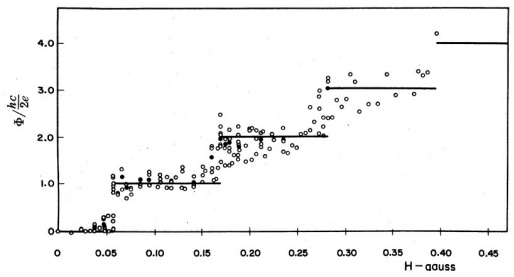
Это можно обеспечить только при обращении интеграла (25.1) в ноль.

Если же контур охватывает неодносвязную область, например, в образце имеется полость (дырка), то при обходе такой дырки изменение фазы может быть ненулевым:

$$\oint \nabla\phi(\mathbf{r}) \cdot d\mathbf{r} = 2\pi n$$

где n целое число, возможно, и ноль. Конкретное значение n определяется физическими условиями в полости.

Например, в сверхпроводнике ве личина n определяется числом квантов магнитного потока, введенного в полость внешним источником.

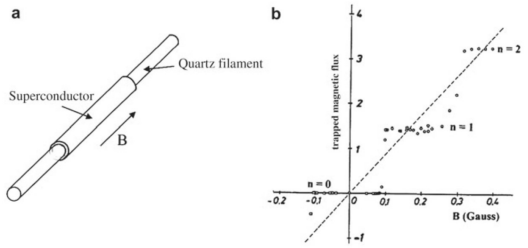


4.1.7 Flux quantization: Experimental confirmation

(????? read articles about it)

Experiments that prove flux quantization

Deaver and Fairbank



Deaver and Fairbank prooved in 1961 that: (?????? how???)

Расплывание потока они свели к погрешностям, а было ли это перемерено еще раз (??????)

Doll and Näbauer

in 1961 showed (?????? how???) that field in rod is quantized if (????)

They did this: 1. The sample was heated above the transition temperature; then a defined field to be frozen in, Hy, was applied. 2. After recooling below the transition temperature, Hy was switched off. 3. The resonance amplitude was measured, and it is proportional to the product (measuring field H) times (magnetic moment of the sample). The latter in turn is proportional to the frozen-in flux. (???? need to discuss it with someone who knows it)

4.1.8 Levitation over Superconductor: Basic understanding

(??? Later I'll create some formulas for it. Currently, nothing is prepared to describe this)

4.1.9 1-2 Diamagnetism by de Gennes

The London Equation

We now extend our energy considerations to situations where there are supercurrents $j_S(r)$ and associated magnetic fields $h(r)$ in the sample. [1] We see that in the limit where all fields, currents, and so on, are weak and have a slow variation in space the condition of minimum free energy leads to a simple relation between fields and currents (F. and H. London, 1935).

We consider a pure metal with a parabolic conduction band; the electrons have an effective mass m. The free energy now has the following form:

$$F = \int F_S dr + E_{\text{kin}} + E_{\text{mag}} \tag{1-1}$$

where F_S is the energy of the electrons in the condensed state at rest and E_{kin} is the kinetic energy associated with the permanent currents. Let us call $v(r)$ the drift velocity of the electrons at point r. It is related to the current density j_S by

$$\mathrm{n_S ev(r) = j_S(r)} \tag{1-2}$$

(where e is the electron charge, and $\mathrm{n_S}$ the number of superconducting electrons per cm^3). Then we have simply

$$\mathrm{E_{kin}} = \int \mathrm{dr} \frac{1}{2} \mathrm{mv^2 n_s} \tag{1-3}$$

the integral being extended over the sample volume. Equation (1-3) would be exact for situations of uniform flow (v = const). It remains approximately correct for our present problem, provided that $\mathrm{v}(\mathbf{r})$ is a slowly varying function of $\mathbf{r}$. (We return to this limitation later.)

Finally, $\mathrm{E_{mag}}$ is the energy associated with the magnetic field $\mathbf{h}(\mathbf{r})$

$$\mathrm{E_{mag}} = \int \frac{\mathrm{h}^2}{8\pi} \mathrm{dr} \tag{1-4}$$

The field is related to j_S by Maxwell's equation

$$\operatorname{curl} h = \frac{4\pi}{c} j_s \tag{1-5}$$

Using (1-3), (1-4), and (1-5) we rewrite the energy E as

$$E = E_0 + \frac{1}{8\pi} \int \left[h^2 + \lambda_L^2 |\operatorname{curl} \ h|^2 \right] dr$$

$$E_0 = \int F_S dr \tag{1-6}$$

where the length λ_L is defined by

$$\lambda_{\mathrm{L}} = \left[\frac{\mathrm{mc}^2}{4\pi \mathrm{n_S e}^2} \right]^{1/2} \tag{1-7}$$

At $\mathrm{T} = 0, \mathrm{n_s}$ is equal to n, the total number of conduction electrons per cubic centimeter. We can then compute λ_L explicitly. In simple metals such as Al, Sn, and so on, where m is

[1] We use **h** to denote a local field value. H will be reserved for the thermodynamic field.

close to the free electron mass, we find $\lambda_L \sim 500$Å. For transition metals and compounds with narrow d bands, m is larger and λ_L is also larger (up to 2000Å).

We wish to minimize the free energy (1-6) with respect to the field distribution $h(r)$. If $h(r)$ changes by $\delta h(r), E$ changes by δE:

$$\begin{aligned}\delta E &= \frac{1}{4\pi}\int \left[h\cdot\delta h + \lambda_L^2 \operatorname{curl} h\cdot\operatorname{curl}\delta h\right] dr \\ &= \frac{1}{4\pi}\int \left[h + \lambda_L^2 \operatorname{curl}\operatorname{curl} h\right]\cdot\delta h dr \end{aligned} \tag{1-8}$$

where we have integrated the second term by parts. The field configuration, in the interior of the specimen, which minimizes the free energy, must therefore satisfy the condition

$$h + \lambda_L^2 \operatorname{curl}\operatorname{curl} h = 0 \tag{1-9}$$

Equation (1-9) was first proposed (with a slightly different notation) by $F.$ and $H.$ London. When combined with the Maxwell equation (1-5), it allows us to calculate the distribution of fields and currents.

Meissner Effect

We now apply the London equation and discuss the penetration of a magnetic field h into a superconductor. We choose the simplest geometry. The surface of the specimen is the xy plane, the region $z < 0$ being empty (Fig. 1-2). The field h and the current j_S depend only

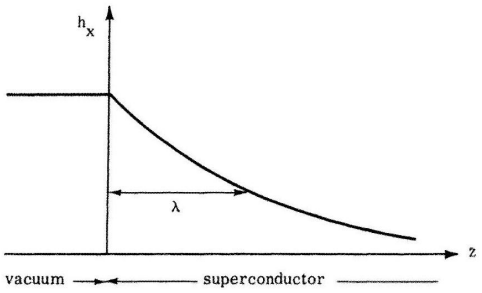


Figure 1-2

Field penetration in a superconductor. The field becomes negligibly small at distances larger than a few penetration depths λ. When the simple London equation (1-9) holds, the penetration is exponential $\mathrm{h} = h_0 \exp(-z/\lambda_L)$.

on z. In addition to the relation (1-9), h and j_s are always related by the Maxwell equations

$$\operatorname{curl}\mathrm{h} = \frac{4\pi \mathrm{J_S}}{\mathrm{c}} \tag{1-10}$$

$$\operatorname{div}\mathrm{h} = 0 \tag{1-11}$$

Two cases are possible:

(1) h is parallel to z. Then $(1-11)$ reduces to $\partial h/\partial z = 0$ and h is spatially constant. Therefore curl $h = 0$ and $j_S = 0$ from Eq. (1-10). Inserting this into Eq. (1-11) we find $h = 0$. Therefore it is not possible to have a field normal to the surface of the specimen.

(2) h is tangential (and directed along the x axis). Then Eq. (1-9) is automatically satisfied. From Eq. $(1-10) j_S$ is directed along the y axis:

$$\frac{dh}{dz} = \frac{4\pi j_S}{c} \tag{1-12}$$

Finally, from Eq. (1-9),

$$\frac{\mathrm{dj}s}{\mathrm{dz}} = \frac{n\mathrm{e}^2}{\mathrm{mc}}\mathrm{h} \tag{1-13}$$

$$\frac{\mathrm{d}^2\ \mathrm{h}}{\mathrm{dz}^2} = \frac{\mathrm{h}}{\lambda_\mathrm{L}^2} \quad \lambda_\mathrm{L}^2 = \frac{\mathrm{mc}^2}{4\pi n\mathrm{e}^2} \tag{1-14}$$

The solution that remains finite in the superconductor is exponentially decreasing,

$$h(z) = h(0)\exp\left(-z/\lambda_L\right) \tag{1-15}$$

The field h penetrates only to a depth λ_L inside the sample. This result, established here for a semiinfinite slab, is easily generalized to a macroscopic specimen of arbitrary shape. As we have seen, the "penetration depth" λ_L is small. Therefore, in all cases, a weak magnetic field practically does not penetrate at all into a macroscopic specimen. [2] The lines of force are excluded as shown on Fig. 1-3.

The superconductor finds an equilibrium state where the sum of *ki* netic and magnetic energies is minimum, and this state, for macroscopic samples, corresponds to the expulsion of magnetic flux.

Experimentally, the expulsion of lines of force was shown by Meissner and Ochsenfeld in 1933. The Meissner result was particularly important in proving that a true equilibrium state was achieved.

Three remarks concerning the above derivation:

(1) Assuming the existence of permanent currents plus thermodynamic equilibrium, we are led to the diamagnetic properties. It is more usual to go the other way round: Taking the Meissner effect as a starting point, conclude that there exist permanent currents. I chose the first way because I wanted to show you the different contributions to the energy in a superconductor (Eq. 1-6). This list of energies will be useful later (Chapter 3).

(2) We obtained Eq. (1-9) from a minimum condition on the free energy $\mathfrak{F}$. This is the correct thermodynamic potential when the external field sources are permanent magnets. When the source is a coil, with a fixed current I, the correct potential is not $\mathcal{F}$ but a different function S (the "Gibbs potential"). Fortunately, both potentials can be shown to lead to the same local equilibrium condition in the sample. (See Chapter 2 for a discussion of $\mathcal{F}$ and $\mathcal{S}$.)

(3) Note that the above calculation is valid only for weak applied fields. In higher fields it may become energetically more favorable

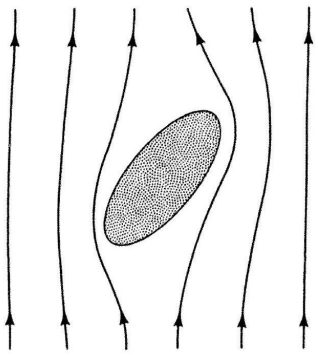

Figure 1-3

Distortion of the magnetic lines of force around a macroscopic superconductor ("macroscopic" means dimensions much larger than the penetration depth). If the fields are not too strong, the superconductor expels the lines completely (Meissner effect).

[2] In higher field different catastrophes may occur.

to destroy superconductivity in some parts of the sample and to allow the flux lines to penetrate. This will be considered in detail in Chapters 2 and 3.

4.1.10 1-3 Absence of low energy excitations by de Gennes

Let us begin by considering a free electron gas without interactions. The ground state is obtained by placing an electron into each individual momentum state p, of energy $p^2/2m$, until the Fermi energy $\mathbf{E}_F = \mathrm{p_F^2}/2$ m is reached. Above the Fermi energy $\mathrm{E_F}$, all the levels are empty. (The condition $p = p_F$ defines the Fermi sphere, in momentum space.) In order to construct an excited state of the gas, it suffices to take an electron of momentum p from an initially occupied state ($p \leq p_F$) and to place it into a state p' initially empty ($p' \geq p_F$) (Fig. 1-4). The excitation energy of this electron-hole pair is

$$E_{pp'} = \frac{p'^2 - p^2}{2m} \geq 0 \tag{1-16}$$

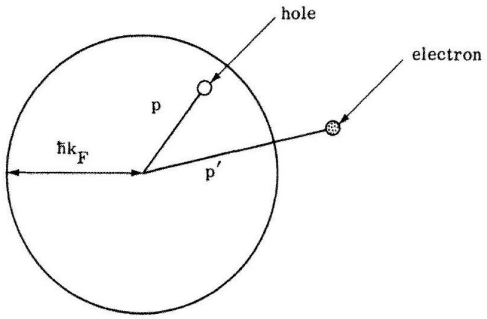

Figure 1-4

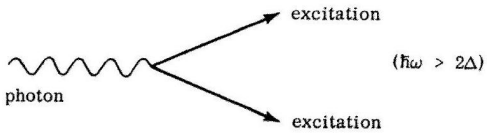
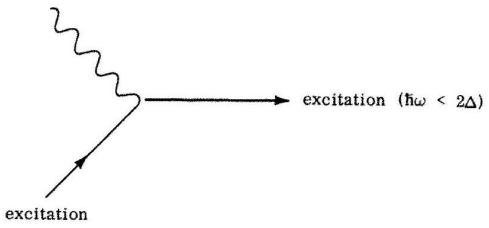
An excited state of the electrongas in a normal metal. One electron has been taken from a state of momenturn p inside the Fermi sphere, to a state of momentum p' outside the Fermi sphere. The excitation energy $\left(p'^2 - p^2\right)/2m$ is very low if p and p' are close to the Fermi momentum $\mathrm{p_F} = \hbar \mathrm{k_F}$.

If both p and p' are close to the Fermi momentum, $E_{pp'}$ is very small; in a free electron gas there are numerous low energy excitations. In a normal metal, this free electron picture is not qualitatively modified. The low energy excitations are displayed by the following experiments:



(a) The specific heat is relatively large and proportional to T (of order $\mathrm{k}_B \cdot (\mathrm{k_B T/E_F})$ per electron).

(b) Strong dissipative effects appear when the electrons are submitted to low frequency external perturbations (electromagnetic waves, ultrasonic waves, nuclear spin precession, and so on).



In most superconductors, the situation is completely different. The energy $E_{pp'}$ necessary to create a pair of excitations is no longer given by Eq. (1-16). It is necessary to at least furnish a certain "pairing energy" 2Δ:

$$E_{pp'} \geq 2\Delta \tag{1-17}$$

Roughly speaking, this "gap" 2Δ is related to the transition temperature by $2\Delta = 3.5\mathrm{k_B T_0}$. Thus typically 2Δ is of order 10°K (Table 1-1).

(a)

(b)

Figure 1-5

Typical dissipative processes in a superconductor. Fig. 1-5a shows the creation of a pair of excitations by one photon. This process can occur only if $\hbar\omega > 2\Delta$. Fig. $1-5$ b shows the absorption of the photon by a preexisting excitation. This process can occur even if $\hbar\omega < 2\Delta$, but it is weak at low temperatures, where there are very few thermal excitations. Similar processes are obtained by replacing "photon" by "phonon" in 1-5a and $1-5b$.

Note that 2Δ is the energy needed to create two excitations. The energy per excitation is Δ.

Various experiments measure Δ. Here are some of them:

(a) The low temperature specific heat is now exponential and proportional to $\exp(-\Delta/k_BT)$.

(b) Absorption of electromagnetic energy. For $\hbar\omega \geq 2\Delta$ a photon of frequency ω can create an electron-hole pair. [This corresponds to photons in the far infrared; typical wavelengths are in the 1 mm range (Fig. 1-5a).]

(c) Ultrasonic attenuation. Here the phonon is of low frequency and cannot decay by creation of a pair of excitations. But it can be absorbed by collision with a preexisting excitation (Fig. 1-5b). This

Table 1-1

Values of the energy gap 2Δ (at 0°K) in °K[a]

	P	A	T

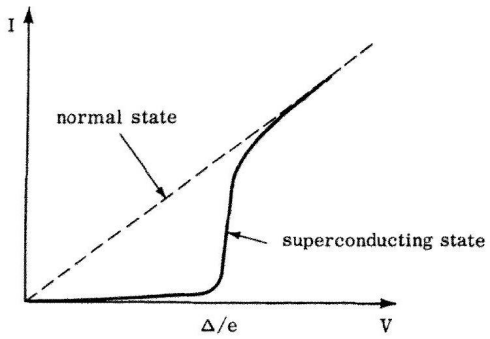
process is proportional to the number of preexisting excitations, thus to $\exp(-\Delta/k_BT)$.

(d) Tunnel effect. A superconductor S and a normal metal N are separated by a thin insulating barrier (typical thickness 25Å) (Fig. 1-6a). The quantum mechanical tunnel effect allows



a For a bibliography on energy gap measurements see D. H. Douglas, Jr., and L. M. Falicov, Low Temperalure Physics, Vol. IV, edited by C. G. Gorter (Amsterdam: North Holland Publishing Co., 1964). The experiments are classified as follows: P photon absorption (microwave or far infrared photons); A ultrasonic attenuation; T tunneling. The ultrasonic experiments are often performed in single crystals, in which case, 2Δ depends slightly on the direction of the sound wave, [Fond]

individual electrons to pass through the barrier. The electron must have been excited from the condensed phase, and this requires an energy Δ. There is no current at low temperatures unless we apply a voltage V across the junction such that the energy gain eV is larger than Δ. The current voltage characteristic has the form shown in Fig. 1-6b.

Question: Is the existence of an energy gap a necessary condition for the existence of permanent current (superfluidity)? The answer is no. A number of situations have been found where superfluidity occurs with no gap in the one particle excitation spectrum. The simplest example is "surface super-

(a)

(b)

Figure 1-6

A tunneling junction between a normal metal and a superconductor. (a) Shows the geometry. (b) Shows the current-voltage characteristic when s is superconducting ($T \ll T_0$) and also when s is normal ($T > T_0$). Typically for a junction 1 mm$\times$ 1 mm the resistance V/I when both metals are normal may range from 10^{-2} to 10^4ohms. When $T \ll T_0$, to extract one electron from the superconducting condensate requires a minimum energy Δ. Essentially no current flows until $eV = \Delta$.

conductivity" - certain metals or alloys, in a suitable range of field, are superconducting only in a thin sheath (typically 1000Å) near the sample surface. Excitations from the inner (normal) regions can leak up to the surface-there is no gap in the energy spectrum. (This has been checked recently by tunneling experiments.) However the sheath is superconducting! There are other examples, some of which we shall discuss later.

4.2 Thermodynamic Effects

4.2.1 Specific heat, Free Energy, Entropy 1

2. Specific heat by AGD

(!! write the background here!!)

To find the different thermodynamic functions, we use the relation derived above for the derivative of the thermodynamic potential with respect to the interaction constant:

$$\frac{\delta\Omega}{\delta\lambda} = \frac{1}{\lambda}\langle H_{\text{int}} \rangle .$$

In our case H_{int} is given by (32.3). If we retain in this average terms which differ from zero only in the superconducting phase, we obtain, since $\lambda < 0$,

$$\frac{\delta\Omega}{\delta|\lambda|} = -\frac{1}{\lambda^2}|\Delta|^2$$

The connection between $1/|\lambda|$ and Δ at a given temperature is determined by the relation (36.1). Hence the difference between the potentials Ω for the metal in the superconducting and normal phases is

$$\Omega_s - \Omega_n = \int_0^{\Delta} \left(\frac{\mathrm{d}\frac{1}{|\lambda|}}{\mathrm{d}\Delta} \right) \Delta^2 \, \mathrm{d}\Delta$$

By a general rule of statistical physics, this added correction, when expressed in suitable variables, is the same for all the thermodynamie potentials. Using (36.2), according to which

$$\frac{1}{|\lambda|} = \frac{mp_0}{2\pi^2} \left\{ \ln \frac{2\omega_D}{\Delta} - 2\sum_{n=1}^{\infty} (-1)^{n+1} K_0 \left(\frac{n\Delta}{T} \right) \right\}$$

and using the familiar formula of Bessel function theory: $K_0'(x) = -K_1(x)$ we get

$$F_s - F_n = -\left(\frac{mp_0}{2\pi^2} \right) \left\{ \frac{A^2}{2} - 2\sum_{n=1}^{\infty} (-1)^{n+1} \frac{T^2}{n^2} \int_0^{n\Delta/T} K_1(x) x^2 \, \mathrm{d}x \right\}$$

At low temperatures $\Delta/T \gg 1$. In this case $\int_0^{n\Delta/T} K_1(x)x^2 \, \mathrm{d}x = 2 - \int_{n\Delta lT}^{\infty} K_1(x)x^2 \, \mathrm{d}x$. The latter integral only needs to be found for $n = 1$. the asymptotic expansion of $K_1(x)$ being used for this purpose.

The remaining series over n is easily summed. We get as a result:

$$F_s - F_n = \frac{mp_0 T^2}{6} - \frac{mp_0}{2\pi^2} \left[\frac{\Delta^2}{2} + \sqrt{2\pi\Delta_0^3 T} \left(1 + \frac{15}{8}\frac{T}{\Delta_0} \right) e^{-\Delta_v/T} \right] \tag{36.7}$$

The first term on the right-hand side is equal to the main term (with reversed sign) in the expansion of the free energy of the normal metal in powers of T. We know that this latter term leads to a linear law for
the electron part of the specific heat in the normal phase:

$$C_n = \frac{mp_0 T}{3}$$

On substituting (36.3), we find that the entropy in the superconducting phase at low temperatures is equal to

$$S_s = \frac{mp_0}{\pi^2} \sqrt{\frac{2\pi\Delta_0^3}{T}} e^{-\Delta_0/T}$$

whilst the specifie heat is

$$C_s = \frac{mp_0}{\pi^2} \left| \frac{\sqrt{2\pi\Delta_0^5}}{\pi^3} e^{-\Delta_d/T} \right.$$

This gives us, with the aid of (34.23), for the ratio of the specific heats of the superconducting phase in the region $T \ll T_c$ and of the normal phase at $T = T_0$:

$$\frac{C_s(T)}{C_n\,(T_c)} = \frac{3}{\gamma}\sqrt{\frac{2}{\pi}}\left(\frac{\Delta_0}{T}\right)^{3/2} \exp\left(-\frac{\Delta_0}{T}\right). \tag{36.8}$$

In order to obtain asymptotic formulae in the temperature region close to T_c, we start from expansion (36.4):

$$\delta\frac{1}{|\lambda|} = -\left(\frac{mp_0}{2\pi^2}\right)\frac{7\zeta(3)}{(2\pi T)^2}\Delta\delta\Delta$$

We find with the aid of (36.6) for the difference between the free energies:

$$F_s - F_n = -\left(\frac{mp_0}{2\pi^2}\right)\frac{7\zeta(3)}{16(\pi T)^2}\Delta^4 = -\frac{2mp_0T_c^2}{7\zeta(3)}\left(1-\frac{T}{T_c}\right)^2 \tag{36.9}$$

Hence the entropy in the superconducting phase is

$$S_s = -\frac{4mp_0T_c}{7\zeta(3)}\left(1-\frac{T}{T_c}\right) + S_n$$

On differentiating a second time and retaining the main terms, we get the following expression for the specific heat of the superconductor at the transition point:

$$C_s\,(T_c) = C_n\,(T_c) + \frac{4mp_0}{7\zeta(3)}T_c$$

Thus the specific heat of a metal has a jump of $4mp_0T_c/7\zeta(3)$ at the point of the phase transition to the superconducting state. If we take into account higher order terms in $T_c - T$ in expansion (36.9), we can find the ratio of the specific heat $C_s(T)$ to the specific heat $C_n\,(T_c)$ in the normal phase close to T_c:

$$\frac{C_s(T)}{C_n\,(T_c)} = 2\cdot 43 + 3\cdot 77\left(\begin{array}{cc} T & \\ T_c & -1\end{array}\right)$$

This behaviour of the electron part of the specific heat of a metal close to T_c is illustrated in Fig. 98 on p. 304.

1.3.1 Critical Field of Bulk Material. Thermodynamic Critical Field

Consider a long cylinder of a type-I superconductor in a uniform longitudinal magnetic field H_0. We shall now work out the value of the field which destroys its superconductivity, that is, we shall find the value of $H_{\rm cm}$.

At $H_0 < H_{\rm cm}, B$ is zero due to the Meissner-Ochsenfeld effect. The

$$M = -H_0/4\pi \tag{1.8}$$

When a value $\mathrm{d}\boldsymbol{H}_0$ is added to the magnetic field $\boldsymbol{H}_0$, an external source of magnetic field does a work on the superconductor, per unit volume, of

$$-\boldsymbol{M}\mathrm{d}\boldsymbol{H}_0 = \boldsymbol{H}_0\ \mathrm{d}\boldsymbol{H}_0/4\pi \tag{1.9}$$

Consequently, when the field changes from 0 to H_0, the work done by the field source is

$$-\int_0^{H_0}\boldsymbol{M}\ \mathrm{d}\boldsymbol{H}_0 = H_0^2/8\pi \tag{1.10}$$

This work is stored in the free energy of the superconductor placed in the field H_0. Thus, if the free energy density of a superconductor in zero magnetic field is $F_{\rm so}$, that of the superconductor in a finite magnetic field is

$$F_{sH} = F_{\rm s0} + H_0^2/8\pi \tag{1.11}$$

A transition to the normal state occurs when the free energy F_{sH} reaches the level of the free energy of the normal metal, i.e., $F_{sH} = F_{\rm n}$ at $H_0 = H_{\rm cm}$. This means that

$$F_{\rm n} - F_{\rm s0} = H_{\rm cm}^2/8\pi \tag{1.12}$$

It follows from (1.12) that the critical field of a bulk superconductor is a measure of the extent to which the superconducting state is preferable to the normal one from the standpoint of free energy. In other words, it measures the difference in free energy between the normal and superconducting states. The field $H_{\rm cm}$ is often called the thermodynamic critical field.

1.3.2 Entropy of a Superconductor

By the first law of thermodynamics we have

$$\delta Q = \delta R + \delta U \tag{1.13}$$

where δQ is the element of the thermal energy density for the body under consideration, δR is the work done by the body on external bodies, per unit volume, and δU is the element of its internal energy. By definition, the free energy density F is

$$F = U - TS \tag{1.14}$$

where T is the temperature of the body and S is the entropy per unit volume. Then

$$\delta F = \delta U - T\delta S - S\delta T$$

Since for a reversible process $\delta Q = T\delta S$, we have

$$\delta F = -\delta R - S\delta T. \tag{1.16}$$

It follows from (1.16) that

$$S = -(\partial F/\partial T)_R \tag{1.17}$$

Let us use (1.17) to calculate the difference in entropy between the normal and superconducting states. Substituting (1.12) into (1.17) we get

$$S_{\rm s} - S_{\rm n} = \frac{H_{\rm cm}}{4\pi}\left(\frac{\partial H_{\rm cm}}{\partial T}\right)_R \tag{1.18}$$

From (1.18), important physical results can be derived.
(1) According to Nernst's theorem, the entropy of a body at $T = 0$ is zero. Therefore $(\partial H_{\rm cm}/\partial T)_{T=0} = 0$, i.e., at $T = 0$ the curve $H_{\rm cm}(T)$ has zero derivative.
(2) It is known from experiment that, as the temperature T increases, the dependence $H_{\rm cm}(T)$ has the form of a monotonically descending curve (see Fig. 1.1). That is, for the entire temperature interval from 0 to $T_{\rm c}$, we have $\partial H_{\rm cn}/\partial T < 0$ and $S_{\rm s} < S_{\rm n}$,
(3) Since $H_{\rm cm} = 0$ at $T = T_{\rm c}$, we get $S_{\rm s} = S_{\rm n}$ at $T = T_{\rm c}$. A sketch of the $S_8 - S_{\rm n}$ dependence

on temperature is shown in Fig. 1.10.

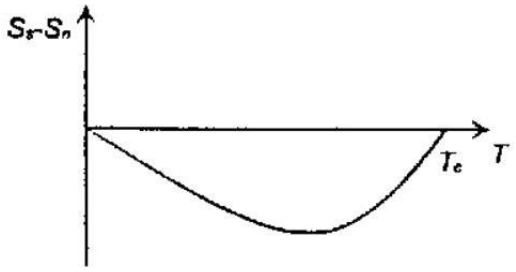


Fig. 1.10. Temperature dependence of the entropy difference $S_k - S_n$

We now arrive at some very important conclusions.

(1) The superconducting state is a more ordered state than the normal one because it is characterised by lower entropy.

(2) Since $S_\mathrm{s} = S_\mathrm{n}$ at $T = T_\mathrm{c}$, the transition at $T = T_\mathrm{c}$ does not involve latent heat. Therefore, the transition at $T = T_\mathrm{c}$ is a second-order phase transition.

(3) At $T < T_\mathrm{c}$, a transition from the superconducting to the normal state occurs when a sufficiently strong magnetic field is applied. Since, as we know, $S_\mathrm{s} < S_\mathrm{n}$, such a transition is accompanied by absorption of latent heat. For the transition from the superconducting to the normal state, it is the other way round, i.e., the latent heat is given up. Therefore, in the presence of a magnetic field, all the transitions at $T < T_\mathrm{c}$ are first-order phase transitions.

It is amazing how a couple of formulas from thermodynamics and a single experimental fact - the dependence of H_cm on T (Fig. 1.1) - have led to such fundamental conclusions! Fundamental indeed, because from our new knowledge that the superconducting state is more ordered (i.e., possesses a lower entropy) than the normal one, we come straight to the understanding that superconductivity is based on the coherent behavior of electrons.

1.3.3 Heat Capacity

The specific heat of matter can be defined as $C = T(\partial S/\partial T)$. Therefore, we can write the difference in specific heat between the superconducting and normal states as

$$C_\mathrm{s} - C_\mathrm{n} = \frac{T}{4\pi}\left[\left(\frac{\partial H_\mathrm{cm}}{\partial T}\right)^2 + H_\mathrm{cm}\frac{\partial^2 H_\mathrm{cm}}{\partial T^2}\right] \tag{1.19}$$

In order to obtain (1.19), we have taken the derivative of (1.18). Now, since $H_\mathrm{cm} = 0$ at $T = T_\mathrm{c}$, we have

$$C_\mathrm{s} - C_\mathrm{n} = \frac{T_\mathrm{c}}{4\pi}\left(\frac{\partial H_\mathrm{cmn}}{\partial T}\right)^2_{T_\mathrm{c}} \tag{1.20}$$

Expression (1.20), known as the Rutgers formula, implies that there must be a discontinuous jump at $T = T_\mathrm{c}$ in the specific heat as a function of temperature. The Rutgers formula defines the height of the jump. The temperature dependence of the specific heat is plotted in Fig.1.11. At $T > T_\mathrm{c}$, the specific heat decreases linearly with decreasing temperature, as is usually the case for normal metals (electronic specific heat).

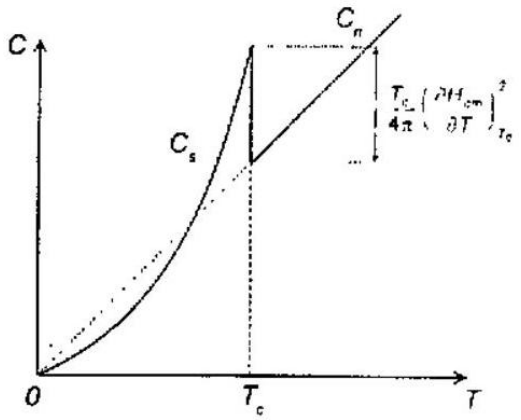

Fig. 1.11. Temperature dependence of the specific heat of a superconductor

For the moment we shall consider the form of the $C(T)$ dependence in Fig. 1.11 simply as an experimental fact, i.e., not supported by theoretical analysis. However, the fact that there exists a point at $T < T_c$ where the two curves - $C_{\rm s}(T)$ and the extrapolation of $C_{\rm n}(T)$ - intersect, fol-

1.3.4 Free Energy

Let us consider in more detail the basic properties of those thermodynamic potentials that we shall often deal with when studying superconductivity. These potentials are equally suitable for analysis of any sori of matter, superconductors in particular. Definitions and detailed arguments can be found in [13].

Consider a body in an external magnetic field H_0 such that its temperature and the magnetic induction in its interior are constant. The body attains thermodynamic equilibrium when the free energy $\mathcal{F} = \int F \, \mathrm{d}V$ is a minimum, where the free energy density F is defined by (1.14). The quantity $\mathcal{F}$ is sometimes referred to as the Helmholtz free energy.

For many calculations, making use of this potential is awkward because normally the quantities presumed to be constant for a body in an external magnetic field are the temperature and the external magnetic field H_0. In the latter case, thermodynamic equilibrium is attained when another thermodynamic potential is a minimum, that is, the Gibbs free energy $\mathcal{G}$ defined as

$$\mathcal{G} = \int G \, \mathrm{d}V, \tag{1.21}$$

$$G = F - \boldsymbol{B} \cdot \boldsymbol{H}_0/4\pi, \tag{1,22}$$

4.2.2 Specific heat, Free Energy, Entropy 2

Typical Derivation of Heat Capacity

To get the Heat Capacity, one needs just to calculate energy and then take a derivative. But first, let us calculate the number of particles, since it is easy and the method is the same.

При низких температурах число возбуждений в сверхпроводнике невелико. Термодинамика любой системы вблизи основного состояния определяется считалочкой: каков спектр возбуждений, такова и теплоёмкость. Для спектра с щелью Δ при $T \ll T_c$ получается экспоненциальная зависимость теплоемкости $C_s \sim \exp(-\Delta/T)$. Такая зависимость является типичной при наличии щели в спектре возбуждений. Покажем это на примере числа квазичастиц в сверхпроводнике. Полное равновесное число квазичастиц равно

$$N(T) = \int_0^\infty \frac{g_s V 4\pi p^2 dp}{(2\pi\hbar)^3 \left(e^{\frac{\varepsilon(p)}{T}} + 1\right)}$$

где $\varepsilon(p) = \sqrt{\Delta^2 + v_F^2 \left(p - p_F\right)^2}, g_s = 2s + 1 = 2$ - кратность вырождения по спину. Поскольку $T \ll \Delta$, экспонента велика по сравнению с единицей; а поскольку $\sqrt{T\Delta} \ll v_F p_F$, интеграл (12.34) «набирается» в узкой $|p - p_F| \approx \sqrt{T\Delta}/v_F \ll p_F$ области около p_F. С экспоненциальной точностью $\exp(-\Delta/T) \ll 1$ получаем

$$N(T) \approx \frac{8V\pi p_F^2}{(2\pi h)^3} e^{-\frac{\Delta}{T}} \int_{-\infty}^{+\infty} dp' e^{\frac{-v_F^2 p^2}{2T\Delta}} = \frac{8V\pi p_F^2 \sqrt{2\Delta}}{(2\pi h)^3 v_F} T^{1/2} e^{-\frac{\Delta}{T}} \propto e^{-\frac{\Delta}{T}}.$$

Число квазичастиц экспоненциально мало, поэтому предэкспоненциальный множитель можно не выписывать.

(??? check these formulas!!!)

Теперь вычислим энергию квазичастиц:

$$E(T) = \int_0^\infty \frac{g_s V 4\pi p^2 dp \varepsilon(p)}{(2\pi\hbar)^3 \left(e^{\frac{\varepsilon(p)}{T}} + 1\right)}$$

Учитывая отмеченные выше приближения, получаем

$$E(T) \approx \frac{8V\pi p_F^2}{(2\pi\hbar)^3} e^{-\frac{\Delta}{T}} \int_0^\infty \left(\Delta + \frac{v_F^2 \left(p - p_F\right)^2}{2\Delta}\right) e^{-\frac{v_F^2 (p-p_F)^2}{2T\Delta}}$$

Поскольку интеграл «набирается» в узкой окрестности $|p - p_F| \ll \sqrt{T\Delta}/v_F \ll p_F$, вторым слагаемым в (12.37) можно пренебречь:

$$E(T) \approx \frac{8V\pi p_F^2 \sqrt{2\pi}\Delta^{3/2}}{(2\pi\hbar)^3 v_F} T^{1/2} e^{-\frac{\Delta}{T}}$$

Учитывая крайнюю малость экспоненты, предэкспоненциальный множитель можно не удерживать. Для теплоемкости это дает

$$C_s(T) \propto e^{-\frac{\Delta}{T}}$$

типичную экспоненциальную зависимость теплоемкости для спектра возбуждений со щелью.

Jump of Heat Capacity

При температуре перехода теплоемкость испытывает скачок. Модель Бардина-Купера-Шриффера предсказывает для него значение $\left(C_s - C_n\right)/C_s = 1.43$.

Let us proof it.

Тепловые свойства сверхпроводника определяются его возбуженими - квазичастицами, которые можно рассматривать как ферми-газ с нулевым химическим потенциалом. Энтропия этого газа равна

$$S = -\sum [n \ln n + (1-n)\ln(1-n)]$$

здесь $n = \left(e^{\beta\varepsilon}+1\right)^{-1}$, $\varepsilon = \sqrt{\xi^2+\Delta^2}$

Теплоемкость дается формулой из термодинамики:

$$C = T\frac{\partial S}{\partial T} = \sum T\frac{\partial S}{\partial n}\frac{\partial n}{\partial T} = -\sum T[\ln n - \ln(1-n)]\frac{\partial n}{\partial T}$$

$$\ln n - \ln(1-n) = \ln\frac{n}{1-n} = -\ln\left(\frac{1}{n}-1\right) = -\beta\varepsilon$$

Таким образом

$$C = \sum \varepsilon\frac{\partial n}{\partial T}$$

При низких температурах теплоемкость экспоненциально мала.

Вблизи критической температуры самое сложное - найти производную от распределения квазичастиц

$$\frac{\partial n}{\partial T} = \frac{\partial n}{\partial \beta\varepsilon}\frac{\partial \beta\varepsilon}{\partial T} = T\frac{\partial n}{\partial \varepsilon}\left(-\frac{\varepsilon}{T^2}+\frac{1}{T}\frac{1}{2\varepsilon}\frac{\partial\Delta^2}{\partial T}\right)$$

Квадрат пели линейно зависит от температуры

$$\frac{\partial\Delta^2}{\partial T} = \frac{\partial}{\partial T}T_c\frac{T_c-T}{A} = -\frac{T_c}{A}$$

Тогда теплоемкость

$$C_s = \sum\left|\frac{\partial n}{\partial\varepsilon}\right|\left(\frac{\varepsilon^2}{T}+\frac{T_c}{2A}\right) = C_n + \frac{T_c}{2A}\sum\left|\frac{\partial n}{\partial\varepsilon}\right| = C_n + \frac{T_c}{2A}\nu(0)$$

Так как $C_n = \frac{\pi^2}{3}\nu(0)T$, то скачек теплоемкости в точке фазового перехода равен

$$\frac{C_s - C_n}{C_n} = \frac{T_c\nu(0)}{2A\frac{\pi^2}{3}\nu(0)T} = \frac{3}{2A\pi^2} = 1,43$$

Флуктуационная теплоемкость сверхпроводника

(write the background!!!!)

Используя уравнения Гинзбурга-Ландау, можно определить флуктуационную поправку к Ω-потенциалу, энтропии и теплоемкости. Это позволяет еще раз независимым образом установить область применимости уравнений Гинзбурга-Ландау.

Решение этой задачи основывается на ранее (см. лекцию 10) полученной формуле для флуктуационной поправки к теплоемкости:

$$\Delta C_\phi = \frac{T_c^2 V a^{3/2}}{16c^{3/2}\pi\sqrt{T-T_c}}$$

Следует только правильно выразить величины a и c через микроскопические параметры сверхпроводника. Выше мы видели, что в функционале (13.2) $c = \hbar^2/4m$ и $a = T_c m\pi^2/p_F^2$. Сравнивая флуктуационую теплоемкость (13.38) со скачком теплоемкости $\Delta C \sim C\left(T_c\right) \approx g_F T_c/\varepsilon_F$, снова получаем критерий (13.37).

4.2.3 Specific Heat: Experimental confirmation

(????? read articles about it)

In Figure 4.1 as an example we show the specific heat of tin as a function of temperature [6]. Tin is a type-I superconductor. The solid curve is observed in the absence of a magnetic field. We clearly see the jump of the specific heat at T_c, indicating a second-order phase transition. In the case of a first-order phase transition, at the transition temperature c_p would have become infinitely large.

In magnetic fields above the critical field B_c, the specific heat c_n of the normal conducting state can also be determined for $T < T_c$ (solid dots in Figure 4.1). In this case no discontinuity is observed, since there is no phase transition.

The specific heat of the normal conductor can be separated into two components, the contribution of the conduction electrons c_{nE} and the contribution of the lattice vibrations c_{nL}, thus $c_n = c_{nE} + c_{nL}$

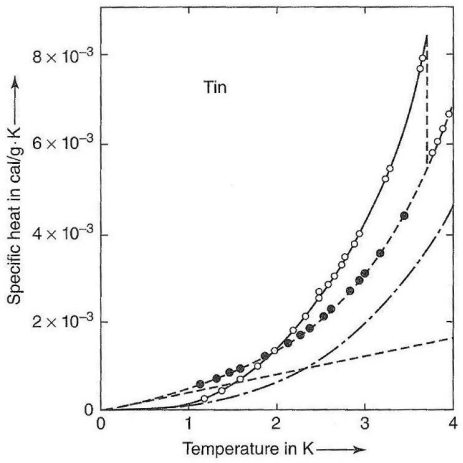

Figure 4.1 Specific heat of tin plotted versus the temperature. Open circles: without a trons for $B > B_c$ dashed-i: with a magnetic field $B > B_c$; dashed line: contribution of the elec(6) $> B_c$; dash

In good approximation we have

$$c_{nE} = \gamma T$$
$$c_{nL} = \alpha \left(T/\Theta_D\right)^3$$

γ and α are constants, and Θ_D is the Debye temperature. The Sommerfeld coefficient γ is proportional to the density of states of the electrons at the Fermi energy (see Section 1.1). It is given by

$$\gamma = \frac{2}{3}\pi^2 k_B^2 N\left(E_F\right)$$

where $k_B = 1.38 \times 10^{-23}$ W s/K is Boltzmann's constant and $N\left(E_F\right)$ is the density of states at the Fermi energy in (W s mol) $^{-1}$.

In the superconducting state for medium temperatures, the temperature dependence of the specific heat is well approximated by a power law of third order According to Eqs. (4.14) and (4.15), this means that the lattice component domi-

Also we want to discuss briefly which temperature dependence of the specific heat in the superconducting state results from the microscopic theory. First we look at conventional superconductors.

For temperatures near T_c, the Cooper pair density and the energy gap chang strongly with temperature. In this temperature range we cannot expect simple theoretical relations. However,

at very low temperatures the energy gap is nearly independent of T. The introduction of energy into the electron system then essentially

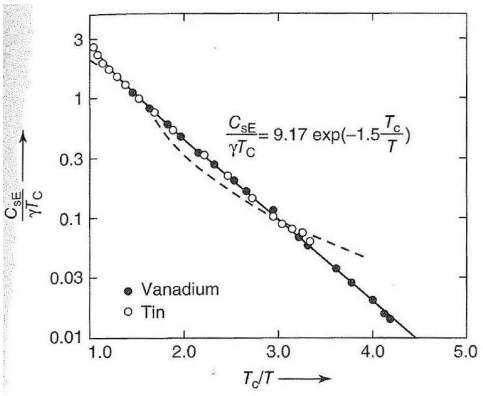

Figure 4.2 Electronic component of the specific heat of tin and vanadium. The straight line represents the relation predicted by the BCS theory. The dashed curve indicates a T^3 law according to Eq. (4.15). (From [7].)

results in the breaking up of Cooper pairs." [8] For this, excitations beyond the energy gap are needed. Since the probability of such excitations should decrease following an exponential function of the kind $\exp(-A/k_{\mathrm{B}}T)$, at very low temperatures we expect essentially an exponential decrease in the electronic component c_{sE} of the specific heat. Here, A is a constant, essentially the excitation energy.

For $T \to 0$, the Bardeen-Cooper-Schrieffer (BCS) theory yields for the specific heat of conventional superconductors

$$c_{\mathrm{sE}} = 9.17\gamma T_{\mathrm{c}} \exp\left(-\frac{1.5T_{\mathrm{c}}}{T}\right)$$

In Figure 4.2 we show an example of this exponential dependence [7]. Corresponding to Eq. (4.17), $c_{\mathrm{S}}/\gamma T_{\mathrm{c}}$ is plotted versus T_{c}/T. The straight line represents sponding to Eq. (4.17), $c_{\mathrm{sE}}/\gamma T_{\mathrm{c}}$ is plotted versus T_{c}/T. The straight line represents the relation (4.17). Also, before the advent of the BCS theory, highly accurate specific-heat measurements had already indicated exponential dependences at very low temperatures. This result confirmed at the time the prediction by Daunt and Mendelssohn [8] of an energy gap in the excitation spectrum of a superconductor For the relative jump of the electronic component of the specific heat, $(c_{\mathrm{sE}} - c_{\mathrm{nE}})/c_{\mathrm{nE}}$, near T_{c}, the BCS theory yields the value 1.43, in excellent agreement with the experimental observations.

On the other hand, in unconventional superconductors, the excitation spectrum does not have an energy gap. Instead, the gap function $\Delta_0(\mathbf{k})$ vanishes along certain directions in $\mathbf{k}$-space. Hence, even at very low temperatures there exist an appreciable number of unpaired electrons, which contribute to the specific heat

The density of the free, unpaired electrons has become so small that its energy absorption can be neglected.

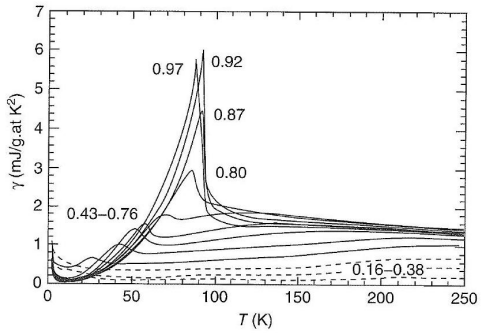

Figure 4.3 Sommerfeld coefficient $\gamma = c_{el}/T$ plotted versus temperature T for $YBa_2Cu_3O_{6+x}$ crystals with different

of the electron system. As we have seen in Section 3.2, the function $\Delta_0(\mathbf{k})$ can vanish at individual points or along extended lines in $\mathbf{k}$-space. Therefore, $c_{sE}(T)$ ncreases with temperature following a power law: $c_{sE}(T) \propto T^a$. Depending on the dimension of the locations with zero gap (points or lines) and on the exponent with which $\Delta_0(\mathbf{k})$ vanishes with $|\mathbf{k}|$ near these locations, one finds $a = 2$ or $a = 3$. Also the relative magnitude of the jump $(c_{sE} - c_{nE})/c_{nE}$ of the electronic specific heat at T_c depends on the exact behavior of $\Delta_0(\mathbf{k})$ near the locations with zero gap. Hence, it yields information about these locations.

For the cuprates it is very difficult to determine the electronic component of the specific heat over a large temperature range, since (except for very low temperatures) the contribution of the phonons to the specific heat is relatively large [9-11]. Furthermore, it is impossible to suppress the superconductivity simply by the application of a magnetic field, because of the large values of the upper critical fields. Therefore, the difference between the specific heat in the normal and in the superconducting states cannot be extracted in the simple way shown in Figure 4.1. Instead, one can use undoped samples for comparison, say, comparing $YBa_2Cu_3O_6$ with $YBa_2Cu_3O_7$. In Figure 4.3 we show the temperature dependence of the quantity $\gamma = c_{el}/T$ for different levels of oxygen doping x in $YBa_2Cu_3O_{6+x}$ The jumps at the different transition temperatures can clearly be seen.

The specific heat c_{sE} has also been analyzed exactly in the limit of low temperatures, and a surprisingly large linear term has been found, that is, $a = 1$ [13] However, for a superconductor with $d_{x^2-y^2}$ symmetry of the pair wave function in the absence of a magnetic field, in the simplest case one would have expected quadratic temperature dependence of c_{sE}.) Subsequent experiments have confirmed the T^2 term [14] and, on the other hand, have identified paramagnetic mpurities as the origin of the linear term [15]. 9) For d-wave superconductors in the vortex state, one expects a linear term increasing proportional to $B^{1/2}$. Such a term was also confirmed experimentally. 4.3 Thermal conductivity 209

For the three examples of superconductors, tin, vanadium, and $YBa_2Cu_3O_7$, we have seen that the transition into the superconducting state represents a secondorder phase transition. [10]

4.2.4 Thermal Conductivity

If we establish a temperature difference ΔT along a rod of length l (taking a simple geometry), heat energy is transported from the hot end to the cold end. The thermal conductivity λ_T is a material parameter and is defined by the equation

$$\frac{\Delta Q}{\Delta t} = \lambda_T \frac{F}{l} \Delta T$$

where $\Delta Q/\Delta t$ is the heat energy per unit time, F and l are the cross-section and length of the rod, respectively, and ΔT is the temperature difference. Here, we assume a linear change of T along the length of the rod.

In a metal, heat transport is due to the conduction electrons as well as lattice vibrations. In general, the contribution of the electrons is much larger than that of the lattice. In this case, from our basic understanding of the superconducting state, we can easily predict how the thermal conductivity should behave for temperatures below T_c . Below T_c, with decreasing temperature more and more conduction electrons are correlated, forming Cooper pairs, and hence are decoupled from the energy exchange. Therefore, below T_c the contribution of the electrons to the thermal conduction becomes smaller and smaller. So we expect that in the superconducting state the thermal conductivity is smaller than in the normal conducting state, as long as it is dominated by the electrons.

This behavior is shown in Figure 4.4 for tin and mercury [17]. Here, we do not want to discuss the temperature dependence of the thermal conductivity in the normal conducting state. We only emphasize the fact that in the superconducting state the thermal conductivity is smaller than in the normal conducting state, as expected. At sufficiently low temperatures, at which practically no free electrons exist anymore in the superconducting state, because of the nearly complete correlation in the form of Cooper pairs, the behavior in a superconductor corresponds exactly to that in an electrically insulating crystal. The electron system is simply decoupled from the thermal behavior. If the superconductivity is suppressed by means of an overcritical magnetic field, then the metal recovers the much larger thermal conductivity of the electron system. Therefore, a superconductor can serve as a thermal switch. In the overcritical fields we have high thermal conductivity; analogous to electric circuits, the switch is closed. At zero field the thermal conductivity is much smaller, and the switch is open. Often such thermal switches represent an important feature of experiments at temperatures below 1mK.

This only applies in the absence of a magnetic field. Otherwise, the phase transition can be of first transition into the normal state, the magnetization changes discontinuously [16].

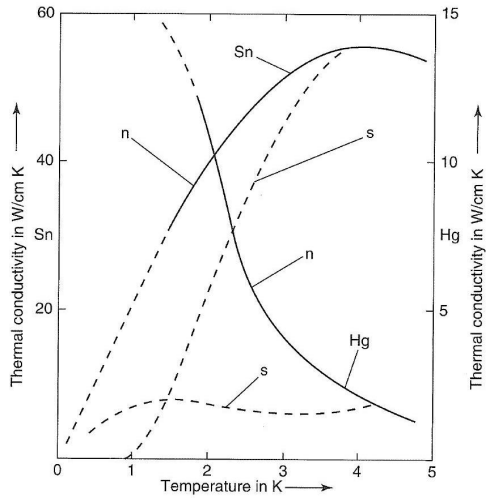

Figure 4.4 Thermal conductivity of pure tin and mercury. (From [16].) The left scale is for

The behavior discussed earlier is characteristic of many metals. However, in alloys or highly impure metals, the situation is much more complex. If chemical impurities are introduced into a metal lattice, the electron mean free path becomes shorter due to collisions between the electrons and the impurities. At low temperatures the corresponding additional electrical resistance is observed in the form of a residual resistance. The reduction of the electron mobility also leads to an increase in the thermal resistance.

In contrast to the electrons, the lattice vibrations, the phonons, are much less hindered in their propagation by atomic lattice defects. [11)] Therefore, the contribution of the phonons to the thermal conductivity is much less affected by such impurities. As a result, the thermal conductivity of the electrons can become smaller than that of the phonons. Then the thermal conductivities in the superconducting and in the normal conducting states differ only little from each other. As an example, we show in Figure 4.5 the thermal conduction of lead-bismuth alloys containing 0.1%Bi[18].

The scattering of a wave at an obstacle becomes strong if the wavelength and the the Fermi energy the matter wave of the electrons has a wavelength of a few

angstroms. Therefore, the electrons are srongly scattered at atomic obstacles. On much longer wavelengths, experience much weaker interaction with the obstacle. If the electronic component of the thermal conductivity becomes much smaller the component due to the phonons, in the superconducting state the thermal than the tivity can become even larger than in the

normal conducting state. This can conductivity in some alloy systems. As an example of this behavior, in Figure 4.5 we show the thermal conductivity of a lead-bismuth alloy containing 0.5%Bi. This behavior can be understood by noting that the electron and phonon systems can also interact with each other, that is, there are collisions between the electrons and the phonons. Such collisions of the electrons with the phonons dominate the total temperature dependence of the electrical resistance. With increasing temperature the lattice vibrations, that is, the number of phonons, increase. As a result, the collisions of the electrons and, hence, the electrical resistance increase with increasing temperature.

In substances in which the phonons provide the dominant contribution to the hermal conduction, we must look at the electron-phonon collisions from the viewpoint of the phonons. These collisions reduce the propagation and, hence, the thermal conduction of the phonons. If the electrons are decoupled in the superconducting state, these collisions are eliminated. The thermal conductivity of the phonon system increases. In this way, we can understand why thermal conduction in the superconducting state can become larger than in the normal conducting state. This is the explanation of the results shown for the Pb − Bi alloys in Figure 4.5. Here we do not want to go any further in our discussion of thermal conductivy. We just mention that, in unconventional superconductors, with decreasing temperature the electronic contribution vanishes much more slowly than in conventional superconductors. This results from the relatively large number of quasiparticles existing in the former also at low temperatures [19]. A similar argument applies if superconducting and normal conducting regions exist next to each other in a sample. This happens in the vortex state of type-II superconductors and also in the so-called intermediate state of type-I superconductors. The latter will be discussed in Section 4.6.4 in more detail.

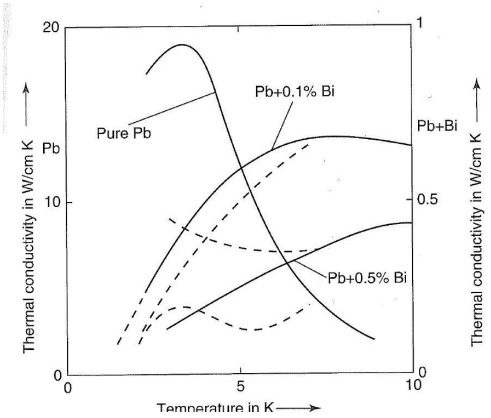

Figure 4.5 Thermal conductivity of lead and lead-bismuth alloys. Solid lines: normal state; dashed lines: superconducting state. (From [18]].)

4.2.5 Vortices: General Properties

Выше мы установили, что для них энергия границы между нормальной и сверхпроводящей фазами $\sigma_{ns} < 0$.

Это означает, что становится энергетически выгодным расслоение образца на области нормальной и сверхпроводящей фаз.

Вначале этой части пособия мы описали, каким образом магнитное поле проникает в сверхпроводник второго рода.

Так, внутри цилиндрического образца образуются вихри.

Каждый вихрь представляет собой цилиндр с нормальной сердцевиной, радиус которого порядка длины когерентности ξ.

В сердцевине параметр порядка $\psi = 0$.

Вокруг этой нормальной сердцевины течет незатухающий сверхток.

Создаваемое им магнитное поле направлено вдоль сердцевины.

Вихревой ток захватывает область радиуса порядка λ - глубины проникновения. Эта область может быть достаточно большой, поскольку для сверхпроводников второго рода $\lambda \gg \xi$.

Один вихрь несет один квант магнитного потока.

Образование вихрей становится энергетически выгодным при внешнем поле $H_0 > H_{c1}$.

Вихри, образовавшись в сверхпроводнике, располагаются на расстоянии порядка λ и образуют в поперечном сечении правильную треугольную решетку.

Возникающее состояние называется смешанным. Это состояние существует при повышении величины внешнего поля до значения H_{c2}, называемого вторым критическим полем.

В этом случае период решетки становится порядка ξ.

Это означает, что вихри соприкасаются своими нормальны ми сердцевинами и параметр порядка ψ обращается в нуль во всем объеме образца.

Вблизи верхнего поля есть область, где решетка плавится.

Кривая намагниченности лля сверхпроводника второго рода ведет себя как показано на рисунке..

(хз как, нет рисунка)

одиночный вихрь

Рассмотрим сверхпроводник второго рода, то есть случай $\lambda \gg \xi$.

Мы хотим показать, что существует область магнитных полей, при которых выгодно образование в толпе сверхпроводника нормальных тонких цилиндрических областей радиуса ξ - вихрей.

Параметр порядка внутри этой области изменяется от 0 до 1.

Вне сердцевины $|\psi|^2 = 1$. Поэтому для больших расстояний $\rho \gg \xi$.

уравнение ГЛ (58) перепишется

$$\operatorname{rotrot} \mathbf{A} = \frac{1}{\lambda^2}\left(\frac{\Phi_0}{2\pi}\nabla\theta - \mathbf{A}\right), \qquad \rho \gg \xi$$

Проинтегрируем его по замкнутому контуру охватывающему нормальную сердцевину вихря.

$$\oint dl \left(\lambda^2 \operatorname{rotrot} \mathbf{A} + \mathbf{A}\right) = \frac{\Phi_0}{2\pi} \oint dl \nabla\theta$$

Если бы не магнитная сердцевина, то фаза волновой функции была бы однозначной аналитической функцией и интеграл в правой части равнялся бы нулю.

Наличие нормальной сердцевины делает сверхпроводянций образец миогосвязным.

В то же время остется требование однозначности волновой функциии.

Это означает, что при обходе по замкнутому контуру фаза может измениться на $2\pi n$ - значение интеграла в правой части (68).

Преобразуем левую часть (68) к поверхностному интегралу, учитывая, что $\operatorname{rot}\mathbf{A} = \mathrm{B}$:

$$\int d\mathbf{S} \left(\lambda^2 \operatorname{rotrot} \mathbf{B} + \mathbf{B}\right) = n\Phi_0$$

Поскольку интеграл в левой части не зависит от контура (главное, что он охватывает сердцевину!), то формально можно считать, что подынтегральная функция есть δ -функция. Поэтому

$$\lambda^2 \operatorname{rot}\, \operatorname{rot}\mathbf{B} + \mathbf{B} = n\Phi_0\delta(\rho)$$

Всюлу вне сердцевины при$\rho \gg \xi$ имеем

$$\text{rotrot}\,\mathbf{B} = -\frac{1}{\lambda^2}\mathbf{B}$$

Раскры вая левую часть этого выражения по известной формуле, получим

$$\Delta \mathrm{B} = \frac{1}{\lambda^2}\ \mathrm{B}$$

В цилинлрических координатах имеется только одна z -компонента h_z. Поэтому для нее имеем

$$\frac{1}{\rho}\frac{\partial}{\partial\rho}\rho\frac{\partial}{\partial\rho}h_z = \frac{\rho}{\lambda^2}$$

$\Pi_{\text{vCTb}} h_z = f(x), x = \rho/\lambda$. Тогда

$$xf'' + f' - xf = 0$$

Это - уравнение Бесселя. Нас инересует его решение в окрестности вихря, то есть при $\rho < \lambda$. При малых значениях аргумента $f = \ln x$.(Это легко проверить непосредственной подстановкой). Поэтому магнитное поле в окрестности оси вихря имеет вид

$$h \sim \ln\left(\frac{\lambda}{\rho}\right), \xi < \rho < \lambda$$

Точное решение уравнения (69) при условии$h(\infty) = 0$ имеет вил

$$h = \frac{\Phi_0}{2\pi\lambda^2}K_0(\rho/\lambda)$$

K_0 - функция Макдональда, ассимптотика которой $K_0(z) \propto \ln(1/z)$ при $z \ll 1$ приводит к (72). Это позволяет оценить поле в центре вихря с логарифмической точностью

$$h(0) \simeq h(\xi) \simeq \frac{\Phi_0}{2\pi\lambda^2}\ln(\xi/\lambda)$$

(???????)

4.2.6 Critical field of superconductors 1

Using the methods of thermodynamics, we look at the stability of the Meissner phase of type-I superconductors as a function of the temperature and of the applied magnetic field. We will see that in the simplest case the critical field of these superconductors, at which the transition from the Meissner phase into the hormal conducting phase sets in, is identical with the thermodynamic critical field discussed in Section 4.4. However, we will also see that one observes a much more complex behavior if the magnetic field at the sample edge differs from the applied field because of the shape of the sample.

We will also use thermodynamics to understand the behavior of superconductors under pressure.

Первое критическое поле

Исходим из функционала Гинзбурга-Ландау для свободной энергии

$$\mathcal{F}_{sH} = \mathcal{F}_n + \int dV\left[\alpha|\Psi|^2 + \tfrac{\beta}{2}|\Psi|^4 + \tfrac{1}{4m}\left|-i\hbar\nabla\Psi - \tfrac{2e}{c}\mathbf{A}\Psi\right|^2 + \tfrac{(\text{rot}\,\mathbf{A})^2}{8\pi}\right]$$

Напомним выражения для длины когерентности и глубины проникновения магнитного поля

$$\xi^2 = \frac{\hbar^2}{4m|\alpha|}$$
$$\lambda^2 = \frac{mc^2}{4\pi n_s e^2} = \frac{mc^2\beta}{8\pi e^2|\alpha|}$$

Если вихря нет, то поскольку внутри сверхпроводника микроскопическое поле B = 0, то вклал в свободнут энергиго (74) дает только верхняя строка.

Энергией вихря будем называть свободную энергиго, определяемую нижней строкой в, то есть будем ее отсчиты вать от свобоной энергии состояния без вихрей. Нас интересует случай $\lambda \gg \xi$.

Поэтому можно пренебречь свободной энергией, сосредоточенной в объеме нормальной сердцевины.

Кроме того, поскольку мы интересуемся расстояниями $\rho > \xi$, где параметр порядка практически не изменяется, можно считать $|\Psi|^2 = |\Psi_0|^2 = \frac{|\alpha|}{\beta}$. По этой причине в (39) можно пренебречь квантовым членом$-i\hbar\nabla\Psi$. Поэтому из (39) для вычисления энергии вихря остается только выражение

$$\varepsilon = \int dV \left(\frac{e^2}{mc^2}\mathbf{A}^2\frac{|\alpha|}{\beta} + \frac{h^2}{8\pi} \right)$$

Во втором уравнении ГЛ (58)

$$\operatorname{rotrot}\mathbf{A} = \frac{|\psi|^2}{\lambda^2}\left(\frac{\Phi_0}{2\pi}\nabla\theta - \mathbf{A}\right)$$

опустим квантовый градиентный член. Тогда

$$\mathbf{A} = \left(\frac{\lambda}{|\psi|}\right)^2 \operatorname{rotrot} A = \left(\frac{\lambda}{|\psi|}\right)^2 \operatorname{rot}\mathbf{B}$$

Подставляя (77) в (78), получим

$$\varepsilon = \frac{1}{8\pi}\int dV \left(\lambda^2(\operatorname{rot}\mathbf{B})^2 + \mathbf{B}^2\right)$$

Заметим, что, как и следовало ожидать при$\lambda \gg \xi$, это есть Лондоновское вы ражение, (20),

$$\operatorname{rotrot}\mathbf{A} = \frac{|\psi|^2}{\lambda^2}\left(\frac{\Phi_0}{2\pi}\nabla\theta - \mathbf{A}\right)$$

опустим квантовый градиентный член. Тогда

$$\mathbf{A} = \left(\frac{\lambda}{|\psi|}\right)^2 \operatorname{rotrot} A = \left(\frac{\lambda}{|\psi|}\right)^2 \operatorname{rot}\mathbf{B}$$

Подставляя (77) в (78), получим

$$\varepsilon = \frac{1}{8\pi}\int dV \left(\lambda^2(\operatorname{rot}\mathbf{B})^2 + \mathbf{B}^2\right)$$

Заметим, что, как и следовало ожидать при$\lambda \gg \xi$, это есть Лондоновское вы ражение, (20),

Применим к выражению $(\mathrm{rot}\,\mathbf{B})^2 = \mathrm{rot}\,\mathbf{B}\cdot\mathrm{rot}\,\mathbf{B}$ формулу

$$\mathrm{arot}\,\mathbf{b} = \mathrm{b\ rota} - \mathrm{div}[\mathbf{a},\mathbf{b}]$$

Tor/a

$$(\mathrm{rot}\,\mathbf{B})^2 = \mathbf{B}\,\mathrm{rotrot}\,\mathbf{B} - \mathrm{div}[\mathrm{rot}\,\mathbf{B},\mathbf{B}]$$

По теореме Гаусса

$$\int \mathrm{div}[\mathrm{rot}\,\mathbf{B}\times\mathbf{B}] = \oint d\mathbf{S}[\mathrm{rot}\,\mathbf{B}\times\mathbf{B}]$$

Напомним, что нас интересует цилиндрическая геометрия, когда вектор B направлен по осиz. Вычислим энергию вихря единичной длины, ограниченного плоскостями$z = 0, z = 1$. Интеграл по торцевым окружностям равен нули, так как вектор [rotB$\times$ B] лежит в плоскости этих торцов. Поскольку поле вихря B $\to$ 0, при $\rho \to \infty$, то интеграл и по бесконечно удаленной цилиндрической поверхности в (81) обрашается в нуль. Итак,

$$\varepsilon = \frac{1}{8\pi}\int dV\left[\mathbf{B}\left(\lambda^2\,\mathrm{rotrot}\,\mathbf{B} + \mathbf{B}\right)\right]$$

В силу уравнения (69), выражение в круглых скобках есть δ -функция. Поэтому, используя (73), получим

$$\varepsilon = \frac{\Phi_0\mathbf{B}(0)}{8\pi} = \left(\frac{\Phi_0}{4\pi\lambda}\right)^2\ln(\xi/\lambda)$$

Во внешнем поле минимум должна иметь энергия Гиббса

$$\varepsilon_1 = \varepsilon - \int\frac{\mathrm{BH_0}}{4\pi}dV$$

$\mathrm{H_0}$ можно вынести за знак интеграла. Если считать, что вихрь несет один квант

$$\int\frac{\mathrm{B}}{4\pi}dV = \int\limits_0^1 dz\int\frac{\mathrm{B}}{4\pi}d\ \mathrm{S} = \frac{\Phi_0}{4\pi}$$

Итак

$$\varepsilon_1 = \left(\frac{\Phi_0}{4\pi\lambda}\right)^2\ln(\xi/\lambda) - \frac{\Phi_0\mathrm{H_0}}{4\pi}$$

Отсюда следует, что в слабом магнитном поле$\varepsilon_1 > 0$ и образование вихря невыгодно. Из (86) следует, что минимальное поле при котором $\varepsilon_1 < 0$ есть

$$H_{c1} = \frac{\Phi_0}{4\pi\lambda^2}\ln(\xi/\lambda) = \frac{\Phi_0}{4\pi\lambda^2}\ln(x)$$

Это поле называется первъи критическим полем, при котором внешнее магнитное поле начинает проникать в сверхпроводник. Вспоминая оценку (66), получим

$$H_{c1}\,(T\to T_c) \sim H_{c1}(0)\,(T_c - T)$$

второе критическое поле

Найдем теперь второе критическое поле, при котором почти весь образец находится в нормальном состоянии, то есть параметр порядка Ψ - мал. Из первого уравнения Гинзбурга-Ландау имеем

$$\xi^2\left(i\nabla + \frac{2\pi}{\Phi_0}\mathbf{A}\right)^2\psi = a\psi, a = 1 - |\psi|^2$$

В сильном поле сверхпроводящая фаза слаба, и в уравнении (89) нелинейность проявляется только в том смысле, что собственное значение линейного уравнения

$$a < 1$$

Подставим в уравнение (89) потенциал $\mathbf{A} = (0, Bx, 0)$:

$$-\xi^2 \frac{\partial^2 \psi}{\partial x^2} + \xi^2/\hbar^2 \left(i\hbar\nabla + \frac{2e}{c} Bx \right)^2 \psi - \xi^2 \frac{\partial^2 \psi}{\partial z^2} = a\psi$$

Похожее уравнение решалось в разделе о магнетизме электронного газа. Если установить соответствие

$$m' = \frac{\hbar^2}{2\xi^2}, e' = 2e$$

то получим уравнение движения электрона в магнитном поле

$$-\frac{\hbar^2}{2m'} \frac{\partial^2 \psi}{\partial x^2} + \frac{1}{2m'} \left(-i\hbar\nabla - \frac{e'}{c} Bx \right)^2 \psi - \frac{\hbar^2}{2m'} \frac{\partial^2 \psi}{\partial z^2} = a\psi$$

Минимальное собственное значение уравнения (91) есть$a = \frac{\hbar e' B}{2m'c} = \frac{2eB\xi^2}{\hbar c}$. Нас интересует решение этого уравнения, когда$a < 1$. Итак, решение уравнения (90) cymecrisyer($npua <$ 1), если

$$\frac{2eB\xi^2}{\hbar c} < 1$$

Тогда верхнее критическое поле опрелелится критерием

$$H_{c2} = \frac{\hbar c}{2e\xi^2}$$

Это условие имеет простой физический смысл. Во внешнем поле $H \sim H_{c2}$ поле почти полностью проникает в образец. Это означает, что расстояние между вихрями становится поря,ха толщины сердцевины вихря.и поле внутри сверхпроводника $h \sim .H_{c2}$. Слеловательно о дин вихрь несет магнитны й поток по порядку величины равный$\xi^2 H_{c2}$. С другой стороны, этот поток равенΦ_0, что и отражает критерий (92)

Заметим, что при приближении H_0 к H_{c2} параметр порядка $|\Psi|^2 = 1 - H_0/H_c$ Строгий анализ, основанный на уравнениях Гинзбурга-ландау, показывает, что в сверхпроводниках второго рода, для которых $x > 1/\sqrt{2}$, в интервале $H_{c1} < H_0 < H_{c2}$ образуются вихри. Эти вихри отталкивалтся друг от друга и образуют двумерную решетку, составленную из равносторонних треугольников. При наличии гралиента внешнего магнитного поля вихри могут двигаться, но примеси их останавливают (пиннинг). Это явление аналогично движению и пиннингу дислокаций в реальных кристаллах.

4.2.7 Critical field of superconductors 2

Critical Field and Magnetization of Rod-Shaped Samples

Figure 4.9 shows again the Meissner-Ochsenfeld effect for a rod-shaped superconductor. If the length l of the rod is much larger than the diameter, the magnetic field is slightly distorted only at the ends. Along the rod practically we have the same field B_2 as in a large distance from the rod. For simple shapes of the sample (ellipsoids with principal axis parallel to the field), we can

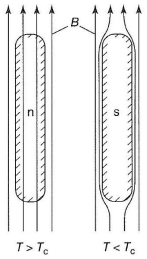

Figure 4.9 Magnetic field expulsion for a rod-shaped sample. The sample is cooled down in the field *B*.

express the influence of the sample geometry by a number, the demagnetization coefficient N_{M}. For a long rod in a magnetic field parallel to its axis, the demagnetization coefficient is $N_{\mathrm{M}} = 0$. In this case, the magnetic field at the surface must not be corrected, since it is identical with the external field B_{a} at a large distance from the sample. This illustrates the particular simplicity of this sample geometry.

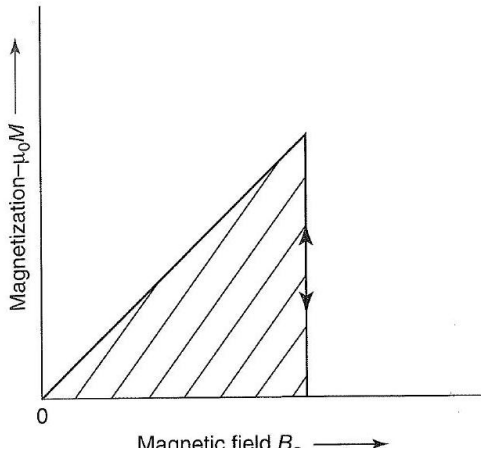
Because of its significance, we want to also present the field expulsion in the Meissner phase in a different way. Because of the shielding currents, which completely compensate the external field in the interior of the rod-shaped sample, the rod carries a magnetic moment m. Formally, we can speak of a magnetization M by writing $M = m/V$, where V is the sample volume. This magnetization corresponds to that of an ideal diamagnet with the susceptibility [17)] $\chi = -1$.

In Figure 4.10 we show this magnetization M as a function of the external field B_{a} for a long rod with its axis oriented parallel to the field. Following the standard custom, the negative magnetization is plotted versus the external magnetic field. The magnetization increases proportional to the external field. The superconductivity breaks down only if the critical field is exceeded.

In Figure 4.11 the magnetic field B_i observed in the interior of the sample, say, within a narrow channel parallel to the axis, is plotted versus the external field B Because of the shielding current, the inner field B_{i} remains exactly zero until the critical field B_{c} is reached. [18)] For all external fields $B_{\mathrm{a}} > B_{\mathrm{c}}$ we have $B_{\mathrm{i}} = B_{\mathrm{a}}$, since the sample is normal conducting in this case.

The thin surface layer, into which the magnetic field penetrates, can be neglected for this integral look at the sample.

Here, we explicitly utilize the fact that the external field is compensated by the macroscopic currents flowing at the surface. To describe the magnetic fields in the interior of a substance, we must know the mechanism causing the magnetic behavior. How the magnetization is accomplished remains for the external magnetic field



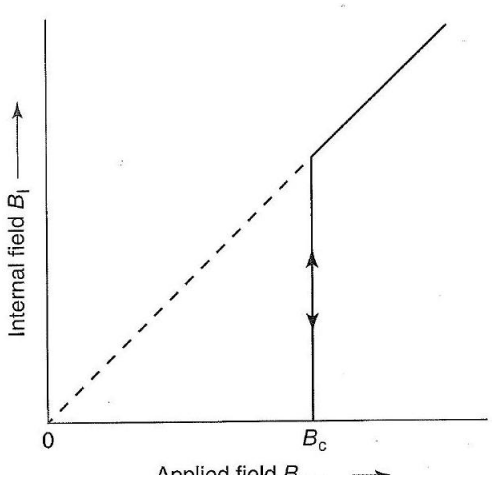


Figure 4.10 Magnetization of a rod-shaped sample ($N_M = 0$) in a magnetic field parallel to the axis, During a reversible transition, the same curve is followed for increasing and decreasing field B.

Applied field B_a $\longrightarrow$ Figure 4.11 Magnetic field in the interior of a rod-shaped sample ($N_M = 0$) in a mag- netic field parallel to the axis. During a reversible transition, the same curve is followed for increasing and decreasing field B.

Figures 4.10 and 4.11 present the same information. Both plots are used frequently, and they are adjusted to different experiments: measurement of M by means of the induction or of B_i, say, by using a Hall probe. [19] The difference between type-I and type-II superconductors is clearly seen from the variation of M or of B_i as a function of B_a (see Section 4.7.1).

Modern Hall probes allow measurements of the magnetic field with high sensitivity. One observes the electrical voltage generated perpendicular to the electric current and to the magnetic fied because of the Lorentz force. The Hall voltage is proportional to the applied magnetic field.

We note that the measurement of the magnetization represents a very simple method for determining the transition temperature T_c. One places the sample within an induction coil and measures the self-inductance as a function of the temperature using a small a.c. magnetic field. The self-inductance drops abruptly if superconductivity sets in. Compared to a measurement of the electrical resistance by means of a current-voltage curve (see Section 1.1), this magnetic measurement of the transition temperature has the advantage that the shielding currents must flow along the total sample surface in order to provide the shielding. Frequently, inhomogeneous samples, where the current-voltage measurement can indicate superconductivity because of a single continuous current path, do not show perfect shielding, in this way signaling the inhomogeneity. [20]

Now we apply the rules of thermodynamics to the Meissner state. We start from the Eq. (4.9):

$$\mathrm{d}G = -S\ \mathrm{d}T + V\ \mathrm{d}p - m\ \mathrm{d}B$$

First, we consider the superconducting phase in the absence of a magnetic field. Then the term mB vanishes. Furthermore, we keep the superconductor at con stant pressure and only vary the temperature. For $T < T$ the Gibbs function G_s of the superconductor must be smaller than G_n, the Gibbs function of the normal conductor. At $T = T_c$, we have $G_s = G_n$

We can determine the difference $G_n - G_s$, which is a measure of the stability of the superconducting state, as a function of the temperature. We use the fact that the superconducting phase becomes unstable in the presence of a sufficiently strong external magnetic field. The reason for this is an increase in G_s with increasing field B, resulting in the fact that above a critical field G_s will be larger than G_n and, hence, will become unstable. Practically, the Gibbs function G_n of the normal conducting phase is independent of the magnetic field, since at least in most cases in the normal conductor the generated magnetic moments are very small.

For obtaining $G_\mathrm{n} - G_\mathrm{s}$ as a function of T, we must determine the critical field B_c at different temperatures. Then the term $\int_0^{B_c} m \, \mathrm{d}B$ yields $G_\mathrm{n} - G_\mathrm{s}$ at the corresponding temperature. We have

$$G_\mathrm{s}(B) - G_\mathrm{s}(0) = -\int_0^B m \, \mathrm{d}B$$
$$G_\mathrm{n}(B) - G_\mathrm{n}(0) = 0$$
$$G_\mathrm{n}\left(B_\mathrm{c}\right) - G_\mathrm{s}\left(B_\mathrm{c}\right) = 0$$

The first equation is found by integrating Eq. (4.9) at constant temperature and constant pressure. At B_c the Gibbs functions G_s and G_n must be just equal. From these three equations, one finds

$$G_\mathrm{n}(T) - G_\mathrm{s}(T) = -\int_0^{B_\mathrm{c}(T)} m \, \mathrm{d}B$$

Since in equilibrium the magnetic moment of the superconductor must always be oriented antiparallel to B, we have $G_\mathrm{n}(T) > G_\mathrm{s}(T)$ for all $T < T_\mathrm{c}$.

For a more quantitative statement about the difference between the Gibbs funcions of the superconducting and normal conducting phases, we must know the agnetic moment m as a function of B. Now we restrict ourselves to the rodhaped sample geometry, and we assume a spatially constant external magnetic field. In this case, the local magnetic moment m and the magnetization M are simply connected with each other:

$$m = MV$$

Here, V is the sample volume, taken to be independent of the magnetic field, the pressure, and the temperature. With these conditions, we have

$$G_\mathrm{n} - G_\mathrm{s} = -V \int_0^{B_\mathrm{c}} M \, \mathrm{d}B$$

For additional information, we must know the magnetization M as a function of B. For a "thick" rod of a type-I superconductor, [21)] we have $\chi = -1$. Then the magnetization is in good approximation

$$M = \chi \frac{B}{\mu_0} = -\frac{B}{\mu_0}$$

where $\mu_0 = 4\pi \times 10^{-7}$ V s/A m. This yields the following simple expression for $G_\mathrm{n} - G_\mathrm{s}$

$$G_\mathrm{n} - G_\mathrm{s} = \frac{V}{\mu_0} \int_0^{B_\mathrm{c}} B \, \mathrm{d}B = V \frac{B_\mathrm{c}^2}{2\mu_0} = V \frac{B_\mathrm{cth}^2}{2\mu_0}$$

Now we can calculate quantitatively the difference $G_n - G$ if we have determined the critical field B_c as a function of T for our simple geometry.

For a "thick" superconductor with fully developed shielding, the critical field B is identical to the thermodynamic field B_cth . We can see this from Eq. (4.21), if we integrate the latter over the sample volume. However, for a "thin" superconductor, with dimensions comparable to the London penetration depth, B_c is larger than B_cth (see Section 4.6.3).

The area under the magnetization curve of the "thick," rod-shaped type-I superconductor, multiplied by the sample volume V, yields the difference of the thermodynamic potentials, $G_{\mathrm{n}} - G_{\mathrm{s}}$, in the field $B = 0$. However, we also emphasize that in

In principle, we can also use Eq. (4.48) for a type-II superconductor. Then we must integrate up to the upper critical field B_{c2}, and the particular dependence $M(b)$ of these superconductors n us be

the case of a more complicated dependence of the magnetization on the external field, as we will see for type-II superconductors, the area under the magnetization curve $M(B)$ always yields the difference of the Gibbs functions, $G_{\mathrm{n}} - G_{\mathrm{s}}$. The only assumption is that the magnetization is reversible, that is, it is established only by means of equilibrium states. Reversibility exists if the same magnetization curve is obtained for increasing and for decreasing external fields. In the case of the "hard superconductors," which we will discuss in Section 5.3.2, this reversibility is absent.

In Figure 4.12 the critical field B_{c} is plotted versus the temperature for different type-I superconductors. For all temperatures $T < T_{\mathrm{c}}$, the experimental data are well approximated by the empirical expression:

$$B_{\mathrm{c}}(T) = B_{\mathrm{c}}(0)\left[1 - (T/T_{\mathrm{c}})^2\right]$$

Near T_{c}, this dependence approaches the linear dependence on temperature, as described by the Ginzburg-Landau theory.

3. Critical field by AGD

The so-called critical magnetic field H_0 is an important thermodynamic quantity in the theory of superconductivity. At a given temperature

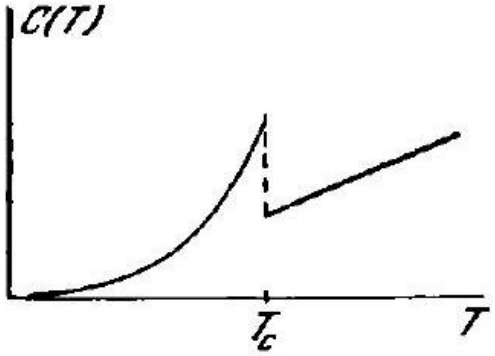

Fig. 98 $T < T_c$, a metal in a magnetic field may find itsclf both in the superconducting and in the normal state.

If a superconductor is situated in a magnetic field, the surface currents screening the field produce a magnetic moment, which interacts with the external field. The additional energy arising from this interaction is - (H.M)/2 (per unit volume). Let us consider a superconducting cylinder located in a field parallel to the cylinder axis. Having found the surface current from the condition that the magnetic field be equal to zero in the body of the superconductor, and having determined the magnetic moment produced by these currents, we discover that the extra magnetic energy is $H^2/8\pi$, i.e. the free energy of the superconductor in the magnetic field is $\boldsymbol{F_{8H}} = \boldsymbol{F_B} + (\boldsymbol{H}^2/8\pi)$. Thus a transition from the superconducting to the normal phase occurs when the magnetic field is increased at a given temperature; this transition is a first order transition. The critical ficld is

$$\frac{H_c^2}{8\pi} = F_n - F_s.$$

We shall again confine ourselves to limiting cases. At low temperatures ($T \ll T_c$), we obtain from (36.3) and (36.7), neglecting exponentially small terms:

$$H_c(0) = \sqrt{\frac{2mp_0}{\pi}}\Delta_0 = T_c\frac{\pi}{\gamma}\left|\frac{\sqrt{2mp_0}}{\pi}\right. \tag{36.10}$$

and

$$H_c(T) = H_c(0)\left(1 - \frac{\gamma^2}{3}\frac{T^2}{T_c^2}\right) \tag{36.11}$$

On using (36.9) and expressing $H_c(T)$ close to the transition point in terms of $H_c(0)$ with the aid of (36.10), the temperature dependence $H_c(T)$ in the region close to T_c is found to be

$$H_c(T) = H_c(0)\gamma/\left.\frac{\overline{8}\bar{\zeta}(3)}{7\bar{\zeta}\left(1-\frac{T}{T_c}\right)}\right) \simeq 1\cdot 73H_c(0)\left(1-\frac{T}{T_c}\right). \tag{36.12}$$

Notice that the experimental data usually correspond to the function

$$H_c(T) = H_c(0)\left(1 - \frac{T^2}{T_c^2}\right) \tag{36.13}$$

The theoretical formulac (36.11) and (36.12) are in fairly close agreement with the experimental relationship (36.13) in both the limiting cases (see [58], [63]).

4.2.8 Critical Magnetic Field of Thin Films in a Field Parallel to the Surface

The behavior of thin films depends sensitively on the penetration depth, if the film thickness d becomes comparable to λ_{L}. We discussed this already in Section 1.4 (Figures 1.14 and 1.15). As a result, we found that the magnetic field varies within the plate as given by Eq. (1.22):

$$B_z(x) = B_{\mathrm{a}}\frac{\cosh\left(x/\lambda_{\mathrm{L}}\right)}{\cosh\left(d/2\lambda_{\mathrm{L}}\right)}$$

The critical field in a thin film represents a highly important subject. As the critical field, we understand the field that must be applied to completely destroy the superconductivity, that is, to make G_{s} equal to G_{n}. With decreasing film thickness, this critical field B_{c} becomes larger and larger. For a thickness $d \ll \lambda_{\mathrm{L}}$ it can be larger by more than a factor 10 than the thermodynamic field B_{cth} we observe, when the shielding layer is fully developed.

This surprising result can be understood in a simple way. In Section 4.1 we saw that the free enthalpy of the superconducting state increases with the external field B_{a}. Because of Eq. (4.45) we have $G_{\mathrm{s}}(B) - G_{\mathrm{s}}(0) = -\int_0^B m\,\mathrm{d}B$, where m denotes the magnetic moment of the sample, which is generated by the shielding toward the interior of the superconductor is fixed current density j_{s} and its decay dently of the macroscopic sample dimensions. For samples that are smaller than or comparable to the penetration depth in at least one dimension, the connection between the external field and the shielding current becomes dependent on the sample geometry. With decreasing thickness, say, of our film, for constant B_{a}, the shielding currents become smaller and smaller. This means that for the thin superconductor, the free enthalpy increases more slowly with increasing B_{a} than for the "thick" superconductor. Therefore, higher fields B_{a} are needed to make G_{s} equal to G_n.

Qualitatively, we can see this very clearly from Figure 1.16. The decrease in the magnetic field in the interior of the layer is a measure of the diamagnetic sample behavior. With decreasing layer thickness, the decrease in the field in the interior and, hence, the diamagnetism become smaller and smaller. In order to make G_s equal to G_n by means of an external magnetic field, with decreasing layer thickness we must apply larger and larger external magnetic fields.

We want to estimate this in the limit $d \ll \lambda_L$. From the general relation $B(x) = B_2 + \mu_0 M(x)$ and Eq. (1.22) or (4.60), within the adopted approximation, we find $M(x) \approx B_a (4x^2 - d^2) / (8\mu_o \lambda_L^2)$. Following a simple calculation, for the magnetization averaged over the plate one finds

$$M \approx -B_a d^2 / \left(12\mu_0 \lambda_L^2\right)$$

which differs from expression (4.49) for the "thick" superconductor by a factor $d^2/(12\lambda_L^2)$. By inserting this magnetization into Eq. (4.48), we obtain a critical magnetic field that is larger than the critical field B_{cth} of the "thick" superconductor by a factor $12^{1/2}\lambda_r/d$.

We summarize the important result of this section: For superconductors that are comparable with the penetration depth in at least one dimension, the external field B_a needed for canceling the superconductivity is larger than the thermodynamic critical field. This result will be highly important in the following.

4.2.9 The Intermediate State

Following the results of the last section, the following question comes up: Why is it possible that the superconducting state becomes unstable because of an overcritical magnetic field? From the results of Section 4.6.3 we could expect that, upon reaching the critical field, the superconductor splits up into very fine domains parallel to the magnetic field and alternately consisting of superconducting and normal conducting phase. Then the superconducting domains could be thin compared to the penetration depth and could sustain a larger magnetic field without becoming unstable.

From experience we know that this is not the case. Instead, the superconducting state of a rod-shaped sample ($N_M = 0$) becomes unstable when the critical field is reached. From this, we must conclude that a separation into many fine domains is energetically unfavorable. This can be understood from a simple idea. Each interface between a normal conducting domain and a superconducting domain carries an additional energy, the wall energy. This energy does not allow the splitting of a type-I superconductor into many fine domains. The energy needed for this would make this state energetically less favorable than the normal conducting state.

This wall energy is taken into account by the gradient term in the Ginzburg-Landau theory (see Eq. (4.26)). It controls the magnetic flux structure of the so-called intermediate state. The intermediate state refers to situation in which a homogeneous type-I superconductor is neither completely superconducting nor completely normal conducting. Such configurations can be realized very simply by means of the geometric shape of the sample.

We consider a superconducting sphere in a homogeneous external field B_a (Figure 4.14). The shielding currents flowing within a thin surface layer keep the interior of the sphere free of magnetic field. As we can see from Figure 4.14, at the surface of the sphere near the equator, this expulsion of the magnetic field results in an enhancement of the field. The actual behavior of the field is given by the superposition of the homogeneous external field B_a and the field generated by the shielding currents.

Apparently the field enhancement results from the sample geometry. For simple geometric shapes it can be taken care of by the demagnetization coefficient (see Section 4.6.1). One can show that homogeneous samples with the shape of an ellipsoid display a homogeneous magnetization in a homogeneous external magnetic field. If one principal axis of the ellipsoid is

oriented parallel to the external field, then the magnetization is also parallel to this field. This magnetization changes the magnetic field experienced by the sample. The maximum value of this field is referred to as the effective magnetic field B_{eff} .

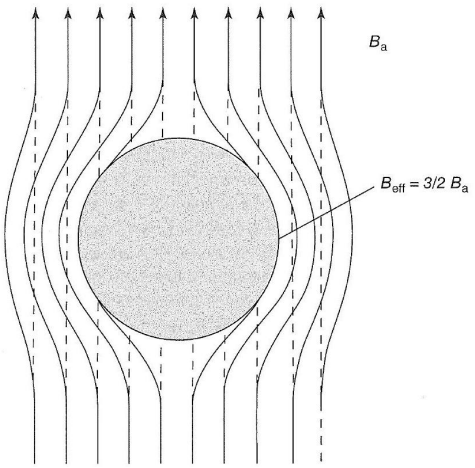

Figure 4.14 Expulsion of magnetic field (solid field lines) from a superconducting sphere. In the absence of the sphere, the field is homogeneous (dashed field lines).

It is given by

$$B_{\text{eff}} = B_{\text{a}} - N_{\text{M}}\mu_0 M$$

For a superconductor with a complete Meissner effect, the magnetization M is related to the effective field B_{eff}

$$M = -\frac{B_{\text{eff}}}{\mu_0}$$

Hence, we have

$$B_{\text{eff}} = B_{\text{a}} + N_{\text{M}} B_{\text{eff}}$$

$$B_{\text{eff}} = \frac{1}{1 - N_{\text{M}}} B_{\text{a}}$$

The effective magnetic field is just the field at the equator at the surface. If the demagnetization coefficient N_{M} is known, the field at the equator can be calculated. For example, for a sphere we have $N_{\text{M}} = 1/3$. Hence, for the ideal diamag netic sphere, we obtain

$$B_{\text{eff}} = \frac{3}{2} B_{\text{a}}$$

Because of the field expulsion, for a demagnetization coefficient $N_{\text{M}} > 0$ it is possible to choose a value of the external field B_{a} at which the superconductor is neither completely superconducting nor completely normal conducting. We look at the sphere somewhat closer. If we increase the external field B_{a}, at the value $B_{\text{a}} = 2/3\ B_{\text{eff}}$ the critical field B_{c} is reached at the equator. If B_{a} is increased further, at the equator the superconductivity must be destroyed. However, the sphere cannot become completely normal conducting, since in this case the field in the interio would be equal to the external field and, hence, would be smaller than B_c. The superconductor enters the intermediate state, that is, it splits up into superconducting and normal conducting domains.

Before we discuss this domain structure in more detail, we want to describe the behavior in the intermediate state phenomenologically. At $B_{\text{a}} = B_{\text{c}}$ the sample must be completely

superconducting. It turns out that, in the total regime $2/3B_c < B_a < B_c$, at the equator exactly B_c is observed. With increasing B_a, the normal conducting fraction in the interior of the sphere increases exactly in such a way that the remaining field expulsion yields the value B_c at the equator.

We could say also that in the intermediate state the demagnetization coefficien N_M becomes dependent on B_a. If we measure the magnetic flux by means of an induction coil wound around the equator, then this flux Φ increases monotonically with increasing B_2. This behavior is shown in Figure 4.15.

The magnetic flux structure of a sphere in the intermediate state has been investigated in detail [29, 30]. There exist normal conducting and superconducting domains next to each other. Hence, there are interfaces separating the normal conducting from the superconducting phase. These interfaces are stabilized because

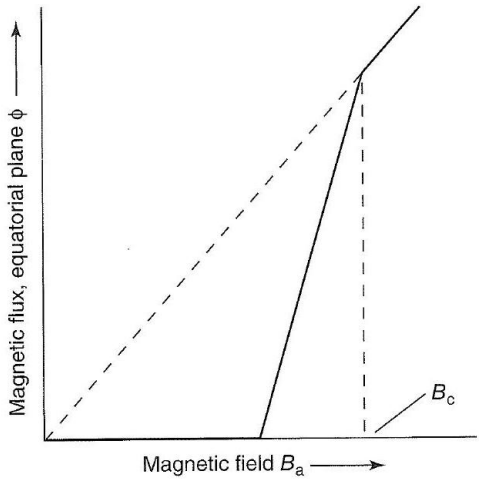

Figure 4.15 Magnetic flux Φ passing through the equatorial plane of a sphere plotted versus the external field B

of the appearance of the critical field parallel to the external magnetic field. For each intermediate state structure, the phase boundaries must be oriented parallel to the magnetic field. This statement is always valid. In the case of more complicated intermediate state structures, as can appear in superconductors in an external magnetic field and for a simultaneous flow of an electric transport current (see Section 5.2), this can lead to surprising effects.

Since the development of the phase boundaries requires an amount of wall energy, the splitting into domains cannot take place on an arbitrarily fine scale. The sample must adopt a state in which larger superconducting and normal conducting domains exist next to each other. This configuration is determined by the fact that the free enthalpy of the system reaches a minimum. This requirement allows us to determine the wall energy from measurements of the intermediate state structure.

We cannot discuss such calculations in detail. We want to mention only a few particularly simple results. In the case of a sphere, the transition into the intermediate state should happen at the field $B_a = 2/3B_c$. However, this transition is accompanied by the generation of interfaces. Because of the positive wall energy, a finite amount of energy is needed for this. This energy must be supplied by the magnetic field. Therefore, the transition into the intermediate state does not occur exactly at $B_2 = 2/3B_c$, but at a slightly higher field instead. The field is expelled beyond the critical field until the stored field energy suffices for generating the necessary interfaces. This excess field was observed for wires in a perpendicular magnetic field and was interpreted in the way we have discussed [29].

The magnetic flux structures in the intermediate state have been investigated in detail by means of different experimental methods. Small bismuth wires were used to probe the

superconducting and normal conducting domains of a sphere fabricated from tin [30]. For this purpose the sphere was cut into two halves along a plane through the equator, and subsequently the two halves were fixed togethe in such a way that a small opening of only a few tenths of a millimeter remained. The bismuth wires acting as magnetic field probes could be inserted into this opening. Then their electrical resistance, which for bismuth depends sensitively on the magnetic field, was measured. The normal conducting domains are detected by means of the magnetic field that they carry. On the other hand, the superconducting domains remain free of field. The small opening between the two hemispheres distorts these domains only very little, since the domain boundaries are oriented parallel to the magnetic field. With this technique the configuration of the intermediate state could be imaged [31]

Much more direct methods have since been utilized, which provide immediately a complete image of the flux structure. Among others, these are the following:22)

the decoration of superconducting domains using a diamagnetic powder; 2) the imaging of normal conducting domains by means of the Faraday effect.

In the first method, a fine powder of a superconducting material is sprinkled onto the sample residing in the intermediate state. Mostly one uses niobium pow der [32], which remains fully superconducting for the magnetic fields needed to establish the intermediate state, in the case of many superconductors with a value superconducting niobium grains are ideal diamagnets. They are expelled from the regions with a high magnetic field, and they accumulate on the locations at the surface where the superconducting domains are. Figure 4.16 shows such an image of the intermediate state of an indium plate [32]. Another example is presented in Figure 5.5 for the case of the intermediate state in a wire carrying an electric transport current [33].

The second method has been described already in Section 12 Compared to the powder decoration, it has the advantage that it can also record movements, that is, temporal changes, of the intermediate state structure. Highly impressive motion pictures of the intermediate state in motion have been produced. In Figure 4.17 we present an image of the intermediate state obtained in this way.

4.2.10 Critical Magnetic Fields for Type-II SC

Fast Estimations of H_{c1}

У сверхпроводников II рода разрушение сверхпроводимости магнитным полем происходит в два этапа. По сложившейся традиции будем считать, что образец представляет собой длинный, вытянутый вдоль поля цилиндр. Тогда из равенства тангенциальных составляющих внешней $\mathcal{H}_0$ и внутренней $\mathcal{H}$ напряженностей следует, что внешнее поле задает внутри сверхпроводника величину именно напряженности магнитного поля $\mathcal{H}$.

Если внешнее магнитное поле меньше нижнего критического поля $\mathcal{H}_{c1}$, то сверхпроводник ведёт себя так же, как и сверхпроводник I рода, обнаруживая идеальный диамагнетизм (полный эффект Мейсснера, $\mathcal{M} = -\mathcal{H}/4\pi$). Выше $\mathcal{H}_{c1}$ становится выгодным проникновение с поверхности вглубь образца вихрей Абрикосова, которые образуют в материале устойчивую треугольную решётку и уменьшают намагниченность. При увеличении внешнего поля вихревая решётка становится всё плотней, и при верхнем критическом поле $\mathcal{H}_{c2}$ «коры» вихрей сливаются. Образец полностью переходит в нормальное состояние. Оценим верхнее и нижнее критические поля.

Первое (нижнее) критическое поле $\mathcal{H}_{c1}$ означает, что величины внешнего поля достаточно, чтобы обеспечить поле в центре вихря (13.27), Или, что то же самое, магнитный поток через сечение вихря $\sim \lambda^2$ достигает кванта потока Φ_0. Это дает нам оценку $\mathcal{H}_{c1} \approx \Phi_0 \ln(\lambda/\xi)/2\pi\lambda^2$. Проверим её точным расчётом. Вычислим свободную энергию единицы длины вихря.

Вихрь возникает в образце с достаточно большой ($\gg \xi, \lambda$) длинной вдоль поля. Как отмечалось выше, будем считать, что образец представляет собой длинный, вытянутый вдоль поля цилиндр. Из граничных условий следует, что при этом в образце тангенциальное поле $\mathcal{H}$ совпадает с внешним $\mathcal{H}_0$. Поскольку задано внешнее поле $\mathcal{H}_0 = \mathcal{H}$, то здесь нам нужно перейти от Ω-потенциала, заданного, как отмечалось выше, в переменных T, V, μ, B к соответствующему потенциалу Гиббса G в переменных $T, V, \mu, \mathcal{H}$. Переход к потенциалу Гиббса осуществляется преобразованием Лежандра, совершенно аналогично тому, как переходят по паре P, V от $F(T, V)$ к $\Phi(T, P)$. Приращение плотности энергии системы поле + вещество равно $d\Omega = \mathcal{H}d\mathcal{B}/4\pi + \ldots$ (см. приложение 26), следовательно, для потенциала Гиббса G получаем:

$$G = \Omega - \frac{\mathcal{H}\mathcal{B}}{4\pi}.$$

Сверхпроводники II рода $\lambda \gg \xi$ представляют собой типично лондоновский случай, когда поправками в (13.2) за счёт $\nabla\psi \sim \xi/\lambda$ можно пренебречь. Энергия единицы длины вихря складывается из энергии поля и кинетической энергии сверхпроводящих электронов:

$$G_1 = \int \left[\frac{\mathcal{B}^2}{8\pi} + \frac{\lambda^2}{8\pi}(\nabla \times \mathcal{B})^2 - \frac{\mathcal{H}\mathcal{B}}{4\pi}\right] dV.$$

Воспользовавшись формулой

$$(\nabla \times \mathcal{B})^2 = \mathcal{B} \cdot \nabla \times \nabla \times \mathcal{B} + \nabla(\mathcal{B} \times \nabla \times \mathcal{B}),$$

получаем

$$G_1 = \int \left[\frac{\mathcal{B}\left(\mathcal{B} + \lambda^2 \nabla \times \nabla \times \mathcal{B}\right)}{8\pi} - \frac{\mathcal{H}\mathcal{B}}{4\pi}\right] dV - \frac{\lambda^2}{8\pi} \int \mathcal{B}\nabla \times \mathcal{B} d\mathbf{S}$$

Поверхностный интеграл берётся по ∞ удалённому цилиндру и горизонтальным плоскостям $z = 0$ и $z = 1$. Поскольку $\mathcal{B} \perp$ этим плоскостям, а $\nabla \times \mathcal{B}$ лежит на них, поверхностный интеграл в (13.31) обращается в ноль. Далее всё просто: используя (13.25), получаем

$$G_1 = \frac{\Phi_0 \mathcal{B}(0)}{8\pi} - \frac{\Phi_0 \mathcal{H}}{4\pi}$$

где $\mathcal{B}(0)$ поле в центре вихря (13.27). Таким образом, возникновение абрикосовского вихря в сверхпроводнике становится энергетически выгодным, когда внешнее поле достигает половины поля в центре вихря:

$$\mathcal{H}_{c1} = \frac{\Phi_0}{4\pi\lambda^2} \ln \frac{\lambda}{\xi}$$

Fast Estimations of H_{c2}

Второе (верхнее) критическое поле $\mathcal{H}_{c2}$ соответствует ситуации, когда вихрей так много, что их коры соприкасаются и весь образец становится нормальным. Это значит,

что поток одного вихря Φ_0 пронизывает площадь $\sim \xi^2$, что соответствует внешнему полю $\mathcal{H}_{c2} \approx \Phi_0/\xi^2$. Подтвердим эту оценку точным расчётом. Вблизи поля $\mathcal{H}_{c2}$ могут существовать только малые зародыши сверхпроводящей фазы. Это значит, что параметр порядка мал $|\psi| \ll 1$ и в уравнении Гинзбурга-Ландау (13.9) можно выбросить нелинейный член:

$$\frac{1}{4m}\left(i\hbar\nabla + \frac{2e}{c}\mathcal{A}\right)^2 \Psi = -\alpha\Psi.$$

При этом в силу $\xi \ll \lambda$ поле $\boldsymbol{\mathcal{A}}(\mathbf{r})$ в зародыше можно считать однородным. Видно, что уравнение (13.34) полностью идентично уравнению

Шредингера для частицы с массой $2m$, зарядом $2e$ и энергией $-\alpha$ в однородном магнитном поле $\mathcal{H} = \nabla \times \mathcal{A}$. Как известно, его собственными значениями являются уровни Ландау, так что спектр ненулевых решений (13.34) начинается с $-\alpha = \hbar\omega/2$, где циклотронная частота $\omega = 2e\mathcal{H}/2m$. С учетом (13.15) это соответствует верхнему критическому полю:

$$\mathcal{H}_{c2} = \frac{\Phi_0}{2\pi\xi^2}$$

Relation of critical field

(add formulas and comment where they come from)

Сравнивая (13.21), (13.33) и (13.35) мы видим, что с логарифмической точностью термодинамическое критическое поле является средним геометрическим верхнего и нижнего критических полей:

$$\mathcal{H}_c = \sqrt{\mathcal{H}_{c1}\mathcal{H}_{c2}}.$$

Theory

As we have already discussed, below the lower critical magnetic field B_{c1} type-II superconductors exist in the Meissner phase, if geometric effects are ignored. However, above B_{c1} the magnetic field penetrates into the sample in the form of 29) Chinese scientists independently also found the system $\mathrm{Y-Ba-Cu-O}$. Upon being questioned by "Since replacing Ba by Sr resulted in an enhancement of T, it appeared obvious to us also to replace La by Y."

quantized flux lines or vortices. Above the upper critical magnetic field B_{c2}, the superconductivity vanishes. In the following, we will look in more detail at these properties from a thermodynamic point of view. [30]

The discussion of the boundary layer between a normal conducting domain and a superconducting domain in Section 4.6.5 has shown that in the case $\lambda_{\mathrm{L}} > \xi_{\mathrm{GL}}$ the formation of the boundary layer is accompanied by an energy gain. In this case the following condition must be (approximately) satisfied:

$$\xi_{\mathrm{GL}} F \frac{1}{2\mu_0} B_{\mathrm{cth}}^2 - \lambda_{\mathrm{L}} F \frac{1}{2\mu_0} B^2 < 0$$

Hence,

$$\xi_{\mathrm{GL}} B_{\mathrm{cth}}^2 < \lambda_{\mathrm{L}} B^2$$

$$\frac{B_{\mathrm{cth}}^2}{B^2} < \frac{\lambda_{\mathrm{L}}}{\xi_{\mathrm{GL}}}$$

Therefore, we expect that, for superconductors with $\lambda_{\mathrm{L}} > \xi_{\mathrm{GL}}$, the magnetic field can penetrate into the superconductor already at fields B that are smaller than B_{cth} . In this case, spatial variations of B and of the Cooper pair density n_{s} are expected, similar to the situation at a boundary layer. From the relations 4.41 and 4.42 in Section 4.5, we see that the condition $\xi_{\mathrm{GL}} < \lambda_{\mathrm{L}}$ can always be achieved by making the electron mean free path l^* sufficiently small. According to Eq. (4.41), λ_{L} increases weakly with decreasing l^*. On the other hand, according to Eq. (4.42), ξ_{GL} decreases with $(l^*)^{1/2}$. The mean free path can be reduced easily by alloying the superconductor with a small amount of impurities. The electrons are scattered at the impurities and, hence, their mean free path is reduced. Indeed, as we will see, alloys are in general type-II superconductors

Already in the 1930s, this particular behavior of superconducting alloys was observed experimentally. De Haas and Voogd reported [50] that in magnetic fields up to about 2 T lead-bismuth alloys still remain superconducting. These are magnetic fields that are larger by more than the factor 20 than the critical field of pure lead. There were attempts to understand such high critical fields in terms of the so-called sponge model proposed by Mendelssohn [51]. According to this model, the high critical fields should be caused by a network of fine precipitates, say, at grain boundaries. If these precipitates were assumed to be small compared to the penetration depth at least in one dimension, then the high critical fields could be understood qualitatively simply because of this geometry (see Section 4.6.3). Today we know that this sponge model may apply to many alloys, but that there exist also homogeneous superconductors, namely the type-II superconductors, which remain superconducting up to very high magnetic fields.

Qualitatively, we can understand in a simple way why a superconductor can tolerate higher magnetic fields, if at least a partial penetration of the field is possible.

A more detailed discussion of the properties of vortices can be found in the monograph [M17].

During the penetration of the field, the expulsion energy, which increases the free enthalpy of the superconducting state in the magnetic field, is reduced. Therefore, higher external fields are needed, in order to make the free enthalpy of the superconducting state equal to that of the normal state. Using similar arguments, we have understood the increase in the effective critical field of thin superconductors, into which the field can also penetrate.

According to Section 4.6.5 we expect that, together with the penetration of the field, also the condensation energy is reduced. However, for $\lambda_{\mathrm{L}} \gg \xi_{\mathrm{GL}}$, the gain due to the reduction of the expulsion energy can be much larger than the loss of condensation energy. Qualitatively, this situation is well accounted for by the Ginzburg-Landau theory. The prediction of the vortex state by Abrikosov [22] was one of the great successes of this theory.

Magnetization Curve and Critical Fields

The difference between type-I and type-II superconductors is clearly seen in the form of the magnetization curve. In Figure 4.23 we schematically show the magnetization curve of a type-II superconductor. Again we consider a rod-shaped sample, the demagnetization coefficient N_M of which is practically zero. At the lower critical field B_{c1}, the gain of expulsion energy due to the field penetration becomes larger than the loss of condensation energy caused by the local variation of the Cooper pair density n_5. As a result, the magnetic field penetrates into the superconductor in the form of quantized flux lines.

As a result of the magnetic field penetration, with increasing field the magnetization of the superconductor decreases monotonically. At a value B_{c2}, the upper

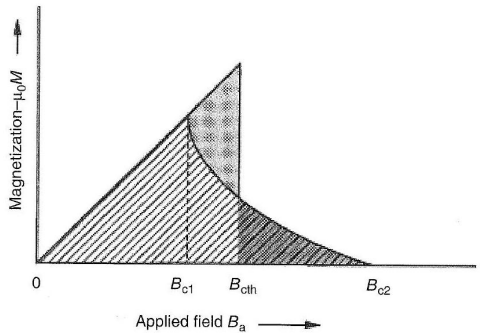

Figure 4.23 Magnetization curve of a type-ll superconductor. Rod-shaped sample with $N_{\mathrm{M}} = 0$. Because of the definition of B_{cth}, the shaded areas must be equal.

critical field, the magnetization reaches zero - the external field has canceled the superconductivity. [31)]

From the general thermodynamic arguments (see Sections 4.1 and 4.6.1), at constant temperature T and constant pressure p, the difference of the free enthalpies is given by

$$G_{\mathrm{n}} - G_{\mathrm{s}} = -\int_0^{B_{\mathrm{c2}}} MV \, \mathrm{d}B$$

If we ignore (as in Section 4.6.1) the very small changes of the volume V as a function of the magnetic field, we can extract V as a constant in front of the integral. The integral is proportional to the area under the magnetization curve

$$\int_0^{B_{\mathrm{c2}}} M \, \mathrm{d}B \propto \mu_0 F_{\mathrm{M}}$$

Here, F_{M} is the area under the magnetization curve. [32)]

If we take a type-I superconductor for comparison, with the same difference of the free enthalpies, its magnetization curve would be given by the vertical line at B_{cth} in Figure 4.23. The areas under both magnetization curves must be equal. Now we see clearly the difference between a type-I superconductor and a typeII superconductor. A type-I superconductor completely expels the field up to the thermodynamic critical field B_{cth} , that is, it stays in the Meissner phase up to this field. On the other hand, at the lower critical field B_{cI} a type-II superconductor enters a state with a penetrated field, the so-called Shubnikov phase. In the Shubnikov phase, with increasing field the magnetization decreases monotonically and completely vanishes only at the upper critical field B_{c2}. The latter field can be much larger than the thermodynamic critical field of the corresponding type-I superconductor

In Figure 4.24 we present this important fact again. Here, the average magnetic field in the interior of the rod-shaped sample is plotted versus the external field. Figure 4.24 exactly corresponds to Figure 4.11 in Section 4.6.1. At B_{c1} the field starts to penetrate into the superconductor However, only at B_{c} is the average starts to penetrate into the superconductor Again the behavior of the corresponding type-I superconductor is indicated by the dashed line. The "corresponding" type-I superconductor denotes again one that has the same difference of the free enthalpies $G_{\mathrm{n}} - G_{\mathrm{s}}$ as the type-II superconductor.

We have already mentioned that a type-I superconductor can turn into a type-II superconductor if the electron mean free path is reduced sufficiently. This result of the Ginzburg-Landau theory has been well confirmed experimentally. By alloying

Under certain conditions, superconductivity can survive within a thin surface layer for fields in the range $B_{\mathrm{c2}} < B_{\mathrm{a}} \leq X, \hat{y}' B_{\mathrm{c3}}$. The value of B_{c3} is about $1.7 B_{\mathrm{c2}}$. Here, we ignore this surface superconductivity.

In Figure 4.23 (as in Figure 4.10) we have plotted the quantity $-\mu_0 M$ instead of the magnetization M. For ideal fiedd expulsion we ha the ordinate, we obtain a straight line with a 45° angle.

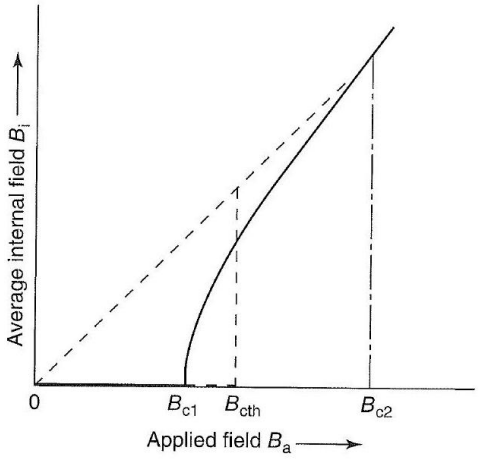

Figure 4.24 Average magnetic field in the interior of a type-ll superconductor plotted versus the external field.

with impurity atoms, which reduce the electron mean free path, all type-I superconductors can be changed into type-II superconductors. One of many examples is shown in Figure 4.25. Here, the ideal magnetization curve of pure lead and the measured curve of a lead-indium alloy with 13.9at% indium are shown [52] Pure lead is a type-I superconductor. The alloy shows typical type-II behavior. The superconductivity of the alloy is completely canceled only at an upper critical field of about 0.24 T(2400G). On the other hand, for the temperature of 4.2 K of this experiment, the thermodynamic field of lead is only about 0.055 T(550G).

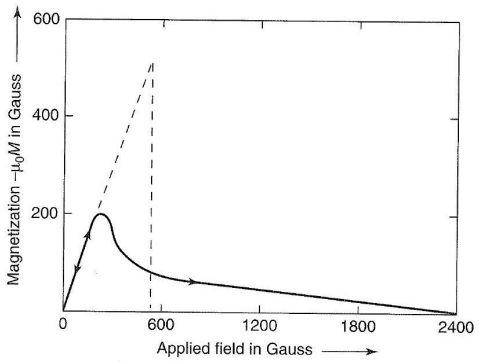

Figure 4.25 Magnetization curve of lead with 13.9 at% of indium (solid line). Rod-shaped sample with a small demagnetization coefficient. The dashed line shows the ideal curve of pure lead ($1\text{G} = 10^{-4}$ T). (From [52],)

Following these qualitative considerations, now we must turn to a few quantitative relations between the fields B_{c1}, B_{c2}, and B_{cth}. All these relations are obtained from the Ginzburg-Landau theory. Here, we must keep in mind that this theory is valid only close to T_c. The crucial parameter is the Ginzburg-Landau parameter κ, that is, the ratio of the penetration depth λ_L and the coherence length ξ_g

Using the Ginzburg - Landau parameter, all the quantitative relations can be formulated in a simple way. For the upper critical field B_{c2}, one obtains

$$B_{c2} = \sqrt{2}\kappa B_{cth}$$

Here, for each type-II superconductor B_{cth} is defined from the difference of the free enthalpies given by Eq. (4.50):

$$G_{\mathrm{n}} - G_{\mathrm{s}} = \frac{1}{2\mu_0} V B_{\mathrm{cth}}^2$$

From the solution of the Ginzburg-Landau equations one also finds [33)] a simple relation between the Ginzburg-Landau coherence length ξ_{GL} and B_{c2}

$$B_{\mathrm{c2}} = \frac{\Phi_0}{2\pi\xi_{\mathrm{GL}}^2}$$

Frequently, this relation is used for determining ξ_{GL} from the measurement of the upper critical field. However, frequently B_{c2} is too large to be measured directly in the limit of low temperatures. In this case, one extrapolates the experimental data from temperatures near T_{c} down to $T \to 0$. For conventional superconductors, the microscopic theory yields the important relation [53]:

$$B_{\mathrm{c2}}(0) \approx 0.7 T_{\mathrm{c}} \left.\frac{\mathrm{d}B_{\mathrm{c2}}}{\mathrm{d}T}\right|_{T_{\mathrm{c}}}$$

Furthermore, we note that Eqs. (4.82) and (4.83) are valid only for isotropic superconductors. If the superconducting properties depend strongly on the crystallographic direction, as in the high-temperature superconductors, Eq. (4.82), for example, must be replaced by $B_{\mathrm{c2}}^a = \Phi_0 / (2\pi\xi_b\xi_c)$. Here, the magnetic field is applied parallel to the crystallographic a direction, and ξ_b and ξ_c are the Ginzburg-Landau coherence lengths in the directions perpendicular to the field, respectively. Analogous expressions are obtained for the field orientation along the other crystal axes. In addition, we note that the results of this section apply to single-band superconductors

Also the lower critical field can be calculated from the Ginzburg-Landau equations. According to Abrikosov [22], in the limit $\kappa \gg 1/\sqrt{2}$ one obtains

$$B_{\mathrm{c1}} = \frac{1}{2\kappa}(\ln\kappa + 0.08) B_{\mathrm{cth}}$$

The value 0.08 in the bracket originates from the interaction between the vortices in the triangular lattice. We see that, with increasing κ, B_{c1} decreases

The details are too complicated to be presented here.

and B_{c2} increases. The lower critical field can also be related to the London penetration depth:

$$B_{\mathrm{c1}} = \frac{\Phi_0}{4\pi\lambda_{\mathrm{L}}^2}(\ln\kappa + 0.08)$$

Equations (4.84) and (4.85) are valid for isotropic superconductors and can be modified for anisotropic superconductors analogously to Eq. (4.82). Equation 4.85 provides a simple possibility for estimating λ_{L} from the measurement of the lower critical field.

Since in alloys the mean free path l^* decreases monotonically with increasing concentration of the impurities, for each system we can indicate a specific "critical" concentration at which the host metal turns into a type-II superconductor This transition is determined by the condition $B_{\mathrm{c2}} \geq B_{\mathrm{cth}}$. According to Eq. (4.81) this condition is equivalent to $\kappa \geq 1/\sqrt{2}$. We see that type-I and type-II superconductors are simply distinguished by the value of κ:

$$\text{type-I superconductors: } \kappa < 1/\sqrt{2}$$

$$\text{type-II superconductors:} \kappa \geq 1/\sqrt{2}$$

This discrimination is strictly valid only near T_c. For $T < T_c$, for κ values only slightly larger than $1/\sqrt{2}$ there exists a transition into a state in which both the Meissner phase and the Shubnikov phase appear next to each other. We will return to this point in Section 4.7.2.

In Table 4.2 some values of κ for In-Bi alloys are indicated. In this system the transition into type-II superconductivity occurs at about 1.5 at% Bi. Similar concentrations were found also for other systems. From this we see that it is very easy to obtain a type-II superconductor. The κ_1 values in the table are obtained from measurements of the upper critical field B_c. However, the κ_2 values are calculated using a formula given by Gor'kov and Goodman. In this formula, the relation between κ and the electron mean free path is summarized as [55]

$$\kappa_2 \approx \kappa_0 + 7.5 \times 10^{-4} \rho \gamma^{1/2}$$

Here, κ_0 is the Ginzburg-Landau parameter of the pure superconductor, that is, for the limiting case $l^* \to, \infty, \gamma$ is the Sommerfeld coefficient of the specific heat of the electron system (in the unit J/cm^3 K^2), and ρ is the resistivity in the normal conducting state (in Ωcm). In this formula, the electron mean free path is expressed in terms of ρ and γ.

Table 4.2 The κ valuesa) of $\ln - Bi$ alloys.

a) $\kappa_1 = \frac{B_c}{\sqrt{2}}$; $\kappa_2 = \kappa_0 + 7.5 \times 10^{-4} \rho \gamma^{1/2}$.
From [54].
Frin

A comparison of lines 2 and 3 in Table 4.2 indicates that the quite differently determined values of κ agree very well. For the application of Eq. (4.87), we must now the values of κ_0. These κ_0 values can be obtained by extrapolating the κ values of alloys to zero concentration of the impurity atoms (Table 4.3)

One might ask if the constant κ_0 for type-I superconductors has a physical meaning. Such a meaning, indeed, results from the GLAG theory. In this case, (4.81) defines a field B which is smaller than B_{cth} . This field yields a definite Eq. (4.81) it for the so-called supercooling experiments.

In a magnetic field the transition from the normal conducting into the superIn a magnetic field the transition from the normal conducting into the supertransitions, supercooling or superheating effects can occur. For example, water can be cooled down carefully to a few degrees below its freezing point withou the formation of ice. For superconductivity this means, for example, that the magric field can be lowered below its critical value without the immediate appearance of the superconducting state. The magnitude of this effect depends on the detailed features of the experiment. For $B < B_{\text{cth}}$ the normal conducting state is thermodynamically unstable. However, the new phase cannot yet form itself. First, nucleation seed for this phase must appear, which subsequently can grow further. During such experiments, the magnetic field cannot fall below the value B_{c2} $(\sqrt{2})\kappa_0 B_{\text{cth}}$ without the appearance of the superconducting state. So if we have a uperconductor with a κ_0 value very close to $1/\sqrt{2}$, no supercooling effects can se observed. However, in superconductors like pure Al or pure In, the magnetic be observed. However, in superconductors cold be well confirmed experimentally.

Finally, we mention another possibility for determining κ. Also the slope of the magnetization curve near B_{c2} is determined by κ, and we have

$$\mu_0(\,\mathrm{d}M/\mathrm{d}B)_{B=B_{c2}} = -\frac{1}{1.16\,(2\kappa^2-1)}$$

So far we have indicated four possibilities for determining κ: Eqs. (4.81), (4.84), (4.87), and (4.88). Near T_c all four methods yield closely similar κ values. However, for temperatures $T \ll T$ the values differ from each other. This is due to the fact hat the Ginzburg-Landau theory is strictly valid only close to T_c. Furthermore, beyond this range of validity, K is temperature-dependent.

Because of their relation to B_{cth}, the two critical fields B_{c1} and B_{c2} are also dependent on the temperature. Neglecting all details, in Figure 4.26 we show schematically the three critical fields of a type-II superconductor. We can clearly see the stability regimes of the different phases. Below B_{c1}, the Meissner phase, that is the phase with complete field expulsion, is stable. Between B_{c1} and B_{c2} we have

Table 4.3 The κ_0 values [a)] of superconducting elements.

Element	Al	In	Pb	Sn	Ta	Tl	Nb	V
κ_0 at T_c	0.03	0.06	0.4	0.1	0.35	0.3	0.8	0.85

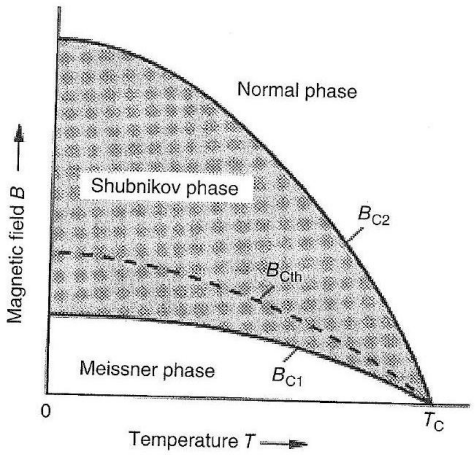

Figure 4.26 Schematics of the phase diagram of a type-Il superconductor.

the mixed state, the Shubnikov phase, as the stable phase; and above B_{c2} there is normal conduction. In Figure 4.27 we show this diagram for an indium-bismuth alloy (In +4 at% Bi) [54].

For some substances, the upper critical field can reach rather large values (see also Chapter 2). In this case one often speaks of "high-field superconductors." For example, the Chevrel phases [57] (ternary molybdenum sulfides, see Section 2.5)

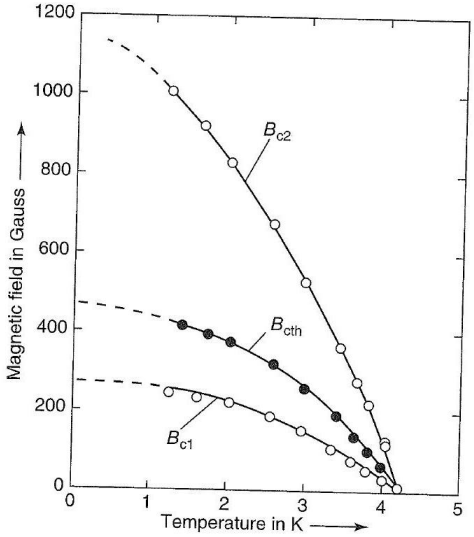

Figure 4.27 The critical fields ($1\text{G} = 10^{-4}$ T) of an indium bismuth alloy, In +4 at% Bi. (From [54].)

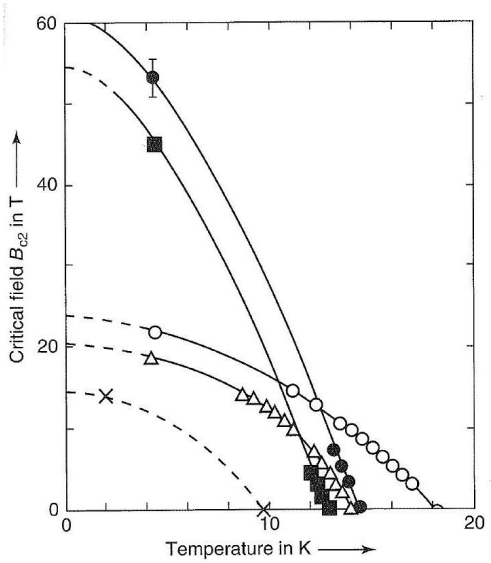

represent materials that can tolerate extreme magnetic fields up to about 60 T without losing their superconductivity [57, 58]. In Figure 4.28 we show B_{c2} plotted versus the temperature for some high-field superconductors. The critical fields of these materials can be a few hundred times larger than those of the type-I superconductors (Figure 4.12).

In the high-temperature superconductors, still larger values of B_{c2} are reached. In this case the layered structure of the materials plays an important role. In order to understand this, we consider a stack of thin superconducting plates of thickness d placed in a magnetic field. The plates should represent the layers of the structure, that is, the CuO_2 planes in the case of the high-temperature superconductors. If the magnetic field is oriented perpendicular to these layers, the supercurrents completely flow within the plates. We do not expect a particular influence of the layered structure. For the upper critical field, one finds the value

$$B_{c2\perp} = \frac{\Phi_0}{2\pi\xi_{\parallel}^2}$$

which essentially is identical to the expression (4.82) for isotropic superconductors. We have only denoted the Ginzburg - Landau coherence length by $\xi_{\parallel}$to indicate that in this case the change of Ψ parallel to the planes is relevant.

On the other hand, if the magnetic field is oriented parallel to the layers, the supercurrents are restricted to a region with the thickness d of the plates, if

Upper critical field of some high-field superconductors: ONb_3Sn, wire ow between neighboring sample [59]; $\times Nb_{5n}Ti_{5n}$ [60]; ■$PbMo_{635}$ S_8 [61]; $PbGd_{03}Mo_6$ S_8 [61]. (See also Ref. [62])

no supercurrents can flow between neighboring plates. If the plate thickness is smaller than the coherence length $\xi_\perp$ perpendicular to the plates, we can expect that in the expression of the upper critical field the plate thickness appears instead of $\xi_\perp$. This is exactly the result one obtains. One finds [63].

$$B_{\mathrm{c2}\|}^{TP} = \sqrt{6}\frac{\Phi_0}{\pi\xi_{||}d}$$

The notation " TP " indicates that we are dealing with the upper critical field of a hin plate. For $d \ll \xi_{\|},, B_{\mathrm{c2}}^{TP}$ is much larger than B_{c2}

For a single thin plate, the upper critical field can be found also in the case of an arbitrary field orientation. If we denote the angle between the magnetic field and the plane of the plate by ϑ, the upper critical field of the plate is obtained from the quadratic equation [61]

$$B_{\mathrm{c2}}^{TP}(\vartheta)\left|\frac{\sin\vartheta}{B_{\mathrm{c2},\perp}}\right| + \left[B_{\mathrm{c2}}^{TP}(\vartheta)\frac{\cos\vartheta}{B_{\mathrm{c2},\|1}^{DP}}\right]^2 = 1$$

The quantity $B_{c2}^{TP}(\vartheta)$ has a sharp peak at $\vartheta = 0°$, and then decreases monotonically with increasing angle. The minimum B_{02} is reached for $\vartheta = 90°$. In Figure 4.29 this curve is shown in comparison with experimental data of the upper critical field for the two high-temperature superconductors $YBa_2Cu_3O_7$ and $Bi_2Sr_2CaCu_2O_8$. Although the measurements were performed only a few

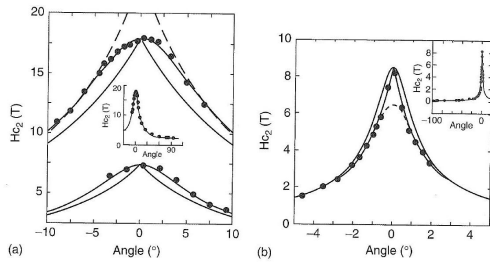

Figure 4.29 Upper critical field $B_{C2} = \mu_0 H_{c2}$ of the two high-temperature superconductors $Ba_2Ca_3O_7$ ($T_c \approx 91$ K, a) and $Bi_2Sr_2CaCu_2O_8$ ($T_c \approx 85$ K, b) obtained from resistance measurements ploted the angle between the cuo planes and the applied field. The main plots show the angles near the parallel orientation. The insets refer to the full range of angles. Measuring temperatures: for $YBa_2Cu_3O_7$, 89 K (upper curve) and 84.5 K (lower curve); for

$Bi_2Sr_2CaCu_2O_8$ 80.4K. The sharply peaked carves correspond to Eq. (4.91) for the angle dependence of the upper critical field of a thin plate. The rounded curves refer to spatially homogneous, superconduct (From [64].) kelvins below the transition temperature, the upper critical field parallel to the kelvins below the transilin the layers already reaches values of 10 T and higherin th the figue wee the experimental data for $Bi_2Sr_2CaCu_2O_8$ closely follow the angle dependence expected for a thin plate (or a stack of such plates). Weak Josephson currents are flowing between the CuO_2 layers of this compound (see Sections 1.5.1 and 6.1.1). However, they are so small that we can speak of a stack of independent plates in good approximation.

For field orientations nearly parallel to the layers, in contrast to $Bi_2Sr_2CaCu_2O_8$ he experimental data for $YBa_2Cu_3O_7$ follow a rounded curve. In the latter matethe coupling between the CuO_2 planes is relatively strong. Hence, this compound is better described in terms of a spatially nearly homogeneous superconductor. However, the superconducting properties depend on direction. In particular, much larger supercurrents can flow within the CuO_2 planes than perpendicular to the planes. This dependence on direction can be well reproduced by the Ginzburg-Landau theory if in the gradient term of the Gibbs function yy (4.26) one introducs difient vales of the effective Foss for the gradients of the upper critical field, in this "anisotropic Ginzburg-Landau theory" one obtains the expressio

$$B_{c2}(\vartheta) = \frac{1}{\sqrt{(\sin\vartheta/B_{c2,\perp})^2 + \left(\cos\vartheta/B_{c2,\parallel}\right)^2}}$$

Here, $B_{c2,\perp}$ is given by Eq. (4.89). For $B_{c2,\|]}$ one obtains

$$B_{c2,\parallel} = \frac{\Phi_0}{2\pi\xi_\parallel\xi_\perp}$$

At low temperatures, for both materials one obtains extremely high values of At special laboratories. For field orientations perpendicular to the layers, for $T \to 0$ in the case of $Bi_2Sr_2CaCu_2O_8$ for the lower limit of $B_{c,2\perp}$ one obtains a value of at least 60 T, and for $YBa_2Cu_3O_7$ even values above 100 T. This correspond to Ginzburg-Landau coherence lengths $\xi_\parallel$(also referred to as ξ_{ab}) of about $1.5 - 3$ nm. For $YBa_2Cu_3O_7$ and for field orientations parallel to the layers, measurements were carried out using explosive flux-compression technique [66]. From this it appears that this material remains superconducting up to at least 240 T. Such fields correspond to coherence lengths $\xi_\perp$ (also referred to as ξ_c) of about 0.3 nm. For $Bi_2Sr_2CaCu_2O_8$ from such measurements near T_c, one even extrapolates critical fields in the range of 1000 T. The latter value corresponds to "plate thickness" d of about 0.4 nm, or to a coherence length $\xi_c \approx 0.1$ nm, if we use Eq. (4.93). These atomically small values, together with the angle dependence of the upper critical field, clearly show that in $Bi_2Sr_2CaCu_2O_8$ the superconductivity is practically exclusively concentrated on the CuO_2 planes.

Actually, the measurements were limited by the fact that the vortices within the material became mobile (see Section 47.2). The true values of B are much higher; for example, see [65].

So far we have discussed a number of superconductors with a very high uppe critical field. From Eq. (4.90) for $B_{c2,||}$ we even conclude that the upper critical fiel can become arbitrarily large if the plate thickness d becomes sufficiently small hysically, this is unreasonable. Therefore, we must look for other mechanisms that limit the superconductivity in high magnetic fields.

In the case of spin-singlet Cooper pairing a limitation is reached by the Zeeman splitting, which the two electrons of the pair experience in the magnetic field We have discussed this in Section 3.2.4. At a sufficiently high magnetic field, this energy splitting becomes so large that it is more favorable to abandon superconductivity and to orient the spins of both electrons parallel to the field. Based on these arguments, one can derive a critical field B_p that is connected with the energy gap Δ_o via the relation [67, 68]

$B_{\mathrm{p}} = \frac{\Delta_0}{\sqrt{2}\mu_{\mathrm{B}}} \approx 1.84[T/K]T_{\mathrm{c}}$

Here, μ_{B} denotes Bohr's magneton. This limitation of the superconducting state is also referred to as the Clogston-Chandrasekhar-limit or the paramagnetic limit. In the case of a strong coupling between the electron spin and the orbital ngular momentum, this value can still be strongly increased, as well as by the Fulde-Ferrell-Larkin-Ovchinnikov (FFLO)-states discussed in Section 3.2.4. For a superconductor with a transition temperature of 10 K, from Eq. (4.94) we obtain a value of 18.4 T, and for a superconductor with $T_{\mathrm{c}} = 100$ K a value of 184 T. For most superconductors, B_{p} is much larger than B_{c2} according to Eq. (4.82). At the end of our discussion of the magnetization curve and the critical fields of type-II superconductors, we emphasize that all the results presented in this section are restricted to magnetization curves that can be followed reversibly. For an increasing external magnetic field, the same curve must appear as in a decreasing field. This is only the case if the thermodynamic equilibrium state is established for each external field B_{a}. In Chapter 5 we will see that generally this is not the case, and that, instead, all kinds of inhomogeneities hinder the spatial equilibrium distribution of the field. In this case, the form of the magnetization curve depends on the previous history of the superconductor. Only the value of B_{c}, at which the superconductivity completely vanishes, remains unequivocally fixed.

4.7.5

The Shubnikov Phase

In the Shubnikov phase, which is stable in a type-II superconductor at external fields B_{a} in the range between B_{c1} and B_{c2}, magnetic flux penetrates into the superconductor in the form of quantized flux lines (vortices). In the case of conventional superconductors, the lowest enthalpy value is obtained for a configuration of the vortices at the corners of equilateral triangles (see Section 1.2).

In Figure 4.30 the Cooper pair density, the spatial field distribution, and the supercurrent density associated with a vortex are shown schematically. In the center of the vortex the density of Cooper pairs is zero, and it reaches its

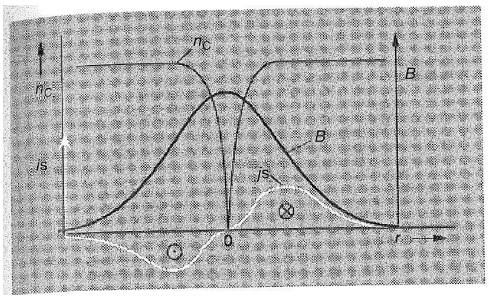

Figure 4.30 Spatial variations of Cooper pair density, magnetic field, and supercurrent density for a planar cut across a vortex, shown schematically.

equilibrium value $n_{\mathrm{s}}(T)$ at a distance of about ξ_{GL}. In the center the magnetic field has its maximum with a value of about $2B_{\mathrm{C1}}$, and it decreases toward the outside This decrease in B is controlled by the penetration depth. Superconducting circulating currents flow around the vortex core, resulting in the spatial variation of the magnetic field.

Only after a lengthy calculation can one show that the lowest enthalpy and thereby the stable state is attained for a state with a triangular vortex lattice with one flux quantum at each lattice site. It is easy to see that only a vortex structure can appear, where each vortex contains exactly an integer multiple of the elementary flux quantum. In Section 1.2 we have derived the flux quantization, or more accurately the fluxoid quantization, from the condition that, during one turn around the superconducting ring, the wave function of the Cooper pairs must just reproduce itself. This condition is also valid for the vortices of the Shubnikov phase. From this we conclude that each vortex can contain only an integer multiple of the flux quantum

Φ_0. If the configuration of a normal conducting core along the axis of a vortex is energetically favorable, we expect that each vortex contains exactly one Φ_0 such that as many vortices can be generated as possible. However, the fact that such a vortex lattice indeed represents the state with the smallest enthalpy can only be shown by detailed calculations. In Figure 4.31 we present the spatial variation of the Cooper pair density and of the magnetic field ang one direction. With increasing external field B, the distance between the vortices becomes smaller. However, at the same time also the average Cooper the vortices becomes smaller. pair density n_s decreases. For external fields only slightly below B_{c2}, the because of approach each other down to a distance of about $2\xi_{GL}$. In this case, because of the strong overlap of the circulating current systems, distinguishing between the individual vortices is no longer meaningful. For $B \to B_{c2}$, the Cooper pair density continuously approaches zero. Because of these features, the phase transition into the normal state at B_{c2} represents a second-order phase transition. On the other hand, in type-I superconductors, the phase transition in a magnetic field is of first order (see Section 4.6.2)

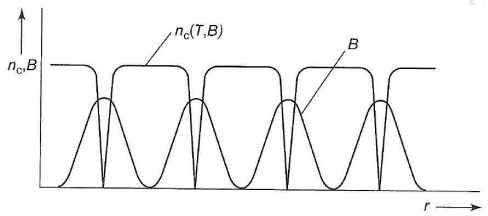

Figure 4.31 Spatial variations of Cooper to the given values of T and B. Since pair density and magnetic field in the $\lambda_L > \xi_L$, with increasing field the magnetic field between the vortices is not completely Between the vortices the Cooper pair density expelled any more. attains the equilibrium value corresponding

Today we can investigate the Cooper pair density near a vortex with high spatial resolution using scanning tunneling microscopy [69] (see Section 1.2, Figure 1.10f). With this method, for example, ξ_{GL} can be determined directly, and the density of states of the unpaired electrons within the vortex can be studied in detail. Such experiments were particularly interesting for the high-temperature superconductors. In this case, ξ_{GL} (more precisely, ξ_{ab}) is so small that the unpaired electrons can occupy only a few discrete energy states, in contrast to many other superconductors, where these electrons can form a continuous energy spectrum.

So far, our discussion of the vortex lattice has been restricted to samples with zero demagnetization coefficient. The magnetic flux penetration was not determined by the geometry as in the case of the intermediate state experiments (see Section 4.6.4). Now the question comes up, whether some kind of intermediate state also exists in a type-II superconductor, and which phases coexist in this intermediate state. As long as the type-II superconductor resides in the Meissner phase, it expels the field in the same way as a type-I superconductor. However, if the field B_{cl} is reached at the surface of the sample, flux must penetrate into the type-II superconductor. In this case, a state is established in which macroscopic domains of the Meissner phase and of the Shubnikov phase exist next to each other. An example of this new state is shown in Figure 4.32. Instead of the normal phase of a type-I superconductor, for the type-II superconductor we have the Shubnikov phase.

Structures of this type are referred to as intermediate-mixed state. They are observed only for values of κ close to $1/\sqrt{2}$. Neumann and Tewordt [70] have extended the Ginzburg-Landau theory to temperatures below T_c. From this extension, one finds that there is a narrow range of κ values near $1/\sqrt{2}$ where the interaction between vortices becomes attractive. Due to this attraction, domains without flux lines coexist with domains containing vortices. Further details can be found in the monograph [M17].

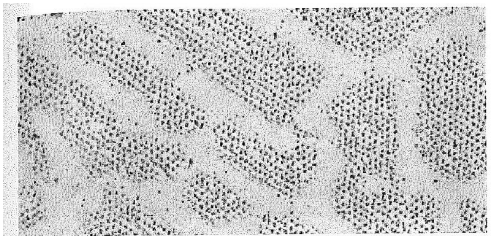

Figure 4.32 Coexistence of the Meissner phase and of the Shubnikov phase in a type-ll superconductor with κ close to $1/\sqrt{2}$. Material: Pb + 1.89at% T

diameter and 1 mm thickness; external field B_a = 36.5mT; magnification 4800x. This state can be established in samples with a finte value of the demagnetization coefficient. (By $\kappa = 0.73, T = 1.2K$; sample: disk with 2 mm courtesy of Dr U. Essmann.)

Turning now to the Shubnikov phase in the high-temperature superconductors, we note that several of their properties have a strong impact on this phase:

the atomically small Ginzburg-Landau coherence length;

the high transition temperature T_c;

the layered structure of the superconducting state in combination with the Josephson coupling between the superconducting CuO_2 layers in many cuprates.

As an additional property, we could mention the $d_{x^2-y^2}$ symmetry of the pair wave function. However, this affects the vortex properties that we want to discuss in the following only very little.

We can treat the "coherence volume" $V_c = {\xi_{ab}}^2 \xi_c$ as the volume element [355] in which the Cooper pair density changes only very little, whereas large variations can appear on larger scales. In the cuprates, this volume is smaller by $2-4$ orders of magnitude compared to that in conventional superconductors. We can write the condensation energy per unit volume of the superconducting state as $E_c = B_{cth}^2/2\mu_0$. In the cuprates, the value of B_{cth} can be about 1 T.

The condensation energy stored within V can be compared to the thermal energy $k_B T$. Here, we use the transition temperature T_c for an upper limit of $k_B T$. Obviously, the ratio $k_B T_c / (E_c V_c)$ represents a characteristic measure indicating the sensitivity of a superconductor against thermal fluctuations. The ratio $(k_B T_c / E_c V_c)^2 / 2$ is also referred to as the Ginzburg number G_i. In materials such as $YBa_2Cu_3O_7$ or $Bi_2Sr_2CaCu_2O_8$ it has a value of about 10^{-2}. However, in conventional superconductors, one obtains values that are smaller by 5 or more orders of magnitude. [36)] This indicates that in the cuprates thermal fluctuations play a much more important role than in conventional superconductors.

In the case of compounds such as $Bi_2Sr_2CaCu_2O_8$, instead of ξ_c, we can use the thickness d of the superconducting layers.

W G_{cice} can can reach values of a few 10^{-3}

In conventional superconductors, the vortices generate a triangular lattice. Due to thermal fluctuations, the vortices can move around their equilibrium lattice site without leaving it altogether. In some sense the vortices form a crystal, which exists up to the upper critical field. However, if the fluctuations around the equilibrium site become comparable to the distance between the vortices, then the vortices will leave their lattice site, and we are dealing with a vortex liquid.

This "melting" of the vortex lattice was proposed in 1985 by Nelson and coworkers [71], and was subsequently studied in many theoretical and experimental papers, in particular for $YBa_2Cu_3O_7$. A summary can be found in the Refs [72-74] and in the monograph [M17]. In $YBa_2Cu_3O_7$ the supercurrents between the CuO_2 planes are relatively strong. So in this case we can speak of a highly anisotropic, but spatially nearly homogeneous, superconductor. [37]

In Figure 4.33 we show schematically the vortex structure in the solid and liquid phases, and also a possible phase diagram. In the liquid phase there can still exist a certain amount of

short-range order of the vortices ("hexatic vortex liquid"). In magnetic fields only slightly above B_{c1}, initially one expects a vortex liquid, which turns into a vortex lattice only with decreasing inter-vortex distance. At very high fields or very small distance between the vortices, the lattice melts again, and one

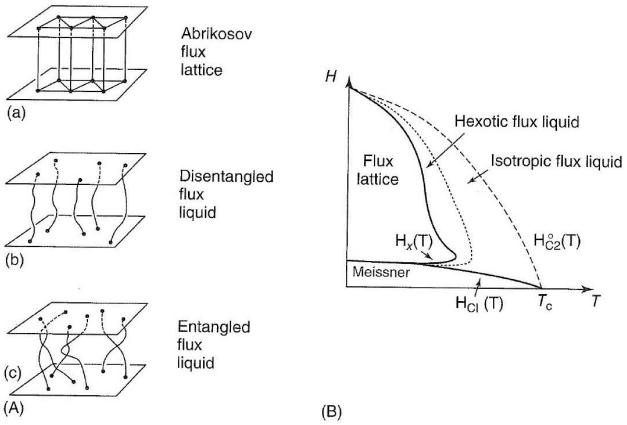

Figure 4.33 Possible phases of the socalled vortex matter in a spatially homogethermal fluctuations play an important role [75]. (A) We see schematically different vortex configurations: (a) vortex lattice, (b) a liquid phase where the vortices still remain

(B)

separated, and (c) a liquid phase with entanis shown 7761 in the liquid phase a diagram amount of short-range order is possible ("hexatic vortex liquid"). One must note also that the liquid phase is inserted between the Meissner phase and the vortex lattice. obains the vortex liquid. It is interesting that this melting represents a first-order obtains transition, in contrast to the second-order phase transition observed in conphastional type-II superconductors at B_{c2}.

In the early experiments, often the dissipation due to the vortex motion was In the early experiments, often the dissipation due to the vortex motion was were discussed highly controversially for a long time. One reason is that the studied materials contain a large concentration of defects. Then, instead of the regular vortex lattice, one obtains a vortex glass. Furthermore, in the liquid phase, the vortices are not freely mobile. However, with improving quality of the crystals, the melting of the vortex lattice could be demonstrated nicely in measurements of the magnetization [78] and even of the specific heat [79]. In Figure 4.34 we show a recent experimental phase diagram obtained from such measurements with $YBa_2Cu_3O_7$[80]. We note that the deviations from the theoretical phase diagram of Figure 4.33 are still very large. In particular, there appears a glass phase caused by the defects in the vortex lattice.

Liquid vortex phases could also be detected in other anisotropic superconductors such as NbSe (indexes?) and also in the iron pnictide $BaCo_xFe_{2-x}As_2$. In the case of these compounds, the Ginzburg number is about 10^{-4}.

Now we turn to the superconducting, lavered compounds, in which the layers are only weakly coupled with each other by means of the Josephson effect. ers are only weakly coupled with each other by means of the Josephson effect. First we consider the case $T = 0$, and we assume that the magnetic field is oriented

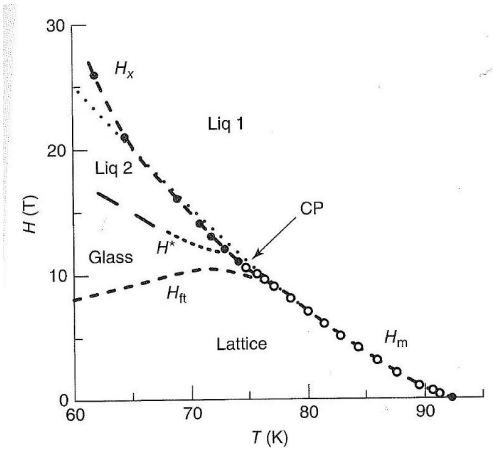

Figure 4.34 Experimental phase diagram state caused by defects in the vortex crystal. of the vortex state in $YBa_2Cu_3O_7$ in mag (???) Above the line H^* the magnetization curves A the planes.

The plot shows the melting line H_m hysteresis. The dashed line corresponds to a $H_{\rm ft}$ separates the vortex lattice from a glassy lattice. (From [80], Θ2001 Nature.)

perpendicular to the layered structure. Also in this case above the field $B_{\rm c1,\perp}$ there appear vortices each carrying one flux quantum Φ_0. The field $B_{\rm c1,\perp}$ is given by

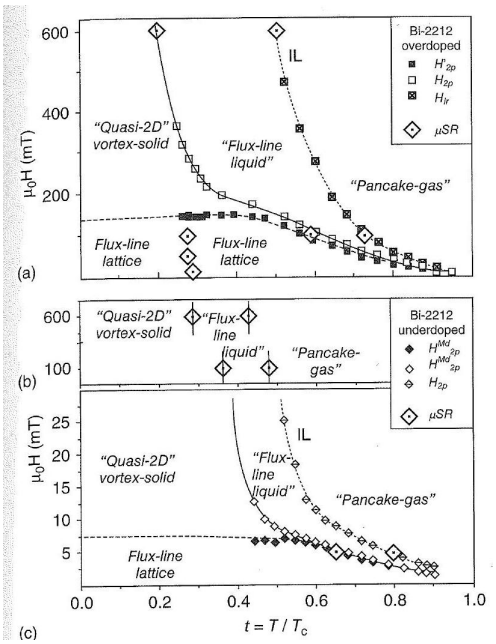
$$B_{\rm c1,\perp} = \frac{\Phi_0}{4\pi\lambda_{ab}^2}\left(\ln\frac{\lambda_{ab}}{\xi_{ab}} + 0.08\right)$$

corresponding exactly to expression 4.85. Here, we have denoted the London penetration depth by λ_{ab}, since the shielding currents flow within the ab plane of the superconducting layers.

In the present case, the supercurrents flow around the vortex axis exclusively in the superconducting layers separated from each other, that is, within the planes marked by the crystallographic a and b axes. Hence, we can speak of stacks of nearly two-dimensional vortices. In each layer the vortex can be imagined as an independent, individual object. J. R. Clem introduced the term pancakes for these vortices [83].

The case of a single thin superconducting layer of thickness d was studied by J. Pearl in 1966 [84]. It was found that within the layer the circulating current around the vortex decay with a characteristic length $\lambda_{\rm eff} = \lambda_{\rm L}^2/d$ from the axis toward the outside. Obviously, for $d \ll \lambda_{\rm I}$ the length $\lambda_{\rm eff}$ can become much larger than $\lambda_{\rm L}$. However, also in this two-dimensional case, the vortices generate a triangular lattice within the layer.

If we have a stack of many superconducting layers, the pancakes within the different planes will interact with each other. This interaction results, on the one hand, from the magnetic field generated by each vortex, and, on the other, from the osephson supercurrents between the planes. Two vortices in neighboring planes attract each other if they have the same sign. Hence, in a perpendicular magnetic field the pancakes order themselves on top of each other along common axes. So one again obtains essentially a triangular lattice of flux lines penetrating the whole sample.



However, now it costs only little energy to shift the individual pancakes away from their common axis. Therefore, at finite temperatures, a number of different vortex phases are possible [85]

the "crystalline" state, in which the pancakes form a triangular flux-line lattice; - a flux-line liquid, in which the pancakes still form flux lines, which are freely mobile;

a quasi-2D vortex solid, in which the pancakes form a triangular lattice within a plane, but where the lattices in different planes are freely shifted relative to each other;

a pancake gas, in which the pancakes are freely mobile within a plane and also are not ordered any more perpendicular to it.

In Figure 4.35 we show a vortex phase diagram of two $Bi_2Sr_2CaCu_2O_{8+x}$ single crystals with different oxygen concentrations, determined from measurements of the muon-spin resonance and magnetization [86]. We can see the phases discussed above. However, we also note that the details strongly depend on the

(c)

Figure 4.35 Vortex phase diagrams of (μSR) and of the magnetization. (a) Overdoped crystal, $T_c = 77$ K[86].

doping level of the samples. Furthermore, disorder plays an important role, similarly as in $YBa_2Cu_3O_7$, such that the "crystalline" phases rather represent glassy states. Similar phase diagrams were also determined using other experimental methods, say, using the vortex penetration into the crystal [87] or using the magnetic permeability [88]. Frequently, these measurements differ in a number of details, but they clearly indicate that in $Bi_2Sr_2CaCu_2O_8$ there exist a number of different vortex states.

Further we note that mostly a Gibbs function serves as the starting point of the theoretical calculations, which is constructed similar to Eq. (4.27) of the Ginzburg-Landau theory. This "Lawrence-Doniach model" [89] was developed in 1970. In this model one considers a stack of two-dimensional superconducting layers, which are coupled to each other by means of Josephson currents. However, the calculation of the different vortex phases is extremely difficult and can be done only using various approximations.

Let us look at the superconducting layered structure at $T = 0$ in a magnetic field oriented parallel to the layers. If the applied field is very weak, the Meissner phase appears again. The shielding currents flow across the superconductin layers. However, the maximum value of this current is much smaller than in the case where the field is applied perpendicular to the layers. As a result the penetration depth λ_c of the magnetic field parallel to the layers is much larger than perpendicular to them. The value of λ_c can reach up to 100μm or more.

Vortices can also be generated in a parallel orientation of the field, if the magnetic field exceeds a lower critical field $B_{c1,\parallel}$. In the Lawrence-Doniach model for $B_{c1,\parallel}$, one finds the expression [90]

$$B_{c1,\parallel} = \frac{\Phi_0}{4\pi\lambda_{ab}\lambda_c}\left(\ln\frac{\lambda_{ab}}{s} + 1.12\right)$$

Here, s is the distance between the superconducting layers. Because of the larg value of $\lambda_c, B_{c1,\parallel}$ is smaller by a factor λ_{ab}/λ_c than the field $B_{c1,\perp}$ for perpendicular field orientation

given by Eq. (4.95). The factor λ_{ab}/λ_c can attain values of 10^{-3} or smaller. Further, we note that in Eq. (4.96) compared to Eq. (4.95) the coherence ength ξ_{ab} is replaced by the layer distance

Within the planes the vortices have a diameter of about $2\lambda_c$ and perpendicular to the planes a diameter of about $2\lambda_{ab}$. Hence, they are very flat objects, extending also over many superconducting planes, since λ_{ab} in general is much larger than the layer distance. Figure 4.36 schematically shows the current distribution of one of these so-called "Iosephson vortices." The magnetic field distribution of such vortices can be imaged experimentally by means of scanning superconducting quantum interference device (SQUID) microscopy (see Section 1.2) [92].

Near the vortex axis the Josephson vortices differ strongly from the Abrikosov vortices in homogeneous type-II superconductors or from the pancake vortices in superconducting layered structures. In the Abrikosov vortices or pancake vortices the Cooper pair density decreases toward the vortex axis down to zero on a length scale ξ_{GL} (see Figure 4.30). On the other hand, in the Josephson vortices the axis is located within a non-superconducting layer, such that the Cooper pair density does not have to be suppressed anymore.

In Figure 4.36 b we show the current density between the two superconducting layers where the vortex axis is located. The supercurrent density increases from the vortex axis toward the outside on a length scale λ_1, the Josephson penetration depth (see Eq. (1.69)). It passes through a maximum value and then decreases gradually. A Josephson vortex also has a core, which is given perpendicular to the ayers by the thickness of the insulating barrier and parallel to the layers by λ_T.

A Josephson vortex can move easily only parallel to the layers. [38)] During a displacement in the z direction the vortex axis must cross a superconducting layer, which is only possible by suppressing the Cooper pair density within this layer at the vortex axis down to zero. However, this costs a large amount of condensation energy, and as a result the superconducting layers develop an energy barrier against the displacement of the Josephson vortex in the z-direction.

In Chapter 6 we will discuss in detail the highly interesting dynamic properties of moving Josephson vortices. (!?!?!?)

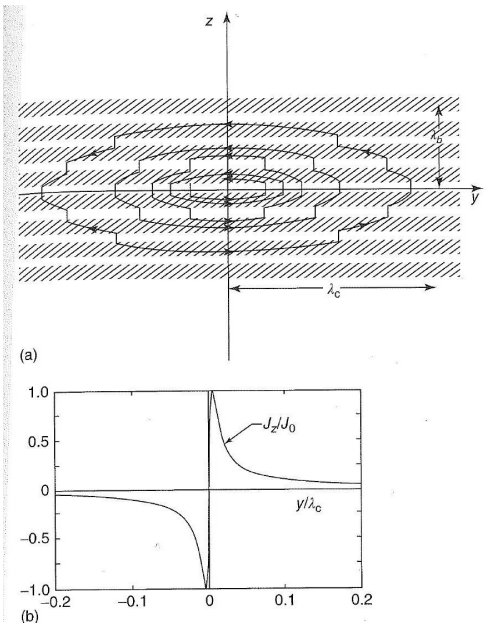


Figure 4.36 (a) Schematic of the circulat- vortex axis runs along the x-direction, that is ing currents around a "Josephson vortex" perpendicular to the paper. (b) The superconducting layers are the hatched two layers, between which the vortex axis is located. (From [91].)

In parallel magnetic fields also the Josephson vortices generate a triangular vortex lattice [93]. If the applied magnetic field is slightly tilted away from the parallel orientation, initially the Josephson vortices cannot cross the superconducting lay ers [94]. We have the situation that

is highly unusual for superconductors in which the magnetization generated by the circulating currents and the applied magnetic field are not parallel to each other. This matching effect, which can be demonstrated, for example, by the measurement of the torque trying to reorient the sample parallel to the field, is frequently used to find out if the superconductor has an internal layered structure.

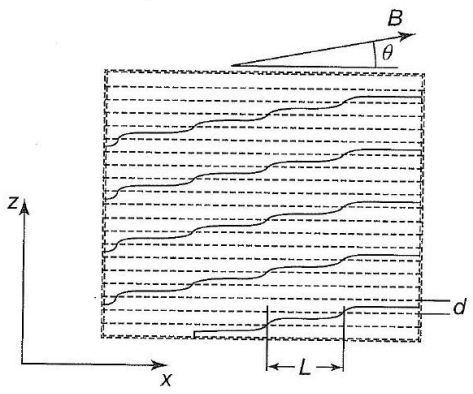

Figure 4.37 Staircase pattern of flux lines in a magnetic field applied at an angle θ to the superconducting layers [95]. The flux lines pass across the planes in the form of pancake vortices joined together by short segments (of length $\llcorner$) of Josephson vortices.

Only when the magnetic field component perpendicular to the layers reaches a value corresponding to about the lower critical field $B_{\mathrm{cl},1}$ can the magnetic field also pass through the superconducting planes. Depending on the magnitude of the maximum supercurrents that can flow between the layers, different types of vortex structures are possible. For example, independent sublattices of Josephson vortices and of pancake vortices can be formed. In the case of strong coupling between the layers, one obtains vortices that are arranged like a staircase around the direction of the applied field. This latter situation is shown schematically in Figure 4.37. The flux lines cut across the superconducting planes in the form of pancake vortices. In between there appear short segments of Josephson vortices.

We expect that at finite temperatures, the situation becomes even more versatile. As an example, in Figure 4.38 we show the vortex phases observed for a $Bi_2Sr_2CaCu_2O_8$ single crystal in the temperature range $77-88$ K by means of Hall magnetometry [96]. The diagram indicates the different vortex phases in the $\left(\mathrm{H}_{\|}, H_{\perp}\right)$ plane. One finds a vortex liquid (VII), slightly tilted lattices from pancake vortices (II), weakly interacting crossing lattices (III), composite lattices (IV), or configurations in which the pancakes are arranged in the form of chain structures above the Josephson vortices (V, 1D chains; or VI, sublimed 1D chain state).

We do not want to discuss the various possibilities any further. However, we emphasize that the special properties of high-temperature superconductors have resulted in a number of novel phenomena, which had not been observed previously in superconductors.

At the end of this section we briefly want to discuss what happens if we deal only with a single, very thin superconducting plane instead of a superconducting layered structure. We have already treated the case of thin plates several times in the context of the Ginzburg-Landau theory or of the critical magnetic fields, but we have ignored the influence of thermal fluctuations.

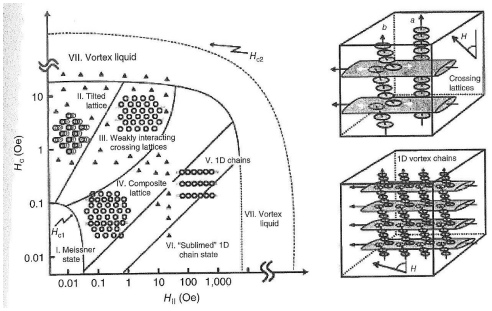

Figure 4.38 Phase diagram of means of Hall probe microscopy. Measuring $Bi_2Sr_2CaCu_2O_8$ single crystal as a function temperature: $77 - 88$ K. The two figures on and H_1 The vortex phases were observed by vortex phases (From [96], @2001 Nature.)

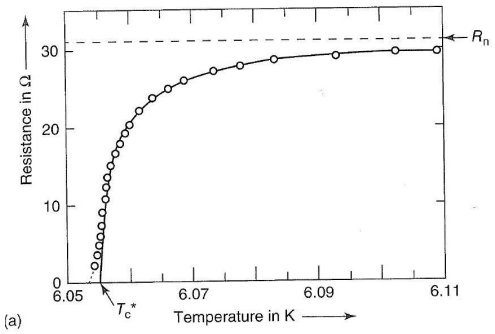
It turns out that for two-dimensional or one-dimensional systems, these fluctuations can become sufficiently large that the macroscopic wave function characterizing the superconducting state is destroyed. This result was derived by Hohenberg [97] and by Mermin and Wagner [98] in the 1960s. We can understand this easily by looking again at the coherence volume $V_c = \xi_{ab}^2 \xi_c$. If the superconducting byer is very thin, we must replace ξ_c by the layer thickness d. However, for $d \to 0$ we have $V_c \to 0$, and the condensation energy stored in V_c vanishes. Then it costs less and less energy to generate a vortex by means of thermal fluctuations. [39] In the absence of an external magnetic field, positive and negative vortices will be generated spontaneously in equal numbers such that the average magnetization of the sample vanishes. If these vortices can move independently of each other they result in dissipation and, hence, in a finite resistance. The superconducting state is destroyed.

Berezinskii [99] as well as Kosterlitz and Thouless [100] have shown that at a somewhat lower temperature, namely at the now so-called Berezinskii-Kosterlitz-Thouless transition temperature T_{BKT}, vortex-antivortex

A more accurate calculation, which takes into account also the energy contribution of the shielding the decay length of the circulating currents in a nearly two-dimensional layer

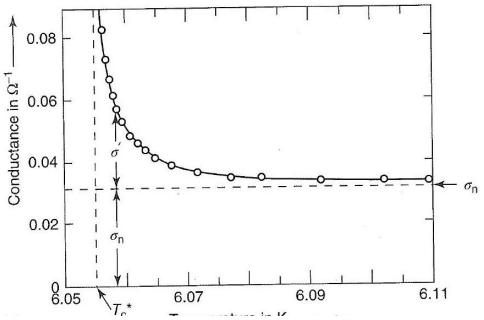
pairs are generated. These pairs again stabilize a superconducting state, in which the Cooper pairs are not correlated with each other anymore over arbitrarily large distances.

If below T_{BKT} a magnetic field is applied perpendicular to the layer, free vortices appear with their orientation given by the applied field. At low temperatures, these vortices again form a triangular lattice. However, this lattice is also highly sensitive to thermal fluctuations. Again one can obtain a vortex liquid, perhaps having a certain hexatic short-range order [101]. Hence, also for the two-dimensional system there exists a phase diagram containing a Meissner phase, a triangular vortex lattice, and liquid vortex phases.



In the last section, but also briefly in Section 1.4, we considered the influence of thermal fluctuations on the vortex state below the transition temperature T_c Obviously, these fluctuations of the equilibrium state also exist above T_c. In the normal conducting state, the deviation from equilibrium can lead to the transient appearance of the superconducting state within certain regions, that is, to the formation of "puddles" of Cooper pairs. These deviations from equilibrium are not stable, and they will disappear more or less quickly. The statistical appearance of Cooper pairs will become more and more rare the higher the temperature, since with increasing temperature the normal conducting state becomes more and more stable compared to the superconducting state. Therefore, with increasing temperature, larger and larger deviations from equilibrium are needed to generate the superconducting state.

If we note further that the puddles of Cooper pairs represent perfectly conducting regions, we understand immediately that already above T_c due to the fluctuations in the normal conducting state the statistically appearing puddles of Cooper pairs result in an additional electrical conductivity, which must strongly increase on approaching $T_.$



This influence of the thermal fluctuations can be clearly detected for a number of super-

conductors. In Figure 4.39a we show the transition curve of a bismuth film near the critical temperature T_c [102]. We see clearly that the full normal resistance is reached only at temperatures considerably above T_c . In Figure 4.39 b the electrical conductance is plotted instead of the resistance. In this plot the additional conductance σ' of the Cooper pair puddles, statistically appearing and vanishing again, is particularly clearly visible. [40)] We note that here and in the following we are not dealing with the specific conductance σ^*, but with the conductance $\sigma' = \sigma^* d\,(d = \text{ thickness})$ in the unit $\mathrm{A/V} = \Omega^{-1}$.

In Figures 4.39 and 4.40, the resistance or the conductance is normalized to the film geometry of square (length l = width b).

(a)

(b)

Figure 439 Transition curve of an amorphous bismuth film of 47 nm thickness: (a) resis-

The additional conductance due to the Cooper pairs can be calculated from the existing theories of superconductivity in combination with the theory of fluctuations. For a film that is thinner than ξ_{GL}, one obtains [103]

$$\sigma'(T) = \frac{e^2}{16\hbar} \frac{T_c^*}{T - T_c^*} \frac{b}{l}$$

where e is the elementary charge, $\hbar$ is Planck's constant $h/2\pi$, T_c^* is the transition temperature obtained by fitting Eq. (4.97) to the experimental data, b is the width and l is the length of the film

We see that the additional conductance σ' must be proportional to $1/\left(T - T^*\right)$. This theoretical result is well confirmed by experiment. The curves shown in Figure 4.39 exactly reproduce this temperature dependence. Furthermore, according to Eq. (4.97), the additional conductance σ' should be independent of

4.2.11 38. Superconductors Close to the T_c in an Arbitrary Magnetic Field

Theory by AGD

The properties of superconductors close to the critical temperature provide a special case. Here the size of the gap is fairly small, as a result of which all the equations are greatly simplified. It is easily scen from the results of 36 (expression (36.4)) that it is now possible to expand the equations in the quantity $1 - T/T_c \gg 1$. In addition, as we have already remarked in the previous section, close to T_c the depth of penetration of a weak magnetic field $\delta \ll \xi_0$, i.e. all the functions in the field, including the field itself, vary at distances which are much greater than the parameters $\xi_0 \sim v/T_c$ of the theory. This fact enables us to develop a theory in this temperature range (Gor'kov [68]), which describes the behaviour of superconductors in arbitrary magnetic fields (of the order of the critical field).

With this aim, we again rewrite cquations (37.6):

$$\left\{ i\omega + \frac{1}{2m}\left(\frac{\partial}{\partial r} - ieA(r)\right)^2 + \mu \right\} \mathfrak{G}_\omega(r, r') + \Delta(r)\mathfrak{F}^+_\omega(r, r') = \delta(r - r')$$
$$\left\{ -i\omega + \frac{1}{2m}\left(\frac{\partial}{\partial r} + ieA(r)\right)^2 + \mu \right\} \mathfrak{F}^+_\omega(r, r') - \Delta^*(r)\mathfrak{G}_\omega(r, r') = 0$$

together with the equation that determines the gap size:

$$\Delta^*(\boldsymbol{r}) = |\lambda| T \sum_{\omega}^{\searrow} \mathfrak{F}^+_\omega(\boldsymbol{r}, \boldsymbol{r}). \tag{38.1}$$

Since $|\Delta|$ is small, we expand $\mathfrak{F}^+_\omega(r, r')$ in powers of $|\Delta|$ and, on substituting this expansion in (38.1), find an equation for $\Delta^*(r)$. It is useful here to introduce the Fourier components of the Green function $\tilde{\mathscr{F}}^{(0)}_\omega(r, r')$ for the electrons in the normal metal (in the given field $A(r)$). The equation which $\tilde{\mathfrak{G}}^{(0)}_\omega(r, r')$ satisfies can be written in two ways:

$$\left\{ i\omega + \frac{1}{2m}\left(\frac{\partial}{\partial r} - ieA(r)\right)^2 + \mu \right\} \tilde{\mathfrak{G}}^{(0)}_\omega(r, r') = \delta(r - r') \tag{38.2}$$

or

$$\left\{ i\omega + \frac{1}{2m}\left(\frac{\partial}{\partial r'} + ieA(r')\right)^2 + \mu \right\} \tilde{\mathfrak{H}}^{(0)}_\omega(r, r') = \delta(r - r'). \tag{38.2'}$$

Taking the second form of the Green function, we can use it to roduce the system of equations for $\mathfrak{B}_\omega$ and $\mathfrak{F}^+_\omega$to the integral form:

$$\mathfrak{G}_\omega(r, r') = \tilde{\mathfrak{G}}^{(0)}_\omega(r, r') - \int \tilde{\mathfrak{G}}^{(0)}_\omega(r, l)\Delta(l)\mathfrak{F}^+_\omega(l, r')\,\mathrm{d}^3 l,$$
$$\mathfrak{F}^+_\omega(r, r') = \int \tilde{\mathfrak{G}}^{(0)}_{-\omega}(l, r)\Delta^*(l)\mathfrak{G}_\omega(l, r')\,\mathrm{d}^3 l. \tag{38.3}$$

Before proceeding further, we find the value of $\mathfrak{S}^{(0)}_\omega(r, r')$. In the absence of a magnetie ficld, $\tilde{\mathscr{F}}^{(0)}_\omega(r - r')$ is equal to ($R = |r - r'|$):

$$\mathfrak{G}^{(0)}_\omega(R) = \begin{cases} -\frac{m}{2\pi R} e^{ip_0 R - |\omega| R/v} \text{ for } \omega > 0, \\ -\frac{m}{2\pi R} e^{-ip_0 R - |\omega| R/v} \text{ for } \omega < 0. \end{cases} \tag{38.4}$$

This can be verified either by direct substitution of (38.4) in (38.2) in the absence of field, or by using the now familiar expression for the Fourier component $\mathrm{G}_\omega^{(0)}(p) = [i\omega - \xi]^{-1}$:

$$\begin{aligned}\mathfrak{G}_\omega^{(0)}(R) &= \frac{1}{(2\pi)^3}\int \mathfrak{G}_\omega^{(0)}(p)\mathrm{d}^3 p e^{i(p\cdot R)} \\ &= -\frac{m}{(2\pi)^2} iR \int \frac{e^{ip_0 R + i\xi R/v} - e^{-ip_0 R - i\xi R/v}}{i\omega - \xi}\mathrm{d}\xi\end{aligned}$$

(we are of course interested in the form of $\mathscr{G}_\omega^{(0)}(R)$ at distances which are larged compared with the atomie distances: $Rp_0 \gg 1$). On integrating over ξ, we obtain (38.4) immediately.

The function $\mathscr{G}_\infty^{(0)}(R)$ oscillates rapidly. Since $p_0 R \gg 1$, this fact enables us to find $\tilde{\mathfrak{G}}_\omega^{(0)}(r, r')$ in a magnetic field by making use of the quasi-classical approximation. In fact, we look for $\widetilde{\mathfrak{S}}_\omega^{(0)}(r, r')$ in the form

$$\tilde{\mathfrak{G}}_\omega^{(0)}(r, r') = e^{iq(r,r')}\mathfrak{G}_\omega^{(0)}(r - r'), \tag{38.5}$$

where $\varphi(r, r) = 0$. On substituting (38.5) into (38.2) and differentiating only the principal terms, we obtain an equation for the extra term $\varphi(r, r')$ in the action:

$$(n \cdot \nabla_r \varphi(r, r')) = e(n, A(r)); \quad \left(n = \frac{R}{|R|}\right). \tag{38.6}$$

We have thrown away the terms quadratic in A in this equation, since the radius of curvature of the electrons ep_0/H in the fields of interest is extremely large by comparison with the depth of penetration: $p_0 \gg Ae \sim eH\delta$ (δ is the order of the depth of penetration).

We now return to equations (38.3) and carry out expansions in them in powers of $|\Delta(r)|$. As is clear from (38.4) and (38.6), it is sufficient to carry out this expansion in $\mathfrak{F}_\omega^+(r, r')$ up to the third power in $|\Delta|$. As regards the Green function $\mathfrak{G}_\omega(r, r')$, we only need to know it up to second order terms in $|\Delta|$:

$$\mathfrak{G}_\omega(r, r') = \tilde{\mathfrak{G}}_\omega^{(0)}(r, r') - \int \tilde{\mathfrak{G}}_\omega^{(0)}(r, l)\Delta(l)\tilde{\mathfrak{G}}_\omega^{(0)}(m, r')\,\Delta^*(m)\tilde{\mathfrak{G}}_{-\omega}^{(0)}(m, l)\mathrm{d}^3 m\ \mathrm{d}^3 l. \tag{38.7}$$

On substituting this expression in the second of equations (38.3), we obtain the expansion of $\mathfrak{F}_\omega^+(r, r')$, with the aid of which the following equation in $\Delta^*(r)$ is obtained from (38.1):

$$\begin{aligned}\Delta^*(r) =& |\lambda| T \sum_\omega \int \widetilde{G}_\omega^{(0)}(l, r)\Delta^*(l)\widetilde{G}_{-\omega}^{(0)}(l, r)\mathrm{d}^3 l \\ &- |\lambda| T \sum_\omega \iiint \widetilde{G}_\omega^{(0)}(l, m)\Delta(m)\widetilde{G}_\omega^{(0)}(s, r)\Delta^*(s)\widetilde{G}_{-\omega}^{(0)}(s, m) \\ &\times \Delta^*(l)\widetilde{G}_{-\omega}^{(0)}(l, r)\mathrm{d}^3 l\ \mathrm{d}^3 m\ \mathrm{d}^3 s\end{aligned} \tag{38.8}$$

The important distances in the integrals in this equation are of order ξ_0, since, as is clear from (38.4) and (38.5), the function $\tilde{\mathcal{G}}_\omega^{(0)}(r, r')$ de-
creases exponentially for $|r - r'| > \xi_0$. The change in the gap $\Delta(r)$ and field $A(r)$ occur at distances of the order of the penetration depth, which is much greater than ξ_0 close to the critical temperature. For the same reasons, the phase $\varphi(r, r')$ in (38.5) can be written as

$$\varphi(r, r') \simeq e\,(A(r) \cdot r - r').$$

Close to T_c, $A(r) \sim H\delta \sim \sqrt{1 - (T/T_c)}$, so that the phase $\varphi(r, r')$ is small and the exponent can be expanded in powers of φ.

We start by considering the first term on the right-hand side. Let

$$K(l,r) = T\sum_{\omega} \mathscr{G}_{\omega}^{(0)}(l,r)\tilde{\mathfrak{G}}_{-\omega}^{(0)}(l,r) = K_0(l-r)\exp[2ie(A(r)\cdot l - r)]$$

Using the representation (38.4) for the Green function in coordinate space and performing a summation over the frequencies, we get the following expression for $K_0(R)$:

$$K_0(R) = \frac{m^2 T}{(2\pi R)^2}\frac{1}{\sinh\frac{2\pi TR}{v}} \tag{38.9}$$

As we have already remarked, all the functions change little over distances of the order of ξ_0, so that we can expand all the functions in the integral

$$\int K_0(l-r)\exp[2ie(A(r)\cdot l - r)]\Delta^*(l)\mathrm{d}^3 l$$

into series in powers of $(l-r)$ about the point r. On confining ourselves to second order terms in $(l-r)$, we get

$$\Delta^*(r)\int K_0(R)\mathrm{d}^3 R + \frac{1}{6}\left(\frac{\partial}{\partial r} + 2ieA(r)\right)^2 \Delta^*(r)\int K_0(R)R^2\ \mathrm{d}^3 R$$

By (38.9), the function $K_0(R)$ tends to infinity as $1/R^3$ at $R=0$. The first of these two integrals is therefore formally divergent. It is more convenient to perform the cut-off of the divergent expression in momentum space. We obtain as a result the familiar expression:

$$\int K_0(R)\mathrm{d}^3 R = \frac{mp_0}{2\pi^2}\int_0^{\omega_D}\tanh\left(\frac{\xi}{2T}\right)\frac{\mathrm{d}\xi}{\xi}$$

The second term contains no singularities on integrating close to $\boldsymbol{R}=0$. On evaluating this integral directly in the coordinate representation, we get:

$$\int R^2 K_0(R)\mathrm{d}^3 R = \frac{7\zeta(3)v^2}{8(\pi T)^2}\cdot\frac{mp_0}{2\pi^2}$$

In the term of third order in $|\Delta|$ in equation (38.8), we can neglect the dependence of $\Delta(r)$ on the coordinates. This term is therefore equal to $\left(\frac{mp_0}{2\pi^2}\right)\Delta^*(r)|\Delta(r)|^2 T\sum\limits_{\omega}\int \mathrm{d}\xi\frac{1}{(\omega^2+\xi^2)^2} = \left(\frac{mp_0}{2\pi^2}\right)\frac{7\zeta(3)}{8(\pi T)^2}\Delta^*(r)|\Delta(r)|^2$.

On collecting the results obtained, we find that $\Delta^*(r)$ satisfies the following equation close to the critical temperature:

$$\left\{\frac{1}{4m}\left(\frac{\partial}{\partial r} + 2ieA(r)\right)^2 + \frac{1}{\varrho}\left[\frac{T_c - T}{T_c} - \frac{7\zeta(3)}{8\left(\pi T_c\right)^2}|\Delta(r)|^2\right]\right\}\Delta^*(r) = 0,$$

where

$$\varrho = \frac{7\zeta(3)}{6\left(\pi T_c\right)^2}\varepsilon_F \tag{38.10}$$

In the absence of a field Δ is constant in space and equation (38.10) is the same as the first terms of expansion (36.4).

We now turn to evaluating the current density $\boldsymbol{j}(\boldsymbol{r})$. Obviously (37.5) of the previous section still holds in this case. If, however, we use the fact that Δ is small by comparison with T_c, we can also carry out here an expansion in A and Δ up to the first non-vanishing terms. Notice that the term in the current density (37.5)

$$-\frac{2e^2A(r)}{m}\mathscr{G}_{l'=t+0}(r,r) \equiv -\frac{e^2}{m}A(r)N.$$

Here N is the density of the total number of electrons, which is equal to its value for a normal metal. Variation of N would contradict the condition for neutrality. (The solution of (38.7) satisfies this requirement, i.e. if

$$\mathfrak{G}_\omega(r,r') = \tilde{\mathfrak{G}}_\omega^{(0)}(r,r') + \delta\mathfrak{G}_\omega(r,r'), \text{ then } T\sum_\omega \delta\mathfrak{G}_\omega(r,r) \equiv 0.\Big)$$

On substituting (38.7) in (37.5), we find that

$$T\sum_\omega \frac{ie}{m}\left(\nabla_{r'} - \nabla_r\right)\underset{r'\to r}{\tilde{\mathfrak{G}}_\omega^{(0)}}(r,r') - \frac{e^2}{m}NA(r) \equiv 0$$

since the current in a normal metal is zero in a constant magnetic field. Therefore

$$j(r) = \frac{ie}{m}\left(\nabla_{r'} - \nabla_r\right)_{r'\to r} T\sum_\omega \delta\mathfrak{G}_\omega(r,r')$$

where

$$\delta\mathfrak{G}_\omega(r,r') = -\int \mathfrak{G}_\omega^{(0)}(r,l)\Delta(l)\tilde{\mathfrak{G}}_\omega^{(0)}(m,r')\,\Delta^*(m)\tilde{\mathfrak{G}}_{-\omega}^{(0)}(m,l)\mathrm{d}^3m\ \mathrm{d}^3l$$

On substituting (38.5) in this, expanding all the functions about the point r up to first order terms and omitting terms which yield zero an integration over the angle, we get:

$$j(r) = \left[\frac{ie}{m}\left(\Delta\frac{\partial\Delta^*}{\partial r} - \Delta * \frac{\partial\Delta}{\partial r}\right) - \frac{4e^2|\Delta|_-^2}{m}A(r)\right]C \tag{38.11}$$

where

$$C = \frac{1}{3}T\sum_\omega \iint \left\{\left[\left(\nabla_r\mathfrak{G}_\omega^{(0)}(r-l)\right)\mathfrak{G}_\omega^{(0)}(m-r) - \mathfrak{G}_\omega^{(0)}(r-l)\right.\right.$$
$$\left.\left.\times\left(\nabla_r\mathfrak{G}_\omega^{0}(m-r)\right)\right]\cdot m\right\}\mathfrak{G}_{-\omega}^{(0)}(m-l)\mathrm{d}^3m\ \mathrm{d}^3l$$

The evaluation of C is best performed in Fourier components, after making the usual substitution $r \to i(\ \mathrm{d}/\mathrm{d}\boldsymbol{p})$. We shall omit the details of this fairly simple calculation and give the final result:

$$C = \frac{7\zeta(3)N}{16\left(\pi T_c\right)^2}$$

The system of equations (38.10) and (38.11) describes the properties of a superconductor in a constant magnetic field close to $\boldsymbol{T_c}$. We introduce the wave function $\psi(r)$, proportional to $\Delta(r)$:

$$\psi(r) = \sqrt{\frac{7\zeta(3)N}{8\left(\pi T_c\right)^2}}\Delta(r). \tag{38.12}$$

On taking the complex conjugate of equation (38.10) and substituting (38.12) throughout, we can derive these equations as follows:

$$\left\{\frac{1}{4m}\left(\frac{\partial}{\partial r}-2ieA(r)\right)^2+\frac{1}{\varrho}\left[\frac{T_c-T}{T_c}-\frac{1}{N}|\psi|^2\right]\right\}\psi(r)=0$$

$$j(r)=-\frac{2ie}{4m}\left(\psi^*\nabla\psi-\psi\nabla\psi^*\right)-\frac{(2e)^2}{2m}A(r)|\psi|^2 \tag{38.13}$$

The point in introducing the wave function $\psi(r)$ now becomes clear: the resulting equations are in a form similar to the quantum mechanical equations for particles with mass $2m$ and charge $2e$. This result is quite obvious physically, since $\Delta(r)$ has the significance of a function which is proportional to the wave function of a bound pair, or, more precisely, the wave function in the centre of mass coordinates. It is of interest that equations of a similar form where proposed in the phenomenological Ginzburg-Landau theory [69], where, however, a single elementary charge occurred. Apart from this essential difference, the new theory of superconductivity, which supports the correctness of the Ginzburg-Landau theory close to T_c, enables us to compute the constants featured in the latter theory.

Let us again mention in conclusion the fact that our derivation employed the smallness of the variation of all the functions over distances of the order ξ_0. Since, as may clearly be seen from (38.13) and (37.19), all the functions are in the general case variable at distances of the order of the London penetration depth close to T_c, whilst this depth becomes greater than ξ_0 only in the immediate neighbourhood of T_c in the case of Pippard metals, the domain of applicability of these equations for metals of the Pippard type is an extremly limited neighbourhood of temperatures close to the critical transition temperature. For metals of the London type, or intermediate metals, the equations are valid in a fairly wide temperature range close to T_c. This is a range of the greatest interest from the experimental point of view, and it must be remarked that equation (38.13) leads to a very good agreement between the theory and experimental results in this range.

5 Details of Fundamental Effects and Other Basic Properties

5.1 Basics of Determination of Physical Parameters

5.1.1 Determination of the value of T_c

(maybe I'll create later a subsection about it. still, it is not clear, how to do it from basic BCS. and how to take into account properties of materials? I'll try to discuss it here, but see special my note about this very big question. It is a big and unsolved problem for science now)

5.2 Important general features of theories of superconductivity

5.2.1 Connection of the Ginzburg-landau and BCS theory

Statements of connection of GL and BCS theories by Shmidt

The Ginzburg-Landau (GL) theory is, as we already know, phenomenological, that is, it does not allow its coefficients to be interpreted on the microscopic level. A detailed interpretation of the quantities involved in the GL theory became possible only after the rigorous microscopic theory of superconductivity had been developed by Bardeen, Cooper, and Schrieffer. This task was accomplished by Gorkov [66]. Here we shall only outline the final results, which

differ for 'clean' and 'dirty' superconductors. In what follows, all quantities corresponding to 'clean' superconductors will be labeled with an index ' p ' and those corresponding to 'dirty' superconductors with an index ' d '. A superconductor is considered clean if $l \gg \xi_0$, where l is the electron mean free path. A dirty superconductor is characterized by $l \ll \xi_0$.

As one should expect, the energy gap $\Delta(T)$ represents the order parameter in the superconductor and, therefore, at $T \to T_c$, must be proportional to the order parameter Ψ of the GL theory. Indeed, the exact result is:

$$\Psi_p = \left[\frac{7\zeta(3)}{2}\frac{mv_F^2 N(0)}{k_B^2 T_c^2}\right]^{1/2}\Delta(r), \quad \zeta(3) \approx 1.202$$
$$\Psi_d = \left[\frac{\pi m v_F}{12}\frac{N(0)l}{k_B T_c}\right]^{1/2}\Delta(r)$$

where $\zeta(x)$ is the Riman function.

At $T \to T_c$ we have

$$\Delta(T) = \left(\frac{8\pi^2}{7\zeta(3)}\right)^{1/2} k_B T_c \left(1 - \frac{T}{T_c}\right)^{1/2}$$

or

$$\Delta(T) \approx 3.1 k_B T_c \left(1 - \frac{T}{T_r}\right)^{1/2}.$$

The coherence length and the magnetic penetration depth are, accordingly,

$$\xi_p = 0.74\xi_0 \left(1 - \frac{T}{T_c}\right)^{-1/2}$$
$$\xi_d = 0.85\left(\xi_0 l\right)^{1/2}\left(1 - \frac{T}{T_c}\right)^{-1/2}$$
$$\lambda_p = \frac{\lambda(0)}{\sqrt{2}}\left(1 - \frac{T}{T_c}\right)^{-1/2}$$
$$\lambda_d = 0.615\lambda(0)\left(\frac{\xi_0}{l}\right)^{1/2}\left(1 - \frac{T}{T_c}\right)^{-1/2}$$
$$\lambda^2(0) = \frac{3c^2}{8\pi e^2 v_F^2 N(0)}$$

The GL coefficients α and β in the expansion of the free energy in powers of the order parameter Ψ are:

$$\alpha_p = 1.83\frac{\hbar^2}{2m}\frac{1}{\xi_0^2}\left(\frac{T}{T_c} - 1\right)$$
$$\alpha_d = 1.36\frac{\hbar^2}{2m}\frac{1}{\xi_0 l}\left(\frac{T}{T_c} - 1\right)$$
$$\beta_p = 0.35\frac{1}{N(0)}\left(\frac{\hbar^2}{2m\xi_0^2}\right)^2\frac{1}{(k_B T_c)^2}$$
$$\beta_d = 0.2\frac{1}{N(0)}\left(\frac{\hbar^2}{2m\xi_0 l}\right)^2\frac{1}{(k_B T_c)^2}$$

The GL parameter takes the values

$$\kappa_{\mathrm{p}} = 0.96\frac{\lambda(0)}{\xi_0}, \quad \kappa_{\mathrm{d}} = 0.725\frac{\lambda(0)}{l}$$

Let us now establish the range of validity for the GL theory. In the series expansion (3.7) of the Gibbs free energy density G_{BH} in powers of $|\mathrm{i}\hbar\nabla\Psi - (2e/c)A\Psi|^2$, only the first term has been kept. This means that only slow changes of Ψ and $\boldsymbol{A}$ are assumed over distances comparable with the characteristic size of an inhomogeneity in the superconductor, that is, over the size of the Cooper pair.

In the case of a clean superconductor, when the electron mean free path satisfies the inequality $l \gg \xi_0$, the GL theory is valid if $\xi(T), \lambda(T) \gg \xi_0$. Since $\xi(T) \sim \xi_0 (1 - T/T_{\mathrm{c}})^{-1/2}$, the quantity $\xi(T)$ always exceeds ξ_0 at $T \sim T_{\mathrm{c}}$ and the first condition of validity is satisfied automatically.

The second condition, $\lambda(T) \gg \xi_0$, represents the requirement that local electrodynamics is applicable, or, in other words, that the superconductor is of the London type. Since $\lambda(T) \sim \lambda(0) (1 - T/T_c)^{-1/2}$ and $\kappa \sim \lambda(0)/\xi_0$, the

$$\kappa^2 \gg 1 - \frac{T}{T_{\mathrm{c}}} \tag{6.47}$$

This is a rather strict condition because κ in type-I superconductors can assume a small value. For example, $\kappa(\mathrm{Al}) = 0.01, \kappa(\mathrm{\ Pb}) = 0.23$. In 'dirty' superconductors ($l \ll \xi_0$), the validity interval for the GL theory is much wider. In this case, the characteristic scale of inhomogeneity is the mean free path l and the GL theory can be applied if $\xi(T), \lambda(T) \gg l$. Since $\xi(T) \sim (\xi_0 l)^{1/2} (1 - T/T_{\mathrm{c}})^{-1/2}$, the condition $\xi(T) \gg l$ reduces to $\xi_0/l \gg 1 - T/T_c$. Furthermore, since $\xi_0 \gg l$, this condition is much less strict than the general condition of validity for the Landau theory of the second-order phase transitions, $T_{\mathrm{c}} - T \ll T_{\mathrm{c}}$.

Consider the second condition: $\lambda(T) \gg l$. Recalling that, for dirty superconductors, $\lambda(T) \sim \lambda(0) (\xi_0/l)^{1/2} (1 - T/T_{\mathrm{c}})^{-1/2}$ and $\kappa \sim \lambda(0)/l$, it can be rewritten as $\kappa^2 (\xi_0/l) \gg 1 - T/T_c$. If $\kappa \sim 1$, we find once again that it is less strict than the general condition $T_{\mathrm{c}} - T \ll T_{\mathrm{c}}$.

Thus, in the case of dirty superconductors (alloys), the GL theory is valid within a rather wide temperature interval - at least, qualitatively - and, provided the condition $T_{\mathrm{c}} - T \ll T_{\mathrm{c}}$ is satisfied, also quantitatively.

Superconducting coherence length from the microscopic theory

The wavefunction of the ground state of the superconductor is already known to us from Sect.6.2.1. The ground state can be represented by the distribution of electron pairs in momentum space given by the function v_k^2. The dependence of v_k^2 on k is plotted in Fig. 6.5.

(add it here)

One can see that large variations of v_k^2 can occur only within the

$$\Delta k \sim 2\Delta_0 \frac{k_{\mathrm{F}}}{\varepsilon_{\mathrm{F}}}$$

Then, in real space, large variations of the ground state wavefunction can be expected within the interval Δx defined by the relation

$$\triangle x \triangle k \sim 1$$

It follows that

$$\Delta x \sim \frac{\varepsilon_{\mathrm{F}}}{2\Delta_0 k_{\mathrm{F}}} = \frac{1}{2\Delta_0 k_{\mathrm{F}}} \frac{\hbar^2 k_{\mathrm{F}}^2}{2m} = \frac{\hbar p_{\mathrm{F}}}{4\Delta_0 m} = \frac{\hbar v_{\mathrm{F}}}{4\Delta_0} \tag{6.26}$$

Here p_{F} is the electron momentum and v_{F} the velocity of electrons on the Fermi surface. But, in terms of its physical significance, the quantity Δx is exactly the same as the quantity that we called the coherence length ξ, when studying the Ginzburg-Landau theory: Hence, we conclude that (6.26) provides an estimate of the coherence length ξ_0 at $T = 0$:

$$\xi_0 \sim \frac{\hbar v_{\mathrm{F}}}{4\Delta_0}. \tag{6.27}$$

It will be demonstrated below that $\Delta_0 \sim k_{\mathrm{B}} T_{\mathrm{c}}$, where k_{B} is the Boltzmann constant and T_{c} is the critical temperature. A rigorous calculation yields

$$\xi_0 = 0.18 \frac{\hbar v_{\mathrm{F}}}{k_{\mathrm{B}}} \frac{T_{\mathrm{c}}}{T_{\mathrm{c}}} \tag{6.28}$$

The quantity ξ_0 can also be treated as the size of a Cooper pair which can be evaluated as

$$\xi_0 \simeq 0.18 \frac{10^{-27} \times 10^8}{1.38 \times 10^{-16} \times 1} \sim 10^{-4} \text{ cm}$$

where $v_{\mathrm{F}} \sim 10^8$ cm s^{-1} and $T_{\mathrm{c}} \sim 1$ K. This is a large, macroscopic distance.

Microscopic Derivation Of The Ginzburg-landau Equations In The Theory Of Superconductivity by Gor'kov

It is shown that the phenomenological Ginzburg-Landau equations follow from the theory of superconductivity in the London temperature region in the neighborhood of $\mathrm{T_c}$. In these equations there occurs, however, twice the electronic charge; this is related to the physical meaning of $\Psi(x)$ as the wave function for Cooper pairs. The constant κ turns out to be small. The problem of the surface energy for the boundary between the normal and superconducting phases in the neighborhood of $\mathrm{T_c}$ is discussed.

Gor'kov's derivations

(???? think about them more later!!!!)

It is well known that the behavior of superconductors in a magnetic field in the neighborhood of the critical temperature is qualitatively well described by Ginzburg and Landau's phenomenological theory. We shall show in the present paper that equations of the same type as those in Ginzburg and Landau's theory follow indeed from the theory of superconductivity.

We shall start from the equations for the thermodynamic Green functions [3,4] which we obtained earlier. [2] These equations are in a magnetic field of the form

$$\left\{ -\frac{\partial}{\partial \tau} + \frac{1}{2m} \left(\frac{\partial}{\partial \mathrm{r}} - ie\mathbf{A}(\mathrm{r}) \right)^2 + \mu \right\} G(x, x') + \Delta(\mathrm{r}) F^+(x, x') = \delta(x - x')$$

$$\left\{ \frac{\partial}{\partial \tau} + \frac{1}{2m} \left(\frac{\partial}{\partial \mathrm{r}} + ie\mathbf{A}(\mathrm{r}) \right)^2 + \mu \right\} F^+(x, x') - \Delta^*(\mathrm{r}) G(x, x') = 0; \tag{1}$$

where

$$\Delta^*(\mathbf{r}) = g F^+(\tau, \mathbf{r}; \tau, \mathbf{r}).$$

The last relation expresses $\Delta(\mathbf{r})$ in terms of the coupling constant and the value of the function $F^+(x, x')$ for equal arguments. If there is no field, $\Delta = \text{const}$. The quantity 2Δ is in that case the energy gap in the spectrum. $\mathrm{F^+(x, x')}$ tends, in fact, logarithmically to infinity as

$x = x'$; this corresponds to the well known logarithmic divergence in the equation determining the gap when one integrates in momentum space. In the papers by Bardeen, Cooper, and Schrieffer [5] and Bogolyubov [6] this divergence was removed by cutting-off the energy of the interacting electrons at distances of the order of the Debye frequency $\widetilde{\omega}$ from the Fermi surface; we
shall do the same in the following. One verifies easily that such a cut-off corresponds in the coordinate representation to a "spread out" in Eq. (1') over a distance of the order $\hbar v/\bar{\omega}$.

Let us go over to the Fourier components of the Green functions $G(x, x')$ and $F^+(x, x')$ with respect to the difference of the variables $u = \tau - \tau'$, for instance,

$$G(\mathbf{r}, \mathbf{r}'; u) = T \sum_n e^{-i\omega_n u} \mathfrak{G}_\omega(\mathbf{r}, \mathbf{r}'),$$
$$\mathfrak{G}_\omega(\mathbf{r}, \mathbf{r}') = \frac{1}{2} \int_{-1/T}^{+1/T} e^{i\omega_n u} G(\mathbf{r}, \mathbf{r}'; u)\, du$$

where $\omega_n = \pi(2n+1)T (n = \ldots -1, 0, 1, \ldots)$. Equations (1) go over into the following equations for the Fourier components $\mathscr{G}_\omega(\mathbf{r}, \mathbf{r}')$ and $\mathfrak{F}^+_\omega(\mathbf{r}, \mathbf{r}')$:

$$\left\{ i\omega_n + \frac{1}{2m}\left(\frac{\partial}{\partial \mathbf{r}} - ie\ \mathrm{A}(\mathbf{r})\right)^2 \div \mu \right\} \mathfrak{G}_\omega(\mathbf{r}, \mathbf{r}') + \Delta(\mathbf{r}) \mathfrak{F}^+_\omega(\mathbf{r}, \mathbf{r}') = \delta(\mathbf{r} - \mathbf{r}'),$$
$$\left\{ -i\omega_n + \frac{1}{2m}\left(\frac{\partial}{\partial r} + ie\ \mathrm{A}(\mathbf{r})\right)^2 + \mu \right\} \mathfrak{F}^+_\omega(\mathbf{r}, \mathbf{r}') - \Delta^*(\mathbf{r}) \mathfrak{G}_\omega(\mathbf{r}, \mathbf{r}') = 0, \tag{2}$$

and condition (1') can be written in the form

$$\Delta^*(\mathbf{r}) = T \sum_n \mathfrak{F}^+_\omega(\mathbf{r}, \mathbf{r}).$$

We introduce, finally, $\tilde{\mathfrak{G}}_\omega(\mathbf{r}, \mathbf{r}')$, the Fourier component of the Green function for an electron in the normal metal in a magnetic field. The equation satisfied by $\mathfrak{G}_\omega(\mathbf{r}, \mathbf{r}')$ can be written in two ways:

$$\left\{ i\omega_n + \frac{1}{2m}\left(\frac{\partial}{\partial \mathbf{r}} - ie\mathbf{A}(\mathbf{r})\right)^2 + \mu \right\} \tilde{\mathfrak{G}}_\omega(\mathbf{r}, \mathbf{r}') = \delta(\mathbf{r} - \mathbf{r}') \tag{3}$$
$$\left\{ i\omega_n + \frac{1}{2m}\left(\frac{\partial}{\partial \mathbf{r}'} + ie\mathbf{A}(\mathbf{r}')\right)^2 + \mu \right\} \tilde{\mathfrak{G}}_\omega(\mathbf{r}, \mathrm{r}') = \delta(\mathbf{r} - \mathbf{r}').$$

It is convenient to use the function $\tilde{\mathfrak{G}}_\omega(\mathbf{r}, \mathbf{r}')$ to write Eqs. (2) in integral form, using the second of Eqs. (3):

$$\mathfrak{G}_\omega(\mathbf{r}, \mathbf{r}') = \tilde{\mathfrak{G}}_\omega(\mathbf{r}, \mathbf{r}') - \int \tilde{\mathfrak{G}}_\omega(\mathbf{r}, \mathbf{s}) \Delta(\mathbf{s}) \mathfrak{F}^+_\omega(\mathbf{s}, \mathbf{r}) d^3\mathbf{s},$$
$$\mathfrak{F}^+_\omega(\mathbf{r}, \mathbf{r}') = \int \mathfrak{G}(\mathbf{s}, \mathbf{r}')\, \Delta^*(\mathbf{s}) \tilde{\mathfrak{G}}_{-\omega}(\mathbf{s}, \mathbf{r}) d^3\mathbf{s} \tag{4}$$

Before we proceed, we find out what the function $\tilde{\mathfrak{G}}_\omega(\mathbf{r}, \mathbf{r}')$ is equal to. If there is no magnetic field, one sees from (3) that

$$\mathfrak{G}^0_\omega(\mathbf{r} - \mathbf{r}') = -\frac{m}{2\pi R} \exp\left\{ \left[i \operatorname{sign} \omega p_0 - \frac{|\omega_n|}{v} \right] R \right\}. \tag{5}$$

Here

$$\operatorname{sign}\omega = \omega/|\omega|, \quad R = |\mathbf{r}-\mathbf{r}'|, \quad \mu = p_0^2/2m \gg |\omega|.$$

$\tilde{\mathfrak{G}}_\omega(\mathbf{r},\mathbf{r}')$ in a magnetic field differs from (5) by a phase factor. Indeed, because p_0 is a large quantity we can use the quasi-classical approximation to determine $\tilde{\mathfrak{G}}_\omega(\mathbf{r},\mathbf{r}')$, i.e., write it in the following form:

$$\tilde{\mathfrak{G}}_\omega(\mathbf{r},\mathbf{r}') = e^{i\varphi(r,r')}\tilde{\mathfrak{G}}^0_\omega(\mathbf{r}-\mathbf{r}'), \qquad \varphi(\mathbf{r},\mathbf{r}')\,|_{\mathbf{r}=\mathbf{r}'} = 0. \tag{6}$$

Substituting (6) into (3) we find for the addition to the action of $\varphi(\mathbf{r},\mathbf{r}')$

$$(\mathbf{n}, \nabla_r\varphi(\mathbf{r},\mathbf{r}')) = \frac{e}{c}(\mathbf{n},\mathbf{A}(\mathbf{r})), \qquad \mathbf{n} = (\mathbf{r}-\mathbf{r}')/|\mathbf{r}-\mathbf{r}'|.$$

Near the transition temperature $\Delta(\mathbf{r})$ (and at the same time $\hat{y}^+_\omega(\mathbf{r},\mathbf{r}')$) is small. We shall therefore expand Eq. (4) in powers of Δ and Δ^* and express $\mathfrak{F}^+_\omega(\mathbf{r},\mathbf{r}')$ up to terms of the fourth order, and $\mathfrak{G}_\omega\omega(\mathbf{r},\mathbf{r}')$ up to terms of second order in Δ, inclusive. The substitution of the expression obtained for $\mathfrak{F}^+_\omega(\mathbf{r},\mathbf{r}')$ into (2′) gives one equation connecting $\Delta(\mathbf{r})$ and A(**r**):

$$\Delta^*(\mathbf{r}) = gT\sum_n \int \tilde{\mathfrak{G}}_\omega(\mathbf{r},\mathbf{r}')\,\tilde{\mathfrak{G}}_{-\omega}(\mathbf{r},\mathbf{r}')\,\Delta^*(\mathbf{r}')\,d^3\mathbf{r}'$$
$$- gT\sum_n \iiint \tilde{\mathfrak{G}}_\omega(\mathbf{s},\mathbf{r})\tilde{\mathfrak{G}}_{-\omega}(\mathbf{s},\mathbf{l})\tilde{\mathfrak{G}}_\omega(\mathbf{m},\mathbf{l})\tilde{\mathfrak{G}}_{-\omega}(\mathbf{m},\mathbf{r})\Delta(\mathbf{s})\Delta^*(\mathbf{l})\Delta^*(\mathbf{m})d^3\mathbf{s}d^3|d^3\mathbf{m} \tag{8}$$

The important distances in Eq. (8) are of the order $\xi = \hbar v/T_c$, since it can be seen from (5) and (6) that the Green function $\tilde{\mathfrak{G}}_\omega(\mathbf{r},\mathbf{r}')$ decreases exponentially for $R > \xi_0$. At the same time, the changes in the gap $\Delta(\mathbf{r})$ and the field $\mathbf{A}(\mathbf{r})$ take place at distances of the order of the penetration depth which is much larger than ξ_0 near the critical temperature. For the same reason the phase $\varphi(\mathbf{r},\mathrm{r}')$ in (6) is small near $\mathrm{T_c}$ and equal to

$$\varphi(\mathbf{r},\mathbf{r}') \approx \frac{e}{c}(\mathbf{A}(\mathbf{r}'),\mathbf{r}-\mathbf{r}') \tag{9}$$

Using these facts we can perform the integration in Eq. (8).

The first term on the right hand side is of the form

$$g\int K(\mathbf{r},\mathbf{r}')\,\Delta^*(\mathbf{r}')\,d^3\mathbf{r}'$$

where the kernel

$$K(\mathbf{r},\mathbf{r}') = K_0(\mathbf{r}-\mathbf{r}')\exp\left\{\frac{2ie}{c}(\mathbf{A}(\mathbf{r}'),\mathbf{r}-\mathbf{r}')\right\}$$

has a singularity for $R = |\mathbf{r}-\mathbf{r}'| = 0$:

$$K_0(R) = m^2T/(2\pi R)^2\sinh(2\pi TR/v)$$

This singularity is connected, as was pointed out already in the foregoing, with the cut-off of the interaction at the Debye frequencies $\tilde{\omega}$.

Introducing this cut-off we get

$$\int K_0(R)d^3R = \frac{m\rho_0}{2\pi^2}\int_0^{\tilde{\omega}}\frac{\tanh(\xi/2T)}{\xi}d\xi = \frac{m\rho_0}{2\pi^2}\ln\left(\frac{2\gamma}{\pi}\frac{\tilde{\omega}}{T}\right) = \frac{m\rho_0}{2\pi^2}\left(\frac{1}{g}+\ln\frac{T_c}{T}\right) \tag{10}$$

*This was pointed out by L. D. Landau.

where the transition temperature $\mathrm{T_c}$ is connected to the gap in the energy spectrum at absolute zero in the well-known way [5]:

$$\frac{\Delta_0 \mathcal{Y}}{\pi} = T_c \quad \left(\frac{1}{g} = \frac{m\rho_0}{2\pi^2} \ln \frac{2\tilde{\omega}}{\Delta_0}\right).$$

Expanding the exponents in the Green functions in terms of $\varphi(\mathbf{r}, \mathbf{r}')$ using the fact that $\Delta(\mathbf{r})$ and $\mathrm{A}(\mathbf{r})$ vary slowly near T_c, and eliminating $\tilde{\omega}$ and g by using (10) we get the following equation

$$\left\{\frac{1}{2m}\left(\frac{\partial}{\partial \mathbf{r}} + 2ie\mathbf{A}(\mathbf{r})\right)^2 + \frac{1}{\lambda}\left[\frac{T_c - T}{T_c} - \frac{7\zeta(3)}{8\left(\pi T_c\right)^2}|\Delta(\mathbf{r})|^2\right]\right\}\Delta^*(\mathbf{r}) = 0 \tag{11}$$

where $\lambda = 7\zeta(3)\epsilon_{\mathrm{F}}/12\left(\pi\ \mathrm{T_c}\right)^2$ (ζ(x) is here Riemann's zeta function).

To get a second equation connecting Δ and A we shall now calculate what the current density f(r) is equal to. To do this we use the relation expressing $j(r)$ in terms of a Green function:

$$\mathrm{j}(\mathbf{r}) = \left\{\frac{ie}{m}\left(\nabla_{\mathbf{r}'} - \nabla_{\mathrm{r}}\right)G\left(x, x'\right) - \frac{2e^2}{mc}\mathbf{A}(\mathbf{r})G\left(x, x'\right)\right\}_{t'=t+0; r=r'}$$

(the additional factor of 2 is due to a summation over spin). We note that if we substitute everywhere the Green function for the normal metal in the form (6) and then sum over frequencies we get no contribution to the expression for the current, as should be the case. The total current is thus equal to

$$\mathrm{j(r)} = \frac{ie}{m}\left(\nabla_{\mathrm{r}'} - \nabla_{\mathrm{r}}\right)\delta G\left(x, x'\right)\Big|_{x=x'}, \tag{12}$$

where

$$\delta G\left(x, x'\right)|_{x=x'} = -T\sum_n \iint \tilde{\mathfrak{G}}_\omega(\mathbf{r}, \mathbf{s})\tilde{\mathfrak{G}}_\omega(\mathbf{l}, \mathbf{r})\tilde{\mathfrak{G}}_{-\omega}(1, \mathbf{s})\Delta^*(\mathbf{l})\Delta(\mathbf{s})d^3\mathbf{s}d^3\mathbf{l}$$

Restricting ourselves in the expression for the current to terms linear in A and assuming $A(r)$ to vary slowly with $\mathbf{r}$ in the London temperature range near $\mathrm{T_c}$ we get

$$\mathrm{j(r)} = \left\{\frac{ie}{m}\left(\Delta\frac{\partial\Delta^*}{\partial \mathrm{r}} - \Delta^*\frac{\partial\Delta}{\partial \mathrm{r}}\right) - \frac{4c^2|\Delta|^2}{mc}\mathbf{A}\right\}\frac{7\zeta(3)N}{16(\pi T)^2} \tag{14}$$

We shall introduce a "wave function" $\Psi(\mathbf{r})$, proportional to $\Delta(\boldsymbol{r})$:

$$\Psi(r) = \Delta(r)\sqrt{7\zeta(3)N}/4\pi T_c \tag{15}$$

The set of Eqs. (11) and (14) takes then a form completely analogous to the equations of the phenomenlogical Ginzburg-Landau theory:

$$\left\{\frac{1}{2m}\left(\frac{\partial}{\partial \mathrm{r}} - ie^*A(\mathrm{r})\right)^2 + \frac{1}{\lambda}\left[\frac{T_c - T}{T_c} - \frac{2}{N}|\Psi(\mathrm{r})|^2\right]\right\}\Psi(\mathrm{r}) = 0 \tag{16}$$

$$\mathrm{j(r)} = -\frac{ie^*}{2m}\left(\Psi^*\frac{\partial\Psi}{\partial \mathrm{r}} - \Psi\frac{\partial\Psi^*}{\partial \mathrm{r}}\right) - \frac{e^{*2}}{mc}\mathbf{A}\left|\Psi^*\right|^2,$$

where $e^* = 2e$, N is the number density of the electrons in the normal metal and λ was defined after Eq. (11). There is a difference, however, in that (16) contains the electronic charge e twice, clearly owing to the physical meaning of $\Psi(r)$ as the wave function of a Cooper pair.

These equations arise thus in a natural way in the theory of superconductivity in the London region* near T_c. The phenomenological constant defined in the same way as in the old theory, but with $e^* = 2e$, can now be evaluated and turns out to be equal to

$$x = 3T_c(\pi/v)^{1/2}\,(c/ep_0)\,\sqrt{2/7\zeta(3)} \tag{17}$$

The region of applicability of Eqs. (16) is small for sharply expressed Pippard metals and occurs very near T_c; at large distances from T_c the local relation (14) ceases to be valid.

For metals of the London type the region of applicability of (16) is determined solely by the smallness of the ratio $(\mathrm{T} - \mathrm{T_c})/\ \mathrm{T_c}$.

The possibility to apply (16) to describe the properties of thin films in a magnetic field with the microscopic value (17) of the constant κ is limited by the fact that usually films are polycrystalline specimens with grain sizes of the order of the film thickness. The presence of boundaries between different crystals will act like the presence of foreign impurities. One must therefore possibly describe real films in the microscopic theory from the same point of view as superconducting alloys.

We note now that to evaluate the difference in the free energy of the metal in the normal state and in the superconducting state in a magnetic field we can use the following formula:

$$F_{sH} - F_n = -(1/\lambda N)\int |\Psi(r)|^4 d^3\mathbf{r} \tag{18}$$

Indeed, we shall use the thermodynamic relation

$$\delta\Omega/\delta g(\mathbf{r}) = -\langle H_{\mathrm{int}}(\mathbf{r})\rangle/g(\mathbf{r})$$

where according to (5)

$$H_{\mathrm{int}}(r) = \frac{1}{2}g(r)\left(\hat{\Psi}^+(r)\left(\hat{\Psi}^+(r)\hat{\Psi}^+(r)\right)\hat{\Psi}^{(r)}(r)\right.$$

Ω is the thermodynamic potential [we introduce here for the sake of convenience a variable "interaction constant" $g(r)$]. Taking averages we get

$$\Omega_s - \Omega_n = -\int d^3r \int_0^g \frac{\delta g(r)}{g^2(r)}|\Delta(r)|^2 \tag{19}$$

Equation (8) determines $1/g(\mathbf{r})$ as a functional of $\Delta(r)$ [for the sake of simplicity we shall consider the real solution for $\Delta(r)$ as is usually done in one-dimensional problems]. Using (8) to integrate (19), and using the fact that small additions to all thermodynamic potentials in the corresponding variables are equal, we get Eq. (18).

The constant κ of (17) is connected with the magnitude of the critical field $\mathrm{H_{cm}}$ of a bulk specimen and the penetration depth δ_0 by the relation (which contains the charge e^*):

$$x = \frac{\sqrt{2}e^*}{\hbar c}H_{cm}\delta_0^2 \tag{20}$$

For metals of the London type or such intermediate metals as tin the region of applicability of Eqs. (16) is fairly large and in that case we should consistently use the experimental data* for $\mathrm{H_{cm}}$ and δ_0^2 to compare the theory with experiments. For Pippard metals δ_0 is the penetration depth only in a very narrow range of temperatures near T_c. It is thus convenient in this case to turn to the theoretical formulae for a definition of κ. It can easily be verified that (17) can be written in the form

$$x \approx 0.96\delta_L/\xi_0 \tag{21}$$

where $\delta_{\mathrm{L}}^{-1} = \left(4\pi \mathrm{Ne}^2/mc^2\right)^{1/2}$ is the London penetration depth and $\xi_0 = 0.18\hbar \mathrm{v}/\mathrm{kT_c}$ is the non-localization parameter introduced in Bardeen, Cooper, and Schrieffer's paper. Using the data given in reference 5 we get from (21) for tin $\kappa \approx 0.14$, and for aluminum $\kappa \approx 0.01$.

We note an interesting consequence of (21). The condition that a superconductor be a London one requires $\kappa \approx \delta_L/\xi_0 \gg 1$. At the same time if $\kappa \gg 1/\sqrt{2}$ a metal displays in a strong field the same behavior as for alloys. A metal which in weak fields at $T = 0$ must be assigned to the London class will thus behave in strong fields near $\mathrm{T_c}$ as an "alloy." At the same time the case of small κ corresponds to a Pippard metal.

Let us now stop a moment at the problem of the surface energy at the boundary between the normal and the superconducting phase. For strongly expressed Pippard superconductors we can, because κ is small, use the limiting solution [1]

$$\sigma_{ns}\left(8\pi/H_{cm}^2\right) = 1.89\delta_0/x \tag{22}$$

where

$$\delta_0 = \delta_L(T=0)/\sqrt{2\,(1-T/T_c)}.$$

We note that for these metals the applicability of Eq. (22) in an appreciable temperature interval near $\mathrm{T_c}$ is just connected with the fact that κ is small, since, as was shown in reference 1, in that case the quantity σ_{ns} does not depend on the distribution of the field in the transition region.

For tin the accuracy of this equation is insufficient and one must use the results of numerical calculations. Estimating σ_{ns} from Ginzburg's calculations [8] we get for $\kappa \approx 0.14$

$$\sigma_{ns}\left(8\pi/H_n^2\right) \approx (2 \div 3)\cdot 10^{-5}/\sqrt{1-T/T_c}$$

According to Sharvin's data [9]

$$\sigma_{ns}\left(8\pi/H_c^2\right) = 2.5\cdot 10^{-5}/\sqrt{1-T/T_c}$$

and according to Faber's data [10]

$$\sigma_{ns}\left(8\pi/H_c^2\right) = 1.88\cdot 10^{-5}/\sqrt{1-T/T_c}$$

These results do, apparently, not contradict the theory (See reference 7).

5.2.2 What is Different in Equilibrium and Non-Equilibrium Superconductors?

(discuss what will chenge? for non-eq sc - see some sections at the end of the note)

5.2.3 Derivation of phenomena of GL theory in the framework of BCS theory

(??? a very hard section, I have no idea how to do it now)

5.2.4 Derivation of phenomena of BCS theory in the framework of GL theory

(??? a very hard section, I have no idea how to do it now)

5.2.5 Existence of 1D superconductors

(here will be a detailed discussion about it, since there are always questions about it!)
(still, often we use such formulas)

5.2.6 General idea of dissipation in superconductors

(!!! I'll crate here theory about basics, more details - in another note or at some latter part of this note)

Formalism for dissipation for BCS model

We can just add a Lindblad operator, because it is often done in open systems.
(????)

Connection of Lindblad operator and physical processes

(??? how can we make if from some coupling???)

Choice of Lindblad operators and dissipator

(????)
(here is about the dissipator that was used in the work with Zala)
(write that it acts on all the momenta, not in the Debye's window because we have electron and hole excitations, all with positive energy)

Lindblad operators for BCS theory: Other questions

Why some Lindblad operators are broken if there are some reasonable parameters in the BCS TB model?

(this is the question which I tried to answer in September 2025)
(remind the form of the lindbladian)
(write that with this code we get these plots, which are broken)
(??? and then answer the question. I don't know yet the answer)

Other about basics of dissipation in superconductivity

5.2.7 Other General Fundamental Concepts

How Exactly Temperature of Superconductor is Established?

Suppose we are in an empty space (where there are only vacuum fluctuations) and we have a material. What will fix its temperature? How would electrons know, if they should be in superconductive state or in normal?

Answer

They "feel" energy of an atom, then collect statistics and compare it with the fundamental constant $\hbar$.
(??? but how exactly??)
(????? this is a question on statistical physics, so I'll write answer there and then these ideas will be applied to the superconductivity)

How Exactly Electrons will know, where spin of each points?

(??? should there be a selected axes? maybe yes, because withought it spin will be in different directions and there will be on +,- spins.)

5.2.8 How can we theoretically prove that other low-energy effects do not destroy SC?

(it is maybe impossible, and also very hard and also not needed at all. but later I'll maybe think about it)

5.3 Other Typical Properties

5.3.1 Velocity of superconductive electrons

(here we will discuss in details the question about what is the velocity of electrons in SC?)

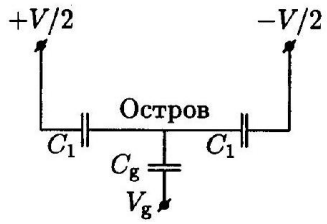
5.3.2 Parity Effect in SC by Shmidt 48*

При температурах $T \ll T_c$ большая часть электронов в сверхпроводнике образует куперовские пары и лишь экспоненциально малая их доля (порядка $e^{-\Delta/k_{\rm B}T}$) находится в возбужденных состояниях с энергией $E > \Delta$ (это следует из выражения (45.9) для функции распределения $f_{\mathbf{k}}$). Это означает, что для изолированного островка сверхпроводящего металла имеет смысл вопрос о четности полного числа электронов на нем. Действительно, если число электронов четно, то при $T = 0$ все они образуют пары; в противном случае какой-то электрон остается неспаренным, т. е. энергия всего островка будет выше на величину минимальной энергии возбуждения Δ_0. Напомним (см. (44.17)), что плотность энергии сверхпроводящего спаривания равна $|W_0| = \frac{1}{2}N(0)\Delta_0^2$, т.е. полное изменение энергии островка объема V из-за сверхпроводящего спаривания состояния имеет порядок $\mathcal{N}_{\text{полн}}\,\Delta_0^2/\varepsilon_{\rm F}$, где $\mathcal{N}_{\text{полн}} \sim N(0)V\varepsilon_{\rm F}$ - полное число электронов. Таким образом, изменение числа куперовских пар на единицу приводит к изменению энергии лишь на величину Δ_0^2/ε_F, много меньшую, чем Δ_0. Пренебрегая этой малой поправкой, получаем, что при добавлении к "нечетному" островку еще одного электрона его полная энергия понизится на Δ_0, т. к. квазичастица (возбуждение) исчезнет и образуется дополнительная куперовская пара (с энергией на уровне Ферми).

Можно ли экспериментально обнаружить периодическое изменение свойств сверхпроводящего островка с периодом $2e$? В работе [147] было впервые продемонстрировано, что это возможно, несмотря на то, что полное число $\mathcal{N}_{\text{полн}}$ электронов на островке было порядка 10^9. Прежде чем описать этот эксперимент, мы выясним, как обобщить приведенное выше простое рассуждение, справедливое при $T = 0$, на случай отличных от нуля температур.

Самое простое соображение таково: полное число квазичастиц на островке есть

$$N_{qp} = \sum_{\mathbf{k}} f_{\mathbf{k}} = N(0)V \int\limits_0^\infty \frac{d\varepsilon}{\exp\left(\sqrt{\varepsilon^2+\Delta^2}/k_{\rm B}T\right)+1} \sim$$
$$\sim \mathcal{N}_{\text{эфф}}\, e^{-\Delta/k_{\rm B}T} \tag{48.1}$$



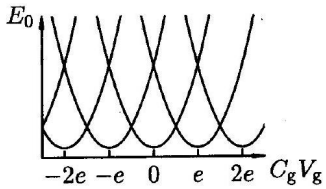
где $\mathcal{N}_{\text{эфф}} \approx N(0)V\sqrt{T\Delta}$ близко по порядку величины к числу электронов на островке, имеющих энергии в полосе порядка Δ_0 вблизи ферми-поверхности (действительно,

электроны с энергиями, много большими Δ_0, в любом случае "ничего не знают" о сверхпроводящем спаривании). Если величина N_{qp} окажется много меньше единицы, то вероятность найти на островке хотя бы одно возбуждение мала и картина такая же, как при $T = 0$; отсюда получается условие $k_{\mathrm{B}}T \ll \Delta_0/\ln \mathcal{N}_{\text{эфф}}$. Более аккуратное рассмотрение необходимо, чтобы понять, что происходит при $k_{\mathrm{B}}T \sim \Delta_0/\ln \mathcal{N}_{\text{эфф}}$. Оно проводится следующим образом: при $T > 0$ вместо энергии неспаренного электрона следует использовать его свободную энергию $F_1(T) = \Delta - TS_1$, где соответствующая энтропия $S_1 = k_{\mathrm{B}} \ln \mathcal{N}_{\text{эфф}}$. В таком случае эффект четности имеет место, если появление неспаренного электрона увеличивает свободную энергию островка, т.е. при $F_1(T) > 0$, что имеет место при температурах

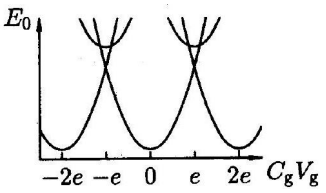
$$T < T^* = \frac{\Delta_0}{k_{\mathrm{B}} \ln \mathcal{N}_{\text{эфф}}} \tag{48.2}$$

Таким образом, можно ожидать (при $\ln \mathcal{N}_{\text{эфф}} \gg 1$), что эффект четности возникает при определенной температуре, как это бывает при фазовом переходе. В условиях экспериментов по эффекту четности [147] число $\mathcal{N}_{\text{эфф}} \sim 10^4$, так что ожидаемое $k_{\mathrm{B}}T^* \simeq 0.1\Delta_0$, что и было подтверждено экспериментально. Точное вычисление (приведенное, например, в книге [2]) показывает, что полученное выше из качественных соображений выражение для $F_1(T)$ является правильным с точностью до численного коэффициента в выражении для $\mathcal{N}_{\text{эфф}}$. Поскольку в ответ входит лишь логарифм $\mathcal{N}_{\text{эфф}}$, это отличие малосущественно.

Рис. 48.1. Электрическая схема электрометра с кулоновской блокадой.

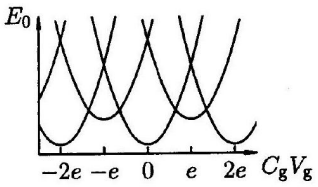


Перейдем теперь к описанию проведенных в [147, 148] экспериментов, где был использован прибор, называемый сверхпроводящим одноэлектронным транзистором (СОЭТ). Его электрическая схема изображена на рис. 48.1: алюминиевый островок в виде тонкой пленки (раэмерами $0.2 \times 0.6 \times 2$ мкм ^{3} в условиях эксперимента [147]) соединялся со включенными в цепь алюминиевыми берегами высокоомными ($R_{1,2} \gg h/e^2 \simeq 26$ кОм, смысл этого условия будет прояснен ниже) туннельными контактами с емкостями C_1, C_2. Кроме того, около островка располагался электрический затвор, позволявший создавать на островке заданный потенциал V_g, от которого зависит электростатическая энергия $U_{el}(n, V_g)$ островка с добавленными на него n электронами:



$$U_{el}(n, V_g) = \frac{(en)^2}{2C} - \frac{ne}{C} C_g V_g, \quad C = C_g + C_1 + C_2 + C_0 \tag{48.3}$$

(здесь C_0-собственная емкость островка). Пусть $k_{\mathrm{B}}T \ll E_C = e^2/2C$, а островок находится в нормальном состоянии (что достигается, например, приложением магнитного поля $H > H_c$, разрушающего сверхпроводимость). Число электронов на островке определяется из условия минимума энергии $U_{el}(n)$ по n и меняется на единицу при полуцелых значениях $C_g V_g/e = m + 1/2$, когда энергии состояний с $n = m, m+1$ совпадают. Графически это удобно представлять как точки пересечения парабол $\widetilde{U}_{el}(n, V_g) = \frac{(\,\mathrm{en} - C_g V_g)^2}{2C}$, изображенных на рис. 48.2, a (добавление не зависящего от n члена $(C_g V_g)^2/2C$ к $U_{el}(n, V_g)$ не меняет результат минимизации энергии по n).



Рассмотрим теперь ту же систему в сверхпроводящем состоянии, причем $T < T^*$, так что свободная энергия одного возбуждения велика: $F_1(T) > E_C \gg k_{\mathrm{B}}T$. Теперь все кривые $\widetilde{U}_{el}(V_g)$ с нечетными n поднимутся вверх на величину $F_1(T) > e^2/2C$, см. рис. 48.2, 6, так что минимум электростатической энергии всегда достигается на кривых с четным числом электронов $n = 2k$ и изменение этого числа происходит при $C_gV_g/e = 2m + 1$. Скачок заряда на островке при этих значениях потенциала означает, что эффективная дифференциальная емкость островка по отношению к затвору $C_{\text{эфф}} = d(en)/dV_g$ имеет резкие пики с периодом $\Delta V_g = 2e/C_g$ (вместо e/C_g в нормальном состоянии). Таким образом, измерение дифференциальной емкости позволяет пронаблюдать возникновение эффекта четности как переход от - к $2e$-периодичности в зависимости $C_{\text{эфф}}(V_g)$. Этот метод был использован в работе [148].

а)

б)

в)

Рис. 48.2. Качественное поведение энергии островка в зависимости от заряда C_gV_g на затворе: a) островок в нормальном состоянии; б) $F_1(T) > E_C \gg k_{\mathrm{B}}T; \theta)\, E_C > F_1(T) \gg k_{\mathrm{B}}T$.

В работе [147] использовался другой метод - измерялась зависимость критического джозефсоновского тока I_c через островок от V_g. Рассмотрим происхождение этой зависимости для слу'ая $F_1(T) > E_C$, когда реализуются только "четные" состояпия на островке. В отличие от обычного джозефсоновского контакта (с прямым туннелированием пар с одного берега на другой), здесь туннелирование куперовской пары с первого берега на второй происходит через промежуточное виртуальное (в квантовомеханическом смысле) состояние островка. Энергия этого промежуточного состояния $U_2(V_g) = U_{el}(n_{\min} + 2) - U_{el}(n_{\min}) = 4E_C \min_k \left|2k + 1 - \frac{C_gV_g}{e}\right|$ зависит от C_gV_g периодически с пе риодом $2e$. В эксперименте с СОЭТ E_C много больше матричного элемента K туннелирования пары в каждом контакте; предполагая также, что $K \ll U_2(V_g)$, получаем с помощью квантовомеханической теории возмущений энергию джозефсоновской связи между берегами $K^{\text{эфф}} = K^2/U_2(V_g)$ (более подробный вывод, аналогичный фейнмановскому выводу выражения (21.9) для джозефсоновского тока, приведен в книге [2]). Поэтому максимальный джозефсоновский ток через СОЭТ равен

$$I_c\left(V_g\right)=\frac{2e}{\hbar}\frac{K^2}{U_2\left(V_g\right)} \tag{48.4}$$

Электростатическая энергия $U_2\left(V_g\right)$ зависит от C_gV_g с периодом $2e$, что и приводит к такой же периодичности в $I_c\left(V_g\right)$ с резкими максимумами при $V_g=\frac{e}{C_g}(2m+1)$, где $U_2\left(V_g\right)$ обращается

в нуль (вблизи этих максимумов $U_2\left(V_g\right)$ становится меньше K, так что формула (48.4) там неприменима; критический ток в максимумах имеет порядок $I_c^{\max}\sim(2e/\hbar)K$, см. [149]).

При выводе (48.4) мы подразумевали, что $F_1(T)>E_C\gg k_{\mathrm{B}}T$, так что "нечетные» состояния островка не реализуются ни при каких V_g. С повышением температуры величина $F_1(T)$ становится меньше E_C, и тогда вырожденными по полной энергии $U_{el}\left(V_g\right)+F_1(T)\frac{1-(-1)^n}{2}$ оказываются состояния различной четности (отличающиеся по заряду на e), см. рис. 48.2, в. Это означает, что состояния островка, переходящие друг в друга при туннелировании одной куперовской пары, т.е. отличающиеся на $2e$ по заряду, имеют разность кулоновских энергий порядка E_C при всех V_g. В результате "кулоновский знаменатель" в (48.4) всегда остается величиной порядка E_C, так что максимальное значение критического тока резко падает; при $F_1(T)\ll E_C$ эффектами четности можно полностью пренебречь, и зависимость $I_c\left(V_g\right)$ имеет период e с максимумами при $V_g=\frac{e}{2C_g}(2m+1)$. Последовательный микроскопический вывод зависимостей $I_c\left(V_g\right)$ во всех упомянутых случаях приведен в работах [149].

Остановимся в конце на вопросе о том, почему для наблюдения эффекта четности с помощью СОЭТ необходимо иметь высокоомные контакты островка с берегами, $R\gg h/e^2$. Рассмотрим сначала случай островка в нормальном состоянии, когда время релаксации неравновесного заряда на островке имеет порядок $\tau=RC$. Согласно соотношению неопределенностей, величина $\Delta E\sim h/\tau$ характеризует ширину возбужденного уровня энергии островка (т.е. уровня с неоптимальным значением n). Требование малости этой ширины по сравнению с характерной энергией возбуждения $E_C=e^2/2C$ и приводит к условию $R\gg\gg R_K=h/e^2$. Для сверхпроводящего состоянии островка то же самое условие следует из требования малости туннельного матричного элемента: $\Delta>E_C\gg K\simeq\frac{\hbar}{Re^2}\Delta$, где для оценки K использовано соотношение (46.14).

5.3.3 Unconventional superconductivity: Relation to the Basic Theory

(just about connection of these two topics)

by par 49 by Schmidt

При обсуждении куперовского спаривания в §§44, 45 мы неявно предполагали, что матричный элемент межэлектронного взаимодействия $V_{\mathrm{k},\mathbf{k}'}$, ответственный за спаривание, не зависит от направлений векторов $\mathbf{k}$ и $\mathbf{k}'$ на поверхности Ферми. В таком слу'ае амплитуда спаривания $v_{\mathbf{k}}$ электронов с импульсами $\hbar\mathbf{k}$ и $-\hbar\mathbf{k}$ и противоположными спинами также не зависит от направления вектора $\mathbf{k}$. Иначе говоря, два электрона, составляющие пару, находятся в состоянии взаимного движения с орбитальным угловым моментом $L=0$, называемом также s-состоянием (по аналогии с классификацией электронных оболочек в атомах). Поскольку полная волновая функция двух электронов должна быть по принципу Паули антисимметрична при их перестановке, а орбитальное s-состояние симметрично, антисимметрия должна быть беспечена за счет спиновой части волновой функции; поэтому лектроны в паре

находятся в синглетном по спину состоянии (полный спин куперовской пары $S = 0$) - это более точная формулировка уже упомянутого в §44 обстоятельства - электроны ппариваются с противоположными спинами.

В действительности, синглетное s-спаривание - самый распространенный, но не единственный возможный тип куперов ских пар. Прежде всего здесь надо напомнить о сверхтекучих фазах ^{3}He, изотопа гелия с фермиевской статистикой атомов (изза полуделого спина ядра ^{3}He). Объединение двух атомов ^{3}He в пару наподобие куперовской происходит аналогично обычному спариванию электронов, описанному в 44. Однако взаимодействие в ^{3}He устроено так, что в s-состоянии атомы отталкиваются, а притяжение возникает только в p-состоянии (взаимный орбитальный момент пары равен $L = 1$). Волновая функция этого орбитального состояния антисимметрична при перестановке, соответственно, и полный спин пары здесь равен $S = 1$ («спиновый триплет»). Такой вид куперовского состояния называется триплетным p-спариванием. Спаривание такого типа, по-видимому, реализуется и в недавно открытом сверхпроводнике Sr_2RuO_4 (см., например, [150]). Мы не будем здесь обсуждать весьма интересные свойства состояний с p-спариванием (об этом можно прочитать в книге [2]), а остановимся на другом примере, связанном с высокотемпературными сверхпроводниками семейств $YBa_2Cu_3O_{7-x}, La_{2-x}Sr_xCuO_4$ и $Bi_2Sr_2CaCu_2O_8$.

Прежде всего заметим; что при синглетном ($S = 0$) спаривании допустимо не только s-состояние, но и все высшие состояния с четными орбитальными моментами пары, $L = 2k$, поскольку такие волновые функции не меняют знака при повороте на угол 180°, т.е. симметричны при перестановке частиц в паре. Считается экспериментально установленным (мы обсудим соответствующие эксперименты позднее), что спаривание в этих ВТСПсоединения имеет такую же качественно структуру, какая получается в обобщении простой БКШ-модели на случай синглетного d-спаривания (орбитальный момент $L = 2$). Микроскопический механизм, приводящий к появлению сильного притяжения в ВТСП-соединениях, до сих пор не вполне ясен, и, скорее всего, он сильно отличается от обычного электрон-фононного механизма притяжения. Однако наиболее важные черты спаривания в ВТСП можно понять на примере «минимального обобщения» теории БКШ, которое состоит в постулировании сильно анизотропного потенциала притяжения $V_{\mathbf{k},\mathbf{k}'}$ подходящего вида (он должен соответствовать тетрагональной симметрии кристаллов ВТСП
и приводить к спариванию с моментом $L = 2$). Основные качественные свойства d-спаривания и вытекающие из них методы экспериментального обнаружения таких состояний мы и обсудим далее в этом параграфе.

В d-состоянии амплитуда (волновая функция) пары $v_{\mathbf{k}}$ меняет знак в зависимости от направления вектора k на поверхности Ферми. Поскольку ВТСП-кристаллы имеют слоистую структуру, в простейшем приближении можно считать поверхность Ферми почти цилиндрической и ограничиться рассмотрением "фермилинии" - сечения ферми-поверхности плоскостью сильной связи (x, y). Тогда соответствующая d-состоянию угловая зависимость волновой функции [1)] пары имеет вид

$$v_{\mathbf{k}} \propto \left(k_x^2 - k_y^2\right) \propto \cos 2\theta_k \tag{49.1}$$

где угол θ_k отсчитывается от направления кристаллографической оси x. Тем самым, в четырех точках на ферми-линии, задаваемых равенствами $k_x = \pm k_y$, волновая функция пары, а вместе с ней и вероятность $v_{\mathbf{k}}^2$ заполнения ячейки $(\mathbf{k}, -\mathbf{k})$ с такими $\mathbf{k}$ обращается в нуль. Это очень важное свойство d-спаривания сейчас мы покажем, что и спектр возбуждений в таком состоянии оказывается анизотропным, причем возбуждения с $k_x = \pm k_y$ могут иметь сколь угодно низкую энергию; о такой ситуации говорят как о нулях щели в спектре на линиях (линии появляются, если вспомнить о наличии импульса $\hbar k_z$).

Амплитуду спаривания вида (49.1) можно получить, выбрав потенциал притяжения электронов, например, в виде $V_{\mathbf{k},\mathbf{k}'} = -2V_d \cos 2\theta_{\mathbf{k}} \cos 2\theta_{\mathbf{k}'}$. Такой выбор означает, что наиболее сильно притягиваются электроны с импульсами, близкими к осям x и y, в то время как вблизи диагоналей $k_x = \pm k_y$ притяжение отсутствует. Проводя с таким потенциалом вывод, совершенно аналогичный сделанному в §44, получим вместо (44.8) - (44.9) следующие уравнения (выражение (44.10) для v_{k}^2 при этом сохраняет свой вид) на спектр при температуре $T = 0$:

$$\Delta_{\mathbf{k}} = 2V_d \cos 2\theta_{\mathbf{k}} \sum_{\mathbf{k}'} v_{\mathbf{k}'} u_{\mathbf{k}'} \cos 2\theta_{\mathbf{k}'} \tag{49.2}$$

$$E_{\mathbf{k}} = \sqrt{\varepsilon_{\mathbf{k}}^2 + \Delta_{\mathbf{k}}^2} \tag{49.3}$$

Обозначив $\Delta_{\mathbf{k}} = \Delta_0 \cos 2\theta_{\mathbf{k}}$, получим уравнение на Δ_0 почти такого же вида, как (44.12),

$$1 = N(0)V_d \int_0^{2\pi} \frac{d\theta}{2\pi} \int_0^{\hbar\omega_{\mathrm{D}}} \frac{d\varepsilon}{\sqrt{\varepsilon^2 + \Delta_0 \cos^2 2\theta}} \tag{49.4}$$

решение которого отличается от (44.14) лишь численным коэффициентом перед экспонентой. Зависимость парной амплитуды $\Delta_{\mathbf{k}}$ от направления вектора $\mathbf{k}$ относительно осей кристалла наглядно изображена на рис. 49.1 в виде "розетки", аналогичной обычной электронной d-орбитали в атоме.

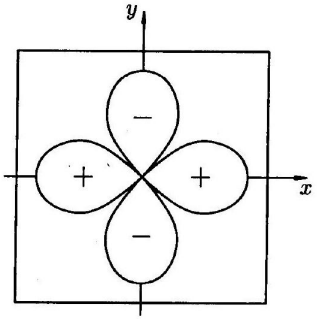


Рис. 49.1. Схематическая зависимость d-волнового параметра порядка $\Delta_{\mathbf{k}}$ от направления импульса пары $\hbar\mathbf{k}$ на фермиповерхности.

Уравнения (49.2), (49.3) имеет важное следствие, проявляющееся при малых энергиях - плотность квазичастичных состояний $\rho(E)$ нигде не обращается в нуль, а лишь плавно убывает при $E \to 0$. Действительно, рассмотрим квазичастичное состояние с $\mathbf{k} = (k_{\mathrm{F}} + q_\perp) \cdot \left(\frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}}\right) + q_\parallel \cdot \left(\frac{1}{\sqrt{2}}, -\frac{1}{\sqrt{2}}\right)$, где обе компоненты вектора q малы по сравнению с k_{F}. Согласно (49.3), его энергия равна

$$E_{\mathbf{q}} = \hbar \sqrt{v_{\mathrm{F}}^2 q_\perp^2 + \left(\frac{2\Delta_0}{\hbar k_{\mathrm{F}}}\right)^2 q_\parallel^2} \tag{49.5}$$

Как видно из выражения (49.5), энергия возбуждения стремится к нулю при $q \to 0$, т.е. при импульсе $\hbar\mathbf{k}$ вблизи точки $\left(\frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}}\right)$. Всего таких выделенных точек на ферми-линии четыре: $\left(\pm\frac{1}{\sqrt{2}}, \pm\frac{1}{\sqrt{2}}\right)$.

[1] В действительности, влияние поля кристаллической решетки в ВТСП столь велико, что фермиповерхность оказывается сильно анизотропной в плоскости (x, y), так что классификация состояний пар по угловому моменту вообще отсутствует, и правильнее говорить просто о смене знака волновой функции пары при дискретных поворотах на угол 90°.

Найдем теперь плотность состояний $\rho(E)$ при $E \ll \Delta_0$. Вводя вектор $\tilde{\mathbf{q}} = \left(q_\perp, q_\parallel \frac{2\Delta_0}{v_\mathrm{F} k_\mathrm{F}}\right)$, запишем энергию возбуждения (49.5) в приведенном к изотропному виде: $E_{\tilde{q}} = \hbar v_\mathrm{F} \tilde{q}$. Переписывая элемент фазового объема $d^3\mathrm{k}/(2\pi)^3$ в виде

$$\frac{dk_z}{2\pi}\frac{dk_x dk_y}{(2\pi)^2} = \frac{dk_z}{2\pi}\frac{dq_\perp dq_\parallel}{(2\pi)^2} = \frac{v_F k_F}{2\Delta_0}\frac{dk_z}{2\pi}\frac{d^2\widetilde{\mathbf{q}}}{(2\pi)^2} = \frac{k_F}{2v_\mathrm{F}\Delta_0}\frac{dk_z}{2\pi}\frac{EdE}{2\pi}$$

Сравнивая с выражением для плотности состояний $N(\varepsilon)$ в нормальном металле и умножая на четыре, получаем низкоэнергетическую плотность состояний в сверхпроводнике с d-спариванием:

$$\rho(E) = N(0)\frac{2E}{\Delta_0} \tag{49.6}$$

Иначе говоря, плотность состояний в d-сверхпроводнике лишь на множитель порядка $E/k_\mathrm{B}T_c$ меньше, чем в нормальном металле. :)то означает, что число элементарных возбуждений $\nu_{qp}(T)$ при низких температурах не является, в отличие от обычного сверхцроводника (см. (48.1)), экспоненциально малым:

$$\nu_{qp}(T) = \sum_{\mathbf{k}} f_{\mathbf{k}} = V\int\limits_0^\infty dE\rho(E)f(E) \sim N(0)V\frac{T^2}{\Delta_0} \tag{49.7}$$

Поэтому условие $\nu_{qp}(T) \ll 1$, необходимое для наблюдения эффекта четности (см. 48), очень трудно выполнить для d-сверхпроводника - оно требует температур $T < T_d^* \simeq (\Delta_0 \delta E)^{1/2}$, где $\delta E = (N(0)V)^{-1}$ - расстояние между электронными уровнями в образце в нормальном состоянии, имеющее порядок 10^{-4} К в экспериментах по эффекту четности [147]. Более того, при низких температурах $T \ll T_d^*$ связанная с присутствием неспаренного электрона дополнительная свободная энергия $F_1(T)$ очень мала, $F_1(0) \sim \delta E$. Дело в том, что квазичастица может занять ячейку k-пространства, сколь угодно близкую к одной из четырех точек вырождения. Можно показать (см. [2]), что максимальная величина $F_1^{\max}(T)$ для d-сверхпроводников имеет порядок $k_\mathrm{B}T_d^*$ и достигается при $T \simeq T_d^*$. Таким образом, отсутствие (или аномальная слабость) эффекта четности может служить одним из доказательств аномальной природы спаривания.

Другое важное свойство d-сверхпроводника - относительно большая величина низкотемпературной электронной теплоемкости $C_s(T)$. Используя комбинаторное выражение (см. [28]) для энтропии ферми-газа

$$S\left(f_{\mathbf{k}}\right) = -\sum_{\mathbf{k}}\left[\left(1-f_{\mathbf{k}}\right)\ln\left(1-f_{\mathbf{k}}\right) + f_{\mathbf{k}}\ln f_{\mathbf{k}}\right]$$

и выражения (45.5) и (49.6) для $\rho(E)$, получим теплоемкость сверхпроводника в следующем виде (окончательные выражения написаны для $T \ll T_c$):

$$\begin{aligned} C_s(T) =& T\frac{\partial S}{\partial T} = \sum_{\mathbf{k}} E_{\mathbf{k}}\frac{\partial f_{\mathbf{k}}}{\partial T} = N(0)\int\limits_0^\infty dE\rho(E)\frac{(E/T)^2}{\left(e^{E/T}+1\right)^2} = \\ &= \begin{cases} N(0)\frac{\pi^2 T}{6}\sqrt{\frac{2\pi\Delta_0^5}{T^5}}e^{-\Delta_0/T} & \text{для } s\text{-спаривания,} \\ 0.55N(0)\frac{T^2}{\Delta_0} & \text{для } d\text{-спаривания.} \end{cases} \end{aligned} \tag{49.8}$$

Отсутствие щели в спектре при d-спаривании приводит к возбуждению большего количества квазичастиц и к существенно более быстрому, чем при s-спаривании,

убыванию параметра спаривания $\Delta_0(T)$ с температурой. Обобщение уравнения (49.4) на ненулевые температуры производится так же, как при выводе (45.15), и имеет вид

$$1 = N(0)V_d \int_0^{2\pi} \frac{d\theta}{2\pi} \int_0^{\hbar\omega_{\rm D}} \frac{d\varepsilon}{\sqrt{\varepsilon^2 + \Delta_0(T)\cos^2 2\theta}} \,\mathrm{th}\, \frac{\sqrt{\varepsilon^2 + \Delta_0(T)\cos^2 2\theta}}{2T}. \tag{49.9}$$

Основной вклад в зависимость $\Delta(T)$ при низких температурах дают низколежащие возбуждения с $\varepsilon \sim k_{\rm B}T$ и $\cos 2\theta \sim k_{\rm B}T\Delta_0 \ll \ll 1$. Вычисляя приближенно разность интегралов (49.4) и (49.9), получаем

$$\Delta_0 - \Delta_0(T) \simeq \frac{2\ln 2}{\pi} \frac{T}{\Delta_0} \tag{49.10}$$

в отличие от экспоненциально малых поправок порядка $e^{-\Delta/T}$ при s-спаривании. В эксперименте бывает удобнее измерять температурную зависимость лондоновской глубины проникновения, которая тоже оказывается линейной [151] : $(\lambda(T)/\lambda(0) - 1) \sim T/\Delta_0$. Соответствующие расчеты проведены в работах [152].

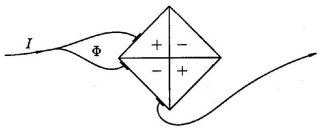

Рис. 49.2. Двухконтактный сквид, подсоединенный к соседним граням тетрагонального кристалла с противоположными знаками параметра порядка.

До сих пор мы обсуждали особые свойства d-сверхпроводника, связанные с наличием в нем бесщелевых возбуждений.

Другая важная черта d-спаривания - зависимость знака парной амплитуды $\Delta_{\mathbf{k}}$ от направления вектора k относительно кристаллических осей.2) Это свойство и было использовано [153] для доказательства существования d-спаривания в $YBa_2Cu_3O_{7-x}$. В работе [153] измерялся критический ток двухконтактного сквид-интерферометра с контактами между обычным сверхпроводником (свинец) и двумя соседними гранями монокристалла $YBa_2Cu_3O_{7-x}$, см. рис. 49.2. Если спаривание в $YBa_2Cu_3O_{7-x}$ имеет вид d-волны, типа изображенной на рис.49.1, то знаки волновых функций куперовских пар, проходящих через контакты a и b, будут противоположны. Рассмотрим (аналогично 25) зависимость критического тока сквида $I_{\max}(\Phi)$ от проходящего через его кольцо магнитного потока Φ. Различие знаков $\Delta_{\mathbf{k}}$ на гранях a и b приведет к замене уравнения (25.2) на $\varphi_a - \varphi_b = 2\pi\Phi/\Phi_0 + \pi$, что эквивалентно сдвигу Φ на величину $\Phi_0/2$. Таким образом, d-спаривание в $YBa_2Cu_3O_{7-x}$ должно приводить к зависимости $I_{\max}(\Phi)$ вида

$$I_{\max}(\Phi) = 2I_c \left| \sin \frac{\pi\Phi}{\Phi_0} \right| \tag{49.11}$$

с максимумами при полуцелых значениях магнитного потока. Именно такая зависимость и была обнаружена в эксперименте [153].

[2)] По этой причине для сверхпроводников с d-спариванием (как и с другими типами нетривиального спаривания) неверна "теорема Андерсона" об отсутствии влияния потенциальных примесей на сверхпроводимость-рассеяние перепутывает состояния с разными направлениями импульса, имеющие теперь разные знаки парных волновых функций, так что спаривание подавляется [2].

Part III
Bulk Properties of Superconductors

6 Methods from De Gennes

6.0.1 3-3 Nonequilibrium Properties

Up to now, we have restricted our attention to the reversible behavior of second type superconductors. We have seen that when the coherence length ξ is small, they can remain superconducting up to very high fields, of order $H_{c_2} \sim \phi_0/\xi^2$.

From a technical point of view, however, what is most interesting is to obtain superconducting wires that can carry high currents. But this condition cannot be realized at thermal equilibrium, as shown by the following argument: Consider a cylindrical wire of radius a carrying a total current I. (When I is weak, this current is, in fact, entirely carried by a surface sheet, of thickness λ, around the cylinder.) The field at the surface of the wire is

$$H = \frac{2I}{ca} \tag{3-69}$$

The situation is stable when $H < H_{c_1}$. When $H > H_{c_1}$, vortex lines begin to appear. They are bent in circles (following the lines of force). Once created at the surface, with radius a, they tend to shrink (to decrease their line energy) and finally annihilate near the axis of the wire. This process dissipates energy. Thus in an ideal specimen we have 0 resistance only if $H < H_{c_1}$ or $I < (ca/2)H_{c_1}$. If we want to carry higher currents with our wire, we need to pin the vortex lines, that is, to quench their motion by suitably chosen lattice defects, and achieve a nonequilibrium situation. While the field H_{c_2} is an intrinsic property of the metal (or alloy), the critical current measured on a wire is extremely sensitive to the metallurgical state of the sample. This distinction between the factors ruling H_{C_2} and I was stressed first by Gorter.

In practice, a favorable defect structure is obtained by the following procedures:
(1) imperfect sintering (e.g., Nb_3Sn)
(2) cold work (e.g., MoRe alloys)
(3) precipitation processes (e.g., lead alloys)

The resulting materials, with high critical currents, are called hard superconductors.

The coupling mechanisms between the lines and the defects are only vaguely known at the present time. A rather simple case is met when we have large cavities, due to imperfect sintering, in the superconducting material. A vortex tends to remain pinned to the cavity, since this corresponds to a smaller length of line in the superconducting material, and thus to a smaller line energy. The mechanical stresses realized by cold work impose slight modifications to the condensation
energy and to the local density of superconducting electrons n_s. This results in local modifications of λ, ξ, and thus of the line energies $\mathfrak{J}$ and interactions U. These interactions are rather complex, and in the following we only present a phenomenological description of their effects.

Critical State at Zero Temperature

Consider a hard superconductor in an applied magnetic field H (along Oz). In equilibrium the line density would have the value $B(H)/\phi_0$ and be the same at all points. We now consider a metastable situation where the induction B is not equal to $B(H)$ but varies from point to point - say in the x direction. Thus (1) the line density is not constant, (2) there is a macroscopic current $J = (c/4\pi)(\partial B/\partial x)$ flowing in the y direction. The forces acting on the line system can

be decomposed in the following way: First, because of the repulsive interactions between lines, the regions of high line density (high B) tend to expand towards the regions of low density. This may be described in terms of the pressure p in our two-dimensional line system. [6] The force (per cm^3) is $-\partial \mathrm{p}/\partial \mathrm{x}$. This has to be balanced by a pinning force due to the structural defects. This pinning force, however, cannot become arbitrarily large. It must stay below a certain threshold value α_m

$$\left|\frac{\partial \mathrm{p}}{\partial \mathrm{x}}\right| < \alpha_m \tag{3-70}$$

If at some point $|\partial \mathbf{p}/\partial \mathbf{x}|$ is larger than α, then the lines start moving and dissipation occurs until condition (3-70) is again satisfied. In practice the line density $(1/\phi_0)\,\mathrm{B(x)}$ will thus adjust itself so that the threshold condition is just realized at all points [equality in (3-70)]. The state thus realized is called the critical state, and was first described by Bean. We can get some physical feeling for this critical state by thinking of a sand hill. If the slope of the sand hill exceeds some critical value, the sand starts flowing downwards (avalanche). The analogy is, in fact, rather good, since it has been shown (by careful experiment with pickup coils) that, when the system becomes overcritical, the lines do not move by single units, but rather in the form of avalanches including typically 50 lines or more.

We now proceed to compute explicitly the pressure p of the line system, to be inserted in (3-70). We consider a group of N lines intersecting a surface S in the xy plane. Their energy (per cm along Oz) is

$$\mathcal{G} = SG$$

where G is the thermodynamic potential introduced by Eq. (3-64). The pressure is obtained from S by differentiating with respect to S (that is, to the volume) at constant N .

$$p = \left(-\frac{\partial G}{\partial S}\right)_N = -G - S\frac{\partial G}{\partial S}$$

For fixed N we have $\mathrm{dS/S} = -\mathrm{dB/B}$

$$p = -G + B\frac{\partial G}{\partial B} \tag{3-71}$$

Thus when we know the form of the thermodynamic potential G, we know $p(B)$, that is, the pressure-density relation. It is, in fact, possible to write the pressure gradient $\partial p/\partial x$ in a very simple way. Set

$$G(B) = F(B) - \frac{BH}{4\pi}$$

where $F(B)$ describes the line self-energies and interaction. The equilibrium relation $B(H)$ or $H(B)$ is obtained by imposing $\partial G/\partial B = 0$. Thus $\mathrm{H(B)} = 4\pi(\partial\ \mathrm{F}/\partial \mathrm{B})$. Now

$$\begin{aligned} \frac{\partial p}{\partial x} &= B\frac{\partial^2 G}{\partial B^2}\frac{\partial B}{\partial x} = \frac{B}{4\pi}\frac{\partial H(B)}{\partial B}\frac{\partial B}{\partial x} \\ \frac{\partial p}{\partial x} &= \frac{B}{4\pi}\frac{\partial H(B)}{\partial x} \end{aligned} \tag{3-72}$$

Thus, if we know H(B), we can immediately compute the pressure gradient as a function of B and $\partial \mathrm{B}/\partial \mathrm{x}$.

[6] We make an isotropic approximation and neglect the tensor properties of p.

In fact, in materials where $H_{c_1} \ll H_{c_2}$, if $H \gg H_{c_1}, H(B)$ is nearly equal to B as is clear from the magnetization curve of Fig. 3-2. In this region we have simply

$$-\frac{\partial p}{\partial x} = -\frac{B}{4\pi}\frac{\partial B}{\partial x} = \frac{BJ_y}{c} \quad (H \gg H_{c_1}) \tag{1'}$$

The critical state is then defined by

$$\left|\frac{B}{4\pi}\frac{\partial B}{\partial x}\right| = \left|\frac{BJy}{c}\right| = \alpha_m \quad (H(B) \gg H_{c_1}) \tag{3-73}$$

(a)

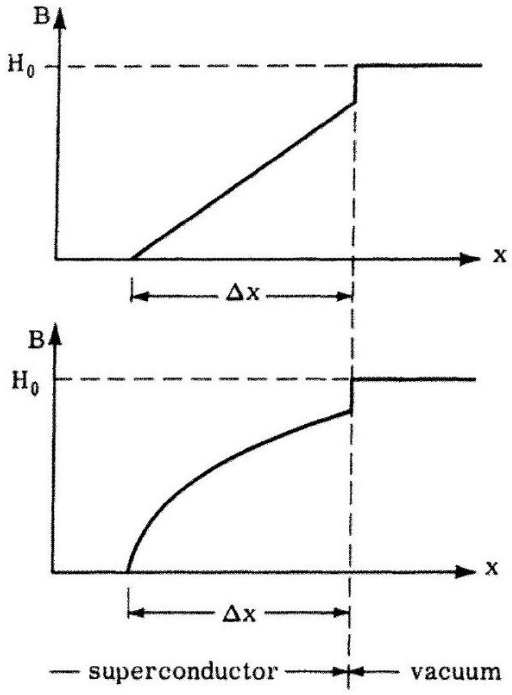

Figure 3-13
Irreversible penetration of flux in a hard superconductor: (a) Bean model; (b) AndersonKim model (parabolic profile).

To compute B(x) in the critical state we now need to know what is the dependence of the maximum pinning force α_m on B (that is,on the line density). It was originally assumed by Bean that α_m was linear in B; that is, J_y was a constant in the critical state. (J_y would typically be of order 10^5 A/cm^2.) A series of experiments by Kim and co-workers on NbZr alloys and on Nb_3Sn indicates that for these systems (in the particular metallurgical condition realized, and for fields in the 10^4Oe range), a good approximation amounts to taking α_m independent of B. This very simple result is not fully explained theoretically at the present time. In particular, we would expect the pinning centers to be most efficient when their size is comparable to the interline distance, and the latter depends on B (like $B^{-1/2}$).

The shape of the profile $B(x)$ in the critical state is represented for the Bean model and for the Kim model (Fig. 3-13). For typical hard superconductors and applied fields of order 10^4Oe, the total thickness Δx of the zone where flux lines have penetrated is of order 1 mm . To determine $B(x)$ experimentally [or equivalently to determine $\alpha_m(B)$], the simplest method amounts to measuring the flux ϕ in cylindrical samples of radius R (Fig. 3-14) for increasing values of the applied field H.

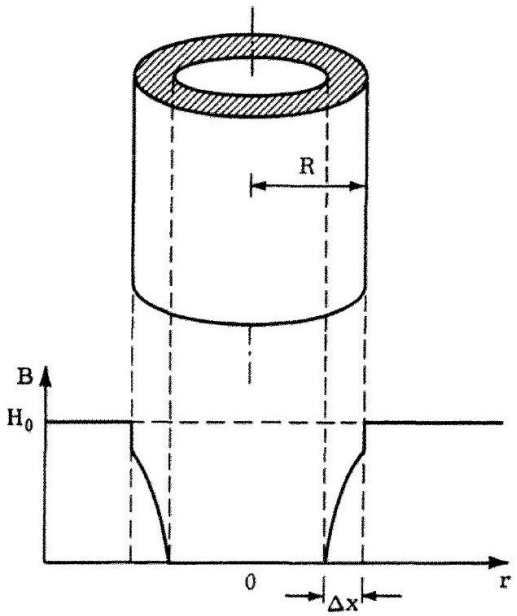

Figure 3-14
Magnetization measurements on a cylinder (external field increasing). The flux lines penetrate only in the hatched area.
(1) If R is much smaller than Δx, the induction is nearly uniform in the sample, B = B(H), $\phi = \pi \mathrm{R}^2$ B(H).[7]
(2) If $R \gg \Delta x$ we have essentially a one-dimensional situation. If x denotes the radial distance, we may write

$$\phi = 2\pi R \int_{R-\Delta x}^{R} dx B(x) \tag{3-74}$$

At the edge of the flux ($x = R - \Delta x$), we have $B = 0, H(B) = H_{C_1}$. At the surface of the cylinder ($x = R$), again assuming no surface barriers, we have the equilibrium value of B corresponding to the external field H. B = B(H). Transforming dx by (3-72) and (3-70), we get

$$\phi = 2\pi R \int_{H_{C_1}}^{H} dH \frac{B^2(H)}{4\pi \alpha_{mH}}$$

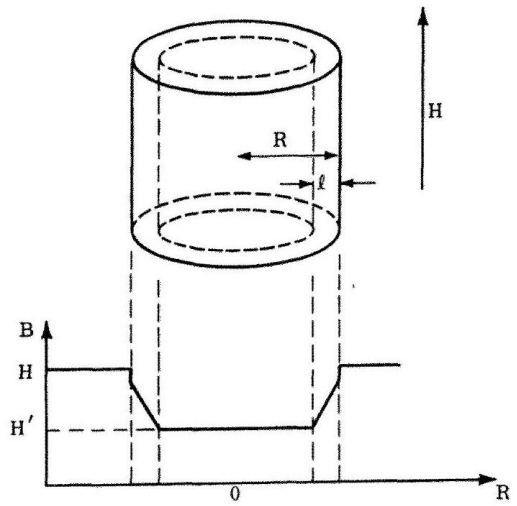

Figure 3-15
Principle of the Kim experiments on hollow cylinders of hard superconductors. An external

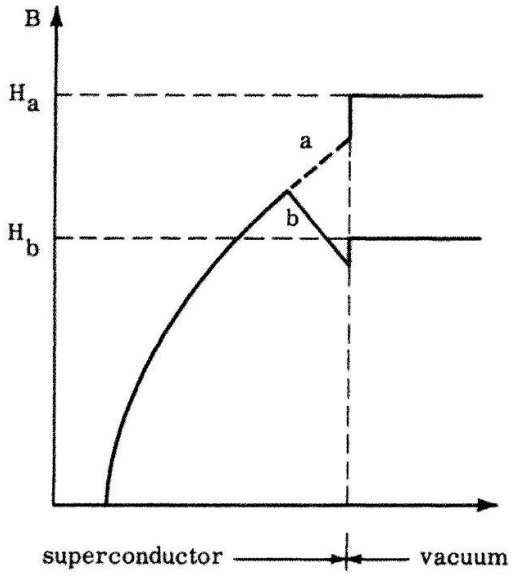
[7] We assume that there is no surface barrier impeding the entrance of vortex lines in the cylinder. Surface barriers do occur sometimes, but their effects can easily be separated.

field H is applied. The field H′ inside the cylinder is measured.
where α_{mH} stands for α_m[B(H)]. Of particular interest is the derivative of ϕ

$$\frac{\mathrm{d}\phi}{\mathrm{dH}} = \frac{\mathrm{R}}{2}\frac{\mathrm{B}^2(\mathrm{H})}{\alpha_{\mathrm{mH}}} \tag{3-75}$$

Thus from magnetization measurements in increasing fields, we may derive α_{mH} and α_m (B). Another method, devised by Kim and coworkers, makes use of hollow cylinders as shown in Fig. 3-15. A field H is applied on the outside of the cylinder and the field H′ in the cylinder is measured. When H is increased from $0, \mathrm{H}'$ first stays strictly equal to 0 . Then, when the flux front reaches the inner surface of the cylinder, H′ starts to increase (ideally H′ would first jump abruptly to H_{c_1}, and then grow steadily). The interest of the method is to give a direct determination of Δx, for that particular value of H where H′ starts to increase.

More complicated situations are met if the field H is alternatively increased and decreased, as shown in Fig. 3-16. Then we meet regions



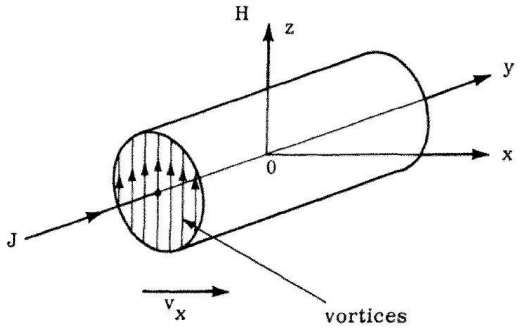


Figure 3-16
Flux distribution in a hard superconductor when the applied field is first raised to $\mathrm{H_a}$ (broken curve) and decreases to $\mathrm{H_b}$ (full curve).
with $\mathrm{dB/dx} > 0$ and regions with $\mathrm{dB/dx} < 0$, but the absolute value $|\partial \mathrm{p}/\partial \mathrm{x}|$ stays equal to α_m. This permits a detailed calculation of all hysteresis cycles when $\alpha_m{}^{(\mathrm{B})}$ is known.

Flux Creep at Finite Temperatures

At finite temperatures, if $\partial \mathrm{p}/\partial \mathrm{x} \neq 0$, the vortex lines will tend to move (from the regions of high B towards the regions of low B) by activated jumps across the pinning barriers. We call the average flow velocity of the lines (in the x direction) v_x. Various methods can be used to detect this flow, or "creep":
(1) Magnetic measurements, with thick cylinders or hollow cylinders. In the latter case, for instance, if H has been raised from 0 to some value and then kept constant, we observe that H′ increases slowly in time.
(2) Electrical measurements. If the lines of force are moving, they create electromotive forces that can be measured directly. The most simple situation is represented in Fig. 3-17. A wire (in the y direction) carries a current of density J, and is submitted to an external

vortex drift velocity
Figure 3-17
Electrical measurements on a hard superconductor wire. There is a current $J = -(c/4\pi)(\partial B/\partial x)$ in the y direction, thus $\partial B/\partial x < 0$. The lines are more closely packed on the left side of the wire: they drift with a velocity v_X towards the positive x axis.
field H in the z direction. Thus we have a nonzero $\partial B/\partial x = 4\pi$ J/c and the lines (pointing along Oz) tend to drift in the x direction. The resulting electric field E_y is along the wire axis (Oy) and in the limit $H \gg H_{c_1}$, it is given by

$$E_y = \frac{Bv_x}{c} \tag{3-76}$$

To prove (3-76) we compute the power dissipation per unit volume; this is the work done by the presence of gradient on the lines, that is. $(\partial p/\partial x)v_x$.
By setting this equal to $E_y J$ and making use of (3-72'), we get (3-76). Thus we need an electric field E_y to maintain the current J. As pointed out by Anderson and Kim, this dissipative effect in the superconducting state explains many features of the resistive behavior of hard superconductors.

The main difference between (1) the magnetic measurements and (2) the electric ones lies in the order of magnitude of the velocities involved. In case (1) the creep typically is measured over intervals of hours or days, and the velocities are of order 1 mm/ day or 10^{-6} cm/sec. In case (2) taking $B = 10^4 E_y = 1\mu$ V/cm, we get $v_x \sim 10^{-2}$ cm/sec. The main difficulty of (2) is related to possible inhomogeneities in the wire; experimentally it is found that different portions of the same wire have different E_y 's.

The results show unambiguously that
(a) the creep velocity has an activation energy behavior

$$v_x = v_0 \exp\left(-E/k_B T\right) \tag{3-77}$$

v_0 is not very accurately known, but may be in the range of 10^3 cm/sec in typical cases. The energy E may be as high as 100°K.
(b) the energy E depends on the pressure gradient $\partial p/\partial x$

$$E = E_0 - \left|\frac{\partial p}{\partial x}\right| \rho^4 \tag{3-78}$$

where ρ has the dimensions of a length, and is typically of order 500Å. We can relate E_0 and ρ to the critical pressure gradient α_m, if we notice that for $T \to 0$ the velocity v_X will depart from 0 only when $E = 0$

$$\alpha_m = \frac{E_o}{\rho^4} \tag{3-79}$$

These results (mainly obtained by Anderson, Kim, and co-workers) have various important consequences. First, since v_x varies rapidly with E according to (3-77), it is possible to extend

the crictical state concept to finite temperatures. Define a limiting velocity $v_{\min}$ below which the line motion cannot be detected. Then, if

$$\frac{E}{k_B^T} > \log \frac{v_0}{v_{\min}}$$

the line structure is frozen. Thus the critical state at temperature T corresponds to

$$\begin{aligned} E_0 - \rho^4 \left|\frac{dp}{dx}\right| &= k_B T \log \frac{v_0}{v_{\min}} \\ \left|\frac{dp}{dx}\right| &= \alpha_m \left(1 - \frac{k_B T}{E_0} \log \frac{v_0}{v_{\min}}\right) \end{aligned} \tag{3-80}$$

In general α_m will depend on T (since α_m involves λ, ξ, and the condensation energy, which are all temperature dependent). But if T is much smaller than the transition point T_0 this dependence may be neglected and all the temperature variation in (3-80) comes from the factor $k_B T$. A linear dependence of |dp/dx| on T has indeed been observed experimentally by Kim on various alloys and compounds the critical currents of hard superconductors are strongly temperature dependent even when $T \ll T_0$.

Another important consequence of (3-77), pointed out by Anderson, is the possibility of severe thermal instabilities. If in a small region of the sample the pinning energy E_0 is slightly smaller than elsewhere, the vortex lines in this region will dissipate a large power, $[(\partial p/\partial x) v_X]$ per cm^3, and this will tend to raise the local temperature, if the thermal conductivity of the material is low. This temperature rise will, in turn, increase the line velocity v_x according to (3-77) and may finally result in an instability. These thermal processes have to be taken into account in the design of superconducting coils.

CONCLUDING REMARKS

Our description of pinning and creep has been strictly phenomenological. Of course, we would like to interpret E_0, ρ, and v_0 in terms of microscopic processes. There are two difficulties: (1) What is the coupling between defects and lines? As pointed out earlier an important term is related to local modifications of the penetration depth λ by strain or by impurity gradients. Another, more obvious, contribution stems from local modifications of the superconducting condensation energy. There may be other contributions.
(2) How can we describe the metastable equilibrium and the irreversible motions of strongly coupled vortex lines in the presence of random perturbations? Coming back to the sand-hill analogy, we need a theory for the equilibrium slope of the sand hill and a theory for the avalanches -both are complicated. For the vortex line system there is an interesting suggestion, due to Frank-creep may take place by a motion of dislocations in the two-dimensional line lattice.

6.1 Description of the Condensed State

6.1.1 4-1 Instability of the Normal State in the Presence of an Attractive Interaction

The ground state of a free electron gas corresponds to complete filling of the one-electron energy levels of wavevector $\mathbf{k}$ and energy $\hbar^2\mathrm{k}^2/2m$ up to a certain energy $E_F = \hbar^2\mathrm{k}_F^2/2m$ (the Fermi energy). However, in the presence of an attractive interaction, no matter how weak, this state becomes unstable (Cooper, 1957). The instability can be understood by considering two particular electrons of coordinates r_1 and r_2, the other electrons still being treated as a free electron gas. The only effect of this electron gas is to forbid the two electrons to occupy all states $\mathrm{k} < \mathrm{k_F}$ by the exclusion principle. Let $\psi(\mathrm{r}_1, \mathrm{r}_2)$ be the wavefunction of the two electrons. Consider only states where the center of gravity of the pair (r_1, r_2) is at rest; ψ is then only a function of $\mathbf{r}_1 - \mathbf{r}_2$. Expand ψ in plane waves

$$\psi(r_1 - r_2) = \sum_k g(k) e^{ik\cdot(r_1 - r_2)} \tag{4-1}$$

$g(k)$ is the probability amplitude for finding one electron in the planewave state of momentum $\hbar\mathrm{k}$ and the other electron in the state $(-\hbar\mathrm{k})$. Since the states $\mathrm{k} < \mathrm{k_F}$ are already occupied, the Pauli principle imposes

$$g(\mathbf{k}) = 0 \text{ for } \mathbf{k} < \mathbf{k_F} \tag{4-2}$$

The Schrdinger equation for our two electrons is

$$-\frac{\hbar^2}{2m}\left(\nabla_1^2 + \nabla_2^2\right)\psi(r_1, r_2) + V(r_1, r_2)\,\psi = \left(E + \frac{\hbar^2 k_F^2}{m}\right)\psi \tag{4-3}$$

(E is the energy of the pair relative to the state where the two electrons are at the Fermi level.) On inserting (4-1) into (4-3), we find an equation for $g(k)$,

$$\frac{\hbar^2}{m}k^2 g(k) + \sum_{k'} g(k')\, V_{kk'} = (E + 2E_F)\, g(k) \tag{4-4}$$

$$V_{kk'} = \frac{1}{L^3}\int V(r) e^{-i(k-k')\cdot r} dr$$

is the matrix element of the interaction between the electronic states $\mathbf{k}$ and $\mathbf{k}'$. L^3 is the volume of the system. Equation (4-4) together with the Pauli condition (4-2) is sometimes called the Bethe-Goldstone equation for the two-electron problem. For $\mathrm{E} > 0$ it has a continuous spectrum describing the collisions of the two electrons from the initial state $(\mathbf{k}, -\mathbf{k})$ towards

final states $(\mathbf{k}', -\mathbf{k}')$ of the same energy. But if the interaction V is attractive there may also be bound state solutions, with $\mathrm{E} < 2\mathrm{E_F}$. To see this, consider the simplified interaction

$$\begin{aligned} V_{kk'} &= -\tfrac{V}{L^3} \text{ for } \quad \tfrac{\hbar^2 k^2}{2m} < E_F + \hbar\omega_D \\ &= 0 \qquad\qquad\qquad\qquad \tfrac{\hbar^2 k^{*2}}{2m} < E_F + \hbar\omega_D \\ &= 0 \qquad\qquad\qquad\qquad \text{otherwise} \end{aligned} \tag{4-5}$$

(This interaction is attractive and constant in an energy band $\hbar\omega_D$ above the Fermi level.) Then (4-4) becomes

$$\left(-\frac{\hbar^2 k^2}{m} + E + 2E_F\right) g(k) = C \tag{4-6}$$

where C is independent of k

$$\mathrm{C} = -\frac{\mathrm{V}}{\mathrm{L}^3} \sum_{\mathrm{k}'} \mathrm{g}\left(\mathbf{k}'\right) \tag{4-7}$$

$$\mathrm{E_F} < \frac{\hbar^2 \mathrm{k}'^2}{2m} < \mathrm{E_F} + \hbar\omega_\mathrm{D}$$

Comparing (4-6) and (4-7), we find the self-consistency condition

$$1 = \frac{V}{L^3} \sum_{k'} \frac{1}{-E + \frac{\hbar^2 k'^2}{m} - 2E_F} \tag{4-8}$$

$$E_F < \frac{\hbar^2 k'^2}{2m} < E_F + \hbar\omega_D$$

If we set

$$\xi' = \frac{\hbar^2 \mathrm{k}'^2}{2m} - \mathrm{E_F} \tag{4-9}$$

and introduce the density of states per unit energy interval

$$\mathrm{N}\left(\xi'\right) = (2\pi)^{-3} 4\pi \mathrm{k}'^2 \frac{\mathrm{dk}'}{\mathrm{d}\xi'}$$

the condition becomes

$$1 = V \int_0^{\hbar\omega} DN\left(\xi'\right) \frac{1}{2\xi' - E} d\xi' \tag{4-10}$$

If we assume $\hbar\omega_\mathrm{D} \ll \mathrm{E_F}, \mathrm{N}\left(\xi'\right)$ can be considered as constant and replaced by its value $N(0)$ at the Fermi level; we can perform the integration

$$1 = \frac{1}{2} N(0) V \ln \frac{E - 2\hbar\omega_D}{E} \tag{4-11}$$

and in the limit of weak interactions $N(0)V \ll 1$

$$E = -2\hbar\omega_D e^{-2/N(0)V} \tag{4-12}$$

Therefore there exists a two-electron bound state of energy $\mathrm{E} < 0$. If we start from a free electron gas, and turn on the interaction V, we predict that the electrons will group themselves in pairs giving up energy to the external world. The normal state is thus unstable.

A few important remarks.

(1) The instability persists even if V is very weak provided that it is attractive. This is a very remarkable difference from the usual two-body problem. If we had only two particles coupled by an attractive interaction of finite range, they would not form bound states unless the attractive interaction exceeded a certain threshold.

For the two-body problem ($k_F = 0$), the density of states N(ξ) varies as $\xi^{1/2}$ as $\xi \to 0$ and the expression

$$f(E) = V \int N(\xi) \frac{d\xi}{-E + 2\xi} \tag{4-13}$$

converges even for E = 0. Therefore, if V is small, f(0) < 1 and f(E) < f(0) < 1 for $E < 0$. The condition $f(E) = 1$ cannot be satisfied in the domain of bound states. On the contrary, for our problem, $N(\xi)$ is nearly constant, $f(0) = \infty$, and there is always a value of E < 0 such that f(E) = 1.

(2) The binding energy is proportional to $e^{-2/NV}$. It cannot be expanded in powers of V for $V \to 0$. This algebraic difficulty considerably hindered the development of the theory of superconductivity.

(3) In the preceding calculation, we have taken account of the exclusion principle between the electron (1) and the electrons in the Fermi sphere and between (2) and the Fermi sphere. It is also necessary to insure that the wavefunction be antisymmetric in $(\mathbf{r}_1, \mathbf{r}_2)$. With the simplified interaction V, of $(4-5), g(k)$ depends only on ξ, that is, the magnitude of k. Therefore the spatial part of the wave function $\psi(r_1, r_2)$ is symmetric from (4-1), and the spin part of the wave function must be antisymmetric, of the form $(1/\sqrt{2})(\alpha_1\beta_2 - \beta_1\alpha_2)$ in Schiff's notation. [1]

This function describes a state where the total spin of the pair is zero, that is, antiparallel coupling. If the interaction V_{kk}', instead of having the simple form (4-5), depended strongly on the angle between k and k', one could find:

(a) several bound states;

(b) spatially anisotropic solutions and therefore more complicated spin dependences. In practice, in the superconducting metals, it appears that the angular dependence of V_{kk} ' is not strong enough to bring in very spectacular effects.

Problem.

Calculate the mean square radius ρ of a Cooper pair.

Solution.

By definition

$$\rho^2 = \frac{\int |\psi(r_1 - r_2)|^2 R^2 dR}{\int |\psi|^2 dR}, \quad R = r_1 - r_2$$

$$\rho^2 = \frac{\Sigma |\nabla_k g(k)|^2}{k\Sigma_k |g(k)|^2}$$

$$\cong \frac{N(0)\left(\frac{\partial \xi}{\partial k}\right)^2_{\xi=0} \int_0^\infty d\xi \left(\frac{\partial g}{\partial \xi}\right)^2}{N(0)\int_0^\infty g^2 d\xi}$$

In the approximation of (4-5), $g = C/(E - 2\xi)$. Also, $(\partial k/\partial \xi)_{\xi=0} = 1/\hbar v_F$ where v_F is the Fermi velocity. Performing the integration, one finds

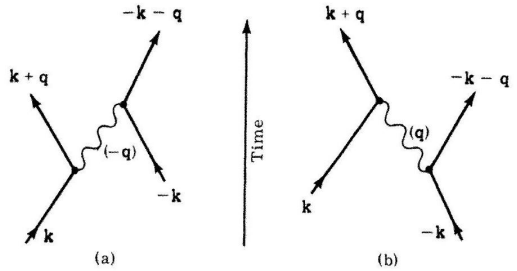
$$\rho = \frac{2}{\sqrt{3}} \frac{\hbar v_F}{E}$$

6.1.2 4-2 Origin of the Attractive Interaction

In a simple electron gas, the only interactions are Coulomb repulsions, and thus not favorable for the Cooper phenomenon. To obtain an attractive matrix element $V_{kk'}$, the electrons must be coupled to

another system of particles, or excitations, in the solid. There are many varieties of such excitations we might try for that purpose-phonons, electrons from other bands, spin waves in magnetic media, and so on. Only one of these couplings is really known to be important (at the present time). This is the electron-phonon interaction, first proposed in that connection by Frlich (1950), which we now discuss.

The Quantum Mechanical Picture



We wish to know the matrix element $V_{kk'}$ of the electron-electron interaction between an initial state (I) where two electrons are in the plane wave states $\mathbf{k}$ and $-\mathbf{k}$, and a final state (II) where the electrons are in $(\mathbf{k}', -\mathbf{k}')$. $V_{kk'}$ will, in general, contain two terms:
(a) There is a direct Coulomb repulsion $U_C(\mathbf{r}_1 - \mathbf{r}_2)$ between the two electrons. The corresponding matrix element is

$$\langle I|\mathscr{H}_c|II\rangle = \int dr_1 dr_2 e^{-i\mathbf{k}\cdot(r_1-r_2)} U_c(r_1 - r_2)\, e^{i\mathbf{k}'\cdot(r_1-r_2)} \tag{4-14}$$

(the wave functions being normalized in a unit volume)

$$\langle I|\mathscr{H}_c|II\rangle = \int U_c(\rho) d\rho e^{iq\cdot\rho} = U_q \quad q = \mathbf{k}' - \mathbf{k} \tag{4-15}$$

(b) One electron may emit a phonon later reabsorbed by the other electron. This process is displayed in Fig. 4-1. The initial state (I) has energy

Electron-electron interaction via phonons. In process (a) the electron k emits a phonon of wave-vector $-q$. The phonon is absorbed later by the second electron. In process (b) the second electron in state $(-\mathbf{k})$ emits a phonon $\mathbf{q}$, subsequently absorbed by the first electron.

$$E_I = 2\xi_k$$

where ξ_K is defined by Eq. (4-9) (for convenience we always measure the one-electron energies from the Fermi level). The final state (II) has energy

$$E_{II} = 2\xi_{k'}$$

[1] L. I. Schiff, Quantum Mechanics(New York: McGraw-Hill, 1955), Chapter 9.

There are two intermediate states allowed by momentum conservation:
(i1): Electron 1 in state $\mathbf{k}' = \mathbf{k} + \mathbf{q}$, electron 2 in $-\mathbf{k}$, one phonon created with wave vector -q, energy $\hbar\omega_{\mathrm{q}}$

$$E_{i1} = \xi_{k'} + \xi_k + \hbar\omega_q$$

(notice that ξ_{k} and ω_{k} are even functions of k)
(i2): electron 1 in state k

$$2 \text{ in state } -\mathbf{k}' = -(\mathbf{k} + \mathbf{q})$$

one phonon created with wave vector q, energy $\hbar\omega_q$

$$E_{i2} = \xi_{k'} + \xi_k + \hbar\omega_q = E_{i1}$$

The second-order matrix element coupling states (I) and (II) is

$$\langle I|\mathscr{H}_{\text{indirect}}\,|II\rangle = \sum_i \langle I|\mathscr{H}_{ep}|i\rangle \frac{1}{2}\left(\frac{1}{E_{II} - E_i} + \frac{1}{E_I - E_i}\right)(i\,|\mathscr{H}_{ep}|\,II) \tag{4-16}$$

Here the sum Σ_{i} is over the allowed intermediate states. $\mathscr{C}_{\mathrm{ep}}$ is the electron phonon coupling, the matrix element of which we shall call $\mathrm{W_q}$ (for emission or absorption of a phonon of wave vector q)

$$\langle I|\mathscr{H}_{\text{indirect}}\,|II\rangle = \frac{|W_q|^2}{\hbar}\left(\frac{1}{\omega - \omega_q} - \frac{1}{\omega + \omega_q}\right) \tag{4-17}$$

where we have defined a frequency ω by

$$\hbar\omega = \xi_{\mathrm{k}'} - \xi_{\mathrm{k}} \tag{4-18}$$

Thus $\hbar\omega$ and $\hbar$q are, respectively, the energy and momentum change of electron 1 in the transition I $\rightarrow$ II. The total matrix element is

$$\langle \mathrm{I}|\mathscr{H}|\mathrm{II}\rangle = \mathrm{U_q} + \frac{2\,|\,\mathrm{W_q}|^2}{\hbar}\frac{\omega_{\mathrm{q}}}{\omega^2 - \omega_{\mathrm{q}}^2} \tag{4-19}$$

When $\omega < \omega_{\mathrm{q}}$ the indirect term is negative (attractive); we have found an attractive interaction, provided that $\mathrm{U_q}$ is not too large.

Description in Terms of a Dielectric Constant

It is also possible to present the effective electron-electron interaction in the following way. The bare Coulomb interaction between the two electrons is e^2/r, leading to a repulsive matrix element $4\pi e^2/q^2$. But this interaction is screened-by the other electrons and also by the positive ions in the lattice. If we work near the resonance frequency (ω_{q}) of the ion motion, the ions give a very large response: They can "overscreen" the negative charge of electron 1 ; the resultant, positive cloud will be attracted by electron 2 .

In practice, we describe this screening effect by a dielectric constant $\epsilon(q\omega)$ (which is a function of wave vector and frequency). The effective interaction is the bare interaction divided by ϵ

$$\langle I|\mathscr{H}|II\rangle = \frac{4\pi e^2}{q^2\epsilon(q,\omega)} \tag{4-20}$$

It only remains to calculate ϵ. We do this for a very simple model, and show that Eqs. (4-19) and (4-20) agree.

JELLIUM

Consider a system formed of n electrons per cm^3 (of mass m and charge -e) and of ions, of mass M and charge + Ze. (The entire system being electrically neutral, the number of ions per cm^3 is n/Z.) We take into account only the electrostatic interactions between particles. Also we treat the ions as fluid, not as an ordered solid. This simple model of a metal has been called "jellium." [2] It neglects mainly
(1) the short-range repulsive interactions between ions due to repulsion of their deep electronic levels;
(2) the fact that the electronic wave functions must be orthogonal to the wave function of the deep-lying levels of each ion. (This gives rise to an effective repulsive electron-ion interaction.)
(3) the possibility of transverse oscillations (transverse phonons) of the ion system, which exist in a real solid, but not in our fluid model.

All these simplifications are rather arbitrary, but the simple model that results is useful for a qualitative understanding of the interactions. The dielectric constant $\epsilon(q\omega)$ is defined in the following way: Assume that small external charges, of density

$$\delta\rho(r) = \delta\rho\cos(q\cdot r)e^{i\omega t} + \text{ C.C.} \tag{4-21}$$

are added to the system. The latter will build up screening charges, of distribution

$$\rho(r) = \rho\cos(q\cdot r)e^{i\omega t} + \text{ C.C.} \tag{4-22}$$

The dielectric constant is the ratio of the external charge to the total charge

$$\epsilon(q\omega) = \frac{\delta\rho}{\rho+\delta\rho} \tag{4-23}$$

We must calculate the charge response ρ. In our case

$$\rho = \rho_{\mathrm{e}} + \rho_{\mathrm{i}}$$

is a sum of an electronic component and an ionic component. Our starting equations are
(a) Poisson's equation relating the electrostatic potential V to the charge densities $\delta\rho, \rho_{\mathrm{i}}, \rho_{\mathrm{e}}$:

$$\nabla^2 V = -4\pi\left(\delta\rho + \rho_i + \rho_e\right) \tag{4-24}$$

(b) the equation of motion of the ions in the presence of the electric field $\mathbf{E} = -\nabla\mathbf{V}$:

$$M\frac{dj_i}{dt} = nZe^2E \tag{4-25}$$

where j_i is the current carried by the ions, related to ρ_i by the continuity equation

$$\frac{\partial\rho_i}{\partial t} + \operatorname{div} j_i = 0 \tag{4-26}$$

In the small motion approximation, the total derivative $\mathrm{dj_j/dt}$ in Eq. (4-25) can be replaced by the partial derivative $\partial j_i/\partial t$. Eliminating j_i between (4-25) and (4-26), we obtain

$$\frac{\partial^2\rho_i}{\partial t^2} = \frac{nZe^2}{M}\nabla^2 V \tag{4-27}$$

Writing $\partial/\partial\mathrm{t} = \mathrm{i}\omega$ and making use of (4-24), we arrive at

[2] The jellium model was first applied to superconductivity by Pines [Phys. Reu., 109, 280 (1958)]; the phonon-induced part of that interaction had been earlier derived by Bardeen and Pines [Phys. Reu., 99, 1140 (1955)]; a description of the electron-ion system in terms of the overall dielectric constant was first worked out by Nozires (unpublished) and generalized slightly by Pines in his 1958 Les Houches lectures.

$$\omega^2\rho_{\mathrm{i}}(\mathrm{q},\omega) = \omega_{\mathrm{i}}^2\left[\rho_{\mathrm{i}}(\mathrm{q},\omega) + \rho_{\mathrm{e}}(\mathrm{q},\omega) + \delta\rho(\mathrm{q},\omega)\right] \tag{4-28}$$

with

$$\omega_{\mathrm{i}} = \sqrt{\frac{4\pi \mathrm{nZe}^2}{\mathrm{M}}} \tag{4-29}$$

As we shall see later, ω_i gives essentially the width of the phonon spectrum for our simple model. Typically $\omega_{\mathrm{i}} \sim 10^{13}\mathrm{sec}^{-1}$.
(c) We need an equation describing the response of the electron gas (that is, ρ_{e}) as a function of the electrostatic potential V. There is one simplifying feature in this calculation-the two characteristic frequencies of the electron gas are $\mathrm{E_F}/\hbar$ and the plasma frequency

$$\omega_p = \left(\frac{4\pi ne^2}{m}\right)^{1/2} \sim \omega_i\left(\frac{M}{m}\right)^{1/2}$$

Both these frequencies are very high. On the other hand ω is low ($\omega \sim \omega_{\mathrm{i}}$). Thus, in this part of the calculation, we may neglect ω completely and compute ρ_{e} simply for a static perturbation V .

We make a further approximation and derive ρ_e by the method of Thomas and Fermi (this is strictly correct only at long wavelengths $q \ll k_F$). In this approximation the electronic density at r is proportional to $[E_F + eV(r)]^{3/2}$. Its relative variation for small V is therefore given by

$$\frac{\rho_{\mathrm{e}}}{-\mathrm{ne}} = \frac{3}{2}\frac{\mathrm{eV}}{\mathrm{E_F}} \tag{4-30}$$

For a Fourier component of wave vector q this may be rewritten, according to Eq. (4-24), in the form

$$\rho_{\mathrm{e}} = \frac{-\mathrm{k_S^2}}{\mathrm{q}^2}(\rho + \delta\rho) \tag{4-31}$$

where

$$\mathrm{k_S^2} = \frac{6\pi n\mathrm{e}^2}{\mathrm{E_F}}$$

Collecting (4-28) and (4-31), we have

$$\rho = \rho_{\mathrm{i}} + \rho_{\mathrm{e}} = \left(\frac{\omega_{\mathrm{i}}^2}{\omega^2} - \frac{\mathrm{k_s^2}}{\mathrm{q}^2}\right)(\rho + \delta\rho)$$

and

$$\epsilon(q\omega) = \frac{\omega^2\left(k_S^2 + q^2\right) - \omega_i^2 q^2}{\omega^2 q^2} \tag{4-32}$$

Let us first determine from this expression the phonon frequency ω_{q}
for wave vector **q**. The spontaneous modes of vibration of our system correspond to 0 external charge $\delta\rho = 0$ or $\epsilon(q\omega) = 0$. For each q this defines one frequency ω_q given by

$$\omega_q^2 = \omega_i^2\frac{q^2}{k_S^2 + q^2} \tag{4-33}$$

For long wavelengths, $\omega_{\mathrm{q}} \sim (\omega_{\mathrm{i}}/\mathrm{k_S})\,\mathrm{q}$ is a linear function of q and the sound velocity ω_i/k_S. This formula gives, in fact, a rather realistic value for the velocity of sound for all the nontransition metals if we choose Z as the valence of the metal. In terms of ω_{q} we may rewrite Eq. (4-32) in the form

$$\frac{1}{\epsilon(q\omega)} = \frac{q^2}{k_s^2 + q^2}\left[1 + \frac{\omega_q^2}{\omega_i^2 - \omega_q^2}\right] \tag{4-34}$$

and the interaction matrix element is

$$\langle II|\mathscr{H}|I\rangle = \frac{4\pi e^2}{q^2\epsilon(q\omega)} = \frac{4\pi e^2}{k_S^2 + q^2} + \frac{4\pi e^2}{k_S^2 + q^2} \times \frac{\omega_q^2}{\omega^2 - \omega_q^2} \tag{4-35}$$

This has exactly the form predicted by Eq. (4-19), but with precise numerical coefficients. The first term is a (screened) Coulomb repulsion. The second term is the phonon-mediated interaction and i^+ is attractive for $\omega < \omega_{\mathrm{q}}$.

For an average phonon: $\omega_{\mathrm{q}} \sim \omega_{\mathrm{D}}$, the Debye frequency of the material. Thus the energy interval in which we find an attraction is of order $\hbar\omega_D = k_B\theta_D$ where k_B is Boltzmann's constant, and Θ_D (the Debye temperature) is typically of order $300°\mathrm{K}$ ($\mathrm{k_B}\ominus_{\mathrm{D}} \sim 0.03\mathrm{eV}$). Note that ω_{q} (or ω_{D}) depends on the mass M of the ions. Equations (4-29) and (4-33) show that $\omega_{\mathrm{q}} \sim \mathrm{M}^{-1/2}$. Thus two isotopes of the same superconductor have different attractive bandwidths, and their transition temperatures differ slightly - such isotope effects were first predicted by Frlich and observed soon after (Maxwell, Reynolds, et al., 1950). They prove that the vibrational motions of the lattice give an important contribution to the electron-electron interactions.

Numerical Values of the Interaction Constants

At the present time we cannot compute the matrix elements $\mathrm{V_{kk'}}$ in a very reliable way - we know too little about the relevant band structures, electron-phonon couplings, and so on. The calculation is particularly difficult for the following reason: At low frequencies ω, there is a rather strong compensation between the Coulomb repulsion and the indirect interaction. For "jellium," in particular, we notice that $\epsilon(\mathrm{q}\omega) \to \infty$ when $\omega \to 0$. In this model a static perturbation $\delta\rho$ is completely screened. Nothing prevents the positive ions from piling up with an arbitrary density in order to neutralize the charges $\delta\rho$.[3] If the short range repulsion between ions is taken into account, this effect disappears, the screening is not complete, and $\epsilon(q, 0)$ is then finite. This remark shows that the width of the attractive band and the attractive force are rather sensitive to the details of the physical model. It is important to make exactly the same approximations in the calculations of the direct and indirect interactions to avoid gross errors in the sum.

Problem.

Estimate $N(0)V_p$ for simple metals, using the "jellium" approximation.

Solution.

We define V_p as being the attractive part of interaction for $\omega = 0$. Then

$$V_p = \frac{4\pi e^2}{k_s^2 + q^2}$$

For q we take the root mean square average $q^2 = \frac{3}{5}q_D^2$ where q_D (the Debye cutoff) is defined by

$$v_0(2\pi)^{-3}\frac{4\pi}{3} \quad q_D^3 = 1$$

v_0 being the atomic volume. Finally

$$N(0) = \frac{mk_F}{2\pi^2\hbar^2} \tag{4-36}$$

$$N(0)V_p = \frac{2}{\pi}\frac{me^2}{\hbar^2}\frac{k_F}{q^2 + k_s^2} \tag{4-37}$$

$\mathrm{k_S^2}$ is defined below Eq. (4-31) as a function of the number n of electrons per cm^3

$$\mathrm{n} = \frac{\mathrm{k_F^3}}{3\pi^2} = \frac{\mathrm{Z}}{\mathrm{v_0}} \tag{4-38}$$

Finally, we recall that $\hbar^2/\mathrm{me}^2 = \mathrm{a_0} = 0.529\text{Å}$ is the Bohr radius. Collecting all these remarks, we find [4]

$$N(0)v_p = \frac{1}{2 + 4.7a_0\,|v_0 Z|^{-1/3}} \tag{4-39}$$

Problem.

Study the sign of the interaction between electrons at low frequencies in a magnetic medium.

Solution.

Suppose that the interaction between an electron situated at the point r, of spin S_i, and the local magnetization $M(r')$ of the medium is of the scalar form

$$\mathrm{H_1} = -\mathrm{TS_i} \cdot \mathrm{M(r)}$$

Since we are only interested in the zero frequency limit, we shall calculate the static response of the magnetic medium to the perturbation $\mathrm{H_1}$. To first order in Γ, this is of the form

$$\delta\mathrm{M}_\alpha(\mathbf{r}') = \sum_\beta \chi_{\alpha\beta}(\mathbf{r} - \mathbf{r}')\,\Gamma\mathrm{S_{i\beta}}$$

where χ is a generalized susceptibility tensor and $\alpha, \beta = \mathrm{x, y, z}$. Consider now the interaction V of δM with a second electron at r', of spin S_j,

$$V(r - r') = -\Gamma S_j \cdot \delta M(r') = -\Gamma^2 \sum_{\alpha\beta} S_{j\alpha}\chi_{\alpha\beta}(r - r')\,S_{i\beta}$$

Here again it is useful to consider the Fourier transform

$$V(q) = -\Gamma^2 \sum_{\alpha\beta} S_{i\alpha}\chi_{\alpha\beta}(q)S_{j\beta}$$

The static susceptibility tensor $\chi_{\alpha\beta}(q)$ is symmetric and can be diagonalized by a convenient choice of axes. The three principal susceptibilities ${\chi_{\alpha\alpha}}^{(q)}$ are necessarily positive. (Otherwise the magnetic material would be unstable with respect to a sinusoidal distortion of the magnetization of wavevector q.) If the spins S_i and S_j are antiparallel (singlet state), the static interaction

[4] This result differs from that of Anderson and Morel (Phys. Rev., 125, 1263 (1962) I. Their equation (14) uses $\omega_q = (\omega_i q)/k_s$ instead of the consistent form

[3] One physical case where this extraordinary screening effect can play an important role seems to be that of protons dissolved in palladium. These protons are very mobile. If a metallic impurity is added to the hydrogenated palladium, the screening charge around the impurity may be made largely of protons and not of electrons.

$$\omega_{\mathrm{q}} = \omega_{\mathrm{i}} \frac{\mathrm{q}}{(\mathrm{k_s^2} + \mathrm{q^2})_{1/2}}$$

A recent discussion of the effective interaction, with the allowance for periodicity, more accurate screening, and so on, may be found in Pines, Elemenlary Excilations in Solids (New York: Benjamin, 1963), Chapter 5.
will be positive (repulsive). By continuity, this will remain true at finite frequencies small compared to the exchange frequencies of the magnetic medium. (In an ordered system, the change of sign occurs for $\omega = \omega_{\mathrm{q}}$, the lowest spin wave frequency for the wave vector q.) Therefore, in the presence of a magnetic medium, there exists an interaction whose low frequency part is repulsive for Cooper pairs of antiparallel spin. On the contrary, for parallel pairs (triplet states), one can, in principle, find an attractive interaction at low frequencies.

6.1.3 4-3 Ground State and Elementary Excitations

Choice of a Trial Wave Function

The Cooper argument (Section 4-1) suggests that in the presence of attractive interactions the normal ground state of a free electron gas becomes unstable. The argument is of course only suggestive. In particular, it does not allow for the scattering of electrons above the Fermi sea against the electrons inside. We now calculate in more detail the structure of the condensed state, treating all electrons on the same footing.

In Section 4-1 we considered a pair of electrons described by a wave function $\psi(r_1 - r_2)$. In order to treat N electrons on the same footing, a natural generalization leads us to look for a wave function of the form

$$\phi_N(r_1, r_2, \ldots, r_N) = \phi(r_1 - r_2)\,\phi(r_3 - r_4) \cdots \phi(r_{N-1} - r_N) \tag{4-40}$$

In the state described by ϕ_N, the electrons are grouped in pairs, each pair having the same wave function ϕ. We can determine the function by minimizing the energy of the state ϕ_{N}.

Three technical remarks.
(a) The function ϕ_N can only be constructed for an even number N of electrons. For odd N, it would be necessary to place the last electron in a separate state. For an electron gas ($\mathrm{N} \sim 10^{23}$), the presence of this electron only gives rise to effects of the order of 1/N on the energy per particle and the other properties of the condensed stat; therefore it will not be important. On the other hand, for superfluids of fermions with small N (atomic nuclei), the even or odd character of N plays an important role especially on the form of the excitation spectrum.
(b) We have not yet included spin indices in ϕ_N. Guided by analogy with the situation in Section 4-1, we select the spin states $\uparrow\downarrow$, opposite for the two electrons of a pair. The function ϕ thus chosen will be the most favorable if the interaction V_{kk} ' is weakly dependent on the angle between k and k'.
(c) The function ϕ_{N} must be antisymmetrized, which we represent by an operator A:

$$\phi_N = A\phi(r_1 - r_2) \cdots \phi(r_{N-1} - r_N)\,(1t)(2t) \cdots (N-1t)(Nt) \tag{4-41}$$

Algebraic Transformations

The form (4-41) of ϕ_N has the merit of being explicit, but on the other hand it would be rather complicated to calculate directly from it. Introduce the Fourier transform of the pair function

$$\phi(r) = \sum_k g_k e^{ik\cdot r} \tag{4-42}$$

$$\phi_N = \sum_{k_1} \cdots \sum_{k_N/2} g_{k_1} \cdots g_{k_N/2} \cdots A e^{ik_1(r_1 - r_2)} \cdots$$
$$e^{ik_N/2\cdot(r_N - 1 - r_N)} (1\uparrow)(2\downarrow)\cdots(Nt) \tag{4-43}$$

The function $A \exp\left[ik_1\left(r_1 - r_2\right)\right] \cdots \exp\left[ik_{N/2}\cdot\left(r_{N-1} - r_N\right)\right] \times (14) \times (2t) \cdots (Nt)$ has a simple interpretation. It describes a state where one electron occupies the state $k_1 t$, another the state $(-k_1 t)$, a third $(\mathbf{k}_2\mathbf{1})$, and so on. Because of A, it is conveniently antisymmetrized. This is what is usually called a Slater determinant formed with the states

$$(k_1 t)\,(-k_1 t)\,(k_2 t)\,(-k_2 t)\cdots\left(k_{N/2}t\right)\left(-k_{N/2}t\right)$$

In order to represent such a Slater determinant, we use the more convenient Wigner-Jordan notation

$$a^{+}_{k_1 t^+} \cdots a^{a^+_{-k_N/2}\,\phi_0}_{k^+_{N/2}} \tag{4-44}$$

The operator $\mathrm{a}^+_{\mathrm{k}\alpha}$creates an electron in the state $(\mathrm{k}\alpha)$ when operating on the vacuum state designated by ϕ_0. We also use the destruction operator $\mathrm{a}_{\mathrm{k}\alpha}$, which is the adjoint of $\mathrm{a}^+_{\mathrm{k}\alpha}$and is such that $\mathrm{a}_{\mathrm{k}\alpha}\phi_0 = 0$. Wigner and Jordan have shown that all properties of the Slater determinant are correctly reproduced by the form (4-44) if anticommutation [5] relations are imposed on the operators a and a^+:

$$\begin{aligned} a^+_{k\alpha}a^+_{\ell\beta} + a^+_{\ell\beta}a^+_{k\alpha} &= 0 \\ a^+_{k\alpha}a_{\ell\beta} + a_{\ell\beta}a^+_{k\alpha} &= \delta_{k\ell}\delta_{\alpha\beta} \\ a_{k\alpha}a_{\ell\beta} + a_{\ell\beta}a_{k\alpha} &= 0 \end{aligned} \tag{4-45}$$

Our function ϕ_N takes the form

$$\phi_N = \sum_{k_1} \cdots \sum_{k_{N/2}} g_{k_1} \cdots g_{k_{N/2}} a^+_{k_1\uparrow} a^+_{-k_1\downarrow} \cdots a^+_{k_{N/2t}} a^+_{-k_{N/2t}} \phi_o \tag{4-46}$$

It is still not very easy to manage. Consider instead the generating function

$$\tilde{\phi} = C \prod_k \left(1 + g_k a^+_{k\uparrow} a^+_{-k\downarrow}\right) \phi_0 \tag{4-47}$$

where the product Π_k extends over all plane wave states [5a] and C is a normalization constant. By comparing (4-46) and (4-47), it is easy to see that to within the factor C, ϕ_N is the part of $\widetilde{\phi}$ that has N creation operators acting upon ϕ_0, that is, the component of $\tilde{\phi}$ that describes an N particle state. We make a slight transformation on $\tilde{\phi}$ by incorporating the factor C into the product Π_k

$$\tilde{\phi} = \prod_k \left(u_k + v_k a^\dagger_{kt} a^\dagger_{-kt}\right) \phi_o \tag{4-48}$$

[5] See Landau and Lifshitz, Nonvelativistic Quantum Mechanics (New York: Pergamon, 1959), Chap. 9.

with

$$\frac{v_k}{u_k} = g_k \quad u_k^2 + v_k^2 = 1 \tag{4-49}$$

The latter condition assures the normalization of $\tilde{\phi}$. We have assumed g_k, u_k, and v_k to be real. (We see later that this restriction is unimportant.) The function $\tilde{\phi}$ was introduced by Bardeen, Cooper, and Schrieffer in their fundamental paper of 1957. $\tilde{\phi}$ is much simpler than ϕ_N. For large N, all calculations can be performed from $\tilde{\phi}$ rather than ϕ_{N}. In order to understand this, write the expansion

$$\tilde{\phi} = \sum_N \lambda_N \phi_N \tag{4-50}$$

with $\Sigma_N \left|\lambda_N\right|^2 = 1$ to assure normalization. (Note that, with the above choice of phase for u_k and v_k, the coefficients λ_N are, in fact, real.)

For large N and whatever is the detailed form of the $\mathrm{g_k}$ ' s, the form of $\left|\lambda_N\right|^2$ as a function of N is that represented in Fig. 4-2. $\left|\lambda_N\right|^2$ has a sharp maximum. We can obtain the position of this maximum by calculating the average number of particles in the state

$$N^* = \langle N \rangle = \sum_k 2v_k^2 = \frac{\Omega}{(2\pi)^3} \int dk 2v_k^2 \tag{4-51}$$

where Ω is the volume of the sample. In the same way we can calculate the mean square of the distribution $\left|\lambda_N\right|^2$. From (4-44), we find

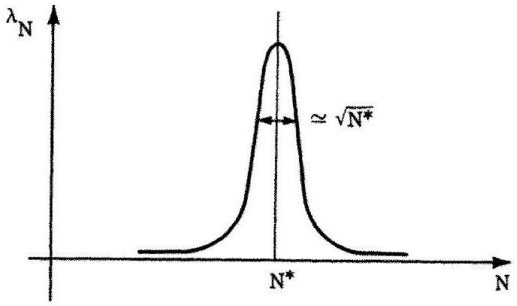


Figure 4-2 The probability amplitude λ_{N} to find a configuration with N particles in the BCS wave function (4-44). λ_N is strongly peaked around $\mathrm{N} = \mathrm{N}^*$.

$$\left\langle N^2 \right\rangle - \langle N \rangle^2 = \sum_k 4v_k^2 u_k^2 = \frac{\Omega}{(2\pi)^3} \int d\mathbf{k} \cdot 4v_k^2 u_k^2 \tag{4-52}$$

$\langle N^2 \rangle - \langle N \rangle^2$ is proportional to Ω, therefore to N^*-the halfwidth of the curve is a quantity of the order of $\sqrt{\mathrm{N}^*}$. Under these conditions, the relative fluctuations of N are of the order $1/\sqrt{\mathrm{N}^*}$-very small. On the contrary, $\sqrt{N^*}$ is still large with respect to 1 and the variations of λ_N are negligible when N varies by one or two

$$\lambda_{\mathrm{N+p}} \sim \lambda_{\mathrm{N}} \quad \text{for } \mathrm{p} \ll \sqrt{\mathrm{N}^*} \tag{4-53}$$

We now investigate the correspondence between the matrix elements of an arbitrary operator F taken between the ϕ_N or $\tilde{\phi}$.

$$\langle \tilde{\phi} | F | \tilde{\phi} \rangle = \sum_{N'} \lambda_{N^*} \lambda_{N'} \left\langle \phi_{N'} \right| F \left| \phi_{N'} \right\rangle \tag{4-54}$$

[52] Note that all factors in the product Π_k commute, as can be seen from (4-45).

Suppose first that F conserves the number of particles, then

$$\langle\tilde{\phi}|F|\tilde{\phi}\rangle = \sum_N |\lambda_N|^2 \langle\phi_N| F |\phi_N\rangle \tag{4-55}$$

The matrix element $\langle\phi_N| F |\phi_N\rangle$ is a slowly varying function of N and we can replace it by its value at the peak. As $\Sigma_N |\lambda_N|^2 = 1$, we obtain

$$\langle\tilde{\phi}|F|\tilde{\phi}\rangle = \langle\phi_{N^*}| F |\phi_{N^*}\rangle \tag{4-56}$$

In the same way, if F acting on ϕ_{N} gives a state of N + p particles,

$$\begin{aligned}\langle\tilde{\phi}|F|\tilde{\phi}\rangle &= \sum_N \lambda_{N^*+p'}\lambda_N \langle\phi_{N+p}| F |\phi_{N'}\rangle \\ &\cong \sum_N |\lambda_{N'}|^2 \langle\phi_{N+p}| F |\phi_N\rangle \\ &= \langle\phi_{N^*+p}| F |\phi_{N^*}\rangle\end{aligned} \tag{4-57}$$

Therefore in practice $\widetilde{\phi}$ gives the same information as ϕ_{N}.

Calculation of the Energy

Let $\mathscr{H}$ be the Hamiltonian of the interacting electron system. With the wave function ϕ_{N} we could apply the variational principle directly and look for the minimum of $\langle\phi_N| \mathscr{H} |\phi_N\rangle$. With the wave function $\widetilde{\phi}$ there is one slight difference-the number of particles is not fixed, and what we must minimize is

$$(\tilde{\phi}|\mathscr{H}|\tilde{\phi}) - E_F(\tilde{\phi}|N|\tilde{\phi}) \tag{4-58}$$

where N is the number of particles and $\mathrm{E_F}$ is a Lagrange multiplier we call the Fermi level. Now list the contributions to $\mathscr{H} - E_F N$. The kinetic energy term is

$$\begin{aligned}\mathscr{H}_0 &= \sum_{\mathrm{k}\alpha} \xi_{\mathrm{k}} \mathrm{a}^+_{\mathrm{k}\alpha} \mathrm{a}_{\mathrm{k}\alpha} \\ \xi_{\mathrm{k}} &= \frac{\hbar^2 \mathrm{k}^2}{2m} - \mathrm{E_F}\end{aligned} \tag{4-59}$$

The potential energy term $\mathcal{H}_{\mathrm{int}}$ has matrix elements describing the scattering of 2 electrons,

$$\begin{aligned}&(\mathbf{k}\alpha)\,(\mathbf{k}'\beta) - (\mathbf{k}+\mathbf{q},\alpha)\,(\mathbf{k}'-\mathbf{q},\beta) \\ \mathscr{H}_{\mathrm{int}} =& \frac{1}{2}\sum_{\mathbf{k},\mathbf{k}',\mathbf{q}} \mathrm{V}\,(\mathbf{k}+\mathbf{q},\mathbf{k}'-\mathbf{q}|\mathbf{k},\mathbf{k}') \\ &\alpha\beta \\ &\times a^+_{\mathbf{k}+\mathbf{q},\alpha} a^+_{\mathbf{k}'} - \mathbf{q},\beta a_{\mathbf{k}'\beta} a_{\mathbf{k}\alpha}\end{aligned} \tag{4-60}$$

The form (4-60) takes into account conservation of momentum and of total spin.

In the state $\widetilde{\phi}$, the probability of finding a state $\mathbf{k}$ occupied is $v^2_{\mathbf{k}}$. Therefore the kinetic energy becomes

$$\langle\tilde{\phi}|\mathscr{H}_0|\tilde{\phi}\rangle = \sum_{\mathrm{k}\alpha} \mathrm{v}^2_{\mathrm{k}} \xi_{\mathrm{k}} \tag{4-61}$$

The only terms contributing in $\mathscr{H}_{\text{int}}$ are
(1) the diagonal terms $\mathbf{V}(\mathbf{kk'kk'})$;
(2) the exchange terms $V(\mathbf{kk'k'k})$;
(3) the terms describing the transition of a pair from the state $(\mathbf{k}\uparrow, -\mathbf{k}\downarrow)$ to the state $(\ell\downarrow, -\ell\downarrow)$, $\mathbf{V}(\ell, -\ell|\mathbf{k}, -\mathbf{k}) = V_{k\ell}$.

The contributions of (1) and (2) are already present in a normal metal. We see later that they can be simply incorporated into ξ_k. We neglect them for the moment. The interesting contribution comes from (3). It is derived in the following way. We can first analyze the wave function $\widetilde{\phi}$ in two parts ϕ_{k1} and ϕ_{k0} in which the pair state $(\mathbf{kt} - \mathbf{kt})$ is, respectively, occupied and unoccupied. From (4-48) we have

$$\tilde{\phi} = v_k\phi_{k1} + u_k\phi_{k0} \tag{4-62}$$

Similarly we can analyze $\widetilde{\phi}$ into four components describing the occupancy of two different pair states $(\mathbf{kt} - \mathbf{kt})$ and $(\boldsymbol{\ell t} - \boldsymbol{\ell t})$

$$\tilde{\phi} = \mathrm{v_k v_\ell}\phi_{\mathrm{k1\ell 1}} + \mathrm{v_k u_\ell}\phi_{\mathrm{k1\ell 0}} + \mathrm{u_k v_\ell}\phi_{\mathrm{k0\ell 1}} + \mathrm{u_k u_\ell}\phi_{\mathrm{k0\ell 0}} \tag{4-63}$$

When computing the contribution of $V_{k\ell}$ to the interaction energy $\langle\widetilde{\phi}|\mathscr{H}_{\text{int}}|\widetilde{\phi}\rangle$, we must use the components

$$\mathrm{v_k u_\ell}\,\langle\phi_{\mathrm{k1\ell 0}}|\,\mathcal{H}_{\text{int}}\,\,|\phi_{\mathrm{k0\ell 1}}\rangle\,\mathrm{u_k v_\ell}$$

and the remaining matrix element is simply $V_{k\ell}$. Thus we find

$$\langle\tilde{\phi}|\mathscr{H} - E_F N|\tilde{\phi}\rangle = 2\sum_k \xi_k v_k^2 + \sum_{k\ell} v_{k\ell}u_k v_k u_\ell v_\ell \tag{4-64}$$

In order to minimize $\langle\tilde{\phi}|\mathscr{H}|\tilde{\phi}\rangle$ taking account of the relation $u_{\mathrm{k}}^2 + v_{\mathrm{k}}^2 = 1$, it is useful to put

$$u_k = \sin\theta_k \quad v_k = \cos\theta_k \tag{4-65}$$

$$\langle\tilde{\phi}|\mathrm{Im}\,C|\tilde{\phi}\rangle = 2\sum_k \xi_k \cos^2\theta_k + \frac{1}{4}\sum_{k\ell}\sin 2\theta_k \sin 2\theta_\ell v_{k\ell} \tag{4-66}$$

The minimization equations are

$$0 = \frac{\partial}{\partial\theta_{\mathrm{K}}}\langle\tilde{\phi}|\mathscr{H}|\tilde{\phi}\rangle = -2\xi_{\mathrm{k}}\sin 2\theta_{\mathrm{k}} + \sum_\ell \cos 2\theta_{\mathrm{k}}\sin 2\theta_\ell \mathrm{V_{k\ell}}$$

or

$$\xi_{\mathrm{k}}\tan 2\theta_{\mathrm{k}} = \frac{1}{2}\sum_\ell \mathrm{V_{k\ell}}\sin 2\theta\ell \tag{4-67}$$

We define

$$\Delta_k = -\sum_\ell v_{k\ell}u_\ell v_\ell \tag{4-68}$$

$$\epsilon_k = \sqrt{\xi_k^2 + \Delta_k^2} \tag{4-69}$$

and we find

$$\tan 2\theta_{\mathrm{k}} = -\frac{\Delta_{\mathrm{k}}}{\xi_{\mathrm{k}}} \tag{4-70}$$

$$2\mathrm{u_k v_k} = \sin 2\theta_{\mathrm{k}} = \frac{\Delta_{\mathrm{k}}}{\xi_{\mathrm{k}}} \tag{4-71}$$

$$-\mathrm{u_k^2} + \mathrm{v_k^2} = \cos 2\theta_{\mathrm{k}} = -\frac{\xi_{\mathrm{k}}}{\epsilon_{\mathrm{k}}} \tag{4-72}$$

(The choice of the sign in the last equation is such that for very large positive $\xi_{\mathrm{K}}, \mathrm{u_k} = 1, \mathrm{v_k} = 0$, and the total number of electrons $\Sigma_{\mathrm{k}} \mathrm{v_k^2}$ converges.)

With the insertion of the value of $u_\ell v_\ell$ into (4-68), we finally obtain an equation for Δ,

$$\Delta_{\mathrm{k}} = -\sum_{\ell} \mathrm{V_{k\ell}} \frac{\Delta_\ell}{2\left(\xi_\ell^2 + \Delta_\ell^2\right)^{1/2}} \tag{4-73}$$

We first notice that this equation always has the trivial solution $\Delta_{\mathrm{k}} = 0$, corresponding to

$$v_k = \begin{cases} 1 & \xi_k < 0 \\ 0 & \xi_k > 0 \end{cases} \tag{4-74}$$

The associated function $\widetilde{\phi}$ is simply

$$\tilde{\phi}_{\mathrm{n}} = \prod_{\mathrm{k}<\mathrm{k_F}} \mathrm{a_k^+ a_{-k}^+} \phi_0 \tag{4-75}$$

This represents a Slater determinant formed of all states of energy less than $E_F = \hbar^2 k_F^2/2m$; and is the wave function of a noninteracting electron gas. To show explicitly that there can be other solutions we choose the simplified interaction

$$V_{k\ell} = \begin{cases} -V & \text{if } |\xi_k|, |\xi_\ell| \leq \hbar\omega_D \\ 0 & \text{otherwise} \end{cases} \tag{4-76}$$

We call this simple form the BCS interaction. V is a positive constant. Then

$$\begin{array}{ll} \Delta_{\mathrm{K}} = 0 & \text{for } |\xi_{\mathrm{K}}| > \hbar\omega_{\mathrm{D}} \\ \Delta_{\mathrm{K}} = \Delta & \text{(independent of k) for } |\xi_{\mathrm{K}}| < \hbar\omega_{\mathrm{D}} \end{array} \tag{4-77}$$

We can then rewrite (4-73) by first summing over all orientations of ℓ for a fixed ξ_ℓ. This gives a factor $\mathrm{N}(\xi_\ell)$, the density of states per unit energy in the normal state for a given spin direction. Since we are interested in an energy interval of width $\hbar\omega_D \ll E_F$, we can replace $\mathrm{N}(\xi_\ell)$ by its value at the Fermi level N(0),

$$\Delta = N(0)V \int_{-\hbar\omega_D}^{\hbar\omega_D} \Delta \frac{d\xi}{2\sqrt{\Delta^2 + \xi^2}} \tag{4-78}$$

$$\frac{1}{N(0)V} = \int_0^{\hbar\omega_D} \frac{d\xi}{\sqrt{\Delta^2 + \xi^2}} = \sinh^{-1}\left(\frac{\hbar\omega_D}{\Delta}\right) \tag{4-79}$$

This equation only has a solution for positive V, that is, an attractive interaction. Then

$$\Delta = \frac{\hbar\omega_D}{\sinh \frac{1}{N(0)V}} \tag{4-80}$$

In everything that follows we are only interested in the weak coupling limit $\mathrm{N(0)V} \ll 1$, for which

$$\Delta = 2\hbar\omega_D e^{-1/N(0)V} \tag{4-81}$$

How is this limit justified? We shall see later that in this simple model the transition temperature is given by $\Delta = 1.75\mathrm{k_B T_0}$. Therefore $e^{-1/N(0)V} = 0.88T_0/\Theta_D$ where Θ_D is the Debye temperature defined by $\hbar\omega_D = \mathrm{k}_B\Theta_D$. For most superconducting metals $\Theta_D \sim 300°\mathrm{K}, \mathrm{T_0} \sim 10°\mathrm{K}$. Therefore we empirically conclude that $\mathrm{N(0)V} < 0.3$. (Lead and mercury are two notable exceptions with very low θ_D 's, giving, respectively, $\mathrm{N(0)V} = 0.39$ and 0.35 .)

Once Δ is known, we can explicitly calculate the kinetic and potential energies. In the weak coupling limit, one finds from (4-64)

$$\langle\tilde{\phi}|\mathscr{H}_0|\tilde{\phi}\rangle = 2\sum_{\mathrm{k}<\mathrm{k_F}} \xi_{\mathrm{k}} + \frac{\Delta^2}{\mathrm{V}} - \frac{\mathrm{N(0)}\Delta^2}{2} \tag{4-82}$$

The first term is the kinetic energy of the normal state ($\Delta = 0$). In the same way, we find

$$\langle\tilde{\phi}|\mathscr{H}_{\mathrm{int}}\,|\tilde{\phi}\rangle = -\frac{\Delta^2}{V} \tag{4-83}$$

The energy difference between the state $\widetilde{\phi}$ and the normal state is

$$\langle\tilde{\phi}|\mathscr{H}|\tilde{\phi}\rangle - \langle\phi_{\mathrm{n}}|\,\mathscr{H}\,|\phi_{\mathrm{n}}\rangle_{(\Delta=0)} = -\frac{\mathrm{N(0)}\Delta^2}{2} \tag{4-84}$$

The condensed state energy is lower than that of the normal state. Thus energy gain is, however, very small, of the order Δ^2/E_F per particle. For $\Delta = 10°\mathrm{K}$ and $\mathrm{E_F} = 10^{4\circ}$ K, this gives $\Delta^2/\mathrm{E_F} = 10^{-2\circ}$ K. We cannot calculate the energy of the normal state with this accuracy. Fortunately the unknown terms are very nearly the same in the normal state and in the condensed state. Each term in (4-82) is incorrect, but the difference is very nearly correct, and it is this difference that is measured experimentally.

Certain simple properties can be determined from the function $\tilde{\phi}$:
(a) Let us study the probability of finding an electron condensed into the state $(\mathbf{k}\alpha)$. It is given by

$$\langle\tilde{\phi}|\mathrm{a}^+_{\mathrm{k}\alpha}\mathrm{a}_{\mathrm{k}\alpha}|\tilde{\phi}\rangle = \mathrm{v}^2_{\mathrm{k}} = \frac{1}{2}\left(1 - \frac{\xi_{\mathrm{k}}}{\sqrt{\xi^2_{\mathrm{k}} + \Delta^2_{\mathrm{k}}}}\right) \tag{4-85}$$

from (4-70) and (4-55). It is shown as a function of k in Fig. 4-3. v_k^2 gives the momentum distribution in the ground state. Ideally v^2_{k} can be measured by the Compton effect, positron annihilation, and so on. In fact, high accuracy would be required to measure v^2_{k} directly in the domain of interest. For $\mathrm{k} \ll \mathrm{k_F}, \mathrm{v_k} = 1$. For $\mathrm{k} \gg \mathrm{k_F}, \mathrm{v_k} = 0$. The distribution function v^2_{K} is continuous in contrast to the normal state where it has a discontinuity at $\mathrm{k_F}$. The transition region, where $\mathrm{v_k}$ goes from 1 to 0, has an energy width Δ and a momentum width $\delta\mathrm{k}$.

$$\begin{aligned} &\frac{\hbar^2}{2m}\left[(k_F + \delta k)^2 - k_F^2\right] \cong \Delta \\ &\delta k = \frac{m\Delta}{\hbar^2 k_F} = \frac{\Delta}{\hbar v_F} \end{aligned} \tag{4-86}$$

(b) Let us add two electrons to the states $\mathbf{k} \notin$ and $-\mathbf{k} \neq$ in the condensed state $\tilde{\phi}_{\mathrm{N}}$. What is the probability amplitude for obtaining the state $\phi_{\mathrm{N}+2}$? This is the quantity

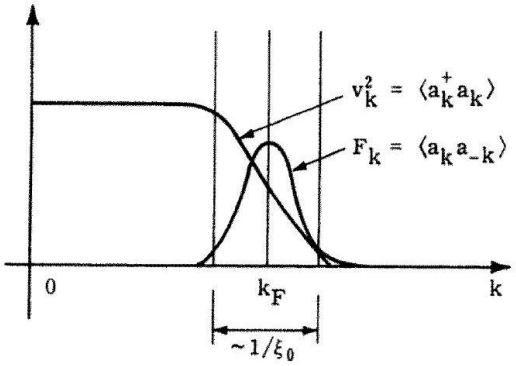

Figure 4-3
The momentum distribution ($|v_k|^2$) of electrons in the BCS ground state. In a normal metal, the distribution drops discontinuously at $k = k_F$. In the superconductor, this drop is smeared out on an interval $\delta \mathrm{k} \sim 1/\xi_0 \sim \Delta/\hbar \mathrm{v_F}$. Also shown is the condensation amplitude $\mathrm{F_k}$.

$$\mathrm{F_k} = \langle \phi_{\mathrm{N}+2} |\, \mathrm{a}^+_{\mathrm{k}\uparrow} \mathrm{a}^+_{-\mathrm{k}\downarrow} \,| \phi_{\mathrm{N}} \rangle = \langle \widetilde{\phi} | \mathrm{a}^+_{\mathrm{k}\downarrow} \mathrm{a}^+_{-\mathrm{k}\downarrow} | \widetilde{\phi} \rangle \tag{4-87}$$

We call $\mathrm{F_k}$ the condensation amplitude in the state $\mathbf{k}$. On using the definition of $\widetilde{\phi}$, we find

$$F_k = u_k v_k \tag{4-88}$$

$\mathrm{F_k}$ is only nonvanishing in the transition zone and is maximum for $\mathrm{k} = \mathrm{k_F}$.

First Excited States

We have constructed a ground state function ϕ_{N} where N particles are coupled in pairs. We now try to add one particle in the plane wave state $(m\alpha)$. We obtain a state

$$\begin{aligned} \phi_{\mathrm{N}+1,\mathrm{m}\,\alpha}\,(\mathrm{r}_1 \cdots \mathrm{r}_{\mathrm{N}+1}) &= \mathrm{A}\phi\,(\mathrm{r}_1 - \mathrm{r}_2) \cdots \phi\,(\mathrm{r}_{\mathrm{N}-1} - \mathrm{r}_{\mathrm{N}}) \\ &\times \exp\,(\mathrm{im} \cdot \mathrm{r}_{\mathrm{N}+1})\,(1\uparrow) \cdots (\mathrm{N}\downarrow)(\mathrm{N}+1, \alpha) \end{aligned} \tag{4-89}$$

We introduce the corresponding generating function

$$\widetilde{\phi}_{m\alpha} = \sum_{\mathrm{N}} \lambda_{\mathrm{N}} \phi_{\mathrm{N}+1}, m\alpha \tag{4-90}$$

By repeating for $\phi_{m\alpha}$ our earlier arguments on ϕ we find

$$\widetilde{\phi}_{m\alpha} = \prod_{k \neq m} \left(u_k + v_k a^+_{k\uparrow} a^+_{-k\downarrow} \right) a^+_{m\alpha} \phi_0 \tag{4-91}$$

$\widetilde{\phi}_{m\alpha}$ is orthogonal to $\widetilde{\phi}$. What is the energy of the state $\phi_{m\alpha}$? For the kinetic energy we find

$$\left\langle \widetilde{\phi}_{m\alpha} \right| \mathscr{H}_0 \left| \tilde{\phi}_{m\alpha} \right\rangle = \langle \widetilde{\phi} | \mathscr{H}_0 | \widetilde{\phi} \rangle + \left(1 - 2\mathrm{v}^2_m\right) \xi_m \tag{4-92}$$

since $\tilde{\phi}_{m\alpha}$ has an electron in the orbital state $m\alpha$, while in the state $\tilde{\phi}$ there is a probability $2v_m^2$ of finding an electron (mt) or (mt). For the potential energy, we notice that only the terms corresponding to the transitions $(\mathbf{k}, \alpha)(-\mathbf{k}, -\alpha) \rightarrow (\mathbf{k}'\alpha)\,(-\mathbf{k}' - \alpha)$ with $\mathbf{k} \neq \mathbf{m}$ and $\mathbf{k}' \neq \mathrm{m}$ contribute since no pair can use the state $m\alpha$. Therefore

$$\left\langle \tilde{\phi}_{m\alpha} \right| \mathscr{H}_{\text{int}} \left| \tilde{\phi}_{m\alpha} \right\rangle = \langle \tilde{\phi} | \mathscr{H}_{\text{int}} | \tilde{\phi} \rangle - 2 \sum_{\ell} \mathrm{v}_{m\ell} \mathrm{u}_m \mathrm{v}_\ell \mathrm{u}_\ell \mathrm{v}_m \tag{4-93}$$

The total energy becomes

$$\begin{aligned} \left\langle \tilde{\phi}_{m\alpha} \right| \varkappa \left| \tilde{\phi}_{m\alpha} \right\rangle &= E_0 + \left(1 - 2v_m^2\right) \xi_m + 2u_m v_m \Delta_m \\ &= E_0 + \frac{\xi_m^2}{\epsilon_m} + \frac{\Delta_m^2}{\epsilon_m} \\ &= E_0 + \epsilon_m \end{aligned} \tag{4-94}$$

Since E_0 is the energy in the ground state $\tilde{\psi}, \epsilon_m = \sqrt{\Delta_m^2 + \xi_m^2}$ is the energy necessary to place a new particle into the state m. Notice that even when $\xi_m = 0, \epsilon_m$ is finite and equal to $\Delta_{\mathrm{k_F}} = \Delta$.

We can try to construct states with $2, 3 \ldots . n$ excitations in the same way. For the states with two excitations. for example, we are tempted to take the function

$$\Xi_{m\alpha, n\beta} = \prod_{k \neq m,n} \left(u_k + v_k a_{kt}^+ a_{-kt}^+\right) a_{m\alpha}^+ a_{n\beta}^+ \phi_0 \tag{4-95}$$

Unfortunately such functions are not necessarily orthogonal to $\widetilde{\phi}$. For example,

$$\left\langle \tilde{\phi} | \Xi_{mt} - m \right\rangle^{\rangle} = \mathrm{v}_m \neq 0 \tag{4-96}$$

Two methods to avoid this difficulty are
(a) Add to Ξ a component $\lambda\widetilde{\phi}$ where λ is chosen in such a way as to make the total function orthogonal to $\widetilde{\phi}$. This is the original BCS method, which is numerically rather tedious.
(b) Reconsider the wave functions of single excitation $\widetilde{\phi}_{m\alpha}$. Let us try to place these functions into the form

$$\tilde{\phi}_{m\alpha} = \gamma_{m\alpha}^* \tilde{\phi} \tag{4-97}$$

where $\gamma_{m\alpha}^+$will appear as a creation operator for one elementary excitation. If the operators $\gamma^+$and their adjoints γ can be found such that
(1) the γ and γ^+obey the fermion commutation rules (analogous to (4-45),
(2) $\gamma_{m\alpha}\widetilde{\phi} = 0$, that is, $\widetilde{\phi}$ is the state of no excitation,
then it is easy to see by manipulating the commutation relations that all the states obtained by applying an arbitrary number of operators $\gamma^+$to $\tilde{\phi}$ are orthogonal to each other, normalized, and orthogonal to the ground state $\widetilde{\phi}$. From the kinematic point of view, these wave functions can therefore conveniently describe states of multiple excitations.

We must now find the γ^+. As a first attempt, we notice that

$$\tilde{\phi}_{m\alpha} = \frac{1}{u_m} a_{m\alpha}^+ \tilde{\phi} \tag{4-98}$$

as is easy to verify from (4-91) by noting that $a_{m\alpha}^+ a_{m\alpha}^+ = 0$ and so on. However $(1/u_m)\, a_{m\alpha}^*$ does not obey the above anticommutation rules. As a second attempt, we notice that

$$\tilde{\phi}_{m\downarrow} = \frac{1}{v_m} a_m \, \phi \tag{4-99}$$

However, we again encounter the same difficulty with the commutation rules. We then try to define γ^+as a linear combination of the preceding forms. If we take

$$\gamma^+_{m\uparrow} = u_m a^+_{m\uparrow} - v_m a_{-m}\dagger$$
$$\gamma^+_{m\neq} = u_m a^+_{m+} + v_m a_{-m\uparrow} \tag{4-100}$$

we find that (4-97) and conditions (1) and (2) are verified. For example, condition (2) becomes

$$\begin{aligned}\gamma_{mt}\tilde{\phi} &= \prod_{k\neq m}\left(u_k + v_k a^+_{kt} a^+_{-kt}\right)\left(u_m a_{mt} - v_m a^+_{-mt}\right)\\ &\times \left(u_m + v_m a^+_{mt} a^+_{-mt}\right)\phi_0\\ &= \prod_{k\neq m}\left(u_k + v_k a^+_{kt} a^+_{-kt}\right) u_m v_m \left(a^+_{-mt} - a^+_{-mt}\right)\phi_0\\ &= 0\end{aligned} \tag{4-101}$$

where we have used the relations $a_{-m\alpha}\phi_0 = 0$, $a_{m\alpha}a^+_{m\alpha}\phi_0 = \phi_0$, and the anticommutation relations. We thus obtain the operators γ^+, which create excited states that are mutually orthogonal and also orthogonal to the ground state. The use of the γ and γ^+enormously simplifies all calculations in which the excited states play a role (Bogolubov, Valatin, 1958). We designate the excitations created by the γ^+'s as quasiparticles.

Physical remarks.

(a) The fact that $\gamma^+_{m\alpha}$is a linear combination of $\mathrm{a}^+_{m\alpha}$and $\mathrm{a}_{m-\alpha}$ expresses the fact that it is possible to create the state $\phi_{\mathrm{N}+1,\mathrm{k}\alpha}$ either by adding an electron $(\mathrm{k}\alpha)$ to the condensed state ϕ_{N} or by removing an electron $(-\mathrm{k}-\alpha)$ from the state $\phi_{\mathrm{N}+2}$.
(b) Suppose we start from the ground state ϕ_N. We have seen that if we add a particle in a state k, it must at least have an energy equal to $E_F + \Delta$. Such an "injection" experiment is not a purely theoretical invention. It can be accomplished by bringing electrons into a superconductor across a thin oxide layer. This is the previously mentioned tunnel effect (Giaever, 1959), which permits us to determine the gap Δ.
(c) However, except from the tunneling experiments, the excited states are usually studied without changing **N** (for example, infrared radiation). If **N** is even, the first excited states of this type correspond to breaking a pair. They correspond to wave functions of the form $\gamma^+_{\mathrm{k}\alpha}\gamma^+_{\ell\beta}(\mathrm{k}\alpha \neq \ell\beta)$. The excitation energy is easily calculated and becomes $\epsilon_k + \epsilon_\ell$. The minimum of this energy (corresponding to the infrared absorption energy gap) is 2Δ. If N is odd (N = 2 K + 1), the state consists of K pairs plus one unpaired electron. There are then 2 kinds of excitations: either a pair is decoupled as previously (gap 2 Δ) or the state of the unpaired electron is changed (gap 0). However the absorption intensity of the first process is $\sim N$ times greater than that of the second process. In practice, since $\mathrm{N} \sim 10^{23}$, one always measures an absorption threshold at 2Δ.
(d) The excitation energy is at least 2Δ, but the energy per excited particle is Δ. At low temperatures the probability of finding a particle excited into a given state k (k near k_F) varies as $\exp(-\Delta/k_B T)$.

Case of Two Coupled Superconductors

Consider two superconductors S and S' separated by an insulating layer. If the layer is thick, the electrons cannot cross it, and S and S' become completely independent. If the layer is thin (thickness < 30Å), the electrons can traverse it by the tunneling effect. This gives rise

to a coupling between the regions S and S', which we consider now. Algebraically, the transfer of the electrons can be described by adding to the Hamiltonian operator $\mathscr{H}_{\mathrm{SS'}}$ of the electrons for S and S', a small term $\mathscr{H}_T$, which causes an electron to tunnel from S to S' and vice versa.

$$\begin{aligned}\mathscr{H} &= \mathscr{H}_{\mathrm{SS'}} + \mathscr{H}_{\mathrm{T}} \\ \mathscr{H}_{\mathrm{T}} &= \sum_{\mathrm{k}\ell} \left(\mathrm{a}^{+}_{\mathrm{ks}}\mathrm{a}_{\ell\mathrm{s'}}\mathrm{T}_{\mathrm{k}\ell} + \mathrm{a}^{+}_{\ell\mathrm{s'}}\mathrm{a}_{\mathrm{ks}}\ \mathrm{T}^{+}_{\mathrm{k}\ell}\right)\end{aligned} \tag{4-102}$$

where a^*_{ks} created an electron in the state k on the side S and $a_{\ell s'}$ destroys an electron in the state ℓ on the side S'. The matrix element $\mathrm{T}_{\mathrm{k}\ell}$ can be calculated explicitly from a solution of the one-electron Schroedinger equation in the barrier. (Notice that $'\mathcal{H}_{\mathrm{SS'}}$ is the complete Hamiltonian of S and S$'$. It contains the electron interactions V.) An eigenstate for $\mathscr{H}_{\mathrm{SS}}$, will be a product of two functions of the type (4-43), one relative to S and one relative to S'. Let

$$\psi_\nu = \phi^{(\mathrm{s'})}_{2(\mathrm{N}-\nu)}\phi^{(\mathrm{s})}_{2\nu} \quad \mathcal{F}_{\mathrm{SS'}}\psi_\nu = \mathrm{E}_\nu\psi_\nu \tag{4-103}$$

ψ_ν describes 2ν electrons coupled in pairs on the side S and $2(\mathrm{N}-\nu)$ electrons coupled in S'. The total number of electrons $2N$ is fixed. On the contrary, ν is not known in advance. How does the energy E_ν vary with respect to ν ? If ν is augmented by 1,2 electrons are created on the side S at the expense of S'. Thermodynamics gives us

$$E_{\nu+1} - E_\nu = 2\left(E^{(s)}_F - E^{(s')}_F\right) \tag{4-104}$$

where $E^{(s)}_F$ is the chemical potential (Fermi level) on the side S. For the moment, let us suppose that there is no voltage applied between S and S'. Then $E^{(S)}_F = E^{(S')}_F$ and the functions ψ_ν are degenerate ($E_\nu =$

E independent of ν). The perturbation $\mathscr{H}_{\mathrm{T}}$ removes this degeneracy. To second order in $\mathscr{H}_{\mathrm{T}}$ there is a matrix element coupling the functions ψ_ν and $\psi_{\nu+1}$

$$\begin{aligned}\mathrm{J}_0 = &\sum_{\substack{\mathrm{k},\ell \\ \mathrm{k'},\ell'}} \langle\nu+1|\mathrm{T}_{\mathrm{k}\ell}\mathrm{a}^{+\,\mathrm{a}}_{\mathrm{ks}}\ell\ \mathrm{s'}|\mathrm{I}\rangle \frac{1}{\mathrm{E}-\mathrm{E}_\mathrm{I}} \\ &\times \langle\mathrm{I}|\mathrm{T}_{\mathrm{k'}\ell'}\mathrm{a}^{+\,\mathrm{a}}_{\mathrm{k's}}\ell'\mathrm{s'}|\nu\rangle\end{aligned} \tag{4-105}$$

where |I) is an intermediate state with $2\nu+1$ electrons on the S side and $2(\mathrm{N}-\nu)-1$ electrons on the S$'$ side. The tunneling Hamiltonian $\mathscr{H}_{\mathrm{T}}$ acting on the state with ν pairs on side S creates a state |I⟩ with one "bachelor electron" of wave vector $\mathbf{k}$ ' on side S . Then $\mathscr{H}_{\mathrm{T}}$ acting on | 1) creates another electron of wave vector k on side S. The final state onto which this is projected is composed of $(\nu+1)$ pairs on side S; thus we must save $k = -k'$. Similarly $\ell = -\ell'$. Then, using the symmetry relation $\mathrm{T}_{-\mathrm{k}-\ell} = \mathrm{T}^{+}_{\mathrm{k}\ell}$and our results on excited states, we find

$$J_0 = -4\sum_{k\ell} |T_{k\ell}|^2 \frac{u_k v_k u_\ell v_\ell}{\epsilon_k + \epsilon_\ell} \tag{4-106}$$

To second order in $\mathscr{H}_{\mathrm{T}}$, one can write

$$\mathscr{H}\psi_\nu = \mathrm{E}\psi_\nu + \mathrm{J}_0\left(\psi_{\nu+1} + \psi_{\nu-1}\right) \tag{4-107}$$

The correct wave function will be a linear combination of the ψ_ν. This problem is formally identical to that of the motion of an electron in a linear atomic chain. ψ_ν is then the analog

of an atomic orbital localized around the ν th atom. In the tight binding approximation, one attempts to form the wave function as a linear combination of the ψ_ν 's. The form of this combination ψ_k is imposed in Bloch's theorem

$$\psi_\mathrm{k} = \sum_\nu \psi_\nu \mathrm{e}^{\mathrm{ik}\nu} \tag{4-108}$$

where k is analogous to a wave vector. The corresponding energy $E(k)$ is

$$E(k) = E + 2J_0 \cos k \tag{4-109}$$

Suppose that we now construct a wave packet of the ψ_k 's corresponding to wave vectors in the interval between k and $k + \Delta k$. In our "linear chain" analogy, the wave packet has a spatial extent $\Delta\nu \sim 1/\Delta\mathrm{k}$. As ν is enormous ($\nu \sim 10^{22}$), we can take $\Delta\nu$ to be very large (for example, $\Delta\nu \sim \sqrt{\nu} \sim 10^{11}$), therefore having a verv small Δk and at
the same time $\Delta\nu/\nu$ very small ($\sim 10^{-11}$). Therefore it is possible to specify k and ν simultaneously with good accuracy. Such a wave packet moves with group velocity

$$\frac{\hbar d\langle\nu\rangle}{dt} = \frac{\partial E(k)}{\partial k} = -2J_0 \sin k \tag{4-110}$$

For the state described by our wave packet, there is a time variation of ν and therefore a current passing from S to S'

$$I = 2e\frac{d\langle\nu\rangle}{dt} = -4e\frac{J_0}{\hbar}\sin k \tag{4-111}$$

In other words, if S and S' are attached to a generator, a current ($< 4\mathrm{eJ}_0/\hbar$) can flow from S to S′ under zero voltage. Equation (4-111) shows us in a simple example why the condensed state has superfluid properties. Note that for a normal system ($u_k v_k \equiv 0$) J_0 vanishes (Eq. 4-106). This effect was predicted by Josephson (1961) and observed first by Anderson and Rowell. The present derivation is due to Ferrel (1963). (Typical current values are of order 10^{-2} A/cm^2.)

How are these results modified when a voltage is applied between S and S' ? We then have $E_{\nu+1} - E_\nu = 2eV$. This is the analog of a uniform electric field applied on the "chain." The wave packet moves according to the force equation

$$\frac{d}{dt}\langle\hbar k\rangle = 2eV \tag{4-112}$$

Equations (4-111) and (4-112) completely determine the behavior of the junction. For example, if the voltage V is held constant, k varies linearly with time and I is an alternating current of frequency $2eV/\hbar$.

Problem.

A Josephson junction SS′ is placed in series with a resistance R′ and connected to a generator of voltage U. Calculate the currents.

Solution.

The voltage across the junction is

$$V = U - RI = U + \frac{4eJ_0R}{\hbar}\sin k$$

From (4-112)

$$\frac{\mathrm{dk}}{\mathrm{dt}} = \frac{2\mathrm{e}}{\hbar}\left(\mathrm{U} + \frac{4\mathrm{eJ_0R}}{\hbar}\sin\mathrm{k}\right) = \omega_0(1 - \lambda\sin\mathrm{k})$$

with

$$\omega_0 = \frac{2\mathrm{eU}}{\hbar} \quad \lambda = -\frac{4\mathrm{eJ_0R}}{\hbar\mathrm{U}} = \frac{\mathrm{RJ}_m}{\mathrm{U}}$$

(J_m = maximum supercurrent allowable through the junction).
The force equation can be integrated in the form

$$\omega_0\,(t - t_0) = \int \frac{\mathrm{dk}}{1 - \lambda\sin k}$$

We consider two cases:
(a) If $\lambda > 1$, the denominator has pole for $k = k_0$, where $\sin k_0 = 1/\lambda$. t tends towards ∞ for $k \to k_0$. The current tends toward the limiting value U/R. When this value is reached, the voltage across the junction $SS', U - RI$, will fall to zero. There is therefore a regime in which there is a permanent continuous current.
(b) If $\lambda < 1$, the denominator never vanishes. The relation between k and t can be integrated explicitly by setting

$$m = \tan\frac{\mathrm{k}}{2} \quad \mathrm{I} = \frac{2\ \mathrm{J}mm}{1 + m^2}$$

One obtains

$$m = \lambda + \sqrt{1 - \lambda^2}\tan\left[\frac{1}{2}\sqrt{1 - \lambda^2}\omega_0\,(t - t_0)\right]$$

m, and consequently k, is a periodic function of time with period $2\pi/\omega_0\sqrt{1 - \lambda^2}$. Notice that the current is not sinusoidal except for $\lambda = 0$.

6.1.4 4-4 Calculations at Finite Temperature

Construction of the Free Energy

For $\mathrm{T} \neq 0$, the states $\gamma_\mathrm{k}^+\tilde{\phi}, \gamma_\mathrm{k}^+\gamma_\ell^+\tilde{\phi}$, and so on, are thermally excited. When $\mathrm{k_B T} \ll \Delta$, there are only a few of these excitations and they are independent. However, when $\mathrm{k_B T} \sim \Delta$, the number of excitations are large. We now study the average effect of the interaction between them, and show that it can be simply described by allowing the energy gap Δ to vary with temperature.

We still define the fermion operators $\gamma_\mathrm{k}^+$by the transformation (4-100) where the u_k and v_k are not yet determined. We treat the excitations of the system as a gas of independent quasiparticles. At temperature T, there is a probability

$$f_{k\alpha} = \left\langle \gamma_{k\alpha}^+\gamma_{k\alpha} \right\rangle = 1 - \left\langle \gamma_{k\alpha}\gamma_{k\alpha}^+ \right\rangle \tag{4-113}$$

of finding a quasiparticle of wave vector $\mathbf{k}$ and spin α.[6] The symbol
denotes a thermal average. We shall calculate the free energy F (where the f_k are arbitrary), then minimize F with respect to u_k and v_k and with respect to f_k.
(1) Calculation of the average kinetic energy from (4-92):

[6] In most usual cases $f_{k\alpha}$ will be independent of the index α and written simply f_k.

$$\langle \mathscr{H}_0 \rangle = \sum_{\mathrm{k}\alpha} \xi_{\mathrm{k}} \left[u_{\mathrm{k}}^2 \left\langle \gamma_{\mathrm{k}\alpha}^+ \gamma_{\mathrm{k}\alpha} \right\rangle + v_{\mathrm{k}}^2 \left\langle \gamma_{\mathrm{k}\alpha} \gamma_{\mathrm{k}\alpha}^+ \right\rangle \right]$$
$$= \sum_{\mathrm{k}} 2\xi_{\mathrm{k}} \left[u_{\mathrm{k}}^2 f_{\mathrm{k}} + v_{\mathrm{k}}^2 \left(1 - f_{\mathrm{k}}\right) \right] \tag{4-114}$$

(2) Potential energy: With our approximations, the only terms that come into play are still those that describe the collisions $(\mathrm{k}\uparrow -\mathrm{k}\downarrow)$ $(lt - lt)$.

$$\langle \mathscr{H}_{\mathrm{int}} \rangle = \sum_{\mathrm{k}\ell} \left\langle \mathrm{a}_{\mathrm{k}t}^+ \mathrm{a}_{-\mathrm{k}t-\ell t}^+ {}^{\mathrm{a}}{}_{\ell t} \right\rangle \mathrm{V}_{\mathrm{k}\ell} \tag{4-115}$$

In Eq. (4-115) the operators a^+, a, are linear combinations of the operators γ^+, γ, and the $\gamma\gamma^+$describe a set of independent fermions. Then we have the simple property

$$\langle 0_1 0_2 0_3 0_4 \rangle = \langle 0_1 0_2 \rangle \langle 0_3 0_4 \rangle + \langle 0_1 0_4 \rangle \langle 0_2 0_3 \rangle - \langle 0_1 0_3 \rangle \langle 0_2 0_4 \rangle \tag{4-116}$$

where each of the 0 is an a or an a^+operator. This property (a particular application of a theorem by Wick) can be checked by writing explicitly the transformation from the a's to the γ 's and then taking the averages. It simplifies the algebra considerably. In the present case, we find 3 terms for the interaction. Two of them involve only averages $\left\langle \mathrm{a}_{\mathrm{k}}^+ \mathrm{a}_{\mathrm{k}} \right\rangle$ and lead to a Hartree and an exchange contributionboth are essentially temperature independent and we drop them as before. The remaining term $\langle a^+ a^+ \rangle \langle a \rangle$ leads to

$$\langle \mathscr{H}_{\mathrm{int}} \rangle = \sum_{\mathrm{k}\ell} v_{\mathrm{k}\ell} u_{\mathrm{k}} v_{\mathrm{k}} u_\ell v_\ell \left(1 - 2f_{\mathrm{k}}\right) \left(1 - 2f_\ell\right) \tag{4-117}$$

(3) Entropy S. The entropy for a system of independent fermions is given by

$$S = -k_B \sum_{k\alpha} \left[f_k \ln f_k + \left(1 - f_k\right) \ln \left(1 - f_k\right) \right] \tag{4-118}$$

(4) The total energy F becomes

$$\mathrm{F} = \langle \mathscr{H}_0 + \mathscr{H}_{\mathrm{int}} \rangle - \mathrm{TS} \tag{4-119}$$

We first require that F be stationary with respect to u_k and v_k. Again setting $u_k = \sin\theta_k, v_k = \cos\theta_k$, we obtain

$$+2\xi_{\mathrm{k}} \left(1 - 2\mathrm{f}_{\mathrm{k}}\right) \sin 2\theta_{\mathrm{k}} = \sum_{\ell} \mathrm{V}_{\mathrm{k}\ell} \cos 2\theta_{\mathrm{k}} \sin 2\theta_\ell \left(1 - 2\mathrm{f}_{\mathrm{k}}\right) \left(1 - 2\mathrm{f}_\ell\right) \tag{4-120}$$

If we define

$$\Delta_{\mathrm{k}} = -\frac{1}{2} \sum_{\ell} \mathrm{v}_{\mathrm{k}\ell} \sin 2\theta_\ell \left(1 - 2\mathrm{f}_\ell\right) \tag{4-121}$$

we recover the solution (4-69)-(4-72). The only modification arises from the fact that Δ_k(4−121) differs from (4-68) by the excitation occupation number f_ℓ. If we now minimize F with respect to f_k, we obtain

$$2\xi_k \left(u_k^2 - v_k^2\right) - 4 \sum_{\ell} v_{k\ell} u_k v_k u_\ell v_\ell \left(1 - 2f_\ell\right)$$
$$+ 2k_B T \ln \left(\frac{f_k}{1 - f_k} \right) = 0 \tag{4-122}$$

Then, using (4-69)-(4-72), we find

$$f_k = \frac{1}{1 + \exp\left(\epsilon_k / k_B T\right)} \tag{4-123}$$

This is the usual form for the distribution function for fermions of energy ϵ_k. However, the variation of f_k with temperature is not simple because ϵ_{K} and Δ_{K} depend on the temperature.

Variation of the Gap with Temperature and Transition Point

The self-consistency equation [analogous to (4-73)] becomes

$$\Delta_{\mathrm{k}} = -\sum_{\ell} \mathrm{v}_{\mathrm{k}\ell} \frac{\Delta_\ell}{2\epsilon_\ell} \left[1 - 2\mathrm{f}\left(\epsilon_\ell\right)\right] \tag{4-124}$$

Let us first take for $V_{k\ell}$ the simple BCS interaction (4-76). The condition becomes

$$1 = \mathrm{N}(0)\mathrm{V} \int_0^{\hbar\omega_{\mathrm{D}}} \frac{\mathrm{d}\xi}{\sqrt{\xi^2 + \Delta^2}} \left[1 - 2\mathrm{f}\left(\sqrt{\xi^2 + \Delta^2}\right)\right] \tag{4-125}$$

This is an implicit relation between T and Δ. For $T = 0$, the Fermi function $f(E)$ is zero (E being positive), and one recovers the condition (4-79). The form of $\Delta(T)$ is given in Fig. 4-4. Δ decreases as T increases, and finally vanishes at a certain temperature T_0. Above T_0.

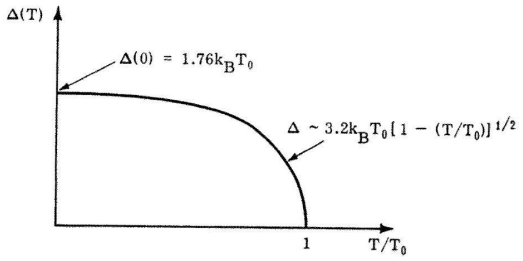

Figure 4-4
Variation of the order parameter Δ with temperature in the BCS approximation.
the normal state ($\Delta_{\mathrm{k}} \equiv 0$) is the only solution of (4-124). T_n is therefore the transition temperature between the (S) and (N) states (in zero magnetic field). Numerically T_0 is defined by setting $\Delta = 0$ in (4-125)

$$1 = \mathrm{N}(0)\mathrm{V} \int_0^{\hbar\omega} \mathrm{D} \frac{\mathrm{d}\xi}{\xi} \tanh \frac{\xi}{2\mathrm{k_B}\ \mathrm{T}_0} \tag{4-126}$$

For $\hbar\omega_D \gg k_B T_0$, it is clear that the integral has the asymptotic form $\ln\left(\hbar\omega_D / k_B T_0\right) + C$ since the hyperbolic tangent is equal to unity in the major part of the domain of integration. A detailed calculation gives $\mathrm{C} = \ln 1.14$. Therefore

$$1 = \mathrm{N}(0)\mathrm{V} \ln \frac{1.14\hbar\omega_{\mathrm{D}}}{\mathrm{kB_B}\ \mathrm{T}_0}$$

or

$$k_B T_0 = 1.14\hbar\omega_D e^{-1/N(0)V} \tag{4-127}$$

Taking $\hbar\omega_D = k_B\theta_D$, where Θ_D is the Debye temperature deduced from specific heat measurements, one can determine the coupling constant $\mathrm{N}(0)\mathrm{V}$ from T_0. The values for the non-transition metals are given in Table 4-1. In most cases, the coupling constant is rather small and $\mathrm{T}_0 \ll \Theta_{\mathrm{D}}$, the only important exceptions being Hg and Pb . (In these two metals, the self-consistent field method is probably inaccurate.) From the exponential form of (4-127). it can be seen that if $N(0)V$ falls below ~ 0.1, with $\Theta_D \sim 200°\mathrm{K}$. then T_0 falls into the region

10^{-30} K. For such small values of T_0. superconductivity might be masked by parasitic effects (such as the magnetic field of the earth. nuclear spins, and so on). It is therefore possible that certain metals

Table 4-1

Metal	θ_{D} (°K)	T_0 (°K)	$[\mathrm{N}(0)\mathrm{V}]_{\mathrm{exp}}$
Zn	235	0.9	0.18
Cd	164	0.56	0.18
Hg	70	4.16	0.35
Al	375	1.2	0.18
In	109	3.4	0.29
Tl	100	2.4	0.27
Sn	195	3.75	0.25
Pb	96	7.22	0.39

not known to be superconducting have, nevertheless, weakly attractive interactions. Finally the qualitative predictions of the "jellium" theory are verified in the sense that $N(0)V$ is large when the valence Z and the atomic volume V_0 are large. [7]

THE ISOTOPE EFFECT

With the BCS interaction (4-76), T_0 is proportional to the cutoff frequency ω_{D}. As already mentioned, for two isotopes, with the same electronic properties but different ionic masses, ω_D will be different and vary as $\mathrm{M}^{-1/2}$. (This is a general result; it comes from the fact that the equation of motion of an ion is of the form $Md^2x/dt^2 = F$ where F is a restoring force independent of M.) Equation (4-127) therefore predicts an isotope effect on the transition temperature ($T_0 \propto \mathrm{M}^{-1/2}$). This dependence on $\mathrm{M}^{-1/2}$ has indeed been observed in a number of nontransition metals (Hg, Pb, Mo, Sn, Tl). However, in many other superconductors (transition metals and compounds), the isotope effect is much smaller, or even nearly absent (Ru, Os). There are various possible explanations for this, notably
(1) The interaction is still mediated by phonons, but the BCS form for $V_{k\ell}$ is oversimplified.
(2) The interaction is mediated by some other low-frequency mode of the solid, involving no lattice motion.
Explanation (2) may well apply in some cases, but it is very hard to prove (or disprove) it experimentally. We discuss only explanation (1).

INCLUSION OF COULOMB REPULSION

In fact, when we discussed the electron-electron interactions earlier in this chapter, we obtained two terms: a repulsive Coulomb term,

essentially frequency independent, and a phonon term (attractive at frequencies $\omega < \omega_D$, and negligible for $\omega \gg \omega_D$).

As before, we neglect completely the dependence of the matrix $V_{k\ell}$ on the angle between $\mathbf{k}$ and $\boldsymbol{\ell}$. We write

$$V_{k\ell} = V(\omega) = V_c - V_p(\omega)$$
$$\omega = \frac{\xi_\ell - \xi_k}{\hbar} \tag{4-128}$$

[7] Numerically, however, the jellium model gives theoretical values for N(0)V which are too large, even when one includes the Coulomb repulsion.

Equation (4-124) for the transition temperature is now replaced by

$$\Delta(\xi) = -\mathrm{N}(0) \int \mathrm{d}\xi' \mathrm{V} \left(\frac{\xi - \xi'}{\hbar} \right) \Delta(\xi') \frac{1 - 2\mathrm{f}(\xi')}{2\xi'} \tag{4-129}$$

Unfortunately, even with the simple interaction (4-128), this integral equation is hard to solve, and we shall discuss it in a sloppy way. We separate the Coulomb term and call its contribution A

$$A = -N(0) \int d\xi' V_C \Delta(\xi') \frac{1 - 2f(\xi')}{2\xi'} \tag{4-130}$$

A is independent of ξ. The equation for Δ is

$$\Delta(\xi) = \mathrm{N}(0) \int \mathrm{d}\xi' \mathrm{V_p} \left(\frac{\xi - \xi'}{\hbar} \right) \Delta(\xi') \frac{1 - 2\mathrm{f}(\xi')}{2\xi'} + \mathrm{A} \tag{4-131}$$

When $|\xi| \gtrsim \hbar\omega_D$ the integral is not large, because the factors $V_p\left(\frac{(\xi-\xi')}{\hbar}\right)$ and $1/\xi'$ cannot be simultaneously large. Thus in this region we may roughly set $\Delta(\xi) = \mathrm{A}$. On the other hand, the integral is important when $|\xi|$ is small. Call B the average value of Δ in the region $\hbar\omega_D > |\xi|$.
Then we have

$$\begin{aligned} B &\cong N(0) V_p \int_{-\hbar\omega_D}^{\hbar\omega_D} d\xi' B \frac{1 - 2f(\xi')}{2\xi'} + A \\ &\cong N(0) V_p \log \frac{\hbar\omega_D}{k_B T_0} + A \end{aligned} \tag{4-132}$$

where V_p is some average of $V_p(\omega)$ over the interval $-\omega_D < \omega < \omega_D$. Finally, Eq. (4-130) defining A may be rewritten as

$$\begin{aligned} A \cong & - N(0) V_c \left[B \int_{-\hbar\omega_D}^{\hbar\omega_D} + A \int_{-\hbar\omega_D}^{\hbar\omega_D} + A \int_{-\hbar\omega_D}^{\hbar\omega_c} + A \int_{-\hbar\omega_c}^{\hbar\omega_D} \right] \\ & \times d\xi' \frac{1 - 2f(\xi')}{2\xi'} \\ \cong & - N(0) V_c \left[B \log \frac{\hbar\omega_D}{k_B T_0} + A \log \frac{\omega_c}{\omega_D} \right] \end{aligned} \tag{4-133}$$

ω_c is a high-frequency cutoff for the Coulomb interaction (in practice, of the order of $\mathrm{E_F}/\hbar$). Writing that (4-133) and (4-130) are compatible, we arrive at the condition

$$\begin{aligned} 1 &= \log \frac{\hbar\omega_D}{K_B T_0} \left(K_p - \frac{K_C}{1 + K_C \log \frac{\omega_C}{\omega_D}} \right) \\ K_p &= N(0) V_p \quad K_C = N(0) V_C \end{aligned} \tag{4-134}$$

An equation of the form (4-134) for the transition temperature was first derived by Bogolubov (1958). It has some remarkable implications:
(1) The Coulomb repulsion described by K_C is not very efficient in counteracting superconductivity, because of the factor

$$\frac{1}{1 + K_C \log \frac{\omega_C}{\omega_D}}$$

In particular, we might have $K_p < K_c$, that is, an over-all interaction constantly repulsive, and still find superconductivity lprovided that $K_p\,(1 + K_c \log\,(\omega_c/\omega_D) > K_c]$.
(2) The isotope effect is modified: If the ionic mass has a relative variation $\delta M/M$, the Debye frequency is changed according to $\delta\omega_D/\omega_D = -\frac{1}{2}\delta M/M$ and the transition temperature shifts according to the law

$$\frac{\delta \mathrm{T}_0}{\mathrm{T}_0} = \frac{\delta \omega_\mathrm{D}}{\omega_\mathrm{D}} \left[1 - \frac{\mathrm{K}_\mathrm{C}^2}{1 + \mathrm{K}_\mathrm{C} \log \frac{\omega_\mathrm{C}}{\omega_\mathrm{D}}}\right]$$

The amplitude of the isotope effect is reduced. This reduction should be particularly strong in metals with narrow bands (ω_c small). This may explain why the isotope effect is strongly reduced in transition metals and in related compounds (Garland, 1963).

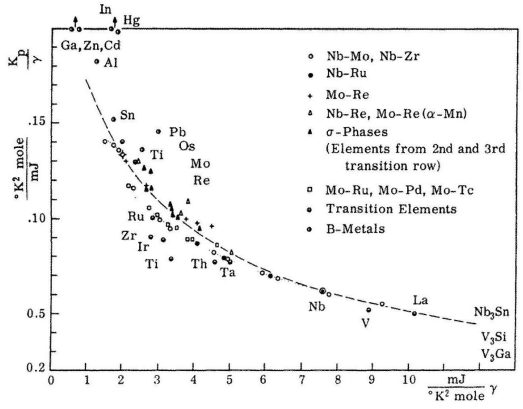

Figure 4-5
An empirical relation between the coupling constant K_p describing the elec-tron-electron interaction via phonons, and the electronic specific heat parameter γ (courtesy J. Muller).

Conversely, from the experimental values of T_0 and of the isotope effect, one can deduce K_p and K_c, assuming that the model is valid. The results for K_p in various metals show a strong correlation between K_p and the electronic specific heat coefficient γ in the normal phase [8] (Muller, 1963) (Fig. 4-5).

Calculation of the Thermodynamic Functions

Combining the expressions for the kinetic and potential energies (4-114) and (4-115) together with the expressions derived for u_k and v_k in the previous section, we obtain for the total energy

$$E = \sum_k \frac{1}{2\epsilon_k} \left[(\epsilon_k + \xi_k)^2 f\,(\epsilon_k) - (\epsilon_k - \xi_k)^2\,(1 - f\,(\epsilon_k))\right] \tag{4-135}$$

In particular, at absolute zero ($f = 0$), we recover the energy calculated in Section 4-3. Writing the entropy (4-118) we find

$$TS = 2\sum_k \left[\epsilon_k f\,(\epsilon_k) + k_B T \ln\,(1 + \exp\,(\epsilon_k/k_B T))\right] \tag{4-136}$$

The specific heat, for example, is determined by

[8] γ is proportional to the density of states at the Fermi level. There is, however, one difference between γ and N(0) : γ is defined per atom, while N(0) is defined per unit volume.

$$C = T\frac{dS}{dT} \tag{4-137}$$

Recalling that ϵ_k depends on T in (4-136), we find

$$\mathrm{C} = 2\beta^2 \mathrm{k_B} \sum_{\mathrm{k}} \mathrm{f}\left(\epsilon_{\mathrm{k}}\right)\left(1 - \mathrm{f}\left(\epsilon_{\mathrm{k}}\right)\right)\left[\epsilon_{\mathrm{k}}^2 + \beta\epsilon_{\mathrm{k}}\frac{\mathrm{d}\epsilon_{\mathrm{k}}}{\mathrm{d}\beta}\right] \tag{4-138}$$

In the BCS approximation, $\epsilon_{\mathrm{k}}\mathrm{d}\epsilon_{\mathrm{k}}/\mathrm{dT} = \Delta\mathrm{d}\Delta/\mathrm{dT}$ is independent of k. Then,

$$\begin{aligned}\mathrm{C} &= 2\beta^2 \mathrm{k_B}\ \mathrm{N}(0)\int_0^\infty \mathrm{d}\xi \mathrm{f}(\epsilon)(1-\mathrm{f}(\epsilon))\left[\epsilon^2 - \mathrm{T}\Delta\frac{\mathrm{d}\Delta}{\mathrm{dT}}\right] \\ \epsilon &= \sqrt{\xi^2 + \Delta^2}\end{aligned} \tag{4-139}$$

The form of this specific heat is represented in Fig. 1-1. At very low temperatures ($\beta\Delta \gg 1$), the term $\Delta\mathrm{d}\Delta/\mathrm{dT}$ is negligible and

$$\begin{aligned}\mathrm{C} &\sim 2\beta^2 \mathrm{k_B}\ \mathrm{N}(0)\Delta^2 \int_0^\infty \mathrm{d}\xi \mathrm{e}^{-\beta\sqrt{\Delta_0^2+\xi^2}} \\ &\sim 2\beta^2 \mathrm{k_B}\ \mathrm{N}(0)\Delta^2 \mathrm{e}^{-\beta\Delta_0}\int_0^\infty \mathrm{d}\xi \mathrm{e}^{-\beta\xi^2/2\Delta_0}\end{aligned} \tag{4-140}$$

where $\Delta_0 = \Delta_{\mathrm{T}} = 0$. The integral is

$$\sqrt{\frac{\pi}{2}}\left(\mathrm{k_B}\ \mathrm{T}\Delta_0\right)^{1/2}$$

The dominant factor in C is the term $e^{-\beta\Delta_0}$, which we have already predicted. A measurement of the low-temperature specific heat allows us to determine Δ_0. Also, Eq. (4-139) predicts a discontinuity in the specific heat at the transition temperature because of the $\Delta d\Delta/dT$ term

$$\begin{aligned}\mathrm{C_S} - \mathrm{C_n} &= \mathrm{k_B}\ \mathrm{N}(0)\beta_0^2\left(\frac{\mathrm{d}\left(\Delta^2\right)}{\mathrm{d}\beta}\right)\mathrm{T_n} \\ \beta_0 &= 1/\mathrm{k_B}\ \mathrm{T}_0\end{aligned} \tag{4-141}$$

Numerically from (4-125), one obtains $\left(\mathrm{d}\Delta^2/\mathrm{d}\beta\right)\ \mathrm{T}_0 = 10.2/\beta_0^3$ and

$$C_s - C_n = 10.2 k_B^2 T_c N(0) \tag{1-142}$$

Finally the Gibbs function is obtained by adding (4-135) and (4-136).

$$\begin{aligned}G &= \sum_k \frac{1}{2\epsilon_k}\left[\left(\epsilon_k + \xi_k\right)^2 f + \left(\epsilon_k - \xi_k\right)(f-1) - 4f\left(\epsilon_k^2 + \xi_k^2\right)\right] \\ &= \sum_k \left[\left(-\epsilon_k + \frac{\Delta^2}{2\epsilon_k}\right)(2f+1) + \xi_k\right]\end{aligned} \tag{4-143}$$

This expression can be transformed by noting that

$$\sum_k \frac{(2f+1)}{2\epsilon_k}\Delta^2 = \sum_k \frac{(2f-1)\Delta^2}{2\epsilon_k} + \sum_k \frac{\Delta^2}{\epsilon_k}$$

The first term on the right is determined from the self-consistency condition (4-124) and is $-\Delta^2/V$. Then

$$G = -2\sum_k \left(\epsilon_k f\left(\epsilon_k\right) - \frac{\Delta^2}{V} + \xi_k - \frac{\xi_k^2}{\epsilon_k}\right) \tag{4-144}$$

Knowing G, we can calculate the critical thermodynamic field defined in Chapter 2, from the equation

$$G_n - G_s = \frac{H_c^2}{8\pi} \tag{4-145}$$

In particular, for $T = 0$, we have $H_c = H_{C_0}$,

$$\mathrm{H}_{\mathrm{C}_0}^2 = 4\pi\ \mathrm{N}(0)|\Delta(0)|^2$$

For finite T, from (4-144), we find a curve $H_c(T)$ rather close to the empirical approximation

$$\frac{\mathrm{H_c}}{\mathrm{H_{C0}}} = 1 - \left(\frac{\mathrm{T}}{\mathrm{T_c}}\right)^2 \tag{4-146}$$

If we look at finer details, we find that, for superconductors where N(0)V is not too large (weakly coupled superconductors), the detailed theoretical curve of $\mathrm{H_c}$ versus T derived from the BCS theory gives even a better fit to the experimental data than does the simplified law (4-146).

Calculation of Transition Probabilities

Suppose that a time-dependent exterior perturbation is applied to a gas of superconducting electrons.

Examples:

(1) Ultrasonics: A longitudinal acoustic wave modifies the potential energy of each electron by a term $\mathrm{U}\theta(\mathrm{rt})$, where θ is the local dilatation of the lattice and U is a constant (the "deformation potential") of the order of several electron volts. The matrix element of this perturbation between the electron plane wave states $\mathbf{k}$ and $\mathbf{k}'$ is $U\theta_{\mathbf{k}-\mathbf{k}'}$ [where θ_{q} is the Fourier transform of $\theta(r)$]. The perturbation acting on the electron system is then

$$\mathscr{H}_1 = \sum_{\mathbf{k},\mathbf{k}',\alpha} \mathrm{U}\theta_{\mathbf{k}-\mathbf{k}'} \mathrm{a}_{\mathbf{k}\alpha}^{+} \mathrm{a}_{\mathbf{k}'\alpha} \tag{4-147}$$

(2) Microwaves: The effect of an electromagnetic perturbation described by a vector potential $A(r,t)$ is given by replacing $p^2/2m$ by $(1/2m)[p-(e/c)A]^2$ in the electronic energy. To first order in A the perturbation is $(-\mathrm{e}/2\mathrm{mc})\ (\mathrm{pA} + \mathrm{Ap})$ and as a function of a and a^{+}it becomes

$$\mathscr{H}_1 = \sum_{\mathrm{k},\mathrm{k}',\alpha} -\frac{\mathrm{e}\hbar}{2\mathrm{mc}}\ \mathrm{A_k} - \mathrm{k}' \cdot (\mathrm{k} + \mathrm{k}')\, \mathrm{a}_{\mathrm{k}\alpha}^{+} \mathrm{a}_{\mathrm{k}'\alpha} \tag{4-148}$$

More generally, the perturbations have the form

$$\mathscr{H}_1 = \sum_{\mathrm{k}\alpha,\mathrm{k}'\alpha'} \mathrm{B}\left(\mathrm{k}\alpha|\mathrm{k}'\alpha'\right) \mathrm{a}_{\mathrm{k}\alpha'}^{+} \mathrm{a}_{\mathrm{k}'\alpha'} \tag{4-149}$$

We find two effects in the presence of $\mathscr{H}_1$:

(1) $\mathfrak{K}_1$ induces transitions between the different excited states described by the γ^{+}. To classify these transitions, we write $\mathfrak{K}_1$ as a function of the γ, γ^{+}operators. Inverting (4-100)

$$\mathrm{a}^{+}_{m\alpha} = \mathrm{u}_m \gamma^{+}_{m\alpha} + \sum_{\beta} \rho_{\alpha\beta} \mathrm{v}_m \gamma_{-m\beta} \tag{4-150}$$

$$\rho = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$$

This gives

$$\begin{aligned} \mathscr{H}_1 = \sum_{\mathrm{k}\alpha} \mathrm{B}\left(\mathrm{k}\alpha|\mathrm{k}'\alpha'\right) \Big\{ & \mathrm{u}_\mathrm{k}\mathrm{u}_{\mathrm{k}'}\gamma^{+}_{\mathrm{k}\alpha}\gamma_{\mathrm{k}'\alpha'} \\ & + \mathrm{v}_\mathrm{k}\mathrm{v}_{\mathrm{k}'} \sum_{\beta,\beta'} \rho_{\alpha\beta}\rho_{\alpha'\beta'}\gamma_{\mathrm{k}\beta}\gamma^{+}_{\mathrm{k}'\beta'} \\ & + \mathrm{u}_\mathrm{k}\mathrm{v}_{\mathrm{k}'} \sum_{\beta} \rho_{\alpha'\beta'}\gamma^{+}_{\mathrm{k}\alpha}\gamma^{+}_{-\mathrm{k}'\beta'} + \mathrm{u}_{\mathrm{k}'}\mathrm{v}_\mathrm{k} \sum_{\beta} \rho_{\alpha\beta}\gamma_{-\mathrm{k}\beta}\gamma_{\mathrm{k}'\alpha'} \Big\} \end{aligned} \tag{4-151}$$

The terms in $\gamma^{+}_i\gamma_j$ and $\gamma_i\gamma^{+}_j$describe transitions where a quasiparticle in the state i is scattered into the state j (and vice versa). The $\gamma^{+}_1\gamma^{+}_2$create two quasiparticles and the terms $\gamma_1\gamma_j$ destroy two of them.

(2) $\mathscr{H}_1$ can also modulate the parameters, such as Δ, which describe the structure of the condensed state, and this modulation also leads to an absorption. In many cases this effect is negligible; consider for instance the ultrasonic attenuation problem. The direct perturbation is $\mathrm{U}\theta(\mathrm{r})$. If the pair potential is also modulated, it will shift by an a mount $\delta\Delta = C\Delta\theta(r)$, where C is a constant of order unity. This gives a modification in the generalized self-consistent field. But U is of order $1 - 10\mathrm{eV}$ and $C\Delta$ is of order $10^{-3}\mathrm{eV}$. Thus the modulation of Δ is unimportant here. In the present paragraph, we neglect it (but we return to it later when we consider the Meissner effect).

We now return to the form (4-151) for $\mathfrak{K}_1$ and consider transitions where a quasiparticle passes from the state $(\mathbf{k}'\alpha')$ into the state $(\mathbf{k}\alpha)$. The matrix element $\mathrm{M}\left(\mathrm{k}\alpha|\mathrm{k}'\alpha'\right)$ is the coefficient of $\gamma^{\dagger}_{\mathrm{k}\alpha}\gamma_{\mathrm{k}'\alpha'}$. The first two terms of (4-151) contribute since $\gamma_1\gamma^{+}_2 = -\gamma^{+}_2\gamma_1$ for $1 \neq 2$. Then

$$\begin{aligned} \mathrm{M}\left(\mathrm{k}\alpha|\mathrm{k}'\alpha'\right) = & \mathrm{B}\left(\mathrm{k}\alpha|\mathrm{k}'\alpha'\right) \mathrm{u}_\mathrm{k}\mathrm{u}_{\mathrm{k}'} \\ & - \mathrm{v}_\mathrm{k}\mathrm{v}_{\mathrm{k}'} \sum_{\sigma,\sigma'} \rho_{\sigma'\alpha'}\rho_{\sigma\alpha}\mathrm{B}\left(-\mathrm{k}'\sigma' \mid -\mathrm{k}\sigma\right) \end{aligned} \tag{4-152}$$

The term $\Sigma_{\sigma\sigma'}\mathrm{B}\left(-\mathrm{k}'\sigma' \mid -\mathrm{k}\sigma\right)\rho_{\sigma'\alpha'}\rho_{\sigma\alpha}$ is essentially the matrix element B where the spins and momenta of the electrons are reversed.

For the interactions $\mathscr{H}_1$, which we consider, it differs at most from $\mathrm{B}\left(\mathrm{k}\alpha|\mathrm{k}'\alpha'\right)$ by a sign

$$\sum_{\sigma\sigma'} \mathrm{B}\left(-\mathrm{k}'\sigma' \mid -\mathrm{k}\sigma\right)\rho_{\sigma\alpha}\rho_{\sigma'\alpha'} = \eta\mathrm{B}\left(\mathrm{k}\alpha|\mathrm{k}'\alpha'\right) \tag{4-153}$$

$$\text{with } \eta = \begin{cases} +1 & \text{case I} \\ -1 & \text{case II} \end{cases}$$

Then

$$\mathrm{M}\left(\mathrm{k}\alpha|\mathrm{k}'\alpha'\right) = \mathrm{B}\left(\mathrm{k}\alpha|\mathrm{k}'\alpha'\right)\left[\mathrm{u}_\mathrm{k}\mathrm{u}_{\mathrm{k}'} - \eta\mathrm{v}_\mathrm{k}\mathrm{v}_{\mathrm{k}'}\right] \tag{4-154}$$

The factor $[u_k u_{k'} - \eta v_k v_{k'}]$ is called the coherence factor of the transition. The number of transitions $(\mathrm{k}'\alpha' \to \mathrm{k}\alpha)$ per unit time less the number of inverse transitions is

$$\begin{aligned}\dot{\nu} =& \frac{2\pi}{\hbar} \left|M\left(k\alpha|k'\alpha'\right)\right|^2 \left\{f\left(\epsilon_{k'}\right)\left[1 - f\left(\epsilon_k\right)\right] - f\left(\epsilon_k\right)\left[1 - f\left(\epsilon_{k'}\right)\right]\right\} \\ & \times \delta\left(\epsilon_k - \epsilon_{k'} - \hbar\omega\right)\end{aligned} \tag{4-155}$$

where we have assumed that $\mathscr{H}_1$ is a sinusoidal perturbation of frequency ω. The power absorbed is

$$\mathrm{W}_1 = \sum_{\mathrm{k},\mathrm{k}'} \nu\hbar\omega \tag{4-156}$$

In order to calculate W_1, we first average over the angles of $\mathbf{k}$ and $\mathbf{k}'$ and the spin indices of the matrix element B,

$$\mathrm{B}^2 = \sqrt{\mathrm{B}\left(\mathrm{k}\alpha|\mathrm{k}'\alpha'\right)\Big|^2}$$

Since $|\xi_\mathrm{k}|$ and $|\xi_{\mathrm{k}'}|$ are small with respect to $\mathrm{E_F}$ [this is ensured by the factors f in (4-155)], B can be treated as a constant, and

$$\begin{aligned}\mathrm{W}_1 = & 2\pi\omega\ \mathrm{B}^2 \int_\Delta^\infty \mathrm{N_S}(\epsilon)\mathrm{N_S}\left(\epsilon'\right) \mathrm{d}\epsilon d\epsilon' \left(uu' - \eta vv'\right)^2 \\ & \times \left[\mathrm{f}\left(\epsilon'\right) - \mathrm{f}(\epsilon)\right] \delta\left(\epsilon - \epsilon' - \hbar\omega\right)\end{aligned} \tag{4-157}$$

In this formula, $N_S(\epsilon) = N(0)|d\xi/d\epsilon|$ is the density of states for the Bogolubov excitations

$$N_S(\epsilon) = N(0)\frac{\epsilon}{\sqrt{\epsilon^2 - \Delta^2}} \quad \epsilon > \Delta \tag{4-158}$$

By using the definitions (4-71) and (4-72) of u and v, we can write

$$\left[\mathrm{uu}' - \eta\mathrm{vv}'\right]^2 = \frac{1}{2}\left[1 + \frac{\xi\xi'}{\epsilon\epsilon'} - \eta\frac{\Delta^2}{\epsilon\epsilon'}\right] \tag{4-159}$$

Each value of ϵ is obtained for two opposite values of ξ. The term $\xi\xi'/\epsilon\epsilon'$ disappears when summed over these two values. Finally

$$\begin{aligned}\mathrm{W}_1 =& 4\pi\omega\ \mathrm{B}^2\ \mathrm{N}(0)^2 \int_\Delta^\infty d\epsilon \int_\Delta^\infty d\epsilon' \frac{\epsilon\epsilon' - \eta\Delta^2}{\left(\epsilon^2 - \Delta^2\right)^{1/2}\left(\epsilon'^2 - \Delta^2\right)^{1/2}} \\ & \times \left[\mathrm{f}\left(\epsilon'\right) - \mathrm{f}(\epsilon)\right] \delta\left(\epsilon - \epsilon' - \hbar\omega\right)\end{aligned} \tag{4-160}$$

An analogous calculation can be made for the power W_2 absorbed by creation and annihilation of two quasiparticles. W_2 is nonzero if $\hbar\omega > 2\Delta$. The final formula for $W = W_1 + W_2$ differs from (4-160) only by the domain of integration,

$$\begin{aligned}W =& 2\pi\omega B^2 N(0)^2 \int_{-\infty}^\infty \int_{-\infty}^\infty d\epsilon d\epsilon' \frac{\epsilon\epsilon' - \eta\Delta^2}{\left(\epsilon^2 - \Delta^2\right)^{1/2}\left(\epsilon'^2 - \Delta^2\right)^{1/2}} \\ & \times \left[f\left(\epsilon'\right) - f(\epsilon)\right] \delta\left(\epsilon - \epsilon' - \hbar\omega\right)\end{aligned} \tag{4-161}$$

Here ϵ and ϵ' are of arbitrary sign, but $|\epsilon| > \Delta$ and $|\epsilon'| > \Delta$. In practice one always compares W to the absorption W_N, which would be obtained in the normal state [W_N is simply obtained from (4-161) by setting $\Delta = 0$],

$$\frac{W}{W_N} = \frac{1}{\hbar\omega} \int d\epsilon d\epsilon' \frac{\epsilon\epsilon' - \eta\Delta^2}{\left(\epsilon^2 - \Delta^2\right)^{1/2} \left(\epsilon'^2 - \Delta^2\right)^{1/2}} \times \left[f\left(\epsilon'\right) - f(\epsilon)\right] \delta\left(\epsilon - \epsilon' - \hbar\omega\right) \tag{4-162}$$

APPLICATIONS

(1) Absorption of sound: In this case $\eta = 1$ and the coherence factor is small when ϵ and ϵ' are simultaneously close to Δ or $-\Delta$. If we study the case where $\hbar\omega$ is small compared to Δ or $k_B T$, then (4-162) reduces to

$$\frac{W}{W_N} = -\int_{|\epsilon|>\Delta} d\epsilon \frac{\epsilon^2 - \Delta^2}{\epsilon^2 - \Delta^2} \frac{\partial f}{\partial \epsilon} = \frac{2}{1 + e^{\beta\Delta}} \tag{4-163}$$

The attenuation is very small at low temperatures and increases rapidly as $T \to T_0$. This therefore gives a way to measure $\Delta(T)$, which has been widely applied, notably by Morse and his co-workers (see Fig. 4-6).

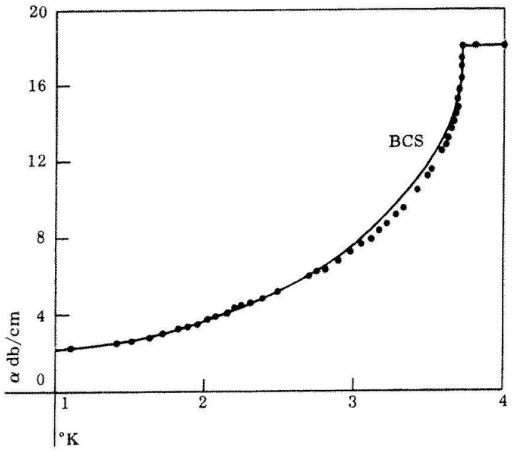

Figure 4-6
Ultrasonic measurements in tin compared with the BCS prediction [after R. W. Morse, IBM J., 6, 58 (1963)].

(2) Nuclear Relaxation: The interaction $\mathscr{H}_1$ between the nuclear spins and the conduction electrons is complicated, but at any rate Case II applies: $\eta = -1$. One can measure the time T_1 for the nuclear spins to equalize their temperature with the electrons in zero field. The ratio T_{1n}/T_1 of the relaxation rates in the superconducting and normalstates is still given by (4-162). The frequency ω, which comes into play here, is the precession frequency of the nuclear spins in the local field of the other nuclei. This is small ($\omega \sim 10^4$). Therefore we can let $\omega \to 0$ and obtain

$$\frac{T_{1n}}{T_1} = -\int_{|\epsilon|>\Delta} d\epsilon \frac{df}{d\epsilon} \frac{\epsilon^2 + \Delta^2}{\epsilon^2 - \Delta^2} \tag{4-164}$$

Here the coherence factor doesn't vanish at the same time as the denominator (for $|\epsilon| = \Delta$): the integral diverges logarithmically. But in a real metal, Δ_k is anisotropic. The singularity in density of states $N_S(\epsilon)$ is then smeared out somewhat and the integral converges. The results depend in detail on the anistropy of Δ_k. In practice, Δ is rather weakly anisotropic; then the

variation of T_{1n}/T_1 with temperature is as shown on Fig. 4-7. The relaxation rate for T slightly less than T_c is greater than in the normal state. This remarkable result arises

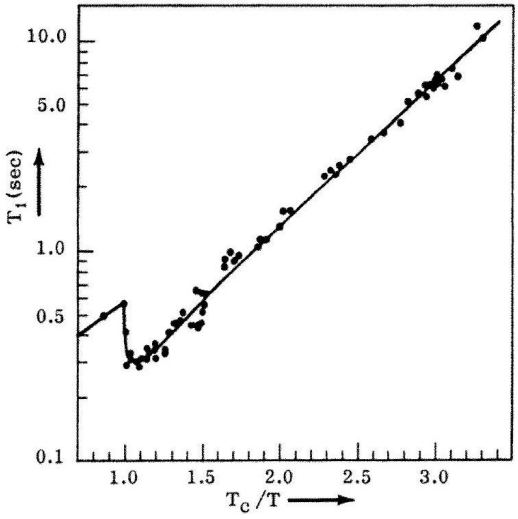

Figure 4-7
Nuclear relaxation rates in aluminum [after A. G. Redfield, Phys. Rev., 125, 159 (1962)]. Notice the dip of T_1 at temperatures below the transition point. The theoretical curve is calculated on the assumption that the peak in the BCS density of states is smeared out on an energy interval $\Delta/5$.

from the increase in the density of states $N_S(\epsilon)$. At low temperatures $T \ll T_c$, on the contrary, the relaxation becomes very slow because of the population factor $df/d\epsilon$. This type of variation of $1/T_1$ with T was first observed in 1957 by Hebel and Slichter. The prediction of the different coherence factors and of the resulting very different behaviors of the ultrasonic attenuation and nuclear relaxation has been one of the great successes of the BCS theory.

6.2 The Self-Consistent Field Method

6.2.1 5-1 The Bogoliubov Equations

In the preceding chapter, we studied a homogeneous electron gas with attractive interactions. We now consider the more general case where the electrons also experience an arbitrary external potential $U_0(r)$ (this will be important to describe the effects of impurities and of the specimen surface) and a magnetic field $\mathbf{H} = \text{curl } \mathbf{A}$.

The most natural method, at first sight, to treat $U_0(r)$ would be the following:

(1) Find the wave function w_n of the one-electron Hamiltonians, which are solutions of

$$\xi_n w_n = \left(-\frac{\hbar^2}{2m}\nabla^2 + U_0(r) - E_F \right) w_n \tag{5-1}$$

(2) Notice that there exist at least two solutions for each energy ξ_n:

$$w_n = w_n(r)|t\rangle \quad \text{and} \quad w_{\bar{n}} = w_n^*(r)|t\rangle \tag{5-2}$$

where $|\alpha\rangle$ denotes the spin states.

(3) Construct a trial function of the BCS type describing a pairing of electrons in the degenerate energy states w_n and $w_{\bar{n}}$,

$$\tilde{\phi} = \prod_n \left(u_n + v_n a_n^+ a_{\bar{n}}^+\right) \phi_0 \tag{5-3}$$

where $a_{\bar{n}}^+$is the creation operator for an electron in the state $w_{\bar{n}}$. The analysis follows that of Section 3.

In fact, this method has several defects: (a) it is not applicable in the presence of a magnetic field; (b) above all, it does not allow enough freedom in the trial function. In fact, the energy can often be lowered if we pair the electrons in states that are better choices than w_n.

We now describe a more powerful method (Bogolubov, 1959), which is essentially a generalization of the Hartree-Fock equations to the case of superconductivity. We begin by rewriting the Hamiltonian $\mathscr{H}$ of the electron system, not with the operators $\mathrm{a_{k\alpha}}$ (which are only ($\alpha =\uparrow$ or $\downarrow$ is again a spin index.) The operators Ψ satisfy the anticommutation rules

$$\begin{aligned} \Psi(r\alpha) &= \sum_k e^{ik\cdot r} a_{k\alpha} \\ \Psi^+(r\alpha) &= \sum_k e^{-ik\cdot r} a_{k\alpha}^+ \end{aligned} \tag{5-4}$$

($\alpha =\uparrow$ or $\downarrow$ is again a spin index.) The operators Ψ satisfy the anticommutation rules

$$\begin{aligned} \Psi(\mathbf{r}\alpha)\Psi\left(\mathbf{r}'\beta\right) + \Psi\left(\mathbf{r}'\beta\right)\Psi(\mathbf{r}\alpha) &= 0 \\ \Psi^+(\mathbf{r}\alpha)\Psi^+\left(\mathbf{r}'\beta\right) + \Psi^+\left(\mathbf{r}'\beta\right)\Psi^+(\mathbf{r}\alpha) &= 0 \\ \Psi^+(\mathbf{r}\alpha)\Psi\left(\mathbf{r}'\beta\right) + \Psi\left(\mathbf{r}'\beta\right)\Psi^+(\mathbf{r}\alpha) &= \delta_{\alpha\beta}\delta\left(\mathbf{r}-\mathbf{r}'\right) \end{aligned} \tag{5-5}$$

The operator associated with the number of particles is

$$N = \sum_{k\alpha} a_{k\alpha}^+ a_{k\alpha} = \sum_\alpha \int dr \Psi^+(r\alpha)\Psi(r\alpha) \tag{5-6}$$

The Hamiltonian $\mathscr{H}$ is also very simply written in terms of Ψ and Ψ^+.[1]

$$\mathscr{H} = \mathscr{H}_0 + \mathscr{H}_1 \tag{5-7}$$

$$\mathscr{H}_0 = \int \mathrm{dr} \sum_\alpha \Psi^+(\mathrm{r}\alpha) \left[\frac{\left(\mathrm{p} - \frac{\mathrm{e}}{\mathrm{c}}\,\mathrm{A}\right)^2}{2m} + \mathrm{U}_0(\mathrm{r})\right] \Psi(\mathrm{r}) \tag{5-8}$$

$$\mathscr{H}_1 = -\frac{1}{2}\,\mathrm{V} \int \mathrm{dr} \sum_{\alpha\beta} \Psi^+(\mathrm{r}\alpha)\Psi^+(\mathrm{r}\beta)\Psi(\mathrm{r}\beta)\Psi(\mathrm{r}\alpha) \tag{5-9}$$

We have taken $U_0(r)$ to be independent of spin (it will eventually be necessary to add a spin-dependent term to describe the exchange potential existing in magnetic media). Also, for the electron-electron coupling $\mathfrak{K}_1$, we have assumed the simplest form describing an interaction, which is

(a) independent of spin (this is correct for a nonmagnetic material),

(b) pointlike and thus characterized by only one coefficient V (BCS approximation).

Also notice that we have neglected the effect of the magnetic field on the conduction electron spins in $\mathscr{H}_0$. (This is correct for $\mathrm{e}\hbar\mathrm{H/mc} < \Delta$.) It will be useful to define

[1] See Landau and Lifschitz, Nonrelativistic Quantum Mechanics (New York: Pergamon, 1959), Chap. 9.

$$H_0 - E_F N = \sum_\alpha \int \Psi^+(r\alpha)\mathscr{H}_e\Psi(r\alpha)dr \tag{5-10}$$

with

$$\mathscr{H}_e(r) = \frac{1}{2m}\left(-i\hbar\nabla - \frac{eA}{c}\right)^2 + U_0(r) - E_F \tag{5-11}$$

Definition of the Effective Potentials

We now replace the interaction $V\Psi^+\Psi^+\Psi\Psi$ by an average potential acting on only one particle at a time (therefore only containing two operators Ψ or Ψ^+). We try an effective hamiltonian of the form

$$\begin{aligned}\mathscr{H}_{\text{eff}} = \int dr \Big\{ &\sum_\alpha \Psi^+(r\alpha)\mathscr{H}_e(r)\Psi(r\alpha) + U(r)\Psi^+(r\alpha)\Psi(r\alpha) \\ &+\Delta(r)\Psi^+(r\uparrow)\Psi^+(r\downarrow) + \Delta^*(r)\Psi(r\downarrow)\Psi(r\uparrow)\Big\}\end{aligned} \tag{5-12}$$

The term U destroys and creates one electron and therefore conserves the number of particles. On the other hand, the terms in Δ increase or decrease the number of particles by two. This should not disturb us, since $\mathscr{H}_{\text{eff}}$ will operate on wave functions such as $\tilde{\phi}$, which are not eigenfunctions of the number operator. In the simple case of the preceding section, an average such as $\langle\widetilde{\phi}|\mathrm{a_k^+ a_{-k}^+}|\widetilde{\phi}\rangle$ is nonzero. Here, in the same way, the mean of the product $\Psi^+\Psi^+$will be nonvanishing and this term will play an important role. We call Δ the pair potential. [Note that terms such as $\Psi(r\uparrow)\Psi(r\uparrow)$ vanish identically because of the commutation rules (5-5).]

Energy Levels of the Effective Hamiltonian $\mathscr{H}_{\text{eff}}$

Let us assume, for the moment, that $\mathscr{H}_{\text{eff}}$ is known; we try to determine its eigenstates and corresponding energies. $\mathscr{H}$ eff is a quadratic
form in Ψ and Ψ^+. We can diagonalize it by performing a unitary transformation which is the exact analog of Eq. (4-100)

$$\begin{aligned}\Psi(r\uparrow) &= \sum_n \left(\gamma_{n\uparrow}u_n(r) - \gamma^+_{n\downarrow}v^*_n(r)\right) \\ \Psi(r\downarrow) &= \sum_n \left(\gamma_{n\downarrow}u_n(r) + \gamma^+_{n\uparrow}v^*_n(r)\right)\end{aligned} \tag{5-13}$$

where the γ and $\gamma^+$are new operators still satisfying the fermion commutation relations

$$\begin{aligned}\gamma^+_{\mathrm{n}\alpha}\gamma_{m\beta} + \gamma_{m\beta}\gamma^+_{\mathrm{n}\alpha} &= \delta_{\mathrm{mn}}\delta_{\alpha\beta} \\ \gamma_{\mathrm{n}\alpha}\gamma_{m\beta} + \gamma_{m\beta}\gamma_{\mathrm{n}\alpha} &= 0\end{aligned} \tag{5-14}$$

The transformation (5-13) must diagonalize $\mathscr{H}_{\text{eff}}$, that is,

$$\mathscr{H}_{\text{eff}} = \mathrm{E_g} + \sum_{\mathrm{n},\alpha} \epsilon_{\mathrm{n}}\gamma^+_{\mathrm{n}\alpha}\gamma_{\mathrm{n}\alpha} \tag{5-15}$$

where E_g is the ground state energy of $\mathscr{H}_{\text{eff}}$ and ϵ_n is the energy of the excitation n . We can also write this condition by taking the commutator of $\mathscr{H}_{\text{eff}}$ with $\gamma_{\mathrm{n}\alpha}$ and $\gamma^+_{\mathrm{n}\alpha}$

$$\begin{aligned}[\mathscr{H}_{\text{eff}}, \gamma_{\text{n}\alpha}] &= -\epsilon_{\text{n}}\gamma_{\text{n}\alpha} \\ \left[\mathscr{H}_{\text{eff}}, \gamma^{+}_{\text{n}\alpha}\right] &= \epsilon_{\text{n}}\gamma^{+}_{\text{n}\alpha}\end{aligned} \tag{5-16}$$

These conditions fix the functions u_n and v_n in (5-13). To derive the equations for u and v, we calculate the commutator $[\mathscr{H}_{\text{eff}}\,, \Psi]$, using the definition (5-12) of $\mathscr{H}_{\text{eff}}$ and the anticommutation properties of the Ψ, obtaining

$$\begin{aligned}[\Psi(r\uparrow), \mathscr{H}_{\text{eff}}\,] &= [\mathscr{H}_{\text{e}} + \text{U}(r)]\,\Psi(r\uparrow) + \Delta(r)\Psi^{+}(r\downarrow) \\ [\Psi(r\downarrow), \mathscr{H}_{\text{eff}}] &= [\mathscr{H}_{\text{e}} + \text{U}(r)]\,\Psi(r\downarrow) - \Delta^{*}(r)\Psi^{*}(r\uparrow)\end{aligned} \tag{5-17}$$

In this equality, we replace the Ψ 's by the γ 's by means of (5-13). Then we apply the commutation relations (5-16). Comparing the coefficients of γ_{n} (and γ^{+}_{n}) on the two sides of the equation, we obtain the Bogolubov equations:

$$\begin{aligned}\epsilon u(r) &= [\mathscr{H}_{e} + U(r)]\,u(r) + \Delta(r)v(r) \\ \epsilon v(r) &= -\,[\mathscr{H}^{*}_{e} + U(r)]\,v(r) + \Delta * (r)u(r)\end{aligned} \tag{5-18}$$

The $\binom{u_n}{v_n}$ are eigenfunctions of a linear system with corresponding eigenvalues ϵ_{n}:

$$\epsilon\begin{pmatrix}u\\v\end{pmatrix} = \hat{\Omega}\begin{pmatrix}u\\v\end{pmatrix} \tag{5-19}$$

Remarks.

(1) The operator $\mathcal{H}^{*}_{\text{e}}$ differs from $\mathcal{H}_{\text{e}}$ when a magnetic field is present:

$$\begin{aligned}\mathscr{H}_{\text{e}} &= \frac{1}{2m}\left(-\text{i}\hbar\nabla - \frac{\text{eA}}{\text{c}}\right)^{2} + \text{U}_0(\text{r}) - \text{E}_{\text{F}} \\ \mathscr{H}^{*}_{\text{e}} &= \frac{1}{2m}\left(\text{i}\hbar\nabla - \frac{\text{eA}}{\text{c}}\right)^{2} + \text{U}_0(\text{r}) - \text{E}_{\text{F}} \neq \mathscr{H}_{\text{e}}\end{aligned}$$

Both $\mathscr{H}_{\text{e}}$ and $\mathscr{H}^{*}_{\text{e}}$ are Hermitian.
(2) The operator $\hat{\Omega}$ is Hermitian; consequently different eigenfunctions $\binom{u}{v}$ are orthogonal.
(3) If $\binom{u}{v}$ is the solution for the eigenvalue ϵ, $\binom{-v^{*}}{u^{*}}$ is the solution for the eigenvalue $-\epsilon$.[2] In agreement with (5-15) we only keep the solutions with positive ϵ.

Choice of the Potentials U and Δ

We now determine $\mathscr{H}_{\text{eff}}$ by requiring that the free energy F calculated from the states which diagonalize $\mathscr{H}_{\text{eff}}$ be stationary. By definition

$$\text{F} = \langle\mathscr{H}\rangle - \text{TS} \tag{5-20}$$

where $\mathscr{H}$ is the initial Hamiltonian $\mathscr{H} = \mathscr{H}_0 + \mathscr{H}_1 (5-7-9)$ and the average $\langle\mathscr{H}\rangle$ is given by

$$\langle\mathscr{H}\rangle = \frac{\Sigma_\phi \langle\phi|\mathscr{H}|\phi\rangle \exp\left(-\beta E_\phi\right)}{\Sigma_\phi \exp\left(-\beta E_\phi\right)} \tag{5-21}$$

The matrix elements are taken with respect to the eigenfunctions $|\phi\rangle$ of $\mathscr{H}_{\text{eff}}$:

$$\mathscr{H}_{\text{eff}}\,|\phi\rangle = E_\phi|\phi\rangle \tag{5-22}$$

A general method to calculate $\langle\mathscr{H}\rangle$ is to replace the Ψ 's (5-7) by the γ 's according to (5-13), then to use the mean value rules

$$\begin{aligned}\left\langle\gamma^+_{\text{n}\alpha}\gamma_{m\beta}\right\rangle &= \delta_{\text{nm}}\delta_{\alpha\beta}\text{f}_\text{n}\\ \langle\gamma_{\text{n}\alpha}\gamma_{m\beta}\rangle &= 0\\ \text{f}_\text{n} &= \frac{1}{\exp(\beta\epsilon_\text{n})+1}\end{aligned} \tag{5-23}$$

However it will not be necessary to perform this entire calculation. We write $\langle\mathscr{H}\rangle$ in the form

$$\begin{aligned}\langle\mathscr{H}\rangle =& \sum_\alpha\int \text{dr}\left\langle\Psi^+(\text{r}\alpha)\mathscr{H}_\text{e}\Psi(\text{r}\alpha)\right\rangle\\ &-\sum_{\alpha\beta}\frac{\text{V}}{2}\int\text{dr}\left\langle\Psi^+(\text{r}\alpha)\Psi^+(\text{r}\beta)\Psi(\text{r}\beta)\Psi(\text{r}\alpha)\right\rangle\end{aligned} \tag{5-24}$$

The product $\langle\Psi^*\Psi^*\Psi\Psi\rangle$ can be simplified thanks to a theorem by Wick, which makes use only of the fact that the $\Psi^+$and Ψ are linear functions of the γ^+,γ. The theorem gives

$$\begin{aligned}\left\langle\Psi^+(1)\Psi^+(2)\Psi(3)\Psi(4)\right\rangle =& \left\langle\Psi^+(1)\Psi(4)\right\rangle\left\langle\Psi^+(2)\Psi(3)\right\rangle\\ &-\left\langle\Psi^+(1)\Psi(3)\right\rangle\left\langle\Psi^+(2)\Psi(4)\right\rangle\\ &+\left\langle\Psi^+(1)\Psi^+(2)\right\rangle\langle\Psi(3)\Psi(4)\rangle\end{aligned} \tag{5-25}$$

We now vary amplitudes $\binom{u}{v}$ to $\binom{\delta u}{\delta v}$ and the occupation numbers f_n to δf_n. The free energy (5-20) then varies by δF:

$$\begin{aligned}\delta\text{F} = \int\text{dr}\Bigg\{&\sum_\alpha\delta\left[\left\langle\Psi^+(\text{r}\alpha)\mathscr{H}_\text{e}\Psi(\text{r}\alpha)\right\rangle\right]\\ &-\text{V}\sum_{\alpha\beta}\left\langle\Psi^+(\text{r}\alpha)\Psi(\text{r}\alpha)\right\rangle\delta\left[\left\langle\Psi^+(\text{r}\beta)\Psi(\text{r}\beta)\right\rangle\right]\\ &+\text{V}\sum_\alpha\left\langle\Psi^+(\text{r}\alpha)\Psi(\text{r}\alpha)\right\rangle\delta\left|\left\langle\Psi^+(\text{r}\alpha)\Psi(\text{r}\alpha)\right\rangle\right|\\ &-\text{V}\left[\langle\Psi^+(\text{r}\uparrow)\Psi^+(\text{r}\downarrow)\rangle\delta(\langle\Psi(\text{r}\downarrow)\Psi(\text{r}\uparrow)\rangle+\text{ C.C. })\right]\Bigg\}-\text{T}\delta\text{ S}(5-26)\end{aligned}$$

where we have assumed $\langle\Psi^+(\mathbf{rt})\Psi(\mathbf{rt})\rangle = 0$ as is correct for our "nonmagnetic" situations. Now notice that the quantity

$$\text{F}_1 = \langle\mathscr{H}_{\text{eff}}\,\rangle - \text{TS} \tag{5-27}$$

is stationary with respect to $\delta\text{u}_\text{n}, \delta\text{v}_\text{n}$, and δf_n since our excitations diagonalise $\mathscr{H}_{\text{eff}}$ exactly. Using (5-12), this condition becomes explicitly:

[2] These two properties allow us to verify that the transformation (5-13) is indeed unitary.

$$
\begin{aligned}
0 =& \delta \left\langle \mathscr{H}_{\text{eff}} \right\rangle - \mathrm{T}\delta\ \mathrm{S} \\
=& \int \mathrm{d}\mathbf{r} \left\{ \sum_{\alpha} \delta \left\langle \Psi^{+}(\mathbf{r}\alpha) \left(\mathscr{H}_{\mathrm{e}} + \mathrm{U}(\mathbf{r})^{n} \right) \Psi(\mathbf{r}\alpha) \right\rangle \right. \\
& \left. + \left\lfloor \Delta(\mathbf{r}) \delta \left(\left\langle \Psi^{+} \left(\mathbf{r}^{\sharp} \right) \Psi^{+}(\mathbf{r}\mathbf{t}) \right\rangle \right) + \text{ C.C. } \right\rceil \right\} - \mathrm{T}\delta\ \mathrm{S}
\end{aligned}
\tag{5-28}
$$

Comparing (5-26) and (5-28), we see that F will be stationary if we take as effective potentials

$$
U(r) = -V \left\langle \Psi^{+}(rt)\Psi(rt) \right\rangle = -V \left\langle \Psi^{+}(rt)\Psi(rt) \right\rangle \tag{5-29}
$$

(the standard Hartree-Fock result for a point interaction), and

$$
\Delta(r) = -V \langle \Psi(r\downarrow)\Psi(r\uparrow) \rangle = V \langle \Psi(r\uparrow)\Psi(r\downarrow) \rangle \tag{5-30}
$$

If we replace the Ψ 's by the γ 's by means of (5-13) and if we use the mean value rules (5-23), we can put these conditions into the explicit form

$$
U(r) = -V \sum_{n} \left[|u_n(r)|^2 f_n + |v_n(r)|^2 (1 - f_n) \right] \tag{5-31}
$$

$$
\Delta(r) = +V \sum_{n} v_n^*(r) u_n(r) (1 - 2f_n) \tag{5-32}
$$

These conditions assure that the potentials U and Δ are self-consistent.

In practice there is an important distinction between $U(r)$ and $\Delta(r)$. The Hartree-Fock potential $U(r)$ comes from an integral Σ_n involving all states below the Fermi level. Consequently, $U(r)$ is nearly independent of temperature, and U can be approximated by the HartreeFock potential calculated in the normal state. This represents a considerable simplification. On the contrary, the pair potential $\Delta(r)$ is a sum of terms of the form $u_n v_n^*$. Such terms, as we already have seen for the homogeneous gas, are nonzero only in the neighborhood of the Fermi surface. For this reason $\Delta(r)$ is a strong function of temperature.

For the case of the homogeneous gas considered in the previous chapter, $\Delta(r)$ is spatially constant and the self-consistency equation (5-31) reduces to a determination of the constant Δ. When $\Delta(r)$ varies spatially, it is much more difficult to ensure the self-consistency of Δ. We shall return several times to this problem.

Problem. Spectrum for a state with a current flow

Discuss the quasiparticle spectrum for a state of uniform current flow, in a pure superconductor. A state of uniform flow is described by a pair potential of the form $\Delta = |\Delta| e^{2iq\cdot r}$ where q is a vector in the direction of flow (the average momentum per electron in this state is $\hbar q$).

Solution.

The solution of (5-18) is then of the form

$$
\begin{aligned}
u(r) &= U_k e^{i(k+q)\cdot r} \\
v(r) &= V_k e^{i(k-q)\cdot r}
\end{aligned}
$$

and the eigenvalue equation reads

$$(\epsilon_{\mathrm{k}} - \xi_{\mathrm{k+q}})\,\mathrm{U_k} - |\Delta|\mathrm{V_k} = 0$$
$$-|\Delta|\mathrm{U_k} + (\xi_{\mathrm{k}} + \xi_{\mathrm{k-q}})\,\mathrm{V_k} = 0$$

The positive eigenvalue ϵ_{k} is given by

$$\epsilon_{\mathrm{k}} = \frac{\xi_{\mathrm{k+q}} - \xi_{\mathrm{k-q}}}{2} + \left[\left(\frac{\xi_{\mathrm{k+q}} + \xi_{\mathrm{k-q}}}{2}\right)^2 + |\Delta|^2\right]^{1/2}$$

As we shall see, the region of major interest is $q \sim \Delta/\hbar v_F$, thus $q \ll k_F$. Retaining only terms of first order in q, we can write

$$\frac{\xi_{k+q} - \xi_{k-q}}{2} = \frac{\hbar^2 k}{m} \cdot q$$
$$\frac{\xi_{k+q} + \xi_{k-q}}{2} \cong \xi_k$$
$$\epsilon_k = \epsilon_k^0 + \frac{\hbar^2 k}{m} \cdot q$$

where ϵ_{k}^0 is the excitation energy for $\mathrm{q} = 0, \epsilon_{\mathrm{k}}^0 = \sqrt{|\Delta|^2 + \xi_{\mathrm{k}}^2}$, and $\hbar\mathrm{q}/m$ is usually called the superfluid velocity $\mathrm{v_s}$. Notice that the gap in the energy spectrum goes to 0 when $v_S = |\Delta|/\hbar k_F = |\Delta|/p_F$. (In application of these
formulas it must be recalled that, in general, the self-consistent value of $|\Delta|$ depends on $\mathrm{v_S}$.)

Theory

In principle, this spectrum could be studied in thin films of pure metals; in practice it cannot for the following reasons: The film thickness d must be smaller than the penetration depth λ (to have a uniform current), but d must be large compared with ξ_0 (if not, the diffuse scattering on the film boundaries can bring some important changes in the spectrum). Thus we would have to work with a pure Type II material, with $\lambda \gg \xi_0$. But then comes another difficulty: for $v_s \sim |\Delta|/p_F$, the current density $n_s e v_s$ is high. The field at the surface of the film is of order

$$\frac{1}{c}\,(\mathrm{n_S e v_S})\,\mathrm{d} \sim \frac{\phi_0\ \mathrm{d}}{\lambda^2 \xi_0} \quad \text{for } \mathrm{T} = 0$$

It is larger than the first penetration field $\mathrm{H_{Cl}}$ by a factor $\sim \mathrm{d}/\xi_0 > 1$. Thus vortex lines come in the film and the situation is not the one desired.

On the other hand, the above calculation can be of use for a discussion of quasiparticles in the Schubnikov phase of bulk, pure, Type II superconductors (M. Cyrot, 1964). Assume that
(a) the Landau-Ginsburg parameter $\kappa = \lambda/\xi$ is much larger than unity,
(b) the field H is much smaller than the upper critical field $\mathrm{H_{C_2}}$.

Then the distance d between lines is much larger than ξ, and most of the excitations (with energies $\epsilon \sim \Delta_\infty$, where Δ_∞ is the amplitude of the pair potential far from the line) can be obtained as follows: At point r compute the superfluid velocity $v_s(r)$ and write that locally the excitations have a shifted BCS spectrum

$$\epsilon(\mathrm{k, r}) = \left\{\Delta_\infty^2 + \xi_{\mathrm{k}}^2\right\}^{1/2} + \hbar \mathrm{v_S} \cdot \mathrm{k} \quad \text{where } \xi_{\mathrm{k}} = \frac{\hbar^2\,(\mathrm{k}^2 - \mathrm{k_F^2})}{2m}$$

Since the minimum spatial extension of wave packets made with these excitations is of order ξ, while the fields and the velocities v_s are modulated on a scale $\mathrm{d} > \xi$, in general, this procedure is correct.

It fails however for the low-lying excited states ($\epsilon \ll \Delta_\infty$) localized very near one line where v_S and the order parameter Δ vary rapidly. These particular excitations are discussed in the next problem, page 153.

6.2.2 5-2 Theorems on the Pair Potential and the Excitation Spectrum

Gauge Invariance

The one-electron Hamiltonian

$$\mathscr{H}_e(A) = \frac{1}{2m}\left(p - \frac{eA}{c}\right)^2 + U - E_F$$

and its complex conjugate

$$\mathscr{H}_e^*(\mathrm{A}) = \frac{1}{2m}\left(\mathrm{p} + \frac{\mathrm{eA}}{\mathrm{c}}\right)^2 + \mathrm{U} - \mathrm{E_F}$$

depend on the choice of the vector potential $\mathbf{A}$. This choice of $\mathbf{A}$ is not unique. If $\mathbf{A}$ is replaced by $\mathbf{A}'$ such as

$$\mathbf{A}' = \mathbf{A} + \nabla \times (\mathbf{r}) \tag{5-33}$$

where X is an arbitrary function, then

$$\operatorname{curl} \mathbf{A}' = \operatorname{curl} \mathbf{A} = \mathrm{h}$$

A and A' are equally acceptable to describe the field configuration $\mathbf{h}(\mathbf{r})$. All physically measurable quantities will have the same values when calculated with A or A'. We shall prove this property for the quasiparticle excitation energies, that is, for the eigenvalues of Eq. (5-18).

Suppose that the eigenfunctions $\binom{u_n}{v_n}$ of (5-18) with vector potential A are known. Now consider Eq. (5-18) with vector potential $\mathbf{A}'$. Two things are modified:
(a) the eigenfunctions $\binom{u'_n}{v'_n}$ differ from $\binom{u_n}{v_n}$.

$$\left.\begin{aligned} u'_n(r) &= u_n(r)\exp\left[\tfrac{\mathrm{ie}}{\hbar \mathrm{c}}\chi(r)\right] \\ v'_n(r) &= v_n(r)\exp\left[-\tfrac{\mathrm{ie}}{\hbar \mathrm{c}}\chi(r)\right] \end{aligned}\right\} \tag{5-34}$$

(b) the pair potential is modified: if $\Delta(r)$ was associated with A, the pair potential $\Delta'(r)$ is given by

$$\Delta'(r) = \Delta(r)\exp\left[\frac{2\mathrm{ie}}{\hbar \mathrm{c}}\chi(r)\right] \tag{5-35}$$

Proof of (5-34): The function u'_n defined by (5-34) satisfies the equation

$$\begin{aligned} \left(p - \frac{eA'}{c}\right) u'_n(r) &= \left(-i\hbar\nabla - \frac{e}{c}A'\right)\exp\left[\frac{ie}{\hbar c}\chi(r)\right] u_n(r) \\ &= \exp\left[\frac{ie}{\hbar c}\chi\right]\left(-i\hbar\nabla - \frac{eA'}{c} + \frac{e}{c}\nabla\chi\right) u_n(r) \\ &= \exp\left[\frac{ie}{\hbar c}\chi\right]\left(p - \frac{e}{c}A\right) u_n \end{aligned} \tag{5-36}$$

where we have made use of (5-33). Iterate this property:

$$\left(p-\frac{eA'}{c}\right)^2 u'_n = \exp\left[\frac{ie}{\hbar c}x\right]\left(p-\frac{eA}{c}\right)^2 u_n \tag{5-37a}$$

$$\mathscr{H}_e\left(A'\right)u'_n = \exp\left[\frac{ie}{\hbar c}x\right]\mathscr{H}_e(A)u_n$$

Similarly

$$\mathscr{H}^*_{\mathrm{e}}\left(\mathrm{A}'\right)\mathrm{v}'_{\mathrm{n}} = \exp\left[\frac{-\mathrm{ie}}{\hbar\mathrm{c}}\chi\right]\mathscr{H}^*_{\mathrm{e}}(\mathrm{A})\mathrm{v}_{\mathrm{n}} \tag{5-37b}$$

Since $\binom{u_n}{v_n}$ is an eigenfunction of (5-18) we have

$$\mathscr{H}_e(\mathrm{A})\mathrm{u}_{\mathrm{n}} + \Delta\mathrm{v}_{\mathrm{n}} = \epsilon_{\mathrm{n}}\mathrm{u}_{\mathrm{n}}$$

Multiply by exp lie χ/hcl and make use of (5-37a). The equation becomes

$$\mathscr{H}_{\mathrm{e}}\left(\mathrm{A}'\right)\mathrm{u}'_{\mathrm{n}} + \Delta'\mathrm{v}'_{\mathrm{n}} = \epsilon_{\mathrm{n}}\mathrm{u}'_{\mathrm{n}} \tag{5-38a}$$

and similarly

$$-\mathscr{H}^*_{\mathrm{e}}\left(\mathbf{A}'\right)v'_{\mathrm{n}} + \Delta'u'_{\mathrm{n}} = \epsilon_{\mathrm{n}}v'_{\mathrm{n}} \tag{5-38b}$$

The $\binom{\mathrm{u}'_{\mathrm{n}}}{\mathrm{v}'_{\mathrm{n}}}$ is the set of eigenfunctions of the vector potential A′ and the pair potential Δ'. Furthermore if Δ satisfied the self-consistency relation (5-32) with the set $\binom{u}{v}$, Δ' also satisfies (5-32) with the set $\binom{u'}{v'}$.

Conclusion: The wave functions, and even the pair potential, have changed by the "gauge transformation" $A \rightarrow A$ '. We say that Δ, for instance, is "gauge covariant." But the eigenvalues ϵ_{n} are unchanged: We say that they are "gauge invariant." We can prove in the same way that all physically measurable quantities (such as the current density at one point...) are gauge invariant.

Remarks.

Restrictions on the possible gauge functions χ. The self-consistent field $\Delta(r)$ must be a single-valued function of r, whatever gauge we choose. Take for instance a sample in the form of a hollow cylinder, $0z$ being the cylinder axis and φ the rotation angle around 0 z . Try a gauge function of the form

$$\chi = \frac{\hbar c}{2e}m\varphi \tag{5-39}$$

where m is an arbitrary constant. Then

$$\Delta'(r) = \Delta(r)e^{im\varphi} \tag{5-40}$$

Both Δ and Δ' must be single values: This imposes that m be an integer. More generally, for an arbitrary ring shaped specimen, the increment of χ when performing one term around the ring must be $2\pi(\mathrm{ch}/2\mathrm{e}) = \mathrm{ch}/2\mathrm{e}$ times an integer.

SPECIAL CHOICES OF GAUGE

Starting from a given A, the transformation function X can be chosen to impose some convenient properties to A'.

Example 1. For a singly connected specimen, we impose

$$\begin{aligned} \operatorname{div} A' &= 0 \text{ in the sample} \\ A' \cdot n &= 0 \text{ at the surface} \end{aligned} \tag{5-41}$$

(where **n** is a unit vector normal to the surface). The transformation function χ is derived from the equations

$$\begin{aligned} \nabla^2 \chi &= -\operatorname{div} \mathbf{A} \text{ in the sample} \\ \mathbf{n} \cdot \nabla \chi &= -\mathbf{n} \cdot \mathbf{A} \text{ at the surface} \end{aligned} \tag{5-42}$$

According to general theorems in electrostatics, the solution χ of (5-42) is unique for a singly connected specimen. Thus A' is well defined. We say that A' is the vector potential in the London gauge.

Example 2. With A as vector potential, we have a certain pair potential $\Delta(r)$. Separate the amplitude and phase of Δ:

$$\Delta(r) = |\Delta(r)| e^{i\varphi(r)} \tag{5-43}$$

Then transform to A' using as gauge function

$$\chi = -\frac{\hbar c}{2e} \varphi \tag{5-44}$$

Since Δ was single valued, this choice χ is always acceptable. [3] The new pair potential is simply

$$\Delta'(r) = |\Delta(r)|$$

Thus it is always possible to choose a gauge where the pair potential is real. For a singly connected superconductor with no external current leads, this gauge coincides in fact with the London gauge, but it is defined for more general situations.

Flux Quantization

Consider the superconducting ring of Fig. 5-1 (diameter and thickness much larger than the penetration depth).

[3] This property was pointed out to the writer by Dr. P. Marcus.

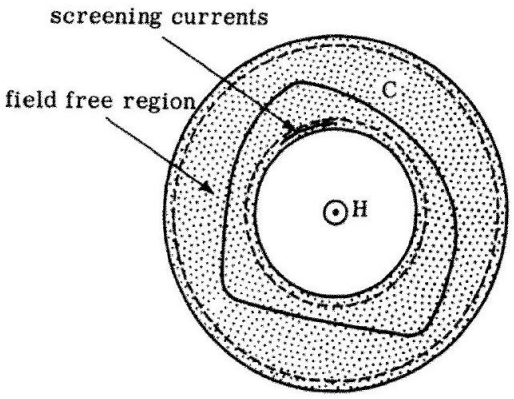

Figure 5-1
Flux trapped in a large superconducting ring. The thickness of the ring is assumed to be very large compared with the penetration depth; then it is possible to find a contour C in the superconductor along which the current and the field are 0 .

Experiments by Doll and Nabauer, and by Deaver and Fairbanks (1961), have shown that the flux ϕ, which passes through the ring, can only take on certain discrete values:

$$\begin{aligned} \phi &= \mathrm{n}\phi_0 \\ \phi_0 &= \frac{\mathrm{ch}}{2\mathrm{e}} \simeq 2.10^{-7}\mathrm{G}\times\mathrm{cm}^2 \\ \mathrm{n} &= \text{ any integer} \end{aligned} \tag{5-45}$$

(Such measurements of small fluxes are done on metallic films deposited on the surface of a capillary $\sim 10\mu$ in diameter. The flux unit ϕ_0 then corresponds to a sizeable field ~ 0.1G.)

This "flux quantization" is a consequence of the condition that $\Delta(r)$ be a single-valued function.

Proof. Introduce a vector

$$u = \hbar\nabla\phi - \frac{2e}{c}A \tag{5-46}$$

where ϕ is the phase of Δ defined as above. Note first that u is gauge invariant, as can be seen from the transformation laws (5-34), (5-35). Physically, for situations where $|\Delta|$ is constant in space, u is proportional to the local supercurrent density (take for instance the situation of uniform flow and $A = 0$ described in the last problem). Now consider an inner point P of the ring (Fig. 5-1). At P, no field penetrates; there is no current and $u = 0$. Integrate this relation around the countour C, which comes nowhere close to the surface ($\mathbf{u} = 0$ along $\mathbf{C}$)

$$\int_{\mathrm{c}} \mathrm{d}\ell \cdot \left(\hbar\nabla\phi - \frac{2\mathrm{e}}{\mathrm{c}}\,\mathrm{A}\right) = 0 \tag{5-47}$$

$\int \mathrm{c}A\cdot d\ell = \phi$ is the flux in the ring. $\int \nabla\phi\cdot d\ell = [\phi]$ is the change of phase of $\Delta(r)$ after one turn around C. Since Δ must be single valued: $[\phi] = 2n\pi$ (n integer). Inserting these results in (5-47) we obtain (5-45).

Flux quantization was first considered by London. He predicted a flux quantization ch/e = twice the experimental value. We now repeat his argument (for a pure metal, at $T = 0$) and then try and correct it. Let $\phi_0\,(r_1\cdots r_N)$ be the ground state wavefunction of the superconducting electrons i (a state of no current). A state of uniform current flow is obtained if we replace ϕ_0 by

$$\phi_0 \exp \mathrm{iq} \cdot \lfloor \mathbf{r}_1 + \mathbf{r}_2 + \ldots + \mathbf{r_N} \rfloor \tag{5-48}$$

leading to a current density $ne\hbar q/m$. A more general state of macroscopic motion would be

$$\phi_0 \exp \mathrm{i} [\, \mathrm{S}(\mathrm{r}_1) + \ldots + \mathrm{S}(\mathrm{r_N})] \tag{5-49}$$

where S(r) is a slowly varying function in space. If there is also a vector potential A, the resulting current has the form

$$j = \frac{ne}{m} \left(\hbar \nabla S - \frac{eA}{c} \right) \tag{5-50}$$

If we assume that the only states that can be realized in the superconductor are of the form (5-49) we immediately find the Meissner effect: Taking the curl of (5-50) leads to the London equation. Furthermore, we find flux quantization: Consider again our superconducting ring. In the interior, far from the surface, $\mathbf{j} = 0$, and the vector potential is given by

$$A = \frac{c\hbar}{e} \nabla S \tag{5-51}$$

If some flux ϕ passes through the annulus, S cannot be single valued. Consider a contour C as shown in Fig. 5-1. If C is nowhere close to the surface, (5-51) is valid along C and the flux enclosed by C is given by

$$\int \mathrm{Hd}_\sigma = \oint \mathrm{A} \cdot \ \mathrm{d}l = \frac{\mathrm{ch}}{\mathrm{e}} \oint \nabla \ \mathrm{S} \cdot \ \mathrm{d}l = \frac{\mathrm{ch}}{\mathrm{e}} \not{\mathrm{S}} \tag{5-52}$$

where the integrals $\oint dl$ are taken along C, and $\varnothing$ is the increase in S when one makes one complete path around the contour. $\not{S}$ cannot take on arbitrary values. The wave function must be a single-valued function of $r_1 \ldots r_N$. If we allow one of the coordinates r_1 to vary along C, after a complete cycle we must find the same function. Since ϕ_0 is single valued, this imposes the condition that $\not{S} = 2n\pi$, where n is an integer. From (5-52) this gives ch/e as the flux quantum.

This argument has one weak point, however (Brenig, 1961). In reality the states $\phi_0 \exp \{i [S(r_1) + \ldots + S(r_N)]\}$ are not the only states of macroscopic motion we can construct in a superconductor. To see this, we have to look into the detailed shape of ϕ. Let us do it on a simple problem: a superconducting electron gas with periodic boundary conditions

$$\phi(x_i \ldots x_i \ldots x_N) \equiv \phi(x_i \ldots x_i + L \ldots x_N) \qquad \text{for all } i \tag{5-53}$$

We construct states of translational motion with momentum hq per electron. Pairing electrons $(\mathbf{k} + \mathbf{q}, \uparrow)$ and $(-\mathbf{k} + \mathbf{q}, \downarrow)$, we can build BCS wave functions:

(1) If $qL = \phi = 2n\pi$ (n integer), we use one-electron states k satisfying the usual periodic boundary conditions

$$k_X L = 2n_X \pi \quad (n_X \text{ integer }) \tag{5-54}$$

Then Eq. (5-53) is obeyed.

(2) If qL = \$ = $(2\mathrm{n} + 1)\pi$ (n integer), we use one-electron states k satisfying the opposite boundary condition

$$k_X L = (2n_X + 1)\, \pi \tag{5-55}$$

Again (5-53) is obeyed.

The functions of class (1) are of the London type: they differ from the BCS function at rest only by the factor $\exp[iq(x_1 + \ldots + x_N)]$. The functions of class (2) are not ot the London type. Both classes are acceptable. In all cases the energy is given by

$$E = E_0 + \frac{\hbar^2 q^2}{2m} N \tag{5-56}$$

Equation (5-56) applies to both classes, provided that

$$\mathrm{k_F\ L} \gg 1 \quad \text{and} \quad \frac{\mathrm{L}}{\xi_0} \gg 1 \tag{5-57}$$

When (5-57) is satisfied, all sums Σ_k on the allowed k values can be replaced by integrals which are independent of the choice of conditions (5-54) or (5-55).

Finally, it is easy to transpose these results to the case of an annulus. Again we find $\$ = n\pi$ and the resulting flux quantum is $ch/2e$.

How do the Bogolubov amplitudes $\binom{u}{v}$ change after one turn around the ring?

Answer.

This of course depends on the gauge chosen. Choose the gauge where Δ is real. Then, after one turn around the ring, the amplitudes are multiplied by $(-1)^n$, where n is the number of flux quanta in the ring.

Solution.

Return again to the simple case of uniform translation with the boundary condition (5-53). In the gauge where $\Delta = |\Delta| e^{21qx}$, we have

$$\binom{u}{v} = \begin{pmatrix} U_k & e^{i(k+q)\cdot r} \\ V_k & e^{i(k-q)\cdot r} \end{pmatrix} \tag{5-58}$$

as discussed in the last problem. For $\not{S} = n\pi$, we have just seen that the one-electron states e^{ikr} must be chosen such that

$$\exp(ik_x L) = (-1)^n$$

Also

$$e^{iqL} = (-1)^n$$

Thus $\binom{u}{v}$ is periodic in this gauge. If we now transform to the gauge where Δ is real, we get the amplitudes

$$\binom{u'}{v'} = \binom{U_k e^{ik\cdot r}}{V_k e^{ik\cdot r}} \tag{5-59}$$

and $\binom{u'}{v'}$ is multiplied by $(-1)^n$ if we change x into $x + L$.

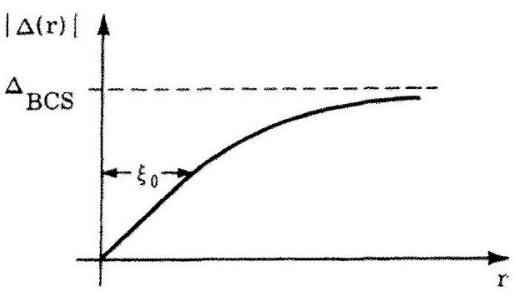

Figure 5-2
The amplitude of the order parameter Δ around a single vortex line in a pure Type II superconductor. Δ vanishes at $z = 0$ and has a finite slope for $r \to 0$. The region in which Δ is lowered from the BCS value has a radius $\sim \xi_0$.

Discuss the low energy excitations in the core of a vortex line

(C. Caroli, P. G. de Gennes, and J. Matricon, 1964).

Solution.

We restrict our attention to pure superconductors of Type II. The starting point is Eq. (5-18). We use cylindrical coordinates $(r\theta z)$, the line being along the z axis, and a gauge where the pair potential $\Delta(r) = |\Delta(r)|e^{-i\theta}$: We call A the vector potential in this particular gauge. $|\Delta(r)|$ vanishes for $r = 0$, then increases (linearly at small r) and finally reaches the BCS value Δ_∞ at distances $r > \xi$. We rewrite (5-18) in a condensed spinor notation $\hat{\phi} = \binom{u}{v}$ and eliminate the phase of Δ by setting

$$\hat{\phi} = \exp\left(-\frac{1}{2}\sigma_z\theta\right)\hat{\psi}$$

where $\sigma_x\sigma_y\sigma_z$ are Pauli matrices. Equation (5-18) becomes

$$\sigma_z\left\{\frac{1}{2m}\left(p - \sigma_z\frac{eA}{c} - \sigma_z\frac{\hbar}{2}\nabla\theta\right)^2 - E_F\right\}\hat{\psi} + \sigma_x\Delta\hat{\psi} = \epsilon\hat{\psi}$$

Note that $\mathrm{A} \sim \mathrm{Hr}$ and

$$\frac{\frac{\mathrm{eA}}{\mathrm{c}}}{\hbar\nabla\theta} \sim \left(\frac{\mathrm{H}}{\phi_0}\right)\mathrm{r}^2$$

(where $\phi_0 = \mathrm{ch}/2\mathrm{e}$ is the flux quantum). For the excitations on interest, $\mathrm{r} \lesssim \xi$ and

$$\frac{\mathrm{eA}}{\mathrm{ch}\,\nabla\theta} \sim \frac{\mathrm{H}_\xi^2}{\phi_0} \sim \frac{\mathrm{H}}{\mathrm{H_{c2}}} \ll 1$$

Thus we can neglect all magnetic field effects.

We then look for solutions of the form $\hat{\psi} = \exp\left(\mathrm{ik_F z}\cos\alpha\right)\exp(\mathrm{i}\mu\theta)\hat{\mathrm{f}}(\mathrm{r})$ where k_F is the Fermi wave vector, α an arbitrary angle, and 2μ an odd integer. The latter condition ensures that ϕ is multiplied by (-1) after one complete turn, as required for one flux quantum in the gauge where Δ is real.

Dropping the Δ term in the equation for $\hat{\psi}$, we get

$$\sigma_z\frac{\hbar^2}{2m}\left\{-\frac{d^2\hat{f}}{dr^2} - \frac{1}{r}\frac{d\hat{f}}{dr} + \left(\mu - \frac{\sigma_z}{2}\right)^2\frac{\hat{f}}{r^2} - k_F^2\sin^2\alpha\hat{f}\right\} + \sigma_x\Delta(r)\hat{f} = \epsilon\hat{f}$$

It is possible to solve this equation completely in the region $0 < \mu \ll \mathrm{k_F}\xi$, which turns out to be the important one. Consider a radius r_c such that

$$(\mu + 1/2)k_F^{-1} \ll r_c \ll \xi$$

For $r < r_c$, the Δ term can be neglected and $\hat{f} = \binom{f^+}{f_-}$is given by

$$f_\pm(r) = A_{\pm\mu\mp1/2}J_{\mu\mp1}\left\{\left(k_F\sin\alpha \pm q\right)r\right\}$$

where J is a Bessel function, A_+, $A_-$are arbitrary coefficients, and $\mathrm{q} = \epsilon/\hbar \mathrm{v_F} \sin\alpha$.

For $r > r_c$, we put

$$\hat{f} = \hat{g}(r) H_m\left(k_F r \sin\alpha\right) + \text{ C.C.} \qquad \left(m = \sqrt{\mu^2 + \frac{1}{4}}\right)$$

where H is a Hankel function and g a slowly-varying envelope. The equation for 8 may be reduced to

$$-i\sigma_z \hbar v_F \sin\alpha \frac{d\hat{g}}{dr} + \Delta\sigma_x \hat{g} = \left(\epsilon + \frac{\mu\hbar^2}{2mr^2}\right)\hat{g} \quad v_F = \frac{\hbar k_F}{m}$$

For $\epsilon \ll \Delta_\infty$ and $k_F r \gg \mu$, the right-hand side is a small perturbation. Treating it to first order, we get

$$\begin{aligned}
\hat{g} &= \text{const } \times \begin{pmatrix} e^{i\psi/2} \\ -ie^{-i\psi/2} \end{pmatrix} e^{-K} \\
K(r) &= \left(\hbar v_F \sin\alpha\right)^{-1} \int_0^r \Delta(r) dr \\
\psi(r) &= -\int_r^\infty \exp\left\{2K(r) - 2K\left(r'\right)\right\} \left(2q + \frac{\mu}{k_F r'^2 \sin\alpha}\right) dr \\
\psi\left(r_c\right) &\cong -\mu\left(k_F r_c \sin\alpha\right)^{-1} + 2qr_c - 2\int_0^\infty dr' e^{-2K(r')} \left(q - \frac{\mu\Delta\left(r'\right)}{\hbar k_F v_F \sin^2\alpha}\right)
\end{aligned}$$

Finally we match the solutions at $r = r_c$, making use of the asymptotic forms

$$J_m(z) = \text{ const } z^{-1/2} \sin\left\{z + \frac{m^2}{2z} - \frac{\pi}{2}\left(m - \frac{1}{2}\right)\right\}$$

etc., and obtain the condition (for $\mu \neq 0$)

$$\psi\left(r_c\right) = 2qr_c - \mu\left(k_F r_c \sin\alpha\right)^{-1}$$

Comparing with our earlier result for $\psi\left(r_c\right)$, we see that all the r_c dependent terms cancel out, and find the eigenvalue

$$\begin{aligned}
\epsilon_{\mu\alpha} = hqv_F \sin\alpha &= \mu\left(k_F \sin\alpha\right)^{-1} \frac{\int_0^\infty \frac{\Delta(r)}{r} e^{-2K(r)} dr}{\int_0^\infty e^{-2K(r)} dr} \\
&= \mu\left(k_F \sin\alpha\right)^{-1} \left(\frac{d\Delta}{dr}\right)_{r=0} g(\alpha) \quad (\mu \neq 0, \mu \ll k_F \xi)
\end{aligned}$$

The dimensionless function $g(\alpha)$ thus defined depends on the exact shape assumed for $\Delta(r)$ but is always close to 1 . In particular $g(0) = g(\pi) = 1$. Thus the eigenvalues are of order $\mu\Delta_\infty/\mathrm{k_F}\xi \sim \mu\Delta^2/\mathrm{E_F}$, the lowest one corresponding to $\mu = \frac{1}{2}$. The density of states N_ℓ associated with the levels is (for one spin direction and for a unit length of line)

$$\mathrm{N}_\ell(\epsilon) = \frac{1}{2\pi}\left\{\left(\frac{\mathrm{d}\Delta}{\mathrm{dr}}\right)_{r=0}\right\}^{-1} \mathrm{k_F^2} \int_0^\pi \mathrm{d}\alpha \frac{\sin^2\alpha}{\mathrm{g}(\alpha)} \quad \left(\frac{\Delta_\infty^2}{\mathrm{E_F}} < \epsilon \ll \Delta_\infty\right)$$

Note that $\mathrm{N}_\ell(\epsilon) \sim \mathrm{N}(0)\xi^2$, that is, each line is equivalent to a normal region of radius $\sim \xi$. The low-lying states occupy only a fraction $\sim (\xi^2/\mathrm{d}^2) \sim (\mathrm{B}/\mathrm{H_{c2}})$ of the volume. They will be of importance mainly at low temperatures T (roughly when $(\xi/\mathrm{d})^2 \exp(\Delta\infty/\mathrm{T}) > 1$). Then the specific heat will be linear in T, the thermal conductivity will be anisotropic (maximum along

the lines) and the nuclear relaxation may, in some cases, become limited by the spin diffusion rate.

Excitation Threshold in Inhomogeneous Systems

Consider a pure metal in the absence of field or currents. Usually the pair potential Δ is constant throughout the sample. The functions u and v are then plane waves and it is easily verified that the energy gap is Δ. However, it is possible for sufficiently thin samples to impose a spatial variation in $\Delta(r)$ (for example, by depositing metals of different characteristics on the superconductor). We now study the particularly simple case described in Fig. 5-3.

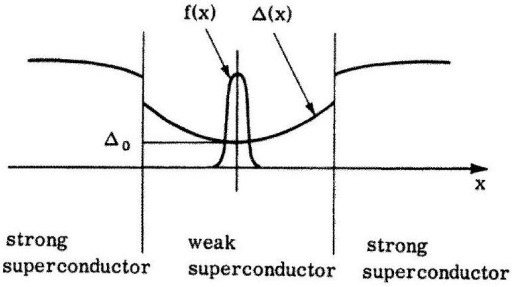

Figure 5-3
The pair potential $\Delta(x)$ for a system of three metallic layers, the central layer being the weakest superconductor. Δ has a minimum Δ_0. It is possible to construct a quasiparticle with an amplitude $f(x)$ very localized around Δ_0; such a quasiparticle has an excitation energy essentially equal to Δ_0

The pair potential varies only in the x direction and it has a minimum Δ_n at $x = 0$. For $x \neq 0$, Δ increases; the spatial scale of the variation in Δ is rather large (at least $\sim \xi_0$). We show that the threshold energy ϵ_0 for the quasiparticles, that is, the smallest positive eigenvalue of (5-18), is nearly equal to Δ_0. Writing (5-18) in a more condensed form, we have

$$\epsilon\hat{\psi} = (\mathscr{H}_{\mathrm{e}}\sigma_{\mathrm{z}} + \Delta\sigma_{\mathrm{x}})\,\hat{\psi} = \hat{\Omega}\hat{\psi} \tag{5-60}$$

where $\hat{\psi} = \binom{u}{v}, \sigma_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$, and $\sigma_x = \binom{01}{10}$ are the Pauli matrices. We wish to use a variational principle to show that ϵ_0 is close to Δ_0. However $\hat{\Omega}$ is not a positive definite operator [ϵ and $(-\epsilon)$ are simultaneously eigenvalues]. It is therefore necessary to study

$$\hat{\Omega}^2 = \mathscr{H}_{\mathrm{e}}^2 + \Delta^2 + \mathrm{i}\,[\mathscr{H}_{\mathrm{e}}, \Delta]\,\sigma_{\mathrm{y}} \tag{5-61}$$

[In order to obtain (5-61), we have used $\sigma_x\sigma_z + \sigma_z\sigma_x = 0$ and $\sigma_x\sigma_z$ - $\sigma_z\sigma_x = -2i\sigma_y$.] Take as a trial function

$$\hat{\psi}(r) = \exp(\mathrm{ik}_F z)\,\mathrm{f(x)}\hat{\phi}_{\mathrm{y}} \tag{5-62}$$

where z designates an arbitrary direction normal to the x axis and $\hat{\phi}_y$ is a constant spinor such that $\sigma_y\hat{\phi}_y = \pm\hat{\phi}_y$. Since $\mathscr{H}_e$ is the energy measured from the Fermi level, we have simply

$$\mathscr{H}_e\hat{\psi} = \exp(\mathrm{ik}_F z)\left(-\frac{\hbar^2}{2m}\right)\frac{d^2 f(x)}{dx^2}\hat{\phi}_y \tag{5-63}$$

(This choice of wave vector leads us to a nodeless function f in the ground state, which is favorable for having a low kinetic energy.) Calculating the average value of $\hat{\Omega}^2$, we obtain

$$\epsilon^2 = \langle\hat{\psi}|\hat{\Omega}^2|\hat{\psi}\rangle = \int dx f^*(x)\left[\frac{\hbar^4}{4m^2}\frac{d^4 f}{dx^4} + |\Delta(x)|^2\right] f(x) \pm i\int dx f^*(x)\left[-\frac{\hbar^2}{2m}\frac{d^2}{dx^2}, \Delta(x)\right] f(x) \tag{5-64}$$

If f is taken as real, the last integral vanishes. If f is chosen as a regular function of spatial extent L, then the kinetic energy term gives a contribution $\alpha\left(\hbar^2/2mL^2\right)^2$ where α is a numerical coefficient of the order unity. For the pair potential term, we assume that Δ varies parabolically around Δ_0,

$$\Delta(\mathrm{x}) = \Delta_0\left(1 + \frac{\mathrm{x}^2}{\delta^2}\right) \tag{5-65}$$

with $\delta \gg L$. Then the potential term becomes $\Delta_0^2\left[1 + \beta\left(L^2/\delta^2\right)\right]$ where β is another numerical coefficient, and finally

$$\epsilon^2 = \Delta_0^2 + \alpha\left(\frac{\hbar^2}{2mL^2}\right)^2 + \beta\Delta_0^2\frac{L^2}{\delta^2} \tag{5-66}$$

Minimizing this expression with respect to L, we obtain

$$\epsilon_0^2 \cong \Delta_0^2\left(1 + \mu^{2/3}\right) \tag{5-67}$$

where $\mu \sim \hbar^2/2m\delta^2\Delta_0$. For $\delta \sim \xi \sim \hbar v_\mathrm{F}/\Delta_0$, we have $\mu \sim 1/\mathrm{k_F}\xi_0 \sim 10^{-2}$ to 10^{-3}. Therefore, in practice, ϵ_0 is very close to Δ_0.

Nonmagnetic Alloys: Anderson's Theorem

We now study the excitation spectrum in a superconducting alloy, in zero field. We must solve the system of equations (5-18):

$$\begin{aligned}\epsilon u &= \left(-\frac{\hbar^2}{2m}\nabla^2 + U(r) - E_F\right)u + \Delta v \\ \epsilon v &= \left(\frac{\hbar^2}{2m}\nabla^2 - U(r) + E_F\right)v + \Delta^* u\end{aligned} \tag{5-68}$$

U(r) is now the complete Hartree potential for one electron in the normal state. In (5-68), we have assumed, as always, that the electronelectron coupling is nearly a point interaction $[-V\delta(r_1 - r_2)]$ and that the potential $U(r)$ does not depend on the spin indices (nonmagnetic alloy). Still $U(r)$ contains the impurity potentials, and (5-68) includes the multiple scattering effects from all of the impurities; it is therefore a very complicated system. The situation is much improved if we assume that $\Delta(r)$ is independent of r even in the presence of impurities. This is not rigorously correct, but has been shown to be acceptable if the impurities are not too different chemically from the matrix (C. Caroli, 1962). Then a large simplification occurs if we introduce the one-electron wave functions in the normal state $w_n(r)$ defined by:

$$\xi_n w_n(r) = \left[-\frac{\hbar^2}{2m}\nabla^2 + U(r) - E_F\right]w_n(r) \tag{5-69}$$

For pure metal, the $w_n(r)$ are Bloch functions. In an alloy, the $w_n(r)$ are complicated functions describing the successive scattering of an electron by all of the impurities. Fortunately, we shall not need to know these wave functions in detail for the following calculation. When

the pair potential $\Delta(r)$ reduces to a constant Δ, the solutions of (5-68) have the same spatial dependence as the $w_n(r)$. If we set

$$\begin{aligned} u_n(r) &= w_n(r) u_n \\ v_n(r) &= w_n(r) v_n \end{aligned} \tag{5-70}$$

it is easy to see that (5-68) is satisfied when

$$\begin{aligned} \left(\epsilon_n - \xi_n\right) u_n - \Delta v_n &= 0 \\ \Delta^* u_n - \left(\epsilon_n + \xi_n\right) v_n &= 0 \end{aligned} \tag{5-71}$$

which implies as usual

$$\epsilon_{\mathrm{n}}^2 = \xi_{\mathrm{n}}^2 + |\Delta|^2 \tag{5-72}$$

The coefficients u_n and v_n depend only on ξ_n. From the normalization condition, they must satisfy

$$|u_n|^2 + |v_n|^2 = 1 \tag{5-73}$$

Using (5-71), one can write explicitly

$$\begin{aligned} |u_n|^2 &= \frac{1}{2}\left(1 + \frac{\xi_n}{\epsilon_n}\right) \\ |v_n|^2 &= \frac{1}{2}\left(1 - \frac{\xi_n}{\epsilon_n}\right) \end{aligned} \tag{5-74}$$

It is convenient to choose u_n, v_n and $w_n(r)$ to be real. This is possible because the $w_n(r)$ are eigenfunctions of a real operator. This choice of standing waves rather than traveling waves will be useful for the discussion of alloys. The self-consistency equation (5-32) becomes

$$\Delta(\mathbf{r}) = V \sum_n |w_n(\mathbf{r})|^2 \frac{\Delta}{2\sqrt{\Delta^2 + \xi_n^2}} \left[1 - 2f\left(\sqrt{\xi_n^2 + \Delta^2}\right)\right] \tag{5-75}$$

It is useful to introduce the density of states $\mathrm{N}(r)$ at the point r in the normal metal, at the Fermi energy

$$N(r) = \sum_n |w_n(r)|^2 \, \delta\left(\xi_n\right) \tag{5-76}$$

The condition (5-75) becomes

$$\Delta(r) = V N(r) \int_{-\hbar\omega_D}^{\hbar\omega_D} d\xi \frac{\Delta(1-2f)}{2\sqrt{\xi^2 + \Delta^2}} \tag{5-77}$$

Thus the self-consistency cannot be exact since Δ was assumed to be constant, but here $\Delta(r)$ is proportional to $N(r)$ and is therefore modified by the impurities. However, if the impurities are chemically similar to the matrix, $N(r)$ is not very different from its average $\bar{N}$ and the self-consistency requirement becomes

$$1 = \bar{N} V \int_{-\hbar\omega_D}^{\hbar\omega_D} d\xi \frac{1 - 2\mathrm{f}}{2\sqrt{\xi^2 + |\Delta|^2}} \tag{5-78}$$

This is of the same form as for a pure metal. To a first approximation, the excitation spectrum and all of the thermodynamic properties are the same for the alloy as for the pure metal. This property was first pointed out by Anderson (1959). Experimentally, it has been verified that nonmagnetic impurities do not have spectacular effects on the transition temperature in superconducting metals. [4]

6.2.3 5-3 The Meissner Effect in Metals and Alloys

The Magnetic Field Treated as a Perturbation

We shall now study the currents j induced by a weak magnetic field $h = \text{curl } A$ in a gas of superconducting electrons. The mathematical machinery necessary for this calculation is contained in the preceding section. We start from the reduced form of the self-consistent field equations with a one-electron energy

$$\mathscr{H}_{\mathrm{e}} = \frac{\left(p - \frac{\mathrm{e}}{\mathrm{c}}\,\mathrm{A}\right)^2}{2m} + \mathrm{U(r)} - \mathrm{E_F} \tag{5-79}$$

We do not demand that $U(r)$ be spatially constant, or even periodic. Thus we are able to discuss simultaneously pure metals and alloys. To first order in h (or A), we set

$$\begin{aligned} u_n(r) &= u_n^{(0)}(r) + u_n^{(1)}(r) \\ v_n(r) &= v_n^{(0)}(r) + v_n^{(1)}(r) \end{aligned} \tag{5-80}$$

where $v_n^{(0)}$ and $u_n^{(0)}$ are the eigenfunctions of the Bogolubov system (5-18) for the case $\mathrm{A} = 0$, and are written more explicitly in Eq. (5-70). Also,

$$\Delta(r) = \Delta_0 + \Delta_1(r)$$

In general Δ_1 is nonzero, that is, the self-consistent field Δ is modified when a magnetic field is applied. This remark, due to Bogolubov, is necessary to preserve the gauge invariance.

A typical case where Δ_1 is nonzero can be found in the following way: Suppose that $A = \nabla\chi(r)$ where χ is an arbitrary function (then $H = \text{curl}\, A = 0$). One can verify that the system of equations (5-18) and the self-consistency equation (5-32) have a solution

$$\begin{aligned} u_n &= e^{(ie/\hbar c)\chi(r)} u_n^0 \\ v_n &= e^{(-ie/\hbar c)\chi(r)} v_n^0 \\ \Delta(r) &= \Delta_0 e^{(2ie/\hbar c)\chi(r)} \end{aligned} \tag{5-81}$$

and that, as expected, $j = 0$. Expanding to first order in χ (or A) we obtain

$$\begin{aligned} u_n^{(1)} &= \frac{ie}{\hbar c} u_n^0 \chi \\ v_n^{(1)} &= \frac{-ie}{\hbar c} v_n^0 \chi \\ \Delta_1 &= \frac{2ie}{\hbar c} \Delta_0 \chi \end{aligned} \tag{5-82}$$

[4] There exist certain effects (??? which???) that cannot be described by our crude interaction - V $\delta\,(r_1 - r_2)$. However the smallness of these effects shows that this interaction is at least a good starting point.

and thus Δ_1 is nonzero for that particular case. More generally, when Δ_1 is first order in A, the most general form it can have is

$$\Delta_1(r) = \sum_\alpha \int p_\alpha (r, r') A_\alpha (r') \, dr' \tag{5-83}$$

where the integral is extended over the entire volume of the sample and $\alpha = \mathrm{x}, \mathrm{y}, \mathrm{z}$. If we are considering an isotropic, homogeneous metal, $P(r, r')$ must only be a function of $R = |r - r'|$ and must be a vector in the direction of $R.P(R)$ can be completely determined by returning to our special case for which

$$\frac{2\mathrm{ie}}{\hbar \mathrm{c}} \Delta_0 \chi(r) = \int \mathrm{P}(r' - r) \cdot \nabla \chi(r') \, \mathrm{d}r' \tag{5-84}$$

Let us now restrict our attention to a particular class of functions $\chi(r')$ such that $\chi(r')$ vanishes at large distances from $r, (|r - r'| \to \infty)$. Then the integration can be performed by parts to give $-\int \chi(r')$ div $\mathbf{P}\times$ $(\mathbf{r}' - \mathbf{r}) \, \mathrm{d}\mathbf{r}'$. Therefore we must have div $\mathbf{P}(\mathbf{r}' - \mathbf{r}) = -(2\mathrm{ie}/\hbar \mathrm{c}) \Delta_0 \delta(R)$. Since $\mathbf{P}$ is a radial vector, the unique solution is

$$P(R) = -\frac{ie\Delta_0}{2\pi\hbar c} \frac{R}{R^3} = \frac{ie\Delta_0}{2\pi\hbar c} \nabla \left(\frac{1}{R} \right) \tag{5-85}$$

This form of $\mathbf{P}(\mathbf{R})$ is also applicable in an alloy if we calculate the average of Δ_1 over all impurity configurations (because on averaging the system becomes homogeneous and isotropic).

Knowing $\mathbf{P}(\mathbf{R})$, the following theorem can be proved: If $\mathbf{A}$ is chosen in the gauge div $A = 0$ and if A has no component normal to the surface of the sample (London gauge), then Δ_1 is zero. In fact,

$$\begin{aligned} \Delta_1(r) &= \frac{ie\Delta_0}{2\pi\hbar c} \int \nabla \left(\frac{1}{R} \right) \cdot A(r') \, dr' \\ &= -\frac{ie\Delta_0}{2\pi\hbar c} \left[\int \frac{1}{R} \operatorname{div} A dr' - \int \frac{1}{R} A \cdot n d\sigma \right] = 0 \end{aligned} \tag{5-86}$$

($\mathbf{n}$ is a unit vector normal to the sample surface). It is important to realize that this theorem is valid only when the following conditions occur: (1) isotropic metal, (2) point interaction between electrons. In fact, if the interaction has a finite range, the pair potential $\Delta(r, r')$ must depend on two arguments. Then the change in Δ takes the form

$$\Delta_1(r, r') = \int dr'' K_\alpha (r, r', r'') A_\alpha (r'') \tag{5-87}$$

We no longer have a symmetry argument to allow us to introduce the gradient of a function. Detailed numerical calculations show that the corrections resulting from such a spread-out interaction are small and have little influence on the diamagnetism: See G. Rickayzen, Phys. Rev., 115, 795 (1959).

We now explicitly calculate the corrections $u^{(1)}$ and $v^{(1)}$ in the London gauge, where $\Delta_1 = 0$; this choice of gauge greatly simplifies the calculations. We first write the system of equations (5-18) with (5-19) only keeping terms to first order in A,

$$\begin{aligned} \left[\epsilon + \frac{\hbar^2}{2m} \nabla^2 - U(r) \right] u_n^{(1)}(r) - \Delta v_n^{(1)}(r) &= \frac{ie\hbar}{2mc} (A \cdot \nabla + \nabla \cdot A) u_n^{(0)}(r) \\ \left[\epsilon - \frac{\hbar^2}{2m} \nabla^2 + U(r) \right] v_n^{(1)}(r) - \Delta^* u_n^{(1)}(r) &= \frac{ie\hbar}{2mc} (A \cdot \nabla + \nabla \cdot A) v_n^{(0)}(r) \end{aligned} \tag{5-88}$$

We now expand $u_n^{(1)}$ and $v_n^{(1)}$ in terms of the orthonormal set $w_n(r)$ (remember incidentally that we choose the w_n 's as real)

$$u_n^{(1)}(r) = \sum_m a_{nm} w_m(r)$$
$$v_n^{(1)}(r) = \sum_m b_{nm} w_m(r) \tag{5-89}$$

replace $u_n^{(0)}$ and $v_n^{(0)}$ by their values (5-70), multiply each of (5-88) by w_m and integrate over r. We then obtain

$$\begin{aligned} a_{nm}(\epsilon_n - \xi_m) - \Delta b_{nm} &= iF_{nm}u_n \\ -\Delta a_{nm} + b_{nm}(\epsilon_n + \xi_m) &= iF_{nm}v_n \end{aligned} \tag{5-90}$$

where

$$F_{nm} = \frac{e\hbar}{2mc}\int w_m(A\cdot\nabla + \nabla\cdot A)w_n dr = -F_{mn} \tag{5-91}$$

The solution of (5-90) is

$$\begin{aligned} \mathrm{a_{nm}} &= \frac{\mathrm{i\ F_{nm}}}{\xi_\mathrm{n}^2 - \xi_m^2}\left[(\epsilon_\mathrm{n} + \xi_m)\,\mathrm{u_n} + \Delta \mathrm{v_n}\right] \\ \mathrm{b_{nm}} &= \frac{\mathrm{i\ F_{nm}}}{\xi_\mathrm{n}^2 - \xi_m^2}\left[(\epsilon_\mathrm{n} - \xi_m)\,\mathrm{v_n} + \Delta \mathrm{u_n}\right] \end{aligned} \tag{5-92}$$

Once $u_n^{(1)}$ and $v_n^{(1)}$ are calculated from these formulas, you can return to the self-consistency equation (5-32) and verify directly that in the London gauge Δ_1 is zero, as predicted.

Relation between the Diamagnetic Response and the Conductivity in the Normal State

Knowing the wave functions to first order in A, we calculate the current

$$j(r) = \mathrm{Re}\left\{\langle\Psi^+(r)\left(p - \frac{eA}{c}\right)\Psi(r)\rangle\right\}$$

We limit our discussion to the case where $T = 0$. To zeroth order in A, $j = 0$. To first order, expressing the Ψ 's in terms of the γ 's, taking the average and expanding $u = u^0 + u'$, and so on, we find

$$\begin{aligned} j(r) &= -\frac{e\hbar i}{2m}\sum_n \left[v_n^{*(0)}\nabla v_n^{(1)} + v_n^{*(1)}\nabla v_n^{(0)} - C.C.\right] \\ &= -\frac{e\hbar i}{2m}\sum_{n,m} v_n\left[w_n\nabla w_n b_{nm} + w_m\nabla w_n b_{nm}^* - C.C.\right] \qquad (5\text{-}93) \\ &= -\frac{e\hbar i}{2m}\sum_{n,m} v_n\left(b_{nm} - b_{nm}^*\right)\left(w_n\nabla w_m - w_m\nabla w_n\right) \qquad (5\text{-}94) \end{aligned}$$

From (5-92), we determine the following properties

$$b_{nm}^{*} = -b_{nm}$$
$$v_n b_{nm} = iF_{nm}R_{nm}$$

where

$$\mathrm{R_{nm}} = \frac{1}{2\epsilon_{\mathrm{n}}\left(\xi_{\mathrm{n}}^2 - \xi_m^2\right)}\left[\left(\epsilon_{\mathrm{n}} - \xi_{\mathrm{n}}\right)\left(\epsilon_{\mathrm{n}} - \xi_m\right) + \Delta^2\right]$$

The symmetric part of $\mathrm{R_{nm}}$ is

$$\frac{1}{2}\,\mathrm{L}\left(\xi_{\mathrm{n}}, \xi_m\right) = \frac{\mathrm{R_{nm}} + \mathrm{R_{mn}}}{2} = \frac{\Delta^2 + \xi_{\mathrm{n}}\xi_m - \epsilon_{\mathrm{n}}\epsilon_m}{\epsilon_{\mathrm{n}}\epsilon_m\left(\epsilon_{\mathrm{n}} + \epsilon_m\right)}$$

The relation between the current and vector potential takes the form (???? why???)

$$j_\mu(r) = \sum_\nu \int dr' A_\nu\left(r'\right) S_{\mu\nu}\left(r, r'\right) \tag{5-95}$$

where $\mu, \nu = \mathrm{x}, \mathrm{y}, \mathrm{z}$ and

$$S_{\mu\nu}\left(r, r'\right) = \left(\frac{e\hbar}{2m}\right)^2 \frac{1}{c}\sum_{n,m} L\left(\xi_n, \xi_m\right) p_{\mu nm}(r) p_{\nu nm}\left(r'\right) - \frac{ne^2}{mc}\delta\left(r - r'\right)\delta_{\mu\nu} \tag{5-96}$$

and we have defined

$$p_{\mu nm}(r) = \left[w_n(r)\frac{\partial}{\partial r_\mu} w_m(r) - w_m(r)\frac{\partial}{\partial r_\mu} w_n(r)\right]$$

For a pure infinite metal, the w_n are plane waves and the p_{nm} can be calculated immediately. However, in practice, we must take account of the presence of impurities and the surface of the sample. It is then impossible to construct the $\mathrm{w_n}$ explicitly.

However, $\mathrm{S}_{\mu\nu}$ can be obtained without much work by noticing that the electrical conductivity $\sigma_{\mu\nu}$ in the normal state involves the same matrix elements. This observation also explains the success of Pippard's phenomenological model, which led to a (j, A) relation for a superconductor analogous to the (j, E) relation in a normal metal.

More precisely, the conductivity $\sigma_{\mu\nu}\left(r, r', \Omega\right)$ at a frequency Ω is defined in the following way: At each point of the sample r', an electric field $\mathbf{E}\left(\mathbf{r}'\right)\mathrm{e}^{-\mathrm{i}\Omega\mathrm{t}}+$ C.C. is applied. The current induced at the point $r, f(r)e^{-i\Omega t}+$ C.C., is measured. The current is a linear function of the fields

$$\mathrm{j}_\mu(r) = \int d_3 r' \sigma_{\mu\nu}\left(rr', \Omega\right)\mathrm{E}_\nu\left(r'\right)$$

In practice we know the explicit form of $\sigma_{\mu\nu}$. The field current relation is given by the Chambers equation

$$j_\mu(r) = \frac{e^2 v_F}{2\pi} N(0)\sum_\nu \int dr' E_\nu\left(r'\right)\frac{R_\mu R_\nu}{R^4}\exp\left[\left(i\Omega/v_F - 1/\ell\right)R\right] \quad R = \left|r' - r\right| \tag{5-97}$$

where $\mathbf{R} = \mathbf{r}' - \mathbf{r}$. In (5-97), ℓ represents the transport mean free path. The integral extends only over the volume of the sample. Three assumptions are necessary to establish (5-97):

(1) The reflection of the electrons from the surface must be diffuse, which is realized in most cases.

(2) The fields **E** and the currents **j** are transverse (div **E** = 0, div j = 0). E and j have no components normal to the surface. This restriction doesn't disturb us since in the superconducting state our perturbation (the vector potential A) will also be transverse (London gauge).

(3) The frequency Ω is less than $k_B T/\hbar$. From (5-97) we see that σ has the form

$$\sigma_{\mu\nu}(rr') = \begin{array}{ll} \dfrac{e^2 v_f}{2\pi} N(0) \dfrac{R_\mu R_\nu}{R^4} \exp(i\Omega R/v_F)\, e^{-R/\ell} & (r, r' \text{ inside the sample}) \\ 0 & (\text{ if } r \text{ or } r' \text{ is outside the sample}) \end{array} \tag{5-98}$$

In fact, we only need the real part of $\sigma_{\mu\nu}$, which gives the power dissipated W

$$\mathrm{W} = \sum_{\mu\nu} \int \mathrm{dr}\ \mathrm{d}\mathbf{r}' \left[\mathrm{E}^*_\mu(\mathbf{r})\mathrm{E}_\nu(\mathbf{r}') + \text{ C.C. }\right] \mathrm{Re}\left\{\sigma_{\mu\nu}(\mathbf{r}, \mathbf{r}', \Omega)\right\} \tag{5-99}$$

We now calculate $\sigma_{\mu\nu}$ from the one-electron wave functions in the normal metal $w_n(r)$ and show that $\mathrm{Re}\,\sigma_{\mu\nu}$ can be expressed by a formula analogous to (5-96) for $S_{\mu\nu}$. In the normal metal the one-electron energy has the form

$$\mathscr{H}_e = \frac{1}{2m}\left(p - \frac{e}{c}A\right)^2 + U_0(r) \tag{5-100}$$

where $U_0(r)$ is the lattice potential energy including impurities and surfaces. On the other hand, the alternating electric field is not in U_0, but derived from the vector potential by

$$E = -\frac{1}{c}\frac{\partial A}{\partial t} = \frac{i\Omega}{c}A \tag{5-101}$$

Because the field **E** is a weak perturbation,

$$\begin{aligned} \mathscr{H}_e &= \mathscr{H}_0 + \mathscr{H}_1 \\ \mathscr{H}_0 &= \frac{\mathrm{p}^2}{2m} + U_0 \\ \mathscr{H}_1 &= -\frac{\mathrm{e}}{2\mathrm{mc}}(\mathrm{p}\cdot\ \mathrm{A} + \mathrm{A}\cdot\mathrm{p}) \end{aligned} \tag{5-102}$$

The eigenfunctions of $\mathscr{H}_0$ are the $w_n(r)$. The oscillating perturbation $\mathscr{H}_1$ induces transitions, $\mathrm{n} \to m$, such that $\xi_m - \xi_\mathrm{n} = \pm\hbar\Omega$. The transition probability per unit time is given by

$$g_{nm} = \frac{2\pi}{\hbar} f(\xi_n)\left[1 - f(\xi_m)\right] |\langle n|\mathscr{H}_1|m\rangle|^2\ \left[\delta(\xi_n - \xi_m + \hbar\Omega) + \delta(\xi_n - \xi_m - \hbar\Omega)\right] \tag{5-103}$$

where

$$\begin{aligned} \langle n|\mathscr{H}_1|m\rangle &= \frac{ei\hbar}{2mc}\int w_n(\nabla\cdot A + A\cdot\nabla)w_m dr \\ &= \frac{ei\hbar}{2mc}\sum_\nu \int A_\nu(r) p_{\nu nm}(r) dr \end{aligned} \tag{5-104}$$

The power dissipated is

$$\mathrm{w} = \sum_{\mathrm{n},m} \mathrm{g_{nm}}\left(\xi_m - \xi_\mathrm{n}\right) \tag{5-105}$$

Comparing this equation with (5-99), we find

$$\mathrm{Re}\left\{\sigma_{\mu\nu}\left(\mathrm{r},\mathrm{r}',\Omega\right)\right\} = \frac{2\pi}{\hbar}\left(\frac{\mathrm{e}\hbar}{m}\right)^2 \sum_{\mathrm{n},m} \frac{\mathrm{f}\left(\xi_\mathrm{n}\right) - \mathrm{f}\left(\xi_m\right)}{\hbar\Omega} \mathrm{p}_{\mu\mathrm{nm}}(\mathrm{r})\mathrm{p}_{\nu\mathrm{nm}}(\mathrm{r}')\delta\left(\xi_\mathrm{n} - \xi_m - \hbar\Omega\right) \tag{5-106}$$

In order to compare this with Chamber's formula we must consider the region $\hbar\Omega \ll \mathrm{k_B T}$. In this region,

$$\frac{f\left(\xi_n\right) - f\left(\xi_m\right)}{\hbar\Omega} = \frac{f\left(\xi_n\right) - f\left(\xi_m\right)}{\xi_n - \xi_n} \cong \frac{\delta f}{\delta\xi}$$

which is nearly $-\delta(\xi)$. Then (5-106) reduces to

$$\mathrm{Re}\left\{\sigma_{\mu\nu}\right\} = \frac{2\pi}{\hbar}\left(\frac{e\hbar}{m}\right)^2 \mathrm{N}(0) \sum_m \overline{\mathrm{p}_{\mu\mathrm{nm}}(\mathrm{r})\mathrm{p}_{\nu\mathrm{nm}}\left(\mathrm{r}'\right)}\delta\left(\xi_\mathrm{n} - \xi_m - \hbar\Omega\right) \tag{5-107}$$

where the symbol () denotes an average over one-electron states at the Fermi surface, in the normal state. [6]

Calculation of the Diamagnetic Currents

Equations (5-107) and (5-96) show that the conductivity $\sigma_{\mu\nu}$ in the normal state involves the same matrix elements as the diamagnetic response $S_{\mu\nu}$ in the superconducting state. Replacing Σ_n by $\mathrm{N}(0)\int \mathrm{d}\xi_\mathrm{n}$ in (5-96), we write the fundamental relation

$$\mathrm{S}_{\mu\nu}\left(\mathbf{r},\mathbf{r}'\right) = \frac{\hbar}{2\pi\mathrm{c}} \int \mathrm{d}\xi\ \mathrm{d}\xi' \mathrm{L}\left(\xi,\xi'\right) \mathrm{Re}\left\{\sigma_{\mu\nu}\left(\mathbf{r},\mathbf{r}',\frac{\xi-\xi'}{\hbar}\right)\right\} - \frac{\mathrm{ne}^2}{\mathrm{mc}}\delta(\mathbf{r})\delta_{\mu\nu} \tag{5-108}$$

We now insert Chambers' formula for $\sigma_{\mu\nu}$ to obtain

$$\mathrm{S}_{\mu\nu}\left(\mathrm{r},\mathrm{r}'\right) = \frac{3\mathrm{ne}^2}{4\pi\mathrm{mc}\xi_0}\frac{\mathrm{R}_\mu\mathrm{R}_\nu}{\mathrm{R}^4}\mathrm{e}^{-\mathrm{R}/\ell}\mathrm{J}(\mathrm{R}) - \frac{\mathrm{ne}^2}{\mathrm{mc}}\delta(\mathrm{R})\delta_{\mu\nu} \tag{5-109}$$

where we have set $\xi_0 = \hbar v_F/\pi\Delta(0), R = r' - r$, and

$$J(R) = \frac{1}{\pi^2\Delta(0)}\int_{-\infty}^{\infty} d\xi d\xi' L\left(\xi,\xi'\right)\cos\left[\frac{\left(\xi-\xi'\right)R}{\hbar v_F}\right] \tag{5-110}$$

From the form of $L\left(\xi,\xi'\right)$ we predict that the important contribution to the integral occurs when $\xi - \xi' \sim \Delta$. This leads to a range for I(R) of the order of ${}^{hv}{}_F/\Delta(0) \sim \xi_0$ (the choice of the numerical coefficient in the definition of ξ_0 will be useful later). For an explicit calculation of I(R), we change variables to: $\xi = \Delta\sinh\theta, \xi' = \Delta\sinh\theta'$, then set $\alpha = \left(\theta - \theta'\right)/2, \beta = \left(\theta + \theta'\right)/2$ to obtain

[6] Note that the average depends strongly on $\hbar\Omega$ but only slightly on ξ_m when $|\xi_n| \ll E_F$.

$$J(R) = \frac{1}{\pi^2}\int d\alpha d\beta \frac{\sinh^2\alpha}{\cosh\alpha\cosh\beta}\cos\left[\frac{2\Delta(0)R}{hv_F}\sinh\alpha\cosh\beta\right]$$
$$= \frac{1}{\pi^2}\int_{-\infty}^{\infty}\frac{d\beta}{\cosh\beta}\int_{-\infty}^{\infty}du\left(1-\frac{1}{1+u^2}\right)\cos\left(\frac{2\Delta(0)R}{\cosh\beta}\right)$$
$$(u=\sinh\alpha) \tag{5-111}$$

and

$$J(R) = \frac{1}{\pi}\frac{hv_F}{\Delta(0)}\delta(R) - \frac{1}{\pi}\int_{-\infty}^{\infty}\frac{d\beta}{\cosh\beta}\exp\left(-2\Delta(0)R\cosh\beta/hv_F\right) \tag{5-112}$$

The first term represents a contribution localized at the origin. On performing the $\mathbf{r}'$ integration in (5-95), we find that this term exactly cancels $(-ne^2/mc)\ \delta(\mathrm{R})\delta_{\mu\nu}$. Then, finally, we have

$$\mathrm{S}_{\mu\nu}\left(\mathrm{r},\mathrm{r}'\right) = \frac{-3\mathrm{ne}^2}{4\pi\mathrm{mc}\xi_0}\frac{\mathrm{R}_\mu\mathrm{R}_\nu}{\mathrm{R}^4}\mathrm{e}^{-\mathrm{R}/\ell}\mathrm{I}(\mathrm{R}) \tag{5-113}$$

where

$$\mathrm{I}(\mathrm{R}) = \frac{2}{\pi}\int_{-\infty}^{\infty}\frac{\mathrm{d}\beta}{\cosh\beta}\exp\left[-(2/\pi)\left(\mathrm{R}/\xi_0\right)\cosh\beta\right] \tag{5-114}$$

Formulas (5-95), (5-113), and (5-114) give a complete solution to the problem of the currents induced by a static, weak, magnetic field in a superconductor.

Conclusions.

(1) For A $\neq 0$ (in the London gauge), permanent currents exist in a superconductor. Unfortunately this crucial result has been obtained only after a long calculation and the physical content is obscure; it will become clearer in Chapter 6.

(2) In a pure metal ($\ell = \infty$), the range of the kernel $S_{\mu\nu}\left(r,r'\right)$ is governed by I(R) and is of the order of ξ_0. Pippard's formula assumes $I(R) = \exp\left(-R/\xi_n\right)$. The exact result (5-114) is not an exponential but only differs from it slightly. Note in particular that

$$I(0) = 1$$
$$\int_0^{\infty} I(R)dR = \xi_0 \quad \text{for } T = 0$$

which are common to the exact result and Pippard's formula.

(3) For a pure infinite metal, if $\mathbf{A}\left(\mathbf{r}'\right)$ varies slowly relative to ξ_0, we can take it outside of the integral (5-95), and integrate to obtain the London relation

$$j(r) = \frac{-ne^2}{mc}A(r) \tag{5-115}$$
$$\operatorname{curl} j = \frac{-ne^2}{cm}H$$

(4) In the presence of impurities, the kernel $S\left(r,r'\right)$ is reduced by the factor $e^{-R/\ell}$, where ℓ is the transport mean free path of the electrons in the normal state. This result was also predicted by Pippard before the development of the microscopic theory.

(5) In an impure metal, if A varies slowly with respect to $\left(\xi_0^{-1}+\ \ell^{-1}\right)^{-1}$, A can still be taken out from under the integral sign and we then obtain a new London relation, which is usually written in the form

$$\begin{aligned} -c\Lambda_0 j(r) &= A(r) \\ -c\Lambda_0 \operatorname{curl} j(r) &= H \end{aligned} \tag{5-116}$$

where

$$\Lambda_0^{-1} = \frac{ne^2}{m}\int_0^\infty \frac{dR}{\xi_0} I(R) e^{-R/\ell} < \frac{ne^2}{m} \quad (T=0) \tag{5-117}$$

In particular for $\ell \ll \xi_0$, I(R) can be taken to be unity and we find

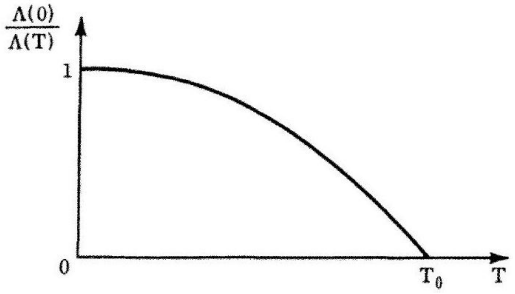

Figure 5-4
Strength of the diamagnetic response of the superconductor as a function of temperature.

$$\Lambda_0^{-1} = \frac{ne^2}{m}\left(\frac{\ell}{\xi_0}\right) \quad (\ell \ll \xi_0) \tag{5-118}$$

(6) We have limited this calculation to $T = 0$. It can be performed in the same way for $\mathrm{T} \neq 0$. The equation (5-95) still applies, but the definitions of $L\left(\xi, \xi'\right)$ must be generalized for $T \neq 0$. The integration must be performed numerically with the following results: The spatial form of the kernel $\mathrm{S}_{\mu\nu}\left(\mathbf{r}, \mathbf{r}'\right)$ is nearly independent of temperature. Its range of pure metal remains ξ_n even for $\mathrm{T} \to \mathrm{T}_0$. On the other hand, its normalization changes: The supercurrents become weaker as T increases, and finally vanish at $\mathrm{T} = \mathrm{T}_0$. This normalization is usually defined in terms of the coefficient Λ_T given by

$$\int S_{\mu\nu}\left(r, r', T\right) dr' = \frac{1}{c\Lambda_\mathrm{T}} \tag{5-119}$$

where Λ_T depends only on temperature. The temperature dependence of $\Lambda_0/\Lambda_\mathrm{T}$ is given in Fig. 5-4. We shall come back later to a discussion of parameters related to Λ_T near $\mathrm{T} = \mathrm{T}_0$ in terms of the Landau-Ginsburg equations.

6.3 Phenomenological Landau-Ginsburg Equations

6.3.1 6-1 Introduction

Let us first recapitulate our knowledge of the microscopic behavior of a superconductor in the presence of a static magnetic field **H**. Our first method of determining the currents j induced by the field was to use the London equation

$$\operatorname{curl} j = \frac{-c}{4\pi\lambda^2(T)} H \tag{6-1}$$

However, Eq. (6-1) is applicable only when the following conditions are satisfied:
(1) $\lambda(T)$ must be much larger than $(1/\xi_0 + 1/\ell)^{-1}$, where $\xi_0 = 0.18^{\hbar} v_F/\mathrm{k}_B T_c$ and ℓ is the mean free path;
(2) H is small and can be treated as a perturbation;
(3) the superconducting electron density $n_S(r)$ is nearly constant in space.

Finally we were able to relax the first condition by replacing (6-1) by the nonlocal Pippard equation. However conditions (2) and (3) remain and we are not able to attack such problems as that of a wall separating a normal region ($H = H_C, n_S = 0$) from a superconducting region ($\mathrm{H} = 0, \mathrm{n_S}$ finite) in a Type I superconductor.

In principle, we can return to the general method:
(a) Write the equations of motion for the excitations

$$\epsilon u(r) = \frac{1}{2m}\left[\left(p - \frac{e}{c}A\right)^2 - E_F\right] u(r) + \Delta(r) v(r)$$
$$\epsilon v(r) = -\frac{1}{2m}\left[\left(p + \frac{e}{c}A\right)^2 - E_F\right] v(r) + \Delta * (r) u(r)$$

(b) Assume a spatial form of the pair potential $\Delta(r)$. (c) Calculate u and v, which give us current densities and other physical properties. (d) Verify that the form chosen for $\Delta(r)$ is correct by means of the self-consistency equation

$$\Delta(r) = \sum_n u_n v_n^* \left[1 - 2f\left(\epsilon_n\right)\right]$$

This program is, however, extremely tedious and difficult in practice.
There is considerable simplification if we restrict our attention to the neighborhood of the transition temperature T_0. For $T \to T_0$:
(1) the penetration depth $\lambda(T)$ becomes large [in the London limit $\lambda(\mathrm{T})$ is proportional to $\mathrm{n_S}^{-1/2}$ and $\mathrm{n_S}$ tends to zero as $\mathrm{T} \to \mathrm{T_0 l}$; (2) the thickness of the walls separating N and S regions also becomes large. Empirically, in a first-kind material, this depth varies roughly as $\xi_0 \lfloor \mathrm{T_0}/\left(\mathrm{T_0} - \mathrm{T}\right)]^{1/2}$ (for a pure metal).

More generally, in many physical situations the current $j(r)$ and the pair potential $\Delta(r)$ have only slow spatial variations if one is sufficiently close to the transition temperature. Under these conditions, the physical properties can be determined from more simple equations, which we now describe.

6.3.2 6-2 Construction of the Free Energy

We consider a homogeneous superconducting metal or alloy. We first form the free energy for a configuration where the pair potential $\Delta(r)$ and the vector potential $A(r)$ have arbitrary, but slowly varying, spatial forms. Then, by minimizing the energy, we obtain explicit equations for $\Delta(r)$ and for the current $j(r)$.

(a) First return to the trivial case when (1) Δ is the same at each point, and (2) there is no magnetic field. If we fix an arbitrary value for Δ, we can determine u and v and calculate, by the methods of Chapter 4, the free energy F (per cm^3) as a function of Δ. In particular, for small Δ, which is the case in the region near T_0, we find

$$\mathrm{F} = \mathrm{F_n} + \mathrm{A(T)}|\Delta|^2 + \frac{\mathrm{B(T)}}{2}|\Delta|^4 + \cdots \tag{6-2}$$

for Δ constant and zero field. Only the even terms in Δ appear in the expansion. F_n is the free energy in the normal phase; A and B are coefficients which in the BCS approximation are given by

$$\begin{aligned} A(T) &= N(0)\frac{T - T_0}{T_0} \\ B(T) &= 0.1066\frac{N(0)}{(k_B T_0)^2} \quad T \to T_0 \end{aligned} \tag{6-3}$$

More generally, we assume that the exact free energy can be represented by an expansion of the type (4-2) with the coefficients A and B having the following properties: A is negative for $T < T_0$ and vanishes at $T = T_0$, the slope $(dA/dT)T_0$ being finite. B is positive and finite at $T = T_0$ and can, in practice, be replaced by its value at T_0.

For $\mathrm{T} < \mathrm{T_0}$, the minimum of F corresponds to a nonvanishing value of Δ,

$$\begin{aligned} \Delta &= \Delta_0(\mathrm{T}) \\ \Delta_0^2 &= -\frac{\mathrm{A}}{\mathrm{B}} = 9.38\mathrm{k_B^2}\ \mathrm{T_0}\,(\mathrm{T_0} - \mathrm{T}) \end{aligned} \tag{6-4}$$

This is the value that will occur in equilibrium in the absence of a magnetic field. The corresponding free energy is

$$F = F_S = F_n - \frac{A^2}{2B} \tag{6-5}$$

Because of our assumptions about A and B, the difference $F_n - F_S = \mathrm{H_C^2}/8\pi$ is proportional to $(\mathrm{T_0} - \mathrm{T})^2$. This is characteristic of all sec-ond-order transitions.

(b) We now allow Δ to have a slow variation from point to point, however, still keeping $\mathbf{H} = \mathbf{A} = 0$. How will the free energy (6-2) be modified? Since in the absence of a magnetic field equilibrium corresponds to $\Delta = \text{const}$, the first significant terms will be of the form $(\partial\Delta/\partial x)^2$ or $(\partial\Delta/\partial x)(\partial\Delta/\partial y)$, and so on. For simplification, from now on we only consider cubic crystals. Then,

$$\mathrm{F} = \mathrm{F_n} + \mathrm{A}|\Delta|^2 + \frac{\mathrm{B}}{2}|\Delta|^4 + \mathrm{C}\left[\left|\frac{\partial\Delta}{\partial \mathrm{x}}\right|^2 + \left|\frac{\partial\Delta}{\partial \mathrm{y}}\right|^2 + \left|\frac{\partial\Delta}{\partial \mathrm{z}}\right|^2\right] \tag{(6-6)}$$

We take C to be nonzero and positive for $\mathrm{T} = \mathrm{T_0}$. In fact, a microscopic calculation will show later that for a pure metal $\mathrm{C} \sim \mathrm{N}(0)\xi_0^2$, that is, the "torsion energy" represented by the last term in (6-6) is of the order $N(0)\Delta^2\xi_0^2[(1/\Delta)(\partial\Delta/\partial x)]^2$.

The relation (6-6) between the free energy F and the order parameter Δ in the neighborhood of the transition temperature has been assumed as a starting point by Landau for a general theory of second-order phase transitions. (In a ferromagnet, for instance, the order parameter is the magnetization. [1])

Problem.

Calculate the fluctuation in the pair potential Δ in the normal phase ($T > T_0$), in zero field.

Solution.

The probability of finding a configuration where the pair potential has a determined spatial form $\Delta(r)$ is proportional to $\exp(-\mathfrak{J}/\mathrm{k_B T})$, where $\mathfrak{J}$ is the free energy of the sample calculated from (6-6). For $T > T_0$, it suffices to keep only the terms of order of Δ^2 in (6-6). In the gauge where $A = 0$ and Δ is real, we have

$$\mathcal{F} = \int \mathrm{dr}\left[A|\Delta(r)|^2 + C|\nabla\Delta(r)|^2\right] = L^3 \sum_k |\Delta_k|^2 \left(A + Ck^2\right)$$

where

$$\Delta_\mathrm{k} = \mathrm{L}^{-3} \int \mathrm{dre}^{\mathrm{ikr}}\Delta(\mathrm{r})$$

and L^3 is the volume of the sample. (As we shall see later, this equation is valid, in a pure superconductor, when $\xi_0 k \ll 1$.) One then finds the thermal averages

$$\langle\Delta_k\rangle = 0$$
$$\left\langle|\Delta_k|^2\right\rangle = \frac{\int \exp\left(-\mathfrak{F}/k_B T\right)|\Delta_k|^2\, d\Delta_k}{\int \exp\left(-\mathfrak{F}/k_B T\right) d\Delta_k} = \frac{1}{2L^3}\frac{k_B T}{A + Ck^2}$$

(??? check the calculations!!!)

On the other hand $\left\langle|\Delta_\mathrm{K}|^2\right\rangle$ is related to the spatial correlation function of Δ:

$$\left\langle|\Delta_\mathrm{k}|^2\right\rangle = \mathrm{L}^{-6}\int \mathrm{d}\mathbf{r}\ \mathrm{d}\mathbf{r}'\left\langle\Delta(\mathbf{r}\rangle\Delta\left(\mathbf{r}'\right)\right\rangle \mathrm{e}^{\mathrm{ik}\cdot(\mathbf{r}-\mathbf{r}')}$$
$$= \mathrm{L}^{-3}\int \mathrm{dR}\langle\Delta(0)\Delta(\mathrm{R})\rangle \mathrm{e}^{\mathrm{ik}\cdot\mathrm{R}}$$

[$\langle\Delta(\mathbf{r})\Delta\left(\mathbf{r}'\right)\rangle$ only depends on $\mathbf{r} - \mathbf{r}'$.] On taking the inverse of this expression we find the correlation function

$$\langle\Delta(0)\Delta(R)\rangle = \frac{1}{(2\pi)^3}\int dk \frac{k_B T}{2\left(A + Ck^2\right)} e^{-ik\cdot R} = \frac{k_B T}{8\pi C R} e^{-qR}$$

where $q^2 = A/C, q > 0$. For a pure metal, ($C \sim N(0)\xi_0^2$):

$$\frac{\langle\Delta(0)\Delta(R)\rangle}{\left(k_B T_0\right)^2} \sim \frac{k_B T}{E_F}\frac{1}{k_F R} e^{-qR}$$

which is very small. Thus short-range order effects are indeed negligible in most superconductors.

(c) Eq. (6-6) must be completed by adding a vector potential $\mathbf{A}$, which gives rise to the field $h = \mathrm{curl}\ A$. The free energy must be independent of the gauge chosen for A. (If we set $A' = A + \nabla\chi$, the magnetic field derived from A' is the same as that derived from A. If H is

[1] For magnetic materials, recent experiments and theoretical calculations indicate that the Landau hypothesis on the analytic form of F is, in fact, too restrictive; the real situation is more complicated. However, in superconductors, (6-6) is excellent. The complications encountered in the magnetic case stem from short-range order effects. These effects are large in magnetic materials, but are very small in superconductors (see problem above).

unchanged, the free energy F must also be unchanged.) As we have seen in Chapter 5, the pair potential does change according to the law

$$\Delta'(r) = \Delta(r)e^{2ie\chi(r)/hc}$$

Thus in order to insure the invariance of F, we must replace (6-6) by

$$\mathrm{F} = \mathrm{F_n} + \mathrm{A}|\Delta|^2 + \frac{\mathrm{B}}{2}|\Delta|^4 + \mathrm{C}\left|\left(-\mathrm{i}\nabla - \frac{2\mathrm{eA}}{\hbar c}\right)\Delta\right|^2 + \frac{\mathrm{h}^2}{8\pi} \tag{6-7}$$

(The last term $h^2/8\pi$ represents the magnetic field energy in the vacuum.) There is a formal analogy between the terms of order $|\Delta|^2$ in (6-7) and the equation giving the energy density of a particle of charge 2 e described by a wave function $\psi(\mathbf{r})$. More precisely, if we set

$$\begin{aligned} &\psi(r) = \frac{(2mC)^{1/2}}{\hbar}\Delta(r), \quad \alpha = \frac{\hbar^2}{2m}\frac{A}{C}, \quad \beta = \left(\frac{\hbar^2}{2m}\right)^2\frac{B}{C^2} \\ &\frac{\alpha^2}{2\beta} = \frac{H_C^2}{8\pi} \end{aligned} \tag{6-8}$$

Then

$$\mathrm{F} = \mathrm{F_n} + \alpha|\psi|^2 + \frac{\beta}{2}|\psi|^4 + \frac{1}{2m}\left|\left(-\mathrm{ih}\nabla - \frac{2\mathrm{eA}}{\mathrm{c}}\right)\psi\right|^2 + \frac{\mathrm{h}^2}{8\pi} \tag{6-9}$$

This is the free energy form proposed by Landau and Ginsburg in 1951 well before the development of the microscopic theory. At that time the physical significance of $\psi(\mathbf{r})$ was far from being clear; furthermore, the value e^* of the charge that appears in $-i\hbar\nabla - e^*A/c$ was not known (initially Landau and Ginsburg took $e^* = e$). This construction of (6-9) independent of any detailed theory of the superconducting state represented a tour de force of physical intuition.

Notice that the choice of the free electron mass m as a factor in (6-8) and (6-9) is entirely arbitrary. We could just as well have chosen the mass of the sun. [2]. So there is no way for theoretical physicist to construct this constant from microscopic theory (??? right???).

On the contrary, the presence of the charge 2 e in the factor 2eA/c is not a convention, but expresses a fundamental property of the pair potential: $\Delta = V\langle\psi t(r)\psi t(r)\rangle$ is the average of the product of two annihilation operators.

6.3.3 6-3 Equilibrium Equations

We must now minimize the free energy with respect to: (1) the order parameter $\Delta(r)$; and (2) the magnetic field distribution, therefore $A(r)$. We set $\mathfrak{F} = \int \mathrm{F}d\mathrm{r}$ where the integral is extended over the volume of the specimen. If we vary $\psi(\mathbf{r})$ by $\delta\psi(\mathbf{r})$ and $\mathbf{A}(\mathbf{r})$ by $\delta\mathbf{A}(\mathbf{r})$, we obtain the variation in the free energy which after an integration by parts becomes

$$\begin{aligned} \delta\mathcal{F} = &\int d\mathbf{r}\left\{\delta\psi^*\left[\alpha\psi + \beta|\psi|^2\psi + \frac{1}{2m}\left(-\mathrm{i}\hbar\nabla - \frac{2\mathrm{eA}}{\mathrm{c}}\right)^2\psi\right] + \text{ C.C. }\right\} \\ &+ \int \mathrm{d}\mathrm{r}\delta\ \mathrm{A}\cdot\left\{\frac{1}{4\pi}\,\mathrm{curl}\ \mathrm{h} - \frac{\mathrm{e}}{\mathrm{mc}}\left[\psi^*\left(-\mathrm{i}\hbar\nabla - \frac{2\mathrm{e}}{\mathrm{c}}\ \mathrm{A}\right)\psi + \text{ C.C. }\right]\right\} \end{aligned} \tag{6-10}$$

In the second term, notice that $(1/4\pi)$ curl h is the current density j/c from Maxwell's equations. By setting $\delta\mathfrak{F} = 0$, we obtain the conditions

$$\alpha\psi + \beta|\psi|^2\psi + \frac{1}{2m}\left(-i\hbar\nabla - \frac{2eA}{c}\right)^2\psi = 0 \tag{6-11}$$

$$j = \frac{e\hbar}{im}\left(\psi^*\nabla\psi - \psi\nabla\psi^*\right) - \frac{4e^2}{mc}\psi^*\psi\mathbf{A} \tag{6-12}$$

Equations (6-11) and (6-12) are the fundamental Landau-Ginsburg equations. The first gives the order parameter and the second gives the currents, that is, the diamagnetic response of a superconductor.

Remarks.

(1) The relation (6-12) giving the current is identical to that which would occur for particles of charge $2e$, mass m, and wavefunction $\psi(r)$.

(2) Boundary condition: In deriving (6-10) we neglected the surface integral

$$\int \delta\psi^*\left(-i\hbar\nabla - \frac{2eA}{c}\right)\psi\frac{i\hbar}{2m}\cdot d\sigma + C.C.$$

If we keep this term and require that it vanishes, we obtain the boundary condition

$$\left(-i\hbar\nabla - \frac{2eA}{c}\right)_n\psi = 0 \tag{6-13}$$

where the subscript n designates the component normal to the surface. This procedure was followed by Landau and Ginsburg in their original paper. It implicitly assumes that the form (6-9) for the free energy remains valid even in the neighborhood of a surface. We shall see, in fact, from the microscope theory that for a superconductor-insulator interface (6-13) is correct, but that for a superconductor-normal metal junction the boundary condition is severely modified.

On substituting (6-13) into the equation (6-12) for the current, we see that $j_n = 0$; that is, there is no current entering or leaving the superconductor. If we do the inverse, and impose $j_n = 0$, we do not obtain (6-13), but only

$$\left(-i\hbar\nabla - \frac{2eA}{c}\right)_n\psi = i\lambda\psi$$

where λ is an arbitrary real constant. In practice, this is the type of boundary condition encountered for a superconductor-normal metal junction.

6.3.4 6-4 The Two Characteristic Lengths

The Landau-Ginsburg equations (6-11) and (6-12) introduce two characteristic lengths, which we now discuss.

[2] Some authors do in fact use 2 m instead of m . Our normalization follows the original paper of Landau and Ginsburg.

First characteristic length

(a) First consider a situation where there are neither currents nor magnetic fields. Choose the gauge in which ψ is real. Then in one dimension, for example, (6-11) becomes simply

$$\frac{-\hbar^2}{2m}\frac{d^2\psi}{dx^2} + \alpha\psi + \beta\psi^3 = 0 \tag{6-14}$$

There are two obvious solutions: (1) $\psi = 0$ which describes the normal state, (2) $\psi = \psi_0$ with

$$\psi_0^2 = -\frac{\alpha}{\beta} > 0 \tag{6-15}$$

which describes the usual superconducting state. This second solution exists and is lower in energy when $\alpha < 0$, that is, $\mathrm{T} < \mathrm{T}_0$. However we would like to consider more general solutions. For example, if,
by means of exterior constraints, we impose that $\psi(x)$ have a different value than ψ_0 at one point, how does the order parameter deform about this point?

In order to fix the length scale, it is useful to write (6-14) in terms of reduced variables

$$\psi = \psi_0 \mathrm{f} \tag{6-16}$$

$$\frac{\hbar^2}{2m|\alpha|} = \xi^2(\mathrm{T}) \tag{6-17}$$

where $\xi(T)$ has the dimensions of a length. Equation (6-14) becomes

$$-\xi^2(\mathrm{T})\frac{\mathrm{d}^2\mathrm{f}}{\mathrm{dx}^2} - \mathrm{f} + \mathrm{f}^3 = 0 \tag{6-18}$$

The natural unit of length for the variation of f is $\xi(\mathrm{T})$, which we call the coherence length at the temperature T. What is its order of magnitude? First notice that $\hbar^2/2m|\alpha| = -\mathrm{C}/\mathrm{A}$ from (6-8). For a pure material we have already mentioned that $\mathrm{A} \simeq \lfloor(\mathrm{T} - \mathrm{T}_0)/\mathrm{T}_0\rfloor\,\mathrm{N}(0)$ and $\mathrm{C} \sim \mathrm{N}(0)\xi_0^2$; thus

$$\xi(\mathrm{T}) = 0.74\xi_0\left(\frac{\mathrm{T}_0}{\mathrm{T}_0 - \mathrm{T}}\right)^{1/2} \tag{6-19}$$

(where we have inserted the exact numerical coefficient).
Conclusion: The variations in ψ, which take place within the length $\xi(\mathrm{T})$, are slow with respect to ξ_0 if T is close to T_0.

Problem.

From (6-18) calculate the energy of a NS wall in a Type I superconductor where the penetration depth is negligible. The field distribution and $|\psi|$ are represented in Fig. 6-1.

Solution.

By hypothesis, the field does not penetrate into the region where ψ is nonzero. We can therefore use (6-18) with the boundary conditions

$$\begin{aligned} f &= 0, \quad x = 0 \\ f &\to 1, \quad x \to \infty \end{aligned}$$

By multiplying (6-18) by df/dx and integrating, we obtain the first integral

$$-\xi^2(T)\left(\frac{df}{dx}\right)^2 - f^2 + \frac{1}{2}f^4 = \text{ const}$$

In order to satisfy the boundary condition as $x \to \infty$, we must take the constant to be equal to $-\frac{1}{2}$. This gives

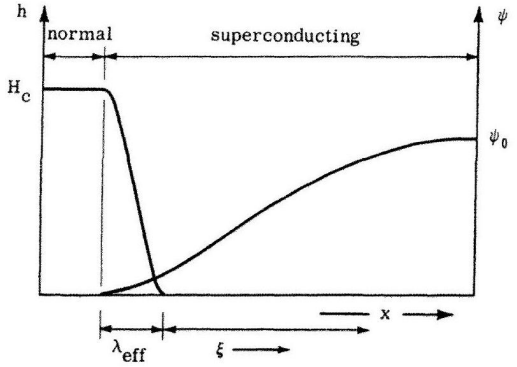

Figure 6-1
Spatial variation of the field and order parameter near a N-S wall for $\xi(T) \gg \lambda(T)$. The effective penetration depth λ_{eff} is of order $\sqrt{\lambda\xi}$ (see problem, page 178).

$$\xi^2(\mathrm{T})\left(\frac{\mathrm{df}}{\mathrm{dx}}\right)^2 = \frac{1}{2}\left(1-\mathrm{f}^2\right)^2$$

The solution satisfying our boundary conditions is

$$f = \tanh\left[\frac{x}{\sqrt{2}\xi(T)}\right]$$

Energy per unit area of the wall:

$$F_p = \int_0^\infty dx \frac{\hbar^2}{2m}|\nabla\psi|^2 + \alpha|\psi|^2 + \frac{\beta}{2}|\psi|^4$$

The surface energy $(\mathrm{H_c^2}/8\pi)\,\delta$ is the difference between $\mathrm{F_p}$ and the condensation energy, which we would find if the medium were uniformly superconducting from the point $x = 0$:

$$\frac{\mathrm{H_c^2}}{8\pi}\delta = \mathrm{F_p} - \int_0^\infty \left(-\frac{\mathrm{H_c^2}}{8\pi}\right)\mathrm{dx}$$

Inserting the reduced parameter f and the relations (6-8), we obtain

$$\delta = \int_0^\infty \mathrm{dx}\left[2\xi^2(\mathrm{T})\left(\frac{\mathrm{df}}{\mathrm{dx}}\right)^2 + \left(1-\mathrm{f}^2\right)^2\right]$$

By making use of the first integral for $\mathrm{df/dx}, \delta$ can be transformed into

$$\delta = 2\int_0^\infty dx\left(1-f^2\right)^2 = 2\int_0^1 \left(1-f^2\right)^2 \frac{dx}{df}df = 2\sqrt{2}\xi(T)\int_0^1 df\left(1-f^2\right) = \frac{4}{3}\sqrt{2}\xi(T) = 1.89\xi(T)$$

Second characteristic length

(b) A second characteristic length comes into play if we introduce electromagnetic effects - for example, the penetration depth in weak fields. In order to define this length, we consider a superconductor occupying the half-space $z > 0$. The region $z < 0$ is either empty or filled with an insulator where the boundary condition (6-13) applies.

In weak fields, and to first order in h. $|\psi|^2$ in the region z > 0 can be replaced by its equilibrium value in the absence of a field $|\psi_0|^2$ defined by (6-15). Because ψ_n is independent of position, when we take the curl of both sides of (6-12), we obtain a London-type equation:

$$\operatorname{curl} j = -\frac{4e^2}{mc}\psi_0^2 h \tag{6-20}$$

On adding Maxwell's equations, we find, as in Chapter 2, nonvanishing solutions only if h is in the xy plane; for example, taking h along the x axis.

$$h_x = h_x(0)e^{-z/\lambda(T)} \tag{6-21}$$

$$\lambda(T)^{-2} = \frac{16\pi e^2\psi_0^2}{mc^2} = \frac{32\pi e^2}{\hbar^2 c^2} C\Delta_0^2 \tag{6-22}$$

where Δ_0 is the equilibrium value of the pair potential. Equation $\frac{32\pi e^2}{\hbar^2 c^2} C\Delta_0^2$ allows C to be related to directly measurable quantities. [3] Note that $\lambda(T)$ is proportional to ψ_0^{-1} and therefore to $[T_0/(T_0 - T)]^{1/2}$. For a pure metal in the free electron approximation, the microscopic calculation in the BCS approximation gives

$$\lambda(T) = \frac{1}{\sqrt{2}}\lambda_L(0)\left(\frac{T_0}{T_0 - T}\right)^{1/2} \quad T - T_0 \tag{6-23}$$

where $\lambda_L(0)$ is the London penetration depth at absolute 0, given in terms of the number of electrons per cm^3n by the equation $\lambda_L{}^2(0) = 4\pi ne^2/mc^2$. Except for the numerical coefficient, (6-23) can be predicted from (6-22) if we guess (as stated earlier) that $C \sim N(0)\xi_n^2$ and that

$$\Delta_0^2 \sim k_B^2\, T_0\,(T_0 - T)$$

Conclusions.

The Landau-Ginsburg hypothesis, in particular the form of the free energy (6-7) in the presence of a field, has led us to a local relation (6-12) between the current and vector potential. We know from the microscopic analysis of Chapter 5 that in the special case where $|\Delta|$ is constant and h small, the exact relation is nonlocal; that is, the current density $j(r)$ depends on $A(r')$ for $|r - r'| \leq \xi_0$ in a pure metal. In order for the local approximation to be valid, it is necessary that A or the current have a slow variation on the scale of ξ_0, therefore, $\lambda(T) \gg \xi_0$,

$$\lambda_L{}^{(0)}\left(\frac{T_0}{T_0 - T}\right)^{1/2} \gg \xi_0 \tag{6-24}$$

For a pure metal, this condition will be satisfied if T is sufficiently close to T_0. [However, for certain nontransition metals, notably aluminum, $\lambda_L(0)$ is so much smaller than ξ_0 that the temperature interval allowed by (6-24) is very small.]

(c) We have defined two characteristic lengths $\xi(T)$ and $\lambda(T)$, which determine the behavior of a superconductor near the transition point. They both diverge as $(T_0 - T)^{-1/2}$ as $T \to T_0$. It is therefore particularly interesting to form their ratio

[3] Note that for a noncubic crystal it is necessary to take into account the tensorial nature of C.

$$\kappa = \frac{\lambda(\mathrm{T})}{\xi(\mathrm{T})} \tag{6-25}$$

By using the definitions (6-17) and $\lambda(T)^{-2} = \frac{16\pi e^2\psi_0^2}{mc^2}$ of $\xi(\mathrm{T})$ and $\lambda(\mathrm{T})$, one obtains

$$\kappa = \frac{\mathrm{mc}}{2\mathrm{e}\hbar}\left(\frac{\beta}{2\pi}\right)^{1/2} = \frac{\hbar\mathrm{c}}{4\mathrm{Ce}}\left(\frac{\mathrm{B}}{2\pi}\right)^{1/2} \tag{6-26}$$

κ is called the Landau-Ginsburg parameter of the substance. When $\kappa \lesssim 1 (\lambda < \xi)$, the material is of the first kind, when $\kappa > 1 (\lambda > \xi)$, material is of the second kind. We see later that the exact separation between the two types of behavior occurs for $\kappa = 1/\sqrt{2}$. For a pure substance we show later that

$$\kappa = 0.96\frac{\lambda_{\mathrm{L}}(0)}{\xi_0} \tag{6-27}$$

It is interesting to notice that κ can be defined directly from experimentally obtained numbers on the penetration depth and thermodynamic field $\mathrm{H_c}$ measured in the region of validity of the Landau-Ginsburg equations. By making use of $\lambda(T)^{-2} = \frac{16\pi e^2\psi_0^2}{mc^2}$, (6-15), (6-9), and (6-8), one can put (6-26) in the form

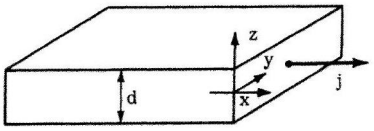
$$\kappa = 2\sqrt{2}\frac{\mathrm{e}}{\hbar\mathrm{c}}\mathrm{H_C}(\mathrm{T})\lambda^2(\mathrm{T}) \tag{6-28}$$

Another way of writing (6-28), often useful for numerical calculations, is the following

$$\mathrm{H_c}(\mathrm{T}) = \frac{\phi_0}{2\pi\sqrt{2}\xi(\mathrm{T})\lambda(\mathrm{T})} \tag{6-29}$$

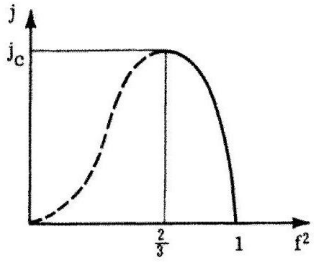
where $\phi_0 = \mathrm{ch}/2\mathrm{e}$ is the flux quantum.
In this chapter we also study other methods that allow the determination of κ.

6.3.5 6-5 Situations Where $|\psi|$ Is Constant



We now apply the Landau-Ginsburg equations to some concrete examples. First, consider the particularly simple cases where the amplitude $|\psi|$ of the order parameter is the same at all points. Such a situation has already been encountered (the penetration depth of a weak magnetic field in a bulk sample). The examples we now consider are rather different. They concern thin samples (films, wires, and so on) where ψ cannot vary through the depth without catastrophically increasing the term $|\nabla\psi|^2$ in the free energy. But allow the field h (or currents j) to be strong and $|\ \psi\ |$, though constant, will not necessarily be equal to its unperturbed value ψ_0.

Critical Current in a Thin Film



The situation envisaged is that represented in Fig. 6-2a. The film of thickness d carries a current density f along the x axis. We assume that

$$\begin{aligned} \mathrm{d} &\ll \xi(\mathrm{T}) \quad \text{in order to have } |\psi| \text{ constant } [4] \\ \mathrm{d} &\ll \lambda(\mathrm{T}) \quad \text{in order to have } j \text{ constant} \end{aligned}$$

Then our equations become particularly simple. If we set $\psi = |\psi|e^{i\phi(r)}$ where $|\psi|$ is independent of r, the current becomes

(a)

(b)

Figure 6-2
(a) Geometry to measure the critical current of a thin film (thickness d). The current flows along the x axis. (b) Current density (normalized to the critical current density) as a function of the order parameter f (normalized to the order parameter in zero current). For $j > j_c$, there is no solution to (6-35) and f falls abruptly to zero.

$$\mathrm{j} = \frac{2\mathrm{e}}{m}|\psi|^2\left(\hbar\frac{\partial\phi}{\partial \mathrm{x}} - \frac{2\mathrm{e}}{\mathrm{c}}\,\mathrm{A_x}\right) = 2\mathrm{e}|\psi|^2\mathrm{v} \tag{6-30}$$

$$\mathrm{v} = \frac{1}{m}\left(\hbar\frac{\partial\phi}{\partial \mathrm{x}} - \frac{2\mathrm{e}}{\mathrm{c}}\,\mathrm{A_x}\right) \tag{6-31}$$

where v is the velocity of the "particles" described by the wave function ψ. The free energy (6-9) is simply

$$\mathrm{F} = \mathrm{F_n} + |\psi|^2\left[\alpha + \frac{\beta}{2}|\psi|^2 + \frac{1}{2}\mathrm{mv}^2\right] + \frac{\mathrm{h}^2}{8\pi} \tag{6-32}$$

and contains a term with the form of a kinetic energy. The minimum of F with respect to $|\psi|$ is obtained for

$$\alpha + \beta|\psi|^2 + \frac{1}{2}mv^2 = 0 \tag{6-33}$$

If we set, as usual, $|\psi| = \psi_0 \mathrm{f}$ with $\psi_0^2 = -\alpha/\beta$ and eliminate v between (6-30) and (6-33), we find

$$j = 2e\psi_0^2\left(\frac{2|\alpha|}{m}\right)^{1/2} f^2\left(1-f^2\right)^{1/2} \tag{6-34}$$

$$= 2e\psi_0^2\left(\frac{\hbar}{m\xi(T)}\right) f^2\left(1-f^2\right)^{1/2} \tag{6-35}$$

The relation between f and j is represented in Fig. 6-2b. For $j = 0$, $f = 1$. As j increases, f decreases. Finally when j becomes larger than $\mathrm{j_c}$ given by

$$\mathrm{j_c} = \frac{4\mathrm{e}\psi_0^2}{3\sqrt{3}}\frac{\hbar}{m\xi(\mathrm{T})} \tag{6-36}$$

[4] It is easy to verify that $|\psi|$ = constant is compatible with the boundary condition (6-13).

there do not exist any solutions with $f \neq 0$. Thus for $j > j_c$ the film becomes normal and f changes abruptly from 0.8 to 0 . The current $\mathrm{j_c}$ is the critical current of the film. It is given in (6-36) as a function of ψ_0^2 and $\xi(\mathrm{T})$, that is, as a function of the Landau-Ginsburg parameters α and β. In order to determine its order of magnitude, it is interesting to rewrite j_c in terms of the velocity v_c. When $j = j_c$, the velocity is $\mathrm{v_c} \sim \mathrm{h}/m\xi(\mathrm{T})$. For a pure metal

$$\xi(T) \sim \xi_0 \left(\frac{T_0}{T_0 - T}\right)^{1/2} \sim \frac{\hbar v_F}{k_B T_0} \left(\frac{T_0}{T_0 - T}\right)^{1/2} \sim \frac{\hbar v_F}{\Delta_0(T)} \tag{6-37}$$

and consequently

$$\mathrm{v_c} \sim \frac{\Delta_0(\mathrm{T})}{\mathrm{m v_F}} \tag{6-38}$$

It is also interesting to compare (6-38) to the maximum velocities associated with the currents giving rise to the Meissner effect in bulk superconductors. If H is an applied field, then the current near the surface is $\sim \mathrm{cH}/\lambda$, where λ is the penetration depth. If one is sufficiently close to T_0, λ is correctly given by $\lambda(T)^{-2} = \frac{16\pi e^2 \psi_0^2}{mc^2}$; the velocity v near the surface becomes

$$\mathrm{v} \sim \frac{\mathrm{j}}{2\mathrm{e}\psi_0^2} \sim \frac{\mathrm{cH}}{2\lambda \mathrm{e} \psi_0^2} \tag{6-39}$$

In a first kind superconductor, the maximum field is $\mathrm{H_c} = (4\pi/\beta)^{1/2}|\alpha|$ which, by using the definition (6-25, 6-26) of κ, becomes

$$\mathrm{v} \sim \frac{\kappa\hbar}{m\lambda} \sim \frac{\hbar}{m\xi(\mathrm{T})}$$

Thus the order of magnitude is the same as (6-38). In a type 2 superconductor, the maximum field for which there is a complete Meissner effect is $H_{C_1} \sim H_C/\kappa$ and $v \sim \hbar/m\lambda(T) \ll \hbar/m\xi(T)$. The supercurrents are less stable because of the possible formation of vortex lines.

The critical velocity is proportional to $(T_0 - T)^{1/2}$ and the critical current varies as $\mathrm{v_C}\psi_0^2$ and thus as $(\mathrm{T_0} - \mathrm{T})^{3/2}$.

Experimentally, the measurement of $\mathrm{j_c}$ is very delicate. (a) It is necessary to control the magnetic field distribution by shielding the film with other superconducting foils. (b) In practice, the transition appears at a "hot point" and then the remainder of the film becomes normal by a purely thermal effect. The situation is improved by using supports that are good thermal conductors and operating in a pulsed regime. (c) The transition as determined by a current-voltage diagram is not abrupt, but continuous.

At any rate, certain careful experiments (Newhouse and Bremer) on thin tin films [$\xi_0 \sim 2300$Å, d ~ 3000Å, $\mathrm{T_0} - \mathrm{T} \sim 3 \times 10^{-2}$ K, $\lambda_\mathrm{L}(\mathrm{T}) \sim$ d, $\xi(\mathrm{T}) \gg$ d] seem to be in agreement with theory. Typically $\mathrm{j_c} \sim 10^4$ A/cm^2 in this temperature region. The variation of $|\psi|$ or $|\Delta|$ with current could, in principle, be followed by a tunneling measurement of the gap. (Detailed calculations show that, for the present geometry, the gap in the excitation spectrum is nearly equal to $|\Delta|$.)

There are two precautions that must be taken in the discussion of critical current experiments:

(1) When $\lambda(T) \sim d$, it is necessary to take account of the variation of the current density through the thickness of the film. This calculation is feasible because in the region of validity of the Landau-Ginsburg equations when $|\psi|$ is constant in space, the current j obeys a simple London equation.

(2) When d $< \xi$(T = 0) in addition to d $< \xi$(T), the bulk Landau-Ginsburg equations no longer apply (see problem, page 225).

The Experiment of Little and Parks

Consider now a superconducting film deposited on a cylindrical insulating support of radius R as is shown in Fig. 6-3. The film has a thickness $d \ll R(d \sim 300 - 1000\text{Å})$. A uniform magnetic field H (typically several tens of gauss) is applied along the axis of the cylinder. How does the transition temperature vary with H?

We shall calculate it by a method due to Tinkham (1962) based on the Landau-Ginsburg equations. We still assume that $d \ll \xi(T)$ and $d \ll \lambda(T)$ and we take $|\psi|$ to be constant in the film. As usual we set $\psi = |\psi|e^{i\theta(r)}$ and the free energy is still given by (6-32).

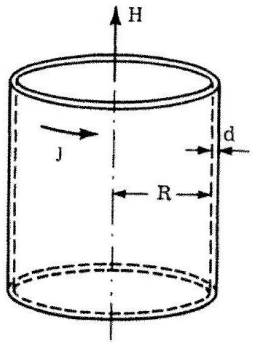


Figure 6-3
Experimental geometry for the Little-Parks experiment. One measures the critical temperature of a thin film (thickness d) deposited on a cylinder (radius $R \gg$ d) in an axial field H .

If the cylinder does not carry a current along its axis, v will be a tangential vector of constant length. How is **v** determined? In the preceding case, the current at the boundaries of the film was fixed and v was determined from the current density by $\mathbf{v} = \text{j}/2\text{e}|\psi|^2$. Here we fix the exterior magnetic field H. In order to relate it to v we study the velocity circulation $\oint \mathbf{v} \cdot \text{d}\boldsymbol{\ell}$ around the cylinder. The contour of integration will be a circle of radius R and the circulation becomes

$$\oint v \cdot d\ell = 2\pi Rv = \frac{\hbar}{m}[\theta] - \frac{2e}{mc}\oint A \cdot d\ell \tag{6-40}$$

[θ] represents the change in phase after a complete revolution about the cylinder. $\psi(r)$, proportional to the self-consistent field $\Delta(r)$, must be a single-valued function as explained in Chapter 5. Therefore $[\theta] = 2\pi\text{n}$, where n is an arbitrary integer. The second term in (6-40) is proportional to

$$\oint \text{A} \cdot \text{ d}\boldsymbol{l} = \int \text{H} \cdot \text{ d}\sigma = \phi = \pi\text{R}^2\text{H} \tag{6-41}$$

which represents the flux contained in the interior of the cylinder. Finally,

$$\text{v} = \frac{\hbar}{\text{mR}}\left[\text{n} - \frac{\phi}{\phi_0}\right] \tag{6-42}$$

where $\phi_0 = \text{hc}/2\text{e}$ is the quantum of flux.
For H fixed, ϕ is fixed, but v can take on an infinity of discrete values from (6-42). However, we see from (6-32) that the free energy will be minimized by choosing the integer n in (6-42) such that $|v|$ is minimum.

$$v = \min\left\{\frac{\hbar}{mR}\left|n - \frac{\phi}{\phi_0}\right|\right\} \tag{6-43}$$

Thus v is a periodic function of H with period $\phi_0/\pi R^2$. For $R = 7 \times 10^3 \text{Å}$, $\phi_0/\pi R^2 \cong 14\text{G}$. Since v is known, we can minimize the free energy with respect to $|\psi|$ and find

$$|\psi|^2 = \left(-\alpha - \frac{mv^2}{2}\right)\beta^{-1} \tag{6-44}$$

This solution exists when $-\alpha > \frac{1}{2}mv^2$. The transition point T_H therefore corresponds to $-\alpha\,(\mathrm{T_H}) = \frac{1}{2}\mathrm{mv}^2$ and $\mathrm{T_H}$ is also a periodic function of H . Since $\alpha(\mathrm{T}) \sim (\mathrm{T} - \mathrm{T_0})$, we see finally that the theoretical curve $\mathrm{T_H}$ is a series of arcs of parabolas. The maximum displacement of the transition point corresponds to

$$\begin{aligned} v &= \frac{\hbar}{2mR} \\ -\alpha\,(T_H) &= \frac{\hbar^2}{2m\xi^2\,(T_H)} = \frac{1}{2}m\left(\frac{\hbar}{2mR}\right)^2 \\ \xi\,(T_H) &= 2R \end{aligned} \tag{6-45}$$

For a pure substance film (for $\mathrm{d} > \xi_0$), we already have the relation $\xi(T) = 0.74\xi_0\,[T_0/\,(T_0 - T)]^{1/2}$, which gives

$$(\mathrm{T_0} - \mathrm{T_H})_{\max} = 0.55\ \mathrm{T_0}\left(\frac{\xi_0}{2\mathrm{R}}\right)^2 \tag{6-46}$$

Remarks

(1) Equation(6-45) shows that the conditions $\mathrm{d} \ll \xi(\mathrm{T})$ and $\mathrm{d} \ll \lambda(\mathrm{T})$ will be satisfied in practice if

$$\mathrm{d} \ll 2\mathrm{R} \qquad \mathrm{d} \ll 2\mathrm{R}\kappa$$

(2) One often uses films for which $\mathrm{d} < \xi_0$. In this case, (6-46) is modified to $(T_0 - T_H) \sim T_0\,[\xi_0 d/(2R)^2]$. We see the justification for this formula later (problem, page 225). The effects we are describing were discovered by Little and Parks (1961) on tin films. In order to have a measurable displacement $T_0 - T_H$, it is evidently necessary to have a small R. As we have already mentioned, R is typically of the order of 0.7μ (the support is a thin plastic fiber) and $\mathrm{d} \sim 350\text{Å}$. The resistance is measured along the axis of the cylinder with as small a current as possible.

(3) In zero field, the relation $\mathrm{R(H} = 0,\ \mathrm{T})$ between resistance and temperature has the form represented in Fig. 6-4a. The transition is spread over $0.05°\mathrm{K}$.

(4) A temperature T^* is chosen in the transition region and the resistance $R\,(H, T^*)$ is measured as a function of field. The result is the curve in Fig. $6-4$ b, which displays the oscillation with a period of 14 G for $\mathrm{R} = 0.7\mu$. The experiment therefore gives a direct determination of the quantum of flux ϕ_0. On the contrary, the amplitude of the oscillations in $R(H)$ is not well understood. The dissipation mechanisms that take place in the transition zone are not fully elucidated. (In particular, in the presence of a field H, the curve R(T) is not only shifted along the temperature axis, but also deformed.]

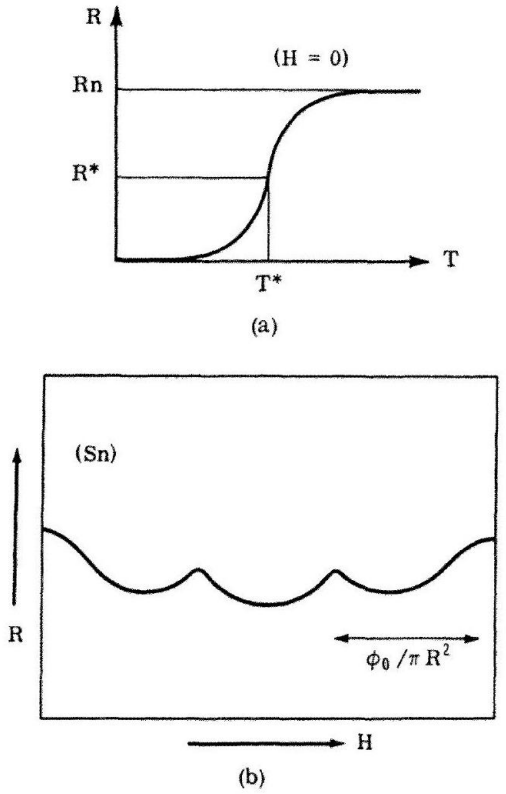

Figure 6-4
(a) Resistance of the film in Fig. 6-3 in zero field as a function of temperature. A temperature is chosen in the transition region (T*). (b) The "quantum scallop." At a fixed temperature T^* (close to T_0), the resistance $R(H)$ oscillates as a function of field. One period corresponds to one quantum of flux in the cylinder $\Delta H = \phi_0/\pi R^2$. [After Little and Parks, Phys. Rev., 133A, 97 (1964).] The parabolic "background" is probably due to a slight misorientation of the field with respect to the axis of the cylinder.

In Fig. 6-4b, there is a continuous increase proportional to H^2 superimposed on the oscillations, which is related to the diamagnetism of the sample. In the preceding calculation we have assumed that H is parallel to the axis of the cylinder and $d \ll \lambda(T)$. Under these conditions, h does not vary through the thickness of the film, and the lines of the force are nearly undisplaced when the sample undergoes the superconducting transition-the diamagnetism is negligible. This is not the case if H is not perfectly aligned along the axis of the cylinder. Then, in the superconducting state, the lines of force are more severely distorted and the energy is increased by a term proportional to H^2. This term is responsible for the continuous increase. (It is experimentally verified that the H^2 contribution is very sensitive to the orientation of the cylinder.)

Plane Film in a Parallel Field

We consider a film of thickness $d[< \xi(T)]$ in an external field H applied parallel to the plane of the film and having the same value at both faces. In this case, the film does not carry a macroscopic current. This is the difference with the previously discussed experiments. In order to understand this, we consider the Maxwell equation curl $h = (4\pi/c)j$ and take h along the y axis, j along the x axis, the film being defined by the planes $z = \pm d/2$. Then

$$\frac{\partial h(z)}{\partial z} = -\frac{4\pi}{c} j$$

$$0 = h\left(\frac{d}{2}\right) - h\left(-\frac{d}{2}\right) = -\frac{4\pi}{c}\int_{-d/2}^{d/2} j dz \tag{6-47}$$

There are currents that cancel on the average and we wish to examine their distribution in detail. We begin with the London equation which, as we have seen previously, is a consequence of the Landau-Ginsburg equation in the case where $|\psi|$ is spatially constant. It is written as

$$\frac{\partial j}{\partial z} = -\frac{4e^2}{mc}|\psi|^2 h \tag{6-48}$$

Therefore

$$\frac{\partial^2 h}{\partial z^2} = \frac{f^2 h}{\lambda^2(T)} \tag{6-49}$$

(as usual we set $\mathbf{f} = |\psi|/\psi_0$). Application of the boundary condition $h(\pm d/2) = H$ gives

$$h = H\frac{\cosh(zf/\lambda(T))}{\cosh(\epsilon f/2)} \tag{6-50}$$

where $\epsilon = \mathrm{d}/\lambda(\mathrm{T})$. From h, we can calculate j from (6-47) or (6-48). As usual, we introduce the drift velocity

$$v = \frac{j}{2e|\psi|^2} = -\frac{2eH\lambda(T)}{mcf}\frac{\sinh(zf/\lambda(T))}{\cosh(\epsilon f/2)} \tag{6-51}$$

A knowledge of v allows us to calculate the free energy from (6-32). We must determine the average value of the kinetic energy through the thickness of the film

$$\overline{v^2} = \frac{1}{d}\int_{-d/2}^{d/2} v^2 dz = \frac{1}{2}\left[\frac{2eH\lambda(T)}{mcf\cosh(\epsilon f/2)}\right]^2\left(\frac{\sinh\epsilon f}{\epsilon f} - 1\right) \tag{6-52}$$

On minimizing (6-32) with respect to f, we obtain

$$\mathrm{f}^2 = 1 + \frac{m\overline{\mathrm{v}^2}}{2\alpha} \tag{6-53}$$

Using our basic equations (6-8), (6-15), and (6-22), we can place this result in the form

$$\left(\frac{\mathrm{H}}{\mathrm{H_c}}\right)^2 = 4\mathrm{f}^2\left(1-\mathrm{f}^2\right)\frac{\cosh^2\frac{\epsilon\mathrm{f}}{2}}{\frac{\sinh\epsilon\mathrm{f}}{\epsilon\mathrm{f}} - 1} \tag{6-54}$$

Equation (6-54) gives the decrease in f as H increases. The behavior for $\epsilon\mathfrak{f} \ll 1$ is

$$\left(\frac{\mathrm{H}}{\mathrm{H_C}}\right)^2 = \frac{24}{\epsilon^2}\left(1-\mathrm{f}^2\right), \quad \mathrm{d} < \frac{\lambda(\mathrm{T})}{\mathrm{f}} \tag{6-55}$$

On the other hand, for $\epsilon f \gg 1$, we later see that f is close to 1 in the important region and then (6-54) reduces to

$$\left(\frac{\mathrm{H}}{\mathrm{H_c}}\right)^2 = 2\epsilon\left(1-\mathrm{f}^2\right), \quad \mathrm{d} > \lambda(\mathrm{T}) \tag{6-56}$$

What is the critical field of the film, that is, the maximum value allowed for H? If the transition to the normal state is first order, we must calculate and compare the Gibbs potential G (at fixed H and T) in the superconducting phase [with f given by (6-54)] and in the normal phase.

We first calculate the free energy F_S (per cm^3) in the superconducting state from (6-32) and (6-52). Upon using the equilibrium condition (6-53) and the equations (6-8), (6-15), we can put it in the form

$$F_s = F_n - \frac{H_c^2}{8\pi} f^4 + \frac{\overline{h^2}}{8\pi} \tag{6-57}$$

where

$$\overline{h^2} = \frac{1}{d}\int_{-d/2}^{d/2} h^2 dz = H^2 \frac{\epsilon f + \sinh \epsilon f}{\epsilon f(1+\cosh \epsilon f)} \tag{6-58}$$

We also need the induction B (which is the average of h)

$$B = H \frac{2}{\epsilon f} \tanh \frac{\epsilon f}{2} \tag{6-59a}$$

The reader can verify that $\mathrm{dF/dB = H/4\pi}$ and therefore that H is the thermodynamic field as could be predicted from the analysis of Chapter 2 . We finally form the Gibbs potential

$$G_S = F_S - \frac{BH}{4\pi} = F_n + \frac{H^2}{8\pi}\left[\frac{\sinh \epsilon f + \epsilon f}{\epsilon f(1+\cosh \epsilon f)} - \frac{4}{\epsilon f}\tanh\left(\frac{\epsilon f}{2}\right)\right] - \frac{H_c^2}{8\pi} f^4 \tag{6-59b}$$

On the other hand, $G_n = F_n - H^2/8\pi$ and the critical field H is obtained by setting $G_n = G_s$ or

$$\left(\frac{\mathrm{H}_\ell}{\mathrm{H_c}}\right)^2 \left[1 + \frac{\epsilon \mathrm{f}_\ell + \sinh \epsilon \mathrm{f}_\ell}{\epsilon \mathrm{f}_\ell\,(1+\cosh \epsilon \mathrm{f}_\ell)} - \frac{4}{\epsilon \mathrm{f}_\ell}\tanh\left(\frac{\epsilon \mathrm{f}_\ell}{2}\right)\right] = \mathrm{f}_\ell^4 \tag{6-60}$$

Equations (6-54) and (6-60) define H_ℓ and the corresponding order parameter $\psi_\ell = \psi_0 \mathrm{f}_\ell$. One can eliminate H_ℓ to obtain

$$1 + \frac{1}{6}\frac{\mathrm{f}_\ell^2}{1-\mathrm{f}_\ell^2} = \frac{1}{3}\frac{\epsilon \mathrm{f}_\ell\,[\cosh \epsilon \mathrm{f}_\ell - 1]}{\sinh(\epsilon \mathrm{f}_\ell) - \epsilon \mathrm{f}_\ell} \tag{6-61}$$

In Fig. 6-5a we plot both sides of (6-61) as a function of f_ℓ on the interval $(0 \to 1)$. For $f \to 0$, the left side behaves as $1 + \frac{1}{6} f_\ell^2$ and the right-hand side as $1 + (\epsilon \mathrm{f}_\ell)^2/30$. If $\epsilon > \sqrt{5}$, the right-hand side increases faster than the left. Since the left-hand side diverges for $\mathrm{f} = 1$, there must be an intersection between $\mathrm{f}_\ell = 0$ and $\mathrm{f}_\ell = 1$. On the contrary, there will be no intersection for $\epsilon < \sqrt{5}$ (see Fig. 6-5b).

Therefore, if $d > \sqrt{5}\lambda(T)$, we have a first-order transition with a critical field H_ℓ deduced from (6-61) and (6-60). If $\mathrm{d} < \sqrt{5}\lambda(\mathrm{T}), \mathrm{G_S}$ always remains less than G_n when the solution exists; ψ decreases as H increases, according to (6-54) and finally vanishes for

$$\mathrm{H} = \mathrm{H}'_\ell = \frac{\sqrt{24}}{\epsilon}\mathrm{H_c} \tag{6-62}$$

The transition that occurs at H'_ℓ is of the second order. These two types of behavior, depending on the ratio $\mathrm{d}/\lambda(\mathrm{T})$, were predicted by Ginsburg in 1952. They have been qualitatively verified in a series of tunneling experiments by Douglass (1961) (metal used: aluminum, $\xi_0 = 16{,}000\text{Å}\Big)$. He showed that

(1) The energy gap ϵ_0 in the excitation spectrum was a decreasing function of the field.
(2) For T $\cong$ 0.75 T_0 in films with thicknesses d > 3.500Å, the gap dropped abruptly from a finite value to 0 when the critical field was reached.
(3) At the same temperature, in films with $d < 3.500\text{Å}, \epsilon_0$ dropped smoothly to 0 when the field was increased up to the critical value.

These results are represented on Fig. 6-5c. The distinction between first- and second-order transitions is very apparent. Unfortunately it is not possible to go beyond this qualitative statement for the following reasons:

Both $\lambda(T)$ and d are much smaller than ξ_0 in all the films. The currents j_S have a rapid variation on the scale ξ_0 (note that j_S reverses its sign when one goes from one side of the film to the other). In such a situation the Landau-Ginsburg equations cannot be applied, even if one allows for a change of κ with thickness. [5] Note: the energy

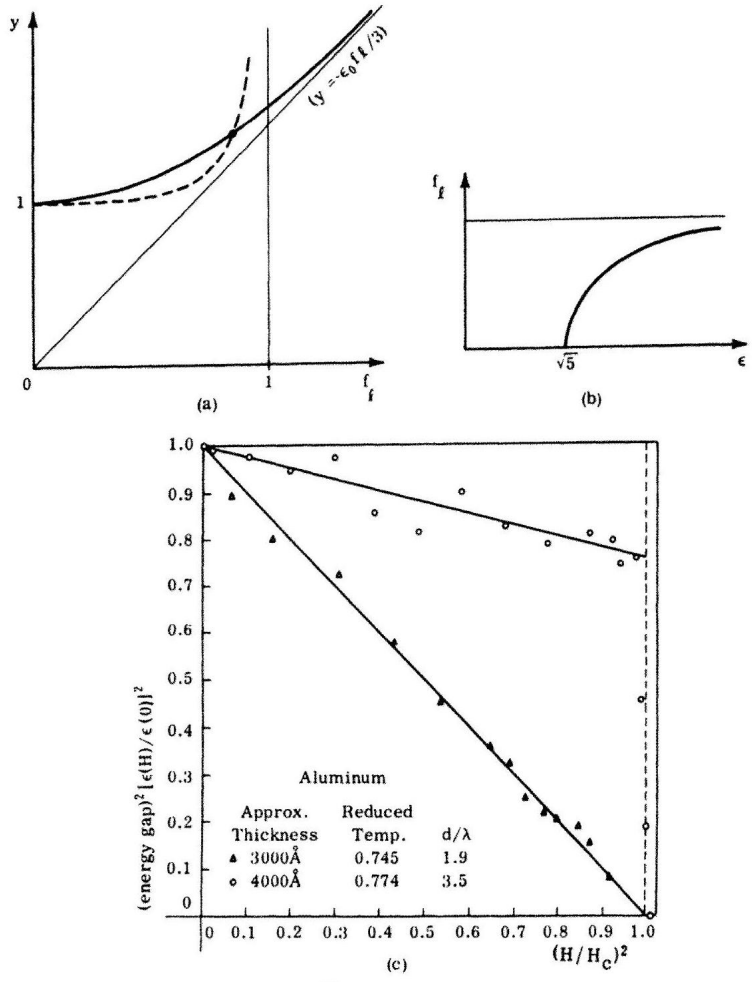

Figure 6-5
(a) A plot of the left-and right-hand sides of Eq. (6-61) as a function of the normalized order parameter f_ℓ. Left side: broken curve. Right side: continuous curve. The two curves have an intersection if $d > \sqrt{5}\lambda$ (T). (b) The dependence of the order parameter at the first-order transition as a function of $\epsilon = \text{d}/\lambda(\text{T})$. Note that for $\epsilon < \sqrt{5}$ there is a second-order transition and the critical value f_ℓ is zero. (c) Tunneling measurement of the energy gap versus magnetic field in two aluminum samples of different thicknesses. For the film with $\varepsilon > \sqrt{5}$, note the first-

[5] The space variations of j_s depend on two parameters d and $\lambda(T)$. Thus, in general, an "effective κ " for the present geometry would depend on $\lambda(T)$ and lose its intrinsic significance. Furthermore, even in the limit $\lambda(T) \gg d$, this effective κ would be numerically different from the one required by a critical current measurement on the same film.

order transition; for the thinner film we see a much less abrupt behavior. [After D. Douglas, Jr., IBM J. Res. Develop., 6, 47 (1962).]
gap ϵ_0 is different from $|\Delta|$ in thin films under strong magnetic fields. In particular there is a finite region of the (H, T) plane where $\epsilon_0 = 0$ while $\Delta \neq 0$ (gapless superconductivity). This complicates somewhat the analysis of the tunneling results.

Problem.

Consider a superconducting cylindrical film (radius R) of thickness 2d ($d \ll R$). A small axial external field h_0 is applied to the cylinder; determine the field in the core when
(a) the fluxoid Φ_f is held fixed,
(b) the fluxoid Φ_f can adjust and reach its most favorable value.

Solution.

By definition, the fluxoid Φ_f is proportional to the change in phase $[\phi]$ of the order parameter after one revolution around the cylinder

$$\Phi_{\mathrm{f}} = \frac{\mathrm{ch}}{2\mathrm{e}}[\phi]$$

In practice the adjustment of $|\phi|$ allowed in (b) can take place only by the penetration of vortices or macroscopic flux bundles.
(a) The current density on the film is given by (6-12)

$$\mathrm{j} = 2\frac{\mathrm{e}}{m}|\psi|^2\left(\mathrm{h}\nabla\phi - \frac{2\mathrm{e}}{\mathrm{c}}\ \mathrm{A}\right)$$

For small $h_0, |\psi|$ is equal to its value ψ_0 in zero field.
Integrating the current density around a circle running along the inner surface of the cylinder, we find

$$\oint \mathrm{j}\cdot\ \mathrm{d}l = \frac{\mathrm{c}}{4\pi\lambda^2}\left(\Phi_{\mathrm{f}} - \Phi_{\mathrm{i}}\right)$$

where λ is the penetration depth defined in $\lambda(T)^{-2} = \frac{16\pi e^2\psi_0^2}{mc^2}$ and Φ_1 is the flux contained within the core of the cylinder. The field distribution is still given by

$$\frac{d^2h}{dx^2} = \frac{h}{\lambda^2}$$

within the film, and thus

$$h = \frac{(h_0 - h_i)}{2}\frac{\sinh(x/\lambda)}{\sinh(d/\lambda)} + \frac{(h_0 + h_i)}{2}\frac{\cosh(x/\lambda)}{\cosh(d/\lambda)}$$

where h_0 is the applied field and h_i is the field within the core (to be determined). Comparing $\Phi \mathrm{j}\cdot \mathrm{d}l$ derived from this field distribution with the previous equation involving the fluxoid, we find

$$\begin{aligned} h_i &= \frac{\frac{\Phi_f}{\pi\lambda R} + \frac{2h_0}{\sinh(2d/\lambda)}}{2\coth(2d/\lambda) + R/\lambda} \\ &\simeq \frac{\Phi_f}{\pi R^2} + \frac{2h_0\lambda}{R\sinh(2d/\lambda)} \quad \left(R \gg \frac{\lambda^2}{d}\right) \end{aligned}$$

If the fluxoid is held fixed, for example, $\Phi_f = 0$, we find

$$h_i \simeq \frac{2h_0\lambda}{R\sinh(2d/\lambda)}$$

h_i is, in general, quite small compared to the applied field h_0, except of course for extremely thin films ($d \leq \lambda^2/R$).
(b) Let us now assume that the fluxoid is allowed to vary. For a fixed applied field h_0, we must minimize the Gibbs potential S with respect to the fluxoid. S may conveniently be written as

$$S = \frac{\lambda^2}{8\hbar}\int\left(\frac{dh}{dx}\right)^2 dr + \frac{1}{8\pi}\int (h-h_0)^2\, dr + \text{ const}$$

Using the explicit form derived above for the field, one finds that the minimum corresponds to $h_i = h_0$.

Thus in thermodynamic equilibrium the field within the core is equal to the applied field. However it often occurs in A.C. experiments that the fluxoid cannot adjust itself to its equilibrium value during the time of observation and we then find a situation where the core field is small.

6.3.6 6-6 Situations Where $|\psi|$ Varies Spatially

Nucleation in the Bulk

We consider a superconducting metal in a high magnetic field. For sufficiently high fields, superconductivity is destroyed and the field is uniform in the sample. If we continuously decrease the field, at a certain field $H = H_{C_2}$, superconducting regions begin to nucleate spontaneously. We see that H_{C_2} does not coincide with the thermodynamic field H_c; depending on the case it can be either larger or smaller.

In the regions where the nucleation occurs, superconductivity is just beginning to appear and therefore $|\psi|$ is small. The Landau-Ginsburg equation can be linearized to give

$$\frac{1}{2m}\left(-i\hbar\nabla - \frac{2eA}{c}\right)^2 \psi = -\alpha\psi \tag{6-63}$$

Also, in (6-63) we can set curl $A = H$ where H is only the applied field. This is valid because the supercurrents are of order $|\psi|^2$ and the resulting corrections to the field are therefore negligible in the linear approximation. Equation (6-63) is then formally identical to the Schrdinger equation for a particle of charge $2e$ and mass m in a uniform magnetic field.

First consider the case of an infinite medium. The particle has a
constant velocity v_z along the field and moves in a circle in the xy plane with the frequency

$$\omega_c = 2eH/mc \tag{\prime}$$

The energies corresponding to the bound states of (6-63) have the form $\frac{1}{2}mv_Z^L + \left(n+\frac{1}{2}\right)\hbar\omega_c$ where n is a positive integer. In particular, the lowest level corresponds to $v_Z = 0, n = 0$, and gives $-\alpha = e\hbar H/mc$.

The field H thus obtained is the field H_{c_2}. (The other levels with n or v_Z nonzero will give, for the same α, lower values of H .) By using the relation $\alpha^2/2\beta = H_C^2/8\pi$ and the definition (6-26) of the Lan-dau-Ginsburg parameter, one finally obtains

$$\begin{aligned} H_{C2} &= \kappa\sqrt{2}H_c \\ &= \frac{\phi_0}{2\pi\xi(T)^2} \end{aligned} \tag{6-64}$$

Discussion of this formula.

(1) When $\kappa > 1/\sqrt{2}, (\mathrm{H_c} < \mathrm{H_{c_2}})$, a condensed phase ($\psi \neq 0$) will appear in the bulk of the sample for fields $\mathrm{H} < \mathrm{H_{C_2}}$. This phase cannot correspond to a complete exclusion of the magnetic flux, since a complete Meissner effect is energetically unfavorable at fields $\mathrm{H} > \mathrm{H_c}$ and we can choose $\mathrm{H_c} < \mathrm{H} < \mathrm{H_{c_2}}$. In fact, what we obtain here below $\mathrm{H_{c_2}}$ is the Schubnikov phase discussed in Chapter 3. As predicted there, we see that the upper critical field is of order $\phi_0/\xi(\mathrm{T})^2$. It corresponds to a close packing of vortex lines, each of them carrying the flux unit ϕ_0 and having a core radius $\xi(\mathrm{T})$.
(2) When $\kappa < 1/\sqrt{2}\,(\mathrm{H_{c_2}} < \mathrm{H_c})$, if we decrease the field we first meet the value H_c, at which a complete Meissner effect takes place-we are dealing here with a first type superconductor.

$$\begin{array}{ll} \kappa < \frac{1}{\sqrt{2}} & \text{first type} \\ \kappa > \frac{1}{\sqrt{2}} & \text{second type} \end{array} \tag{6-65}$$

Nucleation on the Sample Surface

The calculation that led to (6-64) is only valid in an infinite medium. It neglects boundary effects. In fact, for an ideal substance, nucleation always takes place first on the surface (D. Saint-James and P. G. de Gennes, 1963). We now analyze in greater detail the effects of the sample surface in a simple case. The surface is assumed to be a plane [radius of curvature much larger than $\xi(T)$] and the boundary separates the superconductor from either an insulator or a vacuum such
that the boundary conditions (6-13) apply. We consider two cases:
(1) The field (along z) is normal to the surface (xy plane). Then the function ψ corresponding to the lowest level of (6-63) is also an eigenfunction of $\Pi_2 = -i\hbar\partial/\partial z - 2eA_2/c$ with eigenvalue 0 . Therefore (6-13) is automatically satisfied and the surface does not modify the nucleation field.
(2) The field is in the surface of the sample; **H** is directed along the z axis, the surface is in the yz plane and the superconductor occupies the region $x > 0$. We select the gauge $A_Z = A_X = 0, A_Y = Hx$ and look for solutions of the form

$$\psi = e^{iky} f(x) \tag{6-66}$$

Equation (6-63) becomes

$$-\frac{\hbar^2}{2m}\frac{d^2 f}{dx^2} + \frac{1}{2m}\left(\hbar k - \frac{2eHx}{c}\right)^2 f = -\alpha f \tag{6-67}$$

and the boundary condition is

$$\left(\frac{df}{dx}\right)_{x=0} = 0 \tag{6-68}$$

Equation (6-67) is analogous to the Schrdinger equation of a harmonic oscillator of frequency ω given by (6-63), the equilibrium position being the point

$$\mathrm{x_0} = \frac{\hbar \mathrm{kc}}{2\mathrm{eH}} \tag{6-69}$$

However (6-68) introduces a complication. If $\mathrm{x_0} \gg \xi(\mathrm{T})$, the wavefunction will be localized around x_0 and nearly zero at the surface; therefore (6-68) will automatically be satisfied. In this case, we have

$$f \cong \exp\left[-\frac{1}{2}\left(\frac{x-x_0}{\xi(T)}\right)^2\right] \tag{6-70}$$

the eigenvalue still being given by (6-63). If x_0 is zero, on the other hand, the function (6-70) still satisfies the boundary condition (6-68), and (6-63) is still obtained. We now show that between the two extreme cases, namely for $x_0 \sim \xi(T)$, the lowest eigenvalue is lower than (6-63). In order to see this, we can replace (6-67), valid for $x > 0$, by an equation valid over the interval $-\infty < x < \infty$

$$-\frac{\hbar^2}{2m}\frac{d^2f}{dx^2} + V(x)f = -\alpha f \tag{6-71}$$

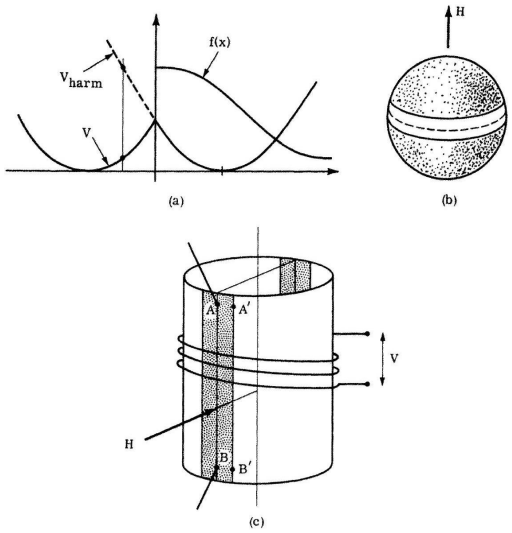

Figure 6-6
(a) The harmonic potential $V_{\text{harm}} = \text{const}\ (x-x_0)^2$ and the symmetrical potential V. Since $V < V_{\text{harm}}$, the first level in V is lower than the first level in V_{harm} . Also shown is the shape of the eigenfunction $f(x)$. (b) Surface superconductivity in a sphere. The band around the equator represents the superconducting sheath when H is just below H_{C3}. As H decreases, this band broadens and reaches the poles at H_{C_2}. (c) Principle of the determination of H_{C2} and H_{C3} on hollow cylinders lafter J. P. Burger, G. Deutscher, E. Guyon, and A. Martinet, Solid State Commun., 2, 101 (1964)]. A field H > H $_{c2}$ is applied normal to the cylinder axis. Two normal strip appears on the cylinder (shaded areas). Their onset is detected with a coil wound around the cylinder: the self-inductance of the coil increases abruptly when the strips appear. The width of the strips is measured with the resistive probes AB. The current flows from A to A', then in the superconducting regions from A' to B', and finally from B' to B. The resistance is proportional to the length AA'.

The potential V(x) coincides with that of (6-67) for x > 0. For x < 0, we continue it symmetrically (Fig. 6-6a):

$$V(x) = \begin{cases} \frac{2e^2H^2}{mc^2}(x-x_0)^2 & x > 0 \\ V(-x) & x < 0 \end{cases} \tag{6-72}$$

The eigenfunction corresponding to the lowest eigenvalue of (6-71) has no nodes, is an even function of x, and automatically satisfies (6-68). For $x < 0$, we see from the figure that the potential $V(x)$ is always less than $(2e^2H^2/mc^2)(x-x_0)^2$ and therefore the lowest eigenvalue of V(x) is lower than (6-63). Hence, nucleation is favored by the presence of a surface.

A detailed calculation shows that the optimum value of x_0 is $0.59\xi(T)$ and that the corresponding eigenvalue becomes

$$-\alpha = 0.59\frac{e\hbar H}{mc} \tag{6-73}$$

The eigenfunction is a rather complicated Weber function. But, as first noticed by C. Kittel, a good approximation to the exact eigenvalue (6-73) can be obtained more simply from the variational principle applied to the Schrdinger equation (6-67). Taking as a trial function a gaussian of adjustable width

$$f(x) = e^{-rx^2}$$

and minimizing $|\alpha|$ with respect to r and x_0, one finds

$$|\alpha| = \sqrt{1 - \frac{2}{\pi}}\frac{e\hbar H}{mc} = 0.60\frac{e\hbar H}{mc}$$

The nucleation field, which we call H_{C3}, is given by (6-73). By making use of (6-64), it can be written as

$$H_{c3} = 2.4\kappa H_c = 1.7H_{c_2} \tag{6-74}$$

Discussion of Eq. (6-74).
(1) Materials of the second type. The above calculation shows us that above H_{c2}, in the interval $H_{c2} < H < H_{c3}$, superconductivity is not entirely destroyed. The bulk of the material is normal, but a superconducting sheath subsists in certain surface regions. For a long cylinder placed in an axial field, this sheath occupies the entire lateral surface of the cylinder. For a sphere, the situation is quite different. When H is slightly less than H_{C_3}, the sheath is limited to a narrow band around the equatorial circle (Fig. 6-6b). As H decreases, this band broadens and finally reaches the poles at $H = H_{C_2}$.

A number of methods have been used to detect the surface sheath: resistance measurements (at low currents, the sheath acts as a short circuit); inductive measurements at low frequencies-a typical geometry is shown in Fig. 6−6c. When the sheath is present on the cylinder surface, flux lines cannot pass it and the self-inductance of the coil is low. When H reaches H_{C3}, the sheath disappears and the full self-inductance is restored (Fig. 6-7a). Similar but more complicated experiments can also be carried out in the microwave region.

In films [much thicker than ξ(T)], various sensitive techniques can be applied: (a) tunneling experiments display a density of states that deviates significantly from the normal state value; (b) the sheath acts as a small diamagnetic region that can be detected by torque measurements.

All these experiments have shown that for clean sample surfaces [radius of curvature $\gg \xi(T)$] there is, indeed, a sheath in an interval $H_{c_2} < H < H_{c_3}(\theta)$, where θ is the angle between the field and the surface. For $\theta = 0$ the experimental value $H_{c_3}(0)$ is close to the theoretical value (6-74). For $\theta \neq 0, H_{C3}(\theta)$ varies as shown on Fig. 6-7b. For $\theta = \frac{1}{2}\pi, H_{C3}(\theta) \to H_{C2}$.
(2) Type 1 superconductors with $0.42 < \kappa < 1/\sqrt{2}$. Here $H_{C2} < H_C$, but $H_{C3} > H_C$. Thus in the field range $H_C < H < H_{C_3}$ there still exists a superconducting

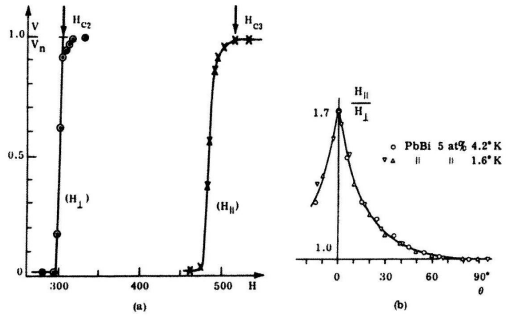

Figure 6-7 (a) Results of induction measurements (with the coil of Fig.6-6c) on hollow cylinders of a Snin alloy. When the field H is normal to the cylinder axis ($H_\perp$), the voltage V (proportional to the self-inductance of the coil) increases for $H = H_{c_2}$. When H is parallel to the axis $\left(H_\parallel\right)$, the increase occurs only when H = H_{c3} (after Burger et al.). (b) Angular dependence of the critical field in PbBi alloys at various temperatures. (After P. Burger, G. Deutscher, E. Guyon, and A. Martinet, Phys. Rev., 137A, 853 (1965).]

sheath (in the regions where H is parallel or nearly parallel to the sample surface). This sheath in a Type I superconductor has been observed in a few cases such as lead and dilute lead alloys. (3) Type I superconductors with $\kappa < 0.42$. Here $H_{c_3} < H_c$ and it is not possible to observe the sheath in a state of thermodynamic equilibrium. It is still possible, however, to measure H_{C_3} in the following way: In very good samples it is possible to lower the field below H_c while still retaining the sample in the normal (metastable) state, In aluminum, for instance, the field can be lowered to $< H_c/10$ with no transition occurring. However, the metastable normal phase never extends down to 0 applied field; the reason is that, when we reach the field H_{c_3}, it becomes possible to create weakly superconducting regions near the sample surface, with no energy expense. The normal phase becomes strictly unstable when $H \leq H_{C3}$. The corresponding nucleation process has, in fact, been studied very carefully by Faber on various Type I superconductors. He showed experimentally that nucleation took place near the sample surface (however, without realizing at the time that this was a fundamental property) and he measured the nucleation field we now identify with H_{C3}. From his results one could, in principle, derive the corresponding κ values by Eq. (6-74). If we do this blindly, we find

$\kappa = 0.015$Al
0.07 In
0.10 Sn

This procedure is probably not quite correct for these pure metals where the Landau-Ginsburg equations are valid only for temperatures T very close to T_0, while the supercooling fields are usually measured at lower temperatures. For the sake of completeness, we quote the "theoretical" values of κ derived from the definition (6-27) where $\lambda_I, (0)$ and ξ_0 are determined from Fermi surface measurements in the normal state (plus the experimental value of T_0). They are

$$\begin{aligned} \kappa &= 0.010\text{Al} \\ &0.05\text{In} \\ &0.15\text{Sn} \end{aligned}$$

6.3.7 6-7 Structure of the Vortex Phase in Strong Fields (H ~ H_{C2})

Consider a cylindrical sample of a second type material ($\kappa > 1/\sqrt{2}$) placed in an exterior field H parallel to the axis of the cylinder. Let H decrease. When H becomes equal to H_{C_2}, nucleation of the superconducting state begins in the volume of the sample. The order parameter $|\psi|$ is small and the form of ψ on nucleation is obtained from the linearized Landau-Ginsburg equations (6-63). If H still decreases,

the nucleation region develops, $|\psi|$ becomes larger and in order to determine the nature of the order it is necessary to solve the complete nonlinearized Landau-Ginsburg equations. This represents a formidable numerical problem.

Things become simpler if H is taken to be only slightly less than H_{C_2} (A. Abrikosov, 1956). By continuity, the solution ψ of the complete Landau-Ginsburg equations must have a strong resemblance to a certain solution ψ_L of the linearized equation. This does not mean that the problem is immediately solved. We only know that the ψ_L satisfies

$$\frac{1}{2m}\left(-i\hbar\nabla - \frac{2eA_0}{c}\right)^2 \psi_L = -\alpha\psi_L \tag{6-75a}$$

with

$$\operatorname{curl} A_0 = (0, 0, H_{C_2}) \tag{6-75b}$$

However, the eigenvalues of (6-75a) are strongly degenerate, that is, there exist many independent solutions describing nucleation in one or another part of the sample. For example, in the gauge ($A_X = A_Z = 0,\ A_y = H_{C_2}x$) we have seen that the solutions are of the form

$$\begin{aligned} \psi_{\mathrm{k}} &= \mathrm{e}^{\mathrm{iky}}\mathrm{e}^{-\left(\frac{1}{2}\right)(\mathrm{x}-\mathrm{x}_0)^2/\xi^2(\mathrm{T})} \\ \mathrm{x}_0 &= \frac{\hbar\mathrm{ck}}{2\mathrm{eH}_{\mathrm{C}_2}} \end{aligned} \tag{6-76}$$

where k is an arbitrary parameter. The nucleation region for such a situation is a band of width $\xi(T)$ perpendicular to the x axis. Its average abscissa x_n depends on the value chosen for k. We know that ψ_L must be a linear combination of the ψ_k. In fact, from our simplified discussion in Chapter 3, we expect to find $|\psi|$ to have a periodic structure in x and y. If $2\pi/q$ is the spatial period in the y direction, such a function ψ_L will be the combination

$$\begin{aligned} \psi_L &= \sum_n C_n e^{inqy} \exp\left[-\frac{1}{2}(x - x_n)^2/\xi^2(T)\right] \\ x_n &= \frac{n\hbar cq}{2eH_{c2}} \end{aligned} \tag{6-77}$$

In order that $|\psi_L|$ also be periodic in x, it is necessary to impose a periodicity on the $C_n's$. The form of condition chosen by Abrikosov was $C_{n+\nu} = C_n$, where ν is a fixed integer. Then

$$\psi_L\left(x + \frac{\nu\hbar cq}{2\mathrm{eH}_{\mathrm{C}_2}}, y\right) = e^{i\nu qy}\psi_L(x, y)$$

However, independent of the detailed structure of ψ_{L} postulated in (6-77), it is possible to establish certain general theorems:
(1) Normalization of ψ_{L}: As the starting equations (6-11) and (6-12) are nonlinear in ψ, the normalization adopted for ψ_L plays a nontrivial role. Let us assume that the free energy (6-9) is stationary if the trial function ψ_L is changed to $(1 + \epsilon)\psi_L$ where ϵ is small and independent of r. To first order in ϵ the variation in the free energy is

$$\delta\mathcal{F} = 2\epsilon \int \mathrm{dr}\left[\alpha\left|\psi_{\mathrm{L}}\right|^2 + \beta\left|\psi_{\mathrm{L}}\right|^4 + \frac{1}{2m}\left|\left(-\mathrm{i}\hbar\nabla - \frac{2\mathrm{eA}}{\mathrm{c}}\right)\psi_{\mathrm{L}}\right|^2\right] \tag{6-78}$$

In order to simplify the notation, we shall write an integral such as $\int \left|\psi_{\mathrm{L}}\right|^2 \mathrm{dr}$ extended over a macroscopic volume V in the form $\mathrm{V}\left|\psi_{\mathrm{L}}\right|^2$. From (6-78). the condition $\delta\mathcal{F} = 0$ can be written

$$\overline{\alpha \left|\psi_L\right|^2} + \overline{\beta \left|\psi_L\right|^4} + \frac{1}{2m}\overline{\left|\left(-i\hbar\nabla - \frac{2eA}{c}\right)\psi_L\right|^2} = 0 \tag{6-79}$$

This equation can be simplified by using (6-75a), which is satisfied by ψ_{L}. Set $\mathrm{A} = \mathrm{A}_0 + \mathrm{A}_1$ where A_0 (defined by 6-75b) is the vector potential which would exist in the presence of the field H_{C_2} and where A_1 represents the modifications due to the facts that (a) the applied field is slightly smaller than H_{C_2}: and (b) there exist supercurrents, which also contribute to the fields. Expanding (6-79) to first order in A_1 and using (6-75a), we obtain

$$\beta \left|\psi_{\mathrm{L}}\right|^4 - \frac{1}{\mathrm{c}}\overline{\mathbf{A}_1 \cdot \mathrm{j_L}} = 0 \tag{6-80}$$

where

$$j_L = \frac{e}{m}\left[\psi_L^*\left(-i\hbar\nabla - \frac{2eA_0}{c}\right)\psi_L + C.C.\right] \tag{6-81}$$

j_L represents the current associated with the unperturbed solution. If we integrate the second term in (6-80) by parts and set curl $A_1 = h_1$ and curl $h_s = (4\pi/c)j_L$, we obtain

$$\beta\overline{\psi_{\mathrm{L}}|^4} - \frac{1}{4\pi}\overline{\mathrm{h_t} \cdot \ \mathrm{h_S}} = 0 \tag{6-82}$$

(2) Relation between field and order parameter: In order to make
the condition (6-82) explicit, we must calculate the fields h_1 and h_s. (From the results of Chapter 3, we predict that h_1 and h_S are everywhere parallel to the z axis.) We can write

$$h_1(r) = H - H_{C_2} + h_S(r) \tag{6-83}$$

The term $\mathrm{H}-\mathrm{H}_{\mathrm{C}_2}$ represents the contribution (α) and $\mathrm{h_S}$ gives the effect of the supercurrents.
6

When ψ_{L} is a solution of (6-75a) corresponding to the lowest eigenvalue $-\alpha = \frac{1}{2}\hbar\omega_{\mathrm{C}}$, the lines of current associated with j_{L} coincide with the lines $|\psi_{\mathrm{L}}| = \text{const}$. This property allows us to calculate $\mathrm{h_S}$ simply.

Proof.

$$\text{Set } \Pi = (2m\hbar\omega_c)^{-1/2}\left(-i\hbar\nabla - \frac{2eA_0}{c}\right)$$

and $\Pi^{\pm} = \Pi_{x^{\pm}} = i\Pi_y$. The commutator $[\Pi^+, \Pi^-]$is one and (6-75a) can be written in the form

$$\Pi^+\Pi^-\psi_L = 0$$

whose bound state solutions correspond to

$$\Pi^-\psi_L = 0 \tag{6-84}$$

We still set

$$\psi_{\mathrm{L}} = |\psi_{\mathrm{L}}|\,\mathrm{e}^{\mathrm{i}\vartheta} \tag{6-85}$$
$$\mathrm{j_L} = \frac{2\mathrm{e}}{m}|\psi_{\mathrm{L}}|^2\left(\hbar\nabla\psi - \frac{2\mathrm{e}}{\mathrm{c}}\ \mathrm{A}_\theta\right)$$

On equating the real and the imaginary parts of $\Pi^+\psi_L$ to zero and using (6-85), we find

$$\mathfrak{j}_{Lx} = -\frac{e\hbar}{m}\frac{\partial}{\partial y}|\psi_L|^2 \tag{6-86}$$
$$\mathfrak{j}_{Ly} = \frac{e\hbar}{m}\frac{\partial}{\partial x}|\psi_L|^2$$

[6] $\int_L = (c/4\pi)$ curl h_s is not exactly the supercurrent since it is A_n and not A_1 which enters in (6.81). However we shall see that $H_{c2} - H$ and $|\psi|^2$ are of the same order and small, and therefore $\overline{(A_0 - A)|\psi|^2}$ is of order $|\psi|^4$ and negligible at this stage

We see that the current lines are the lines of constant $|\psi_L|$.
By comparing (6-86) to the definition curl $h_S = (4\pi/c)j_L$, we find explicitly that the field h_s due to the supercurrents is given by

$$h_s = -4\pi\frac{e\hbar}{mc}|\psi_L|^2 \tag{6-87}$$

The constant of integration is such that, for $\overline{|\psi_L|^2} = 0, h_s$ disappears. By regrouping (6-82), (6-83), and (6-87), we obtain the explicit condition

$$\beta\overline{|\psi_L|^4} + \frac{e\hbar}{mc}\overline{|\psi_L|^2\left(H - H_{C_2} - \frac{4\pi e\hbar}{mc}|\psi_L|^2\right)} = 0 \tag{6-88a}$$

It is again useful to set $|\psi_L| = \psi_0 f$, to use the definition (6-26) of κ, and (6-64) for H_{C_2}, to find

$$\overline{\mathrm{f}^4}\left(1 - \frac{1}{2\kappa^2}\right) - \overline{\mathrm{f}^2}\left(1 - \frac{\mathrm{H}}{\mathrm{H}_{c_2}}\right) = 0 \tag{6-88b}$$

The relation (6-88b) is important because it is independent of the detailed form of the hypothesis for ψ_L, that is, independent of the nature of the lattice formed by the flux lines. If we now select a given lattice, that is, fix q and the periodicity of the coefficients C_n, we can explicitly calculate the ratio

$$\frac{\overline{f^4}}{\left(\overline{f^2}\right)^2} = \beta_A \tag{6-89}$$

which corresponds to this lattice. If β_A is known, (6-88b) and (6-89) can be solved for $\overline{f^4}$ and $\overline{f^2}$. This is all that is necessary to calculate the induction and free energy.
(1) Induction B: This is the average value of the field $\mathrm{H} + \mathrm{h_S}$ and is found from (6-87) to be

$$B = H + \overline{h_S} = H - \frac{4\pi e\hbar}{mc}\sqrt{\psi_L T^2}$$
$$= H - \frac{H_c}{\kappa\sqrt{2}}\overline{f^2} \tag{6-90}$$

(2) The free energy per unit volume F is calculated using (6-11) to simplify (6-9)

$$F = -\frac{\beta}{2}|\psi_L|^4 + \frac{\overline{h^2}}{8\pi} = -\frac{H_C^2}{8\pi}\overline{f^4} + \frac{\overline{h^2}}{8\pi} \tag{6-91}$$

By returning to (6-87) we can express h^2 as a function of H, f^2, and f^4. We then eliminate $\mathrm{H}, \mathrm{f}^2, \mathrm{f}^4$ by means of (6-88b), (6-89), and (6-90) to obtain the free energy only as a function of B:

$$F = \frac{B^2}{8\pi} - \frac{(H_{C_2} - B)^2}{1 + (2\kappa^2 - 1)\beta_A}\frac{1}{8\pi} \tag{6-92}$$

Conclusions.

(1) For fixed B, F is an increasing function of β_A (since $\kappa > 1/\sqrt{2}$). The most favorable "lattice" will correspond to the smallest β_A. (Note that from (6-89) $\beta_A \geq 1$.]

The choice of lattice corresponds algebraically to a certain choice of the periodicity conditions satisfied by the C_n 's in Eq. (6-77). Two lattices have been studied in practice: a square lattice of vortex lines is obtained when all C_n 's are taken as being equal; a triangular lattice is obtained with the conditions

$$C_{n+2} = C_n$$
$$C_1 = iC_0$$

(after minimization of β_A with respect to q). It is found that $\beta_A = 1.18$ for the square lattice, and $\beta_A = 1.16$ for the triangular lattice. The latter is thus slightly more stable. The contour diagram of $|\psi|^2$ for the triangular solution is shown on Fig. 3-5, p. 67.
(2) Once β_A is known, the usual thermodynamic calculations can be performed with the free energy (6-92). We can first verify that

$$4\pi \frac{dF}{dB} = H$$

as expected. Then the magnetization $M = (B - H)/4\pi$ can be calculated. M is of order $|\psi|^2$ as expected, and given explicitly by

$$M = \frac{B - H}{4\pi} = \frac{H - H_{c2}}{4\pi\beta_A (2\kappa^2 - 1)}, \quad \frac{H_{c2} - H}{H_{c2}} \ll 1 \tag{6-93}$$

The magnetization vanishes at $H = H_{c_2}$-the transition at $H = H_{c_2}$ is of second order. (However, if κ is only slightly greater than $1/\sim \ddot{2}$, the slope $|dM/dH|$ becomes very large.) A detailed test of Eq. (6-93) has been carried out by Kinsel, Lynton, and Serin on an alloy In Bi with 2.5%Bi, an example of a Type II superconductor with a nearly reversible magnetization curve. The phase diagram deduced from their magnetic measurements on this alloy is shown in Fig. 6-8. From the experimental values of H_{c2} near T_0, one finds

$$\kappa = \frac{1}{\sqrt{2}} \frac{H_{C2}}{H_C} = 1.80$$

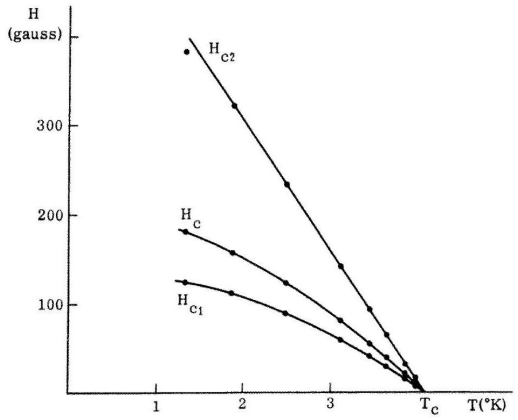

Figure 6-8
The phase diagram of a Type II superconductor (InBi alloy). (After T. Kinsel, E. A. Lynton, and B. Serin, Phys. Letters, 3, 30 (1962).]

From (6-93), taking $\beta_A = 1.16$, one finds from the magnetization curves

$$\kappa = 1.81$$

This very good agreement [7] is further confirmed by a theoretical calculation of κ described later.

Problem.

Show that the wall energy in a Type I superconductor vanishes for $\kappa = 1/\sqrt{2}$.

Solution.

We follow a method due to G. Sarma. By taking the fields h to be along the z direction, we first reduce the Landau-Ginsburg equation to a twodimensional form

$$\frac{1}{2m}\left(n_x^2 + n_y^2\right)\psi + \alpha\psi + \beta|\psi|^2\psi = 0$$

where $\Pi = p - 2eA/c$. By putting $\Pi^{\pm} = \Pi_x \pm i\Pi_y$, we have

$$n_x^2 + n_y^2 = n^- n^+ + \frac{2e\hbar}{c}h$$

We now look for solutions ψ such that

$$\Pi^+\psi = 0$$

For these particular "Sarma solutions" the field h at any point is a known function of the order parameter ψ at the same point, given by

$$\frac{e\hbar}{mc}h + \alpha + \beta|\psi|^2 = 0$$

We must furthermore ensure that the fields and currents associated with the Sarma solution are self-consistent:

$$\begin{aligned}
\operatorname{curl}\mathbf{h} = \frac{4\pi}{\mathrm{c}}\mathbf{j} &= \frac{4}{\mathrm{mc}}\mathbf{e}\left[\psi^*\Pi\psi + \psi\Pi\psi^*\right] \\
\frac{\partial \mathrm{h}}{\partial \mathrm{y}} - \mathrm{i}\frac{\partial\ \mathrm{h}}{\partial \mathrm{x}} &= \frac{4\pi\mathrm{e}}{\mathrm{mc}}\left(\psi^*\Pi^+\psi + \psi\Pi^+\psi^*\right) \\
&= \frac{4\pi\mathrm{e}}{\mathrm{mc}}\psi\Pi^+\psi^*
\end{aligned}$$

This relation must agree with the $h(\psi)$ relation obtained earlier. Differentiation of the $h(\psi)$ relation gives

$$\frac{e\hbar}{mc}\left(\frac{\partial h}{\partial y} - i\frac{\partial h}{\partial x}\right) + \beta\psi^*\left(\frac{\partial\psi}{\partial y} - i\frac{\partial\psi}{\partial x}\right) + \beta\psi\left(\frac{\partial\psi^*}{\partial y} - i\frac{\partial\psi^*}{\partial x}\right) = 0$$

This may be transformed in the following way: The condition $\Pi^+\psi = 0$ may be written as

$$\hbar\left(\frac{\partial\psi}{\partial y} - i\frac{\partial\psi}{\partial x}\right) = \frac{2e}{c}\left(A_x + iA_y\right)\psi$$

from which we obtain

[7] The agreement is even surprising since the experimental magnetization curves are not perfectly reversible, which implies a certain uncertainty in $(\mathrm{dM/dH})^{\mathrm{H_{c_2}}*}$

$$\frac{\partial h}{\partial y} - i\frac{\partial h}{\partial x} = \frac{\beta mc}{e^{\hbar}}\psi\Pi^{+}\psi^{*}$$

This does agree with the equation for the current provided that

$$\frac{4\pi e}{mc} = \frac{\beta mc}{e\hbar^2} \quad \text{or} \quad \kappa = \frac{1}{\sqrt{2}}$$

Consider now more specifically a wall in the yz plane. For $x \to -\infty$ (normal side), $h = H_c$ and $\psi = 0$. For $x \to +\infty$ (superconducting side), $h = 0$ and
$|\psi|^2 = -\alpha/\beta$. These two conditions are in agreement with the $h(\psi)$ relation for the Sarma solution-thus the Sarma solution does apply to the present problem. The thermodynamic potential (per unit area in the yz plane) S is given by

$$S = \int \mathrm{dx}\left[\alpha|\psi|^2 + \frac{1}{2}\beta|\psi|^4 + \frac{1}{2m}|\Pi\psi|^2 + \frac{\mathrm{h}^2}{8\pi} - \frac{\mathrm{hH_c}}{4\pi}\right]$$

The last term is the microscopic analog of the - BH/4π term, the thermodynamic field H being here equal to H_C. Since ψ satisfies the Landau-Ginsburg equation, ρ can be integrated by parts to give

$$\mathrm{s} = \int \mathrm{dx}\left[-\frac{1}{2}\beta|\psi|^4 + \frac{\mathrm{h}^2 - 2\mathrm{H_c\ h}}{8\pi}\right]$$

To obtain the wall energy S_{wall} , we subtract from S the term $\int (H_c^2/8\pi)\, dx$, which corresponds to the potential in the normal (or in the superconducting) phase:

$$\mathrm{S_{wall}} = \int \mathrm{dx}\left[-\frac{1}{2}\beta|\psi|^4 + \frac{(\mathrm{h} - \mathrm{H_c})^2}{8\pi}\right]$$

The $h(\psi)$ relation can be rewritten as

$$\mathrm{h} = \mathrm{H_c} - \frac{\mathrm{mc}}{\mathrm{e}\hbar}\beta|\psi|^2$$

and

$$\frac{(\mathrm{h} - \mathrm{H_c})^2}{8\pi} = \frac{1}{8\pi}\beta^2\left(\frac{\mathrm{mc}}{\mathrm{eh}}\right)^2|\psi|^4 = \frac{1}{2}\beta|\psi|^4 \quad \text{when } \kappa = \frac{1}{\sqrt{2}}$$

Thus $S_{\text{wall}} = 0$ for $\kappa = 1/\sqrt{2}$.
A similar calculation in terms of Sarma solutions can be done for the energy of an isolated vortex line, when $\kappa = 1/\sqrt{2}$. The conclusion there is that the first penetration field $\mathrm{H_{c_1}}$ is equal to $\mathrm{H_c}$. For that particular value of κ, $\mathrm{H_{C_1}}, \mathrm{H_{C2}}$, and $\mathrm{H_C}$ coincide.

REFERENCES

A much more detailed study of the various applications of the Landau-Ginsburg equation is to be published by Saint-James, Sarma, Thomas (Pergamon).

6.4 Microscopic Analysis of the Landau-Ginsburg Equations

6.4.1 7-1 Linearized Self-Consistency Equation

In the preceding chapter we constructed the Landau-Ginsburg equations from a postulated form of the free energy F, which introduces an unknown coefficient [for example, the coefficient

C of (6-7)] giving the energy associated with spatial variations in the order parameter. Gorkov (1959) has shown that it is possible to establish the Landau-Ginsburg equations from the microscopic theory and to calculate in particular the coefficient C. Here we give a simplified version of this calculation.

Δ Treated as a Perturbation

Our starting point will be the self-consistency equation

$$\Delta(r) = V \sum_n v_n^*(r) u_n(r) \left[1 - 2f\left(\epsilon_n\right)\right] \tag{7-1}$$

where u_n and v_n are solutions corresponding to positive eigenvalues of the Bogolubov system

$$\begin{aligned} \epsilon_n u_n &= \left[\frac{1}{2m}\left(p - \frac{e}{c}A\right)^2 + U - E_F\right] u_n + \Delta v_n \\ \epsilon_n v_n &= -\left[\frac{1}{2m}\left(p + \frac{e}{c}A\right)^2 + U - E_F\right] v_n + \Delta^* u_n \end{aligned} \tag{7-2}$$

As usual, the effects of impurities, and so on, are included in U. We expand the right-hand side of (7-1) as a power series in Δ and set

$$\begin{aligned} u_n &= u_n^0 + u_n^1 + \cdots \\ v_n &= v_n^0 + v_n^1 + \cdots \end{aligned} \tag{7-3}$$

From (7-2), we see that u_n^0 and v_n^0 are proportional to the eigenfunctions ϕ_n of one electron in a normal metal, defined by

$$\xi_\mathrm{n}\phi_\mathrm{n} = \left[\frac{1}{2m}\left(\mathrm{p} - \frac{\mathrm{eA}}{\mathrm{c}}\right)^2 + \mathrm{U} - \mathrm{E_F}\right]\phi_\mathrm{n} \tag{7-4}$$

To zeroth order, we have

$$\begin{aligned} u_n^0 &= \phi_n, \quad v_n^0 = 0 \quad (\xi_n > 0) \\ u_n^0 &= 0, \quad\ v_n^0 = \phi_n^* \quad (\xi_n < 0) \end{aligned} \tag{7-5}$$

and $\epsilon_n^0 = |\xi_n|$. Since $u_n^0 v_n^0 = 0$, there is no term of lowest order on the right-hand side of (7-1). In order to determine the first-order corrections u_n^1 and v_n^1, we set

$$\begin{aligned} \mathrm{u_n^1} &= \sum_m \mathrm{e_{nm}}\phi_m \\ \mathrm{v_n^1} &= \sum_m \mathrm{d_{nm}}\phi_m^* \end{aligned} \tag{7-6}$$

If we insert these values into (7-2), multiply the first equation by ϕ_m^*, the second by ϕ_m, and integrate, we find

$$\begin{aligned} \left(|\xi_n| - \xi_m\right) e_{nm} &= \int \Delta(r)\phi_m^*(r) v_n^0(r) dr \\ \left(|\xi_n| + \xi_m\right) d_{nm} &= \int \Delta*(r)\phi_m(r) u_n^0(r) dr \end{aligned} \tag{7-7}$$

As usual, the diagonal terms such as e_{nn} are taken to be zero to preserve the normalization of $\binom{u}{v}$.

We can now insert u_n^1 and v_n^1 defined by (7-6) and (7-7) into the self-consistency equations (7-1). We obtain to first order:

$$\Delta(\mathbf{s}) = \int K(\mathbf{s},\mathbf{r})\Delta(\mathbf{r})d\mathbf{r} \tag{7-8}$$

where

$$\begin{aligned} K(s,r) =& V\sum_{n,m}\left[1-2f\left(|\xi_n|\right)\right] \\ &\times\left[\frac{u_n^{0*}(r)u_n^0(s)}{|\xi_n|+\xi_m}+\frac{v_n^{0*}(s)v_n^0(r)}{|\xi_n|-\xi_m}\right]\phi_m(s)\phi_m^*(r) \end{aligned}$$

u_n^0 is nonzero only for $\xi_n > 0$, while v_n^0 is nonzero for $\xi_n < 0$. Also the function $1-2\mathrm{f}\left(\xi_\mathrm{n}\right) = \tanh\left(\beta\xi_\mathrm{n}/2\right)$ is odd in ξ_n. These remarks enable us to collect the uu and vv terms into one single component. Finally, we can symmetrize the expression with respect to the indices n and m (since it is to be summed over n and m) and obtain

$$\begin{aligned} K(s,r) =& \frac{V}{2}\sum_{nm}\frac{\tanh\left(\frac{\beta\xi_n}{2}\right)+\tanh\left(\frac{\beta\xi_m}{2}\right)}{\xi_n+\xi_m} \\ &\times\phi_n^*(r)\phi_m^*(r)\phi_n(s)\phi_m(s) \end{aligned} \tag{7-9}$$

It is sometimes useful to transform this result in the following manner: Let us write

$$\tanh\frac{\beta\xi}{2} = 2\mathrm{k_B}\ \mathrm{T}\sum_\omega\frac{1}{\xi-\mathrm{i}\hbar\omega} \tag{7-10}$$

where $\hbar\omega = 2\pi k_B T\left(\nu+\frac{1}{2}\right)$ and Σ represents a sum over all positive or negative integers ν. Equation (7-10) can be verified by comparing the poles and residues of both sides of (7-10) in the complex ξ plane. (Also note that we can use either $\pm$i in the denominator of (7-10) since both ω and $-\omega$ contribute.)

Then

$$\begin{aligned} \frac{\tanh\left(\frac{\beta\xi}{2}\right)+\tanh\left(\frac{\beta\xi'}{2}\right)}{\xi+\xi'} &= 2\mathrm{k_B}\ \mathrm{T}\sum_\omega\frac{1}{\xi+\xi'} \\ &\times\left(\frac{1}{\xi-\mathrm{i}\hbar\omega}+\frac{1}{\xi'+\mathrm{i}\hbar\omega}\right) \\ &= 2\mathrm{k_B}\ \mathrm{T}\sum_\omega\frac{1}{\left(\xi-\mathrm{i}\hbar\omega\right)\left(\xi'+\mathrm{i}\hbar\omega\right)} \end{aligned}$$

and

$$K(s,r) = Vk_BT\sum_\omega\sum_{n,m}\frac{\phi_n^*(r)\phi_m^*(r)\phi_n(s)\phi_m(s)}{\left(\xi_n-i\hbar\omega\right)\left(\xi_m+i\hbar\omega\right)} \tag{7-11}$$

Equation (7-8) with the explicit form (7-11) for the kernel constitutes the linearized form of the self-consistency condition (7-7). The enormous advantage over (7-1) is that the functions u and v are eliminated, and $\Delta(r)$ is then the only unknown in (7-8). However we must remember that the linearized form only applies for very small Δ, that is, in the immediate neighborhood of a second-order transition.

Separation of Magnetic Effects

We now assume that the spatial variations in the vector potential are small. Then the eigenfunctions ϕ_n in the normal metal in the presence of A differ from the eigenfunctions w_n in the absence of A by only a phase factor.

$$\phi_n^*(r)\phi_n(s) \to w_n(r)w_n(s)e^{ieA\cdot(s-r)/\hbar c} \tag{7-12}$$

where the w_n are taken to be real. It is easy to verify that (7-12) is compatible with (7-4) and the definition of the w_n if the spatial variations in A are systematically neglected. What is the range of validity of this approximation?
(1) We see later that the range of the kernel K(s, r) in a pure metal is of the order of $\xi_0 = 0.18\hbar v_F/k_B T_0$. The spatial variations in the vector potential must therefore be small on this scale. A condition is thus obtained by requiring the field h to vary slowly, which implies that the penetration depth be large with respect to ξ_0

$$\lambda_{\mathrm{L}}(\mathrm{T}) \gg \xi_0 \tag{7-13}$$

(2) A slow variation of $h = \operatorname{curl} A$ does not guarantee that A varies slowly. Over the distance $|s - r| \sim \xi_0$, A can vary by $\sim \xi_0 h$. This results in an uncertainty in the phase

$$\frac{\mathrm{e}}{\hbar \mathrm{c}}\xi_0\ \mathrm{h}\xi_0 \sim \frac{\hbar\omega_{\mathrm{c}}\mathrm{E_F}}{(\mathrm{k_B}\ \mathrm{T}_0)^2}$$

This must be small compared to one, and we are then led to

$$\frac{(k_B T_0)^2}{E_F} \gg \hbar\omega_c \tag{7-14}$$

where $\omega_c = eh/mc$ is the cyclotron frequency of electrons in the normal metal in the field h. For a bulk, first-kind superconductor, h is at most equal to the thermodynamic field $\mathrm{H_c(T)}$. From Eqs. (6-25) and (6-19) we have, for a pure metal,

$$\mathrm{H_c} \sim \frac{\phi_0}{\kappa\xi_0^2}\frac{\mathrm{T}_0 - \mathrm{T}}{\mathrm{T}_0} \quad (\mathrm{T} - \mathrm{T}_0)$$

where κ is the Landau-Ginsburg parameter and $\phi_n = \mathrm{hc/2e}$ is the quantum of flux. The condition (7-14) then becomes $(T_0 - T)/T_0 < \kappa$. This is less restrictive than condition (7-13) which can be written as $\kappa > [(\mathrm{T}_0 - \mathrm{T})/\mathrm{T}_0]^{1/2}$. For a second-kind superconductor, h is at most of the order of $\mathrm{H_{C_2}} \sim (\phi_0/\xi_0^2)[(\mathrm{T}_0 - \mathrm{T})/\mathrm{T}_0]$ and (7-14) becomes $(\mathrm{T}_0 - \mathrm{T})/\mathrm{T}_0 \ll 1$.
(3) For (7-12) to be correct, it is evident that the radius $R = mcv_F/eh$ of the electronic orbits in the field h must be large with respect to the range of the kernel $K(s, r)$. This requirement assures that all effects related to Landau diamagnetism are negligible. The condition $\mathrm{R} \gg \xi_0$ can also be written

$$\hbar\omega_{\mathrm{c}} \ll \mathrm{k_B}\ \mathrm{T_n} \tag{7-15}$$

again less restrictive than (7-14). We conclude that for pure metals the substitution (7-12) is valid provided that T is close enough to T_n. This, as we shall see, leads directly to the Landau-Ginsburg equations. For "dirty" alloys, we show later that the situation is even more favorable, and that the linear integral equation (7-8) can be replaced at all temperatures by a second-order differential equation of the Landau-Ginsburg form. Finally we are led to

$$\Delta(s) = \int dr K_0(s, r) \exp\left[-\frac{2ie}{\hbar c}A\cdot(s - r)\right]\Delta(r) \tag{7-16}$$

$$K_o(s,r) = Vk_BT \sum_{\omega} \sum_{n,m} \frac{w_n(r)w_m(r)w_n(s)w_m(s)}{(\xi_n - i\hbar\omega)(\xi_m + i\hbar\omega)} \tag{7-17}$$

Infinite Homogeneous Medium

We usually consider the kernel K_n in an infinite homogeneous medium. Then, if this is a pure metal, it is clear that $K_0(s,r)$ depends only on $s-r$. On the contrary, for an alloy, this translational invariance is lost. In this case, the translational invariance is restored by making an additional approximation. In (7-16), the average is taken over all impurity configurations. On the right-hand side of (7-16) appears the average $\overline{K_0(s,r)\Delta(r)}$. We approximate this in the following way:

$$\overline{\mathrm{K_0}(s,r)\Delta(r)} \to \overline{\mathrm{K_0}(s,r)}\,\overline{\Delta(r)} \tag{7-18}$$

Equation (7-18) is not rigorous because it neglects certain distortions of the pair potential in the immediate neighborhood of each impurity. However, detailed calculations (C. Caroli, 1962) have shown that this approximation is reasonable when the impurity potentials can be treated as weak perturbations. We therefore limit our discussion to alloys whose constituents are not too different chemically. Then (7-18) is applicable and the integral equation for $\overline{\Delta(r)}$ can be written completely in terms of the average kernel $\overline{K_0(s,r)}$, which only depends on $\mathbf{s}-\mathbf{r}$.

Relation between K_0 and a Correlation Function

A priori, the product of the four functions $\mathrm{w_n}$ that occurs in (7-17) is rather discouraging. However, it can be shown that this product is related to rather simple physical concepts. Taking, for simplicity, an infinite homogeneous medium, we study the Fourier transform

$$\begin{aligned} K_0(q) &= L^{-3} \int dr ds K_0(s-r) e^{iq\cdot(s-r)} \\ &= VL^{-3}k_BT \sum_{\omega,n,m} \frac{\langle n|e^{iqx}|m\rangle\langle m|e^{-iqx}|n\rangle}{(\xi_n - i\hbar\omega)(\xi_m + i\hbar\omega)} \end{aligned} \tag{7-19}$$

where L^3 is the volume of the sample. We have taken q along the x direction and set

$$\langle n|e^{iqx}|m\rangle = \int w_n(r) e^{iq\cdot r} w_m(r) dr$$

It is useful to first discuss the real function

$$g(q,\Omega) = \sum_m \overline{\langle n|e^{iqx}|m\rangle\langle m|e^{-iqx}|n\rangle}\,\delta(\xi_m - \xi_n - \hbar\Omega) \tag{7-20}$$

sometimes called the spectral density of the one-electron operator e^{iqx}. The symbol represents an average over all states of fixed energy ξ_n (for example, $\xi_\mathrm{n}=0$ corresponds to the Fermi level). In practice, $g(q,\Omega)$ depends strongly on Ω but only slightly on ξ_n and the average will be taken at the Fermi level. If g is known, then $K_n(q)$ is immediately given by

$$K_0(q) = N(0)Vk_BT \sum_{\omega} \int \frac{d\xi d\xi' g\left(q, \frac{\xi-\xi'}{\hbar}\right)}{(\xi - i\hbar\omega)(\xi' + i\hbar\omega)} \tag{7-21}$$

Now $g(q,\Omega)$ has a simple physical significance. Introduce the Heisenberg operator

$$e^{iqx(t)} = \exp\left(i\mathscr{H}_e t/\hbar\right) e^{iqx} \exp\left(-i\mathscr{H}_e t/\hbar\right) \tag{7-22}$$

which describes the evolution of e^{iqx} in time for an electron in the pure normal metal described by the Hamiltonian $\mathscr{H}_e = (p^2/2m) + U(r)$. In terms of the operator $e^{iqx(t)}$, the spectral density takes a very simple form:

$$g(q,\Omega) = \frac{1}{2\pi\hbar}\int dt e^{i\Omega t}\overline{\langle n|e^{-iqx(0)}e^{iqx(t)}|n\rangle} \tag{7-23}$$

Equation (7-23) can be verified by writing explicitly the matrix elements of $e^{iqx(t)}$ between states $|n\rangle$ and $|m\rangle$.

In order to determine g, it is only necessary to determine the correlation function of e^{iqx},

$$\left\langle e^{-iqx(0)}e^{iqx(t)}\right\rangle_{E_F} = \overline{\langle n|e^{-iqx(0)}e^{iqx(t)}|n\rangle} \tag{7-24}$$

for an electron at the Fermi energy in a normal metal.

(1) First for a pure metal, we can assume that at $t = 0$ the electron has abscissa $\mathrm{x_0}$ and velocity $\mathrm{v_F}\cos\theta$ along the x axis (θ is the angle between q and the electron velocity vector).

$$\begin{aligned} e^{-iqx(0)} &= e^{-iqx_0} \\ e^{iqx(t)} &= \exp\left[iq\left(x_0 + v_F t\cos\theta\right)\right] \end{aligned}$$

Thus

$$\left\langle e^{-iqx(0)}e^{iqx(t)}\right\rangle_{E_F} = \frac{1}{2}\int_0^\pi \sin\theta d\theta \exp\left(iqv_F\cos\theta t\right) \tag{7-25}$$

and

$$\begin{aligned} \mathrm{g(q,\Omega)} &= \frac{1}{2\hbar}\int_0^\pi \sin\theta \mathrm{d}\theta\delta\left(\Omega - \mathrm{qv_F}\cos\theta\right) \\ &= \begin{cases} \left(2\mathrm{qv_F}\hbar\right)^{-1} & |\Omega| < \mathrm{qv_F} \\ 0 & |\Omega| > \mathrm{qv_F} \end{cases} \end{aligned} \tag{7-26}$$

(2) For an impure metal where the mean free path ℓ is small compared to the wavelength studied $q^{-1}, e^{iqx(t)}$ is controlled by a diffusion (random walk) process. If $D = v_F\ell/3$ is the diffusion coefficient, we have

$$\begin{aligned} &\left\langle e^{-iqx(0)}e^{iqx(t)}\right\rangle_{E_F} = e^{-Dq^2|t|} \quad q\ell \ll 1 \\ &g(q,\Omega) = \frac{1}{\pi\hbar}\frac{Dq^2}{\Omega^2 + D^2q^4} \end{aligned} \tag{7-27}$$

Explicit Calculation of the Kernel $\mathrm{K_0}$

Using the forms (7-26) and (7-27) for $\mathrm{g(q,\Omega)}$, one can explicitly calculate the kernel $\mathrm{K_0(q)}$ from (7-21). The variables of integration are taken to be ξ and $\hbar\Omega = \xi' - \xi$ and the first integration is performed by the theory of residues over ξ. For the pure metal, one finds

$$\begin{aligned} \mathrm{K_0(q)} &= \frac{\mathrm{N(0)Vk_B\ T}\pi}{\mathrm{qv_F}^{\mathrm{h}}} \sum_{\omega} \int_{-\mathrm{qv_F}}^{\mathrm{qv_F}} \frac{\mathrm{d}\Omega}{2\omega - \mathrm{i}\Omega} \\ &= \frac{2\pi\ \mathrm{N(0)Vk_B\ T}}{\hbar_{\mathrm{qv}}} \sum_{\omega} \tan^{-1}\left(\frac{\mathrm{qv_F}}{2|\omega|}\right) \end{aligned} \tag{7-28a}$$

and for the impure metal

$$\begin{aligned} \mathrm{K_0(q)} &= \mathrm{N(0)Vk_B\ T}\frac{2\mathrm{i}}{\hbar} \sum_{\omega} \int \mathrm{d}\Omega \frac{\mathrm{Dq}^2}{\left(\mathrm{Dq}^2 + \mathrm{i}\Omega\right)(2\mathrm{i}\omega + \Omega)} \\ &= \frac{\mathrm{N(0)Vk_B\ T}}{\hbar} \sum_{\omega} \frac{1}{\mathrm{Dq}^2 + 2|\omega|} \quad (\mathrm{q}\ell \ll 1) \end{aligned} \tag{7-28b}$$

Discussion of these results

(1) Precautions related to the frequency cut-off in the interaction V. Until now we have neglected the fact that the interaction V in the BCS approximation only couples those states of energy $|\xi| < \hbar\omega_D$. This causes the sums in (7-28) to diverge. However, this is easily remedied by writing

$$K_0(q) = K_0(0) + [K_0(q) - K_0(0)] \tag{7-29}$$

The only divergent term is $K_0(0)$, which can be calculated directly from (7-9).

$$\begin{aligned} K_0(0) &= V \sum_n \frac{\tanh(\beta\xi/2)\,|w_n(r)|^2}{2\xi_n} \\ &= N(0)V \int_{-\hbar\omega_D}^{\hbar\omega_D} \frac{d\xi}{2\xi} \tanh\left(\frac{\beta\xi}{2}\right) \\ &= N(0)V \ln\frac{1.14\hbar\omega_D}{k_B T} \end{aligned} \tag{7-30}$$

where the s integration was performed by using the orthogonality of the function $w_n(s)$.[1]
(2) Spatial form of the kernel K_0. On taking the inverse Fourier transform of (7-28), we find

$$K_0(8,r) = K_0(R) = \begin{cases} \frac{N(0)Vk_BT}{2\hbar D} \sum_\omega \frac{1}{R} \exp\left\{-(2|\omega|/D)^{1/2}R\right\} & (R \gg \ell) \\ \frac{N(0)Vk_BT}{2\hbar v_F} \sum_\omega \frac{1}{R^2} \exp\left\{(-2|\omega|R)/v_F\right\} & (R \ll l) \end{cases} \tag{7-31b}$$

$$R = s - r$$

For R $\neq 0$, the sums converge. It is particularly interesting to study the asymptotic form of $K_0(R)$ at large distances. The only important terms are then $\hbar\omega = \pm\pi k_B T\ (\simeq \pm\pi k_B T_0)$. Then we find for $T = T_0$

[1] We had already obtained the result (7-30) in the simpler case of an infinite homogeneous medium without fields or currents where we predicted that $\Delta(r)$ is constant in space. Then the linearized self-consistency equation is simply written $\Delta = K_0(0)\Delta$. This has a nonzero solution only if $K_0(0) = 1$. This condition gives the temperature T_0 at which a nonzero order parameter can appear, that is, the transition temperature.

$$\frac{K_0(R)}{N(0)V} = \frac{k_B T_0}{2\hbar v_F}\frac{1}{R^2}\exp\left[-\frac{2\pi k_B T_0 R}{\hbar v_F}\right] = \frac{k_B T_0}{2\hbar v_F}\frac{1}{R^2}\exp\left(-1.13R/\xi_0\right)$$
$$= \frac{k_B T_0}{\hbar D}\frac{1}{R}\exp\left[-\left(\frac{6\pi k_B T_0}{v_F \ell}\right)^{1/2} R\right] \tag{7-32a}$$
$$= \frac{k_B T_0}{\hbar D R}\exp\left(-1.8R/\sqrt{\xi_0 \ell}\right)$$

Conclusion. For a pure metal and $T \sim T_0$, the range of $K_0(R)$ is of the order of $\xi_0 = 0.18\hbar v_{\mathrm{F}}/\mathrm{kT}_0$ as we previously stated. On the contrary when ℓ is small, (7-32b) gives a range $\sqrt{\xi_n \ell}$. The range of validity of (7-32b) is limited by $\mathrm{R} \gg \ell$, which implies $(\xi_0 \ell)^{1/2} \gg \ell$ or

$$\xi_0 \gg \ell \quad \text{(dirty metal)} \tag{7-33}$$

[When (7-33) is satisfied, the alloy is said to be dirty following the terminology introduced by Anderson.) If the matrix is a nontransition metal, ξ_0 is generally high (for example, $\xi_0 = 16 \times 10^3$Å for Al), and a small fraction of impurities (10^{-3}) is sufficient to make the metal dirty.

It is interesting to compare K_0 with the kernel $S_{\mu\nu}$, studied in Chapter 5, which gives the current responds of a superconductor in the presence of a vector potential A . We have seen that in a dirty alloy the range of $S_{\mu\nu}$ is ℓ, but the range of K_0 is $\sqrt{\xi_0 \ell}$. What is the reason for this difference?

Answer. The kernels $\mathrm{S}_{\mu\nu}$ and K_0 can both be expressed as average one-electron correlation functions in a normal metal in the absence of fields:

$$S_{\mu\nu} = \frac{1}{4}\int d\xi d\xi' \int \frac{dt}{2\pi} L\left(\xi, \xi'\right) e^{i(\xi-\xi')t/\hbar} \left\langle j_\mu\left(r_1, 0\right) j_\nu\left(r_2, t\right)\right\rangle_{E_F}$$
$$K_0 = \frac{1}{2} N(0) V \int d\xi d\xi' \left[\frac{\tanh(\beta\xi/2) + \tanh\left(\beta\xi'/2\right)}{\xi + \xi'}\right] \tag{7-34}$$
$$\times \int \frac{dt}{2\pi} e^{i(\xi-\xi')t/\hbar} \left\langle \delta\left(r(0) - r_1\right) \delta\left(r(t) - r_2\right)\right\rangle_F \tag{7-35}$$

where $\langle j_\mu j_\nu \rangle$ is a transverse current correlation function and $\langle \delta\delta \rangle$ is a density correlation function. Equations (7-34) and (7-35) can easily be verified by explicitly calculating the matrix elements that appear in products such as $\mathrm{j}_\mu \mathrm{j}_\nu$.

For $\mathrm{T} \sim \mathrm{T}_0$, the integrations over ξ and ξ' in (7-34) and (7-35) limit the useful interval to $t \sim h/k_B T_0$. If there are no collisions, the distance traveled by an electron in the time t is $v_F t \sim \xi_0$. Then both $S_{\mu\nu}$ and K_0 have the range ξ_0. If the alloy is dirty, the velocity correlation function falls to zero after the electron travels a distance ℓ: the range of $S_{\mu\nu}$ is ℓ. However the density correlation function is not destroyed by a collision. It obeys a diffusion equation. The average distance traveled in time t is $v\overline{Dt}$, where D is the diffusion coefficient $\mathrm{D} = \frac{1}{3}\mathrm{v}_{\mathrm{F}}\ell$. Thus the range of the kernel K_0 becomes $\sqrt{\mathrm{Dt}} \sim \sqrt{\xi_0 \ell}$.

6.4.2 7-2 Landau-Ginsburg Equations

Addition of Nonlinear Terms to the Self-Consistency Equations

The linearized self-consistency equation (7-8) for the pair potential applies when Δ is infinitesimal, that is, at the transition point (provided that the transition of interest is of second order, that is, Δ goes to 0 continuously when the temperature is raised). Call T^* the highest temperature for which (7-8) has a nonzero solution $\Delta(r)$.T^* is the ordering temperature in the

conditions of the experiment: For instance, in a bulk Type II material, if we impose an external field H, T^* is such that $H_{c_2}(T^*) = H$. Later in this section we make extended use of this property. For the present time, our aim is slightly different. We want to extend our analysis to temperatures (slightly) below T*. Then, it is not sufficient to consider only a first-order approximation in Δ in the right-hand side of (7-1). To extend the calculation, u and v must be calculated to higher order in Δ. The result is of the form

$$\begin{aligned}\Delta(s) = &\int K_0(s,r)e^{-[2ieA\cdot(s-r)]/\hbar c}\Delta(r)dr \\ &+ \int R(s,r,\ell,m)\Delta^*(r)\Delta(\ell)\Delta(m)drd\ell dm \end{aligned} \tag{7-36}$$

Notice in particular that there are no terms of order Δ^2. The kernel $R(s,r,\ell,m)$ can be calculated but its only important property to remember is that in a pure metal its range is of the order of ξ_0. The only contributions to the integral $drd\ell dm$ come from regions where the three points r, ℓ, m are simultaneously near s. In an alloy, the ranges are further reduced. These remarks allow us to avoid a complete calculation of the kernel R.

Hypothesis of Slow Variation

We now assume that quantities such as $\Delta(r)e^{[2ieA\cdot(r-s)]/\hbar c}$ vary slowly with respect to the range of K_0 or of R. This restriction defines the Landau-Ginsburg domain. We can then expand $\Delta(r)$ in a Taylor series about the point s:

$$\begin{aligned}\Delta(r)e^{-2i\phi(r)} =&\Delta(s)e^{-2i\phi(s)} + (r-s)\cdot\nabla\left(\Delta e^{-2i\phi}\right) \\ &+ \frac{1}{2}\sum_{\alpha\beta}(r-s)_\alpha(r-s)_\beta\frac{\partial^2}{\partial r_\alpha \partial r_\beta}\left(\Delta e^{-2i\phi}\right)\end{aligned}$$

where we have introduced the phase parameter

$$\phi_S(r) = e[A(s)\cdot r]/\hbar c$$

By performing the differentiations, we get

$$\begin{aligned}\Delta(r)e^{-2i\phi(r)} =&e^{-2i\phi(s)}\left\{\Delta(s) + \sum_\alpha (r-s)_\alpha\delta_\alpha\Delta\right. \\ &\left. + \frac{1}{2}\sum_{\alpha\beta}(r-s)_\alpha(r-s)_\beta\delta_\alpha\delta_\beta\Delta\right\} \\ \delta_\alpha =&\frac{\partial}{\partial s_\alpha} - \frac{2ieA_\alpha(s)}{\hbar c}\end{aligned} \tag{7-37}$$

We insert the expansion (7-37) into the linear part of (7-36). For the correction term of order Δ^3 in Eq. (7-36), it will be sufficiently accurate to neglect completely the spatial variations of Δ, and to set $\Delta(r) = \Delta(\ell) = \Delta(m) = \Delta(s)$. Finally, in an infinite, homogeneous metal, terms such as $\int K_0(r,s)(r-s)dr$ vanish by symmetry. This finally gives

$$\Delta(s) = Q\Delta(s) + \frac{1}{2}\sum_{\alpha,\beta} L_{\alpha\beta}\delta_\alpha\delta_\beta\Delta(s) + R|\Delta(s)|^2\Delta(s) \tag{7-38}$$

$$\begin{aligned} Q &= \int K_0(s,r)dr \\ L_{\alpha\beta} &= \int K_0(s,r)\,(s_\alpha - r_\alpha)\,(s_\beta - r_\beta)\,dr \\ R &= \int R(s,r,\ell,m)drd\ell dm \end{aligned} \tag{7-39}$$

For a cubic crystal ($L_{\alpha\beta} = L\delta_{\alpha\beta}$), Eq. (7-38) has exactly the form predicted by Landau and Ginsburg (6-11). The coefficients Q, L, R introduced here are related to the coefficients A, B, C in (6-7) by

$$\frac{-Q+1}{A} = \frac{R}{B} = \frac{1}{2}\frac{L}{C} \tag{7-40}$$

Discussion of the Coefficients

We have already determined A and B for the case $A = 0, \Delta = \text{const}$ (6-3). Numerical values for Q and R can also be found by the same method. We know that for $\mathrm{A} = 0, \Delta = \text{const}$, and the complete self-consistency equation (7-1) reduces to

$$\begin{aligned} \Delta &= \mathrm{N(0)V}\int_0^{\mathrm{h}\omega} \mathrm{D}\Delta\frac{\tanh(\beta\epsilon/2)}{\epsilon}\mathrm{d}\xi \\ \epsilon &= \left(\xi^2 + \Delta^2\right)^{1/2} \end{aligned} \tag{7-41}$$

Anderson's theorem (Chapter 5) shows that (7-41) is valid for an alloy as well as for a pure metal. Expanding the right-hand side as a power series in Δ and performing the integration, we find

$$\begin{aligned} \mathrm{Q} &= \mathrm{N(0)V}\left[\ln\frac{1.14\hbar\omega_\mathrm{D}}{\mathrm{k_B\ T}}\right] \sim 1 + \mathrm{N(0)V}\frac{\mathrm{T_0 - T}}{\mathrm{T_0}} \\ \mathrm{R} &= -0.1066\frac{\mathrm{N(0)V}}{(\mathrm{k_B\ T_0})^2} \end{aligned} \tag{7-42}$$

The most interesting coefficient is L. which describes the effects of spatial variations of Δ. From the explicit form of the kernel $K_0(7-31)$, we find for a pure metal

$$\begin{aligned} L &= \frac{\pi}{6}N(0)Vv_F^2k_BT_0\sum_\omega\frac{1}{|\omega|^3} \\ &= 0.033N(0)V\left(\frac{\hbar v_F}{k_BT_0}\right)^2 \end{aligned} \tag{7-43a}$$

and for a dirty metal ($\ell \ll \xi_0$)

$$\begin{aligned} L &= \pi N(0)VD\frac{k_BT_0}{\hbar}\sum_\omega\frac{1}{|\omega|^2} \\ &= \frac{\pi}{12}N(0)V\frac{\hbar v_F\ell}{k_BT_0} \end{aligned} \tag{7-43b}$$

(The sum $\Sigma_\omega 1/|\omega|^3$ must be evaluated numerically while $\Sigma_\omega 1/|\omega|^2$ determined by differentiating (7-10) with respect to ξ and then setting ξ equal to zero.) These results can be expressed in various ways:
(1) The coefficient C of the free energy (6-7) becomes

$$C = \frac{L}{2}\frac{A}{1-Q} = \frac{1}{2}\frac{L}{V} \tag{7-44}$$

(2) The characteristic length $\xi(T)$ that appears in the Landau-Ginsburg equation in the absence of a field is obtained by comparing (6-17) to (6-8)

$$\xi(\mathrm{T}) = \left[\frac{\mathrm{L}}{2(\mathrm{Q}-1)}\right]^{1/2} \tag{7-45}$$

It diverges as $[T_0/(T_0 - T)]^{1/2}$ as predicted in (6-19).
(3) The Landau-Ginsburg parameter κ is given by Eq. (6-26)

$$\kappa = \frac{1}{4}\left(\frac{\mathrm{B}}{2\pi}\right)^{1/2}\frac{\hbar \mathrm{c}}{\mathrm{eC}} \tag{7-46}$$

For a pure metal, this formula leads to the previous result $\kappa = 0.96\lambda_{\mathrm{L}}(0)/\xi_0$. For a dirty metal, we have

$$\kappa = 0.75\frac{\lambda_L(0)}{\ell} \tag{7-47}$$

where $\lambda_L(0) = (mc^2/4\pi ne^2)^{1/2}$ is the London penetration depth in the pure metal at absolute 0 .

This result can be expressed in another way that involves directly measurable quantities in the normal state instead of ℓ and λ_L. The mean free path ℓ is related to the resistivity ρ by the equation [2]

$$\rho^{-1} = 2e^2N(0)D = \frac{2}{3}N(0)e^2v_F\ell \tag{7-48}$$

The Lodon penetration depth is given by [3]

$$\lambda_L(0) = \left(\frac{3c^2}{8\pi N(0)v_F^2e^2}\right)^{1/2} \tag{7-49}$$

Finally, N(0) can be expressed as a function of the electronic specific heat at low temperatures C_e (per cm^3):

$$\mathrm{C_e} = \gamma \mathrm{T}$$
$$\gamma = \frac{2\pi^3}{3}\,\mathrm{N(0)k_B^2}$$

Finally this gives

$$\frac{\lambda_{\mathrm{L}}(0)}{\ell} = \frac{1}{2\pi\sqrt{\pi}}\frac{\mathrm{ce}}{\mathrm{k_B}}\rho\gamma^{1/2} \tag{7-50}$$

If ρ is expressed in ohm.cm instead of cgs units, we find

[2] Proof of (7-48): In the normal state, the current j is given by $j = -eD\nabla n + E/\rho$ where n is the number of electrons per cm^3. At equilibrium, $n = n_0$ 2 N(0)eV where V is the potential such that $\mathrm{E} = \nabla \mathrm{V}$. On setting $\mathrm{j} = 0$ we obtain (7-48).

$$\kappa = 7.5 \times 10^3 \rho\gamma^{1/2} \quad (\xi_0 \gg \ell) \tag{7-51}$$

Remarks about Dirty Alloys.

(1) From (7-47), κ only depends on ℓ, that is, the transport properties of the alloy in the normal state.
(2) If the pure metal is a superconductor of the first kind ($\kappa_{\text{pure}} \ll 1$), then the alloy is of the second type ($\kappa > 1/\sqrt{2}$) when ℓ is less than a critical value $\ell_c = 1.06\lambda_L(0)$. This law has been verified by Seraphim for various impurities in indium. The critical concentrations vary a great deal according to the impurity used (0.8% for Bi, 7% for Tl). However, the value of ℓ_c is nearly independent of the nature of the impurity $\ell_C = 440 \pm 100$Å for Bi, Pb, Su, Cd, Tl, Hg). (The London penetration depth $\lambda_L(0)$ of indium is estimated to be 400Å.
(3) For the alloy InBi (2.5%Bi), studied by Kinsel, Lynton, and Serin, the magnetic measurements give $\kappa = 1.79$. The theoretical value deduced from $(7-51)$ is of the order of 1.7.

Table 7-1
Characteristic Lengths

	Pure Metal
Range of the kernel $S_{\mu\gamma}$ (relation between current and vector potential)	$\xi_0 = 0.18\frac{\hbar v_F}{k_B T_0}$
Range of the kernel K_0 Iself-consistency equation for $\Delta(r)$]	$\sim 5_0$
Scale of the spatial variations of $\lvert\Delta\rvert$ in the Landau-Ginsburg domain	$\xi(T) = 0.74\xi_0 \left(\frac{T_0}{T_0 - T}\right)^{L/2}$
Penetration depth in the Landau-Ginsburg domain	$\lambda(T) = \frac{1}{\sqrt{2}}\lambda_L(0) \left(\frac{T_0}{T_0 - T}\right)^{1/2}$

Final Remarks.

Our discussion has only dealt with the first Landau-Ginsburg equation (6-11), that is, the self-consistency equation for $\Delta(r)$ lor $\psi(r)$]. In order to complete the microscopic analysis, it is also necessary to calculate the current $f(r)$ at each point and show that it is given by a formula of the type (6-12). This calculation is performed just as the preceding one, by expressing $j(r)$ as a function of the Bogolubov u's and v's, and then calculating j to second order in Δ. We do not do this here since it is very analogous to the preceding calculation and gives no new information. The three coefficients A, B, C of the free energy (6-7) have already been determined. We could also have directly treated the free energy itself. All these approaches are equivalent. We chose to discuss the self-consistency equation for Δ, in view of other applications to be discussed later.

Problem.

Construct a Landau-Ginsburg equation for a thin film ($d \ll \xi_0$) with diffuse reflection at the boundaries of the film.

Solution.

In general, there is no solution. No Landau-Ginsburg equation applies to all cases. For instance the effective κ would depend on the angle between the magnetic field and the film

[3] Proof of (7-49): In the presence of a static vector potential A, the entire Fermi surface is displaced by a momentum $\delta p = eA/c$. The corresponding current is $\mathbf{j} = e\Sigma l\,(\partial f/\partial_p)\cdot\delta p|v_p$ where f is the distribution function. This gives $j = -A\left(2e^2/3c\right)N(0)v_F^2$ and thus $(7-49)$.

plane. Even more seriously, it may depend on the ratio d/λ(T) which is strongly temperature dependent.

However, in one case we can construct a well-defined (two-dimensional) Landau-Ginsburg equation. We need two conditions: (1) The amplitude of Δ must be constant in the film thickness. This will be true when d $< \xi_0$, and implies

$$\left(\frac{\partial}{\partial z} - \frac{2ie}{\hbar c}A_z\right)\Delta \to 0$$

(z is the direction normal to the film). (2) The variations of A in the film thickness are negligible. This requires that the field be normal to the film plane, and also that the film be thinner than some effective penetration depth (we come back to that condition later).

On the other hand, Δ and A shall be allowed to vary slowly in the plane of the film (xy plane). The free energy is then of the form

$$\mathrm{F} = \mathrm{A}|\Delta|^2 + \frac{\mathrm{B}}{2}|\Delta|^4 + \mathrm{C}\left\{\left|\left(\frac{\partial}{\partial \mathrm{x}} - \frac{2\mathrm{ie}}{\hbar \mathrm{c}}\ \mathrm{A_x}\right)\Delta\right|^2 + \left(\frac{\partial}{\partial \mathrm{y}} - \frac{2\mathrm{ie}}{\hbar \mathrm{c}}\ \mathrm{A_y}\right)\Delta\right|^2\right\}$$

In order to determine C, we start from the linearized self-consistency equation (7-16) and study the Fourier transform $K_0(q)$ of the kernel, where q is a vector in the xy plane. When d is small ($d \ll \xi_0$), most of the electrons experience several collisions with the walls during the time interval $\hbar/k_B T_0$ and the function $g(q, \Omega)$ is governed by a diffusion equation just as for a dirty superconductor. [4] The calculations are quite analogous to those giving rise to (7-43) and (7-44) and give

$$\mathrm{C} = \frac{\pi}{8}\ \mathrm{N}(0)\frac{\mathrm{hD}}{\mathrm{k_B}\ \mathrm{T_0}}$$

The diffusion coefficient D is no longer equal to $\frac{1}{3}v_F\ell$ but rather of the order of $v_F d$. The coefficient D can be related to the experimental conductivity $\bar{\sigma}$ of the film in the normal state by means of (7-48)

$$\bar{\sigma} = 2e^2 N(0) D$$
$$C = \frac{\pi}{16}\frac{\hbar\bar{\sigma}}{2k_B T_0}$$

Detailed calculations of $\bar{\sigma}$ can be found for instance in the book by Olsen, Electron Transport in Metals (New York: Interscience, 1962), p. 80. In practice of course it is better to extract $\bar{\sigma}$ from a measurement in the normal state on the same film.

Discussion.

(1) The order of magnitude of $\bar{\sigma}$ is $ne^2 d/mv_F$. Thus $C \sim N(0)\xi_0 d$ and $\kappa \sim \lambda_L(0)/d$.
(2) Once C is determined, we can write the equation for the current - in the x direction

$$\mathrm{j_X} = \frac{2\mathrm{eC}}{\mathrm{i}\hbar}\left(\Delta^*\frac{\partial\Delta}{\partial \mathrm{x}} - \Delta\frac{\partial\Delta^*}{\partial \mathrm{x}}\right) - \frac{8\mathrm{e}^2\mathrm{C}}{\hbar \mathrm{c}}\ \mathrm{A_X}$$

[4] There are a few electrons whose velocity is just in the plane of the film and which thus suffer no collisions. One can take account of them exactly. For simplification we here assume that there also exist volume impurities and therefore a bulk mean free path $\ell \lesssim \xi_0$ (but $\ell >$ d). Under this condition there is no significant contribution from these "anomalous electrons."

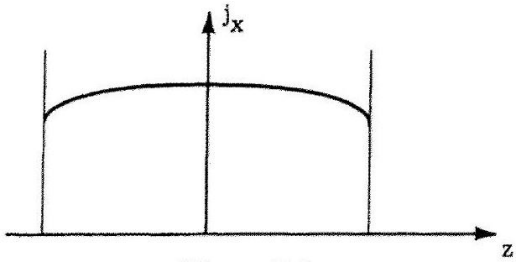

Figure 7-1
Current distribution across a thin film ($d < \xi_0$) with diffuse reflection at the surface.

However it is important to realize that, even if d is small, the current distribution $j_X(z)$ throughout the thickness of the film is not uniform (Fig. 7-1). The current j_X given by the preceding formula is just the average of j_X over the thickness.
(3) Although j is not independent of z, A is to a good approximation independent of z: using the relation $\partial^2 A_X/\partial z^2 = (4\pi/c)j_X$, it is easy to show that, when A_X is an even function of z, the relative variations of A_X through the thickness are of the order $d^3/\xi_0\lambda^2 \ll 1$.

6.4.3 7-3 Surface Problems in the Landau-Ginsburg Region

Boundary Conditions at an Interface

In the preceding section we have reconstructed the Landau-Ginsburg equations from the microscopic theory, for an infinite homogeneous medium. We shall now consider a superconducting specimen occupying the half-space $x > 0$. The region $x < 0$ is either an insulator or normal metal. In all cases, we shall assume that there is no current flowing through the boundary. [5]

Over a width ξ_0 at the surface, [6] $K_0(r, r')$ and $S_{\mu\nu}(r, r')$ are modified. On the microscopic scale it is necessary to calculate these modifications and then to determine the spatial distribution of the currents j and of the pair potential Δ in the perturbed layer. The result of such calculations is represented in (Fig. 7-2a) for Δ. On the other hand, on the Landau-Ginsburg scale [lengths of the order of $\xi(T), \lambda(T) \gg \xi_0$] the effect of the surface can be simply described by means of a boundary condition for $x = 0$ (Fig. 7-2b). What will be the form of this

[5] When normal currents and supercurrents coexist, the implied dissipative effects must be calculated by a dynamic equation more general than the Lan-dau-Ginsburg equations.
[6] We quote here the orders of magnitude that apply for a pure metal. In a dirty alloy, of course, the "transition width" would decrease to $\sqrt{\xi_0 l}$.

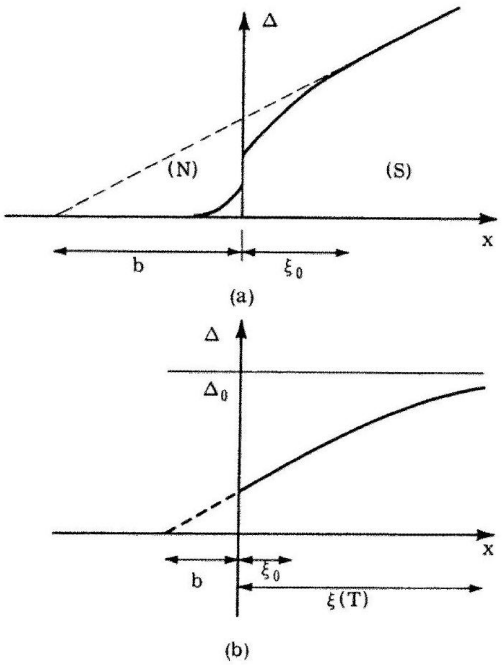

Figure 7-2
(a) The microscopic variation of the order parameter near a superconducting-normal metal boundary. (b) "Macroscopic" description of the same situation, at temperatures where $\xi(T) \gg b$.

condition? Let us first consider the case A = 0, Δ = real. The exact boundary condition will be of the form

$$\left(\frac{d\Delta}{dx}\right)_{x=0} = \frac{1}{b}\Delta_{x=0} + \frac{1}{c}\frac{\Delta^3_{x=0}}{(k_B T_0)^2} + \cdots \tag{7-52}$$

Justification of (7-52):
(1) From the general form of the self-consistency equation, only the odd powers of Δ occur in the expansion. Also the lengths b, c, and so on, are real.
(2) Higher derivatives do not occur in (7-52) because they can be expressed in terms of the first and zeroth derivatives by the Landau-Ginsburg equations.
(3) We expect nonlinear effects to become important when $\Delta \sim k_B T_0$. Thus the quantities $1/b, 1/c$, and so on, are of the same order

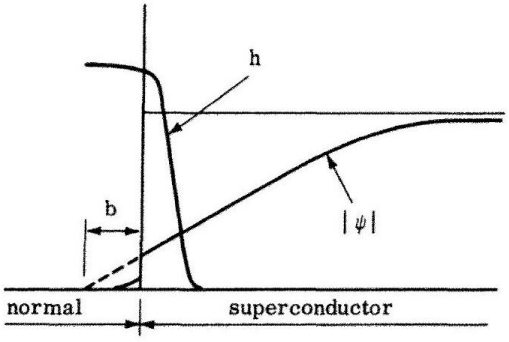

Figure 7-3
The magnetic field distribution at a normal-superconducting boundary.

of magnitude ($\sim 1/\xi_0$). The Δ^3 term in (7-52), smaller than the Δ term by $\sim (\Delta/k_B T_0)^2 \ll 1$, can be neglected. In the Landau-Ginsburg region, the boundary condition is linear, and the coefficient b can be obtained by solving the linearized self-consistency equation (7-8) in the neighborhood of the surface (for $T = T_0, A = 0$). In the presence of a magnetic field, we write, instead of (7-52),

$$\left(\frac{\mathrm{d}\Delta}{\mathrm{dx}} - \frac{2\mathrm{ie}}{\hbar\mathrm{c}}\,\mathrm{A_x}\Delta\right)_{\mathrm{x=0}} = \frac{(\Delta)_{\mathrm{x=0}}}{\mathrm{b}} \tag{7-53}$$

The form of (7-53) assures the gauge invariance dictated by the general formulas of Chapter 5. In (7-53), Δ may be replaced by ψ to which it is proportional. Using (7-53), it is easy to verify that for real b, the current (6-12) crossing the boundary is zero, as desired.

Contact between Superconductor and Insulator (or Vacuum)

We shall now show that $1/b$ is very small when the boundary separates the superconductor from an insulator. The equation to be solved (for A = 0 and T = $\mathrm{T_0}$) is

$$\Delta(s) = \int K_0(s,r)\Delta(r)dr \tag{7-54}$$

$K_0(s,r)$ is defined by (7-17) and therefore $\Delta(s)$ contains in particular a product of two functions $w_n(s)$ and $w_m(s)$, which decrease expotentially in the insulating region. Therefore $\Delta(s)$ vanishes rapidly for $\mathrm{s_x} < 0$.

On the other hand, for $s_x > \xi_0, \Delta(s)$ will have a linear form, [7]

$$\Delta(s) = \Delta_0\left(1 + \frac{s_X}{b}\right) \quad (s_X > \xi_0) \tag{7-55}$$

Proof of (7-55):
For $s_x, r_x > \xi_0$, the kernel $K_0(s,r)$ becomes identical to the kernel $K_p(s-r)$ in the bulk metal. For $T = T_0$, any linear function of the type (7-55) is a solution of $\Delta(s) = \int K_p(s-r)\Delta(r)dr$ because $\int K_p dr = 1$ and $\int K_p(s-r)[\Delta(r) - \Delta(s)]dr$ vanishes by symmetry.

In order to determine the length b in which we are interested, (7-54) is rewritten in the form

$$\begin{aligned}\Delta(s) - \int K_p(r-s)\Delta(r)dr &= \int \left[K_0(s,r) - K_p(r-s)\right]\Delta(r)dr \\ &= -H(s)\end{aligned} \tag{7-56}$$

The function H(s) vanishes for $\mathrm{s_x} > \xi_0$ (because $\mathrm{K_0} \to \mathrm{K_p}$) and also vanishes for $s_x < -\xi_0$ because $\Delta(r)$ is zero for $r_x < 0$ and the range of K_p is ξ_0. The advantage of (7-56) is that a localized perturbation appears on the right. For the moment we assume H(s) as known and solve for Δ by a Laplace transformation

$$\begin{aligned}\Delta(p) &= \int \Delta\left(s_X\right)\exp\left(-ps_X\right)ds \\ H(p) &= \int H\left(s_X\right)\exp\left(-ps_X\right)ds \\ K_p(p) &= \int K_p(r)\exp\left(-pr_X\right)dr \\ &= 1 + \frac{p^2}{2}L\cdots\end{aligned} \tag{7-57}$$

where $L = \int K_p(r)r_X^2 dr$ is given explicitly by (7-39). The transform of (7-56) is

[7] The linear dependence (7-55) might seem physically absurd since it leads to very large Δ 's at large distances from the boundary. In fact, when T is slightly below $\mathrm{T_0}$, the correct Δ(x) has a negative curvature and reaches the BCS values deep in the superconductor $[x > \xi(T)]$. But here we are interested in $x \sim \xi_0 \ll \xi(T)$ and the curvature is negligible.

$$\Delta(p)\left[1-K_p(p)\right]=-H(p) \tag{7-58}$$

Taking the limit $p \to 0$, from (7-57)

$$-\frac{L}{2}p^2\Delta(p) \to -H(0) = -\int H\left(s_X\right) ds$$

As $p \to 0$, the dominant term in (7-55) is the linear part,

$$\Delta(p) - \frac{\Delta_0}{b}\int_0^\infty s_X \exp\left(-ps_X\right) ds = \frac{\Delta_0 \Sigma}{bp^2} \tag{7-59}$$

where Σ is the surface area of the boundary. Combining (7-58) and (7-59), we find

$$\frac{1}{b} = \frac{2}{L\Sigma\Delta_0}\int H\left(s_X\right) ds = \frac{2}{L\Sigma\Delta_0}\int \left[K_p(s-r) - K_0(s,r)\right] \times \Delta(r) dr ds \tag{7-60}$$

In order to simplify (7-60), we shall assume that the interaction V is constant. Then $\int K_0(r,s)$ ds can be integrated by using the orthogonality of the functions $w_n(s)$ and we find

$$\int K_0(r,s) ds = N(r) V \ln \frac{1.14\hbar\omega_D}{k_B T_0} = \frac{N(r)}{N(0)} \tag{7-61}$$

where $N(r) = \Sigma_n \left|w_n(r)\right|^2 \delta\left(\xi_n\right)$ is the local density of states at the Fermi surface and $N(0)$ is its usual value for the bulk metal. Finally

$$\frac{1}{b} = \frac{2}{L}\int_{-\infty}^{\infty} dx \frac{\Delta(x)}{\Delta_0}\left[1 - \frac{N(x)}{N(0)}\right] \tag{7-62}$$

where $\Delta(x)/\Delta_0$ approaches zero in the insulating region and is of the order of 1 in the metallic region. $N(x)/N(0)$ passes from $0 \to 1$ in a few interatomic distances and the integrand is nonvanishing only in a width of order of the interatomic distance a. The effective distance b is given by

$$b \sim \frac{L}{a} \tag{7-63}$$

This is generally enormous: for a pure metal L $\sim \xi_0^2$ with $\xi_0 = 10^{-4}$ cm, which gives b ~ 1 cm. Therefore for a boundary separating
a superconductor from an insulator we can set $1/b = 0$. This leads to the boundary condition (6-13). More precisely, the criterion for the validity of (6-13) is that b $\gg \xi$(T), which is equivalent to $a/\xi_0 \ll \left[\left(T_0 - T\right)/T_0\right]^{1/2}$ [8]

Contact between Superconductor and Normal Metal

We now briefly discuss the case of the boundary between a superconductor and normal metal. If there is a good electrical contact between the N and S regions, the Cooper pairs can diffuse into the normal region. Algebraically this means that $\Delta(s)$ extends up to a rather long distance ξ_N into the N regions $(x < 0)$ $(\xi_N \sim \hbar v_{FN}/k_B T$ if N is a pure metal).

Equation (7-60) remains valid. It is, however, necessary to determine the exact form of $\Delta(x)/\Delta_0$ and therefore solve the integral equation (7-54) completely. Qualitatively the results can be represented in the form

$$\Delta \sim \Delta_0 \frac{^{\mathrm{N}}\mathrm{N}}{\mathrm{N}}\, \mathrm{T_j} \exp\left(\mathrm{x}/\xi_{\mathrm{N}}\right) \quad (\mathrm{x} < 0) \tag{7-64}$$

where $\mathrm{N_N/N}$ is the density of states factor occuring in (7-61) and $\mathrm{T_j}$ is the transmission coefficient at the boundary for an electron at the Fermi surface. By substituting (7-64) into (7-62), we find

$$b \sim \frac{N}{N_N} \frac{1}{T_j} \frac{L}{\xi_N} \tag{7-65}$$

If $(\mathrm{N_N/N})\,\mathrm{T_j} \sim 1$, we can have $\mathrm{b} \sim \xi_{\mathrm{N}}$, b is then short when compared to $\xi(\mathrm{T})$ and the boundary conditions are drastically modified from the insulator case.

Problem.

How is the penetration depth modified in a superconductor S when it is covered by a normal metal layer N? (P.G. de Gennes and J. Matricon, 1965).

Solution.

Consider the Landau-Ginsburg domain (see Fig. 7-3). Assume (as is often the case) that the N metal does not contribute to the screening of magnetic

fields. Then the field at the NS boundary is the applied field. For the order parameter, the presence of N imposes a boundary condition on the type (7-53) at the surface ($x = 0$) of the superconductor.

(1) In zero field, $\psi(x)$ is given by

$$f(x) = \frac{\psi(x)}{\psi_0} = \tanh \frac{x - x_0}{\sqrt{2}\xi(T)}$$

where x_0 is a parameter to be determined by the condition (7-53),

$$\left(\frac{1}{\psi}\frac{d\psi}{dx}\right)_{x=0} = \frac{1}{b}$$

If the electrical contact between N and S is good, if the density of states of N is comparable to S, and if N is thick compared to $\xi_0 \simeq \hbar v_{\mathrm{F}}/\mathrm{k_B T_0}$, b is of the order of ξ_0. Therefore we can make $\mathrm{b} \ll \xi(\mathrm{T})$ and decrease strongly the order parameter at the surface $f(0) \sim b/[\sqrt{2}\xi(T)] \ll 1$.

(2) If we now apply a weak magnetic field $h_z(x) = \partial A_y(x)/\partial x$ along the z axis, its distribution is determined by

$$\frac{\partial^2 A_y}{\partial x^2} = \frac{16\pi e^2}{mc^2} |\psi_0|^2 f^2 A_y = \frac{f^2}{\lambda^2(T)} A_y$$

In a weak field, we can use the unperturbed form f given above. It happens that the equation for A_y is then soluble exactly in terms of hypergeometric functions (for a similar problem, see Landau and Lifshitz, Quantum Mechanics, London: Pergamon Press, 1959, p. 69). We only quote here the result for the limiting case $b/\xi(T) \to 0\,[x_0 \to 0, f(0) \to 0]$. Then

$$\frac{\lambda}{\lambda(\mathrm{T})} = \frac{1}{\kappa\sqrt{2}} \frac{\Gamma\left(-\frac{\mathrm{S}}{2} + \frac{1}{\kappa\sqrt{2}}\right)\Gamma\left(\frac{1}{2} + \frac{\mathrm{S}}{2} + \frac{1}{\kappa\sqrt{2}}\right)}{\Gamma\left(\frac{1}{2} - \frac{\mathrm{S}}{2} + \frac{1}{\kappa\sqrt{2}}\right)\Gamma\left(1 + \frac{\mathrm{S}}{2} + \frac{1}{\kappa\sqrt{2}}\right)}$$

[8] Remark: Notice the difference in this behavior with that of liquid He [4], which is also a superfluid satisfying, at least approximately, a Landau-Ginsburg equation in the neighborhood of $\mathrm{T_C}$. In He^4, ξ_0 is of the order of a and $\mathrm{b} \sim \mathrm{a} \gg \xi(T)$. The correct boundary condition is then completely different and closer to $\psi_{\mathrm{X}=0} = 0$.

For small $\kappa, \lambda/\lambda(T) - 1.75\kappa^{-1/2}$. This could have been guessed by the following argument: If the penetration depth is small, we can replace the exact expression for f (with $x_0 = 0$) by the approximate form $f = x/[\sqrt{2}\xi(T)]$. This approximation will be correct in the region where the field penetrates. Then the equation for A_y reduces to

$$\frac{\partial^2 \mathrm{A}y}{\partial \mathrm{x}^2} = \frac{\mathrm{x}^2}{2\lambda^2\xi^2}\ \mathrm{A_y}$$

and the penetration depth is of the order of $(\lambda\xi)^{1/2}$.
The opposite limit $\kappa \to \infty$ leads to $[\lambda/\lambda(T)] \to 1$. This was also expected since, when $\xi(T) \ll \lambda(T)$, the distortion of $\psi(x)$ near the surface, due to the presence of the N layer, is present only in a small fraction of $\lambda(T)$.
(3) In strong fields, the penetration depth increases spectacularly if $\kappa \sim 1/\sqrt{2}$ and $b \ll \xi(T)$. This can be shown from the complete nonlinear Landau-Ginsburg equations, but has not yet been verified experimentally.

S-N-S' Junction

Consider now the system of three layers $\mathrm{S} - \mathrm{N} - \mathrm{S}'$ represented in Fig. (7-4); two superconductors S and S' separated bv either an insulating film N of thickness $d(\sim 20 - 50\text{Å})$, or a normal metal with d $\sim 10^3$ A. When d is not too large, the Cooper pairs can tunnel from S to S' and vice versa. We shall analyze this effect under the following assumptions:
(1) The conditions for the validity of the Landau-Ginsburg equations are satisfied in S and S'.
(2) The thickness d is small with respect to $\lambda(T)$ and $\xi(T)$.

The effect of the film N is simply to impose boundary conditions relating the values of Δ and $\mathrm{d}\Delta/\mathrm{dx}$ at one surface of N to the values at the other surface. As previously, the boundary conditions can be reduced to be linear. Consider first the case when the vector potential $A = 0$. Then

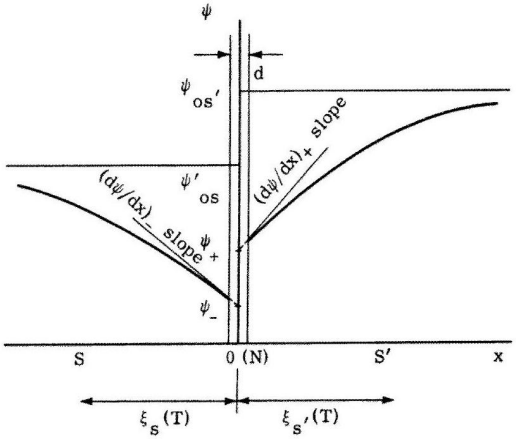

Figure 7-4
An S-N-S' junction where the normal layer may either be an insulator (d $\sim$ 50Å) or a metal (d $\sim 10^3$Å).

$$\begin{aligned} \Delta_+ &= L_{11}\Delta_- + L_{12}\left(\frac{d\Delta}{dx}\right)_- \\ \left(\frac{\partial\Delta}{\partial x}\right)_+ &= L_{21}\Delta_- + L_{22}\left(\frac{\partial\Delta}{\partial x}\right)_- \end{aligned} \tag{7-66}$$

(A=0)

Here the x axis is normal to the film; Δ_+represents the value of $\Delta(x, y, z)$ extrapolated to the point $(0, y, z)$ from the solution of the Lan-dau-Ginsburg equations in the S region as is

shown in Fig. (7-4), and so on. The coefficients L_{ij} are obtained by completely solving the linearized self-consistency equation (7-8) (for A = 0, T = T_0) in and around the N region. For $A = 0$, the kernel $K_0(s, r)$ of their equation is real, therefore, the L_{ij} are real. Sometimes it is more useful to deal with ψ instead of Δ, and then (7-66) can be rewritten

$$\psi_+ = M_{11}\psi_- + M_{12}\left(\frac{\partial\psi}{\partial x}\right)_-$$
$$\left(\frac{\partial\psi}{\partial x}\right)_+ = M_{21}\psi_- + M_{22}\left(\frac{\partial\psi}{\partial x}\right)_- \qquad (\prime)$$

(A=0)

[If the metals S and S' are different, the ratio ψ/Δ defined by (6-8) is not the same in S as in S'. Thus the coefficients M_{ij} are not identical to the L_{ij}. | The M_{ij} are real. They are not all independent, but are related to each other by one relation expressing current conservation through the boundary. The supercurrent I_x crossing a unit area of the wall is given by

$$I_x = \frac{-ie\hbar}{m}\left(\psi^*\frac{\partial\psi}{\partial x} - C.C.\right)_+ = \frac{-ie\hbar}{m}\left(\psi^*\frac{\partial\psi}{\partial x} - C.C.\right)_- \qquad (A = 0) \qquad (7\text{-}67)$$

By comparing (7-67) and (7-66'), we find

$$M_{11}M_{22} - M_{12}M_{21} = 1 \qquad (7\text{-}68)$$

and the current I_x can be written in the form

$$I_X = \frac{-ie\hbar}{m}\left\{\psi_-^*\left(\frac{1}{M_{12}}\psi_+ - \frac{M_{11}}{M_{12}}\psi_-\right) - \text{C.C. }\right\}$$
$$= \frac{-ie\hbar}{M_{12}m}\left(\psi_-^*\psi_+ - \text{C.C. }\right) \qquad (7\text{-}69)$$

Therefore a supercurrent must flow through the junction (B. D. Josephson, 1962). The junction cannot be too thick because then the coefficient M_{12} would become too large. Such currents have first been clearly observed by Anderson and Rowell (1963).

These results are easily generalized to the case $A \neq 0$. We always assume that, on the Landau-Ginsburg scale, the vector potential A is continuous at the boundary. [9] Then, putting $A_x = A_x(0, yz)$, we replace Eq. (7-66') by

$$\psi_+ = M_{11}\psi_- + M_{12}\left(\frac{\partial}{\partial x} - \frac{2ie}{\hbar c}A_x\right)\psi_- \qquad (7\text{-}70)$$
$$\left(\frac{\partial}{\partial x} - \frac{2ieA_x}{\hbar c}\right)\psi_+ = M_{21}\psi_- + M_{22}\left(\frac{\partial}{\partial x} - \frac{2ie}{\hbar c}A_x\right)\psi_-$$

The equation (7-69) for the current is not changed. [10]

In practice, the use of the current formula (7-69) is particularly simple when the region N is only slightly transparent to pairs, that is, when I_X is small relative to the critical currents in S or S' in their bulk states. With this assumption, the absolute values $|\psi_+|$and $|\psi_-|$are only slightly modified by the presence of the current and they can be replaced by their values $\psi_{S'}$ and ψ_S in the state without current:

$$\begin{matrix}\psi_+ \to \psi_{S'}\exp\left(i\phi_{S'}\right) \\ \psi_- \to \psi_S\exp\left(i\phi_S\right)\end{matrix} \qquad (\psi_S, \psi_{S'} \text{ are real })$$

The phases ϕ_{S} and $\phi_{\mathrm{S}'}$, on the other hand, will, in general, be very sensitive to the presence of currents and magnetic fields and nothing can be said about them a priori. With the substitution of these values into (7-69), the current takes the form

$$\mathrm{I_X} = \frac{2\mathrm{e}\hbar}{\mathrm{mM_{12}}}\psi_{\mathrm{S}}\psi_{\mathrm{s}'}\sin\left(\phi_{\mathrm{S}} - \phi_{\mathrm{S}'}\right) \tag{7-71}$$

Its maximum value is

$$\mathrm{I}_m = \frac{2\mathrm{e}\hbar}{\mathrm{mM_{12}}}\psi_{\mathrm{s}'}\psi_{\mathrm{s}'} \tag{7-72}$$

To determine ψ_S and $\psi_{S'}$, it is only necessary to solve the Landau-Ginsburg equation in S and S' in the simple case $A = 0$ and ψ real. We have already encountered the form of these solutions in one dimension

$$\psi(x) = \begin{cases} \psi_{0s'}\tanh\left(\frac{x+x_{s'}}{\sqrt{2}\xi_{s'}(T)}\right) & x > 0 \\ \psi_{0s}\tanh\left(\frac{-x+x_{s'}}{\sqrt{2}\xi_{s}(T)}\right) & x < 0 \end{cases} \tag{7-73}$$

where ψ_{os} and $\xi_{\mathrm{S}}(\mathrm{T})$ are, respectively, the order parameter in the bulk S metal and the coherence length at the temperature T in S . The lengths $\mathrm{x_S}$ and $\mathrm{x_{S'}}$ are related to ψ_{S} and $\psi_{\mathrm{S}'}$ by

$$\psi_S = \psi_{oS}\tanh\left(\frac{x_S}{\sqrt{2}\xi_S(T)}\right) \quad \psi_{S'} = \psi_{oS'}\tanh\left(\frac{x_{S'}}{\sqrt{2}\xi_{S'}(T)}\right) \tag{7-74}$$

They can be determined explicitly by demanding that (7-73) satisfy the boundary (7-66'), which gives

$$\begin{aligned} \psi_{\mathrm{s}'} &= \mathrm{M_{11}}\psi_{\mathrm{S}} - \mathrm{M_{12}}\frac{\psi_{\mathrm{oS}}}{\sqrt{2}\xi_{\mathrm{S}}(\mathrm{T})}\left(1 - \frac{\psi_{\mathrm{S}}^2}{\psi_{\mathrm{oS}}^2}\right) \\ \frac{\psi_{\mathrm{oS}'}}{\sqrt{2}\xi_{\mathrm{S}'}(\mathrm{T})}\left(1 - \frac{\psi_{\mathrm{S}'}^2}{\psi_{\mathrm{os}}^2}\right) &= \mathrm{M_{21}}\psi_{\mathrm{S}} - \mathrm{M_{22}}\frac{\psi_{\mathrm{oS}}}{\sqrt{2}\xi_{\mathrm{S}}}\left(1 - \frac{\psi_{\mathrm{S}}^2}{\psi_{\mathrm{oS}}^2}\right) \end{aligned} \tag{7-75}$$

The system of equations (7-75) can be solved numerically to obtain ψ_{S} and ψ_{S}. Certain limiting cases are simple:
(1) If N is an insulator, ψ(x) is only slightly modified by the presence of N ($\psi_S \sim \psi_{0S}$). Then M_{12} and M_{21} are small, and M_{11} is nearly 1. (See the microscopic calculation that follows later.)
(2) If N is metallic [sufficiently thick for $\mathrm{L_x}$ to be small, but thin compared to $\lambda(T)$ and $\xi(T)$], we predict that

$$\frac{\psi_{\mathrm{s}}}{\psi_{\mathrm{os}}} \sim \frac{\psi_{\mathrm{s}'}}{\psi_{\mathrm{os\ s}'}} \sim \frac{\mathrm{b}}{\xi(\mathrm{T})} \ll 1$$

by analogy with the NS boundary studied previously. In this case, (7-75) can be linearized.

[9] A could be discontinuous if a different choice of gauge was made on the two sides.
[10] A particularly simple case occurs when the junction is symmetric. Then $M_{11} = M_{22}$ and, by taking account of (7-68), we see that the M_{ij} depend on only two independent parameters.

Conclusions.

(1) If N is an insulating layer, the maximum current becomes

$$\mathrm{I}_m = \frac{2\mathrm{e}\hbar}{\mathrm{mM}_{12}}\psi_{0\ \mathrm{s}}\psi_{0\ \mathrm{s}'}$$

M_{12} is finite as $T \to T_0$; ψ_{0S} varies as $(T_0 - T)^{1/2}$ from (6-15) and consequently the maximum current varies as $T_0 - T$.

(2) If N is metallic, $\mathrm{I}_m \sim (\mathrm{e}\hbar/\mathrm{mM})[\mathrm{b}/\xi(\mathrm{T})]^2\psi_{\mathrm{o}S}\psi_{\mathrm{o}S}$, which varies as $(T_0 - T)^2$. (This latter result has not yet been experimentally verified.)

MICROSCOPIC CALCULATION OF $\mathrm{M_{ij}}$

FOR AN INSULATING JUNCTION

We consider a symmetric situation for $\mathrm{d} \ll \xi_0$. We start from the linearized self-consistency equation (7-8) for $A = 0$ and $T = T_0$.

From (7-35), the kernel $K_0(r, r')$ is essentially related to the function $\langle\delta[\mathbf{r} - \mathbf{r}(0)]\delta[\mathbf{r}' - \mathbf{r}(\mathrm{t})]_{\mathrm{E_F}}$, which represents the probability of finding an electron at $\mathbf{r}'$ at the time t (in the normal state) if it has been injected at r at time 0, with the Fermi energy. This allows us to write $K_0(r, r')$ directly in terms of $K_{\text{pure}}(r - r')$ which we have already studied for the infinite metal S. Equation (7-8) becomes

$$\begin{aligned}\Delta(r) = &\int_{\mathrm{I}} \mathrm{K_{pure}}\ (r - r')\,\Delta(r')\,dr' + \int_{\mathrm{II}} \mathrm{K_{pure}}\ (r - r') \\ &\times \left[\mathrm{T_j}\Delta(r') + \mathrm{R_j}\Delta\overline{(r')}dr'\right]\end{aligned} \tag{7-76}$$

where the first integral (I) corresponds to a direct propagation from r to r' and the region of integration is limited by the condition that r and r' be on the same side of the junction. The integral (II) gives the effects of transmission and reflection arising from the presence of the junction. The coefficient $T_j = 1 - R_j$ is the transmission coefficient of the function for an electron of energy E_F in the normal metal. The point $\overline{r'} = (-x', y', z')$ is the image point of r' with respect to the junction. For simplification we assume that the reflection is specular and that the reflection coefficient is independent of the angle of incidence.

Equation (7-76) has an even solution $\Delta(x) = \Delta(-x) =$ constant by virtue of the property $\int K_{\text{pure}}(r - s)dr = 1$ at $T = T_0$. In order to determine M_{12}, it is necessary to construct a second independent solution, for example, the odd solution $\Delta(x) = -\Delta(-x)$.

If we set $\Delta^+(x) = \Delta(s)S(x)$ where

$$S(x) = \begin{cases} 1 & x > 0 \\ 0 & x < 0 \end{cases}$$

Eq. (7-76) can be put into the form

$$\Delta^+(x) = S(x)\int \Delta^+(x')\left[K_0(r, r') + (1 - 2T_j)\,K_0(r, r')\right]dr'$$

or further

$$\begin{aligned}\Delta^+(r) - \int K_0(r, r')\,\Delta^+(r')\,dr' = &\int dr\Delta^+(r')\left[-S(-x)K_0(r, r')\right. \\ &\left.+S(x)\,(1 - 2T_j)\,K_0(r, r')\right] \\ = &-H(x)\end{aligned} \tag{7-77}$$

The function H(x) represents a source localized in the region $|x| < \xi_0$. The equation is very similar to (7-56) and can be solved in the same way,

$$\left(\frac{L}{2}\right)\left(\frac{d\Delta}{dx}\right)_{x\gg\xi_0} = \int H(x)dx = 2T_j \int_\infty^0 dx \int_\infty^0 dx' \times \int dy'dz'\Delta^+(x')\,K_0(r,r') \tag{7-78}$$

As the junction is insulating, $\Delta^*(x')$ does not vary much over the region of integration ($x' \sim \xi_0$), $\Delta^+(x) \to \Delta^+$. The integral that remains can be calculated by recalling the definition of K_{pure} ,

$$\int_{-\infty}^0 dx \int_0^\infty dx' \int dy'dz'K_{\text{pure}}\,(r-r') = \xi_0 \tag{7-79}$$

Finally, we find

$$\frac{\mathrm{L}}{2}\left(\frac{\mathrm{d}\Delta}{\mathrm{dx}}\right)_+ = \mathrm{T_j}\xi_0\Delta_+$$

and comparing this with (7-66),

$$L_{12} = M_{12} = \frac{L}{T_j\xi_0} \tag{7-80}$$

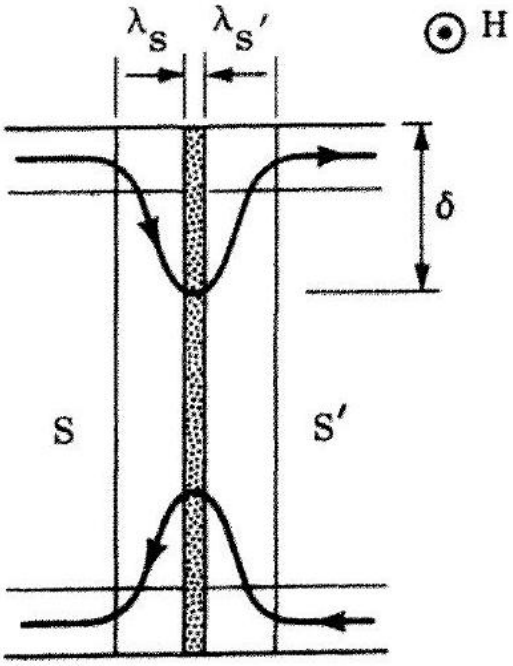
The coefficient $\mathrm{M_{12}}$ is of the order of $\xi_0/\mathrm{T_j}$ since $\mathrm{L} \sim \xi_0^2$. In practice the transmission coefficient T_j across an insulating wall is very small when d is larger than a few angstrms. This implies that the maximum supercurrent flowing across the junction is small

$$\mathrm{I}_m \sim \frac{\mathrm{eh}}{m\xi_0}\,|\psi_0|^2\;\mathrm{T_j} \tag{7-81}$$

DISTRIBUTION OF FIELDS AND CURRENTS NEAR A JUNCTION

A typical situation is shown on Fig. 7-5. The field H is applied in the plane of the junction. Surface currents appear on S and S' to screen out the field. How will the currents manage to go through the junction? Because the maximum current density I_m through the junction is small, the currents must go deep in between S and S'. Typically, for an insulating junction, they will penetrate on a length $\delta \sim 1$ mm. At higher fields, things will become even more dramatic, and vortex lines will pile up in the junction (Fig. 7-6).

The behavior of the junction in this type of situation is governed by a simple equation due to Ferrell and Prange. In order to obtain this equation, we consider a junction occupying the entire xy plane; the magnetic fields are directed along the z axis and it is convenient to describe them by a vector potential directed along the y axis:



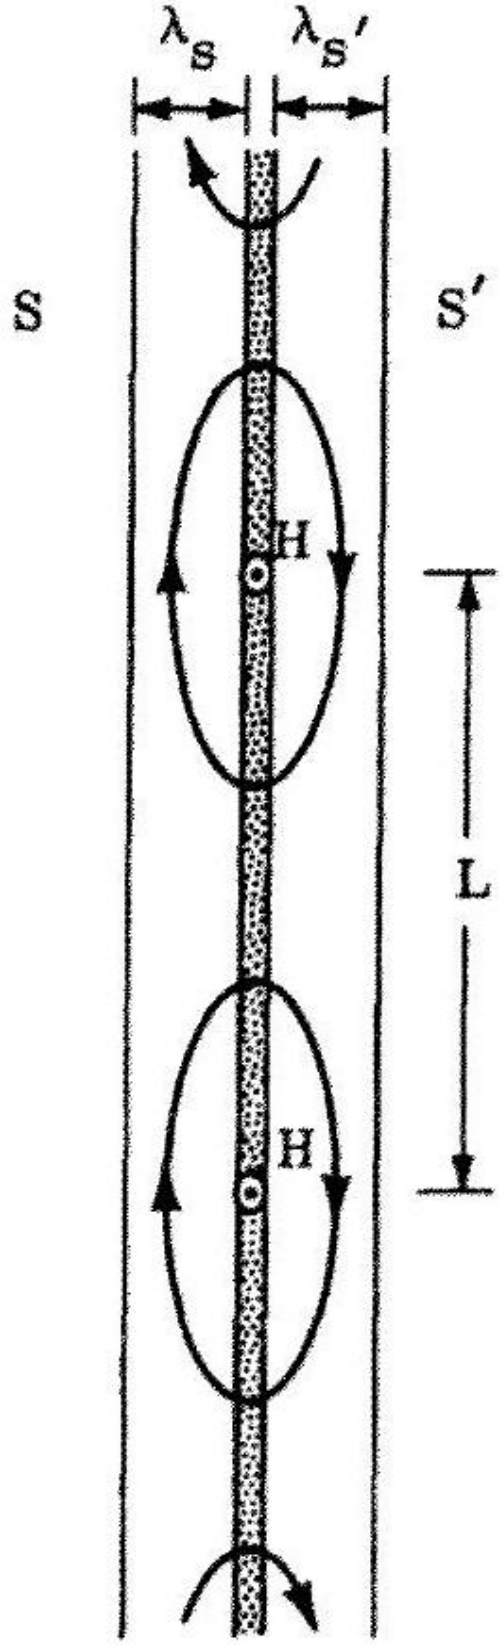


Figure 7-5
Current streamlines around an S-N-S' junction under a very weak applied field. Because of the weak current capacity of the junction, the field penetrates up to a large distance δ.

Figure 7-6 Current distribution in a junction at higher fields: Vortex lines are stacked along the junction.

$$h(x,y) = \frac{\partial}{\partial x} A_y(x,y)$$

We assume a solution of the Landau-Ginsburg equations of the form

$$\psi(x,y) = \begin{cases} \psi(x) \exp\left[i\phi_{S'}(y)\right] & x > 0 \\ \psi(x) \exp\left[i\phi_{S}(y)\right] & x < 0 \end{cases} \tag{7-82}$$

As we shall see, the variations of $\phi_{\mathbf{S}}$ (or $\phi_{\mathbf{S}'}$) take place over distances (δ) much larger than ξ(T). Then ψ(x) is essentially the solution (7-73).

Let us first consider the region $x > 0$ far from the junction ($x \gg \lambda_{s'}$). Here the Meissner effect is complete, no current flows and we find from Eq. (6-12)

$$\frac{2e}{\hbar c} A_y = \frac{\partial \phi_{s'}(y)}{\partial y} \quad (x \gg \lambda_{s'}) \tag{7-83a}$$

and similarly

$$\frac{2eA_y}{\hbar c} = \frac{\partial \phi_s(y)}{\partial y} \quad (x \ll -\lambda_s) \tag{7-83b}$$

Therefore $A_y(x, y)$ has well-defined limiting values, on either side far from the junction. Call these values $A_S(y), A_{S'}(y)$. At the junction itself (x = 0), we can, for convenience, take $\mathrm{A_y(x = 0, y) = 0}$. The magnetic field $\mathrm{H(x = 0, y) = h_0(y)}$ at the junction is simply deduced from the following considerations.

If we let λ_{S} and $\lambda_{\mathrm{S}'}$ be the penetration depths in S and S′ in the neighborhood of the junction, [11] then by definition

$$\begin{aligned} A_{s'} &= \int_0^{\infty} h dx = \lambda_{s'} h_0 \\ A_s &= \int_0^{-\infty} h dx = \lambda_s h_0 \end{aligned} \tag{7-84}$$

and by comparison with (7-83)

$$\mathrm{h_0 = \frac{\hbar c}{2e} \frac{1}{\lambda_{s'}} \frac{\partial \phi_{s'}}{\partial y} = \frac{\hbar c}{2e} \frac{1}{\lambda_s} \frac{\partial \phi_s}{\partial y}} \tag{7-85}$$

We now write the relation between field and current at the junction $\mathrm{curl}\, h = (4\pi/c)j$,

$$\mathrm{\frac{\partial h_0}{\partial y} = \frac{4\pi}{c} I_x = \frac{4\pi}{c} I_m \sin(\phi_s - \phi_{s'})} \tag{7-86}$$

where we have used (7-71). By combining (7-85) and (7-86), we obtain the Ferrell-Prange equation

$$\mathrm{\frac{\partial^2 \phi}{\partial y^2} = \frac{1}{\delta^2} \sin \phi} \tag{7-87}$$

where $\phi = \phi_S - \phi_{S'}$

$$\mathrm{\delta^2 = \frac{\hbar c^2}{8\pi e I_m (\lambda_s + \lambda_{s'})}} \tag{7-88}$$

We now estimate the characteristic length δ for an insulating junction. The order of magnitude of I_m is given by (7-81) and

$$\begin{aligned} \mathrm{\delta^2} &\sim \mathrm{\frac{mc^2}{16\pi e^2 |\psi_0|^2} \frac{\xi_0}{\lambda(T)} \frac{1}{T_j}} \\ &\sim \mathrm{\frac{\lambda(T) \xi_0}{T_j}} \end{aligned} \tag{7-89}$$

[11] When the N region is metallic, ψ(x) becomes small near the junction and the penetration depths must be calculated taking this into account, as we have previously seen for an NS boundary.

For an insulator of thickness $d \sim 20\text{Å}$, the transmission coefficient is typically of the order of 10^{-8}. If $\lambda(\mathrm{T}) \sim \xi_0 \sim 10^3$ A, then $\delta \sim 1$ mm.

Equation (7-87) can be completely discussed by noticing that it is formally identical to the equation of motion of a pendulum.

Two limiting cases are particularly interesting.

(1) Very weak fields. Then (7-87) can be linearized to give solutions of the form

$$\phi = \phi_0 e^{-y/\delta}, \quad h_0 = H_0 e^{-y/\delta} \tag{7-90}$$

where $y = 0$ corresponds to the intersection of the junction and the sample surface, and H_0 is the field just outside of the sample. Thus the penetration depth of the junction in weak fields is δ. This regime holds when $\Phi \ll 1$ or $\mathrm{H} \ll \phi_0/\left(\lambda_\mathrm{S} + \lambda_{\mathrm{S}'}\right)\delta$, that is, the flux that penetrates into the junction must be much less than the flux quantum ϕ_0.

(2) Domain of complete penetration. If $\mathrm{H} \gg \phi_0/\left(\lambda_\mathrm{s} + \lambda_{\mathrm{s}'}\right)\delta$, the field becomes nearly uniform along the junction and $h_0(y) \to H.\phi$ can be determined from (7-85),

$$\phi \approx \frac{2\pi \mathrm{y}}{\mathrm{L}} + \text{ const} \qquad \mathrm{L} = \frac{\phi_0}{\left(\lambda_\mathrm{s} + \lambda_{\mathrm{s}'}\right)\mathrm{H}} \tag{7-91}$$

The structure of the currents is then periodic with period L

$$I_x = I_m \sin\phi \cong I_m \sin\left(\frac{2\pi\left(y - y_0\right)}{L}\right) \tag{7-92}$$

By placing (7-91) into the right-hand side of (7-87), it is easy to verify that $\partial^2\phi/\partial y^2$ and $\partial h_0/\partial y$ are essentially negligible for $L \ll \delta$.

The current structure is shown on Fig. (7-6). Each period carries one quantum of flux. It resembles a series of vortex lines stacked in the plane of the junction. Because the penetration depth δ is very large ($\delta \gg \xi$), the situation is similar to a Type II superconductor where $\lambda \gg \xi$. In the limit $\mathrm{L} \ll \delta$, it can be shown, by a complete calculation of the thermodynamic potential, that the field h_0 is very nearly equal to the applied field.

It is also interesting to calculate the total current that flows from S to S' when the junction has a finite length $0 < y < D$. Per cm of length along the z axis, we have

$$\begin{aligned} I_{\text{total}} &= \int^D I_m \sin\phi dy \\ &\cong \frac{I_m L}{2\pi}\int d\phi \sin\phi \quad (L \ll \delta) \\ &= \frac{I_m L}{2\pi}\left[\cos\phi(0) - \cos\left(\phi(0) + \frac{2\pi D}{L}\right)\right] \end{aligned}$$

The maximum value of I_{total} is obtained when $\phi(0) = \pi/2 - \pi D/L$,

$$\mathrm{I}_{\text{total max}} = \frac{\mathrm{I}_m\ \mathrm{L}}{2\pi}\left|\sin\frac{\pi\mathrm{D}}{\mathrm{L}}\right| \quad (\mathrm{L} \ll \delta) \tag{7-93}$$

The factor D/L is the number of flux quanta in the junction. The total current vanishes when D/L is an integer, and is maximum when D/L is half-integral. Rather detailed verifications of (7-93) have recently been obtained by Fiske and by Rowell.

Problem.

Discuss the maximum superfluid current 1 of a system of two SNS junctions in parallel, as a function of the magnetic field H ("quantum interferometer"). The (schematic) arrangement

and the notation are shown on Fig. 7-7. A flux Φ is enclosed in the ring between the two junctions. For simplicity assume that (a) the junctions A and B are small, the flux trapped in each of the junctions is negligible ($2\ \mathrm{d}\lambda\mathrm{H} \ll \phi_0$); (b) the superconducting pieces (1) and (2) are much thicker than the penetration depth λ.

Solution.

The overall supercurrent flowing from (1) to (2) is

$$I = I_m d\left[\sin\left(\phi_{2A} - \phi_{1A}\right) + \sin\left(\phi_{2B} - \phi_{1B}\right)\right]$$

The different phases ϕ_{1A}, and so on, are coupled by a relation involving the flux ϕ, which we now derive. At any point in superconductor 1, for instance, the current density j_s is proportional to $\hbar\nabla\phi - 2eA/c$ (where ϕ is the local phase of the pair potential). Consider a path C_1 in the superconductor distant enough from the surface, so that $j_s \equiv 0$ on it. Then, on $C_1, \hbar\nabla\phi = 2eA/c$. Integrating this relation we obtain

$$\phi_{1\ \mathrm{B}} - \phi_{1\ \mathrm{A}} = \frac{2\mathrm{e}}{\hbar\mathrm{c}} \int_{\mathrm{C}_1} \mathrm{A} \cdot\ \mathrm{d}\boldsymbol{\ell}$$

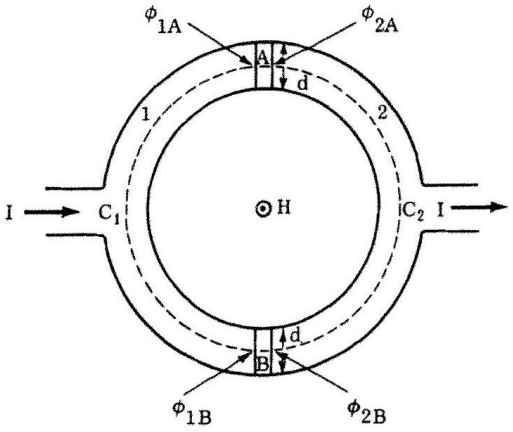

Figure 7-7
Principle of a "quantum interferometer." A and B are two Josephson junctions. The maximum superfluid current 1 is measured as a function of the field H in the loop.

and similarly

$$\phi_{2A} - \phi_{2B} = \frac{2e}{\hbar c} \int_{C_2} A \cdot d\ell$$

Adding these equations we arrive at

$$\phi_{1\ \mathrm{B}} - \phi_{2\ \mathrm{B}} + \phi_{2\ \mathrm{A}} - \phi_{1\ \mathrm{A}} = \frac{2\mathrm{e}}{\mathrm{hc}} \oint \mathrm{A} \cdot\ \mathrm{d}\boldsymbol{\ell} = 2\pi \frac{\Phi}{\Phi_0}$$

where Φ is the total flux in the loop.

Apart from this relation, the phases, ϕ_{1A}, and so on, are arbitrary. The current I is maximum when we choose

$$\phi_{2\ \mathrm{A}} - \phi_{1\ \mathrm{A}} = -\left(\phi_{2\ \mathrm{B}} - \phi_{1\ \mathrm{B}}\right) = \pi \frac{\Phi}{\Phi_0}$$

$$I = 2\mathrm{I}_m\ \mathrm{d} \left|\sin\left(\pi \frac{\Phi}{\Phi_0}\right)\right|$$

The maximum superfluid current is a periodic function of Φ or H . To observe the periodicity in field the surface S of the loop must be small. The experiment has been achieved by Jaklevic, Lambe, Silver, and Mercereau. A and B can be two Josephson junctions, or, even more simply, two mechanical contacts between superconducting wires.

6.5 Effects of Strong Magnetic Fields and of Magnetic Impurities

We shall discuss two apparently very different physical situations:
(1) dirty superconductors and small superconducting samples in high magnetic fields;
(2) superconductors containing magnetic impurities.

There are in fact some crucial features shared by (1) and (2).
(a) In both cases the perturbation acts with opposite signs on the two members of a Cooper pair. In case (1) there is a term $(1/2m)$ $(\mathbf{p}\cdot\mathbf{A}+\mathbf{A}\cdot\mathbf{p})$ if the one-electron Hamiltonian, and this changes sign when going from p to -p. In case (2) we may often describe the effect of the magnetic impurity (i) of spin S_i on a conduction electron (of coordinate r_e and spin S_e) by an interaction of the form

$$\Gamma\,(r_e - r_i)\,S_e \cdot S_i$$

(Γ is called an exchange coupling constant, but in fact its origin is complex.) Γ has an arbitrary sign, and is typically of order 0.1eV $= 10^3$°K.[1] Since the two electrons of a Cooper pair have opposite spins, this Γ coupling acts with opposite signs on each.
(b) Experimentally, such "antisymmetric" perturbations lead to a

[1] Note that Γ has nothing to do with the dipolar field created by the magnetic impurity. The dipolar coupling energy is of order $\mu_B^2/a^3 \sim 1°K$ (μ_B = Bohr magneton, a = atomic distance) and much smaller than Γ (C . Herring, 1958).

Figure 8-1
Superconducting and ferromagnetic transition temperatures of La Gd alloys lafter B. T. Matthias, IBM J., 6, 250 (1962)]. Note the sharp drop of the superconducting transition point when the (magnetic) gadolinium atoms are added to lanthanum.

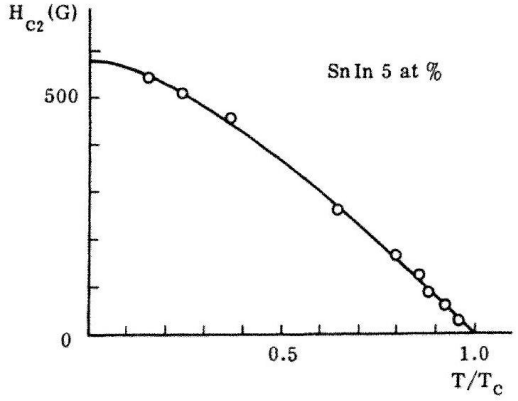

Figure 8-2

strong decrease of the transition temperature. This is shown on examples in Figs. 8-1 and 8-2. Note that the "antisymmetry" is crucial. Recall that nonmagnetic impurities (which give rise only to "symmetric" perturbations) have very little effect on the transition point (Anderson's theorem).

(c) Another important property is shared by classes (1) and (2). Electrons are randomly scattered by impurities or on the sample surface. Thus the "antisymmetric" perturbation seen by one given Cooper pair is modulated in time. This, as we shall see, can lead to a number of strange properties, and in particular to gapless superconductivity (A. Abrikosov and L. P. Gorkov, 1961).

6.5.1 8-1 Relation Between Transition Temperature and Time-Reversal Properties

Our problem is to translate the qualitative asymmetry property of the perturbation into more numerical terms. Consider for instance the calculation of a transition point, in a given field (case 1) or for a given concentration of magnetic impurities (case 2). Experimentally for both cases the transition is found to be of second order. $\Delta(r)$ is small near the transition and a linearized self-consistency equation like (7-8) can be used.

Let us first restrict our attention to case (1), where spin indices play no role, and where (7-8) thus applies directly. We rewrite the kernel $\mathrm{K}(\mathbf{r}_1\mathbf{r}_2)$ of (7-8) under a form equivalent to (7-11).

$$\mathrm{K}(\mathbf{r}_1\mathbf{r}_2) = \mathrm{k_B}\ \mathrm{T}\sum_{\omega} v\ \mathrm{N}(0)\mathrm{V}\int \frac{\mathrm{d}\xi\ \mathrm{d}\xi'}{(\xi - \mathrm{i}\omega\ \mathrm{h})(\xi' + \mathrm{i}\omega\ \mathrm{h})} \times \mathrm{f}\left(\mathbf{r}_1\mathbf{r}_2, \frac{\xi - \xi'}{\hbar}\right) \tag{8-1}$$

$$\mathrm{f}(\mathbf{r}_1\mathbf{r}_2\Omega) = \sum_{m} \langle \phi_{\mathrm{n}}^*(\mathbf{r}_1)\,\phi_m^*(\mathbf{r}_1)\,\phi_m(\mathbf{r}_2)\,\phi_{\mathrm{n}}(\mathbf{r}_2) \times \delta(\xi_m - \xi_{\mathrm{n}} - \hbar\Omega)\rangle \tag{8-2}$$

[U is the sample volume and $N(0)$ the density of states per unit volume in the normal state so that $\mathcal{U}\mathcal{N}(0)$ is the total density of states of the sample when it is normal. We have made the substitution $\Sigma_{\mathrm{n}} \rightarrow \int \cup N(0)\mathrm{d}\xi_{\mathrm{n}}\cdot\big]$ As usual, the sum Σ_ω runs over the values $\pi\left(\mathrm{k_B}T/\hbar\right)\times(2\nu+1)$. The average in Eq. (8-2) is taken over all states n at a fixed energy ξ_{n} (in practice, at the Fermi energy $\xi_{\mathrm{n}}=0$). We would like to express the product of two ϕ' s and two ϕ^* 's in terms of matrix
elements between one-electron states n and m. Obviously, the * symbols are not located as desired. We circumvent this by introducing an ad hoc operator K, which by definition changes a function into its complex conjugate

$$\mathrm{K}\phi_m = \phi_m^* \quad \text{(case 1)} \tag{8-3}$$

We call K the time-reversal operator. In terms of K we may write

$$\begin{aligned}
\phi_{\mathrm{n}}^*\left(\mathrm{r}_1\right)\phi_m^*\left(\mathrm{r}_1\right) &= \left(\mathrm{n}\left|\delta\left(\mathrm{r}-\mathrm{r}_1\right)\mathrm{K}\right|m\right)\\
\phi_{\mathrm{n}}\left(\mathrm{r}_2\right)\phi_m\left(\mathrm{r}_2\right) &= \left(m\left|\ \mathrm{K}^+\delta\left(\mathrm{r}-\mathrm{r}_2\right)\right|\mathrm{n}\right)\\
\mathrm{f}\left(\mathrm{r}_1\mathrm{r}_2\Omega\right) &= \sum_m \Big\langle\left(\mathrm{n}\left|\delta\left(\mathrm{r}-\mathrm{r}_1\right)\mathrm{K}\right|m\right)\left(m\left|\ \mathrm{K}^+\delta\left(\mathrm{r}-\mathrm{r}_2\right)\right|\mathrm{n}\right)\\
&\quad\times\delta\left(\xi_{\mathrm{n}}-\xi_m-\hbar\Omega\right)\Big\rangle
\end{aligned} \tag{8-4}$$

At this stage, as usual, we find it convenient to use the Fourier transform of f

$$\begin{aligned}
f\left(r_1r_2t\right) &= \int d\Omega e^{-i\Omega t} f\left(r_1r_2\Omega\right)\\
&= \left\langle\delta\left[r(t)-r_1\right]K(t)K^+(0)\delta\left[r(0)-r_2\right]\right\rangle
\end{aligned} \tag{8-5}$$

where $K(t)$ and $r(t)$ are Heisenberg operators describing the time evolution of K or r for one electron submitted to the forces described by the Hamiltonian

$$\begin{aligned}
\mathscr{H}_e &= \frac{1}{2m}\left(p-\frac{eA}{c}\right)^2 + U(r) - E_F \quad \text{(case 1)}\\
K(t) &= \exp\left(i\frac{\mathscr{H}_e t}{\hbar}\right)K\exp\left(+i\frac{\mathscr{H}_e t}{\hbar}\right)
\end{aligned} \tag{8-6}$$

(Note the unusual sign in the last exponent, due to the fact that Ki = -iK.) The rate of change of K is given by

$$\frac{dK}{dt} = \frac{i}{\hbar}\left[\mathscr{H}_e, K\right] = \frac{-ie}{m\hbar c}(p\cdot A + A\cdot p)K \quad \text{(case 1}\Big) \tag{8-7}$$

The motion of K is due only to the "antisymmetric" part of the magnetic perturbation in $\mathscr{H}_e$. (Rather than "antisymmetric," we now say: the part that changes sign under time reversal.)

Finally, our result is the following: The kernel $K\left(r_1r_2\right)$ of the integral equation giving the transition temperature is known in terms of a correlation function $f\left(r_1r_2t\right)$ defined in (8-5). This correlation
function is useful because, as in many cases discussed before, it is closely related to the transport properties in the normal state. All the complications due to "antisymmetric" perturbations are described in terms of the time-reversal operator $K(t)$.

These conclusions can be extended directly to cases where there are magnetic impurities, that is, where spin indices must be taken into account. We now briefly describe this extension. The complete Hamiltonian is

$$\begin{aligned}\mathscr{H} = \sum_{\sigma} \int \mathrm{d}\mathbf{r} \Bigg\{ & \psi^{+}(\mathbf{r},\sigma) \left[\frac{\left(\mathbf{p} - \frac{\mathrm{e}}{\mathrm{c}}\mathbf{A}\right)^2}{2m} - \mathrm{E_F} \right] \psi(\mathbf{r},\sigma) \\ & + \sum_{\sigma\nu} \psi^{+}(\mathbf{r},\sigma) \mathrm{U}_{\sigma\nu}(\mathbf{r}) \psi(\mathbf{r},\nu) \\ & - \mathrm{V} \sum_{\sigma\nu} \psi^{+}(\mathbf{r},\sigma)\psi^{+}(\mathbf{r},\nu)\psi(\mathbf{r},\nu)\psi(\mathbf{r},\sigma) \Bigg\} \end{aligned} \tag{8-8}$$

where $\psi^{+}(\mathbf{r},\sigma)$ creates an electron of spin σ at the point $\mathbf{r}$.$\mathrm{U}_{\sigma\nu}$ is the potential acting upon the electrons, which for magnetic alloys is spin dependent. (In order to simplify the notation, we assume that U be a local operator coupling $\psi^{+}$and ψ at the same point.) The main assumption made about the potential U is that it is static. We do not take into account possible motions of the impurity spins. (This, as we later see, is correct only for very dilute alloys. In more concentrated systems, the impurities are coupled among themselves and precess in the exchange field of their neighbors.) The pair potential $\Delta(r)$ is still defined by

$$\Delta(\mathbf{r}) = \mathrm{V}\langle\psi(\mathbf{r}\uparrow)\psi(\mathbf{r}\downarrow)\rangle = -\mathrm{V}\langle\psi(\mathbf{r}\downarrow)\psi(\mathbf{r}\uparrow)\rangle$$

which can be rewritten in the condensed form

$$\Delta = \frac{V}{2} \sum_{\sigma\mu} \rho_{\sigma\mu} \langle\psi(r,\sigma)\psi(r,\mu)\rangle \tag{8-9}$$

where

$$\rho = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$$

As in Chapter 5, we write the equations of motion of ψ and $\psi^{+}$and linearize them, allowing for a nonzero Δ. The linearized equation of motion for ψ is

$$\begin{aligned} \frac{\partial\psi}{\partial \mathrm{t}}(\mathbf{r},\sigma) = & [\mathscr{H}, \psi(\mathbf{r},\sigma)] \\ \mathrm{it} \qquad = & \left(\frac{\mathbf{p}^2}{2m} - \mathbf{E_F} \right) \psi(\mathbf{r},\sigma) \\ & + \sum_{\mu} \mathrm{V}_{\sigma\mu}\psi(\mathbf{r},\mu) + \sum_{\mu} \rho_{\sigma\mu}\Delta(\mathbf{r})\psi^{+}(\mathbf{r},\mu) \end{aligned} \tag{8-10}$$

(As usual, we have subtracted the chemical potential $\mathrm{E_F}$.) The elementary excitations are found by performing the transformation

$$\psi(\mathbf{r},\sigma) = \sum_{\mathrm{n}} \left[\mathrm{u_n}(\mathbf{r},\sigma)\gamma_{\mathrm{n}} + \mathrm{v}^{*}_{\mathrm{n}}(\mathbf{r},\sigma)\gamma^{+}_{\mathrm{n}} \right]$$

and imposing the condition $[\mathscr{H}, \gamma_n] = -E_n\gamma_n$. The $\binom{u}{v}$ are eigenfunctions of the system

$$\begin{aligned}
\epsilon u(r,\sigma) &= \left(\frac{\left(p-\frac{eA}{c}\right)^2}{2m} - E_F\right) u(r,\sigma) \\
&\quad + \sum_\mu \left[V_{\sigma\mu}(r)u(r,\mu) + \Delta(r)\rho_{\sigma\mu}v(r,\mu)\right] \\
-\epsilon v(r,\sigma) &= \left[\left(p+\frac{eA}{c}\right)^2 \frac{1}{2m} - E_F\right] v(r,\sigma) \\
&\quad + \sum_\mu \left[V^*_{\sigma\mu}(r)v(r,\mu) + \Delta^*(r)\rho_{\sigma\mu}u(r,\mu)\right]
\end{aligned}$$

We are interested in the limit $\Delta \to 0$. To zeroth order in Δ, $\binom{u}{v}$ are related to the electronic eigenfunctions ϕ_n in the normal metal, defined by

$$\begin{aligned}
\xi\phi(\mathbf{r},\sigma) &= \left[\frac{1}{2m}\left(\mathbf{p} - \frac{\mathrm{eA}}{\mathrm{c}}\right)^2 - \mathrm{E_F}\right]\phi(\mathbf{r},\sigma) + \sum_\mu \mathrm{U}_{\sigma\mu}(\mathbf{r})\phi(\mathbf{r},\mu) \\
&\equiv \mathscr{H}_\mathrm{e}\phi(\mathbf{r},\sigma) \\
\mathrm{u}^0_\mathrm{n} &= \begin{cases} \phi_\mathrm{n} & \xi_\mathrm{n} > 0 \\ 0 & \xi_\mathrm{n} < 0 \end{cases} \\
\mathrm{v}^0_\mathrm{n} &= \begin{cases} 0 & \xi_\mathrm{n} > 0 \\ \phi^*_\mathrm{n} & \xi_\mathrm{n} < 0 \end{cases} \qquad \epsilon^0_\mathrm{n} = |\xi_\mathrm{n}|
\end{aligned}$$

To first order in Δ we write

$$\begin{aligned}
u_n &= u^0_n + \sum_{m\neq n} a_{nm}\phi_m \\
v_n &= v^0_n + \sum_{m\neq n} b_{nm}\phi^*_m
\end{aligned}$$

The coefficients a_{nm} and b_{nm} are obtained by the usual perturbation method:

$$\mathrm{a_{nm}} = \begin{cases} 0 & (\xi_\mathrm{n} > 0) \\ \frac{-1}{\xi_\mathrm{n}+\xi_m}\sum_{\sigma\mu}\int \mathrm{d}\mathbf{r}_2\phi^*_m(\mathbf{r}_2\sigma)\,\rho_{\sigma\mu}\phi^*_\mathrm{n}(\mathbf{r}_2\mu)\,\Delta(\mathbf{r}_2) & (\xi_\mathrm{n} < 0) \end{cases}$$

$$b_\mathrm{nm} = \begin{cases} \frac{-1}{\xi_\mathrm{n}+\xi_m}\sum_{\sigma\mu}\int \mathrm{d}r_2\phi_\mathrm{n}(r_2\sigma)\,\rho_{\mu\sigma}\phi_\mathrm{n}(r_2\mu)\,\Delta(r_2) & (\xi_\mathrm{n} > 0) \\ 0 & (\xi_\mathrm{n} < 0) \end{cases}$$

We now insert these corrected values for u and v into the self-consistency equation for Δ. The latter, when spin indices are taken into account, takes the form

$$\Delta(r_1) = \frac{1}{2}V\sum_{\sigma\mu}\sum_n \rho_{\sigma\mu}v^*_n(r,\sigma)u_n(r,\mu)\left[1-2f(\xi_n)\right]$$

To first order in Δ this again has the form

$$\Delta(r_1) = \int K(r_1r_2)\,\Delta(r_2)\,dr_2 \tag{8-11}$$

and the kernel can still be expressed in terms of a correlation function by Eq. (8-1) and (8-5). The only change is that the definition of the time-reversal operator in (8-5) now involves the spin indices. Explicitly we have

$$\begin{aligned} \mathrm{K}\phi(\mathrm{r}\uparrow) &= \phi^*(\mathrm{r}\downarrow) \\ \mathrm{K}\phi(\mathrm{r}\downarrow) &= -\phi^*(\mathrm{r}\uparrow) \end{aligned} \tag{$\prime$}$$

In terms of Pauli spin matrices, one often writes

$$K = i\sigma_y C$$

where $\mathrm{C}\phi = \phi^*$ and $i\sigma_y$ coincides with our earlier defined $\rho = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$. Thus in all cases of interest we have reduced our problem to a study of the motion of the operator K for one electron in the normal metal.

At first sight, K is a rather unfamiliar object, but with some practice you can get a very physical understanding of it. Take for instance the case of orbital magnetic fields, where the equation of motion for K is (8-7). In Eq. (8-1) the order of magnitude of $|\xi - \xi'|$ is $\mathrm{k_B T}$. Thus in $f\,(r_1 r_2 t)$ the time scale of interest is $t \sim \hbar/k_B T$. The spatial distances traveled by an electron during such times are very large when compared to the Fermi wavelength. Then we can treat the motion of the operator K classically and write (8-7) in the form

$$\begin{aligned} \frac{dK(t)}{dt} &= -i\frac{d\phi}{dt}K \\ K(t) &= e^{-i\phi(t)}K(0) \\ \phi(t) &= \frac{2e}{\hbar cm}\oint_0^t A \cdot p dt \end{aligned} \tag{8-12}$$

In this last equation, the integral is to be taken along a classical one-electron trajectory in the normal metal. Replacing p by mv (the difference eA/c between p and mv being very small when compared to the Fermi momentum), we may rewrite the phase ϕ in the form

$$\phi = \frac{2e}{\hbar c}\int A \cdot v dt = \frac{2e}{\hbar c}\int A \cdot d\ell \tag{8-13}$$

In this case the correlation function $f\,(r_1 r_2 t)$ may be understood as follows: Consider all one-electron trajectories linking r_1 and r_2 in a time interval t. For a pure metal, there is only one such trajectory - essentially a straight line (the cyclotron radius being very large on our scale $v_F t$). For more "dirty" systems, there are many wiggly trajectories allowed. For each of these we compute $e^{i\phi}$. Finally we sum over the different allowed trajectories, each of them being weighted. according to its probability to occur in a succession of scattering processes: As announced, the calculation of f is reduced to a study of transport properties.

In case 2 (magnetic impurities), the equation of motion of K is derived in the following way: the one-electron Hamiltonian $\mathcal{K}_e$ is of the form

$$\mathscr{H}_e = A + B \cdot S_e \tag{8-14}$$

where A includes the kinetic energy and the spin-independent forces, while **B** stems from the Γ interaction with all impurities. Using the definition $(8-3')$ of K and the corresponding equations for the adjoint K^+, we can show that

$$\mathrm{K}^+ \mathscr{H}_\mathrm{e}\ \mathrm{K} = \mathrm{A}^* - \mathbf{B} \cdot \mathrm{S_e} \tag{8-15}$$

that is, $K^+ \mathscr{H}_e K$ is obtained from $\mathscr{H}_e$ by changing A into A^* (this amounts to changing p into $-p$ in the magnetic coupling term) and S_e into $-\mathrm{S_e}$. (This could be reached by changing the

direction of time for the conduction electrons and justifies the name "time-reversal operator.") We also notice that $K^+K = K^+ = 1$, and write

$$[\mathscr{H}_{\mathrm{e}},\ \mathrm{K}] = \mathscr{H}_{\mathrm{e}}\,\mathrm{K} - \mathrm{K}\mathscr{H}_{\mathrm{e}} = \mathrm{K}\,(\mathrm{K} + \mathscr{H}_{\mathrm{e}}\,\mathrm{K} - \mathscr{H}_{\mathrm{e}}) \tag{8-16}$$

Consider for instance pure case 2 (no orbital magnetic fields $A = A^*$). Then, by (8-15),

$$\frac{\mathrm{dK}}{\mathrm{dt}} = \frac{\mathrm{i}}{\hbar}\,[\mathscr{H}_{\mathrm{e}}, K] = -\frac{2\mathrm{i}}{\hbar}\,\mathrm{KB}\cdot\ \mathrm{S}_{\mathrm{e}} \tag{8-17}$$

Here we might also say that K acquires a time-dependent phase (due to the Γ coupling). However, we cannot treat the phase classically, because the potential B varies strongly in one atomic distance, or in one Fermi wavelength. We see later how the motion of K is analyzed in such situations. Before going into such details, we now discuss some general qualitative properties of $K(t)$ lin both cases (1) and (2) ⌋ related to the shape of the one-electron trajectories.

6.5.2 8-2 Ergodic Versus Nonergodic Behavior - Gapless Superconductivity

For the moment, let us restrict our attention to systems where the pair potential $\Delta(r)$ has an amplitude $|\Delta|$ constant in space. This greatly simplifies the discussion of the linear equations (8-8) or (8-11) and allows us to bring out directly the most important features. Also, it is not an academic case. It is found in the following situations:
(1) small superconducting colloids;
(2) thin superconducting films in fields parallel to the film surface;
(3) superconducting alloys, with magnetic impurities, in zero external field. In colloids, $|\Delta|$ cannot vary very much if all dimensions of the grains are small compared with $\xi(\mathrm{T})$. In thin films, we have to be more careful, since only one of the dimensions is small. In particular, if the field is normal to the film, it often penetrates by means
of vortices as in Type II superconductors (M. Tinkham, 1962), and then $|\Delta|$ is strongly varying in space. To avoid this, we only consider fields parallel to the surface. There is also another requirement on the colloids and films, related to the fact that we discuss second-order transition. In Type I materials, the transition is indeed observed to be of second order only if the sample thickness is smaller than one or two penetration depths.

Finally, for magnetic alloys (in zero field), it is also a reasonable starting point to take $|\Delta| =$ const. (This neglects only some rather weak local modulations of $\Delta(r)$ in the vicinity of each impurity.)

We now write down explicitly the equation for the transition temperature. For a singly connected specimen, we can choose a particular gauge for the vector potential $\mathbf{A}$, such that $\Delta(r)$ is real, and constant in space (since $|\Delta|$ is constant). This enables us to integrate the selfconsistency equation (8-11) on $\mathbf{r}_2$ and $\mathbf{r}_1$, obtaining

$$\Delta U = \int dr_1 dr_2 K\,(r_1 r_2)\,\Delta$$

By making use of (8-1), (8-5), and canceling out a factor Δv on both sides, we reach the condition

$$1 = \mathrm{N}(0)\mathrm{V}\int\ \mathrm{d}\xi\ \mathrm{d}\xi' \sum_{\omega} \frac{\mathrm{k_B\ T}}{(\xi - \mathrm{i}\omega\hbar)\,(\xi' + \mathrm{i}\omega\hbar)}\frac{1}{\hbar}\ \mathrm{g}\left[\frac{(\xi - \xi')}{\hbar}\right] \tag{8-18}$$

$$\mathrm{g}(\Omega) = \int \frac{\mathrm{dt}}{2\pi}\left\langle\ \mathrm{K}^+(0)\mathrm{K}(\mathrm{t})\right\rangle \mathrm{e}^{-\mathrm{i}\Omega\mathrm{t}}$$

$g(\Omega)$ is the power spectrum of the operator K. Instead of using the summation Σ_ω we may also, if we wish, write (8-18) in terms of Fermi functions $f(\xi)$

$$1 = N(0)V \int d\xi \, d\xi' \frac{1 - f(\xi) - f(\xi')}{\xi + \xi'} g\left[\frac{(\xi - \xi')}{\hbar}\right] \qquad (8\text{-}18')$$

[Some features are more striking on (8-18'), but (8-18) is more convenient for computational purposes.]

Discussion of this equation: First we notice that for all cases where the one-electron Hamiltonian $\mathcal{K}_e$ is invariant by time reversal ($[K, \mathscr{H}_e] = 0$), $K(t) = K(0)$:

$$\langle K^*(0)K(t)\rangle \equiv 1$$
$$g(\Omega) = \delta(\Omega)$$

The power spectrum of K has a single line at zero frequency. Then (8-18') reduces to

$$1 = N(0)V \int d\xi \frac{1 - 2f(\xi)}{2\xi}$$

This is the BCS condition for the transition temperature in conventional superconductors.

When $[K, \mathscr{H}_e] \neq 0$, we must study $g(t)$ in more detail. As pointed out, we are interested in $\Omega \sim k_B T/\hbar$ and $t \sim \hbar/k_B T$, that is, a very long time scale. Thus we consider first the limiting behavior of $\langle K^+(0)K(t)\rangle$ at very large times. There can be many types of limiting behavior. Two of them are particularly interesting:

(I) $\lim_{t\to\infty} \langle K^+(0)K(t)\rangle = \eta \neq 0$

(II) $\lim_{t\to\infty} \langle K^+(0)K(t)\rangle = \exp(-t/\tau_K)$

where η and τ_K are certain functions of the strength of the perturbation (the magnetic field, or the magnetic impurity concentration).

If our system is of class I, we say it is nonergodic.

If our system is of class II, we say it is ergodic and Markoffian.

Nonergodic Systems

We may write

$$\left\langle K^+(0)K(t)\right\rangle = \eta + R(t) \qquad (8\text{-}21)$$

where $R(t)$ is a rapidly decreasing function of time [for instance, in small samples of class I, the time constant of $R(t)$ is of order d/v_F where d is the sample dimension, and here $d \ll \xi_0$ or $d/v_F \ll \hbar/k_B T$].

Thus we may, in a first approximation, neglect completely $R(t)$ at the times of interest, and Eq. (8-18') takes again the BCS form

$$1 = N(0)V\eta \int_{-\hbar\omega_D}^{\hbar\omega_D} d\xi \frac{1 - 2f(\xi)}{2\xi} \qquad (8\text{-}22)$$

leading to a transition temperature

$$k_B\, T = 1.14\hbar\omega_D \exp\left(-\frac{1}{N(0)V\eta}\right) \qquad (8\text{-}23)$$

The behavior is close to that of a conventional superconductor in zero field, but the coupling constant $N(0) \vee \eta$ is now dependent on the strength of the perturbation (through η). The following problem discusses a physical system of class I.

Problem.

Discuss the behavior of $\langle K^+(0)K(t)\rangle$ at large times for a thin film (thickness d) with diffuse reflection on the boundaries but no volume defects, in a parallel field H (P. G. de Gennes and M. Tinkham, 1964).

Solution.

Consider an electron starting at point r_0 at time 0 (Fig. 8-3), then suffering collisions alternatively on both sides of the film at times $t_1, t_2, \ldots, t_n$ and finally arriving at r_t at time t. The phase ϕ defined by Eq. (8-13) is a sum of increments:

$$\phi = \Delta\phi_{01} + \Delta\phi_{12} + \cdots + \Delta\phi_{n-1n} + \Delta\phi_{nt}$$

The vector potential, in the gauge where Δ is real, has one nonzero component $A_y = Hx$. Then each of these increments (except $\Delta\phi_{01}$ and $\Delta\phi_{nt}$) is in fact equal to 0, as shown in Fig. 8-3.

$$\Delta\phi_{pp+1} = \frac{2eH}{\hbar c}\int_{x=-d/2}^{x=d/2} x\,dy = 0$$

The trajectory between two successive collisions is essentially a straight line; y is a linear function of x. Thus the above integral, taken between even limits, vanishes and $\phi = \Delta\phi_{01}+\Delta\phi_{\mathrm{nt}}$. Furthermore, when $\mathrm{t} \gg \mathrm{d}/\mathrm{v_F}$, the number of collisions n is large and the relevant time intervals $0 \to t_1$ and $t_n \to t$ are uncorrelated. We may thus write

$$\eta = \langle \exp(\mathrm{i}\Delta\phi_{01})\rangle \langle \exp(\mathrm{i}\Delta\phi_{\mathrm{nt}})\rangle \qquad \eta^{1/2} = \langle \exp(\mathrm{i}\Delta\phi_{01})\rangle$$

η is nonvanishing: in spite of the numerous collisions, the system is not ergodic in our sense. To compute η we consider an electron starting from an arbitrary point $\mathbf{r}$, with a randomly oriented velocity of length v_F, the projection of this velocity on the xy plane making an angle ψ with the x axis.

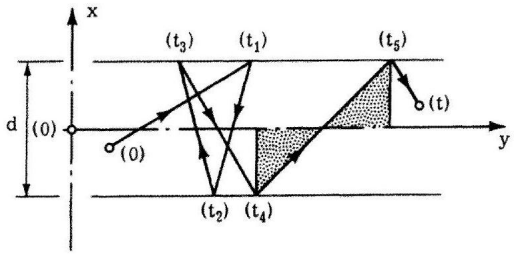

Figure 8-3
Successive collisions of one electron in a thin film with diffuse scattering on the boundaries.

$$\eta^{1/2} = \frac{1}{\pi d}\int_{-\pi/2}^{\pi/2} d\psi \int_{-d/2}^{d/2} dx \exp\left[i\pi\frac{H}{\phi_0}\left(\frac{d^2}{4} - x^2\right)\tan\psi\right]$$
$$= \frac{2}{d}\int_0^{d/2} dx \exp\left[\frac{\pi H}{\phi_0}\left(\frac{x^2 - d^2}{4}\right)\right]$$

where $\phi_0 = \mathrm{ch}/2\mathrm{e}$ is the flux quantum.

$$\eta = \begin{cases} 1 - \frac{\pi}{3}\frac{\mathrm{H}}{\phi_0}\,\mathrm{d}^2 & \mathrm{H} \ll \frac{\phi_0}{\mathrm{d}^2} \\ \left(\frac{2\phi_0}{\pi \mathrm{H d}^2}\right)^2 & \mathrm{H} \gg \frac{\phi_0}{\mathrm{d}^2} \end{cases}$$

Ergodic Markoffian Systems

If the exponential decay law (8-20) is obeyed at the times t of interest, we can write

$$\mathrm{g}(\Omega) = \frac{1}{\pi}\frac{{}^{\tau}\mathrm{K}}{1+\Omega^2\tau_{\mathrm{K}}^2} \tag{8-24}$$

and perform the integrations $\int \mathrm{d}\xi\mathrm{d}\xi'$ in Eq. (8-18). We arrive at the condition

$$1 = \mathrm{N}(0)\mathrm{V}\sum_{\omega} 2\pi\frac{\mathrm{k_B\ T}}{\hbar}\frac{1}{2|\omega| + \frac{1}{\tau_{\mathrm{K}}}} \tag{8-25}$$

The sum Σ_ω diverges. This is because we did not take into account the frequency cutoff ω_{D} of the interaction. A similar complication has been discussed after Eq. (7-28), p. 218. When the cutoff is taken into account, (8-25) becomes

$$1 = \mathrm{N}(0)\mathrm{V}\left[\ln\left(\frac{1.14\hbar\omega_{\mathrm{D}}}{\mathrm{k_B\ T}}\right) + \frac{2\pi\mathrm{k_B\ T}}{\hbar} \times\sum_{\omega}\left(\frac{1}{2|\omega| + \frac{1}{\tau_{\mathrm{K}}}} - \frac{1}{2|\omega|}\right)\right] \tag{I}$$

The sum is now convergent and can be expressed in terms of a tabulated function $\psi(z)$.

$$\psi(z) = \frac{\Gamma'(z)}{\Gamma(z)} = -0.577 - \frac{1}{z} + \sum_{\nu=1}^{\nu=\infty}\left(\frac{1}{\nu} - \frac{1}{\nu+z}\right)$$

$$\frac{2\pi k_B T}{\hbar}\sum_{\omega}\left(\frac{1}{2|\omega| + \frac{1}{{}^{\top}K}} - \frac{1}{2|\omega|}\right)$$

$$= \left(\frac{1}{2}\right) - \psi\left(\frac{1}{2} + \frac{\hbar}{4\pi{}^{\top}K^k k_B T}\right)$$

Finally the relation between $1/\tau_{\mathrm{K}}$ and T takes the implicit form

$$\ln\frac{\mathrm{T_0}}{\mathrm{T}} = -\psi\left(\frac{1}{2}\right) + \psi\left(\frac{1}{2} + \frac{\hbar}{4\pi\tau_{\mathrm{K}}\mathrm{k_B\ T}}\right) \tag{8-26}$$

Since a relation of this form occurs very often in the theory of superconductivity, we give a special name to it. We say that

$$\frac{\hbar}{\tau_K} = k_B T_0 \cup n\left(\frac{T}{T_0}\right) \tag{I}$$

The "universal function" Un(x) is shown in Fig. 8-4. For $\mathrm{x} \to 0$,

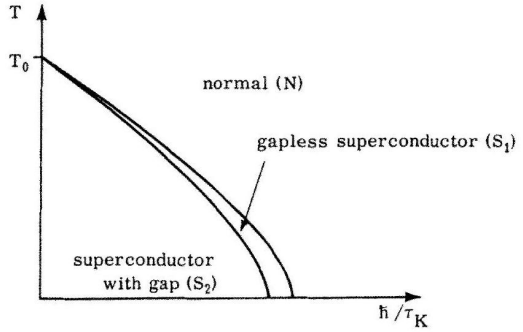

Figure 8-4

Phase diagram for a superconductor with "asymmetric" perturbations on the Cooper pairs + ergodicity. $\hbar/\tau_\kappa$ measures the strength of the perturbation.
Un(x) $\to$ 1.76 and $\hbar/\tau_{\mathrm{K}} \to 1.76\mathrm{k_B T_0} = \Delta_0$ [the BCS gap parameter in the unperturbed superconductor at $(T = 0)$]. For $x \to 1$

$$\mathrm{Un}(x) \to \frac{\pi}{8}(1-x) \tag{8-27}$$
$$\frac{\hbar}{\tau_K} \cong \frac{\pi}{8} k_B\,(T_0 - T) \quad (T \to T_0)$$

EXAMPLES OF "ERGODIC" SYSTEMS

(1) In a field H:
(a) small colloidal particles,
(b) thin films with both surface and volume scattering (for films of well controled thickness, surface scattering is not enough to bring in the ergodicity, as mentioned above) in parallel fields,
(c) thin films of irregular thickness.
(2) Alloys with magnetic impurities.

In the following problems, specific calculations of τ_{K} are described for Markoffian systems. In case (1) for instance, once $^{\top}$K is known as a function of magnetic field, we insert the result in Eq. (8-26) and obtain the critical field versus temperature curve.

Problem.

Compute τ_{K} for a small "dirty" sample of arbitrary shape under a field (K. Maki, 1963).

Solution.

We consider a sample of dimensions d much larger than the mean free path ℓ. It is important to realize, however, that there is an upper bound on d, related to our assumption $|\Delta| =$ const. At larger d's, we know in fact that the order parameter is not constant in space: The superconducting phase nucleates at a field $\mathrm{H_{C2}}$ or $\mathrm{H_{C3}}$, the nucleus having a size

$$\xi(\mathrm{T}) \sim \sqrt{\xi_0 \ell \frac{\mathrm{T_0}}{\mathrm{T_0 - T}}}$$

where $\xi_0 = 0.18\,(\hbar v_F/\mathrm{k}_B T_0)$. Thus, to be sure that $|\Delta|$ is constant, we must have

$$d < \sqrt{\xi_0 \ell \frac{\mathrm{T_0}}{\mathrm{T_0 - T}}}$$

and the inequalities

$$\ell < d < \sqrt{\xi_0 \ell \frac{\mathrm{T_0}}{\mathrm{T_0 - T}}}$$

allow only for a rather narrow range of d values. We discuss this region, however, since it is a simple example of ergodic behavior. From the point of view
of the one-electron trajectories, the condition $\sqrt{\xi_0 l} > d$ means that the diffusion length $\sqrt{Dt}$ (where $D = \frac{1}{3} v_F \ell$ and $t \sim \hbar/k_B T_0$) is larger than d, and consequently that at time t the electron has explored all regions of the sample. Then the phase $\phi(t)$ defined in Eq. (8-13) is a sum of many uncorrelated increments, and has a gaussian distribution. This implies that

$$\left\langle \mathrm{e}^{\mathrm{i}\phi(\mathrm{t})} \right\rangle = \mathrm{e}^{-1/2\left\langle \phi^2(\mathrm{t}) \right\rangle}$$

We write $\phi(\mathrm{t}) = \int_0^{\mathrm{t}} \mathrm{dt}'\omega\,(\mathrm{t}')$ with $\omega = 2\mathrm{ev}\cdot\mathrm{A}/\ \mathrm{hc}$. At times t much larger than the collision time $\tau = \ell/v_F$, we have

$$\left\langle \phi^2 \right\rangle - 2\mathrm{t}\int_0^\infty \langle \omega(0)\omega\,(\mathrm{t}')\rangle\,\mathrm{dt}' \quad (\mathrm{t} \gg \tau)$$

For trajectories originating from point r, we may write

$$\begin{aligned}\langle \omega(0)\omega\,(t')\rangle &= \left(\frac{2e}{\hbar c}\right)^2 \sum_{\alpha\beta} A_\alpha(r) A_\beta\,(r')\,\langle v_\alpha(0) v_\beta\,(t')\rangle \\ &= \left(\frac{2e}{\hbar c}\right)^2 A^2(r)\frac{v_F^2}{3} e^{-t'/\tau} \quad \alpha,\beta = x,y,z\end{aligned}$$

since at times of order τ the change of r along the trajectory is $\sim \ell$ and negligible on the scale of variation of $\mathbf{A}(\sim \mathrm{d})$. Then

$$\begin{aligned}\langle \exp[i\phi(t)]\rangle &= \exp\left(-t/\tau_K\right) \quad (t \gg \tau) \\ \frac{1}{\tau_K} &= \frac{1}{3}\tau\left(\frac{2\mathrm{ev}_F}{\hbar \mathrm{c}}\right)^2 \left\langle A^2(r)\right\rangle\end{aligned}$$

The average of A^2 is to be taken over the sample volume.
It is very important to realize that the choice of gauge for A is imposed by the condition: $\Delta =$ const.

For simple geometries, this gauge can be found by inspection:
(1) Thin film (of thickness d along $0x$) in uniform field (along 0z), carrying no over-all current.

$$\begin{aligned}A_x &= A_z = 0 \\ A_y &= Hx \quad \text{(where } x \text{ is measured from the midplane of the film)} \\ \left\langle A^2\right\rangle &= \frac{H^2 d^2}{12}\end{aligned}$$

(2) Spherical grain of radius R in uniform field

$$\begin{aligned}A &= \frac{1}{2} r \times H \\ \left\langle A^2\right\rangle &= \frac{H^2 R^2}{10}\end{aligned}$$

Problem.

Compute τ_{K} for a magnetic alloy (A. Abrikosov and L. P. Gorkov, 1961).

Solution.

The following is a "lowbrow" derivation. Start from the equation

$$\begin{aligned}g(\Omega) &= \frac{\sum}{m} |(n|K|m)|^2 \delta\left(\frac{\xi_m - \xi_n}{\hbar} - \Omega\right) \\ &= \frac{1}{\pi}\frac{\tau_k}{1+\Omega^2\tau_k^2}\end{aligned}$$

the average being taken over one-electron states at a fixed energy ξ_{n} (and in practice at the Fermi level). Choose a value $\Omega \gg 1/\tau_{\mathrm{k}}$ (although $\Omega \ll \mathrm{E_F}/\hbar$). Then $g(\Omega) \sim 1/\pi\Omega^2\tau_{\mathrm{K}}$ and we can write

$$\begin{aligned}\frac{1}{\tau_{\mathrm{K}}} &= \pi\hbar\sum_m \sqrt{\langle \mathrm{n}|\mathrm{K}|m\rangle|^2}\Omega^2\delta\left(\xi_{\mathrm{n}}-\xi_m-\hbar\Omega\right)\\ &= \frac{\pi}{\hbar}\sum_m \sqrt{\langle \mathrm{n}|\mathrm{K}|m\rangle|^2}\left(\xi_{\mathrm{n}}-\xi_m\right)^2\delta\left(\xi_{\mathrm{n}}-\xi_m-\hbar\Omega\right)\\ &= \frac{\pi}{\hbar}\sum_m \sqrt{\langle \mathrm{n}|\left[\mathcal{K}_{\mathrm{e}},\ \mathrm{K}\right]|m\rangle|^2}\delta\left(\xi_{\mathrm{n}}-\xi_m-\hbar\Omega\right)\end{aligned}$$

The commutator $[\mathscr{H}_e, K]$ has been derived in Eq. (8-17)

$$[\mathscr{H}_{\mathrm{e}}, K] = -2\ \mathrm{KB}\cdot\ \mathrm{S_e}$$

where $\mathrm{B} = \Sigma_{\mathrm{i}}\Gamma\left(r-r_{\mathrm{i}}\right)S_{\mathrm{i}}$.
To second order in the impurity potentials, we may now replace the exact one-electron states $|n\rangle, |m\rangle$ by plane waves $\phi_n \to L^{-3/2}e^{ik\cdot r}$

$$\frac{1}{\tau_{\mathrm{K}}} = \frac{\pi}{2\hbar}\sum_{\sigma,\mu}\sum_{\mathbf{k}'}\left(\sigma\mathbf{k}|2\mathbf{B}\cdot\mathbf{S}\rho|\mu\mathbf{k}'\right)\delta\left(\xi_{\mathbf{k}}-\xi_{\mathbf{k}'}-\hbar\Omega\right)$$

The summation on spin indices (σ, μ) is performed according to the rules

$$\begin{aligned}&\frac{1}{2}\sum_{\sigma\mu}\langle\sigma|\mathrm{S_e^X}|\mu\rangle\langle\mu|\mathrm{S_e^X}|\sigma\rangle = \frac{1}{2}\sum_{\sigma}\langle\sigma|\left(\mathrm{S_e^X}\right)^2|\sigma\rangle = \frac{1}{4}\\ &\frac{1}{2}\sum_{\sigma\mu}\langle\sigma|\mathrm{S_e^X}|\mu\rangle\langle\mu|\mathrm{S_e^Y}|\sigma\rangle = 0,\ \text{and so on}\end{aligned}$$

With the Γ interaction, the orbital part of the matrix element is given by

$$\langle k|\mathbf{B}\,|k'\rangle = L^{-3}\sum_{\mathbf{i}}\exp\left[i\left(k-\mathbf{k}'\right)\cdot\mathbf{r_i}\right]S_{\mathbf{i}}\Gamma\left(\mathbf{k}-\mathbf{k}'\right)$$

where

$$\Gamma(q) = \int_e^{iqr}\Gamma(r)dr$$

On squaring and only keeping terms of the form S_iS_i, not S_iS_j (no correlation between impurities), we obtain

$$\frac{1}{\tau_K} = \frac{\pi}{\hbar}\frac{n}{L^3}\frac{S_i\left(S_i+1\right)}{3}\sum_{k'}\left|\Gamma\left(k-k'\right)\right|^2\delta\left(\xi_k-\xi_{k'}-\hbar\Omega\right)$$

where n is the number of impurities per cm^3.
Finally we may simplify this by taking $\hbar\Omega \to 0$, because Σ_{k} ' is nearly independent of $\hbar\Omega$ (when $\hbar\Omega \ll E_F$) and $\xi_k \to 0$, that is, we calculate $1/\tau_K$ just at the Fermi surface. [2] Then

$$\frac{1}{\tau_K} = \frac{\pi}{\hbar}n\frac{S_i\left(S_i+1\right)}{3}N(0)\int\frac{d\Omega_{k'}}{4\pi}\left|\Gamma\left(k-k'\right)\right|^2$$

where $\int \mathrm{d}\Omega_{\mathrm{k}'}$ is an integration over the polar angles of $\mathbf{k}'$. The lengths are $k = k' = k_F$. If x is the impurity fraction and a^3 the atomic volume ($n = x/a^3$):

$$N(0) = \frac{1}{a^3E_F},\quad \Gamma(q) \sim \Gamma\cdot a^3$$

and thus

$$\frac{\hbar}{\tau_K} \sim x\frac{\Gamma^2}{E_F}$$

Comments on this formula:
(1) At small $x, 1/\tau_K$ is small and Eq. (8-27) may be used to derive the transition point T. Qualitatively, this gives

$$k_B\left(T_0 - T\right) \sim x\frac{\Gamma^2}{E_F}$$

T decreases very rapidly when magnetic impurities are added. Typically $\Gamma \sim 0.2\text{eV}, E_F \sim 2\text{eV}, \Gamma^2/E_F \sim 2.10^{3\circ}\text{K}$. For $x = 10^{-3}, T$ has dropped by 2°. Such rapid drops are indeed observed in practice. They are now, in fact,

one of the best methods to ascertain whether an impurity is, or is not, magnetic in a given matrix.
(2) The whole calculation is valid only when $x\left(\Gamma^2/E_F\right) \ll k_B T_0$. This comes from the following effect: In the presence of the Γ coupling, an indirect interaction appears between the impurities, of the form

$$H_{ij} = S_i \cdot S_j \frac{\Gamma^2}{E_F} f\left(k_F R_{ij}\right)$$

where $E_F = \hbar^2 k_F^2/2m$ is the Fermi energy of the conduction electrons and $f\left(k_F R_{ij}\right)$ is a dimensionless function which behaves at large distances as $\left(k_F R\right)^{-3}\cos 2k_F R$ (M. A. Ruderman and C. Kittel, 1954). Because of H_{ij}, the impurities order magnetically (ferro- or antiferromagnetically) at low temperatures. The magnetic transition point is roughly given by $k_B T_c = x\left(\Gamma^2/E_F\right)$. We need $T_c \ll T$ where T_c is the superconducting transition temperature of the alloy. Under these conditions:
(a) Each impurity is only weakly coupled to the others and its spin direction is nearly independent of time (static impurities).
(b) The spin correlation between two impurities is of the order of T_c/T and is thus negligible (independent impurities).
(3) Note that if a spin-orbit coupling term is added to $\mathscr{H}_e$, it does not contribute to $1/\tau_{\text{K}}$ since it is invariant under time inversion. This shows an important difference between τ_K and the electron spin relaxation time T_1 (the spin-orbit coupling contributes to T_1).
(4) The whole calculation is valid only to order Γ^2. In higher orders, the situation is complicated by the so-called "Kondo effect."

Gapless Superconductivity

At temperatures slightly below the transition point defined by (8-26), Δ is nonzero, but still small. We can treat it as a perturbation, and compute the excitation energies ϵ_{n} of the quasiparticles. As usual, knowledge of the wave functions u, v, to first order in Δ, permits the calculation of the eigenvalues ϵ to order Δ^2. Taking u and v from the calculations before Eq. (8-11), we arrive at

$$\epsilon_{\text{n}} = |\xi_{\text{n}}| + |\Delta|^2 \sum_m \text{p}\frac{|\langle \text{n}|\text{K}|m\rangle\,|^2}{\xi_{\text{n}} + \xi_m} \tag{8-28}$$

(P denotes a principal part, at $\xi_n = -\xi_m$).
If the one-electron Hamiltonian is invariant under time-reversal $[\mathcal{F}_{\text{e}}, K] = 0$ and $\langle \text{n}|\text{K}|m\rangle$ is

[2] We can pass to the limit $\Omega \to 0$ in the final expression even though in the initial expression we took $\Omega \gg 1/\tau_{\text{K}}$. This simplification is introduced when the true states $|\text{n}\rangle$ are replaced by the unperturbed states $|\text{k}\rangle$.

0 unless $\xi_m = \xi_\mathrm{n}$. Then the perturbation calculation is not good: If ξ_n is small, the energy denominator $2\xi_\mathrm{n}$ is small and the correction diverges. This is related to the existence of the BCS energy gap. The same properties appear in all nonergodic systems.

For an ergodic system, $\langle n|K|m\rangle$ is not singular at $\xi_m = \xi_n$ and has nonzero components in a finite band $|\xi_m - \xi_\mathrm{n}| \sim \hbar/\tau_\mathrm{K}$. Thus the energy denominator in (8-28) remains finite, even if ξ_n (or ξ_m) goes to 0 . The perturbation calculation works. The expansion parameter is now $\Delta/(\hbar/\tau_K) = \Delta\tau_K/\hbar$ instead of Δ/ξ_n. We can compute ϵ_n explicitly if we make use of (8-24) for the power spectrum of K; performing the integration, we get

$$\begin{aligned}\epsilon &= |\xi| + |\Delta|^2 \mathrm{P}\int \mathrm{d}\xi' \mathrm{g}\left(\frac{\xi-\xi'}{\hbar}\right)\frac{1}{\xi+\xi'} \\ &= |\xi| + \frac{2|\Delta|^2|\xi|}{(2\xi)^2 + (\hbar/\tau_\mathrm{K})^2} \quad \left(\frac{\Delta\tau_\mathrm{K}}{\hbar} \ll 1\right)\end{aligned} \tag{8-29}$$

The form of this dispersion law is shown on Fig. 8-4. For $\xi \gg \hbar/\tau_K$, $\epsilon \cong \xi + \Delta^2/2\xi \cong (\Delta^2+\xi^2)^{1/2}$. which is the BCS result for conventional superconductors. On the other hand, if $\xi \to 0, \epsilon \to \xi\left[1 + 2\left(\Delta\tau_\mathrm{K}/\hbar\right)^2\right]$ tends toward 0 linearly. There is no gap in the excitation spectrum. Equation (8-29) can also be expressed in terms of a density of states $N_S(\epsilon)$. To order Δ^2 we have

$$\mathrm{N_S}(\epsilon) = \mathrm{N}(0)\frac{\partial\xi}{\partial\epsilon} \cong \mathrm{N}(0)\left[1 + 2\left(\frac{\Delta\tau_\mathrm{K}}{\hbar}\right)^2 \frac{(2\epsilon)^2 - (\hbar/\tau_\mathrm{K})^2}{\left[(2\epsilon)^2 + (\hbar/\tau_\mathrm{K})^2\right]^2}\right] \tag{8-30}$$

$\mathrm{N_S}(\epsilon)$ is lower than the normal state value $\mathrm{N}(0)$ when $\epsilon < \hbar/2\tau_\mathrm{K}$, but still finite (Fig. 8-5).

The material has no gap, but it is still a superconductor. For instance, we can compute the screening currents induced by an applied magnetic field H, and we find that they do not vanish - they are of order Δ^2 as usual.

This remarkable "gapless superconductivity" takes place only in the region of small Δ 's ($\Delta\tau_K/\hbar < 1$) where our perturbation calculation converges. At larger Δ 's we find a gap again. This can be represented in a diagram where we plot along x the strength of the perturbation (measured by $\hbar/\tau_K$) and along y the temperature (Fig. 8-5). In such a plane, we find 3 regions:

$N =$ normal
$S_1 =$ gapless superconductor
$S_2 =$ superconductor with gap

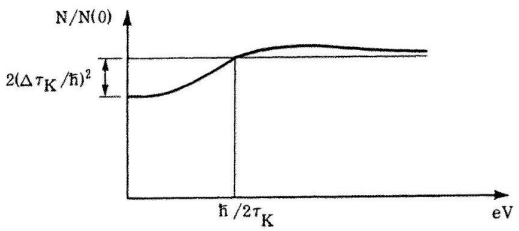

Figure 8-5
Gapless superconductivity: Density of states for Fermi-type excitations as a function of excitation energy. (The curve is valid when the pair potential Δ is small when compared with $\hbar/\tau_K$.) Note that the energy scale is given by $\hbar/\tau_K$ (not by Δ).

The boundary between N and $\mathrm{S_1}$ is given by the universal function of Eq. (8-26'). The boundary between S_1 and S_2 must be computed by more sophisticated techniques (in our language: summing the whole series in powers of Δ).

There is some evidence for the existence of region S_1 in magnetic alloys, from tunneling experiments on InFe (quenched) solid solutions (F. Reif and M. Woolf, 1962). Unfortunately, in the region of greatest interest $[x\,(\Gamma^2/E_F) \sim k_B T_0]$, the impurity spins precess rapidly in their mutual exchange fields and this complicates the interpretation of all data on magnetic alloys. Colloidal particles or films in a parallel field should also exhibit the region S_1, but, in the present state of the art, their dimensions are not accurately controlled (what an experimentalist calls a 500Å film is in most cases an irregular layer with bumps and holes maybe 100Å or more in amplitude). τ_{K} depends on the thickness. To display clearly the region S_1, ${}^{\top}K$ would have to be fixed to a few per cent, as is clear from Fig. 8-4. This is beyond present technical capability.

More convenient examples of gapless superconductivity will be mentioned in the next paragraph, where we allow $|\Delta|$ to vary in space.

6.5.3 8-3 Dirty Superconductors in High Magnectic Fields

From now on, we restrict our attention to "dirty," nonmagnetic alloys. More precisely we assume that the mean free path ℓ is much smaller than $\xi_0 = 0.18\,(\hbar v_{\mathrm{F}}/\mathrm{k_B T_0})$ and also much smaller than all
sample dimensions d. We also assume that the sample is surrounded only by insulators (no normal metal plated on the surface). Apart from these restrictions, the shape of the specimen is arbitrary, and we do not assume that $|\Delta|$ is constant in the whole volume.

We shall now show that, for such conditions, the linear self-consistency equation (7-8) can be replaced by a second-order differential equation generalizing the Landau-Ginsburg equation at all temperatures. Basically, this simplification occurs because the transport properties in the normal state are ruled by a diffusion equation-a second-order differential equation.

As we know, the kernel $\mathrm{K}\,(\mathbf{r}_1\mathbf{r}_2)$ of Eq. (7-8) can be expressed in terms of the correlation function $f\,(r_1 r_2 t)$ defined in Eq. (8-5). In the "dirty" limit, it is not hard to find out what is the differential equation satisfied by f. We consider two successive times $t(>0)$ and $t+\epsilon$ (ϵ being small) and write down that a particle reaching r_1 at time $t+\epsilon$ has come by diffusion from a point r' at time t. The average distance between r_1 and r' is small (of order $\sqrt{\epsilon}$) and thus the corresponding increment in phase $\Delta\phi$ of K is simply

$$\Delta\phi = \frac{2e}{c} A\,(r_1)\cdot(r_1 - r')$$

Thus

$$\mathrm{f}\,(\mathbf{r}_1\mathbf{r}_2, \mathrm{t}+\epsilon) = \int \mathrm{d}_3\mathbf{r}'\mathrm{f}\,(\mathbf{r}'\mathbf{r}_2, \mathrm{t})\,D\,(\mathbf{r}_1\mathbf{r}'|\epsilon)\,\mathrm{e}^{\mathrm{i}\Delta\phi} \tag{8-31}$$

Here $D\,(r_1 r'|\epsilon)$ is the function describing the spread of a point source at point $\mathbf{r}_1$ after a time ϵ has elapsed. It is a solution of the diffusion equation:

$$\frac{\partial}{\partial\epsilon}\mathfrak{D} = D\nabla'^2\mathfrak{D} \quad \nabla' = \left(\frac{\partial}{\partial \mathrm{x}'}, \frac{\partial}{\partial \mathrm{y}'}, \frac{\partial}{\partial \mathrm{z}'}\right)$$

together with the initial condition $\lim D = \delta\,(r_1 - r')$ and appropri-

$$\epsilon \to 0$$

ate boundary conditions on the sample surface $(\nabla' D)_{\mathrm{normal}} = 0$. For an infinite medium, for instance, we have

$$D\,(r_1 r'|\epsilon) = \frac{1}{(4\pi D\epsilon)^{3/2}} e^{-(r_1 - r')^2/4D\epsilon}$$

Expanding $f(r'r_2t)$ in a Taylor series around $r' = r_1$ in (8-31), retaining all terms up to first order in ϵ, and identifying coefficients on both sides, we obtain the required differential equation

$$\frac{\partial f}{\partial t} = D\left(\nabla_1 - \frac{2ieA}{c}\right)^2 f \quad (t > 0) \tag{8-32}$$

A similar calculation near the boundary of the specimen leads to the condition

$$\left(\nabla - \frac{2ieA}{c}\right)_n f = 0 \tag{8-33}$$

where n represents the direction of the normal to the surface. Finally, for $t \to 0$, the function f reduces to a δ function suitably normalized:

$$f(r_1r_2, 0) = V^{-1}\delta(r_2 - r_1) \quad V = \text{ sample volume} \tag{8-34}$$

Let us now assume that we have found the eigenfunctions $g_p(r)$ of the linear operator appearing in (8-32); the g's are defined by

$$-D\left(\nabla - \frac{2ieA}{c}\right)^2 g_p(r) = \frac{\epsilon_p}{\hbar} g_p(r) \tag{8-35}$$

with the boundary condition (8-33). We can then expand the delta function in (8-34) in terms of the g's, obtaining, for any $t > 0$,

$$f(r_1r_2t) = v^{-1}\sum_p g_p^*(r_2)\, g_p(r_1) \exp(-\epsilon_p t/\hbar) \tag{8-36}$$

We insert (8-36) in (8-1) and perform the integration over t, obtaining

$$\begin{aligned} K(r_1r_2) =& k_BT\sum_\omega 2\pi N(0)V \\ &\times \sum_p g_p^*(r_2)\, g_p(r_1)\, \frac{1}{2\hbar|\omega| + \epsilon_p} \end{aligned} \tag{8-37}$$

Finally, if we make use of (8-37), our starting equation (8-8) becomes

$$\begin{aligned} \Delta(r_1) =& N(0)V2\pi k_BT\sum_\omega\sum_p \frac{1}{2\hbar|\omega| + \epsilon_p} g_p(r_1) \\ &\times \int dr_2 \Delta(r_2)\, g_p^*(r_2) \end{aligned} \tag{8-38}$$

The eigenfunctions of this linear integral equation for Δ are simply the g's. For, if we choose $\Delta(r) = g_q(r)$, the orthogonality of the g's leaves only one term $p = q$ in the sum Σ_p and (8-38) is satisfied provided that

$$1 = N(0)V2\pi k_BT\sum_\omega \frac{1}{2\hbar|\omega| + \epsilon_q} \tag{8-39}$$

Equation (8-39) has a familiar form, and leads to

$$\epsilon_q = k_BT_0 \cup n\left(\frac{T}{T_0}\right)$$

where the universal function Un(x) has been discussed earlier. For a fixed field H and a given sample shape, the ϵ_{q} 's are fixed [and can be computed, more or less laboriously, by solving Eq. (8-35)]. What we want to know is the highest temperature T at which (8-38) has a nonzero solution $\Delta(r)$.
Un(x) is a decreasing function of x . Thus we must choose the lowest eigenvalue ϵ_0. Thus the recipe to compute a nucleation field for a "dirty" sample of arbitrary shape is the following: We find the lowest eigenvalue ϵ_0 of Eq. (8-35) plus the boundary condition corresponding to (8-33). This is then a known function of the field ϵ_0(H). To obtain the relation between nucleation field and temperature, we write

$$\frac{\epsilon_o(\mathrm{H})}{\mathrm{k_B\ T_0}} = \mathrm{Un}\left(\frac{\mathrm{T}}{\mathrm{T_0}}\right) \tag{8-40}$$

Problem.

Derive a formula for the critical field $\mathrm{H_{C2}}$ in a dirty superconductor, valid at all temperatures (K. Maki, P. G. de Gennes, and N. Werthamer, 1964).

Solution.

Equation (8-35) has the form of a Schrdinger equation for a particle of mass $\hbar/2D$ and charge $2e$. The cyclotron frequency for such a particle is

$$\omega_c = \frac{4eD}{c\hbar}H = 4\pi\frac{DH}{\phi_0}$$

where ϕ_0 is the flux quantum. The lowest eigenvalue is

$$\epsilon_0 = \frac{1}{2}\hbar\omega_{\mathrm{c}}$$

Writing that $\mathrm{H} = \mathrm{H_{C2}}$ and $\epsilon_0 = \mathrm{Un}\,(\mathrm{T}/\mathrm{T_0})$, we arrive at the implicit equation

$$\ln\left(\frac{\mathrm{T_0}}{\mathrm{T}}\right) = \psi\left(\frac{1}{2}\right) - \psi\left(\frac{1}{2} + \frac{\hbar\mathrm{DH_{C2}}}{2\phi_0\mathrm{k_B\ T}}\right)$$

Discussion of this equation: First, for T close to $T_0, \mathrm{H_{C2}}$ close to 0, we can make use of the aforementioned expansion of Un(T) and get

$$\mathrm{H_{C2}} = \frac{4}{\pi^2}\phi_0\frac{\mathrm{k_B}\,(\mathrm{T_0} - \mathrm{T})}{\hbar\mathrm{D}} \quad (\mathrm{T} - \mathrm{T_0})$$

It is easily verified that this agrees with the Landau-Ginsburg formula $\mathrm{H_{c2}} = \kappa\sqrt{2}\mathrm{H_c}$ when we take for κ the Gorkov expression in the dirty superconductor limit (Eq. 7-47), that is,

$$\kappa = 0.75\frac{\lambda_L(0)}{\ell}$$

For $T = 0$ on the other hand, we have

$$\frac{2\pi\hbar_{\mathrm{L2}}}{\phi_0} = k_{\mathrm{B}}\ \mathrm{T_0 Un}(0) = 1.76\mathrm{k_B\ T_0} = \Delta_{00}$$

while the bulk critical field is given by $H_{\mathrm{C}}^2/8\pi = \frac{1}{2}N(0)\Delta_{00}^2$, or

$$H_c = \sqrt{\frac{3}{2}}\frac{1}{\pi^2}\frac{\phi_0}{\xi_0\lambda_L{}^{(0)}}$$

This leads to

$$\frac{\mathrm{H_{C2}}}{\sqrt{2}\mathrm{H_c}} = \frac{\sqrt{3}}{2}\frac{\lambda_\mathrm{L}(0)}{\ell} = 0.87\frac{\lambda_\mathrm{L}(0)}{\ell}$$

Thus the ratio $\mathrm{H_{c2}}/\sqrt{2}\mathrm{H_c}$ increases only by 20 per cent when one goes from $T = T_0$ to $T = 0$. A similar calculation for a plane boundary shows that in a superconductor the ratio $\mathrm{H_{C3}}/\mathrm{H_{C2}}$ should remain equal to 1.69 at all temperatures. Also, when the field is applied at a finite angle θ from the surface, the angular dependence of $\mathrm{H_{C3}}(\theta)/\mathrm{H_{C2}}(0)$ has a form independent of temperature. Both these properties appear to be well confirmed by experiment. (In fact, it had been a surprise to notice that in dirty superconductors the Landau-Ginsburg linearized equation applied so well at low temperature.)

A THEOREM ON THE LOCAL DENSITY OF STATES

Just as in Section 8-2, we can, if we wish, study our system at temperatures slightly below the nucleation point T. In particular we can compute the density of states $\mathrm{N_S}(\mathbf{r}\epsilon)$ for excitation energy ϵ. It is now a function of the observation point $\mathbf{r}$ since the order parameter $\Delta(r)$ is not constant in space. This function can be measured by tunneling experiments. When N_S is computed to order $|\Delta|^2$, the results are remarkably simple (P. G. de Gennes, 1964).
(1) $\mathrm{N_S}(\mathrm{r}\epsilon)$ depends only on the value of $\Delta(\mathrm{r})$ at the observation point $\mathbf{r}$. This local relationship is at first sight very surprising. In the initial equation it is found in fact that $N_S(r\epsilon)$ depends on the values of $\Delta(r')$ within a radius $\sim \xi(T)$ from r. But just below the nucleation temperature, we know that the function $\Delta(r)$ has a simple shape. It is proportional to one of the eigenfunctions $\mathrm{g_0}(\boldsymbol{r})$ of Eq. (8-35). This remark permits one to carry out explicitly the required integrations in $N_S(r\epsilon)$ and the final result involves only $\Delta(r)$.
(2) $\mathrm{N_S}(\mathrm{r}\epsilon)$ is given by Eq. (8-30) where Δ is now the local value $\Delta(r)$, and where $\hbar/\tau_K = \epsilon_0$ is related to the temperature by Eq. (8-40). Thus, in the region of validity of the calculation $\left[\bar{\Delta}\tau_K/\hbar\tau 1\right.$, or (H nucleation -H) /H $\ll 1$ $\left.\right]$, our dirty systems are all gapless superconductors. These predictions have recently been confirmed by tunneling experiments on various alloys in both the $\mathrm{H_{C_3}}$ and $\mathrm{H_{C_2}}$ regions (E. Guyon and A. Martinet, 1964). In particular, these experiments show that the energy scale (given by $\hbar/\tau_\mathrm{K} = \epsilon_0$) on which the density of states deviates from N(0), is finite even when the order parameter $\Delta(r)$ becomes very small (that is, when H becomes close to the nucleation field). These measurements give in fact an accurate measurement of τ_K.

7 Well-known phenomena of superconductors

7.1 Magnetic properties of first kind superconductors by de Gennes

7.1.1 2-1 Critical field of a long cylinder

A long superconducting cylinder of radius r_0 is placed in a solenoid of radius $r_1 > r_0$ (Fig. 2-1).

A (weak) current I flows in the coil. The resulting field distribution $h(r)$ is shown in Fig. 2-2. Outside the sample, $h(r)$ takes a constant value H. In the sample the field falls rapidly (in a depth $\lambda \sim 500$Å) to 0. We restrict our attention to a macroscopic specimen ($r_0 \gg \lambda$). Then, on the scale r_0, the field does not penetrate into the sample.

This complete flux expulsion is observed for weak external fields H, but, when H reaches a critical value H_c, a radical modification occurs:

(1) The field becomes uniform across the entire section.

(2) The specimen is no longer superconducting (this we can see in principle by measuring the resistivity between the ends of the cylinder). With sufficiently perfect specimens, one can verify that this transition is reversible. If I is now decreased, the superconducting state reappears with total flux expulsion. Typical values of H_c are given in Table 2-1. The critical field decreases with increasing temperature, roughly according to the law

$$H_c(T) = H_c(0)\left[1 - \frac{T^2}{T_0^2}\right] \tag{2-1}$$

(For $T > T_0$ the material is normal even in zero field; T_0 is the

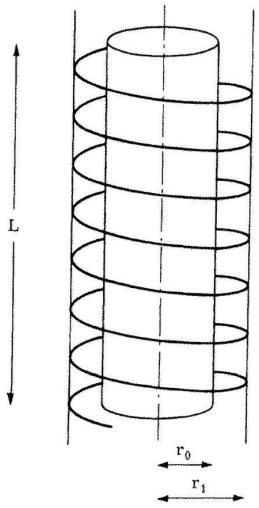

Figure 2-1

Experimental geometry to measure the critical field. The sample is a long cylinder (of length L and radius r_0). It is placed in a coil of radius r_1.

transition temperature in zero field.) From H_c, we can calculate the difference in free energy between the normal and superconducting states:

(a) When the cylinder is normal the field is uniform across the solenoid

$$h = \frac{4\pi NI}{cL} \tag{2-2}$$

(where N is the number of turns in the solenoid and L is its length, which is also the length of the specimen). The free energy of the system becomes

$$\mathcal{F}_{\mathrm{a}} = \pi \mathrm{r}_0^2 L F_{\mathrm{n}} + \pi \mathrm{r}_1^2 L \frac{\mathrm{h}^2}{8\pi} \tag{2-3}$$

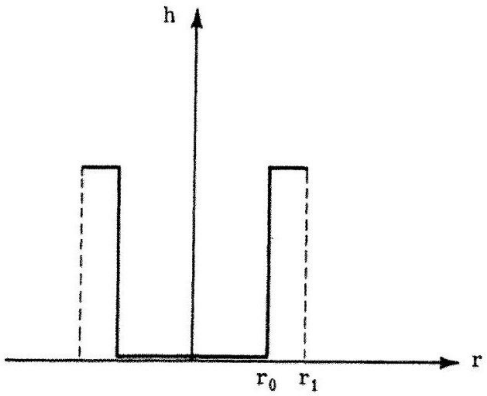

Figure 2-2 The field distribution of the coil and cylinder of Fig. 2-1 while the cylinder is superconducting. The field penetrates only up to one penetration depth in the sample. On the scale of the figure we may say that H drops abruptly to 0 inside the sample.

F_n is the free energy density of the normal sample and the second term is the magnetic energy stored in the coil.

(b) Suppose now that the cylinder becomes superconducting, the current being kept constant in the coil. The field is zero in the sample, but it maintains the value (2-2) in the region $r_0 < r < r_1$[1] The free energy becomes

$$\mathcal{F}_{\mathrm{b}} = \pi \mathrm{r}_0^2 L F_{\mathrm{s}} + \pi \left(\mathrm{r}_1^2 - \mathrm{r}_0^2\right) \mathrm{L} \frac{\mathrm{h}^2}{8\pi} \tag{2-4}$$

where F_S is the free energy density of the superconducting sample. Equation (2-4) neglects the penetration of the field in the thickness and

[1] In order to demonstrate this property, one writes curl $h = (4\pi/c)j$, from which

$$\oint \mathrm{h} \cdot \mathrm{dl} = \frac{4\pi}{\mathrm{c}} \int \mathrm{j} \cdot \mathrm{d}\boldsymbol{\sigma}$$

and one takes for a contour a line of force passing through the coil (in the region $r_0 < r < r_1$). The contributions to $\phi \mathrm{h} \cdot \mathrm{dl}$ from the parts of the line of force enclosing the magnetic current in the exterior of the coil are negligible if the solenoid is long, and one obtains $h = (4\pi \mathrm{NI/cL})$.

Table 2-1

Values of T_c and $\mathrm{H_c}(0)$ for some metals

	Zn	Cd	Hg(α)	Al	Ga	In	Tl	Sn	Pb
$\mathrm{H_c}(0)$(G)	53	30		99	51	283	162	306	803
$\mathrm{T_c}$(K)	0.88	0.56	4.15	1.19	1.09	3.41	1.37	3.72	7.18

also the kinetic energy of the surface currents - both these terms are surface effects, and are negligible for a macroscopic cylinder ($r_0 \gg \lambda$).

Note that $\mathcal{F}_{\mathrm{b}} < \mathcal{F}_{\mathrm{a}}$, because (1) $\mathrm{F_s} < \mathrm{F_n}$ and (2) the magnetic term is smaller in state b. What has become of the energy $\mathcal{F}_a - \mathcal{F}_b$ when the transition occurs? Answer: The flux ϕ passing through the coil diminishes when we go from (a) $\rightarrow$ (b). This induces a voltage V in the coil. The work done by this voltage V on the external circuit is

$$\int \mathrm{VI}dt = \int_{\mathrm{a}}^{\mathrm{b}} - \left(\frac{\mathrm{N}}{\mathrm{c}} \frac{\mathrm{d}\phi}{\mathrm{dt}}\right) \mathrm{I}dt \tag{2-5}$$

The current I is kept constant during the transition. Therefore,

$$\begin{aligned}\int \mathrm{VIdt} &= \frac{\mathrm{N}}{\mathrm{c}}\mathrm{I}\left(\phi_{\mathrm{a}} - \phi_{\mathrm{b}}\right) \\ &= \frac{\mathrm{NI}}{\mathrm{c}}\pi \mathrm{r}_0^2\ \mathrm{h} \\ &= \pi \mathrm{r}_0^2\ \mathrm{L}\frac{\mathrm{h}^2}{4\pi}\end{aligned} \tag{2-6}$$

At equilibrium between the two states ($\mathrm{h} = \mathrm{H_c}$), we must have $\mathcal{F}_{\mathrm{a}} - \mathcal{F}_{\mathrm{b}} = \mathrm{SVI\ dt}$. Using Eqs. (2-3) and (2-4), we obtain

$$F_n - F_S = \frac{H_c^2}{8\pi} \tag{2-7}$$

From these relations one can deduce a series of thermodynamical properties. Fix the current I and vary the temperature. The entropy (per cubic centimeter) of each phase is determined from the formulas

$$S_n = -\frac{dF_n}{dt} \quad S_s = -\frac{dF_s}{dT} \tag{2-8}$$

Therefore the difference in entropy between the two phases at equilibrium becomes

$$S_n - S_S = -\frac{1}{4\pi} H_c \frac{d_c}{dT} \tag{2-9}$$

The latent heat of the transition is

$$L = T\left(S_n - S_S\right) = -\frac{T}{4\pi} H_c \frac{dH_c}{dT} \tag{2-10}$$

This heat is positive; it is necessary to furnish this energy to pass from the superconducting state to the normal state. [2]

L vanishes when one considers the transition in zero field: for $\mathrm{T} = \mathrm{T_c}, \mathrm{H_c} = 0$, and experiment shows that for all superconductors studied until now $\mathrm{dH_c/dT}$ remains finite, therefore $[L]_{\mathrm{H}=0} = 0$.

Thus in zero field the superconducting transition is of the second order. There is a discontinuity in the specific heat

$$\begin{aligned}C_n - C_S &= T\frac{d}{dT}\left(S_n - S_S\right)_T = T_c \\ &= -\frac{T}{4\pi}\left(\frac{dH_c}{dT}\right)_T^2 = T_c\end{aligned} \tag{2-11}$$

Formulas $(2-10)$ and $(2-11)$ have been verified to better than 1% in several metals (notably $\mathrm{Sn}, \mathrm{In}, \mathrm{Ta}$); these experiments demand some care; it is especially necessary to assure that equilibrium has set in, that is, no flux is "frozen" in the superconductor, and so on. The practical interest of the relations $(2-10)$ and $(2-11)$ is to relate the thermodynamic quantities (latent heat and specific heat) to the critical field curve, which is often easier to measure.

[2] Consequence: If one passes from the superconducting state to the normal state in a thermally isolated specimen, the temperature of the sample decreases.

7.1.2 2-2 Penetration depths

Relation between Current and Field in a First Kind Superconductor

On the macroscopic scale, a weak field ($h < H_c$) does not penetrate into a first kind superconductor. However, on the microscopic scale, the field does not vary discontinuously at the surface. It penetrates a certain depth λ in the metal. We would like to compute λ.

In Chapter 1 we derived λ from the London equation

$$\operatorname{curl} j = -\frac{ne^2}{mc} h \tag{2-12}$$

But, in superconductors of the first kind ($\xi_0 > \lambda$), Eq. (2-12) is not valid. We need a more general relation between currents and fields, applicable even when f and h have rapid variations in space.

It turns out that the most convenient variable here is not the field h, but rather the vector potential A such that

$$\operatorname{curl} A = h \tag{2-13}$$

This equation does not define A completely. We often find it convenient to specify **A** exactly by adding the supplementary conditions

$$\begin{aligned} \operatorname{div} A &= 0 \\ A_n &= 0 \quad \text{on the sample surface} \end{aligned} \tag{2-14}$$

(A_n is the component of A normal to the surface). When Eqs. (2-14) are satisfied we say that A is chosen in the London gauge. In the London gauge (2-12) can be rewritten as

$$j = -\frac{ne^2}{mc} A \tag{2-15}$$

since insertion of (2-13) gives (2-12) and insertion of (2-14) gives

$$\begin{aligned} \operatorname{div} j &= 0 \text{ (continuity equation)} \\ j_n &= 0 \text{ on the surface} \end{aligned}$$

The latter surface condition is satisfactory if no external current is fed into the sample.

Equation (2-15) applies only when j and A vary slowly in space on the scale ξ_0. In general, we may guess that the current $j(\boldsymbol{r})$ at one point will depend on the vector potential $\mathbf{A}(\mathbf{r}')$ at all neighboring points $\mathbf{r}'$ such that $|\mathbf{r} - \mathbf{r}'| < \xi_0$. A phenomenological relation constructed to describe this effect, has been proposed by Pippard; in the London gauge it has the form

$$J(r) = C \int \frac{(A(r) \cdot R)R}{R^4} e^{-R/\xi_0} d\mathbf{r}' \quad \mathbf{R} = \mathbf{r} - \mathbf{r}' \tag{2-16}$$

The coefficient C is simply determined by noticing that when A varies slowly spatially (over distances $\sim \xi_n$), it can be taken out of the integral, and one must obtain the London value (2-15). This gives

$$\mathrm{C}\frac{4\pi}{3}\xi_0 = -\frac{\mathrm{ne}^2}{\mathrm{mc}} \quad \mathrm{C} = \frac{-3\mathrm{ne}^2}{\mathrm{mc}}$$

The choice of the simple form (2-16) for the relation between current and vector potential was a guess of Pippard. Later, after the development of the microscopic theory, it was verified that the exact relation between field and current is very close to $(2-16)$ if ones takes

$$\xi_0 = \frac{\hbar v_F}{\pi \Delta} \quad (\text{ for } T = 0) \tag{2-18}$$

The exact relation between j and A will be discussed in Chapter 4. It is much more complicated algebraically than (2-16) and the approximate Pippard form remains very useful. We now apply it to a study of penetration depths.

The Penetration Depth

Eq. $(2-16)$ is valid for a bulk superconductor. But we now want to study penetration phenomena near the sample surface: in general the relation between j and A is then modified. In practice, the following prescription applies: keep Eq. (2-16), but extend the integration $\int \mathrm{d}\mathbf{r}'$ only to points $\mathbf{r}'$ in the superconductor, and, more restrictively, to points $\mathbf{r}'$ from which an electron can travel in a straight line to point r. For instance, if there is a small empty cavity in the metal, one must exclude the "shadow" of the cavity, as shown in Fig. 2-3. (This prescription is the correct one for the (usual) case where reflection of individual electrons on the surface is diffuse. We shall derive it later from the microscopic theory.)

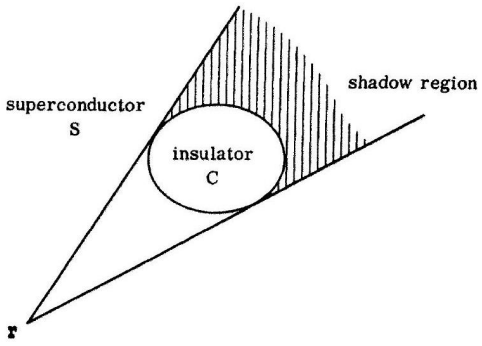

Figure 2-3

"Shadow effect" in the calculation of the current $j(r)$ induced by a magnetic perturbation $\mathbf{A}(\mathbf{r}')$. A cavity or an insulating precipitate occupies region C inside the superconductor S. Electrons are reflected diffusely at the SC boundary. The magnetic potentials $\mathbf{A}(\mathbf{r}')$. in C and in the shadow region do not contribute to $j(\mathbf{r})$.

Consider now a specimen with a plane surface x0y, the superconducting side being $z > 0$, A and j are directed along the x axis. The penetration depth λ can then be estimated by another intuitive argument of Pippard's: if $\mathbf{A}(\mathbf{z})$ was essentially constant on a thickness $\sim \xi_0$ near the surface, we would have, in this region, from Eq. (2-16): $j = -(\mathrm{ne}^2/\mathrm{mc})\,\mathbf{A}$ (the London result). But in fact $\mathbf{A}(\mathrm{z})$ is nonzero only in a smaller thickness λ. Thus the integral $(2-16)$ is reduced, roughly by the factor λ/ξ_0:

$$\mathrm{j} \simeq -\frac{\mathrm{ne}}{\mathrm{mc}} \cdot \frac{\lambda}{\xi_0}\,\mathrm{A} \quad (\lambda \ll \xi_0)$$

Using this relation in conjunction with curl $h = (4\pi/\mathrm{c})\mathrm{j}$, we obtain an (approximate) penetration law of the form $h(z) = h(0)e^{-z/\lambda}$, where λ is defined self-consistently by

$$\frac{1}{\lambda^2} = \frac{4\pi n e^2}{\mathrm{mc}^2}\frac{\lambda}{\xi_0}$$
$$\lambda^3 = \lambda_L^2 \xi_0 \quad (\lambda \ll \xi_0)$$

A (much more complicated) rigorous calculation gives $\lambda^3 = 0.62\lambda_{\mathrm{L}}^2\xi_0$.

The essential conclusions are that, in the Pippard limit, λ becomes larger than the London value $(\lambda/\lambda_L) \sim (\xi_0/\lambda_L)^{1/3} > 1$, but λ remains much smaller than the coherence length $(\lambda/\xi_0) \sim (\lambda_L/\xi_0)^{2/3} < 1$.

Methods to Measure the Penetration Depth

Historically, the first determinations of λ were made by measuring the magnetic susceptibility of very small specimens (colloids or films). Experimentally, one first verifies that the transition temperature of even very fine colloids ($\sim 100\text{Å}$) is not very different from that of bulk samples. One can therefore expect that the parameters $\lfloor n_S, \Delta(0) \rfloor$, which occur in ξ_0 and λ_L, are practically the same in small particles as in the bulk state, and this is encouraging. However, there are several difficulties:

(a) There is a rather large uncertainty in the grain dimensions of the colloid.

(b) In general, one has many lattice defects in such materials and therefore the electronic mean free path ℓ is rather short, and badly known. When ℓ is comparable to ξ_0, the Pippard formula (2-16) must be modified.

The other methods used to determine λ reduce to measuring the value of a self- or mutual inductance in the presence of the superconductor. The principle of the mutual inductance measurement is represented in Fig. 2-4.

The coil 1 creates a field h_e along the exterior of the film and a field $h_i = \rho h_e \ll h_e$ in the interior region. The field h_i is detected by the coil 2. From ρ one can determine λ by suitable theoretical analysis. In practice, one is able to measure coefficients $\rho \sim 10^{-9}$. This allows one to work with relatively thick films ($\sim 10\lambda$) for which the crystallographic state is well defined [and this minimizes objection (b)].

One can also measure the self-inductance of a coil surrounding a superconducting cylinder (method initially suggested by Casimir). If e is the distance between coil and specimen (see Fig. 2-5), the magnetic flux penetrates a surface $\sim \pi R(e + \lambda)$. As $\lambda \sim 10^3\text{Å}$ it is necessary to make e as small as possible (typically e $\sim$ 2 mm, R being 4 mm). In practice e is not known to sufficient precision and the method serves mainly to determine the temperature dependence of λ. Adifferent technique, but similar in principle, is to construct a microwave resonant cavity with the superconducting material.

(1) transmitting coil

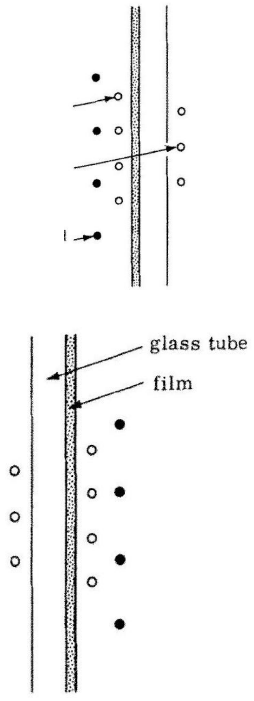

Figure 2-4 Inductive method to measure the penetration depths of thin cylindrical films lafter Sarachik, et al., Phy's. Rol. Lelters, 452(1960)]. The transmitting coil creates a field attenuated in the film. The receiving coil in the central region detects the field that has leaked

through the superconducting film. The solenoid is used to study the field dependence of the penetration depth.

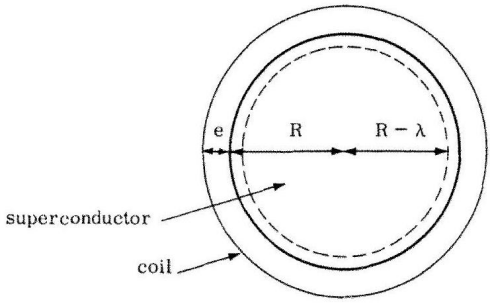

Figure 2-5

Self-induction method to measure penetration depths on a superconducting cylinder of radius R. The cylinder is surrounded by a coil of radius $R + e$. The flux is contained in a ring of thickness $e + \lambda$. In practice e is not known accurately and only the changes of λ with temperature can be measured.

Discussion

PENETRATION IN THE PURE METALS AT ABSOLUTE ZERO

Does the experimental determination of λ permit us to verify the phenomenological Pippard relation? For the pure metals at absolute zero we can calculate separately

$$\xi_0 = \frac{\hbar v_F}{\pi \Delta(0)} \quad \lambda_L = \left(\frac{mc^2}{4\pi n e^2}\right)^{1/2}$$

Taking v_F and n/m from measurements of specific heat, anomalous skin effect, and so on, in the normal state, and $\Delta(0)$ from measurements in the superconducting state, we can then predict a theoretical value for λ ($\lambda^3 = 0.62\lambda\lambda_L^2\xi_0$) for $\lambda_L \ll \xi_0$ (and more complex formulas when $\lambda_L \sim \xi_0$). Table 2-2 gives a comparison between such theoretical values and the experimental data (extrapolated to 0°K). There is satisfactory qualitative agreement, but it would be rather difficult to determine ξ_0 from λ if one had no other information. The detailed form of relation (2-16) cannot be considered established by this type of measurement.

We are now beginning to obtain finer verifications, mainly by measurement of magnetic field transmission through a thin film. In particular, the complete solution of Eq. $(2-16)$ for such a film predicts that when $\xi_0 \gg \lambda$, the field does not have a constant sign, but the ratio ρ can become negative; this has been observed experimentally (Drangeid and Sommerhalder, 1962).

Table 2-2

	λ_{L}	ξ_0	λ_{th}	λ_{exp}
Al	157	16,000	530	$490 - 515$
Sn	355	2,300	560	510
Pb	370	830	480	390

EXTENSION TO ALLOYS

When the electronic mean free path ℓ is limited by the presence of impurities, it is natural to expect that the relation between current (at the point $\mathbf{r}$) and vector potential (at the point $\mathbf{r}'$) contains an attenuation factor $e^{-|\mathbf{r}-\mathbf{r}'|/\ell}$. One is therefore led to assume, with Pippard,

$$j(\mathbf{r}) = C \int \frac{\lfloor \mathbf{A}(\mathbf{r}') \cdot \mathbf{R} \rfloor \mathbf{R}}{R^4} e^{-R(1/\xi_0 + 1/l)} dr \tag{2-19}$$

The normalization coefficient C is assumed to be independent of ℓ (therefore equal to its pure metal value $-3ne^2/4\pi mc\xi_0$); in other words, one assumes that the contributions to $j(r)$ coming from points $\mathbf{r}'$ in the neighborhood of $r, (|r' - r|\, z\ell)$ are not modified by the impurities. This hypothesis has permitted Pippard to explain a series of experiments on the dilute SnIn alloy system. One finds that λ increases with the concentration of impurities (Fig. 2-6) and the results are well interpreted by the formula (2-19). One limiting case is particulary remarkable. When $\lambda \gg \ell$ we can neglect the variations of $A(r')$ in Eq. (2-19) and perform the integration

$$j(\mathbf{r}) = CA(\mathbf{r}) \frac{4\pi}{3} \frac{1}{1/\xi_0 + 1/\ell} \tag{2-20}$$

This is a London type equation, but with a coefficient modified with respect to the pure metal. In particular, if $\ell \ll \xi_0$, we have

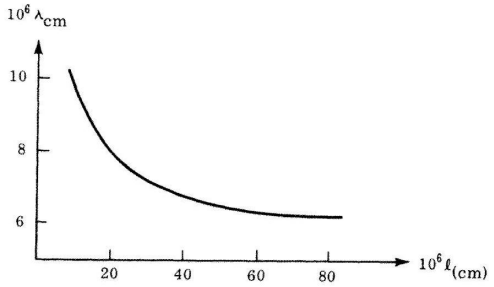

Figure 2-6

The variation of the penetration depth with mean free path in tin-indium alloys. (After A. B. Pippard, Proc. Roy. Soc. (London), A216, 547 (1953).) These results are in excellent agreement with Pippard's prediction (2-21).

$$j(\mathbf{r}) = -\frac{ne^2}{mc} \frac{\ell}{\xi_0} \mathbf{A}(\mathbf{r})$$

which leads to a penetration depth λ

$$\lambda = \lambda_L \left(\frac{\xi_0}{\ell} \right)^{1/2} \qquad (\lambda \gg \ell, \quad \xi_0 \gg \ell) \tag{2-21}$$

In this domain λ is proportional to $\ell^{-1/2}$ and therefore to the square root of the impurity concentration.

The agreement between theory and experiment in the SnIn system gives an excellent justification of the Pippard assumptions. In Chapter 4, we see that the microscopic theory confirms them to a large extent.

VARIATIONS OF λ WITH TEMPERATURE

Until now we have essentially limited our discussion to the case T = 0. For finite T, the situation can qualitatively be described in the following way: The Pippard equation $(2-16)$ remains valid with a value ξ_0 almost temperature independent. The normalization coefficient C is a function of temperature, and vanishes at the transition point T_c. Very near T_c, C is a linear function of $T_C - T$. A theoretical universal curve for C, derived from the microscopic theory, is given in Chapter 4 (Section 5). Once C is known, one computes λ by solving Eq. (2-20). In an attempt to short circuit this heavy machinery, the experimentalists often refer to the empirical law

$$\lambda^2(\mathrm{T}) = \lambda^2(0)\frac{\mathrm{T_c^4}}{\mathrm{T_c^4 - T^4}} \tag{2-22}$$

The form (2-22) gives a good fit to the experimental data on tin. It has also the correct feature that $\lambda \sim (\mathrm{T_c - T})^{-1/2}$ when $\mathrm{T} \to \mathrm{T_c}$. However, it must be emphasized that a universal law such as (2-22) cannot be applied to all superconductors, because two independent parameters (for instance, ξ_0 and the London penetration depth λ_L) are involved in the calculation of λ.

7.1.3 2-3 Magnetic properties of a sample of arbitrary shape: intermediate state

Origin of the Intermediate State

In order to define the critical field $\mathrm{H_c}$ we chose a cylindrical specimen placed in a field parallel to the axis of the cylinder. This geometry assures that the field h be the same over the entire surface of the specimen ignoring end effects. We now consider a less trivial case, for example, a superconducting sphere of radius a placed in a uniform external field $\mathrm{H_0}$. If $\mathrm{H_0}$ is small, the lines of force are expelled from the specimen and assume the form of Fig. 2-7.

The field configuration external to the sphere is determined by the equations

$$\mathrm{div\,h} = \mathrm{curl\,h} = 0 \qquad \mathrm{h} \to \mathrm{H_0 \text{ as } r} \to \infty \tag{2-23}$$

where r is the distance measured from the center of the sphere. Finally, the Meissner effect imposes the condition that no line of force can penetrate into the sphere. The normal component of h vanishes on the surface of the sphere

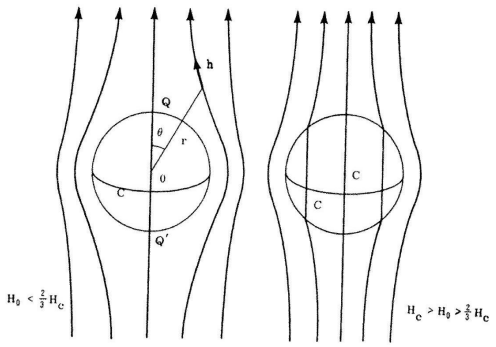

Figure 2-7 The magnetic field distribution about a superconducting sphere of radius a. For applied fields $\mathrm{H_0}$ less than $\frac{2}{3}\mathrm{H_c}$, there is a complete Meissner effect and the field at the equator (at any point on circle C) is $\frac{3}{2}\mathrm{H_0}$; the field at the poles (Q, Q') is zero. For $H_c = H_0 > \frac{2}{3}H_c$, the sphere is in the intermediate state.

$$(h_n)_{r=a} = 0 \tag{2-24}$$

The appropriate solution in the exterior region is

$$\mathrm{h} = \mathrm{H}_0 + \mathrm{H}_0 \frac{\mathrm{a}^3}{2} \nabla \left(\frac{\cos\theta}{\mathrm{r}^2} \right) \tag{2-25}$$

The component of h parallel to the surface of the specimen is

$$|\mathrm{h}_\theta|_{\mathrm{r=a}} = \frac{3}{2} \mathrm{H}_0 \sin\theta \tag{2-26}$$

At points Q and Q′, h is zero. On the equatorial circle ($\theta = \pi/2$) the tangential component is maximum and is $\frac{3}{2}\mathrm{H}_0$. The surface points experience fields between 0 and $\frac{3}{2}\mathrm{H}_0$. When H_0 attains the value $\frac{2}{3}\mathrm{H}_\mathrm{c}$, the field at the equatorial circle becomes equal to H_c. Therefore, for $\mathrm{H}_0 > \frac{2}{3}\mathrm{H}_\mathrm{c}$, certain regions of the sphere pass into the normal state. But there must still exist superconducting regions since $\mathrm{H}_0 < \mathrm{H}_\mathrm{c}$. (If the entire sphere were normal, the field would be equal to H_0 throughout and, because $\mathrm{H}_0 < \mathrm{H}_\mathrm{c}$, the system would be unstable and superconductivity would reappear.) Therefore in the domain

$$\frac{2\mathrm{H}_\mathrm{c}}{3} < \mathrm{H}_0 < \mathrm{H}_\mathrm{c} \tag{2-27}$$

there will be a coexistence of normal and superconducting regions. This situation is called the intermediate state.

Notice that the range of fields H_0 for which one will observe such an equilibrium between the two phases is given by $(2-27)$ only for a specimen in the form of a sphere. If instead of a sphere we had a prolate and/or oblate ellipsoid in the direction of H_0, then the equatorial field would be slightly and/or very different from H_0 and the domain of existence of the intermediate state would be small and/or large. In particular, if we consider a thin metallic slab, H_0 being perpendicular to the plane of the slab, we predict that the intermediate state will exist throughout the domain $0 < \mathrm{H}_0 < \mathrm{H}_\mathrm{c}$. (When H_0 is nonzero, if the slab were to remain entirely superconducting, the field at the edge of the slab would be very large, therefore $> \mathrm{H}_\mathrm{c}$ and it is thus necessary for normal regions to be established.)

Let us consider precisely such a slab of thickness e. The appearance of the normal (N) and superconducting (S) regions is represented in Fig. 2-8. The regions N and S form laminas perpendicular to the plane of the figure. The lines of force only penetrate in the region N. On the contact planes between the N and S regions, the field h must be equal to H_c in order to ensure equilibrium between the two planes.

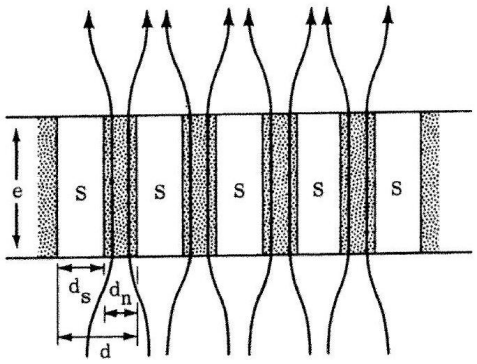

Figure 2-8

Field distribution in a slab in a perpendicular field. For all fields $\mathrm{H} < \mathrm{H}_\mathrm{c}$, the sample is in an intermediate state with a laminar structure of normal and superconducting domains (small distortions of the slabs near the surface are not taken into account).

In the N regions, h is parallel to the z axis, div h = 0 and curl h = 0. Thus h is constant and, therefore, equal to H_c through the N region. In the region S, h = 0. For this simple geometry, the fraction $\rho = d_S/(d_S + d_n)$ of S regions is fixed directly by the condition of conservation of flux-far from the film, the field is uniform, $h = H_0$, and the flux becomes SH_0 (where S is the surface area of the film). In the film, the flux is concentrated through a surface $S(1-\rho)$ and the field is H_c. Therefore

$$SH_0 = S(1-\rho)H_c \tag{2-28}$$
$$\rho = 1 - \frac{H_0}{H_c}$$

An important observation is that, for macroscopic samples (e $\gg \xi_0$) the thicknesses of the layers d_s, d_n are much smaller than the sample dimensions (smaller than e) (this has been verified by detailed experiments to be described later). Thus for many purposes we can ignore the microscopic structure of alternating layers, and we need to know only the relative amount of S regions given by ρ.

The derivation of ρ was very simple for the slab. For more complicated sample shapes, the determination of ρ and of the macroscopic
average field of any point requires a more general analysis (due to Peierls), discussed in the following sections and applied to several typical cases.

Preliminary Thermodynamics

We now define some macroscopic concepts (induction B, thermodynamic field **H**, and so on) useful for the description of situations where there is only a partial penetration of the lines of force. One such case is the intermediate state of macroscopic samples. Other applications will be found in Chapter 3 in connection with Type II superconductors.

DEFINITION OF THE FREE ENERGY

The system consists of a specimen + external objects (coils, generators). We define a free energy as follows: First, we take the energy of the electrons in the sample

$$U = \sum_i \left[\frac{1}{2m} \left(p_i - \frac{eA}{c} \right)^2 + V_i \right] + \sum_{i>j} V_{ij} \tag{2-29}$$

Here A is the vector potential, related to the field $h(r)$ by the relation curl $A = h$.V_{ij} represents the electron-electron interactions and V_i the one electron potentials. Second, we add an entropy term - TS. Then two contributions appear in practice as an integral over the sample volume.

$$U - TS = \int_{\text{sample}} F_S dr \tag{2-30}$$

Third, we include in the free energy the magnetic field energy $\int (h^2/8\pi)\, dr$. The sum of the three contributions we call the free energy

$$\mathcal{F} = \int_{\text{sample}} F_S dr + \int_{\text{all space}} \frac{h^2}{8\pi} dr \tag{2-31}$$

DEFINITION OF THE INDUCTION B

We often meet situations where the microscopic field $h(r)$ in the sample has strong variations in space on a scale Δx much smaller than the sample dimension (Example: the intermediate state pattern of Fig. 2-8). We then find it convenient to introduce a vector B($\mathbf{r}$) giving the average of h in a region around point r of dimensions small compared with the sample, but large compared with Δx.

$$B = \bar{h} \tag{2-32}$$

Outside of the sample, we take by definition $B = h$. On a microscopic scale, h satisfies to the equations

$$\begin{aligned} \operatorname{curl} h &= \frac{4\pi}{c} j \\ \operatorname{div} h &= 0 \end{aligned} \tag{2-33}$$

where f is the local current density. Thus the induction B satisfies to

$$\begin{aligned} \operatorname{curl} B &= \frac{4\pi}{c} j \\ \operatorname{div} B &= 0 \end{aligned} \tag{2-34}$$

j is the macroscopic current density.

DEFINITION OF THE THERMODYNAMIC FIELDH

Suppose that (by changing the currents in the coils) the field distribution $h(r)$ is changed slightly. At each point $\mathbf{r}, \mathbf{B}(\mathbf{r})$ changes by a small amount of $\delta\mathbf{B}(\mathbf{r})$. To first order in $\delta\mathbf{B}$ the change $\delta\mathcal{F}$ of the free energy is, in its most general form,

$$\delta\mathcal{F} = \int \frac{H(r)}{4\pi} \cdot \delta\mathbf{B}(\mathbf{r}) \mathrm{d}\mathbf{r} \tag{2-35}$$

where the factor $(1/4\pi)$ has been inserted for convenience, and $H(r)$ is some vector function of $\mathbf{r}$. We call $\mathbf{H}(\mathbf{r})$ the thermodynamic field at point $\mathbf{r}$[3] Outside of the sample we must have

$$\frac{\mathrm{h} \cdot \delta\mathrm{h}}{4\pi} = \frac{\mathrm{H} \cdot \delta\mathrm{B}}{4\pi} \tag{2-36}$$

and h = B. Thus h = H = B out of the sample. Equation (2-35) is a rather abstract definition of $\mathbf{H}$. To get a physical feeling for $\mathbf{H}$ consider only situations where no external currents are fed into the sample. Then we can write for the current

$$\bar{j} = \bar{j}_s + j_{\mathrm{ext}} \tag{2-37}$$

$\bar{j}_{\mathrm{s}}(\mathbf{r})$ is the average supercurrent at point r in the sample (by definition j_S is 0 out of the sample). j_{ext} is the current in the coils, generators, and so on. Since no current is fed directly into the sample, the distinction between $\mathrm{j_{ext}}$ and $\bar{\mathrm{j}}_{\mathrm{S}}$ is clear cut $\mathrm{j_{ext}} = 0$ in the sample). Then we have simply

$$\operatorname{curl} \mathrm{H} = \frac{4\pi}{\mathrm{c}} \mathrm{J_{ext}} \tag{2-38}$$

[3] Note that in the complete Meissner effect region, B ≡ 0 and H is undetermined.

Proof of Eq. (2-38): When $B(r)$ varies by $\delta B(r)$, in a time δt, an electric field E, given by

$$\operatorname{curl} \mathbf{E} = -\frac{1}{\mathrm{c}} \frac{\delta \mathbf{B}}{\delta \mathrm{t}}$$

is generated. The work done by E on the external currents is $\delta t \int j_{\text{ext}} \cdot \mathbf{E}\, \mathrm{dr}$ or conversely the work done by the external currents is

$$\delta W = -\delta t \int \boldsymbol{E} \cdot j_{\text{ext}}\, d\mathbf{r} \tag{2-39}$$

For a reversible transformation at constant temperature, we know from thermodynamics that $\delta \mathrm{W} = \delta \mp$. We want to compare this expression with (2-35). For that purpose we transform (2-35) as follows:

$$\begin{aligned} \delta \mathscr{F} &= \delta \mathrm{t} \frac{1}{4\pi} \int \mathbf{H} \cdot \frac{\delta \mathrm{B}}{\delta \mathrm{t}} \mathrm{d}\mathbf{r} \\ &= -\delta \mathrm{t} \frac{\mathrm{c}}{4\pi} \int \mathrm{H} \cdot \operatorname{curl} \mathbf{E} \mathrm{d}\mathbf{r} \\ &= -\delta \mathrm{t} \frac{\mathrm{c}}{4\pi} \int \mathbf{E} \cdot \operatorname{curl} \mathbf{H} \mathrm{dr} - \frac{\mathrm{c}\delta \mathrm{t}}{4\pi} \int (\mathbf{E} \times \mathbf{H}) \cdot \mathrm{d}\boldsymbol{\sigma} \end{aligned} \tag{2-40}$$

The last integral is to be taken over a distant surface surrounding the entire system. It represents the radiated energy and for a slow, reversible transformation it is negligible. Then comparing $(2-40)$ and $(2-39)$ we see that $(2-38)$ is satisfied.

Conclusion. All currents contribute to curl B (Eq. 2-34), but only j_{ext} contributes to curl H (Eq. 2-38). We might be tempted to say that H is the field that would exist in the absence of the specimen (the same j_{ext} being kept on the coils). This is correct for the cylindrical geometry of Fig. 2-1 but is wrong in general. Consider, for instance, the spherical sample of Fig. 2-7. Here the lines of force are distorted in the presence of the sphere and this implies a change of $\mathbf{H}(\mathbf{r})$ (though not of curl $\mathbf{H}$).

Remark on boundary conditions. The equation $\operatorname{div} \mathbf{B} = 0$ implies as usual that the normal component of B be continuous at the surface of the specimen. On the other hand, the tangential component of $\mathbf{B}$ is, in general, not continuous. Curl B contains the supercurrent. Often we find supercurrents localized on the surface (physically in a thickness λ near the surface). If we let S be the current per cm on the surface, then by integration of (2-34) we find

$$\mathbf{n} \times (B_{\text{ext}} - B_{\text{int}}) = \frac{4\pi}{c} S \tag{2-41}$$

(n is a unit vector normal to the surface and directed outward).

Thermodynamic Potential for Fixed T and j_{ext}

When both fields and temperatures are allowed to change, the free energy variation (2-35) becomes

$$\delta \mathcal{F} = \frac{1}{4\pi} \int \mathrm{H} \cdot \delta \mathrm{B} d\mathbf{r} - \mathrm{S}\delta \mathrm{T} \tag{2-42}$$

where S is the entropy. When the values of $B(r)$, at each point r, and the temperature T, are fixed, the equilibrium state corresponds to the minimum of $\mathfrak{F}$. Very often, however, this is not the situation of interest. The quantities fixed during the experiment are T and the currents j_{ext} in the coils. We now construct a thermodynamic potential S adapted to this situation. Define

$$\mathcal{S} = \mathcal{F} - \int \frac{\mathrm{B}\cdot\mathrm{H}}{4\pi}\mathrm{d}\mathbf{r} \tag{2-43}$$

Then

$$\delta S = -\int \frac{\mathrm{B}\cdot\delta\mathbf{H}}{4\pi}\mathrm{d}\mathbf{r} - \mathrm{S}\delta\mathrm{T} \tag{2-44}$$

Since $\operatorname{div}\mathbf{B} = 0$ we can set $\mathrm{B} = \operatorname{curl}\overline{\mathrm{A}}$ (where $\overline{\mathrm{A}}$ is the macroscopic vector potential) and integrate by parts

$$\begin{aligned}\mathrm{S}\delta\mathrm{T} + \delta S = -\frac{1}{4\pi}\int \operatorname{curl}\overline{\mathbf{A}}\cdot\delta\mathrm{H}d\mathbf{r} &= -\frac{1}{4\pi}\int \overline{\mathbf{A}}\cdot\operatorname{curl}\delta\mathrm{H}d\mathbf{r} \\ &= -\frac{1}{\mathrm{c}}\int \overline{\mathbf{A}}\cdot\delta j_{\mathrm{ext}}\mathrm{d}\mathrm{r}\end{aligned} \tag{2-45}$$

Thus $\delta\mathcal{G} = 0$ when T and j_{ext} are fixed. The equilibrium state for fixed T and $\mathrm{j_{ext}}$ corresponds to the minimum of G. In practice, we usually construct first $\mathfrak{F}$ and B on a microscopic model; then we form $\mathcal{S}$ and finally on minimizing $\mathcal{S}$ we have a condition defining the equilibrium state. This condition plays the same role as the relation $B = \mu\mathbf{H}$ in a paramagnetic or diamagnetic medium.

Relation between B and H in the Intermediate State

In order to obtain this relation, we calculate the Gibbs potential $\mathrm{G}d\mathbf{r}$ of a volume element dr of a specimen when it is in the intermediate state [a fraction ρ of the volume dr being superconducting (S) and a fraction $(1-\rho)$ being normal (N)]. In (N), the microscopic field takes on a certain value h_n; in (S) it is zero. We show that the condition of minimum S leads to $h_n = H_c$. In terms of ρ

$$\mathrm{B} = (1-\rho)\mathrm{h_n} + \rho\cdot 0 = (1-\rho)\mathrm{h_n} \tag{2-46}$$

The free energy per cubic centimeter becomes

$$F = F_n - \frac{\rho H_c^2}{8\pi} + (1-\rho)\frac{h_n^2}{8\pi} \tag{2-47}$$

The second term represents the condensation energy in the superconducting regions and the third term the magnetic energy. We neglect the (NS) surface energy and also the terms arising from the distortion of the lines of force in the neighborhood of the surface of the specimen; on the macroscopic scale these surface terms are negligible. Expressing F in terms of the variables ρ and $\mathbf{B}$, we obtain

$$\mathrm{F} = \mathrm{F_n} - \frac{\rho\mathrm{H_c^2}}{8\pi} + \frac{\mathrm{B}^2}{8\pi(1-\rho)} \tag{2-48}$$

Now forming the thermodynamic potential G, we find

$$\mathrm{G(B},\rho) = \mathrm{F} - \frac{\mathrm{BH}}{4\pi} = \mathrm{F_n} - \frac{\rho\mathrm{H_C^2}}{8\pi} + \frac{\mathrm{B}^2}{8\pi(1-\rho)} - \frac{\mathrm{BH}}{4\pi} \tag{2-49}$$

If we minimize G: (1) With respect to ρ, we obtain

$$|B| = H_c(1-\rho) \tag{2-50}$$

On comparing Eqs. $(2-50)$ and $(2-46)$, we see that the field in the normal regions h_n is equal to H_c (this property was previously cited for a simple example on page 26).

(2) With respect to B, we obtain

$$\frac{\partial G}{\partial B} = 0 \qquad B = H(1-\rho) \tag{2-51}$$

We conclude that (1) the field $\mathbf{H}$ is parallel to B, (2) the length of $\mathbf{H}$ must be constant and equal to $\mathrm{H_C}$ in the entire specimen. This is the condition equivalent to the relation $\mathrm{B} = \mu\mathrm{H}$ in a paramagnetic medium. But note that here the relation $B(H)$ is not linear. In order to calculate the field distribution in our sample, it it necessary to solve the equations

$$\operatorname{div}\mathbf{B} = 0 \quad (\text{and } \mathbf{B}_{\text{normal}} \text{ continuous at the surface}) \tag{2-52}$$

$$\operatorname{curl}\mathrm{H} = 0 \quad (\text{and } \mathbf{H}_{\text{tangential}} \text{ continuous}) \tag{2-53}$$

$$\mathbf{H} = \mathbf{B}\frac{\mathrm{H_c}}{|\mathrm{B}} \tag{2-54}$$

Equation 2-53 expresses our assumption that no current is fed into the sample (see Eq. 2-38).

Applications

We still limit ourselves to the (most usual) case where the specimen is not directly connected to the current generator. Then the lines of force, inside the sample, are straight lines. In order to show this, we write (proof due to London)

$$\mathrm{H}^2 = \mathrm{H_c^2} \qquad 0 = \nabla\left(\mathrm{H}^2\right) = 2(\mathrm{H}\cdot\nabla)\mathrm{H} + 2\mathrm{H}\times\operatorname{curl}\mathrm{H} \tag{2-55}$$

In the sample, curl $\mathbf{H} = 0$, then $(\mathbf{H}\cdot\nabla)\mathbf{H} = 0$. The vector $\mathbf{H}$ does not vary along a line of forces and therefore the line of force is straight.

Example. Let us return to a spherical sample placed on an exterior field $\mathrm{H_0}$ such that $\frac{2}{3}\mathrm{H_c} < \mathrm{H_0} < \mathrm{H_c}$. We can construct the solution of the system(2-52), $(2-53), (2-54)$ in the following manner.

In the interior of the sphere ($\mathrm{r} < \mathrm{a}$) we take H and B to be parallel to the z axis and constant. In magnitude, $\mathrm{H} = \mathrm{H_c}$ and B has a certain unknown value B_0. In the exterior, on the other hand,

$$\mathbf{H} = \mathbf{B} = \mathrm{H_0} - \mathrm{H_1}\frac{\mathrm{a}^3}{2}\nabla\frac{\cos\theta}{\mathrm{r}^2} \tag{2-56}$$

where $\mathrm{H_1}$ is a constant to be determined. The condition on the continuity of $\mathrm{H_{tang}}$ at the surface imposes

$$\left(\mathrm{H_0} + \frac{\mathrm{H_1}}{2}\right)\sin\theta = \mathrm{H_c}\sin\theta \tag{2-57}$$

The condition of the continuity of $\mathrm{B_{norm}}$ gives

$$(\mathrm{H_0} - \mathrm{H_1})\cos\theta = \mathrm{B_0}\cos\theta \tag{2-58}$$

Upon comparing these two equations we find

$$\begin{aligned} \mathrm{B}_0 &= 3\mathrm{H}_0 - 2\mathrm{H}_\mathrm{c} \\ \mathrm{H}_1 &= 2\,(\mathrm{H}_\mathrm{c} - \mathrm{H}_0) \end{aligned} \tag{2-59}$$

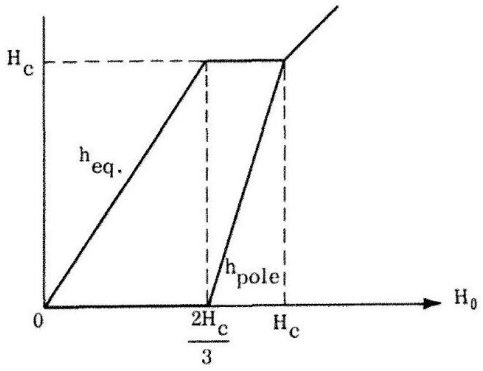

Figure 2-9
The field at the equator and the field at the poles of a superconducting sphere. For $\mathrm{H}_0 < \frac{2}{3}\mathrm{H}_\mathrm{c}$, there is a complete Meissner effect, and the polar field vanishes. For $\frac{2}{3}\mathrm{H}_\mathrm{c} < \mathrm{H}_0 < \mathrm{H}_\mathrm{c}$, the sphere is in the intermediate state; the equatorial field remains constant at H_c while the polar field increases from zero to H_c.

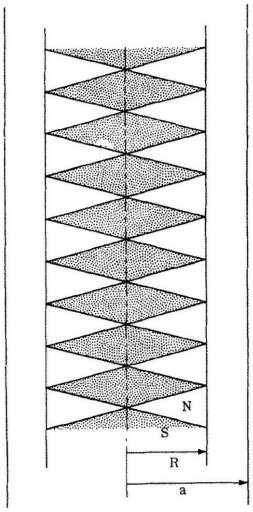

Figure 2-10 A schematic representation of the domain structure in a superconducting wire of radius a carrying a current $\mathrm{I} > I_C(2-60)$. There are a normal surface layer and an intermediate state core of radius R. The interface (R) is determined by $\mathrm{H(R)} = \mathrm{H}_\mathrm{c}$.

Conclusions.

(1) There exists a solution such that B is constant throughout the sphere. The fraction of superconducting regions $\rho = 1 - \mathrm{B}_0/\mathrm{H}_\mathrm{C}$ is therefore the same throughout the sphere.

(2) The induction B_0 is a linear function of the applied field H_0. In practice, one can measure B_0 by placing a magnetic probe in the neighborhood of the poles Q, Q' of the sphere. Since B_{norm} is continuous, the field immediately exterior to the sphere near Q or Q' is equal to B_0. The field H_c is measured by placing the probe on the equatorial circle (from the continuity of $\mathrm{H}_{\mathrm{tang}}$). Ex - perimentally one very nearly obtains diagrams of the theoretical form (Fig. 2-9) in clean samples.

CRITICAL CURRENT OF A SUPERCONDUCTING WIRE

The wire of radius a is connected to the poles of a generator that supplies a current I. The field at the surface of the wire is $H(a) = 2\mathrm{I}/\mathrm{ca}$. When $\mathrm{H(a)} < \mathrm{H_c}$, the wire can be completely superconducting. This defines a critical current

$$I_c = H_c \frac{ca}{2} \tag{2-60}$$

When I becomes larger than $\mathrm{I_c}, \mathrm{H(a)} > \mathrm{H_c}$, and the wire' must become normal near the surface. However it cannot become entirely normal, since, if it were, the current I would be spread uniformly through the section and the field h would be very small in the central region; therefore the wire must remain at least partially superconducting. Finally there is an exterior normal region $\mathrm{R} < \mathrm{r} < \mathrm{a}$ and a superconducting or intermediate interior region $0 < \mathrm{r} < \mathrm{R}$. In the exterior region $B = H$ and at the boundary $H(R) = H_c$. This allows us to predict the current I_1, which flows through the interior region

$$\mathrm{H(R)} = \mathrm{H_c} = \frac{2\mathrm{I_L}}{\mathrm{cR}} \tag{2-61}$$

$$\mathrm{I_1} = \frac{\mathrm{cRH_c}}{2} = \mathrm{I_c}\frac{\mathrm{R}}{\mathrm{a}} < \mathrm{I_c} \tag{2-62}$$

Therefore $\mathrm{I_1} < \mathrm{I_c} < \mathrm{I}$. The exterior region must carry a current $\mathrm{I} - I_1$. Since this is a normal region, there must be an electric field **E** directed along the axis of the wire; this field **E** must be the same throughout the wire since curl $E = 0$.

This shows that the interior region cannot be entirely superconducting since it would short circuit the field **E**. It must, in fact, be in the intermediate state with N and S laminas perpendicular to the axis of the cylinder (Fig. 2-10). This situation is discussed in detail in the book by London.

PRINCIPLE OF THE CRYOTRON

The cryotron is a control device invented by Buck in 1956; the principle is shown on Fig. 2-11. The "control" current I' creates a field $\mathrm{H}' = 4\pi\mathrm{NI}'/\mathrm{cL}$ in the solenoid (where N is the number of turns

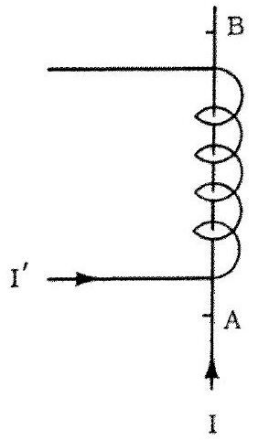

Figure 2-11

The principle of the cryotron. The current passing through the superconducting wire AB is controlled by the current I' flowing through the solenoid. When the field in the coil reaches H_C, the wire AB becomes normal.

and L is the length of the coil). A superconducting wire AB of diameter 2a and critical field H_c passes through the solenoid. For $H' < H_c$, the wire has zero resistance. For $H' > H_c$, the resistance is finite. It is therefore possible to control a current I passing through AB by the current I'. The minimum current value of I' required to make AB normal is

$$I'_m = \frac{cL}{4\pi N} H_c \tag{2-63}$$

On the other hand, the current I cannot be too large; otherwise the line AB passes into the intermediate state as we have previously seen

$$I \leq I_c = \frac{caH_c}{2} \tag{2-64}$$

The current gain of the cryotron is

$$G = \frac{I_c}{I'_m} = 2\pi N \frac{a}{L} \tag{2-65}$$

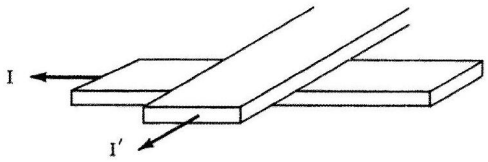

Figure 2-12

A more efficient (shorter time constants) cryotron can be constructed of two crossed metallic films separated by a thin insulated layer.

In Buck's first experiment, the control coil was made of a niobium wire (superconductor with a high critical field $\sim$ 2000G) of diameter $\sim$ 0.1 mm. The wire AB (of tantalum) had $H_c \sim 100$G at 4.2°K and a diameter 2a = 0.2 mm. For a coil of only one turn, this corresponds to Na/L $\sim$ 1, and G $\sim$ 6. In practice it is not useful to increase N for this increases the self-inductance of the coil and finally increases the time constant τ of the cryotron (for only one turn, the τ is not less than 10^{-5}sec). In practice, the time constants are reduced considerably by replacing the set up in Fig. 2-11 by two thin crossed metallic films (Fig. 2-12) separated by an insulating layer approximately 1000Å thick. Since the self-inductance is proportional to this thickness, it is quite small and the time constants fall into the domain $10^{-8} - 10^{-9}$sec.

Microscopic Structure of the Intermediate State

A slab (Fig. 2-13) of thickness e and lateral dimensions $L_x L_y$ (very large) is placed in a perpendicular field H_0 - normal and superconducting domains will occur. We assume that these domains are in the form of layers, as shown on the figure. (Experimentally, this arrangement is often found.) We wish to know the thickness d_n or d_s of the normal and of the superconducting regions, and the period $d = d_n + d_s$ of the domain structure.

To do this, we construct the free energy $\mathcal{F}$, and then minimize it (with respect to d_n, d_s, or equivalent parameters) for fixed H_0 (fixed H_o means fixed flux through the slab; thus the appropriate potential is $\mathcal{F}$, not $\mathcal{S}$).

In a zero-order approximation we consider the S and N domains as exactly plane layers and neglect all surface energies. Then the free energy is simply

$$\mathcal{F}_{\text{macroscopic}} = -\frac{H_c^2}{8\pi} L_x L_y e \frac{d_s}{d} + \frac{H_0^2}{8\pi} \frac{d}{d_n} \text{ e } L_x L_y \tag{2-66}$$

The first term is the condensation energy in the S regions. The second is the magnetic field energy $h^2/8\pi$, in the N regions, where $h = H_0 (d/d_n)$ by flux conservation.

Going now to a first-order approximation, one must add three corrections to $\mathfrak{F}$.

(1) To create a wall between an S region and an N region we need a certain surface energy γ per cm^2 of wall. Dimensionally it is convenient to write this γ in the form

$$\gamma = \frac{\mathrm{H_c^2}}{8\pi}\delta \tag{2-67}$$

where the length δ is of order $10^3 - 10^4$Å. The corresponding contribution to $\mathcal{F}$ is

$$\gamma e L_y \times \Bigg(\text{number of walls)} \ = \frac{H_c^2}{8\pi}\delta e L_y \frac{2L_x}{d} \tag{2-68}$$

(2) The lines of force "open up" near the sample surface and the superconducting domains become thinner near the ends. Thus we lose some condensation energy, in a volume of order $d_S^2 L_y$ for each S domain. This gives a contribution

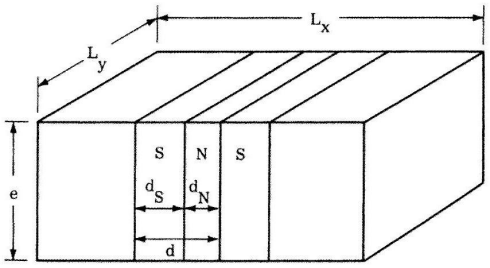

Figure 2-13

Microscopic structure of the normal and superconducting regions in the intermediate state of a slab. The domains form a laminar structure of period $d \sim \sqrt{e\delta}$(e = slab thickness, $\delta \cong$ thickness of a wall).

$$\frac{\mathrm{H_c^2}}{8\pi}\mathrm{d_S^2}\ \mathrm{L_y}\frac{\mathrm{L_x}}{\mathrm{d}}\mathrm{U_0}\left(\rho_\mathrm{s}\right) \tag{2-69}$$

where $\rho_\mathrm{S} = \mathrm{d_S/d}$ and $\mathrm{U_0}\left(\rho_\mathrm{S}\right)$ is a dimensionless function that can be computed when the exact shape of the "thinner" regions is known.

(3) The magnetic field energy $\int \left(\mathrm{h}^2/8\pi\right)\mathrm{dr}$ is also modified near the surface, and this gives a term of the form

$$\frac{\mathrm{H_0^2}}{8\pi}\mathrm{d_S^2}\ \mathrm{L_y}\frac{\mathrm{L_x}}{\mathrm{d}}\mathrm{V_0}\left(\rho_\mathrm{S}\right) \tag{2-70}$$

where $V_0\left(\rho_\mathrm{S}\right)$ is another dimensionless function. (The calculation of $\mathrm{U_0}$ and $\mathrm{V_0}$ is described in Landau and Lifshitz, Electrodynamics of Continuous Media.)

We can choose as independent variables ρ_S and d. If we first minimize the free energy with respect to ρ_S, we find that for a macroscopic sample ($e \gg \xi_0$)

$$1 - \rho_\mathrm{s} = \frac{\mathrm{H_0}}{\mathrm{H_c}} \tag{2-71}$$

This, as we know, expresses that the field in the normal regions is equal to $\mathrm{H_c}$. Then we minimize $\mathcal{F}$ with respect to d. The d-dependent terms are the three correction terms

$$\begin{aligned}\mathcal{F} =& \mathcal{F}_{\text{macroscopic}} + \frac{\mathrm{H_C^2}}{8\pi}\ \mathrm{e}\ L_\mathrm{x}\mathrm{L_y} \\ &\times \left[\frac{2\delta}{\mathrm{d}} + \left(\rho_\mathrm{S}^2\mathrm{U_0} + \rho_\mathrm{S}^2\left(1-\rho_\mathrm{S}\right)^2\ \mathrm{V_0}\right)\frac{\mathrm{d}}{\mathrm{e}}\right]\end{aligned} \tag{2-72}$$

The optimum d is given by

$$\mathrm{d}^2 = \frac{\delta \mathrm{e}}{\phi\left(\rho_{\mathrm{S}}\right)} \tag{2-73}$$

where $\phi = \frac{1}{2}\left[\rho_{\mathrm{S}}^2 \mathrm{U}_0 + \rho_{\mathrm{S}}^2\left(1-\rho_{\mathrm{S}}\right)^2\ \mathrm{V}_0\right]$. Typically, for $\mathrm{H_o/H_c} \sim 0.7$, $\phi \sim 10^{-2}$ and thus $\mathrm{d} \sim 10\sqrt{\delta \mathrm{e}}$. Taking $\mathrm{e} = 1\ \mathrm{cm}, \delta = 3000\mathring{\mathrm{A}}$, we arrive at $\mathrm{d} \sim 0.6$ mm. Near the ends ($\rho_{\mathrm{s}} \to 0$ or $\rho_{\mathrm{n}} \to 1$), ϕ tends toward 0 and d becomes still larger. How can we observe this domain structure? Various methods have been used:

(1) A fine bismuth wire (whose resistance is strongly dependent on field) is moved close to the surface of the sample. The resistance is large in the N regions and small in the S regions (Meshkovsky and Shalnikov, 1947).

(2) Niobium powder is placed on the sample. Niobium has a high critical field ($\sim$ 2000G). Thus the grains are always superconducting and diamagnetic, they tend to avoid the lines of force, and they gather on the S regions.

(3) The specimen is covered with a thin layer of cerium glass (typical thickness ~ 0.1 mm). This glass has a large Faraday rotation. Polarized light traveling along the magnetic field H_0 (normal to the sample surface) has its plane of polarization rotated by an angle θ when it traverses the glass; the total rotation after being reflected from the sample is then 2θ. Since, in general, θ is proportional to the field ($\theta \sim 0.02\%$ mm/G), if the specimen is observed between crossed analyzer and polarizer, the N regions, where $\mathrm{h} \neq 0$, appear bright. Ultimately, these measurements furnish a determination of the wall energy (characterized by the length δ).

Problem.

What are the corrections to the critical field of the plate due to the fact that the thickness e is finite?

Solution.

If we minimize the free energy with respect to d, keeping as other independent variables the reduced field $\mathrm{h_r} = \mathrm{H_0/H_c}$ and $\rho_{\mathrm{s}} = \mathrm{d_s/d}$ we find

$$\mathfrak{F} = \frac{\mathrm{H_c^2}}{8\pi}\mathrm{e_x L_y}\left[-\rho_{\mathrm{s}} + \frac{\mathrm{h_r^2}}{1-\rho_{\mathrm{s}}} + 4\left(\frac{\delta}{\mathrm{e}}\right)^{1/2}\phi^{1/2}\right]$$

$$\phi = \frac{1}{2}\rho_{\mathrm{S}}^2\left[\mathrm{U}_0\left(\rho_{\mathrm{s}}\right) + \mathrm{h_r^2}\ \mathrm{V}_0\left(\rho_{\mathrm{s}}\right)\right]$$

In the region of interest, $\mathrm{h_r}$ is close to 1, ρ_{s} is close to 0, and we may write for ϕ

$$\phi \cong \theta^2 \rho_{\mathrm{S}}^2$$

where $\theta^2 = \frac{1}{2}\left|\mathrm{U}_0(0) + \mathrm{V}_0(0)\right| = (1/\pi)\ln 2 = 0.22$ (this numerical value is obtained in the previously mentioned calculation of Landau and Lifshitz). Minimizing $\mathcal{F}$ with respect to ρ_{S}, we obtain the condition

$$-1 + \left(\frac{\mathrm{h_r}}{1-\rho_{\mathrm{s}}}\right)^2 + 4\theta\left(\frac{\delta}{\mathrm{e}}\right)^{1/2} = 0$$

The critical field of the plate is reached when $\mathcal{F}$ is equal to the normal state free energy $(\mathrm{H_0^2}/8\pi)\ \mathrm{e\ L_y L_x}$. This leads to the condition

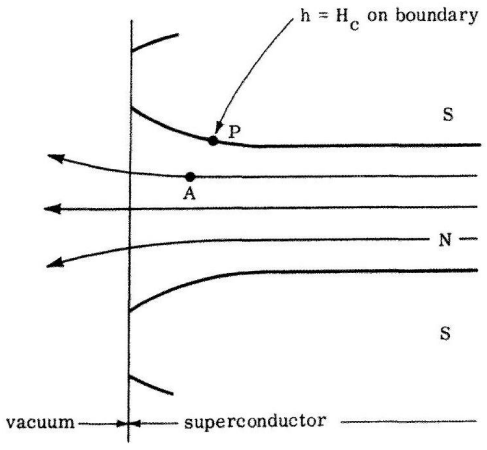
$$\rho_{\mathrm{s}}\left(\frac{\mathrm{h_r^2}}{1-\rho_{\mathrm{s}}} - 1\right) + 4\theta\left(\frac{\delta}{\mathrm{e}}\right)^{1/2}\rho_{\mathrm{s}} = 0$$

Both conditions are satisfied when

$$\rho_s = 0$$
$$1 - h_r^2 = 4\theta \left(\frac{\delta}{e}\right)^{1/2}$$
$$H_0 \cong H_c \left(1 - 2\theta \left(\frac{\delta}{e}\right)^{1/2}\right)$$

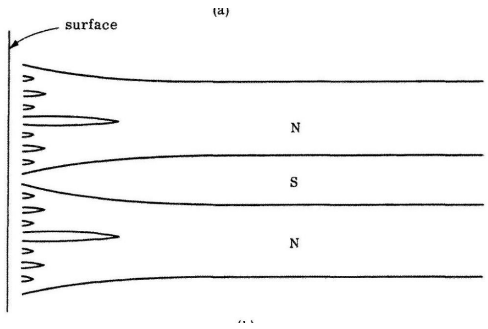
By taking e = 1 mm and $\delta = 10^4$Å, we get a 3% decrease of the critical field. Similar deviations from the macroscopic theory occur in all geometries; very often they are important in the discussion of experimental results in type I superconductors.

A PARADOX



If we look carefully at the domain structure of Fig. 2-14a, we notice that at a point such as A, in the N regions, the lines of force have "opened up." Thus the field is significantly lower than at point P on the boundary, that is, lower than H_c. At first sight this is troublesome. We would expect a region near A to become superconducting again. This complication has been considered by Landau. He concluded that the normal regions should "branch" as shown on Fig. 2-14b, possibly up to such a fine scale that the domain structure would become unobservable. In fact, the simple domain structure is often observed. Branching does not take place in clean samples with dimensions of order 1 cm. The critical field at point A is reduced below H_c by an effect similar to that discussed in the problem above (but here the dimension of interest is d, not e, thus the effect is large). Thus A can remain normal in rather low fields.

If we had a superconductor of thickness $e = 1$ mile, d would be of order 1 cm, we could still apply macroscopic considerations in the neighborhood of P, and some branching would take place. The branching model is not wrong; it is simply not adequate for the usual scale of sample dimensions. (Another way to favor branching is not to increase e, but rather to reduce δ-this could be done in suitable alloy systems.)



ORIGIN OF THE SURFACE ENERGY

We qualitatively discuss two extreme cases:

(1) $\xi_0 \gg \lambda$: In our previous macroscopic discussion, there was a sharp boundary between the normal region N and the superconducting region S (to fix ideas, we shall take this boundary as being the yz plane, the fields being along z and the N region corresponding to x < 0). On the N side, the thermodynamic potential was lowered by the magnetic

(a)

(b)

Figure 2-14

(a) The domain structure near the surface. Note that, at a point such as A, the field is smaller than at point P (as is indicated by the curvature of the lines of flux): $h(a) < h(P) = H_c$. There are some small normal regions near the ends where $h < H_c$! (b) Landau's branching model. Such a branching is required if one wants to keep $h > H_c$ everywhere in the normal regions. In fact branching does nol take place: The condition $h > H_c$ applies only to macroscopic normal regions. Here the small regions of interest near the surface have critical fields significantly lower than H_c; they can remain normal for $h < H_c$ and the simpler model of Fig. $2-14a$ is the correct one.

field terms $H_c^2/8\pi - H_c^2/4\pi$ (see Eq. 2-49). On the S side, S was lowered by the condensation energy $-H_c^2/8\pi$. Now, what does happen on a microscopic scale? If λ is small, it is still correct to assume that the field drops abruptly at the limiting plane $x = 0$. The new feature is that on the S side ($x > 0$), superconductivity is "damaged" in a region of thickness $\sim \xi_0$ near the boundary. Thus we lose the condensation energy $H_c^2/8\pi$ on an interval $\sim \xi_0$ and this gives a wall energy $\gamma \sim (H_c^2/8\pi)\,\xi_0$ (i.e., $\delta \sim \xi_0$).

(2) $\xi_0 \ll \lambda$: In this case the above contribution is negligible. We can calculate the field distribution by using London's equation (Fig. $2-15$). Let us put the wall in the yz plane, the fields being directed along the z axis. In the normal region $(x < 0), h = H_c$. In the S region $(x > 0), h = H_c e^{-x/\lambda}$. The thermodynamic potential becomes

$$S = \int_{x>0} dr \left(F_n - \frac{H_c^2}{8\pi} + \frac{h^2}{8\pi} - \frac{Hh}{4\pi} + \lambda^2 \frac{\left(\frac{dh}{dx}\right)^2}{8\pi} \right) \tag{2-74}$$

The first term is the free energy of the normal phase in zerofield; the second term is the condensation energy ($\rho = 0$ for $x < 0$ and $\rho = 1$ for $x > 0$); the third term is the magnetic field energy; the fourth is the microscopic equivalent of $-BH/4\pi$. Finally, the last term represents the kinetic energy of the currents.

We first verify that, far from the wall, the Gibbs function density is the same in the two phases (equilibrium condition) and $\mathcal{G}$ can be written in the form

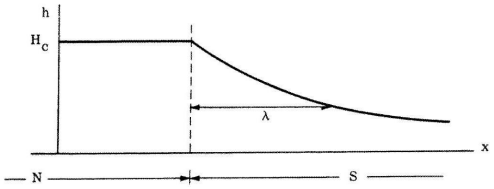


Figure 2-15

Microscopic field distribution at a wall separating normal and superconducting domains. In the normal domain, $h - H_c$; h falls to zero within a penetration depth on the superconducting side.

$$G = \int dr \left(F_n - \frac{H_c^2}{8\pi} \right) + \gamma S$$

where S is the surface area of the wall and γ is the surface tension given by

$$\gamma = \int_0^\infty dx \left[\frac{h^2 + \lambda^2 \left(\frac{dh}{dx}\right)^2}{8\pi} - \frac{hH_c}{4\pi} \right] = -\frac{H_c^2}{8\pi}\lambda \tag{2-75}$$

In this limit, the surface tension is negative and the system decreases its energy by creating new walls; the largest possible number of walls is created, and it is evident that the magnetic properties will be found to be considerably different from those cited previously. It is for this reason that materials having $\xi_0 < \lambda$ are called second kind superconductors. We study them in the next chapter.

7.2 Magnetic properties of second kind superconductors by de Gennes

7.2.1 3-1 Magnetization curves of a long cylinder

Type II superconductors are characterized by the following macroscopic properties:

(1) A cylinder placed in a longitudinal field H does not exhibit a "perfect" total flux expulsion (Meissner effect), except for weak field $H < H_{c_1}$.

If one calculates the critical field H_c defined by the difference in free energies between the normal and superconducting states in zero field:

$$F_n - F_s = \frac{H_c^2}{8\pi} \tag{3-1}$$

one finds that H_{c_1} is clearly smaller than H_c. For example, for the compound V_3Ga, caloric measurements in zero field (giving $F_n - F_S$) indicate $(H_c)_{T=0} \simeq 6000G$, and magnetic measurements give $(H_{C_1})_{T=0} \simeq 200G$.

(2) For $H > H_{C_1}$, lines of force penetrate the cylinder, but even

[1] The notation H_{Cl} for the first penetration field has been recommended by the participants of the Colgate Conference on Superconductivity (1963).

at thermal equilibrium this penetration is not complete. The flux ϕ passing through the cylinder remains less than its value when the sample is in the normal state. This implies the existence of permanent currents in the specimen, which is thus still superconducting. This situation exists for fields $H_{C_1} \leq H \leq H_{C_2}$.$H_{C_2}$ is larger than H_c and is sometimes very large-for V_3Ga $(H_{C_2})_T = 0 \sim 300,000G$.

(3) For $H > H_{C_2}$ a macroscopic sample does not show any expulsion of flux $B \equiv H$. However superconductivity is not completely destroyed. In an interval $H_{C_2} < H < H_{C_3}$ there remains on the surface of the cylinder a superconducting sheath (of typical thickness $10^3 \mathring{A}$). (In most cases $H_{c_3} \sim 1.69 H_{C_2}$.) The existence of this sheath can be shown, for instance, by measuring the resistance between two probes on the sample surface. It is found that for low measuring currents the resistance vanishes. Physically the sheath has the following origin: It is easier to nucleate a small superconducting region near the sample surface - just as it is easier to grow bubbles on the bottom of a glass of beer than to grow them from an arbitrary point in the beer. (A somewhat more sophisticated version of this argument will be discussed in Chapter 5.)

The variation with temperature of the fields $H_{C_1}, H_{c_2}, H_{c_3}$ is represented in Fig. 3-1. We now focus our attention on the region $H_{C_1} < H < H_{C_2}$ where partial flux penetration occurs. The existence of this region of the (H, T) plane was clearly shown for the first time in early

experiments on alloys by Schubnikov (1937). We call it the Schubnikov phase, or sometimes the vortex state. (The latter name comes from the microscopic picture to be derived in Section 3-2.)

The partial flux penetration in the Schubnikov phase can be described in terms of a diagram $B(H)$; the aspect of this diagram is shown in Fig. 3-2. Sometimes, instead of the induction B, the experimentalists prefer to plot the "magnetization" M defined by

$$M = \frac{B - H}{4\pi} \tag{3-2}$$

The $M(H)$ curve is shown in Fig. 3-3.

(In practice the observation of these curves is often complicated by difficulties in attaining equilibrium; for example, structural defects oppose the displacement of the lines of force.)

In Fig. 3-3 the dashed line represents the magnetization curve found for a first kind superconductor with the same H_c. These two curves are related by a remarkable property - the areas they subtend are equal.

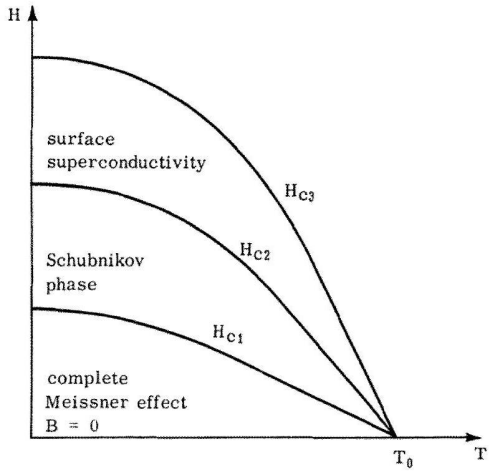

Figure 3-1 Phase diagram for a long cylinder of a Type II superconductor.

Proof: Let G_S be the Gibbs function per unit volume for the superconducting state

$$G_S = F_S(B) - \frac{BH}{4\pi} \tag{3-3}$$

G_S is a minimum for fixed H, that is, at equilibrium

$$\left(\frac{\partial G_S}{\partial B}\right)_H = 0 \tag{3-4}$$

Let G_n be the Gibbs function for the normal state

$$G_n = F_n + \frac{B^2}{8\pi} - \frac{BH}{4\pi} \tag{3-5}$$

At thermodynamic equilibrium in the normal phase $(\partial G_n/\partial B)_H = 0$; therefore, B = H and

$$G_n = F_n - \frac{H^2}{8\pi} \tag{3-6}$$

Let the field vary from H to H + δH. From (3-3) and (3-4)

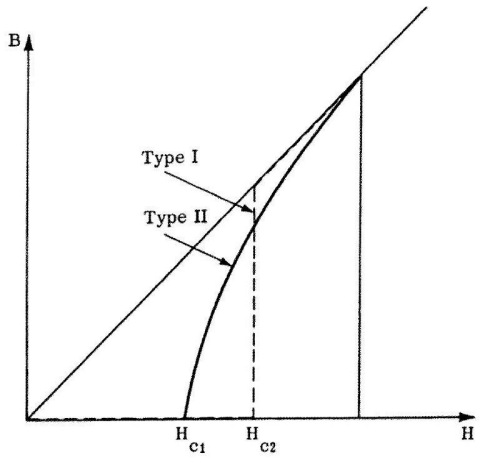

Figure 3-2 The induction (or flux /cm^2) in the cylinder as a function of the applied field H. The full curve applies for a Type II superconductor, the dotted curve for a Type I.

$$\frac{\partial \mathrm{G_S}}{\partial \mathrm{H}} = -\frac{\mathrm{B}}{4\pi} \tag{3-7}$$

and from (3-6)

$$\frac{\partial G_n}{\partial H} = -\frac{H}{4\pi} \tag{3-8}$$

$$\frac{\partial}{\partial H}\left(G_n - G_S\right) = \frac{B-H}{4\pi} = M \tag{3-9}$$

We now integrate this relation between H = 0 and H = $\mathrm{H_{C_2}}$. At H = $\mathrm{H_{C_2}}$, the two phases are in equilibrium and $G_n = G_S$. For $H = 0, B = 0$ we have $G_n = F_n$, $\mathrm{G_S} = \mathrm{F_S}$, and by definition

$$\left(F_n - F_s\right)_{B=0} = \frac{H_c^2}{8\pi}$$

The result is therefore

$$\int_0^{H_{c2}} \mathrm{MdH} = \frac{-\mathrm{H_C^2}}{8\pi} \tag{3-10}$$

and we conclude that the area subtended by the curve of Fig. 3-3 depends only on $\mathrm{H_c}$. From the equilibrium magnetization curves, one can therefore determine $\mathrm{H_c}$ and the condensation energy.

We now discuss the transition occurring when the applied field H becomes equal to one of the limiting values $\mathrm{H_{c_1}}$ or $\mathrm{H_{c_2}}$. Consider first the transition at $\mathrm{H_{C_2}}$. Experimentally this is a second-order transition in all cases studied up to now.

(1) Magnetization measurements show that the B(H) curve is continuous at H = $\mathrm{H_{C_2}}$.

(2) In the few cases ($\mathrm{V_3Ga}$) where thermal measurements have been performed, it appears that there is no latent heat for the transformation, but only a discontinuity in the specific heat.

It is possible to relate this discontinuity to the magnetization curves by a purely ther modynamic analysis (Goodman, 1962). Let i and j be the two phases of interest (for the case at hand i would represent the Schubnikov phase and j the phase with $B \equiv H$, where the bulk of the sample is normal)

$$G_i = F_i\left(T, B_i\right) - \frac{B_i H}{4\pi} \tag{3-11}$$

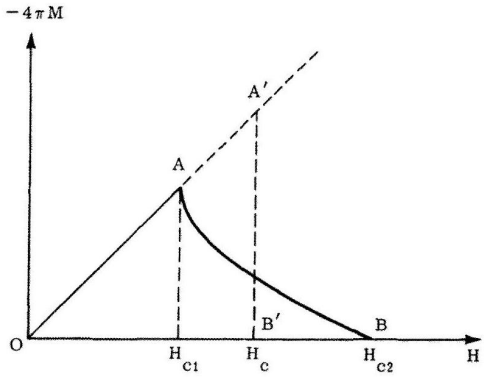

Figure 3-3

The reversible magnetization curve of a long cylinder of Type I (dotted line) or Type II (solid line) superconductor. If the two materials have the same thermodynamic field H_c, the areas OAB and OA′B′ are equal.

is the Gibbs function per cm^3 of the ith phase. The relation between the field H and the induction B in this phase is obtained by minimizing G for fixed H and T

$$\frac{\partial}{\partial B_i} F_i\,(T, B_i) = \frac{H}{4\pi} \tag{3-12}$$

the entropy S_i is deduced from the relations

$$S_i = -\left(\frac{\partial G_i}{\partial T}\right)_H = -\frac{\partial F_i}{\partial T} \tag{3-13}$$

When the field satisfies a certain condition $H = H^*(T)$, there is an equilibrium between the phases i and j (i.e., for the present case $H^* = H_{C2}$). On this curve, one has

$$G_i = G_j \tag{3-14}$$

Suppose that there is no latent heat associated with the transformation. Then, along the curve $H = H^*(T)$, the two phases have the same entropy

$$S_i = S_j \tag{3-15}$$

We first show that this excludes any discontinuity in B at the transition. To show this, we calculate the variation of F_i when one moves along the equilibrium curve $[dH = (dH^*/dT)\,dT]$

$$\frac{dF_i}{dT} = \frac{\partial F_i}{\partial T} + \frac{\partial F_i}{\partial B_i}\frac{dB_i}{dT} \tag{3-16}$$

From this equation and using (3-12) and (3-13), we obtain the variation of G along the equilibrium curve

$$\frac{dG_i}{dT} = -S_i - \frac{B_i}{4\pi}\frac{dH}{dT}d^* \tag{3-17}$$

Along the equilibrium curve we have constantly $G_i = G_j$, therefore $dG_i/dT = dG_j/dT$; if also $S_i = S_j$ we necessarily have $B_i = B_j$; B is continuous at the transition.

We now calculate the specific heat in constant field

$$C_i = T\left(\frac{\partial S_i}{\partial T}\right)_H \tag{3-18}$$

We can transform the second factor by calculating the total derivative of the entropy along the equilibrium curve

$$\frac{\mathrm{dS_i}}{\mathrm{dT}} = \left(\frac{\partial \mathrm{S_i}}{\partial \mathrm{T}}\right)_{\mathrm{H}} + \left(\frac{\partial \mathrm{S_i}}{\partial \mathrm{H}}\right)_{\mathrm{T}} \frac{\mathrm{dH^*}}{\mathrm{dT}} \tag{3-19}$$

From (3-15), $\mathrm{dS_i/dT} = \mathrm{dS_j/dT}$ along the equilibrium curve and

$$C_j - C_i = T\frac{dH^*}{dT}\left[\left(\frac{\partial S_i}{\partial H}\right)_T - \left(\frac{\partial S_j}{\partial H}\right)_T\right] \tag{3-20}$$

We transform $(\partial \mathrm{S_i}/\partial \mathrm{H})_{\mathrm{T}}$ by using (3-13) and (3-12)

$$\begin{aligned}\left(\frac{\partial S_i}{\partial H}\right)_T &= \left(\frac{\partial S_i}{\partial B_i}\right)_T \left(\frac{\partial B_i}{\partial H}\right)_T = -\frac{\partial^2 F_i}{\partial B_i \partial T}\left(\frac{\partial B_i}{\partial H}\right)_T \\ &= -\frac{1}{4\pi}\frac{\partial H\,(B_i T)}{\partial T}\left(\frac{\partial B_i}{\partial H}\right)_T\end{aligned} \tag{3-21}$$

Finally, we write the variation of H^* with respect to T in the form

$$\frac{dH^*}{dT} = \left(\frac{\partial H}{\partial T}\right)_{B_i} + \left(\frac{\partial H}{\partial B_i}\right)_T \frac{dB}{dT} \tag{3-22}$$

where $\mathrm{dB/dT} = \mathrm{dB_i/dT} = \mathrm{dB_j/dT}$ represents the variation of B along the equilibrium curve. On inserting $(\partial \mathrm{H}/\partial \mathrm{T})_B$ from (3-22) into (3-21) we find

$$\left(\frac{\partial S_i}{\partial H}\right)_T = -\frac{1}{4\pi}\frac{d^*}{dT}\left(\frac{\partial B_i}{\partial H}\right)_T + \frac{1}{4\pi}\frac{dB}{dT} \tag{3-23}$$

$$C_j - C_i = \frac{T}{4\pi}\left(\frac{dH^*}{dT}\right)^2\left[\left(\frac{\partial B_j}{\partial H}\right)_T - \left(\frac{\partial B_i}{\partial H}\right)_T\right] \tag{3-24}$$

Therefore, if one knows $H^*(T)$ and the permeabilities $(\partial B_i/\partial H)_T$ for each of the phases, one can predict the discontinuity in the specific heat. For the transition $(i \to j)$ we have a finite permeability (> 1) in the vortex state (i) from Fig. 3-2 and a permeability equal to 1 in the normal state (j). Therefore $C_i > C_j$. At this time all the necessary information is not available to compare (3-24) to experiment. However, for $\mathrm{V_3Ga}$, $\mathrm{C_i - C_j}$ and $\mathrm{dH_{C2}/dT}$ are known and if one makes a reasonable extrapolation for $\partial \mathrm{B}/\partial \mathrm{H}$ in order to predict its value at $\mathrm{H_{C_2}}$ one finds an agreement to within about 10% from magnetic and calorimetric measurements. A similar analysis can be carried out in principle for the transition at $\mathrm{H} = \mathrm{H_{C_1}}$. Here, however, the permeability $(\partial \mathrm{B}/\partial \mathrm{H})_{\mathrm{H}} = \mathrm{H_{C_1}}$ in the Schubnikov phase is probably infinite, as shown by the theoretical calculations of Section 3-2. From (3-24) this leads to an infinite peak in the specific heat at the transition. The singularity is, in fact, weak and easily masked by hysteresis effects. It has been observed recently (on Niobium) by the Rutgers group.

7.2.2 3-2 Vortex state: microscopic description

Negative Surface Energy

We have previously seen that in a London $(\xi < \lambda)$ superconductor the surface tension of a wall separating normal and superconducting regions becomes negative. Under these conditions, we guess that in the presence of a field a state is created where the N and S regions are finely divided and where the wall energy gives an important contribution to the thermodynamic potential. This situation is very different from that encountered for a Pippard superconductor

where the walls are less numerous and where their energy can be neglected in a macroscopic treatment.

Consider, for example, the limit where B is small (that is, few lines of force penetrate the specimen and only a small fraction of the sample is normal). There are essentially two possibilities to maximize the surface to volume ratio for the N regions:

We can form lamina of very small thickness ($\geq \xi$) or filaments of small diameter ($\sim \xi$). In the case of $\lambda \gg \xi$, theoretical calculations show that the second solution is lowest in energy. [2] We therefore find filaments. They are represented in Fig. 3-4a.

Each filament has a hard core of radius ξ where the superconducting electron density n_S falls as is shown in Fig. 3-4c. The lines of force are not confined to the hard core; the field is maximum at the center of the filament but extends a distance λ (Fig. 3-4b). Annular

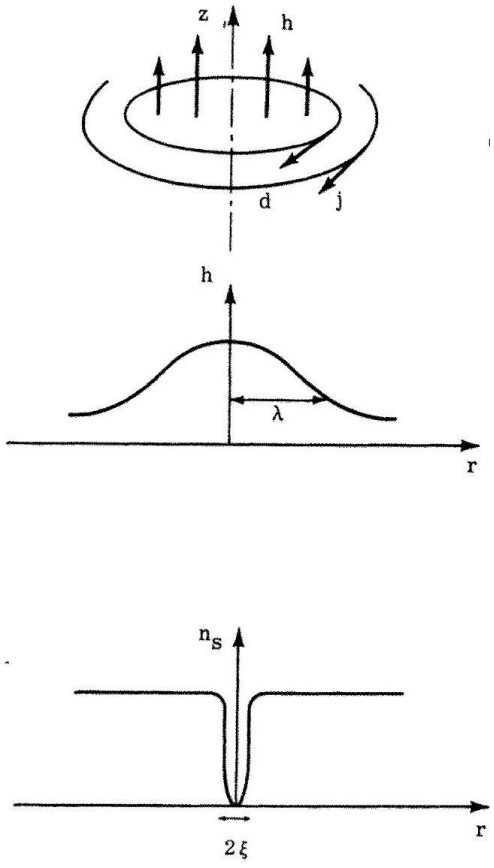

Figure 3-4

Structure of one vortex line in a Type II superconductor. The magnetic field is maximum near the center of the line. Going outwards, h decreases because of the screening in an "electromagnetic region" of radius $\sim \lambda$ (the penetration depth) (Fig. 3-4b). On the other hand, the number of superconducting electrons per $cm^3 n_S$ is reduced only in a small "core region" of radius ξ (Fig. $3-4c$).

currents j encircle the filament and screen out the field for $r > \lambda$. For $r > \xi$, that is, in most of the region of interest, the currents and fields can be simply calculated by London's equations. It will be shown that the radius and exact form of the hard core only appear in the argument of a logarithm; therefore it will not be necessary to know them accurately. In the limit $\xi \ll \lambda$ we shall, in fact, see that the properties of a filament are very easy to calculate.

What is the flux $\phi = \int$ hdo carried by a filament?

Experiment and theory show us that if a bulk superconducting annulus surrounds some lines of force the enclosed flux can only take on discrete values

[2] See problem, page 71.

$$\phi = \mathrm{k}\phi_0 \quad (\mathrm{k\ is\ an\ integer}) \tag{3-25}$$
$$\phi_0 = \frac{\mathrm{ch}}{2\mathrm{e}} = 2 \times 10^{-7}\mathrm{Gcm}^2$$

The explanation of this effect will be given at the end of Chapter 4. The same result applies here. In order to attain the state of maximum subdivision, each filament carries one quantum of flux ϕ_0. This condition fixes the field scale in Fig. $3-4$ b, and the structure of the filament is completely defined.

Such a quantized filament, formed of a very thin hard core surrounded by currents rotating about the axis, is very analagous to the vortex lines found in superfluid He^4 when the helium container is rotated. The only important difference is that the helium atoms are not charged, making $\mathrm{e} = 0$ in Eq. $(1-13)$. We see that the penetration depth λ in He^4 is infinite and the particle currents j, instead of decreasing exponentially for $r > \lambda$, decrease very slowly (as in $1/r$) far from the filament. Historically, vortex lines were first discussed for the He^4 problem by Onsager and Feynman; the generalization to superconductivity is due to Abrikosov (1956). When the superconducting metal contains a finite density of these lines, we say that it is in the vortex state.

Properties of One Isolated Vortex Line

We now study in detail the structure of one vortex line in the limit $\lambda \gg \xi$. The "hard core" of radius ξ is very small and we shall, for the moment, neglect completely its contribution to the energy.

Then the line energy is given by the formula

$$J = \int_{(\mathrm{r}>\xi)} \mathrm{dr} \frac{1}{8\pi} \left[h^2 + \lambda^2 (\mathrm{curl}\, h)^2\right] \tag{3-26}$$

Equation (3-26) has been derived in Chapter 1 (assuming $\lambda \gg \xi$). For a pure superconductor, the penetration depth λ has the London value

$$\lambda_{\mathrm{L}} = \left[\frac{\mathrm{mc}^2}{4\pi \mathrm{n_S e}^2}\right]^{1/2} \tag{3-27}$$

For a superconducting alloy, with $\lambda \gg \xi$, Eq. (3-26) still applies, but with a modified (larger) value of λ, as explained in Chapter 2 (see the discussion after Eq. 2-20). In Eq. (3-26) the integration is carried out in all space outside of the "hard core" ($r > \xi$). We also choose to compute the energy per unit length of line; the resulting energy per cm$J$ is called the line tension. Demanding that J be a minimum leads as usual to the London equation

$$\mathrm{h} + \lambda^2\ \mathrm{curl\ curl\ h} = 0 \quad |\mathrm{r}| > \xi \tag{3-28}$$

In the interior of the hard core Eq. (3-28) must be replaced by something more complicated. But, since the hard core has a very small radius, we can try to replace the corresponding singularity, simply by a two-dimensional delta function $\delta_2(r)$, and write

$$h + \lambda^2\ \mathrm{curl\ curl}\ h = \phi_0 \delta_2(r) \tag{3-29}$$

where ϕ_0 is a vector along the line direction. We now show that the strength ϕ_0 in (3-29) represents the total flux carried by the line.

Integrate (3-29) over the interior surface of a circle C of radius r encircling the axis of the cylinder and use the curl formula:

$$\int \mathrm{h}\cdot \mathrm{d}\sigma + \lambda^2 \oint \mathrm{curl}\,\mathrm{h}\cdot \mathrm{d}\ell = \phi_0 \tag{3-30}$$

if the circle has a radius $\mathrm{r} \gg \lambda$, the currents $j(\mathrm{r}) = \mathrm{c}/4\pi$ curl h are negligible and the line integral along the perimeter of the circle vanishes. Thus the total flux carried by the filament has the value ϕ_0.

We now pass on to the explicit solution of $(3-30)$ to which is added the Maxwell equation

$$\mathrm{div}\, h = 0 \tag{3-31}$$

The field h is directed along the z axis; the current lines are circles in the xy plane. It is easy to predict the value of curl h, that is, the current, in the region $\xi \ll \mathrm{r} \ll \lambda$. In fact, if we reconsider (3-30) with a circle C whose radius is in this domain, the term $\mathrm{Jh}\cdot \mathrm{d}\sigma$ is negligible (only a fraction r^2/λ^2 of the flux ϕ_0 passes through the circle C) and we have

$$\lambda^2 2\pi \mathrm{r}|\ \mathrm{curl}\ \mathrm{h}\ | = \phi_0 \tag{3-32}$$

and

$$|\,\mathrm{curl}\,\mathrm{h}| = \frac{\phi_0}{2\pi\lambda^2}\frac{1}{\mathrm{r}} \quad (\xi < \mathrm{r} \ll \lambda) \tag{3-33}$$

Since h is directed along the z axis, we have $|\,\mathrm{curl}\, h| = -dh/dr$ and upon integrating this relation

$$\mathrm{h} = \frac{\phi_0}{2\pi\lambda^2}\left[\ln\left(\frac{\lambda}{\mathrm{r}}\right) + \mathrm{const}\right] \quad (\xi < \mathrm{r} < \lambda) \tag{3-34}$$

In order to derive the constant of integration in (3-34), it is necessary to write the complete solution to $(3-30)$ and $(3-32)$, which is

$$\mathrm{h} = \frac{\phi_0}{2\pi\lambda^2}\ \mathrm{K}_0\left(\frac{\mathrm{r}}{\lambda}\right) \tag{3-35}$$

where K_0 is the zero-order Bessel function of an imaginary argument defined as in Morse and Feshbach. [3] The important properties of this solution are the asymptotic form (3-34) for $\mathrm{r} \ll \lambda$ (it is found that the constant vanishes) and the asymptotic form for large distances

$$\mathrm{h} = \frac{\phi_0}{2\pi\lambda^2}\sqrt{\frac{\pi\lambda}{2\mathrm{r}}}\mathrm{e}^{-\mathrm{r}/\lambda} \quad (\mathrm{r} \gg \lambda) \tag{3-36}$$

Once the fields are determined, it is easy to calculate the energy J. On integrating the second term in (3-28) by parts,

$$J = \frac{\lambda^2}{8\pi}\int \mathrm{d}\sigma \cdot h \times \mathrm{curl}\, h \tag{3-37}$$

where the integral $\int \mathrm{d}\sigma$ is to be taken over the surface of the hard core (cylinder of radius $\sim \xi$). It is convenient to calculate $\mathfrak{J}$ per cm of length along the filament. Then

$$J = \frac{\lambda^2}{8\pi} 2\pi\xi \mathrm{h}(\xi)|\,\mathrm{curlh}(\xi)| \tag{3-38}$$

which is, from (3-34) and (3-33),

$$J = \left(\frac{\phi_0}{4\pi\lambda}\right)^2 \ln\left(\frac{\lambda}{\xi}\right) \tag{3-39}$$

DISCUSSION OF THIS FORMULA

(1) J only depends upon ξ logarithmically.

(2) J is a quadratic function of the flux. Upon going to a situation where the flux is $2\phi_0$, it is preferable to have two filaments of flux ϕ_0 (total energy 2J) than a filament of double flux (energy 4J). This justifies the choice for ϕ_0 of the minimum flux value, that is, the quantum of flux.

(3) It is possible to rewrite J at $T = 0$ in a rather different form by using the relations

$$\phi_0 = \frac{\mathrm{ch}}{2\mathrm{e}}, \quad \xi = \xi_0 = \frac{\hbar \mathrm{v_F}}{\pi \Delta(0)} \tag{3-40}$$

and a relation (which will be proven by the microscopic theory) between the condensation energy and the energy gap $\Delta(0)$:

$$\frac{\mathrm{H_c^2}}{8\pi} = \frac{1}{2}\,\mathrm{N}(0)\Delta^2(0) \tag{3-41}$$

where $N(0) = m^2 v_F / 2\pi^2\hbar^3$ is the density of states (for one direction of spin) at the Fermi energy in the normal state per unit energy and per cm^3. Upon regrouping these formulas, we obtain

$$J = \frac{\pi^3}{3}\frac{\mathrm{H_c^2}}{8\pi}\xi^2 \ln\frac{\lambda}{\xi} \quad (\mathrm{T} = 0) \tag{3-42}$$

This formula is interesting for the following reason:

Until now we have neglected the contribution of the hard core to the line energy. In fact, superconductivity is more or less destroyed in the hard core section and this takes an extra energy $J_{\mathrm{int}} \sim (\mathrm{H_c^2}/8\pi)\,\xi^2$.

Dimensionally from (3-42) this energy is comparable to $\mathfrak{J}$. Numerically, however, it is much smaller. A more detailed calculation gives for the total energy

$$J = \left(\frac{\phi_0}{4\pi\lambda}\right)^2 \left(\ln\frac{\lambda}{\xi} + \epsilon\right) \quad (\lambda \gg \xi)$$

The numerical constant ϵ includes the effect of the hard core and is of the order of 0.1.

Problem.

Discuss the structure of vortices in a thin film, the applied magnetic field being normal to the film surface (J. Pearl, 1964).

Solution.

Again there is a "hard core" of radius ξ (which we assume to be small) surrounded by current rings. But since the currents are restricted to the thickness d of the film, their screening capacity is weak and the "electromagnetic region" is more spread out than in a long vortex line.

Inside the film, we apply Eq. (3-29)

$$\mathrm{h} + \frac{4\pi\lambda^2}{\mathrm{c}}\,\mathrm{curl\ j} = \phi_0\delta_2(r)\mathrm{n_z}$$

where f is the current density and n_z is a unit vector normal to the film. It is convenient to use the vector potential A rather than the field $h = \mathrm{curl}\,A$. In the London gauge, we find

[3] Methods of Theoretical Physics, (New York: McGraw-Hill, 1953), Chap. 10, p. 1321.

$$A + \frac{4\pi\lambda^2}{\mathrm{c}}\mathrm{J} = \Phi$$

where $\Phi_\mathrm{r} = \Phi_\mathrm{z} = 0$ and $\Phi_\theta = \phi_0/2\pi\mathrm{r}$.

Now average over the thickness d of the film. If $d \ll \lambda, A$ and J are nearly constant in the thickness. Call J the total current $J = jd$. Then

$$J = \frac{c}{4\pi}\frac{1}{\lambda_{\text{eff}}}(\Phi - A)$$
$$\lambda_{\text{eff}} = \frac{\lambda^2}{d}$$

Now replace the film by a infinitesimally small current carrying sheet in the plane z = 0, the current density being $J\delta(z)$. This will be valid when d is much smaller than the range of the electromagnetic region.

In terms of the current sheet the equation valid for all space is

$$\text{curl curl } A = \text{curl}\, h = \frac{4\pi}{c}j = \frac{1}{\lambda_{\text{eff}}}\delta(z)(\Phi - A)$$

or (since curl curl $A = -\nabla^2 A$ in the London gauge)

$$-\nabla^2 A + A\frac{1}{\lambda_{\text{eff}}}\delta(z) = \Phi\frac{1}{\lambda_{\text{eff}}}\delta(z)$$

This result was derived here from the London Eq.(3-29). In actual thin films, such a simple equation does not usually hold. But it is still correct to assume a linear current response of the form $J = (c/4\pi\lambda_{\text{eff}})(\Phi - A)$, where λ_{eff} is some unknown constant, which can be obtained from another experiment (λ_{eff} is, in fact, the effective penetration depth in parallel fields, which could be measured on a hollow cylinder made with the same film).

To solve the equation for A, introduce the three-dimensional Fourier transform

$$A_{qk} = \int A(xyz)\exp i\,(q_x x + q_y y + kz)\,dxdydz$$

and the two-dimensional transforms

$$A_q = \frac{1}{2\pi}\int dk A_{qk} = \int A\delta(z)\exp i\,(q_x x + q_y y)\,dxdydz$$
$$\Phi_q = \int \Phi(xy)\exp i\,(q_x x + q_y y)\,dxdy = i\frac{\phi_0}{q^2}n_z xq$$

Then

$$\left(q^2 + k^2\right)A_{qk} + \frac{1}{\lambda_{\text{eff}}}A_q = \frac{1}{\lambda_{\text{eff}}}\Phi_q$$

Solve for $\mathbf{A}_{\mathrm{qk}}$ and integrate over k:

$$A_q = -\frac{1}{2\pi}\int dk\frac{1}{q^2 + k^2}(A_q - \Phi_q)\frac{1}{\lambda_{\text{eff}}} = -\frac{1}{2q\lambda_{\text{eff}}}(A_q - \Phi_q)$$
$$A_q = \Phi_q\frac{1}{1 + 2q\lambda_{\text{eff}}}$$

From this, all required information can be extracted:

(a) The current has components

$$J_q = \frac{c}{4\pi\lambda_{\text{eff}}}\left(\Phi_q - A_q\right) = \frac{c}{4\pi\lambda_{\text{eff}}}\Phi_q \frac{2q\lambda_{\text{eff}}}{1+2q\lambda_{\text{eff}}}$$

When $q \gg \lambda_{\text{eff}}^{-1}$, J_q is proportional to Φ_q. Thus at small distances r from the center of the vortex

$$J(r) = \frac{c}{4\pi\lambda_{\text{eff}}}\mathbf{\Phi}(r)$$
$$J = \frac{c\phi_0}{8\pi^2\lambda_{\text{eff}}\, r} \quad (\xi \ll r \ll \lambda_{\text{eff}})$$

When $q \ll \lambda_{\text{eff}}^{-1}$

$$J_q \approx \frac{c}{4\pi\lambda_{\text{eff}}} 2q\lambda_{\text{eff}}\, \Phi_q = \frac{c\phi_0}{2\pi}\frac{i_z \times q}{q}$$
$$J = \frac{c\phi_0}{4\pi^2 r^2} \quad (r \gg \lambda_{\text{eff}})$$

The size of the screening region is λ_{eff}. But even beyond λ_{eff}, J decreases only slowly with distance.

(b) The normal field component $\mathrm{h_7}$ in the film is derived from

$$\mathrm{h_{zq}} = \left(-\mathrm{iq} \times \mathbf{A}_{\mathrm{q}}\right)_{\mathrm{z}} = \frac{\phi_{\mathrm{u}}}{1+2\mathrm{q}\lambda_{\text{eff}}}$$

When $q \gg \lambda_{\text{eff}}^{-1}$

$$\mathrm{h_{zq}} \sim \frac{\phi_0}{2\mathrm{q}\lambda_{\text{eff}}}$$
$$\mathrm{h_z(r)} \sim \frac{\phi_0}{4\pi\lambda_{\text{eff}}\,\mathrm{r}} \quad (\xi < \mathrm{r} \ll \lambda_{\text{eff}})$$

At large r we derive h_z most easily from the current J

$$\mathrm{h_2} = -\frac{4\pi\lambda_{\text{eff}}}{\mathrm{c}}\frac{1}{\mathrm{r}}\frac{\mathrm{d}}{\mathrm{dr}}(\mathrm{Jr})$$
$$\cong \frac{2}{\pi}\frac{\phi_0\lambda_{\text{eff}}}{\mathrm{r}^3}$$

(c) The self-energy of the vortex is derived from Eq. (3-26); the required components of h and curl h at the core surface ($\xi \ll \lambda_{\text{eff}}$) are quoted above. The result is

$$E = \left(\frac{\phi_0}{4\pi}\right)^2 \frac{1}{\lambda_{\text{eff}}} \log\frac{\lambda_{\text{eff}}}{\xi} = \frac{137}{16}\frac{\hbar c}{\lambda_{\text{eff}}} \log\frac{\lambda_{\text{eff}}}{\xi}$$

Typically $\lambda_{\text{eff}} \sim 1000\text{Å}$ and $E \sim 30\text{eV}$.

(d) The force between two vortices is

$$\mathbf{F}_{12} = \frac{\phi_0}{\mathrm{c}}\mathbf{n}_{\mathrm{z}} \times J\left(\mathrm{R}_{12}\right)$$

Note that at long distances $J \sim 1/R^2$ and the repulsion energy decreases only like $1/R$. This long range is due to the fact that most of the interaction takes place not through the superconductor, but through the empty space above and below.

Interactions between Vortex Lines

TWO VORTEX LINES

Consider two parallel lines directed along the z axis with positions $r_1 = (x_1, y_1), r_2 = (x_2 y_2)$. The magnetic field distribution is determined by the equations

$$h + \lambda^2 \text{ curl curl } h = \phi_0 \left[\delta\left(\mathbf{r} - \mathbf{r}_1\right) + \delta\left(\mathbf{r} - \mathbf{r}_2\right)\right]$$

which is the generalization of $(3-29)$. The solution h is the superposition of the fields h_1 and h_2 due to the filaments (1) and (2).

$$h(r) = h_1(r) + h_2(r)$$
$$h_1(r) = \frac{\phi_0}{2\pi\lambda^2} K_0\left(\frac{r - r_1}{\lambda}\right)$$

The energy of the system is still written

$$F = \int \frac{h^2 + \lambda^2(\text{curl h})^2}{8\pi} dr = \frac{\lambda^2}{8\pi} \int h \times \text{curl}\, h \cdot d\sigma$$

Here the integral $\int \mathrm{d}\sigma$ is to be taken over the surfaces of the two hard cores ($|r - r_i| = \xi$); writing explicitly the two contributions to h we obtain

$$F = \frac{\lambda^2}{8\pi} \int (d\sigma_1 + d\sigma_2) \cdot (h_1 + h_2) \times (\text{curl}\, h_1 + \text{curl}\, h_2)$$

There are 8 terms that we regroup as follows: First the individual energy of each filament

$$\frac{\lambda^2}{8\pi}\left[\int \mathrm{d}\sigma_1 \cdot h_1 \times \text{curl}\, h_1 + \int d\sigma_2 \cdot h_2 \times \text{curl}\, h_2\right] = 2J$$

then the terms

$$\int (h_1 + h_2) \cdot (\text{curl}\, h_1 \times d\sigma_2 + \text{curl}\, h_2 \times d\sigma_1)$$

which tend toward 0 in the limit where $\xi \ll \lambda$ because $h_1 + h_2$ and curl h_1 are finite in the domain of integration $\int d\sigma_2$. There remains an important contribution

$$U_{12} = \frac{\lambda^2}{8\pi} \int (h_1 \times \text{curl}\, h_2 \cdot d\sigma_2 + h_2 \times \text{curl}\, h_1 \cdot d\sigma_1)$$

In effect, curl h_2 is proportional to $1/|r - r_2|$ for $|r - r_2| \ll \lambda$ from (3-33) and after integration one obtains a finite result as $\xi \to 0$. If we set

$$h_{12} = h_1(r_2) = h_2(r_1) = \frac{\phi_0}{2\pi\lambda^2} K_0\left(\frac{r_1 - r_2}{\lambda}\right)$$

then using (3-33) we obtain

$$U_{12} = \frac{\phi_0 \, \mathrm{h}_{12}}{4\pi}$$

U_{12} represents the interaction energy (per cm) of two filaments. This is a repulsive energy which decreases as $\left(1/\sqrt{r_{12}}\right) \mathrm{e}^{-\mathrm{r}_{12}/\lambda}$ at large distances, and which diverges as $\ln\left(|\lambda/r_{12}|\right)$ at short distances.

A remark about forces. Let us compute the force f_2 experienced by line 2, as due to the interaction U_{12}

$$f_{2x} = -\frac{\partial U_{12}}{\partial x_2} = -\frac{\phi_0}{4\pi}\frac{\partial h_{12}}{\partial x_2}$$

Introduce now the current $f = n_s e v$, which would exist, in the presence of line 1 alone, at the point $x_2 y_2$. Then $j_y = -(c/4\pi)\,(\partial h_{12}/\partial x_2)$ by Maxwell's equation and we have

$$f_{2x} = \frac{\phi_0}{c} j_y = \frac{1}{2} h n v y$$

When more than one line is acting on line 2, Eq. (3-52) remains valid provided we interpret v as the total superfluid velocity at point $(x_2 y_2)$.

Conclusion. A line is in static equilibrium when the superfluid velocity at any point on the line is 0.

MAGNETIZATION CURVES

We now form the Gibbs function, minimize it, and deduce the density of vortices existing in the sample in thermal equilibrium.

$$G = n_L J + \sum_{ij} U_{ij} - \frac{BH}{4\pi}$$

The first term represents the individual energies of the lines, n_L is the number of lines per cm^2, related to the induction B by

$$B = n_L \phi_0$$

(This expresses the fact that each vortex carries a flux ϕ_0.) The second term in (3-53) describes the repulsive interactions between vor tices; the explicit form of U_{ij} is given by (3-49) and (3-50). Finally, the last term gives the effect of the field H and favors large values of B. It plays the role of a pressure that tends to increase the density of vortices.

In order to numerically evaluate the interaction term, it is useful to distinguish several regions:

(1) In the small induction region ($n_L \lambda^2 \ll 1$), only the interaction between nearest neighbor vortices is important and the sum ΣU_{ij} converges rapidly.

(2) When B is larger ($n_L \lambda^2 \gg 1$), the range λ of the interaction becomes large compared to the spacing of the filament lattice, and other methods are preferable to evaluate ΣU_{ij}.

(3) Finally, when n_L becomes comparable to $1/\xi^2$, the hard cores begin to overlap and the elementary methods used in this section are no longer valid. But, qualitatively, we may guess that when the hard cores do overlap, superconductivity is destroyed in the bulk. This corresponds to inductions $B \sim \phi_0/\xi^2$.

THE FIRST PENETRATION FIELD H_{C_1}

At very low line densities (low B), the interaction term in Eq. (3-53) is small and we shall first neglect it completely. Then, using Eq.(3-54) we get

$$G \cong B\left(\frac{5}{\phi_0} - \frac{H}{4\pi}\right)$$

When $H < 4\pi J/\phi_0$, G is an increasing function of B. The lowest G is obtained for $B = 0$ (complete Meissner effect).

When $H > 4\pi J/\phi_0$, we can lower G by choosing $B \neq 0$. There is some flux penetration.

We conclude that the first penetration field is given by

$$H_{c1} = \frac{4\pi J}{\phi_0} = \frac{\phi_0}{4\pi\lambda^2} \log \frac{\lambda}{\xi}$$

H_{c_1} is often much'smaller than the "thermodynamic" field H_c defined by $(3-1)$. For $T = 0$, for example, on using $(3-40)$ and $(3-41)$, we find

$$\frac{H_{c_1}}{H_c} = \frac{\pi}{\sqrt{24}} \frac{\xi}{\lambda} \ln\left(\frac{\lambda}{\xi}\right)$$

The result is therefore $H_{C_1}/H_c \sim \xi/\lambda$ and this may be much smaller than 1. A measurement of H_{c_1} and H_c, in principle, allows a determination of ξ and λ. For example, for V_3Ga, if at $T = 0, H_c \sim 6000G$ and $H_{c_1} \sim 200G$, one finds from (3-57) that $\lambda/\xi \sim 80$ and then, from (3-56), $\lambda \sim 2000$Å and $\xi \sim 25$Å. These orders of magnitude are still rather inaccurate because of current uncertainties in H_c and H_{C_1}, but it is hoped that the situation will improve in the near future.

FIELDS SLIGHTLY LARGER THAN H_{C_1}

For finite line densities (finite B's) we must take into account the interaction term in Eq. (3-53). To minimize this repulsive energy, the lines will take a regular arrangement. Detailed calculations based on (3-53) show that, at all B's, the most favorable arrangement is triangular, as shown on Fig. 3-5 (J. Matricon, 1964).

If H is only slightly larger than H_{c_1}, we can guess that the equilibrium density of lines n will be small, and thus the distance between neighboring lines d will be large. If $d > \lambda$, we may keep only the nearest neighbor contributions to the interaction term in (3-53) and write

$$G \cong \frac{B}{4\pi}\left[H_{c_1} - H + \frac{1}{2} z \frac{\phi_0}{2\pi\lambda^2} K_0\left(\frac{d}{\lambda}\right)\right]$$

where z is the number of nearest neighbors of one line ($z = 6$ for the triangular lattice), d is related to the induction B through the relation

$$B \equiv \phi_0 n_L = \frac{2}{\sqrt{3}} \frac{\phi_0}{d^2} \quad \text{(triangular lattice)}$$

Equation (3-59) can be easily verified on Fig. 3-5. The function $G(B)$ is represented in Fig. 3-6. Since $H > H_{C_1}$, the initial slope $(\partial G/\partial B)_{B=0}$

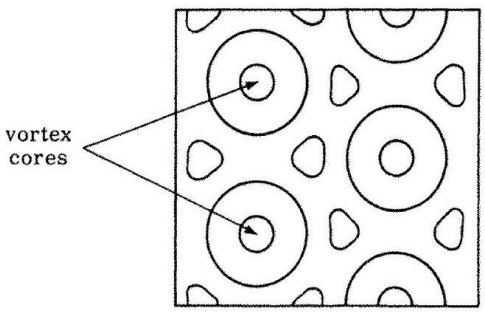

Figure 3-5

A triangular lattice of vortex line (after Kleiner, Roth, and Autler, Phy's. Ren., 133A, 1226 (1964). The plane of the figure is normal to the field direction. The contours give the lines of constant n_s. This figure describes the situation at high fields (nearly overlapping cores).

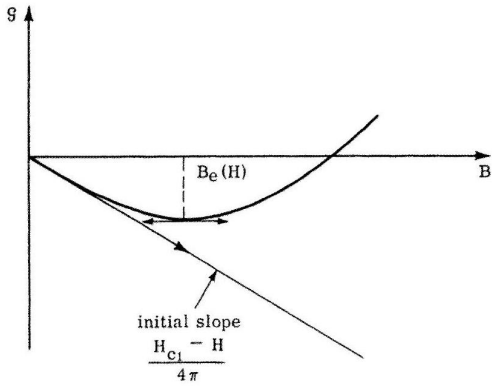

Figure 3-6 The thermodynamic potential S as a function of the induction B ($B = n_L\phi_0$ measures the number of vortices per $\mathrm{cm}^2 \mathrm{n}_L$). The equilibrium value of $B\,[B_e(H)]$ corresponds to the minimum of g.

is negative. As B increases, the interaction term begins to contribute but rather slowly, since it is proportional to $K_0(d/\lambda)$. When $d > \lambda$ we may write, according to (3-36)

$$\mathrm{K}_0\left(\frac{\mathrm{d}}{\lambda}\right) \sim \exp\left(-\frac{\mathrm{d}}{\lambda}\right) = \exp\left[-1.07\sqrt{\frac{\phi_0}{\mathrm{B}\lambda^2}}\right]$$

Thus the interaction term is exponentially small at small B's. At larger B 's however, it dominates the over-all behavior and $G(B)$ increases. There is a minimum of G for some value $B = B(H).B(H)$ is the induction found at equilibrium in the field H. The theoretical $B(H)$ or $M(H)$ has been computed along these lines by Goodman and is shown on Fig. 3-7, together with experimental results on a particularly good MoRe alloy.

The following points must be noticed:

The theoretical curve has an infinite slope $(\partial \mathrm{M}/\partial \mathrm{H})_{\mathrm{H}} = \mathrm{H}_{\mathrm{c}_1} = \infty$ at the first penetration field. Physically, this reflects the fact that the lines repel each other like $e^{-d/\lambda}$, that is, we may think of their interaction as having a finite range λ. At field slightly larger than H_{c_1} it is thus possible to form many lines in the sample without competing against the interaction energy. The experimental curve does not show

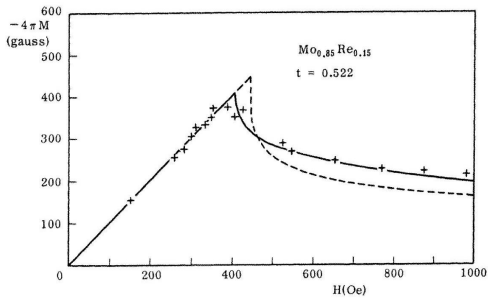

Figure $3-7$

Experimental magnetization of a molybdenum-rhenium alloy at $\mathrm{T} = 0.52\ \mathrm{T}_0$ (after Joiner and Blaugher, Rev. Mod. Phy',, 36, 67 (1964). Also shown are two theoretical magnetization curves (after B. B. Goodman). The broken curve is for a laminar model, the continuous one for vortex lines.

a very large slope $(\partial M/\partial H)_H = H_{c_1}$; this is not very surprising since in the region of interest the interactions between lines are very weak and the lines can easily be pinned by structural defects. However, as we depart from $\mathrm{H}_{\mathrm{c}_1}$ by more than 10%, we get good agreement between theory and experiment.

A similar theoretical curve can be drawn for another model where the flux-carrying units are not vortex lines, but laminas (see problem, p. 71). If the distance between laminas is d, we

again find a repulsion between units proportional to $e^{-d/\lambda}$. However, in this case, the induction B is proportional to d^{-1}, while in the line case it is proportional to d^{-2} as shown by Eq. (3-59). Thus the fall of M(H) for $\mathrm{H} > \mathrm{H}_{\mathrm{C}_1}$ is more rapid in the laminar model than in the vortex line model. The two theoretical curves are compared on Fig. 3-7; it is apparent that the vortex line gives a better fit, as emphasized by Goodman.

DOMAIN $\frac{1}{\lambda^2} \ll \mathrm{n_L} \ll \frac{1}{\xi^2}$

In this region the vortices form a rather dense lattice and the interactions extend to distant neighbors. The interaction energy can then be calculated by the following method: The field $h(r)$ directed along the z axis is the solution of

$$\mathrm{h} + \lambda^2 \ \mathrm{curl\ curl\ h} = \phi_0 \sum_{\mathrm{i}} \delta_2 \left(\mathbf{r} - \mathbf{r}_{\mathrm{i}}\right)$$

$$\mathrm{div\,h} = 0$$

where $r_i = (x_i, y_i)$ denotes the position of the ith vortex. The points $\mathbf{r}_{\mathrm{i}}$ form a two-dimensional periodic lattice. We define the Fourier transform h_J by

$$h_J = n_L \int_{\text{cell}} h\left(x_i, y_i\right) \exp\left[i\left(J_x x + J_y y\right)\right] dxdy$$

Since $h\left(x_i, y_i\right)$ is periodic, h_J is nonvanishing only when J is a reciprocal lattice vector. From (3-61),

$$\mathrm{h}_J = \frac{\mathrm{n_L}\varphi_0}{1 + \lambda^2\ \mathrm{J}^2}$$

Finally the free energy becomes

$$\begin{aligned}
\mathcal{F} &= \frac{1}{8\pi} \int \left(h^2 + \lambda^2 \operatorname{curl}^2 h\right) dr \\
&= \frac{1}{8\pi} \sum_J h_J^2 \left(1 + \lambda^2 J^2\right) = \frac{B^2}{8\pi} \sum_J \frac{1}{1 + \lambda^2 J^2} \\
&= \frac{B^2}{8\pi} + \frac{B^2}{8\pi} \sum_{J \neq 0} \frac{1}{1 + \lambda^2 J^2}
\end{aligned}$$

In the sum $\Sigma_{J\neq 0}$, the minimum magnitude of the vectors J is of the order $1/\mathrm{d} \sim \sqrt{\mathrm{n_L}}$ and $\lambda^2\ \mathrm{J}^2 \sim \mathrm{n_L}\lambda^2 \gg 1$ in the domain of interest. Therefore $1/\left(1 + \lambda^2\ \mathrm{J}^2\right)$ can be replaced by $1/\lambda^2\ \mathrm{J}^2$. Finally we must perform the sum $\Sigma_{J\neq 0} 1/J^2$, which depends on the particular lattice considered. Here, we will simplify the calculation by replacing the sum by an integral

$$\begin{aligned}
&\sum \frac{1}{J^2} \to \frac{1}{(2\pi)^2} \frac{1}{n_L} \int \frac{dJ_x dJ_y}{J^2} \to \frac{1}{2\pi n_L} \int_{J\,\min}^{J\,\max} \frac{JdJ}{J^2} \\
&= \frac{1}{2\pi n_L} \ln \left| \frac{\mathrm{J\,max}}{\mathrm{J\,min}} \right|
\end{aligned}$$

with $\mathrm{J\,min} \sim 1/\mathrm{d}$ and $\mathrm{J\,max} \sim 1/\xi$ (the Fourier components relative to the interior of the hard core must be excluded). We finally find

$$F = \frac{B^2}{8\pi} + \frac{B}{4\pi} H_{c_1} \frac{\ln \beta d/\xi}{\ln \lambda/\xi}$$

$$G = F - \frac{BH}{4\pi}$$

In (3-64) β is a numerical constant of the order unity (for the triangular lattice, Matricon has calculated $\beta = 0.381$). The B(H) relation is ob-tained as usual by imposing $\partial G/\partial B = 0$. This gives

$$H = B + H_{c_1} \frac{\ln\left(\beta' \frac{d}{\xi}\right)}{\ln \frac{\lambda}{\xi}}$$

where $\beta' = \beta e^{-1/2}$ and where d is always related to B by Eq. (3-59). The logarithmic dependences predicted by (3-65) are in rather good agreement with the experimental data on revrsible magnetization curves in materials with $\lambda \gg \xi$.

DOMAIN $n_L \sim \xi^{-2}$

Here, as already pointed out, our simple model breaks down, and we shall need a more elaborate approach based on the Landau-Ginsburg equations (Chapter 6). The upper critical field H_{C_2} is of order φ_0/ξ^2. This, physically, corresponds to the onset of overlap between the hard cores.

Problem.

Compare the Gibbs function in the filamentary structure described above with that of a possible laminar structure.

Solution.

As before, we shall limit our considerations to the case $\lambda \gg \xi$. The laminar structure will be formed of planes, for example, perpendicular to the x axis, and equidistant (spacing d)(Fig. 3-8). In the neighborhood of each of these planes, over a thickness $\sim 2\xi$, the superconductivity is strongly perturbed (N regions). In the remainder (S regions), the density of superconducting electrons has the value n_S. Such a model has been discussed in detail by Goodman (1961). The fields h(x) (parallel to the z axis) are determined by the London equation

$$h = \lambda^2 \frac{d^2 h}{dx^2}$$

except in the thin (N) regions. The solution is of the form

$$h = H_m \cosh(x/\lambda)/\cosh P$$

where $P = d/2\lambda$ and H_m is the field in the N regions. The free energy of the (S) regions becomes, from (3-26),

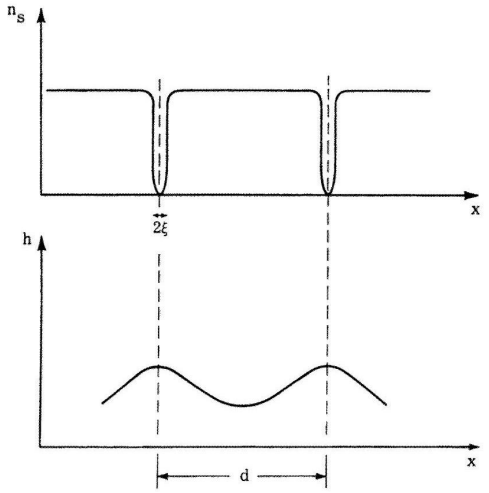

Figure 3-8
The laminar model for the Schubnikov phase. Thin normal sheets N of thickness $\sim 2\xi$ alternate with superconducting sheets S. The N sheets repel each other. The range of the repulsive forces is the penetration depth λ.

$$F_1 = \frac{2}{d}\int_0^{d/2} dx \frac{h^2 + \lambda^2\left(\frac{dh}{dx}\right)^2}{8\pi} = \frac{H_m^2}{8\pi}\frac{\tanh p}{p}$$

It is necessary to add the formation energy of the N regions

$$\mathrm{F_2} \cong \frac{\mathrm{H_c^2}}{8\pi}\frac{2\xi}{\mathrm{d}} = \frac{\mathrm{H_c^2}}{8\pi}\frac{1}{\mathrm{PK}}$$

where $\kappa = \lambda/\xi$. Finally, to obtain the Gibbs function, we must add a term

$$\begin{aligned} -\frac{BH}{4\pi} &= -H\frac{H_m}{4\pi}\frac{\tanh P}{P} \\ G_{\text{laminar}} &= \frac{1}{8\pi}\left[H_m^2\frac{\tanh P}{P} + \frac{H_c^2}{P.K} - 2HH_m\frac{\tanh P}{P}\right] \end{aligned}$$

On minimizing G with respect to H_m we obtain $\mathrm{H} = \mathrm{H}_m$.

$$\mathrm{G_{laminar}} = \frac{1}{8\pi\mathrm{P}}\left[-\mathrm{H^2}\tanh\mathrm{P} + \frac{\mathrm{H_c^2}}{\kappa}\right]$$

For $\mathrm{H} < \mathrm{H_C}/\sqrt{\kappa}$ the minimum G is obtained for infinite P, which corresponds to a complete Meissner effect. For $\mathrm{H} > \mathrm{H_c}/\sqrt{\kappa}$ the minimum occurs for finite P. The initial field for penetration is therefore $H_c/\sqrt{\kappa}$ for the laminar model. This is to be compared with the result for the vortex line model, Eq. (3-56).

$$\mathrm{H_{c1}} = \frac{\pi}{\sqrt{24}}\frac{\mathrm{H_c}}{\kappa}\ln\kappa(\kappa \gg 1)$$

for $\kappa \gg 1, \mathrm{H_{C_1}} < \mathrm{H_C}/\kappa$. For $\mathrm{H_{C1}} < \mathrm{H} < \mathrm{H_c}/\kappa^{1/2}$, we have

$$\begin{aligned} G_{\text{vortex}} &< G_{\text{Meissner}} \\ G_{\text{laminar}} &= G_{\text{Meissner}} \end{aligned}$$

therefore, $G_{\text{vortex}} < G_{\text{laminar}}$; that is, the vortex state is more favorable in the weak induction domain.

It is also possible to make the comparison in the region where H is larger ($\mathrm{H} \sim \mathrm{H_C}$, for example). We are then in the region $\mathrm{P} \ll 1$ for the laminar model By expanding $\tanh \mathrm{P} \cong \mathrm{P} - \mathrm{P}^3/3$ and minimizing G, we obtain

$$\mathrm{G_{laminar}} = -\frac{\mathrm{H^2}}{8\pi} + \left(\frac{3}{2\kappa}\right)^{2/3}\frac{\mathrm{H_c^{4/3}H^{2/3}}}{8\pi}$$

In the vortex line model, the potential is determined from (3-64) and (3-65)

$$\begin{aligned} \mathrm{G_{vortex}} &= -\frac{1}{8\pi}\left(\mathrm{H} - \mathrm{H}'\right)^2 \\ \mathrm{H}' &= \mathrm{H_{c1}}\frac{\ln \mathrm{d}/\xi}{\ln\kappa} = \nu\frac{\mathrm{H_c}}{\kappa} \end{aligned}$$

where ν is a constant of order unity. For $T = 0$

$$\nu = \frac{\pi}{\sqrt{24}} \ln \frac{d}{\xi}$$

In the region of interest $\mathrm{H}' \ll \mathrm{H}$ and

$$\mathrm{G_{vortex}} = -\frac{\mathrm{H}^2}{8\pi} + \nu \frac{H H_\mathrm{c}}{4\pi\kappa}$$

therefore

$$\frac{\mathrm{G_{laminar}} + \frac{\mathrm{H}^2}{8\pi}}{\mathrm{G_{vortex}} + \frac{\mathrm{H}^2}{8\pi}} = \text{ const } \left(\frac{\mathrm{KH}}{\mathrm{c}}\right)^{1/3}$$

when $\mathrm{H} < \kappa \mathrm{H_c}$ (which roughly corresponds to the upper critical field $\mathrm{H_{c2}}$), $\mathrm{G_{laminar}} > \mathrm{G_{vortex}}$. Thus the vortex state is still most stable in the intermediate and high field regions. [4]

Problem.

Discuss the equilibrium magnetization curves for a second kind superconductor in the form of an ellipsoid of revolution, the field being applied along the ellipsoidal axis.

Solution.

The equations $\operatorname{div} B = 0$, curl $H = 0$, and $B = (H/|H|)B_e(H)$, where $B_e(H)$ is the equilibrium induction in the presence of a field H measured for a long cylinder, allow a solution where B and H are constant in the ellipsoid with $\mathrm{H} = \mathrm{H_0} - \mathrm{NM} = \mathrm{H_0} - \mathrm{N(B - H)}/4\pi$ where N is the demagnetizing coefficient of the ellipsoid. The relation between B and the applied field is therefore given by the implicit formula

$$B = B_e \left(\frac{H_0 - \frac{NB}{4\pi}}{1 - \frac{N}{4\pi}} \right)$$

B is nonzero for $\mathrm{H_0} > \mathrm{H_{Cl}}(1 - \mathrm{N}/4\pi)$. The slope $(\mathrm{dB}/\mathrm{dH_0})_{B=0}$ is finite and equal to $4\pi/\mathrm{N}$. The upper critical field remains equal to $\mathrm{H_{C2}}$ since $\mathrm{B}\,(\mathrm{H_{C2}}) = \mathrm{H_{C2}}$ when the transition is second order.

Problem.

Discuss the scattering of slow neutrons by a regular lattice of vortex lines in a superconductor.

Solution.

The interaction between neutron and lines is $\mu_\mathrm{n} \mathrm{h}(\mathbf{r})$ where $\mu_\mathrm{n} = 1.91\mathrm{e}/2\mathrm{Mc}$ is the neutron moment and M the neutron mass. Consider a scattering event where the neutron momentum changes from $\hbar k_0$ to $\hbar\,(k_0 + q)$. The corresponding scattering amplitude is given by the Born approximation formula

$$a = \frac{M}{2\pi\hbar^2} \int \mu_n h(r) e^{iq \cdot r} dr$$

This is nonzero only if $q = J$, where J is a reciprocal lattice vector associated with the two-dimensional "line lattice." From (3-62) we find

These elementary calculations of G are not sufficient in the neighborhood of $\mathrm{H_{c2}}$. We return later to a study of the region using the Landau-Ginsburg equations.

$$\int h(r)e^{iJ\cdot r}dr = \frac{BV}{1+\lambda^2 J^2} = \frac{n_L \phi_0 V}{1+\lambda^2 J^2}$$

where V is the sample volume and n_L the number of lines per cm^2. Thus

$$\mathrm{a_J} = \frac{1}{2} 1.91 \frac{\mathrm{n_L V}}{1+\lambda^2\ \mathrm{J}^2}$$

For a triangular lattice of lines with nearest neighbor distance d, we have $\mathrm{n_L} = (2/\sqrt{3})\,(1/\mathrm{d}^2)$ and, for the first reflection, $\mathrm{J} = (4\pi/\sqrt{3})\mathrm{d}^{-1}$. Taking $\mathrm{B} = 2000\mathrm{G}\,(\mathrm{n_L} = 10^{10})$, we get $\mathrm{d} \sim 10^3 \mathring{\mathrm{A}}$ and $\mathrm{J} \sim 6.710^5\ \mathrm{cm}^{-1}$. For $\lambda = 1000\mathring{\mathrm{A}}$ this gives $(\lambda J)^2 \cong 45 \gg 1$. We compute the amplitude a per atom (since this is the quantity familiar to experimentalists). Inserting for V an atomic volume of $30\mathring{\mathrm{A}}^3$ we get $\mathrm{a} \cong 0.710^{-13}$ cm. The corresponding "coherent scattering cross section" is $4\pi \mathrm{a}^2 \sim 5 \times 10^{-28}\ \mathrm{cm}^2 = 0.5$ millibarns - a small, but measurable value.

The scattering angle θ for this first reflection is very small $\theta \cong (\mathrm{J/k_0}) = (2/\sqrt{3})\,(\lambda_n/d)$ where we have introduced the neutron wavelength $\lambda_n = 2\pi/k_0$. At best, with subthermal neutrons we can make λ_n as large as $\sim 5\mathring{\mathrm{A}}$. For the above example this leads to angles $\theta \sim 6.10^{-3}$rad (or $20'$ of arc). The experiment has been performed on Nb metal (Cribier, Jacrot, et al., 1964). Due to the $1/\left(1+\lambda^2 J^2\right)$ dependence of a, it has been possible only to observe the first reflection (with the smallest J). (See Fig 3-9.)

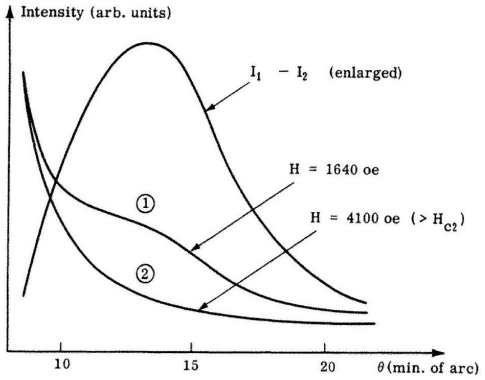

Figure 3-9
Neutron scattering by an array of vortex lines in niobium metal at T = 4.2°K. (Courtesy of D. Cribier.)

Problem.

Calculate the broadening of a nuclear magnetic resonance line arising from the field inhomogeneities associated with the vortex state (P. Pincus, 1964).

Solution.

In intermediate fields $\mathrm{H_{c_1}} \ll \mathrm{H} \ll \mathrm{H_{C2}}$ where the vortices form a dense lattice, the field distribution is given by the Fourier transform of Eq. (3-62). A knowledge of all the moments of the field distribution would completely determine the nuclear magnetic resonance line shape (if this were the only source of broadening). However if the line does not have anomalous wings, as is often the case (Jaccarino and Gossard, 1964), the second moment is a good measure of the line width (see A. Abragam, Principles of Nuclear Magnetism, Clarendon Press, 1961). Thus the line width is given by

$$\Delta H = \left[\left\langle h^2 \right\rangle - \langle h \rangle^2\right\}^{1/2}$$

where \langle\rangle denotes a spatial average. The term $\langle \mathrm{h} \rangle$ is just $\mathrm{n_L}\phi_0 = \mathrm{B}$. $\langle \mathrm{h}^2 \rangle$ can easily be calculated from Eq. (3-62):

$$\left\langle h^2 \right\rangle = S^{-1} \int h^2(r) d\sigma = \sum_J h_J h_{-J} = n_L^2 \phi_0^2 \sum_J \left[1 + (\lambda J)^2\right]^{-2}$$

where S is the surface area of the sample perpendicular to the field. On replacing the sum over reciprocal lattice vectors by an integral in a similar manner as is done in the text after Eq. (3-63), we obtain

$$\Delta H = \frac{B}{\sqrt{4\pi}} \frac{d}{\lambda} \left[1 + \left(\frac{2\pi\lambda}{d}\right)^2\right]^{-1/2}$$

where for simplicity we have assumed a square lattice. This result is valid in the domain $\mathrm{d} \gg \xi$. In the intermediate field region $\mathrm{d} \ll \lambda$, this leads to

$$\Delta H \cong \frac{1}{\sqrt{2}} \times \frac{\phi_0}{(2\pi)^{3/2}\lambda^2}$$

Notice that this width is of the order of $\mathrm{H_{C_1}}$ (for $\mathrm{V_3Ga}, \lambda \sim 2000\mathring{\mathrm{A}}, \Delta\mathrm{H} \approx 20\mathrm{Oe}$) and remains nearly field independent on to fields of the order of $\mathrm{H_{c_2}}$ where the inhomogeneous broadening vanishes. For fields near $\mathrm{H_{C_1}}(\mathrm{d} \approx \lambda)$, the broadening is more severe. More detailed calculations of the line shape using Eq. (3-62) have been performed by Matricon.

Problem.

Compute the energy of a vortex line near the surface of the specimen, the line being parallel to the surface.

Solution.

Let the line, and the fields, be parallel to the z axis, the limiting surface being the $y0z$ plane, the sample occupying the half-space $x > 0$. The field $h(r)$ is governed by the equation

$$\mathrm{h} + \lambda^2 \text{ curl curl } \mathrm{h} = \phi_0 \delta_2 (\mathbf{r} - \mathbf{r}_\mathrm{L})$$

where r_L represents the two-dimensional coordinate of the line lwe shall take $r_L = (x_L, 0)$] and ϕ_0 is a vector, of length ϕ_0, along z. The boundary conditions on the surface are

$$\mathrm{h} = \mathrm{H} \quad (\text{ curl h})_\mathrm{X} = 0 \quad (0 \text{ normal current})$$

where H is the applied field. The solution $h(r)$ will be written as

$$\mathbf{h} = \mathbf{h}_1 + \mathbf{h}_2$$

where $h_1 = H \exp(-x/\lambda_L)$ represents the field penetration in the absence of any line, while h_2 is due to the line, and can be obtained by a method of images. To the line $(x_L, 0)$ we add an image of opposite sign located at $(-x_L, 0)$ and take for h_2 the algebraic sum of the field due to the line and image. Thus h_2 automatically vanishes on the limiting surface $\mathrm{x} = 0$ and the boundary condition is satisfied.

Having constructed $h(r)$, we now compute the thermodynamic potential

$$S = \int dr \left\{ \frac{h^2 + \lambda^2 (\text{curl h})^2}{8\pi} - \frac{H \cdot h}{4\pi} \right\}$$

The integral is taken in the sample volume ($x > 0$) except for the core region of the line, which is excluded. The last term is the microscopic analog of the standard $\mathbf{B} \cdot \mathbf{H}/4\pi$ term for macroscopic systems. We transform S into a surface integral, using the London equation for h, and we obtain

$$S = \frac{\lambda^2}{4\pi} \int_{\text{(core and plane)}} \mathrm{d}\boldsymbol{\sigma} \cdot \left(\frac{1}{2}\,\mathrm{h} - \mathrm{H}\right) \times \operatorname{curl} h$$

The surface integral $\int \mathrm{d}\sigma$ includes the surface of the hard core (giving a contribution S′) and the surface of the specimen (giving a contribution S″). As usual the only important term in $\int_{\text{core}} d\sigma$ (in the limit $\xi \to 0$) comes from the singular term in curl h, and the result is

$$S' = \frac{\phi_0}{4\pi}\left(\frac{1}{2}h\left(r_L\right) - H\right)$$

The second term ς'' may be written as

$$\varrho'' = -\frac{\lambda^2}{8\pi} \int_{\text{plane}} d\sigma \cdot h_1 \times \ \text{curl}\ h$$

since on the sample surface $h = h_1 = H$. Writing curl $h = \operatorname{curl} h_1 + \operatorname{curl} h_2$ we can separate in G'' a term involving $h_1 \times \operatorname{curl} h_1$, which is the energy in the absence of the line, an additive constant we drop from now on. We are left with

$$\mathrm{S}'' = -\frac{\lambda^2}{8\pi} \int_{\text{plane}} \mathrm{d}\sigma \cdot h_1 \times \text{curl}\ \ h_2$$

We rewrite this integral as

$$\int_{\text{plane}} = \int_{\text{core + plane}} - \int_{\text{core}}$$

By making use of London's equation for $\mathbf{h}$, in the region outside the core, we have

$$\int_{\text{core + plane}} \mathrm{d}\sigma \cdot h_1 \times \operatorname{curl} h_2 = \int_{\text{core + plane}} d\sigma \cdot h_2 \times \operatorname{curl} h_1$$

h_1 is not singular near the line axis; thus the core contribution to the righthand side vanishes when $\xi \to 0$. The integral on the plane also vanishes since $(\mathbf{h}_2)_{\mathrm{X}=0} = 0$. Finally

$$S'' = \frac{\lambda^2}{8\pi} \int_{\text{core}} d\sigma \cdot h_1 \times \operatorname{curl} h_2 = \frac{\phi_0 h_1\left(r_L\right)}{8\pi}$$

$$S = \frac{\phi_0}{4\pi}\left[H \exp\left(-x_L/\lambda\right) + \frac{1}{2}h_2\left(r_L\right) - H\right]$$

[Note incidentally that $S = 0$ when $x_L = 0$, that is, when the line is just on the surface, since $h_2(x = 0) = 0$.] If we analyze $h_2\left(r_L\right)$ into a direct term and an image term, the direct term gives as a contribution to g the line self-energy $J = \phi_0 \mathrm{H}_{\mathrm{C}_1}/4\pi$. The image term describes an attraction between line and image, of value $-\left(\phi_0/8\pi\right) h\left(2x_L\right)$ where $h(r)$ is the function giving the field at distance r of a single line (Eq. 3-35). Finally

$$S = \frac{\phi_0}{4\pi}\left[H \exp\left(-x_L/\lambda\right) - \frac{1}{2}h\left(2x_L\right) + H_{C1} - H\right]$$

Discussion

(1) The term $(\phi_0 \mathrm{H}/4\pi)\exp(-\mathrm{x_L}/\lambda)$ describes the interaction of the line with the external field and the associated screening currents. It has the same form as Eq. (3-50). It is a repulsive term.

(2) The term $-\phi_0\ \mathrm{h}\,(2\mathrm{x_L})\,/8\pi$ represents the attraction between the line and its image. The magnitude of this energy differs from Eq. (3-50) by a factor $\frac{1}{2}$. But the force derived from it has the conventional magnitude ϕ_0j/c [when differentiating $h\,(2x_L)$ with respect to x_L, we get a factor 2).

(3) The aspect of $S\,(x_1)$ for various values of the applied field H is shown on Fig. 3-10. When $\mathrm{H} \sim \mathrm{H_{C_1}}$ there is a strong barrier opposing the entry of a line. We can understand this barrier as follows: When $H = H_{c_1}, S\,(x_L = 0) = S\,(x_L = \infty) = 0$. if we start from x_L large and bring the line closer to the surface,

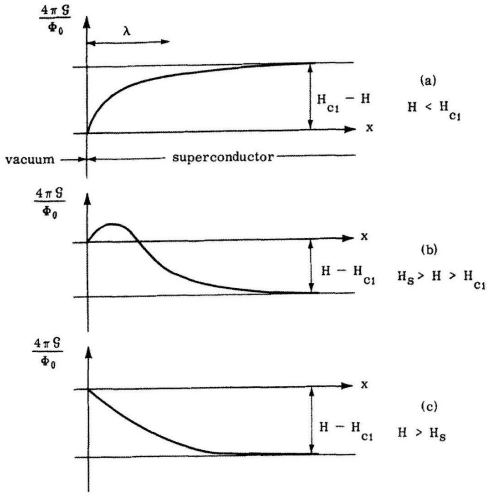

Figure 3-10

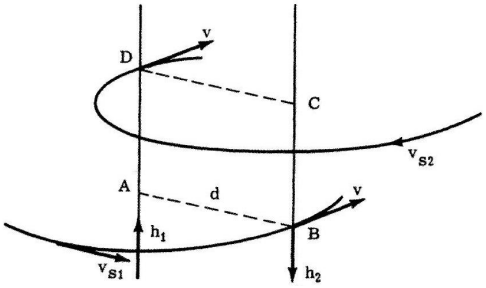
Surface barrier impeding the entry of the first flux line is a Type II superconductor. (a) When $\mathrm{H} < \mathrm{H_{C1}}$, the force on the line always points towards the surface: no lines can exist (in an ideal specimen). (b) When $\mathrm{H_S} > \mathrm{H} > \mathrm{H_{Cl}}$ the line gains an energy $(\phi_0/4\pi)\,(\mathrm{H} - \mathrm{H_{ci}})$ as it reaches the deep inside of the sample. But there is a barrier near the surface, and the line will not enter if the surface is clean. (c) When $\mathrm{H} > \mathrm{H}_S$, the barrier disappears.

the repulsive term $(\sim \exp(-x_L/\lambda)$ dominates the image term $(\sim \exp(-2x_L/\lambda)$. Thus S becomes positive and we have a barrier. The barrier disappears, however, in high fields as is clear in Fig. $3-10$ (c). When $\mathrm{H} > \mathrm{H_S} = \phi_0/4\pi\lambda\xi$, it can be seen from the equation for S that the slope $(\partial S/\partial x_L)\,x_L = \xi$ becomes negative. [5]

[5] We shall see later from the microscopic analysis that the field $\mathrm{H_S}$ thus defined is of the order of the thermodynamic critical field $\mathrm{H_c}$.

The conclusion is that, at field $\mathrm{H} < \mathrm{H}_S$, the lines cannot enter in an ideal specimen (although their entry is thermodynamically allowed as soon as $\mathrm{H} > \mathrm{H_{c1}}$). These surface barrier effects have been predicted independently by Bean and Livingston and by the Orsay group. They have been observed experimentally on lead thallium alloys (Tomash and Joseph) and on niobium metal (de Blois and de Sorbo). (The sample surface must have very few irregularities on the scale of λ.)



Vortex Line Motions

Consider the two antiparallel vortices of Fig. 3-11. According to Eq. $(3-50)$ they attract each other. Will they move under the action of this force, or will they stand still? This question is very much debated at the present time. My personal belief is that in a pure metal each line will drift in the other's velocity field. They will thus both move at right angle from their

common plane, with a velocity

$$v_{\text{drift}} = v_{12}$$

where v_{12} is the superfluid velocity at point 2 due to the presence of line 1.

(1) (2)
Figure 3-11

Two antiparallel vortex lines in a pure superconductor of Type II. $\mathbf{v_{S1}}$ ($\mathbf{v_{S2}}$) is the superfluid velocity induced by line 1 (2). Each line drifts with the local superfluid velocity v. For that particular geometry both lines go with the same velocity. Note that **v** is normal to the plane $ABCD$ of the lines.

Such drift motions should lead to amusing collective modes for an assembly of vortex lines in a very pure metal of Type II. (P. G. de Gennes, J. Matricon, 1962.)

In dirty superconductors, on the other hand, friction between the lines and the lattice will dominate the motion. The two antiparallel vortex lines AD and CB will then move toward one another, as shown on Fig. $3-12$, with a velocity

$$\mathrm{v_{drift}}\ (2) = -\mathrm{v_{drift}}\ \left(1; = \frac{\mathrm{f}}{\eta}\right.$$

where f is the attractive force between the lines, as given by Eq. (3-52) and η is a viscosity coefficient. We can estimate η with the following assumptions: suppose that the currents due to line 1 are not distorted near the core of line 2. This core then carries a current density $j = \mathrm{nev}_{12}$. But this core is essentially normal. Thus we expect a loss (per unit length of line 2)

$$w = \frac{j^2}{\sigma\pi\xi^2}$$

where $\sigma = \mathrm{ne}^2\tau/m$ is the normal state conductivity and ξ the core radius. This power dissipation must also be equal to $\mathrm{fv_{drift}}\ (2) = 1/\eta\mathrm{f}^2$. Recalling from Eq. $(3-52)$ that $f = \frac{1}{2}nhv_{12}$. we obtain

$$\eta = \frac{\mathrm{n}\tau\mathrm{h}^2}{4\pi m\xi^2}$$

Viscous motions which are reasonably well described by this type of damping have been observed in dirty materials by Kim and coworkers.

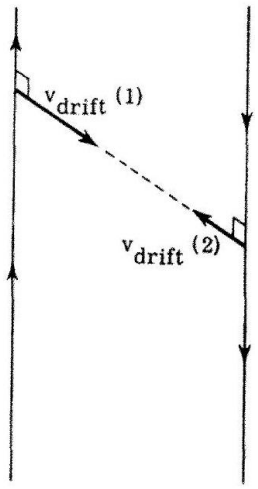


Figure 3-12
Two antiparallel vortex lines in a dirty superconductor of Type II: the lines move toward each other with a drift velocity controlled by friction with the lattice.

7.3 Thin films

7.3.1 3.5 Critical Field of a Thin Film

A thin superconducting film, of thickness less than the penetration depth, can remain superconducting in a parallel magnetic field even if the value of the field is well in excess of H_{cm}. We shall denote the magnetic field destroying the film's superconductivity by H_{c} .

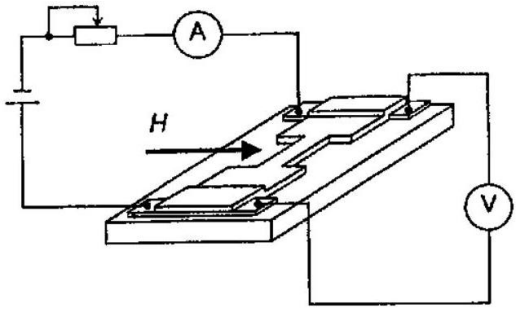

Fig. 3.6. Scheme of the critical magnetic field measurements on a thin film
Consider an experiment shown schematically in Fig. 3.6. A thin film of the material under study is deposited onto a clean glass substrate and connected to a measuring circuit by current and voltage leads. Then the specimen is mounted in a cryostat in such a way that an external magnetic field is parallel to its surface. The external field is increased and at a certain value of the

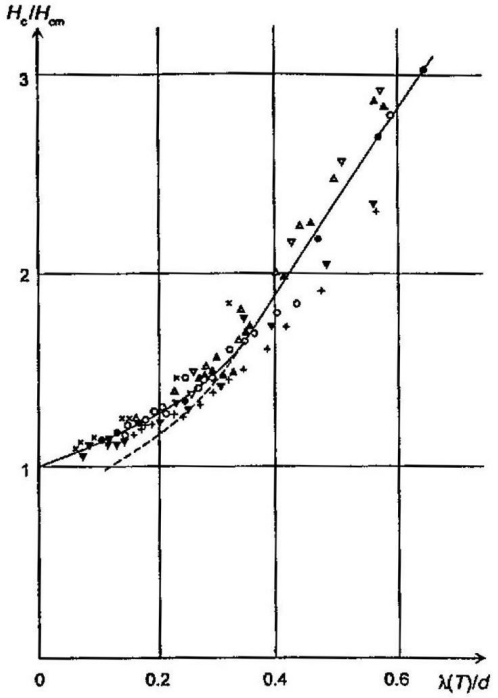

Fig. 3.7. Results of the critical magnetic field measurements on Sn films of various thicknesses [29]; d is the film thickness. The solid curve shows the result of the GinzburgLandau theory

field the film begins to show a finite resistance. This is the critical field of the film. A compilation of the results of such an experiment is shown in Fig. 3.7.

We remember from Sect. 1.3 that a bulk superconductor in an external field $H_{\rm cm}$ undergoes a first-order phase transition. Indeed, one notices in Fig. 3.7 that thick films show supercooling. This means that, when the film is in the normal state and the field decreases, the transition to the superconducting state may not occur at the appropriate value of the field, that is, at the field for which the free energies of the normal and superconducting states are equal. The transition may be delayed down to a lower field called the supercooling field. In Fig. 3.7 the supercooling fields are shown by the dashed curve. Thus we observe that, as the film thickness decreases, the effect of supercooling becomes weaker and weaker and finally, starting from a certain thickness, disappears completely. This leads to a natural conclusion: that the superconducting transition for films of this thickness or thinner is of second order.

Assume now that the thickness of our film is $d \ll \xi, \lambda$. Then we may neglect variations of ψ in the film and assume that the magnetic field penetrates the film completely. THe surfaces of the film are assumed to coincide with the planes $x = \pm d/2$. Since the film is a simply connected body, we can choose a gauge for the vector potential $\boldsymbol{A}$ such that the wavefunction ψ is real. Then the first GL equation can be written in the form

$$-\left[1-\left(\frac{2\pi\xi A}{\Phi_0}\right)^2\right]\psi+\psi^3=0 \tag{3.58}$$

$$\frac{\mathrm{d}^2A}{\mathrm{d}x^2}=\frac{\psi^2}{\lambda^2}A \tag{3.59}$$

Here the vector potential $\boldsymbol{A}$ is along the y axis and the magnetic field is subject to the boundary condition

$$H(\pm d/2)=H_0 \tag{3.60}$$

where H_0 is the external field parallel to the surface of the film. The solution of (3.59) is

$$A = A_1 \cosh(\psi x/\lambda) + A_2 \sinh(\psi x/\lambda)$$

where A_1 and A_2 are integration constants. The magnetic field H can be found simply by differentiating A:

$$H = A_1(\psi/\lambda)\sinh(\psi x/\lambda) + A_2(\psi/\lambda)\cosh(\psi x/\lambda).$$

The boundary conditions (3.60) are satisfied if

$$A_1 = 0, \quad A_2 = \frac{H_0\lambda}{\psi\cosh(\psi d/2\bar{\lambda})}$$

Then

$$H = H_0\frac{\cosh(\psi x/\lambda)}{\cosh(\psi d/2\lambda)}, \quad A = \frac{H_0\lambda}{\psi}\frac{\sinh(\psi x/\lambda)}{\cosh(\psi d/2\lambda)} \tag{3.61}$$

Let us now apply the results to a thin film ($d \ll \lambda$). In this case, $\psi x/\lambda \ll 1$ and $\psi d/2\lambda \ll 1$ and we can expand the hyperbolic functions in a Taylor's series. Keeping only linear terms, we have

$$\cosh(\psi d/2\lambda) = 1, \quad \sinh(\psi x/\lambda) = \psi x/\lambda$$

On substituting this into (3.61), we obtain: $A = H_0 x$ and then, from (3.58),

$$\psi^2 = 1 - \left(\frac{2\pi\xi}{\Phi_0}\right)^2 H_0^2 x^2$$

To find the average of the last expression over the thickness of the film, we integrate with respect to x from $-d/2$ to $+d/2$:

$$\psi^2 d = d - {H_0}^2\frac{1}{12}d^3\left(\frac{2\pi\xi}{\Phi_0}\right)^2$$

Taking into account (3.38), we finally obtain the dependence of the order parameter in the film on the applied magnetic field:

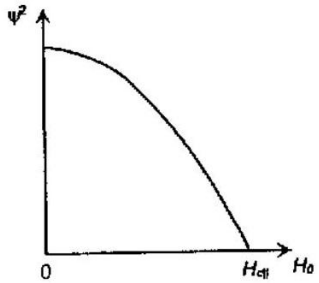

Fig. 3.8. Order parameter as a function of the parallel external magnetic field H_0 for a thin film ($d \ll \lambda$)

$$\psi^2 = 1 - \frac{1}{24}\frac{H_0^2 d^2}{H_{\rm cm}^2\lambda^2}$$

This dependence is sketched in Fig. 3.8. Thus, the order parameter ψ in a thin film is strongly dependent on the applied field H_0 and gradually goes to zero at the value of the field of $2\sqrt{6}H_{\rm cm}\lambda/d$. It is natural to select this field as the critical field of the film, $H_{\rm c\|}$.

Finally, the critical field of a thin film of thickness d in a parallel external field H_0 is

$$H_{c\parallel} = 2\sqrt{6} H_{cn1} \frac{\lambda}{d} \tag{3.62}$$

Thus, as the thickness of the film decreases, its critical field goes up. For example, if the thickness of a film is an order of magnitude less than the penetration depth, $\lambda/d \sim 10$, and $H_{cm} \sim 10^3$ Oe, we obtain, by (3.62), $H_{c\parallel} \sim 40000$ Oe. Physically, this is easy to understand. Since the magnetic field penetrates into the film, the film's diamagnetic moment per unit volume is substantially reduced compared to a bulk specimen. But a small diamagnetic moment in an external field is equivalent to a small magnetic needle oriented against the field. Such a situation is energetically more favorable than in the case of a large diamagnetic moment. Therefore, a film in an external field is much more stable than a bulk specimen and can remain superconducting up to much higher fields.

7.3.2 3.6 Critical Current of a Thin Film

Theory

Let us now consider a film carrying a current I, in the absence of external magnetic field. We assume, as before, that the surfaces of the film coincide with the planes $x = \pm d/2$ and that the current flows in the y direction. The current I is the total current through the film per unit length of the z axis.

The current generates a magnetic field H_I at the surfaces of the film. This imposes the boundary conditions

$$H(\pm d/2) = \mp H_I \tag{3.63}$$

As in the preceding section, we note that the film is a simply connected body and use this to choose a gauge for $\boldsymbol{A}$ so that ψ is real. In addition, we assume that the film is thin: $d \ll \lambda, \xi$. Then we may neglect variations of the order parameter over the thickness of the film and, as a result, we arrive at the GL equations of the form (3.58) and (3.59). We shall analyze these equations again but this time subject to the boundary conditions (3.63). The general solution of (3.59) is

$$A = A_1 \cosh(\psi x/\lambda) + A_2 \sinh(\psi x/\lambda).$$

Since for our problem $H = \mathrm{d}A/\mathrm{d}x$, we have

$$H = (A_1\psi/\lambda) \sinh(\psi x/\lambda) + (A_2\psi/\lambda) \cosh(\psi x/\lambda)$$

On substitution of the boundary conditions (3.63) into this expression we obtain two equations with two unknowns (A_1 and A_2). Their solution is

$$A_1 = \frac{\lambda H_I}{\psi \sinh(\psi d/2\lambda)}, \quad A_2 = 0$$

The final result is

$$H = H_I \frac{\sinh(\psi x/\lambda)}{\sinh(\psi d/2\lambda)}, \quad A = \frac{\lambda H_I \cosh(\psi x/\lambda)}{\psi \sinh(\psi d/2\lambda)} \tag{3.64}$$

Now we take into account that the thickness of the film is small, i.e., $\psi d \ll \lambda$. This implies that in the expression for A in (3.64) we can assume $\cosh(\psi x/\lambda) \approx 1$ and $\sinh(\psi d/2\lambda) \approx \psi d/2\lambda$. Then

$$A = 2\lambda^2 H_J/\psi^2 d$$

Substituting this into (3.58) and using (3.38), we obtain

$$\frac{2\lambda^2 H_I^2}{d^2 H_{\rm cm}^2} = \psi^4 - \psi^6. \tag{3.65}$$

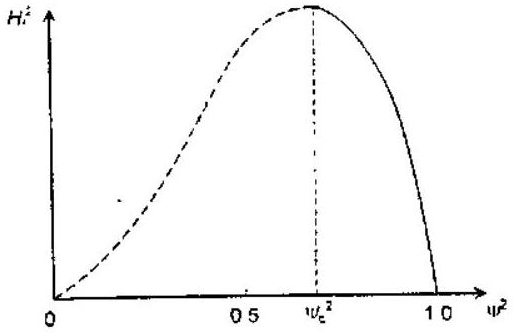

Fig. 3.9. Order parameter in a thin superconducting film as a function of the applied current. The heavy part of the curve corresponds to stable superconductivity

The dependence of $H_I{}^2$ on ψ^2 is plotted in Fig. 3.9. The heavy line emphasizes the part of the plot corresponding to stable states. When the film does not carry any current, equation (3.65) has two solutions: $\psi = 0$ and $\psi = 1$. From general arguments, it is clear that in this case the superconducting state ($\psi = 1$) is more favorable energetically and, therefore, it is this that will he roaligurl rather than the momal etato If wen now owiteh on o
very small current across the film, equation (3.65) will again have two solutions: one corresponding to $\psi \leq 1$, and the other corresponding to $\psi \ll 1$. It then follows from the requirement of continuity that it is the former that corresponds to the stable superconducting state.

But what is the maximum current that the film can sustain while remaining in the superconducting state?

The answer follows directly from the plot of Fig. 3.9: it is the current corresponding to the maximum in the plot. Let us work out its value. First, we find $\psi_{\rm c}$ corresponding to the maximum of $H_I{}^2$:

$$\frac{\rm d}{{\rm d}\psi}\left(2\lambda^2 H_I^2/d^2 H_{\rm cm}^2\right) = 4\psi_{\rm c}^3 - 6\psi_{\rm c}^5 = 0$$

which leads to $\psi_{\rm c}{}^2 = 2/3$.
Then

$$H_{I_{\rm c}} = \frac{\sqrt{2}}{3\sqrt{3}} H_{\rm cm} \frac{d}{\lambda}. \tag{3.66}$$

From (3.66) and the formula $H_{I_{\rm c}} = (4\pi/c) I_{\rm c}$, one can easily find the average critical current density $j_{\rm c}$ across the film:

$$j_{\rm c} = \frac{\sqrt{2}}{12\pi\sqrt{3}} \frac{c H_{\rm cm}}{\lambda}. \tag{3.67}$$

Let us summarize the major results of this section.
(1) The field generated by the critical current at the surface of a film is proportional to the thickness of the film: $H_{I_{\rm c}} \propto d$, namely, it becomes smaller when the thickness of the film decreases. At the same time, the critical field of the film varies as $H_{c\|} \propto 1/d$, that is, it increases when the film becomes thinner. For example, if $d/\lambda \sim 0.1$ and $H_{\rm cm} = 1000$Oe, then $H_{c\|} \sim 4 \times 10^4$ Oe and $H_{I_{\rm e}} \sim 30$Oe. Hence, for a thin film, the destruction of superconductivity by a current is not identical to its destruction by the magnetic field of this current.

(2) The critical current density j_c from (3.67) is independent of the thickness of the film. It follows that j_c is simply a characteristic of the currentcarrying capacity of a particular material. (3) Finally, let us emphasize one more important point. The destruction of superconductivity by a current is not accompanied by a phase transition. This is only true, of course, provided that the film is in good thermal contact with liquid helium such that all the heat given up by the film is immediately thermalized. Then the temperature of the film remains, at any moment, equal to the temperature of the helium bath. In this case, even if the current reaches the value of I_c, the free energy of the superconducting state remains below the free energy of the normal state.

What happens then when the current is $I = I_c$?

Why cannot a supercritical current pass through the film without dissipation? To answer these questions, we shall use the analysis proposed by Bardeen. Since the film is thin, we can neglect the energy of the magnetic field generated by the current and write the free energy density in the form

$$F_s = F_n - |\alpha| n_s + \frac{\beta}{2} n_s^2 + n_s \frac{m}{2} v_s^2$$

Here n_s is the superconducting electron density; α and β are the coefficients of the GL theory, which are already known to us. The last term describes the kinetic energy of the superconducting electrons and v_s is the velocity of their correlated motion, or 'superfluid' velocity.

The equilibrium value of $n_s(v_s)$ as a function of v_s can be found from the requirement that the free energy at equilibrium is a minimum:

$$\frac{\partial F_s}{\partial n_s} = -|\alpha| + \beta n_s + \frac{m v_s^2}{2} = 0$$

This yields

$$n_s = \frac{\left(|\alpha| - \frac{m v_s^2}{2}\right)}{\beta} \tag{3.68}$$

The current density j_s in this case is determined by the well-known expression

$$j_s = n_s e v_s \tag{3.69}$$

The dependences $n_s(v_s)$ and $j_s(v_s)$, corresponding to (3.68) and (3.69), respectively, are sketched in Fig. 3.10. Again, the part of the curve $j_s(v_s)$ corresponding to stable states is shown in bold. What does this plot tell us? As the superconducting current density increases, the electron velocity also increases. But this is accompanied by a decrease of the electron density $n_s(v_8)$. The electron pairs are being broken. Finally, a state is attained such that it is not possible to increase the superconducting current any further, because the superconducting electron density becomes so low. There are simply not enough carriers to maintain a higher current. This is the critical current given by (3.67). It is often called the pair-breaking current.

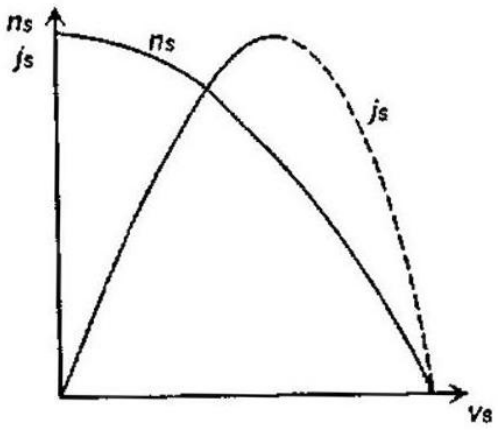

Fig. 3.10. Superconducting electron density n_s and supercurrent density j_s in a thin film as functions of the velocity of the superconducting component of the electron density

Problems

Problem 3.1. Consider a Pb cylinder at 4.2 K in a uniform magnetic field parallel to its axis. The field at the surface of the cylinder is $H_0 = 300$ Oe. Find the density w of the magnetic energy in the specimen at the distance $x = 300$Å from the surface. (The diameter of the cylinder is much larger than the magnetic field penetration depth.)

Problem 3.2. The critical temperature of Pb is 7.18 K . Find the ratio of the value of the penetration depth λ at $T = 7.10$ K to its value at $T = 4.2$ K. Estimate the density of the superconducting electrons at $T = 7.10$ K.

Problem 3.3. Consider a specimen of superconducting Sn. At $T = 0.9T_\mathrm{c}, \lambda = 8.7 \times 10^{-6}$ cm and $\xi = 4.35 \times 10^{-5}$ cm. Find the surface energy of the interface between a normal and a superconducting region, σ_ne.

Problem 3.4. Consider a Sn film of thickness $d = 1000$Å deposited onto a glass substrate. The film is placed in an external magnetic field $H_0 = 10$ Oe parallel to its surface. The temperature is $T = 0.9T_\mathrm{c}$. Find the field at the center of the film and the diamagnetic moment M_0 per unit area of the film's surface.

Problem 3.5. Consider a thick Sn film in a parallel magnetic field. The thickness of the film is 10^{-4} cm and the temperature is $T = 0.9T_c$. Find the critical field of the film, H_cll , on the assumption that the order parameter ψ is independent of the field and equals 1 (the first-order phase transition).

Problem 3.6. Consider a Pb film of thickness $d = 200$Å deposited onto a glass substrate. At $T = 0$, the magnetic field penetration depth is $\lambda(0) = 390$Å, and the thermodynamic critical field is $H_\mathrm{cm}(0) = 803$ Oe. Find the magnetic field generated by the critical current at the surface of the film. Compare it with the parallel critical field of the same film.

Problem 3.7. Find the critical current density for the film of the previous problem.

Problem 3.8. Consider a thin film ($d \ll \lambda$) of In in the superconducting state. The GL parameter of the film is $\kappa = 0.1$. The magnetic field penetration depth is $\lambda = 800$Å. Find the critical velocity of the superconducting electrons.

Problem 3.9. Consider a bulk type-I superconductor in an external magnetic field equal to the thermodynamic critical field H_cm. Compare the density of the Meissner current j_M at the surface of the superconductor with the critical current density j_c of a thin film made of the same material.

7.4 2. Some Effects in Scope of Linear Electrodynamics of Superconductors

7.4.1 2.5 Magnetic Field and Current Distributions in Simple Configurations

2.5.1 Thin Slab in a Parallel Magnetic Field

In this section we shall analyze magnetic field and current distributions in simple configurations of superconductors. We start with the case of an infinite slab of thickness d placed in a uniform magnetic field H_0 parallel to its surface. Assume that the plane $x = 0$ is in the center of the slab and that its surfaces coincide with the planes $x = \pm d/2$. The magnetic field is along the z axis.

In the interior of the slab, the magnetic field H must satisfy (2.13). Then, from symmetry arguments, H is along the z axis and depends only on the x coordinate. Therefore (2.13) can be rewritten as:

$$\mathrm{d}^2H/\mathrm{d}x^2 - \lambda^{-2}H = 0 \tag{2.38}$$

with the boundary conditions $H(\pm d/2) = H_0$. The general solution of (2.38) is

$$H = H_1 \cosh(x/\lambda) + H_2 \sinh(x/\lambda) \tag{2.39}$$

where H_1 and H_2 are integration constants. Substituting the boundary conditions into (2.39), we get two algebraic equations with two unknowns that can be solved easily. The final result is

$$H(x) = H_0 \frac{\cosh(x/\lambda)}{\cosh(d/2\lambda)} \tag{2.40}$$

The supercurrent density in the slab can be found by combining (2.40) and Maxwell's equation curl $\boldsymbol{H} = (4\pi/c)\boldsymbol{j}_\mathrm{s}$:

$$j_\mathrm{s} = -\frac{c}{4\pi}\frac{\mathrm{d}H}{\mathrm{d}x} \tag{2.41}$$

As a result, we get

$$cH_0 \quad \sinh(x/\lambda)$$

If the slab is thick ($d \gg \lambda$), it follows from (2.40) and (2.42) that both the magnetic field and the current penetrate into it only to a certain depth of the order λ. In the other limiting case, a thin film ($d \ll \lambda$), we get, in linear approximation and after expanding the hyperbolic functions in terms of the small parameters x/λ and $d/2\lambda$:

$$H = H_0, \quad j_\mathrm{s} = \frac{cH_0 x}{4\pi\lambda^2}$$

This means that the magnetic field penetrates the entire film, while the supercurrent density varies linearly with depth.

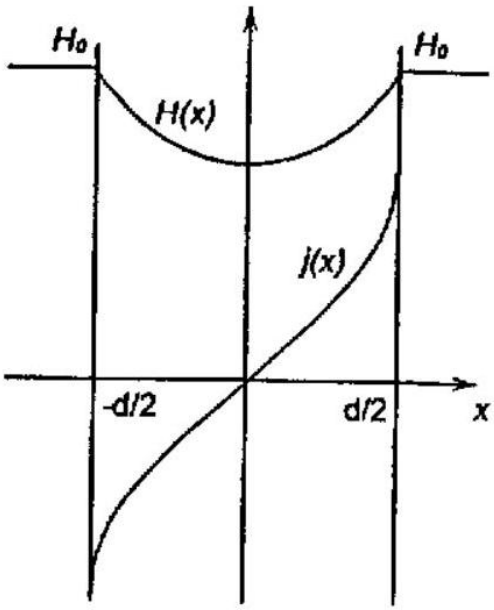

Fig. 2.3. Distribution of current and magnetic field across a thin film placed in a parallel uniform magnetic field

The current and field distributions obtained above are shown in Fig. 2.3. The current circulates at the edges of the slab so that the induced magnetic field cancels out the external field H_0 in its interior.

2,5.2 Thin Slab Carrying a Current

In this section we consider an infinite thin slab carrying a current in the absence of magnetic field. We assume that the slab is the same as in Sect. 2.5.1 and the current flows in the direction of the y axis. Further we assume that the current is uniform along the z axis, that is, edge effects are disregarded. Consider a part of the slab in the form of a strip of unit width parallel to the z axis. The current I flows along the z axis and generates a magnetic field $\pm H_I$ at the surfaces of the slab ($x = \pm d/2$). Substituting these boundary conditions into the general solution (2.39), we find the field distribution in the slab:

$$H(x) = -H_I \frac{\sinh(x/\lambda)}{\sinh(d/2\lambda)} \tag{2.43}$$

Using Maxwell's equation (2.41), we find the distribution of current:

$$j_{\mathrm{s}}(x) = \frac{cH_I}{4\pi\lambda} \frac{\cosh(x/\lambda)}{\sinh(d/2\lambda)} \tag{2.44}$$

It follows from (2.43) and (2.44) that, similarly to the previous case, for $d \gg \lambda$ both the magnetic field and the current are present only within a surface layer of thickness λ. If the film is thin ($d \ll \lambda$), the pattern is different; the current flows through its entire cross-section and the field is a linear function of the coordinate:

$$H = -H_I \frac{2x}{d}, \quad j_{\mathrm{s}} = \frac{cH_I}{2\pi d} = \frac{I}{d}$$

Recall that a uniform current in an infinite thin slab generates a uniform magnetic field outside the slab, independent of the coordinates. The field and current distributions are shown in Fig. 2.4.

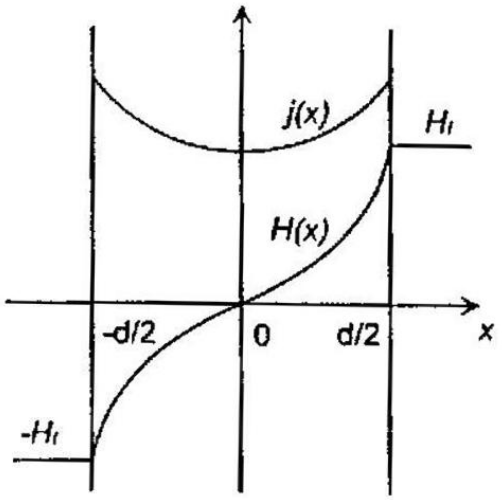

Fig. 2.4. Distribution of current and magnetic field across a thin film carrying a current

2.5.3 Thin Slab Carrying a Current in a Transverse Uniform Field

Consider a thin slab in a uniform external field H_0 parallel to the z axis. The slab carries a current along the y direction which is uniform along the z axis, as in Sect. 2.5.2. The total current through the cross-section of unit height is I. It generates a field $\pm H_I$ at the surfaces of the slab ($x = \pm d/2$). Thus, in this problem we have a superposition of the conditions from the two previous problems. Due to the linearity of the London equations, this should lead to a superposition of their solutions.

Consider a particular case $H_I = H_0$. The external field H_0 in this case cancels out the field generated by the current on one side of the slab and doubles it on the other side. As a result, the current I flows on one side of the

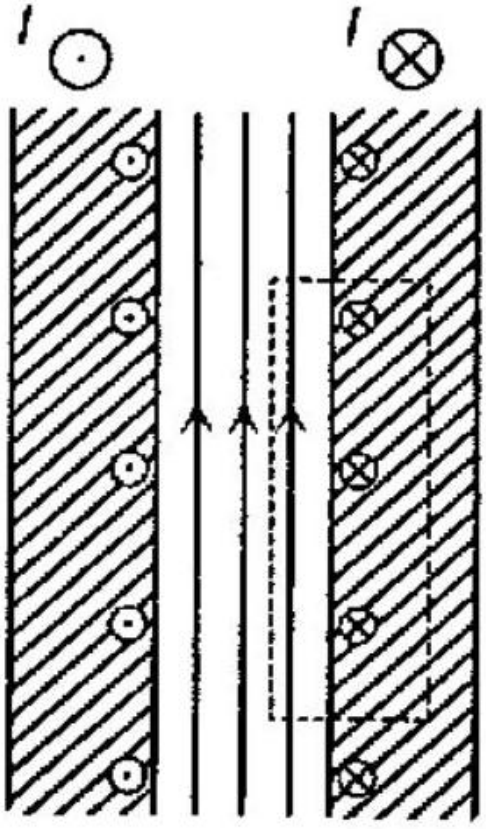

Fig. 2.5. If two parallel superconducting slabs carry currents which are equal in value and opposite in direction, the resulting magnetic field is 'locked' in the gap between the slabs

as in Fig. 2.5. The field in the gap between the slabs [1] is $H = (4\pi/c)I$. One can assume that this field is generated by both currents. Due to the current I flowing in the left-hand slab, there is a uniform field $H_I = 2\pi I/c$ directed upwards everywhere to the right of the slab and downwards everywhere to the left of it. Vice versa, the current from the right-hand slab generates a field H_I directed downwards everywhere to the right of the slab and upwards everywhere to the left of it. The result is that both to the right and to the left of the pair of slabs the fields cancel each other out while in the gap the field is doubled.

2.5.4 Thin Film Above a Superconducting Semispace

In this section we discuss a situation which is particularly important from a practical point of view: a thin film above a semi-infinite superconducting space (we shall refer to the latter as a superconducting screen). In order to find the distribution of the magnetic field when the film carries a certain current, we start with a very simple case.

Consider a rectilinear current-carrying conductor, which is placed above a superconducting screen and oriented along the y axis. Its distance from the screen is a. Let us find the magnetic field above the screen. If there were no screen, the magnetic field lines would form concentric circles centered on the conductor. But because the field lines cannot penetrate a superconductor (due to the Meissner-Ochsenfeld effect), it is obvious that, with the superconducting screen in place, the magnetic field around it will be distorted. Let us find this field.

In the semispace $z > 0$ and outside the conductor, there are no electric currents and curl $\boldsymbol{H} = 0$. Therefore, we can introduce a magnetic field potential satisfying the Laplace equation. On the other hand, we know that the magnetic field at the surface of a superconductor is always tangential to the

surface, that is, $H_z(z = 0) = 0$. This boundary condition assures that the solution of the Laplace equation is single-valued.

The correct field in the region $z > 0$ can be found very simply by means of the method of images. It is easy to see that it will be the field generated by two rectilinear currents, equal in value and opposite in direction, without the superconducting screen. For one of the currents, the distance from the plane $z = 0$ is a, i.e., the coordinates of its cross-section are $(0, a)$, while for the other (the image of the first) the coordinates are $(0, -a)$. Then in the semispace $z > 0$ and outside the conductor, the magnetic field still satisfies the equation curl $\boldsymbol{H} = 0$, and the boundary condition $H_z(z = 0) = 0$ is satisfied automatically due to symmetry of the problem.

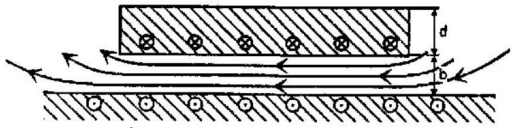

Fig. 2.6. Magnetic field generated by a currentcarrying film placed above a superconducting semispace

Thus we can apply the method of images to derive the field generated by a superconducting film placed above a semi-infinite superconducting screen. Let the thickness of the film be $d > \lambda$ and its width $w \gg \lambda$. The film is placed at a distance b from the screen and carries a current I. Let us find the current distributions in the film and in the screen and the magnetic field in the gap between the film and the screen.

Using the method of images, we replace the effect of the screen with that of an irnage film placed at a distance $2b$ from our film. The image also carries a current, but the direction of this current is opposite to that in the real film. Thus we have arrived at the problem of field and current distributions for two parallel films with opposite currents. This problem has just been solved in Sect. 2.5.3 (Fig. 2.5) and we already know the answer: in the gap between the

[1] Stokes' theorem states that $\oint \boldsymbol{H} \cdot \mathrm{d}\boldsymbol{l} = (4\pi/\mathrm{c})I$, where I is the total current through the surface bounded by the contour along which the path integral is

film and the screen, there is a uniform magnetic field $H_I = \frac{4\pi}{c}\frac{I}{w}$. The
current I in the film flows only near the surface adjacent current I in the film flows only near the surface adjacent to the screen, within a layer $\sim \lambda$. The current in the screen also flows within a layer $\sim \lambda$ near the surface and its surface density is I/w. The direction of this current is opposite to that of the current in the film. The relation between the field H_I and the current in the screen is given by the law of the total current. This situation is shown schematically in Fig. 2.6. The edge effects are disregarded in the above consideration. The magnetic field distribution incorporating the edge effects is shown in Fig. 2.7 [19].

The results that we have just obtained agree with reality if the real film playing the role of the screen can indeed be approximated by a semi-infinite screen. Below there is an example of a situation in which such an approximation is not valid

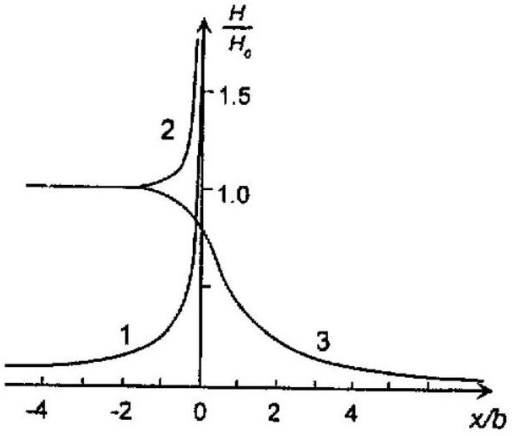

Fig. 2.7. Magnetic field distribution near the edge of a current-carrying superconducting film placed in the vicinity of a superconducting screen: 1 - field at the upper surface of the film; 2field at the lower surface of the screen; 3 - field at the surface of the screen

Consider a thick superconducting film (of thickness $d \geq \lambda$) of width w and length l deposited onto a glass substrate; $w \ll \lambda$. The film has been covered with a thin insulating layer of thickness b, such that $b \ll w$, and then another superconducting film has been deposited on top, also of thickness w and of length well in excess of l. Then a current from an external source is applied to the upper superconducting film. It is easy to realize that the

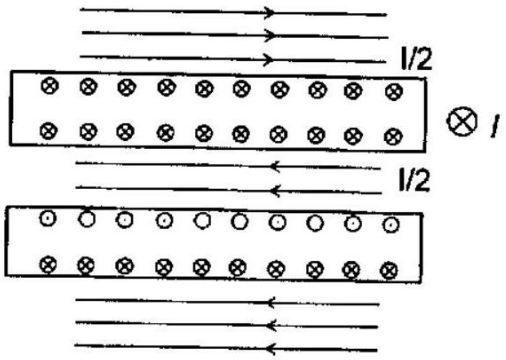

Fig. 2.8. Field and current distributions for two parallel closely spaced films. A current I is applied to the upper film. The lower film is not supplied with current
lower film cannot produce any screening effect in this situation. Indeed, if the upper film carries a certain current I, this current generates a magnetic field in the gap between the films. This means that the currents at the lower surface of the upper film and at the upper surface of the lower film must be equal in value. Furthermore, because the length of the lower film is finite, the current at its upper surface has to close at its lower surface, as in Fig. 2.8. As a result, the magnetic field at this surface is exactly the same as that in the gap between the films. Moreover, the current in the upper film is now split equally between its upper and lower surfaces, as illustrated in Fig. 2.8. Thus, the magnetic fields above and below the pair of films

and in the gap are exactly the same as those in the absence of the lower film. That is, the

2.5.5 Short-Circuit Principle

Quite often in modern superconducting electronics, when complex multilayer systems are being designed, it can be rather difficult to have an instant grasp of how the magnetic fields and electric currents will be distributed in such a system. Great help can be provided here by the so-called short-circuit principle [20]. It can be applied to thick films, of thicknesses larger than the penetration depth, provided their widths and lengths are well in excess of the distances between the films.

Consider two superconducting films separated by an insulating layer. If the films carry electric currents, the currents along the neighboring surfaces must be equal in value and opposite in direction. Indeed, the surface current is determined by the magnetic field at the surface of a superconductor, and the magnetic field in the gap between the two films is common to both of them. If the thickness of the insulating layer is small, the magnetic flux through this layer is also small and the magnetic field at the edges of the films, associated with this flux, is negligible. Hence we can ignore the magnetic field at the edges and argue that the other parts of the films 'are not aware' of the existence of this flux and 'will not notice' if it disappears. And it can disappear as a result of short-circuiting, that is, bringing into contact two neighboring superconducting surfaces carrying electric currents that are equal in value and opposite in direction.

We can now formulate the short-circuit principle [20]: In a complex system of superconducting films, if two neighboring film surfaces are short-circuited, it will not affect the current distribution in any other part of the system other than the two short-circuited surfaces.

Consider several examples illustrating this principle.

(1) Let us find the distribution of currents in two parallel and identical thick films separated by a thin gap. The first film carries a current I_1 and the second one carries a current I_2, in the same direction. The two films are short-circuited. As a result, we have one film carrying a total current $I_1 + I_2$ distributed uniformly over the outer surfaces of the short-circuited films. Thus, the current at each of those surfaces is $(I_1 + I_2)/2$. We now know the currents at the outer surfaces of our system of films. Let i denote the current at the inner surfaces of the films. Because the total current in the first film, I_1, is fixed, we have $(I_1 + I_2)/2 + i = I_1$, i.e., $i = (I_1 - I_2)/2$. All surface currents in our system are now defined.

Note that if $I_2 = 0$, we come straight to the result shown in Fig. 2.8, that is, to the absence of screening by a superconducting film.

(2) If an insulated current-carrying wire is covered with a superconducting sheath, the latter will not be capable of screening the magnetic field generated by the current in the wire. To elucidate this statement, let us short-circuit the inner surface of the sheath and the surface of the wire. Then the entire current from the wire flows at the outer surface of the sheath and generates

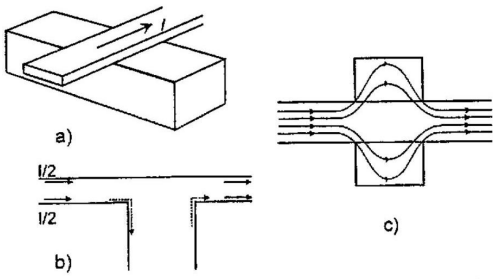

Fig. 2.9. Current-carrying film separated from the flat surface of a bulk superconductor by a thin gap: (a) general view; (b) side view after short-circuiting; (c) top view

(3) Let us find the distribution of currents in a system consisting of a thick superconducting

film carrying a current which is placed above a massive superconducting bar (see Fig. 2.9). If the lower surface of the film and the upper surface of the bar are short-circuited, the resulting distribution of currents is that sketched in Fig. 2.9 (b). Indeed, at first the current from the film spreads over the upper surface of the bar, but a small fraction of it goes around the bar, along its lower surface. As a result, the current density at the upper surface of the film decreases sharply. Taking this into account, one can argue that in the initial system, without the short-circuit, the current in the part of the film immediately above the bar flows predominantly at the lower surface of the film. A current of the same value and opposite in direction must then appear at the upper surface of the bar, in the part situated immediately below the film. Further, this current spreads over the upper surface of the bar and closes there, while a small fraction of it closes over a path around the bar.

One can conclude that the role of the bar in this system approaches the role of the semi-infinite screen (see Fig. 2.7).

7.4.2 2.6 Kinetic Inductance

The inductance of a section of an electric circuit is usually defined by the energy $\mathcal{F}^{\mathrm{M}}$ of the magnetic field generated by a current I through the circuit:

$$\mathcal{F}^{\mathrm{M}} = \frac{1}{8\pi}\int H^2 \,\mathrm{d}V = \frac{1}{2c^2}L^{\mathrm{M}}I^2 \tag{2.45}$$

The integral is taken over the entire space. We shall refer to this inductance as
the current I in the circuit requires a part of the energy to be converted into the kinetic energy $\mathcal{F}^{\mathrm{K}}$ of the current carriers (electrons). With this part of the energy can be associated the so-called kinetic inductance L^{K};

$$\mathcal{F}^{\mathrm{K}} = \int n\frac{mv^2}{2} \,\mathrm{d}V = \frac{1}{2c^2}L^{\mathrm{K}}I^2 \tag{2.46}$$

where n is the number density of the current carriers, m is the mass of one carrier and v is the velocity. The integration is carried out over the volume of the conductor.

If the section of the circuit is normal, the contribution of the kinetic inductance to the total resistivity is very small compared to its active resistivity and usually neglected. The contribution of the kinetic inductance in normal conductors can only be significant at very high frequencies (over 10^{13} Hz). In superconductors, however, the kinetic inductance sometimes plays an important role.

Recall that the supercurrent density is $j_{\mathrm{s}} = n_{\mathrm{s}}\boldsymbol{e}\boldsymbol{v}_{\mathrm{s}}$. Then, from (2.46), we obtain the following definition of the kinetic inductance of a superconductor:

$$L^{\mathrm{K}} = c^2\Lambda\int \frac{j_8^2}{I^2} \,\mathrm{d}V \tag{2.47}$$

where the integral is taken over the volume of the superconductor and I is the total current through the superconductor.

Let us illustrate the concept of kinetic inductance with specific examples.
(1) Consider a superconducting wire of length l and radius R. Assume that $R \gg \lambda$. If the wire carries a current I, this current must circulate near its surface. The current density j_{s} at a distance r from the center of the wire is $j_\varepsilon(x) = j_{30}\mathrm{e}^{-x/\lambda}$, where $x = R - r, j_{80} = j_8(0)$. The total current is $I = 2\pi R\lambda j_{50}$. Substituting these into (2.47) and carrying out the integration, we get $L^{\mathrm{K}} = l\lambda/R$.

Let us now introduce another quantity which is particularly useful in many applications: the inductance per square $L_\square$. For a flat superconductor, the greater its length, the larger

its inductance and resistivity. Furthermore, the greater its width, the smaller the inductance. Therefore, the inductance of a square is always the same for a given superconductor, whether one considers 1 km^2 or 1 mm^2 of it. For our wire, since the circumference of the cross-section is $2\pi R$, the kinetic inductance per square is

$$L_{\rm O}^{\rm K} = 2\pi\lambda. \tag{2.48}$$

If we use (2.45) and calculate the part of the magnetic inductance associated with the magnetic field penetrating the superconductor (more accurately, penetrating the layer of the order λ near the surface) we obtain the same result:

$$L_{\square}^{\rm M} = 2\pi\lambda. \tag{2.49}$$

The total inductance per square of the layer λ at the surface of a bulk superconductor is equal to the sum of (2.48) and (2.49):

$$L_{\square} = 4\pi\lambda \tag{2.50}$$

In the International System of Units (SI), equation (2.50) takes the form: $L_{\square} = \mu_0\lambda$, with $\mu_0 = 4\pi \times 10^{-7}{\rm H}/m$. As follows from (2.48-50), in CGS $L_{\square}$ is measured in cm, and in SI in H, where 1 cm corresponds to $10^{-9}{\rm H} = 1{\rm nH}$.

One can say that λ is a characteristic of the inertia of the current carriers since, for a semispace, $L_{\square}^{\rm K}$ depends only on the penetration depth. If $\lambda \approx 5 \times 10^{-6}$ cm, then $L_{\square} = 4\pi\lambda = 6.3 \times 10^{-5}$ cm $= 6.3 \times 10^{-14}$H.

(2) Consider the kinetic inductance of a thin superconducting film. Assume that the thickness of the film is $d \ll \lambda$ and, therefore, the current in the film is distributed uniformly over its thickness. We shall consider a small section of width w along the width of the film and assume that the current there is also uniform. Restricting the length of the section to the same value w, we obtain for the kinetic energy of the superconducting electrons within this section:

$$\mathcal{F}_{\square}^{\rm K} = \frac{\Lambda}{2} j_{\rm s}^2 w^2 d$$

Recalling that the current I through the cross-section is assumed to be uniform, we have $j_{\rm s} = I/wd$ and

$$\mathcal{F}_{\rm O}^{\rm K} = \frac{1}{2d} A I^2 = \frac{1}{2d}\frac{4\pi\lambda^2}{c^2} I^2 = \frac{1}{2c^2} L_{\rm O}^{\rm K} I^2.$$

From the last expression we immediately obtain $L_{\rm O}^{\rm K}$ for a thin film:

$$L_{\square}^{\rm K} = 4\pi\lambda^2/d \tag{2.51}$$

Now it is obvious that, for $d \ll \lambda$, the kinetic inductance can be significant. For example, for a thin film ($d \sim 10^{-6}$ cm) with the penetration depth $\lambda = 3 \times 10^{-5}$ cm, the kinetic inductance per square is, according to (2.51), $L_{\square}^{\rm K} \approx 10^{-2}$ cm $= 10^{-11}$H.

(3) Finally, consider a thick film above a massive superconducting screen. Assume that the distance between the film and the surface of the screen is b. If the film carries a current, there must be a magnetic field present in the gap between the film and the screen. After calculating the energy of this magnetic field, we find its contribution to the inductance of the film $L_{\square} = 4\pi b$. In addition, the magnetic field penetrates the film to the depth λ_1 and the screen to the depth λ_2. This penetrating field, from (2.50), makes an additional contribution to the inductance of the system as a whole so that its total inductance is

$$L_{\square} = 4\pi\left(b + \lambda_1 + \lambda_2\right). \tag{2.52}$$

One can see from (2.52) that, in order to reduce the inductance, the film should be placed as close to the screen as possible. However, making b sub-
and the kinetic inductance will remain within a layer of the order of the penetration depth, in the film as well as in the screen.

7.4.3 2.7 Complex Conductivity of a Superconductor

This section deals with the complex conductivity of a superconductor in an electromagnetic field. In what follows we assume that the electron mean free path l is small and, therefore, that the normal skin effect approximation is valid. In other words, l is small enough and the frequencies are low enough that l is less than the penetration depth of the electromagnetic field. The frequency of electron collisions is $\tau^{-1} = v_{\mathrm{F}}/l \gg \omega$, where ω is the frequency of the electromagnetic wave and v_F is the electron velocity on the Fermi surface.

In the following analysis we shall partly follow the monograph by Van Duzer and Turner [21].

In order to calculate the conductivity of a superconductor in a highfrequency field, we use the two-fluid model, that is, we assume that there are normal electrons of density n_{n} and superconducting electrons of density n_{s}, and the total density of conduction electrons is $n = n_{\mathrm{s}} + n_{\mathrm{n}}$. The motion of the superconducting electrons is governed by the first London equation (2.2):

$$E = \Lambda \mathrm{d}j_s/\mathrm{d}t \tag{2.53}$$

For the normal electrons we can write

$$eE - \frac{m}{n_{\mathrm{n}}e} j_{\mathrm{n}}^{\tau} = \frac{m}{n_{\mathrm{n}}e} \frac{\mathrm{d}j_{\mathrm{n}}}{\mathrm{d}t} \tag{2.54}$$

The left-hand side of (2.54) describes the forces on the normal electrons: the electric field and the average 'friction' due to electron collisions. The righthand side is the product of the electron mass and acceleration. For one normal electron, this Newton's second law can be written as

$$E = \frac{n_{\mathrm{s}}}{n_{\mathrm{n}}} \Lambda \frac{\mathrm{d}j_{\mathrm{n}}}{\mathrm{d}t} + \frac{n_{\mathrm{s}}}{n_{\mathrm{n}}} \Lambda \frac{j_{\mathrm{n}}}{\tau} \tag{2.55}$$

Assuming $j_s \propto \mathrm{e}^{\mathrm{i}\omega t}$, we can rewrite (2.53) and (2.55) as

$$j_s = -\mathrm{i} \frac{1}{A\omega} E \tag{2.56}$$

$$j_{\mathrm{n}} = \frac{n_{\mathrm{n}}}{n_{\mathrm{s}}} \frac{\tau}{A} \frac{1 - \mathrm{i}\omega\tau}{1 + (\omega\tau)^2} E \tag{2.57}$$

The total current density is $j = j_8 + j_{\mathrm{n}}$, and we finally have

$$j = \sigma E, \quad \sigma = \sigma_1 - \mathrm{i}\sigma_2 \tag{2.58}$$

$$\sigma_2 = \frac{1}{\lambda\omega} \left[1 + \frac{n_{\mathrm{n}}}{n_{\mathrm{B}}} \frac{(\omega\tau)^2}{1 + (\omega\tau)^2} \right] \tag{2.60}$$

Equations (2.58-60) describe the complex conductivity of a superconductor in a high-frequency electromagnetic field.

7.4.4 2.8 Skin Effect and Surface Impedance

2.8.1 Normal Skin Effect

It is well known that an electromagnetic field penetrates a normal metal to the so-called skin depth, or to the depth of a skin layer. In this section we shall consider how the field penetrates a superconductor. The surface of the superconductor coincides with the plane $x = 0$.

Let us write down Maxwell's equations

$$\operatorname{curl} \boldsymbol{H} = \frac{4\pi}{c}\sigma \boldsymbol{E}, \tag{2.61}$$

$$\operatorname{curl} \boldsymbol{E} = -\frac{1}{c}\frac{\partial \boldsymbol{H}}{\partial t}. \tag{2.62}$$

Assuming that the magnetic field in the superconductor is $\boldsymbol{H} \propto \mathrm{e}^{-\mathrm{i}(kx-\omega t)}$ and taking the curl of both sides of (2.61), we get

$$-\nabla^2 \boldsymbol{H} = -\frac{4\pi}{c}\sigma\frac{\partial \boldsymbol{H}}{\partial t}. \tag{2.63}$$

Here we have used the equations $\operatorname{div} \boldsymbol{H} = 0$ and $\operatorname{curl}\operatorname{curl} \boldsymbol{H} = -\nabla^2 \boldsymbol{H}$. Substituting $H \propto \mathrm{e}^{-\mathrm{i}(kx-\omega t)}$ in (2.63), we obtain

$$k^2 = -\mathrm{i}\frac{4\pi}{c^2}\sigma\omega \tag{2.64}$$

and

$$k = (1-\mathrm{i})/\delta \tag{2.65}$$

where

$$\delta = \left(\frac{c^2}{2\pi\sigma\omega}\right)^{1/2} \tag{2.66}$$

Our problem is now essentially solved. Indeed, the field penetration is defined by the quantity k which can be expressed through the conductivity σ using (2.65) and (2.66). Let us make some simplifications. Assume that the temperature is not too close to T_c so that $(n_\mathrm{n}/n_\mathrm{s})\,(\omega\tau)^2 \ll 1$. In addition, we assume, as always, that $\omega\tau \ll 1$. Then we obtain from (2.59) and (2.60)

Substituting (2.67) into (2.66), we get

$$\delta = \frac{\sqrt{2}\lambda}{\left(\frac{n_\mathrm{n}}{n_\mathrm{k}}\omega\tau - \mathrm{i}\right)^{1/2}} \tag{2.68}$$

At low frequencies, when $(n_\mathrm{n}/n_s)\,(\omega\tau) \ll 1$, we have $\delta = \sqrt{2}\mathrm{i}\lambda = \lambda(1+\mathrm{i})$. Substituting this into (2.65), we obtain $k = -\mathrm{i}/\lambda$, i.e., $H \propto \mathrm{e}^{-\mathrm{i}kx} = \mathrm{e}^{-x/\lambda}$. Thus, as one should have expected, a low-frequency magnetic field penetrates a superconductor in the same manner as a dc field, that is, it is exponentially damped over the magnetic field penetration depth. In the general case, the field penetration is described by (2.65) and (2.68).

2.8.2 Surface Impedance

By definition, the surface impedance is

$$Z = \frac{4\pi}{c}\frac{E}{H} \tag{2.69}$$

This expression has a clear physical meaning. Suppose that there are ac electric and magnetic fields at the surface of a metal, such that the vectors $\boldsymbol{E}$ and $\boldsymbol{H}$ are mutually orthogonal and tangential to the surface. Then $c\boldsymbol{H}/4\pi$ is the density of the surface current j_{surf} and, therefore, Z in (2.69) is E/j_{surf} , that is, it expresses the surface impedance per square.

Let us now work out the surface impedance of a superconductor. With the magnetic field written as $\boldsymbol{H} \propto \mathrm{e}^{-\mathrm{i}(kx-\omega t)}$, equation (2.61) becomes

$$\mathrm{i}kH = \frac{4\pi}{c}\sigma E \tag{2.70}$$

Then from (2.69) and (2.65) we have

$$Z\frac{\mathrm{i}k}{\sigma} = \frac{1+\mathrm{i}}{\sigma\delta} \tag{2.71}$$

Substituting (2.66) and (2.67) into (2.71), we get

$$Z = R_{\square} + \mathrm{i}X_{L\square} \tag{2.72}$$

$$R_{\square} = \frac{2\pi\omega^2\lambda}{c^2}\frac{n_{\text{n}}}{n_{\text{s}}}\tau \tag{2.73}$$

$$X_{L\square} = \frac{4\pi\lambda\omega}{c^2} = \frac{\omega L_{\square}}{c^2} \tag{2.74}$$

The real part of the impedance, $R_{\square}$, reflects the energy dissipation due to heating, while the imaginary part, $X_{L\square}$, is the inductive resistance.

Let us find the temperature dependences of $R_{\square}$ and $X_{L\square}$. Recalling the

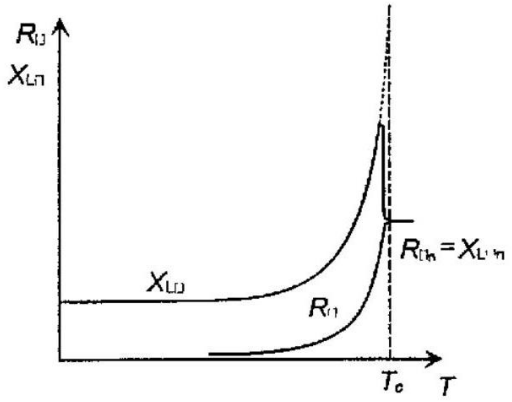

Fig. 2.10. Real and imaginary parts of the surface impedance as functions of temperature [22]

because $\lambda \propto {n_{\text{s}}}^{-1/2}$. Here $t = T/T_{\text{c}}$ and n is the density of free electrons in a metal. Then $n_{\text{n}} = nt^4$ and

$$R_{\square} \propto t^4/\left(1-t^4\right)^{3/2}, \quad X_{L\square} \propto \left(1-t^4\right)^{-1/2} \tag{2.75}$$

The above formulas reproduce the temperature dependences of both active and imaginary components of the impedance rather well (at least qualitatively), with an exception of temperatures close to T_{c}. In this temperature interval, (2.73) and (2.74) are no longer valid.

Recall that, while deriving these formulas, we used (2.67) obtained on the assumption that $(n_n/n_\varepsilon)(\omega\tau)^2 \ll 1$. But no matter how low the frequency is, the superconducting electron density at $T \to T_c$ is $n_s \to 0$ and the inequality is violated. Therefore, at $T \to T_c$ we have from (2.60): $\sigma = (n_n/n_s)\tau/\Lambda - i(n_n/n_s)(\omega\tau)^2/\Lambda\omega$. Neglecting the imaginary part and substituting this expression in (2.65) and (2.71) we obtain

$$Z = \frac{2\pi}{c^2}\left(2\omega\tau\frac{n_s}{n_n}\right)^{1/2}\frac{\lambda}{\tau}(1+i) = \frac{1+i}{\sigma_n\delta_n} \tag{2.76}$$

where σ_n and δ_n are the conductivity and the skin depth of the normal metal, respectively.

It follows from (2.76) that, at $T^\top \to T_c$, $R_\square$ and $X_{L\square}$ are equal in value and independent of temperature, since ${n_s}^{1/2}\lambda = \text{const}$.

The temperature dependences of $R_\square$ and $X_{L\square}$ obtained within the twofluid model are sketched in Fig. 2.10.

As far as high-temperature superconductors are concerned, many experiments indicate that they do not have a 'clean' gap. This means that even at zero temperature they have an intrinsic density of quasiparticle states in the gap down to zero energy. As a consequence, the temperature dependences of the two-fluid model are no longer valid for high- T_c materials.

Problems

Problem 2.1. Consider a bulk superconductor containing a cylindrical hole of 0.1 mm diameter. There are 7 magnetic flux quanta tra ped in the hole. Find the

Problem 2.2. Consider a bulk superconductor containing a cylindrical hole of 2 cm diameter. The magnetic field trapped in the hole is $H = 300$ Oe. Find the vector potential A at the distance $R = 2$ cm from the center of the hole. Find the phase gradient $\nabla\theta$ at the same distance.

Problem 2.3. Consider a thin superconducting film of thickness $d \ll \lambda$ deposited onto a dielectric fllament. The radius of the filament's cross-section is R. At room temperature, the filament is placed in a longitudinal magnetic field and then cooled down to a temperature below T_c. Then the external field is switched off. Find how the magnetic flux trapped by the filament is quantized.

Problem 2.4. Find the distribution of the magnetic field under the conditions of the previous problem.

7.5 Other Bulk Effects in Electromagnetic Field

7.5.1 Superconductors in a Weak Electromagnetic Field by AGD

(??????????????????)

1. Constant weak magnetic field

Let us return to the question of the electromagnetic properties of superconductors. We shall confine ourselves in this section to the behaviour of superconductors in fairly weak fields, which are small compared with the critical magnetic field. Suppose that a superconductor with a plane surface occupies the half-space $z < 0$ as illustrated in Fig. 99, and is located in a constant magnetic field, directed parallel to its surface. We introduce the vector potential A:

$$H = \text{curl}\, A.$$

In vacuo $\boldsymbol{H}$ = const and we can take the vector potential as, say,

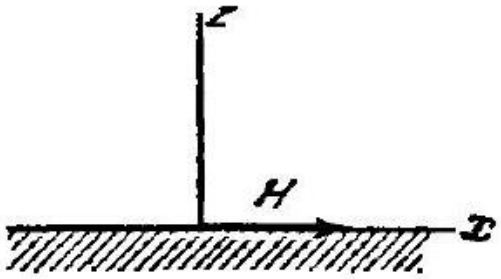

Fig. 99

$$A_y = -Hz, \quad A_x = A_z = 0 \tag{37.1}$$

Current is produced in the superconductor under the action of the magnetie field; the field distribution in the superconductor is subject to Maxwell's equation

$$\nabla^2 A = -4\pi j \tag{37.2}$$

Since the current density is in turn due to the presence of the field, it will be proportional to A in a linear approximation with respect to the field. It follows from uniformity considerations that, in an infinite superconductor, the connection of the current density with the ficld must in general be of the form

$$j(x) = -\int Q(x-y)A(y)\mathrm{d}^4 y \tag{37.3}$$

or in Fourier components:

$$j(k) = -Q(k)A(k) \tag{/}$$

We shall not dwcll in detail below on the solution of the actual electromagnetic problem as defined by (37.2), (37.3) for the half-space, but confine ourselves to deriving an expression for the kernel $Q(x-y)$, with a view to demonstrating the application of quantum field theory methods to this case.

As usual, the current density $\boldsymbol{j}$ at a given point is the thermodynamic average of the familiar quantum mechanical expression for the current operator $\boldsymbol{j}(x)$ in sccond quantisation:

$$j(x) = \frac{ie}{2m}\left(\nabla_{r'} - \nabla_r\right)_{r'\to r} \tilde{\psi}\,(x')\,\tilde{\psi}(x) - \frac{e^2 A(x)}{m}\tilde{\tilde{\psi}}(x)\tilde{\psi}(x) \tag{37.4}$$

The current density $\boldsymbol{j}(x)$ can thus be written directly in terms of the Green function of the system (we have put $c = 1$):

$$j(x) = 2\left\{\frac{ie}{2m}\left(\nabla_{r'} - \nabla_r\right)\circlearrowleft(x,x') - \frac{e^2 A(x)}{m}\circlearrowleft(x,x')\right\}_{r'\to r, z'=\tau+0} \tag{37.5}$$

We proceed to finding the Green function, or more precisely, the correction to the Green function of first order in the field. In a constant magnetic field all the Green functions $\mathfrak{G}, \mathfrak{F}$, and $\mathfrak{F}^+$depend only on the difference of the "time" coordinates $\tau = \tau_1 - \tau_2$. We change to the Fourier components $\mathfrak{K}_\omega$ and $\mathfrak{F}_\omega$. The system of equations for these latter reads as follows in a constant magnetic field:

$$\left\{ i\omega + \frac{1}{2m}\left(\frac{\partial}{\partial \boldsymbol{r}} - ieA(\boldsymbol{r})\right)^2 + \mu \right\} \mathfrak{G}_\omega(\boldsymbol{r}, \boldsymbol{r}') + \Delta(\boldsymbol{r})\mathfrak{F}^+_\omega(\boldsymbol{r}, \boldsymbol{r}') = \delta(\boldsymbol{r} - \boldsymbol{r}'),$$
$$\left\{ -i\omega + \frac{1}{2m}\left(\frac{\partial}{\partial \boldsymbol{r}} + ieA(\boldsymbol{r})\right)^2 + \mu \right\} \mathfrak{F}^+_\omega(\boldsymbol{r}, \boldsymbol{r}') - \Delta^*(\boldsymbol{r})\mathfrak{G}_\omega(\boldsymbol{r}, \boldsymbol{r}') = 0. \tag{37.6}$$

We write the Green functions $\mathfrak{G}$ and $\mathfrak{F}^+$as

$$\mathfrak{G} = \mathfrak{G}_0 + \mathfrak{G}^{(1)}; \quad \mathfrak{F} = \mathfrak{F}_0 + \mathfrak{F}^{(1)}; \quad \mathfrak{F}^+ = \mathfrak{F}^+_0 + \mathfrak{F}^{+(1)},$$

where $\mathfrak{G}_0, {}_0, \mathfrak{F}^+_0$are the Green functions in the absence of a field, and $\mathfrak{G}^{(1)}, \mathfrak{F}^{(1)}, \mathfrak{F}^{+(1)}$ are the added terms, linear in the field. We obtain on linearising equations (37.6):

$$\begin{aligned}
&\left\{ i\omega + \frac{\nabla^2}{2m} + \mu \right\} \mathfrak{G}^{(1)}_\omega(r, r') + \Delta_0 \mathfrak{F}^{+(1)}_\omega(r, r') \\
&\quad = -\Delta^{(1)}(r)\mathfrak{F}^+_{0\omega}(r - r') + \frac{ie}{2m}[(\nabla \cdot A) + (A \cdot \nabla)]\mathfrak{G}_{0\omega}(r - r') \\
&\left\{ -i\omega + \frac{\nabla^2}{2m} + \mu \right\} \mathfrak{F}^{+(1)}_\omega(r, r') - \Delta_0 \mathfrak{G}^{(1)}_\omega(r, r') \\
&\quad = \Delta^{*(1)}(r)\mathfrak{G}_{0\omega}(r - r') - \frac{ie}{2m}[(\nabla \cdot A) + (A \cdot \nabla)]\mathfrak{F}^+_{0\omega}(r - r')
\end{aligned} \tag{37.7}$$

Using these equations, we can very easily express $\mathfrak{W}^{(1)}_\omega(r, r')$ and $\mathfrak{F}^{+(1)}_\omega(r, r')$ in terms of the quantities on the right-hand sides of (37.7). This is best done by using expression (34.32) for the inverse operator to the left-hand sides of (37.7). Before writing down to result for $\mathfrak{G}^{(1)}_\omega(r, r')$, however, let us consider in more detail the structure of equations (37.7),

System (37.6) and hence (37.7) also are gauge-invariant, i.e. are invariant with respect to the transformations (34.26) and (34.27). Thus when finding the current $\boldsymbol{j}(\boldsymbol{r})$, which is equal in the linear approximation to

$$j(r) = \frac{ie}{m} T \sum_\omega (\nabla_{r'} - \nabla_r)_{r' \to r} \mathfrak{G}^{(1)}_\omega(r, r') - \frac{e^2 A(r) N}{m} \tag{37.8}$$

the final result can depend only on the transverse part of the vector potential A. In other words, the addition to A of the gradient of any scalar $\varphi : A \to A + \partial\varphi/\partial r$ cannot change the current $j(r)$.

As regards $\mathfrak{G}^{(1)}_\omega(r, r'), \mathfrak{F}^{+(1)}_\omega(r, r')$, by (34.27), they are by no means invariant with respect to a change of the vector potential. The same
applies to $\Delta^{(1)}(r), \Delta^{*(1)}(r)$, which appear on the right-hand sides of (37.7) and must themselves be determined from the integral equation

$$\Delta^{*(1)}(r) = |\lambda| T \sum_\omega \mathfrak{F}^{+(1)}_\omega(r, r')$$

Given any $A(r), \Delta(r)$ is in general an unknown function of the potential A. It can nevertheless be asserted that, in the linear approximation with respect to the field, by virtue of the uniformity of the problem, the function $\Delta^{*(1)}(r)$, being a scalar, depends only on div A. Owing to this fact, if we choose our gauge such that the vector potential $\boldsymbol{A(r)}$ satisfies the equation

$$\operatorname{div} A = 0$$

it proves possible to simplify the problem considerably, inasmuch as, with this choice of $A(r)$, the function $\Lambda^{*(1)}(r)$ vanishes identically. The result obtained below refers only to a purely "transverse" vector potential $\boldsymbol{A}(r)$.

The method described for making $\Delta^{*(1)}, \Delta^{(1)}$ vanish can be extended in such a way as to make it usable in problems that do not have spatial uniformity in the absence of a field (say superconductors of finite dimensions in a magnetic field). In these cases it is possible to form a scalar from the field $A(r)$ and the vector r or any other vector characterising the problem. In the general case of the non-uniform problem, therefore, the $\Delta^{(1)}(r), \Delta^{*(1)}(r)$ in equations (37.7) (where we now have to understand by $\mathfrak{G}_0$ and $\mathfrak{F}_0$ the Green functions of the body in question with the relevant boundary conditions) depend both on the longitudinal and on the transverse components of the vector $A(r)$. It is always possible, however, to choose the longitudinal part $A_{\text{long}} = \operatorname{grad}\varphi$ in such a way that $\Delta^{(1)}, \Delta^{*(1)}$ vanish. As regards the function φ, for which this condition is fulfilled, it can be found from the condition $\operatorname{div} \boldsymbol{j} = 0$, i.e. from the condition for charge conservation.

Let us now return to equations (37.7) for an infinite superconductor. Putting $\Delta^{(1)}(r) = 0$ and using (34.32), we obtain the following expression for the correction, linear in the field, to the Green function:

$$\mathfrak{G}_{\omega}^{(1)}(r, r') = \frac{ie}{m} \int \{\mathfrak{G}_{0\omega}(r-l)\,(A(l)\cdot\nabla_l)\,\mathfrak{G}_{0\omega}(l-r') + \mathfrak{F}_{0\omega}(l-r)\,(A(l)\cdot\nabla_l)\,\mathfrak{F}_{0\omega}^{+}(r'-l)\}\,\mathrm{d}^3 l \tag{37.9}$$

We have already made use of the condition $\operatorname{div} A = 0$ in this formula, so that it can be assumed that the differentiation in brackets $(A(l)\cdot\nabla)$ refers only to the functions $\mathfrak{G}_{0\omega}(\boldsymbol{l}-\boldsymbol{r'})$ and $\mathfrak{F}_{0\omega}^{+}(\boldsymbol{r'}-\boldsymbol{l})$. By (37.8), the current density $\boldsymbol{j}(\boldsymbol{r})$ is equal to

$$j(r) = \frac{e^2}{m^2} T \sum_{\omega} (\nabla_r - \nabla_{r'}) \int \{\mathfrak{G}_{0\omega}(r-l)\,(A(l)\cdot\nabla_l)\,\mathfrak{G}_{0\omega}(l-r') + \mathfrak{W}_{0\omega}(l-r)\,(A(l)\cdot\nabla_l)\,\mathfrak{F}_{0\omega}^{+}(r'-l)\}_{r'\to r}\,\mathrm{d}^3 l - \frac{Ne^2}{m} A(r) \tag{37.10}$$

It is convenient here to change to the Fourier transforms, introducing the Fourier components for the current density $j(r)$ and the potential $\boldsymbol{A}(\boldsymbol{r})$ in the usual way:

$$j(r) = \frac{1}{(2\pi)^3} \int j(k) e^{i(k-r)} \mathrm{d}^3 k; \quad A(r) = \frac{1}{(2\pi)^3} \int A(k) e^{i(k\cdot r)} \mathrm{d}^3 k$$

The equation for the connection between the components $\boldsymbol{j}(\boldsymbol{k})$ and $\boldsymbol{A}(\boldsymbol{k})$ is as follows:

$$j(k) = -\frac{2e^2 T}{(2\pi)^3} \overline{m^2} \frac{\Sigma}{\omega} \int p! p \cdot A(k) \Big) \{\mathfrak{G}_{\omega}(p_+)\,\mathfrak{G}_{\omega}(p_-) + \mathfrak{F}_{\omega}(p_+)\,\mathfrak{F}_{\omega}^{+}(p_-)\}\,\mathrm{d}^3 p - \frac{Ne^2}{m} A(k) \tag{37.11}$$

where $p_{\pm} = p \pm 1/2k$. Let us emphasise again that our result refers only to the purely transverse gauge. (It can be shown, however, that the formulae obtained remain in force for any gauge, i.e. the longitudinal part falls out from the final result.)

The field $A(r)$ and current $j(r)$ in a superconductor vary at distances of the order of the penetration depth δ, which is usually of the order $\sim 10^{-5}$ to 10^{-6} cm (i.e. at distances much greater than atomic distances). Hence only the components $\boldsymbol{j}(\boldsymbol{k})$ and $\boldsymbol{A}(\boldsymbol{k})$ in the range $k \sim$

$1/\delta \ll p_0$ are important in (37.11). We shall see below that the integration in the kernel (37.11) is performed essentially close to the Fermi surface over a narrow range of values of $|\boldsymbol{p}|$ of the order $||\boldsymbol{p}! - p_0| \sim| \boldsymbol{k} |$. Further, only the two vectors k and $A(k)$ figure in (37.11), and $(k \cdot A) = 0$. On choosing the vector k as the polar axis of coordinates for the variable of integration p and carrying out the averaging over the angle in the azimuthal plane, we find at once that the vector $\boldsymbol{j}(\boldsymbol{k})$ is directed along the vector $A(k)$. In view of what has bcen said above, on substituting expressions (34.35) for the functions (% and $\mathfrak{F}$, we get

$$j(k) = -\frac{Ne^2}{m} Q(k) A(k)$$

where

$$\bar{Q}(k) = 1 + \frac{3T}{4} \sum_{\omega} \int_0^{\pi} \sin^3 0 \, \mathrm{d}\theta \int_{-\infty}^{+\infty} \mathrm{d}\xi \frac{(i\omega + \xi_+)(i\omega + \xi_-) + \Delta^2}{[\omega^2 + \xi_+^2 + 1^2][\omega^2 + \xi_-^2 + \Delta^2]} \tag{37.12}$$

(we have used here the fact that $p_0^3/3\pi^2 = N$). For small $k, \xi_{\pm} = \xi \pm \frac{1}{2}(v \cdot k)$.
It must be borne in mind for future calculations that, for large ω and ξ, the integrand on the right-hand side of (37.12) behaves like ω^{-2} when $\omega \gg \xi$ and like ξ^{-2} when $\xi \gg \omega$. Strictly speaking, therefore, the integral over ξ and sum over the frequencies ω are divergent. To understand the esscuce of the matter, we consider the singularities of the expression for a normal metal (i.e. when $\Delta = 0$):

$$\frac{3}{4} T \sum_{\omega} \int \mathrm{d}\xi \int_0^{\pi} \sin^3 \theta \, \mathrm{d}\theta \frac{1}{(i\omega - \xi_+)(i\omega - \xi_-)}. \tag{37.13}$$

Notice, first of all, that an unusually important role is played in this integral by the order in which we carry out the summation over the frequencies and the integration over ξ. For, if we first integrate over ξ, the poles of the integrand, whatever the sign of ω, lic to one side of the real axis, so that the result is equal to zero. Suppose, now, that we first sum over the frequencics $\omega = (2n+1)\pi T$. It is easily shown that the following is obtained as a result of summation of this simple series:

$$\frac{3}{8} \int_0^{\pi} \sin^3 \theta \, \mathrm{d}\theta \int \frac{\mathrm{d}\xi}{(v \cdot k)} \left[\tanh \frac{\xi_-}{2T} - \tanh \frac{\xi_+}{2T} \right| = -1 \tag{37.14}$$

The reason why the final result changes on interchanging the order of the summation and integration is to be traced to the formal divergence of the entire expression. The essence of the matter is clearly, however, that the result when we first sum over the frequencies only differs from zero in a very narrow range of energies close to the Fermi surface (this region has a width $\sim (\boldsymbol{v} \cdot \boldsymbol{k})$, as follows from (37.14)). In this region the integral over the momentum proves to be rapidly convergent, and the expression for the excitation energy, measured from the Fermi surface, can be written approximately as $\xi = (\boldsymbol{p}^2 - p_0^2)/2m \simeq v(|\boldsymbol{p}| - p_0)$. It is for this reason that, in integrals of the type in question, we must first sum over the frequencies and then carry out the integration over ξ: otherwise, the integration over ξ embraces the domain $||p| - p_0| \sim p_0$, where our expansion of the functions about the Fermi surface becomes unsuitable.

However, it is possible to avoid the need for carrying out the fairly complicated summation over the frequencies in (37.12). We have to proceed as follows. We add to and subtract from the integrand of (37.12) the corresponding expression (37.13) for a normal metal. The integral and sum over the frequencies of the difference of the integrands is now rapidly convergent, as a result of which we can change the order of integration and summation. The relevant expression for the normal metal was evaluated in (37.14); it cancels the unity in (37.12). Integration over ξ gives us

$$Q(k) = \frac{3\pi T}{4} \sum_{\omega} \int_{-1}^{+1} \frac{(1-\beta^2)\,\mathrm{d}\beta}{\sqrt{\omega^2+\Delta^2}} \cdot \frac{1^2}{\omega^2+\Delta^2+\frac{1}{4}v^2|k|^2\beta^2}. \tag{37.15}$$

Further transformation of this kernel is difficult unless some assumptions are made about $|\boldsymbol{k}|$. It is clear from the structure of the integrand that
it is only the ratio of $v|k|$ to the transition temperature T_c that is important. For, when $T \ll T_c$, the gap Δ_0 is of the order T_c; close to T_c, i.e. when $|T-T_c| \ll T_c$, the gap is small, though now $\omega = (2n+1)\pi T \sim T_c$. The quantity $\xi_0 \sim v/T_c$, with the dimension of a length, plays the part of a characteristic parameter in present-day superconductor theory, and is in fact the radius of correlation of the bound electrons. The penetration depth δ can be either greater or less than ξ_0. In the former case the important region $|k| \sim 1/\delta$ satisfies the inequality $v|k| \ll T_c$ whereas in the latter case it is described by the reverse inequality $v|k| \gg T_c$.

Let us start with the first case. Let $v|\boldsymbol{k}| \ll T_0$. We retain in (37.15) only the first non-vanishing term of the expansion in $v|k|$:

$$\bar{Q}(k) = \frac{3\pi}{4}\Delta^2 T \sum_{\omega} \int_{-1}^{+1} \frac{(1-\beta^2)\,\mathrm{d}\beta}{(\omega^2+\Delta^2)^{3/2}} = \pi T \Delta^2 \sum_{\omega} \frac{1}{(\omega^2+\Delta^2)^{3/2}} \tag{37.16}$$

Thus, when $\delta \gg \xi_0$, the kernel $Q(k)$ is independent of k and the connection between the current and ficld is of a local kind, in the sense that the current at a given point r is determined by the field $A(r)$ at this point alone:

$$j(r) = -\frac{e^2 N_s}{m} A(r) \tag{37.17}$$

An equation of this type was first proposed by H. and F. London [64]. It will therefore be natural to describe a superconductor in which $\delta \gg \xi_0$ as a London type superconductor. The function $N_s(T)$ plays the role of the number of "superconducting" electrons. Formula (37.16) expresses the ratio $N_s(T)/N$ as a function of the temperature. Let us emphasise that the gap Δ figuring here is the equilibrium gap in the absence of field at a given temperature, determined by condition (34.37). When $T = 0$, the summation over the frequencies can be replaced by integration: $2\pi T \delta n = \mathrm{d}\omega$. On evaluating the integral, we find that, at $T = 0$, the number of superconducting electrons is equal to their total number N.

Close to T_c, $\Delta(T)$ is small compared with T_c and ω. Neglecting Δ^2 in the denominator, we get the series

$$\frac{N_s(T)}{N} = \frac{2\Delta^2}{\pi^2 T^2} \sum_{n>0} \frac{1}{(2n+1)^3}$$

which has already been evaluated in 36. Using expression (36.6) for the gap close to T_c, we find that in the present case

$$\frac{N_s(T)}{N} = 2\left(1 - \frac{T}{T_c}\right)$$

Let us now consider the second limiting case $v|k| \gg T_c$. The integrand has poles at the points $v|k|\beta/2 = \pm i\sqrt{\omega^2+\Delta^2}$. Since $v|k|$ is large, this means that the integrand has a sharp maximum in the region of
angles $\beta = \cos\theta \simeq T_c/v|k| \ll 1$. Hence the term containing β^2 in the numerator can be neglected by comparison with unity. The remaining expression is a rapidly convergent integral over β, since the integrand decreases as $1/\beta^2$ in the domain $T_d/v|k| \ll \beta \ll 1$. On making the substitution $v|k|\beta = x$ and putting the limits of integration equal to infinity, the integral can be found with the aid of theory of residues:

$$\bar{Q}(k) = \frac{3T\pi^2}{v|k|} \sum_{\omega>0} \frac{4^2}{\omega^2 + \Delta^2} = \frac{3\pi^2}{4v|k|} \Delta \tanh \frac{\Delta}{2T}. \tag{37.18}$$

We see that the kernel $Q(k)$ is in this case essentially dependent on k. Hence, if the field penetration depth $\delta \ll \xi_0$, relationship (37.3) is nonlocal, in other words, the current density $j(r)$ at a given point is determined by the values of the vector potential throughout a neighbourhood of the point with linear dimensions of order ξ_0. The non-local connection between the field and current for certain superconductors was first predicted by Pippard on the basis of an analysis of experimental data [65]. Throughout what follows we shall describe the case when $\delta \ll \xi_0$ as Pippard's case.

There is an important fact that must be mentioned at once. As we have already remarked, the only important factor for deciding which case actually holds is the ratio of the penetration depth δ to the parameter $\xi_0 \sim v/T_c$. If, therefore, the condition $\delta \ll \xi_0$ is fulfilled at low temperatures, the increase in δ as we approach T_c will mean that the reverse situation arises at temperatures sufficiently close to T_c, δ will become much greater than ξ_0. In other words, the London case will always hold in the immediate neighbourhood of T_c. A considerable number of the familiar superconductors belongs to the Pippard type almost throughout the whole temperature range and they only change over to the London type in an extremely narrow neighbourhood $T_c - T \ll T_c$. The remaining pure superconductors represent an intermediate case at low temperatures, i.e. they have a fairly wide London range of temperatures close to T_c We shall not touch here on the subject of alloys (see 39).

Having expression (37.15) for the kernel $\bar{Q}(k)$ at our disposal, we can use Maxwcll's equations to solve the problem of the field penetration into a superconductor with a plane surface. The solution is particularly simple in the London case: on substituting (37.17) into (37.2) and taking all the functions as functions of z only, we find that the vector potential distribution in the superconductor is described by

$$A_y(z) = -H_0 \delta e^{z/\delta}$$

where δ is the London penetration depth

$$\delta = \sqrt{\frac{m}{4\pi N_s e^2}} \left(\text{ in ordinary units } \delta = \int'_{4\pi N_s e^2} mc^2 \right) \tag{37.19}$$

The solution of the problem in the Pippard case is much more difficult and requires the use of special mathematical methods. We shall not dwell on this, but refer the reader who is interested in the theory of superconductors as such to the original literature (see [58], and also [63]).

2. Superconductor in variable fields

We have confined ourselves so far to a discussion of the properties of superconductors in constant magnetic fields. A problem of great physical interest is also the behaviour of a superconductor in an alternating electromagnetic field, or, in more concrete terms, the nature of the absorption and reflection of electromagnetic radiation incident on the surface of a superconductor. The thermodynamic, equilibrium approach on which the previous treatment has been based, is not immediately applicable in the case of an alternating field. We shall find extremely useful in these circumstances the analytic expressions obtained in Chap. III, connecting the various time-dependent functions with the corresponding functions determined by the thermodynamic method. Suppose that an alternating field A (as above, we shall assume that $\varphi = 0$) of frequency ω exists inside an infinite superconductor. The current in the superconductor resulting from the action of the field is obviously connected, as before, with the field

by a relationship of the type (37.3). The difference here is that, with an alternating field, we have to know the Fourier component $Q(k,\omega)$ at non-zero ω. (The kernel $\bar{Q}(k)$ defined above is evidently $\bar{Q}(k) \equiv Q(k,0)$.) We shall again start from the quantum mechanical expression for the current operator:

$$\begin{aligned}\tilde{\hat{j}}(x) &= \frac{ie}{2m}\left(\nabla_{r'} - \nabla_r\right)_{r'\to r} \tilde{\psi}^+(x')\,\tilde{\psi}(x) - \frac{e^2}{m}A(x)\tilde{\psi}^+(x)\tilde{\psi}(x) \\ &\equiv \tilde{\hat{j}}_1(x) - \frac{e^2}{m}A(x)\tilde{\psi}^+(x)\psi(x),\end{aligned}$$

where the operators are written in the Heisenberg representation and contain the field dependence. The connection with the corresponding operators in the interaction representations is, by (6.28), given by

$$\tilde{\hat{j}} = S^{-1}(t) j S(t)$$

where

$$S(t) = T\exp\left\{i\int_{-\infty}^{t}(j(x)A(x))\mathrm{d}^4x\right\}$$

In the approximation linear in the field:

$$\tilde{\hat{\boldsymbol{j}}}_\alpha(x) = \hat{\boldsymbol{j}}_{1\alpha}(x) - \frac{e^2}{m}\boldsymbol{A}_\alpha(x)\psi^+(x)\psi(x) + i\int_{-\infty}^{t}\left[\hat{\boldsymbol{j}}_{1\alpha}(x), \hat{\boldsymbol{j}}_{1\beta}(y)\right]\boldsymbol{A}_\beta(y)\mathrm{d}^4y.$$

The current in the superconductor at a given point and given instant is the average

$$j(x) = \langle\tilde{\hat{j}}(x)\rangle = {}_m\exp\left[\left(\Omega + \mu\nu_m - E_m\right)/T\right]\langle m|\tilde{\hat{j}}(x)|m\rangle$$

Since $\left\langle\hat{j}_1\right\rangle \equiv 0$,

$$j_\alpha(x) = -e_m^{e^2N}A_\alpha(x) + \int P^R_{\alpha\beta}(x-y)A_\beta(y)\mathrm{d}^4y \tag{37.20}$$

where we have introduced the notation

$$P^R_{\alpha\beta}(x-y) = \begin{cases} i\left\langle\left[\hat{j}_\alpha(x), \hat{j}_\beta(y)\right]\right\rangle & \text{for } t_x > t_y \\ 0 & \text{for } t_x < t_y \end{cases} \tag{37.21}$$

On Fourier transforming we get for the kernel of equation (37.3)

$$Q_{\alpha\beta}(k,\omega) = \frac{e^2N}{m}\delta_{\alpha\beta} - P^R_{\alpha\beta}(k,\omega)$$

We now consider the same problem in the technique at finite temperatures, $A(r,\tau)$ and $j(r,\tau)$ being formally regarded as functions of the "time" parameter τ. The following relation now occurs in place of (37.20):

$$\boldsymbol{j}_\alpha(\boldsymbol{r},\tau) = -\frac{e^2N}{m}\boldsymbol{A}_\alpha(\boldsymbol{r},\tau) + \int\mathrm{d}^3\boldsymbol{r}\int_0^\beta \mathscr{P}_{\alpha\beta}(x-y)\boldsymbol{A}_\beta(y)\mathrm{d}\tau_y$$

where

$$\mathscr{P}_{\alpha\beta}(r-r',\tau-\tau') = \left\langle T\left(\hat{j}_{\alpha1}(r,\tau), \hat{j}_{1\beta}(r',\tau')\right)\right\rangle. \tag{37.22}$$

On introducing the Fourier components of the thermodynamic functions, we find that the role of the kernel $Q_{\alpha\beta}(k,\omega_0)$ is played by

$$Q_{\alpha\beta}(k,\omega_0)=\frac{e^2N}{m}\delta_{\alpha\beta}-\mathscr{P}_{\alpha\beta}(k,\omega_0)$$

where the frequencies ω_0 run over the discrete values $\omega_0=2n\pi T$.
We shall shortly prove in a general form that the Fourier components $P^R_{\alpha\beta}(\boldsymbol{k},\omega)$ and $\mathscr{P}_{\alpha\beta}(\boldsymbol{k},\omega_0)$ are values of the same function of a complex variable ω, analytic in the upper half-plane, taken in the first case on the real axis, and in the second at the points $\omega=i\omega_0$. The method of proof is precisely the same as in previous chapters. We expand (37.21) and (37.22) into sums over intermediate states. We now find for the Fourier components, $P^R_{\alpha\beta}$, $\mathscr{P}_{\alpha\beta}$, suitably defined in this case:

$$\begin{aligned}P^R_{\alpha\beta}(\boldsymbol{k},\omega)&=-\sum_{m,p}\varrho_{pm}(\boldsymbol{k})\frac{1}{\omega-\omega_{pm}+i\delta}\\ \mathscr{P}_{\alpha\beta}(\boldsymbol{k},\omega_0)&=-\sum_{m,p}\varrho_{pm}(\boldsymbol{k})\frac{1}{i\omega_0-\omega_{pm}}\end{aligned}\tag{37.23}$$

where

$$\varrho_{pm}(k)=\mathrm{e}^{(\Omega+\mu N_m-E_m)/T}\left(1-\mathrm{e}^{-\omega_{pm}/T}\right)(j_{\alpha1})_{mp}(j_{\beta1})_{pm}(2\pi)^3\delta(k-k_{pm})$$

It is clear from (37.23) that $P^R_{\alpha\beta}(k,\omega)$ is obtained from $\mathscr{P}_{\alpha\beta}(k,\omega_0)$ by replacing ω_0 by $-i\omega$, whilst the values of $P^R_{\alpha\beta}(k,\omega)$ on the real axis must be chosen as the limits when ω tends to the axis from above.

Thus, if we find $\mathscr{P}_{\alpha\beta}(k,\omega_0)$ in the Matsubara technique and continue it analytically onto real frequencies $P^R_{\alpha\beta}(k,\omega)=\mathscr{P}_{\alpha\beta}(k,-i\omega)$ in such a way that the function obtained has no singularities in the upper halfplane of ω, we can in principle find the kernel $Q_{\alpha\beta}(k,\omega)$ which determines the connection between j and A in an alternating electromagnetic field.

Whilst keeping this purpose in mind, let us consider formally the equations for the thermodynamic functions $\mathfrak{G}$ and $\mathfrak{F}^+$in a field alternating in τ of the form $A(r,\tau)=A(k,\omega_0)\,e^{ikr-i\omega_0\tau}$. Instead of (37.11), we now get for the Fourier components of the current $j(k,\omega_0)$:

$$\begin{aligned}j(k,\omega_0)=-\frac{2e^2}{(2\pi)^3m^2}T\sum_{\omega}\int p\,(p\cdot A(k,\omega_0))[&\mathfrak{G}(p_+)\,\mathfrak{W}(p_-)\\ &+\mathfrak{F}(p_+)\,\mathfrak{F}^+(p_-)]\,\mathrm{d}^3p-\frac{Ne^2}{m}A(k,\omega_0)\end{aligned}$$

(here $p_\pm=\{p\pm1/2k;\omega'\pm1/2\omega_0\}$). On repeating the course of the arguments that led us, in the case of a constant field, to expression (37.15), we get after integration over ξ:

$$\begin{aligned}\bar{Q}(k,\omega_0)=&\frac{3\pi T}{4}\sum_{\omega'}\int_{-1}^{+1}(1-\beta^2)\,\mathrm{d}\beta\\ &\times\left\{\frac{i\left(\omega_++\sqrt{\omega_+^2+\Delta^2}\right)\left[i\left(\omega_-+\sqrt{\omega_+^2+\Delta^2}\right)-v|k|\beta\right]+\Delta^2}{\sqrt{\omega_+^2+\Delta^2}\left[\omega_-^2+\Delta^2+\left(v|k|\beta-i\sqrt{\omega_+^2+\Delta^2}\right)^2\right]}\right.\\ &\left.+\frac{i\left(\omega_-+\sqrt{\omega_-^2+\Delta^2}\right)\left[i\left(\omega_++\sqrt{\omega_-^2+\Delta^2}\right)+v|k|\beta\right]+\Delta^2}{\sqrt{\omega_-^2+\Delta^2}\left[\omega_+^2+\Delta^2+\left(v|k|\beta+i\sqrt{\omega_-^2+\Delta^2}\right)^2\right]}\right\}\end{aligned}\tag{37.24}$$

As above, certain assumptions must be made in regard to $v|\boldsymbol{k}|$ in order further to simplify this expression. We shall confine ourselves below to the case of most practical interest. when $v|k| \gg (T_c, \omega_0)$. In this case, as before, the main contribution to the expression for $\bar{Q}(k, \omega_0)$ comes from the range of angles where $\beta \sim T_c/v|k|, \omega'/v|k|$, so that we can neglect β^2 by comparison with unity in the numerator of the integrand. The remaining expression in curly brackets decreases when $\beta \gg T_c/v|k|$, $\omega'/v|k|$ rather more slowly than in the $T = 0$ case, namely, as $1/\beta$. It is therefore advisable to carry out a rearrangement of (37.24), separating out the more slowly decreasing terms:

$$\begin{aligned}
&\bar{Q}(k, \omega_0) \\
&= \frac{3\pi T}{4} \sum_{\omega'} \int_{-1}^{1} \mathrm{d}\beta \left\{ \frac{\Delta^2 - \left(\omega_+ + \sqrt{\omega_+^2 + \Delta^2}\right)\left(\omega_- + \sqrt{\omega_-^2 + \Delta^2}\right)}{\sqrt{\omega_+^{2+} + \Delta^2}\left[\omega_-^2 + \Delta^2 + \left(v|k|\beta - i\sqrt{\omega_+^2 + \Delta^2}\right)^2\right]} \right. \\
&+ \frac{\Delta^2 - \left(\omega_- + \sqrt{\omega_-^2 + \Delta^2}\right)\left(\omega_+ + \sqrt{\omega_+^2 + \Delta^2}\right)}{\sqrt{\omega_-^2 + \Delta^2}\left[\omega_+^2 + \Delta^2 + \left(v|k|\beta + i\sqrt{\omega_-^2 + \Delta^2}\right)^2\right]} \\
&- i \frac{\omega_+ + \sqrt{\omega_+^2 + \Delta^2}}{\sqrt{\omega_+^2 + \Delta^2}\left[v|k|\beta - i\left(\sqrt{\omega_+^2 + \Delta^2} + \sqrt{\omega_-^2 + \Delta^2}\right)\right]} \\
&\left. + i \frac{\omega_- + \sqrt{\omega_-^2 + \Delta^2}}{\sqrt{\omega_-^2 + \Delta^2}\left[v|k|\beta + i\left(\sqrt{\omega_+^2 + \Delta^2} + \sqrt{\omega_-^2 + \Delta^2}\right)^2\right]} \right\}
\end{aligned}$$

On carrying out the integration and passing to the limit as $v|k| \to \infty$, we get

$$\bar{Q}(k, \omega_0) = \frac{3\pi^2 T}{4v|k|} \sum_{\omega_1} \left[1 + \frac{\Delta^2 - \omega'(\omega' - \omega_0)}{\sqrt{\omega'^2 + \Delta^2}\sqrt{(\omega' - \omega_0)^2 + \Delta^2}} \right]. \tag{37.25}$$

When $\omega_0 = 0$ this result tranforms to (37.18).
Since ω runs over the values $(2n+1)\pi T$ in the summation of (37.25), $\bar{Q}(k, \omega_0)$ can be written as the contour integral:

$$\bar{Q}(k, \omega_0) = \frac{3\pi i}{16v|k|} \int_C \tan\frac{\omega'}{2T} \left\{ 1 + \frac{\Delta^2 - \omega'(\omega' - \omega_0)}{\sqrt{\omega^2 + \Delta^2}\sqrt{(\omega' - \omega_0)^2 + \Delta^2}} \right\} \mathrm{d}\omega \tag{37.26}$$

where the contour C consists of two pieces $C_+$and C_-, as illustrated in Fig. 100. The choice of the analytic branches of the functions $\sqrt{\omega^2 + \Delta^2}$ and $\sqrt{(\omega' - \omega_0)^2 + \Delta^2}$ is clear from the same figure: the values of these functions on the cuts are purely imaginary, the imaginary part being positive to the right of the upper cut and to the left of the lower cut. We pass from an integration over the contours C_+ and $C_-$to an integration over the four contours $C_+^{(1,2)}$ and $C_-^{(1,2)}$ (Fig. 101). It is easily seen that the integrals over $C_+^{(2)}$ and $C_-^{(2)}$, considered formally as functions of ω_0, have singularities at $\omega_0 = (2n+1)\pi T$, since the contour of integration passes in this case through the point $\omega' = (2n+1)\pi T$,

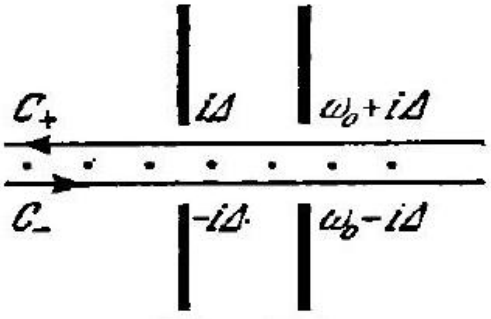

Fig. 100 where $\tan \omega'/2T$ becomes infinite. Hence, in order to find the branch of the function, analytic in the upper half-plane of the variable $\omega = i\omega_0$, we have to transform expression (37.26) at particular points $\omega = 2n\pi Ti$ in such a way that, on later extending this expression to arbitrary values of ω, the contour of integration does not pass through the singularities of the integrand. We observe for this, that if $\omega_0 = 2n\pi T$, by virtue of the periodicity of $\tan \omega'/2T$, the integral over the contour $C_-^{(2)}$ is equal to the integral over $C_+^{(1)}$ (and the same for contours $C_+^{(2)}$ and $C_-^{(1)}$). We can easily verify what has bcen said by replacing the variable of integration, say, in the integral over $C_-^{(2)}$ in accordance with $\omega' - \omega_0 = -\imath$. We can thus write (37.26) as

$$\bar{Q}(k, \omega_0)$$

$$= \frac{3\pi i}{8\vec{v}|\vec{k}|} \left(\int_{c_-^{(1)}} + \int_{c_+^{(1)}} \right) \left\{ \tan \frac{\omega'}{2T} \left[1 + \frac{\Delta^2 - \omega' (\omega' - \omega_0)}{\sqrt{\omega'^2 + \Delta^2} \sqrt{(\omega' - \omega_0)^2 + 1^2}} \right] \right\} d\omega.$$

The expression obtained, regarded formally as a function of $\omega = i\omega_0$, is analytic in the upper half-plane of ω, since the contour of integration, with $\operatorname{Im} \omega > 0$, never passes through a singularity of the integrand.

We can now write down directly the $Q(k, \omega)$ for

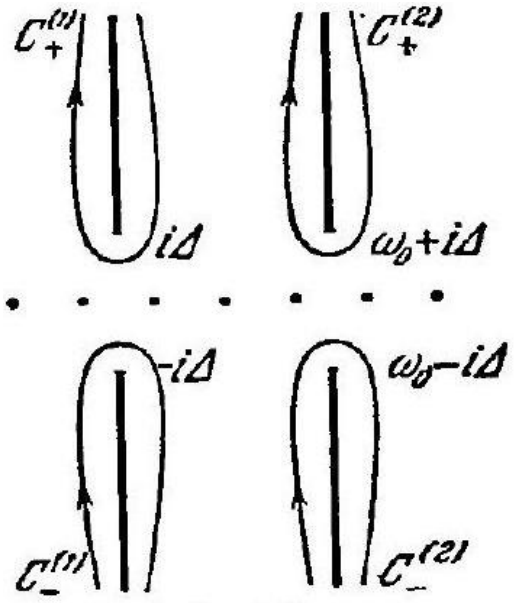

Fig. 101 $\omega > 0$ in which we are interested. Two cases arise: (a) $\omega < 2\Delta$ and (b) $\omega > 2\Delta$. The elementary calculation is performed in both cases in accordance with Fig. 102, where we have indicated in brackets the choice of sign of the imaginary part of the

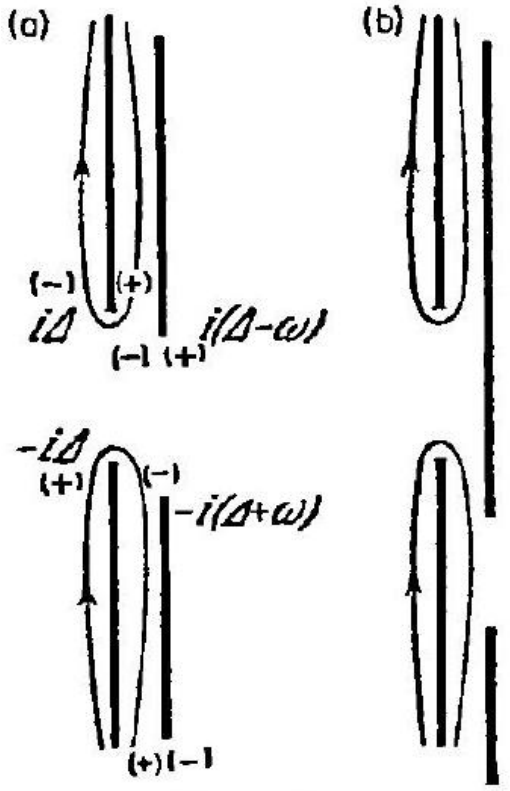

Fig. 102 functions on the different sides of the cuts. Let us quote the results obtained [66, 67]:

(a) $\omega < 2\Delta$:

$$\bar{Q}(k,\omega) = \frac{3\pi}{4v|k|}\left\{\int_{\Delta}^{\Delta+\omega} \tanh\frac{\omega'}{2}\bar{T}\frac{\omega'(\omega'-\omega)+\Delta^2}{\sqrt{\omega^2-\Delta^2}\sqrt{\Delta^2-(\omega'-\omega^2)^2}}\,\mathrm{d}\omega'\right.$$

$$\left.+i\int_{\Delta}^{\infty}\left[\tanh\frac{\omega'}{2T}-\tanh\frac{\omega'+\omega}{2T}\right]\frac{\omega'(\omega'+\omega)+\Delta^2}{\sqrt{\omega'^2-\Delta^2}}\frac{+\omega(\omega'+\omega)^2-\Delta^2}{\sqrt{(\omega'+\omega'}}\right\},$$

(b) $\omega > 24$:

$$\bar{Q}(k,\omega) = \frac{3\pi}{4}\frac{\pi}{i'k'}\left\{\int_{\omega-\Delta}^{\omega+\Delta}\tanh\frac{\omega'}{2T}\frac{\omega'(\omega'-\omega)+\Delta^2}{\sqrt{\omega'^2-\Delta^2}\sqrt{\nu'-(\omega'-\omega)^2}}\,\mathrm{d}\omega'\right.$$

$$+i\int_{\Delta}^{\omega-\Delta}\tanh\frac{\omega'}{2T}\frac{\omega'(\omega'-\omega)+\Lambda^2}{\sqrt{\omega'^2}-\Delta^2\sqrt{(\omega'-\omega^2-\Delta^2}}\mathrm{d}\omega'$$

$$\left.+i\int_{A}^{\infty}\left[\tanh\frac{\omega'}{2T}-\tanh\frac{\omega'+\omega}{2T}\right]\overline{\sqrt{\omega'^2}}(???)\omega'\left(\omega'+\Lambda^2\bar{V}\overline{\overline{(\omega'+\omega)^2-\Lambda^2}}\,\mathrm{d}\omega'\right\}.\right.$$

7.6 5. Type-II Superconductors

7.6.1 5.1 Introduction

The term 'type-II superconductors' was first introduced by Abrikosov in his classic paper [47] where he proposed a detailed phenomenological theory of these materials based on the GL theory and capable of explaining their magnetic properties. Later, with further development of the physics of superconductors, the theory received copious experimental verification.

Here we come across a rare case in which the development of an extensive branch of the

physics of superconductors was initiated by a single theoretical work. Originally, Abrikosov's theory was greeted with a certain skepticism: so much out of the ordinary were its predictions. It was generally accepted only several years later, when it proved to be capable of explaining the complex behavior of superconducting alloys and compounds in a consistent manner. In particular, it explained the very high critical fields of some materials.

We already know that, for type-II superconductors, the energy of an interface between a normal and a superconducting region is $\sigma_{11s} < 0$. This implies that, under certain circumstances, it is energetically favorable for these materials, when placed in an external magnetic field, to become subdivided into alternating normal and superconducting domains.

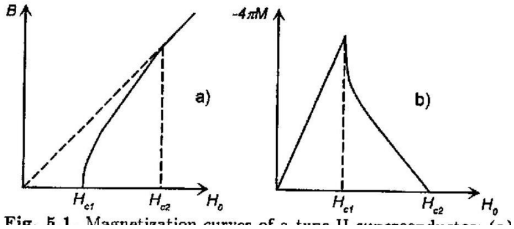

Fig. 5.1. Magnetization curves of a type-II superconductor: (a) magnetic induction B as a function of an external field H_0; (b) magnetic moment per unit volume, M, as a function of H_0

The magnetization curve of a type-II superconductor in the form of a long cylinder placed in a parallel magnetic field is shown schematically in Fig.5.1. As long as the external field is $H_0 < H_{\rm cl}$, the average field in the interior of the specimen is $B = 0$. However, at $H_{\rm c1} < H_0 < H_{\rm c2}$, a steadily increasing field B penetrates the superconductor. This field always remains below the external field H_0 and the specimen's superconductivity is not destroyed. At a certain field $H_0 = H_{\rm c2}$, the average field in the interior, B, becomes equal to H_0 and the bulk superconductivity disappears.

Thus, above $H_{\rm cl}$, a type-II superconductor does not show the MeissnerOchsenfeld effect. Magnetic field penetrates into these materials in a very special way: as quantized vortex filaments. Every filament (or vortex) has a normal core which can be approximated by a long thin cylinder with its axis parallel to the external magnetic field. Inside the cylinder, the order parameter ψ is zero. The radius of the cylinder is of the order ξ, the coherence length. The direction of the supercurrent circulating around the normal core is such that the direction of the magnetic field generated by it coincides with that of the external field and is parallel to the normal core. The vortex current circulates within an area of radius $\sim \lambda$, the penetration depth. The size of this area can be well in excess of ξ because $\lambda \gg \xi$ for type-II superconductors.

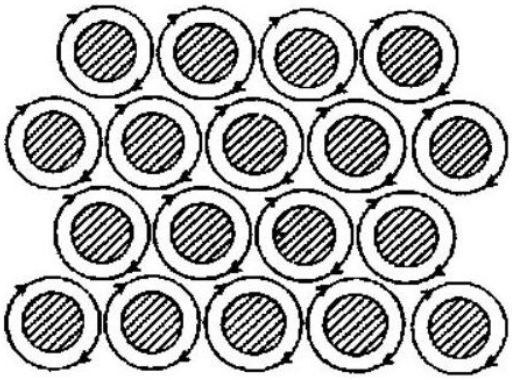

Fig. 5.2. Mixed state of a type-II superconductor. Superconducting vortices form a regular triangular lattice. Vortex cores (dashed areas) are normal

Each vortex carries one magnetic flux quantum. Penetration of vortices into the interior of a superconductor becomes thermodynamically favorable at $H_0 > H_{\rm c1}$. Once inside the superconductor, the vortices arrange themselves at distances $\sim \lambda$ from each other so that in the cross-section they form a regular triangular lattice, as sketched in Fig. 5.2.

This state of the superconductor is referred to as the mixed state because it is characterized

by a partial penetration of the magnetic field in the interior of the specimen. The mixed state is observed at fields from $H_{\rm cl}$ (the lower critical field) to $H_{\rm c2}$ (the upper critical field).

Once formed at $H_{\rm c1}$, the vortex lattice persists at much higher fields. As the external field increases, the lattice period steadily decreases and the density of the vortices rises. Finally, at a field $H_0 = H_{\rm c2}$, the vortex lattice grows so dense that the distance between the neighboring vortices, i.e., the lattice period, becomes of the order ξ. This means that the normal cores of becomes zero over the entire volume of the superconductor. In other words, a second-order phase transition occurs.

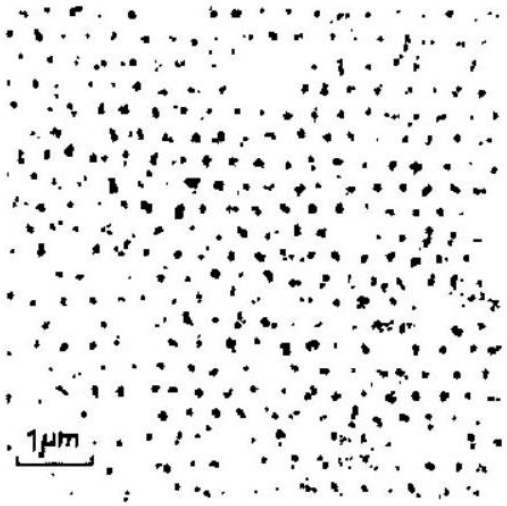

Fig. 5.3. Mixed state in niobium as observed in the electron microscope [48]

The existence of the mixed state in type-II superconductors has been reliably verified by experiment. In addition to numerous indirect proofs, a spectacular direct experimental demonstration of the vortex array is due to Truble and Essmann [48]. They covered the top of a type-II superconducting cylinder with a thin organic film and placed it in a magnetic field so that the specimen was driven to the mixed state. Then a thin layer of fine ferromagnetic particles was sputtered onto the surface covered with the film. As the ferromagnetic particles approached the surface, they were preferentially attracted to the sites where the magnetic field lines emerged from the superconductor, i.c., to the locations of the vortices. Then, having peeled the organic film off the specimen and placed it in the electron microscope, the authors were able to enjoy a direct view of the mixed state (see Fig. 5.3).

7.6.2 5.2 Field of an Isolated Vortex

Let us turn to a systematic study of the mixed state. We start with the simplest case: an isolated vortex. We already know that an isolated vortex in an infinite superconductor comprises a normal core of radius $\sim \xi$ and vortex currents circulating within an area $\sim \lambda$. Assume that the GL parameter is $\kappa \gg 1$. Then $\lambda \gg \xi$. At a distance $r \gg \xi$ we have $|\psi|^2 = 1$. Let us focus on this part of the vortex. The GL equation for the vector potential (3.24) can be written as

$$\text{curlcurl}\, \boldsymbol{A} = \frac{1}{\lambda^2}\left(\frac{\Phi_0}{2\pi}\nabla\theta - \boldsymbol{A}\right). \tag{5.1}$$

Noting that $\text{curl}\, \boldsymbol{A} = \boldsymbol{H}$, we obtain from (5.1)

$$\text{curl}\, \boldsymbol{H} = \frac{1}{\lambda^2}\left(\frac{\Phi_0}{2\pi}\nabla\theta - \boldsymbol{A}\right) \tag{5.2}$$

Evaluatng the curl of both parts of (5.2), we obtain

$$H + \lambda^2 \operatorname{curlcurl} H = \frac{\Phi_0}{2\pi} \operatorname{curl} \nabla\theta \tag{5.3}$$

At any point of the vortex, apart from its center, we have curl $\nabla\theta = 0$, since curl $\nabla_\varphi = 0$, where φ is an arbitrary function. But the center of the vortex represents a singularity, there we have $|\nabla\theta| \to \infty$. To understand how curl $\nabla\theta$ behaves at the center of the vortex, we shall take its integral over the surface of a small circle centered on the center of the vortex:

$$\int_{\odot} \operatorname{curl} \nabla\theta \cdot \mathrm{d}S.$$

By Stokes's theorem,

$$\int_{\odot} \operatorname{curl} \nabla\theta \cdot \mathrm{d}\boldsymbol{S} = \oint \nabla\theta \cdot \mathrm{d}l,$$

where the path integral is taken along the circumference of our circle. Since after every full circle around the center of the vortex, the phase changes by 2π (recall that each vortex carries one flux quantum), we have

$$\int_{\odot} \operatorname{curl} \nabla\theta \cdot \mathrm{d}\boldsymbol{S} = 2\pi \tag{5.4}$$

Thus the function curl $\nabla\theta$ is zero everywhere except for the center of the vortex. At the center, it is infinite but its integral, according to (5.4), equals 2π. This corresponds to the behavior of the δ-function and we therefore can write

$$\operatorname{curl} \nabla\theta = 2\pi\delta(r)e_{\mathrm{v}},$$

where e_v is the unit vector along the vortex.
As a result; (5.3) can be replaced by

$$\boldsymbol{H} + \lambda^2 \operatorname{curl} \operatorname{curl} \boldsymbol{H} = \Phi_0 \delta(\boldsymbol{r}) \boldsymbol{e}_{\mathrm{v}} \tag{5.5}$$

subject to the boundary condition $H(\infty) = 0$. The solution of (5.5) is

$$h = \frac{\Phi_0}{2\pi\lambda^2} K_0(r/\lambda), \tag{5.6}$$

where K_0 is the MacDonald function, or the Hankel function of imaginary argument.
The asymptotic behavior of this function is:

$$K_0(z) \sim \begin{cases} \ln(1/z) & \text{at } z \ll 1, \\ \mathrm{e}^{-z}/z^{1/2} & \text{at } z \gg 1. \end{cases} \tag{5.7}$$

Thus, K_0 diverges logarithmically at small arguments and goes exponentially to zero at large ones. As follows from (5.6) and (5.7), the magnetic field
because these expressions do not hold in the vicinity of the normal core (of radius $\sim \xi$). Therefore, the field at the center of the vortex can be obtained to logarithmic accuracy by setting a cut-off at $r = \xi$:

$$H(0) \approx \frac{\Phi_0}{2\pi\lambda^2} \ln \kappa \tag{5.8}$$

A more accurate value of $H(0)$ can be obtained by taking into account the actual variation of $\psi(r)$ in the vortex core and carrying out numerical integration of the GL equations [47]:

$$H(0) = \frac{\Phi_0}{2\pi\lambda^2}(\ln\kappa - 0.18). \tag{5.9}$$

The above correction is not essential since all the calculations are carried out on the assumption that $\kappa \gg 1$.

The spatial variation of the magnetic field of an isolated vortex is illustrated in Fig. 5.4.

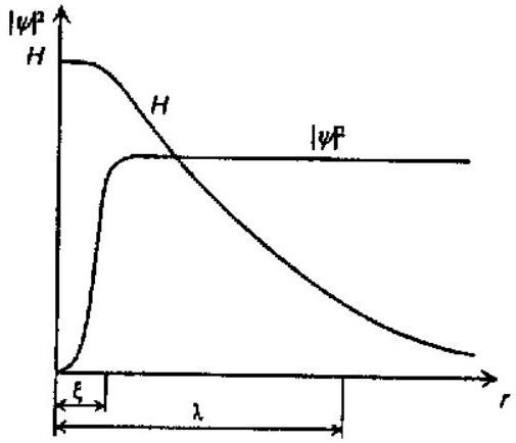

Fig. 5.4. Single vortex in an infinite superconductor. Shown are spatial distributions of the order parameter and the magnetic field of the vortex

7.6.3 5.3 The Lower Critical Field

Let us find the lower critical field $H_{\rm cl}$, that is, the lowest field at which formation of vortices in a type-II superconductor becomes thermodynamically favorable.

First we should find the free energy of a vortex, or, more accurately, the free energy of a superconductor containing one vortex, ε, measured relative to its free energy without the vortex. We shall consider the case $\kappa \gg 1$ or $\lambda \gg \xi$. Our specimen in this case is a typical London superconductor and the corrections due to $\nabla\psi$ are negligible. Therefore, we can use the London expression for the free energy (2.8):

$$\varepsilon = \frac{1}{8\pi}\int \left[\boldsymbol{H}^2 + \lambda^2(\operatorname{curl}\boldsymbol{H})^2\right] \mathrm{d}V, \tag{5.10}$$

where the integration is carried out over the space between two infinite parallel planes perpendicular to the vortex and separated by a unit length. Then (5.10) is simply the sum of the magnetic and kinetic energies of the superconducting electrons contained in the vortex, per unit length of the vortex. Making use of the formula

$$(\operatorname{curl}\boldsymbol{H})^2 = \boldsymbol{H}\cdot\ \operatorname{curl}\operatorname{curl}\ \boldsymbol{H} - \operatorname{div}[(\operatorname{curl}\boldsymbol{H})\times\boldsymbol{H}]$$

we have

$$\varepsilon = \frac{1}{8\pi}\int H\cdot\left(H + \lambda^2\operatorname{curlcurl} H\right)\mathrm{d}V - \lambda^2\int \operatorname{div}[(\operatorname{curl} H)\times H]\mathrm{d}V$$

By Gauss's theorem, we can convert the second integral into a surface integral:

$$\int \operatorname{div}[(\operatorname{curl}\boldsymbol{H})\times\boldsymbol{H}]\mathrm{d}V = \oint[(\operatorname{curl}\boldsymbol{H})\times\boldsymbol{H}]\cdot\mathrm{d}\boldsymbol{S}$$

where the surface integral is taken over an infinitely remote surface and the surfaces $z = 0$ and $z = 1$ (the vortex is assumed to be parallel to the z axis). Since H is perpendicular to the planes $z = 0$ and $z = 1$, the vector $(\operatorname{curl}\boldsymbol{H})\times\boldsymbol{H}$ is parallel to the planes $z = 0$ and $z = 1$ and

the vector $\mathrm{d}\boldsymbol{S}$ is perpendicular to them. Hence the expression under the integral sign is zero over these planes. On the other hand, at $r \to \infty$ we have $H \to 0$ and so the above expression is zero there, too. Then

$$\int \operatorname{div}[(\operatorname{curl} H) \times H]\mathrm{d}V = 0$$

and

$$\varepsilon = \frac{1}{8\pi} \int \boldsymbol{H} \cdot \left(\boldsymbol{H} + \lambda^2 \operatorname{curlcurl} \boldsymbol{H}\right) \mathrm{d}V$$

Noting that $\boldsymbol{H}$ must satisfy (5.5), we have

$$\varepsilon = \frac{\Phi_0}{8\pi} H(0) \tag{5.11}$$

Substituting (5.8) into this expression, we obtain

$$\varepsilon = \left(\frac{\Phi_0}{4\pi\lambda}\right)^2 \ln \kappa \tag{5.12}$$

In deriving (5.12), we neglected a small additional contribution to the vortex energy due to the fact that the core is normal. Indeed, the free energy density of the core exceeds that of the surrounding areas by $F_\mathrm{n} - F_{\mathrm{s}0} = H_\mathrm{cm}^2/8\pi$, that is, by the lost condensation energy. Then, if the core radius is taken to be ξ, the additional energy disregarded in (5.12) is $(H_\mathrm{cm}^2/8\pi)\,\pi\xi^2$. Using (3.38), it is easy to show that this energy is

$$\frac{1}{4}\left(\frac{\Phi_0}{4\pi\lambda}\right)^2 \ll \left(\frac{\Phi_0}{4\pi\lambda}\right)^2 \ln \kappa$$

More rigorous calculations of the condensation energy lost in the core lead to the following final expression for the energy of an isolated vortex line:

$$\varepsilon = \left(\frac{\Phi_0}{4\pi\lambda}\right)^2 (\ln \kappa + 0.08) \tag{5.13}$$

It follows from (5.13) that the energy of an isolated vortex is positive, that is, without an external field, the vortex cannot exist in the interior of a superconductor. Hence, if a bulk superconductor is placed in a weak external field, no vortices are formed: Their formation is not favored by the energy. Instead, the superconductor remains in the Meissner state, just as a type-I superconductor. Let us find the minimum value of the field at which vortex formation in a type-II superconductor becomes favorable.

We already know that, for a superconductor in an external magnetic field, the energy that is a minimum at equilibrium is the Gibbs free energy $\mathcal{G}$. Per unit length of the vortex, this energy is

$$\mathcal{G} = \varepsilon - \int \frac{\boldsymbol{B} \cdot \boldsymbol{H}_0}{4\pi}\, \mathrm{d}V \tag{5.14}$$

where H_0 is the external magnetic field and the free energy of a vortex of unit length is ε. Indeed, by (1.22), the Gibbs free energy density is

$$G = F - B \cdot H_0/4\pi$$

where F is the free energy density. Since H_0 is applied externally, it can be taken out of the integral sign in (5.14). Then, recalling that the vortex carries one magnetic flux quantum Φ_0, we have

$$\mathcal{G} = \varepsilon - \frac{\Phi_0 H_0}{4\pi} \tag{5.15}$$

Clearly, for a sufficiently weak external field $H_0, \mathcal{G} > 0$ and vortex formation is not favored. However, there exists such a field $H_{\rm cl}$, starting from which $\mathcal{G}$ becomes negative, i.e. formation of a vortex reduces the energy. It follows from (5.15) that

$$H_{\rm c1} = 4\pi\varepsilon/\Phi_0 \tag{5.16}$$

Making use of (5.13), we obtain the lower critical field for a type-II superconductor:

$$H_{\rm c1} = \frac{\Phi_0}{4\pi\lambda^2}(\ln\kappa + 0.08) \tag{5.17}$$

Comparing (5.17) and (5.8), one can see that the lower critical field is approximately half the field at the center of an isolated vortex.

Let us emphasize once again that all the above estimates are valid for superconductors with $\kappa \gg 1$ and are of logarithmic accuracy.

The field $H_{\rm cl}$ is a relatively weak field. For instance, if $\kappa \sim 100$ and $H_{r1,1} \sim 10^3$ Oe, we have $H_{r1} \sim 30$ Oe.

7.6.4 5.4 Interaction Between Vortices

In the preceding section we have analyzed the properties of an isolated vortex But the number of vortices in the mixed state is usually large and they interact strongly with each other. The objective of this section is to understand how they interact.

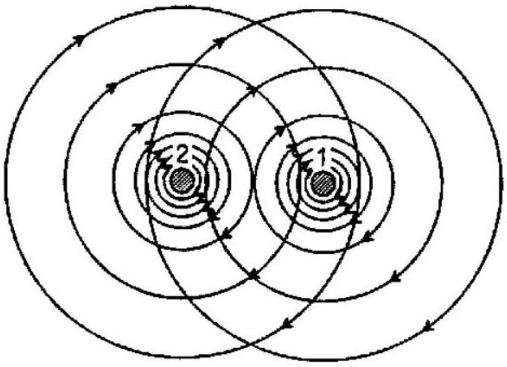

Fig. 5.5. Interaction of two parallel vortices of the same orientation

Consider two parallel vortices of the same orientation in an infinite superconductor. As before, we assume that $\kappa \gg 1$. As long as the distance between the vortices exceeds λ, they do not 'feel' each other. But when their distance becomes less than λ, the core of one vortex moves into the area where the supercurrents of the other vortex circulate, as illustrated in Fig. 5.5. It is evident from the figure that the superfluid components of the electron velocity to the right of vortex 1 and to the left of vortex 2 add up while those in between the vortices subtract from each other. This means that in the area adjoining the core of vortex 1 (to the right of it), the Bernoulli pressure is less than on its left. This results in a difference of Bernoulli pressures exerted on the core of vortex 1 in the direction from left to right. Applying similar arguments to vortex 2, one can conclude that two parallel vortices of the same sign repel each other and the repulsion force acts only on the vortex core.

Let us now work out the force between two parallel vortices. Assume that the coordinates of the vortex cores are r_1 and r_2, respectively. By (2.8), the energy of a superconductor containing two vortices measured from its energy without vortices is

$$\mathcal{F} = \frac{1}{8\pi} \int \left[\boldsymbol{H}^2 + \lambda^2 (\operatorname{curl} \boldsymbol{H})^2 \right] \mathrm{d}V \tag{5.18}$$

Here $\boldsymbol{H}$ is the total magnetic field generated by the two vortices. This field must satisfy an equation constructed by analogy with (5.5):

$$H + \lambda^2 \operatorname{curl} \operatorname{curl} H = \Phi_0 \left[\delta (r - r_1) + \delta (r - r_2) \right] e_{\mathrm{v}}$$

After a series of transformations analogous to those in the foregoing section,

$$\mathcal{F} = \frac{\Phi_0}{8\pi} \left[H (r_1) + H (r_2) \right] \tag{5.19}$$

Here $H (r_1)$ is the field at the center of vortex 1 . It incorporates the field generated by vortex 1 itself and the field $H_{12}(x)$ due to vortex 2 (the latter is separated from vortex 1 by the distance $x = |r_1 - r_2|$). The same applies to the field $H (r_2)$. Then it follows from (5.19) that

$$\mathcal{F} = 2\varepsilon + \frac{\Phi_0}{8\pi} 2 H_{12}(x) \tag{5.20}$$

where ε is the energy of an isolated vortex defined by (5.13).
The physical significance of (5.20) is evident: the first term is the energy of two noninteracting vortices and the second term is the energy of their interaction. Denote the latter by $U(x)$:

$$U(x) = \frac{\Phi_0 H_{12}(x)}{4\pi} \tag{5.21}$$

Then the interaction force per unit length of the vortex is

$$f = -\frac{\mathrm{d}U}{\mathrm{d}x} = -\frac{\Phi_0}{4\pi} \frac{\mathrm{d}H_{12}}{\mathrm{d}x}$$

Taking into account that for two parallel vortices, according to Maxwell's equations,

$$\frac{\mathrm{d}H_{12}}{\mathrm{d}x} = \frac{4\pi}{c} j_{12}(x)$$

where $j_{12}(x)$ is the current density induced by the first vortex at the center of the second vortex (or vice versa), we have

$$|f| = \frac{1}{c} j_{12} \Phi_0 \tag{5.22}$$

The above formula is also valid in a more general case: If there is an externally applied current j circulating around a vortex, it exerts a Lorentz force on the vortex core, per unit length,

$$f_{\mathrm{L}} = \frac{1}{c} \left[j \times \Phi_0 \right] \tag{5.23}$$

where j is the density of the external current at the location of the normal core and $\boldsymbol{\Phi}_0 = \boldsymbol{e}_{\mathrm{v}} \boldsymbol{\Phi}_0$.

7.6.5 5.5 The Upper Critical Field

The mixed state of a homogeneous type-II superconductor is characterized by a regular, usually triangular, vortex lattice. As the external field is increased, the lattice period decreases and when it becomes of the order of the coherence length ξ, a second-order phase transition occurs from the mixed to the normal
state. This happens when the external field reaches the value of the upper critical field H_{c2}.

We can estimate the order of magnitude of H_{c2} even without exact calculations, proceeding from the following arguments. For two neighboring vortices at a distance ξ from each other, the distance ξ can be interpreted as the thickness of a superconducting layer separating their normal cores. It can be roughly approximated by a thin film of thickness ξ. But we know from Sect. 3.5 that a thin film in a parallel magnetic field undergoes a second-order phase transition to the normal state at the field $H_{c||} \sim H_{cm}\,\lambda/d$, where d is the thickness of the film. If, as in our case, the film thickness is ξ, one should expect the transition to the normal state at an external field $\sim H_{cm}\lambda/\xi$. This provides us with a simple estimate of the upper critical field:

$$H_{c2} \sim \kappa H_{cm}. \tag{5.24}$$

Our estimate differs from the result of exact calculations only by a numerical factor $\sqrt{2}$ [47]:

$$H_{c2} = \sqrt{2}\kappa H_{cm} \tag{5.25}$$

The upper critical field can be rather large. For example, for $\kappa \sim 100$ and $H_{cm} \sim 10^3$ Oe we obtain $H_{c2} \sim 10^5$ Oe.

Using (5.25), the expression $\kappa = \lambda/\xi$, and (3.38), namely, $\sqrt{2}H_{cm} = \Phi_0/2\pi\lambda\xi$, we get

$$\Phi_0 = 2\pi\xi^2 H_{c2} \tag{5.26}$$

The last formula is very useful for determining the coherence length ξ because it relates ξ to a quantity which can be easily measured in experiment: the upper critical field.

7.6.6 5.6 Reversible Magnetization of a Type-II Superconductor

Let us work out an expression for the magnetic moment per unit volume of a type-II superconductor, when the latter is in the mixed state and when the external field is $H_0 \gg H_{c1}$. In other words, let us find the dependence $M(H_0)$.

This problem could be handled in the usual way by varying the energy of the system in order to find the equilibrium value of the magnetic moment. But we shall instead employ a somewhat artificial method which will allow us to shorten the computations.

Consider a bulk cylinder of a type-II superconductor, with its axis parallel to the z axis, in a longitudinal magnetic field H_0. Assume that the coherence length ξ depends only on the x coordinate and increases monotonically with x.
field H_{c2} will also depend on x, namely, it will decrease with increasing x. As a result, the magnetic flux density (induction) B will become a function of x, that means that a current j will start in the interior of the sample, in the direction of the y axis:

$$j = \frac{c}{4\pi}\frac{\mathrm{d}B}{\mathrm{d}x}$$

Recalling that $B = H_0 + 4\pi M$, we arrive at $M = M(x)$, that is,

$$j = c\frac{\mathrm{d}M}{\mathrm{d}x}.$$

Furthermore, the current exerts a Lorentz force on each vortex

$$f_{\mathrm{L}} = \frac{1}{c} j \Phi_0 = \Phi_0 \frac{\mathrm{d}M}{\mathrm{d}x}. \tag{5.27}$$

On the other hand, since the system of vortices is at equilibrium, the force f_{L} must be compensated by another force. The origin of this second force is evident: If $\xi = \xi(x)$, the self-energy of a vortex, ε, also becomes a function of x resulting in a force $-\nabla\varepsilon$ on the vortex, where (see (5.12))

$$\varepsilon = \left(\frac{\Phi_0}{4\pi\bar{\lambda}}\right)^2 \ln\kappa = \left(\frac{\Phi_0}{4\pi\bar{\lambda}}\right)^2 \ln\frac{\lambda}{\xi} \tag{5.28}$$

Differentiating (5.28) and equating it to the right-hand side of (5.27), we obtain a condition for equilibrium:

$$\Phi_0 \frac{\mathrm{d}M}{\mathrm{d}x} = \left(\frac{\Phi_0}{4\pi\dot{\lambda}^-}\right)^2 \frac{1}{\xi}\frac{\mathrm{d}\xi}{\mathrm{d}x}$$

Following integration, we obtain

$$M = \frac{\Phi_0}{16\pi^2\lambda^2} \ln\frac{\xi}{l} \tag{5.29}$$

where l is the integration constant with dimensions of length.
Now we seek the dependence $M(H_0)$. The only quantity in (5.29) depending on H_0 is l. We can find the relation between H_0 and l in the following way. Since an increase of x is followed by a monotonic increase of ξ and a monotonic decrease of H_{c2}, it is clear that, at some point x_0, the field H_{c2} becomes equal to the external field H_0. This means that at this particular point $M(x_0) = 0$, i.e., $l = \xi(x_0)$. On the other hand, the relation between ξ and H_{c2} is given by (5.26). Applying it to x_0, we have

$$2\pi l^2 H_0 = \Phi_0.$$

Hence the ratio ξ/l is

$$\frac{\xi}{l} = \left(\frac{H_0}{H_{\mathrm{c2}}}\right)^{1/2} \tag{5.30}$$

Substituting (5.30) in (5.29), we obtain
or

$$M = -\frac{\Phi_0}{16\pi^2\bar{\lambda}^2} \ln\left(\frac{H_{\mathrm{c2}}}{H_0}\right)^{1/2}$$

$$M = -\frac{\Phi_0}{32\pi^2\lambda^2} \ln\frac{H_{\mathrm{c2}}}{H_0} \tag{5.31}$$

From the last expression, one can derive the dependence $B(H_0)$:

$$B = H_0 - \frac{\Phi_0}{8\pi\lambda^2} \ln\frac{H_{\mathrm{c2}}}{H_0} \tag{5.32}$$

The above formulas are correct to logarithmic accuracy, provided $\kappa \gg 1$. Let us employ them to work out the details of the $M(H_0)$ dependence at fields H_0 close to H_{c2}. Writing H_{c2}/H_0 as

$$\frac{H_{\mathrm{c2}} - H_0}{H_0} + 1$$

we obtain, instead of (5.31),

$$M = -\frac{\Phi_0}{32\pi^2\lambda^2}\ln\left(1+\frac{H_{c2}-H_0}{H_0}\right) \approx -\frac{\Phi_0}{32\pi^2\lambda^2}\frac{H_{c2}-H_0}{H_0}.$$

Finally, using (5.26), we have

$$-4\pi M = \frac{H_{c2}-H_0}{4\kappa^2} \tag{5.33}$$

Thus we have found that $|M|$ decreases linearly as $H \to H_{c2}$. An exact calculation of $M(H_0)$ in this field range was carried out by Abrikosov [47] with the result

$$-4\pi M = \frac{H_{c2}-H_0}{1.16\,(2\kappa^2-1)} \tag{5.34}$$

It is easy to see that at $\kappa \gg 1$ we can omit the term -1 in parenthesis, Then the exact formula (5.34) will differ from the approximate one (5.33) only by a numerical coefficient ~ 1.

Let us clarify a question which might cause some confusion: What is $H_{\rm cm}$ for a type-II superconductor? In a type-I superconductor, it is the thermodynamic critical field at which the superconductor goes to the normal state. Now, what happens to a type-II superconductor at $H_{\rm cm}$? The answer is: nothing special. There are no special features on the magnetization curve at $H_{\rm cm}$. For a type-II superconductor, the quantity $H_{\rm cm}$ should be considered simply as a measure of the extent to which the superconducting state of a particular material is favored over its normal state in the absence of magnetic field:

$$F_{\rm n} - F_{\rm s0} = H_{\rm cm}^2/8\pi$$

Alternatively, one can say that, for a type-II superconductor, a transition to the normal state occurs when the work done to magnetize it is $F_n - F_{50}$:

$$-\int_0^{H_{c2}} M\ {\rm d}H_0 = H_{\rm cm}^2/8\pi$$

From the last expression we obtain the following definition of $H_{\rm cm}$ for a type-II superconductor:

$$H_{\rm cm}^2 = 2\int_0^{H_{c2}} [H_0 - B(H_0)]\,{\rm d}H_0 \tag{5.35}$$

7.6.7 5.7 Surface Superconductivity. The Third Critical Field

Consider a type-II superconductor in an external magnetic field H_0 decreasing from $H_0 > H_{c2}$. At the moment when H_0 falls just below H_{c2}, superconducting nuclei appear all over the volume of the superconductor and a tightly packed vortex lattice forms. The order parameter ψ at this field is small ($|\psi| \ll 1$). In other words, a phase transition of second order occurs as the material goes from the normal ($H_0 > H_{c2}$) to the mixed state ($H_0 \le H_{c2}$).

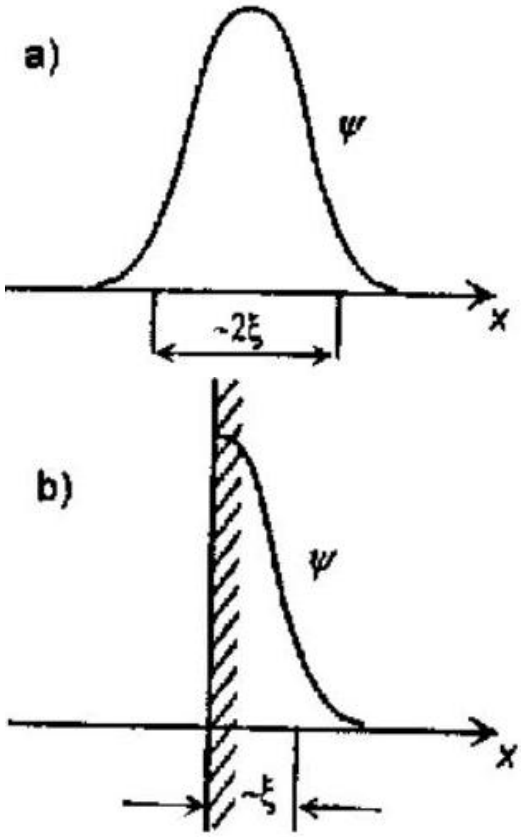

Fig. 5.6. (a) Wavefunction ψ of a nucleus of the superconducting state in an infinite superconductor, the size of the nucleus is $\sim 2\xi$; (b) the same for a superconducting semispace, the size of the nucleus is $\sim \xi$

The nucleus of superconductivity mentioned above is a region between the normal cores of two neighboring vortices. The thickness of this region is of the order $2\xi(T)$ because, if the vortex lattice is close-packed and the radius of the normal core is assumed to be ξ, the distance between the core centers is $\sim 2\xi$. The dependence of the order parameter on the coordinate along the line joining the vortex centers is sketched in Fig. 5.6 (a): The nucleus in this cross-section has the form of a dome-shaped curve.

This is how superconductivity arises in the bulk of a type-II superconductor at H_{c2}. It turns out, however, that at the surface of a superconductor, the superconducting state can exist in much higher fields, provided the surface is parallel to the external field.

Consider a semi-infinite superconducting space occupying the semispace $x > 0$, in an external magnetic field H_0 parallel to the z axis. Since the surface of the superconductor coincides with the plane $x = 0$, a nucleus of superconductivity, which forms at the surface, can be expected to have an
a surface nucleus is shown in Fig. 5.6 (b). Furthermore, the critical field for the formation of such a nucleus can be expected to be larger than the critical field for nucleation of bulk superconductivity. This follows from (3.62), the expression for the critical field of a thin film, which is the most relevant reference case when considering surface superconductivity. A decrease of the film thickness results in an increase of its critical field. Therefore, we should expect the critical field for nucleation of surface superconductivity to be approximately twice the critical field for bulk superconductivity. We shall refer to this new critical field as the third critical field and denote it by H_{c3}. Numerical calculations [49] have shown that

$$H_{c3} = 1.69 H_{c2} \tag{5.36}$$

Now we can draw some conclusions. It follows from the above argumentation that, as the

external magnetic field decreases and reaches the value H_{c3} from above, a thin superconducting layer appears at the surface of a superconductor. The thickness of the layer is of the order $\xi(T)$. The bulk of the superconductor remains normal and the magnetic field there is equal to the external field. In the surface superconducting layer, the magnetic field is somewhat weakened as is the case in thin superconducting films in a parallel magnetic field. The analogy with a thin film also implies the presence of screening currents circulating along both the inner and outer surfaces of the superconducting layer in opposite directions.

What happens to the surface superconducting layer as the external field decreases further, below H_{c3}? According to detailed calculations, both the amplitude of the order parameter, f_0, and the thickness of the superconducting layer, Δ, increase with decreasing field. Their field dependences for several values of the GL parameter κ are shown in Figs. 5.7 and 5.8.

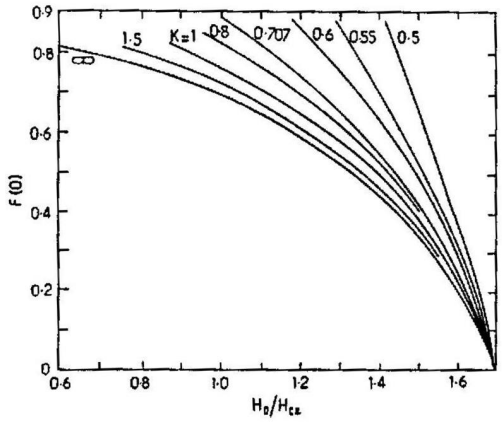

Fig. 5.7. Amplitude of the order parameter, $\mathrm{F}(0) = f_0$, at the surface of a superconductor versus external magnetic field, for several values of κ [50]

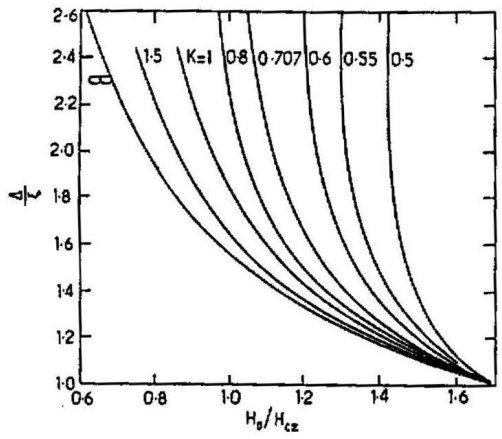

Fig. 5.8. Thickness Δ of a surface superconducting layer as a function of the external magnetic field, for several values of κ [50]

If the surface of a superconductor is covered with a layer of normal metal, it causes a reduction of H_{c3} to a value very close to H_{c2}.

It is interesting to note that the phenomenon of surface superconductivity can also be observed in some type-I superconductors. Indeed, nowhere in the above argumentation was it assumed that $\kappa > 1/\sqrt{2}$, and the result still was $H_{c3} = 1.69H_{c2} = 1.69\sqrt{2}\kappa H_{cm}$. Surface superconductivity arises if H_{c3} is larger than H_{cm}, i.e., provided

$$1.69\sqrt{2}\kappa H_{cm} > H_{crn} \tag{5.37}$$

Thus, the condition for the existence of surface superconductivity in a type-I superconductor is

$$\kappa > \frac{1}{1.69\sqrt{2}} = 0.42.$$

7.6.8 5.8 Surface Barrier. Superheating of the Meissner State

sAll situations considered so far corresponded to thermodynamic equilibrium. For example, we assumed that if penetration of vortices into a type-II superconductor becomes favorable at the lower critical field, the vortices indeed penetrate at that value of the field.

However, a more detailed analysis shows that, in order to penetrate into the interior of a superconductor, vortices must first overcome an energy barrier at the surface.

Consider an ideally smooth surface of a superconductor and an isolated vortex in the interior, parallel to the surface. For convenience, we assume

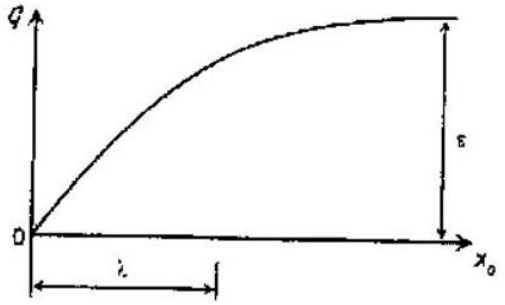

Fig. 5.9. Gibbs free energy of a superconductor containing an isolated vortex, as a function of the vortex distance from the surface, x_0

free energy $\mathcal{G}$ of such a superconductor with a vortex is a function of the distance x_0 between the vortex axis and the surface, as illustrated in Fig. 5.9. It is obvious from the figure that, without an external field, an isolated vortex in the interior of a superconductor is unstable, as expected, and that at sufficiently large distances from the surface, $\mathcal{G}$ is simply equal to the free energy of an isolated vortex, ε. Here, as well as in the following, the energy of a superconductor with a vortex is measured relative to its energy without the vortex.

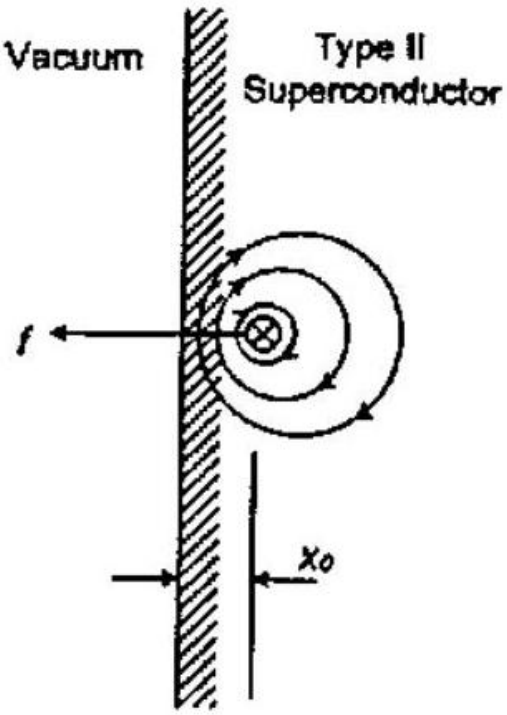

Fig. 5.10. Vortex currents near the surface of a superconductor

Let us explain the form of the function $\mathcal{G}(x_0)$. If $x_0 < \lambda$, the lines of current circulating

around the vortex core are as sketched in Fig. 5.10. It is then evident that, on the left-hand side of the core, the superfluid velocity is larger than on the right-hand side, and the vortex core is subjected to the difference of Bernoulli pressures. This brings about a force pushing the vortex towards the surface. It is easy to see that the same force $f(x_0)$ can be obtained by taking the derivative

$$f = -\mathrm{d}\mathcal{G}/\mathrm{d}x_0 \tag{5.38}$$

which explains the shape of $\mathcal{G}(x_0)$ in Fig.5.9.

To find the force pushing the vortex towards the surface, we shall use the method of images. Since we have assumed $\kappa \gg 1$, the field generated by the vortex satisfies the linear equation (5.5). At the same time, at the surface, the field due to the vortex is zero (this can be proved using arguments similar to those in the well-known problem of a long solenoid: Outside the solenoid, the
condition of zero field at the surface. When solving a linear problem, we may apply the superposition principle and can therefore replace our problem with another, equivalent, one.

Consider an infinite superconductor containing two vortices of opposite signs at $\pm x_0$. Due to the symmetry of the problem, the field at $x = 0$ is zero, while at $x > 0$ equation (5.5) must hold. Since this differential equation has a single-valued solution, the field generated by the two vortices in the semispace $x > 0$ is exactly equal to the field which would be generated by the vortex situated at x_0 if the real surface of a superconductor were present at $x = 0$.

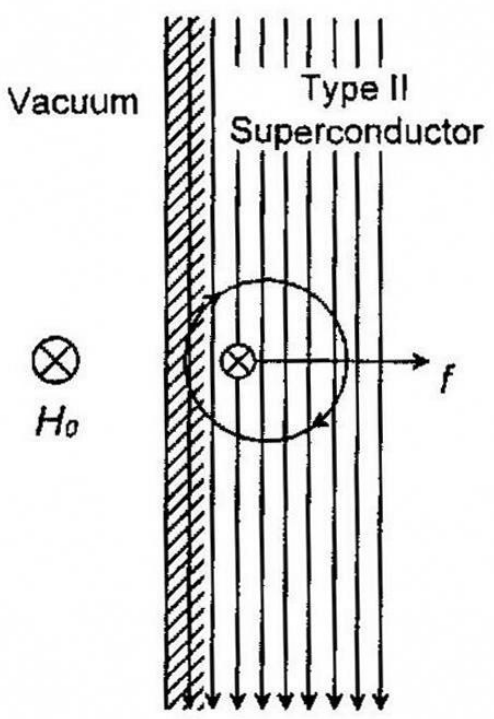

Fig. 5.11. The Meissner current, generated by an external field H_0, pushes the vortex away from the surface

Now it is easy to realize that the interaction of a vortex with the surface (attraction to the surface) can be interpreted as its interaction with its image (also attraction, because the real vortex and the image-vortex have opposite signs).

Let us now switch on an external field H_0 parallel to the surface of the superconductor, as illustrated in Fig. 5.11. This will immediately generate a Meissner current circulating near the surface which will start to push the vortex away from the surface. The result is that, on the one hand, the vortex is attracted to the surface by its own image and, on the other hand, it is repelled from it by the Meissner current. Corresponding variations of the Gibbs free energy with distance, for several values of the external field, are shown in Fig. 5.12. One can see

that at $H_0 < H_{c1}$, a metastable vortex state becomes possible, such that the presence of a vortex in the superconductor is not favored thermodynamically. However, in order to leave the superconductor, the vortex must first overcome an energy barrier. This is the so-called Bean-Livingston barrier.

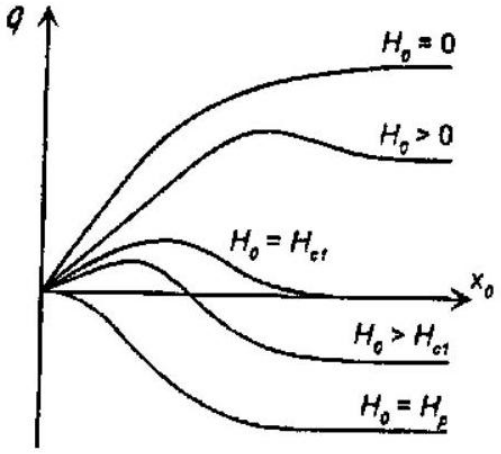

Fig. 5.12. Gibbs free energy of an isolated vortex as a function of its distance from the surface for different values of H_0

The field $H_0 = H_{c1}$ (see Fig. 5.12) is the lowest external field at which it becomes thermodynamically favorable for a vortex to enter the interior of the superconductor. However, the vortex penetration is now hampered by the Bean-Livingston barrier. As we continue to increase the field H_0, the barrier shrinks but does not disappear and the vortex is still unable to penetrate the superconductor. This means that the superconductor remains in the Meissner state which is now metastable and can be understood as a superheated Meissner state.

The barrier finally vanishes at a certain field $H_0 = H_{\mathrm{p}}$, which is sometimes referred to as the superheating field for the Meissner state, or the penetration field. Let us find this field.

Assume that the vortex center is at x_0. The force pushing the vortex towards the surface is the image force, that is, the force due to the interaction of the vortex with the currents generated by its image. From (5.23) we have

$$f_{\mathrm{image}} = \frac{1}{c}\frac{c}{4\pi}\frac{\mathrm{d}H_{\mathrm{v}}}{\mathrm{d}x}\mathbf{\Phi}_0 \tag{5.39}$$

where H_{v} is the field generated by the image vortex and $(c/4\pi)\,(\mathrm{d}H_{\mathrm{v}}/\mathrm{d}x)$ is the current that it generates at $x = x_0$. The interaction force between the vortex and the Meissner current is

$$f_{\mathrm{M}} = \frac{1}{c}\frac{c}{4\pi}\frac{H_0}{\lambda}\mathrm{e}^{-x/\lambda}\Phi_0 \tag{5.40}$$

where $(c/4\pi)\,(H_0/\lambda)\,\mathrm{e}^{-x/\lambda}$ is the current density in the Meissner state.
The Gibbs free energy is

$$\mathcal{G} = -\int f\ \mathrm{d}x \tag{5.41}$$

where $f = f_{\mathrm{M}} + f_{\mathrm{image}}$ is the total force exerted on the vortex. Substituting (5.39) and (5.40) into (5.41) and carrying out the integration, we obtain

$$\mathcal{G}\,(x_0) = -\frac{\Phi_0}{4\pi}H_{\mathrm{v}}\,(2x_0) + \frac{\Phi_0}{4\pi}H_0\mathrm{e}^{-x_0/\lambda} + \ \mathrm{const} \tag{5.42}$$

The field $H_{\mathrm{v}}\,(2x_0)$ in (5.42) is the field generated at x_0 by the image vortex
is still to be determined. At $x_0 \to \infty$, the first two terms in (5.42) are zero. On the other hand, the energy $\mathcal{G}$ at $x_0 \to \infty$ is the Gibbs free energy of a single vortex in an infinite superconductor,

which is defined by (5.15). Using (5.15) and (5.16), we obtain the integration constant in the form

$$\text{const} = \mathcal{G}(\infty) = \frac{\Phi_0}{4\pi}\left(H_{c1} - H_0\right)$$

so that

$$\mathcal{G} = \frac{\Phi_0}{4\pi}\left[H_0 e^{-x_0/\lambda} - H_v\left(2x_0\right) + H_{cl} - H_0\right]. \tag{5.43}$$

It can be easily verified that (5.43) gives a family of curves $\mathcal{G}\left(x_0\right)$ for different values of H_0 which is shown in Fig. 5.12.

The penetration field H_p can be found from a condition which is evident from Fig. 5.12:

$$d\mathcal{G}/dx_{0|x_0=0} = 0. \tag{5.44}$$

Substituting this into the expression for $\mathcal{G}$ (5.43) and using (5.6) and (5.7), we get

$$H_p \approx H_{crn} \tag{5.45}$$

While deriving (5.45) we had to take a derivative of $H_v\left(2x_0\right)$, which caused divergence at $x_0 = 0$. The reason is that at $x_0 = 0$ our approach is no longer appropriate because we have neglected spatial variations of the order parameter ψ. To bypass this difficulty, we assumed that the vortex emerges from the superconductor at $x_0 = \xi$, that is, when it touches the surface with its core, rather than at $x_0 = 0$. The exact calculation, due to de Gennes, leads to precisely the same result:

$$H_p = H_{cm} \tag{5.46}$$

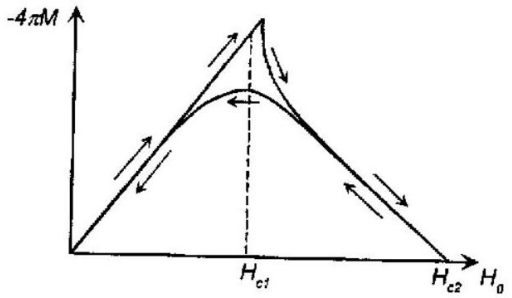

Fig. 5.13. Hysteresis in the magnetization due to the surface barrier

The existence of the Bean-Livingston barrier has been confirmed experimentally. It causes a small hysteresis in the magnetization curve of a homogeneous type-II superconductor near H_{cl}, as illustrated in Fig. 5.13. This hysteresis cannot be removed by improving bulk superconductivity. It is present even if the specimen is made ideally homogeneous.

There have also been direct measurements of H_p: de Blois and de Sorbo [52] studied Nb samples containing small amounts of oxygen, and Nb − Ta alloys. The following results were obtained for specimens with very smooth surfaces finished by electro-polishing: For oxygen-contaminated Nb, the fields were found to be $H_{c1} = 580\text{Oe}, H_{c2} = 7000\text{Oe}, H_{cm} = 1360\text{Oe}$, and $H_p = 1330\text{Oe}$; for Nb − Ta, the fields were $H_{c1} = 110\text{Oe}, H_{c2} = 1600\text{Oe}$, $H_{cm} = 310\text{Oe}$, and $H_p = 180 - 320\text{Oe}$. Comparison of the thermodynamic and penetration fields obtained in these experiments shows that (5.46) is fairly accurate.

In many cases, however, the Bean-Livingston barrier is strongly suppressed. For example, if the surface of a superconductor is rough, the vortices penetrate into it at $H_0 < H_p$.

Let us find the magnetic flux associated with a vortex parallel to the surface and positioned close to it. As follows from the general expression for the Gibbs free energy, for a superconductor with a vortex, one has

$$\mathcal{G} = \mathcal{F} - \Phi H_0/4\pi \tag{5.47}$$

where $\mathcal{F}$ is the free energy of the superconductor containing one vortex (which is independent of the external field H_0) and Φ is the magnetic flux associated with the vortex. On the other hand, the Gibbs free energy $\mathcal{G}$ is given by (5.43). Taking the H_0-dependent terms in (5.43) and comparing them with (5.47), we obtain the following expression for the magnetic flux associated with the vortex near the surface:

$$\Phi = \Phi_0 \left(1 - \mathrm{e}^{-x_0/\lambda}\right) \tag{5.48}$$

According to (5.48), as the vortex moves closer to the surface, its magnetic flux tends to zero. This result can be easily understood. The total magnetic flux of the vortex can be written as

$$\Phi = \int H \, \mathrm{d}S$$

where the integration is carried out over the semiplane $z = 0, x > 0$ and H is the true field due to the vortex. The latter can be considered as the result of a superposition of the fields of the vortex itself and of its image. Taking into account that the sign of the image is opposite to that of the real vortex, we finally have

$$\Phi < \Phi_0$$

7.6.9 5.9 Some Remarks About High-Temperature Superconductors

Despite the fact that there is still no definite theory to explain their high

Table 5.1. Critical temperatures and in-plane coherence lengths ξ_{ab} of some high- T_c superconductors

Material	T_c/K	ξ_{ab} /nm
$(La_{0.925}Sr_{0.075})\,CuO_4$	34	2.9
$YBa_2Cu_3O_7$	92.4	2.5
$Bi_2Sr_2CaCu_2O_8$	84	1.1
$Bi_2Sr_2Ca_2Cu_3O_{10}$	111	1.0
$Tl_2Sr_2Ca_2Cu_3O_{10}$	123	1.6
$HgBa_2Ca_2Cu_3O_8$	133	1.3

the classic sense. This means that the magnetic properties of these materials can be well described by the familiar BCS/Ginzburg-Landau theory. The main differences from the classic superconductors arise from intrinsic material properties such as the extremely short coherence length. Table 5.1 lists the critical temperatures and coherence lengths of some typical materials.

One of the consequences of the short coherence length was already discussed in Chap. 4. Even a grain boundary can be sufficient to suppress superconductivity, and can be used to fabricate weak-link-type Josephson devices from epitaxial films on bicrystalline substrates (see Fig. 4.1).

The second important property of high- T_c superconductors is their huge anisotropy caused by the layered crystal structure. As an example, let us consider the structure of $Bi_2Sr_2CaCu_2O_8$.

The crystal is a stacked sequence

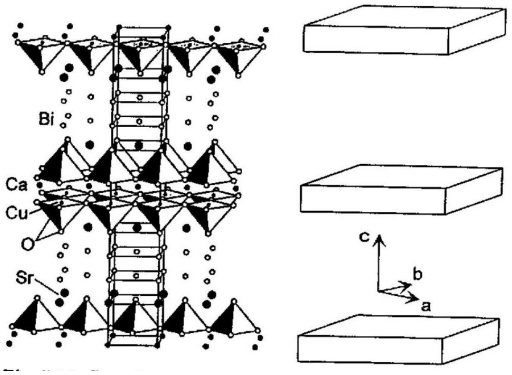

Fig. 5.14. Crystal structure of $Bi_2Sr_2CaCu_2O_8$ (left part). The Cu -O coordination polyhedra are marked for clarity. The right part shows corresponding superconduct-

of CuO_2 planes alternating with other oxide layers (Fig.5.14). The basic building block is the CuO_2 double layer (intercalated by Ca). These blocks are separated by two SrO and two $BiO_{1.5}$ oxide layers. In this structure, there are two principal axes, the in-plane direction and the direction perpendicular to the planes, or c axis. Consequently, we have two critical fields: $H_{c2\parallel}$ and $H_{c2\perp}$, corresponding to the field directions parallel and perpendicular to the planes. The London penetration depth and the coherence length are also anisotropic: $\lambda_{ab}, \lambda_c, \xi_{ab}, \xi_c$. The notation is as follows. Since, for instance, the upper critical field perpendicular to the planes, $H_{c2\perp}$, is determined by vortices whose screening currents flow parallel to the planes, we generalize the coherence length formula (5.26) to

$$H_{c2\perp} = \frac{\Phi_0}{2\pi\xi_{ab}^2} \tag{5.49}$$

Correspondingly, the indices of λ and ξ, 'ab' or 'c', always indicate the direction of the screening currents.

A number of experiments indicate that high- T_c superconductors are inhomogeneous superconductors, i.e., the layered crystal structure is linked to a modulation of the order parameter [53]. Then one can argue that the superconductivity is confined to the CuO_2 planes or double planes. They are separated from neighboring planes by weakly superconducting, normal, or even insulating regions of the crystal. Three-dimensional phase coherence is provided by Josephson currents between the planes.

In order to estimate the critical field parallel to the planes, we neglect the relatively weak coupling between different double planes and consider only a single bilayer. This situation is sketched in the right part of Fig. 5.14. Since the coherence length is about 1.5 nm and the thickness, d, of a CuO_2 double plane is 0.3 nm, we can use the thin film solution of Sect. 3.5. From (3.62) we have:

$$H_{c\parallel} = 2\sqrt{6} H_{cm} \frac{\lambda}{d}$$

The thermodynamic critical field can be calculated from (3.38):

$$H_{cm} = \frac{\Phi_0}{2\sqrt{2}\pi\lambda\xi}$$

which is valid for any pair of λ_i and ξ_i because H_{cm} is an isotropic quantity.
Since only a single bilayer is considered, we obtain:

$$H_{c\parallel} = \sqrt{3}\frac{\Phi_0}{\pi d \xi_{ab}} \tag{5.50}$$

Taking into account (5.49) and (5.50), we obtain for the anisotropy ratio

$$\frac{H_{\mathrm{cl}\parallel}}{H_{\mathrm{c2}\perp}} = 2\sqrt{3}\frac{\xi_{\mathrm{ab}}}{d}$$

This ratio is approximately 17 for $Bi_2Sr_2CaCu_2O_8$. Using the experimen-

10000 kOe, consistent with extrapolations from many experiments. However, in such high fields, pair-breaking effects due to spin-orbit coupling or Pauli paramagnetism are to be expected and these should decrease H_{cll} significantly. We note that, for a less anisotropic material, such as $YBa_2Cu_3O_7$, the assumption of independent superconducting layers might be inappropriate.

If, instead of the above argumentation, we assume a homogeneous order parameter and use the anisotropic Ginzburg-Landau description, $H_{\mathrm{c2}\parallel}$ becomes:

$$H_{\mathrm{c2}\parallel} = \frac{\Phi_0}{2\pi\xi_{\mathrm{ab}}\xi_{\mathrm{c}}}$$

Then the anisotropy ratio is

$$\frac{H_{\mathrm{c2}\parallel}}{H_{\mathrm{c2}\perp}} = \frac{\xi_{\mathrm{ab}}}{\xi_{\mathrm{c}}}$$

In the case of a highly anisotropic material, such as $Bi_2Sr_2CaCu_2O_8$, ξ_{c} would then be of the order of 0.1 nm, i.e., approaching atomic scales. In any case, this is inconsistent with the assumption of a homogeneous order parameter.

The extreme anisotropy is also responsible for many peculiar effects associated with the flux line lattice in high- T_{c} superconductors. A detailed analysis of these effects goes far beyond the scope of this book.

7.6.10 5.10 Critical Current of a Type-II Superconductor. Critical State

Consider a type-II superconductor in the mixed state to which a transport current (that is, a current from an external source) is applied in the direction perpendicular to the vortices. The current gives rise to a Lorentz force on the vortices. If the superconductor were absolutely homogeneous (free of defects), the vortices would start moving at an infinitely small Lorentz force.

Later (in Sect. 5.12) we shall find that vortex motion is accompanied by dissipation of energy. Therefore, the critical current of such an ideally homogeneous superconductor is zero.

In an inhomogeneous type-II superconductor containing various types of defects (grain boundaries, dislocation walls, dislocation tangles, voids, or second-phase precipitates), vortices can be pinned by the defects. A finite transport current is then required to set them moving, such that the Lorentz force produced by it is sufficient to tear the vortices off the defects. The latter are often referred to as pinning centers. The current density corresponding to the initiation of vortex break-off from the pinning centers is called the critical current density, j_{c}.

The critical current density is a structure-sensitive property and can vary by as much as several orders of magnitude as a result of thermal or mechanical
treatment of the material. At the same time, the critical temperature T_{c} and the critical field H_{c2} can remain virtually unaffected. In superconductors which are tailored for superconducting magnets or other superconducting devices, the critical current density can be as large as 10^6 A cm^{-2}.

Let us consider in more detail the flow of the critical current through a type-II superconductor containing a large number of pinning centers. In order for the transport current to

be distributed over the entire cross-section of the specimen, one has to stipulate that the distribution of vortices is inhomogeneous. Indeed, the total current density at a given location is

$$j_{\rm tr} = \frac{c}{4\pi} \operatorname{curl} B \tag{5.51}$$

Furthermore, $B = \Phi_0 n$ is the average field at this location, that is, the average magnetic induction in a region of dimensions much larger than the distance between the vortices; n is the average vortex density. Then it follows from (5.51) that $j_{\rm tr}$ is nonzero only if n is a function of the coordinates: $n = n(r)$.

How does such a state, with the critical current density established across the entire cross-section of the superconductor, set in?

Assume that an infinite plate of thickness d contains a large number of defects which can pin vortices, and $d \gg \lambda$. The surfaces of the plate coincide with the planes $x = \pm d/2$. To begin with, the external magnetic field H_0 is zero and a transport current is applied in the direction of the y axis. At first, the current will flow along the surfaces of the plate (Meissner-Ochsenfeld effect), just as in the case of a homogeneous superconductor. Furthermore, as soon as the field H_I generated by this surface current exceeds the critical value $H_{\rm cl}$, vortices will start to enter the plate from both surfaces, their signs being opposite when they penetrate from the opposite sides. While moving towards the center of the plate, the vortices will be pinned by the defects in the plate and, therefore, will not be able to penetrate far inside. This means that a gradient of the vortex density will appear. Evidently, it will be the maximum possible gradient, that is, the gradient corresponding to the critical value of the current. Thus, certain parts of the plate near the surfaces will carry the critical current while, in the rest of the plate, there will be no current at all. This situation is illustrated in Fig. 5.15 which shows the distribution of the magnetic field in the plate when it carries a current I_1 (per unit length along the z direction).

Let us now increase the current to a certain value I_2. The vortices, while keeping the gradient of their density at $(\nabla n)_c$, will move closer to the center so that only a small central part of the plate will remain free of transport current, while everywhere else the current density will have the critical value. If we continue to increase the current, at some moment it will reach such a value, I_c, that the current density at any point of the plate will be of the critical value, as illustrated in Fig. 5.15 (a). This is the critical state.

Let us now apply an external magnetic field H_0 parallel to the z axis, that is narallel to the surfaces of the nlate and pernendicular to the current.

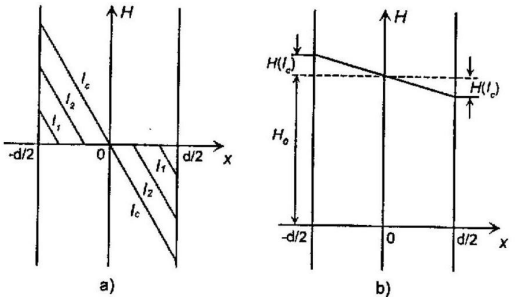

Fig. 5.15. Magnetic field distribution in a plate of thickness d containing pinning centers. The plate carries a current I: (a) the external field is zero and $I_1 < I_2 < I_{\rm c}$ are the currents circulating in the plate; (b) the external magnetic field is finite. Shown is the field distribution in the critical state

Assume that the field is $H_0 \gg H_I$. Neglecting a small difference between $H_0 + H_I$ and $H_0 - H_I$, we can assume that every point of the superconductor is in the field H_0. Then the distribution of current in the critical state will be as shown in Fig. 5.15 (b). The critical gradient of the vortex density in the presence of H_0 is less than that without the field because the critical current is reduced, as explained below.

Indeed, if the Lorentz force per unit length of a vortex is $f_{\mathrm{L}} = j_{\mathrm{tr}}\Phi_0/c$, the Lorentz force per unit volume is $F_{\mathrm{L}} = j_{\mathrm{tr}}B/c$ because the density of the vortices is $n = B/\Phi_0$. When the vortices are at rest, the Lorentz force is balanced by the pinning forces exerted on the vortices. If the average density of the pinning force per unit volume is denoted by F_p, the critical current must satisfy the following equation:

$$\frac{1}{c} j_{\mathrm{c}} B = F_{\mathrm{p}} \tag{5.52}$$

For F_{p} independent of the external field H_0, the critical current is $j_{\mathrm{c}} \propto B^{-1}$. This dependence has indeed been observed in many experiments.

If the distribution of pinning centers in a superconductor is random, they cannot pin an absolutely rigid vortex lattice. To elucidate this statement, let us shift the lattice by a small distance in the direction of the Lorentz force. This displacement obviously does not change the energy of the system because the random distribution of pinning centers relative to the rigid vortex lattice remains essentially the same as before. And since there is no variation of energy, there is no restoring force which would push the vortices to their old positions, that is, there is no pinning.

The situation is quite different if we assume that the vortex lattice is an elastic medium. Then every time when we shift the vortex lattice, it will
that the energy of the vortex system as a whole is a minimum. Therefore, if we try to shift the vortex lattice in this case, a certain effort is needed to overcome the restoring force and tear the vortices off the pinning centers. Clearly, the 'softer' the vortex lattice, i.e., the more pliable it is, the larger the pinning force.

At $H_0 \to H_{c2}$, the elastic moduli of the vortex lattice decrease, that is, the lattice becomes softer and pinning becomes stronger. This results in a maximum of the critical current at $H_0 \to H_{c2}$ (peak effect) which is often observed in experiment (see Fig. 5.16).

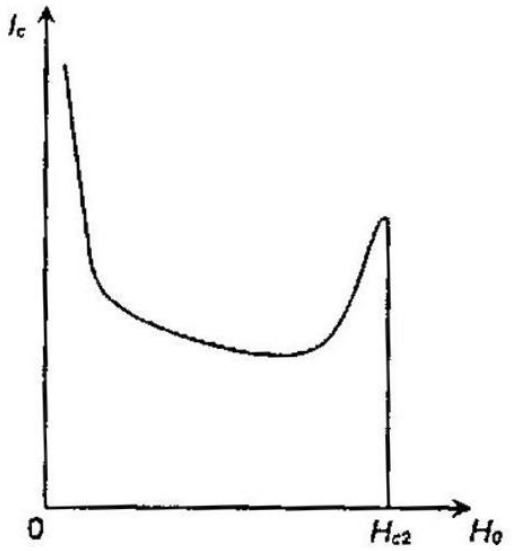

Fig. 5.16. Dependence of the critical current on perpendicular magnetic field. A pronounced peak effect is observed at $H_0 \approx H_{c2}$

7.6.11 5.11 Interaction of Vortices with Pinning Centers

Vortices interact with many different types of defects, which often leads to large values of the critical current. The objective of this section is to study in some detail several simple examples of defects and consider the physical mechanisms by which they interact with vortex lines. One should bear in mind that not every defect can interact with vortices effectively. In the classic

superconductors, for example, vacancies, individual second-phase atoms, or other similar tiny defects are not effective as pinning centers for an obvious reason: as a rule, the characteristic size of a vortex - the coherence length exceeds by far the atomic size, i.e., the characteristic size of such a defect. Therefore, a vortex simply 'does not notice' them. Conversely, structural defects with dimensions $\sim \xi$ and larger are very effective and can be the cause of very large critical current densities.

However, the situation is different for high- T_c superconductors. There, the coherence lengths are so small that point defects have sizes comparable to ξ. We shall discuss some aspects of this qualitatively new situation in Sect. 5.11.2.

5.11.1 Interaction of Vortices with the Surface of a Superconductor

Let us consider an ideally homogeneous type-II superconductor in the form of a plate of thickness $d \gg \lambda$. An external magnetic field H_0 is parallel to the surface of the plate; in addition, $H_{c1} \ll H_0 \ll H_{c2}$ and $\kappa \gg 1$. Then the vortices in the plate form a triangular lattice with period $a \ll d$. According to detailed calculations, the distance between the edge of the plate and the vortex row nearest to it is $\sim a$. To a good accuracy, a can be assumed constant over the plate.

As we switch on a small transport current through the plate, so that it is perpendicular to the magnetic field, the current generates a field H_I, and the total field at one side of the plate becomes $(H_0 + H_I)$ and at the other $(H_0 - H_7)$. We already know that a stable state with a gradient of the vortex density is not possible in a homogeneous superconductor. Therefore, in response to the applied current, the vortex structure must shift as a whole in the direction of the Lorentz force. Since the vortices had been at equilibrium before the current was applied, even a very small displacement from their equilibrium positions ought to bring about a restoring force. The result will be an elastic shift of the whole vortex structure by a certain distance determined by the balance between the Lorentz force and the restoring force. If the Lorentz force, acting against the restoring force, is sufficient to shift the vortices by a distance $\sim a$, a continuous flow of vortices will start. Indeed, as a vortex row comes to the edge of the plate on one side, it is annihilated by its image. At the same time, an identical row enters the plate from the opposite side and moves by a distance $\sim a$ thereby leaving enough room for a new vortex row to enter. Then a new row enters the plate, the whole structure shifts again by the distance $\sim a$, etc. This implies that the transport current shifting the vortex lattice by $\sim a$ is the critical current.

Assume that our superconductor is now in thermodynamic equilibrium. Then a magnetizing current I_M along its surface is determined by the difference between the external field H_0 at the surface and the average field B in the interior:

$$I_M = \frac{c}{4\pi} |B - H_0| = cM$$

The density of the magnetizing current can be written as

$$j_M = \frac{c|M|}{\lambda} \mathrm{e}^{-x/\lambda}, \tag{5.53}$$

where x is the distance of a given point from the edge of the plate. A vortex occupying the position x is then acted upon by the Lorentz force

$$f_M = \frac{1}{c} j_M \Phi_0 = \frac{|M|\Phi_0}{\lambda} \mathrm{e}^{-x/\lambda}$$

If the vortex shifts by a small distance δx, f_M changes by δf_M:

$$|\delta f_M| = \frac{M\Phi_0}{\lambda^2}\mathrm{e}^{-x/\lambda}\delta x$$

The force f_M is applied only to the vortices within a surface layer $\sim \lambda$. Therefore, the net change of the force on the vortex system, as it shifts by δx, is

$$\frac{|M|\Phi_0}{\lambda^2}\delta x\frac{\lambda}{a}$$

In order to obtain the final expression for the restoring force F_{restore} per unit area of the surface, we multiply the last expression by the number of vortices within the unit length along the direction of the current, i.e., by $1/a$, and further multiply it by 2 (in order to take into account the second edge of the plate):

$$F_{\text{restore}} = \frac{2|M|\Phi_0}{\lambda a^2}\delta x \tag{5.54}$$

Recalling that $a^2 \approx \Phi_0/B$, we have

$$F_{\text{restore}} = \frac{2|M|B}{\lambda}\delta x \tag{5.55}$$

As was already mentioned, the condition for equilibrium is that F_{restore} equals the Lorentz force per unit area of the surface,

$$\mathcal{F}_{\text{L}} = \frac{1}{c}I_{\text{tr}}B \tag{5.56}$$

where I_{tr} is the transport current per unit length of the plate. The current I_{tr} reaches its critical value when δx becomes equal to $a \approx (\Phi_0/B)^{1/2}$. Substituting this into (5.55) and equating it to (5.56) we get

$$I_c = \frac{2c|M|\sqrt{\Phi_0}}{\lambda\sqrt{\bar{B}}} \tag{5.57}$$

The average of the critical current density over the cross-section is

$$j_{\text{c}} = \frac{2c|M|\sqrt{\Phi_0}}{\lambda\sqrt{B}d} \tag{5.58}$$

The last formula agrees well with experiment.

Let us draw some conclusions. First, we shall outline our present understanding of the flow of transport current through a superconducting plate in the mixed state. If the current is below the critical value, the Lorentz force causes an elastic shift of the vortex structure as a whole by a certain distance $\delta x < a$. As soon as this happens, the Lorentz force is balanced by a restoring force brought about by the shift, and the vortex lattice comes to rest. The lattice period is the same everywhere; therefore, in the interior of the plate, the transport current is zero. In other words, the transport current flows within the layer $\sim \lambda$ near the surface.

Let us estimate the maximum transport current, i.e., the critical current.
$d \sim 10^{-4}$ cm. Then $|M|$ is $\sim$ 1G. Substituting these into (5.58) we obtain $j_{\text{c}} \sim 10^5$ A cm^{-2}. Thus, even a homogeneous superconducting plate in the mixed state is capable of carrying a rather large transport current. Now let us imagine a thick superconducting plate consisting of a set of thin superconducting plates, already familiar to us, which are separated from each other by thin layers of an insulator or a normal metal. In this construction, the transport current can flow along every surface of every thin plate (within the surface layer $\sim \lambda$, of course) so that the resulting transport current through our composite superconductor will be very large.

An experimental verification of (5.58) was obtained by Campbell, Evetts and Dew-Hughes [55] who studied the interaction of vortices with inclusions of a normal metal in a Pb – Bi alloy.

5.11.2 Interaction of a Vortex with a Cavity in a Superconductor

Consider an infinite superconductor containing a defect in the form of a cylindrical cavity. How will a single vortex parallel to the cavity interact with it?

Assume that the diameter of the cavity satisfies the inequality $d > \xi(T)$. Then the interaction energy can be very easily estimated. If the vortex is far away from the cavity, its normal core (of diameter $\sim 2\xi$) stores a positive energy (relative to the energy of the superconductor without the vortex) because the free energy of the normal state exceeds that of the superconducting state by $H_{\rm cm}^2/8\pi$ per unit volume. Then the energy of the normal core, per unit length, is

$$\frac{H_{\rm cm}^2}{8\pi}\pi\xi^2 \tag{5.59}$$

On the other hand, if the vortex is trapped by the cavity, i.e., passes through its interior, it does not have a normal core and, accordingly, the energy of the system is reduced by the amount of (5.59). This means that the vortex is attracted to the cavity. The interaction force per unit length, f_p, can be found easily if we recall that the energy changes by the value of (5.59) when the vortex changes its position near the edge of the cavity by $\sim \xi$:

$$f_{\rm p} \approx H_{\rm cm}^2\xi/8 \tag{5.60}$$

If, instead of a cylindrical cavity, the superconductor contains a spherical cavity of diameter d, the pinning force $f_{\rm pd}$ on the vortex can be obtained from (5.60):

$$f_{\rm pd} \approx H_{\rm cm}^2\xi d/8 \tag{5.61}$$

To get an idea of how large this force is, let us find the current that must be applied in the direction perpendicular to the vortex in order to produce

We know that the Lorentz force per unit length of a vortex is $j\Phi_0/c$. Then the force applied to the part of the vortex which actually interacts with the defect is $j\Phi_0 d/c$. Equating this to $f_{\rm pd}$(5.61), we get

$$j = \frac{cH_{\rm cm}^2}{8\Phi_0}\xi \tag{5.62}$$

Furthermore, since $H_{\rm cm} = \Phi_0/2\sqrt{2}\pi\lambda\xi$ (see (3.38)), we obtain from (5.62)

$$j = \frac{cH_{cm}}{16\sqrt{2\pi\lambda}}$$

One can easily verify that j in the last expression is of the same order of magnitude as the pair-breaking current considered earlier in Sect.3.6. Thus, in order to tear the vortex off a spherical void, one should apply the maximum possible current for a given superconductor.

The above reasoning is also valid in the case of a superconductor containing tiny dielectric inclusions. It will also remain valid (at least by the order of magnitude) if the inclusions are of a normal metal, provided the size of the inclusions is larger than ξ. The restriction is due to the proximity effect which is essential only at distances of the order ξ from the interface. We can then conclude that various types of normal inclusions represent effective pinning centers in superconductors. This property is widely used in technical applications when large critical currents and fields are involved.

Consider, for example, a Nb − Ti alloy used in many superconducting devices where large critical currents are of importance. A typical thermal treatment of such an alloy is as follows: a Nb-Ti wire is tempered from 800°C and then annealed for a short time ($\sim$ 30 minutes) at $\approx$ 400°C. This results in a partial transformation of the superconducting β-phase into a

nonsuperconducting α-phase, in the form of tiny precipitates of α-phase in the superconducting matrix. As a result of this treatment, the critical current increases by several orders of magnitude.

Among other effective pinning centers in superconductors are dislocations, dislocation walls, grain boundaries, and interfaces between superconductors with different parameters.

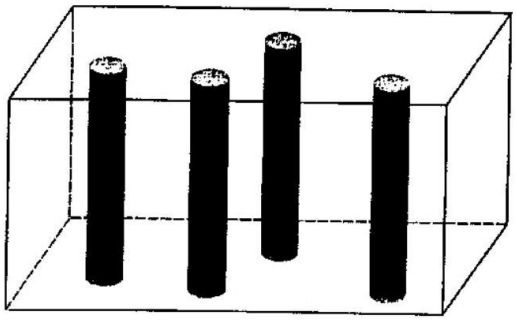

Fig. 5.17. Nuclear tracks of fast heavy ions form cylindrical amorphous regions in high- T_c superconductors

The above analysis of vortex-defect interactions forms the basis for interpreting the effects of the so-called columnar defects [56] produced in highT_c superconductors by heavy-ion irradiation. Nuclear tracks of high-energy heavy ions form cylindrical amorphous regions in the material (see Fig. 5.17). It is generally accepted that the material in the columnar defects is not superconducting.

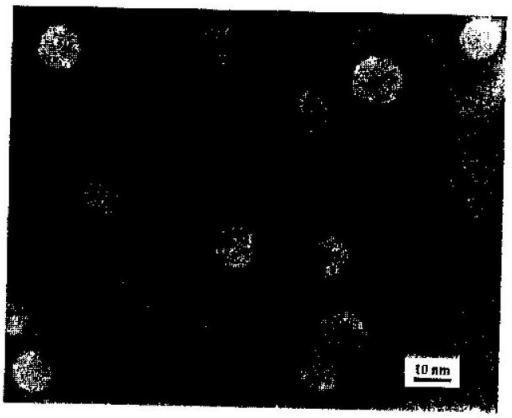

Fig. 5.18. Nuclear tracks in $Bi_2Sr_2CaCu_2O_8$ produced by irradiation with 865 MeV Pb ions. The fluence was 5×10^{10} cm^{-2}

The nuclear tracks have the useful property that their diameter is only $5 - 10$ nm, i.e., of the order of the coherence length. As we have just seen, cavities with such sizes make extremely effective pinning centers. This is one of the very few possibilities for producing artificial defects of sizes comparable with the coherence length of high- T_c superconductors. This length is so short that conventional metallurgical methods used to produce pinning centers such as precipitates or grain boundaries are either ineffective, due to the large sizes of the defects, or not applicable at all, due to the brittleness of the materials.

Fig. 5.18 shows a transmission electron micrograph of the nuclear tracks in $Bi_2Sr_2CaCu_2O_8$ [57]. The view is along the direction of the ion beam. Columnar defects show up as bright circular spots. Each defect is able to trap approximately one vortex. Hence the optimum pinning efficiency can be expected at fields for which the vortex lattice period is less than the average distance between the amorphous tracks. Decoration patterns (c.f. Sect.5.1) obtained on a virgin and an irradiated $Bi_2Sr_2CaCu_2O_8$ crystal (see Fig. 5.19) show the effect of columnar defects when the distance between the vortices just matches the average distance between the defects [58]. The originally regular vortex lattice is heavily deformed due to pinning by columnar defects. The defects were produced by 2.7GeV^{238}U ions.

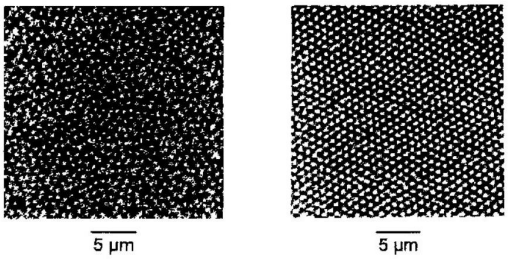

Fig. 5.19. Vortex lattice in $Bi_2Sr_2CaCu_2O_8$ with columnar defects observed by decoration (left part). The applied magnetic field of 40 Oe is such that the vortex spacing just matches the average distance between the defects. For comparison, the right part shows the decoration pattern for the unirradiated sample

7.6.12 5.12 Resistive State

Let us discuss what happens when the Lorentz force due to an applied current becomes larger than the pinning force and vortex flow in the direction perpendicular to the applied current sets in.

We shall show that such a vortex flow results in dissipation of energy and a finite electric resistance. This state of the vortex system is therefore referred to as the resistive state.

By Faraday's law of electromagnetic induction, a flow of magnetic flux generates an electric field E in the same direction as the applied current. [1] This means that an energy dissipation $Ej_{\rm tr}$ arises across the bulk of the superconductor. Assume that the velocity of the vortices in the direction of the Lorentz force, that is, in the direction perpendicular to both the current and the magnetic field, is $v_{\rm L}$. Then the work done by the external source to keep the vortices moving will be $F_{\rm L}v_{\rm L}$, per unit time, where $F_{\rm L}$ is the density of the Lorentz force. Obviously, this work is equal to the energy dissipated by the system per unit volume and unit time, that is,

$$F_{\rm L}v_{\rm L} = Ej_{\rm tr} \tag{5.63}$$

Recalling that $F_{\rm L} = j_{\rm tr}B/c$, we obtain

$$E = Bv_{\rm L}/c \tag{5.64}$$

The resistivity of a superconductor resulting from the flux flow is referred to as the flux-flow resistivity and denoted by $\rho_{\rm f}$:

$$\rho_{\rm f} = E/j_{\rm tr} \tag{5.65}$$

The fact that the vortex motion is accompanied by dissipation of energy allows us to assume that the vortices move in a viscous medium. We introduce
a viscosity coefficient η:

$$f_{\rm friction} = -\eta v_{\rm L}$$

where $f_{\rm friction}$ is the friction exerted on one vortex moving with the velocity $v_{\rm L}$. Neglecting the vortex mass, we obtain an equation of motion for the vortex in the form

$$f_{\rm friction} + f_{\rm L} = 0$$

After substituting the relevant expressions for the forces per unit volume, this equation becomes

$$\frac{B}{\Phi_0}\eta v_{\rm L} = \frac{1}{c}Bj_{\rm tr} \tag{5.66}$$

Using (5.64) and (5.65), we can rewrite (5.66) as

$$\rho_{\rm f} = \frac{\Phi_0 B}{c^2\eta} \tag{5.67}$$

If η is independent of magnetic field, the resistivity $\rho_{\rm f}$ is a linear function of B. The linear dependence is indeed observed in experiments at low temperatures. An empirical formula at $T \to 0$ reads:

$$\rho_{\rm n} = \frac{\Phi_0 H_{\rm c2}}{c^2\eta}$$

It can be used to determine the viscosity coefficient at low temperatures:

$$\eta = \frac{H_{\rm c2}(0)\Phi_0}{c^2\rho_{\rm n}} \tag{5.68}$$

Here $\rho_{\rm n}$ is the normal-state resistivity of the superconductor. It is of interest to evaluate the order of magnitude of the flux flow velocity in a real experiment. Assume that the electric field in the resistive state is $E \sim 10^{-6}$ V cm^{-1} and the magnetic induction is $B \sim 10^4$G. Then, by (5.64), we have

$$v_{\rm L} = \frac{cE}{B} = 3\times 10^{10}\frac{10^{-6}}{300}\frac{1}{10^4} = 10^{-2}\ \text{cm s}^{-1}$$

A typical current-voltage characteristic of a superconductor in the resistive state is shown in Fig. 5.20. A finite voltage appears at a certain value of current (the critical current) and, at small values of the voltage, the characteristic is nonlinear. The nonlinear part corresponds to a flow of vortices that is not yet stabilized, that is, to flux creep, where the vortices jump randomly from one pinning center to another. As the current is increased further, the current-voltage characteristic becomes linear. The linear part corresponds to the flow of the vortex structure as a whole.

There are two ways to define the critical current on an $I-V$ characteristic. The current $I_{\rm cs}$ - the minimum current giving rise to a finite voltage - is the static critical current. At I_{cs}, the process of vortex break-off from pinning

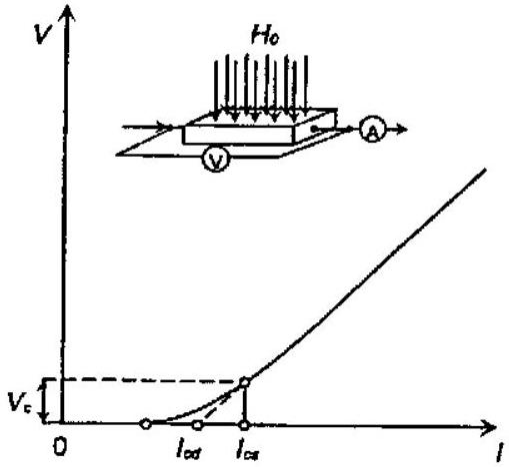

Fig. 5.20. Current-voltage characteristic of a superconductor containing crystal defects. Two ways of defining the critical current are illustrated: I_{cs} is the static and I_{cd} the dynamic critical current

depends on the actual value of the voltage that is assumed to correspond to the critical current.

[2] A series of experiments [59] was intended to clarify the extent to which the critical current I_{cs} depends on the voltage threshold (or, in other words, on the sensitivity of the voltage measurements). It was found that at $H_0 \ll H_{c2}$, an enhancement of the sensitivity by several orders of magnitude leads to negligibly small changes of the critical current.

The second definition of the critical current is I_{cd}, the dynamic critical current. This value is obtained by extrapolating the linear part of a currentvoltage characteristic until it intersects the I axis.

Finally, let us mention some features that are common to the resistive state of a type-11 superconductor and the ac Josephson effect (Josephson radiation) [60].

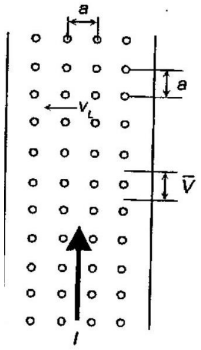

Fig. 5.21. Vortex structure in a type-II superconductor subjected to the Lorentz force moves with velocity v_L

Suppose that a bulk type-II superconductor is in the resistive state and the average magnetic induction in its interior is B. Assume, for the sake of simplicity, that the vortices form a square lattice as illustrated in Fig. 5.21. This assumption does not affect the generality of our discussion.

Under the Lorentz force from a current I applied to the superconductor, the vortex structure moves with velocity v_{L}, thereby generating an electric field

$$E = \frac{1}{c} B v_{\mathrm{L}}$$

The average voltage $\bar{V}$ over the vortex period a is then

$$\bar{V} = \frac{a}{c} B v_{\mathrm{L}} \tag{5.69}$$

(see Fig. 5.21). It is evident that the vortex lattice displacement has a translational symmetry with period a. One can therefore expect that the voltage V will have an ac component of frequency

$$\omega = 2\pi \frac{v_{\mathrm{L}}}{a}. \tag{5.70}$$

Substitution of this in (5.69) yields

$$\bar{V} = \frac{\omega B a^2}{2\pi c}$$

Note that Ba^2 is the magnetic flux associated with one vortex, i.e., the flux quantum Φ_0. Therefore

$$\bar{V} = \frac{\hbar \omega}{2e}$$

We have arrived at an expression identical to (4.21).

[2] A 10^{-6} V threshold is applied in the majority of technical applications, i.e., a

This radiation in type-II superconductors is very difficult to observe. Owing to the inevitable structural defects and inhmogeneities, the motion of the vortex lattice is random and turbulent, rather than coherent and laminar. However, if one takes special precautions to make the vortex motion well-ordered, it should be possible, in principle, to observe features in the resistive state of a type-II superconductor similar to those characteristic of the ac Josephson effect [61].

Problems

Problem 5.1. Two parallel superconducting vortices in an infinite superconductor are fixed at positions a and b. The distance between them is d (see Fig. 5.22). A third vortex of the same sign is allowed to move along the dashed line perpendicular to ab and passing through its middle. Find the force exerted on the third vortex as a function of the distance x from the line ab. All distances in the problem are much smaller than λ and $\kappa \gg 1$.

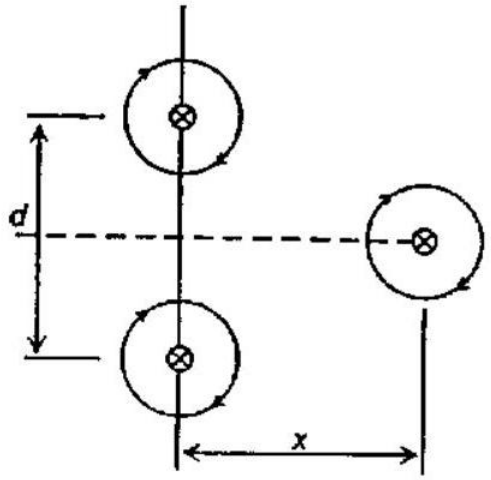

Fig. 5.22. See Problem 5.1. Two vortices are at a fixed distance d from each other. The third vortex is allowed to move along the dashed line

Problem 5.2. A superconducting alloy has an upper critical field of 30 kOe and a thermodynamic critical field of 1500 Oe. Find the magnetic field penetration depth.

Problem 5.3. Find the lower critical field of a superconducting specimen of Nb − Ta if $H_{c2} =$ 4000Oe and $\kappa = 3$.

Problem 5.4. Consider a superconductor with $\kappa \gg 1$. Find the density of vortex currents at the distance $r = \xi$ from the center of an isolated vortex.

Problem 5.5. A superconducting alloy has $H_{c2} =$ 150kOe and $\kappa = 96$. Find the energy of an isolated vortex in this alloy. Compare it with the condensation energy stored in the normal core of the vortex.

Problem 5.6. A superconducting alloy has $H_{c2} =$ 50kOe and $\kappa = 60$. Find the magnetic moment per unit volume, M, for an external field $H_0 =$ 10kOe.

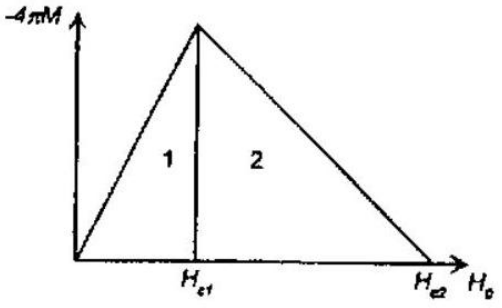

Fig. 5.23. Approximation of the magnetization curve by two triangles. Triangle (1) is defined by $-4\pi M = H_0$, triangle (2) by $-4\pi M = (H_{c2} - H_0) / [1.16\,(2\kappa^2 - 1)]$

Problem 5.7. A Nb -Ta superconducting alloy has an upper critical field $H_{c2} =$ 4000 Oe

and $\kappa = 3$. Approximate the magnetization curve of the alloy by two triangles, as illustrated in Fig. 5.23. Find the lower critical field H_{c1} and the thermodynamic critical field H_{cm}. Compare the value of H_{c1} with the answer to Problem 5.3 and that of H_{cm} with its true value (the latter can be found proceeding from the known value of H_{c2}).

Problem 5.8. Find the third critical field of a superconducting alloy that has $H_{cm} = 900$Oe and $\lambda = 2500$Å.

Problem 5.9. Find the third critical field of a superconductor with the coherence length $\xi = 90$Å.

Problem 5.10. Find the attractive force exerted on a vortex by the surface of a flat superconductor if the vortex is parallel to the surface at a distance $l = 500$Å,

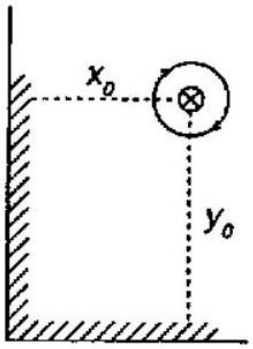

Fig. 5.24. See Problem 5.11

Problem 5.11. An isolated vortex is placed in the vicinity of the surface of a superconductor as shown in Fig. 5.24. Find the total force exerted on the vortex by the surfaces if $\lambda = 1500$Å, $x_0 = 400$Å, and $y_0 = 600$Å.

Problem 5.12. Find the force with which a vortex interacts with the Meissner current if the vortex is parallel to the flat surface of a superconductor and the distance between the surface and the vortex is $l = 400$Å. The external field is $H_0 = 50$Oe and $\lambda = 1000$Å.

Problem 5.13. Find the superheating field of the Meissner state if $\kappa = 24$ and $\lambda = 2000$Å.

Problem 5.14. A perfectly homogeneous superconducting plate of thickness $l = 5$ mm is placed in an external magnetic field $H_0 \approx B = 18$kG. The field is parallel to the surface of the plate and perpendicular to a transport current. Find the critical current of the plate if $H_{c2} = 75$kOe and $H_{c1} = 130$Oe.

Problem 5.15. Estimate the flux flow resistivity ρ_f if the external field is $H_0 = 5 \times 10^3$Oe, $T_c = 10$ K, and $H_{c2}(T = 4.2\text{ K}) = 40$kOe. The remnant normal-state resistivity of the specimen is $\rho_n = 3 \times 10^{-5}\Omega$ cm.

Problem 5.16. A superconducting wire of length $l = 8$ cm is placed in an external field $B = 5$ T and is in the resistive state. Find the velocity v_L of moving vortices if the voltage across the wire is $U = 1.5 \times 10^{-5}$ V.

7.7 Type II Superconductors: Advanced Properties

7.7.1 35*. Anisotropic Type-II Superconductors

Очень многие сверхпроводники II рода имеют сильно анизотропную (слоистую) кристаллическую структуру; таковы все представители семейства BTC, $NbSe_2$ и многие другие соединения. Вследствие этого и их электронные свойства оказываются анизотропными. Энергия электрона может быть выражена через эффективные электронные массы поперек $(m_\perp)$ и вдоль $(m_\parallel)$слоев:

$$E_p = \frac{p_z^2}{2m_\perp} + \frac{p_x^2 + p_y^2}{2m_\parallel}$$

причем $m_\perp \gg m_\parallel \sim m$, где m-обычная электронная масса. В результате оказываются

зависящими от направления и параметры, характеризующие сверхпроводящее состояние - длина когерентности, лондоновская глубина проникновения, первое и второе критические поля. Если интересующий нас анизотропный сверхпроводник имеет $\varkappa \gg 1$, можно применить простой прием, предложенный в работе [94], чтобы найти все эти угловые зависимости.

Начнем наше рассмотрение со свободной энергии ГинзбургаЛандау для анизотропного случая:

$$\mathcal{G}_{sH} = \mathcal{G}_n + \int \left[\alpha|\Psi|^2 + \frac{\beta}{2}|\Psi|^4 + \right.$$
$$+ \frac{1}{4m_\parallel}\left|-i\hbar\nabla_\parallel\Psi - \frac{2e}{c}\mathbf{A}_\parallel\Psi\right|^2 + \frac{1}{4m_\perp}\left|-i\hbar\nabla_z\Psi - \frac{2e}{c}\mathbf{A}_z\Psi\right|^2 +$$
$$\left. + \frac{(\nabla\times\mathbf{A})^2}{8\pi} - \frac{(\nabla\times\mathbf{A})\cdot\mathbf{H}_0}{4\pi}\right] dV \tag{35.1}$$

Далее удобно использовать параметр анизотропии ε, определенный как $m_\parallel/m_\perp = \varepsilon^2 \ll 1$. Сделаем в выражении (35.1) замену координат и компонент векторного потенциала:

$$x = \tilde{x}, \quad y = \tilde{y}, \quad z = \varepsilon\tilde{z}, \quad A_x = \tilde{A}_x, A_y = \widetilde{A}_y, \quad A_z = \frac{\tilde{A}_z}{\varepsilon}. \tag{35.2}$$

В новых переменных члены в (35.1), содержащие градиенты, станут изотропными, однако анизотропия появится в членах с магнитной энергией. Действительно, преобразования (35.2) для компонент вектора индукции $\mathbf{B} = \nabla\times\mathbf{A}$ имеют вид

$$B_x = \frac{\widetilde{B}_x}{\varepsilon}, \quad B_y = \frac{\widetilde{B}_y}{\varepsilon}, \quad B_z = \widetilde{B}_z \tag{35.3}$$

так что магнитная энергия запишется в виде

$$\mathcal{G}_M = \frac{1}{8\pi}\int\left[\frac{\widetilde{B}_\parallel^2}{\varepsilon^2} + \widetilde{B}_\perp^2 - 2\left(\frac{\widetilde{\mathbf{B}}_\parallel\mathbf{H}_\perp}{\varepsilon} + \widetilde{B}_\perp H_\perp\right)\right] dV. \tag{35.4}$$

Для сверхпроводников с очень большим параметром $\varkappa$ магнитную индукцию B можно часто считать постоянной по образцу, в то время как параметр порядка $\Psi(\mathbf{r})$ может быть сильно неоднороден (например, вблизи вихрей). Именно в таких случаях полезно преобразование (35.2): минимизируя G_M по компонентам вектора $\widetilde{\mathbf{B}}$, найдем

$$\widetilde{\mathbf{B}} = (\varepsilon H_x, \varepsilon H_y, H_z)\,, \tag{35.5}$$

что соответствует равенству B = $\mathbf{H}$ для изотропной системы; такое приближение пригодно при $B \gg H_{c1}$. Преобразование (35.2) не меняет длин в плоскости слоев, поэтому мы сохраним обозначения ξ и λ за длиной когерентности в плоскости слоев и глубиной проникновения токов, текущих вдоль них.

В качестве примера найдем с помощью преобразования (35.2) зависимость второго критического поля H_{c2} от угла ϑ между вектором магнитной индукции B и плоскостью слоев. Введем функцию $\varepsilon(\vartheta) \equiv \varepsilon_\vartheta$, определив ее равенством $\varepsilon_\vartheta^2 = \varepsilon^2\cos^2\vartheta + \sin^2\vartheta$. Тогда из соотношения (35.5) следует, что магнитное поле $\mathbf{H}$ действует на анизотропный сверхпроводник так же, как поле $\varepsilon_\vartheta H$ на сверхпроводник изотропный. Отсюда немедленно находим:

$$H_{c2}(\vartheta) = \frac{\Phi_0}{2\pi\varepsilon_\vartheta\xi^2} \tag{35.6}$$

В частном случае, когда поле направлено параллельно слоям, второе критическое поле максимально, $H_{c2}^{\parallel} = \varepsilon^{-1} H_{c2}^{\perp}$. Этот результат можно также выразить как $H_{c2}^{\parallel} = \Phi_0 / (2\pi\xi\xi_\perp)$, где $\xi_\perp = \varepsilon\xi$ длина когерентности в поперечном к слоям направлении; это соотношение между $\xi_\perp$ и ξ следует уже из вида свободной энергии (35.1).

Термодинамическое критическое поле H_{cm} не может зависеть от направления поля (поскольку оно просто определяет плотность энергии, выигранной при переходе в сверхпроводящее состояние, $\mathcal{G}_n - \mathcal{G}_s = H_{cm}^2/8\pi$). С другой стороны, обычно $H_{c1}H_{c2} = H_{cm}^2 \ln(\lambda/\xi)$, т. е. следует ожидать, что первое критическое поле будет зависеть от угла ϑ противоположным (по сравнению с (35.6)) образом. Для определения $H_{c1}(\vartheta)$ метод преобразования (35.2) непригоден, т.к. вблизи первого критического поля распределение $B(\mathbf{r})$ максимально неоднородно. Расчеты [95] в рамках лондоновского приближения дают

$$H_{c1}(\vartheta_H) = \frac{\Phi_0}{4\pi\lambda^2} \frac{\varepsilon}{\varepsilon_{\theta_H}} \ln\frac{\lambda}{\xi} \tag{35.7}$$

где $\theta_H = \pi/2 - \vartheta_H$, а ϑ_H - угол между направлением магнитного поля $\mathbf{H}$ и плоскостью слоев (в полях порядка первого критического направления магнитного поля H и индукции B, вообще говоря, отличаются). Первое критическое поле минимально в направлении слоев, что легко понять - плотность экранирующих токов, текущих в направлении поперек слоев, уменьшена по сравнению с токами вдоль слоев, так что длина экранирования возрастает, $\lambda_\perp = \varepsilon^{-1}\lambda$.

До сих пор мы подразумевали, начиная с выражения для свободной энергии (35.1), что сверхпроводник может быть описан как непрерывная трехмерная среда, хотя и анизотропная. Для того чтобы это было справедливо, поперечная длина когерентности $\xi_\perp(T)$ должна быть велика по сравнению с расстоянием d между сверхпроводящими слоями в слоистой структуре. Если и низкотемпературная длина когерентности $\xi_{0\perp} = \varepsilon\xi_0$ больше d, то сверхпроводник всегда можно считать непрерывным; в случве $\xi_{0\perp}/d < 1$ непрерывное описание пригодно достаточно близко к T_c, где длины когерентности $\xi(T)$ и $\xi_\perp(T)$ возрастают. В области $\xi_\perp(T)/d < 1$ материал естественно рассматривать как набор тонких сверхпроводящих слоев со слабыми (джозефсоновскими) связями между слоями. К этой категории относятся высокотемпературные сверхпроводники семейства $Bi - Sr - Ca - Cu - O$, у которых параметр анизотропии $\varepsilon^{-1} > 100$. В первом приближении при рассмотрении такого вещества джозефсоновской связью между слоями можно вовсе пренебречь и рассматривать его как набор двумерных сверхпроводящих слоев, связанных лишь магнитным взаимодействием. Мы не будем здесь останавливаться подробнее на свойствах слоистых квазидвумерных сверхпроводников; их обсуждение можно найти, например, в обзоре [96].

7.7.2 36*. Разрушение сверхпроводимости в тонкой пленке тепловыми вихрями

36.1. Фазовый переход Березинского-Костерлица Таулеса.

В тонких сверхпроводящих пленках (толщиной $d \ll \lambda$) вихри, аналогичные абрикосовским, могут не только рождаться внешним поперечным магнитным полем, но и возникать при $H_0 = 0$ (чисто флуктуационным образом). В этом случае плотности вихрей с положительной и отрицательной циркуляциями совпадают. Однако возникшие из-за тепловых флуктуаций вихри могут сильно влиять на сверхпроводящие свойства пленки; они приводят к ее переходу в нормальное состояние при температуре $T_{\text{ВКТ}}$,

более низкой, чем определенная по теории Гинзбурга-Ландау температура перехода T_{c0}. Подобный фазовый переход был впервые предсказан (для целого ряда двумерных систем - магнетиков, кристаллов, сверхтекучих пленок) В.Л. Березинским [97], а затем подробнее исследован в работах [98, 99] и (специально для случая сверхпроводников) в [100]; с тех пор его существование подтверждено многочисленными экспериментами. Мы рассмотрим здесь качественную картину фазового перехода Березинского - Костерлица - Таулеса (сокра щенно - БКТ-переход), а в следующем разделе - его наблюдаемые следствия для сверхпроводящих пленок.

В §30 было показано, что энергия взаимодействия (на единицу длины) двух абрикосовских вихрей на расстоянии $R \ll \lambda$, когда экранировкой можно пренебречь, равна $2q_1q_2\epsilon_0 \ln(R/\lambda)$, где $q_{1,2}$ принимают значения $+1$ для вихрей с положительной и -1 для вихрей с отрицательной циркуляцией соответственно, а $\epsilon_0 = (\Phi_0/4\pi\lambda)^2$. Главный вклад в ϵ_0 дает кинетическая энергия сверхтекучего движения вокруг каждого вихря $E_{\text{кин}} = \frac{1}{2}\int d\mathbf{r} m n_s v_s^2(r)$, где сверхтекучая скорость $v_s(r) = \frac{\hbar}{2m}\left(\nabla\theta - \frac{2e}{\hbar c}\mathbf{A}\right) \propto \frac{\hbar}{2mr}$ на малых расстояниях от центров вихрей (где можно пренебречь вкладом векторного потенциала). В случае пленки экранирующий сверхтекучий ток сосредоточен в тонком слое толщины $d \ll \lambda$, в то время как магнитное поле распределено во всем трехмерном пространстве. Поэтому экранировка магнитного поля вихря в пленке оказывается гораздо слабее, чем в объемном сверхпроводнике. Точный расчет, изложенный в книге [7], дает эффективную длину экранировки

$$\lambda_{2d} = \frac{2\lambda^2}{d} \tag{36.1}$$

Этот результат можно угадать и из сравнения формул (10.4) и (10.7) для кинетических индуктивностей поверхности массивного сверхпроводника и тонкой пленки - обе эти формулы можно записать в виде $L_{\square}^k = 2\pi\lambda_{\text{эфф}}$, где $\lambda_{\text{эфф}}$ равно либо λ, либо λ_{2d}.

При расстолниях между вихрями в пленке $R \ll \lambda_{2d}$ экранировкой можно пренебречь, и полная энергия взаимодействия $U_2(R) = 2q_1q_2d\epsilon_0 \ln(R/\lambda_{2d})$, а собственная энергия каждого из вихрей равна $U_1 = d\epsilon_0 \ln(\lambda_{2d}/\xi)$, так что полная энергия пары вихрей противоположных циркуляций равна

$$U_{\text{pair}}(R) = 2\epsilon_0 d \ln\frac{R}{\xi} = \frac{\Phi_0^2}{4\pi^2\lambda_{2d}} \ln\frac{R}{\xi} \tag{36.2}$$

В тонких пленках λ_{2d} может достигать макроскопических размеров. Так, при $\lambda = 3$ мкм (что легко достигается в близкой
окрестности T_{c0}) и толщине пленки $d = 50$Å получим $\lambda_{2d} \simeq \simeq 3.6$ мм. При этом энергия кора вихря, $U_{\text{core}} = d\epsilon_0$, мала: $U_{\text{core}}/k_{\text{B}} \simeq 10$ K, в то время как полная энергия гораздо больше, $U_1/k_{\text{B}} \simeq 100$ K (мы выбрали здесь для оценки $\xi \simeq 0.1$ мкм). Пусть, для примера, $T_{c0} = 5$ K. Тогда вероятность найти (на площади порядка размера кора ξ^2) отдельный вихрь, возникший вследствие тепловой флуктуации в бесконечной пленке, будет очень мала, порядка $e^{-U_1/T} \leqslant 10^{-8}$. Казалось бы, это значит, что такими вихрями всегда можно пренебречь. Однако в бесконечной пленке и число мест, где может находиться каждый вихрь, бесконечно. Для аккуратного анализа надо рассмотреть случай пленки конечного размера L, где есть порядка $(L/\xi)^2$ возможных "посадочных мест" для вихрей.

Поскольку λ_{2d} может быть очень велико, имеет смысл рассмотреть случай размеров L, малых по сравнению с λ_{2d} (мы обсудим влияние конечности длины λ_{2d} позже, в самом конце этого раздела). Тогда энергия вихря равна $U_1(L) = d\epsilon_0 \ln(L/\xi)$, а среднее число вихрей во всей пленке порядка

$$n(L) \simeq (L/\xi)^2 \exp(-U_1(L)/T) = (L/\xi)^{2-\alpha}$$

где $\alpha = \epsilon_0 d/k_\mathrm{B}T = \Phi_0^2/(8\pi^2\lambda_{2d}k_\mathrm{B}T)$. При достаточно низких температурах $\alpha > 2$ и среднее число вихрей во всей пленке убывает с ростом L; иначе говоря, в большой системе при $k_\mathrm{B}T < \epsilon_0 d/2$ отдельных флуктуационных вихрей нет. Напротив, при $\alpha < 2$ вероятность найти вихрь растет с L. Этот же результат можно выразить немного иначе, определив свободную энергию одиночного вихря по обычным правилам статистической механики как $F_1 = U_1 - TS_1$, где энтропия $S_1 = k_\mathrm{B}\ln(L^2/\xi^2)$ есть просто логарифм числа доступных для вихря мест на пленке. Тогда условие $\alpha < 2$ означает, что свободная энергия в расчете на один вихрь отрицательна, то есть вихрям выгодно рождаться (до тех пор, пока их взаимодействие, пока еще нами не учтенное, не остановит этот процесс). Температура $T_\mathrm{BKT} = \Phi_0^2/(16\pi^2 k_\mathrm{B}\lambda_{2d})$, при которой $\alpha = 2$, называется температурой перехода БерезинскогоКостерлица-Таулеса.

Но состояние пленки со свободными вихрями уже не является сверхпроводящим! Это можно понять с помощью двух различных рассуждений. Во-первых, фаза параметра порядка $\theta(\mathbf{r},t)$ в каждой точке сверхпроводника сильно зависит (в каждый данный момент времени) от положений всех вихрей, поскольку фаза меняется на 2π при обходе вокруг каждого вихря. Это означает, что вихри, передвигаясь подобно частицам жидкости, приводят к сильным флуктуациям фазы $\theta(\mathbf{r},t)$. Нетрудно показать, что в случае двумерной жидкости вихрей флуктуации эти столь велики, что среднее значение $\left\langle e^{i\theta(\mathrm{r},t)}\right\rangle$ обращается в нуль. Поэтому обращается в нуль и сверхпроводящий параметр порядка $\Psi \propto \left\langle e^{i\theta(\mathrm{r},t)}\right\rangle$, так что с позиций теории Гинзбурга-Ландау сверхпроводимость отсутствует. Второе рассуждение имеет более "практический" характер. В том случае, когда вихри индуцируются в сверхпроводнике внешним магнитным полем, они обычно образуют решетку, которая зацепляется за примеси и потому остается неподвижной при достаточно малых токах (подробнее это обсуждается в §§38, 39, 41). Транспортный ток с плотностью j, большей критического значения j_c, приводит (как будет объяснено в 40) к движению вихревой решетки, при котором происходит диссипация энергии. Вихри же, возникающие в тонкой пленке вследствие тепловых флуктуаций, взаимодействуют между собой с энергией порядка тепловой и решетки не образуют. Поэтому они не могут и зацепиться за примеси, т. е. движение тепловых вихрей (и потому диссипация) вызывается сколь угодно малым током. Мы пришли к важному выводу: разрушение сверхпроводящего состояния в тонкой пленке происходит в действительности при более низкой температуре, чем это предсказывается в теории Гинзбурга-Ландау, не учитывающей флуктуаций, причем с приближением к температуре T_BKT этого перехода снизу лондоновская глубина проникновения $\lambda(T)$ остается конечной:

$$\frac{1}{\lambda_{2d}(T_\mathrm{BKT})} = \frac{d}{2\lambda_-^2(T_\mathrm{BKT})} = \frac{16\pi^2 k_\mathrm{B}T_\mathrm{BKT}}{\Phi_0^2}. \tag{36.3}$$

Иначе говоря, макроскопическая (с учетом вихрей) сверхтекучая плотность пленки $n_s^{(2)} = n_s d$ испытывает при повышении температуры скачок от значения $n_s^{(2),\min}$, универсальным образом связанного с температурой перехода:

$$n_s^{(2),\min} = \frac{8mk_\mathrm{B}T_\mathrm{BKT}}{\pi\hbar^2} \tag{36.4}$$

до нуля. Найдем, используя теорию Гинзбурга-Ландау, насколько температура БКТ-перехода отличается от «затравочной» критической температуры T_{c0}. Вблизи T_{c0} сверхтекучая плотность $n_s(T) = \mathcal{A}n_s(0)(1 - T/T_{c0})$, где коэффициент $\mathcal{A}$ равен 2 в чистом пределе и примерно 2.6 - в грязном (см. 51), так что получаем

$$\frac{T_{c0} - T_\mathrm{BKT}}{T_{c0}} \simeq \frac{32\pi^2\lambda^2(0)k_\mathrm{B}T_{c0}}{\mathcal{A}\Phi_0^2 d} \tag{36.5}$$

где $\lambda(0)$ - глубина проникновения при $T \to 0$. Оценка (36.5) совпадает (с точностью до численного множителя) с приведенной ранее в 19 оценкой ширины флуктуационной области в двумерной системе Gi^{2D}. Хотя в 19 мы использовали совсем другие аргументы, не имеющие отношения к вихрям, результат получился такой же. Фактически T_{BKT} всегда близко к T_{c0} даже в тонких пленках грязных сверхпроводников: используя (36.5) и формулы из §51, для грязного предела получим

$$\frac{T_{c0} - T_{\mathrm{BKT}}}{T_{c0}} \simeq 3\mathrm{Gi}_d^{(2D)} = \frac{3}{16g} \tag{36.6}$$

где параметр $\mathrm{Gi}_d^{(2D)}$ определен в (19.17). Правая часть (19.17) может стать порядка 1 лишь при g, заметно меньшем единицы, что происходит лишь в окрестности перехода металл - диэлектрик. Во всех остальных случаях зависимость $n_s(T)$ должна иметь вид, изображенный схематически на рис.36.1. Этот вывод подтвержден экспериментально - путем измерения кинетической индуктивности тонких пленок [101].

Аргументы, которые мы использовали выше, чтобы найти условие $\alpha = 2$ фазового БКТ-перехода, были не вполне строги, однако последовательная теория приводит к точно такому

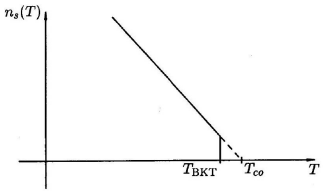

Рис. 36.1. Схематический вид характерной зависимости сверхтекучей плотности от температуры при БКТ-переходе в тонкой сверхпроводящей пленке.

же выводу. Тем не менее, мы сейчас опишем схематически этот более последовательный подход, т.к. эти идеи понадобятся нам ниже при обсуждении вида вольт-амперных характеристик вблизи точки БКТ-перехода.

При $T < T_{\mathrm{BKT}}$ в системе нет одиночных флуктуационных вихрей, однако существуют пары вихрей с противоположными циркуляциями ($q_1 q_2 = -1$), и вероятность найти такую пару с расстоянием R между вихрями есть $P(R) = \exp\left(-U_{\mathrm{pair}}(R)/k_{\mathrm{B}}T\right) \propto$ $\propto (R/\xi)^{-2\alpha}$. Мы можем формально рассматривать вихри как заряженные частицы, а их пары - как нейтральные «вихревые молекулы». Эта аналогия тем более разумна, что в двумерном пространстве обычный кулоновский потенциал точечного заряда (определяемый уравнением Гаусса $\varepsilon_v \nabla \mathbf{E} = -\varepsilon_v \nabla^2 \varphi = 2\pi\delta(\mathbf{r})$) логарифмически растет с расстоянием: $\varphi = \varepsilon_v^{-1} \ln(r)$. Здесь мы ввели обозначение ε_v для "диэлектрической постоянной» газа вихревых молекул. Тогда фазовый переход БКТ можно описать как переход между газом нейтральных вихревых молекул (где величина ε_v конечна) и "вихревой плазмой", состоящей из отдельных «заряженных» частиц, где $\varepsilon_v \to \infty$ и кэлектрическое» поле каждого отдельного «заряда» экранируется другими «зарядами" - вихрями. Начнем с низкотемпературной фазы, где
есть лишь малая плотность вихревых молекул. Они дают вклад в «диэлектрическую восприимчивость" среды $\kappa_v = (\varepsilon_v - 1)/2\pi$, пропорциональный среднему квадрату "дипольного момента" вихревой молекулы:

$$\kappa_v \propto \int_{\xi}^{L} R^2 P(R) 2\pi R dR \propto \int_{\xi}^{L} \frac{dR}{R^{2\alpha-3}}; \quad \alpha = \frac{\epsilon_0 d}{T\varepsilon_v} \tag{36.7}$$

Как видно из (36.7), при α, стремящемся к 2 сверху, интеграл, определяющий κ_v, начинает логарифмически расходиться как функция размера системы L. Второе

равенство в (36.7) учитывает (самосогласованным методом), что параметр α сам зависит от взаимодействия между вихрями (мы здесь подразумеваем, что величина λ, входящая в ϵ_0, определена в рамках теории Гинзбурга-Ландау и вихрей не учитывает). Самосогласованное уравнение типа (36.7) было выведено в работе Костерлица и Таулеса [98], а его аккуратное решение приведено в последующей работе Костерлица [99] (см. также [34]). Результат этого решения, как можно догадаться уже из (36.7), состоит в том, что $\alpha_{\min} = 2$ сохраняется как точное минимальное значение параметра α при учете всех поправок, что подтверждает универсальность скачка сверхтекучей плотности (36.4). Кроме того, это решение позволяет найти зависимость среднего расстояния между свободными вихрями $R_c(T)$ (т.е. масштаба длины, на котором разрушается сверхпроводимость) при $T > T_{\text{ВКТ}}$:

$$\ln \frac{R_c(T)}{\xi} = b \left(\frac{\text{Gi}^{(2D)} T}{T - T_{\text{ВКТ}}} \right)^{1/2} \tag{36.8}$$

где $\xi(T)$ - обычная сверхпроводящая длина корреляции, определяемая с помощью теории Гинзбурга - Ландау, а b - число порядка единицы. Появление множителя $\text{Gi}^{(2D)}$ в правой части (36.8) легко понять: при $\frac{T-T_{\text{ВКТ}}}{T} \geqslant \text{Gi}^{(2D)}$ температура уже столь близка к T_{c0}, что невозможно отличить флуктуационные вихри от обычных флуктуаций, поэтому $R_c(T) \sim \xi(T)$.

Весь предыдущий анализ был основан на логарифмической зависимости энергии пары вихрь-антивихрь от расстояния. На очень больших расстояниях $R \geqslant \lambda_{2D}$ энергия такой пары перестает расти с R; иначе говоря, энергия уединенного вихря остается конечной, а потому и отлична от нуля их концентрация при всякой отличной от нуля температуре. Формально говоря, это означает, что двумерный сверхпроводник всегда находится в резистивном состоянии. Однако фактически концентрация вихрей при $T < T_{\text{ВКТ}}$ имеет порядок $e^{-\alpha \ln(\lambda_{2D}/\xi)} < (\xi/\lambda_{2D})^2$, и ею можно пренебречь везде, кроме совсем узкой окрестности $T_{\text{ВКТ}}$, где корреляционный радиус, определяемый уравнением (36.8), мог бы оказаться больше λ_{2D}.

36.2. Вольт-амперные характеристики вблизи БКТперехода. В сверхпроводящем состоянии, реализующемся при $T < T_{\text{ВКТ}}$, по определению должно быть равно нулю линейное сопротивление, определяемое как $\rho_{\text{лин}} = (dV/dI)_{I=0}$. Это, однако, не означает, что напряжение должно быть равно нулю при малых токах. В тонкой пленке, как мы сейчас увидим, напряжение при низких температурах растет как высокая степень тока, $V \propto I^{\alpha+1}$. Действительно, рассмотрим «нейтральную" пару вихрей, повернутую перпендикулярно протекающему току с плотностью j, так что сила Лоренца стремится увеличить размер пары R. Полная энергия пары с учетом силы Лоренца равна

$$U_{\text{полн}}(R) = 2\epsilon_0 d \ln \frac{R}{\xi} - jd \frac{\Phi_0}{c} R \tag{36.9}$$

где j - плотность транспортного тока. При самых больших $R > R^* = (2c\epsilon_0/j\Phi_0)$ второй член в полной энергии всегда больше первого, т.е. внешний ток приводит к разрыву вихревых молекул на отдельные вихри. Иначе говоря, если по пленке протекает транспортный ток, в ней создается ненулевая плотность неспаренных вихрей $n_v(j)$ на единицу площади пленки. Но движение этих вихрей под действием тока приводит к диссипации энергии, т. е. к конечному сопротивлению $\rho(j) \sim n_v(j)\xi^2(T)\rho_n$ (эту оценку легко получить, сравнивая с проведенным в §40 выводом сопро тивления ρ_f в резистивном состоянии). Поэтому нам осталось найти стационарную плотность одиночных вихрей $n_v(j)$ (обоих знаков) при заданной плотности тока j.

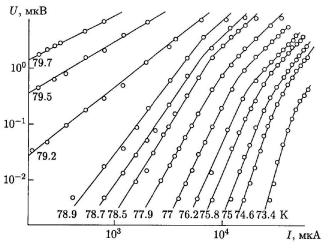

Рис. 36.2. Нелинейные вольт-амперные характеристики монокристалла $Bi_2Sr_2CaCu_2O_x$ при различных температурах $T \lesssim T_c$.

Стационарная величина $n_v(j)$ определяется равенством скорости рождения одиночных вихрей Γ_+из-за разрыва пар током и скорости аннигиляции Γ_-уже имеющихся вихрей противоположных знаков. Величину Γ_+оценим как вероятность термоактивационного процесса преодоления потенциального барьера $U_{\text{полн}}\ (R^*) = 2\epsilon_0 d \ln(2\epsilon_0 c/j\Phi_0\xi)$, определяемого максимумом по R выражения (36.9). Таким образом,

$$\Gamma_+ \sim \Gamma_0 \exp\left(-U_{\text{полн}}\ (R^*)/k_{\text{B}}T\right)$$

где Γ_0 - величина размерности частоты. Величина Γ_-определяется вероятностью (в единицу времени) того, что два вихря про тивоположных знаков приблизятся на расстояние порядка размера кора $\xi(T)$, после чего аннигилируют. При малой концентрации вихрей, $n_v(j)\xi^2(T) \ll 1$, вероятность такого «столкновения» вихрей пропорциональна квадрату их концентрации,

$$\Gamma_- \sim \Gamma_0 \left(n_v(j)\xi^2(T)\right)^2$$

Таким образом, приравнивая Γ_+к Γ_-, получаем равновесную концентрацию вихрей

$$n_v(j)\xi^2(T) \sim \exp\left(-U_{\text{полн}}\ (R^*)/2k_{\text{B}}T\right)$$

и для сопротивления получаем

$$\rho(j) \sim \rho_n j \left(\frac{j}{j_T}\right)^{\boldsymbol{\alpha}} \tag{36.10}$$

где

$$j_T = \frac{c\Phi_0}{16\pi^2\lambda^2(T)\xi(T)}$$

близко к плотности тока распаривания в теории Гинзбурга-Ландау.

Как мы уже знаем, минимальная величина параметра α в низкотемпературной фазе равна 2, так что показатель степени в вольт-амперной характеристике $V(I) \propto I^{1+\alpha}$ испытывает при понижении температуры скачок от 1 к 3. Пример измерения ВАХ, позволившего продемонстрировать существование БКТперехода в сильно анизотропном (слоистом) ВТСП монокристалле $Bi_2Sr_2CaCu_2O_8$ [103], показан на рис. 36.2

Зависимость линейного сопротивления от температуры при $T > T_{\text{ВКт}}$ можно определить аналогично выводу (36.10). Выше точки перехода плотность вихрей n_v остается ненулевой при $j \to \to 0$: по порядку величины $n_v \sim R_c^{-2}(T)$, где радиус корреляции $R_c(T)$ ведет себя согласно уравнению (36.8). Поэтому для сопротивления получаем

$$\rho(T) \sim n_v(T)\xi^2(T)\rho_n \sim \rho_n \exp\left(-2b\left(\frac{\text{Gi}_{2D}T}{T - T_{\text{ВКТ}}}\right)\right) \tag{36.11}$$

Зависимость сопротивления вида (36.11) была с хорошей точностью подтверждена на эксперименте [102].

7.7.3 37*. Melting of the Vortex Lattice

В теории Гинзбурга - Ландау - Абрикосова - Горькова фазовый переход в сверхпроводящее состояние в магнитном поле происходит при значении внешнего поля $H_0 = H_{c2}(T)$, когда одновременно появляется сверхпроводящий параметр порядка $\Psi(\mathbf{r}_\perp, z) \neq \neq 0$, периодически зависящий от координат $\mathbf{r}_\perp$, и возникает решетка вихрей (в центрах которых $\Psi(\mathbf{r}_\perp, z)$ обращается в нуль). С точки зрения изменения симметрии на линии $H_0 = H_{c2}(T)$ одновременно происходят два разных фазовых перехода: нарушается и градиентная инвариантность (параметр порядка Ψ неинвариантен при градиентном преобразовании, см. п. 14.3), и трансляционная инвариантность - поскольку возникает периодическая структура.

В отличие от большинства обычных сверхпроводников, в случае ВТСП тепловыми флуктуациями вблизи фазового перехода пренебрегать нельзя. Даже в отсутствие магнитного поля в $YBa_2Cu_3O_{7-x}$ с температурой перехода около 90 K ширина флуктуационной области имеет порядок 1 K, т.е. параметр Gi $\sim \sim 10^{-2}$, и она еще больше в сильно слоистых соединениях типа $Bi_2Sr_2CaCu_2O_8$. Фазовый переход в сверхпроводящее состояние в магнитном поле еще более чувствителен к флуктуационным эффектам: помимо обычных флуктуаций параметра порядка, имеющихся и при $B = 0$, здесь возможны также флуктуации положений вихревых линий в пространстве, которые очень сильно меняют фазу параметра порядка в окрестности каждой такой линии.

Последовательной теории фазового перехода сверхпроводник-металл в магнитном поле, которая учитывала бы флуктуационные эффекты, не создано до сих пор, однако качественную картину происходящего в ВТСП можно понять, рассмотрев решетку вихрей в лондоновском приближении, справедливом при $B \ll H_{c2}(T)$ (подразумевается сверхпроводник с $\varkappa \gg 1$, что характерно для ВТСП). В этом случае размер сердцевины вихря ξ мал по сравнению с расстоянием между вихрями $a_0 = \sqrt{\Phi_0/B}$, в большей части сверхпроводника абсолютная величина параметра порядка $|\Psi|$ близка к ее значению в отсутствие магнитного поля, и решетку вихрей можно рассматривать как аналог обычной кристаллической решетки. Отличие лишь в том, что вихревал решетка состоит из линий (в среднем параллельных направлению z внешнего магнитного поля $\mathbf{H}_0$). Известно, что всякий кристалл плавится при некоторой температуре, когда амплитуда $u_{\text{тепл}} = \sqrt{\langle u^2 \rangle_{\text{тепл}}}$ тепловых флуктуаций атомов (или электронов - если речь идет о вигнеровском кристалле из электронов на поверхности гелия) становится сравнимой с постоянной решетки a_0. Фактически отношение $u_{\text{тепл}}/a_0$ в точке плавления всегда остается численно малой величиной (называемой постоянной Линдеманна c_{L}, который и предложил использовать равенство $u_{\text{тепл}} = c_{\text{L}} a_0$ в качестве феноменологического критерия плавления обычных трехмерных кристаллов, где $c_{\text{L}} \simeq 0.1 \div 0.15$). Величину $u^2_{\text{тепл}}$ для вихревой решетки можно вычислить как сумму квадратов амплитуд флуктуаций с определенными волновыми векторами $\mathbf{q}$ - аналогичных обычным фононам. Мы не будем приводить здесь этот вывод (см., например, обзор [96]) и дадим вместо этого простую оценку величины поля плавления решетки $B_m(T)$, качественно справедливую в широком интервале полей, $H_{c1} \ll B \ll H_{c2}$. Чтобы ее получить, приравняем по порядку величины тепловую энергию $k_{\text{B}}T$ и энергию $E_{\text{упр}}$ сильной ($|\delta\mathbf{u}| \sim a_0$) деформации вихревой решетки в объеме порядка a_0^3. Для таких коротковолновых возмущений нет существенного различия между деформациями сжатия и сдвига, и потому $E_{\text{упр}}$ можно оценить просто через характерное значение

энергии взаимодействия вихрей на длине порядка постоянной решетки: $E_{\text{упр}} \sim \epsilon_0 a_0$, где $\epsilon_0 = (\Phi_0/4\pi\lambda)^2$. Приравнивая полученную таким образом величину $E_{\text{упр}}$ к тепловой энергии, получим для поля плавления решетки

$$B_m(T) \propto \frac{\Phi_0}{(k_{\text{B}}T)^2}\left(\frac{\Phi_0}{4\pi\lambda}\right)^4 \propto (1-T/T_c)^2 \quad \text{при} \quad T \to T_c. \tag{37.1}$$

Мы получили важный и несколько неожиданный результат: поле плавления решетки убывает с повышением температуры быстрее,
чем верхнее (и нижнее) критическое поле, которое ведет себя линейно вблизи температуры перехода, $H_{c2} \propto (1-T/T_c)$. Вспоминая определение ширины флуктуационной области Gi, данное в §19, оценку (37.1) для поля плавления решетки можно записать в виде

$$\frac{B_m(T)}{H_{c2}(T)} = \alpha_m \frac{1-T/T_c}{\text{Gi}} \tag{37.2}$$

где α_m - численный коэффициент. Более аккуратные аналитические [96] и численные [104] расчеты тоже приводят к результату (37.2), а также показывают, что α_m весьма мало, $\alpha_m \sim \sim 2 \cdot 10^{-2}$ (иначе этот результат может быть выражен в виде значения $k_{\text{B}}T_m(B)/\epsilon_0 a_0 \simeq 0.1$). Численные расчеты [104] позволяют определить и величину параметра Линдеманна для плавления вихревой решетки, $c_{\text{L}} \simeq 0.25$. Результат для линии плавления в форме (37.2) остается справедлив и для анизотропных сверхпроводников типа $YBa_2Cu_3O_{7-x}$, когда исходное выражение (37.1) должно быть модифицировано для учета анизотропии (поскольку характерный пространственный масштаб деформаций в направлении вихрей z теперь отличается от a_0 и имеет порядок ϵa_0, получаем $k_{\text{B}}T_m(B)/\epsilon_0 a_0 \simeq 0.1\epsilon$). Для сильно слоистых соединений типа $Bi_2Sr_2CaCu_2O_8$ оценка для линии $B_m(T)$ несколько отличается от (37.2), но качественно картина остается той же.

Конечно, оценка (37.2) имеет смысл лишь вне области сильных флуктуаций параметра порядка, т.е. при $(1-T/T_c) \geqslant \text{Gi}$. Кроме того, отношение B_m/H_{c2} должно быть мало, поскольку иначе энергия деформации оказывается [105] существенно меньше, чем использованная оценка $E_{\text{упр}} \sim \epsilon_0 a_0$. Эти два условия оказываются совместны в области температур $\text{Gi} \ll (1-T/T_c) \ll \ll \text{Gi} \cdot \alpha_m^{-1}$ в силу малости числа α_m. В результате мы приходим к важному выводу: в некотором интервале температур вблизи T_c смешанное состояние сверхпроводника II рода в форме решетки вихрей неустойчиво по отношению к тепловым флуктуациям - уже при полях B существенно меньших, чем H_{c2}. Обычно плавление кристаллической решетки - фазовый переход I рода (с ненулевым скачком энтропии и плотности). Плотность вихрей пропорциональна магнитной индукции B, поэтому если пла вление вихревой решетки - переход I рода, то на линии перехода должен наблюдаться скачок равновесной намагниченности образца. Именно такой результат был получен в очень красивых экспериментах [106, 107], где фазовые переходы плавления вихревой решетки в очень чистых монокристаллах $Bi_2Sr_2CaCu_2O_8$ и $YBa_2Cu_3O_{7-x}$ были зарегистрированы по слабым скачкам локального значения равновесной намагниченности $\Delta M_{\text{плавл}}$. В полях $B > B_m(T)$ в смешанном состоянии вихревые линии образуют жидкость. Количественной теории этого нового состояния пока не существует; также не вполне ясно, какой смысл следует придавать верхнему критическому полю H_{c2}, когда оно заметно превышает поле плавления $B_m(T)$. В любом случае, эти вопросы имеют практический смысл почти исключительно для высокотемпературных сверхпроводников - в большинстве остальных материалов величина Gi очень мала и эффекты плавления решетки почти ненаблюдаемы. В то же время для ВТСП наблюдаемые следствия плавления вихревой решетки весьма важны, они определяют собой аномальное поведение вольт-амперных характеристик в

смешанном состоянии при относительно высоких полях и температурах. Мы рассмотрим эти явления ниже в 42.

7.7.4 38. Critical current in type-II SC

Если сверхпроводник второго рода находится в смешанном состоянии и в направлении, перпендикулярном вихрям, идет транспортный ток (т.е. ток, созданный каким-то внешним источником), то на вихри действует сила Лоренца. Если бы сверхпроводник был совершенно однороден, бездефектен, то при любой, сколь угодно малой силе Лоренца, вихри бы начали свое движение под действием этой силы.

В 40 будет показано, что такое движение сопровождается диссипацией энергии. Это означает, что у такого абсолютно однородного образца критический ток равен нулю.

В неоднородном сверхпроводнике второго рода, когда существуют разные виды дефектов (границы зерен, включения дру гой фазы, дислокационные стенки, скопления дислокаций, поры и т.п.), вихри могут на них закрепиться. Тогда требуется уже конечный транспортный ток для начала движения вихрей. Этот ток создает такую силу Лоренца, действующую на вихри, которой достаточно для отрыва вихрей от дефектов. Эти дефекты часто называются центрами пиннинга, а закрепление на них вихрей - пиннингом. [1)] Плотность тока, при котором начинается отрыв вихрей от центров пиннинга, называется критической плотностью тока j_c.

Критическая плотность тока может очень сильно (на несколько порядков) меняться в результате термомеханической обработки материала, так как является чрезвычайно структурно чувствительным свойством. При этом критическая температура T_c и второе критическое поле H_{c2} могут практически не измениться. У некоторых сверхпроводников, предназначенных для использования в сверхпроводящих магнитах или других сверхпроводящих устройствах, величина критического тока может достигать значений порядка 10^6 A/cm^2. Такого же порядка величины, до $5 \cdot 10^6$ A/cm^2, достигают критические токи в не очень чистых кристаллах $YBa_2Cu_3O_{7-x}$ и других ВТСП при низких температурах.

Рассмотрим механизм протекания критического тока через сверхпроводник второго рода, в котором имеется много центров пиннинга. Для того чтобы транспортный ток шел по всему ссчению сверхпроводника, необходимо, чтобы существовало неоднородное распределение вихрей. Действительно, плотность полного тока, текущего в данном месте, равна

$$j_{\text{тр}} = \frac{c}{4\pi} \operatorname{rot} \mathbf{B} \tag{38.1}$$

но $B = \Phi_0 n$ - среднее поле в данном месте, т. е. напряженность магнитного поля, усредненная по области, размер которой намного больше расстояния между вихрями, n - средняя плотность вихрей в данном месте. Из (38.1) следует, что $\mathbf{j}_{\text{тр}}$ отличен от нуля в данном месте, если плотность вихрей $n = n(\mathbf{r})$.

Теперь нам надо понять, как возникает такое состояние, когда по всему сечению сверхпроводника устанавливается критическая плотность тока.

Пусть бесконечная пластина толщины d содержит очень много дефектов, на которых сверхпроводящие вихри могут хорошо закрепляться, при этом $d \gg \lambda$. Поверхности пластин совпадают с плоскостями $x = \pm d/2$. Внешнее магнитное поле H_0 пока отсутствует. Начнем пропускать транспортный ток через пластину (в направлении оси y). Сначала, как и у бездефектного сверхпроводника, ток пойдет по поверхности пластины (эффект Мейсснера Оксенфельда). Когда поле, созданное током на

[1)] От английского слова pin - булавка. Дословно pinning - это пришпиливание.

поверхностях, H_I, превысит поле H_{c1} материала пластины, внутрь пластины проникнут вихри. Они будут иметь разные направления на противоположных сторонах. Но далеко внутрь они не проникнут, так как закрепляются на неоднородностях пластины. При этом возникает градиент их плотности. Ясно, что это будет максимально возможный градиент, т.е. такой, который обеспечивает протекание критического тока. Итак, некоторая область вблизи поверхностей пластины будет нести критический ток, а остальная часть пластины вообще тока нести не будет. Это схематически изображено на рис. 38.1, a, где показано распределение магнитного поля внутри пластины при токе через пластину, равном I_1 (на единицу высоты пластины вдоль оси z).

Увеличим теперь ток до величины I_2. Вихри, сохранив критический градиент плотности $(\nabla n)_c$, продвинутся ближе к центру. Теперь только центральная часть пластины свободна от транспортного тока, а остальная часть пластины несет ток, плотность которого равна критической. Если продолжать увеличивать ток через пластину, мы придем к такому току I_c, когда в любой точке пластины плотность тока будет критической. Все это изображено на рис. 38.1, a.

Такое состояние, когда в любом месте поперечного сечения пластины течет критический ток, называется критическим состоянием.

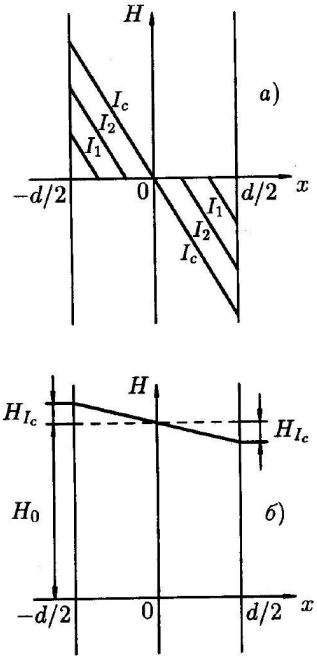

Рис. 38.1. Распределение поля в пластине (толщины d) с центрами пиннинга, когда по пластине течет ток I: а) внешнее поле отсутствует, $I_1 < I_2 < I_c$ - токи в пластине; б) случай пластины с током и во внешнем поле. Показано распределение в критическом состоянии.

Наложим теперь внешнее магнитное поле H_0, параллельное поверхности пластины и перпендикулярное току, т.е. поле H_0 параллельно оси z. Предположим, что $H_0 \gg H_I$. Тогда распределение тока в пластине в критическом состоянии будет таким, как показано на рис. 38.1, б. Пренебрегая небольшой разницей в полях $H_0 + H_I$ и $H_0 - H_I$, можно считать, что все точки проводника находятся в поле H_0. Плотность критического тока в поле H_0 меньше, чем в отсутствие поля, поэтому критический градиент плотности вихрей меньше.

Действительно, если сила Лоренца, действующая на единицу длины вихря, равна $f_{\mathrm{L}} = j_{\mathrm{тр}}\,\Phi_0/c$, то сила Лоренца, отнесенная к единице объема, равна $F_{\mathrm{L}} = j_{\mathrm{гр}}B/c$, поскольку суммарная длина всех вихрей в единице объема равна $n = B/\Phi_0$. Эта сила уравновешивается в стационарном состоянии силой закрепления вихрей на неоднородностях. Пусть удельная сила закрепления (пиннинга) вихрей в единице объема равна F_p. Тогда

критический ток должен удовлетворять уравнению

$$\frac{1}{c} j_c B = F_p \tag{38.2}$$

Если предположить, что F_p не зависит от внешнего поля H_0, то получим $j_c \propto B^{-1}$. Такая зависимость критического тока от внешнего поля наблюдалась во многих экспериментах.

Если дефекты структуры сверхпроводника, т. е. центры пиннинга, распределены хаотично, то абсолютно жесткая решетка вихрей на них не может закрепиться. Чтобы это стало понятно, сдвинем мысленно такую решетку на малое расстояние в направлении действия силы Лоренца. Очевидно, что энергия системы при этом не изменяется, так как новое хаотическое расположение центров пиннинга относительно жесткой вихревой решетки ничем не отличается в принципе от старого. А раз нет изменения энергии, то нет и возвращающей силы, нет и пиннинга.

Совсем другая картина возникает, если предположить, что решетка вихрей - это упругая среда. Тогда вихри каждый раз будут подстраиваться к данному хаотическому распределению центров пиннинга так, чтобы вся система вихрей имела минимум энергии. Поэтому теперь уже будет нужно некоторое усилие, ттобы, сдвинув вихри, превзойти предел возвращающей силы и оторвать их от центров пиннинга. Ясно поэтому, что чем "мягче» решетка вихрей, чем она податливее, тем больше сила пиннинга.

Расчеты [108] показали, что модули упругости вихревой решетки уменьшаются при $H_0 \to H_{c2}$. Решетка становится мягче, а пиннинг сильнее. Это приводит к довольно часто наблюдаемому пику критического тока при $H_0 \sim H_{c2}$ (рис. 38.2). Подробнее этот вопрос мы рассмотрим в конце 41.

7.7.5 41*. Collective Pinning of Vortices by Weak Defects

41.1. Одиночный вихрь в поле слабых примесей.

Как уже упоминалось выше в 39, дефекты кристаллической решетки с размером порядка атомного очень слабо взаимодействуют с вихрями, поскольку размер кора вихря ξ обычно весьма велик в атомном масштабе. Тем не менее, вихрь может быть эффективно зацеплен и такими дефектами, если их плотность достаточно велика. В таком случае говорят о коллективном пиннинге вихрей на многих дефектах одновременно. Такие слабые дефекты-это, например, кислородные вакансии в высокотемпературных сверхпроводниках (ВТСП) и атомные примеси Та (замещающие атомы Nb) в слоистом соединении $NbSe_2$. Теория коллективного пиннинга была развита в работах Ларкина и др. [114, 115, 96, 116]. В этом параграфе мы опишем качественный подход, позволяющий оценить величину критического тока при коллективном пиннинге.

Начнем с самого простого случая: одна вихревая линия в поле слабых дефектов. Как мы знаем (см. (29.3)), вихрь в изотропном чистом сверхпроводнике обладает определенной энергией на единицу длины, равной $\epsilon_1 = \left(\frac{\Phi_0}{4\pi\lambda}\right)^2 \ln\varkappa \equiv \epsilon_0 \ln\varkappa$. Это означает, что если вихревую линию изогнуть, то ее энергия увеличится, т. е. вихрь ведет себя как упругая струна. Добавка к энергии вихря из-за изгиба пропорциональна его удлинению и при плавных изгибах может быть записана как

$$E_{el} = \frac{\epsilon_1}{2} \int dz \left(\frac{d\mathbf{u}}{dz}\right)^2 \tag{41.1}$$

где $\mathbf{u}$-вектор смещения участка вихря, соответствующего координате z вдоль него. Предположим сначала, что коэффициент линейного натяжения ϵ_1 очень велик, так что

можно считать вихрь совершенно прямым, и рассмотрим его взаимодействие с мелкими дефектами. Каждый такой дефект изменяет энергию вихря (если находится вблизи его кора) на величину порядка e (???) прим и случайную по знаку (поскольку среднее изменение энергии вихря из-за дефектов не приводит к его зацеплению, мы можем считать, что среднее значение $\overline{\delta e_{\text{прим}}} = 0$). При концентрации примесей $n_{\text{прим}}$ на длине L вдоль вихря в коре находится примерно $\mathcal{N} \sim n_{\text{прим}}\,\xi^2 L$ дефектов, так что при перемещении вихря в другое положение (на расстояние порядка ξ) энергия взаимодействия с дефектами изменится на величину порядка $E_{\text{пинн}}(L) \simeq e_{\text{прим}}\sqrt{\mathcal{N}} \simeq e_{\text{прим}}\,\xi\,(n_{\text{прим}}\,L)^{1/2}$. Заметим здесь, что именно размер кора вихря ξ определяет характерный пространственный масштаб, на котором меняется энергия взаимодействия вихря с мелкими дефектами. Как видно, возможный выигрыш в энергии взаимодействия с дефектами (из-за того, что вихрь передвинулся в более "подходящее» место) растет с длиной сегмента вихря (если он абсолютно жесткий) как $\sqrt{L}$. Но сила Лоренца, действующая на тот же сегмент вихря со стороны транспортного тока, пропорциональна его длине: $F_{\text{L}}(L) = \frac{1}{c}\Phi_0 j L$, так что и выигрыш в энергии взаимодействия с этим током растет пропорционально L и при достаточно большой длине всегда превысит $E_{\text{пинн}}(L)$, каким бы слабым ни был ток j.

Казалось бы, мы получили "отрицательный» результат-отсутствие пиннинга, нулевой критический ток. Теперь, однако, надо вспомнить о сделанном в начале предположении, что вихрь можно считать совершенно жестким - оно и привело к такому странному результату. В действительности форма вихря определяется конкуренцией между его упругой энергией, возрастающей при изгибе, и выигрышем энергии при помещении его сегментов в наиболее подходящие "потенциальные ямы". Результат этой конкуренции и определяет характерную длину L_p вихревого сегмента, на которой он смещается в поперечном направлении на длину порядка ξ, т.е. «переползает" из одной потенциальной ямы в поле дефектов в другую. Чтобы найти L_p, приравняем по порядку величины упругую энергию $E_{el}(L_p)\,\epsilon_1\frac{\xi^2}{L_p}$ и энергию связи с примесями $E_{\text{пинн}}(L_p) = e_{\text{прим}}\,\xi\,(n_{\text{прим}}\,L_p)^{1/2} \equiv (\gamma\xi^2 L_p)^{1/2}$:

$$\epsilon_1\frac{\xi^2}{L_p} \simeq \left(\gamma\xi^2 L_p\right)^{1/2} \tag{41.2}$$

(мы здесь также ввели обозначение $\gamma = n_{\text{прим}}\,e^2_{\text{прим}}$, которое будет часто использоваться в дальнейшем). Уравнение (41.2) определяет "длину пиннинга" L_p, а с ее помощью и критический ток j_c, задаваемый соотношением $\frac{1}{c}\Phi_0 j_c \simeq E_{\text{пинн}}(L_p)/\xi$ (в правой части здесь стоит характерная сила, действующая на вихрь со стороны ансамбля примесей, расположенных на длине L_p):

$$E_{\text{пинн}}(L_p) \simeq \left(\gamma\epsilon_1\xi^4\right)^{1/3} \simeq H^2_{cm}\xi^3\frac{\xi}{L_p}, \quad L_p \simeq \left(\frac{\epsilon_1^2\xi^2}{\gamma}\right)^{1/3}, \tag{41.3}$$

$$j_c \simeq \frac{c}{\Phi_0}\left(\frac{\gamma}{L_p}\right)^{1/2} \simeq j_0\left(\frac{\xi}{L_p}\right)^2, \tag{41.4}$$

где j_0 - "ток распаривания", определенный выше в (18.5) как критический ток для тонкой пленки. Все величины, входящие в формулу (41.4), подразумеваются зависящими от температуры, эти зависимости вблизи T_c следуют, как правило, из теории Гинзбурга-Ландау. Оценки (41.4) применимы, по смыслу их вывода, для случая слабого пиннинга, $j_c \ll j_0$, что и соответствует относительно большой длине $L_p \gg \xi$. Более того, буквальный вид формул (41.4), в которые входит параметр нлинейного натяжения* вихря ϵ_1, справедлив лишь при более сильном условии $L_p \geqslant \lambda$; в:противном случае

множитель $\ln\kappa = \ln(\lambda/\xi)$ в выражении для ϵ_1 следует заменить на $\ln(L_p/\xi)$. Дело в том, что при коротковолновых ($q > \lambda$) деформациях вихря магнитное поле «не успевает» следовать за изгибом его кора и эффективная жесткость вихря уменьшается, $\epsilon(q) = \epsilon_0 \ln(1/q\xi)$.

Длина L_p (называемая далее длиной пиннинга) имеет важный физический смысл - вихрь можно считать упругой струной лишь на масштабах $L \ll L_p$, в то время как на много больших масштабах отдельные сегменты длины L_p зацепляются примесями почти независимо один от другого. В результате полная энергия пиннинга сегмента большой длины $L \gg L_p$ оказывается пропорциональной длине: $E_{\text{пинн}}(L) \propto L\left(E_{\text{пинн}}(L_p)/L_p\right)$. Таким образом, пиннинг на слабых дефектах возникает из-за того, что вихрь слегка изгибается в поле дефектов, выбирая конфигурации, реализующие локальные минимумы полной энергии. Соот ветственно, увеличение линейного натяжения ϵ_1 должно приводить и к увеличению L_p, и к уменьшению критического тока j_c, как и следует из формул (41.4).

41.2. Коллективный пиннинг вихревой решетки.

В описанной выше картине шла речь о единичном вихре, т. е. предполагалось, что его взаимодействие с другими вихрями много слабее, чем с дефектами. Легко понять, в каких случаях такое представление справедливо: надо сравнить энергию пиннинга на единицу длины $E_{\text{пинн}}/L_p$ и повышение энергии (тоже на единицу длины) упругого взаимодействия вихрей в вихревой решетке, возникающее при относительном сдвиге соседних вихрей на расстояние порядка пространственного масштаба случайного потенциала ξ, т.е. $\epsilon_0\left(\xi/a_0\right)^2$, где $a_0 = \sqrt{\Phi_0/B}$. Сравнивая эти две энергии, обнаруживаем, что упругостью вихревой решетки можно пренебречь, если решетка достаточно редкая, $a_0 \gg L_p$. В обратном случае взаимодействие между вихрями сильное и его надо учитывать с самого начала. Это можно сделать аналогично описанному выше случаю одиночного вихря, разница лишь в том, что вместо упругой линии надо теперь рассмотреть трехмерную упругую решетку. Мы будем сначала считать, что постоянная решетки $a_0 \gg \xi$, т.е. среднее магнитное поле $H \ll H_{c2}$, так что можно использовать лондоновское приближение (что имеет смысл для сверхпроводников "сильно II рода», т.е. имеющих параметр Гинзбурга-Ландау $\varkappa \gg 1$).

Теперь нам надо исходить из упругой энергии деформации трехмерной вихревой решетки, которую можно записать в виде

$$E_{el}^{3D} = \frac{1}{2}\int d^3r \left[\left(C_{11} - C_{66}\right)(\nabla\cdot\mathbf{u})^2 + \right. \\ \left. + C_{66}\left(\nabla_a u_b\right)^2 + C_{44}\left(\frac{d\mathbf{u}}{dz}\right)^2\right]. \tag{41.5}$$

Здесь $\mathbf{u}$ - двумерный вектор локального смещения вихревой решетки, имеющий компоненты в плоскости (x, y), перпендикулярной направлению внешнего поля H; постоянные C_{11}, C_{44}, и C_{66} упругие модули вихревой решетки, соответствующие деформациям сжатия, изгиба и сдвига, соответственно. Заметим, что в (41.5) написан общий вид упругой энергии для треугольной решетки линий с осью симметрии шестого порядка [117]. Далее нам понадобятся значения всех трех упругих модулей:

$$C_{11} - C_{66} = \frac{B^2}{4\pi}\frac{\partial H}{\partial B}, \quad C_{44} = \frac{BH}{4\pi}, \quad C_{66} = \frac{\Phi_0 B}{(8\pi\lambda)^2}. \tag{41.6}$$

Первые две формулы из (41.6) имеют общий характер и легко выводятся (см. ниже), результат же для модуля сдвига C_{66} приведен для наиболее интересного (при $\varkappa \gg 1$)

случая $H_{c1} \ll B \ll H_{c2}$, когда вихри все еще сильно взаимодействуют на длинах гораздо больших, чем a_0, а подавлением параметра порядка из-за близости к H_{c2} еще можно пренебречь. Формулы для C_{11} и C_{44} можно получить из простых макроскопических соображений. Действительно, $\nabla \mathbf{u} = \delta B/B$ есть относительное изменение плотности вихрей, поэтому первый член в интеграле (41.5) можно записать как $\frac{1}{2}(C_{11} - C_{66})(\delta B)^2/B^2$, т.е. $B^{-2}(C_{11} - C_{66}) = \partial^2 F/\partial B^2 = (1/4\pi)\partial H/\partial B$. Чтобы получить второе из равенств (41.6), рассмотрим однородную деформацию вихревой решетки, при которой все вихри наклоняются на малый угол $\theta = \partial u_x/\partial z$ по отношению к исходному направлению поля вдоль оси z. При этом возникает поперечная компонента магнитной индукции $B_\perp = B\theta$ и сохраняется проекция индукции на ось z, т. е. $B_\parallel = B$. В результате полная величина магнитной индукции $B_{\text{полн}} = \left(B_\parallel^2 + B_\perp^2\right)^{1/2}$ изменяется на $\delta|B| = \frac{B}{2}(\partial \mathrm{u}/\partial z)^2$, а свободная энергия - на величину $(\partial F/\partial B)\delta|B| = \frac{H}{4\pi} \cdot \frac{B}{2}(\partial \mathbf{u}/\partial z)^2$. Сравнивая это выражение с соответствующим членом в (41.5), получаем результат для C_{44} из (41.6). Модуль сдвига C_{66} нельзя определить из столь же общих соображений - его необходимо вычислять как некоторую бесконечную сумму по узлам вихревой решетки. Мы здесь не будем останавливаться на этом (в действительности не очень сложном) вычислении [105]; заметим лишь, что малость модуля сдвига C_{66} по сравнению с $C_{11} \simeq C_{44}$ (их отношение, как видно из (41.6), порядка $(n\lambda^2)^{-1} \ll 1$) легко понять: дальнодействующий характер отталкивания между вихрями приводит к очень малой сжимаемости решетки, но слабо влияет на энергию деформаций, не меняющих плотность вихрей; поэтому модуль сдвига можно оценить как энергию взаимодействия ближайших соседей (порядка ϵ_0), умноженную на плотность вихрей $n = B/\Phi_0$, что совпадает по порядку величины с (41.6).

Теперь мы готовы воспроизвести для решетки вихрей оценку силы коллективного пиннинга (по аналогии с (41.2)). Будем считать, что деформация вихревой решетки, вызванная ее подстройкой под случайный потенциал примесей, достаточно мала, так что относительное смещение вихрей $|\mathbf{u}(\mathbf{r}) - \mathbf{u}(\mathbf{r}')|$ достигает величины порядка ξ при $|z - z'| \geqslant L_p^{3D}$, либо $|\rho - \rho'| \geqslant R_p$ (здесь ρ и z - поперечные и продольная (к полю $\mathbf{B}$) компоненты вектора $\mathbf{r}$). Характерные длины пиннинга L_p^{3D} и R_p в продольном и поперечном направлениях существенно отличаются вследствие различия порядков величин упругих модулей C_{66} и C_{44}; кроме того, продольная длина L_p^{3D} отличается и от ранее введенной кодновихревой» длины пиннинга L_p. Для характерной величины энергии взаимодействия с дефектами получим теперь $E_{\text{пинн}}^{3D} \sim (\gamma \xi^2 n V_p)^{1/2}$, где $V_p = L_p^{3D} R_p^2$ - объем области упругого пиннинга. Далее, неравенство $C_{11} \gg C_{66}$ означает, что деформациями сжатия можно пренебречь по сравнению с деформациями сдвига, так что достаточно приравнять по порядку величины энергию взаимодействия с дефектами $E_{\text{пинн}}^{3D}$ и энергии сдвиговых и изгибных деформаций:

$$\frac{C_{44}\xi^2}{\left(L_p^{3D}\right)^2} V_p \simeq \frac{C_{66}\xi^2}{R_p^2} V_p \simeq \left(\gamma \xi^2 n V_p\right)^{1/2} \tag{41.7}$$

Кроме того, для определения критической плотности тока j_c следует, как и выпе, приравнять силу Лоренца $j_c \frac{1}{c} B V_p$ (теперь действующую на единицу объема вихревой решетки) к максимальной объемной силе пиннинга $\mathcal{F}_{\text{пинн}} \simeq E_{\text{пинн}}^{3D}/\xi$. В результате

получим

$$R_p \simeq \lambda \left(\frac{L_p}{a_0}\right)^3, \quad L_p^{3D} \simeq \frac{\lambda}{a_0} R_p \tag{41.8}$$

$$E_{\text{пинн}}^{3D} \simeq H_{cm}^2 \xi^3 \frac{\xi}{L_p} \left(\frac{\lambda}{a_0}\right)^2 \left(\frac{L_p}{a_0}\right)^4 \tag{41.9}$$

$$j_c^{3D} \simeq j_c \left(\frac{a_0}{\lambda}\right)^2 \left(\frac{a_0}{L_p}\right)^4 \propto B^{-3}. \tag{41.10}$$

Как видно из (41.9), (41.10), с увеличением магнитного поля (а потому и жесткости вихревой решетки) характерная энергия пиннинга в объеме V_p растет (вместе с самим объемом), в то время как критическая плотность тока падает. Это происходит потому, что энергия $E_{\text{пинн}}^{3D}$ растет с полем медленнее, чем объем, в то время как полная сила Лоренца при заданном токе пропорциональна объему.

Результаты (41.4) и (41.10) не переходят один в другой при $a_0 \sim L_p$, как этого можно было бы ожидать-формулы для коллективного пиннинга решетки (41.8) приводят к большим длинам пиннинга ($R_p \sim \lambda \gg a_0$) и меньшему критическому току $j_c^{3D} \ll\ll j_c$ по сравнению с формулой (41.4) для пиннинга одиночных вихрей. Дело в том, что при выводе оценок (41.8) - (41.10) мы предполагали, что вихревая решетка описывается обычной теорией упругости с постоянными упругими модулями (пока длина волны деформации много больше постоянной решетки). В действительности, это предположение справедливо для вихревой решетки лишь при длинах волн q^{-1}, больших чем лондоновская длина λ. При меньших длинах волн магнитное поле "не успевает" следовать за деформациями вихревых линий (оно не может меняться на длинах меньше λ) и макроскопический подход к выводу C_{11} и C_{44} отказывает. В области $q\lambda \geqslant 1$ вихревая решетка описывается нелокальной теорией упругости, в рамках которой упругие модули сжатия и изгиба следует рассматривать как функции волнового вектора деформации q (это похоже на ситуацию с нелокальным экранированием токов в пиппардовских сверхпроводниках, см. 7). В интервале волновых векторов $\lambda^{-1} \leqslant q \leqslant a_0^{-1}$ упругие модули $C_{11}(q)$ и $C_{44}(q)$ ведут себя при $B \gg H_{c1}$ одинаково [105, 115]:

$$C_{11}(q) = C_{44}(q) = \frac{B^2}{4\pi} \frac{1}{1 + (q\lambda)^2} \tag{41.11}$$

Аккуратный расчет [115, 116] с использованием (41.11) показывает, что имеется промежуточная область магнитных полей, в которой длина пиннинга и критический ток экспоненциально резко зависят от поля:

$$R_p \simeq a_0 e^{(B/B^*)^{3/2}-1}, \quad j_c^{3D} \simeq j_c \frac{B}{B^*} e^{-2(B/B^*)^{3/2}+2} \tag{41.12}$$

где $B^* \simeq (j_c/j_0)\, H_{c2} < B < B^\dagger$. Результаты же (41.8) - (41.8) справедливы при еще больших полях $B > B^\dagger$, когда длина R_p, определяемая из (41.12), становится больше λ. Как видно из сравнения формул (41.8) - (41.8) и (41.12), величины B^* и $B^\dagger$ всегда довольно близки.

Все полученные выше оценки показывают, что j_c монотонно убывает с ростом внешнего поля B; однако, как уже упоминалось в конце §38, в эксперименте часто наблюдается (например, [118, 35]) пик критического тока при $B \simeq H_{c2}$. Дело в том, что использованные нами здесь формулы (41.6) справедливы лишь в области слабых полей, когда коры соседних вихрей не перекрываются между собой (фактически это условие имеет вид $B \leqslant 0.2 H_{c2}$). Действительно, поскольку при $B > H_{c2}$ сверхпроводник непрерывно (фазовый переход II рода) переходит в нормальное состояние, где

квантованных вихрей вовсе нет, то и упругие модули (41.6), и параметр взаимодействия вихрей с примесями γ уменьшаются при $b = B/H_{c2} \to 1$. Расчеты [115, 105] показывают, что эффект от "смягчения" решетки сильнее, чем от ослабления связи вихрей с дефектами (так, максимальное значение $C_{66}(b)$ достигается при $b \simeq 0.6$, а затем модуль сдвига убывает пропорционально $(1-b)^2$), поэтому с ростом b критический ток $j_c(b)$ растет, а длина коллективного пиннинга R_p падает вплоть до величины порядка a_0 - т.е. происходит переход к одновихревому пиннингу. В области $a_0 < R_p < \lambda$ существенна пространственная дисперсия упругих модулей (41.11), поэтому рост критического тока происходит экспоненциально резко. При дальнейшем увеличении b взаимодействие между вихрями становится несущественным и $j_c(b)$ падает из-за ослабления взаимодействия каждого вихря с примесями ($\gamma_{\text{эфф}}(b) \propto (1-b)^2$). Таким образом, пик критического тока достигается (при слабом коллективном пиннинге) в полях B, близких к H_{c2}.

7.7.6 42*. Magnetic Flux Creep and Nonlinear Conductivity in HTSC

До открытия высокотемпературных сверхпроводников было естественно рассматривать критическое (38) и резистивное (40) состояния вихрей независимо друг от друга. Подразумевалось, что в критическом состоянии плотность тока j, возникшего из-за неоднородного распределения плотности вихрей при их проникновении в образец, равна критическому значению j_c, так что вихри неподвижны - в то время как в резистивном состоянии ток велик по сравнению с j_c, пиннингом вихрей можно вовсе пренебречь, и их движение характеризуется постоянным коэффициентом трения η. Однако ясно, что если потенциальные барьеры для движения вихрей обращаются в нуль при $j = j_c$ непрерывно, то при чуть меньших токах эти барьеры должны быть малы - и преодолимы для тепловых флуктуаций вихрей. Физическая причина, позволяющая провести упомянутое разделение явлений в обычных сверхпроводниках - очень большая при малых токах величина энергетических барьеров U_0 (по сравнению с тепловой энергией $k_{\text{B}}T$). Достаточно иметь плотность тока ниже j_c на малую величину порядка $k_{\text{B}}T/U_0$, чтобы пренебречь вероятностью тепловых перескоков вихрей через барьеры, созданные примесным потенциалом. В высокотемпературных сверхпроводниках характерные значения $k_{\text{B}}T/U_0$ на несколько порядков выше, и область термоактивированного движения (называемого обычно "крип" - от английского "creep", т. е. "переползание") вихрей оказывается широко представленной в эксперименте. Ниже мы рассмотрим с единой точки зрения как релаксацию критического состояния вследствие крипа ви хрей, так и нелинейные вольт-амперные характеристики $V(j)$ в ВТСП.

Вернемся к рассмотренной в 38 задаче о проникновении магнитного поля в пластину сверхпроводника толщиной d. Теперь мы не будем считать постоянным возникший в пластине (при проникновении в нее вихрей) ток и выведем макроскопическое уравнение, определяющее временную эволюцию плотности тока. удем считать магнитное поле направленным вдоль оси z, а ток плотности $\mathbf{j}$ и возникающее из-за движения вихрей электрическое поле $\mathbf{E} = (1/c)[\mathbf{Bv}]$ - вдоль оси y. Используя уравнения Максвелла $\partial B/\partial t = -c\partial E/\partial x$ и $\partial B/\partial x = -(4\pi/c)j$, получим для скорости релаксации тока

$$\frac{\partial j}{\partial t} = \frac{c}{4\pi}\frac{\partial^2(vB)}{\partial x^2} \tag{42.1}$$

В правой части этого уравнения содержится средняя скорость движения вихрей $v \simeq v_0 e^{-U(j)/k_{\text{B}}T}$, где $U(j)$-соответствующий плотности тока j потенциальный барьер. Для

простоты мы рас(:мотрим сейчас случай, когда величина B мало меняется по толщине пластины (см. рис. 38.1, б), а отношение $k_{\rm B}T/U(j)$ мало. Тогда распределение плотности тока по пластине оказывается по'ти однородным, $j(x,t) = j(t) + \delta j(x,t)$, где $\delta j/j \propto k_{\rm B}T/U(j) \ll \ll 1$, и для величины $j(t)$ можно вывести [96, 119] замкнутое уравгение

$$\frac{\partial j}{\partial t} = -\left(\frac{j_c}{\tau_0}\right) e^{-U(j)/k_{\rm B}T} \tag{42.2}$$

где $\tau_0 \sim d^2/c^2\rho_f$ имеет порядок времени диффузии магнитного поля в состоянии течения потока по толщине образца d. Соответствующий "коэффициент диффузии» для магнитного поля имеет вид $D_{\rm B} = c^2\rho_f/4\pi$, как это видно из уравнения $\dot{B} = (c^2\rho_f/4\pi)\,\nabla^2 B$, которое получается комбинированием уравнений Максвелла с законом Ома $E = \rho_f j$. При большой величине показателя экспоненты уравнение (42.2) можно решить приближенно, как говорят в таких случаях - с логарифмической точ ностью:

$$U(j) = k_{\rm B}T \ln\left(1 + \frac{t}{t_0}\right),$$
$$\text{где } t_0 = \tau_0 \frac{k_{\rm B}T}{j_c|\partial U/\partial j|} \sim \frac{k_{\rm B}T}{U_c}\frac{d^2}{c^2\rho_f}. \tag{42.3}$$

Физический смысл решения (42.3) очевиден-к моменту времени t после начала релаксации (крипа) величина плотности тока в образце устанавливается такой, что соответствующие этому току энергетические барьеры $U(j)$ как раз могут быть преодолены вихрями за время порядка t. Важное и заранее неочевидное обстоятельство состоит в том, что характерное "время попыток" t_0 для крипа оказывается зависящим от размера образца и вполне макроскопическим - в интервале $(10^{-6} \div 10^{-2})$ с.

Для того чтобы извлечь из соотношения (42.3) явную зависимость плотности экранирующих токов от времени, необходимо использовать какую-то оценку для функциональной зависимости $U(j)$. Рассмотрим сначала случай токов, близких к критическому. Тогда естественно предположить, что $U\,(j \to j_c) \simeq \simeq U_c\,(1 - j/j_c)^a$, где a - число порядка единицы. Используя это соотношение вместе с (42.3), находим, что

$$\frac{j(t)}{j_c} = 1 - \left[\frac{k_{\rm B}T}{U_c}\ln\left(1 + \frac{t}{t_0}\right)\right]^{1/a}. \tag{42.4}$$

Зависимость вида (42.4) с $a = 1$ была впервые получена в работе [120]. В эксперименте обычно измеряется зависимость магнитного момента сверхпроводника в течение длительного времени после включения (или изменения) внешнего магнитного поля, которое вызвало формирование критического состояния. Измеряемый магнитный момент $M(t)$ (пропорциональный протекающему в образце экранирующему току) в обычных сверхпроводниках ведет себя, как правило, логарифмически со временем, что соответствует показателю $a = 1$ и очень малому значению отношения $k_{\rm B}T/U_c \leqslant 10^{-3}$, так что полное изменение $M(t)$ при экспериментально достижимых временах остается много меньше
исходной величины $M(0)$. Иначе обстоит дело в ВТСП, где характерная величина $k_{\rm B}T/U_c$ часто бывает порядка 0.1 при $T \sim 0.5T_c$. Поскольку логарифмический множитель в (42.4) имеет порядок $10 \div 20$ при характерных временах релаксационных измерений $(10^2 \div 10^4)$ с, ток и намагниченность ВТСП должны релаксировать на величину порядка своих исходных значений, что и наблюдается экспериментально [121], рис. 42.1. Но в таком случае уже нельзя пользоваться формулой (42.4), выведенной в предположении малости изменения тока в процессе релаксации. Другой предельный
