ферми-поверхности на линиях и в изолированных точках для $S=0$ и в точках лля $S=1$. Послешнее утверждсние всрно лишь для случая сильного спин-орбиталыного взаимодействия (коптрпример - параметр порядка для полярной фазы с p-спариванием).

Непременное наличие нулей в спеклре возбужпений есть прямое следствие определенной сдмметрии сверхпроводящего состомния. Поэтому нули этого типа назывзотся симметрийными нулями. Среди симметрийных нулей можно выделить осоБый подкласс топологических нулей. К последним относятся те симметрийные нули, которые не исчезают при непрерывных деформациях, нарушагоцих симметрию кристалла. Не утлубляясь особо в сей предмет, укажем без доказательства, что симметрийныс точки нулсй являются в то же время топологическими, линии - нст.

Симметрийный подход пставляет значительнуо свободу в выборе базисвых фуікдий неприводимых представлений. Конкретный выбор базисных функций данного предстазления Γ может быть сделап только п рамках какойибо микроскопической модели и опрсделяется тотностыо, с которой мы хотим описать параметр порядка даниого сверхпроволящего состояния. Наличие и положение симметрийных нудей в спектре элементарных возбуждений
определяется не видом базисних функций, а симметрией сверхпроводящего состояния. Опрслеленный же выбор базисных фупкший может искусственно породить дополнитслыые нефизические («случайныс») нули в спектрс элемснтарных возбуждений.

Примеры базисных функций для представлений грулпы D_{6h} собраны в табл. 1 и 2. Для илююстрации высказанных утверждений базиспые функции нсчетных представлепий в табл. 1 представлены в видс линейных комбинаций фупкций двух типов. При произвольных значениях коэффициснтов a и b базисные функции $\psi_i^{\Gamma'}(\hat{\mathbf{k}})$ обращаются в нуль только в изолированных точках на ферми-поверхности, лежаших па осях вращений, соответствующих комбитированшымм эдеменгам симметрии данного сверхпроводящего состояния (симметрийныс нули). С другой стороны, при $a = 0$ (или $b = 0$) в каждой из перечисленных сверхпроводящих фаз к симметрийшым пгудя добавлятотся случайные (в том числе и лежащие на линиях) нули параметра порядка.

Базисные функции прсдставлений лля кристаллов с тетрагональной (группа D_{4h}) и кубическон (группа O_h) симметрией приведены в табл. 3-6. Для одномерных представлений указаплы также соответствующие сверхпроводящис классы H. Классы сверхпроводящих состояний, описываемых неодномерными представлениями, будут введены в II, посвященном теории Ландау лля ашизотроптых сверхпроводников.

19.1.5 5. Energy of Elementary Excitations of a Superconductor

Задача о нахождении спектра элемснтарных возбуждений свсрхпроводника решается пугем диагонализации гамильтониаша системы ферми-частиц [1], в котором из всех видов взаимодействий оставлено только сушественное для сверхпроводимости парное притяжение частиц, имеющих противоположные импульсы (гамильтониан Бардина-Купера-Шриффера):

$$H = \sum_{\mathbf{k}} \xi_{\mathbf{k}} a^+_{\mathbf{k}\alpha} a_{\mathbf{k}\alpha} + \frac{1}{2} \sum_{\mathbf{k},\mathbf{k}'} V_{\alpha\beta,\lambda\mu}(\mathbf{k},\mathbf{k}')\, a^+_{-\mathbf{k}\alpha} a^+_{\mathbf{k}\beta} a_{\mathbf{k}'\lambda} a_{-\mathbf{k}'\mu} \tag{5.1}$$

Здесь и ниже по повторяющимся спиновым индексам подразумевается суммирование, $\xi_k = \hbar^2 k^2/(2m^*) - \varepsilon_F$ - эергия возбуждений в нормалыном металле, отсчитанная от энергии Ферми, m^* - эффективная масса. $V_{\alpha\beta,\lambda\mu}(\mathbf{k},\mathbf{k}')$ потенциал парного притяжения, обладаюощий симметрийными свойстзами:

$$V_{\alpha\beta,\lambda\mu}(\mathbf{k},\mathbf{k}') = -V_{\beta\alpha,\lambda\mu}(-\mathbf{k},\mathbf{k}') = -V_{\alpha\beta,\mu\lambda}(\mathbf{k},-\mathbf{k}') = V_{\mu\lambda,\beta\alpha}(\mathbf{k}',\mathbf{k}) \tag{5.2}$$

В отсутствие спин-орбиталшного взаимодействия потенциал факторизуется:

$$V_{\alpha\beta,\lambda\mu}(\mathbf{k},\mathbf{k}') = V(\mathbf{k},\mathbf{k}')\,\Gamma_{\alpha\beta,\lambda\mu} \tag{5.3}$$

[1] Для простоты мы будем рассматривать ферми-газ со сферической ферми-поверхиостью, ие иринимая во внимание влияние кристаллической решетки на энергегический спектр.

[2] Здссь и ниже мы испажьзусм шолновыс функции, нормированные на единичный объем, поэтому $\sum_{\mathbf{k}} \to \int \frac{d^3k}{(2\pi)^3} = N_0 \int d\xi \int \frac{d\Omega}{4\pi}$, где $N_0 = \frac{m^* k_{\mathrm{F}}}{2\pi^2\hbar^2}$ - пиютность состоянии на поверхности Ферми на одгу проекцию спина.

Функшию $V(\mathbf{k},\mathbf{k}')$ будсм счигать опличной от пуля, когда концы векторов $\mathbf{k}$ и $\mathbf{k}'$ лежат в узком слое вблизи ферми-поверхIости:

$$V(\mathbf{k},\mathbf{k}') = V_l(k,k') \sum_{m=-1}^{l} Y_{lm}(\hat{\mathbf{k}}) Y_{lm}^*\left(\hat{\mathbf{k}}'\right) \tag{5.4}$$

$$V_l(k,k') = \begin{cases} -V_l, & \text{при } \varepsilon_\mathrm{F} - \varepsilon_l \le k^2/(2m^*), k^2/(2m^*) \le \varepsilon_\mathrm{F} + \varepsilon_l \\ 0, & \text{вне указанного интервата.} \end{cases}$$

Здесь в разложении функции $V(\mathbf{k},\mathbf{k}')$ по сферическим гармоникам с разными l оставлено лишв взаимодействие V_7, приводящее k максимальной критической температуре (см. 1).

Что касается спиновой зависимости потенциала, то для четных l она записывается через антисимметричные по индексам $\alpha\beta(\lambda\mu)$ матрицы

$$\Gamma_{\alpha\beta,\lambda\mu} = \frac{1}{2} g_{\alpha\beta\beta} g^+_{\lambda\mu} \tag{5.5}$$

$g_{\alpha\beta} = (i\sigma_y)_{\alpha\beta}$, а для нечетных l - черсз симметричные:

$$\Gamma_{\alpha\beta,\lambda,\beta} = \frac{1}{2} \mathbf{g}_{\alpha\beta} \mathbf{b}^+_{\lambda\mu} \tag{5.6}$$

где $\mathrm{g}_{\alpha\beta} = (i\sigma\sigma_y)_{\alpha\beta}$, а g^+и g^+обозначают эрмитово-сопряжепные матрицы.

В кристаллах, где сущсстзешна инвариантность относительно преобразований точечной группы симметрии, парное взаимодействие имеет вид

$$V_{\alpha\beta,\lambda\mu}(\mathbf{k},\mathbf{k}') = V_\Gamma(k,k')\,\Gamma^2_{\alpha\beta,\lambda\mu} \sum_{i=1}^{d_\mathbf{r}} \psi_i^\Gamma(\hat{\mathbf{k}}) \psi_i^{\Gamma^\top}\left(\hat{\mathbf{k}}'\right) \tag{5.7}$$

Здесь оставлено лишь взаимодсйствие V_Γ, относящееся х неприводимому представлению Γ с базисными функциями $\psi_i^\Gamma(\hat{\mathbf{k}})$, которое приводит к спариваниго с максимальной критической тсмпературой. Функдии $\Gamma_{\alpha\beta,\lambda\mu}$ ддя четных и нечетных прсдставлсций задаготся формулами (5.5) и (5.6), соответственіно.

Вцражение (5.7) справедливо для синглетного спаривашия и триплетного спаривания со слабым спин-орбитальным взаимолсйствием. В случае $S = 1$ и сильного спин-орбитального взаимодействия (см. 4) парнос взаимодействие имеет вид

$$V_{\alpha\beta,\lambda\mu}(\mathbf{k},\mathbf{k}') = \frac{1}{2} V_\Gamma(k,k') \sum_{i=1}^{d_\Gamma} \left(\psi_i(\hat{\mathbf{k}}) \mathrm{g}_{\alpha\beta}\right) \left(\psi_i^*\left(\hat{\mathbf{k}}'\right) \mathrm{g}^+_{\lambda\mu}\right) \tag{5.8}$$

Неустойчивость электронного газа, описываемого гамильтонианом (5.1), по отношению к образованию куперовских пар можно учесть [1], записывая волновуо функииюо основного состояния в виде произведения

$$\Psi = \prod_\mathbf{k} \left(u_\mathbf{k} + v_\mathbf{k} a^+_{\mathbf{k}\uparrow} a^+_{-\mathbf{k}\downarrow}\right) |vac\rangle \tag{5.9}$$

Здесь $v_\mathbf{k}$ - амплитуда вероятности заполисния пары опночастичных состоянии ($\mathbf{k}\uparrow, -\mathbf{k}\downarrow$) (для простоты мы имеем в виду синглетное спаривание),
u_k - амплитуда вероятности обнаружить состояние ($\mathbf{k}\uparrow, -\mathbf{k}\downarrow$) незаполнеппым, а $\langle \mathrm{vac}\rangle$ - волновая функция вакуумного состояния, причем выполтяется условие

$$|u_\mathbf{k}|^2 + |u_\mathbf{k}|^2 = 1$$

В нормалыном металле

$$\begin{array}{ll} v_k = 1 : u_k = 0, & \text{при } |\mathrm{k}| < k_F, \\ u_k = 0, u_k = 1, & \text{при } |\mathrm{k}| > k_F, \end{array} \tag{5.10}$$

то есть все состояния иже ферми-уровня запотлсны, выше него - пусты.

В сверхпроводнике при лобом $\mathbf{k}$ имеется ненулевая вероятность обнаружить данное парное состояние пустым, и волновая функция основного состоs1дия (5.9) состоит из большого числа слагаемых, в каждом из которых с различной вероятностью заполнено $0, 2, \ldots, N, N \pm 2, \ldots$ парных одночастичных состояний. Иными словами, основное состояние сверхпроводника предстазляет собой суперпозициюо состояний с разлжчным пислом куперовских пар [3]. Стедствием этого фундаментального факта служит опличие от нуля так называемдх аномальных средних [21]:

$$F_{\mathbf{k},T\downarrow} = \langle \Psi \left| a_{\mathbf{k}\uparrow} a_{-\mathbf{k}\downarrow} \right| \Psi \rangle$$
$$F^{+}_{\mathbf{k},T\downarrow} = \left\langle \Psi \left| a^{+}_{-\mathbf{k}\uparrow} a^{+}_{\mathbf{k}\downarrow} \right| \Psi \right\rangle$$

Такие среднис можно опрсделить и при произволыной температуре [4]:

$$F_{\mathrm{k},\alpha\beta} = \langle a_{\mathbf{k}\alpha} a_{-\mathbf{k}\beta} \rangle$$
$$F^{+}_{\mathrm{k},\alpha\beta} = \left\langle a^{+}_{-k\alpha} a^{+}_{\mathrm{k}\beta} \right\rangle \tag{5.11}$$

Функция $F_{\mathrm{k},\alpha\beta}$, имегощая смысл вопіовой фуікции пары, антисимметрична относитетьно переставшовки частиг:

$$F_{\mathbf{k},\alpha\beta} \to P_{-\mathbf{k},\beta\alpha} = -F_{\mathbf{k},\alpha\beta\beta} \tag{5.12}$$

Для пространственно-четных функций F равенство (5.12) означает антисимметрию по спиновым индексам:

$$F^{\mathrm{g}}_{\mathbf{k}_1\alpha\beta} = -F^{\mathrm{g}}_{\mathbf{k},\beta\alpha}$$

то есть для спаривания в синглетном состояIIии имеем:

$$F^{\mathrm{g}}_{\mathbf{k},\alpha\beta} = F_{\mathbf{k}} g_{\alpha\beta}$$
$$F^{\mathrm{g}}_{\mathbf{k},\alpha\beta} = F^{*}_{\mathbf{k}} g^{+}_{\alpha\beta} \tag{5.13}$$

гле $F_{-\mathrm{k}} = F_{\mathrm{k}}$. Для пространственно-нечетных функший F равенство (5.12) справедливо линь в слугае симметрии по спиновым индексам:

$$F^{\mathrm{U}}_{\mathbf{k},\alpha\beta} = F^{\mathrm{u}}_{\mathbf{k},\beta\alpha}$$

[3] Гтавныд вклад в эту суперпозицию вносят состояния с тислом пар $N_{\mathrm{pairs}} \approx N_{\mathrm{particles}}/2$.

[4] Средиее в формулах (5.11) понимается как

$$\langle A \rangle = \frac{\sum\limits_{n} A_{nnc} - E_n/T}{\sum\limits_{n} e^{-E_n/T}}$$

то есть для спаривания в триплетном состоянии:

$$F^{\mathrm{u}}_{\mathbf{k},\alpha\beta} = \mathbf{F}_{\mathbf{k}}\mathbf{g}_{\alpha\beta}$$
$$F^{\mathrm{u}+}_{\mathbf{k},\alpha\beta} = \mathbf{F}^{*}_{\mathbf{k}}\mathbf{g}^{+}_{\alpha\beta} \tag{5.14}$$

где $\mathbf{F}_{-\mathbf{k}} = -\mathbf{F}_{\mathbf{k}}$.

Для диагонализации гамильтониана в приближении самосогласованного поля [21] предположим, что отклонения произведений пар операторов, входяших в (5.1), от их средних значений (5.11) малы. Воспользовавшись тождественными преобразовапиями:

$$a^{+}_{-\mathbf{k}\alpha}a^{+}_{\mathbf{k}\beta} = F^{+}_{\mathbf{k},\alpha\beta} + \left(a^{+}_{-\mathbf{k}\alpha}a^{+}_{\mathbf{k}\beta} - F^{+}_{\mathbf{k},\alpha\beta}\right) \tag{5.15}$$
$$a_{\mathbf{k}'\lambda}a_{-\mathbf{k}'\mu} = F_{\mathbf{k}',\lambda\mu} + \left(a_{\mathbf{k}'\lambda}a_{-\mathbf{k}'\mu} - F_{\mathbf{k}',\lambda\mu}\right)$$

перепишем гамильтониан (5.1) в линсйном приближении по указанным откдонетиям:

$$H = \sum_{\mathbf{k}} \xi_{\mathbf{k}} a^{+}_{\mathbf{k}\alpha}a_{\mathbf{k}\alpha} + \frac{1}{2}\sum_{\mathbf{k},\mathbf{k}'} V_{\alpha\beta,\lambda\mu}\left(\mathbf{k},\mathbf{k}'\right)\left(-F^{+}_{\mathbf{k},\alpha\beta}F_{\mathbf{k}',\lambda\mu} + \right.$$
$$\left. + F^{+}_{\mathbf{k},\alpha\beta}a_{\mathbf{k}'\lambda}a_{-\mathbf{k}'\mu} + F_{\mathbf{k}',\lambda\mu}a^{+}_{-\mathbf{k}\alpha}a^{+}_{\mathbf{k}\beta}\right) \tag{5.16}$$

Введем теперь функции

$$\Delta_{\mathbf{k},\alpha\beta} = -\sum_{\mathbf{k}'} V_{\beta\alpha,\lambda\mu}\left(\mathbf{k},\mathbf{k}'\right) F_{\mathbf{k}',\lambda,k}$$
$$\Delta^{+}_{\mathbf{k},\lambda,k} = -\sum_{\mathbf{k}'} V_{\alpha\beta,\mu\lambda}\left(\mathbf{k}',\mathbf{k}\right) F^{+}_{\mathbf{k}',\alpha\beta} \tag{5.17}$$

Из (5.2) и (5.12) получаем:

$$\Delta_{k,\alpha\beta} = -\Delta_{-k,\beta\alpha\alpha}.$$

Очевидго, что для четного по импудьсам потенциала взаимодействия функции $\Delta_{\mathbf{k},\alpha\beta}$ и $F_{\mathbf{k},\alpha\beta}$ также должны быть четньмми, что соответствует спариваник в синглетном состоянпи:

$$\Delta_{\mathbf{k},\alpha\beta} = \Delta g(\mathbf{k})\left(i\sigma_y\right)_{\alpha\beta} \tag{5.18}$$

Здесь

$$g(\mathbf{k}) = g'(\mathbf{k}) = \sum_{m=-1}^{l} a_{lm}(k)Y_{lm}(\mathbf{k})$$

а нормировка выбрана стедующим образом:

$$\int \frac{dS}{4\pi}\left|g'(\mathbf{k})\right|^2 = 1 \tag{5.19}$$

Заметим, что

$$\int \frac{d\Omega}{4\pi} g^{l}(\mathbf{k}) = 0$$

ддя всех значепий l, кроме s-спаривапия ($l = 0$).

В случае нечетного потешциала взаимодействия фупкции $\Delta_{\mathbf{k},\alpha\beta}$ и $F_{\mathbf{k},\alpha\beta}$ также нечетны и описывают триплетное спаривание:

$$\Delta_{\mathbf{k},\alpha\beta} = \Delta \mathrm{d}(\mathbf{k}) \left(i\sigma\sigma_y\right)_{\alpha,\beta k} \tag{5.20}$$

Здесь

$$\mathrm{d}(\mathbf{k}) = \mathrm{d}^l(\mathbf{k}) = \sum_{m=-1}^{1} \mathbf{b}_{lm}(k) Y_{lm}(\mathbf{k})$$

и

$$\int \frac{d\Omega}{4\pi} |\mathbf{d}(\mathbf{k})|^2 = 1 \tag{5.21}$$

Коэффициенты $a_{lm}(k)$ и $\mathrm{b}_{lm}(k)$ отличны от нуля лишв в узком слое толшиной $\delta k = \varepsilon_l / v_F$ вблизи поверхіости Ферми.

Испольэуя (5.17), для гамитониана (5.16) получаем [5]:

$$\begin{aligned} H = \frac{1}{2}\sum_{\mathbf{k}} \xi_{\mathbf{k}} \left(a^+_{\mathbf{k}\alpha} a_{\mathbf{k}\alpha} - a_{-\mathbf{k}\alpha} a^+_{-\mathbf{k}\alpha}\right) + \frac{1}{2}\sum_{\mathbf{k}\alpha} \xi_{\mathbf{k}} + \\ + \frac{1}{2}\sum_{\mathbf{k}} \left(\Delta_{\mathbf{k},\alpha\beta} a^+_{\mathbf{k}\alpha} a^+_{-\mathbf{k}\beta} + \Delta^+_{\mathbf{k},\alpha\beta} a_{-\mathbf{k}\alpha} a_{\mathbf{k}\beta} + \Delta_{\mathbf{k},\alpha\beta} F^+_{\mathbf{k},\beta\alpha}\right) \end{aligned} \tag{5.22}$$

Это выражение можно переписать в более компактном виде, определив векторные операторы [22]

$$\begin{aligned} A^+_{k,i} \equiv \left(a^+_{k\alpha}, a_{-k\alpha}\right) \equiv \left(a^+_{k\uparrow}, a^+_{k\downarrow}, a_{-k\uparrow}, a_{-k\downarrow}\right) \\ A_{k,i} \equiv \begin{pmatrix} a_{k\alpha} \\ a^+_{-k\alpha} \end{pmatrix} \equiv \begin{pmatrix} a_{k\uparrow} \\ a_{k\downarrow} \\ a^+_{-k\uparrow} \\ a^+_{-k\downarrow} \end{pmatrix} \end{aligned} \tag{5.23}$$

Имеем:

$$H = \frac{1}{2}\sum_{\mathbf{k}} A^+_{\mathbf{k},i} \varepsilon_{\mathbf{k},ij} A_{\mathbf{k},j} + \frac{1}{2}\sum_{\mathbf{k}} \Delta_{\mathbf{k},\alpha\beta} F^+_{\mathbf{k},\beta\alpha} + \frac{1}{2}\sum_{\mathbf{k}\alpha} \xi_{\mathbf{k}}$$

где мы ввели матрицу 4×4:

$$\varepsilon_{k,ij} = \begin{pmatrix} \xi_k \delta_{\alpha\beta} & \Delta_{k,\alpha\beta} \\ \Delta^+_{k,\alpha\beta} & -\xi_k \delta_{\alpha\beta} \end{pmatrix}$$

Гамильтониан (5.24) приводится к диагональному виду с помощью сохранятощего антикоммуташионные соотношения унитарного преобразования Боголобома [6], прсобразуэощего фермиевские операторы a_k в фермиевские опсраторы $b_{\mathbf{k}\alpha}$:

$$A_{k,i} = U_{ij} B_{k,j} \tag{5.25}$$

гдс

$$U_{ij} = \begin{pmatrix} u_{k,\alpha\beta} & v_{k,\alpha\beta} \\ v^*_{-k,\alpha\beta} & u^*_{-k,\alpha\beta} \end{pmatrix} \tag{5.26}$$

$$B_{k,i} = \begin{pmatrix} b_{k\beta} \\ b^+_{-k\beta} \end{pmatrix} \tag{5.27}$$

Элементы матрицы преобразования являются, в свою очередь, матрицами 2×2 в спиновом пространстве и определяются следующими формулами:

$$u_{k,\alpha\beta} = \frac{(E_k + \xi_k)\,\delta_{a\beta}}{\sqrt{(E_k + \xi_k)^2 + \Delta_k^2}} = u_k \delta_{\alpha\beta} \tag{5.28}$$

$$v_{k,\alpha\beta} = -\frac{\Delta_{k,\alpha\beta}}{\sqrt{(E_k + \xi_k)^2 + \Delta_k^2}}$$

где

$$E_{\mathbf{k}} = \sqrt{\xi_k^2 + \Delta_{\mathbf{k}}^2} \tag{5.29}$$

и введено обозначснис (см. (5.18) и (5.20))

$$\Delta^2_{\mathbf{k}} = \frac{1}{2}\,\mathrm{Sp}\,\Delta^+_{\mathbf{k}}\Delta_{\mathbf{k}} = \begin{cases} \Delta^2 |g(\mathbf{k})|^2, & \text{при } S = 0 \\ \Delta^2 \mathbf{d}(\mathbf{k})\mathbf{d}^*(\mathbf{k}), & \text{при } S = 1 \end{cases} \tag{5.30}$$

В результате получаем:

$$\sum_{\mathbf{k}} A^+_{\mathbf{k},i} \varepsilon_{\mathbf{k},ij} A_{\mathbf{k},j} = \sum_{\mathbf{k}} B^+_{\mathbf{k},i} E_{\mathbf{k},ij} B_{\mathbf{k},j}$$

где

$$E_{\mathrm{k},ij} = \begin{pmatrix} E_{\mathrm{k}}\delta_{\alpha\beta} & 0 \\ 0 & -E_{\mathrm{k}}\delta_{\alpha\beta} \end{pmatrix}$$

Перепишем послелисс выражение в терминах операторов рождения и уничтожения квазичастиц $b_{\mathbf{k}\alpha}$:

$$\frac{1}{2}\sum_{\mathbf{k}} B^+_{\mathbf{k},i}\hat{E}_{\mathbf{k},ij}B_{\mathbf{k},j} = \frac{1}{2}\sum_{\mathbf{k}} E_{\mathbf{k}} b^+_{\mathbf{k}\alpha} b_{\mathbf{k}\alpha} - \frac{1}{2}\sum_{\mathbf{k}} E_{\mathbf{k}} b_{-\mathbf{k}\alpha} b^+_{-\mathbf{k}\alpha} =$$
$$= \sum_{\mathbf{k}} E_{\mathbf{k}} b^+_{\mathbf{k}\alpha} b_{\mathbf{k}\alpha} - \frac{1}{2}\sum_{\mathbf{k}\alpha} E_{\mathbf{k}}$$

Таким образом, гамильтониаи свсрхпроводника окончательно приобретает следующий вид:

$$H = E_0 + \sum_{\mathbf{k}} E_{\mathbf{k}} b^+_{\mathbf{k}\alpha} b_{\mathbf{k}\alpha} \tag{5.31}$$

где

[1] Суммированис по спиновым индсхсам от функции ξ_k, не зависящсй от спинов, означаст $\sum_{k\alpha} \xi_k = 2\sum_k \xi_k$

[6] Все формулы, приводимые ииже, справедливы для произваыьного тита синглетного спаривания, а в случае триптетного спаривания - линъ птя тах называемых уннтарыых фаз. удовлстворяюицих условию: $(\Delta\Delta^+)_{\alpha\beta} \sim \delta_{\alpha\beta}$. Среди персчислснпых в §3 фаз с р-спариваиием к унитарым фазам относятся всс. кроме A_1 - и β-фазы. В неуинарном стучае диагонализация гамильтониана выглядит иесколько сложлее (см. [13], а также 17), и мы не будем здесь на этом останавливаться.

$$E_0 = \frac{1}{2}\sum_{\mathbf{k}} \Delta_{\mathbf{k},\alpha\beta} H^{+}_{\mathbf{k},3\alpha} + \frac{1}{2}\sum_{\mathbf{k}\alpha} (\xi_k - E_{\mathbf{k}}) \tag{5.32}$$

ссть эдергия основного состояния, а величины E_{k} представляют собой энергии элементарных возбуждсний сверхпроводника.

Для сверхпроводиика с синглетным спариваниси имесм:

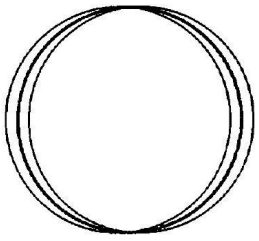
$$E_{\mathbf{k}} = \sqrt{\xi_k^2 + \Delta^2 |g(\mathbf{k})|^2} \tag{5.33}$$

то есть в спектре элементарних возбуждений имеется щель. В полностью изотропном стучае (s-спаривание) $g(\mathbf{k}) = |\Delta| e^{i\varphi}$, и щел отлична от нуля на всей ферми-повсрхности. Как было показано в §4, s-спаривашию в кристалле соответствует сверхпроволящее состолние, преобразуоцееся согласно
единичному представлениюо точечной группы симметрии кристалла. В этом случае $g(k)$ может обращаться в нузь при некоторых значениях k (случайные нули). Для анизотропных типов спаривания с $l \neq 0$, таких, что сверхпроводящее состояние облапает комбинированной (например, поворотной и калибровочной) симметрией, обращение щели в нуль при некоторых $\mathbf{k}$ обязателшно (симметрийные нули).

Для сверхпроводника с триплетным спариванием:

$$E_{\mathrm{k}} = \sqrt{\xi_k^2 + \Delta^2 |\ \mathrm{d(k)}|^2} \tag{5.34}$$

В B-фазе $\mathbf{d} = \hat{\mathbf{k}}$ (см. (3.2) и (5.21)), и



$$E_k^B = \sqrt{\xi_k^2 + |\Delta|^2} \tag{5.35}$$

то есть, как и в случае s-спаривания, на всей ферми-поверхности имеется щель, не зависящая от направления $\mathbf{k}$.

В A-фазе $\mathbf{d} = \sqrt{3/2}\left(\hat{k}_x + i\hat{k}_y, 0, 0\right)$ (см. (3.8) с учетом нормировочного міножителя), и

$$E^A_{\mathbf{k}} = \sqrt{\xi_k^2 + \frac{3}{2}\Delta^2\left(\hat{k}_x^2 + \hat{k}_y^2\right)} = \sqrt{\xi_k^2 + \frac{3}{2}\Delta^2 \sin^2\theta} \tag{5.36}$$

то есть щель в спектре обращается в нуль на северном и южном полюосах ($\theta = 0, \pi$) ферми-сферы (рис. 4). Наличие нулей в спектре A-фазы следует из

Ри с. 4. Щель в спектре A-фазы. Границы щели - товкие дишии, ферми-сфера - жирная линия комбинированной инвариантности состояния (3.8) относительно поворотов на утол α вокрут оси z и одновременного калибровочного преобразования домножения на $\epsilon^{-i\alpha}$ (более подробно см. 4).

Упражиеиие. Показать, что энергия основного состояния сверхпроводника (5.32) определяется следующими выражениями:

$$E_{0\ \mathrm{s}} = E_{0\mathrm{n}} - \frac{1}{2} N_0 \Delta^2 \tag{5.37}$$

для синглетного изотропного спаривания, и

$$E_{0\ \mathrm{s}} = E_{0\mathrm{n}} - \frac{1}{4} N_0\, \mathrm{Sp} \int \frac{d\Omega}{4\pi} \Delta_{\mathrm{k}}^{+} \Delta_{\mathrm{k}} \tag{5.38}$$

для произвольного типа спаривания, где $E_{0\mathrm{n}}$ есть энергия основного состояния нормального металла.

19.1.6 6. Gap in the Excitation Spectrum and Critical Temperature

Для определения температурной зависимости щели в спектре элементарных возбуждений обратимся к формуле (5.17):

$$\Delta_{\mathbf{k},\alpha\beta} = -\sum_{\mathbf{k}'} V_{\beta\alpha,\lambda\mu}\left(\mathbf{k},\mathbf{k}'\right) F_{\mathbf{k}',\lambda\mu} \tag{6.1}$$

Подставляя сода аномальное среднее (5.11) и применяя преобразование Боголобова (5.25), имеем:

$$F_{\mathbf{k},\lambda\mu} = \left\langle a_{\mathbf{k}\lambda} a_{-\mathbf{k}\mu} \right\rangle = \left\langle \left(u_{\mathbf{k},\lambda\gamma} b_{\mathbf{k}\gamma} + v_{\mathbf{k},\lambda\gamma} b_{-\mathbf{k}\gamma}^{+}\right) \left(u_{-\mathbf{k},\mu\delta} b_{-\mathbf{k}\delta} + v_{-\mathbf{k}}\mu\delta b_{\mathbf{k}\delta}^{+}\right) \right\rangle$$

Используя соотношения

$$u_{\mathbf{k},\alpha\beta} = u_{\mathbf{k}}\delta_{\alpha\beta}, \quad v_{\mathbf{k},\alpha\beta} = -v_{-\mathbf{k},\beta\alpha}$$
$$\left\langle b_{-\mathbf{k}\alpha} b_{\mathbf{k}\beta} \right\rangle = \left\langle b_{\mathbf{k}\alpha}^{+} b_{-\mathbf{k}\beta}^{+} \right\rangle = 0$$
$$\left\langle b_{\mathbf{k}\alpha}^{+} b_{\mathbf{k}\beta} \right\rangle = \delta_{\alpha\beta} - \left\langle b_{\mathbf{k}\beta} b_{\mathbf{k}\alpha}^{+} \right\rangle = f_{\mathbf{k}}\delta_{\alpha\beta}$$

где

$$f_{\mathrm{k}} = f\left(E_{\mathrm{k}}\right) = \frac{1}{\exp\left(E_{\mathrm{k}}/T\right) + 1} \tag{6.2}$$

есть фермиевская функция распределения возбуждений с энергией $E_{\mathbf{k}}$, определяемой формулой (5.29), получаем:

$$F_{\mathbf{k},\lambda\mu} = -u_{\mathbf{k}} v_{\mathbf{k},\lambda\mu}\left(1 - 2f_{\mathbf{k}}\right) = \frac{\Delta_{k,\lambda\mu}}{2E_{\mathbf{k}}}\left(1 - 2f_{\mathbf{k}}\right) \tag{6.3}$$

После подстановки в (6.1) окончательно приходим х следующему условию самосогласования:

$$\Delta_{\mathbf{k},\alpha\beta} = -\sum_{\mathbf{k}'} V_{\beta\alpha,\lambda\mu}\left(\mathbf{k},\mathbf{k}'\right) \frac{1 - 2f_{\mathbf{k}'}}{2E_{\mathbf{k}'}} \Delta_{\mathbf{k}',\lambda\mu} \tag{6.4}$$

называемому также «уравнением на щель. Вспоминая выражения (5.33) п (5.34), имеем:

$$g(\mathbf{k}) = -\sum_{\mathbf{k}'} \frac{V\left(\mathbf{k},\mathbf{k}'\right)\left(1 - 2f_{\mathbf{k}'}\right)}{2\sqrt{\xi_{k'}^2 + \Delta^2 \left|g\left(\mathbf{k}'\right)\right|^2}} g\left(\mathbf{k}'\right) \tag{6.5}$$

для синглетного спаривания и

$$\mathbf{d}(\mathbf{k}) = -\sum_{\mathbf{k}'} \frac{V\left(\mathbf{k},\mathbf{k}'\right)\left(1 - 2f_{\mathbf{k}'}\right)}{2\sqrt{\xi_{k'}^2 + \Delta^2 \left|\mathbf{d}\left(\mathbf{k}'\right)\right|^2}}\ \mathrm{d}\left(\mathbf{k}'\right) \tag{6.6}$$

для триплетного спаривания.

При $T \to T_c$ щель в спектре обращается в нуль, и уравнения (6.5) и (6.6) становятся линейными. Это означает, что любая комбинация сферических гармоник с данным l (в общем случае - функций данного неприволимого представления группы симметрии нормальной фазы), имеющая вид

$$g(\mathbf{k}) = \sum_{m=-1}^{l} a_{lm} Y_{lm}(\hat{\mathbf{k}}) \tag{6.7}$$

или

$$\mathrm{d}(\mathbf{k}) = \sum_{m=-l}^{1} \mathrm{b}_{lm} Y_{lm}(\hat{\mathbf{k}}) \tag{6.8}$$

является решением уравнений (6.5) и (6.6), соответственно. Мы вновь пришли к утвержденито, что все сзерхпроводящие состояния, относящисся к данному нсприводимому представлснию группы симметрии нормальной фазы, имеюо одинаковуоо критическуп тсмпературу. Опа определяется уравнением

$$1 = N_0 V_i \int_0^{\varepsilon_i} d\xi \frac{\mathrm{th}\,(|\xi|/2T_c)}{|\xi|} \tag{6.9}$$

которое получается при подстановке в уравиение на щель разложений (6.7) (или (6.8)). Интегрируя по частям правую часть (6.9) и заменяя на бесконсчность верхлий предел быстро сходящегося иптеграла, потучаем:

$$1 = N_0 V_l \left(\ln \frac{\varepsilon_l}{2T_\mathrm{c}} - \int_0^{\infty} dx \frac{\ln x}{\mathrm{ch}^2\, x} \right)$$

Следовательыio,

$$T_\mathrm{C} = \frac{2\gamma}{\pi} \varepsilon_l \,\mathrm{cxp} \left(-\frac{1}{N_0 V_l} \right) \tag{6.10}$$

Здссь $2\gamma/\pi \approx 1.14$, гдс

$$\ln \gamma = C \approx 0.577$$

носит пазвание постоянной Эннтера.

Подставляя в (6.5) и (6.6) разложения (5.4), (5.7) или (5.8) потенциала парного притяжения и используя ортогональность базисных функций неприводимого представления, получаем, что параметр порядка при всех $T < T_c$ имеет вид (6.7) или (6.8). Зависимость молуля параметра порядка и коэффициентов a_{lm} и $\mathbf{b}_{lm}$ от тсмпературы при этом определястся нслинейпыми уравнениями вида [1]:

$$a_{lm}(T) = N_0 V_i \int_0^{\varepsilon_1} d\xi \int \frac{d\Omega}{4\pi} \frac{\mathrm{lh}\left(\sqrt{\xi^2 + \Delta^2(T)|g(\mathbf{k})|^2}/2T \right)}{\sqrt{\xi^2 + \Delta^2\,(T')\,|g(\mathbf{k})|^2}} Y^*_{lm}(\hat{\mathbf{k}}) g(\mathbf{k}) \tag{6.11}$$

для синглстного спаризания, и

$$\mathbf{b}_{lm}(T) = N_0 V_l \int_0^{\varepsilon_1} d\xi \int \frac{d\Omega}{4\pi} \frac{\mathrm{th}\left(\sqrt{\xi^2 + \Delta^2(T)|\mathbf{d}(\mathbf{k})|^2}/2T \right)}{\sqrt{\xi^2 + \Delta^2(T)|\mathrm{d}(\mathbf{k})|^2}} Y^*_{im}(\hat{\mathbf{k}}) \mathrm{d}(\mathbf{k}) \tag{6.12}$$

для триплетного спаривания, дополтенными условиями нормировки (5.19) и (5.21).

В общсм случае необходимо решать аналогичные нелинейныс уравнения для коэффишлентов разложения параметра порядка по базисным функциям неприводимого представлсния группы симметрии кристалла. Ввиду ачитеднного произвола в выборе этих функций (см. 4), а также анизотропти ферми-поверхности, задача количественного описания температурного поведения параметра порядка, а, следовательно, термодиiтамических и кинетидеских свойств анизотропных сверхпроводников, является весьма неопределенiтой.

В некоторьх случаях величину щели в спсктре при $T = 0$ можто пайти аналитически. Так, для s-спаривания из (6.11) получаем:

$$\frac{1}{N_0 V_0} = \int_0^{\varepsilon_0} \frac{d\xi}{\sqrt{\xi^2 + \Delta_0^2}} \approx \ln \frac{2\varepsilon_0}{\Delta_0} \tag{6.13}$$

Следовательно,

$$\Delta_0 = \Delta(T = 0) = 2\varepsilon_0 \exp\left(-\frac{1}{N_0 V_0}\right) \tag{6.14}$$

и, сравнивая с (6.10), имеем:

$$\Delta_0 = \frac{\pi}{\gamma} T_c \approx 1,75 T_c \tag{6.15}$$

Температурнос повсдение шели в спектре для s-спаривапия опредепяется уравнением, следующим из (6.4):

$$\frac{1}{N_0 V_0} = \int_0^{\varepsilon_0} \frac{d\xi}{\sqrt{\xi^2 + \Delta^2}} - 2\int_0^{\varepsilon_0} \frac{f(E) d\xi}{\sqrt{\xi^2 + \Delta^2}}$$

Отсюда, воспользовавиись (6.13), получаем:

$$\ln \frac{2\varepsilon_0}{\Delta_0} = \ln \frac{2\varepsilon_0}{\Delta} - 2\int_0^{\varepsilon_0} \frac{f(E) d\xi}{\sqrt{\xi^2 + \Delta^2}}$$

ипи

$$\ln \frac{\Delta_0}{\Delta} = 2\int_0^{\varepsilon_0} \frac{d\xi}{\left(\exp\left(\sqrt{\xi^2 + \Delta^2}/T\right) + 1\right)\sqrt{\xi^2 + \Delta^2}} \tag{6.16}$$

Ввиду быстрой сходимости верхиий предел интегрирования в этом уравнении можно заменить на бесконечность.

При $T \to 0$ имеем $\Delta/T \to \infty$, и

[11] Если в разложенин потенинала парного притяжсния присутствучт сферические гармоники с другими значениями орбитального момента (в обшем случае - Базисные функции других леприводимых представлснии), соответствующие меньшим критическим температурам, то при $T < T_c$ сверхпроводящее состоянис будет представлять собой супсрпозицию гармоник с разными l. При этом допустимо, разумеетcs, зишь примешиваиие гармоник, не поиижающсе симметрии данного сверхпроводяццего состояния. В противном случае происходит фазовый переход из одной сверхпроводящей фазы в другую.

$$\ln \frac{\Delta_0}{\Delta} \approx \frac{2}{\Delta_1} e^{-\Delta_0/T} \int_0^\infty e^{-\xi^2/(2\Delta T)} d\xi = \sqrt{2\pi \frac{T}{\Delta}} e^{-\Delta_0/T}$$

$$\Delta = \Delta_0 \left(1 - \sqrt{\frac{2\pi T}{\Delta}} e^{-\Delta_0/T} \right) \tag{6.17}$$

Гри $T \to T_c$ иммеем $\Delta/T \to 0$, и

$$\ln \frac{\Delta_0}{\Delta} = \ln \frac{\pi T}{\gamma \Delta} + \frac{7\zeta(3)}{8\pi^2} \left(\frac{\Delta}{T} \right)^2 + \dots$$

Здесь $\zeta(3) = \sum_{n=1}^{\infty} n^{-3}$ - дзета-фуікция Рімана.

Поскольку $\Delta_0 = \pi T_c/\gamma$, го

$$\ln \frac{T_c}{T} \approx \frac{T\zeta(3)}{8\pi^2} \left(\frac{\Delta}{T} \right)^2$$

Отстода

$$\Delta(T) \approx \left(\frac{8\pi^2}{7\zeta(3)} \right)^{1/2} T_{\mathrm{c}} \left(\frac{T_{\mathrm{c}} - T}{T_{\mathrm{c}}} \right)^{1/2} \tag{6.18}$$

Ввиду условий нормировки (5.19) и (5.21) температурное поведение амплитуды энергетической щели в анизотропних сверхпроводниках при $T \to T_\varsigma$ такжс определяется формулой (6.18).

MC-6.1

Найти распрсделение электронов в сверхпроводнике по имгульсам: $n_{\mathrm{k},\alpha\theta} = \left\langle a^+_{\mathbf{k}\alpha} a_{\mathrm{k}\beta} \right\rangle$;

MC-6.2

Найти флуктуашио числа частиц при $J = 0 : \delta N = \frac{\sqrt{\langle N^2 \rangle - \langle N \rangle^2}}{\langle N \rangle}$, где $N = \sum_{\mathbf{k}} a^+_{\mathbf{k}\alpha} a_{\mathrm{k}\alpha}$.

19.1.7 7. Temperature Behavior of Thermodynamic Quantities as $T \to 0$

Наличие щели в спектре сверхпроводников с s-спариванием обуславтивает термоактивационное ($\sim \epsilon^{-\Delta_u/T}$) поведение всех термодинамических и кинетических величин при низких температурах.

Так, электронная теплоемкость сверхпроводника [1]

$$C_{\mathrm{s}} = \sum_{\mathrm{k}\alpha} E_{\mathrm{k}} \frac{\partial f_{\mathrm{k}}}{\partial T} \tag{7.1}$$

в случае s-спаривания равная

$$C_{\mathbf{s}} = 2N_0 \int_{-\infty}^{+\infty} d\xi \sqrt{\xi^2 + \Delta^2} \frac{\partial}{\partial T} \left(\frac{1}{\exp\left(\sqrt{\xi^2 + \Delta^2}/T \right) + 1} \right) \tag{7.2}$$

где

$$S = -\sum_{ka} \{(1 - f_k) \ln (1 - f_k) + f_k \ln f_k\}$$

в пределе $T \to 0$ принимает вид

$$C_s \approx \frac{2N_0\Delta^2}{T^2} e^{-\Delta/T} \int\limits_{-\infty}^{+\infty} d\xi e^{-\xi^2/(2\Delta T)} \approx N_0 \left(\frac{\Delta_0}{T}\right)^2 \sqrt{2\pi T\Delta_0} e^{-\Delta_0/T} \tag{7.3}$$

В необычных свсрхпроводниках с симметрийными нудями в спектре возбуждений естествешно ожидать степенное поведепие термодинамических всличин при низких температурах. Формула, обобщающая (7.2) на случай анизотропного спаривания, имеет вид

$$C_{\rm s} = 2N_0 \int\limits_{-\infty}^{+\infty} d\xi \int \frac{d\Omega}{4\pi} E_{\rm k} \frac{\partial}{\partial T} \frac{1}{c^{E_{\rm k}/T} + 1} \tag{7.4}$$

где спектр возбуждениii $E_{\rm k}$ определяется формулами (5.33) или (5.34).

Рассмотрим в качестве примера теплосмкость в A-фазе [3]. Спектр элементарных возбуждении имеет вид (5.36), то есть щель обращается в нуль на северном и южном полюсах ферми-сферы ($\theta = 0.\pi$), и главный вклал в теплоемкость дают окрестности этих точек [2]:

$$\theta < \frac{\xi}{\Delta}, \quad \pi - \theta < \frac{\xi}{\Delta}.$$

Отсюдда в пределе $T \to 0$ получаем:

$$C_s = \frac{N_0}{T^2} \int\limits_{-\infty}^{+\infty} d\xi \int\limits_0^{\pi} \sin\theta d\theta \frac{E^2 e^{E/T}}{\left(e^{E/T} + 1\right)^2} \approx \frac{N_0}{2T^2} \int\limits_{-\infty}^{+\infty} \frac{d\xi\xi^2}{\mathrm{ch}^2(\xi/2T)} \int\limits_0^{\xi/\Delta} \theta d\theta +$$

$$+ O\left(\exp\left(-\frac{\Delta_0}{T}\right)\right) \approx \frac{N_0}{4T^2\Delta^2} \int\limits_{-\infty}^{+\infty} \frac{d\xi\xi^4}{\mathrm{ch}^2(\xi/2T)} = N_0 \frac{T^3}{\Delta_0^2} I \tag{7.5}$$

где

$$I = 8 \int\limits_{-\infty}^{+\infty} \frac{dz z^4}{\mathrm{ch}^2\, z} = \frac{7\pi^4}{15}$$

Таким образом, элекгронная теплоемкость сверхпроводника, щель в спектре которого обращается в нуль в изолированиы точках на ферми-повсрхности, при $\bar{T} \to 0$ пропорциональна T^3. Аалогичное вычисление лия сверхпроводника с нулями щели на линиях на ферми-поверхности дает $C_{\rm s} \sim T^2$ при $T \to 0$.

[11] Iааломним, что формуду (7.1) ироще всего получить. диффсрепиируя комбинаторнос выражение для эитропин ферми-газа

$$C = T\frac{\partial S}{\partial T}$$

Возможны также сверхпроводящие состояния, в которых щель в спектре воэбуждений имеет изолированные точки нулей более высокого порядка. Например, для аксиальной фазы в случае d-спаривания:

$$g(\mathbf{k}) \propto \left(\hat{k}_x + i\hat{k}_y\right)^2 \tag{7.6}$$

имеюотя два нуля второго порядка на полюсах ферми-поверхности. Для этой фазы вычисления, подобные привсденным выше, дают $C_\mathrm{s} \sim T^2$.

Полученные рсзултаты можно сформулировать так:

$$\left.\frac{C_\mathrm{s}}{C_\mathrm{n}}\right|_{T\to 0} \sim \begin{cases} \left(\frac{T_c}{T}\right)^{5/2} e^{-\Delta_0/T}, & \text{щель в спектре не обращается в нуль,} \\ \left(\frac{T}{T_c}\right)^2, & \text{щель в спектре имеет нули первого порядка в изолированных точках,} \\ \frac{T}{T_c}, & \text{щель в спектре равна нулю на линиях или имеет цули второго порядка в изолированных точках.} \end{cases}$$

Здесь C_n - теплоемкость нормальной фазы.

Довольно просто установить степенное температурное поведение при $T \to 0$ и для друтих термодинамических величин, например, лондоновскоу глубины проникновения, сдвига Найта (парамагнитіоий воспрлимчивости), а такжс кинетических величиі, таких как коэффициент элсктронной теплопроводности или коэффнциент поглощения ультразвука.

Степенное поведснис перечисленных величих при зизких тсмпературах служит прямым указаншием на необычный характер свсрхпровопимости. Болес того, поскольку в случае сильного спин-орбитального взаимодействия для трдплетного спаривания симметрийные нули в спектре могут реализовываться лишь в изолированных точках на ферми-поверхіости (см. \$4), то различие показателей в степенных законах для линий и точек нулей даст принципиальнуюо возможносьь сделать выбор между спип-синглетной и спин-триплетной сверхпроводимостыоо.

На практике, применение этих простых результатов усложняется тсм, что паличис сколь угодно малого количестза примесей превращает линии нулей в полоски конечной ширины, что дает линейное поведенис теплосмкости в обдасти низких температур. Изолированные точки нулей под действием примесей также превращаготся в пятна конечного диаметра, окружающия исходные точки [23]. Эти процессы влияюот на низкотемпературное поведение всех величин, усложняя интсрпретацию эксперименттальных данных. Мы вернемся к этому вопросу в 2I, посвященном влиянио примсссй на свойства необычных сверхпроводников.

19.1.8 8. Parity Effects of the Number of Electrons in Superconductors

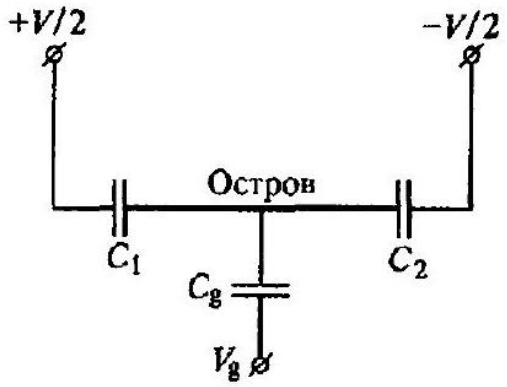
Согласно теории БКШ, основное состоянис сверхпроводника (5.9) представляет собой суперпозицию состояний с различньм числом куперовских пар. Энергия сверхпроводника при $T \to 0$ ниже энергии нормального металла на величину $\delta E_\mathrm{s} \sim N\Delta^2/\varepsilon_\mathrm{F}$ (см. упражнение к §), гдс N - полное число электронов. Возбужденные, то есть неспаренные, состояния в обычном сверхпроводнике отделены от основного состояния энергетической щелью $\triangle$. Поэтому при изменении числа электронов на единигу: $N \to N \pm 1$ велитиита δE_s должна измениться на $\pm\Delta$. Знак пиос иди минус здесь зависит от того, было исходное писло N тетіым или нечетньм. Поскопьку

[12] В этом параграфе для более компактной записи мы используем в A-фазе спектр вида $E_k^A = \sqrt{\xi^2 + \Delta^2 \sin^2\theta}$, отличающийся от (5.36) переопредслением модуля Δ.

величина Δ порядка нескольких гралусов (напомним, что $\Delta \sim T_c$), то измерение δE_s при изменении огромного числа N на единицу являстся, казалось бы, нереальной задачей. Тем ме менее это удалось сделать [24, 25] после создания так называемых транзисторов с кулоновской блокадой.

В этом параграфе мы опишем действие этого прибора, дающщего возможность непосредственно продемонстрировать существование куперовских пар, а таюже вычислим изменение термодинамического потендиала газа элементарных возбуждений сверхпроводника для различных сверхпроводящих состояний при изменении полного исла электронов на единицу [26-28].

Транзистор (электрометр) с кулоновской блокадо представляет собой прямоутольнуоо апоминиевую пленку (островок), занимающуо участок электрической цепи между двумя туннелынми контактами с емкостями C_1 и C_2. Размеры пленки в эксперименте, выполнен-



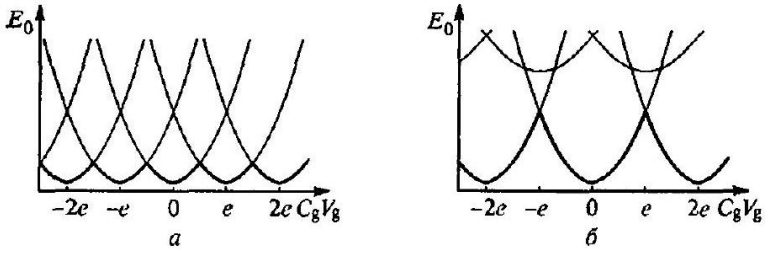


Рис. 5. Элехтрическая схема электрометра с кулоновско бловапой ном в Гарвардском университете [24], были таковы: толшина -200Å, ширина -600Å, длина $-2{\cdot}10^4$Å Островок связан емкостью C_g с затвором, позволянощим менять электростатический потенциал островка, прикладывая напряжение V_g (см. рис. 5).

При достаточно слабой связи островка с внештей цепью, когда сопротивленис каждого из контактов подчиняется условию $R > h/e^2$, квантовомеханические состояния островка характеризутотся определенным числом электронов [1]. Если полная емкость всех контактов $C = C_1 + C_2 + C_g$ достаточно мала, элементарна электростатическая энергия $E_c = e^2/2C$ превышает температуру, и можно пренебречь тепловыми флуктуациями. В этих условиях полная элекхростатическая энергия островка

$$U = \frac{Q^2}{2C} = \min_n \frac{(en + C_g V_g)^2}{2C} \tag{8.1}$$

является периодлческой функцией напряжения на затворе (рис. 6а), поэтому ток через островок при заданном напряжении во внешней цепи V будет также периодической функцией от $C_g V_g$ с псриодом e.

[11] Чтобы ие пирерывать сиязности изложения, вывод указанного неравенства отнесен в конце параграфа.

Ри с.6. Качественное поведение энергии островка как функции заряда $C_{\rm g}V_{\rm g}$ иа затворе: а) при $e^2/(2C) > T, \delta\Omega$; б) при $\delta\Omega > e^2/(2C) > 7$

Так обстоит лело, пока алюминиевый островок нахолится в нормальном состоянии. В свсрхпроводящем состоянии было обнаружено, что при тсмпературах ниже $0,3$ К (что соответствует $0.4T_{\rm c}$) пики тока, ссответствующие нечетному количеству электронов на островс, начинают подавляться, и зависимость $j\left(C_{\rm g}V_{\rm g}\right)$ становится $2e$-периодической. ЕстествеIiное объяснение этого явлешия состоит в том, что свободные энергии (более точно, термодинамические потенциалы Ω) островка в сверхпроводящем состоянии с четным и нечетным числами электронов $\Omega_{\rm odd} - \Omega_{\rm even}$ при $T \to 0$ отличаются на величину порядка щели Δ в спектре элемснтарных возбуждений. Поэтому при выполнении условия $\Delta > E_{\text{с па-}}$ па раболичсские участки, отвечающие нечетным значениям n в зависимости $U\left(C_{\rm g}V_{\rm g}\right)$, поднимутся на высоту $\Omega_{\rm odd} - \Omega_{\rm even}$ и станут ненаблюдаемыми (см. рис. 60). Соответственно, ток $j = j\left(C_{\rm g}V_{\rm g}\right)$ станет $2e$-периодической функцией $C_{\rm g}V_{\rm g}$.

Островок представляет собой два последоватслыо включенных лжозефсоновских контакта. Нас интересует зависимость тока через островок от энсргии островка. Проще всего она выглялит лля нулевой внешней разности потенциалов [2]:

$$j = \frac{2e}{\hbar}\sqrt{n_{\rm s1}n_{\rm s2}}\frac{K^2\sin\Phi}{E_0} \tag{8.2}$$

Здесь - джозефсоновская энергия (матричный элемепт перехода) каждого из контактов, которыс для простоты мы полагаем одинаковыми; $n_{\rm s1}$ и $n_{\rm s2}$ плотности сверхпроводящих электронов в подводящих проводах по обе стороны островка; Φ - «внелшняя» разность фаз (разность фаз между контактами, к которым подключен островок). E_0 - энергия островка, вклюотаюшая как э.ектростатическуюо часть (8.1), так и слагаемое, величина которого меняется на $\delta\Omega = \Omega_{\rm odd} - \Omega_{\rm even}$ при изменениях $C_{\rm g}V_{\rm g}$, сопровождающихся сменой четности числа электронов на островкс:

$$E_0 = U + \begin{cases} \delta\Omega, & \text{если } n \text{ нечетно,} \\ 0. & \text{если } n \text{ тетно.} \end{cases} \tag{8.3}$$

Для вычислсния $\delta\Omega$ заметим, что термодинамический потенциал сверхпровотника склапывается из энергии кондепсата куперовских пар и термодинамического потенциала газа элемсптарных возбуждений. Конденсат пар состоит из четного числа частиш, поэтому разность термодинамических потенциалов сверхпроводника с нечетным и четным числом эдектронов совпадает с разностью Ω-потенциалов ансамблей с нечетным и четньдм числом квазичастиц. Термодинамический потенциал для газа квазичастиц записывается как сумма потенциалов всех состоянии, нумеруемьх кванттовым пислом $i = (\mathbf{k}, \alpha)$, в каждом из котторых может быть $n_i = 0, 1$ квазичастиц с энергией E_i':

$$\Omega = -T\sum_i \ln\left(\sum_{n_i=0.1} e^{-BE_in_1}\right) \tag{8.4}$$

здесь $\beta = 1/T$. Эту формулу можио переписать иначе:

$$\Omega = -T\ln\prod_i\left(1+e^{-\beta E_1}\right) = -T\ln\left(1+\sum_i e^{-\beta E_1} + \frac{1}{2}\sum_i\sum_{j\neq i} e^{-\beta E_1-\beta E_j} + \right.$$

$$\left. +\frac{1}{6}\sum_i\sum_{j\neq i}\sum_{k\neq i,j} e^{-\beta E_1-\beta E_j-\beta E_k} + \ldots\right) = -T\ln\left(Z_{\rm odd} + Z_{\rm even}\right)$$

[12] Вывоп формулы пля тока приведен в конце параграфа.

где

$$Z_{\text{odd}} = \sum_i e^{-\beta E_i} + \frac{1}{6}\sum_i \sum_{j\neq i} \sum_{k\neq i,j} e^{-\beta E_1 - \beta E_j - \beta E_k} + \dots \tag{8.5}$$

$$Z_{\text{even}} = 1 + \frac{1}{2}\sum_i \sum_{j\neq i} e^{-\beta E_i - \beta E_1} + \dots \tag{8.6}$$

предстамлят собой больние статистическис суммы для ансамБлей систем с нечетным и четным числом квазинастиц. Соответствующие термолинамические потспциаы имсюот вид

$$\Omega_{\text{odd/even}} = -T \ln Z_{\text{oidd /even}} = -T \ln \frac{\prod_1 \left(1 + \epsilon^{-\beta E_i}\right) \mp \prod_i \left(1 - \mathrm{e}^{-3E_i}\right)}{2} =$$
$$= \Omega_{\text{BCs}} - T \ln \frac{1}{2}\left(1 \mp \prod_i \text{lh}\, \frac{\beta E_i}{2}\right)$$

Следовательно,

$$\delta\Omega = \Omega_{\text{odd}} - \Omega_{\text{even}} = -T \ln \frac{1 - f(T)}{1 + \rho(T)} \tag{8.8}$$

где

$$f(T) = \prod_{\text{k}\alpha} \text{th}\, \frac{\beta E_{\text{k}}}{2} \tag{8.9}$$

Рассмогрим теперь, как проявляются эффекты четности числа частиц в нормальном металле и различных сверхпроводниках. Для нормального металла

$$f(T) = \prod_{k\alpha} \text{th}\, \frac{\beta\,|\xi_k|}{2} = \exp\left(4N_0 V \int_0^\infty d\xi \ln \text{th}\, \frac{\xi}{2T}\right) = \exp\left(-2\pi^2 N_0 V T\right) \tag{8.10}$$

Здесь N_0 - плотность состояний на одну проскапию спина, а V - объем образиа. Эффекты тетности, таким образом, пренебрежимо маты:

$$\Omega_{\text{odd}} - \Omega_{\text{even}} \approx 2T' \exp\left(-2\pi^2 N_0 V T\right) \tag{8.11}$$

если температура велика по сравиениго с расстоянием между эиергетическими уровнями электронов в островке $\delta E = (N_0 V)^{-1}$ или точнее, если

$$T > T^* \approx \frac{\delta E}{2\pi^2} \tag{8.12}$$

Для микроостровков, испотьзованных в Гарвардских экспериментах, $\delta E \sim 2 \cdot 10^{-4}$ К.

В обычных сверхпроводниках щель в спектре элементарных возбуждений нигде не обращается в гуль, и

$$f_{\text{s}}(T) = \prod_{\mathbf{k}\alpha} \text{th}\, \frac{\beta E}{2} = \exp\left(4N_0 V \int_\Delta^\infty \frac{E dE}{\sqrt{E^2 - \Delta^2}} \ln \frac{1 - e^{-E/T}}{1 + e^{-E/T}}\right) \tag{8.13}$$

Последнее выражение при низких температурах $T < \Delta$ можно представить в виде

$$f_{\mathrm{s}}(T) = \left(\mathrm{th}\,\frac{\Delta}{2T}\right)^{N_{eff}} \tag{8.14}$$

где

$$N_{\mathrm{eff}} = 4N_0V\int\limits_{\Delta}^{\infty}\frac{EdE}{\sqrt{E^2-\Delta^2}}e^{-(E-\Delta)/T} \approx 2\sqrt{2\pi\Delta T}N_0V \tag{8.15}$$

что, в свого очередь, позволяет записать $\delta\Omega$ в виде

$$\delta\Omega \approx \Delta - T\ln N_{\mathrm{off}} \tag{8.16}$$

Эта формула имеет ясный физический смысл: свободная энсргия, связанная с появлением неспаренного электрона, ссть вежмчнна щели в спектре возбуждений минус температура, умноженная на логарифм эффективного числа состояний, в которых размешалотся тепловые возбуждения. В отличие от нормального металла, проявление эффектов четности (подавление нечетных пиков в токе через островок) начинается с температуры

$$T_{\mathrm{s}}^{**} \approx \frac{\Delta}{\ln N_{\mathrm{eff}}} \tag{8.17}$$

При этой температуре на островке будет порядка одной квазичастицы:

$$N_{\mathrm{qp}} \approx e^{-\delta\Omega/T} = N_{\mathrm{eff}}e^{-\Delta/T} \tag{8.18}$$

Для Гарвардских экспериментов $T_{\mathrm{s}}^{*} \approx 0,3$ K.

Обратимся теперь к сверхпроводникам, щель в спектре которых обращается в нуль в изолированных точках, как в A-фазе ^{3}He, ити па изолированных линиях на ферми-поверхности, как это имеет место в полярной фазе. Вычисления, аналогичные тем, что были проделаны для теплоемкости необычных сверхпроводников (см. 7), дают:

$$f_A(T) \approx \exp\left(-\frac{\pi^4}{18}N_0V\frac{T^3}{\Delta^2}\right) \tag{8.19}$$

$$f_{\mathrm{POl}}(T) \approx \exp\left(-CN_0V\frac{T^2}{\Delta}\right) \tag{8.20}$$

где C - постоянная порядка единицы. Следовательно, для сверхпроводников с нулями в изолированных точках имеем:

$$\Omega_{\mathrm{odd}} - \Omega_{\mathrm{even}} = \begin{cases} 2T\exp\left[-(T)T_A^{*}\right)^3], & \text{при } T > T_A^{*} \\ \delta E, & \text{при } T \ll T_A^{*} \end{cases} \tag{8.21}$$

Здесь

$$T_A^{*} = \left(\frac{18}{\pi^4}\Delta^2\delta E\right)^{1/3} \tag{8.22}$$

Мы видим, что значение $\delta\Omega$ в этом случае не достигает величины щели Δ. С понижением температуры $\delta\Omega$ возрастает, а затем начинает падать. В точке максимума $\delta\Omega\,(T_A^{*}) \approx T_A^{*}, T_A^{*}$ - температура, при которой число уровней в

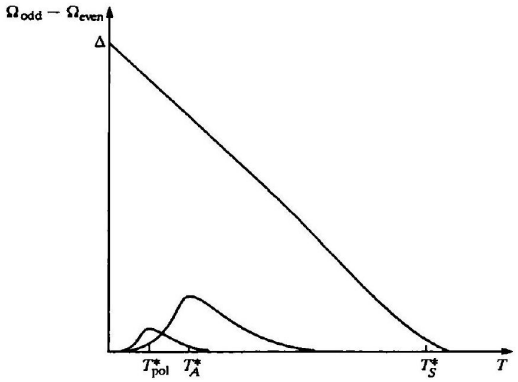

Рис.7. Качественная зависимость от температуры разности термодинамических потенциалов с нечетным и четным числом электронов для обычного сверхпроводника (верхняя линия) и для сверхпроводников, щель в спектре хоторых обращается в ноль в изолированных точках или на линиях

энергетическом интервале $E < T_A^*$ становится порядка единицы (сравните с (8.12)). При температурах $T < T_A^*$ пренебрсжение дискретностью спектра неоправдано, и в этой области $\Omega_{\text{odd}} - \Omega_{\text{even}} \approx \delta E$.

Для свсрхпроводников с нулями параметра порядка на линиях имеем:

$$\Omega_{\text{odd}} - \Omega_{\text{even}} = \begin{cases} 2T \exp\left[-\left(T/T_{\text{pol}}^*\right)^2\right], & \text{при } T > T_{\text{pol}}^* \\ \delta E, & \text{при } T \ll T_{\text{pol}}^* \end{cases} \tag{8.23}$$

где

$$T_{\text{pol}}^* = \left(\frac{\Delta \delta E}{C}\right)^{1/2} \tag{8.24}$$

Как и в предыдущем случае, имеет место немонотонное поведение $\delta\Omega(T)$. В точке максимума $\delta\Omega\left(T_{\text{pol}}^*\right) \approx T_{\text{pol}}^*$. В условиях эксперимента [24]: $T_A^* \approx 0,1 T_c$, $T_{\text{pol}}^* \approx 10^{-2} T_{\text{c}}$.

Качественное поведение $\delta\Omega$ в различных типах сверхпроводников изображено на рис. 7. Эффект четности числа электронов в микроостровках кз необычных сверхпроводников выражен заметно слабее. Он имеет место при существенно более низких температурах и существенно меньше, чем в микроостровках из обычных сверхпроводников.

Имеется и друтое ограничснис возможности наблюдения $2e$-периодичности тока через транзистор с кулоновской блокадой, изготовлешный из сверхпроводника с пулями в спсктре элсментарных возбуждений. Сверхпровопящее состояние в таком транзисторе скорее всего будст подавлено в поверхостном слос толщиной ξ_0. Плотность состояний в этом слое Будст близка к плотности состоянии нормального металла. Поэтому разность $\Omega_{\text{odd}} - \Omega_{\text{even}}$ может остаться экспоненциально малой.

Итак, удвоение периода тока через сверхпроволящий транзистор с кулоновской блокадой реализуемо, по-видимому, лиш в сверхпроводниках без нудей в спектре возбуждений.

В зактючение обсудим два вопроса, рассмотренис которых мы оставили в стороне, чтобы не прерывать связности изложения.

Условяе слабой связи островка с впешней цепью. Островок можно рассматривать как изолированный объект при условии отсутствия в контактах, связывающих островок с внешие й цепыо, делокализованных электронных состояниф, распространенных на весь объем контакта. Элекгронные состояния в контакте не должны испытьвать влияния границ, что количественно можно записать в виде неравенства $\delta E \gg \Delta E$ (условие лохализации). Здесь δE - расстояние между эпергетическими уровнями, $\triangle E$ - сдвит

уровней за счет влияния границы. В плоских контактах толшиной L и площадыо S, имеем $\delta E = 1/(SLN_0)$, где N_0 - плотность состояний, а $\triangle E \sim h/\tau \approx hD/L^2$, где τ - время диффузионного движсния электрона до границы ($L \ll \sqrt{S}$), D коэффициент диффузии, связанный с проводимостью контакта σ соотношением Эйниттейна

$$e^2 DN_0 = \sigma$$

Подставляя все перечисленные выражения в исходное неравснство, окогчательно получим условие локализации [29]:

$$R = \frac{L}{\sigma S} \gg \frac{h}{e^2} \approx 26\text{kO}$$

Ток чсрез два последовательыо включенных джжозефсоновских когтакта. Джозефсоновский ток в схеме, изображенной на рис. 8, легко пайти с помо-

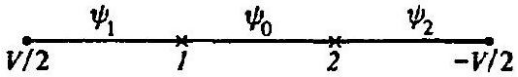

Рис. 8. Два постедовательно вклкчениві джозефсоиовсхих ковтакта щью этементарного обобщения фейнмановского подхода [30] к контакту Джозсфсона как к двухуровневой квантовомсханитеской системе. Вводя в двухуровневую систему с амплитудами состояний $\psi_1 = \sqrt{n_{\text{s1}}/2}e^{i\varphi_1}, \psi_2 = \sqrt{n_{\text{s2}}/2}e^{i\varphi_2}$ промежуточное састояние - острозок с волновой фунпцией ψ_0, запишем уравнения Шредингера:

$$i\hbar\frac{\partial\psi_1}{\partial t} = \frac{eV}{2}\psi_1 + K\psi_0$$
$$i\hbar\frac{\partial\psi_0}{\partial t} = K\psi_1 + K\psi_2 + E_0\psi_0$$
$$i\hbar\frac{\partial\psi_2}{\partial t} = K\psi_0 - \frac{eV}{2}\psi_2$$

Здесь V - внешняя разность потенциалов, K - джозефсоновская энергия (матричньий элемент перехода) каждого из контактов, E_0 - энергия островка. При нулевой внешней разности потеншиалов черсз контакты течет постоянный ток. В этих условиях волновая функция островка, такжс как и разность фаз 0 - φ_1 не зависят от времени. Требование сташионарности состояния ψ_0 приводит к условио

$$\dot{\psi}_0 = -\frac{K(\psi_1 + \psi_2)}{E_0}$$

с учетом которого система уравнений переписывается в виде:

$$i\hbar\frac{\partial\psi_1}{\partial t} = -\frac{K^{-2}}{E_0}(\psi_1 + \psi_2)$$
$$i\hbar\frac{\partial\psi_2}{\partial t} = -\frac{K^2}{E_0}(\psi_1 + \psi_2)$$

Подставляя в первое уравнеиие выражения для ψ_1 и ψ_2 и выделяя мнимуюо часть, получаем:

$$\hbar\frac{\partial\sqrt{n_{s1}}}{\partial t} = -\frac{K^2}{E_0}\sqrt{n_{\text{s2}}}\sin(\varphi_2 - \varphi_1)$$

Поскольку ток пропорционален $\dot{n}_{s1}$, то окончательное выражение для постоянного тока через два последовательно включенных джозефсоновских контакта при нулевой внешней разности потенниалов принимает вид

$$j = \frac{2e}{\hbar}\sqrt{n_{s1}n_{s2}}\frac{K^2\sin(\varphi_2-\varphi_1)}{E_0}.$$

19.1.9 9. Paramagnetic Susceptibility and Knight Shift

Измерение парамагнитной восприимчивости элсхтронного газа в сверхпроводнике является еще одним способом тестирования сверхпроводящего состояния. Хотя слабое магнитное поле, экранируемое незатухающими токами, не проникает в толиу сверхпроводника, тем не менее спиновый (паулиевский) парамагнетизм в сверхпроводниках (а тем более в нейтральной сверхтекучей ферми-жидкости ^{3}He) - наблюдаемое явление. В этом параграфе мы найдем температурную зависимость парамагнитной восприимчивости элекгронного газа в различных сверхпроводяших состояниях.

Для сверхпроводника с синглетным спариванием купсровсхие пары не дают вклада в спиновый парамагнетизм, и спиновый магнитныи момент электронного газа определяется томько вкладом элементарных возбуждений:

$$M = \mu_B \sum_{\mathbf{k}} \left[f\left(E_{\mathbf{k},-}\right) - f\left(E_{\mathbf{k},+}\right)\right] \tag{9.1}$$

Здесь $f(E)$ - фермиевская функиия распределения (6.2),

$$E_{\mathbf{k},\pm} = \sqrt{\xi^2 + \Delta^2|g(\mathbf{k})|^2} \pm \mu_B H \tag{9.2}$$

• энергии возбуждений с ориентацией спинов соответственно по и против направлсния поля H, μ_B - магнетон Бора (в случае ^{3}He - магниттый момент ядра). Из (9.1) имеем:

$$M = -2\mu_B^2 N_0 H \int \frac{d\Omega}{4\pi}\int d\xi \frac{\partial f\left(E_{\mathbf{k}}\right)}{\partial E} = 2\mu_B^2 N_0 H \int \frac{d\Omega}{4\pi} Y(\hat{\mathbf{k}}, T) \tag{9.3}$$

где

$$Y(\hat{\mathbf{k}}, T) = \frac{1}{4T}\int\limits_{-\infty}^{+\infty} \frac{d\xi}{\mathrm{ch}^2\left(E_k/2T\right)} \tag{9.4}$$

а $E_{\mathbf{k}} = \sqrt{\xi^2 + \Delta^2|g(\mathbf{k})|^2}$. Отсюда получаем выражение для магнитной восприимчивости:

$$\chi = \frac{\partial M}{\partial H} = \chi_n Y(T) \tag{9.5}$$

где $\chi_n = 2\mu_B^2 N_0$ - восприимчивость в нормальном состоянии [1], а функция

$$Y(T) = \int \frac{d\Omega}{4\pi} Y(\hat{\mathbf{k}}, T) = \begin{cases} 1, & \text{при } T = T_c \\ 0, & \text{при } T = 0 \end{cases} \tag{9.6}$$

называется функцией Иосида и описывает долю нормальных электронов в сверхпроводнике (рис. 9).

При $0 < T < T_c$ температурное поведение $Y(T)$ для разичшых сверхпроводящих состояний различно. В пределе $T \to 0$ вычисления, аналогичные проделанным в 7 для теплоемкости, дают:

$$Y(T) \sim \begin{cases} e^{-\Delta_0/T}, & g(\mathbf{k}) \neq 0, \\ \left(\frac{T}{T_c}\right)^2, & g(\mathbf{k}) \text{ обращается в нуль в изолирован-} \\ \frac{T}{T_c}, & g(\mathbf{k}) \text{ обращается в нуль на линиях.} \end{cases} \tag{9.7}$$

Парамагнитная восприимчивость сверхпроводника с синглетгым спариванием при $T \to 0$ обращается в нул, что обуславливает проигрыш в энергии $\chi_n H^2/2 = \mu_{\mathrm{B}}^2 N_0 H^2$ сверхпроводника, находящегося в магнитном поле, по сравнению с нормальным металлом. В то же время, при $T = 0$ сверхпроводящее состояние энергетически выгоднее нормального на $N_0\Delta_0^2/2$ (см. (5.37)). Сравнивая эти лве энергии, получаем, что в полях, больших, чем

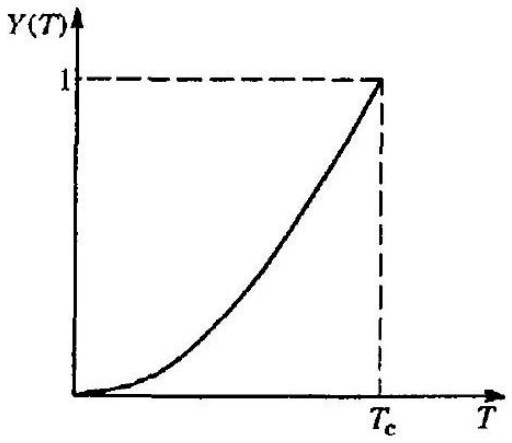
$$H_{\mathrm{p}} = \frac{\Delta_0}{\sqrt{2}\mu_{\mathrm{B}}} \tag{9.8}$$

сверхпроводящее состояние заведомо невыгодно. В поле H_{p}, называемом парамагнитным пределом сверхпроводимости, происходит разрушение синглетного состояния куперовских пар. В обычных свсрхпроводниках $H_{\mathrm{p}} \approx 1$ Тесла. На практике сверхпроводимость разрушается в полях, прсвышаюоших верхнее критическое поле H_{c2} в сверхпроводнихах второго рода (см. ниже 12) или поле абсолютной неустойчивости сверхпроводящего состояния H_{c1} в сверхпроводниках первого рода, значительно меньших парамагнитного предела H_{p}. Кромс парамагнитного предела в сверхпроводниках с ненулевым орбитальным моментом куперовских пар, как при сишглетном $S = 0$, так и при триплетном $S = 1$ спаривании, имеется диамагнитный прсдел [2] $H_{\mathrm{D}} \approx \frac{m^*}{m} H_{\mathrm{p}}$. Поле H_{D} может как превосходить, так и быть меньше парамагнитного предела, в зависимости от отношения эффективной массы электрона к массе электропа в вакууме.

Температурная зависимость (9.5) пзмеряется следующим образом. Ядерные спины атомов вещества, из которого состоит сверхпроводнник, прецессируют в магнитном поле H с частотои

$$\omega = \gamma H \tag{9.9}$$

На этой частоте наблюдается ядерныи магнитный резонанс, то есть резонансное поглошение радиочастотного поля $\mathrm{H_{rf}}$, перпендикулярного постоянному полю $\mathbf{H}$[3]. Из-за конечной вероятности попадания электронов проводимости в точку нахождения ядра R_n, пропорционалшной $|\psi_e(\mathbf{R}_n)|^2$, имеется взаимодсйствие магнитных моментов ядер μ_{n} и магнитных моментов электронов проводимости μ_{e} (контактное взаимодействие):



$$H_{\mathrm{int}} \sim \mu_{\mathrm{n}}\mu_{\mathrm{e}}\delta(\mathbf{r} - \mathbf{R}_{\mathfrak{n}}) \tag{9.10}$$

Среднее значение величины μ_{e} во внешнем поле дается выражением

$$\langle \mu_c \rangle = \frac{\chi \mathrm{H}}{n}$$

где χ есть парамагнитная восприимчи-

[11] Напомннм, что N_0 - плотность состояний на одну проекцию спина.

Ри с.9. Общцй вид функции Иосида вость, а n - плотность электронного газа.

Сдвиг уровней энергии ядерного спина вследствие взаиммодействия (9.10):

$$\delta E \sim \mu_{\mathrm{n}} \frac{\chi}{n} \left|\psi\left(\mathbf{R}_n\right)\right|^2 H$$

приводит к изменению резонансной частоты (9.9), то есть частоты переходов между уровнями в магнитном поле (сдвиг Найта) па величину:

$$\delta\omega \sim \frac{\mu_{\mathrm{n}}\chi}{n\hbar} \left|\psi\left(\mathbf{R}_{\mathrm{n}}\right)\right|^2 H \tag{9.11}$$

При переходе металла в сверхпроводящее состояние изменяется входящая в (9.11) парамагнитная восприимчивость χ, поэтому измерение отношения $\delta\omega_{\mathrm{s}}/\delta\omega_{\mathrm{n}} = \chi_{\mathrm{s}}/\chi_{\mathrm{n}}$ позволяет, согласно (9.5), определить плотность нормальных электронов. Из (9.6) следует, что слвиг Найта в сверхпроводнике с синглетным спариванием должен исчезать по мере уменьшения температуры.

Посмотрим теперь, как обстоит дело в сверхпроводликах с триплетным спариванием. Спиновое состояние куперовсхих пар во всем объеме сверхпроводника задается вектором d, зависящим от направления импульса на ферми-поверхности. Вероятность найти пару в состоянии с нулевой проекцией спина на ось квантования $\hat{z}$ пропорциональна $|d_z(\mathbf{k})|^2$ (см. (2.5) и (2.7)).

Очевидно, что если внешнее поле H (задающее ось квантования) направлено вдоль d)$\mathbf{k}$), то спин пар перпендикулярен $\mathbf{H}$ и не дает вклада в восприимчивость, которая, следовательно, определяется лиш вкладом возбужлений:

$$\chi_{\perp}(\mathbf{k}) = \chi_{\mathrm{n}} Y\left(\hat{\mathbf{k}}, T'\right) \tag{9.12}$$

где $Y(\hat{\mathbf{k}}, T)$ дастся формулой (9.4), а $E_{\mathbf{k}} = \sqrt{\xi^2 + \Delta^2 |\mathbf{d}(\mathbf{k})|^2}$.

Для направления поля (то есть оси $\hat{z}$) в плоскости, псрпендикулярной вектору d($\mathbf{k}$), будут отличны от нуля только x - и y-компонеиты всктора $\mathbf{d}(\mathbf{k})$, из которых составлены амплитуды вероятности $\pm d_x(\mathbf{k}) + i d_y(\mathbf{k})$ найти пары в состояниях с проскциями спина ± 1 на ось квантования. Очевидно, что для такого папранления поля вклад в восприимчивость дают как пары, так и возбуждения, и она совпадает с восприимчивостью ферми-жипкости в нормальном сосгоянии:

$$\chi_{\parallel} = \chi_{\mathrm{n}}. \tag{9.13}$$

[12] См. Н. А. Лjжьянчjж, В. Л. Миесв //Письма в ЖЭТФ, 44, 183 (1986).

[3] Для наблюдения этого эффекта поле в образце должно быть однородно, что имест место при условии матости размера образиа по сравценио с лоцщоновской глубиной проникиовения.

Для произвольной оринстации подл магнитный момент сверхтскучей жидкости определяется тснзором восприимчивости:

$$M_\alpha = \chi_{\alpha\beta} H_\beta,$$

который получается путсм комбинирования выраженнй (9.12) и (9.13):

$$\chi_{\alpha\beta} = \int \frac{d\Omega}{4\pi} \left\{ \chi_\perp(\mathbf{k}) \frac{d^*_\alpha(\mathbf{k}) d_\beta(\mathbf{k})}{\mathrm{d}^*(\mathbf{k})\mathrm{d}(\mathbf{k})} + \chi_\parallel(\mathbf{k}) \left[\delta_{\alpha\beta} - \frac{d^*_\alpha(\mathbf{k}) d_\beta(\mathrm{k})}{\mathbf{d}^*(\mathbf{k})\mathrm{d}(\mathbf{k})} \right] \right\} \tag{9.14}$$

В качестве примера приведем выражения для тензоров восприимчивости в A - и B-фазах гелия-3, которые потучаются из (9.14) после подстаповви соответствуоших параметров порядка [4] $\mathrm{d}^A(\mathbf{k})$ и $\mathrm{d}^B(\mathbf{k})$ (см. 3):

$$\chi^A_{\alpha,3} = \chi_\mathrm{n} \left[\delta_{\alpha\beta} + V_\alpha V_\beta \left(Y_A(T) - 1 \right) \right] \tag{9.15}$$

$$\chi^B_{\alpha\beta} = \chi_\mathrm{n} \delta_{\alpha\beta} \left(\frac{2}{3} + \frac{1}{3} Y_\mathrm{B}(T) \right) \tag{9.16}$$

Мы вилим, что в B-фазе восприимчивость изоропна, и при $T \to 0$ сдвиг Найга в сверхпроводнике со структурой B-фазы исчезает лиш частично. В А-фазе восприимчивость явлнется одиоосншм тензором. На практике, вдали от стенок сосуда с гелием-3, восприимчивость A-фазы всегда совпадает с χ_n, поскольку вектор V разворачивается перпендикулярно магнитному полю, чем достигается энергетически выгопное максимальнос значение восприимчивости. Вблизи стенок из-за спин-орбиталного взаимодействия вектор $\mathbf{V}$ псрпсндикулярен к поверхности, поэтому восприимчивость A-фазы зависит от направления.

Такой же эффект доджен иметь место и в сверхпроводниках с триплетным спариванием и силыпы спин-орбитальным взаимодействием, фиксирующим направление вектора d. Парамагнитные эффекты (в частности, сдзиг Найта) должны в этом случае сильно зависеть от направления внешнего магнитного поля [31-33]. Угловая зависимость восприимчивости лобой из триплетных фаз, переписленных в табл. 1-6, устанавливается после подстановки в (9.14) соответствуоших выражепий для параметров порядка $\mathrm{d}(\mathbf{k}) = \sum_i \eta_i \psi(\hat{k})$. Следует, однако, иметь в виду, что результат вычислений зависит от конкрстного вида базисных функций неприводимого представления. При этом температуріааа зависимость различиых компонент восприимчивости должна опредезяться с учетом зависимости $\eta_i(T)$, диктуемой уравнениями типа (6.12). Парамагнитная восприимчивость в сверхпроводниках с триплетным спариванием и слабым спин-орбитальньм заимодействием совпадает с паулиевской восприимчивостыо в нормальном состоянии.

MC-9.1

Доказать формулы (9.5) и (9.14) прямым выгчислепием спинового магнитного момента.
Указание. Найти прсобразование Боголобова, диагопализирующее гамиштопиан

$$H = H_\mathrm{BCS} - \mu_\mathrm{B} \sum_\mathbf{k} \mathrm{a}^+_{\mathbf{k}\alpha} \left(\sigma_{\alpha\beta} \mathrm{H} \right) a_{\mathbf{k}\beta}$$

[14] При вычислении восприимчивостей A - и B-фаз в реальном гелии-3 необходимо учитывать изменения внешнего поля за счет намагничивания самой жидкости (ферми-жыдкостные поправки) [3, 6]. Этот количественно довольно значительный эффект ие приволит, однако, к качественинм изменениям, и здесь мы сго учнтышать нс будем.

где H_{Bcs} - гамильтониан (5.1). Воспользовавшись этим преобразованием, найти линсйный по пото вктад в средное значешие операгора спинового магнитного момента

Найти поведенис функкший Иосида $Y_A(T)$ и $Y_B(T)$ для A - и B-фаз при $T \to 0$ и $T \to T_c$.

19.1.10 10. Landau Expansion of the Free Energy of Superconductors

Образование сверхпроводящего состояния из нормального происходит посредством фазового перехода второго рода. Согласно теории Ландау, изменение плотности свободной энергии при таком переходе может быть разложено в ряд по степеням параметра порядка. В случае однокомпонентной сверхпроводимости, когда параметром порядка является комплексная скалярная функция $\eta = |\eta| e^{i\varphi} = \Delta e^{i\varphi}$ (см. 4), это разложение имеет вид

$$F_{\text{cond}} = F_{\text{s}} - F_{\text{n}}^2 = \alpha |\eta|^2 + \frac{\beta}{2} |\eta|^4 = \alpha \Delta^2 + \frac{\beta}{2} \Delta^4 \tag{10.1}$$

где $\alpha(T) = \alpha_0 \left(T' - T_c\right) / T_{\text{c}}$ - меняет знак пря $T = T_c$; α_0, β - постоянные положителыные коэффициегты. Минимизация F_{s} по Δ дает следуоцие температурные зависимости щели (параметра порядка):

$$\Delta^2(T) = -\frac{\alpha_0}{\beta} \frac{T - T_c}{T_{\text{c}}} \tag{10.2}$$

и свободноны энергии:

$$F_{\text{cond}} = -\frac{\alpha_0^2}{2\beta} \left(\frac{T - T_c}{T_c} \right)^2 \tag{10.3}$$

вблизи критической температуры. Выражение (10.3) позволяет найти скачок теплоемкости при переходе в сверхпроводящее состояние:

$$(C_{\text{s}} - C_{\text{n}})|_{T=T_{\text{c}}} = -T_{\text{c}} \frac{\partial^2 F_{\text{cond}}}{\partial T^2} \bigg|_{T=T_{\text{c}}} = \frac{\alpha_0^2}{T_{\text{c}} \beta} \tag{10.4}$$

Формула (10.1) и ее обобщение на пространствепно-неоднородный случай ирают важнейшую роль в тсории свсрхпроводимости. Она может быть получена из микроскопической теории Бардина-Купера-Шриффера. Такой вывод для произвольного типа спаривапия и составляет предмет настоящего параграфа.

Свободная энергия сверхпроводника имеет вид

$$F_{\text{s}} = \langle H_{\text{BCS}} \rangle - TS \tag{10.5}$$

Здесь H_{BCS} - гамильтониал БКUU (5.31):

$$H_{\text{BCS}} = \sum_{\mathbf{k}} E_{\mathbf{k}} b^+_{\mathbf{k}\alpha} b_{\mathbf{k}\alpha} + \frac{1}{2} \sum_{\mathbf{k}} \Delta_{\mathbf{k},\alpha\beta} F^+_{\mathbf{k},\alpha\beta} + \frac{1}{2} \sum_{\mathbf{k}\alpha} (\xi_k - E_{\mathbf{k}}) \tag{10.6}$$

а S - энтропия электронного газа, определяемая формулой

$$S = -\sum_{\mathbf{k}\alpha} \left[f_{\mathbf{k}} \ln f_{\mathbf{k}} + (1 - f_{\mathbf{k}}) \ln (1 - f_{\mathbf{k}}) \right] \tag{10.7}$$

где $f_{\mathbf{k}}$ - фермиевская функция распределения (6.2).

Для опрсделенности мы будем рассматривать случай унитарных фаз с триплетным спариванием, когда параметр порядка и энергия элементарных возбуждений даются формулами

$$E_{\mathbf{k}} = \sqrt{\xi_k^2 + \Delta^2(T) \mathrm{d}(\mathbf{k}) \mathrm{d}^*(\mathbf{k})}$$
$$\Delta_{\mathbf{k},\alpha\beta} = \Delta(T) \mathrm{d}(\mathbf{k}) \mathbf{g}_{\alpha\beta}$$
$$F^+_{\mathbf{k},\alpha\beta} = \mathbf{F}^*_{\mathbf{k}} \mathbf{g}^+_{\alpha\beta}$$

(см. 5). Подставляя в (10.5) и выполняя статистическое усреднепие, имеем:

$$\langle H_{\mathrm{BCS}} \rangle = \sum_{\mathbf{k}\alpha} \left[E_{\mathbf{k}} f_{\mathbf{k}} + \frac{1}{2} \left(\Delta(T) \mathbf{d}(\mathbf{k}) \mathbf{F}^*_{\mathbf{k}} + \xi_k - E_{\mathrm{k}} \right) \right]$$

В то же время:

$$\begin{aligned} -TS &= T \sum_{\mathbf{k}\alpha} \ln (1 - f_{\mathbf{k}}) + T \sum_{\mathbf{k}\alpha} f_{\mathbf{k}} \ln \frac{f_{\mathbf{k}}}{1 - f_{\mathbf{k}}} = \\ &= T \sum_{\mathbf{k}\alpha} \ln (1 - f_{\mathbf{k}}) - \sum_{\mathbf{k}\alpha} E_{\mathbf{k}} f_{\mathbf{k}} \end{aligned} \tag{10.8}$$

После подстановки в (10.5) получаем:

$$F_{\mathbf{s}} = \sum_{\mathbf{k}} \left[\Delta(T) \mathrm{d}(\mathbf{k}) \mathbf{F}^*_{\mathbf{k}} + \xi_k + 2T \ln (1 - f_{\mathbf{k}}) - E_{\mathbf{k}} \right] \tag{11.9}$$

Первыдй член в этой формуле преобразуется с помошыо уравненияя (5.17):

$$\Delta \mathbf{d}^*(\mathbf{k}) = -\sum_{\mathbf{k}'} V_l (\mathbf{k}, \mathbf{k}') \mathbf{F}^*_{\mathbf{k}'}$$

Домножая здесь левупо и правую части на $\Delta d(k)$ и интегрируя по углам с помошъю условия нормировки и разложения (5.4) потешциала $V_l (\mathbf{k}, \mathbf{k}')$, имеем:

$$\frac{\Delta^2}{V_l} = \sum_{\mathbf{k}'} \Delta \mathrm{d} (\mathbf{k}') \mathbf{F}^*_{\mathbf{k}'}$$

Отсiода, в своIо очередь, учитывая выражение для критической температуры (6.10), получаем:

$$N_0 \Delta^2 \ln \frac{2\gamma\varepsilon_l}{\pi T_c} = \sum_{\mathbf{k}'} \Delta \mathrm{d} (\mathbf{k}') \mathbf{F}^*_{\mathbf{k}'}$$

Охонтательно:

$$F_{\mathrm{s}} = N_0 \Delta^2 \ln \frac{2\gamma\epsilon_l}{\pi T_k} + \sum_{\mathbf{k}} \left[\xi_k + 2T \ln (1 - f_{\mathbf{k}}) - E_{\mathbf{k}} \right] \tag{10.10}$$

Поскольку нас интересует только энергия конденсации, то есть отклонение энергии сверхпроводника от энергии нормального металла, то, принимая во внимание равснство

$$\frac{\partial}{\partial\Delta}\left[2T\ln\left(1-f_{\mathbf{k}}\right)-E_{\mathbf{k}}\right]=-2\ \mathrm{d}(\mathbf{k})\mathrm{F}_{\mathbf{k}}^{\nu}$$

можно переписать (10.10) в виде

$$F_{\mathrm{cond}}\ =N_0\Delta^2\ln\frac{2\gamma\epsilon_l}{\pi T_c}-2\sum_{\mathbf{k}}\int\limits_0^{\Delta}d\Delta\mathrm{d}(\mathbf{k})\mathbf{F}_{\mathbf{k}}^{*} \tag{10.11}$$

Интегрирование по волновым векторам выполняется в соответствии с правилом (1.8), при этом удобно сначала произвести интегрирование по энергии:

$$N_0\int\limits_{-\varepsilon_1}^{\varepsilon_1}\mathrm{F}_{\mathbf{k}}^{*}d\xi=N_0\Delta\mathrm{d}^{*}(\mathrm{k})\int\limits_{-\varepsilon_1}^{\varepsilon_1}d\xi\frac{1-2f_{\mathrm{k}}}{2E_{\mathrm{k}}}$$

Это выражсние при $\Delta\to 0$ приводится k виду (ср. с выводом формулы (6.18))
$N_0\Delta\mathrm{d}^{*}(\mathbf{k})\left[\ln\frac{2\varepsilon_0}{\Delta}-\ln\frac{\pi T}{\gamma\Delta}-\frac{7\zeta(3)}{8\pi^2}\ \mathrm{d}(\mathbf{k})\mathrm{d}^{*}(\mathbf{k})\left(\frac{\Delta}{T}\right)^2\right]=$

$$=N_0\Delta d^{*}(\mathbf{k})\left[\ln\frac{2\gamma\varepsilon_0}{\pi T}-\frac{7\zeta(3)}{8\pi^2}\ \mathrm{d}(\mathbf{k})\mathrm{d}^{*}(\mathbf{k})\left(\frac{\Delta}{T}\right)^2\right] \tag{10.12}$$

Подставляя (10.12) в (10.11) и выпоодіяя интегрирование по Δ, имеем:

$$F_{\mathrm{cond}}\ =N_0\Delta^2\ln\frac{T}{T_c}+\frac{7\zeta(3)}{16\pi^2}N_0\int\frac{d\Omega}{4\pi}\left(\mathbf{d}(\mathbf{k})\mathrm{d}^{*}(\mathbf{k})\right)^2\frac{\Delta^4}{T^2}$$

Учитывая близость T к T_c, получаем окончательно:

$$F_{\mathrm{cond}}\ =N_0\frac{T-T_c}{T_{\mathrm{c}}}\Delta^2+\frac{7\zeta(3)}{16\pi^2}N_0\int\frac{d\Omega}{4\pi}\left(\mathrm{d}(\mathbf{k})\mathrm{d}^{*}(\mathbf{k})\right)^2\frac{\Delta^4}{T_c^2} \tag{10.13}$$

Аналогичные рассуждения позволяют получить разложение Ландау и для случая синглетного спаривапия:

$$F_{\mathrm{cond}}\ =N_0\frac{T-T_c}{T_c}\Delta^2+\frac{7\zeta(3)}{16\pi^2}N_0\int\frac{d\Omega}{4\pi}\left(g(\mathbf{k})g^{*}(\mathbf{k})\right)^2\frac{\Delta^4}{T_c^2} \tag{10.14}$$

В частности, для обычного сверхпроводника с s-спариванием ($g(\mathbf{k})=e^{i\varphi}$)

$$F_{\mathrm{cond}}\ =N_0\frac{T-T_i}{T_{\mathrm{c}}}\Delta^2+\frac{7\zeta(3)}{16\pi^2}N_0\frac{\Delta^4}{T_{\mathrm{c}}^2} \tag{10.15}$$

Итак, ми полугіи разложения Лаппау шя сзерхпроводников с трипихетным [1] и сингле TILjм спариваниєм, следующие из тсории БКШ. Критическая тсмпература, входящая в (10.13) и (10.14), одинакова дхя всех сверхпроволящих состояний с данным l (относящихся k данному неприводимому представлению группи симметрии нормального состояния). В то же время, эпергии сверхпроводяших состояний с данным l, оличаюошихся паборами коэффициснтов в разложениях (4.8) или (4.9) параметра порядка по сферическим гармоникам (в сбщем случае - по функшиям базиса неприводимого представления (4.10) или (4.11)), будут различньми. В самом деле, равновесная энергия конденсации)10.3)

$$F_{\mathrm{cond}}\ =-\frac{\alpha_0^2}{2\beta}\left(\frac{T-T_c}{T_c}\right)^2\sim\left[\int\frac{d\Omega}{4\pi}\left(\mathrm{d}(\mathbf{k})\mathrm{d}^{*}(\mathbf{k})\right)^2\right]^{-1} \tag{10.16}$$

сушсственно зависит от вида сверхпроводящего состояния. Так, напрммер, для фаз с p-спариванием после подстаповки в (10.16) параметров порядка из 3 мы получаем, тто минимальной энергией среди фаз с p-спариванием будет обладать B-фаза ($\mathrm{d}(\mathbf{k}) = \hat{\mathbf{k}}$). В частности, се энергия оказывастся ниже эгергии A-фазы $\left(\mathrm{d}(\mathbf{k}) = \sqrt{3/2}\left(\hat{k}_x + i\hat{k}_y, 0, 0\right)\right)$ в $6/5$ раз [22].

Действительно, в жидком гелии-3 при низких давлениях фазовый переход из нормальной жидкости происходит в сверхтекучуп B-фазу. Однако, в области высоких давлений (рис. 2) сначала происхолит переход в A-фазу, которая загем сменяется на B-фазу посредством перехола первого рода. Эго означает, что при высоких давлепиях вблизи T_c именно A-фаза наиболес энергетически выгодна. Разренение противоречия с наиим результатом состоит в том, что формуда (10.13), на основании которой сделан вывод о мипимальности энсргии B-фазы, является на самом деле недостаточно общей. В процессе ее вывода использовалось, казалось бы, естественіное предположение о том, что спаривательнос взаимолействие не изменяется в сверхпроводящем состоянии, в частности, является одинаковым во всех сверхпроводящих фазах с данным l (приблискение слабой связи или приближение БКШ). На самом деле это не так, и $V(\mathbf{k}, \mathbf{k}')$ зависит от конкретного вида параметра порядка (сильная связь). Хотя этот факт не сказчвается на утверждении о том, что все фазы с данным l иметот одинаковую критическуюо температуру, вид члена четвертого порядка по Δ в разложении (10.13) прри этом меняется, что делает, вообще говоря, неверным вывод об энергетической вытодности B-фазы при побых температурах и давлениях. Учет влияния вида спаривания ша $V(\mathbf{k}, \mathbf{k}')$ может быть произведен тиш в рамках конкрстной микроскопитеской модели (см. [3, 6]) и мы не булем здесь этим запиматься, тем более что на практике нет возможности количественіо проверить справедливость той или иной модели сильной связи.

19.1.11 11. Superconducting States with Multicomponent Order Parameters

Из рассмотрения в §4 и 10 следует, что возможные сверхпроводящие или сверхтекучие фазы, параметр порядка которых прсобразуетея в соотве гствии с определснным (неодномерным) прсдставтением точечной группы симметрии G, имеют одинаковуто критическую температуру, но различную свободную энергию. Вычисления с помощыо той или иной микроскопичсской модели в принципе позволяют найпи коэффициенты в разложении Ландау и ответить на вопрос, в какос имснно состояние происходит фазовый переход, подобно тому, как это было сделапо в предыдущем параграфе в рамках теории БКШ. Одиако к выводу о том, тто минимальную свободную энергию могут иметь различные состояния, причем каждое - в своей области фазовой диаграммы (напримср, не только B-фаза, но и другие фазы p-спаривания на плоскости давлепие-температура), можно прийти не зависяцим от конкретной микроскопической мопели феноменологическим путем. При этом пля получения разложсния Ландау могут быть использованы лиш весьма общие симмстрийные соображения [34].

Разлжение свободной энергии Лацдау для фаз с p-спариваиием. Параметром порядка в сверхтекутей ферми-жилкости с p-спариванием являстся комплексная 3×3 матрица $A_{\alpha i}$ (см. 3), которая прсобразуется при спиновых вращениях как вектор по индексу α, а при вращениях в координатном пространстве - как вектор по индексу i. Свободиая

[11] Iапомним, что разложепие (10.13) страведтиво лишь дли так называемых уинитарных фаз (см. 5). Вывод разложения Ландау из теории БКI аля произвольныгх сверхпроводяипх фаз с триплетиым спаривапием проделан в 18.

энергия, будучи скалярнои величиной, не зависит от выбора систем координат, в которых заданы эти вектора. Иными словами, разложение должно быть иівариаітно относительно произвольных и независимдх (в отсутствие сппи-орбиталного взаимодействия) трехмерных вращений спинового и координатного пространств. Кроме этого, свободная энергия вещественна, то есть не должна меняться при комплексном сопряжении параметра порядка (симметрия по отношению к обращению времени), а также при домножении парамстра порядка на произвольный фазовый міожитель $e^{i\varphi}$ (калибровочная инвариантность).

Указанным свойствам инвариантности при преобразованиях параметра порядка вила

$$A_{\alpha i} \to \tilde{A}_{\alpha i} = R^{\mathrm{S}}_{\alpha\beta} R^{o}_{ij} e^{i\varphi} R A_{\beta j}$$

где $R^{S}_{\alpha\beta}$ и R^{O}_{ij} - матрицы трехмерных вращений в спиновом и координатном (орбитальном) пространствах, соответственно, а $RA_{\alpha i} = A^{*}_{\alpha i}$ - операция обращсния времени, удовлетворяет выраженис для плотности свободной энергии, содержащее всего пять инвариантных членов четвертого порялка:

$$\begin{aligned} F_{\mathrm{cond}} &= \alpha A_{\alpha i} A^{*}_{\alpha i} + \beta_1 \left|A_{\alpha i} A_{\alpha i}\right|^2 + \beta_2 \left(A^{*}_{\alpha i} A_{\alpha i}\right)^2 + \beta_3 A^{*}_{\alpha i} A_{\beta i} A^{*}_{\alpha j} A_{\beta j} + \\ &+ \beta_4 A^{*}_{\alpha i} A_{\beta i} A^{*}_{\beta j} A_{\alpha j} + \beta_5 A^{*}_{\alpha i} A_{\alpha j} A^{*}_{\beta i} A_{\beta j} \end{aligned} \tag{11.1}$$

Здесь матрицы A и A^{*} встречаются попарно, и во всех слагаемых произведена попарная свертка спиновых индексов со спиновыми, а орбитальных - с орбитальными.

Плотность свободной энергии (11.1) имеет несколько экстрсмумов, определяемых уравнениями $\delta F_{\mathrm{cond}} / \delta A_{\alpha i} = 0$. Какие из этих экстремумов есть минимумы, и какой из минимумов является абсолотным, зависит or соотношения между коэффициентами β_i, которые в свою очередь, зависят от температуры и давления [1]. A - и B-фазы входят в число минимумов F_{cond} Матрицы параметра порядка для них выглядят следующим образом (см. 3):

$$A^{A}_{\alpha i} = \sqrt{\frac{3}{2}} \Delta(T) V_\alpha \left(\Delta'_i + i\Delta''_i\right) \tag{11.2}$$

$$A^{B}_{\alpha i} = \Delta(T) R_{\alpha i} e^{i\varphi} \tag{11.3}$$

где $\mathbf{V}, \Delta', \Delta''$ - единичные векторы (причем $\Delta'\Delta'' = 0$), $R_{\alpha i}$ - матрица трехмерных вращений, а $\Delta(T)$ - модуль параметра порядка. Состояния A-фазы вырождены по ориентациям вектора V и пары векторов Δ' и Δ'', а состояния B-фазы вырождены по отнопению к трехмерным вращениям, задаваемым матрицей параметра порядка $R_{\alpha i}$, и к выбору фазы φ.

В отличие or (10.13), разложение (11.1) дает право на существование А-фазы. Действительо, подставляя (11.2) и (11.3) в (11.1), получаем:

$$\begin{aligned} F^{A}_{\mathrm{cond}} &= 3\alpha\Delta^2 + 9\Delta^4 \left(\beta_2 + \beta_3 + \beta_4\right) \\ F^{B}_{\mathrm{cond}} &= 3\alpha\Delta^2 + 9\Delta^4 \left(\beta_1 + \beta_2 + \frac{\beta_3 + \beta_4 + \beta_5}{3}\right) \end{aligned}$$

Отсюда видно, что A-фаза энергетически выгоднее B-фазы, если значение β_1 (или β_5) достаточно велико.

Многокомпоненттые сверхпроводяппие состояния в кристаллах. Пусть сверхпроводящее состояние соответствует одному из неодномерных представлений

группы точечной симметрии кристалла. В случае сильного спин-орбитального взаимодействия параметр порядка такого состояния имеет вид (см. 4)

$$\begin{array}{rl} g(\mathbf{k}) = \eta_1 \psi_1^{\mathrm{g}}(\hat{\mathbf{k}}) + \eta_2 \psi_2^{\mathrm{g}}(\hat{\mathbf{k}}) + \ldots & \text{при } S = 0 \\ \mathrm{d}(\mathbf{k}) = \eta_1 \psi_1^{\mathrm{u}}(\hat{\mathbf{k}}) + \eta_2 \psi_2^{\mathrm{u}}(\hat{\mathbf{k}}) + \ldots & \text{при } S = 1 \end{array} \tag{11.4}$$

Как для синглетного, так и для триплетного сверхпроводящего состояния плотность свободной эпергии вблизи температуры перехода записывается в виде разложения по степепям комплексных коэффициештов η_i, которое лотжно быть инвариантно относительно прсобразований гругппы симметрии нормапного состояния $\mathcal{G} = U(1) \times R \times G$. При выводе такого разложения необходимо принять во внимание, что транеформационные своиства базисных функкший $\psi_i^{\mathrm{g}}(\hat{\mathbf{k}})$ и $\psi_i^{\mathrm{u}}(\hat{\mathrm{k}})$ при преобразованиях симметрй можно отнести к коэффициентам η_i.

Напримср, для представлений $E_{1\,\mathrm{g}}$ и $E_{1\,\mathrm{и}}$ группы $D_{6\,\mathrm{h}}$ базисные функции пропорциональны компонентам вектора, лежацего в Базисиой плоскости (см. табл. 1), т.е.

$$\begin{array}{c} \left(\psi_1^{\mathrm{g}}(\hat{\mathbf{k}}), \psi_2^{\mathrm{g}}(\hat{\mathbf{k}})\right) \sim (k_z k_x, k_z k_y) \\ \left(\psi_1^{\mathrm{u}}(\hat{\mathbf{k}}), \psi_2^{\mathrm{u}}(\hat{\mathbf{k}})\right) \sim (\hat{z} k_x, \hat{z} k_y) \end{array} \tag{11.5}$$

Поэтому можно считать, что коэффициенты η_1, η_2 прсобразуются под действием эдементов группы $D_{6\,\mathrm{к}}$ как компонснты такого вектора [2]. Скалярные произведения $\boldsymbol{\eta}\boldsymbol{\eta}^*, \boldsymbol{\eta}\boldsymbol{\eta}, \boldsymbol{\eta}^*\boldsymbol{\eta}^*$ инвариантны относительно любых вращений из труппы D_6. Из них можно составить два вещественных инварианта четвертого порядка. Друтих инвариантов в случае гексагональной симметрии нс существует, следовательно, разложснис Ландау имест вид:

$$F = \alpha \boldsymbol{\eta} \eta^2 + \frac{\beta_1}{2} \left(\boldsymbol{\eta} \eta^2\right)^2 + \frac{\beta_2}{2} |\eta\eta|^2 \tag{11.6}$$

Минимуму свободной энергии (11.6) при $\beta_2 < 0$ соответствует параметр порядка

$$\begin{array}{c} \eta = \eta_0 (\cos\lambda, \sin\lambda) e^{i\varphi} \\ \eta_0^2 = -\dfrac{\alpha}{\beta_1 + \beta_2} \end{array} \tag{11.7}$$

где φ и λ - произволыне фазы. Снятие вырождения по отношению к λ происходит только при добавлешии к разложеник (11.6) инварианта шестого порядка:

$$\gamma \,\mathrm{Re}\left(\eta_1 + i\eta_2\right)^3 \left(\eta_1^* + i\eta_2^*\right)^3 \tag{11.8}$$

Если $\gamma < 0$, то минимум своболной энергии достигается при $\lambda = \lambda_n = \pi n/3$, $n = 0, 1, \ldots, 5$, если $\gamma > 0$, то - при $\lambda_n = \pi n/3 + \pi/6$. Все сверхпроводящие состояния, описываемые параметром порядка (11.7) с указанными значениями λ формально принадлежат одному сверхпроводящему классу $D_2\,(C_2) \times R$, однако направление оссй симметрии для разных λ_n различно. Так, например, при $\gamma < 0$ и $\lambda = 0$ сверхпроводящий класс выглядит следующим образом:

$$D_2\,(C_2) \times R = \left\{E, C_{2y}, e^{i\pi} C_{2x}, e^{i\pi} C_{2z}\right\} \times R$$

[11] Общая загача о нахождении всех экстремумов функционага (11.1) решена В. Березинским [35]. Те же результаты независимо получены в работе [36]

При $\beta_2 > 0$ минимум энергии (11.6) достигается при [3]

$$\eta = \eta_0(1, \pm i)e^{i\varphi} \qquad (11.9)$$
$$\eta_0^2 = -\frac{\alpha}{2\beta_1}$$

Этому решению соответствует сверхпроводяиий класс

$$D_6(E) = \left\{\exp\left(\frac{i\pi n}{3}\right) C_n, \exp\left(\frac{i\pi n}{3}\right) RU_n\right\}$$

гдс $n = 0, 1, \ldots, 5$. Аналогично А-фазе гелия-3, состояние (11.9) не илвариантно относитсдьно обращения врсмени, что означает напщчие спонтанного магнетизма купсровских пар. К этому вопросу мы еше вернемся в 15.

Для сверхпроводяших состояний, соответствутоших двумерным представлениям $E_{2\,\mathrm{g}}$ и $E_{2\mathrm{u}}$ группы D_{6h}, свободная энергия сохраняет вил (11.6). Ее минимумы определяготся формупами (11.7) и (11.9) и формалыно относятся к тем же сверхпроводяшим ктассам, вктючающим, оштако, другие элементы симметрии в соответствии с трансформационными свойствами базисных функций представления E_2.

В тетрагональном кристалле ($G = D_{4h}$) базисные функции единственного двумсрного представления E тоже пмеюот вид (11.5), то есть преобразуются как

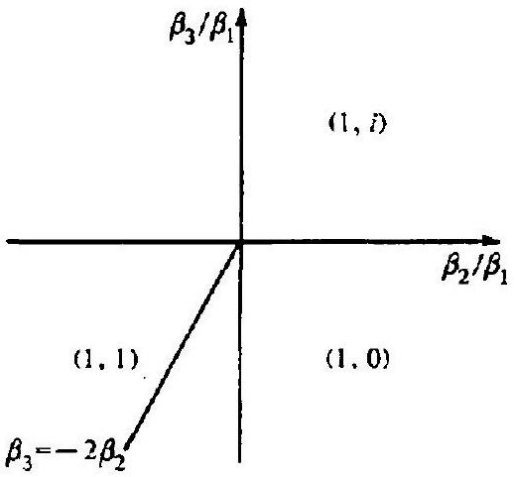

Рис. 10. бласти существования двухкомпонеппиых сверхроводяиих состоянии (1,0), (1,i) и (1,1) в тетрагонатыгом кристалле

компоненты вектора, лежащего в базисной плоскости. Однако, в этом случае симметрия допускает существование трех инвариантов четвергого порядка, и свободная энергия Лаидау принимает вид

$$F = a\eta\eta^* + \frac{\beta_1}{2}(\eta\eta'')^2 + \frac{\beta_2}{2}|\eta\eta|^2 + \frac{\beta_3}{2}\left(|\eta_1|^4 + |\eta_2|^4\right) \qquad (11.10)$$

В зависимости от отношения коэффициентов β_2 и β_3 (см. рис. 10) энергия достигает минимашных значенний на решениях трех типов:

[12] Действие операций хатибровочной группы сводится **x** умножению компонент парачетра порадка на обиций фазовый множитель: $(\eta_1, \eta_2) \to e^{1\varphi}(\eta_1, \eta_2)$, а обращение времени эквивалентно комплексному сопряжению: $(\eta_1, \eta_2) \to (\eta_1^*, \eta_2^*)$

[3] Пользуясь результатами предыдушего параграфа, нетрудно установить, что в теории БК (приближение слабой связи) выполняется соотношение $\beta_1 = 2\beta_2 > 0$.

$$\eta \sim (1.0)(\text{ илии } (0,1)). \quad (1.\pm 1), \quad (1,\pm i) \tag{11.11}$$

Веществепные фазы относятся х классам вида $D_2\,(C_2) \times R$, причсм, как и в гексагональном кристалле, направлсния осей симметрии для различных фаз различно. Комплексныс состояния принадлежат магнитному классу

$$D_4(E) = \left\{ \exp\left(\frac{i\pi n}{2}\right) C_n, \exp\left(\frac{i\pi n}{2}\right) RU_n \right\}$$

где $n = 0, 1, 2, 3$.

В кристаллах с кубической симметрией пля сверхтроводящих состояний, параметры порядка $\boldsymbol{\eta} = (\eta_1, \eta_2, \eta_3)$ которых преобразуются согласно одному из двух трехмсрных представлений труппы O_h (см. табл. 5, 6), плотность свободной энсргии записывается в виде, аналогичном (11.10):

$$F' = \alpha\eta\eta^{=} + \frac{\beta_1}{2}\left(\eta\eta^{-}\right)^2 + \frac{\beta_2}{2}|\eta\eta|^2 + \frac{\beta_3}{2}\left(|\eta_1|^4 + |\eta_2|^4 + |\eta_3|^4\right) \tag{11.12}$$

В случае же двухкомпонентного параметра порядка, сскответствуоощего двумсриому представлению, свободная эергия имеет вид

$$F = \alpha\eta\eta^* + \frac{\beta_1}{2}\left(\eta\eta^*\right)^2 + \frac{\beta_2}{2}|\eta\eta|^2 + \gamma\left(\eta_1^3\eta_2^{*3} + \eta_1^{*3}\eta_2^3\right) \tag{11.13}$$

где мы добавиш ипвариант шестого порядка, спиматощи вырожденис веществснігдх состояний.

Мы не будем здссь останавливаться на перечислении всех возможных минимумов (11.12) ии (11.13) и соответствующих им сверхпроволящих классов. Это может быть сделано (см. [9]) анатогично рассмотренному выие простому случаю тетрагонального кристалла.

Упражиение. Найти разложение Ландау свободиой энсргии изотропного сверхпроводника с d-спариванием.

19.1.12 12. Ginzburg–Landau Equations and the Upper Critical Field

В этом и нескольких следующих параграфах будет изложена теория Гинзбурга-Лапдау для анизотропных сверхпроводяиих состояний. Прелполагая, что читатель знаком с теорией Гинзбурга-Ландау для обычных сверхпроводников (см., например, [37]), мы сосредоточим вниманис на вопросах, специфическдх дия необычной свсрхпроводимости. Напем с постросния функционалов Гинзбурга-Лаплау и вычисления верхіих критических полей в необыгныхх сверхпроводиниках второго рода.

Однокомпопегтиые сверхпроводящие состояния в кристаллах. Функиионал Гинзбурга-Ландау, то есть разность энергий Гиббса [1] свсрхпроводника в неоднородном состоянии вблизи T_c и нормального металла, в стучае однокомпонентного параметра порядка $\eta(\mathbf{r}) = |\eta(\mathbf{r})|e^{i\varphi(\mathbf{r})}$ имеет вид

$$\mathcal{G} = \int d^3r G = \int d^3r \left(F - \frac{\mathbf{HB}}{4\pi}\right) \tag{12.1}$$

где плотность свободной энергии F отлитается от выражсния (10.1) тем, что здесь добавлсна градиегтная энергия и энергия магнитного поля:

$$F = \alpha_0 \left(\frac{T - T_c}{T_\varepsilon} \right) |\eta|^2 + \frac{3}{2}|\eta|^4 + K_{ij} \left(D_i \eta \right)^* \left(D_j \eta \right) + \frac{B^2}{8\pi} \tag{12.2}$$

Здесь

$$D_i = -i\nabla_i + \frac{2\pi}{\Phi_0} A_i \quad (i = x, y, z) \tag{12.3}$$

$\Phi_0 = \pi\hbar c/e$ - кваит магнитного потока [2], а $\mathbf{B} = \operatorname{rot} \mathbf{A}$ - всктор магнитной индукции.

Тепзор K_{ij}, называемый тензором эффективных масс, описывает анизотропию направлений в кристалле. Так, для одноосных кристалов с гексаго- нальной (илщ тетрагональной) симметрией:

$$K_{ij} = \left(\delta_{ij} - \hat{z}_i \hat{z}_j \right) K_1 + \hat{z}_i \hat{z}_j K_4 \tag{12.4}$$

В кристаллах с кубической симметрией $K_1 = K_4$, то есть $K_{ij} = K\delta_{ij}$. Вывод градиентных слагаемых в свободной энергии с помощью михроскопической теории проделан в параграфе 18.

Пространственные распределения параметра порядка η и векторпотенциала A должны обсспечивать минимальность функционала $\mathcal{G}$:

$$\frac{\delta \mathcal{G}}{\delta \eta^*} = 0, \quad \frac{\delta \mathcal{G}}{\delta \mathrm{A}} = 0 \tag{12.5}$$

Варьируя (12.1) по η^* и отбрасывая интеграл по поверхности сверхпроводника (мы обсудим поверхностные эффекты в следующем параграфе), приходим х уравнению Гинзбурга-Ландау:

$$\alpha_0 \left(\frac{T - T_c}{T_c} \right) \eta + \beta |\eta|^2 \eta + K_{ij} D_i D_j \eta = 0 \tag{12.6}$$

Сравнивая первый и последний члены в уравнении (12.6), мы вилим, что в теории имеется характерный пространственный масштаб - корреляционная длина $\xi(T)$, различная для различных кристаллографических направлений i:

$$\xi_i(T) \approx \hbar \left(\frac{K_{11}}{\alpha(T)} \right)^{1/2} \tag{12.7}$$

Буквенная оценка $\xi(T)$ для произвольного направлсния имеет вид

$$\xi(T) \sim \xi_0 \left(\frac{T_c - T}{T_c} \right)^{-1/2} \tag{12.8}$$

где $\xi_0 = \hbar v_{\mathrm{F}} / \left(2\pi T_{\mathrm{c}} \right)$ есть размер куперовской пары (см. 1).

Градиентная энергия сверхпроводника включаст, разумеется, и члены бодее высоких порядков по градиегтам, чем $K_{ij} \left(D_i \eta \right)^* \left(D_j \eta \right)$. Их игнорирование означает, что теория Гиізбурга-Ландау адекватно описывает достаточно медленные пространственные изменения параметра порядка с масшгтабом, превышающим ξ_0.

Верхнее критическое поле. Верхнее критическое поле $H_{c2}(T)$, при котором в сверхпроводниках второго рода происходит фазовый переход в сверхпроводящес состояние, соотвстствует наинизшему собственному значению дифференциаьного

[11] В задавном внешлем мжаннтном поте 11 иместо свободнои энергии $\mathcal{F}(T, B)$ улобно исполызрвать энергио Гиббса $\mathcal{G}(T, IT)$.

[2] Здесь и пиже е обозыачает абсолютнуо величину заряда электрона.

оператора в линеаризованном уравнении Гинзбурга-Ландау. Перед изучением анизотропии верхнего критического поля, специфической для некоторых кристаллических сверхпроводников с многокомпонентным параметром порядка, посмотрим сначала, как обстоит дело для однокомпонентной сверхпроводимости в одноосных кристаллах. В этом случае линеаризованное уравнение Гинзбурга-Лапдау имеет вил

$$\alpha_0 \left(\frac{T - T_c}{T_c} \right) \eta + K_1 \left(D_x^2 + D_y^2 \right) \eta + K_4 D_z^2 \eta = 0 \tag{12.9}$$

Выбирая магнитное поле лежащим в базисной плоскости:

$$\begin{aligned} \mathbf{H} &= H(\cos\varphi, \sin\varphi, 0) \\ \mathbf{A} &= Hz(\sin\varphi, -\cos\varphi, 0) \end{aligned} \tag{12.10}$$

из (12.9) получаем:

$$-K_4 \frac{d^2\eta}{dz^2} + K_1 \left(\frac{2\pi H}{\Phi_0} \right)^2 z^2 \eta + \alpha_0 \left(\frac{T - T_c}{T_\mathrm{c}} \right) \eta = 0 \tag{12.11}$$

Пользуясь тем, что данное уравнешиее формально совпадает с уравнением Шрсдингера для заряженной частицы в магнитном поле, собственные функции и собственные значения которого (уровни Ландау) хорошо известны, находим:

$$H_{c2}(T) = \frac{\Phi_0 \alpha_0}{2\pi\sqrt{K_1 K_4}} \frac{T_c - T}{T_c} \tag{12.12}$$

то есть ведичина верхнего критического поля, лежащего в базиспой плоскости гексагонального (тетрагонального) кристалла, не зависиг от направления.

Такая зависимость появляется лишь при выходе из базисной плоскости. Например, дхя поля, лежацего в плоскости (y, z):

$$\begin{aligned} \mathbf{H} &= H(0, \sin\theta, \cos\theta) \\ \mathbf{A} &= Hx(0, \cos\theta, -\sin\theta) \end{aligned} \tag{12.13}$$

решение уравнения (12.9) дает

$$H_{\mathrm{c}2}(T) = \frac{\Phi_0 \alpha_0}{2\pi\sqrt{K_1 \left(K_1 \cos^2\theta + K_4 \sin^2\theta \right)}} \frac{T_\mathrm{c} - T}{T_\mathrm{c}} \tag{12.14}$$

В кристаллах с кубической симметрией $K_1 = K_4$, и величина верхнего критического поля нс зависит от его ориснтации относительно осей кристаллической решетки.

Миогокомпонентиые сверхпроводящие состояния в кристаллах. Персйдем геперь к рассмотрегию двухкомпонентий сверхпроводимости с векторным параметром порядка $\eta = (\eta_x, \eta_y)$, соответствующим мибо представлению E_1 группы D_6, либо представлению группы E группы D_4 (см. 4). Функционалы Гиизбурга-Ландау записываются в виде разложения по степеням двух комплексных функций η_1 и η_2 и их градиентов, которос должно быть вещественным и инвариантндм относитежно всех преобразований точечной группы D_{6h} (или D_{4h}). Последнее требованис означает, что всякий член разложения имеет один и тот же вид во всех системах координат, связанных между собой преобразованиями из D_{6h} (или D_{4h}). Оставляя лишь квадратичные по параметру порядка слагаемые, существенные

для вычисления верхнего критического поля, запишем фупкционалы Гинзбурга-Ландау для векторного представления в гексагоналыном:

$$F_{\text{hex}} = \alpha_0 \left(\frac{T - T_c}{T_c} \right) \eta\eta^m + K_1 \left(D_i \eta_i \right)^* \left(D_i \eta_j \right) + K_2 \left(D_i \eta_i \right)^* \left(D_j \eta_j \right) + \\ + K_3 \left(D_i \eta_j \right)^* \left(D_j \eta_i \right) + K_4 \left(D_z \eta_i \right)^* \left(D_z \eta_i \right) + \frac{B^2}{8\pi} \tag{12.15}$$

и тетрагональном:

$$F_{\text{tetr}} = F_{\text{hex}} + K_5 \left[\left(D_x \eta_x \right)^* \left(D_x \eta_x \right) + \left(D_y \eta_y \right)^* \left(D_y \eta_y \right) \right] \tag{12.16}$$

кристаллах, $i = x, y$.

Плотность свободной энергии F_{hex} содержит только скалярнъе произведения двух лежащих в базисной плоскости векторов $\boldsymbol{\eta}$ и $\mathbf{D}$ ($\boldsymbol{\eta}\boldsymbol{\eta}^*, \mathrm{D}\boldsymbol{\eta}$ и т. д.),
и поэтому инвариантна относительно любих поворотов в базиспой плоскости. Члены, соответствуошие специфической гексагональной анизсгропии, появдяются только в болсе высоких порядках разложения по градиентам. Полная симметрия свободной энергии по отношению к врашениям на произвольный угол в базисной плоскости привопит к изотропии верхнего критического поля. В эгом можно убедиться нспосредственно, решая два уравнения. получающиеся варьированием (12.15) по η_j^*:

$$K_1 D_i^2 \eta_j + K_2 D_j D_i \eta_i + K_3 D_i D_j \eta_j + K_4 D_z^2 \eta_j + a_0 \left(\frac{T - T_c}{\tau_c} \right) \eta_j = 0 \tag{12.17}$$

в поле вида (12.10). Выбирая систему координат таким образом, чтобы ось $\ddot{x}$ была параллельна магнитному полю, из (12.17) полугаем систему двух независимых лифферснциальных уравнений:

$$\begin{cases} \cdots K_4 \frac{d^2 \eta_x}{dz^2} + K_1 \left(\frac{2\pi I l}{\Phi_0} \right)^2 z^2 \eta_x + \alpha_0 \left(\frac{T - T_c}{T_c} \right) \eta_x = 0 \\ -K_4 \frac{d^2 \eta_y}{dz^2} + \left(K_1 + K_2 + K_3 \right) \left(\frac{2\pi H}{\Phi_0} \right)^2 z^2 \eta_y + \alpha_0 \left(\frac{T - T_c}{T_c} \right) \eta_y = 0 \end{cases} \tag{12.18}$$

с собственыыми знаяениями, определяющиими дзс возможныс величины $H_{\text{c2}}(T)$:

$$H_{\text{c2}}^{(1)}(T) = \frac{\Phi_0 \alpha_0}{2\pi \sqrt{K_1 K_4}} \frac{T_{\text{c}} - T}{T_{\text{c}}} \tag{12.19}$$

$$H_{\text{c2}}^{(2)}(T) = \frac{\Phi_0 \alpha_{\text{G}}}{2\pi \sqrt{\left(K_1 + K_2 + K_3 \right) K_4}} \frac{T_{\text{c}} - T}{T_{\text{c}}} \tag{12.20}$$

Большая из них соответствует верхнему критическому полю, при котором происходит фазовый переход в сверхпроводящее состояние. Таким образом, всрхнее критичсское поле оказывастся изотропным в базисной плоскости гексагонального кристалла и в случае двухкомпонснтной свсрхпроводимости. Для состояния, преобразующегося согласпо представлению E_2, доказательство этого факта можно найти в рабоге [38].

Отмстим сще одно важнюе следствие из уравнений (12.18). Мы видим, что в магнитном поле фазовый переход из нормального состояния происходит в одну из двух сверхпроводяших фаз:

$$\boldsymbol{\eta}_x \propto (1, 0) f_0(z) \tag{12.21}$$

или

$$\eta_y \propto (0,1) f_0(z) \tag{12.22}$$

где $f_0(z)$ - фупкция осповіого состояния Ланлау лля заряженной частицы в мапнитіом поле. С друтой стороны, если переход в нулевом магнитном поле ляя векторного представления происходит в комплексную фазу (см. (11.9))

$$\eta \propto (1, \pm i) \tag{12.23}$$

то при уменышении магиитного поля (при $T < T_c$) трансформация состояния с параметром порядка (12.21) в в состояние (12.23) доджна обязательно сопровождаться переходом, связанным с зарождснисм фазы с параметром
порядка (12.22) (см. рис. 11). Аиалогитное явление должно наблюдаться, если в нулсвом полс переход происходит в вещественнуо фазу

$$\eta \propto (\cos \lambda_n, \sin \lambda_n) \tag{12.24}$$

где величины λ_n опрсдсляются кристаллической анизотропиcй (см. 11).

Свойство изотропии $II_{c2}(T)$ в базисной плоскости гексагонального кристалла, разумсстся, утрачивается при введешии л!обого внешпего воздействия, нарушающего гексагональную симметрию. Так например, слабое орторомбитеское возмущснис, характсризуемое вектором M, лежащим в базиспой птоскости, приводит к появлсиино в фупционале ГинзбургаЛандау слагаемого с орторомбитеской симметрией, имеющсго вил

$$\gamma(\mathbf{M}\boldsymbol{\eta})^*(\mathbf{M}\eta) \tag{12.25}$$

Учет такого вклада приводит как к расщептснию температуры псрсхода (компоненты η, параллельная и перпеідикулярная M, будут появляться при разных температурах), так и к заметной анизотропии верхнего критиче-

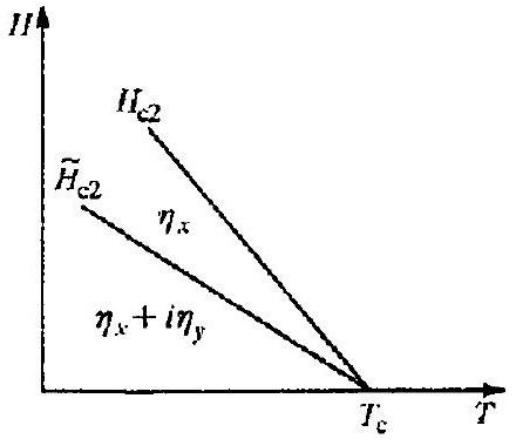

Рис. 11. Фазоsьіе переходы в маагиитгом полс для двухкомпонентіых сверхпроводяших состояин в гексагональном кристалле ского поля [39]. Последное свойство следует из того, что уравнения дпя компонент парамстра порядка перестают быть независимыми (кроме вылелснных направпений H$\|$M и H $\perp$ M).

Рассмотрим теперь кристалл с тетрагональной симметрией. Специфическим для него является дополшительныи млег в грапиенпой энсргии (12.16), обладаюшний симметрией четвсртого порядка относительно поворотов вокруг оси $\hat{z}$. Линеаризованшые уравнения Гинзбурга-Ландау в этом случае нмеюот вип

$$K_1 D_i^2 \eta_j + K_2 D_j D_i \eta_i + K_3 D_i D_j \eta_i + K_4 D_x^2 \eta_j + \\ + K_5 \left(\delta_{xj} D_x^2 \eta_x + \delta_{yj} D_y^2 \eta_y \right) + \alpha_0 \left(\frac{T - T_c}{T_c} \right) \eta_j = 0 \tag{12.26}$$

Положим для простоты $K_2 = K_3 = 0$, тогда уравнения для компонеіт парамета порядка расцспчяются, и, в случае поля вила (12.10), лсжащсго в базиспой плоскости, получаем следупощие значсния $H_{\text{с:2 для компонепт}}$ η_x и η_y, соответственно:

$$I_{c2}^{(1)}(T') = \frac{\Phi_0 \alpha_0}{2\pi \sqrt{K_4 \left(K_1 + K_s \sin^2 \rho \right)}} \frac{T_c - T}{T_c} \tag{12.27}$$

$$H_{c2}^{(2)}(T) = \frac{\Phi_0 \alpha_0}{2\pi \sqrt{K_1 \left(K_1 + K_5 \cos^2 \varphi \right)}} \frac{T_c - T}{T_c} \tag{12.28}$$

При каждом тгаправлении поля $H(\varphi)$ нужно выбрать из этих двух пачений больиес. Таким образом, в тетрагональном кристалле возникает анизотропия верхего критического поля, спешифическая для пвухкомпонснтной сверхпроводимости {40! (рис. 12).

Анизотропия верхнего критического поля той жс природы имеет место в кубитеских кристаллах в случае двух- или трехкомпонентных свсрхпроводя-

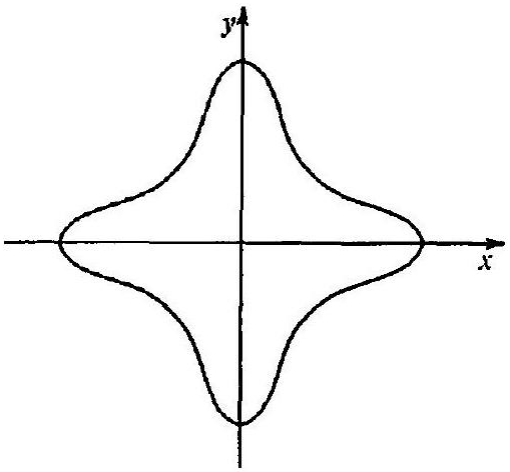

Рис. 12. Анизотрония верхігего критического поля в базисной плоскостн тетрагонального кристалла для двухкомпонентного сверхпроводяицего состояния щих состояний [38].

В общем случае, то есть при произволыной ориентацши внсшнего поля относительно осей кристаллической решетки, верхнее критическое поле для многокомпонентного параметра порядка в области применимости тсории Гицзбурга-Ландау может быпь найдено лишь путем численного апализа. Искточение составляет задача о вычислении $H_{c2}(T)$ для дзухкомпонентного параметра порядка в гексагональном (или тетрагональном) кристалле при $\mathbf{H}$, направленном вдоль оси шестого (или четвертого) порядка, допускающая аналитическое решение [41].

В этом случае постедний член в (12.16) не приводит к качественным отличиям, и мы будем решахь задачу при $K_5 = 0$. Поскольку магнитное поле направлено вдоль оси шестого порядка $\hat{z}$ (калибровка $\mathbf{A} = (0, Hx, 0)$), то можно считать, что параметр порядка от z нс зависит, и из (12.17) мы имеем следутощис уравнения:

$$\begin{cases} \left(K_{123}D_x^2 + K_1 D_y^2\right)\eta_x + \left(K_2 D_x D_y + K_3 D_y D_x\right)\eta_y + \alpha_0\left(\frac{T-T_c}{T_c}\right)\eta_x = 0 \\ \left(K_{123}D_y^2 + K_1 D_x^2\right)\eta_y + \left(K_3 D_x D_y + K_2 D_y D_x\right)\eta_x + \alpha_0\left(\frac{T-T_c}{T_c}\right)\eta_y = 0 \end{cases} \tag{12.29}$$

где $K_{123} = K_1 + K_2 + K_3$. Введем теперь новыс функции $\eta_\pm = \eta_x \pm i\eta_y$ и операторы $D_\pm = D_x \pm iD_y$, а также учтем, что $[D_x, D_y] = -2\pi iH/\Phi_0$. Тогда уравнения перписываются в виде

$$\begin{cases} \left(\alpha_0\left(\frac{T-T_c}{T_c}\right) + K_0\left(D_x^2 + D_y^2\right) - K_-\frac{2\pi H}{\Phi_0}\right)\eta_+ + K_+ D_+^2\eta_- = 0 \\ K_+ D_-^2\eta_+ + \left(\alpha_0\left(\frac{T-T_c}{T_c}\right) + K_0\left(D_x^2 + D_y^2\right) + K_-\frac{2\pi I}{\Phi_0}\right)\eta_- = 0 \end{cases} \tag{12.30}$$

где $K_0 = \left(K_{123} + K_1\right)/2, K_\pm = \left(K_2 \pm K_3\right)/2$.

Парамстр порялка ищем в виде

$$\eta_\pm = \exp(-ipy) f_\pm(x) \tag{12.31}$$

Тогда уравнения Гинзбурга-Лапдау имеют решения двух типов:

$$\begin{pmatrix} f_+(x) \\ f_-(x) \end{pmatrix} \sim \begin{pmatrix} F_{0.1}(x) \\ 0 \end{pmatrix}, \tag{12.32}$$

либо

$$\begin{pmatrix} f_+(x) \\ f_-(x) \end{pmatrix} \sim \begin{pmatrix} qF_{n+2}(x) \\ F_n(x) \end{pmatrix}, \tag{12.33}$$

где q - константа, а функция $F_n(x)$ связана с полиномами Эрмита $H_n(x)$ следующим соотношением:

$$F_n(x) = \exp\left[-\frac{\pi H}{\Phi_0}\left(x - p\frac{\Phi_0}{2\pi H}\right)^2\right] H_n\left[\sqrt{\frac{2\pi H}{\Phi_0}}\left(x - p\frac{\Phi_0}{2\pi H}\right)\right] \tag{12.34}$$

В том, что семейство (12.33) в самом деле является решением уравпений (12.30), легко убсдиться, используя тождества [42]:

$$D_-^2 F_n = -4n(n-1)\frac{2\pi H}{\Phi_0}F_{n-2}$$
$$D_+^2 F_n = -\frac{2\pi H}{\Phi_0}F_{n+2}$$
$$\left(D_x^2 + D_y^2\right)F_n = (2n+1)\frac{2\pi H}{\Phi_0}F_n$$

Подставляя (12.34) в (12.31), получаем выраженис для температур перехода, соответствуоших этому семейству решений:

$$\alpha_0\frac{T-T_c}{T_c} = \\ = \left[-(2n+3)K_0 + \sqrt{\left(2K_0 - K_-\right)^2 + 4(n+1)(n+2)K_+^2}\right]\frac{2\pi H}{\Phi_0} \tag{12.35}$$

Максимальная величина верхнего критического поля соответствует либо решению

$$\begin{pmatrix} f_+(x) \\ f_-(x) \end{pmatrix} \propto \begin{pmatrix} F_0(x) \\ 0 \end{pmatrix} \tag{12.36}$$

при котором

$$H_{c2}^{(1)}(T) = \frac{\Phi_0 \alpha_0}{2\pi \left(K_0 - K_-\right)} \frac{T_c - T}{T_c} \tag{12.37}$$

либо решенийо

$$\begin{pmatrix} f_+(x) \\ f_-(x) \end{pmatrix} \propto \begin{pmatrix} qF_2(x) \\ F_0(x) \end{pmatrix} \tag{12.38}$$

которому соответствует

$$H_{c2}^{(2)}\left(T'\right) = \frac{\Phi_0 \alpha_0}{2\pi \left(3K_0 - \sqrt{\left(2K_0 - K_-\right)^2 + 8K_+^2}\right)} \frac{T_c - T}{T_c} \tag{12.39}$$

Вид состояния, в которос происходит фазовый переход в магнитном поле, зависит от соотношения между коэффигиентами K_i. В частности, в теории БКШ $K_1 = K_2 = K_3$ (см. 18), и большее значение верхнего критического поля имеет состояние)12.38).

При уменьшении внешнего поля нихж $H_{c2}(T)$ сверхпроводящие зародышш, отвечающис различным значениям парамстра вырождения p, формируют периодическуо решетку вихрей Абрикосова, вид которой может существенно отличаться от обычной треугольной (подробнее об этом см. [43]).

Нарушение пространствешной четности и геликоидальные фазы. Всс рассмотренные многокомпонснтные сверхпроводящие состояния возникаюот из нормальной фазы, в группе симметрии которой имеется преобразование пространственной итверсии. В противном случае, во-первых, теряет смысл
разделение на четшые и нечетные сверхпроводящие состояния, ввиду возможности их перемешивания (см. 4), и, во-втирых, появтятся визможность постросния инвариантных слагаемвх в свободной эиергии, лигейных по прострацственным градиептам (инварианты Лифшица).

Например, ссли параметр порядка $\eta = (\eta_x, \eta_y)$ соответствует двумерному представтениio E_1 группы D_6, то кроме членов, входящих в разтожение (12.15), имеется итвариант вида

$$\gamma \left(\eta_1^* D_2 \eta_2 + \text{ k.c. }\right) \tag{12.40}$$

Учет подобных чтенов приводит к значительному изменению термодинамических и магнитных свойств системы, в частности, к возможности существования неоднородикх (геликоидалыьх) фаз в нулевом магнитном поле [7].

MC-12.1

Доказать, что функционал Гинзбурга-Ландау для двухкомпонентного параметра порялка, соответствующего представлению E_2 группы)$_6$ (базисныс функции см. в табл. 1,2), также можно записать в виде (12.15).)Указание. Составьте из компонент D и η комбинации, инвариантные относительно операций группы D_{6h} и найдите преобразование $\eta_i \to \chi_i$, такое, что для функиий $\chi_{1,2}$ градиептная энергия может быть приведена к виду (12.15).)

MC-19.2

Найти критическую температуру и состояния, в которые происходит фазовый переход в гсксагоналыном сверхпроводнике без центра инверсии с учетом слагаемого вида (12.40) в свободіо энергин.

19.1.13 13. Boundary Conditions and Surface Superconductivity

Вблизи поверхности заролыип сверхпроводящей фазы в сверхпроводниках второго рола возникают в магнитном поле, превышающем верхнее критическое поле. Дтя нахождешия поверхностного критичсского поля нсобходимо решить линеаризоваіное уравыение Гинзбурга-Ландау с учетом граничных условий для параметра поряпка. В этом параграфе будут получены граничные условия и изутеп вопрос о поверхостной сверхпрозолимости в кристаллах Возможность образования поверхностных зародыпей в необычных сверхпроводниках сущсственио зависит от ориептации поверхіости по опноченііо к кристаллическим осям. Обпаружение такой зависимости может служить способом илентификации сверхпроводяшпх фаз.

Граничные условия. Одиокомпонентная сверхпроводимоств. Уравнения Гинзбурга-Ландау были потучены в предыдущем параграфе из условия равенства нуло вариации свободной энсргии. Оставшаяся поверхностная часть:

$$\delta\mathcal{F}|_{S,\,\mathrm{grad}} = -i \oint dS n_i K_{ij} \left(D_j \eta\right) \delta\eta^m \tag{13.1}$$

где $\mathbf{n}$ - вектор нормали к поверхности, обращается в пуль при условии

$$n_i K_{ij} D_j \eta l_S = 0 \tag{13.2}$$

которое обеспечивает обращение в пуль нормацнои к поверхпости компоненты тока: $\mathbf{nj}|_{\mathrm{S}} = 0$. Полагая, что параметр порядка волизи поверхности в
нулевом магнитном поле может меняться лишіь вдоль направлешия нормали, получаем:

$$(\mathbf{n}\nabla)\eta|_{\mathrm{S}} = 0 \tag{13.3}$$

Отсюда следует, что на поверхности сверхпроводника в опсутствие магнитного поля параметр порядка имест ту же величиу, тто и в обьеме.

Одиако, даже для обьчных сверхпроводиков этот вывод, полученнъій в рамках теории Гинзбурга-Ландау, нуждается в проверке на основе микроскопитеской теории. Дело в том, что теория Гипзбурга-Лапдау применима лив на пространствепных масштабах, превышаюшпх длну когерентиости ξ_0 и поэтому не уитывает изменение условий возникновения сверхпроводимости непосредственно вблизи повсрхности. Микроскопическое рассмотрение (см. ниже 20) гоказывает, что вблизи границы, на расстояниях порядка атомпьх, волновые функции электронов существснно отличатотся от волновых фупкций в объсме. Это, в своюо очередь, приводит х появлению в свободной энсргии сверхпроводника дополнитслыьх слагаемьх, локатизованных на расстояииях порядка ξ_0 от границы. Даиный факт можно учесть феноменолюгичсски, ввопя в рассмотрепие поверхностную энсртко

$$\mathcal{F}_{\mathrm{S}} = \oint dS a(\mathbf{n}) |\eta|^2 \tag{13.4}$$

которая зависит от ориентации поверхности кристалла по отношению $\mathbf{k}$ осям кристалличсской решетки. Здесь $a(\mathbf{n}) \sim N_0 \xi_0 f(\mathbf{n})$, причем $f(\mathbf{n})$ есть безразмерная

скалярпая функция паправлений гормали, инвариантиая олносительно всех преобразований симмстрии точечной групты кристалла.

Граничныс условия для параметра порядка могут быть получены путем варьирования по η^* полной свободной энергии сверхпроводника

$$\mathcal{F} = \mathcal{F}_\mathrm{V} + \mathcal{F}_\mathrm{S} \tag{13.5}$$

состоящей из общчной обемной части (12.2) и поверхностнои эчергии (13.4). Условие исчезновения вариации на поверхности принимает вид

$$in_i K_{ij} D_j \eta|_\mathrm{S} = a(\mathbf{n})\eta\|_S \tag{13.6}$$

Таким образом, в залаче поямляется новый характерный масштаб - интерполяционная длина, которая зависит от направления нормат:

$$b_i(\mathbf{n}) \sim \frac{K_n}{u(\mathbf{n})} \tag{13.7}$$

Эффективное граничное условие дия параметра порядка вбтизи критической температуры может быть получено путем сравнения $b(\mathbf{n})$ с коррсляционной длиной $\xi(\mathbf{n})$(12.8).

Пусть направление нормали таково, что поверхностный инвариант $f(\mathrm{n})$ и, следовательыно, функция $a(\mathbf{n})$ равны нуло. Тогда из (13.6) мы получаем граничное условие (13.3). Итерполяционная дхина в этом случае обрацается в бесконечность.

Если же лля данного направлсния нормали $f(\mathbf{n}) \neq 0$, то интерполяиионная дпина $b(\mathbf{n})$ конегна и нс зависит от температуры. Следовательно, при $T \to T_c$ выполняется неравснство $b(\mathbf{n}) \ll \xi(\mathbf{n})$, которое, в свого очереш, означает,
что эффективное граничное условие для параметра порядка имеет следуюшбдй вид:

$$\eta l_\mathrm{s} = 0 \tag{13.8}$$

Вывод о том, что при $f(\mathbf{n}) \neq 0$ граничное условие (13.3) должно быть заменено на (13.8), может быть получен также с помошъю простых энергетических соображений. Проигрыш в энергии сверхпроводника вблизи поверхности определяется суммой градиентного (13.1) и поверхіостного (13.4) вкладов. Относителыіый величину этих слагаемых при $T \to T_c$ можно оценить, учитывая, что харахтериьм масшттабом простраплственного изменения параметра порядка является корреляционная длина $\xi(T) \sim \xi_0 (1 - T/T_c)^{-1/2}$, а его значение в объеме кристалла есть $|\eta_0| \propto (1 - T/T_\mathrm{c})^{1/2}$. Тогда из (13.1) имеем

$$\mathcal{F}_\mathrm{S,grad} \propto \left(1 - \frac{T}{T_\mathrm{c}}\right)^{3/2} \tag{13.9}$$

Если $f(\mathbf{n}) \neq 0$, и параметр порядка на позсрхности отличен от нуля, то из (13.4) иммеем

$$\mathcal{F}_\mathrm{S} \propto \left(1 - \frac{T}{T_\mathrm{c}}\right) \tag{13.10}$$

Сравнивая (13.9) и (13.10), мы видим, что вблизи критической температуры $\mathcal{F}_\mathrm{S}$ превосхолит $\mathcal{F}_\mathrm{S,grad}$. Этот существенный проигрыш в поверхностной энергии исчезает лишь при полном подавлении сверхпроводимости на поверхиости, тто приводит к граничному условию (13.8). Если $f(\mathbf{n}) = 0$, то проигрыпа в энергии (13.4) нет, и имеет место граничное условие (13.3).

Очевидно, что на границе сверхпроводника с нормальным металлом условия отражения и прохождения квазичастиц изменяют их волновые функции в поверхностном

слое, то есть $f(\mathbf{n}) \neq 0$ при любом направлении $\mathbf{n}$. Следовательно, в этом случае при $T \to T_c$ всегда имеют место граничныс условия (13.6). Для границы сверхпроводника с диэлектриком или вакуумом следует различать случаи зеркальiого и диффузного отражения квазичастиц от границы. Рассмотрим сначала зеркальное отражение.

В этом случае также $\int(\mathrm{n}) \neq 0$ пля всех ориентаций нормали по отношению к кристашографическим осям, кроме тех, для которых электронный спектр $\varepsilon(\mathbf{k})$ и функции $g(\mathbf{k})$ (или $\mathbf{d}(\mathbf{k})$), описывающие сверхпроводящие состояния и прсобразующиеся согласпо одному из одiомерных неприводимых представлегий группы симметрии кристалла, не меняготся при отражении в плоскости границы:

$$\varepsilon(\mathbf{k} - 2\mathbf{n}(\mathbf{kn})) = \varepsilon(\mathbf{k})$$
$$g(\mathbf{k} - 2\mathbf{n}(\mathbf{kn})) = g(\mathbf{k}), \quad \mathbf{d}(\mathbf{k} - 2\mathbf{n}(\mathbf{kn})) = \mathrm{d}(\mathbf{k}) \tag{13.11}$$

В самом деле, при выпоолнении этих условий траектории квазичастиш, отраженных от границы, представляюот собои зеркальное отражение в плоскости границы траекторий падаюощих на нее частиц, продолхенных в полупространство, занятое диэлектриком (подробнее об этом см. ниже 20). Поэтому задача становится эквиватентшой задаче о нахождснии параметра порядка в сверхпроводнике, заполняющем все пространство, и подавления сверхпроводимости на границе не происходит, то есть имеют место граничные условия (13.3).

Та 6 лица 7. Угловые зависимости парамстра порядка и поверхностной энергии для однокомпоненттых параметров порддка в тетрагональном кристаллс ($S = 0, G = D_{4h}$)

Γ	$g(\mathrm{k})$	$f(\mathrm{n})$
A_{1g}	$\left(k_x^4 + k_y^4\right)$	$an_x^2\left(n_x^2 + n_y^2\right) + bn_x^2 n_y^2\left(n_x^2 - n_y^2\right)^2$
A_{2g}	$k_x k_y\left(k_x^2 - k_y^2\right)$	$\left(n_x^2 + n_y^2\right)$
B_{1g}	$k_x^2 - k_y^2$	$an_z^2\left(n_x^2 + n_y^2\right) + bn_x^2 n_y^2$
B_{2g}	$k_x k_y$	$an_x^2\left(n_x^2 + n_y^2\right) + b\left(n_x^2 - n_y^2\right)^2$

Итак, нуля функции $f(\mathbf{n})$ для данного сверхпроводящего состояния должны соответствовать оринстациям плоскости границы, совпадающим с общими плоскостями симметрии ферми-поверхности и параметра порядка сверхпроводника. Для сферической ферми-поверхности и полностью изотропного сверхпроводяшего состояния (s-спаривание) $f(\mathbf{n})$ тождественно обрашается в нуль для всех ориентаций n. Поэтому общепринято, что в этом случае на транице сверхпроводник-диэлектрик выполнены грагничне условия (13.3).

Для обычной сверхпроводимости, соответствующей единичному представленик $A_{1\ \mathrm{g}}$ в анизотропном кристалле, симметрия параметра порядка совпадает с симметрией ферми-поверхности и включает в себя все преобразования точечной группы кристалла. Функции $f(\mathbf{n})$, обращающиеся в нуль для всех зеркально-симметричных направлений, в кристаллах с кубической, тетрагональнои и гексагональнод симметрией, соответственно, имеют вид

$$f_{A_{1\mathrm{g}}}^{\mathrm{cub}}(\mathbf{n}) = a\left[n_x^2 n_y^2\left(n_x^2 - n_y^2\right)^2 + n_x^2 n_z^2\left(n_x^2 - n_z^2\right)^2 + n_y^2 n_z^2\left(n_y^2 - n_z^2\right)^2\right] \tag{13.12}$$

$$f_{A_{1\mathrm{g}}}^{\mathrm{terr}}(\mathbf{n}) = an_z^2\left(n_x^2 + n_y^2\right)^2 + bn_x^2 n_y^2\left(n_x^2 - n_y^2\right)^2 \tag{13.13}$$

$$f_{A_{1\mathrm{g}}}^{\mathrm{hex}}(\mathbf{n}) = an_z^2\left(n_x^2 + n_y^2\right) + b\left(n_x^3 - 3n_x n_y^2\right)^2\left(n_y^3 - 3n_y n_x^2\right)^2 \tag{13.14}$$

Здесь a и b - числа, определяiошие меру анизотропити, то есть отличие формы ферми-поверхности и щели в спектре от сфсрической или цилиндрической.

Граничныс условия (13.3) имект место в узкой области направлений нормали с шириной $\sim \sqrt{\xi_0/\xi(T)}$[1], для которьх функции $f(\mathrm{n})$ обрашаются в нуль. Для всех остальных ориентаций поверхности сверхпроводникдиэлектрик граиичные условия имеют вид (13.6).

Если мы имеем дело с необычным сверхпроводяшим состоянием, параметр порядка которого преобразуется согласно неединичному представлению, то число ориентаций поверхности, для которых выполняется условие $f(\mathbf{n}) = 0$, может только уменьшиться по сравнению с обычным сверхпроводящим состоянием. В табл. 7 приведены соответствующие функции для однохомпонентных сверхпроводящих состояний с синглетным спариванием в тетрагоналыном кристалле, популярных в настоящее время в связи с исследованиями высокотемпературной сверхпроводимости.

Мы видим, что лля представления $A_{1\ \mathrm{g}}$ поверхностная энергия обрашаехся в нуль для восьми направлений $\mathbf{n}$ в базисной плоскости, а также при $\mathbf{n}\|\hat{z}$. Для представлеиий $B_{1\ \mathrm{g}}$ и $B_{2\ \mathrm{g}}$ из этих нулеи остается лишш по четыре нуля в Базисной плоскости и олин нуль при $\mathbf{n}\|\hat{z}$. Вертикальные плоскости зеркальной симметрии лтя представлений $A_{1\ \mathrm{g}}$ (ферми-поверхность) и $A_{2\ \mathrm{g}}$ (сверхпроводящее состоянис) не совпадаюот, поэтому если параметр порядка прсобразуется согласно $A_{2\ \mathrm{g}}$, то у функции $f_{A_{2g}}(\mathbf{n})$ остается лишь один нуль при $\mathbf{n}\|\hat{z}$, то есть вдоль направления, перпендикулярного обшей горизоптальной плоскости симметрии функцший $\varepsilon(\mathbf{k})$ и $g_{A_{28}}(\mathbf{k})$.

Для пространствешн-нечетных однокомпонентных сверхпроводяших состояний в тетрагональном кристалле ($S = 1$, сильное спин-орбитапьное взаимодействие, см. табл. 3) нет симметрииных причин, по которым функция $f(\mathbf{n})$ должа обратиться в нуль, и поэтому поверхностная энергия прсдставяят собой произвольную комбинацию всех скалярныхх инвариантов тетрагональной группы.

Мы не будем здесь находить функции $f(\mathbf{n})$ для нетривиальных сверхпроводящих состояний в гексагочапных и кубитеских кристаллах, предоставив это читателю (см. упражнение в конце параграфа).

Поверхностная сверхпроводимость. Найденные выие граничные условия (13.3) и (13.6) для параметра порядка позволяют вычислить критическое поле поверхностной сверхпроводимости в области применимости теории Гинзбурга-Ландау.

Рассмотрим тетрагональный сверхпроводних, занимающий полупространство $x > 0$ так, что тетрагональная ось лежит в плоскости границы, а нормашь к границе расположена в базисной плоскости кристалла. Выберем направление магнитного поля вдоль тетрагональной оси:

$$\mathbf{H} = H(0, 0, 1)$$
$$\mathbf{A} = (0, Hx, 0)$$

Подставляя в уравнение Гинзбурга-Ландау (12.9) параметр порядка в виде $\eta(x, y) = f(x)\exp(-ipy)$, получаем:

$$-K_1\frac{d^2f}{dx^2} + K_1\left(\frac{2\pi H}{\Phi_0}\right)^2\left(x - p\frac{\Phi_0}{2\pi H}\right)^2 f + \alpha_0\left(\frac{T - T_\mathrm{c}}{T_\mathrm{c}}\right)f = 0 \qquad (13.15)$$

Решение этого уравнения и величина поверхiостного критического поля определяются граничными условиями.

Для тех ориентаций поверхности, дтя которьх выпольется условие (13.8), ro ecTb

$$\eta(x = 0) = 0$$

[1] Эта оценка получается путем сравнеиня поверхностной градиегтьой энергии (13.1) и поверхностной экергии (13.4) вблизи наиравления, для которого $f(n)$ обраигается в нуль.

сверхпроводящий зародыш образуется вдати от поверхности ($p\xi(T) \gg 1$). Соответствующее решение уравнения (13.15) имеет вид

$$f(x) \propto \exp\left[-\frac{\pi H}{\Phi_0}\left(x - p\frac{\Phi_0}{2\pi H}\right)^2\right]$$

а поле, в котором зарождается сверхпроводящее состояние, совпадает с объемным верхним критичсским полем:

$$H_{c3}(T) = H_{c2}(T) = \frac{\Phi_0\alpha_0}{2\pi K_1}\frac{T_c - T}{T_c} \tag{13.17}$$

Если же поверхность ориентирована так, что выполняется граничное условие (13.3), то есть

$$\left.\frac{\partial\eta}{\partial x}\right|_{x=0} = 0 \tag{13.18}$$

то уравнение (13.15) имеет решение, локализованное вБлизи гранишы:

$$f(x) \propto F_\nu(x) \tag{13.19}$$

$$F_\nu(x) = \exp\left[-\frac{\pi H}{\Phi_0}\left(x - p\frac{\Phi_0}{2\pi H}\right)^2\right] H_\nu\left[\sqrt{\frac{2\pi H}{\Phi_0}}\left(x - p\frac{\Phi_0}{2\pi H}\right)\right]$$

где $H_\nu(x)$ - функция Эрмита (функция параболического цитиндра) с индексom

$$\nu(\lambda) = -\frac{1}{2} + \frac{\lambda}{2} \tag{13.20}$$

Здесь введена безразмерная величина

$$\lambda = \frac{\Phi_0\alpha_0}{2\pi K_1 H}\frac{T_c - T}{T_c}$$

Подстановка (13.19) в граничное условие (13.18) приводит к трансцендентному уравнениio

$$2\nu H_{\nu-1}(-r) = -rH_\nu(-r) \tag{13.21}$$

где

$$r = p\sqrt{\frac{\Phi_0}{2\pi H}}$$

которое позволяет найти зависимость $\lambda(r)$. При этом магнитно поле, в котором зарождается свсрхпроводящая фаза вблизи поверхности образца, соответствует минимальному значению функции $\lambda(r)$. Численнос решение уравнения (13.21) дает [78]: $\lambda_{\min} = 0,59, r = 0,77$, следовательоо,

$$H_{c3}(T) \approx 1,69H_{c2}(T) \tag{13.22}$$

Для обычного свсрхпровопящего состолния (прсдставленис $A_{1\ g}$) граничное условие (13.18) реатизуется, строго говоря, дхя поверхностей с ориентациями нормати $n = (\cos(\pi k/4), \sin(\pi k/4), 0)$, где $k = 0, 1, \ldots, 7$, или $\mathbf{n} = (0, 0, 1)$. Для поверхностей, нормапь к которым откгоняется от указанных значений на утлы, превышаащие

отношение $\sqrt{\xi_0/\xi(T)}$, граничиое условие (13.18) заменяется на условис (13.16), и поверхностной сверхпроводимости не возникает.

На практике анизотропия обычного сверхпроводящего состояния не очеиь выражена. Дело в том, что как рассеяние на примссях, так и усредняющее деистие диффузиого рассеяния на поверхиости, не подавляя сверхпроводимости, привопят к уменьшению функции $f_{A_{18}}(\mathbf{n})$, поэтому поверхностная сверхпроводимость наблюдается для произволыой ориеитации поверхности.

Не так обстоит дело для свсрхпроводяших состояний, преобразующихся согласно неединичным представлениям. Например, в тетрагоналышхх кристаллах для состояния, соотве тствугощего представлению B_{1g}, которос реализуется, по-видимому, в высокотемпературных свсрхпроводниках, поверхноствая сверхпроводимость в стучас зеркатьно отражающей позерхности имеет
место для следующих ориентаций нормали:

$$\mathbf{n} = \left(\cos\frac{\pi k}{2}, \sin\frac{\pi k}{2}, 0\right), \quad k = 0, 1, 2, 3$$

$$\mathbf{n} = (0, 0, 1)$$

Если поверхность отклоняется от указанных направлений на утлы, превышающие $\sqrt{\xi_0/\xi(T)}$, поверхностной сверхпроводимости нст. В отличие от состояния $A_{1\,\mathrm{g}}$, учет диффузности рассеяния на границе ие восстанавливает поверхностную сверхпроводимость для произвощной ориентации поверхности, а, напротив, вызывает усреднение параметра порядка по направлениям импульса и тем самым подавляет поверхностную сверхпроводимость.

Окончательный вывод таков: опсутствие поверхностной сверхпроводимости на диффузно-отражающих поверхостях может служить характерньм признаком необычных сверхпроводящих состоянии. По наличию же поверхностной сверхпроводимости лишв в узких угловьх окрестностях выделенных направлений $\mathbf{n}$ можно установить симметрию сверхпроводящего состояния.

Граничные условия для многокомлонентных параметров порядка. В этом случае выражение для поверхностной энергии находится точно так же, как это дедалось для получения градиентной энсргии в 12. Например, для сверхпроводящего состояния, преобразующегося согласно двумерному представлению E в тетрагональном кристалле, необходимо составить все возможные квадратичные по компонентам параметра порядка (η_x, η_y) и вектора нормали $\mathbf{n}$, комбинации, инвариантные относителыо всех преобразований группы симметрии нормального состояния $U(1) \times R \times D_{4h}$:

$$\mathcal{F}_{\mathrm{S}} = \oint dS \left[a_1(\mathbf{n})\boldsymbol{\eta}\boldsymbol{\eta}^* + a_2(\mathbf{n})|\eta_x n_x + \eta_y n_y|^2 + \right.$$
$$\left. + a_3(\mathbf{n})\left(|\eta_x n_x|^2 + |\eta_y n_y|^2\right)\right] \qquad (13.23)$$

Здесь $a_i(\mathbf{n}) \sim N_0\xi_0 f_i(\mathbf{n})$ $(i = 1, 2, 3)$ - функции, инвариатные относитежно всех преобразований из D_{4h}. За исключением ориегтаций границы, задаваемых кристаллографическими направлениями, обе компонснты параметра порядка, преобразующщеся как $(k_z k_x, k_z k_y)$, пе обладают определенной четностью при отражении в плоскости гранишы (ср. с (13.11)). Отсюда, так же, как и в однокомпонентном случас, следует обращенис в нуль обеих компонент параметра порядка па поверхности и отсутствие поверхностной сверхпроводимости. Ориентации границы, совпадающие с кристаллографическими направлениями, требуот специального исследования. Мы проделаем его для более простого объекта - двухкомпонентного сверхпровопящего состояния в

гексагональном кристалле, где выражение для поверхностной энергии имеет

вид (13.23) без последнего слагаемого, отсутствие которого означает инвариантность по отношениіо к вращениям на произвольный утол вокруг оси шестого порядка.

Поверхностное критическое поле для векторного лараметра порядка в гексагональном кристалле. Аналогично верхнсму критическому полю в объеме, поверхностное критическое поле для многокомпонентной сверхпроводимости может быть вычислено аналитически лиш в искпючительных случаях. В частности, это можно сделатъ для парамстра порядка, соответствующего
представлению E_1 в гексагональном кристалле, если поле иагравлено вдоль оси шестого порядка, а нормаь лежит в Базисной плоскости [44].

Поверхиостная энергия обладает симметрией шестого порядка относительно вращений вокрут гексагонашной оси. Поэтому, при совпадегии ориентации нормали к поверхности с одним из кристаллографических направлений, можно выбрать систему координат так, чтобы ьь $\dot{x}$ совпала с направлением нормали. Тогда перекрестные члены вида $\eta_1^*\eta_2$ исчезают, и поверхностная энергия принимает вид

$$\mathcal{F}_S = \oint dS \left(b_1 \left|\eta_1\right|^2 + b_2 \left|\eta_2\right|^2 \right) \tag{13.24}$$

Поскольку пара (η_1, η_2) преобразуется как $(k_z k_x, k_z k_y)$, то при отражении в плоскости yz компонснта η_1 меняет, а компонента η_2 сохраняет знак. Поэтому на зеркапно-отражающей границе векторный параметра порядка должен удовлетворять граничным условиям:

$$\eta_1\big|_{x=0} = 0, \quad \left.\frac{\partial \eta_2}{\partial x}\right|_{x=0} = 0 \tag{13.25}$$

Для вычисления поверхіостного критического поля сверхпроводника, заниматощего полупространство $x > 0$, в случае поля, направленного вдоль оси шестого порядка, необходимо решить уравнения Гинзбурга-Ландау (12.30)

$$\begin{cases} \left(\alpha_0 \left(\frac{T-T_c}{T_c}\right) + K_0 \left(D_x^2 + D_y^2\right) - K_- \frac{2\pi H}{\Phi_0}\right) \eta_+ + K_+ D_+^2 \eta_- = 0 \\ K_+ D_-^2 \eta_+ + \left(\alpha_0 \left(\frac{T-T_c}{T_c}\right) + K_0 \left(D_x^2 + D_y^2\right) + K_- \frac{2\pi H}{\Phi_0}\right) \eta_- = 0 \end{cases} \tag{13.26}$$

дополненние граничными условиями (13.25).

При нахождении верхнего критического поля в бесконечном объеме необходимо было наложить на параметр порядка условис убывания при $x \to -\infty$, вследствие чсго решение уравнений выражалось через полиномы Эрмита. Теперь же, при рассмотрении поверхностной задачи, мы не фиксируем поведение решения на $-\infty$ и, соответственно, отказьваемся от требования неотрицательности и целочисленности индекса полиномов Эрмита, которые, таким образом, становятся функциями Эрмита $H_\nu(x)$.

Итак, ищем решение уравнений (13.26) в виде

$$\begin{pmatrix} f_+(x) \\ f_-(x) \end{pmatrix} \sim \begin{pmatrix} qF_{\nu+2}(x) \\ F_\nu(x) \end{pmatrix}$$

где $F_\nu(x)$ даются формулой (13.19), а индекс ν должен удовлетворять уравнению

$$\alpha_0 \frac{T - T_c}{T_\mathrm{c}} = \left(-(2\nu+3)K_0 + + \sqrt{\left(2K_0 - K_-\right)^2 + 4(\nu+1)(\nu+2)K_+^2} \right) \frac{2\pi H}{\Phi_0} \tag{13.27}$$

При этом параметр q равен

$$q(\nu) = \frac{-(2K_0 - K_-) + \sqrt{(2K_0 - K_-)^2 + 4(\nu+1)(\nu+2)K_+^2}}{4(\nu+1)(\nu+2)K_+}$$

В отличие от однокомпонеитного случая (см. (13.20)), выражение (13.27) нс позволяет однозначно найти ν как функцию безразмерного параметра

$$\lambda = \frac{\Phi_0 \alpha_0}{2\pi/K_1 H} \frac{T_c - T}{T_c}$$

Будучи квадратпым по ν, это уравнение при заданном λ может иметь два корня:

$$\nu_{1,2}(\lambda) = -\frac{3}{2} + \frac{\lambda K_0 K_1 \pm \sqrt{D}}{2\left(K_0^2 - K_+^2\right)} \tag{13.28}$$

где

$$D = 4K_0^4 + K_+^4 - 5K_0^2 K_+^2 - K_-\left(K_0^2 - K_+^2\right)(4K_0 - K_-) + \lambda^2 K_+^2 K_1^2$$

Соответствующие значения $q_{1,2}$ есть

$$q_{1,2}(\lambda) = \frac{K + \left(K_0^2 - K_+^2\right)}{(2K_0 - K_-)\left(K_0^2 - K_+^2\right) + \lambda K_1 K_+^2 \pm \sqrt{D} K_0} \tag{13.29}$$

Ниже мы будем считать, что дискриминант положителен, а $\nu_{1,2}$ и $q_{1,2}$ вещественны [2].

Собственное значение уравнений (13.26) оказывается двукратно вырожденным, поэтому их общее решение записывается в виде

$$\begin{pmatrix} f_+(x) \\ f_-(x) \end{pmatrix} \propto \begin{pmatrix} q_1 F_{\nu_1+2}(x) \\ F_{\nu_1}(x) \end{pmatrix} + s \begin{pmatrix} q_2 F_{\nu_2+2}(x) \\ F_{\nu_2}(x) \end{pmatrix} \tag{13.30}$$

где s - свободный парамстр, который без потсри общности мы выбираем всщественным. Подстановка в граничные условия (13.25) даст нам систему двух трансцендситиьх уравнений для определения $\lambda(r, s)$ (ср. с (13.21)). Исклгочая из них s, получаем одшо уравнение на $\lambda(r)$:

$$\frac{A_1(\lambda, r)}{B_1(\lambda, r)} = \frac{A_2(\lambda, r)}{B_2(\lambda, r)} \tag{13.31}$$

где

$$\begin{gathered} A_i(\lambda, r) = rH_{\nu_1}(-r) + 2\nu_i H_{\nu_1 - 1}(-r) - \\ -rq_i H_{\nu_1+2}(-r) - 2q_i\left(\nu_i + 2\right) H_{\nu_1+1}(-r) \\ B_i(\lambda.r) = H_{\nu_1}(-r) + q_i H_{\nu_1+2}(-r) \end{gathered}$$

Здесь $\nu_{1,2}$ и $q_{1,2}$ являтотся функциями λ (см. (13.28) и (13.29)). Минимизация решения по r в принципе решает поставленную задату, то сеть позволяет найти температурную зависимость критического поля поверхностной сверхпроводимости $H_{c3}(T)$.

Важным свойством (13.31) является то, что это уравиение не содержит явно зависимости от H, и, следовательно, зависимость $H_{\text{сз}}(T)$, отвечающая $\lambda_{\min}$ - минимапьному по r решению - линейна, однако аналитически найти коэффициент не представляется возможным. Численный расчет для $K_1 = K_2 = K_3$ дает следующий результат: $\lambda_{\min} \approx 0,89, r \approx 0,55$, то есть

[12] Отказ от этого требовалия не вносит никаких принциниальных затрупнений, поскольку функции Эрмита попускают аитлитическос продолжение иа комплекстые значения инлскса. Заметим, что ссли $K_1 = K_2 = K_3$ (теория стабой связи, см. ннже 18), то $D > 0$.

$$H_{c3}(T) \approx 1,24 I_{c2}(T) \tag{13.32}$$

Здесь для всрхнего критичсского поля в объеме использовано выражение (12.39).

Отметим, что в предположении цилиндрической симметрии фермиповерхности поверхностнос критичсское поле одинаково для любых ориенташий поверхности, паралтелыных гексагональной оси. Полученный результат справедлив и для сверхпроводящих фаз с p-спариванием. В обшем случас, так же, как и для однокомпонентных сверхпроволящих состояний, поверхностная сверхпроводимость исчезает при отклонении пормали к поверхiости от кристаллографических направлений на весьма малые углы.

Упражнеиие. Персчислить поверхностныс инварианты $f(\mathbf{n})$ дя всех однокомпонентных сверхпроводящих состояний в гсксагональном и кубическом кристаллах.

19.1.14 14. Meissner and Mixed States in Unconventional Superconductors

Большая часть анизотропных сверхпроводников (высокотемпературные и органические сверхпроводники, сверхпроводящие соединения с тяжелыми фермионами) относится к ярко выраженным сверхпроводникам второго рода. Электродинамика таких сверхпроводников является лондоновской, то есть между плотностью тока и вектор-потенциалом имеется локальная связь во всем температурном интсрвалс вглоть до $T = 0$. В настоящем параграфе мы изучим ряд свойств необычных сверхпроводников, которые можно рассмотреть в рамках лондоновской элсктродинамики. Помимо обычных проявлений анизотропии здесь, как и в термодинамикс, имеются спешифические эффекты, связанные с наличием гулей в спектре элемегтарных возбужденик.

Эффект Мейсснера. Сравнсние уравиения

$$\frac{\delta \mathcal{G}}{\delta \mathbf{A}} = 0$$

(см. 12) с уравнением Максвелла

$$\mathrm{rot}\, B = \frac{4\pi j}{c} \tag{14.1}$$

позволяет найти выражение для плотности тока j. Так, для однокомпонситного сверхпроводящего состояния, гдс плотносгь свободной энергии имеет вид (12.2), плотность тока опрелелястся выражением

$$j_i = -2e\mathrm{Re}_{\,ij} \left[\eta^* \left(D_j \eta\right) + \eta \left(D_j \eta\right)^*\right] \tag{14.2}$$

Для двухкомпонентного сверхпроводящего состояния в гексагонашном кристалле (представление E_1) из (12.15) имесм:

$$j_i = -\frac{2e}{\hbar} \left\{ K_1 \eta_j^* D_i \eta_j + K_2 \eta_i^* D_j \eta_j + K_3 \eta_j^* D_j \eta_i + \text{ к.с. } \right\}, \quad i = x, y \tag{14.3}$$

$$j_z = -\frac{2e}{h} K_4 \left(\eta_i^* D_z \eta_i + \text{ к.с. } \right) \tag{14.4}$$

Подставляя в (14.2) параметр порядка $\eta(\mathbf{r}) = |\eta(\mathbf{r})| e^{i\varphi(\mathbf{r})} = \Delta(\mathbf{r}) e^{i\varphi(\mathbf{r})}$, получаем:

$$j_i = -e n_{ij}^{\mathbf{s}} w_j \tag{14.5}$$

где введены скорость конденсата купсровских пар (сверхгекучая скорость):

$$\mathbf{w} = \frac{\hbar}{2m}\left(\nabla\varphi + \frac{2e}{\hbar c}\mathbf{A}\right) \tag{14.6}$$

)m - масса электрона), и тензор плотности сверхпроводящих электронов (сверхтекучей плотности):

$$n_{ij}^{\mathrm{s}} = \frac{8m}{\hbar^2}\Delta^2 K_{ij} \tag{14.7}$$

Для двухкомпонентной сверхпроводимости с «вещественным» параметром порядка вида (11.7):

$$\boldsymbol{\eta} \sim (\cos\lambda_n, \sin\lambda_n)\, e^{i\varphi(r)}$$

характеризуемым общей фазой φ обеих компонент, плотность тока также можно записать в виде (14.5), причем тензор сверхтекучей плотности n_{ij}^{s} здесь выражастся через коэффиииенты K_1, K_2, K_3, K_4. В магнитных сверхпроводниках с комплексным параметром порядка (11.9) ситуация несколько сложнее, и мы рассмотрим ее в следующем параграфе.

Итак, в немагнитных сверхпроводниках с произвольным числом компонент параметра порядка связь тока с градиентом фазы и вектор-потенциалом в слабых полях имеет вид (14.5). Следует также подчеркнуть, что в немагнитных сверхпроводниках второго рода линейная связь (14.5) имеет место при любьхх температурах. Температурная зависимость тензора $n_{ij}^s(T)$ будет найдена ниже.

Плотность тока, также, как и плотность свободной энергии, инвариантна относителыо калибровочных преобразований:

$$\begin{aligned} \mathbf{A} &\to \mathbf{A} + \boldsymbol{\nabla}\chi \\ \varphi &\to \varphi - \frac{2e}{hc}\chi \end{aligned} \tag{14.8}$$

что позволяет записать (14.5) в виде

$$j_i = -\frac{e^2}{mc} n_{ij}^{\mathrm{s}} A_j \tag{14.9}$$

После подстановки (14.9) в (14.1) получаем уравнение для вектора B (уравнение Лондонов):

$$\frac{mc^2}{4\pi e^2}\,\mathrm{rot}\left((\leftrightarrow^s)^{-1}\,\mathrm{rot}\,\mathrm{B}\right) + \mathrm{B} = 0 \tag{14.10}$$

Для любьх сверхпроводяших состояний в одноосиLx кристаллах (гексагональном и тетрагональном), а также в случае многокомпонентных сверхпроводящих состояний в кубических кристаллах, тензор n_{ij}^{s} имеет одноосую анизотропию и его можно записать в виде

$$n_{ij}^s = n_0\delta_{ij} + n'\nu_i\nu_j \tag{14.11}$$

где ν - ось анизотропии. Подставляя (14.11) в уравиение (14.10), получаем:

$$\delta_0^2[\mathrm{rot}\,\mathrm{rot}\,\mathbf{B} + \lambda\,\mathrm{rot}(\nu(\nu\,\mathrm{rot}\,\mathbf{B}))] + \mathbf{B} = 0 \tag{14.12}$$

гДе

$$\delta_0 = \left(\frac{mc^2}{4\pi n_0 e^2} \right)^{1/2} \tag{14.13}$$

а $\lambda = -n'/(n_0 + n')$.

Пусть ось анизотропии $\nu = \hat{z}$ и внешшее поле $\mathbf{H} = (0, H_y, H_z)$ лежат в плоскости поверхности сверхпроводника, занимаюощего полупространство $x > 0$. Легко убедиться, что решение уравнения (14.12) имеет вид

$$B_y = H_y \exp\left(-\frac{x}{\delta_0 \sqrt{1+\lambda}} \right) \tag{14.14}$$

$$B_z = H_z \exp\left(-\frac{x}{\delta_0} \right) \tag{14.15}$$

то есть магнитнос поле затухает вглубь образца (эффект Мейсснера), при этом поворачиваясь, вследствие анизотропии, вокруг направления $\hat{x}$ [45]. Глубша проникновения поля $\delta(T)$, различная вдоль разнцх направлений, называется лондоновской глубиной проникновения и определяется тензором плотности сверхпроводящих элекгронов $n^{\mathrm{s}}_{ij}(T)$. Ее типичные значения при $T = 0$ порядка $10^{-5} - 10^{-6}$ cm.

Плотность сверхпроводдших электронов. Температурную зависимость тензора n^{s}_{ij} можно найти из следуюощих соображсний. Легко проверить, что формула (5.29) для энергии элементарнвх возбуждений сверххроводника при учете различия направлений $\mathbf{k}$ и $-\mathbf{k}$ прицимает вид

$$E_k = \frac{\xi_k - \xi_{-k}}{2} + \sqrt{\left(\frac{\xi_k + \xi_{-k}}{2} \right)^2 + \Delta_k^2} \tag{14.16}$$

В магиитном поле, достаточно медленно меняющемся в пространстве [1], импульсы эдементарных возбужденин приобретагот одинаковую добавку $m\mathbf{w}$ за счет ненупевои скорости движения сверхтекучей компоненты. С помощью (14.16) получаем:

$$E_{\mathbf{k}} \to E_{\mathbf{k}+m\mathbf{w}} \approx E_{\mathbf{k}} + m\mathbf{v}_F(\mathbf{k})\mathbf{w} \tag{14.17}$$

где $\mathbf{v}_{\mathrm{F}}(\mathbf{k}) = \partial\xi_{\mathrm{k}}/\partial\mathbf{k}$. Пдотность потока возбуждений есть

$$\mathbf{P} = \sum_{\mathbf{k}\alpha} \mathbf{v}_{\mathrm{F}}(\mathbf{k}) f\left(E_{\mathbf{k}} + m\mathbf{v}_{\mathbf{F}}(\mathbf{k})\mathbf{w} \right) \tag{14.18}$$

где $f(E)$ - фермиевская функция распределения. Введсм тензор плотности возбуждеий, как величину, определяющую отклик $\mathbf{P}$ на измснение скоросTY: $\mathbf{w}$:

$$\delta P_i = -n^{\mathrm{n}}_{ij} \delta w_j \tag{14.19}$$

Из (14.18) получаем:

$$n^{\mathrm{n}}_{ij} = -m \sum_{\mathbf{k}\alpha} v_{\mathrm{F},i}(\mathbf{k}) v_{\mathrm{F},j}(\mathbf{k}) \frac{\partial f\left(E_{\mathbf{k}} + m\mathbf{v}_F(\mathbf{k})\mathbf{w} \right)}{\partial E} \tag{14.20}$$

Разность тензоров n^{n}_{ij} в нормальном (то есть при $\Delta = 0$) и сверхпроводящем состояниях дает величину тензора плотности сверхпроводяших электроНОВ

[11] Более точно, в лононовском пределе, когда глубина проникновения превышает длину котерентности, что всегда имеет место в сверхпроводниках второго рода.

$$n_{ij}^{\mathbf{s}} = n_{ij}^{\mathrm{n}}(\Delta = 0) - n_{ij}^{\mathrm{n}} \tag{14.21}$$

Опуская эависимость n_{ij}^{n} от магнитного поля (мы вернемся к этому вопросу нише), получаем

$$n_{ij}^{\mathrm{s}}(T) = 2m \int \frac{dS_{\mathrm{F}}}{(2\pi\hbar)^3} \frac{v_{\mathrm{F},i}(\mathbf{k}) v_{\mathrm{F},3}(\mathbf{k})}{|\mathbf{v}_{\mathrm{F}}(\mathbf{k})|} [1 - Y(\hat{\mathbf{k}}, T)] \tag{14.22}$$

где $Y(\hat{\mathbf{k}}, T)$ - функция Иосида (9.4), а интегрирование происходит по ферми-повсрхности. Формула (14.22) определяет тензор $n_{i,}^{\mathrm{s}}$ для фермиповерхности произвольной формы и произволыгого типа спаривания. В области Гинзбурга-Ландау аналогичное выражение для обычной анизотропной сверхпроводимости впервые получепо в работе [46]. При $T = 0$

$$n_{ij}^{\mathbf{s}}(0) = 2m \int \frac{dS_{\mathbf{F}}}{(2\pi\hbar)^3} \frac{v_{\mathbb{F},i}(\mathbf{k}) v_{\mathbf{F},j}(\mathbf{k})}{|\mathbf{v}_{\mathbf{F}}(\mathbf{k})|} \tag{14.23}$$

При наличии нумей в спектре элементарных возбуждений изменение компонент тензора плотности сверхпроводящих электронов (или лондоновской глубины проникновения) с температурой при $T \to 0$ происходит по степенным законам, аналогично поведению теплоемкости, парамагнитной восприпмчивости и т.д. Так, для A-фазы, где $\Delta_{\mathrm{k}}^2 = \Delta^2 \sin^2\theta$, вычисления, подобные приведенным в 7, дают [47]:

$$[n_{zz}^{\mathrm{s}}(0) - n_{zz}^{\mathrm{s}}(T)]|_{T\to 0} \sim n \left(\frac{T}{T_c}\right)^2 \tag{14.24}$$

$$[n_{xx}^{\mathrm{s}}(0) - n_{xx}^{\mathrm{s}}(T)]|_{T\to 0} \sim n \left(\frac{T}{T_c}\right)^4 \tag{14.25}$$

где n - полная плотность частиц. Аналогично, для полярной фазы ($\Delta_{\mathbf{k}}^2 = \Delta^2 \cos^2\theta$) :

$$[n_{zz}^{\mathrm{s}}(0) - n_{zz}^{\mathrm{s}}(T)]|_{T\to 0} \sim n \left(\frac{T}{T_{\mathrm{c}}}\right)^{\mathbf{3}} \tag{14.26}$$

$$[n_{xx}^{\mathrm{s}}(0) - n_{xx}^{\mathbf{s}}(T)]|_{T\to 0} \sim n\frac{T}{T_c} \tag{14.27}$$

Нструдно установить закопы низкотемпературного поведения и для фаз с другим расположением нулей.

Вблизи критической температуры

$$n_{ij}^{\mathrm{s}}\left(T \to T_{\mathrm{c}}\right) = \frac{7\zeta(3)m}{2\pi^2} \left(\frac{\Delta(T)}{T_{\mathrm{c}}}\right)^2 \int \frac{dS_{\mathrm{F}}}{(2\pi\hbar)^3} \frac{v_{\mathrm{F},i}(\mathbf{k}) v_{\mathrm{F},j}(\mathbf{k})}{|\mathbf{v}_{\mathrm{F}}(\mathbf{k})|} |g(\mathbf{k})|^2 \tag{14.28}$$

Это выражение соответствует случаю синглетного спаривания, для триплетного спаривания надо произвести очевидную замену $|g(\mathbf{k})|^2 \to |\mathrm{d}(\mathbf{k})|^2$. Функция $\Delta(T)$ задана формулой (6.18). Для полностью изотроппого сверхпроводящего состояния из (14.23) и (14.28) получается известное соотношение [48]

$$n^{\mathrm{s}}\left(T \to T_{\mathrm{c}}\right) = 2n^{\mathrm{s}}(0) \left(1 - \frac{T}{T_{\mathrm{c}}}\right) \tag{14.29}$$

Обратим внимание на то, что согласно (14.7) матрица коэффициентов K_{ij}, определяощая пространственные масшштабы изменения параметра порядка (уравнение

(12.6)) и поля (уравпепие (14.10)) пе зависит от массы электрона m, но зависит (чсрез $\mathbf{v}_F(\mathbf{k})$) от той эффективной массы, которуо электрон приобретает в кристалле.

Заметим также, что мы здесь не принимали во внимание псрснормировку массы за счет ферми-жидкостного взаимодействия электрона с молекулярным полем, создаваемьмм током остальных электронов. Это можно сделать вклюочая в скорость w молекулярное поле:

$$w_i \to w_i - mF_{1,ij}P_j$$

и разрешая уравнения (14.18), (14.19) относителыо $\delta\mathbf{P}$. Здесь $F_{1,ij}$ - тензор плотности ферми-жидкостного взаимодействия в кристалле, являющийся обобщснисм всличины $F_1/\left(N_0k_F^2\right)$ в изотропной фсрми-жидкости. Учет ферми-жидкостных эффектов, вообще говоря, изменяет температурную зависимость n_{ij}^{s} даже в изсропном случас [49, 50]. Мы не будем в дальнейшем прииимать во віимание ферми-жидкостіые эффекты, предполагая, тто основная перенормировка массы электрона происходит за счет его взаимодействия с кристаллической решеткой.

Нелипейпый эффект Мейсснера [51]. Кроме степенного убывания лондоновской глубины проникновения $\delta(T)$ при $T \to 0$, наличие нулей в спектре возбуждений приводит к специфическому для каждой сверхпроводящей фазы и геометрии задачи увеличениио $\delta(0)$ с ростом магиитного поля. Для рассмотрения этого эффскта веріемся к формуле (14.20). При $T = 0$ входяшая в эту формулу производная фермисвской функции распредсления обращается в нулг для всех ненулевьхх знатений своего аргументта:

$$n_{ij}^{\mathrm{n}}(0) = m\sum_{\mathbf{k}a} v_{\mathrm{F},i}(\mathbf{k})v_{\mathrm{F},j}(\mathbf{k})\delta\left(E_{\mathbf{k}} + m\mathbf{v}_{\mathrm{F}}(\mathbf{k})\mathbf{w}\right) \tag{14.30}$$

Отсюда видно, что при $T = 0$ в сверхпроводниках с конечной величиной щели на всей ферми-поверхности тснзор нормальной плотности равсн нулю для скоростей $\mathbf{w}$, не превышающих критическуо скор $\propto$ ль Ландау $w_c \approx \Delta/mv_{\mathrm{F}}$.

Если щель обращается в нуль на некотором множестве точек на фермиповерхности, то конечная плотность возбуждений сохраняется и при $T = 0$. Для сверхпроводника со сферической ферми-поверхностью можяо переписать (14.30) следующим образом:

$$n_{ij}^{\mathrm{n}} = 3n\int\frac{d\Omega}{4\pi}\hat{k}_i\hat{k}_j\int\frac{dEE}{\sqrt{E^2-\triangle_{\mathrm{k}}^2}}\delta(E+\mathbf{kw}) = \\ = 3n\int\frac{d\Omega}{4\pi}\hat{k}_i\hat{k}_j\frac{|\mathbf{kw}|}{\sqrt{(\mathbf{kw})^2-\triangle_k^2}} \tag{14.31}$$

тде n - полная плотность электронов, а интегрирование шо утлам производится в пределах, задаваемьх условием $(\mathbf{kw})^2 > \Delta_{\mathbf{k}}^2$.

Пусть щель обращается в нулы на экваторе ферми-сферы, как это имеет место в полярной фазе ($\Delta_{\mathbf{k}}^2 = \Delta\cos^2\theta$), а сверхтекучая скорость $\mathbf{w} = [e/(mc)]\mathbf{A}$ направлена вдоль оси y (сверхпроводник занимает полупространство $z > 0$, внешнее поле направлено вдоль оси x, в выбранной калибровке фаза кон-
денсата постоянна). Тогда из (14.31) мы получаем, что при $T = 0$ имеется ненулевая плотность нормальной компоненты:

$$n_{yy}^{\mathrm{n}} \approx \frac{3nk_F\,|w_y|}{\Delta}\int\limits_0^{2\pi}\frac{d\varphi}{2\pi}\sin^2\varphi|\sin\varphi| = n\frac{4ek_F}{\pi mc\Delta}\,|A_y| \tag{14.32}$$

Следовательно,

$$n_{yy}^{\mathrm{s}} = n\left(1 - \frac{4ck_{\mathrm{F}}}{\pi mc\Delta}\,|A_y|\right) \tag{14.33}$$

Уравнение Максвелла (14.1), с учетом выражений для тока (14.9) и плотности сверхтекучей компоненты (14.33), принимает вид

$$\frac{\partial^2 A_y}{\partial z^2} = \frac{1}{\delta^2} A_y \tag{14.34}$$

где

$$\frac{1}{\delta^2} = \frac{mc^2}{4\pi nc^2}\left(1 - \frac{4ek_F}{\pi mc\Delta}\,|A_y|\right) \tag{14.35}$$

Таким образом, благодаря тому, что щель в спектре возбуждений обращается в нуль на экваторе ферми-сферы, в выражении для лондоповской глубины проникновения появляется неаналитичсское, линейно зависящее от модуля поля слагаемое [3]. Его удобно записать, выражая Δ через термодинамическое критическое поле H_c:

$$\frac{H_c^2}{8\pi} = \frac{N_0}{2}\Delta^2 \tag{14.36}$$

при котором работа по выталкиванию магнитного поля из сверхпроводника равняется выигрышу энергии (5.37) (или (5.38)) при переходе в сверхпроводящее состояние. Оценивая входящий в (14.35) вектор-потенциал как $|A_y| \sim H\delta_0$, гдс δ_0 дается формулой (14.13), получаем:

$$\delta(H) = \delta_0\left(1 + \frac{4}{\pi}\sqrt{\frac{3}{2}}\frac{H}{H_{\mathrm{c}}}\right) \tag{14.37}$$

Смешанное состояпие. Так же, как и в обычных сверхпроводниках второго рода, в полях, превышающих величину

$$H_{c1}(T) \sim \frac{\Phi_0}{4\pi\delta^2(T)} \ln\frac{\delta(T)}{\xi(T)} \tag{14.38}$$

мейсснеровское (цдеально диамагнитное) состояние в иеобычных сверхпроводниках перехоштт в смешанное состояние, в котором в толщу сверхпроводника начинают проникать абрикосовские вихри.

В отличие от изотропного случая, в анизотропных сверхпроводниках направление и расположение вихрей эависят от величины и направления внешиего поля по отношению к кристаллическим осям. Величина нижяего крити- ческого поля H_{c1} также зависит от направления внсшнего поля, а симметрия вихревых решеток может отличаться от правитьной треутольной. Теория смешанного состояния для необычных сверхпроводников в основном совпадает с соответствующей теорией для обычных анизотропных сверхпроводников, охватывающей большое разнообразие различных частных вопросов (распределения полей, утловые зависимости и пр.). Мы не будем останавливаться на этой части тсории (см. [45, 52-54]).

Среди явлений, специфических лля смешанного состояния в необычных сверхпроводниках, следует прежде всего указать на фазовые переходы, связанные с изменением симметрии многокомпонентных сверхпроводящих состояний [43]. Пример

[12] На появление при $T = 0$ плотности нормальной компоненты, неаналитически зависящсй от поля, в сверхтекучих фазах с нулями в щели в спектре возбуждений впервые указано в работе [58].

[3] В обычиых сверхпроводниках добавКа к элубине проникновения квадратична по помю.

такого перехода обсуждался в 12. Другой характеріой чертой многокомпонентіо сверхпроводимости является возможность существования свсрхпроводяших состояний со спонтанным магнетизмом [9]. Свойства таких сверхпроводников мы изучим в следующем параграфе. Наконец, еще один эффект, специфический для сверхпроводников с нетривиальным спариванием - это появление необычной зависимости теплоемкости от магнитного поля в смешанном состоянии [55]. Посмотрим сначала, как обстоит дело в обычных сверхпроводниках.

Как известно, параметр порядка сверхпроводника обращается в нуль на оси вихревой нити и восстанавливает свое равновесное постоянное значение на расстояниях $\rho \sim \xi(T)$ от оси вихря. Такая «яма» в потенциале $\Delta(\rho)$ приводит к образованито локализованных на ядре вихря связанных состояний квазичастиц. Наинизшгуо энергио связанных состояний можно оценить с помощью соотношения неопределенностей как

$$E_0 \approx \frac{\hbar^2}{2m\xi^2(T)} \approx \frac{\Delta^2}{\varepsilon_F} \tag{14.39}$$

Поскольку эта эпергия в $\Delta/\varepsilon_{\mathrm{F}}$ раз меньше наинизшей энергии возбуждений вдали от ядра вихря, то спектр возбуждений, локализованных в ядре, можно считать бесщелевым, практически совпадатошим со спектром возбуждений в нормальном металле. Таким образом, занимаемая ядрами вихрей часть объема сверхпроводника второго рода в смешанном состоянии обладает той же плотностью состояний [4], что и нормальный металл. Следовательно, дополнигельный вклад в плотность состояний пропорционален доле площади, занимаемой ядрами вихрей в плоскости, им перпендикудярной:

$$N_{\mathrm{loc}} \approx N_0 \frac{S_{\mathrm{cores}}}{S} = N_0 \pi \xi^2 n_v \tag{14.40}$$

Здесь N_0 - плотность состояний в нормальном металле, $n_\nu = B/\Phi_0$ - число вихрей на сдиницу площади, B - магнитная индукция (среднее значение микроскопического магнитного поля в образце).

В сильно выраженных сверхпроводниках второго рода, в которых выполняется условие $\delta(T)/\xi(T) \gg 1$, индукция B мало отличается от внешнего поля H практически во всем интервале полей $H_{\mathrm{c1}} < H < H_{\mathrm{c2}}$ (но не в непосредственной окрестности H_{c1}). Учитывая это обстоятельство, а также

[4] Длотность состояний определяется следуююиим образом:

$$N(E) = \sum_{\mathrm{k}\alpha} \delta\left(E - E_{\mathrm{k}}\right)$$

вспоминая, что переход в норманое состояние происходит в поле

$$H_{c2} \approx \frac{\Phi_0}{\pi \xi^2(T)} \tag{14.41}$$

когда расстояние между ядрами вихрсй становится порядка ξ, получаем:

$$N_{\mathrm{loc}} \approx N_0 \frac{II}{H_{c2}} \tag{14.42}$$

В результате, при низких тсмпературах ($T \ll T_c$), теплоемкость сверхпроводника в смешанном состоянии будет определяться в основном вкладом возбуждении, локализованных в ядрах вихрей:

$$C_{\mathrm{s}} \approx \frac{H}{H_{c2}} C_{\mathrm{n}} \tag{14.43}$$

гдс C_{n} - теплоемкость нормалыного металла, линейно зависящая от температуры.

В сверхпроводниках с нетривиальным спариванием результат (14.43), разумеется, сохраняет силу. Однако, если щель в спектре возбуждений обращается в нуль где-либо на ферми-повсрхности, то возможно появление дополнительmьх вкладов в теплоемкость, связанных с плотностьоо состояний в окрестности нулей. В пространстве между ядрами вихрсй текут незатухающие сверхтекучие токи $\mathbf{j} = -en_s\mathbf{w}$, что приводит к сдвигу энсргии элемештарных возбуждсний (14.17). В области полей $H_{c1} < H \ll H_{c2}$ расстояние между вихрями $a \sim n_V^{-1/2} \sim (\Phi_0/H)^{1/2}$ ограничено интервалом $\xi \ll a < \delta$, и распределение сзерхтекучей скорости

$$\mathrm{w} = -\frac{\mathrm{j}}{en_3} = -\frac{c}{4\pi en_3}\,\mathrm{rot\,B}$$

определяется вкладом ближайшего вихря:

$$\begin{aligned}\mathbf{B} &\approx \hat{z}\frac{\Phi_0}{2\pi\delta^2}\ln\frac{\delta}{\rho}\\ \mathbf{w} &= -\frac{\hbar}{2m}\frac{\hat{\varphi}}{\rho}\end{aligned} \tag{14.44}$$

Здесь ρ юбозначает расстояние до оси вихря, а $\hat{\varphi}$ - единичный вектор азимутального направления. Вновь, ограничиваясь для простоты случаем сферической ферми-поверхности, получаем вклад в плотность состояний за счет окрестностей нулей щели в спектре элементарных возбуждений:

$$N_{\mathrm{deloc}} = n_{\mathrm{v}}\int dS\sum_{\mathbf{k}\alpha}\delta\left(E_{\mathbf{k}} + \mathbf{kw}\right) \tag{14.45}$$

Интегрирование ведется здесь по площади элементарной ячейки решетки Абрикосова. Имеем (ср. с выводом формулы (14.31)):

$$\sum_{k\alpha}\delta\left(E_{\mathrm{k}} + \mathrm{kw}\right) = 2N_0\int\frac{d\Omega}{4\pi}\frac{|\mathrm{kw}|}{\sqrt{(\mathrm{kw})^2 - \Delta_{\mathrm{k}}^2}} \tag{14.46}$$

причем интегрирование происходит по области $(\mathrm{kw})^{\,2} > \Delta_{\mathbf{k}}^2$. Дальнейшие вычисления необходимо производить уже для конкретного вида сверхпроводящего состояния.

Рассмотрим в качестве примера полярнуто фазу с p-спариваниcм, гдс $\Delta_{\mathbf{k}}^2 = \Delta^2\cos^2\theta$. Главный вклад в плотность состояний возникает от окрестности экватора ферми-поверхілости. Выполняя в (14.46) интегрироваиие по углам, получаем:

$$N_0\frac{k_{\mathrm{F}}|\mathbf{w}|}{\pi\Delta}\int\limits_0^{2\pi}d\varphi|\cos\varphi| = N_0\frac{4k_{\mathrm{F}}|w|}{\pi\Delta}$$

Подставляя это выражение в (14.45), получаем (с учетом (14.44)):

$$N_{\mathrm{deloc}} \approx n_{\mathrm{v}}N_0\frac{1\hbar v_{\mathrm{F}}}{\Delta}a \sim N_0\sqrt{\frac{II}{H_{c2}}} \tag{14.47}$$

Полученный рсзультат показывает, что в смешанном состоянии при $H \ll H_{c2}$ главньй вклад в электронную плотность состояний свсрхпроводника, иметощего нули параметра порядка па линиях на ферми-поверхности, вносят не ядра вихрей, а пространство между ними, где текут сверхдроводящие токи:

$$\frac{N_{\rm deloc}}{N_{\rm loc}} \sim \sqrt{\frac{H_{\rm cc}}{H}} \gg 1 \tag{14.48}$$

Теплоемкость такого сверхпроводника в смешанном состоянии при достаточно низких температурах должна иметь вид [5]

$$\frac{C_{\rm s}}{C_{\rm n}} = b\sqrt{\frac{H}{H_{\rm c2}}} \tag{14.49}$$

где b - численный коэффициент. Подобная зависимость наблюдалась экспериментально в высокотсмпературных ($YBa_2Cu_3O_{7-6}$[16, 56]) и в тяжелофермионных (UPt_3 [57]) сверхпроводниках.

Упражнение. Показать, что для сверхпроводника с нулями щели в изолированнвх точках на ферми-поверхности имеет место следующее поведение теплоемкости в смешанном состоянии при низких температурах:

$$\frac{C_{\rm s}}{C_{\rm n}} = b\frac{H}{H_{\rm c2}} \ln \frac{H_{\rm c2}}{H} \tag{14.50}$$

19.1.15 15. Magnetic Superconductors

Сверхпроводящие состояния с многокомпонентным параметром порядка могут обладать спонтанным магнитным моментом. Так, орбитальный момент куперовской пары в состояниях, преобразующихся согласпо представлению E_1 группы D_6, с параметрами порядка:

$$g(\mathbf{k}) \propto \hat{k}_z \left(\hat{k}_x + i\hat{k}_y\right), \text{ при } S = 0 \tag{15.1}$$

$$\mathrm{d}(\mathbf{k}) \propto \hat{z} \left(\hat{k}_x + i\hat{k}_y\right), \text{ при } S = 1 \tag{15.2}$$

равеп. Имеются также состояния, обладаiшиие спонтанным спиновым моментом пары, например:

$$\mathbf{d}(\mathbf{k}) \propto \hat{k}_z(\hat{x} + i\hat{y}), \quad \text{при } S = 1 \tag{15.3}$$

С симметрийной точки зрения все такие состояния соответствуют магнитным сверхпроводящим классам (§§4, 11).

Магнитный момент $\mathcal{M}$ сверхпроводящего магнетика складывается из магнитнLx моментов всех куперовских пар и для образца объемом V, в болшшей части которого они ориентированы вдоль общего направления $\hat{\mu}$, дается выражснием

$$\mathcal{M} = \mathbf{MV}, \quad \mathbf{M} \sim \frac{\hbar\gamma n_8}{2}\hat{\boldsymbol{\mu}} \tag{15.4}$$

Здесь $n_{\rm s}$ есть плотность сверхпроводящих электронов, а $\gamma = e/(2mc)$ - гиромагнитное отношение. Легко проверить, что магнитный момент магнитного сверхпроводника с точностью до численного множителя совпадает с магнитным моментом обычного сверхпроводника такого же объема, в котором находится один абрикосовсгяй вихрь.

Магнитный момент (15.4) сверхпроводника создается незатухающими токами, текущими по его поверхности. В то же время магнитный момент единицы объема в толще сверхпроводника ничтожно мал. Дело в том, что спиновый момент пар

[15] См. также Н. Б. Копнин, Г. Е. Воловик //Письма в ЖЭТФ, 64, 641 (1996).

компенсируется моментом неспаренных частиц. С другой стороны, куперовские пары силнно перекрываются между собой, поскольку размер пары ξ_0 велик по сравнению с межатомным расстоянием. По этой причине локалные токи, создающие орбитальный момент, практически полностью компенсируюот друг друга в объеме сверхпроводника. Однако, на поверхности образца такая компенсация отсутствует, и поверхностные токи порождают магнитный момент [58, 59].

Локальный мапнстизм. Рассмотрим ситуацию количественно на примере двухкомпонентного векторного параметра порядка в гексагональном кристалле. Для вычисления плотности внутреннего спонтанного момента вблизи критической температуры мь должны явно выделить в функшионале свободной энергии Тинзбурга-Ландау (12.15) слагаемые, пропорциональные магнитному поло. Для этой цели перепишем градиентіые члены в (12.15) в следующсм виде:

$$\begin{aligned}\mathcal{F}_{\text{grad}} = \int d^3r \{ & K_1 \left(D_i\eta_j\right)^* \left(D_i\eta_j\right) + K_4 \left(D_z\eta_i\right)^* \left(D_z\eta_i\right) + \\ & \frac{K_2+K_3}{2}\left[\left(D_i\eta_i\right)^*\left(D_j\eta_j\right) + \left(D_i\eta_j\right)^*\left(D_j\eta_i\right)\right] + \\ & + \frac{K_2-K_3}{2}\left[\left(D_i\eta_i\right)^*\left(D_j\eta_j\right) - \left(D_i\eta_j\right)^*\left(D_j\eta_i\right)\right]\Big\} \end{aligned} \tag{15.5}$$

Интегрируя по частям последнее слагаемое в правой части и используя тождество

$$[D_i, D_j] \equiv D_iD_j - D_jD_i = -\frac{2\pi i}{\Phi_0} e_{ijk} (\text{rot}\,\mathbf{A})_k$$

находим, что вклад в плотность свободной энергии, пропорциональный магнитному полю, имеет вид

$$F_{MH} = -\frac{\pi i}{\Phi_0}\left(K_2 - K_3\right)\left(\eta^* \times \eta\right) \text{rot}\,\mathbf{A} \tag{15.6}$$

Отсюда получаем выражение дзя плотности внутреннего спонтапного момента:

$$\mathrm{M_i} = \frac{\pi i}{\Phi_0}\left(K_2 - K_3\right)\left(\eta^* \times \eta\right) \tag{15.7}$$

Как мы знаем (см. 11), минимуму свободной энсргии (11.6) при $\beta_2 > 0$ отвечает комплексная сверхпроводящая фаза $\eta = \eta_0(1, \pm i)e^{i\varphi}$. Согласно (15.7), эта фаза обладает ненулевым собственным магнитным моментом в однородном состоянии. Величина этого момента определяется значением разности $K_2 - K_3$ и оказывается ничтожно малой. Микроскопический ажализ (см. 18) показываст, что в теории БКІШ лия векторного параметра порядка $K_1 = K_2 = K_3$, и спонтанный магнетизм отсутствуст. Однако, при учете зависимости плотности состоянии вблизи ферми-повсрхности от энергии (электрон-дырочная асиммстрия), разность $K_2 - K_3$, а вместе с ней и плотность внутреннего момента, становится отличной от нуля:

$$K_2 - K_3 \sim N_0\xi_0^2\left(\frac{T_c}{\varepsilon_F}\right)^2 \ln\frac{\varepsilon_1}{T_c}$$

Можно убедиться в том, что плотность внутреннего магнитного момента сверхпроводника весьма мала и при нулевой температуре. Проще всего это сделать для состояния (15.3). В этом состоянии спарены только электроны со спинами «вверх» (см.

(2.7)). Испожзуя прсобразование Боголюбова ($5), нетрудно проверить, что распределение таких электронов по энергиям имеет вид

$$n_\uparrow(\xi) = \left\langle a^+_{\mathbf{k}\uparrow} a_{\mathbf{k}\uparrow} \right\rangle = \frac{1}{2}\left[1 - \frac{\xi}{E}(1 - 2f(E))\right] \tag{15.8}$$

где $f(E)$ - фсрмиевская функция распрсделения, $E = \sqrt{\xi^2 + \Delta^2_{\mathbf{k}}}$. При $T = 0$

$$n_\uparrow(\xi) = \frac{1}{2}\left(1 - \frac{\xi}{E}\right)$$

В то же время, электроны со спинами «вниз» не спарсны, и их распределение по энергиям

$$n_\downarrow(\xi) = \frac{1}{2}\left(1 - \frac{\xi}{|\xi|}\right)$$

есть фермиевская «ступенька». Спиновый магнитный момент единины объема такой жидкости дается выражением

$$\mathrm{M_i} = \hat{z}\mu_\mathrm{B} \int d\xi N(\xi)\left(n_\uparrow(\xi) - n_\downarrow(\xi)\right) \approx \hat{z}\mu_\mathrm{B} N_0' \Delta^2 \ln\frac{\varepsilon_1}{\Delta} \tag{15.9}$$

Здесь $N(\xi)$ - плотность электронных состояний, N_0' - производная плотности состояний на ферми-поверхности, а ε_1 - параметр обрезания логарифмически расходяшегося интеграла, соответствующий тому, что параметр порядка отличен от нуля в узком слое вблизи ферми-поверхности (см. 5). Таким образом, плотность спогттанного магнитного момента мала в меру малости $(T_c/\varepsilon_1)^2 \ln(\varepsilon_1/T_c)$ и отлична от нуля лишь при наличии асимметрии в раепределении частиц и дырок вблизи ферми-поверхности [3, 60].

Малая плотность внутреннего спинового момента возникает в результате компенсации спиновых моментов куперовских пар, состоящих иэ частиц со спинами вдоль поля и неспаренных частиц с противоположной ориентацией спина. Такой компенсации может и не быть. Для этого надо иметь либо гигантское спаривающее взаимодействие для одного из двух направлений спина, либо создать практически полностью поляризованную ферми жидкость с очень сильіо раздвинутыми ферми-поверхіостями для частиц со спинами «вверх» и «вниз». Для сверхпроводников обс эти возможности в настоящес время выглядят ие очень рсально. В нсйтральнй сверхтекучсй ферми-жидкости (^{3}He) создание силыно спин-поляризованной сверхтекуче ф фазы возможно.

Поверхностные токи и магнитіый момелт образца. Магнитные сверхпроводящие состояния в кристаллах, гдс существенны эффекты кристаллической анизотропии и сильного спин-орбитального взаимодействия, имегот пиить один вил пепрерывного вырождения - вырождение по фазе φ параметра порядка, обсспечивадощее возможность протекания бездиссипативных токов. Токи, іле связанные с градиегтами φ, могут протекать лишь в слоях толщиной порядка ξ вблизи границ образца или гранит магнитных доменов. Для их вычисления воспользуемся выражениsм (15.5) лля градиентной части свободной эергии, подставив в него параметр порядка с явно выделенньм фазовым множителем $\boldsymbol{\eta} \to \boldsymbol{\eta}(\mathbf{r})e^{i\varphi(\mathbf{r})}$. Опуская слагаемыс с K_4, с точностью до полных производных в попынтегральном выраженип ниеем:

$$\begin{aligned}\mathcal{F}_\mathrm{grad} = \int d^3r \Big\{ & K_1\left[v^2|\boldsymbol{\eta}|^2 + iv_i\left(\eta_k\nabla_i\eta_k^* - \eta_k^*\nabla_i\eta_k\right) + \left(\nabla_i\eta_j^*\right)\left(\nabla_i\eta_j\right)\right] + \\ & + \tfrac{K_2+K_3}{2}\left[2|\mathbf{v}\eta|^2 + i\mathbf{v}\,\mathrm{rot}\left(\boldsymbol{\eta}^*\times\eta\right) + \left|\nabla_i\eta_i\right|^2 + \left(\nabla_i\eta_j^*\right)\left(\nabla_j\eta_i\right)\right] - \\ & - \tfrac{K_2-K_3}{2}\tfrac{2\pi i}{\Phi_0}\left(\boldsymbol{\eta}^*\times\eta\right)\mathrm{rot}\,\mathbf{A}\Big\}\end{aligned} \tag{15.10}$$

Здесь

$$\mathbf{v} = \boldsymbol{\nabla}\varphi + \frac{2e}{\hbar c}\mathbf{A}$$

• калибровочно-инвариантньдй градиент фазы (ср. с (14.6)). Соответствующее выражение для плотности тока выгдядит следующим образом:

$$\begin{aligned}
\mathrm{j} &= --\frac{\delta \mathcal{F}_{\mathrm{grad}}}{\delta \mathrm{A}} = -\frac{2e}{\hbar}\frac{\delta \mathcal{F}_{\mathrm{grad}}}{\delta \mathbf{v}} = \\
&= -\frac{2e}{\hbar}\left\{K_1\left[2\mathbf{v}|\boldsymbol{\eta}|^2 + i\left(\eta_i\nabla\eta_i^* - \eta_i^*\nabla\eta_i\right)\right] + \frac{K_2+K_3}{2}\left[2\left(\boldsymbol{\eta}^*(\mathbf{v}\boldsymbol{\eta})+\right.\right.\right. \\
&\left.\left.\left. + (\mathbf{v}\boldsymbol{\eta}^*)\,\boldsymbol{\eta}\right) + i\,\mathrm{rot}\,(\boldsymbol{\eta}^*\times\boldsymbol{\eta})\right] + i\frac{K_2-K_3}{2}\,\mathrm{rot}\,(\boldsymbol{\eta}^*\times\boldsymbol{\eta})\right\} \qquad (15.11)
\end{aligned}$$

Неоднородности в распределении модуля или направления вектора $i\,(\eta^*\times\eta)$ на границе образца (на расстояниях порядка дтиыы когерентности $\xi(T)$) или на границах магнитных доменов порождают незатухаюощие поверхностныс токи, создающие полный магнитный момент:

$$\mathcal{M} = \frac{1}{2c}\int d^3r(r\times j) \qquad (15.12)$$

Величина $\mathcal{M}$ зависит, разумеется, от распределения компонент параметра порядка $\eta_i(\mathbf{r})$ вблизи границы образца.

Рассмотрим цилиндричсский образец радиуса R с осью $\hat{z}$ вдоль гексагональной кристалшческой оси. Для простоты будем считать, что параметр
порядка во всем объсме имеет вид $\eta = \eta_0(r)(1,i)$, где $\eta_0(r)$ в повсрхностном слое толипной ξ гладко спадает от объемного значения η_0 до нуля при $r = R$. В этом случае даже в отсутствие внешнего магнитного поля, то есть при $\mathbf{v} = 0$, выражение вд плотности тока приобретает вид

$$\mathrm{j} = c\,\mathrm{rot}\,\mathrm{M} = -\frac{4\epsilon}{\hbar}K_2\frac{\partial\eta_0^2(r)}{\partial r}\hat{\varphi}$$

где $\hat{\varphi}$ - единичный вектор азимуталного направления. Выполняя теперь интегрирование в (15.12), получаем оценку (15.4) для магнитного момента цилитдра обтема V:

$$\mathcal{M} = \frac{8e}{\hbar c}K2\eta_0^2 V\hat{z} \approx 2\hbar\gamma n_{\mathrm{s}}V\hat{z} \qquad (15.13)$$

Здесь использовано, что $K_2 \sim \hbar^2 n_{\mathrm{s}}/\left(m\eta_0^2\right)$ (см. (14.7)).

Заканчивая обсуждсние вопроса о спонтанном моменте магнитиных сверхпроводников, подчеркнсм, что в выражении для плотности тока (15.11) последнее слагаемое, соответствующее пдотности спонтанного впутреннего момента, и предпоследнее слагаемое, соответствующее поверхностному моменту, неотличимы по своей структуре. Поэтому формулы для плотности тока, полученные на основе микроскопической теории, приводили многих авторов к утверждению о существовании «большой» ($\sim \mu_{\mathrm{B}} n_{\mathrm{s}}$) плотности спонтанного внутреннего момента (см., например, [61]). Для правильной же интерпретации раздичных вкладов в ток необходимо производить микроскопическое вычисление градиентной энергин [62, 63].

Электродинамика магинтых сверхпроводников. При наличих внешнего поля $\mathbf{H}$, параллельного оси цилиндра, уравнение лондоновской электродинамики приобретает вид

$$\operatorname{rot} B = \frac{4\pi j}{c} = -\frac{A}{\delta^2} + 4\pi \operatorname{rot} M \tag{15.14}$$

где δ - лощдоновская глубина проникновсния. Поскольку вклад в ток, обусловленнюи слагаемым с rot M, сосредоточен в поверхностном слос толщиной $\xi \ll \delta \ll R$, то магнитное поле, как обыпно, затухает вглубь образца:

$$\mathbf{B}(r) = \mathbf{B}(R) \exp\left(-\frac{R-\tau}{\delta}\right) \tag{15.15}$$

Однако, за счет того, что по поверхности текут незатухающие токи, граничное условие для уравнении Лондонов приобрстает вид:

$$\mathbf{B}(R) = \mathbf{H} + 4\pi\mathbf{M} \tag{15.16}$$

Таким образом, даже в отсутствие внешнего поля на поверхности сверхпроводника имеется магнитное поле, индуцированное магнетизмом пар:

$$\mathbf{B}_0 = 4\pi\mathbf{M} = 4\pi\frac{c\hbar}{2mc} n_{\mathrm{s}} \hat{\boldsymbol{\mu}} = 4\pi\mu_{\mathrm{B}} n_{\mathrm{s}} \hat{\boldsymbol{\mu}} \tag{15.17}$$

которое подавлятся в толще сверхпроводника, причем величина $\mathbf{B}_0$ оказывается порядка нижнего критического поля:

$$H_{c1} = \frac{\Phi_0}{4\pi\delta^2} \ln\frac{\delta}{\xi} = 2\pi\mu_{\mathrm{B}} n_{\mathrm{s}} \ln\frac{\delta}{\xi} \tag{15.18}$$

Мы видим, что в магнитном сверхпроводнике достичь нижнего критического поля легче, прикладввая внешшее поле параллелыо $\hat{\mu}$, чем антипараллельно ему. Более того, если поверхностное поле (15.17) в каком-то сверхпроводнике окажется больше H_{c1}, то это будет означать отсутствие мсйсснеровского состояния. Вихревые нити будут проникать вглубь такого сверхпроводника при сколь утодно малом внешнем поле.

Вблизи поверхности однодоменного магнитного сверхпроводника конечных размеров должно возникать поле порядка H_{c1} , убывающее с расстоянием от поверхности по тому же закону, что и поле магнитного шиполя.

Мапистизм в сверхпроводниках с p-спариванием. Несколько иная ситуация, по сравнению с рассмотрснной выше, возникает в сверхпроводниках со слабым спин-орбитальным взаимодействием. В этом случае существенно не только вырождение по фазе, но и по пространственным ориенташиям параметра порядка. Так, например, в заряженной сверхтекучей ферми-жидкости со структурой A-фазы гелия-3 (см. §§3, 11), параметр порядка имеет вид

$$A_{\alpha i} \sim V_\alpha \left(\Delta_i' + i\Delta_i''\right) \tag{15.19}$$

где $\mathbf{V}, \Delta', \Delta''$ - сдиничные векторы, причем $\Delta' \perp \Delta''$, а $\Delta' \times \Delta'' = 1$ задает паправление орбиталыного момента куперовских пар. Неоднородная часть свободной энергии Гинзбурга-Ландау в сверхпроводниках с p-спариванием в магнитном поле записывается как

$$\begin{aligned}\mathcal{F}_{\mathrm{grad}} = \int d^3r \Big[& K_1 \left(D_i A_{\alpha j}\right)^* \left(D_i A_{\alpha j}\right) + K_2 \left(D_i A_{\alpha i}\right)^* \left(D_j A_{\alpha j}\right) + \\ & + K_3 \left(D_i A_{\alpha j}\right)^* \left(D_j A_{\alpha i}\right) + K_4 \frac{2e}{\hbar c} i e_{\alpha\beta\gamma} B_\alpha A^*_{\beta i} A_{\gamma i} + \frac{B^2}{8\pi}\Big]\end{aligned} \tag{15.20}$$

Состояния A-фазы вырождены по отношению к вращениям вектора V и репера $(\Delta', \Delta'', 1)$. Поэтому во всем объеме бездиссипативные токи определяются не только калибровочно-инвариантной скоростью $\mathbf{v}$, но и пространственным изменением (текстурой) векторов, задающих параметр порядка (ср. с (15.11)). Выводы, сделанные выпие о величине спонтанного магнетизма в таком сверхпроводнике, сохраняются, однако возможные типы вихрей и структура смешанного состояния оказываются существенно сложнее, нежели для многокомпонентных сверхпроводящих фаз в кристаллах, где ориентационное вырождение подавлсно сильной анизотропией и спин-орбитальным взаимоденствием.

Слагаемое в свободной энергии (15.20), содержащее K_4, описывает взаимодействие спонтанного спинового магнитного момента сверхпроводящей фазы с внешним полем. Для унитарных фаз (определение унитарной фазы см. в сноске 6 к 5), в частности, для A - и B-фаз, такое слагаемое отсутствует. Для неунитарных фаз спиновый момент отличен от нуля, что вызывает расщепление фазового перехода ^{3}He в сверхтекучее состояние на два. Сначала имеет место переход в A_1-фазу, а затем - в A-фазу (см. рис. 2) [64]. Расщепление перехода, однако, оказывается малым, поскольку коэффициент K_4 отличен от нуля лишв в меру малости электрон-дырочной асимметрии (см. §18).

Сверхпроводники с p-спариванием и со структурой A - или A_1-фазы в настоящий момент неизвестны. Отдельные вопросы теории таких сверхпроводящих состояний рассмотрены в работах [31, 65, 66].

19.1.16 16. Эффект Джозефсона

Обобщение феноменологитеской теории эффекта Джозефсона на случай контактов между двумя сверхтроводниками, облалающими различной симметрией, может быть построено в духе полхода, развитого в 13 при анализе поверхностных свойств. Проще всего рассмотреть это явление на примере плоского контакта между двумя сверхпроводниками, находящимися в различных сверхпроводящих состояниях с опнокомпонентными параметрами порядка

$$\eta_1 = |\eta_1|\, e^{i\varphi_1}, \quad \eta_2 = |\eta_2|\, e^{i\varphi_2} \tag{16.1}$$

Для одноосных (гексагональных и тетрагонапыых), а также кубических кристаллов свободная энергия системы дается выражением

$$\mathcal{F} = \mathcal{F}_1 + \mathcal{F}_2 + \mathcal{F}_\mathrm{J} \tag{16.2}$$

тде

$$\mathcal{F}_i = \int\limits_{\mathrm{rn},>0} d^3 r F_i \quad (i = 1, 2) \tag{16.3}$$

есть свободные энергии (12.2) сверхпроводников, занимающих левое и правое полупростраиства с плоской границей, проходящей через начало координат, $\mathbf{n_i}$ - векторы внсишей нормали к соответствующему полупространству ($\mathbf{n}_1 = -\mathbf{n}_2$), а $\mathcal{F}_3$ есть поверхностная (джозефсоновская) энергия, феноменологически описываюшая связь мсжду сверхпроводниками из-за возможности туннелирования куперовских пар:

$$\mathcal{F}_\mathbf{J} = A \oint dS g_1(\mathbf{n}_1)\, g_2(\mathbf{n}_2)\, (\eta_1^* \eta_2 + \eta_1 \eta_2^*) \tag{16.4}$$

Здесь интегрированис происходит по поверхности раздела. Вообще говоря, энергия джозефсоновского контакта представляется бесконечной суммой слагаемых вида (16.4):

$$\sum_{p,q} \oint dS g_1^p(\mathbf{n}_1)\, g_2^q(\mathbf{n}_2)\, (\eta_1^* \eta_2 + \eta_1 \eta_2^*)$$

где каждое произведсние $g_1^p(\mathbf{n}_1)\,\eta_1$ и $g_2^q(\mathbf{n}_2)\,\eta_2$ не должно меняться при всех преобразованиях группы точечной симметрии соответствующсго полупространства. Для дашнейшего, однако, достаточно рассмотреть лишв одно слагаемое в этой сумме.

Энергия $\mathcal{F}_\mathrm{J}$ инвариантна относительно всех преобразований группы симметрии как левого, так и правого кристаллов в нормальном состоянии. Для христаллов с сильным спин-орбиталыным взаимодеиствием всегда имеются -билинейные по η_1 и η_2 комбинации, обладающие ухазанной симметрией. Это означаст, что в принципе пет никаких ограничений на существование джозефсоновской связи между двумя сверхпроводниками с однокомпонентными параметрами порядка, в том числе - между сверхпроводниками с синглетным и триплетным спариванием. При этом, разумеется, возможны такие ориентации поверхности, при которых какая-то из функций $g_i(\mathbf{n}_i)$, а вместе с ней и $\mathcal{F}_\mathrm{J}$, обращаются в нуль. В этом случае нсобходимо принимать во внимание джозефсоновские энергии болес высоких порядков по η_i.

Симметрия $g(\mathbf{n})$ совпадает с симметрией соответствующего сверхпроводящего класса. Для синглетных состояний это означает, что $g(\mathbf{n}) = 0$ для направлении нормали, при которьх параметр порядка обрашается в нуль на ферми-поверхности (см. 4), то есть при $S = 0$ функции $g(\mathbf{n})$ можно считать совпадающими с базисньми функциями соответствуошего представления. Для случая триплетного спаривания функции $g(\mathbf{n})$ найдены в работе [67].

Точно таким же образом, составляя инвариантные комбинации из векторов $\mathbf{n}_i$ и компонент параметров порядка η_i в случае сильной спинорбиталыой связи, можно получить джозефсоновские эиергии $\mathcal{F}_\mathrm{J}$ для многокомпонентных сверхпроводящих состояний.

В отсутствие спин-орбитального взаимодействия, в сверхпроводнике с триплетным спариванием нельзя построить скалярггую линейную функцию из спинового всктора $\boldsymbol{\eta}$ параметра порядка и пространственного вектора нормали n, поэтому джозефсоновская связь вида (16.4) невозможна. Однако в этом случае можно рассмотреть связи (лжозефсоновские энергии) болес высоких порядков по η [68]. То жс самое справсдливо для тех ориентаций поверхности, дтя которых выражение (16.4) обращается в нуль по симметрийным соображениям.

Варьируя гралиентную часть (16.2) по A, находим выражения для плотности тока в правом и левом полупространствах:

$$\begin{aligned}
\mathrm{j}_1 &= -c\frac{\delta \mathcal{F}_{1,\mathrm{grad}}}{\delta \mathbf{A}} = -\frac{2\pi c}{\Phi_0} \operatorname{Re} \eta_1^* \left[K_{11}(D_x + D_y) + K_{12} D_z\right] \eta_1 \\
\mathrm{j}_2 &= -c\frac{\delta \mathcal{F}_{2,\mathrm{grad}}}{\delta \mathbf{A}} = -\frac{2\pi c}{\Phi_0} \operatorname{Re} \eta_2^* \left[K_{21}(D_x + D_y) + K_{22} D_z\right] \eta_2
\end{aligned} \tag{16.5}$$

Как и в 13, граничные условия для уравнений Гинзбурга-Ландау на поверхности коптакта получаготся варьированием полшой эпергии (16.2) по η_1^* и η_2^*:

$$\begin{aligned}
i\left[K_{11}(n_{1,x} D_x + n_{1,y} D_y) + K_{12} n_{1,z} D_z\right] \eta_1|_S &= -\,A g_1(\mathbf{n}_1)\, g_2(\mathbf{n}_2)\, \eta_2|_S \\
i\left[K_{21}(n_{2,x} D_x + n_{2,y} D_y) + K_{22} n_{2,z} D_z\right] \eta_2|_S &= -\,A g_1(\mathbf{n}_1)\, g_2(\mathbf{n}_2)\, \eta_1|_S
\end{aligned} \tag{16.6}$$

С помощьо (16.5) и (16.6) находим плотность тока через джозефсоновский контакт:

$$\mathbf{j} = (\mathbf{j}_1 + \mathbf{j}_2)\,\mathbf{n}_1|_S = \frac{4\pi c A}{\Phi_0} g_1(\mathbf{n}_1)\, g_2(\mathbf{n}_2)\, |\eta_1|\, |\eta_2| \sin(\varphi_2 - \varphi_1) \tag{16.7}$$

Согласно формуле (16.7), температурная зависимость максимаьного джозефсоновского тока определяется произведением модулей параметров порядка на границах контакта. Если правое и левое полупространства заняты сверхпроводниками с одинаковыми критическими температурами, и модуль параметра порядка принимает на границе объемное значение, то максимальный джозефсоновский ток пропорционален $T_c - T$. Ощнако, как мы знаем, в необычных сверхпроводниках величина параметра порядка на границе может быть сильно подавлена по сравнению с его объемным значением из-за проигрыиа в поверхностной энергии, что имеет место при условии $f(\mathbf{n}) \neq 0$, где функция $f(\mathbf{n})$ описываст зависимость поверхностной энсргии от ориеитации нормали (см. 13). В этом случае справедлива следующая оценка

$$\eta|_S \sim \frac{b(\mathrm{n})}{\xi(T)} \eta_0(T) \tag{16.8}$$

где $b(\mathrm{n})$ - интерполяционная длина, определяемая формулой (13.7), $\xi(T) \sim \xi_0 (1 - T/T_c)^{-1/2}$ - корреляционная ллина, $\eta_0(T) \propto (1 - T/T_c)^{1/2}$ - объемное значение модуля параметра порядка. Подставлия (16.8) в (16.7), мы видим, что максимальный джозефсоновский ток пропорционален $(T_c - T)^2$, если параметры порядка обоих сверхпроводников подавлены на границах контакта и пропорционалеи $(T_c - T)^{3/2}$, если подавление имеет место только на одной из границ.

Для обвтного сверхпроводящего состодния $g(\mathbf{n})$ преобразуется как базисная функция едиииичного прсдставления A_1, инвариантная относителыно всех преобразований точсчной группы кристалла. Традиииионно считастся, что $g_{A_1}(\mathbf{n})$ полностью изотропна, поэтому джозефсоновский ток не зависит от оринстации контакта по отношению к кристалтическим осям.

Напротив, для необычных свсрхпроводящих состояний $g(\mathbf{n})$ зависит от направления $\mathbf{n}$. Так, для любого из одномерных пеединичных представлений в тетрагональном кристале $g(n)$ мепяет зак при пересечении линии нудей. Например, $g_{B_1}(\mathbf{n}) \propto n_x^2 - n_y^2$ и меняет знак при изменении ориентации

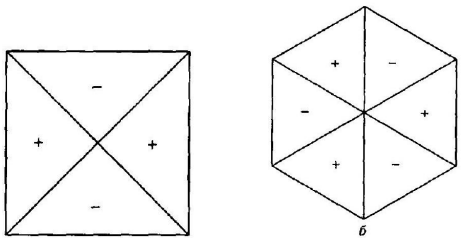

Рис. 13. Знакочередованис функции $g(\mathbf{n})$ для представлсний B_{1_g} па гравях: а) тетрагонатьного и б) гексагонального кристаллов

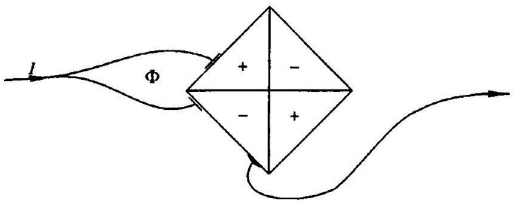
поверханости от одной боковой грани тетрагонального кристалла к другой (рис. 13а). То же самое происходит в гексагональном кристалде для сверхпроводящего состояния B_1 (рис. 130), поскольку $g_B \propto n_x^3 - 3n_x n_y^2$. Поэтому для контакта обычнного сверхпроводиика с различными боковыми гранями идеального тетрагопального или гексагонального кристала в свсрхпроводящем состоянии B_1 выражение для тока, используя формулу (16.7), можно записать в виде



$$I = I_0 \sin(\varphi_1 - \varphi_2 + \pi n) \tag{16.9}$$

где n - номер боковой грани.

Этот результат позволил установить симметрию сверхпроводящего состояния иттриевьх высокотемпературных сверхпроводников. Наиболее надежными выглядят измерения [69, 70] тока через двухконтактный SQUID, в двух джозефсоновских контактах которого провода из обьтчного сверхпроводника (свинсц) подсоединены к двум боковым граням свсрхпроводящего тетрагонального кристалла $YBa_2Cu_3O_{7-x}$ (рис. 14). В предположении, что
контакты 1 и 2 одинаковы, полный ток через SQUID дается выражением

$$I = I_0 \left(\sin \Delta\varphi_1 + \sin \Delta\varphi_2\right) = 2I_0 \sin \frac{\Delta\varphi_1 + \Delta\varphi_2}{2} \cos \frac{\Delta\varphi_1 - \Delta\varphi_2}{2} \tag{16.10}$$

Здесь $\Delta\varphi_1$ и $\Delta\varphi_2$ - скачки фаз на контактах 1 и 2. Их разность, то есть полное измепение фазы параметра порядка при обходе по замкну-

Р и с. 14. Двухконтактны SQUID, подсоединенный к соседним граням тетрагонального кристалта с противоположными знаками параметра порядка

тому контуру SQUID'а, складывается из набега фазы в магнитном поле $(2e/\hbar c) \oint \mathbf{A} d\mathbf{r} = (2\pi\Phi/\Phi_0)$ и «внутрениего» набега фазы δ_{12} между контактамн 1 и 2:

$$\Delta\varphi_1 - \Delta\varphi_2 = \frac{2\pi\Phi}{\Phi_0} + \delta_{12} \tag{16.11}$$

Из формул (16.10) и (16.11) получаем выраженис для максималнного тока как функции внешнего поля:

$$I_{\max} = 2I_0 \cos\left(\frac{\pi\Phi}{\Phi_0} + \frac{\delta_{12}}{2}\right) \tag{16.12}$$

В случас обычной сверхпроводимости в $YBa_2Cu_3O_{7-x}\delta_{12} = 0$, так что в отсутствие внешнего поля ток $I_{\max}(\Phi = 0) = 2I_0$ принимает наибольшее значение. На опыте [69, 70] оказалось, что $I_{\max}(\Phi = 0) = 0$, то есть $\delta_{12} = \pi$, как должно быть в случае необычной синглетной сверхпроводимости, соотвстствующей представлению B_1.

Существование внутреннего набега фазы параметра порядка между боковыми гранями кристалта $YBa_2Cu_3O_{7-x}$ продемонстрировано также прямым измерением полуцелого кванта потока, захваченного сверхпроводящим кольцом, изготовленным из трех иттриевых сверхпроводящих монокристаллов с различной ориентацией [19].

Посколку простейшая функция неприводимого представления B_1 имеет вид

$$g(\mathbf{k}) \propto \hat{k}_x^2 - \hat{k}_y^2 \tag{16.13}$$

то в литературе принято говорить о сверхпроводимости в $YBa_2Cu_3O_{7-x}$ как о сверхпроводимости с d-спариванием (или $d_{x^2} - y^2$-спариванием). Иногда (см. ссылки в работе [18]) также обсуждается так называемое «s + id-спаривание»:

$$g(\mathbf{k}) = \Delta_s + i\Delta_d \left(k_x^2 - k_y^2\right) \tag{16.14}$$

для которого δ_{12} может отклоняться от π в меру отношения Δ_s/Δ_d. Как уже указывалось в 4, фаза вида (16.14) может образоваться непосредственно из

нормального состояния, только если фазовые переходы в сверхпроводящее состояние (нарушение калибровочной симметрии) и в ферромагнитное состояние (нарушение симметрии по отношению к обращению времени) происходят одновременно, для чего не видно особых причин. Поэтому возникновение состояния (16.14) из нормального должо идти через два последоватсльных фазовьдх перехода, что, насколько известио авторам, не наблюдается. Таким образом, интерпретация отклонений δ_{12} от π в терминах смеси s - и d-состояний представляется весьма условной.

19.2 Unconventional Superconductivity by Mineev, V.P. Samokhin, K., part 2

Во второй части книги мы строим теорию необычной сверхпроводимости, используя квантово-полевой подход. Формулировка теории в терминах функций Грина не только придает наглядность и компактиость процедурс вывода основныхх рсзультатов, но и позволяет решать значительно более шхрокчй крут задач, не поддающихся решению методами, изложениыми в первой части. Мы не ставим здесь своей целью систематическое введение в метол функций Грина в теории конденсированного состояния, в частности, в теории обычной свсрхпроволимости (см. [71]), предполагая знакомство читателя с основыыми идеями и понятиями этого метода.

19.2.1 17. Gor'kov Equations

Рассмотрим электрошшый газ с притяжением мсжлу частицами, описываемый следующим гамильтонианом:

$$H = H_0 + H_{\text{int}} = \sum_{\mathbf{k},\mathbf{k}'} (\mathbf{k}\alpha \,|H_0|\, \mathbf{k}'\beta)\, a^+_{\mathbf{k}\alpha} a_{\mathbf{k}'\beta} +$$
$$+\frac{1}{2}\sum_{\mathbf{k},\mathbf{k}',\mathbf{q}} V_{\alpha\beta,\lambda\mu}(\mathbf{k},\mathbf{k}')\, a^+_{-\mathbf{k}+\mathbf{q}/2,\alpha} a^+_{\mathbf{k}+\mathbf{q}/2,\beta} a_{\mathbf{k}'+\mathbf{q}/2,\lambda} a_{-\mathbf{k}'+\mathbf{q}/2,\mu} \tag{17.1}$$
$$H_0 = \frac{1}{2m}\left[-i\nabla + \frac{e}{c}\mathbf{A}(\mathbf{r})\right]^2 + U(\mathbf{r}) - \mu$$

Злссь мы использовали более общее выражение, нежели (5.1), включив в одночастичный гамильтониан H_0 возможную пространственнуто неоднородность системы, возникаюшупо за счет примсссй, поверхности, внешних полей и т. д. Спаривательнос взаимодействие V имеет вил (5.3), (5.7) или (5.8).

Функция Грина сверхпроводника при коиечных температурах (мацубаровская функция Грина) определяется следующим образом:

$$G_{\alpha\beta}(\mathbf{k},\tau_1;\mathbf{k}',\tau_2) = -\left\langle T_\tau a_{\mathbf{k}\alpha}(\tau_1)\, a^+_{\mathbf{k}'\beta}(\tau_2)\right\rangle \tag{17.2}$$

где утловые скобки означаюот гиббсовское усреднение с гамильтонианом (17.1) (см. сноску 4 в §5), $a_{\mathrm{k}\alpha}(\tau) = \exp(\tau H) a_{\mathrm{k}\alpha} \exp(-\tau II)$ - фермионные операторы в мацубаровском предсгавлении, а T'_τ - символ упорядочсния в мнимом времени τ. Через фуікиио Грина (17.2) непосредсгвенно выражаются физические характеристики системы.

Подобно тому, как это деластся в теории обычной сверхпроводимости, иведем еще две, так называемыс аномальные функции Грина:

$$F_{\alpha\beta}(\mathbf{k},\tau_1;\mathbf{k}',\tau_2) = \langle T_\tau a_{\mathbf{k}\alpha}(\tau_1)\, a_{-\mathbf{k}'\beta}(\tau_2)\rangle$$
$$F^+_{\alpha\beta}(\mathbf{k},\tau_1;\mathbf{k}',\tau_2) = \left\langle T_\tau a^+_{-\mathbf{k}\alpha}(\tau_1)\, a^+_{\mathbf{k}'\beta}(\tau_2)\right\rangle \tag{17.3}$$

Отличие от нуля аномальных средних следует из того, что в присутствии бозекондегсата купсровских пар рождснис илі унитгожепис пары электронов практичссски не меняет состояние системы (см. 5). В диаграммной технике нормальные и аномальныс функции Грина (17.2) и (17.3) изображаются липиями со стрелками (рис. 15).

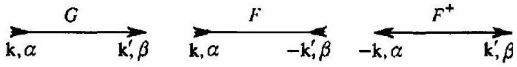


Рис. 15. Графичсскос изображение нормтьной и аномалыных функций Грина

При рассмотрснии статических задач фупкции Грина зависят лишь or разности мнимых времеIi $\tau_1 - \tau_2 = \tau$, и удобно перейти в импульспо-частотное представдение:

$$G_{\alpha\beta}\left(\mathbf{k},\mathbf{k}':\tau\right) = T\sum_n G_{\alpha\beta}\left(\mathbf{k},\mathbf{k}';\omega_n\right)e^{-i\omega_n\tau} \qquad \text{ит.д.}$$

где $\omega_n = (2n+1)\pi T$ - фермионная мацубаровская частота.

Функции G и F удовлетворяют систсме лиффсрснциалышьх уравнений, к выводу которой мы и переходим. Воспользуемся уравнениями движения для операторов $a_{\mathbf{k}\alpha}$:

$$\frac{\partial a_{\mathrm{ka}}}{\partial\tau} = [H, a_{\mathrm{k}\alpha}]$$

Дифференцируем фуікцпо G (17.2) по τ:

$$\frac{\partial G_{\alpha\beta}\left(\mathbf{k},\mathbf{k}';\tau\right)}{\partial\tau} = -\left\langle T_\tau\left[H(\tau), a_{\mathbf{k}\alpha}(\tau)\right]a^+_{\mathbf{k}'\beta}(0)\right\rangle - \delta(\tau)\delta\left(\mathbf{k}-\mathbf{k}'\right)\delta_{\alpha\beta}$$

Подставляя соода гамильтониау (17.1) и используя свойство (5.2), получаем:

$$\frac{\partial G_{\alpha\beta}\left(\mathbf{k},\mathbf{k}';\tau\right)}{\partial\tau} = -\sum_{\mathbf{k}_1}\left(\mathbf{k}\alpha\left|H_0\right|\mathbf{k}_1\gamma\right)G_{\gamma\beta}\left(\mathbf{k}_1,\mathbf{k}'\right) -$$
$$-\sum_{\mathbf{k}_1,\mathbf{q}} V_{\gamma_1\alpha,\gamma_2\gamma_3}\left(\mathbf{k},\mathbf{k}_1\right)\left\langle T_\tau a^+_{-\mathbf{k}+\mathbf{q},\gamma_1}(\tau)a_{\mathbf{k}_1+\mathbf{q}/2,\gamma_2}(\tau)a_{-\mathbf{k}}+\mathbf{q}/2,\gamma_3(\tau)a^+_{\mathbf{k}'\beta}(0)\right\rangle -$$
$$-\delta(\tau)\delta\left(\mathbf{k}-\mathbf{k}'\right)\delta_{\alpha\beta}.$$

Следующий шаг состоит в преобразовапии точного уравнения (17.4) с помощыо расцепления стоящей в правой части двухчаститной фупкции Грипа по следующему рецепту (приближепие средпего поля):

$$\left\langle T_\tau a^+_{-\mathbf{k}+\mathbf{q},\gamma_3}(\tau)a_{\mathbf{k}_1+\mathbf{q}/2,\gamma_2}(\tau)a_{-\mathbf{k}_1+\mathbf{q}/2,\gamma_3}(\tau)a^+_{\mathbf{k}'\beta}(0)\right\rangle \to$$
$$\to\left\langle I_\tau a^+_{-\mathbf{k}+\mathbf{q},\gamma_1}(\tau)a^+_{\mathbf{k}'\beta}(0)\right\rangle\left(T_\tau a_{\mathbf{k}_1+\mathbf{q}/2\cdot\gamma_2}(\tau)a_{-\mathbf{k}_1+\mathbf{q}/2,\gamma_3}(\tau)\right\rangle$$

Остальныс слагаемые в данном расцеплении дают линь алиитивную добавку к входящему в H_0 химическому потенциалу, и поэтому не учитываются.

Введем теперь функциго, являющуюся параметром порядка сверхпроводника:

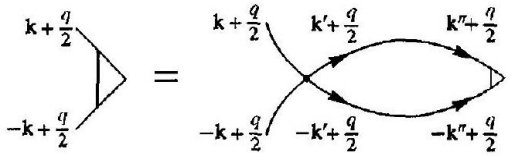
$$\Delta_{\alpha\beta}(\mathbf{k},\mathbf{q}) = -\sum_{\mathbf{k}'} V_{\beta\alpha,\lambda\mu}\left(\mathbf{k};\mathbf{k}'\right)F_{\lambda\mu}\left(\mathbf{k}'+\frac{\mathbf{q}}{2},\tau;\mathbf{k}'-\frac{\mathbf{q}}{2},\tau\right) =$$
$$= -T\sum_n\sum_{\mathbf{k}'} V_{\beta\alpha,\lambda\mu}\left(\mathbf{k},\mathbf{k}'\right)F_{\lambda\mu}\left(\mathbf{k}'+\frac{\mathbf{q}}{2},\mathbf{k}'-\frac{\mathrm{q}}{2};\omega_n\right) \qquad (17.5)$$

а также

$$\Delta^+_{\lambda,}(\mathbf{k},\mathbf{q}) = -T\sum_n\sum_{\mathbf{k}'} V_{\alpha\beta,\mu\lambda}\left(\mathbf{k}';\mathbf{k}\right)F^+_{\alpha\beta}\left(\mathbf{k}'-\frac{\mathbf{q}}{2},\mathbf{k}'+\frac{\mathbf{q}}{2};\omega_n\right)$$

После этого уравнение для функции Грина G в импульсно-частотном прелставлении окончатеьо переписывается в виде

$$\sum_{\mathbf{k}_1} \left(\mathbf{k}\alpha \left| i\omega_n - H_0 \right| \mathbf{k}_1\gamma\right) G_{\gamma\beta}\left(\mathbf{k}_1, \mathbf{k}'; \omega_n\right) + \sum_{\mathbf{q}} \Delta_{\alpha\gamma}(\mathbf{k}, \mathbf{q}) F^{+}_{\gamma\beta}\left(\mathbf{k} - \mathbf{q}, \mathbf{k}'; \omega_n\right) = \\ = \delta\left(\mathbf{k} - \mathbf{k}'\right)\delta_{\alpha\beta} \tag{17.6}$$



Рассуждая аналогичным образом, получаем уравнения для аномашных фукций Грина:

$$\sum_{\mathbf{k}_1} \left\langle -\mathbf{k}_1\gamma \left| i\omega_n + H_0 \right| - \mathbf{k}\alpha \right\rangle F^{+}_{\gamma\beta}\left(\mathbf{k}_1, \mathbf{k}'; \omega_n\right) + \\ + \sum_{\mathbf{q}} \Delta^{+}_{\alpha\gamma}(\mathbf{k}, \mathbf{q}) G_{\gamma\beta}\left(\mathbf{k} + \mathbf{q}, \mathbf{k}'; \omega_{r_n}\right) = \mathbf{0} \tag{17.7}$$

$$\sum_{\mathbf{k}_1} \left(\mathbf{k}\alpha \left| i\omega_n - H_0 \right| \mathbf{k}_1\gamma\right) F_{\gamma\beta}\left(\mathbf{k}_1, \mathbf{k}'; \omega_n\right) - \\ - \sum_{\mathbf{q}} \Delta_{\alpha\gamma}(\mathbf{k}, \mathbf{q}) G_{\beta\gamma}\left(-\mathbf{k}', -\mathbf{k} + \mathbf{q}; -\omega_n\right) = 0 \tag{17.8}$$

Уравнсния (17.6)-(17.8) (дифференциальныс в координатном представлении) называются уравиениями Горькова и составляют, вместе с условием согласования (17.5), основу тсоретичсского описания сверхпроводников.

В далынейшем нам часто придется использовать уравнение, определягощсе темпера-

туру сверхпроводящего персхода T_c для различных ситуаций (Iапример, в присутствие примесей или внешнего магнитного поля), получающееся из уравыений Горькова следутощим образом. Вблизи T_c параметр порядка мал и можно, используя (17.6) и (17.8), разложить аномальнуо фупкцию Грина F до первой степени по Δ, а затем подставить в условис согласования. При этом мы приходим к следующему уравнению:

$$\Delta_{\alpha\beta}(\mathbf{k}, \mathbf{q}) = -T_\mathrm{c} \sum_n \sum_{\mathbf{k}', \mathbf{k}'', \mathbf{q}'} V_{\beta\alpha,\lambda\mu}\left(\mathbf{k}, \mathbf{k}'\right) G^{(0)}_{\lambda\gamma}\left(\mathbf{k}' + \frac{\mathbf{q}}{2}, \mathbf{k}'' + \frac{\mathbf{q}'}{2}; \omega_n\right) \times \\ \times G^{(0)}_{\mu\delta}\left(-\mathbf{k}' + \frac{\mathbf{q}}{2}, -\mathbf{k}'' + \frac{\mathbf{q}'}{2}; -\omega_n\right) \Delta_{\gamma\delta}\left(\mathbf{k}'', \mathbf{q}'\right) \tag{17.9}$$

где $G^{(0)}$ есть функция Грина нормального металла с учетом всех внешних полей. Соответствутощее диаграммное выражение изображено на рис. 16. Критическая температура определяется как температура, при которой у линейного интегрального уравнения (17.9) появляется ненулевое решснис.

Для практичсских вычислсний важно знать функцдии Грина пространственно-однородной системы в опсутствие внешних возмущений. В этом случае уравнепия Горькова значительно упрощаются:

$$G_{\alpha\beta}\left(\mathbf{k}, \mathbf{k}'; \omega_n\right) = G_{\alpha\beta}\left(\mathbf{k}, \omega_n\right)\delta\left(\mathbf{k} - \mathbf{k}'\right) \quad \text{и т. д.} \tag{17.10}$$

Следоватешно, параметр порядка зависит лишь от направлсния импульсов $\hat{k}$ на повсрхности Ферми, но ие от прострапственных координат:

$$\Delta_{\alpha\beta}(\mathbf{k}, \mathbf{q}) = \Delta_{\alpha\beta}(\mathbf{k})\delta(\mathbf{q})$$

причем

$$\Delta_{\alpha\beta}(k) = -\Delta_{\beta\alpha}(-k)$$

Легко видеть, что ввсдснные в §5 аномальные средние пепосредственно выражатотся через функшии Грина однородной системы при совпадающих временніх аргумеIітах:

$$F_{\mathbf{k},\alpha\beta} = F_{\alpha\beta}(\mathbf{k},\tau;\mathbf{k},\tau) = T\sum_n F_{\alpha\beta}\left(\mathbf{k},\omega_n\right)$$
$$F^+_{\mathbf{k},\alpha\beta} = T\sum_n F^+_{\alpha\beta}\left(\mathbf{k},\omega_n\right)$$

Подставляя (17.10) в уравнения (17.6)-(17.8) и учитывая, что одночастичный гамилтониан певозмушенной системы диагопален по импупсам и спинам:

$$\langle \mathbf{k}\alpha \left|H_0\right| \mathbf{k}'\beta\rangle = \xi_{\mathbf{k}}\delta\left(\mathbf{k}-\mathbf{k}'\right)\delta_{\alpha\beta}$$

причем $\xi_{\mathbf{k}} = \xi_{-\mathbf{k}}$, получаем

$$\begin{aligned}
\left(i\omega_n - \xi_k\right) G_{\alpha\beta}\left(\mathbf{k},\omega_n\right) + \Delta_{\alpha\gamma}(\mathbf{k}) F^+_{\gamma\beta}\left(\mathbf{k},\omega_n\right) &= \delta_{\alpha\beta} \\
\left(i\omega_n + \xi_k\right) F^+_{\alpha\beta}\left(\mathbf{k},\omega_n\right) + \Delta^+_{\alpha\gamma}(\mathbf{k}) G_{\gamma\beta}\left(\mathbf{k},\omega_n\right) &= 0 \\
\left(i\omega_n - \xi_k\right) F_{\alpha\beta}\left(\mathbf{k},\omega_n\right) - \Delta_{\alpha\gamma}(\mathbf{k}) G_{\beta\gamma}\left(-\mathbf{k},-\omega_n\right) &= 0
\end{aligned} \tag{17.11}$$

Решение данной алгебраической системы уравнений выглядит следующим образом:

$$\begin{aligned}
G_{\alpha\beta}\left(\mathbf{k},\omega_n\right) &= -\left(i\omega_n + \xi_k\right)\left[\omega_n^2 + \xi_k^2 + \Delta(\mathbf{k})\Delta^+(\mathbf{k})\right]^{-1}_{\alpha\theta} \\
F_{\alpha\beta}\left(\mathbf{k},\omega_n\right) &= \Delta_{\alpha\gamma}(\mathbf{k})\left[\omega_n^2 + \xi_k^2 + \left(\Delta^+(\mathbf{k})\Delta(\mathbf{k})\right)\right]^{-1}_{\gamma\beta}
\end{aligned} \tag{17.12}$$

Для всех свсрхпроводящих фаз с синглетным спариванием, а также для унитарных фаз с триплетным спариванием, выполняется условие $\left(\Delta\Delta^+\right)_{\alpha\beta} \propto \delta_{\alpha\beta}$, и функции Грина принимагот вид

$$\begin{aligned}
G_{\alpha\beta}\left(\mathbf{k},\omega_n\right) &= -\frac{i\omega_n + \xi_k}{\omega_n^2 + \xi_k^2 + \Delta_k^2}\delta_{\alpha\beta} \\
F_{\alpha\beta}\left(\mathbf{k},\omega_n\right) &= \frac{\Delta_{\alpha\beta}(\mathbf{k})}{\omega_n^2 + \xi_k^2 + \Delta_k^2}
\end{aligned} \tag{17.13}$$

где

$$\Delta^2_{\mathbf{k}} = \frac{1}{2}\,\mathrm{Sp}\,\Delta^+(\mathbf{k})\Delta(\mathbf{k})$$

Отсюдда для функшии Грина нормального состояния (то есть при $\Delta = 0$) мы получаем

$$G^{(0)}_{\alpha\beta}\left(\mathbf{k},\omega_n\right) = \frac{\delta_{\alpha\beta}}{i\omega_n - \xi_k} \tag{17.14}$$

Для неунитарных фаз с триплетным спариванием

$$\left(\Delta\Delta^+\right)_{\alpha\beta} = \Delta^2\left(\mathrm{dd}^*\,\delta_{\alpha\beta} + \mathbf{m}\sigma_{\alpha\beta}\right)$$

здесь $\mathrm{m}(\mathbf{k}) = i\,\mathrm{d}(\mathbf{k}) \times \mathrm{d}^*(\mathbf{k}) \neq 0$, и выражения для функций Грина сверхпровопшика выглялят иесколько сложнее:

$$G_{\alpha\beta}\left(\mathbf{k},\omega_n\right)=-\left(i\omega_n+\xi_k\right)\frac{\left(\omega_n^2+\xi_k^2+\Delta^2|\ \mathrm{d}(\mathbf{k})|^2\right)\delta_{\alpha\beta}+\Delta^2\ \mathrm{m}(\mathbf{k})\sigma_{\alpha\beta}}{\left(\omega_n^2+E_{\mathrm{k},-}^2\right)\left(\omega_n^2+E_{k,-}^2\right)}$$

$$F_{\alpha\beta}\left(\mathbf{k},\omega_n\right)=\Delta\left(i\sigma\sigma_y\right)_{\alpha\beta}\frac{\left(\omega_n^2+\xi_k^2+\Delta^2|\ \mathrm{d}(\mathrm{k})|^2\right)\mathrm{d}(\mathbf{k})-i\Delta^2\ \mathrm{m}(\mathbf{k})\times\mathrm{d}(\mathbf{k})}{\left(\omega_n^2+E_{\mathbf{k},\mathrm{t}}^2\right)\left(\omega_n^2+E_{k,-}^2\right)} \tag{17.15}$$

где

$$E_{\mathbf{k},\pm}=\sqrt{\xi_k^2+\Delta^2\left(|\ \mathrm{d}(\mathbf{k})|^2\pm|\mathrm{m}(\mathbf{k})|\right)} \tag{17.16}$$

Уравненис, определяющщее температурное поведение параметра порядка, получается подстановкой выражения (17.13) для функции P в условис согласования (17.5):

$$\Delta_{\alpha\beta}(\mathbf{k})=-T\sum_n\sum_{k'}V_{\beta\alpha,\gamma\delta}\left(\mathbf{k},\mathbf{k}'\right)\frac{\Delta_{\gamma\delta}\left(\mathbf{k}'\right)}{\omega_n^2+\xi_{k'}^2+\Delta_{\mathbf{k}'}^2} \tag{17.17}$$

(аналогитным образом может быть получено и соответствующее уравненис в случае неунитарных фаз (см. [13]). Дчя вычисления суммы по частотам в (17.17) воспользусмся формулой

$$\sum_{n=-\infty}^{\infty}\frac{1}{(2n+1)^2\pi^2+x^2}=\frac{1}{2x}\ln\frac{x}{2} \tag{17.18}$$

Из (17.17) получаем:

$$\Delta_{\alpha\beta}(\mathrm{k})=-\sum_{\mathbf{k}'}V_{\beta\alpha,\gamma\delta}\left(\mathrm{k},\mathrm{k}'\right)\Delta_{\gamma\delta}\left(\mathrm{k}'\right)\frac{1}{2E_{\mathrm{k}'}}\ \mathrm{th}\left(\frac{E_{\mathrm{k}'}}{2T}\right) \tag{17.19}$$

откуда, учитывая, что $\mathrm{th}\ \left(E_{\mathbf{k}'}/2T\right)\ =\ 1-2f_{\mathbf{k}'}$, где $f_{\mathbf{k}'}$ - фермиевская функция распределения, возвращаемся к формулам (6.5) и (6.6). Уравпенис, определяющее критическуо температуру T_c, получается пугем подстановки $\Delta\ =\ 0$ (1. с. замены $E'_{\mathbf{k}'}\to|\varepsilon_{k'}|$) в (17.19).

Техника функций Грина для сверхпроводника может быть сформудирована в болсе компактном виде, формалыо напоминаоощсм диаграммную техику аля нормальной ферми-жидкости, если объединить G,F и F^+в
одну матричную функцию Грина $\hat{G}$, используя векторные операторы (5.23) в мацубаровском представлении. По опредслснию:

$$\hat{G}\left(\mathbf{k}_1,\mathbf{k}_2;\omega_n\right)=-\int_0^{1/T}d\tau e^{i\omega_n\tau}\left\langle T_\tau A_{\mathbf{k}_1}(\tau)A^+_{\mathbf{k}_2}(0)\right\rangle=$$

$$=\begin{pmatrix}G_{\alpha\beta}\left(\mathbf{k}_1,\mathbf{k}_2;\omega_n\right) & -F_{\alpha\beta}\left(\mathbf{k}_1,\mathbf{k}_2;\omega_n\right)\\ -F^+_{\alpha\beta}\left(\mathbf{k}_1,\mathbf{k}_2;\omega_n\right) & -G_{\beta\alpha}\left(-\mathbf{k}_2,-\mathbf{k}_1;-\omega_n\right)\end{pmatrix} \tag{17.20}$$

Матричные элементы $\hat{G}$ являотся, в свою очередь, матрицами 2×2 в спиновом пространстве. В пространственно-однородном случае имеем (см. (17.12)):

$$\hat{G}_0\left(\mathbf{k},\omega_n\right)=-\frac{1}{\omega_n^2+\xi_k^2+\Delta_k^2}\begin{pmatrix}\left(i\omega_n+\xi_k\right)\delta_{\alpha\beta} & \Delta_{\alpha\beta}(\mathbf{k})\\ \Delta^+_{\alpha\beta}(\mathbf{k}) & \left(i\omega_n-\xi_k\right)\delta_{\alpha\beta}\end{pmatrix}=$$

$$=-\frac{i\omega_n\hat{\tau}_0+\xi_k\hat{\tau}_3+\dot{\Delta}(\mathbf{k})}{\omega_n^2+\xi_k^2+\Delta_k^2} \tag{17.21}$$

где $\hat{\tau}_i$ - матрицы Паули в «пространстве» частица-дырка.

Спектральное представление и элергии возбуждепий. При решении конкретных задач необходимо уметь вычислять суммы по мацубаровским частотам. Для этого удобно использовать так называемое спектралыно разложение функций Грина, которое в матричных обозначениях имеет вид

$$\hat{G}\left(\mathbf{k}, \omega_n\right) = \int\limits_{-\infty}^{+\infty} \frac{dz}{2\pi} \frac{\hat{\rho}(\mathbf{k}, z)}{i\omega_n - z}$$

После этого суммы по фермионным частотам легко вычисляются с помощью тождества (ср. с (17.18))

$$T \sum_n \frac{1}{i\omega_n - z} = \frac{1}{2} \text{ th } \frac{z}{2T} \tag{17.22}$$

Вещественная спектралыая плотность $\hat{\rho}$ выражается черсз фурьс-образы запаздываощих и опережаіощих функций Грина [1] следующим образом:

$$\hat{\rho}(\mathbf{k}, \omega) = -2 \operatorname{Im} \hat{G}^R(\mathbf{k}, \omega) = i \left(\hat{G}^R(\mathbf{k}, \omega) - \hat{G}^A(\mathbf{k}, \omega) \right)$$

В свою очередь, запаздывающис (опережающие) функции Грина получаюотся из $\hat{G}\left(\mathbf{k}, \omega_n\right)$ путем аналитического прододжения па верхнюю (нижнюю) полуплоскость комплекстіхх ω:

$$\hat{G}^{R(\boldsymbol{A})}(\mathbf{k}, \omega) = \hat{G}\left(\mathbf{k}, \omega_n\right)\Big|_{i\omega_n \to \omega \pm i0} \tag{17.23}$$

Спектр элементарнцх возбуждений сверхпроводника определяется полюсами функции G^R. Выполняя аналитическое продолжение в (17.13), получаем уравнение, опрспсляющсе спектр:

$$\det \left\| E^2 - \xi_k^2 - \Delta(\mathbf{k}) \Delta^+(\mathbf{k}) \right\| = 0 \tag{17.24}$$

Подставляя сюда выражения (5.18) и (5.20), получаем, что энергии возбуждени даются формулами

$$E_{\mathbf{k}} = \sqrt{\xi_k^2 + \Delta^2 |g(\mathbf{k})|^2}$$

для синглетого спаривания и

$$E_{\mathbf{k}} = \sqrt{\xi_k^2 + \Delta^2 |\ \mathrm{d}(\mathbf{k})|^2}$$

для унитарных фаз с триплетньм спариванием, то есть возвращаемся к результатам (5.33) и (5.34).

Для неунитарных фаз спектр возбуждений расщепляется на две ветви аналогично тому, как это происходит в обычных магнитных материалах, поскольку неунитарные фазы обладают собственным магнитиым моментом:

$$E_{\mathrm{k},\pm} = \sqrt{\xi_k^2 + \Delta^2 \left(|\ \mathrm{d}(\mathbf{k})|^2 \pm |\mathrm{d}^*(\mathbf{k}) \times \mathrm{d}(\mathbf{k})| \right)} \tag{17.25}$$

Отсюда следует, что положение нулей спектра возбуждений для любых фаз триплетного спаривания определяется уравнением $\det \Delta(k) = 0$, то есть $\mathrm{d}^2(\mathbf{k}) = 0$.

[11] Наломним, тто функцни $\hat{G}^R \left(\hat{G}^A \right)$ отличаюгся от мацубаровской функции $\hat{G}$ (17.20) заменой τ-упорядоченного пронзведекия опсраторов на их запаздывающие (опережаюиие) антикоммутаторы.

Плотность состоянии. Плотность состояний квазичастиц по определению

$$N(E) = \sum_{\mathbf{k}\alpha} \delta\left(E - E_{\mathbf{k}}\right) \tag{17.26}$$

Эта величина следующим образом вьражается через функцию Грина:

$$N(E) = \frac{1}{2\pi} \sum_{\mathbf{k}\alpha} \rho(\mathbf{k}, E) = -\frac{1}{\pi} \operatorname{Im} \sum_{\mathbf{k}\alpha} G\left(\mathbf{k}, \omega_n\right) \Big|_{i\omega_n \to E + i0} \tag{17.27}$$

Из (17.26), с учетом вырaженiя (5.29) для спектра возбуждений, получаем:

$$\begin{aligned} N\left(E'\right) &= 2 \int \frac{d^3k}{(2\pi)^3} \delta\left(E - E_{\mathbf{k}}\right) = 2N_0 \int \frac{d\Omega}{4\pi} \int d\xi \delta\left(E - E_{\mathbf{k}}\right) = \\ &= 2N_0 \int \frac{d\Omega}{4\pi} \frac{dE'' E'}{\sqrt{E'^2 - \Delta_{\mathbf{k}}^2}} \delta\left(E' - E'\right) = 2N_0 \int \frac{d\Omega}{4\pi} \frac{E}{\sqrt{E^2 - \Delta_{\mathbf{k}}^2}} \end{aligned} \tag{17.28}$$

где N_0 есть плотность состояний на урозне Ферми в нормалыном металле на одну проекдию спина, а интсгрирование по утлам производится в пределах $\Delta_{\mathbf{k}}^2 < E^2$.

Для обычного изотропного свсрхпроводника с s-спариванием ($g(\mathbf{k}) = 1$) из (17.28) следует, что

$$N(E) = 2N_0 \begin{cases} 0, & \text{при } E < \Delta \\ \frac{E}{\sqrt{E^2 - \Delta^2}}, & \text{при } E > \Delta \end{cases} \tag{17.29}$$

то есть плотность квазичастичных состояний тождественно обращается в нуль при $E < \Delta$.

Посмотрим теперь, что изменится, если в спектре возбуждений имеются нули. В качестве примера рассмотрим сверхпроводник со структурой A-фазы,
параметр порядка в котором имеет вид (3.8), то есть щель обращастся в нуль на северном и юожном полюсах ферми-поверхности. Из (17.28) получаем:

$$N(E) = 2N_0 \int \frac{d\Omega}{4\pi} \frac{E}{\sqrt{E^2 - \Delta^2\left(\hat{k}_x^2 + \hat{k}_y^2\right)}} = N_0 \int \sin\theta d\theta \frac{E}{\sqrt{E^2 - \Delta^2 \sin^2\theta}}$$

причем $\sin\theta < E/\Delta$. При $E \to 0$ основной вклад в интеграл дают окрестности полюосов $\theta < E/\Delta$ и $\pi - \theta < E/\Delta$, следовательно,

$$N(E) \approx N_0 \int_0^{E/\Delta} 0 d\theta \frac{E}{\sqrt{E^2 - \Delta^2\theta^2}} \sim N_0 \left(\frac{E}{\Delta}\right)^2 \tag{17.30}$$

Таким образом, мы имеем ненулевуюо плотность состояний.

Можно убедиться в том, что если щепь в спектре обращается в нуль на целой линии (это имест место, например, для сверхпроводника со структурой полярной фазы), то

$$N(E) \sim N_0 \frac{E}{\Delta}. \tag{17.31}$$

Подобные степенные зависимости плотности состояний квазичастиц от энергии приводят к степенному (а не экспоненциальному) гемпературному поведению термодинамических и кинетических характеристик теобычных сверхпроводников.

19.2.2 18. Ginzburg–Landau Functional

Полученные в предыдущем параграфе уравнения для функций Грина сверхпроводника - уравнения Горькова - позволяют в принципе полностью описать свойства сверхпроводящего состояния. На практике, однако, существует широкий крут задач, в которых нет необходимости использовать эти достаточно сложные уравнения непосредственно. В частности, вблизи критической температуры, когда малы как сам сверхтроводящий параметр порядка ($\Delta \propto (T_c - T)^{1/2}$), так и его градиенты (то есть $\Delta(\mathrm{r})$ медленно меняяется на характсрном масштабе теории сверхпроводимости - размере куперовской пары ξ_0), удобно использовать уравения Гинзбурга-Лашдау (см. 12). Эти уравнения проще всего вывести с использованием техники функций Грина, вычисляя свободную энсргию сверхпроводника $\mathcal{F}_\mathrm{s}$ как функционал от параметра порядка, с последующей ее минимизацией по Δ.

Мы рассмотрим в качестве примера сверхпроводник с p-спариванием вблизи критической температуры в отсутствие примесей (см. [72]), для которого потенциал спаривательного взаимодействия, входящий в гамильтониан (17.1), выгдядит следугощим образом:

$$V(\mathbf{k}, \mathbf{k}') = -3V \frac{\mathbf{k}\mathbf{k}'}{k_\mathrm{F}^2} \tag{18.1}$$

где константа связи V отлична от нуля лишь в узком слое толщиной ε_1 вблизи ферми-сферы (см.)5.4)).

Свободная энергия определяется формупой $\mathcal{F} = -T \ln Z$, где $Z = \mathrm{Sp}\left(e^{-\beta H}\right)$ есть статистическая сумма1. Для гамитьтониапа H мы используем соответствующес приближению среднего поля выражение (5.22), переписав его в виде, содержащем только сверхпроводящий парамстр порядка Δ и фермионньге операторы рождения и уiичтожешия:

$$\begin{aligned} H = \sum_{\mathbf{k}} \xi_k a^+_{\mathbf{k}\alpha} a_{\mathbf{k}\alpha} + \frac{1}{2V} \sum_{\mathbf{k},\mathbf{q}} S_p \Delta^+(\mathbf{k},\mathbf{q}) \Delta(\mathbf{k},\mathbf{q}) + \\ + \frac{1}{2} \sum_{\mathbf{k},\mathbf{q}} \Big(\Delta_{\alpha\beta}(\mathbf{k},\mathbf{q}) a^+_{\mathbf{k}+\mathbf{q}/2,\alpha} a^+_{-\mathbf{k}+\mathbf{q}/2,\beta} + \\ + \Delta^+_{\alpha\beta}(\mathbf{k},\mathbf{q}) a_{-\mathbf{k}+\mathbf{q}/2,\alpha} a_{\mathbf{k}+\mathbf{q}/2,\beta} \Big) \end{aligned} \tag{18.2}$$

В отличие от (5.22), здесь учтена возможная пространственшая неоднородность парамстра порядка [2]

Рассматривая содержашие Δ слагаемыс в (18.2) как возмущение $\hat{H}_\mathrm{int}$ и переходя к мацубаровскому представлению, разложим разность свободных энергий свсрхпроводящсго и нормального состояний

$$-T \ln \left\langle \exp \left[-\int_0^{1/\tau} d\tau \hat{\Pi}_\mathrm{int}(\tau) \right] \right\rangle$$

вплоть до членов тетвертой степени по Δ. Имеем:

$$\mathcal{F}_\mathrm{cond} = \mathcal{F}_\mathrm{s} - \mathcal{F}_\mathrm{n} = \frac{1}{2V} \int d^3 r \int \frac{d\Omega}{4\pi} \mathrm{Sp}\, \Delta^+(\mathbf{k},\mathbf{r}) \Delta(\mathbf{k},\mathbf{r}) + \mathcal{F}_2 + \mathcal{F}_4 \tag{18.3}$$

Здесь

$$\Delta_{\lambda\mu}(\mathbf{k},\mathbf{r}) = \int \frac{d^3q}{(2\pi)^3}\Delta_{\lambda\mu}(\mathbf{k},\mathbf{q})e^{i\mathbf{qr}} = (i\sigma_\alpha\sigma_y)_{\lambda\mu} A_{\alpha i}(\mathbf{r})\hat{k}_i \tag{18.4}$$

• параметр порядка сверхпроводника с p-спариванием,

$$\mathcal{F}_2 = -\int d^3r_1 d^3r_2 A^*_{\alpha i}(\mathbf{r}_1)\, S_{ij,\alpha\beta}(\mathbf{r}_1,\mathbf{r}_2)\, A_{\beta j}(\mathbf{r}_2) \tag{18.5}$$

где ядро S выглядит следуоошим образом:

$$S_{ij,\alpha\beta}(\mathbf{r}_1,\mathbf{r}_2) = \lim_{\mathbf{r}'_{1,2}\to\mathbf{r}_{1,2}} \frac{T}{4k_\mathrm{F}^2}\sum_n \left(\frac{\partial}{\partial r_{1,i}} - \frac{\partial}{\partial r'_{1,i}}\right)\left(\frac{\partial}{\partial \mathbf{r}_{2,j}} - \frac{\partial}{\partial r'_{2,j}}\right)\times$$
$$\times (\sigma_y\sigma_\alpha)_{\lambda\mu} G^{(0)}_{\lambda\gamma}(\mathbf{r}_1,\mathbf{r}_2;\omega_n)(\sigma_\beta\sigma_y)_{\gamma\delta} G^{(0)}_{\mu\delta}(\mathbf{r}'_1,\mathbf{r}'_2;-\omega_n) \tag{18.6}$$

Входящие сюда фуункции $G^{(0)}$ прелставляюот собой функции Грина нормального металла с учетом взаимодействия как зарядов, так и спинов элсктронов с внешним магнитным полем. Наконец члеI четвертого порядка в разложении свободной энергии имеет вид

$$\mathcal{F}_4 = \frac{1}{4}T_\mathrm{c}\sum_n\sum_{\{\mathbf{q}_\mathrm{i}\}}\sum_{\mathbf{k}} \mathrm{Sp}\,\Delta^+(\mathbf{k},\mathbf{q}_1)\, G^{(0)}(\mathbf{k},\omega_n)\times$$
$$\times\,\Delta(\mathbf{k},\mathbf{q}_2)\, G^{(0)}(-\mathbf{k},-\omega_n)\,\Delta^+(\mathbf{k},\mathbf{q}_3)\, G^{(0)}(\mathbf{k},\omega_n)\times$$
$$\times\,\Delta(\mathbf{k},\mathbf{q}_4)\, G^{(0)}(-\mathbf{k},-\omega_n)\,\delta(\mathbf{q}_1+\mathbf{q}_3-\mathbf{q}_2-\mathbf{q}_4) \tag{18.7}$$

Все импупшсы $\mathbf{q}_i$ в функциях Грина положены равными пгулго, так как рассмотрение конечных импульсов пужно лишь при вычислении градиентных члснов чствертой степени по Δ, которыс нас нс интсрссуот.

Если пренебречь дсйствием поля на спины электронов (мы вернемся к этому вопросу позже), то

$$G^{(0)}_{\lambda\gamma}(\mathbf{r}_1,\mathbf{r}_2;w_n) = G^{(0)}(\mathbf{r}_1,\mathbf{r}_2;w_n)\,\delta_{\lambda\gamma}$$

Для квадратичного закона дисперсии при $H=0$ фурье-образ выражсния (17.14) есть

$$G^{(0)}(\mathbf{r},\omega_n) = -\frac{\pi N_0}{k_\mathrm{F} r}\exp\left(ik_\mathrm{F} r\sqrt{1+\frac{i\omega_n}{\varepsilon_\mathrm{F}}}\,\mathrm{sign}\,\omega_n\right)\approx$$
$$\approx -\frac{\pi N_0}{k_\mathrm{F} T}\exp\left(ik_\mathrm{F} r\,\mathrm{sign}\,\omega_n - \frac{|\omega_n|}{v_\mathrm{F}}r\right) \tag{18.8}$$

При $\Delta=0$, но $H\neq 0$, из (17.6) получаем следующее уравнение для функции Грина G:

[11] Более точио, таким образом определяется термодинамический нотенциал Ω, однако, согласно обшим принципам термодинамики, разность $\Omega_\mathrm{s}-\Omega_\mathrm{n}$ равна разности свободных энергий $\mathcal{F}_\mathrm{s}-\mathcal{F}_\mathrm{n}$.

[2] В общем случае второе слагаемое в правой части (18.2) имеет вид:

$$-\frac{1}{2}S_\mathbf{p}\sum \Delta^+(\mathbf{k},q)\hat{V}^{-1}(\mathbf{k},\mathbf{k}')\,\Delta(\mathbf{k}',q)$$

где $\dot{V}^{-1}$ удовлетворяет урависнию $\sum\limits_{\mathbf{k}''}\hat{V}^{-1}(\mathbf{k},\mathbf{k}'')\,\hat{V}(\mathbf{k}'',\mathbf{k}') = \delta(\mathbf{k}-\mathbf{k}')$. Используя ортогоналыость и полноту системы базиспих функций, приходим к выраженик (18.2).

$$\left[i\omega_n - \frac{h^2}{2m}\left(-i\frac{\partial}{\partial \mathbf{r}_1} + \frac{e}{\hbar c}\mathbf{A}\left(\mathbf{r}_1\right)\right)^2 + \epsilon_{\mathbf{F}}\right] G^{(0)}\left(\mathbf{r}_1, \mathbf{r}_2; \omega_n\right) = \delta\left(\mathbf{r}_1 - \mathbf{r}_2\right)$$

В последующих выкладках мы используем систему сдиниц, в которой $\hbar = 1$, при необходимости восстапавливая постоянную Планка в окогчателыных ответах.

Ищем решение этого уравнения в виде $G^{(0)}\left(\mathbf{r}_1, \mathbf{r}_2; \omega_n\right) =$

$$= G^{(0)}\left(\mathbf{r}_1 - \mathbf{r}_2, \omega_n\right) \exp\left[\frac{ie}{c}\int\limits_{\mathbf{r}_1}^{\mathbf{r}_2} \mathbf{A}(\mathbf{r}) d\mathbf{r} + i\psi\left(\mathbf{r}_1 - \mathbf{r}_2, \omega_n\right\}\right] \tag{18.9}$$

Интегрирование в показателе экспоненты идет по прямой линии, соединягощей точки $\mathbf{r}_1$ и $\mathbf{r}_2$. Для функции ψ получаем уравнение [73]:

$$k_F \hat{\mathbf{r}} \operatorname{sign} \omega_n \frac{\partial \psi\left(\mathbf{r}, \omega_n\right)}{\partial \mathbf{r}} + \frac{e^2}{4c^2}(\mathbf{H} \times \mathbf{r})^2 = 0$$

откуда видно, что в даже в полях порядка $H_{c\,2}(0) \sim \Phi_0 / \left(\pi \xi_0^2\right)$ добавка к фазе имест малость $\sim \left(k_{\mathbf{r}} \xi_0\right)^{-1}$ по сравнению с первым членом в показателе экспоненты в (18.9). Поэтому для функции Грина имеем:

$$\begin{aligned} G^{(0)}\left(\mathbf{r}_1, \mathbf{r}_2; \omega_n\right) &= G^{(0)}\left(\mathbf{r}_1 - \mathbf{r}_2; \omega_n\right) \exp\left(\frac{ie}{c}\int\limits_{\mathbf{r}_1}^{\mathbf{r}_2} \mathbf{A}(\mathbf{r}) d\mathbf{r}\right) \approx \\ &\approx G^{(0)}\left(\mathbf{r}_1 - \mathbf{r}_2; \omega_n\right) \exp\left(\frac{ie}{c}\mathbf{A}\left(\mathbf{r}_1\right)\left(\mathbf{r}_2 - \mathbf{r}_1\right)\right) \end{aligned} \tag{18.10}$$

Последнее равенство написано на том основании, что характерный масштаб изменения вектор-потенциала (лондоновская глубина проникновения) вблизи T_c значительно превышает расстояние, на котором спадают нулевые функции Грина (18.8).

Подставляя (18.8) и (18.10) в (18.6), убеждаемся, что главный вклад в ядро происходит от дифференцирования меняющихся на атомных масштабах множителей вида $\exp\left(ik_{\mathrm{F}} r \operatorname{sign} \omega_n\right)$, а поправки первого порядка малости по магнитному полю возникают при дифференцировании зависящих от поля фазовых множителей в (18.10). Имеем [31]:

$$\begin{aligned} &S_{ij,\alpha\beta}\left(\mathbf{r}_1, \mathbf{r}_2\right) = S_{ij}\left(\mathbf{r}_1, \mathbf{r}_2\right) \delta_{\alpha\beta} \\ &S_{ij}\left(\mathbf{r}_1, \mathbf{r}_2\right) = T\left(\frac{\pi N_0}{k_{\mathbf{F}} R}\right)^2 \sum_n \exp\left(-\frac{2\left|\omega_n\right|}{v_{\mathbf{F}}} R\right)\left(\hat{R}_i \hat{R}_j + \frac{ie}{2k_{\mathrm{F}}^2 c} e_{ijk} H_k\right) \times \\ &\times \exp\left(\frac{2ie}{c}\mathbf{A}\left(\mathbf{r}_1\right)\mathbf{R}\right) \end{aligned} \tag{18.11}$$

где $\mathbf{R} = \mathbf{r}_2 - \mathbf{r}_1$ и $\hat{\mathbf{R}} = \mathbf{R}/|\mathbf{R}|$.

Оценим второй член в квадратных скобках в правой части (18.11):

$$\frac{eH}{k_{\mathrm{F}}^2 c} \sim \frac{1}{\left(k_{\mathrm{F}} \xi_0\right)^2} \frac{H}{II_{c2}(0)}$$

В нулевом порядке по параметру квазиклассичности $\left(k_F \xi_0\right)^{-1}$ им можно пренсбречь, тогда

$$S_{ij}\left(\mathbf{r}_1,\mathbf{r}_2\right)=K_{ij}^{(0)}(\mathbf{R})\exp\left(\frac{2ie}{c}\mathbf{A}\left(\mathbf{r}_1\right)\mathbf{R}\right) \tag{18.12}$$

где

$$S_{ij}^{(0)}(\mathbf{R})=T\left(\frac{\pi N_0}{k_F R}\right)^2\sum_n\exp\left(-\frac{2\left|\omega_n\right|}{v_F}R\right)\hat{R}_i\hat{R}_j$$

Мы видим, что ядро $K^{(0)}$ эхспонснциально убывает на расстояниях между $\mathbf{r}_1$ и $\mathbf{r}_2$, превышающих

$$\xi_0=\frac{v_F}{2\pi T_c}$$

и тем самым в теории появляется характерный микроскопичсскй масштаб размер куперовской пары (или длина когерентности) ξ_0. С друтой стороны, параметр порядка сверхпроводника изменяется на масштабе порядка корреляционной длины $\xi(T)$, причем $\xi/\xi_0\sim(1-T/T_c)^{-1/2}\gg 1$ (см. 12). 100

Следовательно, вблизи T_c мы можем разложить в подынтегральном выражении в (18.5) как параметр порядка, так и фазовый множитель в ядре вплоть до второй степени по $\mathbf{r}_2-\mathbf{r}_1=\mathbf{R}$. Имеем:

$$\begin{aligned}\mathcal{F}_2=&-\int d^3r A_{\alpha i}^*(\mathbf{r})\int d^3R S_{ij}^{(0)}(\mathbf{R})\times\\&\times\left[1+\frac{2ie}{c}\mathbf{A}(\mathbf{r})\mathbf{R}+\frac{1}{2}\left(\frac{2ie}{c}\right)^2(\mathbf{A}(\mathbf{r})\mathbf{R})^2\right]\times\\&\times\left[A_{\alpha j}(\mathbf{r})+\frac{\partial A_{\alpha j}}{\partial\mathbf{r}}\mathbf{R}+\frac{1}{2}\frac{\partial^2 A_{\alpha j}}{\partial r_k\partial r_l}R_kR_l\right]\end{aligned}$$

Выделяя явно члсны пулевой степени по $\mathbf{R}$ и интегрируя члены второй степсни по тастям, получаем:

$$\mathcal{F}_2=\mathcal{F}_{\text{uniform}}+\mathcal{F}_{\text{grad}} \tag{18.13}$$

где

$$\mathcal{F}_{\text{uniform}}=-\int d^3r A_{\alpha i}^*(\mathbf{r})A_{\alpha j}(\mathbf{r})\int d^3R S_{ij}^{(0)}(\mathbf{R}) \tag{18.14}$$

$$\mathcal{F}_{\text{grad}}=\frac{1}{2}\int d^3r\left(D_kA_{\alpha i}\right)^*\left(D_lA_{\alpha j}\right)\int d^3R S_{ij}^{(0)}(\mathbf{R})R_kR_l \tag{18.15}$$

а $\mathbf{D}=-i(\partial/\partial\mathbf{r})+(2e/c)\mathbf{A}(\mathbf{r})$ - ковариантная производная.

Вычислим входящие в (18.14) и (18.15) интегралы по R. Для однородной части имеем:

$$\begin{aligned}\int d^3R S_{ij}^{(0)}(\mathbf{R})=&T\left(\frac{\pi N_0}{k_F}\right)^2\sum_n\int_0^\infty dR\exp\left(-\frac{2\left|\omega_n\right|}{v_F}R\right)\int d\Omega\hat{R}_i\hat{R}_j=\\=&\frac{2\pi}{3}\delta_{ij}v_F\left(\frac{\pi N_0}{k_F}\right)^2T\sum_n\frac{1}{|\omega_n|}=\frac{2\pi}{3}\delta_{ij}N_0T\sum_{n\geq 0}\frac{1}{\omega_n}\end{aligned} \tag{18.16}$$

Обрезая логарифмически расходящупося сумму на граничной частоте ε_1, получаем:

$$2\pi T\sum_{n\geq 0}\frac{1}{\omega_n}=\ln\frac{\varepsilon_1}{2\pi T}+\ln 4\gamma=\frac{1}{N_0V}+\ln\frac{T_c}{T}=\frac{1}{N_0V}-\frac{T-T_c}{T_c} \tag{18.17}$$

Здесь мы воспользовались формулой (6.10) и тождеством

$$\lim_{N\to\infty}\sum_{n\geq 0}^{N}\frac{1}{n+1/2}=\ln N+\ln 4\gamma$$

Подставдяя (18.16) и (18.17) в (18.14), получаем:

$$\mathcal{F}_{\text{uniform}}=\frac{1}{3}\left(-\frac{1}{V}+N_0\frac{T-T_c}{T_c}\right)\int d^3rA^*_{\alpha i}(\mathbf{r})A_{\alpha i}(\mathbf{r}) \tag{18.18}$$

Подставляя (18.18) в (18.3), убеждаемся, что однородные слагаемые, явно содержащие константу связи, сокращают друг друга.

Для градиентной части имеем:

$$\begin{aligned}\int d^3RS^{(0)}_{ij}(\mathbf{R})R_kR_l=T\left(\tfrac{\pi N_0}{k_F}\right)^2\sum_n\int_0^\infty dRR^2\exp\left(-\tfrac{2|\omega_n|}{v_{\text{F}}}R\right)\times\\ \times\int d\Omega\hat{R}_i\hat{R}_j\hat{R}_k\hat{R}_l=\tfrac{\pi}{15}\left(\delta_{ij}\delta_{kl}+\delta_{ik}\delta_{jl}+\delta_{il}\delta_{jk}\right)v_{\text{F}}^2N_0T_c\sum_{n\geq 0}\tfrac{1}{\omega_n^3}=\\ =\tfrac{7\zeta(3)}{120}\left(\delta_{ij}\delta_{kl}+\delta_{ik}\delta_{jl}+\delta_{il}\delta_{jk}\right)\tfrac{N_0v_{\text{F}}^2}{\pi^2T_c^2}\end{aligned} \tag{18.19}$$

Сравнивая полученный результат с феномснологическим выражением (15.20) для свободной энергии сверхпроводника с p-спариванием, получаем окончательно следующие значения констант [72]:

$$K_1=K_2=K_3=\frac{7\zeta(3)N_0v_F^2}{240\pi^2T_c^2}=\frac{7\zeta(3)}{60}N_0\xi_0^2 \tag{18.20}$$

Рассмотрим теперь член четвертого порядка в разложении свободной энергии. Подставляя в $\mathcal{F}_4$ выражения (18.4) и (17.13), а затем вычисляя интеграл по углам и след по спиновым индексам с использованием тождества

$$\text{Sp}\left(\boldsymbol{\sigma}\mathbf{d}_1\right)\left(\sigma\mathbf{d}_2\right)\left(\sigma\mathbf{d}_3\right)\left(\sigma\mathbf{d}_4\right)=2\left(\mathbf{d}_1\mathbf{d}_2\right)\left(\mathbf{d}_3\mathbf{d}_4\right)-2\left(\mathbf{d}_1\times\mathbf{d}_2\right)\left(\mathbf{d}_3\times\mathbf{d}_4\right)$$

получаем:

$$\begin{aligned}\mathcal{F}_4=&\frac{B}{4}\sum_{\mathbf{q}_1}\left(-A^*_{\alpha i}A_{\beta j}A^*_{\alpha i}A_{\beta j}+2A^*_{\alpha i}A_{\alpha i}A^*_{\beta j}A_{\beta j}-2A^*_{\alpha i}A_{\beta i}A^*_{\alpha j}A_{\beta j}+\right.\\ &\left.+2A^*_{\alpha i}A_{\beta i}A^*_{\beta j}A_{\alpha j}+2A^*_{\alpha i}A_{\alpha j}A^*_{\beta i}A_{\beta j}\right)\delta\left(\mathbf{q}_1+\mathbf{q}_3-\mathbf{q}_2-\mathbf{q}_4\right)\end{aligned} \tag{18.21}$$

где все слагаемые в фигурных скобках зависят от импульсов следующим образом: $A^*_{\alpha i}A_{\beta j}A^*_{\alpha i}A_{\beta j}=A^*_{\alpha i}\left(\mathrm{q}_1\right)A_{\beta j}\left(\mathrm{q}_2\right)A^*_{\alpha i}\left(\mathrm{q}_3\right)A_{\beta j}\left(\mathrm{q}_4\right)$ и т. п., а

$$B=\frac{2}{15}N_0T_c\sum_n\int d\xi\frac{1}{\left(\omega_n^2+\xi^2\right)^2}=\frac{7\zeta(3)}{60}\frac{N_0}{\pi^2T_{\text{c}}^2}$$

Возвращаясь в (18.21) в координатное представление и сравнивая результат с (11.1), получаем значения коистант [34, 74]:

$$-2\beta_1=\beta_2=-\beta_3=\beta_4=\beta_5=\frac{7\zeta(3)}{120}\frac{N_0}{\pi^2T_6^2} \tag{18.22}$$

Таким образом, плотность функционала (18.3) принимаст следующий окончательный вид:

$$F_{\text{cond}} = \frac{N_0}{3}\frac{T-T_c}{T_c}A_{\alpha i}A^*_{\alpha i} + \frac{7\zeta(3)}{120\pi^2}\frac{N_0}{T_c^2}\left[-\frac{1}{2}\left|A_{\alpha i}A_{\alpha i}\right|^2 + \left(A^*_{\alpha i}A_{\alpha i}\right)^2 - \right.$$
$$\left. - A^*_{\alpha i}A_{\beta i}A^*_{\alpha j}A_{\beta j} + A^*_{\alpha i}A_{\beta i}A^*_{\beta j}A_{\alpha j} + A^*_{\alpha i}A_{\alpha j}A^*_{\beta i}A_{\beta j}\right] +$$
$$+ \frac{7\zeta(3)}{60}N_0\xi_0^2\left[\left(D_iA_{\alpha j}\right)^*\left(D_iA_{\alpha j}\right) + \left(D_iA_{\alpha i}\right)^*\left(D_jA_{\alpha j}\right) + \left(D_iA_{\alpha j}\right)^*\left(D_jA_{\alpha i}\right)\right] \tag{18.23}$$

Найденные параметры функционала Гинзбурга-Ландау соответствуот приближению слабой связи (см. конец 10).

Поправки к квазиклассическому приближению. Орбитальпый магнетизм. Сравнивая (18.20) и (15.7), мы видим, что в рассматриваемом приближении внутренний спонтанный орбитальный магнитный момент в сверхпроволнике с p-спариванием отсутствует в силу равенства $K_2 = K_3$. Посмогрим, что произойдет, если учесть второе слагаемое в квадратной скобке в выражениил (18.11), антисимметричное по индексам i, j и представяющее собой, как уже отмсчалось, поправку второго порядка малости по парамстру квазиктассичности.

Опуская зависящий от поля фазовый множитель в (18.11), получаем следуошую поправку к плотности свободной энсргии:

$$\delta F_{MH} = i\frac{e}{2k_{\text{F}}^2c}\left(\frac{\pi N_0}{k_{\text{F}}}\right)^2 e_{ijk}A^*_{\alpha i}A_{\alpha j}H_k 2\pi T_{\text{c}}\sum_n\int_0^\infty dR\exp\left(-\frac{2\left|\omega_n\right|}{v_{\text{F}}}R\right) =$$
$$= i\frac{e}{4k_{\text{F}}^2c}N_0\ln\frac{\varepsilon_1}{2\pi T_c}e_{ijk}A^*_{\alpha i}A_{\alpha j}H_k$$

Отсюода, восстанавливая постояннуо Планка, полутаем выражение для плотности внутреннего орбитального магнитного момента [75]

$$M_i = -i\frac{ch}{4k_{\text{F}}^2c}N_0\ln\frac{\varepsilon_1}{2\pi T_c}e_{ijk}A^*_{\alpha j}A_{\alpha k}$$

Сравнивая с (15.7), приходим к выводу о том, что при учете поправок порядка $\left(k_F\xi_0\right)^{-2}$ k квазиклассическому приближению разность $K_2 - K_3$, а вместе с ней и плотность внутрсннего спонтанного орбитального момента, становятся отличнымми от пгуля.

Спиновый магнетизм. Рассмотрим теперь эффект взаимодействия спинов электроiов с магнитным полем. В пренебрежении орбитальными эффектами ядро (18.6) зависит только от разности координат. Параметр порядка тогда можно считать ие зависящим от $\mathbf{r}$, и из (18.5) имеем следуощее выражение для плотности свободной энергии:

$$F_{SH} = -\frac{1}{2}A^*_{\alpha i}S_{ij,\alpha\beta}A_{\beta j} \tag{18.24}$$

Входящий сюда коэффицисит K удобно вычислять в импульсном представлснии:

$$S_{ij,\alpha\beta} = T_c\sum_n\int\frac{d^3k}{(2\pi)^3}\hat{k}_i\hat{k}_j\left(\sigma_y\sigma_\alpha\right)_{\lambda\mu}\times$$
$$\times G^{(0)}_{\lambda\gamma}\left(\mathbf{k},\omega_n\right)\left(\sigma_\beta\sigma_y\right)_{\gamma\delta}G^{(0)}_{\mu\delta}\left(-\mathbf{k},-\omega_n\right) \tag{18.25}$$

Выбирая ось квантования (направление магнитного поля $\mathbf{H}$) вдоль оси $\hat{z}$, функции Грина можно записать в следуощем видс (ср. с (17.14) при $\mathbf{H} = 0$):

$$G^{(0)}_{\lambda\gamma}(\mathbf{k},\omega_n) = \frac{i\omega_n - \xi_k}{(i\omega_n - \xi_k)^2 - (\mu_{\rm B}H)^2}\delta_{\lambda\gamma} - \\ - \frac{\mu_{\rm B}H}{(i\omega_n - \xi_k)^2 - (\mu_{\rm B}H)^2}(\sigma_z)_{\lambda\gamma} \qquad (18.26)$$

где $\mu_{\rm B}$ есть магнетон Бора (или магнитный момегтт ядра в ^{3}). Подставляя (18.26) в (18.25) и вычисляя след по спиновым индскcам, получаем линейнупо
по полю поправху к коэффициенту :

$$\delta S_{ij,\alpha\beta} = -ie_{\alpha\beta z}\mu_B H T_c \sum_n \int \frac{d^3k}{(2\pi)^3}\hat{k}_i\hat{k}_j\left[\frac{1}{i\omega_n - \xi_k}\frac{1}{(i\omega_n + \xi_k)^2} + \text{ к.с. }\right] = \\ = -\frac{1}{3}i\delta_{ij}e_{\alpha\beta z}\mu_{\rm B}HT_{\rm c}\sum_n \int d\xi N(\xi)\left[\frac{1}{i\omega_n - \xi}\frac{1}{(i\omega_n + \xi)^2} + \text{ к.с. }\right]$$

где $N(\xi)$ есть плотность электронных состояний. Записывая ее в виде разложения $N(\xi) = N_0 + N_0'\xi$ вблизи энергии Ферми и выполняя интегрирование по ξ, получаем:

$$\delta S_{ij,\alpha\beta} = -\frac{\pi}{2}\delta_{ij}e_{\alpha\beta z}\mu_{\rm B}HN_0T_c\sum_n \frac{\operatorname{sign}\omega_n}{\omega_n^2} - \\ - i\frac{\pi}{2}\delta_{ij}e_{\alpha\beta z}\mu_{\rm B}HN_0'T_c\sum_n \frac{\operatorname{sign}\omega_n}{\omega_n} \qquad (18.27)$$

Первое слагаемое в правой части тождественно обращается в нуль, а расходяшаяся сумма во в'гором слагаемом обрезается на граничной частоте ε_1. Подставляя полученный результат в (18.24), приходим к ответу:

$$\delta F_{SH} = i\frac{\pi}{4}\mu_{\rm B}N_0'\ln\frac{\varepsilon_1}{2\pi T_c}e_{\alpha\beta\gamma}A^*_{\alpha i}A_{\beta i}H_\gamma \qquad (18.28)$$

Сравнивая это выражение с (15.20), видим, что зачение коэффициента K_4, а, следовательно, и плотность внутреннего слонтанного спинового магнитного момента малы в меру малости асимметрии в распределснии части и дырок вблизи поверхности Ферми.

Упражнение. Вычислить коэффициенты в разложении Гинзбурга-Ландау для изотропного сверхпроводника с d-спариванием в модели слабой связи.

19.2.3 19. Upper Critical Field in p-wave Superconductors

В области применимости теории Гинзбурга-Ландау верхнис крититеские поля для сверхпроволников с необычньм параметром порядка вычислялись в § 12. При понивкснии температуры корреляционная длина $\xi(T)$, задающая пространственный масштаб измснения параметра порямка, уменьшается и при $T \ll T_{\rm c}$ становится сравнимой с длиной когерентности ξ_0. В этих условиях градиентное разложенис свободной энергии становится неприменимым, и для вычисления $H_{c2}(T)$ необходимо использовать методы микроскопической теории. В настоящем параграфе мы проведем вычисления для анизотропного сверхпроводника с p-спариванием. В этом случае, также как в случас обычного изотропного сверхпроводиика можно получить аналитические выражепия для верхнего критического поля при $T = 0$. Для многих друтих необытчых сверхпроводящих состояний, даже с однокомпонепттиыми параметрами порядка, не

являтощихся собственными функциями уравпенния типа (19.5) (см. ниже), например, для тетрагоналыного сверхпроводника с $\Delta(\mathbf{r}) \sim \Delta\left(\hat{x}^2 - \hat{y}^2\right)$, верхнее критическое полс можно найти лишь приближенно.

Для вычисления верхнего критического поля $H_{c2}(T)$ в сверхпроводнике с p-спариванием воспользуемся уравнением (17.9). Переходя в координатное представление, с учетом выражения (18.4) для параметра порядка и разложения (18.1) притягивающего взаимодействия, получаем линейное интегральное уравнение [76]:

$$A_{\alpha i}(\mathbf{r}_1) = \int d^3 r_2 K_{ij}(\mathbf{r}_1, \mathbf{r}_2) A_{\alpha j}(\mathbf{r}_2) \tag{19.1}$$

где ядро имеет вид (ср. с (18.5))

$$K_{ij}(\mathbf{r}_1, \mathbf{r}_2) = \lim_{\mathbf{r}'_{1,2} - \mathbf{r}_{1,2}} \frac{3VT}{4k_F^2} \sum_n \left(\frac{\partial}{\partial r_{1,i}} - \frac{\partial}{\partial r'_{1,i}}\right)\left(\frac{\partial}{\partial r_{2,3}} - \frac{\partial}{\partial r'_{2,j}}\right) G(\mathbf{r}_1, \mathbf{r}_2; \omega_n) G(\mathbf{r}'_1, \mathbf{r}'_2; -\omega_n) \tag{19.2}$$

Повторяя дословно рассуждения, использованные в предыдудем параграфе при выводе формулы (18.12), получаем:

$$K_{ij}(\mathbf{r}_1, \mathbf{r}_2) = 3VT\hat{R}_i R_j \left(\frac{\pi N_0}{k_{\mathrm{F}} R}\right)^2 \sum_n \exp\left(-\frac{2|\omega_n|}{v_{\mathbf{F}}} R\right) \exp\left(\frac{2ie}{c} \int\limits_{\mathbf{r}_1}^{\mathbf{r}_2} \mathbf{A}(\mathbf{r}) d\mathbf{r}\right) \tag{19.3}$$

где $\hat{R} = (\mathbf{r}_2 - \mathbf{r}_1) / |\mathbf{r}_2 - \mathbf{r}_1|$.

Воспользовавшись тождеством

$$\exp\left(\frac{2ie}{c} \int\limits_{\mathbf{r}_1}^{\mathbf{r}_2} \mathbf{A}(\mathbf{r}) d\mathbf{r}\right) f(\mathbf{r}_2) = \exp\left(i(\mathbf{r}_2 - \mathbf{r}_1)\mathbf{D}(\mathbf{r}_1)\right) f(\mathbf{r}_1) \tag{19.4}$$

где $\mathbf{D}(\mathbf{r}) = -i(\partial/\partial\mathbf{r}) + (2e/c)\mathbf{A}(\mathbf{r})$ - оператор ковариантного лифференцирования, переписываем уравнение (19.1) в виде

$$A_{\alpha i}(\mathbf{r}) = 3VT\left(\frac{\pi N_0}{k_{\mathrm{F}}}\right)^2 \int d^3 R \frac{\hat{R}_{\mathrm{r}} \hat{R}_3}{R^2} \sum_n \exp\left(-\frac{2|\omega_n|}{\psi_{\mathrm{F}}} R\right) \exp(i\mathbf{R}\mathbf{D}(\mathbf{r})) A_{\alpha j}(\mathbf{r}) \tag{19.5}$$

Заметим, что (19.5) является дифференциалным уравнением бесконечно высокого порядка [77], причсм линсаризованные уравнения Гинзбурга-Ландау получаются, если мы разложим экспонснту в правой части до членов второго порядка по D.

Пусть внешнее полс H направлено вдоль оси z, тогда ищем решение уравнения (19.5) в виде

$$A_{\alpha i}(\mathbf{r}) = e^{ip_z z} A_{\alpha i}(\rho)$$

где $\rho = (x, y)$.

Естественно прсдположить, что максимальному значению верхнего критического поля отвечает $p_z = 0$. Переходя в интеграле в (19.5) к сферическим координатам с полярной осью вдоль z, дегко убедиться, что уравнения расцепляются, т.с. z-компонснты параметра порядка $A_{\alpha z}$ могут быть рассмотрены независимо от x, y-компонент.

Полярная фаза [76]. Начнем с вычисления $H_{c2}(T)$ для сверхпроводящего состояния вида

$$d_{\alpha x} = A_{\alpha z}\hat{k}_z$$

Поскольку уравнение (19.5) диагоналыо по спиновым индсксам, то всем компонентам вектора d соответствует одинаковое значение верхнего критического поля. Полагая $d_1 = d_2 = 0$, убеждаемся, что рассматриваемый случай соответствует полярнои фазе [1]. Итак, пусть $\mathcal{A}_{zz}(\rho) = \int(\rho)$. Метод решения аналогичен применяемому в соответствующей задаче для изотропного сверхпроводника с s-спариваниcм [77].

Введем повышающий и понижающий операторы:

$$D_{\pm} = \frac{D_x \pm iD_y}{\sqrt{2}} \tag{19.6}$$

удовлетворякщие коммутаиионному соотношению $[D_-, D_+] = 2\pi H/\Phi_0$, гдс Φ_0 - квант потока. Тогда уравнение (19.5) принимает вил

$$f(\rho) = 3VT\left(\frac{\pi N_0}{k_F}\right)^2 \sum_n \int_0^\infty dR \exp\left(-\frac{2\left|\omega_n\right|}{v_{\mathrm{F}}}R\right) \int_0^\pi \sin\theta\cos^2\theta d\theta \times$$
$$\times \int_0^{2\pi} d\varphi \exp\left(i\frac{R}{\sqrt{2}}\sin\theta\left(e^{-i\varphi}D_+ + e^{i\varphi}D_-\right)\right) f(\rho) \tag{19.7}$$

Воспользуемся теперь операторным тождеством:

$$e^{\Lambda+B} = e^A e^B e^{-(1/2)[A\cdot B]}$$

верным, если коммутатор операторов A и B есть c-число, и перепишем содержащую $D_\pm$ экспоненту в (19.7) в следующем виде:

$$\exp\left(i\frac{R}{\sqrt{2}}\sin\theta\left(e^{-i\varphi}D_+ + e^{i\varphi}D_-\right)\right) =$$
$$= \exp\left(-\frac{\pi H}{2\Phi_0}R^2\sin^2\theta\right)\exp\left(i\frac{R}{\sqrt{2}}\sin\theta e^{-i\varphi}D_+\right)\exp\left(i\frac{R}{\sqrt{2}}\sin\theta e^{i\varphi}D_-\right) \tag{19.8}$$

Если мы разложим правую часть в ряд по степеням $D_\pm$и подставим в (19.7), то после интегрирования по утлу φ в этом разложении останутся только члены вида $D_+^n D_-^n$, содержащие одитаковое число повышаюоших и понижающих операторов. Эго означает, что рсшгсниями уравiения (19.7) являются соБственные функции $|N\rangle$ оператора D_+D_-, являющегося оператором Гамильтона для гармонического осциллятора:

$$D_+D_-|N\rangle = N\frac{2\pi H}{\Phi_0}|N\rangle$$
$$D_+^n D_-^n|N\rangle = \frac{N!}{(N-n)!}\left(\frac{2\pi H}{\Phi_0}\right)^n|N\rangle$$

В калибровке Ландау $\mathbf{A} = (0, Hx, 0)$ эти собственiые функции выглядят следующим образом:

$f_{N,p}(\rho) \propto e^{ipy}\exp\left[-\frac{\pi H}{\Phi_0}\left(x - \frac{p\Phi_0}{2\pi H}\right)^2\right] \times$

[11] Это справедливо в пренебрсжении взаимодействием $\mu_{\mathrm{B}}H$ спинов электронов с магнитным полем. Если учесть такое взаимодействие, то переход происходит в β-фазу (см. 3) [31].

$$\times H_N\left[\sqrt{\frac{2\pi H}{\Phi_0}}\left(x-\frac{p\Phi_0}{2\pi H}\right)\right] \tag{19.9}$$

где $H_N(x)$ - полиномы Эрмита. С учетом сказанного получаем:

$$\begin{aligned}\int\limits_0^{2\pi} d\varphi \operatorname{cxp}\left(i\tfrac{R}{\sqrt{2}}\sin\theta e^{-i\varphi}D_+\right)\exp\left(i\tfrac{R}{\sqrt{2}}\sin\theta e^{i\varphi}D_-\right)|N\rangle = \\ = 2\pi\sum_{n=0}^{N}\tfrac{N!}{(n!)^2(N-n)!}\left(-\tfrac{\pi H}{\Phi_0}R^2\sin^2\theta\right)^n|N\rangle = \\ = 2\pi L_N\left(\tfrac{\pi H}{\Phi_0}R^2\sin^2\theta\right)|N\rangle\end{aligned} \tag{19.10}$$

где $L_N(x)$ - полиномы Лагерра. Уравнение на собственные значения (19.7) принимает вид

$$\begin{aligned}1 = 6\pi VT\left(\tfrac{\pi N_0}{k_{\mathrm{F}}}\right)^2\sum_n\int\limits_0^{\infty}dR\exp\left(-\tfrac{2|\omega_n|}{v_{\mathrm{F}}}R\right)\times \\ \times\int\limits_0^{\pi}\sin\theta\cos^2\theta d\theta\exp\left(-\tfrac{\pi H}{2\Phi_0}R^2\sin^2\theta\right)\times \\ \times L_N\left(\tfrac{\pi H}{\Phi_0}R^2\sin^2\theta\right)\end{aligned} \tag{19.11}$$

Можно показать, что максималыно значение верхдего критического поля получается пля рсшения, отвсчающцсго нулсвому ($N=0$) уровню гармонического осциллятора, при этом параметр порядка имест вид

$$\mathbf{d}\propto f_{0,p}(x,y)\tilde{k}_z \tag{19.12}$$

Для устранения логарифмической расходимости при суммировании по n в (19.11) вычтем из обеих частей выражения в нулевом поле. Тогла, учитывая (18.17), получаем окончательнос уравнение, опрсделяющсе зависимость $H_{\mathrm{c}2}(T)$ для полярной фазы:

$$\begin{aligned}\ln\frac{T_c}{T} = \sum_n\left[\frac{1}{|2n+1|}-\frac{6\pi T}{N_0}\left(\frac{\pi N_0}{k_F}\right)^2\int\limits_0^{\infty}dR\exp\left(-\frac{2\,|\omega_n|}{v_{\mathrm{F}}}R\right)\times\right. \\ \left.\times\int\limits_0^{\pi}\sin\theta\cos^2\theta d\theta\exp\left(-\frac{\pi H}{2\Phi_0}R^2\sin^2\theta\right)\right]\end{aligned} \tag{19.13}$$

При выводе (19.13) использовапю определение критической температуры T_{c} в нулевом поле:

$$\pi VN_0T_c\sum_n\frac{1}{|\omega_n|}=1$$

где сумма по частотам обрезана на граничной энергии ε_1 (см. предыдущий параграф).

А-фаза и фаза Парнберга-Клемма [76]. Рассмотрим теперь x - и y-компоненты параметра порядка. Обозначим $A_{\alpha i}(\rho)=f_i(\rho)$ и введем новые функции

$$f_{\pm}(\rho)=\frac{1}{\sqrt{2}}\left(f_x\pm if_y\right)$$

тогда уравнение (19.5) принимает вид

$$\begin{pmatrix} f_+ \\ f_- \end{pmatrix} = \frac{3VT}{2}\left(\frac{\pi N_0}{k_{\rm F}}\right)^2 \sum_n \int_0^\infty dR \exp\left(-\frac{2\left|\omega_n\right|}{v_{\rm F}}R\right) \times$$

$$\times \int_0^\pi \sin^3\theta d\theta \int_0^{2\pi} d\varphi \begin{pmatrix} 1 & e^{21\varphi} \\ e^{-21\varphi} & 1 \end{pmatrix} \exp\left(i\frac{R}{\sqrt{2}}\sin\theta\left(e^{-i\varphi}D_+ + e^{i\varphi}D_-\right)\right)\begin{pmatrix} f_+ \\ f_- \end{pmatrix} \qquad (19.14)$$

Если воспользоваться формулой (19.8), разложить зависящие от φ экспоненты в ряд Тейлора, а затем проинтегрироватъ по φ, то диагональные элементы матричного оператора в правой части содержат слагаемые вида $D_+^n D_-^{\rm n}$, наддиагональный элемент - слагаемые вида $D_+^{n+2}D_-^n$, а поддиагоналыный слагаемые вида $D_+^n D_-^{n+2}$. По этой причине ищем решснис уравнения (19.14) в следующем виде:

$$\begin{pmatrix} f_+ \\ f_- \end{pmatrix} = \begin{pmatrix} p_N|N+2\rangle \\ q_N|N\rangle \end{pmatrix}, \quad N \geq 0 \qquad (19.15)$$

где $|N\rangle$ определяется формулой (19.9).

Имеем:

$$\int_0^{2\pi} d\varphi \begin{pmatrix} 1 & e^{2i\varphi} \\ e^{-2i\varphi} & 1 \end{pmatrix} \exp\left(i\frac{R}{\sqrt{2}}\sin\theta e^{-i\varphi}D_+\right)\exp\left(i\frac{R}{\sqrt{2}}\sin\theta e^{i\varphi}D_-\right)\begin{pmatrix} p_N|N+2\rangle \\ q_N|N\rangle \end{pmatrix} =$$

$$= 2\pi \begin{pmatrix} p_N\sqrt{(N+1)(N+2)}\sum_{n=0}^N \frac{N!}{n!(n+2)!(N-n)!}\left(-\frac{\pi H}{\Phi_0}R^2\sin^2\theta\right)^{n+1}|N+2\rangle + \\ +q_N L_{N+2}\left(\frac{\pi H}{\Phi_0}R^2\sin^2\theta\right)|N+2\rangle \\ p_N L_N\left(\frac{\pi H}{\Phi_0}R^2\sin^2\theta\right)|N\rangle + \\ +q_N\sqrt{(N+1)(N+2)}\sum_{n=0}^N \frac{N!}{n!(n+2)!(N-n)!}\left(-\frac{\pi H}{\Phi_0}R^2\sin^2\theta\right)^{n+1}|N\rangle \end{pmatrix}$$

Мы получили линейную однородную систему уравпепий на коэффициенты p_N и q_N, условие разрсшимости которой имсст вид

$$(1-\alpha_N)(1-\alpha_{N+2}) - \beta_N^2 = 0 \qquad (19.16)$$

где

$$\alpha_N(H,T) = 3\pi VT\left(\frac{\pi N_0}{k_F}\right)^2 \sum_n \int_0^\infty dR \exp\left(-\frac{2\left|\omega_n\right|}{v_{\rm F}}R\right) \times$$

$$\times \int_0^\pi \sin^3\theta d\theta \exp\left(-\frac{\pi H}{2\Phi_0}R^2\sin^2\theta\right) L_N\left(\frac{\pi H}{\Phi_0}R^2\sin^2\theta\right)$$

$$\beta_N(H,T) = 3\pi VT\left(\frac{\pi N_0}{k_{\rm F}}\right)^2 \sum_n \int_0^\infty dR \exp\left(-\frac{2\left|\omega_n\right|}{v_{\rm F}}R\right) \times$$

$$\times \int_0^\pi \sin^3\theta d\theta \exp\left(-\frac{\pi H}{2\Phi_0}R^2\sin^2\theta\right)\sqrt{(N+1)(N+2)}\times$$

$$\times \sum_{m=0}^N \frac{N!}{m!(m+2)!(N-m)!}\left(-\frac{\pi H}{\Phi_0}R^2\sin^2\theta\right)^{m+1}$$

при этом $q_N = \left(\left(\alpha_N - 1\right)/\beta_N\right) p_N$.

Итак, мы получили уравненис, определяющее температурпую зависимость верхнего критического поля для решения вида (19.15). Можно показать, что максиматное значение $H_{c2}\left(T\right)$ достигается при $N = 0$. Соответствуоший параметр порядка:

$$\mathrm{d} \propto \left[f_{2,p}(x,y) \left(\hat{k}_x - i\hat{k}_y \right) + \frac{\alpha_0 - 1}{\beta_0} f_{0,p}(x,y) \left(\hat{k}_x + i\hat{k}_y \right) \right] \tag{19.17}$$

описывает так называемую фазу Шариберга-Клсмма. В отсутствие спиновыхх эффектов верхнее критичсскос поле одилаково для всех компонент вектора $\mathbf{d}$.

Осталось рассмотрсть состояние

$$\begin{pmatrix} f_+ \\ f_- \end{pmatrix} = \begin{pmatrix} |0\rangle \\ 0 \end{pmatrix} \tag{19.18}$$

которое также является решешием (19.14), но не принадлежит к семсйству (19.15)[2]. Подставляя (19.18) в (19.14), убсждаемсяя в том, что уравнение на верхнее критическое поле для параметра поряшка

$$\mathbf{d} \propto f_{0,p}(x,y) \left(\hat{k}_x - i\hat{k}_y \right) \tag{19.19}$$

соответствуощщего, как легко видеть, A-фазе [3], имест вид

$$1 - \alpha_0 = 0 \tag{19.20}$$

Мы приходим, таким образом, к следупошему выводу: в заряженной ферми-жидкости с p-спариванием переход из нормального в сверхпроводящее состояние в магнитном поле может произойтн в одлу из трех фаз: полярную фазу, A-фазу или фазу Шарнберга-Клемма. Для ответа на вопрос, какая именно из них имеет максимальнос критическос полс, нсобходимо решить урависния (19.13), (19.20) и (19.16). Хотя в общем случае эта задача может быть решена лишь путсм числснного анализа, оказывается возможным получить аналитические выражения для H_{c2} при $T \to T_c$ (см. §12, 18, а также упражнение в конце параграфа) и при нулевой температуре.

вычисление $H_{c2}\left(0\right)$ [76]. Начнем с исследования полярной фазы. Для сокращения обозначений удобно ввести следующие безразмерные переменные:

$$h = \frac{2H}{H_0}. \quad \rho = \frac{r\sqrt{h}}{\xi_0}, \quad t = \frac{T}{T_{\circ 0}}$$

гдс $H_0 = \Phi_0/\left(\pi\xi_0^2\right)$, а $T_{c:0}$ - критическая темпсратура при $II = 0$. Из (19.13) имеем

$$\ln t = \sum_n \left[\frac{3t}{2\sqrt{h}} \int_0^\infty d\rho \int_0^\pi \sin\theta \cos^2\theta d\theta \times \right.$$
$$\left. \times \exp\left(-\frac{t\rho|2n+1|}{\sqrt{h}} - \frac{\rho^2 \sin^2\theta}{4} \right) - \frac{1}{|2n+1|} \right] \tag{19.21}$$

Прсдслыный переход $t \to 0$ в этом уравнении выполнястся следующим образом. Перепииеем сумму по частотам в виде

[12] у (19.14) имеется также решение вида $\binom{f_+}{f_-} = \binom{|1\rangle}{0}$, однако можно похазать, что оно приводит х заведомо мсныиему значснию верхнего критического погя.

[3] В сверхпроводящей A-фазе орбитальый момент пар орисщтирован против паправлсния поля H.

$$\sum_n \{\ldots\} = 2 \lim_{y\to 1} \sum_{n=0}^{\infty} y^{2n+1} \{\ldots\}$$

Обозначая $x = \cos\theta$ и суммируя по n, получаем:

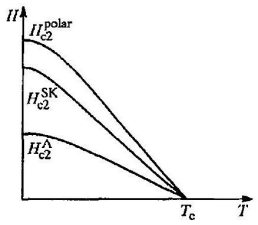
$$\ln t = \lim_{y\to 1} \left[\frac{3i}{\sqrt{h}} \int_0^1 x^2 dx \int_0^\infty d\rho \frac{2y \exp\left(-\frac{t\rho}{\sqrt{h}} - \frac{\rho^2\left(1-x^2\right)}{4} \right)}{1 - y^2 \exp\left(-\frac{2t\rho}{\sqrt{h}} \right)} - \ln \frac{1+y}{1-y} \right]$$

Разложим теперь экспопегты в подыитегральном выражении по стспеням t при $t \to 0$ и запишем правую часть в виде

$$\lim_{y\to 1} \left[3 \int_0^1 dx x^2 \cdot \int_0^\infty d\rho \frac{\exp\left(-\frac{\rho^2\left(1-x^2\right)}{4} \right)}{\rho + \frac{\sqrt{h}(1-y)}{t}} - \ln \frac{2}{1-y} \right] =$$

$$= \lim_{y\to 1} \left\{ 3 \int_0^1 dx x^2 \left[\ln \frac{t}{\sqrt{h}(1-y)} - \frac{1}{2} \left(\ln \frac{1-x^2}{4} + C \right) \right] - \ln \frac{2}{1-y} \right\} =$$

$$= \ln \frac{t}{2\sqrt{h}} - \frac{C}{2} - \frac{3}{2} \int_0^1 dx x^2 \ln \frac{1-x^2}{4} = \ln \frac{t}{2\sqrt{h}} - \frac{C}{2} + \frac{4}{3}$$



где $C = \ln \gamma$ - постоянная Эйлера. Отсюода окончательно получаем, что

$$h = \frac{e^{8/3}}{4\gamma}$$

Вычисления лтя A-фазы и фазы Шариберга-Клемма выполняются аналогитіто. Возвращаясь к размерным величипам, приведем сводку результатов:

$$H_2(T=0) = \frac{e^2}{4\gamma} \frac{\Phi_0}{2\pi\xi_0^2} \begin{cases} e^{2/3}, & \text{полярная фаза,} \\ e^{-1/3}, & \text{A-фаза,} \\ e^{\sqrt{3}-4/3}, & \text{фаза Шариберга-Клемма.} \end{cases} \tag{19.22}$$

Для удобства сравиения мв явно выдслили перед фигурной скобкой значение верхего критического поля при $T = 0$ для изотропного сверхпроводпика

Р ис. 17. Качественное новедение $H_2(T)$ в различных фазах с p-спариванием

с s-спариванием. Мы видим, что максималыое значенис верхнего критипеского поля получается для полярной фазы. Графики $H_{c2}(T)$ для фаз с р-спариванием изображены пта рис. 17.

MC-19.1

Доказать тождество (19.4).

MC-19.2

С помощыо уравнений (19.13), (19.16) и (19.20) зычислить значсние H_{c2} для сверхпроводника с p-спариванисм вблизи критической температуры.

19.2.4 20. Boundary Conditions for the Order Parameter

Из феноменодогического анализа в 13 следует, что ввиду внутренней анизотропии параметра порядка, граничные условия для уравнений ГинзбургаЛандау, определяющие повсрхиостные свойства сверхпроводника, также оказываются существенно анизотропными. Предмет настоящего параграфа составляет микроскопический вывод траничных условий для параметров порядка, соответствующих нетривиалыім типам спаривания. При этом мы ограничимся рассмотрснием сверхпроводников со слабцм спин-орбиталыным взаимодействием и сферической ферми-повсрхностыг.

Зеркалыю отражаюшая поверхность [79, 80]. В области применимости тсории Гиізбурга-Ландау задача сводится к решению линейного иітеграпного уравнения (17.9), в которое входят мацубаровские функции Грина нормального металла в полупространствс $x > 0$, обращающиеся в нуль на поверхности (то ссть при $x = 0$) и имеющис в отсутствис примесей и магнитного поля
следующий вид:

$$G^{(0)}\left(x_1, x_2; \mathrm{k}_{\parallel}, \omega_n\right) = \sum_q \frac{F_q\left(x_1, x_2\right)}{i\omega_n - \xi\left(q, \mathbf{k}_{\parallel}\right)} \tag{20.1}$$

где

$$F_q\left(x_1, x_2\right) = \theta\left(x_1\right)\theta\left(x_2\right)\sin qx_1 \sin qx_2$$

а

$$O(x) = \begin{cases} 1, & \text{при } x > 0 \\ 0, & \text{при } x < 0 \end{cases}$$

Мы использовали смешапное координатчо-импульсное представление, в котором функсии Грина диагональны по компонентам импульса вдоль поверхности.

Рассмотрим ситуашяio па примерс сверхпроводника с синглетным спариванисм, параметр порядка в котором соотвстствует одномерному нетривиальному представлению точечной группы симметрии кристалла (см. 4). Обобщение пга остальные случаи нс составляет труда. Входяший в (17.9) параметр порядка выглядит в смешанном координатно-импульсном представлении следулощим образом:

$$\Delta_{\alpha\beta}(\mathbf{k}, \mathbf{r}) = \left(i\sigma_y\right)_{\alpha\beta} \eta(\mathbf{r})\psi(\hat{\mathbf{k}})$$

Подставляя в (17.9) разложение (5.7) и возвращаясь в координатпое предсгавление по x, получаем линейное интегралыно уравнение для параметра порядка:

$$\eta\left(x_1\right) = \int_0^{\infty} dx_2 K\left(x_1, x_2\right)\eta\left(x_2\right) \tag{20.2}$$

ялро которого имеет вид

$$K\left(x_1,x_2\right)=-VT_c\sum_n\sum_{\mathbf{k}_1,\mathbf{k}_2,q_1,q_2}\exp\left(iq_1x_1-iq_2x_2\right)\times$$
$$\times\psi^*\left(\hat{\mathbf{k}}_1\right)\psi\left(\hat{\mathbf{k}}_2\right)\delta\left(\mathbf{k}_{1,\parallel}-\mathbf{k}_{2,\parallel}\right)G^{(0)}\left(k_{1,x}+\frac{q_1}{2},k_{2,x}+\frac{q_2}{2};\mathbf{k}_{\parallel},,w_n\right)\times$$
$$\times G^{(0)}\left(-k_{1,x}+\frac{q_1}{2},-k_{2,x}+\frac{q_2}{2};-\mathbf{k}_{\parallel},-\omega_n\right)\tag{20.3}$$

гдс $V>0$ есть констапта связи, а базисные фупкции ψ зависят от направлений векторов $\mathbf{k}_i=\left(k_{i,x},\mathbf{k}_{\parallel}\right)$.

Выполняя в (20.1) прсобразование Фурье и подставляя результат в (20.3), полугаем, после интегрирования спачала по модулям k_1, а затем по $q_{1,2}$, следующее выражение для ядра [1]:

$$K\left(x_1,x_2\right)=\frac{\pi VN_0T_c}{v_F}\sum_n\int\limits_0^1\frac{ds}{s}\left[\exp\left(-\frac{2\left|\omega_n\right|}{v_{\mathrm{F}}s}\left|x_1-x_2\right|\right)F^{(-)}(s)+\right.$$
$$\left.+\exp\left(-\frac{2\left|\omega_n\right|}{v_Fs}\left(x_1+x_2\right)\right)F^{(+)}(s)\right]\tag{20.4}$$

где $s=\cos\theta$, а

$$F^{(\pm)}(s)=\int\limits_0^{2\pi}\frac{d\varphi}{2\pi}f^{(\pm)}(s,\varphi)$$

Функшии направлений $f^{(\pm)}(\hat{\mathbf{k}})=f^{(\pm)}(s,\varphi)$ определяются следующим образом. Для фиксчрованных значении углов $0\leq\varphi<2\pi,0\leq\theta<\pi/2$ вводим два единичных вектора:

$$\hat{\mathbf{k}}_{\pm}=\left(\pm\cos\theta,\sin\theta\cos\varphi,\sin\theta\sin\varphi\right)=\left(\pm s,\sqrt{1-s^2}\cos\varphi,\sqrt{1-s^2}\sin\varphi\right)$$

связаиных отражением в плоскости границы. Тогда

$$f^{(\pm)}=\frac{1}{2}\left(\psi^*\left(\hat{\mathbf{k}}_+\right)\psi\left(\hat{\mathbf{k}}_{\mp}\right)+\psi^*\left(\hat{\mathbf{k}}_-\right)\psi\left(\hat{\mathbf{k}}_{\pm}\right)\right)$$

Таким образом, вид ядра $K\left(x_1,x_2\right)$ определяется трансформационными свойствами базисных функций представлешия при отражении в плоскости границы.

Для бесконечного однородного сверхпроводника ядро линейного интегрального уразнения, определяющее параметр порядка, имеет вид:

$$K^{(0)}\left(x_1-x_2\right)=\frac{\pi VN_0T_c}{v_F}\sum_n\int\limits_0^1\frac{ds}{s}\exp\left(-\frac{2\left|\omega_n\right|}{v_Fs}\left|x_1-x_2\right|\right)F^{(-)}(s)\tag{20.5}$$

причем из определения критической температуры:

$$\pi VN_0T_{\mathbf{c}}\sum_n\frac{1}{\left|\omega_n\right|}=1$$

[11] Ланное выражсние сцраведливо в квазиклассическом приближении. Это озпачает, что, поскольку характерный масыгтаб изменения ялра - длина когереттности о - значительно превосходит атомны масыштаб $k_{\bar{F}}^{-1}$, то можно прснебречь быстроосциллирующими вкладами в $K\left(x_1,x_2\right)$, пропордиональными $e^{\pm21k_{\mathrm{F}}x}$.

следует, что

$$\int\limits_{-\infty}^{+\infty} dx_1 K^{(0)}\left(x_1 - x_2\right) = 1 \tag{20.6}$$

По сравнению с бесконечным неограниченным сверхпроводником, учет поверхдости свелся к появлешиіо в правой части (20.4) второго слагаемого, убцваюощего на расстояниях порядка ξ_0 от поверхности и ответственного, как указывалось в §13, за подавление сверхпроводимости в приповерхностном слое.

Граничные условия для уравнений Гинзбурга-Ландау получаются из асимптотики решения интегрального уравнения (20.2) при $x \gg \xi_0$. Непосредственной подстановкой в (20.2) с учетом (20.5), убеждаемся, что искомым асимптотическим репиенисм является линейная функция $\eta(x) = \eta_0(1 + x/b)$ с вещественным b. Эффективное граничное условие тогда выглядит следующим образом:

$$\left.\frac{\partial\eta}{\partial x}\right|_{x=0} = \left.\frac{1}{b}\eta\right|_{x=0} \tag{20.7}$$

Параметр 6 совпадает с интерполяшионной длиной, введенной в 813.

Отметим два существенных симметрийных свойства граничных условий. Если базисная функция не менятся при отражении $x \to -x$, т.е. $\psi\left(\hat{\mathbf{k}}_-\right) = \psi\left(\hat{\mathbf{k}}_+\right)$, то $b = \infty$, т. е. $\partial\eta/\,\partial x|_{x=0} = 0$. Действителыно, в этом случае, распространяя параметр порядка четным образом на «нефизическую» область $x < 0 : \eta(-x) = \eta(x)$, попучим, что ядро (20.4) принимает вид однородного объемного ддра $K^{(0)}$, а уравнение (20.2) в попупространстве становится уравнением во всем пространстве:

$$\eta\left(x_1\right) = \int\limits_{-\infty}^{+\infty} dx_2 K^{(0)}\left(x_1 - x_2\right)\eta\left(x_2\right) \tag{20.8}$$

определяющим темпсратуру сверхпроводящего перехода для бесконечного одлородного кристалла. Четное рештение этого уравнения в силу (20.5) есть просто константа. Граничное условие, таким образом, имеет вид (13.18):

$$\left.\frac{\partial\eta}{\partial x}\right|_{x=0} = 0. \tag{20.9}$$

Покажем, что в другом предельном случа, когда базисная функция меняет ак при отражении, имеем $b = 0$. Параметр порядка теперь также можно продолжить в область $x < 0$, но уже нечетным образом: $\eta(-x) = -\eta(x)$. Тогда уравнение (20.2) вновь переходит в обхемное уравнение, нечетное решетие которого есть линейная функшия x, что дает граничное условие вида (13.16):

$$\left.\eta\right|_{x=0} = 0 \tag{20.10}$$

В общем случае, ссл: базисные функции не имегот опрсделенной четности при отражении в плоскости границы, то интегральнос уравнение, определячощее параметр порядка, не сводится к простому вилу и грашичные условия не совпалакт с (20.9) или (20.10). В этой ситуации можно пользоваться следующцвм приближенньім выражением для интерполяционной дтины b:

$$\frac{b}{\xi_0} = \frac{1}{7\zeta(3)} \frac{1}{\int\limits_0^1 dss^2 F^{(-)}(s)} \left\{ \frac{\pi^4}{24} \int\limits_0^1 dss^3 \left(F^{(-)}(s) + F^{(+)}(s) \right) + \right.$$
$$\left. + \frac{\left[7\zeta(3) \int\limits_0^1 dss^2 \left(P^{(-)}(s) + F^{(+)}(s) \right) \right]^2}{2\pi^2 \int\limits_0^1 dss \left(F^{(-)}(s) - F^{(+)}(s) \right)} \right\} \tag{20.11}$$

Чтобы не прерывать связности изложения, вывод этой формулы вынесен в конец параграфа.

Для сдиничного представления A_{1g}, соответствующего ббычному s волновому параметру порядка, базисная фупкиия $\psi(\hat{\mathbf{k}}) \sim \text{const}$ не изменяет знака при отражении в плоскости транишы, и мы имеем $b = \infty$, что означает существование изотропной в базисной плоскости поверхностной сверхпроводимости.

Совсем по-друтому обстоит дело в случас неединимних представлений. Рассмотрим ситуацию на примере параметра порядка, соответствующсго представлснипо B_{1g} группы $D_{6\,\%}$. В главних осях (X, Y, Z) (см. рис. 18) базисная функция имеет следующий вид:

$$\psi(\hat{\mathbf{k}}) \propto \hat{k}_Z \left(\hat{k}_X^3 - 3\hat{k}_X \hat{k}_Y^2 \right) \tag{20.12}$$

Если поверхдость кристалла совпадает с плоскостью XZ, т.с. $\varphi = \pi/2$, то отражснию в плоскости гранины соответствуст замена $Y \to -Y$. При таком преобразовании Базисная функиия не меняет знак, и мы потучаем $b = \infty$. Следовательно, поверхностнос критическое поле максимально и определяется формулой (13.22). Эгот же результат мы получим, если угол φ принимает значения $\pi/6, 5\pi/6$ и т. д., поскольку во всех элих случаях $\psi(\hat{\mathbf{k}})$ не менятся при отражении в плоскости границы.

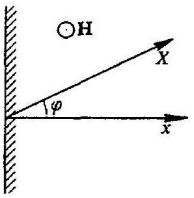


Рис. 18. Ориентация поверхности сверхпроводника (внутренняя нормаль - вдоль $\dot{x}$) относителыо осей кристаллической решетки. Поле H паратлельно оси шестого порядка, внутренняя нормаль направлена вдоль оси x.

Если же поверхность сверхпроводника совпадает с кристаллографической плоскостью YZ, т.е. $\varphi = 0$, то при замене $X \to -X$ базисная функция (20.15) меняет знак. Поэтому $b = 0$ и $f(0) = 0$. В этом случае (а также при $\varphi = \pi/3, 2\pi/3$ и т. д.) поверхностное критическое поле минимально и совпадает с верхним критическим полем в ойъеме (см. (13.17)).

Окончательный вывод:

$$\frac{H_{c3}(T)}{H_{c2}(T)} = \begin{cases} \approx 1,69, & \text{при } \varphi = \frac{(2n+1)\pi}{6} \\ 1, & \text{при } \varphi = \frac{n\pi}{3} \end{cases} \tag{20.13}$$

где $n = 0, 1, \ldots, 5$. Таким образом, граничные условия и поверхностное критическос поле демонстрируіт существенную анизотропию (в данном случае - шестого порядка) [2]. Следует отметить, что результат (20.13) вытекает из общих свойств четности или нечетности базисной функции представления B_1 при отражении в пооскости грапицы и поэтому не зависит от выбора $\psi(\hat{\mathbf{k}})$.

При промсжуточшьх значениях угла φ необходимо пользоваться граничными условиями общего вида (20.7), причсм для вычисления $b(\varphi)$ периодической функции с

периодом $\pi/3$, измсняющейся в пределах 0 до ∞, важе, разумеется, конкретный выбор базисной фупкции. Зависимость $H_{c3}(\varphi)$ должна при этом иметь достаточно резкие пики. Дело в том, что вблизи T_c существует характерный масштаб изменения параметра порядка корредяшопная длина $\xi \gg \xi_0$. Если $b(\varphi) < \xi$, что имеет месго почти всюоду, кроме узких окрсстностей шириной $\delta\varphi$ вблизи угла $\varphi = \pi/2$ и т. д., то эффективное граничное условие имеет вид (20.10) и $H_{c:3} = H_{\mathrm{c}\,2}$ в целом иттервале углов. С другой стороны, при $|\varphi - (2n+1)\pi/6| < \delta\varphi$ имеем $b(\varphi) > \xi$, т.е. эффективно $b = \infty$ и $H_{c3} \approx 1,69H_{c2}$. Ширина пика определяется конкретным видом функции $b(\varphi)$. Для базиспой функции (20.12) вычисление с помошюо (20.11) дает:

$$\frac{b(\varphi)}{\xi_0} \sim \frac{1}{\cos^2 3\varphi}, \qquad \text{при } \varphi \to \frac{(2n+1)\pi}{6}$$

откуда $\delta\varphi \sim \sqrt{\xi_0/\xi}$.

В указанной узкой переходной области утлов, где 6 нзменяется от 0 до ∞, следует ожидать, что сверхпроводящее состояние вблизи поверхіноти будет возникать в некотором поле между $H_{c2}(T)$ и $1,69H_{c2}(T)$, наклон которого становится функцией H. Следует заметить, что анизотропия интерполяционной длины, а следовательно и поверхностной энергии, выгчисленная с помощыо формулы (20.11), не описывается, вообще говоря, простейшими допустимыми по симметрии функциями $f(\mathbf{n})$ (см. (13.12)-(13.14)). Однако, положение нуле этих функций (то есть пиков интерполяшонной длины) обусловлено симметрийными требованиями.

Диффузно-отражагомая поверхность. Для получения граничных условий на диффузно-отражающей поверхности удобно использовать метод квазиклассических траекторий (см. [81, 82]). Исходным пунктом, как и при рассмотрении случая зеркалынй границы, является интегральное уравнение вида (17.9) для компонент параметра порядка.

Принимая во внимание слабую зависимость плотности состояний вблизи ферми-поверхости от энергии и сохраняя только медленно мсняющиеся на атомных масштгабах вклады, получаем слслуюющее выражение для ядра $K(\mathbf{r}_1, \mathbf{r}_2)$:

$$K(\mathbf{r}_1, \mathbf{r}_2) = \pi V N_0 T \sum_n \int_0^\infty dt \exp(-2|\omega|t) \left\langle \psi^*(\hat{\mathbf{n}}_1)\, \psi_j(\hat{\mathbf{n}}_2) \right\rangle_{\varepsilon\mathbf{F},\text{classical}} \tag{20.14}$$

где $\psi(\hat{\mathbf{n}})$ - базисные функции выбранного представлсния. Угловые скобки означают усреднение по всем траекториям классической частишы, движущейся с фермисвской скоростью v_F, которые соединяют точки $\mathbf{r}_1$ и $\mathbf{r}_2$ и удовлетворятот условию $\mathbf{r}(0) = \mathbf{r}_1$. При этом мы должіы рассматривать как траектории, стартующие в момешт врсмени $t = 0$ из r_1 и через время t закапчивающиеся в $\mathbf{r}_2$, так и обращенные во времени, то есть те, которые стартуют при $-t$ из $\mathbf{r}_2$ и заканчиваются в $\mathbf{r}_1$ при $t = 0$ (нихе мы выписываем явные выражения только дъя траекторий псрвого типа, поскольку обращенные во времени дающт лишв эрмитово-сопряженный вклад в ядро). Едипичные векторы $\hat{\mathbf{n}}_1 = \mathbf{n}(\mathbf{r}_1)$ и $\hat{\mathbf{n}}_2 = \mathbf{n}(\mathbf{r}_2)$ обозпачают направления $\mathbf{n}$ скорости частишы в соответствующих точках.

Для того, чтобы вывести формулу (20.14), начнем с микроскопического определения ядра K:

[12] Во избежание недоразумений подчеркнем, что под ацизотропие поверхостной сверхпроводимости здесь имеется в виду анизотропия ваклона ликии $H_{c3}(T)$ ири фиксированном направлении внецисго поля - вдоль главно оси - и разлитчнх направлениях нормали в поверхпости в базисной плоскосги.

$$K(\mathbf{r}_1,\mathbf{r}_2)=VTT_{\mathbf{r}'_{1,2}\to r_{1,2}}\sum_n\psi^*\left(\frac{\nabla_{r_1}-\nabla_{\mathbf{r}'_1}}{2ik_{\mathrm{F}}}\right)\psi\left(\frac{\nabla_{\mathbf{r}'_2}-\nabla_{\mathbf{r}_2}}{2ik_{\mathrm{F}}}\right)\times$$
$$\times G^{(0)}(\mathbf{r}_1,\mathbf{r}_2;\omega_n)\,G^{(0)}(\mathbf{r}'_1,\mathbf{r}'_2;-\omega_n) \tag{20.15}$$

(ср. с выражением (19.2) для случая p-спаривания). Здесь $G^{(0)}$ есть функции Грина нормального состояния, для которых мы используем следуощее представление:

$$G^{(0)}(\mathrm{r}_1,\mathbf{r}_2;\omega_n)=\sum_i\frac{\Psi_i^*(\mathrm{r}_1)\,\Psi_i(\mathrm{r}_2)}{i\omega_n-\varepsilon_i} \tag{20.16}$$

где Ψ_i - собственные функцин однотастичного гамильтониана H_0 (см. 17), а ε_i - соответствутощие собственные значения. Здесь и нижс мы опускаем спиновые индексы.

Подставляя (20.16) в (20.15), получаем:

$$K(\mathbf{r}_1,\mathbf{r}_2)=\frac{VT}{k_{\mathrm{F}}^2}\sum_n\sum_{ij}\frac{(i\,|\psi_i^*\ \mathrm{J}(\mathbf{r}_2)|\,j\rangle\,\langle j\,|\psi\mathrm{J}(\mathbf{r}_2)|\,i\rangle}{(i\omega_n-\varepsilon_i)(-i\omega_n-\varepsilon_j)} \tag{20.17}$$

где $\mathbf{J}(\mathbf{r})$ есть оператор тока:

$$J(r)=\frac{1}{2i}\lim_{r'\to r}\left(\frac{\partial}{\partial r}-\frac{\partial}{\partial r'}\right)$$

Следутошии шаг состоит в использовании того факта, что только медленно меняющщиеся части волновьх функций дают вклады в сверхпроводящее ядро, и поэтому можно применять квазиклассическос приближение. Можно показать [81, 82], что в данном приближении произведение двух матричных элементов в числителе (20.17) может быть переписано в виде

$$\langle i|\hat{A}|j\rangle\langle j|\hat{B}|i\rangle=\frac{1}{2\pi N_0}\int\limits_{-\infty}^{+\infty}dt\exp\left(-i\left(\varepsilon_i-\varepsilon_j\right)t\right)\left\langle\hat{A}(\mathbf{r}_1)\,\hat{B}(\mathbf{r}(t))\delta(\mathbf{r}_2-\mathbf{r}(t))\right\rangle_{\varepsilon_{\mathrm{P}},\ \mathrm{classical}} \tag{20.18}$$

гдс усреднение проводится по всем классическим траекториям $r(t)$, таким, что $\mathbf{r}(0)=\mathbf{r}_1$. Разделим теперь область интегрирования в (20.18) на две части: $(-\infty,0)$ и $(0,\infty)$, и произведем в первой из них замену $t\to -t$. Таким образом, мді получаем интеграл по положительным t от суммы двух вкладов - от «прямых и «обращенных во времени» траекторий, сосдиняіших тодки r_1 и $\mathbf{r}_2$ (t при этом имеет смысл времени пролета частицы по траектории). После суммирования по i и j приходим к формуле (20.14).

Рассмотрим оба типа рассеяния квазичастиц на поверхности: зеркапьнос и диффузное.

Кроме того, мы ограничимся спучаем чистьх свсрхпроводников, следовательно, квазиклассические траектории в объеме образда являются

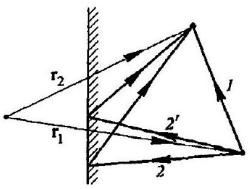

Рис. 19. Прямая (1) и отражсниыс (2 и 2') траектории из точки r_1 в точку $\mathbf{r}_2$ в случас диффузного отражения на границе прямыми линиями, а все вклады в ддро могут быть разделены на два класса: «прямые» и «отраженные» (см. рис. 19).

Первый вклад определяется тривиальной трасктсрией: $\mathbf{r}(t) = \mathbf{r}_1 + \mathbf{v}_\mathrm{F} t$. Ее подстановка в (20.17) дает следующее выражение:

$$K^{(0)}(x_1, x_2) = \frac{\pi V N_0 T}{v_F} \sum_n \int_0^1 \frac{ds}{s} \exp\left(-\frac{2|\omega_n|}{v_F s}|x_1 - x_2|\right) F^{(0)}(s) \tag{20.19}$$

где

$$F^{(0)}(s) = \int_0^{2\pi} \frac{d\varphi}{4\pi} \left(\psi^*(s,\varphi)\psi(s,\varphi) + \psi'^*(-s,\varphi)\psi(-s,\varphi)\right) \tag{20.20}$$

Как и выше, мы ввели обозначение: $s = \cos\theta$, где θ, φ ссть полярный и азимуталыный углы, соответственно (полярная ось направлена вдоль оси $\hat{x}$ - нормали к поверхности). Подразумевастся также, что все суммы по частотам обрезаны на граничной частоте ε_l.

Что касается второго вклапа в ядро, которыдй дают все возможные отраженные траектории, то его вил существснно зависит от характера отражения квазичастиц на поверхности. В случае зеркального отражения мы имеем дело лишь с одной траекторией:

$$\mathbf{r}(t) = \begin{cases} \mathbf{r}_1 + \mathbf{v}_F t, & t < t_0 = -\frac{x_1}{v_{F,x}} \\ \bar{\mathbf{v}}_F (t - t_0), & t > t_0 \end{cases}$$

где t_0 соответствует моменту соударения с поверхностью, а $\bar{\mathbf{v}}_\mathrm{F} = (-v_{F,x}, v_{F,y}\ v_{F,z})$. Подставляя это выражение для $\mathbf{r}(t)$ в (20.17) и выполняя интегрирования, окончательно прихолим к следутошему резуштату:

$$K^{(\mathrm{spec})}(x_1, x_2) = \frac{\pi V N_0 T}{v_F} \sum_n \int_0^1 \frac{ds}{s} \exp\left(-\frac{2|\omega_n|}{v_F s}(x_1 + x_2)\right) F^{(\mathrm{spec})}(s) \tag{20.21}$$

rae

$$F^{(\mathrm{spec})}(s) = \int_0^{2\pi} \frac{d\varphi}{4\pi} \left(\psi^*(-s,\varphi)\psi(s,\varphi) + +\psi^*(s,\varphi)\psi(-s,\varphi)\right) \tag{20.22}$$

Сумма выражений (20.19) и (20.21) совпадает, как и слеловало ожидатъ, с формулой (20.4), полученіой путем непосредственного интегрирования фулкий Грина.

В случае диффузного отражения, принимая во внимание вклады от всех возможных траекторий вида:

$$\mathbf{r}(t) = \begin{cases} \mathrm{r}_1 + \mathbf{v}_\mathrm{F}^{(1)} t, & t < t_0 = -\frac{x_1}{v_{\mathrm{F},x}^{(1)}} \\ v_\mathrm{F}^{(2)}(t - t_0), & t > t_0 \end{cases}$$

где $\mathbf{v}_\mathbf{F}^{(1)}$ и $\mathbf{v}_\mathbf{F}^{(2)}$ - скорости частицы на двух прямых отрезках данной траектории, и интегрируя по всем отраженным траекториям с весовым множителем $(1/\pi)\cos\theta$, получаем:

$$K^{(\mathrm{diff})}(x_1,x_2)=\frac{\pi V N_0 T_c}{v_F}\times$$
$$\times\sum_n^1\int_0^1 ds_1\int_0^1 ds_2\exp\left(-\frac{2|\omega_n|}{v_F}\left(\frac{x_1}{s_1}+\frac{x_2}{s_2}\right)\right)F^{(\mathrm{diff})}(s_1,s_2) \tag{20.23}$$

где

$$F^{(\mathrm{diff})}(s_1,s_2)=\int_0^{2\pi}\frac{d\varphi_1}{2\pi}\int_0^{2\pi}\frac{d\varphi_2}{2\pi}\left(\psi^*(-s_1,\varphi_1)\psi(s_2,\varphi_2)+\right.$$
$$\left.+\psi^*(s_1,\varphi_1)\psi(-s_2,\varphi_2)\right)$$

Окончательно получаем:

$$K(x_1,x_2)=K^{(0)}(x_1,x_2)+K^{(\mathrm{diff})}(x_1,x_2) \tag{20.24}$$

В общем случае анизотропного спаривания и произвольной ориентации поверхоости уравнение (20.2) с ядром (20.24) ие может быть решено точно [3], однако для вычисления b можно использовать вариационный метод. В результате интерполяционная ллина b всегда оказывается порядка длины когерентности ξ_0, то есть эффективное граничное условие в области Гинзбурга-Ландау имеет вид (20.10), и поверхноспная сверхпроводимость отсутствует для всех направлений нормали. В слуqае изотропного s-спаривания можно показать [83], что граничное условие имест вид (20.9) вне зависимости от характера отражения электронов.

Таким образом, поверхостная сверхпроволимость на диффузно отражающей границе оказывается весьма чувствительной к внутренней симметрии параметра порялка, поскольку случайный характер отражения электронов приводит к его изотропизации, а это может быть достигнуто лишв путем подавления сверхпроводимости вблизи поверхности.

Вывод формулы (20.11). Для вычисления коэффициента b в линейной асимптотике параметра порядка воспользуемся вариационным методом.

Перейдем в (20.4) к безразмерной переменной $X=x/\xi_0$. Тогда

$$K(X_1,X_2)=\frac{1}{2}VN_G\sum_n\int_0^1\frac{ds}{s}\left[F_i^{(-)}(s)\exp\left(-\frac{|2n+1|}{s}|X_1-X_2|\right)+\right.$$
$$\left.+F_i^{(+)}(s)\exp\left(-\frac{|2n+1|}{s}(X_1+X_2)\right)\right] \tag{20.25}$$

При $X\gg 1$, ишем решение в виде (индекс i оптскаем): $\eta(X)=C(X+q(X))$, причем $b/\xi_0=\lim_{X\to\infty}q(X)$. Уравнение для $q(X)$ имеет вид

$$q(X_1)=\frac{1}{2}E(X_1)+\int_0^\infty dX_2K(X_1,X_2)\,q(X_2) \tag{20.26}$$

$$E(X_1)=VN_0\sum_n\frac{1}{(2n+1)^2}\int_0^1 ds\,s\left[F^{(-)}(s)+F^{(+)}(s)\right]\exp\left(-\frac{|2n+1|}{s}X_1\right)$$

[13] Если параметр порядка преобразуется согласно неединичному прелставленню точечной группы

Для формулировки вариационного принципа заметим, что интегральное уравнение на параметр порядка получается вариашией функционала: $\delta\Phi/\delta q = 0$, гдс

$$\Phi[q] = \frac{\int\limits_0^\infty dX q(X)\left[q(X) - \int\limits_0^\infty dX'\Psi\left(X,X'\right)q\left(X'\right)\right]}{\left[\int\limits_0^\infty dX q(X)E(X)\right]^2} \tag{20.27}$$

При этом экстремалыне (минимальное) значение функционала есть

$$\Phi_{\min} = \frac{1}{2\int\limits_0^\infty dX E(X)q(X)}$$

Покажем теперь, что нужное нам пределное значение решения уравнения (20.25) при $X \to \infty$ выражается как раз через $\Phi_{\min}$. Пусть $q(X) = b/\xi_0 + Q(X)$, где $Q(X) \to 0$ при $X \to \infty$. Подставляя $q(X)$ в (20.25), получаем уравнение на $Q(X)$, затсм умножаем обе его части на X_1 и, интегрируя по X_1 от 0 до ∞, окончательно имеем:

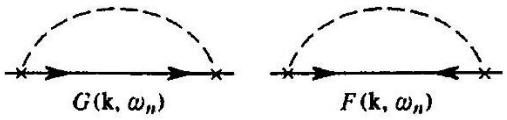
$$\frac{b}{\xi_0} = \frac{1}{7\zeta(3)}\frac{1}{\int\limits_0^1 dss^2F^{(-)}(s)}\left\{\frac{\pi^4}{24}\int\limits_0^1 dss^3\left[F^{(-)}(s) + F^{(+)}(s)\right] + \frac{1}{VN_0\Phi_{\min}}\right\}$$

Величину $\Phi_{\min}$ можно вычислять, используя вариаднонны принцип. Выбирая в качестве пробной функции пулевого приближения произвольную константу и подставляя ее в (20.26), приходим к формуле (20.11).

19.2.5 21. Influence of Impurities on Unconventional Superconductivity

Хорошо известно, что немагнитные примеси нс влияют на термодинамические свойства обычных сверхпроводников. В частности, критическая температура не зависит от концентрации пемагнитных примесей. Эффскт подавления сверхпроводимости возникаст только за счет рассеяния на магнитных примесях, разрушающих когерентность спиновых состояний электронов в куперовских парах с $S = 0$. в необычных сверхпроводпиках к такому же эффекту приводит и рассеяние на обычных примесях, разрушаюощее когсрентность орбитальных состояний спаренных электронов.

Здесь мы рассмотрим два эффекта, связанных с примесями в необычных сверхпроводниках: во-первых, умсньшение критической температуры немагнитными примесями, во-вторцх, изменение плотности состояний квазичастиц и, соответственно, термодинамических и кинетических свойстi при $T \to 0$.



Уравнения Горькова и температура перехода. Функции Грина сверхпроводника при произвольной температуре $T \le T_c$ при наличии примессй определяются путем решения уравнений Горькова (17.6)-(17.8). При этом в одночастичный гамильтониан следует добавить слагаемое вида

$$II_{\text{imp}} = \sum_{\mathbf{k},\mathbf{k}'} u_{\alpha\beta}\left(\mathbf{k},\mathbf{k}'\right)a^+_{\mathbf{k}\alpha}a_{\mathbf{k}'\beta} \tag{21.1}$$

симметрии кристалла, то штя некоторьх выделенных направленнй нормалн вклад K (difi) (x_1, x_2) тохлественно обращается в пуль в результате интегрирования по утлам. Ананотичная ситуация ямеет место аля фаз p-спаривавия при любой ориентации поверхности [72]. Негралыое уравнение (20.2) в этом случае может быть решено методом Виnера-Хопфа.

где $u_{\alpha\beta}(\mathbf{k},\mathbf{k}')$ есть амплитуда рассеяния электрона в поле примесей, в общем случае зависящая от спина.

Поскольку мы интересуемся лишь характеристиками, усреднснными по реализациям случайного потенциала (по положениям примессй), то для нахождения функций Грина следуст воспользоваться уравнениями (17.11), включив в них примесные собственно-энергетические части (см. рис. 20), причем усреднение производится в точности так же, как и в теории обычных сверхпро-

б

Рис. 20. Примесные собственно-энергетические функция. Борновское приближение водящих сплавов [71]. Мы не принимаем во внимание интерференцию волн, рассеянных на разных примесях, предполагая выполнение условия слабого беспорядка $k_F l \gg 1$, где $l = v_F\tau$ - длина свободного пробега. Кроме того, мы пренебрегаем возможностью многократного рассеяния на одлой и той же примеси, что справедливо в слутае малости потенциала примесей по сравнению с характерной энергией электронов ε_F (борновское приближение) [1].

В указанных условиях диаграммы для усредненных собственноэнергетических частей содержат по два примесных креста, соединенных пунктирной линией (рис. 21). Если рассеяние на примесях изотропно и не зависит от спина, то пунктириой лиiии соответствует выражение

$$n_{\text{imp}}u^2 = \frac{1}{2\pi N_0\tau}$$

где n_{imp} - концентрация примессй, u - входящая в (21.1) амплитуда рассеяния, а τ есть время свободного пробега квазичастиц.

В анизотропном сверхпроводнике амплитуда рассеяния на примеси зависит от углов, и пунктиру отвечает выражсние $\hat{\tau}^{-1}(\mathbf{k},\mathbf{k}')$, обладающее точечной симметрией кристалла (см. 4). Мы можем представить его в виде разложения по мепривоДимым представлениям группы G:

$$\tau^{-1}_{\alpha\beta,\gamma\delta}(\mathbf{k},\mathbf{k}') = \sum_{\Gamma}\left(\frac{1}{\tau_{\Gamma,1}}\delta_{\alpha\beta}\delta_{\gamma\delta} + \frac{1}{\tau_{\Gamma,2}}\boldsymbol{\sigma}_{\alpha\beta}\sigma_{\gamma\delta}\right)\sum_{i=1}^{d_\Gamma}\psi_i^\Gamma(\hat{\mathbf{k}})\psi_i^{\Gamma*}\left(\hat{\mathbf{k}}'\right) \tag{21.2}$$

для случая слабого спин-орбитального взаимодействия, или

$$\tau^{-1}_{\alpha\beta,\gamma\delta}(\mathbf{k},\mathbf{k}') = \sum_{\Gamma}\frac{1}{\tau_\Gamma}\sum_{i=1}^{d\text{r}}\left(\psi_i^\Gamma(\hat{\mathbf{k}})\sigma\right)_{\alpha\beta}\left(\psi_i^{\Gamma*}\left(\hat{\mathbf{k}}'\right)\sigma\right)_{\gamma\delta}$$

для случая сильного спин-орбитального взаимодействия. Индекс Г обозначает неприводимыге представления размерности d_Γ группы G, а i нумерует базисные функции $\psi_i^\Gamma(\hat{k})$. Коэффициенты разложения τ^{-1} пропорциональны концентрагии примесей, причем слагаемые с τ_2 в выражении (21.2) соответствуют рассеянию с переворотом спина.

Для простоты ограничимся рассмотрением изотропного рассеяния на немагнитных примесях. Тогда усредиенная нормальная собственноэнергетическая часть (см. рис. 20а) имеет вид:

[11] Iекоторые следствия выхода за пределы борновского приближения будут рассмотрены нихе.

$$\Sigma_{1,\alpha\beta}(\omega_n) = \Sigma(\omega_n)\,\delta_{\alpha\beta} = \frac{1}{2\pi N_0 \tau}\int \frac{d^3k}{(2\pi)^3} G(\mathbf{k},\omega_n)\,\delta_{\alpha\beta} \tag{21.3}$$

Аномальная собственно-энергетическая часть, соответствующая диаграмме на рис. 206:

$$\Sigma_{2,\alpha\beta}(\omega_n) = \frac{1}{2\pi N_0 \tau}\int \frac{d^3k}{(2\pi)^3} F_{\alpha\beta}(\mathbf{k},\omega_n) \tag{21.4}$$

обращается в нуль в результате интегрирования по направлениям k в случас изотропного примесного рассеяния для любого сверхпроводящего состояния с параметром порядка, преобразующимся согласно неединичному представлениоо.

Уравнения Горькова теперь записываются как

$$\begin{gathered}
(i\omega_n - \xi_k - \Sigma(\omega_n))\,G(\mathbf{k},\omega_n)\,\delta_{\alpha\beta} + \Delta_{\alpha\gamma}(\mathbf{k}) F^{+}_{\gamma\beta}(\mathbf{k},\omega_n) = \delta_{\alpha\beta} \\
(i\omega_n + \xi_k - \Sigma(\omega_n))\,F^{+}_{\alpha\beta}(\mathbf{k},\omega_n) + \Delta^{+}_{\alpha\beta}(\mathbf{k}) G(\mathbf{k},\omega_n) = 0 \\
(i\omega_n - \xi_k - \Sigma(\omega_n))\,F_{\alpha\beta}(\mathbf{k},\omega_n) - \Delta_{\alpha\beta}(\mathbf{k}) G(-\mathbf{k},-\omega_n) = 0
\end{gathered} \tag{21.5}$$

Отсгода мы получаем следующие выражения для функций Грина сверхпроводника:

$$\begin{aligned}
G(\mathbf{k},\omega_n) &= -\frac{i\bar{\omega}_n + \xi_k}{\tilde{\omega}_n^2 + \xi_k^2 + \Delta_k^2} \\
F_{\alpha\beta}(\mathbf{k},\omega_n) &= \frac{\Delta_{\alpha\beta}(k)}{\tilde{\omega}_n^2 + \xi_k^2 + \Delta_k^2}
\end{aligned} \tag{21.6}$$

где

$$i\tilde{\omega}_n = i\omega_n - \Sigma(\omega_n) \tag{21.7}$$

Собственно-энергетическая часть должна быть вычислена самосогласованнымм образом. Подставляя выражение для функции G из (21.6) в (21.3) и выполняя интегрирование по энергии в предположснии электрон-дырочной симметрии, приходим к следуюощему уравненио:

$$\Sigma(\omega_n) = -\frac{i\bar{\omega}_n}{2\tau}\int \frac{d\Omega}{4\pi} \frac{1}{\sqrt{\tilde{\omega}_n^2 + \Delta_k^2}} \tag{21.8}$$

При $T < T_c$ решение уравнений (21.7), (21.8) определяется конкретным видом параметра порядка.

Вблизи критической температуры параметр порядка мал, и можно пренебречь зависимостью правой части уравнения (21.8) от Δ_k. Учитывая (21.7), получаем:

$$\tilde{\omega}_n = \omega_n + \frac{1}{2\tau}\operatorname{sign}\tilde{\omega}_n$$

Опсюда

$$\bar{\omega}_n = \omega_n + \frac{1}{2\tau}\operatorname{sign}\omega_n$$

и, следовательно, собственно-энергетическая часть при $\Delta_k \to 0$ имеет вид:

$$\Sigma(\omega_n) = -\frac{i}{2\tau}\operatorname{sign}\omega_n \tag{21.9}$$

то есть совпадает, как и допжно быть, с соответствуошпим выражением дя нормального металла.

Усредненная аномальная функция Грина выглядит тогда следующим образом:

$$F_{\alpha\beta}\left(\mathbf{k},\omega_n\right)=\frac{\Delta_{\alpha\beta}(\mathbf{k})}{\left[\omega_n+(1/2\tau)\operatorname{sign}\omega_{rn}\right]^2+\xi_k^2} \tag{21.10}$$

Подставляя (21.10) в условие самосогласования (17.5) и выполняя интегрирование по ξ, паходим:

$$\Delta_{\alpha\beta}(\mathbf{k})=\pi N_0 VT\sum_n\frac{\operatorname{sign}\omega_n}{\omega_n+(1/2\tau)\operatorname{sign}\omega_n}\int\frac{d\Omega'}{4\pi}V_{\beta\alpha,\gamma\delta}\left(\mathbf{k},\mathbf{k}'\right)\Delta_{\gamma\delta}\left(\mathbf{k}'\right)$$

После подстановки сюода разложсний потенниала парного притяжения V из §5, получаем:

$$\begin{aligned}1&=\pi N_0 VT\sum_n\frac{\operatorname{sign}\omega_n}{\omega_n+(1/2\tau)\operatorname{sign}\omega_n}=\\&=2\pi N_0 VT\sum_{n\geq 0}\frac{1}{\omega_n}+2\pi N_0 VT\sum_{n\geq 0}\left(\frac{1}{\omega_n+1/2T}-\frac{1}{\omega_n}\right)\end{aligned} \tag{21.11}$$

Логарифмически расходящаяся сумма в первом слагаемом обрезается на граничной частоте ε_1. Вспоминая определение критической температуры T_{c0} в чистом сверхпроводнике (см. (18.17)), и переписывая второе (сходящееся) слагаемое в (21.11) с учетом определения дигамма-функции $\psi(x)$, мы приходим к окончательному результату [84]:

$$\ln\frac{T_{\mathrm{c}0}}{T_{\mathrm{c}}}=\psi\left(\frac{1}{2}+\frac{1}{4\pi\tau T_{\mathrm{c}}}\right)-\psi\left(\frac{1}{2}\right) \tag{21.12}$$

Полученное уравнение определяет понижение критической температуры для произвольного сверхпроводящего состояния с нетривиальньм спариванием за счет изотропного рассеяния на немагнитных примесях относительно температуры перехода $T_{\mathrm{c}0}$ чистого сверхпроводника, характерной для представления Г, согласно которому преобразуется параметр порядка. Обратим вниманис на то, что (21.12) (с точностью до обозначений) совпадает с уравнением, описывающим подавление критической температуры парамагнитными примесями в обычном сверхпроводнике [85].

В случае малой концентрации примесей получаем:

$$T_{\mathrm{c}}=T_{c0}-\frac{\pi}{8\tau} \tag{21.13}$$

(мы воспользовались тем, что $\psi'(1/2)=\pi^2/2$).

Таким образом, немагнитные примеси в сверхпроводнике с нетривиальным спариванием подавляют сверхпроводимостъ. Качественно данный эффект можно объяснить следующим образом. Внесение примесей приводит
к изотропизации щели в спектре возбуждений. Однако, если куперовское спаривание происходит в состоянии с нарушенной пространственной симметрией, то единственной возможвостью сделать щель изотропной является тождественное обращение ее в нуль на всей поверхности Ферми, что и происходит при некоторон концснтрации примесей $\tau\Delta_0\sim 1$, гдс Δ_0 - мопуль щели при $T=0$ в отсутствие примесей.

Плотность состоний. Представлет интерес проследить, каким образом происходит подавление параметра порядка и что происходит с нулями щели при увеличении

концентрации примссей. Для ответа на эти вопросы найдем плотность состояний квазитастиц $N(E)$ (см. 17) при $E \to 0$. При этом мы не будем принимать во внимание уравнение самосогласования для параметра порядка в присутствие примесей, так как это пе влияет на поведение $N(E)$ при $E \to 0$, а лиш меняет величину модуля параметра порядка.

Выполним в (21.7) аналитическое прололжение и введем обозначение

$$t(E) = (i\tilde{\omega}_n)|_{i\omega_n \to E+i0} = E - \Sigma^R(E) \tag{21.14}$$

Тогда выражение (17.27) для плотности состояниді может бытть с учетом (21.3), записано следующим образом:

$$N(E) = -\,2N_0\tau\,\mathrm{Im}\,\Sigma\,(\omega_n)|_{i\omega_n+E+i0} = 2N_0\tau\,\mathrm{Im}\,t(E) \tag{21.15}$$

Таким образом, задача свелась к нахождению зависимости $\mathrm{Im}\,t(E)$. Для ее вытисления необходимо произвести в (21.8) аналитическое продолжение на ось вещественных частот. В результате получается зависящее от структуры сверхпроводящего параметра порядка $\Delta(\mathrm{k})$ уравнение самосогласования для функции $t(E)$:

$$t = E + \frac{i}{2\tau} g(t) \tag{21.16}$$

где

$$g(t) = \int \frac{d\Omega}{4\pi} \frac{t}{\sqrt{t^2 - \Delta_k^2}} \tag{21.17}$$

(знак корня при аналитическом продолжении выбирается таким образом, чтобы $\mathrm{Im}\,\Sigma^R < 0$).

В качестве примеров, илшострирупших поведение плотности состояний в необычных сверхпроводниках с примесями, найдем решения уравнения (21.16) для различных фаз с p-спариванием.

B-фаза. Анатогично случато обычной сверхпроводимости, для B-фазы мы имеем $\Delta_{\mathrm{k}}^2 = \Delta^2 = \mathrm{const}$, и (21.16) принимает вид

$$t = E + \frac{i}{2\tau} \frac{t}{\sqrt{t^2 - \Delta^2}}$$

Мнимая часть у решения $t(E)$ данного уравнения (а, следовательно, и ненулевая плотность состояний) появляется лишш при $E > E_c$, где величина порога соответствует максимальному значению функции $E(t) = t - t/2\tau\sqrt{\Delta^2 - t^2}$ (см. [85]):

$$E_c^2 = \Delta \left[1 - \left(\frac{1}{2\tau\Delta} \right)^{2/3} \right]^{3/2} \tag{21.18}$$

Мы видим, что при достаточно высокой концентрации немагнитных примесей такод, что $\tau < 1/2\Delta$, щель в спектре обращается в нул. При этом, однако, критическая темпсратура, определяемая уравнением (21.12), все еще больше нуля, что соответствует бесщелевой свсрхпроводимости, совсршенно аналогично тому, что имеет место в обычных сверхпроводниках с парамагнитными примесями (см. упражнение в конце параграфа).

A-фаза. Параметр порядка имеет вид $\Delta_{\mathrm{k}}^2 = \Delta^2 \sin^2\theta$ (мы выбрали такую же нормировку модуля Δ, как и в 7). Выполняя интегрирование по утлам в (21.17), получаем:

$$t = E + \frac{i}{4\tau\Delta} t \ln \frac{t+\Delta}{t-\Delta}$$

Это уравнение может быть решено при $E \to 0$:

$$t = \frac{E}{1 - \pi/(4\tau\Delta)} + \frac{iE^2}{2\tau\Delta^2[1 - \pi/(4\tau\Delta)]^3}$$

откуда следует, что

$$N(E) = N_0 \frac{1}{[1 - \pi/(4\tau\Delta)]^3} \left(\frac{E}{\Delta}\right)^2$$

С увеличением слепени загрязнения, то есть уменьшением времени пробега τ, коэффициент при E^2 растет и при $\tau\Delta = \pi/4$ обращается в бесконечность. Этим определяется критическая концентрация примесей, выше которой

$$N(E = 0) = 2N_0\tau\Delta \operatorname{tg}\left(\frac{\pi}{2} - 2\tau\Delta\right) \tag{21.19}$$

Физический смысл полученного результата становится ясным при сравнении с (17.30): нули в спектре квазичастиц для A-фазы остатотся изолированньми точками при малом количестве примесей и размываются в «пятна» нулей [23, 86] только выиге критической концснтрации.

Полярная фаза. Параметр порядха имеет вид $\Delta_k^2 = \Delta^2 \cos^2\theta$. Из (21.16) имеем:

$$t = E + \frac{i}{2\tau\Delta} t \arcsin\frac{\Delta}{t}$$

Легко убедиться в том, что это уравнение имеет при $E = 0$ следующее решение

$$t(E = 0) = \frac{i\Delta}{\operatorname{sh} 2\tau\Delta} \tag{21.20}$$

откуда

$$N(E = 0) = N_0 \frac{2\tau\Delta}{\operatorname{sh} 2\tau\Delta} \tag{21.21}$$

Это означает, что при сколь угодно слабом загрязнении линии нулей становятся цельми полосами [23, 86]. Такой эффект приведет к изменению термодинамических свойств сверхпроводника с подобной структурой щели при $T \to 0$, в частности, электронная теплоемкость станет пропорциональной температуре.

Упражнение. С помощью уравнения (21.12) вцчислить значение критической концентрации примесей, при которой T_c обращается в нуль, и найти область существования бесщелевой сверхпроводимости в B-фазе.

Выход за пределы борновского приближения. Приведенный выше анализ базировался на использовании борновского приблихения, то есть на пренебрежении возможностью многократного рассеяния электрона на одной и той же примеси. При учете такого рассеяния необходимая модификация теории сводится к замене собственно-энергетических частей, найденных в борновском приближении, на точпые. Для обычных сверхпроводников при этом сохраняегся основной вывод об отсутствии подавления сверхпроводимости немагнитными примесями. Для необычных сверхпроводников рассеяние на примесях подавляет свсрхпроводимость, а выход за пределы борновского приближения приводит к существенным изменениям в поведении функаий Грина, а, следовательно, и физических величин [87, 88].

Мы рассмотрим случа слабого беспоряшка, то есть достаточно малой концентации примесей, когда выполняется условие $k_F l \gg 1$, позволяющее не учитывать диаграммы с пересекающимися пунктирными линиями. Физически это означает пренебрежение интерференцией волн, рассеянных на разных примесях, и ответ для $\Sigma(\omega_n)$ получается

просто умножением вклада одной примеси $\Sigma_0(\omega_n)$ на их концентрацию: $\Sigma(\omega_n) = n_{\text{imp}}\,\Sigma_0(\omega_n)$. Величина $\Sigma_0(\omega_n)$ непосредственно связана с точной ампитудой рассеяния на нулевой утол на одной примеси, которая определяется суммой диаграмм

Ри с. 21. Диаграммное уравнение для точной амплитуды рассеяния на одной примеси

на рис. 21. Для изотропного точечного потенциала примесей аномальная собственно-энергетическая часть обрашается в нуль для любых сверхпроводящих состояний с параметрами порядка, соответствующими неединичным прсдставлениям группы симметрии кристалла. В этом случае амплитуда рассеяния характеризуется единственной скалярной функаией $f(\omega_n)$, причем

$$\Sigma(\omega_n) = n_{\text{imp}} f(\omega_n) \tag{21.22}$$

В общем же случае амплитуда рассеяния зависит от импульсов и является матрицей 4×4 (T-матрицей) в спиновом пространстве и «пространстве» частица-дырка (см. 17).

Суммирование диаграммного ряда на рис. 21 позволяет выразить $f(\omega_n)$ через затравочную амплитуду рассеяния $\boldsymbol{u}$. Удобнее, однако, записать точную амплитуду рассеяния в несколько ином виде, вводя фазовыи сдвиг δ_0 рассеянной s-волны в нормальном состоянии:

$$f(\omega_n) = \frac{k_{\text{n}}}{1 - k_{\text{n}} \sum\limits_{\mathbf{k}} G(\mathbf{k}, \omega_n)} \tag{21.23}$$

где $k_{\text{n}} = -\operatorname{tg}\delta_0/(\pi N_0)$, а $G(\mathbf{k}, \omega_n)$ есть усредненная функция Грина сверхгроводника [2]. Подставляя (21.23) в (21.22), включая вещественную (четную по ω_n) часть собственно-энергетической функции в перенормировку химического потенциала и выдсляя явно мнимую (нечетную по ω_n) часть, получаем:

$$\Sigma(\omega_n) = \frac{n_{\text{imp}} k_{\text{n}}^2 \sum\limits_{\mathbf{k}} G(\mathbf{k}, \omega_n)}{1 - k_n^2 \left(\sum\limits_{\mathbf{k}} G(\mathbf{k}, \omega_n) \right)^2} \tag{21.24}$$

Здесь мы использовали тот факт, что в случас элскгрон-дырочной симмстрии $\sum\limits_{\mathbf{k}} G(\mathbf{k}, -\omega_n) = -\sum\limits_{\mathbf{k}} G(\mathbf{k}, \omega_n)$ (см. (21.6)). Подставляя в (21.24) выражение для функции Грина (21.6), интегрируя по ξ и выполняя аналитическое продолжение с jчетом (21.14), получаем окончательно уравнение для функции $t(E)$, обобщающее (21.16) на случай неборновского рассеяния:

$$t = E + i\Gamma \frac{g(t)}{\cos^2\delta_0 + \sin^2\delta_0 g^2(t)} \tag{21.25}$$

где

$$\Gamma = \frac{n_{\text{imp}}}{\pi N_0} \sin^2\delta_0$$

а $g(t)$ определяется формулой (21.17). В прсделе слабого рассеяния, устремляя δ_0 К нулюо, имеем:

[12] Чтобы не прерывать связности излохения, вывод формулы (21.23) вынесен в конец параграфа.

$$\Gamma \to \frac{n_{\rm imp}}{\pi N_0}\delta_0^2 = \pi N_0 n_{\rm imp} u^2 = \frac{1}{2\tau_{\rm Born}}$$

и (21.25) переходит в (21.16).

Выражение (21.15) для плотности состояний квазичастиц справедливо лиш в борновском приближении. Для вычисления $N(E)$ в случае произвольных фазовых сдвигов вернемся к опрсделению (17.27):

$$N(E) = -\frac{1}{\pi}\,{\rm Im}\sum_{\mathbf{k}} G\left(\mathbf{k},\omega_n\right)\Big|_{i\omega_n\to E+i0} = -\frac{1}{\pi}\,{\rm Im}\sum_{\mathbf{k}} G^R(\mathbf{k},E) \tag{21.26}$$

Входящая сюда функция Грина получается путем аналитического продолжения в (21.5):

$$G^R(\mathbf{k},E) = \frac{t(E)+\xi_k}{t^2(E)-\Delta_{\mathbf{k}}^2-\xi_k^2} \tag{21.27}$$

Из (21.26), (21.27) и (21.17) окончательно получаем:

$$N(E) = N_0\,{\rm Re}\,g(t(E)) \tag{21.28}$$

В борновском приближении, как мы видели, изолированные точки нулей в сверхпроводнике со структурой, например, A-фазы, являтся устойчивыми по отношению к слабому загрязнению. Покажем теперь, что для достаточно сильного потенциала примессй это не так.

Рассмотрим противоположныи борновскому случай резонансного рассеяния, то есть больших фазовых сдвигов: $\delta_0 \to \pi/2$. Подставляя в (21.25) $\Delta_{\mathbf{k}}^2 = \Delta^2\sin^2\theta$, получаем для $t(E)$ уравнение:

$$t = E + 2i\Gamma\Delta\frac{1}{t}\left(\ln\frac{t+\Delta}{t-\Delta}\right)^{-1} \tag{21.29}$$

имеющее при $E=0$ и $\Gamma \ll \Delta$ следующее решение:

$$t(E) = i\sqrt{\frac{2\Gamma\Delta}{\pi}} \tag{21.30}$$

Подставляя его в (21.17), получаем:

$${\rm Re}\,g(t(E=0)) = \sqrt{\frac{\pi\Gamma}{2\Delta}}$$

Окончательно:

$$N(E=0) = N_0\sqrt{\frac{\pi\Gamma}{2\Delta}} \tag{21.31}$$

Мы видим, что плотность состояний при $E=0$ оказывается конечной, но, разумеется, обращается в нуль при уменьшении степени загрязнения, то есть при $\Gamma \to 0$. Это означает, что внесение сколь утодно малого количества резонансных примссей превращает изолированные нули щели в спектре сверхпроводника в пятна конечного размера [88].

MC-21.1

Найти понижение критической температуры сверхпроводника с p-спариванием вследствие резонансного рассеяния на примесях. Как изменится в этом случае уравнение (21.12)?

MC-21.2

Вычислить плотность состоянnй при $E = 0$ для полярной фазы при резонансном рассеянии на примесях [3].

Вывод формулы (21.23). Диаграммный ряд на рис. 21 сводится, как легко видеть, к следующему уравнению на амплитуду рассеяния:

$$f(\omega) = u + u \sum_{\mathbf{k}} G(\mathbf{k}, \omega) f(\omega) \tag{21.32}$$

Запишем входяшую сюда функцию Грина сверхпроводника как

$$G = G_{\text{off}}^{(0)} + G - G_{\text{off}}^{(0)} \tag{21.33}$$

где

$$G_{\text{off}}^{(0)} = \frac{1}{2}\left(G^{(0)R} + G^{(0)A}\right)$$

есть всщественная часть функции Грина для расссяния на одной примеси в нормалном состоянии. В соответствии с определением функции Грина уравнения Шредингера:

$$G^{(0)}(\omega) = \frac{1}{\omega - \varepsilon + i0} = P\frac{1}{\omega - \varepsilon} - i\pi\delta(\omega - \varepsilon) = G_{\text{off}}^{(0)} + G_{\text{on}}^{(0)}$$

гдс ε есть энергии свободных электронов, взаимодействующих с примесью, а P - символ главного значения интеграла. Индекс «off («оп») у вещественной (мнимой) части функции Грина означает, что промежуточные состояния пе находятся (находятся) на массовой поверхiости.

[3] См. Ю. С. Бараи, В. П. Минеев, А. А. Свидзииский //Письма в ЖЭТФ. 1997. 65. 606.

Подстановка (21.33) в (21.32) и перегруппировка слагаемьх даюот:

$$\begin{aligned} f(\omega) &= \left(u + u^2 \sum_{\mathbf{k}} G_{\text{off}}^{(0)}(\mathbf{k}, \omega) + \ldots\right)\left(1 + \sum_{\mathbf{k}} \left[G(\mathbf{k}, \omega) - G_{\text{off}}^{(0)}(\mathbf{k}, \omega)\right] f(\omega)\right) = \\ &= k_{\text{n}} + k_{\text{n}} \sum_{\mathbf{k}} \left[G(\mathbf{k}, \omega) - G_{\text{off}}^{(0)}(\mathbf{k}, *\omega)\right] f(\omega) \end{aligned} \tag{21.34}$$

Здесь мы ввели величину k_{n}, описываюшую рассеянис на примеси в нормальном металле и удовлетворяющую соотношенино:

$$k_{\text{n}} = u + u G_{off}^{(0)} k_{\text{n}}$$

В общем случае вместо одной скалярной функции k_{n} нсобходимо рассматривать матрицу 4×4 (-матрицу) [88].

Величина k_{n} параметризуется с помошьго фазового сдвига рассеянных волн следующим образом:

$$k_{\text{n}} = -\frac{\operatorname{tg} \delta_0}{\pi N_0} \tag{21.35}$$

Стоящая в правой части (21.34) сумма по димпулесам от $G_{\text{ofT}}^{(0)}(\mathbf{k}, \omega)$ равна нулю и мы приходим к формуле (21.23).

19.2.6 22. Electronic Thermal Conductivity of Unconventional Superconductors

Наличие симметрийпых нулей в спсктре элементарных возбуждений приводит, как мы убсдились выше, к существенному измешению термодинамичсских характсристик сверхпроводиика при низких температурах. В кинетике необычных сверхпроводников нули в спсктре также итраюот важнуо роль.

Наиболее просго неравновесные свойства сверхпроводников описываются с помощью кинетического уравнения Больцмана, которому удовлстворяет функция распределения возбуждсний. Разумеется, больцмановская кинетическая теория справедлива лишш для газа хорошо определешших элементарных возбуждений, энсргия которых велика по сравнснию с обратным врсменсм их жизни. Это условие заведомо нарушается в необычных сверхпроводниках с нулями в спектре элсмен'гарных возбуждений, обладающих конечной плотностью состояний при нулевой энергии. Поэтому описанис релаксационных процессов с помощью уравнения Больцмана справедливо только в области достаточно высоких температур, гдс средняя тепловая энергия возбуждений велика по сравнению с их затуханием γ. В чистьх сверхпроводниках данная область охватывает почти весь диапазон температур, кроме депосредстзенной охрестности нуля, поэтому здесь можно пользоваться уравнением Болцмана. Следует, однако, иметь в виду, что и в этой области вычислсние энергетической зависимости времени свободного пробега возбуждений, черсз которое выражактся кинстические коэффишиенты, требует привлечения микроскопической теории. При $T < \gamma$ кинетические коэффициенты можно выгчислить только теоретико-полевыми методами. Мы изложим здесь оба подхода к кинетике сверхпроводников на примере вычисления электронной теплопроводности.

Метод кинетического уравления. Напомним опрелеление коэффициента теплопроводности §. Поток тепла, переносимый неравновесными возбуждениями, определяется формулой

$$\mathbf{Q}(\mathbf{r}) = 2\int \frac{d^3k}{(2\pi)^3} E_{\mathbf{k}}(\mathbf{r})\mathbf{v}_{\mathbf{k}}(\mathbf{r})f_{\mathbf{k}}(\mathbf{r}) \tag{22.1}$$

где E - энергия, $\mathbf{v} = \partial E/\partial\mathbf{k}$ - скорость квазичастиц в свсрхпроводнике [1], а $f_k(\mathbf{r})$ - неравновесная фупкция распределения возбуждений, взаимодействующих с примесями. Коэффицисит теплопроводности x связывает поток тепла с градиентом температуры

$$Q = -x\nabla T \tag{22.2}$$

Функция $f_{\mathbf{k}}(\mathbf{r}, t)$ удовлетворяет хинетическому уравнению Больцмана, которое имеет следующий вид:

$$\frac{\partial f}{\partial t} + \frac{\partial E}{\partial \mathrm{k}}\nabla f - \nabla E\frac{\partial f}{\partial \mathrm{k}} = \left(\frac{\partial n}{\partial t}\right)_{\mathrm{imp}} \tag{22.3}$$

где в правой части стоит интеграл сголкновений возбуждений с примесями [2]. В сташионарном случас и для слабо неравновесных распределений это уравнение может быть упрощсно. Поскольку интеграл столкновений обрашается в нуль при подстановке локальио-равновесной функции распределения $f^{(0)}_{\mathbf{k}}(\mathbf{r}) = f\left(E_{\mathbf{k}}(\mathbf{r})/T(\mathbf{r})\right)$, где f - фермиевская функция (6.2), то в линейном по отклонению от равновесия приближении в левой части уравнения (22.3) мы можем заменить f на $f^{(0)}$. Имеем

$$\frac{\partial E}{\partial \mathbf{k}}\nabla f_{\mathrm{k}}^{(0)} - \nabla E\frac{\partial f_{\mathbf{k}}^{(0)}}{\partial \mathbf{k}} = \frac{\partial E}{\partial \mathbf{k}}\frac{\partial f_{\mathrm{k}}^{(0)}}{\partial E}T\left(\frac{1}{T}\nabla E - \frac{E}{T^2}\nabla T\right) -$$
$$- \nabla E\frac{\partial f_{\mathrm{k}}^{(0)}}{\partial E}\frac{\partial E}{\partial \mathbf{k}} = -\frac{E}{T}\frac{\partial f_{\mathbf{k}}^{(0)}}{\partial E}\frac{\partial E}{\partial \mathbf{k}}\nabla T \tag{22.4}$$

ОБратим внимание на то, что члены, содержащие градиенты щели Δ, в точности сократили друт друга.

Интеграл столкновений в случае слабого беспорядка получается умножением вклада одной примеси на их концентрацию:

$$\left(\frac{\partial f_{\mathbf{k}}}{\partial t}\right)_{\mathrm{imp}} = n_{\mathrm{imp}}\int\frac{d^3k'}{(2\pi)^3}w\left(\mathbf{k},\mathbf{k}'\right)\left(\delta f_{\mathbf{k}'} - \delta f_{\mathbf{k}}\right) \tag{22.5}$$

где $w\left(\mathbf{k},\mathbf{k}'\right)$ - вероятность упрутого рассеяния квазичастиц, а δf - отклоненис функчии распределения от равновесгой, входящее, согласно (22.1), в формулу для теплового погока:

$$\mathbf{Q} = 2\int\frac{d^{\hat{s}}k}{(2\pi)^3}E_{\mathbf{k}}\mathbf{v}_{\mathbf{k}}\delta f_{\mathbf{k}}(\mathbf{r}) \tag{22.6}$$

В борновском приближснии вероятность w вычисляется с помощью «золотого правила Фермиж:

$$w\left(\mathbf{k},\mathbf{k}'\right) = \frac{2\pi}{\hbar}\left|\left(\mathbf{k}'\left|H_{\mathrm{imp}}\right|\mathbf{k}\right\rangle\right|^2\delta\left(E_{\mathbf{k}} - E_{\mathbf{k}'}\right)$$

Применяя прсобразование Боголюбова (5.25) к гамильтониану (21.1), описывающему взаимодействис электронов с немагнитно примссью, получаем:

$$w\left(\mathbf{k},\mathbf{k}'\right) = \frac{2\pi}{h}u^2\mathcal{C}\left(\mathbf{k},\mathbf{k}'\right)\delta\left(E_{\mathbf{k}} - E_{\mathbf{k}'}\right) \tag{22.7}$$

где так называемый фактор когерентности дается выражением:

$$\mathcal{C}\left(\mathbf{k},\mathbf{k}'\right) = \begin{cases}\frac{1}{2}\left(1 + \frac{\xi_k\xi_{k'} - \mathrm{Re}\,\Delta^2 g(\mathbf{k})g(\mathbf{k}')}{E_{\mathbf{k}}E_{\mathbf{k}'}}\right), & \text{при } S=0\\ \frac{1}{2}\left(1 + \frac{\xi_k\xi_{k'} - \mathrm{Re}\,\Delta^2\mathbf{d}(\mathbf{k})\mathbf{d}(\mathbf{k}')}{E_{\mathbf{k}}E_{\mathbf{k}'}}\right), & \text{при } S=1\end{cases}$$

Мы видим, что в случае анизотропного спаривания вероятность w зависит от утлов даже для изотропной амплитуды рассеяния $u\left(\mathbf{k},\mathbf{k}'\right) = u = \mathrm{const}$.

Перепишем кинетическое уравнение (22.3) с учетом (22.4) и (22.5) в следующем виде:

$$\delta f_{\mathbf{k}} - \tau_{\mathbf{k}}\int\frac{d^3k'}{(2\pi)^3}\tau^{-1}\left(\mathbf{k},\mathbf{k}'\right)\delta f_{k'} = \tau_k E_k\mathbf{v}_{\mathbf{k}}\frac{\partial f_{\mathbf{k}}^{(0)}}{\partial E}\frac{\nabla T}{T} \tag{22.8}$$

где

[11] Пространственная зависчмость E и $\mathbf{v}$ возникает из-за зависимости энергетической щели $\triangle$ от температуры, которая, в свож очередь, является фупгсиней r. Предполагастся, что T медленно меняется на масшттабе корреляционно д длины.

[2] Вывод кннетических уравнении для сверхпррводника представляет собо доволыо слодную задачу, поскольку необходимо учитывать динамику самого параметра порядка. Уравнение (22.3) справедлкво в предлолохении, что возбухдения распространяются в заданном, не зависящем от времени, слабо неоднородном потенциале $\Delta(r)$, а $E_{\mathrm{k}}(\mathrm{r}) = \sqrt{\xi^2 + \Delta_{\mathrm{k}}^2(\mathrm{r})}$.

$$\tau^{-1}(\mathbf{k},\mathbf{k}') = n_{\rm imp}\, w(\mathbf{k},\mathbf{k}')$$
$$\tau_{\mathbf{k}}^{-1} = \int \frac{d^3k'}{(2\pi)^3}\tau^{-1}(\mathbf{k},\mathbf{k}') = \frac{2\pi}{\hbar} n_{\rm imp} u^2 \int \frac{d^3k'}{(2\pi)^3}\mathcal{C}(\mathbf{k},\mathbf{k}')\,\delta(E_{\mathbf{k}} - E_{\mathbf{k}'}) \tag{22.9}$$

причем τ_k имеег смысл времени свободного пробега квазичастиц. Поскольку как при замене частица-дырка (т. е. $\xi_k \to -\xi_k$), так и при пространственной инверсии τ^{-1} остается инвариантнвм, а правая часть (22.8) меняет знак, получаем, что $\delta f_{\rm k}$ долхна быть нечетной относительно ухазанных преобразовании. По этой причине второе слагаемое в левой части (22.8) обращдается в нуль, и

$$\delta f_{\rm k} = \tau_{\rm k} E_{\rm k} \mathbf{v}_{\rm k} \frac{\partial f_{\rm k}^{(0)}}{\partial E}\frac{\nabla T}{T}$$

Подставляя пайденное решение кинетического уравнения в (22.6) и вспоминая определение коэффициента теплопроводности (22.2), окоичательно имеем:

$$\varkappa_{ij} = -\frac{2}{T}\int \frac{d^3k}{(2\pi)^3}\frac{\partial f_{\mathbf{k}}^{(0)}}{\partial E} E_{\mathbf{k}}^2 v_{\mathbf{k},i} v_{\mathbf{k},j}\tau_{\mathbf{k}} \tag{22.10}$$

причем скорость квазичастиц определяется следующим образом

$$\mathbf{v}_{\mathbf{k}} = \frac{\partial E_{\rm k}}{\partial \mathbf{k}} = v_{\rm F}\hat{\mathbf{k}}\frac{\xi_k}{E_{\mathbf{k}}} + O\left(\frac{\Delta}{\varepsilon_{\rm F}}\right) \tag{22.11}$$

Из всех величинт, входящих в (22.10), неизвестным пока осталось лишш время свободного пробега квазичастиц $\tau_{\rm k}$. Для синглетного изотропного спаривания из (22.9) имеем:

$$\begin{aligned}\frac{1}{\tau_{\rm k}} &= \frac{2\pi}{\hbar} n_{\rm imp} u^2 \int \frac{d^3k'}{(2\pi)^3}\left(1 - \frac{\Delta^2}{E_{\rm k}E_{\rm k'}}\right)\delta(E_{\rm k} - E_{\mathbf{k}'}) = \\ &= \frac{1}{\tau_{\rm n}}\frac{1}{N_0}\frac{E_{\rm k}^2 - \Delta^2}{E_{\rm k}^2}\int \frac{d^3k'}{(2\pi)^3}\delta(E_{\rm k} - E_{\rm k'}) = \frac{1}{\tau_{\rm n}}\frac{N(E_{\rm k})}{N_0}\frac{\xi_{\rm k}^2}{E_{\rm k}^2}\end{aligned} \tag{22.12}$$

где

$$\tau_{\rm n}^{-1} = \frac{2\pi}{\hbar} n_{\rm imp}\, N_0 u^2 \tag{22.13}$$

есть время свободного пробега в нормальной фазе [3], а плотность состояний $N(E_{\mathbf{k}}) = \int d^3k'\delta(E_{\mathbf{k}} - E_{\mathbf{k}'})/(2\pi)^3$(cm.(17.26)).

Подставляя (22.11) и (22.12) в (22.10) и учитывая (17.28), находим выражение для коэффициегта теплопроводности [89, 90]:

$$x = \frac{2\tau_n N_0 v_{\rm F}^2}{3T^2}\int\limits_{-\infty}^{\infty} d\xi \frac{E_k^2 e^{E_k/T}}{\left(e^{E_k/T}+1\right)^2}\frac{N_0}{N(E_k)} = \frac{\tau_{\rm n} N_0 v_{\rm F}^2}{3T^2}\int\limits_{\Delta}^{\infty}\frac{dEE^2}{{\rm ch}^2[E/(2T)]} \tag{22.14}$$

При $T \ll \Delta$

$$x(T) = \frac{4}{3}v_F^2\tau_{\rm n}N_0 T\left(\frac{\Delta}{T}\right)^2 \exp\left(-\frac{\Delta}{T}\right)$$

что можно переписать также в виде:

$$\frac{\varkappa(T)}{\varkappa_n\left(T_c\right)}=\frac{T}{T_c}\left(\frac{\Delta}{T}\right)^2\exp\left(-\frac{\Delta}{T}\right)I^{-1} \tag{22.15}$$

где теплопроводность в нормальном состоянии есть

$$\varkappa_{\mathrm{n}}\left(T_{\mathrm{c}}\right)=\frac{1}{3}v_{\mathrm{F}}^2\tau_{\mathrm{n}}N_0T_{\mathrm{c}}I \tag{22.16}$$

а

$$I=\int\limits_0^{+\infty}\frac{dzz^2}{\mathrm{ch}^2(z/2)}=\frac{2\pi^2}{3}$$

В случае анизотропного спаривания параметр порядка преобразуется в соответствии с неединичным представлением группы симметрии, и интеграл от фактора когерентности по направлениям $\mathbf{k}'$ в (22.9) равен единице. Следовательно,

$$\frac{1}{\tau_{\mathrm{k}}}=\frac{2\pi}{\hbar}n_{\mathrm{imp}}u^2\int\frac{d^3k'}{(2\pi)^3}\delta\left(E_{\mathrm{k}}-E_{\mathrm{k}'}\right)=\frac{1}{\tau_{\mathrm{n}}}\frac{N\left(E_{\mathrm{k}}\right)}{N_0} \tag{22.17}$$

Подставляя это выражение в (22.10), получаем, с учетом (22.11):

$$\begin{aligned}x_{ij}&=\frac{2\tau_{\mathrm{n}}v_F^2}{T^2}\int\frac{d^3k}{(2\pi)^3}\frac{\xi_k^2E_{\mathrm{k}}/T}{\left(e^{E_k/T}+1\right)^2}\frac{N_0}{N\left(E_{\mathrm{k}}\right)}\hat{k}_i\hat{k}_j=\\&=\frac{\tau_{\mathrm{n}}N_0v_{\mathrm{F}}^2}{T^2}\int\limits_0^{\infty}\frac{EdE}{\mathrm{ch}^2(E/2T)}\frac{N_0}{N(E)}\int\frac{d\Omega}{4\pi}\hat{k}_i\hat{k}_j\sqrt{E^2-\Delta_{\mathbf{k}}^2}\end{aligned} \tag{22.18}$$

причем интегрирование по углам производится в пределах, задаваемых условием $\Delta_{\mathbf{k}}^2<E^2$.

Для сверхпроводника со структурой B-фазы коэффициент теплопроводности изотропен и экспоненциально мал при $T\to 0$ (см. (22.15)).

Для сверхпроводников с нулями щели на поверхности Фсрми температурное поведение теплопроводности, напротив, будет не экспоненцианым, а степенным, подобно многим другим физическим характеристикам (см. 7). Кроме того, следует ожидать, что ввиду анизотропии щели коэффициенты теплопроводности будут зависеть от направления. В качестве примера рассмотрим сверхпроводник со структурой A-фазы, параметр порядка в котором обращается в нул на полюсах ферми-сферы: $\Delta_k^2=\Delta^2\sin^2\theta$. Ввиду одноосной анизотропии спсктра возбуждений теплопроводность описывается двумя коэффициентами: $x_{\parallel}=x_{zz}$ и $x_{\perp}=x_{xx}=x_{yy}$. Из (22.18) получаем:

$$\begin{aligned}\varkappa_{\parallel}&=\frac{\tau_{\pi}N_0v_{\mathrm{F}}^2}{T^2}\int\limits_0^{\infty}\frac{dEE}{\mathrm{ch}^2(E/2T)}\frac{N_0}{N(E)}\int\frac{d\Omega}{4\pi}\sqrt{E^2-\Delta^2\sin^2\theta}\cos^2\theta\approx\\&\approx\frac{\tau_{\mathrm{n}}N_0v_{\mathrm{F}}^2}{T^2}\int\limits_0^{\infty}\frac{dEE}{\mathrm{ch}^2(E/2T)}\frac{N_0}{N(E)}\int\limits_0^{E/\Delta}\theta d\theta\sqrt{E^2-\Delta^2\theta^2}\sim\\&\sim\frac{\tau_{\mathrm{n}}N_0v_{\mathrm{F}}^2}{T^2}\int\limits_0^{\infty}\frac{dEE}{\mathrm{ch}^2(E/2T)}\frac{N_0}{N(E)}\frac{E^3}{\Delta^2}\end{aligned}$$

[13] С учетом выражения для скорости возбуждснии $v=\partial E/\partial k=v_k\xi_k/E_k$ и формулы (17.28) из (22.13) следует, что длина свободного пробега в сверхпроводящем состоянии с s-спариванием равна длине прробега в нормтьном состояии.

Вспоминая выражение (17.30) для плотности состояний в A-фазе, окончательно получаем:

$$\frac{x_{\parallel}(T)}{x_{\pi}(T_c)} \sim \frac{T}{T_c} \tag{22.19}$$

Аналогично выполняются выписления для поперечного коэффициента теплопроводности:

$x_{\perp} = \frac{\tau_{\mathrm{n}} N_0 v_{\mathrm{F}}^2}{T^2} \int\limits_0^{\infty} \frac{dEE}{\mathrm{ch}^2(E/2T)} \frac{N_0}{N(E)} \int \frac{d\Omega}{4\pi} \sqrt{E^2 - \Delta^2 \sin^2\theta} \sin^2\theta \sim$

$\sim \frac{\tau_{\mathrm{n}} N_0 v_{\mathrm{F}}^2 T^3}{\Delta}$.

Следовательно,

$$\frac{x_{\perp}(T)}{x_n(T_c)} \sim \left(\frac{T}{T_c}\right)^3 \tag{22.20}$$

Если щель в спектрс обращается в нуль на цельх линиях на фермиповерхности, как это имеет место, например, в сверхпроводнике со структурой
полярной фазы: $\Delta_{\mathrm{k}}^2 = \Delta^2 \cos^2\theta$, то выписления с помощыо формулы (22.18), аналогичные проведенным выиге, дают следуишие результаты:

$$\frac{x_{\parallel}(T)}{\varkappa_n(T_c)} \sim \left(\frac{T}{T_c}\right)^3; \quad \frac{\varkappa_1(T)}{x_n(T_c)} \sim \frac{T}{T_c}. \tag{22.21}$$

Из (22.19)-(22.21) видно, что в свсрхпроводниках с нулями щели как на полюсах, так и на экваторе фсрми-поверхности, максимальный коэффицисит теплопроводности линейно зависит от тсмпературы, т. е. $x(T)/T \to \mathrm{const}$ при $T \to 0$.

Резонанснос рассяяние на примесях [87, 91]. Выражение (22.10) для электронной теплопроводности, полученное из кинетического уравнения, справсдливо и при резонансном рассеянии на примесях. Отличие от случая борновского рассеяния состоит в существенно иной зависимости времени свободного пробега возбуждений от энергии $\tau(E)$, которуюо нуждо найти из решения уравнения самосогласования для собственно-энергетической части, выведенного в 21. В этом разделе мы получим $\tau(E)$ и определим область справедливости описания релаксационных явленини в нсобычных сверхпроводниках с помощью уравнения Больдмана.

При наличии рассеяния на примесях квазичастицы приобретаюот консчное время жизпи, которос определяется мнимой частыю запаздывающей собственно-энергетической функции:

$$\frac{1}{\tau(E)} = -2\,\mathrm{Im}\,\Sigma^R(E) = 2\,\mathrm{Im}\,t(E) \tag{22.22}$$

Здесь мы воспользовались определением (21.14). Величина $t(E)$ удовлетворяет уравненио (21.25).

В случае резонансного рассеяния ($\delta_0 \to \pi/2$) уравнение (21.25) принимает вид

$$t = E + i\Gamma \frac{1}{g(t)}$$

где

$$g(t) = \int \frac{d\Omega}{4\pi} \frac{t}{\sqrt{t^2 - \Delta_k^2}}$$

В нормальном состоянии $g(t) = 1$, и

$$t_{\rm n}(E) = E + i\Gamma$$

Сравнивая это выражение с (22.22), получаем, что величина I связана с временем жизни квазичастиц в нормальном металле с резонансными примесями следующим образом:

$$\frac{1}{\tau_n} = 2\Gamma \tag{22.23}$$

и уравнение на функцию $t(E)$ в сверхпроводящем состоянии может быть записано как

$$t = E + \frac{i}{2\tau_{\rm n}}\frac{1}{g(t)} \tag{22.24}$$

Из (22.22), (22.24) и (21.28) имеем

$$\frac{1}{r(E)} = \frac{1}{\tau_{\rm n}}\,{\rm Re}\,\frac{1}{g(t)} = \frac{1}{\tau_{\rm n}}\frac{N(E)}{N_0}\frac{1}{|g(t(E))|^2} \tag{22.25}$$

Таким образом, нахождение врсмени жизни квазичастиц трсбует, вообщс говоря, самосогласованного вычисления собственио-энергетической части с помошию уравнения (22.24). Опнако, в случае достаточно слабого беспорядка лля энергий, превышающих некоторое критическое значение (точный критерий зависит от конкретного вида сверхпроводящего состояния, см. ниже), залача может быть упрощена. В самом деле, если при $E \to 0$

$${\rm Im}\, t(E) \to \gamma = \ {\rm const}\ \neq 0 \tag{22.26}$$

то при $E < \gamma$, как следуст из (22.22), время жизни почти не зависит от энергии, и:

$$\frac{1}{\tau} = 2\gamma \tag{22.27}$$

Энергия квазичастиц становится малой по сравненино с их затуханием, и при $T < \gamma$ больцмановское описание кинетики неприменимо.

Если же $E > \gamma$, то при вычислении малой мнимой добавки к $t(E)$ можно ограничиться низшим порядком теории возмушений по потенциалу примесей. Это, в частности, означает, что в выражении (22.25) мы можем пренебречь оттичием $t(E)$ от E. Тогда

$$\left.\frac{1}{\tau(E)}\right|_{\delta_0 \to \pi/2} = \frac{1}{\tau_{\rm n}}\frac{N(E)}{N_0}\frac{1}{|g(E)|^2} \tag{22.28}$$

причем в правую часть здесь следует подставлять плотность состояний для чистого сверхпроводника.

При вычислении коэффициента теплопроводности в случае резонансного рассеяния на примесях с помощью кинетического уравнения необходимо использовать выражение (22.28). Проделаем эти вычисления для различных фаз с p-спариванием.

Для сверхпроводника со структурой A-фазы из (22.26) и (21.30) имеем

$$\gamma = \sqrt{\frac{2\Gamma\Delta}{\pi}} = \sqrt{\frac{\Delta}{\pi\tau_{\rm n}}} \tag{22.29}$$

Из (21.17) находим функциго $g(E)$ (при $\gamma < E \ll \Delta$):

$$g(E) = \int \frac{d\Omega}{4\pi}\frac{E}{\sqrt{E^2 - \Delta^2\sin^2\theta}} \approx -i\frac{\pi E}{2\Delta}$$

Подставляя это выражение в (22.28) и учитывая (17.30), получаем:

$$\tau(E) \sim \tau_{\mathrm{n}} \tag{22.30}$$

Для сверхпроводника со структурой полярной фазы решение уравиения (22.24) дает с тогарифмической точностью при $\Gamma \ll \Delta$:

$$\gamma = \sqrt{\frac{\Delta}{\tau_{\mathrm{n}}}} \left(\ln \tau_{\mathrm{n}} \Delta\right)^{-1/2} \tag{22.31}$$

Из (21.17) получаем (при $\gamma < E \ll \Delta$):

$$g(E) = \frac{E}{\Delta} \ln \frac{2\Delta}{E}$$

Из (22.28) тогда имеем

$$\tau(E) \sim \tau_{\mathrm{n}} \frac{E}{\Delta} \ln^2 \frac{E}{\Delta} \tag{22.32}$$

Как и следовало ожидать, в случае сильного рассеяния на резонансных примесях время жизни квазичастиц уменьшается по сравнению с борновским случаем. Подставляя (22.30) в (22.10), получаем, что в выражениях для коэффициента теплопроводности в A-фазс появляется дополнительная вторая сгепень тсмпсратуры:

$$\frac{x_{\parallel}(T)}{x_{\mathrm{n}}\left(T_c\right)} \sim \left(\frac{T}{T_c}\right)^3; \quad \frac{x_{\perp}(T)}{x_n\left(T_c\right)} \sim \left(\frac{T}{T_c}\right)^5 \tag{22.33}$$

Аналогичные вычисления с помощью (22.32) для полярной фазы дающот

$$\frac{x_{\parallel}(T)}{x_{\mathrm{n}}\left(T_c\right)} \sim \left(\frac{T}{T_c}\right)^5 \ln^2 \frac{T}{T_{\mathrm{c}}}; \quad \frac{\varkappa_{\perp}(T)}{\varkappa_{\mathrm{n}}\left(T_c\right)} \sim \left(\frac{T}{T_c}\right)^3 \ln^2 \frac{T}{T_{\mathrm{c}}} \tag{22.34}$$

Найденные температурыые зависимости (22.33) и (22.34) согласуются с результатами измерений теплопроводности на монокристаллах $\mathrm{UPt_3}$ [92-94], в соотвстствии с которыми $x(T)/T \propto T^2$ для всех направлений. Совокупность эксперименталынхх данных свидетельствует о том, что сверхпроводящий параметр порядка в $\mathrm{UPt_3}$ прсобразуется согласно представлснию E_{1g} (или E_{2u}) группы $D_{6\,\mathrm{h}}$ (см. 4). В этом случае продольный (вдоль оси шестого порядка) коэффициент теплопроводности опрсдслястся формулой (22.33), а поперечный - формулой (22.34).

Подчеркнем еще раз, что результаты, полученные с помощью кинетического уравнения, справедливы при не слишком низких температурах $\gamma \ll T < \Delta$. При $T < \gamma$ выччисление кинетических коэффипиентов может быть произведено лишь в рамках теории линейного отклика, к иэложениг которой мы и переходим.

Упражнение. Вывести формулу (22.7).

Метод функций Грина: теория линейного отклика. Другой способ вычисления теплопроводности, а также многих друтих термодинамических и кинетических характеристик свсрхпроводника, основан на использовании теории линейного отктика в терминах фупкший Грина [95]. Согласно этой теории, рсакция систсмы на малос возмущение ее параметров (в нашем случае - на градисит тсмпсратуры) описывается запаздывающими коррелятораии сопряженных потоков.

Коэффиииент теплопровошности в этом формапизме выччисляется следующим образом. Введем прежде всего мацубаровскую корреляционную функшпю потоков тепла:

$$K_{ij}\left(\mathbf{r}_1, \tau_1; \mathbf{r}_2, \tau_2\right) = \left\langle T_\tau Q_i\left(\mathbf{r}_1, \tau_1\right) Q_j\left(\mathbf{r}_2, \tau_2\right)\right\rangle \tag{22.35}$$

где Q_i - оператор потока тепла. В реальном времени имеем:

$$Q_i(\mathbf{r},t) = -\frac{1}{2m}\left(\frac{\partial\dot{\psi}_\alpha^+(\mathbf{r},t)}{\partial t}\frac{\partial\psi_\alpha(\mathbf{r},t)}{\partial r_i} + \frac{\partial\psi_\alpha^+(\mathbf{r},t)}{\partial r_i}\frac{\partial\psi_\alpha(\mathbf{r},t)}{\partial t}\right) \tag{22.36}$$

Справедливость такого определения вытекает из операторного уравнения непрерывности для плотности гамильтониана $h(\mathbf{r},t)$ $\left(H=\int d^3r\right.$, глс II - гамильтониан БКШ (17.1) в координатном представлении):

$$\frac{\partial h}{\partial t} + \operatorname{div}\mathbf{Q} = 0$$

Фурье-образ уравнения (22.36) имеет вил $K_{ij}(\mathbf{q},\omega_n)$, где $\omega_n = 2\pi nT$ - бозонная мацубаровская частота. Запаздыватощая коррсляционная функшия потоков тепліа $K_{ij}^R(\mathbf{q},\omega)$ находится путем аналитического продолжения мацубаровской функции на ось вещественных частот $i\omega_n \to \omega + i0$. Согласно теории линейного отклика, коэффишеент теплопроводности связан с $K_{ij}^R(\mathbf{q}=0,\omega)$ следуюшшим образом [95]:

$$\varkappa_{ij} = -\frac{1}{T}\lim_{\omega\to 0}\operatorname{Im}\frac{K_{ij}^R(\omega)-K_{ij}^R(0)}{\omega} = -\left.\frac{1}{T}\frac{d\operatorname{Im}K_{ij}^R(\omega)}{d\omega}\right|_{\omega=0} \tag{22.37}$$

Подставим (22.36) в (22.35) и используем для расцепления стоящего в правой части (22.35) τ-упорядоченного произведения четырех фермионньдх операторов (двухчастичной функции Грина) приближение среднего поля:

$$\begin{aligned}
&\left\langle T_\tau\psi_\alpha^+(\mathbf{r}_1',\tau_1)\,\psi_\alpha(\mathbf{r}_1,\bar{\tau_1})\,\psi_\beta^+(\mathbf{r}_2',\tau_2)\,\psi_\beta(\mathbf{r}_2,\tau_2)\right\rangle \to\\
&\to -G_{\alpha\beta}(\mathbf{r}_1,\tau_1;\mathbf{r}_2',\tau_2)\bar{G}_{\beta\alpha}(\mathbf{r}_2,\tau_2;\mathbf{r}_1',\tau_1) -\\
&- I_{\alpha\beta}(\mathbf{r}_1,\tau_1;\mathbf{r}_2,\tau_2)\bar{F}_{\alpha\beta}^+(\mathbf{r}_1',\tau_1;\mathbf{r}_2',\tau_2) =\\
&= -G_{\alpha\beta}(\mathbf{r}_1,\tau_1;\mathbf{r}_2',\tau_2)\bar{G}_{\beta\alpha}(\mathbf{r}_2,\tau_2;\mathbf{r}_1',\tau_1) +\\
&+ F_{\alpha\beta}(\mathbf{r}_1,\tau_1;\mathbf{r}_2,\tau_2)\bar{F}_{\beta\alpha}^+(\mathbf{r}_2',\tau_2;\mathbf{r}_1',\tau_1)
\end{aligned}$$

где чсрта свсрху обозначает усреднение по положениям примесей. Переходя в импульсно-частотнос представление, перепишем коррелятор (22.35) в следующем виле:

$$\begin{aligned}
K_{ij}(\omega_n) = T\sum_m\int\tfrac{d^3k}{(2\pi)^3}(2\varepsilon_m+\omega_n)^2\tfrac{k_ik_j}{4m^2}\Big(&G_{\alpha\beta}(\mathbf{k},\varepsilon_m+\bar{\omega_n})\,G_{\beta\alpha}(\mathbf{k},\varepsilon_m) -\\
&-F_{\alpha\beta}(\mathbf{k},\varepsilon_m+\bar{\omega_n})\,F_{\beta\alpha}^+(\mathbf{k},\varepsilon_m)\Big) + K_{ij}^{(\text{sing})}
\end{aligned}$$

где $\varepsilon_m = (2m+1)\pi T$. Последпее слагаемое в правой части объепиняет сингупярные вклады вида $\delta(\tau_1-\tau_2)$, происходящие от дифференширования по времени τ-упорядоченівх произведений. Учет таких вклапов позволяет сократить расходимости при суммировании по m в первом слагаемом.

Данную трудность удобнее обойти, используя спектральное разложение (17.22) для функиит Грина. При этом можно показать [96], что апалитически продолженное выражсние для коррелятора имеет вид:

$$\begin{aligned}
K_{ij}^R(\omega) = &\int\frac{d\omega_1}{2\pi}\frac{d\omega_2}{2\pi}\frac{(\omega_1+\omega_2)^2}{\omega_1-\omega_2-\omega-i0}\left(\operatorname{th}\frac{\omega_1+\omega}{2T}-\operatorname{th}\frac{\omega_2}{2T}\right)\times\\
&\times\int\frac{d^3k}{(2\pi)^3}\frac{k_ik_j}{4m^2}\left(\operatorname{Im}G_{\alpha\beta}(\mathbf{k},\omega_1+\bar{\omega})\operatorname{lm}G_{\beta\alpha}(\mathbf{k},\omega_2) -\right.\\
&\left.-\operatorname{Im}F_{\alpha\beta}(\mathbf{k},\omega_1+\bar{\omega})\operatorname{Im}F_{\beta\alpha}^+(\mathbf{k},\omega_2)\right)
\end{aligned}$$

Подставляя сгода вцражение (17.23) для спектральной плотности, можно убедиться, что интеграл по ξ от слагаемых вида $G^R G^R$ и т. д. обращается в нул. Для коэффициента теплопроводиости тогда получаем:

$$\varkappa_{ij} = \frac{1}{4m^2T^2}\int \frac{dE}{2\pi}\frac{E^2}{\mathrm{ch}^2(E/2T)}\int \frac{d^3k}{(2\pi)^3}k_i k_j \left(G^R_{\alpha\beta}(\mathbf{k},E)\bar{G}^A_{\beta\alpha}(\mathbf{k},E) - F^R_{\alpha\beta}(\mathbf{k},E)\bar{F}^{+A}_{\beta\alpha}(\mathbf{k},E)\right) \tag{22.38}$$

Интеграл по импульсам в правой части определяется суммой диаграмм, изображенных на рис. 22, причем сплошным линиям соответствуоот усредненные запаздываюощие и опережающие функции Трина.

Если, как и выше, ограничиться случаем изотропного рассеяния на точечных примесях, то пунктирные линии пе несут никакой зависимости от импульсов. Поэтому для пространственно-четных сверхпроводящих фаз все диаграммы, кроме первой, обращаются в нуль при интегрировании по направлениям k ввиду нечетности вериины k_i.

Дхя пространственно-нечетных фаз, в частности, для p-спаривания, диаграммы с поперечными примесными линиями (так называемые вершинные поправки), вообще говоря, в пуль не обращаются, что значительно усложняет задачу. Однако, здесь мы интересуемся лишш поведением максимального

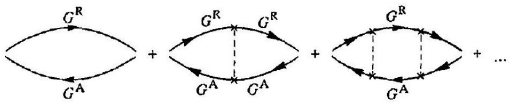


Рис. 22. Совокупность диаграмм, опредсляющих электронную теплопроводность сверхпроводииха при рассеянии электрона на примесях.

коэффицисита теплопроводности $\chi_{\max} = \chi_{ii}$, совпадающего с$\chi_{zz} = \chi_{\|}$для А-фазы, и с $x_{xx} = x_{yy} = x_\perp$ для полярной фазы. В этом случае непосредственное вычисление показывает, что вершинные поправки равны нулю [88] в результате интегрирования по азимутальному углу. Следователыво,

$$\varkappa_{ii} = \frac{1}{8\pi m^2T^2}\int\limits_0^\infty \frac{dEE^2}{\mathrm{ch}^2(E/2T)}L_{ii}(E) \tag{22.39}$$

гпе

$$L_{ii}(E) = \int \frac{d^3k}{(2\pi)^3}k_i^2\left(G^R_{\alpha\beta}(\bar{\mathbf{k}},E)G^A_{\beta\alpha}(\bar{\mathbf{k}},E) - F^R_{\alpha\beta}(\bar{\mathbf{k}},E)F^{+A}_{\beta\alpha}(\bar{\mathbf{k}},E)\right) \tag{22.40}$$

(суммирования по повторяющимся латинским индексам нет).

Усредненные запаздыватощие и опережаюощие функции Грина получаются путем аналитического продолжения в (21.6) и выглядят следующим образом:

$$G^R(\bar{\mathbf{k}},E) = \tfrac{t(E)+\xi_k}{t^2(E)-\Delta^2_{\mathbf{k}}-\xi^2_k},\quad F^R_{\alpha\beta}(\bar{\mathbf{k}},E) = \tfrac{\Delta_{\alpha\beta}(\mathbf{k})}{t^2(E)-\Delta^2_{\mathbf{k}}-\xi^2_k}$$
$$G^A(\mathbf{k},E) = G^{R*}(\mathbf{k},E),\quad F^A(\mathbf{k},E) = F^{R_*}(\mathbf{k},E)$$

причем $t(E)$ находится из уравпения самосогласования (21.16) (или (21.25)). После полстановки в (22.40) потучаем [88]:

$$L_{ii}(E) = 2N_0k_{\mathrm{F}}^2\int\frac{dS}{4\pi}\hat{k}_i^2\int d\xi\frac{|t|^2+\xi^2-\Delta_k^2}{(\xi^2-t^2+\Delta_k^2)(\xi^2-t^{*2}+\Delta_k^2)} =$$
$$= \frac{2\pi N_0k_F^2}{\mathrm{Re}\,i\,\mathrm{Im}\,t}\int\frac{d\Omega}{4\pi}\hat{k}_i^2\,\mathrm{Re}\,\frac{|t|^2+t^2-2\Delta_k^2}{\sqrt{t^2-\Delta_k^2}} \tag{22.41}$$

Подставляя (22.41) в (22.39), приходим к окогчательному ответу:

$$\varkappa_{ii} = \frac{N_0 v_F^2}{4T^2} \int\limits_0^\infty \frac{dE E^2}{\mathrm{ch}^2(E/2T)} \frac{1}{\mathrm{Re}\, t(E) \ln t\,(E^2)} \times$$
$$\times \int \frac{d\Omega}{4\pi} \hat{k}_i^2\, \mathrm{Re}\, \frac{|t(E)|^2 + t^2(E) - 2\Delta_k^2}{\sqrt{t^2(E) - \Delta_k^2}} \tag{22.42}$$

Дашшое выражение определяет максимальный коэффициент теплопроводности лля нечетных фаз и всс компоненты тснзора теплопроводности для четных фаз.

Поскольку основной вклад в интеграл (22.42) происходит от области энергий $E \sim T$, поэтому при не слишком низких температурах и для достаточно малой коншентрации примесей можно, как показано выше, пренебречь опличием $\mathrm{Re}\, t(E)$ от E. Тогда, вводя время жизни квазичастиц согласно (22.22), получаем

$$x_{ii} = \frac{N_0 v_F^2}{T^2} \int\limits_0^\infty \frac{dE E}{\mathrm{ch}^2(E/2T)} \tau(E) \int \frac{d\Omega}{4\pi} \hat{k}_i^2 \sqrt{E^2 - \Delta_{\mathbf{k}}^2} \tag{22.43}$$

Данное выражение справедливо как для борновского, так и для неборновского рассеяния на примесях. В случае борновского рассеяпия, используя (22.17), приходим к формуле (22.18), полученной путсм решения кинетического уравнения.

Уиверсалыность кишстических коэффициентов при очешь низких температурах [97]. Если $T < \gamma$ (то еств $\mathrm{Re}\, t(E) < \gamma$), то, подставляя $t(E) = \mathrm{Re}\, t + i\gamma$ в (22.41), полутаем:

$$I_{ii}(E \to 0) = \frac{4\pi N_0 k_\mathrm{F}^2}{\gamma\, \mathrm{Re}\, t} \int \frac{d\Omega}{4\pi} \ddot{k}_i^2\, \mathrm{Re}\, \frac{i\gamma\, \mathrm{Re}\, t - \Delta_\mathrm{k}^2}{\sqrt{2i\gamma\, \mathrm{Re}\, t - \gamma^2 - \Delta_\mathrm{k}^2}} =$$
$$= 4\pi N_0 k_\mathrm{F}^2 \int \frac{d\Omega}{4\pi} \hat{k}_i^2 \frac{\gamma^2}{(\gamma^2 + \Delta_\mathrm{k}^2)^{3/2}}$$

Отсюда

$$x_{ii} = 4 N_0 v_\mathrm{F}^2 T I \int \frac{d\Omega}{4\pi} \hat{k}_i^2 \frac{\gamma^2}{(\gamma^2 + \Delta_\mathrm{k}^2)^{3/2}} \tag{22.14}$$

где

$$I = \int\limits_0^{+\infty} \frac{dz z^2}{\mathrm{ch}^2 z} = \frac{\pi^2}{12}$$

Таким образом, для сверхпроводящих фаз с нетривиальным спариванием имеет место линейное по T поведение теплопроводности при очень низких температурах, а коэффициент этой линейной зависимости определяется конкретным видом параметра порядка.

Так, для полярной фазы ($\Delta_\mathrm{k}^2 = \Delta^2 \cos^2\theta$) из (22.44) имеем (при условии $\gamma \ll \Delta$) :

$$x_{\parallel\parallel} = 4 N_0 v_\mathrm{F}^2 T I \int\limits_0^\pi \sin\theta d\theta \int\limits_0^{2\pi} \frac{d\varphi}{4\pi} \cos^2\theta \frac{\gamma^2}{(\gamma^2 + \Delta^2 \cos^2\theta)^{3/2}} \approx$$
$$\approx 4 N_0 v_\mathrm{F}^2 T I \frac{\gamma^2}{\Delta^3} \ln \frac{2\Delta}{\gamma e} \tag{22.45}$$

$$x_\perp = 4 N_0 v_\mathrm{F}^2 T I \int\limits_0^\pi \sin\theta d\theta \int\limits_0^{2\pi} \frac{d\varphi}{4\pi} \sin^2\theta \cos^2\varphi \frac{\gamma^2}{(\gamma^2 + \Delta^2 \cos^2\theta)^{3/2}} \approx$$
$$\approx 2 N_0 v_\mathrm{F}^2 I \frac{T}{\Delta} \left(1 + O\left(\frac{\gamma}{\Delta}\right)\right) \tag{22.46}$$

Для фаз с изолированными нулями первого или второго порядка аналогичные вычисления дают:

$$x_{\parallel} = 4N_0 v_{\rm F}^2 TI\frac{\gamma}{\Delta^2}, \quad x_{\perp} = \pi N_0 v_{\rm F}^2 TI\frac{\gamma^2}{\Delta^3}, \quad \text{для } \Delta_{\mathbf{k}}^2 = \Delta^2 \sin^2\theta \tag{22.47}$$
$$x_{\parallel} = 2N_0 v_{\rm F}^2 I\frac{T}{\Delta}, \quad x_{\perp} = N_0 v_{\rm F}^2 TI\frac{\gamma}{\Delta^2}, \quad \text{для } \Delta_{\mathbf{k}}^2 = \Delta^2 \sin^4\theta$$

Мы приходим к заключению, что если тепловой поток направлен параллелыо плоскости, в которой параметр порядка обращается в нуль, или вдоль линии, соединяюощей точечныс нули второго порядка, то коэффициент теплопроводности не зависит от концентрации примесей. Подобная универсальность имеет место и для друтих кинетических коэффициентов [98].

19.3 Eliashberg Theory: a short review by F. Marsiglio

Eliashberg theory is a theory of superconductivity that describes the role of phonons in providing the attractive interaction between two electrons. Phonon dynamics are taken into account, thus giving rise to retardation effects that impact the electrons, in the form of a frequency-dependent electron self-energy. In the superconducting state, this means that the order parameter, generally considered to be a static quantity in the Bardeen-Cooper-Schrieffer (BCS) theory, also becomes frequency dependent. Here we review the finite temperature formulation of Eliashberg theory, both on the imaginary and real frequency axis, and briefly display some examples of the consequences of a dynamical, as opposed to static, interaction. Along the way we point out where further work is required, concerning the validity of some of the assumptions used.

19.3.1 Introduction

Superconductivity is a remarkable phenomenon, not least because it represents a manifestation of the quantum world on a macroscopic scale. It is spectacularly demonstrated with levitating train sets,[1] and indeed this property and many others of superconductors are slowly being utilized in everyday applications.[2] However, the established practice of incorporating superconductors into the real world should not be taken as an indication that "the last nail in the coffin [of superconductivity]"[3] has been achieved. On the contrary, in the intervening half-century since this quote was written, many new superconductors have been discovered, and we have reached a point where it is clear that a deep lack of understanding[4] of superconductivity currently exists. Reference [[5]] compiles a series of articles reviewing the various "families" or classes of superconductors, where one can readily see common and different characteristics. At the moment many of these classes require a class-specific mechanism for superconductivity, a clearly untenable situation, in my opinion. Further classes have been discovered or expanded upon since, such as nickelates,[7] and the hydrides under pressure,[6] for example.

Our "deep lack of understanding" should not be taken to indicate that theoretical contributions have not been forthcoming. In fact there have been remarkable contributions to key theoretical ideas in physics that stem from research in superconductivity, starting with London theory[8] and Ginzburg-Landau[**?**] theory, through to BCS theory.[10] When Gor'kov[11] recast the BCS theory of superconductivity in the language of Green functions, then the stage was set for Eliashberg[12, 13] to formulate the theory that bears his name. It is fitting that we honour the lasting impact of his work with this brief review, on the occasion of his 90th birthday, and the 60th anniversary of the publication of two papers that paved the path for considerable future quantitative work in superconductivity. Based on an index I am fond of

using for famous people, his name appears in titles of papers 248 times, and in abstracts and keywords 1439 times.[16]

Before proceeding further, we wish to make some remarks about the nature of this review. It will necessarily repeat material from previous reviews, which we catalogue as follows. Scalapino[17] and McMillan and Rowell[18] perhaps gave one of the first comprehensive reviews of both calculations and experiments that provide remarkable evidence for the validity of Eliashberg theory for various superconductors. These reviews were provided in the comprehensive monogram by Parks;[19] the reader should refer to this monogram and the references therein, as we cannot possibly properly reference all the primary literature sources before "Parks", as this would consume too many pages here. The author list in Parks is a who's who of experts in superconductivity, with two notable exceptions, John Bardeen and Gerasim (Sima) Eliashberg.

A subsequent very influential review was that of Allen and Mitrović,[20] where mostly superconducting T_c was discussed. These authors highlighted the expediency of doing many calculations on the imaginary frequency axis, a possibility first noted in Ref. [[21]] and utilized to great advantage in subsequent years.[22, 23, 24, 25]

A few years later Rainer wrote a "state-of-the-union" address[26] on first principles calculations of superconducting T_c in which a challenge was issued to both band structure and many-body theorists. For the former, the missing ingredient was a *complete* (italics are mine) calculation of the electron-phonon coupling. These were first calculated in the 1960's (e.g. Ref. [[27]]) but have experienced vast improvement over the past 50 years, through the adoption and improvement of Density Functional Theory methods, plus the increased computational ability achieved in the intervening decades. Excellent summaries of this progress is provided in Refs. [[28],[29],[30]], where two alternative procedures are described. The first follows the original route of determining the electron-phonon interaction and including this as input to the Eliashberg equations, while the second aims to treat both the electron-phonon-induced electron-electron interaction *and* the direct Coulomb interaction on an equal footing. The result is advertised to meet Rainer's challenge and calculate T_c and other superconducting properties without any experimental input. It is noteworthy that in the second formulation (see also Refs. [[31]] and [[32]]) the equations are BCS-like and do *not* depend on frequency, but only momentum. In the usual formulation, the calculation of μ^*, the effective direct electron-electron Coulomb interaction, is often simply assigned a (small) numerical value, and therefore is treated phenomenologically as a fitting parameter. The challenge to many-body theorists remains, as more superconductors have been discovered that seem to extend beyond the weak coupling regime, and likely require descriptions beyond BCS and Eliashberg theory.

In 1990 the review by Carbotte[33] provided a comprehensive update for a number of thermodynamic properties of various superconductors known at the time, including the high temperature cuprate materials. Partly for this reason his review is titled "*Properties of boson-exchange superconductors*," since there was a feeling at the time (and still is in parts of the community) that the Eliashberg framework might apply to these superconductors, but with exchange of a boson other than the phonon. Quite a few years later we wrote a review jointly,[34] focusing on "*electron-phonon superconductivity*." This review summarized known properties and extended results to dynamical properties such as the optical conductivity, building on earlier work in Ref. [[35]] and mini-reviews in Ref. [[36]]. More recently Ummarino has published a mini-review with some generalizations to multi-band and the iron pnictide superconductors.[37]

The other remark we should make is that while Eliashberg theory has been extremely successful, we will also point out the limitations that exist. Indeed, these were recognized right from the beginning, with both Eliashberg[12] and Migdal[38] emphasizing that limitations exist on the value of the dimensionless coupling parameter, λ, due to the expected phonon softening that would occur as λ increases. They claimed an upper limit of $\lambda \approx 1$, which then significantly restricts the domain of validity of the theory. Constraints on the parameters would be a constant

theme over the ensuing years. In 1968 McMillan[39] gave more quantitative arguments for a maximum T_c, based on the expected relationship between the coupling strength and the phonon frequency. This was reinforced by Cohen and Anderson[40] and has been discussed critically a number of times since.[41, 42] Alexandrov[43] has also raised objections, based on polaron collapse, a topic we will revisit later.

Some of the early history regarding the origins of the electron-phonon interaction was provided in Ref. [[34]] and will be omitted here. By the early to mid 1950's Fröhlich[44] and Bardeen and Pines[45] had established that the effective Hamiltonian for the electron-phonon interaction had a potential interaction of the form[46]

$$V^{\rm eff}_{\mathbf{k},\mathbf{k}'} = \frac{4\pi e^2}{(\mathbf{k}-\mathbf{k}')^2 + k^2_{\rm TF}}\left[1 + \frac{\hbar^2\omega^2(\mathbf{k}-\mathbf{k}')}{(\epsilon_{\mathbf{k}}-\epsilon_{\mathbf{k}'})^2 - \hbar^2\omega^2(\mathbf{k}-\mathbf{k}')}\right], \tag{19.1}$$

where $k_{\rm TF}$ is the Thomas–Fermi wave vector, and $\omega(\mathbf{q})$ is the dressed phonon frequency. This part of the Hamiltonian represents the pairing interaction between two electrons with wave vectors $\mathbf{k}$ and $\mathbf{k}'$ in the First Brillouin Zone (FBZ) and energies $\epsilon_{\mathbf{k}}$ and $\epsilon_{\mathbf{k}'}$. The interaction Hamiltonian written in this form is often said to have "the phonons integrated out." It was on the basis of this Hamiltonian that Bardeen, Cooper and Schrieffer (BCS)[10] formulated a model Hamiltonian with an attractive (negative in sign) interaction for electron energies near the Fermi energy, ϵ_F.

19.3.2 The Eliashberg Equations

Eliashberg,[12] following what Migdal[38] had calculated in the normal state, did not "integrate out the phonons," but instead adopted the Hamiltonian

$$\begin{aligned} H &= \sum_{\mathbf{k}\sigma}(\epsilon_{\mathbf{k}}-\mu)c^\dagger_{\mathbf{k}\sigma}c_{\mathbf{k}\sigma} + \sum_{\mathbf{q}}\hbar\omega_{\mathbf{q}}a^\dagger_{\mathbf{q}}a_{\mathbf{q}} \\ &\quad + \frac{1}{\sqrt{N}}\sum_{\substack{\mathbf{k}\mathbf{k}'\\ \sigma}} g(\mathbf{k},\mathbf{k}')\left(a_{\mathbf{k}-\mathbf{k}'} + a^\dagger_{-(\mathbf{k}-\mathbf{k}')}\right)c^\dagger_{\mathbf{k}'\sigma}c_{\mathbf{k}\sigma} \quad . \end{aligned} \tag{19.2}$$

where $c_{\mathbf{k}\sigma}$ ($c^\dagger_{\mathbf{k}\sigma}$) is the annihilation (creation) operator for an electron with spin σ and wave vector $\mathbf{k}$, and $a_{\mathbf{q}}$ ($a^\dagger_{\mathbf{q}}$) is the annihilation (creation) operator for a phonon with wave vector $\mathbf{q}$. The electron-phonon coupling function, $g(\mathbf{k},\mathbf{k}')$ is generally a function of both wave vectors (and not just their difference), and in principle is calculable with the Density Functional Theory Methods mentioned earlier. Very often models are adopted based on simple (e.g. tight-binding) considerations.

Eliashberg then applied the apparatus of field theory to formulate a pairing theory that accounts for the dynamics of the interaction, i.e. for retardation effects. A sketch of the derivation, taken from Rickayzen[47] (see also Ref. [[34]]), is provided in the Appendix. This is my favourite derivation, as it does not rely on a formalism (e.g. the Nambu formalism) whose validity requires an act of faith (or, you simply work through everything anyways, to ensure that the formalism "works").

Following Eliashberg[13] with more modern notation,[17, 20] the "normal" self energy $\Sigma(\mathbf{k}, i\omega_m)$ is separated out into even and odd (in Matsubara frequency) parts, so that two new functions, Z and χ are defined:

$$\begin{aligned} i\omega_m\left[1 - Z(\mathbf{k},i\omega_m)\right] &\equiv \frac{1}{2}\left[\Sigma(\mathbf{k},i\omega_m) - \Sigma(\mathbf{k},-i\omega_m)\right] \\ \chi(\mathbf{k},i\omega_m) &\equiv \frac{1}{2}\left[\Sigma(\mathbf{k},i\omega_m) + \Sigma(\mathbf{k},-i\omega_m)\right]. \end{aligned} \tag{19.3}$$

The equations that emerge are

$$Z(\mathbf{k}, i\omega_m) = 1 + \frac{1}{N\beta}\sum_{\mathbf{k}',m'} \frac{\lambda_{\mathbf{k}\mathbf{k}'}(i\omega_m - i\omega_{m'})}{g(\epsilon_F)} \frac{\left(\omega_{m'}/\omega_m\right) Z(\mathbf{k}', i\omega_{m'})}{\omega_{m'}^2 Z^2(\mathbf{k}', i\omega_{m'}) + \left(\epsilon_{\mathbf{k}'} - \mu + \chi(\mathbf{k}', i\omega_{m'})\right)^2 + \phi^2(\mathbf{k}', i\omega_{m'})} \tag{19.4}$$

$$\chi(\mathbf{k}, i\omega_m) = -\frac{1}{N\beta}\sum_{\mathbf{k}',m'} \frac{\lambda_{\mathbf{k}\mathbf{k}'}(i\omega_m - i\omega_{m'})}{g(\epsilon_F)} \frac{\epsilon_{\mathbf{k}'} - \mu + \chi(\mathbf{k}', i\omega_{m'})}{\omega_{m'}^2 Z^2(\mathbf{k}', i\omega_{m'}) + \left(\epsilon_{\mathbf{k}'} - \mu + \chi(\mathbf{k}', i\omega_{m'})\right)^2 + \phi^2(\mathbf{k}', i\omega_{m'})} \tag{19.5}$$

along with the equation for the order parameter:

$$\phi(\mathbf{k}, i\omega_m) = \frac{1}{N\beta}\sum_{\mathbf{k}',m'} \left[\frac{\lambda_{\mathbf{k}\mathbf{k}'}(i\omega_m - i\omega_{m'})}{g(\epsilon_F)} - V_{\mathbf{k},\mathbf{k}'}\right] \frac{\phi(\mathbf{k}', i\omega_{m'})}{\omega_{m'}^2 Z^2(\mathbf{k}', i\omega_{m'}) + \left(\epsilon_{\mathbf{k}'} - \mu + \chi(\mathbf{k}', i\omega_{m'})\right)^2 + \phi^2(\mathbf{k}', i\omega_{m'})}. \tag{19.6}$$

These are supplemented with the electron number equation, which determines the chemical potential, μ:

$$n_e = 1 - \frac{2}{N\beta}\sum_{\mathbf{k}',m'} \frac{\epsilon_{\mathbf{k}'} - \mu + \chi(\mathbf{k}', i\omega_{m'})}{\omega_{m'}^2 Z^2(\mathbf{k}', i\omega_{m'}) + \left(\epsilon_{\mathbf{k}'} - \mu + \chi(\mathbf{k}', i\omega_{m'})\right)^2 + \phi^2(\mathbf{k}', i\omega_{m'})}. \tag{19.7}$$

Written in this way both Z and χ are even functions of $i\omega_m$ (and, as we've assumed from the beginning, they are also even functions of $\mathbf{k}$). With electron-phonon pairing the anomalous self energy, which determines the anomalous pairing amplitude $\phi(\mathbf{k}, i\omega_m)$, is also an even function of Matsubara frequency. A generalization of this latter result, giving rise to so-called Berezinskii[**?**] "odd-frequency" pairing, is beyond the scope of this review. A survey of Berezinskii pairing is given in Ref. [[49]].

Other symbols in Eqs. (19.4-19.7) are as follows.The number of lattice sites is given by N, the parameter $\beta \equiv 1/(k_B T)$, where k_B is the Boltzmann constant and T is the temperature, μ is the chemical potential, and $g(\epsilon_F)$ is the electronic density of states at the Fermi level in the band. These equations are generally valid for multi-band systems, and then the labels $\mathbf{k}$ and $\mathbf{k}'$ are to be understood to include band indices. However, we shall proceed for simplicity with the assumption of a single band, with single particle energy $\epsilon_{\mathbf{k}}$. Because we are assuming finite temperature right from the start, the equations are written on the imaginary frequency axis, and are functions of the Fermion Matsubara frequencies, $i\omega_m \equiv \pi k_B T(2m-1)$, with m an integer. Similarly the Boson Matsubara frequencies are given by $i\nu_n \equiv 2\pi k_B T n$, where n is an integer. Finally, we have also included a direct Coulomb repulsion in the form of $V_{\mathbf{k},\mathbf{k}'}$, which in principle represents the full (albeit screened) Coulomb interaction between two electrons.

The key ingredient of Eliashberg theory (as opposed to BCS theory) is the presence of the electron-phonon propagator, contained in

$$\lambda_{\mathbf{k}\mathbf{k}'}(z) \equiv \int_0^\infty \frac{2\nu\alpha^2_{\mathbf{k}\mathbf{k}'}F(\nu)}{\nu^2 - z^2} d\nu \tag{19.8}$$

with $\alpha^2_{\mathbf{k}\mathbf{k}'}F(\nu)$ the spectral function of the phonon Green function. This function is sometimes written as $\alpha^2_{\mathbf{k}\mathbf{k}'}(\nu)F(\nu)$ to emphasize that the coupling part (α^2) can have significant frequency dependence. This spectral function is often called the Eliashberg function. Equation (19.8) has been used as a "bosonic glue" to generalize the application of the Eliashberg/BCS formalism to beyond that of phonon exchange. Very often the boson is a collective mode of the very degrees of freedom that are superconducting, i.e. the conduction electrons. Examples include spin fluctuations or plasmons, but this work is on more questionable footing.[50]

A significant anisotropy may exist, specifically through the nature of the coupling in the Eliashberg function. Since the important physical attribute of the Eliashberg formalism beyond BCS is retardation, and therefore in the frequency domain, we will nonetheless neglect anisotropy in what follows.[51] More nuanced arguments for the wave vector dependence of the electron-phonon coupling are provided in Ref. [[20]], connected to the energy scale hierarchy $\epsilon_F \gg \nu_{\rm phonon} \gg T_c$, where $\nu_{\rm phonon}$ is a typical phonon energy scale (note that we have adopted the standard practice of dropping $\hbar$ and k_B, and therefore we refer to temperatures and phonon frequencies as energies). Indeed very often the neglect of anisotropy was justified by the study of so-called "dirty" superconductors, where the presence of impurities served to self-average over anisotropies. We will also drop the wave vector dependence in the direct Coulomb repulsion, although this step is less justified. It means that the direct Coulomb repulsion is represented by a single parameter, which we will call U, since this is what we would obtain by reducing the long-range Coulomb repulsion with an on-site Hubbard interaction with strength given by U. This is one of the weak points of the Eliashberg description of superconductivity — an inadequate description of correlations due to Coulomb interactions. In what follows we will focus more attention on the retardation effects, since this is the part that Eliashberg theory is best designed to handle properly.

Once we drop the wave vector dependence in the coupling function, all quantities (Z, χ and ϕ) become independent of wave vector. The integration over the First Brillouin Zone can then be performed, although here a series of approximations are utilized. The result can lead to confusion, so we provide some detail here. First, once it is determined that the unknown functions in Eqs. (19.4-19.7) do not depend on wave vector, we can replace the sum over wave vectors in the first Brillouin zone with an integration over the electronic density of states,

$$\frac{1}{N}\sum_k \rightarrow \int_{\epsilon_{\rm min}}^{\epsilon_{\rm max}} d\epsilon \; g(\epsilon), \tag{19.9}$$

where $g(\epsilon)$ is the single electron density of states and $\epsilon_{\rm min}$ and $\epsilon_{\rm max}$ are the minimum and maximum energies of the electronic band. Since typically the energy scales are such that $T_c << \nu_{\rm phonon} << \epsilon_F$, the variation of the electronic density of states away from the Fermi level is of little importance, so the approximation $g(\epsilon) \approx g(\epsilon_F)$ is used. Exceptions to this case have been discussed previously, and one is referred to Ref. [[34]] for references. The remaining integration is now elementary and yields a combination of inverse tangent and logarithmic functions.[52]

However, the "standard" practice is to extend these integrations over energy to $\pm\infty$ (and similarly adopt particle-hole symmetry so $\epsilon_{\rm min} \equiv -\epsilon_{\rm max}$, along with $\mu = 0$, and now $\epsilon_{\rm max} \rightarrow \infty$) with the philosophy that the remainder of the integrand ensures that these additional contributions are negligible. This is in fact *not true* and the term proportional to $V_{\mathbf{k},\mathbf{k}'}$ in Eq. (19.6) (now replaced by U as described above) will result in a Matsubara sum that diverges if this procedure is carried out without thought. So in fact the bandwidth parameters are required in the integration for this term and the resulting inverse tangent function results in a soft cutoff at $\omega_m \approx \epsilon_{\rm max}$. This is most often replaced with a hard (step-function) cutoff. Because of the assumptions about particle-hole symmetry the function $\chi(\mathbf{k}, i\omega_m)$ in Eq. (19.5) is identically zero, and Eq. (19.7) becomes meaningless (so the occupation is no longer considered an input parameter).

The more highly simplified equations that result are

$$Z(i\omega_m) = 1 + \frac{\pi T_c}{\omega_m}\sum_{m'=-\infty}^{+\infty} \lambda(i\omega_m - i\omega_{m'}) \frac{\omega_{m'} Z(i\omega_{m'})}{\sqrt{\omega_{m'}^2 Z^2(i\omega_{m'}) + \phi^2(\omega_{m'})}} \tag{19.10}$$

$$\phi(i\omega_m) = \pi T_c \sum_{m'=-\infty}^{+\infty} \left[\lambda(i\omega_m - i\omega_{m'}) - u\ \theta)\frac{W}{2} - |\omega_{m'}|)\right] \frac{\phi(i\omega_{m'})}{\sqrt{\omega_{m'}^2 Z^2(i\omega_{m'}) + \phi^2(\omega_{m'})}}. \quad (19.11)$$

where W is the bandwidth (i.e. $\epsilon_{\max} = -\epsilon_{\min} \equiv W/2$ and the band has been centred around zero for convenience), and $\theta(x)$ is the usual step function, and $u \equiv Ug(\epsilon_F)$. Very often a different order parameter is favoured over $\phi(\omega_m)$, defined as $\Delta(\omega_m) \equiv \phi(\omega_m)/Z(\omega_m)$. Then Eqs. (19.10,19.11) are written as

$$Z(i\omega_m) = 1 + \frac{\pi T_c}{\omega_m} \sum_{m'=-\infty}^{+\infty} \lambda(i\omega_m - i\omega_{m'}) \frac{\omega_{m'}}{\sqrt{\omega_{m'}^2 + \Delta^2(\omega_{m'})}} \quad (19.12)$$

$$Z(i\omega_m)\Delta(i\omega_m) = \pi T_c \sum_{m'=-\infty}^{+\infty} \left[\lambda(i\omega_m - i\omega_{m'}) - u\ \theta)\frac{W}{2} - |\omega_{m'}|)\right] \frac{\Delta(i\omega_{m'})}{\sqrt{\omega_{m'}^2 + \Delta^2(\omega_{m'})}}. \quad (19.13)$$

These are the standard Eliashberg equations, written on the imaginary axis. These components of the self energy (refer back to Eq. (19.3)) are all real functions. One further 'simplification' is usually made before computations are performed. The Matsubara summation is in principle infinite; in practice the summation with the electron-phonon kernel converges with relatively few terms, corresponding to a frequency cutoff $\omega_c << W/2$. Yet in the term with the Coulomb interaction one is required to carry out a summation over many more terms, corresponding to a frequency cutoff of $W/2$. Inspection of Eqs (19.12,19.13) shows that over this range ($\omega_c < \omega_m < W/2$), the gap function is a constant, i.e. $\Delta(\omega_m) \approx \Delta_\infty$, and $Z(\omega_m) \approx 1$. Making use of this allows one to sum this part analytically, with the result that U changes to an effective $U^*(\omega_c)$, where

$$U^*(\omega_c) \equiv \frac{U}{1 + U\ln(\frac{W/2}{\omega_c})}, \quad (19.14)$$

and we have approximated digamma functions with their asymptotic logarithmic form, since it is assumed that both $W/2 \gg T_c$ and $\omega_c \gg T_c$. Now the equations are

$$Z(i\omega_m) = 1 + \frac{\pi T_c}{\omega_m} \sum_{m'=-\infty}^{+\infty} \lambda(i\omega_m - i\omega_{m'}) \frac{\omega_{m'}}{\sqrt{\omega_{m'}^2 + \Delta^2(\omega_{m'})}} \quad (19.15)$$

$$Z(i\omega_m)\Delta(i\omega_m) = \pi T_c \sum_{m'=-\infty}^{+\infty} [\lambda(i\omega_m - i\omega_{m'}) - u^*(\omega_c)\theta)\omega_c - |\omega_{m'}|)] \frac{\Delta(i\omega_{m'})}{\sqrt{\omega_{m'}^2 + \Delta^2(\omega_{m'})}}, \quad (19.16)$$

where $u^*(\omega_c) \equiv g(\epsilon_F)U^*(\omega_c)$. One should note that $U^*(\omega_c) < U$, physically corresponding to the fact that retardation effects allow two electrons to exchange a phonon with one another while not being at the same place at the same time. This means they do not feel the full direct Coulomb interaction with one another.

Thus far we have written the Eliashberg equations as functions of imaginary frequency. As we will see in the next subsection one can solve these equations as they are, to determine many thermodynamic quantities of interest, in particular T_c. However, later we will extend these equations to the upper half-plane, and in particular just above the real axis. This is required for the evaluation of dynamic quantities like the tunneling density of states and the optical conductivity.[17, 36, 34] In anticipation of these results we note here that we use functions $Z(z)$ and $\phi(z)$ [and therefore $\Delta(z)$] with the following properties[53] as a function of complex frequency z

$$Z(z^*) = Z^*(z); \qquad Z(-z) = Z(z), \quad (19.17)$$

$$\phi(z^*) = \phi^*(z); \qquad \phi(-z) = \phi(z), \quad (19.18)$$

$$\Delta(z^*) = \Delta^*(z); \qquad \Delta(-z) = \Delta(z). \quad (19.19)$$

19.3.3 Results on the imaginary axis: T_c

To compute actual results for T_c, along with the gap function $\Delta(\omega_m)$ and the renormalization function $Z(\omega_m)$, we need to specify $\alpha^2F(\nu)$ (now assumed to be isotropic) and $u^*(\omega_c)$. The latter quantity is very difficult to compute, and the former is more tractable through Density Functional Theory. Historically it has been "measured" through tunnelling measurements.[18] We use quotation marks around the word "measured" because in fact the current is measured while the spectral function is extracted through an inversion process that requires theoretical input through the Eliashberg equations themselves.[18] We will simply adopt a model spectral function given by

$$\alpha^2F(\nu) = \frac{\lambda_0\nu_0}{2\pi}\left[\frac{\epsilon}{(\nu-\nu_0)^2+\epsilon^2} - \frac{\epsilon}{\nu_c^2+\epsilon^2}\right]\theta(\nu_c - |\nu-\nu_0|), \tag{19.20}$$

that is, a Lorentzian line shape cut off in such a way that the function goes smoothly to zero in the positive frequency domain. This Lorentzian has a centroid given by ν_0 and a half-width given by ϵ. The cutoff frequency parameter ν_c makes the Lorentzian go to zero at frequency $\nu_0+\nu_c$ and frequency $\nu_0-\nu_c$. For concreteness we will use a variety of values of ν_0 with $\epsilon = 0$, or $\epsilon \approx \nu_0/10$. The first choice results in a δ-function spectrum with weight such that the mass enhancement parameter, λ, defined by

$$\lambda \equiv 2\int_0^\infty d\nu \frac{\alpha^2F(\nu)}{\nu} \tag{19.21}$$

is simply given by λ_0. As ϵ increases λ decreases from λ_0; however in what follows we will adjust λ_0 to keep λ constant.[54] Since the main focus of Eliashberg theory is the effect of retardation, we will often set $u^*(\omega_c) = 0$, but we will nonetheless note how this quantity affects the gap function and T_c.

Superconducting T_c is determined by linearizing the gap equations, Eqs. (19.15,19.16) so that they become

$$Z(i\omega_m) = 1 + \frac{\pi T_c}{\omega_m}\left\{\lambda + 2\sum_{n=1}^{m-1}\lambda(i\nu_n)\right\}. \tag{19.22}$$

$$Z(i\omega_m)\Delta(i\omega_m) = \pi T_c \sum_{m'=-\infty}^{+\infty}\left[\lambda(i\omega_m - i\omega_{m'}) - u^*(\omega_c)\theta)\omega_c - |\omega_{m'}|\right]\frac{\Delta(i\omega_{m'})}{|\omega_{m'}|}. \tag{19.23}$$

The latter of these two equations is an eigenvalue equation and can be solved as such. We use a power method that iterates the eigenvalue and eigenvector simultaneously by requiring that the gap function at the lowest Matsubara frequency,[55] $\Delta(i\omega_1)$, remain at unity. This procedure tends to converge very quickly for stronger coupling, but requires more care for weaker coupling.[56]

We begin with a standard plot of T_c vs λ in Fig. 1, for a simple δ-function spectral function with frequency as shown. There are scaling relations for T_c with typical phonon frequency, but we choose to show the results explicitly in real units to make the result clear. The possibility of determining an expression for T_c analytically has been discussed extensively in the literature[20] and will not be done here. The trends are clear; higher T_c comes from higher values of λ and from higher values of the characteristic phonon frequency, which in the present case is provided by ν_0. The width of the spectrum plays a minor role, and the Coulomb repulsion suppresses T_c, as indicated by the marked points. It is well known that Eliashberg theory predicts that T_c increases with both frequency and coupling strength as $T_c \approx \nu_0\sqrt{\lambda}$ in the asymptotic limit.[57, 24]

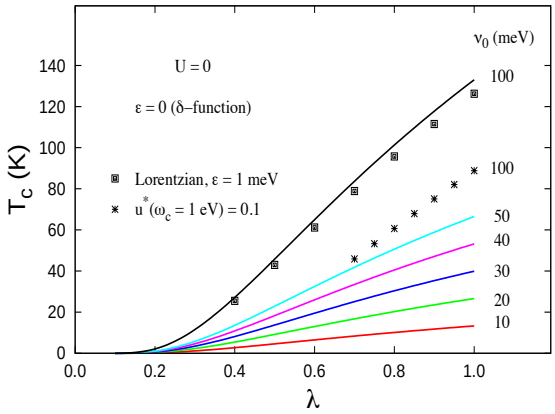

Figure 19.1: The superconducting critical temperature, T_c (K) vs. the dimensionless mass enhancement parameter, λ, for a variety of characteristic phonon frequencies, as indicated. The solid curves are for the Einstein spectrum with $U = 0$. The square points indicate how T_c changes (for $\nu_0 = 100$ meV only) when a Lorentzian is used instead with $\epsilon = 10$ meV and $\nu_c = 80$ meV, according to Eq. (19.20). For the same value of λ there is only a slight reduction in the value of T_c. The points marked with asterisks are again for the same broadened Lorentzian centred at $\nu_0 = 100$ meV, but now with $u^*(\omega_c = 1$ eV. Note that ν_c is used as a practical cutoff for the phonon spectrum whereas ω_c is used for the Matsubara cutoff for the direct Coulomb repulsion. See the discussion in the text for how plausible these parameters might or might not be.

19.3.4 Validity of the Theory

A perhaps more important question is the validity of the parameters used in the calculation. We have shown results up to a value of $\lambda = 1$. Are higher values allowed? In particular, is it possible for a material to have a sizeable value of electron-phonon coupling while maintaining a large phonon frequency? As discussed in the introduction, this question has been the subject of previous investigation,[40, 41, 42] although with only qualitative conclusions. The discovery of (very) high temperature superconductivity in the hydrides[58, 59] under intense pressure has spurred a reassessment of this type of analysis, since a part of the community believes that these superconductors are electron-phonon driven. The main evidence has been an observed isotope shift.[58] Moreover, the prediction of superconductivity in some of these compounds through density functional theory calculations[60] adds plausibility to this explanation. However, very high characteristic phonon frequencies (60 - 120 meV) and rather large electron-phonon coupling values ($\lambda \approx 2$ or more) are required. The latter is well outside the range considered reasonable, *especially* given that the characteristic phonon energy remains so high. Moreover, the superconductivity literature has unfortunately lapsed into simply accepting as "standard" or "conventional" a value for the Coulomb pseudopotential $u^* = 0.1$, and, *especially* given the high value of phonon frequency, the anticipated reduction of the Coulomb interaction through retardation will be much lower than previously thought, and the value of the direct Coulomb repulsion is undoubtedly higher when the phonon frequency is so high.

An additional direction of addressing this question comes from microscopic calculations involving Quantum Monte Carlo (QMC) and Exact Diagonalization (ED) techniques, utilizing specific microscopic models. These methods provide controlled approximations and are therefore suitable for benchmarking more approximate theories like Eliashberg theory. By far the most work in this direction has been done on the Holstein model.[61] The Holstein model retains only the short-range (on-site) interaction between local (Einstein) oscillators and the electron charge density. Because it is a very local model it is more amenable to the exact or controlled methods developed over the past 40 years, and therefore is a "favourite" for understanding the electron-phonon interaction, much like the Hubbard model[62] is heavily used for the study of electron-electron interactions. A short historical account of this activity is provided in the Appendix of Ref. [[34]].

Briefly, early Quantum Monte Carlo studies in one dimension[63] and two dimensions[64, 65] established that charge-density-wave (CDW) correlations dominate at half-filling and close to half-filling. The critical question is whether, sufficiently away from half-filling, where the susceptibility for superconductivity is stronger than that for CDW formation, do the "remnant" CDW correlations *enhance* or *suppress* suppress superconducting T_c? In Ref. [[66]] the present author, based on a comparison of QMC and Migdal-Eliashberg calculations on (very!) small lattices, argued that CDW fluctuations actually *suppress* superconducting T_c. In the so-called *renormalized* Migdal-Eliashberg calculations a phonon self-energy was included; in this manner CDW fluctuations impacted the phonon propagator, resulting in softer phonons and an enhanced coupling constant. Comparisons with the QMC results served to benchmark the Eliashberg-like calculations.

Figure 2, reproduced from Ref. [[66]], illustrates that the so-called *renormalized* calculations agree with the QMC results. These calculations (solid curves) include phonon self-energy effects which are essentially the CDW fluctuations.[65] In contrast, the *unrenormalized* calculations (dashed curves) are the standard Migdal-Eliashberg calculations that omit phonon self-energy effects. Figure 2(a) illustrates that the renormalized calculations are more accurate, and Fig. 2(b) shows that including CDW fluctuations *suppresses* the pairing susceptibility, $\chi^{\rm SP}$. We understand these results to indicate that in the vicinity of a CDW instability, while the effective coupling constant ($\lambda^{\rm eff}$ in Ref. [[65, 66]]) *increases*, superconducting T_c *actually decreases*.

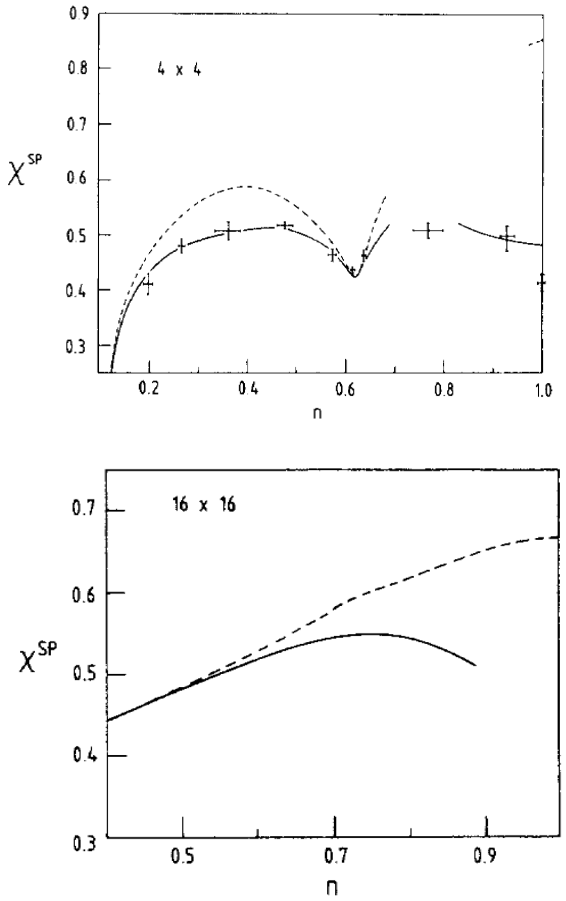

Figure 19.2: The singlet pairing susceptibility vs. electron density for the Holstein model on a 4×4 lattice. See Refs. [[65, 66]] for pertinent definitions. Here a bare dimensionless coupling strength $\lambda_0 = 2$ and phonon (Einstein) frequency $\omega_E = 1t$ are used, and the susceptibility is plotted for a temperature $T = t/6$, where t is the nearest neighbour hopping parameter. In the topmost figure, QMC results are indicated with error bars. The solid curves are the result for Migdal-Eliashberg theory with a renormalized phonon propagator and the dashed curves are the result for the unrenormalized calculations. The renormalized calculations agree very well with the QMC results (both done for a 4×4 lattice), indicating that this (combined Migdal-Eliashberg plus phonon self-energy in the bubble RPA approximation) result accurately captures the impact of CDW fluctuations on the pairing susceptibility. In the bottom figure the renormalized (solid curve) and unrenormalized (dashed curves) are plotted for a larger system. The renormalized calculations stop at an electron density close to $n \approx 0.9$ because a CDW instability occurs there. The unrenormalized calculations carry on to half-filling, because they are oblivious to the CDW instability (and fluctuations). This result indicates that CDW fluctuations at densities less than $n = 0.9$ suppress pairing, and presumably T_c, even though $\lambda^{\text{eff}} \to \infty$. Reproduced from Ref. [[66]].

More recently similar calculations have been performed[67] and other methodologies have been employed.[68] In the latter reference the role of retardation in reducing the direct Coulomb interaction was also addressed; while they found qualitative agreement with the standard arguments, quantitative agreement was lacking, especially for the expected large values of direct Coulomb repulsion. An older calculation with just two electrons,[69] based on Exact Diagonalization studies, also found qualitative support for a retardation-related reduction in the direct Coulomb repulsion. It is worth mentioning that finding this insensitivity to increased Coulomb repulsion, known as the "pseudopotential effect,"[70, 71] has been looked for in QMC studies, but these have mostly been unsuccessful. They may still be there; part of the problem is that QMC results become more difficult as the electronic and phonon energy scales differ from one another by a significant amount. Moreover, it may be that if larger lattices and more realistic phonon frequencies (i.e. significantly less than the electron hopping parameter, t) are used, the result illustrated in Fig. 29.2 could change qualitatively.

An additional concern has been raised about the electron-phonon coupling becoming too strong — that of polaron collapse.[43] Exact studies in the thermodynamic limit[72] have established that a single electron, interacting with Einstein oscillators through the Holstein model, acquires an additional mass which is modest for $\lambda \lessapprox 1$, but becomes quickly (though smoothly!) very, very large beyond this point. This is true independent of dimension,[73, 74] and is especially acute when $\nu_0 << W$,[75] where W is the electronic bandwidth. So we have the intriguing situation where the standard Migdal approximation (upon which Eliashberg theory is based) utilizes a Fermi sea of electrons strongly coupled to phonons, while close examination of *just one* of these constituent quasiparticles (polarons) shows that it acquires a tremendous effective mass. Thus, the properties of the single polaron, out of which a Fermi sea is constructed, appear to be incompatible with the properties of the electrons in that Fermi sea.

For example, in Migdal theory, the effective mass for electrons near the Fermi energy is $m^*/m_e \approx 1 + \lambda$, even for $\lambda \approx 2$ or more, whereas a single electron with this coupling would have an effective mass many orders of magnitude higher. It is important to note that in the quantum treatment polarons never "self-localize," essentially because of Bloch's Theorem. However, with such large effective mass ratios, any impurities (including surfaces), would readily act as localization sites.

There are perhaps a few scenarios to work one's way out of this dilemma. First, as we have already mentioned, perhaps the Holstein model itself is pathological. For this reason it is important to study other models. Unfortunately other models are more difficult to work with, but thus far the conclusions arrived at with the Holstein model seem to hold for these other models as well. For example, in Ref. [[76]] a variational approach was used with the Fröhlich Hamiltonian in the continuum with acoustic phonons, and in Refs. [[77, 78]] the Barisić-Labbé-Friedel/Su-Schrieffer-Heeger (BLF/SSH) model was examined with perturbation theory and the adiabatic approximation. In either case more definitive results as achieved with the Holstein model are still lacking, although all indications are that these models have strong polaronic tendencies as well.

A second scenario is that as one assembles a Fermi sea of polarons, they somehow become increasingly undressed, presumably due to some argument involving Pauli blocking. There are no calculations that we are aware of, however, that provide a demonstration of this.[79] Part of the reason may be psychological; the Migdal approximation is more often called the Migdal Theorem, and so one may be inclined to take it for granted that this is what will happen when we assemble a Fermi sea — the "theorem" will be fulfilled. However, in my opinion this is more a belief than an established argument, as the Migdal approximation does not foresee or account for polaron physics.

This discussion has been a long digression concerning the domain of applicability of Eliashberg theory, and clearly a lot more investigation is required on this question. For now we return

to the properties of the solutions to the Eliashberg equations.

19.3.5 Results on the imaginary axis: in the superconducting state

Returning to Eqs. (19.15,19.16), or their linearized counterparts, Eqs. (19.22,19.23), once T_c is determined then the gap function can be determined both at T_c and below T_c. The gap function is a generalized (frequency-dependent) order parameter. It will grow continuously from zero at T_c to its full value at zero temperature, but it depends on frequency. In Fig. 29.3(a) we show the gap function as a function of Matsubara frequency for a variety of temperatures, for $\lambda = 1$ and $\nu_0 = 10$ meV. Note that these functions are defined on a discrete set of points (the Fermion Matsubara frequencies) that become more closely spaced as the temperature is lowered. For temperatures close to T_c the gap function diminishes gradually to zero at all frequencies, while at the lowest temperature the gap function attains a maximum. In Fig. 29.3(b) we plot the normalized values, $\Delta(i\omega_m)/\Delta(i\omega_1)$ vs. Matsubara frequency, and it is clear that they differ from one another by very little. Returning to Fig. 29.3(a), the lowest frequency function value can be thought of as an order parameter. In Fig. 29.4 we show the lowest frequency gap function value, $\Delta(i\omega_1)$, now normalized to the value at $T = 0$ vs. reduced temperature, T/T_c. These are shown as blue squares, for about 9 temperatures. Also shown is the BCS weak coupling result, given as a red curve. One can see that the differences are small. We have also a plotted many more points (green asterisks) for a weaker coupling, $\lambda = 0.3$ (same phonon frequency), which fall exactly on the BCS curve. The main point is that deviations from the weak coupling BCS result are minor. For much stronger coupling than given here deviations are similarly very small, and experiment confirms this to be the case.[80]

Many measurable properties of the superconducting state can be calculated from the imaginary axis solutions to the gap function. The renormalization function, $Z(i\omega_m)$, is also required but this does not change by very much in the superconducting state. Examples of measurable properties include all thermodynamic quantities like the specific heat, and various critical fields. Systematic changes with coupling strength, as measured by λ, or alternatively the ratio of the critical temperature to a particular phonon frequency moment, $T_c/\omega_{\ln}$, have been reviewed elsewhere,[33, 34] and will not be repeated here.

19.3.6 Results on the real axis

For any dynamical property (tunneling current, optical response, dynamical penetration depth, etc.), the relevant Green function (and therefore self-energy) is required as a function of real frequency. More precisely, for the retarded Green function it is needed at $\omega + i\delta$, i.e. infinitesimally above the real axis. In the original literature[12, 13, 71, 81, 82] the spectral representation was introduced to replace Matsubara sums with real frequency integrals, and these equations were then solved, either analytically (with approximations) or numerically. This was a difficult task (especially with the computers available at that time), and eventually the procedure was adopted that first required a solution on the imaginary axis and then analytic continuation ($i\omega_m \to \omega + i\delta$) through some approximate process. For this type of analytic function, the method of Padé approximants was used,[83] although the degree of precision needed for the gap function on the imaginary axis was very stringent (10^{-12} for relative errors) in order to achieve accurate results on the real axis.

An appreciation for the information imbedded in imaginary axis solutions can be attained by considering the simple example of $g(i\omega_m) = \mathrm{sech}(\omega_m/\nu_0)$, a very smooth function without structure, and monotonically decreasing with frequency on the positive imaginary axis. The analytic continuation can be easily done analytically; it is $g(\omega + i\delta) = \sec[(\omega + i\delta)/\nu_0]$. This function, in contrast to its imaginary axis counterpart, is riddled with divergences and discon-

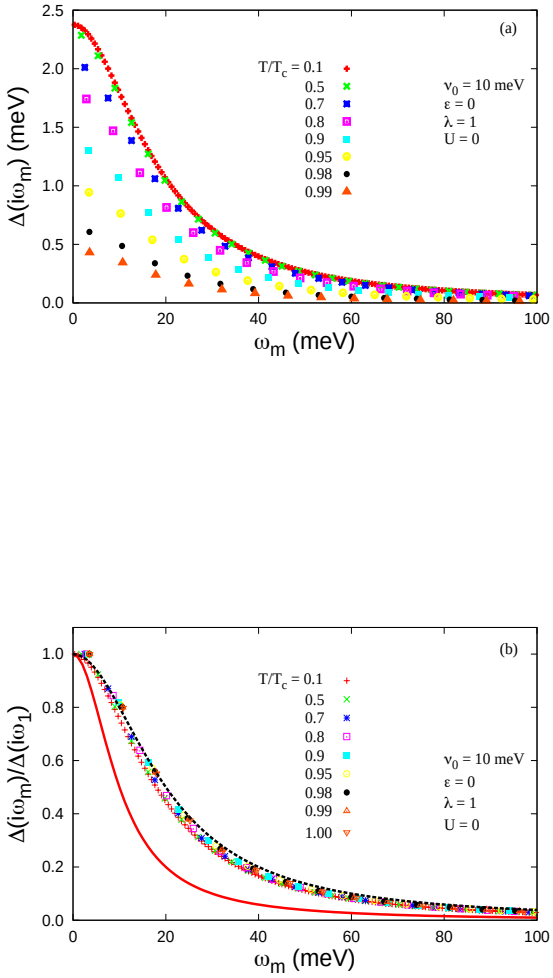

Figure 19.3: (a) The gap function $\Delta(i\omega_m)$ vs. Matsubara frequency, ω_m, for various temperatures. We have used a δ-function phonon spectrum ($\epsilon = 0$) with $\nu_0 = 10$ meV, electron-phonon coupling strength, $\lambda = 1$ and $U = 0$. For these parameters, $T_c = 13.3$ K. Clearly the gap function increases in amplitude with decreasing temperature, and below about $T/T_c = 0.5$ there is very little change in the amplitude and in the frequency dependence. With a broadened phonon spectrum there would be only minor changes. With a nonzero U, the gap function would have a negative asymptote as $\omega_m \to \infty$. In (b), to illustrate that there is very little change in the frequency dependence *at all temperatures* we show the normalized gap function, $\Delta(i\omega_m)/\Delta(i\omega_1)$ vs. ω_m. Now the results look very similar to one another, which makes convergence from one temperature to the next relatively easy. Also shown is the weak coupling expectation[56] at T_c, $\Delta(i\omega_m)/\Delta(i\omega_1) = \omega_E^2/(\omega_E^2 + \omega_m^2)$, indicated with a solid red curve. This result clearly does not resemble the data, since we the numerical results are for $\lambda = 1$. However, the slightly modified result, $\Delta(i\omega_m)/\Delta(i\omega_1) = \omega_E^2/(\omega_E^2 + \omega_m^2/(1+\lambda)^2)$, shown as a dashed black curve, is a fairly good fit.

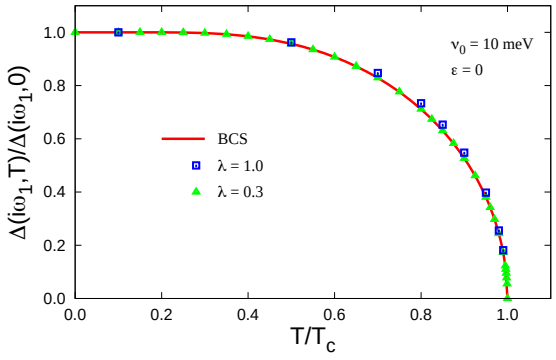

Figure 19.4: The gap function at the first Matsubara frequency (serving as an order parameter), normalized to the zero temperature gap function at the first Matsubara frequency, vs. reduced temperature T/T_c. The blue squares are the results at a few temperatures for calculations using a phonon δ-function spectrum with $\nu_0 = 10$ meV, $\lambda = 1$, and $U = 0$. Shown for comparison is the weak coupling BCS result (red curve). The deviations are very slight. Also shown for comparison are the Eliashberg results for the same phonon spectrum but with $\lambda = 0.3$ (green triangles). These results fall right on the BCS weak coupling result.

tinuities. And yet, in principle at least, this information is embedded in the (smooth) results on the imaginary axis. In practice, the information is contained in the 10^{th} significant digit and beyond.

An alternative, numerically exact procedure was developed in the late 1980's.[84] Here we simply write down the resulting expressions, the derivation of which is available in Ref. [[84]]. They are

$$\begin{aligned}\phi(\omega+i\delta) &= \pi T\sum_{m=-\infty}^{\infty}\left[\lambda(\omega-i\omega_m)-u^*(\omega_c)\theta(\omega_c-|\omega_m|)\right]\frac{\Delta(i\omega_m)}{\sqrt{\omega_m^2+\Delta^2(i\omega_m)}}\\ +i\pi\int_0^\infty d\nu\,\alpha^2F(\nu)\qquad &\left\{\left[N(\nu)+f(\nu-\omega)\right]\frac{\phi(\omega-\nu+i\delta)}{\sqrt{(\omega-\nu)^2Z^2(\omega-\nu+i\delta)-\phi^2(\omega-\nu+i\delta)}}\right.\\ &\left.+\left[N(\nu)+f(\nu+\omega)\right]\frac{\phi(\omega+\nu+i\delta)}{\sqrt{(\omega+\nu)^2Z^2(\omega+\nu+i\delta)-\phi^2(\omega+\nu+i\delta)}}\right\},\end{aligned} \tag{19.24}$$

and

$$Z(\omega+i\delta) = 1+\frac{i\pi T}{\omega}\sum_{m=-\infty}^{\infty}\lambda(\omega-i\omega_m) \tag{19.25}$$

$$\frac{\omega_m}{\sqrt{\omega_m^2+\Delta^2(i\omega_m)}} + \frac{i\pi}{\omega}\int_0^\infty d\nu\,\alpha^2F(\nu)\left\{\left[N(\nu)+f(\nu-\omega)\right]\frac{(\omega-\nu)Z(\omega-\nu+i\delta)}{\sqrt{(\omega-\nu)^2Z^2(\omega-\nu+i\delta)-\phi^2(\omega-\nu+i\delta)}}\right.$$
$$\left.+\left[N(\nu)+f(\nu+\omega)\right]\frac{(\omega+\nu)Z(\omega+\nu+i\delta)}{\sqrt{(\omega+\nu)^2Z^2(\omega+\nu+i\delta)-\phi^2(\omega+\nu+i\delta)}}\right\} \tag{19.26}$$

and of course $\Delta(\omega+i\delta)\equiv\phi(\omega+i\delta)/Z(\omega+i\delta)$. Here $f(\omega)\equiv 1/(\exp(\beta\omega)+1)$ and $N(\nu)\equiv 1/(\exp(\beta\nu)-1)$ are the Fermi and Bose functions respectively. Note that in cases where the square–root is complex, the branch with positive imaginary part is to be chosen. The reason for this can be traced back to Eq. (19.6) [or Eq. (19.4)] where the integration over $\epsilon_{\mathbf{k}'}$ (with the assumptions made there) requires that the pole (given the same square–root that appears here) be *above* the real axis.

It can easily be verified that substituting $\omega+i\delta\to i\omega_n$ instantly recovers the imaginary axis equations (all the Fermi and Bose factors cancel to give zero contributions beyond the initial terms that require Matsubara summations). Clearly the inverse is not true — replacing the Matsubara frequency $i\omega_m$ where it appears in Eqs. (19.15,19.16) produces the first lines in Eqs. (19.24,19.26) involving Matsubara sums, but leaves out the remaining two lines in each case. The strategy for solving these equations is straightforward; the imaginary axis equations [Eqs. (19.15,19.16)] are first solved self-consistently. These are then used in Eqs. (19.24,19.26) and these equations are iterated to convergence. The presence of the first lines in these equations provides a "driving term" that makes the iteration process quite rapid. For example, performing the entire operation (solution of imaginary axis and real axis equations) for a given temperature takes about a tenth of a second on a laptop.

Moreover, $T=0$ is a special case, as is clear from these equations. In fact, this was recognized a long time ago,[85] where they established the following low frequency behaviour at $T=0$,

$$\begin{aligned}\mathrm{Re}\Delta(\omega+i\delta) &= c,\\ \mathrm{Im}\Delta(\omega+i\delta) &= 0,\\ \mathrm{Re}Z(\omega+i\delta) &= d,\\ \mathrm{Im}Z(\omega+i\delta) &= 0.\end{aligned}\qquad T=0 \tag{19.27}$$

where c and d are constants. In contrast, the behaviour at any non-zero temperature is

$$\begin{aligned}\mathrm{Re}\Delta(\omega+i\delta) &\propto \omega^2,\\ \mathrm{Im}\Delta(\omega+i\delta) &\propto \omega,\\ \mathrm{Re}Z(\omega+i\delta) &= d(T),\\ \mathrm{Im}Z(\omega+i\delta) &\propto 1/\omega.\end{aligned}\qquad T>0 \tag{19.28}$$

For conventional parameter choices this distinction has very little consequence, as the differences are barely discernible. For example, the expression of the imaginary part of $Z(\omega+i\delta)$ in the normal state is given by

$$\mathrm{Im}Z(\omega+i\delta)=2\pi\lambda\frac{\nu_0}{\omega}[N(\nu_0)+f(\nu_0)] \tag{19.29}$$

for a δ-function spectrum [$\epsilon \to 0$ in Eq. (19.20)] with strength λ and central frequency ν_0. For $\nu_0 = 10$ meV and $\lambda = 1$ then Fig. 29.1 indicates $T_c \approx 10$ K, and at $T/T_c = 0.1$, the exponent in the Bose and Fermi functions makes this part $\approx 10^{-50}$. Thus, true to Eq. (19.28) the limiting behaviour is $\propto \nu_0/\omega$. However, to see this requires $\omega/\nu_0 < 10^{-45}$, making it unobservable, and indistinguishable from the $T = 0$ case.

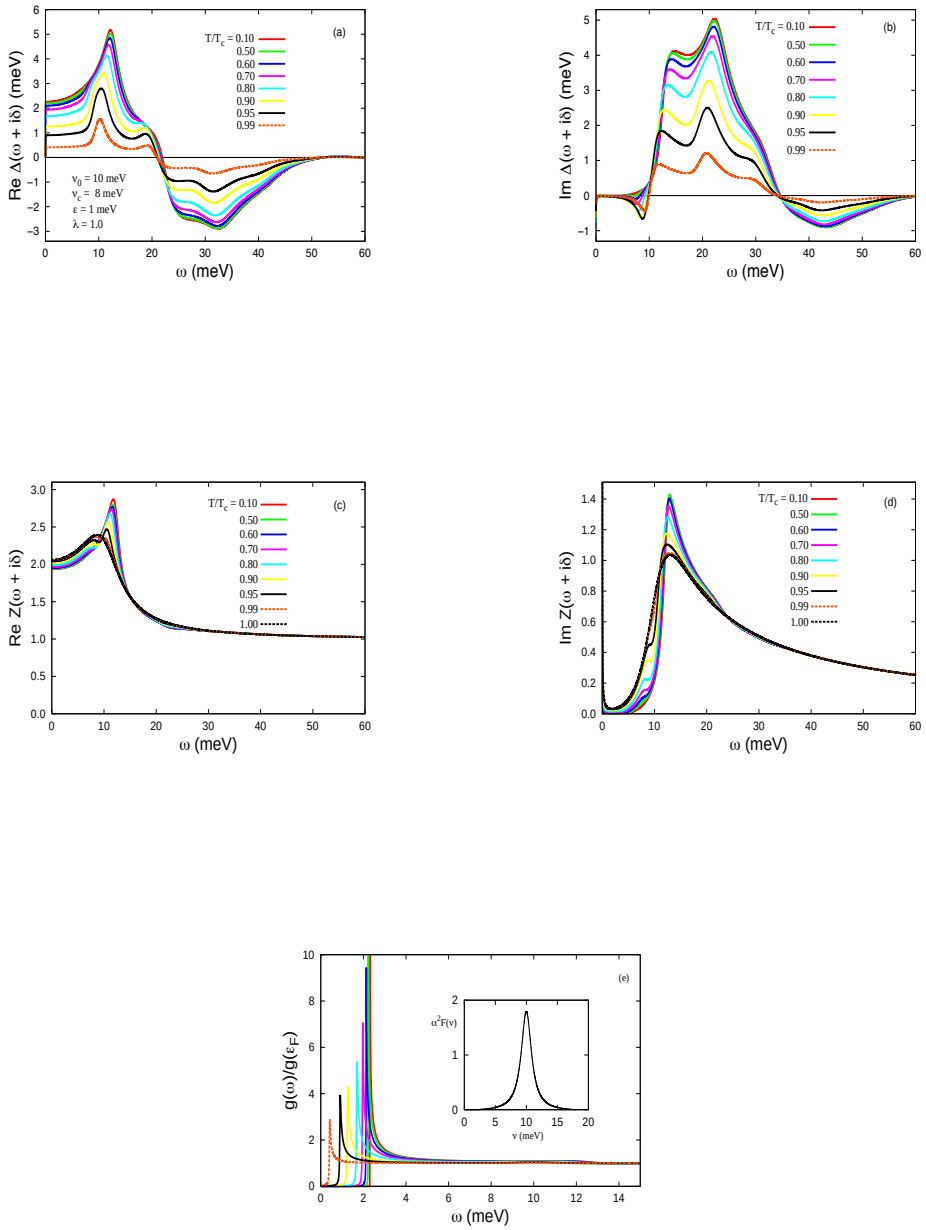

Figure 19.5: Frequency dependence of (a) Re $\Delta(\omega + i\delta)$, (b) Im $\Delta(\omega + i\delta)$, (c) Re $Z(\omega + i\delta)$, (d) Im $Z(\omega + i\delta)$, and (e) $g(\omega)/g(\epsilon_F)$, for various temperatures in the superconducting state. Features are discussed in the text. For the spectral function we have used Eq. (19.20) with $\lambda = 1$, $\nu_0 = 10$ meV, and $\epsilon = 1$ meV. It is displayed in the inset of (e) and was used for all these figures. The colour coding in (e) is the same as the others. We used $U = 0$.

While this expression is for the normal state, the corresponding one of the superconducting state is even more severe, due to the development of the superconducting order parameter, which gives rise to a gap in the spectrum. Again, given the first two lines in Eq. (19.28) there is technically *no gap*, but in practice for reasons like we have just indicated, the practical results more closely follow the behaviour indicated in Eq. (19.27). Where the finite temperature result becomes pronounced and noticeably different than the zero temperature behaviour is in the strong coupling limit,[86] but in this case the parameters are not realistic and undoubtedly beyond the domain of validity of the theory.

Returning to $T = 0$, for cases like the present where the phonon spectrum has a gap there is a special simplification. Basically, no iteration is required — the low frequency gap and renormalization functions come entirely from the first lines of Eqs. (19.24,19.26), and these can be constructed explicitly from the imaginary axis results. For a δ-function phonon spectrum, however, one has to be careful to convert the Matsubara summation to an actual integral, as a discontinuity will occur at the phonon frequency (at non-zero temperature this discontinuity is broadened into a gradual drop). Once the low frequency gap and renormalization functions are so constructed, higher frequency values require the Matsubara sum *and* real axis values of these functions at *lower frequencies only*. Eventually the entire functional forms are so constructed, without the need for iteration. As we will see, low temperature results converge quite rapidly to the zero temperature result, so this non-iterative method can be used as an alternative, for the lowest temperatures. Nonetheless, we will proceed with fully converged (iterative) finite temperature results, since these require such few iterations anyways.

To show real axis results, we utilize a phonon spectrum as in Eq. (19.20) with $\nu_0 = 10$ meV, $\nu_c = 8$ meV, and $\epsilon = 1$ eV, and $\lambda = 1$. Results with a δ-function spectrum tend to have a series of singularities, that are anyways artifacts of the singular spectrum, so we prefer to show results corresponding to this model spectrum. A series of such plots was also shown in Ref. [[34]] for the tunneling-derived Pb spectrum, with a much larger value of λ, and many more such results have been shown in the literature, often using this same method.[87] In Fig. 29.5 we show (a) the real part of the gap function, (b) the imaginary part of the gap function, (c) the real part of the renormalization function, (d) the imaginary part of the renormalization function, and (e) the tunneling density of states,

$$\frac{g(\omega)}{g(\epsilon_F)} = \mathrm{Re}\frac{\omega}{\sqrt{\omega^2 - \Delta^2(\omega + i\delta)}}, \tag{19.30}$$

which is measurable in single-particle tunneling experiments. The first observation, difficult to make with just these results, is that an image of the $\alpha^2F(\nu)$ spectrum is contained in both the real and imaginary parts of the gap function. Here it is the peak structure clearly evident in (a) centred around 10 meV *for the highest temperature shown.* As the temperature decreases this peak shifts to higher frequency, roughly by an amount equal to the value of the gap function at low frequency (about 2 meV in the present case). Experimentation with different spectral functions makes this observation more self-evident. See, for example, the distinctive spectrum for Pb in Fig. 4.35(a) of Ref. [[34]].

Both functions in (a) and (b) go to zero as the critical temperature is approached from below. As discussed earlier, they both go to zero at zero frequency at all temperatures shown, according to Eqs. (19.28), although one cannot see this on the scale shown. Even for the highest temperatures shown this behaviour can barely be seen, but becomes evident when one expands the low frequency scale. For the lowest temperatures shown even expanding the frequency scale by a few orders of magnitude is not enough to reveal the low-frequency behaviour indicated by Eqs. (19.28). For this reason one cannot use $\Delta(\omega + i\delta)$ as an order parameter at any frequency; either one has to revert to $\phi(\omega + i\delta)$ at zero frequency, or one can use the imaginary axis result for $\Delta(i\omega_m)$, as we did in Fig. 29.4. Also note that these functions approach zero at high

frequency. If a Coulomb repulsion is included then the real part of $\Delta(\omega + i\delta)$ approaches a negative constant at high frequency.

In contrast the real and imaginary parts of $Z(\omega + i\delta)$ plotted in (c) and (d) have changed very little in the superconducting state, and remain non-zero at the superconducting critical temperature, as indicated by the black curve. An image of $\alpha^2F(\nu)$ is present in this function as well, particularly in the imaginary part (see also Fig. 4.35 (c) and (d) in Ref. [[34]]). Finally, the tunneling density of states is shown in Fig. 29.5(e), and reveals a "gap" that opens from zero at $T = T_c$ rather quickly and then saturates to a low temperature value as indicated. In fact a plot of this "gap" vs. temperature would follow the result displayed in Fig. 29.4 very closely. However, as first pointed out by Karakozov et al.[85] there is no "gap" (hence the parentheses) and in fact this is evident in Fig. 29.5(e), where there is a noticeable rounding of the curves at frequencies below the sharp peak at almost all temperatures shown. The peak is a remnant of the square-root singularity known from BCS theory, which is evident from Eq. (19.30) if a constant gap function is used, $\Delta(\omega + i\delta) = \Delta_0$. In fact Eliashberg theory predicts smearing of this singularity simply due to the presence of imaginary components of all the functions involved in Eqs. (19.28) for all finite temperatures. It is also worth pointing out that the BCS limit of Eliashberg theory is *not* achieved by setting the gap function to a constant, $\Delta(\omega + i\delta) \to \Delta_0$, but in fact the gap function is a decaying function of frequency in this limit.[85] This frequency dependence and its implications for the weak coupling limit has been further explored in Refs. [[88, 56, 89]].

Finally, though not so evident in Fig. 29.5(e), there are "ripples" in the density of states beyond the "gap" region, caused by the coupling of electrons to phonons. The presence of these ripples in experiments (see, in particular, Refs. [[90, 91, 18]]) is perhaps the strongest evidence of the validity of Eliashberg theory. In fact the most intense scrutiny has been superconducting Pb, where the electron-phonon coupling is particularly strong, $\lambda \approx 1.5$, with a value well beyond the expected domain of validity. These experiments, coupled with an inversion technique that use the Eliashberg equations themselves, result in a consistent description of the superconducting state for Pb and other so-called "strong coupling" superconductors.

Many systematic deviations from BCS theory have been characterized, for example the gap ratio, $2\Delta_0/(k_BT_c)$,[92] the specific heat jump, and many other dimensionless ratios[93, 94] These have all been reviewed in Ref. [[33]], and show very systematic behaviour as a function of the strong coupling index, $T_c/\omega_{\ln}$. On the other hand, when systematics are examined with purely experimental parameters, the picture is not so clear.[95]

19.3.7 Summary and Outlook

I have provided just a sketch of what we consider the essence of Eliashberg theory — retardation effects, in the context of a single featureless band. The generalization of these types of calculations to more complicated scenarios is well documented in a number of places, and have not been reviewed here. These include order parameter anisotropy, multi-band superconductivity, Berezinskii "odd-frequency" pairing, sharply varying electronic density of state, impurity effects, and so on. These additional complications are increasingly taken into account to understand new classes of compounds that exhibit superconductivity, such as the hydrides, MgB_2, and the pnictides. In some cases, these additional effects have been invoked to explain higher critical temperatures as well, but for the most part they are motivated by matching theory to experiment.

In its bare form, Fig. 29.1 presents the possibilities for T_c provided by Eliashberg theory. The conscious decision was made to extend the domain of coupling strength to unity *only* and not beyond, because there are reasons to believe that going beyond this regime is not viable. At the same time, large values of the characteristic phonon frequency have been used, and this is

why the plot extends to beyond ≈ 50 K for the vertical axis, T_c. Are these values of frequency, together with large values of $\lambda \approx 1$ viable? Probably not, but given these sorts of parameter values, this is what Eliashberg in its standard form predicts.

I have also tried to touch on aspects of the theory where more critical scrutiny is possible, by comparing results to those obtained with microscopic models, such as the Holstein model. We believe there are significant difficulties that arise when these comparisons are made. One reaction is to dismiss such comparisons, as the Holstein model (or the Hubbard model, for that matter) may be regarded as "toy models," possibly fraught with pathologies. However, if the Holstein model is lacking in some way, it is important to know why, and what other aspect of the electron-phonon interaction (wave-vector dependence?) is essential to the success of Eliashberg theory. For example, if the super-high-T_c of the hydrides is confirmed to originate in the electron-phonon interaction, then clearly one or more missing gaps in our understanding of how this happens needs to be filled.

Moreover, as presented here, Eliashberg theory focusses on the superconducting instability, and does not consider other, possibly competing, or potentially enhancing, instabilities. This possibility has come up as more and more phase diagrams of families of materials exhibit a nearby antiferromagnetic or charge-density-wave instability, as a function of some tuning parameter (doping, pressure, etc.). It would be desirable to generalize Eliashberg theory to be more "self-regulating," and have the theory itself indicate when a competing instability is limiting superconducting T_c, for example.

The other aspect that goes hand in hand with the electron-phonon coupling is the direct Coulomb interaction. We cannot claim to understand superconductivity to the point of having predictive power until we understand the role of Coulomb correlations, and their detrimental (or perhaps favourable?) effects on pairing. A key advancement has to come in further understanding the role that competitive tendencies or instabilities play in superconductivity. Many of the modern-day methods (Dynamical Mean Field Theory, for example) seek to address the question of competing interactions. Studies with Quantum Monte Carlo methods, like the ones mentioned here, will also aid in furthering our understanding of interacting electrons, and similar studies with the now-accessible much larger lattice sizes would be welcome.

This work was supported in part by the Natural Sciences and Engineering Research Council of Canada (NSERC). I would like to thank the many students and postdoctoral fellows in my own group who have contributed to the work described here. I also want to thank in particular Jules Carbotte, who first taught me about Eliashberg theory, and Ewald Schachinger, who was instrumental in teaching me about programming the Eliashberg imaginary axis equations. I also want to thank Sasha Alexandrov, who over the years continued to question the validity of MIgdal-Eliashberg theory. In the same way, Jorge Hirsch, with whom I have worked a great deal on other matters, has been instrumental in discussions concerning the validity of the work reviewed here. I also want to thank him for critical comments concerning parts of this review. Finally, Jules sadly passed away earlier this year (April 5, 2019), and this review is dedicated to his memory. He was a wonderful man, and I feel extremely fortunate to have first entered the physics world under his guidance.

APPENDIX: Derivation of Eliashberg Theory

In this Appendix, we will first outline a derivation of Eliashberg theory, based on a weak coupling approach. Our primary source for this derivation is Ref. [[47]]. Migdal theory of the normal state follows by simply dropping the anomalous amplitudes in what follows.

If we know the many-body wave function of system, we can calculate the expectation value for any observable. However, usually this is something we do not know, and instead we calculate multi-electron Green functions, which are themselves related to observables. The Green

functions are necessarily almost always approximate, and those computed in Eliashberg theory are no exception. In fact, Eliashberg theory is essentially a mean-field theory, though because of the inherent frequency dependence in the self energy, it is in many ways a precursor to Dynamical Mean Field Theory.[96]

We begin with the definition of the one-electron Green function, defined in momentum space,[97] as a function of imaginary time, τ,

$$G(\mathbf{k}, \tau - \tau') \equiv - < T_\tau c_{\mathbf{k}\sigma}(\tau) c^\dagger_{\mathbf{k}\sigma}(\tau') >, \tag{19.31}$$

where $\mathbf{k}$ is the momentum and σ is the spin. The angular brackets denote a thermodynamic average. We can Fourier-expand this Green function in imaginary frequency:

$$\begin{aligned} G(\mathbf{k}, \tau) &= \frac{1}{\beta} \sum_{m=-\infty}^{\infty} e^{-i\omega_m \tau} G(\mathbf{k}, i\omega_m) \\ G(\mathbf{k}, i\omega_m) &= \int_0^\beta d\tau G(\mathbf{k}, \tau) e^{i\omega_m \tau}. \end{aligned} \tag{19.32}$$

The frequencies $i\omega_m$ are the Fermion Matsubara frequencies, given by $i\omega_m = i\pi T(2m-1)$, $m = 0, \pm 1, \pm 2, ...$, where T is the temperature. Because the c's are Fermion operators, the Matsubara frequencies are *odd* multiples of $i\pi$T. The imaginary time τ takes on values from 0 to $\beta \equiv 1/(k_B T)$.

A similar definition holds for the phonon Green function,

$$D(\mathbf{q}, \tau - \tau') \equiv - < T_\tau A_{\mathbf{q}}(\tau) A_{-\mathbf{q}}(\tau') >, \tag{19.33}$$

where

$$A_{\mathbf{q}}(\tau) \equiv a_{\mathbf{q}}(\tau) \quad + \quad a^\dagger_{-\mathbf{q}}(\tau). \tag{19.34}$$

The Fourier transform is similar to that given in (19.32) except that the Matsubara frequencies are $i\nu_n \equiv i\pi T 2n$, $n = 0, \pm 1, \pm 2, ...$ and occur at *even* multiples of $i\pi T$. These are the Boson Matsubara frequencies.

To derive the Eliashberg equations, we follow Ref. [[47]], and use the equation-of-motion method. The starting point is the time derivative of Eq. (19.31),

$$\frac{\partial}{\partial \tau} G(\mathbf{k}, \tau) = -\delta(\tau) \quad - \quad < T_\tau \big[H - \mu N, c_{\mathbf{k}\sigma}(\tau) \big] c^\dagger_{\mathbf{k}\sigma}(0) >, \tag{19.35}$$

where we have put $\tau' = 0$, without loss of generality. We use the Hamiltonian (19.2), and assume, for the Coulomb interaction, the simple Hubbard model, $H_{Coul} = U \sum_i n_{i\uparrow} n_{i\downarrow}$. Including the Coulomb repulsion, the result is repeated here,

$$\begin{aligned} H \quad = \quad & \sum_{\mathbf{k}\sigma} \epsilon_{\mathbf{k}} c^\dagger_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma} \\ & + \sum_{\mathbf{q}} \hbar\omega_{\mathbf{q}} a^\dagger_{\mathbf{q}} a_{\mathbf{q}} \\ & + \frac{1}{\sqrt{N}} \sum_{\substack{\mathbf{k}\mathbf{k}' \\ \sigma}} g(\mathbf{k}, \mathbf{k}') \big(a_{\mathbf{k}-\mathbf{k}'} + a^\dagger_{-(\mathbf{k}-\mathbf{k}')} \big) c^\dagger_{\mathbf{k}'\sigma} c_{\mathbf{k}\sigma} \\ & + \frac{U}{N} \sum_{\mathbf{k},\mathbf{k}',\mathbf{q}} c^\dagger_{\mathbf{k}\uparrow} c^\dagger_{-\mathbf{k}+\mathbf{q}\downarrow} c_{-\mathbf{k}'+\mathbf{q}\downarrow} c_{\mathbf{k}'\uparrow}, \end{aligned} \tag{19.36}$$

where the various symbols have already been defined in the text. We consider only the Green function with $\sigma =\uparrow$; the commutator in Eq. (19.35) is straightforward and we obtain

$$\left(\frac{\partial}{\partial\tau}+\epsilon_{\mathbf{k}}\right)G_{\uparrow}(\mathbf{k},\tau) =$$
$$-\delta(\tau)-\frac{1}{\sqrt{N}}\sum_{\mathbf{k}'}g_{\mathbf{k}\mathbf{k}'} < T_\tau A_{\mathbf{k}-\mathbf{k}'}(\tau)c_{\mathbf{k}'\uparrow}(\tau)c^\dagger_{\mathbf{k}\uparrow}(0) >$$
$$+\frac{U}{N}\sum_{\mathbf{p}\mathbf{p}'} < T_\tau c^\dagger_{\mathbf{p}'-\mathbf{k}+\mathbf{p}\downarrow}(\tau)c_{\mathbf{p}'\downarrow}(\tau)c_{\mathbf{p}\uparrow}(\tau)c^\dagger_{\mathbf{k}\uparrow}(0) > . \tag{19.37}$$

Various higher order propagators now appear; to determine them another equation of motion can be written, which would, in turn, generate even higher order propagators, and this eventually leads to an infinite set of equations with hierarchical structure. This infinite series is normally truncated at some point by the process of decoupling, which is simply an approximation procedure. For example, in (19.37) the Coulomb term is normally decoupled at this point and becomes

$$< T_\tau c^\dagger_{\mathbf{p}'-\mathbf{k}+\mathbf{p}\downarrow}(\tau)c_{\mathbf{p}'\downarrow}(\tau)c_{\mathbf{p}\uparrow}(\tau)c^\dagger_{\mathbf{k}\uparrow}(0) >\rightarrow$$
$$< T_\tau c^\dagger_{\mathbf{p}'-\mathbf{k}+\mathbf{p}\downarrow}(\tau)c_{\mathbf{p}'\downarrow}(\tau) >< T_\tau c_{\mathbf{p}\uparrow}(\tau)c^\dagger_{\mathbf{k}\uparrow}(0) >\rightarrow$$
$$-\delta_{\mathbf{k}\mathbf{p}}G_{\downarrow}(\mathbf{p}',0)G_{\uparrow}(\mathbf{k},\tau). \tag{19.38}$$

The case of the electron–phonon term is more difficult; in this case we define a 'hybrid' electron/phonon Green function,

$$G_2(\mathbf{k},\mathbf{k}',\tau,\tau_1) \equiv< T_\tau A_{\mathbf{k}-\mathbf{k}'}(\tau)c_{\mathbf{k}'\uparrow}(\tau_1)c^\dagger_{\mathbf{k}\uparrow}(0) >, \tag{19.39}$$

and write out an equation of motion for it. We simply get

$$\frac{\partial}{\partial\tau}G_2(\mathbf{k},\mathbf{k}',\tau,\tau_1) = -\omega_{\mathbf{k}-\mathbf{k}'} < T_\tau P_{\mathbf{k}-\mathbf{k}'}(\tau)c_{\mathbf{k}'\uparrow}(\tau_1)c^\dagger_{\mathbf{k}\uparrow}(0) >, \tag{19.40}$$

where $P_{\mathbf{q}}(\tau) = a_{\mathbf{q}}(\tau) - a_{-\mathbf{q}}(\tau)$. Taking a second derivative yields

$$\left[\frac{\partial^2}{\partial\tau^2}-\omega_{\mathbf{k}-\mathbf{k}'}\right]G_2(\mathbf{k},\mathbf{k}',\tau,\tau_1) =$$
$$\sum_{\mathbf{k}''\sigma}2\omega_{\mathbf{k}-\mathbf{k}'}g_{\mathbf{k}-\mathbf{k}'} < T_\tau c^\dagger_{\mathbf{k}''-\mathbf{k}+\mathbf{k}'\sigma}(\tau)c_{\mathbf{k}''\sigma}(\tau)c_{\mathbf{k}'\uparrow}(\tau_1)c^\dagger_{\mathbf{k}\uparrow}(0) > . \tag{19.41}$$

At this point we *do not simply* decouple the last line of Eq. (19.41). We first need to take the phonon propagator into account, and the standard procedure is to use the "non-interacting" phonon propagator. The adjective "non-interacting" is in quotes because part of the philosophy of proceeding in this way was a desire to *not* compute corrections to the phonon propagator, because the information going into this part of the calculations (e.g. the phonon spectral function) was going to come from experiment. Coming from experiment means that nature "had already done the calculation," and we did not want to double count. Clearly, if the purpose of this calculation is to compare to Quantum Monte Carlo calculations where this is *not* the case, then something different should be done, and this is what motivated the *renormalized* Migdal-Eliashberg calculations of Refs. [[65, 66]].

For now, we proceed with the standard Eliashberg calculations. The equation of motion for the non-interacting phonon propagator is

$$\left)\frac{\partial^2}{\partial\tau^2}-\omega^2_{\mathbf{q}}\right)D(\mathbf{q},\tau-\tau') = 2\omega_{\mathbf{q}}\delta(\tau-\tau'). \tag{19.42}$$

(?? ниже формула испорчена версткой, см. оригинальную статью его!)
Inserting this expression into Eq. (19.41) then yields

$$G_2(\mathbf{k},\mathbf{k}',\tau,\tau) = \frac{1}{N}\sum_{\mathbf{k}''\sigma}\int_0^\beta d\tau' g_{\mathbf{k}'',\mathbf{k}''+\mathbf{k}-\mathbf{k}'} g_{\mathbf{k}\mathbf{k}'} D(\mathbf{k}-\mathbf{k}',\tau-\tau')$$
$$\times < T_\tau c^\dagger_{\mathbf{k}''\sigma}(\tau') c_{\mathbf{k}''+\mathbf{k}-\mathbf{k}'\sigma}(\tau') c^\dagger_{\mathbf{k}''-\mathbf{k}+\mathbf{k}'\sigma}(\tau') c_{\mathbf{k}''\sigma}(\tau') c_{\mathbf{k}'\uparrow}(\tau) c^\dagger_{\mathbf{k}\uparrow}(0) >, \tag{19.43}$$

where now τ_1 has been set equal to τ as is required in (19.37). It is important that this be done only *after* applying Eq. (19.42). The result can be substituted into Eq. (19.37), and then Fourier transformed (from imaginary time to imaginary frequency). Before doing this however, we recall that Gor'kov[11] realized the important role of the so-called Gor'kov anomalous amplitude, in the Wick decomposition [97] of the various two–particle Green functions encountered above. We therefore have to account for these in addition to the pairing of fermion operators used in Eq. (19.38).

The anomalous amplitudes are defined to be

$$F(\mathbf{k},\tau) \equiv - < T_\tau c_{\mathbf{k}\uparrow}(\tau) c_{-\mathbf{k}\downarrow}(0) > \tag{19.44}$$

and

$$\bar{F}(\mathbf{k},\tau) \equiv - < T_\tau c^\dagger_{-\mathbf{k}\downarrow}(\tau) c^\dagger_{\mathbf{k}\uparrow}(0) > . \tag{19.45}$$

Now we need to repeat the same steps as above with F and $\bar{F}$ as we did with G. Skipping the intermediate steps, the result is an equation analogous to Eq. (19.37)

$$\left(\frac{\partial}{\partial\tau} - \epsilon_{\mathbf{k}}\right)\bar{F}(\mathbf{k},\tau) =$$
$$-\frac{1}{\sqrt{N}}\sum_{\mathbf{k}'} g_{-\mathbf{k}',-\mathbf{k}} < T_\tau A_{\mathbf{k}-\mathbf{k}'}(\tau) c^\dagger_{-\mathbf{k}'\downarrow}(\tau) c^\dagger_{\mathbf{k}\uparrow}(0) >$$
$$+\frac{U}{N}\sum_{\mathbf{k}'',\mathbf{q}}(????) < T_\tau c^\dagger_{\mathbf{p}'-\mathbf{k}+\mathbf{p}\downarrow}(\tau) c_{\mathbf{p}'\downarrow}(\tau) c_{\mathbf{p}\uparrow}(\tau) c^\dagger_{\mathbf{k}\uparrow}(0) >, < T_\tau c^\dagger_{\mathbf{k}''\uparrow}(\tau) c^\dagger_{-\mathbf{k}''+\mathbf{q}\downarrow}(\tau) c_{\mathbf{k}+\mathbf{q}\uparrow}(\tau) c^\dagger_{\mathbf{k}\uparrow}(0) > \tag{19.46}$$

and similarly for the function F. This leads to the need for another 'hybrid' electron/phonon anomalous Green function,

$$\bar{F}_2(\mathbf{k},\mathbf{k}',\tau,\tau_1) \equiv < T_\tau A_{\mathbf{k}-\mathbf{k}'}(\tau) c^\dagger_{-\mathbf{k}'\downarrow}(\tau_1) c^\dagger_{\mathbf{k}\uparrow}(0) >, \tag{19.47}$$

and, following the same process as for the regular Green function, we find
(?? ниже формула испорчена версткой, см. оригинальную статью его!)

$$\bar{F}_2(\mathbf{k},\mathbf{k}',\tau,\tau) = \frac{1}{N}\sum_{\mathbf{k}''\sigma}\int_0^\beta d\tau' g_{\mathbf{k}'',\mathbf{k}''+\mathbf{k}-\mathbf{k}'} g_{\mathbf{k}\mathbf{k}'} D(\mathbf{k}-\mathbf{k}',\tau-\tau')$$
$$\times < T_\tau c^\dagger_{\mathbf{k}''\sigma}(\tau') c_{\mathbf{k}''+\mathbf{k}-\mathbf{k}'\sigma}(\tau') c^\dagger_{\mathbf{k}''-\mathbf{k}+\mathbf{k}'\sigma}(\tau') c_{\mathbf{k}''\sigma}(\tau') c^\dagger_{-\mathbf{k}'\downarrow}(\tau) c^\dagger_{\mathbf{k}\uparrow}(0) >, \tag{19.48}$$

where again τ_1 has been set equal to τ *after* applying Eq. (19.42).

The Fourier definitions of the anomalous Green function are the same as Eq. (19.32):

$$\bar{F}(\mathbf{k},\tau) = \frac{1}{\beta}\sum_{m=-\infty}^{\infty} e^{-i\omega_m\tau}\bar{F}(\mathbf{k},i\omega_m)$$
$$\bar{F}(\mathbf{k},i\omega_m) = \int_0^\beta d\tau \bar{F}(\mathbf{k},\tau) e^{i\omega_m\tau}, \tag{19.49}$$

and similarly for F. In frequency space one finds that two self energies naturally arise,

$$\Sigma(\mathbf{k}, i\omega_m) = -\frac{1}{N\beta}\sum_{\mathbf{k}',m'} g_{\mathbf{k}\mathbf{k}'}g_{\mathbf{k}'\mathbf{k}}D(\mathbf{k}-\mathbf{k}', i\omega_m - i\omega_{m'})G(\mathbf{k}', i\omega_{m'}), \tag{19.50}$$

$$\phi(\mathbf{k}, i\omega_m) = -\frac{1}{N\beta}\sum_{\mathbf{k}',m'} g_{\mathbf{k}'\mathbf{k}}g_{-\mathbf{k}'-\mathbf{k}}D(\mathbf{k}-\mathbf{k}', i\omega_m - i\omega_{m'})F(\mathbf{k}', i\omega_{m'}). \tag{19.51}$$

One can show that $g_{\mathbf{k}'\mathbf{k}} = g^*_{\mathbf{k}\mathbf{k}'}$; normally one expects a similar relation with negative wave vectors, and we assume it in what follows. These equations are then written self-consistently and lead to Eqs. (19.4-19.7) once Eq. (19.3) is used.

19.5.1 Superconductor in an Arbitrary Magnetic Field Near the T_c

(специфика)

Теория (???)

Особый случай представляют свойства сверхпроводника вблизи критической температуры. Величина щели при этом достаточно мала, вследствие чего все уравнения значительно упрощаются. Из результатов 36 (выражение (36.4)) легко усмотреть, что в данном случае возможно разложение уравнений по величине $1 - T/T_c \ll 1$. Кроме того, как мы уже отмечали в предыдущем параграфе, вблизи T_c глубина проникновения слабого магнитного поля $\delta \gg \xi_0$, т. е. все величины в поле, в том числе и само поле, меняются на расстояниях, гораздо больших параметра теории $\xi_0 \sim \tau/T_c$. Указанное обстоятельство позволит в этой области температур построить теорию (Горьков [66]), описывающую поведение сверхпроводников в произвольных магнитных полях (порядка величины критического поля).

С этой целью перепишем снова уравнения (37.6)

$$\left\{ i\omega + \frac{1}{2m}\left(\frac{\partial}{\partial r} - ieA(r)\right)^2 + \mu \right\} \mathfrak{G}_\omega(\boldsymbol{r}, \boldsymbol{r}') + \Delta(\boldsymbol{r})\mathfrak{F}^+_\omega(\boldsymbol{r}, \boldsymbol{r}') = \delta(\boldsymbol{r} - \boldsymbol{r}'),$$

$$\left\{-i\omega+\frac{1}{2m}\left(\frac{\partial}{\partial \boldsymbol{r}}+ieA(\boldsymbol{r})\right)^2+\mu\right\}\mathfrak{F}_\omega^+(\boldsymbol{r},\boldsymbol{r}')-\Delta^*(\boldsymbol{r})\mathfrak{G}_\omega(\boldsymbol{r},\boldsymbol{r}')=0$$

вместе с уравнением, определяющим величину щели:

$$\Delta^*(\boldsymbol{r})=|\lambda|T\sum_\omega \mathfrak{F}_\omega^+(\boldsymbol{r},\boldsymbol{r})$$

Поскольку $|\Delta|$ мало, разложим функцию $\mathfrak{J}_\omega^+(\boldsymbol{r},\boldsymbol{r}')$ по степеням $|\Delta|$ и, подставляя это разложение в (38.1), найдем уравнение для $\Delta^*(r)$. При этом полезно ввести компоненты Фурье функции Грина $\tilde{\mathfrak{G}}_\omega^{(0)}(\boldsymbol{r},\boldsymbol{r}')$ для электронов в нормальном металле (в данном поле $\boldsymbol{A}(\boldsymbol{r})$). Уравнение, которому удовлетворяет $\tilde{\mathfrak{G}}_\omega^{(0)}(r,r')$, можно записать двояким образом:

$$\left\{i\omega+\frac{1}{2m}\left(\frac{\partial}{\partial \boldsymbol{r}}-ieA(\boldsymbol{r})\right)^2+\mu\right\}\tilde{\mathfrak{G}}_\omega^{(0)}(\boldsymbol{r},\boldsymbol{r}')=\delta(\boldsymbol{r}-\boldsymbol{r}')$$

или

$$\left\{i\omega+\frac{1}{2m}\left(\frac{\partial}{\partial \boldsymbol{r}'}+ieA(\boldsymbol{r}')\right)^2+\mu\right\}\tilde{\mathfrak{G}}_\omega^{(0)}(\boldsymbol{r},\boldsymbol{r}')=\delta(\boldsymbol{r}-\boldsymbol{r}').$$

С помощью функции

$$\tilde{\mathfrak{G}}_\omega^{(0)}(\boldsymbol{r},\boldsymbol{r}'),$$

привлекая второе из этих уравнений, приведем систему уравнений для $\boldsymbol{G}_\omega$ к интегральной форме:

$$\mathfrak{F}_\omega(\boldsymbol{r},\boldsymbol{r}')=\tilde{\mathfrak{G}}_\omega^{(0)}(\boldsymbol{r},\boldsymbol{r}')-\int\tilde{\mathfrak{G}}_\omega^{(0)}(\boldsymbol{r},\boldsymbol{l})\Delta(\boldsymbol{l})\mathfrak{G}_\omega^+(\boldsymbol{l},\boldsymbol{r}')\,d\boldsymbol{l},$$

$\mathfrak{F}_\omega^+(r,r')=\int\tilde{\mathfrak{G}}_{-\omega}^{(0)}(l,r)\Delta^*(l)\left(\xi_\omega(l,r')\,dl\right.$.

Прежде чем переходить к дальнейшему, найдем, чему: равна функция $\tilde{\mathfrak{G}}_\omega^{(0)}(\boldsymbol{r},\boldsymbol{r}')$. В отсутствие магнитного поля $\left(\overset{(0)}{\omega}(\boldsymbol{r}-\boldsymbol{r}')\right.$ равна ($R=|\boldsymbol{r}-\boldsymbol{r}'|$)

$$\mathfrak{G}_\omega^{(0)}(R)=\begin{cases}-\frac{m}{2\pi R}e^{ip_0R-\frac{|\omega|}{v}R} & \text{при } \omega>0,\\ -\frac{m}{2\pi R}e^{-ip_0R-\frac{|\omega|}{v}R} & \text{при } \omega<0.\end{cases}$$

В этом можно убедиться или непосредственной подстановкой (38.4) в уравнение (38.2) в стсутствие поля, или воспользовавшись известным нам выражением для компоненты Фурье $\mathfrak{G}_\omega^{(0)}(p)=[i\omega-\xi]^{-1}$:

$$\mathfrak{G}_\omega^{(0)}(R)=\frac{1}{(2\pi)^3}\int\mathfrak{G}_\omega^{(0)}(\boldsymbol{p})dpe^{ipR}=\frac{m}{(2\pi)^2iR}\int\frac{e^{ip_0R+i\frac{\xi}{v}R}-e^{-ip_0R-i\frac{\xi}{v}R}}{i\omega-\xi}d\xi$$

(нас интересует, разумеется, вид функции $\mathfrak{G}_\omega^{(0)}(R)$ на расстояниях, больших по сравнению с атомными: $Rp_0\gg1$). Интегрируя по ξ, непосредственно получаем (38.4).

Функция $\mathfrak{G}_\omega^{(0)}(R)$ быстро осциллирует. Поскольку $p_0R\gg1$. это обстоятельство позволяет для определения функции $\tilde{\mathfrak{G}}_\omega^{(0)}(\boldsymbol{r},\boldsymbol{r}')$ в магнитном поле применить своего рода квазиклассическое приближение. В самом деле, будем искать $\tilde{\mathfrak{z}}_\omega^{(0)}(\boldsymbol{r},\boldsymbol{r}')$ в виде

$$\tilde{\mathfrak{G}}_\omega^{(0)}(\boldsymbol{r},\boldsymbol{r}')=e^{i\varphi(\boldsymbol{r},\boldsymbol{r}')}\mathfrak{G}_\omega^{(0)}(\boldsymbol{r}-\boldsymbol{r}'),$$

где $\varphi(\boldsymbol{r},\boldsymbol{r})=0$. Подставляя (38.5) в (38.2) и дифференцируя только главные члены, найдем уравнение для добавки $\varphi(\boldsymbol{r},\boldsymbol{r}')$ к действию

$$(\boldsymbol{n},\nabla_r\varphi(\boldsymbol{r},\boldsymbol{r}'))=e(\boldsymbol{n},A(\boldsymbol{r}));\left(n=\frac{R}{|R|}\right).$$

В этом уравнении мы отбросили квадратичные по $\boldsymbol{A}$ члены, поскольку радиус закручивания электронов $\frac{ep_0}{H}$ в интересующих нас полях очень велик по сравнению с глубиной проникновения: $p_0 \gg eA \sim eH\delta$(δ - порядок глубины проникновения). Вернемся теперь к уравнениям (38.3) и произведем в них разложение по степеням $|\Delta(r)|$. Как видно из (38.4) и (38.6), это разложение в $\mathfrak{F}_\omega^+(\boldsymbol{r},\boldsymbol{r}')$ достаточно произвести до членов третьего порядка по $|\Delta|$ включительно. Что касается функции Грина $\mathfrak{G}_\omega(\boldsymbol{r},\boldsymbol{r}')$, то ее достаточно знать с точностью до членов второго порядка по $|\Delta|$:

$$\mathfrak{G}_\omega(\boldsymbol{r},\boldsymbol{r}') = (\tilde{\mathfrak{G}}_\omega^{(0)}(\boldsymbol{r},\boldsymbol{r}') - \int \tilde{\mathfrak{G}}_\omega^{(0)}(\boldsymbol{r},\boldsymbol{l})\Delta(\boldsymbol{l})\tilde{\mathfrak{G}}_\omega^{(0)}(\boldsymbol{m},\boldsymbol{r}')\,\Delta^*(\boldsymbol{m})\tilde{\mathfrak{G}}_{-\omega}^{(0)}(\boldsymbol{m},\boldsymbol{l})d\boldsymbol{m}d\boldsymbol{l}. \qquad (38.7)$$

Подставляя это выражение во второе из уравнений (38.3), найдем разложение $\mathfrak{F}_\omega^+(\boldsymbol{r},\boldsymbol{r}')$, с помощью которого из (38.1) получаем следующее уравнение относительно $\Delta^*(\boldsymbol{r})$:

$$\Delta^*(\boldsymbol{r}) = |\lambda|T\sum_\omega \int \tilde{\mathfrak{G}}_\omega^{(0)}(\boldsymbol{l},\boldsymbol{r})\Delta^*(\boldsymbol{l})(\tilde{\mathfrak{G}}_{-\omega}^{(0)}(\boldsymbol{l},\boldsymbol{r})d\boldsymbol{l} =$$
$$- |\lambda|T\sum_\omega \iint \tilde{\mathfrak{G}}_\omega^{(0)}(l,m)\Delta(m)\tilde{\mathfrak{G}}_\omega^{(0)}(s,r)\Delta^*(s)\tilde{\mathfrak{G}}_{-\omega}^{(0)}(s,m)\Delta^*(\boldsymbol{l})\tilde{\mathfrak{G}}_{-\omega}^{(0)}(\boldsymbol{l},\boldsymbol{r})d\boldsymbol{l}dmds. \qquad (38.8)$$

Существенные расстояния в интегралах в этом уравнении порядка ξ_0, поскольку, как это видно из (38.4) и (38.5), функция $\tilde{\mathfrak{G}}_\omega^{(0)}(\boldsymbol{r},\boldsymbol{r}')$ экспоненциально убывает при $|\boldsymbol{r}-\boldsymbol{r}'| > \xi_0$. Между тем изменение щели $\Delta(\boldsymbol{r})$ и поля $\boldsymbol{A}(\boldsymbol{r})$ происходит на расстояниях порядка глубины проникновения, которая вблизи критической температуры много больше ξ_0. По тем же причинам фаза $\varphi(\boldsymbol{r},\boldsymbol{r}')$ в (38.5) может быть написана в виде

$$\varphi(r,\dot{r}') \simeq e\left(A(r), r-r'\right).$$

Вблизи $T_cA(\boldsymbol{r}) \sim H\delta \backsim \sqrt{1-\frac{T}{T_c}}$, поэтому фаза $\varphi(\boldsymbol{r},\boldsymbol{r}')$ мала и экспоненту можно разложить по φ.

Рассмотрим сначала первый член в правой части. Пусть

$$K(\boldsymbol{l},\boldsymbol{r}) = T\sum_\omega \tilde{\mathfrak{G}}_\omega^{(0)}(\boldsymbol{l},\boldsymbol{r})\tilde{\mathfrak{G}}_{-\omega}^{(0)}(\boldsymbol{l},\boldsymbol{r}) = K_0(\boldsymbol{l}-\boldsymbol{r})e^{2ie(\boldsymbol{A}(\boldsymbol{r}),\boldsymbol{l}-\boldsymbol{r})}.$$

Воспользовавшись представлением (38.4) для функции Грина в координатном пространстве и произведя суммирование по частотам, найдем для $K_0(R)$ следующее выражение:

$$K_0(R) = \frac{m^2T}{(2\pi R)^2}\frac{1}{\operatorname{sh}\frac{2\pi TR}{v}}.$$

Поскольку, как мы уже отмечали, все величины меняются мало на расстояниях порядка ξ_0, можно в интеграле

$$\int K_0(\boldsymbol{l}-\boldsymbol{r})e^{2ie(\boldsymbol{A}(\boldsymbol{r}),\boldsymbol{t}-\boldsymbol{r})}\Delta^*(\boldsymbol{l})d\boldsymbol{l}$$

разложить все величины в ряд по степеням $(\boldsymbol{l}-\boldsymbol{r})$ около точки $\boldsymbol{r}$. Ограничиваясь членами второго порядка по $(\boldsymbol{l}-\boldsymbol{r})$, получим:

$\Delta^*(\boldsymbol{r})\int K_0(R)d\boldsymbol{R} + \frac{1}{6}\left(\frac{\partial}{\partial\boldsymbol{r}} + 2ieA(\boldsymbol{r})\right)^2\Delta^*(\boldsymbol{r})\int K_0(R)R^2dR.$

Функция $K_0(R)$, согласно (38.9), при $R=0$ обращается

в бесконечность как $1/R^3$. Поэтому формально первый из этих двух интегралов расходится. Обрезание расходящегося выражения удобнее произвести в импульсном пространстве. В результате мы получаем знакомое выражение:

$$\int K_0(R)dR = \frac{mp_0}{2\pi^2}\int\limits_0^{\omega_D} \mathrm{th}\left(\frac{\xi}{2T}\right)\frac{d\xi}{\xi}.$$

Второй член при интегрировании вблизи $R = 0$ особенностей не содержит. Вычисляя этот интеграл непосредственно в координатном представлении, получим:

$$\int R^2 K_0(R)dR = \frac{7\zeta(3)v^2}{8(\pi T)^2}\cdot\frac{mp_0}{2\pi^2}.$$

В члене третьего порядка по $|\Delta|$ в уравнении (38.8) зависимостью $\Delta(\boldsymbol{r})$ от координат можно пренебречь. Этот член равен поэтому

$$\left(\frac{mp_0}{2\pi^2}\right)\Delta^*(\boldsymbol{r})|\Delta(\boldsymbol{r})|^2 T\sum_\omega \int d\xi \frac{1}{\left(\omega^2+\xi^2\right)^2} = \left(\frac{mp_0}{2\pi^2}\right)\frac{7\zeta(3)}{8(\pi T)^2}\Delta^*(\boldsymbol{r})|\Delta(\boldsymbol{r})|^2.$$

Собирая вместе полученные результаты, найдем, что вблизи критической температуры функция $\Delta^*(r)$ удовлетворяет следующему уравнению:

$$\left\{\frac{1}{4m}\left(\frac{\partial}{\partial \boldsymbol{r}}+2ieA(\boldsymbol{r})\right)^2+\frac{1}{\eta}\left[\frac{T_c-T}{T_c}-\frac{7\zeta(3)}{8\left(\pi T_c\right)^2}|\Delta(\boldsymbol{r})|^2\right]\right\}\Delta^*(\boldsymbol{r})=0$$

где

$$\eta = \frac{7\zeta(3)}{6\left(\pi T_c\right)^2}\varepsilon_F$$

В отсутствие поля Δ постоянно по пространству и уравнение (38.10) совпадает с первыми членами разложения (36.4).

Перейдем теперь к вычислению плотности тока $\boldsymbol{j}(\boldsymbol{r})$. Формула (37.5) предыдущего параграфа, конечно, верна и в данном случае. Пользуясь, однако, тем, что величина Δ мала по сравнению с T_c, мы будем и здесь производить раэложение по A и Δ до первых неисчезающих членов. Заметим, что член в плотности тока (37.5)

$$-\frac{2e^2A(\boldsymbol{r})}{m}\mathfrak{G}_{t'=t+0}(\boldsymbol{r},\boldsymbol{r}) \equiv -\frac{e^2}{m}\boldsymbol{A}(\boldsymbol{r})N.$$

Здесь N - плотность полного числа электронов, которая равна своему значению для нормального металла. Изменение N противоречило бы условию электронейтральности. (Решение (38.7) удовлетворяет этому требованию, т. е. если

$\Big(\mathfrak{G}_\omega(\boldsymbol{r},\boldsymbol{r}') = \Big(\tilde{\mathfrak{G}}_\omega^{(0)}(\boldsymbol{r},\boldsymbol{r}')+\delta\mathfrak{G}_\omega(\boldsymbol{r},\boldsymbol{r}')$,

то

$T\sum\limits_\omega \delta\mathfrak{G}_\omega(\boldsymbol{r},\boldsymbol{r}) \equiv 0\Big)$

Подставляя (38.7) в (37.5), найдем:

$$T\sum_\omega \frac{ie}{m}\left(\nabla_{\boldsymbol{r}'}-\nabla_{\boldsymbol{r}}\right)\tilde{\mathfrak{G}}_\omega^{(0)}(\boldsymbol{r},\boldsymbol{r}')\underset{\boldsymbol{r}'\to r}{} - \frac{e^2}{m}NA(\boldsymbol{r})\equiv 0,$$

поскольку в постоянном магнитном поле ток в нормальном металле равен нулю. Таким образом,

$$j(\boldsymbol{r}) = \frac{ie}{m}\left(\nabla_{\boldsymbol{r}'}-\nabla_{\boldsymbol{r}}\right)_{\boldsymbol{r}'\to\boldsymbol{r}} T\sum_\omega^{\top}\delta\left(S_\omega(\boldsymbol{r},\boldsymbol{r}')\right.$$

где

$$\delta\mathfrak{G}_\omega(r,r') = -\int \tilde{\mathfrak{G}}^{(0)}_\omega(\boldsymbol{r},l)\Delta(l)\tilde{\mathfrak{G}}^{(0)}_\omega(\boldsymbol{m},\boldsymbol{r}')\,\Delta^*(\boldsymbol{m})\tilde{\boldsymbol{G}}^{(0)}_{-\omega}(\boldsymbol{m},l)d\boldsymbol{m}d\boldsymbol{l}.$$

Подставляя сюда (38.5), разлагая все величины около точки r до членов лервого порядка и опуская члены, которые дают нуль при интегрировании по углам, получим:

$$\boldsymbol{j}(\boldsymbol{r}) = \left[\frac{ie}{m}\left(\Delta\frac{\partial\Delta^*}{\partial\boldsymbol{r}} - \Delta^*\frac{\partial\Delta}{\partial\boldsymbol{r}}\right) - \frac{4e^2|\Delta|^2}{m}A(\boldsymbol{r})\right]C,$$

где

$$C = \tfrac{T}{3}\sum_\omega \iint \left(\left[\left(\nabla_r\mathfrak{G}^{(0)}_\omega(\boldsymbol{r}-\boldsymbol{l})\right)\mathfrak{G}^{(0)}_\omega(\boldsymbol{m}-\boldsymbol{r}) - \mathfrak{G}^{(0)}_\omega(r-l)\left(\nabla_{\boldsymbol{r}}\mathfrak{G}^0_\omega(\boldsymbol{m}-\boldsymbol{r})\right)\right]\cdot\boldsymbol{m}\right)\mathfrak{G}^{(0)}_{-\omega}(\boldsymbol{m}-\boldsymbol{l})d\boldsymbol{m}d\boldsymbol{l}$$

Вычисление C удобно произвести в компонентах Фурье, заменяя обычным образом $r \to i\frac{d}{dp}$. Не останавливаясь на этом довольно простом вычислении, приведем окончательный результат:

$$C = \frac{7\zeta(3)N}{16\left(\pi T_c\right)^2}$$

Система уравнений (38.10) и (38.11) описывает свойства сверхпроводников в постоянном магнитном поле вблизи T_c. Введем волновую функцию $\psi(\boldsymbol{r})$, пропорциональную $\Delta(\boldsymbol{r})$:

$$\psi(r) = \sqrt{\frac{7\bar{\zeta}(3)N}{8\left(\pi T_c\right)^2}}\Delta(r).$$

Взяв комплексно сопряженное от уравнения (38.10) и подставляя всюду выражение (38.12), приведем эти уравнения к следующему виду:

$$\left\{\frac{1}{4m}\left(\frac{\partial}{\partial\boldsymbol{r}} - 2leA(\boldsymbol{r})\right)^2 + \frac{1}{\eta}\left[\frac{T_c-T}{T_c} - \frac{1}{N}|\psi|^2\right]\right\}\psi(\boldsymbol{r}) = 0$$

$$\boldsymbol{j}(\boldsymbol{r}) = -\frac{2ie}{4m}\left(\psi^*\frac{\partial\psi}{\partial\boldsymbol{r}} - \psi\frac{\partial\psi^*}{\partial\boldsymbol{r}}\right) - \frac{(2e)^2}{2m}A(\boldsymbol{r})|\psi|^2.$$

Теперь становится понятным смысл введения волновой функции $\psi(\boldsymbol{r})$: получающиеся уравнения имеют вид, похожий на квантовомеханические уравнения для частицы с массой $2m$ и зарядом 2e. Физически этот результат совершенно ясен, поскольку $\Delta(\boldsymbol{r})$ имеет смысл величины, пропорциональной волновой функции связанной пары, или, точнее, волновой функции относительно координат ее центра инерции. Интересно, что подобного вида уравнения были предложены в феноменологической теории Гинзбурга-Ландау [67], где, однако, фигурировал однократный элементарный заряд: Помимо этого существенного изменения, новая теория сверхпроводимости, подтверждая правильность теории Гинзбурга Ландау вблизи T_v, дает возможность вычислить фигурирующие в последней теории постоянные.

В заключение отметим еще раз тот факт, что при выводе мы использовали малость изменения всех величин на расстояниях порядка ξ_0. Поскольку, как легко видеть из (38.13) и (37.19), все величины меняются в общем случае на расстояниях порядка лондоновской глубины проникновения вблизи T_c, а для пиппардовских металлов эта глубина проникновения становится больше ξ_0 только в самой близости от T_c, то область применимости этих уравнений для металлов пиппардовского типа представляет собой очень незначительную окрестность температур вблизи критической температуры перехода. Для металлов лондоновского типа, или промежуточных, эти уравнения

справедливы в довольно широкой области температур вблизи T_c. С экспериментальной точки зрения это - весьма интересная область температур, и следует отметить, что уравнения (38.13) приводят к очень хорошему согласию теории с результатами измерений в этой области.

19.5.2 Theory Of Superconducting Alloys by AGD [see cond matter about it]

20 Fluctuation Phenomena in Superconductors by Larkin, Varlamov

20.1 Introduction

A major success of low temperature physics was achieved with the introduction by Landau of the notion of quasiparticles. According to his hypothesis, the properties of many body interacting systems at low temperatures are determined by the spectrum of some low energy, long living excitations (quasiparticles). Another milestone of many body theory is the Mean Field Approximation (MFA), which permitted achieving considerable progress in the theory of phase transitions. Phenomena which cannot be described by the quasiparticle method or by MFA are usually called fluctuations. The BCS theory of superconductivity is a bright example of the use of both the quasiparticle description and MFA. The success of the BCS theory for traditional superconductors was determined by the fact that fluctuations give small corrections with respect to the MFA results.

During the first half of the century after the discovery of superconductivity the problem of fluctuation smearing of the superconducting transition was not even considered. In bulk samples of traditional superconductors the critical temperature T_c sharply divides the superconducting and the normal phases. It is worth mentioning that such behavior of the physical characteristics of superconductors is in perfect agreement both with the Ginzburg-Landau (GL) phenomenological theory (1950) [1] and the BCS microscopic theory of superconductivity (1957)[2].

The characteristics of high temperature and organic superconductors, low dimensional and amorphous superconducting systems studied today, strongly differ from those of the traditional superconductors discussed in textbooks. The transitions turn out to be much more smeared out. The appearance of superconducting fluctuations above critical temperature leads to precursor effects of the superconducting phase occurring while the system is still in the normal phase, sometimes far from T_c. The conductivity, the heat capacity, the diamagnetic susceptibility, the sound attenuation, etc. may increase considerably in the vicinity of the transition temperature.

The first numerical estimation of the fluctuation contribution to the heat capacity of a superconductor in the vicinity of T_c was done by Ginzburg in 1960 [3]. In that paper he showed that superconducting fluctuations increase the heat capacity even above T_c. In this way fluctuations change the temperature dependence of the specific heat in the vicinity of critical temperature, where, in accordance with the phenomenological GL theory of second order phase transitions, a jump should take place. The range of temperatures where the fluctuation correction to the heat capacity of a bulk clean conventional superconductor is relevant was

estimated by Ginzburg [2] to be

$$Gi = \frac{\delta T}{T_c} \sim \left(\frac{T_c}{E_F}\right)^4 \sim 10^{-12} \div 10^{-14}, \tag{20.1}$$

where E_F is the Fermi energy. The correction occurs in a temperature range δT many orders of magnitude smaller than that accessible in real experiments.

In the 1950s and 60s the formulation of the microscopic theory of superconductivity, the theory of type-II superconductors and the search for high-T_c superconductivity attracted the attention of researchers to dirty systems, superconducting films and filaments. In 1968, in the papers of L. G. Aslamazov and A. I. Larkin [5], K.Maki [6] and a little later in the paper of R.S.Thompson [7] the fundaments of the microscopic theory of fluctuations in the normal phase of a superconductor in the vicinity of the critical temperature were formulated. This microscopic approach confirmed Ginzburg's evaluation [3] for the width of the fluctuation region in a bulk clean superconductor. Moreover, was found that the fluctuation effects increase drastically in thin dirty superconducting films and whiskers. In the cited papers was demonstrated that fluctuations affect not only the thermodynamical properties of superconductor but its dynamics too. Simultaneously the fluctuation smearing of the resistive transition in bismuth amorphous films was experimentally found by Glover [8], and it was perfectly fitted by the microscopic theory.

In the BCS theory [2] only the Cooper pairs forming a Bose-condensate are considered. Fluctuation theory deals with the Cooper pairs out of the condensate. In some phenomena these fluctuation Cooper pairs behave similarly to quasiparticles but with one important difference. While for the well defined quasiparticle the energy has to be much larger than its inverse life time, for the fluctuation Cooper pairs the "binding energy" E_0 turns out to be of the same order. The Cooper pair life time τ_{GL} is determined by its decay into two free electrons. Evidently at the transition temperature the Cooper pairs start to condense and $\tau_{GL} = \infty$. So it is natural to suppose from dimensional analysis that $\tau_{GL} \sim \hbar/k_B(T - T_c)$. The microscopic theory confirms this hypothesis and gives the exact coefficient:

$$\tau_{GL} = \frac{\pi\hbar}{8k_B(T - T_c)}. \tag{20.2}$$

Another important difference of the fluctuation Cooper pairs from quasiparticles lies in their large size $\xi(T)$. This size is determined by the distance on which the electrons forming the fluctuation Cooper pair move away during the pair life-time τ_{GL}. In the case of an impure superconductor the electron motion is diffusive with the diffusion coefficient $\mathcal{D} \sim v_F^2\tau$ (τ is the electron scattering time[3]), and $\xi_d(T) = \sqrt{\mathcal{D}\tau_{GL}} \sim v_F\sqrt{\tau\tau_{GL}}$. In the case of a clean superconductor, where $k_BT\tau \gg \hbar$, impurity scattering does not affect any more the electron correlations. In this case the time of electron ballistic motion turns out to be less than the electron-impurity scattering time τ and is determined by the uncertainty principle: $\tau_{bal} \sim \hbar/k_BT$. Then this time has to be used in this case for determination of the effective size instead of τ: $\xi_c(T) \sim v_F\sqrt{\hbar\tau_{GL}/k_BT}$. In both cases the coherence length grows with the approach to the critical temperature as $(T - T_c)^{-1/2}$, and we will write it down in the unique way ($\xi = \xi_{c,d}$):

[2]The expression for the width of the strong fluctuation region in terms of the Landau phenomenological theory of phase transitions was obtained by Levanyuk [4]. So in the modern theory of phase transitions the relative temperature width of fluctuation region is called the Ginzburg-Levanyuk parameter $Gi_{(D)}$, where D is the effective space dimensionality.

[3]Strictly speaking τ in the most part of future results should be understood as the electron transport scattering time τ_{tr}. Nevertheless, as it is well known, in the case of isotropic scattering these values coincide, so for sake of simplicity we will use hereafter the symbol τ.

$$\xi(T) = \frac{\xi}{\sqrt{\epsilon}}, \quad \epsilon = \frac{T - T_c}{T_c}.. \tag{20.3}$$

The microscopic theory in the case of an isotropic Fermi surface gives for ξ the precise expression:

$$\xi^2_{(D)} = -\frac{v_F^2\tau^2}{D}\left\{\psi(\frac{1}{2} + \frac{\hbar}{4\pi k_B T\tau}) - \psi(\frac{1}{2}) - \frac{\hbar}{4\pi k_B T\tau}\psi^{'}(\frac{1}{2})\right\}, \tag{20.4}$$

where $\psi(x)$ is the digamma function and $D = 3, 2, 1$ is the space dimensionality. In the clean (c) and dirty (d) limits:

$$\xi_c = 0.133\frac{\hbar v_F}{k_B T_c}\sqrt{\frac{3}{D}} = 0.74\xi_0\sqrt{\frac{3}{D}}, \tag{20.5}$$

$$\xi_d = 0.36\sqrt{\frac{\hbar v_F l}{k_B T_c}\frac{3}{D}} = 0.85\sqrt{\xi_0 l}\sqrt{\frac{3}{D}}. \tag{20.6}$$

Here $l = v_F\tau$ is the electron mean free path and $\xi_0 = \hbar v_F/\pi\Delta(0)$ is the conventional BCS definition of the coherence length of a clean superconductor at zero temperature. One can see that (20.5) and (20.6) coincide with the above estimations [4].

Finally it is necessary to recognize that fluctuation Cooper pairs can be really treated as classical objects, but these objects instead of Boltzmann particles appear as classical fields in the sense of Rayleigh-Jeans. This means that in the general Bose-Einstein distribution function only small energies $E(p)$ are involved and the exponent can be expanded:

$$n(p) = \frac{1}{\exp(\frac{E(p)}{k_B T}) - 1} = \frac{k_B T}{E(p)}. \tag{20.7}$$

This is why the more appropriate tool to study fluctuation phenomena is not the Boltzmann transport equation but the GL equation for classical fields. Nevertheless at the qualitative level the treatment of fluctuation Cooper pairs as particles with the density $n_{(D)} = \int n(p)\frac{d^D p}{(2\pi\hbar)^D}$ often turns out to be useful [5].

Below will be demonstrated both in the framework of the phenomenological Ginzburg-Landau theory and the microscopic BCS theory that in the vicinity of the transition

$$E(p) = \alpha k_B(T - T_c) + \frac{\mathbf{p}^2}{2m^*} = \frac{1}{2m^*}\left[\hbar^2/\xi^2(T) + \mathbf{p}^2\right]. \tag{20.8}$$

Far from transition temperature the dependence $n(p)$ turns out to be more sophisticated than (20.7), nevertheless one can always write it in the form

[4] Let us stress some small numerical difference between our Exp. (20.4) and the usual definition of the coherence length. We are dealing near the critical temperature, so the definition (20.4) is natural and permits us to avoid many numerical coefficients in further calculations. The cited coherence length $\xi_0 = \hbar v_F/\pi\Delta(0) = 0.18\hbar v_F/k_B T_c$, as is evident, was introduced for zero temperature and an isotropic $3D$ superconductor.

It is convenient to determine the coherence length also from the formula for the upper critical field: $H_{c2}(T) = A(T)\Phi_0/2\pi\xi^2(T)$. $A(T_c) = 1$, while its value at $T = 0$ depends on the impurities concentration. For the dirty case the appropriate value was found by K.Maki [9] $A_d(0) = 0.69$, for the clean case by L.Gor'kov [10] $A_c^{2D}(0) = 0.59$, $A_c^{3D}(0) = 0.72$.

[5] This particle density is defined in the (D)-dimensional space. This means that it determines the normal volume density of pairs in $3D$ case, the density per square unit in $2D$ case and the number of pairs per unit length in $1D$. The real three dimensional density n can be defined too: $n = d^{D-3}n_{(D)}$, where d is the thickness of the film or wire.

$$n(p) = \frac{m^* k_B T}{\hbar^2} \xi^2 (T) \, f \left(\frac{\xi(T) p}{\hbar} \right). \tag{20.9}$$

In classical field theory the notions of the particle distribution function $n(p)$ (proportional to $E^{-1}(p)$ in our case) and Cooper pair mass m^* are poorly determined. At the same time the characteristic value of the Copper pair center of mass momentum can be defined and it turns out to be of the order of $p_0 \sim \hbar/\xi(T)$. So for the combination $m^* E(p_0)$ one can write $m^* E(p_0) \sim p_0^2 \sim \hbar^2/\xi^2(T)$. In fact the particles density enters into many physical values in the combination n/m^*. As the consequence of the above observation it can be expressed in terms of the coherence length:

$$\frac{n_{(D)}}{m^*} = \frac{k_B T}{m^* E(p_0)} (\frac{p_0}{\hbar})^D \sim \frac{k_B T}{\hbar^2} \xi^{2-D}(T), \tag{20.10}$$

p_0^D here estimates the result of momentum integration.

For example we can evaluate the fluctuation Cooper pairs contribution to conductivity by using the Drude formula

$$\sigma = \frac{n e^2 \tau}{m^*} \Rightarrow \frac{k_B T}{\hbar^2} d^{D-3} \xi^{2-D}(T) (2e)^2 \tau_{GL}(\epsilon) \sim \epsilon^{D/2-2}. \tag{20.11}$$

Analogously a qualitative understanding of the increase in the diamagnetic susceptibility above the critical temperature may be obtained from the well-known Langevin expression for the atomic susceptibility[6]:

$$\chi = -\frac{e^2}{c^2} \frac{n}{m^*} \left\langle R^2 \right\rangle \Rightarrow -\frac{4e^2}{c^2} \frac{k_B T}{\hbar^2} d^{D-3} \xi^{4-D}(T) \sim -\epsilon^{D/2-2}. \tag{20.12}$$

Besides these examples of the direct influence of fluctuations on superconducting properties, indirect manifestations by means of quantum interference in the pairing process and of renormalization of the density of one-electron states in the normal phase of superconductor take place. These effects, being much more sophisticated, have a purely quantum nature, and in contrast to the direct Cooper pair contributions require microscopic consideration. This is why, in developing phenomenological methods through the first five Sections of this review, we will deal with the direct fluctuation pair contributions only. The sixth Section is devoted to the microscopic justification of the time dependent Ginzburg-Landau equation. The description of the microscopic theory of fluctuations, including indirect fluctuation effects, discussion of their manifestations in various physical properties of superconductors will be given in the Sections 7-8.

The first seven Sections are written in detail, so they can serve as a textbook. On the contrary, in the last (eighth) Section a wide panorama of fluctuation effects in different physical properties of superconductors is presented. Thus this Section has more of a handbook character, and the intermediate calculations often are omitted.

Finally we would like to mention that the number of articles devoted to superconducting fluctuations published in the last 33 years is of the order of ten thousands, so our bibliography list does not pretend nor at the completeness nor at the establishment of the rigorous priorities.

[6]This formula is valid for the dimensionalities $D = 2, 3$, when fluctuation Cooper pair has the possibility to "rotate" in the applied magnetic field and the average square of the rotation radius is $< R^2 > \sim \xi^2(T)$. "Size" effects, important for low dimensional samples, will be discussed later on.

20.2 Ginzburg-Landau formalism. Thermodynamics

20.2.1 Fluctuation contribution to heat capacity

GL functional.

The complete description of the thermodynamic properties of a system can be done through the exact calculation of the partition function[7]:

$$Z = \mathrm{Tr}\left\{\exp\left(-\frac{\widehat{\mathcal{H}}}{T}\right)\right\}. \tag{20.13}$$

As discussed in the Introduction, in the vicinity of the superconducting transition, side by side with the fermionic electron states, fluctuation Cooper pairs of a bosonic nature appear in the system. As already mentioned, they can be described by means of classical bosonic fields $\Psi(\mathbf{r})$ which can be treated as "Cooper pair wave functions". So the calculation of the trace in (20.13) can be separated into a summation over the "fast" electron degrees of freedom and a further functional integration carried out over all possible configurations of the "slow" Cooper pairs wave functions:

$$Z = \int D\Psi(\mathbf{r})\mathcal{Z}[\Psi(\mathbf{r})], \tag{20.14}$$

where

$$\mathcal{Z}[\Psi(\mathbf{r})] = \exp\left(-\frac{\mathcal{F}[\Psi(\mathbf{r})]}{T}\right) \tag{20.15}$$

is the system partition function in a fixed bosonic field $\Psi(\mathbf{r})$, already summed over the electronic degrees of freedom. Here it is assumed that the classical field dependent part of the Hamiltonian can be chosen in the spirit of the GL approach[8]:

$$F[\Psi(r)] = F_N + \int dV\left\{a|\Psi(\mathbf{r})|^2 + \frac{b}{2}|\Psi(\mathbf{r})|^4 + \frac{1}{4m}|\nabla\Psi(\mathbf{r})|^2\right\}.. \tag{20.16}$$

Let us discuss the coefficients of this functional. In accordance with the Landau hypothesis, the coefficient a goes to zero at the transition point and depends linearly on $T - T_c$. Then $a = \alpha T_c\epsilon$; all the coefficients α,b and m are supposed to be positive and temperature independent. Concerning the magnitude of the coefficients it is necessary to make the following comment. One of these coefficients can always be chosen arbitrary: this option is related to the arbitrariness of the Cooper pair wave function normalization. Nevertheless the product of two of them is fixed by dimensional analysis: $ma \sim \xi^{-2}(T)$. Another combination of the coefficients, independent of the wave function normalization and temperature, is α^2/b. One can see that it has the dimensionality of the density of states. Since these coefficients were obtained by a summation over the electronic degrees of freedom, the only reasonable candidate for this value is the one electron density of states ν. The microscopic theory gives the precise coefficients for the above relations:

$$4m\alpha T_c = \xi^{-2};\ \alpha^2/b = \frac{8\pi^2}{7\zeta(3)}\nu, \tag{20.17}$$

where $\zeta(x)$ is the Riemann zeta function, $\zeta(3) = 1.202$. One can notice that the arbitrariness in the normalization of the order parameter amplitude leads to the unambiguity in the choice

[7] Hereafter $\hbar = k_B = c = 1$.

[8] For simplicity the magnetic field is assumed to be zero.

of the Cooper mass introduced in (20.16) as $2m$. Indeed, this value enters in (20.17) in the product with α so one of these parameters has to be fixed. In the case of a clean D-dimensional superconductor it is natural to suppose that the Copper pair mass is equal to two free electron masses what results in

$$\alpha_{(D)} = \frac{2D\pi^2}{7\zeta(3)}\frac{T_c}{E_F}. \tag{20.18}$$

As the first step in the Landau theory of phase transitions Ψ is supposed to be independent of position. This assumption in the limit of sufficiently large volume V of the system permits a calculation of the functional integral in (20.14) by the method of steepest descent. Its saddle point determines the equilibrium value of the order parameter

$$|\widetilde{\Psi}|^2 = \begin{cases} -\alpha T_c \epsilon/b, & \epsilon < 0 \\ 0, & \epsilon > 0 \end{cases}. \tag{20.19}$$

Choosing α in accordance with (20.18) one finds that this value coincides with the superfluid density n_s of the microscopic theory [2].

The fluctuation part of the free energy related to the transition is determined by the minimum of the functional (20.16):

$$F = (\mathcal{F}[\Psi])_{\min} = \mathcal{F}[\widetilde{\Psi}] = \begin{cases} F_N - \frac{\alpha^2 T_c^2 \epsilon^2}{2b} V, & \epsilon < 0 \\ F_N, & \epsilon > 0 \end{cases}. \tag{20.20}$$

From the second derivative of (20.20) one can find an expression for the jump of the specific heat capacity at the phase transition point:

$$\begin{aligned} \Delta C &= C_S - C_N = \frac{T_c}{V}\left(\frac{\partial S_S}{\partial T}\right) - \frac{T_c}{V}\left(\frac{\partial S_N}{\partial T}\right) = \\ &= -\frac{1}{VT_c}\left(\frac{\partial^2 F}{\partial \epsilon^2}\right) = \frac{\alpha^2}{b}T_c = \frac{8\pi^2}{7\zeta(3)}\nu T_c. \end{aligned} \tag{20.21}$$

Let us mention that the jump of the heat capacity was obtained because of the system volume was taken to infinity first, and after this the reduced temperature ϵ was set equal to zero.

Zero dimensionality: the exact solution.

In a system of finite volume fluctuations smear out the jump in heat capacity. For a small superconducting sample with the characteristic size $d \ll \xi(T)$ the space independent mode $\Psi_0 = \Psi\sqrt{V}$ defines the main contribution to the free energy:

$$\begin{aligned} Z_{(0)} &= \int d^2\Psi_0 \mathcal{F}[\Psi_0] = \pi \int d|\Psi_0|^2 \exp\left(-\frac{(\, a|\Psi_0|^2 + \frac{b}{2V}|\Psi_0|^4)}{T}\right) = \\ &= \sqrt{\frac{\pi^3 VT}{2b}} \exp(x^2)(1 - \mathrm{erf}(x))|_{x=a\sqrt{\frac{V}{2bT}}}. \end{aligned} \tag{20.22}$$

By evaluating the second derivative of this exact result [11] one can find the temperature dependence of the superconducting granular heat capacity (see Fig. 20.1). It is evident that the smearing of the jump takes place in the region of temperatures in the vicinity of transition where $x \sim 1$, i.e.

Figure 20.1: Temperature dependence of the heat capacity of superconducting grains in the region of the critical temperature

$$\epsilon_{cr} = Gi_{(0)} = \frac{\sqrt{7\zeta(3)}}{2\pi} \frac{1}{\sqrt{\nu T_c V}} \approx 13,3 \left(\frac{T_{c0}}{E_F}\right) \sqrt{\frac{\xi_0^3}{V}},$$

where we have supposed that the granule is clean; T_{c0} and ξ_0 are the critical temperature and the zero temperature coherence length (see the footnote 3 in Introduction) of the appropriate bulk material. From this formula one can see that even for granule with the size $d \sim \xi_0$ the smearing of the transition still is very narrow.

Far above the critical region, where $Gi_{(0)} \ll \epsilon \ll 1$, one can use the asymptotic expression for the $\mathrm{erf}(x)$ function and find

$$F_{(0)} = -T \ln Z_{(0)} = -T \ln \frac{\pi}{\alpha\epsilon}. \tag{20.23}$$

Calculation of the second derivative gives an expression for the fluctuation part of the heat capacity in this region:

$$\delta C_{(0)} = 1/\epsilon^2. \tag{20.24}$$

The experimental study of the heat capacity of small Sn particles in the vicinity of transition was done in [12]

Arbitrary dimensionality: case $T \geq T_c$.

It is possible to estimate the fluctuation contribution to the heat capacity for a specimen of an arbitrary effective dimensionality on the basis of the following observation. The volume of the specimen may be divided into regions of size $\xi(T)$, which are weakly correlated with each other. Then the whole free energy can be estimated as the free energy of one such zero-dimensional specimen (20.23), multiplied by their number $N_{(D)} = V\xi^{-D}(T)$:

$$F_{(D)} = -TV\xi^{-D}(T) \ln \frac{\pi}{\alpha\epsilon}. \tag{20.25}$$

This formula gives the correct temperature dependence for the free energy for even dimensionalities. A more accurate treatment removes the $\ln \epsilon$ dependence from it in the case of the odd dimensions.

Let us begin with the calculation of the fluctuation contribution to the heat capacity in the normal phase of a superconductor. We restrict ourselves to the region of temperatures beyond the immediate vicinity of transition, where this correction is still small. In this region one can omit the fourth order term in $\Psi(\mathbf{r})$ with respect to the quadratic one and write down the GL functional, expanding the order parameter in a Fourier series:

$$F[\Psi_{\mathbf{k}}] = F_N + \sum_{\mathbf{k}} [a + \frac{\mathbf{k}^2}{4m}]|\Psi_{\mathbf{k}}|^2 = \alpha T_c \sum_{\mathbf{k}} \left(\epsilon + \xi^2 \mathbf{k}^2\right) |\Psi_{\mathbf{k}}|^2. \tag{20.26}$$

Here $\Psi_{\mathbf{k}} = \frac{1}{\sqrt{V}} \int \Psi(\mathbf{r}) e^{-i\mathbf{kr}} dV$ and the summation is carried out over the vectors of the reciprocal space. Now we see that the free energy functional appears as a sum of energies of the independent modes $\mathbf{k}$. The functional integral for the partition function (20.15) can be separated to a product of Gaussian type integrals over these modes:

$$Z = \prod_{\mathbf{k}} \int d^2\Psi_{\mathbf{k}} \exp\left\{-\alpha(\epsilon + \frac{\mathbf{k}^2}{4m\alpha T_c}\ )|\Psi_{\mathbf{k}}|^2\right\}. \tag{20.27}$$

Carrying out these integrals, one gets the fluctuation contribution to the free energy:

$$F(\epsilon > 0) = -T \ln Z = -T \sum_{\mathbf{k}} \ln \frac{\pi}{\alpha(\epsilon + \frac{\mathbf{k}^2}{4m\alpha T_c})}. \tag{20.28}$$

The appropriate correction to the specific heat capacity of a superconductor at temperatures above the critical temperature may thus be calculated. We are interested in the most singular term in ϵ^{-1}, so the differentiation over the temperature can be again replaced by that over ϵ :

$$\delta C_+ = -\frac{1}{VT_c}\left(\frac{\partial^2 F}{\partial \epsilon^2}\right) = \frac{1}{V} \sum_{\mathbf{k}} \frac{1}{(\epsilon + \frac{\mathbf{k}^2}{4m\alpha T_c})^2}. \tag{20.29}$$

The result of the summation over $\mathbf{k}$ strongly depends on the linear sizes of the sample, i.e. on its effective dimensionality. As it is clear from (20.29), the scale with which one has to compare these sizes is determined by the value $(4m\alpha T_c \epsilon)^{-\frac{1}{2}}$ which, as was already mentioned above, coincides with the effective size of Cooper pair $\xi(T)$. Thus, if all dimensions of the sample considerably exceed $\xi(T)$, one can integrate over $(2\pi)^{-3} L_x L_y L_z dk_x dk_y dk_z$ instead of summing over n_x, n_y, n_z. In the case of arbitrary dimensionality the fluctuation correction to the heat capacity turns out to be

$$\delta C_+ = \frac{V_D}{V} \int \frac{1}{(\epsilon + \frac{\mathbf{k}^2}{4m\alpha T_c})^2} \frac{d^D\mathbf{k}}{(2\pi)^D} = \vartheta_D \frac{V_D}{V} \frac{(4m\alpha T_c)^{\frac{D}{2}}}{\epsilon^{2-\frac{D}{2}}}, \tag{20.30}$$

where $V_D = V, S, L, 1$ for $D = 3, 2, 1, 0$. For the coefficients ϑ_D it is convenient to write an expression valid for an arbitrary dimensionality D, including fractional ones. For a space of fractional dimensionality we just mention that the momentum integration in spherical coordinates is carried out according to the rule: $\int d^D\mathbf{k}/\,(2\pi)^D = \mu_D \int k^{D-1} dk$, where

$$\mu_D = \frac{D}{2^D \pi^{D/2} \Gamma(D/2+1)} \tag{20.31}$$

and $\Gamma(x)$ is a gamma-function. The coefficient in (20.30) can be expressed in terms of the gamma-function too:

$$\vartheta_D = \frac{\Gamma(2 - D/2)}{2^D \pi^{D/2}} \tag{20.32}$$

yielding $\vartheta_1 = 1/4, \vartheta_2 = 1/4\pi$ and $\vartheta_3 = 1/8\pi$.

In the case of small particles with characteristic sizes $d \lesssim \xi(\epsilon)$ the appropriate fluctuation contribution to the free energy and the specific heat capacity coincides with the asymptotics of the exact results (20.23) and (20.24). From the formula given above it is easy to see that the role of fluctuations increases when the effective dimensionality of the sample or the electron mean free path decrease.

Arbitrary dimensionality: case $T < T_c$.

The general expressions (20.14) and (20.16) allow one to find the fluctuation contribution to heat capacity below T_c. For this purpose let us restrict ourselves to the region of temperatures not very close to T_c from below, where fluctuations are sufficiently weak. In this case the order parameter can be written as the sum of the equilibrium $\widetilde{\Psi}$ (see (20.19)) and fluctuation $\psi(\mathbf{r})$ parts:

$$\Psi(\mathbf{r}) = \widetilde{\Psi} + \psi(\mathbf{r}). \tag{20.33}$$

Keeping in (20.16) the terms up to the second order in $\psi(\mathbf{r})$ and up to the fourth order in $\widetilde{\Psi}$, one can find

$$\begin{aligned} \mathcal{Z}[\widetilde{\Psi}] \;=\; & \exp(-\frac{a\widetilde{\Psi}^2 + b/2\widetilde{\Psi}^4}{T}) \prod_{\mathbf{k}} \int d\mathrm{Re}\psi_{\mathbf{k}} d\mathrm{Im}\psi_{\mathbf{k}} \times \\ & \times \exp\left\{ -\frac{1}{T}[(3b\widetilde{\Psi}^2 + a + \frac{\mathbf{k}^2}{4m})\mathrm{Re}^2\psi_{\mathbf{k}} + (b\widetilde{\Psi}^2 + a + \frac{\mathbf{k}^2}{4m})\mathrm{Im}^2\psi_{\mathbf{k}}] \right\}. \end{aligned} \tag{20.34}$$

Carrying out the integral over the real and imaginary parts of the order parameter one can find an expression for the fluctuation part of the free energy:

$$F = -\frac{T}{2} \sum_{\mathbf{k}} \left\{ \ln \frac{\pi T_c}{3b\widetilde{\Psi}^2 + a + \frac{\mathbf{k}^2}{4m}} + \ln \frac{\pi T_c}{b\widetilde{\Psi}^2 + a + \frac{\mathbf{k}^2}{4m}} \right\}. \tag{20.35}$$

Let us discuss this result. It is valid both above and below T_c. The two terms in it correspond to the contributions of the modulus and phase fluctuations of the order parameter. Above T_c $\widetilde{\Psi} \equiv 0$ and these contributions are equal: phase and modulus fluctuations in the absence of $\widetilde{\Psi}$ represent just two equivalent degrees of freedom of the scalar complex order parameter. Below T_c, the symmetry of the system decreases (see (20.19)). The order parameter modulus fluctuations remain of the same diffusive type as above T_c, while the character of the phase fluctuations, in accordance with the Goldstone theorem, changes dramatically.

Substitution of (20.19) to (20.35) results in the disappearance of the temperature dependence of the phase fluctuation contribution and, calculating the second derivative, one sees that only the fluctuations of the order parameter modulus contribute to the heat capacity. As a result the heat capacity, calculated below T_c, turns out to be proportional to that found above:

$$\delta C_- = 2^{\frac{D}{2}-2} \delta C_+.$$

Hence, in the framework of the theory proposed we found that the heat capacity of the superconductor tends to infinity at the transition temperature. Strictly speaking, the restrictions of the above approach do not permit us to discuss seriously this divergence at the critical point itself. The calculations in principle are valid only in that region of temperatures where the fluctuation correction is small. We will discuss in the next Section the quantitative criteria for the applicability of this perturbation theory.

20.2.2 Ginzburg-Levanyuk criterion

The fluctuation corrections to the heat capacity obtained above allow us to answer quantitatively the question: where are the limits of applicability of the GL theory?

This theory is valid not too near to the transition temperature, where the fluctuation correction is still small in comparison with the heat capacity jump. Let us define as the Ginzburg-Levanyuk number $Gi_{(D)}$ [4, 3] the value of the reduced temperature at which the fluctuation correction (20.30) equals the value of ΔC (20.21)[9]:

$$Gi_{(D)} = \frac{1}{\alpha}\left[\frac{V_D}{V}\vartheta_D b(4m)^{\frac{D}{2}}T_c^{\frac{D}{2}-1}\right]^{\frac{2}{4-D}}. \tag{20.36}$$

Substituting into this formula the microscopic values of the GL theory parameters (20.17) one can find

$$Gi_{(D)} = \left[\frac{7\zeta(3)\vartheta_D}{8\pi^2}\left(\frac{V_D}{V}\right)\frac{1}{\nu_D T_c \xi^D}\right]^{\frac{2}{4-D}}. \tag{20.37}$$

Since $\nu_D T_c \sim \nu_D v_F/\xi_c \sim p_F^{D-1}\xi_c^{-1} \sim \mathfrak{a}^{1-D}\xi_c^{-1}$ one can convert this formula to the form

$$Gi_{(D)} \sim \left[\frac{7\zeta(3)\vartheta_D}{8\pi^2}\left(\frac{V_D}{V}\right)\frac{\xi_c \mathfrak{a}^{D-1}}{\xi^D}\right]^{\frac{2}{4-D}},$$

where $\mathfrak{a}$ is the interatomic distance. It is worth mentioning that in bulk conventional superconductors, due to the large value of the coherence length ($\xi_c \sim 10^{-6} \div 10^{-4} cm$), which drastically exceeds the interatomic distance ($\mathfrak{a} \sim 10^{-8} cm$), the fluctuation correction to the heat capacity is extremely small. However, the fluctuation effect increases for small effective sample dimensionality and small electron mean free path. For instance, the fluctuation heat capacity of a superconducting granular system is readily accessible for experimental study.

Using the microscopic expression for the coherence length (20.4), the Ginzburg-Levanyuk number (20.37) can be evaluated for different cases of clean (c) and dirty (d) superconductors of various dimensionalities and geometries (film, wire, whisker and granule are supposed to have $3D$ electronic spectrum):

$Gi_{(3)}$	$Gi_{(2)}$	$Gi_{(1)}$	$Gi_{(0)}$
$80\left(\frac{T_c}{E_F}\right)^4$, (c) $\frac{1.6}{(p_F l)^3}\left(\frac{T_c}{E_F}\right)$, (d)	$\left(\frac{T_c}{E_F}\right)$, (c) $\frac{0.27}{p_F l}$, (d) $\frac{1.3}{p_F^2 l d}$, (d) film	0.5, (c) $1.3\left(p_F^2 S\right)^{-2/3}\left(T_c\tau\right)^{-1/3}$, (d) wire $2.3\left(p_F^2 S\right)^{-2/3}$, (c) whisker	$\frac{\sqrt{7\zeta(3)}}{2\pi}\frac{1}{\sqrt{\nu T_c V}} \approx$ $13.3\frac{T_{c0}}{E_F}\sqrt{\frac{\xi_0^3}{V}}$

Table 1.

One can see that for the three dimensional clean case the result coincides with the original Ginzburg evaluation and demonstrates the negligibility of the superconducting fluctuation effects in clean bulk materials.

[9] One can see that some arbitrariness occurs in this definition. For instance the Gi number could be defined as the reduced temperature at which the AL correction to conductivity is equal to the normal value of conductivity (as it was done in [13, 14]). Such definition results in the change of the numerical factor in Gi number: $Gi_{(2,\sigma)} = 1.44 Gi_{(2,h.c.)}$.

20.2.3 Scaling and renormalization group

In the above study of the fluctuation contribution to heat capacity we have restricted ourselves to the temperature range out of the direct vicinity of the critical temperature: $|\epsilon| \gtrsim Gi_{(D)}$. As we have seen the fluctuations in this region turn out to be weak and neglecting their interaction was justified. In this Section we will discuss the fluctuations in the immediate vicinity of the critical temperature ($|\epsilon| \lesssim Gi_{(D)}$) where this interaction turns out to be of great importance.

We will start with the scaling hypothesis, i.e. with the belief that in the immediate vicinity of the transition the only relevant length scale is $\xi(T)$. The temperature dependencies of all other physical quantities can be expressed through $\xi(T)$. This means, for instance, that the formula for the fluctuation part of the free energy (20.25) with the logarithm omitted is still valid in the region of critical fluctuations[10]

$$F_{(D)} \sim -\xi^{-D}(\epsilon), \tag{20.38}$$

the coherence length is a power function of the reduced temperature: $\xi(\epsilon) \sim \epsilon^{-\nu}$. The corresponding formula for the fluctuation heat capacity can be rewritten as

$$\delta C \sim -\frac{\partial^2 F}{\partial \epsilon^2} \sim \epsilon^{D\nu-2}. \tag{20.39}$$

As was demonstrated in the Introduction, the GL functional approach, where the temperature dependence of $\xi(T)$ is determined only by the diffusion of the electrons forming Cooper pair, $\xi(\epsilon) \sim \epsilon^{-1/2}$ and $\delta C \sim \epsilon^{-1/2}$. These results are valid for the GL region ($|\epsilon| \gtrsim Gi$) only, where the interaction between fluctuations can be neglected. In the immediate vicinity of the transition (so-called critical region), where $|\epsilon| \lesssim Gi$, the interaction of fluctuations becomes essential. Here fluctuation Cooper pairs affect the coherence length themselves, changing the temperature dependencies of $\xi(\epsilon)$ and $\delta C(\epsilon)$. In order to find the heat capacity temperature dependence in the critical region one would have to calculate the functional integral with the fourth order term, accounting for the fluctuation interaction, as was done for $0D$ case. For the $3D$ case up to now it is only known how to calculate a Gaussian type functional integral. This was done above when, for the GL region, we omitted the fourth order term in the free energy functional (20.16).

The first evident step in order to include in consideration of the critical region would be to develop a perturbation series in b [11]. Any term in this series has the form of a Gaussian integral and can be represented by a diagram, where the solid lines correspond to the correlators $\left\langle \Psi(r)\Psi^*(r')\right\rangle$. The "interactions " b are represented by the points where four correlator lines intersect (see Fig. 20.2).

This series can be written as

$$C \sim \sum_{n=0} c_n \left(\frac{Gi_{(D)}}{\epsilon}\right)^{\frac{4-D}{2}n}.$$

For $\epsilon \gtrsim Gi$ it is enough to keep only the first two terms to reproduce the perturbational result obtained above. For $\epsilon \lesssim Gi$ all terms have to be summed. It turns out that the coefficients c_n can be calculated for the space dimensionality $D \to 4$ only. In this case the complex diagrams from Fig. 20.2 (like the diagram similar to an envelope) are small by the parameter $\varepsilon = 4 - D$ and in order to calculate c_n it is sufficient to sum the relatively simple "parquet" type diagrammatic series. Such a summation results in the substitution of the "bare" vertex b by some

[10] The logarithm in (20.25) is essential for the case $D = 2$. This case will be discussed later.

[11] Let us mention that this series is an asymptotic one, i.e. it does not converge even for small b. One can easily see this for small negative b, when the integral for the partition function evidently diverges. This is also confirmed by the exact $0D$ solution (20.22).

Figure 20.2: Examples of diagrams for the fluctuation contribution to b.

effective interaction $\widetilde{b}$ which diminishes and tends to zero when the temperature approaches the transition point. Such a method was originally worked out in quantum field theory [15, 16, 17]. For the problem of a phase transition such a summation was first accomplished in [18].

Instead of a direct summation of the diagrams it is more convenient and physically obvious to use the method of the renormalization group. In the case of quantum field theory this method was known long ago [19, 20]. For phase transition theory it was proposed in [18, 21] but the most simple and evident formulation was presented by Wilson [22]. The idea of the renormalization group method consists in separating the functional integration over "fast" ($\psi_{|k|>\Lambda}$) and "slow"($\psi_{|k|<\Lambda}$) fluctuation modes. If the cut off Λ is large enough the fast mode contribution is small and the integration over them is Gaussian. After the first integration over fast modes the functional obtained depends on the slow ones only. They can, in their turn, be divided on slow ($|k| < \Lambda_1$) and fast ($\Lambda_1 < |k| < \Lambda$), and the procedure can be repeated. Moving step by step ahead in this way one can calculate the complete partition function.

As an example of the first step of renormalization, the partition function calculation below T_c can be recalled. There we separated the order parameter into the space-independent part $\widetilde{\Psi}$ ("slow" mode) and the fluctuation part $\psi(r)$ ("fast" mode) which was believed to be small in magnitude. Being in the GL region it was enough to average over the fast variables just once, while in the critical region the renormalization procedure requires subsequent approximations.

The cornerstone of the method consists in the fact that in the critical region at any subsequent step the free energy functional has the same form. For D close to 4 this form coincides with the initial free energy GL functional but with the coefficients a_Λ and b_Λ depending on Λ. We will perform these calculations by the method of mathematical induction. Let us suppose that after the $(n-1)-$st step the free energy functional has the form:

$$\begin{aligned}\mathcal{F}[\widetilde{\Psi}_{\Lambda_{n-1}}] &= F_{N,\Lambda_{n-1}} + \int dV \left\{ a_{\Lambda_{n-1}} |\widetilde{\Psi}_{\Lambda_{n-1}}|^2 + \right. \\ &\left. + \frac{b_{\Lambda_{n-1}}}{2} |\widetilde{\Psi}_{\Lambda_{n-1}}|^4 + \frac{1}{4m} |\nabla \widetilde{\Psi}_{\Lambda_{n-1}}|^2 \right\}. \end{aligned} \tag{20.40}$$

Writing $\widetilde{\Psi}_{\Lambda_{n-1}}$ in the form $\widetilde{\Psi}_{\Lambda_{n-1}} = \widetilde{\Psi}_{\Lambda_n} + \psi_{\Lambda_n}$ and choosing Λ_n close enough to Λ_{n-1} it is possible to make ψ_{Λ_n} so small, that one can restrict the functional to the quadratic terms in ψ_{Λ_n} only and perform the Gaussian integration in complete analogy with (20.34). The important property of the spaces with dimensionalities close to 4 is the possibility to choose $\Lambda_n \ll \Lambda_{n-1}$ and still to have $\psi_{\Lambda_n} \ll \widetilde{\Psi}_{\Lambda_n}$. In this case $\widetilde{\Psi}_{\Lambda_n}$can be taken as coordinate independent, and one can use the result directly following from (20.34):

$$\mathcal{F}[\widetilde{\Psi}_{\Lambda_n}] = F_{N,\Lambda_{n-1}} + \int dV \left\{ a_{\Lambda_n}|\widetilde{\Psi}_{\Lambda_n}|^2 + \frac{b_{\Lambda_n}}{2}|\widetilde{\Psi}_{\Lambda_n}|^4 + \frac{1}{4m}|\nabla\widetilde{\Psi}_{\Lambda_n}|^2 \right\}$$
$$-\frac{T}{2}\sum_{\Lambda_n<|\mathbf{k}|<\mathbf{\Lambda}_{n-1}} \left\{ \ln\frac{\pi T_c}{(3b_{\Lambda_n}|\widetilde{\Psi}_{\Lambda_n}|^2 + a_{\Lambda_n} + \frac{\mathbf{k}^2}{4m})} + \right.$$
$$\left. \ln\frac{\pi T_c}{b_{\Lambda_n}|\widetilde{\Psi}_{\Lambda_n}|^2 + a_{\Lambda_n} + \frac{\mathbf{k}^2}{4m}} \right\}. \tag{20.41}$$

Expanding the last term in (20.41) in a series in $\widetilde{\Psi}_{\Lambda_n}$ one can get for $\mathcal{F}[\widetilde{\Psi}_{\Lambda_n}]$ the same expression (20.40) with the substitution of $\Lambda_{n-1} \to \Lambda_n$. From (20.41) follows that

$$F_{n,\Lambda_n} = F_{n,\Lambda_{n-1}} - T\sum_{\Lambda_n<|\mathbf{k}|<\mathbf{\Lambda}_{n-1}} \ln\frac{\pi T_c}{(a_{\Lambda_n} + \frac{\mathbf{k}^2}{4m})},$$
$$a_{\Lambda_n} = a_{\Lambda_{n-1}} + 2T\sum_{\Lambda_n<|\mathbf{k}|<\mathbf{\Lambda}_{n-1}} \frac{b_{\Lambda_n}}{(a_{\Lambda_n} + \frac{\mathbf{k}^2}{4m})} \tag{20.42}$$
$$b_{\Lambda_n} = b_{\Lambda_{n-1}} - 5T\sum_{\Lambda_n<|\mathbf{k}|<\mathbf{\Lambda}_{n-1}} \frac{b^2_{\Lambda_n}}{(a_{\Lambda_n} + \frac{\mathbf{k}^2}{4m})^2}.$$

Passing to a continuous variable $\Lambda_n \to \Lambda$ one can rewrite these recursion equations as the set of differential equations:

$$\frac{\partial F(\Lambda)}{\partial\Lambda} = -T\mu_D\Lambda^{D-1}\ln\frac{\pi T_c}{(a(\Lambda) + \frac{\Lambda^2}{4m})}, \tag{20.43}$$

$$\begin{cases} \frac{\partial a(\Lambda)}{\partial\Lambda} = -2T\mu_D\frac{b(\Lambda)\Lambda^{D-1}}{(a(\Lambda)+\frac{\Lambda^2}{4m})} \\ \frac{\partial b(\Lambda)}{\partial\Lambda} = 5T\mu_D\frac{b^2(\Lambda)\Lambda^{D-1}}{(a(\Lambda)+\frac{\Lambda^2}{4m})^2} \end{cases}. \tag{20.44}$$

These renormalization group equations are evidently valid for small enough Λ only, where the transition from discrete to continuous variables is justified. This means at least

$$\Lambda^2/4m \ll T_{c0}Gi_{(D)}. \tag{20.45}$$

in order to move away from the first approximation.

Let us recall that in the framework of the Landau theory of phase transitions the coefficient $a(T_{c0}) = 0$ at the transition point and this can be considered as the MFA definition of the critical temperature T_{c0}. The same statement for the function $a = a(\Lambda)$ in the framework of the renormalization group method can be written as the $a(T_{c0}, \Lambda \sim \xi^{-1}) = 0$. With the decrease of Λ the effect of critical fluctuations more and more is taken into account and the renormalized value of the critical temperature decreases, being defined by the equation: $a(T_c(\Lambda), \Lambda) = 0$. Finally, after the application of the complete renormalization procedure, one can define the real critical temperature T_c, shifted down with respect to T_{c0} due to the effect of fluctuations, from the equation:

$$a(T_c, \Lambda = 0) = 0. \tag{20.46}$$

It is easy to find this shift in the first approximation. Indeed, let us integrate the first equation of (20.44) over Λ in limits $[0, \xi^{-1}]$. The main contribution to the integral will be determined

by the region where $a(\Lambda) \ll \frac{\Lambda^2}{4m}$. Being far from the critical point one can assume that the coefficient $b = const$ and then

$$a(\xi^{-1}) = \alpha\delta T_c = \int\limits_{a(0)}^{a(\xi^{-1})} da = -8mT\mu_D b \int\limits_0^{1/\xi} \Lambda^{D-3} d\Lambda.$$

For the $3D$ case this gives the shift of the critical temperature δT_c due to fluctuations [12]

$$\frac{\delta T_c^{(3)}}{T_c} \sim -\frac{2mb}{\pi\alpha\xi} = -\frac{b}{2\pi T_c\alpha^2}\frac{1}{\xi^3} = -\frac{7\zeta(3)}{16\pi^3\nu T_c\xi^3} = -\frac{8}{\pi}\sqrt{Gi_{(3)}}. \tag{20.48}$$

Let us come back to study of properties of the system of equations (20.44). One can find its partial solution at $T = T_c$ in the form:

$$\begin{aligned} a(T_c,\Lambda) &= \frac{4-D}{4m[5+(4-D)]}\Lambda^2 \\ b(T_c,\Lambda) &= \frac{5}{16m^2T\mu_D}\frac{4-D}{[5+(4-D)]^2}\Lambda^{4-D}. \end{aligned} \tag{20.49}$$

These power solutions are correct in the domain of validity of the system (20.44) itself, i.e. for small enough Λ defined by the condition (20.45). Nevertheless, in a space of dimensionality close to 4 ($D = 4-\varepsilon, \varepsilon \ll 1$) it is possible to extend their validity up to the GL region and to observe their crossover to the GL results: $a(T_c) = 0$; $b(T_c) = b_0 = const$. Indeed, in this case, due to proportionality of $a(\Lambda)$ to $\varepsilon \to 0$, one can omit it in the denominators of the system (20.44) and to write down the solution for $b(\Lambda)$ in the form

$$b^{-1}(T_c,\Lambda) = b_0^{-1} + \frac{80m^2}{(4-D)}T\mu_D(\Lambda^{D-4} - \xi^{4-D}). \tag{20.50}$$

We have chosen the constant of integration as b_0^{-1} - $\frac{80m^2}{(4-D)}T\mu_D\xi^{4-D}$ in order to match the renormalization group and GL solutions at the value of $\Lambda = \Lambda_{\max} \sim \xi^{-1}$.

Now let us pass to study of the function $a(T,\Lambda)$ for the same interesting case of space dimensionality $D \to 4$ for temperatures slightly different (but still close enough) from T_c, where one can write

$$a(T,\Lambda) = a(T_c,\Lambda) + \alpha(T_c,\Lambda)T_c\epsilon.$$

The first term on the right hand side is determined by Eq.(20.49). In order to determine $\alpha(T_c,\Lambda)$ let us expand the first equation in (20.44) in terms of ϵ

$$\frac{\partial\alpha(T_c,\Lambda)}{\partial\Lambda} = 2T\mu_D\frac{b(T_c,\Lambda)\Lambda^{D-1}}{\left(a(T_c,\Lambda)+\frac{\Lambda^2}{4m}\right)^2}\alpha(T_c,\Lambda). \tag{20.51}$$

For

$$\Lambda^2/4m \gtrsim \alpha(T_c,\Lambda)T_c\epsilon \tag{20.52}$$

[12] In the same way we can analyze the shift of the critical temperature in $2D$ case too and obtain:

$$\frac{\delta T_c^{(2)}}{T_c} = -2Gi_{(2)}\ln\frac{1}{4Gi_{(2)}}. \tag{20.47}$$

As we will show below both $3D$ and $2D$ results for δT_c coinside with those obtained by the analysis of the effect of fluctuations on superconducting density in the perturbation approach.

we can again use the solution (20.50) for $b(T_c, \Lambda)$ and omit $a(T_c, \Lambda)$ in the denominator of (20.51). The constant of integration, appearing in the process of solution of (20.51), is chosen in accordance with the condition that for $\Lambda = \Lambda_{\max} \sim \xi^{-1}$ we match $\alpha(T_c, \Lambda) = \alpha(T_{c0}, \xi^{-1}) = \alpha_0$ with the GL theory:

$$\alpha(T_c, \Lambda) = \alpha_0 \left[1 + \frac{80 m^2 b_0}{(4-D)} T \mu_D (\Lambda^{D-4} - \xi^{4-D})\right]^{-2/5}. \tag{20.53}$$

The condition (20.52) can be written as $\Lambda \gtrsim \xi^{-1}(T)$, where $\xi(T)$ is the generalized coherence length, determined by the equation:

$$\xi^{-2}(T) = 4m\alpha\left(T_c, \xi^{-1}(T)\right) T_c \epsilon.$$

Such a definition is valid at any temperature. For example, far enough from the critical point, in the GL region, $\alpha\left(T_c, \xi^{-1}(T)\right) = \alpha_0$ and one reproduces the result (20.3). Vice versa, in the critical region the main contribution on the right hand side of the Eq. (20.53) results from the second term containing Λ^{D-4} so, putting $\xi^{-1}(T) = \Lambda$, one can rewrite the self-consistent equation for $\xi(T)$ and get

$$\xi(T) = (4m)^{(1-D)/2} \frac{4-D}{20 b_0 T \mu_D \sqrt{T_c \alpha_0}} \epsilon^{-\nu}, \tag{20.54}$$

where $2\nu = [1-(4-D)/5]^{-1}$. As was already mentioned, strictly speaking this result was carried out for $\varepsilon = 4 - D \ll 1$, so it is confident up to the first in ε expansion only: $\nu = 1/2 + \varepsilon/10$. Nevertheless extending it to $\varepsilon = 1$ $(D = 3)$ one can obtain $\nu_3 = 3/5$.

Let us pass to the calculation of the critical exponent of the heat capacity in the immediate vicinity of the transition. For this purpose one can calculate the second derivative of equation (20.43) with respect to ϵ:

$$\frac{\partial C(\Lambda)}{\partial \Lambda} = T^2 \mu_D \frac{\Lambda^{D-1} \alpha^2(\Lambda)}{(\alpha(\Lambda) T_c \epsilon + \frac{\Lambda^2}{4m})^2} \tag{20.55}$$

The heat capacity renormalized by fluctuations has the value $C(\Lambda = 0)$ which is the result of integration over all fluctuation degrees of freedom. Carrying out the integration of (20.55) over all $\Lambda \lesssim \xi^{-1}$ one can divide the domain of integration on the right hand side in two: $\Lambda \lesssim \xi^{-1}(T)$ and $\xi^{-1}(T) \lesssim \Lambda \lesssim \xi^{-1}$. In the calculation of the integral over the region $\xi > \Lambda \gtrsim \xi^{-1}(T)$ the inequality $\alpha(\Lambda) T_c \epsilon \ll \frac{\Lambda^2}{4m}$ holds, and the function $\alpha(\Lambda)$ can be omitted in the denominator. In the numerator of (20.55) one can use for $\alpha(\Lambda)$ the solution (20.53). In the region $\Lambda \lesssim \xi^{-1}(T)$ one has to use the partial solution (20.49) for $\alpha(\Lambda)$ and can find that the contribution of this domain has the same singularity as that from the region $\Lambda \gtrsim \xi^{-1}(T)$, but with a coefficient proportional to $(4-D)^2 = \varepsilon^2$, hence negligible in our approximation. The result is:

$$C(\Lambda = 0) = \alpha_0^2 [(4mT)^2 \mu_D]^{\frac{1}{5}} \left[\frac{4}{5} \frac{(4-D)}{b_0}\right]^{4/5} \frac{5}{4-D} \xi^{\frac{4-D}{5}}(T).$$

Substituting the expression for $\xi(T)$ one can finally find

$$C = 2^{12/5} \alpha_0^2 [5 \mu_D \frac{m^2 T^2}{b_0^4 (4-D)}]^{\frac{1}{5}} \epsilon^{-\alpha}, \tag{20.56}$$

confirming the validity of the scaling hypothesis and the relation (20.39). The critical exponent in (20.56) is

$$\alpha = \frac{(4-D)}{10[1-(4-D)/5]} \approx \varepsilon/10.$$

One can see that generally speaking the critical exponents ν and α appear in the form of series in powers of ε. More cumbersome calculations permit finding the next approximations for them in $\varepsilon = 4 - D$. Nevertheless it is worth mentioning that even the first approximation, giving $\nu_3 = 3/5$ and $\alpha_3 = 1/10$ for $\varepsilon = 1$, is already weakly affected by the following steps of the expansion in powers of ε [23].

One can notice that the exercise performed in this Section has more academic than practical character. Indeed, the results obtained turn out applicable to the analysis of the critical region of a $3D$ superconductor only if Gi is so small that the theoretical predictions are hardly experimentally observable. Nevertheless we demonstrated the RG method which helps to see the complete picture of the fluctuations manifestation in the vicinity of the critical temperature.

20.2.4 Fluctuation diamagnetism

Qualitative preliminaries.

In this Section we discuss the effect of fluctuations on the magnetization and the susceptibility of a superconductor above the transition temperature. Being the precursor effect for the Meissner diamagnetism, the fluctuation induced magnetic susceptibility has to be a small correction with respect to the diamagnetism of a superconductor but it can be comparable to or even exceed the value of the normal metal diamagnetic or paramagnetic susceptibility and can be easily measured experimentally. As was already mentioned in the Introduction the temperature dependence of the fluctuation induced diamagnetic susceptibility can be qualitatively analyzed on the basis of the Langevin formula, but some precautions in the case of low dimensional samples have to be made.

As regards the $3D$ case we would like just to mention here that Exp.(20.12), presented in terms of $\xi(T)$, has a wider region of applicability than the GL one. Namely, the scaling arguments are valid for diamagnetic susceptibility too and one can write the general relation

$$\chi_{(3)} \sim -e^2 T\xi(T) \sim -\chi_P \epsilon^{-1/2} \begin{cases} 1, & \epsilon \gtrsim Gi \\ \left(\frac{\epsilon}{Gi}\right)^{1/2-\nu}, & \epsilon \lesssim Gi \end{cases}, \tag{20.57}$$

which is valid in the region of critical fluctuations in the immediate vicinity of the transition temperature too. Here, in order to define the scale of fluctuation effects, we have introduced the Pauli paramagnetic susceptibility $\chi_P = e^2 v_F/4\pi^2$. Moreover, the Langevin formula permits us to extend the estimation of the fluctuation diamagnetic effect to the other side beyond the GL region: to high temperatures $T \gg T_c$. The coherence length far from the transition becomes a slow function of temperature. In a clean superconductor, far from T_c, $\xi(T) \sim v_F/T$, so one can write

$$\chi_{(3c)}(T \gg T_c) \sim -e^2 T\xi(T) \sim -\chi_P \tag{20.58}$$

and see that the fluctuation diamagnetism turns out to be of the order of the Pauli paramagnetism even far from the transition. More precise microscopic calculations of $\chi_{(3)}(T \gg T_c)$ lead to the appearance of $\ln^2(T/T_c)$ in the denominator of (20.58).

In the $2D$ case Exp.(20.12) is applicable for the estimation of $\chi_{(2)}$ in the case when the magnetic field is applied perpendicular to the plane, permitting $2D$ rotations of fluctuation Cooper pairs in it:

$$\chi_{(2c)}(T) \sim e^2 \frac{n}{m} < R^2 > \sim e^2 T\xi^2(T) \sim -\chi_P \frac{E_F}{T - T_c}. \tag{20.59}$$

This result is valid for a wide range of temperatures and can exceed the Pauli paramagnetism by factor $\frac{E_F}{T}$ even far from the critical point (we consider the clean case here).

For a thin film ($d \ll \xi(T)$) perpendicular to the magnetic field the fluctuation Cooper pairs behave like effective $2D$ rotators, and the formula (20.12) still can be used, though one has to take into account that the susceptibility in this case is calculated per unit square of the film. So for the realistic case (from the experimental point of view) of the dirty film, one has just use in (20.59) the expression (20.6) for the coherence length:

$$\chi_{(2d)} \sim \frac{e^2 T}{d}\xi^2(T) \sim -\chi_P \left(\frac{l}{d}\right)\frac{T_c}{T-T_c}. \tag{20.60}$$

Let us discuss now the important case of a layered superconductor (for example, a high temperature superconductor). It is usually supposed that the electrons move freely in conducting planes separated by a distance s. Their motion in the perpendicular direction has a tunneling character, with effective energy J. The related velocity and coherence length can be estimated as $v_z = \partial E(\mathbf{p})/\partial p_\perp \sim J/p_\perp \sim sJ$ and $\xi_{z,(c)} \sim sJ/T$ for clean case. In dirty case the anisotropy can be taken into account in the spirit of formula (20.6) yielding $\xi_{z,(d)} \sim \sqrt{D_\perp/T} \sim sJ\sqrt{\tau/T}$.

We start from the case of a weak magnetic field applied perpendicular to layers. The effective area of a rotating fluctuation pair is $\xi_x(\epsilon)\xi_y(\epsilon)$. The density of Cooper pairs in the conducting layers (20.10) has to be modified for the anisotropic case. Its isotropic $3D$ value is proportional to $1/\xi(\epsilon)$, that now has to be read as $\sim 1/\sqrt{\xi_x(\epsilon)\xi_y(\epsilon)}$. The anisotropy of the electron motion leads to a concentration of fluctuation Cooper pairs in the conducting layers and hence, to an effective increase of the Cooper pairs density of $\sqrt{\xi_x(\epsilon)\xi_y(\epsilon)}/\xi_z(\epsilon)$ times its isotropic value. This increase is saturated when $\xi_z(\epsilon)$ reaches the interlayer distance s, so finally the anisotropy factor appears in the form $\sqrt{\xi_x(\epsilon)\xi_y(\epsilon)}/\max\{s, \xi_z(\epsilon)\}$ and the square root in its numerator is removed in the Langevin formula (20.12), rewritten for this case

$$\chi_{(layer,\perp)}(\epsilon, H \to 0) \sim -e^2 T \frac{\xi_x(\epsilon)\xi_y(\epsilon)}{\max\{s, \xi_z(\epsilon)\}}. \tag{20.61}$$

The existence of a crossover between the $2D$ and $3D$ temperature regimes in this formula is evident: as the temperature tends to T_c the diamagnetic susceptibility temperature dependence changes from $1/\epsilon$ to $1/\sqrt{\epsilon}$. This happens when the reduced temperature reaches its crossover value $\epsilon_{cr} = r$ ($\xi_z(\epsilon_{cr}) \sim s$). The anisotropy parameter

$$r = \frac{4\xi_z^2(0)}{s^2} = \frac{J^2}{T}\begin{cases} \frac{\pi\tau}{4}, & T\tau \ll 1 \\ \frac{7\zeta(3)}{8\pi^2 T}, & T\tau \gg 1 \end{cases} \tag{20.62}$$

plays an important role in the theory of layered superconductors [13].

It is interesting to note that this intrinsic crossover, related to the spectrum anisotropy, has an opposite character to the geometric crossover which happens in thick enough films when $\xi(T)$ reaches d. In the latter case the characteristic $3D$ $1/\sqrt{\epsilon}$ - dependence taking place far enough from T_c (where $\xi(T) \ll d$), is changed to the $2D$ $1/\epsilon$ law (see (20.60)) in the immediate vicinity of transition (where $\xi(T) \gg d$) [24]. It is worth mentioning that in a strongly anisotropic layered superconductor the fluctuation-induced susceptibility may considerably exceed the normal metal dia- and paramagnetic effects even relatively far from T_c [25, 26].

Let us consider a magnetic field applied along the layers. First it is necessary to mention that the fluctuation diamagnetic effect disappears in the limit $J \sim \xi_z \to 0$. Indeed, for the formation of a circulating current it is necessary to tunnel twice, so

$$\chi_{(layer,\parallel)} \sim -e^2 T \frac{\xi_z^2}{\max\{s, \xi_z(T)\}} \sim -\chi_P\left(\frac{sJ}{v_F}\right)\frac{J/T}{\sqrt{\epsilon}\max\{\sqrt{\epsilon}, J/T\}}.$$

[13] We use here a definition of r following from microscopic theory (see Section 6).

In the general case of an anisotropic superconductor, choosing the z axis along the direction of magnetic field H, the following extrapolation of the results obtained may be written

$$\chi \sim -e^2 T \frac{\xi_x^2(\epsilon)\xi_y^2(\epsilon)}{\max\{\mathfrak{a}, \xi_x(\epsilon)\}\max\{\mathfrak{b}, \xi_y(\epsilon)\}\max\{\mathfrak{s}, \xi_z(\epsilon)\}}. \tag{20.63}$$

This general formula is useful for the analysis of the fluctuation diamagnetism of anisotropic superconductors or samples of some specific shape: granular, quasi-1D, quasi-2D, and 3D. It is also applicable to the case of a thin film ($d \ll \xi_z(\epsilon)$) placed perpendicular to the magnetic field: it is enough to replace $\xi_z(\epsilon)$ by d in (20.63). Nevertheless the formula (20.63) cannot be applied to the cases of thin films in parallel fields, wires and granules. In those cases the Langevin formula (20.12) can still be used with the replacement of $\langle R^2 \rangle \to d^2$:

$$\chi_{(D)} \sim -\chi_P \left(\frac{T}{v_F}\right) \xi^{2-D} d^{D-1} \sim \epsilon^{D/2-1}.$$

The magnetic field dependence of the fluctuation part of free energy in these cases is reduced only to account for the quadratic shift of the critical temperature versus magnetic field.

For 3D systems or in the case of a film in a perpendicular magnetic field the critical temperature depends on H linearly, while the magnetic field dependent part of the free energy for $H \ll H_{c2}^*(-\epsilon)$ (the line $H_{c2}^*(-\epsilon)$ is mirror-symmetric to the $H_{c2}(\epsilon)$ with respect to y-axis passing through $T = T_c$) is proportional to H^2. This is why the magnetic susceptibility is determined by Eq.(20.63) for weak enough magnetic fields $H \ll \Phi_0/[\xi_x(\epsilon)\xi_y(\epsilon)] = H_{c2}(\epsilon) \ll H_{c2}(0)$ only. In the vicinity of T_c these fields are small enough.

Zero-dimensional diamagnetic susceptibility.

For quantitative analysis of the fluctuation diamagnetism we start by writing down the GL functional for the free energy (see Exp.(20.16)) in the presence of the magnetic field

$$\begin{aligned} \mathcal{F}[\Psi(\mathbf{r})] &= F_n + \int dV \left\{ a|\Psi(\mathbf{r})|^2 + \frac{b}{2}|\Psi(\mathbf{r})|^4 + \frac{1}{4m}|\left(-i\nabla - 2e\mathbf{A}\right)\Psi(\mathbf{r})|^2 + \right. \\ &\left. + \frac{\mathbf{B}^2}{8\pi} - \frac{\mathbf{H}\cdot\mathbf{B}}{4\pi} \right\}. \end{aligned} \tag{20.64}$$

where $\mathbf{A}$ is vector potential. As long as fluctuation effects are comparatively small, the average magnetic field in the metal $\mathbf{B}$ may be assumed to be equal to the external field $\mathbf{H}$. Thus we omit the last two terms in (20.64) (see later on).

The fluctuation contribution to the diamagnetic susceptibility in the simplest case of a "zero-dimensional" superconductor (spherical superconducting granule of diameter $d \ll \xi(\epsilon)$) was considered by V.Shmidt [11]. In this case the order parameter does not depend on the space variables and the free energy can be calculated exactly for all temperatures including the critical region in the same way as was done for the case of the heat capacity in the absence of a magnetic field. Formally the effect of a magnetic field in this case is reduced to the renormalization of the coefficient a, or, in other words, to the suppression of the critical temperature. This is why one can use the same formula (20.22) for the partition function with the critical temperature T_c shifted by magnetic field as[14]:

$$T_c(H) = T_c(0)(1 - \frac{4\pi^2\xi^2}{\Phi_0^2} < \mathbf{A}^2 >). \tag{20.65}$$

[14]Let us stress the difference between the H^2 shift of the critical temperature for a zero-dimensional granule and the linear shift in the case of bulk material.

Here $\Phi_0 = \frac{\pi}{e}$ is the magnetic flux quantum and $< ..... >$ means the averaging over the sample volume.

Such a trivial dependence of the properties of $0D$ samples on magnetic field immediately allows one to understand its effect on the heat capacity of a granular sample. Indeed, with the growth of the field the temperature dependence of the heat capacity presented in Fig. 20.1 just moves in the direction of lower temperatures.

In the GL region $Gi_{(0)} \lesssim \epsilon$ one can write the asymptotic expression (20.23) for the free energy:

$$F_{(0)}(\epsilon, H) = -T \ln \frac{\pi}{\alpha(\epsilon + \frac{4\pi^2\xi^2}{\Phi_0^2} < \mathbf{A}^2 >)}.$$

In the case of a spherical particle the relation $< \mathbf{A}^2 >= \frac{1}{10} H^2 d^2$ can be used in full analogy with the calculation of the moment of inertia of a solid sphere. In this way an expression for the $0D$ fluctuation magnetization valid for all fields $H \ll H_{c2}(0)$ can be found:

$$M_{(0)}(\epsilon, H) = -\frac{\partial F_{(0)}(\epsilon, H)}{\partial H} = -T \frac{\frac{2\pi^2\xi^2}{5\Phi_0^2} d^2}{(\epsilon + \frac{\pi^2\xi^2}{5\Phi_0^2} H^2 d^2)} H. \tag{20.66}$$

One can see that the fluctuation magnetization turns out to be negative and linear up to some crossover field, which can be called the temperature dependent upper critical field of the granule $H_{c2(0)}(\epsilon) \sim \frac{\Phi_0}{d\xi(\epsilon)} = \frac{\xi}{d} H_{c2}(0)\sqrt{\epsilon}$ at which it reaches a minimum. At higher fields $H_{c2(0)}(\epsilon) \lesssim H \ll H_{c2}(0)$ the fluctuation magnetization of the $0D$ granule decreases as $1/H$. In the weak field region $H \ll H_{c2(0)}(\epsilon)$ the diamagnetic susceptibility is:

$$\chi_{(0)}(\epsilon, H) = -\frac{12\pi T \xi_0^2}{5\Phi_0^2 d} \frac{1}{\epsilon} \approx -2 \cdot 10^2 \chi_P \left(\frac{\xi}{d}\right) \frac{1}{\epsilon}$$

which coincides with our previous estimate in its temperature dependence but the numerical factor found is very large. Let us underline that the temperature dependence of the $0D$ fluctuation diamagnetic susceptibility turns out to be less singular than the $0D$ heat capacity correction: ϵ^{-1} instead of ϵ^{-2}.

The expression for the fluctuation part of free energy (20.28) is also applicable to the cases of a wire or a film placed in a parallel field: as was already mentioned above all its dependence on magnetic field is manifested by the shift of the critical temperature (20.65). In the case of the wire in a parallel field one has to choose the gauge of the vector-potential $\mathbf{A} = \frac{1}{2}\mathbf{H} \times \mathbf{r}$ yielding $\langle \mathbf{A}^2 \rangle_{(wire,\|)} = \frac{H^2 d^2}{32}$ (the calculation of this average is analogous to that of the moment of inertia of a solid sphere). For a wire in a perpendicular field, or a film in a parallel field, the gauge has to be chosen in the form $\mathbf{A} = (0, Hx, 0)$ (to avoid the appearance of currents perpendicular to surface). One can find $\langle \mathbf{A}^2 \rangle_{(wire,\perp)} = \frac{H^2 d^2}{16}$ for a wire and $\langle \mathbf{A}^2 \rangle_{(film,\|)} = \frac{H^2 d^2}{12}$ for a film.

Calculating the second derivative of Eq.(20.28) with the appropriate magnetic field dependencies of the critical temperature one can find the following expressions for the diamagnetic susceptibility:

$$\chi_{(D)}(\epsilon) = -2\pi \frac{\xi T}{v_F} \chi_P \begin{cases} \frac{1}{\sqrt{\epsilon}}, \text{ wire in parallel field} \\ \frac{2}{\sqrt{\epsilon}}, \text{ wire in perpendicular field} \\ \frac{d}{3\xi} \ln \frac{1}{\epsilon}, \text{ film in parallel field} \end{cases}. \tag{20.67}$$

GL treatment of fluctuation magnetization.

Let us analyze quantitatively, on the basis of the GL functional, the temperature and field dependencies of the fluctuation magnetization. We will carry on the discussion for a layered superconductor. As was already mentioned this system has a great practical importance because of its direct applicability to high temperature superconductors, where the fluctuation effects are very noticeable. Moreover, the general results obtained will allow us to analyze $3D$ and $2D$ situations as limiting cases. The effects of a magnetic field are more pronounced for perpendicular orientation, so let us consider first this case.

The generalization of the GL functional for a layered superconductor (Lawrence-Doniach (LD) functional [27]) in a perpendicular magnetic field can be written as

$$\begin{aligned}\mathcal{F}_{LD}\left[\Psi\right] &= \sum_{l}\int d^2r\left(a\left|\Psi_l\right|^2+\frac{b}{2}\left|\Psi_l\right|^4+\frac{1}{4m}\left|\left(\nabla_{\parallel}-2ie\mathbf{A}_{\parallel}\right)\left|\Psi_l\right|^2\right.\right.\\ &\left.\left.+\mathcal{J}\left|\Psi_{l+1}-\Psi_l\right|^2\right),\end{aligned} \tag{20.68}$$

where Ψ_l is the order parameter of the $l-$th superconducting layer and the phenomenological constant $\mathcal{J}$ is proportional to the Josephson coupling between adjacent planes. The gauge with $A_z=0$ is chosen in (20.68). In the immediate vicinity of T_c the LD functional is reduced to the GL one with the effective mass $M=(4\mathcal{J}s^2)^{-1}$ along c-direction, where s is the interlayer spacing. One can relate the value of $\mathcal{J}$ to the coherence length along the c-direction: $\mathcal{J}=2\alpha T_c\xi_z^2/s^2$. Since we are dealing with the GL region the fourth order term in (20.68) can be omitted.

As it is well known the Landau representation is the most appropriate for problems related with the motion of a charged particle in a uniform magnetic field. The fluctuation Cooper pair wave function $\phi_{nk_z}(\mathbf{r})$ can be written as the product of a plane wave propagating along the magnetic field direction and a Landau state wave function. Let us expand the order parameter $\Psi_l(\mathbf{r})$ on the basis of these eigenfunctions:

$$\Psi_l(\mathbf{r})=\sum_{\mathbf{n},k_z}\Psi_{n,k_z}\phi_{nk_z}(\mathbf{r})\exp(ik_zl), \tag{20.69}$$

where $\mathbf{n}$ is the quantum number related with the degenerate Landau state and k_z is the momentum component along the direction of the magnetic field. Substituting this expansion into (20.68) one can find the LD free energy as a functional of the Ψ_{n,k_z} coefficients:

$$\mathcal{F}_{LD}\left[\Psi_{n,k_z}\right]=\sum_{\mathbf{n},k_z}\left\{\alpha T_c\epsilon+\frac{H}{2m\Phi_0}\left(n+\frac{1}{2}\right)+\mathcal{J}\left(1-\cos(k_zs)\right)\right\}\left|\Psi_{n,k_z}\right|^2. \tag{20.70}$$

In complete analogy with the case of an isotropic spectrum the functional integral over the order parameter configurations Ψ_{n,k_z} in the partition function can be reduced to a product of ordinary Gaussian integrals, and the fluctuation part of the free energy in a magnetic field takes the form:

$$F(\epsilon,H)=-\frac{2\pi SH}{\Phi_0}T\sum_{n,k_z}\ln\frac{\pi T}{\alpha T_c\epsilon+\frac{H}{2m\Phi_0}\left(n+\frac{1}{2}\right)+J\left(1-\cos(k_zs)\right)}. \tag{20.71}$$

Here the summation over the degenerate states of each Landau level was performed (S is the sample cross-section) and results in appearance of the number of particle states $(2\pi HS/\Phi_0)$ with the definite quantum numbers n and k_z. The summation over n has to be performed through all occupied states, i.e. the upper limit of the sum is $N\sim 2m\Phi_0E_F/H$.

In the limit of weak fields one can carry out the summation over the Landau states by means of the Euler-Maclaurin's transformation

$$\sum_{n=0}^{N} f(n) = \int_{-1/2}^{N+1/2} f(n) - \frac{1}{24}\left[f^{'}(N+1/2) - f^{'}(-1/2)\right]$$

and obtain

$$F(\epsilon, H) = F(\epsilon, 0) + \frac{\pi S T H^2}{24 m \Phi_0^2} \int_{-\pi/s}^{\pi/s} \frac{\mathcal{N} s dk_z}{2\pi} \left\{ \frac{1}{\alpha T_c \epsilon + \mathcal{J}\left(1 - \cos(k_z s)\right)} \right\}. \tag{20.72}$$

Here $\mathcal{N}$ is the total number of layers. After the momentum integration one gets:

$$F(\epsilon, H) = F(\epsilon, 0) + \frac{\pi V H^2}{24 m \alpha s \Phi_0^2} \frac{1}{\sqrt{\epsilon(\epsilon + r)}}$$

with the anisotropy parameter defined as[15]

$$r = \frac{2\mathcal{J}}{\alpha T} = \frac{4\xi_z^2(0)}{s^2}. \tag{20.73}$$

The magnetic susceptibility in a weak field turns out [28, 29] to be

$$\chi_{(layer,\perp)} = -\frac{e^2 T}{3\pi s} \frac{\xi_{xy}^2}{\sqrt{\epsilon(\epsilon + r)}}. \tag{20.74}$$

These results confirm the qualitative estimation (20.61) additionally providing the exact value of the numerical coefficient and the temperature dependence in the crossover region. In the limit $r \gg \epsilon$ Exp.(20.74) transforms into the diamagnetic susceptibility of the $3D$ anisotropic superconductor [30].

For a film of thickness d the integral over k_z in Exp.(20.72) has to be replaced by a summation over the discrete k_z and when $\xi_z(T) \gg d$ only the term with $k_z = 0$ has to be taken into account:

$$\chi_{(film,\perp)} = -\frac{e^2 T}{3\pi d} \frac{\xi_{xy}^2}{\epsilon}. \tag{20.75}$$

Note that these formulas predict a nontrivial increase of diamagnetic susceptibility for clean metals [29]. The usual statement that fluctuations are most important in dirty superconductors with a short electronic mean free path does not hold in the particular case of susceptibility because here ξ turns out to be in the numerator of the fluctuation correction.

Now we will demonstrate that, besides the crossovers in its temperature dependence, the fluctuation induced magnetization is a nonlinear function of magnetic field too, and these nonlinearities, different for various dimensionalities, take place at relatively low fields. This, strong in comparison with the expected scale of $H_{c2}(0)$, manifestation of the nonlinear regime in fluctuation magnetization and hence, field dependent fluctuation susceptibility, was the subject of the intensive debates in early seventies [30, 31, 32, 33, 34, 35, 36, 37, 38, 39] (see also the

[15] Let us stress the difference between J and $\mathcal{J}$ in the two definitions (20.62) and (20.73) of the anisotropy parameter r. The first one was introduced as the electron tunneling matrix element, while the second one enters in the LD functional as the characteristic Josephson energy for the order parameter. Later on, in the framework of the microscopic theory, it will be demostrated that, in accordance with our qualitative definition, $r \sim J^2$, while $\mathcal{J}$ turns out to be proportional to J^2 too. In the dirty case it depends on the relaxation time of the electron scattering on impurities: $\mathcal{J} \sim \alpha J^2 \max\{\tau, 1/T\}$. Hence both definitions (20.62), appearing in the qualitative consideration, and (20.73), following from the LD model, are consistent.

old but excellent review of W.J. Skocpol and M. Tinkham [40]) and after the discovery of HTS [41, 42, 43, 44] (see also very recent detailed essay of T.Mishonov and E.Penev [45] with references there). We will mainly follow here the paper of Buzdin et al. [46], dealing with the fluctuation magnetization of a layered superconductor, which permits observing in a unique way all variety of the crossover phenomena in temperature and magnetic field.

Let us go back to the general expression (20.71) and evaluate it without taking the magnetic field to small. The difficulty in dealing with it consists in the divergence of the sum over Landau levels n. This divergence can be regularized (see [45, 47]), but let us observe that in order to calculate the magnetization we must know the magnetic field dependent part of the free energy only. So a very convenient method to bypass the divergence problem [48] is to calculate the difference $F(H) - F(0)$, turning the sum over Landau states in $F(\epsilon, 0)$ into an integral and then, in its turn, turning this integral into a sum of integrals over the unit length intervals $x \in [n - 1/2, n + 1/2]$. Then

$$F(\epsilon,0) = -\lim_{H\to 0}\frac{2\pi VH}{\Phi_0}T\int\limits_{-\pi/s}^{\pi/s}\frac{dk_z}{2\pi}\sum_{n=0}^{\infty}\int\limits_{-1/2}^{1/2}dx\times \\ \times\ln\frac{\pi T}{\alpha T_c\epsilon+\frac{H}{2m\Phi_0}\left(x+n+\frac{1}{2}\right)+\mathcal{J}\left(1-\cos(k_z s)\right)}.$$

and by introducing the dimensionless variable [16]

$$h=\frac{H}{H_{c2}(0)},\ H_{c2}(0)=2m\alpha T_c/e=\Phi_0/2\pi\xi_{xy}^2, \tag{20.76}$$

one can write

$$F(\epsilon,H)-F(\epsilon,0)= \tag{20.77}$$
$$=-\frac{TV}{2\pi s\xi_{xy}^2}h\int\limits_{-\pi}^{\pi}dz\sum_{n=0}\int\limits_{-1/2}^{1/2}dx\ln\frac{(2n+1+2x)h+r/2(1-\cos z)+\epsilon}{(2n+1)h+r/2(1-\cos z)+\epsilon}.$$

Performing the integrations over z and x in (20.77) and differentiating with respect to h we finally obtain a very convenient general expression for the fluctuation magnetization in a layered superconductor:

$$M(\epsilon,H)=\frac{T}{\Phi_0 s}\sum_{n=0}^{\infty}\left\{n\ln\frac{\varphi(R_n+1)}{\varphi(R_n)}+\right. \\ \left.\ln\frac{\varphi(R_n+1)}{\varphi(R_n+1/2)}-\frac{n+1/2}{\sqrt{(R_n+1/2)^2-\rho^2}}\right\} \tag{20.78}$$

with $\varphi(x)=x+\sqrt{x^2-\rho^2}$, $R_n=n+\epsilon/2h+\rho$ and $\rho=r/2h$. The sum in (20.78) converges as $1/n^2$ and it provides a volume magnetization expression that can be compared with experiment.

Let us comment on the different crossovers in the $M(\epsilon, H)$ field dependence analyzing the general formula (20.78). Let us fix the temperature $\epsilon \ll r$. In this case the c-axis coherence length exceeds the interlayer distance ($\xi_z \gg s$) and in the absence of a magnetic field the

[16] Let us remind that the exact definition of $H_{c2}(0)$ contains the numerical coefficient $A(0)$ (see footnote 3).

fluctuation Cooper pairs motion has a $3D$ character. Supposing the magnetic field to be not too high ($h \ll r$) we may perform an expansion in (20.78) in$1/\rho$ and obtain

$$M_{(3)}(\epsilon \ll r, h \ll r) = \frac{T\sqrt{2}h^{1/2}}{\Phi_0 \xi_z} \times \sum_n \left\{ (n+1)\left(n+1+\frac{\epsilon}{2h}\right)^{1/2} - n\left(n+\frac{\epsilon}{2h}\right)^{1/2} - \frac{3}{2}\frac{(n+1+\frac{2\epsilon}{3h})}{\sqrt{n+\frac{1}{2}+\frac{\epsilon}{2h}}} \right\}. \tag{20.79}$$

For weak fields ($h \ll \epsilon$) the magnetization grows linearly with magnetic field, justifying our preliminary qualitative results. Nevertheless, this linear growth is changed to the nonlinear $3D$ high field regime $M \sim \sqrt{H}$ already in the region of a relatively small fields $H_{c2}(\epsilon) \lesssim H$ ($\epsilon \lesssim h$). The further increase of magnetic field leads to the next crossover in the magnetization field dependence at $h \sim r$. However the Exp.(20.79) was obtained in the assumption $h \ll r$ as an expansion over $1/\rho$, and it does not work any more. Handling with the Hurvitz zeta-function the summation in (20.78) for $3D$ case can be carried out for an arbitrary field [34]:

$$M_{(3)}(\epsilon \ll r, h) = 3\frac{T}{\Phi_0 s}\left(\frac{2}{r}\right)^{1/2}\sqrt{h} \times \left[\zeta\left(-\frac{1}{2}, \frac{1}{2}+\frac{\epsilon}{2h}\right) - \zeta\left(\frac{1}{2}, \frac{1}{2}+\frac{\epsilon}{2h}\right)\frac{\epsilon}{6h}\right]. \tag{20.80}$$

One can see from this formula that for large fields the magnetization saturates at the value M_∞ [49]:

$$M(h \gg r) \to M_\infty = -\frac{\ln 2}{2}\frac{T}{\Phi_0 s} = -0.346\frac{T}{\Phi_0 s}, \tag{20.81}$$

that is a typical for $2D$ superconductors. Therefore at $h \sim r$ we have a $3D \to 2D$ crossover in $M(H)$ behavior in spite of the fact that all sizes of fluctuation Cooper pair exceed considerably the lattice parameters. The effective "bidimensionalization" of the fluctuations is related to the effect of a strong magnetic field which "freezes out" the rotations along its direction. Let us stress that this crossover occurs in the region of already strongly non-linear dependence of $M(H)$ and therefore for a rather strong magnetic field from the experimental point of view in HTS.

Fixing the temperature $\epsilon \gg r$ in the formula (20.78) one can find the general formula for $2D$ fluctuation regime [45]:

$$M_{(2)}(\epsilon \gg r, h) = \frac{T}{\Phi_0 s}\left\{\ln\Gamma\left(\frac{1}{2}+\frac{\epsilon}{2h}\right) - \frac{1}{2}\ln(2\pi) - \frac{\epsilon}{2h}\left[\psi\left(\frac{1}{2}+\frac{\epsilon}{2h}\right) - 1\right]\right\}, \tag{20.82}$$

where $\Gamma(x)$ is the Euler gamma-function and $\psi(x) = d\ln\Gamma(x)/dx$ is already cited in Introduction digamma-function. Using (20.82) one can directly pass from the linear regime in a weak magnetic field corresponding to (20.59) to the saturation of magnetization (20.81) in strong fields.

Near the line of the upper critical field ($h_{c2}(\epsilon) = -\epsilon$) the contribution of the term with $n = 0$ in the sum (20.78) becomes most important and for the magnetization the expression

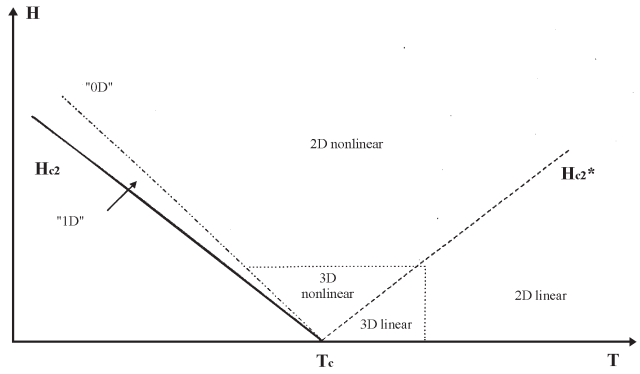

Figure 20.3: Schematic representation of the different regimes for fluctuation magnetization in the (H,T) diagram. The line $H^*_{c2}(T)$ is mirror-symmetric to the $H_{c2}(T)$ line with respect to a y-axis passing through $T = T_c$. This line defines the crossover between linear and non-linear behavior of the fluctuation magnetization above T_c.

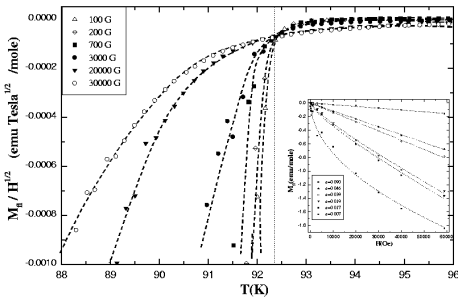

Figure 20.4: Fluctuation magnetization of a YBaCO123 normalized on $\sqrt{H}$ as the function of temperature in accordance with the described theory shows the crossing of the isofield curves at $T = T_c(0) = 92.3K$. The best fit obtained for anisotropy parameter r=0.09. In the inset the magnetization curves as the function of magnetic field are reported.

$$-M(h) \sim \frac{h}{\sqrt{(h-h_{c2})(h-h_{c2}+r)}}$$

can be obtained. It contains the already familiar for us "$0D$" regime ($r \ll h - h_{c2} \ll 1$), where the magnetization decreases as $-M(h) \sim \frac{1}{h-h_{c2}}$ (compare with (20.66)), while for $h - h_{c2} << r$ the regime becomes "$1D$" and the magnetization decreases slower, as $-M(h) \sim \frac{1}{\sqrt{h-h_{c2}}}$.

Such an analogy is observed in the next orders in Gi too. In the Ref. [50] the analogy was demonstrated for the example of the first eleven terms for the $2D$ case and nine for the $3D$ case. Summation of the series of high order fluctuation contributions to the heat capacity by the Pade-Borel method resulted in its temperature dependence similar to the $0D$ and $1D$ cases without magnetic field. Nevertheless a considerable difference has not be forgotten: in the $0D$ and $1D$ cases no phase transition takes place while in the $2D$ and $3D$ cases in a magnetic field a phase transition of first order to the Abrikosov vortex lattice state occurs.

In conclusion, the fluctuation magnetization of a layered superconductor in the vicinity of the transition temperature turns out to be a complicated function of temperature and magnetic field, and it evidently cannot be factorized on these variables. The fit of the experimental data is very sensitive to the anisotropy parameter r and allows determination of the latter with a rather high precision [51, 52]. In Fig. 20.4 the successful application of the described approach to fit the experimental data on $YBa_2Cu_3O_7$ is shown [53].

20.3 Ginzburg-Landau theory of fluctuations in transport phenomena

The appearance of fluctuating Cooper pairs above T_c leads to the opening of a "new channel" for charge transfer. In the Introduction the fluctuation Cooper pairs were treated as carriers with charge $2e$ while their lifetime τ_{GL} was chosen to play the role of the scattering time in the Drude formula. Such a qualitative consideration results in the Aslamazov-Larkin (AL) pair contribution to conductivity (20.11) (so-called paraconductivity[17]).

Below we will present the generalization of the phenomenological GL functional approach to transport phenomena. Dealing with the fluctuation order parameter, it is possible to describe correctly the paraconductivity type fluctuation contributions to the normal resistance and magnetoconductivity, Hall effect, thermoelectric power and thermal conductivity at the edge of transition. Unfortunately the indirect fluctuation contributions are beyond the possibilities of the description by Time-Dependent GL approach and they will be calculated in the framework of the microscopic theory (see Sections 6-8).

20.3.1 Time dependent GL equation

In previous Sections we have demonstrated how the GL functional formalism allows one to account for fluctuation corrections to thermodynamical quantities. Let us discuss the effect of fluctuations on the transport properties of a superconductor above the critical temperature.

In order to find the value of paraconductivity, some time-dependent generalization of the GL equations is required. Indeed, the conductivity characterizes the response of the system to the applied electric field. It can be defined as $\mathbf{E} = -\partial\mathbf{A}/\partial t$ but, in contrast to the previous Section, $\mathbf{A}$ has to be regarded as being time dependent. The general non-stationary BCS equations are very complicated, even in the limit of slow time and space variations of the field and the order parameter. For our purposes it will be sufficient, following [66, 67, 68, 69, 70, 71, 72], to write a model equation in the vicinity of T_c, which in general correctly reflects the qualitative aspects of the order parameter dynamics and in some cases is exact.

Let us keep in mind the GL functional formalism introduced above. If a deviation from equilibrium is assumed, then it is no more possible to derive the GL equations starting from the condition that the variational derivative of the free energy is zero. At the same time, in the absence of equilibrium Ψ begins to depend on time. For small deviations from the equilibrium it is natural to assume that in the process of order parameter relaxation its time derivative $\partial\Psi/\partial t$ is proportional to the variational derivative of the free energy $\delta\mathcal{F}/\delta\Psi^*$, which is equal to zero at the equilibrium. But this is not all: side by side with the normal relaxation of the order parameter the effect of thermodynamical fluctuations on it has to be taken into account. This can be done by the introduction the Langevin forces $\zeta(\mathbf{r}, t)$ in the right-hand side of equation describing the order parameter dynamics. Finally, gauge invariance requires that $\partial\Psi/\partial t$ should be included in the equation in the combination $\partial\Psi/\partial t + 2ie\varphi\Psi$, where φ is the scalar potential of the electric field. By concluding all these speculations one can write the model time-dependent GL equation (TDGL) in the form

$$-\gamma_{GL}\left(\frac{\partial}{\partial t} + 2ie\varphi\right)\Psi = \frac{\delta\mathcal{F}}{\delta\Psi^*} + \zeta(\mathbf{r}, t). \tag{20.83}$$

with the GL functional $\mathcal{F}$ determined by (20.16),(20.64),(20.68). The dimensionless coefficient γ_{GL} in the left-hand-side of the equation can be related to pair life-time τ_{GL} (20.2): $\gamma_{GL} =$

[17] This term may have different origins. First of all, evidently, paraconductivity is analogous to paramagnetism and means excess conductivity. Another possible origin is an incorrect onomatopoeic translation from the Russian "paroprovodimost' " that means pair conductivity

$\alpha T_c \epsilon \tau_{GL} = \pi\alpha/8$ by the substitution in (20.83) of the first term of (20.16) only[18].

Neglecting the fourth order term in the GL functional, equation (20.83) can be rewritten in operator form as

$$[\widehat{L}^{-1} - 2ie\gamma_{GL}\varphi(r,t)]\Psi(\mathbf{r},t) = \zeta(\mathbf{r},t) \tag{20.84}$$

with the TDGL operator $\widehat{L}$ and Hamiltonian $\widehat{\mathcal{H}}$ defined as

$$\widehat{L} = \left[\gamma_{GL}\frac{\partial}{\partial t} + \widehat{\mathcal{H}}\right]^{-1}, \widehat{\mathcal{H}} = \alpha T_c\left[\epsilon - \widehat{\xi}^2(\widehat{\nabla} - 2ie\mathbf{A})^2\right]. \tag{20.85}$$

We have introduced here the formal operator of the coherence length $\widehat{\xi}$ to have the possibility to deal with an arbitrary type of spectrum. For example, in the most interesting case for our applications to layered superconductors, the action of this operator is defined by the Exp.(20.68).

In the absence of an electric field one can write the formal solution of equation (20.84) as

$$\Psi^{(0)}(\mathbf{r},t) = \widehat{L}\zeta(\mathbf{r},t). \tag{20.86}$$

The Langevin forces introduced above must satisfy the fluctuation-dissipation theorem, which means that the correlator $< \Psi^{(0)*}_{\mathbf{p}}(t')\Psi^{(0)}_{\mathbf{p}}(t) >$ at coinciding moments of time has to be the same as $< |\Psi_{\mathbf{p}}|^2 >$, obtained by averaging over fluctuations in thermal equilibrium. This requirement is fulfilled if the Langevin forces $\zeta(\mathbf{r},t)$ and $\zeta^*(\mathbf{r},t)$ are correlated by the Gaussian white-noise law

$$< \zeta^*(\mathbf{r},t)\zeta(\mathbf{r}',t') >= 2T\mathrm{Re}\gamma_{GL}\delta(\mathbf{r}-\mathbf{r}')\delta(t-t'). \tag{20.87}$$

To show it let us restrict ourselves for sake of simplicity to the case of $A = 0$ and calculate the correlator

$$\begin{aligned} &< \Psi^*(\mathbf{r},t)\Psi(\mathbf{r}',t) >=< \zeta^*(\mathbf{r},t)\widehat{\widehat{L}^*}\widehat{L}\zeta(\mathbf{r}',t) >= \\ &= 2T\mathrm{Re}\gamma_{GL}\int\frac{d\mathbf{p}}{(2\pi)^D}e^{i\mathbf{p}(\mathbf{r}-\mathbf{r}')}\int_{-\infty}^{\infty}\frac{d\Omega}{2\pi}L^*(\mathbf{p},\Omega)L(\mathbf{p},\Omega). \end{aligned} \tag{20.88}$$

$L(\mathbf{p},\Omega)$ can be found by making the Fourier transform in (20.85):

$$L(\mathbf{p},\Omega) = (-i\gamma_{GL}\Omega + \varepsilon_{\mathbf{p}})^{-1}, \tag{20.89}$$

resulting in

$$\left\langle\Psi^*(\mathbf{r},t)\Psi(\mathbf{r}',t)\right\rangle_{\mathbf{p}} = 2T\mathrm{Re}\gamma_{GL}\int_{-\infty}^{\infty}\frac{d\Omega}{2\pi}\frac{1}{\gamma_{GL}^2\Omega^2 + \varepsilon_{\mathbf{p}}^2} = \left\langle|\Psi_{\mathbf{p}}|^2\right\rangle, \tag{20.90}$$

where

$$\varepsilon_{\mathbf{p}} = \alpha T_c(\epsilon + \widehat{\xi}^2\mathbf{p}^2). \tag{20.91}$$

is the Cooper pair energy spectrum.

[18]It will be shown below that taking into account the electron-hole asymmetry leads to the appearance of an imaginary part of γ_{GL} proportional to the derivative $\partial\ln(\rho v^2\tau)/\partial E|_{E_F} \sim \mathcal{O}(1/E_F)$. This is important for such phenomena as fluctuation Hall effect or fluctuation thermopower and, having in mind writing the most general formula, we will suppose $\gamma_{GL} = \pi\alpha/8 + i\mathrm{Im}\gamma_{GL}$, where necessary.

20.3.2 Paraconductivity

Let us try to clear up the reason why the simple Drude formula works so well for complex phenomenon like paraconductivity. For this purpose let us try to derive the Boltzmann master equation for the fluctuation Cooper pair distribution function

$$n_{\mathbf{p}}(t) = \int \langle \Psi(\mathbf{r},t)\Psi^*(\mathbf{r}',t)\rangle \exp(-i\mathbf{p}(\mathbf{r}-\mathbf{r}'))d(\mathbf{r}-\mathbf{r}'). \tag{20.92}$$

Let us recall that in the state of thermal equilibrium $n_{\mathbf{p}}^{(0)} =< |\Psi_{\mathbf{p}}|^2 >= T/\varepsilon_{\mathbf{p}}$.

In order to determine the electric field dependence of $n_{\mathbf{p}}$ let us write its time derivative using (20.83)

$$\begin{aligned}\frac{\partial n_{\mathbf{p}}(t)}{\partial t} &= \int d(\mathbf{r}-\mathbf{r}')e^{-i\mathbf{p}(\mathbf{r}-\mathbf{r}')}\left[< \frac{\partial\Psi(\mathbf{r},t)}{\partial t}\Psi^*(\mathbf{r}',t) > + < \Psi(\mathbf{r}',t)\frac{\partial\Psi^*(\mathbf{r},t)}{\partial t} >\right] = \\ &= \int d(\mathbf{r}-\mathbf{r}')e^{-i\mathbf{p}(\mathbf{r}-\mathbf{r}')}\left[2\frac{e}{i}[\varphi(\mathbf{r})-\varphi(\mathbf{r}')] < \Psi(\mathbf{r},t)\Psi^*(\mathbf{r}',t) > + \right. \\ &\left. +\frac{2}{\gamma_{GL}}\mathrm{Re}\left\langle \Psi(\mathbf{r},t)\frac{\delta\mathcal{F}}{\delta\Psi}(\mathbf{r}',t)\right\rangle + \frac{2}{\gamma_{GL}}\mathrm{Re}\left\langle\zeta(\mathbf{r},t)\Psi^*(\mathbf{r}',t)\right\rangle\right],\end{aligned} \tag{20.93}$$

where $\mathcal{F}$ is determined by (20.64). Expressing the scalar potential by the electric field E one can transform the first term of the last integral into $-2e\mathbf{E}\frac{\partial n_{\mathbf{p}}}{\partial\mathbf{p}}$. The term with the variational derivative can be evaluated by means of (20.26) and expressed in the form $-\frac{2}{\gamma_{GL}}\varepsilon_{\mathbf{p}}n_{\mathbf{p}}$. More cumbersome is the evaluation of the last term, containing the Langevin force. To the first approximation it is possible to use here the order parameter $\Psi^{(0)}(\mathbf{r},t)$ (see (20.86)) unperturbed by the electric field as the convolution $\widehat{L}\zeta(\mathbf{r},t)$. In this way, using (20.87) and (20.88) we calculate the last average in (20.93)

$$\begin{aligned}\frac{2}{\gamma_{GL}}\int d(\mathbf{r}-\mathbf{r}')e^{-i\mathbf{p}(\mathbf{r}-\mathbf{r}')}\mathrm{Re}\left\langle\zeta^*(\mathbf{r},t)\widehat{L}\zeta(\mathbf{r},t)\right\rangle &= \\ 4T\int\frac{d\mathbf{p}}{(2\pi)^D}e^{i\mathbf{p}(\mathbf{r}-\mathbf{r}')}\mathrm{Re}\int\limits_{-\infty}^{\infty}\frac{d\Omega}{2\pi}L(\mathbf{p},\Omega) &= \frac{2T}{\gamma_{GL}} = \frac{2}{\gamma_{GL}}\varepsilon_{\mathbf{p}}n_{\mathbf{p}}^{(0)}\end{aligned}$$

and obtain the transport equation

$$\frac{\partial n_{\mathbf{p}}}{\partial t} + 2e\mathbf{E}\frac{\partial n_{\mathbf{p}}}{\partial\mathbf{p}} = -\frac{2}{\gamma_{GL}}\varepsilon_{\mathbf{p}}\left(n_{\mathbf{p}}-n_{\mathbf{p}}^{(0)}\right) = -\frac{2}{\tau_{\mathbf{p}}}\left(n_{\mathbf{p}}-n_{\mathbf{p}}^{(0)}\right). \tag{20.94}$$

In the absence of a magnetic field $\varepsilon_{\mathbf{p}}$ was determined by (20.91) and the momentum dependent lifetime, corresponding to the Ginzburg-Landau one, can be introduced:

$$\tau_{\mathbf{p}} = \gamma_{GL}/\varepsilon_{\mathbf{p}} = \frac{\tau_{GL}(\epsilon)}{1+\xi^2(\epsilon)\mathbf{p}^2}.$$

Let us stress the appearance of the coefficient 2 on the right hand side of the equation (20.94). This means that the real Cooper pair lifetime, characterizing its density decay, is $\tau_{\mathbf{p}}/2$.

The effect of a weak electric field on the fluctuation Cooper pair distribution function in the linear approximation is determined by

$$n_{\mathbf{p}}^{(1)} = -\frac{e\mathbf{E}\gamma_{GL}}{\varepsilon_{\mathbf{p}}}\frac{\partial n_{\mathbf{p}}^{(0)}}{\partial\mathbf{p}} = \frac{eT\gamma_{GL}}{\varepsilon_{\mathbf{p}}^3}\mathbf{E}\cdot\frac{\partial\varepsilon_{\mathbf{p}}}{\partial\mathbf{p}}. \tag{20.95}$$

Substituting this formula into the expression for the electric current side by side with the Cooper pair velocity $\mathbf{v_p} = \partial\varepsilon_\mathbf{p}/\partial\mathbf{p}$ one can find

$$\mathbf{j}^\alpha = \sum_\mathbf{p} (2e\mathbf{v}^\alpha n_\mathbf{p}) = \sigma^{\alpha\beta} E^\beta,$$

where the paraconductivity tensor components are:

$$\sigma^{\alpha\beta}_{(D)} = \frac{\pi}{4} e^2 \alpha T \sum_\mathbf{p} \frac{\mathbf{v}^\alpha_\mathbf{p} \mathbf{v}^\beta_\mathbf{p}}{\varepsilon^3_\mathbf{p}}. \tag{20.96}$$

In the case of isotropic spectrum

$$\sigma^{\alpha\beta}_{(D)} = \frac{\pi}{4} e^2 \alpha T \sum_\mathbf{p} \frac{\mathbf{v}^\alpha_\mathbf{p} \mathbf{v}^\beta_\mathbf{p}}{\varepsilon^3_\mathbf{p}} = \begin{cases} \dfrac{e^2}{32\xi} \dfrac{1}{\sqrt{\epsilon}} & \text{3D case,} \\ \dfrac{e^2}{16d} \dfrac{1}{\epsilon} & \text{2D film, thickness } : d \ll \xi, \\ \dfrac{\pi e^2 \xi}{16 S} \dfrac{1}{\epsilon^{3/2}} & \text{1D wire, cross} - \text{section } : S \ll \xi^2. \end{cases} \tag{20.97}$$

One can compare this result with that carried out in the Introduction from qualitative consideration, based on the Drude formula. Those simple speculations reflect correctly the physics of the phenomenon but were carried out with the assumption of the momentum independence of the relaxation time $\tau_\mathbf{p}$, taken as $\tau_\mathbf{0} = \frac{\pi}{8(T-T_c)}$. As we have just seen, in reality $\tau_\mathbf{p}$ decreases rapidly with increase of the momentum, the excess "2" appeared in (20.94) because of the wave nature of fluctuation Cooper pairs; accounting for this circumstance results in the precise coefficients of (20.97), different from (20.11).

An especially simple form the paraconductivity results in the $2D$ case, where, calculated per unit square, it depends on the reduced temperature only:

$$\sigma_\square(T) = \frac{e^2}{16\hbar} \frac{T}{T - T_c}. \tag{20.98}$$

The coefficient in this formula turns out to be a universal constant and is given by the value $\hbar/e^2 = 4.1k\Omega$. For electronic spectra of other dimensionalities this universality is lost, and the paraconductivity comes to depend on the electron mean free path.

Let us compare $\sigma_\square(T)$ with the normal electron Drude part $\sigma_n = n_e e^2 \tau/m$ by writing the total conductivity

$$\sigma = \frac{e^2}{\hbar} \left(\frac{p_F l}{2\pi\hbar} + \frac{1}{16\epsilon} \right). \tag{20.99}$$

One sees that at $\epsilon_{cr} = 0.4/(p_F l) \sim Gi_{(2c)}$ the fluctuation correction reaches the value of the normal conductivity. Let us recall that the same order of magnitude for the $2D$ Ginzburg-Levanyuk number was obtained above from the heat capacity study. We will discuss the region of applicability of (20.99) below in Section 8.6.

It is worth mentioning that the results derived here for paraconductivity are valid with the assumption of weak fluctuations: for the temperature range $\epsilon \lesssim Gi_{(D)}$ they are not anymore applicable. Nevertheless, one can see that for not very dirty films, with $p_F^2 ld \gg 1$, a wide region of temperatures $Gi_{(2d)} \ll \epsilon \ll 1$ exists where the temperature dependence of conductivity is determined by fluctuations and in this region the localization effects are negligible.

The transport equation (20.94) was originally derived many years ago by L.G.Aslamazov and A.I.Larkin [73]. Recently T.Mishonov et al. [74] rederived Eq.(20.94) and solved it for $n_\mathbf{p}$ in the case of an arbitrary electric field.

20.3.3 General expression for paraconductivity

Unfortunately the applicability of the master equation derived is restricted to weak magnetic fields ($H \ll H_{c2}(\epsilon)$). For stronger fields $H_{c2}(\epsilon) \lesssim H \ll H_{c2}(0)$ the simple evaluation of averages in (20.93) turns out to be incorrect, the density matrix has to be introduced and the master equation loses its attractive simplicity. At the same time, as we already know, namely these fields, quantizing the fluctuation Cooper pair motion, present special interest. This is why in order to include in the scheme the magnetic field and frequency dependencies of the paraconductivity, we return to the analysis of the general TDGL equation (20.83) without the objective to reduce it to a Boltzmann type transport equation.

Let us solve it in the case when the applied electric field can be considered as a perturbation. The method will much resemble an exercise from a course of quantum mechanics. To carry out the necessary generality side by side with a formal simplicity of expressions we will introduce some kind of subscript $\{i\}$ which includes the complete set of quantum numbers and time. By a repeated subscript a summation over a discrete and integration over continuous variables (time in particular) will be supposed.

We will look for the response of the order parameter to a weak electric field applied in the form

$$\Psi_{k_z}(\mathbf{r},t) = \Psi^{(0)}_{\{i\}} + \Psi^{(1)}_{\{i\}}, \tag{20.100}$$

where $\Psi^{(0)}_{\{i\}}$ is determined by (20.86). Substituting this expression into (20.84) and restricting our consideration to linear terms in the electric field we can write

$$(\widehat{L}^{-1})_{\{ik\}}\Psi^{(1)}_{\{k\}} = 2ie\gamma_{GL}\varphi_{\{il\}}\Psi^{(0)}_{\{l\}}$$

with the solution in the form

$$\Psi^{(1)}_{\{i\}} = 2ie\gamma_{GL}\widehat{L}_{\{ik\}}\varphi_{\{kl\}}\widehat{L}_{\{lm\}}\zeta_{\{m\}}.$$

Let us substitute the order parameter (20.100) in the quantum mechanical expression for current

$$\mathbf{j} = 2e\mathrm{Re}\left[\Psi^{(0)*}_{\{i\}}\widehat{\mathbf{v}}_{\{ik\}}\Psi^{(1)}_{\{k\}} + \Psi^{(1)*}_{\{i\}}\widehat{\mathbf{v}}_{\{ik\}}\Psi^{(0)}_{\{k\}}\right], \tag{20.101}$$

where $\widehat{\mathbf{v}}_{\{ik\}}$ is the velocity operator which can be expressed by means of the commutator of $\mathbf{r}$ with Hamiltonian (20.85):

$$\widehat{\mathbf{v}}_{\{ik\}} = i\{\widehat{\mathcal{H}}, \mathbf{r}\}_{\{ik\}}. \tag{20.102}$$

The second term of (20.101) can be written by means of a transposed velocity operator (which is Hermitian) as the complex conjugated value of the first one:

$$\Psi^{(1)*}_{\{i\}}\widehat{\mathbf{v}}_{\{ik\}}\Psi^{(0)}_{\{k\}} = (\Psi^{(0)*}_{\{k\}}\widetilde{\widehat{\mathbf{v}}}_{\{ik\}}\Psi^{(1)}_{\{i\}})^*, \tag{20.103}$$

which results in

$$\begin{aligned}\mathbf{j} &= 2\mathrm{Re}\{\Psi^{(0)*}_{\{i\}}(2e\widehat{\mathbf{v}}_{\{ik\}})\Psi^{(1)}_{\{k\}}\} = \\ &= -8e^2\mathrm{Im}\{\gamma_{GL}\widehat{L}^*_{\{ki\}}\widehat{\mathbf{v}}_{\{il\}}\widehat{L}_{\{lm\}}\varphi_{\{mn\}}\widehat{L}_{\{np\}}\zeta^*_{\{k\}}\zeta_{\{p\}}\}.\end{aligned} \tag{20.104}$$

Let us average now (20.104) over the Langevin forces moving the operator $\widehat{L}^*_{\{ki\}}$ from the beginning to the end of the trace and using (20.87). One finds

$$\mathbf{j} = -16Te^2\mathrm{Re}(\gamma_{GL})\mathrm{Im}\{\gamma_{GL}\widehat{\mathbf{v}}_{\{il\}}\widehat{L}_{\{lm\}}\varphi_{\{mn\}}\widehat{L}_{\{np\}}\widehat{L}^*_{\{pi\}}\}. \tag{20.105}$$

Now we choose the representation where the $\widehat{L}_{\{lm\}}$ operator is diagonal (it is evidently given by the eigenfunctions of the Hamiltonian (20.85)):

$$L_{\{m\}}(\Omega) = \frac{1}{\varepsilon_{\{m\}} - i\Omega\gamma_{GL}}, \tag{20.106}$$

where $\varepsilon_{\{m\}}$ are the appropriate energy eigenvalues. Then we assume that the electric field is coordinate independent but is a monochromatic periodic function of time:

$$\varphi(r,t) = -E^{\beta}r^{\beta}\exp(-i\omega t). \tag{20.107}$$

In doing the Fourier transform in (20.105) one has to remember that the time dependence of the matrix elements $\varphi_{\{mn\}}$ results in a shift of the frequency variable of integration $\Omega \to \Omega - \omega$ in both L-operators placed after $\varphi_{\{mn\}}$ or, what is the same, to a shift of the argument of the previous $\widehat{L}_{\{lm\}}$ for ω :

$$\begin{aligned} \mathbf{j}^{\alpha}_{\omega} &= 16Te^2\mathrm{Re}(\gamma_{GL}) \times \\ &\times \int \frac{d\Omega}{2\pi}\mathrm{Re}\left\{\gamma_{GL}\widehat{\mathbf{v}}^{\alpha}_{\{il\}}\widehat{L}_{\{l\}}(\Omega+\omega)[-ir^{\beta}_{\{li\}}]\widehat{L}_{\{i\}}(\Omega)\widehat{L}^{*}_{\{i\}}(\Omega)\right\}\mathbf{E}^{\beta}, \end{aligned} \tag{20.108}$$

where $\mathrm{Re}\, f(\omega) \equiv [f(\omega) + f^{*}(-\omega)]/2$.

Let us express the matrix element $\mathbf{r}_{\{li\}}$ by means of $\widehat{\mathbf{v}}_{\{li\}}$ using the commutation relation (20.102). One can see that in the representation chosen

$$\widehat{\mathbf{r}}^{\beta}_{\{li\}} = i\frac{\widehat{\mathbf{v}}^{\beta}_{\{li\}}}{\varepsilon_{\{i\}} - \varepsilon_{\{l\}}} \tag{20.109}$$

and, carrying out the frequency integration in (20.108), finally write for the fluctuation conductivity tensor ($\mathbf{j}^{\alpha}_{\omega} = \sigma^{\alpha\beta}(\omega)\mathbf{E}^{\beta}$) :

$$\begin{aligned} \sigma^{\alpha\beta}(\epsilon,H,\omega) &= 8e^2T\mathrm{Re}(\gamma_{GL})\sum_{\{i,l\}=0}^{\infty} \\ &\mathrm{Re}\left[\gamma_{GL}\frac{\widehat{\mathbf{v}}^{\alpha}_{\{il\}}\widehat{\mathbf{v}}^{\beta}_{\{li\}}}{\varepsilon_{\{i\}}(\gamma_{GL}\varepsilon_{\{i\}} + \gamma^{*}_{GL}\varepsilon_{\{l\}} - i|\gamma_{GL}|^2\omega)(\varepsilon_{\{l\}} - \varepsilon_{\{i\}})}\right]. \end{aligned} \tag{20.110}$$

This is the most general expression which describes the d.c., galvanomagnetic and high frequency paraconductivity contribution. In the case when we are interested in diagonal effects only, where it is enough to accept γ_{GL} as real ($\gamma_{GL} = \mathrm{Re}\gamma_{GL} = \pi\alpha/8$) omitting its small imaginary part, the last expression can be simplified by means of symmetrization of the summation variables):

$$\sigma^{\alpha\alpha}(\epsilon,H,\omega) = \frac{\pi}{2}\alpha e^2T\sum_{\{i,l\}=0}^{\infty}\mathrm{Re}\left[\frac{\widehat{\mathbf{v}}^{\alpha}_{\{il\}}\widehat{\mathbf{v}}^{\alpha}_{\{li\}}}{\varepsilon_{\{i\}}\varepsilon_{\{l\}}(\varepsilon_{\{i\}} + \varepsilon_{\{l\}} - i\gamma_{GL}\omega)}\right]. \tag{20.111}$$

Let us demonstrate the calculation of the d.c. paraconductivity in the simplest case of a metal with an isotropic spectrum. In this case we choose a plane wave representation. By using $\varepsilon_{\mathbf{p}}$ defined by (20.91) one has

$$\widehat{\mathbf{v}}_{\{\mathbf{pp}'\}} = \mathbf{v}_{\mathbf{p}}\delta_{\mathbf{pp}'},\ \mathbf{v}_{\mathbf{p}} = \frac{\partial\varepsilon_{\mathbf{p}}}{\partial\mathbf{p}} = 2\alpha T_c\xi^2\mathbf{p}. \tag{20.112}$$

We do not need to keep the imaginary part of γ_{GL}, which is necessary to calculate particle-hole asymmetric effects only. Then the fluctuation conductivity calculated from (20.111) coincides exactly with (20.96).

20.3.4 Fluctuation conductivity of layered superconductor

Let us return to the discussion of our general formula (20.111) for the fluctuation conductivity tensor. A magnetic field directed along the c-axis still permits separation of variables even in the case of a layered superconductor. The Hamiltonian in this case can be written as in (20.70), (20.85):

$$\widehat{\mathcal{H}} = \alpha T_c \left(\epsilon - \xi_{xy}^2 (\nabla_{xy} - 2ie\mathbf{A}_{xy})^2 - \frac{r}{2}(1 - \cos(k_z s)) \right). \tag{20.113}$$

It it is convenient to work in the Landau representation, where the summation over $\{i\}$ is reduced to one over the ladder of the Landau levels $i = 0, 1, 2..$ (each is degenerate with a density $2eH$ per unit square) and integration over the c-axis momentum in the limits of the Brillouine zone. The eigenvalues of the Hamiltonian (20.113) can be written in the form

$$\varepsilon_n = \alpha T_c [\epsilon + \frac{r}{2}(1 - \cos(k_z s)) + h(2n+1)] = \varepsilon_{k_z} + \alpha T_c h(2n+1), \tag{20.114}$$

where $h = \frac{eH}{2m\alpha T_c}$ was already defined by Eq. (20.76). For the velocity operators one can write

$$\widehat{\mathbf{v}}^{x,y} = \frac{1}{2m}(-i\nabla - 2ie\mathbf{A})^{x,y};\ \widehat{\mathbf{v}}^z = -\frac{\alpha r s}{2} T_c \sin(k_z s). \tag{20.115}$$

In-plane conductivity.

Let us start from the calculation of the in-plane components. The calculation of the velocity operator matrix elements requires some special consideration. First of all let us stress that the required matrix elements have to be calculated for the eigenstates of a quantum oscillator whose motion is equivalent to the motion of a charged particle in a magnetic field. The commutation relation for the oscillator's velocity components is well known (see [75]):

$$[\widehat{\mathbf{v}}^x, \widehat{\mathbf{v}}^y] = i\frac{eH}{2m^2} = \frac{i\alpha T_c}{m} h. \tag{20.116}$$

In order to calculate the necessary matrix elements let us present the velocity operator components in the form of boson-type creation and annihilation operators $\widehat{a}^+, \widehat{a}$ with commutation relation $[\widehat{a}, \widehat{a}^+] = 1$:

$$\widehat{\mathbf{v}}^{x,y} = \sqrt{\frac{\alpha T_c h}{2m}} \begin{pmatrix} \widehat{a}^+ + \widehat{a} \\ i\widehat{a}^+ - i\widehat{a} \end{pmatrix}$$

One can check that the correct commutation relation (20.116) is fulfilled. Taking into account that

$$< l|\widehat{a}|n > = < n|\widehat{a}^+|l > = \sqrt{n}\delta_{n,l+1}$$

it is seen that the only non-zero matrix elements of the velocity operator are

$$< l|\widehat{\mathbf{v}}^{x,y}|n > = \sqrt{\frac{\alpha T_c h}{2m}} \begin{pmatrix} \sqrt{l}\delta_{l,n+1} + \sqrt{n}\delta_{n,l+1} \\ i\sqrt{l}\delta_{l,n+1} - i\sqrt{n}\delta_{n,l+1} \end{pmatrix}.$$

Using these relations the necessary product of matrix elements can be calculated:

$$< l|\widehat{\mathbf{v}}^x|n >< n|\widehat{\mathbf{v}}^x|l > = \frac{\alpha T_c h}{2m}(l\delta_{l,n+1} + n\delta_{n,l+1}).$$

Its substitution into (20.111) and accounting of the degeneracy of the Landau levels $2eH = 4m\alpha T_c h$ gives for the diagonal component of the in-plane conductivity tensor

$$\sigma^{xx}(\epsilon,H,\omega) = \frac{\pi\alpha^2T_c^2e^2}{4m}h\sum_{\{n\}=0}^{\infty}\sum_{\{l\}=0}\mathrm{Re}\,[\frac{(l\delta_{l,n+1}+n\delta_{n,l+1})}{\varepsilon_l\varepsilon_n(\varepsilon_l+\varepsilon_n-i\gamma_{GL}\omega)}] \tag{20.117}$$

$$= \pi e^2\left(\alpha T_c\right)^3h^2\int_{-\frac{\pi}{s}}^{\frac{\pi}{s}}\frac{dk_z}{2\pi}\sum_{n=0}^{\infty}\mathrm{Re}\,[\frac{n+1}{\varepsilon_{n+1}\varepsilon_n(\varepsilon_{n+1}+\varepsilon_n-i\gamma_{GL}\omega)}].$$

Expanding the denominator into simple fractions we reduce the problem to the calculation of the c-axis momentum integral, which can be carried out in the general case by use of the identity:

$$\int_0^{2\pi}\frac{dx}{2\pi}\frac{1}{\cos x-z}=-\frac{1}{\sqrt{z^2-1}} \tag{20.118}$$

valid for any complex parameter $z\neq 1$ with the proper choice of the square root branch. Using it we write the general expression for the in-plane component of the fluctuation conductivity tensor

$$\sigma^{xx}(\varepsilon,h,\omega) = \frac{e^2h}{16s}\sum_{n=0}^{\infty}(n+1)\left\{\frac{1}{h-i\widetilde{\omega}}\frac{1}{\sqrt{[\epsilon+h(2n+1)][r+\epsilon+h(2n+1)]}}+\right.$$
$$\frac{1}{h+i\widetilde{\omega}}\frac{1}{\sqrt{[\epsilon+h(2n+3)][r+\epsilon+h(2n+3)]}}- \tag{20.119}$$
$$\left.\frac{2h}{h^2+\widetilde{\omega}^2}\frac{1}{\sqrt{[\epsilon+h(2n+2)-i\widetilde{\omega}][r+\epsilon+h(2n+2)-i\widetilde{\omega}]}}\right\}.$$

where $\widetilde{\omega}=\frac{\pi\omega}{16T_c}$.

Out-of plane conductivity.

The situation with the out-of plane component of paraconductivity turns out to be even simpler because of the diagonal structure of the $\widehat{\mathbf{v}}^z_{\{in\}}=-\frac{\alpha rs}{2}T_c\sin(k_zs)\times\delta_{in}\times\delta(k_z-k_{z'})$. Taking into account that the Landau state degeneracy $2eH=h\xi_{xy}^{-2}$ we write

$$\sigma^{zz}(\epsilon,H,\omega) = \frac{1}{2}\pi\alpha e^2T\sum_{\{i,l\}=0}^{\infty}\mathrm{Re}\left[\frac{\widehat{\mathbf{v}}^{\alpha}_{\{il\}}\widehat{\mathbf{v}}^{\alpha}_{\{li\}}}{\varepsilon_{\{i\}}\varepsilon_{\{l\}}(\varepsilon_{\{i\}}+\varepsilon_{\{l\}}-i\alpha T_c\widetilde{\omega})}\right]=$$
$$= \frac{\pi e^2\left(\alpha T_c\right)^3}{16}\left(\frac{sr}{\xi_{xy}}\right)^2h\sum_{n=0}^{\infty}\int_{-\frac{\pi}{s}}^{\frac{\pi}{s}}\frac{dk_z}{2\pi}\mathrm{Re}\,[\frac{\sin^2(k_zs)}{\varepsilon_n^2(k_z)[\varepsilon_n(k_z)-i\alpha T_c\widetilde{\omega}]}].$$

The following transformations are similar to the calculation of the in-plane component: we expand the integrand into simple fractions and perform the k_z-integration by means of the identity (20.118). The final expression can be written as

$$\sigma^{zz}(\epsilon,H,\omega) = \frac{\pi e^2}{32s}\left(\frac{sr}{\xi_{xy}}\right)^2 h\sum_{n=0}^{\infty}\left(-\frac{\partial}{\partial\lambda}\right)\times \tag{20.120}$$
$$\mathrm{Re}\left(\frac{1}{\lambda+i\widetilde{\omega}}\right)\left\{\frac{1}{\sqrt{(\epsilon+h(2n+1)+\lambda)(\epsilon+h(2n+1)+\lambda+r)}}-\right.$$
$$\left.\frac{1}{\sqrt{(\epsilon+h(2n+1)-i\widetilde{\omega})(\epsilon+h(2n+1)-i\widetilde{\omega}+r)}}\right\}|_{\lambda=0}\,.$$

Analysis of the general expressions.

In principle the expressions derived above give an exact solution for the a.c.($\omega \ll T$) paraconductivity tensor of a layered superconductor in a perpendicular magnetic field $H \ll H_{c2}$ ($h \ll 1$) in the vicinity of the critical temperature ($\epsilon \ll 1$). The interplay of the parameters r, ϵ, ω h entering into (20.119)-(20.120), as we have seen in the example of fluctuation magnetization, yields a variety of crossover phenomena.

1. The simplest and most important results which can be derived are the components of the *d.c.* paraconductivity ($\omega = 0$) of layered superconductor in the absence of magnetic field. Keeping $\omega = 0$ and setting $h \to 0$ one can change the summations over Landau levels into integration and find

$$\sigma^{xx}(\varepsilon, h\to 0, \omega=0) = \frac{e^2}{16s}\frac{1}{\sqrt{[\epsilon(r+\epsilon)]}},$$
$$\sigma^{zz}(\epsilon, h\to 0, \omega=0) = \frac{e^2 s}{32\xi_{xy}^2}\left(\frac{\epsilon+r/2}{[\epsilon(\epsilon+r)]^{1/2}}-1\right).$$

2. The Aslamazov-Larkin contribution to the magnetoconductivity can be studied by putting $\omega = 0$ and keeping magnetic field as arbitrary. We will not go into details and just report the results (following [154] with some revision of the coefficient in $3D$ case)

	$h \ll \epsilon$	$\epsilon \ll h \ll r$ $(3D)$	$\max\{\epsilon, r\} \ll h$ $(2D)$
σ^{xx}	$\sigma^{xx}(\epsilon, h=0) - \frac{e^2}{2^8 s}\frac{[8\epsilon(\epsilon+r)+3r^2]}{[\epsilon(\epsilon+r)]^{5/2}}h^2$	$\frac{e^2}{4s}\frac{1}{\sqrt{2hr}}$	$\frac{e^2}{8s}\frac{1}{h}$
σ^{zz}	$\sigma^{zz}(\epsilon, h=0) - \frac{e^2 s}{2^8\xi_{xy}^2}\frac{r^2(\epsilon+r/2)}{[\epsilon(\epsilon+r)]^{5/2}}h^2$	$\frac{3.24e^2 s}{\xi_{xy}^2}\sqrt{\frac{r}{h}}$	$\frac{7\zeta(3)e^2 s}{2^9\xi_{xy}^2}\frac{r^2}{h^2}$

Table 2.

Here it is worth making an important comment. The proportionality of the fluctuation magnetoconductivity to h^2 is valid when using the parametrization $\epsilon = (T - T_{c0})/T_{c0}$ only. As it well known, a weak field shifts the critical temperature linearly, which often makes it attractive to analyze the experimental data by choosing as the reduced temperature parameter $\epsilon_h = (T - T_c(H))/T_c(H)$. In this parametrization one can get a term in the magnetoconductivity linear in h , which previously was cancelled out by the magnetic field renormalization of the critical temperature. So it is important to recognize that the effect of a weak magnetic field on the fluctuation conductivity cannot be reduced to a simple replacement of T_{c0} by $T_c(H)$ in the appropriate formula without the field. Vice versa, this effect is exactly compensated by the change in the functional dependence of the paraconductivity in magnetic field, and finally it contains the negative quadratic contribution only.

3. Letting the magnetic field go to zero and considering nonzero frequency of the electromagnetic field one can find general expressions for the components of the *a.c* paraconductivity

tensor. They are cumbersome enough and in the complete form can be found, for instance, in [76]. We recall here the simplified asymptotics for the Reσ in the $2D$ regime only:

$$\begin{aligned} \mathrm{Re}\sigma^{xx}_{(2D)}(r \ll \epsilon, \widetilde{\omega}) = \\ = \frac{e^2}{16s}\frac{1}{\epsilon}\left[\frac{2\epsilon}{\widetilde{\omega}}\arctan\frac{\widetilde{\omega}}{\epsilon} - \left(\frac{\epsilon}{\widetilde{\omega}}\right)^2 \ln\left[1+\left(\frac{\widetilde{\omega}}{\epsilon}\right)^2\right]\right] \end{aligned} \tag{20.121}$$

$$\mathrm{Re}\sigma^{zz}_{(2D)}(r \ll \epsilon, \widetilde{\omega}) = \frac{e^2}{2^8 s}\left(\frac{sr}{\xi_{xy}}\right)^2\left(\frac{1}{\widetilde{\omega}}\right)^2 \ln[1+\left(\frac{\widetilde{\omega}}{\epsilon}\right)^2]. \tag{20.122}$$

The general formulas (20.119)-(20.120) allow one to study the different crossovers in the *a.c.* conductivity of layered superconductor in the presence of magnetic field of various intensity. We leave this exercise for the reader having some practical interest in the problem.

20.3.5 Magnetic field angular dependence of paraconductivity

We have seen above that in the case of a geometry with a magnetic field directed along the c-axis many sophisticated fluctuation features of layered superconductors can be studied in the most general form. Nevertheless even the attempt to explore the d.c. conductivity in a longitudinal magnetic field (directed in ab plane) [77] or, moreover, with the field directed at some arbitrary angle θ with the c-axis leads to the appearance of the a vector potential component in the argument of $\cos(k_z s)$ and the problem requires a nontrivial calculation of the matrix elements over the Mathieu functions.

We already learned that at temperatures very near to the critical one ($\epsilon \ll r$) the $3D$ fluctuation regime takes place. Here the size of the Cooper pairs along the c-axis is so large that the peculiarities of the layered structure do not play any more role. This means that only small values of k_z are important in the k_z-integrations, where the $\cos(k_z s)$ in (20.70) can be expanded and the LD functional is reduced to its traditional GL form with an anisotropic effective mass tensor:

$$\begin{aligned} \mathcal{F}[\Psi] = \int d^3\mathbf{r}\left\{a|\Psi|^2 + \frac{B}{2}|\Psi|^4 + \sum_{\mu=1}^{3}\frac{1}{4m_\mu}\left|\left(\frac{1}{i}\frac{d}{dx_\mu} - 2eA_\mu\right)\Psi\right|^2 + \right. \\ \left. + \frac{B^2}{8\pi} - \frac{\mathbf{H}\cdot\mathbf{B}}{4\pi}\right\}. \end{aligned} \tag{20.123}$$

We will demonstrate below that in this case a scaling approach provides a direct access to the most general results by rescaling the anisotropic problem to the corresponding isotropic one on the initial level of the GL approach [78].

Let us suppose that the external field $\mathbf{H}$ is chosen to lie in the $y-z$ plane and makes angle θ with the z - axis. For sake of simplicity and because the oxide superconductors are within high accuracy uniaxial materials, we choose $m_x = m_y = m^*$, while $m_z^{-1} = 2\alpha s^2 r$ (compare with (20.68)). The effective anisotropy parameter $\gamma_a^2 = m^*/m_z = 2\alpha s^2 r m^* < 1$ is introduced. In (20.123) the anisotropy enters only in the gauge-invariant gradient term, so the simple rescaling of the coordinate axes: $x = \widetilde{x}, y = \widetilde{y}, z = \gamma_a\widetilde{z}$ together with the scaling of the vector potential: $\mathbf{A} = (\widetilde{A}_x, \widetilde{A}_y, \widetilde{A}_z/\gamma_a)$ will render this term isotropic. The magnetic field evidently is rescaled to $\mathbf{B} = (\widetilde{B}_x/\gamma_a, \widetilde{B}_y/\gamma_a, \widetilde{B}_z)$ and the last three terms in (20.123), describing the magnetic-field energy, are transformed to

$$\delta\mathcal{F}[\Psi] = \frac{\gamma_a}{8\pi}\int d^3\widetilde{\mathbf{r}}\left[\frac{1}{4m}\sum_{\mu=1}^{3}\left|\left(\frac{\hbar}{i}\frac{d}{d\widetilde{x}_\mu}-\frac{2e}{c}\widetilde{A}_\mu\right)\Psi\right|^2+(\frac{\widetilde{\mathbf{B}}_{xy}^2}{\gamma_a}+\widetilde{B}_z^2)- -2(\frac{\widetilde{\mathbf{B}}_{xy}\cdot\mathbf{H}_{xy}}{\gamma_a}+\widetilde{B}_z H_z)\right].$$

In short, we have removed the anisotropy from the gradient term but reintroduced it into the magnetic energy term. In general it is not possible to make both terms isotropic in the Gibbs energy simultaneously. However, depending on the physical question addressed, we can neglect fluctuations in the magnetic field, as was mostly done above.

Let us demonstrate how the method works for the example of the d.c. fluctuation conductivity tensor which was calculated above for a magnetic field directed along the c-axis. We restrict our consideration to the $3D$ region ($\epsilon \ll r$). One can write the scaling relations between the electric field and current components before and after the scaling transformation by means of a conductivity tensor and the anisotropy parameter:

$$\begin{aligned} j_{x,y} &= \widetilde{j}_{x,y} \qquad j_z \sim ev_z \sim \gamma_a\widetilde{j}_z \\ E_{x,y} &= \widetilde{E}_{x,y} \qquad E_z \sim \frac{\partial\varphi}{\partial z}\sim\frac{1}{\gamma_a}\widetilde{E}_z. \end{aligned} \tag{20.124}$$

Now let us rewrite the relations between the current and electric field vectors before and after the scale transformation

$$\begin{aligned} j_\alpha &= \sigma_{\alpha\beta}E_\beta \\ \widetilde{j}_\alpha &= \widetilde{\sigma}_{\alpha\beta}\widetilde{E}_\beta. \end{aligned}$$

Comparing them with (20.124) and introducing the operator of the direct scaling transformation $T_{\alpha\beta}$

$$T_{\alpha\beta} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & \gamma_a \end{pmatrix},$$

one can write $j_\alpha = T_{\alpha\mu}\widetilde{j}_\mu,\ E_\alpha = (T^{-1})_{\alpha\mu}\widetilde{E}_\mu$ and express the conductivity tensor as

$$\sigma_{\alpha\beta} = T_{\alpha\mu}\widetilde{\sigma}_{\mu\rho}T_{\rho\beta}.$$

Now let us work in the already isotropic coordinate frame. We suppose that initially the magnetic field was directed along the c-axis and now we rotate it in the X-Z plane by the angle $\widetilde{\theta}$ with respect to the initial direction. The conductivity tensor will be transformed by the usual matrix law:

$$\widetilde{\sigma}_{\alpha\beta}(\widetilde{\theta}) = R^T_{\alpha\mu}\widetilde{\sigma}_{\mu\rho}(0)R_{\rho\beta} = R^T_{\alpha\mu}(T^{-1})_{\mu\varsigma}\sigma_{\varsigma\eta}(0)(T^{-1})_{\eta\delta}R_{\delta\beta}$$

and

$$\sigma_{\alpha\beta}(\widetilde{\theta}) = T_{\alpha\gamma}\widetilde{\sigma}_{\gamma\delta}(\widetilde{\theta})T_{\delta\beta} = T_{\alpha\gamma}R^T_{\gamma\mu}(T^{-1})_{\mu\varsigma}\sigma_{\varsigma\eta}(0)(T^{-1})_{\eta\delta}R_{\delta\kappa}T_{\kappa\beta},$$

where

$$R_{\alpha\beta} = \begin{pmatrix} \cos\widetilde{\theta} & 0 & -\sin\widetilde{\theta} \\ 0 & 1 & 0 \\ \sin\widetilde{\theta} & 0 & \cos\widetilde{\theta} \end{pmatrix}.$$

Finally the fluctuation conductivity tensor $\sigma_{\alpha\beta}(\theta)$ in the initial tetragonal system with the magnetic field directed at the angle θ with respect to the c-axis can be expressed by means of the effective transformation operator $M_{\alpha\beta}$:

$$\sigma_{\alpha\beta}(\theta) = M^{T}_{\alpha\varsigma}(\widetilde{\theta})\sigma_{\varsigma\eta}(0,\widetilde{H})M_{\eta\beta}(\widetilde{\theta}),$$

with

$$M_{\alpha\beta}(\widetilde{\theta}) = (T^{-1})_{\alpha\delta}R_{\delta\kappa}T_{\kappa\beta} = \begin{pmatrix} \cos\widetilde{\theta} & 0 & -\frac{1}{\gamma}\sin\widetilde{\theta} \\ 0 & 1 & 0 \\ \gamma_a\sin\widetilde{\theta} & 0 & \cos\widetilde{\theta} \end{pmatrix}.$$

The angle $\widetilde{\theta}$ can be expressed via the renormalized magnitude of the magnetic field $\widetilde{H} = \sqrt{H_c^2 + \gamma_a^2 H_x^2}$:

$$\cos\widetilde{\theta} = \frac{\widetilde{H}_z}{\widetilde{H}} = \frac{\cos\theta}{\sqrt{\cos^2\theta + \gamma_a^2\sin^2\theta}}; \sin\widetilde{\theta} = \frac{\gamma_a\sin\theta}{\sqrt{\cos^2\theta + \gamma_a^2\sin^2\theta}}.$$

In the case of the paraconductivity of a layered superconductor with the magnetic field applied at an arbitrary angle θ the answer can be written in the general form by means of the three diagonal components of conductivity $\sigma_{ii}(0,\widetilde{H})$ in the perpendicular field $\widetilde{H}$:

$$\sigma_{\alpha\beta}(\theta) = \frac{1}{\cos^2\theta + \gamma_a^2\sin^2\theta} \times$$
$$\times \begin{pmatrix} \sigma_{xx}\cos\theta + \\ +\gamma_a^4\sigma_{zz}\sin^2\theta & 0 & \sigma_{zz}^2\gamma_a\sin^2\theta\cos\theta - \\ & & -\sigma_{xx}\sin\theta \\ 0 & \sigma_{yy}(\cos^2\theta + \gamma_a^2\sin^2\theta) & 0 \\ \sigma_{zz}^2\gamma_a\sin\theta\cos\theta & 0 & \sigma_{zz}\cos^2\theta \end{pmatrix}$$

In the simplest case of a longitudinal field $\theta = 90^0$:

$$\sigma_{\alpha\beta}(90^0, H) = \begin{pmatrix} \gamma_a^2\sigma_{zz}(0,\gamma_a H) & 0 & -\gamma_a^{-2}\sigma_{zz}(0,\gamma_a H) \\ 0 & \sigma_{yy}(0,\gamma_a H) & 0 \\ 0 & 0 & 0 \end{pmatrix}. \tag{20.125}$$

20.4 Fluctuations near superconductor-insulator transition

20.4.1 Quantum phase transition

It is usually supposed that the temperature of the superconducting transition does not depend on the concentration of non-magnetic impurities (Anderson's theorem [79, 80]). Nevertheless when the degree of disorder is very high Anderson localization takes place, and it would be difficult to expect that under conditions of strong electron localization superconductivity can exist, even if there is inter-electron attraction. This means that at $T = 0$ the phase transition takes place with a change of the disorder strength or carrier concentration. Such a transition is called a quantum phase transition since at zero temperature the classical fluctuations are

absent. Indeed, one can see from (20.7) that in the limit $T \to 0$ the thermal fluctuation Cooper pairs vanish.

In the metallic phase of a disordered system the conductivity is mostly determined by the weakly decaying fermionic excitations, their dynamics yielding the familiar Drude formula (the method which accounts for the fermionic excitations will be referred to as the Fermi approach later on). Inside the critical region the charge transfer due to fluctuation Cooper pairs turns out to be more important. In some approximation, the pairs may be considered as Bose particles. Therefore the approach dealing with the fluctuation pairs will be called below the Bose approach.

Let us suppose that at temperature $T = 0$ the superconducting state occurs in a weakly disordered system. In principle two scenarios of the development of the situation are possible with an increase of the disorder strength: the system at some critical disorder strength can go from the superconducting state to the metallic state or to the insulating state. The first scenario is natural and takes place in the following cases: if the effective constant of the inter-electron interaction changes its sign with the growth of the disorder; if the effective concentration of magnetic impurities increases together with the disorder growth; if the pairing symmetry of superconducting state is nontrivial it can be destroyed even by the weak disorder level. We will study here the second scenario where the superconductor becomes an insulator with disorder increase. This means that at some disorder degree range, higher than the localization edge when the normal phase does not exist any more at finite temperatures, superconductivity can still survive. From the first glance this statement seems strange: what does superconductivity mean if the electrons are already localized? And if it really can take place beyond the metallic phase, at what value of disorder strength and in which way does the superconductivity finally disappears?

One has to have in mind that localization is a quantum phenomenon in its nature and with the approach to the localization edge the coherence length of localization ℓ grows. From the insulator side of the transition vicinity this means the existence of large scale regions where delocalized electrons exist. If the energy level spacing in such regions does not exceed the value of superconducting gap Cooper pairs still can be formed by the delocalized electrons of this region.

The problem can be reformulated in other, already familiar, way: how does the critical temperature of the superconducting transition decrease with the increase of the disorder strength? In the previous Sections we have already tried to solve it by discussing the critical temperature fluctuation shift. We have seen that the fluctuation shift of the critical temperature is proportional to $\sqrt{Gi_{(3)}}$ for a $3D$ superconductor and to $Gi_{(2)} \ln\{1/Gi_{(2)}\}$ for $2D$. This means that the critical temperature is not changed noticeably as long as the Ginzburg-Levanyuk number remains small. So one can expect the complete suppression of superconductivity when $Gi \sim 1$ only. For further consideration it is convenient to separate the $3D$ and $2D$ cases because the physical pictures of the superconductor-insulator transition for them are quite different.

20.4.2 3D superconductors

As one can see from Table 1 in the $3D$ case the Ginzburg-Levanyuk number remains small at $p_F l \sim 1$: $Gi_{(3d)} \approx \left(\frac{T_c}{E_F}\right) \ll 1$. Nevertheless, approaching the edge of localization, the width of the fluctuation region increases [81]. In the framework of the self-consistent theory of localization [82] such growth of the width of the fluctuation region was found in paper [83].

Instead of the cited self-consistent theory let us make some more general assumptions concerning the character of the metal-insulator (M-I) transition in the absence of superconductivity [13]. We suppose that in the case of very strong disorder and not very strong Coulomb interaction the M-I transition is of second order. The role of "temperature" for this transition is

played by the "disorder strength" which is characterized by the dimensionless value $g = \frac{p_F l.}{2\pi}$ With its decrease the conductivity of the metallic phase decreases and at some critical value g_c tends to zero as

$$\sigma = e^2 p_F (g - g_c)^{\varkappa}. \tag{20.126}$$

This is the critical point of the Anderson (M-I) transition. We assume that the thermodynamic density of states remains constant at the transition point.

The electron motion in metallic phase far enough from the M-I transition has a diffusion character and the conductivity can be related to the diffusion coefficient $\mathcal{D} = p_F l/3m$ by the Einstein relation: $\sigma = \nu e^2 \mathcal{D}$. One can say that diffusion like "excitations" with the spectrum $\omega(q) = iDq^2$ propagate in the system. At the point of the M-I transition normal diffusion terminates and conductivity, together with $\mathcal{D}$, turns zero. In accordance with scaling ideas, the diffusion coefficient can be assumed here to be a power function of q: $\mathcal{D}(q) \sim q^{z-2}$, with the dynamical critical exponent $z > 2$. The anomalous diffusion excitation spectrum in this case would take the form $\omega \sim q^z$.

In the insulating phase ($g < g_c$) some local, anomalous diffusion, confined to regions of the scale ℓ, is still possible. It cannot provide charge transfer through out all the system, so $\mathcal{D}(q = 0) = 0$, but for small distances ($q \gtrsim \ell^{-1}$) anomalous diffusion takes place. Analogously, in the metallic phase ($g > g_c$) the diffusion coefficient in the vicinity of the transition has an anomalous dependence on q for $q \gtrsim \ell^{-1}$ and weakly depends on it for $q \lesssim \ell^{-1}$. So one can conclude that the diffusion coefficient for $q \gtrsim \ell^{-1}$ from both sides of the transition has the same q-dependence as for all q in the transition point. It can be written in the form

$$\mathcal{D}(q) = \frac{g}{3m}\left[\frac{\varphi(q\ell)}{p_F \ell}\right]^{z-2}, \quad \varphi(x) = \begin{cases} x, \ x \gg 1 \\ 1, \ x \ll 1, g > g_c \\ 0, \ x \ll 1, g < g_c \end{cases}, \tag{20.127}$$

where the dimensionless localization length ℓ, characterizing the spatial scale near the transition, grows with the approach to the transition point like

$$\ell(g) = \frac{1}{p_F}(g - g_c)^{-\frac{\varkappa}{z-2}}. \tag{20.128}$$

The critical exponent in this formula is found from the Einstein relation in the vicinity of the M-I transition.

At finite temperatures, instead of the critical point g_c,a crossover from metallic to insulating behavior of $\sigma(g)$ takes place. The width of the crossover region is $\widetilde{g} - g_c$,where $\widetilde{g}$ is determined from the relation $\mathcal{D}\ell^{-2}(\widetilde{g}) \sim E_F[p_F \ell(\widetilde{g})]^{-z} \sim T$ (we have used the second asymptotic of (20.127)). In this region the diffusion coefficient is

$$\mathcal{D}(T) \sim T\ell^2 \sim \frac{T}{p_F^2}\left(\frac{E_F}{T}\right)^{\frac{2}{z}} \tag{20.129}$$

and it depends weakly on the $g - g_c$. Beyond this region the picture of the transition remains the same as at $T = 0$.

Let us consider now what happens to superconductivity in the vicinity of the localization transition. In the mean field approximation (BCS) the thermodynamic properties of a superconductor do not depend on the character of the diffusion of excitations. This should be contrasted with the fluctuation theory, where such a dependence clearly exists. We will show that the type of superconducting transition depends on the dynamical exponent z. If $z > 3$, the transition to superconductivity occurs on the metallic side of the localization transition (we will refer to such a transition as S-N transition). If $z < 3$, the transition to superconductivity occurs from the insulating state directly (S-I transition).

Let us study how the superconducting fluctuations affect the transition under discussion. In spirit of the GL approach fluctuation phenomena in the vicinity of the transition can be described in the framework of the GL functional (20.26). The coherence length in the metallic region, far enough from the Anderson transition, was reported in Introduction to be equal $\xi^2 = \xi_c l = 0.42\mathcal{D}/T$. In the vicinity of the M-I transition we still believe in the diffusive character of the electron motion resulting in the pair formation. The only difference from the previous consideration is the anomalous character of the quasiparticle diffusion. So in order to describe the superconducting fluctuations simultaneously near superconducting (in temperature) and Anderson (in g) transitions let us use the GL functional (20.26) with the k-dependent diffusion coefficient (20.127).

The value of Gi can be estimated from the expression for the fluctuation contribution to heat capacity (20.30) taken at $\epsilon \sim Gi$, where the fluctuation correction reaches the value of the heat capacity jump:

$$1 \sim \frac{T}{\nu}\int \frac{d^3q}{\left(TGi + \mathcal{D}(q)q^2\right)^2}, \tag{20.130}$$

with $T \simeq T_c$. Let us approach the M-I transition from the metallic side. If we are far enough from transition, Gi is small and the integral in (20.130) is determined by the region of small momenta $\mathcal{D}(q)q^2 \lesssim TGi$:

$$Gi \sim \frac{T}{\nu^2\mathcal{D}^3(q=0)}. \tag{20.131}$$

Two scenarios are possible: Gi becomes of the order of 1 in the metallic phase, or it remains small up to the crossover region, where finally reaches its saturation value. In the first case we can use the second asymptotic of (20.127) for $D(q)$ and find:

$$Gi \sim \frac{T_c}{E_F}(p_F\ell)^{3z-6}. \tag{20.132}$$

One can see that Gi becomes of the order of 1 at $p_F\ell_M \sim (E_F/T)^{\frac{1}{3z-6}}$. Comparing this value with $p_F\ell(\widetilde{g}) \sim (E_F/T)^{1/z}$ at the limit of the crossover region we see that for $z > 3$ the first scenario is realized. Concluding the first scenario discussion we see that the superconducting critical temperature goes to zero at $\ell = \ell_M$, still in the metallic phase, so at $T = 0$ a superconductor-normal phase (S-N) type quantum phase transition takes place.

The second scenario takes place for $z < 3$ when Gi remains small even at the edge of crossover region, reaching there the value

$$Gi \sim \left(\frac{T_c}{E_F}\right)^{\frac{2(3-z)}{z}} \ll 1. \tag{20.133}$$

In the crossover region the diffusion coefficient, and hence Gi, almost do not vary. This is why the temperature of superconducting transition remains almost frozen with further increase of disorder driving the system through the Anderson transition. The abrupt growth of Gi and decrease of T_c take place when the system finally goes from the crossover to the insulating region. In the insulator phase the diffusion coefficient $D(q \lesssim l^{-1}) = 0$ and from (20.130) one can find for Gi :

$$Gi \sim \sqrt{\frac{E_F}{T_c}}\frac{1}{(p_F\ell)^{3/2}} \tag{20.134}$$

Comparing this result with the Table 1 it is easy to see that it coincides with the Ginzburg-Levanyuk number for a zero-dimensional granule of size $\ell \ll \xi(T)$. Hence we see that in the

Figure 20.5: Phase diagram in the temperature – disorder plane for a three-dimensional superconductor.

second scenario the Ginzburg number reaches 1 and, respectively, $T_c \to 0$ at $p_F \ell_I \sim \left(\frac{E_F}{T_c}\right)^{1/3}$, which is far enough from the M-I transition point. This is why in this case one can speak about the realization at $T = 0$ of a superconductor-insulator (S-I) type quantum phase transition. The scale ℓ_I determines the size of the "conducting" domains in the insulating phase, where the level spacing reaches the order of the superconducting gap. It is evident that in the domain of scale $\ell \lesssim \ell_I$ superconductivity cannot be realized.

In the vicinity of a quantum phase transition one can expect the appearance of non monotonic dependencies of the resistance on temperature and magnetic field. Indeed, starting from the zero resistance superconducting phase and increasing temperature from $T = 0$, the system passes through the localization region, where the resistance is high, to high temperatures where some hopping charge transfer will decrease the resistance again. The analogous speculations are applicable to the magnetic field effect: first the magnetic field "kills" superconductivity and increases the resistance, then it destroys localization and decreases it.

The phase diagram in the (T, g) plane has the form sketched in Fig. 20.5. For $g_I = g_c - (T_c/E_F)^{3(z-2)/\varkappa}$, an S-I transition takes place at $T = 0$. Increasing the temperature from $T = 0$ in the region $0 \lesssim g \lesssim g_I$ we remain in the insulating phase with exponential dependence of resistance on temperature. For $g_I \lesssim g \lesssim \widetilde{g}_-$ at low temperatures $0 \le T < T_c(g)$ the system stays in the superconducting state which goes to the insulating phase at higher temperatures. In the vicinity of the Anderson transition ($\widetilde{g}_- \lesssim g \lesssim \widetilde{g}_+$) the superconducting state goes with growth of the temperature to some crossover metal-insulator state which is characterized by a power decrease of the resistivity with the increase of temperature. Finally at $g_c \lesssim g$ the superconducting phase becomes of the BCS type and at $T = T_c$ it goes to a metallic phase.

The phase diagram in the magnetic field – disorder plane is similar to that in the (T, g) plane

with the only difference that at $T = 0$ there is no crossover region, instead a phase transition takes place.

20.4.3 2D superconductors

Preliminaries.

As was demonstrated in Section 4, according to the conventional theory of paraconductivity, the sheet conductivity in the vicinity of the superconducting transition is given by a sum of the electron residual conductivity ge^2 (Fermi part) and the conductivity of the Cooper pair fluctuations (Bose part) (see (20.99)). This expression is valid in the Ginzburg Landau region when the second term is a small correction to the first one. The width of the critical region can be determined from the requirement of equality of both contributions in (20.99)[19]:

$$\epsilon_{cr} = \frac{1}{16g} = 1.3Gi_{(2d)}. \tag{20.135}$$

In accordance with general scaling ideas one can believe that inside the fluctuation region the conductivity should obey the form:

$$\sigma(T) = ge^2 f\left(\frac{\epsilon}{Gi_{(2d)}}\right). \tag{20.136}$$

Concerning the scaling function $f(x)$, we know its asymptotes in the mean field region ($x \gg 1$) and just above the BKT transition [56, 57]:

$$f(x) = \begin{cases} 1 + x^{-1}, & x \gg 1 \\ \exp\left[-b(x - x_{\rm BKT})^{-1/2})\right], & x \to x_{\rm BKT} = -4 \end{cases}. \tag{20.137}$$

The BKT transition temperature $T_c^{\rm BKT}$ is determined by

$$n_{s2}(T_c) = \frac{4mT_c}{\pi}. \tag{20.138}$$

and one can find its value by comparing the superfluid density n_s from (20.138) with that found in the BCS scheme:

$$T_c^{\rm BKT} = T_{c0}(1 - 4Gi). \tag{20.139}$$

Here we assumed that the Ginzburg parameter is small, so that the BKT transition temperature does not deviate much from the mean-field BCS transition temperature T_{c0}.

Boson mechanism of the T_c suppression.

The classical and quantum fluctuations reduce n_s and therefore, suppress $T_c^{\rm BKT}$. At some $g = g_c \sim 1$, the superfluid density n_s, and simultaneously $T_c^{\rm BKT}$, go to zero. In the vicinity of this critical concentration of impurities $T_c^{\rm BKT} \ll T_{c0}$. Thus a wide new window of intermediate temperatures $T_c^{\rm BKT} \ll T \ll T_{c0}$ opens up. In this window, according the dynamical quantum scaling conjecture [84], one finds

$$\sigma = e^2\varphi\left(\frac{T}{T_c^{BKT}}\right). \tag{20.140}$$

At $T - T_c^{\rm BKT} \ll T_c^{\rm BKT}$ the Berezinski-Kosterlitz-Thouless law (20.136)-(20.137) should hold, so $\varphi(x) = f(x)$ and is exponentially small. In the intermediate region $T_c^{\rm BKT} \ll T \ll T_c^{\rm BCS}$ the duality hypothesis gives $\varphi(x) = \pi/2$. Let us derive this relation.

[19] It is worth mentioning that this definition of the Ginzburg Levanyuk number ($\widetilde{Gi}_{(2d)} = \frac{\pi}{8p_F l}$) agrees with that defined from the heat capacity fluctuations ($Gi_{(2d)} = \frac{0.3}{p_F l}$).

We will start from the assumption that in the region $T_c^{\rm BKT} \ll T \ll T_{c0}$ the conductivity is a universal function of temperature which does not depend on the pair interaction type. Being in the framework of the classical approach, let us suppose that in a weak electric field pairs move with the velocity $\mathbf{v} = \mathbf{F}/\eta$, where $\mathbf{F} = 2e\mathbf{E}$ is the force acting on the pairs. The current density $\mathbf{j} = 2en\mathbf{v} = \sigma\mathbf{E}$, (here n is the pair density), so one can relate the conductivity with the effective viscosity η: $\sigma = 4e^2 n/\eta$.

Let us recall that we are dealing with a quantum fluid, so another, superconducting, view on the problem of its motion near the quantum phase transition exists. One can say that with the increase of Gi the role of quantum fluctuations grows too and fluctuation vortices carrying the magnetic flux quantum $\Phi_0 = \pi/e$ are generated. With electric current flow in the system the Lorentz (Magnus) force acts on a vortex: $F = j\Phi_0$. The electric field is equal to the rate of magnetic flux transfer, i.e. to the density of the vortex current: $\mathbf{E} = \Phi_0 n_v \mathbf{v}_v = \Phi_0 n_v \mathbf{F}/\eta_{\mathbf{v}}$, where n_v is the density and η_v is the viscosity of the vortex liquid. As a result $\mathbf{E} = \Phi_0^2 n_v \mathbf{j}/\eta_{\mathbf{v}} = \mathbf{j}/\sigma$. So one can conclude that for vortices the velocity is proportional to the voltage, and the force is proportional to the current. For Cooper pairs (bosons) the situation is exactly the opposite.

The duality hypothesis consists in the assumption that at the critical point the pair and the vortex liquid density flows are equal: $n_v \mathbf{v}_v = n\mathbf{v}$. Comparing these quantities, expressed in terms of the conductivity from the above relations, one can find a universal value for the conductivity at the critical point

$$\sigma = \frac{2e}{\Phi_0} = \frac{2e^2}{\pi}. \tag{20.141}$$

One can restrict oneself to a less strong duality hypothesis, supposing the product $n\eta = CT^\delta$ with a universal δ exponent both for the pair and the vortex liquids, while the constant C for them is different. In this case, based on duality, is possible to demonstrate that $\delta = 0$ and the conductivity is temperature independent up to T_{c0} but its value is not universal any more and can vary from one sample to another.

To conclude, let us emphasize that in the framework of the boson scenario of superconductivity suppression, the BCS critical temperature is changed insignificantly, while the "real" superconducting transition temperature $T_c^{\rm BKT} \to 0$.

Fermion mechanism of T_c suppression.

Apart from the above fluctuation (boson) mechanism of the suppression of the critical temperature in the $2D$ case, there exists another, fermionic mechanism. The suppressed electron diffusion results in a poor dynamical screening of the Coulomb repulsion which, in turn, leads to the renormalization of the inter-electron interaction in the Cooper channel. and hence to the dependence of the critical temperature on the value of the high-temperature sheet resistivity of the film. As long as the correction to the non-renormalized BCS transition temperature T_{c0} is still small, one finds [85, 86, 87]:

$$T_c = T_{c0}\left(1 - \frac{1}{12\pi^2 g}\ln^3\frac{1}{T_{c0}\tau}\right). \tag{20.142}$$

At small enough T_{c0} this mechanism of critical temperature suppression turns out to be the principal one. The suppression of T_c down to zero in this case may happen in principle even at $g \gg 1$. A renormalization group analysis gives [88] the corresponding critical value of conductance

$$g_c = \left(\frac{1}{2\pi}\ln\frac{1}{T_{c0}\tau}\right)^2. \tag{20.143}$$

Here we should recall that the typical experimental [89] values of g_c are in the region $g_c \sim 1-2$, and do not differ dramatically from the predictions of the boson duality assumption

$g_c = \frac{2}{\pi}$. If one attempts to explain the suppression of T_c within the fermion mechanism, one should assume that $\ln \frac{1}{T_{c0}\tau} > 5$. Then, according to Eq. (20.143), $g_c > 2/\pi$ and the boson mechanism is not important. On the contrary, if $\ln \frac{1}{T_{c0}\tau} < 4$, then Eq. (20.142) gives a small correction for T_c even for $g_c = 2/\pi$ and the fermion mechanism becomes unimportant. The smallness of the critical temperature T_c compared to the Fermi energy is the cornerstone of the BCS theory of superconductivity and it is apparently satisfied even in high-T_c materials. Nevertheless it is necessary to use the theoretically large logarithmic parameter with care, if one needs $\ln \frac{1}{T_{c0}\tau}$ to be as large as 4.

20.5 Microscopic derivation of the Time-Dependent Ginzburg-Landau equation

20.5.1 Preliminaries

We have seen above how the phenomenological approach based on the GL functional allows one to describe fluctuation Cooper pairs (Bose particles) near the superconducting transition and to account for their contribution to different thermodynamical and transport characteristics of the system. Now we pass to the discussion of the microscopic description of fluctuation phenomena in superconductors. The development of the microscopic approach is necessary for the following reasons:

1. This description permits microscopic determination of the values of the phenomenological parameters of the GL theory.

2. This method is more powerful than the phenomenological GL approach and permits treatment of fluctuation effects quantitatively even far from the transition point and for magnetic fields strong as H_{c2}, taking into account the contributions of dynamical and short wavelength fluctuations.

3. The electron energy relaxation times in metals are relatively large ($\tau_\varepsilon \gg \hbar/T$) which causes the electron low frequency dynamics to be sensitive to the nearness to the superconducting transition. This is why the temperature dependence of fluctuation corrections can be determined generally speaking not only by the Cooper pair motion but also by changes in the single-electron properties.

4. There are some fluctuation phenomena in which the direct Cooper pair contribution is considerably suppressed or even absent altogether. Among them we can mention the nuclear magnetic relaxation rate, tunnel conductivity, c-axis transport in strongly anisotropic layered metals, thermoelectric power and heat conductivity where the fluctuation pairing manifests itself by means of the indirect influence on the properties of the single-particle states of electron system.

Formally in the above consideration averaging over the superconducting order parameter has been accomplished by means of a functional integration over all its possible bosonic field configurations. In this description we have dealt with the fluctuation Cooper pair related effects only and the method of the functional integration turned out to be simple and effective for their description. In the following Sections we will develop the diagrammatic method of Matsubara temperature Green functions which is more adequate for the description of the properties of a Fermi system of interacting electrons.

20.5.2 The Cooper channel of electron-electron interaction

Let us start the microscopic description of fluctuation phenomena in a superconductor from the electron Hamiltonian. We will choose it in the simple BCS form[20]:

$$\mathcal{H} = \sum_{\mathbf{p},\sigma} E(\mathbf{p}) \widetilde{\psi}^{+}_{\mathbf{p},\sigma} \widetilde{\psi}_{\mathbf{p},\sigma} + g \sum_{\mathbf{p},\mathbf{p}',\mathbf{q},\sigma,\sigma'} \widetilde{\psi}^{+}_{\mathbf{p}+\mathbf{q},\sigma} \widetilde{\psi}^{+}_{-\mathbf{p},-\sigma} \widetilde{\psi}_{-\mathbf{p}',-\sigma'} \widetilde{\psi}_{\mathbf{p}'+\mathbf{q},\sigma'}. \tag{20.144}$$

The momentum conservation law side by side with singlet pairing are already taken into account in the interaction term. Here $E(\mathbf{p})$ is the quasiparticle spectrum of the normal metal; g is the negative constant of electron-electron attraction which is supposed to be momentum independent and different from zero in a narrow domain of momentum space in the vicinity of the Fermi surface where

$$p_F - \frac{\omega_D}{v_F} < |\mathbf{p}|, |\mathbf{p}'| < p_F + \frac{\omega_D}{v_F}.$$

$\widetilde{\psi}^{+}_{\mathbf{p},\sigma}$ and $\widetilde{\psi}_{\mathbf{p},\sigma}$ are the creation and annihilation field operators in the Heisenberg representation, so the first term is just the kinetic energy of the non-interacting Fermi gas. The interaction term is chosen in the traditional form characteristic for the electron-phonon mechanism of superconductivity[21].

For the description of the properties of an interacting electron system with the Hamiltonian (20.144) we will use the formalism of the Matsubara temperature diagrammatic technique. The state of a non-interacting quasiparticle is described by its Green function

$$G(\mathbf{p}, \varepsilon_n) = \frac{1}{i\varepsilon_n - \xi(\mathbf{p})}, \tag{20.145}$$

where $\varepsilon_n = (2n+1)\pi T$ is a fermion Matsubara frequency and $\xi(\mathbf{p}) = E(\mathbf{p}) - E_F$ is the quasiparticle energy measured from the Fermi level.

As it is well known the effective electron-electron attraction leads to a reconstruction of the ground state of the electron system which formally manifests itself by the appearance at the critical temperature of a pole in the two particle Green function

$$\mathcal{L}(p, p', q) = < T_\tau [\widetilde{\psi}_{p+q,\sigma} \widetilde{\psi}_{-p,-\sigma} \widetilde{\psi}^{+}_{p'+q,\sigma'} \widetilde{\psi}^{+}_{-p',-\sigma'}] >,$$

where T_τ is the time ordering operator and $4D$ vector notations are used [92]. As it well known the two particle Green function can be expressed in terms of the vertex part [92]. In the case under consideration it is the vertex part of the electron-electron interaction in the Cooper channel $L(\mathbf{q}, \Omega_k)$, which will be called below the fluctuation propagator**.** The Dyson equation for $L(\mathbf{q}, \Omega_k)$, accounting for the e-e attraction in the ladder approximation, is represented graphically in Fig.20.6. It can be written down analytically as

$$L^{-1}(\mathbf{q}, \Omega_k) = g^{-1} - \Pi(\mathbf{q}, \Omega_k), \tag{20.146}$$

where the polarization operator $\Pi(\mathbf{q}, \Omega_k)$ is defined as a loop of two single-particle Green functions:

[20] We suppose that reader is familiar with the BCS formulation of the theory of superconductivity (see for example, [92]).

[21] Fluctuations in the framework of more realistic Eliashberg [90] model of superconductivity were studied by B.Narozhny [91]. He demonstrated that the strong coupling does not change drastically the results of the weak coupling approximation. The critical exponents turn out to be exactly the same as in the framework of the GL theory, which provides an adequate description of paraconductivity in strong coupling superconductors. The robustness of the critical exponents and their dependence in GL region on the space dimensionallity only was stressed in [83] in relation to the discussion of the paraconductivity at the edge of the superconductor-insulator transition.

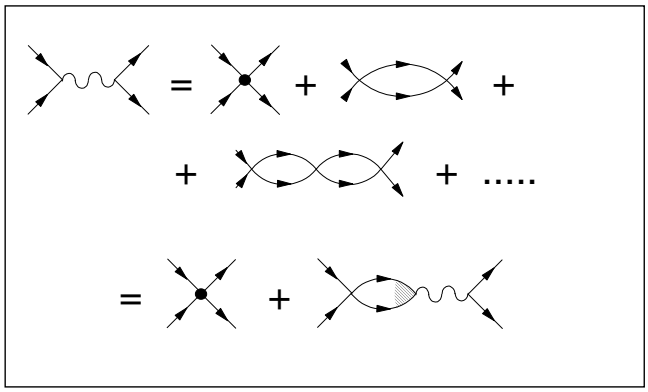

Figure 20.6: The Dyson equation for the fluctuation propagator (wavy line) in the ladder approximation. Solid lines represent one-electron Green functions, bold points correspond to the model electron-electron interaction.

$$\Pi(\mathbf{q},\Omega_k) = T\sum_{\varepsilon_n}\int \frac{d^3\mathbf{p}}{(2\pi)^3} G(\mathbf{p}+\mathbf{q},\varepsilon_{n+k})G(-\mathbf{p},\varepsilon_{-n}). \tag{20.147}$$

Let us emphasize, that the two quantities introduced above, $\mathcal{L}(p,p',q)$ and $L(q)$, are closely connected with each other. The former being integrated over momenta p and p' becomes an average of the product of two order parameters:

$$\int dpdp'\mathcal{L}(p,p',q) = \frac{1}{g^2}\left\langle \Delta_q\Delta_q^*\right\rangle, \tag{20.148}$$

where Δ_q is the superconducting gap proportional to the condensate wave function Ψ. Thus, this quantity represents the coefficient in the linear term in the GL equation. In terms of the polarization operator introduced above it can be written as

$$\int dpdp'\mathcal{L}(p,p',q) \propto \frac{\Pi}{1-g\Pi}.$$

Comparing this equation with Eq.(20.146) for the fluctuation propagator we see that the corresponding expressions are very similar. After analytical continuation to the real frequencies the fluctuation propagator $L(q,i\Omega)$ coincides with the quantity defined by Eq.(20.148) (up to a constant).

One can calculate the propagator (20.146) using the one-electron Green functions of the normal metal (20.145). For sake of convenience of future calculations let us define the correlator of two one-electron Green functions

$$\begin{aligned}\mathcal{P}(\mathbf{q},\varepsilon_1,\varepsilon_2) &= \int \frac{d^3\mathbf{p}}{(2\pi)^3} G(\mathbf{p}+\mathbf{q},\varepsilon_1)G(-\mathbf{p},\varepsilon_2) = \\ &= 2\pi\nu\Theta(-\varepsilon_1\varepsilon_2)\left\langle \frac{1}{|\varepsilon_1-\varepsilon_2| + i\Delta\xi(\mathbf{q},\mathbf{p})|_{\epsilon(\mathbf{p})=E_F}}\right\rangle_{F.S.},\end{aligned} \tag{20.149}$$

where $\Theta(-\varepsilon_1\varepsilon_2)$ is Heavyside step function, ν is the one-electron density of states, $<>_{F.S.}=\int\frac{d\Omega_{\mathbf{p}}}{4\pi}$ means the averaging over the Fermi surface,

$$\Delta\xi(\mathbf{q},\mathbf{p})|_{\epsilon(\mathbf{p})=E_F} = [\xi(\mathbf{q}+\mathbf{p})-\xi(-\mathbf{p})]|_{\epsilon(\mathbf{p})=E_F} \approx (\mathbf{v_p q})_{\xi(\mathbf{p})=0}.$$

The last approximation is valid not too far from the Fermi surface, i.e. when $(\mathbf{v_p q})_{\xi(\mathbf{p})=0} \ll E_F$.

It is impossible to carry out the angular averaging in (20.149) for a general anisotropic spectrum. Nevertheless in the following calculations of fluctuation effects in the vicinity of critical temperature only small momenta $\mathbf{v_p q} \ll T$ will be involved in the integrations, so we can restrict our consideration here to this region, where one can expand the integrand in powers of $\mathbf{v_p q}$. Indeed, the presence of $\Theta(-\varepsilon_1\varepsilon_2)$ leaves the difference of the two fermionic frequencies in (20.149) to be of the order of the temperature which permits this expansion. The first term in $\mathbf{v_p q}$ will evidently be averaged out, so with quadratic accuracy one can find:

$$\mathcal{P}(\mathbf{q},\varepsilon_1,\varepsilon_2) = 2\pi\nu\frac{\Theta(-\varepsilon_1\varepsilon_2)}{|\varepsilon_1-\varepsilon_2|}\left(1-2\frac{\langle(\mathbf{v_p q})^2\rangle_{F.S.}}{|\varepsilon_1-\varepsilon_2|^2}\right). \tag{20.150}$$

Now one can calculate the polarization operator

$$\begin{aligned}\Pi(\mathbf{q},\Omega_k) &= T\sum_{\varepsilon_n}\mathcal{P}(\mathbf{q},\varepsilon_{n+k},\varepsilon_{-n}) = \\ &= \nu\left[\sum_{n\geq 0}\frac{1}{n+1/2+\frac{|\Omega_k|}{4\pi T}} - 2\frac{\langle(\mathbf{v_p q})^2\rangle_{F.S.}}{(4\pi T)^2}\sum_{n=0}^{\infty}\frac{1}{\left(n+1/2+\frac{|\Omega_k|}{4\pi T}\right)^3}\right].\end{aligned} \tag{20.151}$$

The calculation of the sums in (20.151) can be carried out in terms of the logarithmic derivatives of the Γ-function $\psi^{(n)}(x)$. It worth mentioning that the first sum is well known in the BCS theory, one can recognize in it the so-called "Cooper logarithm"; its logarithmic divergence at the upper limit ($\psi(x\gg 1)\approx \ln x$) is cut off by the Debye energy ($N_{\max} = \frac{\omega_D}{2\pi T}$) and one gets:

$$\begin{aligned}\frac{1}{\nu}\Pi(\mathbf{q},\Omega_k) &= \psi\left(\frac{1}{2}+\frac{|\Omega_k|}{4\pi T}+\frac{\omega_D}{2\pi T}\right)-\psi\left(\frac{1}{2}+\frac{|\Omega_k|}{4\pi T}\right)- \\ &\quad -\frac{\langle(\mathbf{v_p q})^2\rangle_{F.S.}}{(4\pi T)^2}\psi''\left(\frac{1}{2}+\frac{|\Omega_k|}{4\pi T}\right).\end{aligned} \tag{20.152}$$

The critical temperature in the BCS theory is determined as the temperature T_c at which the pole of $L(0,0,T_c)$ occurs

$$L^{-1}(\mathbf{q}=0,\Omega_k=0,T_c) = g^{-1}-\Pi(0,0,T_c) = 0,$$

$$T_c = \frac{2\gamma_E}{\pi}\omega_D\exp\left(-\frac{1}{\nu g}\right), \tag{20.153}$$

where $\gamma_E = 1.78$ is the Euler constant. Introducing the reduced temperature $\epsilon = \ln(\frac{T}{T_c})$ one can write the propagator as

$$L^{-1}(\mathbf{q},\Omega_k) = -\nu\left[\epsilon+\psi(\frac{1}{2}+\frac{|\Omega_k|}{4\pi T})-\psi(\frac{1}{2})-\frac{\langle(\mathbf{v_p q})^2\rangle_{F.S.}}{(4\pi T)^2}\psi''\left(\frac{1}{2}+\frac{|\Omega_k|}{4\pi T}\right)\right]. \tag{20.154}$$

We found (20.154) for bosonic imaginary Matsubara frequencies $i\Omega_k = 2\pi i T k$. These frequencies are necessary for the calculation of fluctuation contributions to any thermodynamical characteristics of the system.

In the vicinity of the transition point one can restrict oneself in summations of the expressions with $L(\mathbf{q},\Omega_k)$ over Matsubara frequencies to the so-called static approximation, taking into account the term with $\Omega_k = 0$ only, which turns out to be the most singular term in $\epsilon \ll 1$. This approximation physically means that the product of Heisenberg field operators

$\widetilde{\psi}_{p,\sigma}\widetilde{\psi}_{-p,-\sigma}$ appears here like a classical field Ψ, which in the phenomenological approach describes the Cooper pair wave function and in the vicinity of critical temperature is proportional to the fluctuation order parameter. Having in mind namely this GL region of temperatures we restricted ourselves above by the assumption of small momenta $\mathbf{v_p q} \ll T$. In these conditions the static propagator reduces to

$$L(\mathbf{q},0) = -\frac{1}{\nu}\frac{1}{\epsilon + \xi^2\mathbf{q}^2}. \tag{20.155}$$

With an accuracy of a numerical factor and the total sign this correlator coincides with the expression for $\langle|\Psi_{\mathbf{q}}|^2\rangle$. By this expression we also have finally obtained the microscopic value of the coherence length ξ for a clean superconductor with an isotropic D-dimensional Fermi surface which was often mentioned previously (compare with (20.5))

$$\xi^2_{(D)} = \frac{7\zeta(3)\mathbf{v}_\mathbf{F}^2}{16D\pi^2T^2}.. \tag{20.156}$$

In order to describe the fluctuation contributions to transport phenomena one has to start from the analytical continuation of the propagator (20.154) from the discrete set of $\Omega_k \geq 0$ to the whole upper half-plane of imaginary frequencies. The analytical properties of $\psi^{(n)}(x)-$functions (which have poles at $x = 0, -1, -2...$) permit one to obtain the retarded propagator $L^R(\mathbf{q}, -i\Omega)$ by simple substitution $i\Omega_k \to \Omega$. For small $\Omega \ll T$ the $\psi-$functions can be expanded in $-i\Omega/4\pi T$ and the propagator acquires the simple pole form:

$$L^R(\mathbf{q},\Omega) = -\frac{1}{\nu}\frac{1}{-\frac{i\pi}{8T}\Omega + \epsilon + \xi^2\mathbf{q}^2} = \frac{8T}{\pi\nu}\frac{1}{i\Omega - \left(\tau_{GL}^{-1} + \frac{8T}{\pi}\xi^2\mathbf{q}^2\right)}. \tag{20.157}$$

This expression provides us with the microscopic value of the GL relaxation time $\tau_{GL} = \frac{\pi}{8(T-T_c)}$, widely used above in the phenomenological theory. Moreover, comparison of the microscopically derived (20.157) with the phenomenological expressions (20.85), (20.89) and (20.106) shows that $\alpha T_c = \nu$ and $\gamma_{GL} = \pi\nu/8T_c$.

In evaluating $L(\mathbf{q}, \Omega_k)$ we neglected the effect of fluctuations on the one-electron Green functions. This is correct when fluctuations are small, i.e. not too near to the transition temperature. The exact criterion of this approximation will be discussed in the following.

20.5.3 Superconductor with impurities

Account for impurities.

In order to study fluctuations in real systems like superconducting alloys or high temperature superconductors one has to perform an impurity average in the graphical equation for the fluctuation propagator (see Fig. 20.6). This procedure can be done in the framework of the Abrikosov-Gorkov approach [92], which we shortly recall below.

Let us start from the equation for the electron Green function in the potential of impurities $U(\mathbf{r})$:

$$\left(E - U(\mathbf{r}) - \widehat{H}\right) G_E(\mathbf{r},\mathbf{r}') = \delta(\mathbf{r}-\mathbf{r}') \tag{20.158}$$

If we solve this equation using the perturbation theory for the impurity potential and average the solution, then the average product of two Green functions, can be presented as series, each term of which is associated with a graph drawn according the rules of diagrammatic technique (see Fig. 20.7). In this technique solid lines correspond to bare Green functions and dashed lines to random potential correlators. We assume that the impurity system random potential

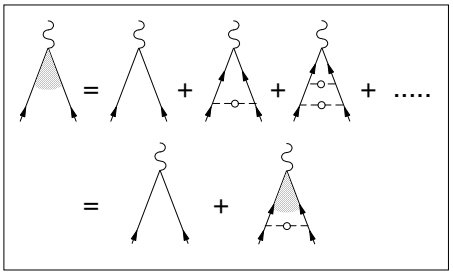

Figure 20.7: The equation for the vertex part $\lambda(q, \omega_1, \omega_2)$ in the ladder approximation. Solid lines correspond to bare one-electron Green functions and dashed lines to the impurity random potential correlators.

$U(r)$ is distributed according to the Gauss $\delta-$correlated law. Then all the correlators can be represented as the products of pair correlators

$$\langle U(r)\rangle = 0,\ \langle U(r)U(r')\rangle = \left\langle U^2\right\rangle \delta(r-r'), \tag{20.159}$$

where the angle brackets denote averaging over the impurity configuration. Equation 20.159 corresponds to the Born approximation for the electron interaction with short range impurities, and $\langle U^2\rangle = C_{imp}\left(\int V(\mathbf{r})d\mathbf{r}\right)^2$ where C_{imp} is the impurity concentration and $V(\mathbf{r})$ is the potential of the single impurity.

In conductors (far enough from the metal-insulator transition) the mean free path is much greater than the electron wavelength $l \gg \lambda = 2\pi/p_F$ (which in practice means the mean free path up to tens of interatomic distances). As is well known [92] for the electron spectra with dimensionality $D > 1$ the angular integration in momentum space reduces considerably the contribution of the diagrams with intersecting impurity lines what permits to omit them to the leading approximation in $(p_F l)^{-1}$. In this approximation the one-electron Green function keeps the same form as the bare one (20.145) with the only substitution

$$\varepsilon_n \Rightarrow \widetilde{\varepsilon}_n = \varepsilon_n + \frac{1}{2\tau} sign(\varepsilon_n), \tag{20.160}$$

where $1/\tau = 2\pi\nu\left\langle U^2\right\rangle$ is the frequency of elastic collisions.

Another effect of the coherent scattering on the same impurity by both electrons forming a Cooper pair is the renormalization of the vertex part $\lambda(\mathbf{q}, \varepsilon_1, \varepsilon_2)$ in the particle-particle channel. Let us demonstrate the details of its calculation. The renormalized vertex $\lambda(\mathbf{q}, \varepsilon_1, \varepsilon_2)$ is determined by a graphical equation of the ladder type (see Fig. 20.7). Here after the averaging over the impurity configurations the value $\langle U^2\rangle = \frac{1}{2\pi\nu\tau}$ is associated with the dashed line. In the momentum representation this, generally speaking, integral equation is reduced to the algebraic one

$$\lambda^{-1}(\mathbf{q}, \varepsilon_1, \varepsilon_2) = 1 - \frac{1}{2\pi\nu\tau}\mathcal{P}(\mathbf{q}, \widetilde{\varepsilon}_1, \widetilde{\varepsilon}_2), \tag{20.161}$$

where $\mathcal{P}(\mathbf{q}, \widetilde{\varepsilon}_1, \widetilde{\varepsilon}_2)$ was defined above by (20.149).

Now one has to perform a formal averaging of the general expression (20.149) over the Fermi surface ($\langle ...\rangle_{F.S.}$). Restricting consideration to small momenta

$$\Delta\xi(\mathbf{q}, \mathbf{p})|_{|\mathbf{p}|=p_F} \ll |\widetilde{\varepsilon}_1 - \widetilde{\varepsilon}_2|. \tag{20.162}$$

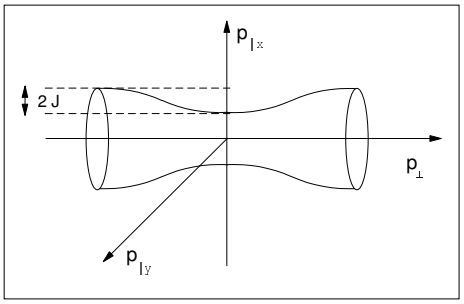

Figure 20.8: The Fermi surface in the form of a corrugated cylinder

the calculation of $\lambda(\mathbf{q},\omega_1,\omega_2)$ for the practically important case of an arbitrary spectrum can be done analogously to (20.150). Indeed, expanding the denominator of (20.149) one can find

$$\lambda(\mathbf{q},\omega_1,\omega_2)=\frac{|\widetilde{\varepsilon}_1-\widetilde{\varepsilon}_2|}{|\varepsilon_1-\varepsilon_2|+\frac{\langle(\Delta\xi(\mathbf{q},\mathbf{p})|_{|\mathbf{p}|=p_F})^2\rangle_{F.S.}}{\tau|\tilde{\omega}_1-\tilde{\omega}_2|^2}\Theta(-\varepsilon_1\varepsilon_2)}. \tag{20.163}$$

It is easy to see that assumed restriction on momenta is not too severe and is almost always satisfied in calculations of fluctuation effects at temperatures near T_c. In this region of temperatures the effective propagator momenta are determined by $|\mathbf{q}|_{eff}\sim[\xi^{GL}(T)]^{-1}=\xi^{-1}\sqrt{\epsilon}\ll\xi^{-1}$, while the Green function $\mathbf{q}$-dependence becomes important for much larger momenta $q\sim\min\{\xi^{-1},l^{-1}\}$, which is equivalent to the limit of the condition (20.162).

The average in (20.163) can be calculated for some particular types of spectra. For example in the cases of $2D$ and $3D$ isotropic spectra it is expressed in terms of the diffusion coefficient $\mathcal{D}_{(D)}$:

$$\langle(\Delta\xi(\mathbf{q},\mathbf{p})|_{|\vec{p}|=p_F})^2\rangle_{F.S.(D)}=\tau^{-1}\mathcal{D}_{(D)}q^2=\frac{v_F^2q^2}{D}. \tag{20.164}$$

Another important example is already familiar case of quasi-two-dimensional electron motion in a layered metal:

$$\xi(\mathbf{p})=E(\mathbf{p}_\parallel)+J\cos(p_zs)-E_F, \tag{20.165}$$

where $E(\mathbf{p}_\parallel)=\mathbf{p}_\parallel^2/(2m)$, $\mathbf{p}\equiv(\mathbf{p}_\parallel,p_z)$, $\mathbf{p}_\parallel\equiv(p_x,p_y)$, J is the effective nearest-neighbor interlayer hopping energy for quasiparticles. We note that J characterizes the width of the band in the c-axis direction taken in the strong-coupling approximation and can be identified with the effective energy of electron tunneling between planes (see (20.62) and footnote 14). The Fermi surface, defined by the condition $\xi(\mathbf{p})=0$, is a corrugated cylinder (see Fig. 20.8). In this case the average (20.164) is written in a more sophisticated form:

$$\langle(\Delta\xi(\mathbf{q},\mathbf{p})|_{|\vec{p}|=p_F})^2\rangle_{F.S.}=\frac{1}{2}(v_F^2\mathbf{q}^2+4J^2\sin^2(q_zs/2))=\tau^{-1}\widehat{\mathcal{D}}q^2, \tag{20.166}$$

where we have introduced the definition of the generalized diffusion operator $\widehat{\mathcal{D}}$ in order to deal with an arbitrary anisotropic spectrum.

Propagator.

In Section 4, in the process of the microscopic derivation of the TDGL equation, the fluctuation propagator was introduced. This object is of first importance for the microscopic fluctuation theory and it has to be generalized for the case of an impure metal with an anisotropic

electron spectrum. This is easy to do using the averaging procedure presented in the previous Section. Formally it is enough to use in equation (20.146) the polarization operator $\Pi(\mathbf{q},\Omega_k)$ averaged over impurity positions, which can be expressed in terms of $\mathcal{P}(\mathbf{q},\widetilde{\varepsilon}_{n+k},\widetilde{\varepsilon}_{-n})$ introduced above:

$$\begin{aligned}\Pi(\mathbf{q},\Omega_k) &= T\sum_{\omega_n}\lambda(q,\varepsilon_{n+k},\varepsilon_{-n})\mathcal{P}(\mathbf{q},\widetilde{\omega}_{n+k},\widetilde{\omega}_{-n}) = \\ &= T\sum_{\omega_n}\frac{1}{\left[\mathcal{P}(\mathbf{q},\widetilde{\varepsilon}_{n+k},\widetilde{\varepsilon}_{-n})\right]^{-1}-\frac{1}{2\pi\nu\tau}}.\end{aligned} \tag{20.167}$$

For relatively small $\mathbf{q}$ ($\Delta\xi(\mathbf{q},\mathbf{p})|_{|E(\mathbf{p})|=E_F} \ll |\widetilde{\varepsilon}_{n+k}-\widetilde{\varepsilon}_{-n}| \sim \max\{T,\tau^{-1}\}$) and $\Omega \ll T$ one can find an expression for the fluctuation propagator, which can be useful in studies of fluctuation effects near T_c ($\epsilon \ll 1$) for the dirty and intermediate but not very clean case ($T\tau \ll 1/\sqrt{\epsilon}$). Expanding (20.163) in powers of $\left(\Delta\xi(\mathbf{q},\mathbf{p})|_{|E(\mathbf{p})|=E_F}/|2\widetilde{\varepsilon}_n+\Omega_k|\right)^2$ it is possible write $L^R(q,\Omega)$ in a form almost completely coinciding with Exp.(20.157):

$$L^R(\mathbf{q},\Omega) = -\frac{1}{\nu}\frac{1}{\epsilon - i\frac{\pi\Omega}{8T}+\xi^2(T\tau)\mathbf{q}^2}. \tag{20.168}$$

Let us stress that the phenomenological coefficient γ_{GL} turns out to be equal to the same value $\frac{\pi\nu}{8T}$ as in clean case, and hence does not depend on the impurity concentration. The only difference in comparison with the clean case is in appearance of a dependence of the natural effective coherence length on the elastic relaxation time. In the isotropic D-dimensional case it can be written as

$$\begin{aligned}\xi^2_{(D)}(T\tau) &= (4m\alpha T)^{-1} = \eta_{(D)} = \\ &-\frac{\tau^2 v_F^2}{D}\left[\psi(\frac{1}{2}+\frac{1}{4\pi T\tau})-\psi(\frac{1}{2})-\frac{1}{4\pi T\tau}\psi'(\frac{1}{2})\right]\end{aligned} \tag{20.169}$$

(we introduced here the parameter $\eta_{(D)}$ frequently used in the microscopic theory)[22].

The generalization of (20.168) for the case of a layered electronic spectrum is evident:

$$L^R(q,\Omega) = -\frac{1}{\nu}\frac{1}{\epsilon - i\frac{\pi\Omega}{8T}+\eta_{(2)}\mathbf{q}_\parallel^2 + r\sin^2(q_z s/2)}. \tag{20.170}$$

One has to remember that the Exp. (20.168) was derived in the assumption of small momenta $\Delta\xi(\mathbf{q},\mathbf{p})|_{|E(\mathbf{p})|=E_F} \ll |\widetilde{\varepsilon}_{n+k}-\widetilde{\varepsilon}_{-n}| \sim \max\{T,\tau^{-1}\}$, so the range of its applicability is restricted to the GL region of temperatures $\epsilon = \ln(\frac{T}{T_c}) \ll 1$, where the integrands of diagrammatic expressions have singularities at small momenta of the Cooper pair center of mass.

Finally let us express the Ginzburg-Levanyuk parameter for the important $2D$ case in terms of the microscopic parameter $\eta_{(2)}$. In accordance with (20.37) and the definition (20.169):

$$Gi_{(2)}(T\tau) = \frac{7\zeta(3)}{16\pi^2}\frac{1}{mT_c\eta_{(2)}(T\tau)}. \tag{20.171}$$

One can see that this general definition in the limiting cases of a clean and dirty metal results in the same values $Gi_{(2c)}$ and $Gi_{(2d)}$ as was reported in Table 1.

[22]Let us recall that its square determines the product of the GL parameter α and the Cooper pair mass entering in the GL functional. In clean case we supposed the letter equal to two free electron masses and defined α in accordance with (20.18). As we just have seen in the case of the impure superconductor ξ depends on impurity concentration and this dependence, in principle, can be attributed both to α or m. For our further purposes it is convenient to leave α in the same form (20.18) as in the case of a clean superconductor. The Cooper pair mass in this case becomes dependent on the electron mean free pass what physically can be attributed to the diffusion motion of the electrons forming the pair.

20.5.4 Microscopic theory of fluctuation conductivity of layered superconductor

Qualitative discussion of different fluctuation contributions

In Section 4 the direct fluctuation effect on conductivity, related with the charge transfer by means of fluctuation Cooper pairs, was discussed in details. Nevertheless, below in this Section we return to its discussion and will demonstrate its calculation by means of the microscopic theory. This will be done in purpose to prepare the basis for studies of the Aslamazov-Larkin contribution in the variety of physical values like magnetoconductivity near the upper critical field, conductivity far from transition point, fluctuation conductivity in ultra-clean limit, Hall conductivity etc.

Microscopic approach permits also to calculate the cited above indirect fluctuation effects like so called DOS and MT contributions. We will start now from their qualitative discussion.

The important consequence of the presence of fluctuating Cooper pairs above T_c is the decrease of the one-electron density of states at the Fermi level. Indeed, if some electrons are involved in pairing they can not simultaneously participate in charge transfer and heat capacity as single-particle excitations. Nevertheless, the total number of the electronic states can not be changed by the Cooper interaction, and only a redistribution of the levels along the energy axis is possible [93, 94]. In this sense one can speak about the opening of a fluctuation pseudo-gap at the Fermi level. The decrease of the one-electron density of states at the Fermi level leads to a reduction of the normal state conductivity. This, indirect, fluctuation correction to the conductivity is called the *density of states (DOS)* contribution and it appears side by side with the *paraconductivity (or Aslamazov-Larkin contribution)*. It has the opposite (negative) sign and turns out to be much less singular in $(T-T_c)^{-1}$ in comparison with the AL contribution, so that in the vicinity of T_c it was usually omitted. However, in many cases [29, 95, 96, 97, 98, 99], when for some special reasons the main, most singular, corrections are suppressed, the DOS correction becomes of major importance. Such a situation takes place in many cases of actual interest (quasiparticle current in tunnel structures, c-axis transport in strongly anisotropic high temperature superconductors, NMR relaxation rate, thermoelectric power).

The correction to the normal state conductivity above the transition temperature related with the fluctuation DOS renormalization for the dirty superconductor can be evaluated qualitatively. Indeed, the fact that some electrons ($\Delta\mathcal{N}_e$ per unit volume) participate in fluctuation Cooper pairing means that the effective number of carriers taking part in one-electron charge transfer diminishes leading to a decrease of conductivity (we deal here with the longitudinal component):

$$\delta\sigma_{xx}^{DOS} = -\frac{\Delta\mathcal{N}_e e^2\tau}{m} = -\frac{2n_s e^2\tau}{m}, \tag{20.172}$$

where n_s is the superfluid density coinciding with the Cooper pairs concentration. The latter can be identified with the average value of the square of the order parameter modulus already calculated as the correlator

$$\langle\Psi^*(0)\Psi(\mathbf{r})\rangle\,(T>T_{c0}) = \sum_{\mathbf{k}}\left\langle|\Psi_k|^2\right\rangle\exp\left(i\mathbf{kr}\right) = \frac{1}{4\pi\alpha\xi^2}\mathbf{K}_0\left(\frac{r}{\xi(\epsilon)}\right), \tag{20.173}$$

with $r\sim\xi$. For the $2D$ case, which is of the most interest to us, one finds:

$$n_s = \frac{1}{4\pi\alpha\xi^2}\frac{1}{s}\mathbf{K}_0(\sqrt{\epsilon}) = \frac{7\zeta\left(3\right)}{\pi^4 v_F^2}\frac{E_F}{s\tau}\ln\ \frac{1}{\epsilon}, \tag{20.174}$$

where we have used the explicit expression (20.18) for α and ξ. As we will see the corresponding expression for the fluctuation DOS correction to conductivity (20.172) coincides with the accuracy of 2 with the microscopic expression (20.185) which will be carried out below.

The third, purely quantum, fluctuation contribution is generated by the coherent scattering of the electrons forming a Cooper pair on the same elastic impurities. This is the so called *anomalous Maki-Thompson (MT)* contribution [6, 7] which can be treated as the result of Andreev scattering of the electron by fluctuation Cooper pairs. This contribution often turns out to be important in conductivity and other transport phenomena. Its temperature singularity near T_c is similar to that of the paraconductivity, although being extremely sensitive to electron phase-breaking processes and to the type of orbital symmetry of pairing it can be suppressed. Let us evaluate it.

The physical origin of the Maki-Thompson correction consists in the fact that the Cooper interaction of electrons with the almost opposite momenta changes the mean free path (diffusion coefficient) of electrons. As we have already seen in the previous Section the amplitude of this interaction increases drastically when $T \to T_c$:

$$g_{eff} = \frac{g}{1 - g \ln \frac{\omega_D}{2\pi T}} = \frac{1}{\ln \frac{T}{T_c}} \approx \frac{T}{T - T_c} = \frac{1}{\epsilon}.$$

What is the reason of this growth? One can say that the electrons scatter one at another in resonant way with the virtual Cooper pairs formation. Or it is possible to imagine that the electrons undergo the Andreev scattering at fluctuation Cooper pairs binding in the Cooper pair themselves. The probability of such induced pair irradiation (let us remind that Cooper pairs are Bose particles) is proportional to their number in the final state, i.e. $n(p)$ (20.7). For small momenta $n(p) \sim 1/\epsilon$.

One can ask why such interaction does not manifest itself considerably far from the transition point? The matter of fact that so intensively interacts just small number of electrons with the total momentum $q \lesssim \xi^{-1}(T)$. In accordance with the Heisenberg principle the minimal distance between such electrons is of the order of $\sim \xi(T)$. From the other hand such electrons in purpose to interact have to approximate one another up to the distance of the Fermi length $\lambda_F \sim 1/p_F$. The probability of such event may be estimated in the spirit of the self-intersection trajectories contribution evaluation in the weak localization theory [100, 102].

In the process of diffusion motion the distance between two electrons increases with the time growth in accordance with the Einstein law: $R(t) \sim (Dt)^{1/2}$. Hence the scattering probability

$$W \sim \int\limits_{t_{\min}}^{t_{\max}} \frac{\lambda_F^{D-1}}{R^D(t)} v_F \, dt.$$

The lower limit of the integral can be estimated from the condition $R(t_{\min}) \sim \xi(T)$ (only such electrons interact in the resonant way). The upper limit is determined by the phase breaking time τ_φ since for larger time intervals the phase coherence, necessary for the pair formation, is broken. In result the relative correction to conductivity due to such processes is equal to the product of the scattering probability on the effective interaction constant: $\delta\sigma^{MT}/\sigma = W \; g_{eff}$. In the $2D$ case

$$\delta\sigma^{MT} \sim \frac{e^2}{8\epsilon} \ln \frac{D\tau_\varphi}{\xi^2(T)}.$$

This result will be confirmed below in the frameworks of the microscopic consideration.

Generalities

Let us pass to the microscopic calculation of the fluctuation conductivity of the layered superconductor. We begin by discussing the quasiparticle normal state energy spectrum. While models with several conducting layers per unit cell and with either intralayer or interlayer

pairing have been considered [103], it has been shown [104] that all of these models give rise to a Josephson pair potential that is periodic in k_z, the wave-vector component parallel to the c-axis, with period s, the c-axis repeat distance. While such models differ in their superconducting densities of states, they all give rise to qualitatively similar fluctuation propagators, which differ only in the precise definitions of the parameters and in the precise form of the Josephson coupling potential. Ignoring the rather unimportant differences between such models in the Gaussian fluctuation regime above $T_c(H)$, we therefore consider the simplest model of a layered superconductor, in which there is one layer per unit cell, with intralayer singlet s-wave pairing. These assumptions lead to the simple spectrum (20.165) and hence to a Fermi surface having the form of a corrugated cylinder (see Fig.20.8).

Some remarks regarding the normal-state quasiparticle momentum relaxation time are necessary. In the "old" layered superconductors the materials were generally assumed to be in the dirty limit (like $TaS_2(\text{pyridine})_{1/2}$). In the high-$T_c$ cuprates, however, both single crystals and epitaxial thin films are nominally in the "intermediate" regime, with $l/\xi_{xy} \approx 2-5$. In addition, the situation in the cuprates is complicated by the presence of phonons for $T \simeq T_c \simeq 100K$, the nearly localized magnetic moments on the Cu^{2+} sites, and by other unspecified inelastic processes. In this Section we assume simple elastic intralayer scattering and restrict our consideration to the local limit in the fluctuation Cooper pair motion. This means that we consider the case of not too clean superconductors, keeping the impurity concentration n_i and reduced temperature such that the resulting mean-free path satisfies the requirement $l < \xi_{xy}(T) = \frac{\xi_{xy}}{\sqrt{\varepsilon}}$ and the impurity vertex can be taken in the local form (20.163) with $\langle(\Delta\xi(\mathbf{q},\mathbf{p})|)^2\rangle_{F.S.}$ determined by (20.166). The phase-breaking time τ_φ is supposed to be much larger than τ.

The most general relation between the current density $\mathbf{j}(\mathbf{r},t)$ and vector-potential $\mathbf{A}(\mathbf{r}',t')$ is given through the so-called electromagnetic response operator $Q_{\alpha\beta}(\mathbf{r},\mathbf{r}',t,t')$ [92]:

$$\mathbf{j}(\mathbf{r},t) = \int Q_{\alpha\beta}(\mathbf{r},\mathbf{r}',t,t')\mathbf{A}(\mathbf{r}',t')\ \mathbf{dr}'\ dt,$$

Assuming space and time homogeneity, one can take the Fourier transform of this relation and compare it with the definition of the conductivity tensor $j_\alpha = \sigma_{\alpha\beta}E_\beta$. This permits us to express the conductivity tensor in terms of the retarded electromagnetic response operator

$$\sigma_{\alpha\beta}(\omega) = -\frac{1}{i\omega}[Q_{\alpha\beta}]^R(\omega). \tag{20.175}$$

The electromagnetic response operator $Q_{\alpha\beta}(\omega_\nu)$, defined on Matsubara frequencies $\omega_\nu = (2\nu+1)\pi T$, can be presented as the correlator of two exact one-electron Green functions [92] averaged over impurities and accounting for interactions, in our case the particle-particle interactions in the Cooper channel. The appropriate diagrams corresponding to the first order of perturbation theory in the fluctuation amplitude are shown in Fig. (20.9).

With each electromagnetic field component A_α we associate the external vertex $ev_\alpha(p) = e\frac{\partial\xi(p)}{\partial p_\alpha}$. For the longitudinal conductivity tensor elements (parallel to the layers, for which $\alpha = x, y$), the resulting vertex is simply ep_α/m. For the c-axis conductivity, the vertex is given by

$$ev_z(p) = e\frac{\partial\xi(p)}{\partial p_z} = -eJs\sin(p_z s). \tag{20.176}$$

Each solid line in the diagrams represents a one-electron Green function averaged over impurities (20.145), a wavy line represents a fluctuation propagator $L(\mathbf{q},\Omega_k)$ (20.168), three-leg vertices were defined by the Exp.(20.163). The four-leg impurity vertex**,** appearing in diagrams 3-4, 9-10 of the Fig. 20.9, is called the Cooperon in the weak localization theory (see, for example,[105]) It is easy to see that it differs from the above three-leg vertex only by the additional factor $(2\pi\nu\tau)^{-1}$. We do not renormalize the current vertices: it is well known (see [92])

Figure 20.9: Feynman diagrams for the leading-order contributions to the fluctuation conductivity. Wavy lines are fluctuation propagators, thin solid lines with arrows are impurity-averaged normal-state Green's functions, shaded semicircles are vertex corrections arising from impurities, dashed lines with central crosses are additional impurity renormalisations and shaded rectangles are impurity ladders. Diagram 1 represents the Aslamazov-Larkin term; diagrams 2–4 represent the Maki-Thompson type contributions; diagrams 5–10 arise from corrections to the normal state density of states.

that this renormalization only leads to the substitution of the scattering time τ by the transport one τ_{tr}. We integrate over the internal Cooper pair momentum $\mathbf{q}$ and electron momentum $\mathbf{p}$ and sum over the internal fermionic and bosonic Matsubara frequencies, with momentum and energy conservation at each internal vertex (fluctuation propagator endpoint) in the analytical expressions for the diagrams presented in Fig. (20.9).

After these necessary introductory remarks and definitions we pass to the microscopic calculation of the different fluctuation contributions.

Aslamazov-Larkin contribution

We first examine the AL paraconductivity (diagram 1 of Fig.(20.9)). Actually this contribution was already studied in the Section 4 in the framework of the TDGL equation but, in order to demonstrate how the method works, we will carry out here the appropriate calculations in the microscopic approach, as was originally done by Aslamazov and Larkin [5].

The AL contribution to the electromagnetic response operator tensor has the form:

$$\begin{aligned} Q^{AL}_{\alpha\beta}(\omega_\nu) &= 2e^2T\sum_{\Omega_k}\int\frac{d^3\mathbf{q}}{(2\pi)^3}B_\alpha(\mathbf{q},\Omega_k,\omega_\nu)L(\mathbf{q},\Omega_k)\times \\ &\times B_\beta(\mathbf{q},\Omega_k,\omega_\nu)L(\mathbf{q},\Omega_k+\omega_\nu), \end{aligned} \tag{20.177}$$

where the three Green function block is given by

$$\begin{aligned} B_\alpha(\mathbf{q},\Omega_k,\omega_\nu) &= T\sum_{\varepsilon_n}\lambda(\mathbf{q},\varepsilon_{n+\nu},\Omega_k-\varepsilon_n)\lambda(\mathbf{q},\varepsilon_n,\Omega_k-\varepsilon_n)\times \\ &\times\int\frac{d^3\mathbf{p}}{(2\pi)^3}v_\alpha(\mathbf{p})G(\mathbf{p},\varepsilon_{n+\nu})G(\mathbf{p},\varepsilon_n)G(\mathbf{q}-\mathbf{p},\Omega_k-\varepsilon_n). \end{aligned} \tag{20.178}$$

Expanding $G(\mathbf{q}-\mathbf{p},\Omega_k-\varepsilon_n)$ over $\mathbf{q}$ one find that the angular integration over the Fermi surface kills the first term and leaves nonzero the second term of the expansion only. Then the $\xi-$integration is performed by means of the Cauchy theorem. The further summation over the fermionic frequency is cumbersome, so we will show it for the example of the simplest case of a dirty superconductor with $T\tau\ll 1$. In this case the main sources of the ε_n-dependence in (20.178) are the λ-vertices and that originating from the Green functions can be neglected by the parameter $T\tau\ll 1$ (indeed, one can see that $\varepsilon_n\sim T$ are important in vertices, while in Green functions $\varepsilon_n\gtrsim\tau^{-1}$ only). The remaining summation in (20.178) is performed in the same way as was done in (20.168) and results in:

$$\begin{aligned} B_\alpha(\mathbf{q},\Omega_k,\omega_\nu) &= \nu\frac{\eta_{(2)}}{v_F^2}\left\langle v_\alpha q_\beta v_\beta\right\rangle_{FS}\times \\ &\times\frac{8T}{\pi\omega_\nu}\left[\psi(\frac{1}{2}+\frac{|\Omega_k|+\omega_\nu+\widehat{D}q^2}{4\pi T})-\psi(\frac{1}{2}+\frac{|\Omega_k|+\widehat{D}q^2}{4\pi T})+\right. \\ &\left.+\psi(\frac{1}{2}+\frac{|\Omega_{k+\nu}|+\omega_\nu+\widehat{D}q^2}{4\pi T})-\psi(\frac{1}{2}+\frac{||\Omega_{k+\nu}|+\widehat{D}q^2}{4\pi T})\right]. \end{aligned} \tag{20.179}$$

Now let us return to the general expression for $Q^{AL}_{\alpha\beta}(\omega_\nu)$ and transform the Ω_k - summation into a contour integral, using the identity [106]

$$T\sum_{\Omega_k}f(\Omega_k)=\frac{1}{4\pi i}\oint_C dz\coth\frac{z}{2T}f(-iz),$$

Figure 20.10: The contour of integration in the plane of complex frequencies.

where $z = i\Omega_k$ is a variable in the plane of complex frequency and the contour C encloses all bosonic Matsubara frequencies over which the summation is carried out. In our case the contour C can be chosen as a circle with radius tending to infinity (see Fig. 20.10):

$$Q^{AL}_{\alpha\beta}(\omega_\nu) = \frac{e^2}{2\pi i}\int \frac{d^3\mathbf{q}}{(2\pi)^3}\oint_C dz \coth\frac{z}{2T} B_\alpha(\mathbf{q}, -iz+\omega_\nu, -iz)\times \\ \times L(\mathbf{q}, -iz) B_\beta(\mathbf{q}, -iz+\omega_\nu, -iz) L(\mathbf{q}, -iz+\omega_\nu). \tag{20.180}$$

One can see that the integrand function in (20.180) has breaks of analyticity at the lines $\mathrm{Im}z = 0$ and $\mathrm{Im}z = -i\omega_\nu$. Indeed, the fluctuation propagator $L(\mathbf{q}, \Omega_k)$ and Green function blocks $B_\alpha(\mathbf{q}, \Omega_k, \omega_\nu)$ were defined on the bosonic Matsubara frequencies only, while now we have to use them as functions of the continuous variable z. As it is well known from the properties of Green functions in the complex plane z two analytical functions, related with $L(\mathbf{q}, \Omega_k)$, can be introduced. The first one, $L^R(\mathbf{q}, -iz)$ (retarded), is analytic in the upper half-plane ($\mathrm{Im}z > 0$), while the second one, $L^A(\mathbf{q}, -iz)$ (advanced), has no singularities in the lower half-plane ($\mathrm{Im}z < 0$). As we have seen above the same lines separate the domains of the analyticity of the Green function blocks, so the functions B^{RR}, B^{RA}, B^{AA} analytic in each domain can be introduced (with the appropriate choices of the $|\Omega_{k+\nu}|$ and $|\Omega_k|$ signs in the arguments of the $\psi-$ functions, see (20.179)). This means that by cutting the z-plane along the lines $\mathrm{Im}z = 0$ and $\mathrm{Im}z = -i\omega_\nu$ we can reduce the calculation of the contour integral in (20.180) to the sum of three integrals along the contours C_1, C_2, C_3 which enclose domains of well defined analyticity of the integrand function. The integral along the large circle evidently vanishes and the contour integral is reduced to four integrals along the cuts of the plane in Fig.20.10:

$$
\begin{aligned}
I(\mathbf{q},\omega_\nu) &= \oint_{C_1+C_2+C_3} dz \coth\frac{z}{2T} B_\alpha(\mathbf{q},-iz)L(\mathbf{q},-iz)B_\beta(\mathbf{q},-iz)L(\mathbf{q},-iz+\omega_\nu) = \\
&= \int_{-\infty}^{\infty} dz \coth\frac{z}{2T} L^R(\mathbf{q},-iz+\omega_\nu)\left[B_\alpha^{RR}B_\beta^{RR}L^R(\mathbf{q},-iz)-\right. \\
&\quad \left. -B_\alpha^{RA}B_\beta^{RA}L^A(\mathbf{q},-iz)\right] + \int_{-\infty-i\omega_\nu}^{\infty-i\omega_\nu} dz \coth\frac{z}{2T} L^A(\mathbf{q},-iz)\times \\
&\quad \left[B_\alpha^{RA}B_\beta^{RA}L^R(\mathbf{q},-iz+\omega_\nu) - B_\alpha^{AA}B_\beta^{AA}L^A(\mathbf{q},-iz+\omega_\nu)\right] ..
\end{aligned}
$$

Now one can shift the variable in the last integral to $z = z' - i\omega_\nu$, take into account that $i\omega_\nu$ is the period of $\coth\frac{z}{2T}$ and get an expression analytic in $i\omega_\nu \to \omega$.

In the vicinity of T_c, due to the pole structure of the fluctuation propagators in (20.177), the leading contribution to the electromagnetic response operator $Q_{\alpha\beta}^{AL(R)}$ arises from them rather than from the frequency dependence of the vertices B_α, so we can neglect the Ω_k- and ω_ν-dependencies of the Green functions blocks and use the expression for $B_\alpha(\mathbf{q},0,0)$ valid for small $\mathbf{q}_{ab}$ only:

$$
B_\alpha(\mathbf{q}) = -2\nu\frac{\eta_{(2)}}{v_F^2}\begin{cases} v_F^2 q_\alpha, & \alpha = x,y \\ sJ^2 \sin q_z s, & \alpha = z \end{cases} .
$$

Detailed calculations demonstrate that this result can be generalized to an arbitrary impurity concentration just by using the expression (20.169) for $\eta_{(2)}$. Finally:

$$
\begin{aligned}
Q_{\alpha\beta}^{AL(R)}(\omega) = \frac{2e^2}{\pi}\int\frac{d^3q}{(2\pi)^3}B_\alpha(\mathbf{q})B_\beta(\mathbf{q}) \quad & \int_{-\infty}^{\infty} dz \coth\left(\frac{z}{2T}\right)\left[L^R(\mathbf{q},-iz-i\omega)\right. \\
& \left. +L^A(\mathbf{q},-iz+i\omega)\right]\mathrm{Im}L^R(\mathbf{q},-iz).
\end{aligned}
$$

Being interested here in the d.c. conductivity one can expand the integrand function in ω. It is possible to show that the zeroth order term is cancelled by the same type contributions from all other diagrams (this cancellation confirms the absence of anomalous diamagnetism above the critical temperature). The remaining integral can be integrated by parts and then carried out taking into account that the contribution most singular in ϵ comes from the region $z \sim \epsilon \ll T$:

$$
\begin{aligned}
\sigma_{xx}^{AL} &= \frac{e^2}{2\pi T}\int\frac{d^3\mathbf{q}}{(2\pi)^3}B_{x,z}^2(\mathbf{q},0,0)\int_{-\infty}^{\infty}\frac{dz}{\sinh^2\frac{z}{2T}}\left[\mathrm{Im}L^R(\mathbf{q},-iz)\right]^2 = \\
&= \frac{\pi^2e^2\eta_{(2)}^2}{s}\int\frac{d^2\mathbf{q}}{(2\pi)^2}\frac{\mathbf{q}^2}{\left[(\eta_{(2)}\mathbf{q}^2+\epsilon)(\eta_{(2)}\mathbf{q}^2+\epsilon+r)\right]^{3/2}} \\
&= \frac{e^2}{16s}\frac{1}{[\epsilon(\epsilon+r)]^{1/2}} \to \frac{e^2}{16s}\begin{cases} 1/\sqrt{\epsilon r}, & \epsilon \ll r \\ 1/\epsilon, & \epsilon \gg r \end{cases} .
\end{aligned}
\tag{20.181}
$$

where the Lawrence-Doniach anisotropy parameter r [27] was already defined by (20.62).

In the same way one can evaluate the AL contribution to the transverse fluctuation conductivity [107, 95, 108]:

$$
\begin{aligned}
\sigma_{zz}^{AL} &= \frac{\pi e^2 s r^2}{32}\int\frac{d^2\mathbf{q}}{(2\pi)^2}\frac{1}{\left[(\eta_{(2)}\mathbf{q}^2+\epsilon)(\eta_{(2)}\mathbf{q}^2+\epsilon+r)\right]^{3/2}} = \\
&= \frac{e^2 s}{32\eta_{(2)}}\left(\frac{\epsilon+r/2}{[\epsilon(\epsilon+r)]^{1/2}}-1\right) \to \frac{e^2 s}{64\eta_{(2)}}\begin{cases} \sqrt{r/\epsilon}, & \text{for } \epsilon \ll r \\ (r/2\epsilon)^2, & \text{for } \epsilon \gg r \end{cases} .
\end{aligned}
\tag{20.182}
$$

Note, that contrary to the case of in-plane conductivity, the critical exponent for σ_{zz} above the Lawrence-Doniach crossover temperature T_{LD} (for which $\epsilon(T_{LD}) = r$) is 2 instead of 1, so the crossover occurs from the 0D to 3D regimes. This is related with the tunneling (so from the band structure point of view effectively zero dimensional) character of electron motion along the c-axis.

Contributions from fluctuations of the density of states

In original paper of Aslamazov and Larkin [5] the most singular AL contribution to conductivity, heat capacity and other properties of a superconductor above the critical temperature was considered. The diagrams of the type 5-6 were pictured and correctly evaluated as less singular in ϵ. Nevertheless the specific form of the AL contribution to the transverse conductivity of a layered superconductor, which may be considerably suppressed for small interlayer transparency, suggested to re-examine the contributions from diagrams 5-10 of Fig.20.9 which are indeed less divergent in ϵ, but turn out to be of lower order in the transmittance and of the opposite sign with respect to the AL one [95, 96]. These, so-called DOS, diagrams describe the changes in the normal Drude-type conductivity due to fluctuation renormalization of the normal quasiparticles density of states above the transition temperature (see Section 8.5). In the dirty limit, the calculation of contributions to the longitudinal fluctuation conductivity σ_{xx} from such diagrams was discussed in [109, 99]. Contrary to the case of the AL contribution, the in-plane and out-of-plane components of the DOS contribution differ only in the square of the ratio of effective Fermi velocities in the parallel and perpendicular directions. This allows us to calculate both components simultaneously. The contribution to the fluctuation conductivity due to diagram 5 is

$$\begin{aligned} Q^5_{\alpha\beta}(\omega_\nu) &= 2e^2T\sum_{\Omega_k}\int\frac{d^3\mathbf{q}}{(2\pi)^3}L(\mathbf{q},\Omega_k)T\sum_{\varepsilon_n}\lambda^2(\mathbf{q},\varepsilon_n,\Omega_k-\varepsilon_n)\times \\ &\int\frac{d^3\mathbf{p}}{(2\pi)^3}v_\alpha(\mathbf{p})v_\beta(\mathbf{p})G^2(\mathbf{p},\varepsilon_n)G(\mathbf{q}-\mathbf{p},\Omega_k-\varepsilon_n)G(\mathbf{p},\varepsilon_{n+\nu}), \end{aligned}$$

and diagram 6 gives an identical contribution. Evaluation of the integrations over the in-plane momenta $\mathbf{p}$ and the summation over the internal frequencies ε_n are straightforward. Treatment of the other internal frequencies Ω_k is less obvious, but in order to obtain the leading singular behavior in the vicinity of transition it suffices to set $\Omega_k = 0$ [99]. After integration over q_z, we have [95, 97]:

$$\begin{aligned} \sigma^{5+6}_{\alpha\beta} &= -\frac{\pi e^2}{2s}A_{\alpha\beta}\kappa_1\eta_{(2)}\int\limits_{|\mathbf{q}|\le\xi^{-1}}\frac{d^2\mathbf{q}}{(2\pi)^2}\frac{1}{\left[(\epsilon+\eta_{(2)}\mathbf{q}^2)(\epsilon+r+\eta_{(2)}\mathbf{q}^2)\right]^{1/2}} \\ &\approx -\frac{e^2\kappa_1}{8s}A_{\alpha\beta}\ln\left(\frac{2}{\epsilon^{1/2}+(\epsilon+r)^{1/2}}\right), \end{aligned} \tag{20.183}$$

where $A_{xx} = A_{yy} = 1, A_{zz} = (sJ/v_F)^2, A_{\alpha\neq\beta} = 0$ and

$$\kappa_1 = \frac{2(v_F\tau)^2}{\pi^2\eta_{(2)}}\left[\psi'\left(\frac{1}{2}+\frac{1}{4\pi T\tau}\right)-\frac{3}{4\pi T\tau}\psi''\left(\frac{1}{2}\right)\right].$$

In order to cut off the ultra-violet divergence in q we have introduced here a cut off parameter $q_{\max} = \xi^{-1} = \eta_{(2)}^{-1/2}$ in complete agreement with Section 3. Let us stress that in the framework of the phenomenological GL theory we attributed this cut off to the breakdown of the GL approach at momenta as large as $q \sim \xi^{-1}$. The microscopic approach developed here permits

to see how this cut off appears: the divergent shortwave-length contribution arising from GL-like fluctuation propagators is automatically restricted by the q-dependencies of the impurity vertices and Green functions, which appear at the scale $q \sim l^{-1}$.

In a similar manner, the equal contributions from diagrams 7 and 8 sum to

$$\begin{aligned}\sigma_{\alpha\beta}^{7+8} &= -\frac{\pi e^2}{2s} A_{\alpha\beta}\kappa_2\eta_{(2)} \int\limits_{|\mathbf{q}|\le q_{\max}} \frac{d^2\mathbf{q}}{(2\pi)^2} \frac{1}{\left[(\epsilon+\eta_{(2)}\mathbf{q}^2)(\epsilon+r+\eta_{(2)}\mathbf{q}^2)\right]^{1/2}} \\ &\approx -\frac{e^2\kappa_2}{8s} A_{\alpha\beta} \ln\left(\frac{2}{\epsilon^{1/2}+(\epsilon+r)^{1/2}}\right), \end{aligned} \tag{20.184}$$

$$\kappa_2 = \frac{(v_F\tau)^2}{2\pi^3 T\tau}\psi''\left(\frac{1}{2}\right).$$

Comparing (20.183) and (20.184), we see that in the clean limit, the main contributions from the DOS fluctuations arise from diagrams 5 and 6. In the dirty limit, diagrams 7 and 8 are also important, having -1/3 the value of diagrams 5 and 6, for both σ_{xx} and σ_{zz}. Diagrams 9 and 10 are not singular in $\epsilon << 1$ at all and can be neglected. The total DOS contribution to the in-plane and c-axis conductivity is therefore

$$\sigma_{\alpha\beta}^{DOS} = -\frac{e^2}{2s}\kappa(T\tau)A_{\alpha\beta}\ln\left(\frac{2}{\epsilon^{1/2}+(\epsilon+r)^{1/2}}\right), \tag{20.185}$$

where

$$\begin{aligned}\kappa(T\tau) &= \kappa_1+\kappa_2 = \frac{-\psi'\left(\frac{1}{2}+\frac{1}{4\pi\tau T}\right)+\frac{1}{2\pi\tau T}\psi''\left(\frac{1}{2}\right)}{\pi^2\left[\psi\left(\frac{1}{2}+\frac{1}{4\pi\tau T}\right)-\psi\left(\frac{1}{2}\right)-\frac{1}{4\pi\tau T}\psi'\left(\frac{1}{2}\right)\right]} \\ &\to \begin{cases} 56\zeta(3)/\pi^4 \approx 0.691, & T\tau \ll 1 \\ 8\pi^2\left(T\tau\right)^2/\left[7\zeta(3)\right] \approx 9.384\left(T\tau\right)^2, & 1 \ll T\tau \ll 1/\sqrt{\epsilon} \end{cases} \end{aligned} \tag{20.186}$$

is a function of τT only. As it will be shown below at the upper limit $T\tau \sim 1/\sqrt{\epsilon}$ the DOS contribution reaches the value of the other fluctuation contributions and in the limit of $T\tau \to \infty$ exactly eliminates the Maki-Thompson one.

Maki-Thompson contribution

We now consider another quantum correction to fluctuation conductivity which is called the Maki-Thompson (MT) contribution (diagram 2 of Fig. 20.9). It was firstly discussed by Maki [6] in a paper which appeared almost simultaneously with the paper of Aslamazov and Larkin [5]. Both these articles gave rise to the microscopic theory of fluctuations in superconductor. Maki found that, in spite of the seeming weaker singularity of diagram 2 with respect to the AL one (it contains one propagator only, while the AL one contains two of them) it can contribute to conductivity comparably or even stronger than AL one.

Since the moment of its discovery the MT contribution became the subject of intense controversy. In its original paper Maki found that in $3D$ case this fluctuation correction is four times larger than the AL one. In $2D$ case the result was striking**:** the MT contribution simply diverged. This paradox was, at least at the level of recipe, resolved by Thompson [7]: he proposed to cut off the infra-red divergence in the Cooper pair center of mass momentum integration by the introduction of the finite length l_s of inelastic scatterings of electrons on paramagnetic impurities. In the further papers of Patton [110], Keller and Korenman [111] it was cleared up that the presence of paramagnetic impurities or other external phase-breaking sources is not necessary: the fluctuation Cooper pairing of two electrons results in a change

of the quasiparticle phase itself and the corresponding phase-breaking time τ_φ appears as a natural cut off parameter of the MT divergence in the strictly 2D case. The minimal quasi-two-dimensionality of the electron spectrum, as we will show below, automatically results in a cut off of the MT divergence.

Although the MT contribution to the in-plane conductivity is expected to be important in the case of low pair-breaking, experiments on high-temperature superconductors have shown that the excess in-plane conductivity can usually be explained in terms of the fluctuation paraconductivity alone. Two possible explanations can be found for this fact. The first one is that the pair-breaking in these materials is not weak. The second is related with the $d-$wave symmetry of pairing which kills the anomalous Maki-Thompson process [112, 113]. We will consider below the case of s-pairing, where the Maki-Thompson process is well pronounced.

The appearance of the anomalously large MT contribution is nontrivial and worth being discussed. We consider the scattering lifetime τ and the pair-breaking lifetime τ_φ to be arbitrary, but satisfying $\tau_\varphi > \tau$. In accordance with diagram 2 of Fig.(20.9) the analytical expression for the MT contribution to the electromagnetic response tensor can be written as

$$Q_{\alpha\beta}^{MT}(\omega_\nu) = 2e^2T\sum_{\Omega_k}\int\frac{d^3\mathbf{q}}{(2\pi)^3}L(\mathbf{q},\Omega_k)I_{\alpha\beta}(\mathbf{q},\Omega_k,\omega_\nu), \tag{20.187}$$

where

$$I_{\alpha\beta}(\mathbf{q},\Omega_k,\omega_\nu) = T\sum_{\varepsilon_n}\lambda(\mathbf{q},\varepsilon_{n+\nu},\Omega_{k-n-\nu})\lambda(\mathbf{q},\varepsilon_n,\Omega_{k-n})\times \tag{20.188}$$

$$\times\int\frac{d^3\mathbf{p}}{(2\pi)^3}v_\alpha(\mathbf{p})v_\beta(\mathbf{q}-\mathbf{p})G(\mathbf{p},\varepsilon_{n+\nu})G(\mathbf{p},\varepsilon_n)G(\mathbf{q}-\mathbf{p},\Omega_{k-n-\nu})G(\mathbf{q}-\mathbf{p},\Omega_{k-n})\ .$$

In the vicinity of T_c, it is possible to restrict consideration to the static limit of the MT diagram, simply by setting $\Omega_k = 0$ in (20.187). Although dynamic effects can be important for the longitudinal fluctuation conductivity well above T_{LD}, the static approximation is correct very close to T_c, as shown in [98, 125]. The main $q-$dependence in (20.187) arises from the propagator and vertices λ. This is why we can assume $q = 0$ in Green functions and to calculate the electron momentum integral passing, as usual, to a $\xi(\mathbf{p})$ integration:

$$\begin{aligned} I_{\alpha\beta}(q,0,\omega_\nu) &= \pi\nu\left\langle v_\alpha(p)v_\beta(q-p)\right\rangle_{FS}\times \\ &\times T\sum_{\varepsilon_n}\frac{1}{\left(|2\varepsilon_{n+\nu}|+\widehat{D}q^2\right)}\frac{1}{\left(|2\varepsilon_n|+\widehat{D}q^2\right)}\frac{1}{|\widetilde{\varepsilon}_{n+\nu}|+|\widetilde{\varepsilon}_n|}\ . \end{aligned} \tag{20.189}$$

In evaluating the sum over the Matsubara frequencies ε_n in (20.189) it is useful to split it into the two parts. In the first ε_n belongs to the domains $]-\infty,-\omega_\nu[$ and $[0,\infty[$, which finally give two equal contributions. This gives rise to the *regular* part of the MT diagram. The second, *anomalous*, part of the MT diagram arises from the summation over ε_n in the domain $[-\omega_\nu,0[$. In this interval, the further analytic continuation over ω_ν leads to the appearance of an additional diffusive pole:

$$\begin{aligned} I_{\alpha\beta}(q,0,\omega_\nu) &= I_{\alpha\beta}^{(reg)}(q,\omega_\nu)+I_{\alpha\beta}^{(an)}(q,\omega_\nu) = \nu\left\langle v_\alpha(p)v_\beta(q-p)\right\rangle_{FS} \\ &\times\left[2\pi T\sum_{n=0}^{\infty}\frac{1}{\left(2\varepsilon_{n+\nu}+\widehat{D}q^2\right)}\frac{1}{\left(2\varepsilon_n+\widehat{D}q^2\right)}\frac{1}{2\varepsilon_n+\omega_\nu+\tau^{-1}}+\right. \\ &\left.+\frac{\pi T}{\omega_\nu+\tau^{-1}}\sum_{n=-\nu}^{-1}\frac{1}{\left(2\varepsilon_{n+\nu}+\widehat{D}q^2\right)}\frac{1}{\left(-2\varepsilon_n+\widehat{D}q^2\right)}\right]. \end{aligned}$$

The limits of summation in the first sum do not depend on ω_ν, so it is an analytic function of this argument and can be continued to the upper half-plane of the complex frequency by the simple substitution $\omega_\nu \to -i\omega$. Then, tending $\omega \to 0$, one can expand the sum over powers of ω and perform the summation in terms of digamma-function:

$$\begin{aligned} I_{\alpha\beta}^{(reg)}(q,\omega_\nu) &= \nu \left\langle v_\alpha(\mathbf{p}) v_\beta(\mathbf{q}-\mathbf{p}) \right\rangle_{FS} \times \\ &\left\{ const + \frac{i\omega}{2} \frac{\partial}{\partial\left(\widehat{D}q^2\right)} \left(\frac{\partial}{\partial\left(\widehat{D}q^2\right)} + \frac{\partial}{\partial\left(\tau^{-1}\right)} \right) \cdot \right. \\ &\left. \frac{1}{\tau^{-1} - \widehat{D}q^2} \left[\psi\left(\frac{1}{2} + \frac{\omega_\nu + \widehat{D}q^2}{4\pi T} \right) - \psi\left(\frac{1}{2} + \frac{\widehat{D}q^2}{4\pi T} \right) \right] \right\}. \end{aligned} \tag{20.190}$$

The values of characteristic momenta $q \ll l^{-1}$ are determined by the domain of convergibility of the final integral of the propagator $L(\mathbf{q},0)$ in (20.187) (analogously to (20.184) and one can neglect $\widehat{D}q^2$ with respect to τ^{-1}. In result

$$\begin{aligned} I_{\alpha\beta}^{(reg)R}(q,\omega \to 0) &= \nu \left\langle v_\alpha(\mathbf{p}) v_\beta(\mathbf{q}-\mathbf{p}) \right\rangle_{FS} \times \\ &\left\{ const + \frac{i\omega\tau^2}{4} \left[\psi'\left(\frac{1}{2} + \frac{1}{4\pi\tau T} \right) - \psi'\left(\frac{1}{2} \right) - \frac{\psi''\left(\frac{1}{2}\right)}{4\pi T\tau} \right] \right\}. \end{aligned} \tag{20.191}$$

The appearance of the constant in $Q_{\alpha\beta}(\omega_\nu)$ was already discussed in the case of the AL contribution and, as was mentioned there, it is cancelled with the similar contributions of the other diagrams [98] and we will not consider it any more.

Now let us pass to the calculation of $I_{\alpha\beta}^{(an)}(q,\omega_\nu)$. Expanding the summing function in simple fractions one can express the result of summation in terms of digamma-functions

$$\begin{aligned} I_{\alpha\beta}^{(an)}(q,\omega_\nu) &= \frac{1}{4} \frac{\nu \left\langle v_\alpha(\mathbf{p}) v_\beta(\mathbf{q}-\mathbf{p}) \right\rangle_{FS}}{\omega_\nu + \tau^{-1}} \frac{1}{\omega_\nu + \widehat{D}q^2} \times \\ &\left[\psi\left(\frac{1}{2} + \frac{2\omega_\nu + \widehat{D}q^2}{4\pi T} \right) - \psi\left(\frac{1}{2} + \frac{\widehat{D}q^2}{4\pi T} \right) \right]. \end{aligned} \tag{20.192}$$

Doing the analytical continuation $i\omega_\nu \to \omega \to 0$ and taking into account that in the further q-integration of $I_{\alpha\beta}^{(an)R}(q,\omega \to 0)$, due to the singular at small q propagator, the important range is $\widehat{D}q^2 \ll T$, one can find

$$I_{\alpha\beta}^{(an)R}(q,\omega \to 0) = -\frac{i\pi\omega\tau}{16T} \frac{\nu \left\langle v_\alpha(\mathbf{p}) v_\beta(\mathbf{q}-\mathbf{p}) \right\rangle_{FS}}{-i\omega + \widehat{D}q^2}. \tag{20.193}$$

Because of the considerable difference in the angular averaging of the different tensor components we discuss the MT contribution to the in-plane and out of plane conductivities separately.

Taking into account that $\left\langle v_x(\mathbf{p}) v_x(\mathbf{q}-\mathbf{p}) \right\rangle_{FS} = -v_F^2/2$ one can find that the calculation of the regular part of MT diagram to the in-plane conductivity is completely similar to the corresponding DOS contribution and here we list the final result [97] only:

$$\sigma_{xx}^{MT(reg)} = -\frac{e^2}{2s}\tilde{\kappa} \ln\left(\frac{2}{\epsilon^{1/2} + (\epsilon + r)^{1/2}} \right),$$

where

$$\begin{aligned}\tilde{\kappa}(T\tau) &= \frac{-\psi'\left(\frac{1}{2}+\frac{1}{4\pi\tau T}\right)+\psi'\left(\frac{1}{2}\right)+\frac{1}{4\pi T\tau}\psi''\left(\frac{1}{2}\right)}{\pi^2\left[\psi\left(\frac{1}{2}+\frac{1}{4\pi\tau T}\right)-\psi\left(\frac{1}{2}\right)-\frac{1}{4\pi\tau T}\psi'\left(\frac{1}{2}\right)\right]} \\ &\to \begin{cases} 28\zeta(3)/\pi^4 \approx 0.346, \text{ for } T\tau \ll 1 \\ \pi^2/\left[14\zeta(3)\right] \approx 0586, \text{ for } 1 \ll T\tau \ll 1/\sqrt{\epsilon} \end{cases}\end{aligned} \tag{20.194}$$

is a function only of τT. We note that this regular MT term is negative, as is the overall DOS contribution.

For the anomalous part of the in-plane MT contribution we have:

$$\begin{aligned}\sigma_{xx}^{MT(an)} &= 8e^2\eta_{(2)}T\int\frac{d^3q}{(2\pi)^3}\frac{1}{[1/\tau_\varphi+\hat{D}q^2][\epsilon+\eta_{(2)}\mathbf{q}^2+\frac{r}{2}(1-\cos q_z s)]} \\ &= \frac{e^2}{4s(\epsilon-\gamma_\varphi)}\ln\left(\frac{\epsilon^{1/2}+(\epsilon+r)^{1/2}}{\gamma_\varphi^{1/2}+(\gamma_\varphi+r)^{1/2}}\right),\end{aligned} \tag{20.195}$$

where, in accordance with [7], the infra-red divergence for the purely 2D case ($r=0$) is cut off at $Dq^2 \sim 1/\tau_\varphi$[23]. The dimensionless parameter

$$\gamma_\varphi = \frac{2\eta}{v_F^2\tau\tau_\varphi} \to \frac{\pi}{8T\tau_\varphi}\begin{cases} 1, & T\tau \ll 1 \\ 7\zeta(3)/\left(2\pi^3 T\tau\right), & 1 \ll T\tau \ll 1/\sqrt{\epsilon} \end{cases}$$

is introduced for simplicity. If $r \neq 0$ the MT contribution turns out to be finite even with $\tau_\varphi = \infty$. Comparison of the expressions (20.181) and (20.195) indicates that in the weak pair-breaking limit, the MT diagram makes an important contribution to the longitudinal fluctuation conductivity: it is four times larger than the AL contribution in the 3D regime, and even logarithmically exceeds it in the 2D regime above T_{LD}. For finite pair-breaking, however, the MT contribution is greatly reduced in magnitude.

We now consider the calculation of the MT contribution to the transverse conductivity. The explicit expressions for $v_z(p)$ and $v_z(q-p)$ (see Exp. (20.176)), result in $\langle v_x(p)v_x(q-p)\rangle_{FS} = \frac{1}{2}J^2s^2\cos q_z s$. We take the limit $J\tau << 1$ in evaluating the remaining integrals, which may then be performed exactly.

The regular part of the MT contribution to the transverse conductivity is

$$\begin{aligned}\sigma_{zz}^{MT(\text{reg})} &= -\frac{e^2s^2\pi r\tilde{\kappa}(T\tau)}{4}\int\frac{d^3q}{(2\pi)^3}\frac{\cos q_z s}{\epsilon+\eta_{(2)}\mathbf{q}^2+\frac{r}{2}(1-\cos q_z s)} \\ &= -\frac{e^2sr\tilde{\kappa}(T\tau)}{16\eta_{(2)}}\left(\frac{(\epsilon+r)^{1/2}-\epsilon^{1/2}}{r^{1/2}}\right)^2\end{aligned}$$

This term is smaller in magnitude than is the DOS one, and therefore makes a relatively small contribution to the overall fluctuation conductivity. In the 3D regime below T_{LD}, it is proportional to J^2, and in the 2D regime above T_{LD}, it is proportional to J^4.

[23] The detailed study of the phase-breaking time, its energy dependence and the effect on the MT contribution was done in [115]

For the anomalous part of the MT diagram one can find

$$\begin{aligned}\sigma_{zz}^{MT(\mathrm{an})} &= \frac{\pi e^2 J^2 s^2 \tau}{4}\int\frac{d^3q}{(2\pi)^3}\frac{\cos q_z s}{[1/\tau_\varphi+\hat{\mathbf{D}}q^2][\epsilon+\eta_{(2)}\mathbf{q}^2+\frac{r}{2}(1-\cos q_z s)]}\\ &= \frac{\pi e^2 s}{4(\epsilon-\gamma_\varphi)}\int\frac{d^2\mathbf{q}}{(2\pi)^2}\left[\frac{\gamma_\varphi+\eta_{(2)}\mathbf{q}^2+r/2}{\left[(\gamma_\varphi+\eta_{(2)}\mathbf{q}^2)(\gamma_\varphi+\eta_{(2)}\mathbf{q}^2+r)\right]^{1/2}}-\right.\\ &\left.-\frac{\epsilon+\eta_{(2)}\mathbf{q}^2+r/2}{\left[(\epsilon+\eta_{(2)}\mathbf{q}^2)(\epsilon+\eta_{(2)}\mathbf{q}^2+r)\right]^{1/2}}\right]\\ &= \frac{e^2 s}{16\eta_{(2)}}\left(\frac{\gamma_\varphi+r+\epsilon}{[\epsilon(\epsilon+r)]^{1/2}+[\gamma_\varphi(\gamma_\varphi+r)]^{1/2}}-1\right). \qquad (20.196)\end{aligned}$$

In examining the limiting cases of (20.196), it is useful to consider the cases of weak ($\gamma_\varphi << r$, $\Longleftrightarrow J^2\tau\tau_\varphi \gg 1/2$) and strong ($\gamma_\varphi \gg r$,$\Longleftrightarrow J^2\tau\tau_\varphi << 1/2$) pair-breaking separately[24]. For weak pair-breaking, we have

$$\sigma_{zz}^{MT(\mathrm{an})} \to \frac{e^2 s}{16\eta_{(2)}}\begin{cases}\sqrt{r/\gamma_\varphi}, & \epsilon \ll \gamma_\varphi \ll r\\ \sqrt{r/\epsilon}, & \gamma_\varphi \ll \epsilon \ll r\\ r/(2\epsilon), & \gamma_\varphi \ll r \ll \epsilon\end{cases}.$$

In this case, there is the usual 3D to 2D dimensional crossover in the anomalous MT contribution at T_{LD}. There is an additional crossover at T_φ(where $T_c < T_\varphi < T_{LD}$), characterized by $\epsilon(T_\varphi)=\gamma_\varphi$, below which the anomalous MT term saturates. Below T_{LD}, the MT contribution is proportional to J, but in the 2D regime above T_{LD}, it is proportional to J^2.

For strong pair-breaking

$$\sigma_{zz}^{MT(\mathrm{an})} \to \frac{e^2 s}{32\eta_{(2)}}\begin{cases}r/\gamma_\varphi, & \epsilon \ll r \ll \gamma_\varphi\\ r^2/(4\gamma_\varphi\epsilon), & r \ll \min\{\gamma_\varphi,\epsilon\}\end{cases}.$$

In this case, the 3D regime (below T_{LD}) is not singular, and the anomalous MT contribution is proportional to J^2, rather than J for weak pair-breaking. In the 2D regime, it is proportional to J^4 for strong pair-breaking, as opposed to J^2 for weak pair-breaking. In addition, the overall magnitude of the anomalous MT contribution with strong pair-breaking is greatly reduced from that for weak pair-breaking.

Let us now compare the regular and anomalous MT contributions. Since these contributions are opposite in sign, it is important to determine which will dominate. For the in-plane resistivity, the situation is straightforward: the anomalous part always dominates over the regular and the latter can be neglected. The case of $c-$axis resistivity requires more discussion. Since we expect $\tau_\varphi \geq \tau$, strong pair-breaking is likely in the dirty limit. When the pair-breaking is weak, the anomalous term is always of lower order in J than the regular term, so the regular term can be neglected. This is true for both the clean and dirty limits. The most important regime for the regular MT term is the dirty limit with strong pair-breaking. In this case, when $\tau_\varphi T \sim 1$, the regular and anomalous terms are comparable in magnitude. In short, it is usually a good approximation to neglect the regular term, except in the dirty limit with relatively strong pair-breaking and only for the out-of-plane conductivity.

Finally let us mention that the contributions from the two other diagrams of the MT type (diagrams 3 and 4 of Fig. 20.9) in the vicinity of critical temperature can be omitted: one can

[24] Physically the value $J^2\tau.$ characterizes the effective interlayer tunneling rate [97, 114]. When $1/\tau_\phi << J^2\tau << 1/\tau$, the quasiparticles scatter many times before tunneling to the neighboring layers, and the pairs live long enough for them to tunnel coherently. When $J^2\tau << 1/\tau_\phi$, the pairs decay before both paired quasiparticles tunnel.

Figure 20.11: The normalised excess conductivity for samples of YBCO-123 (triangles), BSSCO-2212(squares) and BSSCO-2223 (circles) plotted against $\epsilon = \ln T/T_c$ on a ln-ln plot as described in [124]. The dotted and solid lines are the AL theory in 3D and 2D respectively. The dashed line is the extended theory of [125]..

check that they have an additional square of the Cooper pair center of mass momentum q in the integrand of q-integration with respect to diagram 2 and hence turn out to be less singular in ϵ.

Discussion

Although the in-plane and out-of plane components of the fluctuation conductivity tensor of a layered superconductor contain the same fluctuation contributions, their temperature behavior may be qualitatively different. In fact, for σ_{xx}^{fl}, the negative contributions are considerably less than the positive ones in the entire experimentally accessible temperature range above the transition, and it is a positive monotonic function of the temperature. Moreover, for HTS compounds, where the pair-breaking is strong and the MT contribution is in the overdamped regime, it is almost always enough to take into account only the paraconductivity to fit experimental data. Some examples of the experimental findings for in-plane fluctuation conductivity of HTS materials on can see in [116, 117, 118, 119, 120, 121, 122, 123].

In Fig. 20.11 the fluctuation part of in-plane conductivity σ_{xx}^{fl} is plotted as a function of $\epsilon = \ln T/T_c$ on a double logarithmic scale for three HTS samples (the solid line represents the $2D$ AL behavior $(1/\epsilon)$, the dotted line represents the $3D$ one: $3.2/\sqrt{\epsilon})$ [124]. One can see that paraconductivity of the less anisotropic YBCO compound asymptotically tends to the 3D behavior $(1/\epsilon^{1/2})$ for $\epsilon < 0.1$, showing the LD crossover at $\epsilon \approx 0.07$; the curve for more anisotropic 2223 phase of BSCCO starts to bend for $\epsilon < 0.03$ while the most anisotropic 2212 phase of BSCCO shows a $2D$ behavior in the whole temperature range investigated. All three compounds show a universal $2D$ temperature behavior above the LD crossover up to the limits of the GL region. It is interesting that around $\epsilon \approx 0.24$ all the curves bend down and follow the same asymptotic $1/\epsilon^3$ behavior (dashed line). Finally at the value $\epsilon \approx 0.45$ all the curves fall down indicating the end of the observable fluctuation regime.

Reggiani et al. [125] extended the $2D$ AL theory to the high temperature region by taking into account the short wavelength fluctuations. The following universal formula for $2D$ para-

conductivity of a clean 2D superconductor as a function of the generalized reduced temperature $\epsilon = \ln T/T_c$ was obtained[25]:

$$\sigma_{xx}^{fl} = \frac{e^2}{16s} f(\epsilon)$$

with $f(\epsilon) = \epsilon^{-1}$, $\epsilon \ll 1$ and $f(\epsilon) = \epsilon^{-3}$, $\epsilon \gtrsim 1$.

In the case of the out-of-plane conductivity the situation is quite different. Both positive contributions (AL and anomalous MT) are suppressed by the interlayer transparency, leading to a competition between positive and negative terms. This can lead to a maximum in the c-axis fluctuation resistivity which occurs in the 2D regime (in the case discussed $J\tau << 1, r\kappa << 1$ and $\gamma_\varphi \kappa > 1$):

$$\epsilon_m/r \approx \frac{1}{(8r\kappa)^{1/2}} - \frac{1}{8\kappa}\left[\tilde{\kappa} - \frac{1}{2\gamma_\varphi}\right].$$

This nontrivial effect of fluctuations on the transverse resistance of a layered superconductor allows a successful fit to the data observed on optimally and overdoped HTS samples (see, for instance, Fig.20.12) where the growth of the resistance still can be treated as the correction.

The fluctuation mechanism of the growth of the transverse resistance can be easily understood in a qualitative manner. Indeed to modify the in-plane result (20.98) for the case of c-axis paraconductivity one has to take into account the hopping character of the electronic motion in this direction. If the probability of one-electron interlayer hopping is $\mathcal{P}_1$, then the probability of coherent hopping for two electrons during the fluctuation Cooper pair lifetime τ_{GL} is the conditional probability of these two events: $\mathcal{P}_2 = \mathcal{P}_1(\mathcal{P}_1\tau_{GL})$. The transverse paraconductivity may thus be estimated as $\sigma_\perp^{AL} \sim \mathcal{P}_2\sigma_\parallel^{AL} \sim \mathcal{P}_1^2\frac{1}{\epsilon^2}$, in complete accordance with (20.182). We see that the temperature singularity of $\sigma_\perp^{AL}$ turns out to be stronger than that in $\sigma_\parallel^{AL}$, however for a strongly anisotropic layered superconductor $\sigma_\perp^{AL}$ is considerably suppressed by the square of the small probability of inter-plane electron hopping which enters in the pre-factor. It is this suppression which leads to the necessity of taking into account the DOS contribution to the transverse conductivity. The latter is less singular in temperature but, in contrast to the paraconductivity, manifests itself in the first, not the second, order in the interlayer transparency $\sigma_\perp^{DOS} \sim -\mathcal{P}_1 \ln \frac{1}{\varepsilon}$. The DOS fluctuation correction to the one-electron transverse conductivity is negative and, being proportional to the first order of $\mathcal{P}_1$, can completely change the traditional picture of fluctuations just rounding the resistivity temperature dependence around transition. The shape of the temperature dependence of the transverse resistance mainly is determined by competition of the opposite sign contributions: the paraconductivity and MT term, which are strongly temperature dependent but are suppressed by the square of the barrier transparency and the DOS contribution which has a weaker temperature dependence but depends only linearly on the barrier transparency.

20.6 Manifestation of fluctuations in various properties

In this Section we will demonstrate the applications of the microscopic theory of fluctuations. The limited volume does not permit us to deliver here the systematic review of the modern theory and we restrict ourselves only by presentation of the several representative recent studies. The details one can find in the articles cited in subtitles.

It is necessary to underline that the comparison of the results of fluctuation theory with the experimental findings on HTS materials has to be considered sooner in qualitative than quantitative context. Indeed, as is clear now, the superconductivity in the most of HTS compounds has the nontrivial symmetry. Moreover, as was discussed in the previous Section, these

[25] In Section 7.2 we will demonstrate how such a dependence $\left(1/\ln^3(T/T_c)\right)$ appears by accounting for short wavelength fluctuations for the $2D$ fluctuation susceptibility.

Figure 20.12: Fit of the temperature dependence of the transverse resistance of an underdoped BSCCO c-axis oriented film with the results of the fluctuation theory [126]. The inset shows the details of the fit in the temperature range between T_c and 110K.

compounds are rather clean than dirty. Both these complications can be taken into account (see for example [112, 97]) but this was not done in the majority of the cited papers.

20.6.1 The effects of fluctuations on magnetoconductivity [97, 127, 154, 155]

The experimental investigations of the fluctuation magnetoconductivity are of special interest first because this physical value weakly depends on the normal state properties of superconductor and second due to its special sensitivity to temperature and magnetic field. The role of AL contribution for both the in-plane and out-of-plane magnetoconductivities was studied above in the framework of the phenomenological approach. The microscopic calculations of the other fluctuation corrections to the in-plane magnetoconductivity conductivity show that the MT contribution has the same positive sign and temperature singularity as the AL one. In the case of weak pair-breaking it can even considerably exceed the latter. The negative DOS contribution, like in the case of the zero-field conductivity, turns out to be considerably less singular and many authors (see e.g. Refs. [136, 137, 138, 139, 142, 140, 141, 143, 144, 145],[146, 147]) successfully explained the in-plane magnetoresistance data in HTS using the AL and MT contributions only [148, 149, 150, 151].

Turning to the out-of-plane magnetoconductivity of a layered superconductor one can find a quite different situation. Both the AL and MT contributions turn out to be here of the second order in the interlayer transparency and this circumstance makes the less singular DOS contribution, which remains however of first order in transparency, to be competitive with the main terms [127]. The large number of microscopic characteristics involved in this competition, like the Fermi velocity, interlayer transparency, phase-breaking and elastic relaxation times, gives rise to the possibility of occurrence of different scenarios for various compounds. The c-axis magnetoresistance of a set of HTS materials shows a very characteristic behavior above T_{c0}. In contrast to the ab-plane magnetoresistance which is positive at all temperatures, the magnetoresistance along the c-axis has been found in many HTS compounds (BSSCO [128, 130, 131, 132], LSSCO [133], YBCO [134] and TlBCCO [135]) to have a negative sign not too close to T_{c0} and turn positive at lower temperatures. We will show how this behavior find its explanation within the fluctuation theory [97].

We consider here the effect of a magnetic field parallel to the c-axis. In this case both quasiparticles and Cooper pairs move along Landau orbits within the layers. The c-axis dispersion remains unchanged from the zero-field form. In the chosen geometry one can generalize the zero-field results reported in the previous Section to finite field strengths simply by the

replacement of the two-dimensional integration over $\mathbf{q}$ by a summation over the Landau levels

$$\int \frac{d^2\mathbf{q}}{(2\pi)^2} \to \frac{H}{\Phi_0}\sum_n = \frac{h}{2\pi\eta_{(2)}}\sum_n$$

(let us remind that $\eta_{(2)} = \xi_{xy}^2$). So the general expressions for all fluctuation corrections to the c-axis conductivity in a magnetic field can be simply written in the form [97]:

$$\sigma_{zz}^{AL} = \frac{e^2 s r^2 h}{64\xi_{xy}^2}\sum_{n=0}^{\infty}\frac{1}{\{[\epsilon + h(2n+1)][r+\epsilon+h(2n+1)]\}^{3/2}} \tag{20.197}$$

$$\sigma_{zz}^{DOS} = -\frac{e^2 s r\kappa h}{8\xi_{xy}^2}\sum_{n=0}^{1/h}\frac{1}{\{[\epsilon + h(2n+1)][r+\epsilon+h(2n+1)]\}^{1/2}} \tag{20.198}$$

$$\sigma_{zz}^{MT(reg)} = -\frac{e^2 s\tilde{\kappa} h}{4\xi_{xy}^2}\sum_{n=0}^{\infty}\left(\frac{\epsilon + h(2n+1) + r/2}{\{[\epsilon + h(2n+1)][r+\epsilon+h(2n+1)]\}^{1/2}} - 1\right) \tag{20.199}$$

$$\sigma_{zz}^{MT(an)} = \frac{e^2 s h}{8\xi_{xy}^2(\varepsilon-\gamma_\varphi)}\sum_{n=0}^{\infty}\left(\frac{\gamma_\varphi + h(2n+1) + r/2}{\{[(\gamma_\varphi + h(2n+1)][\gamma_\varphi + h(2n+1)+r)]\}^{1/2}} - \right.$$
$$\left. - \frac{\epsilon + h(2n+1) + r/2}{\{[\epsilon + h(2n+1)][r+\epsilon+h(2n+1)]\}^{1/2}}\right). \tag{20.200}$$

For the in-plane component of the fluctuation conductivity tensor the only additional problem appears in the AL diagram, where the matrix elements of the harmonic oscillator type, originating from the $B_\parallel$ ($q_\parallel$) blocks, have to be calculated. How to do this was demonstrated in details in Section 4. The other contributions are essentially analogous to their c-axis counterparts:

$$\sigma_{xx}^{AL} = \frac{e^2}{4s}\sum_{n=0}^{\infty}(n+1)\left(\frac{1}{\{[\epsilon + h(2n+1)][r+\epsilon+h(2n+1)]\}^{1/2}} - \right.$$
$$\frac{2}{\{[\epsilon + h(2n+2)][r+\epsilon+h(2n+2)]\}^{1/2}} +$$
$$\left.\frac{1}{\{[\epsilon + h(2n+3)][r+\epsilon+h(2n+3)]\}^{1/2}}\right), \tag{20.201}$$

$$\sigma_{xx}^{DOS} + \sigma_{xx}^{MT(reg)} = -\frac{e^2 h(\kappa+\tilde{\kappa})}{2s}\sum_{n=0}^{1/h}\frac{1}{\{[\epsilon + h(2n+1)][r+\epsilon+h(2n+1)]\}^{1/2}}, \tag{20.202}$$

and

$$\sigma_{xx}^{MT(an)} = \frac{e^2 h}{4s(\epsilon-\gamma_\varphi)}\sum_{n=0}^{\infty}\left(\frac{1}{\{[(\gamma_\varphi + h(2n+1)][\gamma_\varphi + h(2n+1)+r)]\}^{1/2}} - \right.$$
$$\left.\frac{1}{\{[\epsilon + h(2n+1)][r+\epsilon+h(2n+1)]\}^{1/2}}\right). \tag{20.203}$$

These results can in principle be already used for numerical evaluations and fitting of the experimental data which was indeed successfully done in a series of papers [134, 152, 135].

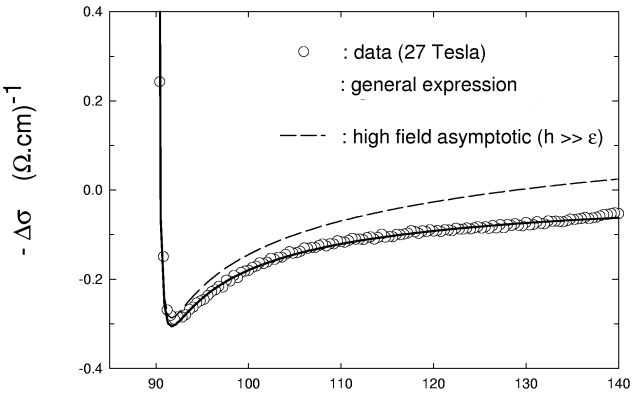

Figure 20.13: Magnetoconductivity versus temperature at 27 T for an underdoped Bi-2212 single crystal. The solid line represents the theoretical calculation. The symbols are the experimental magnetoconductivity $\Delta\sigma_{zz}(B \shortparallel c \shortparallel I)$[155]

The detailed comparison of the cited results with the experimental data [134, 153], especially in strong fields, raised the problem of regularization of the DOS contribution. If in the absence of the magnetic field its ultra-violet divergence was successfully cut off at $q \sim \xi^{-1}$, in the case under consideration the cut off parameter depends on the magnetic field and makes the fitting procedure ambiguous. The solution of this problem was proposed in [154], where the authors calculated the difference $\Delta\sigma_{zz}^{DOS} = \sigma_{zz}^{DOS}(h,\epsilon) - \sigma_{zz}^{DOS}(0,\epsilon)$ applying to formulas (20.198) and (20.202) the same trick which was already used in Section 2 for the regularization of the free energy in magnetic field (Eq. (20.77)). The corresponding asymptotics for all out-of-plane fluctuation contributions are presented in the following table:

	$h \ll \epsilon$	$\epsilon \ll h \ll r \quad (3D)$	$\max\{\epsilon, r\} \ll h \quad (2D)$
$\Delta\sigma_{zz}^{DOS}$	$\frac{e^2 s\kappa}{3\,2^5\xi_{xy}^2}\frac{r(\epsilon+r/2)}{[\epsilon(\epsilon+r)]^{3/2}}h^2$	$0.428\frac{e^2 s\kappa}{16\xi_{xy}^2}r\sqrt{\frac{h}{r}}$	$\frac{e^2 s\kappa}{8\xi_{xy}^2}r\ln\frac{\sqrt{h}}{\sqrt{\epsilon}+\sqrt{\epsilon+r}}$
$\Delta\sigma_{zz}^{MT(reg)}$	$\frac{e^2 s\tilde{\kappa}}{3\,2^6\xi_{xy}^2}\frac{r^2}{[\epsilon(\epsilon+r)]^{3/2}}h^2$	$0.428\frac{e^2 s\tilde{\kappa}}{8\xi_{xy}^2}r\sqrt{\frac{h}{r}}$	$-\sigma_{zz}^{MT(reg)}(0,\epsilon) - \frac{\pi^2 e^2 s\tilde{\kappa}}{2^8\xi_{xy}^2}\frac{r^2}{h}$
$-\Delta\sigma_{zz}^{AL}$	$\frac{e^2 s}{2^8\xi_{xy}^2}\frac{r^2(\epsilon+r/2)}{[\epsilon(\epsilon+r)]^{5/2}}h^2$	$\sigma_{zz}^{AL}(0,\epsilon) - \frac{3.24e^2 s}{\xi_{xy}^2}\sqrt{\frac{r}{h}}$	$\sigma_{zz}^{AL}(0,\epsilon) - \frac{7\zeta(3)e^2 s}{2^9\xi_{xy}^2}\frac{r^2}{h^2}$
$-\Delta\sigma_{zz}^{MT(an)}$ $\min\{\epsilon, r\} \ll \gamma_\varphi$	$\frac{e^2 s}{3\,2^7\xi_{xy}^2}\frac{r^2}{[\epsilon(\epsilon+r)]^2}h^2$	$\sigma_{zz}^{MT(an)}(0,\epsilon) - \frac{e^2 s}{32\xi_{xy}^2}\sqrt{\frac{r}{\gamma_\varphi}}$	$\sigma_{zz}^{MT(an)}(0,\epsilon) - \frac{3\pi^2 e^2 s}{2^8\xi_{xy}^2}\frac{\max\{r,\gamma_\varphi\}}{h}$
$-\Delta\sigma_{zz}^{MT(an)}$ $\gamma_\varphi \ll \min\{\epsilon, r\}$	$\frac{e^2 s}{3\,2^7\xi_{xy}^2}\frac{\sqrt{r}}{\epsilon\gamma_\varphi^{3/2}}h^2$	$\sigma_{zz}^{MT(an)}(0) - \frac{3.24e^2 s}{64\xi_{xy}^2}\sqrt{\frac{r}{h}}$	$\sigma_{zz}^{MT(an)}(0,\epsilon) - \frac{3\pi^2 e^2 s}{2^8\xi_{xy}^2}\frac{(r+\epsilon)}{h}$

Table 3

The procedure described gives an excellent fitting up to very high fields [155] which is shown in Fig. 20.13.

Let us start the analysis from the $2D$ case ($r \ll \epsilon$). One can see that here the positive DOS contribution to magnetoconductivity turns out to be dominant. It grows as H^2 up to $H_{c2}(\epsilon)$ and then crosses to a slow logarithmic asymptote. At $H \sim H_{c2}(0)$ the value of $\Delta\sigma_{zz}^{DOS}(h \sim 1, \epsilon) = -\sigma_{zz}^{DOS}(0,\epsilon)$ which means the total suppression of the fluctuation correction in such a strong field. The regular part of the Maki-Thompson contribution does not manifest itself in this case while the AL term can compete with the DOS one in the immediate vicinity of T_c, where the small anisotropy factor r can be compensated by the additional ϵ^3 in the denominator. The anomalous MT contribution can contribute in the case of small pairbreaking only, which is opposite to what is expected in HTS.

In the $3D$ case ($\epsilon \ll r$) the behavior of the magnetoconductivity is more complex. In weak and intermediate fields the main, negative, contribution to the magnetoconductivity occurs from

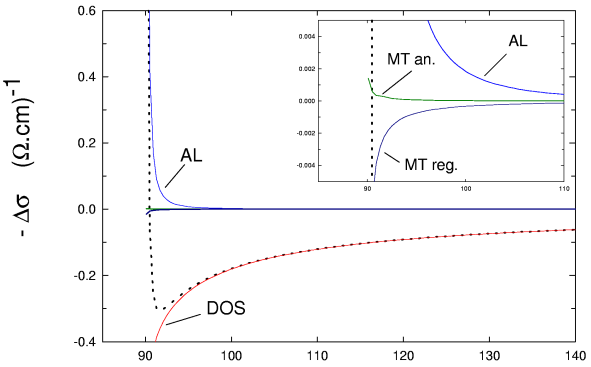

Figure 20.14: Decomposition of the calculation of total theoretical magnetoconductivity for an underdoped Bi-2212 single crystal at 27 T. The inset shows the regular and anomalous parts of the MT contribution which are too small to be presented in the same scale as the AL and DOS contributions [155].

the AL and MT terms. At $H \sim H_{c2}(\epsilon)(h \sim \epsilon)$ the paraconductivity is already considerably suppressed by the magnetic field and the h^2 - dependence of the magnetoconductivity changes through the $\sqrt{\frac{r}{h}}$ tendency to the high field asymptote $-\sigma_{zz}^{(fl)}(0,\epsilon)$. In this intermediate region of fields ($\epsilon \ll h \ll r$), side by side with the decrease ($\sim \sqrt{\frac{r}{h}}$) of the main AL and MT contributions, the growth of the still relatively small DOS term takes place. At the upper limit of this region ($h \sim r$) its positive contribution is of the same order as the AL one and at high fields ($r \ll h \ll 1$) the DOS contribution determines the slow logarithmic decay of the fluctuation correction to the conductivity which is completely suppressed only at $H \sim H_{c2}(0)$. The regular part of the Maki- Thompson contribution is not of special importance in the $3D$ case. It remains comparable with the DOS contribution in the dirty case at fields $h \lesssim r$, but decreases rapidly ($\sim \frac{r}{h}$) at strong fields ($h \gtrsim r$), in the only region where the robust $\Delta\sigma_c^{DOS}(h,\epsilon) \sim \ln\frac{h}{r}$ shows up surviving up to $h \sim 1$.

The temperature dependence of the different fluctuation contributions to the magnetoconductivity calculated for an underdoped Bi-2212 single crystal at the magnetic field 27 T is presented in Fig. 20.14.

The formulas for the in-plane magnetoconductivity are presented in the table:

	$h \ll \epsilon$	$\epsilon \ll h \ll r;\quad \max\{\epsilon, r\} \ll h$
$\Delta\sigma_{xx}^{AL}$	$-\frac{e^2}{2^8 s}\frac{[8\epsilon(\epsilon+r)+3r^2]}{[\epsilon(\epsilon+r)]^{5/2}}h^2$	$-\sigma_{xx}^{AL}(0,\epsilon)+\frac{e^2}{4s}\frac{1}{\sqrt{2hr}};\quad -\sigma_{xx}^{AL}(0,\epsilon)+\frac{e^2}{8s}\frac{1}{h}$
$\Delta\sigma_{xx}^{MT(an)}$ $(\min\{\epsilon, r\} \ll \gamma_\varphi)$	$-\frac{e^2}{3\,2^5 s}\frac{(\epsilon+r/2)}{[\epsilon(\epsilon+r)]^{3/2}}h^2$	$-\sigma_{xx}^{MT}(0,\epsilon)+\frac{e^2}{8s}\frac{1}{\gamma_\varphi}\ln\frac{\sqrt{\gamma_\varphi}}{\sqrt{2h}+\sqrt[4]{2h+r}}$
$\Delta\sigma_{xx}^{MT(an)}$ $(\gamma_\varphi \ll \min\{\epsilon, r\})$	$-\frac{e^2}{3\,2^5 s}\frac{1}{\epsilon\gamma^{3/2}r^{1/2}}h^2$	$-\sigma_{xx}^{MT}(0,\epsilon)+\frac{0.2e^2}{s}\frac{1}{\sqrt{hr}};\quad -\sigma_{xx}^{MT}(0,\epsilon)+\frac{3\pi^2e^2}{32s}\frac{1}{h}$
$\Delta(\sigma_{xx}^{DOS}+$ $\sigma_{xx}^{MT(reg)})$	$\frac{e^2(\kappa+\tilde{\kappa})}{3\,2^7 s}\frac{(\varepsilon+r/2)}{[\varepsilon(\varepsilon+r)]^{3/2}}h^2$	$0.428\frac{e^2(\kappa+\tilde{\kappa})}{2^6 s}\sqrt{\frac{h}{r}};\qquad \frac{e^2(\kappa+\tilde{\kappa})}{32s}\ln\frac{\sqrt{h}}{(\sqrt{\epsilon}+\sqrt{\epsilon+r})}$

Table 4

Analyzing it one can see that in almost all regions the negative AL and MT contributions govern the behavior of in-plane magnetoconductivity. Nevertheless, similar to the c-axis case, the high field behavior is again determined by the positive logarithmic $\Delta(\sigma_{xx}^{DOS}+\sigma_{xx}^{MT(reg)})$ contribution, which is the only one to survive in strong field. It is important to stress that the suppression of the DOS contribution by a magnetic field takes place very slowly. Such robustness with respect to the magnetic field is of the same physical origin as the slow logarithmic dependence of the DOS-type corrections on temperature.

Another important problem which appears in the fitting of the resistive transition shape in relatively strong fields with the fluctuation theory is the much larger broadening of the transition than predicted by the Abrikosov-Gorkov theory [156]. Kim and Gray [96] explained the broadening of the c-axis peak with increasing magnetic field in terms of Josephson coupling, describing a layered superconductor as a stack of Josephson junctions. In Refs. [157, 71] the self-consistent Hartree approach was proposed for the extension of fluctuation theory beyond the Gaussian approximation. It results in the considerable shift of $T_c(H)$ toward low temperatures with a corresponding broadening of the transition. The renormalized reduced temperature $\tilde{\varepsilon}_h$ is determined according to the self-consistent equation [71]:

$$\varepsilon_h = \tilde{\varepsilon}_h - \frac{1}{4}\, Gi_{(2)}\; h \sum_{n=0}^{1/h} \frac{1}{[(\tilde{\varepsilon}_h + hn)(\tilde{\varepsilon}_h + h(n+1) + r)]^{1/2}} \tag{20.204}$$

The authors of [158], following the procedure proposed by Dorsey and Ullah [71], modified the expressions (20.197)- (20.203) by account for (20.204). In result they succeeded to fit quantitatively both in-plane resistivity transition and the transverse resistivity peak for BSCCO films strongly broadened by applied magnetic field.

20.6.2 Fluctuations far from T_c or in strong magnetic fields

As was mentioned above the role of fluctuations is especially pronounced in the vicinity of the critical temperature. Nevertheless for some phenomena they can be still considerable far from the transition too. In these cases the GL theory is certainly unapplicable since the short-wave and dynamical fluctuation contributions have to be taken into account. It can be done in the microscopic approach which we will demonstrate in several examples.

Fluctuation magnetic susceptibility far from transition [29].

The given above qualitative estimations (20.57)-(20.63) for the fluctuation diamagnetic susceptibility, based on the Langevin formula, demonstrate that even at high temperatures $T \gg T_c$ it turns to be of the order of χ_P for clean $3D$ superconductors and exceeds noticeably this value for $2D$ systems. In order to develop the microscopic theory [159, 29, 161] let us start from the general expression for free energy in the one-loop approximation:

$$F = T \sum_{\Omega_k} \mathrm{Tr}\{\ln[1 - g\Pi(\Omega_k, \mathbf{r}, \mathbf{r}')]\}, \tag{20.205}$$

where g is the effective interaction constant related with the transition critical temperature by (20.153). This approximation corresponds to the ladder one (see (20.146)) for the fluctuation propagator. The polarization operator $\Pi(\Omega_k, \mathbf{r}, \mathbf{r}')$ is determined by expression (20.147) but in the case of an applied magnetic field the homogeneity of the system is lost and $\Pi(\Omega_k, \mathbf{r}, \mathbf{r}')$ depends not on the space variable difference $\mathbf{r} - \mathbf{r}'$ but on each separately. Expanding $\Pi(\Omega_k, \mathbf{r}, \mathbf{r}')$ one can express the magnetic susceptibility of a layered superconductor in a weak magnetic field perpendicular to the layers in terms of the derivatives $\Pi_x = \frac{\partial}{\partial q_x}\Pi(\mathbf{q})$ [29]:

$$\chi = -\frac{\partial^2 F}{\partial H^2} = -\frac{2}{3} e^2 T \sum_{\Omega_k} \int \frac{d^3\mathbf{q}}{(2\pi)^3} L^3 \Pi_x (\Pi_x \Pi_{yy} - \Pi_y \Pi_{xy}). \tag{20.206}$$

The final expressions for the fluctuation diamagnetic susceptibility in the clean and dirty cases for wide range of temperatures can be written as:

$$\chi_{fl}^{(3)}(T) = \frac{\chi_P}{3} \begin{cases} 0.05(\ln^{-2}(\omega_D/T_c)) - \ln^{-2}(T/T_c)), & \tau^{-1} \ll T \ll \omega_D \\ 2\sqrt{T\tau}\,\ln^{-1}(T/T_c), & T_c \ll T \ll \tau^{-1} \end{cases} \tag{20.207}$$

$$\chi_{fl}^{(2)}(T) = \frac{0.05}{p_F s}\chi_P \left(\frac{E_F}{T}\right) \frac{1}{\ln^3(T/T_c)} \tag{20.208}$$

Let us stress that these results are valid for the fluctuation diamagnetism of a normal metal with $g > 0$ too, if by T_c one uses the formal value $T_c \sim E_F \exp(\frac{1}{\nu g})$.

Fluctuation magnetoconductivity far from transition [162].

Let us discuss the conductivity of the $2D$ electron system with impurities in a magnetic field at low temperatures. Even in the absence of the field the effects of quantum interference of the non-interacting electrons in their scatterings on elastic impurities already results in the appearance of a nontrivial temperature dependence of the resistance. This result contradicts the statement of the classical theory of metals requiring the saturation of the resistance at its residual value at low temperatures. In a superconductor above the critical temperature this, so-called weak localization (WL), effect is amplified by the Andreev reflection of electrons on the fluctuation Cooper pair leading to appearance of the MT correction to the conductivity. The characteristic feature of both the MT and WL corrections is their extreme sensitivity to the dephasing time τ_φ and to weak magnetic fields.

Beyond the GL region ($T \gtrsim T_c$) the MT correction is determined by the same diagram 2 of Fig. 20.9 but now the dynamic ($\Omega_k \neq 0$) and short-wave-length ($q \sim \xi^{-1}$) fluctuation modes have to be taken into account. The corresponding calculations were performed in [98, 162] and the result can be written in the form:

$$\delta\sigma_{WL+MT} = \frac{e^2}{2\pi^2}\left[\alpha - \beta(T)\right] Y\left(\Omega_L \tau \epsilon\right), \tag{20.209}$$

where we introduced the effective Larmour frequency for the diffusion motion $\Omega_L = 4\mathcal{D}eH$ with the diffusion coefficient $\mathcal{D}$ [26] and the function

$$Y(x) = \ln x + \psi(\frac{1}{2} + \frac{1}{x}) = \begin{cases} \frac{x^2}{24}, & x \ll 1 \\ \ln x, & x \gg 1 \end{cases}. \tag{20.210}$$

The first term in this formula corresponds to the WL contribution ($\alpha = 1$ if the spin-orbit interaction of the electrons with the impurities is small while in the opposite limiting case $\alpha = -1/2$), the second describes the MT contribution to magnetoconductivity. The function $\beta[\ln(T/T_c)]$ was introduced in Ref.[162]. At $T \to T_c$ $\beta(x) = 1/x$ and (20.209) reduces to the already studied MT correction in the vicinity of critical temperature. For $T \gg T_c$ $\beta(x) = 1/x^2$ and the MT contribution gives a logarithmically small correction to the WL result. Its zero-field value, being proportional to $\ln^{-2}(T/T_c)$, decreases with the growth of the temperature faster than both the AL contribution (in the dirty case $\delta\sigma_{AL} \sim 1/\ln(T/T_c)$) and the especially slow DOS contribution ($\delta\sigma_{DOS} \sim \ln\ln(1/T_c\tau) - \ln\ln(T/T_c)$) (see Ref. [98, 99]).

It worth mentioning that for the region of temperatures $T \gg T_c$, analogous to Exp.(20.207)-(20.208), the result (20.209) can be applied both to superconducting and normal metals ($g > 0$), if in place of the critical temperature the formal value $T_c \sim E_F \exp(\frac{1}{\nu g})$ is undermined. The interplay of the localization and fluctuation corrections was extensively studied (see, for example, [163, 164, 165, 166, 167])

[26] Comparison of the expressions (20.76), (20.114) and (20.209) relates the Larmour frequency with the dimensionless field: $h = \Omega_L/2T_c$ introduced in section 2 and the diffusion coefficient with the phenomenological GL constants $\mathcal{D} = 1/m\alpha$.

Fluctuations in magnetic fields near $H_{c2}(0)$ [168].

As one can see from (20.201)- (20.203), in the vicinity of the upper critical field $H_{c2}(T)$ the fluctuation corrections diverge as ϵ_h^{-1} for the $2D$ case and as $\epsilon_h^{-1/2}$ for the $3D$ case [27] (it is enough to keep just the terms with $n = 0$ in these formulas). This behavior is preserved in strong magnetic fields too, but the coefficients undergo changes. A case of special interest is $T \ll T_c$ (which means $H \to H_{c2}(0)$) which represents an example of a quantum phase transition [168]. Microscopic analysis of the magnetoconductivity permits us to study the effect of fluctuations in magnetic fields of the order of $H_{c2}(0)$, where the GL functional approach is inapplicable.

We restrict our consideration to the case of a dirty metal ($T\tau \ll 1$). In this limit $|\tilde{\omega}_{n+\mu} - \tilde{\omega}_{-n}| \approx \tau^{-1}$ and the Green function correlator (20.149) can be written in the form

$$\mathcal{P}(\mathbf{q}, \varepsilon_1, \varepsilon_2) = 2\pi\nu\tau^2\theta(-\varepsilon_1\varepsilon_2)\left(\tau^{-1} - |\varepsilon_1 - \varepsilon_2| - \widehat{\mathcal{D}}q^2\right). \tag{20.211}$$

Expressing $\Pi(\mathbf{q}, \Omega_k)$ in terms of $\mathcal{P}(\mathbf{q}, \varepsilon_1, \varepsilon_2)$ by means of (20.167) and using the definition of the critical temperature one can find an explicit formula for the fluctuation propagator

$$\begin{aligned} L^{-1}(\mathbf{q}, \Omega_k) &= g^{-1} - \Pi(\mathbf{q}, \Omega_k) = \\ &= -\nu\left[\ln\frac{T}{T_c} + \psi\left(\frac{1}{2} + \frac{|\Omega_k| + \widehat{\mathcal{D}}\mathbf{q}^2}{4\pi T}\right) - \psi\left(\frac{1}{2}\right)\right]. \end{aligned} \tag{20.212}$$

The prominent characteristic of this expression is that it is valid even relatively far from the critical temperature (for temperatures $T \ll \min\{\tau^{-1}, \omega_D\}$) and for $|\mathbf{q}| \ll l^{-1}, |\Omega_k| \ll \omega_D$.

One can rewrite this expression in a magnetic field applied along the c-axis in the Landau representation by simply replacing $\left(\widehat{\mathcal{D}}\mathbf{q}^2\right)_{\|} \Rightarrow \Omega_L(n + 1/2)$ [159]:

$$\begin{aligned} L_n^{-1}(q_z, \Omega_k) &= -\nu\left[\ln\frac{T}{T_c} + \psi\left(\frac{1}{2} + \frac{|\Omega_k|}{4\pi T} + \right.\right. \\ &\left.\left. + \frac{\Omega_L(n + 1/2) + 4\tau J^2 \sin^2(q_z s/2)}{4\pi T}\right) - \psi\left(\frac{1}{2}\right)\right]. \end{aligned} \tag{20.213}$$

In the case of arbitrary temperatures and magnetic fields the expression for the AL contribution to the conductivity takes the form:

$$\begin{aligned} \sigma_{xx}^{AL}(\omega_\nu) &= \nu e^2 T \sum_{\Omega_k} \sum_{n,m=0}^{\infty} B_{n,m}(\Omega_k + \omega_\nu, \Omega_k) L_m(\Omega_k) \times \\ &\times B_{m,n}(\Omega_k, \Omega_k + \omega_\nu) L_n(\Omega_k + \omega_\nu) \end{aligned} \tag{20.214}$$

(we have restricted our consideration to the $2D$ case). The expression for $B_{n,m}(\Omega_k, \omega_\nu)$ can be rewritten as

$$\begin{aligned} B_{n,m}(\Omega_k + \omega_\nu, \Omega_k) &= -\frac{2\pi\nu}{\sqrt{eH}}\tau^2\mathcal{D}_{(2)} T \sum_{\varepsilon_i}\left[\sqrt{n+1}\delta_{m,n+1} + \sqrt{n}\delta_{m,n-1}\right] \times \\ &\lambda_n(\varepsilon_i + \omega_\nu, \Omega_k - \varepsilon_i)\lambda_m(\varepsilon_i, \Omega_k - \varepsilon_i) \end{aligned} \tag{20.215}$$

with

[27] ϵ_h is the renormalized by the magnetic field reduced temperature $\epsilon_h = \epsilon + h$

$$\lambda_m(\varepsilon_1,\varepsilon_2)=\frac{1}{\tau}\frac{\Theta\left(-\varepsilon_1\varepsilon_2\right)}{\left|\varepsilon_1-\varepsilon_2\right|+\Omega_L(m+1/2)}. \tag{20.216}$$

The critical field $H_{c2}(T)$ is determined by the equation $L_0^{-1}(q_z=0,\Omega_k=0)=0$. This is why in the vicinity of $H_{c2}(T)$ the singular contribution to (20.214) originates only from the terms with $L_0(0,\Omega_k)$. The frequency dependencies of the functions $B_{n,m}(\Omega_k+\omega_\nu,\Omega_k)$ and $L_1(\Omega_k)$ are weak although we cannot omit them to get nonvanishing answer. It is enough to restrict ourselves to the linear approximation in their frequency dependencies. If the temperature $T\ll T_{c0}$ the sum over frequencies in (20.215) can be approximated by an integral. Transforming the boson frequency Ω_k summation to a contour integration as was done above and making the analytic continuation in the external frequency ω_ν one can get an explicit expression for the d.c. paraconductivity. In the same spirit the contributions of all other diagrams from the Fig. 20.9 which contribute to fluctuation conductivity in the case under discussion are calculated side by side with the AL one. The final answer can be presented in the form:

$$\begin{aligned}\delta\sigma_{tot} \;=\; & \frac{2e^2}{3\pi^2}\left\{-\ln\frac{\pi T_{c0}}{2\gamma T}+\frac{3\gamma_E T}{T_{c0}}\left(\frac{H_{c2}(T)}{H-H_{c2}(T)}\right)+\right.\\ & +\psi\left[\frac{T_{c0}}{2\gamma_E T}\left(\frac{H-H_{c2}(T)}{H_{c2}(T)}\right)\right]+\\ & \left.+\,4\left(\frac{T_{c0}}{2\gamma_E T}\frac{H_{c2}(T)}{H-H_{c2}(T)}\psi'\left[\frac{T_{c0}}{2\gamma_E T}\left(\frac{H-H_{c2}(T)}{H_{c2}(T)}\right)\right]-1\right)\right\},\end{aligned} \tag{20.217}$$

where γ_E is the Euler constant. Let us consider some limiting cases. If the temperature is relatively high $T/T_{c0}\gg\left(H-H_{c2}(T)\right)/H_{c2}(T)$, we obtain the following formula for the fluctuation conductivity:

$$\delta\sigma=\frac{2\gamma_E e^2}{\pi^2}\frac{T}{T_{c0}}\left(\frac{H_{c2}(T)}{H-H_{c2}(T)}\right). \tag{20.218}$$

If $H<H_{c2}(0)$, we can introduce $T_c(H)$ and rewrite Eq.(20.218) in the usual way

$$\delta\sigma=\frac{3e^2}{2\gamma_E\pi^2}\frac{T_{c0}}{T-T_c(H)}. \tag{20.219}$$

If $H>H_{c2}(0)$, in the low-temperature limit $T/T_{c0}\ll\left(H-H_{c2}(T)\right)/H_{c2}(T)$ we have

$$\delta\sigma=-\frac{2e^2}{3\pi^2}\ln\frac{H_{c2}(T)}{H-H_{c2}(T)}. \tag{20.220}$$

One can see, that even at zero temperature a logarithmic singularity remains and the corresponding correction is negative. It results from all three fluctuation contributions, although the DOS one exceeds the others by numerical factor. Let us recall that in the case of the c-axis conductivity of a layered superconductor, or in granular superconductors above T_c, the DOS contribution exceeds the MT and AL ones parametrically [160].

20.6.3 The effect of fluctuations on the Hall conductivity[174]

Let us start with a discussion of the physical meaning of the Hall resistivity ρ_{xy}. In the case of only one type of carriers it depends on their concentration n and turns out to be independent of the electron diffusion coefficient: $\rho_{xy}=H/(en)$. The fluctuation processes of the MT and DOS types contribute to the diffusion coefficient, so their expected contribution to the Hall resistivity is zero. For the Hall conductivity in a weak field one can write

$$\sigma_{xy} = \rho_{xy}\sigma_{xx}^2 = \rho_{xy}\sigma_{xx}^{(n)2} + 2\rho_{xy}\sigma_{xx}^{(n)}\delta\sigma_{xx} = \sigma_{xy}^{(n)}\left(1 + 2\frac{\delta\sigma_{xx}}{\sigma_{xx}}\right) \tag{20.221}$$

so, evidently, the relative fluctuation correction to Hall conductivity is twice as large as the fluctuation correction to the diagonal component. This qualitative speculation is confirmed by the direct calculation of the MT type diagram [169].

The AL process corresponds to an independent charge transfer which cannot be reduced to a renormalization of the diffusion coefficient. It contributes weakly to the Hall effect, and this contribution is related to the Cooper pair particle-hole asymmetry. This effect was investigated in a set of papers: [169, 170, 171, 172, 71, 173, 174]. Let us recall that the proper general expression describing the paraconductivity contribution to the Hall conductivity in the general case of arbitrary magnetic fields and frequencies (in the TDGL theory limits) was already carried out above in the phenomenological approach (see Eq. (20.110)). The microscopic consideration of this value can be done in the spirit of the calculation of σ_{xx}^{AL} (see (20.180)) and after the analytical continuation results in

$$\begin{aligned}\sigma_{xy}^{AL} &= \left(\frac{2h\nu(0)}{\pi}\right)^2 \sum_{n=0}^{\infty}(n+1)\int\limits_{-\pi/s}^{\pi/s}\frac{dk_z}{2\pi}\int\limits_{-\infty}^{\infty}\coth\frac{z}{2T}dz \times \\ &\times\left[\mathrm{Im}L_n^R(z)\frac{\partial}{\partial z}\mathrm{Re}L_{n+1}^R(z) - \mathrm{Im}L_{n+1}^R(z)\frac{\partial}{\partial z}\mathrm{Re}L_n^R(z)\right].\end{aligned} \tag{20.222}$$

where dimensionless magnetic field h was introduced by (20.76). The phenomenological expression (20.110) can be obtained from this formula by carrying out the frequency integration in the same way as was done in the calculation of (20.180) (the essential region of integration is $z \ll T$).

One can see from (20.222) that if $\mathrm{Im}L_n^R(-z) = -\mathrm{Im}L_n^R(z)$ and $\mathrm{Re}L_n^R(-z) = \mathrm{Re}L_n^R(z)$ the Hall conductivity is equal to zero, or, in terms of the phenomenological parametrization, the reality of γ_{GL} results in a zero Hall effect. Physically it is possible to say that this zero is the direct consequence of electron-hole symmetry. However, from the formula (20.147) one can see that an energy dependence of the density of states or the electron interaction constant g immediately results in the appearance of an imaginary part of γ_{GL}. In the weak interaction approximation

$$\mathrm{Im}\gamma_{GL} = \frac{\nu(0)}{2}\left(\frac{\partial \ln T_c}{\partial E}\right)_{E=E_F}. \tag{20.223}$$

Usually this value is small in comparison with $\mathrm{Re}\gamma_{GL}$ by a ratio of the order of T_c/E_F. Taking into account the terms of the order of $\mathrm{Im}\gamma_{GL}$ in (20.222) and using the explicit form of the fluctuation propagator for layered superconductor (20.170) one can find

$$\begin{aligned}\sigma_{xy}^{AL} &= e^2T\frac{\mathrm{Im}\gamma_{GL}}{2\nu(0)}h \\ &\times\int\limits_{-\pi/s}^{\pi/s}\frac{dk_z}{2\pi}\frac{1}{\left[\epsilon + r\sin^2(k_zs/2))\right]^2}F\left(\frac{\epsilon + r\sin^2(k_zs/2))}{2h}\right),\end{aligned} \tag{20.224}$$

where

$$F(x) = 4x^2\left[\psi(x) + x\psi'(x) - 1 - \psi(\frac{1}{2} + x)\right].. \tag{20.225}$$

For $H \to 0$ the expression for the fluctuation Hall paraconductivity takes the form

$$\sigma_{xy}^{AL} = \frac{e^2 T}{6s}\left(\frac{\mathrm{Im}\gamma_{GL}}{\nu(0)}\right) h \frac{\epsilon + r/2}{\left[\epsilon\left(\epsilon + r\right)\right]^{3/2}} = \frac{e^3 \Phi_0 T}{6\pi s}\left(\frac{\mathrm{Im}\gamma_{GL}}{\nu(0)}\right) \frac{\epsilon + r/2}{\left[\epsilon\left(\epsilon + r\right)\right]^{3/2}} h. \tag{20.226}$$

One can see that in the $2D$ case the temperature dependence of the AL fluctuation correction to the Hall conductivity

$$\sigma_{xy}^{AL} \approx \frac{e^3 \Phi_0}{12\pi s}\left(\frac{T_c}{E_F}\right)\frac{h}{\epsilon^2}$$

turns out to be more singular than the MT one.

20.6.4 Fluctuations in the ultra-clean case [175]

When dealing with the superconductor electrodynamics in the fluctuation regime, it is necessary to remember that in the vicinity of the critical temperature the role of the effective size of a fluctuation Cooper pair is played by the GL coherence length $\xi_{GL}(T) = \xi_0/\sqrt{\epsilon}$. So, as was already mentioning above, the case of a pure enough superconductor with electron mean free path $\ell \gg \xi_0$ has to be formally subdivided into the clean ($\xi_0 \ll \ell \ll \xi_{GL}(T)$) and ultra-clean ($\xi_{GL}(T) \ll \ell$) limits. The nontrivial cancellation of the contributions, previously divergent in $T\tau$ (see, for example, (20.186)), will be shown in this Section. This results in a reduction of the total fluctuation correction in the ultra-clean case to the AL term only. We will base on [175] restricting our consideration to the case of a 2D electron system.

In terms of the parameter $T\tau$, used in the theory of disordered alloys, three different domains of the metal purity can be distinguished: $T\tau \ll 1$ (dirty case), $1 \ll T\tau \ll 1/\sqrt{\epsilon}$ (clean case) and $1/\sqrt{\epsilon} \ll T\tau$ (ultra-clean case of non-local electrodynamics). The latter case was rarely discussed in the literature [150, 176, 177] in spite of the fact that it becomes of primary importance for metals of very modest purity, let us say, with $T\tau \approx 10$. Really, in this case the condition $T\tau \geq 1/\sqrt{\epsilon}$, which in terms of the reduced temperature is read as $10^{-2} \leq \epsilon \ll 1$, practically covers all the experimentally accessible range of temperatures for the fluctuation conductivity measurements. As regards the usually considered local clean case ($1 \ll T\tau \ll 1/\sqrt{\epsilon}$) for the chosen value $T\tau \approx 10$, it would not have any range of applicability. Indeed, the equivalent condition for the allowed temperature interval is $\epsilon \ll (T\tau)^{-2}$, and it almost contradicts the $2D$ thermodynamical Ginzburg-Levanyuk criterion for the mean field approximation applicability ($Gi_{(2)} = \frac{T_c}{E_F} \ll \epsilon$). Moreover, as we will show below, for transport coefficients the higher order corrections become comparable with the mean field results much before they are important for thermodynamical quantities, namely at $\epsilon \sim \sqrt{Gi_{(2)}}$ [178, 179]. So in practice one can speak about the dirty and the non-local ultra-clean limits only.

As we saw above the 2D AL contribution turns out to be completely independent of the electron mean free path ℓ [5]. The anomalous Maki-Thompson contribution, being induced by the pairing on the Brownian diffusive trajectories [76], naturally depends on $T\tau$, but in an indirect way. It turns out to be $\tau-$independent up to $T\tau \sim 1/\sqrt{\epsilon}$, (see (20.195)) and diverges as $T\tau \ln(T\tau)$ for $T\tau \gg 1/\sqrt{\epsilon}$ [150, 176]. The analogous problem takes place in the case of the DOS contribution: its standard diagrammatic technique calculations lead to a negative correction (20.186) [95] evidently strongly divergent when $T\tau \to \infty$. In the derivation of all these results the local form of the fluctuation propagator and Cooperons were used. This is why the direct extension of their validity for $T\tau \gg 1/\sqrt{\epsilon} \to \infty$ is incorrect.

One can notice [175] that at the upper limit of the clean case, when $T\tau \sim 1/\sqrt{\epsilon}$, both the DOS and anomalous MT (20.195) contributions turn out to be of the same order of magnitude but of opposite signs. So one can suspect that in the case of a correct procedure of impurity

averaging in the ultra-clean case the large negative DOS contribution can be cancelled with the positive anomalous MT one. In the case of a $2D$ electron spectrum the Cooperon can be calculated exactly for the case of an arbitrary electron mean free path:

$$\lambda(\mathbf{q},\varepsilon_1,\varepsilon_2)=\left(1-\frac{\Theta(-\varepsilon_1\varepsilon_2)}{\tau\sqrt{(\widetilde{\varepsilon}_1-\widetilde{\varepsilon}_2)^2+v_F^2q^2}}\right)^{-1}. \tag{20.227}$$

One can see that this expression can be reduced to (20.163) in the case of $v_Fq\ll|\widetilde{\varepsilon}_1-\widetilde{\varepsilon}_2|$. Let us stress that this result was carried out without any expansion over the Cooper pair center of mass momentum $\mathbf{q}$ and is valid in the $2D$ case for an arbitrary ℓq.

The fluctuation propagator in the $2D$ case of an arbitrary mean free path can be written as [175]

$$\begin{aligned}-[\nu L(\mathbf{q},\Omega_k)]^{-1} &= \ln\frac{T}{T_c}+\sum_{n=0}^{\infty}\left\{\frac{1}{n+1/2}\right. \\ &\left.-\frac{1}{\sqrt{\left(n+\frac{1}{2}+\frac{\Omega_k}{4\pi T}+\frac{1}{4\pi T\tau}\right)^2+\frac{v_F^2\mathbf{q}^2}{16\pi^2T^2}}-\frac{1}{4\pi T\tau}}\right\}.\end{aligned} \tag{20.228}$$

Near T_c $\ln\frac{T}{T_c}\approx\epsilon$ and in the local limit, when only small momenta $\ell q\ll 1$ are involved in the final integrations, the Exp. (20.228) can be expanded in $v_Fq/\max\{T,\tau^{-1}\}$ and reduces to the appropriate local expression.

Let us demonstrate the specifics of the non-local calculations for the example of the Maki-Thompson contribution. We restrict our consideration to the vicinity of the critical temperature, where the static approximation is valid. Using the non-local expressions for the Cooperon and the propagator one can find after integration over electronic momentum:

$$\begin{aligned}Q^{(MT)}(\omega_\upsilon) &= -4\pi\nu v_F^2e^2T^2\sum_{\varepsilon_n}\int\frac{d^2\mathbf{q}}{(2\pi)^2}L(\mathbf{q},0)\times \\ &\times\left[\mathcal{M}\left(\widetilde{\epsilon}_n,\widetilde{\epsilon}_{n+\nu},\mathbf{q}\right)+\mathcal{M}\left(\widetilde{\epsilon}_{n+\nu},\widetilde{\epsilon}_n,\mathbf{q}\right)\right],\end{aligned} \tag{20.229}$$

where

$$\mathcal{M}(\alpha,\beta,\mathbf{q})=\frac{R_q(2\alpha)R_q(\alpha+\beta)-\Theta(\alpha\beta)R_q(2\alpha)R_q(2\beta)}{(\beta-\alpha)^2\left(R_q(2\alpha)-\frac{1}{\tau}\right)\left(R_q(2\beta)-\frac{1}{\tau}\right)R_q(\alpha+\beta)}$$

and $R_q(x)=\sqrt{x^2+v_F^2\mathbf{q}^2}$. The analogous consideration of the DOS diagrams 2 and 4 which are the leading ones in the clean case [95] results in similar expressions.

One can see that, after analytical continuation over the external frequency $\omega_\nu\to-i\omega$ and the consequent tending $\omega\to0$, each of the DOS or MT type diagrams is written in the form of a Laurent series of the type $C_{-2}(T\tau)^2+C_{-1}(T\tau)+C_0+C_1(T\tau)^{-1}+...$ and is divergent at $T\tau\to\infty$ in accordance with (20.186). Nevertheless the expansion in a Laurent series of the sum of these non-local diagrams leads to the exact cancellation of all divergent contributions. The leading order of the sum of the MT and DOS contributions in the limit of $T\tau\gg1$ turns out to be proportional to $(T\tau)^{-1}$ only and disappears in the ultra-clean limit. So the correct accounting for non-local scattering processes in the ultra-clean limit results in a total quantum correction negligible in comparison with the AL contribution. Nevertheless, its formal independence on impurities concentration (see (20.97)) was re-examined for ultra-clean case too in [174] and there it was demonstrated that this statement is valid in a rigorous sense only in the case of direct current and absence of a magnetic field. Let us recall that the normal Drude conductivity in the ultra-clean case takes the form

$$\sigma_{\pm}(\omega) = \sigma_{xx} \pm i\sigma_{xy} = \frac{e^2 n\tau/m}{1 - i(\omega \mp \omega_c)\tau}, \tag{20.230}$$

where ω_c is the cyclotron frequency. When $\tau \to \infty$ the real part of the conductivity vanishes. The analysis of the AL diagram in the ultra-clean case demonstrates that each of the Green functions blocks B acquires the same denominator. As a result the expression for the fluctuation conductivity contains the same Drude like pole but of second order

$$\sigma_{\pm}^{AL}(\omega) = \frac{\sigma_{xx}^{AL(l)} \pm i\sigma_{xy}^{AL(l)}}{(1 - i(\omega \mp \omega_c)\tau)^2} \tag{20.231}$$

($\sigma_{\alpha\beta}^{AL(l)}$ is the component of the paraconductivity tensor calculated above in the local limit (20.97-(20.226)). The origin of this pole can be recognized by means of the following speculation. The electric field does not interact directly with the fluctuation Cooper pairs, but it produces the effect by interaction with the quasiparticles forming these pairs only. The characteristic time of the change of a quasiparticle state is of the order of τ. Consequently the single-particle Drude type conductivity in an a.c. field has a first order pole, while in the AL paraconductivity it is of second order [174]. In spite of this difference one can see that the AL conductivity, like the Drude one, vanishes at $\omega \neq 0, \tau \to \infty$ because in the absence of impurities the interaction of the electrons does not produce any effective force acting on the superconducting fluctuations, while the d.c. paraconductivity conserves its usual $\tau-$independent form. It is impossible to distinguish the motion of the electron liquid from the condensate motion in current experiments without additional scattering.

The non-local form of the Cooperon and fluctuation propagator have to be taken into account not only for the ultra-clean case but in every problem where relatively large bosonic momenta are involved: the consideration of dynamical and short wavelength fluctuations beyond the vicinity of critical temperature, the effect of relatively strong magnetic fields on fluctuations etc. Recently such an approach was developed in a number of studies [176, 175, 180, 181].

20.6.5 The effect of fluctuations on the one-electron density of states and on tunneling measurements

Density of states [94].

The appearance of non-equilibrium Cooper pairing above T_c leads to a redistribution of the one-electron states around the Fermi level. A semi-phenomenological study of the fluctuation effects on the density of states (DOS) of a dirty superconducting material was first carried out while analyzing the tunneling experiments of granular Al in the fluctuation regime just above T_c [182]. The second metallic electrode was in the superconducting regime and its well developed gap gave a bias voltage around which a structure, associated with the superconducting fluctuations of Al, appeared. The measured DOS energy dependence has a dip at the Fermi level [28], reaches its normal value at some energy $E_0(T)$, show a maximum at an energy value equal to several times E_0, finally decreases towards its normal value at higher energies. The characteristic energy E_0 was found to be of the order of the inverse of the GL relaxation time τ_{GL} introduced above.

The presence of a depression at $E = 0$ and of a peak at $E \sim (1/\tau_{GL})$ in the DOS above T_c are precursor effects of the appearance of the superconducting gap in the quasiparticle spectrum at temperatures below T_c. The microscopic calculation of the fluctuation contribution to the one-electron DOS can be carried out within the diagrammatic technique [93, 94].

[28] Here we refer the energy E to the Fermi level, where we assume $E = 0$.

Figure 20.15: The one-electron Green function with the first order fluctuation correction.

Let us start from the discussion of a clean superconductor. As is well known the one-electron DOS is determined by the imaginary part of the retarded Green function integrated over momentum. This definition permits us to express the appropriate fluctuation correction in terms of the fluctuation propagator:

$$\delta\nu^{(c)}(E,\epsilon) = -\frac{1}{\pi}\mathrm{Im}\int\frac{d^D\mathbf{p}}{(2\pi)^D}\delta G^R(\mathbf{p},E) = -\frac{1}{\pi}\mathrm{Im}R^R(E) \tag{20.232}$$

where $R^R(E)$ is the retarded analytical continuation of the expression corresponding to the diagram of Fig. 20.15:

$$R(\varepsilon_n) = T\sum_{\Omega_k}\int\frac{d^D\mathbf{q}}{(2\pi)^D}L(\mathbf{q},\Omega_k)\int\frac{d^D\mathbf{p}}{(2\pi)^D}G^2(\mathbf{p},\varepsilon_n)G(\mathbf{q}-\mathbf{p},\Omega_k-\varepsilon_n). \tag{20.233}$$

The result of the integration of the last expression depends strongly of the electron spectrum dimensionality: for the two important cases of isotropic $3D$ and $2D$ electron spectra one finds [94]

$$\frac{\delta\nu^{(c)}_{(3)}(E,\epsilon)}{\nu_{(3)}(0)} = -\frac{(4\pi)^{3/2}}{7\zeta(3)}\sqrt{Gi_{(3,c)}}\mathrm{Re}\frac{\sqrt{T_c}}{\sqrt{\tau_{GL}^{-1}-2iE+\varkappa_3^2T_c}}\times \left\{\frac{1}{\tau_{GL}^{-1}-iE+\tau_{GL}^{-1/2}\left[\tau_{GL}^{-1}-2iE+\varkappa_3^2T_c\right]^{1/2}}\right\}, \tag{20.234}$$

$$\frac{\delta\nu^{(c)}_{(2)}(E,\epsilon)}{\nu_{(2)}(0)} = -\frac{(4\pi)^2}{7\zeta(3)}Gi_{(2,c)}\frac{T_c^2}{\left[E^2+\varkappa_2^2T_c\tau_{GL}^{-1}\right]}\times \left\{1-\frac{E}{\sqrt{E^2+\varkappa_2^2T_c\tau_{GL}^{-1}}}\ln\frac{E+\sqrt{E^2+\varkappa_2^2T_c\tau_{GL}^{-1}}}{\varkappa\sqrt{T_c\tau_{GL}}}\right\}, \tag{20.235}$$

where $\varkappa_D = \pi\sqrt{\pi D/7\zeta(3)}$.

In a dirty superconductor the calculations may be carried out in a similar way with the only difference that the impurity renormalization of the Cooper vertices has to be taken into account [93]. The value of the fluctuation dip at the Fermi level can be written in the form:

$$\frac{\delta\nu^{(d)}(0)}{\nu(0)} \sim -\begin{cases}\sqrt{Gi_{(3,d)}}\epsilon^{-3/2}, & D=3\\ Gi_{(2,d)}\epsilon^{-2}, & D=2\end{cases}. \tag{20.236}$$

At large energies $E \gg \tau_{GL}^{-1}$ the DOS recovers its normal value, according to the same laws (20.236) but with the substitution $\epsilon \to E/T_c$. It is interesting that the critical exponents of the fluctuation correction of the DOS change when moving from a dirty to a clean superconductor [94]: the analysis of (20.234)-(20.235) gives

Figure 20.16: The theoretical curve of the energy dependence for the normalised correction to the single-particle density of states vs energy for a clean two-dimensional superconductor above T_c.

$$\frac{\delta\nu^{(c)}(0)}{\nu(0)} \sim -\begin{cases} \sqrt{Gi_{(3,c)}}\epsilon^{-1/2}, & D=3 \\ Gi_{(2,c)}\epsilon^{-1}, & D=2 \end{cases} . \tag{20.237}$$

Another important respect in which the character of the DOS renormalization differs strongly for the clean and dirty cases is the energy scale at which this renormalization occurs. In the dirty case this energy turns out to be [93] $E_0^{(d)} \sim T - T_c \sim \tau_{GL}^{-1}$, while in the clean case $E_0^{(c)} \sim \sqrt{T_c(T-T_c)}$ [94]. To understand this important difference one has to study the character of the electron motion in both cases [94]. The relevant energy scale in the dirty case is the inverse of the time necessary for the electron to diffuse over a distance equal to the coherence length $\xi(T)$. This energy scale coincides with the inverse relaxation time: $t_\xi^{-1} = \mathcal{D}\xi^{-2}(T) \sim \tau_{GL}^{-1} \sim T - T_c$. In the clean case, the ballistic motion of the electrons gives rise to a different characteristic energy scale $t_\xi^{-1} \sim v_F\xi^{-1}(T) \sim (T_c\tau_{GL}^{-1})^{1/2} \sim \sqrt{T_c(T-T_c)}$.

One can check that the integration of (20.234)-(20.235) over all positive energies gives zero:

$$\int_0^\infty \delta\nu(E)dE = 0 \tag{20.238}$$

This "sum rule" is a consequence of a conservation law: the number of quasiparticles is determined by the number of cells in the crystal and cannot be changed by the interaction. So the only effect which can be produced by the inter-electron interaction is a redistribution of the energy levels near the Fermi energy. The sum rule (20.238) plays an important role in the understanding of the manifestation of the fluctuation DOS renormalization in the observable phenomena. As we will see in the next Section the singularity in the tunneling current (at zero voltage), due to the density of states renormalization, turns out to be much weaker than that in the DOS itself ($\ln\epsilon$ instead of ϵ^{-1} or ϵ^{-2}, see (20.236)-(20.237)). A similar smearing of the DOS singularity occurs in the opening of the pseudo-gap in the c-axis optical conductivity, in the NMR relaxation rate etc. These features are due to the fact that we must always form the convolution of the DOS with some slowly varying function: for example, a difference of Fermi functions in the case of the tunnel current. The sum rule then leads to an almost perfect cancellation of the main singularity at low energies. The main non-zero contribution then comes from the high energy region where the DOS correction has its 'tail'. Another important

consequence of the conservation law (20.238) is the considerable increase of the characteristic energy scale of the fluctuation pseudo-gap opening with respect to E_0: this is $eV_0 = \pi T$ for tunneling and $\omega \sim \tau^{-1}$ for the c-axis optical conductivity.

The effect of fluctuations on the tunnel current [179].

It is quite evident that the renormalization of the density of states near the Fermi level, even of only one of the electrodes, will lead to the appearance of anomalies in the voltage-current characteristics of a tunnel junction. The quasiparticle current flowing through it may be written as a convolution of the densities of states with the difference of the electron Fermi distributions in each electrode (L and R):

$$I_{qp} = \frac{1}{eR_n\nu_L(0)\nu_R(0)} \times \int_{-\infty}^{\infty} \left(\tanh\frac{E+eV}{2T} - \tanh\frac{E}{2T}\right)\nu_L(E)\nu_R(E+eV)dE, \tag{20.239}$$

where R_n is the Ohmic resistance per unit area and $\nu_L(0)$, $\nu_R(0)$ are the densities of states at the Fermi levels in each of electrodes in the absence of interaction. One can see that for low temperatures and voltages the expression in parenthesis is a sharp function of energy near the Fermi level. Nevertheless, depending on the properties of the DOS functions, the convolution (20.239) may exhibit different properties. If the energy scale of the DOS correction is much larger than T , the expression in parenthesis in (20.239) acts as a delta-function and the zero-bias anomaly in the tunnel conductivity strictly reproduces the anomaly of the density of states around the Fermi level:

$$\frac{\delta G(V)}{G_n(0)} = \frac{\delta\nu(eV)}{\nu(0)}, \tag{20.240}$$

where $G(V)$ is the differential tunnel conductance and $G_n(0)$ is the background value of the Ohmic conductance supposed to be bias independent, $\delta G(V) = G(V) - G_n(0)$. This situation, for instance, occurs in a junction with one amorphous electrode [183], where the dynamically screened Coulomb interaction is strongly retarded, which leads to a considerable suppression of the density of states in the vicinity of the Fermi level, within $\tau^{-1} \gg T$.

It is worth stressing that the proportionality between the tunneling current and the electron DOS of the electrodes is widely accepted as an axiom, but generally speaking this is not always so. As one can see from the previous subsection, the opposite situation occurs in the case of the DOS renormalization due to the electron-electron interaction in the Cooper channel: in this case the DOS correction varies strongly already in the scale of $E_0 \sim E_{\rm ker} \ll T$ and the convolution in (20.239) with the DOS (20.235) has to be carried out without the simplifying approximations assumed to obtain (20.240). We will show that the fluctuation induced pseudo-gap like structure in the tunnel conductance differs drastically from the anomaly of the density of states (20.235), both in its temperature singularity near T_c and in the energy range of its manifestation.

Let us first discuss the effect of the fluctuation suppression of the density of states on the properties of a tunnel junction between a normal metal and a superconductor above T_c. The effect under discussion turns out to be most pronounced in the case of thin superconducting films ($d \ll \xi(T)$) and layered superconductors like HTS cuprates. In order to derive the explicit expression for the fluctuation contribution to the differential conductance of a tunnel junction with one thin film electrode close to its T_c we differentiate (20.239) with respect to voltage, and

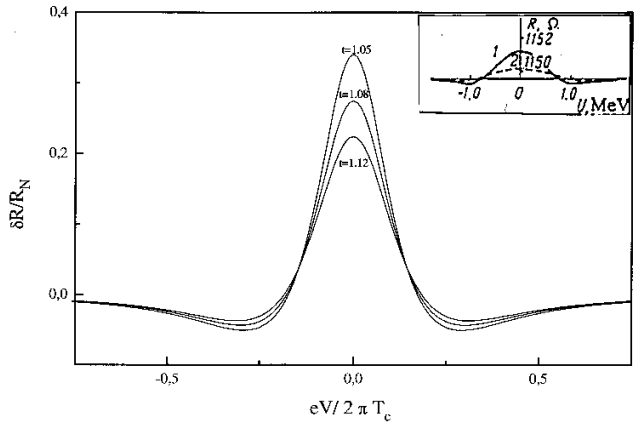

Figure 20.17: The theoretical prediction for the fluctuation-induced zero-bias anomaly in tunnel-junction resistance as a function of voltage for reduced temperatures $\epsilon = 0.05$ (top curve), $\epsilon = 0.08$ (middle curve) and $\epsilon = 0.12$ (bottom curve). The insert shows the experimentally observed differential resistance as a function of voltage in an Al-I-Sn junction just above the transition temperature

substitute the DOS correction given by (20.235). This results in (see [179]):

$$\frac{\delta G_{fl}(V,\epsilon)}{G_n(0)} = \frac{1}{2T}\int_{-\infty}^{\infty}\frac{dE}{\cosh^2\left(\frac{E+eV}{2T}\right)}\delta\nu^{(2)}(E,\epsilon) \sim \tag{20.241}$$

$$\sim Gi_{(2)}\ln\left(\frac{2}{\sqrt{\epsilon}+\sqrt{\epsilon+r}}\right)\mathrm{Re}\psi''\left(\frac{1}{2}-\frac{ieV}{2\pi T}\right).$$

It is important to emphasize several nontrivial features of the result obtained. First, the sharp decrease ($\epsilon^{-2(1)}$) of the density of electron states in the immediate vicinity of the Fermi level generated by fluctuations surprisingly results in a much more moderate growth of the tunnel resistance at zero voltage ($\ln 1/\epsilon$). Second, in spite of the manifestation of the DOS renormalization at the characteristic scales $E_0^{(d)} \sim T - T_c$ or $E_0^{(cl)} \sim \sqrt{T_c(T-T_c)}$, the energy scale of the anomaly developed in the $I-V$ characteristic is much larger: $eV = \pi T \gg E_0$ (see Fig. 20.17).

In the inset of Fig. 20.17 the result of measurements of the differential resistance of the tunnel junction $Al - I - Sn$ at temperatures slightly above the critical temperature of Sn electrode is presented. This experiment was done [184] with the purpose of checking the theory proposed [179]. The non-linear differential resistance was precisely measured at low voltages which permitted the observation of the fine structure of the zero-bias anomaly. The reader can compare the shape of the measured fluctuation part of the differential resistance (the inset in Fig. 20.17) with the theoretical prediction. It is worth mentioning that the experimentally measured positions of the minima are $eV \approx \pm 3T_c$, while the theoretical prediction following from (20.241) is $eV = \pm\pi T_c$. Recently similar results on an aluminium film with two regions of different superconducting transition temperatures were reported [185]. The observations of the pseudogap anomalies in tunneling experiments at temperatures above T_c obtained by a variety of experimental techniques were reported in [186, 187, 188, 189, 190]..

We will now consider the case of a symmetric junction between two superconducting electrodes at temperatures above T_c. In this case, evidently, the correction (20.241) has to be multiplied by a factor of "two" because of the possibility of fluctuation pairing in both electrodes. Furthermore, in view of the extraordinarily weak ($\sim \ln 1/\epsilon$) temperature dependence of the first order correction, different types of high order corrections may manifest themselves

on the energy scale $eV \sim T - T_c$ or $\sqrt{T_c(T-T_c)}$. Among them are the familiar AL and MT corrections which take place in the first order of Gi but in the second order of the barrier transparency. Another type of higher order correction appears in the first order of barrier transparency but in the second of fluctuation strength ($\sim Gi^2$) [179]. Such corrections are generated by the interaction of fluctuations through the barrier and they can be evaluated directly from (20.239) applied to a symmetric junction. The second order correction in Gi can be written as [179]:

$$\delta G_{fl}^{(2)}(0,\epsilon) \sim \int_{-\infty}^{\infty} \frac{dE}{\cosh^2\left(\frac{E}{2T}\right)} \left[\delta\nu^{(2)}(E,\epsilon)\right]^2 \sim \frac{Gi_{(2)}^2}{\epsilon^3} \tag{20.242}$$

This nonlinear fluctuation correction turns out to be small by Gi^2 but its strong singularity in temperature and opposite sign with respect to $\delta G_{fl}^{(1)}$ make it interesting. Apparently it leads to the appearance of a sharp maximum at zero voltage in $G(V)$ with a characteristic width $eV \sim T - T_c$ in the immediate vicinity of T_c (one can call this peak as the hyperfine structure). This result was confirmed in [191] but to our knowledge such corrections were never observed in tunneling experiments.

One can see that $\delta G_{fl}^{(1)}$ and $\delta G_{fl}^{(2)}$ become of the same order at $\epsilon_{cr}^* \sim \sqrt[3]{Gi}$, i.e. the critical region where nonlinear fluctuations effects become important in the problem under consideration starts much before the thermodynamical criterion $\epsilon_{cr} \sim Gi$. In the next Section we will discuss this early manifestation of nonlinear fluctuation effects in transport phenomena.

20.6.6 Nonlinear fluctuation effects [14]

As we have already seen in the temperature region $Gi \ll \epsilon \ll 1$ the thermodynamic fluctuations of the order parameter Ψ can be considered to be Gaussian. Nevertheless the example of the previous Section demonstrates that in transport phenomena nonlinear effects, related with the interaction of fluctuations (higher order corrections) can manifest themselves much earlier. It has been found in paper [178], that nonlinear fluctuation phenomena restrict the Gaussian region in the fluctuation conductivity of a superconducting film to a new temperature scale: $\sqrt{Gi_{(2d)}} \ll \epsilon \ll 1$ (see also [110, 111, 179, 115, 192]). In this Section we obtain expressions for the conductivity in the temperature region $Gi_{(2d)} < \epsilon < \sqrt{Gi_{(2d)}}$, where both the perturbation theory works well and the nonlinear fluctuation effects are important.

Let us start from the correlator (20.168) which can be expressed by means of the $Gi_{(2d)}$ number:

$$\langle \Psi_{\mathbf{k}}^* \Psi_{\mathbf{k}} \rangle = \frac{T}{\nu} \frac{1}{\epsilon + \frac{\pi\mathcal{D}}{8T}\mathbf{k}^2} = \frac{32\pi^3}{7\zeta(3)} Gi_{(2d)} \frac{T^2}{k^2 + \frac{8T\epsilon}{\pi\mathcal{D}}}. \tag{20.243}$$

The long-wave-length fluctuations with $k^2 < k_{\min}^2 = 8T\epsilon/\pi\mathcal{D}$ can be considered as a local condensate. They lead to the formation of the pseudogap

$$\Delta_{pg} = \left[\int_{k^2 \lesssim k_{\min}^2} \frac{d^2k}{(2\pi)^2} \langle \Psi_{\mathbf{k}}^* \Psi_{\mathbf{k}} \rangle\right]^{1/2} \simeq T\sqrt{Gi_{(2d)}}. \tag{20.244}$$

in the single-particle spectrum of excitations.

Not very close to the transition ($\epsilon > \sqrt{Gi_{(2d)}}$) only excitations with energies $E > \Delta_{pg}$ are important. The pseudogap does not play any role for them. Thus, in this region of temperatures it is sufficient to consider fluctuations in the linear approximation only (see [5, 6, 7]). However, in the temperature region $\epsilon < \sqrt{Gi_{(2d)}}$ the nonlinear fluctuation contribution of the excitations with energies $E < \Delta_{pg}$ becomes essential.

To take into account the spatial dependence of the order parameter we will use the results obtained in [193]. It was shown there that the spatial variations of Δ_{pg} act on single-particle excitations in the same way as magnetic impurities do (the analogy between the effect of fluctuations and magnetic impurities was observed in many papers, see for example, [194]). In this case, the total pairbreaking rate Γ can be written as a sum of the pairbreaking rate due to the magnetic impurities and the fluctuation term. Thus, the self-consistent equation for Γ can be written in the following form [193]:

$$\Gamma = \int \frac{d^2k}{(2\pi)^2} \frac{\langle \Psi_k^* \Psi_k \rangle}{E + \frac{1}{2}\mathcal{D}k^2 + \Gamma} + \frac{1}{\tau_s}. \tag{20.245}$$

In the region $E \lesssim \Gamma$, $\Gamma \gg T\epsilon$ we obtain from Eqs.(20.245), (20.243):

$$\Gamma \sim T \left(Gi_{(2d)} \right)^{1/2} \simeq \Delta_{pg}, \tag{20.246}$$

which coincides with the results obtained in [110, 101].

Let us note, that the pair-breaking rate Γ was found to be of the order of the pseudogap Δ_{pg}. Thus, a wide maximum appears in the density of states at $E \sim \Delta_{pg}$. As we already saw (20.195), in purely $2D$ case the Maki-Thompson correction to the conductivity saturates for $T\epsilon < \Gamma$ (where $\Gamma = 8T\gamma_\varphi/\pi$) and takes the form [14]:

$$\frac{\delta\sigma^{MT}}{\sigma_n} \sim \frac{T}{\Gamma} Gi_{(2d)} \ln \frac{\pi\Gamma}{8T\epsilon}. \tag{20.247}$$

As it can be seen from Eqs.(20.246) such a saturation takes place when $\epsilon < \sqrt{Gi_{(2d)}}$. Similar results have been obtained in [110, 111, 115], with slightly different numerical coefficients[29]. However, its exact value is not very important since in the region $T\epsilon < \Gamma$ the Maki-Thompson correction is less singular than the Aslamazov-Larkin one and can be neglected. The latter does not saturate when T tends to T_c but becomes more and more singular.

In the presence of the pseudogap if there is no equilibrium, the fluctuating Cooper pair lifetime increases with respect to the GL one: $\tau_{fl} = a\tau_{GL}$ $(a > 1)$. Recall, that analogous changes in the coefficient a in the TDGL equations appear below the transition temperature (see e.g. [66, 72, 195, 196, 197]). The growth of the coefficient a and, consequently, the increase of the fluctuation lifetime is because the quasiparticles require more time to attain thermal equilibrium (the corresponding time we denote as τ_e). A rough estimate gives $a \sim \Delta_{pg}\tau_e$. In the case of weak energy relaxation, τ_e has to be determined from the diffusion equation taking account of the pseudogap (see [196, 197, 198]). Note, that in this complicated case the coefficient a becomes a non-local operator. Rough estimates give the following value for the thermal equilibrium transition time $\tau_e \sim (\mathcal{D}k_{\min}^2)^{-1} \sim (T\epsilon)^{-1}$. Taking into account Eq.(20.244) we obtain from (20.11) for the paraconductivity contribution in the discussed limit of the weak energy relaxation [14]:

$$\frac{\delta\sigma}{\sigma_n} \sim \frac{Gi_{(2d)}^{3/2}}{\epsilon^2}. \tag{20.248}$$

Let us discuss now the role of the energy relaxation processes, characterized by a quasiparticle lifetime τ_ε. Nonelastic electron scattering off phonons and other possible collective excitations can decrease τ_ε significantly. These processes together with additional pairbreaking processes (due to magnetic impurities or a magnetic field) lead to a decrease of the nonlinear

[29] Note, that the numerical coefficient in Eq.(20.247) depends on the definition of $Gi_{(2d)}$ and how the summation of higher order diagrams is made.

effects. In view of these processes, one can write the following interpolation formula for the non-linear fluctuation conductivity [14]:

$$\frac{\delta\sigma}{\sigma_n} \sim \frac{Gi_{(2d)}^{3/2}}{\epsilon\left(\epsilon+\frac{1}{T\tau_\varepsilon}\right)\left(1+\frac{\Gamma}{T\sqrt{Gi_{(2d)}}}\right)}. \tag{20.249}$$

Note that Eqs.(20.248-20.249) are valid only if the parameters Γ and τ_ε are such that the correction to conductivity $\delta\sigma$ is larger than the usual Aslamazov-Larkin correction Eq.(20.97). If $\Gamma > T$, $T\tau_\varepsilon < \sqrt{Gi_{(2d)}}$ or if $T^2\tau_\varepsilon/\Gamma < Gi_{(2d)}$, than nonlinear effects are negligible and the usual result (20.97) is valid for all $\epsilon > Gi_{(2d)}$.

We see that the paraconductivity can exceed the value of the normal conductivity σ_n in the region $Gi_{(2d)} < \epsilon < Gi_{(2d)}^{3/4}$. Let us recall, that in this region corrections to all the thermodynamic coefficients are still small and the linear theory is well applicable.

20.6.7 The effect of fluctuation on the optical conductivity [199]

The optical conductivity of a layered superconductor can be expressed by the same analytically continued electromagnetic response operator $Q_{\alpha\beta}^{(R)}(\omega)$ (see Exp.(20.175)) but in contrast to the d.c. conductivity case, calculated without the assumption $\omega \to 0$. Let us recall that the paraconductivity tensor in an a.c. field was already studied in Section 4 in the framework of the TDGL equation [31] and the most interesting asymptotics for our discussion (20.121)-(20.122), valid for $\omega \ll T$ in the $2D$ regime, were calculated there. The microscopic calculation of the AL diagram [98] shows that in the vicinity of T_c and for $\omega \ll T$ the leading singular contribution to the response operator $Q_{\alpha\beta}^{AL\,(R)}$ arises from the fluctuation propagators rather than from the B_α blocks, which confirms the TDGL results. Nevertheless the DOS and MT corrections can be calculated only by the microscopic method, as was done in [98, 199]..

Let us note that the external frequency ω_ν enters in the expression for the DOS contribution to $Q_{\alpha\beta}(\omega)$ only by means of the Green's function $G(\mathbf{p},\omega_{n+\nu})$ and it is not involved in q integration. So, near T_c, even in the case of an arbitrary external frequency, we can restrict consideration to the static limit, taking into account only the propagator frequency $\Omega_k = 0$, and to get [199]:

$$\mathrm{Re}\sigma_{\alpha\beta}^{DOS}(\omega) = -\frac{e^2}{2\pi s}\hat{\kappa}\left(\omega,T,\tau\right)A_{\alpha\beta}\ln\left[\frac{2}{\sqrt{\epsilon+r}+\sqrt{\epsilon}}\right],$$

where the anisotropy tensor $A_{\alpha\beta}$ was introduced in (20.183). Let us stress that, in contrast to the AL frequency dependent contribution, this result has been found with only the assumption $\epsilon \ll 1$, so it is valid for any frequency, and impurity concentration. The function $\hat{\kappa}\left(\omega,T,\tau\right)$ was calculated in [199] exactly but we present here only its asymptotics for the clean and dirty cases:

$$\hat{\kappa}_d\left(\omega,T\ll\tau^{-1}\right) = \frac{8}{\pi}\begin{cases}\frac{7\zeta(3)}{2\pi^2}, & \omega\ll T\ll\tau^{-1}\\ \left(\frac{T}{\omega}\right)^2, & T\ll\omega\ll\tau^{-1}\\ -\frac{\pi T^2}{\omega^3\tau}, & T\ll\tau^{-1}\ll\omega\end{cases},$$

$$\hat{\kappa}_{cl}\left(\omega,T\gg\tau^{-1}\right) = \frac{\pi^3}{28\zeta(3)}\begin{cases}(T\tau)^2, & \omega\ll\tau^{-1}\ll T\\ \left(\frac{T}{\omega}\right)^2, & \tau^{-1}\ll\omega\ll T\\ -4\left(\frac{T}{\omega}\right)^3, & \tau^{-1}\ll T\ll\omega\end{cases}.$$

The general expression for the MT contribution is too cumbersome, so we restrict ourselves here to the important $2D$ overdamped regime ($r \ll \epsilon \leq \gamma_\varphi$):

$$\sigma_{zz}^{MT(an)(2D)}(\omega) = \frac{e^2 s}{2^7 \eta_{(2)}} \frac{r^2}{\gamma_\varphi \epsilon} \begin{cases} 1, & \tilde{\omega} \ll \tau_\varphi^{-1} \\ \left(\frac{8T_c\gamma_\varphi}{\pi\omega}\right)^2, & \tilde{\omega} \gg \tau_\varphi^{-1} \end{cases}$$

$$\sigma_{xx}^{MT(an)(2D)}(\omega) = \frac{e^2}{8s} \begin{cases} \frac{1}{\gamma_\varphi} \ln \frac{\gamma_\varphi}{\epsilon}, & \omega \ll \tau_\varphi^{-1} \\ \left(\frac{8T_c\gamma_\varphi}{\pi\omega}\right)^2, & \omega \gg \tau_\varphi^{-1} \end{cases} .$$

Let us discuss the results obtained. Because of the large number of parameters entering the expressions we restrict our consideration to the most interesting c-axis component of the fluctuation conductivity tensor in the $2D$ region (above the Lawrence-Doniach crossover temperature).

The AL contribution describes the fluctuation condensate response to the applied electromagnetic field. The current associated with it can be treated as the precursor phenomenon of the screening currents in the superconducting phase. As was demonstrated above the characteristic "binding energy " of fluctuation Cooper pair is of the order of $T - T_c$, so it is not surprising that the AL contribution decreases when the electromagnetic field frequency exceeds this value. Indeed $\omega^{AL} \sim T - T_c$ is the only relevant scale for σ^{AL}: its frequency dependence does not contain T, τ_φ and τ. The independence from the latter is due to the fact that elastic impurities do not present obstacles for the motion of Cooper pairs. The interaction of the electromagnetic wave with the fluctuation Cooper pairs resembles, in some way, the anomalous skin-effect where the reflection is determined by the interaction with the free electron system.

The anomalous MT contribution also is due to fluctuation Cooper pairs, but this time they are formed by electrons moving along self-intersecting trajectories. Being the contribution related with the Cooper pair electric charge transfer it does not depend on the elastic scattering time but it turns out to be extremely sensitive to the phase-breaking mechanisms. So two characteristic scales turn out to be relevant in its frequency dependence: $T - T_c$ and τ_φ^{-1}. In the case of HTS, where τ_φ^{-1} has been estimated as at least $0.1T_c$, for temperatures up to $5 \div 10K$ above T_c the MT contribution is overdamped, it is determined by the value of τ_φ and is almost temperature independent.

The DOS contribution to $\mathrm{Re}\sigma(\omega)$ is quite different from those above. In the wide range of frequencies $\omega \ll \tau^{-1}$ the lack of electron states at the Fermi level leads to the opposite sign effect in comparison with the AL and MT contributions: $\mathrm{Re}\sigma^{DOS}(\omega)$ turns out to be negative and this means an increase of the surface impedance, or, in other words, decrease of the reflectance. Nevertheless, the applied electromagnetic field affects the electron distribution and at very high frequencies $\omega \sim \tau^{-1}$ the DOS contribution changes its sign. It is interesting that the DOS contribution, as a one-electron effect, depends on the impurity scattering in a similar manner to the normal Drude conductivity. The decrease of $\mathrm{Re}\sigma^{DOS}(\omega)$ starts at frequencies $\omega \sim \min\{T, \tau^{-1}\}$ which for HTS are much higher than $T - T_c$ and τ_φ^{-1}.

The ω-dependence of $\mathrm{Re}\sigma_{zz}^{tot}$ with the most natural choice of parameters ($T_c r \ll T_c\epsilon \leq \tau_\varphi^{-1} \ll \min\{T, \tau^{-1}\}$) is presented in Fig. 20.18.

Let us discuss it referring to a strongly anisotropic layered superconductor. The positive AL and MT contributions to σ_{zz}^{tot} , being suppressed by the square of the interlayer transparency, are small in magnitude and they vary in the low frequency region $\omega \sim \min\{T - T_c, \tau_\varphi^{-1}\}$. The DOS contribution is proportional to the first order of transparency and remains in this region almost invariable. With a further increase of frequency $\min\{T - T_c, \tau_\varphi^{-1}\} \lesssim \omega$ the AL and MT contributions decay; $\mathrm{Re}\sigma_\perp$ remains negative up to $\omega \sim \min\{T, \tau^{-1}\}$, then it changes its sign at $\omega \sim \tau^{-1}$, reaches maximum and rapidly decreases. The following high frequency behavior is governed by the Drude law. So one can see that the characteristic pseudo-gap-like behavior in

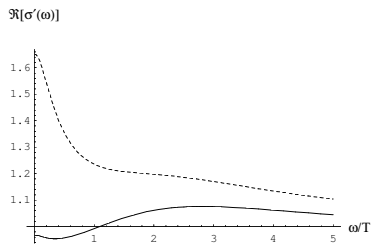

Figure 20.18: The theoretical dependence [199] of the real part of the conductivity, normalized by the Drude normal conductivity, on ω/T, Re $[\sigma'(\omega)]$ = Re $[\sigma(\omega)]/\sigma^{\rm n}$. The dashed line refers to the *ab*-plane component of the conductivity tensor whose Drude normal conductivity is $\sigma^{\rm n}_{\parallel} = N(0)e^2\tau v_F^2$. The solid line refers to the *c*-axis component whose Drude normal conductivity is $\sigma^{\rm n}_{\perp} = \sigma^{\rm n}_{\parallel} J^2 s^2/v_F^2$. In this plot we have put $T\tau = 0.3, E_F/T = 50, r = 0.01, \epsilon = 0.04, T\tau_\varphi = 4$.

the frequency dependence of the c-axis optical conductivity takes place: a transparency window appears in the range $\omega \in [T - T_c, \tau^{-1}]$.

In the case of the *ab*-plane optical conductivity the two first positive contributions are not suppressed by the interlayer transparency, and exceed considerably the negative DOS contribution in a wide range of frequencies. Any pseudo-gap like behavior is therefore unlikely in $\sigma^{tot}_{xx}(\omega)$: the reflectivity will be of the metallic kind.

20.6.8 Thermoelectric power above the superconducting transition [203, 201]

Thermoelectric effects are difficult both to calculate and to measure if compared with electrical transport properties. At the heart of the problem lies the fact that the thermoelectric coefficients in metals are the small resultant of two opposing currents which almost completely cancel. In calculating the thermoelectric power one finds that the electrons above the Fermi level carry a heat current that is nearly the negative of that carried by the electrons below E_F. In the model of a monovalent metal in which band structure and scattering probabilities are symmetric about E_F, this cancellation would be exact; in a real metal a small asymmetry survives. Because of their compensated nature, thermoelectric effects are very sensitive to the characteristics of the electronic spectrum, presence of impurities and peculiarities of scattering mechanisms. The inclusion of many-body effects, such as electron-phonon renormalization, multi-phonon scattering, drag effect, adds even more complexity to the problem of calculating the thermoelectric power. Among such effects, there is also the influence of thermodynamical fluctuations on the thermoelectric transport in a superconductor above the critical temperature. This problem has been attracting the attention of theoreticians for more than twenty years, since the paper of Maki [202] appeared, where the logarithmically divergent AL contribution was predicted for the two-dimensional case. So the AL term turns out to be less singular compared with the corresponding correction to conductivity.

In every case where the main AL and MT fluctuation corrections are suppressed for some reason, the contribution connected with fluctuation renormalization of the one-electron density of states (DOS) can become important. The analogous situation also occurs in the case of the thermoelectric coefficient [200, 201]. Although the DOS term has the same temperature dependence as the AL contribution [202, 203], it turns out to be the leading fluctuation contribution in both the clean and dirty cases, due to its specific dependence on the electron mean free path.

We introduce the thermoelectric coefficient ϑ in the framework of linear response theory as

$$\vartheta = \frac{1}{T}\lim_{\omega\to 0}\frac{\mathrm{Im}[Q^{(eh)R}(\omega)]}{\omega}$$

where $Q^{(eh)R}(\omega)$ is the Fourier representation of the retarded correlation function of electric J^e and heat J^h current operators in Heisenberg representation:

$$Q^{(eh)R}(X-X') = -\Theta(t-t')\langle\langle\left[J^h(X), J^e(X')\right]\rangle\rangle.$$

Here $X = (\mathbf{r}, t)$ and $\langle\langle\cdots\rangle\rangle$ represents both thermodynamical averaging and averaging over random impurity positions. The correlation function $Q^{(eh)R}$ in the diagrammatic technique is represented by a bubble with two exact electron Green's functions and two external field vertices, the first, $e\mathbf{v}$, associated with the electric current operator and the second, $\frac{i}{2}(\varepsilon_n+\varepsilon_{n+\nu})\mathbf{v}$, associated with the heat current operator (ε_n is fermionic Matsubara frequency) [172]. The first order fluctuation corrections to $Q^{(eh)}(\omega_\nu)$ are represented by the same diagrams as for conductivity (see Fig.20.9).

The first diagram describes the AL contribution to thermoelectric coefficient and was calculated in [202, 203] with the electron-hole asymmetry factor taken into account in the fluctuation propagator. Diagrams 2-4 represent the Maki-Thompson contribution, neither anomalous nor regular parts of these diagrams contribute to ϑ in any order of electron-hole asymmetry [172, 203]. The contribution from diagrams 5-10 describes the correction to ϑ due to fluctuation renormalization of the one-electron density of states. Evaluating it in the same way as (20.187) but with one heat current vertex one obtains a vanishing result if electron-hole asymmetry is not taken into account. The first possible source of this factor is contained in the fluctuation propagator; it was used in [203] for the AL diagram but for the DOS contribution this correction results in non-singular contributions to ϑ only and can be neglected. Another source of electron-hole asymmetry is connected with expansion of energy-dependent functions in powers of ξ/E_F near the Fermi level:

$$\nu(\xi)\mathbf{v}^2(\xi) = \nu(0)\mathbf{v}^2(0) + \xi\left[\frac{\partial(\nu(\xi)\mathbf{v}^2(\xi))}{\partial\xi}\right]_{\xi=0}. \tag{20.250}$$

Only the second term in Eq. (30.74) contributes to the thermoelectric coefficient. Performing the integration over ξ, summations over fermionic frequencies and analytical continuation of the result obtained we find that the contribution to the thermoelectric coefficient associated with the DOS renormalization takes the form

$$\vartheta_{2D}^{\mathrm{DOS}} = \frac{1}{4\pi^2}\frac{eT_c}{\nu(0)\mathbf{v}_F^2}\left[\frac{\partial(\nu\mathbf{v}^2)}{\partial\xi}\right]_{\xi=0}\kappa^*(T\tau)\ln[\frac{2}{\sqrt{\epsilon}+\sqrt{\epsilon+r}}], \tag{20.251}$$

where

$$\begin{aligned}\kappa^*(T\tau) &= -\frac{1+\frac{\pi}{8T\tau}}{T\tau\left[\psi\left(\frac{1}{2}+\frac{1}{4\pi T\tau}\right)-\psi\left(\frac{1}{2}\right)-\frac{1}{4\pi T\tau}\psi'\left(\frac{1}{2}\right)\right]} \\ &= \begin{cases}\frac{8\pi^2}{7\zeta(3)}T\tau \approx 9,4T\tau & T\tau\gg 1\\ (T\tau)^{-1} & T\tau\ll 1\end{cases}.\end{aligned} \tag{20.252}$$

Summing Eq. (20.251) with the AL contribution [203] one can find the total correction to the thermoelectric coefficient in the case of a 2D superconducting film of thickness d:

$$\frac{\vartheta^{DOS}+\vartheta^{AL}}{\vartheta_0} = -0.17\frac{1}{E_F\tau}\frac{1}{p_F d}\ln\left(\frac{T_c}{T-T_c}\right)\left[\kappa^*(T_c\tau)+5.3\ln\frac{\omega_D}{T_c}\right],$$

Assuming $\ln(\omega_D/T_c) \approx 2$ one finds that the DOS contribution dominates the AL one for any value of impurity concentration: κ^* has a minimum at $T\tau \approx 0.3$ and even at this point the DOS term is twice as large. In both limiting cases $T\tau \ll 1$ and $T\tau \gg 1$ this difference strongly increases.

In practice, although the Seebeck coefficient $S = -\vartheta/\sigma$ is probably the easiest to measure among the thermal transport coefficients, the comparison between experiment and theory is complicated by the fact that S cannot be calculated directly; it is rather a composite quantity of the electrical conductivity and thermoelectric coefficient. As both ϑ and σ have corrections due to superconducting fluctuations, the total correction to the Seebeck coefficient is given by

$$\Delta S = S_0 \left(\frac{\Delta\vartheta}{\vartheta_0} - \frac{\Delta\sigma}{\sigma_0} \right) \tag{20.253}$$

We see that the fluctuations result in a decrease of the absolute value of the overall Seebeck coefficient as the temperature approaches T_c.

The situation is complicated additionally in HTS materials, where the temperature behavior of the background value of the thermoelectric power remains unknown. This does not permit to extract precisely from the experimental data the fluctuation part $\Delta\vartheta$ to compare it with the theoretical prediction. Nevertheless the very sharp maximum in the Seebeck coefficient experimentally observed in a few papers [204, 205, 206] seems to be unrelated to the fluctuation effects. This conclusion is supported by recent analysis of the temperature dependence of the thermoelectric coefficient close to the transition in Refs. [207].

20.6.9 The effect of fluctuations on NMR characteristics [176]

Preliminaries.

In this Section we discuss the contribution of superconducting fluctuations to the spin susceptibility and the NMR relaxation rate. For both these effects the interplay of different fluctuation contributions is unusual with respect to the case of the conductivity. Like in the case of the optical conductivity, the fluctuation contributions to the spin susceptibility and the NMR relaxation rate can manifest themselves as the opening of a pseudogap already in the normal phase, a phenomenon which is characteristic to HTS compounds.

We begin with the dynamic spin susceptibility $\chi_{\pm}^{(R)}(\mathbf{k},\omega) = \chi_{\pm}(\mathbf{k}, i\omega_\nu \to \omega + i0^+)$ where

$$\chi_{\pm}(\mathbf{k},\omega_\nu) = \int_0^{1/T} d\tau e^{i\omega_\nu\tau} \langle\langle \hat{T}_\tau \left(\hat{S}_+(\mathbf{k},\tau)\hat{S}_-(-\mathbf{k},0) \right) \rangle\rangle. \tag{20.254}$$

Here $\hat{S}_\pm$ are the spin raising and lowering operators, $\hat{T}_\tau$ is the time ordering operator, and the brackets denote thermal and impurity averaging in the usual way. The uniform, static spin susceptibility is given by $\chi_s = \chi_{\pm}^{(R)}(\mathbf{k} \to 0, \omega = 0)$ while the dynamic NMR relaxation rate is given by

$$\frac{1}{T_1 T} = \lim_{\omega\to 0} \frac{A}{\omega} \int \frac{d^3\mathbf{k}}{(2\pi)^3} \mathrm{Im}\chi_{\pm}^{(R)}(\mathbf{k},\omega) \tag{20.255}$$

where A is a positive constant involving the gyromagnetic ratio.

For non-interacting electrons $\chi_{\pm}^0(\mathbf{k},\omega_\nu)$ is determined by the usual loop diagram. Simple calculations lead to the well known results for $T \ll E_F$: $\chi_s^0 = \nu$ (Pauli susceptibility) and $(1/T_1T)^0 = A\pi\nu^2$ (Korringa relaxation). We will present the fluctuation contributions in a dimensionless form by normalizing to the above results.

To leading order in Gi the fluctuation contributions to $\chi_\pm$ can be discussed with the help of the same diagrams drawn for the conductivity in Fig. 20.9. It is important to note that

the role of the external vertices (electron interaction with the external field) is now played by the $\hat{S}_{\pm}(\mathbf{k},\tau)$ operators. This means that the two fermion lines attached to the external vertex must have opposite spin labels (up and down). Consequently, the Aslamazov-Larkin diagram for $\chi_{\pm}$ does not exist since one cannot consistently assign a spin label to the central fermion for spin-singlet pairing. The next set of diagrams to consider is the Maki-Thompson contribution. While the MT diagrams for $\chi_{\pm}$ appear to be identical to those for the conductivity, there is an important difference in topology which arises from their spin structure. It is easy to see, by drawing the fluctuation propagator explicitly as a ladder of attractive interaction lines, that the MT diagram is a non-planar graph with a single fermion loop. In contrast the MT graph for the conductivity is planar and has two fermion loops. The number of loops, in accordance with the rules of diagrammatic technique [92], affects the sign of the contribution.

The diagrams 5 and 6 represent the effect of fluctuations on the single-particle self energy, leading to a decrease in the DOS. The DOS diagrams 7 and 8 include impurity vertex corrections (note that these have only a single impurity scattering line as additional impurity scattering in the form of a ladder has a vanishing effect). Finally 9 and 10 are the DOS diagrams with the Cooperon impurity corrections.

Spin Susceptibility[208, 176].

We note that, when the external frequency and momentum can be set to zero at the outset, as is the case for χ_s, there is no anomalous MT piece (which as we shall see below is the most singular contribution to $1/T_1$). The MT diagram 2 then yields a result which is identical to the sum of the DOS diagrams 5 and 6.

In the clean limit ($T_c\tau \gg 1$) the fluctuation contribution is given by $\chi_s^{\rm fl} = \chi_{s2} + \chi_{s5} + \chi_{s6}$; all other diagrams turn out to be negligible. In the dirty case ($T_c\tau \ll 1$), the DOS diagrams 5 and 6, together with the regular part of the MT diagram (2), yield the same result as in the clean limit (of the order $\mathcal{O}(T_c/E_F)$). One can see, that this contribution is negligible in comparison with the expected dominant one for the dirty case of the order $\mathcal{O}(1/E_F\tau)$. A thorough study of all diagrams shows that the important graphs in the dirty case are those with the Cooperon impurity corrections MT 3 and 4, and the DOS ones 9 and 10. This is the unique example known to us where the Cooperons, which play a central role in the weak localization theory, give the leading order result in the study of superconducting fluctuations. Diagrams 3 and 4 give one half of the final result given below; diagrams 9 and 10 provide the other half. The total fluctuation susceptibility is $\chi_s^{\rm fl} = \chi_{s3} + \chi_{s4} + \chi_{s9} + \chi_{s10}$. Interesting, that in both the clean and dirty cases $\chi_s^{\rm fl}/\chi_s{}^{(0)}$ can be expressed by the same formula if one expresses the coefficient in terms of the GL number $Gi_{(2)}$ (20.171):

$$\frac{\chi_s^{\rm fl}}{\chi_s{}^{(0)}} = -2Gi_{(2)} \ln\left(\frac{2}{\sqrt{\epsilon}+\sqrt{\epsilon+r}}\right). \tag{20.256}$$

It is tempting to explain the negative sign of the fluctuation contribution to the spin susceptibility in Eq. (20.256) as arising from a suppression of the DOS at the Fermi level. But one must keep in mind that only the contribution of diagrams 5 and 6 can strictly be interpreted in this manner; the MT graphs and the coherent impurity scattering described by the Cooperons do not permit such a simple interpretation.

Relaxation Rate[209, 210, 204, 176].

The calculation of the fluctuation contribution to $1/T_1$ requires rather more care than χ_s because of the subtleties of analytic continuation. Let us define the local susceptibility

$$K(\omega_\nu) = \int (d\mathbf{k}) \chi_{+-}(\mathbf{k},\omega_\nu).$$

In order to write down the fluctuation contribution to $1/T_1$ for the case of an arbitrary impurity concentration including the ultra-clean case let us start from the anomalous MT contribution and evaluate it using the standard contour integration techniques

$$\lim_{\omega\to 0}\frac{1}{\omega}\mathrm{Im}K^{(an)R}(\omega)=-\frac{\pi\nu^2}{8}\int(d\mathbf{q})L(\mathbf{q},0)\mathcal{K}(\mathbf{q}), \tag{20.257}$$

$$\mathcal{K}(\mathbf{q}) = 2\tau\int\limits_{-\infty}^{\infty}\frac{dz}{\cosh^2(z/4T\tau)}\frac{1}{\left(\sqrt{l^2q^2-(z-i)^2}-1\right)}\times \frac{1}{\left(\sqrt{l^2q^2-(z+i)^2}-1\right)}. \tag{20.258}$$

We have used the impurity vertices in the general form (20.227). The first simple limiting case for (20.258) is $lq\ll 1$, when the square roots in the denominator can be expanded and $\mathcal{K}(\mathbf{q})=2\pi/\mathbf{D}q^2$. As we already know from Section 8.4 this corresponds to the usual local approximation and covers the domain $T_c\tau\ll 1/\sqrt{\epsilon}$. Introducing the pair breaking rate γ_φ as an infrared cut off one can find:

$$\frac{\delta\left(1/T_1\right)^{MT(an)}}{\left(1/T_1\right)^0}=\frac{28\zeta(3)}{\pi^4}Gi_{(2,d)}\frac{1}{\epsilon-\gamma_\varphi}\ln(\epsilon/\gamma_\varphi). \tag{20.259}$$

The other limiting case is the "ultra-clean limit" when the characteristic q-values satisfy $lq\gg 1$. This is obtained when $T\tau\gg 1/\sqrt{\epsilon}\gg 1$. From (20.258) we then find $\mathcal{K}(\mathbf{q})=4\ln(lq)/vq$, which leads to

$$\frac{\delta(1/T_1)^{MT(an)}}{(1/T_1)^0}=\frac{\pi^3}{\sqrt{14\zeta(3)}}Gi_{(2,cl)}\frac{1}{\sqrt{\varepsilon}}\ln(T\tau\sqrt{\epsilon}). \tag{20.260}$$

We note that in all cases the anomalous MT contribution leads to an *enhancement* of the NMR relaxation rate over the normal state Korringa value. In particular, the superconducting fluctuations above T_c have the *opposite* sign to the effect for $T\ll T_c$ (where $1/T_1$ drops exponentially with T). One might argue that the enhancement of $1/T_1$ is a precursor to the coherence peak just below T_c. Although the physics of the Hebel-Slichter peak (pile-up of the DOS just above gap edge and coherence factors) appears to be quite different from that embodied in the MT process, we note that both effects are suppressed by strong inelastic scattering.

We now discuss the DOS and the regular MT contributions which are important when strong dephasing suppresses the anomalous MT contribution discussed above. The local susceptibility arising from diagrams 5 and 6 can be easily evaluated. The other remaining contribution is from the regular part of the MT diagram. It can be shown that this regular contribution is exactly one half of the total DOS contribution from diagrams 5 and 6. All other diagrams either vanish (as is the case for graphs 7 and 8) or contribute at higher order in $1/E_F\tau$ (this applies to the graphs with the Cooperon corrections). The final results can be presented in a unique way for the clean (but not ultra-clean) and dirty cases by means of the $Gi_{(2)}$ number:

$$\frac{\delta(1/T_1)^{DOS}}{(1/T_1)^0}=-12Gi_{(2)}\ln\left(\frac{2}{\sqrt{\epsilon}+\sqrt{\epsilon+r}}\right). \tag{20.261}$$

The negative DOS contribution to the NMR relaxation rate is evident from the Korringa formula and it sign seems very natural while the sign of the positive Maki-Thompson contribution can generate a questions about its physical origin. Let us consider a self-intersecting trajectory and the motion of the electron along it with fixed spin orientation (let us say "spin

up"). If, after passing a full turn, the electron interacts with the nucleus and changes its spin state and momentum to the opposite value it can pass again along the previous trajectory moving in the opposite direction. Interaction of the electron with itself on the previous stage of the motion is possible due to the retarded character of the Cooper interaction and such a pairing process, in contrast to the AL one, turns out to be an effective mechanism for relaxation near T_c. This purely quantum process opens a new mechanism of spin relaxation, and so contributes positively to the relaxation rate $1/T_1$.

In the case of the nuclear magnetic relaxation rate calculations, the electron interaction causing nuclear spin flip is considered. If one would try to imagine an AL process of this type he would be in trouble, because the electron-nuclei scattering with spin-flip evidently transforms the initial singlet state of the fluctuation Cooper pair in a triplet-one, which is forbidden in the scheme discussed. So the formally discovered absence of the AL contribution to the relaxation rate is evident enough.

It is worth mentioning that the cancellation of the MT and DOS contributions to conductivity found in Section 8.4 is crucial for the fluctuation contributions to the NMR relaxation rate. In fact, the MT and DOS contributions here have the same structure as in the conductivity while the AL contribution is absent. So the full fluctuation correction to the NMR relaxation rate in clean superconductor simply disappears.

Discussion.

The main results of this Section, valid for $\epsilon \ll 1$, can be summarized as follows:

(1) Fluctuations lead to a suppression of the spin susceptibility χ_s, due to the combined effect of the reduction of the single particle density of states arising from the self energy contributions, and of the regular part of the MT process.

(2) "Cooperon" impurity interference terms, involving impurity ladders in the particle-particle channel, are crucial for the χ_s suppression in the dirty limit.

(3) The processes which dominate the results in (1) and (2) above have usually been ignored in fluctuation calculations (conductivity, $1/T_1$, etc.). The spin susceptibility is unusual in that the AL and the anomalous MT terms, which usually dominate, are absent.

(4) For weak pair-breaking ($1/\tau_\varphi \ll T_c$), an enhancement of $1/T_1T$, coming from the positive anomalous MT term, takes place [210, 176].

(5) Strong dephasing suppresses the anomalous MT contribution, and $1/T_1$ is then dominated by the less singular DOS and the regular MT terms. Being negative, these contributions lead to a suppression of spectral weight and a decrease in $1/T_1$.

An intensive controversy took place in recent years in relation to the magnetic field dependence of the fluctuation contribution to $1/T_1$. The situation here resembles much the situation with the magnetoconductivity: a positive MT contribution is suppressed by the magnetic field while the magnetic field dependent part of the DOS contribution increases with the growth of the field. But in contrast to the magnetoconductivity, which can be measured extremely precisely, the NMR relaxation rate measurements are much more sophisticated. The result of this delicate competition, depending on many parameters $(r, \gamma_\varphi, \tau,)$, was found in HTS materials to be qualitatively different in experiments of various groups. The absence of a strong positive AL contribution, possible d-pairing, killing the MT contribution [210], small magnitude of the sum of MT and DOS effects even in the case of s-pairing, lack of the precise values of r, γ_φ, τ, leading to contradictive theoretical predictions[176, 113, 180, 212], the dispersion in the quality of samples and experimental methods were the reason of this discussion [113, 213, 214, 215, 44, 216].

20.7 Conclusions

Several comments should be made in conclusion. As was mentioned in the Introduction the first "fluctuation boom" took place at the end of 60's - beginning of 70's, just after the discovery of the fluctuation smearing of the superconducting transition and formulation of the microscopic theory of fluctuations. The discovery of HTS reanimated this interest and, in order to account for the specifics of these layered structures with high critical temperatures, low charge carrier concentration and other particularities, considerable progress in studies of fluctuation phenomena was achieved (see for instance the conference proceedings [217, 218] and the extensive review article [76]). As it is recognized now the optimally or overdoped phases of HTS compounds present an example of a "bad" Fermi liquid. The accounting for superconducting fluctuations is identical to including of the electron-electron interaction beyond the Fermi-liquid approximation. As a result a lot of anomalies of the normal state properties of such HTS compounds can be explained. The situation was found to be much more sophisticated in underdoped phases where the quasiparticle approach, which from we have started this Chapter, fails.

In the fluctuation theory discussed above, as in modern statistical physics in general, two methods have been used mainly: they are the diagrammatic technique and the method of functional (continual) integration over the order parameter. Each of them as we have seen, has its own advantages and disadvantages and in different parts of this review we used the former or the latter.

The years of the fluctuation boom coincided with the maximum development of the diagrammatic methods of many body theory in Condensed Matter Theory. This methods turns out to be extremely powerful: any physical problem, after its clear formulation and writing down the Hamiltonian, can be reduced to the summation of some classes of diagrams. The diagrammatic technique is especially comfortable for problems containing some small parameter. In the theory of superconducting fluctuations such a small parameter exists: as we have seen, it is the Ginzburg-Levanyuk number $Gi_{(D)}$ which is expressed as some powers of the ratio $\max\{T_c, \tau^{-1}\}/E_F$. This is why superconducting fluctuations led to the appearance of the small corrections to different physical values in a wide range of temperatures, and due to this smallness these corrections can be evaluated quantitatively. On the other hand their specific dependence on nearness to the critical temperature $T - T_c$ permits to separate them in experiment from other effects.

In those cases when fluctuations are small it is possible to restrict their summation to the ladder approximation only. The diagrammatic technique permits in a unique way to describe the quantum and classical fluctuations, the thermodynamical and transport effects

In the description of thermodynamic fluctuations the method of functional integration turned out to be simpler. The ladder approximation in the diagrammatic approach is equivalent to the Gaussian approximation in functional integration. The method of functional integration turns out to be more effective too in the case of strong fluctuations, for instance, in the immediate vicinity of the phase transition. The final equations of the renormalization group carried out by means of functional integrations turn out to be equivalent to the result of the summation of the parquet diagrams series. Nevertheless the former derivation is much more simple.

There is one another reason why we have tried to use both methods and even to carry out some results in both ways. In its explosive development of the last decades physics became an "oral science". In the process of such direct communication near a blackboard it is difficult to write and to read some cumbersome formulas. The language of diagrams is much more comprehensive: by drawing them the speaker demonstrates that this one is small and that one has to be taken into account for this and that reasons clear for the experienced listener. The success of the diagrammatic technique in some sense is similar to the success of geometry in

Ancient Greece, where the science was "oral" too.

This advantage of the diagrammatic technique transforms into its disadvantage when there is no direct communication between the speaker and listener. It is difficult to learn the diagrammatic technique by a textbook on your own, when no one helps you to find the necessary insight on a complex graph. May be because of similar reasons geometry disappeared in Middle Ages when direct communications between scientists was minimal while the "written" algebra had continued to develop. Operating with Osvald Spengler "prosymbols" we can say that the diagrammatic technique belongs more to the Ancient Greece culture style with its "finite body" prosymbol, while functional integration, side by side with the Vikings travels to unknown lands and Leibnitz analysis of infinitesimals, is an evident modern contribution to West-European culture with its "infinite space" prosymbol.

That is why, suspecting that the modern physics in the near future can fall down to a "New Middle Ages" period, we have carried out some results by means of functional integration instead of the diagrammatic technique.

21 Nonequilibrium SC

21.1 General Properties of Nonequilibrium Superconductors

21.1.1 General Understanding of Physics in Nonequilibrium SC

(here, I'll write many paragraphs about which one will work and which one will not. a very important section!)

Suppose the distribution of Bogoliubov particles $\langle n \rangle$ was changed because of an action on the superconductor of laser (or somehow else). Should the $\langle n \rangle$ change during the equilibration?

It will be only because of collision integral, which takes into account collisions with phonons, other excitations, impurities. If this integral is zero or absent in the model because of some restrictions, then there is no change of $\langle n \rangle$ and only the gap will be updated. So, we'll be still in the nonthermal state.

The gap adjusts "instantly" to the change of distribution of excitations

By "instantly" I mean that the update of the gap happens with the speed of Fermi velocity, because there are particles near Fermi surface which are responsible for it.

(???? why - I have no idea, really.)

But it is important to understand that there is no any delay. And there is no numerical discretization which would produce some equations where there are effects of not updated gap and Hamiltonian. All of this equations can be written only because of a not understanding of basics of nonequilibrium superconductivity.

Applicability of GGE ansatz

How exactly the density matrix comes back to the updated GGE manifold during the equilibration?

(write better question and answer)

GGE - это приближение, которое работает, потому что так проверено для пары других моделей, и скорее всего не будет проблем с этой моделью тоже. equilibration - просто обновление щели, потому что у нас обновилась функция распределения, а они всегда

связаны ур самосогласования, которое всегда используется. почему физически так - это я уже не знаю, но все используют это свойство, так что очень вряд ли оно не верное. если бы был не 1д случай и были бы фононы, то были бы еще интегралы столкновений, была бы термализация, но в нашем случае ничего особенного не происходит, просто пишем ур. самосоласования и сделана equilibration.

In a nutshell, all is ok with it.

(examples of proofs that GGE is good)

21.1.2 Choosing a Framework for Nonequilibrium SC

(some extra ideas about what to use and what not to use)

Formalism of Dissipative SC by Lindblad operators

(write here what we are using with Zala)

Formalism of Dissipative SC by non-hermitian Hamiltonians

(see Beenakker and his refs)

Dissipative BCS theory from "Collective Excitations and Nonequilibrium Phase Transition in Dissipative Fermionic Superfluids" by Yamamoto, Nakagawa, et al.

We consider ultracold fermionic atoms described by the three-dimensional attractive Hubbard model

$$H = \sum_{\boldsymbol{k}\sigma} \epsilon_{\boldsymbol{k}} c^\dagger_{\boldsymbol{k}\sigma} c_{\boldsymbol{k}\sigma} - U_{\rm R} \sum_i c^\dagger_{i\uparrow} c^\dagger_{i\downarrow} c_{i\downarrow} c_{i\uparrow}, \tag{21.1}$$

where $U_{\rm R} > 0$, $\epsilon_{\boldsymbol{k}}$ is the single-particle energy dispersion, and $c_{\boldsymbol{k}\sigma}$ ($c_{i\sigma}$) denotes the annihilation operator of a spin-σ fermion with momentum $\boldsymbol{k}$ (at site i). When the system is subject to inelastic collisions, scattered atoms are lost to a surrounding environment, resulting in dissipative dynamics as observed experimentally [**? ? ? ?**] (??? I am not sure, if this is true). Here, we study the time evolution of the density matrix ρ which is described by the Lindblad equation [**? ?**]

$$\frac{d\rho}{dt} = \mathcal{L}\rho = -i[H,\rho] - \frac{\gamma}{2}\sum_i (\{L_i^\dagger L_i, \rho\} - 2L_i \rho L_i^\dagger), \tag{21.2}$$

where $L_i = c_{i\downarrow} c_{i\uparrow}$ is a Lindblad operator that describes two-body loss with loss rate $\gamma > 0$. We note that the kinetic energy of lost atoms is large because of large internal energy of atoms before inelastic collisions. Under such situations, atoms after inelastic collisions are quickly lost into the surrounding environment and the Born-Markov approximation is justified [**? ? ?**].

Figure 21.1: [I'll add it later] (a) Schematic illustration of the amplitude and phase modes in a Mexican-hat free-energy potential as a function of the complex order parameter Δ, when either the interaction $U_{\rm R}$ or the dissipation γ is suddenly switched on. A sudden quench of the interaction $U_{\rm R}$ and that of the dissipation γ kick Δ in a direction parallel and perpendicular to the radial direction, respectively. Note that a finite change of γ excites both the phase and amplitude modes. (b) Two superfluids coupled via a Josephson junction, where one superfluid (system 2) is subject to two-body loss.

We first study how the standard BCS theory is generalized in open dissipative systems by formulating a time-dependent mean-field theory in terms of a closed-time-contour path integral [? ?]. We start with a generating functional defined as

$$Z = \mathrm{tr}\rho = \int \mathcal{D}[c_-, \bar{c}_-, c_+, \bar{c}_+] e^{iS} = 1, \tag{21.3}$$

with an action

$$\begin{aligned} S = \int_{-\infty}^{\infty} dt \Big[\sum_{\boldsymbol{k}\sigma} (\bar{c}_{\boldsymbol{k}\sigma+} i\partial_t c_{\boldsymbol{k}\sigma+} - \bar{c}_{\boldsymbol{k}\sigma-} i\partial_t c_{\boldsymbol{k}\sigma-}) - H_+ \\ + H_- + \frac{i\gamma}{2} \sum_i (\bar{L}_{i+} L_{i+} + \bar{L}_{i-} L_{i-} - 2L_{i+} \bar{L}_{i-}) \Big], \end{aligned} \tag{21.4}$$

where the subscripts + and - denote forward and backward paths, $H_\alpha = \sum_{\boldsymbol{k}\sigma} \epsilon_{\boldsymbol{k}} \bar{c}_{\boldsymbol{k}\sigma\alpha} c_{\boldsymbol{k}\sigma\alpha} - U_{\mathrm{R}} \sum_i \bar{c}_{i\uparrow\alpha} \bar{c}_{i\downarrow\alpha} c_{i\downarrow\alpha} c_{i\uparrow\alpha}$, $L_{i\alpha} = c_{i\downarrow\alpha} c_{i\uparrow\alpha}$, and $\bar{L}_{i\alpha} = \bar{c}_{i\uparrow\alpha} \bar{c}_{i\downarrow\alpha}$ $(\alpha = +, -)$. Note that the action has U(1) symmetry under $c_{i\sigma\alpha} \to e^{i\theta} c_{i\sigma\alpha}$ though the particle number is not conserved [? ?]. By introducing auxiliary fields via the Hubbard-Stratonovich transformation, we rewrite the action in a quadratic form of fermionic Grassmann fields as [? ?]

$$\begin{aligned} S = \int dt \Big\{ \sum_{\boldsymbol{k}} \Big[\bar{\psi}^t_{\boldsymbol{k}+} \begin{pmatrix} i\partial_t - \epsilon_{\boldsymbol{k}} & -\Delta \\ -\Delta^* & -i\partial_t + \epsilon_{\boldsymbol{k}} \end{pmatrix} \psi_{\boldsymbol{k}+} \\ - \bar{\psi}^t_{\boldsymbol{k}-} \begin{pmatrix} i\partial_t - \epsilon_{\boldsymbol{k}} & -\Delta \\ -\Delta^* & -i\partial_t + \epsilon_{\boldsymbol{k}} \end{pmatrix} \psi_{\boldsymbol{k}-} \Big] \Big\}, \end{aligned} \tag{21.5}$$

where $\bar{\psi}_{\boldsymbol{k}\alpha} = (\bar{c}_{\boldsymbol{k}\uparrow\alpha}, \ \ c_{-\boldsymbol{k}\downarrow\alpha})^t$ and $\psi_{\boldsymbol{k}\alpha} = (c_{\boldsymbol{k}\uparrow\alpha}, \ \ \bar{c}_{-\boldsymbol{k}\downarrow\alpha})^t$ $(\alpha = +, -)$. Here Δ is the superfluid order parameter which can be determined from the requirement that the action be extremal as [?]

$$\Delta = -\frac{U}{N_0} \sum_{\boldsymbol{k}} \mathrm{tr}(c_{-\boldsymbol{k}\downarrow} c_{\boldsymbol{k}\uparrow} \rho) \equiv -\frac{U}{N_0} \sum_{\boldsymbol{k}} \langle c_{-\boldsymbol{k}\downarrow} c_{\boldsymbol{k}\uparrow} \rangle, \tag{21.6}$$

where $U = U_R + i\gamma/2$ is an effective complex coupling constant including a contribution from the atom loss [?], and N_0 is the number of sites. Importantly, the order parameter includes the loss rate γ, which leads to dissipation-induced collective modes as discussed below. The action (21.5) describes the mean-field time-evolution equation of the density matrix as

$$\frac{d\rho}{dt} = -i[H_{\mathrm{eff}}, \rho], \tag{21.7}$$

$$H_{\mathrm{eff}} = \sum_{\boldsymbol{k}} \Psi^\dagger_{\boldsymbol{k}} \begin{pmatrix} \epsilon_{\boldsymbol{k}} & \Delta \\ \Delta^* & -\epsilon_{\boldsymbol{k}} \end{pmatrix} \Psi_{\boldsymbol{k}}, \tag{21.8}$$

where $\Psi_{\boldsymbol{k}} = (c_{\boldsymbol{k}\uparrow}, \ \ c^\dagger_{-\boldsymbol{k}\downarrow})^t$ is the Nambu spinor. In the Supplemental Material [?], we show that Eq. (21.7) can be derived from two different methods, i.e. the mean-field theory for the Lindblad equation and the time-dependent Bogoliubov-de Gennes analysis. While Eq. (21.7) appears to describe unitary evolution, it is consistent with the original Lindblad equation (21.2) as a consequence of the time-dependent BCS ansatz [?].

We use Anderson's pseudospin representation defined by $\boldsymbol{\sigma}_{\boldsymbol{k}} = \frac{1}{2} \Psi^\dagger_{\boldsymbol{k}} \cdot \boldsymbol{\tau} \cdot \Psi_{\boldsymbol{k}}$ and $H_{\mathrm{eff}} = 2 \sum_{\boldsymbol{k}} \boldsymbol{b}_{\boldsymbol{k}} \cdot \boldsymbol{\sigma}_{\boldsymbol{k}}$, where $\boldsymbol{\tau} = (\tau_x, \ \ \tau_y, \ \ \tau_z)$ is the vector of the Pauli matrices. The pseudospins satisfy the commutation relations $[\sigma^j_{\boldsymbol{k}}, \sigma^k_{\boldsymbol{k}}] = i\epsilon_{jkl} \sigma^l_{\boldsymbol{k}}$. For simplicity of notation, we omit the

bracket and regard $\boldsymbol{\sigma}_{\boldsymbol{k}}$ as the expectation value of the pseudospin operator. By using the commutation relation of the pseudospins, Eq. (21.7) is mapped to the Bloch equation:

$$\frac{d\boldsymbol{\sigma}_{\boldsymbol{k}}}{dt} = 2\boldsymbol{b}_{\boldsymbol{k}} \times \boldsymbol{\sigma}_{\boldsymbol{k}}, \tag{21.9}$$

$$\boldsymbol{b}_{\boldsymbol{k}} = (\mathrm{Re}\Delta, \quad -\mathrm{Im}\Delta, \quad \epsilon_{\boldsymbol{k}}). \tag{21.10}$$

Equation (21.9) shows that the superfluid dynamics is characterized by precession of a pseudospin in an effective magnetic field $\boldsymbol{b}_k$. Here, the order parameter is determined self-consistently from the pseudospin expectation value as

$$\Delta = |\Delta| e^{i\theta} = -\frac{U}{N_0} \sum_{\boldsymbol{k}} (\sigma^x_{\boldsymbol{k}} - i\sigma^y_{\boldsymbol{k}}). \tag{21.11}$$

It is noteworthy that the norm of the pseudospin is conserved by the Bloch equation (21.9). The time evolution of the particle number due to particle loss is obtained from Eq. (21.7) as

$$\frac{1}{N_0}\frac{dN}{dt} = -\frac{2\gamma|\Delta|^2}{|U|^2}, \tag{21.12}$$

which reflects the dynamics of the order parameter.

Other fundamental questions about construction of models of dissipative SC

In which range the dissipator acts?

(??? should it act in the also Debye's window or how??? or it does not matter? My code was breaking down because of something related to it)

(see special note about it)

21.2 Typical Experiments with Nonequilibrium Superconductors

(write intro to many experimental articles)

21.3 7. Some Nonequilibrium Effects in Superconductors by Shmidt

The question of what happens to a superconductor when its equilibrium is disturbed and how it relaxes back to the equilibrium state has been a subject of intense discussions. Why is this? Why are nonequilibrium properties of superconductors so interesting and important? One would think that the answer lies in the fact that the superconductor comprises several groups of electrons: superconducting electrons, electron-like excitations, and holes. What was elucidated following the publication of the BCS theory was the equilibrium situation, in which all electron groups are in equilibrium not only with each other but also with the crystal lattice. If the equilibrium is disturbed, the behavior of the system becomes more complex. Then, through analyzing the processes of relaxation back to equilibrium, we can learn more about the very basics of the theory and gain insight into the nature of the phenomena. In addition, one should bear in mind that many successful cryoelectronic devices normally operate under conditions which are far from equilibrium. This attaches to studies of nonequilibrium phenomena a practical importance, too.

In this chapter we shall discuss a number of cases in which a nonequilibrium state of a superconductor plays a decisive role in determining its physical properties.

21.3.1 7.1 Quasiparticles: Electrons and Holes

Theory by Schmidt

Elementary excitations in superconductors (electrons and holes) already were the subject of our discussion in Chap. 6. Now we shall define them more accurately.

Consider first the normal metal. Its ground state (at $T = 0$, without elementary excitations) is such that all free electrons occupy all the states inside the Fermi surface while all states outside it are empty. Let us now add one extra electron to the metal. It will occupy one of the states, k_1 in momentum space ($k > k_{\mathrm{F}}$, where k_F is the radius of the Fermi sphere), and the total energy of the electron system will increase by $\hbar^2 \left(k^2 - {k_{\mathrm{F}}}^2\right)/2m$. The energy, as before, is measured from the Fermi energy $\hbar^2 {k_{\mathrm{F}}}^2/2m$. The increase in total energy will therefore be equal to the energy of the elementary excitation and the system's momentum will be k, the momentum of the

Consider once again the ground state of the normal metal, but this time after one electron has been removed from the state $k\,(k < k_F)$. This state can also be treated as an elementary excitation of the system, because its energy is greater than the ground-state energy of electrons remaining in the metal, by $\hbar^2 \left({k_F}^2 - k^2\right)/2m$. Indeed, we can restore the ground state by taking an electron from the Fermi surface and putting it in the vacant state k. The momentum of this elementary excitation is equal to the momentum of the entire electron system, that is, to $-k$. Such an excitation (quasiparticle) behaves in the same way as a positive charge and is called a hole. The elementary excitation energy spectrum for the normal metal is shown in Fig. 7.1 by dashed lines.

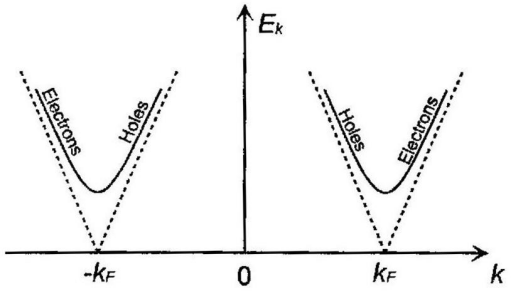

Fig. 7.1. Energy spectrum of the quasiparticles in the superconductor. Dashed lines show the spectrum for the normal metal

In the superconductor, things are somewhat more complicated. We already know (Chap. 6) that the ground state of the superconductor is described by a function ${v_k}^2$ representing the probability that the pair states $(k, -k)$ are occupied by electrons. The behavior of this function is illustrated in Fig. 6.5. Let us now add one extra electron to a superconductor. It will occupy one of the vacant k states in momentum space, while the state $-k$ will remain empty. But, unlike the normal metal, in the superconductor, the state k can be either inside or outside the Fermi surface. Because some of the k states with $k < k_F$ remain empty in the ground state, too! Thus, in the superconductor, the momentum of an electron-like quasiparticle can be not only greater than, but also less than, k_F.

Conversely, if we remove one electron from, say, the state $-k$ in the ground state of a superconductor, the complementary electron in the state k will become uncoupled and start behaving in the same manner as a hole with momentum k which, again, can be not only greater than, but also less than, k_{F}.

Therefore, in the superconductor, an elementary excitation corresponding to the state $\boldsymbol{k}$ being occupied and the state $-\boldsymbol{k}$ being empty behaves partly
relative probabilities of the two states. The probability of its behaving as a hole must be proportional to the probability of the state k being occupied by a superconducting electron, that is, to ${v_k}^2$. On the other hand, its behavior as an electron-like quasiparticle is governed by

the probability that one of the k states in the ground state is vacant, that is, by ${u_k}^2 = 1 - {v_k}^2$.

One may define a quasiparticle of electron type in the superconductor (an almost pure electron) as a quasiparticle with momentum k satisfying the conditions $|k - k_\mathrm{F}|/k_\mathrm{F} \gg \Delta/\varepsilon_\mathrm{F}$ and $k > k_\mathrm{F}$. And an almost pure hole is an excitation with momentum k such that it satisfies the inequalities $|k - k_\mathrm{F}|/k_\mathrm{F} \gg \Delta/\varepsilon_\mathrm{F}$ and $k < k_\mathrm{F}$.

The electron and hole branches of the quasiparticle spectrum for the superconductor are sketched in Fig. 7.1 by solid lines.

It only remains to add that, in real space, the propagation velocity of a quasiparticle is the group velocity well known to be

$$s_k = \frac{\mathrm{d}E_k}{\mathrm{d}p_k} = \frac{1}{\hbar}\frac{\mathrm{d}E_k}{\mathrm{d}k}$$

This means that at $k > 0$ (in the notation of Fig. 7.1) the holes move to the left and the electrons to the right.

21.3.2 7.2 Charge of a Quasiparticle in the Superconductor

Theory by Schmidt

We have just seen that a quasiparticle in the superconductor is an elementary excitation which can be treated to a certain extent as an electron and to a certain extent as a hole. As one moves along the curve of the elementary excitation spectrum, as in Fig. 7.1, the transition from the pure electron to the pure hole happens gradually. This simple observation suggests that one should assign a fractional electric charge to the quasiparticle. In the argumentation below we shall follow Pethick and Smith [67] who were apparently the first to propose this approach. We shall find very soon how convenient it is and how much easier it makes a qualitative analysis of nonequilibrium processes in superconductors. For the sake of simplicity, we agree to measure all charges in normalized units, taking the electron charge equal to unity.

Consider a superconductor at a finite temperature and assume that it contains both coupled (superconducting) electrons and elementary excitations. Suppose that the distribution of the elementary excitations in k space is defined by a distribution function f_k, that is, f_k gives the probability that the state k is occupied by an excited electron. Since the probability that this state was free of a superconducting electron before is ${u_k}^2$, the net probability to find an excited electron in the state k is given by $f_k {u_k}^2$. On the other hand, this state can be filled with one of the superconducting electrons. For this, two conditions must be satisfied simultaneously: first, that this state does not contain an excited electron (the probability of this is $1 - f_k$), and second - it contains a superconductive electron (the probability equals ${v_k}^2$).

Thus, the net probability to find a superconducting electron in the state k is $(1 - f_k)\,{v_k}^2$ and the total charge associated with this state is $f_k {u_k}^2 + (1 - f_k)\,{v_k}^2$. The total charge associated with all electrons in the superconductor is then

$$Q_\mathrm{tot} = \sum_k f_k u_k^2 + \sum_k (1 - f_k)\, v_k^2 \tag{7.1}$$

Suppose that, as a result of an external perturbation, the distributions of both the quasiparticles and the superconducting electrons have changed (the former by the value of δf_k and the latter by the value of $\delta {v_k}^2$). Such a change will result in a variation of the total charge of the electron system by

$$\delta Q_\mathrm{tot} = \sum_k \left(u_k^2 - v_k^2\right) \delta f_k + \sum_k (1 - 2f_k)\, \delta v_k^2. \tag{7.2}$$

Here the first term is obviously a variation of the total charge of the quasiparticles. More specifically, the probability of finding a quasiparticle in the state k has changed by the value of δf_k and been accompanied by a change of the charge associated with this state by $({u_k}^2 - {v_k}^2)\,\delta f_k$. It is obvious then that the quantity

$$q_k = u_k^2 - v_k^2 \tag{7.3}$$

can be treated as the charge of a quasiparticle with momentum k. According to (6.12),

$$v_k^2 = \frac{1}{2}\left(1 - \frac{\varepsilon_k}{E_k}\right) \tag{7.4}$$

Then

$$u_k^2 = \frac{1}{2}\left(1 + \frac{\varepsilon_k}{E_k}\right) \tag{7.5}$$

This leads to

$$q_k = \frac{\varepsilon_k}{E_k} = \frac{\varepsilon_k}{(\varepsilon_k^2 + \Delta^2)^{1/2}} \tag{7.6}$$

The dependence of q_k on k is shown in Fig. 7.2. It implies that the charge of a quasiparticle varies continuously from +1 (pure electron) to -1 (pure hole) and is completely determined by which particular state in k space the quasiparticle occupies. A rather odd result at first sight! But let us add one extra electron to the superconductor and place it in the state k.

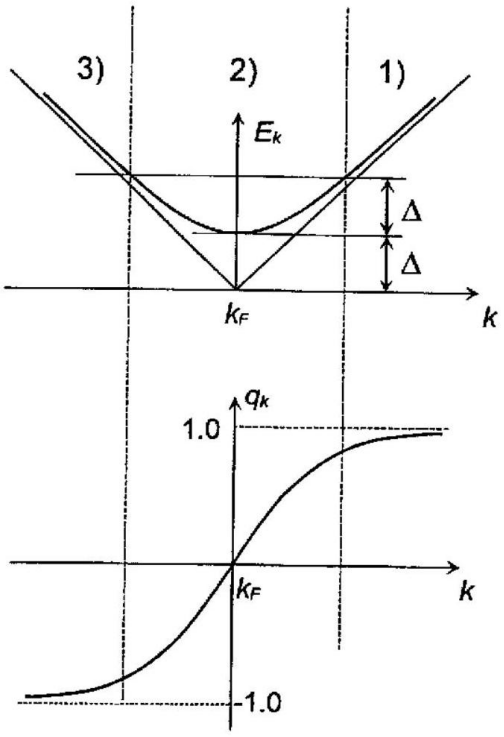

Fig. 7.2. Energy spectrum E_k of quasiparticles in the superconductor and their charge q_k. In region 1 , the quasiparticle charge q_k is close to +1 , in region 3 it is close to -1 , and in region 2 it may assume any value from +1 to -1

As a result, the superconductor as a whole has acquired a charge +1 (recall that it is this value that we agreed to regard as the electron charge), while the state $\boldsymbol{k}$ has got a charge q_k. But where is the difference $1 - q_k$? We know that the total charge must be conserved! The answer is that the charge $1 - q_k$ has been transferred to the superconducting electrons thereby increasing their charge. The whole process can be described as follows. An electron is added

to $-\boldsymbol{k}$ which belongs to the condensate [1] and the pair subsequently joins the condensale. But an electron in the state $\boldsymbol{k}$ is left without a partner, that is, a hole is formed.

We use the name 'condensate' for the entire sea of superconducting electrons, all of them described by a single wavefunction. It is, however, not entirely correct. Not all electron pairs, despite being Bose particles, can make a transition to the lowest energy level (i.e., to join the Bose condensate, in the strict meaning of the word). Owing to their interaction with each other, some of the Bose particles have energies above that of the condensate. Together with the condensate particles, they form the sea of superconducting electrons. There is no sense to see these excitations as a elementary excitations (?????).

Thus the condensate and the elementary excitations in the superconductor are closely interrelated and cannot be treated as independent in the relaxation process. Quasiparticle transitions between different $\boldsymbol{k}$ states are accompanied by changes of their charges q_k resulting in a change of the total charge of the condensate or, in other words, of the number of electrons in the condensate.

21.3.3 7.3 Relaxation Time for the Quasiparticle Charge

Theory by Schmidt

Let us try to estimate the time required for relaxation of the quasiparticle charge, that is, the time required for the charge of a system of quasiparticles to attain its equilibrium value, after the equilibrium has been disturbed by some external perturbation. At this stage, we assume that the total number of quasiparticles remains constant. With this assumption, one may consider an elementary act of charge relaxation as a transition of a quasiparticle from one k state in momentum space to another. Such a transition must be accompanied by either emission or absorption of phonons. If τ_E is the relaxation time, the inverse quantity, τ_E^{-1}, represents the frequency of inelastic collisions between electrons and phonons in a metal, which is independent of whether the metal is in the normal or superconducting state. The order of magnitude of this frequency is [68]

$$\tau_E^{-1} \sim \frac{k_\mathrm{B}T}{\hbar} - \left(\frac{T}{\Theta_\mathrm{D}}\right)^2$$

where k_B is the Boltzmann constant and Θ_D the Debye temperature. Suppose that the temperature of the superconductor is close to T_c. This means that $\Delta \ll k_\mathrm{B}T_\mathrm{c}$. Let us ask: Will every electron-phonon collision then contribute to the charge relaxation? Obviously, it will not. Indeed, if the states of an electron, before and after a collision, are both in region 1 (see Fig. 7.2), the transition leaves its charge practically unaltered. The same applies to region 3. But the electrons in region 2 are completely different. Their transitions, initiated by collisions with phonons, alter the quasiparticle charge by values of the order of unity. At a finite temperature T, the fraction of excitations in region 2 out of the total number of excitations is of the order $\Delta/k_\mathrm{B}T$ since, by definition, the excitation energies E_k in this region fall into the range $\Delta \le E_k \le 2\Delta$. The frequency of transitions resulting in a considerable change of the quasjparticle charge is therefore

$${\tau_Q}^{-1} \sim \frac{\Delta}{k_\mathrm{B}T}{\tau_E}^{-1}$$

At $T \approx T_\mathrm{c}$, rigorous calculations of the quasiparticle charge relaxation time [69] yield

$$\tau_Q = \frac{4}{\pi}\frac{k_\mathrm{B}T_\mathrm{c}}{\Delta}\tau_E \tag{7.7}$$

According to (7.7), the quasiparticle charge relaxation time diverges at $T \to T_c$. Typical values of τ_E are of the order 10^{-10} s. For example, for superconducting tin, $\tau_E = 3 \times 10^{-10}$ s; for lead $\tau_E = 10^{-11}$ s. The above values of τ_E correspond to the respective critical temperatures of the materials. The relaxation time τ_Q can be much longer. It depends entirely on how close one approaches the critical temperature.

21.3.4 7.5 Branch Imbalance of the Elementary Excitation Spectrum and Electric Field in the Superconductor

Theory by Schmidt

At equilibrium, the electron and hole branches of the elementary excitation spectrum are symmetrically populated with quasiparticles. For this reason, at equilibrium, the number of electron-like quasiparticles is exactly equal to the number of holes, and the total charge is zero. Furthermore, the distribution function for the quasiparticles is given by the Fermi distribution

$$f_k = \frac{1}{\exp\left(E_k/k_B T\right) + 1}$$

The equilibrium distribution can be disturbed as a result of an external perturbation. If, for example, a superconductor is exposed to electromagnetic radiation, the latter does not affect the symmetry of the distribution of electrons and holes over the branches of the spectrum. What happens is that the quasiparticles, having absorbed the electromagnetic energy, move up to higher energy levels, which may result in an alteration of the energy gap. Nonequilibrium processes of this type will be considered in Sect.7.8.

Another way to disturb the equilibrium in the neighborhood of the NS interface is to have a flow of electrons coming from the normal metal. Indeed, in this process, electrons with energies $E_k > \Delta(T)$ penetrate the interior of the superconductor and occupy some of the k states on the electron branch of the spectrum. This causes a population imbalance on the two branches. In this section we want to investigate the consequences of this branch imbalance and the characteristic distances for its relaxation.

It is obvious that the existence of the branch imbalance leads to the appearance of a finite quasiparticle charge Q at a given location in the superconductor:

$$Q = \sum_k q_k f_k$$

where f_k is some (in the general case, nonequilibrium) distribution function for the electrons in momentum space.

But the net charge of all electrons at every point of the superconductor must be identical and equal in absolute value to the local charge on the ions of the crystal lattice. This condition assures electroneutrality of the material. Thus, an increase (compared to equilibrium) of the quasiparticle charge at some location by an amount Q must be compensated by a decrease, by the same amount, of the charge of the condensate, thereby modifying the distribution function of the superconducting electrons, ${v_k}^2$. The dotted line in Fig. 7.4 indicates the initial distribution function ${v_k}^2$ corresponding to equilibrium, when $Q = 0$ and the chemical potential of the superconducting electrons, μ_s, coincides with the Fermi energy ε_F of the metal. [2] Since the area under the ${v_k}^2$ curve is proportional to the number of superconducting electrons, a decrease of the latter ought to shift the distribution boundary to the left. This will result in a decrease of the chemical potential μ_5 by the amount $\varepsilon_F - \mu_s$. The new distribution ${v_k}^2$ is shown in Fig. 7.4 by the solid line. Now we can easily count the number of states that have become

free of superconducting electrons: $2N(0)\,(\varepsilon_F - \mu_s)$, where $N(0)$ is the density of states at the Fermi level, and the factor 2 takes into account that there are

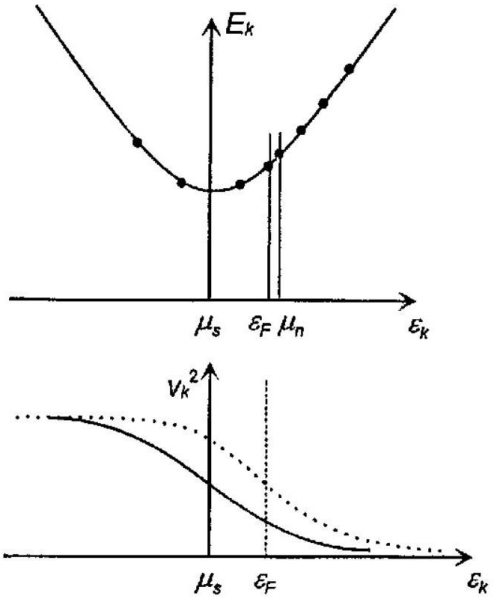

Fig. 7.4. Nonequilibrium distribution of superconducting electrons, ${v_k}^2$, and quasiparticle spectrum E_k for the superconductor in a nonequilibrium state. The dotted line shows the equilibrium distribution ${v_k}^2$ for $\mu_\mathrm{s} = \varepsilon_F$. In the latter case, the energy gap Δ retains its value while the chemical potential μ_n becomes greater than ε_F

two electrons with opposite spins at each energy level. It follows that the condensate has lost the charge

$$Q = 2N(0)\,(\varepsilon_\mathrm{F} - \mu_\mathrm{s})\,, \tag{7.8}$$

which has subsequently been added to the quasiparticles.

Let us analyze the consequences of this process. Since the nonequilibrium quasiparticle charge Q becomes a function of the coordinate x, it is obvious from (7.8) that, in real space, the nonequilibrium chemical potential of the superconducting electrons, μ_s, also becomes a function of x. But this is equivalent to the possibility of having an electric field $\boldsymbol{E}$ in the superconductor, such that it does not accelerate the condensate. Indeed, the most general form of the equation of motion for a superconducting electron reads

$$\frac{\mathrm{d}}{\mathrm{d}t}\,(m\boldsymbol{v}_\mathrm{s}) = -\frac{e}{c}\frac{\mathrm{d}\boldsymbol{A}}{\mathrm{d}t} - e\nabla\varphi - \nabla\mu_\mathrm{s}. \tag{7.9}$$

Here e is the electron charge, m the electron mass, v_s the superfluid velocity of the condensate, φ the electrostatic potential, and $\boldsymbol{A}$ the vector potential. Under stationary conditions, $\mathrm{d}\,(m\boldsymbol{v}_\mathrm{s})\,/\mathrm{d}t = \mathrm{d}\boldsymbol{A}/\mathrm{d}t = 0$, and the superconducting electrons do not accelerate. This implies that the electrochemical potential of the superconducting electrons, $\varphi_{\mathrm{ech}\,,s}$, must be constant in space:

however, it does not oppose the existence of the electric field. The latter is, from (7.10),

$$\boldsymbol{E} = -\nabla\varphi = \frac{1}{e}\nabla\mu_\mathrm{s}$$

Using (7.8) we have

[292] In the nonequilibrium case, the form of the electron distribution function for the condensate is the same as at equilibrium, i.e., ${v_k}^2 = (1 - \varepsilon_k/E_k)\,/2$, but with $\varepsilon_k = \hbar^2k^2/2m - \mu_s$ and $E_k = \left({\varepsilon_k}^2 + \Delta^2\right)^{1/2}$. That is, we assume that there is enough time for the condensate to adjust to a given nonequilibrium distribution of the quasiparticles. One can easily verify that the branch imbalance does not

$$E = -\frac{1}{2eN(0)}\nabla Q \tag{7.11}$$

The above analysis infers that a gradient of the quasiparticle charge in a superconductor under nonequilibrium conditions brings about an electric field. However, this field does not cause the condensate to accelerate, because it is compensated by a gradient of the chemical potential of superconducting electrons. We emphasize once again that superconducting electrons are only affected by the gradient of their electrochemical potential $\nabla\varphi_{\text{ech, s}}$ which, by (7.10), is zero.

For a given site in the superconductor, the presence of a stationary but nonequilibrium quasiparticle charge of density Q indicates that there exists a continuous flow of quasiparticles through this site. The quasiparticles bring with them a certain charge which is immediately transferred to the condensate through the relaxation process.

The entire process can be expressed by a simple relation

$$\operatorname{div} j_{\text{n}} = -eQ/\tau_Q \tag{7.12}$$

where $\boldsymbol{j}_{\text{n}}$ is the normal component of the total current. The relation (7.12) is only approximately valid when the gap is small ($\Delta \ll k_{\text{B}}T_{\text{c}}$), that is, when the temperature is close to T_c. One can find a more rigorous treatment of this process in [67]. In the same approximation, at $T \approx T_c$, the change in the chemical potential of the quasiparticles is small compared to that of the superconducting electrons, and can be neglected, i.e., $\varepsilon_{\text{F}} - \mu_{\text{s}} \gg \mu_{\text{n}} - \varepsilon_{\text{F}}$ (see Fig. 7.4). Indeed, at $T \approx T_{\text{c}}$, the number of superconducting electrons in the condensate is small, while that of normal electrons is substantial. Therefore, the removal of a few electrons from the condensate and their transfer to the sea of normal electrons will result in a considerable alteration of the properties of the condensate (a decrease in μ_s) while leaving the normal electrons almost unaffected.

In view of this, one may write Ohm's law for the excitations in the usual form

$$j_{\text{n}} = \sigma E$$

where σ is the normal conductivity at low temperatures: $\sigma^{-1} = \rho_{\text{res}}$, and ρ_{res} the residual resistivity. [3] Taking the divergence of both sides of this equation and substituting (7.11) and (7.12) yields

$$\nabla^2 Q = \frac{1}{{\lambda_Q}^2} Q \tag{7.13}$$

where

$${\lambda_Q}^2 = \frac{\sigma\tau_Q}{2e^2N(0)} \tag{7.14}$$

Taking into account that the conductivity of the normal metal can be written as [4]

$$\sigma = \frac{2}{3}e^2N(0)lv_{\text{F}}$$

where l is the electron mean free path and v_{F} is the electron velocity on the Fermi surface, we finally have

$$\lambda_Q = \left(\frac{lv_F\tau_Q}{3}\right)^{1/2} = (D\tau_Q)^{1/2} \tag{7.15}$$

where D is the electron diffusion coefficient, $D = lv_{\text{F}}/3$.

Consider now the simplest case. Suppose that the sample is a filament so thin that the problem

can be considered one-dimensional. Let us take the x axis along the filament and assume the material of the filament to be normal for $x < 0$ and superconducting for $x > 0$. Further, suppose that the filament carries a current in the positive x direction. Equation (7.13) then takes the form

$$\frac{\mathrm{d}^2 Q}{\mathrm{d}x^2} = \frac{1}{{\lambda_Q}^2} Q \tag{7.16}$$

It is obvious that far away from the interface (at $x \to \infty$) the charge is $Q \to 0$, because there the superconductor is at equilibrium and the quasiparticle charge is zero. The solution of (7.16) is then given by the function

$$Q \propto \mathrm{e}^{-x/\lambda_Q} \tag{7.17}$$

Accordingly, the charge gradient gives rise to an electric field in the interior of the superconductor which, by (7.11), will be

$$E = E_0 \mathrm{e}^{-x/\lambda_Q} \tag{7.18}$$

where E_0 is the electric field at the interface. If one ignores the Andreev reflection, which is indeed permitted at $T \approx T_\mathrm{c}$, the field E_0 at the interface will be equal to the electric field in the interior of the normal metal, i.e., at $x < 0$.

Thus the quantity λ_Q represents the depth to which the electric field penetrates into the superconductor. According to (7.18), the electric field is exponentially damped over a distance λ_Q from the interface. Let us estimate the electric field penetration depth. According to (7.14), $\lambda_Q \propto {\tau_Q}^{1/2}$ and, according to (7.7), τ_Q is proportional to Δ^{-1}. Taking into account that $\Delta \propto (1 - T/T_c)^{1/2}$, we have

$$\lambda_Q \propto \left(1 - \frac{T}{T_c}\right)^{-1/4} \tag{7.19}$$

that is, the depth λ_Q diverges at $T \to T_c$. Thus, at temperatures sufficiently close to the critical temperature, the electric field can penetrate the superconductor to large distances. Recalling that the characteristic value of τ_Q is of the order $10^{-9} - 10^{-10}$ s, we obtain for $v_\mathrm{F} \sim 10^8$ cm s^{-1} and, say, $l \sim 10^{-5}$ cm: $\lambda_Q \sim 10^{-4} - 10^{-3}$ cm. This means that the electric field penetration depth can surpass all other characteristic lengths of the superconductor. Not too close to T_c, it is possible to have $\lambda_Q \gg \xi(T)$.

Let us summarize. An electric current passing through the interface between a superconductor and a normal metal gives rise to an electric field in the superconductor. The field decays over the distance λ_Q from the interface, where λ_Q can be of a macroscopically large value. Within this region, the divergence of the normal current, $\nabla \boldsymbol{j}_\mathrm{n}$, is nonzero (see (7.12)). But for the total current $\boldsymbol{j} = \boldsymbol{j}_\mathrm{g} + \boldsymbol{j}_\mathrm{n}$ (where $\boldsymbol{j}_\mathrm{g}$ is the supercurrent density) under stationary conditions, the divergence is, naturally, zero. Therefore, we have

$$\nabla j_\mathrm{n} = -\nabla j_\mathrm{s}$$

It means that within the layer of a superconductor of thickness λ_Q near the interface with the normal metal, the normal current is converted into the supercurrent. This can also be interpreted in a different way. According to Fig. 7.4, the chemical potentials in this 'nonequilibrium' region are: $\mu_\mathrm{n} > \mu_\mathrm{g}$. Therefore, one may say that this region hosts a 'chemical reaction' in which a substance with chemical potential μ_n transforms into a substance with chemical potential μ_8.

All the processes analyzed in this section relate to the case where there is a current of electrons passing from a normal metal to a superconductor. However, it is easy to verify

that the entire pattern is symmetric with respect to current reversal. In that case, the particles moving from the normal metal towards the superconductor and entering the interface are holes, and the Andreev-reflected particles are electron-like. Furthermore, the branch imbalance of the elementary excitations in the superconductor, in the region $\sim \lambda_Q$ near the interface, is such that the population of the hole branch exceeds that of the electron branch.

21.3.5 7.6 Experimental Study of a Nonequilibrium State at a Normal Metal-Superconductor Interface

7.6.1 The Experiments of Yu and Mercereau

In this section we shall describe particularly elegant experiments due to Yu and Mercereau [71]. These experiments have clearly demonstrated that, in the presence of an electric current passing through an NS interface, the elec (????? missing text) differ from each other within a region of the superconductor adjacent to the normal metal.

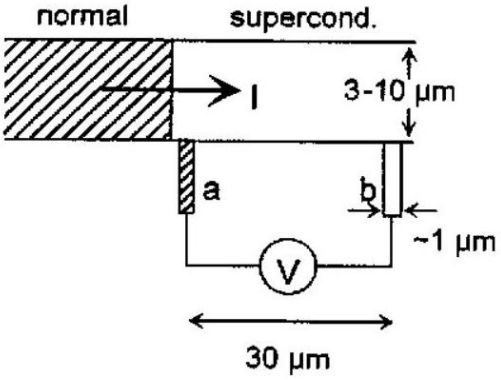

Fig. 7.5. Schematic diagram of the experiment by Yu and Mercereau [71]. Voltage leads a and b are connected to the voltmeter. If lead a is normal, the voltmeter registers the difference between electrochemical potentials of the quasiparticles and the condensate. If lead a is superconducting, the voltmeter reading is zero. Note that the readings do not depend on whether lead b is in the normal or superconducting state

The critical temperature of a thin film of tantalum of thickness of about 250Å is approximately 4.1 K . If a part of the film is made thinner (about 100Å) by anodization, the critical temperature of this part will fall to 3.5 K . Further, if the temperature of the film is kept between 3.5 K and 4.1 K , one part of the film will be normal and the other superconducting.

If we now apply a current to the film, the electrochemical potential of the superconducting electrons, $\varphi_{\text{ech},}$ s, will be constant in space, according to (7.10). Therefore, the superconducting voltage leads a and b (see Fig. 7.5)

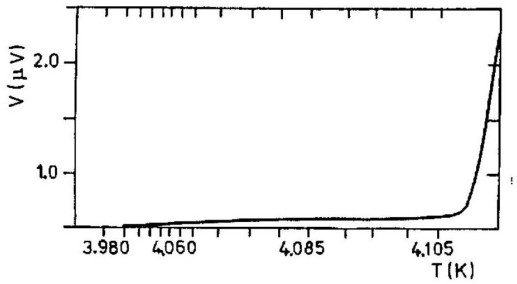

Fig. 7.6. Results of the Yu-Mercereau experiment [71]. The voltmeter registers the difference between the electrochemical potentials of the quasiparticles and the

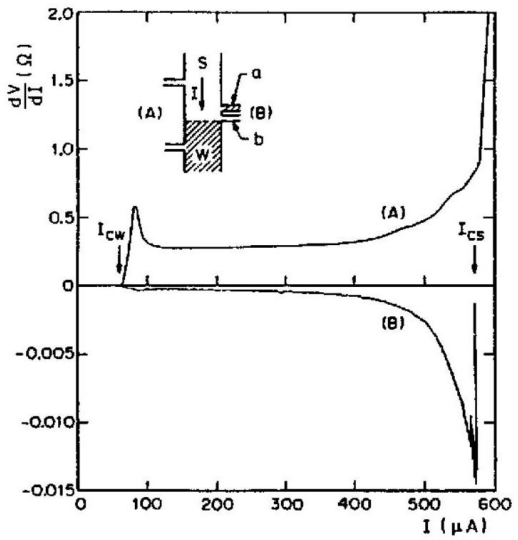

Fig. 7.7. Results of the Yu -Mercereau experiment [71]: differential resistance as a function of current through the film. Voltage A is opposite in sign to voltage B. Current flows in the direction from the superconducting to the normal (dashed area) lead

will convey to the voltmeter equal electrochemical potentials. That is, the voltmeter will register zero voltage. If, however, one of the voltage leads, a, immediately adjacent to the NS interface is made of a normal metal, it will convey to the left input contact of the voltmeter the electrochemical potential of the normal electrons, which in this region differs from $\varphi_{\text{ech.s}}$. This difference relaxes over the distance λ_Q from the interface. If the distance between the voltage leads a and b exceeds λ_Q, the lead b will send to the right contact of the voltmeter the electrochemical potential of the superconducting electrons (in equilibrium conditions, the latter is equal to the electrochemical potential of the quasiparticles). As a result, the voltmeter will measure the difference in electrochemical potential between the normal and superconducting electrons in the vicinity of the NS interface.

The result of the experiment with the lead a normal is shown in Fig. 7.6.

Another experiment by the same authors proved to be even more elegant. By placing the voltage contacts in the nonequilibrium region of a superconductor close to each other (as illustrated in Fig. 7.7) and in such a way that the superconducting lead b was very close to the interface and the normal lead a was some distance away from it, they were able to observe a reversal of the voltage sign for the same direction of current as before.

These experiments have provided ample verification of the ideas discussed in the foregoing sections.

Indeed, if the current in the film passes from S to N (see Fig. 7.7), a 'chemical reaction' takes place in the region of nonequilibrium near the interface: superconducting electrons convert into normal electrons. That is, the chemical potential μ_8 in this region is larger than μ_{n}. As a result, the reading of the voltmeter changes sign.

7.6.2 Excess Resistance of the Normal-Superconducting Interface

Another interesting manifestation of nonequilibrium processes in the vicinity of an NS interface, initiated by a current, is the excess electrical resistance of the interface. Physically, it is easy to understand.

Suppose that there is a current of electrons passing from a normal metal N to a superconductor S. Electrons from N with energies less than the gap $\Delta(T)$ in S will be Andreev-reflected and the current they were carrying will convert into a current of superconducting electrons. This process will take place within a distance $\xi(T)$ from the interface and its contribution to the resistivity will be zero.

But things will be different for the electrons in N of energies higher than the gap $\Delta(T)$.

Upon arriving in S , they move, in momentum space, to the electron branch of the elementary excitation spectrum of the superconductor. This, as was established in the previous section, results in an imbalance of the quasiparticle charge Q and gives rise to an electric field E which extends into the superconductor over a distance λ_Q from the interface. Furthermore, the presence of an electric field in the region λ_Q near the interface implies that this region contributes to the net voltage drop, that is, to the net resistance of the circuit. This additional resistance is called the excess resistance of an NS interface. If all electrons carrying the current were accelerated by the electric field, the excess resistance would simply be

$$R_{\text{exc}} = \rho\lambda_Q/S$$

where ρ is the normal-state resistivity of the superconductor and S its crosssectional area. One should bear in mind, however, that not all electrons are accelerated by the electric field E.

Indeed, as we already know, the electrons of the condensate are not accelerated by the field E, because the effect of the field on superconducting electrons is exactly compensated by the gradient of their chemical potential $\nabla\mu_5$. This property is a characteristic of all electrons passing from N into S with energies that are below the gap $\Delta(T)$ (they are Andreev-reflected), and also of the quasiparticles with energies above the gap: $E_k \geq \Delta(T)$. The number of quasiparticles which do not contribute to the excess resistance is determined by the following process. Consider an electron having a charge g_k which is injected from N into S . Upon entering S , the electron will have 'lost' a part of its charge $1 - q_k$ which has been transferred to the condensate. The transmission of this part of the charge through the NS interface occurs
excess resistance. The latter should then be written as

$$R_{\text{exc}} = \frac{Z(T)}{S}\ \frac{\rho\lambda_{\text{Q}}}{S},$$

where the coefficient $Z(T)$ accounts for the number of electrons which ar not Andreev-reflected at the interface.

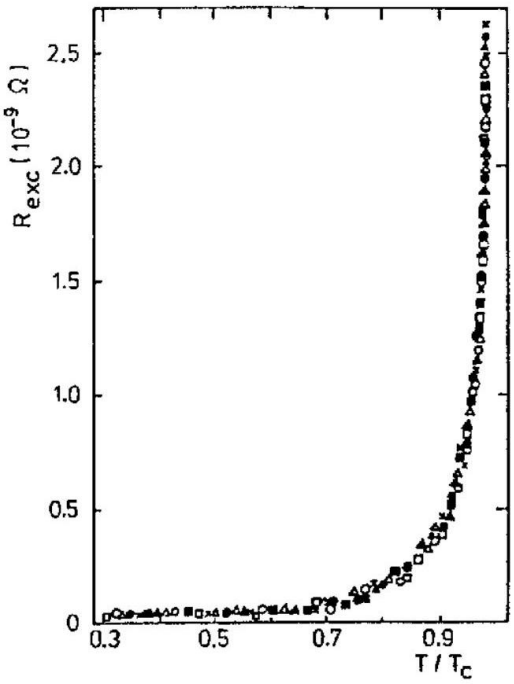

Fig. 7.8. Excess resistance of an NS interface as a function of temperature, me sured on Ta -Cu-Ta sandwiches [72]. The data were obtained from seven differen samples

It is obvious that as $T \to 0$ all electrons passing through the interfac are Andreev-reflected and $Z \to 0$. Conversely, as $T \to T_{\text{c}}$ we have $\Delta(T) \to$ so that the overwhelming majority of

electrons pass through the interfa without being Andreev-reflected and therefore contribute to the resistanc In this limit $Z \to 1$.

Therefore, in the entire temperature range: $R_{\text{cxc}}(T)$ is a monotonic fun tion of temperature:
5

$$R_{\text{exc}}\,(T \to 0) = 0, \quad R_{\text{exc}}\,(T \to T_{\text{c}}) = \rho\lambda_{\text{Q}}/S$$

In the latter case ($T \to T_{\text{c}}$), the temperature dependence of R_{exc} is governe by the temperature dependence of λ_Q (7.19):

$$\lambda_Q \propto \left(1 - \frac{T}{T_{\text{c}}}\right)^{-1/4}$$

This conclusion agrees well with experiment.
As an illustration, the results of experiments on seven different SNS sandwiches are shown in Fig. 7.8. The excess resistances of NS interfaces are plotted as functions of temperature.

21.3.6 7.7 Phase-Slip Centers

Theory by Schmidt

In the present chapter, we have so far considered stationary nonequilibrium processes. Now we are going to address nonstationary nonequilibrium processes.

It was demonstrated in Sect. 3.6, where we examined the critical current of a thin film, that a film driven to the normal state by critical pair-breaking current does not undergo a phase transition. It was established that what happens at $I = I_{\text{c}}$ is simply that the number of superconducting carriers becomes insufficient to sustain a given current I. This means that, at $I > I_c$, there appears a peculiar resistive state which we are going to examine now.

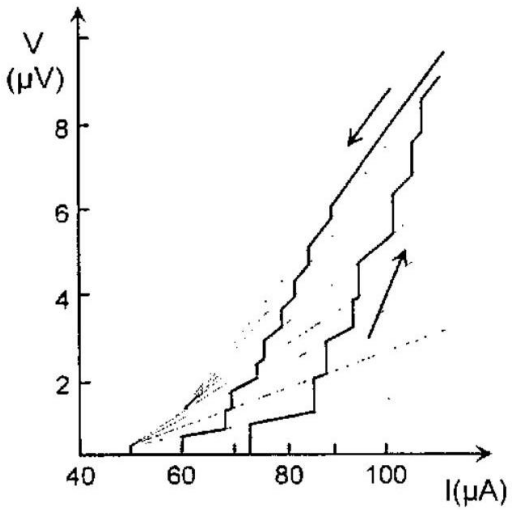

Fig. 7.9. Current-voltage characteristic of a single-crystalline Sn filament: the length of the flament is 0.8 mm and its cross-sectional area is 1.93 mm^2 [75]

Let us start with experimental results. The most suitable objects to study this kind of resistive state are quasi-one-dimensional objects, such as long thin superconducting filaments of diameter $d \leq \xi(T)$. The diameter of such a flament is so small that an Abrikosov vortex having a normal core fof radius
$\sim \xi(T)$) cannot fit into it. Therefore, the resistive state of the filament is not masked by effects typical of the resistive state of type-II superconductors. The current-voltage characteristic of a

[29]–The function $Z(T)$ is calculated in a number of theoretical papers. See, for e: 1 im-1 -11

thin single-crystalline whisker of tin is shown in Fig. 7.9. One can see that the voltage builds up in a stepwise fashion and each upward jump of the voltage is accompanied by an increase of the sample resistivity (the slope of the $I - V$ characteristic).

This behavior in the resistive state is explained by the model proposed by Skocpol, Beasley and Tinkham [76], the so-called phase slip center model,

Suppose that at a certain location (weak spot) in the filament the critical current is somewhat smaller than elsewhere. Then, as we increase the current through the filament, the current will first reach its critical value at the weak spot. A further increase of the current will result in a flow of normal electrons which will induce an electric field. The latter, in turn, will accelerate the normal electrons to the critical velocity. Electron pairs at the weak spot will be broken, the amplitude of the order parameter $|\psi|$ will go to zero and the current will be carried by the normal component alone. But formation of electron pairs remains favored. Therefore, the amplitude of the order parameter $|\psi|$ will become nonzero again and the current will again be carried partly by superconducting electrons, i.e., a supercurrent will appear. Then the entire process will repeat itself. On completion of each cycle, the phase difference of the superconducting electron wavefunctions to the left and to the right of the weak spot will vary by 2π; hence the name phase slip center. The size of the center is given, of course, by the size of the region where the oscillations of $|\psi|$ take place, which is $\sim 2\xi(T)$.

At the moment when $|\psi| = 0$, a phase slip center is in the normal state and the electric field penetrates the parts of the superconductor adjacent to it, to a depth $\sim \lambda_Q$ (see Sect. 7.5). Therefore, formation of one phase slip center is accompanied by the appearance of a finite resistance $\rho 2\lambda_Q/S$, where ρ is the normal-state resistivity of the material of the filament and S is its crosssectional area. The voltage drop across this resistance is produced solely by the normal component of the current: $I_{\rm n} = I - I_{\rm s}$. Let us find the average of this expression over time. I is a given constant current independent of time. The supercurrent $I_{\rm s}$ oscillates between $I_{\rm c}$ and 0 . Therefore, we assume $\bar{I}_{\rm s} = \beta I_{\rm c}$, where $\beta \sim 0.5$. Then, for the average voltage across one phase slip center we have

$$\bar{V} = \frac{2\lambda_Q \rho\,(1 - \beta I_{\rm c})}{S} \tag{7.20}$$

Despite its simplicity, this formula describes the experimental results very well.

A further increase of the current will give rise to a second phase slip center, then a third and so on. The arrival of every new center will cause the total voltage across the filament to increase in a jump, and the slope of the current-voltage characteristic will increase, too, owing to the increased number of resistive regions. One can trace this behavior in the Fig. 7.9.

21.3.7 7.8 Nonequilibrium Enhancement of Superconductivity

Theory by Schmidt

In this section we shall examine the case of a symmetric deviation from the equilibrium distribution function, such that the nonequilibrium distributions of the quasiparticles for the two branches of the elementary excitation spectrum are identical. Contrary to the other nonequilibrium processes which we have already analyzed, a deviation from equilibrium in this case brings about a change of the energy gap Δ.

A symmetric nonequilibrium distribution can be realized, for instance, by exposing a superconductor to electromagnetic radiation of frequency $\omega < 2\Delta/\hbar$. Then a quantum of electromagnetic energy incident on the superconductor will be insufficient to break a pair but will still be enough to move elementary excitations up to the higher energy levels of the excitation spectrum. Such a nonequilibrium distribution of quasiparticles ought to cause an increase of both the energy gap and the critical temperature.

Indeed, by making the lower energy levels of the elementary excitation spectrum vacant, we open the way for the electron pairs of the condensate to make transitions to these k states thereby increasing the number of terms in the sum of (6.34), which defines the energy gap. A number of experimental results support these ideas. For instance, an increase of the critical current of narrow superconducting constrictions was observed in [77], after the sample had been subjected to ultra-high-frequency radiation. Theoretical treatment of these effects can be found in works by Eliashberg [78].

21.3.8 7.9 Thermoelectric Effect in Superconductors

Theory by Schmidt

For a long time it was believed that there are no thermoelectric effects in superconductors. However, this is not true. To find out what really happens in superconductors, let us first consider the ordinary thermoelectric effect in a normal metal.

Suppose that the two ends of a bulk piece of a normal metal have different temperatures, T_1 and T_2, that is, there is a temperature gradient $\nabla T'$ across the metal. Free electrons in the metal are acted upon by a force pushing them in the direction from the 'hot' to the 'cold' end. A subsequent accumulation of opposite charges at the opposite ends of the superconductor produces an electric field in its interior which, in turn, exerts a force on the electrons in the reverse direction, i.e., from the cold to the hot end. Under stationary conditions, the two forces balance each other resulting in a constant voltage drop across the specimen, V, referred to as the thermo-electromotive force (thermo-emf):

$$V = \alpha\,(T_1 - T_2)$$

whare n:- the shoulitathnemanlontrie nower (thermnnower) of the metal.

In the superconductor, the process of heat transfer relates to entirely different electron phenomena. [6] Suppose, again, that two ends of a bulk piece of metal (this time of a superconductor) are at different temperatures, T_1 and T_2. Again, the temperature gradient ∇T will produce a force on normal excitations of the superconductor initiating a current of the normal excitations

$$j_{\mathrm{n}} = \sigma\alpha\nabla T \tag{7.21}$$

where σ is the normal-state conductivity of the superconductor. As an immediate response, a countercurrent of the superconducting component, $\boldsymbol{j}_{\mathrm{s}}$, will start, thereby compensating the normal current $\boldsymbol{j}_{\mathrm{n}}$. Indeed, according to (7.21), the current $\boldsymbol{j}_{\mathrm{n}}$ is a potential current, i.e., curl $\boldsymbol{j}_{\mathrm{n}} = 0$. This means that for the total current $\boldsymbol{j}$ defined as

$$\boldsymbol{j} = \boldsymbol{j}_{\mathrm{n}} + \boldsymbol{j}_{\mathrm{s}}$$

we have curl $\boldsymbol{j} = \operatorname{curl} \boldsymbol{j}_s$. The supercurrent $\boldsymbol{j}_g$ must, under stationary conditions, satisfy the London equation. Taking the curl of both sides of (2.17) we get

$$\operatorname{curl} A j_{\mathrm{s}} = -\frac{1}{c}\boldsymbol{H}$$

which means that in our case the equation

$$\operatorname{curl} A j = -\frac{1}{c}H \tag{7.22}$$

is valid. Using Maxwell's equations curl $\boldsymbol{H} = \frac{4\pi}{c}\boldsymbol{j}$ and div $\boldsymbol{H} = 0$, we then arrive at the well-known equation for the magnetic field:

$$\nabla^2 \boldsymbol{H} = \frac{1}{\lambda^2}\boldsymbol{H}$$

from which the Meissner-Ochsenfeld effect follows directly. This implies that, in the presence of heat flow, the total current in the interior of a bulk isotropic homogeneous superconductor must be zero, too:

$$\boldsymbol{j} = \boldsymbol{j}_{\mathrm{n}} + \boldsymbol{j}_{\mathrm{s}} = 0$$

that is, $j_{\mathrm{n}} = -j_{\mathrm{s}}$.
This means that, as they approach the edge of the superconductor, normal excitations driven by the temperature gradient convert into superconducting carriers, i.e., electron pairs, and move in the reverse direction, thereby forming the countercurrent $\boldsymbol{j}_{\mathbf{s}}$. A graphic illustration of this process is given by the equivalent circuit shown in Fig. 7.10.

Let us assume that the normal excitations are acted upon by an electromotive force (emf) E_T produced by the temperature gradient:

$$E_T = \alpha\,(T_1 - T_2)$$

The emf induces a current $I_{\mathrm{n}} = E_T/R_{\mathrm{n}}$ in the circuit, which flows back

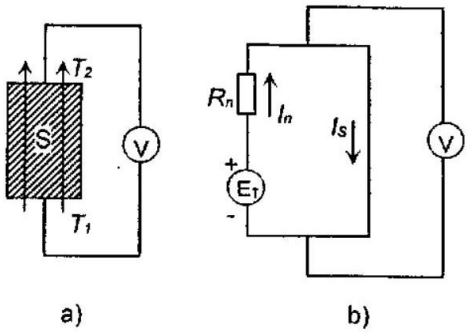

Fig. 7.10. (a) Superconductor carrying a heat flow, $T_1 > T_2$; (b) equivalent circuit for a superconductor subjected to a temperature gradient. R_{n} is the specimen resistance in the normal state, E_T is the thermo-emf acting upon the normal excitations
through the superconducting region as a supercurrent I_5. With this in mind, we can understand why the reading of the voltmeter incorporated in the circuit of Fig. 7.10 is zero: it is shunted by the supercurrent. That is why it was presumed for a long time that there are no thermoelectric effects in superconductors.

21.3.9 7.10 Superconducting 'Thermocouple' and the Magnetic Flux Induced by a Heat Flow

Theory by Schmidt

Now we shall see that thermoelectric effects can indeed be observed in superconductors. Consider two bulk specimens of two dissimilar superconductors, S_1 and S_2, which are brought into contact in such a way that together they form a closed ring, as in Fig. 7.11. We assume that the contact regions have different temperatures, T_1 and T_2.

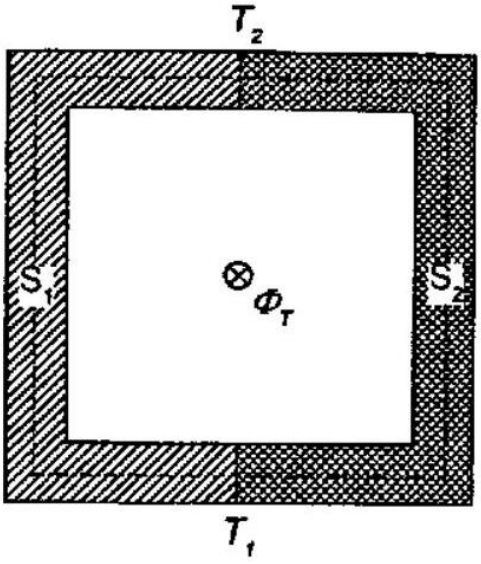

Fig. 7.11. Superconducting 'thermocouple'. The magnetic flux Φ_T through the ring is proportional to the temperature difference $(T_1 - T_2)$

The temperature gradient induces a current $\boldsymbol{j}_{\mathbf{n}} = \sigma\alpha\nabla T$ in each half of the ring, S_1 and S_2. The supercurrent, which starts in response in the interior of the superconductor, is $\boldsymbol{j}_{\mathrm{s}} = -\boldsymbol{j}_{\mathrm{n}}$ and, according to the second Ginzburg-

$$j_{\mathrm{s}} = \frac{\hbar n_8 e}{2m}\nabla\theta - \frac{e^2}{mc}n_{\mathrm{s}}A \tag{7.23}$$

where n_{s} is the superconducting electron density, e and m are the charge and mass of a free electron, respectively, θ is the phase of the superconducting wavefunction of the GL, theory, and A is the vector potential.

Taking into account (7.21), we have

$$\nabla\theta = \frac{2m}{\hbar n_\varepsilon e}(-\sigma\alpha\nabla T) + \frac{2e}{\hbar c}\boldsymbol{A} \tag{7.24}$$

As a next step, we integrate this equation over the dashed contour which passes through the interior of our bimetallic superconducting ring in such a way that its distance from the surfaces of the ring everywhere exceeds the penetration depth λ (see Fig. 7.11). Taking into account the requirement of the GL theory that the wavefunction must be single-valued leads to an equation which is already well-known to us:

$$\oint \nabla\theta \mathrm{d}l = 2\pi n, \quad n = 0, 1, 2, \ldots \tag{7.25}$$

Integrating the right-hand side of (7.24) and using (7.25) yields

$$2\pi n = -\frac{2m}{\hbar e}\int_{T_1}^{T_2}\left(\frac{\sigma_1\alpha_1}{n_{\mathrm{s}1}} - \frac{\sigma_2\alpha_2}{n_{\mathrm{s}2}}\right)\mathrm{d}T + \frac{2\pi\Phi}{\Phi_0}$$

This means that the total magnetic flux through the bimetallic ring can be expressed as

$$\Phi = \Phi_0 n + \Phi r \tag{7.26}$$

where

$$\Phi_T = \Phi_0\frac{m}{\pi e\hbar}\int_{T_1}^{T_2}\left(\frac{\sigma_1\alpha_1}{n_{\mathrm{s}1}} - \frac{\sigma_2\alpha_2}{n_{\mathrm{s}2}}\right)\mathrm{d}T \tag{7.27}$$

The indices 1 and 2 in the integrand refer to S_1 and S_2, respectively.
It follows from (7.26) and (7.27) that even in the case $n = 0$, that is, when the magnetic flux through the ring is zero, the difference in temperature between the contact regions S_1 and S_2 induces a magnetic flux Φ_T. This flux is generated by the supercurrent circulating along the inner surface of the binnetallic ring. If the quantities σ, α and n_s are assumed to be independent of temperature in the interval $T_1 < T < T_2$, (7.27) can be simplified to

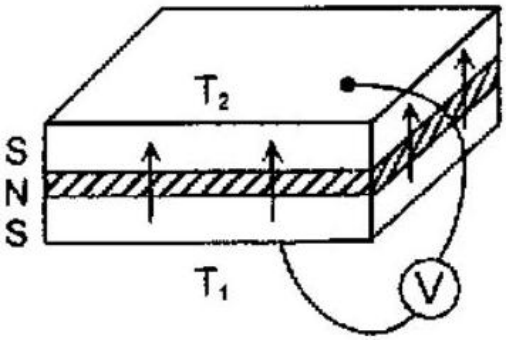
$$\Phi_T = \Phi_0 \frac{m}{\pi e \hbar} \left(\frac{\sigma_1 \alpha_1}{n_{s1}} - \frac{\sigma_2 \alpha_2}{n_{82}} \right) \Delta T$$

where $\Delta T' = T_2 - T_1$.
Taking $\sigma \sim 10^7 (\Omega\ \mathrm{m})^{-1}, \alpha \sim 10^{-6} \mathrm{VK}^{-1}$, and $n_s \sim 10^{28} \mathrm{ml}^{-3}$ we obtain for $\Phi_T / \Delta T$ a value of the order $10^{-5} \Phi_0$ per Kelvin. Measuring such tiny

At temperatures close to T_c, the effect is enhanced, since the superconducting electron density there tends to zero. A magnetic flux Φ_T induced by a temperature gradient in a bimetallic ring was indeed observed in the experiments reported in [82, 83]. Its value, however, proved to be much larger that the theoretical estimate. The cause of this discrepancy is not clear yet.

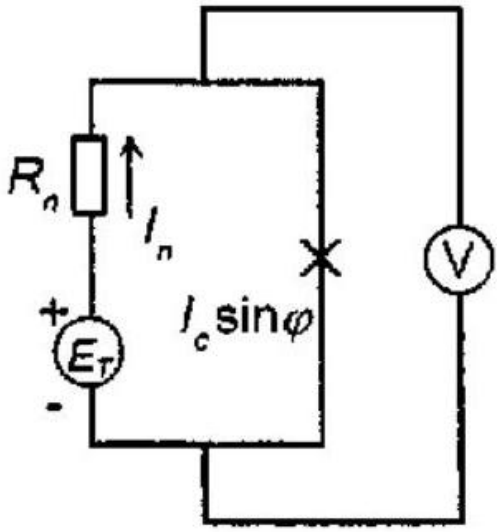
21.3.10 7.11 Thermoelectric Effects in Josephson Junctions

One encounters very interesting and striking thermoelectric effects in Josephson junctions. They are most pronounced in superconductor-normal metalsuperconductor (SNS) junctions. As we are soon to find out, the reason for this lies in the fact that phase coherence in this type of Josephson junctions is established through a fairly thick normal layer ($\sim 10^{-3}$ cm). The typically very low resistance of the normal layer results in very small characteristic values of the voltage across the junction, V_c. In this section we shall first consider the behavior of an SNS junction when its S electrodes have different temperatures or, in other words, when there is a heat flow through the junction. After that, we shall discuss the thermoelectric effects arising when, in addition to carrying a heat flow, the junction is placed in a magnetic field.



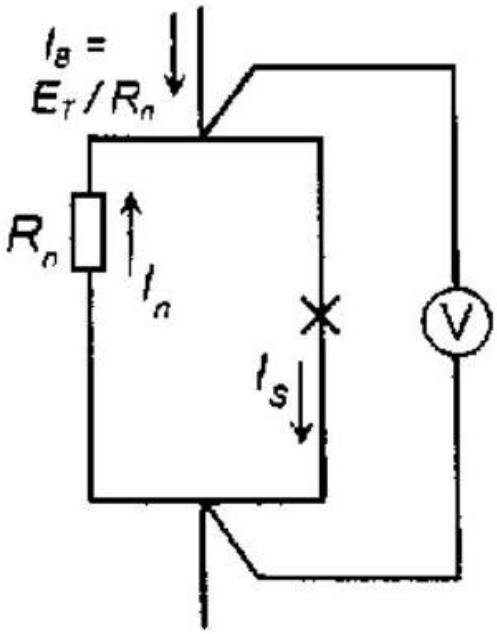
7.11.1 SNS Josephson Junction in a Temperature Gradient

Let us consider an SNS Josephson junction placed in a temperature gradient (Fig. 7.12 (a)). Again, the question to be asked is: what will be the reading of a voltmeter connected in parallel with such an autonomous junction? The answer is suggested by an equivalent circuit of such a junction (Fig. 7.12 (b)) which has been constructed by adding a source of thermo-emf $E_T = \alpha\,(T_1 - T_2)$ to the equivalent circuit of the Josephson junction shown in Fig. 4.5. Here α is the absolute thermopower of the material of the normal layer and T_1 and T_2 are the temperatures of the superconducting electrodes where they make contact with the normal layer. It is clear from Fig. 7.12 (b) that the thermoemf E_T included in the closed circuit produces a current which passes through the normal layer in the form of a normal current I_n; and through the true Josephson part of the junction in the form of a supercurrent $I_s = I_c \sin \varphi$. Here φ is the phase difference between the superconducting electron wavefunctions in the two S electrodes and I_c the critical current of the junction.



The voltage V_{AB} between the points A and B in Fig. 7.12 (b) must satisfy the equation

$$E_T - I_n R_n = V_{AB} \tag{7.28}$$



where R_n is the resistance of the normal layer. On the other hand, Kirchhoff's first law must hold for both the point A and the point B:

a)

b)

c)

Fig. 7.12. (a) SNS Josephson junction with heat flow. The temperature drop across the normal layer is $(T_1 - T_2)$; (b) equivalent circuit for such a junction: E_T is the thermo-emf due to the heat flow across the normal layer; (c) the circuit corresponding to (7.32)

Finally, the part of the circuit carrying the Josephson current ought to obey the Josephson relations:

$$I_{\mathrm{B}} = I_{\mathrm{C}} \sin \varphi \tag{7.30}$$

$$2eV_{\mathrm{AB}} = \hbar \frac{\mathrm{d}\varphi}{\mathrm{d}t} \tag{7.31}$$

Together, equations (7.28-31) give a complete definition of the problem. They can be easily reduced to

$$\frac{\hbar}{2eR_{\mathrm{n}}} \frac{\mathrm{d}\varphi}{\mathrm{d}t} + I_{\mathrm{c}} \sin \varphi = \frac{E_T}{R_{\mathrm{n}}}. \tag{7.32}$$

But the last equation is equivalent to the equation of the Josephson junction in the resistively shunted model (which is already known to us from Chap. 4). The current applied to the Josephson junction from an external source (in our case E_T/R_{rl}) is divided into two branches: a Josephson current $I_{\mathrm{c}} \sin \varphi$ and a current through the normal layer $(\hbar/2eR_{\mathbf{n}})\,\mathrm{d}\varphi/\mathrm{d}t$; see Fig. 7.12 (c). The behavior of such a system with identical temperatures of the S electrodes is well known (see Sect. 4.3). If the external current is less than I_{c}, it flows through the superconducting (Josephson) part of the junction only and the voltage between the points A and B is zero. Hence the reading of the voltmeter will be zero, too. If, however, the current exceeds I_c, an oscillating voltage of frequency $\omega = 2e\bar{V}_{\mathrm{AB}}/\hbar$ appears across the junction, where $\bar{V}_{\mathrm{AB}}$ is the dc component of the oscillating voltage registered by the voltmeter.

Now we are in a position to give a complete description of the behavior of a Josephon junction placed in a temperature gradient. As long as the temperature drop between the two surfaces of the normal layer, $\Delta T = T_1 - T_2$, is less than a certain critical value
the reading of the voltmeter connected to the superconducting electrodes remains zero. If, however, ΔT exceeds ΔT_c, an oscillating voltage appears across the junction, with frequency ω given by

$$\omega = \frac{2e}{\hbar} R_{\mathrm{n}} \left[\left(\frac{\alpha \triangle T}{R_{\mathrm{n}}^{-}} \right)^2 - I_{\mathrm{c}}^2 \right]^{1/2} \tag{7.34}$$

Here we have used (4.20). These thermoelectric effects were proposed by Aronov and Galperin in [84] based on theoretical considerations.

One can see from (7.33) that such effects become observable if the critical difference in temperature $\triangle T_{\mathrm{c}}$ is sufficiently small. This implies that the characteristic voltage across the junction $V_{\mathrm{c}} = I_{\mathrm{c}} R_{\mathrm{n}}$ must also be small. In practice, it is not difficult to fabricate an SNS junction with $V_{\mathrm{c}} \sim 10^{-13}$ V. With $\alpha \sim 10^{-8}\mathrm{VK}^{-1}$, this corresponds to $\Delta T_{\mathrm{c}} \sim 10^{-5}$ K. Such a temperature difference can be fairly easily attained in experiment. Experimental studies of the thermoelectric effects in SNS Josephson junctions [85] have provided ample verification of the above ideas.

7.11.2 Thermoelectric Effects in SNS Josephson Junctions in the Presence of a Magnetic Field

Suppose that, in addition to the heat flow, our SNS Josephson junction is placed in a magnetic field parallel to the plane of the junction (the xz plane). In this case it turns out that one can witness interesting and beautiful phenomena.

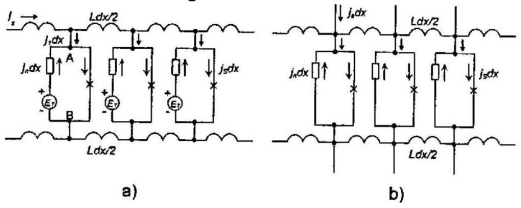


Fig. 7.13. (a) Equivalent circuit for a distributed SNS Josephson junction under a heat flow; (b) alternative representation of the same junction. The source of thermo-emf E_T is replaced by a uniform current j_e

Let us take into account the finite size of the junction, say, along the x axis. Let this size be w. The heat flow is directed along the y axis, perpendicular to the junction, and the magnetic field is in the z direction. The equivalent circuit for such a junction is shown in Fig. 7.13 (a). Here L is the total induc-
and I_x is the current in the direction of the x axis, per unit width. Now, in the same manner as we went from the equivalent circuit of Fig. 7.12 (b) to the circuit of Fig. 7.12 (c), we can go from the circuit of Fig. 7.13 (a) to the equivalent circuit of Fig. 7.13 (b). The latter is the equivalent circuit of an extended (distributed) Josephson junction of uniform temperature (that is, without heat flow) to which an external current of density $j_e = E_T/R_n$ is applied. Here R_n is the resistance per unit area of the normal layer. The behavior of such an object in an external magnetic field parallel to the y axis is well known (see Sect. 4.4). Therefore, one can foresee [86] that the critical temperature difference ΔT_c, corresponding to the appearance of a voltage across the junction, will be a nommonotonic function of the magnetic field. In the ideal case, the dependence to be observed should have the form (see (4.46))

$$\Delta T_c = \frac{j_c R_{n1}}{\alpha} \left| \frac{\sin(\pi\Phi/\Phi_0)}{\pi\Phi/\Phi_0} \right| \tag{7.35}$$

where $\Phi = B_0 w d$. Here B_0 is the magnetic induction of the external field, w is the dimension of the junction along the x axis and $d = d_0 + 2\lambda_L$, with d_0 being the thickness of the normal layer.

The above prediction was verified in the following experiment [87]. The SNS Josephson junction under study was a tantalum-copper-tantalum sandwich with the thickness of the normal layer about 10^{-3} cm, the resistance of the normal layer about $10^{-9}\Omega$, and a critical current of about 10^{-4} A. With these parameters, the characteristic voltage across the junction, V_c, was about 10^{-13} V. The voltage V_c was measured by a SQUID voltmeter. The temperature difference between the two surfaces of the normal layer, $\Delta T'$, was produced by a heater attached to one of the superconducting electrodes of the junction and was therefore proportional to the power supplied by the heater. The critical power of the heater, P_c, was proportional to the critical temperature difference $\triangle T_c$.

The measured critical power P_c as a function of an external magnetic field parallel to the plane of the junction is shown in Fig. 7.14 (the upper curve). The lower curve shows the dependence of the maximum zero-voltage current I_c through the junction on the external magnetic field, corresponding to a uniform temperature over the junction. The position of maximum I_c in Fig. 7.14 is shifted from $B_e = 0$ due to the effect of a background dc magnetic field. Nevertheless, when the scale of the plot was chosen in such a way that the two curves coincided at least at one point, they proved to coincide along their entire lengths. This provided convincing evidence of the validity of the above argumentation.

Let us summarize the main results of this section. Beginning from a certain critical value of the heat flow through an SNS Josephson junction, the latter starts to generate a voltage of thermoelectric nature. The critical value of the heat flow is a nonmonotonic function of the magnetic field. This phenomenom

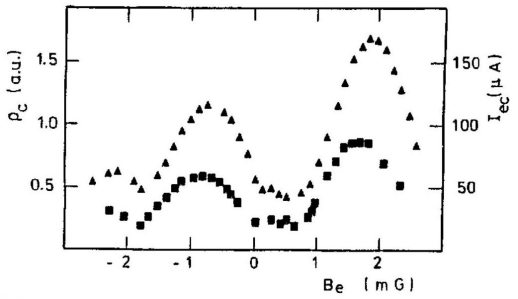

Fig. 7.14. Measurements of the magnetothermoelectric effect in an SNS Josephson junction [87]

It turned out that there also exists a thermal analog of the ac Josephson effect: a steady heat flow through an SNS Josephson junction gives rise to Josephson radiation, that is, to an oscillating voltage across the junction. This effect was observed experimentally [88] two years after the first edition of this book was published in Russian. Later on, several related thermoelectric effects, due to superconducting phase slippage, were observed in the new highT_c materials. The most recent review on this topic is that of Huebener [81].

Problems

Problem 7.1. Find the relaxation time for the quasiparticle charge in Sn if the temperature of the material is 0.01 K below the critical temperature T_c ($T_c = 3.8$ K).

Problem 7.2. Proceeding from the requirement of electroneutrality, we have found that there exists an electric field E in the vicinity of the interface between a superconductor and a normal metal, provided there is an electric current passing through the interface. According to (7.18), div $\boldsymbol{E} \neq 0$. But this suggests that there must exist a finite volume density of the electric charge ρ, in a region of size $\sim \lambda_Q$ near the interface. The charge density is defined by Poisson's equation div $\boldsymbol{E} = 4\pi\rho$. Does this contradict the initial assumption of electroneutrality?

21.3.11 Solutions

Chapter 1

1.1. The surface current density j_{surf} is defined by (1.6). The field H_0 should be set equal to the critical field at $T = 4.2$ K, according to (1.1). As a result we obtain $j_{\text{gurf}} = 422$ A cm^{-1}.
1.2. The difference in free energy is defined by (1.12). The value of H_{cm} at 4.2 K can be calculated using (1.1). Finally, using data from Table 1.1, we have $F_{\text{n}} - F_{\text{s0}} = 1.1 \times 10^4$ergcm^{-3}.
1.3. The latent heat given up by the specimen is $Q = T\,(S_{\text{n}} - S_0)$. Using (1.1) and (1.18), we obtain $Q = 2.30 \times 10^4$erg.

Note. Formula (1.18) expresses the difference in entropy through the quantity $(\partial H_{\text{cm}}/\partial T)_R$. Under the conditions of this particular problem, when the fixed quantity is the external field at infinity, the superconductor does not do any work on external bodies when its temperature changes. Indeed, the only kind of work on external bodies possible for such a superconductor is radiation of electromagnetic waves, which may occur as a result of a change in its internal state. But this is only possible if the integral of the Poynting vector $(c/4\pi)[\boldsymbol{E} \times \boldsymbol{H}]$ over the surface of the superconductor is nonzero. An electric field E can only appear as a result of variations in the magnetic induction B, but $B = 0$. This implies that a change in temperature of a superconductor placed in a magnetic field cannot be accompanied by electromagnetic radiation and $(\partial H_{\text{cm}}/\partial T)_n = (\partial H_{\text{cm}}/\partial T)_H$. That is, we can indeed use (1.18).
1.4. Searching for a minimum of the entropy difference (1.18), we find that the temperature in question is $T_c/\sqrt{3} = 4.16$ K.
1.5. 108 Oe .

1.6. $2.8 \times 10^4 \text{ergcm}^{-3}$.

Chapter 2

2.1. $H = 1.84 \times 10^{-2}\text{Oe}$.
2.2. $A = 75\text{Gcm}; \nabla\theta = 2.36 \times 10^9 \text{radcm}^{-1}$.
2.3. Since $d \ll \lambda$, the current distribution over the film is uniform. Therefore, integrating (2.32) over a closed circular contour of radius R yields

$$\Phi = \Phi_0 n - \frac{2\pi mcR}{n_s e^2} j_s \tag{S.1}$$

On the other hand, the magnetic field in the interior of the cylinder and the current at its surface are related to each other by

$$H = \frac{4\pi}{c} j_s d$$

so that the magnetic flux through the cylinder is $\Phi = (4\pi^2/c)\, j_s d R^2$. Using this to express j_s and substituting it into (S.1) finally yields

$$\Phi = \Phi_0 n \left(1 + \frac{2\lambda^2}{Rd}\right)^{-1}$$

Note. At $Rd \gg 2\lambda^2$, quantization of the magnetic flux through a thin-wolled cylinder ($d \ll \lambda$) is totally analogous to that through a bulk cylinder. In all other cases, the 'flux quantum' is less than Φ_0.
2.4. See Fig. S.1.

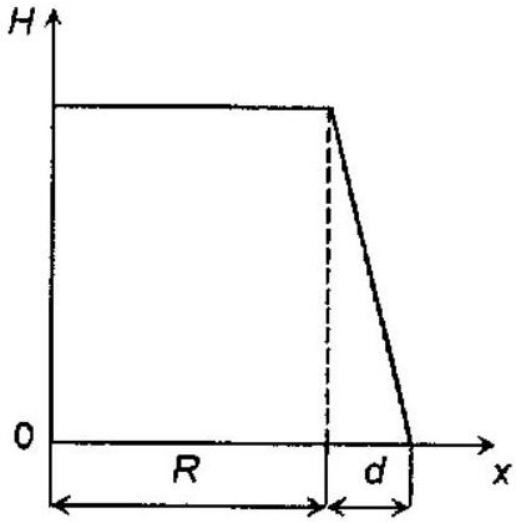

Fig. S.1. Distribution of the magnetic field trapped by a thin-walled superconducting cylinder

Chapter 3

3.1. If $\lambda(0) = 390\text{Å}$, we have $\lambda(4.2\text{ K}) = 415\text{Å}$. The magnetic field at a distance 300Å from the surface will then be $H = H_0 \text{e}^{-x/\lambda} = 145.6$ Oe and $w = H^2/8\pi = 844\text{ergcm}^{-3}$.
3.2. $\lambda(7.10\text{ K})/\lambda(4.2\text{ K}) = 4.49$; $\quad n_s(7.10\text{ K}) = 8.06 \times 10^{20}\text{ cm}^{-3}$.
3.3. Since $\lambda \ll \xi$, we can use (3.56). Finding H_{cm} from (3.38) and substituting it into (3.56), we obtain $\sigma_{\text{ns}} = 1.24 \times 10^{-2}\text{ergcm}^{-2}$.
3.4. Since $\lambda\,(T = 0.9T_c) = 870\text{Å}$ (see Problem 3.3) we have, according to (3.61), $H(x =$

0) = 8.55 Oe. Here we have assumed that the magnetic field is sufficiently small ($H_0 \ll H_{cm}\,(T = 0.9T_c) \approx 60$Oe) so that the order parameter ($\psi = 1$) remains unaffected.

The density of the diamagnetic moment is $M(x) = (1/4\pi)\,[H(x) - H_0]$. Taking, according to (3.61), $H(x) = H_0 \cosh(x/\lambda)/\sinh(x/\lambda)$ and integrating the diamagnetic moment over the thickness of the film, we find M_0:

$$M_0 = \frac{H_0 d}{4\pi}\left(\frac{2\lambda}{d}\tanh\frac{d}{2\lambda} - 1\right). \tag{S.2}$$

It follows that $M_0 = -7.74 \times 10^{-7}$Gcm.

3.5. It follows from (S.2) that the average density of the diamagnetic moment is $\bar{M} = (1/4\pi)H_0[(2\lambda/d)\tanh(d/2\lambda) - 1]$. The work done by the source of magnetic field equals

$$W\,(H_0) = -\int_0^{H_4} \bar{M}\ \mathrm{d}H_0$$

The transition to the normal state occurs when this work becomes equal to $F_\mathrm{n}\ F_{80} = H_{cm}^2/(8\pi)$. Therefore

$$H_{c|} = H_\mathrm{cm}\left(1 - \frac{2\lambda}{d}\tanh\frac{d}{2\lambda}\right)^{-1/2}.$$

Recalling that $\lambda \ll d$, we have $H_\mathrm{cl} = H_\mathrm{cm}(1 + \lambda/d) = 1.087 H_\mathrm{cm}$.

3.6. $H_{J_\mathrm{e}} = 12.5$ Oe; $H_{\mathrm{c}\|} = 1015$ Oe.

3.7. $j_\mathrm{c} = 2.30 \times 10^8$ A cm^{-2}.

3.8. The critical current density is defined by (3.67) and the critical velocity by (3.69). Using (2.7) and (3.37), we have

$$v_\mathrm{c} = \frac{\hbar\kappa}{3\sqrt{3}m\lambda} = 2.81 \times 10^3 \text{ cm s}^{-1}$$

3.9. According to (2.22), $j_\mathrm{M} = cH_\mathrm{cm}/4\pi\lambda$ and $j_\mathrm{M}/j_\mathrm{c} = 3\sqrt{3}/2\sqrt{2} = 1.837$. This means that, if the field at the surface is equal to H_cm, the density of the Meissner current exceeds the pair-breaking current by 1.84 times. This happens because (2.22) does not take into account the decrease of the superconducting electron density n_s caused by the magnetic field H_cm.

Chapter 4

4.1. Since the junctions are connected in parallel, the phase differences φ_1 and φ_2 across them are identical and the currents through the junctions are distributed in proportion to their critical currents: $I_1 = 0.417$ mA, $I_2 = 0.583$ mA.

4.2. $V_\mathrm{max}\ - V_\mathrm{tinin}\ = 2I_\mathrm{c}R$.

4.3. $\bar{V} = 1.33\mathrm{mV}; \nu = 641\mathrm{GHz}$.

4.4. We seek the phase difference across the junction in the form $\varphi = \varphi_0 + \varphi_1$, where φ_0 is the phase difference due to the dc current I_0. The voltage across the junction is $V = (\Phi_0/2\pi)\,\mathrm{d}\varphi/\mathrm{d}t = (\Phi_0/2\pi)\,\mathrm{d}\varphi_1/\mathrm{d}t$, where $\mathrm{d}\varphi_1/\mathrm{d}t = (\mathrm{d}I/\mathrm{d}t)\,(\mathrm{d}I/\mathrm{d}\varphi_1)^{-1}$. Substituting this expression into the expression for V, we obtain

$$V = \frac{\Phi_0}{I_\mathrm{c}\cos\varphi_0}\nu I_1 \sin(2\pi\nu t + \pi/2)$$

With the parameters given in the problem, the amplitude of the ac voltage will be 0.58 nV

.

Note. It follows from the above solution that there is a positive phase angle of $\pi/2$ between the voltage V and the current through the junction. This implies that the junction behaves as

an inductance $L = \Phi_0/(2\pi I_c \cos\varphi_0)$.
4.5. $H_{c1} = 0.290\text{Oe}; H(0) = 0.455\text{Oe}$.
4.6. The first maximum will appear at $H_1 = 1.85$ Oe and the second at $H_2 = 3.18$ Oe.
4.7. The dependence of Φ on Φ_e will not show hysteresis if the critical current of the junction is less than $\Phi_0/(2\pi L) = 0.165 \times 10^{-6}$ A.
4.8. The current in the ring is determined by the phase difference φ across the junction: $\varphi = 2\pi L I_R/\Phi_0$. The current through the junction is $I_J = I_c \sin\varphi$. The total current is $I = 1.34 \times 10^{-6}$ A.
4.9. $\varphi_{AB} = 1.60$ rad, see Fig.S.2.

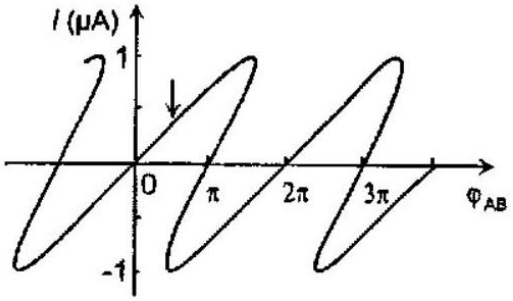

Fig. S.2. Answer to Problem 4.9. Current as a function of the phase difference between points A and B. The arrow marks the phase difference sought, $\varphi_{AB} = 1.60$rad

Chapter 5

5.1. The magnetic field generated by one of the vortices at a distance $r \ll \lambda$ from its center is, according to (5.6) and (5.7),

$$H = \frac{\Phi_0}{2\pi\lambda^2} \ln\frac{\lambda}{r}$$

The density of the current generated by the vortex at the same point is

$$j = \frac{c}{4\pi}\frac{\Phi_0}{2\pi\lambda^2 r}.$$

Finally, using (5.23), we find that the vortex will experience a repulsive force

$$f = \frac{\Phi_0^2}{4\pi^2\lambda^2}\frac{x}{x^2 + (d/2)^2}$$

directed away from the line ab, along the dashed line in Fig. 5.22.
5.2. $\lambda = \frac{1}{H_{cm}}\sqrt{\frac{\Phi_0 H_{c2}}{4\pi}} = 1.48 \times 10^{-5}$ cm.
5.3. $H_{c1} = 244\text{Oe}$.
5.4. Taking into account that $\xi \ll \lambda$ and using (5.6) and (3.38), we find that the field at a distance $r \sim \xi$ is

$$H(r) = \frac{\sqrt{2}H_{cm}}{\kappa} K_0\left(\frac{r}{\lambda}\right)$$

The current density will then be $j = (c/4\pi)\mathrm{d}H/\mathrm{d}r$. This gives

$$|j| = \frac{\sqrt{2}}{4\pi}\frac{cH_{cm}}{\lambda}$$

Note. It follows from the above that, by the order of magnitude, the current density at a distance ξ from the center of the vortex is equal to the pair-breaking current (compare with (3.67)).

5.5. Knowing H_{c2}, we find $\xi = 4.69 \times 10^{-7}$ cm and knowing κ, we find $\lambda = 4.50 \times 10^{-5}$ cm. Further, using (5.12), we find $\varepsilon = 6.12 \times 10^{-7}\text{ergcm}^{-1}$. The vortex core is normal, which implies that its energy density exceeds that of the surrounding medium by $H_{\text{cm}}^2/8\pi$. Therefore, the energy of the core equals $H_{\text{cm}}^2\xi^2/8$, if its radius is assumed equal to ξ. With the parameter values of our problem, the energy is $3.33 \times 10^{-8}\text{ergcm}^{-1}$, that is, many times less than the electromagnetic energy of the vortex, ε.
5.6. $M = -0.445\text{G}$.
5.7. It is evident from Fig. 5.23 that H_{c1} is given by the solution of the following equation: $H_{\text{c1}} = k\,(H_{c2} - H_{\text{c1}})$, where $k^{-1} = 1.16\,(2\kappa^2 - 1)$. Then $H_{\text{cl}} = 193\text{Oe}$. Further, an evaluation of H_{cm} can be obtained from the area enclosed by the magnetization curve, as follows from (5.35). This gives $H_{\text{cm}} = [k/(1+k)]^{1/2} H_{c2} = 879$ Oe. The exact value of H_{cm} can be found using (5.25): $H_{\text{cm}} = 942$ Oe.
5.8. $H_{\text{c3}} = 51900\text{Oe}$.
5.9. $H_{\text{c3}} = 68700\text{Oe}$.
5.10. $f = \frac{(\Phi_0/4\pi\lambda)^2}{l} = 6.03 \times 10^{-2}\text{dyncm}^{-2}$.
5.11. $f_x = -0.208\text{dyncm}^{-1}$; $f_y = -6.20 \times 10^{-2}\text{dyncm}^{-1}$.
5.12. $f = \frac{\Phi_0 H_0}{4\pi\lambda}\text{e}^{-l/\lambda} = 5.52 \times 10^{-2}\text{dyncm}^{-1}$.
5.13. $H_p = \frac{\Phi_0\kappa}{2\sqrt{2}\pi\lambda^2} = 1.40 \times 10^3\text{Oe}$.
5.14. Using (5.17) and (5.26), we find $\kappa = 31$. From (5.17) we find $\lambda = 2.1 \times 10^{-5}$ cm. Finally, approximating the magnetization curve $|M|$ by two triangles (see Fig. 5.23) and using (5.57), we have

$$I_c = \frac{2c\sqrt{\Phi_0}l}{\lambda\sqrt{B}}\frac{H_{c1}}{4\pi}\frac{H_{c2} - B}{H_{c2} - H_{c1}} \approx 13 \text{ A}$$

5.15. It follows from (5.67) and (5.68) that $\rho_{\text{f}} = \rho_{\text{u}} B/H_{\text{c2}}(0)$. Taking approximately $H_{\text{c2}}(T) = H_{\text{c2}}(0)\,(1 - T^2/{T_{\text{c}}}^2)$ and $B = H_0$, we find $\rho_{\text{f}} = 3 \times 10^{-6}\Omega$ cm.
5.16. $v_{\text{L}} = \frac{U}{iB} = 3.75 \times 10^{-5}$ m s^{-1}.

Chapter 6

6.1. $\rho/N(0) = 7.12; 1.34; 1.15$.
6.2. Using (6.37), we obtain $g = 0.245$.
6.3. The critical temperature will decrease by 0.01 K .
6.4. $T_{\text{c}} = \frac{2\Delta_0}{3.52k_{\text{B}}} = 3.49$ K.
6.5. $K_{\text{c}} = \frac{2\Delta_0}{\hbar v_{\text{F}}} = 2.61 \times 10^4$ cm^{-1}, $k_{\text{F}} = \frac{mv_{\text{F}}}{\hbar} = 5.6 \times 10^7$ cm^{-1}.

Chapter 7

7.1. Using the expression for the gap (at $T \approx T_{\text{c}}$): $\Delta(T) = 1.74\Delta(0)\,(1 - T/T_{\text{c}})^{1/2}$, we obtain for Sn : $\tau_Q \approx 2.4 \times 10^{-9}$ s.
7.2. Let us show that the volume charge density ρ, which will indeed appear in the transitional region of width $\sim \lambda_Q$ at the interface, will be many orders of magnitude less than the volume charge density of the quasiparticles, eQ. Poisson's equation can be written approximately as $E/\lambda_Q \sim 4\pi\rho$, or $\rho \sim E/4\pi\lambda_Q$. On the other hand, we have from (7.12):

$$Q \sim \frac{j_{\text{n}}T_Q}{e\lambda_Q} = \frac{\sigma\tau_Q E}{e\lambda_Q}$$

which leads to

$$\frac{\rho}{\varepsilon\bar{Q}} \sim \frac{1}{4\pi\tau_Q\sigma} = \left(\frac{8\pi\tau_Q e^2 N(0) l_{v_F}}{3}\right)^{-1}$$

With the values $\tau_Q \approx 10^{-10}$ s, $N(0) \approx 10^{33}\text{erg}^{-1}$ cm^{-1}, $l \approx 10^{-8}$ cm, and $v_\text{F} \approx 10^8$ cm s^{-1}; we obtain $\rho/eQ \sim 10^{-5}$.

24 BCS-BEC Crossover: From High Temperature Superconductors to Ultracold Superfluids by Chen, Stajic, Tan, Levin

Abstract

We review the BCS to Bose Einstein condensation (BEC) crossover scenario which is based on the well known crossover generalization of the BCS ground state wavefunction Ψ_0. While this ground state has been summarized extensively in the literature, this Review is devoted to less widely discussed issues: understanding the effects of finite temperature, primarily below T_c, in a manner consistent with Ψ_0. Our emphasis is on the intersection of two important problems: high T_c superconductivity and superfluidity in ultracold fermionic atomic gases. We address the "pseudogap state" in the copper oxide superconductors from the vantage point of a BCS-BEC crossover scenario, although there is no consensus on the applicability of this scheme to high T_c. We argue that it also provides a useful basis for studying atomic gases near the unitary scattering regime; they are most likely in the counterpart pseudogap phase. That is, superconductivity takes place out of a non-Fermi liquid state where preformed, metastable fermion pairs are present at the onset of their Bose condensation. As a microscopic basis for this work, we summarize a variety of T-matrix approaches, and assess their theoretical consistency. A close connection with conventional superconducting fluctuation theories is emphasized and exploited.

24.1 Conclusions

In this Review we have summarized a large body of work on the subject of the BCS-BEC crossover scenario. In this context, we have explored the intersection of two very different fields: high T_c superconductivity and cold atom superfluidity. Theories of cuprate superconductivity can be crudely classified as focusing on "Mott physics" which reflects the anomalously small zero temperature superfluid density and "crossover physics", which reflects the anomalously short coherence length. Both schools are currently very interested in explaining the origin of the mysterious pseudogap phase. In this Review we have presented a case for its origin in crossover physics. The pseudogap in the normal state can be associated with meta-stable pairs of fermions; a (pseudogap) energy must be supplied to break these pairs apart into their separate components. The pseudogap also persists below T_c in the sense that there are non

condensed fermion pair excitations of the condensate. These concepts have a natural analogue in self consistent theories of superconducting fluctuations, but for the crossover problem the width of the "critical region" is extremely large. This reflects the much stronger-than-BCS attractive interaction.

It was not our intent to shortchange the role of Mott physics which will obviously be of importance in our ultimate understanding of the superconducting cuprates. There is, however, much in this regard which is still uncertain associated with establishing the simultaneous relevance and existence of spin-charge separation [3], stripes [91], and hidden order parameters [25]. What we do have in hand, though, is a very clear experimental picture of an extremely unusual superconductor in which superconductivity seems to evolve gradually from above T_c to below. We have in this Review tried to emphasize the common ground between high T_c superconductors and ultracold superfluids. These Mott issues may nevertheless, set the agenda for future cold atom studies of fermions in optical lattices [70].

The recent discovery of superfluidity in cold fermion gases opens the door to a new set of fascinating problems in condensed matter physics. Unlike the bosonic system, there is no ready-made counterpart of Gross-Pitaevskii theory. A new mean field theory which goes beyond BCS and encompasses BEC in some form or another will have to be developed in concert with experiment. *As of this writing, there are four experiments where the simple mean field theory discussed in this review is in reasonable agreement with the data.* These are the collective mode studies over the entire range of accessible magnetic fields [74, 66]. In addition in the unitary regime, RF spectroscopy-based pairing gap studies [89], as well as density profile [160] and thermodynamic studies [88] all appear to be compatible with this theory.

The material in this Review is viewed as the first of many steps in a long process. It was felt, however, that some continuity should be provided from another community which has addressed and helped to develop the BCS-BEC crossover, since the early 1990's when the early signs of the cuprate pseudogap were beginning to appear. As of this writing, it appears likely that the latest experiments on cold atoms probe a counterpart to this pseudogap regime. That is, on both sides, but near the resonance, fermions form in long lived metastable pair states at higher temperatures than those at which they Bose condense.

24.2 Introduction to Qualitative Crossover Picture

This review addresses an extended form of the BCS theory of superfluidity (or superconductivity) known as "BCS-Bose Einstein condensation (BEC) crossover theory". Here we contemplate a generalization of the standard mean field description of superfluids now modified so that one allows attractive interactions of arbitrary strength. In this way one describes how the system smoothly goes from being a superfluid system of the BCS type (where the attraction is arbitrarily weak) to a Bose Einstein condensate of diatomic molecules (where the attraction is arbitrarily strong). One, thereby, sees that BCS theory is intimately connected to BEC. Attractive interactions between fermions are needed to form "bosonic-like" molecules (called Cooper pairs) which then are driven statistically to Bose condense. BCS theory is a special case in which the condensation and pair formation temperatures coincide.

The importance of obtaining a generalization of BCS theory which addresses the crossover from BCS to BEC at general temperatures $T \leq T_c$ cannot be overestimated. BCS theory as originally postulated can be viewed as a paradigm among theories of condensed matter systems; it is complete, in many ways generic and model independent, and well verified experimentally. The observation that a BCS-like approach goes beyond strict BCS theory, suggests that there is a larger mean field theory to be addressed. Equally exciting is the possibility that this mean field theory can be discovered and simultaneously tested in a very controlled fashion using ultracold fermionic atoms. We presume here that it may also have applicability to other short

coherence length materials, such as the high temperature superconductors.

This Review is written in order to convey important new developments from one subfield of physics to another. Here it is hoped that we will communicate the recent excitement felt by the cold atom community to condensed matter physicists. Conversely we wish to communicate a comparable excitement in studies of high temperature superconductivity to atomic physicists. There has been a revolution in our understanding of ultracold fermions in traps in the last few years. The milestones in this research were the creation of a degenerate Fermi gas (1999), the formation of dimers of fermions (2003), Bose-Einstein condensation (BEC) of these dimers (late 2003) and finally superfluidity of fermionic pairs (2004).

In high temperature superconductors the BCS-BEC crossover picture has been investigated for many years now. It leads to a particular interpretation of a fascinating, but not well understood phase, known as the "pseudogap state". In the cold atom system, this crossover description is not just a scenario, but has been realized in the laboratory. This is because one has the ability (via Feshbach resonances) to apply magnetic fields in a controlled way to tune the strength of the attraction. We note, finally, that research in this field has not been limited exclusively to the two communities. One has seen the application of these crossover ideas to studies of excitons in solids [101], to nuclear physics [9, 65] and to particle physics [94, 92, 76] as well. There are not many problems in physics which have as great an overlap with different subfield communities as this "BCS-BEC crossover problem".

In this Review, we begin with an introduction to the qualitative picture of the BCS-BEC crossover scenario which is represented schematically in Fig. 24.1. We discuss this picture in the context of both high T_c superconductivity and ultracold atomic superfluidity, summarizing experiments in both. In Section II, we present a more quantitative study of this crossover primarily at and below the superfluid transition temperature T_c. Section III contains a detailed discussion of the superfluid density and gauge invariance issues, in large part to emphasize self consistency checks for different theoretical approaches to crossover. These alternative theories are summarized and compared in Section IV. Sections V and VI, respectively, present the physical implications of crossover physics, in one particular rendition, in the context of ultracold fermionic superfluids and high temperature superconductors. Our conclusions are presented in Section VII and a number of Appendices are included for clarity. A reader interested in only the broad overview may choose to omit Sections II-IV.

The convention and notation as well as a list of abbreviations used in this Review are listed in Appendix 24.11 at the end.

24.2.1 Fermionic Pseudogaps and Meta-stable Pairs: Two Sides of the Same Coin

A number of years ago Eagles [49] and Leggett [187] independently noted[30] that the BCS ground state wavefunction

$$\Psi_0 = \Pi_{\mathbf{k}}(u_{\mathbf{k}} + v_{\mathbf{k}} c^\dagger_{k,\uparrow} c^\dagger_{-k,\downarrow})|0\rangle \tag{24.1}$$

had a greater applicability than had been appreciated at the time of its original proposal by Bardeen, Cooper and Schrieffer (BCS). As the strength of the attractive pairing interaction U (< 0) between fermions is increased, this wavefunction is also capable of describing a continuous evolution from BCS like behavior to a form of Bose Einstein condensation. What is essential is that the chemical potential μ of the fermions be self consistently computed as U varies.

The variational parameters $v_{\mathbf{k}}$ and $u_{\mathbf{k}}$ which appear in Eq. 24.1 are usually represented by the two more directly accessible parameters $\Delta_{sc}(0)$ and μ, which characterize the fermionic system. Here $\Delta_{sc}(0)$ is the zero temperature superconducting order parameter. These fermionic

[30] Through private correspondence it appears that F. Dyson may have made similar observations even earlier.

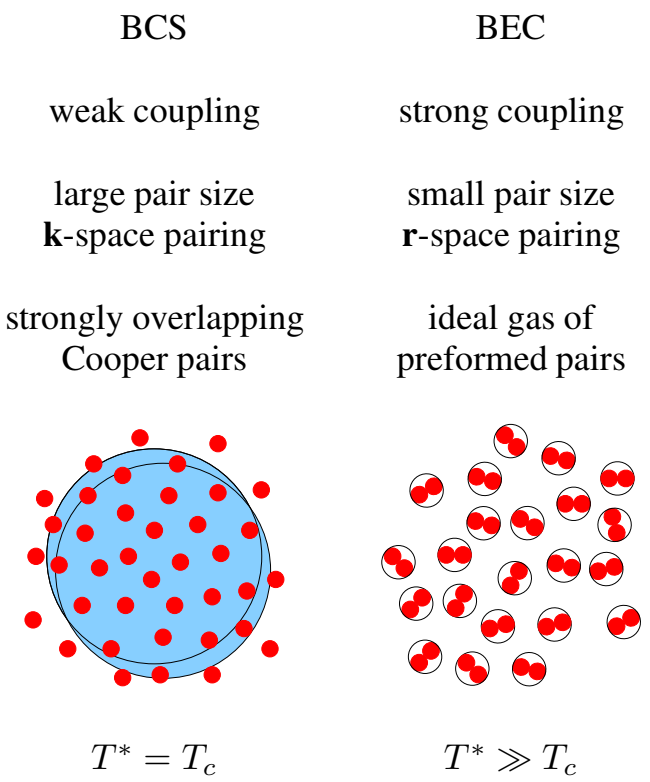

Figure 24.1: Contrast between BCS- and BEC-based superfluids. Here T^* represents the temperature at which pairs form, while T_c is that at which they condense.

parameters are uniquely determined in terms of U and the fermionic density n. The variationally determined self consistency conditions are given by two BCS-like equations which we refer to as the "gap" and "number" equations respectively.

$$\Delta_{sc}(0) = -U \sum_{\mathbf{k}} \Delta_{sc}(0) \frac{1}{2E_{\mathbf{k}}} \tag{24.2}$$

$$n = \sum_{\mathbf{k}} \left[1 - \frac{\epsilon_{\mathbf{k}} - \mu}{E_{\mathbf{k}}} \right] \tag{24.3}$$

where [31]

$$E_{\mathbf{k}} \equiv \sqrt{(\epsilon_{\mathbf{k}} - \mu)^2 + \Delta_{sc}^2(0)} \tag{24.4}$$

and $\epsilon_{\mathbf{k}} = k^2/2m$ is the fermion energy dispersion.[32] Within this ground state there have been extensive studies of collective modes [120, 144, 39], effects of two dimensionality [144], and, more recently, extensions to atomic gases [182, 136]. Noziéres and Schmitt-Rink were the first [128] to address nonzero T. We will outline some of their conclusions later in this Review. Randeria and co-workers reformulated the approach of Noziéres and Schmitt-Rink (NSR) and moreover, raised the interesting possibility that crossover physics might be relevant to high temperature superconductors [144]. Subsequently other workers have applied this picture to the high T_c cuprates [28, 121, 146] and ultracold fermions [123, 131] as well as formulated alternative schemes [61, 139] for addressing $T \neq 0$. Importantly, a number of experimentalists, most notably Uemura [178], have claimed evidence in support [149, 46, 81] of the BCS-BEC crossover picture for high T_c materials.

[31] In general, the order parameter Δ_{sc} and the excitation gap may have a $\mathbf{k}$-dependence, $\Delta_k = \Delta\varphi_{\mathbf{k}}$, except for a contact potential. To keep the mathematical expressions simpler, however, we neglect $\varphi_{\mathbf{k}}$ for the s-wave pairing under investigation of this Review. It can be easily reinserted back when needed in actual calculations. In particular, we use $\varphi_{\mathbf{k}} = \exp(-k^2/2k_c^2)$ with a large cutoff k_c in most of our numerical calculations.

[32] Throughout this Review, we set $\hbar = 1$ and $k_B = 1$.

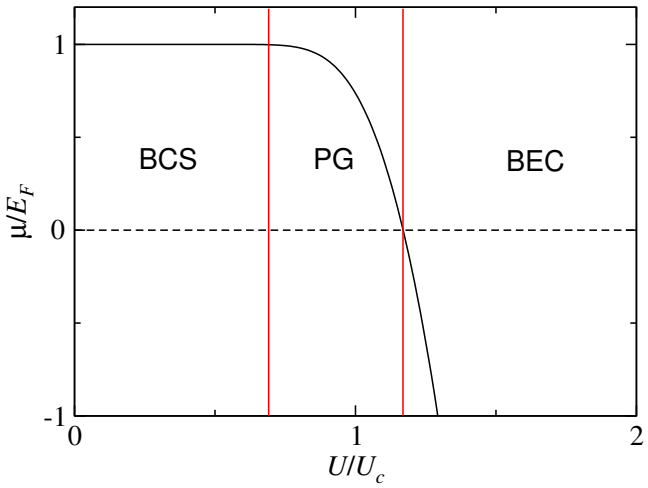

Figure 24.2: Typical behavior of the $T = 0$ chemical potential in the three regimes. As the pairing strength increases from 0, the chemical potential μ starts to decrease and then becomes negative. The character of the system changes from fermionic ($\mu > 0$) to bosonic ($\mu < 0$). The PG (pseudogap) case corresponds to non-Fermi liquid based superconductivity, and U_c corresponds to critical coupling for forming a two fermion bound state in vacuum, as in Eq. (24.17) below.

Compared to work on the ground state, considerably less has been written on crossover effects at nonzero temperature based on Eq. (24.1). Because our understanding has increased substantially since the pioneering work of NSR, and because they are the most interesting, this review is focussed on these finite T effects, at the level of a simple mean field theory. Mean field approaches are always approximate. We can ascribe the simplicity and precision of BCS theory to the fact that in conventional superconductors the coherence length ξ is extremely long. As a result, the kind of averaging procedure implicit in mean field theory becomes nearly exact. Once ξ becomes small, BCS is not expected to work at the same level of precision. Nevertheless even when they are not exact, mean field approaches are excellent ways of building up intuition. And further progress is not likely to be made without investigating first the simplest of mean field approaches, associated with Eq. (24.1).

The effects of BEC-BCS crossover are most directly reflected in the behavior of the fermionic chemical potential μ. We plot the behavior of μ in Fig. 24.2, which indicates the BCS and BEC regimes. In the weak coupling regime $\mu = E_F$ and ordinary BCS theory results. However at sufficiently strong coupling, μ begins to decrease, eventually crossing zero and then ultimately becoming negative in the BEC regime, with increasing $|U|$. We generally view $\mu = 0$ as a crossing point. For positive μ the system has a remnant Fermi surface, and we say that it is "fermionic". For negative μ, the Fermi surface is gone and the material is "bosonic".

The new and largely unexplored physics of this problem lies in the fact that once outside the BCS regime, but before BEC, superconductivity or superfluidity emerge out of a very exotic, non-Fermi liquid normal state. Indeed, it should be clear that Fermi liquid theory must break down somewhere in the intermediate regime, as one goes continuously from fermionic to bosonic statistics. This intermediate case has many names: "resonant superfluidity", the "unitary regime" or, as we prefer (because it is more descriptive of the many body physics) the "pseudogap (PG) regime". The PG regime plotted in Fig. 24.2 is drawn so that its boundary on the left coincides with the onset of an appreciable excitation gap at T_c, called $\Delta(T_c)$; its boundary on the right coincides with where $\mu = 0$. This non-Fermi liquid based superconductivity has been extensively studied[28, 30, 78, 114].

Fermi liquid theory is inappropriate here principally because there is a gap for creating fermionic excitations. The non-Fermi liquid like behavior is reflected in that of the fermionic

spectral function [114] which has a two-peak structure in the normal state, broadened somewhat, but rather similar to its counterpart in BCS theory. Importantly, the onset of superconductivity occurs in the presence of fermion pairs, which reflect this excitation gap. Unlike their counterparts in the BEC limit, these pairs are not infinitely long lived. Their presence is apparent even in the normal state where an energy must be applied to create fermionic excitations. This energy cost derives from the breaking of the metastable pairs. Thus we say that there is a "pseudogap" at and above T_c. But pseudogap effects are not restricted to this normal state. Pre-formed pairs have a natural counterpart in the superfluid phase, as noncondensed pairs.

It will be stressed throughout this Review that gaps in the fermionic spectrum and bosonic degrees of freedom are two sides of the same coin. A particularly important observation to make is that the starting point for crossover physics is based on the fermionic degrees of freedom. Bosonic degrees of freedom are deduced from these; they are not primary. A nonzero value of the excitation gap Δ is equivalent to the presence of metastable or stable fermion pairs. And it is only in this indirect fashion that we can probe the presence of these "bosons", within the framework of Eq. (24.1).

In many ways this crossover theory appears to represent a more generic form of superfluidity. Without doing any calculations we can anticipate some of the effects of finite temperature. Except for very weak coupling, *pairs form and condense at different temperatures*. The BCS limit might be viewed as the anomaly. Because the attractive interaction is presumed to be arbitrarily weak, in BCS the normal state is unaffected by U and superfluidity appears precipitously, that is without warning at T_c. More generally, in the presence of a moderately strong attractive interaction it pays energetically to take some advantage and to form pairs (say roughly at temperature T^*) within the normal state. Then, for statistical reasons these bosonic degrees of freedom ultimately are driven to condense at $T_c < T^*$, just as in BEC.

Just as there is a distinction between T_c and T^*, *there must be a distinction between the superconducting order parameter Δ_{sc} and the excitation gap Δ*. The presence of a normal state excitation gap or pseudogap for fermions is inextricably connected to this generalized BCS wavefunction. In Figure 24.3 we present a schematic plot of these two energy parameters. It may be seen that the order parameter vanishes at T_c, as in a second order phase transition, while the excitation gap turns on smoothly below T^*. It should also be stressed that there is only one gap energy scale in the ground state [187] of Eq. (24.1). Thus at zero temperature

$$\Delta_{sc}(0) = \Delta(0) \; . \tag{24.5}$$

In addition to the distinction between Δ and Δ_{sc}, another important way in which *bosonic degrees of freedom are revealed is indirectly through the temperature dependence of Δ. In the BEC regime where fermion pairs are pre-formed, Δ is essentially constant for all $T \leq T_c$ (as is μ)*. By contrast in the BCS regime it exhibits the well known temperature dependence of the superconducting order parameter. This is equivalent to the statement that bosonic degrees of freedom are only present in the condensate for this latter case. This behavior is illustrated in Fig. 24.4.

Again, without doing any calculations we can make one more inference about the nature of crossover physics at finite T. *The excitations of the system must smoothly evolve from fermionic in the BCS regime to bosonic in the BEC regime*. In the intermediate case, the excitations are a mix of fermions and meta-stable pairs. Figure 24.5 characterizes the excitations out of the condensate as well as in the normal phase. This schematic figure will play an important role in our thinking throughout this review. In the BCS and BEC regimes one is led to an excitation spectrum with a single component. For the PG case it is clear that the excitations now have two distinct (albeit, strongly interacting) components.

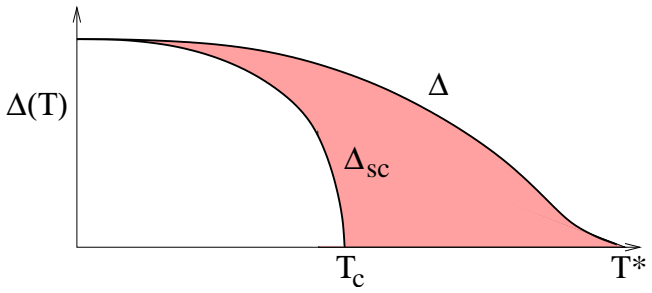

Figure 24.3: Contrasting behavior of the excitation gap $\Delta(T)$ and superfluid order parameter $\Delta_{sc}(T)$ versus temperature. The height of the shaded region roughly reflects the density of noncondensed pairs at each temperature.

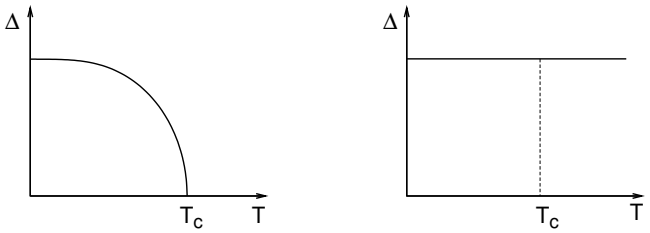

Figure 24.4: Comparison of typical temperature dependences of the excitation gaps in the BCS (left) and BEC (right) limits. For the former, the gap is small and vanishes at T_c; whereas for the latter, the gap is very large and essentially temperature independent.

24.2.2 Introduction to high T_c Superconductivity: Pseudogap Effects

This Review deals with the intersection of two fields and two important problems: high temperature superconductors and ultracold fermionic atoms in which, through Feshbach resonance effects, the attractive interaction may be arbitrarily tuned by a magnetic field. Our focus is on the broken symmetry phase and how it evolves from the well known ground state at $T = 0$ to $T = T_c$. We begin with a brief overview [174, 169] of pseudogap effects in the hole doped high temperature superconductors. A study of concrete data in these systems provides a rather natural way of building intuition about non-Fermi liquid based superfluidity, and this should, in turn, be useful for the cold atom community.

It has been argued by some [29, 121, 146, 140, 189] that a BCS-BEC crossover-induced pseudogap is the origin of the mysterious normal state gap observed in high temperature superconductors. Although, this is a highly contentious subject, a principal supporting rationale is that this above-T_c excitation gap seems to evolve smoothly into the fermionic gap within the

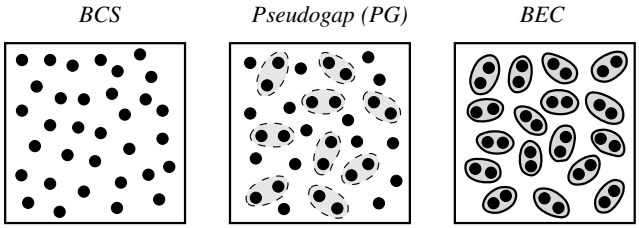

Figure 24.5: The character of the excitations in the BCS-BEC crossover both above and below T_c. The excitations are primarily fermionic Bogoliubov quasiparticles in the BCS limit and bosonic pairs (or "Feshbach bosons") in the BEC limit. In the PG case the "virtual molecules" consist primarily of "Cooper" pairs of fermionic atoms.

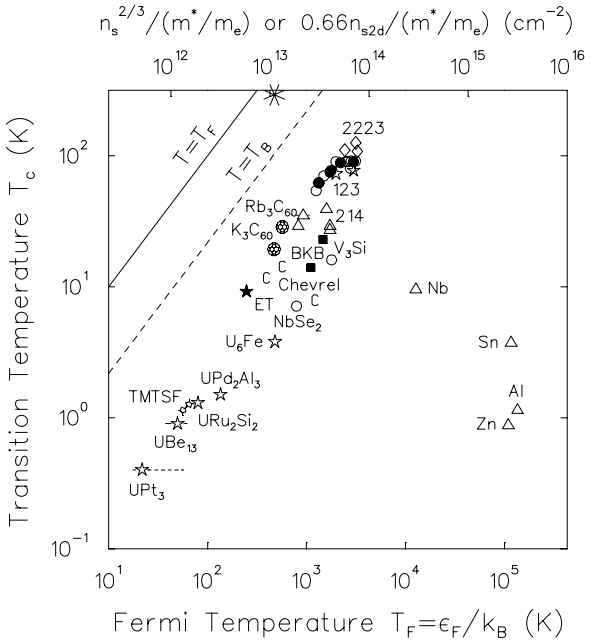

Figure 24.6: Uemura plot [178] of the superconducting transition temperature as a function of Fermi temperature (lower axis) and of the low T superfluid density (upper axis) for various superconductors. The plot indicates how "exotic" superconductors appear to be in a distinct category as compared with more conventional metal superconductors such as Nb, Sn, Al and Zn. Note the logarithmic scales.

superconducting state. This, in conjunction with a panoply of normal state anomalies which appear to represent precursor superconductivity effects, suggests that the pseudogap has more in common with the superconducting phase than with the insulating magnetic phase associated with the parent compound.

The arguments in favor of this (albeit, controversial) crossover viewpoint rest on the following observations: (i) the transition temperature is anomalously high and the coherence length ξ for superconductivity anomalously short, around 10Å as compared more typically with 1000Å. (ii) These systems are quasi-two dimensional so that one might expect pre-formed pairs or precursor superconductivity effects to be enhanced. (iii) The normal state gap has the same d-wave symmetry as the superconducting order parameter [42, 20], and (iv) to a good approximation its onset temperature, called T^*, satisfies [98, 129] $T^* \approx 2\Delta(0)/4.3$ which satisfies the BCS scaling relation. (v) There is widespread evidence for pseudogap effects both above [174, 169] and below [113, 163] T_c. Finally, it has also been argued that short coherence length superconductors may quite generally exhibit a distinctive form of superconductivity [178]. Figure 24.6 shows a plot of data collected by Uemura which seems to suggest that the traditional BCS superconductors stand apart from other more exotic (and frequently short ξ) forms of superconductivity. From this plot one can infer, that, except for high T_c, there is nothing special about the high T_c superconductors; they are not alone in this distinctive class which includes the organics and heavy fermion superconductors as well. Thus, to understand them, one might want to focus on this simplest aspect (short ξ) of high T_c superconductors, rather than invoke more exotic and less generic features.

In Fig. 24.7 we show a sketch of the phase diagram for the copper oxide superconductors. Here x represents the concentration of holes which can be controlled by adding Sr substitutionally, say, to $La_{1-x}Sr_xCuO_4$. At zero and small x the system is an antiferromagnetic (AFM) insulator. Precisely at half filling ($x = 0$) we understand this insulator to derive from Mott effects. These Mott effects may or may not be the source of the other exotic phases indicated

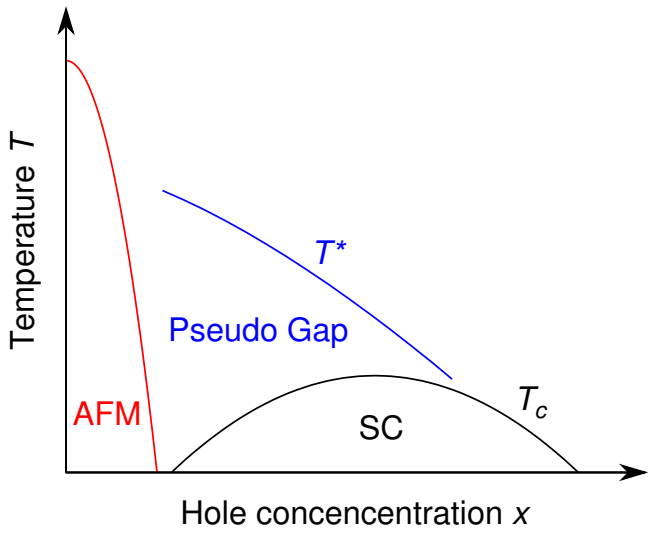

Figure 24.7: Typical phase diagram of hole-doped high T_c superconductors. There exists a pseudogap phase above T_c in the underdoped regime. Here SC denotes superconductor, and T^* is the temperature at which the pseudogap smoothly turns on.

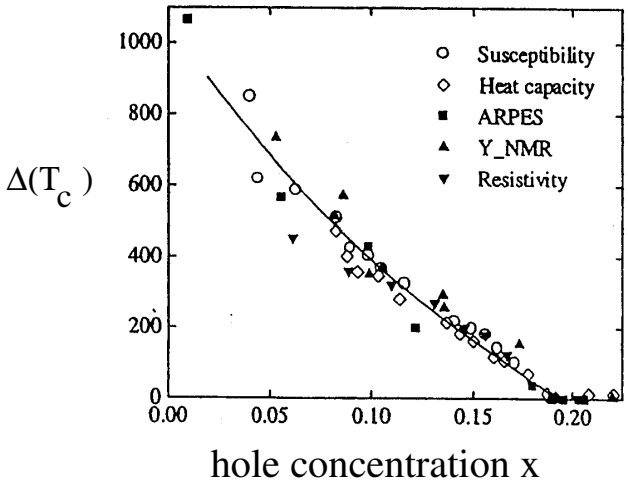

Figure 24.8: Pseudogap magnitude at T_c versus doping concentration in hole doped high T_c superconductors measured with different experimental techniques (from [169]). Units on vertical axis are temperature in degrees K.

in the diagram, as "SC" for superconductivity and the pseudogap phase. Once AFM order disappears the system remains insulating until a critical concentration (typically around a few percent Sr) when an insulator-superconductor transition is encountered. Here photoemission studies [42, 20] suggest that once this line is crossed, μ appears to be positive. For $x \leq 0.2$, the superconducting phase has a non-Fermi liquid (or pseudogapped) normal state [169]. We note an important aspect of this phase diagram at low x. As the pseudogap becomes stronger (T^* increases), superconductivity as reflected in the magnitude of T_c becomes weaker. One way to think about this competition is through the effects of the pseudogap on T_c. As this gap increases, the density of fermionic states at E_F decreases, so that there are fewer fermions around to participate in the superconductivity.

Importantly, there is a clear excitation gap present at the onset of superconductivity which is called $\Delta(T_c)$ and which vanishes at $x \approx 0.2$. The magnitude of the pseudogap at T_c is shown in Fig. 24.8, from [169]. Quite remarkably, as indicated in the figure, a host of different probes seem to converge on the size of this gap.

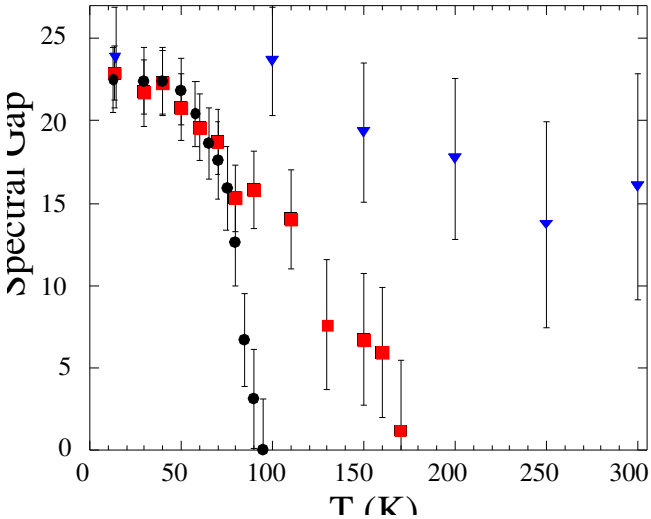

Figure 24.9: (Color) Temperature dependence of the excitation gap from ARPES measurements for optimally doped (filled black circles), underdoped (red squares) and highly underdoped (blue inverted triangles) single-crystal BSCCO samples (taken from [47]). There exists a pseudogap phase above T_c in the underdoped regime.

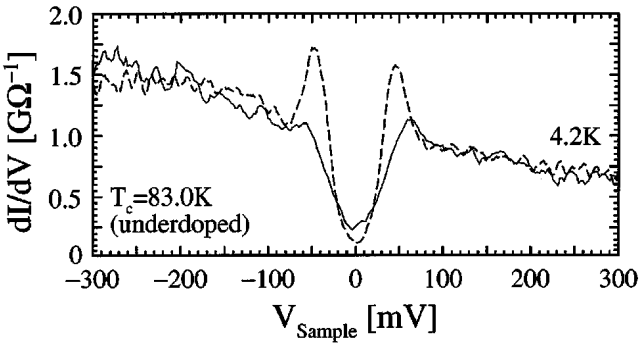

Figure 24.10: STM measurements of the dI/dV characteristics of an underdoped BSCCO sample inside (solid) and outside (dashed) a vortex core at low T from [149]. dI/dV is proportional to the density of states.

Figure 24.9 indicates the temperature dependence of the excitation gap for three different hole stoichiometries. These data were taken [47] from angle resolved photoemission spectroscopy (ARPES) measurement on single-crystal $Bi_2Sr_2CaCu_2O_{8+\delta}$ (BSCCO) samples. For one sample shown as circles, (corresponding roughly to "optimal" doping) the gap vanishes roughly at T_c as might be expected for a BCS superconductor. At the other extreme are the data indicated by inverted triangles in which an excitation gap appears to be present up to room temperature, with very little temperature dependence. This is what is referred to as a highly underdoped sample (small x), which from the phase diagram can be seen to have a rather low T_c. Moreover, T_c is not evident in these data on underdoped samples. This is a very remarkable feature which indicates that from the fermionic perspective there appears to be no profound sensitivity to the onset of superconductivity.

While the high T_c community has focussed on pseudogap effects above T_c, there is a good case to be made that these effects also persist below. Shown in Fig. 24.10 are STM data [149] taken below T_c within a vortex core (solid lines) and between vortices in the bulk (dashed lines). The quantity dI/dV may be viewed as a measure of the fermionic density of states at energy E given by the voltage V. This figure shows that there is a clear depletion of the density of states around the Fermi energy ($V = 0$) in the normal phase within the core. Indeed the size of

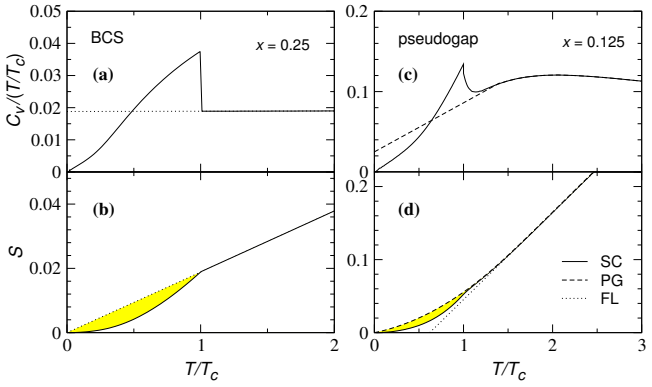

Figure 24.11: Behavior of entropy S and specific heat coefficient $\gamma \equiv C_v/T$ as a function of temperature for (a)-(b) BCS and (c)-(d) pseudogapped superconductors. Dotted and dashed lines are extrapolated normal states below T_c. The shaded areas were used to determine the condensation energy.

the inferred energy gap (or pseudogap) corresponds to the energy separation between the two maxima in dI/dV; this can be seen to be the same for both the normal and superconducting regions (solid and dashed curves). This figure emphasizes the fact that the existence of an energy gap has little or nothing to do with the existence of phase coherent superconductivity. It also suggests that pseudogap effects effectively persist below T_c; the normal phase underlying superconductivity for $T \leq T_c$ is not a Fermi liquid.

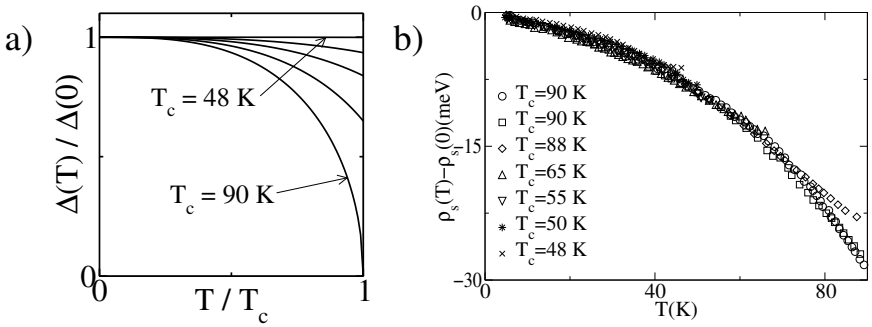

Figure 24.12: Temperature dependence of (a) the fermionic excitation gap Δ and (b) superfluid density ρ_s from experiment for various doping concentrations (from [163]). Figure (a) shows a schematic plot of Δ as seen in the ARPES and STM tunneling data. When $\Delta(T_c) \neq 0$, there is little correlation between $\Delta(T)$ and $\rho_s(T)$; this figure suggests that something other than fermionic quasiparticles (*e.g.*, bosonic excitations) may be responsible for the disappearance of superconductivity with increasing T. Figure (b) shows a quasi-universal behavior for the slope $d\rho_s/dT$ at different doping concentrations, despite the highly non-universal behavior for $\Delta(T)$.

Analysis of thermodynamical data [113, 169] has led to a similar inference. Figure 24.11 presents a schematic plot of the entropy S and specific heat for the case of a BCS superconductor, as contrasted with a pseudogapped superconductor. Actual data are presented in Fig. 24.38. Figure 24.11 makes it clear that in a BCS superconductor, the normal state which underlies the superconducting phase, *is* a Fermi liquid; the entropy at high temperatures extrapolates into a physically meaningful entropy below T_c. For the PG case, the Fermi liquid-extrapolated entropy becomes negative. In this way Loram and co-workers [113] deduced that the normal phase underlying the superconducting state is not a Fermi liquid. Rather, they claimed to obtain proper thermodynamics, it must be assumed that this state contains a persistent pseudogap. They argued for a distinction between the excitation gap Δ and the superconducting

order parameter, within the superconducting phase. To fit their data they presumed a modified fermionic dispersion

$$E_{\mathbf{k}} = \sqrt{(\epsilon_{\mathbf{k}} - \mu)^2 + \Delta^2(T)} \tag{24.6}$$

where

$$\Delta^2(T) = \Delta_{sc}^2(T) + \Delta_{pg}^2 \tag{24.7}$$

Here Δ_{pg} is taken on phenomenological grounds to be T-independent. The authors argue that the pseudogap contribution may arise from physics unrelated to the superconductivity. While others [25, 127] have similarly postulated that Δ_{pg} may in fact derive from another (hidden) order parameter or underlying band structure effect, in general the fermionic dispersion relation $E_{\mathbf{k}}$ will take on a different character from that assumed above, which is very specific to a superconducting origin for the pseudogap.

Finally, Fig. 24.12 makes the claim for a persistent pseudogap below T_c in an even more suggestive way. Figure 24.12(a) represents a schematic plot of excitation gap data such as are shown in Fig. 24.9. Here the focus is on temperatures below T_c. Most importantly, this figure indicates that the T dependence in Δ varies dramatically as the stoichiometry changes. Thus, in the extreme underdoped regime, where PG effects are most intense, there is very little T dependence in Δ below T_c. By contrast at high x, when PG effects are less important, the behavior of Δ follows that of BCS theory. What is most impressive however, is that these wide variations in $\Delta(T)$ are *not* reflected in the superfluid density $\rho_s(T)$, which is proportional to the inverse square of the London magnetic penetration depth and can be measured by, for example, muon spin relaxation (μSR) experiments. Necessarily, $\rho_s(T)$ vanishes at T_c. What is plotted [163] in Fig. 24.12(b) is $\rho_s(T) - \rho_s(0)$ versus T. That these data all seem to sit on a rather universal curve is a key point. The envelope curve in $\rho_s(T) - \rho_s(0)$ is associated with an "optimal" sample where $\Delta(T)$ essentially follows the BCS prediction. Figure 24.12 then indicates that, *despite the highly non-universal behavior for $\Delta(T)$, the superfluid density does not make large excursions from its BCS- predicted form.* This is difficult to understand if the fermionic degrees of freedom through $\Delta(T)$ are dominating at all x. Rather this figure suggests that something other than fermionic excitations is responsible for the disappearance of superconductivity, particularly in the regime where $\Delta(T)$ is relatively constant in T. At the very least pseudogap effects must persist below T_c.

Driving the superconductivity away is another important way to probe the pseudogap. This occurs naturally with temperatures in excess of T_c, but it also occurs when sufficient pair breaking is present through impurities [168, 192, 169] or applied magnetic fields [6]. An important effect of temperature needs to be stressed. With increasing $T > T_c$, the d-wave shape of the excitation gap is rapidly washed out [20, 42]; the nodes of the order parameter, in effect, begin to spread out, just above T_c. The inverse of this effect should also be emphasized: when approached from above, T_c *is marked by the abrupt onset of long lived quasiparticles.*

One frequently, and possibly universally, sees a superconductor-insulator (SI) transition when T_c is driven to zero in the presence of a pseudogap. This suggests a simple scenario: that *the pseudogap may survive when superconductivity is suppressed.* In this way the ground state is no longer a simple metal. This SI transition is seen upon Zn doping [168, 192, 169], as well as in the presence of applied magnetic fields [6]. Moreover, the intrinsic change in stoichiometry illustrated in the phase diagram of Fig. 24.7 also leads to an SI transition. One can thus deduce that the effects of pair-breaking on T_c and T^* are very different, with the former being far more sensitive than the latter.

It is clear that pseudogapped fermions are in evidence in a multiplicity of experiments. Are there indications of bosonic degrees of freedom in the normal state of high T_c superconductors? The answer is unequivocally yes: *meta-stable bosons are observable as superconducting fluctuations.* These bosons are intimately connected to the pseudogap; in effect they are the

other side of the same coin. These bosonic effects are enhanced in the presence of the quasi-two dimensional lattice structure of these materials. Very detailed analyses [103] of thermodynamic and transport properties of the highest T_c or "optimal" samples reveal clearly these pre-formed pairs. Moreover they are responsible [100] for divergences at T_c in the dc conductivity σ and in the transverse thermoelectric [179] response α_{xy}. These transport coefficients are defined more generally in terms of the electrical and heat currents by

$$\mathbf{J}^{\mathbf{elec}} = \sigma \mathbf{E} + \alpha(-\nabla T) \tag{24.8}$$

$$\mathbf{J}^{\mathbf{heat}} = \tilde{\alpha} \mathbf{E} + \kappa(-\nabla T) \tag{24.9}$$

Here σ is the conductivity tensor, κ the thermal conductivity tensor, and $\alpha, \tilde{\alpha}$ are thermoelectric tensors. Other coefficients, while not divergent, exhibit precursor effects, all of which are found to be in good agreement [103] with fluctuation theory. As pseudogap effects become more pronounced with underdoping much of the fluctuation behavior appears to set in at a higher temperature scale associated with T^*, but often some fraction thereof [188, 170].

Figures 24.13 and 24.14 make the important point that precursor effects in the transverse thermoelectric response (α_{xy}) and conductivity σ appear at higher temperatures ($\propto T^*$) as pseudogap effects become progressively more important; the dotted lines which have the strongest pseudogap continue to the highest temperatures on both Figures. Moreover, both transport coefficients evolve smoothly from a regime where they are presumed to be described by conventional fluctuations [103, 179] as shown by the solid lines in the figures into a regime where their behavior is associated with a pseudogap. A number of people have argued [188, 38] that normal state vortices are responsible for the so called anomalous transport behavior of the pseudogap regime. We will argue in this Review that these figures may alternatively be interpreted as suggesting that bosonic degrees of freedom, not vortices, are responsible for these anomalous transport effects.

24.2.3 Introduction to High T_c SC: Mott Physics and Possible Ordered States

Most workers in the field of high T_c superconductivity would agree that we have made enormous progress in characterizing these materials and in identifying key theoretical questions and constructs. Experimental progress, in large part, comes from transport studies [174, 169] in addition to three powerful spectroscopies: photoemission [20, 42], neutron [33, 53, 86, 1, 2, 125, 151, 175] and Josephson interferometry [187, 176, 116]. These data have provided us with important clues to address related theoretical challenges. Among the outstanding theoretical issues in the cuprates are (i) understanding the attractive "mechanism" that binds electrons into Cooper pairs, (ii) understanding the evolution of the normal phase from Fermi liquid (in the "overdoped" regime) to marginal Fermi liquid (at "optimal" doping) to the pseudogap state, which is presumed to occur as doping concentration x decreases, and (iii) understanding the nature of that superconducting phase which evolves from each of these three normal states.

The theoretical community has concentrated rather extensively on special regions and x-dependences in the phase diagram which are presumed to be controlled by "Mott physics". There are different viewpoints of precisely what constitutes Mott physics in the metallic phases, and, for example, whether or not this is necessarily associated with spin-charge separation. For the most part, one presumes here that the insulating phase of the parent compound introduces strong Coulomb correlations into the doped metallic states which may or may not also be associated with strong antiferromagnetic correlations. There is a recent, rather complete review [106] of Mott physics within the scenario of spin-charge separation, which clarifies the physics it entails.

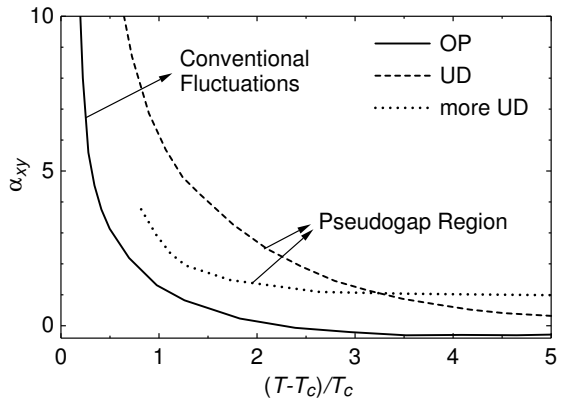

Figure 24.13: Transverse thermoelectric response (which relates to the Nernst coefficient) plotted here in fluctuation regime above T_c. Here OP and UD correspond to optimal and underdoping, respectively. Data were taken from [188].

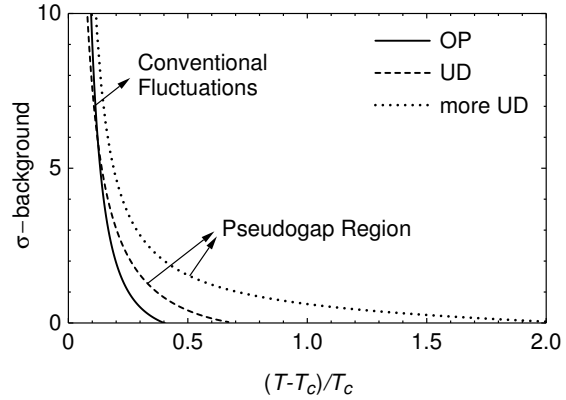

Figure 24.14: Conductivity in fluctuation regime for optimally (OP) and underdoped (UD) cuprate superconductors. Data from [186].

Concrete experimental signatures of Mott physics are the observations that the superfluid density $\rho_s(T = 0, x) \to 0$ as $x \to 0$, as if it were reflecting an order parameter for a metal insulator transition. More precisely it is deduced that $\rho_s(0, x) \propto x$, at low x. Unusual effects associated with this linear- in- x dependence also show up in other experiments, such as the weight of coherence features in photoemission data [20, 42], as well as in thermodynamical signatures [169].

While there is no single line of reasoning associated with these Mott constraints, the low value of the superfluid density has been argued [50] to be responsible for soft phase fluctuations of the order parameter, which may be an important contributor to the pseudogap. However, recent concerns about this "phase fluctuation scenario" for the origin of the pseudogap have been raised [105]. It is now presumed by a number of groups that phase fluctuations alone may not be adequate and an additional static or fluctuating order of one form or another needs to be incorporated. Related to a competing or co-existing order are conjectures [25] that the disappearance of pseudogap effects around $x \approx 0.2$ is an indication of a "quantum critical point" associated with a hidden order parameter which may be responsible for the pseudogap. Others have associated small [183] x or alternatively optimal [180] x with quantum critical points of a different origin. The nature of the other competing or fluctuating order has been conjectured to be RVB [5], "d-density wave" [25], stripes [24, 190] or possibly antiferromagnetic spin fluctuations [141, 36, 45]. The latter is another residue of the insulating phase.

What is known about the "pairing mechanism"? Some would argue that this is an ill-defined question, and that superconductivity has to be understood through condensation energy argu-

ments based for example on the data generated from the extrapolated normal state entropy [113, 169] discussed above in the context of Fig. 24.11. These condensation arguments are often built around the non-trivial assumption that there is a thermodynamically well behaved but meta-stable normal phase which coexists with the superconductivity. Others would argue that Coulomb effects are responsible for d-wave pairing, either directly [108, 111], or indirectly via magnetic fluctuations [153, 141]. Moreover, the extent to which the magnetism is presumed to persist into the metallic phase near optimal doping is controversial. Initially, NMR measurements were interpreted as suggesting [122] strong antiferromagnetic fluctuations, while neutron measurements, which are generally viewed as the more conclusive, do not provide compelling evidence [158] for their presence in the normal phase. Nevertheless, there are interesting neutron-measured magnetic signatures [191, 112, 85] below T_c associated with d-wave superconductivity. There are also analogous STM effects which are currently of interest [184].

24.2.4 Overview of the BCS-BEC Picture of High T_c SC in the Underdoped Regime

We summarize here the physical picture associated with the more controversial BCS-BEC crossover approach to high T_c superconductors, based on the standard ground state of Eq. (24.1). One presumes that the normal state (pseudo)gap arises from pre-formed pairs. This gap $\Delta(T)$ is thus present at the onset of superconductivity, and reflects the fact that Cooper pairs form before they Bose condense, as a result of sufficiently strong attraction. Below T_c, Δ evolves smoothly into the excitation gap of the superconducting phase.

This behavior reflects the fact that T_c corresponds to the condensation of the $q = 0$ pairs, while finite momentum pairs persist into the order phase as excitations of the condensate. As the temperature is progressively lowered below T_c, there are fewer and fewer such bosonic excitations. Their number vanishes precisely at $T = 0$, at which point the system reaches the ground state of Eq. (24.1). Here the superconducting order parameter and the excitation gap become precisely equal. This approach is based on a mean field scheme and is thus not equivalent to treating phase fluctuations of the order parameter. In general, below T_c, the superconducting order parameter Δ_{sc} and the pseudogap contributions add in quadrature in the dispersion of Eq. (24.6) as

$$\Delta^2(T) = \Delta_{sc}^2(T) + \Delta_{pg}^2(T) \tag{24.10}$$

where $\Delta_{pg} \to 0$ as $T \to 0$; this behavior should be contrasted with that in Eq. (24.7).

Transport and thermodynamics in the normal and superconducting phases are determined by two types of quasiparticles: fermionic excitations which exhibit a gap $\Delta(T)$, and noncondensed pairs or bosonic excitations. Contributions from the former are rather similar to their (low T) counterparts in BCS theory, except that they are present well above T_c as well, with substantially larger Δ than in strict BCS theory. In this way, experiments which probe the opening of an excitation gap (such as Pauli susceptibility in the spin channel, and resistivity in the charge channel) will exhibit precursor effects, that is, the gradual onset of superconductivity from around T^* to below T_c.

The contributions to transport and thermodynamics of the bosonic excitations are rather similar to those deduced from the time dependent Ginsburg-Landau theory of superconducting fluctuations, provided that one properly extends this theory, in a quantum fashion, away from the critical regime. It is these contributions which often exhibit divergences at T_c, but unlike conventional superconductors, bosonic contributions (pre-formed pairs) are present, up to high temperatures of the order of $T^*/2$, providing the boson density is sufficiently high. Again, these bosons do not represent fluctuations of the order parameter, but they obey a generically similar dynamical equation of motion, and, in the more general case which goes beyond Eq. (24.1),

they will be coupled to order parameter fluctuations. Here, in an oversimplified sense there is a form of spin-charge separation. The bosons are spin-less (singlet) with charge $2e$, while the fermions carry both spin and charge, but are non-Fermi-liquid like, as a consequence of their energy gap.

In the years following the discovery of high T_c superconductors, attention focused on the so-called marginal Fermi liquid behavior of the cuprates. This phase is associated with near-optimal doping. The most salient signature of this marginality is the dramatically linear in temperature dependence of the resistivity from just above T_c to very high temperatures, well above room temperature. Today, we know that pseudogap effects are present at optimal doping, so that the precise boundary between the marginal and pseudogap phases is not clear. As a consequence, addressing this normal state resistivity in the BCS-BEC crossover approach has not been done in detail, although it is unlikely to yield a strictly linear T dependence at a particular doping. Nevertheless, the bosonic contributions lead to a *decrease* in resistivity as temperature is lowered, while the opening of a d-wave gap associated with the fermionic terms leads to an *increase*, which tends to compensate. These are somewhat analogous to Aslamazov-Larkin and Maki-Thompson fluctuation contributions [103]. The bosons generally dominate in the vicinity of T_c, but at higher T, in the vicinity of T^*, the gapped fermions will be the more important.

The vanishing of T_c with sufficiently large T^* (extreme underdoping) occurs in an interesting way in this crossover theory. This effect is associated with the localization of the bosonic degrees of freedom. Pauli principle effects in conjunction with the extended size of d-wave pairs inhibit pair hopping, and thus destroy superconductivity. One can speculate that, just as in conventional Bose systems, once the bosons are localized, they will exhibit an alternative form of long range order. Indeed, "pair density wave" models have been invoked [26] to explain recent STM data [181, 56]. In contrast to the cold atom systems, for the d-wave case the BEC regime is never accessed. This superconductor-insulator transition takes place in the fermionic regime where $\mu \approx 0.8E_F$.

In the context of BCS-BEC crossover physics, it is not essential to establish the source of the attractive interaction. For the most part we skirt this issue in this Review by taking the pairing onset temperature $T^*(x)$ as a phenomenological input parameter. At the simplest level one may argue that as the system approaches the Mott insulating limit ($x \to 0$) fermions become less mobile; this serves to increase the effectiveness of the attractive interaction at low doping levels.

The variable x in the high T_c problem should be viewed then, as a counterpart to the magnetic field variable in the cold atom problem which tunes the system through a Feshbach resonance; both x and field strength modulate the size of the attraction. However, for the cuprates, in contrast to the cold atom systems, one never reaches the BEC limit of the crossover theory.

It is reasonable to presume based on the evidence to date, that pairing ultimately derives from Coulombic effects, not phonons, which are associated with $l = 0$ pairing. While the widely used Hubbard model ignores these effects, longer ranged screened Coulomb interactions have been found [111] to be attractive for electrons in a d-wave channel. In this context, it is useful to note that, similarly, in He^3 short range repulsion destroys s-wave pairing, but leads to attraction in a higher ($l = 1$) channel [4]. There is, however, no indication of pseudogap phenomena in He^3, so that an Eliashberg extended form of BCS theory appears to be adequate. Eliashberg theory is a very different form of "strong coupling" theory from crossover physics, which treats in detail the dynamics of the mediating boson. Interestingly, there is an upper bound to T_c in both schemes. For Eliashberg theory this arises from the induced effective mass corrections [110], whereas in the crossover problem this occurs because of the presence of a pseudogap at T_c.

Other analogies have also been invoked in comparing the cuprates with superfluid He^3, based on the propensity towards magnetism. In the case of the quantum liquid, however, there is a positive correlation between short range magnetic ordering [110] and superconductivity while the correlation appears negative for the cuprates (and some of their heavy fermion "cousins") where magnetism and superconductivity appear to compete.

Searching for the Definitive High T_c Theory

In no sense should one argue that the BCS-BEC crossover approach precludes consideration of Mott physics. Nor should it be viewed as superior. Indeed, many of the experiments we will address in this Review have alternatively been addressed within the Mott scenario. Presumably both components are important in any ultimate theory. We have chosen in this Review to focus on one component only, and it is hoped that a comparably detailed review of Mott physics will be forthcoming. In this way one could compare the strengths and weaknesses of both schemes. A summary [21] of some aspects of the Mott picture with emphasis on one dimensional stripe states should be referred to as a very useful starting point. Also available now is a new Review [106] of Mott physics, based on spin charge separation.

Besides those discussed in this Review, there is a litany of other experiments which are viewed as requiring explanation in order for a high T_c theory to be taken seriously. Among these are the important linear resistivity in the normal state (at optimal doping) and unusual temperature and x dependences in Hall data. While there has been little insight offered from the crossover scheme to explain the former, aspects of the latter have been successfully addressed within pre-formed pair scenarios [57]. Using fermiology based schemes the major features of photoemission[126] and of neutron scattering and NMR data were studied theoretically and rather early on [158, 191, 85], along with a focus on the now famous 41 meV feature [112]. These and other related approaches to the magnetic data, make use of a microscopically derived [157] random phase approximation scheme which incorporates the details of the Fermi surface shape and d-wave gap. Among remaining experiments in this litany is the origin of incoherent transport along the c-axis [150].

On the basis of the above cited literature which addressed magnetic and c-axis [33] data we are led to conclude that pseudogap effects and related crossover physics are not central to their understanding. The presence of a normal state gap will lead to some degree of precursor behavior above T_c, but d-wave nesting related effects such as reflected in neutron data [191, 85, 112] will be greatly weakened above T_c by the blurring out of the d-wave gap nodes [42, 20]. It should be said, however, that c-axis optical data do appear to reflect pseudogap effects [75] above T_c. (The ab-plane counterparts are discussed in Section 24.7.3). In summary, we are far from the definitive high T_c theory and the field has much to gain by establishing a collaboration with the cold atom community where BCS-BEC crossover as well as Mott physics [70] can be further elucidated and explored.

24.2.5 Many Body Hamiltonian and Two Body Scattering Theory: Mostly Cold Atoms

The existence of Feshbach resonances in a gas of ultracold fermionic atoms allows the interaction between atoms to be tuned arbitrarily, via application of a magnetic field. Figure 24.15 presents a characteristic plot of the two body interaction potentials which are responsible for this resonance. These interaction potentials represent an effective description of all Coulomb interactions between the electrons and nuclei. For definiteness, we consider the case of ^{6}Li

[33] Here the ab-plane refers to the crystal plane in parallel with the layers of the cuprate compounds, and the c-axis refers to the axis normal to the layers.

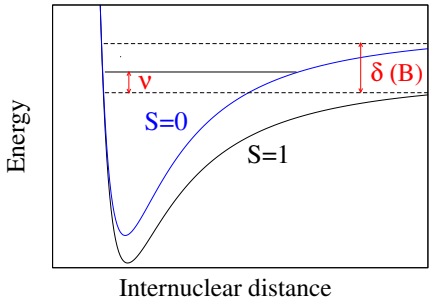

Figure 24.15: A schematic representation of the Feshbach resonance for ^{6}Li. The effective interaction between the scattering of atoms in the triplet state is greatly enhanced, when the energy level of the singlet bound state approaches the continuum of the $S = 1$ channel.

here. In the region of magnetic fields near the "wide" Feshbach resonance, $\approx 837G$, we may focus on the two lowest atomic levels characterized by $|F, m_F\rangle$, where the two quantum numbers correspond to the total spin and its z component. We specify the two states $|1\rangle \equiv |\frac{1}{2}, \frac{1}{2}\rangle$ and $|2\rangle \equiv |\frac{1}{2}, -\frac{1}{2}\rangle$. In place of these quantum numbers one can alternatively characterize the two states in terms of the projections of the electronic (m_s) and nuclear (m_i) spins along the magnetic field. In this way the states 1 and 2 have $m_s = -\frac{1}{2}$ and $m_i = 1$ and 0, respectively.

The curve in Fig. 24.15 labelled $S = 1$ represents the interaction between these two states. This corresponds to the so-called "open" channel and is associated with a triplet (electronic) spin state. A Feshbach resonance requires that there be an otherwise unspecified near-by state which we refer to as in the "closed" channel. The potential which gives rise to this singlet (electronic) spin state is shown by the $S = 0$ curve in Fig. 24.15. A Feshbach resonance arises when this bound state lies near the zero of energy corresponding to the continuum of scattering states in the triplet or open channel. The electronic Zeeman coupling to the triplet state makes is possible to shift the relative position of the two potentials by application of a magnetic field. This shift is indicated by δ in Fig. 24.15. In this way, the resonance is magnetically tunable and the scattering length of the system will vary continuously with field, diverging at that magnetic field which corresponds to the Feshbach resonance. We represent the deviation of this field from the resonance condition by the "detuning parameter" ν. When ν is large and positive, the singlet state is substantially raised relative to the triplet– and it plays relatively little role. By contrast when the magnitude of ν is large, but with negative sign, then the physics is dominated by the singlet or closed channel.

The most general form for the Hamiltonian contains two types of particles: fermions which represent the open channel and "molecular bosons" which represent the two fermion bound state of the closed channel. We will also refer to the latter as "Feshbach bosons". These, in turn, lead to two types of interaction effects: those associated with the direct attraction between fermions, parameterized by U, and those associated with "fermion-boson" interactions, whose strength is governed by g. The latter may be viewed as deriving from hyperfine interactions which couple the (total) nuclear and electronic spins. In the high T_c applications, one generally, but not always, ignores the bosonic degrees of freedom. Otherwise the Hamiltonians are the same, and can be written as

$$\begin{aligned} H \quad - \quad \mu N &= \sum_{\mathbf{k},\sigma} (\epsilon_{\mathbf{k}} - \mu) a^\dagger_{\mathbf{k},\sigma} a_{\mathbf{k},\sigma} + \sum_{\mathbf{q}} (\epsilon^{mb}_{\mathbf{q}} + \nu - 2\mu) b^\dagger_{\mathbf{q}} b_{\mathbf{q}} \\ &+ \sum_{\mathbf{q},\mathbf{k},\mathbf{k}'} U(\mathbf{k},\mathbf{k}') a^\dagger_{\mathbf{q}/2+\mathbf{k},\uparrow} a^\dagger_{\mathbf{q}/2-\mathbf{k},\downarrow} a_{\mathbf{q}/2-\mathbf{k}',\downarrow} a_{\mathbf{q}/2+\mathbf{k}',\uparrow} \\ &+ \sum_{\mathbf{q},\mathbf{k}} \left(g(\mathbf{k}) b^\dagger_{\mathbf{q}} a_{\mathbf{q}/2-\mathbf{k},\downarrow} a_{\mathbf{q}/2+\mathbf{k},\uparrow} + h.c. \right) \end{aligned} \tag{24.11}$$

Here the fermion and boson kinetic energies are given by $\epsilon_{\mathbf{k}} = k^2/(2m)$, and $\epsilon^{mb}_{\mathbf{q}} = q^2/(2M)$, and ν is an important parameter which represents the magnetic field "detuning". $M = 2m$ is the bare mass of the Feshbach bosons. For the cold atom problem $\sigma = \uparrow, \downarrow$ represents the two different hyperfine states ($|1\rangle$ and $|2\rangle$). One may ignore [173] the non-degeneracy of these two states, since there is no known way for state 2 to decay into state 1. In the two channel problem the ground state wavefunction is slightly modified and given by

$$\bar{\Psi}_0 = \Psi_0 \otimes \Psi_0^B \tag{24.12}$$

where the normalized molecular boson contribution Ψ_0^B is

$$\Psi_0^B = e^{-\lambda^2/2 + \lambda b_0^\dagger}|0\rangle \, . \tag{24.13}$$

as discussed originally by [95]. Here λ is a variational parameter. We present the resulting variational conditions for the ground state in Appendix 24.8.

Whether both forms of interactions are needed in either the high T_c or cold atom systems is still under debate. The bosons ($b^\dagger_{\mathbf{k}}$) of the cold atom problem [71, 173] will be referred to as Feshbach bosons. These represent a separate species, not to be confused with the fermion pair ($a^\dagger_{\mathbf{k}} a^\dagger_{-\mathbf{k}}$) operators. Thus we call this a "two channel" model. In this review we will discuss the behavior of crossover physics both with and without these Feshbach bosons (FB). Previous studies of high T_c superconductors have invoked a similar bosonic term [146, 120, 57] as well, although less is known about its microscopic origin. This fermion-boson coupling is not to be confused with the coupling between fermions and a "pairing-mechanism"-related boson ($[b + b^\dagger]a^\dagger a$) such as phonons. The coupling $b^\dagger aa$ and its conjugate represents a form of sink and source for creating fermion pairs, inducing superconductivity in some ways, as a by-product of Bose condensation. We will emphasize throughout that crossover theory proceeds in a similar fashion with and without Feshbach bosons.

It is useful at this stage to introduce the s-wave scattering length, a_s. This parameter is associated with the scattering amplitude in the low energy limit, for a two body scattering process. This scattering length can, in principle, be deduced from Figure 24.15. It follows that a_s is negative when there is no bound state, it tends to $-\infty$ at the onset of the bound state and to $+\infty$ just as the bound state stabilizes. It remains positive but decreases in value as the interaction becomes increasingly strong. The magnitude of a_s is arbitrarily small in both the extreme BEC and BCS limits, but with opposite sign (See Fig. 24.16). *The fundamental postulate of crossover theory is that even though the two-body scattering length changes abruptly at the unitary scattering condition ($|a_s| = \infty$), in the N-body problem the superconductivity varies smoothly through this point.* Throughout this Review, we presume an equivalence between the "pseudogap" and unitary scattering regimes.

An important goal is to understand how to incorporate all the constraints of the two body physics into the superfluid gap equation. As a by-product, one avoids implicit divergences which would also appear in the problem. To begin we ignore Feshbach effects. The way in which the two body interaction U enters to characterize the scattering (in vacuum) is different from the way in which it enters to characterize the N-body processes leading to superfluidity. In each case, however, one uses a T-matrix formulation to sum an appropriately selected but infinite series of terms in U. For the two-body problem in vacuum, we introduce the scattering length, a_s,

$$\frac{m}{4\pi a_s} \equiv \frac{1}{U_0} \, , \tag{24.14}$$

which is related to U via the Lippmann-Schwinger equation

$$\frac{m}{4\pi a_s} \equiv \frac{1}{U} + \sum_{\mathbf{k}} \frac{1}{2\epsilon_{\mathbf{k}}} \, . \tag{24.15}$$

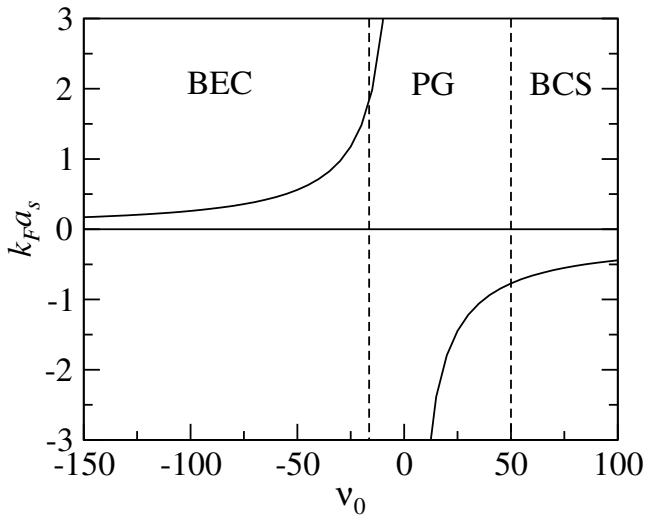

Figure 24.16: Characteristic behavior of the scattering length a_s in the three regimes. a_s diverges when $\nu_0 = 2\mu$. Here, and in subsequent figures ν_0 is always in units of E_F and we estimate 1 G $\approx 60 E_F$ for a typical $E_F = 2\,\mu$K, for either ^{6}Li or ^{40}K.

In this way one may solve for the unknown U in terms of a_s or U_0. The two-body T-matrix equation [Eq. (24.15)] can be rewritten as

$$U = \Gamma U_0, \qquad \Gamma = \left(1 + \frac{U_0}{U_c}\right)^{-1} , \tag{24.16}$$

where we define the quantity U_c as

$$U_c^{-1} = -\sum_{\mathbf{k}} \frac{1}{2\epsilon_{\mathbf{k}}} . \tag{24.17}$$

Here U_c is the critical value of the potential associated with the binding of a two particle state in vacuum. Specific evaluation of U_c requires that there be a cut-off imposed on the above summation, associated with the range of the potential.

Now let us turn to the Feshbach problem, where the superfluidity is constrained by a more extended set of parameters U, g, ν and also μ. Provided we redefine the appropriate "two body" scattering length, Equation (24.15) holds even in the presence of Feshbach effects [131, 123]. It has been shown that U in the above equations is replaced by U_{eff} and a_s by a_s^*

$$\frac{m}{4\pi a_s^*} \equiv \frac{1}{U_{eff}} + \sum_{\mathbf{k}} \frac{1}{2\epsilon_{\mathbf{k}}} . \tag{24.18}$$

Here it is important to stress that many body effects, via the fermionic chemical potential μ enter into a_s^*.

More precisely the effective interaction between two fermions is Q dependent. It arises from a second order process involving emission and absorption of a molecular boson. The net effect of the direct plus indirect interactions is given by

$$U_{eff}(Q) \equiv U + g^2 D_0(Q) , \tag{24.19}$$

where

$$D_0(Q) \equiv 1/[i\Omega_n - \epsilon_{\mathbf{q}}^{mb} - \nu + 2\mu] \tag{24.20}$$

is the non-interacting molecular boson propagator. What appears in the gap equation, however, is

$$U_{eff}(Q = 0) \equiv U_{eff} = U - \frac{g^2}{\nu - 2\mu} . \tag{24.21}$$

Experimentally, the two body scattering length a_s^* varies with magnetic field B. Near resonance, it can be parameterized [93] in terms of three parameters of the two body problem U_0, g_0 and the magnetic field which at resonance is given by B_0. One fits the scattering length to $a_{bg}(1-\frac{w}{B-B_0})$ so that the width w is related to g_0 and the background scattering length a_{bg} is related to U_0. Away from resonance, the crossover picture requires that the scattering length vanish asymptotically as

$$a_s^* \approx 0\,, \qquad \text{in extreme BEC limit,} \tag{24.22}$$

so that the system represents an ideal Bose gas. Here it should be noted that this BEC limit corresponds to $\nu \to \mu^+$. The counterpart of Eq. (24.22) also holds for the one channel problem. Note that the actual resonance of the many body problem will be somewhat shifted from the atomic-fitted resonance parameter B_0.

It is convenient to define the parameter ν_0 which is directly related to the difference in the applied magnetic field B and B_0

$$\nu_0 = (B - B_0)\Delta\mu^0, \tag{24.23}$$

where $\Delta\mu^0$ is the difference in the magnetic moment of the singlet and triplet paired states. *We will use the parameter ν_0 as a measure of magnetic field strength throughout this Review.* The counterpart of Eq. (24.14) is then

$$\frac{m}{4\pi a_s^*} \equiv \frac{1}{U_0 - \frac{g_0^2}{\nu_0 - 2\mu}} \equiv \frac{1}{U^*}\,, \tag{24.24}$$

where $U_0 = \frac{4\pi a_{bg}}{m}$ and $g_0^2 = U_0\Delta\mu^0 w$. For the purposes of this Review we will use the scattering length a_s^*, although for simplicity we often drop the asterisk and write it as a_s.

We can again invert the Lippmann-Schwinger or T-matrix scattering equation [93, 18] to arrive at the appropriate parameters g and ν which enter into the Hamiltonian and thus into the gap equation. Just as in Eq. (24.16), one finds a connection between measurable parameters (with subscript 0) and their counterparts in the Hamiltonian (without the subscript):

$$U = \Gamma U_0, \quad g = \Gamma g_0, \quad \nu - \nu_0 = -\Gamma\frac{g_0^2}{U_c}\,. \tag{24.25}$$

To connect the various energy scales, which appear in the problem, typically $1\text{G} \approx 60\text{E}_\text{F}$ for both ^{6}Li and ^{40}K. Here it is assumed that the Fermi energy is $E_F \approx 2\,\mu$K.

In Fig. 24.16 and using Eq. (24.18), we plot a prototypical scattering length $k_F a_s \equiv k_F a_s^*$ as a function of the magnetic field dependent parameter, ν_0. This figure indicates the BEC, BCS and PG regimes. Here, as earlier, the PG regime is bounded on the left by $\mu = 0$ and on the right by $\Delta(T_c) \approx 0$.

A key finding associated with this plot is that *the PG regime begins on the so-called "BEC side of resonance", independent of whether Feshbach effects are included or not.* That is, the fermionic chemical potential reaches zero while the scattering length is positive. This generic effect of the ground state self consistent equations arises from the Pauli principle. For an isolated system, two particle resonant scattering occurs at $U = U_c$, where U_c is defined in Eq. (24.17). In the many body context, because of Pauli principle repulsion between fermions, it requires an effectively stronger attraction to bind particles into molecules. Stated alternatively, the onset of the fermionic regime ($\mu > 0$) occurs for more strongly attractive interactions, than those required for two body resonant scattering. As a consequence of $\mu > 0$, *there is very little condensate weight in the Feshbach boson channel near the unitary limit, for values of the coupling parameter g_0, appropriate to currently studied (and rather wide) Feshbach resonances.*

Finally, it is useful to compare the two interaction terms which we have defined above, (U_{eff} and U^*), and to contrast their behavior in the BEC and unitary limits. The quantity U^* is

proportional to the scattering length; it reflects the two body physics and necessarily diverges at unitarity, where $U_{eff} = U_c$. By contrast, in the BEC regime, U^*, or a_s^* approaches zero, (under the usual presumption that the interaction is a contact interaction). This vanishing of U^* should be compared with the observation that the quantity U_{eff}, which reflects the many body physics, must diverge in this BEC limit.

Differences Between One and Two Channel Models: Physics of Feshbach bosons

The main effects associated with including the explicit Feshbach resonance are twofold. These Feshbach bosons provide a physical mechanism for tuning the scattering length to be arbitrarily large, and in the BEC limit, they lead to different physics from the one channel problem. As will be illustrated later via a comparison of Figures 24.23 and 24.25, in an artificial way one can capture most of the salient physics of the unitary regime via a one channel approach in which one drops all molecular boson related terms in the Hamiltonian, but takes the interaction U to be arbitrary. In this way there is very little difference between fermion-only and fermion-boson models. There is an important proviso, though, that one is not dealing with narrow resonances which behave rather differently near unitarity, as will be seen in Fig. 24.32. In addition, as in the one channel model a form of universality [68] is found in the ground state at the unitary limit, provided g is sufficiently large. This is discussed later in the context of Fig. 24.30.

We emphasize that, within the BEC regime there are three important effects associated with the Feshbach coupling g. As will become clear later, (i) in the extreme BEC limit when g is nonzero, there are no occupied fermionic states. The number constraint can be satisfied entirely in terms of Feshbach bosons. (ii) The absence of fermions will, moreover, greatly weaken the inter-boson interactions which are presumed to be mediated by the fermions. In addition, as one decreases $|U_{eff}|$ from very attractive to moderately attractive (i.e., increases a_s^* on the BEC side) the nature of the condensed pairs changes. Even in the absence of Feshbach bosons (FB), the size of the pairs increases. But in their presence the admixture of bosonic (i.e., molecular bosons) and fermionic (i.e., Cooper pair) components in the condensate is continuously varied from fully bosonic to fully fermionic. Finally (iii) the role of the condensate enters in two very different ways into the self consistent gap and number equations, depending on whether or not there are FB. The molecular boson condensate appears principally in the number equation, while the Cooper pair condensate appears principally in the gap equation. To make this point clearer we can refer ahead to Eq. (24.81) which contains the FB condensate contribution n_b^0. By contrast the Cooper condensate contribution Δ_{sc} enters into the total excitation gap Δ as in Eq. (24.10) and Δ is, in turn, constrained via Eq. (24.69). Points (i) and (iii), which may appear somewhat technical, have essential physical implications, among the most important of these is point (ii) above.

We stress, however, that *for the PG and BCS regimes the differences with and without FB are, however, considerably less pronounced.*

24.2.6 Cold Atom Experiments: Crossover in the Presence of Feshbach Resonances

There has been an exciting string of developments over the past few years in studies of ultracold fermionic atoms, in particular, ^{6}Li and ^{40}K, which have been trapped and cooled via magnetic and optical means. Typically these traps contain $\sim 10^5$ atoms at very low densities $\approx 10^{13}$ cm^{-3} when cooled to very low T. Here the Fermi temperature E_F in a trap can be estimated to be of the order of a micro-Kelvin. It was argued on the basis of BCS theory alone [73], and rather early on (1997), that the temperatures associated with the superfluid

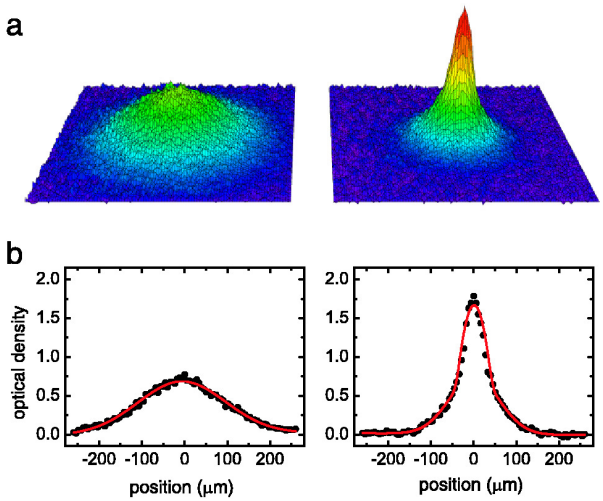

Figure 24.17: (Color) Spatial density profiles of a molecular cloud of trapped ^{40}K atoms in the BEC regime in the transverse directions after 20 ms of free expansion (from [59]), showing thermal molecular cloud above T_c (left) and a molecular condensate (right) below T_c. (a) shows the surface plots, and (b) shows the cross-sections through images (dots) with bimodal fits (lines).

phases may be attainable in these trapped gases. This set off a search for the "holy grail" of fermionic superfluidity. That a Fermi degenerate state could be reached at all is itself quite remarkable; this was was first reported [44] by Jin and deMarco in 1999. By late 2002 reports of unusual hydrodynamics in a degenerate Fermi gas indicated that strong interactions were present [130]. This strongly interacting Fermi gas (associated with the unitary scattering regime) has attracted widespread attention independent of the search for superfluidity, because it appears to be a prototype for analogous systems in nuclear physics [8, 65] and in quark-gluon plasmas [76, 94]. Moreover, there has been a fairly extensive body of analytic work on the ground state properties of this regime [64, 22], which goes beyond the simple mean field wave function ansatz.

As a consequence of attractive s-wave interactions between fermionic atoms in different hyperfine states, it was anticipated that dimers could also be made. Indeed, these molecules formed rather efficiently [148, 165, 40] as reported in mid-2003 either via three body recombination [79] or by sweeping the magnetic field across a Feshbach resonance. Moreover, they are extremely long lived [165]. From this work it was relatively straightforward to anticipate that a Bose condensate would also be achieved. Credit goes to theorists such as Holland [71] and to Timmermans [173] and their co-workers for recognizing that the superfluidity need not be only associated with condensation of long lived bosons, but in fact could also derive, as in BCS, from fermion pairs. In this way, it was argued that a suitable tuning of the attractive interaction via Feshbach resonance effects would lead to a realization of a BCS-BEC crossover.

By late 2003 to early 2004, four groups [59, 80, 193, 16] had observed the "condensation of weakly bound molecules" (that is, on the $a_s > 0$ side of resonance), and shortly thereafter a number had also reported evidence for superfluidity on the BCS side [147, 194, 87, 34]. The BEC side is the more straightforward since the presence of the superfluid is reflected in a bi-modal distribution in the density profile. This is shown in Fig. 24.17 from [59], and is conceptually similar to the behavior for condensed Bose atoms [41]. On the BEC side but near resonance, the estimated T_c is of the order of 500 nK, with condensate fractions varying from 20% or so, to nearly 100%. The condensate lifetimes are relatively long in the vicinity of resonance, and fall off rapidly as one goes deeper into the BEC. However, for $a_s < 0$ there is no clear expectation that the density profile will provide a signature of the superfluid phase.

These claims that superfluidity may have been achieved on the BCS side ($a_s < 0$) of resonance were viewed as particularly exciting. The atomic community, for the most part, felt the previous counterpart observations on the BEC side were expected and not significantly different from condensation in Bose atoms. The evidence for this new form of "fermionic superfluidity" rests on studies [147, 194] that perform fast sweeps from negative a_s to positive a_s across the resonance. The field sweeps allow, in principle, a pairwise projection of fermionic atoms (on the BCS side) onto molecules (on the BEC side). It is presumed that in this way one measures the momentum distribution of fermionic atom pairs. The existence of a condensate was thus inferred. Other experiments which sweep across the Feshbach resonance adiabatically, measure the size of the cloud after release [16] or within a trap [11]. Evidence for superfluidity on the BCS side, which does not rely on the sweep experiments, has also been deduced from collective excitations of a fermionic gas [87, 10]. Pairing gap measurements with radio frequency (RF) probes [34] have similarly been interpreted [89] as evidence for superfluidity, although it appears more likely that these experiments establish only the existence of fermionic pairs. Quite recently, evidence for a phase transition has been presented via thermodynamic measurements and accompanying theory [88]. The latter, like the theory [89] of RF experiments [34], is based on the formalism presented in this Review.

Precisely what goes on during the sweep is not entirely understood. It should be stressed again that where the scattering length changes sign is not particularly important to the N-body physics. *Thus starting on the "BCS side of resonance" and ending on the "BEC side of resonance" involves a very continuous sweep in which the physics is not qualitatively changed.* It has been speculated that for this sweep procedure to work a large percentage of the Cooper pair partners must be closer than the inter-atomic spacing. Others have alternatively viewed the sweep as having little to do with the large Cooper pairs of BCS superconductivity.

It is useful to establish the various pair sizes here. In the PG regime the normal state consists of a significant number of small (compared to BCS) pre-formed pairs. Below T_c, the condensate pair size is also small. Finally, there are excited pair states in the superfluid phase, with characteristic size ξ_{pg}. The Cooper pair size ξ as plotted in Fig. 24.18 was deduced from the condensate [144] at $T = 0$, but this can be shown to be rather similar to ξ_{pg}, corresponding to the size of excited pair states [28, 27] both above and below T_c. It seems plausible that during the sweep there is some rearrangement of excited states (both fermionic and bosonic) and condensate. In addition, all pairs (excited and condensate) contract in size. When, at the end of a sweep, they are sufficiently small, then they are more "visible". What appears to be essential, however, is that the sweep time scales are rapid enough so that the existence of a condensate at the initial starting point is a necessary and sufficient condition for observing a condensate at the end of a sweep.

24.2.7 T-Matrix-Based Approaches to BCS-BEC Crossover in the Absence of Feshbach Effects

In this subsection we introduce the concept of a T-matrix within the pairing channel. This is defined in Eq. (24.26) below and it represents an effectively screened interaction in which the appropriate polarizability (χ) is associated with the particle-particle rather than the particle-hole channel, as in the more conventional dielectric susceptibility. The T-matrix thus appears as an infinite series of two particle "ladder" diagrams.

Away from zero temperature, a variety of different many body approaches have been invoked to address the physics of BCS-BEC crossover. For the most part, these revolve around T-matrix schemes. Here one solves self consistently for the single fermion propagator (G) and the pair propagator (t). That one stops at this level without introducing higher order Green's functions (involving three, and four particles, etc) is believed to be adequate for addressing a leading

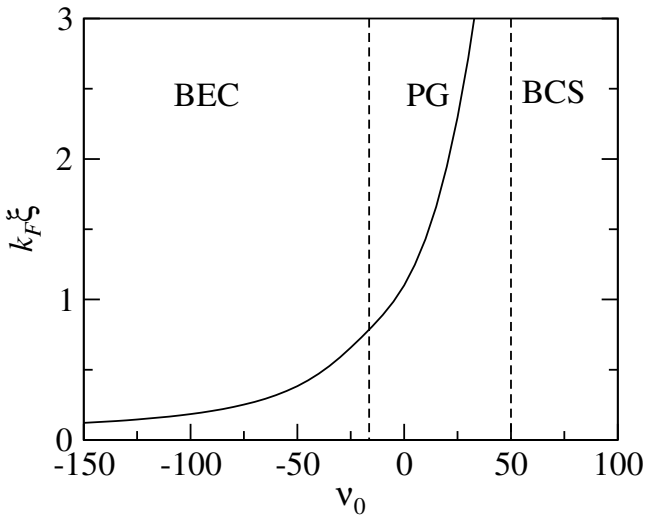

Figure 24.18: Characteristic behavior of Cooper pair size ξ in the condensate in the three regimes. The dotted vertical lines are not sharp transitions but indicate where $\mu = 0$ (left line) and where $\Delta(T_c) \approx 0$ (right line). The dimensionless $k_F\xi$ gives the ratio between pair size ξ and the mean inter-particle spacing $1/k_F$. Pairs shrink and become tightly bound in the deep BEC regime.

order mean field theory such as that represented by Eq. (24.1). One can see that pair-pair (boson-boson) interactions are only treated in a mean field averaging procedure; they arise exclusively from the fermions and are presumed to be sufficiently weak so as not to lead to any incomplete condensation in the ground state, as is compatible with Eq. (24.1).

One can view this approach as the first step beyond BCS in a hierarchy of mean field theories. In BCS, above T_c one includes only the bare fermion propagator G_0. Below T_c, pairs play a role but only through the condensate. At the next level one accounts for the interaction between particles and noncondensed pairs in both the normal and superconducting states. The pairs introduce a self energy Σ into the particles, which represents a correction to BCS theory. The pairs are treated at an effective mean field level. By truncating the equations of motion in this way, the effects of all higher order Green's functions are subsumed into t in an averaged way.

Below we demonstrate that at this T-matrix level there are a number of distinct schemes which can be implemented to address BCS-BEC crossover physics. These same alternatives have also entered into a discussion of pre-formed pairs as they appear in treatments of superconducting fluctuations. Above T_c, quite generally one writes for the T-matrix

$$t(Q) = \frac{U}{1 + U\chi(Q)} \tag{24.26}$$

and theories differ only on what is the nature of the pair susceptibility $\chi(Q)$, and the associated self energy of the fermions. Here and throughout we use Q to denote a four-vector and write $\sum_Q \equiv T\sum_{i\Omega_n}\sum_{\mathbf{q}}$, where Ω_n is a Matsubara frequency. Below T_c one can also consider a T-matrix approach to describe the particles and pairs in the condensate. For the most part we will defer extensions to the broken symmetry phase to Section 24.3.2.

Review of BCS Theory Using the T-matrix Approach

In order to assess alternative schemes, it is useful to review BCS theory within a T-matrix formalism. In BCS theory, pairs explicitly enter into the problem below T_c, but only through

the condensate. These condensed pairs are associated with a T-matrix given by

$$t_{sc}(Q) = -\Delta_{sc}^2 \delta(Q)/T \tag{24.27}$$

with fermionic self energy

$$\Sigma_{sc}(K) = \sum_Q t_{sc}(Q) G_0(Q-K) \tag{24.28}$$

so that $\Sigma_{sc}(K) = -\Delta_{sc}^2 G_0(-K)$. Here, and throughout, G_0 is the Green's function of the non-interacting system. The number of fermions in a BCS superconductor is given by

$$n = 2\sum_K G(K) \tag{24.29}$$

and

$$G(K) = [G_0^{-1}(K) - \Sigma_{sc}(K)]^{-1} \tag{24.30}$$

Doing the Matsubara summation in Eq. (24.29), one can then deduce the usual BCS expression for the number of particles, which determines the fermionic chemical potential

$$n = \sum_{\mathbf{k}} \left[1 - \frac{\epsilon_{\mathbf{k}} - \mu}{E_{\mathbf{k}}} + 2\frac{\epsilon_{\mathbf{k}} - \mu}{E_{\mathbf{k}}} f(E_{\mathbf{k}}) \right] \tag{24.31}$$

where

$$E_{\mathbf{k}} = \sqrt{(\epsilon_{\mathbf{k}} - \mu)^2 + \Delta_{sc}^2(T)} \tag{24.32}$$

We need, however, an additional equation to determine $\Delta_{sc}(T)$. The BCS gap equation can be written as

$$1 + U\chi_{BCS}(0) = 0, \quad T \leq T_c \tag{24.33}$$

where

$$\chi_{BCS}(Q) = \sum_K G(K) G_0(Q-K) \tag{24.34}$$

This suggests that one consider the uncondensed or normal state pair propagator to be of the form

$$t(Q) = \frac{U}{1 + U\chi_{BCS}(Q)} \tag{24.35}$$

then in the superconducting state we have a BEC like condition on the pair chemical potential μ_{pair} defined by

$$t^{-1}(Q=0) = \mu_{pair} \times const. \tag{24.36}$$

where the overall constant is unimportant for the present purposes. Thus we say that the pair chemical potential satisfies

$$\mu_{pair} = 0, \qquad T \leq T_c \, . \tag{24.37}$$

That μ_{pair} vanishes at *all* $T \leq T_c$ is a stronger condition than the usual Thouless condition for T_c. Moreover, it should be stressed that *BCS theory is associated with a particular asymmetric form for the pair susceptibility.* These uncondensed pairs play virtually no role in BCS superconductors but the structure of this theory points to a particular choice for a pair susceptibility. We can then write the self consistent condition on Δ_{sc} which follows from Eq. (24.33). Using Eqs. (24.27- 24.34), we find the expected form for the BCS gap equation. This represents a constraint on the order parameter Δ_{sc}:

$$\Delta_{sc}(T) = -U\sum_{\mathbf{k}} \Delta_{sc}(T) \frac{1 - 2f(E_{\mathbf{k}})}{2E_{\mathbf{k}}} \, . \tag{24.38}$$

The above discussion was presented in a somewhat different way in a paper by Kadanoff and Martin [82].

Three Choices for the T-matrix of the Normal State: Problems with the Noziéres Schmitt-Rink Approach

On general grounds we can say that there are three obvious choices for $\chi(Q)$ which appears in the general definition of the T-matrix in Eq. (24.26). Each of these has been studied rather extensively in the literature. All of these introduce corrections to BCS theory and all were motivated by attempts to extend the crossover ground state to finite T, or to understand widespread pseudogap effects in the high T_c superconductors. In analogy with Gaussian fluctuations, one can consider

$$\chi_0(Q) = \sum_K G_0(K)G_0(Q-K) \tag{24.39}$$

with self energy

$$\Sigma_0(K) = \sum_Q t(Q)G_0(Q-K) \tag{24.40}$$

which appears in G in the analogue of Eq. (24.30). The number equation is then deduced by using Eq. (24.29).

This scheme was adopted by Noziéres and Schmitt-Rink (NSR), although these authors [128, 144] approximated the number equation [155] by using a leading order series for G in Eq. (24.30) with

$$G = G_0 + \ G_0\Sigma_0 G_0 \ . \tag{24.41}$$

It is straightforward, however, to avoid this approximation in Dyson's equation, and a number of groups [78, 139] have extended NSR in this way.

Similarly one can consider

$$\bar{\chi}(Q) = \sum_K G(K)G(Q-K) \tag{24.42}$$

with self energy

$$\bar{\Sigma}(K) = \sum_Q t(Q)G(Q-K) \ . \tag{24.43}$$

This latter scheme (sometimes known as fluctuation-exchange or FLEX) has been also extensively discussed in the literature, by among others, Haussmann [63], Tchernyshyov [171], Micnas and colleagues [119] and Yamada and Yanatse [189].

Finally, we can contemplate the asymmetric form [28, 58] for the T-matrix, so that the coupled equations for $t(Q)$ and $G(K)$ are based on

$$\chi(Q) = \sum_K G(K)G_0(Q-K) \tag{24.44}$$

with self energy

$$\Sigma(K) = \sum_Q t(Q)G_0(Q-K) \tag{24.45}$$

Each of these three schemes determines the superfluid transition temperature via the Thouless condition. Thus $\mu_{pair} = 0$ leads to a slightly different expression for T_c, based on the differences in the choice of T-matrix which appears in Eq. (24.36).

A central problem with the NSR scheme ($\chi \approx G_0G_0$) is that it incorporates self energy effects only through the number equation. The absence of self energy effects in the gap equation is equivalent to the statement that pseudogap effects only indirectly affect T_c: the particles acquire a self energy from the pairs but these self energy effects are not fed back into the propagator for the pairs. On physical grounds one anticipates that the pseudogap must have a direct effect on T_c as a consequence of the associated reduction in the density of states. Other problems related

to the thermodynamics were pointed out [159] when NSR was applied to a two dimensional system. Finally, because only the number equation contains self energy effects, it is not clear if one can arrive at a proper vanishing of the superfluid density ρ_s at T_c within this approach. This requires a precise cancellation between the diamagnetic current contributions (which depend on the number equation) and the paramagnetic terms (which reflect the gap equation).

One might be inclined, then, to prefer [155] the FLEX ($\chi \approx GG$) scheme since it is ϕ-derivable, in the sense of Baym [12]. This means that it is possible to write down a closed form expression for the thermodynamical potential, from which one derives other physical quantities via functional derivatives of this potential. Theoretical consistency issues in this approach have been rather exhaustively discussed by Haussmann [63] above T_c. We are not aware of a fully self consistent calculation of ρ_s below T_c, at the same level of completeness as Haussmann's normal state analysis (or, for that matter, of the counterpart discussion to Section 24.4.1 and accompanying Appendix 24.9). However, in principle, it should be possible to arrive at a proper expression for the superfluid density, providing Ward identities are imposed. There is some ambiguity [14, 171, 119] about whether pseudogap effects are present in the FLEX approach; a consensus has not been reached at this time. Numerical work based on FLEX is more extensive [43, 14] than for the other two alternative schemes.

It will be made clear in what follows that, if one's goal is to extend the usual crossover ground state of Eq. (24.1) to finite temperatures, then one must choose the asymmetric form for the pair susceptibility. Here $\chi \approx GG_0$. This is different from the approach of Noziéres and Schmitt-Rink in which there is no evident consistency between their finite T treatment and the presumed ground state. Some have claimed [144] that an NSR-based approach, when extended below T_c, reproduces Eqs. (24.69) and (24.70). But elsewhere in the literature it has been shown that these ground state self consistency conditions are derived from a lower level theory [95]. They arise from a $T = 0$ limit of what is called the saddle point approximation, or mean field approach. When pairing fluctuations beyond the saddle point [128] are included, the number equation is changed. Then the ground state is no longer that of Eq. (24.1) [139]. In the cold atom literature, the distinction between the NSR-extrapolated ground state and the ground state of Eq. (24.1) has been pointed out in the context of atomic density profiles [137] within traps.

It should be evident from Eq. (24.34) and the surrounding discussion that the asymmetric form is uniquely associated with the BCS-like behavior implicit in Eq. (24.1). The other two T-matrix approaches lead to different ground states which should, however, be very interesting in their own right. These will need to be characterized in future.

Additional support for the asymmetric form, which will be advocated here, was provided by Kadanoff and Martin. In their famous paper they noted that several people had surmised that the form for $\chi(Q)$ involving GG would be more accurate. However, as claimed in [82], "This surmise is not correct." Aside from theoretical counter-arguments which they present, the more symmetric combination of Green's functions "can also be rejected experimentally since they give rise to a T^2 specific heat." Similar arguments in support of the asymmetric form were introduced [62] into the literature in the context of addressing specific heat jumps.

24.2.8 Superconducting Fluctuations: a type of Pre-formed Pairs

While there are no indications of bosonic degrees of freedom, (other than in the condensate), within strict BCS theory, it has been possible to access these bosons via probes of superconducting fluctuations. Quasi-one dimensional, or quasi-2D superconductors in the presence of significant disorder exhibit fluctuation effects [103] or precursor pairing as seen in "paraconductivity", fluctuation diamagnetism, as well as other unusual behavior, often consisting of divergent contributions to transport. One frequently computes [100] these bosonic contribu-

tions to transport by use of a time dependent Ginzburg-Landau (TDGL) equation of motion. This is rather similar to a Gross-Pitaevskii (GP) formalism except that the "bosons" here are highly damped by the fermions.

Alternatively T-matrix based approaches (involving all three choices of $\chi(Q)$) have been extensively used to discuss conventional superconducting fluctuations. The advantage of these latter schemes is that one can address both the anomalous bosonic and fermionic contributions to transport through the famous Aslamazov-Larkin and Maki-Thompson diagrams [103]. We defer a discussion of these issues until Appendix 24.9.

It is useful to demonstrate first how conventional superconducting fluctuations behave at the lowest level of self consistency, called the Hartree approximation. This scheme is closely associated[162] with a GG_0 T-matrix, as is discussed in more detail in Appendix 24.10. It is also closely associated with BCS theory, for one can show that, in the spirit of Eq. (24.1), at this Hartree level the excitation gap $\Delta(T_c)$ and T_c lie on a specific BCS curve (specified by n and U). What is different from strict BCS theory is that the onset of superconductivity takes place in the presence of a finite excitation gap (ie, pseudogap), just as shown in Fig. 24.3. This, then, reflects the fact that there are pre-formed pairs at T_c. By contrast with high T_c superconductors, however, in conventional fluctuation effects, the temperature T^* at which pairs start to form is always extremely close to their condensation temperature T_c. We thus say that there is a very narrow critical region.

In Hartree approximated Ginzburg Landau theory [62] the free energy functional is given by

$$F[\Psi] = a_0(T - T^*)|\Psi|^2 + b|\Psi|^4 \approx a_0(T - T^*)|\Psi|^2 + 2b\Delta^2|\Psi|^2 \tag{24.46}$$

Here Δ^2 plays the role of a pseudogap in the normal state. It is responsible for a lowering of T_c relative to the mean field value T^*. Collecting the quadratic terms in the above equation, it follows that

$$T_c = T^* - \frac{2b}{a_0}\Delta^2(T_c) \; . \tag{24.47}$$

Moreover, self consistency imposes a constraint on the magnitude of $\Delta(T_c)$ via

$$\Delta^2(T) = \int D\Psi e^{-\beta F[\Psi]}\Psi^2 \Big/ \int D\Psi e^{-\beta F[\Psi]} \; . \tag{24.48}$$

It should be noted that Eq. (24.47) is consistent with the statement that $\Delta(T_c)$ and T_c lie on the BCS curve, since for small separation between T_c and T^*, this curve is, below T_c, defined by

$$\Delta^2_{BCS}(T) \approx \frac{a_0}{2b}(T^* - T) \; . \tag{24.49}$$

The primary effect of fluctuations at the Hartree level is that pairing takes place in the presence of a finite excitation gap, reflecting the presence of very short lived, but pre-formed pairs. It should be clear that Δ is not to be confused with the superconducting order parameter Δ_{sc}, as should be evident from Fig. 24.3. We refer the reader to a more detailed discussion which is presented in Appendix 24.10.

Figure 24.19 illustrates how this pseudogap appears experimentally, via a plot of the normalized density of states [37] $\nu_1 \equiv N(E)$ in the normal state. This figure derives from tunneling measurements on Al-based films. Note the depression of $N(E_F)$ at low energies. This is among the first indications for a pseudogap reported in the literature.

Alternatively, fluctuations have also been discussed at the Gaussian (G_0G_0) level in which there is no need for self consistency, in contrast to the above picture. Here because the calculations are so much more tractable there have been very detailed applications [103] of essentially all transport and thermodynamic measurements. This Gaussian analysis led to unexpected

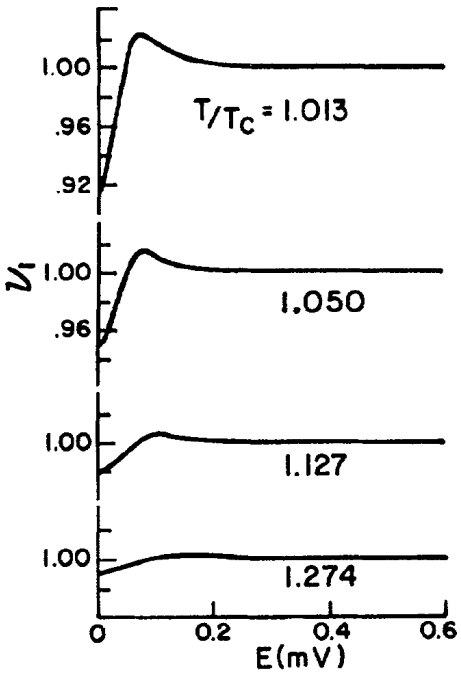

Figure 24.19: Pseudogap in the density of states above T_c in conventional superconductors, from [37]. $\nu_1 \equiv N(E)$ is the normalized density of states.

divergences in the para-conductivity from the so-called Maki-Thompson term which then provided a motivation to go beyond leading order theory. Patton [134, 133] showed how this divergence could be removed within a more self consistent GG_0 scheme, equivalent to self consistent Hartree theory. Others argued [154, 177] that Hartree-Fock (GG) was more appropriate, although in this weak coupling, narrow fluctuation regime, the differences between these latter two schemes are only associated with factors of 2. Nevertheless with this factor of 2, $\Delta(T_c)$ and T_c are no longer on the BCS curve. It should be noted that a consensus was never fully reached [62] by the community on this point.

Dynamics of Pre-formed Pairs Above T_c: Time Dependent Ginzburg-Landau Theory

We turn again to Fig. 24.5 which provides a useful starting point for addressing bosonic degrees of freedom and their implications for experiment. It is clear that transport in the unusual normal state, associated with the pseudogap (PG) phase (as well as thermodynamics) contains contributions from both fermionic and bosonic excitations. The bosons are not infinitely long lived; their lifetime is governed by their interactions with the fermions. In some instances [103], the bosonic contributions to transport become dominant or even singular at T_c. Under these circumstances one can ignore the fermionic contributions except insofar as they lead to a lifetime for the pairs.

To address the transport properties of these more well established pre-formed pairs, one appeals to a standard way of characterizing the dynamics of bosons – a phenomenological scheme known as time dependent Ginsburg- Landau (TDGL) theory. This theory has some microscopic foundations in diagrammatic T-matrix approaches in which one considers only the Aslamazov-Larkin terms (which are introduced in Appendix 24.9). At the Gaussian level both TDGL and the T-matrix approaches are tractable. At the Hartree level things rapidly become more complicated, and it is far easier to approach the problem [170] by adopting a strictly phenomenological TDGL.

The generic Hartree-TDGL equation of motion for classical charged bosons interacting with

electromagnetic fields $(\phi, \mathbf{A})$ is given by

$$\gamma\left(i\frac{\partial}{\partial t} - e^*\phi(\mathbf{x},t)\right)\psi(\mathbf{x},t) = \frac{\left(-i\nabla - e^*\mathbf{A}(\mathbf{x},t)\right)^2}{2M^*}\psi(\mathbf{x},t) - \mu_{pair}(T)\psi(\mathbf{x},t) + D(\mathbf{x},t), \quad (24.50)$$

Here $\psi(\mathbf{x},t)$ is a classical field variable representing the bosons which have vanishing chemical potential μ_{pair} at T_c. The function $D(\mathbf{x},t)$ introduces a noise variable into the equation of motion. Generally γ is complex.

We will explore the implications of this equation in our more quantitative discussion of Section 24.7.5.

24.3 Quantitative Details of Crossover

24.3.1 $T = 0$, BEC Limit without Feshbach Bosons

We begin by reviewing $T = 0$ crossover theory in the BEC limit. Our starting point is the ground state wavefunction Ψ_0 of Eq. (24.1), along with the self consistency conditions of Eq. (24.2). For positive chemical potential μ, the quantity $\Delta_{sc}(0)$ also corresponds to the energy gap for fermionic excitations. In the ground state the two energy scales $\Delta(0)$ and $\Delta_{sc}(0)$ are degenerate, just as they are (at all temperatures) in strict BCS theory.

It is convenient to rewrite these equations [34] in terms of the inter-fermion scattering length a_s

$$\frac{m}{4\pi a_s} = \sum_{\mathbf{k}}\left[\frac{1}{2\epsilon_{\mathbf{k}}} - \frac{1}{2E_{\mathbf{k}}}\right], \quad (24.51)$$

$$n = \sum_{\mathbf{k}}\left[1 - \frac{\epsilon_{\mathbf{k}} - \mu}{E_{\mathbf{k}}}\right], \quad T = 0\,. \quad (24.52)$$

In the fermionic regime ($\mu > 0$) these equations are essentially equivalent to those of BCS theory, although at weak coupling appropriate to strict BCS, little attention is paid to the number equation since $\mu = E_F$ is always satisfied. The more interesting regime corresponds to $\mu \leq 0$ where these equations take on a new interpretation. Deep inside the BEC regime it can be seen that

$$n = \Delta_{sc}^2(0)\frac{m^2}{4\pi\sqrt{2m|\mu|}}, \quad (24.53)$$

which, in conjunction with Eq. (24.51) (expanded in powers of $\Delta_{sc}^2(0)/\mu^2$):

$$\frac{m}{4\pi a_s} = (2m)^{3/2}\frac{\sqrt{|\mu|}}{8\pi}\left[1 + \frac{1}{16}\frac{\Delta_{sc}^2(0)}{\mu^2}\right], \quad (24.54)$$

yields

$$\mu = -\frac{1}{2ma_s^2} + \frac{a_s\pi n}{m}. \quad (24.55)$$

[34] To make the equations simpler, in much of what we present in this review we will consider a contact potential interaction. The momentum sums are assumed to run to infinity. More generally, one can include a cutoff function $\varphi_{\mathbf{k}}$ for the momentum integrals. The gap function thus becomes $\Delta_{\mathbf{k}} = \Delta\varphi_{\mathbf{k}}$. For the cuprate d-wave cuprate superconductors, $\varphi_{\mathbf{k}} = \cos k_x a - \cos k_y a$. For our numerical work on atomic gases we use a Gaussian cutoff $\varphi_{\mathbf{k}}^2 = e^{-k^2/k_0^2}$ with k_0 taken to be as large as is numerically feasible.

This last equation is equivalent [182, 136] to its counterpart in Gross-Pitaevskii theory. This theory describes true bosons, and is associated with the well known equation of state

$$n_{pairs} = \frac{m_B}{4\pi a_B}\mu_B \, . \tag{24.56}$$

To see the equivalence we associate the number of bosons $n_{pairs} = n/2$, the boson mass $m_B = 2m$ and the bosonic scattering length $a_B = 2a_s$. Here the bosonic chemical potential $\mu_B = 2\mu + \epsilon_0$ and we define $\epsilon_0 = 1/(2ma_s^2)$. This factor of 2 in a_B/a_s has received a fair amount of attention in the literature. Although it will be discussed later in the Review, it should be noted now that this particular numerical value is particular to the one channel description[161], and different from what is observed experimentally [138].

Despite these similarities with GP theory, the fundamental parameters are the fermionic $\Delta_{sc}(0)$ and chemical potential μ. It can be shown that in this deep BEC regime the number of pairs is directly proportional to the superconducting order parameter

$$n_{pairs} = \frac{n}{2} = Z_0 \Delta_{sc}^2(0) \tag{24.57}$$

where

$$Z_0 \approx \frac{m^2 a_s}{8\pi} \, . \tag{24.58}$$

One may note from Eq. (24.57) that the "gap equation" now corresponds to a number equation (for bosons). Similarly the number equation, or constraint on the fermionic chemical potential defines the excitation gap for fermions, once the chemical potential is negative. In this way the roles of the two constraints are inverted [144] relative to the BCS regime.

That a Gross-Pitaevskii approach captures the leading order physics at $T = 0$ can also be simply seen by rewriting the ground state wavefunction, as pointed out by Randeria [144]. Define $v_{\mathbf{k}}/u_{\mathbf{k}} \equiv \eta_{\mathbf{k}}$

$$\begin{aligned} \Psi_0 &= const \times \Pi_k (1 + \eta_{\mathbf{k}} c_k^\dagger c_{-k}^\dagger)|0\rangle \\ &= const \times \exp\left(\sum_k \eta_{\mathbf{k}} c_k^\dagger c_{-k}^\dagger\right)|0\rangle \, . \end{aligned} \tag{24.59}$$

Projecting onto a state with fixed particle number N yields

$$\Psi_0 = const \times \left(\sum_{\mathbf{k}} \eta_{\mathbf{k}} c_k^\dagger c_{-k}^\dagger\right)^{N/2} |0\rangle \, . \tag{24.60}$$

This is a GP wavefunction of composite bosons with the important proviso: that the characteristic size associated with the internal wavefunction $\eta_{\mathbf{k}}$ is smaller than the inter-particle spacing. It should be stressed that, except in the BEC asymptotic limit, (where the "bosons" are non-interacting) there are essential differences between Eq. (24.60) and the Gross-Pitaevskii wavefunction. Away from this extreme limit, pair-pair interactions (arising indirectly via the fermions and the Pauli principle), as well as the finite size of the pairs, will differentiate this system from that of true interacting bosons. This same issue arises more concretely in the context of the collective mode spectrum of ultracold gases, as discussed in Section 24.6.3.

24.3.2 Extending conventional Crossover Ground State to $T \neq 0$: BEC limit without Feshbach Bosons

How do we extend [28] this picture to finite T? In the BEC limit, as shown in Fig. 24.4, fermion pairs are well established or "pre-formed" within the entire range of superconducting

temperatures. The fundamental constraint associated with the BEC regime is that: *for all $T \leq T_c$, there should, thus, be no temperature dependence in fermionic energy scales. In this way Eqs. (24.51) and (24.52) must be imposed at all temperatures T.*

$$\frac{m}{4\pi a_s} = \sum_{\mathbf{k}} \left[\frac{1}{2\epsilon_{\mathbf{k}}} - \frac{1}{2E_{\mathbf{k}}} \right], \tag{24.61}$$

$$n = \sum_{\mathbf{k}} \left[1 - \frac{\epsilon_{\mathbf{k}} - \mu}{E_{\mathbf{k}}} \right], \quad T \leq T_c \,. \tag{24.62}$$

It follows that the number of pairs at $T = 0$ should be equal to the number of pairs at $T = T_c$. However, all pairs are condensed at $T = 0$. Clearly, the character of these pairs changes so that at T_c, all pairs are noncondensed. To implement these physical constraints (and to anticipate the results of a more microscopic theory) we write

$$n_{pairs} = \frac{n}{2} = Z_0 \Delta^2 \tag{24.63}$$

$$n_{pairs} = n_{pairs}^{condensed}(T) + n_{pairs}^{noncondensed}(T) \tag{24.64}$$

so that we may decompose the excitation gap into two contributions

$$\Delta^2 = \Delta_{sc}^2(T) + \Delta_{pg}^2(T) \tag{24.65}$$

where $\Delta_{sc}(T)$ corresponds to condensed and $\Delta_{pg}(T)$ to the noncondensed gap component. Each of these are proportional to the respective number of condensed and noncondensed pairs with proportionality constant Z_0. At T_c,

$$n_{pairs}^{noncondensed} = \frac{n}{2} = \sum_{\mathbf{q}} b(\Omega_q, T_c) \,, \tag{24.66}$$

where $b(x)$ is the usual Bose-Einstein function and Ω_q is the unknown dispersion of the noncondensed pairs. Thus

$$\Delta_{pg}^2(T_c) = Z_0^{-1} \sum b(\Omega_q, T_c) = \frac{n}{2} Z_0^{-1} \,. \tag{24.67}$$

We may deduce directly from Eq. (24.67) that $\Delta_{pg}^2 = -\sum_Q t(Q)$, if we presume that below T_c, the noncondensed pairs have propagator

$$t(Q) = \frac{Z_0^{-1}}{\Omega - \Omega_q} \,. \tag{24.68}$$

It is important to stress that the dispersion of the pairs Ω_q cannot be put in by hand. It is not known a priori. Rather, it has be to *derived* according to the constraints imposed by Eqs. (24.61) and (24.62). We can only arrive at an evaluation of Ω_q after establishing the nature of the appropriate T-matrix theory. In what follows we derive this dispersion using the two channel model. We state the one channel results here for completeness. In the absence of FB, $\Omega_q \equiv B_0 q^2$, where $B_0 \equiv 1/(2M_0^*)$. As a consequence of a "bosonic" self energy, which arises from fermion-boson (as distinguished from boson-boson) interactions, the bosonic dispersion is found to be quadratic. This quadratic dependence persists for the two channel case as well.

24.3.3 Extending Conventional Crossover Ground State to $T \neq 0$: T-matrix Scheme in the Presence of Feshbach Bosons

To arrive at the pair dispersion for the noncondensed pairs, Ω_q, we need to formulate a generalized T-matrix based scheme which is consistent with the ground state conditions, and

with the T dependence of strict BCS theory. It is useful from a pedagogical point to now include the effects of Feshbach bosons [164]. Our intuition concerning how true bosons condense is much better than our intuition concerning the condensation of fermion pairs, except in the very limited BCS regime. We may assume that Δ and μ evolve with temperature in such a way as to be compatible *with both the temperature dependences of BCS and with the above discussion for the BEC limit.* We thus take

$$\Delta(T) = -U_{eff} \sum_{\mathbf{k}} \Delta(T) \frac{1 - 2f(E_{\mathbf{k}})}{2E_{\mathbf{k}}}, \tag{24.69}$$

$$n = \sum_{\mathbf{k}} \left[1 - \frac{\epsilon_{\mathbf{k}} - \mu}{E_{\mathbf{k}}} + 2\frac{\epsilon_{\mathbf{k}} - \mu}{E_{\mathbf{k}}} f(E_{\mathbf{k}}) \right], \tag{24.70}$$

where $E_{\mathbf{k}} = \sqrt{(\epsilon_{\mathbf{k}} - \mu)^2 + \Delta^2(T)}$. Note that in the presence of Feshbach bosons, we use n to denote the density of fermionic atoms which is to be distinguished from the constituents of the Feshbach bosons. The total density of particles will be denoted by n^{tot}. *Equations (24.69) and (24.70) will play a central role in this review. They have been frequently invoked in the literature, albeit under the presumption that there is no distinction between $\Delta(T)$ and $\Delta_{sc}(T)$.*

Alternatively one can rewrite Eq. (24.69) as

$$\frac{m}{4\pi a_s^*} = \sum_{\mathbf{k}} \left[\frac{1}{2\epsilon_{\mathbf{k}}} - \frac{1 - 2f(E_{\mathbf{k}})}{2E_{\mathbf{k}}} \right]. \tag{24.71}$$

Clearly Eqs. (24.69) and (24.70) are consistent with Eqs. (24.61) and (24.62) since Fermi functions are effectively zero in the BEC limit. Our task is to find a T-matrix formalism which is compatible with Eqs. (24.69) and (24.70), and to do this we focus first on the *noncondensed* molecular bosons. Their propagator may be written as

$$D(Q) \equiv \frac{1}{i\Omega_n - \epsilon_q^{mb} - \nu + 2\mu - \Sigma_B(Q)}. \tag{24.72}$$

We presume that the self energy of these molecules can be written in the form

$$\Sigma_B(Q) \equiv -g^2 \chi(Q) / [1 + U\chi(Q)], \tag{24.73}$$

where $\chi(Q)$ is as yet unspecified. This RPA-like self energy arises from interactions between the molecular bosons and the fermion pairs, and this particular form is required for self-consistency.

noncondensed bosons in equilibrium with a condensate must necessarily have zero chemical potential.

$$\mu_{boson}(T) = 0, \qquad T \leq T_c. \tag{24.74}$$

This is equivalent to the Hugenholtz-Pines condition that

$$D^{-1}(0) = 0, \quad T \leq T_c. \tag{24.75}$$

Using Eqs. (24.73) and (24.75) it can be seen that

$$U_{eff}^{-1}(0) + \chi(0) = 0, \qquad T \leq T_c. \tag{24.76}$$

This equation can be made compatible with our fundamental constraint in Eq. (24.69) provided we take

$$\chi(Q) = \sum_K G(K) G_0(Q - K), \tag{24.77}$$

where $G(K)$

$$G(K) \equiv [G_0^{-1}(K) - \Sigma(K)]^{-1} \tag{24.78}$$

includes a self energy given by the BCS-form

$$\Sigma(K) = -G_0(-K)\Delta^2\,, \tag{24.79}$$

which now involves the quantity Δ to be distinguished from the order parameter Δ_{sc}. Note that with this form for $\Sigma(K)$, the number of fermions is indeed given by Eq. (24.70).

More generally, we may write the constraint on the total number of particles as follows. The number of noncondensed molecular bosons is given directly by

$$n_b(T) = -\sum_Q D(Q)\,. \tag{24.80}$$

For $T \leq T_c$, the number of fermions is given via Eq. (24.70). The *total* number (n^{tot}) of particles is then

$$n + 2n_b + 2n_b^0 = n^{tot}\,, \tag{24.81}$$

where $n_b^0 = \phi_m^2$ is the number of molecular bosons in the condensate, and ϕ_m is the order parameter for the molecular condensate.

Thus far, we have shown that the condition that noncondensed molecular bosons have zero chemical potential, can be made consistent with Eqs. (24.69) and (24.70) provided we constrain $\chi(Q)$ and $\Sigma(K)$ as above. We now want to examine the counterpart condition on the fermions and their condensate contribution. The analysis leading up to this point should make it clear *that we have both condensed and noncondensed fermion pairs, just as we have both condensed and noncondensed molecular bosons.* Moreover, these fermion pairs and Feshbach bosons are strongly admixed, except in the very extreme BCS and BEC limits. Because of noncondensed pairs, we will see that the excitation gap is distinct from the superconducting order parameter, although in the literature this distinction has not been widely recognized.

Just as the noncondensed molecular bosons have zero chemical potential below T_c we have the same constraint on the noncondensed fermion pairs which are in chemical equilibrium with the noncondensed bosons

$$\mu_{pair} = 0, \qquad T \leq T_c\,. \tag{24.82}$$

The T-matrix scheme in the presence of the Feshbach bosons is shown in Fig. 24.20. Quite generally, the T-matrix consists of two contributions: from the condensed (sc) and noncondensed or "pseudogap"-associated (pg) pairs,

$$t = t_{pg} + t_{sc}\,, \tag{24.83}$$

$$t_{pg}(Q) = \frac{U_{eff}(Q)}{1 + U_{eff}(Q)\chi(Q)}, \qquad Q \neq 0\,, \tag{24.84}$$

$$t_{sc}(Q) = -\frac{\tilde{\Delta}_{sc}^2}{T}\delta(Q)\,, \tag{24.85}$$

where we write $\tilde{\Delta}_{sc} = \Delta_{sc} - g\phi_m$, with $\Delta_{sc} = -U\sum_{\mathbf{k}}\langle a_{-\mathbf{k}\downarrow}a_{\mathbf{k}\uparrow}\rangle$ and $\phi_m = \langle b_{\mathbf{q}=0}\rangle$. Here, the order parameter is a linear combination of both paired fermions and condensed molecules. Similarly, we have two contributions for the fermion self energy

$$\Sigma(K) = \Sigma_{sc}(K) + \Sigma_{pg}(K) = \sum_Q t(Q)G_0(Q-K)\,, \tag{24.86}$$

where, as in BCS theory,

$$\Sigma_{sc}(K) = \sum_Q t_{sc}(Q)G_0(Q-K)\,. \tag{24.87}$$

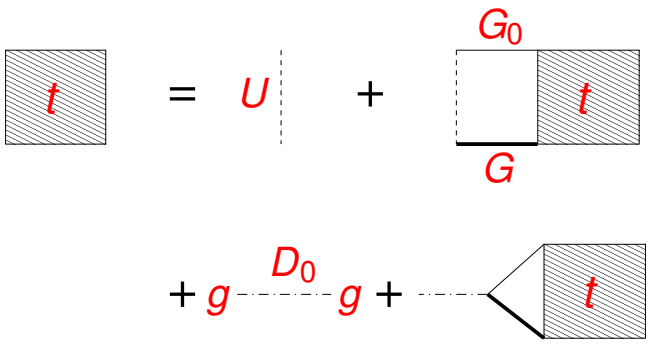

Figure 24.20: Diagrammatic scheme for present T-matrix theory. Here U is the open-channel interaction, g is the coupling between open and closed channels. G_0, G and D_0 are bare fermion, full fermion, and bare Feshbach boson Green's functions, respectively. U and $g_0^2 D_0$ yield an effective pairing interaction, U_{eff}.

Without loss of generality, we choose order parameters $\tilde{\Delta}_{sc}$ and ϕ_m to be real and positive with $g < 0$. Importantly, these two components are connected [93] by the relation $\phi_m = g\Delta_{sc}/[(\nu - 2\mu)U]$.

The vanishing of the pair chemical potential implies that

$$t_{pg}^{-1}(0) = U_{eff}^{-1}(0) + \chi(0) = 0, \qquad T \leq T_c \, . \tag{24.88}$$

This same equation was derived from consideration of the bosonic chemical potential. Most importantly, we argued above that this was consistent with Eq. (24.69) provided the fermion self energy assumes the BCS form. We now verify the assumption in Eq. (24.79). A vanishing chemical potential means that $t_{pg}(Q)$ is strongly peaked around $Q = 0$. Thus, we may approximate [114] Eq. (24.86) to yield

$$\Sigma(K) \approx -G_0(-K)\Delta^2 \, , \tag{24.89}$$

where

$$\Delta^2(T) \equiv \tilde{\Delta}_{sc}^2(T) + \Delta_{pg}^2(T) \, , \tag{24.90}$$

and we define the pseudogap Δ_{pg}

$$\Delta_{pg}^2 \equiv -\sum_{Q \neq 0} t_{pg}(Q). \tag{24.91}$$

This bears a close resemblance to Eq. (24.80), if we write the number of noncondensed fermion pairs and molecular bosons as

$$n_p(T) = Z\Delta_{pg}^2(T) \, . \tag{24.92}$$

Note that in the normal state (where μ_{pair} is nonzero) one cannot make the approximation of Eq. (24.89). Referring back to our discussion of Hartree-approximated TDGL, a strong analogy between Eq. (24.91) and (24.48) should be observed. There is a similar analogy between Eq. (24.69) and (24.49); more details are provided in Appendix 24.10. We thus have that Eqs. (24.51) and (24.89) with Eq. (24.78) are alternative ways of writing Eqs. (24.69) and (24.70). Along with Eq. (24.91) we now have a closed set of equations for addressing the ordered phase. Moreover the propagator for noncondensed pairs can now be quantified, using the self consistently determined pair susceptibility. At moderately strong coupling and at small four-vector Q, we may expand to obtain

$$t_{pg}(Q) = \frac{Z^{-1}}{\Omega - \Omega_q + \mu_{pair} + i\Gamma_Q}, \tag{24.93}$$

Consequently, one can rewrite Eq. (24.91) as

$$\Delta_{pg}^2(T) = Z^{-1} \sum b(\Omega_q, T) \,. \tag{24.94}$$

Here we introduce a simple notation for the small Q expansions:

$$\begin{aligned} \chi(Q) - \chi(0) &= Z_0(i\Omega_n - B_0 q^2), \\ U_{eff}^{-1}(Q) - U_{eff}^{-1}(0) &= Z_g(i\Omega_n - B_g q^2) \end{aligned}$$

with

$$\begin{aligned} Z_0 &= \frac{1}{2\Delta^2}\left[n - 2\sum_{\mathbf{k}} f(\epsilon_{\mathbf{k}} - \mu)\right], \\ Z_g &= \frac{g^2}{[(2\mu - \nu)U + g^2]^2} \,. \end{aligned}$$

We have that $Z = Z_0 + Z_g$, $Z_b = (Z_0 + Z_g)/Z_0$, and the q^2 coefficient $B \equiv 1/(2M^*)$ in $\Omega_q \equiv Bq^2$ is such that

$$B = \frac{B_0 Z_0 + \frac{1}{2M} Z_g}{Z} \,.$$

The strong hybridization between the molecular bosons and fermion pairs should be stressed. Indeed, there is just one branch Ω_q for bosonic-like excitations, so that at small Q

$$D(Q) = \frac{Z_b^{-1}}{\Omega - \Omega_q + \mu_{boson} + i\Gamma_Q}, \tag{24.95}$$

where below T_c, $\mu_{pair} = \mu_{boson} = 0$. Here Γ_Q contains all the imaginary part of the inverse T-matrix and it vanishes rapidly as $Q \to 0$. As the coupling is decreased from the BEC limit towards BCS, the character of the pairs changes from pre-dominantly molecular-boson like to (noncondensed) Cooper pairs, composed only of the fermionic atoms.

24.3.4 Nature of the Pair Dispersion: Size and Lifetime of noncondensed Pairs Below T_c

We may rewrite the pair susceptibility [28, 29] of Eq. (24.77) (after performing the Matsubara sum and analytically continuing to the real axis) in a relatively simple form as

$$\begin{aligned} \chi(Q) = \sum_{\mathbf{k}} \Big[& \frac{1 - f(E_{\mathbf{k}}) - f(\xi_{\mathbf{k}-\mathbf{q}})}{E_{\mathbf{k}} + \xi_{\mathbf{k}-\mathbf{q}} - \Omega - i0^+} u_{\mathbf{k}}^2 \\ & - \frac{f(E_{\mathbf{k}}) - f(\xi_{\mathbf{k}-\mathbf{q}})}{E_{\mathbf{k}} - \xi_{\mathbf{k}-\mathbf{q}} + \Omega + i0^+} v_{\mathbf{k}}^2 \Big] \,, \end{aligned} \tag{24.96}$$

where $u_{\mathbf{k}}^2$ and $v_{\mathbf{k}}^2$ are given by their usual BCS expressions in terms of Δ and $\xi_{\mathbf{k}} \equiv \epsilon_{\mathbf{k}} - \mu$. In the long wavelength, low frequency limit, the inverse of t_{pg} can be written as

$$a_1\Omega^2 + Z_0(\Omega - \frac{q^2}{2M^*} + \mu_{pair} + i\Gamma_Q). \tag{24.97}$$

We are interested in the moderate and strong coupling cases, where we can drop the $a_1\Omega^2$ term in Eq. (24.97), and hence we have Eq. (24.93) with

$$\Omega_{\mathbf{q}} \equiv \frac{q^2}{2M^*} = \frac{q^2 \xi_{pg}^2}{Z_0} \,. \tag{24.98}$$

This establishes a quadratic dispersion and defines the effective pair mass, M^*. Analytical expressions for this mass are possible via a small $\mathbf{q}$ expansion of χ, in Eq. (24.96). It is important to note that the pair mass reflects the effective *size* ξ_{pg} of noncondensed pairs. This serves to emphasize the fact that the q^2 dispersion derives from the compositeness of the "bosons", in the sense of their finite spatial extent. A description of the system away from the BEC limit must accommodate the fact that the pairs have an underlying fermionic character. This pair mass has a different origin from the mass renormalization associated with real interacting bosons. There one finds a mass shift which comes from a Hartree approximate treatment of their q-dependent interactions. Finally, we note that ξ_{pg} is comparable to the size ξ of pairs in the condensate. In the weak coupling BCS limit, a small Q expansion of χ_0 shows that, because the leading order term in Ω is purely imaginary, the Ω^2 contribution cannot be neglected. The T-matrix, then, does not have the propagating q^2 dispersion, discussed above.

It follows from Eq. (24.96) that the pair lifetime

$$\begin{aligned}\Gamma_Q &= \frac{\pi}{Z_0}\sum_{\mathbf{k}}\left[1-f(E_{\mathbf{k}})-f(\xi_{\mathbf{k}-\mathbf{q}})\right]u_{\mathbf{k}}^2\delta(E_{\mathbf{k}}+\xi_{\mathbf{k}-\mathbf{q}}-\Omega)\\ &\quad+\left[f(E_{\mathbf{k}})-f(\xi_{\mathbf{k}-\mathbf{q}})\right]v_{\mathbf{k}}^2\delta(E_{\mathbf{k}}-\xi_{\mathbf{k}-\mathbf{q}}+\Omega)\,. \end{aligned} \tag{24.99}$$

Here Γ_Q reflects the rate of decay of noncondensed bosons into a bare and dressed fermion. Note that the excitation gap in $E_{\mathbf{k}}$ significantly restricts the contribution from the δ functions. Thus, *the decay rate of pair excitations is greatly suppressed, due to the excitation gap (for fermions) in the superconducting phase*. Even in the normal phase pairs live longer than one might have anticipated from "Pauli blocking" arguments which are based on evaluating Γ_Q in a Fermi liquid state. However, the same equations are not strictly valid above T_c, because Eq. (24.89) no longer holds. To compute the pair lifetime in the normal state requires a more extensive calculation involving the full T-matrix self consistent equations and their numerical solution [78, 114, 115].

24.3.5 T_c Calculations: Analytics and Numerics

Calculations of T_c can be performed using Eqs. (24.69) and (24.70) along with Eq. (24.91). The T-matrix is written in the expanded form of Eq. (24.93), which is based on the pair dispersion as derived in the previous section. For the most part the calculations proceed numerically.

A typical curve is plotted in Fig. 24.21, where the three regimes BCS, BEC and PG are indicated. For positive, but decreasing the magnetic detuning ν_0, T_c follows the BCS curve until the "pseudogap" or $\Delta(T_c)$ becomes appreciable. After its maximum (near the unitary limit, at slightly negative ν_0), T_c decreases, (as does μ), to reach a minimum at $\mu \approx 0$. This decrease in T_c reflects the decreasing number of low energy fermions due to the opening of a pseudogap. Beyond this point, towards negative ν_0, the system is effectively bosonic, and the superconductivity is no longer hampered by pseudogap effects. In the presence of FB, the condensate consists of two contributions, although the weight of the fermion pair component rapidly disappears. Similarly T_c rises, although slowly, towards the ideal BEC asymptote, following the inverse effective boson mass. The corresponding curve based on the NSR approach [128] has only one extremum, but nevertheless the overall magnitudes are not so different [131, 123].

Analytic results are obtainable in the near-BEC limit only. The general expression for the effective mass $1/M_0^*$ in this limit is given by

$$\frac{1}{M_0^*} = \frac{1}{Z_0\Delta^2}\sum_{\mathbf{k}}\left[\frac{1}{m}v_{\mathbf{k}}^2 - \frac{4E_{\mathbf{k}}k^2}{3m^2\Delta^2}v_{\mathbf{k}}^4\right], \tag{24.100}$$

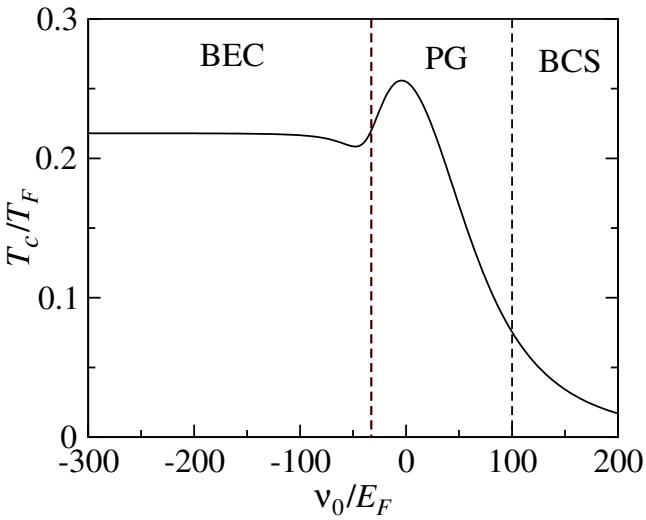

Figure 24.21: Typical behavior of T_c in the homogeneous case. For the purposes of illustration, this calculation includes Feshbach effects. T_c follows BCS for large magnetic detuning parameter ν_0 and approaches the BEC asymptote 0.218 for large negative ν_0. It reaches a maximum at unitarity, and has a minimum when the fermionic chemical potential μ changes sign.

where here FB effects have been dropped for simplicity. In what follows, we expand Eq. (24.100) in powers of na_s^3 and obtain after some algebra

$$M_0^* \approx 2m \left(1 + \frac{\pi a_s^3 n}{2}\right) . \tag{24.101}$$

We now invoke an important constraint, derived earlier in Eq. (24.66) which corresponds to the fact that at T_c all fermions are constituents of uncondensed pairs

$$\frac{n}{2} = \sum_{\mathbf{q}} b(\Omega_{\mathbf{q}}, T_c) . \tag{24.102}$$

From the above equation it follows that $(M^* T_c)^{3/2} \propto n = const.$ which, in conjunction with Eq. (24.101) implies

$$\frac{T_c - T_c^0}{T_c^0} = -\frac{\pi a_s^3 n}{2}. \tag{24.103}$$

Here T_c^0 is the transition temperature of the ideal Bose gas with $M_0 = 2m$. This downward shift of T_c follows the effective mass renormalization, much as expected in a Hartree treatment of GP theory at T_c. Here, however, in contrast to GP theory for a homogeneous system with a contact potential [41], there is a non-vanishing renormalization of the effective mass. This is a key point which underlines the importance in this approach of the fermionic degrees of freedom, even at very strong coupling.

24.4 Self Consistency Tests

All T-matrix approaches to the BCS-BEC crossover problem must be subject to self consistency tests. Among these, one should demonstrate that *normal state* self energy effects within a T-matrix scheme are not associated with superfluidity or superconductivity [96]. While this seems at first sight straightforward, all theories should be put to this test. Thus for a charged system, a meaningful result for the superfluid density ρ_s requires that there be an exact cancellation between diamagnetic and paramagnetic current contributions at T_c. In this way self

energy effects in the number equation and gap equation must be treated in a consistent fashion. In the following we address some of these self consistency issues in the context of the asymmetric ($\chi \approx GG_0$) BCS-BEC crossover scheme. Other crossover theories with different forms for the pair susceptibility should also be subjected to these tests. We begin with a summary of calculations [97, 162] of the Meissner effect, followed by a treatment of the collective mode spectrum. Our discussion in this section is presented for the one channel problem, in the absence of Feshbach effects.

24.4.1 Important check: behavior of ρ_s

The superfluid density may be expressed in terms of the local (static) electromagnetic response kernel $K(0)$

$$n_s = \frac{m}{e^2} K(0) = n - \frac{m}{3\,e^2} P_{\alpha\alpha}(0) \; , \tag{24.104}$$

with the current-current correlation function given by

$$\begin{aligned} P_{\alpha\beta}(Q) &= -2\,e^2 \sum_K \lambda_\alpha(K, K+Q)\, G(K+Q) \\ &\quad \times \Lambda^{EM}_\beta(K+Q, K)\, G(K) \; . \end{aligned} \tag{24.105}$$

Here the bare vertex $\lambda(K, K+Q) = \frac{1}{m}(\mathbf{k} + \mathbf{q}/2)$ and we consider $Q = (\mathbf{q}, 0)$, with $\mathbf{q} \to 0$. We write $\mathbf{\Lambda}^{EM} = \lambda + \delta\mathbf{\Lambda}_{pg} + \delta\mathbf{\Lambda}_{sc}$, where the pseudogap contribution $\delta\mathbf{\Lambda}_{pg}$ to the vertex correction will be shown in Appendix 24.9 to satisfy a Ward identity below T_c

$$\delta\mathbf{\Lambda}^{pg}(K, K) = \frac{\partial \Sigma_{pg}(K)}{\partial \mathbf{k}} \; . \tag{24.106}$$

By contrast for the superconducting contributions, one has

$$\delta\mathbf{\Lambda}^{sc}(K, K) = -\frac{\partial \Sigma_{sc}(K)}{\partial \mathbf{k}} \; . \tag{24.107}$$

This important difference in sign is responsible for the fact that the Meissner effect is associated with superconductivity, and not with a normal state self energy.

The particle density n, after partial integration can be rewritten as $n = -(2/3)\sum_K \mathbf{k} \cdot \partial_{\mathbf{k}} G(K)$. Then, as a result of Dyson's equation, one arrives at the following general expression which relates to the diamagnetic contribution

$$n = -\frac{2}{3} \sum_K G^2(K) \left[\frac{k^2}{m} + \mathbf{k} \cdot \frac{\partial \Sigma_{pg}(K)}{\partial \mathbf{k}} + \mathbf{k} \cdot \frac{\partial \Sigma_{sc}(K)}{\partial \mathbf{k}} \right] \; . \tag{24.108}$$

Now, inserting Eqs. (24.108) and (24.105) into Eq. (24.104) one can see that the pseudogap contribution to n_s drops out by virtue of Eq. (24.106); we find

$$n_s = \frac{2}{3} \sum_K G^2(K)\, \mathbf{k} \cdot \left(\delta\mathbf{\Lambda}_{sc} - \frac{\partial \Sigma_{sc}}{\partial \mathbf{k}} \right) \; . \tag{24.109}$$

We emphasize that the cancellation of this pseudogap contribution to the Meissner effect is the central physics of this analysis, and it depends on treating self energy effects in a Ward-identity-consistent fashion.

We also have that

$$\delta\mathbf{\Lambda}_{sc}(K+Q, K) = \Delta_{sc}^2 G_0(-K-Q) G_0(-K) \lambda(K+Q, K) \; . \tag{24.110}$$

Inserting Eqs. (24.87), (24.89), and (24.110) into Eq. (24.109), after calculating the Matsubara sum, one arrives at

$$n_s = \frac{4}{3}\sum_{\mathbf{k}} \frac{\Delta_{sc}^2}{E_{\mathbf{k}}^2}\epsilon_{\mathbf{k}} \left[\frac{1-2\,f(E_{\mathbf{k}})}{2\,E_{\mathbf{k}}} + f'(E_{\mathbf{k}})\right] . \tag{24.111}$$

This expression can be simply rewritten in terms of the BCS result for the superfluid density

$$\left(\frac{n_s}{m}\right) = \frac{\Delta_{sc}^2}{\Delta^2}\left(\frac{n_s}{m}\right)^{BCS} . \tag{24.112}$$

Here $(n_s/m)^{BCS}$ is just (n_s/m) with the overall prefactor Δ_{sc}^2 replaced with Δ^2.

Finally we can rewrite Eq. (24.112) using Eq. (24.90) as

$$\left(\frac{n_s}{m}\right) = \left[1 - \frac{\Delta_{pg}^2}{\Delta^2}\right]\left(\frac{n_s}{m}\right)^{BCS} . \tag{24.113}$$

In this form it is evident that (via Δ_{pg}^2) *pair excitations out of the condensate are responsible for a suppression of the superfluid density relative to that obtained from fermionic excitations only [163].*

24.4.2 Collective Modes and Gauge Invariance

The presence of pseudogap self energy effects greatly complicates the computation of collective modes [97]. This is particularly apparent at nonzero temperature. Once dressed Green's functions G enter into the calculational schemes, the collective mode polarizabilities and the electromagnetic (EM) response tensor must necessarily include vertex corrections dictated by the form of the self-energy Σ, which depends on the T-matrix which, in turn depends on the form of the pair susceptibility χ. These necessary vertex corrections are associated with gauge invariance in the same way, as was seen for ρ_s, and discussed in Appendix 24.9. Collective modes are important in their own right, particularly in neutral superfluids, where they can be directly detected as signatures of long range order. They also must be invoked to arrive at a gauge invariant formulation of electrodynamics. It is relatively straightforward to introduce these collective mode effects into the electromagnetic response in a completely general fashion that is required by gauge invariance. The difficulty is in the implementation.

In the presence of a weak externally applied EM field, with four-vector potential $A^\mu = (\phi, \mathbf{A})$, the four-current density $J^\mu = (\rho, \mathbf{J})$ is given by

$$J^\mu(Q) = K^{\mu\nu}(Q)A_\nu(Q) , \tag{24.114}$$

where $K^{\mu\nu}(Q)$ is the EM response kernel.

The incorporation of gauge invariance into a general microscopic theory may be implemented in several ways. Here we do so via a generalized matrix Kubo formula [99] in which the perturbation of the condensate is included as additional contributions $\Delta_1 + i\Delta_2$ to the applied external field. These contributions are self consistently obtained (by using the gap equation) and then eliminated from the final expression for $K^{\mu\nu}$. We now implement this procedure. Let $\eta_{1,2}$ denote the change in the expectation value of the pairing field $\hat{\eta}_{1,2}$ corresponding to $\Delta_{1,2}$. For the case of an s-wave pairing interaction $U < 0$, the self-consistency condition $\Delta_{1,2} = U\eta_{1,2}/2$ leads to the following equations:

$$J^\mu = K^{\mu\nu}A_\nu = K_0^{\mu\nu}A_\nu + R^{\mu 1}\Delta_1 + R^{\mu 2}\Delta_2 , \tag{24.115a}$$

$$\eta_1 = -\frac{2\Delta_1}{|U|} = R^{1\nu}A_\nu + Q_{11}\Delta_1 + Q_{12}\Delta_2 , \tag{24.115b}$$

$$\eta_2 = -\frac{2\Delta_2}{|U|} = R^{2\nu}A_\nu + Q_{21}\Delta_1 + Q_{22}\Delta_2 , \tag{24.115c}$$

where

$$K_0^{\mu\nu}(\omega,\mathbf{q}) = P^{\mu\nu}(\omega,\mathbf{q}) + \frac{ne^2}{m} g^{\mu\nu}(1-g^{\mu 0}) \tag{24.116}$$

is the usual Kubo expression for the electromagnetic response. We define the current-current correlation function $P^{\mu\nu}(\tau,\mathbf{q}) = -i\theta(\tau)\langle[j^\mu(\tau,\mathbf{q}), j^\nu(0,-\mathbf{q})]\rangle$. In the above equation, $g^{\mu\nu}$ is a (diagonal) metric tensor with elements $(1,-1,-1,-1)$. We define

$$R^{\mu i}(\tau,\mathbf{q}) = -i\theta(\tau)\langle[j^\mu(\tau,\mathbf{q}), \hat{\eta}_i(0,-\mathbf{q})]\rangle \tag{24.117}$$

with $\mu = 0,\ldots,3$, and $i,j = 1,2$; and

$$Q_{ij}(\tau,\mathbf{q}) = -i\theta(\tau)\langle[\hat{\eta}_i(\tau,\mathbf{q}), \hat{\eta}_j(0,-\mathbf{q})]\rangle \tag{24.118}$$

Finally, it is convenient to define

$$\tilde{Q}_{ii} = 2/U + Q_{ii}\ . \tag{24.119}$$

In order to demonstrate gauge invariance and reduce the number of component polarizabilities, we first rewrite $K^{\mu\nu}$ in a way which incorporates the effects of the amplitude contributions via a renormalization of the relevant generalized polarizabilities,

$$K'^{\mu\nu}_0 = K^{\mu\nu}_0 - \frac{R^{\mu 1}R^{1\nu}}{\tilde{Q}_{11}}\ , \tag{24.120}$$

It can be shown, after some analysis, that the gauge invariant form for the response tensor is given by

$$K^{\mu\nu} = K'^{\mu\nu}_0 - \frac{\left(K'^{\mu\nu'}_0 q_{\nu'}\right)\left(q_{\nu''}K'^{\nu''\nu}_0\right)}{q_{\mu'}K'^{\mu'\nu'}_0 q_{\nu'}}\ . \tag{24.121}$$

The above equation satisfies two important requirements: it is manifestly gauge invariant and, moreover, it has been reduced to a form that depends principally on the four-current-current correlation functions. (The word "principally" appears because in the absence of particle-hole symmetry, there are effects associated with the order parameter amplitude contributions that add to the complexity of the calculations).

The EM response kernel of a superconductor contains a pole structure that is related to the underlying Goldstone boson of the system. Unlike the phase mode component of the collective mode spectrum, this Anderson-Bogoliubov (AB) mode is independent of Coulomb effects. The dispersion of this amplitude renormalized AB mode is given by

$$q_\mu K'^{\mu\nu}_0 q_\nu = 0\ . \tag{24.122}$$

For an isotropic system $K'^{\alpha\beta}_0 = K'^{11}_0\delta_{\alpha\beta}$, and Eq. (24.122) can be rewritten as

$$\omega^2 K'^{00}_0 + \mathbf{q}^2 K'^{11}_0 - 2\omega q_\alpha K'^{0\alpha}_0 = 0\ , \tag{24.123}$$

with $\alpha = 1,2,3$, and in the last term on the left hand side of Eq. (24.123) a summation over repeated Greek indices is assumed.

It might seem surprising that from an analysis which incorporates a complicated matrix linearized response approach, the dispersion of the AB mode ultimately involves only the amplitude renormalized four-current correlation functions, namely the density-density, current-current and density-current correlation functions. The simplicity of this result is, nevertheless, a consequence of gauge invariance.

At zero temperature $K'^{0\alpha}_0$ vanishes, and the sound-like AB mode has the usual linear dispersion $\omega = \omega_{\mathbf{q}} = c|\mathbf{q}|$ with the "sound velocity" given by

$$c^2 = K'^{11}_0/K'^{00}_0\ . \tag{24.124}$$

We may, thus, interpret the AB mode as a special type of collective mode which is associated with $A_\nu = 0$. This mode corresponds to free oscillations of $\Delta_{1,2}$ with a dispersion $\omega = cq$ given by the solution to the equation

$$\det|Q_{ij}| = \tilde{Q}_{11}\tilde{Q}_{22} - Q_{12}Q_{21} = 0 \; . \tag{24.125}$$

The other collective modes of this system are derived by including the coupling to electromagnetic fields. Within self-consistent linear response theory the field $\delta\phi$ must be treated on an equal footing with $\Delta_{1,2}$ and formally can be incorporated into the linear response of the system by adding an extra term $K_0^{\mu 0}\delta\phi$ to the right hand side of Eqs. (24.115a), (24.115b), and (24.115c). Note that, quite generally, the effect of the "external field" $\delta\phi$ amounts to replacing the scalar potential $A^0 = \phi$ by $\bar{A}^0 = \bar{\phi} = \phi + \delta\phi$. In this way one arrives at the following set of three linear, homogeneous equations for the unknowns $\delta\phi$, Δ_1, and Δ_2

$$0 = R^{10}\delta\phi + \tilde{Q}_{11}\Delta_1 + Q_{12}\Delta_2 \; , \tag{24.126a}$$

$$0 = R^{20}\delta\phi + Q_{21}\Delta_1 + \tilde{Q}_{22}\Delta_2 \; , \tag{24.126b}$$

$$\delta\rho = \frac{\delta\phi}{V} = K_0^{00}\delta\phi + R^{01}\Delta_1 + R^{02}\Delta_2 \; , \tag{24.126c}$$

where V is an effective particle-hole interaction which may derive from the pairing channel or, in a charged superconductor, from the Coulomb interaction. The dispersion of the collective modes of the system is given by the condition that the above equations have a nontrivial solution

$$\begin{vmatrix} Q_{11} + 1/U & Q_{12} & R^{10} \\ Q_{21} & Q_{22} + 1/U & R^{20} \\ R^{01} & R^{02} & K_0^{00} - 1/V \end{vmatrix} = 0 \; . \tag{24.127}$$

In the BCS limit where there is particle-hole symmetry $Q_{12} = Q_{21} = R^{10} = R^{01} = 0$ and, the amplitude mode decouples from the phase and density modes; the latter two are, however, in general coupled.

The above formalism (or its equivalent RPA variations [39, 13]) has been applied to address collective modes in the crossover scenario. The most extensive studies have been at $T = 0$ based on the ground state of Eq. (24.1). There one finds a smooth change in the character of the Anderson-Bogoliubov (AB) mode. At weak coupling one obtains the usual BCS value $c = v_F/\sqrt{3}$. By contrast at strong coupling, the collective mode spectrum reflects [13] an effective boson-boson interaction deriving from the Pauli statistics of the constituent fermions. This is most clearly seen in jellium models [61, 97] where the AB sound velocity is equivalent to that predicted for a 3D interacting Bose gas $c = [4\pi n a_B/m_B^2]^{1/2}$. Here, as earlier, the inter-boson scattering length is twice that of the inter-fermionic counterpart, at strong coupling.[35]

The effects of finite temperature on the AB mode have been studied in [97], by making the approximation that the temperature dependence of the order parameter amplitude contribution is negligible. Then the calculation of this dispersion reduces to calculations of the electromagnetic response, as discussed, for example in ρ_s. See also Appendix 24.9. At finite T, the AB mode becomes damped and the real and imaginary parts of the sound velocity have to be calculated numerically. Here one finds, as expected, that the complex $c \to 0$ as $T \to T_c$. The results are plotted in Fig. 24.22 for both moderate and weak coupling. Because the real and imaginary parts are comparable there, the mode is highly damped near T_c.

[35] In the neutral case, for the full collective modes of Eq. (24.127), there are numerical differences (of order unity) in the prefactors of the mode frequency, so that the collective modes of the crossover theory are not strictly the same as in GP theory. In these calculations V in Eq. (24.127) should be associated with the pairing interaction, which enters in the context of fermionic density-density correlation effects within the particle-hole channel.

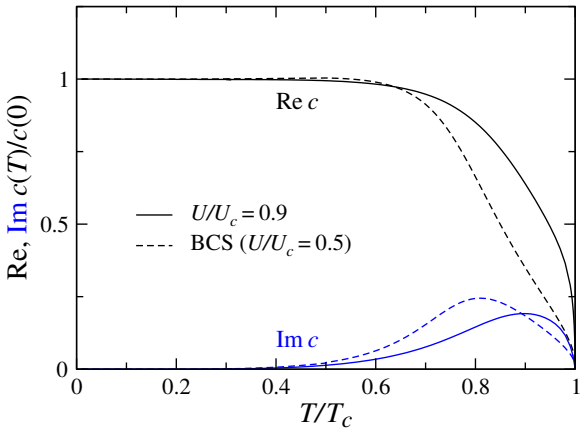

Figure 24.22: Temperature dependence of the real and imaginary parts of the AB collective mode velocity for moderate (solid lines) and weak (dashed lines) coupling. The velocity vanishes at T_c for both cases.

24.4.3 Investigating the Applicability of a Nambu Matrix Green's Function Formulation

Diagrammatic schemes appropriate to BCS superconductors are based on a Nambu matrix Green's function approach. The off-diagonal or anomalous Green's functions in this matrix are given by

$$F(K) \equiv \Delta_{sc} G(K) G_0(-K) \tag{24.128}$$

as well as its Hermitian conjugate. This Nambu formalism was designed to allow study of perturbations to the BCS state, due to, for example, external fields or impurities. For these perturbations the central assumption is that they act on both the "normal" (with BCS Green's function $G(K)$ from Eq. (24.30)) and anomalous channels in a symmetrical way.

Understanding as we now do that BCS theory is a very special case of superconductivity, this raises the caution that once one goes beyond BCS, some care should be taken to justify this Nambu approach. At the very least the distinction between the order parameter Δ_{sc} and the excitation gap Δ raises ambiguity about applying a diagrammatic theory based on Nambu-Gor'kov Green's functions.

More importantly, in treating the effects of the pseudogap self energy Σ_{pg} as we do here, it should be clear that this self energy does *not* play a symmetric role in the anomalous and normal channels. It is viewed here as an entirely normal state effect. However this theory accommodates the equivalent [97] of the Nambu-Gor'kov "F"- function in general response functions such as in the Maki-Thompson diagrams of Appendix 24.9 through the asymmetric combination GG_0 which always arises in pairs (for example, as the FF combinations of BCS theory). In this regard the GG_0 formalism appears to differ from all other T-matrix schemes which are designed to go below T_c, in that the Nambu scheme is not assumed at the start. Nevertheless, many features of this formalism seem to naturally arise in large part because of Eq. (24.128), which demonstrates an intimate connection between GG_0 and the conventional diagrams of BCS theory.

24.5 Other Theoretical Approaches to the Crossover Problem

24.5.1 $T \neq 0$ Theories

We have noted in Section 24.2.7 that there are three main theoretical approaches to the crossover problem based on T-matrix theories. Their differences are associated with differ-

ent forms for the pair susceptibility χ. The resulting calculations of T_c show similar variations. When two full Green's functions are present in χ (as in the FLEX approach), T_c varies monotonically [63] with increasing attractive coupling, approaching the ideal gas Bose-Einstein asymptote from below. When two bare Green's functions are present in χ, as in the work of Noziéres and Schmitt-Rink, and of Randeria and co-workers, then T_c overshoots [128, 144, 118] the BEC asymptote and ultimately approaches it from above. Finally when there is one bare and one dressed Green's function, T_c first overshoots and then decreases to a minimum around $\mu = 0$, eventually approaching the asymptote from below [115]. This last appears to be a combination of the other two approaches. Overall the magnitudes are relatively similar and the quantitative differences are small. There is, finally, another body of work [58] based on the GG_0 scheme which should be noted here. The approach by the Swiss group seeks to make contact with the phase fluctuation scenario for high T_c superconductors and addresses STM and ARPES data.

Bigger differences appear when these T-matrix theories are extended below T_c. Detailed studies are most extensive for the NSR approach. Below T_c one presumes that the T-matrix (or χ) contains only bare Green's functions, but these functions are now taken to correspond to their Nambu matrix form, with the order parameter Δ_{sc} appearing in the dispersion relation for excited fermions [144, 139]. A motivation for generalizing the below- T_c T-matrix in this way is that one wants to connect to the collective mode spectrum of the superconductor, so that the dispersion relation for pair excitations is $\Omega_q \approx cq$. In this way the system would be more directly analogous to a true Bose system.

Self energy effects are also incorporated below T_c but only in the number equation, either in the approximate manner of NSR [144, 61] or through use of the full Dyson resummation [139] of the diagonal Nambu-matrix component $G(\Sigma_0)$. For the latter scheme, Strinati's group has addressed pseudogap effects in some detail with emphasis on the experimentally observed fermionic spectral function. Some concern can be raised that the fermionic excitations in the gap equation do not incorporate this pseudogap, although these pairs are presumed to emerge out of a normal state which has a pseudogap. Indeed, this issue goes back to the original formulation of NSR, which includes self energy effects in the number equation, and not in the gap equation.

Tchernyshyov [171] presented one of the first discussions below T_c for the FLEX-based T-matrix scheme. He also addressed pseudogap effects and found a suppression of the fermion density of states at low energy which allows for long-lived pair excitations inside this gap. At low momenta and frequencies, their dispersion is that of a Bogoliubov-sound-like mode with a nonzero mass. Some of these ideas have been recently extended [48] to apply to the boson-fermion model.

The work of Micnas and collaborators [119] which is also based on the FLEX scheme predates the work of Tchernyshyov, although their initial focus was above T_c in two dimensional Hubbard models. Here the fermionic spectral functions were studied in detail, using a numerically generated solution of the T-matrix equations. A nice review of their large body of work on "real space pairing" in the cuprates was presented based on a variety of different model Hamiltonians [121].

An extensive body of work on the FLEX scheme has been contributed by Yamada and Yanatse [189] both above and below T_c. They point out important distinctions between their approach and that of NSR. The effects of the broken symmetry are treated in a generalized Nambu formalism, much as assumed by Pieri *et al.* ([139]) and by Griffin and Ohashi ([61]), but here the calculations involve self energy effects in both the number and gap equations. Their work has emphasized the effects of the pseudogap on magnetic properties, but they have discussed a wide variety of experiments in high T_c and other exotic superconductors.

The nature of the ground states which result from these two alternatives ($\chi \approx GG$ and

$\chi \approx G_0 G_0$) has yet to be clearly established. It should be noted that, despite the extensive body of work based on the NSR or $G_0 G_0$ scheme, no detailed picture has been presented in the literature of the nature of the ground state which results when their calculations at T_c are extrapolated [139] down to $T = 0$. In large part, the differences between other work in the literature and that summarized in Sections 24.3.3 are due to the whether (as in NSR-based papers) or not (as here) the superconducting order parameter Δ_{sc} alone characterizes the fermionic dispersion below T_c.

One might well ask the question: because the underlying Hamiltonian [Eq. (24.11)] is associated with inter-fermionic, not inter-bosonic interactions, will this be reflected in the near-BEC limit of the crossover problem? The precise BEC limit is, of course, a non-interacting, or ideal Bose gas, but away from this limit, fermionic degrees of freedom would seem to be relevant in ways that may not be accounted for by the analogue treatment of the weakly interacting Bose gas. The most extensive study (albeit, above T_c) of this issue is due to Pieri and Strinati [140]. Their work, importantly, points out the inadequacies of T-matrix schemes, particularly at strong coupling. While the ground state in their calculations is unknown, it is necessarily different from the conventional crossover state of Eq. (24.1). There is much intuition to be gained by studying this simplest of all ground states, as outlined in this Review, but it will clearly be of great value in future to consider states, in which, for example, there is less than full condensation.

Finally, we note that studies of non-s wave orbital pairing states in the context of the BCS-BEC crossover problem have rapidly proliferated in the literature. This is, in large part because of the observed d-wave pairing in the cuprates. Indeed, Leggett's initial work [187], addressed p-wave pairing in ^3He. Randeria and co-workers [144] also considered non-s wave pairing. Studies [7, 67] of this crossover for a d-wave lattice case are plentiful at $T = 0$. Even earlier work was done [29] on extensions of this ground state to include nonzero temperature. Moreover, a d-wave continuum model has also been considered [143]. It is expected that in the near future cold atom experiments will begin to address $l \neq 0$ pairing via appropriate choices of the Feshbach resonances [69].

24.5.2 Boson-Fermion Models for High T_c Superconductors

The notion that it might be appropriate to include bosonic degrees of freedom in high T_c superconductors goes back to T.D. Lee and R. Friedberg who introduced [54, 55] the "boson-fermion" model within three years of the discovery of cuprate superconductivity. The work of Lee and colleagues is based on the Hamiltonian of Eq. (24.11) without the direct fermion-fermion interaction U. To our knowledge this is the first study which argues for something akin to "real space pairing" in these materials. Interestingly, this work was motivated only by the observed short coherence length. Pseudogap effects, which make this case much stronger, had not yet been properly characterized. The analogies with He^4 and a more BEC-like picture of superconductivity were discussed, as well as the superfluid density, and energy gap structure, albeit for s-wave pairing.

Subsequent work on this model Hamiltonian in the context of the high T_c copper oxides was pursued by Ranninger and Micnas and their collaborators. Indeed, Ranninger and Robaszkiewicz [145] were the first to write down the boson-fermion model, although initially, in an entirely different context, the bosons were associated with phonons rather than electron pairs, and they were presumed to be localized. In this context they addressed mean field theoretic solutions below T_c as well as more recently [48] an approach based on renormalization group techniques. The physical picture which emerges leads to two gap structures below T_c, one associated with a pseudogap and another with the superconductivity. In this way it appears to be very different from approaches based on Eq. (24.1).

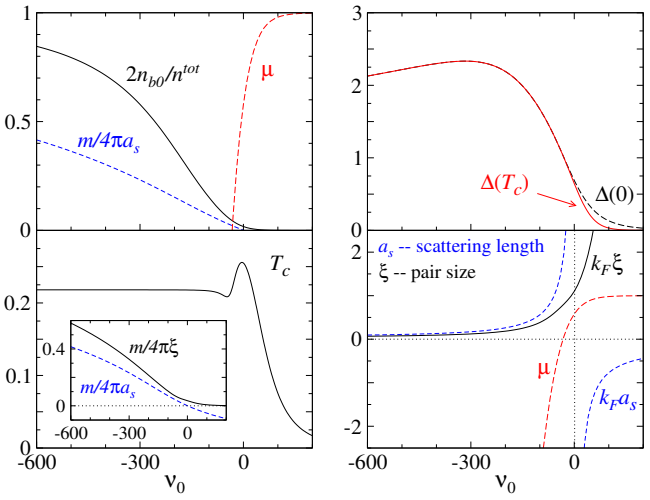

Figure 24.23: (Color) Characteristics of the ground state and T_c as a function of the magnetic detuning ν_0 in a homogeneous case. Shown are the chemical potential μ, fraction of molecular condensate $2n_{b0}/n^{tot}$, inverse scattering length $m/4\pi a_s$, gap $\Delta(0)$, inverse pair size $m/4\pi\xi$, dimensionless relative pair size $k_F\xi$ at $T = 0$ as well as T_c and $\Delta(T_c)$. The pair size is roughly the same as inter-particle spacing, $k_F\xi = 1$, at unitarity. As ν_0 decreases, the gap Δ increases and reaches a maximum, and then decreases slowly and approaches its BEC asymptote (not shown) from above. Here we take $g_0 = -40E_F/k_F^{3/2}$ and $U_0 = -3E_F/k_F^3$, and we use the convention for units $E_F = k_F = \hbar = k_B = 2m = 1$. A large exponential momentum cutoff, $k_c/k_F = 80$ is assumed in the calculations.

24.6 Physical Implications: Ultracold Atom Superfluidity

24.6.1 Homogeneous case

In this section we summarize the key characteristics of fermionic superfluidity in ultracold gases, in the homogeneous situation, without introducing the trap potential. Our results are based on numerical solution of the coupled Eqs. (24.69), (24.70) and (24.91). The upper left panel of Fig. 24.23 plots the fermionic chemical potential, the Feshbach boson condensate ratio and the inverse scattering length as a function of ν_0. Here we have chosen what we believe is the physically appropriate value for the Feshbach coupling $g_0 = -40E_F/k_F^3$ for ^{40}K, as determined from the experimentally measured scattering length data and resonance width.[36] This parameter is roughly an order of magnitude larger for ^{6}Li. Here ν_0, the gaps and μ are all in units of E_F, and the plots, unless indicated otherwise, are at zero temperature.

The upper right panel plots the excitation gap at T_c as well as the gap at $T = 0$. The lower left hand panel indicates T_c along with the inverse pair size ξ^{-1} in the condensate. Finally the lower right panel plots ξ itself, along with a_s.

One can glean from the figure that the Feshbach boson fraction decreases, becoming negligible when the chemical potential passes through zero. This latter point marks the onset of the PG regime, and in this regime the condensate consists almost entirely of fermionic pairs. The upper limit of the PG regime, that is, the boundary line with the BCS phase, is reached once the pseudogap, $\Delta(T_c)$ is essentially zero. This happens when μ is close to its saturation value at E_F. At this point the pair size rapidly increases.

[36] We note that the precise values of g_0 and U_0 are not critical for either ^{6}Li or ^{40}K as long as they give roughly the right (large) resonance width ΔB and background scatter length a_{bg}. In fact, these parameters usually change during experiment since the total particle number N (and hence E_F and k_F) decreases in the process of evaporative cooling. In order to compare with experiment, one needs to compare at the correct value of $k_F a_s$.

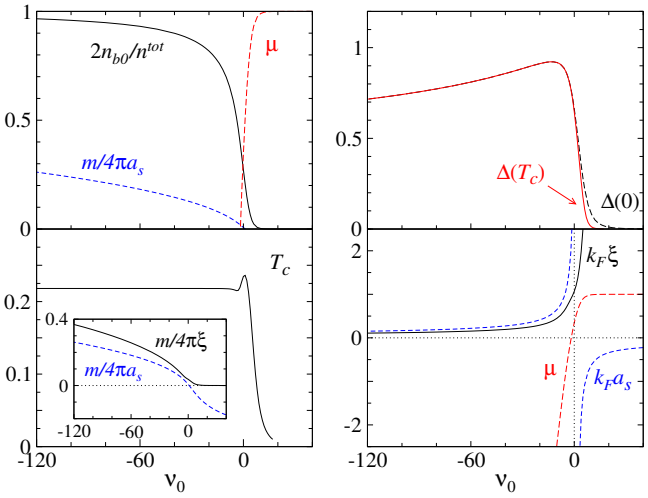

Figure 24.24: (Color) Characteristics of the ground state and T_c, as in Fig. 24.23 except for a smaller g_0. In comparison with Fig. 24.23, the Feshbach resonance becomes much narrower. Here $g_0 = -10E_F/k_F^{3/2}$ and $U_0 = -3E_F/k_F^3$.

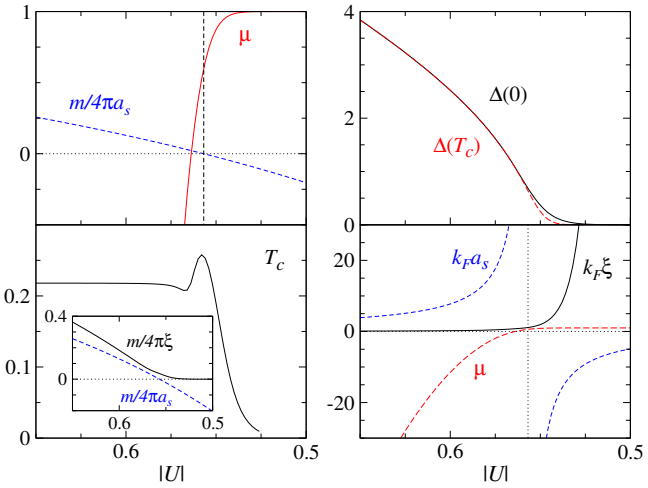

Figure 24.25: (Color) Characteristics of the ground state and T_c in the one-channel model, as in Fig. 24.23 but as a function of the attraction strength U. Here $g_0 = 0$. Different from the two-channel shown in Figs. 24.23-24.24 case, the gap Δ increases indefinitely with $|U|$. The units for U are E_F/k_F^3. Note that $|U|$ increases to the left.

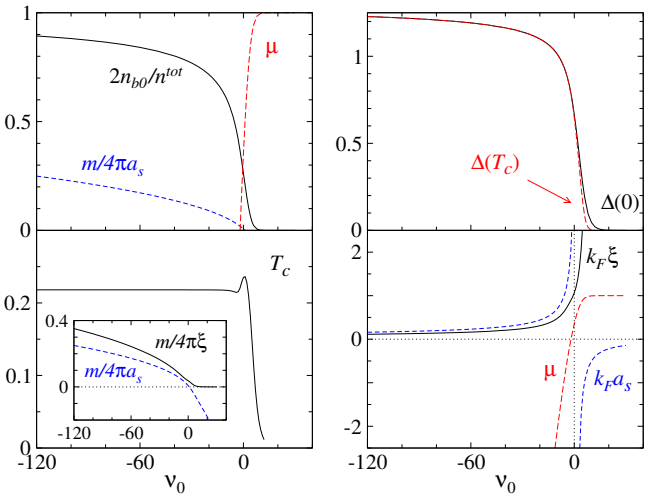

Figure 24.26: (Color) Characteristics of the ground state and T_c, as in Fig. 24.24, except now $U_0 = 0$. As a consequence of the vanishing of U_0, the gap Δ is monotonic and approaches its BEC asymptote from below as ν_0 decreases. Here $g_0 = -10E_F/K_F^{3/2}$.

These results can be compared with those derived from a smaller value of the Feshbach coupling constant $g_0 = -10E_F/k_F^{3/2}$ shown in Fig. 24.24. Now the resonance is effectively narrower. Other qualitative features remain the same as in the previous figure.

One can plot the analogous figures in the absence of Feshbach effects. Here the horizontal axis is the inter-fermionic interaction strength $|U|$, as is shown in Fig. 24.25. Three essential differences can be observed. Note, first the obvious absence of the Feshbach boson or molecular condensate n_{b0}. There is, of course, a condensate associated with pairs of fermions (Δ_{sc}) and these pairs will become bound into "fermionic molecules" for sufficiently strong attraction. Secondly, note that the excitation gap $\Delta(0)$ is monotonically increasing as $|U|$ increases towards the BEC limit. By contrast, from the upper right panels of Fig. 24.24 one can see that when Feshbach effects are present $\Delta(0) \approx \Delta(T_c)$ decreases towards zero in the extreme BEC limit. It can also be seen that the shape of the scattering length curve *vs* U is different from the plots in the previous two figures. Here a_s more rapidly increases in magnitude on either side of the unitary limit. Nevertheless it is important to stress that, *except for the nature of the Bose condensate in the BEC limit, the physics of the Feshbach resonance-induced superfluidity is not so qualitatively different from that associated with a direct inter-fermionic attraction.*

Figure 24.26 presents the analogous plots for the case when the direct attraction between fermions U vanishes. Here the coupling constant g_0 is the same as in Fig. 24.24, and pseudogap effects are present here just as in all other cases. The most notable difference in the physics is that the formation of the Cooper condensate is driven exclusively by coupling to the molecular bosons. A contrast between the two figures is in the behavior of $\Delta(T_c)$ and $\Delta(0)$. For the $U = 0$ case and in the BEC limit, $\Delta(0)$ approaches the asymptotic value $(|g|\sqrt{n_b^0})$ from below. When the system is the fermionic regime ($\mu > 0$), aside from quantitative details, there is very little to distinguish the effects of U from those of g, except when these parameters are taken to very extreme limits.

Finally, in Fig. 24.27 we plot T_c vs ν_0 in the presence of Feshbach effects with variable U_0, from weak to strong background coupling. The lower inset shows the behavior of the excitation gap at T_c. With very strong direct fermion attraction U, we see that T_c has a very different dependence on ν_0. In this limit there is a molecular BEC to PG crossover (which may be inaccessible in actual experiments, since U is not sufficiently high). Nevertheless, it is useful for completeness to illustrate the entire range of theoretical behavior.

Figures 24.28(a)-24.28(c) show the fermionic density of states for the BEC, PG and BCS

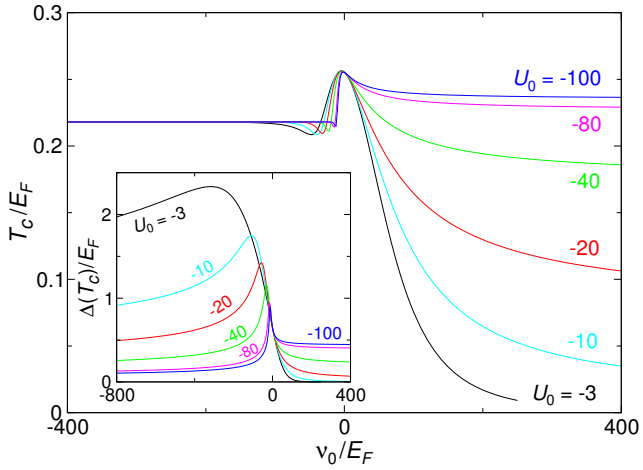

Figure 24.27: (Color) Behavior of T_c (main figure) and $\Delta(T_c)$ (inset) at fixed $g_0 = -40E_F/k_F^{3/2}$ with variable U_0. As $U_0 \to -\infty$, unitarity is approached from the BCS side at large positive ν_0. At the same time, $\Delta \propto |g|$ also decreases.

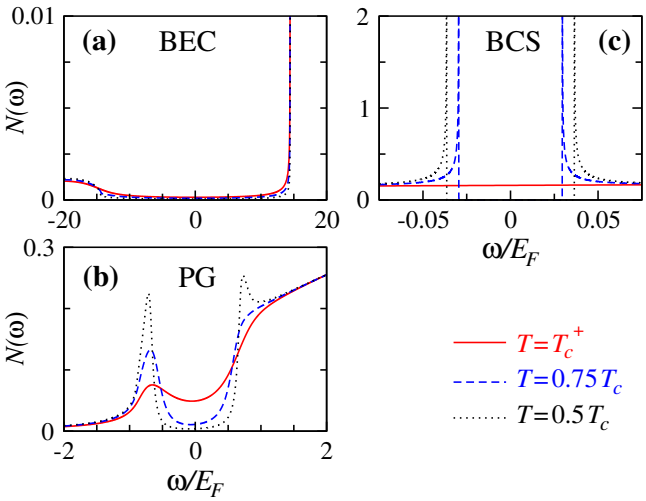

Figure 24.28: Typical density of states (DOS) $N(\omega)$ *vs* energy ω in the three regimes at indicated temperatures. There is no depletion of the DOS at T_c in the BCS case. By contrast, in the BEC case, there is a large gap in DOS at T_c, roughly determined by $|\mu|$. In the intermediate, i.e., pseudogap, regime, there is a strong depletion of the DOS already at T_c. Once T decreases below T_c, the DOS decreases rapidly, signalling the superfluid phase transition.

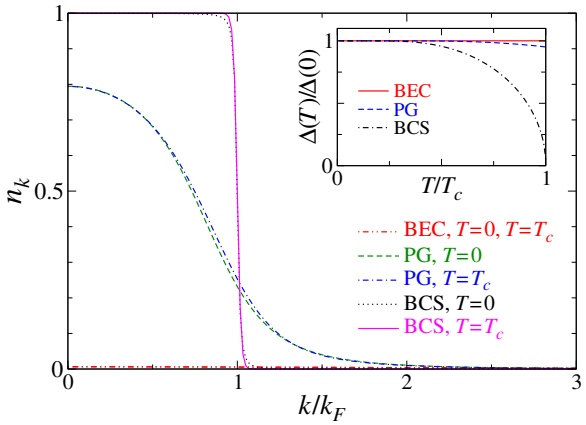

Figure 24.29: Typical behavior of the fermionic momentum distribution function n_k at $T = 0$ and T_c in the three regimes for a homogeneous system. The inset indicates the corresponding normalized gaps as a function of T/T_c. In all three regimes, n_k barely changes between $T = T_c$ and $T = 0$.

limits. These figures are important in establishing a precise visual picture of a "pseudogap". The temperatures shown are just above T_c, and for $T = 0.75T_c$ and $T = 0.5T_c$. The methodology for arriving at these plots will be discussed in the following section, in the context of high T_c superconductors. Only in the BCS case is there a clear signature of T_c in the density of states, but the gap is so small and T_c is so low, that this is unlikely to be experimentally detectable. Since the fermionic gap is well established in the BEC case, very little temperature dependence is seen as the system goes from the normal to the superfluid states. Only the PG case, where T_c is maximal, indicates the presence of superfluidity, not so much at T_c but once superfluid order is well established at $T = 0.5T_c$, through the presence of sharper coherence features, much as seen in the cuprates.

The inset of Fig. 24.29 plots the temperature dependence of $\Delta(T)$. It should be stressed that T_c is only apparent in $\Delta(T)$ in the BCS case. To underline this point, in the main body of Fig. 24.29 we plot the fermionic momentum distribution function n_k, which is the summand in the number equation, Eq. (24.70), at $T = 0$ and $T = T_c$. The fact that there is very little change from $T = 0$ to $T = T_c$ makes the important point that this momentum distribution function in a homogeneous system is not a good indicator of phase coherent pairing. For the PG case, this, in turn, derives from the fact that $\Delta(T)$ is nearly constant. For the BEC limit the excitation gap, which is dominated by μ, similarly, does not vary through T_c. In the BCS regime, $\Delta(T)$ is sufficiently small so as to be barely perceptible on the scale of the figure.

Unitary Limit and Universality

There has been considerable emphasis on the behavior of fermionic gases near the unitary limit where $a_s = \pm\infty$. Attention [68, 182] has concentrated on this limit in the absence of Feshbach bosons. We now want to explore the more general two-channel problem here. At unitarity we require that

$$\frac{4\pi a_s^*}{m} = U_0 + \frac{g_0^2}{2\mu - \nu_0} \tag{24.129}$$

diverges. This will be consistent, provided

$$\nu_0 = 2\mu\,. \tag{24.130}$$

It should be clear that the parameter U_0 is of no particular relevance in the unitary limit. This is to be contrasted with the one channel problem, where Feshbach bosons are absent and unitarity is achieved by tuning the direct inter-fermion interaction, U.

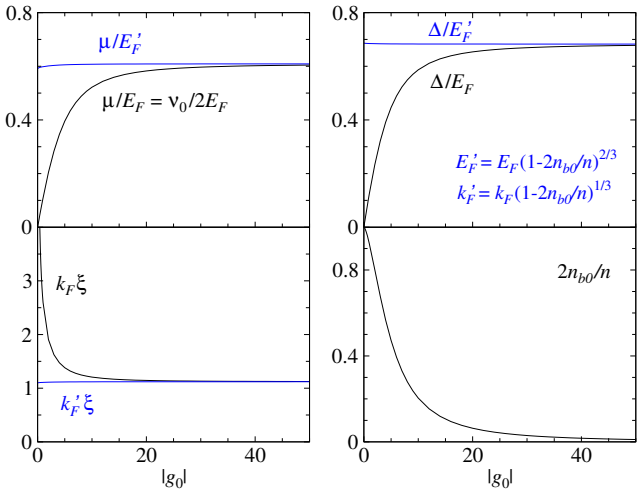

Figure 24.30: (Color) Characteristics of the unitary limit at $T = 0$ as a function of $|g_0|$ in the two-channel problem. Here n_{b0} is the density of condensed Feshbach bosons. $E'_F = k'^2_F/2m$ defines an effective Fermi energy of the fermionic component with a density $n = n^{tot} - 2n_{b0}$. After rescaling, μ/E'_F, Δ/E'_F, and $k'_F\xi$ are essentially a constant in g_0. This indicates that at unitarity, the system can be treated effectively as a two-fluid model at $T = 0$. The units for g_0 are $E_F/k_F^{3/2}$.

In the unitary limit, the $T = 0$ gap and number equations become

$$1 + U_c \sum_{\mathbf{k}} \frac{1}{2E_{\mathbf{k}}} = 0, \tag{24.131}$$

and

$$n^{tot} = 2n_b^0 + n = \frac{2\Delta_0^2}{g_0^2} + \sum_{\mathbf{k}} \left(1 - \frac{\epsilon_{\mathbf{k}} - \mu}{E_{\mathbf{k}}}\right), \tag{24.132}$$

where we have used the fact that at unitarity

$$n_b^0 = \frac{g^2\Delta_0^2}{[(2\mu - \nu)U + g^2]^2} = \frac{\Delta_0^2}{g_0^2}, \tag{24.133}$$

and we define $\Delta_0 \equiv \tilde{\Delta}_{sc}(T = 0)$. Here U_c is the critical coupling, given in Eq. (24.17). From these equations it follows that in this limit the values of μ and Δ_0 in the ground state are entirely determined by the Feshbach coupling g_0.

Figure 24.30 presents a plot of zero temperature properties showing their dependence on g_0. The two endpoints of the curves are of interest. For arbitrarily small but finite g_0 the unitary limit corresponds roughly to $\mu \approx 0$. Moreover, here the condensate consists exclusively of Feshbach bosons. At large g_0, (which appear to be appropriate to current experiments on ^{6}Li and ^{40}K), the behavior at unitarity is closer to that of the one channel problem [68]. Here one finds the so-called universal behavior with parameters $\mu/E_F = 0.59$, and $\Delta/E_F = 0.69$ associated with the simple crossover ground state and a contact potential interaction[37].

To what extent is the unitary limit of the two channel problem universal? It clearly is not in an absolute sense. However, there is a kind of universality implicit in these $T = 0$ calculations, as can be seen from Fig. 24.30 if we take into account the fact that there are a reduced number of fermions, as a result of the Bose condensate. We, thus, divide the two zero temperature energy scales by an effective Fermi energy defined by $E'_F = E_F(n/n^{tot})^{2/3}$ with $n = n^{tot} - 2n_b^0$. Figure 24.30 shows that as g_0 decreases, the effective or rescaled Fermi energy E'_F decreases while the

[37] In our plots we find small numerical corrections associated with our non-infinite cutoff.

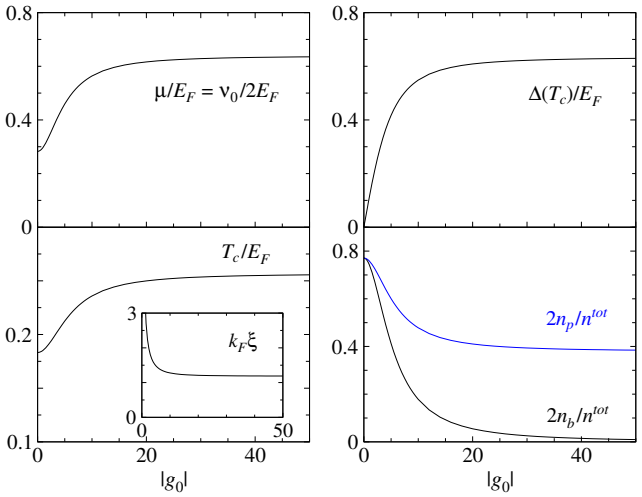

Figure 24.31: (Color) Characteristics of the unitary limit at $T = T_c$ as a function of $|g_0|$ in the two channel problem. In contrast to the previous figure for $T = 0$, there is no rescaling which would lead to universal behavior of μ, Δ or ξ with respect to g_0. More than 20% of the system is composed of fermionic quasiparticles when $|g_0| \to 0$. Here n_b and n_p denote the density of noncondensed Feshbach bosons and of the sum of FB and fermion pairs, respectively. The units for g_0 are $E_F/k_F^{3/2}$.

Bose condensate fraction increases. The rescaled quantities μ/E'_F and Δ/E'_F are universal, that is, they are essentially independent of g_0, as seen in the Figure. A similar scaling can be done for the Cooper pair size ξ. With a reduced effective Fermi momentum $k'_F = k_F(n/n^{tot})^{1/3}$, the dimensionless product $k'_F\xi$ is also independent of g_0. We can arrive at some understanding of this modified universality, by referring back to Sec. 24.6.1. In summary, the breakdown of universality seen in Fig. 24.30 is to be associated with a reduced number of fermions, which, in turn derives from the Bose condensate n_b^0. Once n_b^0 is negligible, the distinction between one and two channel models disappears.

Finite temperature properties, such as T_c and $\Delta(T_c)$ can also be calculated in the unitary limit, as a function of g_0. These are plotted in Fig. 24.31. Just as for the zero temperature energy scales, these parameters [along with $\mu(T_c)$] increase monotonically with g_0. However, at finite temperatures there are noncondensed Feshbach bosons as well as noncondensed fermion pairs, which interact strongly with each other. These noncondensed states are represented in the lower right inset. Plotted there is the fraction of noncondensed bosons $[n_b(T_c)]$ and sum of both noncondensed fermion pairs and noncondensed bosons $[n_p(T_c)]$ at T_c. These quantities correspond to the expressions shown in Eqs. (24.80) and (24.92), respectively.

These noncondensed particles are responsible for the fact that at T_c a simple rescaling will not yield the universality found at $T = 0$. Moreover, these noncondensed bosons and fermion pairs influence calculations of T_c, itself, via pseudogap effects which enter as $\Delta(T_c)$. These pseudogap effects, which are generally ignored in the literature, compete with superconductivity, so that T_c is bounded with its a maximum given by $\approx 0.25T_F$, just as seen in Fig. 24.25, for the one channel problem. Despite the fact that there is no universality, even in the rescaled sense, at T_c one can associate the large g_0 limits with the behavior of the one channel system which has been rather extensively studied in the unitary limit [68]. This large g_0 limit seems to be reasonably appropriate for the currently studied Feshbach resonances in ^{6}Li and ^{40}K. In this sense, these particular atomic resonances are well treated by a one channel problem, near the unitary limit.

In summary, comparison between Fig. 24.30 and Figure 24.31 reveals that (i) at $T = 0$, all Feshbach bosons and pairs are condensed and the two (fermionic and bosonic) condensates

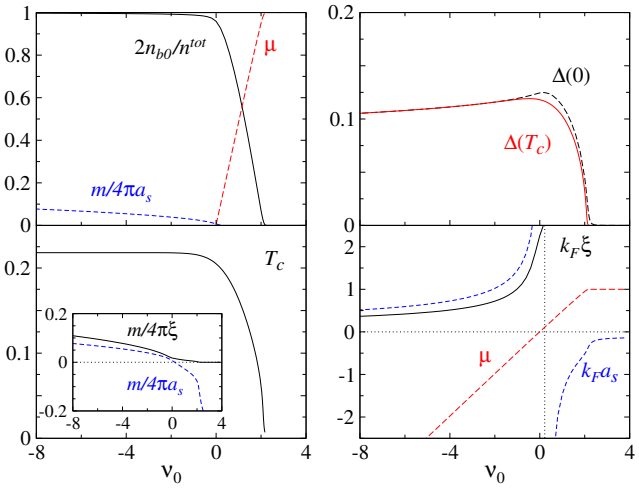

Figure 24.32: (Color) Characteristics of the small g_0 limit as a function of ν_0 in the two-channel model. Unless indicated otherwise the plots correspond to $T = 0$. The molecular condensate fraction is very high and there is no maximum at unitarity. The gap Δ is very small ($\propto g_0$). Here we take $g_0 = -1E_F/k_F^{3/2}$ and $U_0 = -3E_F/k_F^3$. Note the very different scales for the abscissa when comparing with Figs. 24.23 and 24.24.

are relatively independent of each other. (ii) By contrast, at $T = T_c$, fermionic quasiparticles, noncondensed fermion pairs and Feshbach bosons all coexist and interact strongly with each other. This destroys the simple scaling found at $T = 0$.

Weak Feshbach Resonance Regime: $|g_0| = 0^+$

The effects of very small yet finite g_0 lead to a nearly bi-modal description of crossover phenomena. Figure 24.32 presents the behavior for very narrow Feshbach resonances. It shows that there is a rather abrupt change as a function of magnetic field (via ν_0) from a regime in which the condensate is composed only of Feshbach bosons, to one in which it contains only fermion pairs. Depending on the size of g_0, this transition point (taken for concreteness to be where $2n_b^0/n^{tot} \approx 0.5$, for example) varies somewhat, but it seems to occur close to the unitary limit and, importantly, for negative scattering lengths *i.e.*, on the BCS side. This should be contrasted with the large g_0 case). This small g_0 regime of parameter space was explored by Ohashi and Griffin [131]. Indeed the behavior shown in the figure is similar to the physical picture which Falco and Stoof [51] presented.

This figure represents a natural evolution in the behavior already indicated by Figs. 24.23 and 24.24. Here, however, in contrast to these previous figures the behavior of T_c is essentially monotonic, and the weak maximum and minimum found earlier has disappeared. For this regime, the small pseudogap which can be seen in the upper right panel arises predominantly from the contribution of Feshbach bosons via Eqs. (24.84) and (24.91). At the same time it should be noted that the transition from mostly molecular bosons to mostly fermion pairs in the condensate is continuous. While it may look sharp particularly for a plot with a more extended range of ν_0 than shown here, this closeup view gives a more precise picture of a smooth crossover transition.

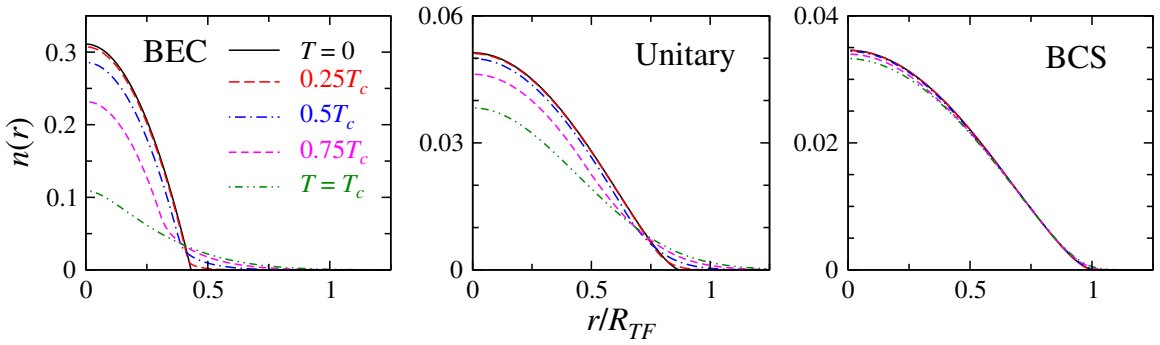

Figure 24.33: (Color) Representative spatial profiles of fermions in a harmonic trap potential at various temperatures from T_c to $T = 0$ in the three indicated regimes. As the system evolves from the BCS to the deep BEC regime, the fermion cloud shrinks, and a bimodal distribution of the density develops below T_c. Note the different scales for the vertical axes.

We end by noting that in this small g_0 regime, the system is far from the one channel limit obtained when g_0 is identically 0, as shown in Fig. 24.25. It should be clear from the above discussion that *Feshbach bosons play a more important role in the regime of unitary scattering the smaller is g_0, provided that it does not strictly vanish.*

24.6.2 Superfluidity in Traps

Most experiments on fermionic superfluids are done in the presence of a trap potential $V(r)$. For the most part, this is most readily included at the level of the local density approximation (LDA). In this section, we summarize the self consistent equations for spherical traps $V(r) = \frac{1}{2}m\omega^2 r^2$. T_c is defined as the highest temperature at which the self consistent equations are satisfied precisely at the center. At a temperature T lower than T_c the superfluid region extends to a finite radius R_{sc}. The particles outside this radius are in a normal state. Also important is the radius R_Δ beyond which the excitation gap is effectively zero, to a chosen level of numerical accuracy.

The self consistent equations (with simplified units $\hbar = 1$, fermion mass $m = \frac{1}{2}$, and Fermi energy $E_F = \hbar\omega(3N)^{\frac{1}{3}} = 1$, where ω is the trap frequency) are given in terms of the Feshbach coupling constant g and inter-fermion attractive interaction U by a gap equation

$$1 + \left[U + \frac{g^2}{2\mu - 2V(r) - \nu}\right] \sum_{\mathbf{k}} \frac{1 - 2f(E_{\mathbf{k}})}{2E_{\mathbf{k}}} = 0 \ . \tag{24.134}$$

which characterizes the excitation gap $\Delta(r)$ at positions r such that $\mu_{pair}(r) = 0$. Moreover, the pseudogap contribution to $\Delta^2(T) = \tilde{\Delta}^2_{sc}(T) + \Delta^2_{pg}(T)$ is given by

$$\Delta^2_{pg} = \frac{1}{Z} \sum_{\mathbf{q}} b(\Omega_q - \mu_{pair}) \ . \tag{24.135}$$

Here b represents the usual Bose function. The density of particles at radius r:

$$\begin{aligned} n(r) \ &= \ 2n_b^0 + \frac{2}{Z_b} \sum_{\mathbf{q}} b(\Omega_q - \mu_{boson}) \\ &\quad + 2 \sum_{\mathbf{k}} \left[v^2_{\mathbf{k}}(1 - f(E_{\mathbf{k}})) + u^2_{\mathbf{k}} f(E_{\mathbf{k}}) \right] \ . \end{aligned} \tag{24.136}$$

The important quantity $\mu_{pair} = \mu_{boson}$ is identically zero in the superfluid region $r < R_{sc}$, and must be solved for self consistently at larger radii. Here M is the bare boson mass equal to $2m$, and the various residues, Z and Z_b and pair dispersion Ω_q are described in Section 24.3.3.

The transition temperature T_c is numerically determined as follows: (i) A chemical potential is assigned to the center of the trap $\mu(0)$. The chemical potential at radius r will then be $\mu(r) = \mu(0) - V(r)$. (ii) The gap equation [Eq. (24.134)] and pseudogap equation [Eq. (24.135)] are solved at the center (setting $\Delta_{pg} = \Delta$) to find T_c and $\Delta(0, T_c)$ (iii) Next the radius R_Δ is determined. (It can be defined as the point where the gap has a sufficiently small value, such as $\Delta(0, T_c)/1000$). (iv) Following this, the pseudogap equation (Eq. (24.135)) is solved for $\Delta(r, T_c)$ up to the radius R_Δ. Then $n(r)$ is determined using Eq. (24.136). (v) Finally, $n(r)$ is integrated over all space ($\int d^3\mathbf{r} n(r)$) and compared with the given total number of fermions N. The procedure is repeated until the prescribed accuracy has been reached. To extend this algorithm below T_c a similar approach is used which now includes an additional step in which R_{sc} is computed.

Figure 24.33 shows a plot of the density profiles obtained from solving the self consistent equations. Here the Thomas-Fermi radius, called R_{TF}, is calculated for the non-interacting case. In the BCS regime there is virtually no temperature dependence in the density profile as expected from the small values for Δ. In the unitary and BEC regimes as the system approaches T_c, $n(r)$ can be reasonably well fit to a Gaussian. A bi-modality in the distribution is evident in the BEC regime, thus providing a clear signature of the superfluid phase. However, in the PG or unitary it is more difficult to establish superfluidity, since the profiles do not show a clear break at the position where the condensate first appears [160].

These observations differ somewhat from other theoretical predictions in the literature [68, 35]. The differences between the present theory and this other work can be associated with the inclusion of noncondensed pairs or pseudogap effects. These noncondensed pairs smooth out the otherwise abrupt transition between the condensate and the fermionic excitations. In contrast to earlier work [137] these studies, which are based on the standard crossover ground state [187], yield only monotonic density distributions. Future experiments will be needed to look for the secondary maxima predicted by Strinati and co-workers [135] in the BEC and unitary regimes.

Finally, Fig. 24.34 shows the behavior of T_c (inset) in a trap, together with the superfluid density (main figure). The latter is computed following the discussion in Sec. 24.4. From the inset one can read off that $T_c/E_F \approx 0.3$ at resonance, which is very close to [135], or slightly smaller than other estimates [132] in the literature.

The structure seen in the plot of T_c for the trapped gas reflects the minimum and maximum found for the homogeneous solution (Fig. 24.23); these are related, respectively, to where $\mu \approx 0$ and where unitary scattering occurs. The T_c curve follows generally the decrease in the density at the center of the trap from BEC to BCS. The temperature dependences of the (integrated over r) superfluid density reflect the nature of excitations of the condensate. The BEC limit has only bosonic, while the BCS has only fermionic excitations. The unitary case is somewhere in between. The fermionic contributions are apparent in the BCS regime, where N_s decreases almost linearly at low T. For an s-wave superfluid this reflects the contributions from low $\Delta(r) \leq T$ regions, near the edge of the trap. These are present to a lesser degree in the unitary case. The bosonic contribution to N_s and to thermodynamics (in both the BEC and unitary regimes) is governed by the important constraint that $\mu_{pair}(r)$ vanishes at positions r where there is a co-existent superfluid. A similar constraint is imposed at the level of Hartree-Fock-Bogoliubov theory for true bosons [156]. These gapless pair excitations are responsible for a $T^{3/2}$ temperature dependence in N_s. In this way the low T power law dependences are similar to their analogues in the homogeneous case of Section 24.7.4, much as found for true Bose gases [23] in a trap.

As for the BEC regime there is an interesting observation to make about the contribution to the density profile associated with the condensate. Experimentalists generally assume a Gaussian form throughout the trap for the noncondensed pairs. In this way they estimate the

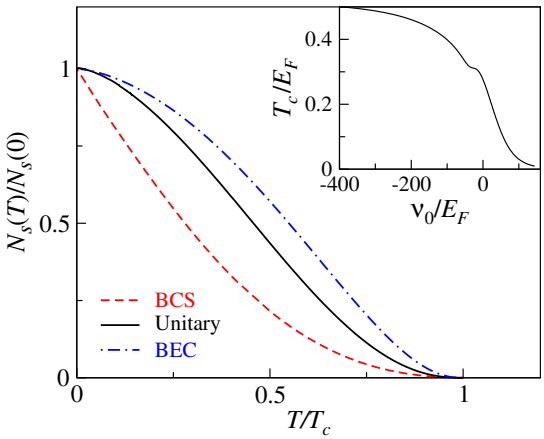

Figure 24.34: Behavior of superfluid density N_s as a function of T in the three different regimes. Note that the negative curvatures at low T for the unitary and BEC cases are different from the linear behavior in the BCS case. In the BEC limit, $N - N_s \propto T^{3/2}$. In the inset we show T_c as a function of magnetic detuning ν_0 in a trap. We have taken $U_0 = -0.9E_F/k_F^3$ and $g_0 = -35E_F/k_F^{3/2}$, based on experimental data for ^{40}K.

condensate fraction. Here we find [160] that this Gaussian form is not correct in the superfluid region of the trap, and that this Gaussian approximation will underestimate (by $\approx$ a factor of 1.5) the condensate fraction in the BEC regime.

24.6.3 Comparison Between Theory and Experiment: Cold Atoms

As time progresses it will be important to assess the assumed ground state wavefunction [187] and its two channel variant [123, 131, 161] in more detail. A first generation set of measurements and theories have indicated an initial level of success in addressing four experiments: RF pairing gap spectroscopy and collective mode measurements, as well as more recently, the particle density profiles [160] and thermodynamics [88] of Fermi gases in the unitary regime. The first of these experiments [34] seem to provide some support for the fact that the Bogoliubov excitations with dispersion, $E_{\mathbf{k}} \equiv \sqrt{(\epsilon_{\mathbf{k}} - \mu)^2 + \Delta^2(T)}$ have a "gap parameter" or pseudogap, $\Delta(T)$ which is in general different from the superconducting order parameter, as a consequence of noncondensed pairs at and above T_c. Törmä and colleagues [90] have used the formalism outlined in Section 24.3.2, to address RF spectroscopy. Subsequently [89] they have combined this analysis with an approximate LDA treatment of the trap to make contact with RF experiments [34]. Important to their work is the fact that the edges of a trap have a free atom character, where there is a vanishing $\Delta(r)$.

Additional support for the wavefunction comes from the collective mode behavior near $T = 0$. The mode frequencies can be connected to an equation of state [166]. Numerical studies [74, 66] of this equation for the standard crossover ground state demonstrate a good fit to the measured breathing mode frequencies [87, 10]. Importantly, in the near-BEC limit the frequencies decrease with increasing magnetic field; this is opposite to the behavior predicted for true bosons [166], and appears to reinforce the notion that for the magnetic fields studied thus far, the "BEC" regime should be associated with composite rather than real bosons.

At $T = 0$, calculations of the collective mode frequencies are based on an equation of state. Moreover, the zero temperature equation of state associated with the mean field ground state can be computed analytically in the near-BEC limit

$$\mu = -\frac{1}{2ma_s^2} + \frac{\pi a_s n}{m} - \frac{3(\pi n a_s^3)^2}{4ma_s^2} + O(n^3),$$

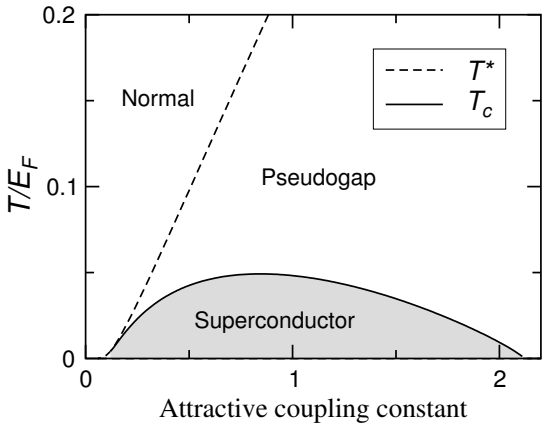

Figure 24.35: Phase diagram for a quasi-two-dimensional (2D) d-wave superconductor on a lattice. Here the horizontal axis corresponds to the strength of attractive interaction $-U/4t$, where t is the in-plane hopping matrix element.

where the first two terms on the right hand side were previously discussed following Eq. (24.55). Importantly, the third term is responsible for the observed agreement between theory and collective mode experiments, in the near-BEC regime.

A serious shortcoming of the wavefunction ansatz has been emphasized in the literature. This is associated with the ratio of the inter-boson to the fermionic scattering length near the unitary regime, but on the BEC side of the Feshbach resonance. Experimentally the numbers are considerably smaller [11, 194] (0.6) than the factor of 2 predicted for the one channel model discussed below Eq. (24.55). They are consistent, however, with more exact few body calculations [138]. These few body calculations apply to a regime of magnetic fields where $k_F a_s$ is smaller than about 0.3 -0.4. This seems to be close to the boundary for the "quasi-BEC" regime which can be accessed experimentally [11] in ^{6}Li.

It is interesting to repeat the $T = 0$ many body calculations now with the inclusion of FB, since these two channel effects begin to be important at $k_F a_s$ smaller than around 0.2 -0.25. Here, one sees [161], that the factor of 2 found in the one channel calculations is no longer applicable, and the values of the ratio (of bosonic to fermionic scattering lengths) are considerably smaller, and, thus, tending in the direction which is more in line with experiment. This reflects the decrease in the number of fermionic states which mediate the interaction between molecular bosons.

In this way the mean field theory presented here looks promising. Nevertheless, uncertainties remain. Current theoretical work [89] on the RF experiments is limited to the intermediate coupling phase, while experiments are also available for the near-BEC and near-BCS regimes, and should be addressed theoretically. In addition, the predictions of alternative approaches [137] which posit a different ground state will need to be compared with these RF data. The collective mode calculations [74, 66] which have been performed have not yet considered the effects of Feshbach bosons, which may change the behavior in the near-BEC regime.

It is, finally, quite possible that incomplete $T = 0$ condensation will become evident in future experiments. If so, an alternative wavefunction will have to be contemplated. Indeed, it has been argued [72] that the failure of the one channel model to match the calculations of Petrov and co-workers [138] is evidence that there are serious weaknesses. At an experimental level, new pairing gap spectroscopies appear to be emerging at a fairly rapid pace [60, 17] which will further test these and subsequent theories.

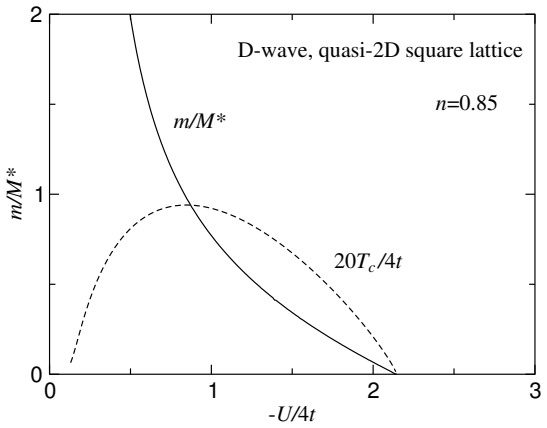

Figure 24.36: Inverse pair mass (solid line) and T_c (dashed line) as a function of coupling strength $-U/4t$ for a d-wave superconductor on a quasi-2D square lattice, where t is the in-plane hopping matrix element. T_c vanishes when the pair mass diverges, before the bosonic regime is reached. The electron density is taken to be $n = 0.85$ per unit cell, corresponding to optimal hole doping in the cuprate superconductors.

24.7 Physical Implications: High T_c Superconductivity

We begin with an important caveat that many of the experiments outlined in this section can alternatively be addressed from a Mott physics point of view [106]. Here we summarize the interpretation of these experiments within BCS-BEC crossover theory with the hope that this discussion will be of value to the cold atom community, and that ultimately, it will help to establish precisely how relevant is the BCS-BEC crossover scenario for understanding high temperature superconductivity.

24.7.1 Phase Diagram and Superconductor-Insulator Transition: Boson Localization Effects

The high T_c superconductors are different from the ultracold fermionic superfluids in one key respect; they are d-wave superconductors and their electronic dispersion is associated with a quasi-two dimensional tight binding lattice. In many ways this is not a profound difference from the perspective of BCS-BEC crossover. Figure 24.35 shows a plot of the two important temperatures T_c and T^* as a function of increasing attractive coupling. On the left is BCS and the right is PG. The BEC regime is not apparent. This is because T_c disappears before it can be accessed. At the point where T_c vanishes, $\mu/E_F \approx 0.8$.

A competition between increasing T^* and T_c is also apparent in Fig. 24.35. This is a consequence of pseudogap effects. There are fewer low energy fermions around to pair, as T^* increases. It is interesting to compare Fig. 24.35 with the experimental phase diagram plotted as a function of x in Fig. 24.7. If one inverts the horizontal axis (and ignores the AFM region, which is not addressed here) the two are very similar. To make an association between the coupling U and the variable x, it is reasonable to simply fit $T^*(x)$. We do not dwell on this last step here, since we wish to emphasize crossover effects which are not complicated by "Mott physics".

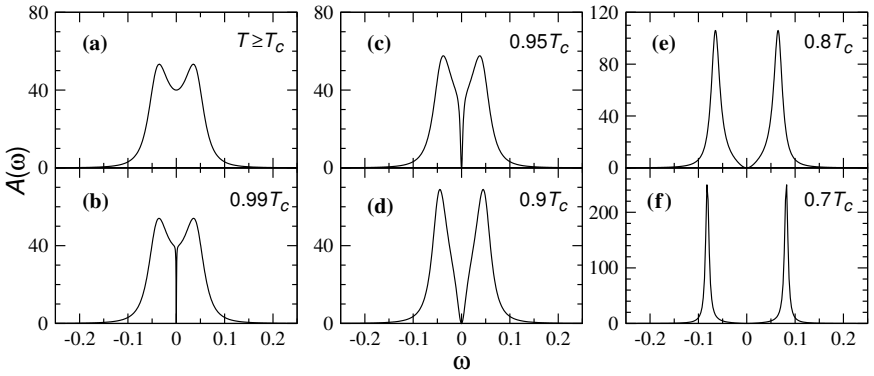

Figure 24.37: Evolution of spectral functions of a pseudogapped superconductor with temperature. As soon as T drops below T_c, the spectral peaks split up rapidly, signalling the onset of phase coherence.

Because of quasi-two dimensionality, the energy scales of the vertical axis in Fig. 24.35 are considerably smaller than their three dimensional analogues. Thus, pseudogap effects are intensified, just as conventional fluctuation effects are more apparent in low dimensional systems. This may be one of the reasons why the cuprates are among the first materials to clearly reveal pseudogap physics. Moreover, the present calculations show that in a strictly $2D$ material, T_c is driven to zero, by bosonic or fluctuation effects. This is a direct reflection of the fact that there is no Bose condensation in $2D$.

Figure 24.36 presents a plot [29] of boson localization effects associated with d-wave pairing. A divergence in the effective mass m/M^* occurs when the coupling strength, or equivalently T^* becomes sufficiently large. Once the bosons localize the system can no longer support superconductivity and T_c vanishes. It is generally believed that a system of bosons with short range repulsion is either a superfluid or a Mott insulator in its ground state [52]. Moreover, the insulating phase is presumed to contain some type of long range order. Interestingly, there are recent reports of ordered phases [56, 181] in the very underdoped cuprates. These appear on the insulating side and possibly penetrate across the superconductor-insulator boundary; they have been interpreted by some as Cooper pair density waves [26, 172, 117]. The observation of boson localization appears to be a natural consequence of BCS-BEC theory; it should be stressed that it is associated with the d-wave lattice case. Because d-wave pairs are more spatially extended (than their s-wave counterparts) they experience stronger Pauli repulsion [29] and this inhibits their hopping.

24.7.2 Superconducting Coherence Effects

The presence of pseudogap effects raises an interesting set of issues surrounding the signatures of the transition which the high T_c community has wrestled with, much as the cold atom community is doing today. For a charged superconductor there is no difficulty in measuring the superfluid density, through the electrodynamic response. Thus one knows with certainty where T_c is. Nevertheless, people have been concerned about precisely how the onset of phase coherence is reflected in thermodynamics, such as C_V or in the fermionic spectral function. One understands how phase coherence shows up in BCS theory, since the ordered state is always accompanied by the appearance of an excitation gap. When a gap is already well developed at T_c, how do these signatures emerge?

To address these coherence effects one has to introduce a distinction between the self energy [31] associated with noncondensed and condensed pairs. This distinction is blurred by the approximation of Eq. (24.89). Above, but near T_c, or at any temperature below we now use an

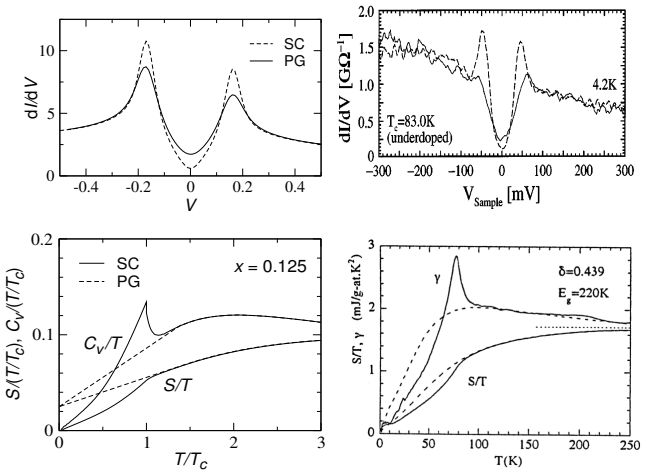

Figure 24.38: Superconducting state (SC) and extrapolated normal state (PG) contributions to SIN tunneling characteristics dI/dV (upper panels) and thermodynamics S/T and C_v/T (lower panels). We compare theoretical calculations (left) with experiments (right) on tunneling for BSCCO from [149] and on specific heat for $Y_{0.8}Ca_{0.2}Ba_2Cu_3O_{7-\delta}$ (YBCO) from [169]. The theoretical SIN curve is calculated for $T = T_c/2$, while the experimental curves are measured outside (dashed line) and inside (solid line) a vortex core. The *dashed and solid* curves in the upper left panel are for SC and PG state, respectively. In both lower panels, the *solid and dashed* curves indicate the SC and PG state, respectively.

improved approximation [114, 115]

$$\Sigma_{pg} \approx \frac{\Delta^2}{\omega + \xi_{\mathbf{k}} + i\gamma} \tag{24.137}$$

This is to be distinguished from Σ_{sc} where the condensed pairs are infinitely long-lived and there is no counterpart for γ. The value of this parameter, and even its T-dependence is not particularly important, as long as it is nonzero.

Figure 24.37 plots the fermionic spectral function at $\xi_{\mathbf{k}} = 0$, called $A(\omega)$, as the system passes from above to below T_c. One can see in this figure that just below T_c, $A(\omega)$ is zero at a point $\omega = 0$, and that as temperature further decreases the spectral function evolves smoothly into approximately two slightly broadened delta functions, which are just like their counterparts in BCS. In this way there is a clear signature associated with superconducting coherence. To compare with experimental data is somewhat complicated, since measurements of the spectral function [42, 20] in the cuprates also reveal other higher energy features ("dip, hump and kink"), not specifically associated with the effects of phase coherence. Nevertheless, this Figure, like its experimental counterpart, illustrates that sharp gap features can be seen in the spectral function, but only below T_c.

Analogous plots of superconducting coherence effects are presented in Fig. 24.38 in the context of more direct comparison with experiment. Shown are the results of specific heat and tunneling calculations and their experimental counterparts [169, 149]. The latter measures, effectively, the density of fermionic states. Here the label "PG" corresponds to an extrapolated normal state in which we set the superconducting order parameter Δ_{sc} to zero, but maintain the the total excitation gap Δ to be the same as in a phase coherent, superconducting state. Agreement between theory and experiment is satisfactory. We present this artificial normal state extrapolation in discussing thermodynamics in order to make contact with its experimental counterpart. However, it should be stressed that in zero magnetic field, there is no coexistent non-superconducting phase. BCS theory is a rather special case in which there are two possible phases below T_c, and one can, thereby, use this coexistence to make a reasonable estimate of

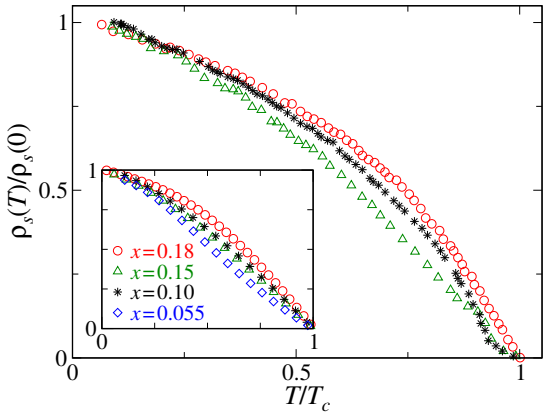

Figure 24.39: Comparison of normalized superfluid density $\rho_s/\rho_s(0)$ versus T/T_c for experiment (main figure) and theory (inset) in high T_c superconductors with variable doping concentration x. Both experiment and theory show a quasi-universal behavior with respect to doping.

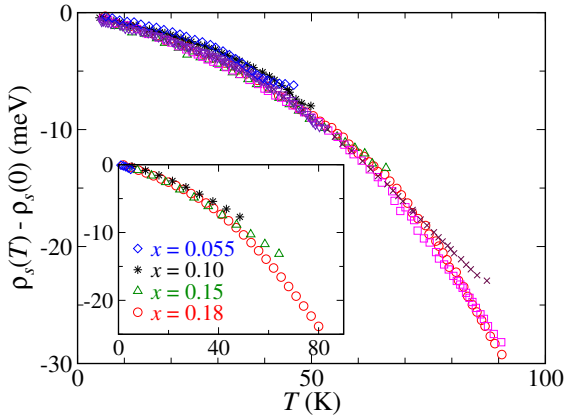

Figure 24.40: Offset plot of superfluid density ρ_s comparing experiment (main figure) with theory (inset). Both experiment and theory show the same quasi-universal slope $d\rho_s/dT$ for different hole concentrations x.

the condensation energy. When Bose condensation needs to be accommodated, there seems to be no alternative "normal" phase below T_c.

24.7.3 Electrodynamics and Thermal Conductivity

In some ways the subtleties of phase coherent pairing are even more perplexing in the context of electrodynamics. Figure 24.12 presents a paradox in which the excitation gap for fermions appears to have little to do with the behavior of the superfluid density. To address these data [163] one may use the formalism of Sec. 24.4.1. One has to introduce the variable x (which accounts for Mott physics) and this is done via a fit to $T^*(x)$ in the phase diagram. Here for Fig. 24.40 it is also necessary to fit $\rho_s(T=0,x)$ to experiment, although this is not important in Fig. 24.39. The figures show a reasonable correspondence [163] with experiment. The paradox raised by Fig. 24.12 is resolved by noting that there are bosonic excitations of the condensate, as in Eq. (24.113) and that these become more marked with underdoping, as pseudogap effects increase. In this way ρ_s does not exclusively reflect the fermionic gap, but rather vanishes "prematurely" before this gap is zero, as a result of pair excitations.

The optical conductivity $\sigma(\omega)$ is similarly modified [174, 77]. Indeed, there is an intimate relation between ρ_s and $\sigma(\omega)$ known as the f-sum rule. Optical conductivity studies in the literature, both theory and experiment, have concentrated on the low ω, T regime and the

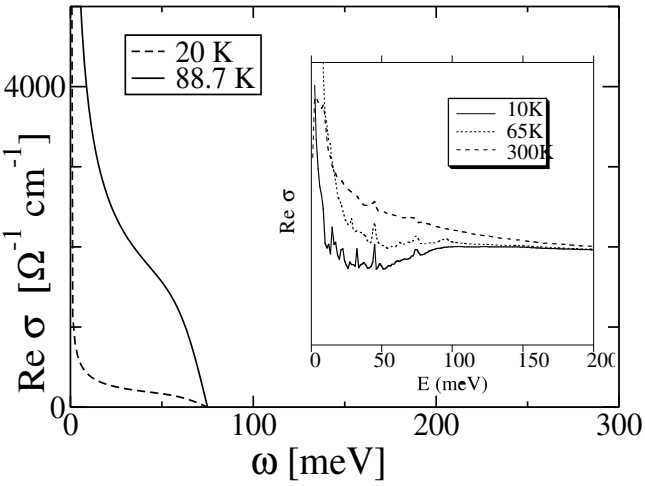

Figure 24.41: Real part of ac conductivity at low and high T below T_c. Here pseudogap effects, which insure that $\Delta(T) \approx$ *constant* below T_c, require that one go beyond BCS theory to explain the data shown in the inset [142]. In the theory, inelastic and other effects which presumably lead to the large constant background term observed in the data have been ignored.

interplay between impurity scattering and d wave superconductivity [15]. Also of interest are unusually high ω tails [124, 152] in the real part of $\sigma(\omega)$ which can be inferred from sum-rule arguments and experiment. Figure 24.12 raises a third set of questions which pertain to the more global behavior of σ. In the strong PG regime, where Δ has virtually no T dependence below T_c, the BCS-computed $\sigma(\omega)$ will be similarly T-independent. This is in contrast to what is observed experimentally where $\sigma(\omega)$ reflects the same T dependence as in $\rho_s(T)$, as dictated by the f-sum rule.

One may deduce a consequence of this sum rule, based on Eq. (24.113). If we associate the fermionic contributions with the first term in square brackets in this equation, and the bosonic contributions with the second. Note that the fermionic transport terms reflect the full Δ just as do the single particle properties. (This may be seen by combining the superconducting and Maki Thompson or PG diagrams in Appendix 24.9). We may infer a sum rule constraint on the bosonic contributions, which vanish as expected in the BCS regime where Δ_{pg} vanishes. We write

$$\frac{2}{\pi}\int_0^\infty d\Omega\, \sigma^{bosons}(\Omega,T) = \frac{\Delta_{pg}^2}{\Delta^2}\left(\frac{n_s}{m}\right)^{BCS}(T)\,. \tag{24.138}$$

The bosonic contributions can be determined most readily from a framework such as time dependent Ginzburg Landau theory, which represents rather well the contributions from the Aslamazov-Larkin diagrams, discussed in Appendix 24.9. The bosons make a maximum contribution at T_c.

The resulting optical conductivity [77] in the superconducting state is plotted in Fig. 24.41 below. The key feature to note is the decrease in width of the so-called Drude peak with decreasing temperature. In the present picture this pseudogap effect can be understood as coming from the contribution of bosonic excitations of the condensate, which are present at T_c, but which disappear at low T. This behavior is reasonably consistent with what is reported experimentally [174], where "the effect of the opening of a pseudogap is a narrowing of the coherent Drude peak at low frequency". The calculations leading to Fig. 24.41, indicate that by 20 K most of the conductivity is fermionic except for a high frequency tail associated with the bosons. This tail may be responsible in part for the anomalously high ω contributions to σ required to satisfy the sum rule [124, 152].

Although the normal state calculations have not been done in detail, once the temperature

is less than T^*, pseudogap effects associated with the fermionic contribution will also lead to a progressive narrowing in the Drude peak with decreasing T, down to T_c, due to the opening of an excitation gap. This mechanism (which is widely ascribed to [174] in the literature) reflects longer lived electronic states, associated with the opening of this gap. However, it cannot be applied to explain the progressive narrowing of the conductivity peaks, once $\Delta(T)$ becomes temperature independent, as is the case at low T. In this way, one can see that pseudogap effects show up in the optical conductivity of underdoped samples, both from the fermionic contributions (near and below T^*) and the bosonic contributions (below T_c) as a narrowing of the Drude peak.

The data shown in the inset of Fig. 24.41 reveal that the condensate is made from frequency contributions primarily up to ≈ 0.15 eV. These data pose a challenge for applying strict BCS theory to this problem, since one consequence of a temperature independent Δ in the underdoped phase is the absence of T dependence in the optical conductivity. This is the same challenge as posed by Fig. 24.12. Strikingly there is no explicit "gap feature" in the optical conductivity in the normal state. Such a gap feature, that is a near vanishing of σ for an extended range of frequencies, will occur in models where the pseudogap is unrelated to superconductivity; it is not seen experimentally, thus far

By contrast with the electrical conductivity, the thermal conductivity is dominated by the fermionic contributions at essentially all T. This is because the bosonic contribution to the heat current (as in standard TDGL theory [103]), is negligibly small, reflecting the low energy scales of the bosons. Thermal conductivity, experiments [167] in the high T_c superconductors provide some of the best evidence for the presence of fermionic d-wave quasiparticles below T_c. In contrast to the ac conductivity, here one sees a universal low T limit [104], and there is little to suggest that something other than conventional d-wave BCS physics is going on here. This cannot quite be the case however, since in the pseudogap regime, the temperature dependence of the fermionic excitation gap is highly anomalous, as shown in Fig. 24.3, compared to the BCS analogue.

24.7.4 Thermodynamics and Pair-breaking Effects

The existence of noncondensed pair states below T_c affects thermodynamics, in the same way that electrodynamics is affected, as discussed above. Moreover, one can predict [30] that the q^2 dispersion will lead to ideal Bose gas power laws in thermodynamical and transport properties. These will be present in addition to the usual power laws or (for s-wave) exponential temperature dependences associated with the fermionic quasiparticles. Note that the q^2 dependence reflects the spatial extent ξ_{pg}, of the composite pairs, and this size effect has no natural counterpart in true Bose systems. It should be stressed that numerical calculations show that these pair masses, as well as the residue Z are roughly T independent constants at low T. As a result, Eq. (24.94) implies that $\Delta_{pg}^2 = \Delta^2(T) - \Delta_{sc}^2(T) \propto T^{3/2}$.

The consequences of these observations can now be listed [30]. For a quasi-two dimensional system, C_v/T will appear roughly constant at the lowest temperatures, although it vanishes strictly at $T = 0$ as $T^{1/2}$. The superfluid density $\rho_s(T)$ will acquire a $T^{3/2}$ contribution in addition to the usual fermionic terms. By contrast, for spin singlet states, there is no explicit pair contribution to the Knight shift. In this way the low T Knight shift reflects only the fermions and exhibits a scaling with $T/\Delta(0)$ at low temperatures. Experimentally, in the cuprates, one usually sees a finite low T contribution to C_v/T. A Knight shift scaling is seen. Finally, also observed is a deviation from the predicted d-wave linear in T power law in ρ_s. The new power laws in C_v and ρ_s are conventionally attributed to impurity effects, where $\rho_s \propto T^2$, and $C_v/T \propto const.$ Experiments are not yet at a stage to clearly distinguish between these two alternative explanations.

Pair-breaking effects are viewed as providing important insight into the origin of the cuprate pseudogap. Indeed, the different pair-breaking sensitivities of T^* and T_c are usually proposed to support the notion that the pseudogap has nothing to do with superconductivity. To counter this inference, a detailed set of studies was conducted, (based on the BEC-BCS scenario), of pair-breaking in the presence of impurities [32, 84] and of magnetic fields [83]. These studies make it clear that the superconducting coherence temperature T_c is far more sensitive to pair-breaking than is the pseudogap onset temperature T^*. Indeed, the phase diagram of Fig. 24.35 which mirrors its experimental counterpart, shows the very different, even competing nature of T^* and T_c, despite the fact that both arise from the same pairing correlations.

24.7.5 Anomalous Normal State Transport: Nernst and Other Precursor Transport Contributions

Much attention is given to the anomalous behavior of the Nernst coefficient in the cuprates [188]. This coefficient is rather simply related to the transverse thermoelectric coefficient α_{xy} which is plotted in Fig. 24.13. In large part, the origin of the excitement in the literature stems from the fact that the Nernst coefficient behaves smoothly through the superconducting transition. Below T_c it is understood to be associated with superconducting vortices. Above T_c if the system were a Fermi liquid, there are arguments to prove that the Nernst coefficient should be essentially zero. Hence the observation of a non-negligible Nernst contribution has led to the picture of normal state vortices.

Another way to view these data is that there are bosonic degrees of freedom present in the normal state, as in the BCS-BEC crossover approach. To describe this dynamics we begin with the TDGL scheme outlined in Sec. 24.2.8. This formalism must be modified somewhat however. When "pre-formed" pairs are present at temperatures T^* high compared to T_c, the classical bosonic fields of conventional TDGL must be replaced by their quantum counterparts [170]. We investigate this fairly straightforward extension of TDGL in the next sub-section, and subsequently explore the resulting implications for transport.

Quantum Extension of TDGL

To make progress on the quantum analogue of TDGL we study a Hamiltonian describing bosons coupled to a particle reservoir of fermion pairs. The latter are addressed in a quantum mechanical fashion. Our treatment of the reservoir has strong similarities to the approach of Caldeira and Leggett [19]. These bosons are in the presence of an electromagnetic field, which interacts with the fermion pairs of the reservoir as well, since they have charge $e^* = 2e$. For simplicity we assume that the fermions are dispersionless. This Hamiltonian is given by

$$H = \sum_{\mathbf{lm}} \varepsilon_{\mathbf{lm}} \psi_{\mathbf{l}}^\dagger(t) \exp\bigl(-ie^* C_{\mathbf{lm}}(t)\bigr) \psi_{\mathbf{m}}(t) + \sum_{\mathbf{l}} e^* \phi \psi^\dagger \psi + \sum_{i\mathbf{l}} \Bigl\{ (a_i + e^*\phi) w_i^\dagger w_i + \eta_i \psi^\dagger w_i + \eta_i^* w_i^\dagger \psi \Bigr\} + \sum_{i\mathbf{l}} \Bigl\{ (b_i - e^*\phi) v_i^\dagger v_i + \zeta_i \psi^\dagger v_i^\dagger + \zeta_i^* v_i \psi \Bigr\}. \quad (24.139)$$

Here $\varepsilon_{\mathbf{lm}}$ is the hopping matrix element for the bosons. $C_{\mathbf{lm}}(t)$ is the usual phase factor associated with the vector potential. Annihilation operators for the reservoir, w_i and v_i (with infinitesimal coupling constants η_i and ζ_i), represent positive and negative frequencies respectively and need to be treated separately. The energies a_i and b_i of the reservoir are both positive.

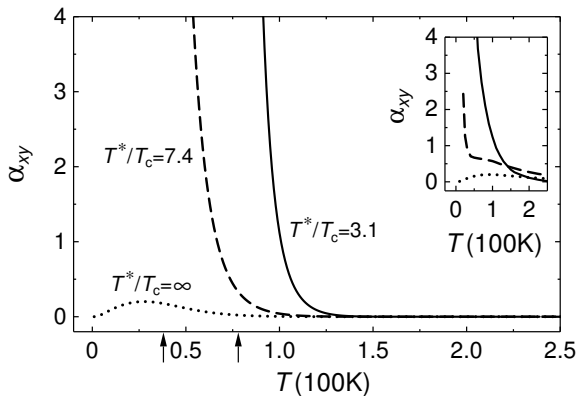

Figure 24.42: Calculated transverse thermoelectric response, which appears in the Nernst coefficient. Inset plots experimental [188] data. Both the theoretical and experimental values of α_{xy} are normalized by the value of α_{xy} for an optimally doped sample at $2T_c$, $0.0232(B/\mathrm{T})$ V/(KΩm).

The bosonic propagator $T(\mathbf{k},\omega)$ can be exactly computed from the equations of motion. Here $A(\mathbf{k},\omega) = \mathrm{Re}2iT(\mathbf{k},\omega)$ is the boson spectral function, and

$$T(\mathbf{k},\omega) \equiv \Big(\omega - \varepsilon(\mathbf{k}) - \Sigma_1(\omega) + \frac{i}{2}\Sigma_2(\omega)\Big)^{-1} \tag{24.140}$$

We have

$$\Sigma_2(\omega) \equiv 2\pi \sum_i |\eta_i|^2 \delta(\omega - a_i) - 2\pi \sum_i |\zeta_i|^2 \delta(\omega + b_i), \tag{24.141}$$

with $\Sigma_1(\omega)$ defined by a Kramers Kronig transform.

The reservoir parameters a_i, b_i, η_i and ζ_i which are of no particular interest, are all subsumed into the boson self energy $\Sigma_2(\omega)$. From this point forward we may ignore these quantities in favor of the boson self energy. We reiterate that this theory makes an important simplification, that the reservoir pairs have no dispersion. *For this case one can solve for the exact transport coefficients.*

For small, but constant magnetic and electric fields and thermal gradients we obtain the linearized response. For notational convenience, we define $v_{ab}(\mathbf{k}) \equiv \frac{\partial^2}{\partial k_a \partial k_b}\varepsilon(\mathbf{k})$. Then we can write a few of the in-plane transport coefficients which appear in Eqs. (24.8) and (24.9) as

$$\sigma = -\frac{e^{*2}}{2} \int \frac{\mathrm{d}^3k}{(2\pi)^3} \frac{\mathrm{d}\omega}{2\pi} v_x v_x A^2(\mathbf{k},\omega) \frac{\partial b(\omega)}{\partial \omega} \tag{24.142}$$

and

$$\alpha_{xy} = -\frac{e^{*2} B_z}{6T} \int \frac{\mathrm{d}^3k}{(2\pi)^3} \frac{\mathrm{d}\omega}{2\pi} v_x v_x v_{yy} \omega A^3(\mathbf{k},\omega) \frac{\partial b(\omega)}{\partial \omega}\,. \tag{24.143}$$

These equations naturally correspond to their TDGL counterparts (except for different phenomenological coefficients) when $T \approx T_c$.

Comparison with Transport Data

The formalism of the previous sub-section and in particular, Eqs. (24.142) and (24.143), can be used to address transport data within the framework of BCS-BEC crossover. The results for α_{xy}, which relates to the important Nernst effect, are plotted in Fig. 24.42 with a subset of the data plotted in the upper right inset. It can be seen that the agreement is reasonable. In this way a "pre-formed pair" picture is, at present, a viable alternative to "normal state vortices".

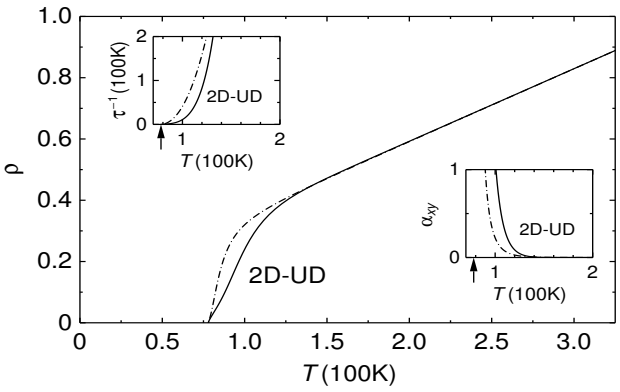

Figure 24.43: dc resistivity ρ (normalized by $\rho_Q \equiv s/e^2$) vs. T, for quasi-2D underdoped (UD) samples with two different forms for $\mu_{\rm pair}$. These are shown plotted in the left inset as $\tau^{-1} \equiv -\mu_{\rm pair}/{\rm Im}\gamma$. The right inset shows corresponding α_{xy}, and arrows indicate T_c.

Within the crossover scenario, just as in TDGL, there are strong constraints on other precursor transport effects: paraconductivity, diamagnetism and optical conductivity are all indirectly or directly connected to the Nernst coefficient, in the sense that they all derive from the same dynamical equation of motion for the bosons. Analogous inferences have been made [57], based on similar bosonic generalizations of TDGL.

The calculated behavior of a number of these other properties is summarized [170] in Figs. 24.43 and 24.44 below, which indicate both quasi-two dimensional and more three dimensional behavior. In the plots for the resistivity, ρ, a fairly generic [109] linear-in-T contribution [38] from the fermions has been added, as a background term. A central theme of concern in the literature is whether one can understand the behavior of ρ simultaneously with that of α_{xy}. Experiments [109, 186] indicate that there is a small feature corresponding to T^* at which ρ deviates from the background linear fermionic term, but that the deviation is not noticeably large except in the immediate vicinity of T_c. This is in contrast to the behavior of α_{xy} which shows a significant high temperature onset. A key observation from the theoretical calculations shown in the figures is that the onset temperatures for the Nernst coefficient and the resistivity are rather different with the former being considerably higher than the latter. Moreover all onsets appear to be significantly less than T^*. Qualitative agreement with experiment is not unreasonable. However, a more quantitative comparison with experiment has not been established, since it depends in detail on a phenomenological input: the temperature dependence of the pair chemical potential $\mu_{\rm pair}$.

Another important feature of these plots is the fact that there is virtually no diamagnetic precursor, as was also found to be the case in simple TDGL. To see this, note that the magnetization can be written [154, 170]

$$\frac{\mu_0 M}{B} = -\frac{4}{3}\frac{\alpha k_B T}{\hbar c}\frac{\xi_{ab}^2}{s\sqrt{1+(2\xi_c/s)^2}},$$

where α is the fine structure constant, c is the speed of light, s is the interlayer spacing, and ξ_{ab} (ξ_c) are coherence lengths in the direction parallel (perpendicular) to the planes. From this result we can estimate the order of magnitude of the diamagnetic susceptibility due to preformed pairs. For a typical high T_c superconductor, $T \sim 50$K, so that $\lambda \equiv \frac{hc}{k_B T} \sim 3\times 10^{-4}$m, and $\lambda/\alpha \sim 4\times 10^{-2}$m. Because the coherence lengths and the interlayer spacing are on the nanometer length scale, precursor effects in the diamagnetic susceptibility are of the order 10^{-6}, and thus extremely small, as is consistent with experiment [185].

[38] In reality, one should include an additional temperature dependence from pseudogapped fermions which presumably has a small upturn, relative to a linear curve, as T decreases.

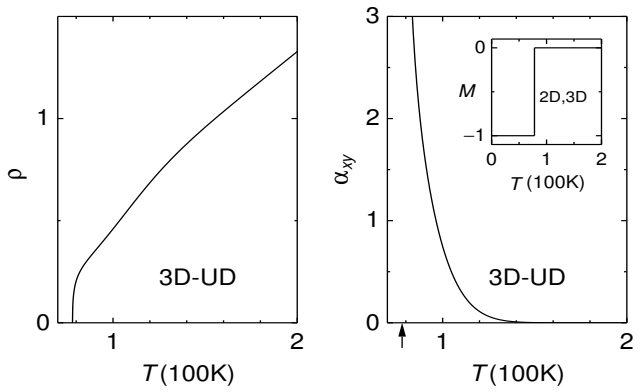

Figure 24.44: dc resistivity and α_{xy}, for an underdoped, more three-dimensional, system like YBCO. The arrow indicates T_c. The magnetization M is plotted as the inset, and is independent of dimensionality.

In order to make the BCS-BEC scenario more convincing it will be necessary to take these transport calculations below T_c. This is a project for future research and in this context it will ultimately be important to establish in this picture how superconducting state vortices are affected by the persistent pseudogap. Magnetic field induced magnetic order which has been associated with vortices [102] will, moreover, need to be addressed. The analogous interplay of vortices and pseudogap will also be of interest in the neutral superfluids.

24.8 Derivation of the $T = 0$ variational conditions

The ground state wavefunction is given by

$$\bar{\Psi}^0 = e^{-\lambda^2/2+\lambda b_0^\dagger}|0\rangle \otimes \Pi_{\mathbf{k}}(u_{\mathbf{k}} + v_{\mathbf{k}} a_{\mathbf{k}}^\dagger a_{-\mathbf{k}}^\dagger)|0\rangle \tag{24.144}$$

Thus one has three variational parameters $\lambda, u_{\mathbf{k}}, v_{\mathbf{k}}$ with normalization condition $u_{\mathbf{k}}^2 + v_{\mathbf{k}}^2 = 1$. We can define $\theta_{\mathbf{k}}$ such that $u_{\mathbf{k}} = \sin\theta_{\mathbf{k}}$ and $v_{\mathbf{k}} = \cos\theta_{\mathbf{k}}$, so that we have only two variational parameters, λ and $\theta_{\mathbf{k}}$.

We then have

$$\begin{aligned}\langle\bar{\Psi}^0|H-\mu N|\bar{\Psi}^0\rangle &= (\nu-2\mu)\lambda^2 + 2\sum_{\mathbf{k}}(\epsilon_{\mathbf{k}}-\mu)v_{\mathbf{k}}^2 \\ &+ 2U\sum_{\mathbf{k},\mathbf{k}'} u_{\mathbf{k}}v_{\mathbf{k}}u_{\mathbf{k}'}v_{\mathbf{k}'} + 2g\lambda\sum_{\mathbf{k}} u_{\mathbf{k}}v_{\mathbf{k}}\ ,\end{aligned}$$

where we have chosen $\varphi_{\mathbf{k}} = 1$ in Eq. (24.11) for simplicity.

Let us define

$$\Delta_{sc} = -2U\sum_{\mathbf{k}} u_{\mathbf{k}}v_{\mathbf{k}}. \tag{24.145}$$

The variational conditions are

$$\frac{\delta\langle H-\mu N\rangle}{\delta\lambda} = 0 \tag{24.146}$$

and

$$\frac{\delta\langle H-\mu N\rangle}{\delta\theta_{\mathbf{k}}} = 0 \tag{24.147}$$

These conditions yield two equations: a relationship between the two condensates

$$\frac{g\lambda}{\Delta_{sc}} = \frac{1}{U}\frac{g^2}{\nu-2\mu} \tag{24.148}$$

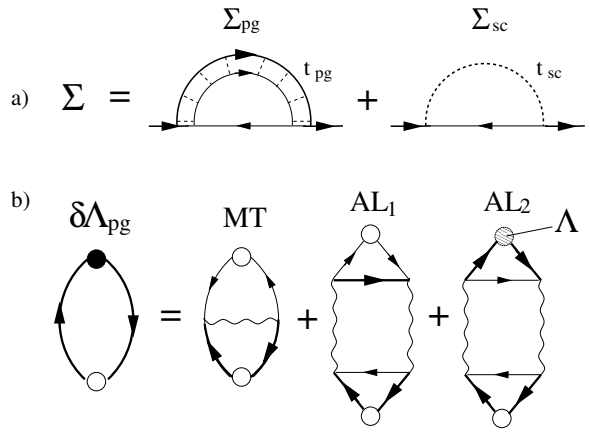

Figure 24.45: Self energy contributions (a) and response diagrams for the vertex correction corresponding to Σ_{pg} (b). Heavy lines are for dressed, while light lines are for bare Green's functions. Wavy lines indicate t_{pg}. See text for details.

and the $T = 0$ gap equation:

$$1 + (U + \frac{g^2}{2\mu - \nu}) \sum_{\mathbf{k}} \frac{1}{2E_{\mathbf{k}}} = 0 \; . \tag{24.149}$$

Similarly, we can write an equation for the total number of fermions

$$\begin{aligned} n^{tot} &= \langle \bar{\Psi}^0 | 2 \sum_{\mathbf{k}} b^\dagger_{\mathbf{k}} b_{\mathbf{k}} + 2 \sum_{\mathbf{k}} a^\dagger_{\mathbf{k}} a_{\mathbf{k}} | \bar{\Psi}^0 \rangle = 2\lambda^2 \\ &+ \sum_{\mathbf{k}} \left[1 - \frac{\epsilon_{\mathbf{k}} - \mu}{E_{\mathbf{k}}} \right] \end{aligned}$$

where

$$E_{\mathbf{k}} = \sqrt{(\epsilon_{\mathbf{k}} - \mu)^2 + \tilde{\Delta}^2_{sc}}, \tag{24.150}$$

with $\tilde{\Delta}_{sc} = \Delta_{sc} - g\lambda$. Thus we have obtained the three equations which characterize the system at $T = 0$. It should be clear that the variational parameter λ is the same as the condensate weight so that $\lambda = \phi_m \equiv \langle b_{\mathbf{q}=0} \rangle$.

24.9 Proof of Ward Identity Below T_c

We now want to establish that the generalized Ward identity in Eq. (24.106) is correct for the superconducting state as well. The vertex $\delta\mathbf{\Lambda}_{pg}$ may be decomposed into Maki-Thompson (MT) and two types of Aslamazov-Larkin (AL_1, AL_2) diagrams, whose contribution to the response is shown here in Fig. 24.45b. We write

$$\delta\mathbf{\Lambda}_{pg} \equiv \delta\mathbf{\Lambda}_{MT} + \delta\mathbf{\Lambda}^1_{AL} + \delta\mathbf{\Lambda}^2_{AL}(\mathbf{\Lambda}) \; . \tag{24.151}$$

Using conventional diagrammatic rules one can see that the MT term has the same sign reversal as the anomalous superconducting self energy diagram. This provides insight into Eq. (24.107). Here, however, the pairs in question are noncondensed and their internal dynamics (via t_{pg} as distinguished from t_{sc}) requires additional AL_1 and AL_2 terms as well, which will ultimately be responsible for the absence of a Meissner contribution from this normal state self energy effect.

Note that the AL_2 diagram is specific to our GG_0 scheme, in which the field couples to the full G appearing in the T-matrix through a vertex $\mathbf{\Lambda}$. It is important to distinguish the vertex $\mathbf{\Lambda}$ which appears in the AL_2 diagram from the full EM vertex Λ^{EM}.

In particular, we have

$$\mathbf{\Lambda} = \boldsymbol{\lambda} + \delta\mathbf{\Lambda}_{pg} - \delta\mathbf{\Lambda}_{sc}\,, \tag{24.152}$$

where the sign change of the superconducting term (relative to $\mathbf{\Lambda}^{EM}$) is a direct reflection of the sign in Eq. (24.107).

We now show that there is a precise cancellation between the MT and AL_1 pseudogap diagrams at $Q = 0$. This cancellation follows directly from the normal state Ward identity

$$Q \cdot \lambda(K, K+Q) = G_0^{-1}(K) - G_0^{-1}(K+Q)\,, \tag{24.153}$$

which implies

$$Q \cdot [\delta\Lambda^1_{AL}(K, K+Q) + \delta\Lambda_{MT}(K, K+Q)] = 0 \tag{24.154}$$

so that $\delta\mathbf{\Lambda}^1_{AL}(K,K) = -\delta\mathbf{\Lambda}_{MT}(K,K)$ is obtained exactly from the $Q \to 0$ limit.

Similarly, it can be shown that

$$Q \cdot \Lambda(K, K+Q) = G^{-1}(K) - G^{-1}(K+Q) \tag{24.155}$$

The above result can be used to infer a relation analogous to Eq. (24.154) for the AL_2 diagram, leading to

$$\delta\mathbf{\Lambda}_{pg}(K,K) = -\delta\mathbf{\Lambda}_{MT}(K,K)\,, \tag{24.156}$$

which expresses this pseudogap contribution to the vertex entirely in terms of the Maki-Thompson diagram shown in Fig. 24.45b. It is evident that $\delta\mathbf{\Lambda}_{MT}$ is simply the pseudogap counterpart of $\delta\mathbf{\Lambda}_{sc}$, satisfying

$$-\delta\mathbf{\Lambda}_{MT}(K,K) = \frac{\partial\Sigma_{pg}(K)}{\partial\mathbf{k}}\,. \tag{24.157}$$

Therefore, one observes that for $T \leq T_c$

$$\delta\mathbf{\Lambda}_{pg}(K,K) = \frac{\partial\Sigma_{pg}(K)}{\partial\mathbf{k}}\,, \tag{24.158}$$

which establishes that Eq. (24.106) applies to the superconducting phase as well. As expected, there is no direct Meissner contribution associated with the pseudogap self-energy.

24.10 Quantitative Relation between BCS-BEC crossover and Hartree-TDGL

In this appendix we make more precise the relation between Hartree-approximated TDGL theory and the T-matrix of our GG_0 theory. The Ginzburg-Landau (GL) free energy functional in momentum space is given by [62]

$$\begin{aligned} F[\Psi] &= N(0)\sum_{\mathbf{q}} |\Psi_{\mathbf{q}}|^2(\epsilon + \xi_1^2 q^2) \\ &\quad + \frac{b_0}{2}\sum_{\mathbf{q}_i} \Psi^*_{\mathbf{q}_1}\Psi^*_{\mathbf{q}_2}\Psi_{\mathbf{q}_3}\Psi_{\mathbf{q}_1+\mathbf{q}_2-\mathbf{q}_3}\,, \end{aligned} \tag{24.159}$$

where $\Psi_{\mathbf{q}}$ are the Fourier components of the order parameter $\Psi(\mathbf{r},t)$, $\epsilon = \frac{T-T^*}{T^*}$, ξ_1 is the GL coherence length, $b_0 = [1/T^2\pi^2]\frac{7}{8}\zeta(3)$, T^* is the critical temperature when feedback effects from the quartic term are neglected, and $N(0)$ is the density of states at the Fermi level in the normal state. The quantity $\langle|\Psi_{\mathbf{q}}|^2\rangle$ is determined self-consistently via

$$\langle|\Psi_{\mathbf{q}}|^2\rangle = \frac{\int D\Psi e^{-\beta F[\Psi]}|\Psi_{\mathbf{q}}|^2}{\int D\Psi e^{-\beta F[\Psi]}}\,, \tag{24.160}$$

where $F[\Psi]$ is evaluated in the Hartree approximation [163]. Our self consistency condition can be then written as

$$\langle|\Psi_{\mathbf{q}}|^2\rangle = \frac{T}{N(0}\left[\epsilon + b_0 \sum_{\mathbf{q}'}\langle|\Psi_{\mathbf{q}'0}|^2\rangle + \xi_1^2 q^2\right]^{-1} . \tag{24.161}$$

If we sum Eq. (24.161) over $\mathbf{q}$ and identify $\sum_{\mathbf{q}}\langle|\Psi_{\mathbf{q}0}|^2\rangle$ with Δ^2, we obtain a self-consistency equation for the energy "gap" (or pseudogap) Δ above T_c

$$\Delta^2 = \sum_{\mathbf{q}} \frac{T}{N(0)}\left[\epsilon + b_0\Delta^2 + \xi_1^2 q^2\right]^{-1} , \tag{24.162}$$

$$\Delta^2 = \sum_{\mathbf{q}} \frac{T}{N(0)} \frac{1}{-\bar{\mu}_{pair}(T) + \xi_1^2 q^2} , \tag{24.163}$$

where

$$\bar{\mu}_{pair}(T) = -\epsilon - b_0\Delta^2 . \tag{24.164}$$

Note that the critical temperature is renormalized downward with respect to T^* and satisfies

$$\bar{\mu}_{pair}(T_c) = 0 . \tag{24.165}$$

To compare with GL theory we expand our T-matrix equations to first order in the self energy correction. The T-matrix can be written in terms of the attractive coupling constant U as

$$t(Q) = \frac{U}{1 + U\chi_0(Q) + U\delta\chi(Q)} , \tag{24.166}$$

where

$$\chi_0(Q) = \sum_K G_0(Q-K)G_0(K) . \tag{24.167}$$

Defining

$$\Delta^2 = -\sum_Q t(Q) \tag{24.168}$$

we arrive at the same equation as was derived in Section 24.3.3

$$\Sigma(K) \approx -G_0(-K)\Delta^2 \tag{24.169}$$

where one can derive a self consistency condition on Δ^2 in terms of the quantity $\delta\chi(0)$ (which is first order in Σ), which satisfies

$$\delta\chi(0) = -b_0 N(0)\Delta^2, \tag{24.170}$$

implying that

$$\delta\chi(0) = -b_0 T\sum_{\mathbf{q}} \frac{1}{\epsilon + \xi_1^2 q^2 - \delta\chi(0)/N(0)} , \tag{24.171}$$

which coincides with the condition derived earlier in Eq. (24.162).

24.11 Convention and Notation

24.11.1 Notation

We follow standard notations as much as possible. They are summarized below.
E_F — Fermi energy
k_F — Fermi momentum
$\hbar$ — Planck constant
k_B — Boltzmann constant
c — Speed of light
e — Electron charge
T_c — Critical temperature for (superfluid/superconducting) phase transition
T^* — Pair formation or pseudogap onset temperature.
T — Temperature
μ, μ_{pair}, μ_B — Fermionic, pair and bosonic chemical potential, respectively.
Δ — Fermionic excitation gap
Δ_{sc} — Superconducting/superfluid order parameter
Δ_{pg} — Pseudogap
Four vector $K \equiv (i\omega_n, \mathbf{k})$, $\sum_K \equiv T\sum_n \sum_{\mathbf{k}}$, where $\omega_n = (2n+1)\pi T$ is the odd (fermionic) Matsubara frequency.
Four vector $Q \equiv (i\Omega_n, \mathbf{q})$, $\sum_Q \equiv T\sum_n \sum_{\mathbf{q}}$, where $\Omega_n = 2n\pi T$ is the even (bosonic) Matsubara frequency.
$f(x) = 1/(e^{x/k_BT}+1)$ — Fermi distribution function
$b(x) = 1/(e^{x/k_BT}-1)$ — Bose distribution function
$G(K)$, $G_0(K)$ — Full and bare Green's functions for fermions
$D(Q)$, $D_0(Q)$ — Full and bare Green's functions for Feshbach bosons.
$\Sigma(K)$, $\Sigma_B(Q)$ — Self energy of fermions and bosons, respectively.
$\chi(Q)$ — Pair susceptibility
$t(Q)$ — T-matrix
$\boldsymbol{\lambda}$, $\boldsymbol{\Lambda}$ — Bare and full vertex, respectively.
ν, ν_0 — Magnetic detuning parameter.
a_s, a_s^* — S-wave inter-fermion scattering length
U, U_0 — Renormalized and bare strength of the attractive interaction between fermions in the open-channel. $U_0 \propto a_s(\nu = +\infty)$.
U_c — Critical coupling strength at which the two-body scattering length diverges.
$A = (\phi, \mathbf{A})$ — Four vector potential
$J = (\rho, \mathbf{J})$ — Four current
$K^{\mu\nu}(Q)$ — Electromagnetic response kernel
$\epsilon_{\mathbf{k}} = k^2/2m$ — Bare fermion dispersion in free space
$\xi_{\mathbf{k}} = \epsilon_{\mathbf{k}} - \mu$ — Bare fermion dispersion measured from chemical potential.
$E_{\mathbf{k}}$ — Bogoliubov quasiparticle dispersion
$u^2_{\mathbf{k}} = \frac{1}{2}(1 + \xi_{\mathbf{k}}/E_{\mathbf{k}})$, $v^2_{\mathbf{k}} = \frac{1}{2}(1 - \xi_{\mathbf{k}}/E_{\mathbf{k}})$ — Coherence factor as given in BCS theory.
$n^{tot} = n + 2(n_b + n_{b0})$ — Total, fermion, finite momentum boson, condensed boson density, respectively.
$V(r) = \frac{1}{2}m\omega^2 r^2$ — Harmonic trap potential
We use alphabetic ordering when multiple authors appear together.
We always refer to the absolute value when we refer to the interaction parameters U, U_0, g, g_0 as increasing or decreasing.

24.11.2 Convention for units

Throughout this Review, we use the convention for units where it is not explicitly spelled out:

$\hbar = k_B = c = 1$.

$E_F = T_F = k_F = 2m = 1$.

In a harmonic trap, E_F, T_F and k_F are defined by the noninteracting Fermi gas with the same total particle number N. $E_F = \hbar\omega(3N)^{1/3}$. We further take the Thomas-Fermi radius $R_{TF} = 1$.

In this convention, the fermion density in a homogeneous gas in three dimensions is $n = 1/3\pi^2$, the harmonic trap frequency $\omega = 2$, and the total fermion number in a trap is $N = 1/24$.

In the two-channel model, the units are E_F/k_F^3 for U and U_0, and $E_F/k_F^{3/2}$ for g and g_0.

Our fermionic chemical potential μ is measured with respect to the bottom of the energy band, which leads to (i) $\mu = E_F$ in the non-interacting limit at $T = 0$, and (ii) μ changes sign when the system crosses the boundary between fermionic and bosonic regimes.

24.11.3 Abbreviations

BCS — Bardeen-Cooper-Schrieffer (theory)
BEC — Bose-Einstein condensation
GL — Ginzburg-Landau (theory)
TDGL — Time-dependent Ginzburg-Landau (theory)
RPA — Random phase approximation
LDA — Local density approximation
GP — Gross-Pitaevskii
TF — Thomas-Fermi (approximation)
NSR — Noziéres and Schmitt-Rink
FLEX — FLuctuation EXchange
AB — Anderson-Bogoliubov (mode)
PG — Pseudogap
SC — Superconductor
AFM — Antiferromagnet
FB — Feshbach boson
LSCO — $La_{1-x}Sr_xCuO_4$
BSCCO — $Bi_2Sr_2CaCu_2O_{8+\delta}$
YBCO — $YBa_2Cu_3O_{7-\delta}$

Part IX
High Temperature Superconductivity

25 High Temperature Superconductivity in the Cuprates: Materials, Phenomena and a Mechanism by Banerjee, Dasgupta, Mukerjee, Ramakrishnan, Sarkar

Abstract

Superconductivity in the cuprates, discovered in the late 1980's and occurring at unprecedentedly high temperatures (up to about 140K) in about thirty chemically distinct families, continues to be a major problem in physics. In this article, after a brief introduction of these square planar materials with weak interlayer coupling, we mention some of the salient electronic properties of hole doped cuprates such as the pseudogap phase and the Fermi arc . We then outline a phenomenological, Ginzburg Landau like theory developed by some of us for the emergent d-wave symmetry superconductivity in these materials, and confronted successfully with a large amount of experimental information. A more recent application of the approach to fluctuation diamagnetism and to the anomalously large Nernst effect is also discussed.

25.1 Introduction

Superconductivity was discovered more than a century ago, and seemed to be a very low temperature phenomenon confined to temperatures below about 20K. Therefore the discovery of high temperature superconductivity in a family of cuprates around 1987 or so took the Physics world by surprise, not only because the temperatures (T_c) for transition to superconductivity are high (by values prevalent till then in the field; the cuprate T_c's range from about 30K to about 140K), but also because these materials have unusual physical properties. Major unexpected experimental discoveries continue to be made, and there is no single broadly accepted theoretical framework in which the wide range of observed properties can be understood and calculated. In this article, we will outline some of the broad materials characteristics of these systems, some of their basic properties, and outline a novel phenomenological approach which is used to compute a wide range of experimental properties.

The article is organized as follows. Section 25.2 of this article is an introduction to the family of cuprate materials with a description of their structure and a *minimal* electronic model appropriate to the cuprates. A long section (Section 25.3) describes the phase diagram of the hole doped cuprates, which in addition to antiferromagnetically ordered insulating phase and a superconducting region, hosts 'pseudogap' and strange metal regions. The unusual electronic properties of these phases are also described. (This is what makes the section long). Section 25.4 introduces our phenomenological, superficially Ginzburg-Landau-like approach to the system. In Section 25.5, we outline further extensions of this phenomenological theory to describe transport properties (especially the unusual Nernst or thermo-magneto-electric effect) and electron spectra as measured in ARPES (Angle Resolved Photo Emission Spectroscopy). Section 25.6 mentions some of the major results obtained from the theory for a broad range of equilibrium and nonequilibrium phenomena, above and below T_c and for a range of doping x. The concluding section (Section 25.7) mentions some future directions.

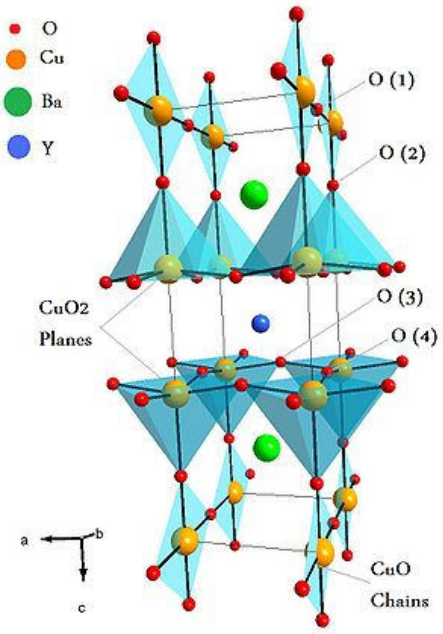

Figure 25.1: Orthorhombic unit cell of $YBa_2Cu_3O_{7-x}$ (YBCO or Y123) with $a = 3.82$ Å along [100] and $b = 3.89$ Å along [010]. The c axis dimension is around 12 Å.

25.2 Materials, structure and minimal electronic model

The cuprates , e.g. $La_{2-x}Sr_xCuO_4$, $YBa_2Cu_3O_{7-x}$, $Bi_2Sr_2Ca_{n-1}Cu_nO_{2n+4+x}$ (n=1,2,3) can be thought of as being made up of highly distorted corner sharing octahedra derivable from the ABO_3 perovskite family. The O^{2-} ions are at the corners of the octahedron, the Cu^{2+} ions at the centre, and the transition metal or rare-earth ions in the space between the octahedra. The Jahn-Teller distortion due the Cu^{2+} ions is very large; the plane of the octahedron is split in two, with a large splitting. (Fig.25.1 shows the structure of $YBa_2Cu_3O_{7-x}$). A good approximation for the electronic properties of these systems is to regard the materials as consisting of Cu-O planes; the Cu and O ions are arranged in squares in the plane, with O ions at the midpoint of the nearest Cu-Cu line. The low energy electronic degrees of freedom arise from the unfilled d shell electrons of the Cu^{2+} ions which are in the d^9 configuration. The Cu ions are at the vertices of a square whose length in most cuprates is about 3.9Å. Crudely, at the single site level, the occupation of the nine d electrons of the Cu^{2+} ion can be described as follows. The tenfold atomically degenerate d level is split into t_{2g} and e_g configurations, with the former lying lower in energy. Its six states are fully occupied by d electrons. That they do not take part in any low energy electron processes, and are strongly bonded with O^{2-} electrons, is clear from the fact that the relevant bond lengths, reflected in the Cu-Cu distances, are about the same in almost all cuprates. The twofold degenerate e_g level is strongly split in two by the Jahn-Teller distortion mentioned above; the lower one is fully occupied and the higher one is half occupied in the d^9 configuration.

For large local Coulomb repulsion or Mott Hubbard U (as is widely believed to be the case in cuprates from both theoretical and experimental evidence) the fluctuations in the number of local d electrons is strongly suppressed, and the material is an insulator for exactly one e_g electron per site (Mott insulator). If the cuprate is hole doped (for example, the trivalent La is partially substituted by the divalent Sr) both naively, and from a more sophisticated model which includes the oxygen p electrons, it is clear that the system can be thought of electronically as consisting (on the average) of $(1 - x)$ electrons per unit cell where a fraction x of the trivalent La ions is substituted by Sr ions. These electrons move on a square lattice,

and in a tight binding picture can be regarded as hopping from one site to another on a square planar lattice with hopping amplitudes t, t' etc.. There is an energy penalty of U for double occupation of a particular site by electrons. There is an amplitude λt ($\lambda << 1$) for electron hopping perpendicular to the plane. We will neglect this in what follows. Based on the above picture, a one-band Hubbard model on a square lattice is believed to be a reasonable microscopic description for most of the universal aspects of the cuprate phase diagram. The most widely used values for these parameters which define the electron dynamics of the model are, $t = 300$ meV, $t'/t = -1/4$ [1] and $U = 2 - 4$ eV [2]. The large value of U ($U \gg 4t$, the half bandwidth) implies that the material is a strongly correlated metal in which the electron of the Cu hops from site to site, avoiding other d electrons. In the large U limit the one-band model Hubbard model reduces to the well-known $t - J$ model,

$$\hat{\mathcal{H}}_{t-J} = -\sum_{<ij>,\sigma} \mathbb{P}_G \left(t_{ij} a^\dagger_{i\sigma} a_{j\sigma} + \text{h.c.} \right) \mathbb{P}_G + J \sum_{<ij>} (\hat{\mathbf{S}}_i . \hat{\mathbf{S}}_j - \frac{1}{4} \hat{n}_i \hat{n}_j), \tag{25.1}$$

which has been used extensively [3] in the context of cuprates. Here the $a^\dagger_{i\sigma}$ is the usual fermion creation operator on site i, $n_i = \sum_\sigma a^\dagger_{i\sigma} a_{i\sigma}$ and $\hat{\mathbf{S}}_i$ are the electron number and spin operators, respectively, and $\mathbb{P}_G = \prod_i (1 - \hat{n}_{i\uparrow} \hat{n}_{i\downarrow})$ is a projection operator excluding double occupancy of any site; J can be estimated to be around 0.13 eV [4].

25.3 Phase diagram and phenomena

An idealized 'phase diagram' of hole doped cuprates, in the hole density x and temperature T plane, is shown in Fig.25.2. Interestingly, it is nearly the same for the entire cuprate family. The parent compound is a Mott insulator which undergoes a Ne'el transition at T_N to an antiferromagnetic state. Upon doping, the T_N drops very rapidly and goes to zero beyond a small value of doping ($x \simeq 0.03$). The superconducting state sets in, preceded by a messy disordered low-temperature phase exhibiting spin glass like behavior till $x \simeq 0.05$. The superconducting transition temperature, $T_c(x)$, detected unambiguously by the onset of the zero resistance state, exhibits a well known parabolic (the 'superconducting dome') dependence with increasing x and reaches a maximum at $x \simeq 0.16$ and ultimately declines to zero for $x \gtrsim 0.25$. The x value corresponding to the maximum T_c is called the *optimal doping* (x_{opt}) and the regimes, $x < x_{\text{opt}}$ and $x > x_{\text{opt}}$, are denoted as *underdoped* and *overdoped* regions, respectively. The high temperature region corresponding to the *normal states* of the superconductor above the superconducting dome is rather *abnormal* ones among known states of matter found in Nature. This region can be broadly classified into three parts, the so-called *pseudogap* region for small x (underdoped), the *strange metal* phase for intermediate values of x and a more 'normal' (i.e. conventional) metal for large x, i.e. the overdoped region. The pseudogap state goes into the strange metal phase, above a temperature scale depicted as the pseudogap sclae T^* (see Fig.25.2), which seems more like a crossover (as opposed to a true phase transition) from variety of measurements. Below, we briefly discuss superconducting, strange metal phases and pseudogap phases and summarize some of their unusual features. We also include a separate detailed discussion of spectroscopic characteristics of these phases, as probed by angle-resolved photoemission (ARPES) and scanning tunneling (STS) spectroscopies.

25.3.1 Superconducting state

The superconducting state is less unconventional compared to the other parts of high-T_c phase diagram. The superconducting order parameter is a charge $2e$ complex field with d-wave symmetry as has been unambiguously demonstrated by phase sensitive measurements [6, 7]. In conventional superconductors the Cooper pair amplitude or the energy gap [8] that appears

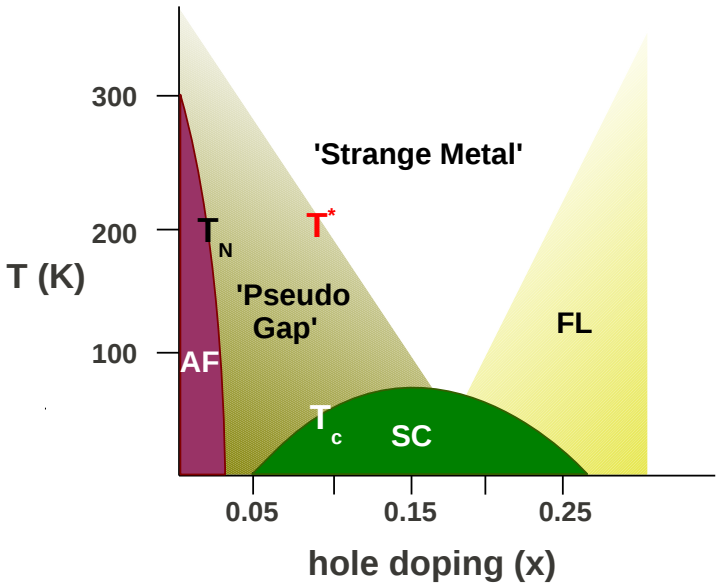

Figure 25.2: The famous phase diagram of hole doped cuprates, showing superconductive (SC), antiferromagnetic (AF), *pseudogap*, *strange metal* and more conventional Fermi liquid (FL) metal regions. Also indicated are the Ne'el temperature (T_N), superconducting transition temperature (T_c) and somewhat *ill defined* pseudogap temperature scale (T^*).

in the spectrum of electronic excitations with momentum $\mathbf{k}$ on the Fermi surface, namely $\Delta_{\mathbf{k}}$, is generally independent of $\mathbf{k}$, whereas in cuprates it is strongly $\mathbf{k}$ dependent and has nodes i.e. vanishes along certain $\mathbf{k}$ directions. An approximate two dimensional representation of d-wave symmetry superconducting gap, whose validity for cuprates has been established by ARPES [9, 10, 11] and phase-sensitive Josephson junction measurements (see later), is $\Delta_{\mathbf{k}} = (\Delta_0/2)(\cos k_x a - \cos k_y a)$ (see Fig.25.3, a is Cu-O-Cu bond length in the plane and Δ_0 is the maximum gap magnitude). This can arise in a lattice system through nearest neighbor pairing such that magnitude of pair amplitude (a complex number) along x and y bonds is same but the phases differ by π (see Fig.25.1). A gap function of this kind implies nodal Bogoliubov quasiparticles leading to substantial density of gapless excitations (see Fig.25.3) and these would dominate the behavior of various physical properties at low temperatures ($T \ll T_c$). Particularly, since the density of states (DOS) vanish linearly in energy, the nodal excitations give rise to, e.g., a non-activated T^2 term in electronic specific heat[12] and similar power law T dependences of various other quantities [13, 14], unlike that in a s-wave superconductor. An interesting effect [15] can be seem in the presence of a magnetic field H due to a shift of the quasiparticle spectrum by an amount $\propto H^{1/2}$; this has been verified experimentally [16].

The superconductivity in cuprates has several unusual characteristics. Here we list a few of them.

1. Short coherence length: The length scale associated with pairing, namely the coherence length (ξ_0), is very small in cuprate superconductors - around $15 - 20$ Å in the plane and, between planes 2 Å, even smaller than the interlayer spacing, implying that the superconductivity related phenomena in the cuprates can be thought of as effectively having Josephson coupled [8] planes.

2. Low superfluid density: Cuprates superconductors are characterized by very small

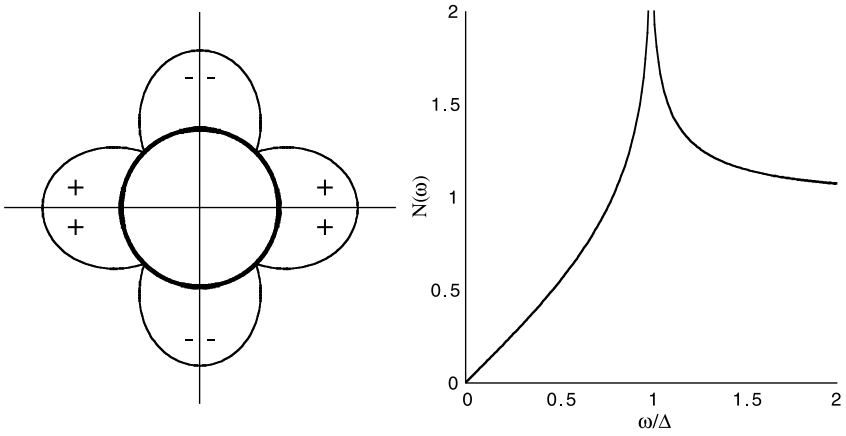

Figure 25.3: Variation of the d-wave gap on the Fermi surface is shown in the left figure, $k_x = \pm k_y$ is the nodal direction. The density of states (DOS) is plotted in the right figure. A DOS divergence appears at the maximum gap magnitude $\omega = \Delta$. (From Ref.[5])

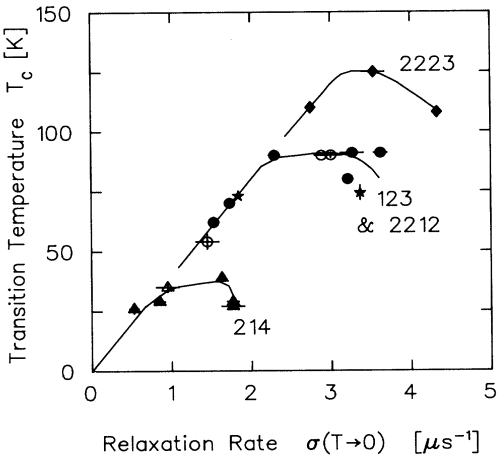

Figure 25.4: The superconducting transition temperature T_c as a function of low temperature muon spin-relaxation rate $\sigma(T \to 0) \propto 1/\lambda_{ab}^2(0) \propto \rho_s(0)$ for different cuprate compounds. At the low doping values data fall on the *universal* straight line indicating the Uemura correlation $\rho_s \propto T_c$. (See Ref.[17] for more details).

in-plane superfluid density or stiffness ρ_s. The low temperature superfluid density ρ_s for small doping goes as x, as also does T_c. This is the so-called Uemura scaling [17], $\rho_s \propto T_c$ for small x (see Fig.25.4). Such a scaling is unusual for conventional superconductors, typically having very large ρ_s and much smaller T_c [18]. Since the in-plane penetration depth $\lambda_{ab} \propto 1/\rho_s^{1/2}$, cuprates have very large penetration depth (~ 1500 Å), implying the extreme type-II limit [8] for these superconductors. Small superfluid density of phase stiffness indicates the importance of phase fluctuations, which are expected to be very strong, especially in the underdoped regime. This fact is corroborated by the observation of large Nernst effect[19] and enhanced fluctuation diamagnetism[20] by Ong and coworkers over an unusually large temperature range above T_c. A phase fluctuation related theory for this is described later here.

3. Gap to T_c ratio: Another important experimental observation about the superconducting state is that the zero temperature superconducting gap Δ_0 inferred, e.g., from STM [21] or ARPES [10, 11] increases, whereas T_c declines, as mentioned above, in the underdoped side with decreasing doping. Both the measured ratio $(2\Delta_0/k_B T_c)$ and the x dependence imply the violation of the BCS relation between Δ_0 and T_c i.e. $2\Delta_0/k_B T_c \simeq 4.3$ for d-wave[22]. However, of late, the large gap seen via spectroscopy has been attributed to other competing

order [23, 24] or as having non-pairing origin [25, 26, 27].

4. Emergence from pseudogap state: In the underdoped side, the precedence of *pseudogap phase* (see Fig.25.2) while approaching the superconducting state from high temperatures suggests that the transition is not a sudden gap appearance one, as in BCS. This is related with the pseudogap phenomena which we discuss below in more detail.

5. Anomalous high-field vortex states: The mixed state of cuprate superconductor at high field and low temperature is rather anomalous, showing mangetoconductivity (Shubnikov-deHaas (SdHvA)) and magnetization (deHaas-van Alphen (dHvA)) oscillations as a function of $(1/H)$, e.g. in clean $YBa_2Cu_4O_8$ and $HgBa_2CuO_{4+\delta}$ [28, 29, 30]. These quantum oscillations have been seen with an accompanying long-range charge-density wave (CDW) order even far below the irreversiblity field for superconducting to non-superconducting transition [31, 32, 33], presumably related to vortex lattice or vortex glass depinning [34].

25.3.2 Strange metal

The strange metal is one of the most enigmatic phases in the cuprate phase diagram (Fig.25.2). Transport measurements reveal that the resistivity is linear in temperature over a large range, the most fascinating example being the single layer Bi2201, where linearity persists down to $T_c \simeq 7$ K [35], starting from an amazingly high temperature (~ 700 K). This behaviour is in strong contrast to what one expects on the basis of Fermi liquid theory. We discuss a few of the strange properties of the strange metal phase below.

1. T-linear resistivity: In conventional low-temperature superconductors, the temperature dependence of resistivity ρ is well described by $\rho \approx \rho_0 + bT^5$, at low T ($> T_c$). This T dependence well below the phonon Debye temperature θ_D arises from the scattering of electrons by phonons. At higher temperatures ($T \gtrsim \theta_D$), a linear behavior is expected, and the interpolation between the two regimes is given by the Grüneisen-Bloch formula. The residual resistivity ρ_0 at $T = 0$ is caused by scattering by impurities. However, the behaviour of ρ observed in high-T_c superconductors is strikingly different. Resistivity in the CuO_2 planes for several different cuprate compounds near optimal doping exhibits an approximate linear behavior over a large temperature window [36, 37] as shown in Fig.25.5. The resistivity values are very large at high temperature, e.g., in comparison to that of copper at room temperature, which has a resistivity of 1.7 $\mu\Omega$cm. This seems to be one of the defining characteristics of strongly correlated metals i.e. typical resistivity values are quite large, often of the same order or even larger than the Ioffe-Regel limit and increase linearly with temperature without any saturation. Fig.25.5 demonstrates clear linear behaviour with very similar slopes for the various compounds, suggesting a possible common origin for in-plane transport.

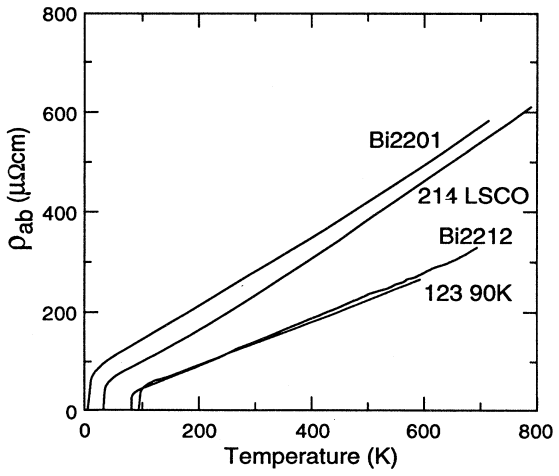

Figure 25.5: Temperature dependence of the in-plane resistivity ρ_{ab} for various optimally doped cuprates. (From Ref.[36]).

The linear T dependence [37] is something not fundamentally understood, and is generally associated with strong correlation in the system. As is well known, electron-electron interaction in Fermi liquid systems leads to a T^2 dependence of resistivity, unlike what is observed in optimally doped cuprates. With increasing doping, the temperature dependence is of the form $\rho_{ab} \propto T^{\alpha}$ with α increasing smoothly from 1 to 2 from optimum to overdoped [38]. This behaviour is also not understood, but presumably can be broadly described as due to the system changing from strongly correlated non-Fermi liquid to weakly interacting Fermi liquid.

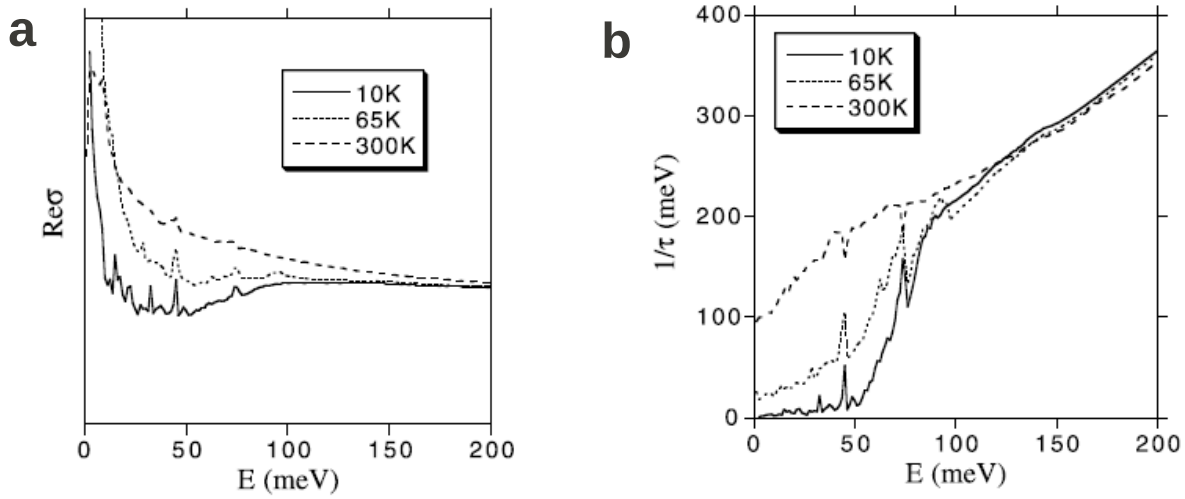

Figure 25.6: **a**, Real part of in-plane infrared optical conductivity of underdoped YBCO for the superconducting state (10 K), pseudogap phase (65 K), and normal state (300 K). A gap-like suppression develops at around 50 meV in the pseudogap regime. **b**, Variation of extracted optical scattering rate $1/\tau(\omega)$ with frequency for underdoped YBCO. (From Ref.[39]).

2. ω-linear scattering rate: Optical conductivity, which probes the current-current correlation function, gives further evidence of the unconventional nature of the strange metal phase. In plane, the normal state (both strange metal and pseudogap states) of cuprates is characterized by a broad, Drude-like response centered at frequency $\omega = 0$ (Fig.25.6 **a**) for optical conductivity $\sigma(\omega)$. The data are phenomenologically represented by a generalized Drude form [39]

$$\sigma(\omega) = \frac{1}{4\pi} \frac{\omega_{\rm pl}^2}{1/\tau(\omega) - i\omega[1+\lambda(\omega)]}, \tag{25.2}$$

where $\omega_{\rm pl}$ (the plasma frequency) is given by the sum rule $\int_0^\infty d\omega {\rm Re}\sigma(\omega) = (\omega_{\rm pl}^2/8)$ (here, $\sigma = {\rm Re}\sigma + i{\rm Im}\sigma$ and the integral has a high frequency cut off ~ 1 eV). In the above form, $1/\tau(\omega)$ and $1+\lambda(\omega)$ are the frequency dependent scattering rate and mass renormalization, respectively. The analysis of the experimental data using eq.(25.2) reveals that the scattering rate has the form $a + b\omega$ (see Fig.25.6 **b**), unlike a Fermi liquid where $1/\tau \sim \omega^2$. The ω-linear term is expected from a marginal Fermi liquid theory [40, 41].

25.3.3 Pseudogap phase

One of the most controversial aspects of the cuprate phase diagram is the nature of *pseudogap phase*. This is associated with a set of ill-understood apparent crossover phenomena [42, 43, 44, 45], which are widely observed in underdoped cuprates and, to some extent, in optimally and even slightly overdoped materials. As we summarize below, signatures of gap

are observed through different experimental probes, e.g., spin susceptibility, thermodynamic, transport and optical measurements, and in the quasiparticle excitations investigated through ARPES and scanning tunneling microscopy (STM),. As shown in Fig.25.2, these gap-like features ('pseudogap' as opposed to true gap) become prominent below a temperature scale T^* (the pseudogap temperature), which varies somewhat when detected using different probes. In the underdoped samples, T^* is way above the superconducting transition temperature T_c, which is traditionally detected through the onset of zero resistance state, indicating that superconducting long range order (LRO) is not present in the pseudogap state even though there are clear hallmarks of a gap of the kind resembling that of the d-wave symmetry superconducting state. Below, we touch upon some of the salient fetures of the pseudogap phase.

1. "Spin gap" in spin susceptibility: The first experimental indication [46] of a pseudogap phase came from NMR measurements in underdoped YBCO, which showed that the spin lattice relaxation rate (which depends on the number of conduction electron spin states at the Fermi energy) starts to decrease much above T_c. A similar decrease is seen in the related Knight shift [47] (Fig.25.7). NMR experiments probe the spin channel, unlike optical conductivity which probes the charge degrees of freedom. The decrease of Knight shift indicates decrease of spin susceptibility with temperature in the pseudogap state of cuprates, initially supporting the hypothesis of spin gap [46]. Subsequent experiments, however, have demonstrated that the pseudogap exists in both spin and charge channels, as evident from, e.g., ARPES or optical conductivity.

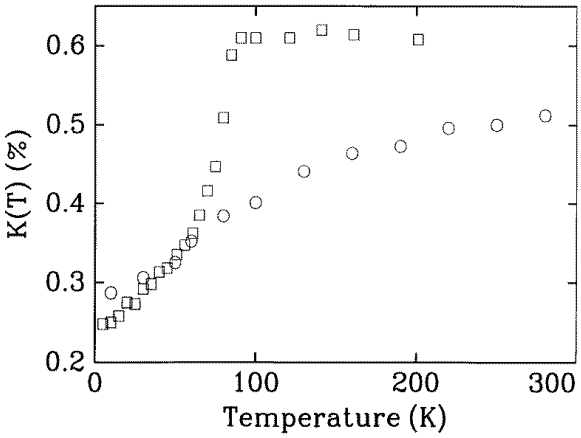

Figure 25.7: Knight shift in $YBa_2Cu_3O_{6.95}$ (squares) and underdoped $YBa_2Cu_3O_{6.64}$ (circles). The normal-state susceptibility is temperature independent above T_c in the optimally doped compound, but decreases with temperature in the underdoped compound even above T_c. (From Ref.[42]).

2. Suppression of specific heat: Another evidence of pseudogap comes from the electronic specific heat [45, 42]. The electronic specific heat provides thermodynamic evidence for a gap in the normal state of the cuprates [49]. The specific heat is generally found to be linear in temperature $C_v \approx \gamma T$ above the pseudogap temperature scale T^*. Below T^*, C_v/T begins to decrease with decreasing temperature (Fig.25.25), indicating presence of a normal state gap. For YBCO, above T_c, overdoped samples show (Fig.25.25 **a**) a temperature- and doping-independent γ. The underdoped samples have a depression of the specific heat coefficient in the normal state below T^* (Fig.25.25 **b**) [49] and the specific heat jump at T_c is diminished with decreasing doping. Evidence of pseudogap in specific heat measurements has also been found in other cuprates [50, 51].

3. Transport signatures of pseudogap: There is a significant deviation of in-plane or the ab-plane resistivity from the T linear temperature dependence of strange metal at higher temperature. A pseudogap temperature [37] is identified as the point below which temperature-dependence of in-plane resistivity deviates significantly from its high temperature behavior (see, e.g., Fig.25.9 **a**). A similar temperature scale can be inferred from the Hall resistance which,

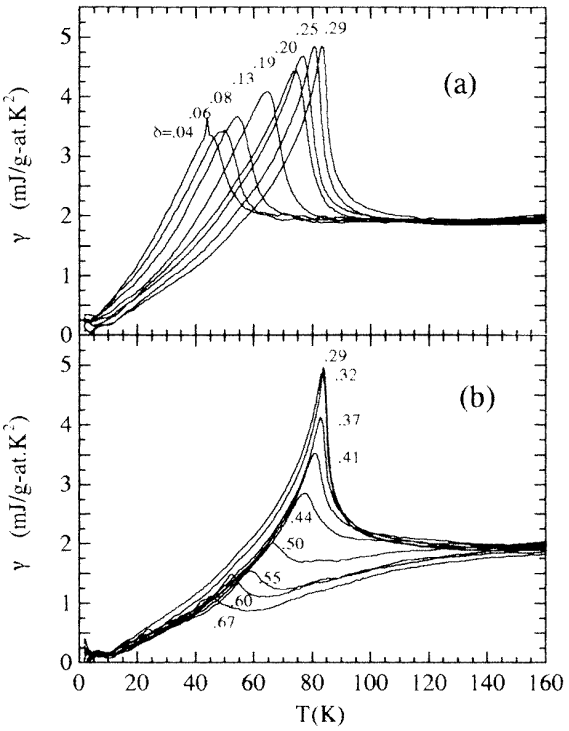

Figure 25.8: Specific heat coefficient γ for (a) overdoped and (b) underdoped $Y_{0.8}Ca_{0.2}Ba_2Cu_3O_{7-\delta}$. In the overdoped material a gap opening, signalled by a peak and the subsequent suppression of γ, occurs below T_c. In the underdoped materials a gap appears to form much above T_c, around 140K, in the normal state itself. (From Ref.[48]).

quite remarkably, is strongly temperature dependent [52]. The pseudogap also appears in the c-axis resistivity ρ_c [53, 54] as an insulator-like increase with decreasing temperature.

4. Optical gap: A signature of a gap is also observed in infrared measurements exhibiting a suppression in the ab-plane optical conductivity $\sigma'_{ab}(\omega)$ separating the low energy Drude peak from 'bump'-like feature at mid-infrared [55, 56] (see Fig.25.6 **a**). Interestingly, c-axis optical conductivity $\sigma_c(\omega)$ reveals more dramatic effect of a pseudogap; $\sigma_c(\omega)$ does not have a Drude peak at low energies and shows a significant gap below a characteristic frequency scale. The gap becomes more prominent as one approaches T_c.

5. Temperature and doping dependent Drude peak: The other interesting observation is that the width of the Drude peak in σ_{ab} decreases with temperature, but the area (spectral weight) under it is independent of temperature [57]. Intriguingly, the integrated area under the Drude peak is found to be linear in x [58, 59] indicating a connection to the doped holes [3] and this weight transforms to form the delta function superfluid peak in the superconducting state suggesting $\rho_s \propto x$. However, as we discuss below, ARPES shows a Fermi surface with an area corresponding to $1-x$ electrons [3].

6. Anomalous Nernst and fluctuation diamagnetism regime in the pseudogap phase: Experiments have found a very large diamagnetic and Nernst response in the pseudogap phase of the cuprates. A large diamagnetic signal naturally points towards fluctuating superconductivity as one of the possible origins. Also, the fact that the Nernst response is usually very small in typical nonmagnetic metals and a much stronger response is observed in the vortex-liquid regime of superconductors supports this point of view. Compared to conventional superconductors, the Nernst and diamagnetic response have been found to exist over an anomalously large region [61, 60] in the pseudogap phase, extending to temperatures far above the superconducting transition temperature T_c (see however ref. [62, 63, 64]). Another important piece of the debate is related to the fact that the putative boundary [61, 60] of the large Nernst and diamagnetic response regime, the so-called 'onset' temperature $T_{\rm onset}$, tracks $T_c(x)$ and so follows a dome-shaped curve as a function of doping x instead of tracking the pseudogap temperature scale $T^*(x)$, which monotonically decreases with x (see Fig.25.12) .

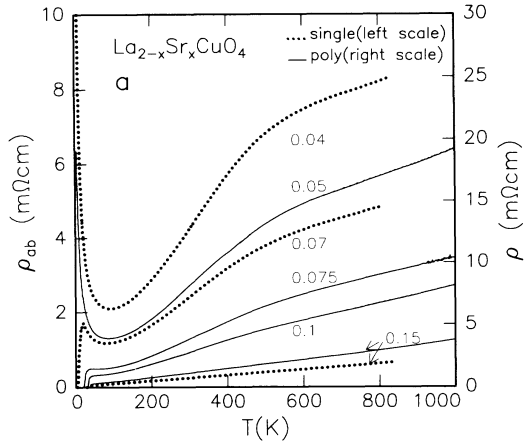

Figure 25.9: Temperature dependence of in-plane resistivity for underdoped LSCO ($0 \leq x \leq 0.15$). Around the pseudogap temperature scale, the resistivity starts deviating from nearly linear in T high-temperature behavior. (From Ref.[37]).

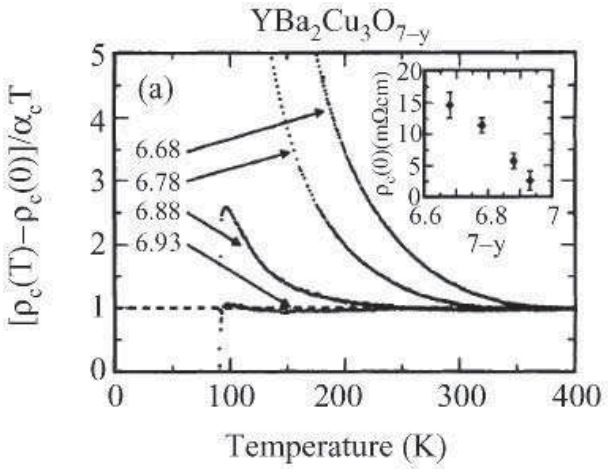

Figure 25.10: The temperature dependence of the c-axis resistivity in underdoped and optimally doped $YBa_2Cu_3O_{7-\delta}$ after the subtraction of the intercept of a approximately linear-T metallic part; α_c is the slope of the linear-T part. (From Ref.[53]).

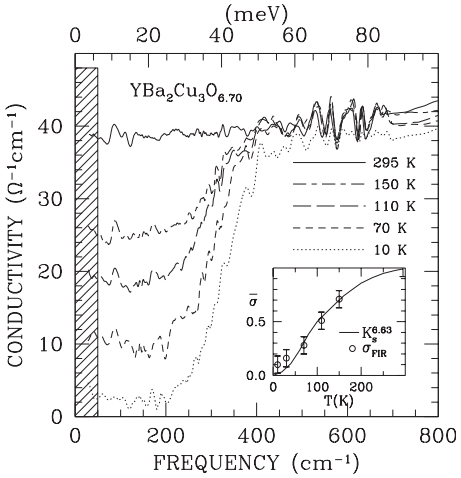

Figure 25.11: c-axis optical conductivity for underdoped YBCO demonstrating a pseudogap which fills in with temperature (From Ref.[39])

This has been argued as evidence against a pairing origin of the pseudogap, mainly due to the expectation that if the pseudogap arises from pairing then superconducting fluctuations and associated Nernst and diamagnetic responses should persist all the way up to pseudogap temperature [3].

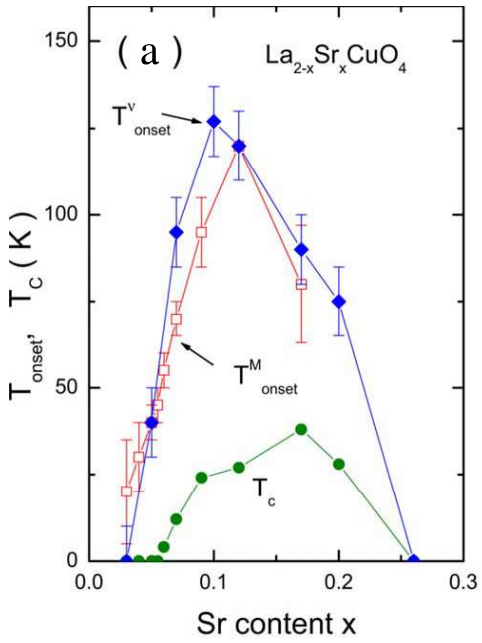

Figure 25.12: The phase diagram of LSCO showing the onset temperatures, $T^{\nu}_{\rm onset}$ and $T^{M}_{\rm onset}$, determined by enhanced Nernst and diamagnetic signal, respectively, as a function of doping. $T_c(x)$ is shown for comparison (From Ref.[60]).

25.3.4 Spectroscopic characteristics of superconducting, strange metal and pseudogap phases

Angle-resolved photoemission spectroscopy (ARPES) and scanning tunneling microscopy (STM) have emerged as two of the major tools for probing condensed matter systems mainly due to their success in directly accessing electronic excitations in cuprates. Here we discuss in somewhat more detail the major findings and phenomenologies that have emerged out of the ARPES and STM studies on cuprates.

1. ARPES: It is really the ARPES experiments [10, 11] that unambiguously demonstrated the pseudogap. Reviews by Damascelli *et al.* [10] and Campuzano *et al* [11] provide an in-depth discussion on this topic. Cuprates are ideal candidates for ARPES experiments owing to their approximate 2d nature that enables easy cleavage and possibility of experiments on atomically 2d surfaces that are representative of the bulk. One can also infer the in-plane electron momentum **k** with high precision. ARPES, a modern version of familiar photoelectric effect, measures the spectrum of electrons (photoemission intensity as a function of energy ω and momentum **k** of electron in the sample) ejected due to incident photons. In this way, ARPES probes the electronic spectral function or spectral density $A(\mathbf{k},\omega)$, that quantifies the probability of finding an electron with momentum **k** and energy ω (measured from the Fermi energy or the chemical potential). The energy corresponding to the position of a peak (if there is one, as in the case of a quasiparticle in a Fermi liquid) in $A(\mathbf{k},\omega)$ for a fixed **k** gives the information of energy of electronic excitations for that **k**, and their dispersion; the width of the peak is a measure of the life time of such excitations. ARPES can map out the Fermi surface from the **k**-space locus of the minimum energy excitation [10, 11] in the Brillouin zone. Peak in $A(\mathbf{k},\omega)$ for a particular **k** on the Fermi surface appearing at a nonzero energy indicates a gap in the electronic excitation. The gap can either be traced from the raw data of energy distribution curve (EDC, photoemission intensity as a function of energy for a fixed **k**) through the pulling back of the leading edge of the electronic spectrum from the Fermi energy (Figs.25.27 **a-c**) or

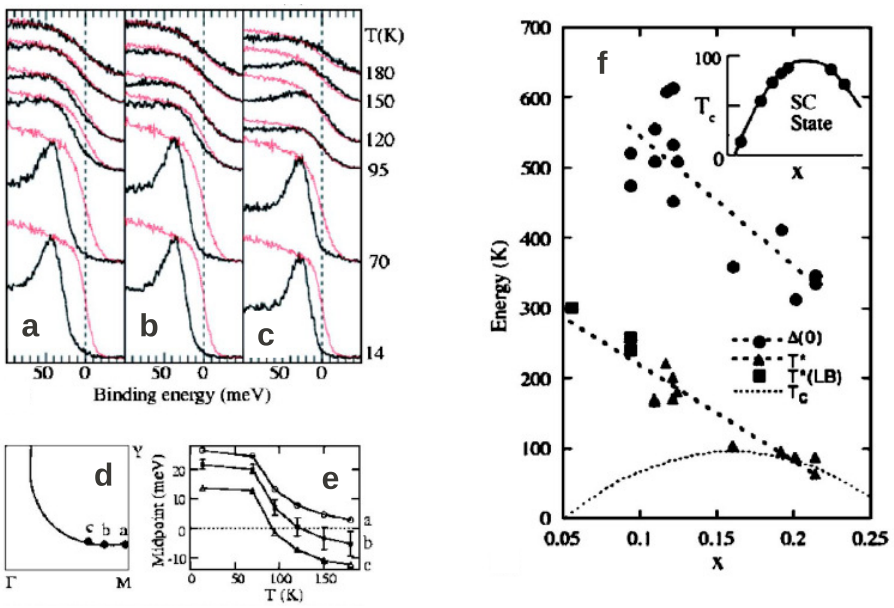

Figure 25.13: ARPES of underdoped cuprates. **a-c** Unsymmetrized energy distribution curves (EDC) for underdoped Bi2212 $T_c = 85$ K at different **k** points on the Fermi surface (panel **d**). The existence of a gap for $T > T_c$ is signaled by the pullback of the spectrum from the Fermi surface determined by the Pt reference (red lines). **e**, Temperature dependence of the gap determined from the leading-edge midpoints. (From Ref.[65]). **f**, The temperature T^* corresponding to the appearance of the pseudogap is plotted as a function of doping for Bi2212. Triangles are determined from data shown in **a**. Circles show the energy gap $\Delta(0)$ measured at the antinodal point at low temperatures in the superconducting state. (From Ref.[11]).

from the peak position of symmetrized EDC [10, 11] (Figs.25.14 **a-e**).

Angle-resolved photoemission spectroscopy shows that an energy gap is observed on the Fermi surface crossing along the direction $(\pi, 0)$ to (π, π) i.e. at the antinodal point, even above T_c for underdoped sample (Figs.25.27 **a-c**). Although, above T_c, a finite spectral weight can be detected at zero energy ($\omega = 0$), justifying the nomenclature 'pseudogap'. With increasing temperature the pseudogap *fills in* rather than closing in. Intriguingly, the spectral line width is large implying an incoherent spectra above T_c. The appearance of a coherent peak at the gap edge (Figs.25.27 **a-c**) indicates the appearance of superconductivity. The size of the pullback of the leading edge and the energy gap measured by the location of the coherence peak in the superconducting state are basically same. As shown in Fig.25.27 **f**, the estimated gap increases with decreasing doping in contrast to T_c which decreases.

As shown in Fig.25.14, below T_c, the energy gap is maximal near $(0, \pi)$ and vanishes along the line connecting $(0, 0)$ and (π, π) i.e. the nodal direction ($k_x = k_y$), giving rise to gapless nodal quasiparticles, confirming the d-wave nature of the superconductivity. Above T_c the gapless region expands to cover a finite region near the nodal point giving rise to the so-called 'Fermi arcs'[67, 68, 69] (see Fig.25.14 **f**). Strangely, spectral line shape is relatively sharp in the nodal direction even above T_c, unlike that along the antinodal direction.

The spectral weight of the antinodal coherence peak, that marks the onset of superconductivity, decreases with decreasing doping [11]. This behaviour is unlike that in any conventional superconductors [3]. A more recent and very detailed ARPES study [70] gives an overall perspective (Fig.25.15) of the cuprate phase diagram based on the existence of gap and/or sharp spectral peak in the ARPES spectra. For example, the strange metal phase is characterized as

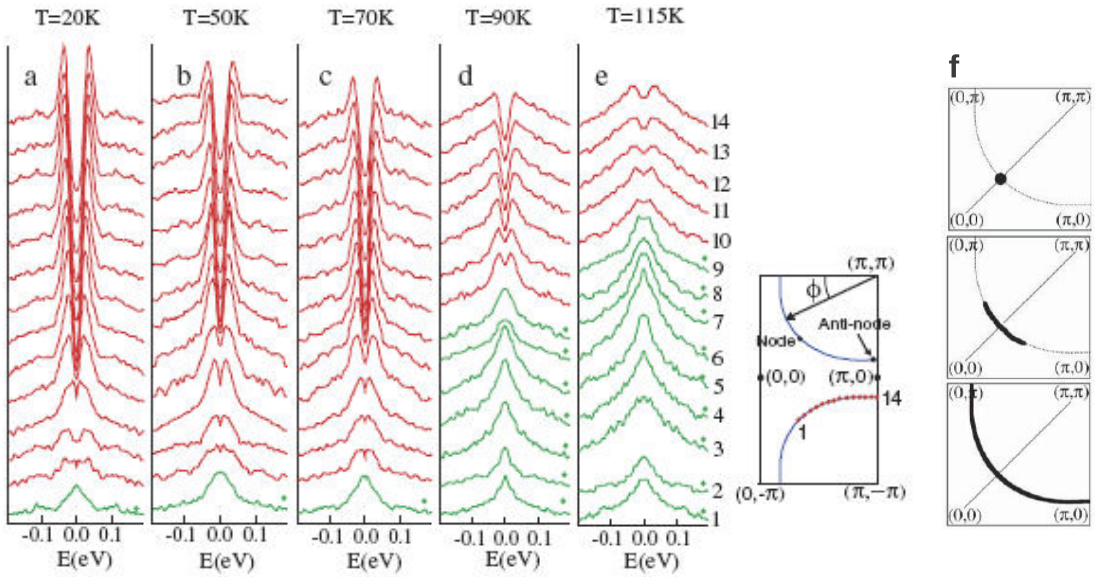

Figure 25.14: **a-e**, Evolution of the symmetrized energy distribution curves (EDCs) for underdoped Bi2212 $Tc = 80$ K with temperature. The different EDCs correspond to different **k** points from the node (lowest curve) to the antinode (uppermost curve). Gapless spectra having a peak at zero energy are shown in green. (From Ref.[66]). **f**, Schematic illustration of the development of Fermi arcs with temperature in the pseudogap phase. The d-wave node below T_c (top panel) becomes an extended gapless arc above T_c (middle panel) which expands in length with increasing T to form the full Fermi surface at T^* (bottom panel). (From Ref.[11]).

the one with neither gap nor sharp peak, whereas the pseudogap has a gapped spectrum but no sharp peak. Interestingly, there is a narrow region above the superconducting dome around optimal doping having both gap and sharp spectral peak, similar to the superconducting state below T_c.

2. Tunneling spectroscopy: In scanning tunneling spectroscopy (STS) or scanning tunneling microscopy (STM) one measures the tunneling current that flows between a sharp metallic tip and typically a conducting sample separated by thin insulating barrier, generally vacuum [8, 21]. STM allows one to probe the local density of states (LDOS) $\rho(\omega = eV, \mathbf{r})$ at position $\mathbf{r}$ directly from the differential tunneling conductance dI/dV obtained by measuring tunneling current $I(V, \mathbf{r})$ due to applied voltage difference V between the tip and the sample i.e. $dI(V, \mathbf{r})/dV \propto \rho(\omega = eV, \mathbf{r})$.

STM provides direct real-space information and hence is complementary to ARPES. By virtue of probing the local density of states with very high energy resolution, STM gives direct information [21] about the gap in the excitation spectrum as well as other spectroscopic features such as scattering rate etc. The Pseudogap was first detected in tunneling spectroscopy by Tao *et al.* [72]. A gap-like suppression of LDOS was found in the tunneling conductance of Bi2212 in the normal state. STM studies [71] on underdoped Bi2212 have again shown a disappearance of the coherence peaks at T_c and the existence of a V-shaped LDOS suppression in the normal state up to room temperature (see Fig.25.16). This feature can be identified with the signature of pseudogap.

The magnitude of the gap in the superconducting state, measured via the separation between the peaks, is effectively temperature independent, unlike that of a BCS gap which closes as the temperature is raised through T_c. The same phenomenology applies to the magnitude of the

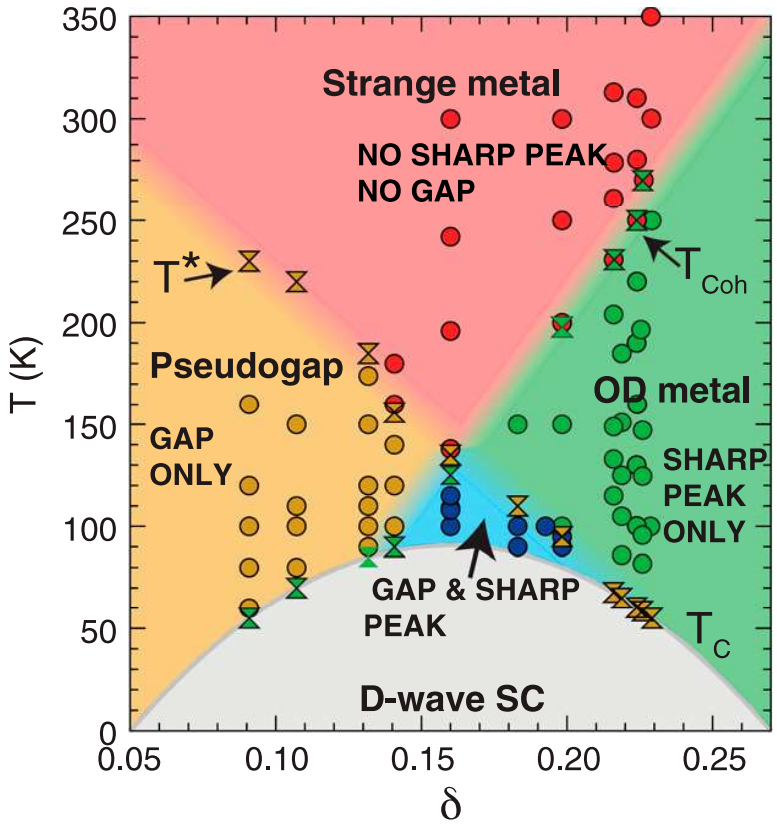

Figure 25.15: The cuprate phase diagram based on either the presence or absence of spectral gap and/or sharp peak. The latter indicates the existence of well-defined quasiparticle excitations, e.g., as in the more conventional metallic state in the overdoped region (From Ref.[70]).

pseudogap which, as in ARPES, fills in with temperature but retains its magnitude up to room temperature in underdoped samples. The magnitude of the gap however does decrease with increasing x (Fig.25.17). This is just the opposite to what is expected from BCS theory when the dome-shaped doping dependence of T_c is taken into account (Fig.25.27 **f**).

STM reveals several important relations between the superconducting gap below T_c and pseudogap above T_c and between T_c and T^* [73].Firstly, the superconducting gap and pseudogap has the same scaling with doping, i.e. increasing with decreasing doping. However the ratios of these two gaps are nearly the same over different compounds and doping in spite of the fact that their absolute magnitudes change substantially between different compounds and doping. Also the ratio $2\Delta_p/k_{\rm B}T_c \approx 4.3$ amazingly follows the BCS d-wave relation [22] with T^* replacing T_c (Fig.25.18). Here Δ_p denotes half of the separation between two superconducting peaks.

25.4 Phenomenological theory of superconducting and pseudogap states

A variety of approximate microscopic theories based on many different scenarios and ideas, from both strong and weak coupling perspectives, have been proposed to understand the cuprate phase diagram, and numerical techniques at various levels of sophistication have been tried to

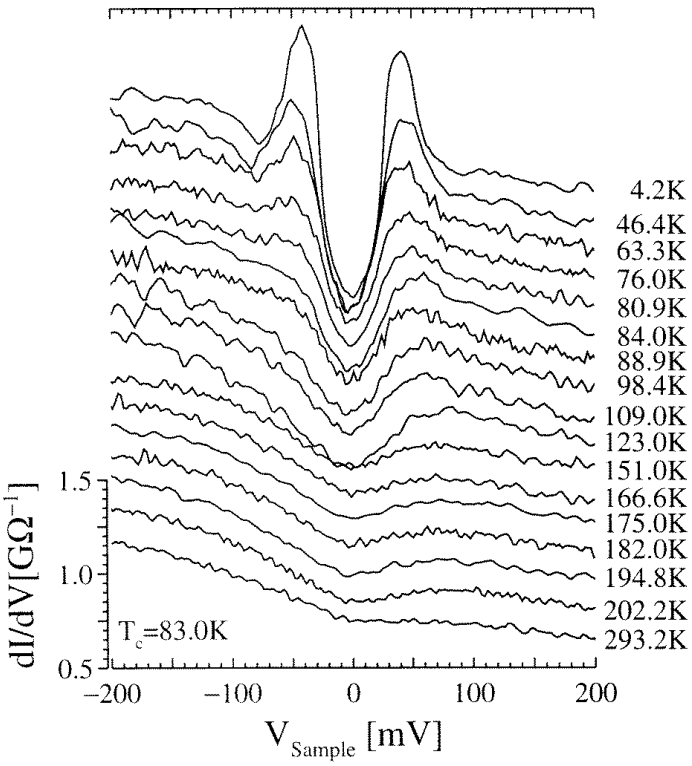

Figure 25.16: LDOS measured via differential tunneling conductance for an underdoped Bi2212 with $T_c = 83$ K and pseudogap temperature $T^* \simeq 300K$). A gap-like feature indicated by the suprresion of LDOS at low energies is seen even above T_c till T^* indicating a pseudogap. Two coherence peaks can be seen below T_c. (From Ref.[71]).

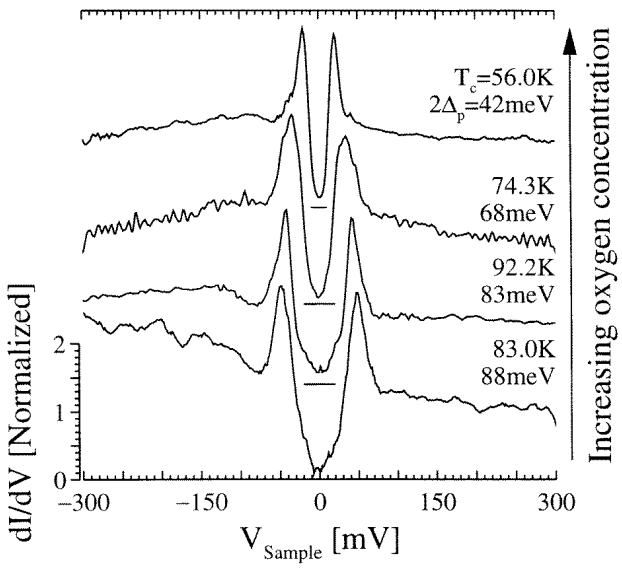

Figure 25.17: Doping dependence of LDOS measured through STS at low temperature. The separation between the peaks $2\Delta_p$ quantifies a superconducting gap that decreases with x. (From Ref.[71]).

address the issue of strong correlations in Hubbard and $t-J$ models. On the other hand, in conventional superconductors and, in general, for the study of phase transitions, phenomenological Ginzburg-Landau (GL) functionals [74] written down from very general symmetry grounds have provided useful descriptions for a variety of systems [75]. Specially, Ginzburg-Landau theory has been proven to be complementary to BCS theory for attacking a plethora of situations in superconductors, e.g., inhomogeneities, structures of isolated vortex and vortex lattice etc. [8].

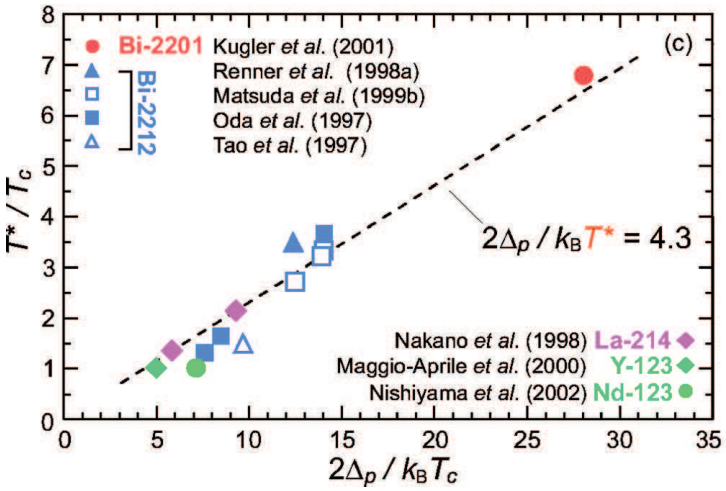

Figure 25.18: T^*/T_c as a function of $2\Delta_p/k_BT_c$ obtained for various cuprates from STS. Dashed line corresponds to the mean-field d-wave relation $2\Delta_p/k_BT^* = 4.3$, but with T_c replaced by pseudogap temperature scale T^*. (From Ref.[73], see Ref.[21] for references within the figure).

In the same spirit, some of us have proposed and developed a phenomenological approach [76] for the superconducting and pseudogap states of the cuprates.

In the phenomenological theory we attribute the pseudogap to short-range local spin-singlet pairing. This is in line with a large number of theories for cuprate superconductivity within the so-called "preformed pair scenarios" [5], especially those from the strong coupling point of view [3]. We discuss below a possible microscopic underpinning of our theory from a strong correlation picture. However, we emphasize that we do not tie ourselves down to any particular microscopic calculation. Our theory essentially has two main empirical inputs, namely

1. A pairing temperature scale $T^*(x)$, mimicking the pseudogap temperature scale (Fig.25.2), below which local pairing amplitude becomes substantial.

2. A 'bare' superfluid density $\rho_s \propto x$, that linearly increases with doping for small x, as implied by the Uemura correlation [17] discussed before.

As we discuss below, based on the above basic ingredients built into the proposed GL functional, we can encapsulate a large number of well known cuprate phenomenologies in the form of a low-energy effective lattice functional of complex spin-singlet pair amplitudes that resides on the Cu-Cu bonds of the CuO_2 planes of cuprates. We summarize our results for average pairing amplitude in the superconducting and pseudogap phases, superfluid density, specific heat, vortex properties , fluctuation diamagnetism as well as thermoelectric transport quantity like Nernst coefficient [76, 77, 78] obtained using the proposed functional and compare them successfully with experiments.

Motivated by the picture that emerges from our GL-like approach, we have also extended [79] it to obtain the electron spectral density that inevitably results from coupling between electrons and Cooper pair fluctuations. These results, and their implications for low energy electronic spectra measured through ARPES and STM, are also discussed.

25.4.1 Phenomenological GL-like functional

Based on our central assumption of the pairing origin of pseudogap, we propose that, as a minimal description, the free energy of a cuprate in the superconducting and pseudogap states can be expressed as a functional solely of the complex pair amplitude. We hypothesize a lattice free-energy functional similar in structure to the conventional GL functional [8], but defined

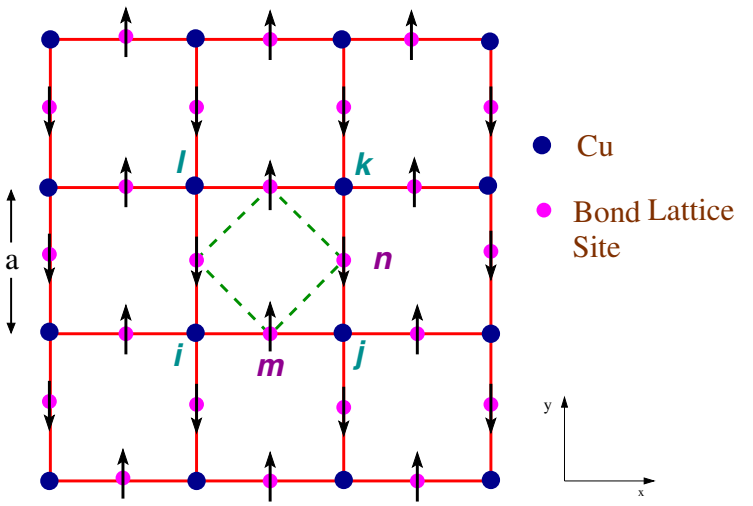

Figure 25.19: The square Cu lattice sites in the CuO_2 plane and construction of the bond-centre lattice out of the centers of the Cu-O-Cu bonds. The arrows indicate the direction of equivalent planar spins, with $\mathbf{S}_m = (\Delta_m \cos\phi_m, \Delta_m \sin\phi_m)$ representing the complex order parameter $\psi_{ij} \equiv \psi_m = \Delta_m \exp(i\phi_m)$ and antiferromagnetic ordering of spins translating into a long-range d-wave superconducting order.

on the CuO_2 square lattice. Fig.25.19 shows the square planar lattice schematically. The free energy is assumed to be a functional of the complex spin-singlet pair amplitude $\psi_{ij} \equiv \psi_m = \Delta_m \exp(i\phi_m)$, where i and j are nearest-neighbour sites of the square planar Cu lattice and m labels the bond-center lattice site located at the bond between the lattice site i and j (see Fig.25.19). The highly anisotropic cuprate superconductivity is modelled as a weakly coupled stack of CuO_2 planes and we ignore, as a first approximation, the interplane coupling. The free-energy functional for a single plane is assumed to have the lattice version of the conventional GL functional [8], i.e.

$$\mathcal{F}(\{\Delta_m, \phi_m\}) = \sum_m \left(A\Delta_m^2 + \frac{B}{2}\Delta_m^4 \right) + C \sum_{<mn>} \Delta_m \Delta_n \cos(\phi_m - \phi_n), \qquad (25.3)$$

We posit the above lattice functional to be more fundamental, in principle, than the conventional continuum GL functional due to underlying strongly correlated nature of the cuprate superconductors and owing to the fact that they have very short coherence length ($\sim 15-20$Å). A Gor'kov like [80] microscopic interpretation of ψ_{ij} is as an average spin-singlet nearest-neighbor Cooper pair amplitude, i.e., $\psi_{ij} \equiv \langle \hat{b}_{ij} \rangle / \sqrt{2} \equiv (1/2)\langle a_{i\downarrow} a_{j\uparrow} - a_{i\uparrow} a_{j\downarrow} \rangle$. The sites i and j are different because strong electron repulsion U disfavors on-site pairing, while the existence of large nearest-neighbor antiferromagnetic spin-spin interaction in the parent (undoped) cuprate is identically equivalent for spin-$\frac{1}{2}$ electrons to attraction between nearest-neighbor pairs, i.e. $J(\hat{\mathbf{S}}_i.\hat{\mathbf{S}}_j - \frac{1}{4}\hat{n}_i\hat{n}_j) = -J\hat{b}_{ij}^\dagger \hat{b}_{ij}$. This favours the formation of nearest-neighbour bond spin-singlet pairs.

The 'on-site' part of the above functional [eq.(25.3)] has been written down in a bare minimum form, as a sum of quadratic and quartic terms in Δ_m in the image of conventional GL theory, for simplicity. We remark that unlike in the original GL theory where the parameters A and B are proposed near T_c, we propose this simple form for all T and all x, as a qualitatively correct one. The parameters A and B depend, in general, on x and T. We assume that B is a positive constant independent of x and T and choose $A(x,T) \propto (T - T^*(x))$ to change sign along a straight line $T^*(x) = T_0(1 - x/x_c)$ running from $T = T_0$ at $x = 0$ to $T = 0$ at $x = x_c$. As a first approximation, this line can be identified with the pseudogap temperature $T^*(x)$ because the magnitude of the local pair ampliitude, $\langle \Delta_m \rangle$, can increase dramatically as the temperature crosses this line due to sign change of A.

The occurrence of superconductivity in the model is characterized by a nonzero stiffness for long-wavelength phase fluctuations and is determined by the phase coupling term C [eq.(25.3)]. The parameter C is taken to be proportional to x in conformity with the Uemura correlation

[17]. Also, $C > 0$ so that the zero-temperature superconducting state has d-wave symmetry [see Fig.25.19]. We discuss the choice of doping and temperature dependences of the parameters A, B and C in more detail in Appendix 25.8.

Effect of magnetic field: An applied magnetic field perpendicular to the CuO_2 planes giving rise to, e.g., the orbital magnetization and magnetothermoelectric effects [77, 78], is incorporated in our model through a bond flux $A_{mn} = (2\pi/\Phi_0)\int_m^n \mathbf{A}\cdot d\mathbf{r}$, which modifies $(\phi_m - \phi_n)$ to $(\phi_m - \phi_n - A_{mn})$ in eq.(25.3), as usual in a lattice GL functional. Here $\mathbf{A}$ is the vector potential. Assuming extreme type-II limit as appropriate for the cuprate superconductors, the magnetic field H is given by the condition $\sum_\square A_{mn} = \Phi$, where $\sum_\square$ is a sum over a plaquette of the lattice and $\Phi = Ha^2/\Phi_0$ is the magnetic flux per plaquette in units of the universal flux quantum.

Effect of quantum phase fluctuations: As we discuss below, the superconducting transition temperature T_c obtained in our model follows a dome-shaped curve as a function of x. However, on the extreme underdoped and overdoped regimes the superfluid density becomes small in our model [76]. In these regimes, one needs to take into account the effect of quantum phase fluctuations. These would renormalize T_c to zero at finite doping in the underdoped side and their importance is well-supported by experiments [81, 82] and theoretical analysis [83]. We can incorporate quantum phase fluctuation effects in our formalism [76] by supplementing the free-energy functional of eq.(25.3) with the following term

$$\mathcal{F}_Q(\{\hat{q}_m\}) \;=\; \frac{1}{2}\sum_{mn}\hat{q}_m V_{mn}\hat{q}_n \tag{25.4}$$

Here $\hat{q}_m$ is the Cooper pair number operator at site m, and ϕ_m in eq.(25.3) should be treated as a quantum mechanical operator $\hat{\phi}_m$, canonically conjugate to $\hat{q}_m$ so that $[\hat{q}_m, \hat{\phi}_n] = i\delta_{mn}$. We take the simplest possible form for V_{mn} i.e. $V_{mn} = V_0\delta_{mn}$, where V_0 is the strength of on-site Cooper pair interaction, an additional phenomenological parameter that can fixed such that $T_c(x)$ curve computed in the phenomenological theory matches the experimental one [76]. We do not include these quantum fluctuations explicitly for calculating thermodynamic quantities, e.g. specific heat, magnetization etc., associated with pairing fluctuations, since quantum phase fluctuations bring about qualitative changes only at the extreme end of the dome on the underdoped side. For other values of x, these fluctuations only renormalize the values of the parameters A, B and C of our functional (25.3). We assume that such renormalizations have already been taken into account while choosing these parameters in tune with experiments. Next we discuss some general aspects of our model and its possible microscopic origin.

General aspects of the phenomenological theory: As clearly evident from eq.(25.3), since $\Delta_m\Delta_n\cos(\phi_m - \phi_n) = -(|\psi_m - \psi_n|^2 - \Delta_m^2 - \Delta_n^2)$, the intersite term can be readily identified with the discretized version of usual spatial derivative term $|\nabla\psi|^2$. The model is thus of the form of a conventional GL model, albeit one that is defined on a lattice at the outset. As discussed above, defining the complex singlet pair amplitude to reside on the $Cu-Cu$ bonds (Fig.25.19) and choosing the phase coupling term C to be positive, we immediately get a d-wave superconducting order at low temperature. The negative sign of C corresponds to more conventional s-wave BCS like case. For quantitative comparison with experiments, the lattice should be thought of more appropriately as a phenomenological one that emerges upon coarse graining, albeit with a coarse graining length only three to five times larger than microscopic lattice spacing a [77]. Hence, our model, in practice, can be thought of as the discretized version of a continuum theory with the lattice spacing a as a suitable ultraviolet cutoff to describe long wavelength physics. In the presence of magnetic field H, the lattice constant is also equivalent to a field scale $H_0 = \Phi_0/(2\pi a^2)$, defined through the flux quantum $\Phi_0 = hc/2e$. In principle, the field scale H_0 can be obtained by fitting the field dependence of magnetization with that of experiment [77].

The free-energy functional in eq. (25.3) can also be viewed as the Hamiltonian of an XY model with fluctuations in the magnitude of 'planar spin' ψ_m, where the on-site term in eq.(25.3) simply controls the temperature and doping dependence of the magnitude. The form of the free-energy functional might seem superficially similar to the widely used model of granular superconductors [84]. However, we would like to re-emphasize that we do not assume any underlying granularity of our system, as mentioned above. Such phenomenological lattice models, in the extreme XY limit, have been employed in the past to study superconductivity in non-granular lattice systems, especially in the context of cuprates [85, 86, 83, 87].

Additionally, even though the form of our functional is mainly motivated by cuprate phenomenology, as we discuss below, a similar functional arises quite naturally in a strong correlation framework for a doped Mott insulator [88, 89, 90]. In general, in such a functional, the single-site term of eq.(25.3) will have more complicated form[89, 90], having many terms in a power series expansion of Δ_m, in addition to the quadratic and quartic ones that our functional does. But, as we discuss below, the superconducting dome is reproduced quite reasonably by truncating the functional to quartic order. In addition, several other experimentally observed thermodynamic properties of the cuprates over the entire pseudogap regime are also reproduced by this simplified form of the functional [76].

Microscopic underpinning: GL theories for cuprates have been proposed by a large number of authors, arising either out of a particular model for electronic behavior and often coupled with the assumption of a particular 'glue' for binding electrons into pairs [88, 89, 91], or out of lattice symmetry considerations [92, 93]. The functional in eq.(25.3) is consistent with square lattice symmetry and, in principle, does not assume any particular electronic approach, e.g. weak coupling or strong correlation. However, some of the properties of the coefficients are natural in a strong electron correlation framework. For example, mobile holes in such a system can cause a transition between a state in which there is a Cooper pair in the x directed ij bond (Fig.25.19) to one in which the Cooper pair is in an otherwise identical but y directed bond jk nearest to it (or vice versa), thus leading to a nonzero intersite phase coupling term in eq.(25.3). This is probably connected with the observed [94] empirical correlation between T_c and the diagonal or next-nearest-neighbor hopping amplitude t' of electrons in the Cu lattice.

A phenomenological approach such as ours does not point to a specific 'glue' which binds electrons on nearest-neighbor sites into spin singlet pairs. However, as mentioned before, in a strong correlation picture, a natural source is J. In general therefore, the nearest-neighbor interaction can be thought of as a mixture of antiferromagnetic spin exchange and pair attraction. As the Mott insulator is doped and the holes become mobile, it seems likely (from experiment) that the interaction is more conveniently described as latter than the former in a mean-field sense. A number of microscopic variational $T = 0$ calculations appropriate for competing spin density wave and d-wave superconducting ground states as a function of hole doping exist in the literature [95, 96, 97]; they generally suggest a magnetic ground state or a coexistence of magnetism and superconductivity for low hole doping and a superconducting ground state for higher doping. Here, we consider only the pair degrees of freedom and disregard the spin. So, if this description is appropriate, the limiting ($x \to 0$) pseudogap or bound pair energy scale T_0 is expected to be of order J from which the pair attraction originates in the strong correlation picture. Nevertheless, T_0 is a factor of two or three smaller than J. The decrease of the pseudogap energy scale with x is presumably due to holes because their presence implies at the very least a decrease in the number of nearest-neighbor electron pairs that can be formed. Some early results [98] suggest a mean-field 'effective' $J_{\rm eff} \simeq J - xt$ where t is the nearest-neighbor hopping. This may be relevant to the linear decrease of $T^*(x)$ with doping x.

25.4.2 Thermodynamic quantities obtained from the phenomenological theory

The main objective of our phenomenological approach is to investigate whether the free energy functional defined in eq.(25.3) provides a good description of experimental results over a wide range of x and T. To this end, we have calculated large number of thermodynamic quantities associated with pairing fluctuations [76, 77] and directly compared them with the experimental observations discussed in section 25.3. Here we list some of the quantities computed within the phenomenological theory. The details of the calculations and the results can be found in Refs.[76, 77, 78]. In section 25.6, we summarize our main results and briefly discuss how these compare with the cuprate phenomena discussed in section 25.3.

We have calculated the zero-temperature gap $\Delta_0(x)$ and superfluid density $\rho_s^0(x)$ as a function of doping by minimizing the free-energy functional (25.4) with respect to pairing amplitude Δ_m at $T = 0$ for the uniform d-wave state shown in Fig.25.19. Thermodynamic quantities, such as average local pairing amplitude $\langle\Delta_m\rangle$, specific heat C_v and orbital magnetization M etc., are calculated via canonical thermal averages, $\langle\dots\rangle = (1/Z)\int\prod_m d\phi_m d\Delta_m(\dots)e^{-\beta\mathcal{F}(\Delta_m,\phi_m)}$, where Z is the partition function. The calculations have been done via standard techniques like mean-field theory, Monte-Carlo (MC) simulation etc. We have also calculated properties, e.g. core-structure and core-energy $E_c(x)$, of topological defects, i.e. a superconducting vortex, via numerical optimization with appropriate boundary condition [76]. The vortex core-energy has important implications for the transport coefficients in the underdoped regime, as discussed in Ref.[77].

25.5 Extensions of the phenomenological theory to describe thermoelectric transport and low-energy electronic spectra

We have extended the phenomenological theory in several ways, e.g., to study the contributions of pairing fluctuations to thermoelectric transport, such as Nernst coefficient, and also to look into the effects of these fluctuations on low-energy electronic spectral density as directly probed via ARPES and STM. We discuss these extensions below.

25.5.1 Relaxation dynamics using the phenomenological theory

To study the influence of pairing fluctuations on transport properties we implement[78] "model A" dynamics [74] for a time-dependent complex pair amplitude $\psi_m(t) = \Delta_m(t)e^{i\phi_m(t)}$ given by the stochastic equation

$$\tau D_t\psi_m(,t) = -\frac{\partial\mathcal{F}(\{\psi_m,\psi_m^*\})}{\partial\psi_m^*(t)} + \eta_m(t). \tag{25.5}$$

Here $\mathcal{F}(\{\psi,\psi^*\})$ is a the free energy functional [eq.(25.3)], that incorporates the effect of electromagnetic field in the inter-site phase coupling term, as discussed earlier, via a vector potential $\mathbf{A}_{mn}(t)$, which can be time-dependent in general. We define a covariant time derivative $D_t = (\frac{\partial}{\partial t} + iV_m(t))$, where $V_m(t)$ is a scalar potential at site m. The time scale τ, which provides the characteristic temporal relaxation scale of the order parameter dynamics, can in general be complex. However it is required to be real in the presence of particle-hole symmetry, that translates to the requirement that the equation of motion for ψ_m^* be the same as for ψ_m under the simultaneous transformation of complex conjugation ($\psi_m \to \psi_m^*$) and magnetic field inversion ($H \to -H$). Evidence of particle-hole symmetry in the form of no appreciable Hall or Seebeck effect is seen in the experimentally accessible regime of the superconductors we study here, and

thus we take τ to be real in our calculations. The thermal fluctuations are introduced through $\eta_m(t)$ with the complex Gaussian white noise correlator $\langle \eta_n^*(t)\eta_m(t')\rangle = 2k_{\rm B}T\tau\delta_{mn}\delta(t-t')$.

The dynamical model Eq. 25.5 is the simplest one which yields an equilibrium state in the absence of driving potentials. For conventional superconductors, it can be derived microscopically within BCS theory above and close to the transition temperature T_c. However, it has been used phenomenologically to study transport previously in situations where the microscopic theory is not known, such as for the cuprates [99, 100, 87]. We employ the model in a similar spirit here.

Transport coefficients: To compute transport coefficients, we numerically integrate the dynamical equations (25.5), in the presence of either temperature gradient ∇T or electric field $\mathbf{E}$, applied via suitable choice of gauge potentials $A_{mn}(t)$ and $V_m(t)$. The transport current densities, obtained in our model after appropriate subtractions of magnetization currents [78], can be related to ∇T and $\mathbf{E}$ using standard linear response relations

$$\begin{pmatrix} \mathbf{J}^e_{\rm tr} \\ \mathbf{J}^Q_{\rm tr} \end{pmatrix} = \begin{pmatrix} \hat{\sigma} & \hat{\alpha} \\ \hat{\tilde{\alpha}} & \hat{\kappa} \end{pmatrix} \begin{pmatrix} \mathbf{E} \\ -\nabla T \end{pmatrix},$$

where $\hat{\sigma}$, $\hat{\alpha}$, $\hat{\tilde{\alpha}}$, $\hat{\kappa}$ are the electrical, thermoelectric, electro-thermal and thermal conductivity tensors, respectively. We have mainly studied the Nernst signal e_N, which is the electric field (E_y) response to a temperature gradient ($\nabla_x T$) in the direction transverse to the electric field in the presence of a magnetic field H along z-direction, i.e. $e_N \equiv E_y/\nabla_x T$ with open circuit boundary conditions. Under reasonable assumptions [78], the Nernst coefficient, $\nu = e_N/H$ can be connected to the thermoelectric coefficients via the simple relation $\nu = \alpha_{xy}/(H\sigma_{xx})$, that we use. We summarize our results of Nernst coefficient calculated over the whole doping-temperature range in section 25.6.

25.5.2 Pairing fluctuations and low-energy electronic spectra in cuprates

Decipherment of the physics of high-T_c cuprates should necessarily involve the understanding of electronic excitations and properties related to them in the various parts of cuprate phase diagram (Fig.25.2). Hence a phenomenological theory, such as ours, which aims to describe the pseudogap phase as one consisting of preformed pairs of *a specific type*, is required to include both electrons and Cooper pairs of the same electrons coexisting and *necessarily* coupled with each other. In our GL-like approach only the latter are explicit, while the former are *integrated out*. However, effects connected with the pair degrees of freedom are often explored via their coupling to electrons, e.g. via ARPES and STM, as discussed earlier. Here we develop a unified theory of electronic excitations in the superconducting and pseudogap phases, using a model of electrons coupled to spatially and temporally fluctuating nearest-neighbor bond singlet Cooper pairs. We discuss the theory, its basic principles and assumptions here, and a number of its consequences with respect to cuprate phenomena are summarized in section 25.6.

Basic notions and assumptions behind the approach: The main difficulty in a theory of the above kind is the description of electrons in a presumably strongly correlated system such as a cuprate, which is perhaps best described as a doped Mott insulator [3] with strong low-energy antiferromagnetic correlation between electrons as well as various other types long-and short-range ordering tendencies. This is the major problem for constructing a microscopic theory in the entire field of strongly correlated electrons and dealing with such problems in a controlled manner would probably continue to be an active field of research and one of the most challenging tasks in condensed matter physics for years to come .

However, irrespective of the microscopic origin, the interacting pair degrees of freedom probably still can be described by a phenomenological theory of the kind described here. To

pursue this path, one needs to commit to some kind of model for electron dynamics which therefore implies an approach to the coupling between single electronic and pair degrees of freedom. We develop what we believe is a minimal theory, appropriate for low-energy physics. We assume that for energies $|\omega| \lesssim \Delta$ (Δ is of the order of zero temperature superconducting gap), well defined electronic states, namely tight binding lattice states with a renormalized hopping/bandwidth exist and couple to low energy pair fluctuations. Superconducting ordering/phase stiffness and fluctuations are reflected in the pair-pair correlation function. This correlation function has a generic form, especially near T_c, which, for example, may be obtained from the GL-like functional [eq.(25.3)] or, as we show in Ref.[79], can be deduced from various experiments. The *inevitable* coupling between electrons and low lying fluctuations of pairs, made of the same electrons leads to a self energy with a significant structure for electron momentum $\mathbf{k}$ along the Fermi surface and low electronic excitation energy ω.

Physically, we have electrons (e.g. those with energy near the Fermi energy) moving in a medium of evanescent pairs which have finite range d-wave correlation for $T > T_c$ and have long range order of this kind for $T < T_c$ in addition to 'spin wave' like fluctuations. On approaching T_c from above, collective d-wave symmetry superconducting correlations develop among the pairs with a characteristic superconducting coherence length scale ξ which diverges at the second-order transition temperature T_c. These correlations have a generic form at large distances (>> the lattice spacing a). Our theory captures the effects of these correlations on low-energy unpaired electronic degrees of freedom in the superconducting and pseudogap phases.

Model: To motivate the microscopic coupling between the spin-singlet bond pair and electrons, we take the tJ model (25.1) as the basic starting point. However to circumvent the daunting task of treating the no double occupancy constraint discussed in section 25.2, we use the following simplified Hamiltonian, the so-called 'plain vanilla' [101] version of tJ model, i.e.

$$\hat{\mathcal{H}} \;=\; -\sum_{ij,\sigma} \tilde{t}_{ij} a^{\dagger}_{i\sigma} a_{j\sigma} - \tilde{J} \sum_{<ij>} \hat{b}^{\dagger}_{ij} \hat{b}_{ij}. \tag{25.6}$$

Here the effective hopping $\tilde{t}_{ij} = g_t t_{ij}$ and effective antiferromagnetic exchange $\tilde{J} = g_s J$, which acts as a pair attraction, are strongly affected by correlations via single-site Gutzwiller renormalization factors $g_t = 2x/(1+x)$ and $g_s = 4/(1+x^2)$ [101]. The bare hopping amplitude t_{ij} involves the nearest neighbor (t), next-nearest neighbor (t') and further neighbor (t'') hopping terms. In our calculations, we use the above mentioned homogeneous Gutzwiller approximation with standard values for t_{ij} ($t = 300$ meV, $t'/t = -1/4$ and $t'' = 0$, see e.g. [1]).

Very generally, assuming pairing fluctuations to be relevant at low energies, the bond-pair attraction term term eq.(25.6), can be written via Hubbard-Stratonovich transformation as a time and space dependent bond pair potential acting on electrons and characterized by a field $\psi_m(\tau)$ [τ is the imaginary time; $0 < \tau < \beta = 1/(k_B T)$]. The saddle point of the resulting action in the static limit gives rise to the conventional mean field approximation in which the second term in eq.(25.6) is written as

$$-\tilde{J}_{ij}(\langle \hat{b}^{\dagger}_{ij} \rangle \hat{b}_{ij} + \hat{b}^{\dagger}_{ij} \langle \hat{b}_{ij} \rangle - \langle \hat{b}^{\dagger}_{ij} \rangle \langle \hat{b}_{ij} \rangle) \tag{25.7}$$

and the average $\psi_m = \psi_{ij} \equiv \tilde{J}_{ij} \langle \hat{b}_{ij} \rangle$ is determined self-consistently (mean field theory).

The effective Hamiltonian we use is of the form of eq.(25.6) with the second term in it replaced by eq.(25.7). This describes two coupled fluids, namely a fermionic fluid and a bosonic fluid, represented respectively by the on-site electron field $a^{\dagger}_{i\sigma}$ and the bond Cooper pair field $\psi_{ij} = \psi_m$. The properties of ψ_m needed in our calculation are its mean value $\langle \psi_m \rangle$ (nonzero below T_c) and the fluctuation part of the correlation function $\langle \psi_m \psi^*_n \rangle$, whose *universal* form for large $|\mathbf{R}_m - \mathbf{R}_n|$ near T_c is what we use. These arise from an inter-site term of the form shown in eq.(25.3).

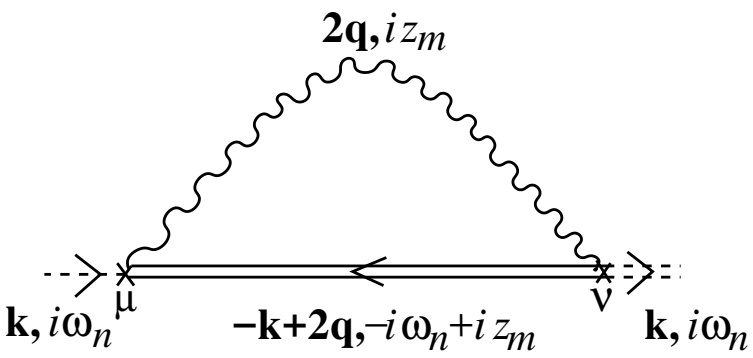

Figure 25.20: **The pair fluctuation exchange process for the self energy of electrons.** Feynman diagram of the process in which an electron $(\mathbf{k}, i\omega_n)$ virtually becomes another electron $(-\mathbf{k}+2\mathbf{q}, -i\omega_n + iz_m)$ and absorbs a Cooper pair $(2\mathbf{q}, iz_m)$ in the intermediate state. The curly line denotes the Cooper pair propagator $D_{\mu\nu}(2\mathbf{q}, iz_m)$ (here $z_m = 2m\pi/\beta$ is the bosonic Matsubara frequency, m being an integer).

For a translationally invariant system described by eq.(25.6), the electron Green's function satisfies the Dyson equation

$$G^{-1}(\mathbf{k}, i\omega_n) \;=\; (G_0)^{-1}(\mathbf{k}, i\omega_n) - \Sigma(\mathbf{k}, i\omega_n), \tag{25.8}$$

where $\Sigma(\mathbf{k}, i\omega_n)$ [$\omega_n = (2n+1)\pi/\beta$ is the fermionic Matsubara frequency with n as an integer] is the irreducible self energy, originating from the coupling between bond pairs and electrons with bare propagator $G_0(\mathbf{k}, i\omega_n) = (i\omega_n - \xi_{\mathbf{k}})^{-1}$, $\xi_{\mathbf{k}} = \epsilon_{\mathbf{k}} - \mu$ and $\epsilon_{\mathbf{k}}$ is the Fourier transform of the hopping $\tilde{t}_{ij} = \tilde{t}_{\mathbf{i-j}}$ (μ is the chemical potential). We use the well-known lowest-order bosonic fluctuation exchange approximation for $\Sigma(\mathbf{k}, i\omega_n)$ shown diagrammatically in Fig.25.20.

Close to T_c, the temporal decay of long-wavelength fluctuations is specially slow due to critical slowing down [74], so that they can be regarded as quasistatic. The self energy Σ can then be expressed as [76]

$$\Sigma(\mathbf{k}, i\omega_n) \;=\; -\frac{1}{N}\sum_{\mathbf{q},\mu,\nu} G_0(-\mathbf{k}+2\mathbf{q}, -i\omega_n) D_{\mu\nu}(2\mathbf{q}) f_\mu(\mathbf{k}, \mathbf{q}) f_\nu(\mathbf{k}, \mathbf{q}) \tag{25.9}$$

where N is the total number of Cu sites on a single CuO_2 plane and μ, ν refer to the direction of the bond i.e. x or y (see Fig.25.19). $D_{\mu\nu}(2\mathbf{q}) = \sum_{\mathbf{R}} D_{\mu\nu}(\mathbf{R}) \exp(-i2\mathbf{q}.\mathbf{R})$ is the static pair propagator of Cooper pair fluctuations with

$$D_{\mu\nu}(\mathbf{R}_{i\mu} - \mathbf{R}_{j\nu}) = \langle \psi_{i\mu} \psi^*_{j\nu} \rangle. \tag{25.10}$$

The quantity $f_\mu(\mathbf{k}, \mathbf{q}) = \cos[(k_\mu - q_\mu)a]$ is a form factor arising from the coupling between a tight-binding lattice electron and a nearest-neighbour bond pair. Because of the d-wave long-range order (LRO) described as 'Ne′el' order (Fig.25.19) of the 'planar spin' ψ_m in the bipartite bond-centre lattice, the standard sublattice transformation [i.e. $\psi_m \rightarrow \tilde{\psi}_m = \Delta_m \exp(i\tilde{\phi}_m)$ where $\tilde{\phi}_m = \phi_m$ for x-bonds and $\tilde{\phi}_m = \phi_m + \pi$ for y-bonds] implies

$$D_{xx}(\mathbf{R}) = D_{yy}(\mathbf{R}) = -D_{xy}(\mathbf{R}) = -D_{yx}(\mathbf{R}) \equiv D(\mathbf{R}), \tag{25.11}$$

where $D(\mathbf{R})$ can be written as

$$D(\mathbf{R}_m - \mathbf{R}_n) = \langle \tilde{\psi}_m \rangle \langle \tilde{\psi}^*_n \rangle + \widetilde{D}(\mathbf{R}_m - \mathbf{R}_n)\,. \tag{25.12}$$

Here $\widetilde{D}(\mathbf{R})$ is the fluctuation term. The LRO part $\langle \tilde{\psi}_m \rangle \equiv \Delta_d$ leads to a d-wave Gor'kov like gap with $\Delta_{\mathbf{k}} = (\Delta_d/2)(\cos k_x a - \cos k_y a)$; the corresponding electron self energy is $\Sigma(\mathbf{k}, i\omega_n) = \Delta^2_{\mathbf{k}}/(i\omega_n + \xi_{\mathbf{k}})$. In widely used phenomenological analyses [102] of ARPES data, this form is

used above T_c with lifetime effects, both diagonal and off-diagonal in particle number space added to Σ, i.e.

$$\Sigma(\mathbf{k},\omega) \;=\; -i\Gamma_1 + \frac{\Delta_{\mathbf{k}}^2}{\omega + \xi_{\mathbf{k}} + i\Gamma_0} \tag{25.13}$$

Here Γ_1 is single-particle scattering rate and Γ_0 is assumed to originate due to finite life-time of *preformed* d-wave pairs [102].

We propose here that as described above, the electrons move (above T_c) *not* in a pair field with d-wave LRO which decays in time at a rate put in by hand, but in a nearly static pair field with growing correlation length ξ. We assume, as appears quite natural for a system with characteristic length scale ξ that $\widetilde{D}(\mathbf{R}) \sim \exp(-R/\xi)$ for large R, while ξ diverges at T_c. This natural form for $\widetilde{D}(R)$ is found, for example, in the Berezinskii-Kosterlitz-Thouless (BKT) theory [74] for two dimensions and in a GL theory for all dimensions. For large correlation lengths, $\Sigma(\mathbf{k}, i\omega_n)$ obtained in our theory is nearly the same as that for preformed d-wave symmetry pairs. Below T_c, $\widetilde{D}(R)$ decays as a power law (i.e. $\widetilde{D}(R) \sim R^{-\eta}$ with $\eta > 0$) due to order parameter phase or 'spin wave'-like fluctuations [79]. We find here the consequences of these for the spectral function, i.e.

$$A(\mathbf{k},\omega) \;\equiv\; -\frac{2}{\pi}\mathrm{Im}\left[G(\mathbf{k}, i\omega_n \to \omega + i\delta)\right], \tag{25.14}$$

measured in ARPES. $G(\mathbf{k}, i\omega_n)$ is obtained from eq.(25.8) with the self energy calculated from eq.(25.9) using the aforementioned forms of the pair propagator $\widetilde{D}(\mathbf{R})$ (or $D(\mathbf{R})$) for temperatures above and below T_c.

In a regime where the fluctuations in the real pair magnitude Δ_m are short ranged,

$$D(\mathbf{R}) \simeq \langle \Delta(\mathbf{R})\Delta(\mathbf{0})\rangle \langle e^{i[\tilde{\phi}(\mathbf{R}) - \tilde{\phi}(\mathbf{0})]}\rangle \equiv \bar{\Delta}^2 \bar{D}(R) \tag{25.15}$$

for large R ($R >> a$) [as evident from eq.(25.12), $\widetilde{D}(R) \simeq \bar{\Delta}^2(\bar{D}(R) - |< e^{i\tilde{\phi}(\mathbf{0})} >|^2)$]. This decoupling between magnitude and long distance phase correlations is accurate for $x \lesssim x_{\rm opt}$, a manifestation of which is the separation between T^* and T_c. Our calculations based on eq.(25.15) are therefore reliable in this doping range. For strictly two-dimensional system mostly considered here, we use the general form [74] for the phase correlator,

$$\bar{D}(R) = (\tilde{\Lambda}R)^{-\eta} \exp\left(-R/\xi\right) \tag{25.16}$$

(with $\tilde{\Lambda} \sim a^{-1}$) in eq.(25.9). An analytical expression can be obtained for the self energy in this case [79], namely

$$\Sigma(\mathbf{k}, i\omega_n) \;\simeq\; \frac{-i\ \mathrm{sgn}(\omega_n)\Gamma(1-\eta)\bar{\Delta}_{\mathbf{k}}^2}{\left(\tilde{\Lambda} \mathrm{v}_{\mathbf{k}}\right)^{\eta} \left(v_{\mathbf{k}}/\xi - i\ \mathrm{sgn}(\omega_n)(i\omega_n + \xi_{\mathbf{k}})\right)^{1-\eta}} \tag{25.17}$$

In this equation, Γ is the well known gamma function and $\mathbf{v}_{\mathbf{k}} = \frac{1}{a}\frac{\partial \xi_{\mathbf{k}}}{\partial \mathbf{k}}$ (with $v_{\mathbf{k}} = |\mathbf{v}_{\mathbf{k}}|$) is the velocity (expressed in units of energy) obtainable from the energy dispersion $\xi_{\mathbf{k}}$. The above self energy does not affect the nodal quasiparticles owing to the $\mathbf{k}$ dependence of $\bar{\Delta}_{\mathbf{k}} = (\bar{\Delta}/2)(\cos k_x a - \cos k_y a)$. We have also obtained electronic self-energy for an anisotropic three-dimensional system with small interlayer coupling, as appropriate for the cuprates [79]. We have used inputs from our phenomenological theory as well as from experimental data to estimate various parameters, such as $\bar{\Delta}$, ξ, η, that enter into the self-energy [79]. We summarize the main results of our calculations for low-energy electronic spectral properties in the next section.

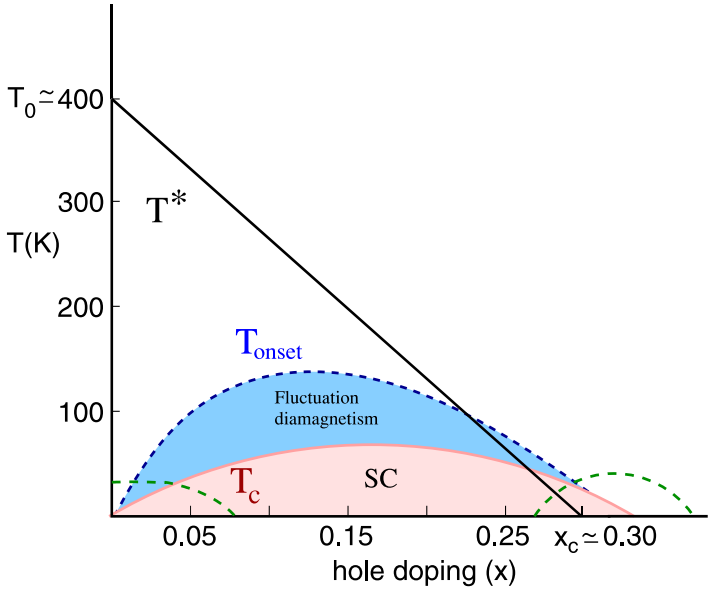

Figure 25.21: A schematic phase diagram for the model [eq. (25.3)] in the hole doping x and temperature T plane. The local pairing temperature scale $T^*(x)$, (solid black line) is an input to our phenomenological model [eq. (25.3)] and it mimics the experimental pseudogap temperature scale. The model reproduces a dome-shaped superconducting region (drawn in pink). The region of enhanced fluctuation diamagnetism and Nernst signal (shaded in blue) in the pseudogap phase and corresponding onset temperature $T_{\rm onset}$ are shown. Between T_c and T^*, electronic spectral functions shows an antinodal pseudogap. The pseudogap state is also characterized by Fermi arcs that emerges from d-wave node at T_c and persist all the way up to T^*. The two arcs shown by dotted lines denote regions where quantum fluctuation effects, as well as other low-energy degrees of freedom, such as electronic and spin plus their coupling with pair degrees of freedom, need to be explicitly included in the free energy functional.

25.6 Results from the phenomenological theory and comparison with experiments

Fig.25.21 shows overall phase diagram obtained from our phenomenological theory and its extensions to capture thermoelectric transport and low-energy electronic spectra. We summarize our main results below and indicate how they compare with the cuprate phenomenology discussed in Section 25.3.

1. Superconducting and pseudogap phases: The pseudogap and superconducting states are both described by a non-zero thermal average of local pairing amplitude, i.e. $\Delta(T) = \langle \Delta_m \rangle \neq 0$. The superconducting state has long-range phase coherence characterized by superfluid density $\rho_s(x,T)$ becoming non-zero below a transition temperature $T_c(x)$ (Fig.25.21), that reproduces the nearly parabolic superconducting dome of Fig.25.2. The results for the zero-temperature gap, T_c as a function of x and superfluid density as function of x and T are shown in Figs.25.22,25.23. We have also calculated the effect of quantum phase fluctuations on T_c in the underdoped regime; T_c is pushed to zero at nonzero x, leading to a $T_c(x)$ dome [76] in close agreement with experiment.

2. Pseudogap crossover: The onset of pesudogap state is characterized by rapid but smooth crossover of various quantities across $T^*(x)$ which is an input incorporated via change of sign of the coefficient A [eq.(25.3)] in our theory. For example, the local pairing amplitude $\Delta(T)$ rises rapidly with decreasing temperature across $T^*(x)$ and the pairing contribution to the specific heat has a broad 'hump' around the same temperature [76]. Both of these are consistent with experiments, namely spin gap seen in Knight shift (Section 25.3.3) and broad feature seen in specific heat measurements [103]. In our theory, a similar crossover also appears at a

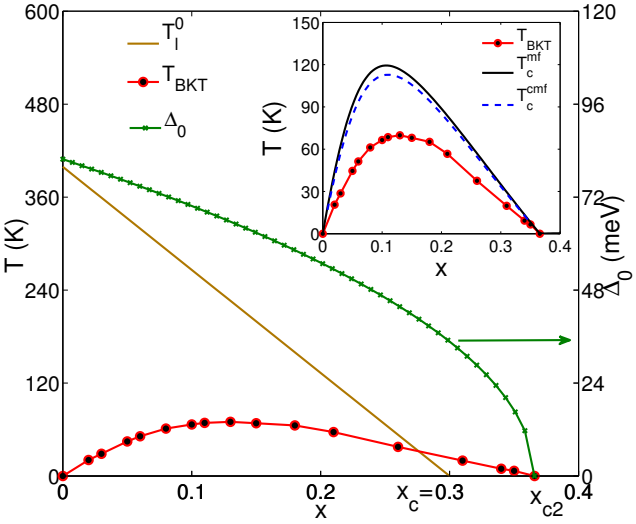

Figure 25.22: Doping dependence of different temperature scales ($T^* = T_l^0$ and $T_{\rm BKT}$, the Berezinskii-Kosterlitz-Thouless transition temperature, as appropriate for the purely 2d system considered here) and the zero temperature gap Δ_0 are shown in the main plot.

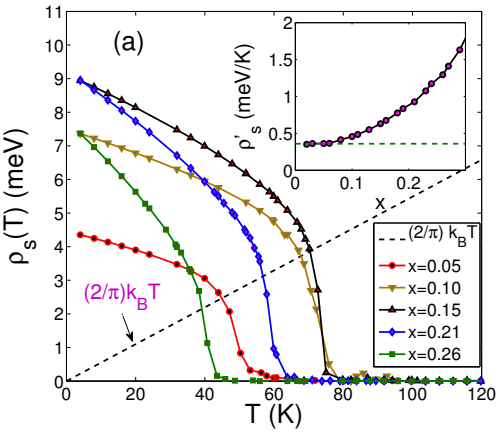

Figure 25.23: Finite temperature superfluid density calculated via MC simulation for different x values. The dashed line corresponds to the size of universal Nelson-Kosterlitz jump expected at a BKT transition. $T_{\rm BKT}(x)$ has been obtained from the intersection of this line with $\rho_s(x,T)$ vs. T curves.

temperature where the antinodal pseudogap in electronic spectral function is completely filled up or, in other words, the Fermi arc extends over the full Fermi surface [79]. All these various crossovers appears around temperature $T^*(x)$, however not all at exactly same temperature but over a somewhat broad range around $T^*(x)$ [76](see Fig.25.21), justifying the pseudogap temperature scale as a crossover rather than a sharp transition, as seen in the experiments 25.3.3. The results for pseudogap crossover seen in local pairing amplitude and specific heat are shown in Figs.25.24,25.25.

3. Large region of fluctuation diamagnetism and Nernst effect above T_c: We obtain a region of enhanced fluctuation diamagnetism in the pseudogap phase extending far above (around 1.5 times) the transition temperature T_c and show that the boundary of the region, namely the onset temperature $T_{onset}(x)$, follows a dome shaped curve tracking T_c as a function of doping (Fig.25.21). The results for Nernst regime computed from our theory is shown in Fig.25.26. Similar feature is also seen for magnetization [77].

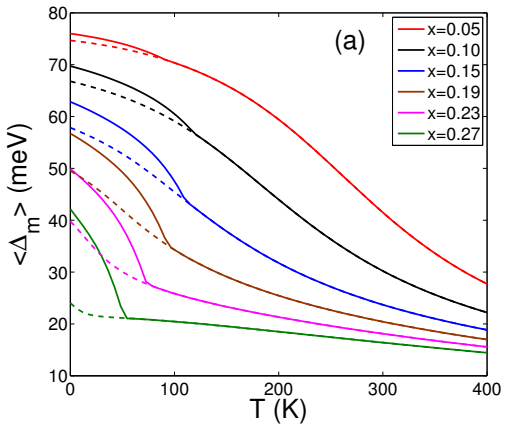

Figure 25.24: The figure shows a crossover $\langle \Delta_m \rangle$ from small to large values around $T^*(x)$ and an onset of the second gap feature at T_c.

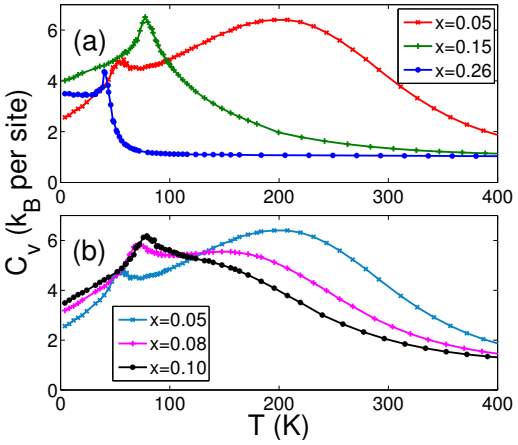

Figure 25.25: (a) Specific heat obtained from MC simulation of our model. Panel (b) shows the evolution of the broad maximum around T^* with doping in the underdoped region.

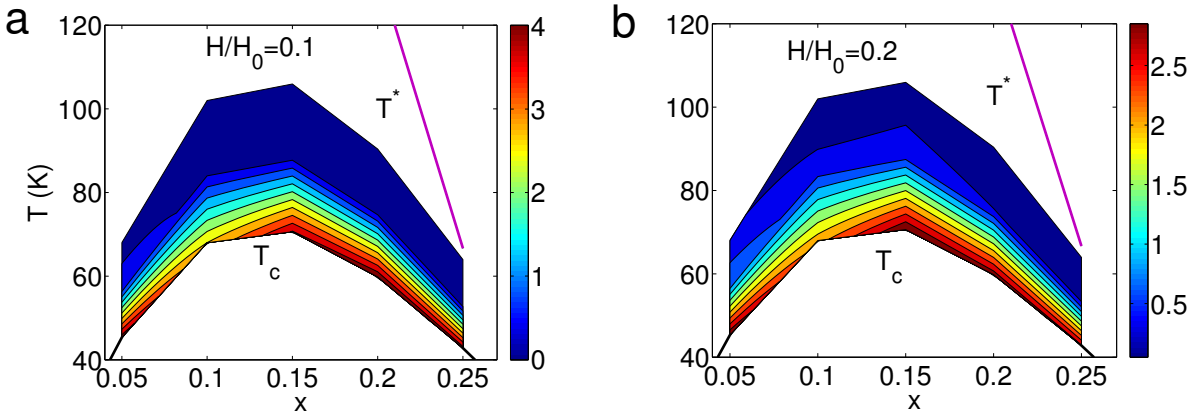

Figure 25.26: α_{xy} in the $x-T$ plane for two different values of the magnetic field (a) $H/H_0 = 0.1$ and (b) $H/H_0 = 0.2$. The lines of constant α_{xy} follow the superconducting dome. This indicates that the equilibrium superconducting fluctuations responsible for the suppression of the superfluid stiffness also determine the thermoelectric response.

Experimentally, both the Nernst effect [61] and diamagnetism [60] have been seen to track the superconducting dome. As mentioned earlier, the persistence of the Nernst and diamagnetism signal over a dome-shaped region above T_c, instead of the entire pseudogap state till $T^*(x)$, has been argued as evidence against the pairing origin of the pseudogap line. This is due to the expectation that if the pseudogap line is related to pairing then superconducting fluctuations should continue till T^*. However, on the basis of our results, we can argue that this expectation is not justified since pairing fluctuations identifiable as superconducting fluctuations, e.g. those detected through Nernst or diamagnetism, are mainly controlled by ρ_s or the T_c scale. The GL-like model we study has the pseudogap temperature $T^*(x)$ explicitly set as the local pairing scale by construction, but, even then, the diamagnetic signal tracks the superconducting T_c that is governed by the superfluid density rather than the pairing scale T^* on the underdoped side. The suggestion is that the long wavelength anomalies in Nernst effect and fluctuation diamagnetism require a large correlation length for superconducting phase fluctuations as happens near T_c.

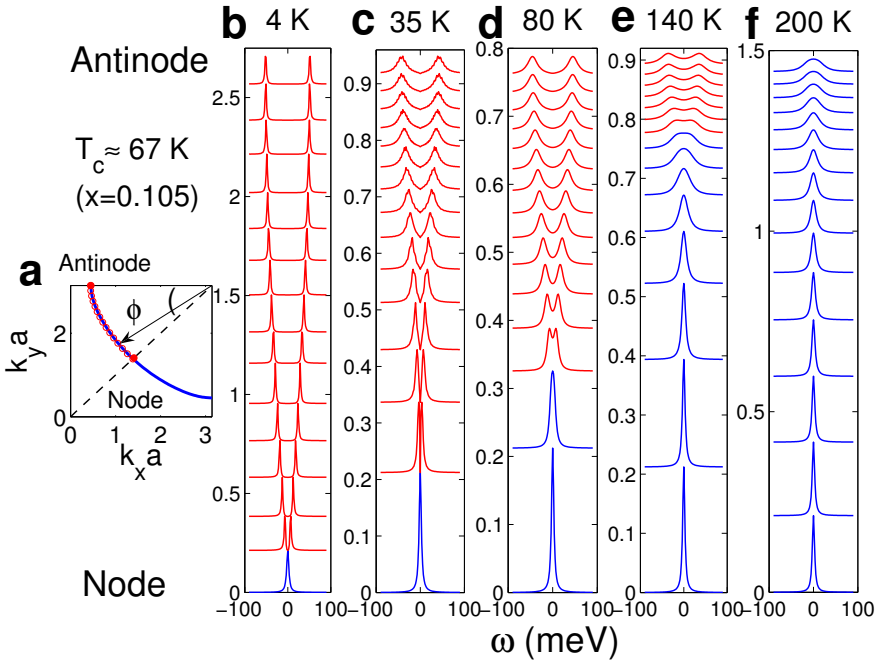

Figure 25.27: **The Fermi surface and the spectral density along it.** **a**, Fermi surface (FS) in the first quadrant of the Brillouin zone for $x \simeq 0.11$, a typical value. The angular position ϕ on the Fermi surface is shown. **b-f**, Single-particle spectral density $A(\mathbf{k}, \omega)$ at 15 equally spaced points (red circles) on the Fermi surface in **a** shown vertically shifted from node (bottom) to antinode (top), as a function of temperature at $x \simeq 0.11$. Blue and red lines correspond to Fermi arc and gapped portions of FS, respectively. (From Ref.[76])

4. Filling up of pseudogap and evolution of Fermi arc with doping and temperature: We show that, in remarkable agreement with ARPES experiments, non-zero local pairing amplitude above T_c manifests itself as pseudogap in the electronic spectral function on the *putative* Fermi surface that exists above the pseudogap temperature scale. Two spectral peaks appear away from the $\omega = 0$, however their is finite spectral weight at the zero energy. Above T_c, finite near-nodal gapless regions on the Fermi surface, or Fermi arcs, emerges from the d-wave node below T_c. The arcs expands with increasing temperatures and finally take over the whole Fermi surface at a temperature $T_{\rm an} \approx T^*(x)$, where the antinodal pseudogap gets completely filled up. The results are shown in Figs.25.27,25.28.

5. Deviation from d-wave gap structure below T_c due to phase fluctuations: 'Two gaps' from one gap:

Possibly the most widely explored property of a superconductor is the energy gap $\Delta_{\mathbf{k}}$ or $\Delta(\phi)$. The apparent deviation ('bending') of the gap below T_c, inferred from ARPES [105], from the d-wave form has been the subject of a great deal of current interest, leading to speculation

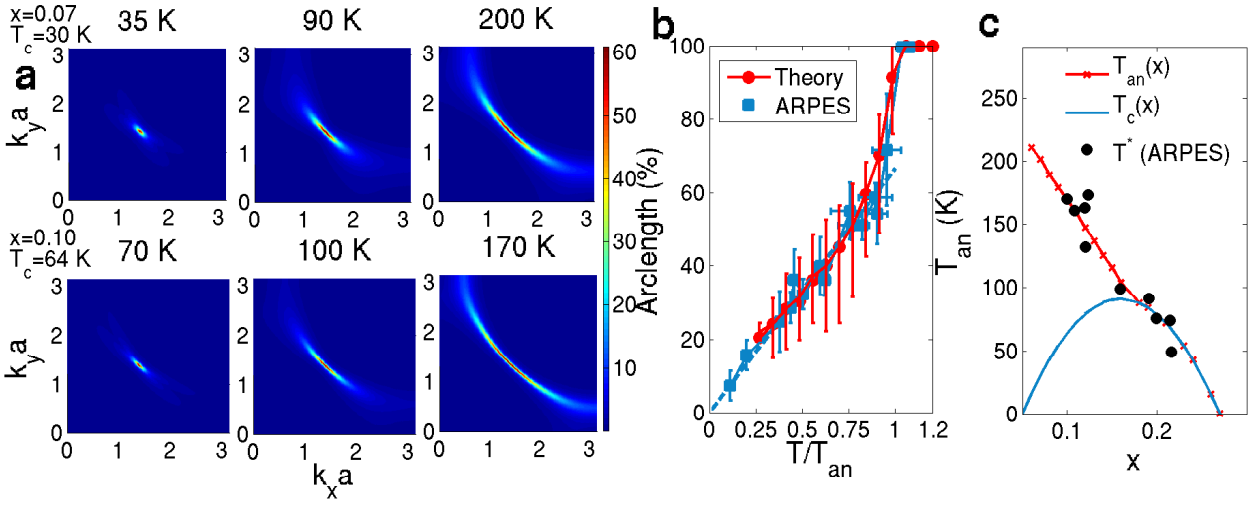

Figure 25.28: **Fermi arcs above T_c.** **a**, Colourmap of $A(\mathbf{k}, \omega = 0)$ over the first quadrant of the Brillouin zone for two values of x at different temperatures. The Fermi arc is easily picked out visually. The color bar indicates the value of $A(\mathbf{k}, \omega = 0)$. **b**, The arc length vs. $T/T_{\rm an}$ curve, averaged over the entire doping range ($x \lesssim x_{\rm opt}$). On the y-axis, 0% is the node and 100% is the antinode. The experimental data are from Ref.[104]. The vertical error bars in the theoretical points indicate the variation of the arc length at different x for a given $T/T_{\rm an}(x)$. **c**, The antinodal pseudogap filling temperature $T_{\rm an}$ as a function of x is compared with the data for the pseudogap temperature T^* from ARPES [66]. (From Ref.[79])

that there are two gaps in high-T_c superconductors [106]. We have obtained the gap $\Delta_{\mathbf{k}}$ from the peak position of the calculated spectral function $A(\mathbf{k}, \omega)$ for a fixed $\mathbf{k}$ as mentioned earlier and conclude from the results (see Fig.25.29**a**) that the 'bending' is due to the coupling of the electron to thermal phase fluctuations ('spin waves') below T_c. As expected from such an origin, it is large close to T_c, and small as $T \to 0$. These results confirm that there is only one gap, but that to 'uncover' it, effects of coupling to pair fluctuations ('spin waves') have to be factored in.

25.7 Conclusion and future directions

The cuprate superconductors are unusual materials both in their superconducting and non-superconducting states. After a description of some of their strangeness (Section 25.3), we have described a phenomenological theory that focuses on their superconductivity and on the properties connected with pairing fluctuations. We have also described a simple model which couples the fluctuations to electrons. Our aim has been to show that such an approach, in principle and in practice, successfully makes sense of the large amount of experimental information accumulated over decades on these materials, and that it does this both qualitatively and quantitatively. Given that such an approach is made in the background of our already strong and increasing knowledge of electrons in condensed matter, and given the repeated discovery of major novel experimental facts, some directions suggest themselves, in addition to several extensions, such as the inclusion of quantum phase fluctuations in the GL theory, already mentioned. One direction, within the ambit of phenomenological theory, is to enlarge it to include competing order. In the last several years, CDW (charge density wave) correlations have been clearly seen in these materials [107, 108, 62, 109]. Their dependence on doping, temperature and magnetic field [108, 62, 109, 31, 32, 33], whether the order is short or long range [108, 62, 109], whether they are bond CDW's or not [110], have all been documented extensively. Whether this is a competing order and whether there is ineluctable complexity in

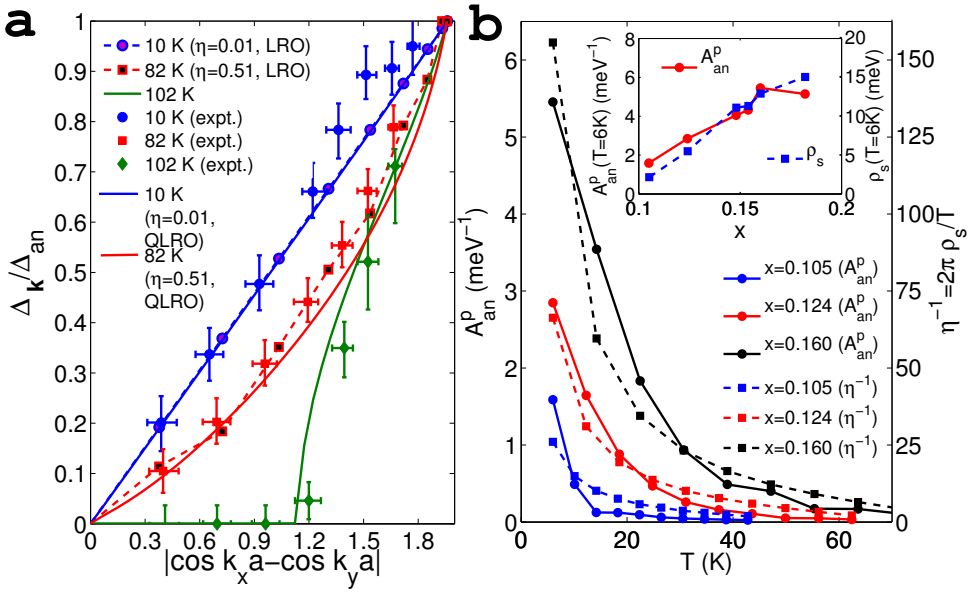

Figure 25.29: **Spectral properties below T_c. a**, Deviation of $\Delta_{\mathbf{k}}$ from the d-wave form, $|\cos k_x a - \cos k_y a|$, below T_c for $x = 0.16$ is compared with $\Delta_{\mathbf{k}}$ obtained in ARPES [105]. At low temperature ($T = 10$ K), $\Delta_{\mathbf{k}}$ follows the canonical d-wave form (a straight line), but bends away considerably from it close to T_c. For $T < T_c$, we have shown $\Delta_{\mathbf{k}}$ obtained for both the true LRO phase [i.e. $D(R \to \infty) = |\langle\psi_m\rangle|^2 \neq 0$] and the quasi-LRO or QLRO phase [i.e. $D(R) \sim R^{-\eta} \xrightarrow{R\to\infty} 0$]. **b**, The antinodal peak height $A^p_{\rm an}$ vs. T tracks $\rho_s(T)/T$ vs. T. **Inset** At low temperatures ($T = 6$ K) $A^p_{\rm an}(x)$ closely follows $\rho_s(x)$, especially in the underdoped side ($x \lesssim 0.16$).

these compounds, are important questions. There is again considerable experimental support for other non Cooper pair correlations such as electronic liquid crystal like effects [111, 107], SDW (spin density wave) like correlations [112].

The approach emphasizes the importance of phase fluctuations and is really a theory in which Cooper pair magnitude Δ_m and the phase ϕ_m are both relevant low-energy degrees of freedom whose significance varies with doping x and temperature T. For small x, the amplitude fluctuations are not important. This is like in interacting spin models where spin length fluctuations are not important, only there directional fluctuations which are like phase angle (ϕ_m) fluctuations are thermally excited. As x increases, amplitude Δ_m fluctuations have decreasing energies, till presumably for large x, one has the BCS like limit where both these are indistinguishable energetically. This raises several important questions. One is that there are and must be other phase angle fluctuations besides the d-wave like ones in which we constrain the nearest neighbor x, y-bond angles to be $(\pi/2)$ out of phase. These have been investigated recently [] and have important consequences. The other is whether there is indeed a BCS limit, given the short coherence length. Questions connected with time-reversal symmetry breaking [113, 114], anomalous Kerr effect [115] etc. are other basic directions. Can the effects be understood in the above framework?

An overarching issue is the need for a microscopic theory with *electrons* as basic ingredients. The analogue is the celebrated BCS theory which followed the original GL theory in seven or so years. Here, nearly a quarter of century after the discovery of cuprate superconductivity, and in the background of a large number of well developed many-body electronic approaches, a phenomenological theory has been proposed. The underlying question is the well known problem of a theoretical description of strongly correlated mobile electrons. Many phenomena of the strange metal phase itself, depend for their theoretical understanding on the development of such a theory, so that the development of a 'reliable' many-particle approach for strongly cor-

related electrons with inevitable pairing correlations is a pressing necessity for a comprehensive theory of electronic matter.inductable

25.8 Parameters of the phenomenological theory

As natural in a phenomenological theory, the parameters of the functional in eq.(25.3) are chosen to be consistent with experiment. The doping and temperature dependence of the coefficients are parametrized as $A(x,T) = (f/T_0)^2[T - T^*(x)]e^{T/T_0}$, $B = bf^4/T_0^3$ and $C(x) = xcf^2/T_0$; f, b, c are dimensionless and $T^*(x) = T_0(1 - x/x_c)$ with the single energy scale T_0 and doping concentration $x_c = 0.3$ controlling the pseudogap temperature scale. The phenomenological parameters f, b, c vary for different cuprates and T_0 is the bare pseudogap temperature extrapolated to zero doping. The exponential factor e^{T/T_0} appearing in A is not very crucial in the temperature range of our interest, i.e. below the pseudogap temperature. This factor suppresses average local gap magnitude $\langle \Delta_m \rangle$ at high temperatures ($T \gtrsim T^*(x)$) with respect to its otherwise temperature independent equipartition value $\sqrt{T/A(x,T)}$ which will result from the simplified form of the functional [Eq.(25.3)] being used over the entire range of temperature. Such a suppression is natural in a degenerate Fermi system; the relevant local electron pair susceptibility is rather small above the pair binding temperature and below the degeneracy temperature.

The forms of the parameters A, B and C specified above allow us to reproduce the superconducting dome. However, it is also important to mention that having chosen A, B and C to reproduce the superconducting dome, the doping and temperature dependences of other physical properties like the superfluid density, the magnitude of the local gap, specific heat, orbital magnetization and Nernst coefficient also agree very well with experiments [76, 77, 78].

While, underdoped phenomenology plays an important part in determining the form of our model, e.g. to determine the doping dependence of the parameter C as mentioned above, it also produces the standard GL theory for conventional superconductors on the overdoped side. The amplitude of pairing approaches zero at T_c, or in other words the actual or 'renormalized' pairing scale $\widetilde{T}^*(x) \approx T_c(x)$, on the overdoped side in our theory [76]. This is in conformity with the common expectation that the BCS theory or mean-field GL theory is more appropriate for overdoped cuprates.

For specific values of the parameters, e.g. for Bi2212, which has a $T_c^{\rm opt} \simeq 91$ K at $x = x_{\rm opt} \simeq 0.15$, we choose $f \simeq 1.33$, $b = 0.1$, $c \simeq 0.3$ with $T_0 \simeq 400$ K. This choice of parameters leads to an optimal BKT transition temperature $T_{\rm KT}^{\rm opt} \approx 75K$ for the 2D system that we study. In the cuprates, the small but finite inter-layer coupling between CuO_2 planes is expected to lead to a slightly higher T_c. The interlayer coupling can be easily incorporated in our model in the manner of Lawrence and Doniach[116]. Since this coupling is, in practice, quite small (e.g. the measured anisotropy ratio in Bi2212 is about 100), it makes very little difference quantitatively to most of our estimates.

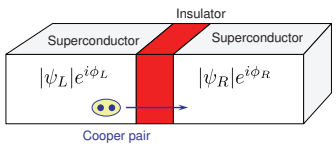
29 Atomic physics and quantum optics using SC circuits by You, Nori

Abstract

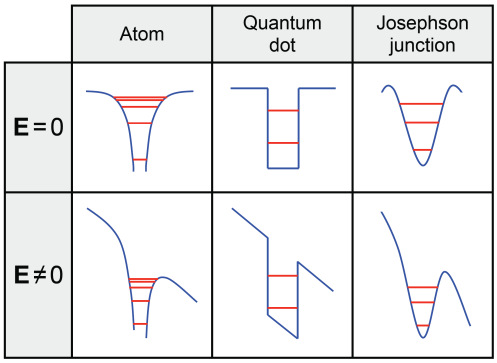


Superconducting circuits based on Josephson junctions exhibit macroscopic quantum coherence and can behave like artificial atoms. Recent technological advances have made it possible to implement atomic-physics and quantum-optics experiments on a chip using these artificial atoms. This review presents a brief overview of the progress achieved so far in this rapidly advancing field. We not only discuss phenomena analogous to those in atomic physics and quantum optics with natural atoms, but also highlight those not occurring in natural atoms. In addition, we summarize several prospective directions in this emerging interdisciplinary field.

Superconducting circuits with Josephson junctions can behave as artificial atoms. In these quantum circuits, the Josephson junctions act as nonlinear circuit elements (see Box 1). Such nonlinearity in a circuit ensures an unequal spacing between energy levels, so that the lowest levels can be individually addressed by using external fields (see, e.g., [5, 6, 7, 8, 9, 1, 2, 3, 4]). Experimentally, these circuits are fabricated on a micrometer scale and operated at mK temperatures. Because of the reduced dimensionality and thanks to the superconductivity, the environment-induced dissipation and noise are greatly suppressed, so the circuits can behave quantum mechanically.

Superconducting circuits based on Josephson junctions have recently become subjects of intense research because they can be used as qubits—controllable quantum two-level system—for quantum computing (see, e.g., [1, 2, 3, 4] for reviews). Even though the typical decoherence times of these circuits fall short of the requirements for quantum computation, their macroscopic quantum coherence is sufficient for them to exhibit striking quantum behaviors. These circuits can have a number of superconducting eigenstates with discrete eigenvalues lower than the energy levels of the quasi-particle excitations that involve breaking Cooper pairs. This property allows these circuits to behave like superconducting artificial atoms. Indeed, there is a deep analogy between natural atoms and the artificial atoms made from superconducting circuits (see Box 2). Both have discrete energy levels and can exhibit coherent quantum oscillations between these levels. Whereas natural atoms may be controlled using visible or microwave photons that excite electrons from one state to another, the artificial atoms in the circuits are driven by currents, voltages and microwave photons that excite the system from one macroscopic quantum state to another.

Differences between superconducting circuits and natural atoms include the different energy scales in the two systems, and how strongly each system couples to its environment; the coupling is weak for atoms and strong for circuits. In contrast to naturally occurring atoms, artificial atoms can be designed with specific characteristics and fabricated on a chip using standard lithographical technologies. With a view to applications, this degree of tunability is an important advantage over natural atoms. Thus, in a controllable manner, superconducting circuits can be used to test fundamental quantum mechanical principles at a macroscopic scale, as well as to demonstrate atomic physics and quantum optics on a chip. Moreover, artificial atoms can be designed to have exotic properties that do not occur in natural atoms.



Box 1. The Josephson junction as a nonlinear inductor

A superconductor contains many paired electrons, called Cooper pairs, which condense into the same macroscopic quantum state described by the wavefunction $|\psi|e^{i\phi}$, with $|\psi|^2$ being the density of Cooper pairs. In the absence of applied currents or magnetic fields, the phase ϕ is the same for all Cooper pairs. A Josephson junction is composed of two bulk superconductors separated by a thin insulating layer through which Cooper pairs can tunnel (see the figure

above). The supercurrent through the junction is $I = I_c \sin\varphi$, where the critical current I_c is related to the Josephson coupling energy E_J of the junction by $I_c = (2e/\hbar)E_J$, and $\varphi = \phi_L - \phi_R$ is the phase difference of the two superconductors across the junction. The time variation of this phase difference is related to the potential difference V between the two superconductors: $\dot{\varphi} = \left(\frac{2\pi}{\Phi_0}\right) V$, where $\Phi_0 = h/2e$ is the magnetic-flux quantum. From the definition of the inductance $V = L_J \dot{I}$, it follows that $L_J = \frac{\Phi_0}{2\pi I_c \cos\varphi}$, indicating that the Josephson junction behaves like a nonlinear inductor.

Box 2. Artificial and natural atoms

Potential energy (in blue) and discrete energy levels (in red) for an atom, a quantum dot and a Josephson junction in the absence ($\mathbf{E} = 0$) and presence ($\mathbf{E} \neq 0$) of an externally applied electric field, respectively (see the figure above). Owing to their confinement, the electrons in the atom and the quantum dot have discrete energy levels. The Cooper pairs confined in the potential well of the Josephson coupling energy also have discrete energy levels and the junction can be regarded as a superconducting artificial atom.

In this review, we highlight the atomic-physics and quantum-optics phenomena found in superconducting circuits. The novel physics in these artificial atoms will be emphasized, including phenomena that do not occur in natural atoms. We also summarize several prospective directions in this emerging interdisciplinary field. Some of the examples in this brief overview relate to our work, because we are more familiar with them.

Superconducting circuits as artificial atoms

Two important energy scales determine the quantum mechanical behavior of a Josephson-junction circuit: The Josephson coupling energy E_J and the electrostatic Coulomb energy $E_c = (2e)^2/2C$ for a single Cooper pair, where e is the electronic charge, and C is either the capacitance C_J of a Josephson junction or the capacitance of a superconducting island called a Cooper-pair box (i.e., the sum of the gate capacitance C_g and the relevant junction capacitance), depending on the circuit. Figure 29.1 summarizes three kinds of superconducting circuits implemented in different regimes of E_J/E_c; Fig. 1(a) shows the voltage-driven box (also known as a Cooper-pair box) for a charge qubit [5], Fig. 1(b) the flux-driven three-junction loop for a flux qubit [6] and Fig. 1(c) the current-driven junction for a phase qubit [8, 9]. As a typical example, energy levels of the flux qubit are shown in Fig. 1(d). Moreover, hybrid superconducting qubits are possible. For instance, a Cooper-pair box can behave like a charge-flux qubit [7] when $E_J/E_c \sim 1$. As for the flux qubit, by reducing the ratio E_J/E_c, the charge noise can become dominant over the flux noise [10] and the circuit behaves more like a charge qubit. In this circuit, when $\alpha < 0.5$ (here α is the ratio of the Josephson coupling energy between the smaller and larger junctions in the loop), the double-well potential converts to a single-well potential and the circuit behaves like a phase qubit [10, 11]. One can shunt a large

capacitance to the small junction [10, 11] to suppress the charge noise in this circuit. Also, this large capacitance shunted to the Josephson junction can be used to reduce the charge noise in the Cooper-pair box [12], so as to implement the circuit in the phase regime. Below we highlight several aspects of the atomic-physics and quantum-optics phenomena found in superconducting circuits.

Cavity quantum electrodynamics. A quantized electromagnetic field can coherently exchange energy with a two-level system, usually in a tiny (micrometer-scale) cavity. This energy exchange process involves a fundamental phenomenon called Rabi oscillation; the two-level system and the field exchange a quantum of energy back and forth at a characteristic frequency known as the Rabi frequency. When the field is in resonance with the system, the Rabi frequency is proportional to the system-field coupling strength. The most elementary of such coherent processes involves the interaction of a two-level system with a single photon in the cavity. The exchange of energy between the system and the single photon is observable when the Rabi frequency is larger than the decay rates of the two-level system and the cavity. This photon-atom coupling has been achieved for a variety of atoms interacting with the light field in a cavity and forms the basis of cavity quantum electrodynamics (QED). Cavity QED with superconducting circuits was proposed [13, 14] and experimentally achieved [15, 16] in systems where superconducting qubits were employed as two-level artificial atoms. For the cavity, a single-mode LC resonator [15] and a multi-mode coplanar waveguide resonator [16] have been used. Significantly, the strong-coupling limit for a superconducting qubit in a cavity can be attained much more easily than for a natural atom in a cavity [4, 14] by suitably designing the system parameters. It allows, e.g., the observation of the Lamb shift for a superconducting qubit in the cavity [17]. Moreover, both the superconducting qubit and the cavity can be fabricated on the same chip. For a review on cavity QED with superconducting qubits, see, e.g., [4].

Because they can be designed with specific system parameters, superconducting quantum circuits are suited for achieving the so-called ultrastrong-coupling regime, where the qubit-photon coupling strength is comparable to the energy scales of the qubit and the photon [18]. Indeed, there have been a number of theoretical studies of this system, analyzing some of its rich static and dynamical properties (see, e.g., [19, 20, 21]). Also, the ultrastrong coupling between a superconducting flux qubit and a coplanar waveguide [22] or an LC resonator [23] has recently been demonstrated in experiments. One can expect to find new phenomena in this ultrastrong-coupling regime which are not present in the conventional weak- and moderately strong-coupling regimes. In addition, dressed states of a superconducting charge qubit and an intense microwave field were experimentally observed by embedding the circuit in an LC oscillator [22]. The tunability of these dressed states allows one to explore both resonant and dispersive coupling regimes.

Selecting quantum transitions. In natural atoms, the electronic state at each orbital level has a well-defined parity symmetry, either even or odd. Under the dipole approximation, the interaction Hamiltonian between the atom and the time-dependent electric field has an odd parity. Thus, to have a nonzero dipole transition matrix element, there should be a parity change between the initial and final states, in addition to the constraints on azimuthal and magnetic quantum numbers of the electronic states. This optical selection rule dictates that only three types of three-level systems, called Λ-, V-, and Ξ-type atoms [see Fig. 29.2(a)], exist for the natural atoms, where no dipole transition between electronic states with the same parity are allowed. However, selection rules can be different for superconducting artificial atoms. For instance, in the dipole approximation, the interaction Hamiltonian between a flux qubit circuit and a time-dependent magnetic field does not have a well-defined parity, except at the point with a static magnetic flux $f \equiv \Phi/\Phi_0 = \frac{1}{2}$, where Φ is the static magnetic flux applied to the

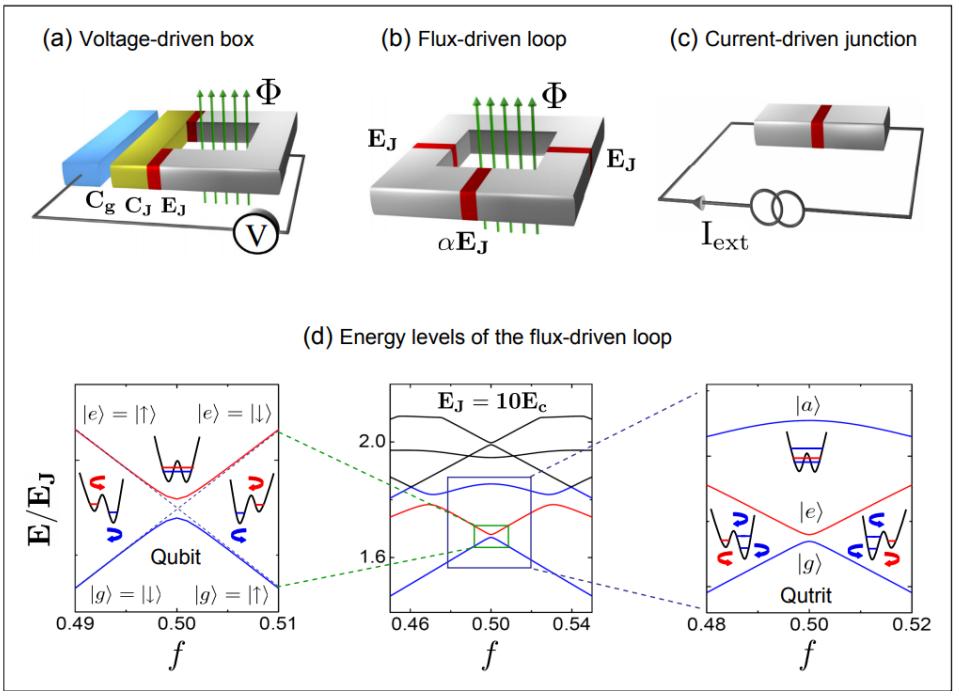


Figure 29.1: **Superconducting circuits as artificial atoms. (a)** A Cooper-pair box biased by a gate voltage V_g and implemented in the charge regime $E_J/E_c \ll 1$. The SQUID loop provides an effective Josephson coupling energy tuned by the threading magnetic flux Φ. See main text for nomenclature. **(b)** A superconducting loop interrupted by three Josephson junctions and implemented in the phase regime $E_J/E_c \gg 1$. The two identical Josephson junctions have coupling energy E_J and capacitance C, while both the Josephson coupling energy and the capacitance of the smaller junction are reduced by a factor α, where $0.5 < \alpha < 1$. The three-junction loop is biased by a flux Φ such that $f \equiv \Phi/\Phi_0 \sim \frac{1}{2}$. **(c)** A Josephson junction biased by a current $I_{\rm ext}$, which is also implemented in the phase regime and has a much larger ratio E_J/E_c. **(d)** Energy levels of the flux-driven three-junction loop (the curves in the middle panel). With the lowest two energy levels involved (the curves in the left panel, which are enlarged from the smaller rectangle in the middle panel), the flux-driven loop can behave like a coherent and controllable quantum two-level system (qubit), while the circuit can behave like a coherent and controllable three-level system (qutrit) when using the lowest three levels (the curves in the right panel, which are enlarged from the larger rectangle in the middle panel). Moreover, in the left, top and right insets of the left (right) panel, the two (three) energy levels are also displayed in the double potential well for $f < \frac{1}{2}$, $f = \frac{1}{2}$ and $f > \frac{1}{2}$, where the clockwise and anticlockwise arrows represent the circulating supercurrent states in the flux-driven three-junction loop. In **(a)-(c)**, the qubit employs the charge states on a single island, the persistent-current states in a double potential well, and the anharmonic-oscillator states in a single potential well, respectively. Also, a flux-driven superconducting loop with a different number of Josephson junctions, e.g., one [89] or four junctions [90], can be used for a flux qubit. Furthermore, a flux-driven single-junction loop can be used as a phase qubit when working with the energy levels in a tilted potential well [91], as in a current-driven junction.

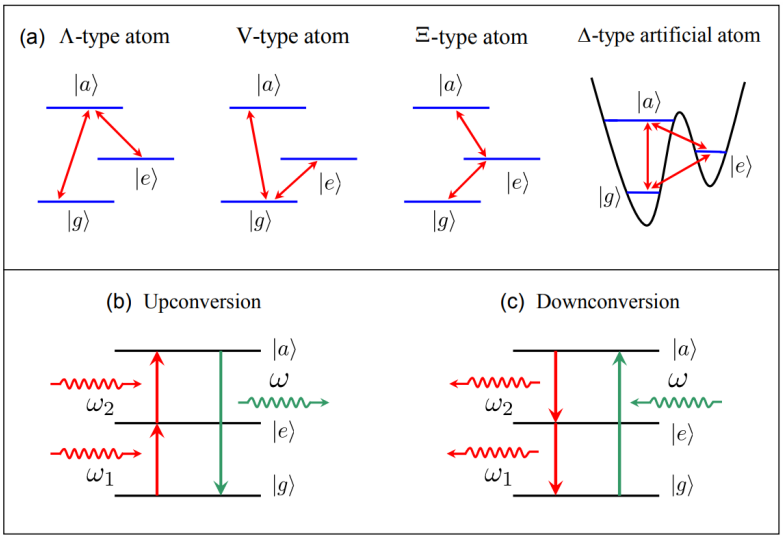

Figure 29.2: **Three-level atoms and frequency conversion.** **(a)** Energy levels of natural atoms of the Λ, V, and Ξ types, as well as a Δ-type artificial atom consisting of a flux-driven three-junction loop. The allowed dipole transitions between energy levels are indicated in red. In contrast to naturally occurring atoms, the three dipole transitions among the states $|g\rangle$, $|e\rangle$ and $|a\rangle$ are all allowed in the Δ-type three-level artificial atom. Here $|g\rangle$ and $|e\rangle$ denote the ground and first excited states, while $|a\rangle$ denotes either the second or another excited state. **(b)** Frequency upconversion in a Δ-type artificial atom. Here $\omega_1 = (E_e - E_g)/\hbar$, $\omega_2 = (E_a - E_e)/\hbar$, and $\omega = (E_a - E_g)/\hbar$, with E_i ($i = g, e$ or a) being the energy level of the state $|i\rangle$. When two microwave photons, one with frequency ω_1 and the other with ω_2, are successively absorbed by the artificial atom, it can emit a microwave photon with frequency $\omega = \omega_1 + \omega_2$ via the transition $|a\rangle \to |g\rangle$. **(c)** Frequency downconversion in the Δ-type artificial atom. When a microwave photon with frequency ω is absorbed by the artificial atom, the sequential transitions $|a\rangle \to |e\rangle$ and $|e\rangle \to |g\rangle$ can produce two microwave photons with frequencies ω_1 and ω_2, respectively. In particular, when $E_a - E_e = E_e - E_g$, the upconversion in **(b)** converts two photons with frequency $\frac{1}{2}\omega$ to one photon with frequeny ω, while the downconversion in **(c)** converts one photon with frequency ω to two photons with frequeny $\frac{1}{2}\omega$. Natural atoms cannot perform up- or down-conversion, unless aided by nonlinear effects. However, artificial atoms can.

loop and Φ_0 the magnetic-flux quantum. At this particular point, the interaction Hamiltonian has an odd parity. Owing to the parity symmetries of the artificial-atom states at $f = \frac{1}{2}$, the lowest three levels of the circuit behave like a Ξ-type or ladder-type artificial atom [25]. In this case, the dipole transition between $|g\rangle$ and $|a\rangle$ is forbidden, while the other two transitions (among states $|g\rangle$, $|e\rangle$ and $|a\rangle$) are allowed [see Fig. 2(a) for nomenclature]. However, when $f \neq \frac{1}{2}$, the parity symmetry is broken for the interaction Hamiltonian. Therefore, all three dipole transitions among $|g\rangle$, $|e\rangle$ and $|a\rangle$ are possible, allowing the atom to be Δ-type because of the triangle-shaped transitions among the three energy levels. Now (when $f \neq \frac{1}{2}$) the superconducting circuit behaves as a Δ-type cyclic artificial atom, where one- and two-photon processes can coexist [25].

This Δ-type artificial atom can be used for the upconversion and downconversion of the photon frequency [see Figs. 29.2(b) and 29.2(c)]. In these frequency conversions, all transitions involve only linear processes; this is in sharp contrast to the conventional frequency conversion in nonlinear optics, where a nonlinear medium is used and the nonlinear effect facilitates converting the frequency of the photons. Recently, the frequency upconversion of a microwave photon was experimentally demonstrated in a flux qubit [26]. This experiment explained the observed coexistence of one- and two-photon processes as due to the symmetry-breaking of the system Hamiltonian, when varying the applied magnetic flux away from $f = \frac{1}{2}$.

In the experiment reported in [27], two microwave fields were applied simultaneously to a superconducting circuit containing two coupled flux qubits. The interference between the processes that correspond to a selected excitation by the applied microwave fields can be controlled and used to activate or suppress a given transition. Thus, this method effectively creates artificial and controllable selection rules.

Electromagnetically induced transparency. Quantum interference can be introduced to control the propagation of light through an atomic medium consisting of three-level atoms or qutrits. We now consider a Λ-type three-level atom; to control the propagation of a probe light field in resonance with the dipole transition $|a\rangle \leftrightarrow |g\rangle$ (that is, at the probe frequency ω_p), one can drive the atom by a second (control) field that is in resonance with the transition $|a\rangle \leftrightarrow |e\rangle$ at the control frequency ω_c (see Fig. 29.3). Now the amplitude of the wavefunction for the state $|a\rangle$ is driven by two terms; one proportional to the probability amplitude of the ground state $|g\rangle$ and the other proportional to the probability amplitude of state $|e\rangle$. The combined effect of these two fields is to pump the atom into a coherent superposition of the states $|g\rangle$ and $|e\rangle$ known as a dark state. In such a case, the two driving terms can interfere and cancel each other, i.e., they have equal magnitudes but opposite signs. Under this destructive quantum interference, the occupation probability at state $|a\rangle$ is zero, leading to a vanishing light absorption even in the presence of light fields. This effect is called electromagnetically induced transparency (EIT) in quantum optics [28, 29] and also applies to V- and Ξ-type atoms. This important effect has a variety of applications. For instance, a medium with EIT can slow down and even stop or trap light.

We now consider EIT in a more quantitative manner. Let Ω_p (Ω_c) be the Rabi frequency that quantifies the coupling strength between the probe (control) light and the atom. Here we assume that a Λ-type atom can be prepared in the initial state $|\Psi(0)\rangle = (\Omega_c|g\rangle - \Omega_p|e\rangle)/\Omega$, where $\Omega = \sqrt{\Omega_p^2 + \Omega_c^2}$. When the EIT occurs, the atom will be trapped in this dark state, i.e., $|\Psi(t)\rangle = (\Omega_c|g\rangle - \Omega_p|e\rangle)/\Omega$, for a time which is dependent on the decoherence rate of the atom. Usually, it is not easy for an atom to be prepared in the initial state $|\Psi(0)\rangle$, when Ω_p is comparable to Ω_c. Instead, the atom can be naturally prepared in the ground state $|g\rangle$. If strong control and weak probe fields are chosen so that $\Omega_c \gg \Omega_p$, the dark state $|\Psi(t)\rangle$ is close to the initial state $|g\rangle$. In such a case, the combined action of the control and probe fields can easily drive the atom from the ground state into the dark state [29]. This is the reason why

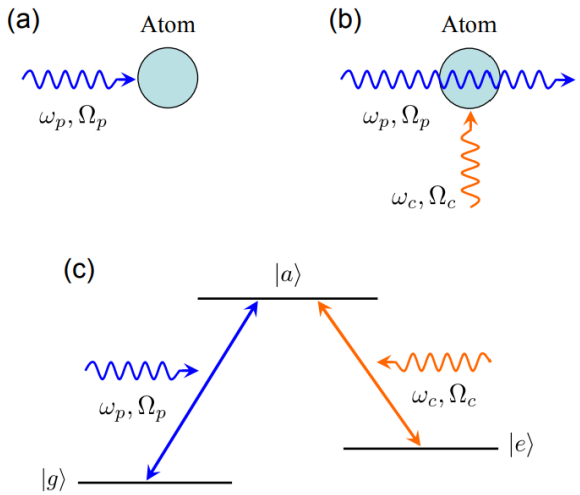

Figure 29.3: **Electromagnetically induced transparency. (a)** A probe light field is absorbed by natural or artificial atoms when the frequency of the light field is resonant with a particular separation between two atomic energy levels. **(b)** However, the probe light field can go through the natural or artificial atoms when a suitable control light field also drives the atoms. **(c)** Λ-type three-level atomic system for EIT. The frequency ω_p of the probe light field is resonant with the energy separation between states $|a\rangle$ and $|g\rangle$, and the frequency ω_c of the control light field is resonant with the energy separation between states $|a\rangle$ and $|e\rangle$. The Rabi frequency Ω_p (Ω_c) quantifies the coupling strength between the probe (control) light field and the atom.

a strong control field and a weak probe field are used to experimentally implement EIT in an atomic medium.

At $f = \frac{1}{2}$, the flux qubit circuit can behave like a Ξ-type artificial atom [25, 30]. The circuit can also behave approximately like a Λ-type artificial atom when $f \neq \frac{1}{2}$, if the dipole transition rate between $|g\rangle$ and $|e\rangle$ is much smaller than the rates for the other two transitions [30]. As discussed above, these selection rules are related to the parity symmetries of the artificial-atom states. In contrast to natural atoms, the tunability of a superconducting circuit can be used to prepare the artificial atom in an initial state that is close to the dark state $|\Psi\rangle$ with arbitrary Ω_c and Ω_p. Therefore, it is experimentally feasible to produce EIT in a single artificial atom for either strong or weak control and probe fields. This is an important advantage of superconducting circuits compared to natural atoms. EIT using superconducting circuits has been studied theoretically (e.g., [31, 32, 33]) and experimentally [34, 35]. In [35], this phenomenon was experimentally shown using a four-junction loop biased at $f = \frac{1}{2}$, where the circuit behaves as a Ξ-type artificial atom.

State population inversion and lasing. A laser is composed of an amplifying medium inside a resonant optical cavity. When the system is driven, a state population inversion (SPI) can be achieved for the atoms or molecules in the amplifying medium. Moreover, there is a positive feedback between the emitted light and the amplifying medium. Because of this positive feedback and the nature of the stimulated photon emission, the laser has a large net optical gain and the emitted photons have the same direction, phase and polarization. These advantages mean that the laser has a variety of applications in different fields. Recently, several studies have considered lasing using only a single artificial atom, both theoretically [30, 36, 37, 38] and experimentally [39, 40].

With suitable junction parameters, the flux qubit circuit can have the following dipole transition rates [30] when $f \neq \frac{1}{2}$: $\Gamma_{ga} > \Gamma_{ae} \gg \Gamma_{eg}$, where the rate Γ_{ij} is proportional to

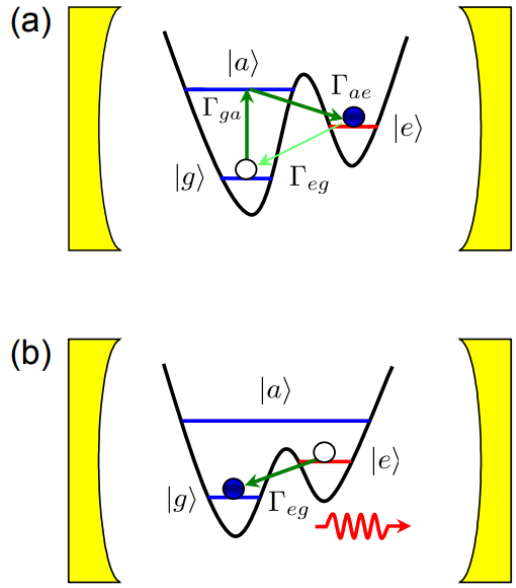

Figure 29.4: **Lasing. (a)** State population inversion (for lasing) between states $|e\rangle$ and $|g\rangle$ in a three-junction loop at $f > \frac{1}{2}$, where the artificial atom is quickly pumped from $|g\rangle$ to $|a\rangle$ by a strong microwave pulse (for example, by a quick Rabi oscillation) and then decays from $|a\rangle$ to $|e\rangle$ via photon emission. Here the dipole transition rate from $|e\rangle$ to $|g\rangle$ is small because of a higher inter-well barrier between them; the dipole transition rate from $|a\rangle$ to $|e\rangle$ is larger owing to a lower barrier; and the rate is even larger for the dipole transition $|g\rangle \to |a\rangle$ because no potential barrier is involved in the single well. **(b)** Photon emission of the artificial atom to build up a lasing field, where the inter-well barrier is lowered so as to have a strong transition rate between $|e\rangle$ and $|g\rangle$ and to tune the transition $|e\rangle \to |g\rangle$ into resonance with the cavity.

$|t_{ij}|^2$, with t_{ij} being the dipole transition matrix element between states $|i\rangle$ and $|j\rangle$. Because the transition $|a\rangle \to |e\rangle$ can be dominant over $|e\rangle \to |g\rangle$, an SPI between states $|e\rangle$ and $|g\rangle$ [Fig. 29.4(a)] can be quickly achieved by pumping the artificial atom (via the transition $|g\rangle \to |a\rangle$) using a strong microwave field. Here the artificial atom can be placed in, e.g., a coplanar waveguide resonator [16] by sharing a segment of the circuit loop with the transmission line. In the process of SPI, the weak-coupling regime is assured by having the flux qubit circuit off-resonant with respect to the cavity.

While the SPI is being established, the biasing flux can be adjusted to give a value of f near $\frac{1}{2}$, where the rate Γ_{eg} for the transition $|e\rangle \to |g\rangle$ becomes large and the cavity is resonant with this transition. However, the adiabatic condition is not easy to satisfy near this anticrossing point ($f = \frac{1}{2}$), where the Landau-Zener transition is strong, so the biasing flux cannot be changed very fast while approching this point. Fortunately, away from this anticrossing point, the Landau-Zener transition is weak, so it is easy to satisfy the adiabatic condition [30] and the flux can be changed very quickly. To take advantage of this property, the small Josephson junction in the flux-driven loop can be replaced by a tunable superconducting quantum interference device (SQUID). In this d.c. SQUID, the magnetic field applied to the loop causes the critical current to oscillate with period $2\Phi_0$. With the SPI established at a biasing flux away from $f = \frac{1}{2}$, one can quickly change the flux in the SQUID loop to lower the inter-well barrier, so as to both increase the transition rate Γ_{eg} and tune this transition $|e\rangle \to |g\rangle$ into resonance with the cavity mode [Fig. 29.4(b)]. This can yield a strong coupling between the circuit and the cavity.

To build up a lasing field, in addition to the above two conditions for quickly establishing SPI and then achieving a strong circuit-cavity coupling, the cavity used should have a high quality factor Q (Q-factor), i.e., a small leak or decay rate. This can be implemented using a

coplanar waveguide resonator [16].

Indeed, lasing was experimentally observed using a Cooper-pair box in an on-chip cavity [39]. In contrast to the proposal [30] using a flux-driven loop, this experiment [39] employs a different three-level system: the two lowest superconducting states $|g\rangle$ and $|e\rangle$ and a quasi-particle state $|a\rangle$. The gate voltage is tuned to $V_g > e/C_g$ (above the degeneracy point), so the state $|2\rangle$ with an extra Cooper pair in the box becomes the ground state $|g\rangle$ of the artificial atom, and the state $|0\rangle$ with zero extra Cooper pair in the box is the excited state $|e\rangle$. Also, the box is connected to a lead via a tunnel barrier. When driving the box with a voltage across the tunnel barrier, an SPI between $|e\rangle \equiv |0\rangle$ and $|g\rangle \equiv |2\rangle$ is achieved, following quasi-particle tunneling processes [36]. In [39], lasing was achieved continuously, with emitted light escaped from one end of the cavity.

Cooling. There are different methods for cooling atoms, including Dopper cooling, Sisyphus cooling, side-band cooling, subrecoil cooling, and evaporative cooling. Some of these techniques can be adapted to cool a solid-state artificial atom. For instance, the Sisypus cooling technique was used to cool a flux qubit (i.e., a flux-driven three-junction or four-junction loop) [40].

Another important advancement [42] is the cooling of a flux qubit implemented via the inverse process of SPI. In [42], the temperature of the superconducting qubit was lowered by up to two orders of magnitude when its surroundings reached a temperature as low as tens of mK. This cooling of the flux qubit is achieved when the biasing flux is shifted away from $f = \frac{1}{2}$, where the dipole transition rates for the lowest three levels of the flux qubit satisfy the relations $\Gamma_{ag} > \Gamma_{ea} \gg \Gamma_{ge}$. By optically pumping the qubit via the transition $|e\rangle \to |a\rangle$, the qubit is excited to the high-energy state $|a\rangle$ and then decays to the ground state by way of the transition $|a\rangle \to |g\rangle$ [see Fig. 29.5(a)], with a net energy, extracted from the qubit, emitted to the outside environment. This experiment also provides fine analogies between solid-state artificial atoms and natural atoms, as well as showing how these analogies can inspire new applications.

Although the superconducting qubit in [42] was greatly cooled ($k_B T \ll E_e - E_g$) in experiments, the noise sources surrounding the qubit were not. So the qubit will quickly return to the temperature of its environment. To overcome this difficulty, the superconducting qubit can be redesigned to increase its controllability by replacing the small Josephson junction in the flux-driven loop with a tunable SQUID [43]. The cooling process can now be described as follows [see Figs. 29.5(b)-29.5(d)]: First, as in the experiment [42], the qubit is initially cooled, following the inverse process of the SPI. Then, the tunable qubit is switched on for a period of time in order to resonantly interact with the noise source (e.g., local two-level fluctuators) surrounding the qubit. This process extracts energy from the noise source to heat the qubit. Repeating these two processes [43], both the qubit and its neighboring noise source can be simultaneously cooled. This will significantly enhance the quantum coherence of the qubit, because the cooled qubit is then thermally activated only very slowly to the first excited state.

Recent technical advances allow the fabrication of a nanomechanical resonator with both a high Q-factor and a sufficiently high frequency, close to the typical frequencies of superconducting circuits [44]. This has stimulated researchers to propose different ways to use superconducting circuits to achieve the ground-state cooling of coupled nanomechanical resonators [45, 46, 47, 37, 43, 48]. Moreover, the experimental cooling of such a resonator, by coupling it to a superconductor single-electron transistor [49] or to a microwave-frequency superconducting resonator [50], has also been reported. When a nanomechanical resonator is cooled to the ground state [51], it provides a good platform for exploring various quantum phenomena and for observing the quantum-to-classical transition in such a macroscopic object. This will give rise to the new subject of quantum acoustics.

Photon generation. Superconducting qubits have the advantage of manipulating quantum states in a controllable manner. If these stationary qubits are spatially separated, one

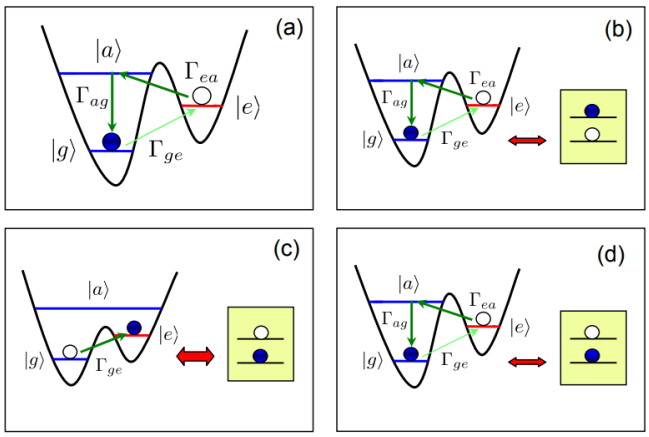

Figure 29.5: **Cooling a three-level artificial atom and a nearby two-level system. (a)** Cooling the three-junction loop to its ground state $|g\rangle$. While the artificial atom is thermally excited to $|e\rangle$, one can drive the atom to $|a\rangle$ by a microwave field. Because of a large transition rate for $|a\rangle \rightarrow |g\rangle$, the atom can decay quickly from the unstable state $|a\rangle$ to the ground state, emitting net energy, extracted from the atom, to the outside environment. The levels in the double potential well correspond to the lowest three energy levels of a three-junction loop biased at $f > \frac{1}{2}$. **(b)** While the noise source is thermally excited, the artificial atom is shifted off-resonance to the noise source by tuning the externally applied flux and also driven to the cooled state via the inverse process of the state population inversion in (a). The box to the right of the energy level diagram represents a two-level fluctuator acting as a noise source. **(c)** The inter-well barrier of the artificial atom is lowered by tuning the externally applied flux so as to have both a strong transition rate between $|g\rangle$ and $|e\rangle$ and the transition $|g\rangle \rightarrow |e\rangle$ in resonance with the two-level system, so as to extract energy from the two-level system. **(d)** Shifting the artificial atom off-resonance from the two-level system and cooling the atom again, with the net energy extracted from the two-level system emitted to the outside environment.

can use single photons generated in an extended cavity as a quantum bus, similar to a flying qubit, to implement quantum communication among them [see Fig. 29.6(a)]. Technologically, this requires the generation of single photons by manipulating a superconducting qubit and the transfer of information between the superconducting qubits and the photons. Using an on-chip cavity, it becomes feasible to achieve this quantum communication process on a chip.

Recent experiments show that a single-photon source can be achieved using a superconducting qubit coupled to an on-chip cavity [52, 53, 54, 55]. When the qubit is prepared in the excited state $|e\rangle$ by a control pulse, it can decay to the ground state $|g\rangle$ by emitting one (and only one) photon in the on-chip cavity; this decay is possible because of the interaction between the qubit and the cavity. If the cavity was originally in the vacuum state $|0\rangle$, it now changes to the single-photon state $|1\rangle$. When the qubit is prepared in an arbitrary superposition state $\alpha|g\rangle + \beta|e\rangle$, in an ideal manner, the coupling between the qubit and the cavity can map the qubit state into a superposition state of zero and one photon in the cavity: $\alpha|0\rangle + \beta|1\rangle$ [see Figs. 29.6(b)-29.6(d)]. Furthermore, the experiment in [52] shows how to transfer the information from a cavity to a stationary qubit [see Figs. 29.6(d)-29.6(f)]. These experiments demonstrate that both single-photon sources and quantum communication between superconducting qubits can be achieved on a chip. However, because of the relaxation and decoherence in both qubit and cavity, after each step for transferring the information between a stationary qubit and a cavity, the amplitudes α and β of the photon (qubit) state can be different from the amplitudes α and β of the previous qubit (photon) state. Improving relaxation rates and qubit decoherence times would allow higher-fidelity state transfers between qubits and cavities.

In addition to single-photon generation, one can also generate, as proposed in [56, 57], multi-photon Fock states $|n\rangle$ (i.e., the number states of photons) and arbitrary superposition states $\sum_n c_n|n\rangle$. Indeed, in a recent experiment [58], the controlled generation of pure Fock states with up to 15 photons was achieved using a superconducting phase qubit coupled to a microwave on-chip cavity. Moreover, thanks to the advantages of both on-chip cavity and tunable superconducting circuits, complex superpositions of states with different number of photons were also generated in a controlled and deterministic manner [55], which is a beautiful experimental realization of the protocol described in [56]. Recently, the N-photon entangled NOON states, $|N0\rangle + |0N\rangle$, have also been generated in two superconducting resonator [59]. These experiments further reveal the quantum behavior of the on-chip cavity and provide a useful on-demand multi-photon source for future quantum-technology applications.

Quantum state tomography. A crucial step in quantum information processing is the measurement of the output quantum states. However, a quantum state cannot be ascertained by a single quantum measurement. This is because quantum states may comprise many complementary features which cannot be measured simultaneously and precisely, owing to uncertainty relations. Nevertheless, all complementary aspects can in principle be observed by a series of measurements on a large enough number of identically prepared copies of the quantum system. Then, one could reconstruct an unknown quantum state from such a complete set of measurements of system observables. Such a process of reconstructing quantum states is called quantum state tomography. Using state tomography, the noisy channel of the quantum system can also be determined. This procedure of determining the dynamics of an open quantum system is known as quantum process tomography.

Tomographic measurements on the quantum states of superconducting charge qubits, either single or multiple qubits, were proposed in [60]. Recently, there were many experiments on the quantum state tomography of single superconducting phase qubits [61, 62] and of two coupled superconducting phase [63] and charge [64] qubits. Also, quantum process tomography was experimentally implemented on single [65] and two [66] phase qubits. Indeed, quantum state tomography is an essential tool in qubit-state measurements, and quantum process tomography

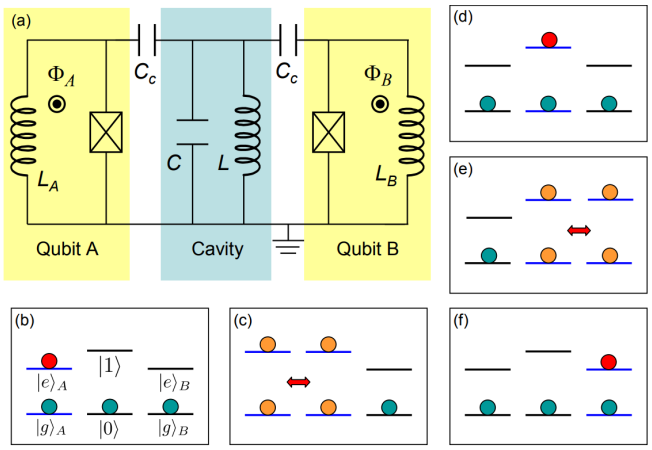

Figure 29.6: **Transferring quantum information between two stationary qubits via a cavity**. **(a)** Schematic diagram of two flux-driven phase qubits capacitively coupled by an on-chip cavity (an LC resonator). **(b)** Qubit A is prepared in a superposition state $\alpha|g\rangle_A + \beta|e\rangle_A$, while both qubit B and the resonator are prepared in their ground states. In this step, both qubits A and B are off-resonance with the cavity. **(c)** Qubit A is shifted into resonance with the resonator, for a time interval $t_1 = \pi/2g_A$, with $\hbar g_A$ being the interaction energy between qubit A and the resonator. This step maps the state of qubit A to the superposition state $\alpha|0\rangle + \beta|1\rangle$ of the resonator, where $|0\rangle$ and $|1\rangle$ are two Fock states of the resonator with zero and one photon, respectively. **(d)** Shift qubit A off-resonance with the resonator again, and store the quantum information in the resonator for a time duration t_2. **(e)** Shift qubit B in resonance with the resonator for a time interval $t_3 = \pi/2g_B$, where $\hbar g_B$ is the interaction energy between qubit B and the resonator. This step maps the state of the resonator to the superposition state $\alpha|g\rangle_B + \beta|e\rangle_B$ of qubit B. **(f)** Shift qubit B off-resonance with the resonator again, and store the quantum information in qubit B. Note that a high-fidelity state transfer between qubits A and B can be implemented if both the relaxation and decoherence of the state are negligibly small during the above processes.

can be used to probe the noise properties and temporal dynamics of qubit systems.

Future prospects

With technological advances, superconducting circuits can be used to test quantum mechanics on a macroscopic scale (see Box 3). Also, they can be used to demonstrate many novel phenomena in quantum science. A few examples are listed below.

Dynamical Casimir effect. When two mirrors are placed in empty space, their presence affects the vacuum fluctuations of the electromagnetic field. Because of the different densities of the vacuum modes inside and outside of the space between the two mirrors, a net force on the mirrors can be generated. This effect of quantum electrodynamics is known as the static Casimir effect.

If the mirrors move, there is also a mismatch between vacuum modes at different times. It has been predicted that this may result in the creation of real photons out of vacuum fluctuations. This dynamical Casimir effect also holds for a single mirror subject to a nonuniform acceleration in empty space. Although receiving considerable interest since its theoretical prediction, there is still no experimental verification of the dynamical Casimir effect. This is mainly due to the fact that the rate of photon production is non-negligible only when the mirror velocity approaches the speed of light, making the use of massive mirrors very challenging. A coplanar waveguide terminated by a SQUID was proposed [67] for experimentally observing the dynamical Casimir effect. Changing the magnetic flux threading the SQUID loop parametrically modulates the boundary condition of the waveguide and thereby its effective length. Because there is no massive mirror moving, the velocity of the effective boundary can approach the speed of light. Photon production from the vacuum can thus be made experimentally detectable.

Coherent population transfer. Elementary logic gates in quantum computing networks are usually implemented using precisely-designed resonant pulses. However, the various fluctuations and operational imperfections that exist in practice limit these designs. Also, the difficulty of switching interqubit couplings on and off strongly limits the precise design of the required pulses for two-qubit gates. To overcome these difficulties, Ref. [68] proposes an approach to coherently transfer the populations of qubit states by using Stark-chirped rapid adiabatic passages. As in the case of geometric phases, these population transfers are insensitive to the dynamical evolution times of the qubits, as long as they are adiabatic. The rapid adiabatic passages of populations could offer an attractive approach to implementing high-fidelity single- and two-qubit gates for quantum computing.

The key of these rapid adiabatic passages is how to produce time-dependent detunings by chirping the qubit levels. For most natural atomic or molecular systems, where each bound state possesses a definite parity, the required detuning chirps could be achieved by making use of the Stark effect via, eg., two-photon excitations of the qubit levels [69]. The breaking of parity symmetries in the bound states in superconducting circuits such as current-biased Josephson junctions provides an advantage [68], because the desirable detuning chirps can be produced by single-photon pulses. Recently, rapid adiabatic passage was achieved for the tranfer of a single photon in a superconducting circuit [70].

Tunable mirrors and interferometers. Superconducting circuits can be used for Landau-Zener-Stückelberg interferometry [71], but they can also be used for other types of interferometry—including Fano and Fabry-Perot interferometry [72, 73]—by coupling superconducting qubits to a coplanar waveguide. When injected into the waveguide, the photons interact with the qubits along the way, controlled by changing the applied electric

and/or magnetic fields on the qubits. These artificial atoms, working as tunable mirrors, can change the reflection and transmission coefficients of the photons confined in the waveguide.

Box 3. Testing quantum mechanics with macroscopic superconducting circuits

Bell inequality

The Bell inequality shows that the predictions of quantum mechanics can contradict those of local hidden variable theories (see, e.g., [92]) if one looks at correlations between spatially separated measurements. It can alternatively be stated that no physical theory of local hidden variables can reproduce all of the predictions of quantum mechanics. Tests of the Bell inequality have been proposed, using superconducting circuits such as charge [93] and phase qubits [94]. Recently, the violation of the Bell inequality has been experimentally verified [95] in phase qubits. Because the Bell inequality is violated by a quantum mechanical prediction, this experiment provides strong evidence that these macroscopic superconducting circuits indeed behave quantum mechanically. Recent experimental results [96, 97] on Greenberger-Horne-Zeilinger states do not require statistical arguments for a violation of the Bell inequality to be seen.

Leggett-Garg inequality

Leggett and Garg derived an inequality for a single degree of freedom undergoing coherent oscillations and being measured at successive times [98]. The Leggett-Garg inequality can be regarded as a temporal version of Bell's inequality, and it should be violated by a quantum two-level system. Very recently, this has been verified experimentally [99] using a voltage-driven box (i.e., the Cooper-pair box) acting as a quantum two-level system, showing that the time correlations present at the detector output violate the inequality.

Kochen-Specker theorem

This theorem elucidates the conflict between quantum mechanics and noncontextual hidden-variable theories [92]. Noncontextuality means that the measured value of an observable is independent of the choice of other co-measurable (commuting) observables that are measured previously or simultaneously. Quantum mechanics is contextual, because outcomes depend on the context of measurement. This theorem is an important complement to Bell's theorem; testing it can disprove noncontextual hidden-variable theories without referring to locality. To confirm such a counterintuitive phenomenon on a macroscopic scale, it was proposed [100] to use two charge qubits which are controllably coupled by a two-level data-bus built from a phase qubit. The analysis [100] showed that by performing joint nondestructive quantum measurements of two distinct qubits, the proposed superconducting circuits could demonstrate quantum contextuality at a macroscopic level.

For a system consisting of a superconducting qubit in an array of coupled cavities, the photon transmission exhibits a more general line shape [72], beyond the Breit-Wigner and Fano line shapes, because of the nonlinear photonic dispersion relation. At a particular matching condition between the photon wavelength and the lattice constant [72], the photonic dispersion relation can become linear and the photon transmission has the Breit-Wigner line shape, just as in an open transmission line [74]. Recently, this phenomenon was observed in a superconducting flux qubit coupled to an open transmission line [75]. When two superconducting qubits are placed in an array of coupled cavities, they can be used as tunable mirrors to form a Fabry-Perot interferometer [73]. Such a controllable on-chip interferometer is expected to have various applications in quantum optics.

Quantum nondemolition measurements. In a quantum measurement, a signal observable of a quantum system is measured by detecting the change in an observable of the detector that is coupled to the quantum system during the process of measurement. Generally, the

process of measurement will disturb the state of the quantum system owing to the interplay between the system and the detector. A quantum nondemolition (QND) measurement does not perturb the subsequent evolution of the quantum system; this can be achieved by using a particular type of system-detector coupling that preserves the eigenstates of the signal observable in the quantum system. In quantum optics, a QND measurement of the photon number can be implemented using the optical Kerr effect and a dispersive atom-field coupling (see, e.g., [29]).

The first successful QND measurement on a superconducting qubit was implemented using the dispersive atom-field coupling technique [16, 76]. Recent experiments [77, 78] show that QND measurements can also be implemented for a single superconducting qubit by using a nonlinear resonator as the detector. In [77], the detector was composed of a SQUID shunted with a capacitance, while in [78] the detector was a bifurcation amplifier, which is a r.f.-driven Josephson junction working near the dynamical bifurcation point [79]. Very recently, a fast QND measurement of a flux qubit was implemented in the weakly-projective regime by employing a hysteretic d.c. SQUID detector [80]. A quantum device can have multiple qubits, so QND measurements on quantum states of multiple qubits (e.g., entangled states) should be an appealing topic for future investigations.

Generating squeezed states. Squeezed states have been extensively studied in quantum optics, and are now being studied in condensed matter systems. Owing to their tunable nonlinearity and low losses in the microwave regime, Josephson-junction superconducting circuits are promising devices for producing squeezed states. In superconducting circuits, LC oscillators have been successfully used for quantum control and readout devices in conjunction with superconducting qubits. As parametric transducers (essentially, a radio-frequency auto-oscillator), superconducting resonant tank circuits have been used to measure the quantum state of flux qubits [81]. When squeezed states are generated in these resonant tank circuits acting as quantum-state detectors, the noise of the detectors can be decreased below the standard quantum limit. A recent theoretical study [82] shows that a superconducting parametric transducer can naturally implement this approach, as it can be used both to produce squeezed states and to use them in order to minimize quantum fluctuations. An immediate application of this method would be to suppress the effective noise temperature of the amplifier connected to the parametric transducer, at least to the nominal temperature of the cooling chamber.

Topological phases. A topologically-protected quantum state degeneracy cannot be lifted by any local perturbations [83]. It is therefore natural to consider using topological phases for applications requiring a high degree of quantum coherence. With superconducting circuits as building blocks, various artificial lattices can be constructed that possess interesting topological phases. For instance, it has been proposed that a triangular Josephson junction array may have a two-fold degenerate ground state, which could be used for constructing topologically-protected qubits [75]. Recently, an experiment [85] was implemented for a prototype device that consisted of twelve physical qubits made of nanoscale Josephson junctions. Owing to properly tuned quantum fluctuations, this system was protected against magnetic flux variations well beyond linear order. This suggests that topologically protected superconducting qubits are feasible. Also, superconducting circuits were proposed [86] as a way to construct the Kitaev honeycomb model, which requires that the spin (natural or artificial) at each node of a honeycomb lattice interacts with its three nearest neighbors through three different types of interactions [87]. Depending on the bond parameters, this anisotropic spin model supports both Abelian and non-Abelian anyons, which are particles obeying unusual statistics (they are neither bosons nor fermions). Its realization would provide exciting opportunities for experimentally demonstrating anyons.

Final remarks. The superconducting circuits that we have described above contain Josephson junctions that can act as nonlinear inductors. Using suitably designed superconducting circuits, it is therefore possible to fabricate field-controlled nonlinear resonators, which can be used to demonstrate the Kerr effect (either quadratic electro-optic or quadratic magneto-optic). If such circuits were used as a Kerr medium, one could carry out a variety of nonlinear optics experiments, e.g., coupling microwave photons, implementing quantum gates for photon qubits, and performing QND measurement. Superconducting circuits could have many other applications. For instance, it has been suggested that a coplanar waveguide with the center conductor replaced by an array of SQUIDs could be used to simulate Hawking radiation [88]. Indeed, superconducting circuits have the advantage of enabling the study of complex controllable quantum dynamics. This could lead to quantum simulations and on-chip studies of many-body physics. Numerous new phenomena and applications will continue to be discovered using superconducting circuits, and these will play an important part in future quantum technologies.

30 Spin-polarized supercurrents for spintronics: a review of current progress by Eschrig

Abstract

During the past 15 years a new field has emerged, which combines superconductivity and spintronics, with the goal to pave a way for new types of devices for applications combining the virtues of both by offering the possibility of long-range spin-polarized supercurrents. Such supercurrents constitute a fruitful basis for the study of fundamental physics as they combine macroscopic quantum coherence with microscopic exchange interactions, spin selectivity, and spin transport. This report follows recent developments in the controlled creation of long-range equal-spin triplet supercurrents in ferromagnets and its contribution to spintronics. The mutual proximity-induced modification of order in superconductor-ferromagnet hybrid structures introduces in a natural way such evasive phenomena as triplet superconductivity, odd-frequency pairing, Fulde-Ferrell-Larkin-Ovchinnikov pairing, long-range equal-spin supercurrents, π-Josephson junctions, as well as long-range magnetic proximity effects. All these effects were rather exotic before 2000, when improvements in nanofabrication and materials control allowed for a new quality of hybrid structures. Guided by pioneering theoretical studies, experimental progress evolved rapidly, and since 2010 triplet supercurrents are routinely produced and observed. We have entered a new stage of studying new phases of matter previously out of our reach, and of merging the hitherto disparate fields of superconductivity and spintronics to a new research direction: super-spintronics.

30.1 Introduction: historical background

30.1.1 Superconductivity interacting with magnetism

Quantum phenomena fascinate us and challenge our imagination for over 100 years since the theoretical foundations of quantum physics were laid. The two prime examples for macroscopic quantum phenomena are magnetism and superconductivity. Soon after the discovery of superconductivity in 1911 in Leiden by Kamerlingh-Onnes [1, 2] it became clear that a magnetic field acts in peculiar ways on superconductors. Silsbee unified in 1927 the observations of Kamerlingh-Onnes of a critical transport current density and a critical magnetic field [3], and in 1933, following a suggestion by von Laue, Meißner and Ochsenfeld performed experiments showing that the new state of matter is a true thermodynamic phase and that it expels magnetic

fields from its interior [4]. Following this pivotal discovery, Shubnikov pioneered in the 1930's the field of interplay between superconductivity and magnetic field, culminating in the discovery of what is now called the intermediate state, or the Shubnikov phase [5],[39] where magnetic flux partially penetrates the superconductor in a well defined region of the temperature-field phase diagram. After the notion of a macroscopic quantum wave function was introduced for the superconducting state by Ginzburg and Landau in 1950 [9], Abrikosov theoretically explained in the 1950's type II superconductivity, where a magnetic field penetrates the superconductor in a regular array of flux lines carrying quantized flux [7]. Abrikosov's vortex phase exists between the upper critical field H_{c2} and the lower critical field H_{c1} in type II superconductors.

Soon the microscopic theories of superconductivity by Bardeen, Cooper, and Schrieffer (BCS) in 1957 [8], by Bogoliubov in 1958 [9], and by Gor'kov in 1958-59 [10] brought all previous studies on a firm ground.

Ginzburg, in an attempt to formulate a theory for ferromagnetic superconductors (he considered the possibility of superconductivity in gadolinium), concentrated in 1956 on the electromagnetic (or so-called orbital) mechanism, where a suppression of superconductivity occurs via the interaction of the Cooper pairs with the vector potential of the magnetic field due to their charge [11]. In the orbital mechanism the magnetic field leads to an additional kinetic energy of the condensate, and when this energy exceeds the condensation energy, the superconducting state is destroyed. As shown in 1966 by Werthamer, Helfand, and Hohenberg, the orbital critical field for conventional isotropic, diffusive superconductors in the absence of spin-orbit and spin paramagnetic effects is $H_{\rm orb} \equiv H_{c2}|_{T=0} \approx 0.7 T_c [-dH_{c2}/dT]_{T=T_c}$ [12], where T_c is the superconducting transition temperature.

An alternative mechanism, the exchange mechanism, was suggested in 1958 by Matthias, Suhl, and Corenzwit [13] in order to explain the variation of T_c in lanthanum with rare earth impurities and the correlation between the appearance of ferromagnetism and superconductivity in ruthenides. They observed that it is not the dipole field of the effective moments of the rare earth elements that causes decrease of superconductivity in these systems, but the spin of the solute atoms; the T_c does not correlate with van Vleck's famous curve of $\mu_{\rm eff}$ [14], but rather with spin. In these cases an exchange interaction mediated by conduction electrons, responsible for ferromagnetism, occurs in a material that by itself is superconducting. The exchange interaction via conduction electrons tries to align spins in a ferromagnet, whereas the spins in a Cooper pair are opposite for the usual case of singlet superconductors. These antagonistic tendencies led to the so-called paramagnetic effect of pair breaking.

In 1959, Anderson and Suhl showed in a seminal paper [15] that in a system with coexisting superconductivity and ferromagnetism the magnetism is modified due to the suppression of the spin susceptibility at small wavevectors. As a consequence, magnetism becomes under certain conditions inhomogeneous with a new, finite, wavevector. This new state was termed the cryptoferromagnetic state. The wavelength of the magnetic inhomogeneity is much smaller than the superconducting coherence length (the typical extend of a Cooper pair) and much larger than the lattice spacing, thus keeping neighboring spins almost parallel, however reducing the exchange field averaged over a typical Cooper pair volume. In real (anisotropic) materials the corresponding magnetic structure is often a one-dimensional magnetic domain structure.

30.1.2 Pair breaking by paramagnetic impurities and external fields

If one introduces paramagnetic impurities into a singlet superconductor, there is the effect of pair breaking due to scattering from paramagnetic impurities, which reduces T_c with increasing

[39] Unfortunately, Shubnikov's work ended abruptly when he was arrested on the 6th of August and executed on the 10th of November 1937 during the Stalin-Yezhov terror on the basis of falsified charges of antirevolutionary activities; he was officially rehabilitated in 1957.

impurity concentration. Following previous works by Herring [16] and by Suhl and Matthias [17] for the limit of small concentrations, Abrikosov and Gor'kov developed in 1960 a theory covering the full range of concentrations up to the critical value, when superconductivity is destroyed; the T_c dependence vs. concentration is described in terms of a single "pair breaking parameter" ρ by the Abrikosov-Gor'kov formula [18]. In particular, these authors showed that the possibility of gapless superconductivity exists in metals with paramagnetic impurities (this peculiar state was further studied in 1964 by Skalski, Betbeder-Matibet, and Weiss [19], by Maki [20], and by de Gennes [21]). The Abrikosov-Gor'kov model, which employs the Born approximation, works well, e.g. for rare earth (except cerium) impurities. For transition metal impurities in superconductors Yu [22], Shiba [23], and Rusinov [24] discovered within the framework of a full t-matrix treatment of the problem that local states (now called the Yu-Shiba-Rusinov states) are present within the BCS energy gap due to multiple scattering between conduction electrons and paramagnetic impurities.

De Gennes and Tinkham noted in 1964 [25] that for a time-reversal invariant superconducting order parameter, pair breaking can be related to the asymptotic long-time behavior of the time-reversal correlation function, $\eta(t) = \lim_{t\to\infty}\langle\hat{\Theta}^\dagger(0)\hat{\Theta}(t)\rangle$, with the time reversal operator $\hat{\Theta}$. An exponential decay, $\eta(t) = \exp^{-2t/\tau_\Theta}$, with τ_Θ some correlation time, corresponds to pair breaking with pair breaking parameter $\rho = (2\pi T\tau_\Theta)^{-1}$. If, on the other hand, a nonzero limiting value $0 < \eta < 1$ appears, then this leads to an effective weakening of the pairing interaction.

When applying a magnetic field to a superconductor, apart from the orbital effect of the penetrating field, there is also an appreciable Zeeman coupling between the electronic spins and the magnetic field. It leads to a splitting between the electronic spin bands similarly as in a weak ferromagnet the exchange energy leads to a band splitting. This effect has been experimentally studied in the early 1970's by Meservey and Tedrow in a series of classical papers (see [26] for a review). If the magnetic field exceeds a certain value, superconductivity becomes energetically unfavorable due to this Zeeman coupling. This limiting field is the Pauli paramagnetic limiting field or the so-called Chandrasekhar-Clogston limiting field, and was predicted independently in 1962 by Chandrasekhar [27] and by Clogston [28]. It amounts to $H_p = \sqrt{2}\Delta(T = 0)/g\mu_B$, where Δ is the excitation gap in the superconductor at zero magnetic field, $g \approx 2$ the electron g-factor, and μ_B the Bohr magneton. The ratio $\alpha = \sqrt{2}\tilde{H}_{orb}/H_p$, where $\tilde{H}_{orb}$ is the upper critical field in the absence of the Pauli term, was discussed in 1966 by Maki, and is known as the Maki parameter [29].

30.1.3 Ferromagnetic superconductors

Coexisting singlet superconductivity and ferromagnetism is rare, and can be achieved either by finding suitable crystalline materials (classical examples are the rare-earth ternary compounds $ErRh_4B_4$ [30] and $HoMo_6S_8$ [31] in a narrow temperature region below the Curie temperature), or by introducing magnetic ions in a superconducting material that order ferromagnetically. In the latter case, at high impurity concentrations, the possibility to obtain coexistence between ferromagnetism and superconductivity was theoretically predicted in 1964 by Gor'kov and Rusinov [32]. Furthermore, for the case that ferromagnetism and superconductivity coexist or an external magnetic field is applied, Fulde and Maki [33] showed that the Abrikosov-Gor'kov formula holds with a modified pair breaking parameter. For an early review on magnetic superconductors see [34].

In addition to the above cases of conventional singlet superconductors, there has been discovered a large number of unconventional superconductors, which are distinguished from the conventional ones by the fact that they break additional symmetries, e.g. the lattice symmetry of the normal state, or the spin rotational symmetry. The latter is the case for superconductors exhibiting spin-triplet pairing (see figure 30.1). In particular ferromagnetic

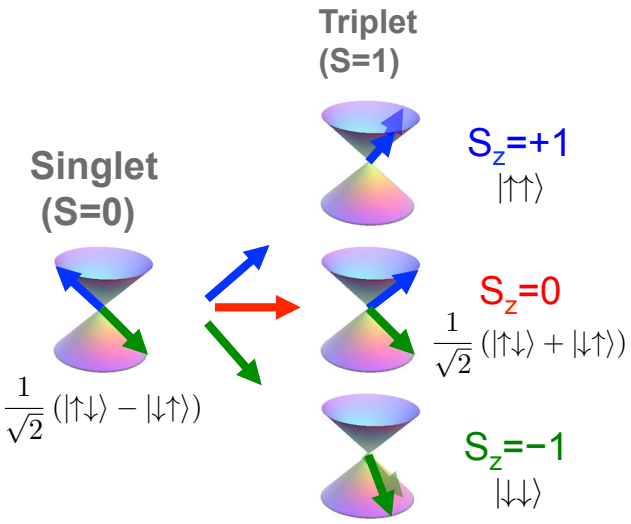

Figure 30.1: Two electrons, each of which has spin $s = \frac{1}{2}$, can combine their spin angular momenta $\mathbf{s}_1$ and $\mathbf{s}_2$ to build a pair with total spin $S = 0$ or a pair with total spin $S = 1$. In the first case, the pair is in a spin-singlet state (shown on the left). In the second case, the pair is in one of the three possible spin-triplet states: with spin projection $S_z = 0, \pm 1$ (shown on the right). The pairs with $S_z = \pm 1$ are called "equal-spin" pairs with respect to the spin quantization axis (here z-axis). The spin state $|S, S_z\rangle$ is fully characterized by the two quantum numbers S and S_z. We use a spin-vector representation to visualize pair angular momenta, where the expectation value of the cosine of the relative angle between the two spin vectors within a pair, $\langle S, S_z|\mathbf{s}_1 \cdot \mathbf{s}_2|S, S_z\rangle / \sqrt{\mathbf{s}_1^2 \mathbf{s}_2^2}$, is -1 for singlet states, and $\frac{1}{3}$ for triplet states. Thus, angular momenta can be visualized as antiparallel for singlet pairs, whereas for triplet pairs they enclose in average a relative angle of $\approx 70.53^o$ (even for "equal spin" pairs).

superconductors are under suspicion of such a pairing state, as equal-spin triplet pairing is not sensitive to the exchange mechanism in the way singlet pairing is. This refers to some heavy fermion compounds, like UGe_2 [35], URhGe [36], UCoGe [37], and UIr [38], in which superconductivity can coexist with ferromagnetism, and which have been studied in the past 15 years [39].

The main problem for coexistence between superconductivity and ferromagnetism is that a strong exchange effect destroys superconductivity unless the pairing is of the triplet kind. However, not many superconductors support triplet pairing. Furthermore, such systems are typically p-wave superconductors [40], which are very sensitive to pair breaking by normal impurities (conventional superconductors are insensitive to scattering from normal impurities, which is the content of a theorem by Abrikosov, Gor'kov, and Anderson [41, 42]). For this reason new avenues have been chosen to study such systems for s-wave and d-wave superconductors, which are much more common in nature. These avenues combine the phenomena of proximity induced superconductivity, Cooper pairs with finite center of mass momentum, and odd-frequency s-wave spin-triplet pairs.

30.1.4 Cooper pairs with finite center of mass momentum

When the paramagnetic limiting field is smaller than the orbital critical field, then the possibility of an inhomogeneous superconducting state with finite pair momentum arises near H_p. Such a state was theoretically predicted in 1964 independently by Fulde and Ferrell [43] and by Larkin and Ovchinnikov [44]. It is known in the western literature as FFLO state and

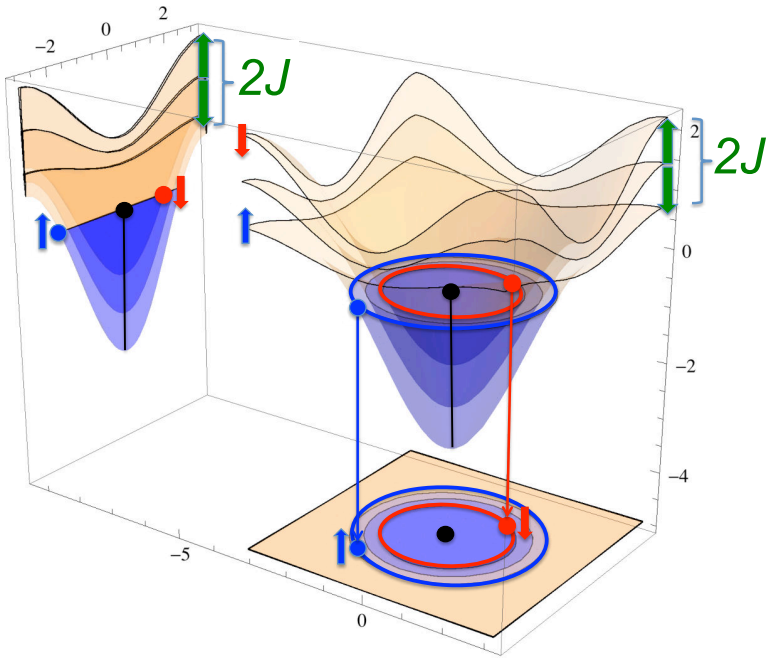

Figure 30.2: The FFLO effect: due to the exchange splitting of the energy bands (filled states are shaded blue in the picture) by $\pm J$ the Fermi surfaces split as well. A Cooper pair with opposite spins can be accommodated at the Fermi surface only on the cost of a finite center of mass momentum. Note that spin is quantized here in direction of the exchange field $\boldsymbol{J}$, entering the Hamiltonian as $\mathcal{H}_{\text{exch}} = -\boldsymbol{J} \cdot \boldsymbol{\sigma}$.

in the eastern as LOFF state.

Consider superconductivity in a weakly spin-polarized ferromagnetic material (or in an external magnetic field). Electronic spin bands are shifted in energy with respect to each other by an amount $2J$ (which in general can be anisotropic): $\varepsilon(\boldsymbol{p}) \to \varepsilon(\boldsymbol{p}) - \boldsymbol{J}(\boldsymbol{p}) \cdot \boldsymbol{\sigma}$. The exchange field can be related to an effective magnetic field via $\mu \boldsymbol{B}_{\text{eff}} = \boldsymbol{J}$ (for free electrons the magnetic moment is $\mu = \mu_{\text{e}} < 0$). We use the convention that spin is quantized in direction of the exchange field. The energy shift translates into a splitting of the Fermi surface for the two spin species (see Figure 30.2), which results e.g. for small J from the relation

$$\hbar \boldsymbol{v}_f \cdot \boldsymbol{Q} = \boldsymbol{v}_f \cdot (\boldsymbol{p}_{f\uparrow} - \boldsymbol{p}_{f\downarrow}) = 2J(\boldsymbol{p}_f) \tag{30.1}$$

obtained by linearizing the dispersion relation around the Fermi energy [here the Fermi velocity $\boldsymbol{v}_f$ is assumed to be approximately equal for the two spin bands due to the small splitting, and $\boldsymbol{p}_f = (\boldsymbol{p}_{f\uparrow} + \boldsymbol{p}_{f\downarrow})/2$]. Thus, the system only allows for opposite-spin Cooper pairs $\{\boldsymbol{p}_{f\uparrow}, -\boldsymbol{p}_{f\downarrow}\}$ and $\{\boldsymbol{p}_{f\downarrow}, -\boldsymbol{p}_{f\uparrow}\}$ built from electrons at the Fermi energy if they carry a finite center of mass momentum $\pm\hbar\boldsymbol{Q}/2 = \pm(\boldsymbol{p}_{f\uparrow} - \boldsymbol{p}_{f\downarrow})/2$ ($\hbar\boldsymbol{Q}$ is the momentum of the Cooper pair). This can lead to an order parameter characterized by a linear combination of terms with different Cooper pair momenta

$$\Delta_{\text{FFLO}}(\boldsymbol{R}) = \sum_{\nu} \Delta_\nu e^{i\boldsymbol{Q}_\nu \cdot \boldsymbol{R}}. \tag{30.2}$$

The preferred directions are chosen by the system (spontaneously or due to crystal anisotropy and boundary conditions). Fulde and Ferrell suggested an order parameter characterized by only one wavevector $\boldsymbol{Q}$, leading to a spatially homogeneous modulus and a spatially varying phase. If the order parameter is characterized by more than one wavevector $\boldsymbol{Q}_\nu$, then the FFLO state exhibits an inhomogeneous order showing a periodic structure. Larkin and Ovchinnikov proposed that the ground state may show a one-dimensional modulation (neglecting orbital

effects). However, more complex structures are possible in the general case of anisotropic metals. In general, the pair amplitudes develop an $|S = 1, S_z = 0\rangle$ spin-triplet component, and the inhomogeneous modulus of the order parameter is accompanied by an oscillation of the magnetization around its average, determined by the product of the singlet and triplet pair amplitudes.

Originally the state had been studied for a superconductor with ferromagnetically aligned impurities. However, it is known today that the FFLO state is very sensitive to disorder [45, 46], and thus most likely is found in clean materials in an external field. Gruenberg and Gunther studied in 1966 the influence of orbital effects in type II superconductors on the possibility to observe an FFLO state and found that although orbital effects are detrimental to the formation of the FFLO state, such a state can exist at finite temperatures in the mixed state of a pure superconductor provided the Maki parameter α exceeds 1.8 [47]. Interesting candidates are quasi-two-dimensional superconductors in a magnetic field applied nearly parallel to the conducting layers. The theory for such systems was developed by Bulaevskiĭ [48] in 1973, by Burkhardt and Rainer [49] and by Shimahara [50] in 1994, and by Buzdin and Brison [51] in 1996. For quasi-one-dimensional systems theories in terms of soliton lattice solutions were developed by Buzdin and Tugushev in 1983 [52], by Buzdin and Polonskii in 1987 [53], and by Dupuis in 1995 [54]. In compounds with large spin susceptibility and high H_{c2}, as in heavy fermion and intermediate-valence systems, a generalized FFLO state was discussed by Tachiki and co-workers, where the order parameter is spatially modulated, and planar nodes of the order parameter are periodically aligned perpendicular to the vortices [55].

The FFLO state only appears below a certain temperature T^*, which determines a tri-critical point (T^*, H^*) in the (T, H)-diagram at which the normal, BCS, and the FFLO phases meet. A generalized Ginzburg-Landau theory for the vicinity of this tri-critical point was derived by Buzdin and Kachkachi [56]. A self-consistent calculation of the field versus temperature phase diagram and order parameter structures for the FFLO states of quasi-two-dimensional d-wave superconductors is presented in Ref. [57]. Recently, a symmetry classification of the pairing amplitudes in FFLO states coexisting with vortices was suggested [58]. For reviews on this topic see Refs. [59, 60, 61, 62].

The FFLO state has not been unambiguously found in bulk materials to date, although there are currently candidates under debate, as the heavy fermion material $CeCoIn_5$ [63, 64, 65, 66], or some organic superconductors such as κ-(BEDT-TTF)$_2$Cu(NCS)$_2$ [67, 68, 69, 70]. However, a similar state can be realized in superconductor-ferromagnet hybrid structures, where superconducting pairs leak into a ferromagnet due to the superconducting proximity effect, as we discuss in detail further below (for earlier reviews see [71, 72, 73, 74, 75]).

30.1.5 Proximity effect

The pivotal role for realizing the FFLO state in such hybrid structures is played by the proximity effect between a superconducting and a normal conducting material. The theory for the proximity effect was developed largely by de Gennes [76, 77, 78, 79], and by Werthamer [80, 81] in the 1960's. It describes the effect of penetration of Cooper pairs in a normal metal where the two conduction electrons (or holes) of the pair stay correlated with each other over a distance that depends on the amount of disorder in the normal material and on temperature. In a clean material, the penetration depth is determined by the thermal coherence length $\xi_{N,c} = \hbar v_f / 2\pi k_B T$. It gives the distance, a quasiparticle with velocity v_f travels during time $\hbar/2\pi k_B T$, before thermal decoherence sets in. For ballistic motion and atomically smooth interfaces, the penetration depth depends on the angle of impact of the quasiparticles, i.e. the Fermi velocity should be replaced by the Fermi velocity component in the normal metal perpendicular to the interface, $v_{f,x}$. The notion of a coherence length determined by the Fermi

velocity and a characteristic superconducting energy scale was introduced by Pippard in 1953 [82].

In the presence of impurities, scattering decreases the penetration of Cooper pairs into the normal metal. If the mean free path is ℓ, and the motion is diffusive, then the quasiparticle travels in average between two scattering events a time $\tau = \ell/v_f$. For a random walk, the variance for the x-component is given by $\sigma_x^2 = \frac{1}{3}\frac{t}{\tau}\ell^2 = tv_f\ell/3$, where t is the elapsed time. Coherence is lost when the total path traversed during the random walk is equal to $\xi_{\rm N,c}$, i.e. $v_f t = \xi_{\rm N,c}$. If we define the diffusive coherence length by $\xi_{\rm N,d}^2 = \sigma_x^2$, we obtain $\xi_{\rm N,d}^2 = \xi_{\rm N,c}\ell/3$. Hence, the diffusive coherence length is given by $\xi_{\rm N,d} = \sqrt{\xi_{\rm N,c}\ell/3}$, or in other words, $\xi_{\rm N,d} = \sqrt{\hbar D/2\pi k_{\rm B}T}$ with the diffusion constant $D = v_f\ell/3$.[40]

The proximity amplitude is proportional to the pair potential in the superconductor, Δ, and the product of the transmission amplitudes through the interface of the two particles comprising a pair. Inversely, the loss of Cooper pairs in the superconductor leads to the so-called inverse proximity effect of a weakening of the superconducting pair potential near the interface in the superconductor.

30.1.6 Andreev reflection

A very closely related phenomenon is the so-called Andreev reflection, discovered by Andreev in 1964 [83] and by de Gennes and Saint-Jaimes in 1963/64 [84, 85] (see Ref. [86] for a review). It describes the correlations between particles and holes at the normal side of the interface due to penetration of pairs. In fact, Andreev reflection and proximity effect are two sides of one and the same coin.

Let us assume that a spin $\uparrow$ conduction electron in the normal metal with energy $\mu + \varepsilon$ near the chemical potential μ moves in positive x-direction towards a superconductor. The excitation energy ε is assumed to be within the energy gap Δ of the superconductor. The electron can be transmitted into the superconductor only together with another electron with spin $\downarrow$, energy $\mu-\varepsilon$, and momentum approximately opposite, to build a Cooper pair that enters the condensate at the pair chemical potential 2μ (after some momentum relaxation has taken place). For $\Delta \ll \mu$ it is possible to approximate the electronic dispersion $E(\boldsymbol{p}) \approx \mu + \boldsymbol{v}_f\cdot(\boldsymbol{p}-\hat{\boldsymbol{p}}_f)$, with the Fermi momentum $\hat{\boldsymbol{p}}_f$ and Fermi velocity $\boldsymbol{v}_f \equiv \boldsymbol{v}(\hat{\boldsymbol{p}}_f)$. Within this approximation, the group velocity of the incoming electron is equal to $\boldsymbol{v}_f$, and its excitation energy $\varepsilon = \boldsymbol{v}_f\cdot(\boldsymbol{p}-\hat{\boldsymbol{p}}_f)$.

Let us consider a Landau quasiparticle with momentum $\boldsymbol{p}_1 = \boldsymbol{p}_{f1} + \delta\boldsymbol{p}_1$, spin $\uparrow$, and excitation energy $\varepsilon_1 = \boldsymbol{v}_{f1}\cdot\delta\boldsymbol{p}_1$. We will consider pairing with another quasiparticle with momentum $\boldsymbol{p}_2 = -\boldsymbol{p}_{f1} + \delta\boldsymbol{p}_2$, spin $\downarrow$, and excitation energy $\varepsilon_2 = -\boldsymbol{v}_{f1}\cdot\delta\boldsymbol{p}_2$ (see Figure 30.3). We require that $\varepsilon_2 = -\varepsilon_1$. This leads to the relation $\boldsymbol{v}_{f1}\cdot(\delta\boldsymbol{p}_2 - \delta\boldsymbol{p}_1) = 0$, which allows us to choose $\boldsymbol{p}_{f1}$ such that $\delta\boldsymbol{p}_1 = \delta\boldsymbol{p}_2 = \delta\boldsymbol{p}$ holds[41]. The missing electron in the spin-$\downarrow$ band is equivalent to a hole excitation characterized by energy $-\varepsilon_2 = +\varepsilon_1$, momentum $-\boldsymbol{p}_2 = \boldsymbol{p}_{f1} - \delta\boldsymbol{p}$, group velocity $\boldsymbol{v}(\boldsymbol{p}_2) \approx -\boldsymbol{v}_{f1}$, and spin $\uparrow$ (a missing spin $\downarrow$). The process can be considered as a scattering of a particle with charge e, momentum $\boldsymbol{p}_f + \delta\boldsymbol{p}$, and velocity $\boldsymbol{v}_f$ into a hole with charge $-e$, momentum $\boldsymbol{p}_f - \delta\boldsymbol{p}$ and velocity $-\boldsymbol{v}_f$. The electron-hole pair gives rise to a current density of $e\boldsymbol{v}_f + (-e)(-\boldsymbol{v}_f) = 2e\boldsymbol{v}_f$, twice the current density of the incoming particle. The incoming electron (velocity $\boldsymbol{v}_{f1}$) is approximately "retro-reflected" (velocity $\approx -\boldsymbol{v}_{f1}$) as a hole [83]. This process is called Andreev reflection, contrasting the familiar specular reflection.

A possible small angle between the reflected hole and the incoming particle is due to variation of the Fermi velocity between the momenta $\boldsymbol{p}_f$ and $\boldsymbol{p}_f \pm \delta\boldsymbol{p}$, and is of order of ε/E_f, with Fermi

[40] In d dimensions the factor of 3 is replaced by a factor of d.

[41] Choose $\tilde{\boldsymbol{p}}_{f1} = \boldsymbol{p}_{f1} + (\delta\boldsymbol{p}_1 - \delta\boldsymbol{p}_2)/2$, then $\boldsymbol{p}_1 - \tilde{\boldsymbol{p}}_{f1} = \boldsymbol{p}_2 + \tilde{\boldsymbol{p}}_{f1} = \delta\boldsymbol{p} = (\delta\boldsymbol{p}_1 + \delta\boldsymbol{p}_2)/2$. This is again (in leading order) a Fermi surface point due to $\boldsymbol{v}_{f1}\cdot(\tilde{\boldsymbol{p}}_{f1} - \boldsymbol{p}_{f1}) = 0$, i.e. the shift is tangential to the Fermi surface.

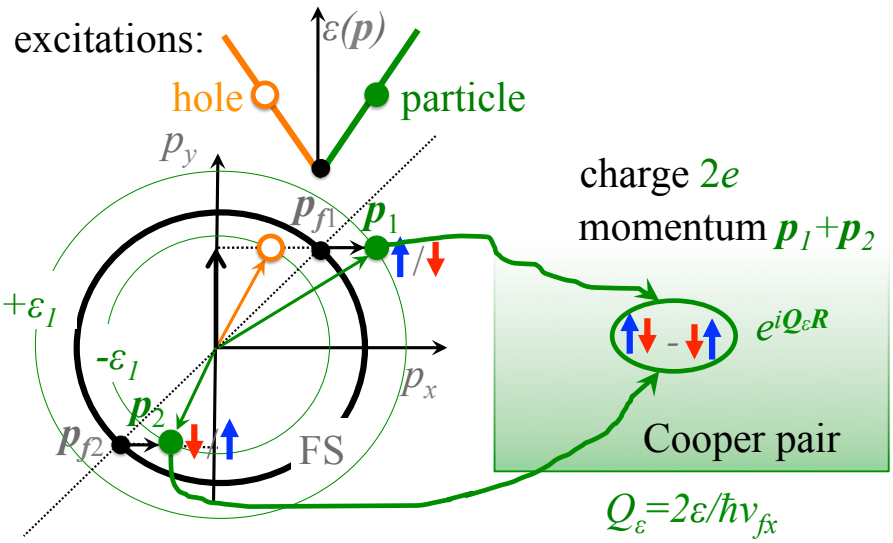

Figure 30.3: Andreev reflection: An electron at crystal momentum $\boldsymbol{p}_1$ pairs with another one at $\boldsymbol{p}_2$ under the conditions that their energies and p_y-component of momentum are opposite to each other. This leads to a finite p_x component and a resulting center of mass momentum $\hbar\boldsymbol{Q}_\varepsilon/2$ of the Cooper pair. A hole is reflected, which is drawn in this plot at the negative momentum and energy of the missing electron (in the excitation picture all excitation states inside the Fermi surface have reversed momentum and energy and are considered as hole excitation with positive excitation energy). The resulting Cooper pair transfers its momentum partially to the interface between the normal metal and the superconductor (for the case that there is a Fermi surface or Fermi velocity mismatch), and partially to the condensate in the superconductor when entering it. The amount transferred to the condensate results in a supercurrent consistent with current conservation in the scattering process.

energy E_f [87]. Retroreflection is perfect for perpendicular impact if no supercurrent flows along the surface. In the Andreev particle-hole conversion process, energy and spin are conserved, however charge is not, and momentum is only approximately conserved. The charge $2e$ and (partially) the momentum $\hbar\boldsymbol{Q} = 2\delta\boldsymbol{p}$ are transferred to the superconducting condensate: two electrons with opposite spin enter the superconductor to create a Cooper pair with non-zero pair momentum, which joins the condensate, leading to a (small) supercurrent for finite excitation energies. The momentum $\hbar\boldsymbol{Q}$ is thereby partially transferred to the interface (provided a Fermi surface or Fermi velocity mismatch exists), and partially to the condensate resulting into a supercurrent consistent with total charge conservation. In equilibrium, and in the absence of a macroscopic supercurrent, this current is exactly canceled by the inverse process when a Cooper pair enters the normal metal and converts a hole into an electron.

For an atomically clean interface, if there is a macroscopic supercurrent with Cooper pair momentum $\boldsymbol{p}_S$ parallel to the interface present in the superconductor, then momentum conservation requires that the created Cooper pair enters the condensate with the required Cooper pair momentum parallel to the interface, such that $2\delta\boldsymbol{p}_{||} = \boldsymbol{p}_S$. One obtains (we assume $v_{fx} > 0$) $2\delta p_x = (2\varepsilon - \boldsymbol{v}_f \cdot \boldsymbol{p}_S)/v_{fx}$. In particular, for $\boldsymbol{p}_S = 0$ only p_x can change in the Andreev scattering process. In this case, as $\delta\boldsymbol{p}_{||}$ must be zero, the Cooper pair momentum is given by $Q_\varepsilon = 2\varepsilon/v_{fx}$ (see Figure 30.3).

The Andreev reflection process is phase coherent, i.e. the phases of the incoming particle and the Andreev-reflected hole are correlated. For a superconducting order parameter $\Delta = |\Delta|e^{i\chi}$, the phase difference is $\varphi(\varepsilon) - \chi$, between an incoming electron and retroreflected hole, and is $\varphi(\varepsilon) + \chi$ between an incoming hole and retroreflected electron, where $\varphi(\varepsilon) = -\arccos(\varepsilon/|\Delta|)$ describes the phase delay due to the fact that during Andreev reflection the particle and hole amplitudes penetrate into the superconductor over a length scale $\xi_\varepsilon^{(\mathrm{S})} = \hbar v_f^{(\mathrm{S})}/\sqrt{|\Delta|^2 - \varepsilon^2}$.[42]

During their motion in the normal metal, the phase coherence is lost due to the slight difference in momentum of the electron and the hole, given by $2\delta p_x = 2\varepsilon/v_{fx}$. When averaged over all momentum directions, the pair correlation function decays away from the interface algebraically $\sim \xi_{\mathrm{c}}^{(\mathrm{N})}/x$ as function of x, where we define $\xi_{\mathrm{c}}^{(\mathrm{N})} = \hbar v_f/2\varepsilon$. For observables in equilibrium, the decay length can be obtained by replacing ε in the expression for the momentum δp_x by the lowest Matsubara energy [89] $i\pi k_{\mathrm{B}}T$. This leads to an exponential decay on the length scale $\hbar v_f/2\pi k_{\mathrm{B}}T$ along each ballistic trajectory, which is precisely the coherence length from the proximity effect.

For diffusive motion, non-magnetic scattering events conserve the time reversal symmetry, and thus scatter time-reversed states in a similar way. In particular a particle-hole pair with momenta both close to $\boldsymbol{p}_f$ will scatter in a particle hole pair with momenta both close to $\boldsymbol{p}'_f$ (as scattering amplitude for $\boldsymbol{p}_f \to \boldsymbol{p}'_f$ is the same as for $-\boldsymbol{p}'_f \to -\boldsymbol{p}_f$ due to time reversal symmetry). Thus, scattering events change the momentum of particle and hole by the same amount, however do not destroy their coherence. This means, the dephasing between the particle and hole takes place on a semiclassical trajectory as in the clean case, however the trajectory changes direction multiple times in a random way. The diffusive process away from the interface is characterized by a diffusion equation for the pair amplitude f, given by $\partial_t f = D\partial_x^2 f$. With $f \sim e^{i(k_x x - 2\varepsilon t/\hbar)}$ this implies $-2i\varepsilon = -\hbar D k_x^2$, resulting in a complex wave vector given for decay in positive x direction by $k_x = (i \pm 1)\sqrt{|\varepsilon|/\hbar D}$. This gives rise to an exponential decay on the length scale $\sqrt{\hbar D/|\varepsilon|}$, accompanied by an oscillation on the same length scale. For observables in equilibrium we can replace $\varepsilon \to i\pi k_{\mathrm{B}}T$, leading to $k_x^2 = -2\pi k_{\mathrm{B}}T/\hbar D$ and an exponential decay on the length scale $\xi_{\mathrm{d}}^{(\mathrm{N})} = \sqrt{\hbar D/2\pi k_{\mathrm{B}}T}$, again matching the length scale for the proximity

[42] For a supercurrent along the interface, $\chi(\boldsymbol{R}) = \chi(\boldsymbol{R}_0) + \frac{1}{\hbar}\boldsymbol{p}_{\mathrm{S}} \cdot (\boldsymbol{R} - \boldsymbol{R}_0)$, with $\boldsymbol{R}$ the spatial coordinate on the interface. The time the Cooper pair needs to enter the condensate is $\tau_\varepsilon^{(\mathrm{S})} = \xi_\varepsilon^{(\mathrm{S})}/v_f^{(\mathrm{S})}$, which also determines the time delay between the maximum of an incoming electron wave packet and the maximum of the retroreflected hole wave packet, $\tau_\varepsilon^{(\mathrm{S})} = \hbar\partial_\varepsilon\varphi(\varepsilon) = \hbar/\sqrt{|\Delta|^2 - \varepsilon^2}$ [88].

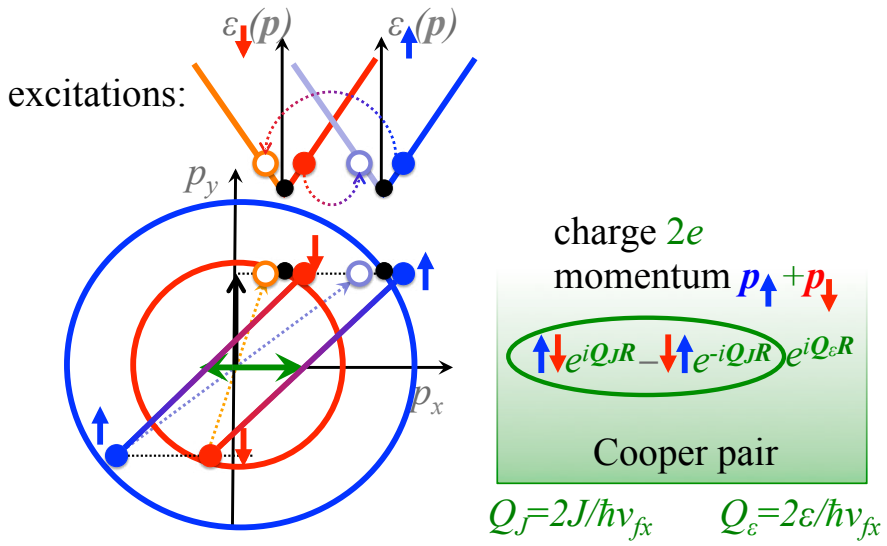

Figure 30.4: Andreev reflection in a ferromagnet: an electron with energy ε and spin $\uparrow$ pairs with an electron with energy $-\varepsilon$ and spin $\downarrow$, resulting into a total momentum of $\hbar(\boldsymbol{Q}_\varepsilon \pm \boldsymbol{Q}_J)$. For sufficiently small spin band splitting a Cooper pair of the form shown to the right results, which contains singlet and triplet components with amplitudes $\cos(Q_J x)$ and $i\sin(Q_J x)$, respectively. The Cooper pair enters the condensate in the superconductor, transferring its momentum partially to the interface and partially to the singlet condensate, ensuring current conservation. The triplet component decays on the superconducting coherence length scale into the superconductor.

effect in diffusive metals. The two phenomena, proximity effect and Andreev reflection are intertwined and cannot be discussed separately from each other. The above discussion assumes that the phase coherence is not weakened by additional effects. If phase coherence is weakened by inelastic processes, as for example magnetic scattering, this puts limitations on the proximity effect. In this case, one has to replace ε by $\bar{\varepsilon} = \varepsilon + i\alpha_s$ with the spin-flip scattering rate $\alpha_s = \hbar/\tau_s$, where τ_s is the corresponding life time. This means that in the ballistic limit exponential decay of pair correlations sets in on the length scale $\hbar v_f/2\alpha_s = v_f\tau_s/2$ (the factor 2 takes into account that both particles and holes are affected). The corresponding coherence lengths are obtained by replacing $\pi k_B T$ by $\pi k_B T + \alpha_s$.

A similar mechanism works for a weakly ferromagnetic normal metal, as for example a ferromagnetic alloy (see Figure 30.4) [90]. In this case, the electronic bands are spin-split due to the exchange interaction by an amount of $\pm J \ll E_f$. The Andreev reflection mechanism now requires that the x-component of the momentum of the incoming electron with spin $\uparrow$ is $p_{1x} = p_{fx} + (\varepsilon + J)/v_{fx}$, which pairs with an electron with momentum $p_{2x} = -p_{fx} + (\varepsilon + J)/v_{fx}$. This leads to a Cooper pair momentum of $2(\varepsilon + J)/v_{fx}$. On the contrary, if the incoming electron has spin $\downarrow$, it pairs with a spin $\uparrow$ electron, and the sign of J reverses in the above expressions, leading to a center of mass momentum of $2(\varepsilon - J)/v_{fx}$. Denoting $Q_J = 2J/\hbar v_{fx}$ and $Q_\varepsilon = 2\varepsilon/\hbar v_{fx}$, we see that instead of a singlet Cooper pair $(\uparrow\downarrow - \downarrow\uparrow)e^{iQ_\varepsilon x}$ as in the case of a non-magnetic normal metal, a Cooper pair of the form

$$(\uparrow\downarrow e^{iQ_J x} - \downarrow\uparrow e^{-iQ_J x})e^{iQ_\varepsilon x} \tag{30.3}$$

is created. This is exactly the FFLO type of pair, as it was considered in the original work. Only it is now induced as a proximity amplitude instead of a bulk phase. It can be decomposed into a spin singlet $(\uparrow\downarrow - \downarrow\uparrow) \equiv |S = 0, S_z = 0\rangle$ and a spin triplet $(\uparrow\downarrow + \downarrow\uparrow) \equiv |S = 1, S_z = 0\rangle$

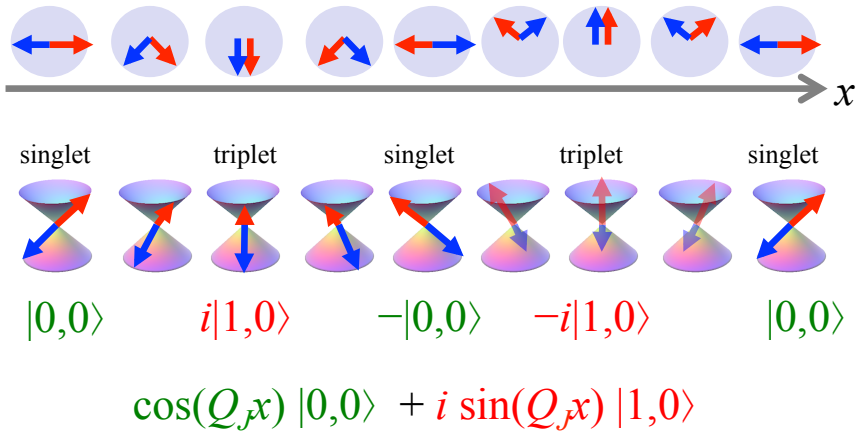

Figure 30.5: Singlet-triplet mixtures between $|S=0, S_z=0\rangle$ and $|S=1, S_z=0\rangle$ spin angular momentum states in an exchange field (or in an applied external magnetic field) in z-direction. Singlet and triplet spin states oscillate spatially out of phase relative to each other. Within the spin-vector representation the relative azimuthal angle between the two spin vectors within a pair varies as $\pi + 2Q_J x$, and its deviation from 0 (triplet) and π (singlet) is a measure for the degree of singlet-triplet mixing. The top row shows a top-view of the bottom row.

(where S is the total spin of the pair and S_z its projection on the z-axis), leading to (see figure 30.5)

$$[\cos(Q_J x)|0,0\rangle + i\sin(Q_J x)|1,0\rangle]\, e^{iQ_\varepsilon x}. \tag{30.4}$$

The proximity amplitudes in the ferromagnet are such mixtures. The triplet component also penetrates over a coherence length into the singlet superconductor, thus leading to singlet-triplet mixing in the superconductor close to the interface. The excess momentum during the Andreev reflection process is transferred partially to the interface and partially to the condensate (with the rate determined by the continuity equation for total charge conservation).

In the diffusive limit the wave vector is given by $Q_\pm = (i+1)\sqrt{(\varepsilon \pm J)/\hbar D}$ (where a small positive imaginary part of ε determines the root), i.e. the pair amplitudes oscillate and decay on the same length scale.

30.1.7 Josephson effect

If two superconducting materials are brought in contact via a sufficiently narrow non-superconducting region (or via a weak link), the macroscopic wave functions of the two superconductors may overlap. Under the condition that a phase difference exists between the superconductors, a supercurrent may flow between them directly through the non-superconducting region even under zero applied voltage. This effect was discovered by Josephson in 1962 [91, 92] and first observed by Anderson and Rowell in 1963 [93]. The Josephson effect is a hallmark of macroscopic quantum coherence, proving the macroscopic character of the pair wave function as originally predicted by Ginzburg and Landau [9]. Originally, the effect described the zero resistance tunneling of Cooper pairs between two superconductors through an insulating barrier, an SIS junction. The Josephson current from superconductor 2 to superconductor 1 (i.e.

electrons are flowing from 1 to 2), I, is given by the set of Josephson relations

$$I = F(\Delta\chi), \quad F(\Delta\chi + 2\pi) = F(\Delta\chi), \tag{30.5a}$$

$$\Delta\chi = \chi_2 - \chi_1 - \frac{q^*}{\hbar}\int_1^2 \boldsymbol{A}\cdot d\boldsymbol{r}, \tag{30.5b}$$

$$\frac{\partial\Delta\chi}{\partial t} = -\frac{q^*}{\hbar}(\Phi_2 - \Phi_1) \tag{30.5c}$$

where $q^* = 2e = -2|e|$, χ_1 and χ_2 are the phases of the superconducting condensate wave function on either side of the contact, $\boldsymbol{A}$ is the electromagnetic vector potential, and $q^*\Phi$ is the pair electrochemical potential ($\Phi_2 - \Phi_1 = V$ is the voltage across the junction). The function F describes the current-phase relation. The critical Josephson currents in positive and negative flow directions are defined via

$$I_{c+} = \max_{\Delta\chi} F(\Delta\chi), \qquad I_{c-} = -\min_{\Delta\chi} F(\Delta\chi). \tag{30.6}$$

For non-magnetic barriers in the *tunneling limit*, $I_{c+} = I_{c-} = I_c$ and $I = I_c\sin(\Delta\chi)$, where I_c is positive. The relations (30.5a)-(30.5c) are invariant against gauge transformations $\boldsymbol{A}' = \boldsymbol{A} + \nabla\zeta$, $\Phi' = \Phi - \partial_t\zeta$, $\chi' = \chi + \frac{q^*}{\hbar}\zeta$. The function $F(\Delta\chi)$ may not be single valued, for example for the case of a weak link multiple solutions can exist, and a hysteresis when sweeping $\Delta\chi$ may appear. If a flux Φ penetrates the junction, a characteristic Fraunhofer pattern appears when I_c is plotted vs. the flux. A multitude of interesting effects and devices based on the Josephson relations exist, and the reader is referred to review articles, e.g. [94, 95, 96, 97, 98].

Here we are mainly concerned with the dc Josephson effect for the case when the non-superconducting material is an extended region of normal metal or metallic ferromagnet. With the help of the proximity effect via Andreev reflections, the Josephson effect can also occur in such devices. The current passing through the normal region is carried by the Andreev states, which build bound states below the superconducting gaps within the normal conducting region. The number and distribution of the bound states depend on details such as interface transmission, mean free path, and length of the normal metal. In general, there is a characteristic energy, the Thouless energy [99], given by $\hbar v_f/L$ for the clean limit, and by $\hbar D/L^2$ for the diffusive limit. In normal metals coupled to conventional superconductors, there will be a low-energy gap in the spectrum of Andreev states, which for long junctions approximately scales with the Thouless energy and the transmission probabilities between the superconductors and the normal metal (possibly further reduced by inelastic scattering processes). This is the so-called minigap, found first by McMillan [100]. This minigap can be probed by scanning tunneling microscopy [101, 102]. When a supercurrent flows across the junction, or when an external magnetic field is applied, the minigap is reduced and eventually closes.

In the ballistic limit, each Andreev bound state with energy $E_{\text{b.s.}}$ disperses as function of phase difference $\Delta\chi$, and the current is given by $(q^*/\hbar)\partial E_{\text{b.s.}}/\partial\Delta\chi$. Apart from the current carried by the Andreev bound states, there is also a contribution from continuum states above the gap.

The current-phase relation $F(\Delta\chi)$ is in general strongly dependent on the details of the Josephson junction. Sinusoidal behavior is only observed under special circumstances, like for example in the tunneling limit. The critical Josephson current depends strongly on the length of the junction. For more details I refer the reader to the above mentioned review articles.

30.2 Symmetry classification of Cooper pairs in superconductors

30.2.1 Consequences of Pauli principle and Fermi statistics

Due to the Fermi statistics the pair correlation function, or the Gor'kov "anomalous Green function" [10], fulfills fundamental symmetries following from fermionic anti-commutation re-

lations of the field operators. For fermions, the definition of the anomalous Green function [92, 104] in Matsubara representation [89] is given by

$$\begin{aligned} -F^{\mathrm{M}}_{\alpha\beta}(\mathbf{r}_1,\mathbf{r}_2;\tau) &= \langle \mathbf{T}_\tau \left\{ \Psi_\alpha(\mathbf{r}_1,-i\tau)\Psi_\beta(\mathbf{r}_2,0)\right\}\rangle \\ &\equiv \theta(\tau)\langle \Psi_\alpha(\mathbf{r}_1,-i\tau)\Psi_\beta(\mathbf{r}_2,0)\rangle - \theta(-\tau)\langle \Psi_\beta(\mathbf{r}_2,0)\Psi_\alpha(\mathbf{r}_1,-i\tau)\rangle \end{aligned} \tag{30.7}$$

where the θ-function is defined as $\theta(\tau)=1$ for $\tau\geq 0$ and 0 for $\tau<0$, and where $|\tau|<|\hbar/k_{\mathrm{B}}T|$. The function F^{M} fulfills the fundamental identity

$$F^{\mathrm{M}}_{\alpha\beta}(\mathbf{r}_1,\mathbf{r}_2;\tau) \;=\; -F^{\mathrm{M}}_{\beta\alpha}(\mathbf{r}_2,\mathbf{r}_1;-\tau). \tag{30.8}$$

which expresses the fermionic nature of the constituents of a pair. Going over to relative and center of mass coordinates, $\mathbf{r}=\mathbf{r}_1-\mathbf{r}_2$, $\mathbf{R}=(\mathbf{r}_1+\mathbf{r}_2)/2$, the corresponding relation reads

$$F^{\mathrm{M}}_{\alpha\beta}(\mathbf{r},\tau;\mathbf{R}) \;=\; -F^{\mathrm{M}}_{\beta\alpha}(-\mathbf{r},-\tau;\mathbf{R}), \tag{30.9}$$

or after Fourier transformation in the relative coordinates $\mathbf{r}\to\mathbf{p}$, $\tau\to z$,

$$F^{\mathrm{M}}_{\alpha\beta}(\mathbf{p},z;\mathbf{R}) \;=\; -F^{\mathrm{M}}_{\beta\alpha}(-\mathbf{p},-z;\mathbf{R}). \tag{30.10}$$

Kubo-Martin-Schwinger (KMS) boundary conditions [105, 106] allow for anti-periodicity in τ with period $\hbar/k_{\mathrm{B}}T$: $F^{\mathrm{M}}_{\alpha\beta}(\mathbf{r},\tau-i\hbar/k_{\mathrm{B}}T;\mathbf{R})=-F^{\mathrm{M}}_{\alpha\beta}(\mathbf{r},\tau;\mathbf{R})$. This leads to discrete Matsubara energies $z=\varepsilon_n=(2n+1)\pi k_{\mathrm{B}}T$,

$$F^{\mathrm{M}}_{\alpha\beta}(\mathbf{p},\varepsilon_n;\mathbf{R}) \;=\; -F^{\mathrm{M}}_{\beta\alpha}(-\mathbf{p},-\varepsilon_n;\mathbf{R}). \tag{30.11}$$

We consider now spin-singlet (spin-antisymmetric) and spin-triplet (spin-symmetric) components:

$$F^{\mathrm{M}}_{s/t} = \frac{1}{2}\left(F^{\mathrm{M}}_{\alpha\beta} \mp F^{\mathrm{M}}_{\beta\alpha}\right) \tag{30.12}$$

(suppressing the spin indices hereafter), which fulfill

$$F^{\mathrm{M}}_{s}(\mathbf{p},\varepsilon_n;\mathbf{R}) \;=\; F^{\mathrm{M}}_{s}(-\mathbf{p},-\varepsilon_n;\mathbf{R}) \tag{30.13a}$$

$$F^{\mathrm{M}}_{t}(\mathbf{p},\varepsilon_n;\mathbf{R}) \;=\; -F^{\mathrm{M}}_{t}(-\mathbf{p},-\varepsilon_n;\mathbf{R}). \tag{30.13b}$$

Each of these we can classify according to parity. We define even-parity and odd-parity functions

$$F^{\mathrm{M}}_{\pm}(\varepsilon_n;\mathbf{R}) \;=\; \frac{1}{2}\left(F^{\mathrm{M}}(\mathbf{p},\varepsilon_n;\mathbf{R}) \pm F^{\mathrm{M}}(-\mathbf{p},\varepsilon_n;\mathbf{R})\right) \tag{30.14}$$

(we suppress the momentum argument hereafter) and find

$$F^{\mathrm{M}}_{s+}(\varepsilon_n;\mathbf{R}) \;=\; F^{\mathrm{M}}_{s+}(-\varepsilon_n;\mathbf{R}) \tag{30.15a}$$

$$F^{\mathrm{M}}_{s-}(\varepsilon_n;\mathbf{R}) \;=\; -F^{\mathrm{M}}_{s-}(-\varepsilon_n;\mathbf{R}) \tag{30.15b}$$

$$F^{\mathrm{M}}_{t+}(\varepsilon_n;\mathbf{R}) \;=\; -F^{\mathrm{M}}_{t+}(-\varepsilon_n;\mathbf{R}) \tag{30.15c}$$

$$F^{\mathrm{M}}_{t-}(\varepsilon_n;\mathbf{R}) \;=\; F^{\mathrm{M}}_{t-}(-\varepsilon_n;\mathbf{R}). \tag{30.15d}$$

Thus, $F^{\mathrm{M}}_{s+}(\varepsilon_n;\mathbf{R})$ and $F^{\mathrm{M}}_{t-}(\varepsilon_n;\mathbf{R})$ are even in Matsubara frequency, whereas $F^{\mathrm{M}}_{s-}(\varepsilon_n;\mathbf{R})$ and $F^{\mathrm{M}}_{t+}(\varepsilon_n;\mathbf{R})$ are odd.

After it was realized that in diffusive heterostructures with ferromagnets the type $F^{\mathrm{M}}_{t+}(\varepsilon_n;\mathbf{R})$ appears, which is according to the above a so-called odd-frequency pair amplitude (for a review see [73]), a systematic classification according to symmetry of pairing correlations was undertaken along the lines explained above. Pair amplitudes are classified into four types according

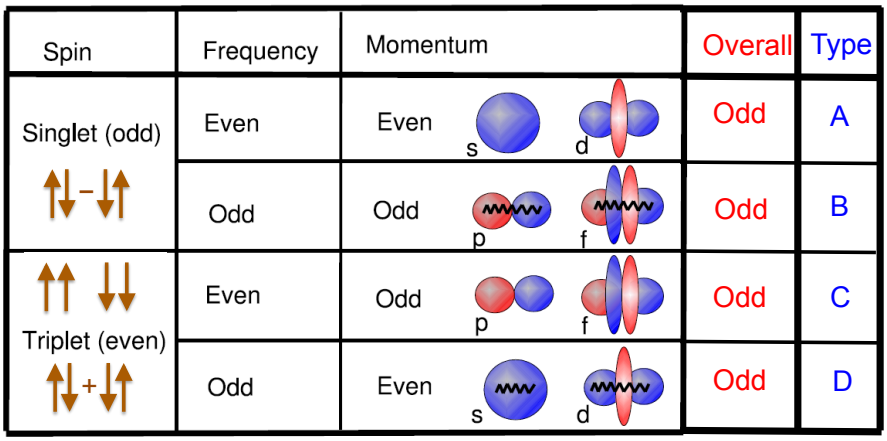

Figure 30.6: Symmetry classification of Cooper pairs in inhomogeneous systems. The wavy lines symbolize odd-frequency symmetry of the pair amplitude. After [107, 133].

to their behavior with respect to frequency, momentum (parity), and spin (see Fig. 30.6) [107]:

Type A:	spin singlet, even frequency, even parity
Type B:	spin singlet, odd frequency, odd parity
Type C:	spin triplet, even frequency, odd parity
Type D:	spin triplet, odd frequency, even parity.

An identical classification scheme was independently proposed in Refs. [108, 109]. The four symmetry states above exhaust all possibilities compatible with Fermi statistics and the Pauli exclusion principle.[43] The usual spin singlet, s-wave Bardeen-Cooper-Schrieffer (BCS) superconductor [8] is of type A, while the spin triplet, p-wave superfluid formed in ^{3}He [110, 111] is of type C. Type D was first considered by Berezinskiĭ [112] in connection with early research on superfluid ^{3}He. Finally, type B was introduced in connection with unconventional superconductors by Balatsky, Abrahams and others [116, 117, 118].

Suggestions for realization of Type B superconductivity include generalized one-dimensional $t-J$ and Hubbard models [119, 120], two-channel Kondo models and Kondo lattices [121, 122, 123, 124], and quantum critical points [125]. Realizations suggested for the Type D state include disordered two-dimensional electron fluids in semiconductors [113, 114, 115], triangular antiferromagnets [126], composite spin and orbital triplet superconductivity in two-channel Anderson lattices [127], Hund's coupled pairing in double orbital Hubbard models [128], strong-coupling triplet superconductivity in Holstein Hubbard models [129], and one-dimensional systems with strong charge fluctuations [130].

30.2.2 Odd-frequency pairing amplitudes

To date an odd-frequency superconductor has not been found in nature. However, in contrast to all cases discussed above, where the appearance of an order parameter due to spontaneous symmetry breaking (global phase symmetry in superconductors) was in the focus, in this review we are interested in the case of explicit symmetry breaking taking place locally in some spatial region, e.g. near interfaces, line defects, or inclusions. For this case an overwhelming

[43] If more discrete degrees of freedom than the ones considered here are relevant (e.g. orbital) then the classification must be extended accordingly.

number of experiments support the picture of the existence of proximity induced pairing states of type D. In its pure form (i.e. without additional components of different symmetry), it has been first predicted theoretically for a superconductor-ferromagnet proximity structure with a spiral inhomogeneous magnetization near the interface in Ref. [131]. Previous work had predicted the appearance of similar odd-frequency triplet anomalous functions in a model of coexistence of a superconducting phase and a helical ordering of localized spins, motivated by experiments on the superconductor $ErRh_4B_4$ [132].

In fact, the Pauli principle requires odd-frequency amplitudes to be present in any inhomogeneous superconducting state, not necessarily spin-polarized [107]. For example, the case of a normal metal coupled to a superconductor involves pair amplitudes of Type B. Thus, odd-frequency amplitudes appear in heterostructures naturally due to breaking of translational symmetry at interfaces (similarly as Rashba spin-orbit coupling appears at interfaces in semiconductor heterostructures). They have been present in all treatments of inhomogeneous superconductivity for a long time, however were not explicitly named as such. Similarly, pair amplitudes of Type D appear as soon as spin rotational symmetry is broken, e.g. by an external magnetic field via the Zeeman coupling. If both spin rotational symmetry and parity are broken, e.g. at an interface between a superconductor and a ferromagnet, all four types of pair amplitudes are generated at the interface [107, 133]. Similar conclusions have been reached in Refs. [108, 109]. The important issue in discussing odd-frequency amplitudes in Ref. [131] is not the presence of Type D correlations per se, but their only presence. Thus, in diffusive structures those s-wave odd-frequency triplet pair amplitudes have a definite symmetry, and thus are of special interest for fundamental research. In regions where all amplitudes are mixed, simply all symmetries are absent, and a symmetry classification is not very useful. However, once such regions are coupled to reservoirs in which symmetries are asymptotically (far away from the spatial regions where the symmetry breaking takes place) re-established, then it is useful to discuss processes at interfaces in the light of those asymptotic symmetries.

To date it remains a great challenge to find direct experimental verification of the odd-frequency symmetry. There have been a number of proposals for indirect experimental verification via tunneling density of states studies, by inducing odd-frequency triplet superconducting correlations in a normal metal [134, 135, 136].

The odd-frequency pairing aspect in superconductor ferromagnet heterostructures was reviewed in Ref. [73]. A recent review dealing with odd-frequency pairing states and their relation to topological edge states can be found in Ref. [137]. Newer developments in finding odd-frequency order parameters include odd-frequency pairing states in multi-band superconductors [138, 139], at the surface of topological insulators [140], in a controllable double-quantum dot system [141], and in two-particle Bose-Einstein condensates [142], as well as odd-frequency density wave states [143, 144].

Odd-frequency symmetry requires that the equal time pair correlator vanishes, i.e. electrons in a pair avoid each other in time. It has been argued that in such a case certain particle-hole symmetries based on a Green function approach are not appropriate and a Lagrangian formalism must be used [145, 146]. In particular, these arguments were brought forward for homogeneous odd-frequency states with an odd-frequency pair potential appearing due to spontaneous symmetry breaking. However, these arguments do not take into account that symmetries following from the full many body Hamiltonian of the system are fundamental. Should they be violated in a model Lagrangian approach, for which a corresponding model Hamiltonian cannot be found, then this simply means that the model Lagrangian is not appropriate for the problem in question [147]. It has also been pointed out that spatially homogeneous odd-frequency states might be thermodynamically unstable in reality [148].

30.3 Magnetically active interfaces

30.3.1 Scattering phase delays

Let us consider the basic quantum mechanical problem of a (quasi)-particle being reflected from an insulating region (which we assume at $x > 0$, potential V). Let us assume the particle has energy $0 < E < V$ with $E = (k^2 + k_{||}^2)/2m = V + (-\kappa^2 + k_{||}^2)/2m$, and thus $\kappa(E) = [2m(V-E) + k_{||}^2]^{1/2}$, $k(E) = [2mE - k_{||}^2]^{1/2}$. It is described by a wave function $\Psi(x, \mathbf{r}_{||}) = e^{i\mathbf{k}_{||}\mathbf{r}_{||}}(e^{ikx} + r\, e^{-ikx})$ at $x < 0$ and $\Psi(x, \mathbf{r}_{||}) = te^{i\mathbf{k}_{||}\mathbf{r}_{||}}e^{-\kappa x}$ at $x > 0$. The reflection amplitude for such a process is $r = (k - i\kappa)/(k + i\kappa) = e^{-2i\arctan(\kappa/k)}$, where k is the momentum component perpendicular to the interface and κ determines the exponential decay of the wave function in the insulating region. In the limit for large κ the phase of the reflected wave is flipped by π with respect to the incoming wave. For finite κ there is a *phase delay* with respect to this, given by $\varphi(E) = \pi - 2\arctan(\kappa/k)$. This phase delay results from the fact that the particle penetrates the insulator over a length scale $\hbar/\kappa$, and it corresponds to a *time delay* between the maximum of an incoming wave packet and the corresponding reflected wave packet [149] of $\tau_d = \hbar\partial_E\varphi(E) = 2m\hbar/(\kappa k)$ (accompanied by a Goos-Hänchen shift along the interface of $s = 2\hbar k_{||}/(\kappa k)$ [150]).

30.3.2 Spin-mixing angle and spin-dependent scattering phase shifts

We now assume that an exchange field $\boldsymbol{J}$ is present, leading to a contribution to the Hamiltonian given by $\mathcal{H}_{\text{exch}} = -\boldsymbol{J}\cdot\boldsymbol{\sigma}$. This can also be written as $\mathcal{H}_{\text{exch}} = -\mu\, \boldsymbol{B}_{\text{eff}}\cdot\boldsymbol{\sigma}$, with $\boldsymbol{B}_{\text{eff}} = \boldsymbol{J}/\mu$, and μ is the (effective) magnetic moment of the charge carriers (negative for free electrons). Let us now consider a ferromagnetic insulating region, so that the two spin directions σ have different reflection amplitudes $r_\sigma = (k - i\kappa_\sigma)/(k + i\kappa_\sigma) = e^{-2i\arctan(\kappa_\sigma/k)}$, with $\Psi_\sigma \sim e^{-\kappa_\sigma x}$ in the ferromagnetic insulating region (see Figure 30.7). As throughout this review, we take the spin quantization axis along the exchange field, i.e. $\kappa_\sigma(E) = [2m(V - E - \sigma J) + k_{||}^2]^{1/2}$, such that the majority Fermi surface is assigned spin projection $\sigma = 1$.[44] The scattering phase delays now are spin dependent, $\varphi_\sigma(E) = \pi - 2\arctan(\kappa_\sigma/k)$, and we can define a quantity $\vartheta = \varphi_\uparrow - \varphi_\downarrow$, which is called *spin-mixing angle* [151] or *spin dependent interface scattering phase shift* [152] in the literature (it is associated with a delay time $\tau_\vartheta = \hbar\partial_E\vartheta(E) = 2m\hbar/(\kappa_\uparrow k) - 2m\hbar/(\kappa_\downarrow k)$ between the two spin components). For our example we have $\kappa_\uparrow < \kappa_\downarrow$, and consequently $\vartheta > 0$, $\tau_\vartheta > 0$. Together with the spin-independent averaged phase $\varphi = (\varphi_\uparrow + \varphi_\downarrow)/2$, we write the reflection amplitude in a more general way as [151]

$$r(\varphi, \vartheta, \hat{\mathbf{n}}) = -e^{i\varphi}\cdot e^{i\frac{\vartheta}{2}\hat{\mathbf{n}}\cdot\boldsymbol{\sigma}} \tag{30.16}$$

with respect to a spin quantization axis $\hat{\mathbf{n}}$. The spin-mixing angle also describes the rotation angle of the spin components perpendicular to the axis $\hat{\mathbf{n}}$ under reflection. This can be interpreted as a precession that the spins undergo around the axis $\hat{\mathbf{n}}$ as a result of quantum mechanical penetration into the magnetic and insulating region.

If one considers the Cooper instability in the presence of an interface with a ferromagnetic insulator, it becomes clear that pairing near the interface will be affected by these spin-mixing angles. In particular, a spin-up electron with momentum pointing towards the interface will have a relative phase shift with respect to a spin-down electron with momentum pointing away from the interface if the Cooper pair volume overlaps with the interface region. As the Cooper pair's size is determined by the superconducting coherence length, Cooper pairs in a layer that extends a coherence length from the interface into the bulk will feel the spin-mixing phase

[44] For free electrons (negative magnetic moment) this quantization axis would point opposite to the effective magnetic field. For a quantization axis in field direction, spin up and down would simply switch their roles.

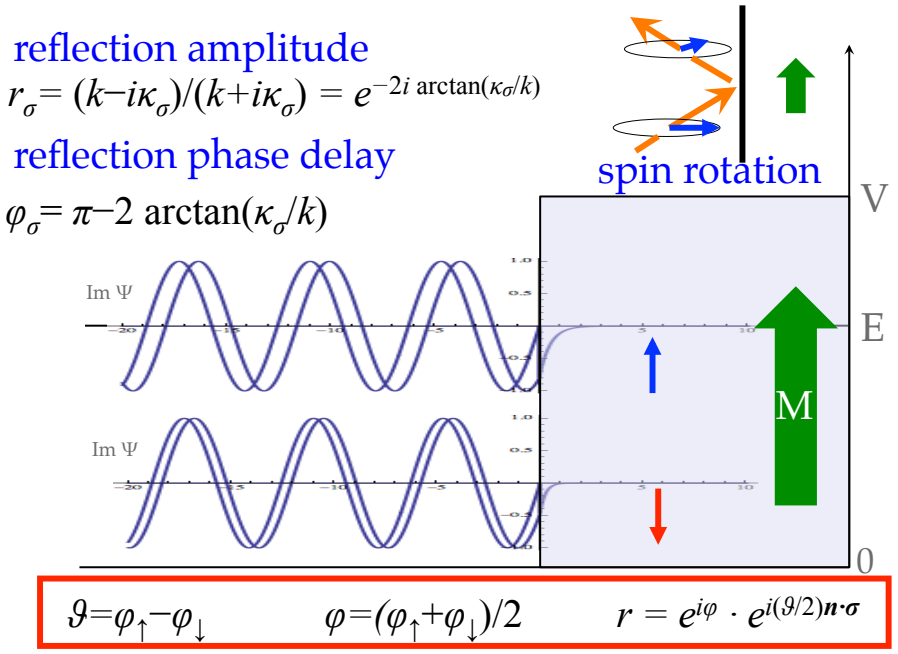

Figure 30.7: When a Bloch wave is reflected from a ferromagnetic insulator, a phase delay appears between the reflected waves and the incoming waves, which differs for both spin directions. As a result, the spin-down reflected wave is delayed with respect to the spin-up reflected wave. If the incoming wave is polarized perpendicular to the ferromagnet's magnetization, then the reflected wave has its spin rotated with respect to the spin of the incoming wave (see top part of the drawing).

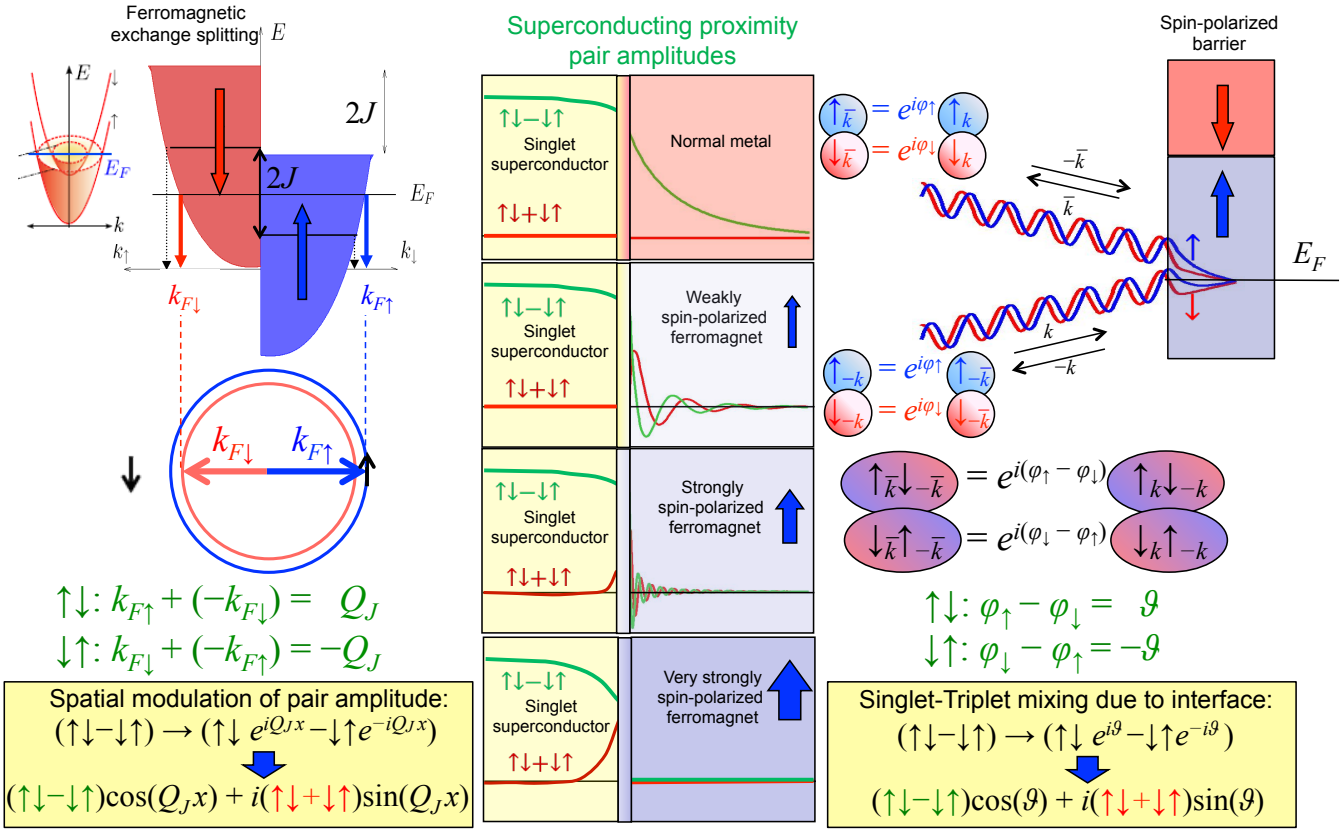

Figure 30.8: Creation mechanisms for triplet pair correlations by direct and inverse proximity effect. See text for explanation. Reproduced and modified with permission from [153]. Copyright (2011) American Institute of Physics.

shifts of the interface. This is shown in Figure 30.8 on the right. Near the interface, only a singlet-triplet mixed Cooper pair of the form

$$(\uparrow\downarrow e^{i\vartheta} - \downarrow\uparrow e^{-i\vartheta}) \equiv \cos(\vartheta)|0,0\rangle + i\sin(\vartheta)|1,0\rangle \tag{30.17}$$

can be present. According to this, we can consider the parameter ϑ also as the parameter that governs the *degree of singlet-triplet mixing* at a spin-active interface. As seen in Figure 30.8, there is a certain analogy between the creation of FFLO correlations in a ferromagnetic metal and the creation of singlet-triplet mixtures near a magnetically active interface in a superconductor. The role of the phase $Q_J x$ in the former is played by the spin-mixing angle ϑ in the latter. As demonstrated in the middle column of Figure 30.8, with increasing spin polarization of the ferromagnet in a superconductor-ferromagnet heterostructure, a shift from the creation of FFLO correlations in the ferromagnet to the creation of singlet-triplet mixtures in the superconductor takes place. This is because for very weak spin polarizations, the spin-mixing angle of the interface usually is of similarly small order and should be neglected in a consistent expansion in small parameters of the theory. For strong spin-polarization it is important and must be taken into account. The FFLO correlations in the ferromagnet show an inverse behavior: they are important for weak spin polarizations, however are restricted to atomically small distances from the interface for strongly spin polarized ferromagnets.

The presence of spin-mixing angles has many consequences. For example, it leads to Andreev bound states at the interface, as predicted theoretically [154, 155, 156, 157, 158, 159], and verified experimentally [160]. It also is responsible for giant thermoelectric effects in non-local setups [161, 162] and is the main ingredient for creating triplet supercurrents in strongly spin-polarized ferromagnets [155, 133]. It also crucially affects point contact spectra [163, 164, 158,

165, 166, 167, 168, 169]. Finally, it is the main cause of the inverse proximity effect and the magnetic proximity effect in strongly spin polarized hybrid structures [155, 133, 170, 171].

30.3.3 Scattering matrix and induced triplet correlations

The interface scattering matrix connects incoming Bloch waves with outgoing Bloch waves at an interface between two itinerant electron materials (metals, half metals, itinerant ferromagnets), or at a surface of such a material with an insulator. Relevant for transport are Bloch waves with energy close to the Fermi energy and momentum close to the Fermi momentum, in which case the Bloch waves are assumed to describe quasiparticle excitations. "Incoming" and "outgoing" refers to the projection of the quasiparticle's Fermi velocity on the surface normal. We distinguish between electron-like and hole-like quasiparticles. For electron-like quasiparticles the projection of the group velocity on the Fermi momentum is positive, for hole-like quasiparticles it is negative. This means that electron-like and hole-like quasiparticles associated with the same Fermi momentum have opposite group velocity projections on the surface normal and consequently have different scattering matrices. For atomically ordered interfaces the crystal momentum component parallel to the interface, $\boldsymbol{p}_{||}$, is conserved, and then the relation between hole (h) and electron (e) like scattering matrices is $S_{\rm h}^{\dagger}(\boldsymbol{p}_{||}) = S_{\rm e}^{*}(-\boldsymbol{p}_{||})$.

In relation to superconductivity, it is sufficient to consider the normal state scattering matrix for quasiparticles at Fermi momentum and Fermi energy. This results from a systematic classification of all terms during a perturbation expansion in the small phase space volume associated with quasiparticles, which leads to quasiclassical theory of superconductivity [188, 196]. In terms of the normal-state scattering matrix,

$$\hat{\mathbf{S}} = \begin{pmatrix} \hat{R}_1 & \hat{T}_1 \\ \hat{T}_2 & -\hat{R}_2 \end{pmatrix} \tag{30.18}$$

we can study the superconducting amplitudes induced by the presence of a singlet pair potential on either side of the interface. To simplify algebra and to gain some intuition we limit ourselves to the case of small pair amplitudes, in which case one can linearize the boundary conditions in the pair amplitudes. In our notation, $\hat{R}_1$ describes reflection into the superconductor, and $\hat{R}_2$ describes reflection into the ferromagnet. All reflection and transmission parameters in Eq. (30.18) are 2x2 spin matrices. We consider the ballistic case, for which the reflected and transmitted pair amplitudes $\hat{f}_{\rm out}^{\rm SC}$, $\hat{f}_{\rm out}^{\rm FM}$ are given in terms of the incoming singlet pair amplitude $\hat{f}_{\rm in}^{\rm SC} = f_0(i\sigma_y)$ by boundary conditions at the interface between the superconductor and the magnetic material, which in linear order read

$$\hat{f}_{\rm out}^{\rm SC} = f_0\, \hat{R}_1\, (i\hat{\sigma}_y)\, \hat{R}_1^{*} \tag{30.19}$$

$$\hat{f}_{\rm out}^{\rm FM} = f_0\, \hat{T}_2\, (i\hat{\sigma}_y)\, \hat{T}_1^{*}. \tag{30.20}$$

The simplest case is that of total reflection from an interface with a magnetic insulator. In this case we have (choosing the quantization axis appropriately, and with a scalar phase ψ)

$$\hat{R}_1 = e^{i\psi} \begin{pmatrix} e^{\frac{i}{2}\vartheta} & 0 \\ 0 & e^{-\frac{i}{2}\vartheta} \end{pmatrix}. \tag{30.21}$$

The reflected amplitudes for this case follow from Eq. (30.19) and are given by

$$\hat{f}_{\rm out}^{\rm SC} = [f_0 \cos(\vartheta) + i f_0 \sin(\vartheta)\hat{\sigma}_z]\, i\hat{\sigma}_y. \tag{30.22}$$

This justifies the expression obtained by the simple arguments leading to Eq. (30.17).

symmetry	even frequency	odd frequency
even parity	Type A, singlet$\|0,0\rangle$ $f_s^s = \frac{\pi\Omega_n\Delta\left(1-\sin^2\frac{\vartheta}{2}\right)}{\Omega_n^2-\|\Delta\|^2\sin^2\frac{\vartheta}{2}}$	Type D, triplet$\|1,0\rangle$ $f_{t_0}^s = \frac{i\pi\varepsilon_n\Delta\,\frac{1}{2}\sin\vartheta}{\Omega_n^2-\|\Delta\|^2\sin^2\frac{\vartheta}{2}}$
odd parity	Type C, triplet$\|1,0\rangle$ $f_{t_0}^a = \frac{-i\pi\Omega_n s_\mu\Delta\,\frac{1}{2}\sin\vartheta}{\Omega_n^2-\|\Delta\|^2\sin^2\frac{\vartheta}{2}}$	Type B, singlet$\|0,0\rangle$ $f_s^a = \frac{\pi\varepsilon_n s_\mu\Delta\sin^2\frac{\vartheta}{2}}{\Omega_n^2-\|\Delta\|^2\sin^2\frac{\vartheta}{2}}$

Table 2: Symmetry components of the interface amplitudes inside a ballistic superconductor in contact with a ferromagnetic insulator, assuming a constant singlet order parameter Δ. Here, $\Omega_n = \sqrt{|\Delta|^2+\varepsilon_n^2}$, $\vartheta \equiv \vartheta(\mu)$, and $s_\mu = \mathrm{sign}(\mu)$ (μ is the cosine of the impact angle). From Supplementary Material of Ref. [133].

Next, we consider the case of arbitrarily large pair amplitudes in a ballistic superconductor with spatially constant pair potential. This is justified for sufficiently small spin-mixing angles ϑ. Incoming and reflected directions are parameterized by the polar angle $\theta_{\hat{\boldsymbol{p}}_f}$, measured from the surface normal. The cosine of this angle is called μ. Defining even parity (symmetric) and odd parity (antisymmetric) functions with respect to the propagation direction, $f^a = [f(\mu)-f(-\mu)]/2$ and $f^s = [f(\mu)+f(-\mu)]/2$, we obtain all four possible symmetry components as summarized in Table 2. It can be seen that the corrections to the singlet amplitudes are $\sim \sin^2(\vartheta/2)$. Thus, to linear order in ϑ the pair potential stays unaffected. With increasing ϑ the singlet pair potential is reduced, leading to corrections to the expressions in Table 2.

For the case of an interface with a strongly spin-polarized ferromagnet, one has to consider Fermi surface geometry, due to the presence of different Fermi surfaces for the two spin projections in the ferromagnet. Various cases can occur, depending on the scattering channel (parameterized in the ballistic case by $\boldsymbol{p}_{||}$, see figure 30.9): for example for reflection from the interface on the superconducting side, there can occur total reflection from the ferromagnet, total reflection of only one spin component from the ferromagnet (so-called half-metallic channels), or partial reflection for both spin components. Depending on the geometry of the Fermi surface in the superconductor, one, two, or all three cases may occur.

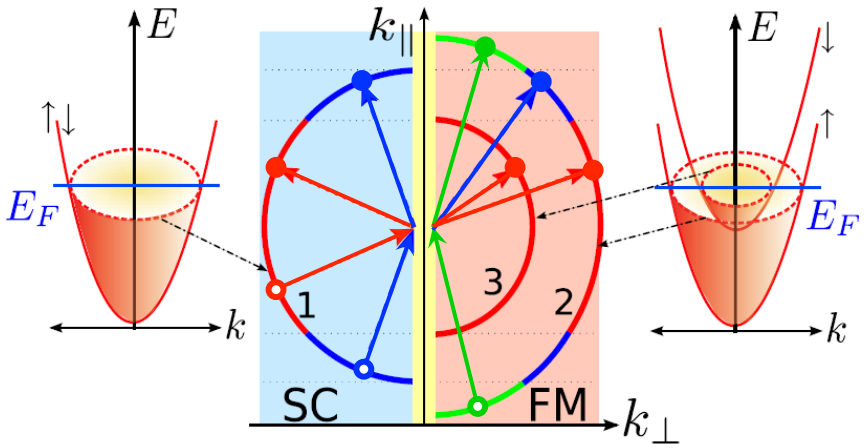

Figure 30.9: Fermi surface geometry for a superconductor (left)-ferromagnet (right) interface. Various types of scattering events include total reflection (green), involvement of only one (blue) or of both spin bands (red). After [172], Copyright (2009) by the American Physical Society.

For illustrative purposes we will consider a simple model of an interface potential of width d

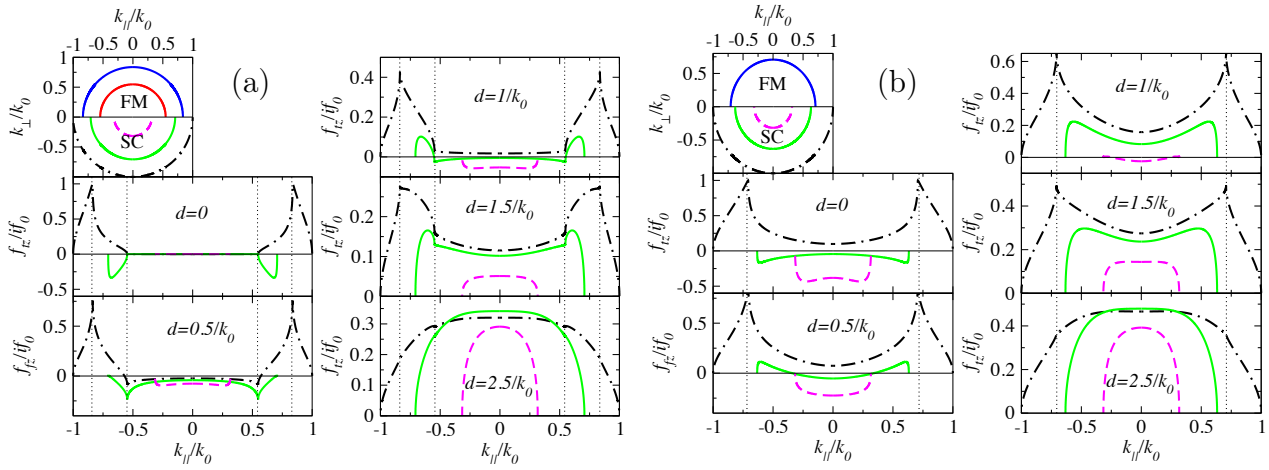

Figure 30.10: Induced triplet components at a superconductor-ferromagnet interface with an interface barrier of width d. Model free-electron dispersions are: $V_{\rm S}+\boldsymbol{k}^2/2m$ (superconductor), $V_{\rm I}-\sigma J+\boldsymbol{k}^2/2m$ (barrier), $V_{\rm FM}-\sigma J+\boldsymbol{k}^2/2m$ (ferromagnet). The singlet amplitude in the superconductor is f_0, the induced triplet component is f_{tz} (and f_{tz}/f_0 is purely imaginary). The Fermi wavevectors for the spin bands in the ferromagnet are fixed in (a) and (b). The various curves correspond to various Fermi wavevectors in the superconductor (as illustrated in the top left diagram in each panel). Wavevectors are normalized to $k_0=\sqrt{2mE_F}$. For (a) $V_{\rm I}=1.3$, $V_{\rm FM}=0.5$, $J=0.2$, $V_{\rm S}=0$ (black dashed-dotted), 0.5 (green full line), 0.9 (magenta dashed); for (b) $V_{\rm I}=1.4$, $V_{\rm FM}=0.8$, $J=0.3$, $V_{\rm S}=0$ (black dashed-dotted), 0.6 (green full line), 0.9 (magenta dashed); energies are in units of the Fermi energy E_F. (b) corresponds to a half-metallic ferromagnet, with only one spin projection itinerant (i.e. a Fermi surface exists only for $\sigma=1$).

between a superconductor and a ferromagnet, with corresponding (free) electronic dispersions $V_{\rm S}+\boldsymbol{k}^2/2m$ in the superconductor, $V_{\rm I}-\sigma J+\boldsymbol{k}^2/2m$ in the interface region, and $V_{\rm FM}-\sigma J+\boldsymbol{k}^2/2m$ in the ferromagnet. If the magnetization in the interface region is collinear with that in the ferromagnet, there will be no transmitted pair amplitudes, as for a strongly spin-polarized ferromagnet only $\uparrow\uparrow$ and $\downarrow\downarrow$ pairs are supported, which both are not generated in such a system. There is, however, an induced triplet component on the superconducting side, with spin projection zero on the spin quantization axis. It is shown in Figure 30.10, for the case of a strongly spin polarized ferromagnet in (a), and for the case of a half-metallic ferromagnet (with only spin projection $\sigma=1$ itinerant) in (b). When the barrier is absent, there is no induced triplet component for the regions connecting wave vectors that support Bloch waves for both spin projections. Only wave vectors for which maximally one spin projection in the ferromagnet supports Bloch waves contribute to the induced triplet amplitudes in the superconductor. This shows that for high-transmission contacts half-metallic ferromagnets are most effective for including triplet correlations in the superconductor. If a spin-polarized barrier is present, triplet amplitudes are created also in the barrier region, and their sign depends on the relative size of the Fermi surfaces in the superconductor and in the ferromagnet. In the tunneling limit, the creation of triplet correlations happens mainly in the barrier region, such that they become insensitive to the Fermi surface geometry.

In order to allow for proximity induced triplet amplitudes in the ferromagnet, one needs an inhomogeneous non-collinear magnetization in the interface region. We study a simple model where the interface barrier is magnetized in direction perpendicular to the magnetization in the ferromagnet. We again assume a spin quantization axis in direction of the exchange field in the ferromagnet, which we take as the z-axis, and a barrier exchange field pointing along the x-axis in spin space. In Figure 30.11 we show for two values of barrier thickness all triplet amplitudes

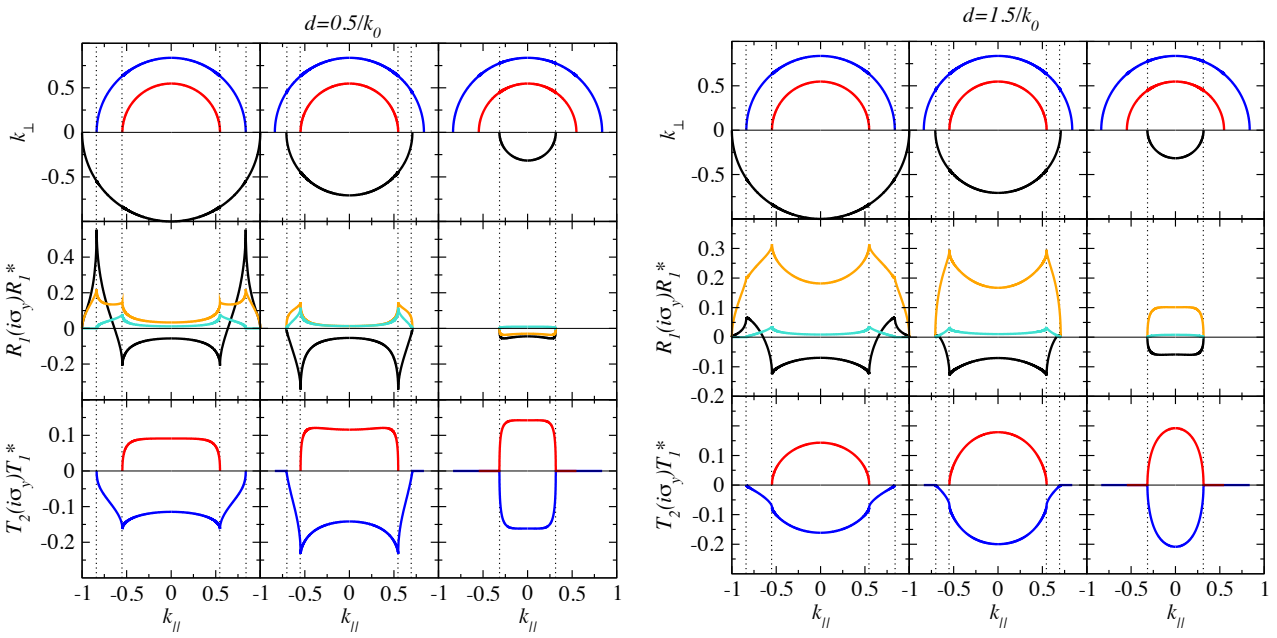

Figure 30.11: Induced triplet components at a superconductor-ferromagnet interface with an interface barrier of width d, spin polarized in x-direction, perpendicular to the ferromagnet's spin polarization in z-direction. Other parameters are as in Fig. 30.10 (a), with $V_{\rm S} = 0, 0.5E_F, 0.9E_F$ for each thickness d. The components shown are: in the superconductor $f^{\rm SC}_{tz}/(if_0) = f^{\rm SC}_{\frac{1}{2}(\uparrow\downarrow+\downarrow\uparrow)}/(if_0)$ (black); $f^{\rm SC}_{tx}/(if_0) = f^{\rm SC}_{\frac{1}{2}(-\uparrow\uparrow+\downarrow\downarrow)}/(if_0)$ (orange); $f^{\rm SC}_{ty}/f_0 = f^{\rm SC}_{\frac{1}{2i}(\uparrow\uparrow+\downarrow\downarrow)}/f_0$ (turquoise); in the ferromagnet $f^{\rm FM}_{\uparrow\uparrow}/(if_0)$ (blue); $f^{\rm FM}_{\downarrow\downarrow}/(if_0)$ (red).

generated in the superconductor and in the ferromagnet. For each value of barrier thickness we show three representative Fermi surface geometries. In the ferromagnet the spin bands support only triplet amplitudes of the form $f^{\rm FM}_{\uparrow\uparrow}$ and $f^{\rm FM}_{\downarrow\downarrow}$, whereas in the superconductor we show all three triplet amplitudes $f^{\rm SC}_{tz} = f^{\rm SC}_{\frac{1}{2}(\uparrow\downarrow+\downarrow\uparrow)}$, $f^{\rm SC}_{tx} = f^{\rm SC}_{\frac{1}{2}(-\uparrow\uparrow+\downarrow\downarrow)}$, and $f^{\rm SC}_{ty} = f^{\rm SC}_{\frac{1}{2i}(\uparrow\uparrow+\downarrow\downarrow)}$.

It is interesting to note that for intermediate barrier thicknesses, also a component $f^{\rm SC}_{ty}$ is generated, although the magnetization always lies in the $x-z$ plane. This is due to the fact that spins polarized in z-direction, precessing around the x-direction, develop a y-component (and similarly for spins polarized in x-direction and precessing around the z-direction). In a real gauge of the singlet pair potential, $f^{\rm SC}_{tz}$ and $f^{\rm SC}_{tx}$ are purely imaginary, and $f^{\rm SC}_{ty}$ is purely real. As a consequence, only the former two contribute to the magnetization in the superconductor.

Furthermore, depending on the barrier thickness, the vector of the triplet amplitudes in the superconductor changes direction rapidly as function of impact angle with respect to the surface normal. Only for tunneling barriers the direction of the triplet vector is dominated by the barrier exchange field.

The equal-spin triplet amplitudes generated in the ferromagnet have opposite sign for the two spin projections. This reflects the fact that a triplet component with zero spin projection along the exchange field in the barrier region (x-direction) decomposes into equal-spin pairs with respect to the z-direction with equal magnitude and opposite sign: $(\uparrow\downarrow + \downarrow\uparrow)_x = (-\uparrow\uparrow + \downarrow\downarrow)_z$. Whereas in the tunneling limit the largest contributions to triplet amplitudes arise from near-normal impact, for thin barriers the dominating contributions arise from wavevectors that have for at least one spin projection evanescent solutions in the ferromagnet.

For a general orientation of the interface barrier exchange field we parameterize its direction by polar and azimuthal angles, α and φ,[45] respectively, measured from the z-axis in spin space.

[45] In the following the scalar scattering phase φ will not appear anymore in this review, such that no confusion

	microscopic model	**quasiclassical**
wave function methods:	Bogoliubov-de Gennes equations	Andreev equations
Green function methods:	Gor'kov equations	Eilenberger-Larkin-Ovchinnikov equations

Table 3: Theories for inhomogeneous superconductivity can be classified into four types, as shown in this table.

The well-known transformation formulas for basis vectors quantized along the direction α, φ in terms of basis vectors quantized along the z-axis read

$$\uparrow_{\alpha,\varphi} = \cos\frac{\alpha}{2}e^{-i\frac{\varphi}{2}}\uparrow_z + \sin\frac{\alpha}{2}e^{i\frac{\varphi}{2}}\downarrow_z \tag{30.23a}$$

$$\downarrow_{\alpha,\varphi} = -\sin\frac{\alpha}{2}e^{-i\frac{\varphi}{2}}\uparrow_z + \cos\frac{\alpha}{2}e^{i\frac{\varphi}{2}}\downarrow_z \tag{30.23b}$$

and can be used to find the transformation for pair amplitudes, for example

$$(\uparrow\downarrow - \downarrow\uparrow)_{\alpha,\varphi} = (\uparrow\downarrow - \downarrow\uparrow)_z \tag{30.24a}$$

$$(\uparrow\downarrow + \downarrow\uparrow)_{\alpha,\varphi} = -\sin\alpha\left[e^{-i\varphi}(\uparrow\uparrow)_z - e^{i\varphi}(\downarrow\downarrow)_z\right] + \cos\alpha(\uparrow\downarrow + \downarrow\uparrow)_z. \tag{30.24b}$$

It can be seen from this that if a triplet component of the form (30.24b) is created in the barrier region, it gives rise to $f_{\uparrow\uparrow}^{\mathrm{FM}}$ and $f_{\downarrow\downarrow}^{\mathrm{FM}}$ correlations in the ferromagnet with relative phase of $\pi + 2\varphi$. This leads to a non-trivial current-phase relation in Josephson devices, in which two singlet superconductors are connected by the two spin bands of the ferromagnet, each with their own separate current-phase relation [172]. The azimuthal angle φ plays a crucial role in such devices [107, 133, 173].

For the case of a long-wavelength magnetic inhomogeneity one has to deal with the spatial variation of the pair amplitudes, which can be done within the framework of quantum transport equations, which we discuss in the next section. In general, the scattering matrix should be calculated from first principles or from microscopic models, taking into account disorder, band anisotropy, and micromagnetics.

30.4 Theoretical tools

Theoretical treatments of superconductor-ferromagnet heterostructures can be separated into two types: microscopic treatments and quasiclassical treatments. There are two main methods, which both can be applied to the two types of theories: wave-function methods and Green function methods. Green function methods are based on an asymptotic expansion of the fundamental many-body Hamiltonian, whereas wave function methods work preferably with an effective mean-field Hamiltonian. Green function methods allow in an easier way for the treatment of disorder, and for generalization to strong coupling with bosonic excitations and to non-equilibrium situations. The resulting four theoretical frameworks with their corresponding equations of motion are shown in table 3. The Bogoliubov-de Gennes equations [78, 9] lead in quasiclassical approximation to the Andreev equations for the envelopes of the waves [83]. Alternatively, one can start from the microscopic Nambu-Gor'kov matrix Green functions obeying the Gor'kov equations [10, 174]. These lead in quasiclassical approximation to the

with the azimuthal angle φ should arise.

Eilenberger-Larkin-Ovchinnikov equations [175, 176], where the concepts of BCS pairing theory of superconductors [8] were merged with the concepts of Boltzmann transport equations within Landau's Fermi-liquid theory [177]. An extension to non-equilibrium was developed by Eliashberg [178] and by Larkin and Ovchinnikov [179]. In quasiclassical approximation the Gor'kov equations result into envelope Green functions that vary on the superconducting coherence length scale and are free of irrelevant fine-scale structures on the Fermi wavelength scale. Dynamical phenomena are described in Green function methods within the Keldysh technique [180].

In this review we concentrate on two, which have been mostly used so far in the literature: microscopic wave function methods based on the Bogoliubov-de Gennes equations, and quasiclassical Green function methods, based on Eilenberger-Larkin-Ovchinnikov equations and their counterpart for diffusive systems, the Usadel equations. The two other frameworks, not covered in this review, are formulated in terms of Andreev equations and in terms of Gor'kov equations.

30.4.1 Bogoliubov-de Gennes equations

The Hartree-Fock-Bogoliubov (HFB) mean-field Hamiltonian

$$\mathcal{H}_{\rm HFB} = \int\int d^3\mathbf{r}d^3\mathbf{r}' \sum_{\sigma\sigma'\in\{\uparrow,\downarrow\}} \Big(H_{\mathbf{r}\sigma,\mathbf{r}'\sigma'}\, \psi^\dagger_{\mathbf{r}\sigma}\psi_{\mathbf{r}'\sigma'} + \frac{1}{2}\Delta_{\mathbf{r}\sigma,\mathbf{r}'\sigma'}\psi^\dagger_{\mathbf{r}\sigma}\psi^\dagger_{\mathbf{r}'\sigma'} + \frac{1}{2}\Delta^*_{\mathbf{r}\sigma,\mathbf{r}'\sigma'}\psi_{\mathbf{r}'\sigma'}\psi_{\mathbf{r}\sigma}\Big) \tag{30.25}$$

is the basis for the Bogoliubov-de Gennes theory. Hermiticity requires $H_{\mathbf{r}\sigma,\mathbf{r}'\sigma'} = H^*_{\mathbf{r}'\sigma',\mathbf{r}\sigma}$, and Fermi statistics leads to $\Delta_{\mathbf{r}\sigma,\mathbf{r}'\sigma'} = -\Delta_{\mathbf{r}'\sigma',\mathbf{r}\sigma}$. The Hamiltonian can be rewritten in a compact form using the 4×4 matrix

$$\hat{H}(\mathbf{r},\mathbf{r}') \equiv \begin{pmatrix} [H_{\mathbf{r}\sigma,\mathbf{r}'\sigma'}]_{2\times2} & [\Delta_{\mathbf{r}\sigma,\mathbf{r}'\sigma'}]_{2\times2} \\ -[\Delta^*_{\mathbf{r}\sigma,\mathbf{r}'\sigma'}]_{2\times2} & -[H^*_{\mathbf{r}\sigma,\mathbf{r}'\sigma'}]_{2\times2} \end{pmatrix} \tag{30.26}$$

where, for example,

$$[H_{\mathbf{r}\sigma,\mathbf{r}'\sigma'}]_{2\times2} = \begin{pmatrix} H_{\mathbf{r}\uparrow,\mathbf{r}'\uparrow} & H_{\mathbf{r}\uparrow,\mathbf{r}'\downarrow} \\ H_{\mathbf{r}\downarrow,\mathbf{r}'\uparrow} & H_{\mathbf{r}\downarrow,\mathbf{r}'\downarrow} \end{pmatrix}. \tag{30.27}$$

With the definitions $\hat{\Psi}^\dagger(\mathbf{r}) = (\psi^\dagger_{\mathbf{r}\uparrow}, \psi^\dagger_{\mathbf{r}\downarrow}, \psi_{\mathbf{r}\uparrow}, \psi_{\mathbf{r}\downarrow})$, $\hat{\Psi}(\mathbf{r}) = (\psi_{\mathbf{r}\uparrow}, \psi_{\mathbf{r}\downarrow}, \psi^\dagger_{\mathbf{r}\uparrow}, \psi^\dagger_{\mathbf{r}\downarrow})^{\rm T}$ (here T denotes a transpose) the Hartree-Fock-Bogoliubov Hamiltonian reads

$$\mathcal{H}_{\rm HFB} = \frac{1}{2}\int\int d^3\mathbf{r}d^3\mathbf{r}' \left(\hat{\Psi}^\dagger(\mathbf{r})\, \hat{H}(\mathbf{r},\mathbf{r}')\, \hat{\Psi}(\mathbf{r}')\right) + \text{const.} \tag{30.28}$$

This Hamiltonian is diagonalized by a Bogoliubov-Valatin transformation [181, 182]. To achieve this, we introduce the notation for the Bogoliubov amplitudes ($\alpha \in \{+,-\}$)

$$U_{n\alpha}(\mathbf{r}) \equiv \begin{pmatrix} u_{\mathbf{r}\uparrow,n\alpha} \\ u_{\mathbf{r}\downarrow,n\alpha} \\ v_{\mathbf{r}\uparrow,n\alpha} \\ v_{\mathbf{r}\downarrow,n\alpha} \end{pmatrix}, \quad \bar{U}_{n\alpha}(\mathbf{r}) \equiv \begin{pmatrix} v^*_{\mathbf{r}\uparrow,n\alpha} \\ v^*_{\mathbf{r}\downarrow,n\alpha} \\ u^*_{\mathbf{r}\uparrow,n\alpha} \\ u^*_{\mathbf{r}\downarrow,n\alpha} \end{pmatrix}. \tag{30.29}$$

Here, the index α may, e.g., refer to another spin basis, or to a helicity basis if strong spin-orbit interactions are present. The quantum numbers n, α fully characterize the eigenstates of the

set of Bogoliubov-de Gennes equations given by

$$\int d^3\mathbf{r}'\hat{H}(\mathbf{r},\mathbf{r}')U_{n\alpha}(\mathbf{r}') = E_{n\alpha}U_{n\alpha}(\mathbf{r}) \tag{30.30a}$$

$$\int d^3\mathbf{r}'\hat{H}(\mathbf{r},\mathbf{r}')\bar{U}_{n\alpha}(\mathbf{r}') = -E_{n\alpha}\bar{U}_{n\alpha}(\mathbf{r}). \tag{30.30b}$$

For each eigenvalue $E_{n\alpha} > 0$ there exists an eigenvalue $-E_{n\alpha}$, with corresponding eigenvectors obtained by the substitution $u_{\mathbf{r}\sigma,n\alpha} \to v^*_{\mathbf{r}\sigma,n\alpha}$, $v_{\mathbf{r}\sigma,n\alpha} \to u^*_{\mathbf{r}\sigma,n\alpha}$. One can divide the quantum numbers n in disjunct sets $\mathcal{Z}$, $\mathcal{P}$ and $\mathcal{N}$ (and relabel them if necessary) such that for $n \in \mathcal{Z}$ we have $E_{n\alpha} = 0$, for $n \in \mathcal{P}$ we have $E_{n\alpha} > 0$ and for $n \in \mathcal{N}$ we have $E_{n\alpha} < 0$. The eigenvectors can be chosen to build an orthonormal set, e.g. for n, n' within $\mathcal{P}$

$$\int d^3\mathbf{r}\sum_\sigma \left(u_{\mathbf{r}\sigma,n\alpha}u^*_{\mathbf{r}\sigma,n'\alpha'} + v_{\mathbf{r}\sigma,n\alpha}v^*_{\mathbf{r}\sigma,n'\alpha'}\right) = \delta_{nn'}\delta_{\alpha\alpha'}, \tag{30.31a}$$

$$\int d^3\mathbf{r}\sum_\sigma \left(u_{\mathbf{r}\sigma,n\alpha}v_{\mathbf{r}\sigma,n'\alpha'} + v_{\mathbf{r}\sigma,n\alpha}u_{\mathbf{r}\sigma,n'\alpha'}\right) = 0. \tag{30.31b}$$

We build for $n \in \mathcal{P}$ a 4×4 matrix $\hat{U}_n(\mathbf{r})$ from the four orthogonal eigenvectors $U_{n+}(\mathbf{r}), U_{n-}(\mathbf{r}), \bar{U}_{n+}(\mathbf{r}), \bar{U}_{n-}(\mathbf{r})$ (or a 4×2 matrix if only one value for α belongs to n). Similarly, for $n \in \mathcal{Z}$ we build a 4×2 matrix $U_{n+}(\mathbf{r}), U_{n-}(\mathbf{r})$ (or a 4×1 matrix if only one value for α belongs to n). Then the completeness relation

$$\sum_{n\in\bar{\mathcal{P}}} \hat{U}_n(\mathbf{r})\hat{U}^\dagger_n(\mathbf{r}') = \delta(\mathbf{r}-\mathbf{r}')\hat{1} \tag{30.32}$$

(with the 4×4 unit matrix $\hat{1}$, and with $\bar{\mathcal{P}} = \mathcal{Z} \cup \mathcal{P}$) holds, which reads explicitly

$$\sum_{n\in\bar{\mathcal{P}},\alpha} \left(u_{\mathbf{r}\sigma,n\alpha}u^*_{\mathbf{r}'\sigma',n\alpha} + s_n v^*_{\mathbf{r}\sigma,n\alpha}v_{\mathbf{r}'\sigma',n\alpha}\right) = \delta_{\sigma\sigma'}\delta(\mathbf{r}-\mathbf{r}') \tag{30.33a}$$

$$\sum_{n\in\bar{\mathcal{P}},\alpha} \left(u_{\mathbf{r}\sigma,n\alpha}v^*_{\mathbf{r}'\sigma',n\alpha} + s_n v^*_{\mathbf{r}\sigma,n\alpha}u_{\mathbf{r}'\sigma',n\alpha}\right) = 0 \tag{30.33b}$$

($s_n = 0$ for $n \in \mathcal{Z}$, $s_n = 1$ else). With this, the Hartree-Fock-Bogoliubov Hamiltonian is diagonalized by

$$\hat{\Psi}(\mathbf{r}) = \sum_{n\in\bar{\mathcal{P}}} \hat{U}_n(\mathbf{r})\hat{\gamma}_n, \quad \hat{\gamma}_n = \int d^3\mathbf{r}\; \hat{U}^\dagger_n(\mathbf{r})\hat{\Psi}(\mathbf{r}), \tag{30.34}$$

with, e.g., $\hat{\gamma}^\dagger_n = (\gamma^\dagger_{n+}, \gamma^\dagger_{n-}, \gamma_{n+}, \gamma_{n-})$, $\hat{\gamma}_n = (\gamma_{n+}, \gamma_{n-}, \gamma^\dagger_{n+}, \gamma^\dagger_{n-})^{\mathrm{T}}$ denoting Bogoliubov quasiparticle operators and $\hat{E}_n \equiv \mathrm{diag}(E_{n+}, E_{n-}, -E_{n+}, -E_{n-})$ corresponding energies, leading to

$$\hat{H}(\mathbf{r},\mathbf{r}') = \sum_{n\in\mathcal{P}} \hat{U}_n(\mathbf{r})\hat{E}_n\hat{U}^\dagger_n(\mathbf{r}') \tag{30.35}$$

$$\mathcal{H}_{\mathrm{HFB}} = \frac{1}{2}\sum_{n\in\mathcal{P}} \hat{\gamma}^\dagger_n\hat{E}_n\hat{\gamma}_n. \tag{30.36}$$

Explicitly, Eq. (30.34) reads

$$\psi_{\mathbf{r}\sigma} = \sum_{n\in\bar{\mathcal{P}},\alpha} \left(u_{\mathbf{r}\sigma,n\alpha}\gamma_{n\alpha} + s_n v^*_{\mathbf{r}\sigma,n\alpha}\gamma^\dagger_{n\alpha}\right) \tag{30.37a}$$

$$\gamma_{n\alpha} = \int d^3\mathbf{r}\sum_\sigma \left(u^*_{\mathbf{r}\sigma,n\alpha}\psi_{\mathbf{r}\sigma} + v^*_{\mathbf{r}\sigma,n\alpha}\psi^\dagger_{\mathbf{r}\sigma}\right). \tag{30.37b}$$

The Majorana property $\gamma_{n\alpha} = \gamma_{n\alpha}^\dagger$ holds if $v_{\mathbf{r}\sigma,n\alpha} = u_{\mathbf{r}\sigma,n\alpha}^*$; for $n \in \mathcal{Z}$ a solution of the Bogoliubov-de Gennes equations can always be chosen of this form provided this is compatible with the boundary conditions. The single-particle part $H^0_{\mathbf{r}\sigma,\mathbf{r}'\sigma'}$ of $H_{\mathbf{r}\sigma,\mathbf{r}'\sigma'}$ has typically the form

$$H^0_{\mathbf{r}\sigma,\mathbf{r}'\sigma'} = \delta(\mathbf{r}-\mathbf{r}')\left\{\varepsilon(\hat{\mathbf{P}}) - \mu + \mathbf{g}(\hat{\mathbf{P}})\cdot\boldsymbol{\sigma} - \mathbf{h}(\mathbf{r})\cdot\boldsymbol{\sigma}\right\}_{\sigma\sigma'} \tag{30.38}$$

with $\hat{\mathbf{P}} = -i\hbar\nabla_{\mathbf{r}} - e\mathbf{A}(\mathbf{r})$. Here, $\varepsilon(\hat{\mathbf{P}})$ is even in $\hat{\mathbf{P}}$ and $\mathbf{g}(\hat{\mathbf{P}})$ is odd in $\hat{\mathbf{P}}$. The last two terms in Eq. (30.38) describe spin-orbit coupling and Zeeman coupling, and μ is the electrochemical potential. The order parameter is given self-consistently by

$$\Delta_{\mathbf{r}\sigma,\mathbf{r}'\sigma'} = \int\int d^3\mathbf{r}_1 d^3\mathbf{r}_1' \sum_{\sigma_1\sigma_1'} V_{\sigma\sigma'\sigma_1\sigma_1'}(\mathbf{r},\mathbf{r}',\mathbf{r}_1,\mathbf{r}_1')\langle\psi_{\mathbf{r}_1'\sigma_1'}\psi_{\mathbf{r}_1\sigma_1}\rangle. \tag{30.39}$$

with

$$\langle\psi_{\mathbf{r}'\sigma'}\psi_{\mathbf{r}\sigma}\rangle = -\frac{1}{2}\sum_{n\in\mathcal{P},\alpha}\left\{u_{\mathbf{r}\sigma,n\alpha}v^*_{\mathbf{r}'\sigma',n\alpha} - v^*_{\mathbf{r}\sigma,n\alpha}u_{\mathbf{r}'\sigma',n\alpha}\right\}\tanh\frac{E_{n\alpha}}{2k_{\mathrm{B}}T}. \tag{30.40}$$

The spin-dependence of these equations simplifies when the pairing interaction can be split into singlet and triplet parts,

$$V_{\sigma\sigma'\sigma_1\sigma_1'} = \frac{1}{2}(i\sigma_2)_{\sigma\sigma'}V^s(i\sigma_2)^*_{\sigma_1\sigma_1'} + \frac{1}{2}(\boldsymbol{\sigma}i\sigma_y)_{\sigma\sigma'}\cdot\overleftrightarrow{V}^t\cdot(\boldsymbol{\sigma}i\sigma_y)^*_{\sigma_1\sigma_1'}, \tag{30.41}$$

and similarly for the order parameter,

$$\Delta_{\mathbf{r}\sigma,\mathbf{r}'\sigma'} = \Delta^s_{\mathbf{r},\mathbf{r}'}(i\sigma_2)_{\sigma\sigma'} + \boldsymbol{\Delta}^t_{\mathbf{r},\mathbf{r}'}\cdot(\boldsymbol{\sigma}i\sigma_y)_{\sigma\sigma'}. \tag{30.42}$$

The gap equation for spin singlet and triplet ferromagnetic superconductors has been scrutinized by Powell, Annett, and Györffy [183].

In order to study odd-frequency amplitudes one uses a Heisenberg representation

$$\psi_{\mathbf{r}\sigma}(t) = \sum_{n\in\bar{\mathcal{P}},\alpha}\left(u_{\mathbf{r}\sigma,n\alpha}e^{\frac{i}{\hbar}E_{n\alpha}t}\gamma_{n\alpha} + s_n v^*_{\mathbf{r}\sigma,n\alpha}e^{-\frac{i}{\hbar}E_{n\alpha}t}\gamma^\dagger_{n\alpha}\right) \tag{30.43}$$

and evaluates the pair correlation function [184]

$$F_{\mathbf{r}\sigma,\mathbf{r}'\sigma'}(t) = \langle\psi_{\mathbf{r}\sigma}(t)\psi_{\mathbf{r}'\sigma'}(0)\rangle \tag{30.44}$$

using $\langle\gamma^\dagger_{n\alpha}\gamma_{n\alpha}\rangle = f(E_{n\alpha})$, $\langle\gamma_{n\alpha}\gamma^\dagger_{n\alpha}\rangle = 1 - f(E_{n\alpha})$, with $f(E_{n\alpha}) = [1-\tanh(E_{n\alpha}/2k_{\mathrm{B}}T)]/2$ the fermionic distribution function. Concentrating on local correlation functions, one obtains [184, 185]

$$F_{\mp}(\mathbf{r},t) \equiv F_{\mathbf{r}\uparrow,\mathbf{r}\downarrow}(t) \mp F_{\mathbf{r}\downarrow,\mathbf{r}\uparrow}(t) = \sum_{n\in\mathcal{P},\alpha}\left(u_{\mathbf{r}\uparrow,n\alpha}v^*_{\mathbf{r}\downarrow,n\alpha} \mp u_{\mathbf{r}\downarrow,n\alpha}v^*_{\mathbf{r}\uparrow,n\alpha}\right)\zeta^{\mp}_{n\alpha}(t,T) \tag{30.45a}$$

$$F_{\sigma\sigma}(\mathbf{r},t) \equiv F_{\mathbf{r}\sigma,\mathbf{r}\sigma}(t) = \sum_{n\in\mathcal{P},\alpha}u_{\mathbf{r}\sigma,n\alpha}v^*_{\mathbf{r}\sigma,n\alpha}\zeta^{+}_{n\alpha}(t,T) \tag{30.45b}$$

for the singlet (F_-) and the three triplet ($F_+, F_{\uparrow\uparrow}, F_{\downarrow\downarrow}$) components, where

$$\zeta^-_{n\alpha}(t,T) \equiv \cos\left(\frac{E_{n\alpha}t}{\hbar}\right)\tanh\left(\frac{E_{n\alpha}}{2k_{\mathrm{B}}T}\right) - i\sin\left(\frac{E_{n\alpha}t}{\hbar}\right), \tag{30.46a}$$

$$\zeta^+_{n\alpha}(t,T) \equiv \cos\left(\frac{E_{n\alpha}t}{\hbar}\right) - 1 - i\sin\left(\frac{E_{n\alpha}t}{\hbar}\right)\tanh\left(\frac{E_{n\alpha}}{2k_{\mathrm{B}}T}\right). \tag{30.46b}$$

The triplet correlations show a time dependence according to $\zeta^{+}_{n\alpha}$ and consequently vanish identically for $t = 0$, whereas the singlet correlations, governed by $\zeta^{-}_{n\alpha}$, survive. This expresses the odd-frequency nature of the local triplet pair correlations in contrast to the even-frequency nature of the local singlet pair correlations. In particular, for $t \to -i\tau$ with $\hbar/k_{\rm B}T > \tau \geq 0$, and applying KMS boundary conditions $\zeta^{\mp}_{n\alpha}(-i\tau + i\hbar/k_{\rm B}T, T) = -\zeta^{\mp}_{n\alpha}(-i\tau, T)$, the relations $\zeta^{\mp}_{n\alpha}(i\tau, T) = \pm\zeta^{\mp}_{n\alpha}(-i\tau, T)$ follow.

Similarly, measurable quantities like magnetization, current density, and charge density can be expressed in terms of Bogoliubov quasiparticle operators using Eq. (30.37a) and evaluated using the solutions of the Bogoliubov-de Gennes equations.

30.4.2 Quasiclassical theory of superconductivity

The treatment of a superconductor in the presence of a Zeeman spin-splitting induced by an external magnetic field has been theoretically investigated in detail by Alexander, Orlando, Rainer, and Tedrow in 1985 [186] within quasiclassical theory of superconductivity. This theory, a generalization of previous studies for superfluid ^{3}He [187, 110, 188], includes Fermi liquid effects self-consistently, as well as impurity scattering (including ballistic and diffusive limits), internal exchange fields, and spin-orbit effects[46]. It is formulated in terms of generalized Landau parameters $A^{s,a}(\hat{\boldsymbol{p}}_f, \hat{\boldsymbol{p}}'_f)$ as well as singlet and triplet pairing interactions $V^{s,t}(\hat{\boldsymbol{p}}_f, \hat{\boldsymbol{p}}'_f)$, based on Leggett's treatment for clean systems [187, 110], and combines previous theories of Fulde [189] and Buchholtz and Zwicknagl [190]. First experimental tests of these theories were performed by Tedrow and Meservey [191]. Generalized Landau parameters lead for example to anisotropic renormalizations of the quasiparticle magnetic moment by coupling to electrons outside the phase space regions where quasiparticles live ("high-energy electrons").

For reviews of quasiclassical theory of superconductivity see Refs. [192, 193, 188, 194, 195, 196, 197, 198, 199, 200, 201]. Quasiclassical theory is an expansion in quantities like temperature or gap divided by Fermi energy, or Fermi wavelength divided by superconducting coherence length [188, 202, 203, 204, 205]. It predicts its own breakdown in low dimensions [206].

The central quantity in quasiclassical theory of superconductivity is the quasiclassical 4×4 matrix propagator or Green function $\hat{g}(\hat{\boldsymbol{p}}_f, \boldsymbol{R}; \varepsilon)$, which depends on the spatial coordinate $\boldsymbol{R}$, on energy ε, and on the momentum directions $\hat{\boldsymbol{p}}_f$ on the Fermi surface (out of equilibrium there is in addition a time dependence and the formalism can be extended to 8×8 Keldysh matrices [180]). The 2×2 Nambu-Gor'kov matrix structure of $\hat{g}$ reflects the particle-hole degree of freedom [10, 174]. Its matrix elements are 2×2 spin matrices (if the spin-splitting of the energy bands is not comparable to the energy band width, otherwise they are scalar). We will use a notation of unit matrices and Pauli matrices in spin space and particle hole space, where $(\sigma_0, \sigma_1, \sigma_2, \sigma_3)$ refers to spin and $(\hat{\tau}_0, \hat{\tau}_1, \hat{\tau}_2, \hat{\tau}_3)$ to particle-hole degrees of freedom. We expand the elements in Nambu-Gor'kov space into spin-scalars and spin-vectors,

$$\hat{g} = \begin{pmatrix} g\sigma_0 + \boldsymbol{g}\cdot\boldsymbol{\sigma} & (f\sigma_0 + \boldsymbol{f}\cdot\boldsymbol{\sigma})i\sigma_2 \\ i\sigma_2(\tilde{f}\sigma_0 - \tilde{\boldsymbol{f}}\cdot\boldsymbol{\sigma}) & \sigma_2(\tilde{g}\sigma_0 - \tilde{\boldsymbol{g}}\cdot\boldsymbol{\sigma})\sigma_2 \end{pmatrix}. \tag{30.47}$$

with e.g. $\boldsymbol{g} = (g_x, g_y, g_z)$ the vector part of $\hat{g}_{11}$, and g its scalar part. Of particular interest for this review are $\boldsymbol{f}$, $\tilde{\boldsymbol{f}}$, describing spin-triplet correlations, and $\boldsymbol{g}$, $\tilde{\boldsymbol{g}}$ describing the spin magnetization and the spin current that develop as a result of the generation of triplet correlations.

[46] The derivation in this work is more rigorous than in the later work by Demler *et al.* in 1997 [90].

30.4.3 Eilenberger equations

We discuss first the case when the spin splitting of the energy bands is small (comparable to the superconducting energy scales), so that it can be treated as a perturbation around the un-split Fermi surface. In this case one can integrate out the energy dependence of the Green's functions identically for the spins $\uparrow$ and $\downarrow$ [164] and assume spin-independent Fermi velocities $\boldsymbol{v}_f(\hat{\boldsymbol{p}}_f)$. The propagator $\hat{g}$ obeys the Eilenberger transport equation [175, 176]

$$\Big[\varepsilon\hat{\tau}_3 - \hat{h},\, \hat{g}\Big] + i\hbar\, \boldsymbol{v}_f \cdot \nabla_{\boldsymbol{R}}\, \hat{g} = \hat{0} \tag{30.48}$$

with the normalization condition [175]

$$\hat{g}^2 = -\pi^2 \hat{\tau}_0, \tag{30.49}$$

where $\boldsymbol{v}_f(\hat{\boldsymbol{p}}_f)$ is the Fermi velocity for the direction $\hat{\boldsymbol{p}}_f$ at the Fermi surface, and with

$$\hat{h} = \hat{v}_{\rm ext} + \hat{\sigma}_{\rm mf} + \hat{\sigma}_{\rm imp} \tag{30.50}$$

where $\hat{v}_{\rm ext}$ are external potentials, $\hat{\sigma}_{\rm mf}$ are Fermi liquid mean fields (both diagonal and off-diagonal), and $\hat{\sigma}_{\rm imp}$ is the impurity self energy. The matrix $\hat{h}(\hat{\boldsymbol{p}}_f, \boldsymbol{R}; \varepsilon)$ entering the Eilenberger equation (30.48) has a similar structure as $\hat{g}$,

$$\hat{h} = \begin{pmatrix} \nu\sigma_0 + \boldsymbol{\nu}\cdot\boldsymbol{\sigma} & (\Delta\sigma_0 + \boldsymbol{\Delta}\cdot\boldsymbol{\sigma})i\sigma_2 \\ i\sigma_2(\tilde{\Delta}\sigma_0 - \tilde{\boldsymbol{\Delta}}\cdot\boldsymbol{\sigma}) & \sigma_2(\tilde{\nu}\sigma_0 - \tilde{\boldsymbol{\nu}}\cdot\boldsymbol{\sigma})\sigma_2 \end{pmatrix} \tag{30.51}$$

The Nambu-Gor'kov matrix structure contains some redundancy, which results into symmetries between the particle and hole elements [188]. They are expressed by the tilde operation $\tilde{q}(\hat{\boldsymbol{p}}_f, \boldsymbol{R}; \varepsilon) = q(-\hat{\boldsymbol{p}}_f, \boldsymbol{R}; -\varepsilon^*)^*$ for $q \in \{g, f, \boldsymbol{g}, \boldsymbol{f}, \nu, \Delta, \boldsymbol{\nu}, \boldsymbol{\Delta}\}$. Matsubara propagators are obtained by $(\varepsilon \to i\varepsilon_n)$ (where $\varepsilon_n = \pi k_{\rm B} T(2n+1)$ is the Matsubara energy), retarded propagators by $(\varepsilon \to \varepsilon + i\delta)$, and advanced propagators by $(\varepsilon \to \varepsilon - i\delta)$. Further fundamental symmetry relations are: $g(\varepsilon^*) = g(\varepsilon)^*$, $\boldsymbol{g}(\varepsilon^*) = \boldsymbol{g}(\varepsilon)^*$, $f(\varepsilon^*) = \tilde{f}(\varepsilon)^*$, $\boldsymbol{f}(\varepsilon^*) = -\tilde{\boldsymbol{f}}(\varepsilon)^*$ (we omitted here for brevity the other arguments).

The self-consistency equations for the impurity self energy $\hat{\sigma}_{\rm imp}$ for impurity types i with impurity potential $\hat{v}_i$ and impurity concentration n_i is

$$\hat{\sigma}_{\rm imp}(\hat{\boldsymbol{p}}_f, \boldsymbol{R}; \varepsilon) = \sum_i n_i \hat{t}_i(\hat{\boldsymbol{p}}_f, \hat{\boldsymbol{p}}_f, \boldsymbol{R}; \varepsilon) \tag{30.52}$$

with the quasiclassical T-matrix equation

$$\begin{aligned} \hat{t}_i(\hat{\boldsymbol{p}}_f, \hat{\boldsymbol{p}}'_f, \boldsymbol{R}; \varepsilon) &= \hat{v}_i(\hat{\boldsymbol{p}}_f, \hat{\boldsymbol{p}}'_f) + \\ &+ \langle N_f(\hat{\boldsymbol{p}}''_f)\hat{v}_i(\hat{\boldsymbol{p}}_f, \hat{\boldsymbol{p}}''_f)\hat{g}(\hat{\boldsymbol{p}}''_f, \boldsymbol{R}; \varepsilon)\hat{t}_i(\hat{\boldsymbol{p}}''_f, \hat{\boldsymbol{p}}'_f, \boldsymbol{R}; \varepsilon)\rangle_{\hat{\boldsymbol{p}}''_f} \end{aligned} \tag{30.53}$$

$\langle \dots \rangle_{\hat{\boldsymbol{p}}_f} = \int d^2\hat{\boldsymbol{p}}_f/(2\pi\hbar)^2 \dots$ denotes a Fermi-surface integral, and $N_f(\hat{\boldsymbol{p}}_f) = (2\pi\hbar|\boldsymbol{v}_f|)^{-1}$ is for a fixed Fermi surface point the (one-dimensional) density of states in perpendicular direction to the Fermi surface, per spin projection, in the normal state.

The Fermi-liquid mean-field self energies $\hat{\sigma}_{\rm mf}$ are self-consistently determined from

$$\nu_{\rm mf}(\hat{\boldsymbol{p}}_f, \boldsymbol{R}) = k_{\rm B}T \sum_{\varepsilon_n} \big\langle N_f(\hat{\boldsymbol{p}}'_f) W^s(\hat{\boldsymbol{p}}_f, \hat{\boldsymbol{p}}'_f) g(\hat{\boldsymbol{p}}'_f, \boldsymbol{R}; \varepsilon_n)\big\rangle_{\hat{\boldsymbol{p}}'_f} \tag{30.54a}$$

$$\boldsymbol{\nu}_{\rm mf}(\hat{\boldsymbol{p}}_f, \boldsymbol{R}) = k_{\rm B}T \sum_{\varepsilon_n} \big\langle N_f(\hat{\boldsymbol{p}}'_f)\, \overleftrightarrow{W}^a\, (\hat{\boldsymbol{p}}_f, \hat{\boldsymbol{p}}'_f)\boldsymbol{g}(\hat{\boldsymbol{p}}'_f, \boldsymbol{R}; \varepsilon_n)\big\rangle_{\hat{\boldsymbol{p}}'_f} \tag{30.54b}$$

$$\Delta_{\rm mf}(\hat{\boldsymbol{p}}_f, \boldsymbol{R}) = k_{\rm B}T \sum_{\varepsilon_n} \big\langle N_f(\hat{\boldsymbol{p}}'_f) V^s(\hat{\boldsymbol{p}}_f, \hat{\boldsymbol{p}}'_f) f(\hat{\boldsymbol{p}}'_f, \boldsymbol{R}; \varepsilon_n)\big\rangle_{\hat{\boldsymbol{p}}'_f} \tag{30.54c}$$

$$\boldsymbol{\Delta}_{\rm mf}(\hat{\boldsymbol{p}}_f, \boldsymbol{R}) = k_{\rm B}T \sum_{\varepsilon_n} \big\langle N_f(\hat{\boldsymbol{p}}'_f)\, \overleftrightarrow{V}^t\, (\hat{\boldsymbol{p}}_f, \hat{\boldsymbol{p}}'_f)\boldsymbol{f}(\hat{\boldsymbol{p}}'_f, \boldsymbol{R}; \varepsilon_n)\big\rangle_{\hat{\boldsymbol{p}}'_f}. \tag{30.54d}$$

Fermi-liquid interactions are parameterized by dimensionless Fermi-liquid parameters $A^s(\hat{\boldsymbol{p}}_f,\hat{\boldsymbol{p}}'_f) = N_f W^s(\hat{\boldsymbol{p}}_f,\hat{\boldsymbol{p}}'_f)$ and $\overleftrightarrow{A}^a\ (\hat{\boldsymbol{p}}_f,\hat{\boldsymbol{p}}'_f) = N_f\ \overleftrightarrow{W}^a\ (\hat{\boldsymbol{p}}_f,\hat{\boldsymbol{p}}'_f)$, with $N_f = \langle N_f(\hat{\boldsymbol{p}}_f)\rangle_{\hat{\boldsymbol{p}}_f}$ the density of states per spin projection at the Fermi level, and the superconducting pair potentials by singlet and triplet pairing interactions V^s and $\overleftrightarrow{V}^t$ (where $\overleftrightarrow{W}^a$, $\overleftrightarrow{A}^a$, and $\overleftrightarrow{V}^t$ are in general tensors).

Finally, $\hat{v}_{\rm ext}$ contains the coupling to external fields, for example the electro-magnetic coupling to a magnetic vector potential $\boldsymbol{A}(\boldsymbol{R})$,

$$\hat{v}_{\rm orbital}(\hat{\boldsymbol{p}}_f,\boldsymbol{R}) = -e\boldsymbol{v}_f(\hat{\boldsymbol{p}}_f)\cdot\boldsymbol{A}(\boldsymbol{R})\hat{\tau}_3 \tag{30.55}$$

($e=-|e|$), and the Pauli-coupling to the quasiparticle spin

$$\hat{v}_{\rm spin}(\hat{\boldsymbol{p}}_f,\boldsymbol{R}) = -\boldsymbol{B}(\boldsymbol{R})\cdot\overleftrightarrow{\mu}_{\rm eff}\ (\hat{\boldsymbol{p}}_f)\cdot\hat{\boldsymbol{S}} \tag{30.56}$$

with the effective quasiparticle magnetic moment[47]

$$\overleftrightarrow{\mu}_{\rm eff}\ (\hat{\boldsymbol{p}}_f) = \big[\hat{1} - \overleftrightarrow{A}^a\ (\hat{\boldsymbol{p}}_f)\big]\mu_{\rm e} \tag{30.57}$$

where $\overleftrightarrow{A}^a\ (\hat{\boldsymbol{p}}_f) = N_f^{-1}\langle N_f(\hat{\boldsymbol{p}}'_f)\ \overleftrightarrow{A}^a\ (\hat{\boldsymbol{p}}_f,\hat{\boldsymbol{p}}'_f)\rangle_{\hat{\boldsymbol{p}}'_f}$, and the spin matrix in particle-hole space

$$\hat{\boldsymbol{S}} = \begin{pmatrix} \boldsymbol{\sigma} & 0 \\ 0 & -\sigma_2\boldsymbol{\sigma}\sigma_2 \end{pmatrix}. \tag{30.58}$$

$\mu_{\rm e}$ is the electron magnetic moment ($\mu_{\rm e} = -|\mu_{\rm e}|$).[48] The vector potential $\boldsymbol{A}$ and hence the magnetic field ($\boldsymbol{B} = \nabla\times\boldsymbol{A}$) are calculated from the current density as

$$\nabla\times\nabla\times\boldsymbol{A}(\boldsymbol{R}) = \mu_0\boldsymbol{j}(\boldsymbol{R}) \tag{30.59}$$

with the permeability of free space μ_0. The scalar electrochemical potential follows from local charge quasi-neutrality, and is zero in equilibrium. The charge current density is obtained from $\hat{g}(\hat{\boldsymbol{p}}_f,\boldsymbol{R};\varepsilon_n)$ via

$$\boldsymbol{j}(\boldsymbol{R}) = 2ek_{\rm B}T\sum_{\varepsilon_n}\big\langle N_f(\hat{\boldsymbol{p}}_f)\boldsymbol{v}_f(\hat{\boldsymbol{p}}_f)g(\hat{\boldsymbol{p}}_f,\boldsymbol{R};\varepsilon_n)\big\rangle_{\hat{\boldsymbol{p}}_f}, \tag{30.60}$$

the spin current density for spin projection along the axis $\boldsymbol{e}_\alpha$ via

$$\boldsymbol{J}_\alpha(\boldsymbol{R}) = 2ek_{\rm B}T\sum_{\varepsilon_n}\big\langle N_f(\hat{\boldsymbol{p}}_f)\boldsymbol{v}_f(\hat{\boldsymbol{p}}_f)[\boldsymbol{e}_\alpha\cdot\boldsymbol{g}(\hat{\boldsymbol{p}}_f,\boldsymbol{R};\varepsilon_n)]\big\rangle_{\hat{\boldsymbol{p}}_f} \tag{30.61}$$

and the spin magnetization via

$$\boldsymbol{M}(\boldsymbol{R}) = \overleftrightarrow{\chi}_{\rm n}\,\boldsymbol{B}(\boldsymbol{R}) + 2k_{\rm B}T\sum_{\varepsilon_n}\big\langle N_f(\hat{\boldsymbol{p}}_f)\ \overleftrightarrow{\mu}_{\rm eff}(\hat{\boldsymbol{p}}_f)\boldsymbol{g}(\hat{\boldsymbol{p}}_f,\boldsymbol{R};\varepsilon_n)\big\rangle_{\hat{\boldsymbol{p}}_f}, \tag{30.62}$$

where $\overleftrightarrow{\chi}_{\rm n} = 2N_f(\hat{1} - \overleftrightarrow{A}^a_0)\mu_{\rm e}^2$ is the normal state spin susceptibility, defined in terms of the parameter $\overleftrightarrow{A}^a_0 = N_f^{-1}\langle N_f(\hat{\boldsymbol{p}}_f)\overleftrightarrow{A}^a\ (\hat{\boldsymbol{p}}_f)\rangle_{\hat{\boldsymbol{p}}_f}$. The local density of states for a given spin direction $\boldsymbol{e}$ is calculated at real energies as

$$N_{\boldsymbol{e}}(\boldsymbol{R};\varepsilon) = -\frac{1}{\pi}{\rm Im}\langle N_f(\hat{\boldsymbol{p}}_f)[g(\hat{\boldsymbol{p}}_f,\boldsymbol{R};\varepsilon_+) + \boldsymbol{e}\cdot\boldsymbol{g}(\hat{\boldsymbol{p}}_f,\boldsymbol{R};\varepsilon_+)]\rangle_{\hat{\boldsymbol{p}}_f} \tag{30.63}$$

[47] $\hat{1}$ denotes a 3×3 unit tensor.

[48] $\mu_{\rm e} = -g\mu_{\rm B}/2$, with the Bohr magneton $\mu_{\rm B} = |e|\hbar/2m_e c$ and $g = 2.0$

with $\varepsilon_+ = \varepsilon + i\delta$ ($\delta > 0$ infinitesimal). The Eilenberger equation for $\hat{g}$, its normalization condition, the equations for the self energies $\hat{\sigma}$, and Maxwell's equation for $\boldsymbol{A}$, must be solved self consistently by iteration together with the appropriate boundary conditions imposed on the propagator and the vector potential [207, 208, 209, 210, 211]. Boundary conditions in quasiclassical theory are notoriously difficult to derive, as the quasiclassical propagators show in general jumps at interfaces (see figure 30.12), in contrast to microscopic propagators which are continuous.

A powerful way to implement boundary conditions and to solve Eilenberger equations is the Riccati method [212, 213, 214, 215]. Modern versions of boundary conditions for Eilenberger equations using these techniques are presented e.g. in Refs. [214, 154, 216, 215].

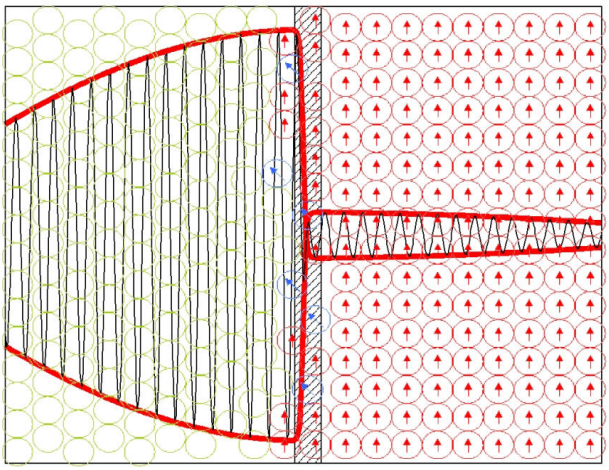

Figure 30.12: In quasiclassical approximation boundary conditions involve relations between the envelope functions of Bloch waves on the two sides of an interface. These envelope functions in general show a jump, even when the Bloch wave functions themselves are continuous.

Instead of applying an external field $\boldsymbol{B}(\boldsymbol{R})$, a superconductor can be spin-polarized via the inverse (or magnetic) proximity effect when in contact with a ferromagnetic material. This effect already appears when the ferromagnet is insulating. A theory for the spin polarization and the associated induced exchange field in the superconductor has been developed by Tokuyasu, Sauls, and Rainer in 1988 [151]. Although differing in details, the general mechanism presented there is essentially the same as for all subsequent studies of the inverse proximity effect in superconductor/ferromagnet heterostructures in the last decade: the appearance of a Cooper pair spin polarization, or of triplet pair correlations, in the superconductor creates a finite spin magnetization inside the superconducting region, extending roughly a coherence length away from the interface. This decay length is dictated by the decay of triplet pair correlations as the bulk of the singlet superconductor is approached.

30.4.4 Normalization condition and transport equation in spin-space

The interrelation between triplet amplitudes and induced magnetic moment can be understood within quasiclassical theory already by the normalization condition for the propagator. The normalization condition (30.49) encodes important information about the spin structure of the diagonal and off-diagonal propagators [217]. In equilibrium, physical solutions require the condition

$$\mathrm{Tr}\,(\hat{g}) = 0, \quad \text{i.e.} \quad \tilde{g}_0 = -g_0 \tag{30.64}$$

which also ensure local charge neutrality to leading order in the Fermi liquid expansion parameters. It is useful to introduce the notation $\boldsymbol{g}_\pm = (\boldsymbol{g} \pm \tilde{\boldsymbol{g}})/2$, $\boldsymbol{\nu}_\pm = (\boldsymbol{\nu} \pm \tilde{\boldsymbol{\nu}})/2$, $\nu_\pm = (\nu \pm \tilde{\nu})/2$. The external and internal fields are distributed according to: $\hat{v}_{\rm orbital}$ in ν_-; $\hat{v}_{\rm spin}$ in $\boldsymbol{\nu}_+$, which also contains the internal exchange field $\boldsymbol{J}$; spin-orbit band splitting in $\boldsymbol{\nu}_-$. In terms of measurable quantities, $\boldsymbol{g}_+$ determines the magnetization, $\boldsymbol{g}_-$ the spin current density, and g_0 the charge current density. One obtains from (30.49) and (30.64) for the spin components in (30.47) [217]

$$g_0^2 + \pi^2 = f\tilde{f} - \boldsymbol{f}\cdot\tilde{\boldsymbol{f}} - \boldsymbol{g}_+^2 - \boldsymbol{g}_-^2 \tag{30.65a}$$

$$2g_0\boldsymbol{g}_- = i\,\tilde{\boldsymbol{f}}\times\boldsymbol{f} \tag{30.65b}$$

$$2g_0\boldsymbol{g}_+ = \tilde{f}\boldsymbol{f} - f\tilde{\boldsymbol{f}} \tag{30.65c}$$

with $\boldsymbol{g}_\pm^2 = g_{x,\pm}^2 + g_{y,\pm}^2 + g_{z,\pm}^2 = \boldsymbol{g}_\pm\cdot\boldsymbol{g}_\pm$. It follows immediately that $\boldsymbol{g}_+\cdot\boldsymbol{g}_- = 0$, $f\boldsymbol{g}_- = i\boldsymbol{f}\times\boldsymbol{g}_+$ and $\boldsymbol{f}\cdot\boldsymbol{g}_- = \tilde{\boldsymbol{f}}\cdot\boldsymbol{g}_- = 0$. According to (30.65b), $\boldsymbol{g}_- = \boldsymbol{0}$ when $\boldsymbol{f} \parallel \tilde{\boldsymbol{f}}$. Moreover, from (30.65b)-(30.65c) it follows that $\boldsymbol{g}_+ = \boldsymbol{g}_- = \boldsymbol{0}$ when $\boldsymbol{f} = \tilde{\boldsymbol{f}} = \boldsymbol{0}$. The Eilenberger equations read

$$\frac{1}{2}\,i\hbar\,\boldsymbol{v}_f\cdot\nabla_{\boldsymbol{R}}\,f + (\varepsilon - \nu_-)\,f = \boldsymbol{\nu}_+\cdot\boldsymbol{f} - g\Delta - \boldsymbol{g}_+\cdot\boldsymbol{\Delta} \tag{30.66a}$$

$$\begin{aligned}\frac{1}{2}\,i\hbar\,(\boldsymbol{v}_f\cdot\nabla_{\boldsymbol{R}})\,\boldsymbol{f} + (\varepsilon - \nu_-)\,\boldsymbol{f} &- i\boldsymbol{\nu}_-\times\boldsymbol{f} = \\ &= \boldsymbol{\nu}_+ f - \boldsymbol{g}_+\Delta - g\boldsymbol{\Delta} - i\boldsymbol{g}_-\times\boldsymbol{\Delta},\end{aligned} \tag{30.66b}$$

which must be solved together with (30.65a), (30.65b) and (30.65c). These equations have to be complemented by self-consistency equations for the self-energies. Near $T_{\rm c}$ all off-diagonal quantities (f, $\boldsymbol{f}$, Δ, $\boldsymbol{\Delta}$) are small, and then from (30.65a)-(30.65c) follows that $\boldsymbol{g}_\pm$ can be neglected being second order in $\boldsymbol{f}$, $\tilde{\boldsymbol{f}}$, and g can be replaced by its normal state value [$-i\pi{\rm sign}(\varepsilon_n)$ in Matsubara representation]. If one introduces the matrices

$$\overleftrightarrow{V} = \begin{pmatrix} \nu_- & \nu_{+,x} & \nu_{+,y} & \nu_{+,z} \\ \nu_{+,x} & \nu_- & i\nu_{-,z} & -i\nu_{-,y} \\ \nu_{+,y} & -i\nu_{-,z} & \nu_- & i\nu_{-,x} \\ \nu_{+,z} & i\nu_{-,y} & -i\nu_{-,x} & \nu_- \end{pmatrix} \tag{30.67}$$

and

$$\overleftrightarrow{G} = \begin{pmatrix} g & g_{+,x} & g_{+,y} & g_{+,z} \\ g_{+,x} & g & ig_{-,z} & -ig_{-,y} \\ g_{+,y} & -ig_{-,z} & g & ig_{-,x} \\ g_{+,z} & ig_{-,y} & -ig_{-,x} & g \end{pmatrix} \tag{30.68}$$

as well as the vectors

$$\mathbf{F} = \begin{pmatrix} f \\ f_x \\ f_y \\ f_z \end{pmatrix}, \quad \mathbf{\Delta} = \begin{pmatrix} \Delta \\ \Delta_x \\ \Delta_y \\ \Delta_z \end{pmatrix}, \tag{30.69}$$

then the system (30.66a)-(30.66b) can be written compactly as

$$(i\hbar\,\boldsymbol{v}_f\cdot\nabla_{\boldsymbol{R}} + 2\varepsilon - 2\overleftrightarrow{V})\mathbf{F} = 2\overleftrightarrow{G}\,\mathbf{\Delta}. \tag{30.70}$$

The four eigenvalues of $2(\varepsilon - \overleftrightarrow{V})/\hbar v_f$ determine the wavevectors in the system, and can be calculated as

$$\left[2(\varepsilon - \nu_-) \pm \sqrt{\nu_x^2 + \nu_y^2 + \nu_z^2} \pm \sqrt{\tilde{\nu}_x^2 + \tilde{\nu}_y^2 + \tilde{\nu}_z^2}\right]/(\hbar v_f). \tag{30.71}$$

For a singlet superconductor in proximity contact with a ferromagnet with exchange field $\boldsymbol{J}$, assuming for the following discussion $\nu_- = 0$, $\boldsymbol{\nu}_- = \mathbf{0}$, $\boldsymbol{\nu}_+ = -\boldsymbol{J}$, $\boldsymbol{\Delta} = 0$, the Eilenberger equations simplify to

$$\left(\tfrac{1}{2}\, i\hbar\, \boldsymbol{v}_f \cdot \nabla_{\boldsymbol{R}} + \bar{\varepsilon}\right) f = -\boldsymbol{J}\cdot\boldsymbol{f} - g\Delta \tag{30.72a}$$

$$\left(\tfrac{1}{2}\, i\hbar\, \boldsymbol{v}_f \cdot \nabla_{\boldsymbol{R}} + \bar{\varepsilon}\right) \boldsymbol{f} = -\boldsymbol{J} f - \boldsymbol{g}_+ \Delta. \tag{30.72b}$$

where we have introduced $\bar{\varepsilon} = \varepsilon + i\alpha_\mathrm{s}$ for $\mathrm{Im}(\varepsilon) > 0$ and $\bar{\varepsilon} = \varepsilon - i\alpha_\mathrm{s}$ for $\mathrm{Im}(\varepsilon) < 0$ to account for possible spin-flip scattering with rate $\alpha_\mathrm{s} = \hbar/\tau_\mathrm{s}$, and τ_s is the spin-flip scattering time. The wavevectors are then given by

$$k_{1,2} = 2(\bar{\varepsilon} \pm |\boldsymbol{J}|)/\hbar v_f, \quad k_{3,4} = 2\bar{\varepsilon}/\hbar v_f. \tag{30.73}$$

In a superconductor-ferromagnet hybrid structure, the superconducting order parameter vanishes in the ferromagnetic regions, $\Delta_\mathrm{mf} = 0$. The proximity effect manifests itself in nonzero pair amplitudes $f, \boldsymbol{f} \neq 0$ in the ferromagnet. In the superconductor, the exchange field vanishes, $\boldsymbol{J} = \mathbf{0}$, expressing the non-coexistence of superconducting and ferromagnetic orders. 30.73 defines the propagation and decay of Cooper pairs into the ferromagnet. If one replaces ε by the first Matsubara energy $i\pi k_\mathrm{B}T$, then one obtains an exponential decay on the length scale $\xi_T = \hbar v_f/2(\pi k_\mathrm{B}T + \alpha_\mathrm{s})$. In addition, two of the components oscillate on the length scale $\xi_J = \hbar v_f/2|\boldsymbol{J}|$ (with wavelength $2\pi\xi_J$) along the direction $\boldsymbol{v}_f$. After averaging over all directions, this leads to an algebraic decay $\sim 1/x$ in x-direction away from the interface, before on a larger length scale ξ_T exponential decay sets in [107]. The components with wavevectors $k_{1,2}$, oscillating on the scale ξ_J, correspond to eigenvectors with $\boldsymbol{f} = \pm f\boldsymbol{J}/|\boldsymbol{J}|$ (i.e. $\boldsymbol{f}\times\boldsymbol{J} = \mathbf{0}$), and represent an equal weight superposition of the singlet amplitude ($S = 0, S_z = 0$) and the triplet amplitude with zero spin-projection to $\boldsymbol{J}$ ($S = 1, S_z = 0$). The (degenerate) components with wavevectors $k_{3,4}$, insensitive to $\boldsymbol{J}$, correspond to an eigenvector where $f = 0$, $\boldsymbol{f}\cdot\boldsymbol{J} = 0$, and represent equal-spin pairing amplitudes with respect to the quantization axis $\boldsymbol{J}$ ($S = 1, S_z = \pm 1$). For increasing exchange field, the pre-factor for the proximity amplitudes oscillating with wavelength ξ_J is of order $\Delta/|\boldsymbol{J}|$, and thus vanishes in the limit of large exchange splitting.

30.4.5 Usadel equations

In the dirty (diffusive) limit, the transport equation (30.48) can be greatly simplified. A strong scattering by impurities averages the quasiclassical propagator over momentum directions. The Green's function may be expanded in the small parameter τT_c (τ is the momentum relaxation time) following the standard procedure [218, 186]

$$\hat{g}(\hat{\boldsymbol{p}}_f, \boldsymbol{R}, \varepsilon_n) \approx \hat{g}^{(0)}(\boldsymbol{R}, \varepsilon_n) + \hat{g}^{(1)}(\hat{\boldsymbol{p}}_f, \boldsymbol{R}, \varepsilon_n) \tag{30.74}$$

where the magnitude of $\hat{g}^{(1)}$ is small compared to that of $\hat{g}^{(0)}$. The impurity self-energy is related to an (in general anisotropic) lifetime function $\tau(\hat{\boldsymbol{p}}_f', \hat{\boldsymbol{p}}_f)$ [186]. Substituting (30.74) into (30.48) and (30.49), multiplying with $N_f(\hat{\boldsymbol{p}}_f')v_{f,j}(\hat{\boldsymbol{p}}_f')\tau(\hat{\boldsymbol{p}}_f', \hat{\boldsymbol{p}}_f)$, averaging over momentum directions, and considering that $J\tau/\hbar \ll 1$, one obtains (with the help of the normalization condition) $\langle N_f(\hat{\boldsymbol{p}}_f)v_{f,j}(\hat{\boldsymbol{p}}_f)\hat{g}^{(1)}(\hat{\boldsymbol{p}}_f)\rangle_{\hat{\boldsymbol{p}}_f} = N_f \sum_k (D_{jk}/i\pi)\hat{g}^{(0)}\nabla_k\hat{g}^{(0)}$, where

$$D_{jk} = \frac{1}{N_f^2}\Big\langle\Big\langle N_f(\hat{\boldsymbol{p}}_f')v_{f,j}(\hat{\boldsymbol{p}}_f')\,\tau(\hat{\boldsymbol{p}}_f', \hat{\boldsymbol{p}}_f)\,N_f(\hat{\boldsymbol{p}}_f)v_{f,k}(\hat{\boldsymbol{p}}_f)\Big\rangle_{\hat{\boldsymbol{p}}_f}\Big\rangle_{\hat{\boldsymbol{p}}_f'} \tag{30.75}$$

is the diffusion constant tensor. The function $\hat{g}^{(0)}$ obeys the Usadel transport equation (hereafter we omit the superscript (0) and apply the Einstein summation convention)

$$\left[\varepsilon\hat{\tau}_3 - \hat{h}_0,\, \hat{g}\right] + \frac{\hbar D_{ij}}{\pi}\nabla_i\left(\hat{g}\nabla_j\hat{g}\right) = 0 \tag{30.76}$$

where $\hat{h}_0 = \langle N_f(\hat{\boldsymbol{p}}_f)[\hat{v}_{\rm ext}(\hat{\boldsymbol{p}}_f) + \hat{\sigma}_{\rm mf}(\hat{\boldsymbol{p}}_f)]\rangle_{\hat{\boldsymbol{p}}_f}/N_f$, together with the normalization condition

$$\hat{g}^2 = -\pi^2\hat{\tau}_0. \tag{30.77}$$

The diffusion constant is a material property. It is spin independent in agreement with the approximation of treating all exchange energy effects as perturbation. In the diffusive limit, the different components of g and f in the spin space are related through (30.65a), (30.65b) and (30.65c), since the Green's function $\hat{g}$ averaged over momentum fulfills the same normalization condition as before averaging. A vector potential enters in a gauge invariant manner by replacing the spatial derivative operators by (see e.g. [219])

$$\nabla_i\hat{X} \to \hat{\partial}_i\hat{X} \equiv \nabla_i\hat{X} - i\left[\frac{e}{\hbar}\hat{\tau}_3 A_i, \hat{X}\right]. \tag{30.78}$$

The charge current density is obtained from $\hat{g}(\boldsymbol{R};\varepsilon_n)$ via

$$j_k = \frac{2eN_f D_{kj}}{\pi} k_{\rm B}T \sum_{\varepsilon_n} {\rm Im}\left[f^*\,\overline{\partial}_j f - \boldsymbol{f}^*\,\overline{\partial}_j \boldsymbol{f}\right], \tag{30.79}$$

with $\overline{\partial}_j = \nabla_j - \frac{2ie}{\hbar}A_j$, and the spin-vector current density in spatial k-direction

$$\boldsymbol{J}_k = \frac{2eN_f D_{kj}}{\pi} k_{\rm B}T \sum_{\varepsilon_n} {\rm Re}\left[\boldsymbol{g}\times\nabla_j\boldsymbol{g} + \boldsymbol{f}^*\times\overline{\partial}_j\boldsymbol{f}\right]. \tag{30.80}$$

Note that from Eqs. (30.65b)-(30.65c) follows that $\boldsymbol{g} = \left[{\rm Im}(f^*\boldsymbol{f}) + i{\rm Re}(\boldsymbol{f})\times{\rm Im}(\boldsymbol{f})\right]/{\rm Im}(g_0)$ at Matsubara frequencies. As for the case of Eilenberger equations, an important part of the problem is the formulation of appropriate boundary conditions [220, 221]. In quasiclassical theory this is usually a highly non-trivial task, as boundary conditions are in general non-linear. A powerful way to implement boundary conditions and to solve Usadel equations is also here the Riccati method [72, 222, 223]. Modern versions of boundary conditions for Usadel equations are found in Ref. [152] for weak spin polarization, small spin-dependent scattering phase shifts, and small transmission. A general formulation appropriate for arbitrary transmission, spin polarization, and spin-dependent phase shifts has been derived in Ref. [224]. The tunneling limit of this boundary condition has been used in Ref. [161], and was independently introduced in Ref. [359].[49]

Near the critical temperature T_c, the pair amplitudes f and $\boldsymbol{f}$ are small and the Green's function g deviates only slightly from its value in the normal state, so that the Usadel equations can be linearized and take the simpler form [73, 226, 74]

$$\left(\tfrac{\hbar}{2i}\nabla_j D_{jk}\nabla_k + \bar{\varepsilon}\right) \quad f = \quad -\mathbf{J}\cdot\boldsymbol{f} + i\pi\Delta \tag{30.81}$$

$$\left(\tfrac{\hbar}{2i}\nabla_j D_{jk}\nabla_k + \bar{\varepsilon}\right) \quad \boldsymbol{f} = \quad -\mathbf{J}f, \tag{30.82}$$

where $\bar{\varepsilon}$ is defined as after Eq. (30.72b). The characteristic wavevectors for isotropic systems ($D_{ij} \to D\delta_{ij}$) are now given by (we chose the roots such that ${\rm Im}(k) > 0$)

$$k_{1,2} = (1+i)\sqrt{(\bar{\varepsilon} \pm |\boldsymbol{J}|)/\hbar D}, \quad k_{3,4} = (1+i)\sqrt{\bar{\varepsilon}/\hbar D}. \tag{30.83}$$

If we again substitute $\varepsilon \to i\pi k_{\rm B}T$, this leads to exponential decays for all four solutions. However, there are two long-range solutions with decay length

$$\xi_T = \left(\frac{\hbar D}{2(\pi k_{\rm B}T + \alpha_{\rm s})}\right)^{\frac{1}{2}}, \tag{30.84}$$

[49] A recently suggested alternative boundary condition [225] assumes the simplified case of coinciding spin-quantization axes for reflection and transmission matrix elements of each scattering channel within a channel-conserving approximation, and has a considerably narrower range of applicability.

and two short-range solutions showing damped spatial oscillations with decay length [239]

$$\xi_1 = \left(\frac{\hbar D}{\sqrt{(\pi k_\mathrm{B} T + \alpha_\mathrm{s})^2 + |\boldsymbol{J}|^2} + (\pi k_\mathrm{B} T + \alpha_\mathrm{s})} \right)^{\frac{1}{2}} \tag{30.85}$$

and inverse oscillation wavevector

$$\xi_2 = \left(\frac{\hbar D}{\sqrt{(\pi k_\mathrm{B} T + \alpha_\mathrm{s})^2 + |\boldsymbol{J}|^2} - (\pi k_\mathrm{B} T + \alpha_\mathrm{s})} \right)^{\frac{1}{2}} . \tag{30.86}$$

Note that $\xi_1 < \xi_2$ except when $T = 0$ and $\hbar/\tau_\mathrm{s} = 0$, thus the oscillations are strongly damped, so that one cannot expect to observe many oscillation periods. This is in contrast to the clean case, where the oscillation wavelength is entirely decoupled from the decay length, which can become very long for low temperatures. Thus, many oscillation periods are expected to be observable in experiment. For the diffusive case, on the other hand, both length scales are temperature dependent. This allows for oscillatory behavior as a function of temperature, an effect absent in the clean limit. For $|\boldsymbol{J}| \gg k_\mathrm{B} T, \alpha_\mathrm{s}$ both length scales merge and approach [227]

$$\xi_{1,2} = \sqrt{\frac{\hbar D}{|\boldsymbol{J}|}} \left(1 \mp \frac{\pi k_\mathrm{B} T + \alpha_\mathrm{s}}{2|\boldsymbol{J}|} \right) .$$

With increasing exchange splitting, the decay length shrinks to zero and the short-range proximity amplitudes are expected to be suppressed to unmeasurable size, unless one finds a mechanism to create new types of proximity amplitudes.

30.4.6 General features of the S/F proximity effect

It can be noticed from the transport equation (30.72b) or (30.82) that the triplet vector $\boldsymbol{f}$ obeys in the ferromagnet an inhomogeneous differential equation, implying that $\boldsymbol{f}$ is necessarily non-zero if the singlet component f penetrates in the ferromagnet. For spatially constant exchange field $\boldsymbol{J}$, the triplet vector aligns with $\boldsymbol{J}$. The singlet component and the triplet component with the zero spin-projection on $\boldsymbol{J}$ coexist always in the ferromagnet near the S/F interface. As they both involve electrons from both spin bands, both are characterized by short-range penetration lengths in the ferromagnet.

On the contrary, if the triplet vector $\boldsymbol{f}$ is non-collinear with $\boldsymbol{J}$, triplet components with nonzero spin-projection on $\boldsymbol{J}$ are produced. Since these correspond to equal-spin pairing, they are not limited locally by the paramagnetic interaction with the local exchange field and have long-range scales in the ferromagnet. A misalignment between the triplet vector $\boldsymbol{f}$ and the moment $\boldsymbol{J}$ occurs in presence of sudden changes in orientation of $\boldsymbol{J}$. The reason is that $\boldsymbol{f}$ obeys a differential equation and its variations in orientation have thus to be relatively smooth.

The counterpart for the production of triplet components ($\boldsymbol{f} \neq \boldsymbol{0}$) in the pair amplitudes is the presence of $\boldsymbol{g} \neq \boldsymbol{0}$ in the diagonal components of the Green function [217]. As a direct consequence, the density of states for the up and down spin projections differs [see 30.63]. This feature of the S/F proximity effect has been found numerically as early as in 1999 [228]. In the presence of long-range triplet components, the particle-hole diagonal Green function components contain also off-diagonal terms in the spin-space, a signature of a spin-flip scattering process.

As a result of the spin splitting in the density of states generated by the S/F proximity effect, a spin magnetization $\delta\boldsymbol{M}$ is also induced near the S/F interface. This magnetization

leakage has been investigated in Ref. [229] within a model considering a fixed exchange field. In the dirty limit the spin magnetization induced by the proximity effect is given by [186, 151]

$$\delta \boldsymbol{M}(\boldsymbol{R}) = 2N_f k_{\mathrm{B}} T \overleftrightarrow{\mu}_{\mathrm{eff}} \sum_n \mathrm{Re}\left[\boldsymbol{g}\left(\boldsymbol{R}, \varepsilon_n\right)\right], \tag{30.87}$$

with $\overleftrightarrow{\mu}_{\mathrm{eff}} = (\hat{1} - \overleftrightarrow{A}_0^a)\mu_{\mathrm{e}}$. Since the triplet vector $\boldsymbol{f}$ is also induced in the superconductor near the S/F interface via an inverse proximity effect, the vector $\boldsymbol{g}$ characterizing the magnetic correlations penetrates also in the superconductor according to the relation (30.65c), which for the diffusive limit reads $\mathrm{Im}(g_0)\mathrm{Re}(\boldsymbol{g}) = \mathrm{Im}(f^* \boldsymbol{f})$ (all functions of ε_n).

It is possible to convince oneself that the sum over Matsubara frequencies in the expression (30.87) is nonzero. Indeed, as noticed in Refs. [131, 230, 231], in the diffusive limit the triplet components are odd functions of the Matsubara frequencies ε_n, while the singlet amplitude f is an even function of ε_n. Note that in the diffusive limit

$$g_0(-\varepsilon_n) = -g_0(\varepsilon_n), \quad \boldsymbol{g}(-\varepsilon_n) = \tilde{\boldsymbol{g}}(\varepsilon_n). \tag{30.88}$$

For unitary pairing states, $\boldsymbol{f} \times \tilde{\boldsymbol{f}} = \boldsymbol{0}$, the relations (30.65b)-(30.65c) between the vectors $\boldsymbol{g}$ and $\boldsymbol{f}$ get simplified. In this case, it can be seen that if the gap Δ can be chosen real (and thus the singlet amplitude $f(\varepsilon_n)$ is real), then the triplet vector $\boldsymbol{f}(\varepsilon_n)$ is purely imaginary, i.e. $\tilde{\boldsymbol{f}} = \boldsymbol{f}^* = -\boldsymbol{f}$ (taking into account that $\tilde{g}_0 = -g_0$, i.e. g_0 is purely imaginary). As a result, one obtains the simpler relations

$$\boldsymbol{g} = \tilde{\boldsymbol{g}}, \qquad g_0 \boldsymbol{g} = f \boldsymbol{f}. \tag{30.89}$$

These simplifications arise also when $\boldsymbol{f} \parallel \boldsymbol{J}$ [229]. Combining the relations (30.89) and (30.88), it follows that the spin-vector part $\boldsymbol{g}$ is an even function of ε_n in the diffusive limit, which demonstrates that the induced spin magnetization $\delta \boldsymbol{M}$ is in general non-zero.

Near T_c, the singlet amplitude f and the triplet vector amplitude are small so that $\boldsymbol{g}$ and thus $\delta \boldsymbol{M}$ appear to be second order terms [see 30.65c]. Accordingly, the induced spin magnetization $\delta \boldsymbol{M}$ penetrating the superconductor, which is negligibly small near T_c, increases significantly by reaching temperatures well below T_c.

30.4.7 Strongly spin-polarized ferromagnets

In the case that the spin splitting of the spin bands in a ferromagnet is much larger than the superconducting gap in the adjacent superconductor, the above mentioned theories must be modified in various respects. First, Usadel approximation assumes that the inverse life time of quasiparticles due to impurity scattering averaged over the Fermi surface, $\hbar/\tau$, is much larger than all energy scales appearing in the Usadel equation, including the magnitude of the exchange field $|\boldsymbol{J}|$. If this is not the case, the spatial variation of superconducting correlations into the ferromagnet happens on length scales comparable to or shorter than the mean free path, and Usadel theory cannot be used within the ferromagnet on the same footing as the exchange field. One must resort to Eilenberger equations in this case. If the exchange splitting is, however, not much smaller than the Fermi energy scale, then even Eilenberger-Larkin-Ovchinnikov theory cannot accommodate the exchange field in the way described in the previous sections. A modified version of Eilenberger and Usadel equations can be used for the case that $|\boldsymbol{J}| \sim E_F$. In this case, there exist two well separated fully spin-polarized Fermi surfaces in the system, and the length scale associated with $\hbar/|\hat{\boldsymbol{p}}_{f\uparrow} - \hat{\boldsymbol{p}}_{f\downarrow}|$ is much shorter than the coherence length scale in the ferromagnet. Superconducting pairs of the type $\uparrow\uparrow$ and $\downarrow\downarrow$ are still long-ranged in such a system, however pairs of the type $\uparrow\downarrow$ and $\downarrow\uparrow$ are negligible within quasiclassical approximation. Both Fermi velocity and density of states at the Fermi level are spin-dependent. The same holds

for diffusion constant, and coherence length. The quasiclassical propagator is then spin-scalar for each quasiclassical trajectory in the ferromagnet,

$$\hat{g}_{\uparrow\uparrow} = \begin{pmatrix} g_{\uparrow\uparrow} & f_{\uparrow\uparrow} \\ \tilde{f}_{\uparrow\uparrow} & \tilde{g}_{\uparrow\uparrow} \end{pmatrix}, \quad \hat{g}_{\downarrow\downarrow} = \begin{pmatrix} g_{\downarrow\downarrow} & f_{\downarrow\downarrow} \\ \tilde{f}_{\downarrow\downarrow} & \tilde{g}_{\downarrow\downarrow} \end{pmatrix}, \tag{30.90}$$

and only has a particle-hole discrete degree of freedom. Similarly, all mean field self energies have the same structure (spin-scalar, only 2x2 particle-hole matrices), and the Fermi liquid interactions are replaced by spin-scalar interactions, which in the simplest case do not mix the spin bands: $A^s, \overset{\leftrightarrow}{A^a} \to A_{\uparrow\uparrow}, A_{\downarrow\downarrow}$, $V^s, \overset{\leftrightarrow}{V^t} \to V_{\uparrow\uparrow}, V_{\downarrow\downarrow}$ (in a more general case, the Fermi liquid interactions could be of the form $A_{\uparrow\uparrow,\uparrow\uparrow}$, $A_{\uparrow\uparrow,\downarrow\downarrow}$ etc). Eilenberger equation and Usadel equation have the same form as before for each separate spin band. The spin-resolved current densities are given in the ballistic case by

$$\boldsymbol{j}_{\uparrow} = ek_{\mathrm{B}}T \sum_{\varepsilon_n} \left\langle N_{f\uparrow} \boldsymbol{v}_{f\uparrow} g_{\uparrow\uparrow} \right\rangle_{\hat{\boldsymbol{p}}_{f\uparrow}}, \quad \boldsymbol{j}_{\downarrow} = ek_{\mathrm{B}}T \sum_{\varepsilon_n} \left\langle N_{f\downarrow} \boldsymbol{v}_{f\downarrow} g_{\downarrow\downarrow} \right\rangle_{\hat{\boldsymbol{p}}_{f\downarrow}}, \tag{30.91}$$

and the spin magnetization by

$$M_z \;=\; M_{\mathrm{n}}(B_z) + k_{\mathrm{B}}T \sum_{\varepsilon_n} \left(\left\langle N_{f\uparrow} \mu_{\mathrm{eff}\uparrow} g_{\uparrow\uparrow} \right\rangle_{\hat{\boldsymbol{p}}_{f\uparrow}} - \left\langle N_{f\downarrow} \mu_{\mathrm{eff}\downarrow} g_{\downarrow\downarrow} \right\rangle_{\hat{\boldsymbol{p}}_{f\downarrow}} \right). \tag{30.92}$$

The expressions in the diffusive limit are modified accordingly: e.g. for the spin-resolved current density one obtains

$$j_{k\uparrow} = -\frac{e}{\pi} k_{\mathrm{B}}T \sum_{\varepsilon_n} \mathrm{Im} \left[N_{f\uparrow} D_{kj\uparrow} f^*_{\uparrow\uparrow} \, \overline{\partial}_j f_{\uparrow\uparrow} \right], \tag{30.93}$$

and analogously for spin down.

30.5 Pair amplitude oscillations and π-Josephson junctions

30.5.1 $0-\pi$ transitions in Josephson junctions

Proximity-induced pairs in a superconductor-ferromagnet bilayer are subject to the FFLO effect, leading to spatially oscillating pair amplitudes in the ferromagnetic regions. These act back on the superconducting singlet pair potential in the superconducting region. How exactly this interaction between pair potential and FFLO amplitudes takes place depends on details of the interfaces and must be determined numerically, however for a sufficiently thin superconducting layer the oscillating nature of the FFLO amplitudes ultimately leads to oscillations in the modulus of the pair potential of the superconductor (and thus in the transition temperature) as function of the geometric dimensions of the hybrid structure. In addition, the oscillatory nature of the FFLO pairs in the ferromagnet affects the properties of superconductor-ferromagnet-superconductor Josephson devices, leading to the possibility of oscillations between junctions with a phase difference of zero and junctions with a phase difference of π in the ground state when a certain control parameter is changed.

The idea of Josephson junctions with a π phase difference in its ground state when a magnetic impurity is inserted in the junction was introduced by Bulaevskiĭ, Kuziĭ, and Sobyanin in 1977 [232]. Similar ideas had also been proposed by Kulik in 1965 [233]. In 1982 it was also shown in a classical paper by Buzdin, Bulaevskiĭ, and Panyukov that the pair amplitude oscillates in ferromagnets in contact with a superconductor [234]. Further early studies of this effect followed in Refs. [235, 236, 237]. One technological problem that became evident quickly was that weakly spin-polarized systems, like ferromagnetic Cu-Ni or Pd-Ni alloys, are better suited to observe $0-\pi$ oscillations, as otherwise the proximity amplitudes become

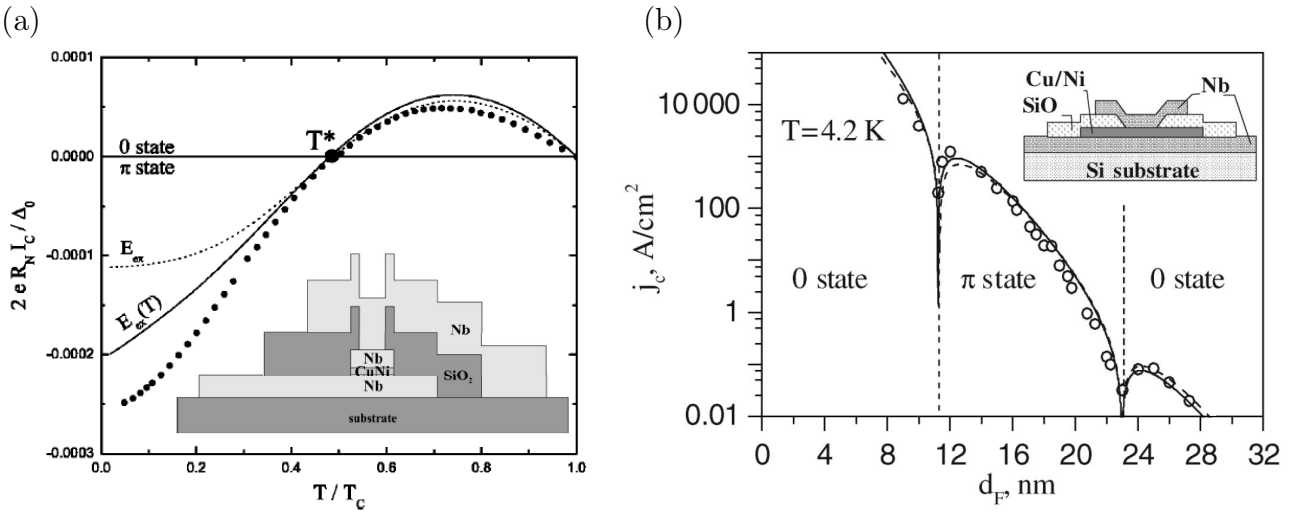

Figure 30.13: (a) Temperature dependence of the critical Josephson current in a $Nb/Cu_{52}Ni_{48}/Nb$ trilayer device, shown in the inset, for a ferromagnet layer thickness $d = 18$ nm. (The lines correspond to theoretical models with constant (dotted line) or temperature dependent (solid line) exchange energy.) From Sellier *et al.* [243]. Copyright (2003) by the American Physical Society. (b) The ferromagnet-layer thickness dependence of the critical current density for $Nb/Cu_{0.47}Ni_{0.53}/Nb$ junctions at temperature 4.2 K. Open circles represent experimental results; solid and dashed lines show model calculations. The inset shows a schematic cross section of the SFS junctions. From Oboznov *et al.* [227]. Copyright (2006) by the American Physical Society.

so short ranged that extremely thin layers are necessary. Typical ferromagnetic alloys that have been used are $Cu_{1-x}Ni_x$ (CuNi) and $Pd_{1-x}Ni_x$ (PdNi). The real break-through came in the beginning of the 2000's with the experimental verification of the switching between 0 and π-Josephson junctions based on the effect predicted theoretically before. Pioneering work was done by Ryazanov and co-workers who studied transitions between zero- and π-states as function of temperature [238, 239, 240, 227] and thickness of the ferromagnet layer [240, 227] in Nb/CuNi/Nb trilayers (see Figure 30.13). Closely following were experiments by Kontos and co-workers who studied the zero-π transition as function of barrier thickness in $Nb/Al/Al_2O_3/PdNi/Nb$ junctions [241], by Blum *et al.* [242], who use Nb/Cu/Ni/Cu/Nb junctions and vary both temperature and thickness of the Ni layer (thus employing a much stronger spin-polarized ferromagnet than the ferromagnetic alloys that were used by the other groups), and by Sellier *et al.* studying a temperature induced $0-\pi$ transition in Nb/CuNi/Nb (see Figure 30.13), as well as the appearance of half-integer Shapiro steps [243, 244].

The critical Josephson current density as function of layer thickness in the limit $k_B T, \alpha_s \ll |\boldsymbol{J}|$ is described in the clean limit by formula [74]

$$I_c(d_F) \sim \frac{\sin\left(\frac{2|\boldsymbol{J}|}{\hbar v_f}(d_F - d_0)\right)}{\frac{2|\boldsymbol{J}|}{\hbar v_f}(d_F - d_0)} \tag{30.94a}$$

where d_0 is a fit parameter which is usually assigned to a "dead layer",i.e. a layer of suppressed magnetism at the interface. In the diffusive limit the corresponding expression for long ($d_F \gg \xi_1$) junctions is

$$I_c(d_F) \sim e^{-d_F/\xi_1} \cos\left(\frac{d_F - d_0}{\xi_2}\right) \tag{30.94b}$$

with the length scales $\xi_{1,2}$ as in (30.85) and (30.86). A study by Pugach *et al.* [245] bridging the two limiting cases showed that the two length scales ξ_1 and ξ_2 may exhibit a non-monotonic

dependence on the properties of the ferromagnetic layer such as exchange field or electron mean-free path.

Further studies of strongly spin-polarized interlayers were performed, using various materials, among those Ni in Ref. [246], Co, Ni, and Py ($Ni_{80}Fe_{20}$) in Ref. [247], and Py ($Fe_{0.75}Co_{0.25}$) barriers in Ref. [248]. A detailed study, presented in Ref. [249], with Ni interlayers using the formulas (30.94a), (30.94b) above has been done recently, indicating that these structures are in the dirty limit. The thicknesses of the Ni layers ranged between 1 and 5 nm. In Figure 30.14 examples for $0-\pi$ oscillations in a Nb/Co/Nb structure are shown. In order to eliminate unwanted effects due to the variation of the electromagnetic vector potential across the junction due to the intrinsic magnetic flux in the junction, a special geometry was used where two Co layers were exchange coupled by a thin Ru layer in between to align antiferromagnetically. This cancels all the unwanted effects to a high degree, and a previously wildly fluctuating critical current vs. magnetic field curve turns into an excellent Fraunhofer pattern when the Ru interlayer present, as seen in Figure 30.14 (b) [250]. With this improvement high-quality $0-\pi$ transitions are observed both as function of temperature and of ferromagnet thickness. These

results complement the results shown in Figure 30.13, which are for ferromagnetic alloys. The main difference is a one order of magnitude smaller ferromagnet layer thickness necessary to observe the effect, which is an experimental challenge.

The effect of additional normal and/or insulating layers between the superconductor and the ferromagnet was studied theoretically in detail in Ref. [251]. It was found that even a thin additional normal conducting layer may shift the 0-π transitions to larger or smaller values of the thickness of the ferromagnet, depending on its conducting properties, and for certain parameter ranges a 0-π transition can even be achieved by changing only the normal layer thickness.

A promising setup are so-called double-proximity structures, in which two superconductors are connected by a weak link of a normal-metal/ferromagnet bilayer or a ferromagnet/normal-metal/ferromagnet trilayer forming a bridge between the superconducting banks. The proximity effect acts here twice: first to provide pair amplitudes from the superconducting banks into the bilayer or trilayer, and second at the interface between the normal metal and ferromagnet. Such structures have been proposed by Karminskaya and Kupriyanov [252], and experimental realization in terms of hybrid planar Al-(Cu/Fe)-Al submicron bridges is reported in Ref. [253]. The oscillation periods and damping lengths of the critical Josephson current can be much longer in such devices than in the conventional setup. Various geometries have been theoretically studied in subsequent work, including (SN)-(NF)-(SN), (SNF)-(NF)-(SNF), (SNF)-N-(SNF), and S-(NF)-S junctions, in order to optimize practical performance [254].

30.5.2 Phase sensitive measurements

The current-phase relation (CPR) as a function of temperature in a Nb/CuNi/Nb junction was measured by Frolov *et al.* (see Figure 30.15) [255]. Using an rf SQUID, the change of the current-phase relation from zero to π-junction behavior is clearly visible. This allows to observe the *sign* of the supercurrent. A π-junction is a Josephson junction with a negative critical current I_c, as its current-phase relation (CPR) is $I_J(\varphi) = |I_c| \sin(\varphi + \pi) = -|I_c| \sin(\varphi)$. As conventional measurement of the current-voltage characteristic of a Josephson junction is not sensitive to the sign of the supercurrent, it was necessary to include the Josephson junction in a multiply connected geometry. The sign was in Ref. [255] observed in an rf SQUID configuration [see Figure 30.15(a)] by shorting the electrodes of the junction with a superconducting loop. If that loop contains a π junction in zero external field it will exhibit a spontaneous circulating current, generating a flux of $\Phi_0/2$ which can be detected by a SQUID magnetometer or a Hall probe. In Figure 30.15 (b) the transition between a zero and a π state is unambiguously observed (although residual magnetic fields leading to shifts in the CPR curves did not allow to pin down if it was a 0-π or a π-0 transition).

Phase sensitive measurements of the ground state of ferromagnetic Josephson junctions using a single dc SQUID have been performed by Ryazanov and co-workers [256] for Nb/NbO_y/CuNi/Nb junctions, and by Guichard *et al.* [257] for Nb/NbO_y/PdNi/Nb junctions, showing that the sign change of the Josephson coupling is observed as a shift of half of a flux quantum $\Phi_0 = \frac{h}{2|e|}$ in the SQUID diffraction pattern (see Figure 30.15). A 0-0 and a π-π junction show identical critical current modulations with flux, whereas a 0-π junction exhibits a pattern shifted by $\Phi_0/2$ with respect to that for 0-0 and π-π junctions. In this experiment a single dc SQUID with two SFS junctions embedded. The ferromagnetic layer thickness d_{F1} and d_{F2} can then be chosen to correspond to zero or π coupling independently, leading to the possibility of a $0-0$, a π-π, a 0-π, or a π-0 SQUID. For a dc SQUID with negligible loop inductance and equal junction critical currents the modulation of

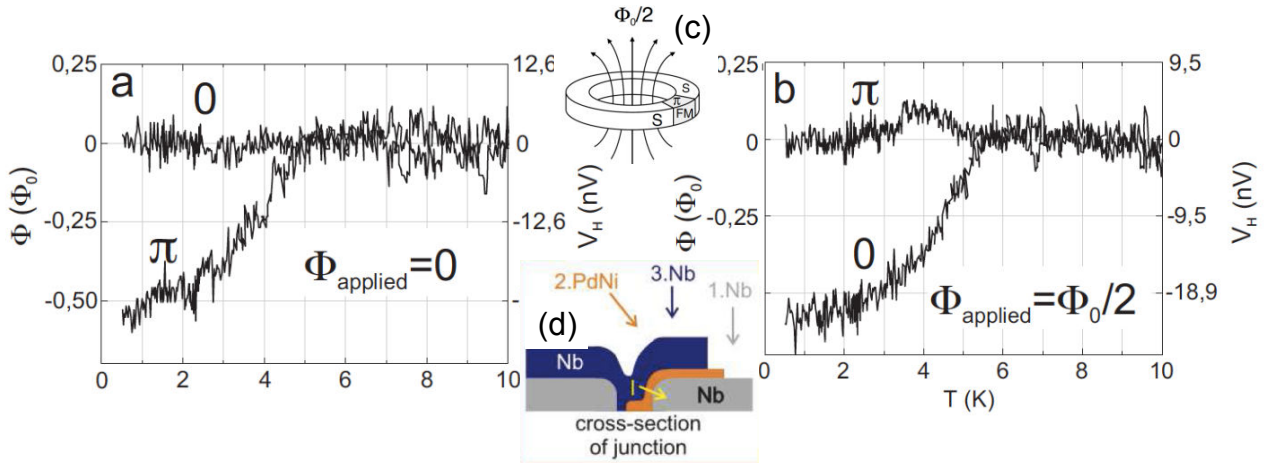

Figure 30.16: Temperature dependent magnetic flux produced by a π- and a 0-loop when cooling (a) in zero field and (b) in a magnetic field equal to half a flux quantum in the loop. Below $T \approx 5$ K the loop develops a spontaneous current when cooling down in zero field, while the magnetic flux through the 0−loop remains zero. When applying a field equal to half a flux quantum Φ_0 the roles of the π- and the 0-loops are interchanged. At low temperatures the spontaneous flux saturates at a value close to $\Phi_0/2$ in each case. (c) In zero external magnetic field, a spontaneous flux $\Phi = \Phi_0/2$ is required to maintain the condition of fluxoid quantization if a π-junction is inserted into a superconducting loop (d) Cross section of the planar Josephson junction. From Bauer *et al.* [258]. Copyright (2004) by the American Physical Society.

the critical current with applied flux is given by [96]

$$I_c(\Phi_{ext}) = 2I_0 \left| \cos\left(\pi \frac{\Phi_{ext}}{\Phi_0} + \frac{\delta_{12}}{2} \right) \right| \tag{30.95}$$

where δ_{12} is the sum of the internal phases (0 or π) in the two junctions of the SQUID. Thus, for a $0-0$ and a π-π SQUID the $I_c(\Phi_{ext})$ patterns are identical, whereas they are shifted by half a flux quantum if $\delta_{12} = \pi$, i.e. a $0-\pi$ or a π-0 SQUID. This shift is shown in Figure 30.15 (d).

The presence of spontaneous magnetic moments in superconducting (Nb) loops containing a ferromagnetic (PdNi) π junction was experimentally demonstrated by Bauer *et al.* (see Figure 30.16) [258]. The loops were prepared on top of a micro-Hall sensor. The authors observed asymmetric switching of the loop between different magnetization states when reversing the sweep direction of the magnetic field. The presence of a spontaneous current near zero applied field was studied as function of temperature, and the magnetic moment approached half a flux quantum at low temperatures.

An rf SQUID geometry where the macroscopic ground state of a ferromagnetic (PdNi) Josephson junction shorted by a 0 weak link was experimentally investigated by Della Rocca *et al.* and showed spontaneous half quantum vortices with random sign ($\pm\Phi_0/2$) [259]; it was found that $0-\pi$ junctions behave as classical spins.

30.5.3 φ-Josephson junctions

An interesting separate development concerns a geometry where a step in the thickness of the ferromagnet is present in a superconductor-ferromagnet bilayer, coupled to another superconductor via an insulating barrier. On one side of the step one has a 0 junction, on the other side a π junction. A half flux quantum (semifluxon) is trapped in such a structure at the step [260, 261, 262], and a supercurrent circulates in the structure, similarly as in a $0-\pi$

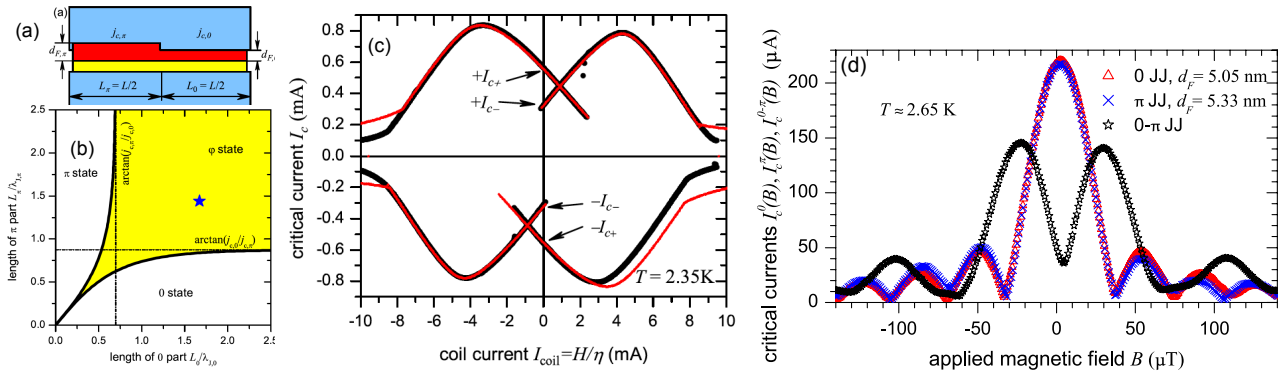

Figure 30.17: (a) Sketch (cross section) of the investigated SIFS 0-π Josephson junctions (Nb/Al-Al_2O_3/$Ni_{0.6}Cu_{0.4}$/Nb) with a step in the ferromagnet layer thickness. SQUID [263, 264, 265, 266]. Such structures were studied in detail by Weides, Kohlstedt, Koelle, Kleiner, Goldobin and co-workers. In particular, there exists in such structures the possibility of a φ-junction, which has neither 0 nor π phase difference as a ground state. A method to realize a φ Josephson junction by combining alternating 0 and π parts with intrinsically non-sinusoidal current-phase relation was suggested in Ref. [267]. The realization of an SIFS φ-junction has been experimentally achieved in 2012 (see Figure 30.17) [268]. Properties of zero-π junctions which act as a Josephson junction with an equilibrium phase difference $0 < \varphi < \pi$ are discussed in Ref. [269], where the current-phase relation is calculated numerically and in certain limiting cases analytically.

In Refs. [270, 271], a planar Josephson junction with a ferromagnetic weak link located on top of a thin normal metal film is considered. It is shown that this Josephson junction is a promising candidate for the realization of a φ-junction.

30.6 Long-range triplet supercurrents

30.6.1 Length scales for superconducting correlations in ferromagnets

As detailed in the sections 30.4.4 and 30.4.5, proximity induced superconducting correlations in ferromagnets with sufficiently strong exchange splitting $|\boldsymbol{J}|$ come in pairs of short-range and long-range amplitudes. The former ones are the singlet amplitude and the triplet pair amplitude with zero spin projection, $S_z = 0$, on the magnetization axis of the ferromagnet. These short-range amplitudes decay in ballistic structures algebraically with a reduced magnitude of order $\Delta/|\boldsymbol{J}|$, and in diffusive structures exponentially on the length scale $\xi_J = \sqrt{\hbar D/|\boldsymbol{J}|}$. The other two components, called long-range amplitudes, decay on the thermal coherence length scale ξ_T, given for ballistic structures by $\hbar v_f/(2\pi k_B T + 2\alpha_s)$ and for diffusive structures by $\sqrt{\hbar D/(2\pi k_B T + 2\alpha_s)}$. They are characterized by triplet amplitudes with a spin projection $S_z = \pm 1$ on the magnetization direction of the ferromagnet. Consequently, they are called equal-spin triplet pair correlations. Equal spin pairs do not suffer from having to populate spin-split pairs of Fermi surfaces. Both electrons of the pair are situated on the same spin

component of the Fermi surface. For this reason, they behave like in a normal metal, with the coherence length determined by the Fermi surface properties of one spin component only (which in general differ for $S_z = +1$ and $S_z = -1$). The quest for such long-range pair amplitudes has a long history, and is one of the success stories of interaction between experiment and theory.

30.6.2 Experimental "pre-history"

As in the 1990's the field of spintronics, i.e. functional nanometer-size devices based on spin-dependent transport phenomena, developed rapidly [272], a strong motivation to search for a long-range proximity effect in ferromagnets was established. Such long-range amplitudes would lead to long-range supercurrents in Josephson devices, and would ultimately lead to valuable applications. The ultimate goal is to obtain completely spin-polarized supercurrents, which would necessarily have to be triplet supercurrents.

It was for this reason that in the second half of the 1990's experimental efforts intensified to study proximity effects in strongly spin-polarized ferromagnets. Petrashov, Antonov, Maksimov, and Shaĭkhaĭdarov found in 1994 that the effect of superconducting islands, deposited on the surface of ferromagnetic Ni, can be still seen in the resistance of the Ni layer distances greater than 2 μm (exceeding by more than 30 times what the length $\hbar v_f/|\boldsymbol{J}|$ would suggest) away [273].

Lawrence and Giordano studied in 1996 the resistance as a function of temperature and magnetic field in structures containing a narrow ($\sim 2\mu$m) ferromagnetic strip connecting two superconducting films (In/Ni/In and Pb/Ni/Pb) [274]. They observed a magnetoresistance dip as function of magnetic field much too large to be accounted for by weak localization effects. In addition they found implausibly long phase coherence lengths, inconsistent with the usual superconducting proximity effect. In a later study of Sn/Ni/Sn structures, where the Ni was a narrow wire (~ 40 nm wide), they measured an unexpectedly long proximity length of about 50 nm (theory predicted 4 nm for these structures) when the Sn/Ni interfaces are clean, however with an oxide layer at the interfaces they observed an unexplained re-entrant behavior [275]. They also noted that their proximity length was of the order of the thermal length $\sqrt{\hbar D/k_{\rm B}T}$ which would appear in a normal metal.

Giroud and co-workers studied in 1998 Co/Al structures with a ferromagnetic Co wire in contact with superconducting Al [276]. They observed below the superconducting transition that the Co resistance exhibited a significant dependence on temperature and voltage, and the differential resistance showed that the decay length for the proximity effect was much larger than expected from the exchange field of Co.

Petrashov and co-workers found in 1999 a giant mutual proximity effect in Ni/Al structures with an proximity-induced conductance on the Ni side two orders of magnitude larger than predicted by theory [277]. Aumedato and Chandrasekhar, by performing multi-probe measurements on Ni/Al structures, re-evaluated these studies and came to the conclusion that superconducting correlations cannot extend into a ferromagnet over distances larger than the exchange length, and associated the large changes in resistance seen in the previous experiments with the superconductor/ferromagnet interface or the superconductor, which had been measured in series or in parallel with the ferromagnet [278]. The controversy lead to a vivid discussion about the existence of such long-range proximity components.

30.6.3 Theory of long-range proximity amplitudes

Spiral magnetic inhomogeneities and domain walls

The renewed interest created by the lack of understanding of long-range superconducting proximity effects in ferromagnets lead in the beginning of the 2000's to new theoretical develop-

ments. Pivotal was a series of papers by Bergeret, Volkov, Efetov, and coworkers, who studied the effect of a spiral Bloch-type inhomogeneity close to an S/F interface, where the magnetization vector rotates along the junction direction. They found that an equal-spin triplet pair amplitude shows a long-range penetration into the ferromagnet [131, 73, 222, 279, 280]. The authors also noted that this, as an isotropic ("s-wave") triplet pair component, must be a realization of odd-frequency pairing. As impurities suppress all anisotropic pairing components, this odd-frequency amplitude is the only superconducting pairing amplitude present in the ferromagnet. Shortly after that, Kadigrobov, Shekhter and Jonson found a similar effect [281]. A realization of these ideas motivated by experiment [282] was studied in Ref. [283], where the focus of study was a setup of a Ho/Co/Ho trilayer sandwiched between conventional s-wave superconducting leads. Holmium is a conical ferromagnet with an intrinsic spiral structure. In Ref. [284] a bilayer consisting of an ordinary singlet superconductor and a magnet with a spiral magnetic structure of the holmium or erbium type was investigated by solving self-consistently Bogoliubov-de Gennes equations. A re-entrance behavior as function of temperature is observed for certain parameter ranges.

Another type of magnetic structure discussed in the literature is a domain structure of the Néel type, in which the magnetization vector lies parallel to the interface and rotates along a direction parallel to the interface. A setup with a chiral ferromagnet, exhibiting a homogeneous cycloidal spiral, placed between two conventional superconductors was studied in Ref. [285]. Depending on the spiral wave length, 0-π transitions can be induced. In the case of a uniformly rotating spiral, however, it was shown that only short-range components exist [285]. In a more general case, with magnetic domains separated by Néel walls, long-range triplet components are present and arise at the domain walls, decaying inside the domains [286, 287].

Refs. [288, 289] investigate diffusive SF and SFS structures with a domain wall in the F layer, using a Riccati representation of the non-linear Usadel equations [72] and including spin-mixing parameters for interfaces. They study local density of states, induced magnetization, and spin-polarized Josephson currents. It is found that the spin polarization of the spin current in SFS structures is determined by the magnetization profile and that the spin current shows discontinuities at the zero-π transition points of the critical Josephson current. Similar as in Ref. [172], a non-zero spin-current even for zero superconducting phase difference is reported. In Ref. [290] the contribution of domain walls to the Josephson current through a ferromagnetic metal is examined for both ballistic and diffusive systems. It is found that in the clean limit domain walls enhance the Josephson current even for a collinear magnetic domain structure, whereas in the diffusive limit a non-collinear domain structure is necessary to enhance the effect. In Ref. [291] the influence of the location of a domain wall within a Josephson junction on the ground state properties of the junction was the topic of investigation. The authors considered both the diffusive and ballistic limits. They find that the location of the domain wall determines if the junction is in a zero-state or in a π-state and influences the transition temperature of the junction.

A different type of system with inhomogeneous magnetic structure was studied in Refs. [292, 293], where a ferromagnetic vortex in a mesoscopic ferromagnetic disc is brought in contact with a singlet superconductor. Proximity-induced long-range triplet components are generated by the ferromagnetic vortex under certain circumstances, leading to zero- or π-junction behavior depending on the contact geometry.

Multi-layer geometries

Instead of considering inhomogeneous magnetization profiles within a ferromagnetic layer as sources of long-range triplet correlations, one can also obtain the same effect in a multi-layer geometry with non-collinear arrangement of the magnetizations of the various layers. In Ref. [294] a diffusive SFIFS junction is investigated by self-consistently solving Usadel equations

with appropriate boundary conditions. It is found that for antiparallel ferromagnet magnetizations the critical current is enhanced by the exchange energy, and for parallel magnetization the junction exhibits a transition to a π-state. A switching behavior between zero- and π-state can be observed when going from the antiparallel to the parallel alignment. In Refs. [230, 231] a multilayered superconductor-ferromagnet structure with non-collinear alignment of the magnetizations of the ferromagnetic layers is considered, and the resulting long-range odd-frequency triplet condensate amplitude is calculated. It is found that this setup allows for a Josephson effect with possible zero- or π-junction behavior. It is also pointed out that the chirality of the magnetization profile matters for the direction of the Josephson current. In Ref. [295] a fully self-consistent calculation was performed for a ferromagnet-superconductor-ferromagnet trilayer setup with non-collinear magnetization, and the induced spin magnetization in the entire structure was determined. This work includes self-consistency of the order parameter in the superconducting layer at arbitrary temperatures, arbitrary interface transparency, and any relative orientation of the exchange fields in the two ferromagnets. The long-range Josephson effect through a ferromagnetic trilayer was the topic of Ref. [296], where conditions were derived under which the long-range triplet proximity effect dominates the short-range proximity effect. Both diffusive and clean limits were studied.

Halterman and Valls have investigated numerically ballistic S/F/S trilayer and S/F/S/F/S pentalayer Josephson junctions by self-consistently solving Bogoliubov-de Gennes equations, concentrating on the thermodynamic stability of zero- and π-junctions as function of material parameters and geometry [297, 298].

Zero-π transitions in Josephson junctions with a diffusive pentalayer-structure of the form F/S/F/S/F with misaligned magnetizations in the three ferromagnetic layers were explored in Ref. [299]. The transition temperatures for zero- and π-junctions as function of misalignment angle were determined numerically using an effective and fast procedure, which is described in detail in this publication. In Ref. [300] a diffusive S/F′/FF/F′/S structure is discussed, with two different ferromagnetic materials F and F′. The middle FF double layer is considered to be parallel or antiparallel magnetized, whereas the F′ layers were allowed to be non-collinear. This setup is in particular adapted to the experiments by Khaire *et al.* [301]. A similar study for clean or moderately diffusive materials was performed in Ref. [302].

An SF_1F_2S junction in the ballistic case (including moderate disorder in the ferromagnets) was considered in Refs. [303, 304], with misaligned ferromagnetic layers F_1 and F_2. It was found that the long-range spin-triplet correlations lead to a dominant second harmonic in the Josephson current-phase relation of asymmetric junctions [305], an effect also found for diffusive structures in Ref. [306]. In the latter reference this phenomenon is traced to the long-range coherent propagation of two triplet pairs of electrons, a process first pointed out and discussed in Ref. [172], and called there "crossed pair transmission".

Magnetic moment manipulation by triplet Josephson currents in Josephson junctions with multilayered ferromagnetic weak links is discussed in Ref. [307]. It is reported that by tuning the Josephson current, one may control a long-range induced magnetic moment, which appears due to non-collinear magnetization of the layers. Alternatively, applying a voltage one can in such a geometry generate an oscillatory magnetic moment. The spin-switching behavior as function of rotation of the magnetization in one ferromagnetic layer in diffusive SFSFS and SFSFFS Josephson junctions was investigated in Ref. [308].

The proximity effect in clean superconductor-ferromagnet structures caused by either the spatial or momentum dependence of the exchange field was discussed in Ref. [309]. It was shown that in symmetric junctions the long-ranged proximity effect is present for any non-collinear ferromagnetic moment orientation and a dominant second harmonic appears for any asymmetric junction. The Josephson coupling between two s-wave superconductors separated by a ferromagnetic trilayer with non-collinear magnetization was reconsidered in Ref. [310], where

in particular the dependence on strength of the exchange field and thickness of the interface layers was studied, and the competition between long-range and short-range components was investigated.

The appearance of a spin supercurrent in a diffusive SF_1F_2S Josephson junction was subject of study in Ref. [311]. It was found that a spin current with spin polarization normal to the magnetization vectors flows between the ferromagnetic domains. This spin current is even as function of superconducting phase difference, and odd as function of misalignment angle between F_1 and F_2.

A diffusive S-(FNF)-S double proximity structure, in which an FNF trilayer with mutually misaligned ferromagnetic magnetization vectors bridges two superconducting banks, was investigated in Ref. [312]. In this case long-range equal-spin triplet correlations are generated by the misalignment of the two ferromagnetic layers in the bridge.

Singlet-Triplet conversion at interfaces

The mechanisms discussed in the previous subsections employ a quasiclassical approximation, which is not valid for length scales as small as the Fermi wavelength. In fact, for the mechanism to work it is crucial that short-range components can enter the ferromagnet over a sufficiently long distance to feel the magnetic inhomogeneity, which was assumed to vary on the scale much larger than the Fermi wavelength. This poses the problem of what happens at interfaces between a superconductor and a ferromagnet with large exchange splitting, so that the length scale ξ_J becomes comparable to the Fermi wave length.

An appropriate mechanism for structures with strong exchange splittings was proposed, and first exemplary studied for the extreme case of a half-metallic ferromagnet (where one spin band is insulating and one spin band metallic), in [155, 164, 107, 215]. The mechanism is based on spin-dependent scattering phases under reflection and transmission, which in combination with a misalignment with respect to the ferromagnetic bulk magnetization of the interface magnetic moment in an atomically thin interface layer leads to the creation of long-range triplet pairs. It was shown subsequently, that this mechanism persists for the full range from ballistic to diffusive systems [133]. Note that such a mechanism invokes the magnetic inhomogeneity directly in an *interface barrier*, rather than in a metallic region. It thus differs from the mechanism suggested by Bergeret *et al.* Indeed, the two mechanisms are complementary, with the first one being important for ferromagnets where the exchange splitting is small compared to the Fermi energy, and the second one being important for the case of comparable exchange splitting and Fermi energy, both being much larger than all superconducting energy scales. The crossover between these two asymptotic cases cannot be described within either theory, as no useful expansion parameter is present in the crossover region.

The mechanism of long-range triplet pair creation at interfaces was generalized to Josephson structures involving strongly spin-polarized ferromagnets with two itinerant spin bands in Ref. [172].

Supercurrents in strongly spin-polarized itinerant ferromagnets and half metals

We discuss first the main predictions of a long-range Josephson effect in a structure involving a long half-metallic ferromagnetic region, as discussed in Refs. [155, 107, 133, 215, 224]. As shown in Fig. 30.18, which is for a fully self consistent calculation using a model barrier as in Fig. 30.10 (b), all possible symmetry components shown in Fig. 30.6 are indeed generated at the interface. This simply reflects the fact that both spin rotational symmetry and inversion symmetry are broken by the interface. The calculation assumes that the effective magnetic moment of the interfaces is perpendicular to the bulk magnetization of the half-metallic ferromagnet. As a consequence, according to Eq. (30.24b), long-range amplitudes are generated,

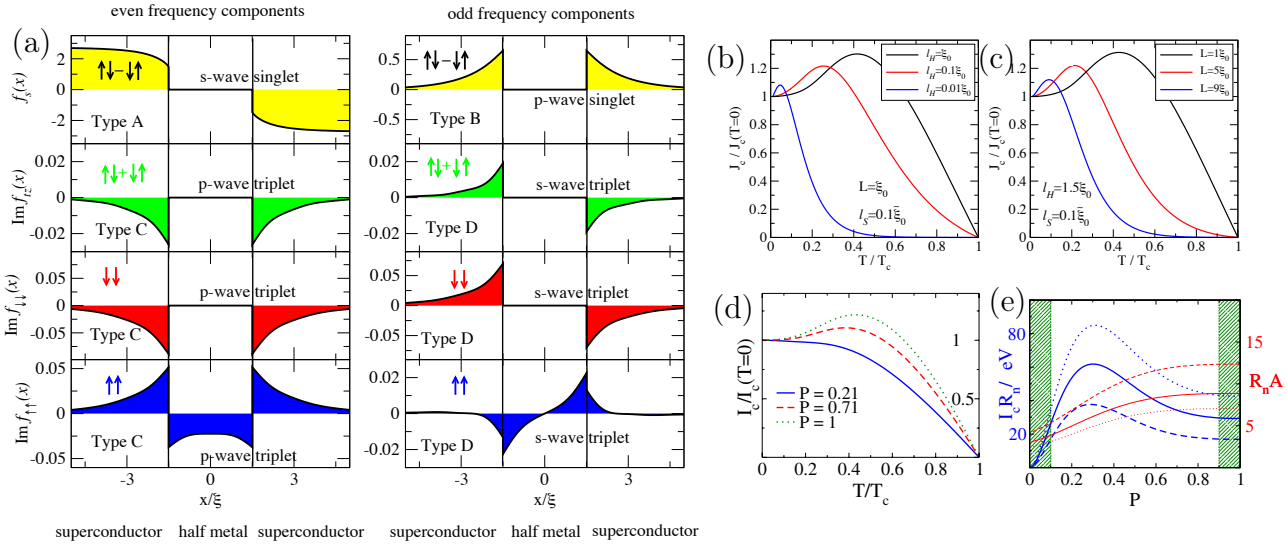

Figure 30.18: (a) All symmetry components in a ballistic S/F/S π-Josephson junction with a half-metallic ferromagnet (H) as F-layer (self-consistent calculation for model barrier as in Fig. 30.10 (b), with $V_S = 0.5$, $d = 0.5/k_0$); barrier spin-polarized in x-direction, half-metal spin-polarized in z-direction; temperature $T = 0.2T_c$; (b)-(e) Non-monotonic temperature dependence of critical Josephson current density in an S/F/S junction, normalized to its value at zero temperature; (b) for half-metallic ferromagnet, dependence on the mean free path ℓ_H in H for a fixed junction length $L = \xi_c = \hbar v_H/2\pi T_c$, where v_H is the Fermi velocity in H; (c) as in (b), but showing the dependence on junction length L for fixed $\ell_H = 1.5\xi_c$; (d) for a ferromagnet in the ballistic limit, with various spin polarizations $P = (p_{F\downarrow} - p_{F\uparrow})/(p_{F\downarrow} + p_{F\uparrow})$; $L = \hbar v_F/2\pi T_c$ with v_F the Fermi velocity in F. (e) I_cR_n product and normal-state resistance R_nA [in units of $(e^2N_Sv_S)^{-1}$, where N_S and v_S are density of states per spin at the Fermi level and the Fermi velocity in the superconductor, respectively] as function of P for $T = 0.5T_c$, and various strengths of interface transmission. In all plots the interface misalignment angle is $\alpha = \pi/2$. (b) and (c) after [133], (d) and (e) from [215]. Copyright (2009) by the American Physical Society.

linking the two singlet superconductors [see lower panels in Fig. 30.18 (a)]. Thus, we have an example of an *indirect* Josephson coupling [155], via a long-range triplet component which is generated in the first place from the singlet component by microscopic processes in the interface region. Note also, that the thermodynamically stable configuration for identical interfaces is a π-junction (for asymmetric junctions the appearence of a φ_0-junction is predicted [107, 133]), for which the system tries to minimize the odd-frequency triplet amplitudes of Type D in the structure. This is a general principle, as odd-frequency amplitudes *increase* the free energy density, instead of decreasing it as even-frequency singlet amplitudes do. Only if the p-wave components (and all higher orbital components) are suppressed by impurity scattering, can the odd-frequency triplet amplitude dominate.

A prominent feature in such a structure is a non-monotonous temperature dependence of the critical Josephson current density, with a pronounced maximum at a temperature which can be linked to the Thouless energy of the ferromagnetic layer (see Fig. 30.18 (c) and Ref. [133]). When the junction becomes effectively long compared with the diffusive-limit coherence length, $L \gg \xi_d = \sqrt{\xi_0 \ell_H/3}$, the current is dramatically suppressed and the peak is shifted to a lower temperature. This maximum moves also to low temperatures in diffusive structures, as is seen in Fig. 30.18 (b), which shows its dependence on the mean free path in the ferromagnet. If one replaces the half-metallic ferromagnet by a strongly spin-polarized ferromagnet with two itinerant spin bands, then the maximum remains only for sufficiently strong spin polarization, as seen in Fig. 30.18 (d). If one projects the Fermi surfaces on the contact plane, then only the "half-metallic" momentum directions contribute to the maximum, which are inside the Fermi sea for one spin projection and outside for the other [172]. Furthermore, there is an optimal spin polarization which maximizes the $I_c R_n$-product of the Josephson junction, which for the particular model interface studied in Ref. [172] is around $P \sim 0.3$. The green shadowed regions in Fig. 30.18 (d) for small and large spin polarizations are regions beyond the validity of the theory, as other processes which are neglected become relevant.

Following the early theoretical work on triplet supercurrents in half-metallic ferromagnets [155, 164], which treats a fully developed triplet proximity effect self-consistently, numerous groups confirmed the existence of triplet supercurrents under various conditions in half-metallic ferromagnets. In Ref. [133] the work of Refs. [155, 164, 107] was generalized to include impurity disorder bridging between the two limits of ballistic and diffusive transport. In this work, the full Eilenberger equations with impurity self energy in self-consistent Born approximation was solved. In Ref. [173] a fully developed triplet proximity effect, just like in Ref. [155] for the clean limit, was treated for the diffusive limit. Further studies in the diffusive limit were performed in Refs. [313, 314, 224]. The role of magnon creation in the half-metallic ferromagnet was studied in [315], with a resulting temperature dependence of the critical current reproducing the temperature dependence found in [155, 107]. The case when the superconductor is unconventional was studied in [316, 317, 318]. In Refs. [319, 215] the problem was advanced on the analytical level assuming a constant singlet order parameter in the superconductor. Self-consistent solution of Bogoliubov-de Gennes equations in the clean limit [320] found results in agreement with Ref. [155, 107], including a strong influence of the junction behavior by subgap Andreev bound states.

Most of these theoretical studies deal with either the diffusive limit within the Usadel approximation or the clean limit. The full range of impurity scattering from clean to diffusive limit for a superconductor-half metal proximity structure was first covered in the theory of Ref. [133]. A treatment in the quantum limit was given by Béri *et al.* [321].

In Ref. [172] a number of effects were pointed out that are absent in the half-metallic case, and which are due to the phase coherent transport of Cooper pairs in the two itinerant spin bands of a ferromagnet. These are illustrated in Fig. 30.19. As seen from Eq. (30.24b), equal-spin triplet correlations in the ferromagnet acquire an additional phase from the configuration

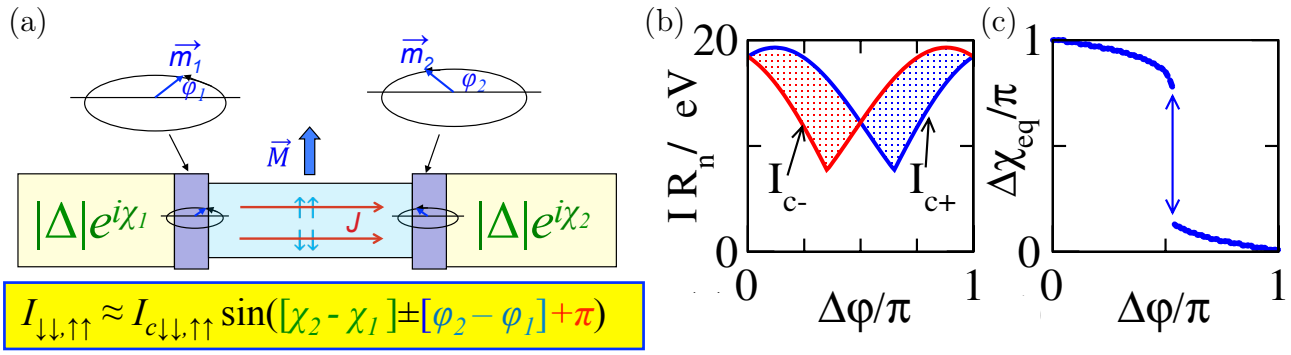

Figure 30.19: (a) S/F/S Josephson junction with a strongly spin-polarized ferromagnet with magnetization $\mathbf{M}$, having interface barriers with misaligned magnetic moments $\mathbf{m}_1$ and $\mathbf{m}_2$. Only equal-spin pair amplitudes are present in each of the spin bands of the ferromagnet. The azimuthal angles of $\mathbf{m}_1$ and $\mathbf{m}_2$ with respect to the magnetization axis $\mathbf{M}$ are denoted φ_1 and φ_2. (b) Critical current in positive (I_{c+})/negative (I_{c-}) bias direction vs $\Delta\varphi = \varphi_2 - \varphi_1$. (c) The zero current equilibrium phase difference $\Delta\chi_{\rm eq} = (\chi_2 - \chi_1)_{\rm eq}$ vs $\Delta\varphi$ varies from π to 0. Here, $T = 0.2T_c$, $P = 0.21$. The polar angle of $\mathbf{m}_1$ and $\mathbf{m}_2$ is $\alpha = \pi/2$. The length of the junction is $L = \hbar v_S/2\pi T_c$, with v_S the Fermi velocity of the superconductor. (b) and (c) from [172]. Copyright (2009) by the American Physical Society.

of the magnetic moments in the interface region, $\mathbf{m}_1$ and $\mathbf{m}_2$, with respect to the bulk magnetization $\mathbf{M}$. If the three magnetizations are *non-coplanar*, there is an important geometric phase involved, which is related to the projection of the interface magnetic moments of the two interfaces to the plane perpendicular to the bulk ferromagnetic magnetization[50]. The relative angle between these two projected magnetic moments defines the angle $\Delta\varphi = \varphi_2 - \varphi_1$, which is a gauge invariant quantity independent of the choice of the global spin quantization axis. This angle directly enters the current-phase relation for each spin band, and precisely with opposite sign for the two spin projections. Thus, the first-order processes (single Cooper pair tunneling) lead to contributions of the form

$$I_{\uparrow\uparrow} = -I_{c\uparrow\uparrow} \sin(\Delta\chi + \Delta\varphi) \tag{30.96a}$$

$$I_{\downarrow\downarrow} = -I_{c\downarrow\downarrow} \sin(\Delta\chi - \Delta\varphi) \tag{30.96b}$$

with $\Delta\chi = \chi_2 - \chi_1$ the difference of the superconducting phases of the singlet pair potential on either side of the Josephson junction. The equilibrium configuration for zero current amounts to[51]

$$\Delta\chi_{\rm eq} = \pi - \arctan\left(\frac{I_{c\uparrow\uparrow} - I_{c\downarrow\downarrow}}{I_{c\uparrow\uparrow} + I_{c\downarrow\downarrow}} \tan\Delta\varphi\right). \tag{30.97}$$

Thus, the system can act as a phase battery. For the half-metal case ($I_{c\downarrow\downarrow} = 0$) this has been noted using Eilenberger equations in Refs. [107, 133] and using Usadel equations in Ref. [224]. Going beyond the tunneling limit, we find a non-zero equilibrium phase difference between the superconducting leads, which shows a jump as function of $\Delta\varphi$, indicating a first order transition (two competing minima of the free energy located at different values of phase difference $\Delta\chi$), which is illustrated in Fig. 30.19 (c). Note that the current-phase relation fulfills the symmetry $I(-\Delta\chi, \Delta\varphi) = -I(\Delta\chi, -\Delta\varphi)$ following from the behavior of the current density under time reversal. The equilibrium configuration carries a non-zero spin current density

[50] In the coplanar but non-collinear case there still can be an important geometric phase of π introduced by the triple of magnetic vectors if $(\mathbf{m}_1 \times \mathbf{M}) \cdot (\mathbf{m_2} \times \mathbf{M}) < 0$.

[51] For zero phase difference a spontaneous current $I(\Delta\chi = 0) = -(I_{c\uparrow\uparrow} - I_{c\downarrow\downarrow}) \sin(\Delta\varphi)$ appears.

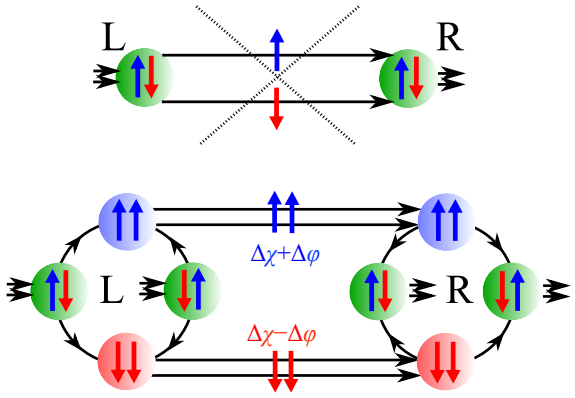

Figure 30.20: Schematic drawing of the crossed pair transmission process. Cooper pairs with opposite spin projection on the magnetization vector do not contribute to the spin supercurrent in strongly spin-polarized ferromagnets (top panel). However, due to magnetic inhomogeneity across the interfaces singlet-triplet conversion processes generate out of two singlet pairs two equal-spin triplet pairs with opposite spin polarization. These two equal-spin pairs are transmitted simultaneously in a crossed pair transmission process (bottom panel). Their phases correspond to $\Delta\chi \pm \Delta\varphi$. A geometric phase shift $2\Delta\varphi$ appears between the two types of Cooper pairs. Copyright (2009) by the American Physical Society [172].

$I_s = 2I_{\uparrow\uparrow}(\Delta\chi_{\rm eq}, \Delta\varphi) \neq 0$. The presence of a Josephson current at zero superconducting phase difference $\Delta\chi$ was confirmed in calculations using Bogoliubov-de Gennes equations in a tri-layer geometry [322]. A study of a superconductor/ferromagnetic-insulator/superconductor junction on the surface of a three-dimensional topological insulator revealed similar effects [323].

The first-order processes described by Eqs. (30.96a)-(30.96b) compete with a second order process, where two (or an even number of) pairs are transmitted simultaneously. In analogy to the so-called crossed Andreev reflection process, we call this process *crossed pair transmission* (see figure 30.20). For transmission of all pairs in equal direction, this process involves phases which are multiples of $(\Delta\chi+\Delta\varphi)+(\Delta\chi-\Delta\varphi) = 2\Delta\chi$, for which the dependence on $\Delta\varphi$ drops out. Consequently, the corresponding contribution to the Josephson current, $I_{\rm cp}$, is independent of $\Delta\varphi$ and π-periodic. More generally, a transmission process of m spin-$\uparrow\uparrow$ pairs and n spin-$\downarrow\downarrow$ pairs involves a phase $(m+n)\Delta\chi+(m-n)\Delta\varphi+(m+n)\pi$. Thus, the corresponding Josephson charge current can be written as

$$I = 2e\,\frac{1}{2}\sum_{mn}(m+n)(-1)^{n+m} I_{mn}\sin[(m+n)\Delta\chi+(m-n)\Delta\varphi] \qquad (30.98a)$$

whereas the spin current is

$$I_s = \hbar\,\frac{1}{2}\sum_{mn}(m-n)(-1)^{n+m} I_{mn}\sin[(m+n)\Delta\chi+(m-n)\Delta\varphi]. \qquad (30.98b)$$

As $I_{-m,-n} = I_{mn}$, the factor $\frac{1}{2}$ can be omitted if we restrict the summation to $m \geq 0$, and for $m = 0$ to positive n. Note that the spin-current is even present in the case $\Delta\chi = 0$, provided that $\Delta\varphi \neq 0$. An example of such a case was discussed in [172], where one of the superconductors was replaced by an insulator, and a pure spin supercurrent remains, giving rise to a *spin-Josephson effect*. In this case only terms with $m+n=0$ remain, with a pure spin supercurrents $I_s = \hbar\sum_m 2mI_{m,-m}\sin(2m\Delta\varphi)$. On the other hand, crossed pair transmission processes in equal direction have zero spin current and correspond to $m = n$, leading to a contribution to charge current of the form $2e\sum_m 2mI_{mm}\sin(2m\Delta\chi)$. For illustrative purposes

we consider the example of only first order terms and leading order crossed pair transmission terms, i.e. only terms associated with I_{01},I_{10}, I_{11}, and $I_{1,-1}$. Then

$$I/2e = -I_{10}\sin(\Delta\chi+\Delta\varphi) - I_{01}\sin(\Delta\chi-\Delta\varphi) + 2I_{11}\sin(2\Delta\chi) \quad (30.99a)$$

$$I_s/\hbar = -I_{10}\sin(\Delta\chi+\Delta\varphi) + I_{01}\sin(\Delta\chi-\Delta\varphi) + 2I_{1,-1}\sin(2\Delta\varphi). \quad (30.99b)$$

The last term in each of these equations corresponds to the crossed pair transmission process (in equal and opposite direction, correspondingly). The critical current density for positive and negative current bias differs for this case, similar as shown in Fig. 30.19 (b). Furthermore, for sufficiently large I_{11} multiple minima of the free energy as function of $\Delta\chi$ appear, leading to the characteristic jump at a certain value of $\Delta\varphi$ as illustrated in Fig. 30.19 (c). If $\Delta\varphi$ were continuously varied, a hysteresis would occur, typical for a first order phase transition. Finally, when one of the superconductors is replaced by an insulating material then $I = 0$ and the spin-Josephson current is $I_s = 2\hbar I_{1,-1}\sin(2\Delta\varphi)$ [172].

30.6.4 Recent experimental observations

Triplet supercurrents in half-metallic ferromagnets

Half-metallic ferromagnets are especially promising for applications, as they are fully spin polarized and thus give the largest spin filtering effect possible. The recent developments and applications for half-metallic ferromagnets have been reviewed e.g. in Refs. [324, 325, 326].

First indications for an coupling of superconductors through a half-metallic ferromagnet came from experiments by Peña *et al.* on ferromagnetic $La_{0.7}Ca_{0.3}MnO_3$, coupled with the high-temperature d-wave singlet superconductor $YBa_2Cu_3O_{7-\delta}$ in trilayers and superlattices [327, 328]. These authors found a long-range proximity effect over a length scale of 100 nm.

In 2006, Keizer *et al.* reported a triplet supercurrent in the half metal CrO_2 [329]. The authors used NbTiN as superconducting electrodes and CrO_2 grown on TiO_2. After it had proved difficult to reproduce the effect, it was in 2010 when finally Anwar *et al.* in the group of Aarts reported that they had found long-range supercurrents through CrO_2 grown on Al_2O_3 (sapphire) [330]. The current was observed over a distance of 700 nm between two superconducting amorphous $Mo_{70}Ge_{30}$ electrodes. The effect was interpreted in terms of odd-frequency pairing correlations (although really the experiment only indicates equal-spin pairing correlations and does not provide experimental insight about the orbital and frequency symmetry of the pairs). However, the group was not able to find the long-range supercurrent in CrO_2 grown on TiO_2, the material used by Keizer *et al.* They noted that their CrO_2 films showed a uniaxial anisotropy in contrast to the biaxial anisotropy present in the Keizer *et al.* samples [330, 331].

There had been criticism that based on previous point contact spectroscopy experiments, CrO_2 might not be fully spin-polarized. These data were summarized by Löwfander *et al.* in 2010, and it was shown that all point contact data on CrO_2 are indeed consistent with full spin polarization, if the theory is extended to take into account realistic interfaces [158].

Anwar *et al.* have in a subsequent study extended their work [332] and find that if a Ni/Cu sandwich between the CrO_2 film and the $Mo_{70}Ge_{30}$ electrodes is used, a long-range supercurrent is observed also for TiO_2 substrate over a distance of almost a micrometer. The critical current density is 100 times larger in these Ni/Cu/CrO_2 junctions on TiO_2 substrate than if sapphire is used as a substrate, and is comparable to that observed by Keizer *et al.* This proves that in addition to the substrate on which CrO_2 is grown, the interface characteristics between CrO_2 and the superconductor play a decisive role, and spin-mixing due to misaligned spins as predicted before by theory [155] is the crucial ingredient for explaining the singlet-triplet conversion in these structures.

Further evidence for triplet supercurrents came from a report by Sprungman *et al.*, who found a Josephson effect with ferromagnetic Cu_2MnAl Heusler barriers [333]. It was observed

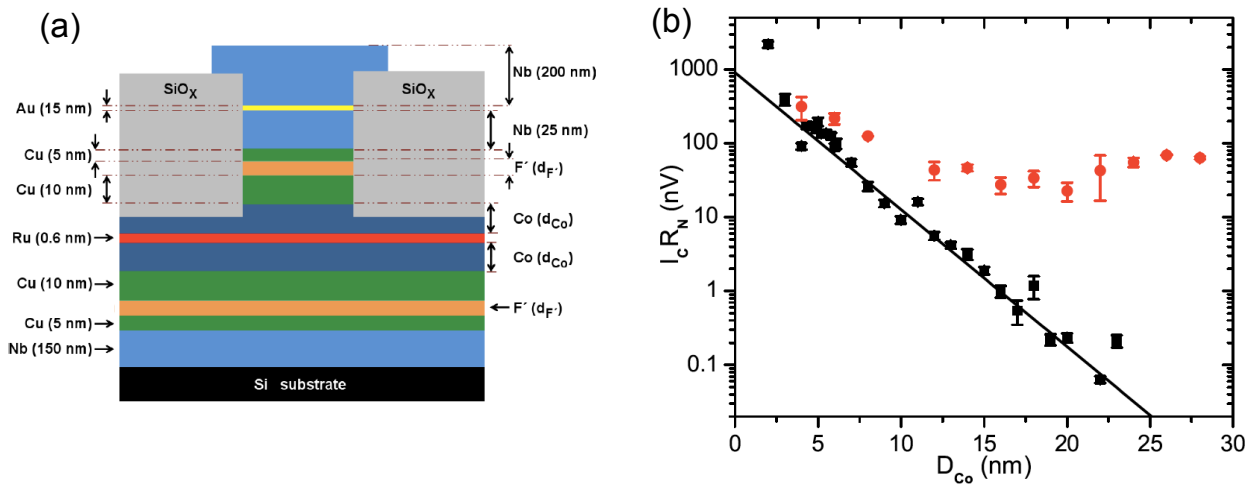

Figure 30.21: (a) Schematic diagram of the Josephson junctions used in the work of Khaire *et al.*, shown in cross-section. From Klose *et al.* [337]. Copyright (2012) by the American Physical Society. (b) Product of critical current times normal state resistance, I_cR_N, as a function of total Co thickness, $D_{Co} = 2d_{Co}$. Red circles represent junctions with F'=PdNi and d_{PdNi} =4 nm, whereas black squares represent junctions with no F' layer (taken from Ref. [250]). As D_{Co} increases above 12 nm, I_cR_N hardly drops in samples with PdNi, but drops very rapidly in samples without. (The solid line is a fit of the data without PdNi to a decaying exponential, from Ref. [250].) From Khaire *et al.* [301]. Copyright (2010) by the American Physical Society.

that the critical current density versus temperature shows a pronounced peak around 4.5 K (electrodes were Nb), decreasing towards lower and higher temperatures. Such a maximum was predicted in [155, 133, 215]. However, there is some intrinsic gradient of the degree of $L2_1$-type Heusler structure ordering inside the Heusler layers, with a low degree if order at the interfaces and higher degree of order in the interior [333]. For that reason, it is too early to decide about the origin of this maximum in $I_c(T)$ in these experiments.

Another half-metallic ferromagnet is $La_{0.7}Ca_{0.3}Mn_3O$, which has been studied in the context of $YBa_2Cu_3O_7/La_xCa_{1-x}MnO_3$ multilayers by Peña *et al.* in 2005. Kalcheim *et al.* [334] performed scanning tunneling spectroscopy experiments on $La_{0.7}Ca_{0.3}Mn_3O$ film epitaxially grown on superconducting $Pr_{1.85}Ce_{0.15}CuO_4$, and find long-range penetration of superconductivity into half-metallic $La_{0.7}Ca_{0.3}Mn_3O$. Visani *et al.* [335] find quasiparticle and electron interference effects in the conductance across a $La_{0.7}Ca_{0.3}Mn_3O/YBa_2Cu_3O_7$ interface that demonstrate long-range propagation of superconducting correlations across the half metal. The effect is interpreted in terms of equal-spin Andreev reflections (equal-spin Andreev reflection was introduced in Ref. [165] under the term "spin-flip Andreev reflection", or SAR). The peculiarities of Andreev reflection at a half-metal interface with a singlet superconductor are connected with the spin-active interfaces that unavoidably will be involved, and have been clarified in Appendix C of Ref. [215], and in Refs. [165, 158, 167, 168].

Multilayer converter

Experiments utilizing a multilayer geometry, in some sense manufacturing an inhomogeneous magnetization profile by using different materials for the various layers, led to a successful generation of triplet supercurrents in a thick Co layer by the group of Birge in 2010 [301]. In these experiments two layers of ferromagnetic alloys were used to generate triplet amplitudes, which then are passed as long-range supercurrent through a strongly spin-polarized ferromag-

net. The crucial role of the misalignment of the magnetizations was demonstrated. With this breakthrough a simple and reliable way was found to produce long-range triplet supercurrents. The geometry is shown in Figure 30.21 together with the results. It makes use of the previously acquired knowledge of the group that a Co/Ru/Co trilayer instead of a single Co layer will give much better control over the junction behavior [see Figure 30.14(b)] [250]. When the extra outer layers are present, a long-range effect persists, whereas if they are absent, there are only short-range supercurrents present [301, 336]. It was later shown experimentally that the triplet supercurrent is enhanced up to 20 times after the samples are subject to a large in-plane magnetizing field aligning the two Co layers perpendicular to the magnetizations of the two thin outer layers [337], exactly as predicted e.g. in [155, 107, 296]. In Ref. [338] a triplet supercurrent in S/F'/F/F'/S Josephson junctions was studied, where S was superconducting Nb, F' a thin Ni layer with in-plane magnetization, and F a Ni/$[Co/Ni]_n$ multilayer with out-of-plane magnetization. It was found that the supercurrent decays very slowly with F-layer thickness and is much larger when the F' layer are present than if not. This confirmed that the spin-triplet supercurrent is maximized by the orthogonality of the magnetizations in the F and F' layers.

Theoretical treatments of the geometry used by Khaire *et al.* have appeared in Refs. [300, 302, 283]. It was subsequently demonstrated experimentally that the critical current scales linearly with area in magnetized junctions, confirming the homogeneity of the superconducting phase difference across the junction area [339].

Long-range effects in ferromagnetic nanowires

There have been also reports for a long-range proximity effect in long ferromagnetic nanowires. An early overview over studies of ferromagnetic nanowires with superconducting electrodes was given by Petrashov *et al.* [340]. The controlled growth of nanowires has improved over the last decade, allowing to create crystalline nanowires of several hundreds nanometers length. Wang and coworkers used a single-crystalline ferromagnetic Co nanowire and reported zero resistance in wires up to 600 nm length [341]. A theory for a long-range singlet proximity effect in ferromagnetic nanowires was given by Konschelle *et al.* [342]. Takei *et al.* developed a theory of a ferromagnetic nanowire-superconductor proximity structure based on Rashba spin-orbit coupling in the barrier that induces p-wave superconductivity in the ferromagnet [343].

Almog *et al.* [344] report measurements of the dynamical conductance of a double In/Co/In device, where two Co wires are connected to superconducting In electrodes, running parallel less than a coherence length apart from each other. They find a spin polarization of the superconducting order parameters at the interfaces which depends on the relative spin polarization of the two wires. Colci *et al.* [345] study a similar structure with two superconducting electrodes being bridged by two parallel ferromagnetic wires forming an SFFS junction. They concentrate on the phenomenon of crossed Andreev reflection. At low temperatures and excitation energies below the superconducting gap, they find that the resistance corresponding to antiparallel alignment of the magnetization of the ferromagnetic wires is higher than that of parallel alignment. Spin-dependent interface scattering was found to be important in order to understand these findings [346].

Spiral magnetic order

A realization of the ideas by Bergeret, Volkov, and Efetov was reported in Ref. [347], by employing the conical ferromagnet holmium. A long-range proximity effect was observed. In this work, superconducting phase-periodic conductance oscillations in ferromagnetic Ho wires in contact with conventional superconductors were measured. The distance between the interfaces

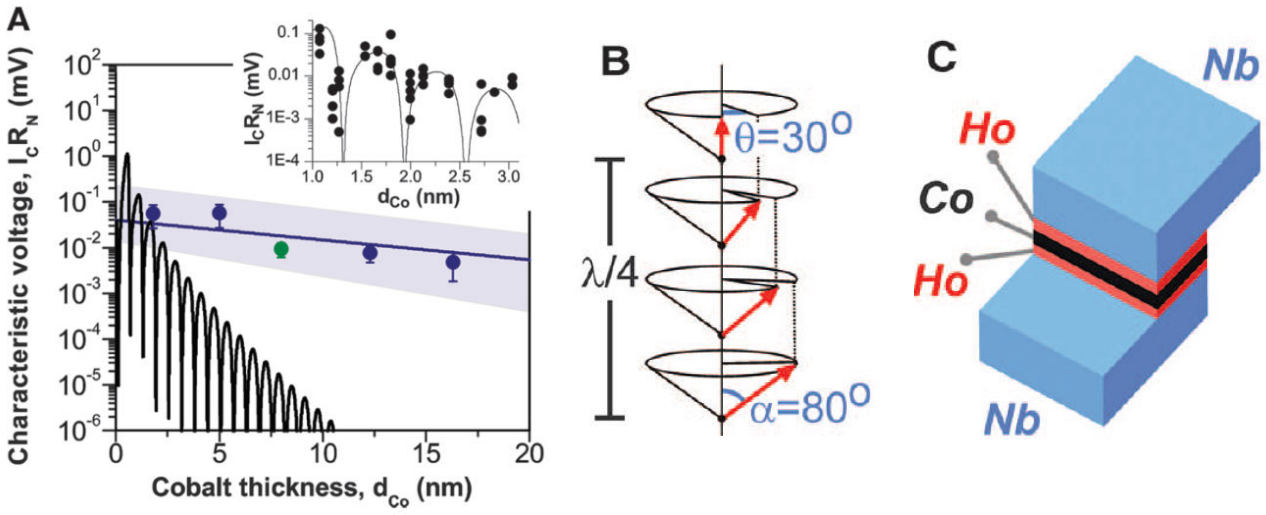

Figure 30.22: (A) Slow decay at 4.2 K in the characteristic voltage I_cR_N of Nb/Ho(4.5 nm)/Co(d_{Co})/Ho(4.5 nm)/Nb junctions (blue circles) and a Nb/Ho(10 nm)/Co(d_{Co})/Ho(10 nm)/Nb junction (green circle) versus Co barrier thickness (d_{Co}). Inset: Comparative data (black circles) from [348] showing the behavior of Nb/Rh/Co/Rh/Nb junctions. The oscillating curves in the inset and main panel are theoretical fits to the experimental data in the inset, as described in [348]. (B) The conical magnetic configuration of idealized Ho below its Curie temperature (20 K), showing an antiferromagnetic spiral rotating in-plane $\theta = 30^o$ per atomic plane and pitched $\alpha = 80^o$ out-of-plane. The moments (arrows) rotate about the surface of a cone with the spiral wavelength, λ, corresponding to a Ho thickness of 3.4 nm. (C) Device layout consisting of two superconducting Nb electrodes coupled via a Ho/Co/Ho trilayer. From Robinson *et al.* [282]. Reprinted with permission from AAAS.

was much larger than the singlet superconducting penetration depth.

A triplet supercurrent has been found by Robinson, Witt, and Blamire with a setup using a cobalt layer sandwiched between two holmium layers, constituting another breakthrough in 2010 [282]. The main results of this work are shown in Fig. 30.22. Without the Ho layers between the Nb and Co (or with the Ho replaced by Rh) the characteristic voltage I_cR_N shows fast oscillations and a short-range decay over six orders of magnitude on a scale of 10 nm. If additional Ho layers are inserted between Nb and Co, the characteristic voltage decays very slowly, by about an order of magnitude on a scale of 50 nm. The effect is spectacular especially for Co thicknesses above 10 nm. Theoretical treatments of this geometry have been given in Refs. [349, 350, 185].

Further reports concentrate on creating artificial non-collinear magnetic structures that can be brought in contact with superconductors. In Ref. [351] it is reported that a new structure using an exchange-spring magnet was fabricated that can be tuned from a collinear to a non-collinear state by a rotating external magnetic field in a controllable way. With this setup the authors found an increase of superconductivity in the structure (transition temperature and conductance) when going to a non-collinear state.

Robinson *et al.* studied Nb/Fe/Cr/Fe/Nb junctions where the thickness of the Cr layer determines the relative alignment of the Fe layers, and find a substantial enhancement of the critical Josephson current when a non-parallel configuration was realized [352].

Witt *et al.* find that in structures with a conical magnetic spacer layer of Ho the critical Josephson current decays exponentially with layer thickness, corresponding to a coherence length of 4.34 nm in Ho, and without showing any oscillatory behavior [353]. Comparing this with the mean free path of 0.28-0.87 nm, they conclude that their Ho structures are in the dirty

limit.

A realization of field-tunable in-plane Bloch domain walls in the rare-earth magnet gadolinium if grown between non-collinearly aligned ferromagnets was suggested in Ref. [354]. It was found that supercurrents flow through magnetic Ni/Gd/Ni nanopillars, the magnitude of which strongly depends on the domain wall state in Gd. The authors explain this result in terms of the inter-conversion of triplet and singlet pairs, the efficiency of which depends on the magnetic helicity of the structure.

For a recent review by Blamire and Robinson see [355].

30.7 Modern developments

In the following I selectively give examples for exciting modern developments of the field, without claiming to cover the entire spectrum of activities.

30.7.1 Spin-valve devices and spin-filter junctions

Although currently the research still concentrates on studying fundamental questions, applications can be imagined in various ways. The most obvious application would be the development of a spin-valve device. Re-entrant phenomena are predicted not only as function of thickness of the adjacent ferromagnetic layers, but also as function of other parameters, e.g. the degree of magnetic inhomogeneity, as in ferromagnets with spiral order. A high degree of experimental control has been achieved in producing large batches of samples with gradually varying thicknesses, allowing for a tailoring of the Fulde-Ferrell-Larkin-Ovchinnikov state [356]. A controllable Josephson spin-valve has been realised recently [357].

Superconducting spin-filter tunnel junctions have been studied recently experimentally [358] and theoretically [359]. In Ref. [358], GdN barriers are used as ferromagnetic insulator barriers, and it is shown that the field and temperature dependence of the critical Josephson current is strongly modified by the ferromagnetic insulator. It is found that the strong suppression of Cooper pair tunneling by the spin filtering of the barrier can be modified by magnetic inhomogeneity in the barrier. In theoretical work [359] it was also demonstrated that the differential conductance may exhibit peaks at different values of the voltage depending on the polarization of the spin filter, and the relative angle between the exchange fields and the magnetization of the barrier.

30.7.2 Flux Qubits and semifluxons

Superconducting electronics is undergoing a revival at present, with pressing need for cryogenic memory for flux quantum logic applications as well as new superconducting Qubit applications. Metal spintronics is already widely employed in computer hard disc technology, and superconducting spintronics may lead to energy efficient memory and logic for supercomputing applications. Superconducting digital single-flux-quantum circuits using superconductor-ferromagnet-superconductor sandwich technology to insert π-Josephson junctions into a circuit is promising due to its high operation speed and low energy consumption [360]. Such systems also solve the problem of high element densities on-chip for operating and holding magnetic flux quanta. A combination of magnetic Josephson junctions and conventional Josephson junctions can be used to form addressable memory cells, energy-efficient memory periphery circuits and programmable logic elements [361, 362].

Another interesting development is semifluxon physics in zero-π Josephson junctions. Fluxons are traveling, solitonic waves of magnetic flux in long Josephson junctions, created by external magnetic fields. In a zero-π-junction a Josephson vortex of fractional magnetic flux

is pinned at the zero-π-boundary. A memory cell based on a φ-Josephson junction has been suggested [363], where writing is done by applying a magnetic field and reading by applying a bias current. Storage at low temperatures is passive, without any bias or magnetic field applied.

A high-frequency cryogenic generator operating at about 200 GHz, and based on flipping a semifluxon in a Josephson junction has recently been demonstrated in Ref. [366]. A π junction is artificially created by current injection using a technique by Ustinov [364], giving rise to a semifluxon [365]. A conversion efficiency of $\sim 10\%$ of dc input power to ac output power was achieved, including the losses on the way from the generator to the on-chip detector. This type of Josephson oscillator is comparable with those based on flux-flow, with advantages like small size and insensitivity to injection current.

Realization of a 0-π junction in an atomic bosonic quantum gas has been proposed in Refs. [367, 368]. In Ref. [368] it is suggested that two-state atoms in a double-well trap are coupled and an all-optical 0-π Josephson junction is created by the phase of a complex-valued Rabi frequency, exhibiting modes similar to semifluxons. It is suggested that pairs of semifluxons can be created by starting from a flat-phase state in long, optical 0-π-0 Josephson junctions formed with internal electronic states of atomic Bose-Einstein condensates [369].

30.7.3 Non-equilibrium quasiparticle distribution

A particular exciting subject is the possibility to utilize non-equilibrium quasiparticle distribution in conjunction with quantum coherence in so-called Andreev interferometer geometries. These devices were introduced by Petrashov, Antonov, Delsing, and Claeson in 1994 [370]. A superconducting wire (e.g. aluminum) is attached at two points to a normal mesoscopic conductor (e.g silver or antimony) to form a loop. The conductance of the wire then oscillates as function of the magnetic flux through the loop. The oscillations are attributed to phase transfer from the superconducting condensate to normal electrons via Andreev reflections at the N-S interfaces. The so-called π-SQUID employs an idea of Volkov [371], where by applying a control voltage directly to a normal metal the electron distribution function in the normal metal is modified. This non-equilibrium distribution spreads to the superconductor and influences the transport in a nonlocal way. This allows for a direct control of the supercurrent through the device, including switching between zero-junction and π-junction behavior. Such a device was realized experimentally by Morpurgo, Baselmans, van Wees, and Klapwijk in 1998-99 [372, 373]. Corresponding effects are intricately connected with non-locality. Cadden-Zimansky, Wei, and Chandrasekhar [374] combined an Andreev interferometer arrangement with injection of non-equilibrium excitations into a normal wire, giving rise to a current that adds to the supercurrent in the Andreev interferometer and leads to a voltage at the contacts. Due to current conservation each current influences the other, and together they allow for tuning of the contact voltage by changing the flux through the Andreev interferometer that controls the supercurrent [375]. Coherent voltage oscillations as functions of external flux are the result.

The combination of non-equilibrium quasiparticle distribution with the Josephson effect seems particularly exciting, and is largely unexplored so far. Recent studies by Bobkova and Bobkov [376, 377] address the problem of spin-dependent non-equilibrium quasiparticle distribution. It is found that the interplay between the spin-dependent quasiparticle distribution and the triplet superconducting correlations induced by the proximity effect between the superconducting leads and ferromagnetic elements of the interlayer leads to the appearance of an additional contribution to the Josephson current. The interplay between short-range and long-range proximity effect is elucidated, and a long-range penetration of opposite-spin Cooper pairs under non-equilibrium conditions is proposed. An increase of the critical Josephson current by few orders of magnitude as a result of the non-equilibrium population in the ferromagnetic layer is suggested. Long-range spin and charge accumulation in mesoscopic superconductors

with Zeeman splitting was recently also studied by Silaev *et al.* [378].

A quantum interference transistor involving textured ferromagnets was suggested in Ref. [379]. It was shown that such a device acts as an ultra-sensitive magnetometer and allows for singlet-triplet switching by tuning a bias voltage. A combination of two spin injectors with an SFS Josephson junction was discussed in Refs. [380, 381].

30.7.4 Dynamical effects

Dynamical effects in superconductor-ferromagnet structures have moved in the focus of interest recently. In particular, it is clear that magnetization dynamics will be linked closely with Josephson dynamics, leading to potentially new effects. The geometric phases discussed in section 30.6.3, when time dependent, are expected to lead to spin accumulation effects via an imbalance between the equal-spin pair electrochemical potentials, very similar to the voltage linked to a dynamical superconducting phase in the ac Josephson effect [172].

The Josephson current in a diffusive superconductor-ferromagnet-superconductor junction with precessing bulk magnetization was calculated in Ref. [382]. It was found that when the junction is phase biased, a dc Josephson current without ac component can still flow under this non-equilibrium condition. Long-range triplet amplitudes are induced by the precessing magnetization.

In Refs. [383, 384] non-equilibrium effects in a Josephson junction with two s-wave singlet superconducting leads coupled via a precessing spin in a quantum dot was examined. An external magnetic field leads to a Larmor precession of the spin, rendering the magnetically active interface time-dependent. The authors analyze the non-equilibrium population of Andreev sidebands and dynamical spin currents. It is found that the supercurrent is enhanced and the critical Josephson current density shows a non-monotonous behavior as function of temperature, accompanied by a corresponding change in spin-transfer torques acting on the precessing spin.

Supercurrent-induced magnetization dynamics in superconductor-ferromagnet Josephson junctions was explored in Refs. [385, 386, 387, 388, 389, 390]. It is found that the spin supercurrent can induce magnetization switching that is controlled by the superconducting phase difference. The authors in Refs. [388, 389] confirm the finding of Ref. [172], that the effect of chiral spin symmetry breaking of the structure leads to additional geometric phases that allow for the stabilization of a φ-junction.

In Ref. [391] the dynamics of superconductor-ferromagnet-insulator-ferromagnet-superconductor (SFIFS) junctions with a thin ferromagnetic layers investigated. The coupled dynamics of the magnetization and the Josephson phase leads to Josephson plasma waves coupled to oscillations of the magnetization, affecting the form of the current-voltage characteristics in weak magnetic fields.

30.7.5 Spin-orbit coupling and topological materials

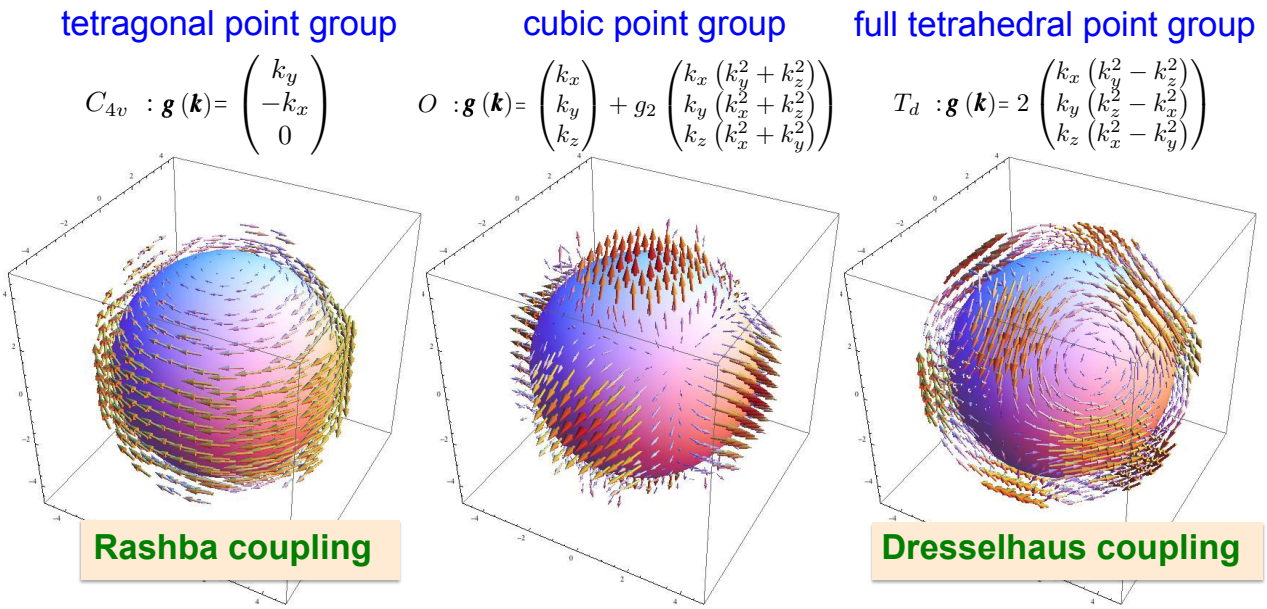

Figure 30.23: Various types of spin-orbit coupling in crystals, relevant for topological superconductivity. The crystal point group sets restrictions to the allowed spin-orbit vector fields. The lowest order expansion terms in crystal momentum are shown.

Spin-orbit effects play an important role whenever the inversion symmetry is broken, either in the bulk material (when it is lacking a center of inversion), or at interfaces and surfaces [392]. A prominent example for spin-orbit effects at surfaces is the Rashba-Bychkov spin-orbit coupling [393], and in the bulk an example is the Dresselhaus coupling due to bulk-inversion asymmetry [394].

Whereas in materials with a center of inversion all band-diagonal matrix elements of the spin-orbit coupling vanish, this is not the case in non-centrosymmetric materials. Spin-orbit coupling in non-centrosymmetric materials is strongly enhanced due to band-diagonal contributions, leading to a splitting of the Fermi surface into spin-orbit bands, sometimes also called 'helicity bands' (although a well defined helicity is only in special cases present). The kinetic part of the Hamiltonian in a one-band model has the form

$$\mathcal{H}_{\text{kin}} = \sum_{\mathbf{k}} \sum_{\sigma\sigma' \in \{\uparrow,\downarrow\}} \left[\varepsilon(\mathbf{k}) + \mathbf{g}(\mathbf{k}) \cdot \boldsymbol{\sigma}\right]_{\sigma\sigma'} a^\dagger_{\mathbf{k}\sigma} a_{\mathbf{k}\sigma'} \tag{30.100}$$

with the spin-orbit vector being odd in $\mathbf{k}$: $\mathbf{g}(-\mathbf{k}) = -\mathbf{g}(\mathbf{k})$. In figure 30.23 various spin-orbit vector fields compatible with the point group of the crystal are visualized on a hypothetical spherical Fermi surface. All three cases are relevant for materials: C_{4v} for $CePt_3Si$ [395], $CeRhSi_3$ [396] and $CeIrSi_3$ [397], T_d for Y_2C_3 [398], and O for $Li_2(Pd_{1-x}Pt_x)_3B$ [399]. The kinetic part of the Hamiltonian can be diagonalized, leading to the above-mentioned helicity bands. The spin-orbit interaction locks the orientation of the quasiparticle spin with respect to its momentum in each band.

One interesting aspect of a non-centrosymmetric ferromagnetic Josephson junction is the modification of the Josephson relation from an odd function in the superconducting phase difference to a current-phase relation where this symmetry is broken. For example, near the critical temperature the current-phase relation $I = I_c \sin(\Delta\chi)$ can be modified to

$$I = I_c \sin(\Delta\chi - \varphi_0), \tag{30.101}$$

where $\Delta\chi$ is the superconducting phase difference, and φ_0 is a phase shift proportional to the magnetic moment perpendicular to the gradient of the asymmetric spin-orbit potential [401]. The possibility of a φ_0-junction has been already taken into account by Josephson [91], and was later considered in Josephson junctions involving unconventional superconductors [400]. Examples in Josephson junctions with half-metals and strongly spin-polarized ferromagnets we discussed in Section 30.6.3. A similar effect has also been predicted for Josephson junctions with a spin-polarized quantum point contact in a two-dimensional electron gas with spin-orbit coupling in an external magnetic field [402]. The spin-dynamics with such a φ_0 Josephson junction has been discussed in Ref. [386]. The competition between a Zeeman interaction and a Rashba spin-orbit interaction has been in the center of attention since a while. In connection with one-dimensional quantum wires, an anomalous φ_0 shift was predicted in Refs. [403, 404]. In a model for a mesoscopic multilevel quantum dot the conditions for an anomalous Josephson current Eq. (30.101) were found to be a finite spin-orbit coupling, a suitably oriented Zeeman field, and the dot being a chiral conductor [405, 406]. In Refs. [322, 407] an anomalous Josephson current was predicted in junctions coupled with a two-dimensional electron gas exhibiting coexistence of spin-orbit coupling and Zeeman field.

A recent development concerns a gauge-covariant approach to establish the transport equations, treating the charge and spin degrees of freedom on equal footing. In this approach both the electromagnetic and spin interactions are described in terms of U(1) Maxwell and SU(2) Yang-Mills equations, respectively [408, 409]. The starting point is a quasiclassical expansion of the microscopic Gor'kov equations in a gauge-covariant manner [410, 411]. The idea is that one can re-write a Hamiltonian of the type

$$H_{\rm kin} = \frac{p_x^2 + p_y^2}{2m} - \mu + \mathbf{h}\cdot\boldsymbol{\sigma} + v_{\rm s.o.}(\hat{\mathbf{z}}\times\mathbf{p})\cdot\boldsymbol{\sigma} \tag{30.102}$$

as

$$H_{\rm kin} = \frac{(p_x - mv_{\rm s.o.}\sigma_y)^2}{2m} + \frac{(p_y + mv_{\rm s.o.}\sigma_x)^2}{2m} - \mu - \frac{mv_{\rm s.o.}^2}{2} + \mathbf{h}\cdot\boldsymbol{\sigma}, \tag{30.103}$$

which motivates to introduce $A_x = -mv_{\rm s.o.}\sigma_y/\hbar$ and $A_y = mv_{\rm s.o.}\sigma_x/\hbar$ as two non-abelian gauge potentials. In this approach, the covariant derivative

$$\mathfrak{D}G = \partial_{\mathbf{R}}G + i[\mathbf{A}, G] \tag{30.104}$$

with the gauge potential $\mathbf{A}$ is associated with the gauge field

$$\mathbf{F}_{\mu\nu} = \partial_\mu\mathbf{A}_\nu - \partial_\nu\mathbf{A}_\mu + i[\mathbf{A}_\mu, \mathbf{A}_\nu] \tag{30.105}$$

which is antisymmetric in its indices, and has only one component, $\mathbf{F}_{xy} = -2(mv_{\rm s.o.})^2\sigma_z/\hbar^2$. This leads in the transport equation to the modification

$$i\hbar\mathbf{v}_f\cdot\nabla_{\mathbf{R}}\hat{g} \to i\hbar\mathbf{v}_f\cdot\nabla_{\mathbf{R}}\hat{g} + imv_{\rm s.o.}^2\partial_\varphi\{\sigma_z, \hat{g}\} \tag{30.106}$$

with ∂_φ the derivative along the Fermi surface (which is assumed a circle for simplicity). Using this modified equation, the role of spin-orbit coupling as source of long-range triplet proximity effect in superconductor-ferromagnet structures has been explored in Ref. [411]. Furthermore, the connection to φ_0 Josephson junction behavior has been elucidated [412, 413]. It should be, however, cautened that the modification in Eq. (30.106) does not contain all terms of the same order as the additional term. A quasiclassical theory of disordered Rashba superconductors has also been proposed in Ref. [414].

One way to manipulate spin in spintronics devices is the so-called spin Hanle effect [415, 416, 417], which describes the coherent rotation of a spin in an external magnetic field. A recent theoretical study of this effect is given in Ref. [418]. It is demonstrated that superconductivity

can strongly influence the coherent spin rotation, depending on the type of spin relaxation mechanism being dominated either by spin-orbit coupling or spin-flip scattering at impurities.

Another manifestation of coherence in systems with spin-orbit coupling is the Aharonov-Casher effect [419], leading to a phase on the Josephson current through a semiconducting ring attached to superconducting leads [420]. This effect is the charge-spin dual effect to the Aharonov-Bohm effect [421], which describes the relative phase shift between two charged particle paths enclosing a magnetic flux. Both effects are manifestations of geometric phases acquired by the quantum mechanic wave function under adiabatic changes [422, 423]. The particle's spin acquires such a geometric phase in systems with spin-orbit interaction [424, 425, 426, 427, 428, 429, 430]. The Aharonov-Casher effect was, e.g., observed experimentally in ring structures of HgTe/HgCdTe quantum wells [431]. In superconducting Josephson rings, or closed Josephson junction arrays, such phases lead to oscillations of the Josephson current due to the Aharonov-Casher phase [432, 420, 433, 434]. The effect allows for control of the Josephson current through the control of the Aharonov-Casher phase by the gate voltage. Thus, this effect is a promising candidate for realizing new types of controllable devices in superconducting spintronics based on geometric phases.

Recently Mironov *et al.* [435] studied double path interference during Cooper pair transport through a single nanowire with two conductive channels. It is found that multi-period magnetic oscillations appear due to quantum mechanical interference between channels affected by spin-orbit coupling and Zeeman coupling. The model is relevant to recent observations of interference phenomena in Bi nanowires [436].

A Josephson junction containing a spacer with strong spin-orbit interaction was considered in Ref. [437]. A nonlinear dynamical coupling between magnetic moment and charge current was found, and magnetic torque and charge pumping was investigated in such a system. The intricate coupling between spin and charge currents in systems with strong spin-orbit coupling is previously known from non-centrosymmetric superconductors, where spin-polarized Andreev states play a prominent role [438].

This connects to the current hot topic of topological materials, in particular topological insulators and superconductors, both systems with strong spin-orbit coupling. As an example for the extremely rich plethora of effects involving topological materials we mention here the possibility to observe chiral Majorana modes in one-dimensional channels built at a superconductor/ferromagnetic-insulator/superconductor junction on top of a topological insulator [323], where a φ_0 junction is predicted. The effect is interpreted as tunneling process between two Majorana edge channels at the two interfaces between the superconductor and the ferromagnetic insulator. Majorana fermions have the property of being their own antiparticle, i.e. their field operators fulfill $\gamma_\alpha = \gamma_\alpha^\dagger$ [439, 440]. A non-trivial superconducting phase is also obtained in proximity junctions involving semiconductors with Rashba spin-orbit coupling and a time-reversal symmetry breaking Zeeman term in the Hamiltonian [441, 442].

The combined effect of spin-orbit interaction, magnetic field, and Coulomb charging for a multilevel quantum dot tunnel contacted by two superconductors was analyzed in Ref. [443]. Majorana bound states in a double dot variant of this system are predicted to leave a clear signature in the 2π-periodic current-phase relation. Majoranas in spin-orbit coupled ferromagnetic Josephson junctions were investigated in Ref. [444], were it was shown that two delocalized Majorana fermions with no excitation gap appear in a π-junction. Josephson currents through Majorana bound states in topological insulators have been studied in Refs. [445, 446, 447, 448, 449, 450, 451, 452, 453, 454]. Such Josephson junctions carry 4π-periodic bound states [445]. It has been shown that under certain conditions this periodicity manifests itself by an even-odd effect in Shapiro steps [447, 453]. In addition, a peak in the current noise spectrum at half the Josephson frequency has been predicted [454].

The diverse spectrum of effects and phenomena in hybrid systems between singlet super-

conductors and topological insulators (see e.g. Refs. [455, 456, 457, 458, 459, 137, 460, 461]) are promising examples of how the field can be brought forward, playing a prominent role in various modern developments at the forefront of international research.

Part XI
Appendix

A Introduction to Superconductivity

A.1 Other Motivation

Обсудим всю мотивацию, которая позволит нам познать предмет без проблем.

A.1.1 Other General Motivation

(I'll write it very not soon)

Польза в плане развития как профессионала

(потом раскрою)

Польза в плане саморазвития

A.3 Acknowledgements

Currently, no one except me has worked on the sections of this note (with the exception of sections taken from books).

A.4 Literature

A.4.1 Main Literature

Основная обучающая

[1] В.В. Шмидт Введение в физику сверхпроводников
Большая книга, где многое разобрано, лучше книг для начала и общего обзора не знаю. Note that English version don't have many chapters that Russian have, so here I refer to the Russian version.

[2] Kittel C. Introduction to Solid State Physics, 8th 2005
Отличная книга, где есть раздел с основами сверхпроводимости, этих тем и достаточно для минимального знакомтсва.

Основная профессиональная

[3] Abrikosov Fundamentals of Theory of Metals
A big book that tells a lot about superconductors (and not only) that one would never read somewhere else.

[4] Mineev, V.P. Samokhin, K. Introduction to Unconventional Superconductivity
Очень крутая книга, где описывается много явлений и методов, о которых ну уж очень сложно подумать, пройдя обычный вводный курс сверхпроводимости.

Books With Many Solved Problems

Таких прямо отдельных задачников нет, но тут приведу книги, в которых много задач решено.
(потом напишу)

A.4.2 Additional Literature and Articles on Various Phenomena and Methods

Дополнительная обучающая

[5] Ya. V. Fominov, N. M. Shchelkachev The Josephson Effect: An educational and methodological guide

32 страницы про эффект Джозефсона, интересное изложение, описываются некоторые детали, которые мало кто обсуждает.

[6] Варламов Ларкин Теория флуктуаций в сверхпроводниках

Очень крутая книга, где много ответов и специфических явлений. Можно было бы брать ее основным учебником, но так не делают наверное, потому что слишком много информации появится. Но точно попробовать найти в ней ответ на какой-то вопрос - отличная идея.

[7] Li, Chuan Superconducting proximity effect in graphene and Bi nanowire based junctions

кандидатская просверхпроводящие контакты, очень хорошее изложение много чего, наверняка еще многое прочту из нее.

[8] Gross, R. and Marx, A. and Deppe, F. Applied Superconductivity: Josephson Effect and Superconducting Electronics

В открытом доступе только 60 страниц 2005го года, полистал, понял, что много там деталей, которую минимум неделю учить пришлось бы. Просто много теории, может, на самом деле приложения и раскрыты, не знаю.

[9] Lifshitz, E.M. and Pitaevskii, L.P. Statistical Physics: Theory of the Condensed State

Типичный учебник по код. средам, в котором многому можно научиться, в том числе некоторым важным, но не супер актуальным вопросам про сверхпроводимость.

Дополнительная по теоретической сверхпроводимости

Reinhold Kleiner and Werner Buckel. Superconductivity: A An Introduction, Third Edition.

Big book about basics of superconductivity with overview with many experiments. KU Leuven course was following it. Use Annas' archive to get it, as usual.

[10] Blatter, G. and Feigel'man, M. V. and Geshkenbein, V. B. and Larkin, A. I. and Vinokur, V. M. Vortices in high-temperature superconductors

По сути книга про вихри в high-temperature superconductors, там очень много всякого, минимум месяца 4 изучал ее бы, если бы нужно было.

[11] Suppression of the Josephson current through a narrow, mesoscopic, semiconductor channel by a single impurity Bagwell, Philip F.

Мне показалось, что тут хорошо написано про Андреевские уровни, так что добавил эту статью, потом поизучаю, не на пару дней тема.

[12] McMillan, W. L. Transition Temperature of Strong-Coupled Superconductors

Статья с умными формулами и таблицами экспериментальных данных. Обычной подготовки по Левитову Шитову достаточно для понимания её, в ней всего 2 страницы сложных формул. Если буду заниматься теорией и будет свободное время - изучу её.

Articles about superconductive junctions: theoretical methods

Barone A., Paterno G. Physics and aplication of the josephson effect
A big and very good book about Josephson junctions, maybe it is top 5 books one should read about them.

Blonder Tinkham Klapwijk Transition from metallic to tunneling regimes in SC microconstrictions: Excess current, charge imbalance, and supercurrent conversion
One of the most famous articles about superconducting weak leaks.

[13] Chamon, C. and Jackiw, R. and Nishida, Y. and Pi, S.-Y. and Santos, L. Quantizing Majorana fermions in a superconductor
Кирилл сказал, что там про Намбу базис и про Боголюбова де Жена хорошая теория, потом почитаю пару раз, не такая полезная статья, но тоже вроде как что-то там есть, чему можно поучиться.

C. W. J. Beenakker Universal limit of critical-current fluctuations in mesoscopic Josephson junctions
A very famous article with a very useful method.

Articles about superconductive junctions: experiments, applications

I.K. Yanson, V.M. Svistunov, I.M. Dmitrenko Experimental Observation of the Tunnel Effect for Cooper Pairs with the Emission of Photons 1964
First observation of Josephson radiation.

Статьи о других теоретических методах и особых моделях

[14] Likharev, K. K. Superconducting weak links
Очень известная статья на 60 страниц про сверхпроводимость и джозефсонику, когда-то поизучаю скорее всего.

[15] Yu. A. Bychkov and l. P. Gor'kov and I. E. Dzyaloshinskiĭ Possibility of superconductivity type phenomena in a one-dimensional system
Статья про 1Д сверхпроводимость, интересная, по идее учебник их как раз дает полностью к этому подготовку.

[16] Possibility of Synthesizing an Organic Superconductor Little, W. A.
Статья про 1Д сверхпроводимость, интересная и самая первая.

[17] Marsiglio, F. Eliashberg theory: A short review
Вроде хороший обзор этой теории, когда-то поизучаю, интересно, но не на пару дней.

Статьи про разные явления, специфические конструкции

[18] Doll, R. and Näbauer, M. Experimental Proof of Magnetic Flux Quantization in a Superconducting Ring
Кольцом можно доказать, что поток квантуется, на 2 страницы это написано, я так и не дошел разобраться в этом.

[19] Deaver B, Fairbank W. Experimental Evidence for Quantized Flux in Superconducting Cylinders

Самая известная и мб первая статья про квантование потока. Я так и не понял, потратив 15 минут, что там за странные графики есть? Потом когда-то еще почитаю, статья на 4 страницы.

[20] Andreev, A F Thermal conductivity of the intermediate state of superconductors

Оригинальная небольшая статья Андреева про его связные состояния, наверняка есть много хороших идей.

[21] Ryazanov, V. V. et al. Coupling of Two Superconductors through a Ferromagnet: Evidence for a π Junction

Известная статья про SFS контакт, там вообще много статей про это, может, когда-то изучу, пока нечего сказать про это.

[22] Magnetization of Hard Superconductors Bean, C. P.

Очень цитируемая статья, видел из нее график, доступа к ней не нашел. Видимо, там какие-то явления интересные происходят.

[23] Magnetization of multiple-quanta vortex lattices Moshchalkov, V. V. et. al.

Там график, что типа намагниченность возрастает в некоторых точках скачками, когда число его квантов равно числу вихрей. Видел на лекции, статью не читал, не актуально.

[24] Wiedenmann, J. 4π-periodic Josephson supercurrent in HgTe-based topological Josephson junctions

Статья про особый эффект Джозефсона со многим про шаги Шапиро. Много интересных графиков, но нет времени в ней пока разбираться, все равно нужно основы доучивать.

[25], Giaever, Ivar Energy Gap in Superconductors Measured by Electron Tunneling

Статья на страницу, за которую автор получил часть Нобелевской премии, потому что предложил по производной мерить щель. Я доучу наконец-то, как конкретно это делать?

[26], Hamilton, Clark A Josephson voltage standards

Статья с обзором применений эф. Джозефсона, про схемы с тысячами СКВИД-ами, джозефсоновские стандарты. Я совсем мало что знаю про это, нужно будет - отдельно читать нужно будет несколько дней. Во многих статьях видел картинки из нее, видимо, известная.

[27] Schulz, R. Chesca, B. et.al. Design and realization of an all d-wave dc π-superconducting quantum interference device

Небольшая статья, где есть график тока от потока для пи-СКВИДов, а также умные мысли про них.

[28] Jaklevic, R. C. and Lambe, J. and Mercereau, J. E. and Silver, A. H. Macroscopic Quantum Interference in Superconductors

Одна из первых статей про СКВИД-ы, есть несколько графиков интерференции. Киттель потом его у себя тоже привел. Вообще, типичная теория про них там, основные идеи в ней уже в учебниках.

A.7 History of Superconductivity in a Nutshell

Overview of the Development of the Theory of Superconductivity by Shmidt

The first theory which proved successful in describing the electrodynamics of superconductors was the London theory (1935). The theory was phenomenological, that is, it had introduced two equations, in addition to Maxwell's equations, governing the electromagnetic field in a superconductor. These equations provided a correct description of the two basic properties of superconductors: absolute diamagnetism and zero resistance to a dc current. The London theory did not attempt to resolve the microscopic mechanism of superconductivity on the level of electrons, that is, the question: "Why does a superconductor behave according to the London equations?" remained beyond its scope.

According to the London theory, electrons in a superconductor may be considered as a mixture of two groups: superconducting electrons and normal electrons. The number density of the superconducting electrons, n_s, decreases with increasing temperature and eventually becomes zero at $T = T_c$. At $T = 0$ it is the other way round, that is, n_s is equal to the total density of conduction electrons. These are the postulates of the so-called two-fluid model of a superconductor. A flow of superc ducti g ele trons meets no
in a superconductor because, if it did, it would cause the superconducting electrons to accelerate infinitely. Therefore, under stationary conditions, that is, without an electric field, the normal electrons are at rest. In contrast, in the presence of an ac electric field, both the normal and the superconducting components of the current are finite and the normal current obeys Ohm's law.

In the framework of this concept, a real superconductor can be modeled by an equivalent circuit consisting of a normal resistor and an ideal conductor connected in series. The ideal conductor in the circuit must have a finite inductance to mimic the inertia of the superconducting electrons.

The London equations provided a description for the behavior of the superconducting component of the electronic liquid in both dc and ac electromagnetic fields. They also helped to understand a number of aspects of the superconductors' behavior in general. However, by the end of the 1940s, it was clear that to one question at least the London theory gave a wrong answer. For an interface between adjacent normal and superconducting regions, the theory predicted a negative surface energy $\sigma_{ns} < 0$. This implied that a superconductor in an external magnetic field could decrease its total energy by turning into a mixture of alternating normal and superconducting regions. In order to make the total area of the interface within

the superconductor as large as possible, the size of the regions must be as small as possible. This was supposed to be the case even for a long cylinder in a longitudinal magnetic field, in contradiction to experimental evidence existing at that time. Experiment showed that such a separation of the normal and superconducting regions occurred only for specimens having a nonzero demagnetizing factor (the intermediate state, see Sect. 1.2.2). In addition, the layers were rather thick (~ 1 mm as in Fig. 1.7), which could only be the case if $\sigma_{\rm ns} > 0$, again in contradiction to the predictions of the London theory.

The above contradiction was reconciled by a theory proposed by V.L. Ginzburg and L.D. Landau (the so-called GL theory) which was also phenomenological but took account of quantum effects. Why it is so important to include quantum effects will become clear in a moment. Assume that there exists a wavefunction Ψ describing the superconducting electrons quantum-mechanically. Then the squared amplitude of this function (which is proportional to $n_{\rm s}$) must be zero in a normal region, increase smoothly through the normal-superconducting (NS) interface and finally reach a certain equilibrium value in a superconducting region. Therefore, a gradient of Ψ must appear at the interface. At the same time, as is well known from quantum mechanics, $|\nabla\Psi|^2$ is proportional to the density of the kinetic energy. Thus, by taking into account quantum effects, we also take into account an additional positive energy stored at the NS interface, which creates the opportunity to obtain $\sigma_{\rm ns} > 0$.

The GL theory will be discussed in detail in Chap. 3. Here we shall only outline its most important ideas which have determined the tremendous importance of the GL theory for the entire field of superconductivity.

The GL theory introduced quantum mechanics into the description of superconductors. It assigned to the entire number of superconducting electrons a wavefunction depending on a single spatial coordinate [recall that, generally speaking, a wavefunction of n electrons in a metal is a function of n coordinates, $\Psi(r_1, r_2, \ldots, r_n)$]. By doing so, the theory established the coherent behavior of all superconducting electrons. Indeed, in quantum mechanics, a single electron in the superconducting state is described by a function $\Psi(r)$. If we now have n_8 absolutely identical electrons (where n_8, the superconducting electron number density, is a macroscopically large number) and all these electrons behave coherently, it is clear that the same wavefunction of a single parameter is sufficient to describe all of them. This idea was a breakthrough that enabled the prediction of many beautiful quantum, and at the same time macroscopic, effects in superconductivity.

The GL theory was built on the basis of the theory of second-order phase transitions (the Landau theory) and, therefore, it is valid only in the vicinity of the critical temperature, that is, within the temperature range $T_{\rm c} - T \ll T_{\rm c}$. The scope of its validity will be discussed in more detail in Sect. 6.6.

Having applied the GL theory to superconducting alloys, A.A. Abrikosov developed a theory of the so-called type-II superconductors (1957). It turned out that superconductors do not necessarily have to have $\sigma_{\rm ns} > 0$. Those that do have $\sigma_{\rm rs} > 0$ are type-I superconductors. But the majority of superconducting alloys and chemical compounds show $\sigma_{\rm nB} < 0$; they are type-II superconductors. For type-II superconductors, there is no Meissner effect and the magnetic field does penetrate inside the material, but penetrates in a very unusual way, that is, in the form of quantized vortex lines (quantum effect on the macroscopic scale!). Superconductivity in these materials can survive up to very high magnetic fields.

Still, neither the London, nor the GL theory could answer the question: "What are those 'superconducting electrons' whose behavior they were intended to describe?" It was 46 years since the discovery of superconductivity but at the microscopic level a superconductor remained a mystery.

This question was finally resolved in 1957 by the work of J. Bardeen, L. Cooper and J. Schrieffer (the BCS theory). An important contribution was also made by N.N. Bogolyubov

(1958) who developed a mathematical method now widely used in studies of superconductivity.

The decisive step in understanding the microscopic mechanism of superconductivity is due to L. Cooper (1956). The essence of his work can be outlined as follows. Consider a normal metal in the ground state: in k space, all states for non-interacting electrons inside the Fermi sphere are occupied, while all those outside it are empty. Then an extra pair of electrons is brought
face (the arrows indicate the directions of electron spins). It turned out that if, for whatever reason, the two electrons become attracted to each other, they form a bound state regardless of how weak the attraction is. In real space, these electrons form a bound pair - a Cooper pair.

What the BCS theory has demonstrated is that taking into account the interaction between electrons and phonons can, under certain circumstances, lead to electron-electron attraction. As a result, a part of the electrons form Cooper pairs. The total spin of a Cooper pair is zero, which means that it represents a Bose particle (that is, obeys Bose-Einstein statistics). Such particles possess a remarkable property: if the temperature of a system falls below a certain temperature T_c, they can all gather at the lowest energy level (in the ground state). Furthermore, the larger the number of the particles that have accumulated there, the more difficult it is for one of them to leave this state. This process is called Bose condensation. All the particles in the condensate have the same wavefunction, depending on a single spatial coordinate. One can easily understand that the flow of such a condensate must be superfluid, that is, dissipation-free. Indeed, it is not easy at all for one of the particles to be scattered by, say, an impurity atom or by any other defect of the crystal lattice. In order to become scattered, the particle would first have to overcome the 'resistance' of the rest of the condensate.

Thus one can briefly describe the phenomenon of superconductivity as follows. At $T < T_c$, there exists a condensate of the Cooper pairs. This condensate is superfluid. It means that the dissipation-free electric current is carried by the Cooper pairs, i.e., the charge of an elementary current carrier is $2e$.

The microscopic theory of superconductivity was elaborated further by L.P. Gorkov (1958) who developed a method to solve the model BCS problem using Green's functions. He applied this method, in particular, to find microscopic interpretations for all phenomenological parameters of the GL theory as well as to define the theory's range of validity (see Sect.6.6). The works by Gorkov have completed the development of the Ginzburg-Landau-Abrikosov-Gorkov theory (the GLAG theory).

Then everything seemed to be settled until the critical temperature made a quantum leap. In 1987 J. Bednorz and K.A. Mller discovered the first high- T_c superconductor ($LaBaCuO_4, T_c \sim$ 40 K). Subsequently, materials have been found that raise T_c to temperatures of up to ~ 130 K ($HgBa_2Ca_2Cu_3O_8$). The classic BCS theory was unable to account for many of the properties of the high- T_c materials. The electron-phonon mechanism became questionable. New mechanisms - such as the so-called d-wave pairing - have been proposed. At present, the question of why the high- T_c superconductors have such high T_c values is still largely unanswered. Let us hope that the definitive answer need not be awaited for another 46 years.

A.8 Puzzles for Different Situations in Life

Обсудим в порядке интересности задачки и вопросы

A.8.1 Typical Puzzles

A.8.2 Everyday Puzzles

A.8.3 Fundamental Puzzles

A.8.4 Puzzles about Details

A.8.5 Puzzles for Mastering Typical Concepts

Допустим, видим человека, который в принципе хотел бы понять суть, опишем, какие в какой последовательности будем задавать, чтобы в типичном случае ему было бы интереснее въезжать. В частности это могут быть младшие студенты или редко школьники.

Головоломки для освоения школьного уровня

Головоломки для освоения уровня теормина

Головоломки для освоения других особенностей

B Mathematics and Physics for Reference

B.0.1 Quantum Mechanics for Superconductivity (??)

Особое понимание квантовой механики для сверхпроводимости

Волновая функция как очевидный ответ к природе сверхпроводимости (??????)

(??? почему выгодно пользоваться волновой функцией??? почему именно с ней решится задача??? напишу четко, пока что не понимаю, что такое макроскопическая волновая функция огромного количества электронов.)

B.0.2 Some Mathematics for Superconductivity (??)

(тут многое может быть)

Типичный интеграл БКШ

(?? строчка - откуда он???)

$$I(u) = \int\limits_0^\infty \frac{dx}{\sqrt{x^2+u^2}\left(e^{\sqrt{x^2+u^2}}+1\right)}.$$

Получим его асимптотики при низких температурах ($u \gg 1$) и при температурах вблизи точки перехода ($u \ll 1$). При $u \gg 1$ раскладываем по степеням u^{-1}:

$$I(u) \approx \int\limits_0^\infty \frac{dx}{u} e^{-u\left(1+\frac{x^2}{2u^2}\right)} = \left(\frac{\pi}{2u}\right)^{1/2} e^{-u}.$$

При малых $u \ll 1$ представим $I(u) \equiv I_1(u) + I_2(u)$, в

$$I_1(u) := \frac{1}{2}\int\limits_0^\infty \left(\frac{1}{\sqrt{x^2+u^2}} - \frac{1}{x}\ \mathrm{th}\ \frac{x}{2}\right) dx$$

первый член подынтегрального выражения интегрируется элементарно, а второй интегрируется по частям, в итоге

$$I_1(u) = \frac{1}{2}\ln\frac{u}{2} + \frac{1}{4}\int\limits_0^\infty \frac{\ln x dx}{\mathrm{ch}^2(x/2)}.$$

(?у Пухова тут видимо опечатка, перерешаю??) Стоящая в (16.4) константа равна $(1/2)$ $\ln(\pi/2\gamma)$, $\ln\gamma = C = 0,577$.

$$I_2(u) := \frac{1}{2}\int\limits_0^\infty \left(\frac{1}{x}\mathrm{th}\frac{x}{2} - \frac{1}{\sqrt{x^2+u^2}}\mathrm{th}\frac{\sqrt{x^2+u^2}}{2}\right) dx$$

$$I_2(0) = 0 \qquad\qquad I_2(u) \approx \frac{u^2}{2}\int\limits_0^\infty \frac{dx}{x}\left(\frac{1}{x}\ \mathrm{th}\ \frac{x}{2}\right)'.$$

Интеграл в (16.6) равен $7\zeta(3)/4\pi^2$. Таким образом, для обоих предельных случаев имеем

$$I(u) = \begin{cases} \left(\frac{\pi}{2u}\right)^{1/2} e^{-u} & \text{при } u \gg 1, \\ \ln\frac{\pi}{\gamma u} + \frac{7\zeta(3)}{8\pi^2}u^2 & \text{при } u \ll 1. \end{cases}$$

[50] Having said this, in the spirit of phenomenological exploration even the present author has used this formalism to explore other types of "bosonic glue." See, for example, S. Verga, A. Knigavko and F. Marsiglio, *Inversion of angle-resolved photoemission measurements in high-Tc cuprates* Phys. Rev. B**67**, 054503 (2003).

[51] This is not without irony, as one of the most celebrated electron-phonon-driven superconductors is MgB_2, with a $T_c \approx 39$ K. Ab initio calculations have explained this by finding *considerable* anisotropy in the coupling function. See Hyoung Joon Choi, David Roundy, Hong Sun, Marvin L. Cohen and Steven G. Louie, *The origin of the anomalous superconducting properties of MgB_2*, Nature **418**, 758-760 (2002).
Not everyone agrees with this interpretation. See, for example, J.E. Hirsch and F. Marsiglio, *Electron-phonon or hole superconductivity in MgB_2*, Phys. Rev. B **64**, 144523 (2001).

[54] We could have elected to keep the area, $\int_0^\infty d\nu \alpha^2 F(\nu)$ constant as well, for example.

[55] There are undoubtedly references that describe this procedure in more detail, but I learned it primarily from a mentor at the time, Ewald Schachinger, who was a frequent visitor at McMaster University during the course of my PhD.

[79] There is, however, a calculation that describes the "undressing" of polarons as the number of carriers is increased when those carriers are holes, but this occurs due to an inherent electron-hole asymmetry in the model that is not present in the Holstein model. See J.E. Hirsch, *Polaronic superconductivity in the absence of electron-hole symmetry,* Phys. Rev. B**47**, 5351 (1993), and J.E. Hirsch, *Electron-hole asymmetric polarons*, in *"Polarons and Bipolarons in High-T_c Superconductors and Related Materials"*, ed. by E.K.H. Salje, A.S. Alexandrov and W.Y.
