случай, в котором можно ожидать простой зависимости $U(j)$, - случай малых токов $j \ll j_c$. В случае коллективного пиннинга вихревой решетки слабыми примесями (или пиннинга отдельных вихревых линий) удается показать, что эта зависимость должна быть степенной, $U(j) \simeq U_c\,(j_c/j)^{\mu}$. Полуколичественная теория, приводящая к такому результату, была развита в работе [122] и называется теорией коллективного крипа (см. также [96]). Значение показателя μ в теории коллективного крипа зависит от соотношения длины пиннинга R_p, постоянной решетки a_0 и лондоновской длины λ, а также от отношения j/j_c и может меняться от значений порядка 0.1 до больших единицы. Простейшая интерполяционная формула, содержащая в себе и область $j \ll j_c$, и область $j_c - j \ll j_c$, может быть написана в виде

$$U(j) \simeq U_c \left[\left(\frac{j_c}{j} \right)^{\mu} - 1 \right] \tag{42.5}$$

Используя формулу (42.5) вместе с (42.3), получаем закон релаксации тока в виде

$$j(t) = j_c \left[1 + \frac{\mu k_{\mathrm{B}} T}{U_c} \ln \left(1 + \frac{t}{t_0} \right) \right]^{-1/\mu} \tag{42.6}$$

В тех случаях, когда $\mu \ll 1$, как, например, в случае слабо взаимодействующих между собой вихревых линий (т.е. при низких полях и температурах), выражение (42.6) можно приближенно эаписать в виде $j(t) \simeq j_c \exp\left[-\left(k_{\mathrm{B}}T/U_c\right) \ln\left(t/t_0\right)\right]$, т. е. измеряемый на
некотором масштабе времени t экранирующий ток оказьвается экспоненциальной функцией температуры и при этом степенной функцией времени t, что и наблюдалось экспериментально [123]. M, ед. СГСМ

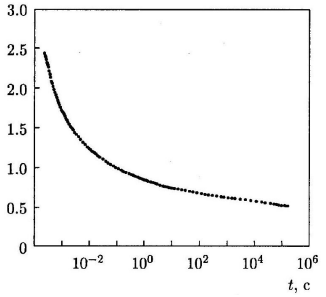

Рис. 42.1. Релаксация остаточной намагниченности в кристалле ВТСП на интервале времени в 9 порядков [121].

В общем случае величина, удобная для анализа экспериментальных данных по релаксации, - логарифмическая производная $S(t) = \partial \ln j(t)/\partial \ln t$. Используя (42.6), получаем предсказание для $S(t)$ в теории коллективного крипа:

$$S(t) = \frac{k_{\mathrm{B}} T}{U_c + \mu k_{\mathrm{B}} T \ln\left(1 + t/t_0\right)} \tag{42.7}$$

Важной чертой зависимости (42.7) является насыщение роста S как функции температуры при больших T и ее уменьшение как функции $\ln\left(t/t_0\right)$ в пределе больших времен. Оба эти предсказания, проистекающие из картины роста энергетических барьеров крипа по мере "старения" системы и релаксации в ней тока, нашли экспериментальное подтверждение; подробное обсуждение этих экспериментов можно найти в обзоре [124].

В теории коллективного крипа энергетические барьеры $U(j)$ растут при стремлении плотности тока j к нулю неограниченно. Следовательно, скорость движения вихрей

$v(j) \propto E(j)$, а дифференциальное сопротивление $dE/dj \propto \rho_f e^{-U(j)/k_B T}$ экспоненциально падает при уменьшении плотности тока. Это свойство очень важно - оно показывает, что равновесное состояние коллективного пиннинга вихревой решетки имеет нулевое линейное сопротивление, т.е. отличается от высокотемпературного состояния с конечной проводимостью качественным образом и потому должно быть отделено от него некоторым фазовым переходом.

Обычный способ нахождения линии перехода $H_{c2}(T)$ в сверхпроводящее состояние состоит в измерении линейного сопротивления $\rho(T, H)$ как функции температуры при различных значениях H: температура перехода $T_c(H)$ определяется по обращению $\rho(T, H)$ в нуль (функция же $H_{c2}(T)$ является обратной к $T_c(H)$). Фактически "нулевым» считается сопротивление ниже некоторой выбранной величины, например, 0.1 (или 0.01) от сопротивления в нормальном состоянии ρ_n, так что положение линии перехода определяется не вполне однозначно. У низкотемпературных сверхпроводников $\rho(T, H)$ очень резко падает с понижением температуры или поля ниже линии перехода, так что неоднозначность в определении $H_{c2}(T)$ очень мала. Совсем иначе дело обстоит в случае ВТСП; характерное семейство кривых $\rho(T, H)$ для $YBa_2Cu_3O_{7-x}$ показано на рис. 42.2. С увеличением H температурный интервал, в котором происходит падение сопротивления, очень заметно уширяется (причем верхние части кривых $\rho(T)$ зависят от величины H гораздо слабее, чем нижние), так что раэличные варианты выбора "нулевого" сопротивления (например, 0.1 или 0.01 от ρ_n) привели бы к существенно различным значениям температуры перехода $T_c(H)$. Поэтому в экспериментах с ВТСП фазовый переход приходится регистрировать по изменению (с температурой или полем) вида вольт-амперных характеристик $V(j)$: измерение ВАХ в широком (несколько порядков) интервале токов и напряжений позволяет надежно определить точку обращения линейного сопротивления в нуль.

На рис. 42.3 приведен в двойной логарифмической шкале на-

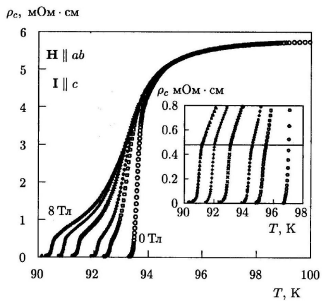

Рис. 42.2. Температурные зависимости сопротивления монокристалла YBaCuO при различных значениях H внешнего магнитного поля [125]. На вставке в более крупном масштабе показаны данные для области низких сопротивлений; участки кривых ниже сплошной линии практически совпадают для различных значений H.

бор вольт-амперных характеристик из эксперимента [126] на тонкой (толщина 0.4 мкм) пленке $YBa_2Cu_3O_{7-x}$, соответствующих различным значениям температуры, во внешнем поле $H_0 = 1$ Тл. Весь набор вольт-амперных характеристик делится на две части с качественно различным поведением. На графиках для температур $T < T_g \simeq 84.6$ К видна отрицательная кривизна в области малых токов, т.е. электрическое поле $E(j)$ убывает при $j \to 0$ по закону более быстрому, чем степенной, что качественно соответствует обсуждавшейся выше зависимости (42.5) энергии активации крипа. С другой стороны, кривые, соответствующие $T > T_g$, E, В/m

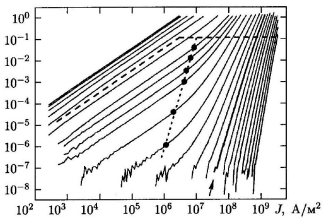

Рис. 42.3. Вольт-амперные характеристики тонкой пленки YBaCuO во внешнем магнитном поле 1 Тл [126] для различных температур в интервале между 80.5 и 91 K. Фазовый переход вихревая жидкость-вихревое стекло происходит при температуре $T_g = 84.6$ K, соответствующая вольт-амперная характеристика помечена стрелкой.

линейны в области малых токов, причем имеют единичный наклон, что означает линейную зависимость $E = \rho_{\text{эфф}}\, j$ при $j \to 0$. При этом значения эффективного сопротивления $\rho_{\text{эфф}}$ меняются на несколько порядков в довольно узком интервале температур чуть выше T_g. Наконец, в области не слишком малых токов $j > j_*(T)$ все кривые ведут себя примерно одинаково - линейно с наклоном больше единицы, что соответствует степенной зависимости $E(j) \propto j^{1+\alpha_j}$. С приближением T к T_g характерная величина тока $j_*(T)$ падает, так что сепаратрисе ($T = T_g$) семейства кривых соответствует степенное поведение ВАХ при всех значениях плотности тока. Оказывается возможным [126] представить совокупность всех этих данных единым образом при по мощи двух безразмерных функций $\mathcal{E}_\pm(x)$, соответствующих областям выше и ниже T_g:

$$\frac{E}{j\rho_f} \sim R\left(\frac{T-T_g}{T_g}\right)\mathcal{E}_\pm\left(\frac{j}{j_*}\right), \qquad \text{где} \qquad j_* \propto |T-T_g|^{\beta_j} \tag{42.8}$$

а безразмерные "скейлинговые" функции $\mathcal{E}_\pm(x)$ имеют асимптотики

$$\begin{aligned} &\mathcal{E}_\pm(x)|_{x\to\infty} \propto x^{\alpha_j}, \quad \mathcal{E}_+(x\to 0) = \text{const}, \\ &\mathcal{E}_-(x\to 0) \propto e^{-1/x^\mu} \end{aligned} \tag{42.9}$$

Функция $R(y)$ также ведет себя степенным образом, а показатель степени определяется тем, что ВАХ универсальны (т. е. слабо зависят от $T - T_g$) при относительно больших токах: из условия сокращения зависящих от T множителей в (42.8) при $j \gg j_*$ получаем, учитывая (42.9), что $R(y) \propto y^{\alpha_j\beta_j}$. Анализ ВАХ из эксперимента [126] приводит к значениям показателей $\alpha_j \simeq 4.0$ и $\beta_j \simeq 3.3$.

Масштабно-инвариантное поведение (scaling) описанного выше типа характерно для фазовых переходов II рода с сильно развитыми флуктуациями [28, 34]. Обычно свойства таких фазовых переходов можно описать теоретически как следствие изменения симметрии и появления параметра порядка, характеризующего степень нарушения симметрии в одной из фаз. В данном случае такое описание весьма затруднено, поскольку свойства уже самой низкотемпературной фазы определяются неоднородностями (примесями), приводящими к пиннингу вихревой решетки и, как следствие, к разрушению ее периодичности: корреляции положений вихревых линий пропадают на достаточно больших расстояниях (см. 41). Иначе говоря, низкотемпературная фаза, сформированная взаимодействием решетки вихрей с примесями, представляет собой «вихревое стекло", находящееся в одном из многих возможных метастабильных состояний, как это характерно вообще для стекол.

Что же представляет собой состояние, реализующееся при $T > T_g$? Как было объяснено в 37, идеальная (беспримесная)
вихревая решетка плавится при $B = B_m(T) < H_{c2}(T)$, вследствие чего образуется

жидкость из вихревых линий. Это фазовый переход I рода, но довольно близкий ко II роду (скачки энтропии и намагниченности малы). Пусть теперь в сверхпроводнике имеются примеси, создающие слабый случайный потенциал. В области на фазовой диаграмме сверхпроводника, достаточно удаленной (вверх) от линии плавления, выигрыш в свободной энергии за счет выгодного расположения вихрей в случайном потенциале меньше, чем разность свободных энергий твердого и жидкого состояний. Поэтому здесь беспорядок не меняет качественно состояния вихревой системы, однако он создает энергетические барьеры для течения вихревой жидкости [127]. Величины этих барьеров конечны при малых токах, $U(j,T,B) \underset{j\to 0}{\to} U_{\max}(T,B)$. В таком состоянии имеется ненулевое линейное сопротивление $(dE/dj)|_{j\to 0} = \rho_f e^{-U_{\max}/k_{\rm B}T}$. При совсем слабом беспорядке род фазового перехода не может измениться, так что переход из вихревой жидкости в стекло происходит скачком. Именно такая ситуация реализовалась в очень чистых монокристаллах, использованных в экспериментах [106, 128, 107, 129, 125]. При этом величина $U_{\max}$ может существенно превышать $k_{\rm B}T$, так 'то сопротивление в таком состоянии (называемом «термоактивированное течение потока», а в англоязычной литературе "thermally assisted flux flow", или сокращенно - TAFF) хотя и отлично от нуля, но может быть на несколько порядков меньше, чем сопротивление течения потока ρ_f. В особенно широкой области полей и температур термоактивированное течение потока наблюдается в слоистых ВТСП-материалах типа $Bi_2Sr_2CaCu_2O_8$, где зависимости $\rho_{\rm taff}\,(T,B)$ хорошо описываются как следствие поведения максимального энергетического барьера $U_{\max}(T,B) \propto \propto (T_c - T)\ln(H_{c2}/B)$ (см., например, работу [130]).

В образцах с большим количеством дефектов (особенно в тонких пленках, как в [126]) линия фазового перехода сдвигается по сравнению с линией плавления идеальной решетки, поэтому мы и обозначаем температуру этого перехода $T_g(B)$ новым подстрочным индексом g (от английского "glass»-стекло). Более того, скачки энтропии и намагниченности "размываются" беспорядком и фазовый переход становится непрерывным. В этом случае величина $U_{\max}$ неограниченно возрастает с приближением к линии перехода сверху, а линейное сопротивление обращается в нуль пропорционально $(T - T_g)^{\alpha_j\beta_j}$, как было объяснено в связи с рис. 42.3. В некоторых случаях при "промежуточном» количестве дефектов фазовый переход принадлежит к I роду при малых B и $(T_c - T)$ и становится непрерывным в более сильных полях, когда относительная роль случайного потенциала увеличивается; фазовая диаграмма такого типа приведена, в частности, в работе [131]. Теоретическое описание таких фазовых переходов еще недостаточно хорошо разработано.

8 Superconductivity by Abrikosov

8.1 15 Macroscopic theory of superconductivity

8.1.1 15.1. General properties of superconductors

In Part I we have been concerned with the various mechanisms of electrical resistance. Some of these mechanisms give a gradual decrease in resistance with temperature and other lead to a constant value or even to an increase in resistance at very low temperatures. However, in 1911 H. Kamerlingh Onnes, while studying the variation with temperature of the electrical resistance of mercury, observed that the resistance dropped sharply to zero at a temperature of 4.2 K . The same properties were later detected in some other metals. The new phenomenon was termed "superconductivity" and the corresponding metals were called "superconductors".

The temperature at which the resistance disappears is called the critical temperature, T_c; it

is different in different superconductors. The highest critical temperature among pure metals is shown by niobium: $T_c = 9.25$ K; the lowest has been found in tungsten: $T_c = 0.0154$ K. Although these are both low temperatures, in fact the temperature range is very wide, since the two extremes differ by about a factor of a thousand.

In what follows we shall also mention the practical applications of superconductors. Even at this moment they are rather numerous. However the recent discovery of so-called high-temperature superconducting ceramics arouses hopes for a further development of such applications. At the moment this book was written the highest critical temperature was registered for a composition $YBa_2Cu_3O_{7-8}$ and is equal to 93-95 K. But the discovery of even higher critical temperatures is not excluded. The importance of these discoveries is based on the fact that the superconductivity in such ceramics can be maintained in cryostats with liquid nitrogen (boiling point 77.4 K).

Subsequent investigations of the properties of superconductors have shown that superconductivity can be destroyed not only by increasing the temperature but also by applying a sufficiently strong magnetic field (Kamerlingh Onnes 1914). The critical field in which superconductivity is destroyed decreases with increasing temperature. It has been established empirically that the dependence $H_c(T)$ is described well by the formula

$$H_c(T) = H_c(0)\left[1 - \left(\frac{T}{T_c}\right)^2\right]. \tag{15.1}$$

Superconductivity is also destroyed by a strong electric current. If the superconductor is not too thin (see below), the critical current, at which resistance appears, satisfies Silsbee's rule (Silsbee 1916): the magnetic field produced by the critical current at the surface of a superconductor must be equal to H_c.

One of the basic properties of superconductors is the so-called Meissner effect (Meissner and Ochsenfeld 1933). If a metal is placed in a magnetic field smaller than H_c, then upon transition into the superconducting state the field is expelled from its interior, i.e., the true field $\boldsymbol{B} = \boldsymbol{0}$ in the superconductor (recall that the magnetic induction $\boldsymbol{B}$ is the average microscopic field)*. This is shown in fig. 93: (a) a superconductor; (b) a normal metal.

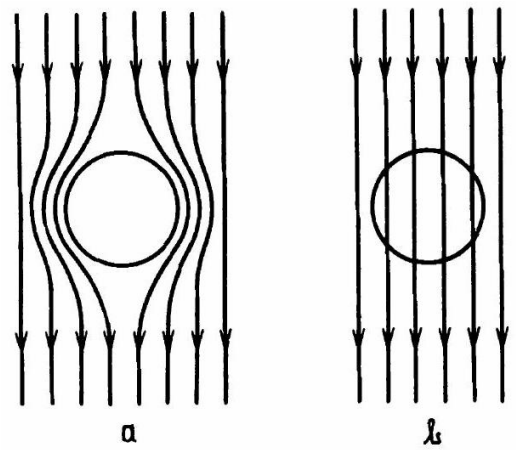

Fig. 93.

In more detailed investigations it has been found that the magnetic field is equal to zero only in the bulk of a massive sample. In a thin surface layer the field gradually decreases from a given value at the surface to zero. The thickness of this layer, which is called the penetration depth (δ), is usually of the order of $10^{-5} - 10^{-6}$ cm.

When a superconductor is placed in an external magnetic field, an undamped current appears in the surface layer, which produces a magnetic field of its own, and the latter compensates completely the external field inside the superconductor.

This can be traced out most simply on a cylinder in a longitudinal magnetic field. Suppose we have a solenoid with current i. Inside the solenoid a magnetic field is created, $H = (4\pi/c)i \cdot n$, where n is the number of turns in a coil per 1 cm of length. Instead of $i \cdot n$ we can write J, which is the current per 1 cm of the solenoid length. If the superconducting cylinder is placed in a field H, a current $J = cH/4\pi$ will

flow in the surface layer, which is directed so that the field produced by it will compensate the external field H.

The penetration depth δ depends on various factors, in particular on temperature. When the temperature approaches T_c, the penetration depth $\delta \to \infty$. The empirical formula that reflects in general aspects the temperature dependence of δ has the form

$$\delta(T) = \frac{\delta(0)}{\left[1 - (T/T_c)^4\right]^{1/2}} \tag{15.2}$$

As for the thermodynamic character of the transition of a metal from the superconducting to the normal state, it has been found that if the transition occurs at $H = 0$, i.e., at $T = T_c$, it is a second-order phase transition (see Appendix II). Upon this transition the latent heat of transition is not absorbed, but a jump in heat capacity takes place instead. But if the transition occurs at $H \neq 0$, i.e., at $T < T_c$, then it is a first-order transition at which the latent heat of transition is absorbed.

This change in the character of the transition may be associated with the behavior of the penetration depth. With $T \to T_c$ the penetration depth $\delta \to \infty$ and a superconductor does not differ at all at the transition point from a normal metal (with respect to the penetration of an infinitely weak field). Hence, the quantity δ that may serve as a characteristic of the extent of difference between a superconductor and a normal metal varies continuously and the transition should be second order. But if the transition occurs in a finite magnetic field, a discontinuous variation takes place in δ from a finite value in the superconducting phase to an infinite value in the normal phase (the field penetrates a normal metal completely, i.e., formally $\delta = \infty$).

The continuous variation of δ at T_c indicates that the state of the electron liquid in a metal varies continuously. This is also evidenced by measurements of thermal conductivity.

In Part I it has been pointed out that usually the major role in the thermal conductivity of a metal is played by electrons. But the vanishing of the resistance might indicate that the electrons cease to interact with the crystal lattice and, hence, are incapable of participating in thermal conductivity. In such a case, the overall coefficient of thermal conductivity at the transition point should decrease abruptly to a value determined by phonons alone. This does not occur. At $T = T_c$ the quantity x varies continuously.

The last of the fundamental properties that should be mentioned here is the behavior of heat capacity at low temperatures. In Part I we have described a construction (fig. 11), which enables one to separate the electronic part of the heat capacity from the lattice part. In this way we can find the coefficient in the Debye law $C = BT^3$ for the lattice (phonon) heat capacity. Assuming that the lattice heat capacity does not vary upon transition to the superconducting state, it is possible to determine the electronic heat capacity of a superconductor by subtracting BT^3 from the total value. As a result of such measurements it turned out that the electronic

- In superconducting alloys the behavior in a magnetic field is more complicated; in particular, the Meissner effect may be incomplete. We shall defer the discussion of this question until ch. 18.

heat capacity of a superconductor at temperatures substantially lower than T_c depends on temperature by an exponential law (Corak and Satterthwaite 1954,

Corak et al. 1954, 1956):

$$C_{\text{es}} = a \exp\left(\frac{-\Delta}{T}\right). \tag{15.3}$$

This means that the excited states of the electronic system are separated from the ground state by an "energy gap", just as in a semiconductor. On the other hand, a superconductor differs very strongly from a semiconductor in its electrical properties. Moreover, the phase transition at T_c is a second-order phase transition, which implies that the energy gap vanishes at T_{c}, i.e., the energy spectrum depends strongly on temperature. Such a dependence of the energy spectrum on temperature (in other words, on the state of the electron system) is contained in the Landau theory of the Fermi liquid (ch. 13). We shall use it in the derivation of the microscopic theory.

8.1.2 15.2. Thermodynamics of the superconducting transition

Let us consider a cylindrical sample in a longitudinal magnetic field. The condition for the superconducting transition is the equality of the free energies:

$$F_{\text{s}}(H,T) = F_{\text{n}}(H,T). \tag{15.4}$$

Here and henceforth the subscripts s and n designate the superconducting and the normal phase, respectively. Equilibrium may occur only at a field of $H = H_c(T)$.

The magnetic field enters a superconductor only to the penetration depth. In the presence of the field a superconducting current flows in the surface layer and screens the field in the bulk of the sample. This introduces a contribution to the energy of the order of $H_{\text{c}}^2/8\pi$ per unit volume of the surface layer. The total contribution to F_{s} from the currents and the field is of order $(H_{\text{c}}^2/8\pi)\,\delta S/V$, where S is the surface area of the sample (the free energy is referred to the unit volume).

The field penetrates a normal metal completely. Since we consider the equilibrium in a given field, we have to use the formula for F_{H} (Appendix III, formula AIII.10). Usually, superconducting metals are nonmagnetic, i.e., there $\mu \approx 1$. Hence, $F_{\text{n}}(H_{\text{c}},T) = F_{\text{n}}(T) - H_{\text{c}}^2/8\pi$. From this we see that the magnetic contribution to F_{n} is much larger than that to F_{s}, namely D/δ times as larger (D is the diameter of the sample). Therefore, for a massive cylinder the field contribution to F_{s} may be neglected; as a result, we obtain from eq. (15.4)

$$F_{\text{n}}(T) - F_{\text{s}}(T) = \frac{H_{\text{c}}^2}{8\pi} \tag{15.5}$$

Differentiating with respect to T, we find the entropy difference ($S = -\partial F/\partial T$):

$$S_{\text{n}} - S_{\text{s}} = \frac{-H_{\text{c}}}{4\pi}\frac{\mathrm{d}H_{\text{c}}}{\mathrm{d}T} \tag{15.6}$$

Corak et al. 1954, 1956):

$$C_{\text{es}} = a \exp\left(\frac{-\Delta}{T}\right). \tag{15.3}$$

This means that the excited states of the electronic system are separated from the ground state by an "energy gap", just as in a semiconductor. On the other hand, a superconductor differs very strongly from a semiconductor in its electrical properties. Moreover, the phase transition at T_c is a second-order phase transition, which implies that the energy gap vanishes at

T_c, i.e., the energy spectrum depends strongly on temperature. Such a dependence of the energy spectrum on temperature (in other words, on the state of the electron system) is contained in the Landau theory of the Fermi liquid (ch. 13). We shall use it in the derivation of the microscopic theory.

8.1.3 15.2. Thermodynamics of the superconducting transition

Let us consider a cylindrical sample in a longitudinal magnetic field. The condition for the superconducting transition is the equality of the free energies:

$$F_{\rm s}(H,T) = F_{\rm n}(H,T). \tag{15.4}$$

Here and henceforth the subscripts s and n designate the superconducting and the normal phase, respectively. Equilibrium may occur only at a field of $H = H_c(T)$.

The magnetic field enters a superconductor only to the penetration depth. In the presence of the field a superconducting current flows in the surface layer and screens the field in the bulk of the sample. This introduces a contribution to the energy of the order of $H_c^2/8\pi$ per unit volume of the surface layer. The total contribution to $F_{\rm s}$ from the currents and the field is of order $(H_c^2/8\pi)\,\delta S/V$, where S is the surface area of the sample (the free energy is referred to the unit volume).

The field penetrates a normal metal completely. Since we consider the equilibrium in a given field, we have to use the formula for $F_{\rm H}$ (Appendix III, formula AIII.10). Usually, superconducting metals are nonmagnetic, i.e., there $\mu \approx 1$. Hence, $F_{\rm n}\,(H_{\rm c},T) = F_{\rm n}(T) - H_c^2/8\pi$. From this we see that the magnetic contribution to $F_{\rm n}$ is much larger than that to $F_{\rm s}$, namely D/δ times as larger (D is the diameter of the sample). Therefore, for a massive cylinder the field contribution to $F_{\rm s}$ may be neglected; as a result, we obtain from eq. (15.4)

$$F_{\rm n}(T) - F_{\rm s}(T) = \frac{H_c^2}{8\pi}. \tag{15.5}$$

Differentiating with respect to T, we find the entropy difference ($S = -\partial F/\partial T$):

$$S_{\rm n} - S_{\rm s} = \frac{-H_{\rm c}}{4\pi}\frac{{\rm d}H_{\rm c}}{{\rm d}T}. \tag{15.6}$$

The quantity $q = T\,(S_{\rm n} - S_{\rm s})$ gives the latent heat of transition. Since ${\rm d}H_{\rm c}/{\rm d}T < 0$ (see eq. 15.1) it turns out that $q > 0$, i.e., the heat is absorbed upon transition from the superconducting to the normal phase.

A further differentiation with respect to temperature gives the difference in heat capacities ($C = T(\partial S/\partial T)_{\rm V}$

$$C_{\rm n} - C_{\rm s} = -\frac{T}{4\pi^i}\left[H_{\rm c}\frac{{\rm d}^2H_{\rm c}}{{\rm d}T^2} + \left(\frac{{\rm d}H_{\rm c}}{{\rm d}T}\right)^2\right]. \tag{15.7}$$

In particular, at $T = T_{\rm c}$ the field $H_{\rm c} = 0$ and we have

$$C_{\rm s}\,(T_{\rm c}) - C_{\rm n}\,(T_{\rm c}) = \frac{T_{\rm c}}{4\pi}\left(\frac{{\rm d}H_{\rm c}}{{\rm d}T}\right)^2 \tag{15.8}$$

It is interesting to note that this simple treatment, in which use is made of only a single experimental fact - the Meissner effect, enables one to derive rigorous formulae relating the critical magnetic field to the thermodynamic characteristics of the superconductor.

8.1.4 15.3. The intermediate state

So far we have considered a cylindrical geometry. Now suppose that the sample has an arbitrary shape or that, even if it is a cylinder, the field is not longitudinal. In this case the superconducting sample distorts the field, which becomes inhomogeneous in space. Let us see what happens if the specimen has the form of an ellipsoid. In such a case, the Maxwell field $\boldsymbol{H}_{\text{i}}$ inside it is homogeneous, although different from the external field at infinity $\boldsymbol{H_0}$. They are connected by the relation (Appendix III):

$$H_{\text{i}} = H_0 - 4\pi n M, \tag{15.9}$$

where M is the magnetization and n is the demagnetization factor.
Since the metal is in the superconducting state, inside $B = 0$, i.e.,

$$H_i + 4\pi M = H_0 + 4\pi(1-n)M = 0,$$

that is,

$$M = -\frac{H_0}{4\pi(1-n)}, \quad H_{\text{i}} = \frac{H_0}{1-n}. \tag{15.10}$$

According to the boundary conditions of the Maxwell theory, the normal component of $\boldsymbol{B}$ and the tangential component of $\boldsymbol{H}$ are continuous at the interface between the media. Outside the superconductor $\boldsymbol{B} = \boldsymbol{H}$. From the fact that $\boldsymbol{B} = 0$ in the superconductor one can conclude that $\boldsymbol{H}$ at the superconductor boundary has only a tangential component, i.e., the lines of force "by-pass" the superconductor (fig. 93a). From the continuity of the tangential component $\boldsymbol{H}$ at the interface one may conclude that at those points where the direction of $\boldsymbol{H}$ coincides with the
external field $\boldsymbol{H}_0$ the field at the boundary is at a maximum and equals $\boldsymbol{H}_0/(1-\boldsymbol{n})$, i.e., is larger than H_0. The superconductor moves apart the force lines of the field, which leads to their concentration outside the superconductor. We also see that along the superconductor surface the field varies and in some portions it may attain values of H_c, while $H_0 < H_c$.

Suppose that in a certain portion of the superconductor surface the field exceeds H_{c}. Then the superconductivity must vanish there. It will be most natural to presume that the picture will be as shown in fig. 94, where the shaded portion of the sample has passed to the normal state. However, this assumption leads to a contradiction. If the metal in the normal state is nonmagnetic, then for the magnetic field there is no difference between the normal metal and vacuum. Hence, departing from the superconducting region the field must decrease. If it is accepted that at the interface between the normal and the superconducting region $H = H_c$, then in the normal region the field $H < H_{\text{c}}$. But in this case the metal must be superconducting.

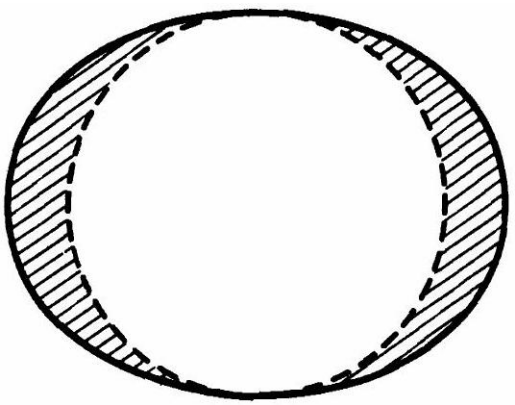

Fig. 94.

The way to remove this contradiction has been suggested by Peierls and London (Peierls 1936, London 1936) who advanced the idea of the "intermediate state". According to this idea, in the region of the external field

$$(1-n)H_c < H_0 < H_c \tag{15.11}$$

the superconductor passes to a special state characterized by the condition

$$H_i = H_c. \tag{15.12}$$

From eq. (15.9) we obtain

$$M = -\frac{H_c - H_0}{4\pi n}. \tag{15.13}$$

Substituting into the formula for the induction, we find

$$B = H_\mathrm{i} + 4\pi M = \frac{H_0}{n} - H_\mathrm{c}\frac{1-n}{n}. \tag{15.14}$$

From this we see that $B = 0$ at $H_0 = (1-n)H_2$ and $B = H_\mathrm{c}$ at $H_0 = H_\mathrm{c}$, and in the interval between these values the dependence of B on H_0 is linear. For the cylinder in the field perpendicular to its axis ($n = \frac{1}{2}$) the dependence $B\,(H_0)$ is shown in fig. 95.

In the Maxwell theory the field H_i does not always have a clear-cut microscopic meaning. Therefore, although the assumption $H_\mathrm{i} = H_\mathrm{c}$ and formula (15.14), which follows from it, agree well with experiment, they leave a feeling of dissatisfaction. Therefore, the intermediate state has been studied in more detail. It has been found that when a cylindrical specimen is placed in a perpendicular field and undergoes a transition to the intermediate state, its electrical resistance becomes anisotropic. Along the axis of the cylinder there is a finite resistance, and across the axis the resistance is equal to zero. This indicates that the cylinder splits up into thin layers of normal and superconducting phases perpendicular to its axis. When a current is passed along the axis, the layers are connected in series, but when it is passed across the axis they are connected in parallel, and the normal layers are shunted by the superconducting ones.

The picture in an infinite plate perpendicular to the magnetic field must be the simplest. In this case, $n = 1$, i.e., the intermediate state begins with $H_0 = 0$. If it is assumed that in the normal layers the field is $\boldsymbol{H}_\mathrm{c}$ and in the superconducting layers it is equal to zero, then the mean field, i.e., the induction in the plate, is $B = xH_c$, where x is the fraction of the normal phase. Outside the superconductor $B = H_0$. In this case, the field is directed normally to the interface. From the continuity condition for the normal component of $\boldsymbol{B}$ (i.e., in this particular case, $\boldsymbol{B}$ itself) we have

$$x = \frac{H_0}{H_c}. \tag{15.15}$$

No further conclusions can be made without studying the structure of the layers.
A detailed investigation of the structure of the intermediate state has been carried out by Landau (1937). We shall present here a simplified version of this theory. Let

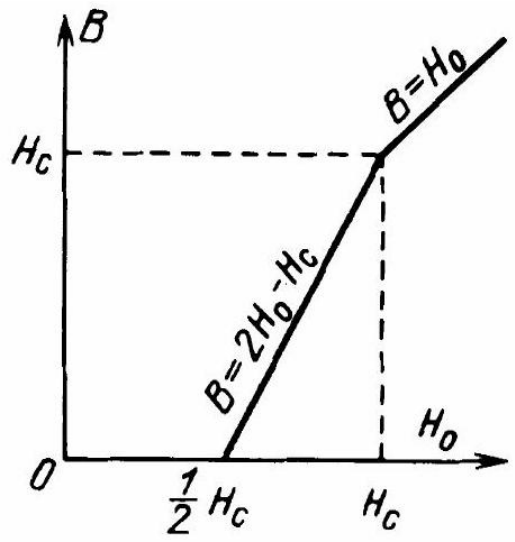

Fig. 95.

us consider a plate in a perpendicular field. If we assume that alternating plane layers of the normal and superconducting phases are formed in the plate, then the interfaces between the layers will coincide with the lines of force of the field. A kink in the lines of force would have led to a large additional energy. Therefore, we have to assume that the normal layers are slightly widened near the surface (fig. 96). If the thickness of the normal layers is a and that of the superconducting layer is b, then the characteristic size of the "corner" is of the order of

$$c \sim \frac{ab}{a+b}. \tag{15.16}$$

As $a \to 0$ or $b \to 0$ the "corners" disappear, as should be expected.
Let us calculate the energy of this structure. We use the formulas of Appendix III (AIII.12) and (AIII.13) for the free energy of a body of an arbitrary shape in a magnetic field. The magnetization M is defined with respect to the field H_0. But since outside the sample $B = H_0$ and B does not vary upon intersection of the boundary, the induction of the body $B = H_0$, i.e., $M = 0$. Hence, we may presume that the normal layers have an energy F_{n} and the superconducting layers an energy F_{s} per unit volume. We assume that the thickness of the plate (i.e., the length of the layers) is equal to L. The size in the direction perpendicular to the plane of the drawing is assumed to be equal to unity. If the free energy is counted off from F_{s}, the superconducting layers give a zero contribution and the total free energy will be equal to $H_c^2/8\pi$ multiplied by the volume of the normal phase. Considering that the number of layers per cm of length is $(a+b)^{-1}$, the energy per unit area of the plate will be

$$\frac{H_{\mathrm{c}}^2}{8\pi}\frac{1}{a+b}\left[La + \gamma\left(\frac{ab}{a+b}\right)^2\right], \tag{15.17}$$

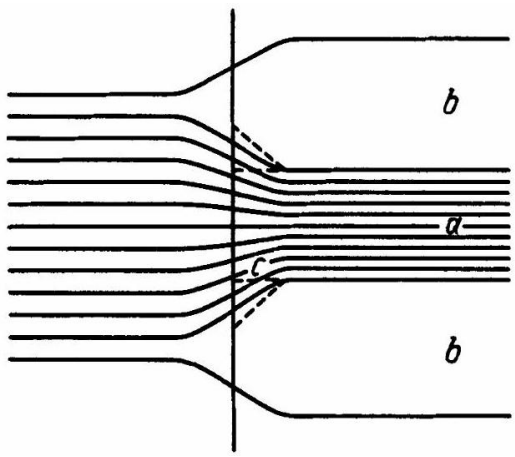

Fig. 96.

where $\gamma \sim 1$. The second term takes account of the "corners", i.e., the expansion of the normal layers near the surface.

However, if only this energy is taken into account, layers of finite size cannot be obtained. Therefore, Landau assumed the existence of an additional surface energy at the interface between the normal and the superconducting phase. The energy per unit area of the interface σ_{ns} has the dimension of erg/cm^2, while $H_{\mathrm{c}}^2/8\pi$ has the dimension of erg/cm^3. This makes it possible to introduce a new convenient parameter ξ having the dimension of length:

$$\sigma_{\mathrm{ns}} = \frac{H_{\mathrm{c}}^2}{8\pi}\xi. \tag{15.18}$$

At a later stage we shall see that the parameter ξ plays a fundamental role in the theory of superconductivity.

Considering that each normal layer has two boundaries of length $L + \beta c$, where $\beta \sim 1$ and c is the length of the corner (15.16), we obtain a contribution to the energy per unit area of the plate surface arising from the boundaries:

$$\frac{H_{\mathrm{c}}^2}{8\pi}\xi\frac{1}{a+b}2\left[L + \beta\frac{ab}{a+b}\right]. \tag{15.19}$$

Before finding the minimum of the total free energy, one has to take into account that the widths of the layers a and b are not independent but are determined by the external field H_0. According to eq. (15.19), we find the concentration of the normal phase:

$$x = \frac{a}{a+b} = \frac{H_0}{H_c}. \tag{15.20}$$

In the following all the lengths will be expressed in terms of a. Using eq: (15.20), we have

$$a + b = a\frac{H_{\mathrm{c}}}{H_0}, \quad b = a\frac{H_{\mathrm{c}} - H_0}{H_0}. \tag{15.21}$$

Substituting this into eqs. (15.17) and (15.19), we obtain the total free energy:

$$F = \frac{H_{\mathrm{c}}^2}{8\pi}\left\{L\frac{H_0}{H_{\mathrm{c}}} + \gamma a\frac{H_0}{H_{\mathrm{c}}}\frac{(H_{\mathrm{c}} - H_0)^2}{H_{\mathrm{c}}^2} + 2\xi\left[\frac{L}{a}\frac{H_0}{H_{\mathrm{c}}} + \beta\frac{H_0\,(H_{\mathrm{c}} - H_0)}{H_{\mathrm{c}}^2}\right]\right\}. \tag{15.22}$$

In this expression only two terms depend on a. Taking the minimum with respect to a, we find

$$a = \left(\frac{2\xi L}{\gamma}\right)^{1/2} \frac{H_c}{H_c - H_0}, \quad b = \left(\frac{2\xi L}{\gamma}\right)^{1/2} \frac{H_c}{H_0},$$
$$a + b = \left(\frac{2\xi L}{\gamma}\right)^{1/2} \frac{H_c^2}{H_0 (H_c - H_0)}. \tag{15.23}$$

In practice, $\xi \sim 10^{-5}$ cm. For a plate with a thickness of the order of 1 cm the period of the structure is of the order of 10^{-3} cm and it increases with thickness as $L^{1/2}$. Note the similarity between these results and the structure of diamagnetic domains (section 10.6). Chronologically, the theory of the intermediate state had been worked out earlier. According to eq. (15.23), the period of the structure $a + b$ increases at both boundaries of the intermediate state, i.e., with $H_0 \to 0$ and $H_0 \to H_c$. If $H_0 \to 0$, then $b \to \infty$ and $a \to$ const. and, conversely, with $H_0 \to H_c, a \to \infty$ and $b \to$ const.

The exact theory (Landau 1937) permits one to determine the shape of the layers from the condition that the interface between the normal and superconducting phase coincides with the line of force. The results of this theory are in qualitative agreement with those given above, the only difference being that at the boundaries of the intermediate state the thickness of the "foreign" layers does not remain constant and decreases slightly. For example, $a \sim [\xi L / \ln (H_c/H_0)]^{1/2}$ as $H_0 \to 0$.

In the experimental determination of the structure of the intermediate state, use is made of the inhomogeneity of the magnetic field which arises due to phase separation. The first experiments made use of a magnetic-field detector in the form of a bismuth wire of a very small size, whose resistance varied, depending on the magnetic field. The use of such a detector made it possible to trace out the emergence of the layers of the intermediate state to the sample surface (Meshkovskii and Shal'nikov 1947). In another method, ferromagnetic powders were used. If the sample is sprinkled with such a powder, the ferromagnetic particles are concentrated at the regions where the normal layers emerge (Sharvin and Balashova 1956, Sharvin 1957). Figure 97 shows a photograph of the normal layers obtained in this way in a superconducting plate. The field $\boldsymbol{H}_0$ is tilted relative to the normal n. The layers are parallel to the plane in which n and H_0 lie.

A further method of determining the structure of the intermediate state is covering the sample surface with a thin layer of a transparent substance having a large Faraday effect, i.e., capable of rotating the plane of polarization of light in a magnetic field. Illumination with polarized light and the observation of the reflected light with the aid of a polaroid gives a very contrasty picture of the layers of the normal and superconducting phases. It is also possible to follow their dynamics upon variation of the external field (Laeng and Rinderer 1972).

Owing to these experiments it has been possible to establish the existence of layers in the intermediate state and to determine the parameter ξ, i.e., the surface energy at the interface between the phases.

In conclusion, we return to the Maxwell field H_i. Although, as has been pointed out earlier (see Appendix III), the true physical significance is exhibited not by the Maxwell field H_i but by the induction B, which corresponds to the average of the microscopic field in the sample, the condition (15.12) $\boldsymbol{H}_i = \boldsymbol{H}_c$ must have a physical meaning. It turns out that in going from the microscopic description of the intermediate state to the "macroscopic" one, in which the averaging is made over distances larger than the thickness of the layers, it is necessary to introduce an additional

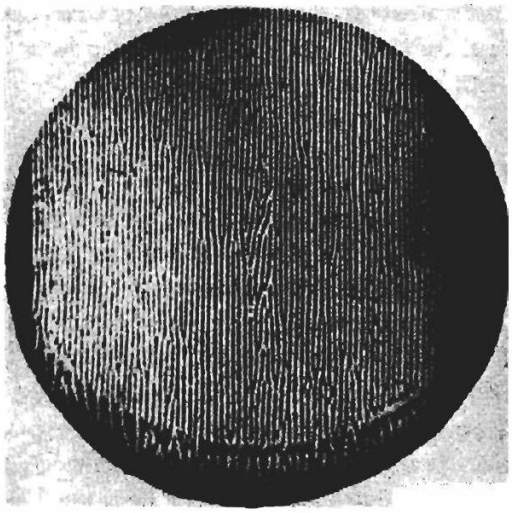

Fig. 97.

variable, namely, the average of the magnetic field taken only over the normal layers (Andreev 1966). It is exactly this average that corresponds to H_i; this clarifies the meaning of the condition (15.12).

8.1.5 15.4. Destruction of superconductivity by a current

Now we shall deal with another problem of the intermediate state. Suppose a current flows in a thick superconducting wire of radius r_0. In accordance with Silsbee's rule (Silsbee 1916), resistance can appear when the field generated by the current reaches the value H_c. Consider the Maxwell equation

$$\operatorname{rot} H = \left(\frac{4\pi}{c}\right) j.$$

Integrating over a circle of radius $r < r_0$ and using the rule of transformation of the curl, we obtain

$$\int \operatorname{rot} H \, \mathrm{d}S = \oint H \, \mathrm{d}l = H \cdot 2\pi r = \frac{4\pi}{c} \int j \, \mathrm{d}S = \left(\frac{4\pi}{c}\right) J(r).$$

Hence,

$$H(r) = 2\frac{J(r)}{cr}, \tag{15.24}$$

where $H(r)$ is the field at a distance r from the cylinder axis and $J(r)$ is the current flowing through a circle of radius r.

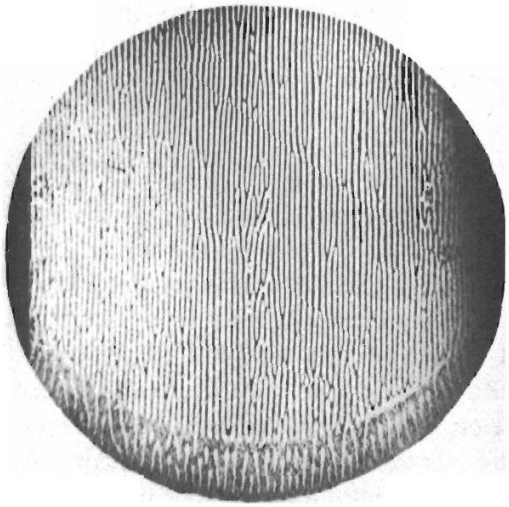

Fig. 97.

variable, namely, the average of the magnetic field taken only over the normal layers (Andreev 1966). It is exactly this average that corresponds to H_{i}; this clarifies the meaning of the condition (15.12).

8.1.6 15.4. Destruction of superconductivity by a current

Now we shall deal with another problem of the intermediate state. Suppose a current flows in a thick superconducting wire of radius r_0. In accordance with Silsbee's rule (Silsbee 1916), resistance can appear when the field generated by the current reaches the value H_{c}. Consider the Maxwell equation

$$\operatorname{rot} \boldsymbol{H} = \left(\frac{4\pi}{c}\right) \boldsymbol{j}$$

Integrating over a circle of radius $r < r_0$ and using the rule of transformation of the curl, we obtain

$$\int \operatorname{rot} \boldsymbol{H} \mathrm{d}\boldsymbol{S} = \oint \boldsymbol{H} \mathrm{d}\boldsymbol{l} = \boldsymbol{H} \cdot 2\pi r = \frac{4\pi}{c} \int \boldsymbol{j} \ \mathrm{d}\boldsymbol{S} = \left(\frac{4\pi}{c}\right) J(r).$$

Hence,

$$H(r) = 2\frac{J(r)}{cr}, \tag{15.24}$$

where $H(r)$ is the field at a distance r from the cylinder axis and $J(r)$ is the current flowing through a circle of radius r.

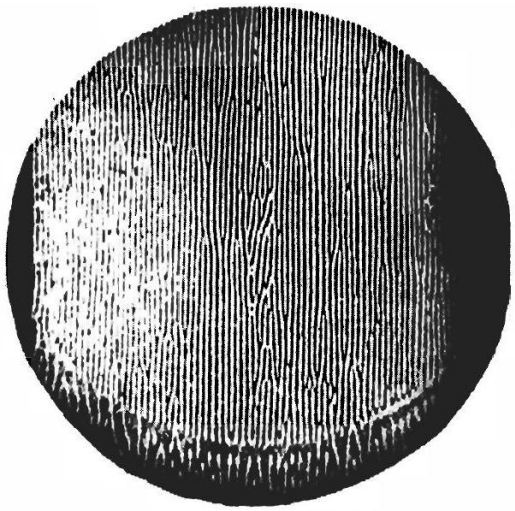

Fig. 97.

variable, namely, the average of the magnetic field taken only over the normal layers (Andreev 1966). It is exactly this average that corresponds to H_{i}; this clarifies the meaning of the condition (15.12).

8.1.7 15.4. Destruction of superconductivity by a current

Now we shall deal with another problem of the intermediate state. Suppose a current flows in a thick superconducting wire of radius r_0. In accordance with Silsbee's rule (Silsbee 1916), resistance can appear when the field generated by the current reaches the value H_{c}. Consider the Maxwell equation

$$\operatorname{rot} H = \left(\frac{4\pi}{c}\right) j.$$

Integrating over a circle of radius $r < r_0$ and using the rule of transformation of the curl, we obtain

$$\int \operatorname{rot} H \ \mathrm{d}S = \oint H \ \mathrm{d}l = H \cdot 2\pi r = \frac{4\pi}{c} \int j \ \mathrm{d}S = \left(\frac{4\pi}{c}\right) J(r).$$

Hence,

$$H(r) = 2\frac{J(r)}{cr}, \tag{15.24}$$

where $H(r)$ is the field at a distance r from the cylinder axis and $J(r)$ is the current flowing through a circle of radius r.

In the superconducting state the current flows only in a thin surface layer. Hence, $H = 0$ everywhere, except for this layer. The maximum field exists at the surface. It becomes equal to H_{c} with a current given by

$$J_{\text{c}} = \frac{1}{2} c r_0 H_{\text{c}}.$$

where r_0 is the radius of the conductor.

Let $J > J_c$. In this case, the superconductivity in the surface layer begins to be destroyed. It would appear as if a normal tube and a superconducting core were formed (fig. 98a). As a matter of fact, the entire current flows inside the superconducting cylinder. But it has a smaller

radius and from (15.24) it follows that with the same current the field H at the interface will be stronger. Hence, the process of destruction will go through the whole wire. But in this case the entire sample will become normal and the current will be distributed uniformly along the cross section. Then, $J(r) = j\pi r^2$, where j is the constant current density. According to eq. (15.24), the field in the vicinity of the cylinder axis will become lower than H_c; thus, the normal state is also unstable.

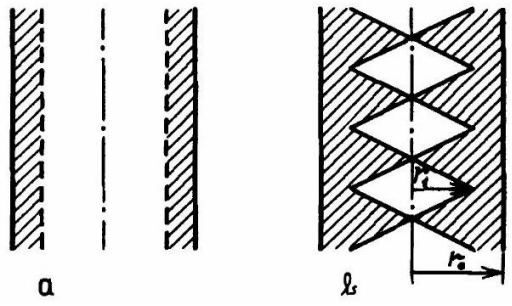

Fig. 98.

The solution lies in the assumption of the existence of the intermediate state (London 1937)*. We shall assume that the interior of the cylinder, with a radius r_1, is in the intermediate state and the external tube is in the normal state (fig. 98b). In the interior $\boldsymbol{H}(\boldsymbol{r}) = \boldsymbol{H}_c$. From eq. (15.24) we obtain

$$J(r) = \frac{1}{2} cr H_c. \tag{15.25}$$

The current density is given by

$$j_{r<r_1}(r) = \frac{\mathrm{d}J(r)}{\mathrm{d}S} = \frac{\mathrm{d}J(r)}{2\pi r\ \mathrm{d}r} = cH_c(4\pi r). \tag{15.26}$$

On the other hand, in the outer normal tube the current is distributed uniformly, i.e.,

$$j_{r>r_1}(r) = \frac{J - J\,(r_1)}{\pi\,(r_0^2 - r_1^2)} \tag{15.27}$$

In the superconducting state the current flows only in a thin surface layer. Hence, $H = 0$ everywhere, except for this layer. The maximum field exists at the surface. It becomes equal to $\boldsymbol{H}_c$ with a current given by

$$J_c = \frac{1}{2} cr_0 H_c.$$

where r_0 is the radius of the conductor.

Let $J > J_c$. In this case, the superconductivity in the surface layer begins to be destroyed. It would appear as if a normal tube and a superconducting core were formed (fig. 98a). As a matter of fact, the entire current flows inside the superconducting cylinder. But it has a smaller radius and from (15.24) it follows that with the same current the field H at the interface will be stronger. Hence, the process of destruction will go through the whole wire. But in this case the entire sample will become normal and the current will be distributed uniformly along the cross section. Then, $J(r) = j\pi r^2$, where j is the constant current density. According to eq. (15.24), the field in the vicinity of the cylinder axis will become lower than H_c; thus, the normal state is also unstable.

*The same idea was put forward at the same time by L.D. Landau (unpublished, see Shoenberg 1955).

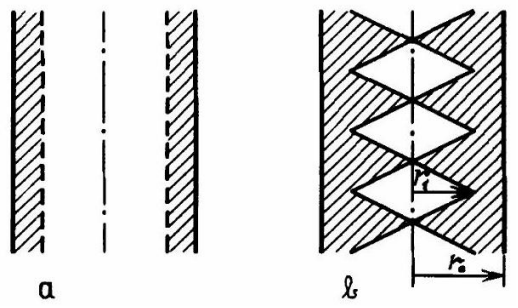

Fig. 98.

The solution lies in the assumption of the existence of the intermediate state (London 1937)*. We shall assume that the interior of the cylinder, with a radius r_1, is in the intermediate state and the external tube is in the normal state (fig. 98b). In the interior $H(r) = H_c$. From eq. (15.24) we obtain

$$J(r) = \frac{1}{2} cr H_c. \tag{15.25}$$

The current density is given by

$$j_{r<r_1}(r) = \frac{\mathrm{d}J(r)}{\mathrm{d}S} = \frac{\mathrm{d}J(r)}{2\pi r\ \mathrm{d}r} = cH_c(4\pi r). \tag{15.26}$$

On the other hand, in the outer normal tube the current is distributed uniformly, i.e.,

$$j_{r>r_1}(r) = \frac{J - J\,(r_1)}{\pi\,(r_0^2 - r_1^2)} \tag{15.27}$$

From the condition of the continuity of current density at $r = r_1$ we find that

$$\frac{cH_c}{4\pi r_1} = \frac{J - \frac{1}{2} cr_1 H_c}{\pi\,(r_0^2 - r_1^2)} \tag{15.28}$$

(here we have substituted $J\,(r_1)$ from eq. 15.25).
We now introduce new variables:

$$\frac{r_1}{r_0} = \rho, \quad \frac{J}{J_c} = \frac{2J}{cr_0 H_c} = \lambda. \tag{15.29}$$

Equation (15.28) will now be rewritten in the form

$$\rho^2 - 2\lambda\rho + 1 = 0.$$

The roots of this equation are

$$\rho = \lambda \pm \left(\lambda^2 - 1\right)^{1/2}.$$

Only one must be retained because the physical solution evidently corresponds to $\rho \to 0$ with $\lambda \to \infty$. Thus,

$$\rho = \lambda - \left(\lambda^2 - 1\right)^{1/2}. \tag{15.30}$$

• The same idea was put forward at the same time by L.D. Landau (unpublished, see Shoenberg 1955).

Let us draw two cross sections of the conductor at a certain distance from each other. Evidently, the potential must be constant along each cross section. The potential difference is the product of the current and the resistance. Let us denote the resistance of a normal metal by R_n. In such a case the resistance of the normal tube of $r_1 < r < r_0$ will be $R_n r_0^2/\left(r_0^2 - r_1^2\right)$. The potential difference is equal to the product of this resistance and the current flowing through the normal tube, on the one hand, and to the product of the total current and the total resistance R on the other:

$$JR = \left[J - J\left(r_1\right)\right] R_n \frac{r_0^2}{r_0^2 - r_1^2}. \tag{15.31}$$

Substituting $J\left(r_1\right)$ and passing over to the dimensionless variables ρ and λ, we obtain:

$$\frac{R}{R_\mathrm{n}} = \frac{1}{2}\left[1 + \left(1 - \lambda^{-2}\right)^{1/2}\right]. \tag{15.32}$$

This formula is applicable in the region of the intermediate state, i.e., for $\lambda > 1$. From this formula it follows that at $\lambda = 1$ a jump occurs in the resistance up to $\frac{1}{2}R_\mathrm{n}$, and then with increasing λ the resistance approaches asymptotically to R_n (the solid line in fig. 99). This prediction is in qualitative agreement with experiment, but the quantitative results are different. A jump $J = J_\mathrm{c}(\lambda = 1)$ occurs up to a value greater than $\frac{1}{2}R_\mathrm{n}$, and the subsequent asymptotic approach to R_n occurs more rapidly (the dashed line in fig. 99). This can be accounted for in the following manner. According to formula (15.26), the current density in the core is inversely proportional to r.

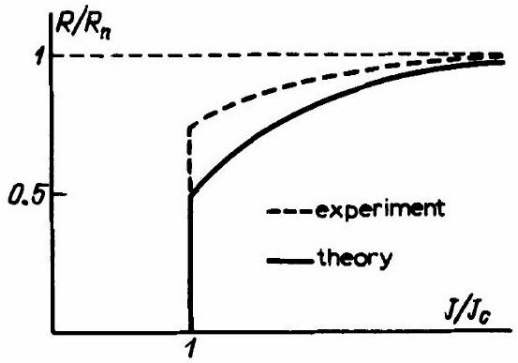

Fig. 99.

Hence, the structure of the intermediate state is such that the thickness of the normal layers increases proportionately to r, as shown in fig. 98b. If we recall the presence of the surface energy σ_ns, it will become clear that a boundary with a kink would have led to an infinite energy. Hence, the "discs" of the superconducting phase must have rounded edges, this being responsible for a certain delay in the transition and for the attainment of a larger total resistance. It is interesting to note that with an increase in the wire diameter the initial jump in the resistance decreases and tends towards $\frac{1}{2}R_\mathrm{n}$. This is in accord with the conceptions presented above, since the relative role of roundings-off decreases with increasing radius of the layers.

We do not describe here the complete microscopic theory (Andreev 1968). The result of this theory is as follows: the period of the structure at $J = J_c$ is of order $\left(\xi^2 r_0\right)^{1/3}$ and falls off with increasing current. The theory also predicts the value of the true critical current and the magnitude of the jump in the resistance at J_c, which are in good agreement with experiment. It is interesting to note that in accordance with the microscopic (BCS) theory the picture of the

intermediate state outlined above is observed only in the case of a not-too-pure metal. But if the metal is so pure that the Hall components of the resistivity tensor are comparable with the diagonal components, then the superconducting layers bend along the axis, forming a system of cones (a Christmas tree) instead of a system of planar discs, and move along the axis of the conductor.

In concluding this section, let us consider formula (15.32) from a somewhat different standpoint. Substituting λ into it according to eq. (15.29) and expressing $H_c(T)$ in accordance with formula (15.1), we obtain

$$\frac{R}{R_\mathrm{n}} = \frac{1}{2}\left\{1 + \left[1 - \left(\frac{cr_0 H_\mathrm{c}(0)}{2J}\right)^2 \left(1 - \frac{T^2}{T_\mathrm{c}^2}\right)^2\right]^{1/2}\right\}. \tag{15.33}$$

The formula can be applied as long as the expression in brackets is positive.
Let us specify the current J and consider $R(T)$. If $J \to 0$, then, according to this formula, the resistance appears near T_c and immediately becomes equal to R_n. But if we take a large current, the transition will be extended to a finite temperature range (fig. 100). From this it follows that we may speak of the jump in the resistance

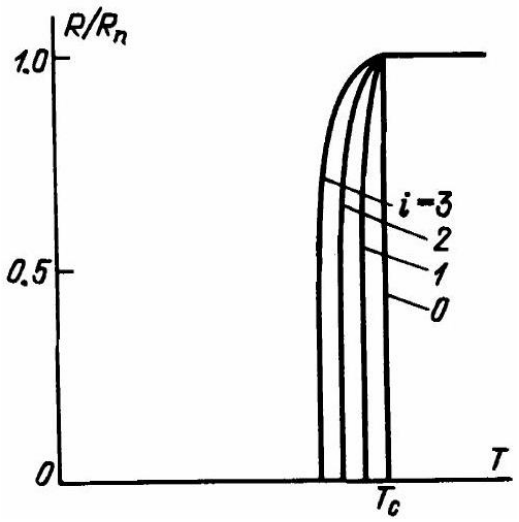

Fig. 100.

from zero to $\boldsymbol{R}_\mathrm{n}$ in the superconducting transition only if we mean a measurement in an infinitesimal current.

8.1.8 15.5. The London equations

The first attempt to develop the electrodynamics of superconductors was undertaken by the brothers F. London and H. London (1935). The purpose of this theory was to express in mathematical form the basic experimental facts: the absence of resistance and the Meissner effect, without consideration of the microscopic factors responsible for superconductivity.

If an electron does not undergo scattering, it is accelerated by an external field and, hence,

$$m\frac{\mathrm{d}v}{\mathrm{d}t} = eE. \tag{15.34}$$

This refers to all electrons. Hence, we can rewrite formula (15.34) for the current density. Introducing $j = n_e e v$, where n_e is the electron density and e is the charge, we get:

$$\frac{\mathrm{d}}{\mathrm{d}t}(\Lambda j) = E,$$

where $\Lambda = m/\left(n_e e^2\right)$.
In Part I we have already noted that the full derivative signifies the variation of the quantity in a given volume element moving together with the liquid. It is connected with the partial derivative, which describes the variation at a given point
of space by the relation

$$\frac{\mathrm{d}}{\mathrm{d}t} = \frac{\partial}{\partial t} + v\nabla.$$

Since the real current velocities v in a metal are small compared to the Fermi velocity, we can replace the total derivative by a partial derivative, in which case we have

$$\frac{\partial(\Lambda j)}{\partial t} = E. \tag{15.35}$$

According to the general equation of electrodynamics:

$$\operatorname{rot} E' = -c^{-1}\frac{\partial H}{\partial t}. \tag{15.36}$$

Taking the curl of eq. (15.35) and substituting (15.36), we get

$$\frac{\partial}{\partial t}\left(\operatorname{rot}\Lambda j + c^{-1}H\right) = 0.$$

This means that the quantity in parentheses does not change with time. But in the bulk of a massive superconductor $\boldsymbol{j} = 0$ and $\boldsymbol{H} = 0$. Hence, the quantity in parentheses is not simply conserved but is always equal to zero:

$$\operatorname{rot}\Lambda\boldsymbol{j} + c^{-1}\boldsymbol{H} = 0 \tag{15.37}$$

Equations (15.36) and (15.37) constitute the basis of London electrodynamics.
Let us consider the simplest problem: a bulk superconductor in an external magnetic field. According to the Maxwell equation,

$$\operatorname{rot} H = \frac{4\pi}{c} j \tag{15.38}$$

We take the curl of this equation:

$$\operatorname{rot}\operatorname{rot} H = \operatorname{grad}\operatorname{div} H - \Delta H = \frac{4\pi}{c}\operatorname{rot} j$$

Using the fact that $\operatorname{div}\boldsymbol{H} = \boldsymbol{0}$ and substituting $\operatorname{rot}\boldsymbol{j}$ from (15.37), we obtain

$$\Delta H - \delta^{-2}H = 0, \tag{15.39}$$

where

$$\delta = \left(\frac{\Lambda c^2}{4\pi}\right)^{1/2} = \left(\frac{mc^2}{4\pi n_{\mathrm{e}} e^2}\right)^{1/2} \tag{15.40}$$

of space by the relation

$$\frac{\mathrm{d}}{\mathrm{d}t} = \frac{\partial}{\partial t} + v\nabla.$$

Since the real current velocities v in a metal are small compared to the Fermi velocity, we can replace the total derivative by a partial derivative, in which case we have

$$\frac{\partial(\Lambda j)}{\partial t} = E. \tag{15.35}$$

According to the general equation of electrodynamics:

$$\operatorname{rot} E' = -c^{-1}\frac{\partial H}{\partial t}. \tag{15.36}$$

Taking the curl of eq. (15.35) and substituting (15.36), we get

$$\frac{\partial}{\partial t}\left(\operatorname{rot}\Lambda j + c^{-1}H\right) = 0.$$

This means that the quantity in parentheses does not change with time. But in the bulk of a massive superconductor $\boldsymbol{j} = 0$ and $\boldsymbol{H} = 0$. Hence, the quantity in parentheses is not simply conserved but is always equal to zero:

$$\operatorname{rot}\Lambda j + c^{-1}H = 0. \tag{15.37}$$

Equations (15.36) and (15.37) constitute the basis of London electrodynamics.
Let us consider the simplest problem: a bulk superconductor in an external magnetic field. According to the Maxwell equation,

$$\operatorname{rot} H = \frac{4\pi}{c}j \tag{15.38}$$

We take the curl of this equation:

$$\operatorname{rot}\operatorname{rot} H = \operatorname{grad}\operatorname{div} H - \Delta H = \frac{4\pi}{c}\operatorname{rot} j$$

Using the fact that $\operatorname{div}\boldsymbol{H} = \boldsymbol{0}$ and substituting $\operatorname{rot}\boldsymbol{j}$ from (15.37), we obtain

$$\Delta H - \delta^{-2}H = 0 \tag{15.39}$$

where

$$\delta = \left(\frac{\Lambda c^2}{4\pi}\right)^{1/2} = \left(\frac{mc^2}{4\pi n_{\mathrm{e}}e^2}\right)^{1/2} \tag{15.40}$$

of space by the relation

$$\frac{\mathrm{d}}{\mathrm{d}t} = \frac{\partial}{\partial t} + v\nabla.$$

Since the real current velocities v in a metal are small compared to the Fermi velocity, we can replace the total derivative by a partial derivative, in which case we have

$$\frac{\partial(\Lambda j)}{\partial t} = E. \tag{15.35}$$

According to the general equation of electrodynamics:

$$\operatorname{rot} E' = -c^{-1}\frac{\partial H}{\partial t}. \tag{15.36}$$

Taking the curl of eq. (15.35) and substituting (15.36), we get

$$\frac{\partial}{\partial t}\left(\operatorname{rot}\Lambda j + c^{-1}H\right) = 0$$

This means that the quantity in parentheses does not change with time. But in the bulk of a massive superconductor $\boldsymbol{j} = 0$ and $\boldsymbol{H} = 0$. Hence, the quantity in parentheses is not simply conserved but is always equal to zero:

$$\operatorname{rot}\Lambda j + c^{-1}H = 0 \tag{15.37}$$

Equations (15.36) and (15.37) constitute the basis of London electrodynamics.
Let us consider the simplest problem: a bulk superconductor in an external magnetic field. According to the Maxwell equation,

$$\operatorname{rot} H = \frac{4\pi}{c} j \tag{15.38}$$

We take the curl of this equation:

$$\operatorname{rot}\operatorname{rot} H = \operatorname{grad}\operatorname{div} H - \Delta H = \frac{4\pi}{c}\operatorname{rot} j$$

Using the fact that $\operatorname{div}\boldsymbol{H} = \boldsymbol{0}$ and substituting rot $\boldsymbol{j}$ from (15.37), we obtain

$$\Delta\boldsymbol{H} - \boldsymbol{\delta}^{-2}\boldsymbol{H} = \boldsymbol{0}, \tag{15.39}$$

where

$$\delta = \left(\frac{\Lambda c^2}{4\pi}\right)^{1/2} = \left(\frac{mc^2}{4\pi n_{\mathrm{e}} e^2}\right)^{1/2} \tag{15.40}$$

(we have used here the definition of Λ). Suppose the superconductor occupies the half-space $x > 0$ and the field is applied parallel to its surface in the direction z. From eq. (15.39) we find

$$H = H_0 \exp\left(\frac{-x}{\delta}\right) \tag{15.41}$$

where H_0 is the field at the surface. From eq. (15.37) we get

$$j_y = \frac{cH_0}{4\pi\delta}\exp\left(\frac{-x}{\delta}\right). \tag{15.42}$$

Thus, we conclude that London electrodynamics provides a correct qualitative description of the fact that the field and current are present only in a thin surface layer of the superconductor. Moreover, according to eq. (15.40), the quantity δ is of the order of $10^{-5} - 10^{-6}$ cm, consistent with experimental data.

Of course, in the derivation given above we proceeded from the assumption that all the electrons participate in the superconducting current. This contradicts the fact that δ depends on temperature and also that a second-order phase transition occurs at T_c, i.e., the state of electrons varies continuously. The theory may be "corrected" to a certain extent by introducing, instead of the total number of electrons, a certain number of "superconducting electrons" $n_{\mathrm{s}}(T)$, which decreases with temperature and turns to zero at T_c.

In conclusion, we note that eqs. (15.35) and (15.37) may be written in a different form, which will prove useful at a later stage. We introduce the vector potential A; $\boldsymbol{H}$ and $\boldsymbol{E}$ are expressed by the relations

$$H = \operatorname{rot} A, \quad E = -c^{-1}\frac{\partial A}{\partial t}.$$

Using A, we can write both London equations in the form of a single equation:

$$j = -\frac{1}{\Lambda c}A = -\frac{n_e e^2}{mc}A \tag{15.43}$$

At first glance this means that only one London equation is important and the second one is its corollary. But this is not the case: taking div of the Maxwell equation (15.38), we obtain the law of charge conservation:

$$\operatorname{div} j = 0. \tag{15.44}$$

But this is compatible with eq. (15.43) only if

$$\operatorname{div} A = 0. \tag{15.45}$$

This means that eq. (15.43) is valid not for any vector potential A but only for one that satisfies the condition (15.45). Thus, instead of the two London equations (15.35) and (15.37), we again have two equations, (15.43) and (15.45).

8.2 16 Basic ideas of the microscopic theory

8.2.1 16.1. The superfluidity condition

The microscopic theory of superconductivity was developed by J. Bardeen, L.N. Cooper and J.R. Schrieffer in 1957 and independently by N.N. Bogoliubov in 1957 (Bardeen et al. 1957, Bogoliubov 1958, Bogoliubov et al. 1958). It is quite natural to ask why superconductivity remained a puzzling phenomenon for nearly half a century after its discovery. Science was advancing; a great deal of experimental information was obtained and several useful phenomenological theories were developed (for example, the theory described in ch. 1).

The main cause is as follows. The phenomenon of superconductivity is very similar to the superfluidity of liquid helium discovered by P.L. Kapitza (Kapitza 1938). The theory of this phenomenon was developed by L.D. Landau in 1941 (Landau 1941a, b, 1944, 1947). One of the manifestations of superfluidity is the frictionless flow of helium in capillaries. It was natural to interpret superconductivity as the superfluidity of the electron liquid.

The Landau theory introduced a criterion for superfluidity. Imagine helium flowing in a capillary with a velocity v. If we pass to the coordinate system associated with helium, it will be at rest while the walls of the tube will move at a velocity - v. If viscosity arises, the moving tube will begin to entrain the resting helium. This means that the momentum $\boldsymbol{P}$ and the energy E of the helium will be changed. But, as we know from ch. 2, in a homogeneous quantum system the variation of energy and momentum occurs by way of the appearance of quasiparticles. Suppose a quasiparticle with momentum p and energy $\varepsilon(p)$ has appeared. Let us now pass to the laboratory coordinate system associated with the tube. In this system the energy and momentum are given by

$$\boldsymbol{P}' = \boldsymbol{P} + Mv, \quad E' = E + \boldsymbol{P}v + \frac{1}{2}\mathbf{M}v^2.$$

(M is the mass of the liquid). The variation of the energy resulting from the creation of a quasiparticle is $E + Pv = \varepsilon(p) + pv$. Hence, in order for the creation of a quasiparticle to be energetically favorable it is necessary that

$$\varepsilon(p) + pv < 0.$$

The lowest value of $\varepsilon + pv$ is attained with the opposite orientation of p and v; hence, in any case, $\varepsilon - pv < 0$ or

$$v > \frac{\varepsilon(p)}{p}.$$

This is the lowest velocity at which quasiparticles of momentum p and energy $\varepsilon(p)$ can appear. But we are interested in the velocity at which any quasiparticles can be created. Evidently, for this to occur it is necessary that

$$v > v_c = \min\left(\frac{\varepsilon(p)}{p}\right) \tag{16.1}$$

Thus, viscosity arises if the velocity exceeds v_c. In liquid helium the energy spectrum is such that v_c is a finite quantity. This means that at low flow velocities there is no viscosity.

We shall consider the Fermi liquid from this standpoint. The excitation of such a system consists of the creation of a particle-antiparticle pair. If such a pair is generated directly at the surface of the Fermi sphere, the energy may be as small as possible. At the same time, the total change in the momentum may reach $2p_0$ if the particle and the antiparticle are located on the opposite sides of the Fermi sphere. From this it follows that $v_c = 0$, i.e., in the Fermi system there is viscosity at any flow velocity.

Attempts have been made to find the solution on the assumption that electrons combine into pairs which are Bose particles and are analogous to helium atoms. However, no causes for such a combination could be found, since electrons have the same charge and according to the Coulomb law they repel each other. It is this circumstance that held back the development of the theory of superconductivity.

8.2.2 16.2. Phonon attraction

In 1950 a phenomenon was discovered which is known as the isotope effect (Maxwell 1950; Reynolds et al. 1950). In determining the T_c and H_c of superconductors of different isotopic composition it was found that T_c and H_c depend on the mass of ions forming the crystal lattice:

$$T_c \propto M^{-1/2}, \quad H_c \propto M^{-1/2} \tag{16.2}$$

The mass of the ions manifests itself only when lattice vibrations are taken into account. Hence, superconductivity is not a purely electronic phenomenon; phonons are also involved in it. On the basis of this fact Frölich (1950) and Bardeen (1950, 1951a, b) demonstrated independently that the electrons, while residing in the crystal lattice, are also capable of attracting one another*.

Let us consider the process shown schematically in fig. 101a. One electron with momentum p_1 emits a phonon of momentum $\hbar k$. The momentum of the electron

---

- We shall describe here the phonon mechanism of electron attraction which takes place in all superconductors known to date. The possibility is not excluded that the excitonic mechanism is operating in the newly found high-temperature ceramics (section 16.11). However, its principal scheme is very similar to phonon attraction.

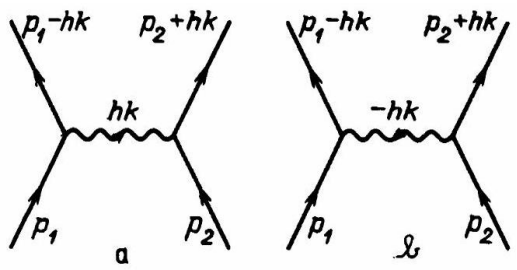

Fig. 101.

then becomes equal to $\boldsymbol{p}_1' = \boldsymbol{p}_1 - \hbar\boldsymbol{k}$. The phonon is absorbed by a second electron, which has had momentum p_2 before the absorption; after the phonon is absorbed the second electron acquires a momentum $\boldsymbol{p}_2' = \boldsymbol{p}_2 + \hbar\boldsymbol{k}$. The amplitude of this process, which is of second order according to perturbation theory, is given by

$$\frac{|V_k|^2}{\varepsilon(p_1) - \varepsilon(p_1 - \hbar k) - \hbar\omega(k),}$$

where $V_k = V_{p-ik,p}$ (section 4.3, formula 4.13).
On the other hand, the same finite momenta result if the electron of $\boldsymbol{p}_2$ emits a phonon with momentum - $\hbar k$, which is then absorbed by the electron of p_1 (fig. 101b). The amplitude of this process is

$$\frac{|V_k|^2}{\varepsilon(p_2) - \varepsilon(p_2 + \hbar k) - \hbar\omega(k)}.$$

Here it is taken into account that $\omega(k)$ and V_k are invariant under the replacement of $\boldsymbol{k}$ by $-\boldsymbol{k}$. The amplitudes obtained above must add up. Here one has to take account of the energy conservation law:

$$\varepsilon(p_1) + \varepsilon(p_2) = \varepsilon(p_1') + \varepsilon(p_2').$$

As a result, for the total amplitude we find

$$-\frac{2|V_k|^2 \hbar\omega(k)}{[\hbar\omega(k)]^2 - [\varepsilon(p_1) - \varepsilon(p_1 - \hbar k)]^2}.$$

Substituting expression (4.13) for V_k ($n_k = 0$ in this case), we obtain the order of magnitude of the total amplitude:

$$-\frac{\hbar^3}{p_0 m V}\frac{[\hbar\omega(k)]^2}{[\hbar\omega(k)]^2 - [\varepsilon(p_1) - \varepsilon(p_1 - \hbar k)]^2}. \tag{16.3}$$

Let us analyze this expression. At $\varepsilon(p_1) - \varepsilon(p_1') < \hbar\omega(k)$ we obtain a negative constant, which is independent of $\boldsymbol{k}$. If the electrons were involved in a direct point interaction with one another, i.e., $U = U_0\delta(r_1 - r_2)$, the matrix element corresponding to the first order perturbation theory for the scattering amplitude would be equal
to U_0. Hence, the interaction between the electrons transmitted by phonons is equivalent, with slight variations in the energy, to a point interaction, its sign corresponding to attraction.

Note also that since the interaction is independent of $\boldsymbol{k}$, i.e., of the rotation angle of the electron momenta, it follows that this is an interaction in the s-state, i.e., in a state with an orbital moment $l = 0$. Thus, the coordinate wave function of the interacting electrons is symmetric with respect to the interchange of particles. But since the electrons are Fermi

particles, their total wave function is antisymmetric under interchange. Hence, their spin wave function must be antisymmetric, i.e., the spins of the interacting electrons must be directed in opposite directions. The same may be put in a different way. The interaction found is equivalent to the attraction of particles if their coordinates coincide. The Pauli principle forbids two identical Fermi particles to be at a single point. Hence, they must differ in the spin direction.

If we take into account that the density of states of phonons is proportional to $k^2(\,\mathrm{d}k/\mathrm{d}\omega)$, i.e., falls off rapidly with decreasing k, and that the resultant amplitude is independent of k, then it becomes clear that the key role will be played by phonons with the largest k.values, i.e., with $k \sim k_\mathrm{D} \sim \pi/a$ and $\hbar\omega \sim \hbar\omega_\mathrm{D}$. At $\varepsilon(p) - \varepsilon(p') > \hbar\omega_\mathrm{D}$ the interaction rapidly decreases. Since the major role is played by electrons in the neighborhood of the Fermi boundary, it may be said that the phonon attraction occurs in a narrow layer near the Fermi boundary, whose thickness is of order $\hbar\omega_\mathrm{D}$ on the energy scale and of order $\Delta_p \sim \hbar\omega_\mathrm{D}/v$ on the momentum scale.

The fact that the interaction spreads over an energy interval $\Delta\varepsilon \sim \hbar\omega_\mathrm{D}$ implies, according to quantum mechanics, that it is "retarded" or, in other words, it operates during a finite time interval $\Delta t \sim \hbar/(\hbar\omega_\mathrm{D}) \sim \omega_\mathrm{D}^{-1}$. Its magnitude is of order $\left(p_0 m/\hbar^3\right)^{-1} \sim \nu^{-1}\mu\Big)$.

Simultaneously, Coulomb repulsion is operating. Taking account of the Debye screening (section 14.1), one can show that it operates at interatomic distances and may be written in the form $e^2a^2\delta(r_1 - r_2)$. for the same reason it is retarded with a characteristic time of order $\hbar/\varepsilon_\mathrm{F}$. The ratio of the interaction constants is of order

$$\frac{e^2a^2}{\hbar^3/p_0 m} \sim \frac{e^2\hbar^2}{p_0^2}\frac{p_0 m}{\hbar^3} \sim \frac{e^2}{\hbar v} \sim 1$$

that is, both interactions are of the same order of magnitude. Hence, in some metals phonon attraction may be dominant, while in others Coulomb repulsion predominates. This explains why some metals become superconductive and others remain normal at all temperatures.

To be more precise, it should be said that quantitative calculations always give some preference to the Coulomb repulsion. But its time of action is much shorter than that of the phonon attraction. This leads to an effective damping of the Coulomb repulsion: it is divided by the log of the time ratio, i.e., by $\ln(\varepsilon_\mathrm{F}/\hbar\omega_\mathrm{D}) = \ln(M/m)$.

In most cases, the two interactions differ quantitatively rather strongly to one or the other side, so that in studying superconductivity one may limit oneself to taking account of phonon attraction alone. Instead of the exact formula (16.3), we shall simulate its amplitude by a constant $-g\,(g \sim \hbar^3/p_0 m \sim (\nu/\mu)]^{-1}\Big)$ in the energy interval $\mu - \hbar\omega_\mathrm{D} < \varepsilon < \mu + \hbar\omega_\mathrm{D}$ and by zero at other energies.

8.2.3 16.3. Cooper pairs

It would appear that after the discovery of the attraction it became immediately possible to work out the theory of superconductivity. Nevertheless, several years were needed for this to be accomplished. The difficulty that had to be overcome was as follows. As has been explained earlier, the superfluidity of the electron liquid could have arisen upon binding of electrons into pairs. But from quantum mechanics it is known that if the interaction is not strong enough or has a small action radius, a bound state cannot be produced. Exceptions are the purely one- and twodimensional cases when the motion of particles is limited by a straight line or a plane; in these cases, any attraction leads to the formation of a bound state. But at first sight such models have nothing to do with the case under consideration.

A measure of the binding energy of a pair may be the critical temperature. If one considers that it is of the order of degrees, i.e., 10^4 times lower than the kinetic energy of electrons (the Fermi energy), the binding of electrons into pairs seems to be impossible.

The resolution of this paradox was found by Cooper (Cooper 1956), who noticed that pairs are formed not by free isolated electrons but by quasiparticles of the Fermi liquid. We shall present here a slightly modified version of Cooper's derivation which provides an answer correct in order of magnitude, in contrast to the original paper in which actually only quasiparticles of particle type were taken into account and this led to an incorrect result.

For the sake of simplicity we will consider the isotropic case. The energy spectrum of quasiparticles is shown in fig. 102 by a solid line (section 2.2). Here the right branch refers to quasiparticles of particle type and the left to quasiparticles of antiparticle type. On the whole, the energy spectrum may be written in the form $|\xi(p)|$, where $\xi = v\,(p - p_0)$. One should, however, keep in mind that antiparticles have a different sign of the charge. As will be seen below, we are interested in the

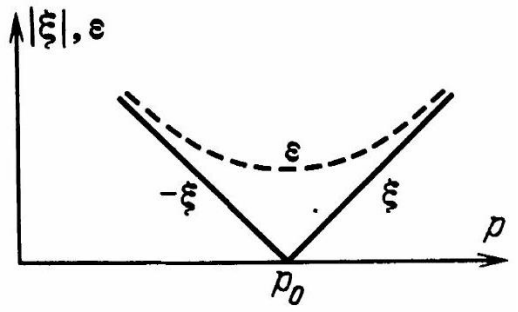

Fig. 102.

simulate its amplitude by a constant $-g\,(g \sim \hbar^3/p_0 m \sim (\nu/\mu)]^{-1}\Big)$ in the energy interval $\mu - \hbar\omega_{\mathrm{D}} < \varepsilon < \mu + \hbar\omega_{\mathrm{D}}$ and by zero at other energies.

8.2.4 16.3. Cooper pairs

It would appear that after the discovery of the attraction it became immediately possible to work out the theory of superconductivity. Nevertheless, several years were needed for this to be accomplished. The difficulty that had to be overcome was as follows. As has been explained earlier, the superfluidity of the electron liquid could have arisen upon binding of electrons into pairs. But from quantum mechanics it is known that if the interaction is not strong enough or has a small action radius, a bound state cannot be produced. Exceptions are the purely one- and twodimensional cases when the motion of particles is limited by a straight line or a plane; in these cases, any attraction leads to the formation of a bound state. But at first sight such models have nothing to do with the case under consideration.

A measure of the binding energy of a pair may be the critical temperature. If one considers that it is of the order of degrees, i.e., 10^4 times lower than the kinetic energy of electrons (the Fermi energy), the binding of electrons into pairs seems to be impossible.

The resolution of this paradox was found by Cooper (Cooper 1956), who noticed that pairs are formed not by free isolated electrons but by quasiparticles of the Fermi liquid. We shall present here a slightly modified version of Cooper's derivation which provides an answer correct in order of magnitude, in contrast to the original paper in which actually only quasiparticles of particle type were taken into account and this led to an incorrect result.

For the sake of simplicity we will consider the isotropic case. The energy spectrum of quasiparticles is shown in fig. 102 by a solid line (section 2.2). Here the right branch refers to quasiparticles of particle type and the left to quasiparticles of antiparticle type. On the whole, the energy spectrum may be written in the form $|\xi(p)|$, where $\xi = v\,(p - p_0)$. One should,

however, keep in mind that antiparticles have a different sign of the charge. As will be seen below, we are interested in the

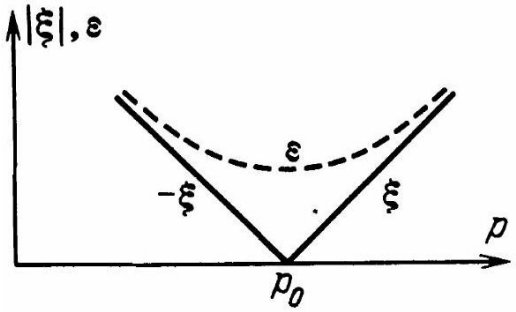

Fig. 102.

interaction of quasiparticles with the same $|p|$, i.e., the interaction of either two particles or two antiparticles. In either case, phonons produce attraction.

Let us write the Schrödinger equation for two quasiparticles:

$$\left[\mathscr{H}_0(r_1) + \mathscr{H}_0(r_2) + U(r_1, r_2)\right]\Psi(r_1, r_2) = E\Psi(r_1, r_2). \tag{16.4}$$

Here $\mathscr{H}_0(r_1)$ is the Hamiltonian of a free quasiparticle, i.e.,

$$\mathscr{H}_0(r_1)\,\psi_p(r_1) = |\xi(p)|\psi_p(r_1) \tag{16.5}$$

(in the free-quasiparticle model $\psi_p = V^{-1/2}\mathrm{e}^{\mathrm{i}pr/\hbar}$). In the ground state the total momentum and spin of a bound pair must be equal to zero. Hence, the wave function of the pair will be a superposition of the states of two free quasiparticles having opposite momenta and spins, i.e.,

$$\Psi(r_1, r_2) = \sum_p c_p \psi_{p,+}(r_1)\,\psi_{p,-}(r_2), \tag{16.6}$$

where the subscripts $\pm$ signify the projection of spin $\pm\frac{1}{2}$. Substituting this into eq. (16.4), we obtain

$$2|\xi(p)|c_p + \sum U_{pp'}c_{p'} = Ec_p. \tag{16.7}$$

We put

$$U_{pp'} = \begin{cases} -g, & p_0 - \frac{\hbar\omega}{v} < |p|, |p'| < p_0 + \frac{\hbar\omega_{\mathrm{D}}}{v}, \\ 0, & \text{outside this interval,} \end{cases} \tag{16.8}$$

and solve eq. (16.7) for c_p :

$$c_p = \frac{g\bar{I}}{2|\xi(p)| - E}, \tag{16.9}$$

where

$$I = \sum_{|p'|=p_0-\hbar\omega_{D'}/v}^{|p'|=p_0+\hbar\omega_{D'}/v} c_{p'} \tag{16.10}$$

Taking into account that we are looking for a bound state (a negative energy value), denoting $E = -2\Delta$ and substituting c_p from eq. (16.9) into eq. (16.10) we find

$$I = \frac{1}{2} \sum_{|p|=p_0-\hbar\omega_D/v}^{|p|=p_0+\hbar\omega_D/v} \frac{1}{|\xi(p)| + \Delta}.$$

Passing to integration over $\boldsymbol{\xi}$ and taking into account that the integral is taken over neighborhood of the Fermi surface, we get

$$1 = \frac{1}{2} g\nu(\mu) \ln\left(\frac{\hbar\omega_D}{\Delta}\right)$$

(the factor $\frac{1}{2}$ has appeared because the summation is carried out over states of one of the quasiparticles, for which the spin projection is specified, whereas the density of states defined earlier, $\nu = p_0 m/(\pi^2\hbar^3)$, included both projections of the spin).

Solving for Δ, we find

$$\Delta = \hbar\omega_D \exp\left(\frac{-2}{g\nu(\mu)}\right) \tag{16.11}$$

Thus, a pair of quasiparticles has a finite binding energy 2Δ. Such bound pairs are called Cooper pairs. At $T = 0$ they form a Bose condensate.

Below we shall obtain Δ from the exact theory. It will be twice as large as (16.11). The difference is associated with the fact that in the derivation given above we were concerned with the creation of a pair against the background of the unreconstructed ground state with a "normal" energy spectrum*.

In spite of a certain inaccuracy, the result (16.11) makes it possible to draw certain conclusions. First of all, note that since $g \sim \nu^{-1}(\mu)$, the expression in the exponent is formally of the order of unity. In fact, $g\nu$ is always somewhat smaller than unity. A certain numerical smallness in the exponent turns to a substantial smallness of the ratio $\Delta/\hbar\omega_D$, which, judging by the known values of T_c (it will be shown below that $\Delta \sim T_c$), is usually 10^{-2} or less**.

Further, from the result obtained it is seen that the binding energy of a Cooper pair 2Δ is finite at any g, which is not consistent with the above-given reasoning concerning the impossibility of the formation of a bound complex upon week interaction. In fact, we are speaking not of isolated particles but of quasiparticles with the Fermi sphere being occupied. This actually leads to the replacement of the three-dimensional problem by a two-dimensional one: the integrals over the momenta are transformed in accordance with the rule $\int d^3p/(2\pi\hbar)^3 \to \frac{1}{2}\nu \int d\xi$, and for the two-dimensional problem $\int d^2p/(2\pi\hbar)^2 \to 2\pi \int p\, dp/(2\pi\hbar)^2 \to 2\pi m \int d\varepsilon/(2\pi\hbar)^2$, since $\varepsilon = p^2/2m$. In a two-dimensional model, as has been said above, any attraction will be sufficient for the particles to be bound.

We thus see that the presence of a filled Fermi sphere plays a most important role in the formation of Cooper pairs.

It is clear that any change in temperature will have an effect on the binding energy. It is because of this that $\Delta(T)$ decreases with increasing temperature and vanishes at $T_c \sim \Delta(0)$. Such is the physical picture. We will now turn our attention to a more detailed description of the Bardeen-Cooper-Schrieffer (BCS) theory***.

8.2.5 16.4. The energy spectrum

While considering the quantization of lattice vibrations in section 4.3, we introduced operators u_k and u_k^+. Let us write these operators in the following

form:

$$u_k = \left(\frac{\hbar}{2nM\omega(k)}\right)^{1/2} b_k, \quad (b_k)_{n_k}^{n_k-1} = n_k^{1/2}$$

The operator b_k thus introduced is called the phonon annihilation operator and b_k^+, its Hermitian conjugate, is the phonon creation operator. The operator $b_k^+ b_k$ is diagonal with the matrix elements being equal to n_k. Thus,

$$b_k^+ b_k = n_k$$

is the operator of the number of particles in state $\boldsymbol{k}$. Analogously,

$$b_k b_k^+ = n_k + 1$$

Hence, the commutator of the operators $\boldsymbol{b_k}$ and $\boldsymbol{b_k^+}$is

$$b_k b_k^+ - b_k^+ b_k = \left[b_k b_k^+\right] = 1$$

Since operators with different $\boldsymbol{k}$ commute, we may write:

$$\left[b_k, b_k^+\right] = \delta_{kk'}$$

All this refers to phonons, which obey Bose statistics. Let us now consider electrons, which obey Fermi statistics. For them we can also introduce particle creation and annihilation operators. Consider a system of noninteracting Fermi particles. According to the Pauli principle, no more than one particle may exist in each state. We shall conventionally write the wave function of this system, noting in which states there are particles and in which there are no particles at all. For example,

$$\Phi\left(1_{p_1}, 0_{p_2}, 1_{p_3}, 1_{p_4}, 0_{p_5}\right)$$

denotes a system in which the states p_1, p_3 and p_4 are occupied and the states p_2 and p_5 are free.

Let the system be described by the wave function $\Phi\left(\ldots 0_p \ldots\right)$. Then the annihilation operator a_p acting on this system gives zero, because there are no particles in the state $\boldsymbol{p}$:

$$a_p \Phi\left(\ldots 0_p \ldots\right) = 0$$

But if there is a wave function $\Phi\left(\ldots 1_p \ldots\right)$, then under the action of the operator a_p it is transformed to $\Phi\left(\ldots 0_p \ldots\right)$, i.e.,

$$a_p \Phi\left(\ldots 1_p \ldots\right) = \Phi\left(\ldots 0_p \ldots\right).$$

Let us now act on these functions by means of the operator $a_p^+ a_p$. Since $a_p^+$is the creation operator, we obtain

$$\begin{aligned} a_p^+ a_p \Phi\left(\ldots 0_p \ldots\right) &= a_p^+ \cdot 0 = 0 = 0 \cdot \Phi\left(\ldots 0_p \ldots\right) \\ a_p^+ a_p \Phi\left(\ldots 1_p \ldots\right) &= a_p^+ \Phi\left(\ldots 0_p \ldots\right) = \Phi\left(\ldots 1_p \ldots\right) \\ &= 1 \cdot \Phi\left(\ldots 1_p \ldots\right) \end{aligned}$$

*The derivation performed in the original work (Cooper 1956) leads to a substantial error, giving an exponent twice as large in absolute magnitude.

** As for the high-temperature ceramics, if the idea of the excitonic mechanism of their superconductivity is confirmed, $\hbar\omega_D$ in formula (16.11) should be replaced by an essentially larger quantity (section 16.11).

*** As noted above, the same theory was developed practically at the same time by Bogoliubov. We shall refer to it as the BCS theory because this name has been generally adopted.

From these formulae if follows that the operator $a_p^+ a_p$ is diagonal and equal to the number of particles:

$$a_p^+ a_p = n_p.$$

Analogously, we find

$$a_p a_p^+ \Phi\left(\ldots 1_p \ldots\right) = 0, \quad a_p a_p^+ \Phi\left(\ldots 0_p \ldots\right) = \Phi\left(\ldots 0_p \ldots\right),$$

and, hence,

$$a_p a_p^+ = 1 - n_p, \quad \left\{a_p, a_p^+\right\} = a_p a_p^+ + a_p^+ a_p = 1.$$

This rule is known as the anticommutation rule of Fermi operators.
Consider now the action of operators $a_p^+ a_{p'}$ and $a_{p'} a_p^+$with different p and p'. In the first case we have

$$\begin{aligned} a_p^+ a_{p'} \Phi\left(\ldots 0_p \ldots 1_{p'} \ldots\right) &= a_p^+ \Phi\left(\ldots 0_p \ldots 0_{p'} \ldots\right) \\ &= \Phi\left(\ldots 1_p \ldots 0_{p'} \ldots\right) \end{aligned}$$

and in the second

$$\begin{aligned} a_{p'} a_p^+ \Phi\left(\ldots 0_p \ldots 1_{p'} \ldots\right) &= a_{p'} \Phi\left(\ldots 1_p \ldots 1_{p'} \ldots\right) \\ &= -a_{p'} \Phi\left(\ldots 1_{p'} \ldots 1_p \ldots\right) = -\Phi\left(\ldots 0_{p'} \ldots 1_p\right) \\ &= -\Phi\left(\ldots 1_p \ldots 0_{p'} \ldots\right) \end{aligned}$$

The change in sign is associated with the fact that when two particles are interchanged the wave function changes sign. This must be taken into account when there are several occupied states. From this it follows that the anticommutator $\left\{a_p^+ a_{p'}\right\}$ with different $\boldsymbol{p}$ and $\boldsymbol{p}'$ is equal to zero and, hence,

$$\left\{a_{p'}, a_p^+\right\} = a_{p'} a_p^+ + a_p^+ a_{p'} = \delta_{pp'}. \tag{16.12}$$

The use of the occupation numbers of the states as variables and the introduction of the operators $a_p, a_p^+$is called second quantization.

Using the operators of second quantization we can write the Hamiltonian of an interacting system of electrons. For a normal metal we have used two descriptions: quasiparticles with the energy spectrum $\varepsilon_{\mathbf{qp}} = |\xi|$ and the gas model. The difference between these two models consists, in particular, in that the former specifies the chemical potential while the latter specifies the total number of particles. As has been shown in section 2.4, the variation of the chemical potential in cases of physical interest is insignificant. Therefore, both descriptions are practically equivalent.

For superconductors it is more convenient to use the picture of quasiparticles, and this also corresponds to the specification of the chemical potential. With the chemical potential being specified the role of the Hamiltonian is played by $\mathscr{H} - \mu N$, where N is the operator of the total number of particles. As a matter of fact, this reduces to the replacement of the electron energy by $\xi = \varepsilon - \mu$, i.e., to a shift in the origin of the energy. Exactly such a Hamiltonian will be used here for the determination of the energy spectrum of quasiparticles.

Below we shall always consider the isotropic model of the metal because in this case it is easier to trace out the main properties of superconductors. For those cases where anisotropy is of fundamental importance a special analysis will be given.

After what has been said above we can write the Hamiltonian*:

$$\mathscr{H} - \mu N = \sum_{p,\sigma} \xi_p a^+_{p,\sigma} a_{p,\sigma} - g \sum_{p_1+p_2=p'_1+p'_2} a^+_{p'_1}, a^+_{p'_2}, , a_{p_2}, , a_{p_1}, , \cdot \tag{16.13}$$

The first term is simply $\sum_{p,\sigma} \xi_p n_{p,\sigma}$. The summation runs over momenta and spins ($\sigma = \pm$). The second term corresponds to the interaction of electrons. It describes how two electrons with initial momenta p_1 and p_2 acquire new momenta, p'_1 and p'_2, as a result of the interaction; in other words, electrons with initial momenta disappear and instead of them there are created electrons with new momenta. Here, the law of conservation of the total momentum is taken into account**. The sums over the momenta run over the intervals $p_0 \pm \hbar\omega_{\mathrm{D}}/v$; it is taken into account that at a single point only electrons with opposite spins are interacting. The coefficient in this term should have been written in the form g/V, but for simplicity we assume the normalizing volume $V = 1$ in this part of the book.

For a normal metal we may pass from electrons to quasiparticles. To do this, we have to assume that $a_{p,\sigma} = \alpha_{p,\sigma}$ at $p > p_0$ and that $a_{p,\sigma} = \alpha^+_{-p,-\sigma}$at $p < p_0$, where $\alpha_{p,\sigma}$ are the operators of second quantization for quasiparticles. As a matter of fact, the destruction of a particle with $p < p_0$ means the creation of a quasiparticle of antiparticle type. Thus, even in an ordinary Fermi system the ground state is such that the transition to quasiparticles requires the redefinition of the creation and annihilation operators.

In a superconductor an even more complicated change in the ground state takes place. For this change to be found and for the energy of quasiparticles to be calculated, we employ a variational method (Abrikosov and Khalatnikov 1958)***. We introduce the creation and annihilation operators for quasiparticles, $\alpha_{p,+}$ and $\alpha_{p,-}$ by using the Bogoliubov relations (Bogoliubov 1958):

$$a_{p,+} = u_p \alpha_{p+} + v_p \alpha^+_{-p,-}, \quad a_{p,-} = u_p \alpha_{p,-} - v_p \alpha^+_{-p,+}. \tag{16.14}$$

Note that with these transformations the momentum and spin are conserved.
Let us write the anticommutator $\left\{a_{p,+} a^+_{p,+}\right\}$and substitute into it formulae (16.14). As a result, we have

$$\begin{aligned}\left\{a_{p,+} a^+_{p,+}\right\} =& u_p^2 \left\{\alpha_{p,+} \alpha^+_{p,+}\right\} + v_p^2 \left\{\alpha^+_{-p,-} \alpha_{-p,-}\right\} \\ &+ u_p v_p \left\{\alpha_{p,+} \alpha_{-p,-}\right\} + u_p v_p \left\{\alpha^+_{-p,-} \alpha^+_{p,+}\right\} = 1\end{aligned}$$

Below we shall always consider the isotropic model of the metal because in this case it is easier to trace out the main properties of superconductors. For those cases where anisotropy is of fundamental importance a special analysis will be given.

After what has been said above we can write the Hamiltonian*:

$$\mathscr{H} - \mu N = \sum_{p,\sigma} \xi_p a^+_{p,\sigma} a_{p,\sigma} - g \sum_{p_1+p_2=p'_1+p'_2} a^+_{p'_1,+} a^+_{p'_2}, , a_{p_2}, , a_{p_1,+} \tag{16.13}$$

The first term is simply $\sum_{p,\sigma} \xi_p n_{p,\sigma}$. The summation runs over momenta and spins ($\sigma = \pm$). The second term corresponds to the interaction of electrons. It describes how two electrons

---

- Here and below $\xi_p \equiv \xi(p)$.
  ** In the second term of the Hamiltonian we omitted the term with $p_1 = p'_1$. This term is responsible for a slight variation in the chemical potential and can be compensated if we write $\xi - \Delta\mu$ in the first term. For simplicity we dispense with this procedure as being unimportant for the derivation.
  *** The method described here is simpler than the one used in the original work of Bardeen, Cooper and Schrieffer and is a generalization of the Bogoliubov method (Bogoliubov 1958; Bogoliubov et al. 1958) to finite temperatures.

with initial momenta p_1 and p_2 acquire new momenta, p_1' and p_2', as a result of the interaction; in other words, electrons with initial momenta disappear and instead of them there are created electrons with new momenta. Here, the law of conservation of the total momentum is taken into account**. The sums over the momenta run over the intervals $p_0 \pm \hbar\omega_{\mathrm{D}}/v$; it is taken into account that at a single point only electrons with opposite spins are interacting. The coefficient in this term should have been written in the form g/V, but for simplicity we assume the normalizing volume $V = 1$ in this part of the book.

For a normal metal we may pass from electrons to quasiparticles. To do this, we have to assume that $a_{p,\sigma} = \alpha_{p,\sigma}$ at $p > p_0$ and that $a_{p,\sigma} = \alpha^+_{-p,-\sigma}$at $p < p_0$, where $\alpha_{p,\sigma}$ are the operators of second quantization for quasiparticles. As a matter of fact, the destruction of a particle with $p < p_0$ means the creation of a quasiparticle of antiparticle type. Thus, even in an ordinary Fermi system the ground state is such that the transition to quasiparticles requires the redefinition of the creation and annihilation operators.

In a superconductor an even more complicated change in the ground state takes place. For this change to be found and for the energy of quasiparticles to be calculated, we employ a variational method (Abrikosov and Khalatnikov 1958)***. We introduce the creation and annihilation operators for quasiparticles, $\alpha_{p,+}$ and $\alpha_{p,-}$ by using the Bogoliubov relations (Bogoliubov 1958):

$$a_{p,+} = u_p\alpha_{p+} + v_p\alpha^+_{-p,-}, \quad a_{p,-} = u_p\alpha_{p,-} - v_p\alpha^+_{-p,+}. \tag{16.14}$$

Note that with these transformations the momentum and spin are conserved.
Let us write the anticommutator $\left\{a_{p,+}a^+_{p,+}\right\}$and substitute into it formulae (16.14). As a result, we have

$$\begin{aligned}\left\{a_{p,+}a^+_{p,+}\right\} =& u_p^2\left\{\alpha_{p,+}\alpha^+_{p,+}\right\} + v_p^2\left\{\alpha^+_{-p,-}\alpha_{-p,-}\right\} \\ &+ u_pv_p\left\{\alpha_{p,+}\alpha_{-p,-}\right\} + u_pv_p\left\{\alpha^+_{-p,-}\alpha^+_{p,+}\right\} = 1\end{aligned}$$

For the operators $\boldsymbol{\alpha_{p,\sigma}}$ to satisfy the ordinary anticommutation rules, it is necessary that

$$u_p^2 + v_p^2 = 1. \tag{16.15}$$

Thus, there is only one independent function, say v_p. We choose it so that the average energy be a minimum*. Here for the moment we leave the occupation numbers for quasiparticles undetermined. The average energy corresponds to the diagonal matrix element of the Hamiltonian (16.13). Substituting into it formulas (16.14) and retaining only

$$\left\langle\alpha^+_{p,-} - \alpha_{p,-}\right\rangle = n_{p,-}, \quad \left\langle\alpha^+_{p,+}\alpha_{p,+}\right\rangle = n_{p,+}$$

(here $\langle\cdots\rangle$ signifies the average over states with given occupation numbers), we obtain

---

- Here and below $\xi_p = \xi(p)$.
  ** In the second term of the Hamiltonian we omitted the term with $p_1 = p_1'$. This term is responsible for a slight variation in the chemical potential and can be compensated if we write $\xi - \Delta\mu$ in the first term. For simplicity we dispense with this procedure as being unimportant for the derivation.
  *** The method described here is simpler than the one used in the original work of Bardeen, Cooper and Schrieffer and is a generalization of the Bogoliubov method (Bogoliubov 1958; Bogoliubov et al. 1958) to finite temperatures.

$$
\begin{aligned}
E-\mu N &= \langle \mathscr{H} - \mu N \rangle \\
&= \sum_p \xi_p \left[u_p^2 \left(n_{p,+} + n_{p,-} \right) + v_p^2 \left(2 - n_{p,-} - n_{p,+} \right) \right] \\
&\quad - g \sum_p u_p v_p \left(1 - n_{p,+} - n_{p,-} \right) \sum_{p'} u_{p'} v_{p'} \left(1 - n_{p',+} - n_{p',-} \right). \qquad (16.16)
\end{aligned}
$$

Expressing u_p in accordance with (16.15) and varying with respect to v_p leads to the condition

$$
2\xi_p = \frac{\Delta \left(1 - 2v_p^2 \right)}{u_p v_p}, \qquad (16.17)
$$

where we have introduced the notation

$$
\Delta = g \sum_p u_p v_p \left(1 - n_{p,+} - n_{p,-} \right). \qquad (16.18)
$$

The solution of eq. (16.17) is

$$
u_p^2 = \frac{1}{2} \left(1 + \frac{\xi_p}{\varepsilon_p} \right), \quad v_p^2 = \frac{1}{2} \left(1 - \frac{\xi_p}{\varepsilon_p} \right), \qquad (16.19)
$$

where

$$
\varepsilon_p = \left(\xi_p^2 + \Delta^2 \right)^{1/2} \qquad (16.20)
$$

Substitution into eq. (16.18) leads to the condition

$$
\Delta = \frac{1}{2} g \sum_p \frac{\Delta}{\varepsilon_p} \left(1 - n_{p,+} - n_{p,-} \right). \qquad (16.21)
$$

For calculating the energy of quasiparticles we use the ideas of Landau's Fermi liquid theory (section 13.1). The energy of quasiparticles is defined as a variational
derivative of the total energy with respect to the distribution function

$$
\delta(E - \mu N) = \sum_p \varepsilon_{p,+} \delta n_{p,+} + \sum_p \varepsilon_{p,-} \delta n_{p,-} \qquad (16.22)
$$

With such a definition the equilibrium distribution function will be a Fermi function with $\varepsilon_{p,\sigma}$ as the energy*. Since $n_{p,+}$ and $n_{p,-}$ are included in the functional (16.16) in the same manner, the corresponding $\varepsilon_{p,\sigma}$ will also be the same. Varying (16.16) with respect to $\boldsymbol{n}_{\boldsymbol{p},+}$, for example**, we obtain

$$
\begin{aligned}
\varepsilon_{p,+} &= \frac{\delta(E - \mu N)}{\delta n_{p,+}} = \xi_p \left(u_p^2 - v_p^2 \right) + 2 u_p v_p \Delta \\
&= \left(\xi_p^2 + \Delta^2 \right)^{1/2} = \varepsilon_p.
\end{aligned}
$$

Thus, ε_p defined by formula (16.20) corresponds to the energy of quasiparticles (fig. 102, the dashed line). At $|\xi_p| > \Delta$, ε_p turns to $|\xi_p|$, which corresponds to quasiparticles of a normal metal.

- As has been said in section 14.1, the variational principle with the condition of the minimum average energy is equivalent to the Schrödinger equation.

This can also be seen from formulae (16.14) and (16.9). At $|\xi_p| \gg \Delta$ we have $u_p \to 1, v_p \to 0$ at $\xi_p > 0$ and $u_p \to 0$ and $v_p \to 1$ at $\xi_p < 0$. In such a case $\alpha_{p,+}$ and $\alpha_{p,-}$ play the role of the annihilation operators for quasiparticles of a normal metal.

From formula (16.20) it follows that there is an energy gap Δ in the quasiparticles spectrum. This not only agrees with experimental data but also accounts for the superconductivity. The critical velocity according to the Landau criterion (16.1) is finite: $v_c \sim \Delta/p_0$, i.e., at lower velocities the electron fluid exhibits superfluidity. Note also that the binding energy of a Cooper pair is equal to 2Δ. When it is broken up, two quasiparticles are formed, i.e., an energy Δ has to be consumed for each.

There arises, however, the following question: Are there excitations that are associated not with the breakdown of Cooper pairs but with their translational motion? The study of this question leads to the following results, which are rather understandable from a physical viewpoint. Cooper pairs form an interacting system. At low temperatures it may be regarded as a liquid and, hence, excitations with a low energy correspond to the propagation of sound waves (phonons). But sound is accompanied by density oscillations, and the liquid of Cooper pairs is charged. The density oscillations give rise to electric fields, which must be taken into account.

On the whole, we arrive at a situation resembling the problem of propagation of zero sound in the electron liquid (section 13.5). It has been found in section 13.5 that with the electric field taken into account the spectrum of vibrations is no longer linear, $\omega = ck$, and starts with a finite energy of order μ. This also occurs in

superconductors. It is clear that quasiparticles with such an energy cannot be of interest in a study of superconductivity.

Of course, just as in a normal metal, oscillations are possible, in principle, with a more complicated variation of the distribution function, which do not lead to a change in the electron density. However, because of a lack of clear-cut experimental evidence indicating their existence we shall not consider them.

A question may also be raised about pairing with a non-zero orbital moment, $l \neq 0$. The study of this question shows that if the amplitude of electron scattering is strongly dependent on the angle and there are negative coefficients in its expansion in spherical harmonics (each corresponding to a certain l), pairing may take place corresponding to the negative coefficient that is largest in absolute magnitude (see Abrikosov et al. 1962). An example of this kind in nature is a Fermi liquid - superfluid ^{3}He. In superfluid ^{3}He pairing actually occurs of quasiparticles with an orbital moment of $l = 1$ and parallel spins, which leads to superfluidity (see the review articles by Leggett 1975 and Wheatley 1975), but ^{3}He is a neutral Fermi liquid. Among metals a pairing with a nonzero orbital moment can possibly occur in so-called "systems with heavy fermions" (section 16.11), but this question has so far received no definite answer.

The difficulty lies in that scattering with a nonzero orbital moment implies a nonlocal interaction. However, as has been indicated in this book, phonon attraction and Coulomb repulsion are, in fact, local (i.e., they occur when electrons reside at a single point). Hence, we may speak only of some new, nonphonon mechanism of electron attraction, whose origin is not known at present (see the discussion of this question in section 16.11). In view of this, we shall not consider pairing with $l \neq 0$.

- In accordance with the generally adopted convention, here we denote the energy of quasiparticles by ε_p. It enters into the Fermi distribution without subtracting μ, i.e., $n_p = \left(e^{\varepsilon_p/T} + 1\right)^{-1}$. It should not be confused with the electron energy in the gas model, $\varepsilon(p)$, which has been used in Part I.
** Upon variation with respect to $n_{p,\sigma}$ the quantities u_p and v_p must be assumed to be constant, because these functions are themselves determined from the condition $\delta(E - N\mu)/\delta v_p = 0$.

8.2.6 16.5. Temperature dependence of the energy gap

We will begin the study of the thermodynamics of superconductors with the calculation of $\Delta(T)$. Substituting the Fermi function into formula (16.21) and passing to an integration over momenta, we arrive at the equation for determination of Δ :

$$\begin{aligned} 1 &= \frac{1}{2} g \int \frac{\mathrm{d}^3 p}{(2\pi\hbar)^3} \frac{1-2n_{\mathrm{F}}(\varepsilon)}{\varepsilon} \\ &= \frac{1}{2} g\nu(\mu) \int_0^{\hbar\omega_{\mathrm{D}}} \frac{\tanh\left[\left(\xi^2+\Delta^2\right)^{1/2}/2T\right]}{\left(\xi^2+\Delta^2\right)^{1/2}}\,\mathrm{d}\xi. \end{aligned} \tag{16.23}$$

Here we singled out the integration over ξ, took into account the symmetry with respect to $\xi \to -\xi$ and introduced the density of states $\nu(\mu) = p_0 m/\pi^2\hbar^3$) (remember that we are dealing with the isotropic model).

With $T \to 0, \tanh \to 1$. Taking the integral, we obtain:

$$1 = \frac{1}{2} g\nu(\mu) \ln\left(\frac{2\hbar\omega_{\mathrm{D}}}{\Delta(0)}\right)$$

(we assume that $g\nu(\mu) < 1$; therefore $\Delta < \hbar\omega_D$). From this it follows that

$$\Delta(0) = 2\hbar\omega_D \exp\left(\frac{-2}{g\nu}\right) \tag{16.24}$$

This formula differs from eq. (16.11) by a factor 2 , which results from taking account of the transformation of the energy spectrum.

As $T \to T_{\mathrm{c}}$, the energy gap tends to zero. In this case we have

$$1 = \frac{1}{2} g\nu(\mu) \int_0^{\hbar\omega_{\mathrm{D}}} \frac{\tanh(\xi)/2T_{\mathrm{c}}}{\xi}\,\mathrm{d}\xi = \frac{1}{2} g\nu(\mu) \ln\frac{2\hbar\omega_{\mathrm{D}}\gamma}{\pi T_{\mathrm{c}}}$$

where $\gamma = e^c = 1.78$. It follows that

$$T_c = \frac{2\hbar\omega_{\mathrm{D}}\gamma}{\pi} \exp\left(\frac{-2}{g\nu}\right). \tag{16.25}$$

Comparing this with eq. (16.23), we get

$$\Delta(0) = \frac{\pi}{\gamma} T_{\mathrm{c}} = 1.76 T_{\mathrm{c}}. \tag{16.26}$$

Let us consider the behavior of Δ near $T = 0$ and $T = T_{\mathrm{c}}$. Near $T = 0$ formula (16.23) is rewritten as follows: we divide it by $\frac{1}{2} g\nu(\mu)$ and then subtract and add $\left(\xi^2+\Delta^2\right)^{-1/2}$ under the integral. As a result we obtain

$$\ln\frac{\Delta(0)}{\Delta(T)} = \int_0^{\infty} \frac{1-\tanh\left[\left(\xi^2+\Delta^2\right)^{1/2}/2T\right]}{\left(\xi^2+\Delta^2\right)^{1/2}}\,\mathrm{d}\xi = 2f\left(\frac{\Delta}{T}\right) \tag{16.27}$$

where

$$f(x) = \int_1^{\infty} \frac{\mathrm{d}y\,\left(y^2-1\right)^{-1/2}}{1+\mathrm{e}^{yx}} \tag{16.28}$$

(the variable y corresponds to $\left(\xi^2+\Delta^2\right)^{1/2}/\Delta$). Since the integral in (16.27) converges at $\xi\sim\Delta$, we extended its upper limit to ∞. Since we are interested in large values of $x=\Delta/T$, we expand the integrand in (16.28) in e^{-yx} :

$$f(x)=\int_1^\infty\sum_{n=1}^\infty(-1)^{n+1}\mathrm{e}^{-nyx}\left(y^2-1\right)^{-1/2}\,\mathrm{d}y$$

Using the integral representation of the MacDonald functions (the Hankel function of imaginary argument)

$$K_\nu(z)=\frac{\Gamma\left(\frac{1}{2}\right)}{\Gamma\left(\nu+\frac{1}{2}\right)}\left(\frac{1}{2}z\right)^\nu\int_1^\infty\mathrm{e}^{-zy}\left(y^2-1\right)^{\nu-1/2}$$

($\Gamma(x)$ is the gamma function), we obtain

$$f(x)=\sum_{n=1}^\infty(-1)^{n+1}K_0(nx)\tag{16.29}$$

With large values of the argument the functions $\boldsymbol{K_0}$ fall off exponentially. Retaining only the first term and using the asymptotic

$$K_0(x)=\left(\frac{\pi}{2x}\right)^{1/2}\mathrm{e}^{-x}$$

we obtain, at $T<T_\mathrm{c}$,

$$\Delta\approx\Delta(0)-[2\pi\Delta(0)T]^{1/2}\mathrm{e}^{-\Delta(0)/T}.\tag{16.30}$$

This dependence is a consequence of the fact that the variation of Δ is associated with the appearance of quasiparticles and the number of quasiparticles is proportional to $\exp[-\Delta(0)/T]$.

If conversely $T\to T_\mathrm{c}$, then $\Delta\to0$. In this case, formula (16.23) can be conveniently expanded in Δ. We will proceed just as in the previous case. We divide (16.23) by $\frac{1}{2}\,\mathrm{g}\nu(\mu)$ and then subtract and add $\xi^{-1}\tanh(\xi/2T)$ in the integrand. As a result, we get

$$\ln\frac{T_c}{T}=\int_0^\infty\left(\frac{\tanh(\xi/2T)}{\xi}-\frac{\tanh\left[\left(\xi^2+\Delta^2\right)^{1/2}/2T\right]}{\left(\xi^2+\Delta^2\right)^{1/2}}\right)\mathrm{d}\xi\tag{16.31}$$

(because of the convergence of the integral at $\xi\sim T$, we again extended it up to ∞).
Let us use the following formula:

$$\tanh\frac{1}{2}\pi x=\frac{4x}{\pi}\sum_{k=0}^\infty\frac{1}{(2k+1)^2+x^2}$$

Substituting this into (16.31), expanding in Δ and integrating over ξ, we find that

$$\ln\frac{T_\mathrm{c}}{T}=2\sum_{n=1}^\infty(-1)^{n+1}\frac{(2n-1)!!}{2n!!}\left(\frac{\Delta}{\pi T}\right)^{2n}\sum_{k=0}^\infty\frac{1}{(2k+1)^{2n+1}},\tag{16.32}$$

where $n!!=n(n-2)(n-4)\ldots$. If we retain the first term, we will have

$$\Delta\approx\pi\left(\frac{8}{7\zeta(3)}\right)^{1/2}\left[T_\mathrm{c}\left(T_\mathrm{c}-T\right)\right]^{1/2}=3.06\left[T_\mathrm{c}\left(T_\mathrm{c}-T\right)\right]^{1/2}\tag{16.33}$$

($\zeta(x)$ is the Riemann zeta function: $\zeta(x)=\sum_{n=1}^\infty n^{-x}$).
This behavior is rather natural. In fact, Δ, while being finite at $T<T_\mathrm{c}$ and equal to zero at

$T > T_c$, may serve as the order parameter of the superconducting transition. The temperature dependence (16.33) is consistent with Landau's theory of secondorder phase transitions (see Appendix II). The question of the validity of this theory for superconductors will be discussed at a later time.

The graph of the function $\Delta(T)$ is shown in fig. 103.

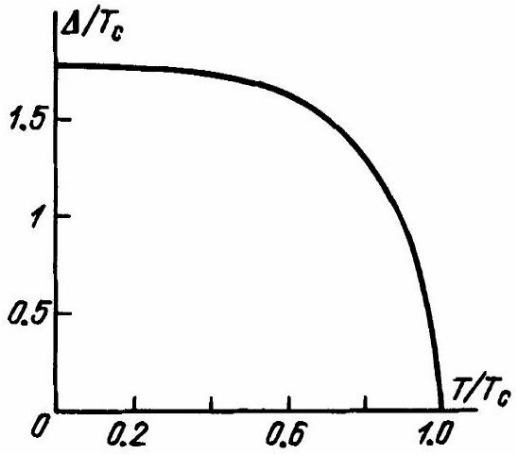

Fig. 103.

8.2.7 16.6. Thermodynamics of superconductors

Statistical physics gives the following expression for the thermodynamic potential*:

$$\Omega = -T \ln Z, \quad Z = \sum_{n,N} \exp\left(\frac{-E_{nN} + N\mu}{T}\right) \tag{16.34}$$

where $E_{n,N}$ are the energy levels, i.e., the eigenvalues of the Hamiltonian operator of a system of N particles. The expression for the statistical sum may be written in the form of a trace of the matrix $Z_{nm} = \int \Phi_n^* Z \Phi_m \, \mathrm{d}V$; $Z = \mathrm{e}^{-(\mathscr{H}-N\mu)/T}$ and Φ_n are wave functions of the system (the operation Sp is invariant with respect to the choice of the orthonormalized system of the functions $\boldsymbol{\Phi_n}$):

$$Z = \mathrm{Spe}^{-(\mathscr{H}-N\mu)/T}. \tag{16.35}$$

We substitute $\mathscr{H} - N\mu$ in the form of (16.13) and differentiate Ω (16.34) with respect to the interaction constant g. As a result, we have

$$\frac{\partial \Omega}{\partial g} = g^{-1} \frac{\mathrm{Sp}\left[\mathscr{H}_{\mathrm{int}} \, \mathrm{e}^{-(\mathscr{H}-N\mu)/T}\right]}{\mathrm{Spe}^{-(\mathscr{H}-N\mu)/T}} = g^{-1} \left\langle \mathscr{H}_{\mathrm{int}} \right\rangle, \tag{16.36}$$

where we have denoted the second term in the Hamiltonian (16.23) as $\mathscr{H}_{\mathrm{int}}$ (it describes the interaction of electrons). The angular brackets $\langle \cdots \rangle$ denote the average over the Gibbs distribution.

We express in (16.36) the operators $a_{p,\sigma}$ in terms of $\alpha_{p,\sigma}$ (16.15) and take the average. To within a factor we obtain the second term in formula (16.16). Using the definition of Δ (16.18), we can write:

$$\frac{\partial \Omega}{\partial g} = -\frac{\Delta^2}{g^2}. \tag{16.37}$$

Passing from the variable g to the variable Δ, we obtain

$$\Omega_{\rm s} - \Omega_{\rm n} = \int_0^{\Delta} \frac{{\rm d}g^{-1}\left(\Delta_1\right)}{{\rm d}\Delta_1} \Delta_1^2 \, {\rm d}\Delta_1. \tag{16.38}$$

Here we have used the fact that at $\Delta = 0$ the superconductor is converted to a normal metal. The expression for g^{-1} as a function of Δ is obtained from formulae (16.24) and (16.27):

$$g^{-1} = \frac{1}{2}\nu(\mu)\left[\ln\left(\frac{2\hbar\omega_{\rm D}}{\Delta}\right) - 2f\left(\frac{\Delta}{T}\right)\right]. \tag{16.39}$$

The function f is expressed by formula (16.28).
Let us find the asymptotic values of $\Omega_{\rm s} - \Omega_{\rm n}$ for $T \to 0$ and $T \to T_{\rm c}$. In the first case we use formula (16.29) for f. Substituting into eq. (16.38), we find

$$\Omega_{\rm s} - \Omega_{\rm n} = -\frac{1}{2}\nu(\mu)\left[\frac{1}{2}\Delta^2 - 2\sum_{n=1}^{\infty}(-1)^{n+1}\frac{T^2}{n^2}\int_0^{n\Delta/T} K_1(x)x^2 \, {\rm d}x\right]$$

where we have employed the relation $K_0'(x) = -K_1(x)$. The integral in brackets is taken in explicit form, $\int x^2 K_1(x) = -x^2 K_2(x)$. While inserting the lower limit we shall take into account that $\left[x^2 K_2(x)\right]_{x\to 0} = 2$. As a result, we obtain the sum

$$2T^2\nu(\mu)\sum_{n=1}^{\infty}(-1)^{n+1}n^2 = \frac{1}{6}\pi^2 T^2 \nu(\mu)$$

The free energy of a normal metal on the left-hand side is equal to $-\frac{1}{6}\pi^2 T^2\nu(\mu)$. This follows from formula (2.27) for the heat capacity and from the relation $C = -T\,(\,\partial^2\Omega/\partial T^2\,)$. Cancelling $-\Omega_{\rm n}$ on the left- and right-hand sides, we obtain

$$\Omega_{\rm s} = -\frac{1}{2}\nu(\mu)\left[\frac{1}{2}\Delta^2 + 2\sum_{n=1}^{\infty}(-1)^{n+1}K_2(n\Delta/T)\Delta^2\right]. \tag{16.40}$$

At $T = 0$ the second term vanishes and we obtain

$$\Omega_{\rm s}(0) = -\frac{1}{4}\nu(\mu)\Delta^2(0) \tag{16.41}$$

This formula is quite natural. It corresponds to the fact that the electrons in an energy band with a width of order Δ [their number is of order $\nu(\mu)\Delta$] are bound into pairs with a binding energy of order Δ.

At low temperatures we take into account the correction to $\Delta(0)$ and the term with $n = 1$ in the second term of (16.40). As a result, we find

$$\begin{aligned}\Omega_{\rm s}(T) - \Omega_{\rm s}(0) &= \nu(\mu)\Delta^2(0)\left[K_0\left(\frac{\Delta(0)}{T}\right) - K_2\left(\frac{\Delta(0)}{T}\right)\right] \\ &= -2\nu(\mu)\Delta(0)TK_1\left(\frac{\Delta(0)}{T}\right) \\ &\approx -\nu(\mu)\left[2\pi T^3\Delta(0)\right]^{1/2}{\rm e}^{-\Delta(0)/T}\end{aligned} \tag{16.42}$$

from which we obtain the entropy per unit volume,

- The potential Ω depends on the variables T, V and μ, while the free energy F is a function of T, V and N.

$$S_{\rm s} = -\frac{\partial \Omega_{\rm s}}{\partial T} \approx \nu(\mu) \left(\frac{2\pi \Delta^3(0)}{T} \right)^{1/2} {\rm e}^{-\Delta(0)/T} \tag{16.43}$$

and the heat capacity,

$$C_{\rm s} = T \frac{\partial S_{\rm s}}{\partial T} = \nu(\mu) \left(\frac{2\pi \Delta^5(0)}{T^3} \right)^{1/2} {\rm e}^{-\Delta(0)/T}. \tag{16.44}$$

Now we pass to the case $T \to T_{\rm c}$. We use formula (16.32). Expressing $T_{\rm c}$ via g with the aid of formula (16.25), we find g^{-1} as a function of Δ :

$$\begin{aligned} g^{-1} = & \frac{1}{2}\nu(\mu) \left[\ln \left(\frac{2\hbar\omega_{\rm D}\gamma}{\pi T} \right) \right. \\ & \left. -2 \sum_{n=1}^{\infty} (-1)^{n+1} \frac{(2n-1)!!}{(2n)!!} \left(\frac{\Delta}{\pi T} \right)^{2n} \sum_{k=0}^{\infty} (2k+1)^{-(2n+1)} \right]. \end{aligned}$$

Substitution into eq. (16.38) yields

$$\begin{aligned} \Omega_{\rm s} - \Omega_{\rm n} = & -\nu(\mu) \sum_{n=1}^{\infty} (-1)^{n+1} \frac{(2n-1)!!2n}{(2n+2)!!} \\ & \times \frac{\Delta^{2n+2}}{(\pi T)^{2n}} \sum_{k=0}^{\infty} (2k+1)^{-(2n+1)} \end{aligned} \tag{16.45}$$

Retaining only the first term, we find from eq. (16.45)

$$\Omega_{\rm s} - \Omega_{\rm n} \approx -\nu(\mu) \frac{7}{32} \zeta(3) \frac{\Delta^4}{(\pi T)^2} \tag{16.46}$$

Inserting the value of Δ for $T \to T_{\rm c}$ (16.33), we obtain

$$\Omega_{\rm s} - \Omega_{\rm n} \approx -\frac{2}{7\zeta(3)} \frac{p_0 m}{\hbar^3} \left(T_{\rm c} - T \right)^2 \tag{16.47}$$

from which we find the entropy:

$$S_{\rm s}(T) \approx S_{\rm n}(T) + \frac{4}{7\zeta(3)} \frac{p_0 m}{\hbar^3} \left(T - T_{\rm c} \right) \tag{16.48}$$

Differentiating once more, we obtain the heat capacity at the transition point:

$$C_{\rm s}\left(T_{\rm c}\right) = C_{\rm n}\left(T_{\rm c}\right) + \frac{4}{7\zeta(3)} \frac{p_0 m}{\hbar^3} T_{\rm c} \tag{16.49}$$

Recall (see eq. 2.29) that

$$C_{\rm n}(T) = S_{\rm n}(T) = \frac{p_0 m}{3\hbar^3} T \tag{16.50}$$

From (16.49) it follows that the heat capacity undergoes a jump at the transition point equal to $[4/7\zeta(3)]\,({\rm p_0\ m}/\hbar^3)\,{\rm T_c}$. In order to trace out the temperature course of the heat capacity in the vicinity of $T_{\rm c}$, it is necessary to take into account the following terms of the expansion in Δ in formulae (16.45) and (16.32). This being done, we substitute the numbers and obtain

$$\frac{C_{\rm s}(T)}{C_{\rm n}\left(T_{\rm c}\right)} = 2.42 + 4.76 \frac{T - T_{\rm c}}{T_{\rm c}}. \tag{16.51}$$

The dependence $C_{\rm s}(T)$ is shown in fig. 104.
A knowledge of the thermodynamic potentials makes it possible to determine the critical field H_c. For this purpose we use relation (15.5). We take into account that, according to thermodynamics, the corrections to all thermodynamic potentials are identical if they are expressed in terms of the corresponding variables. In particular,

$$(\delta F)_{N,T,V} = (\delta\Omega)_{\mu,T,V}$$

This enables one to determine H_c from the relation

$$\Omega_{\rm n} - \Omega_{\rm s} = \frac{H_{\rm c}^2}{8\pi} \tag{16.52}$$

First of all, at $T = 0$ we obtain from eq. (16.41) (recall that we assume $\Omega_{\rm n}(0) = 0$)

$$H_{\rm c}(0) = [2\pi\nu(\mu)]^{1/2}\Delta(0). \tag{16.53}$$

At low temperatures $\Omega_{\rm n}(T) = -\frac{1}{6}\pi^2T^2\nu(\mu)$, and the temperature conrection to $\Omega_{\rm s}(0)$ is exponentially small in accordance with (16.42). Hence,

$$\frac{H_{\rm c}^2(T)}{8\pi} = \Omega_{\rm n}(T) - \Omega_{\rm s}(T) \approx -\frac{1}{6}\pi^2T^2\nu(\mu) + \frac{1}{4}\nu(\mu)\Delta^2(0).$$

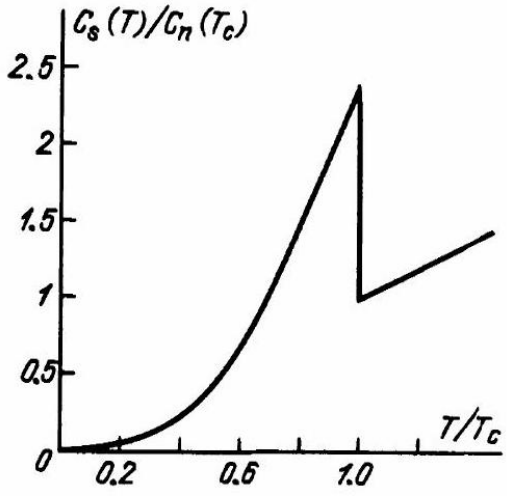

Fig. 104.

From (16.49) it follows that the heat capacity undergoes a jump at the transition point equal to $[4/7\zeta(3)]\,(\mathrm{p_0\ m}/\hbar^3)\,\mathrm{T_c}$. In order to trace out the temperature course of the heat capacity in the vicinity of T_c, it is necessary to take into account the following terms of the expansion in Δ in formulae (16.45) and (16.32). This being done, we substitute the numbers and obtain

$$\frac{C_{\rm s}(T)}{C_{\rm n}\,(T_{\rm c})} = 2.42 + 4.76\frac{T - T_{\rm c}}{T_{\rm c}}. \tag{16.51}$$

The dependence $C_{\rm s}(T)$ is shown in fig. 104.
A knowledge of the thermodynamic potentials makes it possible to determine the critical field $H_{\rm c}$. For this purpose we use relation (15.5). We take into account that, according to thermodynamics, the corrections to all thermodynamic potentials are identical if they are expressed in terms of the corresponding variables. In particular,

$$(\delta F)_{N,T,V} = (\delta\Omega)_{\mu,T,V}$$

This enables one to determine $\boldsymbol{H_c}$ from the relation

$$\Omega_{\rm n} - \Omega_{\rm s} = \frac{H_{\rm c}^2}{8\pi} \tag{16.52}$$

First of all, at $T = 0$ we obtain from eq. (16.41) (recall that we assume $\Omega_{\rm n}(0) = 0$)

$$H_c(0) = [2\pi\nu(\mu)]^{1/2}\Delta(0). \tag{16.53}$$

At low temperatures $\Omega_{\rm n}(T) = -\frac{1}{6}\pi^2T^2\nu(\mu)$, and the temperature conrection to $\Omega_{\rm s}(0)$ is exponentially small in accordance with (16.42). Hence,

$$\frac{H_c^2(T)}{8\pi} = \Omega_{\rm n}(T) - \Omega_{\rm s}(T) \approx -\frac{1}{6}\pi^2T^2\nu(\mu) + \frac{1}{4}\nu(\mu)\Delta^2(0).$$

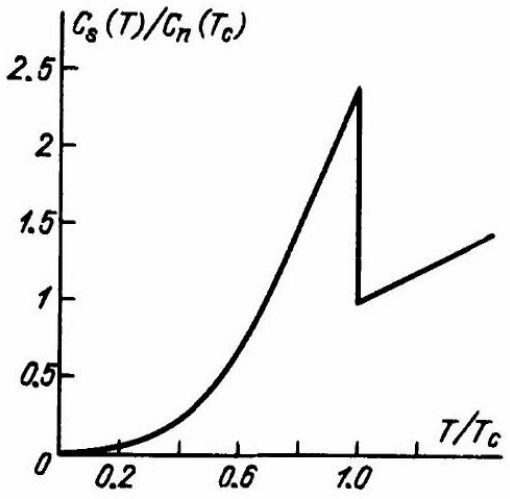

Fig. 104.

With the aid of eq. (16.53) we find from the last relation

$$\begin{aligned} H_c(T) &\approx H_c(0)\left(1 - \frac{1}{3}\pi^2\frac{T^2}{\Delta^2(0)}\right) \\ &= H_c(0)\left(1 - \frac{1}{3}\gamma^2\frac{T^2}{T_c^2}\right) = H_c(0)\left(1 - 1.05\frac{T^2}{T_c^2}\right) \end{aligned} \tag{16.54}$$

Here we have used the relationship between $\Delta(0)$ and $T_{\rm c}$(16.26).
Near $T_{\rm c}$ obtain in accordance with eq. (16.47):

$$\begin{aligned} H_c &\approx \left(16\pi\frac{p_0m}{7\zeta(3)\hbar^3}\right)^{1/2}(T_c - T) \\ &= H_c(0)\gamma\left(\frac{8}{7\zeta(3)}\right)^{1/2}\left(1 - \frac{T}{T_c}\right) \\ &= 1.735H_c(0)\left(1 - \frac{T}{T_c}\right) \end{aligned} \tag{16.55}$$

Formulae (16.55) and (16.49) are consistent with formula (15.8) for the jump in heat capacity, as was to be expected.

Let us consider certain consequences of the results obtained. According to formulas (16.26) and (16.53), the critical temperature T_c and the critical field $H_c(0)$ are proportional to $\Delta(0)$. In accordance with formula (16.24), $\Delta(0)$ is proportional to the Debye frequency ω_D, which depends on the mass of lattice ions by the law $\omega_D \propto M^{-1/2}$. This is in accord with the formulae for the isotope effect (16.2). Further, at low temperatures the heat capacity is described by the exponential law (16.44), this being in agreement with the experimental result (15.3). Finally, although the results for the critical field do not coincide completely with the empirical formula (15.1), the asymptotic formulas for $T < T_c$ and $T \to T_c$ (16.54) and (16.55) are rather close to it.

All the results given above refer to the isotropic model, whereas true metals are anisotropic. Therefore, it is surprising that these formulas agree well with experiment not only qualitatively but quantitatively as well. But there are certain differences, which call for consideration. First of all it should be noted that, according to the theory described here, any thermodynamic quantity expressed in dimensionless units, say $C_s(T)/C_n(T_c)$ or $H_c(T)/H_c(0)$, depends only on the ratio T/T_c, where T_c is connected with the gap in the energy spectrum at $T = 0$ by relation (16.26).

In an anisotropic metal the energy spectrum of quasiparticles looks somewhat different:

$$\varepsilon(\boldsymbol{p}) = \left[\Delta^2(\boldsymbol{n}) + \xi^2(\boldsymbol{n})\right]^{1/2} \tag{16.56}$$

where $\xi(n) = v(n)\,[p - p_0(n)]$, and n is the unit vector in the direction p. Thus, Δ depends on the direction $\boldsymbol{p}$. At low temperatures the role of the energy gap is played by the minimum value of $\Delta(n, 0)$, which we denote by Δ_{min}. It is exactly this value
that governs the temperature course of the heat capacity with $T \to 0 : C_s \propto \exp(-\Delta_{min}/T)$. On the other hand, $\Delta(n, T)$ depends on temperature: at $T \to T_c \Delta(n, T) \approx \Delta_0(n) f(T/T_c)$, where $f \to 0$ when $T \to T_c$ (Pokrovskii 1961).

For an anisotropic metal the statement that $C_s(T)/C_n(T_c)$ depends only on T/T_c over the entire temperature range from 0 to T_c does not conform to reality. As a matter of fact, if $\Delta(0)$ is determined from formula (16.26), we obtain a certain averaged value of $\Delta(0)$ and, hence, the low-temperature formula $C_s \propto \exp[-\Delta(0)/T]$ will differ from the true law, which includes Δ_{min}. Therefore, if we compare the experimental data for C_s with the theoretical curve for the isotropic model, then with $T \to 0$ the experimental points should be expected to lie above the theoretical curve, which is what occurs in reality. However, the anisotropy of Δ is not large in reality: $\left(\overline{\Delta(0)} - \Delta_{min}\right)/\overline{\Delta(0)} < 10\%$. This may be accounted for as follows: the phonon forces of attraction are mainly determined by short-wave length phonons with a frequency of order ω_D. Upon exchange of such phonons with $\hbar k \sim p_0$ the momenta of electrons vary significantly. This leads to a certain effective averaging along the entire Fermi surface.

Another assumption of the theory described above is that the interaction between the electrons is weak:

$$g\nu(\mu) < 1.$$

This assumption is not always justifiable. In fact, for lead, for example, $T_c = 7.2$ K and $\hbar\omega_D = 94.5$ K; hence, $g\nu(\mu) = 0.76$. It is not surprising that for such metals the above-described theory differs somewhat from experiment (this refers mainly to the dependence $H_c(T)$). However, after an appropriate correction of the theory the disagreement is markedly reduced.

8.2.8 16.7. London and Pippard superconductors (qualitative theory)

Before considering the microscopic derivation of the basic relations that characterize the behavior of superconductors in an electromagentic field, we shall give a simple qualitative analysis. In section 15.5 we have derived the equations of London electrodynamics. In particular, it has been noted that these equations may be written in the form (15.43), i.e.,

$$j = -QA, \quad (\operatorname{div} A = 0),$$

where

$$Q = \frac{n_e e^2}{mc}$$

In deriving the London equations it was assumed that the superconducting current is transported by electrons. At present, however, we know that the carriers of superconducting current are Cooper pairs. The main difference is that Cooper pairs
have a finite size. This size can be determined on the basis of the following considerations. The energy spectrum of quasiparticles $\varepsilon = \left[v^2 (p - p_0)^2 + \Delta^2\right]^{1/2}$ indicates that binding into pairs involves the momenta in the region of $\delta p \sim \Delta/v$ near the Fermi boundary. According to the uncertainty principle, $\delta p \delta r \sim \hbar$. From this we may infer that the size of the pair is $\hbar v/\Delta$. If we substitute here $v \sim 10^8$ cm/s, $\Delta \sim 10$ K $\sim 10^{-3}$eV $\sim 10^{-15}$erg, we obtain

$$\frac{\hbar v}{\Delta} \sim 10^{-4} \text{ cm}$$

that is, thousands of interatomic distances.
Hence, the pairs are very loose formations. A natural question arises: How could they be accommodated in a metal without interfering with one another? Of course, the Cooper pairs cannot, in fact, be visualized as a classical gas composed of particles, the distance between which is much larger than their size. The pairs penetrate each other and at the same time, just as gas particles, they are free and there is practically no interaction between them. This is, of course, possible only in quantum mechanics, in the same way as the flow of this gas through the lattice without scattering. In order to emphasize this nonclassical behavior, in the rigorous theory one speaks not of pairs having a certain size but of a pair correlation between electrons extending to a certain distance - a "correlation length", which is of order $\xi \sim \hbar v/\Delta^*$.

In view of the presence of a correlation the current is determined by the electromagnetic field not only directly at the point of observation but also in the entire region around this point, with a radius of order ξ. Therefore, the relationship between the current and the field becomes nonlocal and is expressed by the relation

$$j_i(r) = -\sum_k \int Q_{ik}(r - r') A_k(r') \, dV' \tag{16.57}$$

where the kernel Q_{ik} falls off at a distance of order ξ.
In the limiting case, when the field varies very slowly in space, in the integral of (16.57) $A_K(r')$ may be replaced by $A_k(r)$, which is taken outside the integral sign. Denoting $\int Q_{ik}(r - r') \, dV' = \delta_{ik} Q$, we obtain the London relationship between the current and the field. The characteristic length that determines the variation of the field in a superconductor is obviously the penetration depth δ. As a matter of fact, at this distance the field varies from a given value at the surface of the superconductor to zero. Hence, in a case where $\delta > \boldsymbol{\xi}$, we return to London electrodynamics. This limit is called the London limit.

In the opposite limiting case $\delta < \xi$ we may apply the inefficiency concept, just as in the anomalous skin effect (section 7.2). Indeed, the electrons (or, more exactly, pairs) that move at large angles to the surface of the superconductor emerge rapidly

from the penetration depth and practically do not interact with the field. Only those electrons which move at an angle not exceeding $\theta \sim \delta/\xi$ are effective. But the number of such electrons is $n_e\theta \sim n_e\delta/\xi$. Substituting this number into expression (16.40) for the penetration depth, we obtain

$$\delta \sim \left(\frac{mc^2}{4\pi e^2 n_e \delta \xi^{-1}}\right)^{1/2}.$$

This is an equation for δ. Solving it, we get

$$\delta_P \sim \left(\frac{mc^2}{4\pi n_e e^2}\xi\right)^{1/3} \sim \delta_L^{2/3}\xi^{1/3} \tag{16.58}$$

(the London penetration depth defined by eq. (15.40) was denoted as δ_L). The case $\delta < \xi$ was first considered by Pippard (1953). Therefore, such superconductors are called Pippard superconductors.

In experiment all pure superconductors are Pippard superconductors or intermediate superconductors, i.e., in them $\xi \geqslant \delta$. However, as we shall see below, the correlation length can be reduced and δ increased by introducing impurities or structural defects, from which the electrons are scattered. As a result, we can arrive at the London limit. Moreover, near T_c all superconductors become London superconductors.

In concluding this section we note that the expression for the London coefficient Q and the corresponding penetration depth does not depend on whether electrons or pairs are considered to be carriers. Indeed, making the replacement $e \to 2e, n_e \to \frac{1}{2}n_e$ and $m \to 2m$, we obtain the same formulas for Q and δ, (15.43) and (15.40), respectively.

8.2.9 16.8. The Meissner effect at $T = 0$

Now we shall deal with a quantitative microscopic derivation. Since the equations derived in the general case are cumbersome, we will consider here the simplest case: the behavior of superconductors at $T = 0$ in a weak magnetic field, which is independent of time.

The Hamiltonian is known from quantum mechanics to vary with the variations of the vector potential (Landau and Lifshitz 1974):

$$\delta\mathscr{H} = -\frac{1}{c}\int j\delta A \, \mathrm{d}V. \tag{16.59}$$

Here on the left under the integral is the current operator. Averaging this formula over a given state, say the equilibrium state, at temperature T, we obtain

$$\delta E = -\frac{1}{c}\int \langle j\rangle \delta A \, \mathrm{d}V, \tag{1'}$$

where $\langle \boldsymbol{j}\rangle$ is the average current. Thus, in order to find $\langle \boldsymbol{j}\rangle^*$, we are to find the average energy as a function of A, and to vary it with respect to A.

Since in the absence of the field $\boldsymbol{j} = 0$, it follows that at not too large fields the current is proportional to the field. From this we see that in order to find the current, we are to find the energy in the presence of the field to within terms that are second order in $\boldsymbol{A}$ and then to vary it with respect to $\boldsymbol{A}$.

*The symbol $\boldsymbol{\xi}$ is generally adopted for the correlation length. We use it because the correlation length and the electron energy $\xi = v\,(p - p_0)$ will not be encountered in the same formulas.

In the presence of a field the Hamiltonian (16.13) is transformed in such a manner that instead of the momentum operators $-\mathrm{i}\hbar\nabla$ the combination $-\mathrm{i}\hbar\nabla - (e/c)A$ is included. Hence, in the Hamiltonian we obtain

$$\frac{1}{2m}\left[-\hbar^2\nabla^2 + \mathrm{i}\hbar\frac{e}{c}(A\nabla + \nabla A) + \left(\frac{e}{c}\right)^2 A^2\right]. \tag{16.60}$$

While the first term retains the momentum of the particle, the other terms do not. If we expand $\boldsymbol{A}$ into a Fourier integral,

$$A(r) = \sum_q A_q \mathrm{e}^{\mathrm{i}qr} \tag{16.61}$$

we may interpret $\boldsymbol{A_q}$ as the operator of the absorption of an electromagnetic quantum with momentum $\hbar q$. In view of this, the operator A_q transfers a particle of momentum $\boldsymbol{p} - \boldsymbol{\hbar q}$ to a state of momentum $\boldsymbol{p}$. The terms of the Hamiltonian containing $\boldsymbol{A}$, which are of interest to us, may be written in the following form with the aid of the second-quantization operators:

$$\mathscr{H}_1 = -\frac{e}{2mc}\sum_{p,q,\sigma}\left[(p-\hbar q)a^+_{p,\sigma}a_{p-\hbar q,\sigma} + pa^+_{p,\sigma}a_{p-\hbar q,\sigma}\right]A_q, \tag{16.62}$$

$$\mathscr{H}_2 = \frac{e^2}{2mc^2}\sum_{p,q,q',\sigma} a^+_{p,\sigma}a_{p-\hbar q-\hbar q',\sigma}A_qA_{q'}. \tag{16.63}$$

Here it is taken into account, for example, that

$$-\mathrm{i}\hbar\nabla A_q\mathrm{e}^{\mathrm{i}qr} = A_q\mathrm{e}^{\mathrm{i}qr}(-\mathrm{i}\hbar\nabla + \hbar q).$$

Let us express the combinations $\sum_\sigma a^+_{p,\sigma}a_{p',\sigma}$ contained in $\mathscr{H}_1$ and $\mathscr{H}_2$ in terms of the operators $\alpha_+$and α_-. Substituting formulas (16.14) and collecting the terms, we find

$$\begin{aligned}\sum_\sigma a^+_{p,\sigma}a_{p',\sigma} =& u_pu_{p'}\left(\alpha^+_{p,+}\alpha_{p',+} + \alpha^+_{p,-}\alpha_{p',-}\right)\\ &+ v_pv_{p'}\left(\alpha_{-p,-}\alpha^+_{-p',-} + \alpha_{-p,+}\alpha^+_{-p',+}\right)\\ &+ u_pv_{p'}\left(\alpha^+_{p,+}\alpha^+_{-p',-} - \alpha^+_{p,-}\alpha^+_{-p',+}\right)\\ &+ v_pu_{p'}\left(\alpha_{-p,-}\alpha_{p',+} - \alpha_{-p,+}\alpha_{p',-}\right)\end{aligned} \tag{16.64}$$

Since the part of Hamiltonian $\mathscr{H}_2$(16.63) is second order in A, it is sufficient to take it into account only in the first order of perturbation theory, i.e., it will suffice to average it over the ground state. As a result, only the term with $v_pv_{p'}$ from expression (16.64) makes a contribution, and it appears that $p = p'$, i.e., $q = -q'$. Considering that $n_{p,+} = n_{p,-} = 0$ at $T = 0$, we obtain from this term

$$E_2 = \frac{e^2}{mc^2}\sum_{p,q} v_p^2A_qA_{-q} \tag{16.65}$$

The first order of perturbation theory in $\mathscr{H}_1$ turns to zero. Indeed, upon averaging over the ground state we obtain $\sum_p pv_p^2\delta_{q,0} = 0$, since v_p depends only on $|p|$. Therefore, we are to find the second order of perturbation theory:

*In the following we will omit the angular brackets for the average current.

$$E_1 = \sum_{m\neq 0} \frac{|(\mathscr{H}_1)_{m0}|^2}{E_{(0)} - E_{(m)}}$$

Since there are no quasiparticles in the ground state, the contribution to E_1 comes only from transitions involving the creation of two quasiparticles and their annihilation. Thus, we obtain

$$\begin{gathered}(\mathscr{H}_1)_{m0} = -\frac{e}{2mc}\left(u_p v_{p-\hbar q} - v_p u_{p-\hbar q}\right)(2p - \hbar q),\\ E_{(0)} - E_{(m)} = -\left(\varepsilon_p + \varepsilon_{p-\hbar q}\right),\\ E_1 = -\left(\frac{e}{2mc}\right)^2 \sum_p \frac{[(2p-\hbar q)A_q]\,[(2p-\hbar q)A_{-q}]}{\varepsilon_p + \varepsilon_{p-\hbar q}}\\ \times \left(u_p v_{p-\hbar q} - v_p u_{p-\hbar q}\right)^2. \qquad (16.66)\end{gathered}$$

Here we have used the reality of $\boldsymbol{A}(\boldsymbol{r})$. According to (16.61), it follows that $\boldsymbol{A}_{\boldsymbol{q}}^* = \boldsymbol{A}_{-\boldsymbol{q}}$. Moreover, it has been taken into account that the operators $\alpha_{p,-}$ and $\alpha_{p',+}$ anticommute, i.e., their permutation leads to a change in sign.

Before performing further calculations one remark should be made. As is known from electrodynamics, a correct theory must have the property of gauge invariance. In the static case this reduces to the invariance of the equations under the transformation $A \to A + \nabla\varphi$, where φ is any scalar function. This is because only the magnetic field $\boldsymbol{H} = \operatorname{rot}\boldsymbol{A}$ has a physical meaning. But if the Fourier component of the vector potential enters explicitly into the equations, then only the following combination is permissible:

$$A_{q\perp} = A_q - \frac{q\,(qA_q)}{q^2}$$

Indeed, the gauge transformation in the Fourier components has the form

$$A_q \to A_q + \mathrm{i}q\varphi_q.$$

With such a replacement $\boldsymbol{A}_{\mathbf{q}\perp}$ does not change.
The invariance under a gauge transformation is provided in quantum mechanics as a result of the vector potential entering into the Hamiltonian in combination with thc momentum operator $p - (e/c)A$. The addition of the gradient to A can be
compensated for by a change of the phase of the wave function. In view of this, there is no need to test the gauge invariance of the resultant equations and one can use the gauge of $\boldsymbol{A}$ that is most convenient. We will use a vector potential that satisfies the condition $\operatorname{div} A = 0$ or, in Fourier components, $qA_q = 0$ (section 15.5), because in such a case the derivation is simplified.

In order to obtain explicitly gauge-invariant equations that are valid for any gauge, we should have taken into account the change of the Bogoliubov transformation formulas (16.14) under the action of the field. Since u_p and v_p are scalars, they may have only corrections proportional to $\boldsymbol{qA_q}$, i.e., the ones which vanish in our gauging $\boldsymbol{qA_q} = 0$. But if this condition is not imposed, we obtain the same equations, but with $\boldsymbol{A_q}$ being replaced by $\boldsymbol{A}_{\boldsymbol{q}\perp}$. We shall not perform this complicated derivation here, since in choosing the correct initial Hamiltonian the result is known in advance.

We make the replacement $\boldsymbol{p} \to \boldsymbol{p} + \frac{1}{2}\hbar\boldsymbol{q}$ and introduce the notations

$$\xi_{p+\hbar q/2} \equiv \xi_+, \quad \xi_{p-\hbar q/2} \equiv \xi_-, \quad \xi = v\,(p - p_0)$$

and analogous ones for the other quantities. Substituting into eq. (16.66) the values of u_p and v_p in accordance with eq. (16.19), we have

$$E_1 = -\frac{1}{2}\left(\frac{e}{mc}\right)^2 \sum_p \frac{(pA_q)\,(pA_{-q})\,(\varepsilon_+\varepsilon_- - \xi_+\xi_- - \Delta^2)}{\varepsilon_+\varepsilon_-\,(\varepsilon_+ + \varepsilon_-)}. \tag{16.67}$$

Relation (16.59′) in Fourier components has the form

$$\delta E = -c^{-1}\sum_q j_q \delta A_q. \tag{16.68}$$

From eqs. (16.65) and (16.66) we obtain

$$\begin{aligned} j_q = &-\frac{2e^2}{mc}\sum_p v_p^2 A_q \\ &+ \frac{e}{m^2 c}\sum_p \frac{p\,(pA_q)\,(\varepsilon_+\varepsilon_- - \xi_+\xi_- - \Delta^2)}{\varepsilon_+\varepsilon_-\,(\varepsilon_+ + \varepsilon_-)}. \end{aligned} \tag{16.69}$$

In the first term $2\sum_p v_p^2 = n_\mathrm{e}$ is the electron density (recall that the normalization volume V has been assumed equal to unity). This equality can be obtained if in the expression for the operator of the number of particles (section 16.4)

$$n_\mathrm{e} = \sum_{p,\sigma} a_{p,\sigma} a_{p,\sigma} \tag{16.70}$$

we perform the Bogoliubov transformation and then average it over the ground state.
In the second term we assume that $|q| < p_0$. In such a case,

$$\xi_\pm = \frac{1}{2m}\left[\left(p + \frac{1}{2}\hbar q\right)^2 - p_0^2\right] \approx \xi \pm \frac{1}{2} v\hbar q\cos\theta,$$

where $v = p_0/m$; for the vector p we have introduced polar coordinates with the axis along q (the z axis). In accordance with our choice of $\boldsymbol{A}_q$, the current component along q is missing, and we shall find j_x (evidently, $j_x = j_y$). Passing from $\sum_p$ to
$(2\pi\hbar)^{-3}\int \mathrm{d}^3 p$, we have

$$j_{q_\perp} = -Q(q) A_{q_\perp} \tag{16.71}$$

where

$$\begin{aligned} Q(q) = &\frac{n_\mathrm{e} e^2}{mc} - \frac{1}{(2\pi\hbar)^3}\frac{e^2}{m^2 c} \\ &\times \frac{p_0^4}{v}\int_{-\infty}^{\infty} \mathrm{d}\xi\; \mathrm{d}\Omega \cos^2\varphi \sin^2\theta \frac{\varepsilon_+\varepsilon_- - \xi_+\xi_- - \Delta^2}{\varepsilon_+\varepsilon_-\,(\varepsilon_+ + \varepsilon_-)}. \end{aligned} \tag{16.72}$$

Since ξ of order Δ are important in the integral, we have put $p \approx p_0$ and passed from integration over p to integration over ξ, which may be extended to the interval $(-\infty, \infty)$. Without making further assumptions, we can take the integrals over φ and ξ. This leaves only the integral over $\mathrm{d}(\cos\theta)$. We introduce the notation $\cos\theta = t$. As a result, we have

$$Q(q) = \frac{n_e e^2}{mc}\left\{1 - \frac{3}{4}\int_{-1}^{1} \mathrm{d}t\,(1-t^2)\left[1 - \frac{4\Delta^2(0)}{\hbar q t v}\frac{\operatorname{arcsinh}[\hbar q t v/2\Delta(0)]}{[4\Delta^2(0) + (\hbar q t v)^2]^{1/2}}\right]\right\}$$
$$= \frac{3e^2 n_e \Delta(0)}{mc\hbar q v}\int_0^1 \frac{\mathrm{d}t}{t}\,(1-t^2)\,\frac{\operatorname{arcsinh}[\hbar q t v/2\Delta(0)]}{\{1 + [\hbar q t v/2\Delta(0)]^2\}^{1/2}} \tag{16.73}$$

The integral over t cannot be taken in explicit form in the general case. Therefore, we confine ourselves to the limiting formulas for large and small q.

The expression $Q(q)$ depends on the combination $q\hbar v/\Delta(0)$. The wave vector q characterizes the rapidity of the spatial variation of the current and field. The corresponding characteristic length is q^{-1}. In physical problems evidently $q^{-1} \sim \delta$ (the penetration depth). The quantity $\xi = \hbar v/\Delta(0)$ is the correlation length, as has been pointed out in the preceding section. Thus, the kernel Q depends on the ratio δ/ξ. A large value of this ratio corresponds to $q \to 0$. In this case we find from eq. (16.73)

$$Q = \frac{n_e e^2}{mc} \tag{16.74}$$

This formula corresponds to the London limit (see the preceding section and formula 15.43).

Conversely, large values of q corresponds to the Pippard limit $\delta/\xi < 1$. In the integral of (16.73) small values of t are important. Neglecting t^2 compared to unity and evaluating the integral, we obtain

$$Q(q) \approx \frac{3}{4}\pi^2 \frac{n_e e^2}{mc}\frac{\Delta(0)}{\hbar q} q^{-1} \tag{16.75}$$

This formula corresponds to the inefficiency concept. Indeed, assuming that $q^{-1} \sim \delta$, we see that formula (16.75) differs from (16.74) by the replacement of n_e by $n_e\delta/\xi$.

In coordinate space the relationship $\boldsymbol{j}(\boldsymbol{q}) = -\boldsymbol{Q}(\boldsymbol{q})\boldsymbol{A}(\boldsymbol{q})$ is expressed by formula (16.57). At $\xi > \delta$ the coupling is basically nonlocal because the field $A(r')$ varies rapidly at distances characteristic for the kernel $Q(r - r')$. Here, strictly speaking, the results we have obtained cannot be used because we have found Q for an infinite space, whereas in the problem of the penetration of the field the metal has a surface, i.e., let us say, it occupies a half-space $x > 0$. In such problems it is necessary to impose boundary conditions for electrons.

The condition of specular reflection from the boundary proves to be the simplest. In this case, just as for the anomalous skin effect, one may use the kernel Q for an infinite space, but then it is necessary to extend the vector potential in an even manner through the boundary (section 7.3). If the magnetic field is directed parallel to the surface of the metal along the z axis, then we may choose $A_y(x)$ along the y axis. On the strength of what has been said, $A_y(x) = A_y(-x)$.

According to the Maxwell equation

$$\operatorname{rot} H = \operatorname{rot}\operatorname{rot} A = \operatorname{grad}\operatorname{div} A - \nabla^2 A = \frac{4\pi}{c} j$$

The first term on the left-hand side is equal to zero, since $\operatorname{div}\boldsymbol{A} = 0$. The extension of the vector potential in an even manner through the boundary implies a kink in the $A_y(x)$ curve. Hence, if the field H_0 is given at the metal surface, i.e., $(\mathrm{d}A_y/\mathrm{d}x)_{x=+0} = H_0$, then $(\mathrm{d}A_y/\mathrm{d}x)_{x=-0} = -H_0$. But then the second derivative $\mathrm{d}^2A_y/\mathrm{d}x^2$ acquires a correction $2H_0\delta(x)$. Thus, we have

$$\frac{\mathrm{d}^2 A_y}{\mathrm{d}x^2} = 2H_0\delta(x) - \frac{4\pi}{c}j \tag{16.76}$$

Passing to Fourier components, substituting eq. (16.71) and solving the resultant equation, we find

$$A_q = -2H_0 \frac{1}{q^2 + \frac{4\pi}{c}Q(q)} \tag{16.77}$$

In the coordinate representation we have

$$A(x) = -\frac{2H_0}{\pi}\int_0^\infty \frac{\cos qx \ \mathrm{d}q}{q^2 + \frac{4\pi}{c}Q(q)} \tag{16.78}$$

(here it has been taken into account that Q depends on $|\boldsymbol{q}|$ alone). Differentiating with respect to H, we find the magnetic field*

$$H(x) = \frac{2H_0}{\pi}\int_0^\infty \frac{q\sin qx \ \mathrm{d}q}{q^2 + \frac{4\pi}{c}Q(q)} \tag{16.79}$$

We shall not analyze the behavior of the field in the general case; we only find the penetration depth, which we define as follows:

$$\delta = \frac{1}{H_0}\int_0^\infty H \ \mathrm{d}x = -\frac{A(0)}{H_0} = \frac{2}{\pi}\int_0^\infty \frac{\mathrm{d}q}{q^2 + \frac{4\pi}{c}Q(q)} \tag{16.80}$$

Let us assume that small q are important in the integral. In such a case, $Q(q)$ has the form (16.74) and we obtain from the integral the London penetration depth:

$$\delta_{\mathrm{L}} = \left(\frac{mc^2}{4\pi n_{\mathrm{e}} e^2}\right)^{1/2}. \tag{16.81a}$$

Note that in the integral $q \sim \delta^{-1}$ are important and, hence, our calculation is correct at $\delta > \hbar v/\Delta \sim \xi$.

In the opposite limiting case we substitute Q from eq. (16.75). Evaluating the integral, we find

$$\begin{aligned}\delta_{\mathrm{P}} &= 4\times 3^{-11/6}\pi^{-1}\left(\frac{mc^2}{n_{\mathrm{e}}e^2}\right)^{1/3}\left(\frac{\hbar v}{\Delta(0)}\right)^{1/3} \\ &= 2^{8/3}3^{-11/6}\pi^{-2/3}\delta_{\mathrm{L}}^{2/3}\left(\frac{\hbar v}{\Delta(0)}\right)^{1/3}\end{aligned} \tag{16.81b}$$

This formula corresponds to the estimate for the Pippard case (16.58) described in the previous section.

Upon passing to coordinate representation (16.57) in the general case it is essential that the kernel $Q(q)$ couples only the transverse components j and A (see eq. 16.71), i.e., strictly speaking, it is necessary to replace $Q(q)$ by $Q(q)\,(\delta_{ik} - q_i q_k/q^2)$. For the Pippard limit this leads to the following form for $Q_{ik}\,(r - r')$ in formula (16.57):

- In order to obtain H at the surface one cannot put $x = 0$ under the integral; instead, it is necessary to calculate it for small $x > 0$, after which x is made to tend towards zero.

$$Q_{ik}(r-r') = \frac{3}{4} n_e e^2 \frac{\Delta(0)}{hv} n_i n_k |r-r'|^{-2}, \tag{16.71'}$$

where

$$n = \frac{(r-r')}{|r-r'|}.$$

8.2.10 16.9. The relationship between current and field at finite temperatures. The London limit

We shall not examine the general case at finite temperatures because of its complexity. We only note the following points. When the temperature increases, the role of the correlation length in the kernel $Q(r-r')$ which couples the current to the field (16.57) gradually goes over from $\hbar v/\Delta(0)$ to $\hbar v/T$. Since $\Delta(0) \sim T_c$, at all
temperatures the correlation length is of order $\hbar v/T_c$. Use is commonly made of the standard correlation length equal to

$$\xi_0 = \frac{\hbar v}{\pi \Delta(0)} = \frac{\gamma}{\pi^2} \frac{\hbar v}{T_c} = 0.18 \frac{\hbar v}{T_c}. \tag{16.82}$$

In section 15.1 it has been pointed out that the penetration depth δ increases indefinitely as $T \to T_c$. This will also be obtained below. But it follows that even if $\delta(0) < \xi_0$ at $T = 0$, then $\delta(T)$ will sooner or later exceed ξ_0 with $T \to T_c$. Here the London situation occurs, i.e., the Fourier component of the kernel $Q(q)$ can be substituted by $Q(0)$. Hence the calculation of $Q(0)$ at a finite temperature enables one to establish the relationship between the current and the field at all temperatures for London superconductors, for which $\delta(0) > \xi_0$, and also at a temperature near T_c for Pippard superconductors, for which $\delta(0) < \xi_0$ (and, of course, for intermediate superconductors, for which $\delta(0) \sim \xi_0$).

We could have followed the previous path, i.e., we could have found $E\{A\}$ according to perturbation theory and calculated the current by varying with respect to $\boldsymbol{A}$. However, the result can be obtained more simply. At finite temperatures some of the Cooper pairs break down and quasiparticles appear. The latter interact with impurities and phonons and therefore make no contribution to the superconducting current. Hence, the effective number of electrons entering into formula (15.43) or formula (16.74), which coincides with (15.43), must begin to decrease, i.e., is replaced by a certain function $n_s(T)$, which had been known as the "number of superconducting electrons" before the appearance of the microscopic theory. The replacement of n_e by $n_s(T)$ in the London theory made it possible to account qualitatively for the temperature dependence of the penetration depth. We will define this quantity quantitatively.

Suppose that all the quasiparticles move with velocity $\boldsymbol{u}$. In this case, the argument of the distribution function will be $\varepsilon - pu$ rather than $\varepsilon(p)$. The motion of the quasiparticles will lead to the appearance of a momentum $\boldsymbol{P}$ given by

$$\begin{aligned} \boldsymbol{P} &= \int p\,(n_{p,+} + n_{p,-})\,\frac{\mathrm{d}^3 p}{(2\pi\hbar)^3} \\ &= 2\int p n_F(\varepsilon - pu)\frac{\mathrm{d}^3 p}{(2\pi\hbar)^3} \end{aligned}$$

(n_F is the Fermi function). Assuming u to be small and expanding in u, we obtain

$$P = -2\int p(pu)\frac{\partial n_F}{\partial \varepsilon}\frac{\mathrm{d}^3 p}{(2\pi\hbar)^3} \tag{16.83}$$

We transform the integral over $\mathrm{d}^3\boldsymbol{p}$ to an integral over $\mathrm{d}\xi$ and over the solid angle, as has been done in Part I. Here, however, one has to take into account that ε does not coincide with ξ, the energy of a normal metal. We have

$$2\int \frac{\mathrm{d}^3 p}{(2\pi\hbar)^3} \to \nu(\mu)\int \mathrm{d}\xi \frac{\mathrm{d}\Omega}{4\pi}.$$

Here we have taken account of the fact that the integral goes over the neighborhood of the Fermi surface. This also makes it possible to assume that $|p| = p_0$ in formula (16.83). Integrating over the solid angle, we obtain

$$\int p(pu)\frac{\mathrm{d}\Omega}{4\pi} \approx \frac{1}{3}p_0^2 u$$

Substituting $\varepsilon = (\xi^2 + \Delta^2)^{1/2}$ and introducing a new variable $\xi = \Delta \sinh\varphi$, we find (we have taken into account the rapid fall of the integral with increasing $|\xi|$ and replaced the limits of integration by $-\infty$ and ∞):

$$P = \frac{2}{3}p_0^2 u\nu(\mu)\frac{\Delta}{T}\int_0^\infty \frac{\cosh\varphi \mathrm{d}\varphi}{(\mathrm{e}^{\Delta\cosh\varphi/T}+1)\,(\mathrm{e}^{-\Delta\cosh\varphi/T}+1)}.$$

The proportionality factor between $\boldsymbol{P}$ and $\boldsymbol{mu}$ is called here the number of "normal electrons" n_n. Substituting $\nu(\mu) = p_0 m/\pi^2\hbar^3$ and taking into account that the total number of electrons is $n_\mathrm{e} = p_0^3/3\pi^2\hbar^3$, we obtain

$$\frac{n_\mathrm{n}}{n_\mathrm{e}} = 2\frac{\Delta}{T}\int_0^\infty \frac{\cosh\varphi \mathrm{d}\varphi}{(\mathrm{e}^{\Delta\cosh\varphi/T}+1)\,(\mathrm{e}^{-\Delta\cosh\varphi/T}+1)}. \tag{16.84}$$

If we make the same replacement of variables in formula (16.27), we get

$$\ln\frac{\Delta(0)}{\Delta(T)} = 2\int_0^\infty \frac{\mathrm{d}\varphi}{\mathrm{e}^{\Delta\cosh\varphi/T}+1}. \tag{16.85}$$

Differentiating with respect to temperature, we have

$$\Delta^{-1}\frac{\mathrm{d}\Delta}{\mathrm{d}T} = 2\int_0^\infty \frac{\cosh\varphi \mathrm{d}\varphi}{(\mathrm{e}^{\Delta\cosh\varphi/T}+1)\,(\mathrm{e}^{-\Delta\cosh\varphi/T}+1}\frac{\mathrm{d}}{\mathrm{d}T}\left(\frac{\Delta}{T}\right).$$

comparing with (16.84), we find

$$\frac{n_\mathrm{n}}{n_\mathrm{e}} = \frac{1}{T}\frac{\mathrm{d}\Delta}{\mathrm{d}T}\frac{1}{\frac{d}{\mathrm{d}T}\frac{\Delta}{T}}. \tag{16.86}$$

At $T = T_\mathrm{c}$ this quantity is equal to unity (which is seen from the fact that $\Delta \propto (T_\mathrm{c} - T)^{1/2}$), but with $T < T_\mathrm{c}$ it is less than unity. Hence, in contrast to a normal metal, the movement of quasiparticles alone does not correspond to the movement of the entire electron liquid. The remaining number of electrons is just the sought-for "number of superconducting electrons". Thus,

$$\frac{n_\mathrm{s}}{n_\mathrm{e}} = 1 - \frac{n_\mathrm{n}}{n_\mathrm{e}} = -\left[\frac{\mathrm{d}\ln(\Delta/T)}{\mathrm{d}\ln T}\right]^{-1}. \tag{16.87}$$

It is exactly this number that appears in the kernel $Q(T)$ instead of n_e.
Thus, in the London situation at $T \neq 0$ we have

$$Q = \frac{n_\mathrm{s}e^2}{mc}. \tag{16.88}$$

The same result is obtained by way of more lengthy calculations analogous to those in the preceding section. From eq. (16.88) it follows that the penetration depth is expressed, instead of (15.40), by the formula

$$\delta = \left(\frac{mc^2}{4\pi n_s e^2}\right)^{1/2} \tag{16.89}$$

Let us consider the limiting cases. At $T < T_c$ we obtain with the aid of formula (16.30)

$$\frac{n_s}{n_e} \approx 1 - \left(\frac{2\pi\Delta(0)}{T}\right)^{1/2} e^{-\Delta(0)/T}, \tag{16.90}$$

$$\delta_L(T) \approx \delta_L(0)\left[1 + \left(\frac{\pi\Delta(0)}{2T}\right)^{1/2} e^{-\Delta(0)/T}\right]. \tag{16.91}$$

At $T_c - T \ll T_c$ we find from eq. (16.33) that

$$\frac{n_s}{n_e} \approx \frac{T_c - T}{T_c} \tag{16.92}$$

$$\delta_L(T) \approx \delta_L(0)\left(\frac{T_c}{2(T_c - T)}\right)^{1/2}. \tag{16.93}$$

In concluding this section we note the following. In the limit $T \to T_c$ all superconductors become London superconductors and their penetration depth is described by the formulas derived above; but in a case where $\delta_L(0) < \xi_0$ at $T = 0$, the transition to the London limit occurs only in the immediate vicinity of T_c. For such superconductors, the Pippard situation exists practically over the entire temperature range; in particular, it also persists at $T_c - T < T_c$; for example, for aluminum the London Limit occurs only at $1 - T/T_c \sim 10^{-3}$. The complete derivation for the Pippard case, which is not given here, yields a result qualitatively similar to formula (16.81) for $T = 0$ with $\delta_L(0)$ replaced by $\delta_L(T)$. Hence, $\delta_P(T) \sim \delta_P(0)\,(1 - T/T_0)^{1/3}$ as $T \to T_c$. The complete formula has the form

$$\delta_P(T) = \delta_P(0)\left[\frac{\Delta}{\Delta(0)}\tanh\left(\frac{\Delta}{2T}\right)\right]^{-1/3}. \tag{16.94}$$

8.2.11 16.10. The superconducting correlation and surface energy. Two types of superconductors. The role of impurities

The concept of correlation length introduced in the preceding sections explains the surface energy at the interface between the normal and the superconducting phase, which was proposed by L.D. Landau in his theory of the intermediate state (section 15.3). Imagine a planar interface between the normal and superconducting phases,
which is formed in the intermediate state. Let us show how Δ and the magnetic field vary in the vicinity of the interface (fig. 105)*. The superconducting correlation does not allow Δ to vary discontinuously, because the states of electrons are correlated at a distance of order $\xi(T) = \hbar v/\Delta(T)$. It should be noted that the detailed theory yields somewhat different correlation lengths for different quantities. In section 16.8 it has already been said that in electrodynamics this is ξ_0(16.82), i.e., a temperature-independent quantity. The characteristic length over which Δ varies is $\xi(T) = \hbar v/\Delta(T)$. The difference manifests itself near T_c, where $\xi(T) \to \infty$.

Thus, in the region of contact between the normal and superconducting phases Δ varies as shown in fig. 105. On the other hand, the equilibrium between the normal and superconducting

phases can occur only if there is a magnetic field equal to H_c in the normal phase. The field is damped in the superconducting phase at a distance δ. Figure 105 shows the Pippard situation corresponding to $\xi \gg \delta$.

For the convenience of reasoning we replace the true picture by a rougher one with sharp boundaries along H (the line A) and along Δ (the line B) drawn so that the total free energy and the average field are the same as before. In such a case, there arises a region AB of order ξ, in which, on the one hand, $\Delta = 0$, corresponding to the normal phase, and, on the other hand, there is no magnetic field. Taking into account that $F_n - F_s = H_c^2/8\pi$, we obtain an excess energy equal to $H_c^2/8\pi$ per cm^3 of the region AB . But we are interested in the excess energy per cm^2 of the interface area. This is equal to $(H_c^2/8\pi) \cdot \mathrm{AB}$, i.e.,

$$\sigma_{ns} \sim \xi \frac{H_c^2}{8\pi}$$

(it is this parameter, ξ, that we introduced in section 15.3 instead of σ_{ns}).
As has been pointed out, the derivation described, just as fig. 105, refers to the Pippard case $\xi > \delta$. But if, conversely, $\delta \gg \xi$, then we find in the same way that at the interface there appears a negative surface energy of order $-\delta H_c^2/8\pi$. Naturally, this also occurs at $\xi = 0$, i.e., in the London theory. The impossibility of explaining the origin of the positive surface energy within the framework of the London theory has long been thought to be one of its main shortcomings.

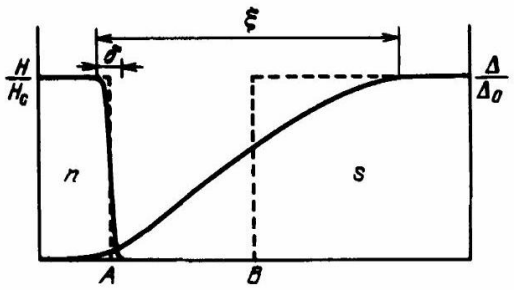

Fig. 105.

It has turned out that there really exist superconductors with a negative surface energy. Such superconductors exhibit an extremely unusual behavior in a magnetic field, which will be described in detail in ch. 18 . The existence of such superconductors was first predicted by Abrikosov and Zavaritsky (Abrikosov 1952; Zavaritsky 1952) on the basis of the analysis of experimental data on the critical fields of thin superconducting films prepared by different methods. They were called superconductors of the second group. At present they are known as type II superconductors. Accordingly, ordinary superconductors with $\sigma_{ns} > 0$ are called type I superconductors.

Since the sign of the surface energy depends on the ratio of the penetration depth δ and the correlation length ξ, it is natural to classify superconductors according to the value of the ratio δ/ξ. Especially attractive is the circumstance that with $T \to T_c$ this ratio tends to a constant, because both $\delta(T)$ and $\xi(T)$ depend on temperature by the law $(T_c - T)^{-1/2}$. The precise boundary between type I and type II superconductors is determined by the condition $x = \frac{1}{2}\sqrt{2}$, where, with $T \to T_c$, according to Gor'kov (1959) (see the derivation in ch. 17)

$$\varkappa(T_c) = \left(\frac{24}{7\zeta(3)}\right)^{1/2} \frac{\gamma}{\pi} \frac{\delta_L(0)}{\xi_0} = 0.96 \frac{\delta_L(0)}{\xi_0}. \qquad (16.95)$$

*The reasoning given below stems from Pippard (1955).

The quantity x was first introduced in the Ginzburg-Landau theory (ch. 17) and has come to be known as the Ginzburg-Landau parameter. Thus, in the vicinity of T_c we have

$$\begin{array}{ll} x < \frac{1}{\sqrt{2}}, & \sigma_{ns} > 0, \quad \text{type I}, \\ x > \frac{1}{\sqrt{2}}, & \sigma_{ns} < 0, \quad \text{type II}. \end{array} \tag{16.96}$$

This condition may also be extended to temperature far from T_c. To do this, the quantity x must be considered to be temperature-dependent, i.e.,

$$\varkappa(T) = \varkappa(T_c)\, A(T). \tag{16.97}$$

Calculations show that the function $A(T)$ varies little with temperature. This dependence is shown in fig. 106 (Gor'kov 1959).

Among pure metals presumably no type II superconductors are encountered. However, there is a method by means of which any type I superconductor can be converted to a type II superconductor. To this end, one has to introduce impurities.

The scattering from impurities first of all reduces the superconducting correlation*. Indeed, imagine an electron moving in the field of impurities. It performs a diffusive motion with a mean free path l and a velocity v; its mean displacement will be of order (section 3.5):

$$x \sim (Dt)^{1/2},$$

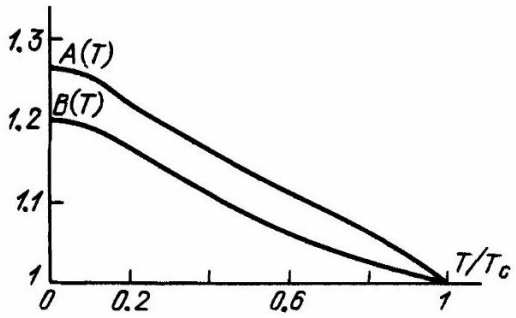

Fig. 106.

where D is the diffusion coefficient, which is of order $D \sim lv$. But its total path length is $t \cdot v$. If we take $tv \sim \xi$, then

$$x \sim \xi' \sim \left(lv \cdot \frac{\xi}{v}\right)^{1/2} \sim (\xi l)^{1/2}. \tag{16.98}$$

In other words, the effective correlation length decreases and becomes equal to ξ'. Of course, all these reasonings are valid as long as $\xi > l$. In case $l > \xi$, scattering on impurities practically has no effect on the superconducting correlation.

The incorporation of impurities alters the penetration depth too. In a case where $l < \xi$, one can estimate the modified quantity δ' rather simply. The presence of a finite mean free path leads to the appearance in the kernel $Q(r - r')$ of a damping at distance l, which can be taken into account by introducing a factor $f(r - r') = \exp(-|r - r'|/l)$. The Fourier

* The estimate given below refers to temperatures far from T_c.

component of the product of the functions $Q_0(r)f(r)$ is equal, as can be easily seen, to $\int Q_0(q-q_1)\,f(q_1)\,\mathrm{d}^3q_1(2\pi)^3$ (Q_0 refers to a pure metal). In our case, the characteristic length for $f(r)$ is l and, hence, for its Fourier component the characteristic values of $q_1 \sim l^{-1}$. The scale of the kernel $Q_0(q-q_1)$ is ξ^{-1}. If $l > \xi$, then $q_1\xi \sim \xi/l > 1$, i.e., the argument for Q_0 is large and one has to make use of the Pippard limit (16.75).

In subsequent calculations $q \sim \delta^{-1}$ are important. If $\delta/l < 1$, then $q > q_1$. In such a case

$$\int Q_0(q-q_1)\,f(q_1)\,\frac{\mathrm{d}^3q_1}{(2\pi)^3} = Q_0(q)\int f(q_1)\,\frac{\mathrm{d}^3q_1}{(2\pi)^3}$$

The last integral is $f(r)$ at $r=0$, i.e., unity. Thus, formula (16.75) is reproduced. But if $\delta/l > 1$, then $q < q_1$. In this case,

$$\int Q_0(q-q_1)\,f(q_1)\,\frac{\mathrm{d}^3q_1}{(2\pi)^3} \approx \int Q_0(q_1)\,f(q_1)\,\frac{\mathrm{d}^3q_1}{(2\pi)^3} \sim \frac{n_\mathrm{e}e^2}{mc}\,\frac{l}{\xi}$$

(here we have substituted expression (16.75) for Q_0). Since the resultant kernel is independent of q, we have the London situation. The penetration depth is $\delta = (4\pi Q/c)^{-1/2}$. Thus, we find

$$\delta' \sim \delta_\mathrm{L}\left(\frac{\xi}{l}\right)^{1/2} \tag{16.99}$$

Hence, in the presence of impurities

$$x \sim \frac{\delta'}{\xi'} \sim \frac{\delta_\mathrm{L}}{l}.$$

The values given by the exact theory at $l < \xi$ are* (Abrikosov and Gor'kov 1958, Gor'kov 1959, Helfand and Werthamer 1966):

$$\delta(T) = \left[\frac{mc^2\hbar}{4\pi n_\mathrm{e}e^2\tau_\mathrm{tr}\Delta\tanh(\Delta/2T)}\right]^{1/2}, \tag{16.100}$$

$$\tau_\mathrm{tr}^{-1} = \int W(\theta)(1-\cos\theta)\frac{\mathrm{d}\Omega}{4\pi},$$

$$x(T) = x(T_\mathrm{c})\,\mathrm{B}(T), \quad l = v\tau_\mathrm{tr},$$

$$x(T_\mathrm{c}) = [42\zeta(3)]^{1/2}\pi^{-2}\frac{\delta_\mathrm{L}(0)}{l} = 0.72\frac{\delta_\mathrm{L}(0)}{l}. \tag{16.101}$$

The plot of the function $B(T)$ is given in fig. 106. This value of $\varkappa$ must be substituted into the criterion (16.97). In the intermediate cases of $\xi \sim l$ one may use the interpolation

$$\varkappa(T) \approx \delta_\mathrm{L}(0)\left(0.96\frac{A(T)}{\xi_0} + 0.72\frac{B(T)}{l}\right). \tag{16.102}$$

At $\xi_0^{-1}l \gg 1$ this expression becomes equivalent to eqs. (16.97) and (16.95) and at $\xi_0^{-1}l \ll 1$ it transforms to eq. (16.101).

From what has been said above one may conclude that by reducing the mean free path, i.e., by increasing the impurity concentration (since $l \propto n_\mathrm{i}^{-1}$, section 4.1), one can increase x and convert any type I superconductor to a type II superconductor.

The following question may, however, arise: How do the impurities affect Δ, T_c and other thermodynamic characteristics of the superconductor? Investigations of this topic (Abrikosov and Gor'kov 1958, 1959, Anderson 1963) show that the variation of all these quantities is of order a/l, where a is the atomic dimension. Taking into account that $l \sim (n_i a^2)^{-1} \sim (c_i n a^2)^{-1} \sim a/c_i$, we find (section 4.1) that

the corrections to the thermodynamic quantities are of a relative order c_i, the atomic concentration of impurities. Hence, as long as $c_i < 1$ these corrections are small, in contrast to the correction to δ, which has a relative order of $\delta/l \sim 10^2 - 10^3 c_i$. The smallness of the corrections to thermodynamic quantities is a consequence of the fact that they are governed by the local properties of the superconductor, i.e., the properties at a given point, and are not associated with the motion of electrons from one point to another. Evidently, any damping of the type of $\exp(-|r - r'|/l)$ with $\boldsymbol{r} \to \boldsymbol{r}'$ becomes inefficient. As for the local properties, they are determined by the density of states, which will vary only by an amount of order c_i*.

Of course, if $c_i \sim 1$, all the quantities may vary strongly, but in this case we are dealing with a different substance.

The superconducting correlation helps us to understand one more result. In section 16.6 we have calculated the heat capacity, and it has been found to exhibit a discontinuity at T_c but with no singularities. This behavior of the heat capacity is associated with the neglect of fluctuations (Appendix II). However, in this particular case there is every ground to expect that the fluctuational region corresponds to an extrememly small neighborhood of T_c. In Appendix II it is shown that the size of this region is determined by the ratio of the mean separation between the particles and the correlation length far from T_c. In the case under discussion this ratio is of order

$$\frac{\hbar/p_0}{\hbar v/T_c} \sim \frac{T_c}{p_0 v} \sim \frac{T_c}{\mu} \sim 10^{-4},$$

that is, it is very small. The exact size of the fluctuational region will be found in section 17.1.

8.2.12 16.11. High-temperature superconductivity

As has been said in section 15.1, the highest critical temperature attained to date is 93−95 K for the compound $YBa_2Cu_30_{7-\delta}$. However, this composition is at present not satisfactory in its mechanical properties. Technological superconducting alloys are Nb_3Sn ($T_c = 17 - 18$ K) and $Nb - Zr - Ti$ ($T_c = 9 - 11$ K). In order to maintain such low temperatures, one has to employ special cryostats with liquid helium (boiling point at atmospheric pressure 4.2 K). Nevertheless, as will be seen in what follows, superconductivity has already found practical applications in spite of the difficulties

associated with cooling, since some properties that are important in practice are exhibited

---

• Here $W(\theta)$ is the probability of scattering of an electron from an impurity introduced in section 3.2 and τ_{tr} is the corresponding collision time (in section 3.2 it is denoted as τ; we use here the symbol adopted in the literature on superconductivity, τ_{tr}).

*The reasoning given is valid for the isotropic model. For an anisotropic superconductor the situation is different. In this case, the scattering of electrons from an impurity mixes the components of the wave function of a Cooper pair corresponding to different values of the momentum, i.e., different Δ. This leads to a decrease in the binding energy of the pair and to a change of all thermodynamic quantities. The exact theory (Hohenberg 1963) shows that the relative corrections are of order $\left[(\Delta(n) - \bar{\Delta})^2/\bar{\Delta}^2\right] \xi_0/l$. Since the anisotropy in real superconductors is small, $(\Delta(n) - \bar{\Delta})^2/\bar{\Delta}^2 \leqslant 10^{-2}$, these corrections, in fact, differ little from the corrections for an isotropic superconductor, which are of order c_i.

only by superconductors.

It is not difficult to visualize the technical revolution that could be brought about by substances exhibiting superconductivity at room temperatures. In the first place, this would include the possibility of producing lines transmitting electrical power over any distance without loss. It would be possible to solve the problem of energy storage in small volumes and, hence, to use electric motors for all transport facilities that run on petroleum products. Many other perspectives could also be visualized.

This is why at present many laboratories in several countries are concerned with the study of high-temperature ceramics. On the one hand, it is necessary to define the limiting critical temperature and to develop standard technology for preparing the substances required. On the other hand, a construction method for superconducting equipment must be designed, which could be of practical use. The possibility is not excluded that the latter will be a formidable task for ceramics and the search for high-temperature superconductors will be continued. Moreover, the mechanism of superconductivity in ceramics has not been definitely established. Therefore, we shall present here some ideas concerning high-temperature superconductivity [detailed information on this topic can be found in the book edited by Ginzburg and Kirzhnits (1977)].

We begin with a more detailed discussion of the familiar interaction between electrons: Coulomb repulsion and phonon attraction. Then we shall consider "quasiphonon" mechanisms for the interaction of electrons and, finally, turn to nonphonon or so-called "exciton" mechanisms for the interaction. At the end of the section we shall discuss the possibility of producing high critical magnetic fields.

The formula for the critical temperature was derived in the BCS theory (16.25). It took into account only electron-phonon interaction in its simplified form. A more detailed formula was found by McMillan (1968), who carried out a more accurate examination of the electron-phonon interaction and took account of Coulomb repulsion; the formula has the form

$$T_{\mathrm{c}} = \frac{\hbar\omega_{\mathrm{D}}}{1.45} \exp\left[-\frac{1.04(1+\lambda)}{\lambda - \mu^*(1+0.62\lambda)}\right], \tag{16.103}$$

where λ characterizes the electron-phonon interaction (λ corresponds to $\frac{1}{2}g\nu$ in the simplified theory) and μ^* characterizes the electron-electron repulsion. Since the Coulomb interaction is screened at interatomic distances, it may be treated as a point interaction and described by a constant μ. The quantity μ^* is connected with this constant by the relation*

$$\mu^* = \frac{\mu}{1 + \mu \ln(\varepsilon_{\mathrm{F}}/\hbar\omega_{\mathrm{D}})} \tag{16.104}$$

The large logarithm in the denominator results from the different action times of the Coulomb repulsion ($t_{\mathrm{c}} \sim \hbar/\varepsilon_{\mathrm{F}}$) and phonon attraction ($t_{\mathrm{ph}} \sim \omega_{\mathrm{D}}^{-1}$); $t_{\mathrm{c}}/t_{\mathrm{ph}} \sim \hbar\omega_{\mathrm{D}}/\varepsilon_{\mathrm{F}} < 1$. For $\lambda < 1$ and $\mu^* = 0$ formula (16.103) takes a form similar to eq. (16.25).

Since λ and μ^* appear in the exponent, it is clear that these constants are of prime interest. The Coulomb interaction constant μ is formally of the order of unity. However, μ^*, which enters into T_{c} according to (16.104), is weakened by the large logarithm. Estimates give $\mu^* \sim 0.1-0.2$. As for the constant λ, it is also formally of the order of unity. But it must be taken into account that electron-phonon interaction eventually occurs as a result of the interaction of electrons with ions, which is described by a small pseudopotential. Therefore, λ usually does not reach unity. On the whole, the difference $\lambda - \mu^*(1+0.62\lambda)$ appearing in (16.103) may have any sign, but

---

- We use the symbol μ for the dimensionless Coulomb interaction constant ($\mu \sim e^2/\hbar v$) since it is generally accepted in the literature. It should not be confused with the chemical potential, which is denoted here as ε_{F}.

substances for which this difference is close to zero are rare. At relatively small λ the substance is not a superconductor* and at relatively large λ the term with μ^* may be neglected.

It is therefore reasonable to concentrate our attention on the constant λ. This constant determines not only the critical temperature but also the magnitude of the electrical resistance that appears as a result of the scattering of electrons as phonons. Since at room temperature this mechanism dominates over others, a paradoxical consequence arises: poor conductors (at room temperature) are good superconductors (i.e., they have a high T_c). Examples illustrating this are Pb : $\rho\,(18^\circ\mathrm{C}) = 20.8\times10^{-6}\mathrm{ohm\cdot cm}, T_c = 7.2$ K, and Al: $\rho\,(18^\circ\mathrm{C}) = 3.2\times10^{-6}\mathrm{ohm\cdot cm}, T_c =$ 1.2 K. The superconducting ceramics that have lately been found are extremely bad conductors ($\rho \sim 10^{-3}\mathrm{ohm\cdot cm}$ at room temperature). If in formula (16.103) we assume that $\mu^* = 0$, then T_c will increase monotonically with increasing λ. Actually this formula does not apply when $\lambda > 1$. It has been shown (Allen and Mitrovic 1982) that

$$T_c \approx 0.18\hbar \left(\overline{\omega^2}\right)^{1/2} \lambda^{1/2},$$

i.e. grows monotonically with λ. However in reality the value of λ never exceeds unity by order of magnitude. The idea has been proposed that λ can increase strongly if the lattice is close to a structural transition. Such a transition is usually preceded by the formation of a "soft mode", i.e., by a pronounced decrease of $\omega(k)$ at a certain $\boldsymbol{k}$. Such a decrease could imply an increase in the action time of phonon attraction and this was the basis for speculations on the subject. However, it should be taken into account that a soft mode at a particular $\boldsymbol{k}$ has a very small statistical weight (the integral includes $k^2\,\mathrm{d}k$) and therefore it cannot play an essential role.

A special situation could take place for the "nesting" type of transitions in which, due to the change of the lattice period and the formation of a new Brillouin zone, some parts of the Fermi surface would be almost entirely superposed on each other. In the vicinity of such a transition an increase of the state density $\nu(\mu)$ would take place, i.e., an increase of λ in eq. (16.103) [more details can be found in the book edited by Ginzburg and Kirzhnits (1977)]. Such transitions are known to exist in nature, but their relation to superconductivity has not yet been established.

Apart from the increase of λ, one may think also of the increase of $\hbar\omega_D$. Considering that $\hbar\omega_D \sim sp_0 \sim \varepsilon_F(m/M)^{1/2}$, where M is the mass of the ion, an attempt must be made to reduce this mass. A unique possibility in this respect could be provided by solid hydrogen if it were a metal. Unfortunately, under ordinary conditions solid hydrogen is a dielectric crystal consisting of H_2 molecules. Theoretical calculations show that with increased pressure a phase transition must occur from molecular hydrogen to the atomic phase, which is analogous to alkali metals. The pressure of the transition is very high, of the order of 2.5 Mbar .

Of course, such a pressure is difficult to reach and to maintain and it is of no practical value. There exists, however, a possibility that, because of the large difference in specific volume between the molecular and the atomic phase, the latter can be preserved as a metastable phase even when the pressure is removed (an example is diamond, which is the metastable phase of carbon under ordinary conditions). Also, various methods have been proposed for producing

---

- Actually, the situation is in all probability more complicated. The interaction forces between electrons at large distances presumably always correspond to attraction. This may give rise to Cooper pairs with a nonzero orbital moment (if we deal with the isotropic model of course; in the anisotropic case there is no conserved orbital momentum, but there is another analogous classification of states, so that the qualitative conclusions do not change). The binding energy of such pairs is small, so that T_c will also be low. Nevertheless, this reasoning leads one to the conclusion that at sufficiently low temperatures any pure metal will become superconducting.

metallic hydrogen directly from the gas phase without applying high pressures (adsorption on carbon, condensation in a strong magnetic field, etc.). However, the question of the existence of a metastable metallic phase and the possibility of its prepration in the absence of pressure has not yet been clarified.

The difficulty in calculations for solid hydrogen lies in the fact that, in contrast to all other elements, its ions have no electron shells and are simply protons. Because of this, for hydrogen the pseudopotential coincides with the real coulomb potential and is not small (section 14.2). Usually, calculations for metallic hydrogen are based on the strongly compressed matter approximation (section 14.4). However, the resultant series do not converge rapidly enough, so that it is difficult to choose the energetically most favorable structure and to solve the problem of the possibility of the metastable state. At the same time the strong electron-ion interaction implies also a strong electron-phonon interaction, which may bring about a certain increase in λ in formula (16.103). Preliminary calculations show that $T_c \sim 100 - 200$ K (Schneider 1969).

It has also been suggested that the difficulties associated with the preparation of metallic hydrogen can be overcome by producing the hydrides, i.e., compounds of metals with hydrogen. In the phonon energy spectrum of such compounds branches may appear that correspond mainly to the vibrations of protons and exhibit high frequencies. However, the hydrides are dielectrics. Therefore, attempts have been made to take advantage of the good solubility of hydrogen in some metals, especially in platinum. Since the natural solubility is still insufficient, special methods have been applied to produce metastable solid solutions with an increased hydrogen concentration. Although these compounds were superconductors, however their T_{c} was below 10 K . It is possible that the interaction of electrons with the high-frequency vibrations of protons is weak for some reasons.

There is one more theoretical possibility, which in fact, makes use of the same advantages exhibited by metallic hydrogen (Abrikosov 1978). It concerns the production of a substance that might be called "metallic excitonium". Imagine an even metal containing equal numbers of electrons and holes. If the mass of the holes is much larger than the mass of electrons due to the specific nature of the energy spectrum*, their potential energy will then exceed their kinetic energy. As a result, the holes will become classical objects and will form a periodic superstructure, i.e., a "lattice in the lattice" (Herring 1968, see Halperin and Rice 1968). The periods of such a superstructure are determined by the density of electrons and holes and must not necessarily coincide with the periods of the main lattice. For the hole lattice to be stable, it is necessary that the amplitude of the zero-point vibrations of the holes be much less than (not more than $\frac{1}{5}$) the lattice period, which leads to the requirement $m_{\mathrm{h}}^*/m_{\mathrm{e}}^* > 50$. If, besides, m_{e} is less than the mass of a free electron m, then the ratio m_{h}^*/m must not be very large.

As a result, a "substance" is produced, which resembles metallic hydrogen, but with the protons being replaced by heavy holes [Abrikosov (1978) proposed the term "metallic excitonium" for this substance]. In such a substance "phonons" can propagate. Their velocity will be determined by the mass of holes, which may be of the order of $10 - 20$ m at best, i.e., 100 times less than the mass of the proton. With a not-too-small density of electrons and holes this may lead to $\hbar\omega_D$ in formula (16.103) being 10 times larger than in the case of hydrogen.

At present no such substances are known to exist and, of course, we still do not know whether they can be produced. They should most likely be sought for among compounds containing transition metals (and also metals similar to them, such as $\mathrm{Cu}, \mathrm{Ag}, \mathrm{Au}$) or rare-earth elements for the valence band to be formed from the weakly overlapping d - or f -shells of the atoms. In this case, the formation of heavy holes is possible. The search for such compounds is not a simple matter. However, on the other hand, there is no need for high pressures and the problem of the stability of the metastable metallic phase does not arise, as is the case with metallic hydrogen.

We have so far been concerned with the mechanism of electron attraction accomplished by

phonons (or by similar hole lattice vibrations in the hypothetical "metallic excitonium"). There naturally arises the question of the possibility of a different attraction mechanism. Since the direct interaction of electrons is a repulsion, we are to seek in metals a "transmitting system" different from the phonon system.

The general scheme of the interaction of electrons via the transmitting system A may be outlined as follows:

$$e_1 + A \to e_1' + A^*, \quad e_2 + A^* \to e_2' + A, \tag{16.105}$$

where e_i corresponds to an electron of momentum p_i; A is the ground state; A^* is the excited state of the transmitting system. As a result of this double "reaction" the system A reverts to the initial state and the momenta of electrons e_1 and e_2 undergo a change, i.e., they are scattered from each other. It can easily be shown that such an interaction is necessarily an attraction and if it is not too strong, we have

$$T_c \sim \Delta E \exp\left(-\frac{1}{\lambda}\right) \tag{16.106}$$

where ΔE is the energy difference between the states A and A^* and λ depends on the interaction of electrons with the system A. As a matter of fact, phonon attraction occurs according to an analogous scheme.

Let us examine some variants. The role of the transmitting system A could be played by a system of spins in a magnetic metal. The excitation of this system is described by a gas of quasiparticles called magnons or spin waves. Since ferromagnetism is antagonistic to superconductivity (see section 21.2 for more detail), we may speak here of antiferromagnetic metals. However, estimates of the quantities ΔE and λ, which determine T_c, provide no advantages in this case compared to phonons.

A mechanism of a rather similar type is an exchange of "virtual paramagnons". If the substance is close to the magneto-ordered state (ferro- or antiferromagnetic), there can exist strong fluctuations corresponding to the magnetic phase and they produce a strong interaction between quasiparticles. Such virtual paramagnons are involved in explaining the unusual properties of almost ferromagnetic metals (which have been mentioned in ch. 13) and the formation of Cooper pairs in superfluid He^3; they are also proposed as a possible explanation of the high-temperature superconductivity in ceramics (Anderson 1987, Fukuyama and Yoshida 1987) and of the unusual superconductivity in metals with "heavy fermions" (see pp. 378-379).

Another transmitting system could be electrons that are separated in some way from conduction electrons (i.e., their states are not mixed). The excitations of such electron systems are called "excitons" and therefore this fundamentally possible mechanism of superconductivity is called the "exciton" mechanism (Little 1964; Ginzburg 1964, 1968, 1970, 1976).

In particular, the electrons of the inner shells of atoms that are retained in the lattice ions of metals could be such an isolated system. The excitation energy ΔE is here of the order of 10 eV , i.e., 10^5 K. If this mechanism were efficient, all metals would be high-temperature superconductors. This is not the case in reality because of the weak interaction of the conduction electron with the inner-shell electrons and, accordingly, the smallness of λ in (16.105).

Let us consider the matrix element corresponding to the first of the processes (16.105). It is given by

$$M_{12} = \int \psi_{A^*}^* (r_1)\, \psi_A (r_1)\, V (|r_1 - r_2|)\, \mathrm{e}^{-\mathrm{i}(p'-p)r_2/\hbar} \times u_{p'}^* (r_2)\, u_p (r_2)\, \mathrm{d}V_1\, \mathrm{d}V_2$$

*This may occur if holes appear in a narrow band generated from the d- or f-levels of the atoms, whereas the electrons come from the s- or p-states of the atoms.

where $V(r)$ is the interaction; the functions ψ_A and ψ_A^* are the wave functions of one of the ionic electrons; the conduction electron is described here by the Bloch function $e^{ipr/\hbar}u_p(r)$. The essential values of r_2 in the integral over r_2 are $r_2 \sim a$, where a is the interatomic separation. The order of magnitude of the quantity r_1 is determined by the ionic radius r_i, which is appreciably smaller than a. Hence, we can expand $V(|r_1 - r_2|)$ in r_1/r_2, i.e.,

$$V(|r_1 - r_2|) \approx V(r_2) - \frac{r_1 r_2}{r_2} V'(r_2).$$

Since the functions ψ_A and ψ_A^* are orthogonal, the zeroth expansion term $V(r_2)$ gives no contribution and the matrix element M_{12} may be expected not to be larger than r_i/a in order of magnitude. Such smallness also results from the second process in (16.105). Hence, the effective electron interaction constant g will contain $(r_i/a)^2$, and this smallness will be included in λ (because $\lambda = \frac{1}{2}g\nu(\mu)$). It may be said that the ionic shells exhibit low polarizability.

Thus, an attempt must be made to find a transmitting system of electrons with high polarizability. Little was the first (Little 1964) to suggest the use of long polymeric organic molecules with so-called alternating bonds of carbon atoms, which behave as if they were one-dimensional metals. If the structure of the molecule includes strongly polarizable side atomic groups (fig. 107), these groups could serve as the transmitting system $\boldsymbol{A}$. In fact, apart from the technical infeasibility of manufacturing such conductors from unruptured polymeric molecules, a fundamental objection arises against this idea. The point is that a purely one-dimensional superconductor cannot exist because fluctuations of the order-parameter phase destroy the long-range order at any finite temperature (Rice 1965)*.

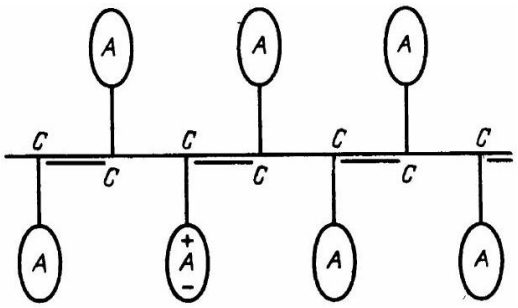

Fig. 107.

where $V(r)$ is the interaction; the functions ψ_A and ψ_A^* are the wave functions of one of the ionic electrons; the conduction electron is described here by the Bloch function $e^{ipr/\hbar}u_p(r)$. The essential values of r_2 in the integral over r_2 are $r_2 \sim a$, where a is the interatomic separation. The order of magnitude of the quantity r_1 is determined by the ionic radius r_i, which is appreciably

* What is really calculated is the correlation function $Z(x_1 - x_2) = \langle \Psi(x_1)\Psi(x_2)\rangle$, where Ψ is the Ginzburg-Landau order parameter which is proportional to Δ (ch. 17), and the average value is used with thermodynamic fluctuations taken into account. As a result, it is found that $Z \propto \exp\left(-|x_1 - x_2| mT/\Psi_0^2 h^2\right)$ with $|x_1 - x_2| \to \infty$. Here Ψ_0 is the equilibrium value of Ψ (in the one-dimensional problem Ψ_0^2 is normalized to the number of electrons per cm of length). Hence, $Z \to 0$ with $|x_1 - x_2| \to \infty$; this is an indication of the absence of long-range order at a finite temperature. In the presence of long-range order Ψ is coherent over the entire space and, hence, Z has a finite limit with $|x_1 - x_2| \to \infty$. The destruction of long-range order occurs because of the fluctuations in the phase of the complex function $\Psi = |\Psi|e^{i\varphi}$.

smaller than a. Hence, we can expand $V(|r_1 - r_2|)$ in r_1/r_2, i.e.,

$$V(|r_1 - r_2|) \approx V(r_2) - \frac{r_1 r_2}{r_2} V'(r_2).$$

Since the functions ψ_A and ψ_A^* are orthogonal, the zeroth expansion term $V(r_2)$ gives no contribution and the matrix element M_{12} may be expected not to be larger than r_i/a in order of magnitude. Such smallness also results from the second process in (16.105). Hence, the effective electron interaction constant g will contain $(r_\text{i}/a)^2$, and this smallness will be included in λ (because $\lambda = \frac{1}{2} g\nu(\mu)$). It may be said that the ionic shells exhibit low polarizability.

Thus, an attempt must be made to find a transmitting system of electrons with high polarizability. Little was the first (Little 1964) to suggest the use of long polymeric organic molecules with so-called alternating bonds of carbon atoms, which behave as if they were one-dimensional metals. If the structure of the molecule includes strongly polarizable side atomic groups (fig. 107), these groups could serve as the transmitting system A. In fact, apart from the technical infeasibility of manufacturing such conductors from unruptured polymeric molecules, a fundamental objection arises against this idea. The point is that a purely one-dimensional superconductor cannot exist because fluctuations of the order-parameter phase destroy the long-range order at any finite temperature (Rice 1965)*.

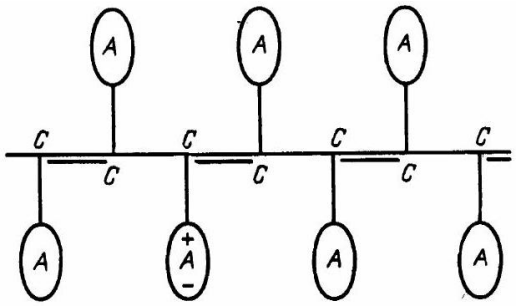

Fig. 107.

In order to overcome this difficulty, numerous "quasi-one-dimensional" compounds have been synthesized. These are mostly molecular crystals, which may be identified in the sense of conducting properties with bundles of weakly bound conducting filaments. The conductivity along the filaments is high, but the probability of an electron to be transferred from filament to filament is low, and therefore the conductivity anisotropy $\sigma_\parallel/\sigma_\perp$ may reach a few thousands. Apart from molecular crystals, polymers (for example, $(\text{SN})_x$ and $(\text{CH})_x$, where x stands for the multiple repetition of the group) have also been studied. Some of these compounds have been found to exhibit superconductivity, but with $T_c \leqslant 8$ K; the corresponding crystals were presumably more "three-dimensional" and the superconductivity mechanism was the ordinary phonon mechanism.

- What is really calculated is the correlation function $Z(x_1 - x_2) = \langle \Psi(x_1)\, \Psi(x_2) \rangle$, where Ψ is the Ginzburg-Landau order parameter which is proportional to Δ (ch. 17), and the average value is used with thermodynamic fluctuations taken into account. As a result, it is found that $Z \propto \exp\left(-|x_1 - x_2|\, mT/\Psi_0^2 h^2\right)$ with $|x_1 - x_2| \to \infty$. Here Ψ_0 is the equilibrium value of Ψ (in the one-dimensional problem Ψ_0^2 is normalized to the number of electrons per cm of length). Hence, $Z \to 0$ with $|x_1 - x_2| \to \infty$; this is an indication of the absence of long-range order at a finite temperature. In the presence of long-range order Ψ is coherent over the entire space and, hence, Z has a finite limit with $|x_1 - x_2| \to \infty$. The destruction of long-range order occurs because of the fluctuations in the phase of the complex function $\Psi = |\Psi| e^{i\varphi}$.

In this connection, it should be noted that the basic idea of Little was not one-dimensionality, which, as has already been pointed out, interferes with superconductivity, but rather the presence of strongly polarizable side groups that surround the main filament by a thick "coat". In currently available molecular quasi-onedimensional crystals the conductivity anisotropy occurs not because of the large distances between the filaments but because of the high anisotropy of the electronic wave functions, which overlap strongly along the filaments and weakly in the transverse direction. Hence, in compounds of this type there is no room for a strongly polarizable "coat".

The idea of Ginzburg (Ginzburg 1964) consists in producing heterogeneous structures, in which metal and insulator films would alternate [a semiconductor has also been proposed in place of an insulator (Allender et al. 1973)]. Due to the quantum tunnelling effect some of the electrons of the metal could get into the insulator and exchange the excitons of the insulator. A theoretical estimation of T_c is very difficult because it depends on the detailed assumptions of the properties of the interface. High T_c cannot probably be attained by this method because of the smallness of the layer in which the pairing occurs and because of the weakness of the effective interaction. No substantial increase in T_c has been achieved in experiments with this type of structure.

The following remark may be made concerning the possibility of superconductivity in thin boundary layers of a metal. We have already discussed superconducting correlation (sections 16.7 and 16.10). One of its manifestations is the so-called "proximity effect - the mutual influence of a superconductor and a normal metal which are in contact with each other (see section 20.1 for more detail). In particular, superconductivity in a film applied onto a normal metal will be destroyed if its thickness is smaller than ξ. Hence, even if superconductivity could have arisen in a thin layer near the point of contact between a metal and any polarizable dielectric medium, it would have been suppressed if the thickness of this layer is less than ξ. Superconductivity could be preserved provided the value of T_c attained is so high that $\xi_0 \sim \hbar v/T_c$ is of the order of the thickness of the superconducting layer; note that to room temperature there corresponds $\xi \sim 10^{-5} - 10^{-6}$, i.e., several hundreds of interatomic distances. The way out of this situation could be the use of thin
superconducting films between layers of an insulator, which is what has been done in experiments, though with no success yet.

The limiting case of heterogeneous structures are quasi-two-dimensional superconductors, in which the conducting layers have a thickness of one molecule and are separated by relatively thick nonconducting layers. Such compounds have readily been synthesized on the basic of lamellar chalcogenides, such as TaS_2 and $NbSe_2$. Due to the weakness of the interaction, large organic molecules (say pyridine, C_6H_5 N) can be incorporated into the spaces between the layers of a chalcogenide. Such crystals are called intercalation compounds. Here the separation between the layers may strongly increase (up to 50Å), which, in particular, affects the conductivity anisotropy (it may increase from 10 up to 10^5).

Although purely two-dimensional conductivity is impossible for the same reason as purely one-dimensional superconductivity [the fluctuational destruction of the long-range order (Rice 1965)], it turns out that even an insignificant interaction between the layers suppresses the fluctuations and restores the superconductivity (Dzyaloshinskii and Katz 1968). In experiments in some cases upon intercalation there has been observed an increase in T_c. For example, upon intercalation of TaS_2 by pyridine T_c increased from 0.3 K up to 3.5 K (Gamble et al. 1976). Although high critical temperatures have not yet been reached in such compounds, this path should nonetheless be regarded as promising*.

In connection with superconductivity of two-dimensional systems mention should be made of the increase in T_c at the twinning plane of crystals (Khaikin and Khlyustikov 1981, 1983). This phenomenon is considered in detail in section 20.2.

The effect of twinning planes may be of prime importance in the high-temperature ceramic $YBa_2Cu_3O_{7-\delta}$, in which, due to a phase transition at 750 K , twinning planes appear spontaneously upon lowering the temperature at a distance of $500 - 1500$Å. It appears that their critical temperature is 93 K , while the "bulk" T_c is $\sim$ 89 K; this could explain many peculiarities in the interval $89 - 93$ K. Traces of higher- T_c superconductivity sometimes observed in this ceramic could possibly be due to the occasional formation of dense arrays of twinning planes (Abrikosov and Buzdin 1988).

Recently one more variant has been proposed of the system transmitting the interaction between conduction electrons - the so-called two-level systems in metallic "glasses" with a strongly disordered crystalline structure. In such compounds, entire groups of atoms can be transferred from some positions to others, these transfers being associated with relatively small changes in energy. Such groups are called two-level systems. Usually, at each temperature T those systems are important, which have a level difference of order T.

Theoretical investigations (Harris et al. 1983) show that the interaction of electrons through two-level systems adds to the phonon attraction and brings about an increase

superconducting films between layers of an insulator, which is what has been done in experiments, though with no success yet.

The limiting case of heterogeneous structures are quasi-two-dimensional superconductors, in which the conducting layers have a thickness of one molecule and are separated by relatively thick nonconducting layers. Such compounds have readily been synthesized on the basic of lamellar chalcogenides, such as TaS_2 and $NbSe_2$. Due to the weakness of the interaction, large organic molecules (say pyridine, C_6H_5 N) can be incorporated into the spaces between the layers of a chalcogenide. Such crystals are called intercalation compounds. Here the separation between the layers may strongly increase (up to 50Å), which, in particular, affects the conductivity anisotropy (it may increase from 10 up to 10^5).

Although purely two-dimensional conductivity is impossible for the same reason as purely one-dimensional superconductivity [the fluctuational destruction of the long-range order (Rice 1965)], it turns out that even an insignificant interaction between the layers suppresses the fluctuations and restores the superconductivity (Dzyaloshinskii and Katz 1968). In experiments in some cases upon intercalation there has been observed an increase in T_c. For example, upon intercalation of TaS_2 by pyridine T_c increased from 0.3 K up to 3.5 K (Gamble et al. 1976). Although high critical temperatures have not yet been reached in such compounds, this path should nonetheless be regarded as promising*.

In connection with superconductivity of two-dimensional systems mention should be made of the increase in T_c at the twinning plane of crystals (Khaikin and Khlyustikov 1981, 1983). This phenomenon is considered in detail in section 20.2.

The effect of twinning planes may be of prime importance in the high-temperature ceramic $YBa_2Cu_3O_{7-8}$, in which, due to a phase transition at 750 K , twinning planes appear spontaneously upon lowering the temperature at a distance of $500 - 1500$Å. It appears that their critical temperature is 93 K , while the "bulk" T_c is $\sim$ 89 K; this could explain many peculiarities in the interval $89 - 93$ K. Traces of higher- T_c superconductivity sometimes observed in this ceramic could possibly be due to the occasional formation of dense arrays of twinning planes (Abrikosov and Buzdin 1988).

Recently one more variant has been proposed of the system transmitting the interaction between conduction electrons - the so-called two-level systems in metallic "glasses" with a

---

- Taking into account that high-temperature ceramics have a layered structure and that their conductivity is due to layers containing Cu and O , which are separated by relatively large distances, one may suppose that these ceramics are superconductors of the excitonic type.

strongly disordered crystalline structure. In such compounds, entire groups of atoms can be transferred from some positions to others, these transfers being associated with relatively small changes in energy. Such groups are called two-level systems. Usually, at each temperature T those systems are important, which have a level difference of order T.

Theoretical investigations (Harris et al. 1983) show that the interaction of electrons through two-level systems adds to the phonon attraction and brings about an increase

in T_c. An estimation of this effect in real metallic glasses shows that T_c may increase by $2-7\%$. This is in accord with experimental facts: the critical temperature of a disordered metal always decreases upon annealing (heating which leads to recrystallization); for example, it drops from 2.34 to 2 K in the alloy $Cu_{33}Zr_{67}$ and from 3.15 K to 3 K in $Zr_{76}Ni_{24}$. Although this effect is not strong, it is interesting from the standpoint of the demonstration of a nonphonon superconductivity mechanism.

Another idea has been proposed associated with the special centers in inhomogeneous metals (Schütter et al. 1987). Let us imagine that there exist centers for which it is energetically favorable to bind two electrons with opposite spins since attraction occurs between electrons of such centers. Although the existence of such centers can be justified, strictly speaking, only in semiconducting glasses, nevertheless their appearance in metals is not ruled out. In the latter case the hybridization of conduction electrons with these states, i.e., the possibility of virtual transitions from the band states to the centers, leads to an attraction and to the formation of Cooper pairs. The effectiveness of such a mechanism depends on the concentration of these special centers. In particular, such special centers may be regular structural units. This idea has also been proposed for the ceramics. For example, as an explanation of high-T_c superconductivity in ceramics it has been proposed that the holes of the conduction band (which transmit the current in those materials) can be localized at the double-negative oxygen ion (Zvezdin and Khomskii 1987).

Unusual superconductivity takes place in a number of compounds containing rare-earth metals and actinides, say YBe_{13} and $CeCu_2Bi_2$ (see Brandt and Moshchalkov 1984). Although the critical temperature of these compounds is not high ($T_c < 1$ K), their other properties are very interesting. First of all, they exhibit relatively strong critical fields. This may be interpreted as a consequence of an increase of the effective mass of carriers; estimates give values of m^* of the order of $200-400m$, where m is the mass of the free electron. It is for this reason that the term "heavy fermions" is used.

The study of the various characteristics in the normal state indicates that in such compounds the density of states has a narrow and large peak at the Fermi level (recall that the density of states $\nu = p_0 m^* / (\pi^2 \hbar^3)$. The origin of this peak is presumably associated with the electron screening of the spin of magnetic atoms of rare-earth elements and actinides. If the magnetic atoms are minor impurities, this leads to the Kondo effect in conductivity (section 4.6), but has no noticeable effect on the energy spectrum and thermodynamic properties. However, if the magnetic atoms become regular structural units and the exchange interaction constant J is so high that the Kondo temperature is higher than the freezing temperature of the spins, the Abrikosov-Suhl resonance in conductivity (see formula 4.49) may manifest itself as a peak in the density of states.

A further interesting property consists in that the low-temperature electronic heat capacity in UBe_{13} has been found to be proportional to T^3 or T^2. This is evidence
that at certain points or contours of the Fermi surface the energy gap Δ vanishes. In all proba-

- Taking into account that high-temperature ceramics have a layered structure and that their conductivity is due to layers containing Cu and O , which are separated by relatively large distances, one may suppose that these ceramics are superconductors of the excitonic type.

bility, the latter is associated with the nonphonon mechanism of electron attraction (probably the virtual paramagnons mentioned before).

Apart from increasing T_c, high critical fields are also important. In principle, in order to attain high critical fields two things are required: (a) the localization of electrons must be as large as possible; and (b) there must be attraction in the localized state. In this case, Cooper pairs could be "prepared in advance" from localized electrons and a certain probability of jumps could provide the supercurrent (Abrahams and Kulik 1977, Kulik and Pedan 1980, 1982, 1983, Bulaevskii et al. 1984, Alexandrov et al. 1986). In section 18.1 we shall see that the strongest critical fields can be attained in type II superconductors, and these are limited by two mechanisms: (1) Larmor twisting of pairs, and (2) the tendency of the magnetic field to flip the electron spins parallel to each other. These two mechanisms of pair collapse could be challenged successfully by superconductors of the "localized" type: the first mechanism could be challenged due to the large effective mass of carriers and the second due to the strong attraction of carriers with opposite spins in a single "well". However, it is still unknown whether such superconductors can be produced*. Metallic glasses in which a random potential could lead to localization of electrons could be of interest from this stand-point (section 11.6) (Kulik 1984).

8.3 17 The Ginzburg-Landau theory

8.3.1 17.1. Derivation of the Ginzburg-Landau equations

In ch. 16 we have been concerned with the application of the microscopic (BCS) theory for describing the thermodynamic properties of superconductors and their behavior in a weak magnetic field. A generalization of this theory (Gor'kov 1958) allows one to consider the behavior of superconductors in strong fields, including alternating fields. However, the corresponding equations are extremely complicated, which is why they are seldom used in practice for solution of physical problems. Instead, use is made of a simplified theory, which we shall describe in the present chapter.

In 1950, i.e., even before the microscopic (BCS) theory was developed, Ginzburg and Landau had proposed a theory currently known as the Ginzburg-Landau theory (Ginzburg and Landau 1950), which describes the properties of superconductors near T_c; this theory has successfully surmounted the difficulties of London electrodynamics. For example, it explained the origin of the positive surface energy σ_{ns}. The equations of this theory were derived on the basis of the ideas of Landau's theory of second-order phase transitions (Appendix II).

Later, Gor'kov (Gor'kov 1959a,b) demonstrated that the equations of the Ginzburg-Landau theory are the limit of the BCS equations provided that the following two conditions are satisfied: (a) $T_c - T < T_c$, and (b) $\delta > \xi_0$. For London superconductors the second condition is fulfilled at all temperatures and only the first condition (a) remains. For Pippard superconductors, conversely, the requirement (b) is more stringent. We shall deal here with the simple derivation given in the fundamental work of Ginzburg and Landau (1950).

We start with the definition of the order parameter. We take it as the wave function of Cooper pairs present in the Bose condensate. For an ideal Bose condensate under homogeneous conditions, the ground state is a state with $p = 0$. Below the point of Bose condensation in this state there is a finite number of particles with a wave function $\Psi = \text{const}$. (i.e., $e^{ipr/\hbar + i\alpha}$ at $p = 0$) identical for all particles; this is called coherence. It is believed that with a slight (long-wavelength) inhomogeneity due to the application of an external field, the coherence is preserved and the function $\Psi(r)$ characterizes all particles of the condensate.

*The possibility is not excluded that Chevrel phases and superconductors with "heavy fermions" could be such superconductors.

Near the critical temperature Ψ is small and the free energy Ω may be expanded into a series in Ψ. In the absence of an external field in a bulk superconductor Ψ
is independent of the coordinates. Since Ψ is a complex quantity and Ω is real, the expansion is carried out in powers of $|\Psi|^2$. Thus, we have (for unit volume)

$$\Omega_{\mathrm{s}} = \Omega_{\mathrm{n}} + a|\Psi|^2 + \frac{\mathrm{l}}{2}\,\mathrm{b}|\Psi|^4 + \cdots . \tag{17.1}$$

Since the theory is built up for the vicinity of T_{c}, the coefficients a and b can be expanded in $\tau = (T - T_{\mathrm{c}})/T_{\mathrm{c}}$ and only the first nonvanishing terms need be retained. Since the minimum of Ω_{s} corresponds to $\Psi = 0$ above T_{c} and $\Psi \neq 0$ below T_{c}, the coefficient a changes sign at the transition point; therefore, $a = \alpha\tau$, where $\alpha > 0$. From the condition that $\Psi = 0$ must correspond to the minimum of Ω_{s} at the transition point too, we have

$$b \approx b\,(T_c) > 0.$$

Differentiating with respect to Ψ^*, we obtain the condition of the minimum of Ω_{s} :

$$\Psi\left[\alpha\tau + |\Psi|^2\right] = 0$$

This yields the equilibrium values:

$$\begin{aligned} &\Psi = 0, \quad T > T_{\mathrm{c}}, \\ &|\Psi|^2 = -\frac{\alpha\tau}{b} \equiv \Psi_0^2, \quad T < T_{\mathrm{c}} \end{aligned} \tag{17.2}$$

Substituting the equilibrium value of $|\Psi|^2 = \Psi_0^2$ into (17.2) and comparing with (15.5), we have

$$\Omega_{\mathrm{n}} - \Omega_{\mathrm{s}} = \frac{(\alpha\tau)^2}{2b} = \frac{H_{\mathrm{cm}}^2}{8\pi} \tag{17.3}$$

In the present chapter we use the notation $\boldsymbol{H}_{\mathrm{cm}}$ for the thermodynamic critical field of a bulk superconductor in order to distinguish it from the critical field of a thin film and also from other critical fields that will be introduced later. Comparing eq. (17.3) with formula (16.55), we see that the Ginzburg-Landau theory gives a correct temperature dependence of H_{cm}. From this comparison we can also derive a microscopic formula for a certain combination of the coefficients α and b :

$$\frac{\alpha^2}{b} = \frac{4}{7\zeta(3)}T_{\mathrm{c}}^2\frac{mp_0}{\hbar^3} = \frac{4\pi^2}{7\zeta(3)}\nu(\mu)T_{\mathrm{c}}^2 \tag{17.4}$$

Suppose now that an external magnetic field is applied to the superconductor. In this case, both the field in the superconductor and Ψ depend on the coordinates. Here one has to examine the total free energy of the entire superconductor. The energy of the field per unit volume is $H^2/8\pi$. Moreover, one has to add the energy associated with the inhomogeneity of Ψ. We will assume that the variation of Ψ in space occurs slowly. This permits one to consider only the correction $|\nabla\Psi|^2$ to the free energy. However, the order parameter Ψ has the meaning of the wave function of Cooper pairs. In view of this, the momentum operator -i $\hbar\nabla$ must necessarily is independent of the coordinates. Since Ψ is a complex quantity and Ω is real, the expansion is carried out in powers of $|\Psi|^2$. Thus, we have (for unit volume)

$$\Omega_{\mathrm{s}} = \Omega_{\mathrm{n}} + a|\Psi|^2 + \frac{\mathrm{l}}{2}\,\mathrm{b}|\Psi|^4 + \cdots . \tag{17.1}$$

Since the theory is built up for the vicinity of T_c, the coefficients a and b can be expanded in $\tau = (T - T_c)/T_c$ and only the first nonvanishing terms need be retained. Since the minimum of Ω_s corresponds to $\Psi = 0$ above T_c and $\Psi \neq 0$ below T_c, the coefficient a changes sign at the transition point; therefore, $a = \alpha\tau$, where $\alpha > 0$. From the condition that $\Psi = 0$ must correspond to the minimum of Ω_s at the transition point too, we have

$$b \approx b(T_c) > 0.$$

Differentiating with respect to Ψ^*, we obtain the condition of the minimum of Ω_s :

$$\Psi\left[\alpha\tau + |\Psi|^2\right] = 0.$$

This yields the equilibrium values:

$$\begin{aligned} &\Psi = 0, \quad T > T_c, \\ &|\Psi|^2 = -\frac{\alpha\tau}{b} \equiv \Psi_0^2, \quad T < T_c. \end{aligned} \tag{17.2}$$

Substituting the equilibrium value of $|\Psi|^2 = \Psi_0^2$ into (17.2) and comparing with (15.5), we have

$$\Omega_n - \Omega_s = \frac{(\alpha\tau)^2}{2b} = \frac{H_{cm}^2}{8\pi} \tag{17.3}$$

In the present chapter we use the notation H_{cm} for the thermodynamic critical field of a bulk superconductor in order to distinguish it from the critical field of a thin film and also from other critical fields that will be introduced later. Comparing eq. (17.3) with formula (16.55), we see that the Ginzburg-Landau theory gives a correct temperature dependence of H_{cm}. From this comparison we can also derive a microscopic formula for a certain combination of the coefficients α and b :

$$\frac{\alpha^2}{b} = \frac{4}{7\zeta(3)} T_c^2 \frac{mp_0}{\hbar^3} = \frac{4\pi^2}{7\zeta(3)} \nu(\mu) T_c^2 \tag{17.4}$$

Suppose now that an external magnetic field is applied to the superconductor. In this case, both the field in the superconductor and Ψ depend on the coordinates. Here one has to examine the total free energy of the entire superconductor. The energy of the field per unit volume is $\boldsymbol{H^2/8\pi}$. Moreover, one has to add the energy associated with the inhomogeneity of Ψ. We will assume that the variation of Ψ in space occurs slowly. This permits one to consider only the correction $|\nabla\Psi|^2$ to the free energy. However, the order parameter Ψ has the meaning of the wave function of Cooper pairs. In view of this, the momentum operator $-i\hbar\nabla$ must necessarily is independent of the coordinates. Since Ψ is a complex quantity and Ω is real, the expansion is carried out in powers of $|\Psi|^2$. Thus, we have (for unit volume)

$$\Omega_s = \Omega_n + a|\Psi|^2 + \frac{1}{2}\, b|\Psi|^4 + \cdots . \tag{17.1}$$

Since the theory is built up for the vicinity of T_c, the coefficients a and b can be expanded in $\tau = (T - T_c)/T_c$ and only the first nonvanishing terms need be retained. Since the minimum of Ω_s corresponds to $\Psi = 0$ above T_c and $\Psi \neq 0$ below T_c, the coefficient a changes sign at the transition point; therefore, $a = \alpha\tau$, where $\alpha > 0$. From the condition that $\Psi = 0$ must correspond to the minimum of Ω_s at the transition point too, we have

$$b \approx b(T_c) > 0.$$

Differentiating with respect to Ψ^*, we obtain the condition of the minimum of Ω_s :

$$\Psi\left[\alpha\tau + |\Psi|^2\right] = 0.$$

This yields the equilibrium values:

$$\begin{aligned} &\Psi = 0, \quad T > T_c, \\ &|\Psi|^2 = -\frac{\alpha\tau}{b} \equiv \Psi_0^2, \quad T < T_c \end{aligned} \tag{17.2}$$

Substituting the equilibrium value of $|\Psi|^2 = \Psi_0^2$ into (17.2) and comparing with (15.5), we have

$$\Omega_\mathrm{n} - \Omega_\mathrm{s} = \frac{(\alpha\tau)^2}{2b} = \frac{H_\mathrm{cm}^2}{8\pi} \tag{17.3}$$

In the present chapter we use the notation H_cm for the thermodynamic critical field of a bulk superconductor in order to distinguish it from the critical field of a thin film and also from other critical fields that will be introduced later. Comparing eq. (17.3) with formula (16.55), we see that the Ginzburg-Landau theory gives a correct temperature dependence of $\boldsymbol{H}_\mathrm{cm}$. From this comparison we can also derive a microscopic formula for a certain combination of the coefficients α and b :

$$\frac{\alpha^2}{b} = \frac{4}{7\zeta(3)} T_\mathrm{c}^2 \frac{mp_0}{\hbar^3} = \frac{4\pi^2}{7\zeta(3)} \nu(\mu) T_\mathrm{c}^2. \tag{17.4}$$

Suppose now that an external magnetic field is applied to the superconductor. In this case, both the field in the superconductor and Ψ depend on the coordinates. Here one has to examine the total free energy of the entire superconductor. The energy of the field per unit volume is $H^2/8\pi$. Moreover, one has to add the energy associated with the inhomogeneity of Ψ. We will assume that the variation of Ψ in space occurs slowly. This permits one to consider only the correction $|\nabla\Psi|^2$ to the free energy. However, the order parameter Ψ has the meaning of the wave function of Cooper pairs. In view of this, the momentum operator $-\mathrm{i}\hbar\nabla$ must necessarily be included in the combination $-\mathrm{i}\hbar\nabla - (2e/c)A$, where A is the vector potential*; we took into account that the pair has a charge $2e$.

In order to impart the ordinary form to the new term in the free energy, we write it as the kinetic energy of a particle of mass $2m$ **:

$$\frac{1}{4m}|(-\mathrm{i}\hbar\nabla - (2e/c))A\Psi|^2.$$

Thus, we have

$$\begin{aligned} \int \Omega_\mathrm{s}\, \mathrm{d}V = &\int \Omega_\mathrm{n}^{(0)} \mathrm{d}V \\ &+ \int \left\{ \alpha\tau|\Psi|^2 + \frac{1}{2}b|\Psi|^4 + \frac{1}{4m}\left| \left(-\mathrm{i}\hbar\nabla - \frac{2e}{c}A\right)\Psi \right|^2 + \frac{H^2}{8\pi} \right\} \mathrm{d}V \end{aligned} \tag{17.5}$$

(here we have introduced the notation $\Omega_\mathrm{n}^{(0)}$ for the free energy of the normal phase without the field).

In order to obtain the minimum of the total free energy, we vary expression (17.5) with respect to Ψ^*. In such a case, we obtain

$$\int \left\{ \alpha\tau\Psi\delta\Psi + b|\Psi|^2\delta\Psi^* \right.$$
$$\left. + \frac{1}{4m}\left(-\mathrm{i}\hbar\nabla - \frac{2e}{c}A\right)\Psi\left(\mathrm{i}\hbar\nabla - \frac{2e}{c}A\right)\delta\Psi^* \right\} \mathrm{d}V = 0$$

In order to get rid of $\nabla\delta\Psi^*$, we integrate the corresponding term by parts and use Gauss' theorem. We find

$$\frac{\mathrm{i}\hbar}{4m}\int \delta\Psi^* n\left(-\mathrm{i}\hbar\nabla - \frac{2e}{c}A\right)\Psi \mathrm{d}S$$
$$+ \frac{1}{4m}\int \delta\Psi^*\left(-\mathrm{i}\hbar\nabla - \frac{2e}{c}A\right)^2\Psi \ \mathrm{d}V$$

where the integration in the first term runs over the surface of the superconductor (n is the unit vector of the normal).

The variation of $\delta\Psi^*$ is arbitrary. Assuming that $\delta\Psi^* = 0$ at the surface and equating to zero the factor at $\delta\Psi^*$ in the integral over the volume, we obtain the equation for Ψ :

$$\frac{1}{4m}\left(-\mathrm{i}\hbar\nabla - \frac{2e}{c}A\right)^2\Psi + \alpha\tau\Psi + b|\Psi|^2\Psi = 0. \tag{17.6}$$

be included in the combination - i $\hbar\nabla - (2e/c)A$, where A is the vector potential*; we took into account that the pair has a charge $2e$.

In order to impart the ordinary form to the new term in the free energy, we write it as the kinetic energy of a particle of mass $2m$ ** :

$$\frac{1}{4m}|(-\mathrm{i}\hbar\nabla - (2e/c))A\Psi|^2.$$

Thus, we have

$$\int \Omega_\mathrm{s}\ \mathrm{d}V = \int \Omega_\mathrm{n}^{(0)}\mathrm{d}V$$
$$+ \int \left\{ \alpha\tau|\Psi|^2 + \frac{1}{2}b|\Psi|^4 + \frac{1}{4m}\left|\left(-\mathrm{i}\hbar\nabla - \frac{2e}{c}A\right)\Psi\right|^2 + \frac{H^2}{8\pi} \right\} \mathrm{d}V \tag{17.5}$$

(here we have introduced the notation $\Omega_\mathrm{n}^{(0)}$ for the free energy of the normal phase without the field).

In order to obtain the minimum of the total free energy, we vary expression (17.5) with respect to Ψ^*. In such a case, we obtain

$$\int \left\{ \alpha\tau\Psi\delta\Psi + b|\Psi|^2\delta\Psi^* \right.$$
$$\left. + \frac{1}{4m}\left(-\mathrm{i}\hbar\nabla - \frac{2e}{c}A\right)\Psi\left(\mathrm{i}\hbar\nabla - \frac{2e}{c}A\right)\delta\Psi^* \right\} \mathrm{d}V = 0$$

- Recall that the theory must be invariant under a gauge transformation of the vector potential $A \to A + \nabla\varphi$. In the expression $[-\mathrm{i}\hbar\nabla - (2e/c)A]\Psi$ this is provided by the fact that $\nabla\varphi$ is compensated for by the change in the phase of the function Ψ.

**The mass m in this term is quite arbitrary, but it is convenient to take it to be equal to the mass of the electron (see below).

In order to get rid of $\nabla\delta\Psi^*$, we integrate the corresponding term by parts and use Gauss' theorem. We find

$$\frac{\mathrm{i}\hbar}{4m}\int \delta\Psi^* n\left(-\mathrm{i}\hbar\nabla-\frac{2e}{c}A\right)\Psi \mathrm{d}S + \frac{1}{4m}\int \delta\Psi^*\left(-\mathrm{i}\hbar\nabla-\frac{2e}{c}A\right)^2\Psi\ \mathrm{d}V$$

where the integration in the first term runs over the surface of the superconductor (n is the unit vector of the normal).

The variation of $\delta\Psi^*$ is arbitrary. Assuming that $\delta\Psi^*=0$ at the surface and equating to zero the factor at $\delta\Psi^*$ in the integral over the volume, we obtain the equation for Ψ :

$$\frac{1}{4m}\left(-\mathrm{i}\hbar\nabla-\frac{2e}{c}A\right)^2\Psi+\alpha\tau\Psi+b|\Psi|^2\Psi=0. \tag{17.6}$$

If now we assume $\delta\Psi^*$ to be arbitrary at the surface of the superconductor, the surface integral will give the following boundary condition:

$$n\left(-\mathrm{i}\hbar\nabla-\frac{2e}{c}A\right)\Psi\Big|_{\mathrm{b}}=0 \tag{17.7}$$

Variation of (17.5) with respect to $\delta\Psi$ gives an equation and a boundary condition which are complex-conjugate to (17.6) and (17.7).

Now we vary (17.5) with respect to the vector potential $\boldsymbol{A}$, assuming that $\boldsymbol{H}=\operatorname{rot}\boldsymbol{A}$. The variation of H^2 gives $2\operatorname{rot}A\operatorname{rot}\delta A$. We may use the formula $\operatorname{div}[ab]=b\operatorname{rot}a-a\operatorname{rot}b$. This yields $2\delta A\operatorname{rot}\operatorname{rot}A+2\operatorname{div}[\delta A\operatorname{rot}A]$. The volume integral of div is transformed to a surface integral and vanishes. Equating the variation to zero, we find

$$\operatorname{rot}\operatorname{rot}A=\operatorname{rot}H=\frac{4\pi}{c}j, \tag{17.8}$$

$$j=-\frac{ie\hbar}{2m}\left(\Psi^*\nabla\Psi-\Psi\nabla\Psi^*\right)-\frac{2e^2}{mc}|\Psi|^2A. \tag{17.9}$$

Equation (17.8) is a Maxwell equation. The boundary condition is the specification of the field at the superconductor surface. Expression (17.9) corresponds to the quantum-mechanical current in magnetic field if the wave function is equal to Ψ, the charge is $2e$ and the mass $2m$.

We now pass over to new units which will allow us to drop most of the constants in (17.6)-(17.9). We introduce the following notations:

$$\begin{array}{ll} \Psi'=\frac{\Psi}{\Psi_0}, & H'=\frac{H}{H_{\mathrm{cm}}\sqrt{2}},\\ r'=\frac{r}{\delta}, & \delta=\sqrt{\frac{2mc^2}{4\pi\Psi_0^2(2e)^2}},\\ A'=\frac{A}{H_{\mathrm{cm}}\sqrt{2}\delta}, & H_{\mathrm{cm}}=\frac{2\sqrt{\pi}\alpha\tau}{b^{1/2}},\\ \Psi_0^2=\alpha\frac{|\tau|}{b}. & . \end{array} \tag{17.10}$$

- Recall that the theory must be invariant under a gauge transformation of the vector potential $A\to A+\nabla\varphi$. In the expression $[-\mathrm{i}\hbar\nabla-(2e/c)A]\Psi$ this is provided by the fact that $\nabla\varphi$ is compensated for by the change in the phase of the function Ψ.
  ** The mass m in this term is quite arbitrary, but it is convenient to take it to be equal to the mass of the electron (see below).

As a result, the equations become (we omit the primes in the new quantities):

$$\left(-\frac{i\nabla}{x} - A\right)^2 \Psi - \Psi + |\Psi|^2\Psi = 0, \tag{17.6'}$$

$$n\left(-\frac{i\nabla}{x} - A\right)\Psi\Big|_{\mathrm{b}} = 0, \tag{17.7'}$$

$$\operatorname{rot}\operatorname{rot} A = -\frac{i}{2x}\left(\Psi^*\nabla\Psi - \Psi\nabla\Psi^*\right) - |\Psi|^2 A. \tag{17.8'}$$

Equations (17.6'), (17.7') and (17.8') contain only one constant, x, which is called the Ginzburg-Landau parameter; it is defined as

$$x = 2^{3/2} e H_{\mathrm{cm}} \frac{\delta^2}{\hbar c}. \tag{17.11}$$

This is the same constant introduced in section 16.9 (formula 16.95). This point will be discussed later.

Let us consider the simplest problem: the penetration of a weak magnetic field into the bulk of a superconductor with a planar boundary. Let the superconductor occupy the half-space $x = 0$. The field is applied to it along the z axis. The field penetrates the superconductor and decreases rapidly in the bulk, i.e., it depends on x. Therefore, we choose the vector potential A along the direction y. In this case,

$$H(x) = \frac{\mathrm{d}A_y}{\mathrm{d}x}.$$

It is natural to assume that Ψ is also dependent only on x. From eqs. (17.6) and (17.7) we obtain

$$-x^2\frac{d^2\Psi}{dx^2} - \Psi + A^2\Psi + |\Psi|^2\Psi = 0,$$

$$\frac{d\Psi}{dx}\Big|_b = 0.$$

We assume that $x < 1$. Then we obtain $\Psi = \text{const}$. From the condition in the bulk of the superconductor it follows that $|\Psi|^2 = 1$. The function Ψ may be chosen real. Equation (17.8') yields

$$\frac{\mathrm{d}^2 A}{\mathrm{d}x^2} - A = 0.$$

Differentiating with respect to x, we derive a similar equation for H. The solution that satisfies the boundary condition $H = H_0$ is $H = H_0\mathrm{e}^{-x}$ or, in conventional units,

$$H = H_0\mathrm{e}^{-x/\delta}, \tag{17.12}$$

where δ is defined in (17.10). But we know that this must give the London penetration depth near T_c. Choosing m in (17.10) to be equal to the mass of the electron, we find that $|\Psi_0|^2 = \frac{1}{2}n_s$, i.e., the number of Cooper pairs. Comparing (17.2) with the BCS formula (16.92), we find that

$$\frac{\alpha}{b} = n_{\mathrm{c}}. \tag{17.13}$$

Using formulae (17.13) and (17.14), we can define α and $b\,(n_{\mathrm{e}} = p_0^3/3\pi^2\hbar^3)$:

$$\alpha = \frac{12\pi^2}{7\zeta(3)}\frac{mT_c^2}{p_0^2}, \quad b = \frac{\alpha}{n_e}. \tag{17.14}$$

Substituting formulae (16.55) for $H_{cm}(T)$ and (16.93) for $\delta(T)$ into the expression for x (17.11), we obtain

$$x = 3\left(\frac{2}{7\zeta(3)}\right)^{1/2}\left(\frac{\pi\hbar}{v}\right)^{3/2}\frac{cT_c}{\hbar p_0}. \tag{17.15}$$

The constant x may be expressed through the ratio of $\delta_L(0) = (mc^2/4\pi n_e e^2)^{1/2}$ and $\xi_0 = (\gamma/\pi^2)\,\hbar v/T_c$ (see formula 16.82). As a result, we obtain formula (16.95).

Thus, all the constants that appear in the theory have a microscopic interpretation. Only the microscopic meaning of the order parameter Ψ remains unclear. However, this can be found by comparison with the microscopic theory. It is rather evident that Ψ is proportional to Δ. These two quantities are complex scalars in the general case, both are equal to zero at $T > T_c$ and proportional to $|\tau|^{1/2}$ at $T_c - T < T_c$. Therefore it is sufficient to compare the coefficients at $|\tau|^{1/2}$ for Ψ (17.2) and for Δ when $T \to T_c$ (16.33). From this we get

$$\Psi(r) = \frac{1}{\pi}\left(\frac{7}{8}\zeta(3)\right)^{1/2} n_e^{1/2}\frac{\Delta(r)}{T_c}. \tag{17.16}$$

The Ginzburg-Landau theory refers also to superconductors that contain impurities; such superconductors are usually called superconducting alloys or dirty superconductors in the literature. As has already been remarked in section 16.9, impurities in a small concentration exert but a slight effect on the thermodynamic properties, i.e., on T_c, Δ, and H_{cm}, but at $l < \xi$ they appreciably change the penetration depth. Inserting expressions (16.55) for H_{cm} and (16.100) for δ with $T \to T_c$ into the general formula (17.11) for x, we obtain formula (16.101), where $l = v\tau_{tr}$.

For convenience of comparison with experiment x may be expressed via the conductivity of a normal metal $\sigma = n_e e^2 l/p_0$ and the coefficient in the linear law of heat capacity $C_n = \gamma_c T, \gamma_c = p_0 m/3\hbar^3$ (Gor'kov 1959a,b):

$$x = \left(\frac{21\zeta(3)}{2\pi}\right)^{1/2}\frac{ce}{\pi^3}\frac{\gamma_c^{1/2}}{\sigma}. \tag{17.17}$$

In conventional units, when the temperature is measured in Kelvin and the heat capacity in erg/cm$^3\cdot$ K, our γ_c is measured in $\left(\text{erg}\cdot\text{cm}^{-3}\cdot\ \text{K}^{-2}\right)/k_B^2$, where k_B is Boltzmann's constant. Substituting the numerical values of c and e and expressing the resistivity $\sigma^{-1} = \rho$ in ohm ·cm, we obtain

$$\varkappa = 7.5\times 10^3\left[\gamma_c\left(\text{erg}\cdot\ \text{cm}^{-3}\cdot\ \text{K}^{-2}\right)\right]^{1/2}\rho(\text{ohm}\cdot\ \text{cm}). \tag{17.17'}$$

Using relation (17.4) derived from H_{cm}, which we assume to be constant, and expressions (16.100) and (17.10) for δ together with formula (16.33) for Δ (which
remains unchanged too), we find the coefficients α and b and the relationship between Δ and Ψ :

$$\alpha = \frac{6}{\pi}\frac{\hbar T_c}{\tau_{tr}}\frac{m}{p_0^2}, \quad \frac{\alpha}{b} = \frac{2\pi^3}{7\zeta(3)}\frac{T_c\tau_{tr}}{\hbar}n_e \tag{17.18}$$

$$\Psi(r) = \left(\frac{1}{4}\pi\right)^{1/2}\left(\frac{n_e\tau_{tr}}{hT_c}\right)^{1/2}\Delta(r)$$

Inserting these expressions into eq. (17.6), we obtain the form of this equation that is frequently used for alloys:

$$\frac{\pi D\hbar}{8T_{\rm c}}\left(\nabla-\frac{2{\rm i}e}{\hbar c}A\right)^2\Delta+\left(\frac{T_{\rm c}-T}{T_{\rm c}}\right)\Delta-\left(\frac{7\zeta(3)}{8\pi^2T_{\rm c}^2}\right)|\Delta|^2\Delta=0, \qquad (\prime\prime)$$

where $D=\frac{1}{3}v^2\tau_{\rm tr}$ is the diffusion coefficient (section 3.5). The corresponding expression for the current is

$$j=-{\rm i}\frac{\pi e\nu D}{4T_{\rm c}}\left(\frac{1}{2}\left(\Delta^*\nabla\Delta-\Delta\nabla\Delta^*\right)-\frac{2ie}{\hbar c}A|\Delta|^2\right) \qquad (\prime)$$

where $\nu=p_0m/\pi^2\hbar^3$ is the density of states.
For subsequent applications we transform the expression for the free energy (17.5). Passing to the reduced quantities and using formulas (17.10), we have

$$\int\Omega_{\rm s}\,{\rm d}V=\int\Omega_{\rm n}^{(0)}{\rm d}V + \frac{H_{\rm cm}^2}{4\pi}\int\left\{-|\Psi|^2+\frac{1}{2}|\Psi|^4+\left|\left(-{\rm i}\frac{\nabla}{\varkappa}-A\right)\Psi\right|^2+H^2\right\}{\rm d}V. \qquad (17.19)$$

As before, in the derivation of the equations, we integrate the term with $\nabla\Psi^*$ by parts. Here the surface integral vanishes due to the boundary condition (17.7) and in the volume integral left we use the fact that Ψ satisfies eq. (17.6'). As a result, we have

$$\int\Omega_{\rm s}\,{\rm d}V=\int\Omega_{\rm n}^{(0)}{\rm d}V+\frac{H_{\rm cm}^2}{4\pi}\int\left(H^2-\frac{1}{2}|\Psi|^4\right){\rm d}V \qquad (\prime)$$

In what follows we will be interested in the transition from the normal to the superconducting state under the influence of an external field. For a cylindrical geometry the free energy in a given external field is obtained by subtracting $\boldsymbol{H}_0\boldsymbol{B}/4\pi$, where $\boldsymbol{H}_0$ is the external field and $\boldsymbol{B}$ is the induction equal to the average field in the sample, $\boldsymbol{B}=\boldsymbol{V}^{-1}\int\boldsymbol{H}\,{\rm d}V$ (see Appendix III). For the normal phase $\Omega_{{\rm n}H}=\Omega_{\rm n}^{(0)}-H_0^2/8\pi$.

Thus, we obtain (in reduced units):

$$\int\left(\Omega_{{\rm s}H}-\Omega_{{\rm n}H}\right){\rm d}V=\frac{H_{\rm cm}^2}{4\pi}\int\left[\left(H-H_0\right)^2-\frac{1}{2}|\Psi|^4\right]{\rm d}V \qquad (17.20)$$

In concluding this section we evaluate the size of the region where the GinzburgLandau theory based on the Landau approximation for second-order phase transitions becomes inapplicable because of the fluctuational effects. According to Appendix II, the range of validity of the Landau approximation is determined by condition (AII.20):

$$1>|\tau|>\frac{b^2T_c^2}{\alpha c^3},$$

where $\tau=\left(T-T_{\rm c}\right)/T_{\rm c}$. In the Ginzburg-Landau theory the coefficients α and b have the same meaning as in the model considered in Appendix II, and the role of the parameter c (the coefficient in front of $\nabla\varphi$, where φ is the real scalar order parameter) is played by $\hbar^2/m$. Hence,

$$1>|\tau|>\frac{m^3b^2T_c^2}{\alpha\hbar^6}$$

Substituting α and b for a pure superconductor, we obtain in accordance with (17.14)

$$1 > |\tau| > \left(\frac{T_c}{\varepsilon_F}\right)^4, \tag{17.21}$$

where $\varepsilon_F \sim p_0^2/m$ is the Fermi energy. Usually, T_c/ε_F does not exceed 10^{-3}, i.e., the quantity that stands on the right is less than 10^{-12}, which is many orders of magnitude smaller than the fluctuations in temperature that can be controlled in experiments.

For superconductors containing impurities at $l < \xi$ in accordance with (17.18) we have

$$1 > |\tau| > \left(\frac{\hbar}{\tau_{tr}}\right)^3 \frac{T_c}{\varepsilon_F^4}. \tag{17.22}$$

This requirement is less stringent than (17.21), but it also practically rules out the fluctuational region.

From this it follows that the fluctuations are unimportant in the thermodynamics of bulk superconductors. The physical cause for this is the large correlation length, as has already been pointed out at the end of section 16.9*. Nevertheless, situations are possible where the role of fluctuations increases noticeably, and these are responsible for the observed effects. This occurs for the kinetic effects in small objects, say for the conductivity of thin films and filaments. This point will be discussed in section 19.6.

Thus, the Ginzburg-Landau theory can be applied practically up to the very critical temperature. What is the range of its validity on the low-temperature side? One of these conditions is known: this is $|\tau| < 1$. The other is $\delta < \xi_0$, i.e., the London

region. The latter can be seen, for example, from the fact that, according to section 16.7, the relation between the current and the field is nonlocal in the general case and changes to the local theory only in the London region. In the Ginzburg-Landau theory the relation between the current and the field is local.

As has been said above, the Ginzburg-Landau equations are the exact limit of the BCS theory at $|\tau| < 1$. We will not give the corresponding derivation here because it is cumbersome (see Gor'kov 1959a, b). We note only that the relation that generalizes formula (16.18) for Δ to the inhomogeneous case $\Delta(r)$ (here we are speaking of $T \to T_c$, i.e., small Δ) is a complex integral relation: the right-hand side contains terms of the type

$$\int K(r, r')\,\Delta(r')\,dV'$$

$$\int K(r, r', r'', r''')\,\Delta(r')\,\Delta(r'')\,\Delta(r''')\,dV'dV''dV'''$$

The distances that are important in the kernels of the integrals are of order ξ_0. On the other hand, the distances over which Δ varies are of order $\xi(T) \sim \hbar v/\Delta(T) > \xi_0$ (at $|\tau| < 1$). This makes it possible to consider the variations of $\Delta(r)$ to be slow and to pass from the integral to differential relations. An analogous situation occurs with the vector potential A if the condition $\delta(T) > \xi_0$ is satisfied.

Both requirements can be expressed in the form of a single relation. For this purpose we use the fact that $\xi_0 \sim \xi(0) \sim \delta_L(0)/x$ and also that $\delta(T) \sim \delta_L(0)|\tau|^{-1/2}$ at $|\tau| < 1$. The condition $\delta(T) > \xi_0$ may be written in the form $|\tau|^{1/2} < x$. Thus, the general condition for the validity of the Ginzburg-Landau theory reads

$$1 - \frac{T}{T_c} < \min\left(\chi^2, 1\right). \tag{17.23}$$

*There are indications that in high- T_c ceramics the fluctuation region is relatively large. Specific-heat data show that its width is ~ 2 K, i.e. $|\tau| \sim 0.02$. This could be due to the small correlation length (~ 30Å) or to the relatively large value of T_c/ε_F. Nevertheless this region is not so large as to make G-L theory inapplicable.

Although we have been speaking all the time of pure superconductors, formula (17.23) is also valid for dirty superconductors.

The Ginzburg-Landau theory is much simpler than the complete BCS theory for superconductors in an external field. Nevertheless, its content has proved to be very rich, since it has made it possible to account for all the basic equilibrium properties of superconductors. In spite of the limitation (17.23), it has turned out that GinzburgLandau theory provides a satisfactory quantitative agreement with experiment even at temperatures well below T_c if all the parameters are expressed in reduced units. This is associated with the slowness of the variation of x with temperature [the function $A(T)$ in eq. (16.97) and the function $B(T)$ in eq. (16.101)].

8.3.2 17.2. Surface energy at the interface between the normal and superconducting phases

Below we will demonstrate the solution of several problems using the GinzburgLandau theory. Consider a case where Ψ and A depend only on a single coordinate,
region. The latter can be seen, for example, from the fact that, according to section 16.7, the relation between the current and the field is nonlocal in the general case and changes to the local theory only in the London region. In the Ginzburg-Landau theory the relation between the current and the field is local.

As has been said above, the Ginzburg-Landau equations are the exact limit of the BCS theory at $|\tau| < 1$. We will not give the corresponding derivation here because it is cumbersome (see Gor'kov 1959a, b). We note only that the relation that generalizes formula (16.18) for Δ to the inhomogeneous case $\Delta(r)$ (here we are speaking of $T \to T_c$, i.e., small Δ) is a complex integral relation: the right-hand side contains terms of the type

$$\int K(\boldsymbol{r}, \boldsymbol{r}') \Delta(\boldsymbol{r}') \, \mathrm{d}V'$$

$$\int K(\boldsymbol{r}, \boldsymbol{r}', \boldsymbol{r}'', \boldsymbol{r}''') \Delta(\boldsymbol{r}') \Delta(\boldsymbol{r}'') \Delta(\boldsymbol{r}''') \, \mathrm{d}V' \mathrm{d}V'' \mathrm{d}V'''$$

The distances that are important in the kernels of the integrals are of order ξ_0. On the other hand, the distances over which Δ varies are of order $\xi(T) \sim \hbar v/\Delta(T) > \xi_0$ (at $|\tau| < 1$). This makes it possible to consider the variations of $\Delta(r)$ to be slow and to pass from the integral to differential relations. An analogous situation occurs with the vector potential A if the condition $\delta(T) > \xi_0$ is satisfied.

Both requirements can be expressed in the form of a single relation. For this purpose we use the fact that $\xi_0 \sim \xi(0) \sim \delta_L(0)/x$ and also that $\delta(T) \sim \delta_L(0)|\tau|^{-1/2}$ at $|\tau| < 1$. The condition $\delta(T) > \xi_0$ may be written in the form $|\tau|^{1/2} < x$. Thus, the general condition for the validity of the Ginzburg-Landau theory reads

$$1 - \frac{T}{T_c} < \min\left(x^2, 1\right). \tag{17.23}$$

Although we have been speaking all the time of pure superconductors, formula (17.23) is also valid for dirty superconductors.

The Ginzburg-Landau theory is much simpler than the complete BCS theory for superconductors in an external field. Nevertheless, its content has proved to be very rich, since it has made it possible to account for all the basic equilibrium properties of superconductors. In spite of the limitation (17.23), it has turned out that GinzburgLandau theory provides a satisfactory quantitative agreement with experiment even at temperatures well below T_c if all the parameters are expressed in reduced units. This is associated with the slowness of the variation of x with temperature [the function $A(T)$ in eq. (16.97) and the function $B(T)$ in eq. (16.101)].

8.3.3 17.2. Surface energy at the interface between the normal and superconducting phases

Below we will demonstrate the solution of several problems using the GinzburgLandau theory. Consider a case where Ψ and A depend only on a single coordinate,
say x, with A being directed perpendicular to x. Here the general equations (17.6'), (17.7') and (17.8') simplify and take the form

$$\frac{1}{x^2}\frac{\mathrm{d}^2\Psi}{\mathrm{d}x^2} + \Psi\left(1 - A^2\right) - \Psi^3 = 0, \tag{17.24}$$

$$\left.\frac{\mathrm{d}\Psi}{\mathrm{d}x}\right|_{\mathrm{b}} = 0, \tag{17.25}$$

$$\frac{\mathrm{d}^2 A}{\mathrm{d}x^2} - \Psi^2 A = 0 \tag{17.26}$$

(it is easy to see that Ψ may be taken to be real).
The integrals of eqs. (17.24) and (17.26) are easily evaluated. To this end, we multiply eq. (17.24) by $\mathrm{d}\Psi/\mathrm{d}x$ and eq. (17.26) by $\mathrm{d}A/\mathrm{d}x$, add up and integrate over x. With the boundary condition in the bulk of the superconductor being taken into account, we get

$$\frac{1}{x^2}\left(\frac{\mathrm{d}\Psi}{\mathrm{d}x}\right)^2 + \left(\frac{\mathrm{d}A}{\mathrm{d}x}\right)^2 + \Psi^2\left(1 - A^2\right) - \frac{1}{2}\Psi^4 = \text{ const. } = \frac{1}{2} \tag{17.27}$$

(the value of the constant is taken from the boundary conditions 17.28).
Let us find the surface energy between the normal and superconducting phases (Ginzburg and Landau 1950). Suppose that as $x \to \infty$ there is a superconducting phase and for $x \to -\infty$ there is a normal phase. We assume that $\boldsymbol{H} \| z, \boldsymbol{A} \| y$ and $H = \mathrm{d}A/\mathrm{d}x$. Then we have the following boundary conditions:

$$\begin{array}{lllll} x \to \infty: & \Psi = 1, & H = A = 0, & \frac{\mathrm{d}\Psi}{\mathrm{d}x} = 0, \\ x \to -\infty: & \Psi = 0, & H = H_0 = \frac{1}{\sqrt{2}}, & \frac{\mathrm{d}\Psi}{\mathrm{d}x} = 0 \end{array} \tag{17.28}$$

(in conventional units $\Psi = 1$ corresponds to Ψ_0 and $H_0 = 1/\sqrt{2}$ corresponds to H_{cm}). Since eqs. (17.24), (17.25) and (17.26) are not integrable in the general case, we will consider the limiting case $x < 1$.

This case corresponds to $\xi \gg \delta$ and is shown in fig. 105. Obviously, the major part of the surface energy arises from the region in which H and A are small. Assuming that $A = H = 0$ in eq. (17.27), we obtain

$$\frac{\mathrm{d}\Psi}{\mathrm{d}x} = \frac{x}{\sqrt{2}}\left(1 - \Psi^2\right). \tag{17.29}$$

The solution of this equation that satisfies the boundary condition $\Psi = 1$ for $x \to \infty$ and decreases towards diminishing x is

$$\Psi = \tanh\left(\frac{xx}{\sqrt{2}}\right). \tag{17.30}$$

Of course, we have to take into account that such a solution becomes incorrect in the region where the field penetrates, but this region makes a small contribution to surface energy. For convenience, we have chosen the origin at point $x = 0$, where $\Psi \approx 0$ (the boundary A in fig. 105).

Consider now the formula for the free energy difference (17.30). The integrand vanishes as $x \to \infty$ and also with $x \to -\infty$. A contribution comes only from the transition region. It is this region that corresponds to the excess energy associated with the boundary, i.e., σ_{ns} . Substituting into eq. (17.20) $H_0 = 1/\sqrt{2}, H = 0$ and Ψ according to (17.30), we obtain

$$\begin{aligned}
\sigma_{\text{ns}} &= \frac{H_{\text{cm}}^2}{8\pi} \int_0^\infty \left(1 - \Psi^4\right) \mathrm{d}x \\
&= \frac{H_{\text{cm}}^2}{8\pi} \int_0^\infty \left(1 - \tanh^4\left(\frac{xx}{\sqrt{2}}\right)\right) \mathrm{d}x \\
&= \frac{H_{\text{cm}}^2}{8\pi} \int_0^\infty \cosh^{-2}\left(\frac{xx}{\sqrt{2}}\right)\left(1 + \tanh^2\left(\frac{xx}{\sqrt{2}}\right)\right) \mathrm{d}x \\
&= \frac{H_{\text{cm}}^2}{8\pi} \frac{4\sqrt{2}}{3x}.
\end{aligned} \tag{17.31}$$

The lower limit of the integral over x is chosen where Ψ becomes small and the field begins to penetrate, i.e., $x = 0$. In conventional units we have

$$\delta_{\text{ns}} = \frac{H_{\text{cm}}^2}{8\pi} \frac{4\sqrt{2}\delta}{3x}. \tag{17.32}$$

For $x \geqslant 1$ the calculation of σ_{ns} is possible only by a numerical method. It turns out that σ_{ns} vanishes at $x = 1/\sqrt{2}$, and becomes negative at larger values of x. Since this contradicted the superconductivity picture known by the time the GinzburgLandau theory was developed (1950), this case was not considered. The experimental data on the size of the layers in the intermediate state (section 15.3) make it possible to determine x. For pure superconductors the values of x obtained are small: 0.16 for mercury, 0.15 for tin, and 0.026 for aluminum*.

Since the vanishing of σ_{ns} at $x = 1/\sqrt{2}$ is important, we shall give here a rigorous proof (Lifshitz and Pitaevskii 1978). Consider the complete free-energy expression (17.20) at $H_0 = H_{\text{cm}}$, or in reduced units $H_0 = 1/\sqrt{2}$. Evidently, the integrand and, hence, the whole integral turns to zero at

$$H = \frac{\mathrm{d}A}{\mathrm{d}x} = \frac{1 - \Psi^2}{\sqrt{2}}.$$

Substituting this expression into eq. (17.26), we find

$$\frac{\mathrm{d}\Psi}{\mathrm{d}x} = -\frac{A\Psi}{\sqrt{2}}.$$

It is easy to see that these formulae satisfy eq. (17.27) at $x = 1/\sqrt{2}$.

8.3.4 17.3. The critical field and magnetization of a thin film. Supercooling and superheating

Since $x < 1$ for many pure superconductors, it will be reasonable to solve the problems in this approximation, which considerably facilitates calculations. We shall consider the question

- It is easier to determine x experimentally from the supercooling field (section 18.4), though, strictly speaking, there is a risk of obtaining overestimated values of x.

of the properties of a thin superconducting film placed in a parallel magnetic field H_0 (Ginzburg and Landau 1950, Ginzburg 1952). Suppose $H \| z$ and the film occupies a volume $-\frac{1}{2}d < x < \frac{1}{2}d$. Equation (17.24) is rewritten in the form

$$\frac{\mathrm{d}^2\Psi}{\mathrm{d}x^2} = \varkappa^2\Psi\left(A^2 - 1 + \Psi^2\right). \tag{17.33}$$

At $x \ll 1$ in the zeroth approximation we neglect the right-hand side. As a result, we have (with eq. 17.25 taken into account):

$$\frac{\mathrm{d}^2\Psi}{\mathrm{d}x^2} = 0 \quad \text{and} \quad \left.\frac{\mathrm{d}\Psi}{\mathrm{d}x}\right|_{x=\pm\frac{1}{2}d} = 0.$$

This gives

$$\Psi = \text{ const.} \tag{17.34}$$

Substituting this, as yet unknown, constant into eq. (17.26) and using $H = \mathrm{d}A/\mathrm{d}x$ and the boundary condition $H\left(\pm\frac{1}{2}d\right) = H_0$, we get

$$H = H_0\frac{\cosh(\Psi x)}{\cosh\left(\frac{1}{2}\Psi d\right)} \tag{17.35}$$

$$A = \frac{H_0}{\Psi}\frac{\sinh(\Psi x)}{\cosh\left(\frac{1}{2}\Psi d\right)} \tag{17.36}$$

Let us consider eq. (17.33) in the next approximation. Substituting $\Psi + \Psi_1$ into it, we have

$$\frac{\mathrm{d}^2\Psi_1}{\mathrm{d}x^2} = \chi^2\Psi\left(A^2 - 1 + \Psi^2\right).$$

For this inhomogeneous equation to have a solution, it is necessary that the righthand side be orthogonal to the solution of a homogeneous equation with correct boundary conditions; such a solution is $\Psi_1 = \text{const}$. Hence,

$$\int_{-\frac{1}{2}d}^{\frac{1}{2}d}\left(A^2 - 1 + \Psi^2\right)\mathrm{d}x = 0 \tag{17.37}$$

whence we find the relation between Ψ and H_0 :

$$H_0^2 = \frac{2\Psi^2\left(1-\Psi^2\right)\cosh^2\left(\frac{1}{2}\Psi d\right)}{(\sinh(\Psi d)/\Psi d) - 1} \tag{17.38}$$

This relation is valid at any H_0 and gives an implicit expression for Ψ in terms of $\boldsymbol{H}_0$. From this we can find the magnetization of the film (in units of $\boldsymbol{H}_{\mathrm{cm}}\sqrt{2}$):

$$\begin{aligned} 4\pi M = B - H_0 &= \frac{1}{d}\int_{-\frac{1}{2}d}^{\frac{1}{2}d} H\ \mathrm{d}x - H_0 \\ &= -H_0\left[1 - \frac{\tanh\left(\frac{1}{2}(\Psi d)\right)}{\frac{1}{2}\Psi d}\right]. \end{aligned} \tag{17.39}$$

At $\Psi d > 1, 4\pi M = -H_0$, which corresponds to the Meissner effect - the nonpenetration of the field into the superconductor. If $\Psi d < 1$, then from (17.39) and (17.38) we find

$$4\pi M \approx -\frac{1}{12} H_0 \, \mathrm{d}^2\Psi^2, \quad H_0^2 \approx \frac{12\,(1-\Psi^2)}{d^2}, \tag{17.40}$$

from which we obtain

$$4\pi M \approx -\frac{1}{12} H_0 d^2 \left(1 - \frac{H_0^2 d^2}{12}\right). \tag{17.41}$$

For further applications we will find the free-energy difference for the superconducting and normal states in a given external field H_0 and a given $\Psi = \text{const}$. without using the equation for Ψ and relation (17.38) which follows from it. This means that we are dealing with a nonequilibrium state characterized by some constant Ψ. Adding $-\mathrm{H}_0\ \mathrm{B}/4\pi + \mathrm{H}_0^2/8\pi$ to (17.19) and passing to the reduced quantities, we obtain

$$\int_{-\frac{1}{2}d}^{\frac{1}{2}d} (\Omega_{\mathrm{sH}} - \Omega_{\mathrm{nH}})\, \mathrm{d}x = \frac{H_{\mathrm{cm}}^2}{4\pi} \int_{-\frac{1}{2}d}^{\frac{1}{2}d} \left[-\Psi^2 + \frac{1}{2}\Psi^4 + (H - H_0)^2 + A^2\Psi^2\right] \mathrm{d}x. \tag{17.42}$$

Note that the minimization of this expression with respect to Ψ^2 leads to the condition (17.38) and substitution of this condition into (17.42) gives the equilibrium formula (17.20).

Let us substitute the formulae for H and A, (17:35) and (17.36), into (17.42). This yields

$$\begin{aligned} &\int_{-\frac{1}{2}d}^{\frac{1}{2}d} (\Omega_{\mathrm{sH}} - \Omega_{\mathrm{nH}}) \frac{\mathrm{d}x}{(H_{\mathrm{cm}}^2/4\pi)\, d} \\ &\quad = H_0^2 \left(1 - \frac{\tanh\left(\frac{1}{2}\Psi d\right)}{\frac{1}{2}\Psi d}\right) - \Psi^2 + \frac{1}{2}\Psi^4. \end{aligned} \tag{17.43}$$

In a field equal to the critical field H_c this expression must be equal to zero. Hence,

$$H_{\mathrm{c}}^2 = \frac{\Psi^2\,(2-\Psi^2)}{2\left(1 - \frac{\tanh\frac{1}{2}\Psi d}{\frac{1}{2}\Psi d}\right)}. \tag{17.44}$$

Formulae (17.38) and (17.39) give the dependence of H_{c} on the film thickness.

Consider the limiting cases. If the film thickness is large, then at the transition point Ψ is close to unity. We put $\Psi = 1 - \varphi$, where $\varphi < 1$. Substituting this into (17.38) yields

$$\varphi \approx \frac{H_0^2}{2d}$$

that is, really $\varphi < 1$. Inserting $\Psi = 1 - \varphi$ into (17.44), we find that

$$H_{\mathrm{c}}^2 \approx \frac{(1-2\varphi)(1+2\varphi)}{2(1-2/d)} \approx \frac{1}{2}\left(1 + \frac{2}{d}\right)$$

Hence,

$$H_{\mathrm{c}} \approx \frac{1}{\sqrt{2}}\left(1 + \frac{1}{d}\right) \tag{17.45}$$

or, in conventional units,

$$H_{\mathrm{c}} \approx H_{\mathrm{cm}}\left(1 + \frac{\delta}{d}\right) \tag{17.46}$$

For a thin film we have already the expansion of formulae (17.38) in d - this is expression (17.40). From (17.44) at $d \ll 1$ we have

$$H_c^2 \approx \frac{6\,(2-\Psi^2)}{d^2} \tag{17.47}$$

Comparing with (17.40), we obtain at the transition point:

$$\Psi = 0, \quad H_c = \frac{2\sqrt{3}}{d} \tag{17.48}$$

or, in conventional units,

$$H_{\rm c} = 2\sqrt{6} H_{\rm cm} \frac{\delta}{d} \tag{17.48'}$$

Thus, while for $d \gg 1$ the transition to the normal state with $\Psi = 0$ occurs from the state with $\Psi \approx 1$ which means a first-order transition for $d < 1$ upon approach to the transition point $\Psi \to 0$, i.e., this is a second-order transition. Here H_c increases with decreasing thickness according to the law $H_c \propto d^{-1}$. The complete plot of $H_{\rm c}/H_{\rm cm}$ against δ/d is given in fig. 108.

Thus, at a certain film thickness the first-order phase transition changes to a second-order phase transition. In order to find out how this occurs, we return to the nonequilibrium formula (17.43). The graph of the function on the right-hand side (we denote it by Ω) versus Ψ^2 at various H_0 is shown in fig. 109, where (a) corresponds to $d/\delta = 4$ and (b) to $d/\delta = 1.6$. From these graphs it is seen that with small thickness Ω has one minimum, which corresponds to $\Psi \neq 0$ for low fields

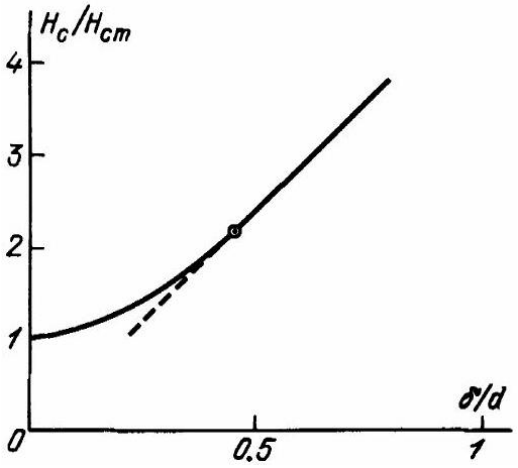

Fig. 108.

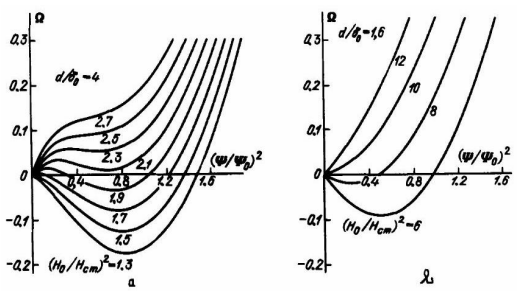

Fig. 109.

and to $\Psi = 0$ for high fields. This is the case of a second-order phase transition. For large film thicknesses in a general case we have two minima, one at $\Psi = 0$ and the other at finite Ψ. The field at which the depths of the minima become equal is just the transition field. This is obviously a first-order phase transition.

The boundary situation between (a) and (b) is the case where both minima merge at the point $\Psi = 0$. Evidently, at this point we have simultaneously $\Psi = 0$, $\mathrm{d}\Omega/\mathrm{d}(\Psi^2) = 0$ and $\mathrm{d}^2\Omega/(\mathrm{d}(\Psi^2))^2 = 0$. From these conditions we obtain

$$d_\mathrm{c} = \sqrt{5} \tag{17.49}$$

or, in conventional units,

$$d_\mathrm{c} = \sqrt{5}\delta \tag{17.49'}$$

(the circle in fig. 108).

In the case of a first-order phase transition, the lower of the two minima corresponds to the equilibrium state, and the higher-lying minimum corresponds to a metastable state. Indeed, a slight deviation of Ψ^2 from the value in the minimum
brings about an increase in free energy. When the magnetic field is changed, the metastable phase persists until the high minimum disappears. The result is that a hysteresis may be observed in an investigation of the transition in increasing and decreasing fields. The occurrence of hysteresis is the simplest way for identifying a first-order transition.

The limiting fields of the retardation of metastable phases are called the supercooling field (retardation of the normal phase) and the superheating field (retardation of the superconducting phase). The superheating field is difficult to observe because at the edges of the specimen there always occurs a concentration of the field lines of force, i.e., an increase in the field strength. Hence, the edges may serve as nucleation sites for the normal phase. It is much easier to observe the supercooling field. The disappearance of the minimum at $\Psi = 0$ occurs at $\mathrm{d}\Omega/\mathrm{d}(\Psi^2) = 0$. As has been pointed out, this condition gives formula (17.38). Substituting $\Psi = 0$ into it leads to

$$H_0 = H_{\mathrm{c}2} = \frac{2\sqrt{3}}{d}, \tag{17.50}$$

which coincides with (17.48). Hence, the critical field formula for a thickness $d < d_\mathrm{c}$ also determines the supercooling field for a thickness $d > d_\mathrm{c}$ (the dashed line in fig. 108).

In fact, this conclusion is valid only for not-too-large film thicknesses. The point is that it has been derived from the formula for the nonequilibrium free energy (17.43) obtained under the assumption $\Psi = \mathrm{const}$. At the same time it is clear that in a bulk specimen the minimal nucleus of the superconducting phase will be localized in a certain region of space, i.e., we shall have $\Psi(r) \neq \mathrm{const}$. (this will be shown in sections 18.2 and 18.4). The assumption of $\Psi = \mathrm{const}$. is evidently valid at $d < \xi$ or, in our units, $d < x^{-1}$, i.e., at $x < 1$ up to thicknesses much larger than d_c. At thicknesses $d \gg \xi$ the supercooling field coincides with the field $H_{\mathrm{c}3}$ (section 18.4.).

The experimental determination of magnetic properties of thin superconducting plates is carried out on films prepared by evaporation of drops of a molten metal on a dielectric substrate. Of course, in such a case it is rather difficult to control the film thickness. In view of this, use may be made of the fact that all the theoretical formulas contain the ratio d/δ, where δ is expressed by formula (18.93), i.e., it increases when the temperature approaches T_c. This makes it possible to use a single film instead of many films, and to carry out measurements at various temperatures. The reduced length that appears in the formulas will then be expressed, according to (16.93), by the following formula:

$$d_{\text{red}} = \frac{\mathrm{d}}{\delta_{\text{L}}(0)} \left[\frac{2\,(T_{\text{c}} - T)}{T_{\text{c}}}\right]^{1/2}.$$

The results of measurements on films deposited by sputtering onto the substrate at room temperature (Zavaritskii 1951) have confirmed the Ginzburg-Landau theory.

8.3.5 17.4. The critical current of a thin wire with $x \ll 1$

We will now consider another problem of the Ginzburg-Landau theory - the critical current of a thin cylindrical wire of radius R^*. According to the Maxwell equation, we have (see eq. 15.23):

$$H_J = \frac{2J}{cR}. \tag{17.51}$$

Hence, the specification of the total current is equivalent to specifying the field at the interface. We introduce cylindrical coordinates: ρ, φ, and z. Since the current flows along z, the field $\boldsymbol{H}$ has only the component $\boldsymbol{H}_\varphi$. We choose the vector potential A along the z axis. Then, from the general equations (17.6'), (17.7') and (17.8') we obtain

$$\frac{\mathrm{d}^2\Psi}{\mathrm{d}\rho^2} = \chi^2\left(A^2 - 1 + \Psi^2\right)\Psi, \tag{17.52}$$

$$\left.\frac{\mathrm{d}\Psi}{\mathrm{d}\rho}\right|_{\rho=R} = 0, \tag{17.53}$$

$$\frac{\mathrm{d}^2 A}{\mathrm{d}\rho^2} + \frac{1}{\rho}\frac{\mathrm{d}A}{\mathrm{d}\rho} - \Psi^2 A = 0, \tag{17.54}$$

$$H = -\frac{\mathrm{d}A}{\mathrm{d}\rho}. \tag{17.55}$$

From eqs. (17.52) and (17.53) it follows that in a first approximation with respect to $x < 1$ we have $\Psi = \text{const}$. Substituting this into eq. (17.54), we find that A is proportional to $I_0(\Psi\rho)$, where I_0 is the Bessel function of imaginary argument. According to (17.55), $H(\rho)$ is proportional to $I_1(\Psi\rho)$; due to the boundary condition we have

$$H = \frac{H_J I_1(\Psi\rho)}{I_1(\Psi R)} \tag{17.56}$$

$$A = -\frac{H_J}{\Psi}\frac{I_0(\Psi\rho)}{I_1(\Psi R)} \tag{17.57}$$

The solvability condition of the equation for the correction to Ψ is analogous to (17.37):

$$\int_0^R \left(A^2 - 1 + \Psi^2\right)\rho\mathrm{d}\rho = 0$$

- In their original work, Ginzburg and Landau (1950) considered a thin film and assumed that the current density varies only in the transverse direction and that along the film width the current is uniform. This does not correspond to reality because the current is redistributed over the film and becomes nonuniform in two directions. It is for this reason that we consider a cylinder with a current.

8.3.6 17.4. The critical current of a thin wire with $x \ll 1$

We will now consider another problem of the Ginzburg-Landau theory - the critical current of a thin cylindrical wire of radius R^*. According to the Maxwell equation, we have (see eq. 15.23):

$$H_J = \frac{2J}{cR}. \tag{17.51}$$

Hence, the specification of the total current is equivalent to specifying the field at the interface. We introduce cylindrical coordinates: ρ, φ, and z. Since the current flows along z, the field $\boldsymbol{H}$ has only the component $\boldsymbol{H}_\varphi$. We choose the vector potential A along the z axis. Then, from the general equations (17.6'), (17.7') and (17.8') we obtain

$$\frac{\mathrm{d}^2\Psi}{\mathrm{d}\rho^2} = \varkappa^2 \left(A^2 - 1 + \Psi^2\right)\Psi, \tag{17.52}$$

$$\left.\frac{\mathrm{d}\Psi}{\mathrm{d}\rho}\right|_{\rho=R} = 0, \tag{17.53}$$

$$\frac{\mathrm{d}^2 A}{\mathrm{d}\rho^2} + \frac{1}{\rho}\frac{\mathrm{d}A}{\mathrm{d}\rho} - \Psi^2 A = 0, \tag{17.54}$$

$$H = -\frac{\mathrm{d}A}{\mathrm{d}\rho}. \tag{17.55}$$

From eqs. (17.52) and (17.53) it follows that in a first approximation with respect to $x < 1$ we have $\Psi = \text{const}$. Substituting this into eq. (17.54), we find that A is proportional to $I_0(\Psi\rho)$, where I_0 is the Bessel function of imaginary argument. According to (17.55), $H(\rho)$ is proportional to $I_1(\Psi\rho)$; due to the boundary condition we have

$$H = \frac{H_J I_1(\Psi\rho)}{I_1(\Psi R)} \tag{17.56}$$

$$A = -\frac{H_J}{\Psi}\frac{I_0(\Psi\rho)}{I_1(\Psi R)} \tag{17.57}$$

The solvability condition of the equation for the correction to Ψ is analogous to (17.37):

$$\int_0^R \left(A^2 - 1 + \Psi^2\right)\rho \mathrm{d}\rho = 0$$

From this we get

$$H_J^2 = \frac{\Psi^2\left(1 - \Psi^2\right) I_1(\Psi R)}{I_0^2(\Psi R) - I_1^2(\Psi R)}. \tag{17.58}$$

We begin with the case $R < 1$. Assuming that $\Psi \leq 1$, we expand the right-hand side of (17.58) in R :

- In their original work, Ginzburg and Landau (1950) considered a thin film and assumed that the current density varies only in the transverse direction and that along the film width the current is uniform. This does not correspond to reality because the current is redistributed over the film and becomes nonuniform in two directions. It is for this reason that we consider a cylinder with a current.

$$H_J^2 \approx \frac{1}{4}\Psi^4\left(1-\Psi^2\right)R^2 \tag{17.59}$$

Evidently, the value of H_J is small at $R < 1$, i.e., superconductivity cannot be destroyed due to H_J becoming equal to $H_{\rm cm}$ (in conventional units), as in the case of a bulk specimen according to Silsbee's rule (section 15.4). The mechanism of destruction of superconductivity is different here. If we consider H_J^2 (17.59) as a function of Ψ^2, then we shall see that it vanishes at $\Psi = 0$ and $\Psi = 1$, and has a maximum in between. Hence, there is a certain maximum value of H_J which is compatible with superconductivity; at larger values of H_J superconductivity cannot exist. What happens at such large currents will be discussed in section 22.9. Here we will find the maximum of H_J.

Differentiating with respect to Ψ^2, we obtain for the maximum point:

$$\Psi^2 = \frac{2}{3}, \quad H_{J,\max} = \frac{R}{3^{3/2}}. \tag{17.60}$$

Passing to conventional units and using formula (17.51), we obtain the value of the critical current:

$$J_{\rm c} = \frac{{\rm c}R^2}{3\sqrt{6}}\frac{H_{\rm cm}}{\delta}. \tag{17.61}$$

Since $J_c \propto R^2$, it is reasonable to introduce the critical current density:

$$j_{\rm c} = \frac{J_{\rm c}}{\pi R^2} = \frac{1}{3\pi\sqrt{6}}\frac{cH_{\rm cm}}{\delta}. \tag{17.62}$$

The quantity $\boldsymbol{j_{\rm c}}$ is independent of size and is a characteristic of the superconducting metal.

The physical significance of this quantity can be understood if we substitute the BCS expressions for δ and $H_{\rm cm}$. Then we obtain

$$j_{\rm c} = \frac{1}{3\sqrt{2}}\frac{n_{\rm s}{\rm e}\Delta(T)}{p_0} \tag{17.63}$$

[here we have introduced $\Delta(T)$ in accordance with eq. (17.33) and $n_{\rm s}$ according to eq. (16.92)]. From this formula it follows that $j_{\rm c}$ corresponds to the motion of electrons with a velocity of the order of $\Delta(T)/p_0$. Thus, we conclude that Cooper pairing and, hence, superconductivity exists until the pairs begin to move at a velocity larger than Δ/p_0. This occurs not only near $T_{\rm c}$ but also at any temperature and is consistent with the Landau criterion (16.1).

It should be noted that the critical current density (17.62) is very large. If we substitute typical values for pure superconductors, $H_{\rm cm} \sim 10^2 - 10^3{\rm Oe}, \delta \sim 10^{-5} - 10^{-6}$ cm, we obtain:

$$j_c \sim 10^7 - 10^9 \ {\rm A/cm^2}. \tag{17.64}$$

For large thicknesses, $R > 1$, we obtain from formula (17.58):

$$H_J^2 \approx \Psi^3\left(1-\Psi^2\right)R.$$

At the maximum value of H_J^2 we have $\Psi^2 = \frac{3}{5}$ and

$$H_{J,\max} \approx 3^{3/4}2^{1/2}5^{-5/4}R^{1/2}.$$

Passing to conventional units and expressing J_c, we find

$$J_{\rm c} \approx 3^{3/4}5^{-5/4}cH_{\rm cm}R^{3/2}\delta^{-1/2}. \tag{17.65}$$

The complete curve of H_J^2 versus R in reduced units is shown in fig. 110 (curve 1).
The above-described mechanism of superconductivity destruction by the current occurs only as long as the radius of the cylinder is not too large. According to formula (17.59), the magnetic field of the current is of order $\boldsymbol{H}_{\rm cm}$ at $\boldsymbol{R} \sim \boldsymbol{\delta}$. Here the destruction of superconductivity by the magnetic field is possible according to Silsbee's rule. If the sample were massive, an intermediate state would arise (see section 15.4). However, in the intermediate state the sample must consist of layers of the normal and superconducting phases, i.e., the order parameter must vary in space. This is possible only at distances of order $\xi \sim \delta/x > \delta$. Thus, there exists a whole region of thicknesses from δ to ξ (or in reduced units from 1 to x^{-1}) at which neither the superconducting state nor the normal state (the field in the middle of the film is weaker than $\boldsymbol{H}_{\rm cm}$) nor the intermediate state can be realized at first sight.

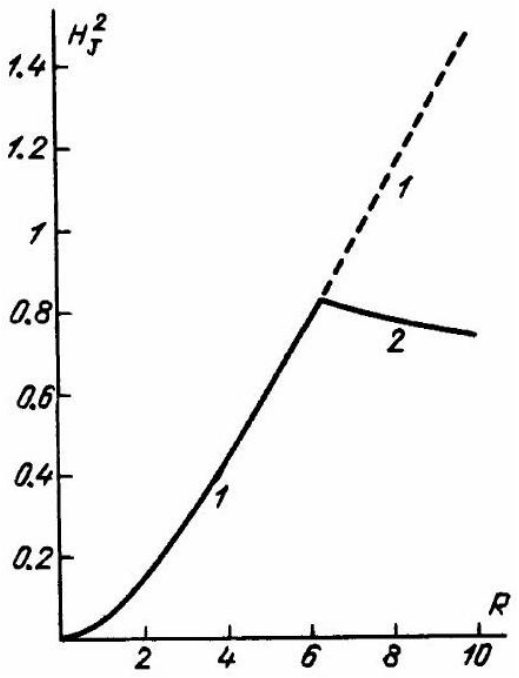

Fig. 110.

This means, in fact, that at a certain thickness a discontinuous transition occurs from the superconducting to the normal state. Strictly speaking, such a transition cannot be treated as a phase equilibrium because in the normal state energy is dissipated in the presence of a current, and the state is not an equilibrium state. However, because of the high conductivity of the metal the departure from equilibrium is very small. For the same reason the electric field is always small compared to the magnetic field. This enables one to consider the transition of the wire with a current as a first-order phase transition and to take into account the magnetic field alone.

In this particular case, the condition for the transition is the equality of the energies in a given field since the specification of the total current is equivalent to the specification of the field at the interface. Since the field is inhomogeneous in the normal phase too, we cannot use formula (17.20) and we have to find $\Omega_{{\rm s}H}$ and $\Omega_{{\rm n}H}$ with an appropriate distribution of H. From eq. (17.19) we have

$$\int \Omega_{\mathrm{sH}}\, \mathrm{d}V = \int \Omega_{\mathrm{n}}^{(0)} \mathrm{d}V + \frac{1}{2} H_{\mathrm{cm}}^2 \int_0^R \left(H^2 - \frac{1}{2}\Psi^4 - 2HH_J \right) \rho \mathrm{d}\rho, \tag{17.66}$$

$$\int \Omega_{\mathrm{nH}}\, \mathrm{d}V = \int \Omega_{\mathrm{n}}^{(0)} \mathrm{d}V + \frac{1}{2} H_{\mathrm{cm}}^2 \int_0^R \left(H^2 - 2HH_J \right) \rho \mathrm{d}\rho. \tag{17.67}$$

For a superconductor formula (17.56) must be substituted as $\boldsymbol{H}(\boldsymbol{\rho})$. For a normal metal we have $j = \text{const.} = J/\left(\pi R^2\right)$;

$$H = \frac{2J(\rho)}{c\rho} = \frac{2j\pi\rho^2}{c\rho} = \frac{2J\rho}{cR^2} = \frac{H_J \rho}{R} \tag{17.68}$$

(the last expression is also valid in reduced units).
Let us consider in more detail the case $R \gg 1$. Using the asymptotics of the functions I_ν at $z \gg 1$,

$$I_\nu(z) \approx \frac{1}{(2\pi z)^{1/2}} \mathrm{e}^z \left(1 - \frac{1}{2z} \left(\nu^2 - \frac{1}{4} \right) \right), \tag{17.69}$$

we find from eqs. (17.58) and (17.56)

$$\Psi \approx 1 - O\left(R^{-1}\right) \tag{17.70}$$

$$H \approx H_J \left(\frac{R}{\rho} \right)^{1/2} \mathrm{e}^{\rho - R}. \tag{17.71}$$

From this it follows that in the superconducting phase H is different from zero only in a layer of order δ, i.e., to within terms of order R^{-1} we may replace the integrand in (17.66) by $-\frac{1}{2}\Psi^4 \approx -\frac{1}{2}$. Calculating $\Omega_{\mathrm{n}H}$ with H (17.68) and using the condition $\Omega_{\mathrm{n}H} = \Omega_{\mathrm{s}H}$, we obtain $H_{J\mathrm{c}} = \sqrt{\frac{3}{5}}$ or, in conventional units,

$$H_{Jc} = \sqrt{\frac{6}{5}} \mathrm{H}_{\mathrm{cm}}. \tag{17.72}$$

As should be expected, $H_{J\mathrm{c}}$ is somewhat larger than H_{cm} since the field in the normal state varies from 0 to $H_{J\mathrm{c}}$ at the surface. However, this difference is only 10%. Since H_J is proportional to J, then from eq. (17.68) we obtain

$$J_c = J_{\text{Silsbee}} \sqrt{\frac{6}{5}}. \tag{17.73}$$

In the case $R \sim 1$, it is impossible to express $H_{J\mathrm{c}}$ in analytical form. The corresponding curve (2) is given in fig. 110. The intersection of curves 1 and 2 occurs at a rather large value of $R (R = 6.24)$. In this region J_{c} is well described by the asymptotics (17.65) on the left of the point of intersection. Note that continuation of curve 2 beyond the point of intersection to the left is meaningless since $\boldsymbol{H}_{\mathrm{J,max}}$ corresponds to the maximum field compatible with superconductivity.

Just as in any first-order phase transition, hysteresis is likely to occur. As the current increases the transition may be retarded up to the stability limit of the metastable superconducting state corresponding to the maximum of the field H_J (17.58) (curve 1 in fig. 110). When the current decreases, the transition may probably be retarded until $J = 0$.

Note that all the reasonings given in the present section are valid as long as $R \ll \xi$ ($R < x^{-1}$ in reduced units). At larger thicknesses an intermediate state is formed.

8.3.7 17.5. Quantization of the magnetic flux

Let us now consider a hollow cylinder or, to put it differently, a tube with wall thickness larger than δ. Suppose this cylinder is placed in an external longitudinal magnetic field weaker than the critical field ($H < H_{c1}$ in the case of a type II superconductor, ch. 18). Imagine that the external field varies with time. We have not considered the extension of the Ginzburg-Landau equations to nonstationary problems, but for our purposes it will suffice to use the London equation (17.36). We integrate this equation along a closed path, lying entirely within the superconductor and surrounding the cavity in the cylinder. Here we obtain

$$\frac{\partial}{\partial t}\oint \Lambda j \ \mathrm{d}l = \oint E \ \mathrm{d}l = \int \mathrm{d}S \,\mathrm{rot}\, E = -\frac{1}{c}\int \ \mathrm{d}S\frac{\partial H}{\partial t}$$

(we have used the Maxwell equation here). Hence,

$$\oint \Lambda j \ \mathrm{d}l + \frac{1}{\mathrm{c}}\int H \ \mathrm{d}S = \ \mathrm{const} \ .$$

Since the current can flow only in a surface layer, then along the closed path lying in the bulk of the superconductor $\boldsymbol{j} = 0$. Consequently,

$$\Phi = \int H \ \mathrm{d}S = \ \mathrm{const} \tag{17.74}$$

Thus, we have come to the conclusion that the magnetic flux through a loop lying within the superconductor cannot vary with time.

Note that this conclusion is valid not only for the problem of a hollow cylinder under consideration but also for an inhomogeneous superconductor, whose different portions have different critical parameters. In such a specimen multiply connected superconducting regions may form enclosing normal regions, as a result of which a phenomenon known as "trapped magnetic flux" arises with decreasing magnetic field.

Let us return, however, to the problem of the tube. We will now show that the magnitude of the magnetic flux trapped by the superconducting tube cannot be arbitrary. For this purpose we consider the expression for the superconducting current (17.9). We write the function Ψ in the form $\Psi = |\Psi|e^{ix}$, i.e., we introduce the modulus and the phase. The current is then written in the form

$$j = \frac{\hbar e}{m}|\Psi|^2\left(\nabla\chi - \frac{2e}{\hbar c}A\right) \tag{17.75}$$

We divide j by $|\Psi|^2$ and integrate along the same loop as before, i.e., along a closed path, which encloses the hole and passes in the bulk of the tube wall. Here we obtain

$$\oint \frac{j}{|\Psi|^2} \ \mathrm{d}l = \frac{\hbar e}{m}\left(\oint \nabla\chi \ \mathrm{d}l - \frac{2e}{\hbar c}\oint A \ \mathrm{d}l\right). \tag{/}$$

If the loop passes inside the wall, then $\boldsymbol{j} = 0$ on it. The second integral on the right-hand side is equal to

$$\oint A \ \mathrm{d}l = \int \mathrm{rot}\, A \ \mathrm{d}S = \int H \ \mathrm{d}S = \Phi.$$

As for the first integral, at first glance it must be equal to zero, just as any integral of the gradient of a function along a closed loop. However, in fact, this is not necessarily the case. For the function $\Psi = |\Psi|\mathrm{e}^{\mathrm{i}\chi}$ to be single-valued it is not required that the phase of χ return to the same value when we make a complete turn around the loop; it is sufficient only that it varies by $2\pi n$, where n is an integer. Thus, in a general case $\oint \nabla\chi \mathrm{d}l = 2\pi n$. We obtain

$$\Phi = n\Phi_0 \tag{17.76}$$

$$\Phi_0 = \pi\frac{\hbar c}{e} = 2.07 \times 10^{-7}\text{Oe}\cdot\ \text{cm}^2 \tag{17.77}$$

Thus, the magnetic field passing through the loop may take only a discrete series of values. This phenomenon is called magnetic flux quantization, and the quantity Φ_0 is known as the flux quantum.

The phenomenon of flux quantization in a superconductor was first predicted by F. London (1950). However, being unaware of Cooper pairing, London assumed the charge of the carriers to be equal to e instead of $2e$, and obtained a flux quantum equal to $2\Phi_0$. Recall that a flux quantum also appears in the theory for a normal
metal. In a metal placed in a magnetic field, the electrons move along spiral trajectories (in the case of a closed Fermi surface); these trajectories enclose a magnetic flux equal to $n \cdot 2\Phi_0$ (section 10.4). The magnetic flux quantum Φ_0 determines the period of interference oscillations of the resistance of a hollow normal cylinder (section 11.4).

In the case under consideration, the quantized magnetic flux Φ is the sum of the flux passing through the hole and the flux in the surface layer of the superconductor, of thickness δ, which adjoins the cavity. If the radius of the tube is much larger than δ, then the latter may be neglected.

For the experimental determination of the magnitude of the flux through the cavity it is not sufficient to simply vary the external field. According to the condition (17.74) the internal flux will not change in such a case. Therefore, one has to proceed as follows (Doll and Näbauer 1961, Deaver and Fairbank 1961). The superconductor is cooled in a given external field from a temperature above T_c to a certain temperature below T_c. Upon transition to the superconducting state a certain magnetic flux is frozen in it. The magnitude of this flux can be determined from the minimum condition for the free energy difference (17.20):

$$\int (\Omega_{\text{s}H} - \Omega_{\text{n}H})\,\mathrm{d}V$$
$$= \frac{H_\text{cm}^2}{4\pi}\left\{(H_\text{int} - H_0)^2\,\pi R_1^2 + \int_{R_1}^{R_2}\left[(H - H_0)^2 - \frac{1}{2}|\Psi|^4\right] 2\pi\rho\ \mathrm{d}\rho\right\} \tag{17.78}$$

where R_1 and R_2 are the inner and outer radii of the tube; H_int is the field inside the tube. The first term in brackets refers to the cavity, and the second to the superconducting tube. We are to find H_int satisfying the quantization condition (17.76) and corresponding to the minimum of expression (17.78). Since in the second term the dependence on $\boldsymbol{H}_\text{int}$ extends only to the layer of thickness $\boldsymbol{\delta}$, we may neglect it.

The minimization of the first term leads to the following result: a magnetic flux through the core equal to $\Phi_\text{int} = n\Phi_0$, is realized in that interval of the field H_0 in which $\Phi_\text{ext} = H_0\pi R_1^2$ lies within the interval $\left(n - \frac{1}{2}\right)\Phi_0 < \Phi_\text{ext} < \left(n + \frac{1}{2}\right)\Phi_0$. When the boundary of this interval is crossed, the transition to the next n occurs. This situation is shown in fig. 111.

According to the derivation given above, the quantization of magnetic flux is a consequence of the variation of the phase of the order parameter Ψ by $2\pi n$ upon making a complete turn around the closed loop. This behavior of the phase has been demonstrated in a very ingenious experiment (Little and Parks 1962, 1964). Let us take a thin cylindrical superconducting film whose thickness is much less than the penetration depth and apply the magnetic field along the axis of the cylinder. Such a thin film does not practically screen out the magnetic field (its magnetization in the field is equal to zero according to formula 17.40) and, hence, the field inside and outside the film is the same. The radius of the cylinder is assumed to be much

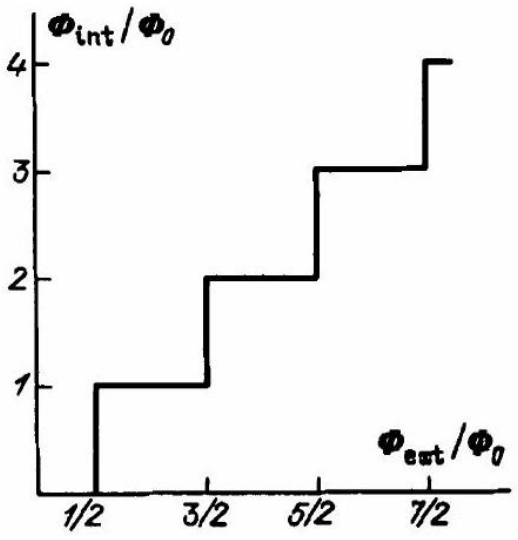

Fig. 111.

larger than the penetration depth. In this case all the quantities, including the vector potential A, do not practically vary along the film thickness.

Let us choose A such that it has only the component A_φ in cylindrical coordinates. We substitute $\Psi = |\Psi|e^{ix}$ into the free energy (17.5). The integrand has the form

$$\Omega_{\rm s} - \Omega_{\rm n}^{(0)} = \alpha\tau|\Psi|^2 + \frac{1}{2}b|\Psi|^4 + \frac{\hbar^2}{4m}\left(\nabla\chi - \frac{2e}{c\hbar}A\right)^2|\Psi|^2 + \frac{H^2}{8\pi} \tag{17.79}$$

(in accordance with the result of section 17.4 it may be assumed that $|\Psi| = \text{const.}$). The combination $\boldsymbol{A} - (c\hbar/2e)\nabla\chi$ is gauge invariant since any gradient added to $\boldsymbol{A}$ may be compensated by the variation of the phase.

Using the fact that $\nabla\chi$ and A are constant along the superconducting film, we write the combination that appears in parentheses in eq. (17.79) in the form of the average value:

$$\begin{aligned}\nabla\chi - \frac{2e}{c\hbar}A &= \frac{1}{2\pi R}\oint\left(\nabla\chi - \frac{2e}{c\hbar}A\right)\mathrm{d}l \\ &= \frac{1}{2\pi R}\left(2\pi n - \frac{2e}{c\hbar}\Phi\right) = \frac{1}{R}\left(n - \frac{\Phi}{\Phi_0}\right)\end{aligned}$$

where the integral is taken over the contour of the cylinder cross section perpendicular to the axis; $\Phi = H\pi R^2$ is the magnetic flux through the cylinder; Φ_0 is the flux quantum. Substituting into eq. (17.79) gives

$$\begin{aligned}\Omega_{\rm s} - \Omega_{\rm n}^{(0)} =& \alpha\tau|\Psi|^2 + \frac{\hbar^2}{2mR^2}\left(n - \frac{\Phi}{\Phi_0}\right)^2|\Psi|^2 \\ &+ \frac{1}{2}b|\Psi|^4 + \frac{H^2}{8\pi}.\end{aligned} \tag{17.80}$$

The number n has to be chosen so as to correspond to the minimum of the free energy, i.e., a given n is realized at

$$n - \frac{1}{2} < \frac{\Phi}{\Phi_0} < n + \frac{1}{2}. \tag{17.81}$$

In the formula (17.80) the second term can be added to the first term with τ being replaced by τ' :

$$\tau' = \tau + \frac{\hbar^2}{4mR^2\alpha}\left(n - \frac{\Phi}{\Phi_0}\right)^2.$$

From the condition $\tau' = 0$ we obtain the variation of the critical temperature:

$$\frac{\Delta T_c}{T_c} = -\frac{\hbar^2}{4mR^2\alpha}\left(\frac{\Phi}{\Phi_0} - n\right)^2. \tag{17.82}$$

Substituting the BCS expression for α from formulae (17.14) and (17.18), we find

$$-\frac{\Delta T_c}{T_c} = \begin{cases} C_1 \frac{\xi_0^2}{R^2}\left(\frac{\Phi}{\Phi_0} - n\right)^2, & \xi_0 < l, \\ C_2 \frac{\xi_0 l}{R^2}\left(\frac{\Phi}{\Phi_0} - n\right)^2, & \xi_0 > l, \end{cases} \tag{17.83}$$

where

$$C_1 = \frac{7\pi^2\zeta(3)}{48\gamma^2} = 0.55, \quad C_2 = \frac{\pi^3}{24\gamma} = 0.72, \quad l = v\tau_{\rm tr}$$

From (17.83) it follows that the dependence of $-\Delta T_c/T_c$ on Φ/Φ_0 consists of periodically recurring parabolic pieces, each of which corresponds to the interval (17.81) with the corresponding n (fig. 112). This prediction is consistent with experiment (Little and Parks 1962, 1964). Note that in the experiment carried out by Little and Parks the superconductor cannot trap the magnetic flux because of its small thickness, which is why no flux quantization occurs; however, the nonuniqueness of the phase is observed and it is the phase that is measured in the experiment.

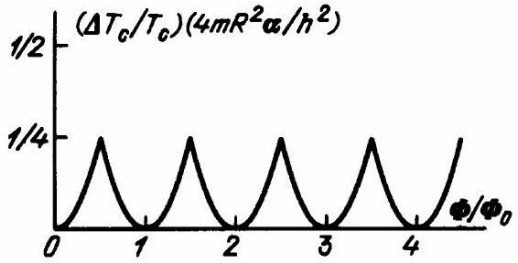

Fig. 112.

The number n has to be chosen so as to correspond to the minimum of the free energy, i.e., a given n is realized at

$$n - \frac{1}{2} < \frac{\Phi}{\Phi_0} < n + \frac{1}{2}. \tag{17.81}$$

In the formula (17.80) the second term can be added to the first term with τ being replaced by τ' :

$$\tau' = \tau + \frac{\hbar^2}{4mR^2\alpha}\left(n - \frac{\Phi}{\Phi_0}\right)^2.$$

From the condition $\tau' = 0$ we obtain the variation of the critical temperature:

$$\frac{\Delta T_c}{T_c} = -\frac{\hbar^2}{4mR^2\alpha}\left(\frac{\Phi}{\Phi_0} - n\right)^2. \tag{17.82}$$

Substituting the BCS expression for α from formulae (17.14) and (17.18), we find.

$$-\frac{\Delta T_c}{T_c} = \begin{cases} C_1 \frac{\xi_0^2}{R^2}\left(\frac{\Phi}{\Phi_0} - n\right)^2, & \xi_0 < l, \\ C_2 \frac{\xi_0 l}{R^2}\left(\frac{\Phi}{\Phi_0} - n\right)^2, & \xi_0 > l, \end{cases} \tag{17.83}$$

where

$$C_1 = \frac{7\pi^2\zeta(3)}{48\gamma^2} = 0.55, \quad C_2 = \frac{\pi^3}{24\gamma} = 0.72, \quad l = v\tau_{\text{tr}}$$

From (17.83) it follows that the dependence of $-\Delta T_c/T_c$ on Φ/Φ_0 consists of periodically recurring parabolic pieces, each of which corresponds to the interval (17.81) with the corresponding n (fig. 112). This prediction is consistent with experiment (Little and Parks 1962, 1964). Note that in the experiment carried out by Little and Parks the superconductor cannot trap the magnetic flux because of its small thickness, which is why no flux quantization occurs; however, the nonuniqueness of the phase is observed and it is the phase that is measured in the experiment.

8.4 18 Type II superconductivity

8.4.1 18.1. Magnetic properties of type II superconductors. The qualitative picture

In this chapter we shall be concerned with the properties of type II superconductors, for which, according to eq. (16.96), $x > 1/\sqrt{2}$ and $\sigma_{\text{ns}} < 0$. First of all, we note that with $\sigma_{\text{ns}} < 0$ a first-order phase transition to the normal state is impossible, even if we are dealing with a superconducting cylinder in a longitudinal field. Indeed, suppose that the superconductor has been divided up into layers of the normal and superconducting phases parallel to the magnetic field. In section 17.4 we have defined the critical field of a thin layer, which was found to be proportional to $H_{\text{cm}}\delta/d$; this may considerably exceed H_{cm}. Hence, it is energetically favorable for such layers to retain superconductivity in fields stronger than $\boldsymbol{H_{\text{cm}}}$. In ordinary type I superconductors the splitting up into layers does not occur because of the surface energy σ_{ns} at the layer boundaries. But if $\sigma_{\text{ns}} < 0$, then nothing will hinder the splitting up of the superconductor into layers of the n - and s -phases.

Thus, the phase transition of a type II superconductor will proceed by way of a gradual expulsion of the superconducting phase, and the metal will become normal at a field in which even an infinitesimal superconducting region can no longer exist. Thus, it may be concluded

that the transition will extend over an interval of magnetic fields, and in this interval the external magnetic field will partially penetrate the superconductor, i.e., the Meissner effect will be incomplete. The superconductor will be in a special state, called the mixed state, which adjoins the superconducting phase at a certain field $H_{\rm cl}$ (the lower critical field) and the normal phase at another field $H_{\rm c2}$ (the upper critical field) (Abrikosov 1957).

The fields $H_{\rm c1}$ and $H_{\rm c2}$ can be determined in order of magnitude from qualitative considerations. We begin with $H_{\rm c2}$, the field at which the superconductivity disappears altogether. The breakup of Cooper pairs occurs as a result of curving of their trajectory in the magnetic field. Evidently, a pair can be preserved as long as the Larmor radius is larger than its size, i.e.,

$$r_{\rm L} \sim \frac{cp_\perp}{eH} > \xi.$$

In this formula $p_\perp$ is the perpendicular component of the momentum corresponding to the motion of the pair as a whole. Therefore, $p_\perp \leqslant p \sim mv_{\rm s}$, where $v_{\rm s}$ is the velocity of the pair. From the Landau criterion (see also formula 17.63) it follows that $v_{\rm s} < \Delta/p_0$, otherwise the pair will break up. The same condition may be written in the form $p_\perp < \hbar/\xi$. Thus, we have

$$\xi < \frac{cp_\perp}{eH} < \frac{ch}{\xi eH}$$

or

$$H < \frac{c\hbar}{e\xi^2} \sim H_{\rm c2} \tag{18.1}$$

The field $\boldsymbol{H}_{\rm c2}$ may be expressed in terms of $\boldsymbol{H}_{\rm cm}$:

$$\begin{aligned} H_{\rm c2} &\sim \frac{c\hbar}{e\xi}\frac{\Delta}{hv} \sim \frac{c}{e\xi v}\frac{H_{\rm cm}\hbar^{3/2}}{(mp_0)^{1/2}} \\ &\sim H_{\rm cm}\frac{\delta_{\rm L}}{\xi} \sim H_{\rm cm}x. \end{aligned} \tag{18.2}$$

We have so far considered a pure superconductor. But if it contains impurities and $l < \xi$, then in formula (18.1) ξ must be replaced by $\xi' \sim (\xi l)^{1/2}$. In this case we obtain

$$H_{c2} \sim \frac{c\hbar}{e\xi l} \sim \frac{c\hbar}{el}\frac{\Delta}{\hbar v} \sim H_{\rm cm}\frac{\delta_{\rm L}}{l} \sim H_{\rm cm}x. \tag{18.3}$$

Thus, in both cases the field $H_{\rm c2}$ is of order $H_{\rm cm}\varkappa$. However, the second case is more important. It follows from eq. (18.3) that by increasing the impurity concentration and, hence, by decreasing the mean free path (i.e. $l \propto n_i^{-1}$), one can strongly increase $\boldsymbol{H}_{\rm c2}$. Up to $\boldsymbol{H}_{\rm c2}$ the metal retains superconducting regions, i.e., a zeroresistance supercurrent can flow in it. The mean free path can, in principle, be decreased down to interatomic distances. Considering that the usual values of $H_{\rm cm} \sim 10^2 - 10^3$Oe and that $\delta_{\rm L} \sim 10^{-5} - 10^{-6}$ cm, we obtain a limiting estimate for the fields $\boldsymbol{H}_{\rm c2}$ (Gor'kov 1963):

$$H_{\rm c2} < 10^3\frac{10^{-5}}{10^{-8}}\text{Oe} \sim 10^6\text{Oe} \tag{18.4}$$

These fields are so high that a question arises: Would not the pairs be broken up earlier due to orientation of the spins of both electrons parallel to the magnetic field? (the Clogston paramagnetic limit; Clogston 1962). The order of magnitude of this limit is evidently determined by the condition

$$\beta H_{\rm cp} \approx 2\Delta, \tag{18.5}$$

where β is the Bohr magneton. Considering that the highest $T_{\rm c}$ value is of the order of 20 K , we obtain

$$H_{\rm cp} < 10^6 {\rm Oe} \tag{18.6}$$

hence, the upper limits for $H_{\rm cp}$ and $H_{\rm c2}$ coincide and the value 10^6Oe may be regarded as limiting.

What happens when the field is decreased below $H_{\rm c2}$? If the field penetrates the superconductor partially, then persistent eddy currents must exist in it. Near the limiting field $H_{\rm c1}$ the metal must be almost completely superconducting, i.e., regions with eddy currents must be rare. The field $H_{\rm c1}$ can be determined if it is taken into account that an elementary vortex is a quantum entity. This was first detected in the study of the superfluidity of liquid helium (Onsager 1949, Feynman 1955).

Suppose that Cooper pairs execute a vortex motion around a certain axis. Let us draw a circular loop around the axis. The velocity of the pairs along this loop is evidently constant. According to the Bohr quantization rule,

$$\oint p \, {\rm d}q = 2m \oint v_{\rm s} \, {\rm d}l = 2m v_{\rm s} \cdot 2\pi\rho = 2\pi n\hbar$$

Hence,

$$v_{\rm s} = n\hbar/(2m\rho),$$

that is, the velocity of the pairs falls off proportionately to the distance from the axis. This inference becomes invalid when $\rho \leqslant \xi$, the size of the pairs. On the other hand, we ignored the fact that the pairs are charged and their motion implies the generation of electric current and a magnetic field. The latter must vanish at a distance of the order of the penetration depth δ. Hence, the formula derived is valid only at $\rho < \delta$. Below we shall assume that $\delta > \xi$, i.e., $x > 1$.

As regards the number n, it may, in principle, be arbitrary. However, it is rather clear that we must take $n = 1$. First of all, it is evident that a small vortex is created more readily than a large one and therefore the lower critical field $H_{\rm cl}$ corresponds to the creation of the smallest vortex. With higher fields the problem is solved from the condition of the minimum free energy. From this condition one has to find the positions of the vortex axes. Suppose, for example, that $n = 2$. This corresponds to two fused vortices with $n = 1$. In order to find the position of the vortex axis we have to find the minimum free energy varying the coordinates of the axes, i.e., the points x and y of its intersection with the plane perpendicular to the magnetic field (the z-axis). But if the vortices did not stick together, we would be able to minimize Ω with respect to $x_1 y_1$ and $x_2 y_2$, i.e., a larger number of variables. In a general case this leads to a lower minimum of Ω. Thus, we will assume $n = 1$ and, hence*,

$$v_{\rm s} = \frac{\hbar}{2m\rho}, \quad \xi < \rho < \delta. \tag{18.7}$$

hence, the upper limits for $H_{\rm cp}$ and $H_{\rm c2}$ coincide and the value 10^6Oe may be regarded as limiting.

- Quantum vortices of supercurrent which are attenuated at a distance δ and which carry one magnetic flux quantum $\mathbf{\Phi_0}$ (see sections **18.2** and 18.3) are usually called fluxoids or Abrikosov vortices.

What happens when the field is decreased below H_{c2} ? If the field penetrates the superconductor partially, then persistent eddy currents must exist in it. Near the limiting field H_{cl} the metal must be almost completely superconducting, i.e., regions with eddy currents must be rare. The field H_{c1} can be determined if it is taken into account that an elementary vortex is a quantum entity. This was first detected in the study of the superfluidity of liquid helium (Onsager 1949, Feynman 1955).

Suppose that Cooper pairs execute a vortex motion around a certain axis. Let us draw a circular loop around the axis. The velocity of the pairs along this loop is evidently constant. According to the Bohr quantization rule,

$$\oint p \, \mathrm{d}q = 2m \oint v_\mathrm{s} \, \mathrm{d}l = 2mv_\mathrm{s} \cdot 2\pi\rho = 2\pi n\hbar.$$

Hence,

$$v_\mathrm{s} = n\hbar/(2m\rho),$$

that is, the velocity of the pairs falls off proportionately to the distance from the axis. This inference becomes invalid when $\rho \leqslant \xi$, the size of the pairs. On the other hand, we ignored the fact that the pairs are charged and their motion implies the generation of electric current and a magnetic field. The latter must vanish at a distance of the order of the penetration depth δ. Hence, the formula derived is valid only at $\rho < \delta$. Below we shall assume that $\delta > \xi$, i.e., $x > 1$.

As regards the number n, it may, in principle, be arbitrary. However, it is rather clear that we must take $n = 1$. First of all, it is evident that a small vortex is created more readily than a large one and therefore the lower critical field H_{cl} corresponds to the creation of the smallest vortex. With higher fields the problem is solved from the condition of the minimum free energy. From this condition one has to find the positions of the vortex axes. Suppose, for example, that $n = 2$. This corresponds to two fused vortices with $n = 1$. In order to find the position of the vortex axis we have to find the minimum free energy varying the coordinates of the axes, i.e., the points x and y of its intersection with the plane perpendicular to the magnetic field (the z-axis). But if the vortices did not stick together, we would be able to minimize Ω with respect to x_1y_1 and x_2y_2, i.e., a larger number of variables. In a general case this leads to a lower minimum of Ω. Thus, we will assume $n = 1$ and, hence*,

$$v_\mathrm{s} = \frac{\hbar}{2m\rho}, \quad \xi < \rho < \delta. \tag{18.7}$$

The energy of such a vortex is basically the kinetic energy of Cooper pairs. The energy per unit length of the vortex is given by (the density of the pairs is $\frac{1}{2}n_s$):

$$\begin{aligned}\xi_0 &= \frac{1}{2}n_\mathrm{s}\int_\xi^\delta \frac{2mv_\mathrm{s}^2}{2} 2\pi\rho \, \mathrm{d}\rho \\ &= \frac{\pi n_\mathrm{s}h^2}{4m}\int_\xi^\delta \frac{\mathrm{d}\rho}{\rho} = \frac{\pi n_\mathrm{s}\hbar^2}{4m}\ln\left(\frac{\delta}{\xi}\right) \\ &= \frac{\pi n_\mathrm{s}\hbar^2}{4m}\ln x\end{aligned}$$

* Quantum vortices of supercurrent which are attenuated at a distance δ and which carry one magnetic flux quantum $\boldsymbol{\Phi_0}$ (see sections 18.2 and 18.3) are usually called fluxoids or Abrikosov vortices.

(here we have substituted formula 18.7). The magnetic moment of the vortex per unit length is equal to

$$M = \frac{1}{2} n_s \frac{2e}{c} \int_\xi^\delta \rho v_s 2\pi\rho \, \mathrm{d}\rho = \pi \frac{e\hbar n_s}{mc} \int_\xi^\delta \rho \mathrm{d}\rho$$
$$\approx \frac{\pi e\hbar n_s}{2mc} \delta^2$$

(we have neglected ξ^2 as compared to δ^2).
In the presence of a magnetic field H the vortex acquires a magnetic energy -MH. The smallest field at which an elementary vortex can appear corresponds to $\varepsilon_0 - MH = 0$ or

$$H_{c1} = \frac{\varepsilon_0}{M} \sim \frac{c\hbar}{e\delta^2} \ln x.$$

Using the BCS formulae, we obtain

$$H_{c1} \sim \frac{H_{cm}}{x} \ln x. \tag{18.8}$$

Just as in the case of $\boldsymbol{H_{c2}}$, this formula also refers both to a pure superconductor and to the case $l < \xi_0$. From formula (18.8) it follows that the higher H_{c2} (i.e., the greater x) the lower ΔH_{cl}, i.e., the earlier the magnetic field begins to penetrate the superconductor.

In the following two sections we shall present the quantitative theory of the magnetic properties of type II superconductors based on the Ginzburg-Landau equations (Abrikosov 1957). Although this theory is valid, strictly speaking, only near T_c, yet, as has already been noted, all the basic conclusions are valid at any temperatures.

8.4.2 18.2. Magnetic properties of type II superconductors. Quantitative theory for the vicinity of H_{c2}

We begin with H_{c2}. Since this is the limiting field for the existence of superconductivity, it follows that an infinitesimal nucleus of the superconducting phase must
decrease with time at $H > H_{c2}$ and increase with time at $H < H_{c2}$. This means that at $H = H_{c2}$ there may exist a stationary infinitesimal superconducting nucleus.

Let us consider the homogeneous Ginzburg-Landau equations (17.24), (17.25) and (17.26)*. Assuming Ψ to be infinitesimal, we retain only terms of lower order in Ψ. In this case, we get

$$\frac{1}{x^2} \frac{\mathrm{d}^2\Psi}{\mathrm{d}x^2} + \Psi\left(1 - A^2\right) = 0, \tag{18.9}$$
$$\frac{\mathrm{d}^2 A}{\mathrm{d}x^2} = 0. \tag{18.10}$$

From eq. (18.10) we obtain $A = H_0 x$ (we assume that $H \| z, A \| y$); the origin $x = 0$ may be chosen at an arbitrary point. Substituting into (18.9), we have

$$-\frac{\mathrm{d}^2\Psi}{\mathrm{d}x^2} + \chi^2 H_0^2 x^2 \Psi = \chi^2 \Psi \tag{18.11}$$

We must find the solution that vanishes as $x \to \pm\infty$.
We have deliberately placed the terms of eq. (18.22) in such a manner that it becomes similar to the Schrödinger equation for a harmonic oscillator:

$$-\frac{\hbar^2}{2m} \frac{\mathrm{d}^2\Psi}{\mathrm{d}x^2} + \frac{1}{2} k x^2 \Psi = \varepsilon\Psi \tag{18.12}$$

As is well known from quantum mechanics, the last equation has solutions which vanish with $x \to \pm\infty$ at

$$\varepsilon = \hbar\omega\left(n + \frac{1}{2}\right)$$

where $\omega = (k/m)^{1/2}$. If we denote the coefficient in front of the first term of (18.12) as a and that the second term as b, then $\hbar\omega = 2\sqrt{ab}$. Comparing eq. (18.11) with eq. (18.12), we obtain $2\sqrt{ab} = 2\varkappa H_0$ and, hence, the required solutions exist at $\chi^2 = 2\chi H_0\left(n + \frac{1}{2}\right)$ or**

$$H_0 = \frac{x}{2n+1}.$$

We are interested in the strongest field at which the solution $\Psi \neq 0$ is possible. It corresponds to $n = 0$ and is equal to

$$H_{c2} = \varkappa \tag{18.13}$$

or, in conventional units,

$$H_{c2} = \varkappa\sqrt{2}H_{cm}. \tag{18.14}$$

This value is consistent with the qualitative estimate (18.2) and (18.3). Note that $H_{c2} > H_{cm}$ at $x > 1/\sqrt{2}$.

The solution corresponding to the lowest level of the oscillator has the form $\Psi \propto \exp\left[-\left(\sqrt{km}/2\hbar x^2\right]\right.$. Again, denoting the coefficients in (18.12) as a and b, we have $\Psi \propto \exp\left[-\frac{1}{2}(b/a)^{1/2}x^2\right]$. In our case we obtain $\Psi \propto \exp\left(-\frac{1}{2}xH_0x^2\right)$ or, in view of $H_0 = x$,

$$\Psi \propto \exp\left(-\frac{1}{2}\varkappa^2x^2\right). \tag{18.15}$$

As has been pointed out above, we may choose the coordinate origin $x = 0$ at any point, i.e., the nucleus of the superconducting phase may appear at any point in the superconductor. The change in the coordinate origin corresponds to the change in the gauge of the vector potential if we wish to use real Ψ. But if we wish to use a unified gauge, then we have to take a complex Ψ. Indeed, writing $\Psi = |\Psi|e^{i\chi}$ and substituting into (17.6'), we obtain

$$\left(-i\varkappa^{-1}\nabla + \varkappa^{-1}\nabla\chi - A\right)^2|\Psi| - |\Psi| + |\Psi|^3 = 0. \tag{18.16}$$

It is sufficient to take $\chi = ky$ and we obtain the same equation with the replacement $A_y \to A_y - k/x = H_0(x - k/xH_0)$. Hence, the small nucleus may not only have the form (18.15) but also

$$\Psi \propto \exp\left[iky - \frac{1}{2}\varkappa^2\left(x - \frac{k}{x^2}\right)^2\right]. \tag{18.17}$$

- At first sight, it may seem that the search for a nucleus which is dependent only on a single coordinate is a limitation on generality. In fact, for homogeneous magnetic field the vector potential depends linearly on the coordinates. Choosing $A_y = H_0x$, we see that the equation for Ψ contains explicitly only the coordinate x.

** The possibility of superconducting regions with small Ψ at $H_0 = x(2n+1)$ was pointed out by Ginzburg and Landau (1950). But they considered only type I superconductors with $x < 1/\sqrt{2}$, for which these values of H_0 were lower than H_{cm}, and the statement of the problem of small Ψ was meaningless (the supercooling field was not studied by Ginzburg and Landau).

Evidently, the solution may also be any linear combination of functions of the type (18.17). Since the conditions along the entire superconductor are uniform, it is most natural to suppose a linear combination of solutions centered through equal intervals, i.e.,

$$\Psi = \sum_{n=-\infty}^{\infty} C_n \exp\left[ikny - \frac{1}{2}\varkappa^2\left(x - \frac{kn}{\chi^2}\right)^2\right]. \tag{18.18}$$

Let us now consider the solution of eq. (17.6') at H_0 slightly smaller than $\varkappa$. We apply the method of successive approximations. First of all, we take into account
the term with Ψ in equation (17.8') for A. Substituting eq. (18.18), we obtain two equations:

$$\begin{aligned}
\frac{\partial^2 A}{\partial x \partial y} &= \frac{\partial H}{\partial y} \\
&= \frac{i}{2x}\sum_{n,m} C_n C_m^* \exp\left[ik(n-m)y - \frac{1}{2}x^2\left(x - \frac{kn}{x^2}\right)^2\right. \\
&\quad \left. -\frac{1}{2}x^2\left(x - \frac{km}{x^2}\right)\right]\cdot k(m-n), \\
-\frac{\partial^2 A}{\partial x^2} &= -\frac{\partial H}{\partial x} \\
&= \frac{1}{2x}\sum_{n,m} C_n C_m^* \exp\left[ik(n-m)y - \frac{1}{2}x^2\left(x - \frac{kn}{x^2}\right)^2\right. \\
&\quad \left. -\frac{1}{2}x^2\left(x - \frac{km}{x^2}\right)^2\right]\cdot\left[k(n+m) + 2x^2 x\right]
\end{aligned}$$

(we have taken $A = H_0 x$ on the right-hand side of eq. (17.8')). From this it is easy to see that

$$H = \frac{\partial A}{\partial x} = H_0 - \frac{|\Psi|^2}{2x}, \quad A = H_0 x - \frac{1}{2x}\int |\Psi|^2 \, \mathrm{d}x. \tag{18.19}$$

Consider now the next approximation to eq. (17.6'). We write

$$\Psi = \Psi^{(0)} + \sum_n \mathrm{e}^{\mathrm{i}kny}\psi_n^{(1)}(x),$$

where $\Psi^{(0)}$ is the function (18.18). We shall assume the second term to be a small correction and write eq. (17.6') to first order in this correction. Here we obtain a linear inhomogeneous equation, which may be split into equations for individual $\psi_n^{(1)}$. The vector potential is inserted in the form (18.19), the first term being written in the form $xx + (H_0 - x)\,x$ and the second term is assumed to be a first-order correction, just as the second term in (18.19). As a result, we find

$$\begin{aligned}
&\left(\frac{kn}{x} - xx\right)^2 \psi_n^{(1)} - \frac{1}{x^2}\frac{d^2\psi_n^{(1)}}{\mathrm{d}x^2} - \psi_n^{(1)} \\
&= 2\,(x - H_0)\,xx\left(x - \frac{kn}{x^2}\right) C_n \psi_n(x) \\
&\qquad + \sum_{m,p} C_p C_m^* C_{n-p+m}\left[\left(x - k\frac{n - \frac{1}{2}(p-m)}{x^2}\right)\psi_{n-p+m}(x)\int^x \psi_p\,(x')\,\psi_m\,(x')\,\mathrm{d}x'\right. \\
&\qquad\qquad \left. -\psi_p(x)\psi_m(x)\psi_{n-p+m}\right]
\end{aligned} \tag{18.20}$$

the term with Ψ in equation (17.8') for A. Substituting eq. (18.18), we obtain two equations:

$$\begin{aligned}
\frac{\partial^2 A}{\partial x \partial y} &= \frac{\partial H}{\partial y} \\
&= \frac{i}{2x} \sum_{n,m} C_n C_m^* \exp\left[\mathrm{i}k(n-m)y - \frac{1}{2}x^2 \left(x - \frac{kn}{x^2} \right)^2 \right. \\
&\quad \left. - \frac{1}{2}x^2 \left(x - \frac{km}{x^2} \right) \right] \cdot k(m-n), \\
-\frac{\partial^2 A}{\partial x^2} &= -\frac{\partial H}{\partial x} \\
&= \frac{1}{2x} \sum_{n,m} C_n C_m^* \exp\left[\mathrm{i}k(n-m)y - \frac{1}{2}x^2 \left(x - \frac{kn}{x^2} \right)^2 \right. \\
&\quad \left. - \frac{1}{2}x^2 \left(x - \frac{km}{x^2} \right)^2 \right] \cdot \left[k(n+m) + 2x^2 x \right]
\end{aligned}$$

(we have taken $A = H_0 x$ on the right-hand side of eq. (17.8')). From this it is easy to see that

$$H = \frac{\partial A}{\partial x} = H_0 - \frac{|\Psi|^2}{2x}, \quad A = H_0 x - \frac{1}{2x} \int |\Psi|^2 \, \mathrm{d}x \tag{18.19}$$

Consider now the next approximation to eq. (17.6'). We write

$$\Psi = \Psi^{(0)} + \sum_n \mathrm{e}^{\mathrm{i}kny} \psi_n^{(1)}(x),$$

where $\Psi^{(0)}$ is the function (18.18). We shall assume the second term to be a small correction and write eq. (17.6') to first order in this correction. Here we obtain a linear inhomogeneous equation, which may be split into equations for individual $\psi_n^{(1)}$. The vector potential is inserted in the form (18.19), the first term being written in the form $xx + (H_0 - x)\, x$ and the second term is assumed to be a first-order correction, just as the second term in (18.19). As a result, we find

$$\begin{aligned}
&\left(\frac{kn}{x} - xx \right)^2 \psi_n^{(1)} - \frac{1}{x^2} \frac{d^2 \psi_n^{(1)}}{\mathrm{d}x^2} - \psi_n^{(1)} \\
&\qquad = 2\,(x - H_0)\, xx \left(x - \frac{kn}{x^2} \right) C_n \psi_n(x) \\
&\qquad\quad + \sum_{m,p} C_p C_m^* C_{n-p+m} \left[\left(x - k \frac{n - \frac{1}{2}(p-m)}{x^2} \right) \psi_{n-p+m}(x) \int^x \psi_p(x')\, \psi_m(x')\, \mathrm{d}x' \right. \\
&\qquad\qquad \left. - \psi_p(x) \psi_m(x) \psi_{n-p+m} \right]
\end{aligned} \tag{18.20}$$

where

$$\psi_n(x) = \exp\left[-\frac{1}{2}x^2 \left(x - \frac{kn}{x^2} \right)^2 \right]. \tag{18.21}$$

In order for this inhomogeneous equation to have a solution, it is necessary that its right-hand side be orthogonal to the solution of a homogeneous equation with the same boundary conditions. Such is $\psi_n(x)$. From the orthogonality condition we obtain

$$2^{-1/2}\left(\frac{1}{2x^2}-1\right)\sum_{p,m}C_pC_m^*C_{n-p+m}\exp\left(-k^2\frac{(p-n)^2+(p-m)^2}{2x^2}\right)$$
$$+C_n\frac{x-H_0}{x}=0 \tag{18.22}$$

We multiply this equation by C_n^* and sum over n. The resultant relation may be written in the form (see eq. 18.18)

$$\left(\frac{x-H_0}{x}\right)\overline{|\Psi|^2}+\left(\frac{1}{2x^2}-1\right)\overline{|\Psi|^4}=0. \tag{18.23}$$

The induction, i.e., the average field, is obtained from formulae (18.19) and (18.23):

$$B=\bar{H}=H_0-\frac{\overline{|\Psi|^2}}{2\varkappa}=H_0-\frac{\overline{\left(|\Psi|^2\right)^2}}{\overline{|\Psi|^4}}\frac{\overline{|\Psi|^4}}{2\varkappa|\Psi|^2}$$
$$=H_0-\frac{1}{\beta_A}\frac{\varkappa-H_0}{2\varkappa^2-1} \tag{18.24}$$

where

$$\beta_A=\frac{\overline{|\Psi|^4}}{\overline{\left(|\Psi|^2\right)^2}} \tag{18.25}$$

is a quantity which does not depend on H_0.
Let us find the free energy using formula (17.19). Substituting eqs. (18.18) and (18.19) into it and expressing H_0 in terms of B, according to (18.24), we obtain (with all $\overline{|\Psi|^2}$ and $|\Psi|^4$ calculated using formulae 18.25 and 18.23):

$$\frac{\Omega_{\rm s}-\Omega_{\rm n}^{(0)}}{H_{\rm cm}^2/4\pi}=B^2-\frac{(\varkappa-B)^2}{1+(2\varkappa^2-1)\,\beta_A}. \tag{18.26}$$

This is the thermodynamic potential with respect to B. In order to obtain the external field from it, we have to calculate $\frac{1}{2}\partial\Omega_{\rm s}/\partial B$. So, we have

$$H_{\rm ext}=B+\frac{x-B}{1+(2x^2-1)\,\beta_A}. \tag{18.27}$$

Solving formula (18.24) for H_0, we obtain the same expression, i.e., $H_0=H_{\rm ext}$.
The minimum of free energy (18.26) is reached at the minimum value of β_A. This allows one to choose the coefficients C_n and k in formula (18.18) for Ψ. Note that,
according to eq. (18.25), $\beta_A>1$. Indeed, if $|\Psi|^2=\overline{|\Psi|^2}+q$, then $\bar{q}=0$. At the same time

$$\overline{|\Psi|^4}=\overline{\left(|\ \overline{\Psi|^2}+q\right)^2}=\overline{\left(|\Psi|^2\right)^2}+\overline{q^2}>\overline{\left(|\Psi|^2\right)^2}.$$

It is not difficult to see that eq. (18.22), which we derived from the solvability condition for the inhomogeneous equation (18.22), may be written in the following form:

$$\frac{\partial\beta_A}{\partial C_n^*}=0, \tag{18.28}$$

that is, it follows from the requirement of the minimum of $\boldsymbol{\beta}_A$.
A detailed analysis of the problem of choosing the correct solution is very time-consuming, so

we do not give it here (see Saint-James et al. 1969). If we consider the simplest variant, namely if all the coefficients C_n in (18.18) are assumed to be equal, it turns out that

$$\beta_A = \frac{k}{x\sqrt{2\pi}} \left[\sum_{n=-\infty}^{\infty} \exp\left(\frac{-k^2 n^2}{2x^2} \right) \right]^2 .$$

The minimum value is reached at $k = x(2\pi)^{1/2}$ and is equal to

$$\beta_A^{\square} = \left[\sum_{n=-\infty}^{\infty} \exp\left(-\pi n^2\right) \right]^2 = \vartheta_3^2(1;0) = 1.18, \tag{18.29}$$

where $\boldsymbol{\vartheta}_3$ is the theta function defined in the general case by

$$\vartheta_3(X;Y) = \sum_{n=-\infty}^{\infty} \exp\left(-\pi X n^2 + 2\pi \,\mathrm{i}\, n Y\right). \tag{18.30}$$

The function Ψ itself may be written in the form

$$\Psi^{\square} = C \exp\left(-\frac{1}{2} x^2 x^2 \right) \vartheta_3 \left(1; (2\pi)^{1/2} x \mathrm{i}(x + \mathrm{i}y)\right). \tag{18.31}$$

Using the properties of the ϑ_3-functions, one can show that upon rotation of the coordinate system by $\frac{1}{2}\pi$ the function Ψ is multiplied by a phase factor $\exp(\mathrm{i}x^2 xy)$, remaining unaltered in other respects. Thus, $|\Psi|^2$ has the symmetry of a square lattice. At points $x = (\sqrt{2\pi}/x)\left(m + \frac{1}{2}\right), y = (\sqrt{2\pi}/x)\left(n + \frac{1}{2}\right)$ (m and n are integers) the function Ψ vanishes. According to formula (18.19), the magnetic field at these points reaches the maximum value H_0.

As a result of a detailed analysis (Kleiner et al. 1964), it has been found that the lowest value of β_A is exhibited by a solution that has the symmetry of a triangular lattice; it may be written in the form

$$\Psi^{\Delta} = C \sum_{n=-\infty}^{\infty} \exp\left[\frac{1}{2}\pi \mathrm{i} n(n-1) - \frac{1}{2}\varkappa^2 \left(x - \frac{kn}{\varkappa^2} \right)^2 + \mathrm{i}kny \right], \tag{18.32}$$

where $k = x(\pi\sqrt{3})^{1/2}$. Other notations may also be used, but they differ only in the choice of the coordinate system. Comparison with formula (18.18) shows that in this case the coefficients C_n are chosen such that $C_{n+4} = C_n$ and $C_0 = C_1 = C$, $C_2 = C_3 = -C$. The solution (18.32) may be written in the following form:

$$\Psi^{\Delta} = \exp\left(-\frac{1}{2}\varkappa^2 x^2 \right) \vartheta_3 \left[\exp\left(-\frac{1}{6}\mathrm{i}\pi \right); \frac{1}{2}\varkappa \left(\frac{\sqrt{3}}{\pi} \right)^{1/2} (y - \mathrm{i}x) - \frac{1}{4} \right]. \tag{18.33}$$

The triangular lattice has a period $a = (2/x)(\pi/\sqrt{3})^{1/2}$ (the side of the triangle). The function Ψ^{Δ} vanishes at points $x = -\left(\frac{1}{2}a\sqrt{3}\right)\left(m + \frac{1}{2}\right), y = a\left(1 + \frac{1}{2}m + n\right)$, where m and n are integers. For this lattice

$$\beta_A^{\Delta} = 1.16. \tag{18.34}$$

We see that the two solutions considered are periodic and both have points at which $\Psi = 0$. In the neighborhood of each of these points Ψ is proportional to $x + \mathrm{i}y$, where x and y are counted off from the point where $\Psi = 0$. This may also be written in the form $\Psi \propto \rho \mathrm{e}^{\mathrm{i}\theta}$, where $\rho = (x^2 + y^2)^{1/2}, \theta = \arctan(y/x)$. The phase χ coincides with the angle of the cylindrical

coordinate system. We see that the phase varies by 2π upon each trip around such a point. Let us now examine formula (17.75) for the current written in conventional units and expressed in terms of the modulus and the phase Ψ. In cylindrical coordinates $\nabla\chi = \rho^{-1}\partial\chi/\partial\theta = \rho^{-1}$. At sufficiently small $\rho, \nabla\chi > (2e/\hbar c)A$. Hence,

$$j = \frac{\hbar e}{m}\frac{|\Psi|^2}{\rho}$$

If we write $j = en_s v_s$, we obtain ($|\Psi|^2 = \frac{1}{2}n_s$):

$$v_s = \frac{\hbar}{2m\rho},$$

which coincides exactly with formula (18.7) for a quantum vortex.

At the point $\rho = 0, v_s$ tends to infinity. For the physical quantity - electric current to be finite, it is necessary that $\Psi \to 0$ with $\rho \to 0$, and this does really occur. Another argument may be also be given: the vanishing of Ψ at $\rho = 0$ is necessary for the uniqueness of Ψ at this point. Such behavior of the wave function of the Bose condensate in the presence of a quantum vortex was first predicted by Feynman (1955) for superfluid liquid helium.

A natural question arises: we constructed the solutions of the Ginzburg-Landau equations without any preliminary assumptions and, in spite of this, in all the solutions there appear points where $\Psi = 0$ and the phase varies by 2π in each trip around this point. What is this associated with? The answer consists in the following. The equations contain the vector potential $\boldsymbol{A}$. If the magnetic field inside the superconductor is directed parallel to the external field, then $A_y = \int^x H\,\mathrm{d}x$ must increase with increasing x. But the physical quantity is not the vector potential but the magnetic field, which does not increase on the average in the specimen. Hence, the increase of the vector potential must be compensated. This is what really occurs. The point is that the equations always include the combination $\boldsymbol{x}^{-1}\boldsymbol{\nabla\chi} - \boldsymbol{A}$ (in reduced units).

Consider the solution $\Psi^{\square}$ (18.31) in the xy-plane (fig. 113). The solid circles designate the points where $\Psi = 0$. For the phase to be single-valued, we draw through these points branch cuts parallel to the y-axis. If one moves $\|y$ staying on the right

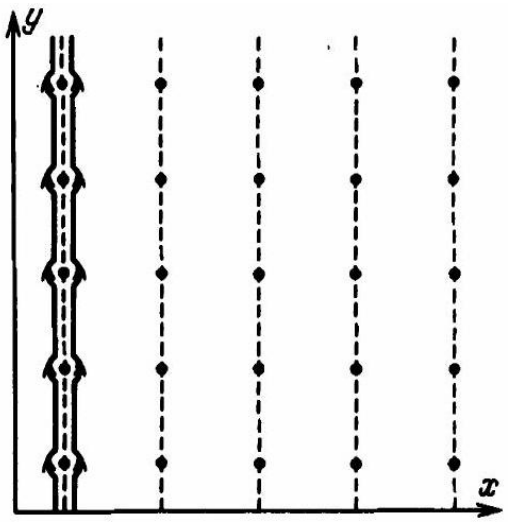

Fig. 113.

of such a branch cut, χ will vary according to the law

$$\chi(y) = \chi_{\mathrm{reg}}(y) + \pi\frac{y}{a}$$

where a is the period of the structure; $\chi_{\text{reg}}(y)$ is the regular part not associated with the vortices. But if one moves $\|y$ staying on the left of the branch cut, then

$$\chi(y) = \chi_{\text{reg}}(y) - \pi\frac{y}{a}$$

From this it follows that at each of the branch cuts the phase gradient undergoes a discontinuity:

$$\Delta\left(\frac{\partial\chi}{\partial y}\right) = \frac{2\pi}{a}$$

At the same time the vector potential increases by xa per period with increasing x ($A_y \approx H_0 x, H_0 \approx x$). In order to compensate this increase, it is necessary that

$$xa = \frac{1}{x}\Delta\left(\frac{\partial\chi}{\partial y}\right) = \frac{2\pi}{xa}.$$

It follows then that

$$a^{\square} = \frac{\sqrt{2\pi}}{x}.$$

This is what was exactly obtained for the square lattice.
As for the triangular lattice, the separation between the branch cuts is $\frac{1}{2}a\sqrt{3}$ and the compensation condition is

$$\frac{1}{2}xa\sqrt{3} = \frac{2\pi}{xa}$$

Hence,

$$a^{\Delta} = 2\left(\frac{\pi}{\sqrt{3}}\right)^{1/2}\frac{1}{x}$$

which corresponds to the solution of (18.33).
Let us find the current lines. Substituting eq (18.18) into the expression for the current (the right-hand side of eq. 18.8'), we obtain

$$\begin{aligned} j_x =& \sum_{n,m} C_n C_n^* \left(k\frac{n+m}{2x} - xx\right) \\ & \times \exp\left[\mathrm{i}(n-m)y - \frac{1}{2}x^2\left(x - \frac{kn}{x^2}\right)^2 - \frac{1}{2}x^2\left(x - \frac{km}{x^2}\right)^2\right] \\ =& -\frac{1}{2x}\frac{\partial|\Psi|^2}{\partial y} \\ j_y =& \frac{1}{2x}\frac{\partial|\Psi|^2}{\partial x} \end{aligned}$$

The equation for the current lines is

$$\frac{dx}{j_x} = \frac{dy}{j_y}.$$

Substituting j_x and j_y, we obtain

$$\frac{\partial|\Psi|^2}{\partial x}\,\mathrm{d}x + \frac{\partial|\Psi|^2}{\partial y}\,\mathrm{d}y = 0$$

or

$$|\Psi|^2 = \text{ const.}$$

According to eq. (18.19), these are simultaneously the lines of constant field. These lines are shown in fig. 114 for the quadratic solution (the numbers are the values of $|\Psi|^2/|\Psi|^2_{\max}$).

Consider the square contour in fig. 114 with vertices at the points marked by 1. It is not difficult to see that the integral $\oint j \, \mathrm{d}l$ taken along this contour is equal to zero. Hence, according to section 17.6, an integer number of magnetic flux quanta passes through this contour. We will show that this is one flux quantum. Indeed, we have

$$\Phi = BS^{\square} \approx x\frac{2\pi}{x^2} = \frac{2\pi}{x}. \tag{18.35}$$

Using conventional units and substituting the value of $\boldsymbol{\chi}$ (17.11), we get

$$\Phi = \frac{2\pi}{x} H_{\mathrm{cm}} \sqrt{2}\delta^2 = \frac{\pi\hbar c}{e} = \Phi_0. \tag{/}$$

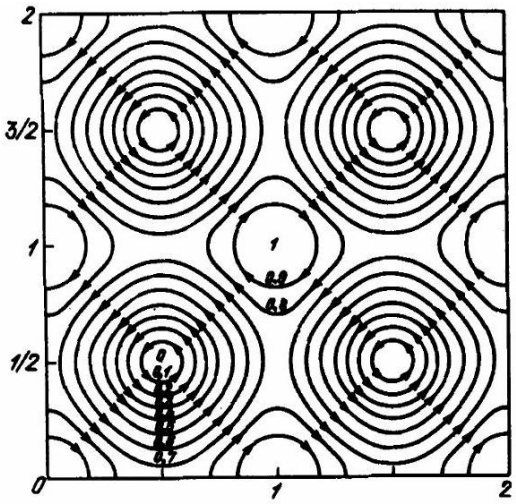

Fig. 114.

The situation is analogous for the triangular lattice (the contour is a hexagon which surrounds the point at which $\Psi = 0$).

In conclusion, we write formula (18.24) in a form more convenient for comparison with experiment:

$$-4\pi M = \frac{H_{c2} - H_0}{(2\varkappa^2 - 1)\,\beta_{\mathrm{A}}}, \tag{18.36}$$

that is, the dependence $M\,(H_0)$ near $H_0 = H_{c2}$ is linear.

8.4.3 18.3. Magnetic properties of type II superconductors. Metals with $x > 1$

In the present section we shall use an approximation that can be applied with fields smaller than H_{c2}. In order for this approximation to correspond to a real mixed state, it is necessary that $H_{c1} < H_{c2}$ or, according to the results of section 18.1, $x \gg 1$.

In the preceding section we have found the solution at fields close to H_{c2}. It is rather obvious that the main qualitative property of the function Ψ - the presence of points where $\Psi = 0$ and the fact that in going around these points the phase varies by 2π - must be preserved at lower fields too. This is associated with the necessity of the compensation of the increase of the vector potential by discontinuities in the phase gradient. But the lower the field the slower is the increase of A_y and, hence, the more seldom are the discontinuities. Indeed, the compensation condition (for the square lattice) with an arbitrary field has the form

$$\frac{2\pi}{xa} = A_y(a) - A_y(0) = \int_0^a H(x)\mathrm{d}x = \bar{H}a = Ba.$$

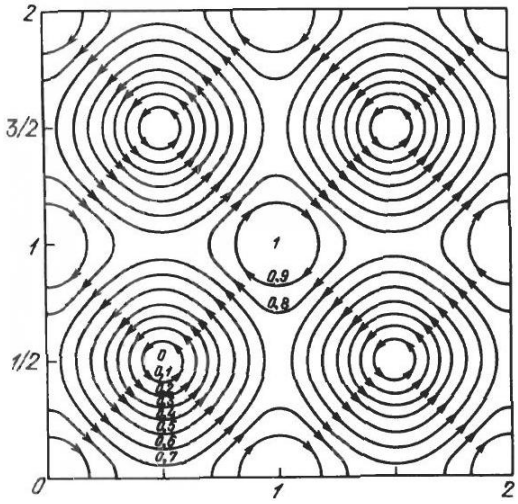

Fig. 114.

The situation is analogous for the triangular lattice (the contour is a hexagon which surrounds the point at which $\Psi = 0$).

In conclusion, we write formula (18.24) in a form more convenient for comparison with experiment:

$$-4\pi M = \frac{H_{c2} - H_0}{(2\varkappa^2 - 1)\,\beta_A}, \tag{18.36}$$

that is, the dependence $M\,(H_0)$ near $H_0 = H_{c2}$ is linear.

8.4.4 18.3. Magnetic properties of type II superconductors. Metals with $x \gg 1$

In the present section we shall use an approximation that can be applied with fields smaller than H_{c2}. In order for this approximation to correspond to a real mixed state, it is necessary that $H_{c1} \ll H_{c2}$ or, according to the results of section 18.1, $x \gg 1$.

In the preceding section we have found the solution at fields close to H_{c2}. It is rather obvious that the main qualitative property of the function Ψ - the presence of points where $\Psi = 0$ and the fact that in going around these points the phase varies by 2π-must be preserved at lower fields too. This is associated with the necessity of the compensation of the increase of the vector potential by discontinuities in the phase gradient. But the lower the field the slower is the increase of A_y and, hence, the more seldom are the discontinuities. Indeed, the compensation condition (for the square lattice) with an arbitrary field has the form

$$\frac{2\pi}{xa} = A_y(a) - A_y(0) = \int_0^a H(x)\mathrm{d}x = \bar{H}a = Ba.$$

From this it seen that $a = (2\pi/xB)^{1/2}$, i.e., the period of the structure increases with decreasing B.

At small fields the distance between the vortex lines becomes so large that they are almost independent and to a first approximation we may consider a single vortex line. We introduce the cylindrical system of coordinates (ρ, θ, z) and the z-axis is directed along the axis of the vortex line. The vector potential is chosen to be perpendicular to the radius-vector ρ, i.e., $A = A_\theta$.

If we write $\Psi = f\mathrm{e}^{\mathrm{i}x}(f = |\Psi|)$, then the current in Ginzburg-Landau units has the form $j = f^2(\nabla\chi/\chi - A)$. Since $f^2 = \frac{1}{2}n_\mathrm{s}$ is the density of pairs in the condensate (n_s is the density of "superconducting electrons"), then it follows that $\nabla\chi/x - A$ plays the role of their velocity. Therefore we introduce the following notation:

$$v_\mathrm{s} = \frac{\nabla\chi}{\chi} - A.$$

We emphasize that the vector $\boldsymbol{v}_\mathrm{s}$, which is convenient for the solution of equations, is not a true physical quantity, in contrast to the current $j = f^2 v_\mathrm{s}$, which can be measured. Equations (17.6) and (17.8) assume the following form in terms of the new notation:

$$-\frac{1}{\chi^2\rho}\frac{\mathrm{d}}{\mathrm{d}\rho}\left(\rho\frac{\mathrm{d}f}{\mathrm{d}\rho}\right) + v_\mathrm{s}^2 f = f - f^3, \tag{18.37}$$

$$-\frac{\mathrm{d}H}{\mathrm{d}\rho} = v_\mathrm{s} f^2, \tag{18.38}$$

$$H = (\mathrm{rot}\, A)_z = -\frac{1}{\rho}\frac{\mathrm{d}}{\mathrm{d}\rho}(\rho v_\mathrm{s}) + \frac{2\pi}{\chi}\delta(\rho). \tag{18.39}$$

In the last formula it is taken into account that in the vicinity of an individual filament $\chi = \theta$, i.e., it varies by 2π on encircling the line $\rho = 0$. Because of this, $\nabla\chi$ has an unusual property. If we take the integral of $\nabla\chi$ over an infinitesimal loop around the point $\rho = 0$, this will give, on the one hand

$$\oint \nabla\chi \mathrm{d}l = 2\pi$$

and on the other hand

$$\oint \nabla_\chi \mathrm{d}l = \int \mathrm{rot}\, \nabla_\chi \mathrm{d}S$$

Hence,

$$(\mathrm{rot}\, \nabla\chi)_z = 2\pi\delta(\rho) \tag{18.40}$$

The magnetic field $\boldsymbol{H} = \mathrm{rot}\, \boldsymbol{A} = -(\mathrm{rot}\, v_\mathrm{s} - \chi^{-1}\, \mathrm{rot}\, \nabla\chi)$, from which we obtain (18.39). The boundary conditions for eqs. (18.37), (18.38) and (18.39) are as follows. With $\rho \to \infty$ we have $f \to 1$ and $H \to 0$ (and, consequently, $v_s \to 0$). With $\rho \to 0$ we have $v_\mathrm{s} \to (x\rho)^{-1}$; this is associated with the fact that

$$\nabla_\theta\chi = \frac{1}{\rho}\frac{\partial\chi}{\partial\theta} \to \frac{1}{\rho}.$$

As for f, it must not increase indefinitely at any ρ.
The solution of the equations in a general case can be obtained only by numerical integration. However, at $x > 1$ the situation is substantially simplified. To demonstrate this, we note that the distances over which the function v_8 varies significantly is $\rho \sim 1$. As regards the function f, it varies appreciably at distances of $\rho \sim x^{-1} < 1$. In view of this, in eq. (18.38) the function f may be supposed to have reached the value $f = 1$ already. Substituting (18.39) for $\rho \neq 0$, we obtain the equation for v_s; its solution is

$$v_\mathrm{s} = \frac{K_1(\rho)}{\varkappa} \tag{18.41}$$

where K_1 is the MacDonald function, which has been introduced in section 16.5.
In the equation for f we may use the asymptotic form of v_s for small distances, i.e., $v_\mathrm{s} \approx (x\rho)^{-1}$. Inserting this into eq. (18.37) gives

$$\frac{1}{\chi^2}\left[\frac{1}{\rho}\frac{\mathrm{d}}{\mathrm{d}\rho}\left(\rho\frac{\mathrm{d}f}{d}\right) - \frac{f}{\rho^2}\right] = f^3 - f. \tag{18.42}$$

The solution of this equation at distances $\rho > x^{-1}$ (but, of course, $\rho < 1$) is

$$f^2 = 1 - \frac{1}{(x\rho)^2}. \tag{18.43}$$

At $\rho < x^{-1}$ we assume that $f < 1$ and find that

$$f = Cx\rho, \tag{18.44}$$

where C is a numerical constant, which can be found by numerical solution of eq. (18.42). The result $\Psi \propto \rho$ corresponds to what was observed in the vicinity of H_{c2}.

Let us determine the free energy per unit length of the vortex line. It must be measured from the energy of the superconductor in the absence of magnetic field. Using formula (17.19'), we obtain (in units of $\boldsymbol{H}_\mathrm{cm}^2\boldsymbol{\delta}^2/\boldsymbol{4\pi}$):

$$\varepsilon_0 = 2\pi\int\left[\Omega_\mathrm{s} - \Omega_\mathrm{s}^{(0)}\right]\rho\mathrm{d}\rho = 2\pi\int\left[H^2 + \frac{1}{2}\left(1 - f^4\right)\right]\rho\mathrm{d}\rho. \tag{18.45}$$

The principal part of this integral arises from the second term and is associated with distances much larger than x^{-1}. Substituting eq. (18.43) yields

$$\varepsilon_0 \approx \frac{2\pi}{x^2}\int\frac{1}{\rho}\,\mathrm{d}\rho \approx \frac{2\pi}{x^2}\ln x.$$

As a result of numerical integration, we find a more accurate result:

$$\varepsilon_0 = \frac{2\pi}{x^2}(\ln x + 0.081). \tag{18.46}$$

For the formation of vortex lines to be energetically favorable, we must have a field strength at which the free energy $\Omega_\mathrm{s} - \Omega_\mathrm{ns}^{(0)} - 2H_0B$ becomes negative. If the density of the vortex lines, i.e., the number of lines that intersect the unit area, is labeled as n, then

$$\Omega_\mathrm{s} - \Omega_\mathrm{s}^{(0)} = n\varepsilon_0, \quad B = \bar{H} = n\int H\,\mathrm{d}S = n\oint A\,\mathrm{d}l. \tag{18.47}$$

Because the contour passes at a distance $\rho = \infty$ and at such distances $v_\mathrm{s} = 0$ (see 18.41), we conclude that $A = \nabla\chi/x$ and is equal in magnitude to $(x\rho)^{-1}$. Hence,

$$B = \frac{2\pi n}{x}. \tag{18.48}$$

But since B is also the magnetic flux per unit area, it follows that the magnetic flux per vortex line is $2\pi/x$ or, according to eq. (18.35), one flux quantum Φ_0.

From the condition $\Omega_s - \Omega_s^{(0)} - 2H_0B = 0$ we obtain the value of the first critical field:

$$H_{cl} = \frac{\varepsilon_0 \chi}{4\pi}. \tag{18.49}$$

This formula applies for any x. In the case $x \gg 1$ we can substitute formula (18.46) for ε_0. In conventional units we have

$$H_{c1} = \frac{H_{cm}}{x\sqrt{2}}(\ln x + 0.08). \tag{18.50}$$

It is interesting to note that the field in the center of the vortex line is twice as large as H_{c1}. Indeed, according to eq. (18.38), $H(0) = \int_0^\infty v_s f^2 \, d\rho$. The principal part of the integral is taken over the region $x^{-1} < \rho < 1$. Inserting $f \approx 1$ and $v_s \approx (x\rho)^{-1}$, we find $H(0) \approx x^{-1} \ln x$. Numerical integration gives a more accurate formula:

$$H(0) = \frac{1}{x}(\ln x - 0.18). \tag{18.51}$$

The distribution of the field and $f(\rho)$ in the vortex is shown in fig. 115.
When $H_0 > H_{cl}$, there appear many vortices which begin to interact. In order to find the distribution of the fields and currents in this case and also the dependence

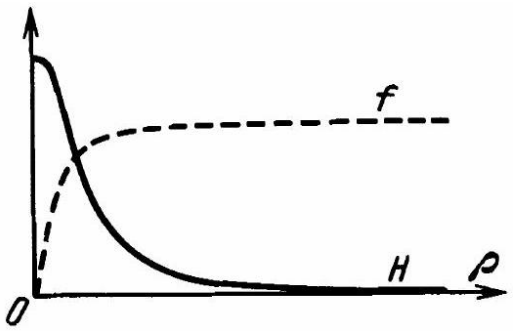

Fig. 115.

$B(H_0)$, we use the fact that the vortex axes come closer together to a distance of order x^{-1} only with $H_0 \to H_{c2}$, and at smaller fields the intervortex distance is substantially larger. In view of this, the vortex cores (of order x^{-1}) will simply play the role of singularities in the solution, and their detailed structure will be unimportant. We write the Maxwell equation in the form

$$\operatorname{rot} H = f^2 v_s$$

substitute $f = 1$, and take the curl. Taking into account that each vortex line gives a δ-function according to eq. (18.40), we obtain

$$\Delta H - H = -\frac{2\pi}{x} \sum_m \delta(\rho - \rho_m), \tag{18.52}$$

where ρ_m corresponds to the centers of the vortices ($\rho = (x, y)$). The solution of this equation is

$$H = \frac{1}{\chi} \sum_m K_0 \left(|\rho - \rho_m| \right), \tag{18.53}$$

where K_0 is the MacDonald function.
The free energy will be measured from the value for the superconducting phase in the absence of the field. We use formula (17.19), in which we assume that $\Psi = f e^{ix}$ and $\boldsymbol{f} = \mathbf{1}$. So, we have

$$\int \left(\Omega_s - \Omega_s^{(0)} \right) dV = \int \left(v_s^2 + H^2 \right) dV \tag{18.54}$$

Considering that in our approximation $\boldsymbol{v}_s = \operatorname{rot} \boldsymbol{H}$, integrating the first term by parts and substituting (18.52), we find that

$$\bar{\Omega}_s - \Omega_s^{(0)} = \overline{H(H - \Delta H)} = \frac{2\pi n}{x^2} \sum_m K_0 \left(|\rho_m| \right) \tag{18.55}$$

(n is the number of vortices intersecting 1 cm^2). The term that corresponds to $\rho_m = 0$ must be replaced by $n\varepsilon_0$.

Just as in the previous section, we are to choose the vortex lattice using the criterion of the minimal free energy. The triangle lattice turns out to be the most favorable. The period of the lattice is chosen in accordance with formula (18.48), i.e., on the basis of the fact that $B = n\Phi_0 = n(2\pi/x)$. So, we obtain $n^{-1} = a \cdot a\sqrt{3}/2$, from which it follows that

$$a = 2 \left(\frac{\pi}{\sqrt{3}} \right)^{1/2} \frac{1}{(Bx)^{1/2}} \tag{18.56}$$

(a is the side of the triangle).
The vector ρ_m is given by

$$\rho_m = a_1 q + a_2 l$$

where l and q are integers, and the basis vectors a_1 and a_2 have a length a and make an angle of 60°. In accordance with this,

$$|\rho_m| = a \left(q^2 + l^2 + ql \right)^{1/2}$$

Thus, we obtain

$$\Omega_s - \Omega_s^{(0)} = \frac{xB\varepsilon_0}{2\pi} + \left(\frac{B}{x} \right) \sum_{x_{q,l} \neq 0} K \left(x_{q,l} \right), \tag{18.57}$$

where

$$x_{q,l} = \left(4\pi \frac{q^2 + l^2 + ql}{\sqrt{3}Bx} \right)^{1/2} \tag{18.58}$$

The external field is expressed with the aid of the relation

$$H_0 = \frac{1}{2} \frac{\partial \left(\Omega_s - \Omega_s^{(0)} \right)}{\partial B}. \tag{18.59}$$

Substituting eq. (18.56) and using $K_0'(x) = -K_1(x)$, we obtain

$$x \left(H_0 - H_{c1} \right) = \frac{1}{4} \sum_{x_{q,l} \neq 0} \left[2K_0 \left(x_{q,l} \right) + x_{q,l} K_1 \left(x_{q,l} \right) \right] \tag{18.60}$$

We see that the dependence of xB on $x\,(H_0 - H_{c1})$ is a universal function. Let us examine the asymptotic forms of this dependence. With $H_0 - H_{c1} \to 0, B$ tends to zero, i.e., $x_{q,l} \to \infty$. Because of the exponential decrease of the MacDonald function it will be sufficient to retain only terms with the lowest x corresponding to $q^2 + l^2 + q^l = 1$. Since in the triangular lattice there are 6 neighbors at each point, a factor 6 appears in eq. (18.60). Using the asymptotics of the MacDonald functions $K_0(x) \approx K_1(x) \approx (\pi/2x)^{1/2} e^{-x}$, we get

$$x\,(H_0 - H_{c1}) \approx \frac{3}{2}\left(\frac{1}{2}\pi\right)^{1/2}\left(\frac{4\pi}{\sqrt{3}Bx}\right)^{1/4}\exp\left[-\left(\frac{4\pi}{\sqrt{3}Bx}\right)^{1/2}\right]. \tag{18.61}$$

It is not difficult to see that with $H_0 \to H_{cl}, B \to 0$ and $\mathrm{d}B/\mathrm{d}H_0 \to \infty$, i.e., the $B\,(H_0)$ curve has a vertical tangent at point H_{c1}.

Another limit that can be obtained is the relation between H_0 and B for fields at which the lattice period is much larger than ξ but less than δ, i.e., in reduced units $x^{-1} \ll a < 1$ or

$$x > B > \frac{1}{x}. \tag{18.62}$$

At $x \gg 1$ this occurs in most of the region of the mixed state, except the immediate neighborhood of H_{c1} and H_{c2}. We pass in formula (18.60) to the Fourier transforms of K_0 and K_1 :

$$x\,(H_0 - H_{cl}) = \pi \int \frac{2 + k^2}{(1 + k^2)^2} \sum_{\rho_{q,l} \neq 0} \mathrm{e}^{ik\rho_{q,l}} \frac{\mathrm{d}^2 k}{(2\pi)^2}. \tag{18.63}$$

If we add the term with $\rho_{q,l} = 0$ to the sum over $\rho_{q,l}$, we obtain

$$\sum_{\boldsymbol{\rho}_{q,l}} \mathrm{e}^{\mathrm{i}k\boldsymbol{\rho}_{q,l}} = (2\pi)^2 n \sum_{K} \delta(k - K) \tag{18.64}$$

where n is the number of vortices per cm^2; $\boldsymbol{K}$ are the reciprocal lattice vectors with respect to the planar lattice formed by the vectors $\rho_{q,l}$. These vectors are given by

$$\begin{aligned} &K = p_1 K_1 + p_2 K_2, \\ &K_1 = 2\pi\,[a_1 \times z_0]\,n, \quad K_2 = 2\pi\,[z_0 \times a_2]\,n, \end{aligned} \tag{18.65}$$

where n^{-1} is the area of the unit cell; a_1 and a_2 are basis vectors; z_0 is the unit vector with respect to z. Since $n = xB/2\pi$, it follows that K_1 and K_2 are equal, in magnitude, to $2(\pi/\sqrt{3})^{1/2}(xB)^{1/2}$ and the angle between them is equal to $\pi/3$, just as in the main lattice. Substituting (18.64) into (18.63), we get

$$x\,(H_0 - H_{c1}) = \pi\left(n \sum_{K} \frac{2 + K^2}{(1 + K^2)^2} - \int_0^\infty \frac{2 + k^2}{(1 + k^2)^2} \frac{\mathrm{d}^2 k}{(2\pi)^2}\right) \tag{18.66}$$

(the subtraction of the last integral corresponds to absence of the term with $\boldsymbol{\rho_{q,l}} = \mathbf{0}$ in (18.63).

Each of the expressions in brackets diverges logarithmically, but taken together they give a finite expression. We single out out from the first sum the term with $K = 0$. It is equal to $2\pi n = \varkappa B$. In the remaining terms and in the integral we shall first confine ourselves to the values $|K|, |k| < K_1 P = 2(\pi/\sqrt{3})^{1/2}(xB)^{1/2}P$; we shall then find the difference and pass to the limit $P \to \infty$. Since in the remaining sum over K the lowest K^2 is $K_1^2 \gg 1$ (according to eq 18.62), it may be replaced by

$$n\sum_K \frac{1}{K^2} = \frac{n}{K_1^2}\sum_{p_1\cdot p_2}\frac{1}{p_1^2+p_2^2+p_1p_2} = \frac{\sqrt{3}}{8\pi^2}\sum_{p_1,p_2}\frac{1}{p_1^2+p_2^2+p_1p_2}.$$

Evaluating the integral over k with the limit $K_1P \gg 1$, we get

$$\int_0^{K_1P}\frac{2+k^2}{(1+k^2)^2}\frac{d^2k}{(2\pi)^2} = \frac{1}{2\pi}\left(\ln K_1 + \ln P + \frac{1}{2}\right).$$

Collecting together all the terms, we find

$$\begin{aligned}\varkappa(H_0-H_{\rm cl}) \approx& \varkappa B - \frac{1}{4}\ln(\varkappa B) - \frac{1}{4}\ln\left(\frac{4\pi}{\sqrt{3}}\right) - \frac{1}{4} \\ &+ \lim_{P\to\infty}\left(\frac{\sqrt{3}}{8\pi}\sum_{0<\left(p_1^2+p_2^2+p_1p_2\right)<P^2}\frac{1}{p_1^2+p_2^2+p_1p_2} - \frac{1}{2}\ln P\right) \\ =& \varkappa B - \frac{1}{4}\ln(\varkappa B) - 0.49 \end{aligned} \tag{18.67}$$

If we substitute here formula (18.49) for $H_{\rm c1}$, we obtain

$$H_0 \approx B + \frac{1}{4\chi}\ln\left(\frac{\chi}{B}\right) - 0.45\frac{1}{\chi}. \tag{18.68}$$

From this formula we see that at $B \sim \varkappa, H_0 \approx B$ to within terms of order $\varkappa^{-1}$, as should be expected. On the basis of the limiting expressions (18.68) and (18.27) one can write an interpolation formula which reflects the logarithmic dependence of $H_0 - B$ on B in the region where the distance between the vortex cores is large and which changes to (18.27) with $B \to x \quad (x > 1)$:

$$H_0 \approx B + \frac{1}{2\beta_A x}\ln\left(\frac{x}{B}\right). \tag{18.69}$$

Of course, first this is only an interpolation and second it does not apply near $H_{\rm c1}$.
In concluding this section we will show that at $x = 1/\sqrt{2}$ the critical fields $H_{\rm cl}$, $H_{\rm c2}$ and $H_{\rm cm}$ coincide with each other. We put $x = 1/\sqrt{2}$ in eq. (18.37). It can be shown that

$$H = 2^{-1/2}\left(1-f^2\right) \tag{18.70}$$

Indeed, substituting into eq. (18.38), we get

$$fv_{\rm s} = 2^{1/2}\frac{\partial f}{\partial \rho} \tag{18.71}$$

We multiply eq. (18.37) (with $x = 2^{-1/2}$) by f and substitute eq. (18.71):

$$-\frac{1}{\rho}f\frac{\mathrm{d}}{\mathrm{d}\rho}\left(\rho\frac{\mathrm{d}f}{\mathrm{d}\rho}\right) + \left(\frac{\mathrm{d}f}{\mathrm{d}\rho}\right)^2 = \frac{1}{2}\left(1-f^2\right)f^2.$$

On the other hand, if we multiply eq. (18.39) by $\boldsymbol{f}^2$ and substitute eqs. (18.70) and (18.71), the same relation is obtained; this confirms the assumption (18.70). Now let us find ε_0 by using eq. (18.45). Substitution of eq. (18.70) yields

$$\varepsilon_0 = 2\pi \int \left(1 - f^2\right) \rho \mathrm{d}\rho = 2\pi\sqrt{2} \int H\rho \, \mathrm{d}\rho$$
$$= \sqrt{2}\Phi = \sqrt{2}\frac{2\pi}{x} \tag{18.72}$$

Here we have taken into account that there is one flux quantum per vortex, i.e., $2\pi/x$. Substituting this into (18.49), we obtain $H_{\mathrm{cl}} = 2^{-1/2}$ or, in conventional units, $H_{\mathrm{c1}} = H_{\mathrm{cm}}$. For H_{c2} this follows from (18.14). Thus, when x decreases to $1/\sqrt{2}$, the region of the mixed state is narrowed until it eventually disappears.

Thus, on the basis of qualitative arguments and quantitative calculations we have come to the conclusion that in type II superconductors in a magnetic field a mixed state arises with an incomplete Meissner effect, when the external field penetrates the superconductor in the form of filaments of the magnetic flux. Each filament is a tiny vortex current and carries one quantum of the magnetic flux. The order parameter is equal to zero on the vortex axis and is restored to the equilibrium value in the absence of the field at a distance $\xi = \delta/x$. This region is called the vortex core. The region of the mixed state disappears at $x \leqslant 1/\sqrt{2}$ and becomes large
at $x > 1$. Typical magnetization curves ($-4\pi M$ as a function of H_0) are shown in fig. 116.

Direct observation of the vortex structure was first made with the aid of neutron diffraction (Cribier et al. 1964). Since neutrons have a magnetic moment, they can be used for the analysis of magnetic structures in the same way as X-rays are used for the investigation of the electron density distribution. It is in this way that the existence of the vortex lattice was proved directly for the first time.

At a later time ferromagnetic powders were used for the observation of the vortex structure (Essmann and Träuble 1967), similar to what had been done for the intermediate state of type I superconductors. However, since the period of the structure is much smaller in this case, powders consisting of very small particles (diameter ~ 40Å) had to be used and the resultant picture was studied with the aid of an electron microscope using the replica technique (fig. 117). Usually, a triangular vortex lattice is obtained. However, when the magnetic field is directed along a fourth-order axis, a square lattice results. This is due to the small difference in energy between the two structures, which leads to the possibility of reconstitution under the influence of crystal anisotropy.

8.4.5 18.4. Surface superconductivity

Up until now we have dealt with an infinite superconducting space or, in other words, with phenomena that take place in the interior of a bulk superconductor. Investigations show that in the surface layer superconductivity may be retarded up to fields larger than H_{c2} (Saint-James and De Gennes 1963). The physical cause of this phenomenon consists in the following. While considering the nucleus of the superconducting phase in infinite space in section 18.2, we used the boundary condition $\Psi \to 0$ for $x \to \pm\infty$. In the presence of a surface the boundary condition is $\mathrm{d}\Psi/\,\mathrm{d}x|_{\mathrm{b}} = 0$.

Figure 118 shows the various possible cases: (a) a nucleus in the bulk; (b) a nucleus with its center at the surface; (c) a nucleus near the surface, but with a shifted center and, finally, (d) a nucleus in a thin film. In the last two cases the boundary condition on the surface requires an increase in Ψ near the surface as compared to the case of infinite space. This leads to an increase in the eigenvalue in the equation for Ψ(18.11) (the role of the energy is played by x^2), as a result, the value of the critical field increases. An example is the critical field of thin films (section 17.4), which is the same for type I and II superconductors with thicknesses of $d \ll \min(1, x^{-1})$ (section 18.6) and which increases with decreasing thickness.

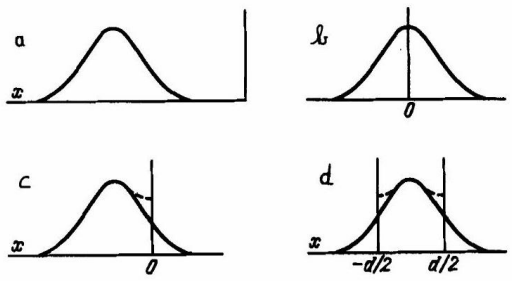

Fig. 118.

It is easy to see that the solutions with the center far from the surface and with the center directly at the surface differ only by the shift of the coordinate origin (in both cases $\mathrm{d}\Psi/\,\mathrm{d}x|_{\mathrm{b}} = 0$, see fig. 118) and, hence, they correspond to the same value of the field $H_0 = \varkappa$. The solution with the maximum slightly shifted relative to the surface corresponds to a larger value of the field. From this it follows that there exists a certain single solution, for which the field will have a maximum. Let us find this solution.

We begin with the case of the external field parallel to the surface. Here we may take the vector potential in the form $A = H_0(x - x_0)$ and use the boundary conditions $\Psi = 0$ for $x \to \infty$

and $\mathrm{d}\Psi/\mathrm{d}x = 0$ at $x = 0$. In this case, Ψ will depend only on x. Instead of this, we could have taken $A = H_0 x$, looking for Ψ in the form $\mathrm{e}^{\mathrm{i}ky}\Psi(x)$,
but, as has been shown in sections 18.2, these are equivalent statements of the problem. Thus, substituting $A = H_0\,(x - x_0)$ into eq. (18.9), we obtain

$$-\frac{\mathrm{d}^2\Psi}{\mathrm{d}x^2} + \chi^2 H_0^2\,(x - x_0)^2\,\Psi = \chi^2\Psi. \tag{18.73}$$

The solution of this equation in the general case is

$$\Psi = \exp\left(-\frac{1}{2}\zeta^2\right)\left\{C_1 F\left[\frac{1}{4}(1-\beta), \frac{1}{2}, (\zeta-\zeta_0)^2\right]\right.$$
$$\left. +\zeta C_2 F\left[\frac{1}{4}(3-\beta), \frac{3}{2}, (\zeta-\zeta_0)^2\right]\right\}, \tag{18.74}$$

where

$$\zeta = (xH_0)^{1/2}\,x, \quad \zeta_0 = (xH_0)^{1/2}\,x_0, \quad \beta = \frac{x}{H_0},$$

$F(\alpha, \gamma, z)$ is a degenerate hypergeometric function satisfying the equation

$$zF'' + (\gamma - z)F' - \alpha F = 0, \tag{18.75}$$

and C_1 and C_2 are arbitrary constants (see Landau and Lifshitz 1974).
The boundary conditions enable one to determine the ratio C_2/C_1 and β as a function of x_0. After this, minimizing β with respect to x_0, we obtain $\beta_{\min}$ or $H_{0,\,\max}$. This turns out to be equal to

$$H_{c3} = 1.695x = 1.695H_{c2}. \tag{18.76}$$

This is the critical field of surface superconductivity. It is larger than H_{c2}.
The procedure described allows one to obtain the exact value of H_{c3}, but requires cumbersome numerical calculations. We can, instead, use a simpler procedure, which will prove useful later on (Abrikosov 1964b). We write eq. (18.73) using the variables introduced earlier, ζ, ζ_0 and β :

$$-\frac{\mathrm{d}^2\Psi}{\mathrm{d}\zeta^2} + (\zeta - \zeta_0)^2\,\Psi = \beta\Psi \tag{18.77}$$

The problem of solving this equation may be presented as a variational problem of finding the minimum of a quantity:

$$\beta = \frac{\int_0^\infty \left[\left(\frac{\mathrm{d}\Psi}{\mathrm{d}\zeta}\right)^2 + (\zeta-\zeta_0)^2\,\Psi^2\right]\mathrm{d}\zeta}{\int_0^\infty \Psi^2\;\mathrm{d}\zeta}$$

Indeed, varying with respect to Ψ, we arrive at eq. (18.77).
We substitute into the functional (18.77) the trial function $\Psi = \exp\left(-\frac{1}{2}b\zeta^2\right)$, which satisfies the correct boundary conditions: $\Psi(\infty) = 0,\ \mathrm{d}\Psi/\mathrm{d}\zeta = 0$. The coefficient b
but, as has been shown in sections 18.2, these are equivalent statements of the problem. Thus, substituting $A = H_0\,(x - x_0)$ into eq. (18.9), we obtain

$$-\frac{\mathrm{d}^2\Psi}{\mathrm{d}x^2} + \chi^2 H_0^2\,(x - x_0)^2\,\Psi = \chi^2\Psi. \tag{18.73}$$

The solution of this equation in the general case is

$$\Psi = \exp\left(-\frac{1}{2}\zeta^2\right)\left\{C_1 F\left[\frac{1}{4}(1-\beta), \frac{1}{2}, (\zeta-\zeta_0)^2\right] + \zeta C_2 F\left[\frac{1}{4}(3-\beta), \frac{3}{2}, (\zeta-\zeta_0)^2\right]\right\} \tag{18.74}$$

where

$$\zeta = (xH_0)^{1/2}\, x, \quad \zeta_0 = (xH_0)^{1/2}\, x_0, \quad \beta = \frac{x}{H_0},$$

$F(\alpha, \gamma, z)$ is a degenerate hypergeometric function satisfying the equation

$$zF'' + (\gamma - z)F' - \alpha F = 0, \tag{18.75}$$

and C_1 and C_2 are arbitrary constants (see Landau and Lifshitz 1974).
The boundary conditions enable one to determine the ratio C_2/C_1 and β as a function of x_0. After this, minimizing β with respect to x_0, we obtain $\beta_{\min}$ or $H_{0,\,\max}$. This turns out to be equal to

$$H_{c3} = 1.695\chi = 1.695 H_{c2}. \tag{18.76}$$

This is the critical field of surface superconductivity. It is larger than $\boldsymbol{H_{c2}}$.
The procedure described allows one to obtain the exact value of H_{c3}, but requires cumbersome numerical calculations. We can, instead, use a simpler procedure, which will prove useful later on (Abrikosov 1964b). We write eq. (18.73) using the variables introduced earlier, ζ, ζ_0 and β :

$$-\frac{\mathrm{d}^2\Psi}{\mathrm{d}\zeta^2} + (\zeta - \zeta_0)^2\,\Psi = \beta\Psi \tag{18.77}$$

The problem of solving this equation may be presented as a variational problem of finding the minimum of a quantity:

$$\beta = \frac{\int_0^\infty \left[\left(\frac{\mathrm{d}\Psi}{\mathrm{d}\zeta}\right)^2 + (\zeta-\zeta_0)^2\,\Psi^2\right]\mathrm{d}\zeta}{\int_0^\infty \Psi^2\,\mathrm{d}\zeta}$$

Indeed, varying with respect to Ψ, we arrive at eq. (18.77).
We substitute into the functional (18.77) the trial function $\Psi = \exp\left(-\frac{1}{2}b\zeta^2\right)$, which satisfies the correct boundary conditions: $\Psi(\infty) = 0,\ \mathrm{d}\Psi/\mathrm{d}\zeta = 0$. The coefficient b
must be determined from the minimum condition for β. Evaluating the integrals, we get

$$\beta = \frac{1}{2}b + \frac{1}{2b} - \frac{2\zeta_0}{(\pi b)^{1/2}} + \zeta_0^2$$

Minimizing with respect to b, we obtain $\beta\,(\zeta_0)$. Then, we are to find the minimum with respect to ζ_0. Instead, we proceed in the reverse order, i.e., first we find the minimum with respect to ζ_0 and then with respect to b. By simple calculations we obtain

$$\beta_{\min} = b = \left(1 - \frac{2}{\pi}\right)^{1/2}, \quad \zeta_0 = \frac{1}{(\pi b)^{1/2}}. \tag{18.78}$$

This yields

$$H_0 = 1.66x,$$

which differs from the true value (18.76) by 2%.
Thus, we conclude that the superconductivity is retained in the surface layer up to fields larger than H_{c2} and, hence, in this layer persistent currents may be circulating. However, these currents cannot screen out the field inside the specimen. In fact, if the field inside the specimen were different from the external field, this would give rise to an additional bulk energy:

$$\int (H - H_0)^2 \ \mathrm{d}V$$

which could not be compensated by a decrease in energy in the surface sheath. Hence, the current density in the surface sheath is distributed so that $\int_0^\infty j_y \, \mathrm{d}x = 0$, i.e., j_y changes sign with depth. This is seen from the fact that j_y is equal to $-A\Psi^2 = -H_0 (x - x_0) \Psi^2$. If the result of the variational calculation is substituted, we obtain

$$\int_0^\infty (\zeta - \zeta_0) \exp(-b\zeta)^2 \, \mathrm{d}\zeta = \frac{1}{2} \left[\frac{1}{b} - \zeta_0 \left(\frac{\pi}{b} \right)^{1/2} \right]$$

According to eq. (18.79) this integral is equal to zero. This is also valid for the exact solution.

It is interesting to note that at $1/\sqrt{2} > x > (1.69\sqrt{2})^{-1}$ the superconductor will belong to type I, i.e., it passes to the normal state discontinuously at H_{cm}. However, the superconductivity in the surface sheath will persist up to $H_{c3} = 1.69\sqrt{2}\varkappa H_{\mathrm{cm}}$. From all this it follows that the determinations of the transition to the normal state in a magnetic field from the disappearance of the diamagnetic moment at the one hand and the appearance of resistance between contacts applied to the superconductor surface on the other may give different results.

The field H_{c3} plays another important role. In section 17.3 we have noted that the normal phase in type I superconductors may be retained when the field is decreased below the critical value. This retardation may occur up to the limiting supercooling field, when the free energy minimum corresponding to the normal phase vanishes. In the case of a bulk type I superconductor the supercooling field is determined from the condition of the possibility of existence of a small stationary nucleus of the superconducting phase in a normal conductor. As a matter of fact, at larger fields it must decrease with time and increase at lower fields. But this is exactly the condition from which the fields H_{c2} and H_{c3} were determined. Since $H_{c3} > H_{c2}$, the supercooling field is defined exactly as the field H_{c3}. Of course, this makes sense only for those type *I* superconductors for which $H_{c3} < H_{\mathrm{cm}}$, i.e., $x < (1.69\sqrt{2})^{-1}$. But if $1/\sqrt{2} > x > (1.69\sqrt{2})^{-1}$, the retardation of the normal phase does not occur because a superconducting nucleus appears at the surface even before the transition.

However, the surface can be "spoiled" deliberately, say by way of absorption of magnetic atoms (section 21.1) or by sputtering a film of a normal metal (section 20.1). In such a case, surface superconductivity is impossible, and the role of the supercooling field will be played by H_{c2}.

Let us now examine a case where the external field is directed at an angle to the sample surface. Let the superconductor occupy the half-space $x > 0$ and let the magnetic field have the following components:

$$H_z = H_0 \cos\theta, \quad H_x = H_0 \sin\theta. \tag{18.79}$$

The vector potential is chosen along the y axis:

$$A_y = H_0(x \cos\theta - z \sin\theta). \tag{18.80}$$

The equation for Ψ in the linear approximation is written as

$$-\frac{\partial^2\Psi}{\partial x^2}+\left[\mathrm{i}\frac{\partial}{\partial y}+\varkappa H_0(x\cos\theta-z\sin\theta)\right]^2\Psi-\frac{\partial^2\Psi}{\partial z^2}=x^2\Psi. \tag{18.81}$$

The boundary conditions are the same as before.
Along the boundary plane, in particular along the z direction, the conditions must be uniform. It is not difficult to see that the variation of z in eq. (18.81) can be compensated by the phase factor $\exp(\mathrm{i}ky)$ in the function Ψ, i.e., we are dealing here with a situation very similar to what occurs close to H_{c2} (section 18.2). But in order to obtain the critical field, it is sufficient to solve the linear equation, and the solution may be a superposition of the solutions localized near any z, and in particular, one solution of such a type. Therefore, it is sufficient to find Ψ which vanishes as $z\to\pm\infty$. Substituting $\Psi(x,y,z)=\exp(\mathrm{i}xH_0x_0y)\,\Psi(x,z)$ and introducing the variables

$$\zeta=(xH_0)^{1/2}\,x,\quad \zeta_0=(xH_0)^{1/2}\,x_0,\quad \eta=(xH_0)^{1/2}\,z,\quad \beta=x/H_0,$$

we obtain the generalization of eq. (18.77):

$$-\frac{\partial^2\Psi}{\partial\zeta^2}-\frac{\partial^2\Psi}{\partial\eta^2}+\left[(\zeta-\zeta_0)\cos\theta-\eta\sin\theta\right]^2\Psi=\beta\Psi$$

This equation is equivalent to the variational principle for determination of the minimum of β :

$$\beta=\frac{\int_0^\infty \mathrm{d}\zeta\int_{-\infty}^\infty \mathrm{d}\eta\left\{\left(\frac{\partial\Psi}{\partial\zeta}\right)^2+\left(\frac{\partial\Psi}{\partial\eta}\right)^2+\left[(\zeta-\zeta_0)\cos\theta-\eta\sin\theta\right]^2\Psi^2\right\}}{\int_0^\infty \mathrm{d}\zeta\int_{-\infty}^\infty \mathrm{d}\eta\Psi^2} \tag{18.82}$$

We shall assume the trial function $\Psi=\exp\left(-\frac{1}{2}a\eta^2-\frac{1}{2}b\zeta^2\right)$, which would satisfy the boundary conditions. We get

$$\beta=\frac{1}{2}\left(b+\frac{1}{b}\cos^2\theta\right)+\frac{1}{2}\left(a+\frac{1}{a}\sin^2\theta\right)+\cos^2\theta\left(\zeta_0^2-\frac{2\zeta_0}{(\pi b)^{1/2}}\right).$$

Minimizing this expression with respect to $\boldsymbol{a},\boldsymbol{b}$ and ζ_0, we find

$$\begin{aligned}&\beta=\cos\theta\left(1-\frac{2}{\pi}\right)^{1/2}+\sin\theta,\quad b=\cos\theta\left(1-\frac{2}{\pi}\right)^{1/2},\\&a=\sin\theta,\quad \zeta_0=\frac{1}{(\pi b)^{1/2}}.\end{aligned} \tag{18.83}$$

Substituting

$$\beta=\frac{\chi}{H_{c3}(\theta)},\quad H_{c3}(0)=\chi\left(1-\frac{2}{\pi}\right)^{-1/2},\quad H_{c2}=x,$$

we have

$$\frac{1}{H_{c3}(\theta)}=\frac{1}{H_{c3}(0)}\cos\theta+\frac{1}{H_{c2}}\sin\theta, \tag{18.84}$$

that is, a smooth variation of H_{c3} from $H_{c3}(0)$ at $\theta=0$ to H_{c2} at $\theta=\frac{1}{2}\pi$. This gives, in particular,

$$-\left(\frac{1}{H_{c3}}\frac{\mathrm{d}H_{c3}}{\mathrm{d}\theta}\right)_{\theta=0}=\frac{H_{c3}(0)}{H_{c2}}=1.66.$$

An exact calculation gives the value 1.35 (Saint-James 1965).
In order to determine the current distribution at fields somewhat lower than $\boldsymbol{H_{c3}(\theta)}$, we have to solve the nonlinear Ginzburg-Landau equation. The solution is
again taken in the form of a superposition of solutions of the type we found earlier, centered around various z :

$$\Psi = \exp\left(\mathrm{i}xH_0x_0y\right)\sum_{n=-\infty}^{\infty} C_n \mathrm{e}^{\mathrm{i}kny}\Psi_0\left(x, z - \frac{nk}{xH_0\sin\theta}\right). \tag{18.85}$$

A superposition of the same type, (18.18), was obtained close to $\boldsymbol{H_{c2}}$. The subsequent line of reasoning is quite analogous to section 18.2, and we shall not give it here. The result is a solution containing vortices, i.e., points which make the phase Ψ change by 2π when they are encircled (Kulik 1968a).

The periods of the vortex structure can be found using the idea that the rise of the vector potential is compensated by jumps of the phase gradient at branch cuts drawn through the vortex points parallel to the y axis. If the period along the y axis is a, then the jump in $\partial\varphi/\partial y$ at each line is $2\pi/a$. Compensation of the increase of the term $H_0z\sin\theta$ in (18.81) occurs with the condition

$$-\frac{2\pi}{a} + xH_0b\sin\theta = 0,$$

where b is the period in the z direction, or

$$ab = \frac{2\pi}{xH_0\sin\theta}. \tag{18.86}$$

In the case under consideration, as opposed to the neighborhood of $\boldsymbol{H_{c2}}$, anisotropy arises: the directions y and z are not equivalent because the field H lies in the xz plane. Nevertheless, if we assume a rectangular vortex lattice, the minimization of the free energy will lead to the result $a = b$, i.e., it will give a square lattice with a period given by

$$a = b = \left(\frac{2\pi}{xH_0\sin\theta}\right)^{1/2}. \tag{18.87}$$

Other variants have not been studied.
From formula (18.87) it follows that the period of the vortex structure increases with decreasing θ according to the law $a \sim \theta^{-1/2}$ (at small θ). Moreover, one of the basis vectors of the vortex lattice is directed along the component H in the plane of the surface (this is the z axis in the case under consideration).

The field H_{c3} has been detected in numerous experiments. There are also data in favor of the vortex structure of the surface currents with a tilted field. They refer to the critical current for surface superconductivity. A theoretical calculation of the critical current for the field parallel to the surface (Abrikosov 1964b), which is not given here, yields

$$J_c \sim j_c\xi,$$

where J_c is the critical current flowing through a cross-sectional area of length 1 cm (along the surface) and extending to infinity into the bulk of the metal; j_c is the
absolute critical value of the current density corresponding to the Landau criterion (see eq. 17.63). This result is obvious since the thickness of the superconducting sheath in the case of surface superconductivity is of order ξ. Formula (18.88) is an estimate of the value of the critical current within the interval $H_{c2} < H_0 < H_{c3}$. Actually the current depends on H_0 and vanishes at H_{c3}.

Much lower values of the critical current are always obtained in experiments. This may be accounted for by the fact that a field orientation exactly parallel to the surface cannot be realized in practice, and with a tilted field a vortex structure is formed. When current is flowing, the vortices are acted on by a force, which makes them move. As a result, electrical resistance arises (this point will be discussed in more detail in section 18.8). Strictly speaking, we must obtain zero critical current. However, in fact, the vortices cling to surface irregularities (pinning, see section 18.8) and therefore with a sufficiently small current they remain immobile. This effect can be enhanced by deliberately making the surface rougher. Indeed, in this case the critical current increases (Akhmedov et al. 1969).

8.4.6 18.5. Type II superconductors at low temperatures

In this section we shall draw certain conclusions concerning the behavior of type II superconductors at temperatures far from T_c, where the Ginzburg-Landau theory does not apply. We use conventional units.

It is rather obvious that at low temperatures the qualitative picture of the magnetic properties of superconductors is the same as in the vicinity of T_c. There is a surface energy σ_{ns}, which may be positive or negative. In type I superconductors it is positive; a first-order transition occurs at the field H_{cm}, and there is a supercooling field H_{c3} or H_{c2}. For type II superconductors σ_{ns} is negative, and the transition to the normal phase takes place by way of a second-order transition in the field $\boldsymbol{H}_{c2}$. Therefore, the ratio

$$\frac{H_{c2}(T)}{H_{cm}(T)\sqrt{2}} = \varkappa(T) \tag{18.89}$$

is a quantity that distinguishes the two types of superconductors (with $x < 1/\sqrt{2}$ and with $x > 1/\sqrt{2}$), and exactly this quantity was given in formulae (16.97) and (16.101).

In type II superconductors at all temperatures there arises a mixed state in a magnetic field. By order of magnitude the field H_{cl} has been defined in section 18.1. However, in case $x \gg 1$ (recall that, according to formulae 16.97 and 16.101x varies little with temperature) one can determine the value of H_{c1} rather precisely. To do this, we take into account that the major part of the vortex energy builds up in the region $\xi < \rho < \delta$, and in this region the detailed structure of its core, which has a radius of order ξ, is unimportant. The only important point is that the order parameter
and, hence, the current, begins to decrease at such distances and vanishes in the center.

Just as near T_c, each vortex carries one quantum of magnetic flux. This follows from the fact that at $\delta \gg \boldsymbol{\xi}$ far from the vortex axis the London equation (section 16.7) is valid. According to this equation, the current is connected with the vector potential by the relation $\mathbf{j} = -QA$, but in such a form the current is not gaugeinvariant, i.e., it depends on the choice of $\boldsymbol{A}$. To provide gauge invariance, it is necessary that $\boldsymbol{A}$ be included in the combination with the gradient of the phase of the complex order parameter $\Delta = |\Delta|e^{i\chi}$:

$$j = -Q\left(A - \frac{\hbar c}{2e}\nabla\chi\right). \tag{18.90}$$

But this expression is quite analogous to eq. (17.75).
Considering that far from the vortex axis $|\Delta|$ and, hence, Q are equal to their values in a superconductor in the absence of the field, i.e., are independent of the coordinates, it may be asserted that the flux is equal to an integer number of flux quanta inside the loop, for which $\oint j\, \mathrm{d}l = 0$. If we are dealing with a single vortex, then it is sufficient to choose the loop at $\rho \gg \delta$, where $j = 0$. In a case where there are many vortices and they form a lattice, one

can find such a loop around each vortex, on which $\oint j\ \mathrm{d}l = 0$ due to the lattice symmetry. Evidently, each vortex carries only one flux quantum.

As has been noted, at $\rho > \boldsymbol{\xi}$ we may consider Δ to be equal to its value in the absence of the field, which is why for H the London equation (15.39) is valid. Thus, we have

$$\Delta H - \delta^{-2} H = -\delta^{-2}\Phi_0 \delta(\rho). \tag{18.91}$$

The right-hand side takes account of the presence of a vortex with a magnetic flux Φ_0. Integrating over the cross-sectional area perpendicular to the vortex axis, we can see that the choice of the right-hand side is correct. The solution of eq. (18.91) is

$$H = \frac{1}{2\pi\delta^2}\Phi_0 K_0\left(\frac{\rho}{\delta}\right). \tag{18.92}$$

Now we must write the expression for the free energy corresponding to the London equation. It is made up of the field energy and the kinetic energy of the supercurrent. For unit volume we have

$$\Omega_\mathrm{s} - \Omega_\mathrm{s}^{(0)} = \frac{H^2}{8\pi} + \frac{1}{2} n_\mathrm{s} m v_\mathrm{s}^2 = \frac{H^2}{8\pi} + \frac{1}{2} n_\mathrm{s} m \left(\frac{j}{n_\mathrm{s} e}\right)^2 = \frac{H^2}{8\pi} + \frac{1}{2}\Lambda j^2, \tag{18.93}$$

where use is made of the expression $\Lambda = m/n_\mathrm{s}e^2$ (see eq. 15.35). Note that with this derivation it is immaterial whether we use the concept of superconducting electrons with density n_s, charge e and mass m or the concept of pairs with density $\frac{1}{2}n_\mathrm{s}$, charge $2e$ and mass $2m$.

The integral over the volume of the last term can be transformed using the Maxwell equation $\mathrm{rot}\,\boldsymbol{H} = (\boldsymbol{4}\pi/c)\boldsymbol{j}$:

$$\begin{aligned}
\frac{1}{2}\Lambda \int j^2\ \mathrm{d}V &= \frac{1}{2}\Lambda\left(\frac{c}{4\pi}\right)^2 \int (\mathrm{rot}\, H)^2\ \mathrm{d}V \\
&= \frac{\delta^2}{8\pi}\int \{\mathrm{div}[H\,\mathrm{rot}\,H] + H\,\mathrm{rot}\,\mathrm{rot}\,H\}\mathrm{d}V \\
&= \frac{\delta^2}{8\pi}\left\{\int_S [H\,\mathrm{rot}\,H]\mathrm{d}S - \int H\Delta H\ \mathrm{d}V\right\}
\end{aligned}$$

Here we have used the formula $\mathrm{div}[\boldsymbol{ab}] = \boldsymbol{b}\ \mathrm{rot}\ \boldsymbol{a} - \boldsymbol{a}\ \mathrm{rot}\ \boldsymbol{b}$, transformed the integral of div to an integral over the sample surface and took advantage of the fact that $\mathrm{rot}\,\mathrm{rot}\,\boldsymbol{H} = \mathrm{grad}\,\mathrm{div}\,\boldsymbol{H} - \Delta\boldsymbol{H}$ and $\mathrm{div}\,\boldsymbol{H} = 0$. Thus, we have

$$\begin{aligned}
\int \Omega_\mathrm{s}\ \mathrm{d}V = \int \Omega_\mathrm{s}^{(0)}\mathrm{d}V + \frac{\delta^2}{8\pi}\int_\mathrm{S} [H\,\mathrm{rot}\,H]\mathrm{d}S \\
+ \frac{1}{8\pi}\int H\left(H - \delta^2\Delta H\right)\mathrm{d}V
\end{aligned} \tag{18.94}$$

We give also another form of this expression. Since

$$[H\ \mathrm{rot}\ H] = \frac{1}{2}\nabla\left(H^2\right) - (H\nabla)H, \quad H\Delta H = \mathrm{div}\left[\frac{1}{2}\nabla(H)^2\right] - (\nabla H)^2,$$

we can obtain from eq. (18.94), for a case where $(\boldsymbol{H}\nabla)\boldsymbol{H} = 0$, i.e., $\boldsymbol{H}$ is directed along z and depends only on ρ :

$$\int \Omega_\mathrm{s}\ \mathrm{d}V = \int \Omega_s^{(0)} + \frac{1}{8\pi}\int \left[H^2 + \delta^2(\nabla H)^2\right]\mathrm{d}V \tag{18.94'}$$

In the case of a single vortex under consideration the surface integral in (18.94) is equal to zero. We must substitute formulae (18.91) and (18.92) into the second integral of (18.94). The logarithmic infinity $K_0(\rho)$ at $\rho = 0$ must be replaced by $\ln(\delta/\xi)$ because at a distance of order ξ from the axis eq. (18.91) is no longer valid and H ceases to depend on the coordinate (with a logarithmic accuracy). As a result, we obtain an extra energy per unit length of the vortex:

$$\varepsilon_0 \approx \frac{1}{(4\pi\delta)^2}\Phi_0^2 \ln\left(\frac{\delta}{\xi}\right) \tag{18.95}$$

We have limited ourselves to the calculation of the dominant term with $\ln(\delta/\xi)$ because higher accuracy requires a knowledge of the core structure.

The condition of the nucleation of a vortex is

$$\varepsilon_0 - \frac{1}{4\pi}H_0 \int H \ \mathrm{d}S = \varepsilon_0 - \frac{1}{4\pi}H_0\Phi_0 = 0$$

From this relation we obtain

$$H_{\mathrm{c1}} = 4\frac{\pi\varepsilon_0}{\Phi_0} \approx \frac{1}{4\pi}\frac{\Phi_0}{\delta^2}\ln\left(\frac{\delta}{\xi}\right) \tag{18.96}$$

This formula is consistent in order of magnitude with eqs. (18.8) and (18.50). Note that, in accordance with formula (18.91), the field in the vortex core is equal with logarithmic accuracy to

$$H(0) \approx \frac{1}{2\pi}\frac{\Phi_0}{\delta^2}\ln\left(\frac{\delta}{j}\right)$$

that is, just as near $T_{\mathrm{c}}, H(0)$ is about twice as large as H_{cl}.

The expression for the current is derived from the Maxwell equation $\boldsymbol{j} = (c/4\pi)\ \mathrm{rot}\ H$. In the case under consideration,

$$j_\varphi = \frac{c}{2\delta}\frac{1}{(2\pi\delta)^2}\Phi_0 K_1\left(\frac{\rho}{\delta}\right) \tag{18.97}$$

At $\rho < \delta, \quad K_1 \approx \delta/\rho$. Substituting $\Phi_0 = \pi\hbar c/e, \quad \delta = (mc^2/4\pi n_{\mathrm{s}}e^2)^{1/2}$ gives

$$j_\varphi \approx n_{\mathrm{s}}e\frac{\hbar}{2m\rho}$$

From this it follows that the velocity of Cooper pairs in the vortex at a distance of $\xi < \rho < \delta$ is equal to $\hbar/2m\rho$ and this is in agreement with formula (18.7) deduced from the Bohr quantization rule. At distances of $\rho \geqslant \delta$ it becomes important that the liquid consists of charged particles and its motion leads to generation of a magnetic field. As a result, at $\rho > \delta$ the current is damped according to the law $\exp(-\rho/\delta)$.

Taking into account the agreement between eq. (18.52) near T_{c} and eq. (18.91) and also between expressions (18.55) and (18.94) for the free energy, and considering that each vortex carries one flux quantum, we conclude that formulae (18.60) and (18.58) are also valid, provided that correct units are used, namely x has to be replaced by $2\pi\delta^2/\Phi_0$. This refers also to the limiting expressions (18.61) and (18.67) and also to formula (18.68) without the last term, which cannot be determined accurately because of the logarithmic accuracy in the calculation of H_{c1}. All these results characterize the dependence $B\,(H_0)$ at $H_{\mathrm{cl}} \leqslant H_0 < H_{\mathrm{c2}}$.

In what follows the estimates for critical fields expressed in terms of $\boldsymbol{\Phi_0}$ and characteristic lengths will be useful. Formula (18.96) gives an estimate for H_{c1}. With the field H_{c2} the vortices are moved together to distances of order ξ and since there is one flux quantum per vortex, it

follows that $\boldsymbol{H}_{c2} \sim \boldsymbol{\Phi}_0/\boldsymbol{\xi}^2$. Finally, because of $H_{c2} \sim H_{cm}x \sim H_{cm}\delta/\xi$, we have $H_{cm} \sim \Phi_0/\delta\xi$. Thus,

$$H_{c1} \sim \frac{\Phi_0}{\delta^2}, \quad H_{cm} \sim \frac{\Phi_0}{\delta\xi}, \quad H_{c2} \sim \frac{\Phi_0}{\xi^2}. \tag{18.98}$$

While comparing the theory with experiment, it is necessary to take into account a number of circumstances. First of all, large x values are attained only in superconductors with a large impurity concentration. We have already noted in section 16.9 that impurities present in a small concentration have a very slight effect on the thermodynamic properties of the superconductor, in particular on H_{cm}. However, at a large impurity concentration of the order of tens of percent, we are actually dealing with a new substance.

The boundaries of the mixed state are the fields H_{cl} and H_{c2}, which are sufficiently clearly seen in the $\boldsymbol{B}(\boldsymbol{H}_0)$ curve. It turns out that from this curve one can also easily determine $\boldsymbol{H}_{cm}$. Indeed, at $\boldsymbol{H}_{c2}$

$$\Omega_s(H_{c2}) = \Omega_n(H_{c2}).$$

From this it follows (see Appendix III) that

$$\Omega_s^{(0)} - \frac{1}{4\pi}\int_0^{H_{c2}} B(H_0)\,dH_0 = \Omega_n^{(0)} - \frac{H_{c2}^2}{8\pi}.$$

But since $\Omega_n^{(0)} - \Omega_s^{(0)} = H_{cm}^2/8\pi$, we find that

$$\frac{1}{2}H_{cm}^2 = \int_0^{H_{c2}} [H_0 - B(H_0)]\,dH_0 = \int_0^{H_{c2}} [-4\pi M(H_0)]\,dH_0. \tag{18.99}$$

In other words, H_{cm} is determined by the area under the curve of $-\boldsymbol{4\pi M}$ versus $\boldsymbol{H}_0$.
In experiments one often has to work with specimens of noncylindrical shape. If the specimen has the form of an ellipsoid, the role of the external field H_0 is played by the "internal" field H_i (Appendix III):

$$H_i = H_0 - 4\pi nM,$$

where M is the magnetization and n is the demagnetization factor. The magnetization M is connected with B by the relation

$$B = H_i + 4\pi M$$

Expressing M by this relation and substituting into the preceding formula, we obtain

$$(1-n)H_i + nB = H_0.$$

If the dependence $B(H_0)$ for cylindrical geometry obtained earlier is written in the form $H_0 = f(B)$, the same function will now relate H_i to B. As a result, we have

$$(1-n)f(B) + nB = H_0. \tag{18.100}$$

This is just the relation between B and H_0 for the ellipsoid. In particular, the onset of the mixed state corresponds to $B = 0, f(B) = H_{cl}$. Hence, for the ellipsoid it begins at

$$H_0 = (1-n)H_{c1}. \tag{18.101}$$

In particular, for an infinite plate in a perpendicular field ($n = 1$) it begins at $H_0 = 0$. The termination of the mixed state corresponds to $B = f(B) = H_0 = H_{c2}$.

While speaking of comparison with experiment, one more circumstance must be borne in mind. The variation of the induction with H_0 in the mixed state is the result of the variation of the vortex density. Hence, upon gradual variation of H_0 there is a displacement of the vortices. This displacement can be hindered by the microscopic irregularities of the specimen (pinning). We defer a more detailed discussion of this point until section 18.7; for the moment we only note that the dependence $B(H_0)$ for real specimens may prove to be rather far from the theoretical equilibrium curve, so that comparison of theory with experiment may be made only for specially prepared homogenized specimens. Homogenization can be achieved, in particular, by prolonged annealing at a temperature close to the melting point.

However, even in this case there is a certain inevitable potential barrier which impedes the free motion of the vortices. It is associated with the sample surface (Bean and Livingston 1964). Let us consider a vortex which is approaching the surface (fig. 119). We assume that $x > 1$, that the vortex axis is parallel to the sample surface (along the z axis), and that the distance x_1 from the axis to the surface by far exceeds the radius of the core. In the absence of the vortex the field is equal to $H_0 e^{-x/\delta}$. The vortex adds its own magnetic field, which is distorted by the surface so as, first, not to produce an extra field at the surface (because the field is specified and equals $\boldsymbol{H}_0$) and, second, to make the current normal to the surface vanish.

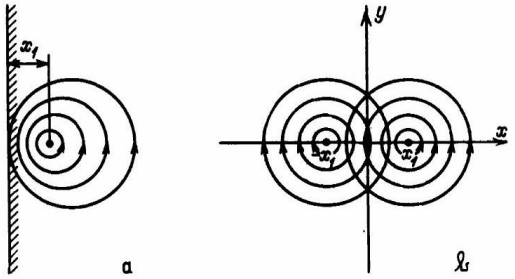

Fig. 119.

This can be realized if we add to the vortex its mirror image relative to the surface with the opposite direction of the field and current (fig. 119b). The vortex field will satisfy the London equation with two sources:

$$\Delta H - \frac{1}{\delta^2} H = -\frac{1}{\delta^2} \Phi_0 \left[\delta(\rho - \rho_1) - \delta(\rho - \rho_2)\right], \tag{18.102}$$

where $\rho_1 = (x, 0)$ and $\rho_2 = (-x_1, 0)$; the total magnetic field will be given by

$$H = H_0 e^{-x/\delta} + \frac{\Phi_0}{2\pi\delta^2} \left[K_0\left(\frac{|\rho - \rho_1|}{\delta}\right) - K_0\left(\frac{|\rho - \rho_2|}{\delta}\right)\right]. \tag{18.103}$$

Let us find the energy in a given field using these formulas:

$$\int \Omega_{sH} \, dV = \int \Omega_s \, dV - \frac{1}{4\pi} H_0 \int H \, dV.$$

We shall calculate the energy per unit length along z and integrate over the half-plane $x > 0$. In this case, as opposed to a single vortex in infinite space, the integral over the surface does not vanish, so we must be careful.

Let us, first, integrate eq. (18.102) over the half-plane $x > 0$. Then we obtain (the normal to the surface is directed along $-x$):

$$\int H \, dV = \Phi_0 + \delta^2 \int \Delta H \, dx \, dy = \Phi_0 - \delta^2 \int_{x=0} \frac{\partial H}{\partial x} \, dy.$$

Hence,

$$-\frac{H_0}{4\pi}\int H\ \mathrm{d}V = -\frac{H_0\Phi_0}{4\pi} + \frac{\delta^2 H_0}{4\pi}\int_{x=0}\frac{\partial H}{\partial x}\ \mathrm{d}y.$$

The surface integral in (18.94) is equal to

$$\frac{\delta^2}{8\pi}\int [H\,\mathrm{rot}\,H]\mathrm{d}S = -\frac{\delta^2}{8\pi}H_0\int_{x=0}\frac{\partial H}{\partial x}\ \mathrm{d}y.$$

The volume integral in eq. (18.94) is evaluated with the aid of formulae (18.102) and (18.103). Here we replace $K_0(0)$ by $\ln(\delta/\xi)$ because at distances smaller than ξ the theory presented here is no longer valid and we have to extrapolate H from $x \sim \xi$. We also make use of formula (18.96). Substituting formulas (18.103) for H into the integral $(\delta^2/8\pi)\,H_0\int_{x=0}(\partial H/\partial x)\mathrm{d}y$, we see that the first term gives $-(\delta H_0^2/8\pi)\int \mathrm{d}y$, which corresponds to the field energy in the layer δ without a vortex. This energy is neglected here.

As a result, the energy associated with the vortex is given by

$$U(x_1) = \frac{\Phi_0}{4\pi}\left\{H_0\exp\left(-\frac{x_1}{\delta}\right) - \frac{\Phi_0}{4\pi\delta^2}K_0\left(\frac{2x_1}{\delta}\right) - H_0 + H_{c1}\right\}. \tag{18.104}$$

At distances $x_1 \leqslant \xi$, $K_0(2x_1/\delta)$ must be replaced by $\ln(\delta/\xi)$. Comparing with (18.96), we see that over such distances $U(x_1)$ vanishes. With $x_1 \to \infty$ the first two terms of (18.104) vanish; $U(\infty) < 0$ at $H_0 > H_{c1}$ and $U(\infty) > 0$ at $H_0 < H_{c1}$, as should be expected. The graph of the function $U(x_1)$ is given in fig. 120 . We see that a potential barrier appears near the surface, which hinders both the entry of the vortex into the superconductor and its escape from it. An increase in the field leads to the disappearance of the barrier only at a certain field $H_0 = H'_{c1} > H_{c1}$.

This field can be estimated as follows. The condition $U'(x_1) = 0$ yields

$$\frac{\Phi_0}{4\pi\delta^2}\frac{2}{\delta}K_1\left(\frac{2x_1}{\delta}\right) - \frac{H_0}{\delta}\exp\left(-\frac{x_1}{\delta}\right) = 0.$$

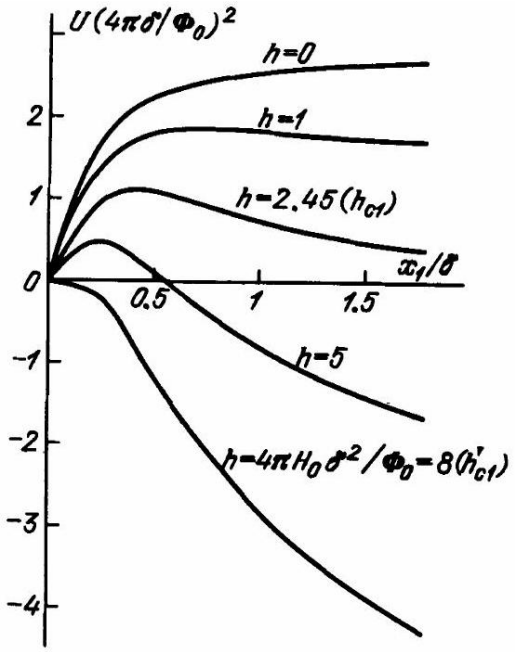

Fig. 120.

We are interested in the case where the top of the barrier reaches the surface, i.e., $x_1 = 0$. But as $x_1 \to 0, K_1(2x_1/\delta) \approx \delta/2x_1$. As has already been pointed out, at small x_1 we have to replace x_1 by ξ, i.e., $K_1(2x_1/\delta) \sim \delta/\xi$. As a result, we have (see eq. 18.97):

$$H'_{\rm cl} \sim \frac{\Phi_0}{\delta\xi} \sim H_{\rm cm}.$$

As the field decreases the barrier disappears only at $\boldsymbol{H_0} = \mathbf{0}$.
In real experiments, the field lines of force are always concentrated at the edges of the sample, and thus at these sites the external field may exceed $H'_{\rm c1}$. It is these edges that will be "weak places" through which the vortices will enter the sample. Therefore, the $B(H_0)$ curve taken in an increasing field may be regarded as an equilibrium curve*. However, when the field falls off, the sample surface has no portions where the field is zero and, hence, the barrier is preserved everywhere. Therefore, the magnetization curve taken in a decreasing field even in the most homogenized samples will be nonequilibrium. This is supported by experimental data (fig. 121).

We will now consider another property of the mixed state. As has been found earlier, at the vortex axis $\Delta = 0$. But the spectrum of quasiparticles in a superconductor begins with the energy Δ. In view of this, the possibility is not excluded that there exist special quasiparticles localized near the vortex axis, with zero excitation

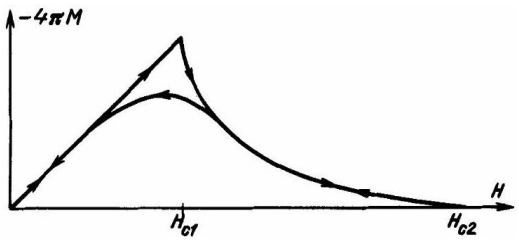

Fig. 121.

energy. This idea is confirmed by rigorous theoretical calculations (Caroli and Matricon 1965, Caroli et al. 1965). Indeed, in the mixed state the superconductor has quasiparticles which move along the vortex axis and which have finite density of states as $\varepsilon \to 0$, just as in cylinders of a normal metal with a radius of order ξ.

Since the cross-sectional area of the core of a single vortex is of the order of ξ^2 and the number of vortices that pass through 1 cm^2 is $n = B/\Phi_0$, the fraction of "normal metal" is $\xi^2 B/\Phi_0$ and, accordingly, the density of states is given by

$$\nu \sim \nu_n \xi^2 \frac{B}{\Phi_0},$$

where $\nu_{\rm n}$ is the density of states for a normal metal. At the field $H_{\rm c2}$ the vortices approach each other to a distance of the order of ξ; in this case $B \approx H_{\rm c2} \sim \Phi_0/\xi^2$ (see eq. 18.97). Hence, the density of states may be written as

$$\nu = \nu_{\rm n} \frac{B}{H_{\rm c2}} \tag{18.105}$$

- In specially prepared samples with a very smooth surface it is possible to succeed in retarding the transition in an increasing field. This provides good agreement with the result of the exact theory, $H'_{\rm c1} = H_{\rm cm}$.

(the equality sign is used because of the condition of matching with a normal metal at $B = H_{c2}$). But the finite density of states leads to a linear dependence of heat capacity on temperature. Thus, we arrive at the conclusion that at $T < T_c$ in type II superconductors in the mixed state the heat capacity is linear in temperature:

$$\Delta C(B) = \frac{1}{3}\pi^2 \nu_n \frac{TB}{H_{c2}} = C_n(T)\frac{B}{H_{c2}}. \tag{18.106}$$

In conclusion we note that, just as in the vicinity of $\boldsymbol{T}_c$, the generation of a superconducting nucleus near the surface is possible at fields larger than $\boldsymbol{H}_{c2}$. The ratio H_{c3}/H_{c2} depends on temperature and on electron scattering conditions at the sample surface. A calculation performed by means of a variational method similar to that employed in section 18.4 gives, at $T = 0, H_{c3}/H_{c2} \geqslant 1.99$ for specular reflection of electrons from the surface and $H_{c3}/H_{c2} \geqslant 2.09$ for diffuse reflection (Kulik 1968). We see that all the magnetic properties of type II superconductors are not only qualitatively similar to those observed in the vicinity of T_c but differ little quantitatively from them (in the corresponding units).

8.4.7 18.6. A thin film of a type II superconductor in a magnetic field

The critical field of thin films of type I superconductors with $x < 1$ has been calculated in section 17.3. The condition $x < 1$ enabled us to assume $\Psi \approx$ const. throughout the superconductor. In all subsequent computations x did not appear. Some of the results of section 17.3 may also be extended to type II superconductors. Indeed, with thicknesses of $d < \xi$ (in reduced units $d < x^{-1}$) Ψ must not vary throughout the film thickness. But for type II superconductors $\xi < \delta$ and, hence, one must employ the formulas for $d < \delta$ (in reduced units $d < 1$). In particular, the critical field of the transition to the normal state is expressed by formulae (17.48) or (17.48'). Note that for such films the ratio δ/d plays the role of the "effective" parameter $\varkappa$, therefore formula (17.48) is completely consistent with formulae (18.2) and (18.3) for the upper critical field of type II superconductors.

As far as real experimental objects are concerned, films of type II superconductors are prepared by vaporization of a small piece of metal and condensation of the vapor onto a non-metallic substrate kept at helium temperature. It turns out that the atoms of the metal upon contact with the substrate immediately stick to it and are not displaced. Therefore, the film formed is almost entirely amorphous, i.e., has a small mean free electron path and therefore belongs to type II, even if the parent pure metal was a type I superconductor and had $x < 1$. Thus, we see that a film of a type II superconductor is a rather common object. When such a film is annealed, i.e., its temperature is raised to several tens of degrees, recrystallization occurs, and it becomes a type I superconductor with H_{cm} and T_c close to the characteristics of the bulk material. The same occurs if the metal is vaporized onto a substrate kept at room temperature.

A question arises as to the possibility of realizing a mixed state in a film with $x > 1/\sqrt{2}$. The qualitative answer to this question is rather obvious: the mixed state is possible with thicknesses of $d \geqslant \xi$. From this it follows that with decreasing film thickness the field H_{cl} must increase more rapidly than the field H_{c2} and they must become equal at $d \sim \xi$.

Let us now consider the problem quantitatively. In order to find H_{cl}, we are to find the conditions for the creation of one vortex. From symmetry considerations it is clear that the lowest energy will be exhibited by a vortex in the center of the film. In the preceding section it has been shown that the boundary conditions on a planar boundary may be fulfilled by introduction of a specularly reflected vortex with an opposite direction of the field and current. In the case under consideration, there are two boundaries and, as a result, there arises an infinite

system of reflections which are alternating in field and current, with a distance d between the nearest vortices. Instead of eq. (18.102), we have

$$\Delta H - \frac{1}{\delta^2} H = \frac{1}{\delta^2} \Phi_0 \sum_{n=-\infty}^{\infty} (-1)^n \delta(\rho - \rho_n), \tag{18.107}$$

where $\rho_n = (nd, 0)$ and n assumes all integer values, positive and negative.

The total magnetic field, which satisfies the conditions $H = H_0$ at $x = \pm\frac{1}{2}d$ will be equal to (see eq. 18.102 and 18.103)

$$\begin{aligned} H =& H_0 \frac{\cosh(x/\delta)}{\cosh(d/2\delta)} \\ &+ \frac{\Phi_0}{2\pi\delta^2} \sum_{n=-\infty}^{\infty} (-1)^n K_0 \left(\frac{|\rho - \rho_n|}{\delta} \right). \end{aligned} \tag{18.108}$$

Let us now find the free energy. Using the same procedure as in the preceding section, we find the energy of one vortex in the field (per unit length):

$$\begin{aligned} \int \left(\Omega_{\mathrm{s}H} - \Omega_{\mathrm{s}H}^{(0)} \right) \mathrm{d}V = & \int \left(\Omega_{\mathrm{s}} - \Omega_s^{(0)} \right) \mathrm{d}V \\ & - \frac{1}{4\pi} H_0 \int \left[H(\rho) - H^{(0)}(\rho) \right] \mathrm{d}V, \end{aligned}$$

where $\Omega_{\mathrm{sH}}^{(0)}$ and $\Omega_{\mathrm{s}}^{(0)}$ correspond to the absence of a vortex and $H^{(0)}(\rho)$ is the first term in (18.108). Calculation gives

$$\begin{aligned} & \int_{-d/2}^{d/2} \mathrm{d}x \int_{-\infty}^{\infty} \mathrm{d}y \left(\Omega_{\mathrm{s}H} - \Omega_{\mathrm{sH}}^{(0)} \right) \\ & = \frac{1}{4\pi} \frac{\Phi_0 H_0}{\cosh(d/2\delta)} \\ & \quad + 2 \left(\frac{\Phi_0}{4\pi\delta} \right)^2 \sum_{n=1}^{\infty} (-1)^n K_0 \left(\frac{nd}{\delta} \right) + \frac{1}{4\pi} \left[H_{\mathrm{c}1}(\infty) - H_0 \right] \Phi, \end{aligned}$$

where $H_{\mathrm{c}1}(\infty)$ corresponds to an infinite sample. Equating this expression to zero, we obtain the first critical field for a sample of thickness d (Abrikosov 1964a):

$$H_{\mathrm{c}1}(d) = \frac{H_{\mathrm{c}1}(\infty) - \frac{\Phi_0}{2\pi\delta^2} \sum_{n=1}^{\infty} (-1)^{n+1} K_0 \left(\frac{nd}{\delta} \right)}{1 - \frac{1}{\cosh(d/2\delta)}} \tag{18.109}$$

The limiting formulas are as follows:

$$\begin{aligned} & H_{\mathrm{c}1}(d) \approx H_{\mathrm{c}1}(\infty) \left[1 + 2\exp\left(\tfrac{-d}{2\delta} \right) \right], && d > \delta \\ & H_{\mathrm{c}1}(d) \approx \tfrac{2\Phi_0}{\pi d^2} \ln\left(\tfrac{d}{\xi} \right), && d < \delta \end{aligned} \tag{18.110}$$

In the last formula we used the integral representation of the MacDonald function (preceding eq. 16.29) and expression (18.95) for $H_{\mathrm{c}1}$ at $x > 1$ (the expression is written with logarithmic accuracy). The asymptotic of (18.110) for $d < \delta$ is suitable
only at $d \gg$. From this asymptotic it follows that $H_{\mathrm{c}1}$ increases with decreasing thickness proportionately to d^{-2}, whereas $H_{\mathrm{c}2}$ increases proportionately to d^{-1} (see eq. 17.48). From the BCS theory it follows that $H_{\mathrm{cm}} \sim \Phi_0/(\delta\xi)$ (see eq. 18.98). Comparing $H_{\mathrm{c}2} \sim H_{\mathrm{cm}}\delta/d \sim \Phi_0/(\xi d)$ with $H_{\mathrm{c}1} \sim \Phi_0/d^2$, we see that the two fields become equal at $d \sim \xi$.

We shall now consider a thin plate in a perpendicular magnetic field. We assume the plate thickness to be much smaller than the penetration depth. Let us show that in this case vortices are also generated, and not only in a type II superconductor but in a type I superconductor as well (Pearl 1964).

Suppose that such a vortex has been formed and that the field and current are damped at a distance much larger than ξ. In this case, outside the core with a radius of order ξ we may use the London equation with the vortex (18.91), which is more conveniently written in the form

$$H + \frac{4\pi\delta^2}{c} \operatorname{rot} j = \Phi_0 z^0 \delta(\rho) \tag{18.111}$$

(we assume that the plate is perpendicular to the z axis and the vortex is at the point $\rho = 0$). We introduce a vector potential! $\boldsymbol{H} = \operatorname{rot} \boldsymbol{A}$. If use is made of a cylindrical system of coordinates, the current will apparently have only the component j_θ. In view of this, A is also chosen in the form $A = (0, A_\theta, 0)$.

Equation (18.111) may be integrated and the current density expressed through it:

$$j = \frac{c}{4\pi\delta^2}(S - A), \tag{18.112}$$

where $S = (0, S_\theta, 0)$,

$$S_\theta = \frac{\Phi_0}{2\pi\rho} \tag{18.113}$$

(in fact, rot $S = 0$ everywhere, except for $\rho = 0$, and $\int \operatorname{rot} S \, \mathrm{d}s = \oint S \, \mathrm{d}l = \Phi_0$ for any contour around $\rho = 0$).

If the plate thickness d is smaller than the penetration depth, the current and field vary slightly along the plate thickness. As will be shown later, the characteristic distance over which the field varies significantly is much larger than d and δ, and therefore we may assume the plate to be infinitesimally thin and use the following as the current density:

$$j(r) = J\delta(z) = j \, \mathrm{d}\delta(z) = \frac{cd}{4\pi\delta^2}(S - A)\delta(z). \tag{18.114}$$

This current produces a magnetic field throughout the entire surrounding space, which is determined from the Maxwell equation

$$\operatorname{rot} H = \frac{4\pi}{d} j = \frac{d}{\delta^2}(S - A)\delta(z).$$

only at $d > \boldsymbol{\xi}$. From this asymptotic it follows that $\boldsymbol{H}_{c1}$ increases with decreasing thickness proportionately to d^{-2}, whereas H_{c2} increases proportionately to d^{-1} (see eq. 17.48). From the BCS theory it follows that $H_{cm} \sim \Phi_0/(\delta\xi)$ (see eq. 18.98). Comparing $H_{c2} \sim H_{cm}\delta/d \sim \Phi_0/(\xi d)$ with $H_{c1} \sim \Phi_0/d^2$, we see that the two fields become equal at $d \sim \xi$.

We shall now consider a thin plate in a perpendicular magnetic field. We assume the plate thickness to be much smaller than the penetration depth. Let us show that in this case vortices are also generated, and not only in a type II superconductor but in a type I superconductor as well (Pearl 1964).

Suppose that such a vortex has been formed and that the field and current are damped at a distance much larger than ξ. In this case, outside the core with a radius of order ξ we may use the London equation with the vortex (18.91), which is more conveniently written in the form

$$H + \frac{4\pi\delta^2}{c} \operatorname{rot} j = \Phi_0 z^0 \delta(\rho) \tag{18.111}$$

(we assume that the plate is perpendicular to the z axis and the vortex is at the point $\rho = 0$). We introduce a vector potential: $H = \operatorname{rot} A$. If use is made of a cylindrical system of coordinates, the current will apparently have only the component j_θ. In view of this, $\boldsymbol{A}$ is also chosen in the form $\boldsymbol{A} = (0, \boldsymbol{A}_\theta, 0)$.

Equation (18.111) may be integrated and the current density expressed through it:

$$j = \frac{c}{4\pi\delta^2}(S - A), \tag{18.112}$$

where $S = (0, S_\theta, 0)$,

$$S_\theta = \frac{\Phi_0}{2\pi\rho} \tag{18.113}$$

(in fact, rot $S = 0$ everywhere, except for $\rho = 0$, and $\int \operatorname{rot} S \, \mathrm{d}s = \oint S \, \mathrm{d}l = \Phi_0$ for any contour around $\rho = 0$).

If the plate thickness d is smaller than the penetration depth, the current and field vary slightly along the plate thickness. As will be shown later, the characteristic distance over which the field varies significantly is much larger than d and δ, and therefore we may assume the plate to be infinitesimally thin and use the following as the current density:

$$j(r) = J\delta(z) = j \, \mathrm{d}\delta(z) = \frac{cd}{4\pi\delta^2}(S - A)\delta(z). \tag{18.114}$$

This current produces a magnetic field throughout the entire surrounding space, which is determined from the Maxwell equation

$$\operatorname{rot} H = \frac{4\pi}{d} j = \frac{d}{\delta^2}(S - A)\delta(z).$$

Substituting $\boldsymbol{H} = \operatorname{rot} \boldsymbol{A}$ and using the condition $\operatorname{div} \boldsymbol{A} = 0$, we obtain the equation for A :

$$-\Delta A + \delta_{\text{eff}}^{-1} A\delta(z) = \delta_{\text{eff}}^{-1} S\delta(z), \tag{18.115}$$

where the following definition is introduced:

$$\delta_{\text{eff}} = \frac{\delta^2}{d}. \tag{18.116}$$

This parameter, which has the dimension of length, will be the characteristic dimension of the problem. In order for our treatment to make sense, it is necessary that this characteristic dimension be much larger than ξ. For a type II superconductor, this follows from the fact that $\delta > \xi$ and $d < \delta$, and for a type I superconductor it is necessary that

$$d < \frac{\delta^2}{\xi} \sim \delta x \sim \xi x^2 \tag{18.117}$$

In order to solve eq. (18.115), we introduce the Fourier transformation

$$A(\rho, z) = \int A_{qk} \exp(\mathrm{i}q\rho + \mathrm{i}kz) \mathrm{d}^2 q \frac{\mathrm{d}k}{(2\pi)^3}$$

Here

$$A(\rho, z)\delta(z) = A(\rho, 0)\delta(z) = \int A_{qk} \exp(\mathrm{i}q\rho) \mathrm{d}^2 q \frac{\mathrm{d}k}{(2\pi)^3} \int_{-\infty}^{\infty} \exp(\mathrm{i}k_1 z) \frac{\mathrm{d}k_1}{2\pi}$$

From eq. (18.115) we get

$$\left(q^2+k^2\right)A_{qk}+\frac{1}{\delta_{\text{eff}}}A_q=\frac{1}{\delta_{\text{eff}}}S_q \tag{18.118}$$

where

$$\boldsymbol{A}_q=\int_{-\infty}^{\infty}\boldsymbol{A}_{qk}\frac{\mathrm{d}k}{2\pi} \tag{18.119}$$

and S_q is the Fourier component of $S(\rho)$.
Solving eq. (18.118), we find

$$A_{qk}=\frac{\left(S_q-A_q\right)\delta_{\text{eff}}^{-1}}{q^2+k^2} \tag{18.120}$$

Substitution of eq. (18.120) into eq. (18.119) gives

$$A_q=\frac{S_q}{1+2q\delta_{\text{eff}}} \tag{18.121}$$

The Fourier component $\boldsymbol{S_q}$ can easily be obtained from the condition

$$\operatorname{rot}S=\Phi_0 z^0\delta(\rho)$$

Inserting the Fourier expansion, we have

$$S_q=\mathrm{i}\Phi_0\frac{[qz^0]}{q^2} \tag{18.122}$$

According to formulae (18.112), (18.119) and (18.122), we obtain

$$\begin{aligned}J_q&=\frac{c}{4\pi\delta_{\text{eff}}}\left(S_q-A_q\right)=\frac{c}{2\pi}\frac{q}{1+2q\delta_{\text{eff}}}S_q\\&=\frac{c}{2\pi}\frac{\mathrm{i}\Phi_0\left[qz^0\right]}{q\left(1+2q\delta_{\text{eff}}\right)}.\end{aligned} \tag{18.123}$$

Considering that $\boldsymbol{H}=\operatorname{rot}\boldsymbol{A}$, we have for the field at $z=0$

$$H_q=\frac{\mathrm{i}\left[qS_q\right]}{1+2q\delta_{\text{eff}}}=\frac{z^0\Phi_0}{1+2q\delta_{\text{eff}}}. \tag{18.124}$$

From these formulas it is seen that there are two asymptotic regions: $q>\delta_{\text{eff}}^{-1}$, which corresponds to $\rho<\delta_{\text{eff}}$, and $q<\delta_{\text{eff}}^{-1}$, which corresponds to $\rho>\delta_{\text{eff}}$. In the first of these regions

$$J_q\approx\frac{c}{4\pi\delta_{\text{eff}}}S_q.$$

Hence, $\boldsymbol{J}(\boldsymbol{\rho})$ is simply proportional to $\boldsymbol{S}(\boldsymbol{\rho})$ and, according to eq. (18.113),

$$J(\rho)=\frac{\Phi_0 c}{8\pi^2\delta_{\text{eff}}\rho},\quad \rho<\delta_{\text{eff}} \tag{18.125}$$

At large distances, from (18.123) we obtain

$$\begin{aligned}J(\rho)&=\int J_q\mathrm{e}^{\mathrm{i}q\rho}\frac{\mathrm{d}^2q}{(2\pi)^2}=\operatorname{rot}\left[\frac{c\Phi_0 z^0}{2\pi}\int_0^{\infty}\mathrm{d}q\int_0^{2\pi}\mathrm{d}\theta\frac{\mathrm{e}^{\mathrm{i}q\rho\cos\theta}}{(2\pi)^2}\right]\\&=\operatorname{rot}\left[\frac{c\Phi_0 z^0}{4\pi^2}\int_0^{\infty}J_0(q\rho)\mathrm{d}q\right]=\frac{\Phi_0 c}{4\pi^2}\operatorname{rot}\left(\frac{z^0}{\rho}\right)\end{aligned}$$

($J_0(q\rho)$ is the Bessel function). From this we find that the current J has only a θ-component, equal to

$$J(\rho) \approx \frac{\Phi_0 c}{4\pi^2 \rho^2} \quad \rho > \delta_{\text{eff}} \tag{18.126}$$

The limiting expression for the magnetic field at $z = 0$ and $\rho < \delta_{\text{eff}}$ is derived with the aid of formula (18.124):

$$H(\rho, 0) \approx \frac{\Phi_0}{4\pi\delta_{\text{eff}}} \int_0^\infty \mathrm{d}q J_0(q\rho) = \frac{\Phi_0}{4\pi\delta_{\text{eff}}\rho}, \quad \rho < \delta_{\text{eff}} \tag{18.127}$$

For the case $\rho > \delta_{\text{eff}}$ it is better to use the London equation (18.111) and formula (18.126):

$$H(\rho, 0) = -\frac{4\pi\delta_{\text{eff}}}{c} \operatorname{rot}_z J = \frac{\Phi_0 \delta_{\text{eff}}}{\pi\rho^3}, \quad \rho > \delta_{\text{eff}}. \tag{18.128}$$

The distribution of the field outside the plate can be deduced using formula (18.120). Substituting eqs. (18.121) and (18.122), we obtain

$$A_{qk} = \frac{2qS_q}{(1 + 2q\delta_{\text{eff}})(q^2 + k^2)} = \frac{2\mathrm{i}\Phi_0 [qz^0]}{q(1 + 2q\delta_{\text{eff}})(q^2 + k^2)}.$$

Taking the curl, we find

$$\begin{aligned} H_{zqk} &= \mathrm{i}[qA_{qk}]_z = \frac{2\Phi_0 q}{(1 + 2q\delta_{\text{eff}})(q^2 + k^2)} \\ H_{\perp qk} &= -\frac{2\Phi_0 qk}{q(1 + 2q\delta_{\text{eff}})(q^2 + k^2)} \end{aligned} \tag{18.129}$$

In the coordinate representation we have

$$\begin{aligned} H &= -\nabla\varphi \operatorname{sign} z \\ \varphi &= \frac{\Phi_0}{2\pi} \int_0^\infty \frac{\mathrm{d}q}{1 + 2q\delta_{\text{eff}}} J_0(q\rho) \mathrm{e}^{-q|z|} \end{aligned} \tag{18.130}$$

At large distances we have $q < \delta_{\text{eff}}^{-1}$. Here

$$\varphi = \frac{\Phi_0}{2\pi r}, \quad H = \frac{\Phi_0}{2\pi} \frac{r}{r^3} \operatorname{sign} z. \tag{18.131}$$

It should be noted that, according to eq. (18.130), $\boldsymbol{H}_\perp \neq 0$ at $z = 0$. But if from the start we set $z = 0$, i.e., if we find $\int_{e-\infty}^{\infty} \boldsymbol{H}_{\perp qk}\, \mathrm{d}k/2\pi$, we shall obtain zero. This is associated with the replacement of the plate by an infinitesimally thin plane with a current. For such a film we have from the Maxwell equation rot $\boldsymbol{H} = (4\pi/c)\boldsymbol{j}$:

$$H_\perp(\rho, +0) - H_\perp(\rho, -0) = \frac{4\pi}{c} J(\rho).$$

This condition is satisfied by formulae (18.129) and (18.123). The changeover from $H_\perp(\rho, +0)$ to $H_\perp(\rho, -0)$ occurs at a distance $\Delta z \sim d$. Here, in the center of the plate $H_\perp = 0$.

We have considered one isolated vortex. In fact, of course, vortices arise when the plate is placed in a perpendicular magnetic field. This gives rise to a regular vortex structure. From the symmetry of the problem it is seen that, as before, around each vortex a contour can be drawn on which $\oint j\, \mathrm{d}l = 0$ and, hence, each vortex carries one flux quantum $\boldsymbol{\Phi}_0$. If the core

centers are located at the points $\boldsymbol{\rho}_m$, then in place of eq. (18.111) we obtain an equation with $\sum \delta(\rho - \rho_m)$ instead of $\delta(\rho)$.

All the subsequent expressions in which S_q is not specified are retained. A new $\boldsymbol{S_q}$ results from the condition

$$\operatorname{rot} S = \Phi_0 z^0 \sum_m \delta(\rho - \rho_m)$$

and is given by (compare with eq. 18.122)

$$S_q = \mathrm{i}\Phi_0 \left[q z^0\right] \sum_m \frac{\exp(-\mathrm{i}q\rho_m)}{q^2}. \tag{18.132}$$

Using formulae (18.121) and (18.120), we obtain $\boldsymbol{A_{qk}}$ and $\boldsymbol{H_{qk}}$. In particular, at $\boldsymbol{z} > 0$

$$H_z(\rho, z) = -\frac{\partial}{\partial z}\frac{\Phi_0}{2\pi}\int_0^\infty \frac{\sum_m J_0(q|\rho - \rho_m|)\, e^{-qz}}{1 + 2q\delta_{\text{eff}}}\, \mathrm{d}q.$$

At $z \gg \delta_{\text{eff}}$ we put $q\delta_{\text{eff}} < 1$. Taking the integral, we get

$$H_z(\rho, z) \approx \frac{\Phi_0}{2\pi} z \sum_m \left[z^2 + (\rho - \rho_m)^2\right]^{-3/2}. \tag{18.133}$$

At a distance z much larger than the period of the structure we can make the replacement

$$\sum_m \to n \int d^2\rho_m,$$

where n is the number of vortices per cm^2. Taking the integral, we obtain the obvious result

$$H_z(\rho, z) \approx n\Phi_0 = H_0 \tag{18.134}$$

(H_0 is the external field at infinity). The same result could have been obtained from the continuity condition for the normal component of the induction.

The formulae obtained are valid as long as the intervortex spacings are much larger than ξ, i.e., at

$$H_0 < \frac{\Phi_0}{\xi^2} \sim H_{c2}$$

(recall that for type I superconductors H_{c2} is the supercooling field).

8.4.8 18.7 Anisotropic type II superconductor in a magnetic field

Up until now our analysis was confined to isotropic superconductors. Since however the new high-temperature superconductors are highly anisotropic we shall consider here some properties of such substances. We shall limit ourselves to the case of uniaxial symmetry, because the new substances have layered structures of either
tetragonal or orthorhombic symmetry. However even in the latter case the anisotropy in the basal plane is small.

In the GL free energy (17.5) one has instead of the electron mass m the mass tensor

$$m_{ik} = m_t \delta_{ik} + (m_l - m_t)\, n_i n_k, \tag{18.135}$$

where n is the unit vector along the main axis (it is normal to the basal plane or to the conducting layers). The principal values of m_{ik} are m_t and m_l. The corresponding term in (17.5) takes the form

$$\frac{1}{4}\left(\hat{m}^{-1}\right)_{ik}\left(\mathrm{i}\hbar\frac{\partial}{\partial x_i}-\frac{2e}{c}A_i\right)\Psi^*\left(-\mathrm{i}\hbar\frac{\partial}{\partial x_k}-\frac{2e}{c}A_k\right)\Psi$$

In accordance with this the first term in the GL equation (17.6) is replaced by

$$\frac{1}{4}\left(\hat{m}^{-1}\right)_{ik}\left(-\mathrm{i}\hbar\frac{\partial}{\partial x_i}-\frac{2e}{c}A_i\right)\left(-\mathrm{i}\hbar\frac{\partial}{\partial x_k}-\frac{2e}{c}A_k\right)\Psi$$

and the current instead of (17.9) becomes

$$j_i = e\left(\hat{m}^{-1}\right)_{ik}\left[-\frac{i\hbar}{2}\left(\Psi^*\frac{\partial}{\partial x_k}\Psi-\Psi\frac{\partial}{\partial x_k}\Psi^*\right)-\frac{2e}{c}A_k|\Psi|^2\right]. \tag{18.136}$$

We start with the field H_{c2}. In this case Ψ is small and we must write eq. (17.6) for Ψ in the linear approximation. We can take the field to be uniform. We choose the z-axis along the magnetic field and we place the main crystal axis in the xz-plane. As before, we take the vector potential $A_y = Hx$. Assuming that Ψ depends only on x we obtain

$$-\frac{1}{4}\hbar^2\left(\frac{n_z^2}{m_t}+\frac{n_x^2}{m_l}\right)\frac{\mathrm{d}^2\Psi}{\mathrm{d}x^2}+\frac{e^2H^2}{c^2m_t}x^2\Psi=\alpha|\tau|\Psi$$

Similarly to section 18.2 we find the critical field $\boldsymbol{H_{c2}}$ (Morris et al. 1972):

$$H_{c2}=\frac{\Phi_0}{2\pi\xi_t^2}\left(\cos^2\theta+\varepsilon^2\sin^2\theta\right)^{-1/2}, \tag{18.137}$$

where

$$\xi_t=\frac{\hbar}{\sqrt{4m_t\alpha|\tau|}},\quad \xi_l=\frac{\hbar}{\sqrt{4m_l\alpha|\tau|}}$$

are the correlation lengths,

$$\varepsilon=\sqrt{\frac{m_t}{m_l}}=\frac{\xi_l}{\xi_t},$$

θ is the angle between the main axis and the magnetic field. The limiting values of $\boldsymbol{H}_{c2}$ are $\boldsymbol{\Phi}_0/\left(2\pi\xi_t^2\right)$ for $\boldsymbol{n}\|\boldsymbol{H}$ and $\boldsymbol{\Phi}_0/\left(2\pi\xi_t\xi_l\right)$ for $\boldsymbol{n}\perp\boldsymbol{H}$. Although these formulae were derived for the vicinity of T_c they reflect also the situation at low temperatures.

Now we pass to the first critical field. Assuming $x>1$ and limiting ourselves to logarithmic accuracy we can make calculations for arbitrary temperatures, like in section 18.5. We can put $\Psi=\sqrt{\left(\frac{1}{2}n_s\right)}\mathrm{e}^{\mathrm{i}\chi}$ where $n_s=\mathrm{const}$. We introduce also the penetration depths

$$\delta_t=\sqrt{\frac{m_tc^2}{4\pi n_se^2}},\quad \delta_l=\sqrt{\frac{m_lc^2}{4\pi n_se^2}}.$$

Inserting into eq. (18.136) expression (18.135) for m_{ik}, taking rot from the Maxwell equation $\mathrm{rot}\,\boldsymbol{H}=(4\pi/c)\boldsymbol{j}$ and assuming one vortex line along l we obtain the generalisation of eq. (18.91):

$$H+\delta_t^2\,\mathrm{rot}\,\mathrm{rot}\,H+\left(\delta_l^2-\delta_t^2\right)\mathrm{rot}(n(n\,\mathrm{rot}\,H))=l\Phi_0\delta(\rho), \tag{18.138}$$

where ρ is the radius vector in the plane perpendicular to l. From eq. (18.138) it follows that $\mathrm{div}\,\boldsymbol{H}=0$.

The important part of the free energy has the form

$$\varepsilon_0 = \int \left[\frac{H^2}{8\pi} + \frac{1}{8}\left(\hat{m}^{-1}\right)_{ik} n_\mathrm{s}\left(\hbar\frac{\partial\chi}{\partial x_i} - \frac{2e}{c}A_i\right)\left(\hbar\frac{\partial\chi}{\partial x_k} - \frac{2e}{c}A_k\right)\right]\mathrm{d}V$$
$$= \frac{1}{8\pi}\int \left[H^2 + \delta_t^2(\mathrm{rot}\, H)^2 + \left(\delta_l^2 - \delta_t^2\right)(n\,\mathrm{rot}\, H)^2\right]\mathrm{d}V.$$

Integrating by parts and using eq. (18.138) we get

$$\varepsilon_0 = \frac{1}{8\pi}\Phi_0 H(0) l \tag{18.139}$$

The first critical field is determined by the condition

$$n\varepsilon_0 - \frac{BH_{\mathrm{c}1}}{4\pi} = n\varepsilon_0 - \frac{n\Phi_0 l H_{\mathrm{c}1}}{4\pi} = 0, \tag{18.140}$$

where n is the number of vortices per cm^2 of the cross-sectional plane (actually we consider only one vortex; n is introduced only for convenience of presentation).

Due to axial symmetry the vortex l will be oriented in the plane of the vector n and the external field $\boldsymbol{H}_{\mathrm{cl}}$ but in general will coincide with neither of them. We denote this plane by xz and we direct the z-axis along l. Performing the Fourier transformation

$$H = \int H_k \mathrm{e}^{\mathrm{i}k\rho}\frac{\mathrm{d}^2k}{(2\pi)^2}$$

with $k = (k_x, k_y)$ we get from eq. (18.138)

$$\left(1 + k^2\delta_t^2\right)H_k + \left(\delta_l^2 - \delta_t^2\right)[n\times k]\,(H_k[n\times k]) = l\Phi_0.$$

Now we pass to the first critical field. Assuming $x \gg 1$ and limiting ourselves to logarithmic accuracy we can make calculations for arbitrary temperatures, like in section 18.5. We can put $\Psi = \sqrt{\left(\frac{1}{2}n_s\right)}\mathrm{e}^{\mathrm{i}\chi}$ where $n_s = \mathrm{const}$. We introduce also the penetration depths

$$\delta_t = \sqrt{\frac{m_t c^2}{4\pi n_s e^2}}, \quad \delta_l = \sqrt{\frac{m_l c^2}{4\pi n_s e^2}}.$$

Inserting into eq. (18.136) expression (18.135) for m_{ik}, taking rot from the Maxwell equation $\mathrm{rot}\,\boldsymbol{H} = (4\pi/c)\boldsymbol{j}$ and assuming one vortex line along l we obtain the generalisation of eq. (18.91):

$$H + \delta_t^2\,\mathrm{rot}\,\mathrm{rot}\,H + \left(\delta_l^2 - \delta_t^2\right)\mathrm{rot}(n(n\,\mathrm{rot}\,H)) = l\Phi_0\delta(\rho), \tag{18.138}$$

where ρ is the radius vector in the plane perpendicular to l. From eq. (18.138) it follows that $\mathrm{div}\,\boldsymbol{H} = 0$.

The important part of the free energy has the form

$$\varepsilon_0 = \int \left[\frac{H^2}{8\pi} + \frac{1}{8}\left(\hat{m}^{-1}\right)_{ik} n_\mathrm{s}\left(\hbar\frac{\partial\chi}{\partial x_i} - \frac{2e}{c}A_i\right)\left(\hbar\frac{\partial\chi}{\partial x_k} - \frac{2e}{c}A_k\right)\right]\mathrm{d}V$$
$$= \frac{1}{8\pi}\int \left[H^2 + \delta_t^2(\mathrm{rot}\, H)^2 + \left(\delta_l^2 - \delta_t^2\right)(n\,\mathrm{rot}\, H)^2\right]\mathrm{d}V.$$

Integrating by parts and using eq. (18.138) we get

$$\varepsilon_0 = \frac{1}{8\pi}\Phi_0 H(0) l \tag{18.139}$$

The first critical field is determined by the condition

$$n\varepsilon_0 - \frac{BH_{c1}}{4\pi} = n\varepsilon_0 - \frac{n\Phi_0 l H_{c1}}{4\pi} = 0, \tag{18.140}$$

where n is the number of vortices per cm^2 of the cross-sectional plane (actually we consider only one vortex; n is introduced only for convenience of presentation).

Due to axial symmetry the vortex l will be oriented in the plane of the vector n and the external field $\boldsymbol{H}_{\rm cl}$ but in general will coincide with neither of them. We denote this plane by xz and we direct the z-axis along l. Performing the Fourier transformation

$$H = \int H_k \mathrm{e}^{\mathrm{i}k\rho} \frac{\mathrm{d}^2 k}{(2\pi)^2}$$

with $k = (k_x, k_y)$ we get from eq. (18.138)

$$\left(1 + k^2\delta_t^2\right) H_k + \left(\delta_l^2 - \delta_t^2\right) [n \times k] \left(H_k [n \times k]\right) = l\Phi_0.$$

Multiplying by $[n \times k]$ and solving the resulting equation we find

$$\begin{aligned} H_k[n \times k] &= \frac{l[n \times k]\Phi_0}{1 + \delta_l^2 k^2 + [n \times k]^2 \left(\delta_l^2 - \delta_t^2\right)} \\ &= \frac{n_x k_y \varphi_0}{1 + \delta_l^2 k^2 + \left(\delta_t^2 - \delta_l^2\right) n_x^2 k_x^2} \end{aligned}$$

Multiplying eq. (18.141) by $\boldsymbol{l}$ and substituting $\boldsymbol{H_k}[\boldsymbol{n} \times \boldsymbol{k}]$ we get

$$lH_k = \frac{\Phi_0 \left[1 + \left(\delta_t^2 n_x^2 + \delta_l^2 n_z^2\right) k^2\right]}{\left(1 + \delta_t^2 k^2\right) \left[1 + \delta_l^2 k^2 + \left(\delta_t^2 - \delta_l^2\right) n_x^2 k_x^2\right]}. \tag{18.142}$$

Expression (18.139) for ε_0 contains $\boldsymbol{H}(0)\boldsymbol{l} = (2\pi)^{-2} \int \boldsymbol{H}_k \boldsymbol{l}\, \mathrm{d}^2\boldsymbol{k}$. According to eq. (18.142) this is a logarithmic integral. It must be limited from above by $k \sim \xi^{-1}$. Within logarithmic accuracy we obtain

$$\varepsilon_0 = \left(\frac{\Phi_0}{4\pi\delta_t}\right)^2 \ln x \frac{\sqrt{\delta_t^2 \sin^2\theta + \delta_l^2 \cos^2\theta}}{\delta_l} \tag{18.143}$$

where θ is the angle between n and l ($n_z = \cos\theta, n_x = \sin\theta$). Denoting the angle between $\boldsymbol{H}_{\rm cl}$ and $\boldsymbol{n}$ by $\boldsymbol{\theta}_1$ we get from eq. (18.140)

$$H_{c1}(\theta_1, \theta) = \frac{\Phi_0 \ln \varkappa}{4\pi\delta_t^2} \frac{\left(\varepsilon^2 \sin^2\theta + \cos^2\theta\right)^{1/2}}{\cos(\theta_1 - \theta)} \tag{18.144}$$

where as before $\varepsilon = (m_t/m_l)^{1/2} = \delta_t/\delta_l$. The true value of $\boldsymbol{H}_{c1}$ is obtained by minimization over $\boldsymbol{\theta}$. We find (Balatskii et al. 1986)

$$\tan\theta_0 = \frac{1}{\varepsilon}\tan\theta_1 \tag{18.145}$$

$$H_{c1} = \frac{\Phi_0 \ln x}{4\pi\delta_t^2} \frac{1}{\sqrt{\cos^2\theta_1 + \varepsilon^{-2}\sin^2\theta_1}} \tag{18.146}$$

Consider the limiting cases. The case $\varepsilon \ll 1$ corresponds to a layered structure with $m_l > m_t$. The electrons in this case rarely jump from one layer to another. Therefore the field normal to the layers is easily screened while a field having a component within the layer plane is screened with much greater difficulty. Hence the vortices corresponding to field penetration exhibit a trend towards lying in the layer plane and at $\boldsymbol{H}_{\rm cl} \perp \boldsymbol{n}$ they are formed at relatively small

fields (at $\theta_1 = \frac{1}{2}\pi$ one has $H_{\rm cl} = \Phi_0 \ln x/4\pi\delta_l\delta_t$). The opposite case $\varepsilon > 1$ corresponds to a quasi-onedimensional structure. Here the field directed along the main axis is poorly screened. Therefore the vortices appear preferably in this direction ($\theta_0 \to 0$) even if the external field makes a large angle with the axis.

We shall not analyse here the whole structure of the mixed state at $H_{\rm c1} < H < H_{\rm c2}$. Physically it is clear that with increasing vortex density their orientation will approach that of the external field.

Multiplying by $[n \times k]$ and solving the resulting equation we find

$$H_k[n \times k] = \frac{l[n \times k]\Phi_0}{1 + \delta_t^2 k^2 + [n \times k]^2 (\delta_l^2 - \delta_t^2)} = \frac{n_x k_y \varphi_0}{1 + \delta_l^2 k^2 + (\delta_t^2 - \delta_l^2) n_x^2 k_x^2}$$

Multiplying eq. (18.141) by l and substituting $\boldsymbol{H}_k[\boldsymbol{n} \times \boldsymbol{k}]$ we get

$$lH_k = \frac{\Phi_0 \left[1 + (\delta_t^2 n_x^2 + \delta_l^2 n_z^2) k^2\right]}{(1 + \delta_t^2 k^2)\left[1 + \delta_l^2 k^2 + (\delta_t^2 - \delta_l^2) n_x^2 k_x^2\right]} \tag{18.142}$$

Expression (18.139) for ε_0 contains $\boldsymbol{H}(0)\boldsymbol{l} = (2\pi)^{-2} \int \boldsymbol{H}_k \boldsymbol{l}\, \mathrm{d}^2\boldsymbol{k}$. According to eq. (18.142) this is a logarithmic integral. It must be limited from above by $k \sim \xi^{-1}$. Within logarithmic accuracy we obtain

$$\varepsilon_0 = \left(\frac{\Phi_0}{4\pi\delta_t}\right)^2 \ln x \frac{\sqrt{\delta_t^2 \sin^2\theta + \delta_l^2 \cos^2\theta}}{\delta_l} \tag{18.143}$$

where θ is the angle between n and l ($n_z = \cos\theta, n_x = \sin\theta$). Denoting the angle between $\boldsymbol{H}_{\rm c1}$ and $\boldsymbol{n}$ by $\boldsymbol{\theta}_1$ we get from eq. (18.140)

$$H_{\rm c1}(\theta_1, \theta) = \frac{\Phi_0 \ln x}{4\pi\delta_t^2} \frac{\left(\varepsilon^2 \sin^2\theta + \cos^2\theta\right)^{1/2}}{\cos(\theta_1 - \theta)} \tag{18.144}$$

where as before $\varepsilon = (m_t/m_l)^{1/2} = \delta_t/\delta_l$. The true value of $H_{\rm c1}$ is obtained by minimization over θ. We find (Balatskii et al. 1986)

$$\tan\theta_0 = \frac{1}{\varepsilon^2} \tan\theta_1 \tag{18.145}$$

$$H_{\rm cl} = \frac{\Phi_0 \ln \varkappa}{4\pi\delta_t^2} \frac{1}{\sqrt{\cos^2\theta_1 + \varepsilon^{-2}\sin^2\theta_1}} \tag{18.146}$$

Consider the limiting cases. The case $\varepsilon \ll 1$ corresponds to a layered structure with $m_l > m_t$. The electrons in this case rarely jump from one layer to another. Therefore the field normal to the layers is easily screened while a field having a component within the layer plane is screened with much greater difficulty. Hence the vortices corresponding to field penetration exhibit a trend towards lying in the layer plane and at $\boldsymbol{H}_{\rm c1} \perp \boldsymbol{n}$ they are formed at relatively small fields (at $\theta_1 = \frac{1}{2}\pi$ one has $H_{\rm c1} = \Phi_0 \ln x/4\pi\delta_l\delta_t$). The opposite case $\varepsilon > 1$ corresponds to a quasi-onedimensional structure. Here the field directed along the main axis is poorly screened. Therefore the vortices appear preferably in this direction ($\theta_0 \to 0$) even if the external field makes a large angle with the axis.

We shall not analyse here the whole structure of the mixed state at $\boldsymbol{H}_{\rm c1} < \boldsymbol{H} < \boldsymbol{H}_{\rm c2}$. Physically it is clear that with increasing vortex density their orientation will approach that of the external field.

In conclusion we consider the anisotropy of the penetration depth of a weak magnetic field. To this purpose we must use the reduced eq. (18.138) or eq. (18.141) without the right-hand side. This time we direct k along the z-axis (this is the normal to the surface of the superconducting half-space) and we choose n in the xz-plane. One can easily prove that the components H_y and H_x have different penetration depths, namely

$$\delta(H_x) = \delta_t, \quad \delta(H_y) = \delta_t \sqrt{\cos^2\theta + \varepsilon^{-2}\sin^2\theta}. \tag{18.147}$$

This behaviour is again easily understood from the viewpoint of the anisotropy of electron hopping. For $\varepsilon \to 0$, i.e. for the layered structure, the field is poorly screened by currents demanding electron hopping between the layers, and the corresponding penetration depth increases.

8.4.9 18.8. Superconducting magnets. Pinning

The idea of the application of superconductors instead of ordinary metals with the purpose of eliminating ohmic losses has been put forward since the discovery of superconductivity. The obstacle is the necessity of attaining low temperatures. The high cost of the equipment and of the operation of superconducting cables with helium cooling makes the use of superconductivity for the transmission of electric power economically inefficient*.

The situation is different as far as the cooling of a limited volume is concerned. It is for this reason that at present the use of superconductors for the production of powerful magnets is rapidly expanding. A conventional electromagnet, which is a coil made of copper or aluminum wire, consumes a power which increases proportionately to H^2, where H is the magnetic field it produces. Maintaining a field of 100 kOe in an aperture of diameter 2.5 cm thus require a power of the order of a megawatt. This energy is almost completely released in the form of Joule heat, and in order to remove this heat, a huge and expensive water cooling system is needed**.

If the coil (solenoid) is made of a superconductor, energy is required only for maintaining the helium temperature. This may be several orders of magnitude smaller than the energy consumed by the corresponding electromagnet; besides, the entire installation is much more compact. It should be noted that the superconducting coil can be short-circuited and in this case it is converted to a permanent magnet. As we know, the field flux through a hollow superconductor does not vary with time because any change in the external conditions is compensated for by supercurrents. Therefore, a superconducting permanent magnet is characterized by unique constancy of the magnetic field produced.

The idea of superconducting magnets was first advanced by H. Kamerlingh Onnes. But the superconductors known at that time had low critical fields, of the order of hundreds of oersteds. The situation changed in the 1960s, when superconductors appeared with critical fields above 100 kOe ; also, cryostats, i.e., devices for maintaining helium temperatures, were highly improved and became less expensive. The subsequent investigations showed that the new materials exhibiting high critical fields are type II superconductors, which are well described by the theory presented in the preceding sections.

The highest critical fields known have been produced in the so-called Chevrel phases: compounds of the type $\mathrm{Me}_x\,(\mathrm{Mo}_6\,\mathrm{S}_8)_y$ (Me = metals: Pb, Li, and others). They reach 600 kOe . There are predictions that superconducting ceramics may have even higher critical fields, up to 2 MO . However, good mechanical properties of alloys are required for practical needs and

*This conclusion will probably change if ways are found for the technology of application of ceramics which are superconducting at liquid nitrogen temperatures.

** It must be noted that water pumps generate vibrations which are very detrimental in most cases.

therefore at present use is made of $\mathrm{Nb-Zr-Ti}$ alloys with critical fields of up to $110-120$kOe and Nb_3Sn with a critical field up to 230 kOe .

Nevertheless, the possibility of using type II superconductors to produce high fields is not quite evident. In fact, as has been established in the preceding sections, at $x \gg 1$ there is a large region of the mixed state, starting with the field $H_{c1} \sim H_{cm}/x$ and ending with $H_{c2} \sim H_{cm}\varkappa$. Hence, if there is a high field, the superconductor is certainly in the mixed state and is threaded by vortices. The current that creates a field in the solenoid flows perpendicular to the vortices. But in this case, the vortices are acted on by a Lorentz force in a direction perpendicular to $\boldsymbol{H}$ and $\boldsymbol{j}$.

This force can be found as follows. Suppose there is a single vortex with current $\boldsymbol{j}$ in the superconductor and that an external current $\boldsymbol{j}^{\text{ext}}$ is passed through it. The total current will then be $\boldsymbol{j}+\boldsymbol{j}^{\text{ext}}$. Substituting into eq. (18.93), we obtain the current interaction energy:

$$\Lambda \int j^{ext} j dV$$

(the interaction energy for magnetic fields is relatively small). In this particular case, $\boldsymbol{j}$ depends on $\boldsymbol{\rho}-\boldsymbol{\rho}_0$, where $\boldsymbol{\rho}_0$ is the coordinate of the vortex axis. The component of the force that acts on the vortex axis is a derivative of the potential energy with respect to its coordinate with a minus sign:

$$\begin{aligned}
-\frac{\partial}{\partial x_{0k}}\Lambda \int j^{\text{ext}} j \, \mathrm{d}V &= -\Lambda \sum_{i=1,2} \int j_i^{\text{ext}} \frac{\partial}{\partial x_{0k}} j_i \, \mathrm{d}V \\
&= \Lambda \sum_{i=1,2} \int j_i^{\text{ext}} \frac{\partial}{\partial x_k} j_i \, \mathrm{d}V \\
&= \Lambda \sum_{i=1,2} \int j_i^{\text{ext}} \left(\frac{\partial}{\partial x_k} j_i - \frac{\partial}{\partial x_i} j_k \right) \mathrm{d}V + \Lambda \sum_{i=1,2} \int j_i^{\text{ext}} \frac{\partial}{\partial x_i} j_k \, \mathrm{d}V
\end{aligned}$$

(we have used the fact that j depends on $\rho-\rho_0$).

The last term is equal to zero, because integrating by parts we obtain $-\Lambda \int j_k \operatorname{div} j^{\text{ext}} \, \mathrm{d}V = 0 \, (\operatorname{div} j^{\text{ext}} = 0)$. The factor in parentheses in the first term is equal to zero at $i=k$, and at $i \neq k$ it is the component of rot j along the z axis (because $i,k = x,y$). It is not difficult to see that on the whole the integral is equal to

$$\Lambda \int \left[j^{\text{ext}} \operatorname{rot} j \right] \mathrm{d}V.$$

But for the vortex

$$\begin{aligned}
\operatorname{rot} j &= -\frac{1}{\Lambda c} \operatorname{rot} \left(A - \frac{\hbar c}{2e} \nabla \chi \right) \\
&= \frac{1}{\Lambda c} \frac{\hbar c}{2e} 2\pi \delta \left(\rho - \rho_0 \right)
\end{aligned}$$

(see formulae 18.90 and 18.40).
Hence, the force that acts on a unit length of the vortex is

$$f_{\text{L}} = \frac{\Phi_0}{c} \left[j^{\text{ext}} \cdot b \right], \tag{18.148}$$

where $\Phi_0 = \pi\hbar c/e$ is the flux quantum and b is the unit vector along the vortex axis. Multiplying by the number of vortices per unit cross-sectional area, $n = B/\Phi_0$, we obtain the Lorentz force per unit volume ($nb = B/\Phi_0$):

$$F_L = \frac{1}{c}\left[j^{\text{ext}}\, B\right]. \tag{18.149}$$

Under the action of this force the vortex lattice must begin to move. Suppose that this motion is opposed by a viscous force, which is proportional to the velocity. Let us assume that for one vortex

$$f_{\text{v}} = -\eta v_{\text{L}}, \tag{18.150}$$

where v_L is the velocity of vortex motion and η is a certain "viscosity coefficient". At equilibrium $f_{\text{L}} + f_{\text{v}} = 0$, i.e.,

$$v_{\text{L}} = \frac{\Phi_0}{\eta \text{c}}\left[j^{\text{ext}}\, b\right]. \tag{18.151}$$

Hence, the vortices move perpendicular to $\boldsymbol{B}$ and $\boldsymbol{j}^{\text{ext}}$. This motion of the vortex lattice leads to the generation of an electric field. Indeed, if in the coordinate system moving together with the lattice with a velocity v_{L} there is an average magnetic field (induction) $\boldsymbol{B}$, then in accordance with the rules of electrodynamics an extra electric field arises upon transformation to the laboratory coordinate system:

$$E = \frac{1}{c}\left[B v_{\text{L}}\right]. \tag{18.152}$$

Substituting eq. (18.138) and taking into account that $\boldsymbol{b} = \boldsymbol{B}/\boldsymbol{B}$ and $\boldsymbol{B} \perp \mathbf{j}^{\text{ext}}$, we obtain

$$E = \frac{\Phi_0 B}{\eta c^2} j^{\text{ext}} \tag{18.153}$$

But the generation of an electric field along $\boldsymbol{j^{ext}}$ implies the appearance of electrical resistance:

$$\rho = \frac{E}{j^{\text{ext}}} = \frac{\Phi_0 B}{\eta c^2} \tag{18.154}$$

If the superconductor is completely homogeneous, then upon attainment of the field H_{c2} the resistance ρ must be equal to ρ_{n}, the resistance of a normal metal. From this it follows that

$$\rho_{\text{n}} = \frac{\Phi_0 H_{\text{c2}}}{\eta c^2}$$

and therefore we find that

$$\eta = \frac{\Phi_0 H_{\text{c2}}}{\rho_n c^2} \tag{18.155}$$

and

$$\rho = \rho_{\text{n}} \frac{B}{H_{\text{c2}}}. \tag{18.156}$$

The last formula is very simple and resembles the formula for the heat capacity (18.106). It could also be interpreted as arising from the fact that the vortex cores with a diameter of the order of ξ are in the normal state. However, if the vortex lattice were at rest, the supercurrent would easily go around the normal cores and no resistance would arise. The appearance of resistance is the result of the motion of the vortices under the action of the Lorentz force.

In fact, however, formulae (18.155) and (18.156) are valid only by order of magnitude, mostly far from T_{c} and H_{c2}. The true viscosity η depends on many mechanisms and not only on the

energy dissipation in the normal cores, and is a complex function of field and temperature. Besides, the simple linear relation (18.150) does not always hold.

Thus, we come to the conclusion that superconductivity is destroyed as soon as vortices appear, i.e., at a field equal to $H_{c1} \sim H_{cm}/x$. This means that not only we gain nothing with increasing x but, on the contrary, we strongly lose in the critical field. However, there is a way for coping with this shortcoming. To do this, the motion of the vortex lattice must be stopped, in which case, in accordance with formula (18.152), $E = 0$ and, hence, $\rho = 0$ too. To this end, we have to fasten the vortices at certain points in the sample. This phenomenon is known as pinning.

We have already dealt in section 18.5 with the surface barrier that hinders the entry of vortices into the sample and their escape from it. From this example it is
seen that irregularities may be responsible for the formation of barriers impeding the motion of vortices. It is clear that irregularities with a size larger than ξ will be very effective for pinning*.

Consider, as an example, a pore in a superconductor with a size of $d \gg$. We know that the core energy per unit length of the vortex is of order $(\Phi_0/\delta)^2$ (see eq. 18.95). This may be put in a different way. As soon as the core is in the normal state there is an excess energy $\boldsymbol{H}_{cm}^2/8\pi$ per cm^3 and an excess energy $\boldsymbol{H}_{cm}^2 \cdot \boldsymbol{\xi}^2$ per unit length. The identity of these expressions follows from (18.97).

If the vortex passes through the pore, the corresponding part of the core energy is absent. This means that the total energy is lower, i.e., the vortex is attracted to the pore. The force of this attraction can be found if one takes into account that the vortex disappears, merging with its image at a distance of order ξ from the edge of the pore (section 18.5). Hence, the force equal to the energy gradient will be of the order of the energy itself divided by ξ. For a pore with a size d,

$$f_p \sim H_{cm}^2 d\xi. \tag{18.157}$$

When the current is passing, the vortex is acted on by the Lorentz force, which, in accordance with (18.148), after being multiplied by the length d is of the order of ($H_{cm} \sim \Phi_0/\delta\xi$):

$$f_L d \sim \Phi_0 j^{ext} \frac{d}{c} \sim H_{cm} j^{ext} \delta\xi \frac{d}{c}.$$

Equating these forces, we find the critical current density capable of unpinning the vortex from the pore:

$$j^{ext} \sim H_{cm} \frac{c}{\delta}. \tag{18.158}$$

Comparing with formula (17.62), we see that this value is comparable with the current density required to break up Cooper pairs.

In fact, of course, we must take into account that the pinning force acts on a limited portion of the vortex line, whereas the Lorentz force pulls the entire vortex. Moreover, in real cases there are many interacting vortices that form a lattice, and therefore in calculations of the critical current density one has to take account of the lattice distortion and of the elastic forces that arise in this case. We shall not discuss particular models and the results obtained, especially as the nature of the pinning centers in superconductors employed in technology has not been studied in detail.

Moreover, it is not always clear how the current is actually distributed throughout the superconductors in the mixed state with pinning. Although we know, for example, that in the absence of a magnetic field the current flows only in a surface layer of

thickness δ, experiment shows that in the case under consideration the situation is different, and a considerable part of the current flows through the inner portion of the superconductor. This is associated with the fact that the current is a function of the field: $j_c(B)$. The passage of the current leads to the formation of a "critical profile" of the current, such that the induction and current at each point of the cross section of the conductor corresponds to $j_c(B)$. At $x > 1$ and a high defect density the current is distributed almost uniformly along the cross section. In a general case, we may speak only of the "current-carrying capacity", which is conventionally expressed in terms of the average current density. So far, critical values have been attained of the order of 10^6 A/cm^2 (for ceramics much less, $< 10^3$ A/cm^2).

Thus, according to what has been said above, we get the impression that before the critical current is attained the resistance is equal to zero, and then resistance arises in a jumpwise manner. It is easy, however, to see that this occurs only at $T = 0$. In fact, the pinning centers create for the vortex lattice a potential relief consisting of "valleys" separated by "mountain chains" - potential barriers. At finite temperature a transition from one valley to another is possible due to thermal fluctuations. The result is that even before the true critical current density is achieved there arises a "creep": the fluctuational jumpwise displacement of the vortex lattice. This gives rise to resistance. It should be emphasized that this occurs at any finite temperature, and therefore in the strict sense of the word the critical current in the mixed state at $T > 0$ is equal to zero.

However, in reality the situation is not that hopeless. Suppose we have a superconducting permanent magnet - a short-circuited solenoid. It is used under operating conditions for a limited period of time, because during all this time the energy has to be consumed on cooling. The resistance associated with the creep of vortices is so small that the current flowing through the solenoid does not change appreciably during, say 100 years; from a practical viewpoint the resistance is equal to zero.

We shall not describe here the creep theory (see Anderson 1962; Anderson and Kim 1964). We note only that according to this theory the field in the hole of the solenoid falls off by a very slow law:

$$B(t) = B(0)(1 - \alpha \ln t)$$

with the coefficient $\alpha \sim 10^{-3}$. Hence, the decrease of the current in the solenoid and of the magnetic field created by it takes enormous periods of time.

We may conclude that the creep is not dangerous and that it may be neglected, i.e., we may presume that from the practical standpoint the situation is the same as at $T = 0$, and unless the critical current is not attained the sample is superconducting. As a matter of fact, the creep may cause another hazard. If a bundle of vortices slips at some point, heat is released. This leads to a sharp decrease in the values of the critical field and current and may drive a portion of the magnet normal. In such a case, the heat release increases drastically and, as a result, an instability arises, which may destroy the magnet.

In order to avoid these processes, superconducting cables or ribbons for magnets are made multicore, and a normal metal (usually copper) is used as an insulator. [In comparison with a superconductor, any substance with finite resistance is an insulator.] However, while the superconductor exhibits low thermal conductivity, because the heat can be transferred only by quasiparticles, whose number at low temperatures is exponentially small (section 19.1), a normal metal is a good heat conductor. It is the normal metal that removes heat in the case

---

- A detailed investigation shows that smaller-scale irregularities can exert a collective action on the entire vortex lattice and also lead to pinning.

of sudden heating. Moreover, if current ceases to flow through the superconductor, the thick normal conductor connected in parallel will play the role of a shunt.

8.5 19 Kinetics of superconductors

Up until now we have been concerned only with equilibrium phenomena taking place in superconductors, i.e., with their behavior upon variation of temperature and of the external static magnetic field. The only exception was section 18.8, where we considered qualitatively the kinetics of the vortex structure upon passage of current.

A rigorous treatment of the kinetics of superconductors calls for the application of detailed equations of the BCS microscopic theory, which requires very complicated calculations. In most cases the answer cannot be found in analytical form. A certain simplification can be achieved for fields that vary gradually in space and in time: $\omega < \Delta/h, k < \xi_0^{-1}$, where ω and k are the frequency and the wave vector of the field.

Nevertheless, even in this case the resultant "kinetic equation" (see Aronov et al. 1981) is rather complicated and does not cover all the interesting phenomena. For this reason, we will confine ourselves in some cases to a qualitative description and try, where possible, to give estimates on the basis of simple physical considerations. We begin with phenomena that occur in weak fields or with a low temperature gradient, when the state of the superconductor deviates little from equilibrium; then we will discuss certain effects associated with strong nonequilibrium.

8.5.1 19.1. Electronic thermal conductivity

The transport of heat in superconductors is accomplished, just as in normal metals, by quasiparticles of the electron liquid and by phonons. At not too low temperatures the major contribution comes from electrons. As for the lowest temperatures, in this case too the electron contribution can be separated from the phonon contribution. For example, in a magnetic field above H_c the electrons become normal and thus we can find the difference in thermal conductivity between the superconducting and the normal state. As regards the electronic thermal conductivity of a normal metal, this can be either extrapolated from the region of $T > T_c$ or separated with the aid of a strong magnetic field, as described in Part I. Thus, the electronic thermal conductivity of a superconductor can be deduced from experimental data.

In calculating the thermal conductivity of a normal metal we were faced with the fact that the temperature gradient leads to the generation of an electric field, which
is determined from the condition of the absence of current. However, this effect introduces only a small correction, of the order of $(T/\mu)^2$ (see section 6.1). In superconductors there is no electric field, but the current of quasiparticles is balanced by a countercurrent of Cooper pairs (this point will be discussed in detail in section 19.2). In calculating thermal conductivity one may neglect the motion of Cooper pairs since it makes only a correction of order $(T/\mu)^2$.

At temperatures below T_c the dominant mechanism of electron scattering is the scattering from impurities. Therefore we will be concerned only with this mechanism here. The kinetic equation for quasiparticles has the usual form

$$\frac{\partial \varepsilon}{\partial p}\frac{\partial n}{\partial r} - \frac{\partial \varepsilon}{\partial r}\frac{\partial n}{\partial p} = I(n), \tag{19.1}$$

where ε is the energy of quasiparticles and $-\partial\varepsilon/\partial r$ is the force that acts on quasiparticles.

The form of the collision integral is determined as follows. Suppose that the impurities have no spin. In this case, the electrons conserve their spin on scattering. Moreover, the collisions

with impurities are elastic, i.e., the energy of quasi-particles is conserved. In view of this, the scattering of electrons from impurities may be described by the term in the Hamiltonian:

$$\mathscr{H}_{\text{imp}} = \sum_{\sigma,p,p'} a^{+}_{p',\sigma} a_{p,\sigma} V_{p'p}, \tag{19.2}$$

where $V_{p'p}$ is the interaction matrix element, which is a function only of $\theta = \left(\widehat{p,p'}\right)$. Expression (19.2) corresponds to the disappearance of an electron of momentum $\boldsymbol{p}$ and to the creation, in place of it, of another electron of momentum $\boldsymbol{p}'$.

In order to pass to quasiparticles, we substitute the Bogoliubov transformation (16.14). Here only those terms are retained which are not associated with a change in energy, i.e., the terms describing the creation or annihilation of two quasiparticles are omitted. As a result, we find

$$\mathscr{H}_{\text{imp}} = \sum_{\sigma,p'p'} \alpha^{+}_{p'\sigma} \alpha_{p\sigma} V_{p'p} \left(u_p u_{p'} - v_p v_{p'}\right). \tag{19.3}$$

The energy of quasiparticles is conserved upon scattering from impurities. Hence, $\varepsilon_p = \varepsilon_{p'}$. From this it follows that $\xi_p = \pm\xi_{p'}$. If $\xi_{p'} = \xi_p$, then $u_{p'} = u_p, v_{p'} = v_p, u_p^2 - v_p^2 = \xi_p/\varepsilon_p$. But if $\xi_{p'} = -\xi_p$, then $v_{p'} = u_p$ and $u_{p'} = v_p$ and expression (19.3) vanishes.

Let us now find the scattering probability per unit time, in other words, the function that replaces τ^{-1} in section 3.2*. So, we have

$$\begin{aligned}\tau_{\text{str}}^{-1} =& \frac{2\pi}{\hbar} \int |V_{p'p}|^2 \left(1 - \cos\theta\right) \left(u_p u_{p'} - v_p v_{p'}\right)^2 \\ & \times \delta\left(\tau_p \cdot \varepsilon_{r'}\right) \frac{d^3 p'}{(2\pi\hbar)^3}\end{aligned}$$

$$\begin{aligned}=& \frac{\pi}{\hbar} \nu(\mu) \left(\frac{\xi_p}{\varepsilon_p}\right)^2 \\ & \times \left|\frac{d\xi_p}{d\varepsilon_p}\right| \int |V(\theta)|^2 (1 - \cos\theta) \frac{d\Omega}{4\pi} \\ =& \tau_{\text{tr}}^{-1} \frac{|\xi_p|}{\varepsilon_p}\end{aligned} \tag{19.4}$$

we have made the replacements

$$\begin{aligned}& \mathrm{d}^3 p' \to p_0^2 \, \mathrm{d}p' \mathrm{d}\Omega \to p_0^2 \left(\frac{\mathrm{d}\xi'}{v}\right) \mathrm{d}\Omega \\ & \delta\left(\varepsilon - \varepsilon'\right) = \left|\frac{\mathrm{d}\xi}{\mathrm{d}\varepsilon}\right| \delta\left(|\xi| - |\xi'|\right) \to \left|\frac{\mathrm{d}\xi}{\mathrm{d}\varepsilon}\right| \delta\left(\xi - \xi'\right)\end{aligned}$$

since for $\xi' = -\xi$ we have $\tau_{\text{str}}^{-1} = 0$. From eq. (19.4) it follows that the collision integral is given by

$$I(n) = -\frac{|\xi_p|}{\varepsilon_p} \frac{n - n_{\text{F}}}{\tau_{\text{tr}}}. \tag{19.5}$$

- Recall that in Part II we use the notation τ_{tr} instead of τ.

Substituting into the left-hand side of the kinetic equation the equilibrium function

$$n_F = \frac{1}{\exp(\varepsilon/T)+1} \tag{19.6}$$

and using the fact that

$$\frac{\partial n_{\mathrm{F}}}{\partial r} = -\frac{\varepsilon}{T}\frac{\partial n_{\mathrm{F}}}{\partial \varepsilon}\nabla T, \tag{19.7}$$

$$\frac{\partial \varepsilon}{\partial p} = \frac{\partial \varepsilon}{\partial \xi}\frac{\mathrm{d}\xi}{\mathrm{d}p} = v\left(\frac{\xi}{\varepsilon}\right), \tag{19.8}$$

where $v = p/m$, we find*:

$$-\frac{\xi}{T}\frac{\partial n_{\mathrm{F}}}{\partial \varepsilon} v\nabla T = -\left(n - n_{\mathrm{F}}\right)\left(\frac{|\xi|}{\varepsilon}\right)\frac{1}{\tau_{\mathrm{tr}}}, \tag{19.9}$$

from which it follows that the nonequilibrium correction is

$$n^{(1)} = n - n_{\mathrm{F}} = \frac{\varepsilon}{T}\frac{\partial n_{\mathrm{F}}}{\partial \varepsilon}\tau_{\mathrm{tr}}\operatorname{sign}\xi v\nabla T \tag{19.10}$$

$$\operatorname{sign}\xi = \frac{\xi}{|\xi|}$$

The heat flux is expressed by

$$q = 2\int \varepsilon\frac{\partial \varepsilon}{\partial p} n\frac{\mathrm{d}^3 p}{(2\pi\hbar)^3}. \tag{19.11}$$

The factor 2 arises as a result of summation over the spin projections. Since n_F depends only on ε, the only contribution here comes from $n^{(1)}$. Substituting (19.10) and (19.8) and passing to the integration over ε, we obtain

$$\begin{aligned} q &= \frac{2\nu}{T}\int_{\Delta}^{\infty}\mathrm{d}\varepsilon\int\frac{\mathrm{d}\Omega}{4\pi}\varepsilon^2\tau_{\mathrm{tr}} v(v\nabla T)\frac{\partial n_{\mathrm{F}}}{\partial \varepsilon} \\ &= \frac{2\nu\nabla T}{3T}v^2\tau_{\mathrm{tr}}\int_{\Delta}^{\infty}\mathrm{d}\varepsilon\varepsilon^2\frac{\partial n_{\mathrm{F}}}{\partial \varepsilon} \\ &= -\left(n_{\mathrm{e}}\frac{\tau_{\mathrm{tr}}}{2mT^2}\right)\int_{\Delta}^{\infty}\mathrm{d}\varepsilon\frac{\varepsilon^2}{\cosh^2(\varepsilon/2T)}\nabla T \end{aligned} \tag{19.12}$$

(here the 2 arises from the integration over the regions $\xi > 0$ and $\xi < 0; n_{\mathrm{e}} = p_0^3/3\pi^2\hbar^3$). Hence, we have (Geilikman 1958)*:

$$x = \frac{n_{\mathrm{e}}\tau_{\mathrm{tr}}T}{2m}\int_{\Delta/T}^{\infty}\frac{x^2}{\cosh^2\left(\frac{1}{2}x\right)}\mathrm{d}x.$$

With $T \to T_{\mathrm{c}}$, from the above equation we obtain expression (3.28) for a normal metal. But if $T \to 0$, then $\cosh\left(\frac{1}{2}x\right) \approx \frac{1}{2}\exp\left(\frac{1}{2}x\right)$ and

---

- While substituting the equilibrium function n_{F} into the left-hand side of eq. (19.1), we must, strictly speaking, take into account that $\varepsilon = \left(\xi^2 + \Delta^2\right)^{1/2}$, where Δ depends on T and, hence, on r. However, the corresponding contributions from the two terms on the left-hand side of eq. (19.1) cancel.

$$\varkappa \approx \frac{2n_{\mathrm{e}}\tau_{\mathrm{tr}}T}{m}\left(\frac{\Delta(0)}{T}\right)^{2}\exp\left(\frac{-\Delta(0)}{T}\right). \tag{19.13}$$

The graph of x/x_{n} against T/T_{c} is given in fig. 122 .

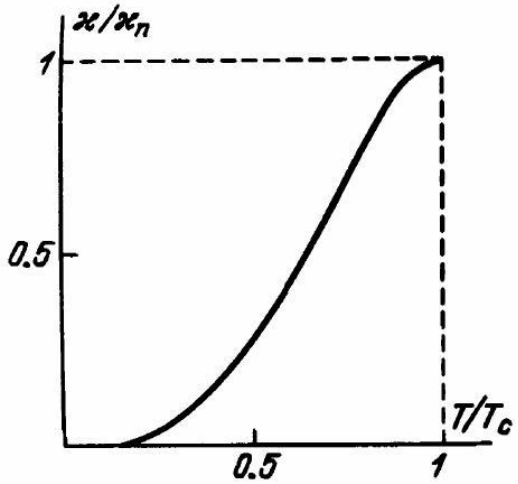

Fig. 122.

8.5.2 19.2. Thermoelectric phenomena

As has been pointed out in the preceding section, a temperature gradient leads to the appearance not only of a heat flux but also of a flux of quasiparticles, i.e., a "normal current". However, it is balanced by a superconducting current which flows in the opposite direction, because in the bulk of the superconductor the current must be equal to zero (otherwise the Meissner effect would not have occurred). Therefore, it has long been thought that there are no thermoelectric phenomena in a super-conductor. It has turned out, in fact, that the appearance of a supercurrent is amenable to detection.

The presence of a supercurrent implies that the momentum of Cooper pairs is no longer equal to zero, i.e., the Bose condensate of Cooper pairs comes into motion. In this case, the Bogoliubov transformation formulae (16.14) must be replaced by the following:

$$\begin{aligned} a_{p,+} &= u_p\alpha_{p,+} + v_p\alpha^{+}_{-p+q,-} \\ a_{p,-} &= u_{-p+q}\alpha_{p,-} - v_{-p+q}\alpha^{+}_{-p+q,+} \end{aligned} \tag{19.14}$$

The meaning of these transformations is as follows: the term with v in each of the formulae corresponds to the binding of electrons into a Cooper pair with momentum q and to its escape into the condensate (evidently $q = 2mv_{\mathrm{s}}$). Instead, an electron appears with momentum $-p+q$ and opposite spin projection.

The subscripts for u and v in the second formula are chosen such that the following condition is satisfied:

- In this and subsequent sections x is the coefficient of thermal conductivity.

$$\{a_{p,+}, a_{-p+q,-}\} = -u_p v_p + u_p v_p = 0$$

The coefficients u and v are connected by the same relation as before:

$$|u_p|^2 + |v_p|^2 = 1. \tag{19.15}$$

Substituting formulae (19.14) into the Hamiltonian (16.13) and averaging, we obtain

$$\begin{aligned}\langle \mathscr{H} - \mu N \rangle = \sum_p \big\{ & \xi \left[n_{p,+} + |v_p|^2 \left(1 - n_{p,+} - n_{-p+q,-}\right)\right] \\ & + \xi' \left[n_{-p+q,-} + |v_p|^2 \left(1 - n_{p,+} - n_{-p+,q-}\right)\right] \big\} - \frac{|\Delta|^2}{g},\end{aligned} \tag{19.16}$$

where

$$\Delta = g \sum_p u_p v_p \left(1 - n_{p,+} - n_{-p+q,-}\right), \tag{19.17}$$

$$\xi' = \xi(-p+q). \tag{19.18}$$

We will find the real solution for u and v (this does not alter the result but simplifies the computations). In this case, Δ is also real. Minimizing with respect to v_p and using (19.15), we get

$$u^2 = u^2_{-p+q} = \frac{1}{2}\left(1 + \frac{\xi + \xi'}{2\varepsilon}\right), \tag{19.19}$$

$$v_p^2 = v^2_{-p+q} = \frac{1}{2}\left(1 - \frac{\xi + \xi'}{2\varepsilon}\right), \tag{19.20}$$

$$\varepsilon = \left[\frac{1}{4}\left(\xi + \xi'\right)^2 + \Delta^2\right]^{1/2}. \tag{19.21}$$

Varying eq. (19.16) with respect to $n_{p,+}$ and $n_{p,-}$, we find the value of energy in the Fermi distribution functions (19.17):

$$\varepsilon_{p,+} = \varepsilon + \frac{1}{2}\left(\xi - \xi'\right), \quad \varepsilon_{-p+q,-} = \varepsilon - \frac{1}{2}\left(\xi - \xi'\right). \tag{19.22}$$

Let us calculate the electric current. Here we must take into account the difference between charge transfer and energy transfer. Whereas the energy is transferred by quasi-particles, which have an energy $\varepsilon = (\xi^2 + \Delta^2)^{1/2}$ and velocity $\partial\varepsilon/\partial p$, the charge is transferred by initial electrons with velocity p/m (the corresponding operators are a and $a^+$and not α and α^+). Thus, the current operator has the form

$$j = \frac{e}{m} \sum_{p,\sigma} p a^+_{p,\sigma} a_{p,\sigma}. \tag{19.23}$$

The same result has been obtained earlier (see formulae 16.59′ and 16.62 at $\boldsymbol{A} = 0$ and $\boldsymbol{q} = 0$).

Substituting here the transforms (19.14) and averaging gives

$$j = \sum_p p \left[u_p^2 n_{p,+} + v_p^2 \left(1 - n_{-p+q,-}\right) + u_n^2 n_{p,-} + v_p^2 \left(1 - n_{-p+q,+}\right)\right]$$

(here we have used qualities 19.20,19.21). We pass now to a new variable: $\boldsymbol{p} \to \boldsymbol{p} + \frac{1}{2}\boldsymbol{q}$. Assuming that $|\boldsymbol{q}| < p_0$, we obtain

$$\begin{array}{lll} \xi \to \xi + \frac{1}{2}vq, & \xi' \to \xi - \frac{1}{2}vq, & \frac{1}{2}(\xi + \xi') \to \xi \\ \varepsilon \to (\xi^2 + \Delta^2)^{1/2}, & \varepsilon_p \to \varepsilon + \frac{1}{2}vq/2, & \varepsilon_{-p+q} \to \varepsilon - \frac{1}{2}vq. \end{array} \tag{19.24}$$

The expression for the current takes the form

$$j = 2\sum_p \left(p + \frac{1}{2}q\right)\left[u_p^2 n_p + v_p^2(1 - n_{-p+q})\right] \tag{19.25}$$

The momentum of the pairs is connected with the velocity of the condensate by the relation $q = 2mv_\mathrm{s}$. Since $v = p/m$, we have

$$\frac{1}{2}vq = pv_\mathrm{s}. \tag{19.26}$$

The result obtained may be interpreted as follows. In the coordinate system associated with the moving condensate the energy of quasiparticles is ε and the momentum of electrons is $\boldsymbol{p}$. But if we pass to the laboratory coordinate system, the energy of quasiparticles becomes equal to $\varepsilon + pv_\mathrm{s}$ and the electron momentum to $p + mv_\mathrm{s}$.

In the preceding section, while calculating the thermal conductivity we should have replaced, strictly speaking, ε in expression (19.11) by $\varepsilon + pv_\mathrm{s}$ and $\partial\varepsilon/\partial p$ by $\partial\varepsilon/\partial p + v_\mathrm{s}$. But here one must take into account that the superconducting current arises only as a result of the appearance of a temperature gradient, i.e., $v_\mathrm{s} \propto \nabla\mathrm{T}$. Substitution into eq. (19.11) of the equilibrium distribution function n_F instead of n under the integral yields the gradient in momentum space of a certain function $f(\varepsilon + pv_\mathrm{s})$. The integral over d^3p is transformed to a surface integral and is equal to zero because $n_F(\infty) = 0$. Therefore, only the integral of the nonequilibrium contribution $n^{(1)}$ is left, which itself is proportional to ∇T. Hence, in this integral we may put $v_\mathrm{s} = 0$.

Let us return to formula (19.25). We substitute into it $n = n_\mathrm{F} + n^{(1)}$, where $n^{(1)} < n_\mathrm{F}$, and limit ourselves to the terms of first order in $n^{(1)}$ and v_s (of order ∇T). This gives

$$\begin{aligned} j =& 2ev_\mathrm{s}\sum_p \left[u_p^2 n_\mathrm{F} + v_p^2(1 - n_\mathrm{F})\right] \\ &+ 2\frac{e}{m}\sum_p p(pv_\mathrm{s})\frac{\partial n_\mathrm{F}}{\partial\varepsilon} + 2\frac{e}{m}\sum_p pn^{(1)} \end{aligned} \tag{19.27}$$

In the last term it is taken into account that $n_{-p}^{(1)} = -n_p^{(1)}$ (see 19.10). We have also used the condition (19.15).

If we perform the Bogoliubov transformation (16.14) in the electron density operator

$$n_\mathrm{e} = \sum_p a_{p,\sigma}^+ a_{p,\sigma}$$

and average, we obtain

$$n_\mathrm{e} = 2\sum_p \left[u_p^2 n_\mathrm{F} + v_p^2(1 - n_\mathrm{F})\right].$$

Thus, the first term in (19.27) is equal to $n_e v_s e$. We compare the second term in (19.27) with formula (16.83) for the momentum of quasiparticles moving with velocity $\boldsymbol{u}$ (in our case

the role of $\boldsymbol{u}$ is played by $-\boldsymbol{v}_\mathrm{s}$). The proportionality factor between $\boldsymbol{P}$ and $\boldsymbol{mu}$ is the "number of normal electrons" $\boldsymbol{n}_\mathrm{n}$. Hence, the first two terms in (19.27) give

$$(n_\mathrm{e} - n_\mathrm{n})\, ev_\mathrm{s} = n_\mathrm{s} ev_\mathrm{s} = j_\mathrm{s}$$

This is just the superconducting current.
The last term in eq. (19.27) is the current of quasiparticles, which arises under the action of the temperature gradient. Substituting (19.10) and passing to integration over ξ, we get

$$j_\mathrm{n} = \mathrm{e} \int \frac{\varepsilon}{T} \frac{\partial n_\mathrm{F}}{\partial \varepsilon} \tau_\mathrm{tr} \operatorname{sign} \xi v (v \nabla T) \nu \mathrm{d}\xi \frac{\mathrm{d}\Omega}{4\pi}$$

This integral vanishes in the first approximation in ξ because of the presence of the factor sign ξ. Therefore, just as in a normal metal, we must expand the factor $\tau_\mathrm{tr} v^2 \nu$ in the integrand in ξ :

$$\tau_\mathrm{tr} v^2 \nu = \left(\tau_\mathrm{tr} v^2 \nu\right)_\mu + \xi \frac{\partial}{\partial \mu} \left(\tau_\mathrm{tr} v^2 \nu\right)_\mu$$

The second term gives a nonzero result. Here

$$\int_{-\infty}^{\infty} \xi \operatorname{sign} \xi \mathrm{d}\xi \to \int_{-\infty}^{\infty} |\xi| \mathrm{d}\xi \to 2 \int_0^{\infty} |\xi| \mathrm{d}|\xi| \to 2 \int_\Delta^{\infty} \varepsilon \mathrm{d}\varepsilon$$

The result is given by (Gal'perin et al. 1973, 1974)

$$\begin{aligned} j_\mathrm{n} &= \frac{2}{3} e \left[\frac{\partial}{\partial \mu} \left(\tau_\mathrm{tr} v^2 \nu\right)_\mu\right] \frac{\nabla T}{T} \int_\Delta^{\infty} \varepsilon^2 \frac{\partial n}{\partial \varepsilon}\, \mathrm{d}\varepsilon \\ &= -\frac{2}{3} e \left(\frac{\partial}{\partial \mu} \left(\tau_\mathrm{tr} v^2 \nu\right)_\mu\right) T \nabla T \int_{\Delta/T}^{\infty} \frac{x^2}{\cosh^2\left(\frac{1}{2}x\right)} \mathrm{d}x \\ &= -e \left(\frac{\partial}{\partial \mu} \ln \left(\tau_\mathrm{tr} v^2 \nu\right)_\mu\right) x \nabla T \end{aligned} \tag{19.28}$$

where x is the thermal conductivity coefficient. Taking into account that in a normal metal $j_\mathrm{n} = -\beta \nabla T$ and comparing formulas (3.24) and (6.19), we see that the expression for j_n written in terms of x does not differ from a normal metal. Since $T \to T_\mathrm{c}$ and $x \to x_\mathrm{n}$, the same is valid for j_n. Taking into account that for impurity scattering $\tau_\mathrm{tr} = l/v \propto \mu^{-1/2}, v^2 \propto \mu$ and $\nu \propto p_0 \propto \mu^{1/2}$, we finally obtain

$$j_\mathrm{s} = -j_\mathrm{n} = \frac{e}{\mu} \varkappa \nabla T \tag{19.29}$$

The asymptotics are found with the aid of the formulas for x : (3.24) with $T \to T_\mathrm{c}$ and (19.13) with $T \to 0$.

A question now arises as to whether we can determine experimentally the presence of a supercurrent. To this end, we use the expression for the supercurrent in terms of the phase of the order parameter (17.75):

$$j_\mathrm{s} = \frac{\hbar e n_\mathrm{s}}{2m} \left(\nabla \chi - \frac{2e}{\hbar c} A\right) \tag{19.30}$$

(here we have substituted $|\Psi|^2 = n_\mathrm{s}/2$, the number of Cooper pairs). Comparing expressions (19.30) and (19.29), we find

$$\nabla \chi = \frac{2m}{\hbar e n_\mathrm{s}} \frac{e\chi}{\mu} \nabla T + \frac{2e}{\hbar c} A. \tag{19.31}$$

Suppose now that we have a ring consisting of two different superconductors (fig. 123). We assume that the junctions are at different temperatures, T_1 and T_2. We integrate expression (19.31) over a closed loop C , which passes through the bulk

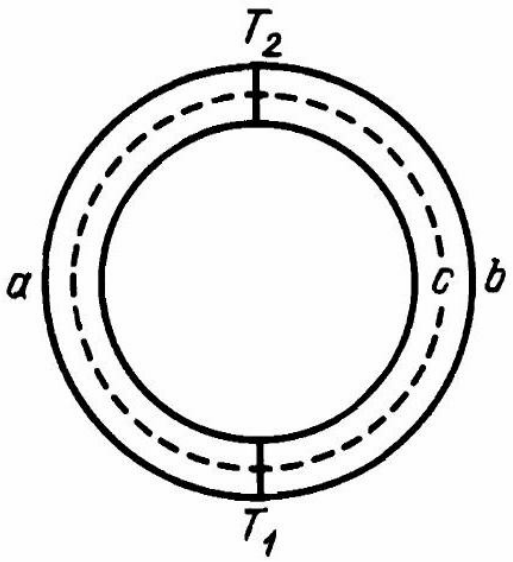

Fig. 123.

of superconductors. The change of the phase along the closed loop must be equal to $2\pi n$, where n is an integer. Hence, we have

$$2\pi n = \frac{2m}{\hbar}\oint_C \frac{x}{\mu n_\mathrm{s}}\nabla T\ \mathrm{d}l + \frac{2e}{\hbar c}\oint_\mathrm{C} A\ \mathrm{d}l$$
$$= \frac{2m}{\hbar}\int_{T_1}^{T_2}\left[\left(\frac{x}{\mu n_\mathrm{s}}\right)_\mathrm{b} - \left(\frac{x}{\mu n_\mathrm{s}}\right)_\mathrm{a}\right]\mathrm{d}T + 2\pi\frac{\Phi}{\Phi_0}$$

or

$$\frac{\Phi}{\Phi_0} = n + \frac{m}{\pi\hbar}\cdot\int_{T_1}^{T_2}\left[\left(\frac{x}{\mu n_\mathrm{s}}\right)_\mathrm{a} - \left(\frac{x}{\mu n_\mathrm{s}}\right)_\mathrm{b}\right]\mathrm{d}T. \tag{19.32}$$

From this formula it follows that the magnetic flux passing through the loop is not equal to an integer number of flux quanta and has a correction which depends on temperature. This correction is a manifestation of thermoelectricity in superconductors.

At first glance it seems paradoxical that a magnetic flux can pass through the ring in the absence of current. In fact, the statement that $\boldsymbol{j} = \mathbf{0}$ refers only to the bulk of the superconductor. A superconducting current is circulating along the inner surface of the ring and it is this supercurrent that produces the magnetic flux.

Let us estimate the magnitude of the correction to the magnetic flux. We assume that $T \sim T_\mathrm{c}$ and, hence, $n_\mathrm{s} \sim n_\mathrm{e}$ and $x \sim x\,(T_\mathrm{c})$. The expression for $x(T)$ is derived from formula (3.28). We have

$$\frac{\Delta\Phi}{\Phi_0\Delta T} \sim \frac{m}{\hbar}\frac{x}{\mu n_\mathrm{e}} \sim \frac{m}{\hbar}\frac{n_\mathrm{e}\tau_\mathrm{tr}}{m\mu n_\mathrm{e}}T_\mathrm{c}$$
$$\sim \frac{T_\mathrm{c}}{\mu}\frac{\tau_\mathrm{tr}}{\hbar} \sim 10^{-4}\frac{l}{v\hbar} \sim 10^{12}\mathrm{erg}^{-1} \sim 10^{-4}\ \mathrm{K}^{-1}$$

(we assume here that the mean free path $l \sim 10^{-3}$ cm and $T_\mathrm{c}/\mu \sim 10^{-4}$). Thus, the temperature contribution is very small (10^{-4} flux quantum per 1 K). Its measurement

is hindered also by the fact that it is difficult to protect the superconducting ring against a small trapped magnetic flux. Therefore, in practice one has to measure the difference effect with $T_1 \rightleftharpoons T_2$. The corresponding measurement has been carried out (Zavaritskii 1974) with the aid of a SQUID (section 22.8) and has qualitatively confirmed the theory. However, other results exceed the theoretical predictions*.

8.5.3 19.3. The behavior of superconductors in a weak high-frequency field

The behavior of superconductors in a weak, time-independent field has been considered in sections 16.7 and 16.8. In principle, the same method can be used to find the relationship between the current and a field of finite frequency. We do not give the relevant calculations here because they are very cumbersome (see, for example, Abrikosov and Khalatnikov 1958). Instead, we present some of the fundamental results (Abrikosov et al. 1958, 1959, Mattis and Bardeen 1958).

First of all let us consider the case $T = 0$. In this case the superconductor does not contain quasiparticles that could have absorbed quanta of any energy. The absorption of electromagnetic waves begins only when

$$\hbar\omega = 2\Delta(0). \tag{19.33}$$

This is the energy required for the breakdown of Cooper pairs. In the limit, when $\hbar\omega > 2\Delta$ the difference between a super-conductor and a normal metal disappears, i.e., the relationship between the current and the field tends to that existing in a normal metal.

The absorption of electromagnetic energy is proportional to the real part of the impedance. For a pure superconductor in the limiting Pippard case the following relation holds:

$$\frac{Z_\mathrm{s}}{R_\mathrm{n}} = -2\mathrm{i}\left[\frac{\pi\hbar\omega}{\Delta Q_1(\omega)}\right]^{1/3}, \tag{19.34}$$

where $Q_1(\omega)$ enters into the proportionality factor between the current and the field:

$$j = -Q(q,\omega)A(q,\omega), \quad Q(q,\omega) = \frac{3}{4}\frac{n_\mathrm{e}e^2}{mc}\frac{\Delta}{\hbar vq}Q_1(\omega), \tag{19.35}$$

and R_n is the value of R for a normal metal.

The real part of the impedance manifests itself only if the imaginary part Q_1 is nonzero. A plot of $\operatorname{Im} Q_1(\omega)$ at $T = 0$ is shown in fig. 124. The $R_\mathrm{s}(\omega)/R_\mathrm{n}$ plot has

is hindered also by the fact that it is difficult to protect the superconducting ring against a small trapped magnetic flux. Therefore, in practice one has to measure the difference effect with $T_1 \rightleftharpoons T_2$. The corresponding measurement has been carried out (Zavaritskii 1974) with the aid of a SQUID (section 22.8) and has qualitatively confirmed the theory. However, other results exceed the theoretical predictions*.

- V. I. Kozub (1985) proposed the following explanation. In order to enhance the effect, the superconductors making up the ring are usually chosen such that they differ in their parameters, particularly in T_c. For one of the superconductors the temperature is very low and the energy transport is mainly realized by phonons. These phonons are irradiated into the other superconductor and produce a phonon wind, which drags the quasiparticles. An estimate shows that this effect can increase the observed magnetic flux by two orders of magnitude.

8.5.4 19.3. The behavior of superconductors in a weak high-frequency field

The behavior of superconductors in a weak, time-independent field has been considered in sections 16.7 and 16.8. In principle, the same method can be used to find the relationship between the current and a field of finite frequency. We do not give the relevant calculations here because they are very cumbersome (see, for example, Abrikosov and Khalatnikov 1958). Instead, we present some of the fundamental results (Abrikosov et al. 1958, 1959, Mattis and Bardeen 1958).

First of all let us consider the case $\boldsymbol{T} = 0$. In this case the superconductor does not contain quasiparticles that could have absorbed quanta of any energy. The absorption of electromagnetic waves begins only when

$$\hbar\omega = 2\Delta(0). \tag{19.33}$$

This is the energy required for the breakdown of Cooper pairs. In the limit, when $\hbar\omega > 2\Delta$ the difference between a super-conductor and a normal metal disappears, i.e., the relationship between the current and the field tends to that existing in a normal metal.

The absorption of electromagnetic energy is proportional to the real part of the impedance. For a pure superconductor in the limiting Pippard case the following relation holds:

$$\frac{Z_\mathrm{s}}{R_\mathrm{n}} = -2\mathrm{i}\left[\frac{\pi\hbar\omega}{\Delta Q_1(\omega)}\right]^{1/3}, \tag{19.34}$$

where $Q_1(\omega)$ enters into the proportionality factor between the current and the field:

$$j = -Q(q,\omega)A(q,\omega), \quad Q(q,\omega) = \frac{3}{4}\frac{n_\mathrm{e}e^2}{mc}\frac{\Delta}{\hbar vq}Q_1(\omega), \tag{19.35}$$

and R_n is the value of R for a normal metal.

The real part of the impedance manifests itself only if the imaginary part Q_1 is nonzero. A plot of $\mathrm{Im}\, Q_1(\omega)$ at $T = 0$ is shown in fig. 124. The $R_\mathrm{s}(\omega)/R_\mathrm{n}$ plot has

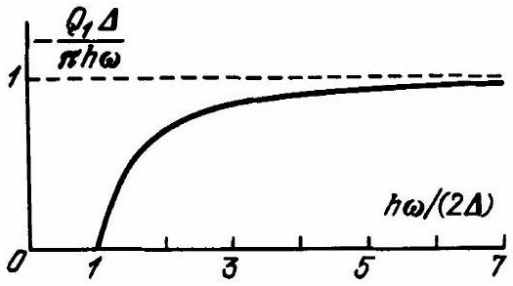

Fig. 124.

- V. I. Kozub (1985) proposed the following explanation. In order to enhance the effect, the superconductors making up the ring are usually chosen such that they differ in their parameters, particularly in T_c. For one of the superconductors the temperature is very low and the energy transport is mainly realized by phonons. These phonons are irradiated into the other superconductor and produce a phonon wind, which drags the quasiparticles. An estimate shows that this effect can increase the observed magnetic flux by two orders of magnitude.

qualitatively the same form. Near the absorption threshold

$$\operatorname{Im} Q_1 \approx -\pi^2 \left(\frac{\hbar\omega}{2\Delta} - 1 \right). \tag{19.35'}$$

The ratio $R_s(\omega)/R_n$ is also proportional to this quantity.
At $T > 0$ there are quasiparticles in the superconductor which can absorb electromagnetic quanta of any frequency. If $T < T_c$, the number of quasiparticles is exponentially small ($\sim \exp[-\Delta(0)/T]$). In the case $\omega < \Delta$ the same exponential is contained in the imaginary part of $Q_1(\omega)$ and in the real part of the impedance. The expression for $\operatorname{Im} Q_1$ for $\omega, T \ll \Delta$ reads

$$\operatorname{Im} Q_1 \approx -4\pi \sinh\left(\frac{\omega}{2T}\right) K_0\left(\frac{\omega}{2T}\right) \exp\left(\frac{-\Delta(0)}{T}\right), \tag{19.35"}$$

where K_0 is the MacDonald function.
Starting with $\hbar\omega = 2\Delta(0) = 3.52T_c$ a finite absorption also occurs at $T = 0$. This is clearly seen in the experimental plots obtained for aluminum at various frequencies and temperatures (fig. 125) (Biondi and Garfunkel 1959). Note that with $\omega \to 0$ the dependence $R_s(T)$ assumes the same form as the resistivity curve at constant current: $R = 0$ at $T < T_c$ and $R_s = R_n$ at $T > T_c$.

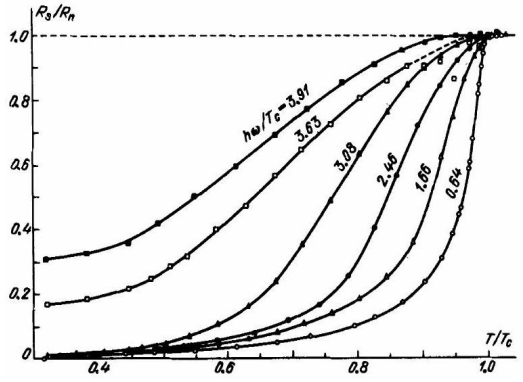

Fig. 125.

The characteristic wavelengths corresponding to the condition (19.33) lie within a range of the order of $1 - 0.1$ mm and the corresponding frequencies are of the order of $\nu = \omega/2\pi \sim 10^{11} - 10^{12}$ Hz. Note that in the optical range $\nu \sim 10^{15}$ Hz. For these frequencies the impedance of superconductors does not differ from that of normal metals.

However, in principle, apart from elastic reflection at an unshifted frequency, one can also observe Raman light scattering when part of the quantum energy is transferred to the electronic system. In this case (Abrikosov and Fal'kovsii 1961, 1987, Abrikosov and Genkin 1973) the spectral dispersion of the reflected light contains "satellites", i.e., quanta with an altered frequency. In this case, we are speaking of the breakup of the pairs and therefore at low temperatures a "Stokes satellite" appears, with a continuous frequency distribution $\hbar\omega \leqslant \hbar\omega_0 - 2\Delta$ (ω_0 is the frequency of the incident light). The intensity of the satellite is rather low because the interaction of light with the electronic system occurs only in a thin skin layer. Here, special care must be taken in order for the line of the incident light to be narrow (in the sense of the spectral width) and the intensity not to be very high, otherwise the specimen will be heated. The value of Δ is also important. For substances with large Δ the line needs not be so narrow. Thus Raman scattering was first definitely observed in the high- T_c ceramic $YBa_2Cu_3O_{7-\delta}$ (Bazhenov et al: 1987, Lyons et al. 1987). In an anisotropic superconductor $\Delta_{\min}$ is established in this way (Abrikosov and Fal'kovskii 1987).

In conclusion, we give one more relation between the current and the field for a dirty superconductor in the London limit ($q = 0$) in the vicinity of the critical temperature and also for a low frequency: $\omega \lll T_c$ (this case is of interest for what follows). We have

$$j = \left(\frac{-c}{4\pi\delta^2} + \frac{i\omega\sigma}{c} \right) A,$$

where $\sigma = n_e e^2 \tau_{tr}/m$ is the conductivity of a normal metal; δ depends on the ratio of ξ_0 to l, but in all cases it corresponds to the static penetration depth (sections 16.9 and 16.10). In other words, for the case under consideration

$$\boldsymbol{j} = \boldsymbol{j}_s + \boldsymbol{j}_n$$

where j_s is expressed by the formula for constant field and $j_n = \boldsymbol{\sigma E}\,(\boldsymbol{E} = -\boldsymbol{c^{-1}}\partial \boldsymbol{A}/\partial t = (\mathrm{i}\omega/c)\boldsymbol{A}$. This is consistent with the concepts of London electrodynamics. However, with other relationships between ω, Δ and T there is no such agreement.

8.5.5 19.4. Absorption of ultrasound

In accordance with section 12.1, the variation of the electron energy in a field of sound waves may be considered to be equal to $\Lambda_{ik}(p)u_{ik}(r,t)$, where u_{ik} is the strain tensor and Λ_{ik} is the deformation potential. This quantity plays the role of the potential energy. The relevant operator may be written similarly to eq. (19.2). The frequency of the sound that can actually be generated does not exceed 10^9 Hz, whereas $\Delta/(2\pi\hbar) \sim 10^{11}$ Hz. Hence, $\hbar\omega < \Delta$. In view of this, in transformating to operators of quasiparticles we have again to drop the terms corresponding to creation and annihilation of two quasiparticles. As regards the terms corresponding to scattering, one has to take account of the fact that the electron energy upon absorption of a phonon increases by an amount $\hbar\omega$. Therefore, $\varepsilon \neq \varepsilon'$ in formula (19.3).

We assume that $\omega\tau_{tr} > 1$ and apply the quantum approach described in section 12.2. The only difference from formula (12.20) lies in the appearance of the factor $(uu' - vv')^2$. Inserting the expressions for u and v, we obtain (assuming that the normalization volume $V = 1$):

$$Q = -\pi\omega^2 \sum_{p,p'} |U_{p'p}|^2\, \delta\left(\omega_{p'p} - \omega\right) \frac{\partial n_F}{\partial \varepsilon} \frac{1}{2} \left(1 + \frac{\xi_p \xi_{p'} - \Delta^2}{\varepsilon_p \varepsilon_{p'}} \right). \tag{19.36}$$

The matrix element $U_{p'p}$ is given by (at $k < p_0$)

$$U_{p'p} = \Lambda_{ik}(p) u^0_{ik} \delta_{p',p+\hbar k}, \tag{19.37}$$

where $u^0_{ik} = \frac{1}{2}\mathrm{i}\left(k_i u^0_k - k_k u^0_i\right)$ and u^0 is the amplitude of the sound wave. Passing from the sums over momenta to integrals $\sum_p = (2\pi\hbar)^{-3} \int \mathrm{d}^3 p$ and considering that

$$\delta^2_{p'p} = \delta_{p'p} \to (2\pi\hbar)^3 \left(\delta\left(p' - p\right)\right.,$$

we get

$$Q = -\pi\omega^2\hbar \int \frac{\mathrm{d}^3 p}{(2\pi\hbar)^3} \left|\Lambda_{ik}(p) u^0_{ik}\right|^2 \delta\left(\varepsilon_{p'} - \varepsilon_p - \hbar\omega\right) \frac{\partial n_F}{\partial \varepsilon} \frac{1}{2} \left(1 + \frac{\xi_p \xi_{p'} - \Delta^2}{\varepsilon_p \varepsilon_{p'}} \right), \tag{19.38}$$

where $\boldsymbol{p'} = \boldsymbol{p} + \boldsymbol{\hbar k}$.

In formula (19.38) $\int \mathrm{d}^3 p (2\pi\hbar)^{-3}$ corresponds to $\frac{1}{4}\nu \int \mathrm{d}\xi\, \mathrm{d}\cos\frac{1}{2}\theta$, where $\theta = \widehat{(v,k)}$. Taking into

account that $\xi' = \xi + vk\cos\theta$ and $vk \gg \omega$ (because $v \gg s$; s is the sound velocity), we can pass to the integration over $\boldsymbol{\xi}$ and $\boldsymbol{\xi}'$ and write

$$\int \frac{d^3p}{(2\pi\hbar)^3} \to \frac{\nu}{4\hbar vk} \int_{-\infty}^{\infty} d\xi \int_{-\infty}^{\infty} d\xi'$$

(instead of $|\Lambda_{ik}(p)|^2$ we must take $\overline{|\Lambda_{ik}(p)|^2}$, which signifies the average over the line on the Fermi surface, where $\cos\theta = 0$ or $v \perp k$). The integration over ξ and ξ' leads to the cancellation of the odd terms with respect to ξ and ξ' in eq. (19.38). After this we may pass over to the integration over ε, taking account of the two possible signs of ξ : $\int_{-\infty}^{\infty} \mathrm{d}\xi \to 2\int_{\Delta}^{\infty} \varepsilon \left(\varepsilon^2 - \Delta^2\right)^{-1/2} \mathrm{d}\varepsilon$. As a result, we obtain

$$Q = -\frac{\pi\omega^2\nu}{vk} \int_{\Delta}^{\infty} \left|\Lambda_{ik} u_{ik}^0\right|^2 \left[\varepsilon(\varepsilon + \hbar\omega) - \Delta^2\right] \times \left(\varepsilon^2 - \Delta^2\right)^{-1/2} \left[(\varepsilon + \hbar\omega)^2 - \Delta^2\right]^{-1/2} \frac{\partial n_{\mathrm{F}}}{\partial \varepsilon}\, \mathrm{d}\varepsilon. \tag{19.39}$$

tensor and Λ_{ik} is the deformation potential. This quantity plays the role of the potential energy. The relevant operator may be written similarly to eq. (19.2). The frequency of the sound that can actually be generated does not exceed 10^9 Hz, whereas $\Delta/(2\pi\hbar) \sim 10^{11}$ Hz. Hence, $\hbar\omega < \Delta$. In view of this, in transformating to operators of quasiparticles we have again to drop the terms corresponding to creation and annihilation of two quasiparticles. As regards the terms corresponding to scattering, one has to take account of the fact that the electron energy upon absorption of a phonon increases by an amount $\hbar\omega$. Therefore, $\varepsilon \neq \varepsilon'$ in formula (19.3).

We assume that $\omega\tau_{\mathrm{tr}} > 1$ and apply the quantum approach described in section 12.2. The only difference from formula (12.20) lies in the appearance of the factor $(uu' - vv')^2$. Inserting the expressions for u and v, we obtain (assuming that the normalization volume $\boldsymbol{V} = \mathbf{1}$):

$$Q = -\pi\omega^2 \sum_{p,p'} |U_{p'p}|^2\, \delta\left(\omega_{p'p} - \omega\right) \frac{\partial n_{\mathrm{F}}}{\partial \varepsilon} \frac{1}{2} \left(1 + \frac{\xi_p \xi_{p'} - \Delta^2}{\varepsilon_p \varepsilon_{p'}}\right). \tag{19.36}$$

The matrix element $U_{p'p}$ is given by (at $k < p_0$)

$$U_{p'p} = \Lambda_{ik}(p) u_{ik}^0 \delta_{p',p+hk}, \tag{19.37}$$

where $u_{ik}^0 = \frac{1}{2}\mathrm{i}\left(k_i u_k^0 - k_k u_i^0\right)$ and u^0 is the amplitude of the sound wave. Passing from the sums over momenta to integrals $\sum_p = (2\pi\hbar)^{-3} \int \mathrm{d}^3p$ and considering that

$$\delta_{p'p}^2 = \delta_{p'p} \to (2\pi\hbar)^3 \left(\delta\left(p' - p\right)\right.,$$

we get

$$Q = -\pi\omega^2\hbar \int \frac{\mathrm{d}^3p}{(2\pi\hbar)^3} \left|\Lambda_{ik}(p) u_{ik}^0\right|^2 \delta\left(\varepsilon_{p'} - \varepsilon_p - \hbar\omega\right) \frac{\partial n_{\mathrm{F}}}{\partial \varepsilon} \frac{1}{2} \left(1 + \frac{\xi_p \xi_{p'} - \Delta^2}{\varepsilon_p \varepsilon_{p'}}\right), \tag{19.38}$$

where $\boldsymbol{p}' = \boldsymbol{p} + \boldsymbol{\hbar k}$.

In formula (19.38) $\int \mathrm{d}^3p(2\pi\hbar)^{-3}$ corresponds to $\frac{1}{4}\nu \int \mathrm{d}\xi\ \mathrm{d}\cos\frac{1}{2}\theta$, where $\theta = \widehat{(v,k)}$. Taking into account that $\xi' = \xi + vk\cos\theta$ and $vk \gg \omega$ (because $v \gg s$; s is the sound velocity), we can pass to the integration over $\boldsymbol{\xi}$ and $\boldsymbol{\xi}'$ and write

$$\int \frac{d^3p}{(2\pi\hbar)^3} \to \frac{\nu}{4\hbar vk} \int_{-\infty}^{\infty} d\xi \int_{-\infty}^{\infty} d\xi'$$

(instead of $|\Lambda_{ik}(p)|^2$ we must take $\overline{|\Lambda_{ik}(p)|^2}$, which signifies the average over the line on the Fermi surface, where $\cos\theta = 0$ or $v \perp k$). The integration over ξ and ξ' leads to the cancellation of the odd terms with respect to ξ and ξ' in eq. (19.38). After this we may pass over to the integration over ε, taking account of the two possible signs of ξ : $\int_{-\infty}^{\infty} \mathrm{d}\xi \to 2\int_{\Delta}^{\infty} \varepsilon\,(\varepsilon^2-\Delta^2)^{-1/2}\ \mathrm{d}\varepsilon$. As a result, we obtain

$$Q = -\frac{\pi\omega^2\nu}{vk}\int_{\Delta}^{\infty} \left|\Lambda_{ik}u_{ik}^0\right|^2 \left[\varepsilon(\varepsilon+\hbar\omega)-\Delta^2\right] \times \left(\varepsilon^2-\Delta^2\right)^{-1/2}\left[(\varepsilon+\hbar\omega)^2-\Delta^2\right]^{-1/2}\frac{\partial n_{\mathrm{F}}}{\partial\varepsilon}\,\mathrm{d}\varepsilon. \tag{19.39}$$

Since $\hbar\omega < \Delta$, all the brackets under the integral sign give unity. Comparing with the expression for a normal metal (at $\Delta = 0$) and taking into account that for the absorption coefficient to be obtained the quantity Q is divided in both cases by the same sound energy flux I, we obtain (Bardeen et al. 1957):

$$\frac{\Gamma_{\mathrm{s}}}{\Gamma_{\mathrm{n}}} = -2\int_{\Delta}^{\infty}\frac{\partial n_{\mathrm{F}}}{\partial\varepsilon}\,\mathrm{d}\varepsilon = 2n_{\mathrm{F}}(\Delta) = \frac{2}{\mathrm{e}^{\Delta/T}+1}. \tag{19.40}$$

As $T \to T_{\mathrm{c}}$ this ratio tends to unity and at low temperatures it falls off as $\exp(-\Delta/T)$, i.e., proportionally to the number of quasiparticles. The curve showing the dependence of $\Gamma_{\mathrm{s}}/\Gamma_{\mathrm{n}}$ on T/T_{c} is given in fig. 126.

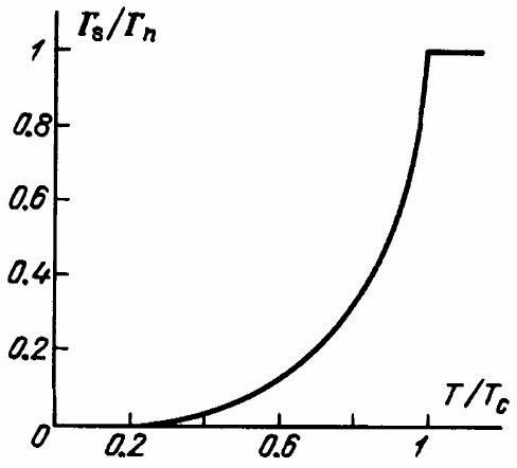

Fig. 126.

8.5.6 19.5. Stimulation of superconductivity by high-frequency, high-intensity field and sound

Up until now, while dealing with the behavior of superconductors under the influence of various external factors, we have limited our treatment to linear problems. Examples are the calculation of the current under the action of a small external field, and heat flux and electric current in the presence of a small temperature gradient. Such calculations are called calculations of the linear response of the system.

However, as the amplitude of external perturbations increases the nonlinear response may also become significant. In particular, under the action of a varying electromagnetic field a current with a frequency twice as high may be generated, which will lead to the emission of an electromagnetic wave at a doubled frequency. Hence, when an electromagnetic wave falls on

the metal surface, a reflected wave of doubled frequency may appear. Other nonlinear effects may also arise.

Since $\hbar\omega < \Delta$, all the brackets under the integral sign give unity. Comparing with the expression for a normal metal (at $\Delta = 0$) and taking into account that for the absorption coefficient to be obtained the quantity Q is divided in both cases by the same sound energy flux I, we obtain (Bardeen et al. 1957):

$$\frac{\Gamma_{\mathrm{s}}}{\Gamma_{\mathrm{n}}} = -2\int_{\Delta}^{\infty} \frac{\partial n_{\mathrm{F}}}{\partial \varepsilon}\, \mathrm{d}\varepsilon = 2n_{\mathrm{F}}(\Delta) = \frac{2}{\mathrm{e}^{\Delta/T}+1}. \tag{19.40}$$

As $T \to T_{\mathrm{c}}$ this ratio tends to unity and at low temperatures it falls off as $\exp(-\Delta/T)$, i.e., proportionally to the number of quasiparticles. The curve showing the dependence of $\Gamma_{\mathrm{s}}/\Gamma_{\mathrm{n}}$ on T/T_{c} is given in fig. 126.

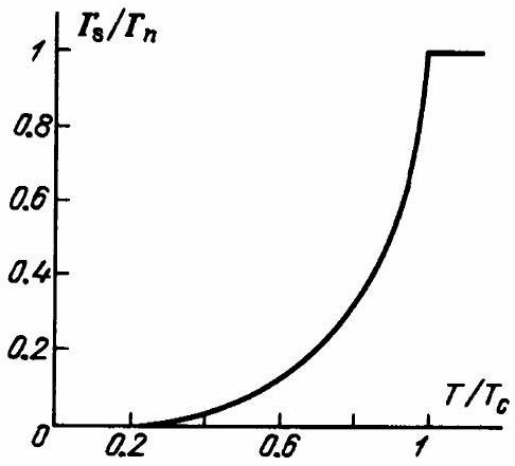

Fig. 126.

8.5.7 19.5. Stimulation of superconductivity by high-frequency, high-intensity field and sound

Up until now, while dealing with the behavior of superconductors under the influence of various external factors, we have limited our treatment to linear problems. Examples are the calculation of the current under the action of a small external field, and heat flux and electric current in the presence of a small temperature gradient. Such calculations are called calculations of the linear response of the system.

However, as the amplitude of external perturbations increases the nonlinear response may also become significant. In particular, under the action of a varying electromagnetic field a current with a frequency twice as high may be generated, which will lead to the emission of an electromagnetic wave at a doubled frequency. Hence, when an electromagnetic wave falls on the metal surface, a reflected wave of doubled frequency may appear. Other nonlinear effects may also arise.

We shall consider a specific nonlinear action of a high-frequency field (electromagnetic wave or sound), on superconductors which leads to a qualitatively new effect - an increase in the critical temperature of the superconducting transition, or, stimulation of superconductivity (Eliashberg 1970, Ivlev and Eliashberg 1971).

In sections 16.4 and 16.5 we have found the energy spectrum of quasiparticles in a superconductor and the equation for Δ. Formula (16.21), which relates Δ to the distribution function,

is valid for an arbitrary distribution and not only for the equilibrium distribution expressed by the Fermi function. Thus, we have

$$1 = \frac{1}{2} g \int \frac{d^3p}{(2\pi\hbar)^3} \frac{1-2n}{\varepsilon} \tag{19.41}$$

where $\varepsilon = (\xi^2 + \Delta^2)^{1/2}$.
With an equilibrium distribution we have seen that in the case $T = 0$, when no quasiparticles are present, Δ is at a maximum. At finite temperatures the appearance of quasiparticles leads to a decrease in Δ. Here, in the integral (19.41) quasi-particles with an energy of the order of Δ were the most important.

Suppose now that the electronic system absorbs quanta of energy $\hbar\omega$. If $\hbar\omega > 2\Delta$, new quasiparticles will be created and, hence, Δ will decrease. However, if $\hbar\omega < \Delta$, new quasiparticles cannot be created and the quanta are absorbed by the quasiparticles already present. This leads to their redistribution over the energies. If an appreciable number of quasiparticles receive an extra energy larger than Δ, it means that they move into another energy region. Hence, they leave the region which is relevant in the integral (19.41), and in this sense the situation begins to resemble that observed at $T = 0$. As a result, Δ increases.

To simplify the calculation, we assume that the temperature is close to T_c, i.e., $\Delta < T_c$ but still $\omega < \Delta$. Besides, we presume that the intensity of the external field is not too high, so the relative change of Δ is small.

We substitute $n = n_F(\varepsilon) + n - n_F$ into eq. (19.41). The integral with n_F is expanded in Δ, as was done in section 16.5 (formula 16.32). So, we obtain

$$\ln\left(\frac{T_c}{T}\right) - \frac{7}{8}\zeta(3)\frac{\Delta^2}{\pi^2 T_c^2} - 2\int_\Delta^\infty \mathrm{d}\varepsilon \left(\varepsilon^2 - \Delta^2\right)^{-1/2} \overline{(n - n_F)} = 0, \tag{19.42}$$

where the overbar in the last integral signifies averaging over the angles. We used here formula (16.25) for T_c; in the integral of $n - n_F$ we passed to the variable ε and took into account two signs of ξ. With our assumptions $\ln(T_c/T) \approx (T_c - T)/T_c$. If the distribution function depends on time, then in the integral we have to take the time-averaged quantity.

The distribution function n can be determined from the kinetic equation.
The calculations based on the detailed microscopic (BCS) theory, which takes account of the dependence of the quantities on time, involve very complicated kinetic equations, which are different, depending on the character of the external force. The difficulty is aggravated by the fact that the scattering from impurities, while being elastic, does not give rise to the relaxation of quasiparticles with respect
to energy, and therefore we must take into account the interaction with phonons. The latter circumstance leads to complication of the collision integral. Therefore, instead of detailed calculations, we shall make a simple estimate*.

Suppose we have a thin specimen, which is smaller than the penetration depth, onto which a high-frequency electromagnetic wave falls. As has been noted at the end of section 19.3, a normal current $j_n = \sigma E$ arises in it, which gives rise to ohmic losses. The energy received by the electronic system per unit time is given by

$$\frac{\partial Q}{\partial t} = \sigma\overline{E^2} = \frac{1}{2}\sigma E_0^2, \tag{19.43}$$

where $E = E_0 \cos\omega t$. Near T_c the quantity σ is equal to the conductivity of a normal metal, i.e., $\sigma = n_e e^2 \tau_{tr}/m$. This includes the time of scattering from impurities, because this process is the dominant one.

The electronic system transfers the received energy to the lattice in the form of phonons. However, this process is slow, taking a time $\tau_{\rm ph}$. Therefore, the effective temperature of the electronic system increases. It is rather obvious that

$$\tau_{\rm ph}\frac{\partial Q}{\partial t}\sim C_{\rm e}\delta T, \tag{19.44}$$

where $C_{\rm e}$ is the electronic heat capacity, which has the same order of magnitude as that in a normal metal, i.e., $C_{\rm e}\sim p_0 mT/\hbar^3$.

From formulae (1943) and (19.44) we find

$$\delta T\sim\frac{\tau_{\rm ph}\sigma E_0^2}{C_{\rm e}}\sim\frac{\tau_{\rm ph}n_{\rm e}e^2\tau_{\rm tr}E_0^2\hbar^3}{m\cdot mp_0T}\sim\frac{\left(evE_0\right)^2\tau_{\rm ph}\tau_{\rm tr}}{T}. \tag{19.45}$$

When the quasiparticles are heated by the field, their number is not changed because $\omega\ll\Delta$. This may be taken into account if we introduce the effective chemical potential. The new distribution will have the form

$$n=\frac{1}{\exp\left(\frac{\varepsilon-\delta\mu}{T+\delta T}\right)+1}$$

From the condition

$$\int_0^\infty n\,{\rm d}\xi=\int_\Delta^\infty\frac{n\varepsilon}{\left(\varepsilon^2-\Delta^2\right)^{1/2}}\,{\rm d}\varepsilon=\int_\Delta^\infty\frac{n_{\rm F}\varepsilon}{\left(\varepsilon^2-\Delta^2\right)^{1/2}}\,{\rm d}\varepsilon=\ {\rm const}$$

we find, by expanding in $\delta\mu$ and δT,

$$-\delta\mu\int_\Delta^\infty\frac{\partial n_{\rm F}}{\partial\varepsilon}\frac{\varepsilon}{\left(\varepsilon^2-\Delta^2\right)^{1/2}}\,{\rm d}\varepsilon-\frac{\delta T}{T}\int_\Delta^\infty\frac{\partial n_{\rm F}}{\partial\varepsilon}\frac{\varepsilon^2}{\left(\varepsilon^2-\Delta^2\right)^{1/2}}=0.$$

Since $\Delta<T$, we may put $\Delta=0$ everywhere. So, we obtain

$$\delta\mu=-2\delta T\ln 2.$$

Substituting

$$n\approx n_{\rm F}-\frac{\partial n_{\rm F}}{\partial\varepsilon}\left(\delta\mu+\frac{\varepsilon}{T}\delta T\right)$$

into the last term of eq. (19.42), we find

$$\begin{aligned}\int_\Delta^\infty{\rm d}\varepsilon\frac{1}{\left(\varepsilon^2-\Delta^2\right)^{1/2}}\frac{-\partial n_{\rm F}}{\partial\varepsilon}\left(\delta\mu+\frac{\varepsilon}{T_{\rm c}}\delta T\right)\\ \approx\frac{\delta\mu}{4T_{\rm c}}\ln\left(\frac{T_{\rm c}}{\Delta}\right)+\frac{\delta T_{\rm c}}{2T_{\rm c}}\approx-\frac{\delta T}{2T_{\rm c}}\ln 2\ln\left(\frac{T_{\rm c}}{\Delta}\right).\end{aligned}$$

We have confined ourselves to logarithmic accuracy with respect to $\ln\left(T_{\rm c}/\Delta\right)$. It is important that the integral is negative. Equation (19.42) is now written in the form

$$\frac{T-T_{\rm c}}{T_{\rm c}}=a\tau_{\rm ph}\tau_{\rm tr}\frac{\left(evE_0\right)^2}{T_{\rm c}^2}-\left[\frac{7}{8}\zeta(3)\right]\frac{\Delta^2}{\pi^2T_{\rm c}^2}, \tag{19.46}$$

where a is a coefficient of the order of unity (we assume that $\ln\left(T_{\rm c}/\Delta\right)$ is not large). A plot of $\left(T-T_{\rm c}\right)/T_{\rm c}$ against Δ is given in fig. 127. The lower curve corresponds to the equilibrium case $E_0=0$. In the presence of a wave, i.e. at $E_0\neq 0$, we obtain the upper curve, which

*The reasoning given here stems from B. I. Ivlev.

reaches a certain positive value with decreasing Δ. However, the theory outlined here may be applied only for $\Delta > \frac{1}{2}\omega$. At lower Δ the creation of new quasiparticles begins. The coefficient of Δ^2 in eq. (19.46) decreases and may even change sign (the dashed curve).

Thus, we come to the conclusion that the curve in fig. 127 exhibits a maximum at $\Delta \neq 0$ corresponding to $T - T_c > 0$. This means that if the film is kept at a temperature above T_c and irradiated, it can pass in a jumpwise manner to the superconducting state with a finite Δ. Of course, this effect may occur only at temperatures not too far from T_c.

The results obtained can be extended without any difficulty to the case where the excitation is accomplished by a sound wave. Comparing the two terms on the

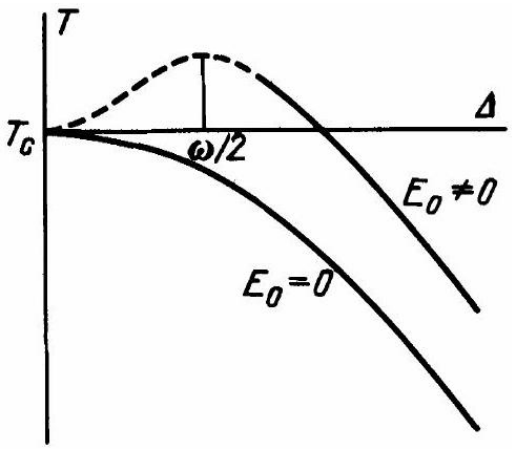

Fig. 127.

right-hand side of the kinetic equation (12.6), we arrive at the conclusion that in this case evE_0 in (19.46) must be replaced by $\Lambda_{ik}\dot{u}_{ik} \sim \omega\varepsilon_F k u^0 = \omega^2\varepsilon_F u^0/s$, where u^0 is the wave amplitude and s is the sound velocity.

The ideas presented here are in qualitative agreement with experiment (Wyatt et al. 1966). The measurement of the critical current of a film subjected to electromagnetic irradiation has shown that the current increases, depending on the irradiation dose. The effect has been observed near T_c and at not too high intensities.

It should, however, be noted that the experiments have been carried out on so-called bridges, i.e., films with a constriction. In this case, apart from the mechanism described, there is another mechanism of stimulation of superconductivity (Aslamazov and Larkin 1978), which will not be described here.

8.5.8 19.6. Paraconductivity

In section 17.1 we have given an estimate of the fluctuational region near T_c. According to formulae (17.21) and (17.22), it proved to be extremely small. As has already been said, this is caused by a large correlation length. The estimate made was based on a fluctuational correction to the heat capacity of a bulk metal. However, relative fluctuations are always larger for systems of smaller dimensions, i.e., filaments and films having a thickness smaller than δ and ξ. Actually, in such specimens it is not convenient to determine the heat capacity and it is much simpler to measure the conductivity. As will be shown below, the fluctuational correction to the conductivity of thin films is found to be so high that it can be measured. The physical cause for extra conductivity lies in the possibility of fluctuational creation of Cooper pairs, which produces an additional "channel" for current. This effect has become known as paraconductivity (Aslamazov and Larkin 1968).

In order to find the value of paraconductivity, a time-dependent generalization of the Ginzburg-Landau equations is required. This is associated with the fact that the electric field can be defined as $\boldsymbol{E} = -\boldsymbol{c}^{-1}\partial\boldsymbol{A}/\partial t$, where $\boldsymbol{A}$ is the vector potential; but in this case, $\boldsymbol{A}$ has to be regarded as being dependent on time. It may also be assumed that $\boldsymbol{E} = -\Delta\varphi$ and $\boldsymbol{A} = 0$, but, as will be shown below, the scalar potential φ is contained in the equation for Ψ in combination with $\partial\Psi/\partial t$. In other words, the electric field in superconductors leads necessarily to nonstationary phenomena. The London equation $\partial(\Lambda\boldsymbol{j})/\partial t = \boldsymbol{E}$ also corresponds to this.

The general nonstationary BCS equations are very complicated, even in the limit of slow time and space variations of the field and order parameter. It is for this reason that we shall not give their derivation here; instead, we write the model equation for the vicinity of T_c, which in general correctly reflects the qualitative aspects of the behavior of the order parameter and in some cases is exact.

If a departure from equilibrium is assumed, then $\delta\int\Omega_{\mathrm{s}}\mathrm{d}V/\delta\Psi^*$ is no longer equal to zero (in ch. 17 we derived the Ginzburg-Landau equation for Ψ on the condition that this variational derivative be zero). At the same time, in the absence
of equilibrium Ψ begins to depend on time. At small deviations from equilibrium it is natural to assume that $\partial\Psi/\partial t$ is proportional to $\delta\int\Omega_{\mathrm{s}}\mathrm{d}V/\delta\Psi^*$.

However, gauge invariance requires that $\partial\Psi/\partial t$ should be included in the equation in the following combination:

$$\frac{\partial\Psi}{\partial t} + 2\mathrm{i}\frac{e}{\hbar}\varphi\Psi,$$

where φ is the scalar potential of the electric field. The complete condition of gauge invariance requires, in fact, the invariance of the electric and magnetic fields:

$$E = -\frac{1}{c}\frac{\partial A}{\partial t} - \nabla\varphi, \quad H = \operatorname{rot} A$$

upon variation of the potentials $A \to A + \nabla\eta$, and $\varphi \to \varphi - c^{-1}\partial\eta/\partial t$, where η is a scalar. It is not difficult to see that in a case where $\boldsymbol{A}$ is included in the equation in the combination $[-\mathrm{i}\hbar\nabla - (2e/c)A]\Psi$ and φ in the combination $[\partial/\partial t + 2\mathrm{i}(e/\hbar)\varphi]\Psi$, the guage transformation is compensated by the variation of the phase of the function Ψ. Thus, we have

$$-\gamma\left(\frac{\partial\Psi}{\partial t} + 2\mathrm{i}\frac{e}{\hbar}\varphi\Psi\right) = \frac{\delta\int\Omega_{\mathrm{s}}\,\mathrm{d}V}{\sigma\Psi^*}. \tag{19.47}$$

The microscopic derivation shows that in the paraconductivity problem eq. (19.47) gives an exact answer if the correct choice of the constant γ is made.

The constant γ can be determined from the following considerations. On the right-hand side of eq. (19.47) there is a term $-(\hbar^2/4m)\,\Delta\Psi$. On the whole this equation resembles the diffusion equation (see section 3.5):

$$\frac{\partial n}{\partial t} = D\Delta n.$$

The role of the diffusion coefficient D is played by $\hbar^2/(4m\gamma)$. On the other hand, in the presence of impurities the Ginzburg-Landau equation may be written in the form (17.6″). It is easy to see that in this equation the coefficient $\pi D\hbar/8T_{\mathrm{c}}$ plays the same role as the coefficient $\hbar^2/4m\alpha$ in a pure superconductor. Writing

$$\frac{\hbar^2}{4m} = \frac{\pi D\hbar\alpha}{8T_c} = D\gamma$$

we have

$$\gamma = \frac{\pi\hbar\alpha}{8T_{\rm c}}. \tag{19.48}$$

This value coincides with the value obtained in the BCS microscopic theory.
We are interested in the fluctuational correction to Ψ that arises under the action of a constant electric field. It is assumed to be small and therefore to first order the
correction we look for will be proportional to $\boldsymbol{E}$. But since $\boldsymbol{E}$ does not depend on time, the same will also refer to the correction to Ψ. In view of this, the derivative $\partial\Psi/\partial t$ may be omitted from (19.47). Assuming Ψ to be small, we retain the terms linear in Ψ. Substituting the Ginzburg-Landau functional into (19.47) yields

$$2\gamma \mathrm{i}\frac{e}{\hbar}\varphi\Psi + \alpha\tau\Psi - \frac{\hbar^2}{4m}\Delta\Psi = 0 \tag{19.49}$$

We have chosen the gauge at which $\boldsymbol{A} = 0$ and $\boldsymbol{E} = -\nabla\varphi$. Since $\boldsymbol{E}$ is homogeneous, it follows that $\varphi = -Er$. Recall that $\tau = (T - T_{\rm c})\,T_{\rm c}$.

In the absence of an electric field Ψ undergoes equilibrium fluctuations. The probability of fluctuations is proportional to (see Appendix II)

$$\begin{aligned} W &\propto \exp\left(-\frac{1}{T}\int \Omega_{\rm s}\ \mathrm{d}V\right) \\ &\propto \exp\left[-\frac{1}{T}\sum_p \left(\alpha\tau + p^2/4m\right)|\Psi_p|^2\right] \end{aligned} \tag{19.50}$$

where $\Psi_p = \int \Psi(r)\mathrm{e}^{-\mathrm{i}pr/\hbar}\mathrm{d}V$. Hence, the average equilibrium fluctuation $\left|\Psi_p^{(0)}\right|^2$ is given by

$$\begin{aligned} \left\langle\left|\Psi_p^{(0)}\right|^2\right\rangle &= \frac{\int |\Psi_p|^2 \exp\left[-\frac{1}{T}\left(\alpha\tau + \frac{p^2}{4m}\right)|\Psi_p|^2\right] \mathrm{d}\,|\Psi_p|^2}{\int \exp\left[-\frac{1}{T}\left(\alpha\tau + \frac{p^2}{4m}\right)|\Psi_p|^2\right] \mathrm{d}\,|\Psi_p|^2} \\ &= \frac{T}{\alpha\tau + p^2/4m} \end{aligned} \tag{19.51}$$

where $\langle\cdots\rangle$ signifies the statistical average.
In the presence of a weak electric field we have $\Psi_p = \Psi_p^{(0)} + \Psi_p^{(1)}$. Since the momentum representation of the quantity $\boldsymbol{r}\boldsymbol{\Psi}(\boldsymbol{r})$ is $\mathrm{i}\hbar(\partial/\partial\boldsymbol{p})\Psi_p$, we obtain in the first approximation in E :

$$2\gamma eE\frac{\partial\Psi_p^{(0)}}{\partial p} + \left(\alpha\tau + \frac{p^2}{4m}\right)\Psi_p^{(1)} = 0$$

from which it follows that

$$\Psi_p^{(1)} = -2\frac{\gamma e}{\alpha\tau + p^2/4m}E\frac{\partial\Psi(0)}{\partial p} \tag{19.52}$$

The average electric current in the Ginzburg-Landau theory is

$$\begin{aligned} j &= -\mathrm{i}\frac{e\hbar}{2m}\left\langle\Psi^*\nabla\Psi - \Psi\nabla\Psi^*\right\rangle \\ &= \sum_p \frac{ep}{m}\left\langle|\Psi_p\right|^2\right\rangle \end{aligned} \tag{19.53}$$

If we substitute $\left\langle \left|\Psi_p^{(0)}\right|^2 \right\rangle$ into this formula in accoradance with (19.51), we obtain zero. In the next approximation we have

$$\begin{aligned} j &= \sum_p \frac{ep}{m} \left\langle \Psi_p^{(0)} \Psi_p^{(1)*} + \Psi_p^{(1)} \Psi_p^{(0)*} \right\rangle \\ &= -2\frac{\gamma e^2}{m} \sum_p \frac{p}{\alpha\tau + p^2/4m} \left\langle E \frac{\partial \Psi_p^{(0)*}}{\partial p} \Psi_p^{(0)} + E \frac{\partial \Psi_p^{(0)}}{\partial p} \Psi_p^{(0)*} \right\rangle \\ &= -2\frac{\gamma e^2}{m} \sum_p \frac{p}{\alpha\tau + p^2/4m} \left(E \frac{\partial}{\partial p} \right) \left\langle \left|\Psi_p^{(0)}\right|^2 \right\rangle . \end{aligned}$$

Substituting eq. (19.51) into the last formula, we find

$$j = \frac{T\gamma e^2}{m^2} \sum_p p \frac{(pE)}{(\alpha\tau + p^2/4m)^3}. \tag{19.54}$$

The change from summation to integration is carried out according to the following rules*:

$$\sum_p \to \begin{cases} \int \frac{\mathrm{d}^3 p}{(2\pi\hbar)^3} & \text{three-dimensional case ,} \\ \frac{1}{d} \int \frac{\mathrm{d}^2 p}{(2\pi\hbar)^2} & \text{thin film, thickness } d < \frac{\hbar}{(4m\alpha\tau)^{1/2}} \sim \xi, \\ \frac{1}{S} \int \frac{\mathrm{d}p}{2\pi\hbar} & \text{thin wire, cross section } S < \xi^2. \end{cases}$$

*These rules are established as follows. We have the sum over the momenta, which converges at $p^2 \sim (\hbar/\xi)^2$. In a specimen with dimensions L_1, L_2 and L_3 the components of the momentum take on the values

$$p_x = 2\pi \frac{\hbar n_x}{L_1}, \quad p_y = 2\pi \frac{h n_y}{L_2}, \quad p_z = 2\pi \frac{\hbar n_z}{L_3},$$

where n_x, n_y and n_z are integers. If one of the dimensions (say $L_z = d$) is found to be smaller than ξ, then in the sum over the corresponding n a substantial contribution comes only from $n_z = 0$. Therefore, the sum over momenta, divided by the volume, assumes the form

$$\frac{1}{V} \sum_p \to \frac{1}{dL_1 L_2} \int \mathrm{d}^2 p \frac{L_1 L_2}{(2\pi\hbar)^2}$$

We have an analogous situation with a wire. This must be taken into account because we do not explicitly write out the normalization volume, assuming it to be unity in the ordinary three-dimensional case.

If we substitute $\left\langle \left|\Psi_p^{(0)}\right|^2 \right\rangle$ into this formula in accoradance with (19.51), we obtain zero. In the next approximation we have

$$\begin{aligned} j &= \sum_p \frac{ep}{m} \left\langle \Psi_p^{(0)} \Psi_p^{(1)*} + \Psi_p^{(1)} \Psi_p^{(0)*} \right\rangle \\ &= -2\frac{\gamma e^2}{m} \sum_p \frac{p}{\alpha\tau + p^2/4m} \left\langle E \frac{\partial \Psi_p^{(0)*}}{\partial p} \Psi_p^{(0)} + E \frac{\partial \Psi_p^{(0)}}{\partial p} \Psi_p^{(0)*} \right\rangle \\ &= -2\frac{\gamma e^2}{m} \sum_p \frac{p}{\alpha\tau + p^2/4m} \left(E \frac{\partial}{\partial p} \right) \left\langle \left|\Psi_p^{(0)}\right|^2 \right\rangle . \end{aligned}$$

Substituting eq. (19.51) into the last formula, we find

$$j = \frac{T\gamma e^2}{m^2} \sum_p p \frac{(pE)}{(\alpha\tau + p^2/4m)^3} \tag{19.54}$$

The change from summation to integration is carried out according to the following rules*:

$$\sum_p \to \begin{cases} \int \frac{d^3p}{(2\pi\hbar)^3} & \text{three-dimensional case,} \\ \frac{1}{d}\int \frac{d^2p}{(2\pi\hbar)^2} & \text{thin film, thickness } d < \frac{\hbar}{(4m\alpha\tau)^{1/2}} \sim \xi \\ \frac{1}{S}\int \frac{dp}{2\pi\hbar} & \text{thin wire, cross section } S < \xi^2 \end{cases}$$

*These rules are established as follows. We have the sum over the momenta, which converges at $p^2 \sim (\hbar/\xi)^2$. In a specimen with dimensions L_1, L_2 and L_3 the components of the momentum take on the values

$$p_x = 2\pi\frac{\hbar n_x}{L_1}, \quad p_y = 2\pi\frac{hn_y}{L_2}, \quad p_z = 2\pi\frac{\hbar n_z}{L_3}$$

where n_x, n_y and n_z are integers. If one of the dimensions (say $L_z = d$) is found to be smaller than ξ, then in the sum over the corresponding n a substantial contribution comes only from $n_2 = 0$. Therefore, the sum over momenta, divided by the volume, assumes the form

$$\frac{1}{V}\sum_p \to \frac{1}{dL_1L_2}\int \mathrm{d}^2p \frac{L_1L_2}{(2\pi\hbar)^2}$$

We have an analogous situation with a wire. This must be taken into account because we do not explicitly write out the normalization volume, assuming it to be unity in the ordinary three-dimensional case.

Taking the integrals in (19.54) for all three cases and substituting γ according to (19.48), we obtain the values of paraconductivity:

$$\sigma' = \begin{cases} \frac{1}{8\pi}\left(\frac{e}{\hbar}\right)^2\left(\frac{\alpha m}{\tau}\right)^{1/2} & \text{three-dimensional case ,} \\ \frac{1}{16}\frac{e^2}{\hbar\ \mathrm{d}\tau} & \text{film, thickness } d < \xi, \\ \frac{\pi}{32}\frac{e^2}{\alpha^{1/2}\tau^{3/2}Sm^{1/2}} & \text{wire, cross section } S < \xi^2. \end{cases} \tag{19.55}$$

We can substitute here the formulae for α in accordance with eq. (17.14) for a pure superconductor ($\xi_0 < l$) and eq. (17.18) for an alloy ($\xi_0 > l$). To order of magnitude we have: $\sigma' \sim (e^2/\xi_0\hbar)\,\tau^{-1/2}$ for the three-dimensional case, $\sigma' \sim (e^2/d\hbar)\,\tau^{-1}$ for the two-dimensional case, and $(e^2\xi_0/S\hbar)\,\tau^{-3/2}$ for the onedimensional case.

The two-dimensional case is the most interesting since formula (19.55) for this case contains no characteristics of the film, except its thickness and T_c. Moreover, as has already been pointed out, the fluctuations in a film are stronger than in a three-dimensional specimen; this is also seen from formulae (19.55). Finally, such a film is easy to prepare. Experimental data (Glover 1967) have completely confirmed the formula (19.55) for this case.

Formulae (19.55) turn to infinity as $T \to T_c$, which is evidence that they are not valid in the immediate vicinity of T_c. The range of validity is set up by the requirement that the fluctuational correction be much less than the normal conductivity $\sigma = n_e e^2\tau_{tr}/m$.

Another source of error is the neglect of the interaction of electrons with fluctuating Cooper pairs. This effect also enhances the conductivity, but it cannot be interpreted so simply as in the above-described paraconductivity of fluctuational Cooper pairs. The corresponding "anomalous Maki-Thompson conductivity" (Maki 1968, Thompson 1970) proves to be small in many cases*, in particular under experimental conditions (Glover 1967), which makes it possible to obtain a confirmation of formulae (19.55).

Taking the integrals in (19.54) for all three cases and substituting γ according to (19.48), we obtain the values of paraconductivity:

$$\sigma' = \begin{cases} \frac{1}{8\pi}\left(\frac{e}{\hbar}\right)^2\left(\frac{\alpha m}{\tau}\right)^{1/2} & \text{three-dimensional case,} \\ \frac{1}{16}\frac{e^2}{\hbar\ \mathrm{d}\tau} & \text{film, thickness } d < \xi, \\ \frac{\pi}{32}\frac{e^2}{\alpha^{1/2}\tau^{3/2}Sm^{1/2}} & \text{wire, cross section } S < \xi^2. \end{cases} \tag{19.55}$$

We can substitute here the formulae for α in accordance with eq. (17.14) for a pure superconductor ($\xi_0 < l$) and eq. (17.18) for an alloy ($\xi_0 > l$). To order of magnitude we have: $\sigma' \sim (e^2/\xi_0\hbar)\,\tau^{-1/2}$ for the three-dimensional case, $\sigma' \sim (e^2/d\hbar)\,\tau^{-1}$ for the two-dimensional case, and $(e^2\xi_0/S\hbar)\,\tau^{-3/2}$ for the onedimensional case.

8.6 20 The interface between a superconductor and a normal metal

8.6.1 20.1. The proximity effect

The superconducting correlation manifests itself not only in a superconductor but also at the interface between a superconductor and a normal metal. It is rather natural to guess that the normal metal has an effect on the superconductor, bringing about a decrease in Δ at a distance of order ξ. In particular, if the thickness of the superconductor is less than ξ, it ceases to be superconductive altogether. On the other hand, the superconductor must be expected to exert an effect on the normal metal. A thin film of a normal metal deposited onto a bulk superconductor must be superconducting. These phenomena have been detected experimentally (Meissner 1958, 1959) and have come to be known as proximity effects.

We shall consider the proximity effects using the Ginzburg-Landau equations. In order not to go beyond the framework of the Ginzburg-Landau theory, we deal with two models. In the first model we consider a superconductor at a temperature close to T_c, which has an interface with a normal metal that either does not become a superconductor at all or has a critical temperature far below T_c. The second model is the interface between two superconductors with close critical temperatures, T_{c1} and T_{c2}; it is assumed that $T_{c1} < T < T_{c2}$, i.e., one metal is in the superconducting state and the other in the normal state.

Let us consider the first model. We assume first that we have two bulk metals. In section 17.1 we obtained the boundary condition (17.7) on the surface of the superconductor, assuming the variation of $\delta\Psi$ at the interface to be arbitrary. This condition makes sense at the interface with a vacuum or a dielectric, since the influence of such an interface on electrons in the superconductor is extended over distances of the order of interatomic spacings. From the boundary condition (17.7), it follows, in particular, that the normal component of the supercurrent vanishes at the interface:

$$jn\big|_{\mathrm{b}} = 0. \tag{20.1}$$

Condition (20.1) must also be fulfilled at the interface with a normal metal, because no nondissipative current can flow in a normal metal. However, the mutual effect of the electrons of the two metals can be extended much farther than the
interatomic distances. In view of this we apply, instead of eq. (17.7), a different boundary condition:

$$n\left[\nabla - \frac{2\mathrm{i}e}{c\hbar}A\right]\Psi\Big|_{\mathrm{b}} = \frac{1}{t}\Psi\Big|_{\mathrm{b}}. \tag{20.2}$$

- The Maki-Thompson conductivity disappears if, for example, the superconductor contains magnetic impurities.

This condition is also consistent with (20.1). The coefficient t must be of the order of ξ, but its exact value can be determined only with the aid of the BCS theory. The result proves to be (Zaitsev 1965):

$$t = \begin{cases} 0.6\xi_{0\mathrm{n}} & \text{pure superconductor,} \\ 0.3\,(\xi_{0\mathrm{n}} l)^{1/2} & \text{superconductor with } \xi_0 > l, \end{cases} \tag{20.2'}$$

where $\xi_{0\mathrm{n}} = (\gamma/\pi^2)\,(\hbar v_n/T_\mathrm{c}) = 0.18\hbar v_\mathrm{n}/T_\mathrm{c}$ (formula 16.82) and v_n is the Fermi velocity in a normal metal.

Consider a planar interface. In this case, the boundary condition (20.2) assumes the following form:

$$\left.\frac{\mathrm{d}\Psi}{\mathrm{d}x}\right|_{x=0} = \frac{1}{t}\Psi(0). \tag{20.3}$$

Instead of the Ginzburg-Landau equation for Ψ we may take its integral (17.27), which in the absence of a magnetic field ($A = 0$) is given by

$$\xi^2\left(\frac{\mathrm{d}\Psi}{\mathrm{d}x}\right)^2 + \Psi^2 - \frac{\mathrm{t}}{2}\Psi^4 = \frac{1}{2} \tag{20.4}$$

[here we have expressed Ψ in units of $\Psi_0 = (\alpha|\tau|/b)^{1/2}$ and introduced the notation $\xi^2 = \hbar^2/(4m\alpha|\tau|)$]; the constant on the right-hand side is determined from the condition that in the bulk of the superconductor $\Psi = 1,\ \mathrm{d}\Psi/\mathrm{d}x = 0$.

Equation (20.4) has been solved in section 17.2 in calculations of the surface energy at the interface between a superconductor and a normal metal. The solution has the form

$$\Psi = \tanh\left(\frac{x - x_0}{\sqrt{2}\xi}\right). \tag{20.5}$$

The value of x_0 is determined from the boundary condition (20.3). This gives

$$\sinh\left(\frac{x_0\sqrt{2}}{\xi}\right) = -\frac{2t}{\xi}. \tag{20.6}$$

According to eq. (20.5), the characteristic scale of variation of Ψ is the length $\xi(T)$, which increases upon approach to T_c as $(T_\mathrm{c} - T)^{-1/2}$. At the same time, the quantity t does not depend on temperature. According to formulae (17.14) and (17.18) for α and formulae (20.2') for t, the ratio t/ξ is of order $\tau^{1/2}$ in all cases. In accordance with eq. (20.6), this means that upon approach to T_c, the relation x_0/ξ falls off. This implies that the value of the function Ψ at the interface decreases with increasing ξ. It should be noted that the Ginzburg-Landau theory can actually
be applied only to a case where all the quantities involved vary over distances much larger than ξ_0 or $(\xi_0 l)^{1/2}$, i.e., we necessarily have $\xi > t$ and $x_0 \approx 0$ (the Fermi velocities are all of the same order of magnitude in all good metals, which is why $\xi_{0n} \sim \xi_{0s}$). This means that, strictly speaking, within the range of validity of the GinzburgLandau theory the boundary condition is $\Psi(0) = 0$ rather than (20.3).

Let us now consider the problem of a superconducting film deposited onto the surface of a bulk metal. The ordinary boundary condition $\mathrm{d}\Psi/\mathrm{d}x = 0$ is fulfilled at the interface with vacuum. It is not difficult to see that the thin-film problem is equivalent to the problem of a sandwich, i.e., a superconducting layer between two bulk layers of the same normal metal. Evidently, the function Ψ must be symmetrical, i.e., $\mathrm{d}\Psi/\mathrm{d}x = 0$ in the middle of the film. A deposited film of thickness d is thus equivalent to a sandwiched film of thickness $2d$.

We introduce a new variable, $u = x/(\xi\sqrt{2})$ and write the integral of the GinzburgLandau equation for Ψ. In a specimen of finite thickness we can no longer assume that the constant on the right-hand side of (20.4) is $\frac{1}{2}$. We designate it by $\frac{1}{2}(1-s^2)$. So, we obtain

$$\left(\frac{\mathrm{d}\Psi}{\mathrm{d}u}\right)^2 = \left(1-\Psi^2\right)^2 - s^2 \tag{20.7}$$

Let the interface with the metal lie at $x = 0$ and that with the vacuum at $x = d$. From the foregoing it is clear that near the interface with the metal Ψ is small and in moving away from it Ψ increases. On this basis we find from eq. (20.7) that

$$\frac{\mathrm{d}\Psi}{\mathrm{d}u} = \left[\left(1-\Psi^2\right)^2 - s^2\right]^{1/2} \tag{20.8}$$

$$\int_0^{\Psi} \frac{1}{(1-s-\Psi_1^2)^{1/2}} \frac{1}{(1+s-\Psi_1^2)^{1/2}}\, \mathrm{d}\Psi_1 = u \tag{20.9}$$

Here it is taken into account that $\Psi \approx 0$ at $u = 0$. At $u = d/(\xi\sqrt{2}), \mathrm{d}\Psi/\mathrm{d}u = 0$, i.e., according to eq. (20.8),

$$\Psi \frac{d}{\xi\sqrt{2}} = (1-s)^{1/2} \tag{20.10}$$

Substitution into eq. (20.9) gives

$$\int_0^{(1-s)^{1/2}} \frac{1}{(1-s-\Psi_1^2)^{1/2}} \frac{1}{(1+s-\Psi_1^2)^{1/2}}\, \mathrm{d}\Psi_1 = \frac{d}{\xi\sqrt{2}} \tag{20.11}$$

We make the replacement of the integration variable $\Psi_1 = (1-s)^{1/2}\sin\varphi$. The last formula then becomes

$$(1+s)^{-1/2} \int_0^{\frac{1}{2}\pi} \mathrm{d}\varphi \frac{1}{(1-k^2\sin\varphi)^{1/2}} = \frac{1}{(1+s)^{1/2}} K(k) = \frac{d}{\xi\sqrt{2}} \tag{20.12}$$

where $k^2 = (1-s)/(1+s)$ and $K(k)$ is the complete elliptic integral of the first kind. Let d be fixed. Upon approach to T_c the value of ξ increases, i.e., the right-hand side in eq. (20.12) decreases. The lowest value of the elliptic integral is obtained at $k = 0$, i.e., at $s = 1$, and is equal to $\frac{1}{2}\pi$. Hence, ξ cannot increase indefinitely and the permissible maximum value is

$$\xi_{\max} = \frac{2}{\pi} d \tag{20.13}$$

But this means that superconductivity cannot be preserved up to T_c. In other words, the critical temperature must decrease. In accord with the definition of $\boldsymbol{\xi}$ we obtain (Werthamer 1963):

$$\frac{T_\mathrm{c} - T_\mathrm{c}(d)}{T_\mathrm{c}} = \frac{1}{16}\pi^2 \frac{\hbar^2}{m\alpha} \frac{1}{\mathrm{d}^2}. \tag{20.14}$$

On the other hand, with $k \to 1$, i.e., $s \to 0$, the elliptic integral increases indefinitely, which corresponds to large values of d. Putting $s = 0$ in formula (20.9), we arrive at the dependence (20.5) with $x_0 = 0$.

Let us examine the behavior of Ψ near T_c. To do this, we assume that $1 - s = r < 1$. Then, $k^2 \approx \frac{1}{2}r < 1$ and $K(k) \approx \frac{1}{2}\pi\left(1 + \frac{1}{4}k^2\right) \approx \frac{1}{2}\pi\left(1 + \frac{1}{8}r\right)$. Hence, according to eq. (20.12),

$$r \approx \frac{16}{\pi}\left(\frac{d}{\xi} - \frac{d}{\xi_{\max}}\right)$$

From (20.9) we obtain in this case

$$\Psi \approx \sqrt{r}\sin(u\sqrt{2}) = \frac{4}{\sqrt{\pi}}\left(\frac{\mathrm{d}}{\xi} - \frac{\mathrm{d}}{\xi_{\max}}\right)^{1/2}\sin\left(\frac{x}{\xi_{\max}}\right). \tag{20.15}$$

This formula can naturally be applied only for $r < 1$. It enables one to assert that the transition to the normal state is still a second-order phase transition. If we express formula (20.15) in the form of a temperature dependence and assume that $T_{\mathrm{c}}(d) - T < T_{\mathrm{c}} - T_{\mathrm{c}}(d)$, the result will be

$$\Psi \approx 2\left(\frac{T_{\mathrm{c}}(d) - T}{T_{\mathrm{c}} - T_{\mathrm{c}}(\ \mathrm{d})}\right)^{1/2}\sin\left(\frac{\pi x}{2d}\right). \tag{20.16}$$

Although the derivation made is valid only for the neighborhood of T_{c}, we can draw a qualitative conclusion concerning what will occur at lower temperatures. Evidently, as $T \to 0, \xi \to \xi_0$ (or $(\xi_0 l)^{1/2}$ for a dirty superconductor). From eq. (20.13) (which may be written in the form $d_{\min} = \frac{1}{2}\pi\xi$) it follows that at thicknesses smaller than ξ_0 the superconductivity of the deposited film will be absent at any temperatures.

In order to trace out the behavior of a thin film of a normal metal on the surface of a bulk superconductor, one has to use the second of the models described at the beginning of this section. Suppose that two superconductors with slightly different
where $k^2 = (1-s)/(1+s)$ and $K(k)$ is the complete elliptic integral of the first kind. Let d be fixed. Upon approach to T_{c} the value of ξ increases, i.e., the right-hand side in eq. (20.12) decreases. The lowest value of the elliptic integral is obtained at $k = 0$, i.e., at $s = 1$, and is equal to $\frac{1}{2}\pi$. Hence, ξ cannot increase indefinitely and the permissible maximum value is

$$\xi_{\max} = \frac{2}{\pi}d \tag{20.13}$$

But this means that superconductivity cannot be preserved up to T_{c}. In other words, the critical temperature must decrease. In accord with the definition of $\boldsymbol{\xi}$ we obtain (Werthamer 1963):

$$\frac{T_{\mathrm{c}} - T_{\mathrm{c}}(d)}{T_{\mathrm{c}}} = \frac{1}{16}\pi^2\frac{\hbar^2}{m\alpha}\frac{1}{\mathrm{d}^2}. \tag{20.14}$$

On the other hand, with $k \to 1$, i.e., $s \to 0$, the elliptic integral increases indefinitely, which corresponds to large values of d. Putting $s = 0$ in formula (20.9), we arrive at the dependence (20.5) with $x_0 = 0$.

Let us examine the behavior of Ψ near T_c. To do this, we assume that $1 - s = r < 1$. Then, $k^2 \approx \frac{1}{2}r < 1$ and $K(k) \approx \frac{1}{2}\pi\left(1 + \frac{1}{4}k^2\right) \approx \frac{1}{2}\pi\left(1 + \frac{1}{8}r\right)$. Hence, according to eq. (20.12),

$$r \approx \frac{16}{\pi}\left(\frac{d}{\xi} - \frac{d}{\xi_{\max}}\right)$$

From (20.9) we obtain in this case

$$\Psi \approx \sqrt{r}\sin(u\sqrt{2}) = \frac{4}{\sqrt{\pi}}\left(\frac{\mathrm{d}}{\xi} - \frac{\mathrm{d}}{\xi_{\max}}\right)^{1/2}\sin\left(\frac{x}{\xi_{\max}}\right). \tag{20.15}$$

This formula can naturally be applied only for $r < 1$. It enables one to assert that the transition to the normal state is still a second-order phase transition. If we express formula

(20.15) in the form of a temperature dependence and assume that $T_c(d) - T < T_c - T_c(d)$, the result will be

$$\Psi \approx 2\left(\frac{T_{\mathrm{c}}(d) - T}{T_{\mathrm{c}} - T_{\mathrm{c}}(\ \mathrm{d})}\right)^{1/2} \sin\left(\frac{\pi x}{2d}\right) \tag{20.16}$$

Although the derivation made is valid only for the neighborhood of T_c, we can draw a qualitative conclusion concerning what will occur at lower temperatures. Evidently, as $T \to 0, \xi \to \xi_0$ (or $(\xi_0 l)^{1/2}$ for a dirty superconductor). From eq. (20.13) (which may be written in the form $d_{\min} = \frac{1}{2}\pi\xi$) it follows that at thicknesses smaller than ξ_0 the superconductivity of the deposited film will be absent at any temperatures.

In order to trace out the behavior of a thin film of a normal metal on the surface of a bulk superconductor, one has to use the second of the models described at the beginning of this section. Suppose that two superconductors with slightly different
critical temperatures ($T_{c2} - T_{c1} < T_{c1}$) are in contact with each other and let us assume that $T_{c1} < T < T_{c2}$. In such a case, metal (1) will be normal and metal (2) will be a superconductor. According to Zaitsev (1965), in the case of slightly different parameters of the metals, the boundary conditions reduce to the continuity of Ψ and $\mathrm{d}\Psi/\mathrm{d}x$:

$$\Psi_1(0) = \Psi_2(0), \quad \left.\frac{\mathrm{d}\Psi_1}{\mathrm{d}x}\right|_{x=0} = \left.\frac{\mathrm{d}\Psi_2}{\mathrm{d}x}\right|_{x=0}, \tag{20.17}$$

where the interface is assumed at $x = 0$.
First, just as in the first model, we assume that the two metals are bulk metals. Let the normal metal occupy the half-plane $x > 0$ and the superconductor the half-plane $x < 0$. Then, at $x < 0$ eq. (20.4) is satisfied. The solution of this equation is

$$\Psi_2 = \tanh\left[\frac{x_0 - x}{\sqrt{2}\xi_2}\right], \quad x < 0. \tag{20.18}$$

At $x > 0$ in the Ginzburg-Landau equation $\tau > 0$. Therefore, in passing to dimensionless variables the term with Ψ^2 in (20.4) will have a different sign. Moreover, the constant on the right-hand side will be equal to zero and not to $\frac{1}{2}$, since $\Psi \to 0$ and $\mathrm{d}\Psi/\mathrm{d}x \to 0$ as $x \to \infty$. Thus, we obtain

$$\xi_1^2\left(\frac{\mathrm{d}\Psi_1}{\mathrm{d}x}\right)^2 = \Psi_1^2 + \frac{1}{2}\Psi_1^4, \quad x > 0 \tag{20.19}$$

Suppose that $x_0 < \xi_2$ in formula (20.18). Then, $\Psi_2(0) < 1$ at $x = 0$ and, hence, according to (20.17) $\Psi_1(0)$ is also much less than unity, but since according to (20.19) Ψ_1 decreases monotonically as $x \to \infty$, it follows that everywhere $\Psi_1(x) < 1$. Solving eq. (20.19) under this assumption, we obtain

$$\Psi_1 = C\exp\left(-\frac{x}{\xi_1}\right).$$

From the boundary conditions (20.17) we find $C = x_0\left(\sqrt{2}\xi_2\right), x_0 \approx \xi_1$ and, hence,

$$\begin{aligned} \Psi_1 &= \tfrac{\xi_1}{\sqrt{2}}\xi_2 \exp\left(-\tfrac{x}{\xi_1}\right), \quad x > 0, \\ \Psi_2 &= \tanh\left(\tfrac{\xi_1 + |x|}{\sqrt{2}\xi_2}\right), \qquad x < 0. \end{aligned} \tag{20.20}$$

From formulae (20.19) it follows that Ψ falls off rapidly in the bulk of the normal metal but also that it decreases significantly in the superconductor near the interface.

Let us now assume that the normal plate has a finite thickness d, i.e., $\mathrm{d}\Psi/\mathrm{d}x = 0$ at $x = d$. In this case eq. (20.19) will contain an unknown constant and we write it in the form

$$2\xi_1^2 \left(\frac{\mathrm{d}\Psi_1}{\mathrm{d}x}\right)^2 = \left(1 + \Psi_1^2\right)^2 - s^2$$

critical temperatures ($T_{c2} - T_{c1} < T_{c1}$) are in contact with each other and let us assume that $T_{c1} < T < T_{c2}$. In such a case, metal (1) will be normal and metal (2) will be a superconductor. According to Zaitsev (1965), in the case of slightly different parameters of the metals, the boundary conditions reduce to the continuity of Ψ and $\mathrm{d}\Psi/\mathrm{d}x$:

$$\Psi_1(0) = \Psi_2(0), \quad \left.\frac{\mathrm{d}\Psi_1}{\mathrm{d}x}\right|_{x=0} = \left.\frac{\mathrm{d}\Psi_2}{\mathrm{d}x}\right|_{x=0}, \tag{20.17}$$

where the interface is assumed at $x = 0$.
First, just as in the first model, we assume that the two metals are bulk metals. Let the normal metal occupy the half-plane $x > 0$ and the superconductor the half-plane $x < 0$. Then, at $x < 0$ eq. (20.4) is satisfied. The solution of this equation is

$$\Psi_2 = \tanh\left[\frac{x_0 - x}{\sqrt{2}\xi_2}\right], \quad x < 0. \tag{20.18}$$

At $x > 0$ in the Ginzburg-Landau equation $\tau > 0$. Therefore, in passing to dimensionless variables the term with Ψ^2 in (20.4) will have a different sign. Moreover, the constant on the right-hand side will be equal to zero and not to $\frac{1}{2}$, since $\Psi \to 0$ and $\mathrm{d}\Psi/\mathrm{d}x \to 0$ as $x \to \infty$. Thus, we obtain

$$\xi_1^2 \left(\frac{\mathrm{d}\Psi_1}{\mathrm{d}x}\right)^2 = \Psi_1^2 + \frac{1}{2}\Psi_1^4, \quad x > 0 \tag{20.19}$$

Suppose that $x_0 < \xi_2$ in formula (20.18). Then, $\Psi_2(0) < 1$ at $x = 0$ and, hence, according to (20.17) $\Psi_1(0)$ is also much less than unity, but since according to (20.19) Ψ_1 decreases monotonically as $x \to \infty$, it follows that everywhere $\Psi_1(x) < 1$. Solving eq. (20.19) under this assumption, we obtain

$$\Psi_1 = C \exp\left(-\frac{x}{\xi_1}\right).$$

From the boundary conditions (20.17) we find $C = x_0\left(\sqrt{2}\xi_2\right), x_0 \approx \xi_1$ and, hence,

$$\begin{aligned} \Psi_1 &= \tfrac{\xi_1}{\sqrt{2}}\xi_2 \exp\left(-\tfrac{x}{\xi_1}\right), \quad x > 0, \\ \Psi_2 &= \tanh\left(\tfrac{\xi_1 + |x|}{\sqrt{2}\xi_2}\right), \qquad x < 0. \end{aligned} \tag{20.20}$$

From formulae (20.19) it follows that Ψ falls off rapidly in the bulk of the normal metal but also that it decreases significantly in the superconductor near the interface.

Let us now assume that the normal plate has a finite thickness d, i.e., $\mathrm{d}\Psi/\mathrm{d}x = 0$ at $x = d$. In this case eq. (20.19) will contain an unknown constant and we write it in the form

$$2\xi_1^2 \left(\frac{\mathrm{d}\Psi_1}{\mathrm{d}x}\right)^2 = \left(1 + \Psi_1^2\right)^2 - s^2$$

which leads to

$$\frac{\mathrm{d}\Psi_1}{\mathrm{d}x} = -\frac{1}{\sqrt{2}\xi_1}\left[\Psi_1^2 - (s-1)\right]^{1/2}\left[\Psi_1^2 + s + 1\right]^{1/2} \tag{20.21}$$

and

$$\int_{(s-1)^{1/2}}^{\Psi_1} \mathrm{d}\Psi_3 \frac{1}{\left[\Psi_3^2-(s-1)\right]^{1/2}} \frac{1}{\left(\Psi_3^2+s+1\right)^{1/2}} = \frac{d-x}{\sqrt{2}\xi_1} \tag{20.22}$$

(here we have already taken into account that $\mathrm{d}\Psi_1/\mathrm{d}x = 0$ at $x = d$, i.e., $\Psi_1 = (s-1)^{1/2}$).

Suppose, as before, that the condition (20.20) is satisfied. It is clear that as long as the thickness of the normal film is not too small we still have $x_0 < \xi_2$ in (20.18), i.e.,

$$\Psi_2(0) \approx \frac{x_0}{\sqrt{2}\xi_2}, \quad \left.\frac{\mathrm{d}\Psi_2}{\mathrm{d}x}\right|_{x=0} \approx -\frac{1}{\sqrt{2}\xi_2}.$$

From the boundary conditions (20.17) we determine s and x_0. Since $\Psi_1(0) = \Psi_2(0) < 1$, it follows that, as before, $\Psi_1(x) < 1$. Hence, in the second factor of the integrand in eq. (20.22) we may put $\Psi_3 \approx 0$. The integral is then taken and we obtain

$$\operatorname{arccosh}\left(\frac{\Psi_1}{(s-1)^{1/2}}\right) = \frac{d-x}{\xi_1}. \tag{20.23}$$

It is obvious that s is close to unity. This has been taken into account in eq. (20.23). Substituting $\Psi_1(0)$ and $x = 0$, we have

$$\operatorname{arccosh}\left(\frac{x_0}{\sqrt{2}\xi_2(s-1)^{1/2}}\right) = \frac{d}{\xi_1}. \tag{20.24}$$

Taking into account that Ψ_1^2 is small and that s is close to unity, we obtain from the equality of the derivatives at $x = 0$ and formula (20.21)

$$\left[\left(\frac{x_0}{\sqrt{2}\xi_2}\right)^2-(s-1)\right]^{1/2} = \frac{\xi_1}{\sqrt{2}\xi_2}. \tag{20.25}$$

First, let $d \gg \xi_1$. Then, according to eq. (20.24), $x_0/\xi_2 \gg (s-1)^{1/2}$. From eq. (20.25) we obtain $x_0 = \xi_1$. Substituting into eq. (20.24), we find $(s-1)^{1/2} = \left(\sqrt{2}\xi_1/\xi_2\right)\exp\left(-d/\xi_1\right)$. Substitution into eq. (20.23) yields

$$\Psi_1 = \frac{\xi_1}{\sqrt{2}\xi_2}\left[\exp\left(-\frac{x}{\xi_1}\right)+\exp\left(\frac{x-2d}{\xi_1}\right)\right]. \tag{20.26}$$

But if $d < \xi_1$, then the argument of arccosh in (20.24) must be close to unity. Expanding in d/ξ_1, we obtain

$$(s-1)^{1/2} = \left(\frac{x_0}{\sqrt{2}\xi_2}\right)\left(1-\frac{d^2}{2\xi_1^2}\right).$$

We insert this expression into eq. (20.25) and find

$$x_0 = \frac{\xi_1^2}{d}$$

Finally, from eq. (20.23) we obtain Ψ_1 :

$$\Psi_1 = \frac{\xi_1^2}{\sqrt{2}\xi_2 d}\left(1-\frac{dx}{\xi_1^2}-\frac{x^2}{2\xi_1^2}\right) \tag{20.27}$$

In order that the condition $x_0 < \xi_2$ be satisfied, it is necessary that

$$\xi_1 > d > \frac{\xi_1^2}{\xi_2}. \tag{20.28}$$

Thus, it turns out that even with the thickness of the normal film being smaller than ξ_1 the function Ψ_1 in it will still be small. Only at still smaller thicknesses does Ψ_1 begin to approach unity. Under the assumption $x_0 > \xi_2$, which corresponds to $d < \xi_1^2/\xi_2$, we obtain, just as in the preceding case,

$$\Psi_1 = 1 - \sqrt{2}\frac{d\xi_2}{\xi_1^2} - \frac{2dx}{\xi_1^2} + \frac{x^2}{\xi_1^2} \tag{20.29}$$

Within the framework of the Ginzburg-Landau theory we cannot consider the behavior of a normal film with the critical temperature being much lower than in a superconductor or in a nonsuperconducting film. However, from the foregoing it is sufficiently clear that due to the proximity effect it will be superconductive if its thickness is sufficiently small, and that with a large thickness it will remain normal.

8.6.2 20.2. Superconductivity of twinning planes

As was already mentioned in section 16.11, in several metals an increase of T_c at twinning planes of crystals has been reported (Khaikin and Khlyustikov 1981; see also Khlyustikov and Buzdin 1987). When a "bicrystal" was prepared, i.e., two single crystals of different orientation were grown approaching each other, a contact plane appeared. In the general case of arbitrary relative orientation such a boundary behaves by no means extraordinarily. However, if the relative orientation is especially chosen so that the boundary is a crystallographic plane (a plane filled by crystalline atoms) for both crystals then they are called "twins". The appearance of such a plane means a new symmetry element which was absent in the crystallographic group (see e.g. fig. 128).

It appeared that, in the vicinity of the twinning boundary thus created in tin, niobium, rhenium and thallium, superconductivity prevails up to a temperature slightly higher than T_{c0} - the critical temperature of the sample without such a boundary. For tin this increase was 0.04 K ($T_{c0} = 3.7$ K), for niobium it was 0.11 K

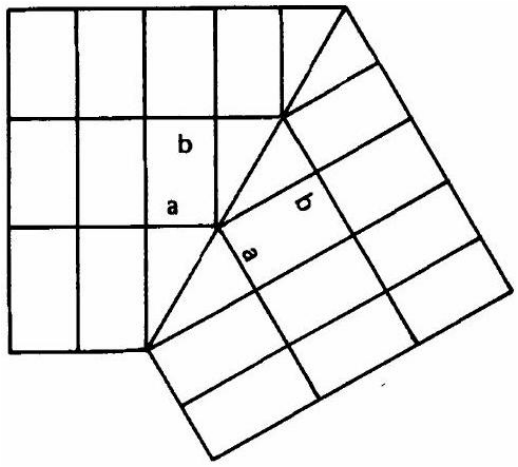

Fig. 128.

($T_{c0} = 9.3$ K). Of course this increase is not large. However, it should be kept in mind that the superconducting region is surrounded by the normal metal, which suppresses

its superconductivity due to the proximity effect. To reduce this effect, samples were prepared consisting of small particles with sizes less than ξ or pellets of powders consisting of small particles, which were pressed so that one could expect twin boundaries with a small spacing. In such a way it was possible to detect signs of superconductivity (diamagnetism) in tin up to 12 K , i.e. to a temperature exceeding $T_{\rm co}$ by more than a factor of 3 .

The properties of twinning planes became of special interest recently because they appear spontaneously in the high-temperature superconductor $YBa_2Cu_3O_{7-\delta}$. The reason is that such samples must be prepared at high temperature, over 900°C. This is necessary either for sintering of the ceramic or for growing single crystals. When the temperature is lowered a phase transition takes place (at $\sim$ 750°C) from a tetragonal to an orthorhombic phase: $a = 3.823\mathring{\rm A}, b = 3.884\mathring{\rm A}, c = 11.674\mathring{\rm A}$. An abrupt reduction of the volume takes place and the crystal is split into flat domains with different orientation of the a and b axes. The domains are separated by twin boundaries parallel to the c-axis and dividing the basal rectangular face along the diagonal (see fig. 128)*. The spacing between these boundaries depends on the preparation method and varies between 500 and 1500Å. Since the correlation length in this substance is small (in the basal plane $\xi_0 \approx 16\mathring{\rm A}$), one can practically assume these planes to be isolated. As will be shown below the spontaneous appearance of twinning planes leads to several interesting phenomena near $T_{\rm c0}$.

The increase of $T_{\rm c}$ in the vicinity of the twin boundary can be explained in various ways. First of all special types of lattice vibrations may exist which are connected particularly with the twinning planes, similar to the Rayleigh waves at the surface. The exchange by these phonons can enhance the electron attraction. Secondly a weakening of Coulomb repulsion close to the boundary is possible. Finally special electronic states are possible in which the electrons move freely along the boundary

but cannot leave it due to the rapid damping of the wave function. Such states are called Tamm states. Superconductivity can be associated with such electrons. If the boundary is not a twinning plane then it contains a large concentration of dislocations or other defects which can destroy the singular electronic or phonon states. This can explain why T_c does not increase at an arbitrary boundary.

In what follows we shall assume that the reason of the increase of $T_{\rm c}$ is the local increase of interaction between electrons due either to new types of phonons or to the reduction of Coulomb repulsion. Let us assume that the dimensionless constant of Cooper pairing entering eq. (16.23) for $\Delta, \lambda = \frac{1}{2}g\nu$, has a sharp peak near the twinning plane: $\lambda = \lambda_0 + \delta\lambda(x)$, where x is directed along the normal to the boundary plane. Let us denote the relative increase of the critical temperature by τ_0 :

$$\tau_0 = \frac{T_{\rm c} - T_{\rm c0}}{T_{\rm c0}}. \tag{20.30}$$

This quantity can be estimated from the following argument. In the vicinity of the boundary local superconductivity appears in a layer of the order of $\xi_{\rm c} \approx \xi_0 \tau_0^{-1/2}$, where ξ_0 is defined by formula (16.82). If the peak of λ has a width d ($d < \xi_0 < \xi_c$; actually, d should be of the order of interatomic distances) then due to the proximity effect the effective increase of λ will be of the order of $\delta\lambda d/\xi_{\rm c}$. But since T_c is proportional to $\exp(-1/\lambda)$ we get the estimate

$$\frac{\delta T_{\rm c}}{T_{\rm c}} = \tau_0 \approx \frac{\delta\lambda}{\lambda_0^2}\frac{d}{\xi_{\rm c}}.$$

- Recently it has become clear that domain boundaries in YBaCuO can be of several kinds, and that some of these suppress superconductivity. Here we consider only true twinning planes.

Substituting ξ_c we get

$$\tau_0 \sim \left(\frac{\delta\lambda}{\lambda_0^2}\frac{d}{\xi_0}\right)^2. \tag{20.31}$$

Now we consider this question in greater detail. The order parameter for a uniform superconductor was obtained from eq. (16.21). Particularly, at $\Delta \to 0$ the expression for T_c was derived. In the inhomogeneous case, assuming g to depend on x, one can obtain a generalisation of (16.21) for the nonuniform case (limit $\Delta \to 0$):

$$\begin{aligned}\Delta(x) &= \int \lambda(x) K\left(r-r'\right)\Delta\left(x'\right)\mathrm{d}V' \\ &= \lambda_0 \int K\left(r-r'\right)\Delta\left(x'\right)\mathrm{d}V' + \int \delta\lambda(x) K\left(r-r'\right)\Delta\left(x'\right)\mathrm{d}V'\end{aligned} \tag{20.32}$$

Here we suppose that $\lambda = \lambda_0 + \delta\lambda(x)$ where $\delta\lambda(x)$ is finite in an interval of the order of d. Since the kernel $K\left(r-r'\right)$ varies on a scale of order of ξ_0 (see section 16.9) and $\Delta(x)$ varies on a scale ξ_c, both of these distances being much larger than d, it is possible to substitute in the second term of (20.32) x' entering $K\left(r-r'\right)\Delta\left(x'\right)$ by
zero. Denoting

$$\Lambda = \int \delta\lambda(x)\mathrm{d}x \sim \delta\lambda d$$

one arrives at

$$\Delta(x) = \lambda_0 \int K\left(x-x',\rho\right)\Delta\left(x'\right)\mathrm{d}x'\mathrm{d}\rho + \Lambda\Delta(0)\int K(x,\rho)\mathrm{d}\rho \tag{20.33}$$

We have now separated the dependences on x and on $\rho = y, z$.
To solve eq. (20.33) we pass to the Fourier transform,

$$\Delta(p) = \lambda_0 K\left(p, q_\perp = 0\right)\Delta(p) + \Lambda\Delta(x=0)K\left(p, q_\perp = 0\right).$$

The solution is

$$\Delta(p) = \frac{\Lambda\Delta(x=0)K(p,0)}{1-\lambda_0 K(p,0)}. \tag{20.34}$$

Here p is the momentum along x and $q_\perp$ is the momentum in the transverse direction. Taking into account that

$$\Delta(x=0) = \int \Delta(p)\frac{\mathrm{d}p}{2\pi}$$

we get the self-consistency relation, defining the critical temperature,

$$1 = \Lambda \int \frac{K(p)}{1-\lambda_0 K(p)}\frac{\mathrm{d}p}{2\pi}. \tag{20.35}$$

It is easy to see that the critical temperature for a bulk superconductor is obtained from the condition

$$1 - \lambda_0 K\left(T_{co}, p=0\right) = 0. \tag{20.36}$$

We transform the denominator of formula (20.35) accordingly:

$$1-\lambda_0 K\left(T_{\mathrm{c}}, p\right)=\lambda_0\left[K\left(T_{\mathrm{c} 0}, 0\right)-K\left(T_{\mathrm{c}}, 0\right)\right]+\lambda_0\left[K\left(T_{\mathrm{c}}, 0\right)-K\left(T_{\mathrm{c}}, p\right)\right]$$
$$=\lambda_0\left[\ln\left(\frac{T_{\mathrm{c}}}{T_{\mathrm{c} 0}}\right)+\frac{7\zeta(3)}{48\pi^2}\left(\frac{vp}{T_{\mathrm{c}}}\right)^2\right]. \tag{20.37}$$

In the last formula the first term corresponds to the first bracket and it is obtained just as in the derivation of formula (16.25) for T_{c}. In order to find the second term, it is necessary to know K for a finite p, which corresponds to a moving Bosecondensate of Conper pairs. The corresponding derivation is done in section 21.2 and the expression for $K(p)$ corresponds to the rignt-nand side of formula (21.24), divided by $\lambda_0=\frac{1}{2}g\nu$, with $I=0$ and $|q|=p$. Expanding in powers of p, we get the
zero. Denoting

$$\Lambda=\int\delta\lambda(x)\mathrm{d}x\sim\delta\lambda d$$

one arrives at

$$\Delta(x)=\lambda_0\int K\left(x-x',\rho\right)\Delta\left(x'\right)\mathrm{d}x'\mathrm{d}\rho+\Lambda\Delta(0)\int K(x,\rho)\mathrm{d}\rho \tag{20.33}$$

We have now separated the dependences on x and on $\rho=y,z$.
To solve eq. (20.33) we pass to the Fourier transform,

$$\Delta(p)=\lambda_0 K\left(p,q_\perp=0\right)\Delta(p)+\Lambda\Delta(x=0)K\left(p,q_\perp=0\right).$$

The solution is

$$\Delta(p)=\frac{\Lambda\Delta(x=0)K(p,0)}{1-\lambda_0 K(p,0)} \tag{20.34}$$

Here p is the momentum along x and $q_\perp$ is the momentum in the transverse direction. Taking into account that

$$\Delta(x=0)=\int\Delta(p)\frac{\mathrm{d}p}{2\pi}$$

we get the self-consistency relation, defining the critical temperature,

$$1=\Lambda\int\frac{K(p)}{1-\lambda_0 K(p)}\frac{\mathrm{d}p}{2\pi} \tag{20.35}$$

It is easy to see that the critical temperature for a bulk superconductor is obtained from the condition

$$1-\lambda_0 K\left(T_{c0},p=0\right)=0 \tag{20.36}$$

We transform the denominator of formula (20.35) accordingly:

$$1-\lambda_0 K\left(T_c,p\right)=\lambda_0\left[K\left(T_{c0},0\right)-K\left(T_c,0\right)\right]+\lambda_0\left[K\left(T_c,0\right)-K\left(T_c,p\right)\right]$$
$$=\lambda_0\left[\ln\left(\frac{T_c}{T_{c0}}\right)+\frac{7\zeta(3)}{48\pi^2}\left(\frac{vp}{T_c}\right)^2\right]. \tag{20.37}$$

In the last formula the first term corresponds to the first bracket and it is obtained just as in the derivation of formula (16.25) for T_c. In order to find the second term, it is necessary to know K for a finite p, which corresponds to a moving Bosecondensate of Conper pairs. The corresponding derivation is done in section 21.2 and the expression for $K(p)$ corresponds to the rignt-nand side of formula (21.24), divided by $\lambda_0 = \frac{1}{2}g\nu$, with $I = 0$ and $|q| = p$. Expanding in powers of p, we get the
expression in (20.37). Since in the integral (20.35) only small p 's are essential, we can put in the numerator $K(p) \approx K(0) \approx \lambda_0^{-1}$, after which the integral takes the form

$$1 = \frac{\Lambda}{\lambda_0^2} \int \frac{\mathrm{d}p}{2\pi} \left[\tau_0 + \frac{7\zeta(3)}{48\pi^2} \frac{v^2 p^2}{T_c^2} \right]^{-1} \tag{20.38}$$

(here, as before, $\tau_0 = (T_c - T_{c0})/T_{c0}$). Calculating the integral and expressing τ_0 we obtain

$$\tau_0 = 0.45 \left(\frac{\Lambda}{\lambda_0^2 \xi_0} \right)^2, \tag{20.39}$$

which corresponds to the estimate (20.31).
A similar derivation can be performed for a superconductor containing impurities with $l < \xi_0$. In this case in (20.31) $\xi_0^2 \to \xi_0 l$. For pure tin $\xi_0 = 3.1 \times 10^{-5}$ cm, $\lambda \approx 0.3$. In order to have $\Delta T_c = 0.04$ K, i.e. $\tau_0 = 0.011$, one should have $\Lambda \approx 4 \times 10^{-7}$. Even if we put $d \sim 40\mathring{\mathrm{A}}$ we get $\delta\lambda \approx 1$; but d is probably even smaller. Thus, a seemingly small displacement of the critical temperature leads to a considerable value of the interaction constant.

Since we consider a narrow vicinity of T_{c0} we may apply Ginzburg-Landau theory. As we shall see below, this will be insufficient for calculating the critical magnetic field of the twinning plane superconductivity at $T < T_{co}$, but we shall not consider this case. The appearance of a twinning plane with a larger critical temperature can be naturally taken into account by adding a term $-\frac{1}{2}\gamma\delta(x)|\Psi|^2$ to the GL free energy. After that the GL functional in a given external field H_0 takes the form

$$\begin{aligned} \int \Omega_{\mathrm{sH}}\, \mathrm{d}V = &\int \Omega_{\mathrm{nH}}\, \mathrm{d}V \\ &+ \int \left\{ \frac{(H - H_0)^2}{8\pi} + \frac{1}{4m} \left| \left(-i\hbar\nabla - \left(\frac{2e}{c} \right) A \right) \Psi \right|^2 + \alpha\tau|\Psi|^2 + \frac{1}{2} b|\Psi|^4 \right. \\ &\left. -\gamma\delta(x)|\Psi|^2 \right\} \mathrm{d}V \end{aligned} \tag{20.40}$$

Variation over Ψ^* yields

$$\frac{1}{4m} \left[-i\hbar\nabla - \left(\frac{2e}{c} \right) A \right]^2 \Psi + \alpha\tau\Psi + b|\Psi|^2\Psi = \gamma\delta(x)\Psi. \tag{20.41}$$

First let us consider the case where there is no magnetic field. It is natural to assume in this case that Ψ depends only on x and that it is real. Then we find

$$-\frac{\hbar^2}{4m} \frac{d^2\Psi}{dx^2} + \alpha\tau\Psi + b\Psi^3 = \gamma\delta(x)\Psi. \tag{20.42}$$

The right-hand side of this equation corresponds to a discontinuity of $\mathrm{d}\Psi/\mathrm{d}x$.
Therefore, instead of the δ-function term we can write a boundary condition

$$\left. \frac{\mathrm{d}\Psi}{\mathrm{d}x} \right|_0 = -\frac{2m\gamma}{\hbar^2} \gamma\Psi(0) \tag{20.43}$$

Actually, instead of adding the δ-function term to the free energy we could write the "surface invariant" (Andreev 1987):

$$\int \mathrm{d}S \left[A\left|\Psi_+\right|^2 + B\left|\Psi_-\right|^2 + C\left(\Psi_+^*\Psi_- + \Psi_-^*\Psi_+\right)\right]$$

where

$$\Psi_+ = \Psi(x+0), \quad \Psi_- = \Psi(x-0)$$

After that variation of Ψ on both sides of the surface would yield more general boundary conditions than (20.43). However, it should be remembered that the twinning plane is necessarily connected with the appearance of a new symmetry element, e.g. a mirror reflection plane. In the corresponding transformation $|\Psi_+|^2 \rightleftarrows |\Psi_-|^2$. Thus, for $\Psi_+$and Ψ_-themselves a symmetrical transformation is possible, namely $\Psi_+ = \Psi_-$, as well as an antisymmetrical one: $\Psi_+ = -\Psi_-$. In the last case Ψ must turn to zero at interatomic distances from the twinning plane. This would lead to an energy increase, but there is no necessity for such a phase jump (such as an increasing vector potential, ch. 18, or a phase slip center, ch. 22). The symmetrical case coincides completely with the addition of the $\delta(x)$ term, and only this case are we going to consider.

First of all we show that the new parameter γ in (20.41) is uniquely connected with the increase of the critical temperature at the twinning plane. To this purpose consider eq. (20.42) in the linear approximation,

$$-\frac{h^2}{4m}\frac{d^2\Psi}{\mathrm{d}x^2} + \alpha\tau\Psi = 0$$

The solution of this equation, descending at $x \to \pm\infty$, is proportional to $\exp(-q|x|)$, where $q = \sqrt{4m\alpha\tau}/\hbar$. From the boundary condition (20.43) we find $q = 2m\gamma/\hbar^2$ and hence

$$\tau_0 = \frac{T_\mathrm{c} - T_{\mathrm{c}0}}{T_{\mathrm{c}0}} = \frac{m\gamma^2}{\hbar^2\alpha}. \tag{20.44}$$

Now we introduce new dimensionless variables:

$$\varphi = \frac{\Psi}{\Psi_0}, \quad t = \frac{T - T_{\mathrm{c}0}}{T_\mathrm{c} - T_{\mathrm{c}0}}, \quad x' = \frac{x}{\xi_\mathrm{c}},$$

where

$$\xi_\mathrm{c} = \frac{1}{q\left(T_\mathrm{c}\right)} = \frac{h}{\sqrt{4m\alpha\tau_0}}, \quad \Psi_0 = \sqrt{\frac{\alpha\tau_0}{b}} = \Psi\left(-\tau_0\right).$$

With these variables equation (20.42) does not contain any characteristics of the superconductor:

$$-\frac{d^2\varphi}{dx^2} + t\varphi + \varphi^3 = 2\delta(x)\varphi \tag{20.45}$$

(we omit the prime on $\boldsymbol{x}$). The right-hand side is equivalent to the boundary condition

$$\varphi'(0) = -\varphi(0) \tag{20.46}$$

Equation (20.45) (without the right-hand side) has a first integral. Multiplying by $\mathrm{d}\varphi/\mathrm{d}x$ and integrating with respect to x we get

$$-\left(\frac{\mathrm{d}\varphi}{dx}\right)^2 + t\varphi^2 + \frac{1}{2}\varphi^4 = \text{ const.} \tag{20.47}$$

Since at $x = \pm\infty$ we have $\varphi = 0$, it follows that const. $= 0$. Solving the equation thus obtained we have

$$\varphi = \frac{\sqrt{2t}}{\sinh(|x|\sqrt{t} + p)}. \tag{20.48}$$

The constant p is found from the boundary condition (20.46)

$$p = \frac{1}{2} \ln \left(\frac{1 + \sqrt{t}}{1 - \sqrt{t}} \right). \tag{20.49}$$

So the function φ in the general case decays exponentially while departing from the twinning plane, with a characteristic distance $\xi_c/\sqrt{t} = \xi(T)$, as expected. However, this happens only far from T_{co}, the critical temperature of the bulk specimen. Close to T_{c0} we have $t \to 0, p \approx \sqrt{t}, \varphi \approx \sqrt{2}/(|x| + 1)$, i.e. the exponential decay is replaced by a power law.

Now we shall consider the thermodynamics of twinning-plane superconductivity. It is evident that a single plane makes a negligible contribution to the thermodynamic functions, of the order of ξ_c/L, where L is the size of the sample. However, as mentioned above, in the high-temperature oxide $YBa_2Cu_3O_{7-\delta}$ a whole system of parallel twinning planes appears spontaneously. Therefore the corresponding contribution will not be negligible, particularly close to T_{c0}.

So we assume that there exists a system of parallel periodic twinning planes perpendicular to the x-axis, with a spacing L. Let us put the origin in the middle between two planes (fig. 129). Evidently φ will have a minimum at this point which we denote as φ_1. At this point $\mathrm{d}\varphi/\mathrm{d}x = 0$. Therefore in the first integral (20.47)

$$\text{const.} \;= t\varphi_1^2 + \frac{1}{2}\varphi_1^4. \tag{20.50}$$

At the twinning plane φ reaches a maximal value, which we denote by φ_0. According to the boundary condition (20.46) $(\varphi')^2 = \varphi_0^2$. Inserting this into (20.47) we find

$$\text{const.} \;= (t-1)\varphi_0^2 + \frac{1}{2}\varphi_0^4. \tag{20.51}$$

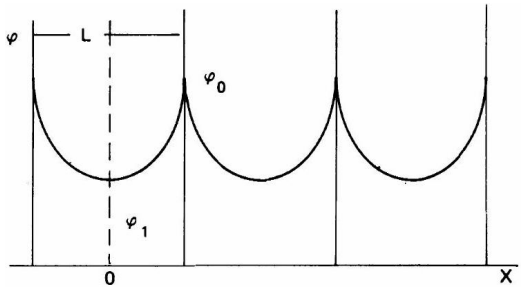

Fig. 129.

Comparing eqs. (20.50) and (20.51) we get the first relation

$$2t\varphi_1^2 + \varphi_1^4 = 2(t-1)\varphi_0^2 + \varphi_0^4. \tag{20.52}$$

Substituting (20.50) into (20.47) and expressing $\mathrm{d}x$ in terms of $\mathrm{d}\varphi$ we find

$$\mathrm{d}x = \frac{\sqrt{2}\;\mathrm{d}\varphi}{\left[(\varphi^2 - \varphi_1^2)\,(2t + \varphi^2 + \varphi_1^2)\right]^{1/2}}.$$

Integrating from $x = 0$ to $x = \frac{1}{2}L$ (i.e. $x = L/2\xi_c$ in dimensionless units) we find

$$\frac{L}{2\xi\,(T_c)} = \int_{\varphi_1}^{\varphi_0} \frac{\sqrt{2}\;\mathrm{d}\varphi}{\left[(\varphi^2 - \varphi_1^2)\,(2t + \varphi^2 + \varphi_1^2)\right]^{1/2}}. \tag{20.53}$$

Relations (20.52) and (20.53) are implicit formulae defining φ_1 and φ_0 as functions of t for a given spacing between the planes L.

The entropy is equal to

$$\begin{aligned}\int S_\mathrm{s}\;\mathrm{d}V &= -\frac{\partial}{\partial T}\int \Omega_\mathrm{s}\;\mathrm{d}V \\ &= -\int \left(\frac{\partial \Omega_\mathrm{s}}{\partial T}\right)_\Psi \mathrm{d}V - \int \frac{\partial \Psi}{\partial t}\left(\frac{\partial \Omega_\mathrm{s}}{\partial \Psi}\right)_T \mathrm{d}V\end{aligned}$$

But the latter term turns to zero since the condition $\partial\Omega_\mathrm{s}/\partial\Psi$ defined the GL equation. So only the first term remains and we get per unit volume

$$S = -\frac{\alpha}{T_{c0}}\int_0^{L/2} |\Psi|^2 \frac{\mathrm{d}x}{\frac{1}{2}L}.$$

Transforming to dimensionless variables, we get

$$\begin{aligned}S &= -\frac{2\alpha\xi_c\,|\Psi_0|^2}{LT_{c0}}\int_0^{L/2\xi_c} \varphi^2\;\mathrm{d}x \\ &= -\frac{2\xi_c\alpha^2\tau_0}{LT_{c0}b}\int_{\varphi_1}^{\varphi_0} \frac{\sqrt{2}\varphi^2\;\mathrm{d}\varphi}{\left[(\varphi^2 - \varphi_1^2)\,(2t + \varphi^2 + \varphi_1^2)\right]^{1/2}}.\end{aligned} \tag{20.54}$$

According to Landau phase transition theory (see Appendix II) the jump of the heat capacity of the bulk specimen at the transition point is

$$\Delta C_0 = \frac{\alpha^2}{bT_{c0}}$$

(this formula can also be obtained from relations 15.8 and 12.3). Differentiating S with respect to temperature and dividing by ΔC_0 we get (Abrikosov and Buzdin 1988)

$$\frac{C}{\Delta C_0} = -\frac{2\xi_\mathrm{c}}{L}\frac{T}{T_{c0}}\frac{\partial}{\partial T}\left\{\int_{\varphi_1}^{\varphi_0} \frac{\sqrt{2}\varphi^2\;\mathrm{d}\varphi}{\left[(\varphi^2 - \varphi_1^2)\,(2t + \varphi^2 + \varphi_1^2)\right]^{1/2}}\right\}. \tag{20.55}$$

Hence formulae (20.52), (20.53) and (20.55) present the temperature dependence of the heat capacity and depend on the parameter L/ξ_c. Figure 130 presents the experimental data on the temperature dependence of the heat capacity of a single crystal $YBa_2Cu_3O_{7-\delta}$ (Inderhees et al. 1987) together with the theoretical curve for $L/\xi_\mathrm{c} = 12$ giving the best fit. Excluding the small peak in the vicinity of T_{c0}, which

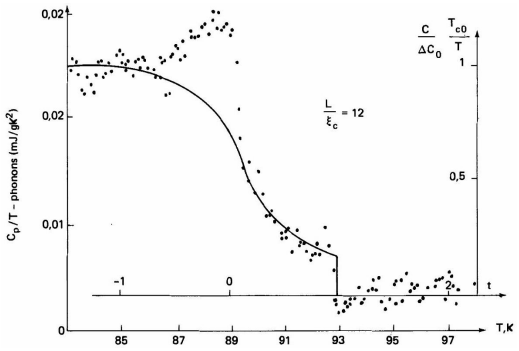

Fig. 130.

can be ascribed to fluctuations not taken into account in GL theory, the fitting is good. So one may conclude that 93 K corresponds to T_c i.e. to the critical temperature of the twinning plane superconductivity, whereas the bulk critical temperature T_{c0} is 89 K . Since $\xi_c \sim \xi_0 \tau_0^{-1/2}$, we have, with $\xi_0 \approx 16\text{Å}, \xi_c \approx 75.5\text{Å}$. So $L \approx 900\text{Å}$, which is reasonable.

According to Landau phase transition theory (see Appendix II) the jump of the heat capacity of the bulk specimen at the transition point is

$$\Delta C_0 = \frac{\alpha^2}{bT_{c0}}$$

(this formula can also be obtained from relations 15.8 and 12.3). Differentiating S with respect to temperature and dividing by ΔC_0 we get (Abrikosov and Buzdin 1988)

$$\frac{C}{\Delta C_0} = -\frac{2\xi_c}{L}\frac{T}{T_{c0}}\frac{\partial}{\partial T}\left\{\int_{\varphi_1}^{\varphi_0} \frac{\sqrt{2}\varphi^2 \, \mathrm{d}\varphi}{\left[(\varphi^2 - \varphi_1^2)\,(2t + \varphi^2 + \varphi_1^2)\right]^{1/2}}\right\}. \tag{20.55}$$

Hence formulae (20.52), (20.53) and (20.55) present the temperature dependence of the heat capacity and depend on the parameter L/ξ_c. Figure 130 presents the experimental data on the temperature dependence of the heat capacity of a single crystal $YBa_2Cu_3O_{7-8}$ (Inderhees et al. 1987) together with the theoretical curve for $L/\xi_c = 12$ giving the best fit. Excluding the small peak in the vicinity of T_{c0}, which

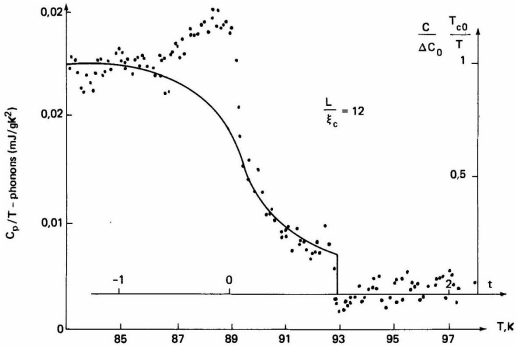

Fig. 130.

can be ascribed to fluctuations not taken into account in GL theory, the fitting is good. So one may conclude that 93 K corresponds to T_c i.e. to the critical temperature of the twinning plane superconductivity, whereas the bulk critical temperature T_{c0} is 89 K . Since $\xi_c \sim \xi_0 \tau_0^{-1/2}$, we have, with $\xi_0 \approx 16\text{Å}, \xi_c \approx 75.5\text{Å}$. So $L \approx 900\text{Å}$, which is reasonable.

According to Landau phase transition theory (see Appendix II) the jump of the heat capacity of the bulk specimen at the transition point is

$$\Delta C_0 = \frac{\alpha^2}{bT_{c0}}$$

(this formula can also be obtained from relations 15.8 and 12.3). Differentiating S with respect to temperature and dividing by ΔC_0 we get (Abrikosov and Buzdin 1988)

$$\frac{C}{\Delta C_0} = -\frac{2\xi_c}{L}\frac{T}{T_{c0}}\frac{\partial}{\partial T}\left\{\int_{\varphi_1}^{\varphi_0}\frac{\sqrt{2}\varphi^2\,\mathrm{d}\varphi}{\left[(\varphi^2-\varphi_1^2)\,(2t+\varphi^2+\varphi_1^2)\right]^{1/2}}\right\}. \tag{20.55}$$

Hence formulae (20.52), (20.53) and (20.55) present the temperature dependence of the heat capacity and depend on the parameter L/ξ_c. Figure 130 presents the experimental data on the temperature dependence of the heat capacity of a single crystal $YBa_2Cu_3O_{7-\delta}$ (Inderhees et al. 1987) together with the theoretical curve for $L/\xi_c = 12$ giving the best fit. Excluding the small peak in the vicinity of T_{c0}, which

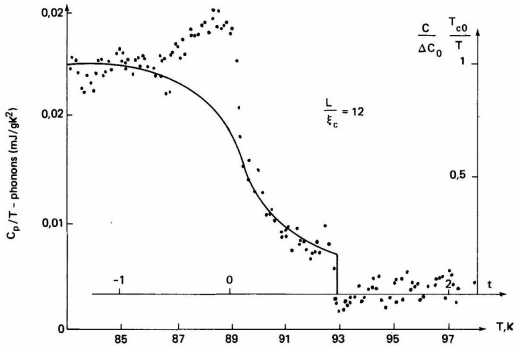

Fig. 130.

can be ascribed to fluctuations not taken into account in GL theory, the fitting is good. So one may conclude that 93 K corresponds to T_c i.e. to the critical temperature of the twinning plane superconductivity, whereas the bulk critical temperature T_{c0} is 89 K . Since $\xi_c \sim \xi_0\tau_0^{-1/2}$, we have, with $\xi_0 \approx 16\text{Å}, \xi_c \approx 75.5\text{Å}$. So $L \approx 900\text{Å}$, which is reasonable.

We now proceed to the calculation of the critical magnetic field. Let us consider only the case when the magnetic field is parallel to the twinning plane. Obviously, if the superconductor is of type II the disappearance of twinning plane superconductivity will proceed as a second-order transition. Let us assume H along the z-axis and choose the vector potential as $A_y(x)$. Then we should add a term e^2A^2/mc^2 to the left-hand side of (2.41). Let us introduce some quantities:

- the penetration depth

$$\delta = \sqrt{\frac{2mc^2}{4\pi\psi_0^2(2e)^2}}$$

$$\kappa = \frac{\delta}{\xi_c} = \frac{mc}{e}\sqrt{\frac{b}{2\pi}}$$

- the Ginzburg-Landau parameter

$$H_{\mathrm{cm}}\left(-\tau_0\right)=2\alpha\tau_0\sqrt{\frac{\pi}{b}}$$

- the scale for the critical field

$$H_{\mathrm{c2}}\left(-\tau_0\right)=\kappa\sqrt{2}H_{\mathrm{cm}}\left(-\tau_0\right)=2\alpha\tau_0\frac{mc}{e}.$$

Close to the critical field we can assume $A_y(x)=H_0x$. With dimensionless variables we get

$$-\varphi''(x)+h^2x^2\varphi(x)+t\varphi(x)-2\delta(x)\varphi(x)=0 \tag{20.56}$$

where $h=H_0/H_{\mathrm{c2}}\left(-\tau_0\right)$. We first find the solutions of eq. (20.56) in the limiting cases. First we consider the vicinity of T_c, i.e. $t\to 1$. In this case h will be small and therefore the corresponding term can be treated as a perturbation. Let us rewrite eq. (20.56) in the following form:

$$-\varphi''(x)+\varphi(x)+h^2x^2\varphi(x)=(1-t)\varphi(x)$$

with the boundary condition $\varphi'(0)=-\varphi(0)$. In the case under consideration $1-t$ plays the role of energy. In the zeroth approximation $1-t=0$ and the eigenfunction is

$$\varphi\propto \mathrm{e}^{-|x|}.$$

In the first approximation the perturbation has to be averaged over the unperturbed state. So we get

$$1-t=\frac{\int_{-\infty}^{\infty}h^2x^2\mathrm{e}^{-2|x|}\mathrm{d}x}{\int_{-\infty}^{\infty}\mathrm{e}^{-2|x|}\mathrm{d}x}$$

We find therefrom

$$1-t=\frac{1}{2}h^2$$

i.e.

$$h=[2(1-t)]^{1/2} \tag{20.57}$$

We now proceed to the calculation of the critical magnetic field. Let us consider only the case when the magnetic field is parallel to the twinning plane. Obviously, if the superconductor is of type II the disappearance of twinning plane superconductivity will proceed as a second-order transition. Let us assume H along the z-axis and choose the vector potential as $A_y(x)$. Then we should add a term e^2A^2/mc^2 to the left-hand side of (2.41). Let us introduce some quantities:

- the penetration depth

$$\delta=\sqrt{\frac{2mc^2}{4\pi\psi_0^2(2e)^2}}$$

$$\kappa=\frac{\delta}{\xi_c}=\frac{mc}{e}\sqrt{\frac{b}{2\pi}}$$

- the Ginzburg-Landau parameter

$$H_{\mathrm{cm}}\left(-\tau_0\right) = 2\alpha\tau_0\sqrt{\frac{\pi}{b}}$$

- the scale for the critical field

$$H_{\mathrm{c2}}\left(-\tau_0\right) = \kappa\sqrt{2}H_{\mathrm{cm}}\left(-\tau_0\right) = 2\alpha\tau_0\frac{mc}{e}.$$

Close to the critical field we can assume $A_y(x) = H_0 x$. With dimensionless variables we get

$$-\varphi''(x) + h^2x^2\varphi(x) + t\varphi(x) - 2\delta(x)\varphi(x) = 0, \tag{20.56}$$

where $h = H_0/H_{\mathrm{c2}}\left(-\tau_0\right)$. We first find the solutions of eq. (20.56) in the limiting cases. First we consider the vicinity of T_c, i.e. $t \to 1$. In this case h will be small and therefore the corresponding term can be treated as a perturbation. Let us rewrite eq. (20.56) in the following form:

$$-\varphi''(x) + \varphi(x) + h^2x^2\varphi(x) = (1-t)\varphi(x)$$

with the boundary condition $\varphi'(0) = -\varphi(0)$. In the case under consideration $1-t$ plays the role of energy. In the zeroth approximation $1 - t = 0$ and the eigenfunction is

$$\varphi \propto \mathrm{e}^{-|x|}.$$

In the first approximation the perturbation has to be averaged over the unperturbed state. So we get

$$1 - t = \frac{\int_{-\infty}^{\infty} h^2x^2\mathrm{e}^{-2|x|}\mathrm{d}x}{\int_{-\infty}^{\infty}\mathrm{e}^{-2|x|}\mathrm{d}x}$$

We find therefrom

$$1 - t = \frac{1}{2}h^2$$

i.e.

$$h = [2(1-t)]^{1/2}. \tag{20.57}$$

Now we pass to conventional units. Since H_{c2} varies linearly with temperature close to T_{co} we can write

$$H_{\mathrm{c2}}\left(-\tau_0\right) = \left.\frac{\mathrm{d}H_{\mathrm{c2}}}{\mathrm{d}T}\right|_{T_{\mathrm{c0}}}\left(T_{\mathrm{c}} - T_{\mathrm{c0}}\right).$$

Keeping in mind that $t = \left(T - T_{\mathrm{c0}}\right)/\left(T_{\mathrm{c}} - T_{\mathrm{c0}}\right)$ we find:

$$1 - t = \frac{T_c - T}{T_c - T_{c0}}.$$

Hence the critical field of the twinning plane is

$$H^{\mathrm{t}}_{\mathrm{c2}}(T) = \left|\frac{\mathrm{d}H_{\mathrm{c2}}}{\mathrm{d}T}\right|\left[2\left(T_{\mathrm{c}} - T\right)\left(T_{\mathrm{c}} - T_{\mathrm{c0}}\right)\right]^{1/2}. \tag{20.58}$$

One sees that $H_{c2}^{t} \sim (T_c - T)^{1/2}$. This behaviour corresponds to a thin film having a thickness ξ_c (see 17.48′).

Another limiting case is the field at temperature $t < 0, |t| > 1$ i.e. on the scale $T_c - T_{c0}$ deep in the superconducting region, not so far however from T_{c0} as to violate the applicability condition of GL theory: $T_{c0} - T < T_{c0}$. Under these conditions the twinning plane itself is a perturbation. Let us rewrite eq. (20.56) in the form

$$-\varphi''(x) + h^2x^2\varphi(x) - 2\delta(x)\varphi(x) = -t\varphi(x) \qquad (\prime)$$

Neglecting the term with $\delta(x)$ we have solutions of (20.56′) descending with $x \to \pm\infty$ if $-t = h(2n+1)$. The smallest eigenvalue is $-t = h$. The corresponding eigenfunction is $\varphi_0 = (h/\pi)^{1/4} \exp\left(-\frac{1}{2}hx^2\right)$. Considering the term with $\delta(x)$ as a perturbation we obtain the first approximation,

$$-t = h + \int \varphi^2[-2\delta(x)]\mathrm{d}x = h - 2\sqrt{\frac{h}{\pi}}.$$

Since h is large in this case the second term is in fact a correction. Solving with respect to h we find

$$h = -t + \sqrt{\frac{2|t|}{\pi}} \qquad (20.59)$$

Multiplying by $H_{c2}(-\tau_0) = |\mathrm{d}H_{c2}/\mathrm{d}T|_{T_{c0}}(T_c - T_{c0})$ we see that $h = -t$ corresponds to $H_{c2}^{t}(T) = |\mathrm{d}H_{c2}/\mathrm{d}T|(T_{c0} - T) = H_{c2}$. Hence

$$\frac{H_{c2}^{t}(T) - H_{c2}(T)}{H_{c2}(T)} = \frac{2}{\sqrt{\pi|t|}}. \qquad (20.60)$$

It follows that $H_{c2}^{t}(T) > H_{c2}(T)$ at any temperature (fig. 131) and hence in type-II superconductors twinning plane superconductivity can exist in the absence of bulk superconductivity in the proper interval of magnetic fields up to $T = 0$. Of course the critical field H_{c2}^{t} at low temperature cannot be calculated from the GL equations and demands a more complete microscopic theory.

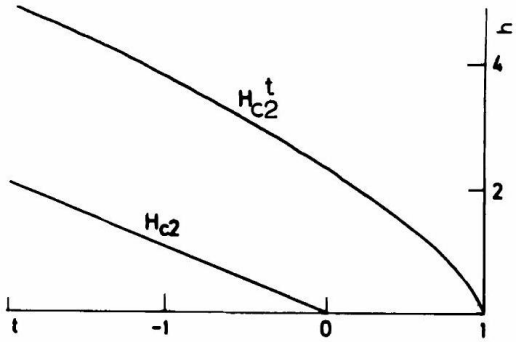

Fig. 131.

We have considered until now the limiting cases. An expression for h which is valid for any t (within the applicability region of GL-theory) can be obtained in the following way. We assume for the general solution of eq. (20.56') the following form:

$$\varphi(x) = \sum_n c_n\varphi_n(x), \qquad (20.61)$$

where φ_n are eigenfunctions, corresponding to the eigenvalues of the parameter $t : \varepsilon_n = h(2n+1)$; substituting into (20.56'), multiplying by $\varphi_n(x)$ and integrating with respect to x we find

$$c_n = \frac{2\varphi(0)\varphi_n(0)}{t+\varepsilon_n}. \tag{20.62}$$

Taking into account the self-consistency condition

$$\varphi(0) = \sum_n c_n \varphi_n(0)$$

we find

$$1 = \sum_n \frac{2\varphi_n^2(0)}{t+\varepsilon_n}. \tag{20.63}$$

The normalized eigenfunctions of eq. (20.56) (without the δ-term) are expressed by (see Landau and Lifshitz 1974)

$$\varphi_n = \left(\frac{h}{\pi}\right)^{1/4} (2^n n!)^{-1/2} \exp\left(-\frac{1}{2}hx^2\right) \mathrm{H}_n(x\sqrt{h}), \tag{20.64}$$

where H_n are the Hermite polynomials

$$\mathrm{H}_n(x) = (-1)^n \mathrm{e}^{x^2} \frac{\mathrm{d}^n}{\mathrm{d}x^n} \mathrm{e}^{-x^2}. \tag{20.65}$$

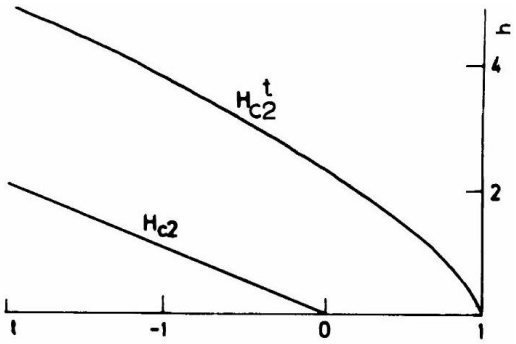

Fig. 131.

We have considered until now the limiting cases. An expression for h which is valid for any t (within the applicability region of GL-theory) can be obtained in the following way. We assume for the general solution of eq. (20.56') the following form:

$$\varphi(x) = \sum_n c_n \varphi_n(x), \tag{20.61}$$

where φ_n are eigenfunctions, corresponding to the eigenvalues of the parameter $t : \varepsilon_n = h(2n+1)$; substituting into (20.56'), multiplying by $\varphi_n(x)$ and integrating with respect to x we find

$$c_n = \frac{2\varphi(0)\varphi_n(0)}{t+\varepsilon_n}. \tag{20.62}$$

Taking into account the self-consistency condition

$$\varphi(0) = \sum_n c_n \varphi_n(0)$$

we find

$$1 = \sum_n \frac{2\varphi_n^2(0)}{t + \varepsilon_n}. \tag{20.63}$$

The normalized eigenfunctions of eq. (20.56) (without the δ-term) are expressed by (see Landau and Lifshitz 1974)

$$\varphi_n = \left(\frac{h}{\pi}\right)^{1/4} (2^n n!)^{-1/2} \exp\left(-\frac{1}{2}hx^2\right) \mathrm{H}_n(x\sqrt{h}), \tag{20.64}$$

where $\mathbf{H_n}$ are the Hermite polynomials

$$\mathrm{H}_n(x) = (-1)^n \mathrm{e}^{x^2} \frac{\mathrm{d}^n}{\mathrm{d}x^n} \mathrm{e}^{-x^2}. \tag{20.65}$$

Putting $x = 0$ we have

$$\mathrm{H}_{2n}(0) = (-1)^n 2^n (2n-1)!!, \quad \mathrm{H}_{2n+1}(0) = 0.$$

Substituting into eq. (20.63) we get an equation for h :

$$\begin{aligned} h^{1/2} &= \frac{2}{\pi^{1/2}} \sum_{k=0}^{\infty} \frac{(2k)!}{(k!)^2 2^{2k}(t/h + 4k + 1)} \\ &= \frac{1}{2\sqrt{\pi}} B\left(\frac{1}{2}, \frac{1}{4}\left(1 + \frac{t}{h}\right)\right) \end{aligned} \tag{20.66}$$

where $\mathrm{B}(x, y) = \Gamma(x)\Gamma(y)/\Gamma(x + y)$ is the beta-function. From the general expression the limiting cases (20.52) and (20.59) can also be obtained.

With respect to the high-temperature oxide $\mathrm{Y - Ba - Cu - O}$, the formula (20.58) is of the main interest. Experiments with samples having parallel c-axes of the crystallites and the magnetic field also in the same direction (Fang et al. 1987) showed that around the critical temperature the critical field is proportional to $(T_c - T)^{1/2}$ rather than to $T_\mathrm{c} - T$. Hence it can be concluded that this is due to twinning plane superconductivity. If we use the value $|\mathrm{d}H_{\mathrm{c}2}/\mathrm{d}T| \sim 10\mathrm{kOe/K}$ which is known from other sources then we obtain $T_c - T_{c0} \approx 5 - 6$ K, which fits the result for the specific heat.

Now let us consider the case when the twinning boundary is formed in a type-I superconductor. First of all it should be mentioned that there exists an effective GL parameter for twinning plane superconductivity, namely

$$\kappa_{\mathrm{eff}} \sim \frac{\lambda_{\mathrm{L}}[\psi]}{\xi_{\mathrm{c}}} \sim \frac{\lambda_{\mathrm{L}0}}{\psi\xi_{\mathrm{c}}} \sim \frac{\lambda_{\mathrm{L}0}}{\xi_{\mathrm{c}}\left[\left(T_{\mathrm{c}} - T\right)/T_{\mathrm{c}0}\right]^{1/2}}. \tag{20.67}$$

Hence close to T_c we have $\kappa_{\mathrm{eff}} > 1$ and there is a second-order phase transition which is described by the preceding formulae. At some temperature where $\kappa_{\mathrm{eff}} \approx 1$ a "tricritical point" occurs and the transition becomes first-order.

In order to calculate the first-order transition critical field we apply a method similar to the one we used for the calculation of the surface energy (section 17.2). Let us assume $\kappa < 1$, i.e., $\xi > \delta$. Then the field practically does not penetrate into the superconducting region. We shall suppose this region to be $-L < x < L$ (its size is still to be determined). So we arrive at eq.

(20.42) or (20.45) but with another boundary condition: $\varphi(\pm L/\xi_c) = 0$. We have to calculate the free energy of this region which is equal to (see 20.40 ; we have passed to reduced variables)

$$\begin{aligned}\Omega &\equiv \int \Omega_{\mathrm{sH}}\,\mathrm{d}x - \int \Omega_{\mathrm{nH}}\,\mathrm{d}x \\ &= \frac{H_{\mathrm{c}}^2}{4\pi}\xi_{\mathrm{c}}\left\{\int_{-L/\xi_{\mathrm{c}}}^{L/\xi_0}\left[\varphi'^2 + t\varphi^2 + \frac{1}{2}\varphi^4 + \frac{1}{2}h_0^2\right]\mathrm{d}x - 2\varphi^2(0)\right\}\end{aligned} \tag{20.68}$$

where $h_0 = H_0/H_{\mathrm{cm}}\,(-\tau_0)$.
Putting $x = 0$ we have

$$\mathrm{H}_{2n}(0) = (-1)^n 2^n (2n-1)!!, \quad \mathrm{H}_{2n+1}(0) = 0.$$

Substituting into eq. (20.63) we get an equation for h :

$$\begin{aligned}h^{1/2} &= \frac{2}{\pi^{1/2}}\sum_{k=0}^{\infty}\frac{(2k)!}{(k!)^2 2^{2k}(t/h + 4k + 1)} \\ &= \frac{1}{2\sqrt{\pi}}B\left(\frac{1}{2}, \frac{1}{4}\left(1 + \frac{t}{h}\right)\right)\end{aligned} \tag{20.66}$$

where $\mathrm{B}(x,y) = \Gamma(x)\Gamma(y)/\Gamma(x+y)$ is the beta-function. From the general expression the limiting cases (20.52) and (20.59) can also be obtained.

With respect to the high-temperature oxide $\mathrm{Y-Ba-Cu-O}$, the formula (20.58) is of the main interest. Experiments with samples having parallel c-axes of the crystallites and the magnetic field also in the same direction (Fang et al. 1987) showed that around the critical temperature the critical field is proportional to $(T_c - T)^{1/2}$ rather than to $\boldsymbol{T_{\mathrm{c}}} - \boldsymbol{T}$. Hence it can be concluded that this is due to twinning plane superconductivity. If we use the value $|\mathrm{d}H_{c2}/\mathrm{d}T| \sim 10\mathrm{kOe/K}$ which is known from other sources then we obtain $T_c - T_{c0} \approx 5 - 6$ K, which fits the result for the specific heat.

Now let us consider the case when the twinning boundary is formed in a type-I superconductor. First of all it should be mentioned that there exists an effective GL parameter for twinning plane superconductivity, namely

$$\kappa_{\mathrm{eff}} \sim \frac{\lambda_{\mathrm{L}}[\psi]}{\xi_{\mathrm{c}}} \sim \frac{\lambda_{\mathrm{L0}}}{\psi\xi_{\mathrm{c}}} \sim \frac{\lambda_{\mathrm{L0}}}{\xi_{\mathrm{c}}\left[\left(T_{\mathrm{c}} - T\right)/T_{\mathrm{c0}}\right]^{1/2}}. \tag{20.67}$$

Hence close to T_{c} we have $\kappa_{\mathrm{eff}} \gg 1$ and there is a second-order phase transition which is described by the preceding formulae. At some temperature where $\kappa_{\mathrm{eff}} \approx 1$ a "tricritical point" occurs and the transition becomes first-order.

In order to calculate the first-order transition critical field we apply a method similar to the one we used for the calculation of the surface energy (section 17.2). Let us assume $\kappa < 1$, i.e., $\xi > \delta$. Then the field practically does not penetrate into the superconducting region. We shall suppose this region to be $-L < x < L$ (its size is still to be determined). So we arrive at eq. (20.42) or (20.45) but with another boundary condition: $\varphi(\pm L/\xi_c) = 0$. We have to calculate the free energy of this region which is equal to (see 20.40; we have passed to reduced variables)

$$\begin{aligned}\Omega &\equiv \int \Omega_{\mathrm{sH}}\,\mathrm{d}x - \int \Omega_{\mathrm{nH}}\,\mathrm{d}x \\ &= \frac{H_{\mathrm{c}}^2}{4\pi}\xi_{\mathrm{c}}\left\{\int_{-L/\xi_{\mathrm{c}}}^{L/\xi_0}\left[\varphi'^2 + t\varphi^2 + \frac{1}{2}\varphi^4 + \frac{1}{2}h_0^2\right]\mathrm{d}x - 2\varphi^2(0)\right\}\end{aligned} \tag{20.68}$$

where $h_0 = H_0/H_{\mathrm{cm}}\,(-\tau_0)$.

This time we shall use the full equations containing the field. Choosing the vector potential as $A_y(x)$ we get

$$-\frac{\hbar^2}{4m}\frac{\mathrm{d}^2\Psi}{\mathrm{d}x^2}+\frac{e^2}{mc^2}A^2\Psi+\alpha\tau\Psi+\frac{1}{2}b\Psi^3=\gamma\delta(x)\Psi \tag{20.69}$$

$$\frac{\mathrm{d}^2A}{\mathrm{d}x^2}=\frac{8\pi e^2}{mc^2}\Psi^2A \tag{20.70}$$

We introduce a new scale for $\boldsymbol{A}$:

$$A_0=H_{\mathrm{c}}\,(-\tau_0)\,\delta\,(-\tau_0)=\left(\alpha\tau_0\frac{mc^2}{2e^2}\right)^{1/2}$$

Multiplying eq. (20.69) without the right-hand side by $\mathrm{d}\Psi/\mathrm{d}x$ and eq. (20.70) by $(8\pi)^{-1}\,\mathrm{d}\boldsymbol{A}/\mathrm{d}x$, adding them up and integrating with respect to x we obtain in dimensionless variables the first integral

$$-2\varphi'^2+(2t+A)^2\varphi^2+\varphi^4-\left(A'\right)^2x^2=-h_0^2 \tag{20.71}$$

The constant is chosen from the condition at the boundary of the superconducting region $\varphi=0, H=H_0$.

From this integral we have inisde the region under consideration at $x<0$

$$\frac{\mathrm{d}\varphi}{\mathrm{d}x}=-\left(t\varphi^2+\frac{1}{2}\varphi^4+\frac{1}{2}h_0^2\right)^{1/2} \tag{20.72}$$

(we have put $\boldsymbol{A}=\boldsymbol{A}'=0$). On the other hand, using the boundary condition at the twinning plane we get from eq. (20.72):

$$h_Q^2=2(1-t)\varphi^2(0)-\varphi^4(0) \tag{20.73}$$

Using the first integral (20.72) we get from eq. (20.68)

$$\Omega=\frac{H_{\mathrm{cm}}^2\,(-\tau_0)}{4\pi}\xi_{\mathrm{c}}\left\{\int_{-L/\xi_{\mathrm{c}}}^{L/\xi_{\mathrm{c}}}2\left(\varphi'\right)^2\,\mathrm{d}x-2\varphi^2(0)\right\}$$

With the aid of eq. (20.72) we pass over to the integration over φ and introduce the new variable $y=\varphi/\varphi(0)$; we apply also eq. (20.73):

$$\Omega=\frac{1}{\pi}H_{\mathrm{cm}}^2\,(-\tau_0)\,\varphi^2(0)\xi_{\mathrm{c}}\left\{\int_0^1\left[1-t\left(1-y^2\right)+\frac{1}{2}\left(y^4-1\right)\varphi^2(0)\right]^{1/2}\,\mathrm{d}y-\frac{1}{2}\right\}$$

The first-order transition is defined by the condition $\Omega=0$. This gives an implicit definition of $\varphi(0)$:

$$\int_0^1\left[1-t\left(1-y^2\right)+\frac{1}{2}\left(y^4-1\right)\varphi^2(0)\right]^{1/2}\,\mathrm{d}y=\frac{1}{2} \tag{20.74}$$

Having obtained $\varphi(0)$ we can find the critical field from eq. (20.73). Actually this can be done only numerically. It appears that the transition curve crosses the curve

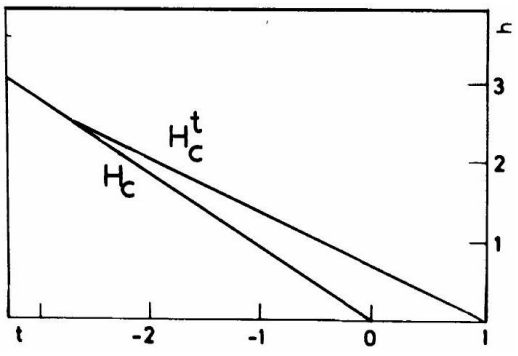

Fig. 132.

for the transition of the bulk material (fig. 132), i.e., the region of twinning plane superconductivity is thus limited to the vicinity of T_{c0}.

The width of the superconducting region is of the order of ξ_c; it can be found easily from the integral (20.72)

$$\frac{2L}{\xi_c} = \int_0^{\varphi(0)} \frac{\mathrm{d}\varphi}{\left(t\varphi^2 + \frac{1}{2}\varphi^4 + \frac{1}{2}h_0^2\right)^{1/2}}. \tag{20.75}$$

Since the field is completely expelled from a region of width $2L$, the magnetic moment of such a plane per unit area is equal to

$$\mu_d = -\frac{1}{2\pi} HL(H). \tag{20.76}$$

The calculation performed here is valid for $\kappa = 0$. However it can be generalized to finite κ 's. Since nothing is used here apart from the constants of the bulk superconductor the results are universal. A numerical calculation for $\kappa = 0.13$ (tin) gives excellent agreement with experiment (fig. 133).

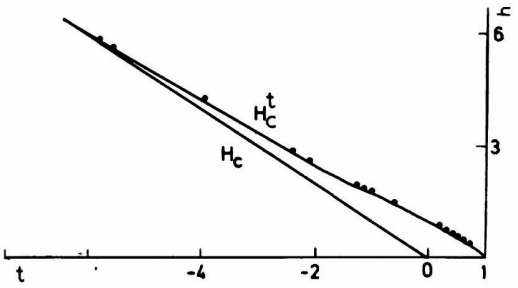

Fig. 133.

The existence of twinning planes can explain some other properties of the superconducting oxide Y − Ba − Cu − O. For example, films which are prepared by another technology contain no twinning planes and their critical temperature does not exceed 89 K . Furthermore, as already mentioned the superconductivity of an isolated twinning plane is suppressed by its normal surroundings due to the proximity effect. Hence the critical temperature could be raised if the twinning planes could be placed at distances less than ξ_c or if they were formed in granules of the proper size. As was mentioned already, Khaikin and Khlyustikov (1981) in pressing samples from a powder of pure tin managed to discover traces of superconductivity up to 12 K , i.e. at temperatures higher than $3T_{c0}$. It is not excluded that communications about signs of

superconductivity in $Y-Ba-Cu-O$ up to 500 K appearing from time to time, are connected with the existance of regions with dense arrays of twinning planes.

For more details about twinning-plane superconductivity see the review by Khlyustikov and Buzdin (1987).

8.6.3 20.3. Andreev reflection

In section 20.1 we have been concerned with the behavior of the superconducting order parameter in the vicinity of the contact between a superconductor and a normal metal. Let us now consider another aspect of such a contact.

As has been said in Part I, the chemical potentials of electrons in both metals must be equal. But the electrons in the ground state of a superconductor are bound into Cooper pairs, and in a normal metal they exist one by one. Hence, the chemical potentials of two separate electrons in a normal metal and of a Cooper pair in a superconductor must be equal. Suppose an electron has been transferred from the normal metal to the superconductor. In this case, it will have no partner, with which it could have been bound into a Cooper pair, which means that its energy will be higher by half the binding energy, i.e., by an amount Δ. Hence, for an individual electron the energy levels in the superconductor begin by Δ higher than in the normal metal. Thus, if its excitation energy above the Fermi level is less than Δ, it must be reflected from the interface.

Such reflection occurs in a rather peculiar manner. In order to ascertain this, it will be better to use the language of the quasiparticle concept. Suppose, for the sake of simplicity, that we deal with the interface between the normal and superconducting layers in the intermediate state of a superconductor. In this case the metals are identical, in principle, and Δ varies from zero to an equilibrium value in the bulk superconductor at a distance $\xi \sim \hbar v/\Delta$. The energy spectrum of quasiparticles expressed by the formula $\varepsilon = (\xi^2 + \Delta^2)^{1/2}$ varies in the manner shown in fig. 134. Quasiparticles with an energy less than Δ in the bulk superconductor must be reflected back into the normal metal. Upon such reflection the energy must be conserved.

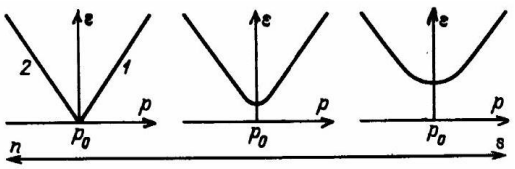

Fig. 134.

As for the variation of the quasimomentum δp, it can be evaluated in the following way. The quantity δp is of order $\mathrm{d}p/\mathrm{d}t$ multiplied by the time passed in the interface region, i.e., ξ/v. As regards $\mathrm{d}p/\mathrm{d}t$, it is equal to the acting force: $-\mathrm{d}V/\mathrm{d}x \sim \Delta/\xi$. This gives

$$\delta p \sim \frac{\xi}{v}\frac{\Delta}{\xi} \sim \frac{\Delta}{v} \sim p_0\frac{\Delta}{p_0 v} \sim p_0\frac{\Delta}{\varepsilon_\mathrm{F}} < p_0.$$

This means that the variation of the quasimomentum is smaller than the quasimomentum itself. But the motion of the electron after reflection must be directed away from the interface.

All these conditions can be fulfilled only in a single way, namely, if the quasiparticle is transferred, say, from branch 1 of the energy spectrum to branch 2 (fig. 134), i.e., is converted from a "particle" to an "antiparticle" with a close quasimomentum. The energy and the quasimomentum do not change. As regards the velocity, it will be equal after reflection to

$$v_{\text{ref}} = \frac{\partial \left[v \left(p_0 - p \right) \right]}{\partial p} = -\frac{vp}{p} = -v_{\text{inc}}$$

Thus, upon such reflection the "particle" is converted to an "antiparticle". The quasimomentum and energy are conserved and the velocity changes sign. Such reflection is radically different from the specular reflection of electrons, where only the normal component of the electron velocity changes sign with respect to the interface. The specificity of this reflection, called Andreev reflection (Andreev 1964), is associated with the slowness of the variation of the potential, the role of which is played by Δ.

A question may arise as to the conservation of charge. The answer is: an electron residing at the Fermi boundary slightly above it picks up another electron with an opposite quasimomentum, which lies slightly below the Fermi boundary, and forms with it a Cooper pair, which goes into the superconductor condensate. An "antiparticle" is left, with a momentum opposite to the momentum of the picked-up electron, i.e., a momentum coinciding with the momentum of the original electron.

Evidently, upon Andreev reflection the transfer from branch 2 to branch 1 of the energy spectrum is also possible, i.e., the antiparticle may be converted to a particle with the opposite velocity. Moreover, it is clear that due to the proximity effect the slowness of variation of the potential will also be conserved for quasiparticles upon contact of the normal metal with a completely foreign superconductor, which means that the reflection law will remain valid.

Direct observation of Andreev reflection is possible by means of the nonresonant size effect described in section 8.3. The effect consist in the following: as soon as the extremal diameter of the trajectory in the magnetic field (or an integer number of such diameters) fits into the plate thickness, a singularity of surface impedance arises. Figure 135 sketches the situation in a case where half the extremal trajectory fits into a layer of a normal metal applied onto a superconductor surface. An electron approaching the interface is converted to an antiparticle with an opposite velocity. This antiparticle travels the same electron trajectory in the opposite direction and eventually approaches the interface. The antiparticle is then converted to an electron and the process repeats itself.

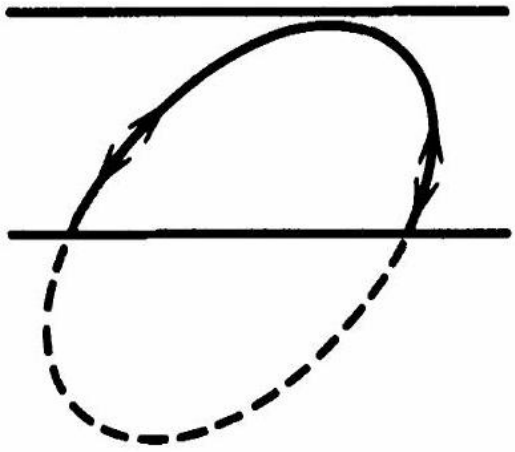

Fig. 135.

Thus, the singularities of the impedance will arise not only in those fields where an integer number of diameters fit into the thickness of the normal plate but also when their number is half-integral. In other words, extra singularities of $Z(H)$ will arise in the middle between the original ones. This is actually observed in experiments (Krylov and Sharvin 1970, 1973).

Note that if the extremal cross section is not the central one, then in an ordinary experiment on the size effect a spiral trajectory corresponds to it in coordinate space, i.e., the electron is displaced along the field. But if the trajectory corresponds to an extra resonance, the velocity component along the field will also change sign upon reflection and the antiparticle will pass its half of the turn of the coil in the opposite direction. Hence, each quasiparticle stays within one half of the turn of the helix, and on the average, no displacement occurs along the field.

8.6.4 20.4. Low-temperature heat capacity of the intermediate state

In the previous section we have already considered the case where the reflection from the n − s (normal-superconducting) interface leads to the replacement of translational motion by periodic motion. Let us now consider another case of the same kind: the intermediate state. We assume that the layers are plane-parallel. For microscopic samples the layer thickness is usually of the order of 10^{-3} cm, i.e., much
larger than ξ, and the n − s interfaces may be taken into account by using the boundary condition. We obtain a periodic picture of the motion of quasiparticles in a normal layer: a quasiparticle of particle-type reaches the interface and is converted to an antiparticle; It then flies back to another interface and is converted to a particle, and the entire process is repeated.

The presence of a magnetic field in the normal layers does not alter the situation because the curved trajectory of the antiparticle exactly repeats the trajectory of the particle that has travelled in the opposite direction. As a matter of fact, in real type I superconductors the Larmor radius in the critical field ($\sim 100 - 1000$ Oe) is not less than 10^{-2} cm and this implies that the trajectories may be assumed to be straight (fig. 136).

The periodic motion is quantized according to the Bohr rule:

$$\oint p \, \mathrm{d}l = 2\pi\hbar[n + \gamma(n)], \tag{20.77}$$

where $\gamma(n) < 1$. Since for the particle $\varepsilon = \xi = v\,(p_\mathrm{p} - p_0)$, it follows that its quasimomentum is given by (here we use the symbol ε in place of ε_qp):

$$p_\mathrm{p} = p_0 + \frac{\varepsilon}{v}.$$

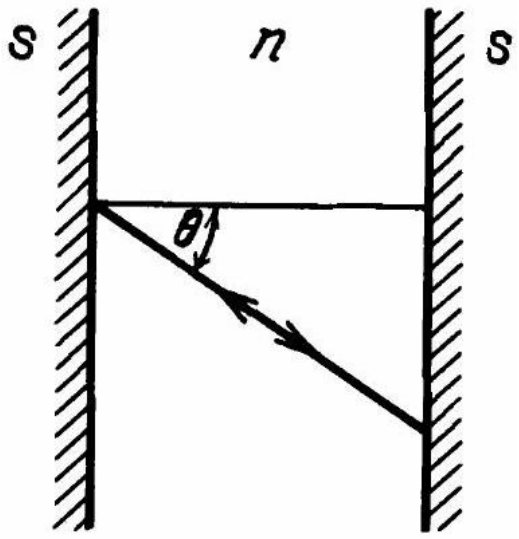

Fig. 136.

The reflected antiparticle has an energy $\varepsilon = -\xi = v\,(p_0 - p_\mathrm{a})$ and, hence, its quasimomentum is

$$p_\mathrm{a} = p_0 - \frac{\varepsilon}{v}.$$

In the integral (20.77) p is the same on both halves of the trajectory, but $\mathrm{d}l$ changes sign. If the width of the layer is a, then the pathlength in one direction is $a/|\cos\theta|$, where θ is the angle between the trajectory and the normal to the interface (fig. 136). As a result, we obtain from eq. (20.77)

$$(p_\mathrm{p} - p_\mathrm{a}) \cdot \frac{a}{|\cos\theta|} = 2\pi(n+\gamma).$$

Substituting the expressions for p_p and p_a, we obtain (Andreev 1965):

$$\varepsilon(n,\theta) = \pi\hbar(n+\gamma)v\frac{|\cos\theta|}{a} \tag{20.78}$$

This is the formula for the energy spectrum of quasiparticles in the intermediate state. The energy depends on the discrete variable n and the continuous angle variable θ.

Let us now find the density of states. The vector $n = p/p$ is uniquely determined by its projections onto the plane of the layer boundary. The number of states is expressed by the formula

$$2S\ \mathrm{d}p_x\frac{\mathrm{d}p_y}{(2\pi\hbar)^2}$$

where S is the area of the interface and the factor 2 stems from two spin projections. We introduce the angle φ in the p_x, p_y plane. In such a case, for the number of states we have

$$2Sp_\perp dp_\perp\frac{d\varphi}{(2\pi\hbar)^2}$$

where $p_\perp = \left(p_x^2 + p_y^2\right)^{1/2}$. But since $p_\perp^2 + p_z^2 = p_0^2$, it follows that $p_\perp \mathrm{d}p_\perp \to |p_z|\,\mathrm{d}p_z = p_0^2|\cos\theta|\mathrm{d}(\cos\theta)$. Thus, we find that the number of states per quantum number n in eq. (20.78) is

$$2Sp_0^2|\cos\theta|\mathrm{d}(\cos\theta)\frac{\mathrm{d}\varphi}{(2\pi\hbar)^2} = 2Sp_0^2|\cos\theta|\frac{\mathrm{d}\Omega}{(2\pi\hbar)^2} \tag{20.79}$$

where $\mathrm{d}\Omega$ is an element of the solid angle for the directions of the vector p.
For the free energy per unit volume of the normal layer we obtain (see eq. 10.11):

$$\Omega(T) = -\frac{T}{a}\sum_n \int\ \mathrm{d}\Omega 2p_0^2\frac{|\cos\theta|}{(2\pi h)^2}\ln\left[1+\exp\left(-\frac{\varepsilon(n,\theta)}{T}\right)\right].$$

Since ε depends only on $|\cos\theta|$, the integral $\int \mathrm{d}\Omega = \int_{-1}^{1}\mathrm{d}\cos\theta\int\ \mathrm{d}\varphi$ may be replaced by $4\pi\int_0^1\ \mathrm{d}\cos\theta$. Here we find

$$\Omega(T) = -\frac{2p_0^2T}{a\pi\hbar^2}\sum_n\int_0^1 x\ \mathrm{d}x\ln\left[1+\exp\left(-\frac{\varepsilon(n,x)}{T}\right)\right] \tag{20.80}$$

Further we consider two temperature regions. If $T > \hbar v/a$, the summation over n may be replaced by an integration. In this case, introducing the variable ε in place n, we have in accordance with (20.78):

$$\Omega(T) = -\frac{2p_0^2 T}{v\pi^2\hbar^3}\int_0^\infty \mathrm{d}\varepsilon \ln\left(1+\mathrm{e}^{-\varepsilon/T}\right)$$
$$= -\frac{p_0^2 T}{v\pi^2\hbar^3}\int_{-\infty}^\infty \mathrm{d}\varepsilon \ln\left(1+\mathrm{e}^{-|\varepsilon|/T}\right)$$

This is the usual expression for a normal metal. Evaluation of the integral gives

$$\Omega(T) = -\frac{1}{6}\frac{p_0^2}{v\pi^2\hbar^3}\pi^2 T^2$$

This yields the usual formula for the electronic heat capacity of a normal metal (see eq. 2.29):

$$C = -T\frac{\partial^2\Omega}{\partial T^2} = \frac{p_0 m}{3\hbar^3}T$$

But if $T < \hbar v/a$, the procedure is different. In the integral (20.79), instead of the variable x we introduce, using formula (20.78), the variable $y = \varepsilon/T$. So, we obtain

$$\Omega(T) = -\frac{2p_0^2T^3a}{\pi^3\hbar^4v^2}\sum_n \frac{1}{(n+\gamma)^2}\int_0^{\pi\hbar(n+\gamma)v/aT} y\ \mathrm{d}y \ln\left(1+\mathrm{e}^{-y}\right)$$

The limit of integration over y may be put equal to infinity because of the rapid convergence of the integral. The sum over n converges and gives a number of the order of unity, which we designate by α. On the whole, after taking the integral over y we obtain

$$\Omega(T) = -3\zeta(3)\frac{\alpha p_0^2 T^3 a}{2\pi^3\hbar^4 v^2}$$

from which we have

$$C = -T\frac{\partial^2\Omega}{\partial T^2} = \beta\frac{p_0^2T^2a}{\hbar^4v^2}$$

where

$$\beta = 9\frac{\zeta(3)}{\pi^3}\sum_n (n+\gamma)^{-2}$$

Taking into account that the fraction of normal layers is always equal to $x_n = B/H_{\mathrm{cm}}$ (the dependence of B on the external field being determined by the geometry of the experiment), we find for the heat capacity of the entire sample (Andreev 1965):

$$C = \begin{cases} \frac{p_0 mB}{3\hbar^3 H_{\mathrm{cm}}}T, & T > \frac{\hbar v}{a}, \\ \beta\frac{m^2aB}{\hbar^4 H_{\mathrm{cm}}}T^2, & T < \frac{\hbar v}{a}. \end{cases} \tag{20.81}$$

Experimental measurements of the heat capacity of superconductors in the intermediate state (Zavaritskii 1965) have confirmed formulae (20.81).

8.7 21 Superconductivity and magnetism

8.7.1 21.1. Superconductors containing magnetic impurities. Gapless superconductivity

As has been pointed out in section 16.9, impurities in a small concentration exert only a slight effect on the thermodynamic properties of superconductors. The variation of these

properties is of the relative order of $a/l \sim c_\mathrm{i}$, where a is the atomic dimension, l is the mean free path, and c_i the atomic concentration. The behavior of the magnetic impurities described in sections 4.6 and 13.7 is completely different. The action of these impurities is measured by the quantity ξ/l_s, where l_s is the mean free path relative to the spin flip associated with these impurities. The same may be written in the form $\hbar/(\tau_\mathrm{s}T_\mathrm{c})$, where $\tau_\mathrm{s} = l_\mathrm{s}/v$ is the corresponding mean free time. This is associated with the completely different action of ordinary nonmagnetic (potential) impurities and magnetic atoms on Cooper pairs.

Usually, impurities act only on the electric charge and, hence, scatter both electrons of a Cooper pair identically, and this does not lead to its collapse. As for magnetic impurities, they are capable of flipping the electron spin. Hence, upon scattering from such an impurity the pair can pass to a state with parallel spins (triplet state), where the Pauli principle requires that the electrons comprising the pair be not at a single point and be described by an antisymmetric coordinate wave function. The pair is thus broken up.

It has been shown in section 4.6 that to first order the probability of scattering of an electron from a magnetic impurity is proportional to $(J/n)^2 S(S+1)$. This quantity replaces $|V_{p'p}|^2$ in the probability of scattering from an ordinary impurity. In fact, the interaction of an electron with each impurity contains both the potential part (V) and the exchange part ($-(J/n)(\sigma S)$); the former is, as a rule, larger than the latter; however, in the effect of interest to us the potential part does not play a role and will be neglected here. The scattering time associated only with the exchange interaction will be denoted as τ_s.

The theory that provides an accurate description of the action of magnetic impurities (Abrikosov and Gor'kov 1960a) is based on the application of the methods of quantum field theory and it is too complicated to be described here. Therefore, we shall make an attempt to present the basic features of such objects with the aid of simple reasonings.

We begin with the critical temperature. The general formula for the dependence $\Delta(T)$ for pure superconductors is given in section 16.5 (formula 16.23). It may be rewritten in a different form by using the property of the hyperbolic tangent

$$\tanh\left(\frac{1}{2}\pi x\right) = \frac{4x}{\pi}\sum_{k=1}^{\infty}\frac{1}{(2k-1)^2+x^2} \tag{21.1}$$

On the basis of this formula we obtain from eq. (16.23):

$$1 = 2g\nu(\mu)T\sum_{\omega_k=\pi T}^{\hbar\omega_\mathrm{D}}\int_0^\infty \frac{\mathrm{d}\xi}{\omega_k^2+\xi^2+\Delta^2}, \tag{21.2}$$

where $\omega_k = \pi T(2k-1)$. Here we have transferred the summation in finite limits to ω_k, which will be convenient in what follows and, strictly speaking, is more correct than the limitation on ξ.

If the integrand is treated formally, it has imaginary poles at $\omega_k = \pm\mathrm{i}\left(\xi^2+\Delta^2\right)^{1/2} = \pm\mathrm{i}\varepsilon$. The possibility of the breakup of pairs under the action of magnetic impurities leads to a finite lifetime. This point has already been discussed in section 2.2. The wave function of the state $\exp(-\mathrm{i}\xi t/\hbar)$ takes on a damping factor $\exp(-\gamma t/\hbar)$. This may be interpreted as if the energy of quasiparticles acquires an imaginary correction $-\mathrm{i}\gamma$. In view of this, it becomes clear why in the exact theory ω_k is replaced by $\omega_k + \hbar\tau_\mathrm{s}^{-1}$ in expression (21.2). In fact, the new integrand has poles at points $\omega_k = \pm\mathrm{i}\left(\varepsilon \pm \mathrm{i}\hbar\tau_\mathrm{s}^{-1}\right)$.

In order to obtain $\boldsymbol{T}_\mathrm{c}$, we put $\boldsymbol{\Delta} = \mathbf{0}$. So, we have

$$1 = 2g\nu T\sum_{\omega_k=\pi T}^{\hbar\omega_0}\int_0^\infty \frac{\mathrm{d}\xi}{\left(\omega_k+\hbar\tau_\mathrm{s}^{-1}\right)^2+\xi^2}$$

The integral over $\boldsymbol{\xi}$ gives

$$1 = g\nu\pi T \sum_{\omega_k=\pi T}^{\hbar\omega_\mathrm{D}} \frac{1}{\omega_k + \hbar\tau_\mathrm{s}^{-1}} = g\nu \sum_{k=1}^{\hbar\omega_\mathrm{D}/2\pi T} \frac{1}{2k-1+\rho},$$

where we have substituted $\omega_k = \pi T(2k-1)$ and introduced the dimensionless parameter $\rho = \hbar/(\tau_\mathrm{s}\pi T)$.

We subtract and add to the last sum a similar sum with $\rho = 0$. The difference rapidly converges, and therefore the limit of the sum over k may be extended to infinity. Substituting the value of the sum of $(2k-1)^{-1}$, we have

$$\begin{aligned} 1 =& \frac{1}{2} g\nu \ln\left(\frac{2\gamma\omega_\mathrm{D}\hbar}{\pi T_\mathrm{c}}\right) \\ &+ g\nu \sum_{k=1}^{\infty} \left(\frac{1}{2k-1+\rho} - \frac{1}{2k-1}\right), \quad \gamma = 1.78 \end{aligned}$$

Let us use the following property of the Γ-functions:

$$\psi(x) - \psi(y) = \sum_{k=0}^{\infty} \left(\frac{1}{y+k} - \frac{1}{x+k}\right), \tag{21.3}$$

where $\psi(x) = \Gamma'(x)/\Gamma(x)$ is the logarithmic derivative of the Γ-function; the latter is determined as follows: $\Gamma(n) = (n-1)\,!$ for integer values of $x = n$, and for noninteger values we have

$$\Gamma(x) = \int_0^\infty \mathrm{e}^{-t} t^{x-1}\, \mathrm{d}t \tag{21.4}$$

Dividing by $\frac{1}{2}g\nu$, rearranging the terms and using formula (16.25), we obtain

$$\ln\left(\frac{T_{\mathrm{c}0}}{T_\mathrm{c}}\right) = \psi\left(\frac{1}{2} + \frac{1}{2}\rho\right) - \psi\left(\frac{1}{2}\right), \tag{21.5}$$

where $T_{\mathrm{c}0}$ is the critical temperature of a pure superconductor. This formula is exact and holds for any $\rho = \hbar/(\pi T_\mathrm{c}\tau_\mathrm{s})$. As for τ_s itself, from the foregoing it is clear that τ_s^{-1} is proportional to $\pi\nu(\mu)(J/n)^2 S(S+1)n_\mathrm{m}$ and the exact value of the quantity appearing in eq. (21.5) is

$$\frac{\hbar}{\tau_\mathrm{s}^{-1}} = \frac{7}{24}\pi\nu(\mu)\frac{J}{n}S(S+1)n_\mathrm{m}, \tag{21.6}$$

where n_m is the concentration of magnetic atoms.

Let us now consider the asymptotic values of formula (21.5). At $\rho < 1$ we use the following expansion:

$$\psi\left(\frac{1}{2} + \frac{1}{2}\rho\right) \approx \psi\left(\frac{1}{2}\right) + \frac{1}{2}\psi'\left(\frac{1}{2}\right)\rho = \psi\left(\frac{1}{2}\right) + \frac{1}{4}\pi^2\rho.$$

Expanding $\ln(T_{\mathrm{c}0}/T_\mathrm{c}) \approx (T_{\mathrm{c}0} - T_\mathrm{c})/T_{\mathrm{c}0}$, we obtain

$$T_\mathrm{c} \approx T_{\mathrm{c}0} - \frac{\pi\hbar}{4\tau_\mathrm{s}}. \tag{21.7}$$

From this we see that, in contrast to ordinary impurities, magnetic impurities lower T_c significantly.

Obviously, at $\hbar\tau_s^{-1} \sim T_{c0}$ the superconductivity must disappear altogether, i.e., T_c must vanish. In the vicinity of this point in formula (21.5) $\rho \gg 1$. Consider the corresponding asymptotics. At large x

$$\psi(x) \approx \ln x - \frac{1}{2x} - \frac{1}{12x^2}$$

and $\psi\left(\frac{1}{2}\right) = -\ln(4\gamma)$. Expanding in ρ^{-1}, we have

$$\ln\left(\frac{T_{co}\pi\tau_s}{2\gamma\hbar}\right) \approx \frac{1}{6}\left(\frac{\pi T_c\tau_s}{\hbar}\right)^2. \tag{21.8}$$

From this it follows that the critical concentration at which $T_c = 0$ corresponds to

$$\frac{\hbar}{\tau_{sc}^{-1}} = \frac{\pi T_{co}}{2\gamma}. \tag{21.9}$$

In the vicinity of the critical concentration the critical temperature is given by

$$T_c \approx \sqrt{6}\frac{\hbar}{\pi}\frac{(\tau_s - \tau_{sc})^{1/2}}{\tau_{sc}^{3/2}} \tag{21.10}$$

A further fundamental consequence of the presence of magnetic impurities is gapless superconductivity. The point is that magnetic impurities not only reduce the binding energy of Cooper pairs but, as exact calculations show (Abrikosov and Gor'kov 1960a), the result is that not all pairs have the same binding energy. In this sense, the situation is similar to a weakly nonideal Bose gas (see, for example, Abrikosov et al. 1962). Whereas in an ideal Bose gas at $T = 0$ all the particles are present in the condensate, i.e., have $\boldsymbol{p}$ and ε equal to zero and are described by a coherent wave function $\Psi = \text{const.}$, in a nonideal gas at $T = 0$ only a certain part of the particles are present in the condensate, and the remaining particles have an energy and momentum different from zero. However, in this case too the order parameter is the coherent wave function of the condensate particle.

In superconductors containing magnetic impurities the situation is the same. The Bose condensate of Cooper pairs does not contain all the pairs: some of these have smaller binding energies. Evidently, for such pairs to be broken up it is necessary to consume a smaller energy than that required for the collapse of the pairs present in the condensate. Up until now the quantity Δ alone has described both the number of pairs in the condensate and the binding energy. However, in application to superconductors with magnetic impurities this statement becomes invalid. Whereas one quantity described the order parameter (we still denote it as Δ), i.e., the wave function of the condensate, a completely different quantity characterizes the minimum binding energy of the pairs or the energy gap, which manifests itself in the low-temperature heat capacity, thermal conductivity, absorption of electromagnetic radiation and ultrasound, etc.

It is exactly the order parameter that determines the basic specific features of superconductors: the Meissner effect and the absence of electrical resistance. As long as Δ is finite all these properties are operative. At the same time, the energy gap may vanish; this is actually observed in superconductors containing magnetic impurities in a given concentration range (n_{mc} corresponds to τ_{sc} according to formulas 21.9 and 21.6):

$$0.91 n_{mc} < n_m < n_{mc}.$$

A natural question may arise: How does this agree with the Landau criterion? According to this criterion superconductivity is impossible in the absence of a gap in the energy spectrum. However, the Landau criterion has been deduced for pure systems, in which spatial homogeneity

exists and the momentum is conserved. For systems containing impurities this criterion cannot be applied.

We give here, without derivation, the formula for the energy gap,

$$\hbar\omega_0 = \left[\Delta_0^{2/3} - \left(\frac{\hbar}{\tau_\mathrm{s}}\right)^{2/3}\right]^{3/2} \tag{21.11}$$

In the vicinity of the critical concentration the critical temperature is given by

$$T_\mathrm{c} \approx \sqrt{6}\frac{\hbar}{\pi}\frac{(\tau_\mathrm{s} - \tau_\mathrm{sc})^{1/2}}{\tau_\mathrm{sc}^{3/2}}. \tag{21.10}$$

A further fundamental consequence of the presence of magnetic impurities is gapless superconductivity. The point is that magnetic impurities not only reduce the binding energy of Cooper pairs but, as exact calculations show (Abrikosov and Gor'kov 1960a), the result is that not all pairs have the same binding energy. In this sense, the situation is similar to a weakly nonideal Bose gas (see, for example, Abrikosov et al. 1962). Whereas in an ideal Bose gas at $T = 0$ all the particles are present in the condensate, i.e., have $\boldsymbol{p}$ and ε equal to zero and are described by a coherent wave function $\Psi = \mathrm{const.}$, in a nonideal gas at $T = 0$ only a certain part of the particles are present in the condensate, and the remaining particles have an energy and momentum different from zero. However, in this case too the order parameter is the coherent wave function of the condensate particle.

In superconductors containing magnetic impurities the situation is the same. The Bose condensate of Cooper pairs does not contain all the pairs: some of these have smaller binding energies. Evidently, for such pairs to be broken up it is necessary to consume a smaller energy than that required for the collapse of the pairs present in the condensate. Up until now the quantity Δ alone has described both the number of pairs in the condensate and the binding energy. However, in application to superconductors with magnetic impurities this statement becomes invalid. Whereas one quantity described the order parameter (we still denote it as Δ), i.e., the wave function of the condensate, a completely different quantity characterizes the minimum binding energy of the pairs or the energy gap, which manifests itself in the low-temperature heat capacity, thermal conductivity, absorption of electromagnetic radiation and ultrasound, etc.

It is exactly the order parameter that determines the basic specific features of superconductors: the Meissner effect and the absence of electrical resistance. As long as Δ is finite all these properties are operative. At the same time, the energy gap may vanish; this is actually observed in superconductors containing magnetic impurities in a given concentration range (n_mc corresponds to τ_sc according to formulas 21.9 and 21.6):

$$0.91 n_\mathrm{mc} < n_\mathrm{m} < n_\mathrm{mc}.$$

A natural question may arise: How does this agree with the Landau criterion? According to this criterion superconductivity is impossible in the absence of a gap in the energy spectrum. However, the Landau criterion has been deduced for pure systems, in which spatial homogeneity exists and the momentum is conserved. For systems containing impurities this criterion cannot be applied.

We give here, without derivation, the formula for the energy gap,

$$\hbar\omega_0 = \left[\Delta_0^{2/3} - \left(\frac{\hbar}{\tau_\mathrm{s}}\right)^{2/3}\right]^{3/2} \tag{21.11}$$

and the formula for the electronic heat capacity in the gapless region:

$$C = \frac{1}{3}\pi^2\nu(\mu)\left[1 - \left(\frac{\tau_s\Delta_0}{\hbar}\right)^2\right]^{1/2} T, \tag{21.12}$$

where Δ_0 is the order parameter at $T = 0$, which depends in a complicated way on τ_s. At the boundary of the gapless region $\Delta_0(\tau_s) = \hbar/\tau_s$.

The disappearance of the gap can conveniently be traced out from the density of states. For a normal metal $\nu_n = p_0 m/(\pi^2\hbar^3) = \text{const}$. For a pure superconductor

$$\nu(\varepsilon) = \frac{1}{\pi^2\hbar^3} p_0 m \frac{d\xi}{d\varepsilon} = \nu_n \varepsilon \left(\varepsilon^2 - \Delta^2\right)^{-1/2}$$

at $\varepsilon > \Delta$ and 0 at $\varepsilon < \Delta$. Note that $\nu(\varepsilon)$ has a square root singularity for $\varepsilon \to \Delta$. The density of states $\nu(\varepsilon)$ is given in fig. 137 at various values of τ_s. The ordinate represents $\nu(\varepsilon)/\nu_n$ and the abscissa represents $\varepsilon/\Delta_0(\tau_s)$. The curves are labeled with the corresponding values of

$$\hbar/\tau_s\Delta_0.$$

It should be noted that magnetic impurities do not provide the only pair-breaking mechanism. It was later found that the same effect is exhibited by any perturbations giving rise to terms in the Hamiltonian that are noninvariant under change of the sign of time (see Maki 1969).

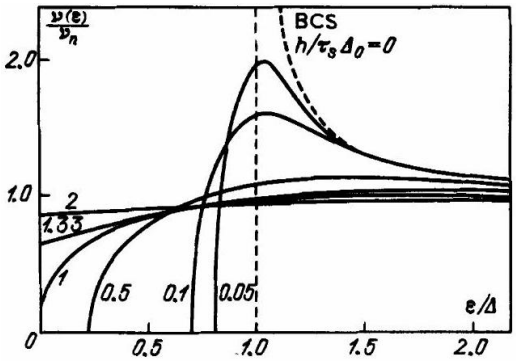

Fig. 137.

Cooper pairs constitute a superposition of the states of electrons with opposite momenta and spins. These states result from one another by inversion of the sign of time (the momentum and spin change sign with $t \to -t$). A perturbation which is noninvariant under the change of the sign of time acts differently on the electrons contained in a Cooper pair and, as it were, pulls it apart.

An example is an external magnetic field. Of course, the field does not penetrate a bulk superconductor, and therefore we assume that we are dealing here with a
thin film with a thickness smaller than δ and ξ. The main perturbation from the magnetic field is $-(e/mc)pA$. The wave function of the electron is proportional to $\exp(-i\varepsilon t/\hbar)$. From this we see that in the presence of a magnetic field between the electrons that form a pair, i.e., have momenta p and $-p$, there arises a phase difference, which varies with time according to the law

$$\frac{d\theta}{dt} = \frac{2e}{\hbar c} vA, \qquad \text{with} \qquad v = p_0/m. \tag{21.13}$$

However, the electrons are scattered by impurities or at the boundaries of the sample. Therefore, they execute a Brownian diffusive motion with, according to sections 3.5 and 5.5,

$$\overline{x^2} \sim Dt \sim lvt \sim v^2 t\tau_{\rm tr},$$

where $D \sim lv \sim v^2\tau_{\rm tr}$ is the diffusion coefficient. This relation may be extended to any quantity: the mean square of the sought-for quantity is of the order of the square of the instantaneous rate of its change multiplied by $t\tau_{\rm tr}$. In our case,

$$\overline{\theta^2} \sim \left(\frac{{\rm d}\theta}{{\rm d}t}\right)^2 t\tau_{\rm tr}.$$

Hence, for θ to be of the order of 2π, a time τ_H is needed, with

$$\frac{1}{\tau_{\rm H}} \sim \left(\frac{{\rm d}\theta}{{\rm d}t}\right)^2 \tau_{\rm tr},$$

where $({\rm d}\theta/{\rm d}t)^2$ is the mean square value of eq. (21.13). Thus, we have ($A \sim Hd$)

$$\frac{1}{\tau_{\rm H}} \sim v^2\tau_{\rm tr}\left(\frac{e}{\hbar c}\right)^2 H^2 d^2 \sim D\left(\frac{e}{\hbar c}\right)^2 H^2 d^2. \tag{21.14}$$

Other examples could also be given, namely the mixed state in a bulk type II superconductor and in a film in a perpendicular magnetic field, small particles, etc. It can be shown (see Maki 1969) that all the formulas derived for magnetic impurities remain to be valid for all pair-breaking mechanisms. Only the physical meaning of the constant ρ is changed.

8.7.2 21.2. The inhomogeneous superconducting state

In the preceding section we have said that magnetic impurities destroy superconductivity. The situation is even worse in a case where there is ferromagnetic ordering. In such a case, the number of electrons with different orientations of the spin is different, which means that the corresponding Fermi surfaces are also different. If ferromagnetism is strong, i.e., the Curie temperature is of the order of hundreds of degrees, as is the case with ordinary ferromagnets based on transition metals, superconductivity is impossible.

However, with rare-earth metals or actinides the situation may be different. The magnetism of such atoms is associated with the unfilled 4 f and 5 f shells. These are inner shells with a small radius. In neighboring atoms they practically do not overlap. In view of this, the exchange interaction of the spins is realized by way of an indirect exchange through conduction electrons. In other words, one may proceed from the picture of localized spins which interact with conduction electrons by the mechanism discussed in section 4.1.

In the next section we shall consider in more detail the interaction between two localized spins, which is transmitted by conduction electrons (RKKY). Of importance at this point is only the circumstance that the resultant magnetism is "weak" with a Curie temperature of the order of a few degrees. It is for this reason that the question arises as to the mutual effect of ferromagnetism and superconductivity.

Two extreme situations may be encountered. If the Curie temperature of the ferromagnetic transition θ is somewhat higher than the critical temperature of the superconducting transition $T_{\rm c}$ (not much higher), superconductivity may arise against the background of existing ferromagnetism. But if the temperature of the superconducting transition is higher than the Curie temperature, ferromagnetism arises against the background of superconductivity. It is possible that the phases that will be considered in this and subsequent sections do not cover the entire variety of existing possibilities, but they give an idea of the specific features of the mutual effect of such antagonistic phenomena, as ferromagnetism and superconductivity.

We begin with the case where superconductivity appears against the background of ferromagnetism. Instead of eq. (16.13), we write the Hamiltonian

$$\mathscr{H} - \mu N = \sum_{p,\sigma} (\xi_p - \sigma_z I)\, a^+_{p,\sigma} a_{p,\sigma} - g \sum a^+_{p'_1,+} a^+_{p'_2,-} - a_{p_2,-} a_{p_1,+}, \tag{21.15}$$

where I is the self-consistent "molecular field", under the action of which the electron energy begins to depend on the projection spins ($\sigma_z = \pm 1$). Further, we introduce the operators $\alpha_{p,+}$ and $\alpha_{p,-}$ in accordance with formulas (16.14) and repeat the entire derivation given in section 16.4 taking account of the altered Hamiltonian. In such a case we obtain the same formulas for the coefficients u and v and formula (16.21) for Δ, but the energies included in the Fermi distributions $n_{p,+}$ and $n_{p,-}$ have the form

$$\varepsilon_{p,+} = \varepsilon_p - I, \quad \varepsilon_{p,-} = \varepsilon_p + I,$$

as before,

$$\varepsilon_p = \left(\xi_p^2 + \Delta^2\right)^{1/2}.$$

Let us consider only the case $T = 0$. Since $\varepsilon_p > 0$, it follows that $n_{p,-} = 0$. Therefore, the sum over p in (16.21) is bounded from below by the condition $\varepsilon_{p,+} > 0$ or $\varepsilon_p > I$. Two cases are possible. If $\Delta > I$, the condition $\varepsilon_{p,+} > I$ does not impose restrictions on the domain of integration over p and we obtain $\Delta = \Delta_0$. But if $\Delta < I$, then, passing
to the integral, we have

$$\frac{2}{g\nu} = \ln \frac{2\hbar\omega_{\mathrm{D}}}{\Delta_0} = \int_{(I^2-\Delta^2)^{1/2}}^{\hbar\omega_{\mathrm{D}}} \frac{\mathrm{d}\xi}{\varepsilon} = \ln \frac{2\hbar\omega_{\mathrm{D}}}{I + (I^2 - \Delta^2)^{1/2}}. \tag{21.16}$$

From this we see that $I + (I^2 - \Delta^2)^{1/2} = \Delta_0$ or

$$\Delta = \left[\Delta_0 (2I - \Delta_0)\right]^{1/2}. \tag{21.17}$$

Thus, we obtain two branches of the solution of eq. (21.16), which are shown in fig. 138. However, the nonzero solution for Δ implies only the local minimum of the free energy; this may correspond to a metastable rather than to the equilibrium state. In order to find out whether the transition to the superconducting state really occurs, we must find the free-energy difference $\Omega_{\mathrm{s}} - \Omega_{\mathrm{n}}$. For this purpose we use formula (16.38).

In the region where $\Delta_1 > I$ we have, as before,

$$\frac{\partial g^{-1}(\Delta_1)}{\partial \Delta_1} = -\frac{\nu}{2\Delta_1}. \tag{21.18}$$

In the region where $\Delta_1 < I$ we obtain from (21.16)

$$\begin{aligned} \frac{\partial g^{-1}(\Delta_1)}{\partial \Delta_1} &= \frac{1}{2}\nu \frac{\Delta_1}{I + (I^2 - \Delta_1^2)^{1/2}} \frac{1}{(I^2 - \Delta_1^2)^{1/2}} \\ &= \frac{\nu}{2\Delta_1} \frac{\left[I - (I^2 - \Delta_1^2)^{1/2}\right]}{(I^2 - \Delta_1^2)^{1/2}} \end{aligned} \tag{21.19}$$

On the lower branch of fig. 138, formula (21.19) holds for all Δ_1; substituting it into (16.38), we find

$$\begin{aligned} \Omega_{\mathrm{s}} - \Omega_{\mathrm{n}} &= \frac{1}{4}\nu \left[I - \left(I^2 - \Delta^2\right)^{1/2}\right]^2 \\ &= \frac{1}{4}\nu (2I - \Delta_0)^2 \end{aligned} \tag{21.20}$$

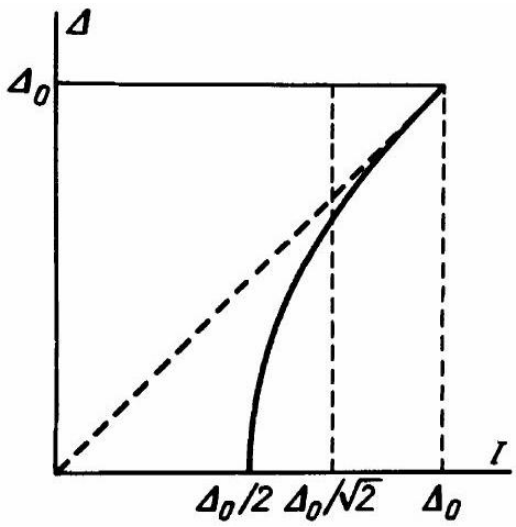

Fig. 138.

to the integral, we have

$$\frac{2}{g\nu} = \ln\frac{2\hbar\omega_{\mathrm{D}}}{\Delta_0} = \int_{(I^2-\Delta^2)^{1/2}}^{\hbar\omega_{\mathrm{D}}} \frac{\mathrm{d}\xi}{\varepsilon} = \ln\frac{2\hbar\omega_{\mathrm{D}}}{I+(I^2-\Delta^2)^{1/2}}. \tag{21.16}$$

From this we see that $I + (I^2 - \Delta^2)^{1/2} = \Delta_0$ or

$$\Delta = \left[\Delta_0\,(2I - \Delta_0)\right]^{1/2}. \tag{21.17}$$

Thus, we obtain two branches of the solution of eq. (21.16), which are shown in fig. 138. However, the nonzero solution for Δ implies only the local minimum of the free energy; this may correspond to a metastable rather than to the equilibrium state. In order to find out whether the transition to the superconducting state really occurs, we must find the free-energy difference $\Omega_{\mathrm{s}} - \Omega_{\mathrm{n}}$. For this purpose we use formula (16.38).

In the region where $\Delta_1 > I$ we have, as before,

$$\frac{\partial g^{-1}(\Delta_1)}{\partial\Delta_1} = -\frac{\nu}{2\Delta_1}. \tag{21.18}$$

In the region where $\Delta_1 < I$ we obtain from (21.16)

$$\begin{aligned}\frac{\partial g^{-1}(\Delta_1)}{\partial\Delta_1} &= \frac{1}{2}\nu\frac{\Delta_1}{I+(I^2-\Delta_1^2)^{1/2}}\frac{1}{(I^2-\Delta_1^2)^{1/2}}\\ &= \frac{\nu}{2\Delta_1}\frac{\left[I-(I^2-\Delta_1^2)^{1/2}\right]}{(I^2-\Delta_1^2)^{1/2}}\end{aligned} \tag{21.19}$$

On the lower branch of fig. 138, formula (21.19) holds for all Δ_1; substituting it into (16.38), we find

$$\begin{aligned}\Omega_{\mathrm{s}} - \Omega_{\mathrm{n}} &= \frac{1}{4}\nu\left[I - \left(I^2-\Delta^2\right)^{1/2}\right]^2\\ &= \frac{1}{4}\nu\,(2I-\Delta_0)^2,\end{aligned} \tag{21.20}$$

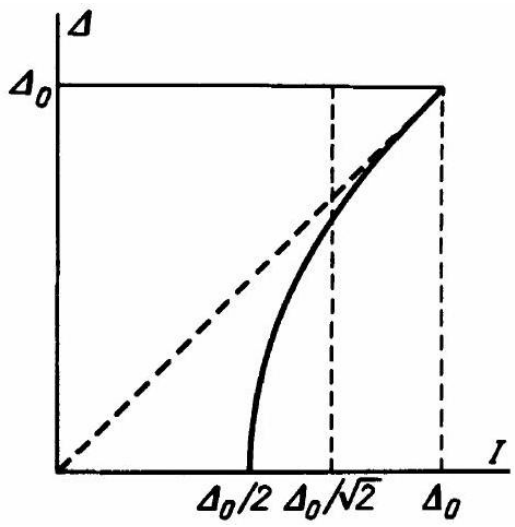

Fig. 138.

where we have substituted (21.17) and have taken into account that $I < \Delta_0$. So, in this case $\Omega_s - \Omega_n > 0$, i.e., the superconducting transition does not occur.

On the upper branch of fig. 132, $\Delta = \Delta_0 > I$. Therefore, there are two domains of integration: $\Delta_1 < I$ and $\Delta_1 > I$. Inserting formulas (21.18) and (21.19) into (16.38), we obtain

$$\Omega_s - \Omega_n = \frac{1}{4}\nu\left(2I^2 - \Delta_0^2\right), \tag{21.21}$$

from which follows that the upper branch in fig. 138, i.e. $\Delta = \Delta_0$, corresponds to equilibrium superconductivity at

$$I < \frac{\Delta_0}{\sqrt{2}} = 0.707\Delta_0. \tag{21.22}$$

Thus, in the model under discussion, as I increases at the point $I = \Delta_0/\sqrt{2}$ a first-order phase transition occurs from the superconducting phase with $\Delta = \Delta_0$ to the normal phase with $\Delta = 0$. The remaining portions of the solid curves in fig. 138 correspond to the metastable phases.

However, a more detailed investigation shows that the real situation is more complicated. In the preceding treatment we were concerned only with the possibility of the appearance of superconductivity with $\Delta = \text{const}$. It turns out that at values of I larger than the critical value (21.22) there may appear a superconducting phase with an inhomogeneous order parameter $\Delta(r)$ by way of a second-order phase transition (Larkin and Ovchinnikov 1964, Fulde and Ferrell 1964). This new phase is sometimes called the LOFF phase.

In order to demonstrate this transition, we make use of the fact that near the transition point, Δ is small and the equation for Δ will necessarily be linear. This will permit us to use a Fourier expansion and raise the question of the generation of a single Fourier harmonic, i.e.

$$\Delta(r) = \Delta \exp(\mathrm{i}qr/\hbar). \tag{21.23}$$

If we recall that $\Delta(r)$ plays the role of the coherent wave function of the condensate of Cooper pairs, then formula (21.23) corresponds to the moving condensate, in which the pairs have a momentum $\boldsymbol{q}$, i.e., the velocity $\boldsymbol{v}_s = \boldsymbol{q}/2\boldsymbol{m}$.

The problem of the moving condensate has been considered in section 19.2. We substitute formulae (19.19)-(19.21) into the equation for Δ derived in section 19.2, following which we make the transformation of the momentum variable $p \to p + \frac{1}{2}q$ and use formulas (19.24).

Taking into account that for quasiparticles with spin $+\frac{1}{2}$ the energy contains a term with $-I$, and in the opposite case a term with $+I$, we finally obtain

$$1 = \frac{1}{2} g \sum_p \frac{1 - n_+ - n_-}{\varepsilon}, \tag{21.24}$$

where $n_+$and $n_-$are the equilibrium Fermi functions with energies given by

$$\varepsilon_+ = \varepsilon + \frac{1}{2} vqx - I, \quad \varepsilon_- = \varepsilon - \frac{1}{2} vqx + I, \tag{21.25}$$

where $\varepsilon = (\xi^2 + \Delta^2)^{1/2}$ and $x = \cos(p, q)$. We assumed that $vq > 2I$ (this is confirmed by subsequent calculations). Since we are interested in the transition region, we assume that $\Delta < I$. Just as before, we set $T = 0$.

The integral on the right-hand side of eq. (21.24) is different from zero if $n_+ = n_- = 1$, i.e. $\varepsilon_+, \varepsilon_- < 0$, or $n_+ = n_- = 0$, i.e., $\varepsilon_+, \varepsilon_- > 0$; the latter condition, which gives $2(I + \varepsilon)/vq > x > 2(I - \varepsilon)/vq$, is realized. Taking into account that x varies in the region $-1 \leqslant x \leqslant 1$, and $0 < |\xi| \leqslant \hbar\omega_D$, we obtain from (21.24):

$$\begin{aligned}
\frac{2}{g\nu} &= \ln \frac{2\hbar\omega_{\mathrm{D}}}{\Delta_0} + \frac{1}{2} \ln \frac{2\hbar\omega_{\mathrm{D}}}{\frac{1}{2}vq - I + \left[\left(\frac{1}{2}vq - I\right)^2 - \Delta^2\right]^{1/2}} \\
&+ \frac{1}{2} \ln \frac{2\hbar\omega_{\mathrm{D}}}{\frac{1}{2}vq + I + \left[\left(\frac{1}{2}vq + I\right)^2 - \Delta^2\right]^{1/2}} \\
&- \frac{I}{vq} \ln \frac{1}{\frac{1}{2}vq + I + \left[\left(\frac{1}{2}vq + I\right)^2 - \Delta^2\right]^{1/2}} \\
&+ \frac{1}{vq} \left\{ \left[\left(\frac{1}{2}vq - I\right)^2 - \Delta^2\right]^{1/2} + \left[\left(\frac{1}{2}vq - I\right)^2 - \Delta^2\right]^{1/2} \right\}
\end{aligned} \tag{21.26}$$

Transposing terms and introducing new variables $z = I/\Delta_0, y = vq/2I$ and $s = \Delta/I$, we see that

$$\begin{aligned}
\ln(1/z) = &\Big\{ (y-1) \ln \left[y - 1 + \left((y-1)^2 - s^2\right)^{1/2} \right] \\
&+ (y+1) \ln \left[y + 1 + \left((y+1)^2 - s^2\right)^{1/2} \right] \Big\} (2y)^{-1} \\
&+ \left\{ \left((y-1)^2 - s^2\right)^{1/2} + \left((y+1)^2 - s^2\right)^{1/2} \right\} (2y)^{-1}
\end{aligned} \tag{21.27}$$

At the transition point $s = 0$, so we have

$$\ln(1/z) + 1 - \ln 2 = [(y-1)\ln(y-1) + (y+1)\ln(y+1)](2y)^{-1}. \tag{21.28}$$

The right-hand side has the asymptotics of $\ln y$ with $y \to \infty$ and $-(y-1)\ln[1/(y-1)]$ with $y \to 1$. From this it can be seen that at a certain y it has a minimum. Evidently, it has a corresponding maximum value of $z = I/\Delta_0$ at which $\Delta \neq 0$ appears for the first time. If the minimum of the right-hand side is found numerically, we obtain $y_{\mathrm{c}} = 1.19$ and $z_{\mathrm{c}} = 0.754$. Thus, it turns out that $\Delta \neq 0$ appears for the first time at

$$I_c = 0.754\Delta_0, \tag{21.29}$$

$$(vq)_c = 2.38 I_c. \tag{21.30}$$

The quantity $\boldsymbol{I_c}$ is larger than the values obtained earlier, (eq. 21.22), for an immobile condensate at rest (i.e. $\Delta(r) = \text{const.}$).

Now we have to check whether the appearance of a finite Δ corresponds to a decrease in free energy. Here, however, we should make a remark. When we were concerned with the problem of solving the equation for Δ in the limit $\Delta \to 0$, we could use the linearity of this equation and consider a single Fourier harmonic. We found out that a harmonic with a definite $q_c = 2.38 I/v$ appears for the first time.

But the isotropy and linearity of the problem implies that any linear combination of harmonics with different q equal in magnitude to q_c may also appear equally well.

The question of the choice of a particular combination is solved by comparing their free energies, where Δ is expressed as a function of $I_c - I$. However, this requires the solution of a nonlinear problem, for which the method used here is inapplicable. Of course, we can generalize the Bogoliubov transformation, just as has been done in the literature (De Gennes 1966). However, we shall not give the cumbersome calculations here; we shall only show that even in the simplest case of a single Fourier harmonic, which has been considered above, the free energy decreases as a result of superconducting pairing. We also note that a detailed analysis of the problem of the most favorable structure of $\Delta(r)$ has not yet been carried out, which to a certain extent is accounted for by the lack of experimental observations of the LOFF phase.

Thus, we are to find the free energy. Using formula (21.26), we obtain

$$\begin{aligned} \frac{\partial g^{-1}}{\partial \Delta} = \frac{\nu}{2\Delta} \Bigg\{ -1 + \frac{1}{vq} \left[\left(\tfrac{1}{2} vq - I \right)^2 - \Delta^2 \right]^{1/2} \\ + \frac{1}{vq} \left[\left(\tfrac{1}{2} vq + I \right)^2 - \Delta^2 \right]^{1/2} \Bigg\}. \end{aligned} \tag{21.31}$$

Expanding in Δ and substituting into (16.38) lead to

$$\Omega_s - \Omega_n = -\frac{\omega \Delta^4}{16 I_c^2 \left(y_c^2 - 1 \right)}. \tag{21.32}$$

In order to express Δ in terms of $I_c - I$, we expand eq. (21.27) in $s = \Delta / I$. The result is

$$\frac{I_c - I}{I_c} = \frac{1}{4 \left(y_c^2 - 1 \right)} \left(\frac{\Delta}{I_c} \right)^2.$$

Substituting $y_c = 1.19$, we find

$$\Delta \approx 1.3 \left[\left(I_c - I \right) I_c \right]^{1/2}. \tag{21.33}$$

Using this value and $I_c = 0.754\Delta_0$, we obtain

$$\Omega_s - \Omega_n = -0.42 \nu \left(I_c - I \right)^2. \tag{21.34}$$

Thus, as a result of the formation of an inhomogeneous superconducting condensate, the free energy is really lowered.

As has been said above, the structure considered is only the simplest example. As a matter of fact, one should expect the generation of a three-dimensional structure (for example, with a set of $\boldsymbol{q}$ directed along the principal axes of the tetrahedron) with periods of the order of $\hbar v / \Delta_0 \sim \xi(0)$. The possibility is not excluded that in such a case $\Delta(r) = 0$ at certain points, i.e.,

the superconductivity will appear to be gapless. This will lead to a non-exponential temperature dependence of the heat capacity. For instance, $C \propto \ln^{-3}(\Delta/T)$ for $\Delta(r) \propto \cos(qr/\hbar)$ (Larkin and Ovchinnikov 1964).

Since under actual conditions it is difficult to avoid the generation of structural defects, the question arises as to the stability of the inhomogeneous superconducting phase towards defects. Analysis shows (Aslamazov and Larkin 1968) that, in principle, the LOFF phase persists in the presence of any defect concentration, i.e., the free energy decreases with the appearance of $\Delta(r)$. However, the corresponding value of I_c decreases with defect concentration, and at a concentration corresponding to the mean free path $l < \xi(0), I_c$ becomes less than the value determined by formula (21.22). Here the equilibrium phase will be the homogeneous superconducting phase with $\Delta = \Delta_0$; it is formed by way of a transition of first order in I. The quantity I_c in this case plays the role of the supercooling limit for the normal phase. When I_c further decreases, the inhomogeneous superconductivity of the LOFF phase may appear as a metastable phase.

The LOFF phase has so far not been observed experimentally and it would be rather difficult to create the necessary conditions (see section 21.3).

8.7.3 21.3. Ferromagnetic superconductors

Let us now consider another possibility, namely the case $\theta < T_c$ (θ is the Curie temperature), where ferromagnetism appears against the background of superconductivity (see the review article by Bulaevskii et al. 1985). This situation occurs, for example, in the compounds $HoMo_6\ S_8$ and $ErRh_4\ B_4$. In compounds of this type, as the temperature decreases a superconducting transition occurs first (at temperature T_{c1}).

As the temperature decreases further, a magnetic transition arises against the superconductivity background, which leads to a very peculiar lamellar or domain magnetic structure, in which the magnetization in neighboring layers has an opposite direction (temperature T_M). Since the superconducting current screens off the magnetic field, this magnetic structure can be recognized only with the aid of neutron diffraction. Neutrons, which have a magnetic moment, "feel" the magnetic structure and are diffracted on it, just as light on a diffraction grid or X-radiation in a crystal.

Finally, when the temperature continues to decrease, a first-order phase transition to a non-superconducting ferromagnetic state (temperature T_{c2}) occurs. The values of these temperatures are $T_{c1} = 1.8$ K, $T_M = 0.7$ K, $T_{c2} = 0.65$ K for $HoMo_6\ S_8$; $T_{c1} = 8.7$ K, $T_M = 0.8$ K, $T_{c2} = 0.75$ K for $ErRh_4\ B_4$. In order to understand the sequence of these transitions, let us examine, first of all, the mechanism of an indirect exchange interaction of spins via conduction electrons.

We begin with the Hamiltonian of the interaction of spins with conduction electrons (eq. 4.39), which is written in terms of the operators a and a^+:

$$\mathscr{H}_{eS} = -\frac{J}{n} \sum_{\substack{p,p' \\ \sigma,\sigma'}} a^+_{p',\sigma'}, \sigma_{\sigma',\sigma} a_{p,\sigma} \exp\left[\frac{i}{\hbar}(p - p')\, r_i\right] S_i, \tag{21.35}$$

where σ are the Pauli matrices; S_i are the spin operators of magnetic atoms*; σ, σ' are the projections of the electron spin; r_i are the positions of the atoms.

Expression (21.35) describes the interaction of an electron with spins, in which the electron's momentum is $\boldsymbol{p}$ in the initial state and $\boldsymbol{p}'$ in the final state, σ and σ' being the initial and final spin projections, respectively.

As for the factor that depends on $\boldsymbol{r}_i$, the replacement of the sum over $\boldsymbol{r}_i$ by an integral over the volume would have led to the appearance of the Fourier component of the function $\boldsymbol{S}(\boldsymbol{r})$. In this case, the resultant expression obtained would be analogous to the Hamiltonian (16.60),

which describes the interaction of electrons with an electromagnetic field. It may be treated as the change of the momentum and spin of the electron upon absorption of a quantum of the external field. The presence of the sum over r_i in (21.35) takes into account the discreteness in the position of the spins.

Let us first consider a nonsuperconducting metal. Taking the second order of perturbation theory and separating in it the terms with $\boldsymbol{r}_i \neq \boldsymbol{r}_k$, which describe the interaction of the spins, we obtain

$$\begin{aligned} E_{\mathrm{SS}} =& \sum_{m\neq 0} \frac{\left|\left(\mathscr{H}_{\mathrm{eS}}\right)_{m0}\right|^2}{E_0 - E_m} \\ =& \left(\frac{J}{n}\right)^2 \sum_{\substack{p,p';\sigma,\sigma' \\ i\neq k}} \frac{n_p\left(1-n_{p'}\right)}{\xi_p - \xi_{p'}} \\ & \times \exp\left(\frac{\mathrm{i}}{\hbar}\left(p-p'\right)\left(r_i - r_k\right)\right) \sigma^l_{\sigma',\sigma}\sigma^m_{\sigma,\sigma'} S^l_i S^m_k \\ =& 2\left(\frac{J}{n}\right)^2 \sum_{\substack{p,p' \\ i\neq k}} \frac{n_p\left(1-n_{p'}\right)}{\xi_p - \xi_{p'}} \\ & \times \exp\left(\frac{\mathrm{i}}{\hbar}\left(p-p'\right) r_{ik}\right) S_i S_k \end{aligned}$$

where $\boldsymbol{r}_{ik} = \boldsymbol{r}_i - \boldsymbol{r}_k$ and the factor $\boldsymbol{n}_p\left(1-\boldsymbol{n}_{p'}\right)$ takes account of the presence of electrons in the initial state and their absence in the final state. We introduce new variables $p \to p + \frac{1}{2}q, p' = p - \frac{1}{2}q$.

We take into account the fact that finite temperature leads only to corrections of order $(T/\mu)^2$ and we therefore set $T = 0$. Then $\xi_p < 0$ and $\xi_{p'} > 0$. The expression obtained may be written in the form

$$E_{\mathrm{SS}} = -2\left(\frac{J}{n}\right)^2 \sum_{i\neq k} \int \frac{\mathrm{d}^3 q}{(2\pi\hbar)^3} F(q) \exp\left(\frac{\mathrm{i}qr_{ik}}{\hbar}\right) S_i S_k, \tag{21.36}$$

where

$$F(q) = \int \frac{\mathrm{d}^3 p}{(2\pi\hbar)^3} \frac{1}{\xi' - \xi} \theta\left(\xi'\right)\theta(-\xi), \tag{21.37}$$

and $\theta(x) = 1$ at $x > 0$ and $\theta(x) = 0$ at $x < 0, \xi = \xi\left(p + \frac{1}{2}q\right) = (2m)^{-1}\left[\left(p + \frac{1}{2}q\right)^2 - p_0^2\right]$, $\xi' = \xi\left(p - \frac{1}{2}q\right)$. Integration gives

$$F(q) = \frac{1}{4}\nu f\left(q/2p_0\right), \tag{21.38}$$

where $\nu = p_0 m/\left(\pi^2\hbar^3\right)$ is the density of states and

$$f(x) = \frac{1}{2}\left(1 + \frac{1-x^2}{2x}\ln\left|\frac{1+x}{1-x}\right|\right) \tag{21.39}$$

is the so-called Lindhard function.
Substitution of eqs. (21.38) and (21.39) into (21.36) and integration over $\boldsymbol{q}$ leads to

---

- Here we do not consider the Kondo effect and therefore we assume that S_i are classical vectors.

$$E_{\mathrm{SS}} = \left(\frac{J}{n}\right)^2 \nu \frac{p_0^3}{\pi\hbar^3} \times \sum_{i\neq k} \left[\cos\left(\frac{2p_0 r_{ik}}{\hbar}\right)\left(\frac{2p_0 r_{ik}}{\hbar}\right)^{-3} - \sin\left(\frac{2p_0 r_{ik}}{\hbar}\right)\left(\frac{2p_0 r_{ik}}{\hbar}\right)^{-4}\right] S_i S_k, \tag{21.40}$$

which is called the RKKY interaction after the authors (Ruderman and Kittel 1954, Kasuya 1956 and Yosida 1957).

Suppose that the interaction of the spins (eq. 21.40), leads to the formation of a helicoidal magnetic structure, for which $\boldsymbol{S} = \boldsymbol{S}(\boldsymbol{r})$, with

$$\begin{aligned} S_x &= S\cos(qz/\hbar), \\ S_y &= S\sin(qz/\hbar), \\ S_z &= 0. \end{aligned} \tag{21.41}$$

This means that the end of the vector $\boldsymbol{S}$ describes in space a spiral line around the z axis. Upon substitution into (21.36) we pass from the summation over i, k to integration according to the formula $\sum_i \to n\int \mathrm{d}V$, where n is the number of spins per unit volume. As a result, we have per unit volume

$$E_{\mathrm{SS}} = -2J^2S^2F(q) = -\frac{1}{2}J^2\nu S^2 f\left(q/2p_0\right). \tag{21.42}$$

A maximum of $f(q)$ corresponds to the lowest energy. The Lindhard function (21.39) is equal to unity at $q = 0$ and decreases monotonically with increasing x [the asymptotic with $x \to \infty$ is $f(x) \approx 2/(3x^2)$]. Hence, for the energy minimum we have $q = 0$, i.e. ferromagnetic ordering.

This conclusion is not general, as a matter of fact. If we take into account that the spins occupy certain positions in space, we cannot pass from the summation over r_i to the integration over the volume. For certain lattices, other types of spin ordering are more favorable, namely antiferromagnetic or helicoidal ordering with $\boldsymbol{q} \neq 0$. But here we confine ourselves to the simplest case.

How does the situation change in a superconductor? In order to find the answer to this question, we must express in the Hamiltonian (21.35) the operators a and a^+in terms of α and α^+in accordance with the Bogoliubov formulas (16.14). We assume from the start that spin ordering is helocoidal and is described by formulas (21.41). In this case, we obtain

$$\begin{aligned} \mathscr{H}_{eS} = -\frac{J}{n}\sum_{p,p',i} &\left(S_i^x - \mathrm{i}S_i^y\right)\left(u_{p'}\alpha^+_{p',+} + v_{p'}\alpha_{-p',-}\right)\left(u_p\alpha_{p,-} - v_p\alpha^+_{-p,+}\right) \\ &+ \left(S_i^x + \mathrm{i}S_i^y\right)\left(u_{p'}\alpha^+_{p',-} - v_{p'}\alpha_{-p',+}\right)\left(u_p\alpha_{p,+} + v_p\alpha^+_{-p,-}\right) \end{aligned}$$

Let us find, as before, the second order of perturbation theory and retain the terms with $i \neq k$. We assume that $T = 0$. This means that all the numbers $n_{p,+}$ and $n_{p,-}$ for quasiparticles are taken to be equal to zero. Of course, strictly speaking, this is justifiable only for the limiting case, when the temperature of magnetic ordering T_{M} is much lower than T_{cl}. As a result, we obtain

$$E_{\rm SS} = -\sum_{\substack{p,p'\\ i\neq k}} \frac{\left(u_p v_{p'} - u_{p'} v_p\right)^2}{\varepsilon + \varepsilon'} \exp\left[\frac{\mathrm{i}}{\hbar}\left(p - p'\right) r_{ik}\right] S_i S_k.$$

Substituting formulas (16.19) for u and v yields

$$E_{\rm SS} = -\frac{1}{2}\left(\frac{J}{n}\right)^2 \sum_{p,p';i\neq k} \left(1 - \frac{\xi\xi' + \Delta^2}{\varepsilon\varepsilon'}\right) \times \frac{1}{\varepsilon + \varepsilon'} \exp\left[\frac{\mathrm{i}}{\hbar}\left(p - p'\right) r_{ik}\right] S_i S_k \tag{21.43}$$

We introduce the same variables as before. Then, instead of formula (21.36), we obtain a formula of the same type, which however, will contain $F_1(q)$:

$$F_1(q) = \frac{1}{4}\int \frac{\mathrm{d}^3 p}{(2\pi\hbar)^3}\left(1 - \frac{\xi\xi' + \Delta^2}{\varepsilon\varepsilon'}\right)\frac{1}{\varepsilon + \varepsilon'}. \tag{21.44}$$

First of all, note that $F_1(q) = 0$ at $q = 0$. In fact, here $\xi = \xi'$ and $\xi^2 + \Delta^2 = \varepsilon^2$. The physical explanation of this circumstance consists in the following. An indirect exchange interaction between the spins arises from the fact that the spin S_i at point $\boldsymbol{r}_i$ polarizes the surrounding electrons and they in turn polarize the other spin S_k. But if we are dealing with a superconductor, the electrons in the ground state are not polarized, and the excited state is separated from the ground state by an energy gap. The static spin cannot change the energy of the electronic system and, hence, cannot polarize it. From this it follows that while ferromagnetism hinders superconductivity, the latter in turn impedes the generation of ferromagnetism.

In what follows, we need, as before, the maximum of function $F_1(q)$. It will be seen that this maximum corresponds to $\Delta/v \sim \hbar/\xi < q < 2p_0$. Therefore, instead of a detailed calculation of function F_1, we can find its asymptotics, assuming that $\Delta < vq < 2p_0 v$. To this end, we add and subtract in eq. (21.44) the corresponding expression with $\Delta = 0$. The difference converges at $p \sim \Delta/v, vq \sim \Delta$. In view of this, we may differentiate the difference with respect to Δ and then, introducing the variables ξ and ξ' in place of p and $\theta = (p, q)$, we assume the limits of integration over these variables to be infinite. As a result, we find

$$\begin{aligned}\frac{\partial}{\partial\Delta^2}[F_1(q) - F(q)] &= \frac{\nu}{4vq}\int_0^\infty \mathrm{d}\xi \int_0^\infty \mathrm{d}\xi' \\ &\times \frac{-3 + \frac{1}{\varepsilon^2} + \frac{1}{\varepsilon'^2} + \frac{1}{\varepsilon\varepsilon'}}{2\varepsilon\varepsilon'\left(\varepsilon + \varepsilon'\right)} \\ &= \frac{\nu}{8vq\Delta}\int_0^\infty \mathrm{d}\varphi_1 \int_0^\infty \mathrm{d}\varphi_2 \\ &\times \frac{-3 + \frac{1}{\cosh^2\varphi_1} + \frac{1}{\cosh^2\varphi_2} + \frac{1}{\cosh\varphi_1\cosh\varphi_2}}{\cosh\varphi_1 + \cosh\varphi_2}\end{aligned}$$

where we have introduced the variables $\xi = \Delta\sinh\varphi_1, \xi' = \Delta\sinh\varphi_2$. The resultant dimensionless integral over φ_1 and φ_2 is found to be equal to $-\frac{1}{2}\pi^2$.

Integrating over Δ, we obtain

$$F_1(q) - F(q) = -\frac{\nu\pi^2\Delta}{8vq} = -\frac{\nu\pi\hbar}{8\xi_0 q}$$

where we have introduced the notation $\xi_0 = \hbar v/\pi\Delta$, which has already been used before. The remaining part equal to $F(q)$ may be expanded in a series in q because of the smallness of q. Using expressions (21.38) and (21.39), we have

$$F_1(q) \approx \frac{\nu}{4}\left(1 - \frac{q^2}{12p_0^2} - \frac{\pi\hbar}{2\xi_0 q}\right). \tag{21.45}$$

In order to avoid confusion, we should remark that this formula cannot be applied for both too small and too large values of q.

Analogously to eq. (21.42), the energy per unit volume is given by

$$E_{\mathrm{SS}} = -2J^2S^2F_1(q) \tag{21.46}$$

The maximum of function $F_1(q)$ is attained at

$$q = \left(\frac{2\pi\hbar p_0^2}{\xi_0}\right)^{1/3}. \tag{21.47}$$

This means that magnetic ordering has a helicoidal structure with a period given by

$$d = \frac{2\pi\hbar}{q} = \frac{2}{3^{1/2}}\left(\frac{\pi\hbar}{p_0}\right)^{2/3}\xi_0^{1/3} \sim a^{2/3}\xi_0^{1/3}, \tag{21.48}$$

where $a \sim \hbar/p_0$ is of the order of atomic dimensions (Anderson and Suhl 1959).
The resultant period is large compared to atomic dimensions but it is small compared to ξ_0. Since the events that occur at distances of order ξ_0 are important in superconductors, it may be said that magnetization changes so rapidly that it averages out at distances of order ξ_0 and therefore may exist together with superconductivity.

In fact, apart from the exchange interaction of the spins, there also occurs a spin-orbit interaction, which is very strong in rare-earth elements because of their large atomic number. In contrast to the exchange interaction, this interaction depends on the spin orientation relative to the crystallographic axes. This gives rise to a so-called anisotropy field. The latter selects, among the spin directions, the so-called easy directions of magnetization. The simplest case is a uniaxial crystal with an easy direction of magnetization along the axis. In such a crystal, the orientations of the spin along the axis in the forward and reverse directions are energetically the most favorable. The presence of such an anisotropy field "remodels" the helicoidal magnetic structure into a domain structure composed of planar layers (domains) with opposite magnetization of the successive layers.

Since the magnetization in each domain is homogeneous, it follows that in formula (21.45), in place of the second term, we must write the energy of the interdomain boundary. In each such wall there occurs a gradual spin flip from one easy direction of magnetization to another. This can happen by gradual rotation of the magnetic moment with conservation of its magnitude as well as by a gradual change of its magnitude with the direction staying parallel to the easy magnetization axis. In the substances under consideration a change of direction of the moment is unfavourable due to the large anisotropy energy; therefore walls of the second type actually occur (they are called "linear walls"). Since the exchange energy is minimal if the moment does not vary in space, the wall has an additional exchange energy $J^2S^2\nu\,(a/\delta_{\mathrm{w}})^2\,\delta_{\mathrm{w}}$, where δ_{w} is the thickness of the wall and a is the interatomic distance [this energy corresponds to the term $\int c(\nabla\varphi)^2\,\mathrm{d}V$ in formula (AII.15)]. On the other hand the value of the order parameter in the wall is less than the bulk value and this contributes an additional energy of the order of $J^2S^2|\tau|\nu\delta_{\mathrm{w}}$, where $\tau = (T - T_{\mathrm{m}})/T_{\mathrm{m}}$ [this corresponds to $\int \alpha\tau\varphi^2\,\mathrm{d}V$ in (AII.15)]. Minimizing the total energy with respect to δ_{w},

$$E_{\rm w} = J^2 S^2 \nu \left(\frac{a^2}{\delta_{\rm w}} + \delta_{\rm w} |\tau| \right)$$

we get

$$\delta_{\rm w} \sim \frac{a}{|\tau|^{1/2}}, \quad E_{\rm w} \sim J^2 S^2 \nu a |\tau|^{1/2}$$

Strictly speaking this is true for $|\tau| < 1$, but in fact it gives a correct estimate even for $|\tau| \sim 1$.

If the period of the domain structure is d, then, on the average, we have $E_{\rm w}/d \sim J^2 S^2 \nu a/d$ per unit volume. Moreover, we have to add the exchange energy that arises from the superconductivity, represented by the third term in eq. (21.45). Taking into account that $q \sim \hbar/d$, we obtain the total extra energy dependent on d :

$$\Delta E(d) \sim J^2 S^2 \nu \left(\frac{a}{d} + \frac{d}{\xi_0} \right)$$

Minimizing with respect to d, we find

$$d \sim (a \xi_0)^{1/2} \tag{21.49}$$

$$\Delta E(d) \sim J^2 S^2 \nu \left(\frac{a}{\xi_0} \right)^{1/2}. \tag{21.50}$$

Again, the period of the structure is found to be smaller than ξ_0, and therefore the magnetization has a slight effect on superconductivity.

In order to solve the problem of the transition to a normal ferromagnetic material, let us compare the corresponding energies at $T = 0$. From formula (21.42) at $q = 0$ we obtain $E_{\rm n} = \frac{1}{2} J^2 S^2 \nu$. The excess energy associated with the domain walls is expressed by formula (21.50). However, the onset of superconductivity gives rise to an extra negative energy given by formula (16.41). If

$$J^2 S^2 \nu \left(\frac{a}{\xi_0} \right)^{1/2} < \nu \Delta^2(0) \tag{21.51}$$

the superconductivity with the domain magnetic structure will persist up to $T = 0$. This is what happens in $HoMo_6Se_8$. If the opposite inequality is fulfilled, then at some finite temperature T_{c2} a first-order phase transition takes place from the domain superconducting structure to a normal ferromagnetic substance. This is observed in $HoMo_6\ S_8$ and $ErRh_4\ B_4$. The criterion (21.51) may be rewritten by taking advantage of the fact that

$$\Delta(0) \sim T_{\rm cl1}, \quad \xi_0 \sim \frac{\hbar v}{T_{\rm cl}}, \quad a \sim \frac{\hbar}{p_0}, \quad p_0 v \sim \varepsilon_{\rm F}, \quad \frac{J^2 S^2}{\varepsilon_{\rm F}} \sim \theta$$

(θ is the Curie point) (see below):

$$\theta \frac{\varepsilon_{\rm F}^{1/2}}{T_{\rm c1}^{3/2}} < 1. \tag{21.51'}$$

In superconductors that pass to the normal ferromagnetic phase below T_{c2} the following interesting phenomenon can be observed. If a current is passed through such a superconductor at a temperature below T_{c2}, then due to finite resistance it will heat the sample and the temperature will become higher than T_{c2}. But in this

case the heating will stop and the temperature will fall below T_{c2} and the process will repeat itself. This may result in the following: alternating domains of the normal and the superconducting phase will move throughout the sample with the current; such domains are called autowaves (Buzdin and Mikhailov 1986).

Let us now consider the lower boundary of the domain phase. Since the energy of domain walls is only a small correction to the main exchange energy of the spin-spin interaction, the Curie temperature θ will differ little from the value for a normal ferromagnetic material. To find the latter value, we employ the self-consistent field method (Abrikosov and Gor'kov 1962b). Suppose a ferromagnetic state has been formed and, as a result, the electron spin has been polarized, i.e., $\langle\sigma\rangle$, where $\langle\cdots\rangle$ signifies the equilibrium average at a given temperature referred to unit volume. In accordance with the Hamiltonian (4.39), this is equivalent to the action of an effective magnetic field on each spin of a rare-earth ion, in which case the role of $g\beta H$ is played by $(J/n)\langle\sigma\rangle$ ($g\beta S$ is the magnetic moment of the ion, g is the gyromagnetic ratio and β is the Bohr magneton). The free energy of the entire system of ionic spins per unit volume is ($n_{\mathrm{m}} = n$):

$$\begin{aligned} F_{\mathrm{i}} &= -nT \ln \sum_{M=-S}^{S} \exp\left(\frac{J}{n}\langle\sigma\rangle\frac{M}{T}\right) \\ &= -nT\left[\ln\sinh\left(\frac{J}{n}\langle\sigma\rangle\frac{S+\frac{1}{2}}{T}\right) - \ln\sinh\left(\frac{J}{n}\frac{\langle\sigma\rangle}{2T}\right)\right]. \end{aligned} \tag{21.52}$$

On the other hand, the polarization of electron spins implies their redistribution among the energy levels, i.e., the generation of different Fermi surfaces for $\sigma = +1$ and -1 , which is also equivalent to the action of a certain magnetic field. According to section 10.1, under the action of the magnetic field H a paramagnetic moment arises in the electronic system ($s = \frac{1}{2}\sigma$):

$$M = \beta\langle\sigma\rangle = \beta^2\nu H = \chi H,$$

where χ is the magnetic susceptibility. On the other hand, the change in free energy for a given moment M is (see eq. 10.2):

$$F_{\mathrm{e}} = \int H\ \mathrm{d}M = \frac{1}{2}\chi H^2 = \beta^2\frac{\langle\sigma\rangle^2}{2\chi} = \frac{\langle\sigma\rangle^2}{2\nu}. \tag{21.53}$$

Let us find the minimum of $F_{\mathrm{e}} + F_{\mathrm{i}}$. Differentiating with respect to $\langle\sigma\rangle$, we get

$$\frac{\langle\sigma\rangle}{\nu} - JSB_{\mathrm{s}}\left(\frac{J}{n}\frac{\langle\sigma\rangle}{T}\right) = 0, \tag{21.54}$$

where $\mathbf{B}_{\boldsymbol{S}}(\boldsymbol{x})$ is the Brillouin function defined by

$$\mathrm{B}_S(x) = \left(\frac{S+\frac{1}{2}}{S}\right)\coth\left[\left(S+\frac{1}{2}\right)x\right] - \frac{1}{2S}\coth\left(\frac{1}{2}x\right). \tag{21.55}$$

In order to find the Curie temperature θ, we assume that $\langle\sigma\rangle \to 0$. Taking into account that at $x \ll 1$

$$\mathrm{B}_S(x) \approx \frac{1}{3}(S+1)x$$

we obtain from (21.52)

$$\theta = J^2\nu S\frac{(S+1)}{3n}. \tag{21.56}$$

Taking into account that $\nu \sim n_e/\varepsilon_F$ and $n_e \sim n$, we find

$$\theta \sim \frac{J^2 S^2}{\varepsilon_F}. \qquad (\prime)$$

Two situations are possible. If ε_F is of the same order as in ordinary metals, then at $\theta \sim 1$ K we have $JS \sim 10^2$ K, i.e. $JS > \Delta(0)$ (cf., with 21.22, $JS = I$). In this case, the coexistence of superconductivity and ferromagnetism is possible only at $\theta < T_{cl}$, and the change of the phases with decreasing temperature will occur in the sequence described in the present section. But if $\theta > T_c$, then superconductivity will not appear at all.

However, there is still another possibility, in principle. As has already been said in section 16.10, a sharp peak may appear in the density of states at the Fermi boundary; this peak, known as the Abrikosov-Suhl resonance, manifests itself in various properties at low temperatures. It may be interpreted as an increase in the effective mass - "heavy fermions". Evidently, in such a case in formula (21.56) ν will be anomalously high and, hence, JS may be found to be of order Δ. In this case, superconductivity may arise at $\theta \geqslant T_c$ and also the inhomogeneous superconducting LOFF phase described in the preceding section may appear. Actually, for this to occur it is necessary that $m^* > 10^3 m, \theta, T_c > 10$ K, which has never been observed.

The exchange interaction of electrons with ions (4.39) in the case of a large negative J may give rise to the unusual effect of reentrant superconductivity (Jaccarino and Peter 1962). We are speaking here of antiferromagnetic superconductors or of ferromagnetic superconductors at a temperature above the Curie point. Under the action of an external field an average polarization of the nuclear spin $\langle \boldsymbol{S} \rangle$ appears. Because of this, the electron spins will be acted on by an effective field given by

$$I = \frac{J}{n}\langle S \rangle + \beta H \qquad (21.57)$$

If J is sufficiently large in absolute magnitude, then the first term in this formula is larger than the second. Under the influence of the field the superconductivity is destroyed by a paramagnetic mechanism. As H increases further the first term tends towards saturation because $|\langle \boldsymbol{S} \rangle|$ cannot exceed $n\boldsymbol{S}$, where $\boldsymbol{S}$ is the spin of an individual ion. If $J < 0$, this may lead to a decrease in the magnitude of I and to

In order to find the Curie temperature θ, we assume that $\langle \sigma \rangle \to 0$. Taking into account that at $x \ll 1$

$$\mathrm{B}_S(x) \approx \frac{1}{3}(S+1)x$$

we obtain from (21.52)

$$\theta = J^2 \nu S \frac{(S+1)}{3n}. \qquad (21.56)$$

Taking into account that $\nu \sim n_e/\varepsilon_F$ and $n_e \sim n$, we find

$$\theta \sim \frac{J^2 S^2}{\varepsilon_F}. \qquad (21.56')$$

Two situations are possible. If ε_F is of the same order as in ordinary metals, then at $\theta \sim 1$ K we have $JS \sim 10^2$ K, i.e. $JS > \Delta(0)$ (cf., with 21.22, $JS = I$). In this case, the coexistence of superconductivity and ferromagnetism is possible only at $\theta < T_{cl}$, and the change of the phases with decreasing temperature will occur in the sequence described in the present section. But if $\theta > T_c$, then superconductivity will not appear at all.

However, there is still another possibility, in principle. As has already been said in section 16.10, a sharp peak may appear in the density of states at the Fermi boundary; this peak, known

as the Abrikosov-Suhl resonance, manifests itself in various properties at low temperatures. It may be interpreted as an increase in the effective mass - "heavy fermions". Evidently, in such a case in formula (21.56) ν will be anomalously high and, hence, JS may be found to be of order Δ. In this case, superconductivity may arise at $\theta \geqslant T_c$ and also the inhomogeneous superconducting LOFF phase described in the preceding section may appear. Actually, for this to occur it is necessary that $m^* > 10^3 m, \theta, T_c > 10$ K, which has never been observed.

The exchange interaction of electrons with ions (4.39) in the case of a large negative J may give rise to the unusual effect of reentrant superconductivity (Jaccarino and Peter 1962). We are speaking here of antiferromagnetic superconductors or of ferromagnetic superconductors at a temperature above the Curie point. Under the action of an external field an average polarization of the nuclear spin $\langle \boldsymbol{S} \rangle$ appears. Because of this, the electron spins will be acted on by an effective field given by

$$I = \frac{J}{n}\langle S \rangle + \beta H \tag{21.57}$$

If J is sufficiently large in absolute magnitude, then the first term in this formula is larger than the second. Under the influence of the field the superconductivity is destroyed by a paramagnetic mechanism. As H increases further the first term tends towards saturation because $|\langle \boldsymbol{S} \rangle|$ cannot exceed $n\boldsymbol{S}$, where $\boldsymbol{S}$ is the spin of an individual ion. If $J < 0$, this may lead to a decrease in the magnitude of I and to
the onset of superconductivity. In still larger fields the superconductivity is completely destroyed, due mainly to the second term in eq. (21.57) with the aid of the paramagnetic mechanism or due to the orbital effect of pair rotation. An example is the compound $Eu_{0.75}Sn_{0.25}Mo_6\ S_{7.2}Se_{0.8}$.

More detailed information about ferromagnetic and antiferromagnetic superconductors can be found in the literature (Bulaevskii et al. 1985, Buzdin and Bulaevskii 1986).

8.7.4 21.4. The Knight shift

One of the highly sensitive methods of determination of internal magnetic fields in a solid, which is also frequently used to determine structural details is the nuclear magnetic resonance (NMR) method. If the nucleus has a spin, it also has a magnetic moment.

$$\mu_{\mathrm{n}} = \gamma \hbar S_{\mathrm{n}}. \tag{21.58}$$

Nuclear magnetic moments are thousands of times lower than the electronic moments:

$$\gamma\hbar \sim \frac{e\hbar}{M_{\mathrm{p}}c} \sim \frac{\beta m}{M_{\mathrm{p}}},$$

where m is the mass of the electron and M_{p} is the mass of the proton. If the nuclear moment is placed in a magnetic field, its energy has the usual form

$$\varepsilon = -\mu_{\mathrm{n}}\boldsymbol{H} = -\gamma\hbar M H, \tag{21.59}$$

where M is the magnetic quantum number (the projection of the nuclear spin onto $\boldsymbol{H}$). This system with equidistant levels is capable of absorbing electromagnetic quanta with an energy $\gamma\hbar H$. Considering that $\beta \sim 10^{-20}$ and $\gamma\hbar \sim 10^{-23}$, we obtain $\omega \sim \gamma H$, i.e., $\omega \sim 10^8$ s^{-1} in a field of the order of 10^4Oe. This makes nuclear magnetic resonance a convenient tool for the various investigations.

The nuclear spin interacts with electrons when the electrons create a magnetic field. In a nonmagnetic metal in the absence of a magnetic field the electronic system has no magnetic moment and the nuclear spin does not interact with the electrons. If an external magnetic

field is turned on, it is capable not only of directly acting on the nuclear spin but, through the orientation of the electron spin, it can also produce a nonzero electronic field in the region of the nucleus. However, in practice only the field created by the spin of s-electrons is important because only these electrons have a finite wave function at the point of location of the nucleus (according to quantum mechanics, $\psi(r) \propto r^l$, where l is the orbital moment).

In metals, the electron spins are polarized under the action of a magnetic field. Since among the valence electrons there are always electrons for which the wave function in the vicinity of the nucleus is close to the atomic s-function, their
polarization generates an extra field, which acts on the nuclear spin. This leads to a shift of the NMR frequency; this shift is known as the Knight shift (Knight 1949).

The magnitude of the Knight shift can be calculated as follows. The Hamiltonian of the magnetic dipolar interaction of electrons with a nucleus may be written in the form

$$\mathscr{H}_{\text{en}} = -2\beta \left[3(sr)\frac{\mu_{\text{n}} r}{r^5} - \frac{s\mu_{\text{n}}}{r^3}\right] = -2\beta s \operatorname{rot} A, \tag{21.60}$$

where $\boldsymbol{A}$ is the vector potential of the field created by the spin:

$$A = \frac{[\mu_{\text{n}} r]}{r^3} = \operatorname{rot}\left(\frac{\mu_{\text{n}}}{r}\right). \tag{21.61}$$

Substituting into (21.60), we obtain

$$\begin{aligned}\mathscr{H}_{\text{en}} &= -2\beta s \operatorname{rot}\operatorname{rot}\left(\frac{\mu_{\text{n}}}{r}\right) = -2\beta s \left(\operatorname{grad}\operatorname{div} - \nabla^2\right)\frac{\mu_{\text{n}}}{r} \\ &= -2\beta\left[(s\nabla)(\mu_{\text{n}}\nabla) - (s\mu_{\text{n}})\nabla^2\right]\frac{1}{r} \\ &= -2\beta\left[(s\nabla)(\mu_{\text{n}}\nabla) - \frac{1}{3}(s\mu_{\text{n}})\nabla^2\right]\frac{1}{r} + \frac{4}{3}\beta(s\mu_{\text{n}})\nabla^2\frac{1}{r}.\end{aligned} \tag{21.62}$$

The Hamiltonian obtained must be averaged over the electronic wave function. Here the first term in (21.62) gives a nonzero result only with wave functions that behave in the vicinity of the nucleus as atomic states with $l \neq 0$; therefore, it makes a small contribution. The second term, by virtue of Coulomb's law

$$\nabla^2\frac{1}{r} = -4\pi\delta(r)$$

is equal to

$$\mathscr{H}_{\text{en}} = -\frac{16}{3}\pi\beta s\mu_{\text{n}}\delta(r).$$

On averaging this gives*

$$E_{\text{en}} = -\frac{16}{3}\pi\beta\langle s\rangle\mu_{\text{n}}\frac{|\psi_{\text{s}}(0)|^2}{n}, \tag{21.63}$$

where n is the density of atoms.
In a magnetic field the average electron spin of unit volume is equal to

$$\langle s\rangle = \frac{\chi H}{2\beta},$$

polarization generates an extra field, which acts on the nuclear spin. This leads to a shift of the NMR frequency; this shift is known as the Knight shift (Knight 1949).

The magnitude of the Knight shift can be calculated as follows. The Hamiltonian of the magnetic dipolar interaction of electrons with a nucleus may be written in the form

$$\mathscr{H}_{\text{en}} = -2\beta \left[3(sr)\frac{\mu_{\text{n}} r}{r^5} - \frac{s\mu_{\text{n}}}{r^3}\right] = -2\beta s \operatorname{rot} A, \tag{21.60}$$

where $\boldsymbol{A}$ is the vector potential of the field created by the spin:

$$A = \frac{[\mu_{\text{n}} r]}{r^3} = \operatorname{rot}\left(\frac{\mu_{\text{n}}}{r}\right). \tag{21.61}$$

Substituting into (21.60), we obtain

$$\begin{aligned}\mathscr{H}_{\text{en}} &= -2\beta s \operatorname{rot}\operatorname{rot}\left(\frac{\mu_{\text{n}}}{r}\right) = -2\beta s \left(\operatorname{grad}\operatorname{div} - \nabla^2\right)\frac{\mu_{\text{n}}}{r} \\ &= -2\beta\left[(s\nabla)(\mu_{\text{n}}\nabla) - (s\mu_{\text{n}})\nabla^2\right]\frac{1}{r} \\ &= -2\beta\left[(s\nabla)(\mu_{\text{n}}\nabla) - \frac{1}{3}(s\mu_{\text{n}})\nabla^2\right]\frac{1}{r} + \frac{4}{3}\beta(s\mu_{\text{n}})\nabla^2\frac{1}{r}\end{aligned} \tag{21.62}$$

The Hamiltonian obtained must be averaged over the electronic wave function. Here the first term in (21.62) gives a nonzero result only with wave functions that behave in the vicinity of the nucleus as atomic states with $l \neq 0$; therefore, it makes a small contribution. The second term, by virtue of Coulomb's law

$$\nabla^2\frac{1}{r} = -4\pi\delta(r)$$

is equal to

$$\mathscr{H}_{\text{en}} = -\frac{16}{3}\pi\beta s\mu_{\text{n}}\delta(r).$$

On averaging this gives*

$$E_{\text{en}} = -\frac{16}{3}\pi\beta\langle s\rangle\mu_{\text{n}}\frac{|\psi_{\text{s}}(0)|^2}{n}, \tag{21.63}$$

where n is the density of atoms.
In a magnetic field the average electron spin of unit volume is equal to

$$\langle s\rangle = \frac{\chi H}{2\beta},$$

from which we have

$$E_{\text{en}} = -\frac{8}{3}\pi\chi\frac{|\psi_{\text{s}}(0)|^2}{n}(\mu_{\text{n}}\boldsymbol{H}).$$

Thus, the nuclear spin is acted on by an extra magnetic field:

- In order to derive formula (21.63), use may be made of the electron wave function written in terms of the Wannier function (1.22) and account may be taken of the fact that $w_n(r) \approx \psi_s(r - a_n)$ falls off rapidly as r moves away from a_n.

- In order to derive formula (21.63), use may be made of the electron wave function written in terms of the Wannier function (1.22) and account may be taken of the fact that $w_n(r) \approx \psi_s(r - a_n)$ falls off rapidly as r moves away from a_n.

$$\Delta H = \frac{8}{3}\pi\chi\frac{|\psi_{\rm s}(0)|^2}{n}H. \tag{21.64}$$

Experimental determination of the NMR frequency and, hence, of the Knight shift, makes it possible to measure the spin magnetic susceptibility χ directly. Of course, for a normal metal this method becomes less valuable because the magnitude of $|\psi_s(0)|^2$, the probability density of finding electrons at the nucleus, cannot be calculated exactly. But if the metal passes to the superconducting state, the ratio $\chi_{\rm s}(T)/\chi_{\rm n}$ can be studied.

Of the greatest interest is $\chi_{\rm s}(0)$. At first sight it must be equal to zero. Indeed, in the ground state the electrons are bound into Cooper pairs with zero spin and the excited states are separated from the ground state by an energy gap. Hence, a small magnetic field is not capable of generating magnetization, i.e., $\chi_{\rm s}(0) = 0$. However, in practice $\chi_{\rm s}(0)$ is always found not only to be finite but often even to be close to $\chi_{\rm n}$ (recall that at low temperatures $\chi_{\rm n}$ is practically independent of temperature).

Attempts have been made to explain this paradox by the assumption of triplet pairing, i.e., Cooper pairs with parallel spins and $l = 1, 3\ldots$ (the oddness of l is the result of the symmetry of the wave function of Fermi particles: if it is symmetric with respect to spin transposition, then it must be antisymmetric with respect to the coordinates), but this idea has not been confirmed.

In order to understand the origin of finite $\chi_{\rm s}(0)$, we must take into account that NMR experiments with a superconductor must be carried out on small particles (or very thin films) with a size less than the penetration depth. Otherwise, the magnetic field will not penetrate the superconductor or will be strongly inhomogeneous, which will not make it possible to observe the resonance. In small particles, even if they are single-crystalline, the electrons are inevitably scattered from the boundaries, i.e., we certainly have $l < \delta$. It can be shown that ordinary potential scattering does not give rise to $\chi_{\rm s}(0)$.

However, apart from this there necessarily is spin-orbit scattering, which has already been considered in section 11.4. The Hamiltonian of the spin-orbital part of the electron-impurity interaction is proportional to $(mc)^{-1}[-{\rm i}\hbar\nabla V, p]s$, where V is the potential of the impurity*; this Hamiltonian gives a correction to the scattering amplitude proportional to $[pp']\,s$, where p and p' are the electron momentum before and after scattering. Since the correction in the Hamiltonian is symmetric with respect to a change in sign of time (with $t \to -t, p \rightleftharpoons -p'$ and $s \to -s$), it does not

lead to a noticeable change in the thermodynamic quantities of superconductors (section 21.1).

However, in the presence of this interaction the electron spin is not conserved. Hence, the states cannot be classified in accordance with the total spin of the electronic system S, and in the ground state of the superconductor there is an admixture of states with $S \neq 0$. In view of this, polarization in a weak field is also possible.

The results of calculation of this effect (Abrikosov and Gor'kov 1960b, 1962a) are as follows. The ratio $\chi_{\rm s}/\chi_{\rm n}$ depends on temperature and on the parameter $l_{\rm s0}/\xi_0$, where $l_{\rm s0}$ is the spin-orbital mean free path associated with the corresponding contribution to the scattering amplitude:

$$f\,(p,p') = a + \frac{{\rm i}b}{p_0^2}\,([pp']\,\sigma)\,, \quad l_{\rm s0} = v\tau_{\rm s0}$$
$$\frac{1}{\tau_{\rm s0}} = n_{\rm i}\nu\frac{\pi}{\hbar}\int |b|^2\sin^2\theta\frac{{\rm d}\Omega}{4\pi} \tag{21.65}$$

*The explanation of the physical origin of the spin-orbit interaction and its estimate are given at the beginning of section 10.7.

where n_i is the impurity concentration.
At $T = 0$ we obtain

$$\frac{\chi_\mathrm{s}(0)}{\chi_\mathrm{n}} \approx \frac{1}{6}\pi^2\frac{\xi_0}{l_{\mathrm{s}0}},$$
$$\frac{\chi_\mathrm{s}(0)}{\chi_\mathrm{n}} \approx 1 - \frac{3}{4}\frac{l_{\mathrm{s}0}}{\xi_0}, \quad \xi_0 < l_{\mathrm{s}0} \tag{21.66}$$

(recall that $\xi_0 = \hbar v/(\pi\Delta(0))$. From formulae (21.63) it follows that with a weak spin-orbital scattering $\chi_\mathrm{s}(0)$ is small and with a strong scattering $\chi_\mathrm{s}(0)$ approaches unity. This result is in agreement with experiment.
lead to a noticeable change in the thermodynamic quantities of superconductors (section 21.1).

However, in the presence of this interaction the electron spin is not conserved. Hence, the states cannot be classified in accordance with the total spin of the electronic system S, and in the ground state of the superconductor there is an admixture of states with $S \neq 0$. In view of this, polarization in a weak field is also possible.

The results of calculation of this effect (Abrikosov and Gor'kov 1960b, 1962a) are as follows. The ratio $\chi_\mathrm{s}/\chi_\mathrm{n}$ depends on temperature and on the parameter $l_{\mathrm{s}0}/\xi_0$, where $l_{\mathrm{s}0}$ is the spin-orbital mean free path associated with the corresponding contribution to the scattering amplitude:

$$f\,(p, p') = a + \frac{\mathrm{i}b}{p_0^2}\,([pp']\,\sigma)\,, \quad l_{\mathrm{s}0} = v\tau_{\mathrm{s}0} \tag{21.65}$$
$$\frac{1}{\tau_{\mathrm{s}0}} = n_\mathrm{i}\nu\frac{\pi}{\hbar}\int |b|^2 \sin^2\theta \frac{\mathrm{d}\Omega}{4\pi}$$

where n_i is the impurity concentration.
At $T = 0$ we obtain

$$\frac{\chi_\mathrm{s}(0)}{\chi_\mathrm{n}} \approx \frac{1}{6}\pi^2\frac{\xi_0}{l_{\mathrm{s}0}}, \quad \xi_0 < l_{\mathrm{s}0},\ \xi_\mathrm{s}, l_{\mathrm{s}0} \geqslant 1 - \frac{3}{4}\frac{l_{\mathrm{s}0}}{\xi_0}, \quad \xi_\mathrm{n} \geqslant l \tag{21.66}$$

(recall that $\xi_0 = \hbar v/(\pi\Delta(0))$. From formulae (21.63) it follows that with a weak spin-orbital scattering $\chi_\mathrm{s}(0)$ is small and with a strong scattering $\chi_\mathrm{s}(0)$ approaches unity. This result is in agreement with experiment.

8.8 22 Tunnel junctions. The Josephson effect

8.8.1 22.1. Single-particle tunnel current

The tunneling effect is one of the most familiar phenomena of quantum mechanics, since it demonstrates clearly the difference between quantum mechanics and classical mechanics. According to quantum mechanics, a particle can pass through a potential barrier even in those cases where the barrier height exceeds its energy. This phenomenon has already been considered in section 10.7 in connection with the discussion of magnetic breakdown.

The probability of passing through the barrier is primarily determined by an exponential factor:

$$W \sim \exp\left(-\frac{2}{\hbar}\int \mathrm{Im}\,(p_x)\,\mathrm{d}x\right)$$
$$= \exp\left\{-\frac{2(2m)^{1/2}}{\hbar}\int_{x_1}^{x_2}[U(x)-E]^{1/2}\,\mathrm{d}x\right\}. \qquad (22.1)$$

The integration is carried out over the region where $U(x) > E$ (see fig. 139). From the above formula it follows that the probability of passing through the barrier falls off with increasing barrier height ($U_{\max} - E$) and width ($x_2 - x_1$) and also with increasing mass of the particle.

We may actually speak of electrons and if the barrier is a layer of an insulator, then its thickness must not exceed a few interatomic distances. It is simpler to use a natural oxide layer which is formed at the surface of many metals: aluminum,

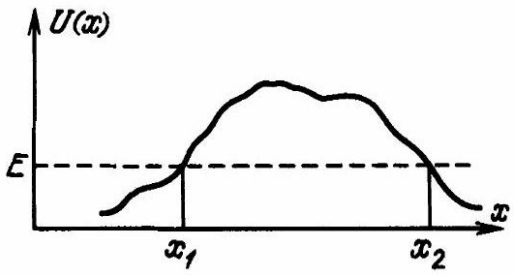

Fig. 139.

tin, lead, etc. Vaporization of a layer of the same or another metal gives rise to a so-called tunnel junction or contact (Giaever 1960a); this simple electronic device is an exceedingly valuable tool for the investigation of superconductivity.

We begin the study of the tunnel junction with two normal metals. At equilibrium the chemical potentials are equal (fig. 140a). If we apply a potential difference, this will fall entirely over the high-resistance dielectric layer. The chemical potentials of the two metals will then be at different heights (the level difference eV, fig. 140b). Assuming the barrier height to be much larger than eV, we find that the number of electrons that can be transferred to the free levels of another metal is proportional to eV and that all of them pass through the barrier with equal probability. From this it follows that the current will be proportional to V, and this is consistent with Ohm's law (fig. 141, curve 1).

Now let one of the metals be normal and the other a superconductor. We assume that $T = 0$. At equilibrium in the absence of a potential difference the chemical potentials must be equal. But the electrons in the superconductor are bound into Cooper pairs, and these are in the Bose condensate. This energy level is just the chemical potential of the pair. From the side of the normal metal, this pair corresponds to two free quasiparticles of the gas model at the Fermi level. Suppose that an electron has been transferred from the normal metal into the superconductor. But, as a matter of fact, it does not enter into the composition of the pair. If the binding energy is 2Δ, then the energy of one unpaired electron exceeds by Δ the energy of an electron in a Cooper pair. Hence, in order to transport an electron from a normal metal into a superconductor, it must receive extra energy.

Fig. 140.

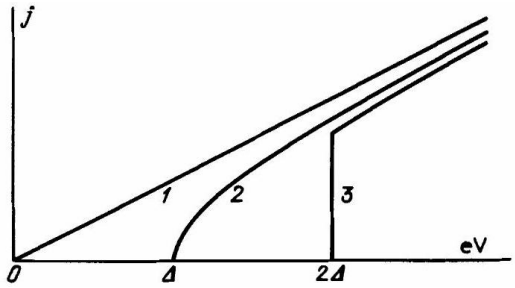

Fig. 141.

The same must be done in order to transport an electron from a superconductor to a normal metal. First we must break up a pair, which requires an energy Δ per electron, following which the electron can pass into the normal metal.

A natural question arises here: Why cannot the pairs be transferred as a whole? Within the framework of the concepts outlined above this is associated with the fact that the pair has a double charge (this increases U in formula 22.1) and a double mass as compared to an individual electron, and therefore the probability of passing through the barrier is vanishingly small for it.

The situation just described may be sketched by an electron level diagram (fig. 142). The superconductor is on the left and the normal metal on the right. The hatched regions correspond to filled levels. The band $\pm\Delta$ on the left around the dashed line is the forbidden band. Above it are the allowed states. The diagram in fig. 142 reflects the fact that for one electron to be transported through the barrier in any direction, so being transferred from a filled state to a free state, it must acquire an energy Δ. With this diagram we need not think of its origin (i.e., of the pairs); we are to deal only with quasiparticles.

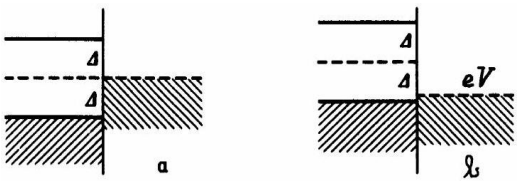

Fig. 142.

When a potential difference is applied, one side of the diagram begins to shift relative to the other and when the filled levels are found to be opposite the empty levels, an electric current will flow. Hence, the condition for the flow of current is

$$eV = \Delta. \tag{22.2}$$

Let us now find the complete dependence $j(V)$. In order to be able to integrate over the energy, we must know the density of states. For the electrons of a normal metal it is given by

$$\nu_{\mathrm{n}} = \frac{p_0 m}{\pi^2 \hbar^3} = \text{ const } .$$

For the quasiparticles of a superconductor we have

$$\nu_{\mathrm{s}} = 8\pi p^2 \frac{\mathrm{d}p}{(2\pi\hbar)^3 \, \mathrm{d}\varepsilon} = \frac{p_0^2 \, \mathrm{d}\xi}{v\pi^2\hbar^3 \, \mathrm{d}\varepsilon} = \frac{p_0 m}{\pi^2\hbar^3} \frac{\mathrm{d}\xi}{\mathrm{d}\varepsilon}$$

The same must be done in order to transport an electron from a superconductor to a normal metal. First we must break up a pair, which requires an energy Δ per electron, following which the electron can pass into the normal metal.

A natural question arises here: Why cannot the pairs be transferred as a whole? Within the framework of the concepts outlined above this is associated with the fact that the pair has a double charge (this increases U in formula 22.1) and a double mass as compared to an individual electron, and therefore the probability of passing through the barrier is vanishingly small for it.

The situation just described may be sketched by an electron level diagram (fig. 142). The superconductor is on the left and the normal metal on the right. The hatched regions correspond to filled levels. The band $\pm\Delta$ on the left around the dashed line is the forbidden band. Above it are the allowed states. The diagram in fig. 142 reflects the fact that for one electron to be transported through the barrier in any direction, so being transferred from a filled state to a free state, it must acquire an energy Δ. With this diagram we need not think of its origin (i.e., of the pairs); we are to deal only with quasiparticles.

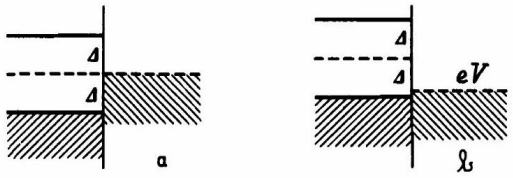

Fig. 142.

When a potential difference is applied, one side of the diagram begins to shift relative to the other and when the filled levels are found to be opposite the empty levels, an electric current will flow. Hence, the condition for the flow of current is

$$eV = \Delta. \tag{22.2}$$

Let us now find the complete dependence $j(V)$. In order to be able to integrate over the energy, we must know the density of states. For the electrons of a normal metal it is given by

$$\nu_{\mathrm{n}} = \frac{p_0 m}{\pi^2 \hbar^3} = \text{ const } .$$

For the quasiparticles of a superconductor we have

$$\nu_{\mathrm{s}} = 8\pi p^2 \frac{\mathrm{d}p}{(2\pi\hbar)^3 \, \mathrm{d}\varepsilon} = \frac{p_0^2 \, \mathrm{d}\xi}{v\pi^2\hbar^3 \, \mathrm{d}\varepsilon} = \frac{p_0 m}{\pi^2\hbar^3} \frac{\mathrm{d}\xi}{\mathrm{d}\varepsilon}$$

$$= \frac{\nu_n \varepsilon}{(\varepsilon^2 - \Delta^2)^{1/2}}, \quad \varepsilon > \Delta$$

(this formula has already been given in section 21.1).
This is the true density of states. However, if we wish to use the level diagram given in fig. 136, we have to assume that ε may be negative and

$$\nu_s = \begin{cases} \nu_n |\varepsilon| / (\varepsilon^2 - \Delta)^{1/2}, & |\varepsilon| > \Delta \\ 0, & |\varepsilon| < \Delta \end{cases} \tag{22.3}$$

Here $\varepsilon > 0$ corresponds to the generation of quasiparticles in a superconductor upon transport of electrons from the normal metal and $\varepsilon < 0$ corresponds to the breakup of the pairs and to the transport of the electrons in the opposite direction*. Of importance is the fact that $\nu_s(|\varepsilon| \to \Delta) \to \infty$, although this infinity is integrable, i.e., the total number of states within an infinitesimal energy interval near $|\varepsilon| = \Delta$ is an infinitesimal quantity.

The current that flows from one metal to another must be proportional to the tunneling probability, the number of occupied states in the first metal, the number of empty states in the second, and also to the densities of states in both metals.

Suppose a potential difference is applied as in fig. 142. Let us find the total current flowing from the superconductor to the normal metal in the forward and reverse directions. In accordance with what has been said above, we have

$$\begin{aligned} j &\propto \int W \nu_1(\varepsilon - eV) \nu_2(\varepsilon) \{ n_1(\varepsilon - eV) [1 - n_2(\varepsilon)] - n_2(\varepsilon) [1 - n_1(\varepsilon - eV)] \} \, \mathrm{d}\varepsilon \\ &= \int W \nu_1(\varepsilon - eV) \nu_2(\varepsilon) [n_1(\varepsilon - eV) - n_2(\varepsilon)] \, \mathrm{d}\varepsilon \\ &= W \nu_{1n} \nu_{2n} \int |\varepsilon - eV| \left[(\varepsilon - eV)^2 - \Delta^2 \right]^{-1/2} [n_1(\varepsilon - eV) - n_2(\varepsilon)] \, \mathrm{d}\varepsilon \end{aligned} \tag{22.4}$$

Since $T = 0$, it follows that $n(\varepsilon) = 0$ at $\varepsilon > 0$ and $n(\varepsilon) = 1$ at $\varepsilon < 0$. Hence, the difference $n_1 - n_2$ gives unity in the interval $0 < \varepsilon < eV$ and zero outside. The density of states under the integral is different from zero at $|\varepsilon - eV| > \Delta$, i.e., in this case $\varepsilon < eV - \Delta$. From this it follows that there is no current at $eV < \Delta$. At $eV > \Delta$ we have

$$\begin{aligned} j &\propto W \nu_{1n} \nu_{2n} \int_0^{eV - \Delta} (eV - \varepsilon) \left[(eV - \varepsilon)^2 - \Delta^2 \right]^{-1/2} \, \mathrm{d}\varepsilon \\ &= W \nu_{1n} \nu_{2n} \left[(eV)^2 - \Delta^2 \right]^{1/2} \end{aligned} \tag{22.5}$$

At $eV > \Delta$ the difference between the normal metal and the superconductor must disappear, i.e., the current must be the same as in the tunnel junction between two
normal metals, in which case we have

$$\frac{j}{j_n} = \frac{\left[(eV)^2 - \Delta^2 \right]^{1/2}}{eV} \tag{22.6}$$

- The introduction of negative ε is analogous to the transition in a normal metal from $|\xi|$ to ξ, i.e., from quasiparticles of particle- and antiparticle-type to the gas model.

The result is given in fig. 141 (curve 2).
Let us now consider the tunnel junction between two superconductors, which are assumed here, for simplicity, to be identical. Analogously to the foregoing, we find

$$j \propto W\nu_{\mathrm{n}}^2 \int_{\Delta}^{eV-\Delta} (eV-\varepsilon)\left[(eV-\varepsilon)^2-\Delta^2\right]^{-1/2} \varepsilon\left(\varepsilon^2-\Delta^2\right)^{-1/2}\ \mathrm{d}\varepsilon \tag{22.7}$$

The current is different from zero at $eV > 2\Delta$. Evaluation of the integral yields the following result:

$$\frac{j}{j_{\mathrm{n}}} = \mathrm{E}\left(\frac{\left[(eV)^2-(2\Delta)^2\right]^{1/2}}{eV}\right) - 2\left(\frac{\Delta}{eV}\right)^2\ \mathrm{K}\left(\frac{\left[(eV)^2-(2\Delta)^2\right]^{1/2}}{eV}\right), \tag{22.8}$$

where K and E are complete elliptic integrals of the first and second kind:
$K(k) = \int_0^{\pi/2}\ \mathrm{d}\varphi\left(1-k^2\sin^2\varphi\right)^{-1/2}$, $\mathrm{E}(k) = \int_0^{\pi/2}\ \mathrm{d}\varphi\left(1-k^2\sin^2\varphi\right)^{1/2}$.

As must be the case, $j/j_{\mathrm{n}} \to 1$ as $eV \to \infty$. However, in contrast to the junction between a superconductor and a normal metal, the threshold for the generation of current is at $eV = 2\Delta$ and at the threshold the current remains finite, i.e., as eV increases gradually, at the point $eV = 2\Delta$ a jump occurs in current from zero to a finite value. According to eq. (22.8), at $eV = 2\Delta$

$$\frac{j}{j_{\mathrm{n}}} = \frac{1}{4}\pi \tag{22.10}$$

The results are shown in fig. 141 (curve 3).
In principle, one can easily find the expressions for the tunnel current at $T \neq 0$. To this end, one must substitute into the general formula (22.4) the corresponding densities of states (with $\Delta(T)$) and the distribution functions at finite temperatures. We will not perform this calculation, because it involves cumbersome formulae with complex integrals; instead, we will describe the physical picture.

In the case of the $s-n$ junction at finite temperature in a superconductor there is a certain number of broken Cooper pairs. Therefore, individual electrons can pass through the barrier into the normal metal without an extra energy Δ. On the other hand, the electrons of the normal metal can pass into the superconductor, where there are partners with which they can form pairs. From this it is seen that electric current is generated at an arbitrary small potential difference and increases with increasing V. If the temperature is not close to T_{c}, the current increases especially
noticeably at $eV = \Delta(T)$, since the pair-breaking mechanism comes into play. In view of this, $\Delta(T)$ can be found experimentally directly from the maximum of the derivative $\mathrm{d}j/\mathrm{d}V$. It is even better to use for this purpose the junction between two identical superconductors, in which the current increases more drastically in the vicinity of $V = 2\Delta(T)/e$.

Consider now the characteristic of the tunnel junction of two different superconductors. It is easy to see that at $T = 0$ it will have a form similar to curve 3 in fig. 141 , with a discontinuity in the current at $V = (\Delta_1 + \Delta_2)/e$. The characteristic at finite temperature is more interesting. We shall assume that $T_{\mathrm{c}2} > T_{\mathrm{c}1}$ and $T \leqslant T_{\mathrm{c}1}$. Instead of the level diagram shown in fig. 142, we plot the density of states along the horizontal axis; for the left metal it will be plotted to the left and for the right metal to the right (fig. 137). Thermal excitation is represented conventionally as a certain number of carriers in the left upper band and a certain

number of empty states in the left lower band (in the superconductor on the right the excitation is small because of $T \ll T_{c2}$).

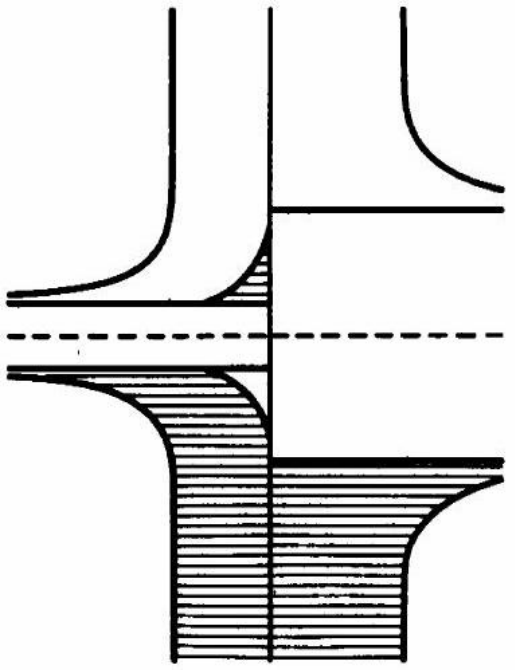

Fig. 143.

As the potential difference increases the left part of fig. 143 is shifted upwards relative to the right part. The current increases due to an increase in the number of thermally excited electrons which reside opposite the empty states in the right upper band. This will continue until the edge of the left upper band coincides with the edge of the right one, i.e., up to $V = (\Delta_2 - \Delta_1)/e$. Following this, the number of electrons capable of passing from left to right will remain constant and the number of empty states, which is proportional to the density of states, will decrease. Hence, the current-voltage characteristic $j(V)$ will bend downwards. This will continue until the upper edge of the lower left band is opposite the lower edge of the upper right band, i.e., up to $V = (\Delta_1 + \Delta_2)/e$, following which $j(V)$ will begin to increase. So, in the case under consideration the current-voltage characteristic will be nonmonotonic (fig. 144) (Giaever 1960b, Nicol et al. 1960).
noticeably at $eV = \Delta(T)$, since the pair-breaking mechanism comes into play. In view of this, $\Delta(T)$ can be found experimentally directly from the maximum of the derivative $\mathrm{d}j/\mathrm{d}V$. It is even better to use for this purpose the junction between two identical superconductors, in which the current increases more drastically in the vicinity of $V = 2\Delta(T)/e$.

Consider now the characteristic of the tunnel junction of two different superconductors. It is easy to see that at $T = 0$ it will have a form similar to curve 3 in fig. 141 , with a discontinuity in the current at $V = (\Delta_1 + \Delta_2)/e$. The characteristic at finite temperature is more interesting. We shall assume that $T_{c2} > T_{c1}$ and $T \leqslant T_{c1}$. Instead of the level diagram shown in fig. 142, we plot the density of states along the horizontal axis; for the left metal it will be plotted to the left and for the right metal to the right (fig. 137). Thermal excitation is represented conventionally as a certain number of carriers in the left upper band and a certain number of empty states in the left lower band (in the superconductor on the right the excitation is small because of $T \ll T_{c2}$).

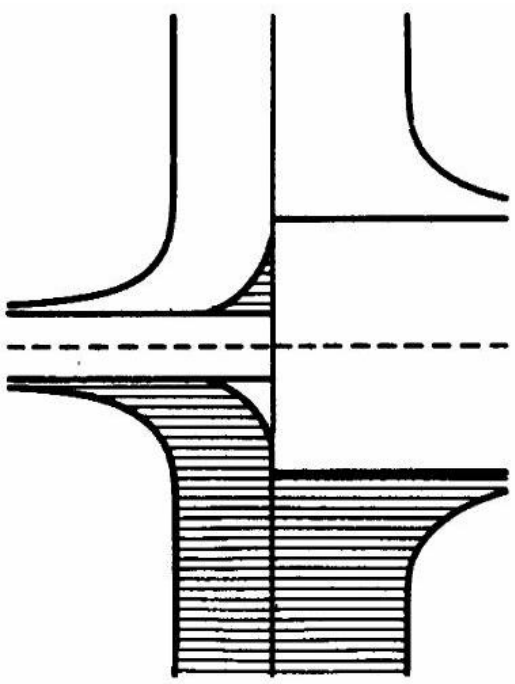

Fig. 143.

As the potential difference increases the left part of fig. 143 is shifted upwards relative to the right part. The current increases due to an increase in the number of thermally excited electrons which reside opposite the empty states in the right upper band. This will continue until the edge of the left upper band coincides with the edge of the right one, i.e., up to $V = (\Delta_2 - \Delta_1)/e$. Following this, the number of electrons capable of passing from left to right will remain constant and the number of empty states, which is proportional to the density of states, will decrease. Hence, the current-voltage characteristic $j(V)$ will bend downwards. This will continue until the upper edge of the lower left band is opposite the lower edge of the upper right band, i.e., up to $V = (\Delta_1 + \Delta_2)/e$, following which $j(V)$ will begin to increase. So, in the case under consideration the current-voltage characteristic will be nonmonotonic (fig. 144) (Giaever 1960b, Nicol et al. 1960).

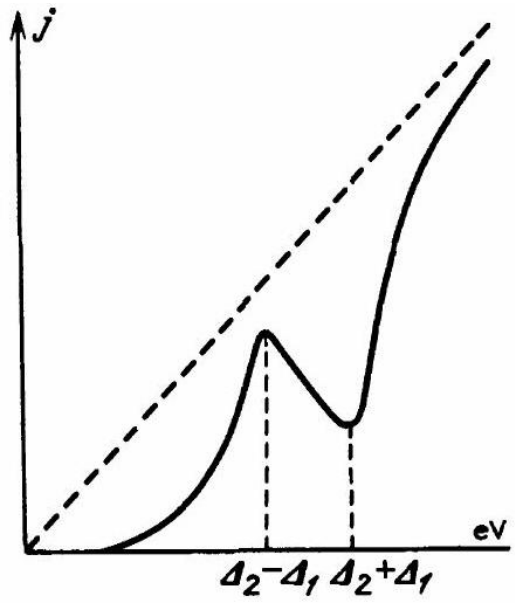

Fig. 144.

Tunnel junctions have played an important role in the direct determination of the energy gap Δ and the density of states and of their temperature dependence. In particular, with the aid of tunneling measurements it has been proved that gapless superconductivity is possible and the theory (Abrikosov and Gor'kov 1960a) has been confirmed quantitatively. Moreover, it has turned out that in the more exact theory, which takes account of the phonon spectrum and the energy dependence of the electron-phonon interaction, the tunneling characteristic makes it possible to determine the parameter $\alpha^2(\omega)\rho(\omega)$, where α is the electron-phonon interaction constant and $\rho(\omega)$ is the density of states of phonons. Since $\rho(\omega)$ can be determined independently, one can find $\alpha(\omega)$.

In concluding this section, we note that, apart from the tunnel current considered here, which is associated with the transfer of quasiparticles from one metal to another and which arises in the presence of a finite potential difference (a singleparticle current), there also exists a superconducting current flowing through the junction. The latter current will be considered in the sections that follow. There is no superconducting current in experiments if the insulating layer is rather thick (though in any case we may speak only of a few interatomic distances). In the case of a very thin insulating layer the two types of current are both generated, which manifest themselves in a peculiar manner in different circumstances. This point will be discussed below.

8.8.2 22.2. The Josephson effect

Up until now we have considered the metals on both sides of the junction separately, assuming that the coherent electronic states are formed on both sides independently. In fact, the passage of electrons through the barrier is the result of penetration of the electron wave function through the junction, and therefore a consistent theory
must deal with the formation of a coherent state in the electronic system as a whole. It may be said that at the junction between two superconductors the formation of Cooper pairs of electrons belonging to different metals is possible.

This circumstance leads to the possibility of pair tunneling with a probability comparable with the probability of tunneling of one electron and of the formation of a general condensate. Hence, at $V = 0$ a finite supercurrent can flow across the junction. This phenomenon was

predicted by Josephson (1962, 1964).

The magnitude of the Josephson superconducting current can be found from the following considerations (Josephson 1962, 1964). Let us find the excess energy associated with the existence of a tunnel junction and the presence of superconductivity. We shall evidently obtain an expression proportional to Δ_1 and Δ_2 and symmetrical with respect to these quantities. The simplest form is

$$\begin{aligned} E &= C \int \left[|\Delta_1 \Delta_2| - \frac{1}{2} \left(\Delta_1 \Delta_2^* + \Delta_1^* \Delta_2 \right) \right] \mathrm{d}y \ \mathrm{d}z \\ &= 2C \int |\Delta_1 \Delta_2| \left[1 - \cos \left(\chi_2 - \chi_1 \right) \right] \mathrm{d}y \ \mathrm{d}z \end{aligned}$$

(C is a constant and yz is the junction plane). We have assumed that $\Delta_{1,2}$ are complex and that the energy is normalized to zero at $\chi_1 - \chi_2 = 0$ (see below).

The dependence of the energy on the phase difference can be understood as follows. Suppose that a magnetic field parallel to the junction plane is applied; it is described by a vector potential $\boldsymbol{A}$. From the condition of gauge invariance it follows that the phase enters into the following combination with the vector potential:

$$\nabla \chi - \frac{2e}{\hbar c} A$$

We choose the vector potential to be normal to the junction plane (the x axis) and integrate the above-given combination over x from point 2 in the bulk of the left superconductor to point 1 in the bulk of the right one. As a result, we obtain

$$\chi_1 - \chi_2 - \frac{2e}{\hbar \dot{c}} \int_2^1 A_x \ \mathrm{d}x$$

Thus, in the presence of a magnetic field at the junction the energy is

$$E = C \int |\Delta_1 \Delta_2| \left[1 - \cos \left(\chi_1 - \chi_2 - \frac{2e}{ch} \int_2^1 A_x \ \mathrm{d}x \right) \right] \mathrm{d}y \ \mathrm{d}z \tag{22.11}$$

By varying with respect to $\boldsymbol{A_x}$ we have

$$\delta E = -\frac{2e}{c\hbar} C \int |\Delta_1 \Delta_2| \sin \left(\chi_1 - \chi_2 - \frac{2e}{c\hbar} \int_2^1 A_x \ \mathrm{d}x \right) \delta A_x \ \mathrm{d}V$$

However, according to the general formula of electrodynamics, the change in energy upon variation of the vector potential is given by

$$\delta E = -\frac{1}{c} \int j \delta A \ \mathrm{d}V$$

where $\boldsymbol{j}$ is the current density. Comparing the last two formulas, we obtain (we have changed the sign of the argument):

$$j = 2 \frac{e}{\hbar} C \left| \Delta_1 \Delta_2 \right| \sin \left(\chi_1 - \chi_2 - \frac{2e}{c\hbar} \int_2^1 A_x \ \mathrm{d}x \right).$$

The maximum magnitude of the sine is unity. Therefore we may write the following expression for the current:

$$j = j_c \sin \left(\chi_1 - \chi_2 - \frac{2e}{c\hbar} \int_2^1 A_x \ \mathrm{d}x \right), \tag{22.12}$$

where j_c is the critical current across the junction. In particular, in the absence of a field

$$j = j_c \sin(\chi_1 - \chi_2). \tag{22.13}$$

Thus, a phase difference for the functions Δ_1 and Δ_2 corresponds to the presence of a superconducting current.

According to the above derivation, j_c must be proportional to Δ_1 and Δ_2; it must also be proportional to the probability of electron tunneling through the junction. But the conductivity of the junction in the normal state, or R^{-1}, where R is the junction resistance, is proportional to the same quantity. In contrast to ordinary conductivity, it will be reasonable to write here $j = R^{-1}V$ (V is the potential difference) instead of $j = \sigma E$. The quantity R corresponds to the total resistance of 1 cm^2 of the junction area and has the dimensions of s $\cdot$ cm (or ohm $\cdot$cm^2).

The complete formula for two different superconductors at $T = 0$ has the form (Ambegoakar and Baratoff 1963)

$$j_c = \frac{2}{eR}\frac{\Delta_1\Delta_2}{\Delta_1 + \Delta_2}\,\mathrm{K}\left(\frac{|\Delta_1 - \Delta_2|}{\Delta_1 + \Delta_2}\right), \tag{22.14}$$

where K is a complete elliptic integral of the first kind (see formula 22.9). For two identical superconductors, we substitute $K(0) = \frac{1}{2}\pi$ and obtain

$$j_c = \frac{\pi\Delta}{2eR}. \tag{22.15}$$

At a finite temperature, instead of (22.15) we have (Ambegoakar and Baratoff 1963)

$$j_c = \frac{\pi\Delta(T)}{2eR}\tanh\left(\frac{\Delta(T)}{2T}\right). \tag{22.16}$$

In particular, near T_c,

$$j_c \approx \frac{\pi\Delta^2(T)}{4eRT_c}. \tag{22.17}$$

The microscopic derivation of formulas (22.14), (22.15) and (22.16) will be given in the next section.

For the Josephson effect to be observed in experiments, junctions with a resistivity of 0.1ohm $\cdot$ mm^2 are required. Actually, it is possible to attain even lower resistivities: 10^{-4}ohm $\cdot$ mm^2 and lower. The corresponding critical current density can reach $10^2 - 10^3$ A/cm^2. If we compare this value with the current density corresponding to the breakup of the pairs in a bulk superconductor (17.63), which is of the order of 10^8 A/cm^2, then the maximum Josephson effect appears to be much lower. Therefore, the Josephson effect and the associated phenomena are sometimes called weak superconductivity.

Thus, apart from the single-particle current found in the preceding section, a superconducting current not exceeding j_c may also flow across the tunnel junction. The Josephson effect is actually observed as follows. The current across the junction is varied and the potential difference is measured. At low magnitudes of the current V remains equal to zero. When the current exceeds j_c, there occurs a switching to the single-particle characteristic and when the current continues to increase the $V(j)$ follows the single-particle curve. However, when the current falls off, a hysteresis occurs rather commonly, namely the single-particle characteristic continues down to the point $j = 0, V = 2\Delta/e$ as V decreases, following which V vanishes in a jumpwise manner (see the oscillogram in fig. 145 for the two directions of the current).

Even in this simple example we see that the theoretical dependence of the current on the potential difference and the experimental determination of $V(j)$ give, in fact, different results,

which are accounted for by an abrupt jump of the characteristics measured from one regime to another and by the appearance of "steps", i.e., by a

Fig. 145.

In particular, near T_c,

$$j_c \approx \frac{\pi\Delta^2(T)}{4eRT_c}. \tag{22.17}$$

The microscopic derivation of formulas (22.14), (22.15) and (22.16) will be given in the next section.

For the Josephson effect to be observed in experiments, junctions with a resistivity of $0.1\text{ohm} \cdot \text{mm}^2$ are required. Actually, it is possible to attain even lower resistivities: 10^{-4} ohm $\cdot\text{mm}^2$ and lower. The corresponding critical current density can reach $10^2 - 10^3$ A/cm^2. If we compare this value with the current density corresponding to the breakup of the pairs in a bulk superconductor (17.63), which is of the order of 10^8 A/cm^2, then the maximum Josephson effect appears to be much lower. Therefore, the Josephson effect and the associated phenomena are sometimes called weak superconductivity.

Thus, apart from the single-particle current found in the preceding section, a superconducting current not exceeding j_c may also flow across the tunnel junction. The Josephson effect is actually observed as follows. The current across the junction is varied and the potential difference is measured. At low magnitudes of the current V remains equal to zero. When the current exceeds j_c, there occurs a switching to the single-particle characteristic and when the current continues to increase the $V(j)$ follows the single-particle curve. However, when the current falls off, a hysteresis occurs rather commonly, namely the single-particle characteristic continues down to the point $j = 0, V = 2\Delta/e$ as V decreases, following which V vanishes in a jumpwise manner (see the oscillogram in fig. 145 for the two directions of the current).

Even in this simple example we see that the theoretical dependence of the current on the potential difference and the experimental determination of $V(j)$ give, in fact, different results, which are accounted for by an abrupt jump of the characteristics measured from one regime to another and by the appearance of "steps", i.e., by a

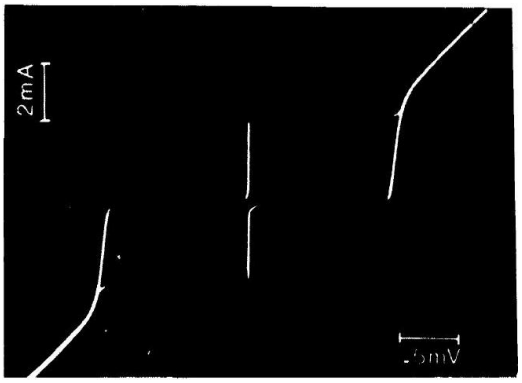

Fig. 145.

In particular, near T_c,

$$j_c \approx \frac{\pi \Delta^2(T)}{4eRT_c}. \tag{22.17}$$

The microscopic derivation of formulas (22.14), (22.15) and (22.16) will be given in the next section.

For the Josephson effect to be observed in experiments, junctions with a resistivity of 0.1ohm $\cdot$ mm^2 are required. Actually, it is possible to attain even lower resistivities: 10^{-4} ohm $\cdot$mm^2 and lower. The corresponding critical current density can reach $10^2 - 10^3$ A/cm^2. If we compare this value with the current density corresponding to the breakup of the pairs in a bulk superconductor (17.63), which is of the order of 10^8 A/cm^2, then the maximum Josephson effect appears to be much lower. Therefore, the Josephson effect and the associated phenomena are sometimes called weak superconductivity.

Thus, apart from the single-particle current found in the preceding section, a superconducting current not exceeding j_c may also flow across the tunnel junction. The Josephson effect is actually observed as follows. The current across the junction is varied and the potential difference is measured. At low magnitudes of the current V remains equal to zero. When the current exceeds j_c, there occurs a switching to the single-particle characteristic and when the current continues to increase the $V(j)$ follows the single-particle curve. However, when the current falls off, a hysteresis occurs rather commonly, namely the single-particle characteristic continues down to the point $j = 0, V = 2\Delta/e$ as V decreases, following which V vanishes in a jumpwise manner (see the oscillogram in fig. 145 for the two directions of the current).

Even in this simple example we see that the theoretical dependence of the current on the potential difference and the experimental determination of $V(j)$ give, in fact, different results, which are accounted for by an abrupt jump of the characteristics measured from one regime to another and by the appearance of "steps", i.e., by a

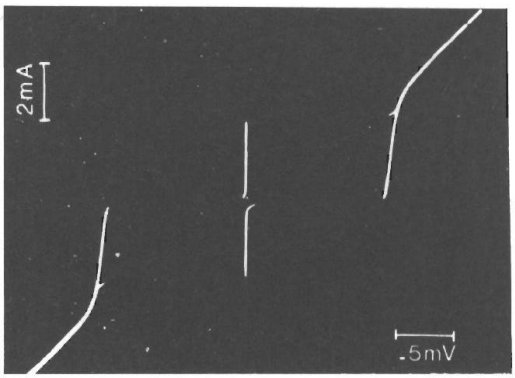

Fig. 145.

discontinuous variation of V at a given current. Since our purpose is to describe the fundamental aspect of the main physical phenomena, we will be concerned, as a rule, with the dependence $j(V)$, making qualitative reservations regarding the events that occur in actual measurements of $V(j)$.

Let us now examine the following problem. At first sight it seems that since the Josephson current and the single-particle current are proportional to the same quantity, namely R^{-1}, they must be observed under identical conditions. However, as has already been pointed out, in practice the Josephson effect disappears much earlier than the single-particle current with increasing $\boldsymbol{R}$. The cause is the fluctuational potential difference in the junction. This potential difference destroys the Josephson superconducting current but it has little effect on the single-particle current. This is associated with the fact that the single-particle current is generated at a finite potential difference and therefore small fluctuations are not important, whereas the Josephson current occurs at $V = 0$. According to the Nyquist theorem, the fluctuations in V increase proportionately to R (see Lifshitz and Pitaevskii 1978), which just accounts for the difference in behavior of the Josephson and single-particle currents. We shall confine ourselves to this qualitative explanation without describing the theory of fluctuations in the Josephson junctions (see Barone and Paterno 1982).

In concluding this section, we give a simple quantitative derivation of the Josephson current based on the Ginzburg-Landau theory (Aslamazov and Larkin 1969). The Josephson effect can be observed not only in a tunnel junction but also in any superconductor with a "weak link". One example is a film with a constriction (fig. 146) called a bridge. Upon passage of the current its density in the bridge may exceed the critical value (section 17.4). As a result, the bridge begins to play the same role with respect to the wider portions of the film as does the insulating layer in the tunnel junction between two superconductors. In particular, a Josephson current can flow across the bridge.

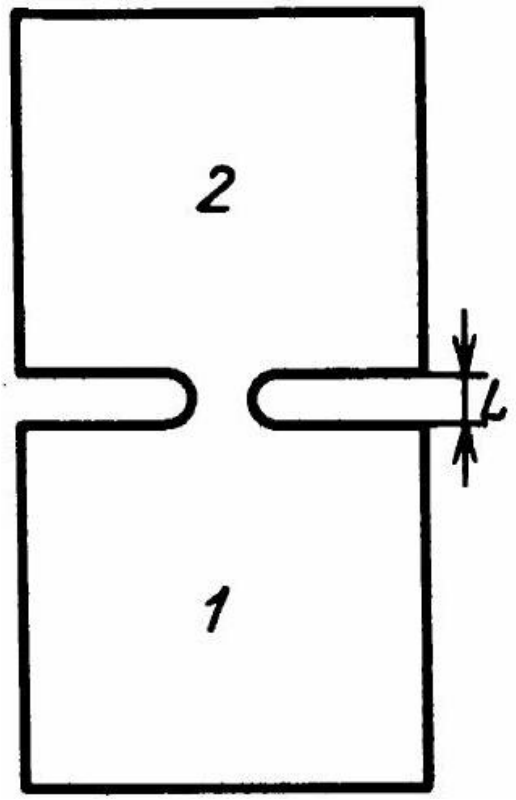

Fig. 146.

Because of the weakness of the Josephson current we may ignore the magnetic field generated by it. Let us write the first Ginzburg-Landau equation (17.6') in the absence of the field:

$$-\frac{1}{\chi^2}\Delta\Psi - \Psi + |\Psi|^2\Psi = 0. \tag{22.18}$$

Suppose that the bridge length L is much smaller than ξ (or, in reduced units, $L/\delta < x^{-1}$). In such a case the first term in eq. (22.18), which is of order $(\delta/xL)^{-2}$, is considerably larger than the remaining ones and we may retain only this term in eq. (22.18). So we obtain

$$\Delta\Psi = 0. \tag{22.19}$$

Far from the constriction $\Psi \to$ const. We assume that the constant is equal to $\exp(\mathrm{i}\chi_1)$ in the lower part and to $\exp(\mathrm{i}\chi_2)$ in the upper one (since in the bulk the current density is low and $|\Psi| = 1$). The solution of eq. (22.19) will be sought for in the form

$$\Psi = f(r)\exp(\mathrm{i}\chi_1) + [1 - f(r)]\exp(\mathrm{i}\chi_2)\,. \tag{22.20}$$

Evidently, the function $f(r)$ tends to unity in the bulk of film 1 and to zero in the bulk of film 2. Substituting into eq. (22.19) gives

$$\Delta f = 0.$$

The solution of this equation depends on the particular assumptions concerning the shape of the bridge.

Since we are interested only in the fundamental aspect of the problem, we will not consider the particular models; we substitute Ψ in the form (22.20) into the expression for the current (17.9) (with $\boldsymbol{A} = 0$) and use the ordinary units (here eq. 22.20 is multiplied by Ψ_0). As a result, we have

$$j = \frac{e\hbar}{m}\Psi_0^2 \nabla f \sin(\chi_1 - \chi_2) \tag{22.21}$$

This expression corresponds in form to (22.13) ($\nabla f \sim L^{-1}$), with $j_c \propto \Psi_0^2(T) \propto \Delta^2(T)$, just as in formula (22.17) for the tunnel junction in the neighborhood of T_c.

8.8.3 22.3. Microscopic derivation of the Josephson current

We shall employ the method of the so-called tunneling Hamiltonian. We assume that the creation and annihilation of electrons in the left superconductor is described by the operators $a^+_{p,\sigma}$and $a_{p,\sigma}$ and in the right one, accordingly, by $b^+_{p,\sigma}$and $b_{p,\sigma}$ and introduce an additional term into the Hamiltonian:

$$\mathscr{H}_T = \sum_{p,q,\sigma} T_{pq} a^+_{p,\sigma} b_{q,\sigma} + T^*_{pq} b^+_{q,\sigma} a_{p,\sigma}. \tag{22.22}$$

Because of the weakness of the Josephson current we may ignore the magnetic field generated by it. Let us write the first Ginzburg-Landau equation (17.6') in the absence of the field:

$$-\frac{1}{\chi^2}\Delta\Psi - \Psi + |\Psi|^2\Psi = 0. \tag{22.18}$$

Suppose that the bridge length L is much smaller than ξ (or, in reduced units, $L/\delta < x^{-1}$). In such a case the first term in eq. (22.18), which is of order $(\delta/xL)^{-2}$, is considerably larger than the remaining ones and we may retain only this term in eq. (22.18). So we obtain

$$\Delta\Psi = 0. \tag{22.19}$$

Far from the constriction $\Psi \to$ const. We assume that the constant is equal to $\exp(i\chi_1)$ in the lower part and to $\exp(i\chi_2)$ in the upper one (since in the bulk the current density is low and $|\Psi| = 1$). The solution of eq. (22.19) will be sought for in the form

$$\Psi = f(r)\exp(i\chi_1) + [1 - f(r)]\exp(i\chi_2). \tag{22.20}$$

Evidently, the function $f(r)$ tends to unity in the bulk of film 1 and to zero in the bulk of film 2. Substituting into eq. (22.19) gives

$$\Delta f = 0$$

The solution of this equation depends on the particular assumptions concerning the shape of the bridge.

Since we are interested only in the fundamental aspect of the problem, we will not consider the particular models; we substitute Ψ in the form (22.20) into the expression for the current (17.9) (with $\boldsymbol{A} = 0$) and use the ordinary units (here eq. 22.20 is multiplied by Ψ_0). As a result, we have

$$j = \frac{e\hbar}{m}\Psi_0^2 \nabla f \sin(\chi_1 - \chi_2) \tag{22.21}$$

This expression corresponds in form to (22.13) ($\nabla f \sim L^{-1}$), with $j_c \propto \Psi_0^2(T) \propto \Delta^2(T)$, just as in formula (22.17) for the tunnel junction in the neighborhood of T_c.

8.8.4 22.3. Microscopic derivation of the Josephson current

We shall employ the method of the so-called tunneling Hamiltonian. We assume that the creation and annihilation of electrons in the left superconductor is described by the operators $a^+_{p,\sigma}$and $a_{p,\sigma}$ and in the right one, accordingly, by $b^+_{p,\sigma}$and $b_{p,\sigma}$ and introduce an additional term into the Hamiltonian:

$$\mathscr{H}_{\mathrm{T}} = \sum_{p,q,\sigma} T_{pq} a^+_{p,\sigma} b_{q,\sigma} + T^*_{pq} b^+_{q,\sigma} a_{p,\sigma}. \tag{22.22}$$

Because of the weakness of the Josephson current we may ignore the magnetic field generated by it. Let us write the first Ginzburg-Landau equation (17.6') in the absence of the field:

$$-\frac{1}{\chi^2}\Delta\Psi - \Psi + |\Psi|^2\Psi = 0 \tag{22.18}$$

Suppose that the bridge length L is much smaller than ξ (or, in reduced units, $L/\delta < x^{-1}$). In such a case the first term in eq. (22.18), which is of order $(\delta/xL)^{-2}$, is considerably larger than the remaining ones and we may retain only this term in eq. (22.18). So we obtain

$$\Delta\Psi = 0. \tag{22.19}$$

Far from the constriction $\Psi \to$ const. We assume that the constant is equal to $\exp(\mathrm{i}\chi_1)$ in the lower part and to $\exp(\mathrm{i}\chi_2)$ in the upper one (since in the bulk the current density is low and $|\Psi| = 1$). The solution of eq. (22.19) will be sought for in the form

$$\Psi = f(r)\exp(\mathrm{i}\chi_1) + [1 - f(r)]\exp(\mathrm{i}\chi_2). \tag{22.20}$$

Evidently, the function $f(r)$ tends to unity in the bulk of film 1 and to zero in the bulk of film 2. Substituting into eq. (22.19) gives

$$\Delta f = 0.$$

The solution of this equation depends on the particular assumptions concerning the shape of the bridge.

Since we are interested only in the fundamental aspect of the problem, we will not consider the particular models; we substitute Ψ in the form (22.20) into the expression for the current (17.9) (with $\boldsymbol{A} = 0$) and use the ordinary units (here eq. 22.20 is multiplied by Ψ_0). As a result, we have

$$j = \frac{e\hbar}{m}\Psi_0^2 \nabla f \sin(\chi_1 - \chi_2) \tag{22.21}$$

This expression corresponds in form to (22.13) ($\nabla f \sim L^{-1}$), with $j_{\mathrm{c}} \propto \Psi_0^2(T) \propto \Delta^2(T)$, just as in formula (22.17) for the tunnel junction in the neighborhood of T_{c}.

8.8.5 22.3. Microscopic derivation of the Josephson current

We shall employ the method of the so-called tunneling Hamiltonian. We assume that the creation and annihilation of electrons in the left superconductor is described by the operators $a^+_{p,\sigma}$and $a_{p,\sigma}$ and in the right one, accordingly, by $b^+_{p,\sigma}$and $b_{p,\sigma}$ and introduce an additional term into the Hamiltonian:

$$\mathscr{H}_{\mathrm{T}} = \sum_{p,q,\sigma} T_{pq} a^+_{p,\sigma} b_{q,\sigma} + T^*_{pq} b^+_{q,\sigma} a_{p,\sigma}. \tag{22.22}$$

This additional term describes the transport of electrons from one metal to the other. Such a Hamiltonian, in fact, does not completely correspond to the problem under consideration because instead of the real potential barrier (22.22) it actually implies the transfer of free electrons from one phase space to another. However, with correct normalization of the transition matrix T_{pq} it is equivalent to the physical problem under consideration and therefore makes it possible to express the super-current in terms of the junction resistance in the normal state. It is this problem that we shall begin with.

The total current $\langle I \rangle$ from left to right is evidently equal to the rate of decrease of the number of electrons in the left metal multiplied by the electron charge. In accordance with quantum mechanics (see Landau and Lifshitz 1974), the current operator is given by

$$J = -e\dot{N}_{\mathrm{L}} = -\frac{ie}{\hbar}\left[\mathscr{K} N_{\mathrm{L}}\right] = -\frac{ie}{\hbar}\left[\mathscr{H}_{\mathrm{T}} N_{\mathrm{L}}\right], \tag{22.23}$$

where only the part $\mathscr{H}_T$ of the total Hamiltonian is left because it is only this part of the Hamiltonian that leads to nonconservation of the numbers of electrons in the left and the right metal separately, i.e., it does not commute with N_{L} and N_{R}. Substituting expression (22.22) for $\mathscr{H}_T$ into eq. (22.23) and

$$N_L = \sum_{p,\sigma} a^+_{p,\sigma} a_{p,\sigma} \tag{22.24}$$

(section 16.4), we obtain

$$J = \frac{ie}{\hbar}\left(\sum_{p,q,\sigma} T_{pq} a^+_{p,\sigma} b_{q,\sigma} - \sum_{p,q,\sigma} T^*_{pq} b^+_{q,\sigma} a_{p,\sigma}\right). \tag{22.25}$$

The above expression is the operator which is to be averaged over the state of the system. For a normal metal, to within the terms of order $(T/\mu)^2$ we can average over the state at $T = 0$. Thus,

$$\langle J \rangle = \langle \psi_0^* J \psi_0 \rangle . \tag{22.26}$$

Because of the smallness of the electron tunneling probability, we could have taken ψ_0 in a first approximation for the principal part of the Hamiltonian without $\mathscr{H}_T$. However, such an average is equal to zero. In view of this, we find the first approximation to the function ψ_0.

According to perturbation theory (see Landau and Lifshitz 1974),

$$\psi_0 \approx \psi_0^{(0)} + \psi_0^{(1)} = \psi_0^{(0)} + \sum_m \frac{(\mathscr{H}_{\mathrm{T}})_{m0}}{E_0^{(0)} - E_m^{(0)} + \mathrm{i}\delta} \psi_m^{(0)}, \tag{22.27}$$

where the sum runs over the excited states of the system and the superscript (0) signifies that we are dealing with the eigenstates and functions of the Hamiltonian without $\mathscr{H}_{\mathbf{T}}$. The correction i δ in the denominator takes account of the circumstance

This additional term describes the transport of electrons from one metal to the other. Such a Hamiltonian, in fact, does not completely correspond to the problem under consideration because instead of the real potential barrier (22.22) it actually implies the transfer of free electrons from one phase space to another. However, with correct normalization of the transition matrix T_{pq} it is equivalent to the physical problem under consideration and therefore makes it possible to express the super-current in terms of the junction resistance in the normal state. It is this problem that we shall begin with.

The total current $\langle I \rangle$ from left to right is evidently equal to the rate of decrease of the number of electrons in the left metal multiplied by the electron charge. In accordance with quantum mechanics (see Landau and Lifshitz 1974), the current operator is given by

$$J = -e\dot{N}_{\mathrm{L}} = -\frac{ie}{\hbar}\left[\mathscr{K} N_{\mathrm{L}}\right] = -\frac{ie}{\hbar}\left[\mathscr{H}_{\mathrm{T}} N_{\mathrm{L}}\right], \tag{22.23}$$

where only the part $\mathscr{H}_{\mathrm{T}}$ of the total Hamiltonian is left because it is only this part of the Hamiltonian that leads to nonconservation of the numbers of electrons in the left and the right metal separately, i.e., it does not commute with N_{L} and N_{R}. Substituting expression (22.22) for $\mathscr{H}_T$ into eq. (22.23) and

$$N_L = \sum_{p,\sigma} a^+_{p,\sigma} a_{p,\sigma} \tag{22.24}$$

(section 16.4), we obtain

$$J = \frac{ie}{\hbar}\left(\sum_{p,q,\sigma} T_{pq} a^+_{p,\sigma} b_{q,\sigma} - \sum_{p,q,\sigma} T^*_{pq} b^+_{q,\sigma} a_{p,\sigma}\right). \tag{22.25}$$

The above expression is the operator which is to be averaged over the state of the system. For a normal metal, to within the terms of order $(T/\mu)^2$ we can average over the state at $T = 0$. Thus,

$$\langle J\rangle = \langle \psi_0^* J \psi_0\rangle .$$

Because of the smallness of the electron tunneling probability, we could have taken ψ_0 in a first approximation for the principal part of the Hamiltonian without $\mathscr{H}_{\mathrm{T}}$. However, such an average is equal to zero. In view of this, we find the first approximation to the function ψ_0.

According to perturbation theory (see Landau and Lifshitz 1974),

$$\psi_0 \approx \psi_0^{(0)} + \psi_0^{(1)} = \psi_0^{(0)} + \sum_m \frac{(\mathscr{H}_{\mathrm{T}})_{m0}}{E_0^{(0)} - E_m^{(0)} + \mathrm{i}\delta}\psi_m^{(0)}, \tag{22.27}$$

where the sum runs over the excited states of the system and the superscript (0) signifies that we are dealing with the eigenstates and functions of the Hamiltonian without $\mathscr{H}_{\boldsymbol{T}}$. The correction i δ in the denominator takes account of the circumstance
that the spectrum is, in fact, continuous (see Landau and Lifshitz 1974). Substitution into (22.26) yields

$$\langle J\rangle = \left\langle \psi_0^{(1)*} J \psi_0^{(0)}\right\rangle + \left\langle \psi_0^{(0)*} J \psi_0^{(1)}\right\rangle . \tag{22.28}$$

Using formulae (22.25), (22.27) and (22.22), we easily find that only those terms are nonzero which enter into the products $T_{pq}T^*_{pq} = |T_{pq}|^2$. The resultant expression contains the differences

$$\frac{1}{E_0^{(0)} - E_m^{(0)} + \mathrm{i}\delta} - \frac{1}{E_0^{(0)} - E_m^{(0)} - \mathrm{i}\delta} = -2\pi\mathrm{i}\delta\left(E_0^{(0)} - E_m^{(0)}\right),$$

because the principal values of such denominators cancel and only the residue in the pole is retained. The final result is

$$\begin{aligned}\langle J\rangle =& \frac{2\pi e}{\hbar}\sum_{m,p,q,\sigma} |T_{pq}|^2\,\delta\left(E_0^{(0)} - E_m^{(0)}\right)\\ &\times\left[\left(a^+_{p,\sigma}b_{q,\sigma}\right)_{0m}\left(b^+_{q,\sigma}a_{p,\sigma}\right)_{m0} - \left(b^+_{q,\sigma}a_{p,\sigma}\right)_{0m}\left(a^+_{p,\sigma}b_{q,\sigma}\right)_{m0}\right].\end{aligned} \tag{22.29}$$

The expression in brackets gives

$$n_{p,\sigma}\left(1-n_{q,\sigma}\right)-n_{q,\sigma}\left(1-n_{p,\sigma}\right)=n_{p,\sigma}-n_{q,\sigma}$$
$$=n_{\mathrm{F}}\left(\xi_p-eV\right)-n_{\mathrm{F}}\left(\xi_q\right)$$

where n_{F} are the Fermi functions and their arguments correspond to the fact that a potential difference is applied to the junction. Passing from the summation over the momenta to integration and taking into account that only the electrons in the vicinity of the Fermi boundary are involved in the current, we obtain

$$\sum_p \to V_1\left(\frac{1}{2}\nu_1\right)\int \mathrm{d}\xi_p$$

where V_1 is the volume of the left metal and ν_1 is the density of states; then

$$\langle J\rangle = \frac{4\pi e}{\hbar}V_1V_2\left(\frac{1}{2}\nu_1\right)\left(\frac{1}{2}\nu_2\right)\overline{|T_{pq}|^2}$$
$$\times\int \mathrm{d}\xi_p\int \mathrm{d}\xi_q\delta\left(\xi_p-\xi_q\right)\left[n_{\mathrm{F}}\left(\xi_p-eV\right)-n_{\mathrm{F}}\left(\xi_q\right)\right]$$

where $\overline{|T_{pq}|^2}$ signifies the average over both Fermi surfaces. Taking the integral and dividing by the junction area, we obtain the current density

$$j=\frac{\pi e}{\hbar}eV\nu_1\nu_2\overline{|T_{pq}|^2}\frac{V_1V_2}{S}.$$

Writing this expression in the form $j=V/R$, we have

$$\frac{1}{R}=\frac{\pi e^2}{\hbar}\nu_1\nu_2\left|\overline{T_{pq}|^2}\frac{V_1V_2}{S}.\right. \tag{22.30}$$

It is not difficult to see that since T_{pq} has the dimensions of the energy R has the correct dimensions cm.s. At the same time it is clear that the correct normalization of T_{pq} must include the factor $\left(V_1V_2/S\right)^{-1/2}$.

Let us now find the Josephson current for two superconductors, expressing it first in terms of $|T_{pq}|^2$ and then with the aid of formula (22.30) in terms of R. To do this, we return to formulas (22.28), (22.27) and (22.25). The expressions thus obtained contain terms of two types: terms that contain a^+a and b^+b and those which include the combination a^+a^+bb or aab^+b^+. We have used terms of the first type in the derivative of the current flowing across the normal junction and they vanish at $V=0$. In a superconductor they give a single-particle current, which we derived with the aid of a more concise method in section 22.1, and they are also equal to zero in the absence of a potential difference.

The remaining terms have the form

$$\mathrm{i}\frac{e}{\hbar}\sum_{p,q,\sigma,m}\left[T_{pq}T_{p_1q_1}\left(a^+_{p,\sigma}b_{q,\sigma}\right)_{0m}\left(a^+_{p_1,\sigma_1}b_{q_1,\sigma_1}\right)_{m0}\right.$$
$$\times\left(\frac{1}{E_0^{(0)}-E_m^{(0)}+\mathrm{i}\delta}+\frac{1}{E_0^{(0)}-E_m^{(0)}-\mathrm{i}\delta}\right)$$
$$-T^*_{pq}T^*_{p_1q_1}\left(b_{q,\sigma}a_{p,\sigma}\right)_{0m}\left(b^+_{q_1,\sigma_1}a^+_{p_1,\sigma_1}\right)_{m0}$$
$$\left.\times\left(\frac{1}{E_0^{(0)}-E_m^{(0)}+\mathrm{i}\delta}+\frac{1}{\left(E_0^{(0)}+E_m^{(0)}+\mathrm{i}\delta\right.}\right)\right]$$

We transform the operators $a_{p,\sigma}$ and $b_{q,\sigma}$ using the Bogoliubov formulas (16.14). However, in this particular case, there is no ground for considering the coefficients u_p and v_p to be real since, in contrast to the thermodynamic quantities, the Josephson current depends not only on the moduli but also on the phases of these quantities. In view of this, we write the Bogoliubov transformation in a somewhat modified form:

$$a_{p,+} = u_p \alpha_{p,+} + v_p^* \alpha_{-p,-}^+, \quad a_{p,-} = u_p \alpha_{p,-} - v_p^* \alpha_{-p,+}^+, \tag{22.31}$$

where $|u_p|^2 + |v_p|^2 = 1$. Here, having performed all the calculations of section 16.4, we get

$$\begin{aligned} &|u_p|^2 = \tfrac{1}{2}\left(1 + \tfrac{\xi_p}{\varepsilon_p}\right), \quad |v_p|^2 = \tfrac{1}{2}\left(1 - \tfrac{\xi_p}{\varepsilon_p}\right), \\ &\varepsilon_p = \left(\xi_p^2 + |\Delta|^2\right)^{1/2}, \quad \Delta = g \textstyle\sum_p u_p v_p^* \left(1 - n_{p,+} - n_{p,-}\right). \end{aligned} \tag{22.32}$$

Averaging of the operator at $T \neq 0$ must be carried out, strictly speaking, in two stages: first over the given quantum states and then over the Gibbs distribution. However, we can use the fact that the entire system composed of a large number of particles is in a certain quantum state with an accuracy of up to small fluctuations, this state being characterized by the equilibrium occupation numbers $n_F(\varepsilon)$.

One more property of the matrix T_{pq} will be required here. As has been noted in section 1.1, the Schrödinger equation is invariant under the transformation $t \to -t$ and $\psi \to \psi^*$. With this transformation the momenta p and q change sign [$\exp(\mathrm{i}pr/\hbar) \to \exp(-\mathrm{i}pr/\hbar)$] and there also occurs the inversion of the tunneling transition, i.e., $b_q \rightleftharpoons a_{-p}$. This means that T_{pq} has the following property:

$$T_{pq} = T_{-p-q}^* \tag{22.33}$$

After performing rather simple but time-consuming calculations we obtain an expression proportional to $u_p^* v_p u_q v_q^* - u_p v_p^* u_q^* v_q$. If we assume that $u_p^* v_p = |u_p|\,|v_p| \exp(\mathrm{i}\chi_1)$, $u_q^* v_q = |u_q|\,|v_q| \exp(\mathrm{i}\chi_2)$, then this difference is equal to $|u_p v_p u_q v_q|\, 2\mathrm{i} \sin(\chi_1 - \chi_2)$. As regards the energy denominators, it follows that, in contrast to a normal metal, the terms with $+\mathrm{i}\delta$ and $-\mathrm{i}\delta$ add up, i.e., the doubled principal value of the integral is retained. On the whole, we obtain

$$\begin{aligned} \langle J \rangle =& 8\frac{e}{\hbar} \sum_{p,q} |u_p v_p u_q v_q|\, |T_{pq}|^2 \sin(\chi_1 - \chi_2) \\ &\times \left[\frac{n_p (1 - n_q)}{\varepsilon_p - \varepsilon_q} - \frac{n_p n_q}{\varepsilon_p + \varepsilon_q} + \frac{(1 - n_p)(1 - n_q)}{\varepsilon_p + \varepsilon_q} - \frac{(1 - n_p) n_q}{\varepsilon_p - \varepsilon_q} \right]. \end{aligned}$$

Collecting terms with identical denominators, using the formula

$$|u_p v_p| = \frac{|\Delta|}{2\varepsilon_p} \tag{22.34}$$

and passing over from summation to integration first over ξ_p and ξ_q and then over ε_p and ε_q (with account taken of two possible signs of ξ), and, finally, expressing the Fermi functions via the hyperbolic tangents, we obtain

$$\begin{aligned} j =& -\frac{2e}{\hbar} \overline{|T_{pq}|^2} \frac{V_1 V_2}{S} \sin(\chi_1 - \chi_2)\, \nu_1 \nu_2 \Delta_1 \Delta_2 \\ &\times \int_{\Delta_1}^{\infty} \mathrm{d}\varepsilon_1 \int_{\Delta_2}^{\infty} \mathrm{d}\varepsilon_2 \frac{\left[\varepsilon_1 \tanh\left(\frac{\varepsilon_2}{2T}\right) - \varepsilon_2 \tanh\left(\frac{\varepsilon_1}{2T}\right)\right]}{\left(\varepsilon_1^2 - \varepsilon_2^2\right) \xi_1 \xi_2} \end{aligned}$$

where $\xi_{1,2} = \left(\varepsilon_{1,2}^2 - \Delta_{1,2}^2\right)^{1/2}$.

Let us first consider the integral over ε_1. It may be written in the form of a contour integral in

a complex plane with branch cuts along the real axis from Δ to ∞ and from $-\infty$ to $-\Delta$ (fig. 147a). Following this, the contour of integration can may be "straightened up" (fig. 147b) and, as a result, we obtain the sum of residues from

One more property of the matrix T_{pq} will be required here. As has been noted in section 1.1, the Schrödinger equation is invariant under the transformation $t \to -t$ and $\psi \to \psi^*$. With this transformation the momenta p and q change sign [$\exp(ipr/\hbar) \to \exp(-ipr/\hbar)$] and there also occurs the inversion of the tunneling transition, i.e., $b_q \rightleftharpoons a_{-p}$. This means that T_{pq} has the following property:

$$T_{pq} = T^*_{-p-q}. \tag{22.33}$$

After performing rather simple but time-consuming calculations we obtain an expression proportional to $u_p^* v_p u_q v_q^* - u_p v_p^* u_q^* v_q$. If we assume that $u_p^* v_p = |u_p|\,|v_p| \exp(i\chi_1)$, $u_q^* v_q = |u_q|\,|v_q| \exp(i\chi_2)$, then this difference is equal to $|u_p v_p u_q v_q|\, 2i \sin(\chi_1 - \chi_2)$. As regards the energy denominators, it follows that, in contrast to a normal metal, the terms with $+i\delta$ and $-i\delta$ add up, i.e., the doubled principal value of the integral is retained. On the whole, we obtain

$$\begin{aligned}\langle J \rangle =& 8\frac{e}{\hbar} \sum_{p,q} |u_p v_p u_q v_q|\, |T_{pq}|^2 \sin(\chi_1 - \chi_2) \\ &\times \left[\frac{n_p (1 - n_q)}{\varepsilon_p - \varepsilon_q} - \frac{n_p n_q}{\varepsilon_p + \varepsilon_q} + \frac{(1 - n_p)(1 - n_q)}{\varepsilon_p + \varepsilon_q} - \frac{(1 - n_p) n_q}{\varepsilon_p - \varepsilon_q} \right].\end{aligned}$$

Collecting terms with identical denominators, using the formula

$$|u_p v_p| = \frac{|\Delta|}{2\varepsilon_p} \tag{22.34}$$

and passing over from summation to integration first over ξ_p and ξ_q and then over ε_p and ε_q (with account taken of two possible signs of ξ), and, finally, expressing the Fermi functions via the hyperbolic tangents, we obtain

$$\begin{aligned} j =& -\frac{2e}{\hbar} \overline{|T_{pq}|^2} \frac{V_1 V_2}{S} \sin(\chi_1 - \chi_2)\, \nu_1 \nu_2 \Delta_1 \Delta_2 \\ &\times \int_{\Delta_1}^{\infty} d\varepsilon_1 \int_{\Delta_2}^{\infty} d\varepsilon_2 \frac{\left[\varepsilon_1 \tanh\left(\frac{\varepsilon_2}{2T}\right) - \varepsilon_2 \tanh\left(\frac{\varepsilon_1}{2T}\right)\right]}{(\varepsilon_1^2 - \varepsilon_2^2)\, \xi_1 \xi_2} \end{aligned}$$

where $\xi_{1,2} = \left(\varepsilon_{1,2}^2 - \Delta_{1,2}^2\right)^{1/2}$.

Let us first consider the integral over ε_1. It may be written in the form of a contour integral in a complex plane with branch cuts along the real axis from Δ to ∞ and from $-\infty$ to $-\Delta$ (fig. 147a). Following this, the contour of integration can may be "straightened up" (fig. 147b) and, as a result, we obtain the sum of residues from

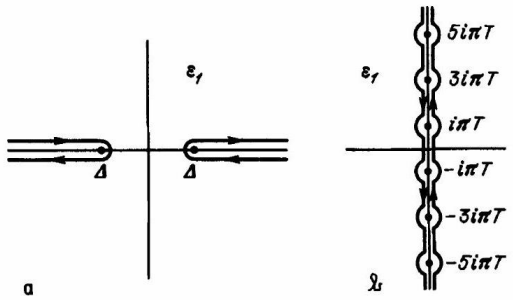

Fig. 147.

$\tanh(\varepsilon_1/2T)$, which are located at the points $\mathrm{i}\pi T(2n+1)$:

$$\int_\Delta^\infty \mathrm{d}\varepsilon_1 \cdots = \frac{1}{4}\int_C \mathrm{d}\varepsilon_1 \cdots$$
$$= \frac{1}{4}\cdot 2T\cdot 2\pi \sum_{n=-\infty}^{\infty} \varepsilon_2 \frac{1}{[\pi^2T^2(2n+1)^2+\varepsilon_2^2]\,[\pi^2T^2(2n+1)^2+\Delta_1^2]^{1/2}\,(\varepsilon_2^2-\Delta_2^2)^{1/2}}$$

Now the same procedure will be used for the integral over ε_2. In each of the terms of the sum over n there are two residues with respect to ε_2 at $\pm\mathrm{i}\pi T(2n+1)$. As a result, we get $j = j_\mathrm{c}\sin(\chi_1-\chi_2)$, where

$$j_\mathrm{c} = \frac{2}{eR}\pi T\Delta_1\Delta_2 \sum_{n=0}^{\infty} \frac{1}{[\pi^2T^2(2n+1)^2+\Delta_1^2]^{1/2}} \frac{1}{[\pi^2T^2(2n+1)^2+\Delta_2^2]^{1/2}}.$$

Let us consider two cases. Suppose the metals are identical. In this case, using relation (21.1),

$$\sum_{n=1}^{\infty} \frac{1}{(2n-1)^2+x^2} = \frac{\pi}{4x}\tanh\left(\frac{1}{2}\pi x\right),$$

we have

$$j_\mathrm{c} = \frac{\pi}{2eR}\Delta\tanh\left(\frac{\Delta}{2T}\right),$$

which corresponds to formulae (22.13) and (22.16).
Suppose now that the metals are different but $T\to 0$. Here the intervals between the values of $\pi T(2n+1)$ are small as compared with Δ and we may replace the sum by an integral. As a result, we have

$$j_\mathrm{c} = \frac{1}{eR}\Delta_1\Delta_2\int_0^\infty \frac{\mathrm{d}\omega}{(\omega^2+\Delta_1^2)^{1/2}\,(\omega^2+\Delta_2^2)^{1/2}}$$
$$= \frac{2}{eR}\frac{\Delta_1\Delta_2}{\Delta_1+\Delta_2}K\left(\frac{|\Delta_1-\Delta_2|}{\Delta_1+\Delta_2}\right)$$

that is, formula (22.14).

8.8.6 22.4. The Josephson effect in a magnetic field

Suppose that a magnetic field is applied parallel to the plane of the tunnel junction (yz). Let, for example, H be directed along z. In this case, we may introduce a vector potential:

$$A_x = H_z(x)y. \tag{22.35}$$

The area of the junction is assumed to be so small that the effect of the field created by the current may be neglected. The relevant condition will be derived later. In the presence of the field the current density has the form of (22.12). Taking into account that H_z does not depend on x in the insulating layer (d') and falls off in the superconductor by the law $\exp(-x/\delta)$, we get

$$\int_2^1 A_x\,\mathrm{d}x = H_{z0}yd \tag{22.36}$$

where

$$d = 2\delta(T) + d' \approx 2\delta(T). \tag{22.37}$$

Here we have taken into account that $d' \sim 10^{-7} - 10^{-8}$ cm and $\delta(T) \sim 10^{-5} - 10^{-6}$ cm. Hence, the current density in the presence of a steady field has the form ($H \equiv H_{z0}$)

$$j = j_c \sin\left(\chi_1 - \chi_2 + \frac{2eHdy}{c\hbar}\right). \tag{22.38}$$

Thus, the current density in the presence of a field varies in a direction perpendicular to the field and even changes sign.

In practice, naturally it is the total current that is measured or, what is the same thing, the average current density. Since in the direction of the field the current is homogeneous, the average current density is given by

$$\begin{aligned}\bar{j} &= \frac{1}{L}\int_0^L j(y)\mathrm{d}y \\ &= j_c \frac{c\hbar}{2eHLd}\left[-\cos\left(\chi_1 - \chi_2 + \frac{2e}{c\hbar}HLd\right) + \cos\left(\chi_1 - \chi_2\right)\right]\end{aligned} \tag{22.38'}$$

where L is the length of the junction along y. It is not difficult to see that $HLd = \Phi$ is the field flux across the junction. Introducing the flux quantum $\Phi_0 = \pi\hbar c/e$, we may write expression (22.38) in the form

$$\bar{j} = j_c \frac{\Phi_0}{\pi\Phi}\sin\left(\frac{\pi\Phi}{\Phi_0}\right)\sin\left(\theta_0 + \frac{\pi\Phi}{\Phi_0}\right), \tag{23.39}$$

where $\theta_0 = \chi_1 - \chi_2$.

From eq. (22.39) it follows that $\bar{j}$ vanishes at $\Phi = n\Phi_0$, i.e., when the field flux across the junction is equal to an integer number of quanta. The maximum value of current in the intervals between these values is obtained by the choice of the phase difference and evidently corresponds to $\sin\left[\theta_0 - (\pi\Phi/\Phi_0)\right] = \pm 1$. As a result, it turns out that (Rowell 1963)

$$\bar{j}_{\max} = j_c \left|\frac{\sin\left(\pi\Phi/\Phi_0\right)}{\pi\Phi/\Phi_0}\right|. \tag{22.40}$$

The graph of this function is given in fig. 148. The importance of the dependence (22.40) lies in the fact that it allows one to measure the value of d, i.e., $\delta(T)$ from the points in which $\bar{j}_{\max} = 0$. In principle, one could also use this dependence for measuring the magnetic field, but in practice Josephson interferometers are used for this purpose (section 22.8).

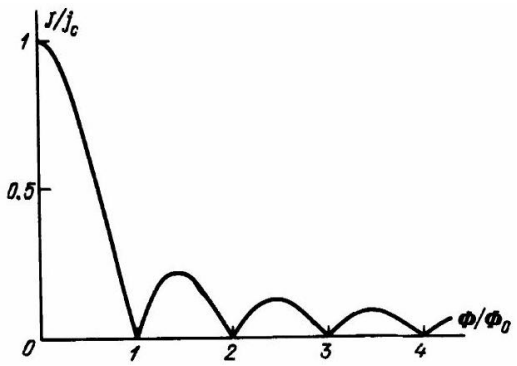

Fig. 148.

Now we shall be concerned with the study of a wide junction, in which case we cannot neglect the field generated by the Josephson current. Here, even in the absence of the external field the distribution of current along the junction becomes nonuniform. Let θ denote the complete argument in formula (22.12). Although the inhomogeneity of the field along y no longer permits us to take the vector potential in the form (22.35), the difference $\theta(y+dy)-\theta(y)$ may still be written as

$$\theta(y+\mathrm{d}y)-\theta(y)=\frac{2e}{\hbar c}H(y)d\cdot\ \mathrm{d}y=\frac{2\pi}{\Phi_0}H(y)d\cdot\ \mathrm{d}y$$

(we assume that H has only one component, H_z). From this we see that

$$H(y)=\frac{\Phi_0}{2\pi d}\frac{\mathrm{d}\theta}{\mathrm{d}y}. \tag{22.41}$$

According to Maxwell's equation

$$j=\frac{c}{4\pi}\frac{\mathrm{d}H}{\mathrm{d}y}. \tag{22.42}$$

At the same time, $j=j_\mathrm{c}\sin\theta$. Substituting this into eq. (22.42) and using eq. (22.41), we arrive at the equation for $\boldsymbol{\theta}$ (Ferrell and Prange 1963)

$$\frac{\mathrm{d}^2\theta}{\mathrm{d}y^2}=\frac{\sin\theta}{\delta_\mathrm{J}^2}, \tag{22.43}$$

where

$$\delta_\mathrm{J}=\left(\frac{c\Phi_0}{8\pi^2 j_\mathrm{c}d}\right)^{1/2} \tag{22.44}$$

Let us consider a case where there is a field $H_y=H$ but there is no net current across the junction. If the field is low, the quantity θ may be assumed to be small. Replacing $\sin\theta$ by θ, we obtain

$$\frac{\mathrm{d}^2\theta}{\mathrm{d}y^2}=\frac{\theta}{\delta_\mathrm{J}^2}, \tag{22.45}$$

the solution of which is

$$\theta=\theta_0\exp\left(\frac{-y}{\delta_\mathrm{J}}\right).$$

Inserting this into eq. (22.41) gives

$$H(y)=H_0\exp\left(\frac{-y}{\delta_\mathrm{J}}\right). \tag{22.46}$$

The result obtained is easy to interpret. If the super-conducting current can flow across the junction, it can screen out the applied field. The corresponding penetration depth δ_J is given by formula (22.44). If we substitute into it the orders of magnitudes of the parameters, then for $j_\mathrm{c}\sim 10^2$ A/cm^2 we obtain $\delta_\mathrm{J}\sim 10^{-2}$ cm, which is much larger than the ordinary penetration depth. The junction may be regarded as narrow if its width $L<\delta_\mathrm{J}$. In this case, the field of the current may be neglected and no screening of the external magnetic field takes place. But if $L>\delta_\mathrm{J}$, the junction is wide and the screening must be taken into account.

Thus, the Josephson junction is, to a certain extent, a two-dimensional superconductor with the corresponding Meissner effect. As a matter of fact, of course, the current lines are closed

in the three-dimensional space: the current flows in both superconductors perpendicular to the field in a layer of thickness δ (fig. 149a).

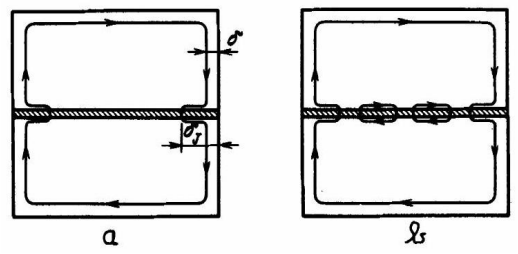

Fig. 149.

So far we have considered the field to be weak and made the replacement $\sin\theta \approx \theta$. In the case of a strong field this cannot be done. Let us return to eq. (22.43); we multiply both sides by $\mathrm{d}\theta/\mathrm{d}y$ and integrate over y. As a result, we get

$$\left(\frac{\mathrm{d}\theta}{\mathrm{d}y}\right)^2 = -2\frac{\cos\theta}{\delta_\mathrm{J}^2} + C \tag{22.47}$$

(C is a constant). This gives (it is convenient here to fix the point where $\theta = \pi$)

$$y - y_0 = \int_\pi^\theta \mathrm{d}\theta_1 \left(C - 2\frac{\cos\theta_1}{\delta_\mathrm{J}^2}\right)^{-1/2}. \tag{22.48}$$

Let us find a solution of the "soliton" type, in which the current is nonzero in a narrow vicinity of some point and is equal to zero far from it. Then, $\mathrm{d}\theta/\mathrm{d}y \to 0$ as $y \to \pm\infty$. This can be attained by assuming that $\theta \to 0$ with $y \to -\infty$ and $\theta \to 2\pi$ with $y \to \infty$. In this case $C = 2\delta_\mathrm{J}^{-2}$ in eq. (22.47). The integral (22.48) is easily evaluated in such a case; as a result, we obtain

$$\theta(y) = 4\arctan\left[\exp\left(\frac{y - y_0}{\delta_\mathrm{J}}\right)\right]. \tag{22.49}$$

The plots for $\theta(y)$, the field and current are given in fig. 150. From these plots it is seen that the solution obtained corresponds to a vortex with the center at y_0*. The picture of current lines (for two vortices) is shown in fig. 149b.

Let us find the field flux in a single vortex. According to (22.41),

$$\Phi = d\int_{-\infty}^{\infty} H\ \mathrm{d}y = \frac{\Phi_0}{2\pi d} d[\theta(\infty) - \theta(-\infty)] = \Phi_0.$$

Thus, the vortex carries a magnetic flux quantum. We come to the conclusion that the Josephson junction in the external field is the two-dimensional analog of a type II superconductor.

*The idea of the appearance of such vortices was advanced by Josephson (Josephson 1965).

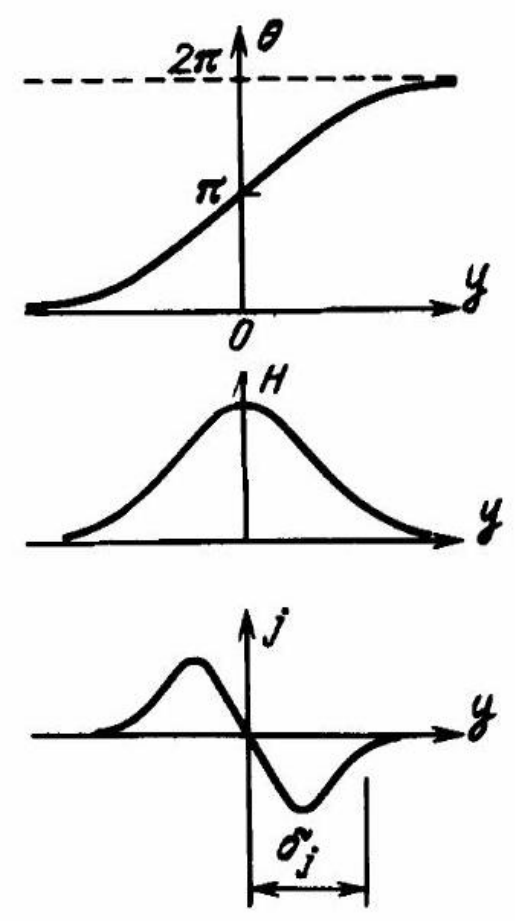

Fig. 150.

Vortices begin to be formed in an external field $H = H_{c1}$, which is of the order of the average field in the vortex, i.e., $H_{c1} \sim \Phi_0/(d\delta_J)$. The exact formula reads (Josephson 1965):

$$H_{c1} = \frac{2\Phi_0}{\pi^2 \delta_J d}. \tag{22.50}$$

The vortex concentration increases with increasing field, but since the Josephson vortex has no "normal core", in which the order parameter decreases strongly, it follows that no transition occurs to the normal state at any field H_{c2}.

In the limiting case at high fields the vortices overlap and the field in the junction is almost homogeneous*. From (22.41) it follows that mainly $\theta \approx H(2\pi d/\Phi_0)(y - y_0)$, i.e., $\mathrm{d}\theta/\mathrm{d}y = \text{const}$. According to eqs. (22.47) and (22.48), the second term in parentheses of the integrand (22.48) is much smaller than the first and we can carry out an expansion. Finally, we find

$$\theta \approx H\frac{2\pi d}{\Phi_0}(y - y_0) - \left(\frac{H_{c1}\pi}{4H}\right)^2 \sin\left(2\pi d H \frac{y - y_0}{\Phi_0}\right), \tag{22.51}$$

where we have used formula (22.50). Thus, in addition to the regular increase of the phase in the junction plane in a direction perpendicular to the field there occur small oscillations of the phase, which fall off rapidly in amplitude with increasing field.

*In this sense, a strong field leads to the same situation that occurs in a narrow junction. This is natural: in both cases the Josephson current cannot screen out the field.

8.8.7 22.5. The ac Josephson effect

Suppose that the current passing through the Josephson junction becomes larger than the critical current. In this case, superconductivity is destroyed and a potential difference appears. From the condition of gauge invariance it follows that in the equations the potential always appears together with the derivative of the phase with respect to time in the combination (section 19.6)

$$2e\varphi + \hbar\frac{\partial\chi}{\partial t}$$

that is, $(2e/\hbar)\int^t \varphi(t_1)\,\mathrm{d}t_1$ is added to the phase χ. This means that in the presence of the potential difference the phase difference satisfies the equation

$$\frac{\partial\theta}{\partial t} = \frac{2e}{\hbar}V \tag{22.52}$$

where $V = \varphi_1 - \varphi_2$. If $V = \text{const.}$, then the phase difference is given by

$$\theta = \theta_0 + \frac{2eV}{\hbar}t. \tag{22.53}$$

This relation was first derived by Josephson (Josephson 1962, 1964) for the tunnel junction, but, as was found out later, it describes the so-called resistive state of superconductors in various cases (for example, see formula 22.91, section 22.9). Thus, if a constant potential difference is maintained at the junction, an alternating current will flow across the junction:

$$j = j_\mathrm{c}\sin\left(\theta_0 + \frac{2eV}{\hbar}t\right). \tag{22.54}$$

The frequency

$$\omega = 2eV/\hbar \tag{22.55}$$

corresponds to 10^{11} s^{-1} for $V \sim 10^{-4}V$.
As has been noted in section 22.2, the potential difference is measured experimentally at a given current. The current is made up of a normal (single-particle) and a superconducting current. The normal current is V/R (we are considering a case where V is not too close to $2\Delta/e$) or, according to eq. (22.52), $(\hbar/2eR)\partial\theta/\partial t$. Thus, we have

$$j = j_\mathrm{c}\sin\theta + \frac{\hbar}{2eR}\frac{\partial\theta}{\partial t}. \tag{22.56}$$

Integration of this equation gives

$$\theta = 2\arctan\left\{\left[1 - \left(\frac{j_c}{j}\right)^2\right]^{1/2}\tan\left[eRt\frac{(j^2 - j_c^2)^{1/2}}{\hbar}\right] + \frac{j_c}{j}\right\}. \tag{22.57}$$

8.8.8 22.5. The ac Josephson effect

Suppose that the current passing through the Josephson junction becomes larger than the critical current. In this case, superconductivity is destroyed and a potential difference appears. From the condition of gauge invariance it follows that in the equations the potential always appears together with the derivative of the phase with respect to time in the combination (section 19.6)

$$2e\varphi + \hbar\frac{\partial\chi}{\partial t}$$

that is, $(2e/\hbar)\int^t \varphi(t_1)\,\mathrm{d}t_1$ is added to the phase χ. This means that in the presence of the potential difference the phase difference satisfies the equation

$$\frac{\partial\theta}{\partial t} = \frac{2e}{\hbar}V \tag{22.52}$$

where $V = \varphi_1 - \varphi_2$. If $V = \text{const.}$, then the phase difference is given by

$$\theta = \theta_0 + \frac{2eV}{\hbar}t. \tag{22.53}$$

This relation was first derived by Josephson (Josephson 1962, 1964) for the tunnel junction, but, as was found out later, it describes the so-called resistive state of superconductors in various cases (for example, see formula 22.91, section 22.9). Thus, if a constant potential difference is maintained at the junction, an alternating current will flow across the junction:

$$j = j_\mathrm{c}\sin\left(\theta_0 + \frac{2eV}{\hbar}t\right). \tag{22.54}$$

The frequency

$$\omega = 2eV/\hbar \tag{22.55}$$

corresponds to $10^{11}\ \mathrm{s}^{-1}$ for $V \sim 10^{-4}V$.
As has been noted in section 22.2, the potential difference is measured experimentally at a given current. The current is made up of a normal (single-particle) and a superconducting current. The normal current is V/R (we are considering a case where V is not too close to $2\Delta/e$) or, according to eq. (22.52), $(\hbar/2eR)\partial\theta/\partial t$. Thus, we have

$$j = j_\mathrm{c}\sin\theta + \frac{\hbar}{2eR}\frac{\partial\theta}{\partial t}. \tag{22.56}$$

Integration of this equation gives

$$\theta = 2\arctan\left\{\left[1 - \left(\frac{j_c}{j}\right)^2\right]^{1/2}\tan\left[eRt\frac{(j^2 - j_c^2)^{1/2}}{\hbar}\right] + \frac{j_c}{j}\right\}. \tag{22.57}$$

From this, using $V = (\hbar/2e)\mathrm{d}\theta/\mathrm{d}t$, we find (Aslamazov and Larkin 1969)

$$V(t) = \frac{Rj\,(j^2 - j_\mathrm{c}^2)}{\left[j^2 + j_\mathrm{c}^2\cos\omega t + j_\mathrm{c}\,(j^2 - j_\mathrm{c}^2)^{1/2}\sin\omega t\right]}, \tag{22.58}$$

where

$$\omega = \frac{2eR}{\hbar}\left(j^2 - j_\mathrm{c}^2\right)^{1/2}. \tag{22.59}$$

This formula may be rewritten in the form

$$V(t) = R\frac{(j^2 - j_\mathrm{c}^2)}{j + j_\mathrm{c}\cos(\omega t - \theta_1)}, \tag{/}$$

where $\theta_1 = \arccos(j_\mathrm{c}/j)$. As $j \to \infty, V \to Rj$, i.e., tends to the value for a normal metal. The plot of V/Rj_c against ωt is given in fig. 151 for several values of j_c/j.

Averaging of formula (22.58) over time gives

$$\bar{V} = \frac{1}{2\pi}\int_0^{2\pi} V(t)\mathrm{d}(\omega t) = R\left(j^2 - j_\mathrm{c}^2\right)^{1/2} = \frac{\omega\hbar}{2e}. \tag{22.60}$$

This dependence $\bar{V}(j)$ has been confirmed experimentally. Note also that when a steady current is maintained the average voltage and the frequency ω (22.59) are connected by the Josephson relation (22.55). The average values $\bar{V}/(Rj_\mathrm{c})$ are marked by dashed lines in fig. 151.

Since the tunnel junction is simultaneously a planar capacitor, it has a certain capacitance, i.e., there is a charge on the capacitor plates equal to $Q = CV$, the capacitance being given by $C = \varepsilon/(4\pi d')$, where d' is the thickness of the insulator

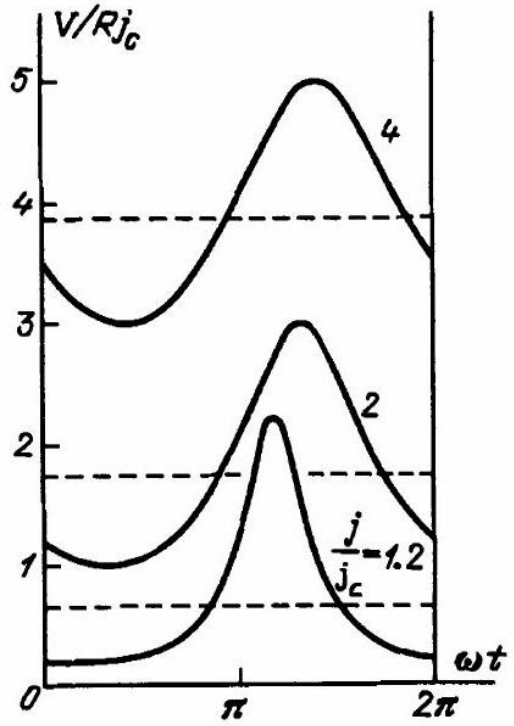

Fig. 151.

layer and ε is its dielectric constant. The change of this charge Q with time also makes a contribution to the current, which is equal to $\partial Q/\partial t = C\partial V/\partial t = (C\hbar/2e)\partial^2\theta/\partial t^2$, so that the complete equation is written, instead of (22.56), in the form (McCumber 1968, Stewart 1968, Johnson 1968)

$$j = j_\mathrm{c}\sin\theta + \frac{\hbar}{2eR}\frac{\partial\theta}{\partial t} + \frac{C\hbar}{2e}\frac{\partial^2\theta}{\partial t^2}. \tag{22.61}$$

We shall not consider her all the possible limiting cases. The limit considered above corresponds to a small capacitance or, more exactly, to a case where the third term in (22.61) is small compared to the second term, i.e., $\omega C/R \sim CeR^2 j/\hbar < 1$.

Associated with the ac Josephson effect is also another peculiar phenomenon: the appearance of steps in the voltage-current characteristic when a varying external field is applied (Josephson 1962, 1964, Shapiro 1963, Shapiro et al. 1964)*. The experiment is carried out as follows. A steady current j is passed across the Josephson junction and, besides, a varying potential difference $v\cos\Omega t$ is applied. The timeaveraged current-voltage characteristic, i.e., $\overline{V(t)}$, is taken as a function of j. Here, for the sake of simplicity, we state the problem in a different manner; we assume that the following potential difference is applied to the junction:

$$V(t) = V_0 + v\cos\Omega t, \tag{22.62}$$

and we find the current.
From (22.52) we have

$$\theta(t) = \frac{2e}{\hbar}\left(V_0 t + \frac{v}{\Omega}\sin\Omega t + \theta_0\right). \tag{22.63}$$

The Josephson current is equal to

$$\begin{aligned} j =& j_\mathrm{c}\sin\theta(t) = j_\mathrm{c}\sin\left[\frac{2e}{\hbar}\left(V_0 t + \theta_0\right)\right]\cos\left(\frac{2ev}{\hbar\Omega}\sin\Omega t\right) \\ &+ j_\mathrm{c}\cos\left[\frac{2e}{\hbar}\left(V_0 t + \theta_0\right)\right]\sin\left(\frac{2ev}{\hbar\Omega}\sin\Omega t\right) \end{aligned} \tag{22.64}$$

The anharmonic factor appearing in this expression may be expanded in Fourier series:

$$\begin{aligned} \cos(a\sin\Omega t) &= \sum_{n=-\infty}^{\infty} A_n \exp(\mathrm{i}n\Omega t), \\ \sin(a\sin\Omega t) &= \sum_{n=-\infty}^{\infty} B_n \exp(\mathrm{i}n\Omega t), \end{aligned}$$

where

$$\begin{aligned} A_n &= \frac{1}{2\pi}\int^{2\pi} \cos(a\sin x)\exp(-\mathrm{i}nx)\mathrm{d}x = \mathrm{J}_{2k}(a), \quad n = 2k \\ B_n &= \frac{1}{2\pi}\int_0^{2\pi} \sin(a\sin x)\exp(-\mathrm{i}nx)\mathrm{d}x \\ &= -\mathrm{i}\mathrm{J}_{2k+1}(a), \quad n = 2k+1 \end{aligned}$$

where J_n are Bessel functions. Substituting into formula (22.64) and using the rule $\mathrm{J}_n(x) = (-1)^n\ \mathrm{J}_{-n}(x)$, we obtain

$$\begin{aligned} j = j_\mathrm{c}\sin&\left[\frac{2e}{\hbar}\left(V_0 t + \theta_0\right)\right]\left[\mathrm{J}_0\left(\frac{2ev}{\hbar\Omega}\right) + 2\sum_{k=1}^{\infty}\mathrm{J}_{2k}\left(\frac{2ev}{\hbar\Omega}\right)\cos(2k\Omega t)\right] \\ &+ j_\mathrm{c}\cos\left[\frac{2e}{\hbar}\left(V_0 t + \theta_0\right)\right]\left[2\sum_{k=1}^{\infty}\mathrm{J}_{2k-1}\left(\frac{2ev}{\hbar\Omega}\right)\sin[(2k-1)\Omega]\right]. \end{aligned} \tag{22.65}$$

Separating some particular term of the first sum, we get

$$\begin{aligned} j_\mathrm{c}\sin&\left[\frac{2e}{\hbar}\left(V_0 t + \theta_0\right)\cdot 2\ \mathrm{J}_{2k}\left(\frac{2ev}{\hbar\Omega}\right)\cos(2k\Omega t)\right] \\ &= j_\mathrm{c}\ \mathrm{J}_{2k}\left(\frac{2ev}{\hbar\Omega}\right)\left\{\sin\left[\left(\frac{2ev_0}{\hbar} + 2k\Omega\right)t + \theta_0\right]\right. \\ &\qquad \left. + \sin\left[\left(\frac{2eV_0}{\hbar} - 2k\Omega\right)t + \theta_0\right]\right\}. \end{aligned}$$

Any term of the second sum transforms to the following form in an analogous way:

*They are usually called Shapiro steps after the author of the experimental discovery.

$$j_c\ \mathrm{J}_{2k-1}\left(\frac{2ev}{\hbar\Omega}\right)\left\{\sin\left[\left(\frac{2eV_0}{\hbar}+(2k-1)\Omega\right)t+\theta_0\right]\right.$$
$$\left.-\sin\left[\left(\frac{2eV_0}{\hbar}-(2k-1)\Omega\right)t+\theta_0\right]\right\}.$$

Thus, we see that in a case where

$$\frac{2eV_0}{\hbar}=n\Omega, \tag{22.66}$$

where n is an integer, a time-independent term appears in the current, which is proportional to

$$\bar{j}_n=(-1)^n j_c\ \mathrm{J}_n\left(\frac{2ev}{\hbar\Omega}\right)\sin\theta_0. \tag{22.67}$$

This means that in the $\bar{j}_n(V_0)$ curve resonance peaks add up to the single-particle current (section 22.1) at values of V_0 given by formula (22.66).

As has already been said, in experiments actually the potential difference is measured at a given current. In order to obtain an exact answer, we have to solve the equation for the phase, as has been done in the absence of a high-frequency field. However, if resonance corrections are not too large, we may use the following procedure. We plot the $\bar{j}(V_0)$ curve by adding to the single-particle characteristic vertical portions corresponding to the maximum values of resonance corrections, i.e., $\max\bar{j}_n = j_c\,|J_n(2eV/\hbar\Omega)|$ at $V_0 = V_{0n} = n\hbar\Omega/2e$. An increase in the current leads to a jumpwise change in regime, from purely superconducting ($V_0 = 0$) to the case with a finite V_0; this occurs whenever the current reaches the end of the corresponding vertical portion. This gives rise to a stepped curve (fig. 152)*. Actually, this was the first experimental demonstration of the ac Josephson effect (Shapiro 1963, Shapiro et al. 1964).

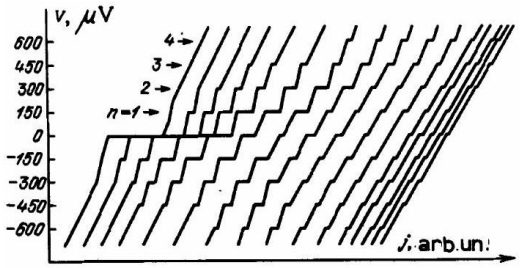

Fig. 152.

In concluding this section, we give a physical interpretation of relations (22.55) and (22.66). While passing the static potential difference, the Cooper pair receives an excess energy and can emit it in the form of a quantum with $\hbar\omega = 2eV$. But if the junction is in an external field, there occurs an exchange of energy with the external field, in which emission and absorption of many quanta of the external field are possible. This is described by formula (22.66).

8.8.9 22.6. Waves in the Josephson junction

Suppose that the Josephson junction is simultaneously subjected to the action of a steady magnetic field and a steady potential difference. In such a case, the phase

difference has simultaneously space and time components. In accordance with formulas (22.38) and (22.54) we find

$$j = j_c \sin\left[\theta_0 + \frac{2eV}{\hbar}t + \frac{2eHd}{\hbar c}y\right]. \tag{22.68}$$

But this is nothing but the moving wave formula. The frequency of this wave is $\omega = 2eV/\hbar$ and the wave vector $k = 2eHd/\hbar c$. Hence, the phase velocity is given by

$$v_0 = \frac{\omega}{k} = \frac{cV}{Hd}. \tag{22.69}$$

The physical meaning of this formula consists in that upon application of the potential difference the sinusoidal current density (22.38) begins to shift along the junction with a constant velocity (22.69) (Eck et al. 1964).

The result (22.68) refers to a case where a steady potential difference and a steady magnetic field are maintained in the junction. Let us now find the waves that propagate spontaneously along the junction. To this end, we make use of the formula for the current (22.61) and substitute into it the Maxwell equation (22.42), expressing H with the aid of formula (22.41). As a result, we obtain the equation

$$\frac{\partial^2\theta}{\partial y^2} - \frac{1}{c_0^2}\left(\frac{\partial^2\theta}{\partial t^2} + \gamma\frac{\partial\theta}{\partial t}\right) = \frac{\sin\theta}{\delta_J^2}, \tag{22.70}$$

where

$$c_0 = \left(\frac{ec}{4\pi^2 dC\hbar\Phi_0}\right)^{1/2} = c\left(\frac{d'}{\varepsilon d}\right)^{1/2}, \tag{22.71}$$

$$\gamma = \tau^{-1} = \frac{1}{RC}. \tag{22.72}$$

The penetration depth δ_J is expressed by formula (22.44) and the capacitance is given by $C = \varepsilon/(4\pi d')$.

If we assume that there is no Josephson current i.e., if we put $j_c = 0$, then $\delta_J = \infty$ and the right-hand side of eq. (22.70) vanishes. If we also neglect damping, i.e., if we set $\gamma = 0$, we will obtain the equation for the propagation of waves with a velocity c_0. From formula (22.71) it follows that this velocity is much less than the velocity of light. Although the equation is written for a somewhat unusual quantity - the phase difference - we may rewrite it in the form of an equation for H by differentiating with respect to z, and in the form of the an equation for E by differentiating with respect to t. Thus, we see that in the absence of a Josephson current along the junction between two superconductors separated by an insulating barrier, waves can propagate with the velocity c_0. Such waves are called Swihart waves (Swihart 1961).

Let us now consider eq. (22.70) in detail, i.e., we assume that a Josephson current is possible. Without damping (i.e., at $\gamma = 0$) this equation is usually called the sine-Gordon equation (upon replacement of $\sin\theta$ by θ it corresponds to the Klein-Gordon-Fock equation for elementary particles with zero spin). It is rather evident
that in the presence of a potential difference and magnetic field a peculiar resonance may arise when the phase velocity of Josephson waves v_0 coincides with the velocity c_0(22.71) (Eck et al.

- Figure 146 shows the experimental characteristics of a point Nb – Nb junction (Grimes and Shapiro 1968). The abscissa is the current and the ordinate represents the potential difference. Each of the curves corresponds to both directions of the current. The different curves correspond to different amplitudes of the high-frequency field and are shifted relative to one another along the abscissa (the null current is taken as the center of symmetry of a given curve). Actually, in the problem with a given current the steps are not exactly rectangular: instead of a jump at some critical j there is a variation $V(j)$.

1964). In order to find the result, we assume that the right-hand side of (22.70) is small and look for a solution in the form (Kulik 1965)

$$\theta = \theta^{(0)} + \theta^{(1)},$$

where $\theta^{(1)} < \theta^{(0)}$ and

$$\theta^{(0)} = \theta_0 + \frac{2eV}{\hbar}t + \frac{2eHd}{\hbar}y = \theta_0 + \omega t + ky.$$

To first order we obtain from eq. (22.70)

$$\frac{\partial^2\theta^{(1)}}{\partial y^2} - \frac{1}{c_0^2}\left(\frac{\partial^2\theta^{(1)}}{\partial t^2} + \gamma\frac{\partial\theta^{(1)}}{\partial t}\right) = \frac{\sin\left(\theta_0 + \omega t + ky\right)}{\delta_\mathrm{J}^2}. \tag{22.73}$$

From this we find

$$\theta^{(1)} = \frac{c_0^2}{\delta_\mathrm{J}^2}\,\mathrm{Im}\left\{\frac{\exp\left[\mathrm{i}\left(\theta_0 + \omega t + ky\right)\right]}{\omega^2 - c_0^2k^2 - \mathrm{i}\omega\gamma}\right\}. \tag{22.74}$$

We substitute expression (22.74) into the complete formula for the Josephson current $j = j_\mathrm{c}\sin\theta$ and average it over time and coordinate*:

$$\begin{aligned}\bar{j} &= \lim_{\substack{T\to\infty\\L\to\infty}}\frac{1}{T}\int_0^T \mathrm{d}t\frac{1}{L}\int_0^L \mathrm{d}y j_\mathrm{c}\sin\theta(y,t)\\ &\approx \lim_{\substack{T\to\infty\\L\to\infty}}\frac{1}{T}\int_0^T \mathrm{d}t\frac{1}{L}\int_0^L \mathrm{d}y j_\mathrm{c}\cos\theta^{(0)}(y,t)\theta^{(1)}(y,t)\\ &= j_\mathrm{c}\frac{\omega c_0^2\gamma}{2\delta_\mathrm{J}^2}\frac{1}{\left(\omega^2 - c_0^2k^2\right)^2 + \omega^2\gamma^2}\end{aligned} \tag{22.75}$$

Thus, we obtain a sharp maximum of the average current at $\omega = c_0k$ or $v_0 = c_0$, i.e., according to eq. (22.69),

$$v_0 = \left(\frac{c_0}{c}\right)Hd \tag{22.76}$$

(fig. 153). In this case, there is a resonance with respect to the phase velocities of Josephson and Swihart waves. The condition for the applicability of the result obtained is the smallness of $\bar{j}$ as compared with j_c. Taking $\bar{j}$ in the maximum, we find

$$\frac{c_0^2}{\delta_\mathrm{J}^2} < \omega\gamma, \tag{22.77}$$

that is, the damping γ must not be too small.

*The remaining current components (the single-particle current and the capacitive current) are proportional to the time derivatives of θ and upon averaging they give zero.

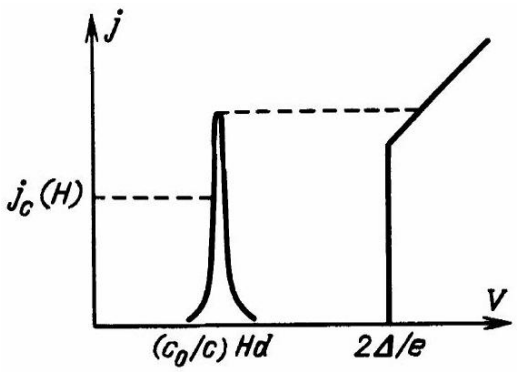

Fig. 153.

As has been repeatedly noted, in practice a steady current across the junction is specified and the steady part of the arising potential difference is recorded. Just as upon application of a varying field, in the case under consideration the current increases up to a limiting value at a given voltage, which is followed by a discontinuous switch to a different regime with a different voltage, i.e., steps appear in the characteristic (see fig. 153).

In order for the above-described resonance effect $v_0 = c_0$ to be observed, it is necessary that the principal Josephson maximum at $V = 0$ be not greater than the resonance maximum with the condition (22.76). Otherwise, a switch will occur of the characteristics with $V = 0$ to the single-particle branch. In view of this, one has to choose the value of the magnetic field close to the value that makes the principal Josephson current vanish (see formula (22.40).

Up until now we have considered the junction to be infinite. A finite junction of width L permits the generation of standing electromagnetic waves if there is an integer number of half-waves within a distance L, i.e., $L = \frac{1}{2}n\lambda$ or $k_n = n\pi/L$. The corresponding frequencies are

$$\omega_n = \frac{c_0 n\pi}{L}. \tag{22.78}$$

Such frequencies correspond to potential differences $V_n = \hbar\omega_n/2e$, i.e.,

$$V_n = \frac{\hbar c_0}{2e}\frac{n\pi}{L}. \tag{22.79}$$

Therefore, instead of a single resonance for an infinite junction, we obtain a set of discrete resonances. We shall not give here a detailed derivation; we confine ourselves to a description of the qualitative picture.

Calculation (Kulik 1965, Dmitrenko et al. 1965) shows that at V_n defined by condition (22.79) sharp maxima of the average current $\bar{j}$ appear at $V = V_n$. The height of these maxima depends on n in such a manner that the highest maximum
is that which most closely corresponds to the resonance condition for phase velocities, (22.76), i.e., that for which

$$\left|V_{n_0} - \frac{c_0}{c}Hd\right| = \min. \tag{22.80}$$

Hence, by varying H we can shift the modulation of the "fence" of the maxima (22.79). Since in actual experiments one is concerned with the measurement of $\bar{V}(j)$ instead of $\bar{j}(V)$, a stepped characteristic is obtained (fig. 154), whose shape is essentially governed by the magnetic field H (the term adopted in the literature is "Fiske steps" after the author who discovered them (Fiske 1964).

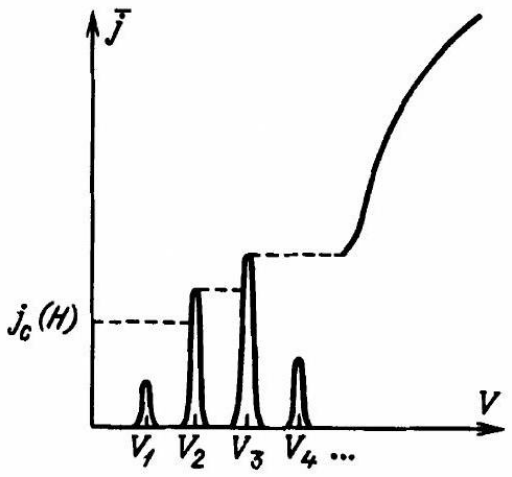

Fig. 154.

As the width of the junction increases the spacing between the adjacent maxima decreases in accordance with formula (22.79). The maxima begin to overlap, and in the limit $L \to \infty$ the curve (22.75) is obtained (cf. figs. 154 and 153).

These properties of the characteristic of finite junctions have been used for the generation of electromagnetic waves with the aid of Josephson junctions (Yanson et al. 1965; Langenberg et al. 1965). One of the resonances (22.79) was used; its amplitude was increased by choosing the magnetic field in accordance with condition (22.80).

8.8.10 22.7. Josephson junctions with a normal metal or a semiconductor layer

In the section that follows we will consider various methods used to prepare Josephson junctions. One of the most widespread is still a tunnel junction with an insulating barrier. However, it is rather difficult to prepare such a junction in a controlled manner. As has already been said, the insulator barrier must be very thin and have no short-circuited portions. The usual procedure is the oxidation of a
is that which most closely corresponds to the resonance condition for phase velocities, (22.76), i.e., that for which

$$\left| V_{n_0} - \frac{c_0}{c} Hd \right| = \min . \tag{22.80}$$

Hence, by varying H we can shift the modulation of the "fence" of the maxima (22.79). Since in actual experiments one is concerned with the measurement of $\bar{V}(j)$ instead of $\bar{j}(V)$, a stepped characteristic is obtained (fig. 154), whose shape is essentially governed by the magnetic field H (the term adopted in the literature is "Fiske steps" after the author who discovered them (Fiske 1964).

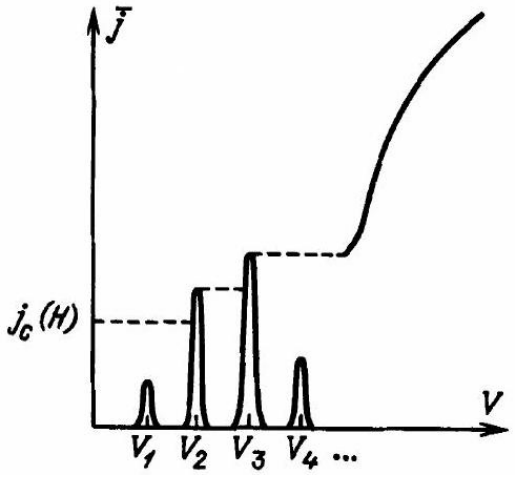

Fig. 154.

As the width of the junction increases the spacing between the adjacent maxima decreases in accordance with formula (22.79). The maxima begin to overlap, and in the limit $L \to \infty$ the curve (22.75) is obtained (cf. figs. 154 and 153).

These properties of the characteristic of finite junctions have been used for the generation of electromagnetic waves with the aid of Josephson junctions (Yanson et al. 1965; Langenberg et al. 1965). One of the resonances (22.79) was used; its amplitude was increased by choosing the magnetic field in accordance with condition (22.80).

8.8.11 22.7. Josephson junctions with a normal metal or a semiconductor layer

In the section that follows we will consider various methods used to prepare Josephson junctions. One of the most widespread is still a tunnel junction with an insulating barrier. However, it is rather difficult to prepare such a junction in a controlled manner. As has already been said, the insulator barrier must be very thin and have no short-circuited portions. The usual procedure is the oxidation of a
metal followed by sputtering a film of another superconducting metal. But here gaps may appear in the oxide layer and, hence, short-circuited regions. But if the oxide layer is made too thick, no Josephson current will flow.

In view of this, attempts are being made to use a normal metal or semiconductor layer instead of an insulator. The transparency of such a layer, as will be seen below, is much larger than that of an insulator and, hence, it may be made thicker. In such a case it is easier to control the barrier transparency and, hence, to prepare junctions with required properties.

We begin with a normal layer ($s-n-s$ junctions). We use the model described in section. 20.1: the junction between two metals with slightly differing critical temperatures. We assume that $T_{c2} - T_{c1} < T_{c1}$ and $T_{c1} < T < T_{c2}$. Suppose that the metals form a sandwich, in which the first, normal metal forms a layer of thickness d between two superconducting plates of the second metal. We assume, as before, that $\xi_2 > \xi_1$ and put $d > \xi_1$. In this case, the critical current flowing across the junction [which will evidently turn out to be proportional to $\exp(-d/\xi_1)$] will be so small that it will not affect the Ψ functions in both superconductors. Therefore, they may be taken in the form (20.18) with some phase factor. Thus, for the metals on the right and left sides we have respectively:

$$\begin{aligned}\Psi_{\mathrm{r}} &= \tanh\left(\frac{x-\frac{1}{2}d+x_{0\mathrm{r}}}{\sqrt{2}\xi_2}\right)\exp\left(\mathrm{i}\chi_1\right), \quad x > \tfrac{1}{2}d \\ \Psi_1 &= \tanh\left(\frac{\frac{1}{2}d+x_{01}-x}{\sqrt{2}\xi_2}\right)\exp\left(\mathrm{i}\chi_2\right), \quad x < -\tfrac{1}{2}d\end{aligned} \tag{22.81}$$

In the normal metal which forms the strip $-\frac{1}{2}d < x < \frac{1}{2}d$, use may be made of the linearized Ginzburg-Landau equation

$$\xi_1^2 \frac{\mathrm{d}^2\Psi}{\mathrm{d}x^2} = \Psi$$

of which the solution is

$$\Psi = A\exp\left(\frac{x}{\xi_1}\right) + B\exp\left(\frac{-x}{\xi_1}\right). \tag{22.82}$$

Using the continuity condition $\mathrm{d}\Psi/\mathrm{d}x$ at the boundaries (the continuity of Ψ is determined by $x_{0\mathrm{r}}$ and x_{01}, which are of no interest in this particular problem) and taking into account that $x_{0\mathrm{r}}, x_{01} < \xi_2$ (section 20.1), we find

$$\begin{aligned}A &\approx \frac{\xi_1}{\sqrt{2}\xi_2}\exp\left(\mathrm{i}\chi_1 - \frac{d}{2\xi_1}\right) \\ B &\approx \frac{\xi_1}{\sqrt{2}\xi_2}\exp\left(\mathrm{i}\chi_2 - \frac{d}{2\xi_1}\right)\end{aligned} \tag{22.83}$$

The current is given by

$$j = -\frac{ie\hbar}{2m}\Psi_0^2\left(\Psi^*\nabla\Psi - \Psi\nabla\Psi^*\right),$$

where $\Psi_0^2 = \alpha|\tau|/b$. Substituting eqs. (22.82) and (22.83), we see that the current does not depend on x and is equal to

$$\begin{aligned}j &= -\frac{\mathrm{i}e\hbar\alpha|\tau|}{2mb}\left(B^*A - A^*B\right) \\ &= \frac{e\hbar\alpha|\tau|}{2mb}\frac{\xi_1}{\xi_2^2}\exp\left(-\frac{d}{\xi_1}\right)\sin\left(\chi_1 - \chi_2\right).\end{aligned} \tag{22.84}$$

Considering that Ψ^2 at the boundary is equal to $(\alpha|\tau|/b)\,(\xi_1^2/2\xi_2^2)$ (see eq. 20.19), we may write

$$j = \frac{e\hbar}{m\xi_1}\left|\Psi\left(\frac{1}{2}d\right)\right|^2\exp\left(-\frac{d}{\xi_1}\right)\sin\left(\chi_1 - \chi_2\right), \tag{22.85}$$

which is strongly reminiscent of formula (22.21).
In this case, the smallness of the Josephson current is due primarily to the violation of the superconducting correlation in the normal metal, this being responsible for the appearance of the factor $\exp\left(-d/\xi_1\right)$. Although the derivation given refers to a very special model, the basic qualitative inference about the critical current being proportional to $\exp\left(-d/\xi_1\right)$, where ξ_1 is the correlation length in the normal metal, is valid in all cases. Note that, in contrast to an ordinary tunnel junction with an insulating layer, where the smallness of the Josephson current is due to the small permeability of the potential barrier to electrons, here it is due to the loss of the coherence of the Cooper pairs in the normal metal.
$\mathrm{s}-\mathrm{n}-\mathrm{s}$ junctions have not found wide application in practice. This is due to the low resistance

of the metal to normal current, which proves to be inconveient for instruments that make use of Josephson elements. This explains why Josephson elements with a semiconductor barrier s-sm-s have lately been studied intensively (see Alfeev 1979; Aslamazov and Fistul' 1979, 1981, 1982, 1984).

As is known, the electric properties of semiconductors are determined to a considerable extent by the presence of impurities. The impurities in semiconductors create additional electron energy levels in the forbidden region between the last filled band (valence band) and the first empty band (conduction band). The levels may be shallow, i.e., they may lie close to the edge of the valence band (acceptors) or of the conduction band (donors), or deep, i.e., they may lie in the bulk of the forbidden region. If the impurity concentration that creates shallow levels is high, the impurity levels extend into the band that "creeps" on the conduction or valence band. Here, the semiconductor becomes "degenerate", i.e., a finite number of current carriers arises in a band at $T = 0$. Such a semiconductor is, in fact, a semimetal, i.e., in this case the s-sm-s junction becomes a s-n-s junction.

At lower impurity concentrations the electrons or holes in the bands are generated only by way of thermal excitation. However, since the critical temperatures of superconductors are low as compared with the excitation energy, the presence of thermally activated carriers may be neglected. In such a case, the semiconductor is,
in fact, an insulator and the height of the potential barrier is equal to the lowest energy required for the generation of electrons in the valence band or of holes in the conduction band or, in other words, to the energy gap. Comparing the exponents of the temperature excitation (V/T) and of the tunneling probabilities ($d\sqrt{mV}/\hbar$) (see section 22.1), where V corresponds to $U(x) - \mu$, we see that for $V > 10^{-2}$eV and $d < 10^{-3}$ cm the thermal excitation may really be ignored.

In real determinations of the tunneling probability (Aslamazov and Fistul' 1979, 1981, 1982, 1984) one must take into account the effects that arise at the metalsemiconductor interface. In section 6.1 we have considered the contact between two metals. It has been pointed out that part of the electrons are transferred from one metal to the other, as a result of which an electrical double layer is formed in the vicinity of the interface; at this double layer there is a jump in the potential - a contact potential difference. The thickness of the double layer is of the order of interatomic distance because it is at such distances that the electric field is screened.

The situation is different in semiconductors, where the screening is much weaker. If the semiconductor layer is very thin, it may happen that all the electrons residing at the impurity levels will move into the metal and, as a result, the potential barrier will increase almost up to the spacing between the valence band and the conduction band. On the other hand, with the escape of electrons the semiconductor will acquire an electric charge, which in turn will reduce the effective barrier to a certain extent.

In the thicker layers of the semiconductor the electrons will pass into the metals from the boundary regions. In such a case the potential barrier in the middle will be determined by the energy gap for the impurity levels, and at the edges high but narrow "Schottky barriers" will be generated.

Besides, there exist other effects which exert an influence on the tunneling probability. They include fluctuations in the impurity concentration, leading to the formation of narrow channels with lowered barriers (Aslamazov and Fistul' 1982), the formation of "resonance" trajectories along the periodic arrays of impurity states in a semiconductor (Aslamazov and Fistul' 1984) and, finally, the illumination effects. It has been found experimentally that some s-sm-s junctions, in which no Josephson effect has been observed, exhibit the effect as a result of illumination and retain it when the illumination is turned off (see Barone and Paterno 1982). This is presumably associated with the formation of long-lived metastable electronic states on impurities.

8.8.12 22.8. Practical applications of the Josephson effect

It has been shown in section 22.4 that the critical Josephson current depends strongly on the magnetic field. This property can be used for the measurement of small magnetic fields. In fact, for this purpose use is made not of Josephson elements but of so-called Josephson interferometers of SQUIDs (superconducting quantum interference devices).

One of the schemes of such an interferometer is given in fig. 155. It shows two Josephson elements connected in parallel. The total current across the first element is equal to $I_{c1} \sin \theta_1$ and that flowing across the second is $I_{c2} \sin \theta_2$. The overall current across both junctions is given by

$$I = I_{c1} \sin \theta_1 + I_{c2} \sin \theta_2. \tag{22.86}$$

Suppose that a magnetic field is applied normal to the junction plane. Let us carry out a derivation analogous to that made in section 17.6, where magnetic flux quantization was discussed. From the fact that $\mathbf{j} = \mathbf{0}$ in the bulk of a superconductor it may be concluded that the order-parameter phase satisfies the condition

$$\nabla \chi = \frac{2e}{c\hbar} A$$

Integrating along the dashed contour, we see that the variation of the phase along the entire contour is

$$\theta_1 - \theta_2 + \frac{2d}{ch} \Phi,$$

where Φ is the field flux across the contour and θ_1 and θ_2 are the jumps in the phase at the Josephson junctions.

For the order parameter to be single-valued, it is necessary that the total change in the phase be equal to $2\pi n$, where n is an integer, i.e.,

$$\theta_1 - \theta_2 + \frac{2\pi\Phi}{\Phi_0} = 2\pi n$$

(we have substituted $\Phi_0 = \pi c\hbar/e$, the magnetic flux quantum). We may introduce a certain quantity θ and write

$$\theta_1 = \theta - \frac{\pi\Phi}{\Phi_0} + 2\pi n, \quad \theta_2 = \theta + \frac{\pi\Phi}{\Phi_0}.$$

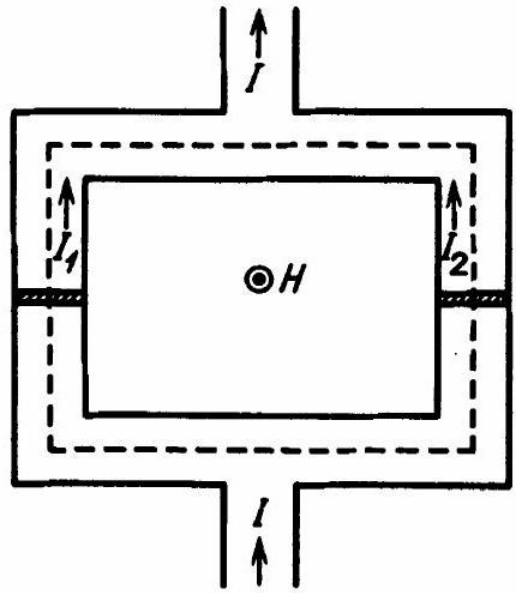

Fig. 155.

Substituting this into formula (22.86) (we assume the magnetic field to be so small that it has no effect on I_{c1} and I_{c2}), we have

$$I = I_{c1} \sin\left(\theta - \frac{\pi\Phi}{\Phi_0}\right) + I_{c2} \sin\left(\theta + \frac{\pi\Phi}{\Phi_0}\right).$$

If both junctions are identical, i.e., $I_{c1} = I_{c2} = I_c$, then

$$I_{\max} = \max\left[2I_c \sin\theta \cos\left(\frac{\pi\Phi}{\Phi_0}\right)\right] = 2I_c \left|\cos\left(\frac{\pi\Phi}{\Phi_0}\right)\right|. \tag{22.87}$$

It follows from this that the total critical current vanishes at

$$\Phi = \left(n + \frac{1}{2}\right)\Phi_0. \tag{22.88}$$

But in this case we are dealing not with the magnetic flux across an isolated junction, HLd, but with the flux through a large cavity, $\Phi = HS$ (S is the area of the cavity). Since the magnetic flux quantum is a very small quantity, $\Phi_0 = 2 \times 10^{-7}\text{Oe}\cdot\text{cm}^2$, it follows that with the aid of the Josephson interferometer we can measure a field as small as 10^{-10}Oe (recall that the magnetic field of the Earth is 0.5 Oe).

The scheme described above is not the only one possible. There are others, which are more convenient in some cases.

One of the important problems in measuring such small fields is the protection against numerous noises, i.e., random fields that result from various sources, especially in cities. Of course, the creation of such protection would have limited the application of SQUIDs considerably. However, it has been possible to avoid this in practice. The point is that noise sources are usually at a large distance from the object studied and the fields resulting from such sources vary very little in space. Circuits have been developed, which record only the magnetic field gradient or even its second derivative. Although the sensitivity is reduced to a certain extent, the protection may be dispensed with.

Apart from applications for physical investigations, SQUIDs have been employed in biology and medicine. The weak currents that flow in organisms produce, in space, magnetic

fields that can be measured. Thus, it is possible to obtain magnetocardiograms and magnetoencephalograms (records of the variation with time of magnetic fields associated with the electrical activity of the heart and the brain). These methods of investigation provide much more details than do the ordinary measurements of the electric potentials (electrocardiography and electroencephalography) and are carried out by a contactless method. Moreover, by recording the magnetic fields at various points of space relative to the object under examination one can calculate the distribution of currents producing these fields with the aid of computers. Although these investigations have been started only recently, it is clear even today that SQUIDs have provided biology and medicine with unique methods of investigation and diagnostics.

The extraordinary sensitivity of SQUIDs to magnetic fields makes it possible to use them for developing supersensitive galvanometers and voltmeters. It has become
possible to measure alternating currents of down to 10^{-14} A and potential differences of down to 10^{-15} V.

The capability of closed superconducting circuits to retain undamped current and also the possibility of destroying the superconductivity by magnetic field are used to develop superconducting memory elements for computers - cryotrons. Some of these devices make use of Josephson elements. Two circumstances are important here: miniaturization and high-speed response. For miniaturization use is made of sputtered superconducting films. The smallest contact area produced in this way is 10^{-9} cm^2 (edge contact, fig. 156a). As regards the high-speed response, the switch of the tunnel junction from the Josephson mode, $j < j_c, V = 0$, to the single-particle mode, $j > j_c, V > 2\Delta/e$, is accomplished during a time less than 10^{-10} s.

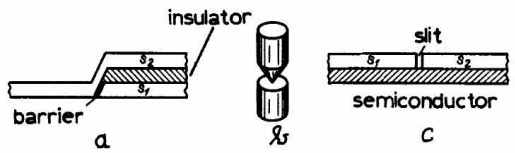

Fig. 156.

One of the key problems in the development of increasingly compact microcircuits, i.e., containing an ever increasing number of elements in a given volume, is the removal of heat released inside such a microcircuit during its operation. The contact with the cooling liquid or gas occurs only along the surface, and heat conduction cannot provide efficient heat removal from the volume. And an increase in temperature can lead to the destruction of the entire structure. In this sense, Josephson elements possess an important advantage because the heat release upon their switching is negligible.

We have so far been concerned with the use of the dc Josephson effect. As regards the ac Josephson effect, in spite of the existence of many ideas, it is still used in rare cases. It would be most natural to use Josephson elements for the generation of electromagnetic oscillations with a retunable frequency. The main difficulty is bringing the waves outside the junction. The use of the resonance of Josephson waves with Swihart waves (section 22.6) has made it possible to obtain a radiation power of up to 10^{-10} W with an efficiency of 2%. Of course, this figure is very low, and at present there exist other devices which enable one to obtain a much higher power at the same frequencies.

In principle, the following two applications of Josephson generation are possible: (a) in low-temperature low-noise devices that do not require a high power; and (b) for measurement of potential differences smaller than 10^{-15} V using the relation $\omega = 2eV/\hbar$, since frequency determinations are carried out with a high accuracy and allow one to bring the measured voltage down to 10^{-17} V.

A further application of the ac Josephson effect is the detection of external radiation. The simplest application is to use the decrease of the critical Josephson current in the presence of an external electromagnetic field. According to formula (22.67),

$$j_{0c} = j_c \left| J_0 \left(\frac{2eV}{\hbar\Omega} \right) \right|, \tag{22.89}$$

where J_0 is the Bessel function. In principle, one can also use the other steps of the characteristic (at $V_n = n\hbar\Omega/2e$).

In conclusion, let us consider various methods for the preparation of Josephson elements. We have already considered two types: the tunnel junction and the bridge. In the first case, the surface of a superconductor is subjected to oxidation or a layer of a normal metal or a semiconductor is deposited onto it by sputtering. This is followed by sputtering a film of a second superconductor over the first one. One of the versions of the tunnel junction is the edge, in which the junction is made along the edge of a thin film (fig. 156a).

As for the bridge, it can be prepared in the form of a film with a constriction (fig. 146) or a film of varying thickness. A further type of bridge is a point junction (fig. 156b).

Finally, the use of a normal metal or semiconductor as the barrier makes it possible to produce so-called palanar elements (fig. 156c), in which a superconductor film with a very narrow slit is sputtered onto a semiconductor substrate. Here, the substrate serves as the barrier. In planar elements it is easier to control the properties of the barrier mateirial; this may be an ordinary bulk single-crystalline sample with a certain amount of dopant (if we deal with a semiconductor).

8.8.13 22.9. The dynamical resistive state of a thin superconductor at supercritical currents

It has been shown in section 17.5 that for a very thin superconductor there exists a critical current density above which the superconductivity is destroyed. On the basis of this result one could come to the conclusion that when the current increases up to this value there occurs a transition to the normal phase and the characteristic changes to the linear dependence $\boldsymbol{j} = \sigma \boldsymbol{E}$ (fig. 157). In fact, the experimental findings are dependences of the type shown in fig. 158 (Meyer and Minnigerode 1972), i.e., a gradual approach to the normal resistance, and jumps in the electric field. This strongly resembles the picture considered in section 22.5 for the Josephson junction, and shows that superconductivity is retained in some form in the presence of the electric field as well.

At first sight this conclusion seems paradoxical. As a matter of fact, from the London equation $\partial(\Lambda \boldsymbol{j})/\partial t = \boldsymbol{E}$ it follows that in the presence of an electric field the current must increase with time. Hence, it will certainly exceed the critical value,

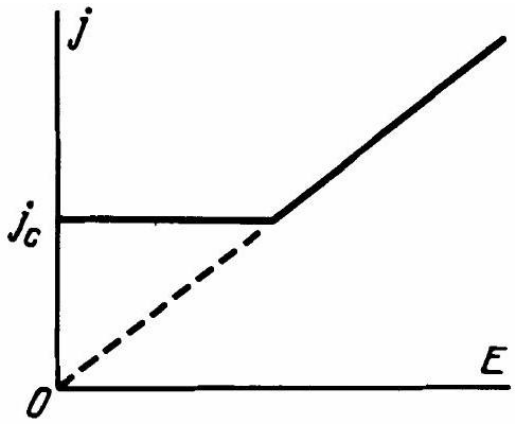

Fig. 157.

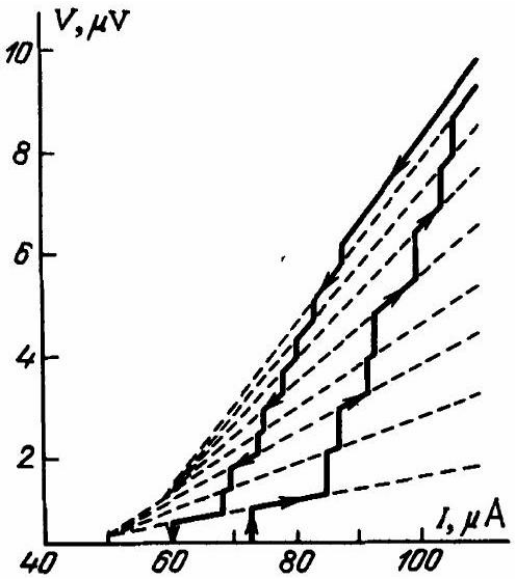

Fig. 158.

which will lead to the destruction of superconductivity. On the other hand, we have already encountered a similar phenomenon: the motion of the vortex lattice in a type II superconductor under the action of a magnetic field and a current perpendicular to it leads to the generation of an electric field with the superconducting order parameter being retained. Another example is the Josephson junction at $j > j_c$.

The appearance of an electric field certainly leads to nonstationarity, i.e., time dependence of the quantities. As has already been noted, the nonstationary equations of the theory of superconductivity are very complicated, even in the limit of slow time and space variations. Therefore, we use the model equation (19.47) for the vicinity of T_c.

However, in this case we have to overcome the following difficulty. Suppose we have an infinite superconducting wire. It is clear that the electric field that arises in it must be, on an average, homogeneous along the wire. But in this case Ψ must also be homogeneous on an average. At the same time, the potential φ appearing in eq. (19.47) must increase in magnitude.

A difficulty of the same kind has been enountered in ch. 18, where we dealt with type II superconductors in a magnetic field. It has been shown that the rise of the vector potential is compensated by the appearance of vortices. They give rise to jumps in the phase gradient at the cut lines that pass through the vortex centers (see fig. 113).

We shall now consider a superconducting wire (a whisker) having a diameter much smaller than both δ and ξ. Here all the quantities will depend only on the coordinate along the wire and on time. Thus, instead of the (x, y) plane in this case we have the (x, t) plane. Since the magnetic field of the current in the whisker is small, we may choose $\boldsymbol{A} = 0$ and $\boldsymbol{E} = -\nabla\varphi$. In this case we can establish the similarity with the vortex picture:

$$-\mathrm{i}\frac{\partial}{\partial x} \to -\mathrm{i}\frac{\partial}{\partial x}, \quad -\mathrm{i}\frac{\partial}{\partial y} - \frac{2e}{\hbar c}A_y \to -\mathrm{i}\frac{\partial}{\partial t} + \frac{2e}{\hbar}\varphi. \tag{22.90}$$

Comparing with fig. 113 and the reasonings given in section 18.2, we come to the conclusion that a vortex lattice appears in the (x, t) plane (Ivlev and Kopnin 1978). On encircling each vortex the phase must vary by an amount 2π. The compensation of the increase of the scalar potential will occur due to the jumps in the phase derivative at the cut line along the t axis. The compensation condition reads

$$\frac{2\pi}{t_0} = \frac{2e}{\hbar}\langle E\rangle a, \tag{22.91}$$

where t_0 is the time period, a is the space period and $\langle E\rangle$ is the average electric field (with respect to the coordinate and time). Solving condition (22.91) for the electric field, we obtain

$$\langle E\rangle = \frac{\Phi_0}{ct_0}\frac{n}{L}, \tag{22.92}$$

where $\boldsymbol{\Phi}_0$ is the flux quantum, L is the length of the conductor and n is the number of "vortex" centers ($n = L/a$).

The physical interpretation of the resultant picture is different from that observed with magnetic vortices. At certain points along the conductor there a jump occurs in the time derivative of the phase $\partial\chi/\partial t$, i.e., the rate of variation of the phase with time. This process is periodic. During the larger part of the period the rate of change of the phase on two sides of the points on the conductor is the same. However, at certain moments the phase changes more sharply, and this occurs differently on the two sides from this point, so that a phase difference equal to 2π results. Therefore, such points are called "phase slip centers"*. Since the function $\Psi = |\Psi|\exp(\mathrm{i}\chi)$ must be single-valued, it follows that at the center itself $|\Psi| = 0$ at the moment of phase slip.

Note that fig. 113 shows a rectangular lattice corresponding to the time-independent location of the phase slip centers along the superconductor. However, generally speaking, the lattice may also be oblique, which would correspond to the motion of the entire structure along the superconductor with a constant velocity. This is possible, in principle, for a finite superconductor if there is a mechanism of creation and destruction of the phase slip centers at the edges.

Let us now consider the events that occur in a thin superconductor of finite length. At $\boldsymbol{A} = 0$ the expression for the current has the form

$$j = |\Psi|^2\frac{\hbar e}{m}\frac{\partial\chi}{\partial x}. \tag{22.93}$$

If we plot a three-dimensional graph in which x is the coordinate along the superconductor, z corresponds to $\mathrm{Re}\,\Psi$, and y corresponds to $\mathrm{Im}\,\Psi$, then the spiral curve will correspond to a state with current (fig. 159a). However, in the presence of an electric field the current increases with time; this means that the spiral is "compressed", i.e., the density of its turns increases. But this process cannot continue for an indefinitely long time because the current reaches a

*The idea of the phase slip centers was first put forward by Anderson (1966) and Little (1967) and described in detail by Langer and Ambegoakar (1967).

value j_c. There is only one possibility: to dispose of one of the turns of the spiral. But to do this, we have to "straighten out" the spiral at some place. This exactly corresponds to the appearance of a phase slip center and, in particular, $|\Psi| = 0$ (fig. 159b).

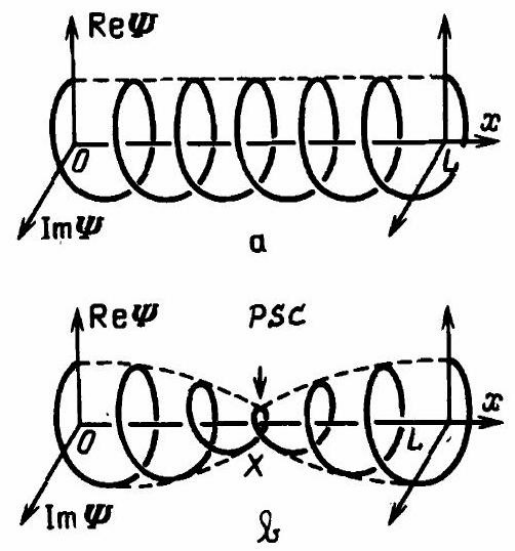

Fig. 159.

Let us consider a simple model (Skocpol et al. 1974), which explains the characteristic curve in fig. 158 with jumps in the potential difference. Suppose that the thin superconductor under study is connected on both sides to bulk specimens of the same metal. Such a construction is called a bridge and we have already described it as a possible realization of the Josephson junction. In this particular case, the constricted portion is assumed to be long. For bulk superconductors the flowing
current is weak and they are in a state of equilibrium. If the temperature is close to T_c and eq. (19.47) is applicable, then in the junctions its right-hand side must equal zero and, hence, the left-hand side must also vanish. Substituting $\Psi = |\Psi| e^{ix}$, we obtain

$$\frac{\partial |\Psi|}{\partial t} + i \left(\frac{\partial \chi}{\partial t} + \frac{2e}{\hbar} \varphi \right) |\Psi| = 0.$$

Separating the real and imaginary parts, we have

$$\frac{\partial |\Psi|}{\partial t} = 0, \tag{22.94}$$

$$\frac{\partial \chi}{\partial t} + \frac{2e}{\hbar} \varphi = 0. \tag{22.95}$$

These equation are the boundary conditions for the thin superconductor under study. Condition (22.95) is also realized at temperatures far from T_c. It may be interpreted as the equality of the chemical potentials of "normal electrons" ($\mu_n = e\varphi$) and of electrons constituting the Cooper pairs ($\mu_s = -\frac{1}{2}\hbar \partial \chi / \partial t$). We introduce the notation

$$\eta = \mu_n - \mu_s = e\varphi + \frac{1}{2}\hbar \frac{\partial \chi}{\partial t}. \tag{22.96}$$

According to (22.95), $\eta = 0$ in a bulk superconductor. However, just as in the case of a magnetic field, this quantity cannot vanish abruptly and has a finite penetration depth.

Indeed, let us visualize the interface between a superconductor and a normal metal. If an electron is "injected" into the superconductor, then in order to assume an equilibrium state it has to lose an energy Δ because the equilibrium electrons are bound into pairs with a binding energy 2Δ (per two particles).

The electron loses its energy in collisions. However, collisions with impurities are inefficient because they are elastic, and collisions with quasiparticles are rare ($\propto \mathrm{e}^{-\Delta/T}$). Therefore, the only process that provides energy relaxation is the emission of phonons. At low temperatures the characteristic time of such a process, τ_{ph}, is large. As a result of this, the penetration depth for the quantity η is large compared to the correlation length ξ (of order $\xi\,(T_{\mathrm{c}}\tau_{\mathrm{ph}}/\hbar)^{1/2}$ for a pure superconductor). We label this quantity by δ_E, since it also determines the spatial variation of the electric field in the superconductor.

By analogy with the London equation we write

$$\frac{\partial^2\eta}{\partial x^2} - \delta_E^{-2}\eta = 0 \tag{22.97}$$

(the exact theory confirms this equation; see Ivlev and Kopnin 1984). Suppose the junctions of the superconductor are located at points 0 and L. Solving eq. (22.97)
with the boundary condition $\eta = 0$ at $x = 0$, we get

$$\eta = C_1 \sinh\left(\frac{x}{\delta_E}\right) \tag{22.98}$$

On the other hand, we can solve eq. (22.97) by using the boundary condtion $\boldsymbol{\eta} = \mathbf{0}$ at $x = L$. This gives

$$\eta = C_2 \sinh\left(\frac{x-L}{\delta_E}\right) \tag{22.99}$$

If there are no phase slip centers in the superconductor, the general solution is $\eta = 0$. This is possible only as long as the current is less than j_{c}.

When the current exceeds j_c, a phase slip center appears. Let it be located at point X. Here we obtain

$$\eta(X-0) = C_1 \sinh\left(\frac{X}{\delta_E}\right), \quad \eta(X+0) = C_2 \sinh\left(\frac{X-L}{\delta_E}\right).$$

But at the phase slip center the phase derivative $\partial\chi/\partial t$ undergoes a discontinuity: $\Delta(\partial\chi/\partial t) = 2\pi/t_0$. In accordance with (22.96), it follows that

$$C_2 \sinh\left(\frac{X-L}{\delta_E}\right) - C_1 \sinh\left(\frac{X}{\delta_E}\right) = \frac{\pi\hbar}{t_0}. \tag{22.100}$$

Due to the phase slip all the quantities depend periodically on time with a period t_0. In experiments the time-averaged current and potential difference are measured (such averages are designated by a bar). According to (22.96), $\eta = e\bar{\varphi}$ (since $\overline{\partial\chi}/\partial t = 0$). The average electric field on the left from the point of phase slip ($0 < x < X$) is deduced from formula (22.98):

$$\bar{E} = -\frac{\partial\varphi}{\partial x} = -\frac{1}{e}\frac{\partial\eta}{\partial x} = -\frac{C_1}{e\delta_E}\cosh\left(\frac{x}{\delta_E}\right). \tag{22.101}$$

On the right of $X (X < x < L)$ we have

$$\bar{E} = -\frac{C_2}{e\delta_E}\cosh\left(\frac{x-L}{\delta_E}\right) \tag{22.102}$$

The constants C_1 and C_2 are found on the basis of the following considerations.
In experiments the total current j is specified most easily. It consists of the superconducting and normal parts:

$$j = j_\mathrm{s} + j_\mathrm{n}$$

This formula is exact near T_c (see the end of section 19.3); j_s was determined in section 16.8 ($j_\mathrm{s} = -QA$, where Q is expressed by formulae 16.88 and 16.92) and $j_\mathrm{n} = \sigma E$, where σ is the normal conductivity. However, in principle, an analogous formula may be written at any temperatures. To do this, one must use the relation
$j = -QA$ in the limit $q = 0, \omega < \Delta$ (here we mean the gauge $\varphi = 0, E = -c^{-1}\partial A/\partial t$) and expand in ω :

$$j = -Q(0)A + \frac{i\omega}{c}\sigma A,$$

where σ is a certain constant, which depends on Δ. The second term plays the role of j_n since $(\mathrm{i}\omega/c)A = -c^{-1}\partial A/\partial t = E$.

According to fig. 153, at the phase slip center the supercurrent fluctuates from the maximum value to zero. The maximum value must not exceed j_c. In view of this, in such a center $\bar{j}_\mathrm{s} = \alpha j_\mathrm{c}$, where $\alpha < 1$. We assume that even in the presence of several centers in each of them $\bar{j}_\mathrm{s} = \alpha j_\mathrm{c}$ with the same α, which is independent of the number of centers. Of course, this is a model assumption but, as will be seen below, it enables one to account for the stepped characteristic in fig. 158. At this point we will consider a single center. Thus, we have

$$\bar{j}_\mathrm{s}(X) = j - \bar{j}_\mathrm{n}(X) = \alpha j_\mathrm{c}. \tag{22.103}$$

Substituting $j_\mathrm{n} = \sigma E$ and E into eq. (22.103) in accordance with eqs. (22.101) and (22.102), we find

$$C_1 = -\frac{(j - \alpha j_c)\, e\delta_E}{\sigma \cosh\left(X/\delta_E\right)}, \quad C_2 = -\frac{(j - \alpha j_c)\, e\delta_E}{\sigma \cosh\left[(L - X)/\delta_E\right]}. \tag{22.104}$$

The period t_0 is associated with the potential difference. Inserting the length of the conductor L as a space period into formula (22.91) gives

$$\frac{2\pi}{t_0} = \frac{2e}{\hbar}\langle E\rangle L = \frac{2e}{\hbar}\int_0^L \bar{E}\ \mathrm{d}x = \frac{2e}{\hbar}[\varphi(0) - \bar{\varphi}(L)] = \frac{2eV}{\hbar}. \tag{22.105}$$

This is none other than the Josephson relation (22.55).
Formula (22.105) can also be derived directly from the problem under examination. Since at the ends of the conductor $\boldsymbol{\eta} = 0$, it follows that

$$\varphi(0) - \varphi(L) = \frac{\hbar}{2e}\left[\left(\frac{\partial\chi}{\partial t}\right)_L - \left(\frac{\partial\chi}{\partial t}\right)_0\right].$$

If we take the time average, then the regular part of the derivative $\partial\chi/\partial t$ gives zero and there will remain only a jump equal to $2\pi/t_0$, i.e., $\bar{\varphi}(0) - \bar{\varphi}(L) = \hbar\pi/et_0$, which is consistent with formula (22.105).

Inserting the expressions for C_1 and C_2 into eq. (22.100) and expressing the right-hand side in terms of V, we obtain

$$V = (j - \alpha j_\mathrm{c})\,\frac{\delta_E}{\sigma}\left[\tanh\left(\frac{X}{\delta_E}\right) + \tanh\left(\frac{L - X}{\delta_E}\right)\right].$$

From symmetry considerations it may be presumed that the phase slip center is located in the middle of the conductor, i.e., $X = \frac{1}{2}L$. Here we have

$$V = 2\left(j - \alpha j_{\rm c}\right)\frac{\delta_E}{\sigma}\tanh\left(\frac{L}{2\delta_E}\right). \tag{22.106}$$

In accord with eqs. (22.101) and (22.102) $\bar{E}$ and also the normal current increase from the edges to the middle portion of the conductor. Hence, the supercurrent is at a maximum at the edges. Here it cannot exceed j_c. This leads to the following condition:

$$j_{\rm s}(0) = j - \frac{(j - \alpha j_{\rm c})}{\cosh\left(L/2\delta_E\right)} \leqslant j_{\rm c}$$

At the same time, we must have $j \geqslant j_c$. From this we obtain the interval of values of the current j within which formula (22.106) applies:

$$j_{\rm c} \leqslant j \leqslant j_{\rm c}\frac{1 - \alpha\,\mathrm{sech}\left(L/2\delta_E\right)}{1 - \mathrm{sech}\left(L/2\delta_E\right)} \tag{22.107}$$

At $j = j_c$ there is a jump in the potential from zero to

$$V_1 = 2(1-\alpha)j_{\rm c}\frac{\delta_E}{\sigma}\tanh\left(\frac{L}{2\delta_E}\right) \tag{22.108}$$

This is followed by a linear portion of the characteristic up to the upper limit of the current given by formula (22.107). Here we have

$$V_1' = \frac{2(1-\alpha)j_{\rm c}\left(\delta_E/\sigma\right)\tanh\left(L/2\delta_E\right)}{1 - \mathrm{sech}\left(L/2\delta_E\right)}. \tag{22.109}$$

At a current j exceeding the upper limit in (22.107) two phase slip centers appear. It is rather natural to assume that they will be located so that the current $j_{\rm n}$ is symmetric with respect to either of them. This is possible if they are located at $X_1 = \frac{1}{4}L, X_2 = \frac{3}{4}L$. In such a case,

$$\begin{aligned}
\eta &= C_1 \sinh\left(\tfrac{x}{\delta_E}\right), && 0 < x < X_1,\\
\eta &= C_2 \sinh\left(\tfrac{x-\frac{1}{2}L}{\delta_E}\right), && X_1 < x < X_2,\\
\eta &= C_3 \sinh\left(\tfrac{x-L}{\delta_E}\right), && X_2 < x < L.
\end{aligned}$$

Let us define the coefficients C_1, C_2 and C_3, from the condition requiring that in the phase slip centers $\bar{j}_{\rm s} = j - \bar{j}_{\rm n}$ be equal to $\alpha j_{\rm c}$. This gives

$$C_1 = C_2 = C_3 = -\left(j - \alpha j_c\right)\frac{\left(e\delta_E/\sigma\right)}{\cosh\left(L/4\delta_E\right)}.$$

From the condition of the jump in η in the phase slip center we obtain the relation between the coefficients C_i and the period t_0, and from a formula analogous to

In accord with eqs. (22.101) and (22.102) $\bar{E}$ and also the normal current increase from the edges to the middle portion of the conductor. Hence, the supercurrent is at a maximum at the edges. Here it cannot exceed j_c. This leads to the following condition:

$$j_{\rm s}(0) = j - \frac{(j - \alpha j_{\rm c})}{\cosh\left(L/2\delta_E\right)} \leqslant j_{\rm c}$$

At the same time, we must have $j \geqslant j_c$. From this we obtain the interval of values of the current j within which formula (22.106) applies:

$$j_c \leqslant j \leqslant j_c \frac{1-\alpha \operatorname{sech}(L/2\delta_E)}{1-\operatorname{sech}(L/2\delta_E)}. \tag{22.107}$$

At $j = j_c$ there is a jump in the potential from zero to

$$V_1 = 2(1-\alpha) j_c \frac{\delta_E}{\sigma} \tanh\left(\frac{L}{2\delta_E}\right) \tag{22.108}$$

This is followed by a linear portion of the characteristic up to the upper limit of the current given by formula (22.107). Here we have

$$V_1' = \frac{2(1-\alpha) j_c (\delta_E/\sigma) \tanh(L/2\delta_E)}{1-\operatorname{sech}(L/2\delta_E)}. \tag{22.109}$$

At a current j exceeding the upper limit in (22.107) two phase slip centers appear. It is rather natural to assume that they will be located so that the current j_n is symmetric with respect to either of them. This is possible if they are located at $X_1 = \frac{1}{4}L, X_2 = \frac{3}{4}L$. In such a case,

$$\begin{aligned}
\eta &= C_1 \sinh\left(\tfrac{x}{\delta_E}\right), && 0 < x < X_1, \\
\eta &= C_2 \sinh\left(\tfrac{x-\frac{1}{2}L}{\delta_E}\right), && X_1 < x < X_2, \\
\eta &= C_3 \sinh\left(\tfrac{x-L}{\delta_E}\right), && X_2 < x < L.
\end{aligned}$$

Let us define the coefficients C_1, C_2 and C_3, from the condition requiring that in the phase slip centers $\bar{j}_s = j - \bar{j}_n$ be equal to $\alpha \bar{j}_c$. This gives

$$C_1 = C_2 = C_3 = -(j - \alpha j_c) \frac{(e\delta_E/\sigma)}{\cosh(L/4\delta_E)}.$$

From the condition of the jump in η in the phase slip center we obtain the relation between the coefficients C_i and the period t_0, and from a formula analogous to (22.105) (but this time we have $4\pi/t_0$ on the left-hand side) we deduce the relation between t_0 and V. This gives the following portion of the characteristic:

$$V = 4(j - \alpha j_c) \frac{\delta_E}{\sigma} \tanh\left(\frac{L}{4\delta_E}\right). \tag{22.110}$$

Formula (22.110) holds at currents starting from the upper limit (22.107) up to the point where the maximum of the supercurrent reaches the value j_c. Such a maximum is attained at $x = 0, \frac{1}{2}L$ and L. This yields

$$j_c \frac{1-\alpha \operatorname{sech}(L/2\delta_E)}{1-\operatorname{sech}(L/2\delta_E)} \leqslant j \leqslant \frac{1-\alpha \operatorname{sech}(L/4\delta_E)}{1-\operatorname{sech}(L/4\delta_E)}. \tag{22.111}$$

At the lower edge of this interval there occurs a jump in the voltage from the value V_1'(22.109) to

$$V_2 = \frac{4(1-\alpha) j_c (\delta_E/\sigma) \tanh(L/4\delta_E)}{1-\operatorname{sech}(L/2\delta_E)} \tag{22.112}$$

(it is not difficult to see that $\boldsymbol{V_2} > \boldsymbol{V_1'}$). This is followed by a linear portion of the characteristic in accordance with formula (22.110), which continues up to the upper limit of the interval (22.111), on which the voltage becomes equal to

$$V_2' = \frac{4(1-\alpha) j_c (\delta_E/\sigma) \tanh(L/4\delta_E)}{1-\operatorname{sech}(L/4\delta_E)}. \tag{22.113}$$

A further increase in the current leads to the appearance of a large number of phase slip centers and to the analogous dependences $V(j)$. A plot of $\sigma E/j_c$ against $j/j_c (E = V/L)$ for $L/\delta_E = 16$ is given in fig. 160. Here we take $\alpha = 0.09$ (see below).

Thus, it turns out that the characteristic consists of jumps in voltage and portions with a linear dependence $V(j)$. This is in agreement with experiment. As L increases

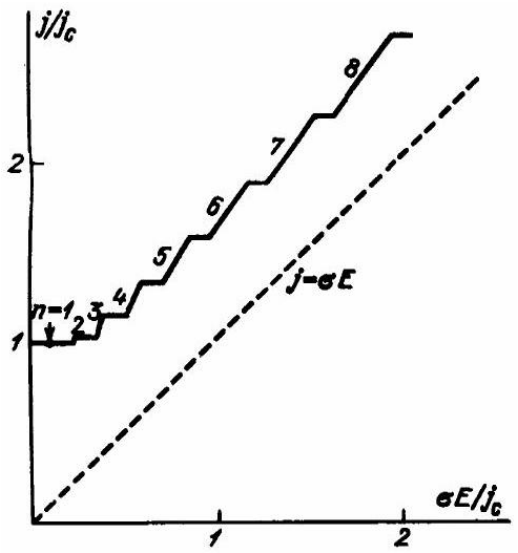

Fig. 160.

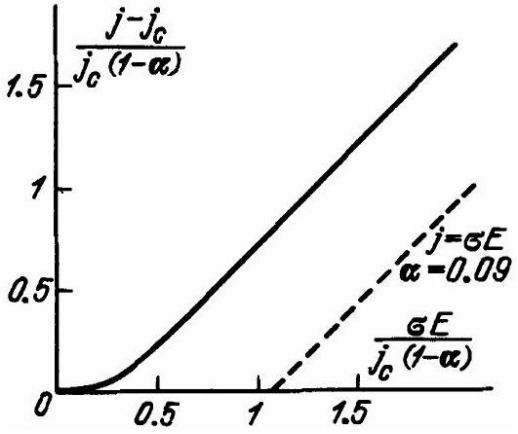

Fig. 161.

the intervals (22.107) and (22.111) and all the subsequent ones decrease and the characteristic approaches a continuous $V(j)$ curve. This dependence is not difficult to find by generalizing the preceding derivation to n phase slip centers. The linear portion of the characteristic of the number n has the form

$$V_n(j) = 2n \tanh\left(\frac{L}{2n\delta_E}\right)(j - \alpha j_c)\frac{\delta_E}{\sigma}. \tag{22.114}$$

The magnitude of the total current at which the maximum supercurrent reaches the critical value is given by

$$j_n = j_c \frac{1 - \alpha \operatorname{sech}(L/2n\delta_E)}{1 - \operatorname{sech}(L/2n\delta_E)}. \tag{22.115}$$

Inserting (22.115) into (22.114) yields

$$V_n\left(j_n\right)=\frac{2nj_c(1-\alpha)\left(\delta_E/\sigma\right)\sinh\left(L/2n\delta_E\right)}{\cosh\left(L/2n\delta_E\right)-1}. \tag{22.116}$$

With $n\to\infty$ the number n may be treated as a continuous variable. It is even more convenient to introduce the variable $z=L/\left(2n\delta_E\right)$. From eqs. (22.115) and (22.116) we obtain

$$\frac{(j-j_c)}{j_c(1-\alpha)}=\frac{1}{\cosh z-1}, \tag{22.117}$$

$$\frac{\sigma E}{j_c(1-\alpha)}=\frac{\sinh z}{z}\frac{1}{\cosh z-1}, \tag{22.118}$$

where $E=V/L$. This is a parametric representation of the dependence $E(j)$ in the limit $L>\delta_E$.

With a large current $j>j_{\rm c}$ we have $z\ll 1$. In such a case we find from eqs. (22.117) and (22.118)

$$j=\sigma E+\frac{1}{3}(2+\alpha)j_c, \tag{22.119}$$

that is, the characteristic is a straight line parallel to Ohm's law. Conversely, large z values correspond to the vicinity of $j_{\rm c}$. From eqs. (22.117) and (22.118) we obtain in this case

$$\frac{j-j_{\rm c}}{j_{\rm c}}\approx 2(1-\alpha)\exp\left(-\frac{j_{\rm c}(1-\alpha)}{\sigma E}\right). \tag{22.120}$$

The $j(V)$ curve with $V\to 0$ and $j\to j_{\rm c}$ has a horizontal tangent. The plot of the curve (22.117) and (22.118) is given in fig. 161.

The results of the phenomenological model described above are in good agreement with the results of the exact theory (Ivlev and Kopnin 1984)*. Comparing the formulae derived by both methods, we may conclude that $\alpha\leqslant 0.09$.

The $j(V)$ curve with $V\to 0$ and $j\to j_{\rm c}$ has a horizontal tangent. The plot of the curve (22.117) and (22.118) is given in fig. 161.

The results of the phenomenological model described above are in good agreement with the results of the exact theory (Ivlev and Kopnin 1984)*. Comparing the formulae derived by both methods, we may conclude that $\alpha\leqslant 0.09$.

- The exact theory is not free from some arbitrariness either, but many of the data provide evidence in favor of the principle of "minimum entropy production". If this principle is used, in the exponential law (22.119) we obtain the coefficient 0.91 (as $1-\alpha$) and in the formula for $j>j_c$ we obtain an extra current $\Delta j=0.68j_c$. If $\alpha=0.09$ is inserted into formula (22.119), we obtain $\Delta j=0.696j_c$.

Junctions, tunneling

9 Typical Methods for Junctions with Examples

9.1 Reminder of Tunneling in Mesoscopic Physics and in Semiconductors

(a brief review of mesoscopic physics, since it is used here. just paragraphs with main ideas, details - in the note on mesoscopic physics)

9.2 Josephson Junction: Basic Models and Effects

9.2.1 4.1 Phase Coherence and Types of Weak Links

In 1962 B. Josephson published a theoretical paper [10] predicting the existence of two fascinating effects. One was supposed to find them in superconducting tunnel junctions. The basic idea of the first effect was that a tunnel junction [1] should be able to sustain a zero-voltage (superconducting) current. The critical value of this current was predicted to depend on the external magnetic field in a very unusual way: If the current exceeds its critical value, which is a characteristic of a particular junction, the junction begins to generate high-frequency electromagnetic waves. This is the second Josephson effect.

Both effects were thoroughly verified by experiment [11, 30] shortly after [10] was published. Moreover, it soon became clear that the Josephson effects exist not only in tunnel junctions, but also in other kinds of the so-called weak links, that is, short sections of superconducting circuits where the critical current is substantially suppressed [20, 31, 32].

The effects of weak superconductivity have their origin in the quantum nature of the superconducting state. We already know that the foundation of the superconducting state is the existence of the Bose condensate. That is to say, all electron pairs in the superconducting state occupy the same quantum level and are described by a single wavefunction, common to all of them. Their behavior is mutually conditioned, they are coherent.

Imagine two bulk pieces of a superconductor at the same temperature, completely isolated from each other. When both pieces are in the superconducting state, the superconducting electrons in each of them have their own superconducting wavefunction. Furthermore, since the temperatures and the materials of the superconductors are identical, the amplitudes of the wavefunctions must also be the same. This does not hold for the phases, however, which are arbitrary. This situation remains as long as the superconductors are isolated from each other. Let us now establish a weak contact between them, i.e., a contact that is weak enough so as not to change radically the electron states of the two pieces but sufficient to play the role of a perturbation. A new wavefunction will then emerge for the superconductor as a whole, which can be considered as a result of interference between the wavefunctions from the two pieces. As mentioned above, the amplitudes of the two wavefunctions had been equal even before the weak link was established. But not their phases: the phase coherence is a direct result of establishing the weak link. It is therefore often said that phase coherence sets up in weakly-coupled superconductors.

High-quality tunnel Josephson junctions, typically made of niobium with a barrier of aluminum oxide, presently serve as basic elements for low-temperature superconducting electronics.

Here it should be noted that a weak link between two superconductors is merely a convenient place for letting interference effects become visible. As to the interference effects in superconductors themselves, they were known long before the discovery of the Josephson effects. The most famous example is the magnetic flux quantization in a superconducting ring: the magnetic flux frozen in such a ring can assume only quantized values because the supercurrent, circulating in the ring and generating this magnetic flux, is quantized. And the quantization of the supercurrent is a typical interference effect. The current can assume only those values that yield an integral number of wavelengths of the superconducting wavefunction over the length of the ring. This situation is exactly analogous to the quantization of electron orbits in the Bohr atom.

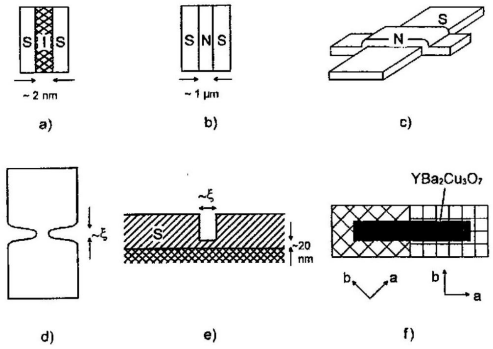

Fig. 4.1. Different types of weak links: (a) tunnel junction (SIS); (b) sandwich (SNS): (c) normal film N causes local suppression of the order parameter of a superconducting film S; (d) Dayem bridge, top view; (e) bridge of variable thickness, longitudinal cross-section; (f) grain-boundary junction (??? why is is grain? The pic. is different from rus book).

Let us now consider different types of weak links. First, there are devices without a concentration of a current (see Fig. 4.1. a)) (????). The thickness of an insulating layer is typically about $1-2$ nm and the critical current density is in the range $10-10^4$ A cm^{-2}, i.e., much less than the critical current density of the bulk superconductors. [2]

In superconductor-normal metal-superconductor (SNS) sandwiches, the normal layer can be as thick as 10^{-4} cm (Fig. 4.1 (b)). The wavefunctions of the superconducting electrons penetrate the normal metal due to the proximity effect. In the region of their overlap, the wavefunctions interfere, with the consequence that phase coherence is established between the bulk superconductors. If the amplitude of the superconducting wavefunction in the weak link is small, the critical current is also small.

The same effect can be achieved if the normal layer between the two superconductors is replaced by a doped semiconductor or another superconductor with a small critical current density. For example, if a narrow superconducting film is covered with a narrow film of a normal metal (Fig. 4.1 (c)), the amplitude of the superconducting electron wavefunction in the film is reduced where the film is in contact with the normal metal, due to the proximity effect. This causes a local decrease of the critical current density, that is, a weak link is established.

In devices with concentration of current, the critical current density in the weak link is the same as in the bulk, but the absolute value of the critical current is much less. A superconducting film with a short narrow constriction (Dayem bridge) falls into this category, provided the size of the constriction is of the order of the coherence length ξ (see Fig. 4.1 (d)). Another example is a bridge of variable thickness, such that the thickness of the main film is hundreds of nm while the thickness of the bridge itself is only several dozen nm (Fig. 4.1 (e)).

Finally, a weak link typical of high-temperature superconductors is shown in Fig. 4.1 (f). It

is called a grain boundary (or bi-crystal) junction. Due to the extremely short coherence length in high- T_c materials ($\xi \sim 1$ nm), defects in their crystal structure can act as weak links. The best-controlled defects can be produced between two regions of an epitaxially grown high- T_c film with different crystal orientations (grain boundary). The critical current density of such a weak link can be varied by changing the misorientation angle between the two crystallites.

Different types of weak links based on conventional low- T_c superconductors are described in a classic review by Likharev [31]. Various weak links and SNS structures made of high- T_c superconducting materials have been recently reviewed by Gross [33].

9.2.2 4.2 The DC Josephson Effect

Background for Derivation of Josephson Effect

Let us start with the first Josephson effect which is a dc effect. The physics behind it is essentially as follows. A sufficiently small current can pass through a weak link (Josephson junction) without dissipation. In other words, when such a current passes through the weak link, no voltage is generated across the junction. Since the current is always small, the magnetic field generated by it can be neglected and, following the Ginzburg-Landau theory, we can argue that the density of the current is determined by the phase gradient $\nabla\theta$ of the superconducting electron wavefunction.

An important characteristic of the weak link is that the phase gradient $\nabla\theta$ is very large compared to the phase gradients inside the bulk superconductors (in the following we shall refer to them as 'electrodes'). For a tunnel junction, strictly speaking, the expression 'phase gradient' is inappropriate and one should rather speak of a discontinuous phase jump across the junction. Therefore, from now on we shall always analyze the phase difference across the weak link:

$$\varphi = \theta_2 - \theta_1$$

where θ_1 and θ_2 are the phases of the superconducting electron wavefunctions in the first and second electrodes, respectively.

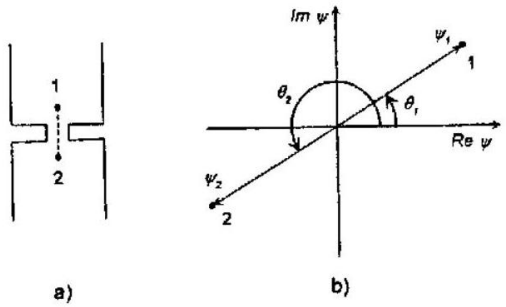

Fig. 4.2. (a) Example of weak link (Dayem bridge). The phase gradient $\nabla\theta$ is taken along the dashed line from point 1 to point 2; (b) representation of the order parameter in the complex plane. Passing from point 1 to point 2 in the weak link corresponds to passing from ψ_1 to ψ_2 in the complex plane, along the line $1-2$.

General relation

(????????? I don't understand that this is obvious????)

Now our task is to find the relation between the current through the weak link, I_s, and the phase difference φ. Let us first establish some general and almost self-evident relations.

(1) If the current through the junction is $I_8 = 0$, the phase difference is also $\varphi = 0$.

(2) Since the variation of the phase θ by 2π in one of the electrodes does not change anything physically, it is evident that $I_s(\varphi)$ is a periodic function with period 2π, that is, $I_s(\varphi) = I_s(\varphi + 2\pi)$.

(3) Changing the sign of the current must cause a change of the sign of the phase difference; therefore, $I_\mathrm{s}(\varphi) = -I_\mathrm{s}(-\varphi)$.

(4) The last relation, $I_\mathrm{a}(\pi) = 0$, is somewhat less obvious. Let us assume [3] that the length of the weak link is small but finite so that we can introduce a phase gradient $\nabla\theta$ across it. On going along the dashed line (Fig. 4.2 (a)) from point 1 to point 2, the complex order parameter runs through values varying from ψ_1 to ψ_2 along the straight line $1-2$ in the complex plane of ψ (see Fig. 4.2 (b)).

It is obvious that $\nabla\theta$ along the line is zero, resulting in $I_\mathrm{s} = 0$. At this point one can raise an objection. What happens if we go from ψ_1 to ψ_2 not along the straight line but along, say, a semicircle of radius $|\psi|$? The answer is $\nabla\theta \neq 0$ and $I_\mathrm{s} \neq 0$. Such a situation indeed occurs in long thin superconducting filaments. In that case, however, two paths are possible to go from ψ_1 to ψ_2: anticlockwise and clockwise, so that the corresponding gradients $\nabla\theta$ will be of opposite signs. This means that $I_8(\varphi)$ will become a multiple-valued function. However, by definition, such junctions can no longer be regarded as Josephson junctions.

Now let us ask: what is the simplest representation of $I_s(\varphi)$ having all four of the above properties? The function $\sin\varphi$ is an obvious satisfactory answer, and we can propose

$$I_\mathrm{s}(\varphi) = I_\mathrm{c}\sin\varphi, \tag{4.1}$$

where I_c is the maximum dissipation-free current through the junction often referred to as the critical current.

Derivation of Josephson Equations by Quantum Mechanics

Let us prove that our proposal is indeed appropriate. Two derivations of (4.1) will be given. The first, applicable to tunnel Josephson junctions, is due to Feynman [34] and the second, relevant to the case of short narrow constrictions, is by Aslamazov and Larkin [35].

But first a short foray into quantum mechanics.
The evolution of a quantum-mechanical system with time is described by a wavefunction $\Psi(t)$ which is the solution of the Schrdinger equation:

$$\mathrm{i}\hbar\frac{\partial\Psi}{\partial t} = \hat{H}\Psi \tag{4.2}$$

where $\hat{H}$ is the Hamilton operator of the system. If the system is allowed only discrete states ψ_α (where α is a series of indices each characterizing a given state), its wavefunction can be expanded in a series

$$\Psi(t) = \sum_\alpha C_\alpha(t)\psi_\alpha \tag{4.3}$$

Substitution of this in (4.2) gives

$$\mathrm{i}\hbar\frac{\mathrm{d}C_\beta}{\mathrm{d}t} = \sum_\alpha H_{\beta\alpha}C_\alpha(t) \tag{4.4}$$

Here

$$H_{\beta\alpha} = \int \psi_\beta^*\hat{H}\psi_\alpha \mathrm{d}V$$

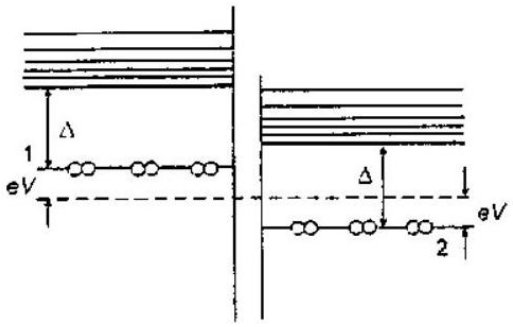

Fig. 4.3. Energy-level diagram for a tunnel Josephson junction with a finite voltage V applied to it. Levels 1 and 2 are separated by $2e$ V

One can see that $H_{\beta\beta}$ is the energy of the system in the state ψ_β, and $H_{\beta\alpha}$ is the matrix element characterizing the probability of a transition from the state ψ_α to the state ψ_β. The function $C_\alpha(t)$ represents the amplitude of the state ψ_α, and $|C_\alpha|^2$ gives the probability of finding the system in the state ψ_α.

Let us now go back to a tunnel Josephson junction. Assume that, in the general case, the current through the junction is so large ($I_8 > I_C$) that a voltage V appears across the junction. The corresponding energy diagram is shown in Fig. 4.3. Following Feynman [34], we consider a system of superconducting electrons, or Cooper pairs, as a two-level quantum-mechanical system. That is, we suppose that an electron pair with charge $2e$ can occupy either level 1 or level 2 . Then its energy will be either H_{11} or H_{22}, respectively, where $H_{11} = eV$ and $H_{22} = -eV$. The transition from level 1 to level 2 is governed by the matrix element $H_{12} = H_{21} = K$. Then (4.4) becomes

$$\begin{aligned} \mathrm{i}\hbar\frac{\mathrm{d}C_1}{\mathrm{d}t} &= eVC_1(t) + KC_2(t) \\ \mathrm{i}\hbar\frac{\mathrm{d}C_2}{\mathrm{d}t} &= KC_1(t) - eVC_2(t) \end{aligned} \tag{4.5}$$

Here C_1 is the amplitude of the pair state at level t and $|C_1|^2$ is normalized in such a way that $|C_1|^2 = n_5$, where n_5 is the superconducting electron density in the junction electrodes. For the sake of simplicity, we assume that both electrodes are made of the same material. Expressing the amplitudes C_1 and C_2 as

$$C_1 = \sqrt{n_\mathrm{R}}\mathrm{e}^{\mathrm{i}\theta_1}, \quad C_2 = \sqrt{n_\mathrm{R}}\mathrm{e}^{\mathrm{i}\theta_2}$$

substituting these in (4.5), and separating real and imaginary parts, we obtain
(!!! here I'll add a detailed derivation, see wiki about it for now!!!)

$$\frac{\mathrm{d}n_\mathrm{s}}{\mathrm{d}t} = \frac{2Kn_\mathrm{s}}{\hbar}\sin\varphi \tag{4.6}$$

$$\frac{\mathrm{d}\theta_1}{\mathrm{d}t} = -\frac{K}{\hbar}\cos\varphi - \frac{eV}{\hbar} \tag{4.7}$$

$$\frac{\mathrm{d}\theta_2}{\mathrm{d}t} = -\frac{K}{\hbar}\cos\varphi + \frac{eV}{\hbar} \tag{4.8}$$

The current through the tunnel junction is proportional to $\mathrm{d}n_5/\mathrm{d}t$. Indeed, when the current is switched on, the superconducting electron density starts to vary at the rate $\mathrm{d}n_5/\mathrm{d}t$ thereby giving rise to a current $I_5 = \mathrm{d}n_5/\mathrm{d}t$. This means that electrons start to leave the superconducting electrode. But this process is immediately compensated by the arrival of new

electrons from an external current source, because the junction is a part of a closed electric circuit. Therefore, the density n_s remains constant due to electroneutrality of the system as a whole. However, for defining the supercurrent, it is sufficient to assume $I_6 \propto \mathrm{d}n_5/\mathrm{d}t$. Then from (4.6) we immediately obtain the equation for the dc Josephson effect

$$I_s = I_c \sin\varphi \tag{4.9}$$

Derivation from Ginzburg-Landau Equations

(????)

Another way to derive the same equation, as applied to a weak link formed by a short narrow constriction, has been proposed by Aslamazov and Larkin [35]. Assume that a bridge, as in Fig. 4.4, is so short that its length is $L \ll \xi$.

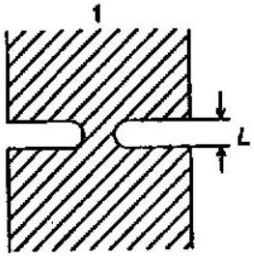

Fig. 4.4. Short narrow constriction (bridge) of length $L \ll \xi$ links together two wide films 1 and 2

In the absence of external magnetic field, the first Ginzburg-Landau equation (3.12) for such a bridge takes the form

$$-\xi^2\nabla^2\psi - \psi + \psi|\psi|^2 = 0. \tag{4.10}$$

The order parameter in a short bridge varies substantially over the length of the bridge, L. In this case, $\nabla^2\psi$ can be estimated as

$$\nabla^2\psi \sim \psi/L^2.$$

On the other hand, the amplitude of the order parameter is $|\psi| \sim 1$. It follows that the dominant term in (4.10) is the first one, since

$$\xi^2/L^2 \gg 1,$$

while all other terms are of the order 1 . This allows us to simplify (4.10):

$$\nabla^2\psi = 0 \tag{4.11}$$

Now assume that, far away from the constriction, the order parameter ψ in film 1 is

$$\psi = \psi_1 \mathrm{e}^{\mathrm{i}\theta_1}$$

and in film 2 it is

Here ψ_1, ψ_2, θ_1, and θ_2 are constants independent of the coordinates. Within the area of the constriction, the two wavefunctions interfere and we therefore seek the solution of (4.11) in the form

$$\psi = \psi_1 \mathrm{e}^{\mathrm{i}\theta_1} f(r) + \psi_2 \mathrm{e}^{\mathrm{i}\theta_2}[1 - f(r)] \tag{4.12}$$

subject to the conditions $f(r) \to 1$ in the interior of film 1 and $f(r) \to 0$ in the interior of film 2.

Substituting (4.12) into (4.11), we obtain the equation for $f(r)$:

$$\nabla^2 f(r) = 0$$

However, there is no need to solve this equation here. It suffices to know that the solution exists, and we can immediately go over to calculating the supercurrent which, by the second Ginzburg-Landau equation (3.17), is

$$j_{\rm s} = \frac{|\alpha|\hbar e}{\beta m} \operatorname{Im}(\psi^* \nabla \psi)$$

Substituting here (4.12) and applying simple algebra, we obtain for the supercurrent density through the bridge:

$$j_s = j_c \sin\varphi, \tag{4.13}$$

(??? this j_c is not a critical current of the SC, it is just a maximal current that can flow through the link, right??)

where again $\varphi = \theta_2 - \theta_1$.

Thus we have arrived at the same simple relation between the supercurrent and the phase difference of the superconducting wavefunctions in the junction electrodes as before. In the following we shall always assume that this relation holds.

Derivation of Josephson equations from GL: Second Way (???)

(still, I am not sure, how to do it)

Proof from GL eq:

$$\mathbf{n} \cdot \left(\nabla_{\mathbf{r}} - i\frac{2e}{\hbar c}\mathbf{A} \right) \Delta = 0$$

$$\mathbf{n} \cdot \left(\nabla_{\mathbf{r}} - i\frac{2e}{\hbar c}\mathbf{A} \right) \Delta_1 = \mathbf{n} \cdot \left(\nabla_{\mathbf{r}} - i\frac{2e}{\hbar c}\mathbf{A} \right) \Delta_2 = \frac{\Delta_2 - \Delta_1}{\Lambda}.$$

Вид правой части можно было бы угадать, исходя из требования линейности по Δ_1 и Δ_2 (так как параметр порядка мал), а также из того, что при перестановке местами полупространств 1 и 2 ток должен менять направление - поэтому должна войти разность Δ_1 и Δ_2. Параметр Λ имеет размерность длины и равен $\Lambda = \sigma R \mathcal{A} \sim l/\mathcal{T}$, $\sigma = 2e^2\nu D$ - проводимость сверхпроводника в нормальном состоянии (при нагревании выше T_c), R и $\mathcal{A}$ - сопротивление и площадь границы, l - длина свободного пробега, а $\mathcal{T} < 1$ - вероятность туннелирования электрона с энергией порядка энергии Ферми через границу между сверхпроводниками при $T > T_c$. Из $\mathbf{j}_s = 4eaD \operatorname{Im}\Delta^* \left(\nabla_{\mathbf{r}} - i\frac{2e}{\hbar c}\mathbf{A} \right) \Delta$

$$\mathbf{n} \cdot \mathbf{j_{s1}} = \mathbf{n} \cdot \mathbf{j_{s2}} = \frac{\pi}{4eT_c R\mathcal{A}} \operatorname{Im}(\Delta_1^* \Delta_2)$$

Если граница малопрозрачна, то модули параметров порядка с двух сторон от границы совпадают со своими значениями в объёме, и параметры порядка отличаются только фазами: $\Delta_{1(2)} = \Delta_0 e^{i\varphi_{1(2)}}$. Поэтому

$$j_s = \frac{\pi\Delta_0^2}{4eT_c R\mathcal{A}} \sin(\varphi_2 - \varphi_1)$$

$$I_s = I_c \sin(\varphi_2 - \varphi_1), \quad I_c = \frac{\pi\Delta_0^2}{4eT_c R}$$

$$I_c(T) = C\frac{T_c - T}{R_N}, \quad C := \frac{2\pi^3}{7\zeta(3)e} \approx 635\frac{\text{mKB}}{\text{K}},$$

ибо $|\Delta| \equiv \Delta_0 = \sqrt{-\frac{\hbar T_c}{\tau_{\text{GL}} b}} = \sqrt{\frac{\alpha T_c (T_c - T)}{b}}$.

9.2.3 4.3 The AC Josephson Effect

Relation of the voltage on the junction and the phase

So far we have considered the case of a small current $I < I_c$ through a weak link. If the current supplied by an external source exceeds the critical value I_c, it causes a voltage V to appear across the junction. What consequences should then be expected?

The behavior of a quantum-mechanical system is described by the Schrdinger equation

$$\mathrm{i}\hbar\frac{\partial\psi}{\partial t} = \hat{H}\psi \tag{4.14}$$

where $\hat{H}$ is the system's Hamiltonian.

The wavefunction of a stationary state ψ_1 satisfies the equation

$$\hat{H}\psi_1 = E\psi_1$$

where E is the energy of the state and $\psi_1 = |\psi_1|\, e^{\mathrm{i}\theta(t)}$, with $|\psi_1|$ being independent of time. On substitution of this wavefunction into (4.14) we get

$$-\hbar\frac{\partial\theta}{\partial t} = E \tag{4.15}$$

The presence of the voltage V across the weak link suggests that the Cooper pair energies in superconductors on either side of the junction, E_1 and E_2, are related to each other by

$$E_1 - E_2 = 2eV \tag{4.16}$$

because the charge of a pair is $2e$.

Substituting (4.16) into (4.15), we obtain the second fundamental Josephson relation:

$$2eV = \hbar\frac{\partial\varphi}{\partial t} \tag{4.17}$$

The same relation can be obtained by subtracting (4.7) from (4.6).

Current, which is more then I_c (RSJ model)

Now, what happens to a Josephson junction if we apply a constant current $I > I_c$ to it? Since the supercurrent cannot exceed I_c, now a current of normal electrons I_n must start flowing through the junction, in addition to the supercurrent. This conclusion leads us directly to the so-called resistively shunted model of the Josephson junction (RSJ) in which the latter is considered as a circuit made up of the Josephson junction itself and a normal resistance connected in parallel (Fig. 4.5).

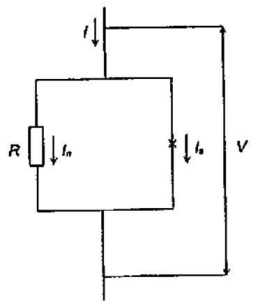

Fig. 4.5. Resistively shunted model of a Josephson junction. The supercurrent through the junction is $I_g = I_c \sin\varphi$

The total current I is then a sum of the normal current V/R and the supercurrent $I_s = I_c \sin\varphi$:

$$I = I_c \sin\varphi + \frac{\hbar}{2eR}\frac{\partial\varphi}{\partial t} \tag{4.18}$$

where R is the normal-state resistance of the junction. This differential equation can be easily integrated. Substituting the solution into (4.17), we obtain the voltage across the junction as

$$V(t) = R\frac{I^2 - I_c^2}{I + I_c \cos\omega t} \tag{4.19}$$

$$\omega = \frac{2e}{\hbar}R\sqrt{I^2 - I_c^2} \tag{4.20}$$

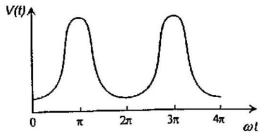

Fig. 4.6. Voltage across the Josephson junction at $I \geq I_c$

Thus we have found a fascinating property of the Josephson junction. If an external dc current I through the junction exceeds the critical current I_c, it causes a voltage V to appear across the junction, which oscillates periodically with time. This phenomenon is often referred to as Josephson radiation. (??? why?? currently, we said nothing about radiation, however, maybe it is a consequence of this formula???)

The time dependence of V is sketched in Fig. 4.6. The frequency of the ac voltage depends on the amount by which the current through the junction, I, exceeds the critical value I_c (see (4.20)).

If we now connect the junction to a dc voltmeter, the latter will register the average value over one period, $\bar{V}$. Averaging of (4.19) over time gives (???? how???)

$$2e\bar{V} = \hbar\omega \tag{4.21}$$

This formula has a very clear physical interpretation. If the average separation between the energy levels of the Cooper pairs in the superconducting electrodes is $2e\bar{V}$, then, as a result of the transfer of one pair through the weak link, this energy is released by the junction in the form of one quantum of electromagnetic radiation.

The current-voltage characteristic of the junction predicted by (4.20) and (4.21) is shown in Fig. 4.7.

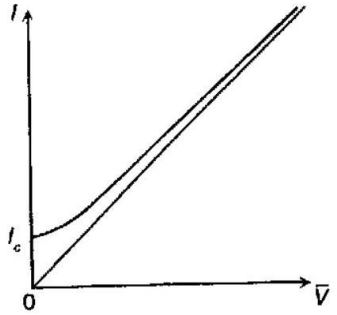

Fig. 4.7. Current-voltage characteristic of a Josephson junction

Note that the relations (4.17) and (4.21) are absolutely precise and fundamental and exact. They have been confirmed by numerous experiments. The first experimental observation of the Josephson radiation was reported in 1964 by Yanson, Svistunov and Dmitrenko [11].

9.2.4 1001 Questions about what exactly happens in JJ?

What is the most exact CPR in JJ?

(??? I don't know, this theory predicts that there is these features, another - that there are another and so on. I'll answer later)

(actually, there is a big article about it Current-phase relation in Josephson junctions by Golubov, Kupriyanov, Il'ichev, so I'll write main statements from it here)

What was approximated?

(discuss all these approximations)

Was self-consistency taken into account in Josephson relations?

(??????discussion of it. see de gennes book)

9.2.5 Experimental Confirmation of CPR in JJ

(!!! write this! for which experiments which results?)

9.2.6 Shapiro Steps

(about them)

9.2.7 Josephson Junction in an External Magnetic Field

Model of Josephson Junction in a Weak External Magnetic Field

In this section we shall restrict our attention to Josephson junctions without concentration of current, that is, to sandwiches and tunnel junctions. Suppose, for example, that such a junction consists of two bulk superconducting slabs separated by a thin insulating layer, as in Fig. 4.8.

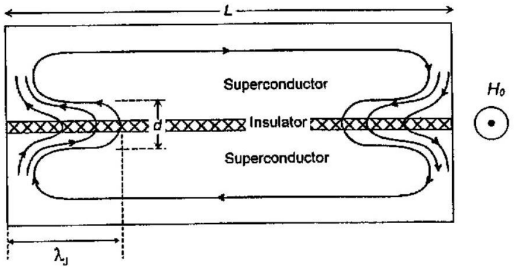

Fig. 4.8. Tunnel Josephson junction in a magnetic field H_0. The distribution of the screening (Meissner) supercurrent is shown by lines with arrows

If this system is placed in an external magnetic field parallel to the plane of the junction, a screening supercurrent will be generated at the outer surfaces of the slabs. This current circulates within a surface layer of thickness λ and, in doing so, has to cross the weak link, where the critical current density is very small. Therefore, in order to maintain its dissipation-free flow, the current must spread over a rather wide area protruding into the junction. This situation is illustrated in Fig. 4.8. Let us try to describe it in mathematical terms.

Consider a Josephson junction in an external magnetic field. The plane of the junction coincides with the x axis and the magnetic field is directed along the z axis. The length along the y axis of the region penetrated by the current and the magnetic field is $d = 2\lambda + t$ (see Fig. 4.8). Here t is the thickness of the insulating layer. Consider two closely spaced pairs of points in the vicinity of the junction: 1, 2 and 3, 4, as in Fig. 4.9. All the points are chosen outside the area penetrated by the magnetic field and the distance between them is

The generalized momentum of a Cooper pair has the form

$$\hbar\nabla\theta = 2mv_\mathrm{s} + \frac{2e}{c}\boldsymbol{A} \tag{4.22}$$

where θ is the phase of the wavefunction, v_s the pair velocity, m the electron mass, e the electron charge, and $\boldsymbol{A}$ the vector potential. Let us integrate this equation along the dashed curves shown in Fig. 4.9.

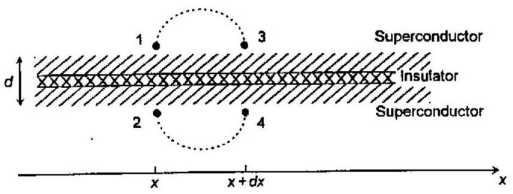

Fig. 4.9. Section near the edge of the Josephson junction. The dashed area is the region penetrated by the magnetic field

Since both curves are outside the area penetrated by the supercurrent, we have $v_\mathrm{s} = 0$:

$$\hbar\left[\int_1^3 \nabla\theta\cdot\,\mathrm{d}\boldsymbol{l} + \int_4^2 \nabla\theta\cdot\,\mathrm{d}\boldsymbol{l}\right] = \frac{2e}{c}\left[\int_1^3 \boldsymbol{A}\cdot\,\mathrm{d}\boldsymbol{l} + \int_4^2 \boldsymbol{A}\cdot\,\mathrm{d}\boldsymbol{l}\right]. \tag{4.23}$$

The distance d is assumed to be negligibly small. Then the right-hand side of (4.23) can be approximated by

$$\frac{2e}{c}\oint A\cdot\,\mathrm{d}l = \frac{2e}{c}\,\mathrm{d}\Phi, \tag{4.24}$$

where $\mathrm{d}\Phi$ is the magnetic flux enclosed by the contour comprising the dashed curves $1-3$ and $4-2$ which are supplemented with missing sections $3-4$ and 2-1. Carrying out the integration on the left-hand side we get

$$\hbar\left(\theta_3-\theta_1+\theta_2-\theta_4\right)=\frac{2e}{c}\,\mathrm{d}\Phi$$

Taking into account that $\theta_3-\theta_4=\varphi(x+\mathrm{d}x)$ and $\theta_1-\theta_2=\varphi(x)$, we have

$$\varphi(x+\mathrm{d}x)-\varphi(x)=\frac{2e}{\hbar c}\,\mathrm{d}\Phi,$$

or, recalling that $\Phi_0=\pi\hbar c/e$,

$$\frac{\mathrm{d}\varphi}{\mathrm{d}x}=\frac{2\pi}{\Phi_0}\frac{\mathrm{d}\Phi}{\mathrm{d}x}. \tag{4.25}$$

Noting that $(1/d)\mathrm{d}\Phi/\mathrm{d}x$ is the magnetic field H at the point x of the junction, we can write

$$H=\frac{\Phi_0}{2\pi d}\frac{\mathrm{d}\varphi}{\mathrm{d}x}. \tag{4.26}$$

This magnetic field H is directed along the z axis. By Maxwell's equations, the supercurrent through the junction in the direction of the y axis is

$$j_\mathrm{s}=\frac{c}{4\pi}\frac{\mathrm{d}H}{\mathrm{d}x}.$$

Inserting (4.26) and recalling the fundamental Josephson relation between the current and the phase difference, $j_\mathrm{s}=j_\mathrm{c}\sin\varphi$, we arrive at the so-called Ferrell-Prange equation [36]:

$$\frac{\mathrm{d}^2\varphi}{\mathrm{d}x^2}=\frac{1}{{\lambda_\mathrm{J}}^2}\sin\varphi, \tag{4.27}$$

where λ_J is

$$\lambda_\mathrm{J}=\left(\frac{c\Phi_0}{8\pi^2 j_\mathrm{c} d}\right)^{1/2}. \tag{4.28}$$

But, actually, nearly no one knows, what is the Ferrell-Prange equation, so it is better to name it "equation of phase when magnetic field is present".

The solution of (4.27), $\varphi(x)$, gives the phase difference distribution over the junction. Consider the case of a very weak external field $H_0\ll\Phi_0/\left(2\pi\lambda_\mathrm{J}d\right)$. Both the currents through the junction and the phase difference φ are then small. Hence we can rewrite (4.27) as

$$\frac{\mathrm{d}^2\varphi}{\mathrm{d}x^2}=\frac{1}{\lambda_\mathrm{J}^2}\varphi.$$

This equation can be easily solved to give

$$\varphi(x)=\varphi(0)\exp\left(-x/\lambda_\mathrm{J}\right). \tag{4.29}$$

Substituting this solution into (4.26), we find the magnetic field in the junction:

$$H(x)=H_0\exp\left(-x/\lambda_\mathrm{J}\right).$$

(!!! add some plot about it here!!!)

One can see that the quantity λ_J, which has the dimensions of length, represents the depth of magnetic field penetration into the Josephson junction. λ_J is usually referred to as the Josephson penetration depth.

In the International System of Units (SI), equation (4.28) takes the form:

$$\lambda_{\mathrm{J}} = \left(\frac{\Phi_0}{2\pi\mu_0 j_{\mathrm{c}} d} \right)^{1/2}$$

where $\mu_0 = 4\pi \times 10^{-7}\mathrm{Hm}^{-1}, \Phi_0 = 2.07 \times 10^{-15}$ Wb, j_{c} is the density of the critical current through the junction in Am^{-2}, and d is taken in m . Taking parameters typical of a tunnel Josephson junctions $d \sim 10^{-5}$ cm, $j_{\mathrm{c}} \sim 10^2 \mathrm{Acm}^{-2}$, we obtain $\lambda_{\mathrm{J}} \sim 0.1$ mm, i.e., it is a macroscopic length.

Not Weak Magnetic Field Penetration into a Josephson Junction. Josephson Vortices

What happens if the external field in JJ becomes not weak? It turned out that the behavior of a Josephson junction in an external magnetic field is reminiscent of the behavior of a type-II superconductor. Just as with type-II superconductors, when the external field exceeds a certain critical value H_{cl}, which is a characteristic of the junction, the field starts to penetrate into the junction in the form of superconducting vortices, each carrying one magnetic flux quantum Φ_0. In the case of a Josephson junction, they are called Josephson vortices.

Indeed, one of the solutions of the Ferrell-Prange equation (4.27) has the form

$$\varphi_0(x) = 4 \arctan \left\{ \exp \left(x/\lambda_{\mathrm{J}} \right) \right\}. \tag{4.30}$$

One can easily verify that this solution satisfies (4.27). The functions $\varphi_0(x)$, $\mathrm{d}\varphi_0/\mathrm{d}x \sim H$, and $\mathrm{d}^2\varphi_0/\mathrm{d}x^2 \sim j_{\mathrm{s}}$ are shown in Fig. 4.10.

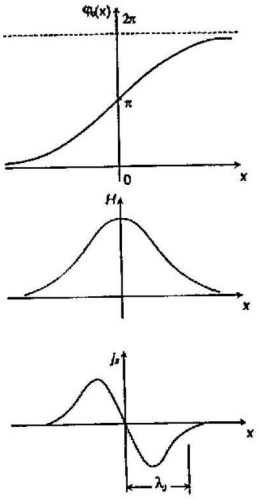

Fig. 4.10. Phase difference $\varphi_0(x)$, magnetic field $H(x)$, and supercurrent $j_s(x)$ for a Josephson vortex

A Josephson vortex represents a so-called soliton, that is, it is a localized solitary excitation of an extended Josephson junction.

These are the static properties of Josephson vortices, also known as Josephson fluxons. When a dc bias current is applied to a Josephson junction, the vortices can move along the junction and their motion leads to the appearance of a dc voltage accompanied by Josephson radiation, according to (4.21). This dynamic state is described by the so-called perturbed sine-Gordon equation [37], which is a more general case of (4.27) for the spaceand time-dependent φ. Moving Josephson fluxons exhibit relativistic properties of solitons (nonlinear solitary electromagnetic waves) and have been extensively studied both theoretically and experimentally. (!!! I'll add this to the theory later!!!)

The size of a static vortex along the x axis of the junction is $\sim 2\lambda_{\mathrm{J}}$ and along the y axis $\sim d \ll 2\lambda_{\mathrm{J}}$.

Thus, beginning at the field $H_{\rm cl}$, penetration of Josephson vortices into the junction becomes energetically favorable. Having penetrated into the junction, the vortices form a linear chain and the junction goes into the mixed state. So far we have a complete analogy with a type-II superconductor. But is the analogy really complete? The answer is 'no'.

The thing is that, unlike an Abrikosov vortex (see Chap.5), a Josephson vortex does not have a normal core. The existence of the normal core in typeII superconductors relates to the second critical field H_{c2}: Superconductivity disappears when an external magnetic field presses the vortices so close together that their normal cores come into contact. The absence of a normal core for Josephson vortices implies that there is no upper critical field for a Josephson junction. Nevertheless, as we shall soon find out, the dependence of the maximum current through the junction on magnetic field can be rather curious.

Let us find the lower critical field of the junction, $H_{\rm cl}$. In order to do that, we shall analyze the free energy of the junction.

As the current through the junction increases from zero to a certain value $j_{\rm s}$ over a time t, a certain amount of energy is being stored by the junction. Per unit area of the junction, this energy is

$$w_{\rm J} = \int_0^t j_{\rm s} V \, {\rm d}t$$

Here V is the voltage across the junction, which appears during the process of increasing the current and obeys the general relation (4.17). Substituting here $j_{\rm s} = j_{\rm c} \sin\varphi$ and (4.17), we obtain, after carrying out elementary integration,

$$w_{\rm J} = \frac{\hbar}{2e} j_{\rm c} (1 - \cos\varphi) \tag{4.32}$$

One notices that the Josephson junction plays the role of a nonlinear inductance which stores the energy. In addition to this energy, there is also a magnetic energy, which, per unit area of the junction, is given by

$$w_H = \frac{H^2}{8\pi} d \tag{4.33}$$

Taking the sum of (4.32) and (4.33) and carrying out integration over the length of the junction L (see Fig. 4.8), we obtain the total free energy of the junction, per unit length along the direction of the magnetic field (i.e., the z direction):

$$W = \int_0^L {\rm d}x \left[\frac{H^2}{8\pi} d + \frac{\hbar}{2e} j_{\rm c} (1 - \cos\varphi) \right]$$

Substituting (4.26) into this equation, we can modify the expression for W to

$$W = \int_0^L {\rm d}x \left[\frac{\Phi_0^2}{32\pi^3 d} \left(\frac{{\rm d}\varphi}{{\rm d}x} \right)^2 + \frac{\hbar}{2e} j_{\rm c} (1 - \cos\varphi) \right] \tag{4.34}$$

Using the variational method to minimize W, we arrive once again at the Ferrell-Prange equation (4.27).

From (4.34), one can easily derive the free energy W_0 of an individual Josephson vortex in an infinite junction. To do so, the expression for $\varphi_0(x)$ (4.30) should be substituted into (4.34) and the integration carried out. As a result we get

$$W_0 = \frac{4\Phi_0 j_c}{\pi c}\lambda_J \tag{4.35}$$

If the junction is placed in an external magnetic field H_0, the Gibbs free energy of a Josephson vortex becomes, by (1.22),

$$\mathcal{G}_0 = W_0 - \Phi_0 H_0/4\pi \tag{4.36}$$

Thus, if the external field is sufficiently weak, the energy is $\mathcal{G}_0 > 0$ and the existence of a Josephson vortex in the interior of the junction is energetically unfavorable. Penetration of a vortex into the junction becomes favorable beginning at a certain value of the external field H_0 which corresponds to $\mathcal{G} = 0$. This field is called the lower critical field H_{c1}:

(???? this is not the lower cr field in type 2 SC, right???)

$$H_{c1} = \frac{2}{\pi^2}\frac{\Phi_0}{\lambda_J d} \tag{4.37}$$

The field H_{c1} is obviously less than the field at the center of the vortex, $H(0)$. The latter, from (4.30) and (4.26), is

$$H(0) = \frac{\Phi_0}{\pi\lambda_J d} \tag{4.38}$$

The field $H(0)$ is effectively the superheating field for the Meissner state of the junction.

4.4.3 Maximum Zero-Voltage Current of a Josephson Junction. High Magnetic Fields

Let us turn to high magnetic fields:

$$H_0 \gg \frac{\Phi_0}{2\pi\lambda_J d} \tag{4.39}$$

We assume that the size of the junction is $L \ll 2\lambda_J$. Thus we can ignore the self-induced field due to the current passing through the junction, because it is much less than H_0. The inequality (4.39) can be interpreted as a condition on the distance between the neighboring Josephson vortices in the chain: their distance must be much less than λ_J. Then it follows from (4.26) that

$$\frac{\mathrm{d}\varphi}{\mathrm{d}x} = \frac{2\pi d}{\Phi_0}H_0$$

and, carrying out integration, we get

$$\varphi(x) = \frac{2\pi d}{\Phi_0}H_0 x + C \tag{4.40}$$

where C is an arbitrary integration constant. Substituting (4.40) into the first Josephson relation (4.13) we obtain

$$j_s = j_c \sin\left(\frac{2\pi x}{a} + C\right) \tag{4.41}$$

where we use the notation

$$a = \Phi_0/H_0 d \tag{4.42}$$

It follows from (4.41) that the chain of Josephson vortices in this limit is indeed very dense. It is sketched in Fig. 4.11, together with the corresponding distribution of the tunneling supercurrent.

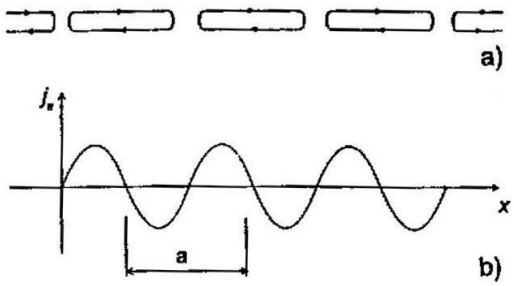

Fig. 4.11. (a) Densely packed chain of vortices representing the mixed state in a tunnel Josephson junction; (b) corresponding distribution of the tunneling supercurrent through the junction

The total current through the junction can be found by integration of j_s in (4.41) over the entire length of the junction:

$$I_{\mathrm{B}} = j_{\mathrm{c}} \int_{-L/2}^{L/2} \sin(2\pi x/a + C)\mathrm{d}x.$$

As a result we have:

$$I_{\mathrm{s}} = j_{\mathrm{c}} L \frac{\sin(\pi L/a)}{\pi L/a} \sin C \tag{4.43}$$

It follows from (4.43) that, in a fixed magnetic field, a change of the total current through the junction, I_s (which is supplied by an external source) causes a subsequent change of the constant C. The latter adjusts itself to each value of I_s. Then the maximum total current, $I_{\max}$, which can pass through the junction without dissipation is simply the amplitude of the quantity written in (4.43) before $\sin C$:

$$I_{\max} = I_{\mathrm{c}} \left| \frac{\sin(\pi L/a)}{\pi L/a} \right| \tag{4.44}$$

$$I_{\mathrm{c}} = j_{\mathrm{c}} L$$

The expression for $I_{\max}$, equation (4.44), can be written in a more convenient form if we note that, according to (4.42),

$$\pi L/a = \pi \Phi/\Phi_0 \tag{4.45}$$

where Φ is the total magnetic flux through the Josephson junction:

$$\Phi = H_0 L d.$$

On substitution of (4.45) into (4.44), we obtain the final result:

$$I_{\max} = I_{\mathrm{c}} \left| \frac{\sin\left(\pi\Phi \frac{\Phi/\Phi_0)}{\pi\Phi}\right.}{\pi/\Phi_0} \right|. \tag{4.46}$$

The dependence of $I_{\max}$ on the external magnetic field $H_0 = \Phi/(Ld)$ is shown in Fig. 4.12.

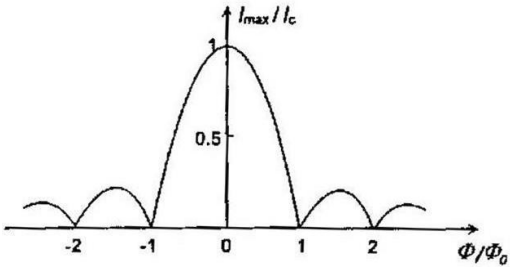

Fig. 4.12. Maximum supercurrent through a Josephson junction versus the external magnetic field parallel to the plane of the junction

As one can conclude from the plot and from (4.46), the mixed state in the junction is absolutely unstable (that is, a negligibly small current suffices to destroy it) when the total magnetic flux Φ is equal to an integral number of Φ_0. In contrast, it is most stable whenever there are a half-integral number of flux quanta enclosed in the junction. Experiment [40] has given a spectacular verification of (4.46), as one can see from Fig. 4.13.

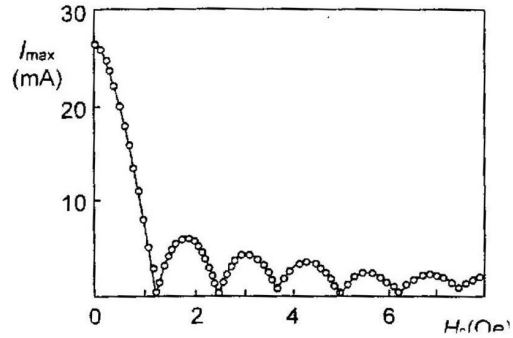

Fig. 4.13. Experimentally observed dependence of the maximum supercurrent through a $Sn - SnO_x$-Sn junction on magnetic field [40]

9.2.8 SQUIDs (Superconducting Quantum Interferometers): Basic Concepts

This section is concerned with the basic principles underlying the devices known as superconducting quantum interference devices (SQUIDs). These devices, though very simple in design, have opened new horizons in lowtemperature measurement techniques. Many SQUID-based instruments are unique in their sensitivity. The most celebrated examples are SQUID magnetometers, which are able to resolve flux increments of $\sim 10^{-10}$G, and precision voltmeters with the sensitivity of $\sim 10^{-15}$ V.

So, what is SQUID? There are two basic types of SQUIDs to distinguish: a two-junction dc SQUID and a single-junction rf SQUID.

4.5.1 The Two-Junction SQUID (DC SQUID)

This device consists of two Josephson junctions connected in parallel. In practice, the circuit consists of two bulk superconductors which, together with the Josephson junctions a and b, form a ring as in Fig. 4.14. The flux through the loop of the SQUID is generated by a magnetic coil placed in the interior of the ring. To understand how this type of SQUID operates, we need to know how the maximum zero-voltage current $I_{\max}$ through the device depends on the total magnetic flux Φ enclosed in the SQUID loop.

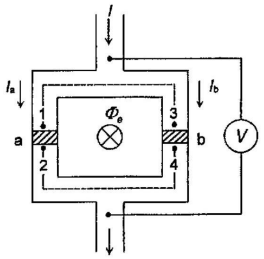

Fig. 4.14. Superconducting interferometer: two Josephson junctions, a and b, are connected in parallel. The interior of the SQUID loop is threaded by a magnetic flux Φ

Consider two pairs of points in the interiors of the superconductors: (1,2) and (3.) all of which are rigse to the iunctions a and h as illustrated in

Fig. 4.14. Carrying out integration of (4.22) along the dashed contour from point 1 to point 3 and from point 4 to point 2, we obtain [5]

$$\theta_3 - \theta_1 + \theta_2 - \theta_4 = \frac{2e}{\hbar}\left(\int_1^3 \boldsymbol{A}\cdot\ \mathrm{d}\boldsymbol{l} + \int_4^2 \boldsymbol{A}\cdot\ \mathrm{d}\boldsymbol{l}\right) \tag{4.47}$$

The term $2mv_\mathrm{s}$ has been omitted because the contour passes everywhere through the interior of the superconductor, well away from the edges. There is no supercurrent there and $v_\mathrm{s} = 0$. The distance between points 1 and 2, as well as between 3 and 4, is small compared to the length of the dashed contour. In addition, the vector potential $\boldsymbol{A}$ does not have any special features near the junctions. Therefore, the right-hand side of (4.47) can be supplemented by an integral along the sections $3-4$ and 1-2. As a result we get

$$\varphi_\mathrm{a} - \varphi_\mathrm{b} = \frac{2e}{\hbar}\oint A\cdot\ \mathrm{d}l$$

or

$$\varphi_\mathrm{a} - \varphi_\mathrm{b} = 2\pi\Phi/\Phi_0 \tag{4.48}$$

where Φ is the total magnetic flux enclosed in the loop of the interferometer, $\varphi_\mathrm{a} = \theta_2 - \theta_1, \varphi_\mathrm{b} = \theta_4 - \theta_3$, and $\Phi_0 = \pi\hbar c/e$ is the magnetic flux quantum.

The current through the junction a is, from (4.1),

$$I_\mathrm{a} = I_\mathrm{c}\sin\varphi_\mathrm{a},$$

and through the junction b,

$$I_\mathrm{b} = I_c\sin\varphi_\mathrm{b}$$

(the junctions are assumed to be identical and characterized by the same value of the critical current, I_c). The total current through the interferometer is then the sum of I_a and I_b:

$$I = I_\mathrm{c}\left(\sin\varphi_\mathrm{a} + \sin\varphi_\mathrm{b}\right) \tag{4.49}$$

Noting that $\sin\varphi_\mathrm{a} + \sin\varphi_\mathrm{b} = 2\sin\left[\left(\varphi_\mathrm{a} + \varphi_\mathrm{b}\right)/2\right]\cos\left[\left(\varphi_\mathrm{a} - \varphi_\mathrm{b}\right)/2\right]$ and using (4.48), we can modify (4.49) to the form

$$I = 2I_\mathrm{c}\cos\frac{\pi\Phi}{\Phi_0}\sin\left(\varphi_\mathrm{b} + \frac{\pi\Phi}{\Phi_0}\right). \tag{4.50}$$

If the total flux enclosed in the loop of the SQUID is fixed, the only parameter which adjusts itself to a given total current I is, from (4.50), φ_b. It follows (just as in the preceding section when (4.44) was being derived) that the maximum dissipation-free current of the device is

$$I_{\max} = 2I_c \left|\cos\left(\pi\Phi/\Phi_0\right)\right| \tag{4.51}$$

The dependence of $I_{\max}$ on Φ is illustrated in Fig. 4.15. The superconducting state of the ring is most stable with respect to the external current I when an

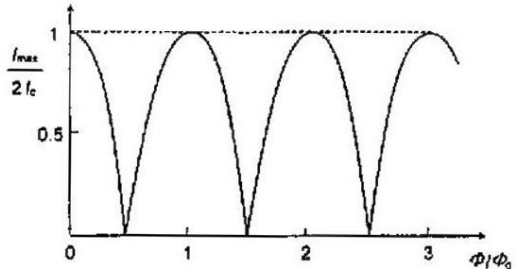

Fig. 4.15. Dependence of the maximum supercurrent through the two-junction interferometer on the total magnetic flux through its interior

integral number of flux quanta are enclosed in the interferometer. In contrast, a half-integral number of flux quanta in the loop corresponds to an unstable superconducting state. That is to say, a negligibly small current I suffices in the latter case to drive the device to the resistive state, with a finite voltage across the junction (see Fig. 4.14).

We would like to emphasize that Φ is the total flux through the loop of the interferometer. The flux supplied externally by the magnetic coil, Φ_e, is related to Φ by

$$\Phi = \Phi_{\mathrm{e}} - LI_{\mathrm{sc}},$$

where L is the inductance of the interferometer and I_{BC} is the screening current circulating in it. The critical current of the SQUID is periodic in Φ_e, too, with period Φ_0. This dependence is illustrated in Fig. 4.16.

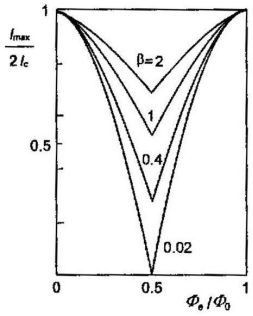

Fig. 4.16. Critical current of the two-junction SQUID versus external magnetic flux, for several values of the parameter $\beta = 2LI_{\mathrm{c}}/\Phi_0$[41]

A detailed analysis of the two-junction SQUID operation is given by Clarke in [41].

The unique sensitivity of dc SQUIDs can be employed in many situations where a variation of the quantity of interest can be converted into a variation of magnetic flux. The only limit on it is set by thermal noise in Josephson junctions which is estimated as several units per $10^{-5}\Phi_0$, provided the time of the measurements is longer than 1 s . Therefore, in principle, it is possible to resolve increments of magnetic field of the order of $10^{-10} - 10^{-11}$G. For comparison, the Earth's magnetic field is about 0.5 G .

After the discovery of high- T_{c} superconductors, SQUIDs made of these materials were shown to operate well at the temperature of liquid nitrogen (77 K). Since this temperature range is much easier to attain than liquid helium temperature (4.2 K), the high- T_{c} SQUIDs have the potential to fill a broad range of applications. These include biomagnetic measurements, nondestructive evaluation, and geomagnetic probing. The present status of highT_{c} SQUIDs is described in a recent review [42].

4.5.2 The Single-Junction SQUID (RF SQUID)

The basic element of a single-junction SQUID is a superconducting ring containing a Josephson junction. Consider two points, 1 and 2, in the vicinity of the junction, as shown in Fig. 4.17. The dashed contour 1-2 passes through the interior of the superconductor in such a way that its distance from the edges is everywhere larger than λ. Therefore, there is no supercurrent at any point of the contour and $v_6 = 0$.

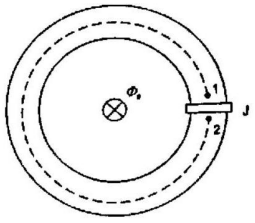

Fig. 4.17. Single-junction SQUID: a single junction J closes a superconducting ring. An external flux Φ_e is generated by a magnetic coil inserted in the ring

Let us go back to the general equation (4.22) and integrate along the dashed contour from point 1 to point 2 . Taking into account that $v_s = 0$, we have

$$\hbar\,(\theta_2 - \theta_1) = 2e \int_1^2 \boldsymbol{A} \cdot \, \mathrm{d}\boldsymbol{l} \tag{4.52}$$

The distance between points 1 and 2 across the junction is much shorter than their distance along the dashed contour, and the vector potential does not have peculiarities in the vicinity of the junction. Therefore, the variation of the right-hand side of (4.52) will be negligible if we supplement it with an integral $\int_2^1 \boldsymbol{A} \cdot \, \mathrm{d}l$ across the junction. Then (4.52) can be rewritten as

$$\sin = 2\rho \oint A \cdot \, \mathrm{d}I \tag{4.53}$$

where φ is the phase difference across the junction J. Equation (4.53) can be further reduced to

$$\varphi = 2\pi\Phi/\Phi_0, \tag{4.54}$$

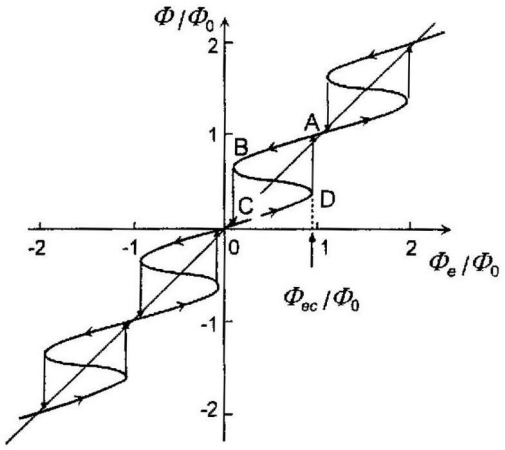
where Φ is the total magnetic flux enclosed in the SQUID loop. In general, this flux Φ is not equal to the externally supplied flux Φ_e. Their difference is due to the screening current circulating in the superconducting ring:

$$\Phi = \Phi_e - LI_{sc}, \tag{4.55}$$

where L is the inductance of the ring. Since the current I_{sc} passes through both the ring and the junction, its relation to the phase difference of the superconducting electron wavefunction is given by the well-known expression (4.1). Together with (4.54) and (4.55), this yields

$$\Phi_e = \Phi + LI_c \sin\,(2\pi\Phi/\Phi_0) \tag{4.56}$$

This formula can be considered as an implicit relation between Φ and Φ_e. It is illustrated graphically in Fig. 4.18.



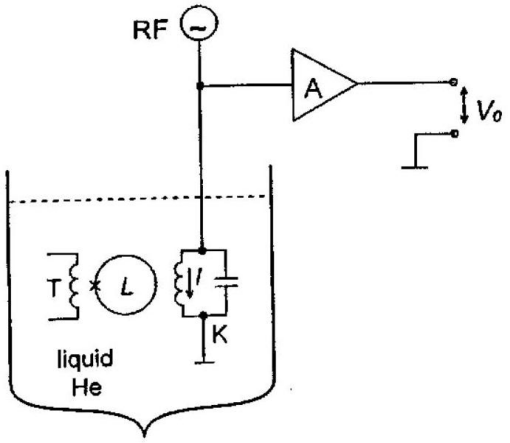


Fig. 4.18. Total magnetic flux Φ enclosed in the loop of a single-junction interferometer versus the external flux Φ_e through the loop

Let us now analyze the physics of SQUID operation. First we increase the external flux Φ_e (that is, we increase the current through the magnetic coil inserted in the SQUID loop). As an immediate response, a screening current I_{sc} starts to flow in the ring and generates its own magnetic flux which partially cancels the external flux Φ_e. Therefore, the total flux is less than Φ_e. Why is the cancellation only partial? If the ring were solid, without the weak link, the cancellation would be complete and the total flux would be $\Phi = 0$.

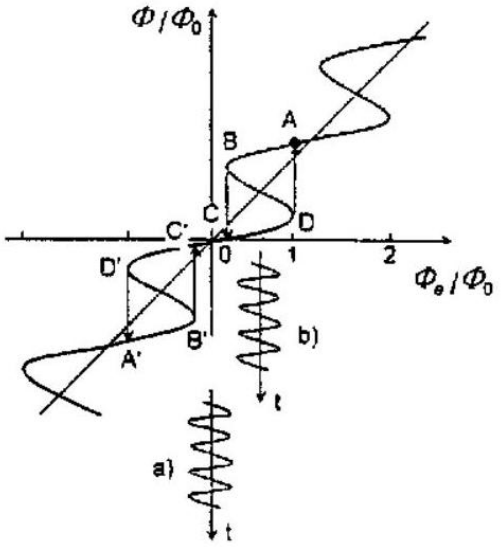
Fig, 4.19. Block-diagram of an rf SQUID. RF is a high-frequency current supply (of large internal resistance), A a high-frequency amplifier, L a single-junction interferometer, T a secondary coil of a flux transformer, and K a highfrequency resonant circuit

This situation can also be described in a different way. In order to supply the external flux Φ_e, it is not always necessary to place a magnetic coil in the loop of the device; it is merely convenient in practice. Alternatively, the loop can be placed in a homogeneous external field. Then Φ_e is simply the product of the induction of the external field and the area of the loop (here we assume that the plane of the loop is perpendicular to the external magnetic field). Then it is easy to see that, if the superconducting ring were solid, that is, without a weak link, the total flux Φ through it would be zero. On the other hand, when the weak link is present, it can be identified with a region where the external magnetic field can penetrate into the ring's interior. As a result, the screening is not perfect.

As the external flux Φ_e is increased further, the screening current increases, too, until it reaches its critical value at $\Phi_e = \Phi_{ec}$, as illustrated in Fig. 4.18. At this moment (point D in Fig. 4.18) the system becomes unstable and jumps to the next quantum state (point A in Fig. 4.18). As a result, the total magnetic flux through the loop exceeds the external flux and the screening current changes its direction. However, as the external flux continues to increase and at some moment reaches the value of the flux quantum Φ_0, the total flux also becomes equal

to Φ_0 and the screening current vanishes, which is effectively equivalent to $\Phi_e = 0$ (see Fig. 4.18). With further increase of Φ_e, this switching process repeats itself with period Φ_0. If Φ_e is decreased, the jumps will start from points analogous to point B. Thus, a cyclic variation of the external flux Φ_e is accompanied by a hysteresis loop CDABC. The area of the loop is proportional to the energy dissipated in the junction.

Now our knowledge of the properties of a superconducting ring with a single Josephson junction is sufficient to understand how the rf SQUID operates. Its block-diagram is shown in Fig. 4.19. A current of frequency ν is supplied by a high-impedance ac current source to the resonant circuit K .
(Frequencies $\nu \approx 10 - 20$MHz are used most often. However, there are also SQUIDs operating at higher frequencies such as several GHz). The coil of the resonant circuit is coupled to the loop of the interferometer I. The rf voltage across the circuit K is amplified by the amplifier A . This voltage, V_0, is the output of the device. The device input is the coil T inductively coupled to the SQUID loop L.



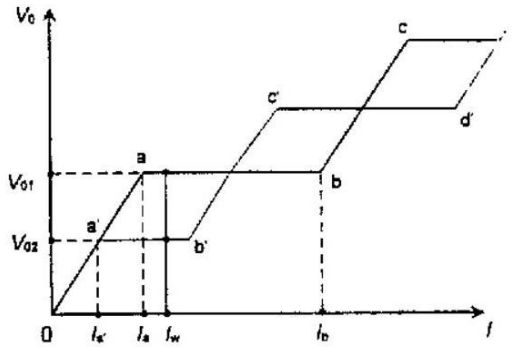


Fig. 4.20. Variation of the external flux with time: (a) when zero flux is generated by the input coil T ($\Phi_T = 0$); (b) when $\Phi_T = \Phi_0/2$

Now let us work out how the output V_0 relates to the value of the current I through the resonant circuit K. Assume that the current through the input coil T is zero. Then the external flux Φ_e is generated entirely by the circuit K and has the frequency ν, as in Fig. 4.20 (a). In turn, the sinusoidal variation of Φ_e causes a sinusoidal variation of the total flux Φ (see Fig. 4.20) resulting in an rf voltage V_0 at the output. An increase of the bias current I causes a proportional increase of the amplitude of Φ_e and, as a consequence, of Φ and V_0. Thus the dependence of V_0 on I is linear (at the initial part 0a of the rf current-voltage characteristic in Fig. 4.21) until the current reaches a value such that $\Phi_e = \Phi_{ec}$ (see Fig. 4.18). At this moment, a discontinuous jump of the total flux occurs, corresponding to closing a hysteresis loop on the $\Phi(\Phi_e)$ curve, and an amount of heat proportional to the area of the loop is

Fig. 4.21. RF current-voltage characteristic of the SQUID; bold line (Oabc...) corresponds to the input flux $\Phi_T = 0$, thin line (0a′b′c′d′ . . .) - to $\Phi_T = \Phi_0/2$

dissipated. The necessary amount of energy, which is quite large, is borrowed from the resonant circuit K . As a result, the amplitude of the current I sharply decreases and it takes a long time (a large number of rf oscillation periods) for the current to recover its initial value. A further increase of the amplitude of current supplied by the generator will not result in an increase of the output voltage V_0 because the above process will repeat itself again and again. The only difference will be that the time required for the current I to recover will steadily decrease, that is, a smaller number of rf periods will be needed. This means that we arrive at the horizontal part ab of the current-voltage characteristic in Fig. 4.21. Finally, at a certain value of the bias current, the current I will reach a value (I_b) such that the time of one period will be sufficient for the rf current supply to replenish the energy of the circuit K that has been absorbed by the interferometer during two hysteresis cycles DABC and D′A′B′C′ shown in Fig. 4.20. At $I > I_\mathrm{b}$, the total magnetic flux Φ and the output voltage V_0 will start to increase again and their increase will continue until Φ_e reaches the second critical value. At that point, hysteretic energy losses will occur again and the whole process will repeat itself resulting in the second plateau on the current-voltage characteristic.

Let us now turn to the case when there is a finite current through the input coil T generating a dc flux $\Phi_T = \Phi_0/2$. The time dependence of Φ_e in this case is illustrated in Fig. 4.20 (b). Clearly, the critical value Φ_{ec} is now reached at a significantly smaller current $I_{a'} < I_a$ through the resonant circuit. In addition, the length of the first plateau is only half as long because the current supply now has to compensate for the energy loss during just one hysteresis cycle. However, all subsequent plateaus on the current-voltage characteristic are of normal length again, since the energy to be recovered is dissipated during pairs of hysteresis cycles.

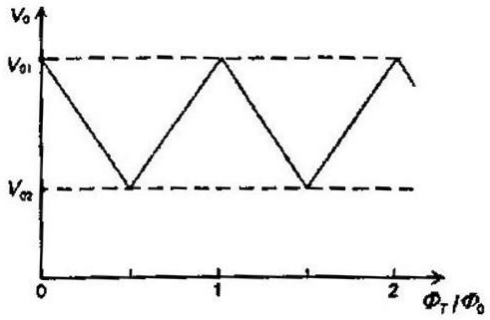

Fig. 4.22. Dependence of the output rf voltage V_0 on the external flux Φ_T generated by the input coil T

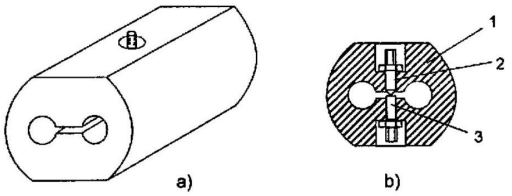
As the final stage of our analysis of SQUID operation, let us supply the device with some bias ac current I_w, as in Fig. 4.21. If $\Phi_T = 0$, the output voltage will be V_{01}; if $\Phi_T = \Phi_0/2$, the output voltage will be V_{02}. The question is: how will the voltage V_0 change if we increase the input flux Φ_T from 0 to $\Phi_0/2$? Obviously, it will gradually decrease from V_{01} to V_{02}. However, if $\Phi_T = \Phi_0$, the situation is analogous to the case $\Phi_T = 0$, as one can see

so-called 'triangular' dependence of the output voltage V_0 on the input flux (Fig. 4.22). It follows from this figure that the device is sensitive to variations of the magnetic flux Φ_T, with sensitivity much better than one flux quantum. Theoretical analysis of the sensitivity of rf SQUIDs has demonstrated that devices with sensitivity of the order of $10^{-5}\Phi_0$ are feasible, provided the measuring time is not less than 1 s .



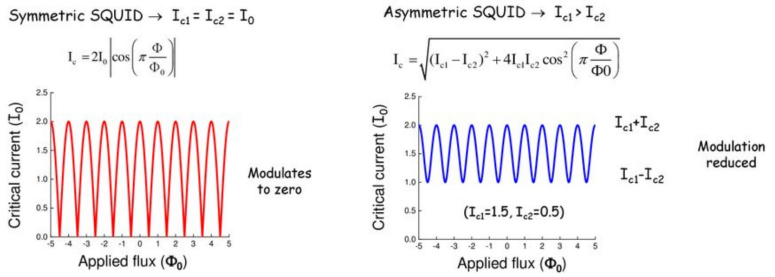


Fig. 4.23. Single-contact SQUID proposed by Zimmerman: (a) general view; (b) cross-section along the central plane: 1 - solid niobium frame, 2 - pointed niobium screw, 3 - flat niobium screw

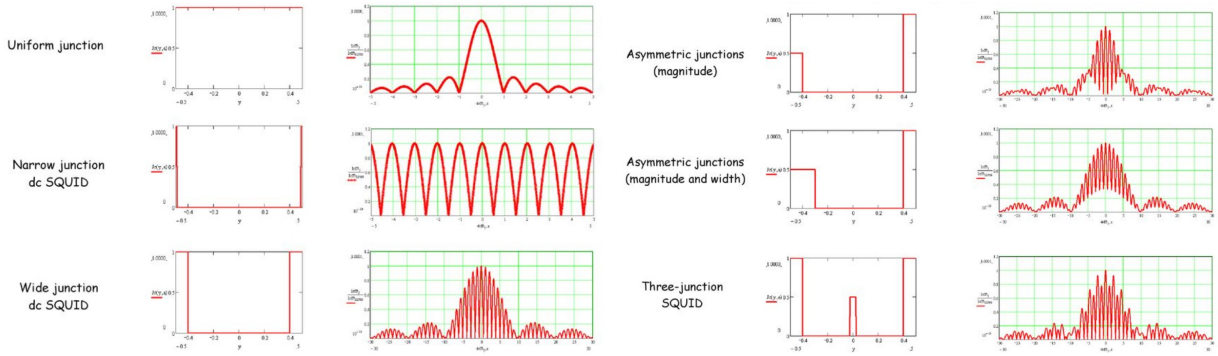

A classic bulk SQUID design which has proved to be very useful in practice is the symmetric single-weak-link device proposed by Zimmerman (Fig. 4.23). Here the Josephson junction is implemented as a point contact. The input coil T and the coil of the resonant circuit K (see Fig. 4.19) are inserted in the two holes of the device. Nowadays, the best low- and high- T_c SQUIDs are made using the planar multilayer thin film technology [42].

9.2.10 46. Tunneling Effects by Shmidt

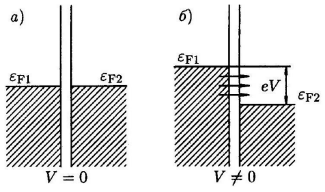
Наиболее прямое измерение энергетической щели в сверхпронодниках может быть проведено с помощью туннельных экспериментов. Эту методику разработал Гевер в 1960 г. [133]. В принцине она очень проста (рис. 46.1). На стеклянную пластинку с заранее подготовленными контактами наносится узкая полоска пленки первого металла. Затем эта полоска окисляется так, чтобы пленка оказалась покрытой слоем изолирующего окисла толщиной в несколько десятков ангстрем (барьерный слой). После этого в поперечном направлении наносится узкая полоска пленки второго металла. Место пересечения этих двух полосок (площадью порядка 1m^2) и представляет собой туннельный переход. Исследование заключается в изучении вольт-амперной характеристики такого перехода. Физика дела заключается в том, что здесь испольэуется специфическое квантовомеханическое свойство электрона проходить тонкие потенциальные барьеры (в данном случае - слой окисла) посредством так называемого туннельного перехода.

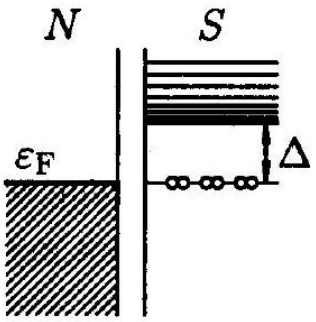
46.1. Туннельные характеристики.

Обсудим теперь, какой вид будут иметь вольт-амперные характеристики для разных случаев туннельных переходов.

Простейший случай - когда и первый, и второй металлы нормальные металлы. При установлении контакта между металлами их уровни Ферми уравниваются за счет возникновения контактной разности потенциалов. Энергетическая диаграмма изображена на рис. 46.2, а. Если теперь на туннельный переход подать разность потенциалов V (рис. 46.2, б), то уровни Ферми металлов разойдутся на величину eV, и возникнет туннельный ток. Если предположить, что плотность состояний в интересующей нас области энергий остается постоянной ($N(0)$), то из рис. 46.2, б ясно, что сила тока будет пропорциональна eV, т. е. будет выполняться закон Ома.

Рассмотрим теперь случай, когда первый металл - нормальный, а второй - сверхпроводник. Мы уже знаем, какой вид имеет спектр элементарных возбуждений сверхпроводника (рис. 45.1 и 45.2). Энергия элементарных возбуждений отсчитывается от уровня основного состояния сверхпроводника. В нормальном металле энергия элементарного возбуждения отсчитывается от уровня Ферми. Поэтому при создании туннельного контакта между нормальным металлом и сверхпроводником за счет контактной разности потенциалов должны уравняться уровень Ферми нормального металла и уровень основного состояния сверхпроводника. Именно это состояние изображено на рис. 46.3, *а*.





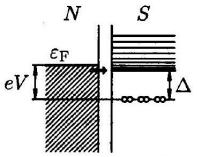


Рис. 46.2. Энергетическая диаграмма для случая контакта двух нормальных металлов: $a)V = 0$; б) $V \neq 0$, идет туннельный ток, пропорциональный eV.

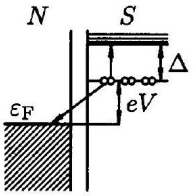
Рассмотрим сперва случай, когда $T = 0$.



Приложим к туннельному переходу некоторую разность потенциалов V. Пусть в результате этого уровень Ферми нормального металла поднялся над уровнем основного состояния сверхцроводника на величину eV. Из рис. 46.3, б ясно, что туннельный ток электронов из N в S может начаться только тогда, ко'да величина eV станет равной энергетической щели Δ в S или «ревзойдет ее. Тот же результат получится, если поменять по лярность приложенного к переходу напряжения. Теперь туннелирование электрона из S в N будет происходить тогда, когда окажется энергетически допустимым разрыв электронной пары в S, т. е. когда энергия, выделившаяся при туннелировании одного электрона пары, окажется достаточной, чтобы закинуть второй электрон этой пары в область разрешенных энергий для одиночных электронов, т.е. выше щели (см. рис. 46.3, в).

Рис. 46.3. Энергетическал диаграмма для туннельного NS-перехода: а) $V = 0$, уровень ε_F противостоит уровню основного состояния сверхпроводника; б) $V \neq 0, |eV| > \Delta$, идет туннельный ток электронов из N в S; в $)V \neq 0, |eV| > \Delta$, идет туннельный ток электронов из S в N.

Таким образом, вольт-амперная характеристика такого туннельного перехода будет нечетной функцией V. Она изображена на рис. 46.4.

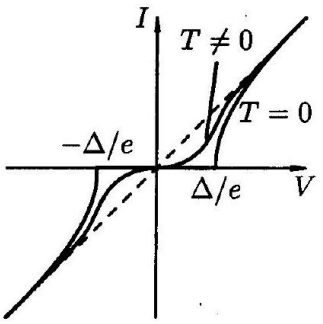

Рис. 46.4. Вольт-амперная характеристика туннельного NIS-перехода.

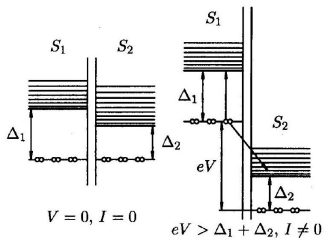
В случае, если $T \neq 0$, как нетрудно сообразить, вольт-амперная характеристика будет несколько размазанной.

Переходим к рассмотрению туннельных эффектов в S_1IS_2 переходах, когда оба металла (S_1 и S_2), разделенные туннельным слоем изолятора (I), являются сверхпроводниками.

Сперва рассмотрим случай $T = 0$. Согласно рис. 46.5, туннельный ток может возникнуть только тогда, когда к туннельному переходу будет приложено напряжение $V > (\Delta_1 + \Delta_2)/e$. Действительно, только в этом случае возможен процесс, изображенный на этом рисунке: электронная пара в S_1 разрывается, один из электронов этой пары туннелирует в S_2 с выделением энергии, равной или большей, чем Δ_1. При этом второй электрон разорванной пары, поглощая эту энергию, возбуждается в состояния спектра квазичастиц S_1.



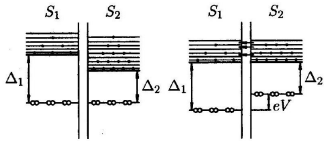


Рис. 46.5. Энергетические диаграммы для туннельного перехода S_1IS_2, $T = 0$.

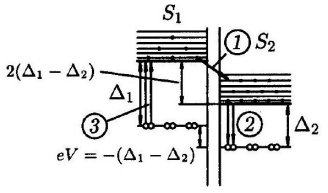
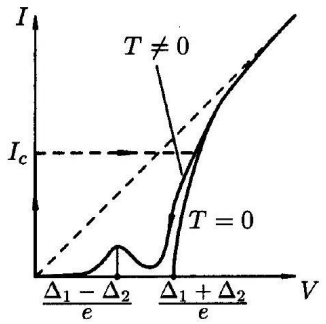


Для реального случая, когда $T \neq 0$, картина будет несколько более сложной. Теперь в каждом из сверхпроводников имеется какое-то количество возбужденных одиночных электронов, равновесное количество которых определяется температурой.

Энергетические диаграммы туннельного перехода в этом 'лучае изображены на рис.46.6. Количество возбуждений в данний области спектра схематично изображается количеством то'лек на данном энергетическом уровне. Видно, что если $V = 0$

а)

б)



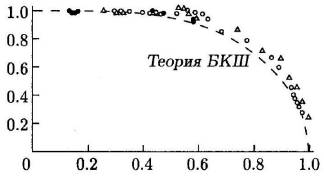
в)

Рис. 46.6. Туннелирование между двумя сверхпроводниками при $T \neq 0$: а) $V = 0$, концентрация возбуждений с одинаковой энергией в S_1 и S_2 одинакова, поэтому ток равен нулю; б) $eV = \Delta_1 - \Delta_2$, ток обусловлен переходом возбужденных частиц из S_2 в S_1; в) $eV = -(\Delta_1 - \Delta_2)$, возбужденная частица переходит из S_1 в S_2, (процесс 1), объединившись с электронами в S_2, она образует пару и попадает на основной уровень (процесс 2), выделившейся энергии $2\Delta_1$ достаточно для разрыва пары в S_1 (процесс 3).

(рис. 46.6, a), то несмотря на то, что щели в S_1 и S_2 разные, количество возбуждений на противостоящих друг другу уровнях в S_1 и S_2 будет одинаково. Поэтому количество частиц, туннелирующих из S_1 в S_2, будет равно тому же числу частиц, туннелирующих из S_2 в S_1, т.е. как это и должно быть, в равновесных условиях полный туннельный ток $I = 0$.

Если теперь приложить даже небольшое напряжение V, то равновесие нарушится и возникнет ток квазичастиц из одного сверхпроводника в другой. Не будем, однако, забывать, что плотность состоянии квазичастиц в сверхпроводнике имеет особен-

Рис. 46.7. Сверхпроводящие и квазичастичные ветви вольтамперных характеристик туннельного S_1IS_2-перехода для $T = 0$ и $T \neq 0$.



ность при $E = \Delta$ (см. (45.5) и рис. 45.2). Поэтому если приложить к переходу разность потенциалов V такую, что $eV = \Delta_1 - \Delta_2$ (рис. 46.6,), то друг против друга окажутся области с. плотностью состояний $\rho = \infty$ и в S_1, и в S_2. Естественно, это зызовет большой всплеск туннельного тока. Дальнейшее увеличение V приведет к тому, что уровни с $\rho = \infty$ разойдутся и полный туннельный ток уменьшится. Отсюда можно сделать вывод, что при $V = (\Delta_1 - \Delta_2)/e$ на вольт-амперной характеристике должен наблюдаться максимум тока (рис. 46.7). При изменении знака V возникнет диаграмма, изображенная на рис. 46.6, в. Здесь тоже возникнет всплеск тока при $|V| = (\Delta_1 - \Delta_2)/$. Таким образом, и в случае контакта двух сверхпроводников вольт-амперная характеристика будет нечетной функцией напряжения V.

В заключение приведем результат туннельного эксперимента Гевера и Мегерле [134] по изучению величины энергетической цели в различных сверхпроводниках и ее зависимости от температуры (рис. 46.8). Штриховой линией показана зависимость, 'ледующая из теории Бардина-Купера-Шриффера.

46.2*. Энергия связи SIS-перехода и температурная зависимость критического тока.

Прежде чем приступить к исследованию SIS-перехода мы приведем вычисление проводимости туннельного перехода в нормальном состоянии. Это окажется полезно для дальнейшего, т.к. мы будем сейчас использовать в более простой ситуации тот же самый метод "туннельного$\Delta(T)/\Delta(0)$

T/T_c

Рис. 46.8. Экспериментальные результаты изучения температурной зависимости энергетической щели в индии (светлые кружки), олове (треугольники) и свинце (черные кружки). Штриховая линия - зависимость $\Delta(T)$ согласно теории БКШ.

гамильтониана", который нам понадобится для решения основной задачи. Рассмотрим два куска нормального металла, разделенных потенциальным барьером из изолятора. Электрон с импульсом $\hbar\mathbf{k}$ в 1 -м куске металла, подлетающий к барьеру, может протуннелировать под барьером и оказаться во 2 -м куске уже с импульсом $\hbar\mathbf{q}$. Заметим, что как правило $\mathbf{q} \neq \mathbf{k}$, поскольку туннельный барьер вовсе не обязан быть однородным. Квантовомеханическую амплитуду этого процесса мы обозначим через $t_{\mathbf{k},\mathbf{q}}$. Будем теперь считать, что к 1-му куску металла приложено напряжение V относительно 2-го, и вычислим вероятность перехода электрона в единицу времени из любого занятого состояния 1 -го металла в любое свободное состояние 2-го. Для этого мы используем "золотое правило Ферми» для вероятности переходов (в единицу времени) в непрерывном спектре [49]:

$$\Gamma^{\rightarrow}(V) = \frac{2\pi}{\hbar}\frac{1}{\mathcal{V}_1\mathcal{V}_2}\sum_{\mathbf{k},\mathbf{q},\sigma}\left|t_{\mathbf{k},\mathbf{q}}\right|^2\delta\left(\varepsilon_k - \varepsilon_q - eV\right)f\left(\varepsilon_k\right)\left(1 - f\left(\varepsilon_q\right)\right) \tag{46.1}$$

где $\mathcal{V}_{1,2}$-объемы двух металлов, $f(\varepsilon) = \left(e^{\varepsilon/k_{\mathrm{B}}T} + 1\right)^{-1}$ - фермиевская функция заполнения для электрона с энергией ε, а σ проекция электронного спина (подразумевается, что переворота спина при туннелировании не происходит). Переходя от суммирования по импульсам к интегрированию по энергиям электрона в начальном и конечном состояниях и считая туннельные матричные элементы и плотности состояний $N_{1,2}(\varepsilon)$ металлов не зависящими от энергии вблизи ферми-поверхности, получим (суммирование по спину дает лишнюю двойку):

$$\Gamma^{\rightarrow}(V) = \frac{4\pi}{\hbar}N_1(0)N_2(0)\left\langle\left|t_{\mathbf{k},\mathbf{q}}\right|^2\right\rangle\int d\varepsilon f(\varepsilon)(1 - f(\varepsilon + eV)), \tag{46.2}$$

где $\left\langle\left|t_{\mathbf{k},\mathbf{q}}\right|^2\right\rangle$ - усредненные по Ферми-поверхности матричные элементы. Для вычисления среднего тока при $T > 0$ надо также написать аналогичное выражение для вероятности перехода $\Gamma^{\leftarrow}(V)$ в обратную сторону, однако в уже сделанном приближении $N(\varepsilon) = N(0)$ результат для туннельной проводимости от гемпературы не зависит, так что можно ограничиться вычислением интеграла (46.2) при $T = 0$, дающего $I(V) = e\Gamma^{\rightarrow}(V)$. В результате

$$\frac{I(V)}{V} = \frac{1}{R_n} = \frac{4\pi e^2}{\hbar}N_1(0)N_2(0)\left\langle\left|t_{\mathbf{k},\mathbf{q}}\right|^2\right\rangle \tag{46.3}$$

ЗЗаметим, что мы определили плотности состояний $N(\varepsilon)$ в расчете на одну проекцию спина.

Вернемся к сверхпроводящему туннельному S_1IS_2-контакту и нокажем, что энергетические щели сверхпроводников и значение нормального сопротивления R_n определяют не только поведение квазичастичной (возвратной) ветви вольтамперной характеристики, но и величину ее прямой ветви, т. е. величину критического

сверхпроводящего тока I_c (рис. 46.7). Для этого рассмотрим детально процесс парного туннелирования в S_1IS_2-переходе.

Наличие туннельного взаимодействия между сверхпроводниками S_1 и S_2 приводит к тому, что полная энергия системы оказывается меньше суммы энергий отдельных сверхпроводников на величину энергии связи $E_{\text{св}}$. Мы подробно обсудим вычисление этой величины при $T = 0$. Как и ранее, туннельный барьер можно
рассматривать как источник упругого рассеяния, который переводит электрон из состояния с импульсом $\mathbf{k}$ в сверхпроводнике S_1 в состояние с импульсом q в сверхпроводнике S_2. Однако теперь нам удобнее вычислять поправку к энергии системы, связанную с такими переходами, которая может быть определена с помощью второго порядка квантовомеханической теории возмущений [49]:

$$E_{\text{cB}} = \sum_{\mathbf{k},\mathbf{q}} \frac{|H_t|^2_{\mathbf{kq}}}{E_0 - E_{\mathbf{kq}}} \tag{46.4}$$

Здесь H_t - туннельный гамильтониан, описывающий (точно так же, как и в нормальном состоянии) переход $(1,\mathbf{k}) \rightarrow (2,\mathbf{q})$ электрона с импульсом $\hbar\mathbf{k}$ из сверхпроводника S_1 в состояние с импульсом $\hbar\mathbf{q}$ в сверхпроводнике S_2, а также обратный процесс $(2,\mathbf{q}) \rightarrow (1,\mathbf{k})$; через E_0 и E_{kq} обозначены соответственно энергии основного и возбужденного состояний системы. Возбужденное состояние возникает в связи с переходом одного электрона из состояния $\mathbf{k}$ (или $-\mathbf{k}$) в S_1 в состояние $\mathbf{q}(-\mathbf{q})$ в S_2, т. е. с возникновением возбуждений, по одному в каждом сверхпроводнике. Нужно отметить, что процесс парного туннелирования, по существу, не является двухчастичным, поскольку туннелирование электронов из состояний $\mathbf{k}$ и $-\mathbf{k}$ происходит по одному и определяется одночастичными туннельными матричными элементами, а возбуждения в сверхпроводниках S_1 и S_2 являются виртуальными, т.е. существующим в течение короткого периода между туннелированием первого и второго электронов пары. Следуя [64] (см. также [112]), представим энергию связи (46.4) через матричные элементы одночастичного туннелирования $t_{\text{k,q}}$ и факторы когерентности $u_{\mathbf{k}}, v_{\mathbf{k}}, u_{\mathbf{q}}, v_{\mathbf{q}}$, смысл которых был подробно рассмотрен в 44:

$$E_{\text{CB}} = -2\sum_{k,q} |t_{\mathbf{k},\mathbf{q}}|^2 \frac{|v_{\mathbf{k}}u_{\mathbf{q}} + v_{\mathbf{q}}u_{\mathbf{k}}|^2}{E_k + E_q} \tag{46.5}$$

В (46.5) величина $v_{\mathbf{k}}u_{\mathbf{q}} + v_{\mathbf{q}}u_{\mathbf{k}}$ - амплитуда вероятности того, что при $T = 0$ состояния $(\mathbf{k}, -\mathbf{k})$ в S_1 заняты, а состояния $(\mathbf{q}, -\mathbf{q})$
в S_2 - свободны или наоборот, а множитель 2 учитывает вырождение виртуальных состояний по спину; наконец, $E_k + E_q$ - суммарная энергия двух виртуальных возбуждений, возникающих в процессе парного туннелирования. Используя формулу (45.13) и следующие из нее соотношения

$$\begin{aligned} 2u_{\mathbf{k}}v^*_{\mathbf{k}} &= \tfrac{\widetilde{\Delta}_1}{E_k}, \qquad 2u_{\mathbf{q}}{v_{\mathbf{q}}}^* = \tfrac{\widetilde{\Delta}_2}{E_q} \\ |u_{\mathbf{k}}|^2 - |v_{\mathbf{k}}|^2 &= \tfrac{\varepsilon_k}{E_k}, \qquad |u_{\mathbf{q}}|^2 - |v_{\mathbf{q}}|^2 = \tfrac{\varepsilon_q}{E_q} \end{aligned} \tag{46.7}$$

преобразуем (46.5) к виду

$$E_{\text{CB}} = -\sum_{k,q} \frac{|t_{\text{k},\mathbf{q}}|^2}{E_k + E_q}\left[1 - \frac{\varepsilon_k\varepsilon_q}{E_kE_q} + \text{Re}\,\frac{\widetilde{\Delta}_1\widetilde{\Delta}^*_2}{E_kE_q}\right] \tag{46.8}$$

Здесь Re - действительная часть. При записи соотношений (46.6) и (46.8) учитывалось, что $\widetilde{\Delta}_{1,2}$ - комплексные функции, которые, по существу, представляют собой комплексные

параметры порядка в сверхпроводниках S_1 и S_2 и могут быть выражены (аналогично тому, как это сделано в 21 при выводе джозефсоновского соотношения для мостика Асламазова - Ларкина) через амплитуду и фазу параметра порядка:

$$\tilde{\Delta}_1 = \Delta_1 e^{i\theta_1}, \quad \tilde{\Delta}_2 = \Delta_2 e^{i\theta_2}, \quad \tilde{\Delta}_2^* = \Delta_2 e^{-i\theta_2} \tag{46.9}$$

Здесь $\Delta_{1,2}$ - действительные величины, представляющие собой щели в берегах S_1IS_2-перехода.

Рассмотрим сначала последний член в квадратных скобках в (46.8) - единственный, который зависит от разности фаз $\varphi = \theta_1 - \theta_2$ - и обозначим его через $-E_J \cos\varphi$. Переходя от суммирования по k и q к интегрированию по энергиям электронного спектра в S_1 и S_2, с учетом (46.3) и (46.9) получим для E_J при $T = 0$:

$$E_J(T=0) = \frac{\hbar}{4\pi e^2 R_n} \Delta_1 \Delta_2 \int\limits_{-\infty}^{\infty} \int\limits_{-\infty}^{\infty} \frac{d\varepsilon_1 d\varepsilon_2}{E_1 E_2 (E_1 + E_2)} \tag{46.10}$$

Расширение пределов интегрирования в (46.10) до $\pm\infty$ допустимо, поскольку интегралы быстро сходятся при $\varepsilon_{1,2} \sim |\Delta|$. Заменой переменных $\varepsilon_{1,2} = \Delta_{1,2} \operatorname{sh} x_{1,2}$ и несложными выкладками интеграл в выражении (46.10) приводится к эллиптическому, и в результате получаем

$$E_J(T=0) = \frac{\hbar}{e^2 R_n} \frac{\Delta_1 \Delta_2}{\Delta_1 + \Delta_2} K\left(\frac{|\Delta_1 - \Delta_2|}{\Delta_1 + \Delta_2}\right) \simeq \frac{\pi\hbar}{2e^2 R_n} \frac{\Delta_1 \Delta_2}{\Delta_1 + \Delta_2}, \tag{46.11}$$

где последнее равенство приближенно верно, когда Δ_1 и Δ_2 отличаются не более чем в $2-3$ раза, и является точным при $\Delta_1 = \Delta_2$.

Второй член в квадратных скобках в уравнении (46.8) обращается в нуль (ввиду нечетности) при интегрирования по $\varepsilon_k, \varepsilon_q$, в то время как первый член формально расходится при $|\varepsilon_{k,q}| \to \to \infty$. Однако нас интересует только вклад в энергию, связанный с наличием сверхпроводимости в берегах контакта, поэтому мы вычтем из этого расходящегося интеграла его аналог, вычисленный для нормального состояния берегов. Обозначая полученное выражение через $E_1(T=0)$, получаем

$$E_1(T=0) = \frac{\hbar}{4\pi e^2 R_n} \Delta_1 \Delta_2 \int\limits_{-\infty}^{\infty} \int\limits_{-\infty}^{\infty} d\varepsilon_1 d\varepsilon_2 \left(\frac{1}{|\varepsilon_1| + |\varepsilon_2|} - \frac{1}{E_1 + E_2}\right) \tag{46.12}$$

Легко проверить, [1)] что значение интеграла (46.12) совпадает со значением $E_J(T=0)$, определенным в (46.10). Поэтому

1)Рассмотрим для примера случай одинаковых сверхпроводников, $\Delta_1 = \Delta_2$. Разность $E_1 - E_J$ приводится заменой переменных $\varepsilon_1 = \Delta x, \varepsilon_2 = \Delta y$ к выражению, пропорциональному интегралу

$$\int\limits_0^{\infty} dxdy \left[\frac{1}{x+y} - \left(1 + \frac{1}{\sqrt{1+x^2}\sqrt{1+y^2}}\right) \frac{1}{\sqrt{1+x^2} + \sqrt{1+y^2}}\right],$$

который равен нулю.

полное выражение для энергии SIS-контакта $E_{\text{св}}(\varphi)$ совпадает с (22.11). Соответственно, величина критического тока туннельного S_1IS_2-перехода связана со значениями энергетической щели в S_1 и S_2 следующим выражением:

$$I_c(T=0) \simeq \frac{\pi}{e}\frac{\Delta_1\Delta_2}{R_n\left(\Delta_1+\Delta_2\right)} \tag{46.13}$$

При отличных от нуля температурах вычисление $E_J(T)$ изложенным методом весьма усложняется, т.к. приходится учитывать фермиевскую функцию распределения квазичастиц, а также процессы их туннелирования между берегами S_1 и S_2. Температурная зависимость критического тока SIS-перехода может быть вычислена аналитически для случая одинаковых сверхпроводящих берегов ($\Delta_1 = \Delta_2 = \Delta$). Эта зависимость получена Амбегаокаром и Баратовым [135] (см. [112, 136, 137]):

$$I_c(T) = \frac{\pi\Delta(T)}{2eR_n}\,\mathrm{th}\left(\frac{\Delta(T)}{2k_{\mathrm{B}}T}\right) \tag{46.14}$$

При стремлении T к нулю выражение (46.14) переходит в (46.13) (с $\Delta_1 = \Delta_2 = \Delta$).

При $T \to T_c$ критический ток джозефсоновского перехода пропорционален $\Delta^2(T) \propto (T_c - T)$. Вывод о том, что вблизи точки перехода энергия связи симметричного перехода $E_J(T) \propto (T_c- \ -T)$, можно было сделать и с помощью свободной энергии Гинзбурга-Ландау: вклад в энергию, связанный с наличием туннелирования между двумя сверхпроводниками, должен быть пропорционален произведению обоих параметров порядка, $E_J(T) \propto \psi_1(T)\psi_2(T)$. В случае одинаковых сверхпроводников получаем, как и выше, $E_J(T) \propto \psi^2(T) \propto (T_c - T)$. В то же время, если берега контакта имеют различные температуры сверхпроводящего перехода T_c, джозефсоновская энергия и критический ток стремятся к нулю пропорционально $\left(T_c^{\min} - T\right)^{1/2}$. Все эти выводы о поведении вблизи T_c сделаны для случая SIS-перехода, когда туннелирование слабое, и потому мало влияет на параметры порядка обоих сверхпроводников. Иначе дело обстоит с SNS-пере ходами, когда параметр порядка вблизи NS-границы может быть сильно подавлен из-за эффекта близости (подробнее см. [136]).

Формулу (23.8) для случая SIS-перехода с одинаковыми сверхпроводящими берегами удобно также записать, используя определение квантового сопротивления, введенное в (23.8),

$$\frac{E_J}{\Delta} = \frac{1}{2}\frac{R_Q}{R_n} \tag{46.15}$$

9.2.11 7.4 Andreev Reflection

Theory by Schmidt

Let us examine the process in which the normal current converts into superconducting current. We shall try to understand what happens at the normal metal-superconductor interface and how far from the interface the conversion of the normal current into supercurrent takes place.

Before beginning our analysis, let us agree on what the term 'interface' means exactly. In its most pure form, it is the interface between a normal and a superconducting domain in the intermediate state of a superconductor, In this case, the order parameter (energy gap) has its maximum value $\Delta(T)$ deep inside the superconducting domain and is zero deep inside the normal region. The transition from one value to the other occurs over the coherence length $\xi(T)$. It is this transitional region to which we shall refer as the NS interface. In the case of mechanical contact between two metals - normal and superconducting - the situation remains the same, at least qualitatively. At $T \approx T_c$, the width of the interface, $\xi(T)$, is rather large and we can apply to it the following analysis. We are interested in what happens to an electron in the normal metal when, while moving towards the superconductor, it encounters the NS interface. We

assume that the electron's energy is less than the energy gap of the superconductor. This process is illustrated in Fig. 7.3. At some moment of time while approaching the superconducting region, the normal electron reaches a point x which already belongs to the superconducting region but where the value of the gap $\Delta(x)$ is still small. At this moment it converts into an electron-like quasiparticle of the superconductor and, in momentum space, fills an appropriate $\boldsymbol{k}$ state, in accordance with the value of its energy E_k. At the next moment, as the quasiparticle moves closer to the superconducting region, it reaches the area with a larger value of the gap thereby moving, in momentum space, to another $\boldsymbol{k}$ state, closer to k_{F}. This results in an increase of the quasiparticle charge.

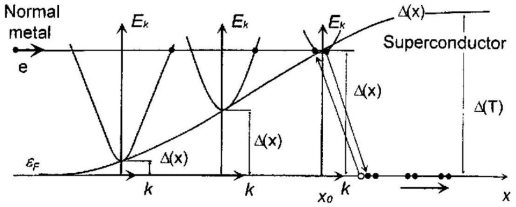


Fig. 7.3. Schematic diagram of Andreev reflection. Once in the vicinity of an NS interface, a quasiparticle (electron) moves from one $\boldsymbol{k}$ state to another, gradually changing its charge as it moves closer to the superconducting region

Thus, as an electron-like excitation moves from the normal metal towards the NS interface, it gradually reduces its charge. Finally, as one can see from the sketch in Fig. 7.3, the momentum of the quasiparticle becomes k_F, its group velocity zero and, according to (7.6), its charge reduces to zero ($q_{k_{\mathrm{F}}} = 0$). This happens when the quasiparticle reaches the point x_0, where its energy is equal to the energy gap. At this point, the quasiparticle is reflected back from the interface and, in momentum space, moves to the left-hand branch of the energy spectrum, which is populated by holes. Now its group velocity is directed to the left, that is, in the direction from the superconductor towards the normal metal, and its charge becomes negative. But propagation of a negative charge to the left is equivalent to propagation of a positive charge to the right. Therefore, the process of reflection we have just analyzed gives rise to a charge transfer from the normal metal to the superconductor, i.e., to an electric current.

This process was first proposed theoretically by Andreev [70] and is called Andreev reflection.

The decrease of the quasiparticle charge, as it approaches the superconducting region, gives a clear indication that the condensate is also involved in the process of Andreev reflection. The quasiparticle charge does not disappear, it is transferred to the condensate! Physically, this means that: having reached the interface, the quasiparticle finds itself a partner and together they enter the condensate, while the newly formed hole goes back to the normal metal. This process accounts for the transfer through the NS interface of the part of the current that is carried by excitations with energies below the energy gap $\Delta(T)$. The process of normal current conversion into the supercurrent takes place within the region $\sim \xi(T')$. The behavior of excitations with energies $E_k > \Delta(T)$ is entirely different. As we are soon to find out, they can penetrate the interior of the superconductor to distances well in excess of the coherence length $\xi(T)$.

9.2.12 Andreev Reflection: Experimental Consequences

(here is preparation to experiments, what and how can be detected?)

9.3 Overview and Comparison of Methods for different JJ

Overview of well-known methods for describing tunneling

(write that there is BdG method and key formulas)

Different forms of Josephson relation for different junctions

(write that the formula below is a more general case)
After approximation of small area:

$$J_1(\varphi) = \frac{DE_J\pi}{2\Phi_0}\tanh\left(\beta E_J\sqrt{1-D\sin^2\frac{\varphi}{2}}/2\right)\frac{\sin\varphi}{\sqrt{1-D\sin^2\frac{\varphi}{2}}}$$

Overview of well-known methods for evaluation of a current

$$J_Q(x) = e\sum_n f_n\left\{J_{u_n}(x) + J_{v_n}(x)\right\}$$

$$f_n = f\left(E_n\right) = \frac{1}{1+e^{E_n/k_BT}} \qquad J_{u_n}(x) = \frac{\hbar}{m}\operatorname{Im}\left\{u_n^*(x)\left[\nabla u_n(x)\right]\right\} \qquad J_{v_n}(x) = \frac{\hbar}{m}\operatorname{Im}\left\{v_n^*(x)\left[\nabla v_n(x)\right]\right\}$$

(this is from Chang, Bagwell. write this method below!!!!)
Then, there are complicated formulas for the total current.
(I'll derive them in separate note, then I'll write something here about them)

Overview of exotic methods for evaluation of a current

Here, I'll collect not tasted methods, which may produce a correct result, but also may not.
(Piasotski's strange method)

Which method to chose to describe some typical JJ?

(!!!!! a very important question, I'll answer later!!!)

there is a GL method. Maybe it is a good one?

there is a GF in TB model method. Maybe it is a good one? A lot of people are using it...

there is a Beenakker's method. Maybe it is a good one?

there is a GF in continual model method. Maybe it is a good one? I have no idea how to use it.

Which method to chose to describe some JJ with disorder?

(I'LL WRITE LATER METHODS FOR OTHER EFFECTS IN JJ)

9.4 Special properties and Deeper Understanding of SC Contacts

9.4.1 22. Nonstationary Josephson Effect, Resistive Characteristics

Если ток, задаваемый внешним источником, превысит критическое значение I_c, на слабой связи появится напряжение V. К каким это приведет последствиям?

22.1. Джозефсоновская генерация.

Поведение квантовомеханической системы определяется решением уравнения Шредингера

$$i\hbar\frac{\partial\psi}{\partial t} = \widehat{H}\psi \tag{22.1}$$

где $\widehat{H}$ - гамильтониан системы.

Волновая функция стационарного состояния ψ_1 удовлетворяет уравнению

$$\widehat{H}\psi_1 = E\psi_1$$

где E-энергия этого стационарного состояния, $\psi = \psi_1 e^{i\theta(t)}$, причем ψ_1 не зависит от времени. Подставляя эту волновую функцию в (22.1), получим

$$-\hbar\frac{\partial\theta}{\partial t} = E \tag{22.2}$$

Если на слабой связи установилась разность потенциалов V, то это означает, что энергии куперовских пар в берегах перехода E_1 и E_2 связаны соотношением

$$E_1 - E_2 = 2eV \tag{22.3}$$

так как заряд одной пары равен $2e$.

Подставляя (22.3) в (22.2), получим второе фундаментальное соотношение Джозефсона

$$2eV = \hbar\frac{\partial\varphi}{\partial t} \tag{22.4}$$

Точно то же самое соотношение получится, если из формулы (21.8) вычесть формулу (21.7).

Что же происходит с джозефсоновским переходом, когда по нему течет заданный извне постоянный ток $I > I_c$? Поскольку сверхток не может быть больше I_c, ясно, что теперь, кроме сверхтока, возникнет ток нормальной компоненты, т.е. возникнет ток одиночных электронов. Это утверждение сразу приводит нас к так называемой резистивной модели, т.е. рассматрению джозефсоновского перехода как параллельного включения собственно джозефсоновского контакта, пропускающего только сверхток, и нормального участка (рис. 22.1). Полный ток I равен сумме нормального тока V/R и сверхтока $I_s = I_c \sin\varphi$:

$$I = I_c \sin\varphi + \frac{\hbar}{2eR}\frac{\partial\varphi}{\partial t} \tag{22.5}$$

где R-сопротивление перехода в нормальном состоянии. Это дифференциальное уравнение относительно функции $\varphi(t)$ элементарно интегрируется. Подставляя решение в (22.4), получим напряжение на переходе в виде

$$V(t) = R\frac{I^2 - I_c^2}{I + I_c\cos\omega t} \tag{22.6}$$

$$\omega = \frac{2e}{\hbar}R\sqrt{I^2 - I_c^2} \tag{22.7}$$

Так мы обнаруживаем удивительное свойство джозефсоновского перехода. Если заданный извне постоянный ток I больше критического тока перехода, на нем возникает напряжение V, периодически зависящее от времени. Это явление получило название

джозефсоновской генерации. Схематическая зависимость $V(t)$ от времени дана на рис. 22.2. Частота колебаний напряжения зависит от того, насколько превышает ток через переход I его критическое значение I_c (см. (22.7)).

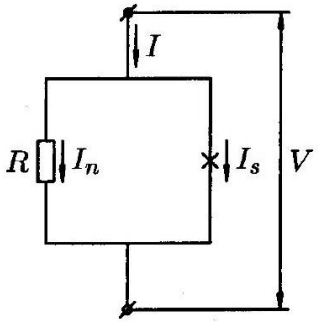

Рис. 22.1. Резистивная модель джозефсоновского перехода. Сверхток через собственно джозефсоновский переход равен $I_s = I_c \sin\varphi$.

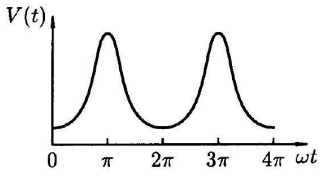

Рис. 22.2. Напряжение на переходе (джозефсоновская генерация).

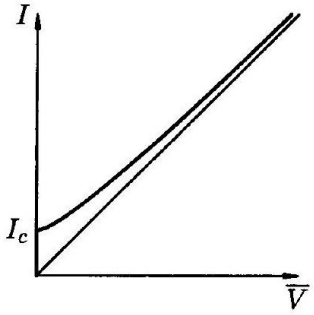

Вольтметр постоянного тока, подключенный к переходу, покажет, конечно, среднее по периоду значение $\bar{V}$. Усреднение по
времени формулы (22.6) дает

$$2e\bar{V} = \hbar\omega. \tag{22.8}$$

Эта формула имеет совершенно ясную интерпретацию. Если среднее расстояние по энергиям между уровнями куперовских пар в двух половинках перехода равно $2e\bar{V}$, то при переходе одной пары через область слабой связи такая энергия выделяется в виде кванта электромагнитного излучения.

Вольт-амперная характеристика перехода, которая следует из формул (22.7) и (22.8), показана на рис. 22.3.

Рис. 22.3. Вольт-амперная характеристика джозефсоновского перехода.

При токе через переход $I = I_s + I_n$, достаточно близком к I_c, значительная его доля протекает в виде сверхпроводящего тока I_s через джозефсоновский элемент на эквивалентной схеме рис.22.1. При $I \gg I_c$ практически весь постоянный ток течет через резистивный элемент ($I \simeq I_n$), и вольт-амперналл характеристика на этом участке выходит на характеристику перехода в нормальном состоянии. Чтобы подробнее

пояснить такое поведение, представим скорость изменения разности фаз на переходе в таком виде:

$$\frac{d\varphi}{dt} = \frac{2e}{\hbar}V = \frac{2e}{\hbar}R\,(I - I_s) = \frac{2e}{\hbar}R\,(I - I_c \sin\varphi) \tag{22.9}$$

Можно заметить, что в течение первого полупериода джозефсоновского тока, когда $I_s = I_c \sin\varphi$ совпадает по направлению с полным током I через переход ($\sin\varphi > 0$), скорость иэменения
разности фаз меньше, чем в течение второго полупериода, когда сверхпроводящий ток имеет обратное направление ($\sin\varphi < 0$). Усреднение по полному периоду даст сверхпроводящую компоненту, совпадающую по направлению с I, что обеспечит уменьшение доли нормальной компоненты I_n в полном токе. С увеличением I доля I_s в (22.9), ограниченная I_c, будет уменьшаться, и скорости изменения разности фаз на положительном и отрицательном полупериодах в конце концов сравняются. Это приведет к исчезновению сверхпроводящей компоненты в среднем по времени токе и выходу вольт-амперной характеристики на линейную зависимость $V = RI$.

Здесь необходимо отметить, что соотношения (22.4) и (22.8) являются совершенно фундаментальными и точными. Многочисленные эксперименты подтвердили их с громадной точностью.

Впервые джозефсоновская генерация наблюдалась советскими физиками И. К. Янсоном, В. М. Свистуновым и И. Д. Дмитренко [14] в 1964 г.

При нарастании тока через переход от нуля до величины I_s за время t в переходе запасается некоторая энергия:

$$E_{\text{сВ}} = \int_0^t I_s V dt \tag{22.10}$$

Здесь V-это напряжение, возникающее на переходе в процессе нарастания тока согласно общей формуле (22.4). Подставляя сюда $I_s = I_c \sin\varphi$ и (22.4), после элементарного интегрирования получим

$$E_{\text{СВ}} = E_{\text{J}}(1 - \cos\varphi), \tag{22.11}$$

где

$$E_J = \hbar I_c/2e = \Phi_0 I_c/2\pi \tag{22.12}$$

есть максимальная величина понижения энергии перехода за счет наличия слабой связи между сверхпроводящими берегами. Энер гию (22.12) мы в дальнейшем будем называть просто джозефсоновской энергией. Джозефсоновский переход является фактически нелинейной индуктивностью, запасающей энергию при изменении тока через него.

При вычислении полной свободной энергии замкнутой системы, в которую включен джозефсоновский переход, нужно учитывать также энергию, затрачиваемую источником тока:

$$E_{\text{ист}} = \int_0^t IV dt = \frac{\hbar I}{2e}\varphi = \frac{\Phi_0}{2\pi} I\varphi \tag{22.13}$$

Таким образом, свободная энергия для рассматриваемого случая перехода с заданным током (т.е. потенциальный "рельеф" вдоль угловой координаты φ) определяется соотношением

$$E = E_{\mathrm{J}}(1 - \cos\varphi) - \frac{\Phi_0}{2\pi} I\varphi \tag{22.14}$$

которое графически изображено на рис. 22.4. С увеличением тока через переход средний наклон изображенного рельефа (часто называемого "стиральной доской») возрастает, а глубина локальных минимумов, расположенных в точках $\varphi_0 = \arcsin(I/I_c) + +2\pi n$, уменьшается. При $I = I_c$ потенциальные барьеры U_0 на кривой (22.14) исчезают, что соответствует непрерывному изменению фазы и появлению напряжения на переходе.

22.2*. Критический ток и “ток возврата” джозефсоновского перехода с емкостью.

Механизмы токопереноса в туннельных сверхпроводящих переходах будут подробно рассмотрены в 46. Покажем здесь, что поведение туннельного джозефсоновского перехода, в котором два сверхпроводящих берега разделены тонкой прослойкой изолятора, как это изображено на рис. 20.1, а, сходно с поведением массивной частицы в потенциале, изображенном на рис. 22.4. Для описания туннельного перехода в рамках резистивной модели необходимо дополнить эквивалентную схему (рис. 22.1) параллельно включенной емкостью C. Ток

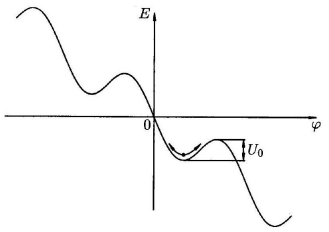

Рис. 22.4. Потенциальный рельеф $E(\varphi)$ джозефсоновского перехода с заданным током.

смещения через емкостной элемент

$$I_D = C\frac{dV}{dt} = \frac{\hbar C}{2e}\frac{d^2\varphi}{dt^2} \tag{22.15}$$

должен быть добавлен в соотношение (22.5), которое примет вид

$$\frac{\hbar C}{2e}\ddot{\varphi} + \frac{\hbar}{2eR}\dot{\varphi} + I_c \sin\varphi = I \tag{22.16}$$

или

$$\left(\frac{\hbar}{2e}\right)^2 C\ddot{\varphi} + \left(\frac{\hbar}{2e}\right)^2 R^{-1}\dot{\varphi} + E_{\mathrm{J}} \sin\varphi = E_{\mathrm{J}}\frac{I}{I_c} \tag{22.17}$$

где $\ddot{\varphi}$ и $\dot{\varphi}$ означает производные φ по времени второго и первого порядка. Уравнение (22.17) - фактически уравнение движения малтника с моментом инерции $J = \left(\frac{\hbar}{2e}\right)^2 C$, коэффициентом вязкости $\eta = \left(\frac{\hbar}{2e}\right)^2 R^{-1}$, максимальным гравитационным моментом $mgl = E_{\mathrm{J}}$ и приложенным вращающим моментом $E_{\mathrm{J}}(I/I_c)\,;\ddot{\varphi}$ и $\dot{\varphi}$ - угловое ускорение и угловая скорость маятника. Легко видеть, что собственная частота малых колебаний $(\mathrm{mgl/J})^{1/2}$, на зываемая в джозефсоновском случае плазменной частотой перехода, выражается соотношением

$$\omega_p = \left(\frac{E_{\mathrm{J}}}{J}\right)^{1/2} = \left(\frac{2\pi I_c}{C\Phi_0}\right)^{1/2} \tag{22.18}$$

Плазменная частота может рассматриваться также как резонансная частота

$$\omega_p = (L_\mathrm{J} C)^{-1/2} \tag{22.19}$$

высокочастотного контура с емкостью C и индуктивностью L_J. Сравнение (22.19) и (22.18) дает для собственной индуктивности джозефсоновского перехода следующее значение (для малых изменений φ!):

$$L_\mathrm{J} = \frac{\Phi_0}{2\pi I_c} \tag{22.20}$$

Выражение (22.17) часто бывает удобно представлять также как уравнение движения массивной частицы в периодическом потенциале, представленном на рис. 22.4. В этом случае величина $\left(\frac{\hbar}{2e}\right)^2 C$ играет роль массы m частицы. С точностью до замены φ на линейную координату x мы получаем уравнение движения частицы в вязкой среде с $\eta = \left(\frac{\hbar}{2e}\right)^2 R^{-1}$ в одномерном периодическом потенциале $E_\mathrm{J}(1 - \cos x)$ под действием приложенной силы $E_\mathrm{J}\,(I/I_c)$. «Масса», определяющая «инерционное» поведение перехода при изменении φ, связана с величиной емкости C. «Кинетическая энергия" $mv^2/2$ такой частицы, пропорциональная m и $\dot{\varphi}^2$, в точности равна электрической энергии $CV^2/2$, запасаемой в переходе при возникновении напряжения $V = \frac{\hbar}{2e}\dot{\varphi}$, пропорционального скорости изменения разности фаз φ на переходе.

Выше мы показали, что массивная частица начинает непрерывно двигаться при наклоне "стиральной доски», соответствующем $I = I_c$. Однако в связи с инерцией частицы остановить ее можно только несколько уменьшив угол наклона по сравнению с критическим, т. е. при некотором «токе возврата» $I_r < I_c$.

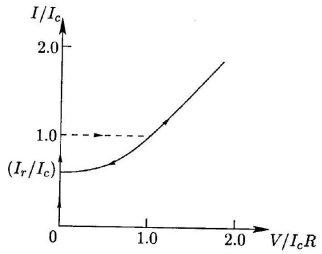

Рис. 22.5. Вольт-амперная характеристика перехода с $\beta_\mathrm{C} = 4$.

Ток возврата (или «ток захвата») тем меньше, чем выше емкость («масса») и чем меньше вязкость, т.е. выше сопротивление туннельного перехода. Гистерезисное поведение вольт-амперной характеристики туннельного перехода показано на рис. 22.5. Количественно ток возврата и необратимость резистивных свойств определяются величиной параметра Маккамбера [52]:

$$\beta_\mathrm{C} = (2e/\hbar) I_c C R^2 \tag{22.21}$$

Использование параметра β_C и характержой джозефсоновской частоты $\omega_c = (2e/\hbar) I_c R$ позволяет упростить (22.17):

$$I/I_c = \beta_\mathrm{C} \omega_c^{-2} \ddot{\varphi} + \omega_c^{-1} \dot{\varphi} + \sin\varphi \tag{22.22}$$

При $\beta_\mathrm{C} \leqslant 1$ можно пренебречь «емкостным» членом в (22.22) и получить снова (22.5). В этом случае вольт-амперная характеристика однозначна и описывается соотношением (22.7) для переходов с непосредственной проводимостью:

$$V = R\sqrt{I^2 - I_c^2} \tag{22.23}$$

При $\beta_C > 1$ вольт-амперные характеристики приобретают гистерезисный вид, показанный на рис. 22.5. Прямая ветвь представляет собой вертикальную ступеньку тока от 0 до I_c при нулевом
напряжении, после которой следует срыв на возвратную ветвь (называемую также часто «квазичастичной ветвью). Численные расчеты [52, 53] дают зависимость тока возврата I_r от β_C, показанную на рис. 22.6. Для $\beta_C \to \infty$ имеем $I_r \to 0$. Это означает, что возвратная часть вольт-амперной характеристики линейна [1)] ($V = RI$), как показано на рис. 22.7, т.е. в эквивалентной схеме резистивной модели, которая представляет собой параллельное включение R, C и собственно джозефсоновского элемента (переносящего сверхпроводящий ток $I_c \sin\varphi$), транспортный ток течет только через нормальное сопротивление. Чтобы объяснить физическую природу изменения поведения обратного хода характеристики при увеличении емкости перехода, представим β_C (см. (22.21)) через проводимость $\omega_c C$ емкостного элемента эквивалентной схемы на характерной джозефсоновской частоте ω_c и проводимости резистивного элемента $G = 1/R$:

$$\beta_C = \omega_c C/G \tag{22.24}$$

Легко видеть, что при $\beta_C \gg 1$ емкостной элемент полностью шунтирует переменный джозефсоновский ток, зануляя сверхпроводящую часть в полном транспортном токе через джозефсоновский контакт. При малых C среднее по времени значение сверхпроводящей компоненты не равно нулю, поэтому напряжения в интервале от нуля до нескольких $V_c = I_c R$ понижаются по сравнению со случаем нормального туннельного контакта.

Ш-з.

22.1. Два джозефсоновских перехода с критическими токами $I_{c1} = 500$ мкА и $I_{c2} = 700$ мкА включены параллельно в сверхпроводящую цепь. Полный ток через оба перехода равен 1 мА. Чему равны токи в каждом из переходов?

Solution

Поскольку переходы включены параллельно, разности фаз φ_1 и φ_2 на переходах будут равны. Поэтому токи по переходам распределяются пропорционально их критическим токам: $I_1 = 0.417\text{MA}, I_2 = 0.583\text{MA}$.

• Мы пренебрегаем здесь для простоты щелью в энергетическом спектре нормальных носителей в сверхпроводнике и особенностью в плотности их состояний, которые будут обсуждаться в §$45 – 46. Вольт-амперные характеристики с квазичастичными (возвратными) ветвями, рассчитанные с учетом этих особенностей, приведены на рис. 46.7.

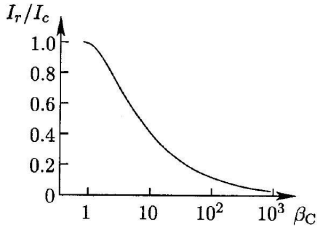

Рис. 22.6. Зависимость тока возврата от величины β_C [52].

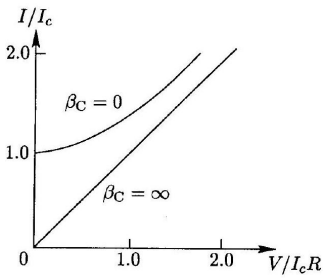

Рис. 22.7. Вольт-амперные характеристики джозефсоновских переходов, рассчитанные в рамках резистивной модели (см. примечание на с. 131) для случаев незначительной ($\beta_C = 0$) и доминирующей ($\beta_C = \infty$) емкостей.

Ш-з.

22.2. Найти разность между максимальным и минимальным значениями V на графике рис. 22.2.

Ответ. $V_{\max} - V_{\min} = 2I_cR$.

Ш-з.

22.3. Точечный контакт имеет критический ток $I_c = 1$ мА и сопротивление в нормальном состоянии $R = 2$ Ом. Найти величину постоянного напряжения на контакте $\bar{V}$ и частоту джозефсоновской генерации ν, если через контакт течет ток $I = 1.2$ mA.

Ответ. $\bar{V} = 1.33$МВ; $\nu = 641$ ГГц.

Ш-з.

22.4. Критический ток джозефсоновского перехода равен $I_c = 100$ мкА. Через переход пропускается постоянный ток $I_0 = 70$ мкА и слабый переменный ток с амплитудой $I_1 =$ 2МКА и частотой $\nu = 10$М ц, т.е. $I = I_0 + I_1 \sin 2\pi\nu t$. Найти напряжение на переходе, пользуясь СИ.

Solution

Разность фаз на переходе ищем в виде $\varphi = \varphi_0 + \varphi_1$, где φ_0 - разность фаз, создаваемая постоянным током I_0. Напряжение на переходе $V = (\Phi_0/2\pi)\, d\varphi/dt = (\Phi_0/2\pi)\, d\varphi_1/dt$, но $d\varphi_1/dt = (dI/dt)\,(dI/d\varphi_1)^{-1}$. Подставляя это выражение в выражение для V, получим

$$V = \frac{\Phi_0}{I_c \cos\varphi_0} \nu I_1 \sin(2\pi\nu t + \pi/2)$$

При условиях задачи амплитуда переменного напряжения будет 0.58 нВ.

Замечание. Из решения задачи следует, что напрлжение V опережает по фазе ток через переход на угол $\pi/2$. Это значит, что переход ведет себя как индуктивность $L = \Phi_0/\left(2\pi I_c \cos\varphi_0\right)$.

9.4.2 23*. Fluctuations of Critical Current, Macroscopic Tunneling

23.1. Тепловые флуктуации критического тока в джозефсоновском переходе.

Величина I_c является фундаментальной характеристикой джозефсоновского перехода, определяемой энергией связи E_J (22.12). Мы видели выше, что при токе через переход $I = I_c$ исчезают барьеры (U_0) в потенциальном рельефе $E(\varphi)$. Однако и при

несколько более низких токах возможен распад метастабильных состояний джозефсоновского перехода путем преодоления потенциальных барьеров за счет шума в измерительных цепях, за счет тепловых и квантовых флуктуаций фазы. Таким образом, реально наблюдаемый критический ток, выше которого начинается непрерывное изменение фазы во времени и возникает напряжение на переходе, несколько меньше, чем $I_c = \frac{2e}{\hbar} E_J = \frac{2\pi}{\Phi_0} E_\mathrm{J}$. Здесь нужно оговориться, что если затухание велико (т.е. величина параметра Маккамбера β_C достаточно мала), то единичная флуктуация «перебросит" переход в состояние, соответствующее следующему локальному минимуму; возникающий короткий импульс напряжения, соответствующий отдельному флуктуационному процессу, зафиксировать практически невозможно. В переходах с малым затуханием ($\beta_\mathrm{C} \gg 1$) из за большой инерции система не задержится в соседнем минимуме, а будет разгоняться пока $\dot{\varphi}$ (т. е. V) не достигнет стационарного значения за счет возрастания диссипативного члена в (22.17). Этому процессу соответствует скачок на вольт-амперной характеристике, показанный на рис. 22.5.

Рассмотрим термоактивационный распад метастабильного состояния джозефсоновского перехода с током, т.е. термоактивационное преодоление барьера U_0, изображенного на рис.22.4. Высота этого барьера при токах чуть ниже критического ($|I - I_c| \ll I_c$) невелика и определяется выражением [54, 55]

$$U_0(I) = \frac{4\sqrt{2}}{3} E_\mathrm{J} \left(1 - I/I_c\right)^{3/2} \tag{23.1}$$

Частота собственных колебаний перехода на дне потенциальной ямы есть

$$\omega(I) = \omega_p \left[1 - (I/I_c)^2\right]^{1/4} \tag{23.2}$$

где ω_p - плазменная частота (22.18). Скорость распада состояния пропорциональна частоте попыток (23.2) и больцмановскому фактору $\exp\left(-U_0/k_\mathrm{B}T\right)$. Вероятность распада при конечных температурах сильно возрастает с приближением I к $I_c\,(U_0 \to 0)$. Дополнительные предэкспоненциальные множители, полученные из точных количественных расчетов, подробно обсуждались в работах [56, 57, 55]. На рис. 23.1 представлены расчеты [58] вольтамперных характеристик для переходов с $\beta_\mathrm{C} \geqslant 1$, учитывающие тепловые флуктуации. (Параметр $\gamma = 2E_\mathrm{J}/\left(k_\mathrm{B}T\right)$.) Эксперименты, проведенные как на переходах со слабым затуханием [54], так и на переходах с сильным затуханием [59], показали хорошее согласие с расчетами. В последней работе переход с сильным затуханием включался в сверхпроводящее кольцо, ток I через переход задавался путем приложения внешнего магнитного поля, а распад метастабильного состояния фиксировался по проникновению магнитного потока в кольцо. Для измерения магнитного потока использовался чувствительный сквид-магнитометр, описапио работы которого посвящены последние разделы данной главы.

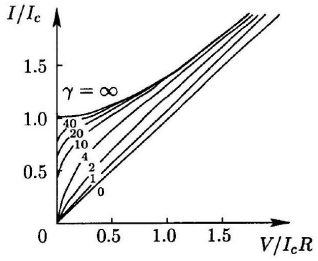

Рис. 23.1. Влияние тепловых флуктуаций на вольт-амперные характеристики джозефсоновских переходов с $\beta_\mathrm{C} \geqslant 1\,(\gamma = 2E_\mathrm{J}/\left(k_\mathrm{B}T\right))$. Расчеты взяты из работы [58].

23.2. Макроскопические квантовые эффекты.

Прежде чем обратиться к процессам квантового распада метастабильных состояний джозефсоновского перехода, рассмотрим условия, при которых джозефсоновский контакт становится по-настоящему квантовым макроскопическим объектом, т.е. одна из макроскопических степеней свободы (сверхпроводящая фаза) становится настоящей квантовомеханической переменной.

Явление сверхпроводимости в целом невозможно описать без привлечения квантовой механики. Эффекты Джозефсона - наиболее яркий пример установления когерентных волновых свойств между двумя массивными слабосвязанными сверхпроводниками. Движение сверхпроводящих электронов является существенно квантовым, и фаза сверхпроводящей волновой функции явно проявляется в различных интерференционных эффектах. Тем не менее, в большинстве случаев изменение фазы во времени может быть достаточно точно описано классической механикой. Мы видели это в предыдущем разделе в случае динамики разности фаз в одиночном туннельном джозефсоновском переходе. При выводе другого важного квантовомеханического эффекта, квантования магнитного потока, мы также фактически пользовались квази классическими выражениями и правилами квантования. Главной особенностью квазиклассического приближения, справедливого для макроскопических объектов с огромным числом степеней свободы, является то, что канонически сопряженные переменные могут иметь одновременно точные значения. Однако существуют условия, при которых фаза параметра порядка становится настоящей квантовомеханической переменной. Это приводит к т. наз. макроскопическим квантовым эффектам [55].

Вернемся к случаю малтника, уравнение движения которого аналогично уравнению (22.17) для разности фаз в одиночном джозефсоновском туннельном переходе. В случае маятника канонически сопряженными переменными (аналогичными координате и импульсу) являются угловая координата φ и момент импульса M. Если масса маятника стремится к нулю, необходимо учитывать квантовые эффекты в динамике, вообще говоря, макроскопической степени свободы φ. Из соотношения неопределенности

$$\Delta\varphi\Delta M \sim \hbar \tag{23.3}$$

следует, что величины φ и M не могут быть определены точно одновременно. Даже при нулевой температуре центр масс маятника не может находится в состоянии покоя, поскольку это означало бы, что и φ, и M точно определены ($\varphi = 0, M = 0$). Следовательно, в квантовом пределе центр масс маятника должен испытывать, кроме тепловых флуктуаций, флуктуации квантовой природы. Таким образом, если обычные когерентные эффекты - это квантовое когерентное движение микрочастиц (например, электронов в сверхпроводнике), то в макроскопических квантовых эффектах проявляется квантовое поведение макрообъекта в целом [60, 61].

Для перехода к квантовому пределу в джзефсоновском случае к нулю должна стремиться емкость C туннельного контакта, играющая роль массы. Квантовые флуктуации становятся значительными при приближении электрической («кулоновской») энергии перехода

$$E_{\mathrm{C}} = e^2/2C \tag{23.4}$$

к джозефсоновской энергии E_{J} (22.12). Для экспериментального наблюдения квантовых эффектов важно, чтобы тепловые флуктуации были малы, т.е. выполнялось неравенство $k_{\mathrm{B}}T < E_{\mathrm{C}}, E_{\mathrm{J}}$. Необходимые условия достигаются в джозефсоновских туннельных переходах с субмикронными размерами и емкостью, меньшей примерно 10^{-15}Ф, при температурах ниже 0.1 К. Напряжению $V \sim 100$ мкВ в таких переходах соответствует разность зарядов на обкладках $Q = CV \sim 10^{-19}$К, т.е. порядка одного заряда электрона.

В нормальном состоянии высокая электрическая энергия e^2/C, возникающая в туннельном переходе в связи с туннелированием одного электрона, приводит к "кулоновской блокаде» туннелирования при напряжениях $V \leqslant e/C$[62, 63]. Появление дополнительного кулоновского члена $Q^2/2C$ в энергии джозефсоновского перехода (22.14) также сильно изменяет динамику туннелирования сверхпроводящих пар [64, 65]. На рис. 23.2 приведена экспериментальная вольт-амперная характеристика из [66], полученная при $T < 0.1$ K для джозефсоновского туннельного перехода с площадью 0.01 мкм ^{2}, емкостью $5 \cdot 10^{-16}$Ф, джозефсоновской энергией $E_\text{J} \simeq 10^{-4}$ эВ и кулоновской энергией $E_\text{C} \simeq \simeq 1.6 \cdot 10^{-4}$ эВ. Легко видеть, что «зарядовые эффекты" приводят к исчезновению джозефсоновского критического тока и появлению области кулоновской блокады туннелирования куперовских пар при напряжениях, близких к нулю (от нуля до V_b).

Рассмотрим подробнее, с какими канонически сопряженными макроскопическими квантовыми переменными мы имеем дело в случае джозефсоновского перехода. "Момент импульса" перехода $M = J\dot{\varphi}$ с учетом того, что $J = (\hbar/2e)^2 C$ (см. обсуждение (22.17)), равен

$$M = J\dot{\varphi} = \left(\frac{\hbar}{2e}\right)^2 C\dot{\varphi} = \frac{\hbar}{2e} CV = \frac{Q\hbar}{2e} \tag{23.5}$$

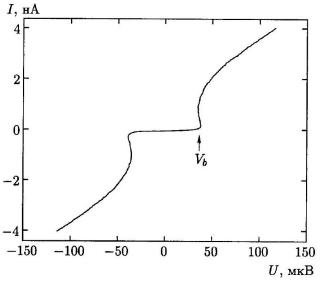

Рис. 23.2. Вольт-амперная характеристика джозефсоновского туннельного перехода с субмикронными размерами [66]; V_b - критическое напряжение «кулоновской блокады».

где Q-электрический заряд на «обкладках» туннельного перехода, индуцированный напряжением V (пропорциональным $\dot{\varphi}$) на переходе. Таким образом, соотношение (23.3) принимает вид

$$\Delta\varphi\Delta Q \sim 2e \tag{23.6}$$

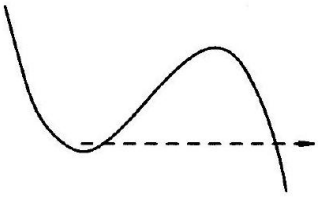
или

$$\Delta\varphi\Delta n \sim 1 \tag{23.7}$$

где $n = Q/2e$ - разбаланс количества сверхпроводящих пар, создающих заряд на обкладках туннельного перехода. В области величин токов и напряжений, где проявляются квантовые эффекты (рис. 23.2), через туннельный переход с $E_\text{J} \sim E_\text{C}$ проходят единицы электронов, т. е. величина n хорошо определена. Это означает, что разность фаз φ должна быть сильно размыта квантовыми флуктуациями, что и приводит к почти полному исчезновению критического тока. Подробнее этот вопрос мы рассмотрим в следующем параграфе.

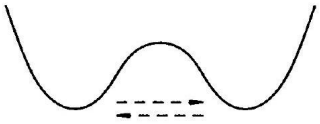
Сильные флуктуации сверхпроводящей фазы могут возникать не только в туннельных переходах с кулоновской блокадой носителей. Локализация заряда возникает и в сверхпроводящих структурах с непосредственной проводимостью с увеличением беспорядка в области слабых связей и при приближении их нормального сопротивления к "квантовому сопротивлению"

$$R_Q \equiv \frac{h}{(2e)^2} \simeq 6.5\text{КОМ} \tag{23.8}$$



В этом случае уменьшение подвижности носителей заряда, приводящее к затруднению переноса пар через высокоомную слабую связь, также должно сопровождаться увеличением квантовых флуктуаций сверхпроводящей фазы [67, 68].

23.3. Макроскопическое квантовое туннелирование и когерентность.



Если понижать температуру, скорость распада метастабильного состояния в потенциале, изображенном на рис. 22.4, выйдет на константу, которая определяется квантовыми флуктуациями. При таком распаде система в целом (как квантовая частица!) туннелирует под барьером U_0 (рис. 23.3, а). Впервые влияние квантовых флуктуаций на наблюдаемый критический ток туннельных джозефсоновских переходов малых размеров было вычислено в работе [69]. Скорость квантового распада при $T = 0$ можно оценить, полагая, что теперь в роли $k_\text{B}T$ в «больцмановском факторе» (ср. с обсуждением после (23.2)) выступает энергия нулевых колебаний, равная по порядку величины $\hbar\omega(I)$:

$$\tau_Q^{-1} = a_q \frac{\omega(I)}{2\pi} \exp\left(-\alpha \frac{U_0}{\hbar\omega(I)}\right) \tag{23.9}$$

Точные вычисления α и предэкспоненциального множителя a_q проведены в [55, 70, 71]. Наличие затухания в системе, $\eta = (\hbar/2e)^2 R^{-1}$, приводит к появлению в (23.9) дополнительного
множителя [72] $\exp\left(-2\pi U_0/\left(2eI_c R\right)\right)$. Таким образом, вероятность квантовых процессов распада действительно должна возрастать с уменьшением емкости джозефсоновского перехода (в связи с возрастанием плазменной частоты перехода) и увеличением его сопротивления (в связи с уменьшением затухания), как это указывалось в предыдущем разделе.

а)

б)

Рис. 23.3. Макроскопическое квантовое туннелирование (а) и макроскопическая квантовая когерентность (б) в джозефсоновских системах.

Первые же эксперименты [73, 74] по измерению времени жизни метастабильного сверхпроводящего состояния малых джозефсоновских туннельных контактов подтвердили теоретические предсказания того, что ширина распределения плотности вероятности перехода в резистивное состояние таких контактов не зависит от температуры при достаточно низких ее значениях, причем температура выхода на квантовый режим преодоления барьера определяется величиной плазменной частоты контакта. Еще одним фактором, влияющим на время жизни метастабильного состояния туннельного перехода с током, является наличие квантованных уровней энергии

джозефсоновского перехода [75] в ямах потенциала «стиральной доски» (рис. 23.4). Скорость распада с уровня E_i определяется как вероятностью заселенности данного уровня при конечной температуре, так и шириной потенциального барьера на этом уровне. Скорость распада можно увеличить, прикладывая к образцу высокочастотное электромагнитное поле $\hbar\Omega$, соответствующее расстоянию между уровнями, и, таким образом, увеличивая заселенность вышележащих уровней. Эксперименты [76] прекрасно подтвердили резонансное увеличение скорости распада при совпадении частоты приложен ного высокочастотного поля и расстояния между квантованными уровнями энергии в джозефсоновских переходах с малой емкостью.

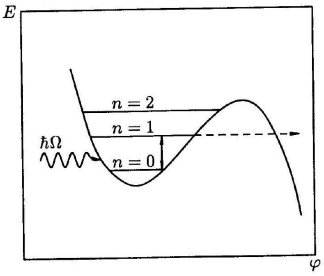


Рис. 23.4. Дискретные энергетические состояния в субмикронных туннельных джозефсоновских контактах и переходы между ними под действием высокочастотного электромагнитного поля.

Систематические экспериментальные исследования зависимости квантовых процессов в туннельных контактах от величины их сопротивления выполнены в работах [77, 78, 79]. Обнаружен фазовый переход из сверхпроводящего в диэлектрическое состояние при приближении сопротивления туннельного контакта к квантовому сопротивлению (23.8), который связывается с резким возрастанием флуктуаций сверхпроводящей фазы в контакте за счет макроскопического квантового туннелирования.

Еще одно важное понятие, которое возникло при исследовании структур с джозефсоновскими контактами, находящимися в "квантовом пределе", это понятие о макроскопической квантовой когерентности. В таких системах (например, сверхпроводящем кольце с тремя джозефсоновскими переходами во внешнем магнитном поле, равном половине кванта магнитного потока) джозефсоновская энергия может иметь два почти вырожденных
минимума при значениях фазы φ_1 и φ_2, разделенных потенциальным барьером (рис. 23.3, б).

Если диссипацию в контактах удается сделать очень слабой, становится возможным квантовомеханическое туннельное проникновение фазы из одного минимума в другой (обозначим амплитуду такого процесса $\mathcal{T}$), и правильными собственными состояниями системы являются смеси состояний, локализованных в первой и второй ямах. Иначе говоря, весь джозефсоновский контакт описывается волновой функцией $\Psi(\varphi)$, зависящей от фазы φ : $\Psi(\varphi) = a_1\Psi_1(\varphi) + a_2\Psi_2(\varphi)$, где волновые функции $\Psi_{1,2}(\varphi)$ соответствуют состояниям, локализованным в первой и второй ямах. Состояние с волновой функцией $\Psi(\varphi)$, в котором обе амплитуды $a_{1,2}$ отличны от нуля, является когерентной смесью исходных (локализованных) состояний. Так, если энергии $E_{1,2}$ локализованных состояний 1,2 точно равны, то правильными собственными состояниями будут симметричное (основное) с $a_1 = a_2$ и возбужденное антисимметричное, $a_1 = -a_2$, а расщепление их энергетических уровней равно $2\mathcal{T}$. При увеличении исходного расщепления уровней $|E_1 - E_2|$ до величин, больших $\mathcal{T}$, роль туннелирования падает, а когерентные состояния становятся все более близкими к исходным локализованным. Экспериментальное подтверждение существования макроскопически когерентных

состояний в системах джозефсоновских контактов было получено совсем недавно в работах [80, 81].

9.4.3 Ambegoakar-Baratoff formula

(see LS for now, later I'll read something related)

Derivation of Ambegoakar-Baratoff formula

(I'll write later)

О большом токе через контакт

Что произойдет, если пропустить через контакт ток, больший чем I_0? Детальный ответ на этот вопрос зависит от свойств цепи, в которую включен контакт. Однако джозефсоновский контакт используемый в таком режиме обладает одним весьма общим свойством. При токе превосходящем I_0 на контакте появится конечное напряжение $V(t)$, в общем случае зависящее от времени. Это напряжение приводит к изменению фазы $\varphi = \varphi_b - \varphi_a$ согласно соотношению Джозефсона для фазы

$$\hbar \frac{d\varphi}{dt} = 2eV(t)$$

которое следует из калибровочной инвариантности. Таким образом, фаза и ток оказываются зависящими от времени. Зная свойства внешней цепи, можно самосогласованно связать напряжение на контакте $V(t)$ и туннельный ток $I(t)$, и таким образом определить динамику системы.

9.5 Bogliubov-de Gennes Equations for Superconductors in the Continuum Model

9.5.1 1.2 Hopping in a Quantum Many-Body Hamiltonian

Theory

A typical solid consists of the order of 10^{23} atoms. Each atom has the atomic number of electrons. In addition to interacting with nuclei, these electrons are interacting among themselves. In principle, one can start with a Hamiltonian to describe the motions of both electrons and nuclei:

$$\mathscr{H} = \sum_i \frac{\mathbf{p}_i^2}{2m_e} - \sum_{i,I} \frac{Z_I e^2}{|\mathbf{r}_i - \mathbf{R}_I|} + \frac{1}{2}\sum_{i,j} \frac{e^2}{|\mathbf{r}_i - \mathbf{r}_j|} + \sum_I \frac{\mathbf{P}_I^2}{2M_I} + \frac{1}{2}\sum_{I,J} \frac{Z_I Z_J e^2}{|\mathbf{R}_I - \mathbf{R}_J|} \tag{1.1}$$

Here the first and the fourth terms are the kinetic energy of the electrons and nuclei while the second, third, fifth terms represent the potential energy due to the Coulomb interaction between electrons and nuclei and among the electronic and nuclear degrees of freedom themselves. The variables $\mathbf{p}_i$ and $\mathbf{P}_I$ denote the momentum of each individual electron and nucleus, while the coordinates $\mathbf{r}_i$ and $\mathbf{R}_I$ are the variables conjugate to $\mathbf{p}_i$ and $\mathbf{P}_I$. The quantities m_e, M_I, and Z_I are the mass of electron and nucleus, and the atomic number, respectively. Note that each electron carries a negative charge $-e(e > 0)$ and each nucleus carries a positive charge $Z_I e$. Therefore, the interaction between electrons and nuclei is attractive while that among electrons or nuclei themselves is repulsive. A schematic drawing of this many-particle problem for a frozen lattice of nuclei is shown in Fig. 1.1.

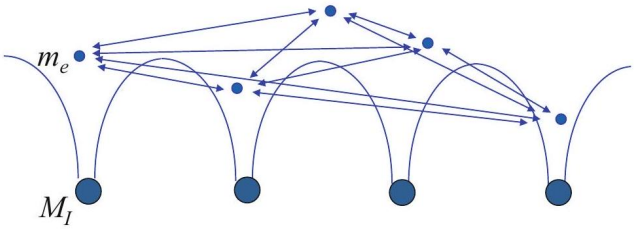

Fig. 1.1 Many-particle Hamiltonian of a solid consisting of electrons in a frozen lattice of nuclei

Classically, the equations of motion of the whole system are given by the Hamilton's equations

$$\dot{r}_{i,\alpha} = \frac{\partial \mathscr{H}}{\partial p_{i,\alpha}}, \quad \dot{p}_{i,\alpha} = -\frac{\partial \mathscr{H}}{\partial r_{i,\alpha}}, \tag{1.2}$$

for the electronic degrees of freedom, and

$$\dot{R}_{I,\alpha} = \frac{\partial \mathscr{H}}{\partial P_{I,\alpha}}, \quad \dot{P}_{I,\alpha} = -\frac{\partial \mathscr{H}}{\partial R_{I,\alpha}}, \tag{1.3}$$

for the nuclear degrees of freedom. These equations are precisely equivalent to the Newton's laws of motion. Here $\alpha(= x, y, z)$ denotes the three components of a vector in the cartesian coordinate system. Unfortunately, many important physical properties of electronic phenomena in solids cannot be captured by the classical mechanics and require a description within the quantum mechanics. There the coordinates and momenta no longer commutate with each other. Instead they should follow the Heisenberg uncertainty principles as represented by the commutators:

$$[r_{i,\alpha}, p_{j,\beta}]_- = i\hbar\delta_{ij}\delta_{\alpha\beta} \text{ and } [R_{I,\alpha}, P_{J,\beta}]_- = i\hbar\delta_{IJ}\delta_{\alpha\beta} \tag{1.4}$$

Here $\hbar$ is the reduced Planck's constant. The commutators by Eq. (1.4) indicate the coordinates and momenta are now quantum mechanical operators. In the coordinate representation, the momentum operator can be written as

$$\mathbf{p}_i = \frac{\hbar}{i}\nabla_i \text{ and } \mathbf{P}_I = \frac{\hbar}{i}\nabla_I. \tag{1.5}$$

Correspondingly, the operator form of the Hamiltonian (1.1) becomes

$$\mathscr{H} = -\sum_i \frac{\hbar^2}{2m_e}\nabla_i^2 - \sum_{i,I} \frac{Z_I e^2}{|\mathbf{r}_i - \mathbf{R}_I|} + \frac{1}{2}\sum_{i,j} \frac{e^2}{|\mathbf{r}_i - \mathbf{r}_j|} - \sum_I \frac{\hbar^2}{2M_I}\nabla_I^2 + \frac{1}{2}\sum_{I,J} \frac{Z_I Z_J e^2}{|\mathbf{R}_I - \mathbf{R}_J|}. \tag{1.6}$$

As such, the evolution of a state of the whole system is described by a quantum many-body wave-function, described by the Schrödinger equation [1]:

$$i\hbar\frac{\partial \Psi}{\partial t} = \mathscr{H}\Psi \tag{1.7}$$

where the many-body wave-function is the function of the variables $(\{\mathbf{r}_i\}, \{\mathbf{R}_I\}; t)$. When there are no external potentials or when they are time independent, the wave function can take the form

$$\Psi(\{\mathbf{r}_i\}, \{\mathbf{R}_I\}; t) = \Phi(\{\mathbf{r}_i\}, \{\mathbf{R}_I\})\, e^{-iEt/\hbar} \tag{1.8}$$

with the $\Phi(\{\mathbf{r}_i\}, \{\mathbf{R}_I\})$ satisfying the steady-state Schrödinger equation:

$$\mathscr{H}\Phi\left(\{\mathbf{r}_i\},\{\mathbf{R}_I\}\right)=E\Phi\left(\{\mathbf{r}_i\},\{\mathbf{R}_I\}\right). \tag{1.9}$$

Here E is the total energy of the many-particle system. Theoretically, the wavefunctions $\Phi\left(\{\mathbf{r}_i\},\{\mathbf{R}_I\}\right)$ contain all information needed to describe every property of the system. In practice, a direct solution of Eq. (1.9) is prohibitively difficult and a hierarchy of theoretical approximations are in order. Notice that the only small term in Eq. (1.6) is the kinetic energy of nuclear motion, which is smaller than that of electronic motion by a factor of m_e/M_I. Therefore, within the Born-Oppenheimer approximation [10], the wave function for the entire system can be written as

$$\Phi_{\alpha n}\left(\{\mathbf{r}_i\},\{\mathbf{R}_I\}\right)=\Psi_\alpha\left(\{\mathbf{r}_i\}:\{\mathbf{R}_I\}\right)u_{n\alpha}\left(\{\mathbf{R}_I\}\right). \tag{1.10}$$

Here $\Psi_\alpha\left(\{\mathbf{r}_i\}:\{\mathbf{R}_I\}\right)$ are the wave-functions for the electrons with the nuclei positions $\{\mathbf{R}_I\}$ as a fixed set of parameters and satisfying the equation

$$\begin{aligned}&\left[-\sum_i\frac{\hbar^2}{2m_e}\nabla_i^2-\sum_{i,I}\frac{Z_Ie^2}{|\mathbf{r}_i-\mathbf{R}_I|}+\frac{1}{2}\sum_{i,j}\frac{e^2}{|\mathbf{r}_i-\mathbf{r}_j|}+\frac{1}{2}\sum_{I,J}\frac{Z_IZ_Je^2}{|\mathbf{R}_I-\mathbf{R}_J|}\right]\Psi_\alpha\left(\{\mathbf{r}_i\}:\{\mathbf{R}_I\}\right)\\&=W_\alpha\left(\{\mathbf{R}_I\}\right)\Psi_\alpha\left(\{\mathbf{r}_i\}:\{\mathbf{R}_I\}\right)\end{aligned} \tag{1.11}$$

while $u_{n\alpha}\left(\{\mathbf{R}_I\}\right)$ are the wave-functions for the nuclear motion, and they satisfy the equation

$$\left[-\sum_I\frac{\hbar^2}{2M_I}\nabla_I^2+W_\alpha\left(\{\mathbf{R}_I\}\right)-E\right]u_{n\alpha}\left(\{\mathbf{R}_I\}\right)=0, \tag{1.12}$$

within the so-called "frozen phonon" approximation. By going beyond the Born-Oppenheimer approximation, a perturbation theory can be developed for the electron-phonon interactions, which are responsible for the inelastic scattering of electrons in metals, polaron formation in ionic crystals, and pairing of electrons in some metals and compounds. As such, it is important to focus on the electronic dynamics as described by Eq. (1.11) with the nuclear positions $\{\mathbf{R}_I\}$ as parameters. It has no effect whether we solve for W including nucleus-nucleus repulsive interaction or solve the following equation

$$\left[-\sum_i\frac{\hbar^2}{2m_e}\nabla_i^2-\sum_{i,I}\frac{Z_Ie^2}{|\mathbf{r}_i-\mathbf{R}_I|}+\frac{1}{2}\sum_{i,j}\frac{e^2}{|\mathbf{r}_i-\mathbf{r}_j|}\right]\Psi_\alpha\left(\{\mathbf{r}_i\}:\{\mathbf{R}_I\}\right)=E_\alpha\left(\{\mathbf{R}_I\}\right)\Psi_\alpha\left(\{\mathbf{r}_i\}:\{\mathbf{R}_I\}\right) \tag{1.13}$$

and add the nucleus-nucleus repulsive interaction afterwards. Equation (1.13) must be solved with the appropriate boundary conditions for the wave-functions. For example, $\Psi_\alpha\left(\{\mathbf{r}_i\}:\{\mathbf{R}_I\}\right)$ must be vanishing when the electrons are infinitely far away from an isolated atom or molecule, or must be satisfying the periodic boundary condition for crystalline solids. Also since electrons are spin- $\frac{1}{2}$ fermions, the wavefunctions Ψ_α must be antisymmetric with the interexchange of two electrons. Even so, due to the inter-electron Coulomb repulsion, Eq.(1.13) cannot be solved directly except for problems with few number of electrons. The difficulty in solving it numerically grows exponentially with the increase in the number of correlated electrons. This exponential problem will not be overcome for the cases involving many correlated electrons, which are typical in solids, regardless of the fact that the computational power is continuing to grow rapidly.

[1] For simplicity, the discussion is restricted to the non-relativistic limit. For a fully relativistic description, the kinetic energy at least for the electronic degrees of freedom should be replaced by the Dirac Hamiltonian.

To approach this problem, two strategies are mostly taken. One is to directly deal with Eq. (1.13) and map it onto a single-particle Hamiltonian while the other is to dramatically reduce Eq. (1.13) to an effective quantum many-body Hamiltonian so that electronic correlation effects can be qualitatively understood. The former is borne out within density functional theory (DFT) [11], in which the problem is made equivalent to solving the single-particle Kohn-Sham equations [12]:

$$\left[-\frac{\hbar^2}{2m_e}\nabla^2 + V_{\mathrm{KS},s}(\mathbf{r})\right]\psi_{s,\alpha}(\mathbf{r}) = E_{s,\alpha}\psi_{s,\alpha}(\mathbf{r}) \tag{1.14}$$

with

$$V_{\mathrm{KS},s}(\mathbf{r}) = -\sum_I \frac{Z_I e^2}{|\mathbf{r}-\mathbf{R}_I|} + \int d^3r' \frac{e^2 n(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|} + V_{\mathrm{xc},s}(\mathbf{r}) \tag{1.15}$$

In Eq. (1.14), $\psi_{s,\alpha}$ and $E_{s,\alpha}$ are the Kohn-Sham eigenfunctions and the corresponding eigenvalues for spin projection s. In the DFT framework, the electronic correlation effects are encoded in the exchange-correlation potential $V_{\mathrm{xc},s}(\mathbf{r})$.[2] A schematic drawing of this single-particle problem is shown in Fig. 1.2.

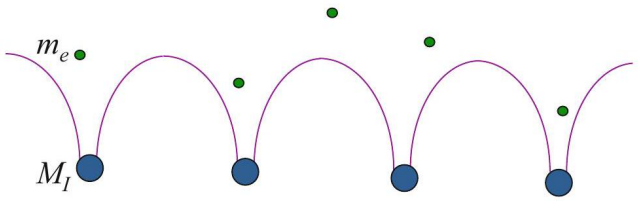

Fig. 1.2 Single-particle Hamiltonian of a solid consisting of electrons in a frozen lattice of nuclei

Since the single-particle Kohn-Sham potential $V_{\mathrm{KS},s}$ is in turn determined by the Kohn-Sham eigenfunctions via the local electron density $n(\mathbf{r}) = \sum_s \sum_{\alpha=1}^{N_s} |\psi_{s,\alpha}(\mathbf{r})|^2$ with the total number of $N_e = N_\uparrow + N_\downarrow$ electrons occupying N_e lowest-lying spin-orbitals, the KohnSham equations (1.14) should be solved self-consistently. Although the mapping from Eq.(1.13) to Eq.(1.14) is exact under the Hohenberg-Kohn theorem [13] for the ground state, the construction of the functional itself is nontrivial. So far the local density approximation (LDA) and its variants like generalized-gradient approximation (GGA) are the most often used. The LDA- or GGA-based DFT theory has been very successful in describing many materials for both groundstate energies and band structures, suggesting weak electronic correlations in these materials. However, the LDA-based DFT is not successful in describing other important classes of materials with open d - and f-shell orbitals (i.e., with partially occupied valence electrons occupying these orbitals). For example, LDA-based DFT predicts such transition metal oxides as La_2CuO_4, MnO, and NiO to be metals but they are insulators in reality. Similarly, for intermetallic f-electron systems like lanthanides and actinides, the LDA-based DFT usually gives effective mass of quasiparticles around the Fermi energy one or two orders of magnitude smaller than the experimental values. This failure demonstrates that the LDA-based DFT does not adequately address the electronic correlations in these materials, where the electrons experience very strong Coulomb repulsion when they occupy these narrow orbitals. The construction of more powerful exchange-correlation functionals for these narrow band materials remains a challenge in the DFT community [14].

Instead in the latter strategic approach, the electronic correlations are addressed directly by treating the competition between electron kinetic energy and interelectron potential energy in a quantum many-body manner but within a much simplified low-energy model Hamiltonian

[15, 16]. Some representative low-energy models will be presented after we introduce the second quantization in the next section.

9.5.2 1.3 Second Quantization of Hopping Hamiltonians

Theory

The direct treatment of the quantum many-body systems through the Schrödinger wave-function method is cumbersome and is not practical. It is convenient to use the second quantization to discuss the many identical interacting particles. As we recall, in the first quantization, the physical observables become quantum mechanical operators and the total energy is the expectation value of the Hamiltonian operator against the many-particle wave-function, which is the summation of the contributions for the single-particle kinetic energy and two-particle potential energy. In the second quantization, the wave-function itself becomes field operators, which can be expressed in the particle occupation number representation. In this representation, the many-particle state can be described by the occupation of identical particles in each single-particle state and the statistics symmetry regarding the particle being of Bose or Fermi character is protected in each step. This field quantization method is not only essential for the description of particle creation and destruction in the relativistic quantum field theory, but also powerful to describe the strongly correlated electronic systems.

For the correlated electrons as described by the Schrödinger equation (1.13), the Hamiltonian can be rewritten as

$$\mathscr{H}_e = \sum_i h\left(\mathbf{r}_i\right) + \frac{1}{2}\sum_{ij} v_{ee}\left(|\mathbf{r}_i - \mathbf{r}_j|\right), \tag{1.16}$$

where the single-particle operator

$$h\left(\mathbf{r}_i\right) = -\frac{\hbar^2}{2m_e}\nabla_i^2 - \sum_I \frac{Z_I e^2}{|\mathbf{r}_i - \mathbf{R}_I|} \tag{1.17}$$

and the two particle operator

$$v_{ee}\left(|\mathbf{r}_i - \mathbf{r}_j|\right) = \frac{e^2}{|\mathbf{r}_i - \mathbf{r}_j|} \tag{1.18}$$

Since electrons are fermions, the Hamiltonian (1.16) in the second quantized form is given by Fetter and Walecka [17], Mahan [18]

$$\hat{\mathscr{H}_e} = \int d\mathbf{x}\hat{\psi}^\dagger(\mathbf{x})h(\mathbf{x})\hat{\psi}(\mathbf{x}) + \frac{1}{2}\iint d\mathbf{x}d\mathbf{x}'\hat{\psi}^\dagger(\mathbf{x})\hat{\psi}^\dagger\left(\mathbf{x}'\right)v_{ee}\left(\mathbf{x},\mathbf{x}'\right)\hat{\psi}\left(\mathbf{x}'\right)\hat{\psi}(\mathbf{x}) \tag{1.19}$$

The first term on the right-hand side describes the non-interacting (also called single-particle) part of electrons while the second term the electron-electron interaction. Here the variable $\mathbf{x}$ denotes both the real-space coordinates $\mathbf{r}$ and the spin projection (usually along the z-axis) s, that is, $\mathbf{x} \equiv (\mathbf{r}, s)$. Different from the continuous variable $\mathbf{r}$, the spin projection can only take the discretized values,
$s = \pm\hbar/2$.[3] Therefore, a summation is implied in the integral over the spin index in $\mathbf{x}$. In Eq. (1.19), the field operator $\hat{\psi}^\dagger(\mathbf{x})(\hat{\psi}(\mathbf{x}))$ creates (annihilates) an electron at a coordinate $\mathbf{x}$, and they satisfy the anticommutation rules as

[2] A spin index is introduced to allow for possible magnetic states. However, for simplicity of the discussion, the spin-orbit coupling effect is neglected.

$$\left\{\hat{\psi}(\mathbf{x}), \hat{\psi}\left(\mathbf{x}'\right)\right\} = 0 \tag{1.20a}$$

$$\left\{\hat{\psi}^{\dagger}(\mathbf{x}), \hat{\psi}^{\dagger}\left(\mathbf{x}'\right)\right\} = 0 \tag{1.20b}$$

$$\left\{\hat{\psi}(\mathbf{x}), \hat{\psi}^{\dagger}\left(\mathbf{x}'\right)\right\} = \delta\left(\mathbf{x}-\mathbf{x}'\right) \tag{1.20c}$$

We note that the field operator $\hat{\psi}^{\dagger}(\mathbf{x})$ is the hermitian conjugate of $\hat{\psi}(\mathbf{x})$. Here the curly brackets represent the anticommutator, i.e., for two operators $\hat{A}$ and $\hat{B}$,

$$\{\hat{A}, \hat{B}\} = \hat{A}\hat{B} + \hat{B}\hat{A} \tag{1.21}$$

The δ-function is understood as Dirac-type for the continuous spatial coordinates while as Kronecker-type for the discrete variables, that is,

$$\delta\left(\mathbf{x}-\mathbf{x}'\right) = \delta\left(\mathbf{r}-\mathbf{r}'\right)\delta_{ss'} \tag{1.22}$$

More generally, if the single-particle Hamiltonian is non-local in the $\mathbf{x}$ coordinate space, which is especially true when the spin-orbit coupling due to the relativistic effect is included, the single-particle Hamiltonian takes the form of $h\left(\mathbf{x}, \mathbf{x}'\right)$. The system Hamiltonian of correlated electrons is then written as

$$\hat{\mathscr{H}_e} = \iint d\mathbf{x}d\mathbf{x}'\hat{\psi}^{\dagger}(\mathbf{x})h\left(\mathbf{x}, \mathbf{x}'\right)\hat{\psi}\left(\mathbf{x}'\right) + \frac{1}{2}\iint d\mathbf{x}d\mathbf{x}'\hat{\psi}^{\dagger}(\mathbf{x})\hat{\psi}^{\dagger}\left(\mathbf{x}'\right)v_{ee}\left(\mathbf{x}, \mathbf{x}'\right)\hat{\psi}\left(\mathbf{x}'\right)\hat{\psi}(\mathbf{x}). \tag{1.23}$$

Similarly, for any single-particle operator having

$$\mathscr{O} = \sum_i O\left(\mathbf{r}_i\right) \tag{1.24}$$

in the first quantization, its second quantized form is given by

$$\mathscr{O} = \int d\mathbf{x}\hat{\psi}^{\dagger}(\mathbf{x})O(\mathbf{x})\hat{\psi}(\mathbf{x}) \tag{1.25}$$

or

$$\mathscr{O} = \iint d\mathbf{x}d\mathbf{x}'\hat{\psi}^{\dagger}(\mathbf{x})O\left(\mathbf{x}, \mathbf{x}'\right)\hat{\psi}\left(\mathbf{x}'\right) \tag{1.26}$$

for the non-local case. In addition, although the original electron-electron interaction v_{ee} is repulsive, the second quantized Hamiltonian for the low-energy modeling remains to have the similar form even if inter-particle interaction is attractive.

Depending on the specific form of the Hamiltonian to be studied, the field operators can be expanded in terms of a complete set of basis functions, which are usually the eigenstates of the single-particle part of the Hamiltonian.

In the jellium model, where an interacting electron gas is placed in a background of the uniformly distributed positive charges, it is convenient to write the field operators as a linear combination of creation and annihilation operators corresponding to plane waves

$$\psi_{\sigma}(\mathbf{r}) = \frac{1}{\sqrt{\mathscr{V}}}\sum_{\mathbf{k}} e^{i\mathbf{k}\cdot\mathbf{r}}c_{\mathbf{k}\sigma}, \tag{1.27a}$$

$$\psi_{\sigma}^{\dagger}(\mathbf{r}) = \frac{1}{\sqrt{\mathscr{V}}}\sum_{\mathbf{k}} e^{-i\mathbf{k}\cdot\mathbf{r}}c_{\mathbf{k}\sigma}^{\dagger}, \tag{1.27b}$$

[3] Later on, we will also interchangeably use the symbol $\sigma = \pm 1$ for the spin variables, $s = (\hbar/2)\sigma$.

where $\mathscr{V}$ denotes the volume of the gas, and the annihilation and creation operators $c_{i\sigma}$ and $c_{i\sigma}^{\dagger}$ satisfy the anticommutation relation for fermions

$$\left\{c_{\mathbf{k}\sigma}, c_{\mathbf{k}'\sigma'}^{\dagger}\right\} = \delta_{\mathbf{k}\mathbf{k}'}\delta_{\sigma\sigma'} \tag{1.28a}$$

$$\{c_{\mathbf{k}\sigma}, c_{\mathbf{k}'\sigma'}\} = \left\{c_{\mathbf{k}\sigma}^{\dagger}, c_{\mathbf{k}'\sigma'}^{\dagger}\right\} = 0. \tag{1.28b}$$

Accordingly, the second quantized Hamiltonian for the interacting electron gas is given by

$$\mathscr{H} = \sum_{\mathbf{k}\sigma} \varepsilon_{\mathbf{k}} c_{\mathbf{k}\sigma}^{\dagger} c_{\mathbf{k}\sigma} + \frac{1}{2\mathscr{V}} \sum_{\mathbf{q}\neq 0} \sum_{\mathbf{k}\mathbf{k}'} \sum_{\sigma\sigma'} v_{ee}(\mathbf{q}) c_{\mathbf{k}+\mathbf{q},\sigma}^{\dagger} c_{\mathbf{k}'-\mathbf{q},\sigma'}^{\dagger} c_{\mathbf{k}'\sigma'} c_{\mathbf{k}\sigma} \tag{1.29}$$

where

$$\varepsilon_{\mathbf{k}} = \frac{\hbar^2 k^2}{2m_e} \tag{1.30}$$

is the single-particle energy dispersion and

$$v_{ee}(\mathbf{q}) = \frac{4\pi e^2}{q^2} \tag{1.31}$$

is the Fourier transform of the long-ranged Coulomb repulsion.

For the narrow band materials, the electronic correlations are significant. It is convenient to represent the field operators in terms of local orbitals. Representative examples of these local orbitals are Wannier orbitals or local atomic orbitals within the tight-binding approximation (TBA) to the systems with large atomic distances. If we consider only a single narrow band to be partially filled in a solid, the field operators can be represented as

$$\psi_{\sigma}(\mathbf{r}) = \sum_{i} \phi\left(\mathbf{r} - \mathbf{R}_i\right) c_{i\sigma} \tag{1.32a}$$

$$\psi_{\sigma}^{\dagger}(\mathbf{r}) = \sum_{i} \phi^{*}\left(\mathbf{r} - \mathbf{R}_i\right) c_{i\sigma}^{\dagger} \tag{1.32b}$$

where $\phi\left(\mathbf{r} - \mathbf{R}_i\right)$ is the localized orbital at atomic site $\mathbf{R}_i$, and the annihilation and creation operators $c_{i\sigma}$ and $c_{i\sigma}^{\dagger}$ satisfy the anticommutation relation for fermions

$$\left\{c_{i\sigma}, c_{j\sigma'}^{\dagger}\right\} = \delta_{ij}\delta_{\sigma\sigma'}, \tag{1.33a}$$

$$\{c_{i\sigma}, c_{j\sigma'}\} = \left\{c_{i\sigma}^{\dagger}, c_{j\sigma'}^{\dagger}\right\} = 0. \tag{1.33b}$$

The Hamiltonian for the single-orbital Hubbard model is given by Hubbard [1]

$$\mathscr{H} = -\sum_{ij} t_{ij} c_{i\sigma}^{\dagger} c_{j\sigma} + \frac{U}{2} \sum_{i\sigma} n_{i\sigma} n_{i\bar{\sigma}} \tag{1.34}$$

where $\bar{\sigma} = -\sigma$ with $\sigma = +1$ or $\uparrow$ for spin up and $\sigma = -1$ or $\downarrow$ for spin down,

$$t_{ij} = -\int d\mathbf{r} \phi^{*}\left(\mathbf{r} - \mathbf{R}_i\right) h(\mathbf{r}) \phi\left(\mathbf{r} - \mathbf{R}_j\right) \tag{1.35}$$

is the hopping integral between two atomic sites,

$$U = e^2 \iint d\mathbf{r} d\mathbf{r}' \frac{|\phi(\mathbf{r} - \mathbf{R}_i)|^2 |\phi(\mathbf{r}' - \mathbf{R}_i)|^2}{|\mathbf{r} - \mathbf{r}'|} \tag{1.36}$$

To derive this Hubbard model, the multi-center integral for the Coulomb interaction has been neglected.

Similarly, within the TBA, the Anderson lattice model is defined as [19]

$$\mathscr{H} = -\sum_{i,\sigma} t_{ij} c_{i\sigma}^{\dagger} c_{j\sigma} + \sum_{ij,\sigma\alpha} \left(V_{i\sigma,j\alpha} c_{i\sigma}^{\dagger} f_{j\alpha} + \text{ H.c. } \right) + \sum_{i,\alpha} \varepsilon_i^f f_{i\alpha}^{\dagger} f_{i\alpha} + \frac{U_f}{2} \sum_i n_{i\alpha}^f n_{i\bar{\alpha}}^f \tag{1.37}$$

Here the localized f-orbitals with energy level ε_i^f is hybridized with the conduction band while the electrons within the localized f-orbital electrons experience Hubbard- U repulsion. The quantity $V_{i\sigma,j\alpha}$ is the hybridization strength and the index α represents a two-component quantum state of the f-orbital.

These minimal models have been intensively used for understanding such emergent phenomena as localization-delocalization, heavy fermion, magnetism and superconductivity in transition metal oxides and intermetallic f-electron systems in condensed matter physics community. The creation and annihilation operators in the second quantization are also the central elements in the definition of Green's functions, which are used in quantum many-body theory. In particular, the Green's functions have been used as convenient quantities to evaluate the dynamic self-energies within the dynamical mean-field theory (DMFT) [20] for strongly correlated electronic systems, which maps the quantum lattice manybody problem to an effective quantum impurity one (still strongly correlated!). Recently, the LDA+DMFT approach [21-23] has been developed to investigate strongly correlated electronic materials. The approach incorporates the merits from both LDA and DMFT, and has been successful in giving a unified description of electronic states from weak to strong coupling limits, on the aspects of quasiparticle renormalization and magnetism. As for the phenomenology of superconductivity and related ordering states, the above quantum many-body approaches also lay down the foundations for the effective modeling description covered in the following chapters.

9.5.3 1.5 Derivation of the BdG Equations in the Continuum Model

The BdG [9] approach relies on the assumption that there exist well-defined quasiparticles in the superconductor. It has the advantage of providing information about the one-particle excitations of the system. The quasiparticle excitation spectrum can be obtained, together with the corresponding quasiparticle amplitudes. The BdG formalism is essentially correct in the weak-coupling regime, but also yields qualitative results in situations of very strong coupling, as was pointed out by Bishop et al. [24]. The interest in microscopic electronic structure calculations of this type was revived by low-temperature scanning-tunneling-microscopy (STM) experiments which provided extremely detailed, spatially resolved, excitation spectra around a single impurity, near the interface/surface, and around a vortex core in the presence of an Abrikosov flux lattice. An explanation of these results requires the knowledge of the one-particle local density of states of the system, which is best described in the framework of the BdG theory.

1.5.1 Derivation

We start with the second-quantized Hamiltonian for electrons experiencing an effective two-particle attractive interaction:

$$\mathscr{H} = \int d\mathbf{r}\psi_\alpha^\dagger(\mathbf{r})h_\alpha(\mathbf{r})\psi_\alpha(\mathbf{r}) - \frac{1}{2}\iint d\mathbf{r}d\mathbf{r}' V_{\text{eff}}\left(\mathbf{r},\mathbf{r}'\right)\psi_\alpha^\dagger(\mathbf{r})\psi_\beta^\dagger\left(\mathbf{r}'\right)\psi_\beta\left(\mathbf{r}'\right)\psi_\alpha(\mathbf{r}) \tag{1.38}$$

Here $\psi_\alpha^\dagger(\mathbf{r})$ and $\psi_\alpha(\mathbf{r})$ are creation and annihilation field operators of an electron with spin α at position $\mathbf{r}$. They obey the anti-commutation relation

$$\left\{\psi_\alpha(\mathbf{r}), \psi_\beta^\dagger\left(\mathbf{r}'\right)\right\} = \delta\left(\mathbf{r}-\mathbf{r}'\right)\delta_{\alpha\beta}, \tag{1.39}$$

$$\left\{\psi_\alpha(\mathbf{r}), \psi_\beta\left(\mathbf{r}'\right)\right\} = \left\{\psi_\alpha^\dagger(\mathbf{r}), \psi_\beta^\dagger\left(\mathbf{r}'\right)\right\} = 0. \tag{1.40}$$

The single particle Hamiltonian is given by

$$h_\alpha(\mathbf{r}) = \frac{\left[\frac{\hbar}{i}\nabla_{\mathbf{r}} + \frac{e}{c}\mathbf{A}(\mathbf{r})\right]^2}{2m_e} - e\phi(\mathbf{r}) + \alpha\mu_B H(\mathbf{r}) - E_F, \tag{1.41}$$

with $\mathbf{A}(\mathbf{r})$ and $\phi(\mathbf{r})$ the vector and scalar potentials. The magnetic field $H(\mathbf{r})$ has assumed to be along the z direction. The single particle energy is measured relative to the Fermi energy E_F. We have also chosen $V_{\text{eff}}\ (\mathbf{r},\mathbf{r}')$ to be positive while introduced a prefactor "-" to denote the attractive interaction in the second term of Eq. (1.38). Of course, the symmetry relation $V_{\text{eff}}\ (\mathbf{r}',\mathbf{r}) = V_{\text{eff}}\ (\mathbf{r},\mathbf{r}')$ still holds. The repeated spin index means the summation. Since we are most interested in the electron pairing in a superconductor, we can perform a Hartree-Fock-like meanfield approximation to the second term of Eq.(1.38) but in the particle-particle pairing channel. [4] A caution should be taken that this assumption is reasonable at low temperatures when the system is deep into the superconducting state, and the superconducting phase fluctuation, which is important near the transition temperature, is neglected. The mean-field Hamiltonian can then be written as follows:

$$\mathscr{H}_{eff} = \int d\mathbf{r}\psi_\alpha^\dagger(\mathbf{r})h_\alpha(\mathbf{r})\psi_\alpha(\mathbf{r}) + \iint d\mathbf{r}d\mathbf{r}'\left[\Delta\left(\mathbf{r},\mathbf{r}'\right)\psi_\uparrow^\dagger(\mathbf{r})\psi_\downarrow^\dagger\left(\mathbf{r}'\right) + \text{ H.c. }\right] + \iint d\mathbf{r}d\mathbf{r}'\frac{\left|\Delta\left(\mathbf{r},\mathbf{r}'\right)\right|^2}{V_{\text{eff}}\ (\mathbf{r},\mathbf{r}')} \tag{1.42}$$

where the pair potential is given by

$$\Delta\left(\mathbf{r},\mathbf{r}'\right) = -V_{\text{eff}}\ \left(\mathbf{r}-\mathbf{r}'\right)\left\langle\psi_\downarrow\left(\mathbf{r}'\right)\psi_\uparrow(\mathbf{r})\right\rangle = V_{\text{eff}}\ \left(\mathbf{r}-\mathbf{r}'\right)\left\langle\psi_\uparrow(\mathbf{r})\psi_\downarrow\left(\mathbf{r}'\right)\right\rangle, \tag{1.43}$$

$$\Delta^*\left(\mathbf{r},\mathbf{r}'\right) = -V_{\text{eff}}\ \left(\mathbf{r}-\mathbf{r}'\right)\left\langle\psi_\uparrow^\dagger(\mathbf{r})\psi_\downarrow^\dagger\left(\mathbf{r}'\right)\right\rangle = V_{\text{eff}}\ \left(\mathbf{r}-\mathbf{r}'\right)\left\langle\psi_\downarrow^\dagger\left(\mathbf{r}'\right)\psi_\uparrow^\dagger(\mathbf{r})\right\rangle. \tag{1.44}$$

The effective Hamiltonian equation (1.42) is in a bi-linear form and can be diagonalized exactly. By using the commutation relation for fermionic operators $\hat{A},\hat{B},\hat{C}$

$$[A,BC]_- = \{A,B\}C - B\{A,C\}, \tag{1.45}$$

and the function property

$$\int dx' f\left(x'\right)\frac{d\delta\left(x-x'\right)}{dx'} = -\frac{df(x)}{dx} \tag{1.46}$$

we obtain the following relations

$$[\psi_\uparrow(\mathbf{r}), \mathscr{H}_{eff}]_- = h_\uparrow(\mathbf{r})\psi_\uparrow(\mathbf{r}) + \int d\mathbf{r}'\Delta(\mathbf{r},\mathbf{r}')\,\psi_\downarrow^\dagger(\mathbf{r}'), \tag{1.47a}$$

$$\left[\psi_\uparrow^\dagger(\mathbf{r}), \mathscr{H}_{eff}\right]_- = -h_\uparrow^*(\mathbf{r})\psi_\uparrow^\dagger(\mathbf{r}) - \int d\mathbf{r}'\Delta^*(\mathbf{r},\mathbf{r}')\,\psi_\downarrow(\mathbf{r}'), \tag{1.47b}$$

$$[\psi_\downarrow(\mathbf{r}), \mathscr{H}_{eff}]_- = h_\downarrow(\mathbf{r})\psi_\downarrow(\mathbf{r}) - \int d\mathbf{r}'\Delta(\mathbf{r}',\mathbf{r})\,\psi_\uparrow^\dagger(\mathbf{r}'), \tag{1.47c}$$

$$\left[\psi_\downarrow^\dagger(\mathbf{r}), \mathscr{H}_{eff}\right]_- = -h_\downarrow^*(\mathbf{r})\psi_\downarrow(\mathbf{r}) + \int d\mathbf{r}'\Delta^*(\mathbf{r}',\mathbf{r})\,\psi_\uparrow(\mathbf{r}'). \tag{1.47d}$$

Note that $h^*(\mathbf{r}) \neq h(\mathbf{r})$. Equations (1.47)(a)-(d) show that the electron field operator can be expressed as a linear combination of electron- and hole-like quasiparticle excitations, which enables us to perform a Bogoliubov canonical transformation [25, 26]:

$$\psi_\sigma(\mathbf{r}) = \sum_n \left[u_{n\sigma}(\mathbf{r})\gamma_n - \sigma v_{n\sigma}^*(\mathbf{r})\gamma_n^\dagger\right]. \tag{1.48}$$

Be reminded the summation is over the excitation states with positive energy. In the expanded form for each individual spin projection, the transformation becomes

$$\psi_\uparrow(\mathbf{r}) = \sum_n \left[u_\uparrow^n(\mathbf{r})\gamma_n - v_\uparrow^{n*}(\mathbf{r})\gamma_n^\dagger\right], \qquad \psi_\uparrow^\dagger(\mathbf{r}) = \sum_n \left[u_\uparrow^{n*}(\mathbf{r})\gamma_n^\dagger - v_\uparrow^n(\mathbf{r})\gamma_n\right], \tag{1.49}$$

$$\psi_\downarrow(\mathbf{r}) = \sum_n \left[u_\downarrow^n(\mathbf{r})\gamma_n + v_\downarrow^{n*}(\mathbf{r})\gamma_n^\dagger\right], \qquad \psi_\downarrow^\dagger(\mathbf{r}) = \sum_n \left[u_\downarrow^{n*}(\mathbf{r})\gamma_n^\dagger + v_\downarrow^n(\mathbf{r})\gamma_n\right]. \tag{1.50}$$

In the above transformation, the quasiparticle operators γ_n and $\gamma_n^\dagger$ are also fermionic operators obeying the anti-commutation relation

$$\left\{\gamma_n, \gamma_m^\dagger\right\} = \delta_{nm}, \tag{1.51}$$

$$\{\gamma_n, \gamma_m\} = \left\{\gamma_n^\dagger, \gamma_m^\dagger\right\} = 0. \tag{1.52}$$

The anti-communication relation between the quasiparticle operators also ensures the anti-communication relation for the original electron field operators given in Eqs. (1.39) and (1.40).

The remaining task is to establish the eigen-equation for the quasiparticle wave functions $(u_\sigma(\mathbf{r}), v_\sigma(\mathbf{r}))^{\mathrm{T}}$. Assume the diagonalized Hamiltonian to be

$$\mathscr{H}_{eff} = E_g + \sum_n E_n\gamma_n^\dagger\gamma_n \tag{1.53}$$

where the excitation energy is positive and E_g is the ground state energy. We first observe the following commutation relations

$$\left[\gamma_n^\dagger, \mathscr{H}_{eff}\right]_- = -E_n\gamma_n^\dagger, \tag{1.54}$$

$$[\gamma_n, \mathscr{H}_{eff}]_- = E_n\gamma_n. \tag{1.55}$$

[4] We notice that the normal-state Hartree-Fock term can be absorbed into the chemical potential, which will not modify the results qualitatively.

[5] Here we only consider the spin-singlet pairing, in which a spin-up electron is paired with a spin-down electron. The spin-triplet pairing, in which electrons are paired with equal spin, can be discussed similarly.

(add the derivation of them here!!!)

Upon the substitution of Eqs. (1.49) and (1.50), and with the aid of Eqs. (1.54) and (1.55), we can compare the coefficients of these terms with γ_n and $\gamma_n^\dagger$ and arrive at the following set of equations:

$$\begin{cases} h_\uparrow(\mathbf{r})u_\uparrow^n(\mathbf{r}) + \int d\mathbf{r}'\Delta\left(\mathbf{r},\mathbf{r}'\right)v_\downarrow^n\left(\mathbf{r}'\right) = E_n u_\uparrow^n(\mathbf{r}), \\ h_\downarrow(\mathbf{r})u_\downarrow^n(\mathbf{r}) + \int d\mathbf{r}'\Delta\left(\mathbf{r}',\mathbf{r}\right)v_\uparrow^n\left(\mathbf{r}'\right) = E_n u_\downarrow^n(\mathbf{r}), \\ \int d\mathbf{r}'\Delta^*\left(\mathbf{r},\mathbf{r}'\right)u_\downarrow^n\left(\mathbf{r}'\right) - h_\uparrow^*(\mathbf{r})v_\uparrow^n(\mathbf{r}) = E_n v_\uparrow^n(\mathbf{r}), \\ \int d\mathbf{r}'\Delta^*\left(\mathbf{r}',\mathbf{r}\right)u_\uparrow^n\left(\mathbf{r}'\right) - h_\downarrow^*(\mathbf{r})v_\downarrow^n(\mathbf{r}) = E_n v_\downarrow^n(\mathbf{r}). \end{cases} \tag{1.56}$$

To see the structure of the above set of equations more clearly, we can write it into a compact matrix form:

$$\int d\mathbf{r}'\hat{M}\left(\mathbf{r},\mathbf{r}'\right)\hat{\phi}\left(\mathbf{r}'\right) = E_n\hat{\phi}(\mathbf{r}) \tag{1.57}$$

where

$$\hat{M}\left(\mathbf{r},\mathbf{r}'\right) = \begin{bmatrix} h_\uparrow(\mathbf{r})\delta\left(\mathbf{r}-\mathbf{r}'\right) & 0 & 0 & \Delta\left(\mathbf{r},\mathbf{r}'\right) \\ 0 & h_\downarrow(\mathbf{r})\delta\left(\mathbf{r}-\mathbf{r}'\right) & \Delta\left(\mathbf{r}',\mathbf{r}\right) & 0 \\ 0 & \Delta^*\left(\mathbf{r},\mathbf{r}'\right) & -h_\uparrow^*(\mathbf{r})\delta\left(\mathbf{r}-\mathbf{r}'\right) & 0 \\ \Delta^*\left(\mathbf{r}',\mathbf{r}\right) & 0 & 0 & -h_\downarrow^*(\mathbf{r})\delta\left(\mathbf{r}-\mathbf{r}'\right) \end{bmatrix} \tag{1.58}$$

and

$$\hat{\phi}\left(\mathbf{r}'\right) = \begin{pmatrix} u_\uparrow^n(\mathbf{r}) \\ u_\downarrow^n(\mathbf{r}) \\ v_\uparrow^n(\mathbf{r}) \\ v_\downarrow^n(\mathbf{r}) \end{pmatrix}. \tag{1.59}$$

From Eq. (1.58), we can see that in the absence of spin-orbit coupling and other spin-flip scattering interactions, the set of equations as given by Eq. (1.58) is blocked diagonalized into two subsets of equations:

$$\begin{cases} h_\uparrow(\mathbf{r})u_\uparrow^{\tilde{n}1}(\mathbf{r}) + \int d\mathbf{r}'\Delta\left(\mathbf{r},\mathbf{r}'\right)v_\downarrow^{\tilde{n}1}\left(\mathbf{r}'\right) = E_{\tilde{n}1}u_\uparrow^{\tilde{n}1}(\mathbf{r}), \\ \int d\mathbf{r}'\Delta^*\left(\mathbf{r}',\mathbf{r}\right)u_\uparrow^{\tilde{n}1}\left(\mathbf{r}'\right) - h_\downarrow^*(\mathbf{r})v_\downarrow^{\tilde{n}1}(\mathbf{r}) = E_{\tilde{n}1}v_\downarrow^{\tilde{n}1}(\mathbf{r}), \end{cases} \tag{1.60}$$

and

$$\begin{cases} h_\downarrow(\mathbf{r})u_\downarrow^{\tilde{n}2}(\mathbf{r}) + \int d\mathbf{r}'\Delta\left(\mathbf{r}',\mathbf{r}\right)v_\uparrow^{\tilde{n}2}\left(\mathbf{r}'\right) = E_{\tilde{n}2}u_\downarrow^{\tilde{n}2}(\mathbf{r}), \\ \int d\mathbf{r}'\Delta^*\left(\mathbf{r},\mathbf{r}'\right)u_\downarrow^{\tilde{n}2}\left(\mathbf{r}'\right) - h_\uparrow^*(\mathbf{r})v_\uparrow^{\tilde{n}2}(\mathbf{r}) = E_{\tilde{n}2}v_\uparrow^{\tilde{n}2}(\mathbf{r}). \end{cases}$$

That is, the spin-up electron-like component of wave function $u_\uparrow(\mathbf{r})$ is coupled only to the spin-down hole-like component of wave function $v_\downarrow(\mathbf{r})$ while the spin-down electron-like component of wave function $u_\downarrow(\mathbf{r})$ is coupled only to the spin-up holelike component of wave function $v_\uparrow(\mathbf{r})$. Each of these two subsets of equations are now a 2 by 2 matrix equation in the Nambu space. By breaking the $U(1)$ gauge symmetry, this unusual space allows the emergence

of superconducting pairing state. The mathematical structure of these equations looks similar to those describing the coupling between particles in conduction band and holes in the valence band in semiconductor physics. However, we should be cautioned that the origin of these equations in superconductors is really due to an effective electronelectron pairing. To be clear, we have redefined the number of eigenstate index. If the original set of eigen-equations as given in Eq. (1.56) has N number of eigenvalues, each subset of eigen-equations will have $N/2$ number of eigenvalues. In this decoupling, the diagonalized Hamiltonian as given in Eq.(1.53) can be written as:

$$\mathscr{H}_{eff} = E_g + \sum_{\tilde{n}\mu} E_{\tilde{n}\mu}\gamma^{\dagger}_{\tilde{n}\mu}\gamma_{\tilde{n}\mu} \tag{1.62}$$

with $\mu = 1, 2$. Correspondingly, the canonical transform can also be re-written as:

$$\begin{aligned}
\psi_{\uparrow}(\mathbf{r}) &= \sum_{\tilde{n}} \left[u^{\tilde{n}1}_{\uparrow}(\mathbf{r})\gamma_{\tilde{n}1} - v^{\tilde{n}2*}_{\uparrow}(\mathbf{r})\gamma^{\dagger}_{\tilde{n}2} \right], \qquad \psi^{\dagger}_{\uparrow}(\mathbf{r}) = \sum_{\tilde{n}} \left[u^{\tilde{n}1*}_{\uparrow}(\mathbf{r})\gamma^{\dagger}_{\tilde{n}1} - v^{\tilde{n}2}_{\uparrow}(\mathbf{r})\gamma_{\tilde{n}2} \right], \\
\psi_{\downarrow}(\mathbf{r}) &= \sum_{\tilde{n}} \left[u^{\tilde{n}2}_{\downarrow}(\mathbf{r})\gamma_{\tilde{n}2} + v^{\tilde{n}1*}_{\downarrow}(\mathbf{r})\gamma^{\dagger}_{\tilde{n}1} \right], \qquad \psi^{\dagger}_{\downarrow}(\mathbf{r}) = \sum_{\tilde{n}} \left[u^{\tilde{n}2*}_{\downarrow}(\mathbf{r})\gamma^{\dagger}_{\tilde{n}2} + v^{\tilde{n}1}_{\downarrow}(\mathbf{r})\gamma_{\tilde{n}1} \right].
\end{aligned} \tag{1.63}$$

We now prove that the set of equations given by Eqs. (1.60) and (1.61) has the following symmetry property: If $\left(u^{\tilde{n}1}_{\uparrow}, v^{\tilde{n}1}_{\downarrow}\right)^{\mathrm{T}}$ is the eigenfunction of Eq. (1.60) with eigenvalue $E_{\tilde{n}1}$, then $\left(v^{\tilde{n}1*}_{\downarrow}, -u^{\tilde{n}1*}_{\uparrow}\right)^{\mathrm{T}}$ is also the eigensolution to Eq. (1.61) with eigenvalue $-E_{\tilde{n}1}$. We take the complex conjugation to Eq.(1.60), which yields to

$$\begin{cases} h^{*}_{\uparrow}(\mathbf{r})u^{\tilde{n}1*}_{\uparrow}(\mathbf{r}) + \int d\mathbf{r}'\Delta^{*}(\mathbf{r},\mathbf{r}')\, v^{\tilde{n}1*}_{\downarrow}(\mathbf{r}') = E_{\tilde{n}1}u^{\tilde{1}1*}_{\uparrow}(\mathbf{r}), \\ \int d\mathbf{r}'\Delta(\mathbf{r}',\mathbf{r})\, u^{\tilde{n}1*}_{\uparrow}(\mathbf{r}') - h_{\downarrow}(\mathbf{r})v^{\tilde{n}1*}_{\downarrow}(\mathbf{r}) = E_{\tilde{n}1}v^{\tilde{n}}_{\downarrow}(\mathbf{r}) \end{cases} \tag{1.65}$$

Multiplying the second expression in the above set of equations by a minus sign on both sides, we re-arrange the whole set of equations into

$$\begin{cases} h_{\downarrow}(\mathbf{r})v^{\tilde{n}1*}_{\downarrow}(\mathbf{r}) + \int d\mathbf{r}'\Delta(\mathbf{r}',\mathbf{r})\left(-u^{\tilde{n}1*}_{\uparrow}(\mathbf{r}')\right) = -E_{\tilde{n}1}v^{\tilde{n}1*}_{\downarrow}(\mathbf{r}), \\ \int d\mathbf{r}'\Delta^{*}(\mathbf{r},\mathbf{r}')\, v^{\tilde{n}1*}_{\downarrow}(\mathbf{r}') - h^{*}_{\uparrow}(\mathbf{r})\left(-u^{\tilde{n}1*}_{\uparrow}(\mathbf{r})\right) = -E_{\tilde{n}1}\left(-u^{\tilde{N}1*}_{\uparrow}(\mathbf{r})\right). \end{cases} \tag{1.66}$$

Equation (1.66) is just identical to Eq. (1.61) with the equivalence:

$$\begin{pmatrix} u^{\tilde{n}2}_{\downarrow}(\mathbf{r}) \\ v^{\tilde{n}_2}_{\uparrow}(\mathbf{r}) \end{pmatrix} \equiv \begin{pmatrix} v^{\tilde{n}1*}_{\downarrow}(\mathbf{r}) \\ -u^{\tilde{n}1}_{\uparrow}(\mathbf{r}) \end{pmatrix}, \tag{1.67}$$

and $E_{\tilde{n}2} \equiv -E_{\tilde{n}1}$. This property has a significant consequence. It suggests that we merely need to solve one set of equations, e.g., Eq.(1.60), instead of both Eqs. (1.60) and (1.61), and obtain all information essential for the measurable. It saves the computational time significantly, which is desirable for the real-space inhomogeneous or disordered problems, even in a collinear spin-polarization. Note again here that this simplification exists in the absence of the spin-orbit coupling and other spin-flip scattering terms in the Hamiltonian. However, a more general symmetry property, as will be shown in the next chapter, can be derived even in the presence of these terms. We note that Eqs. (1.60) and (1.61) involve the pair potential $\Delta(\mathbf{r},\mathbf{r}')$. Substituting Eqs. (1.49) and (1.50) into Eq. (1.43), we arrive at

$$\begin{aligned}\Delta(\mathbf{r},\mathbf{r}') &= V(\mathbf{r}-\mathbf{r}')\langle\psi_\uparrow(\mathbf{r})\psi_\downarrow(\mathbf{r}')\rangle \\ &= V(\mathbf{r}-\mathbf{r}')\sum_{\tilde{n}}{}'\left[u_\uparrow^{\tilde{n}1}(\mathbf{r})v_\downarrow^{\tilde{\tilde{1}}*}(\mathbf{r}')f(-E_{\tilde{n}1})-v_\uparrow^{\tilde{n}2*}(\mathbf{r})u_\downarrow^{\tilde{\tilde{2}}2}(\mathbf{r}')f(E_{\tilde{n}2})\right] \\ &= V(\mathbf{r}-\mathbf{r}')\sum_{\tilde{n}}u_\uparrow^{\tilde{n}1}(\mathbf{r})v_\downarrow^{\tilde{n}1*}(\mathbf{r}')f(-E_{\tilde{n}1}) \qquad (1.68)\end{aligned}$$

On the other hand,

$$\begin{aligned}\Delta(\mathbf{r},\mathbf{r}') &= -V(\mathbf{r}-\mathbf{r}')\langle\psi_\downarrow(\mathbf{r}')\psi_\uparrow(\mathbf{r})\rangle \\ &= -V(\mathbf{r}-\mathbf{r}')\sum_{\tilde{n}}{}'\left[-u_\downarrow^{\tilde{n}2}(\mathbf{r}')v_\uparrow^{\tilde{n}2*}(\mathbf{r}')f(-E_{\tilde{n}2})+v_\downarrow^{\tilde{n}1*}(\mathbf{r}')u_\uparrow^{\tilde{n}1}(\mathbf{r}')f(E_{\tilde{n}1})\right] \\ &= -V(\mathbf{r}-\mathbf{r}')\sum_{\tilde{n}}u_\uparrow^{\tilde{n}1}(\mathbf{r})v_\downarrow^{\tilde{n}1*}(\mathbf{r}')f(E_{\tilde{n}1}) \qquad (1.69)\end{aligned}$$

Here we have used the symmetry property in the derivation, and the statistical average

$$\left\langle\gamma_{\tilde{n}\mu}^\dagger\gamma_{\tilde{m}\nu}\right\rangle=\delta_{\tilde{n}\tilde{m}}\delta_{\mu\nu}f(E_{\tilde{n}\mu}), \qquad (1.70)$$

and

$$\langle\gamma_{\tilde{n}\mu}\gamma_{\tilde{m}\nu}\rangle=\left\langle\gamma_{\tilde{n}\mu}^\dagger\gamma_{\tilde{m}\nu}^\dagger\right\rangle=0, \qquad (1.71)$$

where the Fermi distribution function

$$f(E_{\tilde{n}\mu})=\frac{1}{\exp(E_{\tilde{n}\mu}/k_BT)+1}, \qquad (1.72)$$

with k_B the Boltzmann constant and T the temperature. Notice the disappearance of "$'$" above the summation symbol, meaning the summation is over both positive and negative eigenvalues. Combination of Eqs. (1.68) and (1.69) gives

$$\Delta(\mathbf{r},\mathbf{r}')=\frac{V(\mathbf{r}-\mathbf{r}')}{2}\sum_{\tilde{n}}u_\uparrow^{\tilde{n}1}(\mathbf{r})v_\downarrow^{\tilde{n}1*}(\mathbf{r}')\tanh\left(\frac{E_{\tilde{n}1}}{2k_BT}\right). \qquad (1.73)$$

For spin-singlet pairing, $\Delta(\mathbf{r},\mathbf{r}')=\Delta(\mathbf{r}',\mathbf{r})$, and we can have a more symmetric form of the expression

$$\Delta(\mathbf{r},\mathbf{r}')=\frac{V(\mathbf{r}-\mathbf{r}')}{4}\sum_{\tilde{n}}\left[u_\uparrow^{\tilde{n}1}(\mathbf{r})v_\downarrow^{\tilde{n}1*}(\mathbf{r}')+u_\uparrow^{\tilde{n}1}(\mathbf{r}')v_\downarrow^{\tilde{n}1*}(\mathbf{r})\right]\tanh\left(\frac{E_{\tilde{n}1}}{2k_BT}\right) \qquad (1.74)$$

When there is no spin-polarization effect, Eqs. (1.60) and (1.61) are identical and they recover the original formalism proposed by de-Gennes [9] for an s-wave superconductor and that for an anisotropic superconductor [27]. Since a Bogoliubov canonical transformation is involved in the development of the formalism, these sets of equations are called the Bogoliubov-de Gennes equations.

1.5.2 Local Density of States

Once the solution to the BdG equations is obtained, the local density of states can be evaluated according to

$$\rho(\mathbf{r}, E) = \sum_{n,\sigma}{}' \left\{ \left|u_\sigma^n(\mathbf{r})\right|^2 \delta\left(E - E_n\right) + \left|v_{\bar{\sigma}}^n(\mathbf{r})\right|^2 \delta\left(E + E_n\right) \right\}, \tag{1.75}$$

where $\delta(x)$ is the Dirac delta function and can approximated numerically as

$$\delta(x) = \frac{1}{\pi} \frac{\Gamma}{x^2 + \Gamma^2}, \tag{1.76}$$

with Γ a lifetime broadening parameter. In the absence of the spin-orbit coupling and spin-flip scattering, Eq.(1.75) becomes

$$\rho(\mathbf{r}, E) = \sum_n \left\{ \left|u_\uparrow^n(\mathbf{r})\right|^2 \delta\left(E - E_n\right) + \left|v_\downarrow^n(\mathbf{r})\right|^2 \delta\left(E + E_n\right) \right\}. \tag{1.77}$$

Equivalently, the thermalized local density of states can be written as

$$\rho(\mathbf{r}, E) = \sum_n \left\{ \left|u_\uparrow^n(\mathbf{r})\right|^2 \left(-\frac{\partial f\left(E - E_n\right)}{\partial E} \right) + \left|v_\downarrow^n(\mathbf{r})\right|^2 \left(-\frac{\partial f\left(E + E_n\right)}{\partial E} \right) \right\}. \tag{1.78}$$

The local density of states is proportional to the local tunneling conductance as measured by the scanning tunneling microscopy.

In the following discussion, unless specified otherwise the BdG equation (1.60) will be mainly used. We will drop the spin subscript to u and v, and the quasiparticle branch index, as well as the symbol tilde on the eigenstate index. We keep only the spin index for the single-particle Hamiltonian itself.

1.5.3 Gauge Invariance

The choice of the vector potential $\mathbf{A}$ is not unique, since $\mathbf{A}'(\mathbf{r}) = \mathbf{A}(\mathbf{r}) + \nabla\chi(\mathbf{r})$, with χ an arbitrary function, will give the same magnetic field as that determined from $\mathbf{A}$, that is, $\nabla \times \mathbf{A}'(\mathbf{r}) = \nabla \times \mathbf{A}(\mathbf{r}) = \mathbf{H}(\mathbf{r})$. Thus $\mathbf{A}$ and $\mathbf{A}'$ are equally acceptable to describe the field $\mathbf{H}(\mathbf{r})$. All physically measurable quantities will have the same expectation values when calculated with $\mathbf{A}$ and $\mathbf{A}'$.

Suppose that the eigenfunctions (u, v) of the BdG equation with the vector potential $\mathbf{A}$ are known. It can be easily proved that the eigenfunctions (u', v') with the vector potential $\mathbf{A}' = \mathbf{A} + \nabla\chi(\mathbf{r})$ differs from (u, v) as

$$\begin{pmatrix} u'(\mathbf{r}) \\ v'(\mathbf{r}) \end{pmatrix} = \begin{pmatrix} e^{-ie\chi(\mathbf{r})/\hbar c} & 0 \\ 0 & e^{ie\chi(\mathbf{r})/\hbar c} \end{pmatrix} \begin{pmatrix} u(\mathbf{r}) \\ v(\mathbf{r}) \end{pmatrix}, \tag{1.79}$$

while the pair potential is modified as

$$\Delta'\left(\mathbf{r}, \mathbf{r}'\right) = \Delta\left(\mathbf{r}, \mathbf{r}'\right) e^{-ie[\chi(\mathbf{r}) + \chi(\mathbf{r}')]/\hbar c} \tag{1.80}$$

9.5.4 1.7 Solution to the BdG Equations in Homogeneous Systems

Theory

Let us start with the non-spin-polarization situation. In homogeneous systems, there exists the translational symmetry. In the limit of homogeneous electron gas, the translation symmetry

itself is continuous. Therefore, it would be convenient to expand the BdG wave function in terms of plane waves:

$$\begin{pmatrix} u(\mathbf{r}) \\ v(\mathbf{r}) \end{pmatrix} = \frac{1}{\sqrt{\Omega}} \begin{pmatrix} u_{\mathbf{k}} \\ v_{\mathbf{k}} \end{pmatrix} e^{i\mathbf{k}\cdot\mathbf{r}}, \tag{1.98}$$

where Ω is the volume of the entire system. Substitution of Eq.(1.98) into Eq. (1.60) leads to

$$\xi_{\mathbf{k}} u_{\mathbf{k}} + \Delta_{\mathbf{k}} v_{\mathbf{k}} = E_{\mathbf{k}} u_{\mathbf{k}}, \tag{1.99a}$$
$$\Delta^*_{\mathbf{k}} u_{\mathbf{k}} - \xi_{\mathbf{k}} v_{\mathbf{k}} = E_{\mathbf{k}} u_{\mathbf{k}}, \tag{1.99b}$$

where

$$\xi_{\mathbf{k}} = \frac{\hbar k^2}{2m_e} - E_F \tag{1.100}$$

is the single-particle energy dispersion, while

$$\Delta_{\mathbf{k}} = \int d\mathbf{r}' \Delta(\mathbf{r}, \mathbf{r}') \, e^{-i\mathbf{k}\cdot(\mathbf{r}-\mathbf{r}')}, \tag{1.101}$$

is the Fourier transform of the real-space superconducting pair potential. Using the definition of the pair potential $\Delta(\mathbf{r}, \mathbf{r}')$ given by Eq. (1.74) into Eq. (1.101), we obtain

$$\Delta_{\mathbf{k}} = \frac{1}{2\Omega} \sum_{\mathbf{k}'} V_{\mathbf{k}\mathbf{k}'} u_{\mathbf{k}} v^*_{\mathbf{k}'} \tanh\left(\frac{E_{\mathbf{k}'}}{2k_B T}\right) \tag{1.102}$$

with the term

$$V_{\mathbf{k}\mathbf{k}'} = \int d\mathbf{r}' V(\mathbf{r}, \mathbf{r}') \, e^{-i\mathbf{k}\cdot(\mathbf{r}-\mathbf{r}')} \cos(\mathbf{k}\cdot(\mathbf{r}-\mathbf{r}')) \tag{1.103}$$

retaining only the pairing interaction of allowed orbital harmonics. For an isotropic s-wave pairing symmetry, we use the ansatz

$$V_{\mathbf{k}\mathbf{k}'} = V_s, \tag{1.104}$$

and correspondingly

$$\Delta_{\mathbf{k}} = \Delta_s \tag{1.105}$$

which has no momentum dependence. For a d-wave pairing symmetry in a two-dimensional system, we have the ansatz

$$V_{\mathbf{k}\mathbf{k}'} = V_d \cos(2\phi_{\mathbf{k}}) \cos(2\phi_{\mathbf{k}'}), \tag{1.106}$$

and correspondingly

$$\Delta_{\mathbf{k}} = \Delta_d \cos(2\phi_{\mathbf{k}}) \tag{1.107}$$

with $\phi_{\mathbf{k}}$ being the azimuthal angle of $\mathbf{k}$ around the Fermi energy. We note that in the summation on the right-hand-side of Eq.(1.102), both positive and negative energy eigenvalues are still taken into account. The profile of the energy gap around the Fermi surface for these two types of pairing symmetry is depicted in Fig. 1.4.

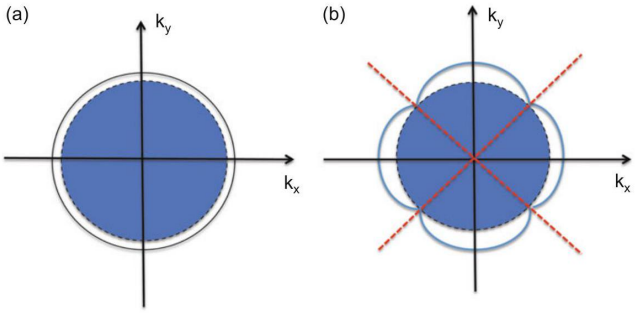

Fig. 1.4 A schematic drawing of quasiparticle excitation gap for an s-wave (a) and a $d_{x^2-y^2}$-wave pairing superconductor (b)

For the isotropic s-wave superconductors, the quasiparticle gap is uniform along the Fermi surface. For the $d_{x^2-y^2}$-wave superconductors, the quasiparticle gap is closed at some special momentum directions $\varphi = \frac{\pi}{4}, \frac{3\pi}{4}, \frac{5\pi}{4}, \frac{7\pi}{4}$. These gapless quasiparticles are called nodal quasiparticles.

A little algebra yields the eigensolutions

$$\begin{pmatrix} u_{\mathbf{k}} \\ v_{\mathbf{k}} \end{pmatrix} = \begin{pmatrix} u_{\mathbf{k}}^{(0)} e^{i\varphi_{\mathbf{k}}} \\ v_{\mathbf{k}}^{(0)} \end{pmatrix} \tag{1.108}$$

corresponding to the eigenvalue

$$E_{\mathbf{k}} = \sqrt{\xi_{\mathbf{k}}^2 + |\Delta_{\mathbf{k}}|^2} \tag{1.109}$$

and

$$\begin{pmatrix} u_{\mathbf{k}} \\ v_{\mathbf{k}} \end{pmatrix} = \begin{pmatrix} -v_{\mathbf{k}}^{(0)} e^{i\varphi_{\mathbf{k}}} \\ u_{\mathbf{k}}^{(0)} \end{pmatrix} \tag{1.110}$$

corresponding to the eigenvalue $-E_{\mathbf{k}}$. Here the BdG wave function amplitude is given by

$$\begin{pmatrix} u_{\mathbf{k}}^{(0)} \\ v_{\mathbf{k}}^{(0)} \end{pmatrix} = \begin{pmatrix} \sqrt{\frac{1}{2}\left(1 + \frac{\xi_k}{E_k}\right)} \\ \sqrt{\frac{1}{2}\left(1 - \frac{\xi_k}{E_k}\right)} \end{pmatrix} \tag{1.111}$$

and $\varphi_{\mathbf{k}}$ is the phase angle of $\Delta_{\mathbf{k}}$. Therefore, we obtain the self-consistency equation for the pair potential

$$\Delta_s = \frac{1}{(2\pi)^3} \int d\mathbf{k} V_s \frac{\Delta_s}{2E_{\mathbf{k}}} \tanh\left(\frac{E_{\mathbf{k}}}{2k_B T}\right), \tag{1.112}$$

for a three-dimensional s-wave superconductor with the quasiparticle excitation energy $E_{\mathbf{k}} = \sqrt{\xi_{\mathbf{k}}^2 + \Delta_s^2}$; and

$$\Delta_d = \frac{1}{(2\pi)^2} \int d\mathbf{k} V_d \cos^2(2\varphi) \frac{\Delta_d}{2E_{\mathbf{k}}} \tanh\left(\frac{E_{\mathbf{k}}}{2k_B T}\right), \tag{1.113}$$

for a two-dimensional $d_{x^2-y^2}$-wave superconductor with the quasiparticle excitation energy $E_{\mathbf{k}} = \sqrt{\xi_{\mathbf{k}}^2 + (\Delta_d \cos(2\varphi))^2}$.

We can convert the three-dimensional integral into

$$\int d\mathbf{k} \to \int_0^{2\pi} d\phi \int_0^{\pi} \sin\theta d\theta \int_0^{\infty} k^2 dk \to 4\pi \int_0^{\infty} k^2 dk$$

when the integrand has the spherical symmetry;
while we can convert the two-dimensional integral into

$$\int d\mathbf{k} \to \int_0^{2\pi} d\phi \int_0^{\infty} kdk \to 2\pi \int_0^{\infty} kdk,$$

when the integrand has the cylindrical symmetry. Therefore, for a parabolic normalstate single-particle energy dispersion, $\xi_{\mathbf{k}} = \frac{\hbar^2 k^2}{2m_e} - E_F$, the integral over momentum amplitude k can be changed to the integral over the energy as

$$\frac{1}{(2\pi)^D} \int d\mathbf{k} \to \int g(\epsilon) d\epsilon, \tag{1.114}$$

where $D = 2$ and 3 and $g(\epsilon)$ denotes the density of states for electrons of one spin orientation, and is given by

$$g(\epsilon) = \frac{1}{4\pi^2} \left(\frac{2m_e}{\hbar^2} \right)^{3/2} \epsilon^{1/2} \tag{1.115}$$

for the three-dimensional system, while

$$g(\epsilon) = \frac{m_e}{2\pi\hbar^2} \epsilon \tag{1.116}$$

for the two-dimensional system.

These expressions of density of states are shown in Fig. 1.5.

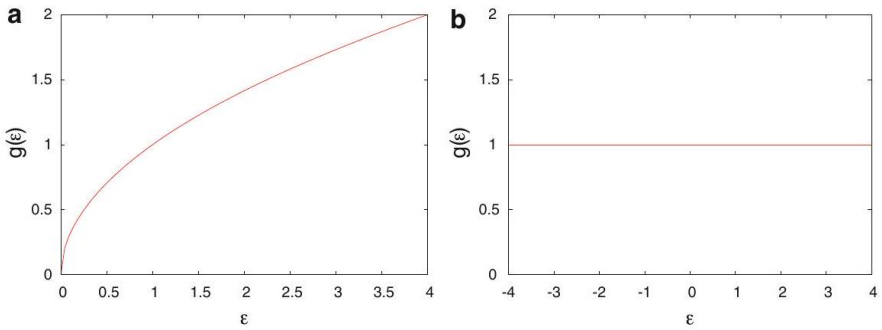

Fig. 1.5 Density of states for a three-dimensional (a) and a two-dimensional (b) electron gas

In the BCS-type weak-coupling theory for superconductivity, the pairing interaction is limited to a range of $[-\hbar\omega_c, \hbar\omega_c]$ around the Fermi surface. The cutoff ω_c is the Debye frequency of phonons in conventional superconductors. In most strongly correlated superconductors, ω_c is the energy scale characterizing spin, charge, or orbital fluctuations and is approximated by the width of a renormalized narrow band. One should be cautioned that for the strongly correlated superconductivity, the description of retardation effect is beyond the scope of BCS-based BdG theory.

Now the self-consistency equations (1.112) and (1.113), for the non-trivial $\Delta_s \neq 0$ and $\Delta_d \neq 0$, become

$$1 = \int_{-\hbar\omega_c}^{\hbar\omega_c} d\epsilon g(\epsilon) V_s \frac{1}{2E} \tanh\left(\frac{E}{2k_B T} \right) \approx g(0) V_s \int_0^{\hbar\omega_c} d\epsilon \frac{1}{E} \tanh\left(\frac{E}{2k_B T} \right), \tag{1.117}$$

for the s-wave superconductivity; and

$$\begin{aligned} 1 &= \frac{1}{2\pi}\int_{-\hbar\omega_c}^{\hbar\omega_c}\int_0^{2\pi} d\epsilon d\varphi g(\epsilon) V_d \cos^2(2\varphi)\frac{1}{2E}\tanh\left(\frac{E}{2k_BT}\right) \\ &= \frac{g(0)V_d}{2\pi}\int_0^{\hbar\omega_c}\int_0^{2\pi} d\epsilon d\varphi \cos^2(2\varphi)\frac{1}{E}\tanh\left(\frac{E}{2k_BT}\right), \end{aligned} \tag{1.118}$$

for the d-wave superconductivity. To derive the second line in each of the above two equations, we use the assumption that the density of states changes slightly in the range of $[-\hbar\omega_c, \hbar\omega_c]$ around the Fermi surface and can be approximated by that at the Fermi energy, i.e., $g(0)$. For the temperature $T = 0$ K, an analytical expression for the s-wave superconductors can be obtained

$$\Delta_s(T=0) = \hbar\omega_c \sinh^{-1}\left[\frac{1}{g(0)V_s}\right] \approx 2\hbar\omega_c \exp\left[-\frac{1}{g(0)V_s}\right], \tag{1.119}$$

for $g(0)V_s \ll 1$; while for the d-wave superconductivity, the following numerical solution needs to be found

$$1 = \frac{g(0)V_d}{2\pi}\int_0^{\hbar\omega_c}\int_0^{2\pi} d\epsilon d\varphi \frac{\cos^2(2\varphi)}{\sqrt{\epsilon^2 + \Delta_d^2(T=0)\cos^2(2\varphi)}} \tag{1.120}$$

The condition for the superconducting transition temperature is $\Delta_s = 0$ for s-wave superconductors while $\Delta_d = 0$ for the d-wave superconductors, which leads to

$$1 = g(0)V_s\int_0^{\hbar\omega_c} d\epsilon \frac{1}{\epsilon}\tanh\left(\frac{\epsilon}{2k_BT}\right), \tag{1.121}$$

and

$$1 = \frac{g(0)V_d}{2}\int_0^{\hbar\omega_c} d\epsilon \frac{1}{\epsilon}\tanh\left(\frac{\epsilon}{2k_BT}\right). \tag{1.122}$$

In the condition of $\hbar\omega_c/k_BT_c \gg 1$, we have

$$\begin{aligned} T_c &= \frac{2e^\gamma}{k_B\pi}\hbar\omega_c \exp\left[-\frac{1}{g(0)V_s}\right] \\ &= 1.13\hbar\omega_c \exp\left[-\frac{1}{g(0)V_s}\right] \end{aligned} \tag{1.123}$$

and

$$\begin{aligned} T_c &= \frac{2e^\gamma}{k_B\pi}\hbar\omega_c \exp\left[-\frac{1}{2g(0)V_d}\right] \\ &= 1.13\hbar\omega_c \exp\left[-\frac{1}{2g(0)V_d}\right]. \end{aligned} \tag{1.124}$$

Here the Euler constant $\gamma \approx 0.5772$ is used.
With the BdG solutions as given by Eqs. (1.108) and (1.110), we can find the bulk density of states

$$\frac{\rho_s(E)}{g(0)} = \begin{cases} \frac{E}{\sqrt{E^2-\Delta_s^2}}, & E > \Delta_s \\ 0, & E < \Delta_s \end{cases} \tag{1.125}$$

for the uniform s-wave superconductors, and

$$\frac{\rho_d(E)}{g(0)} = \begin{cases} \int_0^{2\pi} \frac{d\varphi}{2\pi} \frac{E}{\sqrt{E^2-\Delta_d^2\cos^2(2\varphi)}}, & E > |\Delta_d \cos(2\varphi)| \\ 0, & E < |\Delta_d \cos(2\varphi)| \end{cases} \tag{1.126}$$

for the uniform d-wave superconductors. A schematic density of states for both s-wave and d-wave superconductors is shown in Fig. 1.6.

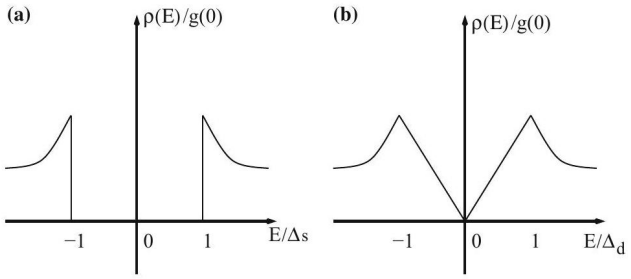

Fig. 1.6 Quasiparticle density of states for a uniform three-dimensional s-wave (a) and a uniform two-dimensional d-wave (b) superconductor

For the s-wave superconductors, a sharp gap feature is seen with vanishing density of states inside the energy range of $[-\Delta_s, \Delta_s]$, while for the d-wave superconductors, the density of states is linear in energy inside $[-\Delta_d, \Delta_d]$, due to the existence of nodal quasiparticles.

All the above discussions demonstrate that, in the homogeneous superconductors, the BdG equations can reproduce all the known results obtained through the Bogoliubov-Valatin canonical transformation. However, as will be demonstrated in later chapters, the BdG equations are more convenient to study the properties of inhomogeneous superconductors.

9.5.5 1.8 Relation of BdG Method to the Abrikosov-Gor'kov Equations

(??? this is what I don't understand now. I'll first write about Abrikosov equation explicitly, then thin about their connection)

Derivation of Abrikosov equations in a new formalism

We should also be aware that the Hamiltonian (1.42) can also be solved via the Green's function technique. We first define a two-component field operator in the Nambu space [44, 45]:

$$\hat{\Psi}(\mathbf{r},\tau) = \begin{pmatrix} \psi_\uparrow(\mathbf{r},\tau) \\ \psi_\downarrow^\dagger(\mathbf{r},\tau) \end{pmatrix}, \tag{1.127}$$

where

$$\psi_\sigma(\mathbf{r},\tau) = e^{\mathscr{H}_{eff}\tau/\hbar}\psi_\sigma(\mathbf{r})e^{-\mathscr{H}_{eff}\tau/\hbar} \tag{1.128}$$

$$\psi_\sigma^\dagger(\mathbf{r},\tau) = e^{eff\tau/\hbar}\psi_\sigma^\dagger(\mathbf{r})e^{-\mathscr{H}_{eff}\tau/\hbar}. \tag{1.129}$$

are the field operators defined in the Heisenberg picture. Note that $\psi_\sigma^\dagger(\mathbf{r},\tau) \neq [\psi_\sigma(\mathbf{r},\tau)]^\dagger$. We can then introduce the Green's function

$$\begin{aligned}\mathscr{G}\left(\mathbf{r}\tau;\mathbf{r}'\tau'\right) &= -\left\langle T_\tau\left[\hat{\Psi}(\mathbf{r},\tau)\otimes\hat{\Psi}^\dagger\left(\mathbf{r}',\tau'\right)\right]\right\rangle \\ &= -\theta\left(\tau-\tau'\right)\left\langle\hat{\Psi}(\mathbf{r},\tau)\otimes\hat{\Psi}^\dagger\left(\mathbf{r}',\tau'\right)\right\rangle+\theta\left(\tau'-\tau\right)\left\langle\hat{\Psi}^\dagger\left(\mathbf{r}',\tau'\right)\otimes\hat{\Psi}(\mathbf{r},\tau)\right\rangle \end{aligned} \tag{1.130}$$

Here $\otimes$ means the direct product of two vector fields. The bracket $\langle\ldots\rangle$ means the statistic average

$$\langle\hat{O}\rangle = \mathrm{Tr}\left[e^{-\beta\left(\mathscr{H}_{eff}-\Omega\right)}\hat{O}\right] \tag{1.131}$$

with the thermodynamic potential Ω given by

$$e^{-\beta\Omega} = \mathrm{Tr}\left[e^{-\beta\mathscr{H}_{eff}}\right] \tag{1.132}$$

The factor T_τ is a τ-ordering operator, which arranges operators with earliest time τ to the right. The subscript τ is affixed to T to distinguish T_τ from the temperature. In expanded form, the Green's function becomes

$$\mathscr{G}(\mathbf{r}\tau;\mathbf{r}'\tau') = \begin{pmatrix} -\langle T_\tau[\psi_\uparrow(\mathbf{r},\tau)\psi_\uparrow^\dagger(\mathbf{r}',\tau')]\rangle - \langle T_\tau[\psi_\uparrow(\mathbf{r},\tau)\psi_\downarrow(\mathbf{r}',\tau')]\rangle \\ -\langle T_\tau[\psi_\downarrow^\dagger(\mathbf{r},\tau)\psi_\uparrow^\dagger(\mathbf{r}',\tau')]\rangle - \langle T_\tau[\psi_\downarrow^\dagger(\mathbf{r},\tau)\psi_\downarrow(\mathbf{r}',\tau')]\rangle \end{pmatrix}, \tag{1.133}$$

(?? this is 4x4 matrix, right?)

Since the trace is unchanged upon a cyclic variation of operators, we can easily prove that the Green's function is a function of the difference $\tau-\tau'$, that is,

$$\mathscr{G}\left(\mathbf{r}\tau;\mathbf{r}'\tau'\right) = \mathscr{G}\left(\mathbf{r},\mathbf{r}';\tau-\tau'\right), \tag{1.134}$$

with $\tau-\tau'$ restricted in the range of $[-\beta,\beta]$ and the factor $\beta = 1/k_BT$. Therefore, the Fourier transform is given by

$$\mathscr{G}\left(\mathbf{r},\mathbf{r}';i\omega_n\right) = \int_0^{\beta\hbar} d\tau e^{i\omega_n\tau}\mathscr{G}\left(\mathbf{r},\mathbf{r}';\tau\right) \tag{1.135}$$

$$\mathscr{G}\left(\mathbf{r},\mathbf{r}';\tau\right) = \frac{1}{\beta}\sum_n e^{-i\omega_n\tau}\mathscr{G}\left(\mathbf{r},\mathbf{r}';i\omega_n\right) \tag{1.136}$$

where the Matsubara frequency $\omega_n = (2n+1)\pi k_BT/\hbar$ with $n=-\infty,\ldots,-1,0,1,\ldots,\infty$. Using the equation of motion for $\psi_\sigma(\mathbf{r},\tau)$ and $\psi_\sigma^\dagger(\mathbf{r},\tau)$:

$$\begin{aligned} -\hbar\tfrac{\partial\psi_\sigma(\mathbf{r},\tau)}{\partial\tau} &= \left[\psi_\sigma(\mathbf{r},\tau),\mathscr{H}_{eff}\right]_-, \\ -\hbar\tfrac{\partial\psi_\sigma^\dagger(\mathbf{r},\tau)}{\partial\tau} &= \left[\psi_\sigma^\dagger(\mathbf{r},\tau),\mathscr{H}_{eff}\right]_-, \end{aligned} \tag{1.138}$$

and Eq.(1.47), we can obtain the equation of motion for the Green's function

$$\int d\mathbf{r}''\hat{M}\left(\mathbf{r},\mathbf{r}'';\tau\right)\mathscr{G}\left(\mathbf{r}''\tau;\mathbf{r}'\tau'\right) = \delta\left(\mathbf{r}-\mathbf{r}'\right)\delta\left(\tau-\tau'\right)\hat{1} \tag{1.139}$$

with

$$\hat{M}\left(\mathbf{r},\mathbf{r}',\tau\right) = \begin{pmatrix} \left(-\frac{\partial}{\partial\tau}-h_\uparrow(\mathbf{r})\right)\delta\left(\mathbf{r}-\mathbf{r}'\right) & -\Delta\left(\mathbf{r},\mathbf{r}'\right) \\ -\Delta^*\left(\mathbf{r}',\mathbf{r}\right) & \left(-\frac{\partial}{\partial\tau}+h_\downarrow^*(\mathbf{r})\right)\delta_{ij} \end{pmatrix}. \tag{1.140}$$

for the spin-single pairing case, and subject to the self-consistency condition:

$$\Delta(\mathbf{r},\mathbf{r}') = -V(\mathbf{r},\mathbf{r}')\mathscr{G}_{12}\left(\mathbf{r}\tau \to \tau' + 0^+, \mathbf{r}'\tau'\right) \tag{1.141}$$

$$\Delta^*(\mathbf{r},\mathbf{r}') = -V(\mathbf{r},\mathbf{r}')\mathscr{G}_{21}\left(\mathbf{r}'\tau \to \tau' + 0^+, \mathbf{r}\tau'\right) \tag{1.142}$$

Equation (1.139) is the famous Abrisokov-Gorkov equations [46] for superconductivity in the continuum model.

(????? why?????)

This set of equations is also the starting point for the derivation of Ginzburg-Landau theory. When the order parameter varies slowly in space, the approximate Ginzburg-Landau theory is simpler to solve than the original Abrisokov-Gorkov theory.

Relation between BdG and AG equations

The Abrikosov-Gorkov theory is closely related to the BdG theory. With the time dependence of the quasiparticle operators:

$$\gamma_n(\tau) = \gamma_n e^{-E_n\tau/\hbar} \tag{1.143}$$

$$\gamma_n^\dagger(\tau) = \gamma_n^\dagger e^{E_n\tau/\hbar}. \tag{1.144}$$

and the canonical transformation, we can obtain for example:

$$\begin{aligned}\mathscr{G}_{11}(\mathbf{r},\mathbf{r}';\tau) =& -\theta(\tau)\sum_{\tilde{n}}\left[u_\uparrow^{\tilde{n}1}(\mathbf{r})u_\uparrow^{\tilde{n}1*}(\mathbf{r}')f(-E_{\tilde{n}1})e^{-E_{\tilde{n}1}\tau/\hbar} + v_\uparrow^{\tilde{n}2*}(\mathbf{r})v_\uparrow^{\tilde{n}_2}(\mathbf{r}')f(E_{\tilde{n}2})e^{E_{\tilde{n}2}\tau/\hbar}\right]\\ &+\theta(-\tau)\sum_{\tilde{n}}\left[u_\uparrow^{\tilde{n}1*}(\mathbf{r}')u_\uparrow^{\tilde{n}1}(\mathbf{r})f\left(E_{\tilde{n}1}e^{-E_{\tilde{n}1}\tau/\hbar} + v_\uparrow^{\tilde{n}2*}(\mathbf{r}')v_\uparrow^{\tilde{n}2}(\mathbf{r})f(-E_{\tilde{n}2})e^{E_{\tilde{n}2}\tau/\hbar}\right],\end{aligned} \tag{1.145}$$

and

$$\begin{aligned}\mathscr{G}_{22}(\mathbf{r},\mathbf{r}';\tau) =& -\theta(\tau)\sum_{\tilde{n}}\left[u_\downarrow^{\tilde{n}2*}(\mathbf{r})u_\downarrow^{\tilde{n}2}(\mathbf{r}')f(E_{\tilde{n}2})e^{E_{\tilde{n}2}\tau/\hbar} + v_\downarrow^{\tilde{n}1}(\mathbf{r})v_\downarrow^{\tilde{n}1*}(\mathbf{r}')f(-E_{\tilde{n}1})e^{-E_{\tilde{n}1}\tau/\hbar}\right]\\ &+\theta(-\tau)\sum_{n}\left[u_\downarrow^{\tilde{n}2}(\mathbf{r}')u_\downarrow^{\tilde{n}_2}(\mathbf{r})f(-E_{\tilde{n}2})e^{E_{\tilde{n}2}\tau/\hbar} + v_\downarrow^{\tilde{n}1*}(\mathbf{r}')v_\downarrow^{\tilde{1}1}(\mathbf{r})f(E_{\tilde{n}1})e^{-E_{\tilde{n}1}\tau/\hbar}\right].\end{aligned} \tag{1.146}$$

It is straightforward to obtain the Green's function in the frequency domain

$$\begin{aligned}&\mathscr{G}_{11}(\mathbf{r},\mathbf{r}';i\omega_n) = \int_0^{\beta\hbar} d\tau e^{i\omega_n\tau}\mathscr{G}_{11}(\mathbf{r},\mathbf{r}';\tau)\\ =& -{\sum_{\tilde{n}}}'\left[u_\uparrow^{\tilde{n}1}(\mathbf{r})u_\uparrow^{\tilde{n}1*}(\mathbf{r}')f(-E_{\tilde{n}1})\int_0^{\beta\hbar}d\tau e^{(i\omega_n - E_{\tilde{n}1}/\hbar)\tau} + v_\uparrow^{\tilde{n}2*}(\mathbf{r})v_\uparrow^{\tilde{n}2}(\mathbf{r}')f(E_{\tilde{n}2})\int_0^{\beta\hbar}d\tau e^{(i\omega_n + E_{\tilde{n}2}/\hbar)\tau}\right]\\ =& -{\sum_{\tilde{n}}}'\left\{\frac{u_\uparrow^{\tilde{n}1}(\mathbf{r})u_\uparrow^{\tilde{n}1*}(\mathbf{r}')}{i\omega_n - E_{\tilde{n}1}/\hbar}f(-E_{\tilde{n}1})\left(e^{\beta\hbar(i\omega_n - E_{\tilde{n}1}/\hbar)} - 1\right) + \frac{v_\uparrow^{\tilde{n}2*}\left((\mathbf{r})v_\uparrow^{\tilde{n}2}(\mathbf{r}')\right.}{i\omega_n + E_{\tilde{n}2}/\hbar}f(E_{\tilde{n}2})\left(e^{\beta\hbar(i\omega_n + E_{\tilde{n}2}/\hbar)} - 1\right)\right\}\\ =& {\sum_{\tilde{n}}}'\left[\frac{u_\uparrow^{\tilde{n}1}(\mathbf{r})u_\uparrow^{\tilde{n}1*}(\mathbf{r}')}{i\omega_n - E_{\tilde{n}1}/\hbar} + \frac{v_\uparrow^{\tilde{n}2*}(\mathbf{r})v_\uparrow^{\tilde{n}2}(\mathbf{r}')}{i\omega_n + E_{\tilde{n}2}/\hbar}\right],\end{aligned} \tag{1.147}$$

and

$$
\begin{aligned}
&\mathscr{G}_{22}(\mathbf{r},\mathbf{r}';i\omega_n)=\int_0^{\beta\hbar}d\tau e^{i\omega_n\tau}\mathscr{G}_{22}\left(\mathbf{r},\mathbf{r}';\tau\right)\\
&=-\sum_{\tilde{n}}{}'\left[u_{\downarrow}^{\tilde{n}2*}(\mathbf{r})u_{\downarrow}^{\tilde{n}2}\left(\mathbf{r}'\right)f\left(E_{\tilde{n}2}\right)\int_0^{\beta\hbar}d\tau e^{(i\omega_n+E_{\tilde{n}2}/\hbar)\tau}+v_{\downarrow}^{\tilde{n}1}(\mathbf{r})v_{\downarrow}^{\tilde{n}1*}\left(\mathbf{r}'\right)f\left(-E_{\tilde{n}1}\right)\int_0^{\beta\hbar}d\tau e^{(i\omega_n+E_{\tilde{n}1}/\hbar)\tau}\right]\\
&=-\sum_{\tilde{n}}{}'\left\{\frac{u_{\downarrow}^{\tilde{n}2*}(\mathbf{r})u_{\downarrow}^{\tilde{n}2}\left(\mathbf{r}'\right)}{i\omega_n+E_{\tilde{n}2}/\hbar}f\left(E_{\tilde{n}2}\right)\left(e^{\beta\hbar(i\omega_n+E_{\tilde{n}2}/\hbar)}-1\right)+\frac{v_{\downarrow}^{\tilde{n}1}(\mathbf{r})v_{\downarrow}^{\tilde{n}1*}\left(\mathbf{r}'\right)}{i\omega_n-E_{\tilde{n}1}/\hbar}f\left(E_{\tilde{n}1}\right)\left(e^{\beta\hbar(i\omega_n-E_{\tilde{n}1}/\hbar)}-1\right)\right\}\\
&=\sum_{\tilde{n}}{}'\left[\frac{u_{\downarrow}^{\tilde{n}2*}(\mathbf{r})u_{\downarrow}^{\tilde{n}}\left(\mathbf{r}'\right)}{i\omega_n+E_{\tilde{n}2}/\hbar}+\frac{v_{\downarrow}^{\tilde{n}1}(\mathbf{r})v_{\downarrow}^{\tilde{n}1*}\left(\mathbf{r}'\right)}{i\omega_n-E_{\tilde{n}1}/\hbar}\right].
\end{aligned}
\tag{1.148}
$$

Here we have used the fact that

$$
e^{i\omega_n\beta\hbar}=-1 \tag{1.149}
$$

In addition, if we know the solution to the Abrikosov-Gorkov equations of motion for the Green's functions, the local density of states can be calculated as

$$
\begin{aligned}
\rho_{\uparrow}(\mathbf{r},E)&=-\frac{1}{\hbar\pi}\operatorname{Im}\left[\mathscr{G}_{11}\left(\mathbf{r},\mathbf{r};i\omega_n\rightarrow E/\hbar+i0^{+}\right)\right]\\
&=\sum_{\tilde{n}}{}'\left[\left|u_{\uparrow}^{\tilde{n}1}(\mathbf{r})\right|^2\delta\left(E-E_{\tilde{n}1}\right)+\left|v_{\uparrow}^{\tilde{n}2}(\mathbf{r})\right|^2\delta\left(E+E_{\tilde{n}2}\right)\right],
\end{aligned}
\tag{1.150}
$$

and

$$
\begin{aligned}
\rho_{\downarrow}(\mathbf{r},E)&=\frac{1}{\hbar\pi}\operatorname{Im}\left[\mathscr{G}_{22}\left(\mathbf{r},\mathbf{r};-i\omega_n\rightarrow-\left(E/\hbar+i0^{+}\right)\right)\right]\\
&=\sum_{\tilde{n}}{}'\left[\left|u_{\downarrow}^{\tilde{\tilde{2}}2}(\mathbf{r})\right|^2\delta\left(E-E_{\tilde{n}2}\right)+\left|v_{\downarrow}^{\tilde{n}1}(\mathbf{r})\right|^2\delta\left(E+E_{\tilde{n}2}\right)\right].
\end{aligned}
\tag{1.151}
$$

Here we have used the following identity for the real frequency ω

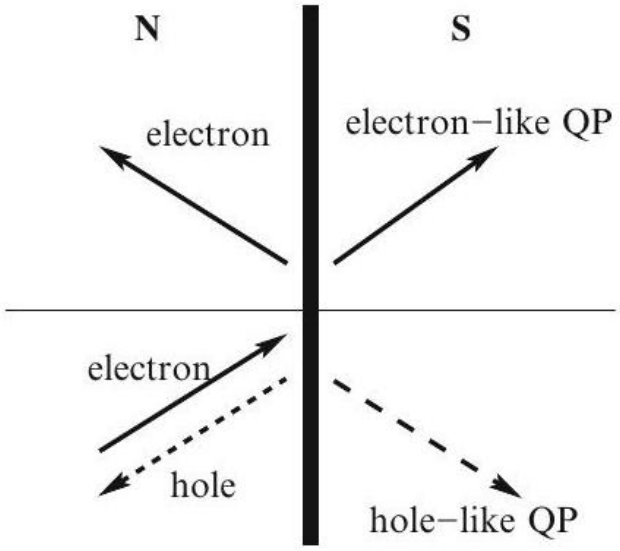
$$
\frac{1}{\omega\pm i0^{+}}=\mathscr{P}\frac{1}{\omega}\mp i\pi\delta(\omega) \tag{1.152}
$$

with $\mathscr{P}$ denotes a Cauchy principal value. Therefore, we have demonstrated an exact relation between the BdG theory and the Abrikosov-Gorkov theory.

(????? what is it???)

9.6 Transport Across Normal-Metal/Superconductor Junctions

I'LL ADD THEORY BELOW FROM ORIGINAL PAPERS TO THIS SECTION!!!



9.6.1 6.1 Blonder-Tinkham-Klapwijk Scattering Formalism

(!!! I'll later WRITE WHAT IS BTK FORMALISM IN ONE LINE!!!! TO MAKE SURE THAT I UNDERSTAND IT.)

Theory

In a phase-coherent normal-superconducting hybrid structure, electrons are not only intrinsically coherent in the superconducting part but also retain phase memory all through the normal conducting region. Therefore, the transport properties are determined in detail by the quasiparticle states produced by elastic scattering from inhomogeneities and boundaries. In the presence of superconductivity, a scattering process known as the Andreev reflection [1] occurs: As shown schematically in Fig.6.1, an electron incident from the normal conductor with an energy below the superconducting quasiparticle energy gap cannot drain off individually into the superconductor. It is instead coherently reflected from the normal-metal/superconductor (NS) interface as a hole by transferring a charge $-2e$ to the superconductor. This process goes beyond the lowest-order description within the tunneling Hamiltonian model for the NS junction, which predicts that the tunneling conductance is proportional to the density of states. In 1982, Blonder, Tinkham, and Klapwijk [2] (BTK) pointed out that the contribution to the subgap conductance from the Andreev reflection can be significant, and further developed a scattering theory of transport through an NS interface with the arbitrary barrier strength.

Fig. 6.1 Schematic drawing of the scattering process for an incident electron beam impinged upon a normal-metal superconductor interface

We now discuss the derivation of the BTK formula. The time-dependent BdG equations can be directly generalized from Eq.(1.60)

$$h_{\uparrow}(\mathbf{r})f(\mathbf{r},t)+\int d\mathbf{r}'\Delta\left(\mathbf{r},\mathbf{r}'\right)g\left(\mathbf{r}',t\right)=i\hbar\frac{\partial f(\mathbf{r},t)}{\partial t} \tag{6.1a}$$

$$\int d\mathbf{r}'\Delta^{*}\left(\mathbf{r}',\mathbf{r}\right)f\left(\mathbf{r}',t\right)-h_{\downarrow}^{*}(\mathbf{r})g(\mathbf{r},t)=i\hbar\frac{\partial g(\mathbf{r},t)}{\partial t} \tag{6.1b}$$

Now the time dependence of the potentials is included implicitly. From the above equation, we derive the continuity equation for BdG quasiparticles. We multiply Eq. (6.1a) on both sides from the left by $f^{*}(\mathbf{r},t)$ while Eq. (6.1b) by $g^{*}(\mathbf{r},t)$ such that

$$f^{*}(\mathbf{r},t)h_{\uparrow}(\mathbf{r})f(\mathbf{r},t)+\int d\mathbf{r}'f^{*}(\mathbf{r},t)\Delta\left(\mathbf{r},\mathbf{r}'\right)g\left(\mathbf{r}',t\right)=i\hbar f^{*}(\mathbf{r},t)\frac{\partial f(\mathbf{r},t)}{\partial t}$$

$$\int d\mathbf{r}'g^{*}(\mathbf{r},t)\Delta^{*}\left(\mathbf{r}',\mathbf{r}\right)f\left(\mathbf{r}',t\right)-g^{*}(\mathbf{r},t)h_{\downarrow}^{*}(\mathbf{r})g(\mathbf{r},t)=i\hbar g^{*}(\mathbf{r},t)\frac{\partial g(\mathbf{r},t)}{\partial t}$$

We then take the complex conjugation to the above two expressions

$$-f(\mathbf{r},t)h_{\uparrow}^{*}(\mathbf{r})f^{*}(\mathbf{r},t)-\int d\mathbf{r}'f(\mathbf{r},t)\Delta^{*}\left(\mathbf{r},\mathbf{r}'\right)g^{*}\left(\mathbf{r}',t\right)=i\hbar f(\mathbf{r},t)\frac{\partial f^{*}(\mathbf{r},t)}{\partial t}$$
$$-\int d\mathbf{r}'g(\mathbf{r},t)\Delta\left(\mathbf{r}',\mathbf{r}\right)f^{*}\left(\mathbf{r}',t\right)+g(\mathbf{r},t)h_{\downarrow}(\mathbf{r})g^{*}(\mathbf{r},t)=i\hbar g(\mathbf{r},t)\frac{\partial g^{*}(\mathbf{r},t)}{\partial t}$$

Combine the above two sets of equations together, we arrive at

$$\frac{\partial|f(\mathbf{r},t)|^{2}}{\partial t}+\nabla\cdot\mathbf{J}_{1}=S_{1}, \tag{6.4}$$
$$\frac{\partial|g(\mathbf{r},t)|^{2}}{\partial t}+\nabla\cdot\mathbf{J}_{2}=S_{2} \tag{6.5}$$

where

$$\mathbf{J}_{1}=\mathrm{Re}\left[f^{*}(\mathbf{r},t)\mathbf{v}_{e}f(\mathbf{r},t)\right] \tag{6.6}$$
$$\mathbf{J}_{2}=-\mathrm{Re}\left[g^{*}(\mathbf{r},t)\mathbf{v}_{h}g(\mathbf{r},t)\right] \tag{6.7}$$

with the mechanical velocity of electron and hole as

$$\mathbf{v}_{e}=(\mathbf{p}+e\mathbf{A})/m_{e},\quad \mathbf{v}_{h}=(\mathbf{p}-e\mathbf{A})/m_{e} \tag{6.8}$$

The source term are respectively given by

$$S_{1}=\frac{2}{\hbar}\,\mathrm{Im}\left[f^{*}(\mathbf{r},t)\Delta\left(\mathbf{r},\mathbf{r}'\right)g\left(\mathbf{r}',t\right)\right] \tag{6.9}$$

and

$$S_{2}=\frac{2}{\hbar}\,\mathrm{Im}\left[g^{*}(\mathbf{r},t)\Delta^{*}\left(\mathbf{r}',\mathbf{r}\right)f\left(\mathbf{r}',t\right)\right] \tag{6.10}$$

The total particle density is defined as the probability density for finding an electron or a hole at a particular time t and position $\mathbf{r}$,

$$P(\mathbf{r},t)=2\sum_{n}f\left(E_{n}\right)\left[|f^{n}(\mathbf{r},t)|^{2}+|g^{n}(\mathbf{r},t)|^{2}\right]. \tag{6.11}$$

Correspondingly, the quasiparticle current density is given by

$$\mathbf{J}_{P}=2\sum_{n}f\left(E_{n}\right)\left[\mathbf{J}_{1}^{n}+\mathbf{J}_{2}^{n}\right], \tag{6.12}$$

and the source term

$$S_{P}=2\sum_{n}f\left(E_{n}\right)\left[S_{1}^{n}+S_{2}^{n}\right] \tag{6.13}$$

The charge density is defined as follows

$$Q(\mathbf{r},t)=-2e\sum_{n}\left\{f\left(E_{n}\right)|f^{n}(\mathbf{r},t)|^{2}+\left[1-f\left(E_{n}\right)\right]|g^{n}(\mathbf{r},t)|^{2}\right\} \tag{6.14}$$

Correspondingly, the electrical current density should be

$$\begin{aligned}\mathbf{J}_Q &= -2e\sum_n \left\{f\left(E_n\right)\mathbf{J}_1^n + \left[1-f\left(E_n\right)\right]\mathbf{J}_2^n\right\} \\ &= -2e\sum_n \left\{f\left(E_n\right)\mathrm{Re}\left[f^{n*}(\mathbf{r},t)\mathbf{v}_e f^n(\mathbf{r},t)\right]\right. \\ &\quad \left.-\left[1-f\left(E_n\right)\right]\mathrm{Re}\left[g^{n*}(\mathbf{r},t)\mathbf{v}_h g^n(\mathbf{r},t)\right]\right\}, \\ &= \frac{-2e\hbar}{m}\sum_n \left\{f\left(E_n\right)\mathrm{Im}\left[f^{n*}(\mathbf{r},t)(\nabla + ie\mathbf{A}/\hbar c)f^n(\mathbf{r},t)\right]\right. \\ &\quad \left.-\left[1-f\left(E_n\right)\right]\mathrm{Im}\left[g^{n*}(\mathbf{r},t)(\nabla - ie\mathbf{A}/\hbar c)g^n(\mathbf{r},t)\right]\right\}, \end{aligned} \tag{6.15}$$

and the source term is

$$S_Q = -2e\sum_n \left\{f\left(E_n\right)S_1^n + \left[1-f\left(E_n\right)\right]S_2^n\right] \tag{6.16}$$

The vector potential $\mathbf{A}(\mathbf{r})$ entering the BdG equations is in turn related to the electrical current distribution $\mathbf{J}_Q(\mathbf{r})$ by Maxwell's equation

$$\nabla \times (\nabla \times \mathbf{A}) = \frac{4\pi}{c}\mathbf{J}_Q \tag{6.17}$$

It should be pointed out that the two-fold spin degeneracy has been included explicitly. At a first glance, the current are not conserved. However, if we take into account the self-consistency condition about the pair potential, we can check that the source term S_Q is zero. For this reason, in non-self-consistent theory the current is evaluated in the normal region (where the current is conserved since the pair potential is zero) and the current in the superconducting region is inferred indirectly. Obviously, the source term S_P can never become zero, which is allowed by the mother nature itself in the superconductivity. We refer to [2-4] for more discussion of these definitions. The present current expression has been used to study the transport properties through a superconducting point contact [5].

The BTK transport theory is based on the assumption that the electrons are ballistically accelerated without scattering before they hit the NS interface. In addition, one assumes that the distribution functions of all incoming particles are given by equilibrium Fermi-Dirac functions, apart from the energy shift due to the voltage bias. It is convenient to choose the electrochemical potential of the electrons in the superconductor as the reference since it remains a well-defined quantity even when the quasiparticle populations are far from equilibrium. With this convention, all incoming electrons from the superconductor side have the distribution function $f_{FD}(E)$, while those coming in from the normal-metal side have the distribution function $f_{FD}(E-eV)$. Since the current must be conserved, we can evaluate it in any plane for an actual two-dimensional or three-dimensional geometry. For a planar junction, we can always first calculate the current for a given incident direction of electron beams, with angle θ, as shown in Fig. 6.1, from which the total current can be obtained by integrating over the transverse momentum. Assuming the current flow along the x-direction, which is perpendicular the NS junction, we can write the current as

$$I(\theta, V) = 2N(0)ev_{F,x}\mathscr{A}\int_{-\infty}^{\infty}\left[f_{\rightarrow}(E) - f_{\leftarrow}(E)\right]dE. \tag{6.18}$$

Here $\mathscr{A}$ is the cross-sectional area of the interface, $N(0)$ is the one-spin density of states at the Fermi energy at ϵ_F, and $v_{F,x} = v_F\cos\theta$. With the assumption about the incoming populations, it follows that

$$f_{\rightarrow}(E) = f_{FD}(E - eV), \tag{6.19}$$

while

$$f_{\leftarrow}(E) = A(E)\left[1 - f_{\rightarrow}(E)\right] + B(E)f_{\rightarrow}(E) + [C(E) + D(E)]f_{FD}(E). \tag{6.20}$$

Here the probabilities $A(E), B(E), C(E)$, and $D(E)$ are for normal reflection, Andreev reflection, transmission through the interface with a wave vector on the same side of the Fermi surface and that crossing the Fermi surface. We have represented the current incident from the superconducting side in terms of the summation of $C(E)$ and $D(E)$. Substituting Eqs. (6.19) and (6.20) into Eq. (6.18), we arrive at

$$I(\theta, V) = 2N(0)ev_{F,x}\mathscr{A}\int_{-\infty}^{\infty}\left[f_{FD}(E - eV) - f_{FD}(E)\right]\left[1 + A(E) - B(E)\right]dE. \tag{6.21}$$

Here we have used the symmetry that the probabilities $A(E), B(E), C(E)$, and $D(E)$ are even functions of E, and $f_{FD}(-E) = 1 - f_{FD}(E)$. The quantity $1 + A(E) - B(E)$ can be referred as the transmission coefficient for electrical current. It shows that while the ordinary reflection (described by $B(E)$) reduces the current, the Andreev reflection (described by $A(E)$) increases the current by giving one electron to form a Cooper pair together with the incident electron. From Eq. (6.21), we can also obtain the differential conductance for a given incident direction of electrons as:

$$G_{NS}(\theta, V) = \frac{\partial I(\theta)}{\partial V} = 2N(0)e^2v_{F,x}\mathscr{A}\int_{-\infty}^{\infty}\left[-\frac{f_{FD}(E - eV)}{\partial E}\right]\left[1 + A(E) - B(E)\right]dE. \tag{6.22}$$

At zero temperature, we have

$$-\frac{\partial f_{FD}(E - eV)}{\partial E} = \delta(E - eV), \tag{6.23}$$

which leads to

$$G_{NS}(\theta, V) = 2N(0)e^2v_{F,x}\mathscr{A}[1 + A(eV) - B(eV)] \tag{6.24}$$

Equations (6.22) and (6.24) represent the BTK scattering formalization for the transport across the NS junction, while the BdG equations provide a framework to evaluate the reflection probability quantitatively. Interestingly, the BTK formula can also be considered as the revised version of the Landauer-Büttiker formula [6, 7] for an NS junction. The latter has been extensively used to describe the quantum coherent transport in mesoscopic normal conductors. We first point out that the original BTK theory is applicable to a junction with translational invariance along the NS interface. A more general Landauer-Büttiker-like theory has been developed [8-12] to describe the quantum phase-coherence transport through normalmetal superconductor hybrid structures. With this generalized theory, the zero-bias conductance anomaly observed in the differential conductance of a semiconductor in contact with a conventional s-wave superconductor [13-15] has been interpreted as a combined consequence of multiple impurity scattering inside the semiconductor and the Andreev reflection at the interface [11, 16]. The generalized scattering formalism can also be cast into the random matrix theory [17] to study the excess conductance of semiconductor-superconductor junctions, where the elastic impurity scattering in the normal region is important.

In this chapter, we consider no impurity scattering at the NS interface and instead focus on the consequence of superconducting pairing symmetry on the conductance. Part of the

motivation comes from the observation of zero-bias conductance peak (ZBCP) when electrons are tunneling into the *ab*-oriented thin films of high-temperature superconductors [18-21]. This ZBCP cannot be explained by conventional tunneling theories. Although the feature was originally analyzed based on the conventional *s*-wave tunneling model by introducing the spin-flip scattering of the tunnel electrons from magnetic impurities speculated to exist in the insulating barrier, the mechanism is inconsistent with the experimentally observed nonlinear splitting of the ZBCP with the magnetic field and the absence of the ZBCP in the tunneling conductance of *c*-axis-oriented YBaCuO/Pb junctions. Now it has become clear [22-25] that the ZBCP observed in high-temperature cuprates originates instead from the *d*-wave pairing symmetry.

9.6.2 6.2 Tunneling Conductance Through a NS Junction

Theory

Without loss of generality, we consider a two-dimensional normal-metal /superconductor junction. The setup is relevant to the high-temperature cuprates, where the superconductivity emerges mainly in the two-dimensional copper-oxide plane. As we have derived in Chap. 1, the motion of quasiparticles in a normal-metal superconductor junction can be described by the BdG equation (1.60)

$$\mathscr{H}_e(\mathbf{r})u(\mathbf{r}) + \int d\mathbf{r}'\Delta\left(\mathbf{r},\mathbf{r}'\right)v\left(\mathbf{r}'\right) = Eu(\mathbf{r}) \tag{6.25a}$$

$$-\mathscr{H}_e^*(\mathbf{r})v(\mathbf{r}) + \int d\mathbf{r}'\Delta^*\left(\mathbf{r}',\mathbf{r}\right)u\left(\mathbf{r}'\right) = Ev(\mathbf{r}) \tag{6.25b}$$

Here $(u(\mathbf{r}), v(\mathbf{r}))$ is the quasiparticle wave function of the BdG equations. $\mathscr{H}_e(\mathbf{r}) = -\hbar^2\nabla_{\mathbf{r}}^2/2m_e + V(\mathbf{r}) - E_F$ is the single-particle Hamiltonian, where $V(\mathbf{r})$ is the usual static potential, and E_F is the Fermi energy. Therefore, the excitation energy is
measured with respect to the Fermi energy E_F. Again we have dropped the spin indices to the quasiparticle wave function for the case without spin-polarization and spin-flip scattering. $\Delta\left(\mathbf{r},\mathbf{r}'\right)$ is the pair potential, the dependence of which on $\mathbf{r}$ and $\mathbf{r}'$ cannot be reduced to a dependence on the difference of the two coordinates, that is, $\mathbf{r}-\mathbf{r}'$, for an inhomogeneous case. By introducing the center-of-mass coordinates $\mathbf{R} = \left(\mathbf{r}+\mathbf{r}'\right)/2$ and the relative coordinates $\mathbf{s} = \mathbf{r}-\mathbf{r}'$, we can write the pair potential in terms of $\mathbf{R}$ and $\mathbf{r}$

$$\tilde{\Delta}(\mathbf{R},\mathbf{s}) \equiv \Delta\left(\mathbf{r},\mathbf{r}'\right) \tag{6.26}$$

By performing the Fourier transform with respect to the relative coordinate s, we can write the pair potential in the mixed representation

$$\tilde{\Delta}(\mathbf{R},\mathbf{k}) = \int d\mathbf{s}\tilde{\Delta}\left(\mathbf{R}+\frac{\mathbf{s}}{2},\mathbf{R}-\frac{\mathbf{s}}{2}\right)e^{-i\mathbf{k}\cdot\mathbf{s}} \tag{6.27}$$

This shows clearly that for an unconventional superconductor like that with d wave pairing symmetry, the pair potential depends not only on the center-of-mass coordinate $\mathbf{R}$ but also on the relative wave vector $\mathbf{k}$, which in the weak-coupling theory is fixed on the Fermi surface such that only its direction $\hat{\mathbf{k}}_F = \mathbf{k}_F/k_F$ is a variable, where k_F is the magnitude of the Fermi wave vector.

An investigation of the BdG equations shows that $u(\mathbf{r})$ and $v(\mathbf{r})$ oscillate on the scale of the superconducting coherence length $\xi_0 = \hbar v_F/2\Delta_0$, which is much larger than the inverse Fermi wave vector k_F^{-1}. Here v_F is the Fermi velocity and Δ_0 is the maximum value of the pair potential in the bulk region of the superconductor. Therefore, we can introduce a new set of wave functions

$$\begin{pmatrix}\bar{u}(\mathbf{r})\\ \bar{v}(\mathbf{r})\end{pmatrix} = e^{-i\mathbf{k}_F\cdot\mathbf{r}}\begin{pmatrix}u(\mathbf{r})\\ v(\mathbf{r})\end{pmatrix}, \tag{6.28}$$

to divide out the fast oscillation. The substitution of Eq. (6.28) into Eq. (6.25) leads to the Andreev equations [1, 26]:

$$E\bar{u}(\mathbf{r}) = -i\left(\hbar^2/m_e\right)\mathbf{k}_F\cdot\nabla\bar{u}(\mathbf{r}) + \tilde{\Delta}\left(\mathbf{r},\hat{\mathbf{k}}_F\right)\bar{v}(\mathbf{r}) \tag{6.29a}$$

$$E\bar{v}(\mathbf{r}) = i\left(\hbar^2/m_e\right)\mathbf{k}_F\cdot\nabla\bar{v}(\mathbf{r}) + \tilde{\Delta}^*\left(\mathbf{r},\hat{\mathbf{k}}_F\right)\bar{u}(\mathbf{r}) \tag{6.29b}$$

when we retain only terms of the lowest order in $(k_F\xi_0)^{-1}$. We show this by looking at

$$\int d\mathbf{r}'\Delta\left(\mathbf{r},\mathbf{r}'\right)\bar{v}\left(\mathbf{r}'\right)e^{-i\mathbf{k}\cdot(\mathbf{r}-\mathbf{r}')} = \int d\mathbf{s}\tilde{\Delta}(\mathbf{r}-\mathbf{s}/2,\mathbf{s})\bar{v}(\mathbf{r}-\mathbf{s})e^{-i\mathbf{k}\cdot\mathbf{s}} \tag{6.30}$$

Assuming that $\bar{v}(\mathbf{r})$ is a slowly varying function as is $\tilde{\Delta}(\mathbf{R},\mathbf{s})$ in the first argument

$$\begin{aligned}\tilde{\Delta}(\mathbf{r}-\mathbf{s}/2,\mathbf{s}) &\approx \tilde{\Delta}(\mathbf{r},\mathbf{s}) - \mathbf{s}\cdot\nabla_{\mathbf{r}}\tilde{\Delta}(\mathbf{r},\mathbf{s})/2,\\ \bar{v}(\mathbf{r}-\mathbf{s}) &\approx \bar{v}(\mathbf{r}) - \mathbf{s}\cdot\nabla_{\mathbf{r}}\bar{v}(\mathbf{r}),\end{aligned}$$

we have

$$\begin{aligned}&\int d\mathbf{s}\tilde{\Delta}(\mathbf{r}-\mathbf{s}/2,\mathbf{s})\bar{v}(\mathbf{r}-\mathbf{s})e^{-i\mathbf{k}\cdot\mathbf{s}} = \int d\mathbf{s}\left[\tilde{\Delta}(\mathbf{r},\mathbf{s}) - \mathbf{s}\cdot\nabla_{\mathbf{r}}\tilde{\Delta}(\mathbf{r},\mathbf{s})/2\right]\left[\bar{v}(\mathbf{r}) - \mathbf{s}\cdot\nabla_{\mathbf{r}}\bar{v}(\mathbf{r})\right]\\ \approx&\int d\mathbf{s}\tilde{\delta}(\mathbf{r},\mathbf{s})\bar{v}(\mathbf{r})e^{-i\mathbf{k}\cdot\mathbf{s}} - \int d\mathbf{s}\frac{\mathbf{s}}{2}\cdot\nabla_{\mathbf{r}}\tilde{\Delta}(\mathbf{r},\mathbf{s})e^{-i\mathbf{k}\cdot\mathbf{s}} - \int d\mathbf{s}\tilde{\Delta}(\mathbf{r},\mathbf{s})\mathbf{s}\cdot\nabla_{\mathbf{r}}\bar{v}(\mathbf{r})e^{-i\mathbf{k}\cdot\mathbf{s}}\\ =&\tilde{\Delta}(\mathbf{r},\mathbf{k}) - i\left[\nabla_{\mathbf{r}}\bar{v}(\mathbf{r}) + \frac{\bar{v}(\mathbf{r})}{2}\nabla_{\mathbf{r}}\right]\cdot\nabla_{\mathbf{k}}\tilde{\Delta}(\mathbf{r},\mathbf{k})\end{aligned} \tag{6.31}$$

Here we have used the identities

$$\begin{aligned}\int d\mathbf{s}\nabla_{\mathbf{r}}\frac{\mathbf{s}}{2}\cdot\tilde{\Delta}(\mathbf{r},\mathbf{s})\bar{v}(\mathbf{r})e^{-i\mathbf{k}\cdot\mathbf{s}} &= \frac{\bar{v}(\mathbf{r})}{2}\nabla_{\mathbf{r}}\cdot\int d\mathbf{s}\tilde{\Delta}(\mathbf{r},\mathbf{s})\mathbf{s}e^{-i\mathbf{k}\cdot\mathbf{s}}\\ &= \frac{\bar{v}(\mathbf{r})}{2}\nabla_{\mathbf{r}}\cdot\int d\mathbf{s}i\nabla_{\mathbf{k}}e^{-i\mathbf{k}\cdot\mathbf{s}}\tilde{\Delta}(\mathbf{r},\mathbf{s})\\ &= i\frac{\bar{v}(\mathbf{r})}{2}\nabla_{\mathbf{r}}\cdot\nabla_{\mathbf{k}}\tilde{\Delta}(\mathbf{r},\mathbf{k}),\end{aligned}$$

and similarly

$$\begin{aligned}\int d\mathbf{s}\tilde{\Delta}(\mathbf{r},\mathbf{s})\mathbf{s}\cdot\nabla_{\mathbf{r}}\bar{v}(\mathbf{r})e^{-i\mathbf{k}\cdot\mathbf{s}} &= \nabla_{\mathbf{r}}\bar{v}(\mathbf{r})\cdot\int d\mathbf{s}\tilde{\Delta}(\mathbf{r},\mathbf{s})\mathbf{s}e^{-i\mathbf{k}\cdot\mathbf{s}}\\ &= i\nabla_{\mathbf{r}}\bar{v}(\mathbf{r})\cdot\int d\mathbf{s}i\nabla_{\mathbf{k}}e^{-i\mathbf{k}\cdot\mathbf{s}}\tilde{\Delta}(\mathbf{r},\mathbf{s})\\ &= i\nabla_{\mathbf{r}}\bar{v}(\mathbf{r})\cdot\nabla_{\mathbf{k}}\tilde{\Delta}(\mathbf{r},\mathbf{k})\end{aligned}$$

Therefore, it is clear that the second term of the sum in Eq.(6.31) is down by a factor of $(k_F\xi_0)^{-1}$ as compared with the first term. If we restrict ourselves to the terms in lowest order of the small parameters, we are left with Eq.(6.29), a firstorder differential equation in which $\mathbf{k}$ is treated as a parameter. Since $\tilde{\Delta}(\mathbf{r},\mathbf{k})$ is defined only for $\mathbf{k}$ around the Fermi wave vector, we can replace the $\mathbf{k}$-dependence of $\tilde{\Delta}(\mathbf{r},\mathbf{k})$ by one on the direction $\hat{\mathbf{k}}_F$.

From now on we assume that the edge interface is specular, runs along the y direction, and the transport direction is normal to the interface (i.e., along the x-axis) (see Fig. 6.1 for the setup). In this case, $\bar{u}, \bar{v}$, and $\tilde{\Delta}$ spatially depend only on the variable x since the system is translational invariant along the interface. The Andreev equations then reduce to the form:

$$E\bar{u}(x) = -i\left(\hbar^2/m_e\right) k_{Fx} \frac{d\bar{u}(x)}{dx} + \tilde{\Delta}\left(\hat{\mathbf{k}}_F, x\right) \bar{v}(x) \tag{6.32a}$$

$$E\bar{v}(x) = i\left(\hbar^2/m_e\right) k_{Fx} \frac{d\bar{v}(x)}{dx} + \tilde{\Delta}\left(\hat{\mathbf{k}}_F, x\right) \bar{u}(x) \tag{6.32b}$$

Here we have assumed the superconducting pair potential to be real. We further choose the interface at $x = 0$. The region $x < 0$ is occupied by the normal conductor while the region $x > 0$ is occupied by the superconductor. At the NS interface, quasiparticles (e.g., electron like excitations) are partially reflected as electron-like and hole-like excitations due to the non-zero pair potential in the superconductor. When the wave vectors of electron-like and hole-like excitations are different, the pair potentials experienced by electron-like and hole-like excitations should be different for an unconventional superconductor. We denote the incident and reflected wave vectors by $\mathbf{k}_+ = (k_x, k_y)$ and $\mathbf{k}_- = (-k_x, k_y)$, respectively. The pair potential then takes the form

$$\tilde{\Delta}\left(\mathbf{k}_\pm, x\right) = \begin{cases} 0, & x < 0 \\ \Delta_0, & 0 \le x \end{cases} \tag{6.33}$$

for the s-wave superconductor, while

$$\tilde{\Delta}\left(\mathbf{k}_\pm, x\right) = \begin{cases} 0, & x < 0 \\ \Delta_0 \cos\left(2\theta_\pm\right), & 0 \le x \end{cases} \tag{6.34}$$

for the $d_{x^2-y^2}$-wave superconductor. Here $\theta_\pm = \theta \mp \alpha$ with θ the incident angle of electron excitations injected from the normal conductor and α the disorientation angle of the crystalline axis along which the $d_{x^2-y^2}$-wave superconducting pair potential reaches the maximum. Both θ and α are measured relative to the positive x-axis. In addition, to capture the essential interfacial scattering at the interface, we include a δ-function potential

$$V(x) = H\delta(x) \tag{6.35}$$

The metallic contact and the tunnel junction correspond to the two limiting cases of the barrier strength $H = 0$ and $H \to \infty$.

In the condition of an electron beam incident from the normal conductor at an angle θ, the solution to the Andreev equations (6.29),

$$\Psi(x) = \begin{pmatrix} \bar{u}(x) \\ \bar{v}(x) \end{pmatrix}$$

is given by

$$\Psi_{\mathrm{I}}(x) = \begin{pmatrix} 1 \\ 0 \end{pmatrix} e^{iq_e x} + a \begin{pmatrix} 0 \\ 1 \end{pmatrix} e^{iq_h x} + b \begin{pmatrix} 1 \\ 0 \end{pmatrix} e^{-iq_e x} \tag{6.36}$$

for $x < 0$, and

$$\Psi_{\mathrm{II}}(x) = c \begin{pmatrix} u_+ e^{i\phi_+} \\ v_+ \end{pmatrix} e^{ik_{e,+}x} + d \begin{pmatrix} v_- e^{i\phi_-} \\ u_- \end{pmatrix} e^{-ik_{h,-}x} \tag{6.37}$$

for $x \geq 0$. Here the wave vectors are determined from the energy dispersion:

$$q_{e,h} = k_{fx} \pm \frac{m_e E}{\hbar^2 k_{Fx}} \tag{6.38}$$

$$k_{e(h),+} = k_{Fx} \pm \frac{m_e \sqrt{E^2 - \left|\tilde{\Delta}\left(\mathbf{k}_+\right)\right|^2}}{\hbar^2 k_{Fx}} \tag{6.39}$$

$$k_{e(h),-} = k_{Fx} \pm \frac{m_e \sqrt{E^2 - \left|\tilde{\Delta}\left(\mathbf{k}_-\right)\right|^2}}{\hbar^2 k_{Fx}} \tag{6.40}$$

For a given pair potential, these wave vectors are schematically described in Fig. 6.2. The coherence factors in the superconducting regions are

$$u_\pm^2 = \frac{1}{2}\left(1 + \frac{\sqrt{E^2 - \left|\tilde{\Delta}\left(\mathbf{k}_\pm\right)\right|^2}}{E}\right), \tag{6.41}$$

$$v_\pm^2 = \frac{1}{2}\left(1 - \frac{\sqrt{E^2 - \left|\tilde{\Delta}\left(\mathbf{k}_\pm\right)\right|^2}}{E}\right) \tag{6.42}$$

respectively. The characteristic phases are given by

$$\phi_\pm = \cos^{-1}\left(\frac{\cos 2(\theta \mp \alpha)}{|\cos 2(\theta \mp \alpha)|}\right). \tag{6.43}$$

Imposing the boundary conditions at the interface

$$\Psi_{\mathrm{II}}(0) = \Psi_{\mathrm{I}}(0), \tag{6.44a}$$

$$\Psi'_{\mathrm{II}}(0) - \Psi'_{\mathrm{I}}(0) = \left(\frac{2m_e H}{\hbar^2}\right)\Psi'_{\mathrm{I}}(0), \tag{6.44b}$$

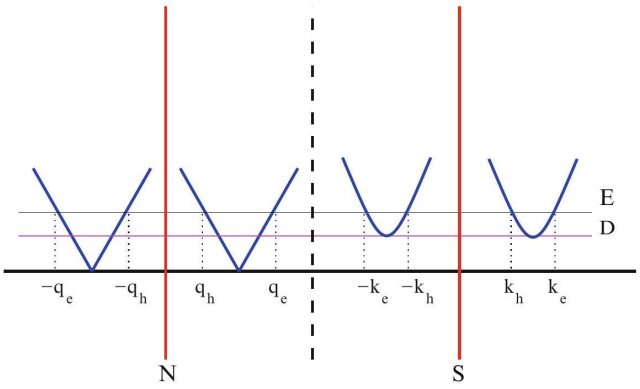


Fig. 6.2 Schematic diagram of energy versus momentum at the normal-metal/superconductor interface

and carrying out the algebraic reduction, we obtain

$$a = \frac{u_- v_+}{(1+Z^2)\, u_+ u_- e^{i\phi_+} - Z^2 v_+ v_- e^{i\phi_-}}, \tag{6.45}$$

and

$$b = -\frac{(iZ+Z^2)\left(u_+ u_- e^{i\phi_+} - v_+ v_- e^{i\phi_-}\right)}{(1+Z^2)\, u_+ u_- e^{i\phi_+} - Z^2 v_+ v_- e^{i\phi_-}} \tag{6.46}$$

where $Z = m_e H/\hbar^2 k_F \cos\theta = Z_0/\cos\theta$ with $Z_0 = m_e H/\hbar^2 k_F$. The corresponding normal and Andreev reflection probabilities are then given by $B(E,\theta) = |b(E,\theta)|^2$, and $A(E,\theta) = |a(E,\theta)|^2$, respectively. Therefore, the differential conductance can be determined upon the substitution of Eqs. (6.45) and (6.46) into Eq. (6.24). For the normal-metal/normal-metal junction, that is, the superconductor in the region $x \geq 0$ replaced by the normal metal, the Andreev and normal reflection amplitudes are given by

$$a = 0 \tag{6.47}$$

and

$$b(E,\theta) = -\frac{Z(1+iZ)}{1+Z^2} \tag{6.48}$$

which leads to the differential conductance

$$G_{NN}(E,\theta) = 2N(0)e^2 \mathscr{A} \frac{v_{F,x}}{1+Z^2} \tag{6.49}$$

For the 2D model we are considering, we shall take an average over the incident angle

$$\begin{aligned}\bar{G}_{NS}(E) &= \frac{1}{\pi}\int_{-\pi/2}^{\pi/2} d\theta G_{NS}(E,\theta) \\ &= \frac{2N(0)e^2\mathscr{A}v_F}{\pi}\int_{-\pi/2}^{\pi/2} d\theta \cos\theta [1 + A(E,\theta) - B(E,\theta)],\end{aligned} \tag{6.50}$$

for the NS junction, and

$$\begin{aligned}\bar{G}_{NN}(E) &= \frac{1}{\pi}\int_{-\pi/2}^{\pi/2} d\theta G_{NN}(E,\theta) \\ &= \frac{2N(0)e^2\mathscr{A}v_F}{\pi}\int_{-\pi/2}^{\pi/2} d\theta \frac{\cos\theta}{1+Z^2} \\ &= \frac{2N(0)e^2\mathscr{A}v_F}{\pi}\left[2 - \frac{Z_0^2}{\sqrt{1+Z_0^2}}\ln\frac{\sqrt{1+Z_0^2}+1}{\sqrt{1+Z_0^2}-1}\right],\end{aligned} \tag{6.51}$$

for the NN junction. Therefore, we can define a normalized differential conductance

$$\begin{aligned} g_{NS}(E) &= \frac{\bar{G}_{NS}(E)}{\bar{G}_{NN}(E)} \\ &= \frac{1}{\mathscr{N}}\int_{-\pi/2}^{\pi/2} d\theta \cos\theta [1 + A(E,\theta) - B(E,\theta)],\end{aligned} \tag{6.52}$$

where

$$\mathscr{N} = 2 - \frac{Z_0^2}{\sqrt{1+Z_0^2}} \ln \frac{\sqrt{1+Z_0^2}+1}{\sqrt{1+Z_0^2}-1}. \tag{6.53}$$

This normalized conductance is useful to the comparison with the standard transport measurement across the NS junction. For the orifice model of the point contact spectroscopy, we can set a specific incident angle and do not perform an average. In this case, we can still define a normalized conductance but now for a given incident angle θ.

$$g_{NS,PCS}(E,\theta) = \left(1+Z^2\right)\left[1 + A(E,\theta) - B(E,\theta)\right] \tag{6.54}$$

In the following, we discuss a few representative cases of the transport across the NS junction.

s-Wave NS Junction For the s-wave NS junction, the superconducting pair potential has no momentum dependence and as such is independent of the incident angle. Therefore, we have

$$u_\pm^2 = u_0^2 = \frac{1}{2}\left(1 + \frac{\sqrt{E^2 - \left|\tilde{\Delta}_0\right|^2}}{E}\right) \tag{6.55}$$

and

$$v_\pm^2 = v_0^2 = \frac{1}{2}\left(1 - \frac{\sqrt{E^2 - \left|\tilde{\Delta}_0\right|^2}}{E}\right) \tag{6.56}$$

In addition, $\phi_\pm = 0$. The Andreev reflection and normal reflection amplitudes are given by

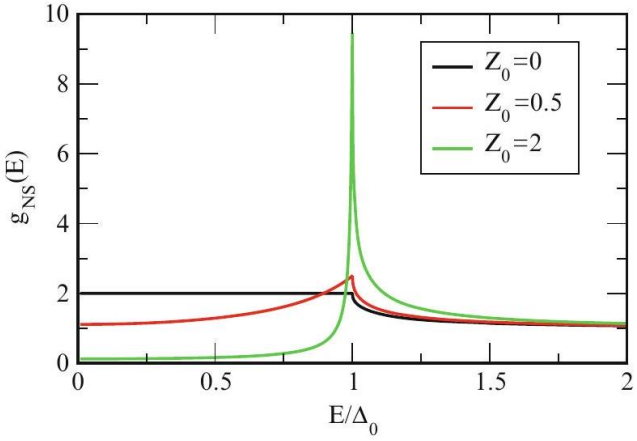
$$a = \frac{u_0 v_0}{u_0^2 + \left(u_0^2 - v_0^2\right) Z^2}, \tag{6.57}$$

and

$$b = \frac{-\left(Z^2 + iZ\right)\left(u_0^2 - v_0^2\right)}{u_0^2 + \left(u_0^2 - v_0^2\right) Z^2} \tag{6.58}$$

respectively. These expressions suggest that, for the contact case $Z_0 = 0$, when the energy E is smaller than the superconducting gap $\tilde{\Delta}_0$, $A(E) = |a|^2 = 1$ and $B(E) = |b|^2 = 0$, explaining the double of the conductance as compared with that for the NN junction. In the tunneling limit $Z_0 \to \infty$, we have $A(E) = 0$ and $B(E) = 1$ so that the conductance is zero for $E < \tilde{\Delta}_0$. The numerical results of the differential conductance for the NS junction with s-wave pairing symmetry are shown in Fig. 6.3. The Andreev reflection is suppressed with increased interface barrier strength in the s-wave NS junction and the resulting differential conductance has the profile of the s-wave density of states in the tunneling limit.

d-Wave NS Junction As we have mentioned before, for the NS junction with an unconventional pairing symmetry, the energy experienced by electronic-like and hole-like excitations are sensitive to both the relative crystalline orientation between the normal metal and the superconductor and the incident angle. To demonstrate this, we consider the $d_{x^2-y^2}$-wave pairing symmetry of the superconductor, choosing $\alpha = \pi/4$ and $\theta = \pi/4$.[1] This angle of the relative crystalline orientation



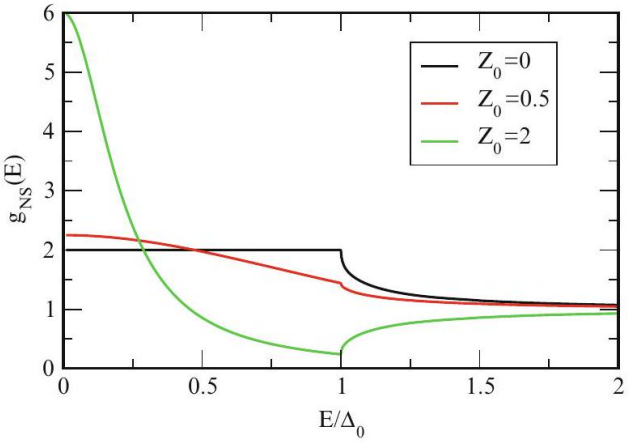


Fig. 6.3 Differential conductance for a normal-metal/s-wave superconductor junction for various values of interface barrier strength. The energy is measured in units of the superconducting pair potential. The incident angle is chosen to be $\theta = 0$ corresponds to the square lattice of copper-oxide plane of high-temperature cuprates interfaced with the normal metal along the [110] direction. These angles determine $\tilde{\Delta}(\mathbf{k}_+) = \tilde{\Delta}_0$ while $\tilde{\Delta}(\mathbf{k}_-) = -\tilde{\Delta}_0$. The BdG wave function amplitudes $u_\pm$and $v_\pm$ are still given by the formula similar to the s-wave case presented above. However, we have now the characteristic phase $\phi_+ = 0$ while $\phi_- = \pi$ due to the sign change of the pair potential experienced by electron-like and hole-like excitations. In this case, the Andreev and normal-state reflection amplitudes are found as

$$a = \frac{u_0 v_0}{u_0^2 + Z^2} \tag{6.59}$$

and

$$b = -\frac{iZ + Z^2}{u_0^2 + Z^2} \tag{6.60}$$

These expressions suggest that for the perfect contact $Z_0 = 0$, the Andreev reflection is still complete with $A(E) = 1$ and $B(E) = 0$ for $E < \Delta_0$. Even more interestingly, for the tunneling limit $Z_0 \to \infty$, as $E \to 0, A(E) \to 1$ while $B(E) \to 0$, indicating a conductance anomaly. The numerical results on the differential conductance for the d-wave NS junction are shown in Fig. 6.4 for $\alpha = \theta = \pi/4$. It shows clearly that the zero-energy conductance peak appears in the limiting case of tunneling barrier. This anomaly is solely due to the sign change of $d_{x^2-y^2}$-wave superconducting order parameter under the above condition. This existence of the zero-bias conductance peak has been used to identify the $d_{x^2-y^2}$-wave pairing symmetry in the hightemperature cuprates.

[1] The results for $\alpha = \theta = 0$ are very similar to the s-wave NS junction.

Fig. 6.4 Differential conductance for a normal-metal/d-wave superconductor junction for various values of interface barrier strength. The energy is measured in units of the superconducting pair potential. The crystalline orientation between the normal metal and the d-wave superconductor and the incident angle is chosen to be $\alpha = \pi/4$ and $\theta = \pi/4$, respectively

9.6.3 6.3 Suppression of Andreev Reflection in a FS Junction

Theory

In the Andreev reflection process, the incoming electron and the Andreev reflected hole occupy energy bands with opposite spins. For the case of normal metals, due to the spin degeneracy of the energy levels, no spin effects occur with the Andreev reflection. However, in a metallic ferromagnet, the energy band is split. The interplay of superconductivity and ferromagnetism in hybrid structures has been a very interesting topic. A lot of works have focused on the changes of the critical temperature of the superconductor in s-wave superconductor/ferromagnet multilayers [27-34], the Josephson critical current in superconductor/ferromagnet/superconductor junctions [35-38], and the magnetic coupling in ferromagnet/superconductor/ferromagnet multilayers [39, 40]. In tunneling regime, the Andreev reflection is unimportant [41]. However, in the contact regime, the spin splitting effect on the Andreev reflection in ferromagnet/superconductor cannot be ignored [42-44]. To model the spin splitting effect on the Andreev reflection in a ferromagnet/s-wave superconductor junction, we consider the Stoner model, in which the motion of conduction electrons inside the ferromagnet can be described by an effective single-particle Hamiltonian with an exchange interaction while the influence of the magnetization of the ferromagnet on the orbital motion of conduction electrons is neglected. As we have discussed in previous chapters, in the absence of spin-flip scattering, the spin-dependent (four-component) BdG equations are decoupled into two sets of (two-component) equations, one for the spin-up electron and spin-down hole quasiparticle wave functions $(u_\uparrow, v_\downarrow)^T$, while the other for spin-down electron and spin-up hole quasiparticle wave functions $(u_\downarrow, v_\uparrow)^T$. The set of BdG equations for $(u_\uparrow, v_\downarrow)^T$ can be written as:

$$[\mathscr{H}_e(\mathbf{r}) - h(\mathbf{r})]\, u_\uparrow(\mathbf{r}) + \int d\mathbf{r}' \Delta(\mathbf{r}, \mathbf{r}')\, v_\downarrow(\mathbf{r}') = E u_\uparrow(\mathbf{r}) \tag{6.61a}$$

$$-[\mathscr{H}_e^*(\mathbf{r}) + h(\mathbf{r})]\, v_\downarrow(\mathbf{r}) + \int d\mathbf{r}' \Delta^*(\mathbf{r}', \mathbf{r})\, u_\uparrow(\mathbf{r}') = E v_\downarrow(\mathbf{r}) \tag{6.61b}$$

Compared with the case of a NS junction considered in the previous section [cf. Eq.(6.25)], an exchange field $h(\mathbf{r}) = h_0\Theta(-x)$ in the ferromagnet is now introduced. The set of BdG equations for $(u_\downarrow, v_\uparrow)^T$ is obtained by simply changing the sign before $h(\mathbf{r})$ in Eq. (6.61). Following the same procedure as given in the previous section, we have the solution to the Andreev equations as:

$$\Psi_{\mathrm{I}}(x) = \begin{pmatrix}1\\0\end{pmatrix} e^{iq_e x} + r_{\downarrow\uparrow}\begin{pmatrix}0\\1\end{pmatrix} e^{iq_h x} + r_{\uparrow\uparrow}\begin{pmatrix}1\\0\end{pmatrix} e^{-iq_e x} \tag{6.62}$$

for $x < 0$, and

$$\Psi_{\mathrm{II}}(x) = c\begin{pmatrix}u_+ e^{i\phi_+}\\ v_+\end{pmatrix} e^{ik_{e,+}x} + \begin{pmatrix}v_- e^{i\phi_-}\\ u_-\end{pmatrix} e^{-ik_{h,-}x} \tag{6.63}$$

for $x \geq 0$. Here the wave vectors are determined from the energy dispersion:

$$q_{e\uparrow,h\downarrow} = \sqrt{k_{Fx}^2 \pm \frac{2m_e}{\hbar^2}(E + h_0)}, \tag{6.64}$$

$$k_{e(h),+} = k_{Fx} \pm \frac{m_e\sqrt{E^2 - \left|\tilde{\Delta}(\mathbf{k}_+)\right|^2}}{\hbar^2 k_{Fx}} \tag{6.65}$$

$$k_{e(h),-} = k_{Fx} \pm \frac{m_e\sqrt{E^2 - \left|\tilde{\Delta}(\mathbf{k}_-)\right|^2}}{\hbar^2 k_{Fx}} \tag{6.66}$$

Since the Andreev reflection for the s-wave NS junction is most pronounced in the contact case, we consider the barrier strength $H = 0$. Therefore, the boundary conditions now become:

$$\Psi_{\mathrm{II}}(0) = \Psi_{\mathrm{I}}(0) \tag{6.67a}$$

$$\Psi'_{\mathrm{II}}(0) = \Psi'_{\mathrm{I}}(0) \tag{6.67b}$$

The important difference between the NS and FS junctions are now revealed by the momentum difference in the ferromagnet. To show this, we expand the boundary conditions:

$$\begin{pmatrix} u_+ e^{i\phi_+} c + v_- e^{i\phi_-} d \\ v_+ c + u_- d \end{pmatrix} = \begin{pmatrix} 1 + r_{\uparrow\uparrow} \\ r_{\downarrow\uparrow} \end{pmatrix}, \tag{6.68a}$$

and

$$\begin{pmatrix} u_+ e^{i\phi_+} c - v_- e^{i\phi_-} d \\ v_+ c - u_- d \end{pmatrix} = \begin{pmatrix} \frac{q_{e\uparrow}}{k_{Fx}}(1 - r_{\uparrow\uparrow}) \\ \frac{q_{\downarrow\downarrow}}{k_{Fx}} r_{\downarrow\uparrow} \end{pmatrix}, \tag{6.68b}$$

which gives

$$r_{\downarrow\uparrow} = \frac{4u_- v_+ \bar{q}_e \uparrow}{(1 + \bar{q}_{e\uparrow})(1 + \bar{q}_{h\downarrow}) u_+ u_- e^{i\phi_+} - (1 - \bar{q}_e \uparrow)(1 - \bar{q}_{h\downarrow}) v_+ v_- e^{i\phi_-}}, \tag{6.69}$$

and

$$r_{\uparrow\uparrow} = \frac{-(1 - \bar{q}_{e\uparrow})(1 + \bar{q}_{h\downarrow}) u_+ u_- e^{i\phi_+} + (1 + \bar{q}_{e\uparrow})(1 - \bar{q}_{h\downarrow}) v_+ v_- e^{i\phi_-}}{(1 + \bar{q}_{e\uparrow})(1 + \bar{q}_{h\downarrow}) u_+ u_- e^{i\phi_+} - (1 - \bar{q}_{e\uparrow})(1 - \bar{q}_{h\downarrow}) v_+ v_- e^{i\phi_-}} \tag{6.70}$$

Here the normalized wave vectors in the ferromagnet are given by

$$\bar{q}_{e\uparrow(h\downarrow)} = \sqrt{1 \pm \bar{h}}, \tag{6.71}$$

with $\bar{h} = 2m_e h_0/\hbar^2 k_{Fx} = \bar{h}_0/\cos\theta$.
We can follow the similar discussion on the NS junction and write down the differential conductance for the FS junction, for a given incident angle, as:

$$g_{FS,PCS} = \frac{1}{2}\Sigma_\sigma \left[1 + (\bar{q}_{h\bar{\sigma}}/\bar{q}_{e\sigma})\left|r_{\bar{\sigma}\sigma}\right|^2 - \left|r_{\sigma\sigma}\right|^2\right], \tag{6.72}$$

which has been normalized to the conductance for the NN junction. The prefactor $\bar{q}_{h\bar{\sigma}}/\bar{q}_{e\sigma}$ before the Andreev reflection amplitude takes care of the fact that the electron and hole have different velocity in the ferromagnet. In Fig. 6.5, the differential conductance is shown for a ferromagnet/s-wave superconductor junction for various values of the exchange interaction

strength in the ferromagnet. The suppression of subgap conductance is seen clearly with the increase of exchange coupling strength. Experimental study has also been extended to ferromagnet/highT_c superconductor junctions [45]. The corresponding theory with a $d_{x^2-y^2}$-wave pairing symmetry has also been developed along the same line discussed above but with an emphasis on the zero-bias conductance [46] and the Fermi wave vector mismatch between the ferromagnet and superconductor [47].

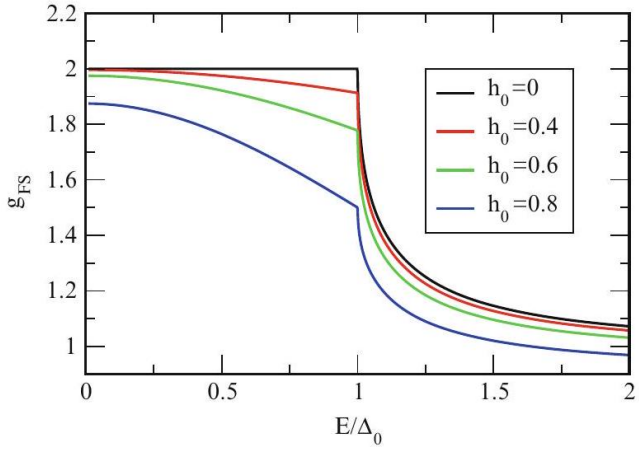

Fig. 6.5 Differential conductance for a ferromagnet/s-wave superconductor junction for various values of exchange interaction strength in the ferromagnet. The energy is measured in units of the superconducting pair potential. The crystalline orientation between the normal metal and the s-wave superconductor and the incident angle is chosen to be $\alpha = 0$ and $\theta = 0$, respectively

9.6.4 Transport Properties Through a Topological-Insulator/Superconductor Junction

Theory

So far, we have discussed the transport properties across the junctions involving conventional metals and ferromagnets. There is another class of quantum materials, so-called topological insulators (TI). They are insulating in bulk but host a gapless surface states with a Dirac-like linear dispersion [48, 49]. Like in graphene, the Dirac-like linear dispersion has a fundamental implication to various new phenomena. In TI, the surface states are topologically protected by time-reversal symmetry, and are robust against nonmagnetic disorder and perturbations. More interestingly, topological superconductivity can be induced in TIs through chemical doping [50] or proximately induced at the TI/superconductor interfaces [51-53]. Therefore, the transport through the topological superconductor junctions should be very interesting. Especially, the possible existence of Majorana fermions in the condensed matter systems is of significant implication to the technology like quantum computers and other electronic devices [54-58]. The property of the antiparticle of an Majorana fermion being itself holds a key to quantum coherence protection.

Here we consider a Dirac-normal-metal/ferromagnet insulator/s-wave topological superconductor junction. The Dirac-BdG equations can be written as:

$$\begin{pmatrix} H_{\uparrow\uparrow}(\mathbf{r}) & H_{\uparrow\downarrow} & 0 & \Delta(\mathbf{r}) \\ H_{\downarrow\uparrow}(\mathbf{r}) & H_{\downarrow\downarrow}(\mathbf{r}) & \Delta(\mathbf{r}) & 0 \\ 0 & \Delta^*(\mathbf{r}) & -H^*_{\uparrow\uparrow}(\mathbf{r}) & H^*_{\uparrow\downarrow}(\mathbf{r}) \\ \Delta^*(\mathbf{r}) & 0 & H^*_{\downarrow\uparrow}(\mathbf{r}) & -H^*_{\downarrow\downarrow}(\mathbf{r}) \end{pmatrix} \begin{pmatrix} u_\uparrow(\mathbf{r}) \\ u_\downarrow(\mathbf{r}) \\ v_\uparrow(\mathbf{r}) \\ v_\downarrow(\mathbf{r}) \end{pmatrix} = E \begin{pmatrix} u_\uparrow(\mathbf{r}) \\ u_\downarrow(\mathbf{r}) \\ v_\uparrow(\mathbf{r}) \\ v_\downarrow(\mathbf{r}) \end{pmatrix}. \tag{6.73}$$

Here the single-particle Hamiltonian matrix in the spin-space is given by

$$\hat{H} = \hat{h}(\mathbf{r}) + \hat{M}(\mathbf{r}), \tag{6.74}$$

where the Dirac-like Hamiltonian for the topological surface state is

$$\hat{h}(\mathbf{r}) = v_F \left(p_x\sigma_y - p_y\sigma_x\right) - E_F[\Theta(-x) + \Theta(x-d)] \tag{6.75}$$

with E_F is the Fermi energy, the potential for the ferromagnetic insulator is

$$\begin{aligned}\hat{M} &= \mathbf{m}\cdot\sigma\Theta(x)\Theta(d-x),\\ &= \begin{pmatrix} m_z & m_x - im_y \\ m_x + im_y & -m_z \end{pmatrix}.\end{aligned} \tag{6.76}$$

with $\mathbf{m}$ being the magnetization vector and the σ the Pauli matrices. The pair potential for the s-wave superconductor is given by

$$\Delta(\mathbf{r}) = \Delta\Theta(x-d) \tag{6.77}$$

The quasiparticle energy is measured with respect to the Fermi energy $E_F = \hbar v_F k_F$ with v_F and k_F being the Fermi velocity and wave vector.

When a beam of electrons is incident from the Dirac-like normal metal with an angle θ, the wave function is given by

$$\Psi_{\mathrm{I}}(x) = \begin{pmatrix} 1 \\ ie^{i\theta} \\ 0 \\ 0 \end{pmatrix} e^{ik_x x} + a \begin{pmatrix} 0 \\ 0 \\ 1 \\ -ie^{-i\theta} \end{pmatrix} e^{ik_x x} + b \begin{pmatrix} 1 \\ -ie^{-i\theta} \\ 0 \\ 0 \end{pmatrix} e^{-ik_x x} \tag{6.78}$$

for $x < 0$;

$$\begin{aligned}\Psi_{\mathrm{II}}(x) =& c_{e,+} \begin{pmatrix} 1 \\ \Gamma_{e,+} \\ 0 \\ 0 \end{pmatrix} e^{ik^+_{e,x}x} + c_{e,-} \begin{pmatrix} 1 \\ \Gamma_{e,-} \\ 0 \\ 0 \end{pmatrix} e^{ik^-_{e,-}x} \\ &+ c_{h,+} \begin{pmatrix} 0 \\ 0 \\ 1 \\ \Gamma_{h,+} \end{pmatrix} e^{ik_{h,+}x} + c_{h,-} \begin{pmatrix} 0 \\ 0 \\ 1 \\ \Gamma_{h,-} \end{pmatrix} e^{ik_{h,-}x},\end{aligned} \tag{6.79}$$

for $0 \le x \le d$. Here

$$k_x = k_F \cos\theta \tag{6.80}$$

$$k_y = k_F \sin\theta \tag{6.81}$$

$$k_{e,\pm} = -\frac{m_y}{\hbar k_F} \pm \frac{i}{\hbar k_F}\sqrt{m_z^2 + \left(\hbar v_F k_y - m_x\right)^2}, \tag{6.82}$$

$$k_{h,\pm} = \frac{m_y}{\hbar k_F} \mp \frac{i}{\hbar k_F}\sqrt{m_z^2 + \left(\hbar v_F k_y + m_x\right)^2} \tag{6.83}$$

$$\Gamma_{e,\pm} = -\frac{m_z}{-\hbar v_F\left(ik_{e,\pm} + k_y\right) + \left(m_x - im_y\right)} \tag{6.84}$$

$$\Gamma_{h,\pm} = -\frac{m_z}{\hbar v_F\left(ik_{h,\pm} - k_y\right) + \left(m_x + im_y\right)} \tag{6.85}$$

For the wave function in the topological superconducting region, we would like to give a more expanded discussion because the BdG equations become a set of 4×4 coupled matrix equations. We first write the wave function in the form

$$\begin{aligned}\Psi(x,y) &= \Psi(x)e^{ik_y y} \\ &= \begin{pmatrix} u_{0,\uparrow} \\ u_{0,\downarrow} \\ v_{0,\uparrow} \\ v_{0,\downarrow} \end{pmatrix} e^{iq_x x + ik_y y}. \end{aligned} \tag{6.86}$$

On substitution of Eq. (6.86) into Eq. (6.73), we arrive at the matrix equations

$$\begin{pmatrix} E+E_F & -\hbar v_F(-iq_x - k_y) & 0 & -\Delta \\ -\hbar v_F(iq_x - k_y) & E+E_F & -\Delta & 0 \\ 0 & -\Delta & E-E_F & \hbar v_F(iq_x - k_y) \\ -\Delta & 0 & \hbar v_F(-iq_x - k_y) & E-E_F \end{pmatrix} \begin{pmatrix} u_{0,\uparrow} \\ u_{0,\downarrow} \\ v_{0,\uparrow} \\ v_{0,\downarrow} \end{pmatrix} = 0 \tag{6.87}$$

which leads to the eigenvalue equation
$[(E+|\Pi|+E_F)(E-|\Pi|-E_F)-\Delta^2][(E-|\Pi|+E_F)(E+|\Pi|-E_F)-\Delta^2]=0.$
In the above equation, we have denoted

$$\Pi = i\hbar v_F(q_x - ik_y) = i|\Pi|e^{-i\gamma} \tag{6.89}$$

with $\gamma = \tan^{-1}(q_x/k_y)$. Equation (6.88) can be decoupled as

$$(E+|\Pi|+E_F)(E-|\Pi|-E_F)-\Delta^2 = 0 \tag{6.90}$$

and

$$(E-|\Pi|+E_F)(E+|\Pi|-E_F)-\Delta^2 = 0, \tag{6.91}$$

which gives four eigenvalues

$$E_{1,2} = \pm\sqrt{(-|\Pi|-E_F)^2+\Delta^2}, \tag{6.92}$$

$$E_{3,4} = \pm\sqrt{(|\Pi|-E_F)^2+\Delta^2}, \tag{6.93}$$

respectively.
We now derive the eigenfunctions corresponding to the above eigenvalues. We first write Eq. (6.87) in an expanded form

$$(E+E_F)u_{0,\uparrow} + \Pi u_{0,\downarrow} - \Delta v_{0,\downarrow} = 0 \tag{6.94a}$$

$$\Pi^* u_{0,\uparrow} + (E+E_F)u_{0,\downarrow} - \Delta v_{0,\uparrow} = 0 \tag{6.94b}$$

$$-\Delta u_{0,\downarrow} + (E-E_F)v_{0,\uparrow} - \Pi^* v_{0,\downarrow} = 0 \tag{6.94c}$$

$$-\Delta u_{0,\uparrow} - \Pi v_{0,\uparrow} + (E-E_F)v_{0,\downarrow} = 0. \tag{6.94d}$$

These wavefunctions are also subjected to the normalization condition:

$$|u_{0,\uparrow}|^2 + |u_{0,\downarrow}|^2 + |v_{0,\uparrow}|^2 + |v_{0,\downarrow}|^2 = 2. \tag{6.95}$$

Here we have used an unusual normalization factor "2" to be consistent with the intensity of the incident beam. Since there are four unknowns but five equations, we use only Eqs. (6.94a)-(6.94c) together with the normalization condition. From Eqs. (6.94a) and (6.94b), we can express $u_{0,\uparrow}$ and $u_{0,\downarrow}$ in terms of $v_{0,\uparrow}$ and $v_{0,\downarrow}$. A little algebra yields:

$$u_{0,\uparrow} = \frac{\Delta}{\left(E+E_F\right)^2 - |\Pi|^2}\left[\left(E+E_F\right)v_{0,\downarrow} - \Pi v_{0,\uparrow}\right] \tag{6.96a}$$

$$u_{0,\downarrow} = \frac{\Delta}{\left(E+E_F\right)^2 - |\Pi|^2}\left[\left(E+E_F\right)v_{0,\uparrow} - \Pi^* v_{0,\downarrow}\right] \tag{6.96b}$$

Substitution of Eqs. (6.96a) and (6.96b) into Eq. (6.94c) gives

$$\begin{aligned} v_{0,\uparrow} &= -\frac{i|\Pi|e^{i\gamma}\left[-\Delta^2 + \left(E+E_F\right)^2 - |\Gamma|^2\right]}{-\Delta^2\left(E+E_F\right) + \left(E-E_F\right)\left[\left(E+E_F\right)^2 - |\Pi|^2\right]} v_{0,\downarrow} \\ &= \begin{cases} ie^{i\gamma}v_{0,\downarrow}, \text{ for } E_{3,4} \\ -ie^{i\gamma}v_{0,\downarrow}, \text{ for } E_{1,2} \end{cases} \end{aligned} \tag{6.97}$$

which in turn gives

$$u_{0,\downarrow} = \begin{cases} ie^{i\gamma}u_{0,\uparrow}, & \text{for } E_{3,4}, \\ -ie^{i\gamma}u_{0,\uparrow}, & \text{for } E_{1,2}, \end{cases} \tag{6.98}$$

We can then substitute Eqs. (6.97) and (6.98) back into Eq. (6.96a) and obtain:

$$u_{0,\uparrow} = \frac{\Delta}{\left(E+E_F\right) - |\Pi|}v_{0,\downarrow}, \tag{6.99}$$

for $E_{3,4}$, while

$$u_{0,\uparrow} = \frac{\Delta}{\left(E+E_F\right) + |\Pi|}v_{0,\downarrow} \tag{6.100}$$

for $E_{1,2}$. Substituting these relations into the normalization condition Eq. (6.95), we are able to arrive at

$$\left(u_{0,\uparrow}^{(3,4)}\right)^2 = \frac{1}{2}\left(1 + \frac{|\Pi| - E_F}{E_{3,4}}\right), \tag{6.101a}$$

$$\left(v_{0,\downarrow}^{(3,4)}\right)^2 = \frac{1}{2}\left(1 - \frac{|\Pi| - E_F}{E_{3,4}}\right), \tag{6.101b}$$

and

$$\left(u_{0,\uparrow}^{(1,2)}\right)^2 = \frac{1}{2}\left(1 - \frac{|\Pi| - E_F}{E_{1,2}}\right) \tag{6.101c}$$

$$\left(v_{0,\downarrow}^{(1,2)}\right)^2 = \frac{1}{2}\left(1 + \frac{|\Pi| - E_F}{E_{1,2}}\right) \tag{6.101d}$$

Eigenfunctions as given by Eq. (6.101) suggest that for an incident wave from the normal metal with energy E, the transmitted wave function should have the form

$$\Psi_{\rm III}(x) = t_e \begin{pmatrix} u_0 \\ iu_0 e^{i\theta} \\ iv_0 e^{i\theta} \\ v_0 \end{pmatrix} e^{ik_x x} + t_h \begin{pmatrix} v_0 \\ -iv_0 e^{i\theta} \\ -iu_0 e^{i\theta} \\ u_0 \end{pmatrix} e^{-ik_x x} \tag{6.102}$$

for $x \geq d$, where the coherence factors

$$u_0 = \sqrt{\frac{1}{2}\left(1 + \frac{\sqrt{E^2 - \Delta^2}}{E}\right)}, \tag{6.103a}$$

$$v_0 = \sqrt{\frac{1}{2}\left(1 - \frac{\sqrt{E^2 - \Delta^2}}{E}\right)}. \tag{6.103b}$$

Here we have used the Andreev approximation to take the x-component of the wave vector to be the same as that projected from $\mathbf{k}_F$, that is, $q_x = k_x = k_F \cos\theta$ with $\gamma \approx \theta$.

We can now impose the boundary conditions

$$\Psi_{\rm I}(x = 0) = \Psi_{\rm II}(x = 0), \tag{6.104}$$

at $x = 0$, and

$$\Psi_{\rm II}(x = d) = \Psi_{\rm III}(x = d), \tag{6.105}$$

at $x = d$. A straightforward but tedious algebra yields the reflection amplitudes

$$a = \frac{1 + e^{2i\theta}}{(\mathscr{M}_{11} - ie^{-i\theta}\mathscr{M}_{12}) - (ie^{i\theta}\mathscr{M}_{21} + \mathscr{M}_{22})} \tag{6.106a}$$

$$b = \frac{\left(\mathscr{M}_{11} - ie^{-i\theta}\mathscr{M}_{12}\right) e^{i2\theta} + \left(ie^{i\theta}\mathscr{M}_{21} + \mathscr{M}_{22}\right)}{(\mathscr{M}_{11} - ie^{-i\theta}\mathscr{M}_{12}) - (ie^{i\theta}\mathscr{M}_{21} + \mathscr{M}_{22})} \tag{6.106b}$$

where

$$\begin{aligned}
\mathscr{M}_{11} =& \mathscr{D}^{-1}\Big[-ie^{i\theta}e^{i\left(k_{h,+}+k_{e,+}\right)d}\left(1+\Gamma_{h,+}\right)\left(\Gamma_{h,+}+\Gamma_{h,-}-\Gamma_{e,+}\right) \\
&+\left(u_0^2-v_0^2\right)e^{i\left(k_{h,+}+k_{e,-}\right)d}\left(1+\Gamma_{h,+}\right)\left(\Gamma_{h,+}+\Gamma_{h,-}-\Gamma_{e,-}\right) \\
&+\left(u_0^2-v_0^2\right)e^{2i\theta}e^{i\left(k_{h,-}+k_{e,-}\right)d}\left(1+\Gamma_{-}\right)\left(\Gamma_{h,+}+\Gamma_{h,-}-\Gamma_{e,+}\right) \\
&+ie^{i\theta}e^{i\left(k_{h,-}+k_{e,-}\right)d}\left(1+\Gamma_{h,-}\right)\left(\Gamma_{h,+}+\Gamma_{h,-}-\Gamma_{e,-}\right)\Big]
\end{aligned} \tag{6.107a}$$

$$\begin{aligned}
\mathscr{M}_{12} =& \mathscr{D}^{-1}\Big[ie^{i\theta}e^{i\left(k_{h,-}+k_{e,+}\right)d}\left(1+\Gamma_{h,+}\right)\left(1+\Gamma_{e,+}\right) \\
&-\left(u_0^2-v_0^2\right)e^{i\left(k_{h,-}+k_{e,-}\right)d}\left(1+\Gamma_{h,+}\right)\left(1+\Gamma_{e,-}\right) \\
&-\left(u_0^2-v_0^2\right)e^{2i\theta}e^{i\left(k_{h,-}+k_{e,-}\right)d}\left(1+\Gamma_{h,-}\right)\left(1+\Gamma_{e,+}\right) \\
&-ie^{i\theta}e^{i\left(k_{h,-}+k_{e,-}\right)d}\left(1+\Gamma_{h,-}\right)\left(1+\Gamma_{e,-}\right)
\end{aligned} \tag{6.107b}$$

$$\begin{aligned}
\mathscr{M}_{21} =& \mathscr{D}^{-1}\Big[-ie^{i\theta}e^{i\left(k_{h,+}+k_{e,+}\right)d}\left(\Gamma_{e,+}+\Gamma_{e,-}\Gamma_{h,-}\right)\left(\Gamma_{h,+}+\Gamma_{h,-}\Gamma_{e,-}\right) \\
&+\left(u_0^2-v_0^2\right)e^{i\left(k_{h,+}+k_{e,-}\right)d}\left(\Gamma_{e,+}+\Gamma_{e,-}\Gamma_{h,+}\right)\left(\Gamma_{h,+}+\Gamma_{h,-}\Gamma_{e,-}\right)
\end{aligned}$$

$$+\left(u_0^2-v_0^2\right)e^{2i\theta}e^{i\left(k_{h,-}+k_{e,+}\right)d}\left(\Gamma_{e,+}+\Gamma_{e,-}\Gamma_{h,-}\right)\left(\Gamma_{h,+}+\Gamma_{h,-}\Gamma_{e,+}\right)$$
$$+ie^{i\theta}e^{i\left(k_{h,-}+k_{e,-}\right)d}\left(\Gamma_{e,+}+\Gamma_{e,-}\Gamma_{h,-}\right)\left(\Gamma_{h,+}+\Gamma_{h,-}\Gamma_{e,-}\right)\Big] \tag{6.107c}$$

$$\begin{aligned}\mathscr{M}_{22}=&\mathscr{D}^{-1}\Big[ie^{i\theta}e^{i\left(k_{h,+}+k_{e,-}\right)d}\left(\Gamma_{e,+}+\Gamma_{e,-}\Gamma_{h,+}\right)\left(1+\Gamma_{e,+}\right)\\&-\left(u_0^2-v_0^2\right)e^{i\left(k_{h,-}+k_{e,-}\right)d}\left(\Gamma_{e,+}+\Gamma_{e,-}\Gamma_{h,+}\right)\left(1+\Gamma_{e,-}\right)\\&-\left(u_0^2-v_0^2\right)e^{2i\theta}e^{i\left(k_{h,-}+k_{e,-}\right)d}\left(\Gamma_{e,+}+\Gamma_{e,-}\Gamma_{h,-}\right)\left(1+\Gamma_{e,+}\right)\\&-ie^{i\theta}e^{i\left(k_{h,-}+k_{e,-}\right)d}\left(\Gamma_{e,+}+\Gamma_{e,-}\Gamma_{h,-}\right)\left(1+\Gamma_{e,-}\right)\Big]\end{aligned} \tag{6.107d}$$

with

$$\mathscr{D}=\frac{2iu_0v_0e^{i\theta}e^{i(k_{e,+}+k_{e,-})d}}{\left(\Gamma_{e,+}-\Gamma_{e,-}\right)\left(\Gamma_{h,+}-\Gamma_{h,-}\right)}. \tag{6.108}$$

With these coefficients, the differential conductance can be calculated as $G_S(\theta)=1+|a|^2-|b|^2$. Also we can evaluate the differential conductance when the superconductor is set into the normal state, which has the expression

$$G_N(\theta)=\frac{1}{\cosh^2\left(\kappa_e d\right)+\tan^2\theta\sinh^2\left(\kappa_e d\right)\left(k_y-m_x/\hbar v_F\right)^2/\kappa_e^2} \tag{6.109}$$

where

$$\kappa_e=\sqrt{m_z^2+\left(\hbar v_F k_y-m_x\right)^2}/\hbar v_F \tag{6.110}$$

The normalized differential conductance can be calculated according to

$$\sigma=\frac{\int_{-\pi/2}^{\pi/2}G_S(\theta)\cos\theta d\theta}{\int_{-\pi/2}^{\pi/2}G_N(\theta)\cos\theta d\theta} \tag{6.111}$$

When $m_x=0$, the differential conductance is reduced to [55]:

$$G_S(\theta)=\frac{G_N\left[1+G_N|\Gamma|^2-\left(1-G_N\right)|\Gamma|^4\right]}{\left|1+\left(1-G_N\right)e^{i\varphi}\Gamma^2\right|^2} \tag{6.112}$$

where

$$e^{i\varphi}=\frac{m_z\cos\theta+iE_F\sin\theta}{m_z\cos\theta-iE_F\sin\theta]}, \tag{6.113}$$

and

$$\Gamma=\frac{\Delta}{E+\sqrt{E^2-\Delta^2}}. \tag{6.114}$$

In the insulating limit, $G_N\to 0$, the pole of Eq. (6.112) leads to the bound state energy

$$E_b=-\frac{\Delta E_F\sin\theta\,\mathrm{sgn}\left(m_z\right)}{\sqrt{E_F^2\sin^2\theta+m_z^2\cos^2\theta}}. \tag{6.115}$$

These states are the manifestation of chiral Majorana mode (CMM) [51], which has a dispersion along the interface between the ferromagnetic insulator and conventional s-wave superconductor. However, these states are localized in the direction perpendicular to the interface.

Equation (6.115) suggests that the conductance is contributed mainly by these bound states in the tunneling limit. The representative results of the conductance are reported by Tanaka and co-workers [55]. As shown in Fig. 6.6, the bound state energy is dispersive as a function of the incident angle. In addition, the slope in the energy near the vertical incident angle $\theta = 0$ becomes more flat when the ferromagnetic exchange interaction increases (see Fig. 6.6a). The flatted band of bound states near $\theta = 0$ will then make dominant contribution to the integrated conductance. Therefore, the zero-bias conductance peak is enhanced with increased m_z (see Fig. 6.6b). These results are remarkable in view of the fact that the ferromagnetic exchange interaction in ferromagnet/conventional superconductor junctions suppresses the zero-bias differential conductance. Interesting results from the topological nature of the superconductor have also been found in thermal transport properties [59].

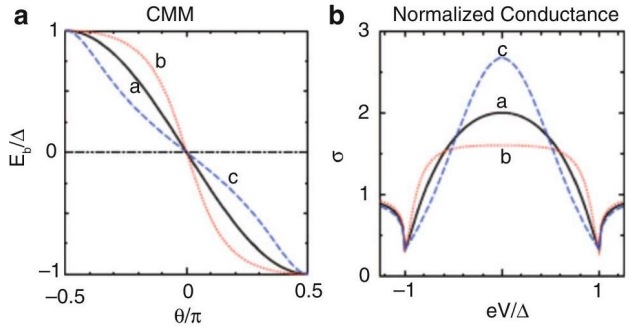

Fig. 6.6 Chiral Majorana mode energy dispersion E_b as a function of the incident angle θ (a) and integrated tunneling conductance σ in N/FI/S junctions (b). The parameter $(m_z/E_F)\, k_F d = 1$ is fixed and $m_x = m_y = 0$. The other variation parameter $m_z/E_F = 1, 0.5, 2$ for curves a, b, and c, respectively. From [55]

9.7 BdG Equations in Tight-Binding Model

9.7.1 2.1 Derivation of BdG Equations in a Tight-Bind Model

Theory

In the previous chapter, we have derived the BdG equations in the continuum model. The continuum model is reasonable to describe weak-coupling superconductors, especially when they have a wide-band metallic normal state. For the superconductors like high-temperature cuprates, the electronic band is quite narrow. Therefore, as we are encountered in solid state physics [1], the tight-binding model, either constructed from atomic orbitals or from Wannier orbitals, is appropriate to be used for studying narrow band behaviors arising from electronic correlation effects.

We generalize the second-quantized Hamiltonian given by Eq. (1.38) to include the spin-orbit coupling and spin-flip scattering interactions, in addition to the regular potential scattering. The single-particle part of the Hamiltonian is of the form:

$$H_0 = \iint d\mathbf{r} d\mathbf{r}' \psi_\alpha^\dagger(\mathbf{r}) h_{\alpha\beta}(\mathbf{r}, \mathbf{r}')\, \psi_\beta(\mathbf{r}') \tag{2.1}$$

where $h_{\alpha\beta}(\mathbf{r}, \mathbf{r}')$ is general enough to include the non-local and spin-flip effects. The field operators are now expressed in the localized-state basis as

$$\psi_\alpha(\mathbf{r}) = \sum_i w(\mathbf{r} - \mathbf{R}_i)\, c_{i\alpha} \tag{2.2a}$$

$$\psi_\alpha^\dagger(\mathbf{r}) = \sum_i w^*(\mathbf{r} - \mathbf{R}_i)\, c_{i\alpha}^\dagger \tag{2.2b}$$

where $c_{i\alpha}^{\dagger}\left(c_{i\alpha}\right)$ creates (annihilates) an electron of spin α at site i, and $w\left(\mathbf{r}-\mathbf{R}_i\right)$ is a localized orbital around the atomic site $\mathbf{R}_i$. The atomic orbitals or maximally localized Wannier orbitals are most amenable to have a physical interpretation. Substitution of these expressions into Eq. (2.1) gives

$$\begin{aligned} H_0 &= \sum_{ij,\sigma\sigma'} c_{i\sigma}^{\dagger} h_{i\sigma,j\sigma'} c_{j\sigma} \\ &= -\sum_{i\neq j,\sigma\sigma'} t_{i\sigma,j\sigma'} c_{i\sigma}^{\dagger} c_{j\sigma'} + \sum_{i\sigma} \epsilon_i c_{i\sigma}^{\dagger} c_{i\sigma} + \sum_{i,\sigma\sigma'} \Omega_{i,\sigma\sigma'} c_{i\sigma}^{\dagger} c_{i\sigma'} \end{aligned} \tag{2.3}$$

Here the summation over the site indices ij in the kinetic energy (and also the nearest-neighbor interaction in Eq. 2.4 below) excludes those term with $i=j$. In the kinetic energy, the spin-orbit term has also been included by identifying the spin flip when an electron hops from one site to its nearest neighbor. The on-site single particle energy is introduced to consider the disorder or such inhomogeneity problems as those with a (non-magnetic) single impurity; while the third term accounts for the magnetic impurity effects (with the internal dynamics of the magnetic impurity neglected here).

We then follow the same ansatz for the extended Hubbard model [2], and write down an effective model Hamiltonian for superconductivity:

$$\begin{aligned} \mathscr{H} &= H_0 - \mu \sum_{i\sigma} c_{i\sigma}^{\dagger} c_{i\sigma} + U \sum_i \left(n_{i\uparrow} - \frac{1}{2}\right)\left(n_{i\downarrow} - \frac{1}{2}\right) - \frac{V}{2} \sum_{i\neq j} n_i n_j = \\ &= \sum_{ij,\sigma\sigma'} c_{i\sigma}^{\dagger} \left[h_{i\sigma,j\sigma'} - \left(\mu + \frac{U}{2}\right)\delta_{ij}\delta_{\sigma\sigma'}\right] c_{j\sigma'} + U \sum_i n_{i\uparrow} n_{i\downarrow} - \frac{V}{2} \sum_{i\neq j} n_i n_j. \end{aligned} \tag{2.4}$$

Here $n_i = \sum_{\sigma} n_{i\sigma}$ with $n_{i\sigma} = c_{i\sigma}^{\dagger} c_{i\sigma}$ is the particle number operator on site i. The on-site and nearest-neighbor electron-electron interaction strengths are, respectively, U and V. Positive values of U and negative values of V represent the repulsive interaction while negative values of U and positive values of V represent the attractive interaction since we have assigned a minus sign before the nearestneighbor interaction term. Note that the single particle energy is measured with respect to the chemical potential μ.

The derivation of the BdG equations for the on-site and nearest-neighbor pairing interaction is similar to that for the continuum model in Chap. 1. To be distinct, the above extended Hubbard model enables a description of possible competing orders. We show one example here by considering on-site repulsion ($U>0$), which drives magnetic instability, and nearest-neighbor attraction ($V>0$) for the d-wave pairing superconductivity. Therefore, we retain the standard Hartree-Fock term for the onsite repulsion and the anomalous Hartree-Fock terms for nearest-neighbor attraction. The inclusion of an onsite repulsion in the mean-field approximation helps stabilize the d-wave pairing state, which comes from the nearest-neighbor pairing interaction. The effective mean-field Hamiltonian with a singlet pairing symmetry is now given by:

$$\mathscr{H}_{eff} = \sum_{ij,\sigma\sigma'} c_{i\sigma}^{\dagger} \tilde{h}_{i\sigma,j\sigma'} c_{j\sigma'} + \sum_{ij} \left[\Delta_{ij} c_{i\uparrow}^{\dagger} c_{j\downarrow}^{\dagger} + \Delta_{ij}^{*} c_{j\downarrow} c_{i\uparrow}\right] + E_{const} \tag{2.5}$$

Here the effective single-particle Hamiltonian is given by

$$\tilde{h}_{i\sigma,j\sigma'} = h_{i\sigma,j\sigma'} - \left(\mu + \frac{U}{2} - U\left\langle n_{i\bar{\sigma}}\right\rangle\right)\delta_{ij}\delta_{\sigma\sigma'}, \tag{2.6}$$

the singlet-pairing potential

$$\Delta_{ij} = \frac{V}{2}\left(\langle c_{i\uparrow}c_{j\downarrow}\rangle - \langle c_{i\downarrow}c_{j\uparrow}\rangle\right), \tag{2.7}$$

$$\Delta_{ij}^{*} = \frac{V}{2}\left(\left\langle c_{j\downarrow}^{\dagger}c_{i\uparrow}^{\dagger}\right\rangle - \left\langle c_{j\uparrow}^{\dagger}c_{i\downarrow}^{\dagger}\right\rangle\right), \tag{2.8}$$

and the constant energy term is given by

$$E_{\text{const}} = -U\langle n_{i\uparrow}\rangle\langle n_{i\downarrow}\rangle + \sum_{ij}\frac{|\Delta_{ij}|^2}{V} \tag{2.9}$$

It is evident that the singlet pairing potential satisfies the symmetry properties: $\Delta_{ji} = \Delta_{ij}$. Also we note again that the single particle energy is measured with respect to the chemical potential μ.

We then obtain the following commutation relations:

$$[c_{i\uparrow}, \mathscr{H}_{eff}]_{-} = \sum_{j\sigma'}\tilde{h}_{i\uparrow,j\sigma'}c_{j\sigma'} + \sum_{j}\Delta_{ij}c_{j\downarrow}^{\dagger}, \tag{2.10a}$$

$$\left[c_{i\uparrow}^{\dagger}, \mathscr{H}_{eff}\right]_{-} = -\sum_{j\sigma'}\tilde{h}_{j\sigma',i\uparrow}c_{j\sigma'}^{\dagger} - \sum_{j}\Delta_{ij}^{*}c_{j\downarrow}, \tag{2.10b}$$

$$[c_{i\downarrow}, \mathscr{H}_{eff}]_{-} = \sum_{j\sigma'}\tilde{h}_{i\downarrow,j\sigma'}c_{j\sigma'} - \sum_{j}\Delta_{ji}c_{j\uparrow}^{\dagger}, \tag{2.10c}$$

$$\left[c_{i\downarrow}^{\dagger}, \mathscr{H}_{eff}\right]_{-} = -\sum_{j\sigma'}\tilde{h}_{j\sigma',i\downarrow}c_{j\sigma'}^{\dagger} + \sum_{j}\Delta_{ji}^{*}c_{j\uparrow}. \tag{2.10d}$$

Equations (2.10)(a)-(d) show that the electron field operator can be expressed as a linear combination of electron- and hole-like quasiparticle excitations, which
enables us to perform a Bogoliubov canonical transformation:

$$c_{i\sigma} = \sum_{n}{}'\left(u_{i\sigma}^{n}\gamma_n - \sigma v_{i\sigma}^{n*}\gamma_n^{\dagger}\right), \quad c_{i\sigma}^{\dagger} = \sum_{n}{}'\left(u_{i\sigma}^{n*}\gamma_n^{\dagger} - \sigma v_{i\sigma}^{n}\gamma_n\right), \tag{2.11}$$

where $\sigma = \pm 1$ denotes the up and down spin orientations. The operators $\gamma_n^{\dagger}(\gamma_n)$ create (annihilate) a Bogoliubov quasiparticle at state n. The prime sign above the summation in the transformation means only those states with positive energy are counted. The quasiparticle operators satisfy the anti-commutation relations:

$$\left\{\gamma_n, \gamma_m^{\dagger}\right\} = \delta_{nm}, \tag{2.12}$$

$$\{\gamma_n, \gamma_m\} = \left\{\gamma_n^{\dagger}, \gamma_m^{\dagger}\right\} = 0 \tag{2.13}$$

These relations also guarantee the anti-commutation relations among the original electronic field operators.

With the above canonical transformation, the Hamiltonian is diagonalized in the following form:

$$H_{eff} = \sum_{n}E_n\gamma_n^{\dagger}\gamma_n + E'_{\text{const}}, \tag{2.14}$$

where the index n also includes the pseudo-spin state index. Upon substitution of Eq. (2.11) into Eq. (2.10), and with the aid of the following commutation relations,

$$\left[\gamma_n^\dagger, H_{eff}\right]_- = -E_n\gamma_n^\dagger, \tag{2.15}$$

$$\left[\gamma_n, H_{eff}\right]_- = E_n\gamma_n, \tag{2.16}$$

we compare the coefficients of the terms with γ_n and $\gamma_n^\dagger$ and arrive at

$$E_n u_{i\uparrow}^n = \sum_{j\sigma'} \tilde{h}_{i\uparrow,j\sigma'} u_{j\sigma'} + \sum_j \Delta_{ij} v_{j\downarrow}^n, \tag{2.17}$$

$$E_n u_{i\downarrow}^n = \sum_{j\sigma'} \tilde{h}_{i\downarrow,j\sigma'} u_{j\sigma'}^n + \sum_j \Delta_{ji} v_{j\uparrow}^n, \tag{2.18}$$

$$E_n v_{i\uparrow}^n = -\sum_{j\sigma'} \sigma' \tilde{h}_{i\uparrow,j\sigma'}^* v_{j\sigma'}^n + \sum_j \Delta_{ij}^* u_{j\downarrow}^n, \tag{2.19}$$

$$E_n v_{i\downarrow}^n = \sum_{j\sigma'} \sigma' \tilde{h}_{i\downarrow,j\sigma'}^* v_{j\sigma'}^n + \sum_j \Delta_{ji}^* u_{j\uparrow}^n. \tag{2.20}$$

This set of BdG equations can be cast into a matrix form:

$$\sum_j \hat{M}_{ij}\hat{\phi}_j = E_n\hat{\phi}_i \tag{2.21}$$

where

$$\hat{M}_{ij} = \begin{bmatrix} \tilde{h}_{i\uparrow,j\uparrow} & \tilde{h}_{i\uparrow,j\downarrow} & 0 & \Delta_{ij} \\ \tilde{h}_{i\downarrow,j\uparrow} & \tilde{h}_{i\downarrow,j\downarrow} & \Delta_{ji} & 0 \\ 0 & \Delta_{ij}^* & -\tilde{h}_{i\uparrow,j\uparrow}^* & \tilde{h}_{i\uparrow,j\downarrow}^* \\ \Delta_{ji}^* & 0 & \tilde{h}_{i\downarrow,j\uparrow}^* & -\tilde{h}_{i\downarrow,j\downarrow}^* \end{bmatrix}, \tag{2.22}$$

and

$$\hat{\phi}_i = \begin{pmatrix} u_{i\uparrow} \\ u_{i\downarrow} \\ v_{i\uparrow} \\ v_{i\downarrow} \end{pmatrix} \tag{2.23}$$

This set of BdG equations is subjected to the self-consistency conditions:

$$n_{i\uparrow} = \sum_n{}' \left[\left|u_{i\uparrow}^n\right|^2 f\left(E_n\right) + \left|v_{i\uparrow}^n\right|^2 f\left(-E_n\right)\right], \tag{2.24}$$

$$n_{i\downarrow} = \sum_n{}' \left[\left|u_{i\downarrow}^n\right|^2 f\left(E_n\right) + \left|v_{i\downarrow}^n\right|^2 f\left(-E_n\right)\right], \tag{2.25}$$

and

$$\Delta_{ij} = \frac{V}{4}\sum_n{}' \left[\left(u_{i\uparrow}^n v_{j\downarrow}^{n*} + u_{j\downarrow}^n v_{i\uparrow}^{n*}\right) + \left(u_{i\downarrow}^n v_{j\uparrow}^{n*} + u_{j\uparrow}^n v_{i\downarrow}^*\right)\right] \tanh\left(\frac{E_n}{2k_BT}\right), \tag{2.26}$$

where $f(E)$ is the Fermi-Dirac distribution function defined in Eq. (1.72).

From Eqs. (2.17)-(2.20), it is not difficult to prove the following theorem:
If $\left(u_{i\uparrow}^{n}, v_{i\downarrow}^{n}, u_{i\downarrow}^{n}, v_{i\uparrow}^{n}\right)$ is the solution to the BdG equations with eigenvalue E_n, then $\left(-v_{i\uparrow}^{n*}, u_{i\downarrow}^{n*}, v_{i\downarrow}^{n*}, -u_{i\uparrow}^{n*}\right)$ is the solution to the same equations with eigenvalue $-E_n$. Using this symmetry property, we can also rewrite Eqs. (2.24)-(2.26) as

$$n_{i\uparrow} = \sum_{n} \left|u_{i\uparrow}^{n}\right|^{2} f\left(E_n\right), \tag{2.27}$$

$$n_{i\downarrow} = \sum_{n} \left|v_{i\downarrow}^{n}\right|^{2} f\left(-E_n\right), \tag{2.28}$$

and

$$\Delta_{ij} = \frac{V}{4} \sum_{n} \left[u_{i\uparrow}^{n} v_{j\downarrow}^{n*} + u_{j\uparrow}^{n} v_{i\downarrow}^{*}\right] \tanh\left(\frac{E_n}{2k_B T}\right). \tag{2.29}$$

In the absence of spin-orbit coupling and other spin-flip scattering terms, that is $\tilde{h}_{i\uparrow,j\downarrow} = \tilde{h}_{i\downarrow,j\uparrow} = 0$, the BdG equations become block-diagonalized into two sets of equations:

$$\begin{cases} E_{\tilde{n}1} u_{i\uparrow}^{\tilde{n}1} = \sum_j \tilde{h}_{i\uparrow,j\uparrow} u_{j\uparrow}^{\tilde{n}1} + \sum_j \Delta_{ij} v_{j\downarrow}^{\tilde{n}1}, \\ E_{\tilde{n}1} v_{i\downarrow}^{\tilde{n}1} = -\sum_j \tilde{h}_{i\downarrow,j\downarrow}^{*} v_{j\downarrow}^{\tilde{n}1} + \sum_j \Delta_{ji}^{*} u_{j\uparrow}^{\tilde{n}1}, \end{cases} \tag{2.30}$$

and

$$\begin{cases} E_{\tilde{n}2} u_{i\downarrow}^{\tilde{n}2} = \sum_j \tilde{h}_{i\downarrow,j\downarrow} u_{j\downarrow}^{\tilde{n}2} + \sum_j \Delta_{ji} v_{j\uparrow}^{\tilde{n}}, \\ E_{\tilde{n}2} v_{i\uparrow}^{\tilde{n}2} = -\sum_j \tilde{h}_{i\uparrow,j\uparrow}^{*} v_{j\uparrow}^{n} + \sum_j \Delta_{ij}^{*} u_{j\downarrow}^{n}. \end{cases} \tag{2.31}$$

This block-diagonalization structure leads to a distinct nature of the canonical transformation:

$$c_{i\uparrow} = \sum_{\tilde{n}}{}' \left(u_{i\uparrow}^{\tilde{n}1} \gamma_{\tilde{n}1} - v_{i\uparrow}^{\tilde{n}2*} \gamma_{\tilde{n}2}^{\dagger}\right), \qquad c_{i\uparrow}^{\dagger} = \sum_{\tilde{n}}{}' \left(u_{i\uparrow}^{\tilde{n}1} * \gamma_{\tilde{n}1}^{\dagger} - v_{i\uparrow}^{\tilde{n}2} \gamma_{\tilde{n}2}\right), \tag{2.32}$$

$$c_{i\downarrow} = \sum_{\tilde{n}}{}' \left(u_{i\downarrow}^{\tilde{n}2} \gamma_{\tilde{n}2} + v_{i\downarrow}^{\tilde{n}1*} \gamma_{\tilde{n}1}^{\dagger}\right), \qquad c_{i\downarrow}^{\dagger} = \sum_{\tilde{n}}{}' \left(u_{i\downarrow}^{\tilde{n}2*} \gamma_{\tilde{n}2}^{\dagger} + v_{i\downarrow}^{\tilde{n}1} \gamma_{\tilde{n}1}\right). \tag{2.33}$$

The block diagonalization and the symmetry property suggest that we merely need to solve Eq. (2.30) subject to the self-consistency condition:

$$n_{i\uparrow} = \sum_{\tilde{n}} \left|u_{i\uparrow}^{\tilde{n}1}\right|^{2} f\left(E_{\tilde{n}1}\right), \tag{2.34}$$

$$n_{i\downarrow} = \sum_{\tilde{n}} \left|v_{i\downarrow}^{\tilde{n}1}\right|^{2} f\left(-E_{\tilde{n}1}\right), \tag{2.35}$$

and

$$\Delta_{ij} = \frac{V}{4} \sum_{\tilde{n}} \left[u_{i\uparrow}^{\tilde{n}1} \tilde{p}_{j\downarrow}^{\tilde{n}1*} + u_{j\uparrow}^{\tilde{n}1} v_{i\downarrow}^{\tilde{1}1*}\right] \tanh\left(\frac{E_{\tilde{n}1}}{2k_B T}\right). \tag{2.36}$$

Therefore, by reducing the diagonalization of a $4N$ by $4N$ matrix down to that of a $2N$ by $2N$ matrix, the computational efficiency is improved significantly. Here N would be $N_x N_y$ for

a two-dimensional lattice while $N_xN_yN_z$ for a three-dimensional lattice with N_x, N_y, and N_z being the linear dimension of the system. When it is obvious that no spin-flip effect occurs, the reduced set of BdG equations, Eq. (2.30), will be used with the hat symbol on the energy eigenvalue index and the set index dropped. It will be encountered frequently in the later discussions.

It is straightforward for us to obtain the BdG equations for an s-wave superconductor in the lattice model. There we first replace U by $-U(U > 0)$ so that the Hamiltonian becomes

$$\mathscr{H} = \sum_{ij,\sigma\sigma'} c^{\dagger}_{i\sigma} \left[h_{i\sigma,j\sigma'} - \mu\delta_{ij}\delta_{\sigma\sigma'} \right] c_{j\sigma'} - U \sum_{i} n_{i\uparrow} n_{i\downarrow} \tag{2.37}$$

which leads to the BdG equations:

$$E_n u^n_{i\uparrow} = \sum_{j\sigma'} \tilde{h}_{i\uparrow.j\sigma'} u_{j\sigma'} + \Delta_{ii} v^n_{i\downarrow}, \tag{2.38}$$

$$E_n u^n_{i\downarrow} = \sum_{j\sigma'} \tilde{h}_{i\downarrow,j\sigma'} u^n_{j\sigma'} + \Delta_{ii} v^n_{i\uparrow}, \tag{2.39}$$

$$E_n v^n_{i\uparrow} = -\sum_{j\sigma'} \sigma' \tilde{h}^*_{i\uparrow.j\sigma'} v^n_{j\sigma'} + \Delta^*_{ii} u^n_{j\downarrow}, \tag{2.40}$$

$$E_n v^n_{i\downarrow} = \sum_{j\sigma'} \sigma' \tilde{h}^*_{i\downarrow,j\sigma'} v^n_{j\sigma'} + \Delta^*_{ii} u^n_{i\uparrow}. \tag{2.41}$$

Here

$$\tilde{h}_{i\sigma,j\sigma'} = h_{i\sigma,j\sigma'} - \mu\delta_{ij}\delta_{\sigma\sigma'}, \tag{2.42}$$

and the self-consistency condition

$$\Delta_{ii} = \frac{U}{2} \sum_{n}{}' \left[u^n_{i\uparrow} v^{n*}_{i\downarrow} + u^n_{i\downarrow} v^{n*}_{i\uparrow} \right] \tanh\left(\frac{E_n}{2k_BT} \right). \tag{2.43}$$

In the absence of spin-orbit coupling and spin-flip scattering, the BdG equations become

$$\begin{cases} E_{\tilde{n}1} u^{\tilde{n}1}_{i\uparrow} = \sum_j \tilde{h}_{i\uparrow,j\uparrow} u^{\tilde{n}1}_{j\uparrow} + \Delta_{ii} v^{\tilde{n}1}_{i\downarrow}, \\ E_{\tilde{n}1} v^{\tilde{n}1}_{i\downarrow} = -\sum_j \tilde{h}^*_{i\downarrow,j\downarrow} v^{\tilde{n}1}_{j\downarrow} + \Delta^*_{ii} u^{\tilde{n}1}_{i\uparrow}, \end{cases} \tag{2.44}$$

and

$$\begin{cases} E_{\tilde{n}2} u^{\tilde{n}2}_{i\downarrow} = \sum_j \tilde{h}_{i\downarrow,j\downarrow} \tilde{u}^{\tilde{2}}_{j\downarrow} + \Delta_{ii} v^{\tilde{n}2}_{i\uparrow}, \\ E_{\tilde{n}2} v^{\tilde{n}2}_{i\uparrow} = -\sum_j \tilde{h}^*_{i\uparrow,j\uparrow} v^n_{j\uparrow} + \Delta^*_{ii} u^*_{i\downarrow} \end{cases} \tag{2.45}$$

with

$$\Delta_{ii} = \frac{U}{2} \sum_{\tilde{n}} u^{\tilde{n}1}_{i\uparrow} v^{\tilde{n}1*}_{j\downarrow} \tanh\left(\frac{E_{\tilde{n}1}}{2k_BT} \right). \tag{2.46}$$

Unless explicitly specified, we will focus on Eq. (2.44) with the tilde on the eigenenergy index and set index dropped.

The tight-binding model, from which the BdG equations are derived, has the origin from such strongly correlated models as the $t - J$ model [3] for hightemperature cuprates. The derived BdG equations in the tight-binding model have been used not only for unconventional superconductors with narrow electron band [4-9] but also for s-wave superconductors [10]. The calculated quantities range from the local density states to the superfluid density, which will be discussed in more details in later chapters.

9.7.2 Local Density of States and Bond Current in the Lattice Model

Theory

From Eqs. (2.24), (2.25), we extract the expression for the local density of states:

$$\rho_{i\sigma}(E) = \sum_{n}{}' \left[\left| u_{i\sigma}^{n} \right|^2 \delta \left(E_n - E \right) + \left| v_{i\sigma} \right|^2 \delta \left(E_n + E \right) \right] \tag{2.47}$$

and the corresponding thermalized density of states

$$\rho_{i\sigma}(E) = -\sum_{n}{}' \left[\left| u_{i\sigma}^{n} \right|^2 f' \left(E_n - E \right) + \left| v_{i\sigma} \right|^2 f' \left(E_n + E \right) \right]. \tag{2.48}$$

The bond current can be derived in the following way. The Heisenberg equation of motion for $\langle n_i \rangle = \langle n_{i\uparrow} \rangle + \langle n_{i\downarrow} \rangle$ is:

$$\begin{aligned} i\hbar \frac{\partial \langle n_i \rangle}{\partial t} &= \left\langle \left[n_i, H \right]_- \right\rangle \\ &= \left\langle \left\{ - \sum_{j \neq i, \sigma, \sigma'} \left[-t \left(j\sigma', i\sigma \right) c_{j\sigma'}^{\dagger} c_{i\sigma} + t \left(i\sigma, j\sigma' \right) c_{i\sigma}^{\dagger} c_{j\sigma'} \right] \right\} \right\rangle \end{aligned} \tag{2.49}$$

where H is the system Hamiltonian given by Eq. (2.4). The electrical current operator from site j to site i is then found to be:

$$\hat{J}_{ij} = \frac{e}{i\hbar} \sum_{\sigma, \sigma'} \left[t \left(i\sigma, j\sigma' \right) c_{i\sigma}^{\dagger} c_{j\sigma'} - t \left(j\sigma', i\sigma \right) c_{j\sigma'}^{\dagger} c_{i\sigma} \right], \tag{2.50}$$

and the average bond current is given by:

$$J_{ij} = \frac{e}{i\hbar} \sum_{\sigma, \sigma'} \sum_{n}{}' \left\{ t \left(i\sigma, j\sigma' \right) \left[u_{i\sigma}^{n*} u_{j\sigma'}^{n} f \left(E_n \right) + \sigma\sigma' v_{i\sigma}^{n} v_{j\sigma'}^{n*} \left(1 - f \left(E_n \right) \right) \right] - \text{ c.c. } \right\} \tag{2.51}$$

Using the symmetry property of the BdG equations, we can also write the physical quantities in the following form:

$$n_{i\sigma} = \sum_{n} \left| u_{i\sigma}^{n} \right|^2 f \left(E_n \right) = \sum_{n} \left| v_{i\sigma}^{n} \right|^2 \left[1 - f \left(E_n \right) \right], \tag{2.52}$$

$$\begin{aligned} J_{ij} &= \frac{e}{i\hbar} \sum_{\sigma, \sigma'} \sum_{n} \left\{ t \left(i\sigma, j\sigma' \right) u_{i\sigma}^{n*} u_{j\sigma'}^{n} f \left(E_n \right) - \text{ c.c. } \right\} \\ &= \frac{e}{i\hbar} \sum_{\sigma, \sigma'} \sum_{n} \left\{ t \left(i\sigma, j\sigma' \right) \sigma\sigma' v_{i\sigma}^{n} v_{j\sigma'}^{n*} \left(1 - f \left(E_n \right) \right) - \text{ c.c. } \right\}, \end{aligned} \tag{2.53}$$

and

$$\rho_{i\sigma}(E) = -\sum_{n} \left| u_{i\sigma}^{n} \right|^2 f' \left(E_n - E \right) = -\sum_{n} \left| v_{i\sigma}^{n} \right|^2 f' \left(E_n + E \right). \tag{2.54}$$

These new formulations are especially useful when we study the ferromagnetic impurity or Zeeman effect because the wavefunction of quasiparticles can be solved in a 2×2 spin space.

9.7.3 Nambu Notation for SC Junctions

(??? see my thesis, I'll write here it later)

Theory

9.7.4 Optical Conductivity and Superfluid Density in the Lattice Model

(??? what is the meaning of both values??)

Derivation by (???)

The BdG solutions can not only describe the local density of states, which is a direct measure of single particle properties, but also the eigenfunctions can be used to study the two-particle correlations. In particular, the optical superconductivity reveals the information about the coherent peak [11], while the superfluid stiffness [12] and its temperature dependence set a criterion for superconductivity. Both quantities are directly measurable in experiments. Theoretically, the formulae for these quantities, as derived from the BdG method, are also valid for inhomogeneous superconductors.

The formula of the superfluid density in a lattice model was first derived by Scalapino et al. [12, 13] in a Hubbard model. It was then used for calculations in other models. In the following, we give the derivation for the model with the Hamiltonian defined by Eq. (2.4) in the absence of spin-orbit coupling and other spin-flip scattering, that is,

$$\mathscr{H} = \sum_{ij,\sigma} c_{i\sigma}^{\dagger} \left[-t_{ij} - \left(\mu + \frac{U}{2} - U_i^{\mathrm{imp}} \right) \delta_{ij} \right] c_{j\sigma} + U \sum_i n_{i\uparrow} n_{i\downarrow} - \frac{V}{2} \sum_{i \neq j} n_i n_j$$

Here the impurity potential is represented by U_i^{imp} .
In the presence of an electric field pointing to the x-direction,

$$E_x \left(\mathbf{r}_i, t \right) = \Xi_x e^{i(\mathbf{q} \cdot \mathbf{r}_i - \omega t)} \tag{2.56}$$

The current density along the x-direction is defined as

$$J_x \left(\mathbf{r}_i, t \right) = \sigma_{xx} \left(\mathbf{r}_i, \omega \right) E_x \left(\mathbf{r}_i, t \right) \tag{2.57}$$

where $\sigma_{xx} \left(\mathbf{r}_i, \omega \right)$ is the local conductivity. In the Coulomb gauge, which dictates $\nabla \cdot \mathbf{A} = 0$ and the scalar potential $\phi = 0$, the electric field can be expressed in terms of a vector potential

$$A_x \left(\mathbf{r}_i, t \right) = -\frac{i}{\omega} E_x \left(\mathbf{r}_i, t \right) \tag{2.58}$$

Therefore, the total Hamiltonian becomes

$$H_{\mathrm{t}} = -\sum_{ij,\sigma} \tilde{t}_{ij} c_{i\sigma}^{\dagger} c_{j\sigma} + \sum_{i\sigma} \left(U_i^{\mathrm{imp}} - \frac{U}{2} - \mu \right) c_{i\sigma}^{\dagger} c_{i\sigma} + U \sum_i n_{i\uparrow} n_{i\downarrow} - \frac{V}{2} \sum_{ij} n_i n_j \tag{2.59}$$

where

$$\tilde{t}_{ij} = t_{ij} e^{i\phi_{ij}(t)} \tag{2.60}$$

with the gauge phase $\phi_{ij}(t) = eA_{ij} = eA_x \left(\mathbf{r}_i, t \right) (x_i - x_j)$. Hereafter the charge e for electrons includes the sign. In the linear response limit, we expand this hopping term up to the second order of $A_x \left(\mathbf{r}_i, t \right)$:

$$\tilde{t}_{ij} \approx t\left[1 + i\phi_{ij} + \frac{1}{2!}\left(i\phi_{ij}\right)^2\right]. \tag{2.61}$$

The total Hamiltonian can then be rewritten as:

$$H_{\mathrm{t}} = H - i\sum_{ij,\sigma}\phi_{ij}(t)t_{ij}c_{i\sigma}^{\dagger}c_{j\sigma} + \frac{1}{2}\sum_{ij,\sigma}\phi_{ij}^2(t)t_{ij}c_{i\sigma}^{\dagger}c_{j\sigma} \tag{2.62}$$

If we limit the hopping integral only between the nearest neighbors, we have

$$\begin{aligned}
H_{\mathrm{t}} =& H - iea\sum_{i,\sigma}\left[-A_x\left(\mathbf{r}_i,t\right)t_{i,i+\hat{x}}c_{i\sigma}^{\dagger}c_{i+\hat{x},\sigma} + A_x\left(\mathbf{r}_{i+\hat{x}},t\right)t_{i+\hat{x},i}c_{i+\hat{x},\sigma}^{\dagger}c_{i\sigma}\right] \\
&+ \frac{e^2a^2}{2}\sum_{i,\sigma}\left[A_x^2\left(\mathbf{r}_i,t\right)t_{i,i+\hat{x}}c_{i\sigma}^{\dagger}c_{i+\hat{x},\sigma} + A_x^2\left(\mathbf{r}_{i+\hat{x}},t\right)t_{i+\hat{x},i}c_{i+\hat{x},\sigma}^{\dagger}c_{i\sigma}\right] \\
\approx& H - iea\sum_{i,\sigma}A_x\left(\mathbf{r}_i,t\right)\left[-t_{i,i+\hat{x}}c_{i\sigma}^{\dagger}c_{i+\hat{x},\sigma} + t_{i+\hat{x},i}c_{i+\hat{x},\sigma}^{\dagger}c_{i\sigma}\right] \\
&+ \frac{e^2a^2}{2}\sum_{i,\sigma}A_x^2\left(\mathbf{r}_i,t\right)\left[t_{i,i+\hat{x}}c_{i\sigma}^{\dagger}c_{i+\hat{x},\sigma} + t_{i+\hat{x},i}c_{i+\hat{x},\sigma}^{\dagger}c_{i\sigma}\right] \\
\approx& H - ea\sum_{i}A_x\left(\mathbf{r}_i,t\right)J_x^P\left(\mathbf{r}_i\right) - \frac{e^2a^2}{2}\sum_{i}A_x^2\left(\mathbf{r}_i,t\right)K_x\left(\mathbf{r}_i\right) \\
=& H + H'(t)
\end{aligned} \tag{2.63}$$

where the particle current and the local kinetic energy associated with the x-oriented links are defined as

$$\begin{aligned}
J_x^P\left(\mathbf{r}_i\right) &= i\sum_{\sigma}\left[t_{i+\hat{x},i}c_{i+\hat{x},\sigma}^{\dagger}c_{i\sigma} - t_{i,i+\hat{x}}c_{i\sigma}^{\dagger}c_{i+\hat{x},\sigma}\right] \\
&= it\sum_{\sigma}\left[c_{i+\hat{x},\sigma}^{\dagger}c_{i\sigma} - c_{i\sigma}^{\dagger}c_{i+\hat{x},\sigma}\right]
\end{aligned} \tag{2.64}$$

and

$$\begin{aligned}
K_x\left(\mathbf{r}_i\right) &= -\sum_{\sigma}\left[t_{i,i+\hat{x}}c_{i\sigma}^{\dagger}c_{i+\hat{x},\sigma} + t_{i+\hat{x},i}c_{i+\hat{x},\sigma}^{\dagger}c_{i\sigma}\right] \\
&= -t\sum_{\sigma}\left[c_{i\sigma}^{\dagger}c_{i+\hat{x},\sigma} + c_{i+\hat{x},\sigma}^{\dagger}c_{i\sigma}\right]
\end{aligned} \tag{2.65}$$

The x-oriented current density operator is then found to be

$$J_x^Q\left(\mathbf{r}_i\right) = -\frac{\delta H'(t)}{\delta A_x\left(\mathbf{r}_i,t\right)} = eJ_x^P\left(\mathbf{r}_i\right) + e^2K_x\left(\mathbf{r}_i\right)A_x\left(\mathbf{r}_i,t\right). \tag{2.66}$$

Here we have set the lattice constant $a = 1$.
An alternative derivation of the current density operator is to start with the electric polarization operator:

$$\mathbf{P} = e\sum_{i}\mathbf{r}_i n_i \tag{2.67}$$

with its x-component

$$P_x = e\sum_i x_i n_i \tag{2.68}$$

The time-derivative is

$$\begin{aligned} J_x^Q(\mathbf{r}_i) &= i\left[H_{\mathrm{t}}, P_x\right] \\ &= ie\sum_{ij,\sigma} x_i\left[\tilde{t}_{ij}c_{i\sigma}^\dagger c_{j\sigma} - \tilde{t}_{ji}c_{j\sigma}^\dagger c_{i\sigma}\right] \\ &= ie\sum_{ij,\sigma}\left(x_i - x_j\right)\tilde{t}_{ij}c_{i\sigma}^\dagger c_{j\sigma} \\ &= ie\sum_{ij,\sigma}\left(x_i - x_j\right)t_{ij}\left(1 + i\phi_{ij}\right)c_{i\sigma}^\dagger c_{j\sigma} \\ &= eJ_x^P(\mathbf{r}_i) + e^2K_x(\mathbf{r}_i)A_x(\mathbf{r}_i,t) \end{aligned} \tag{2.69}$$

Now let us calculate the expectation value of the current density operator. In the linear response theory, the statistical operator in the interaction picture is given by:

$$\hat{\rho}_I(t) = \hat{\rho}_I(-\infty) - \frac{i}{\hbar}\int_{-\infty}^{t}\left[H_I'(t'), \hat{\rho}_I(-\infty)\right] - dt' \tag{2.70}$$

The expectation of a physical variable is found to be:

$$\langle\hat{O}\rangle = \mathrm{Tr}\left[\hat{\rho}_I(-\infty)\hat{O}_I\right] - \frac{i}{\hbar}\int_{-\infty}^{t}\mathrm{Tr}\left\{\hat{\rho}_I(-\infty)\left[\hat{O}_I(t), H_I'(t')\right]_-\right\}dt' \tag{2.71}$$

$$= \left\langle\hat{O}_I\right\rangle_0 - \frac{i}{\hbar}\int_{-\infty}^{t}\left\langle\left[\hat{O}_I(t), H_I'(t')\right]_-\right\rangle_0 dt' \tag{2.72}$$

where

$$\hat{O}_I = e^{iHt}\hat{O}e^{-iHt} \tag{2.73}$$

and

$$H_I'(t) = e^{iHt}H'(t)e^{-iHt} \tag{2.74}$$

with the term proportional to $A^2(t)$ in $H'(t)$ neglected. The particle current density is then given by

$$\left\langle J_x^P(\mathbf{r}_i)\right\rangle = -i\int_{-\infty}^{t}\left\langle\left[J_x^P(\mathbf{r}_i,t), H_I'(t)\right]\right\rangle, \tag{2.75}$$

where the particle operator and the perturbation term in the Heisenberg picture with respect to the unperturbed Hamiltonian H are given by, respectively,

$$J_x^P(\mathbf{r}_i,t) = e^{iHt}J_x^P(\mathbf{r}_i)e^{-iHt} \tag{2.76}$$

We notice that the first term in $H'(t)$ can be rewritten as

$$-e\sum_{i,\sigma}A_x(\mathbf{r}_i,t)J_x^P(\mathbf{r}_i) = \frac{ie}{\omega}J_x^P(-\mathbf{q})\Xi_x e^{-i\omega t} \tag{2.77}$$

where the Fourier transform of the particle density operator is given by

$$J_x^P(\mathbf{q}) = \sum_i e^{-i\mathbf{q}\cdot\mathbf{r}_i} J_x^P(\mathbf{r}_i) \tag{2.78}$$

We then obtain

$$\left\langle J_x^P(\mathbf{r}_i)\right\rangle = \frac{e}{\omega} E_x(\mathbf{r}_i,t)\, e^{-i\mathbf{q}\cdot\mathbf{r}_i} \int_{-\infty}^{t} dt' e^{i\omega(t-t')} \left\langle \left[J_x^P(\mathbf{r}_i,t), J_x^P(-\mathbf{q},t')\right]\right\rangle. \tag{2.79}$$

Finally, the current density is found to be

$$\begin{aligned}\left\langle J_x^Q(\mathbf{r}_i)\right\rangle =& \frac{e^2}{\omega} E_x(\mathbf{r}_i,t)\, e^{-i\mathbf{q}\cdot\mathbf{r}_i} \int_{-\infty}^{t} dt' e^{i\omega(t-t')} \left\langle \left[J_x^P(\mathbf{r}_i,t), J_x^P(-\mathbf{q},t')\right]\right\rangle \\ & - \frac{ie^2}{\omega} \left\langle K_x(\mathbf{r}_i)\right\rangle E_x(\mathbf{r}_i,t)\end{aligned} \tag{2.80}$$

The local conductivity is then given by

$$\begin{aligned}\sigma_{xx}(\mathbf{r}_i,\omega) =& \frac{\left\langle J_x^Q(\mathbf{r}_i)\right\rangle}{E_x(\mathbf{r}_i,t)} \\ =& \frac{e^2}{\omega} e^{-i\mathbf{q}\mathbf{r}_i} \int_{-\infty}^{t} dt' e^{i\omega(t-t')} \left\langle \left[J_x^P(\mathbf{r}_i,t), J_x^P(-\mathbf{q},t')\right]\right\rangle - \frac{ie^2}{\omega}\left\langle K_x(\mathbf{r}_i)\right\rangle\end{aligned} \tag{2.81}$$

To eliminate the atomic fluctuations, we take an average over the spatial variable $\mathbf{r}_i$ and obtain the conductivity

$$\sigma_{xx}(\mathbf{q},\omega) = \frac{e^2}{N\omega} \int_{-\infty}^{t} dt' e^{i\omega(t-t')} \left\langle \left[J_x^P(\mathbf{q},t), J_x^P(-\mathbf{q},t')\right]\right\rangle - \frac{ie^2}{\omega}\left\langle K_x\right\rangle.$$

where

$$\left\langle K_x\right\rangle = \frac{1}{N}\sum_i \left\langle K_x(\mathbf{r}_i)\right\rangle \tag{2.82}$$

Since the correlation function in Eq. (2.82) is only a function of the time difference $t-t'$, we can express the conductivity as

$$\begin{aligned}\sigma_{xx}(\mathbf{q},\omega) &= \frac{e^2}{N\omega}\int_0^{\infty} dt e^{i\omega t} \left\langle \left[J_x^P(\mathbf{q},t), J_x^P(-\mathbf{q},0)\right]\right\rangle - \frac{ie^2}{\omega}\left\langle K_x\right\rangle \\ &= \frac{e^2}{i\omega}\left[\frac{i}{N}\int_{-\infty}^{\infty} dt\theta(t) e^{i\omega t} \left\langle \left[J_x^P(\mathbf{q},t), J_x^P(-\mathbf{q},0)\right]\right\rangle + \left\langle K_x\right\rangle\right] \\ &= \frac{e^2}{i\omega}\left[-\Pi_{xx}(\mathbf{q},\omega) + \left\langle K_x\right\rangle\right],\end{aligned} \tag{2.83}$$

where we define the retarded correlation function of the particle current operator as

$$\Pi_{xx}(\mathbf{q},t) = -\frac{i}{N}\theta(t)\left\langle \left[J_x^P(\mathbf{q},t), J_x^P(-\mathbf{q},0)\right]\right\rangle, \tag{2.84}$$

with its Fourier transform

$$\Pi_{xx}(\mathbf{q},\omega) = \int_{-\infty}^{\infty} dt e^{i\omega t}\Pi_{xx}(\mathbf{q},t) \tag{2.85}$$

The frequency-dependent, uniform electrical conductivity is given by taking the limit $\mathbf{q} \to 0$:

$$\sigma_{xx}(\omega) = \frac{e^2}{i\omega} \left[-\Pi_{xx}(\mathbf{q} = 0, \omega) + \langle K_x \rangle \right]. \tag{2.86}$$

The dc conductivity is obtained by taking first the limit $\mathbf{q} \to 0$ and then the limit $\omega \to 0$.

$$\sigma_{xx} = -\lim_{\omega \to 0} \frac{e^2}{i\omega} \left[-\Pi_{xx}(\mathbf{q} = 0, \omega) + \langle K_x \rangle \right]. \tag{2.87}$$

Be reminded that the order of these limits cannot be reversed.
Similarly the transverse conductivity can also be derived as:

$$\sigma_{xy}(\mathbf{q}, \omega) = \frac{e^2}{i\omega} \left[-\Pi_{xy}(\mathbf{q}, \omega) \right]. \tag{2.88}$$

It is convenient to calculate the retarded correlation function in the Matsubara formalism. First define the equivalent current-current correlation function in the Matsubara formalism:

$$\Pi_{xx}(\mathbf{q}, \tau) = -\frac{1}{N} \left\langle T_\tau \left[J_x^P(\mathbf{q}, \tau) J_x^P(-\mathbf{q}, 0) \right] \right\rangle, \tag{2.89}$$

$$\Pi_{xx}\left(\mathbf{q}, i\omega_n\right) = \int_0^\beta d\tau e^{i\omega_n \tau} \Pi_{xx}(\mathbf{q}, \tau), \tag{2.90}$$

where $\omega_n = 2n\pi T$ since the current density operator is regarded as a bosonic operator acting as a composite particle. The Matsubara function is evaluated as best one can. Then the desired retarded function is obtained by performing the analytical continuation $i\omega_n \to \omega + i\delta$:

$$\Pi_{xx}(\mathbf{q}, \omega) = \Pi_{xx}\left(\mathbf{q}, i\omega_n \to \omega + i\delta\right). \tag{2.91}$$

Technically, we always write the conductivity formula as:

$$\sigma_{xx}(\mathbf{q}, \omega) = \frac{e^2}{i(\omega + i\delta)} \left[-\Pi_{xx}(\mathbf{q}, \omega) + \langle K_x \rangle \right], \tag{2.92}$$

and its uniform counterpart

$$\sigma_{xx}(\omega) = \frac{e^2}{i(\omega + i\delta)} \left[-\Pi_{xx}(\mathbf{q} = 0, \omega) + \langle K_x \rangle \right] \tag{2.93}$$

If the numerator approaches a finite limit as $\omega \to 0$, the real part of $\sigma_{xx}(\omega)$ will contain a delta function contribution $D\delta(\omega)$ with the "Drude weight" given by

$$\frac{D}{\pi e^2} \equiv \frac{\rho^*}{4\pi} = -\langle K_x \rangle + \Pi_{xx}(\mathbf{q} = 0, \omega \to 0) \tag{2.94}$$

with ρ^* an effective density of the mobile charge carriers in units of their mass. This implies a zero resistance state.

In a superconductor, the Meissner effect is the current response to a static, i.e., $\omega = 0$ and transverse gauge potential $\mathbf{q} \cdot \mathbf{A}(\mathbf{q}, \omega = 0) = 0$. In this case, the electric field $\mathbf{E} = 0$. When we only apply a transverse electric field along the x direction, we should have $q_x A_x(\mathbf{q}, \omega = 0) = 0$, which requires $q_x = 0$. Following the same procedure as before, we can find the expectation value of the electrical current operator

$$\left\langle J_x^Q\left(\mathbf{r}_i\right) \right\rangle = ie^2 A_x\left(\mathbf{r}_i\right) e^{-i\mathbf{q}\cdot\mathbf{r}_i} \int_{-\infty}^{t} dt' \left\langle \left[J_x^P\left(\mathbf{r}_i, t\right), J_x^P\left(-\mathbf{q}, t'\right) \right] \right\rangle + e^2 \left\langle K_x\left(\mathbf{r}_i\right) \right\rangle A_x\left(\mathbf{r}_i\right) \tag{2.95}$$

We then have

$$\frac{\left\langle J_x^Q\left(\mathbf{r}_i\right)\right\rangle}{e^2 A_x\left(\mathbf{r}_i\right)}=ie^{-i\mathbf{q}\cdot\mathbf{r}_i}\int_{-\infty}^{t}dt'\left\langle\left[J_x^P\left(\mathbf{r}_i,t\right),J_x^P\left(-\mathbf{q},t'\right)\right]\right\rangle+\left\langle K_x\left(\mathbf{r}_i\right)\right\rangle. \tag{2.96}$$

By performing an average over the spatial variable $\mathbf{r}_i$ to eliminate the atomic fluctuations, we define an effective "Drude weight" as

$$\frac{D_s}{\pi e^2}=\frac{\rho_s^*}{4\pi}=-\left\langle K_x\right\rangle+\Pi_{xx}\left(q_x=0,q_y\to 0,\omega=0\right). \tag{2.97}$$

The quantity D_s measures the superfluid density in units of the mass. The crucial difference between ρ^* and ρ_s^* is the order in which the momentum and frequency approach zero.

For a superconductor, we perform the BdG transformation:

$$c_{i\sigma}=\sum_{n(E_n\geq 0)}\left(u_{i\sigma}^n\gamma_n-\sigma v_{i\sigma}^{n*}\gamma_n^\dagger\right) \tag{2.98}$$

The kinetic energy can be found readily:

$$\left\langle K_x\right\rangle=-\frac{t}{N}\sum_{i,n,\sigma}\left\{f\left(E_n\right)\left[u_{i+x,\sigma}^{n*}u_{i\sigma}^n+\text{ c.c. }\right]+\left(1-f\left(E_n\right)\right)\left[v_{i+x,\sigma}^n v_{i\sigma}^{n*}+\text{ c.c }\right]\right\} \tag{2.99}$$

However, the re-expression of the current-current correlation function is much more tedious. In the expansion form, the commutator:

$$\left[J_x^P(\mathbf{q},t),J_x^P(-\mathbf{q},0)\right]=(it)^2\sum_{i\sigma}\sum_{i'\sigma'}e^{-i\mathbf{q}\cdot\left(\mathbf{r}_i-\mathbf{r}_i\right)}[\hat{A}+\hat{B}+\hat{C}+\hat{D}], \tag{2.100}$$

where

$$\hat{A}=\left[c_{i+\hat{x},\sigma}^\dagger(t)c_{i\sigma}(t),c_{i'+\hat{x},\sigma'}^\dagger c_{i'\sigma'}\right], \tag{2.101}$$

$$\hat{B}=-\left[c_{i+\hat{x},\sigma}^\dagger(t)c_{i\sigma}(t),c_{i'\sigma'}^\dagger c_{i'+\hat{x},\sigma'}\right], \tag{2.102}$$

$$\hat{C}=-\left[c_{i\sigma}^\dagger(t)c_{i+\hat{x},\sigma}(t),c_{i'+\hat{x},\sigma'}^\dagger c_{i'\sigma'}\right], \tag{2.103}$$

$$\hat{D}=\left[c_{i\sigma}^\dagger(t)c_{i+\hat{x},\sigma}(t),c_{i'\sigma'}^\dagger c_{i'+\hat{x},\sigma'}\right], \tag{2.104}$$

with

$$\begin{aligned}c_{i+\hat{x},\sigma}^\dagger(t)c_{i\sigma}(t)&=\sum_{n_1,n_2}\left[\left(u_{i+\hat{x},\sigma}^{n_1*}\gamma_{n_1}^\dagger(t)-\sigma v_{i+\hat{x},\sigma}^{n_1}\gamma_{n_1}(t)\right)\left(u_{i\sigma}^{n_2}\gamma_{n_2}(t)-\sigma v_{i\sigma}^{n_2*}\gamma_{n_2}^\dagger(t)\right)\right]\\&=\sum_{n_1n_2}\Big[u_{i+\hat{x},\sigma}^{n_1*}u_{i\sigma}^{n_2}e^{i\left(E_{n_1}-E_{n_2}\right)t}\gamma_{n_1}^\dagger\gamma_{n_2}-\sigma u_{i+\hat{x},\sigma}^{n_1*}v_{i\sigma}^{n_2*}e^{i\left(E_{n_1}+E_{n_2}\right)t}\gamma_{n_1}^\dagger\gamma_{n_2}^\dagger\\&\quad-\sigma v_{i+\hat{x},\sigma}^{n_1}u_{i\sigma}^{n_2}e^{-i\left(E_{n_1}+E_{n_2}\right)t}\gamma_{n_1}\gamma_{n_2}+v_{i+\hat{x},\sigma}^{n_1}v_{i\sigma}^{n_2*}e^{-i\left(E_{n_1}-E_{n_2}\right)t}\gamma_{n_1}\gamma_{n_2}^\dagger\Big],\end{aligned} \tag{2.105}$$

and

$$
\begin{aligned}
c^{\dagger}_{i\sigma}(t)c_{i+\hat{x},\sigma}(t) &= \sum_{n_1,n_2}\left[\left(u^{n_1*}_{i\sigma}\gamma^{\dagger}_{n_1}(t)-\sigma v^{n_1}_{i\sigma}\gamma_{n_1}(t)\right)\left(u^{n_2}_{i+\hat{x},\sigma}\gamma_{n_2}(t)-\sigma v^{n_2*}_{i+\hat{x},\sigma}\gamma^{\dagger}_{n_2}(t)\right)\right] \\
&= \sum_{n_1 n_2}\Big[u^{n_1*}_{i\sigma}u^{n_2}_{i+\hat{x},\sigma}e^{i\left(E_{n_1}-E_{n_2}\right)t}\gamma^{\dagger}_{n_1}\gamma_{n_2}-\sigma u^{n_1*}_{i\sigma}v^{n_2*}_{i+\hat{x},\sigma}e^{i\left(E_{n_1}+E_{n_2}\right)t}\gamma^{\dagger}_{n_1}\gamma^{\dagger}_{n_2} \\
&\quad -\sigma v^{n_1}_{i\sigma}u^{n_2}_{i+\hat{x},\sigma}e^{-i\left(E_{n_1}+E_{n_2}\right)t}\gamma_{n_1}\gamma_{n_2}+v^{n_1}_{i\sigma}v^{n_2*}_{i+\hat{x},\sigma}e^{-i\left(E_{n_1}-E_{n_2}\right)t}\gamma_{n_1}\gamma^{\dagger}_{n_2}\Big] \qquad (2.106)
\end{aligned}
$$

Using the following relations

$$
\begin{aligned}
\left\langle\left[\gamma^{\dagger}_{n_1}\gamma_{n_2},\gamma^{\dagger}_{n_3}\gamma_{n_4}\right]\right\rangle &= \left(\left\langle\gamma^{\dagger}_{n_1}\gamma_{n_1}\right\rangle-\left\langle\gamma^{\dagger}_{n_2}\gamma_{n_2}\right\rangle\right)\delta_{n_1n_4}\delta_{n_2n_3}, \qquad (2.107)\\
\left\langle\left[\gamma^{\dagger}_{n_1}\gamma_{n_2},\gamma_{n_3}\gamma^{\dagger}_{n_4}\right]\right\rangle &= -\left(\left\langle\gamma^{\dagger}_{n_1}\gamma_{n_1}\right\rangle-\left\langle\gamma^{\dagger}_{n_2}\gamma_{n_2}\right\rangle\right)\delta_{n_1n_3}\delta_{n_2n_4}, \qquad (2.108)\\
\left\langle\left[\gamma^{\dagger}_{n_1}\gamma^{\dagger}_{n_2},\gamma_{n_3}\gamma_{n_4}\right]\right\rangle &= \left(\delta_{n_1n_4}\delta_{n_2n_3}-\delta_{n_1n_3}\delta_{n_2n_4}\right)\left(\left\langle\gamma^{\dagger}_{n_1}\gamma_{n_1}\right\rangle-\left\langle\gamma^{\dagger}_{n_2}\gamma^{\dagger}_{n_2}\right\rangle\right), \qquad (2.109)\\
\left\langle\left[\gamma_{n_1}\gamma_{n_2},\gamma^{\dagger}_{n_3}\gamma^{\dagger}_{n_4}\right]\right\rangle &= \left(\delta_{n_1n_4}\delta_{n_2n_3}-\delta_{n_1n_3}\delta_{n_2n_4}\right)\left(\left\langle\gamma_{n_1}\gamma^{\dagger}_{n_1}\right\rangle-\left\langle\gamma^{\dagger}_{n_2}\gamma_{n_2}\right\rangle\right), \qquad (2.110)\\
\left\langle\left[\gamma_{n_1}\gamma^{\dagger}_{n_2},\gamma^{\dagger}_{n_3}\gamma_{n_4}\right]\right\rangle &= -\left(\left\langle\gamma_{n_1}\gamma^{\dagger}_{n_1}\right\rangle-\left\langle\gamma_{n_2}\gamma^{\dagger}_{n_2}\right\rangle\right)\delta_{n_1n_3}\delta_{n_2n_4}, \qquad (2.111)\\
\left\langle\left[\gamma_{n_1}\gamma^{\dagger}_{n_2},\gamma_{n_3}\gamma^{\dagger}_{n_4}\right]\right\rangle &= \left(\left\langle\gamma_{n_1}\gamma^{\dagger}_{n_1}\right\rangle-\left\langle\gamma_{n_2}\gamma^{\dagger}_{n_2}\right\rangle\right)\delta_{n_1n_4}\delta_{n_2n_3}, \qquad (2.112)
\end{aligned}
$$

we obtain

$$
\begin{aligned}

By defining

$$A_{n_1,n_2}(\mathbf{q}) = \sum_{i\sigma}e^{-i\mathbf{q}\cdot\mathbf{r}_i}\left[u^{n_1*}_{i+\hat{x},\sigma}u^{n_2}_{i\sigma}-u^{n_1*}_{i\sigma}u^{n_2}_{i+\hat{x},\sigma}\right],\tag{2.117}$$

$$B_{n_1,n_2}(\mathbf{q}) = \sum_{i\sigma}\sigma e^{-i\mathbf{q}\cdot\mathbf{r}}\left[u^{n_1*}_{i+\hat{x},\sigma}v^{n_2*}_{i\sigma}-u^{n_1*}_{i\sigma}v^{n_2*}_{i+\hat{x},\sigma}\right]\tag{2.118}$$

$$C_{n_1,n_2}(\mathbf{q}) = \sum_{i\sigma}\sigma e^{-i\mathbf{q}\cdot\mathbf{r}}\left[v^{n_1}_{i+\hat{x},\sigma}u^{n_2}_{i\sigma}-v^{n_1}_{i\sigma}u^{n_2}_{i+\hat{x},\sigma}\right]\tag{2.119}$$

$$D_{n_1,n_2}(\mathbf{q}) = \sum_{i\sigma}e^{-i\mathbf{q}\cdot\mathbf{r}_i}\left[v^{n_1}_{i+\hat{x},\sigma}v^{n_2*}_{i\sigma}-v^{n_1}_{i\sigma}v^{n_2*}_{i+\hat{x},\sigma}\right]\tag{2.120}$$

we find the current-current correlation function

$$
\begin{aligned}
\Pi_{xx}(\mathbf{q},\omega) =& -\frac{1}{N}\sum_{n_1,n_2}\left\{\frac{A_{n_1,n_2}(\mathbf{q})\left[-A^*_{n_1,n_2}(\mathbf{q})-D_{n_1,n_2}(-\mathbf{q})\right]}{\omega+(E_{n_1}-E_{n_2})+i\delta}\left(\left\langle\gamma^\dagger_{n_1}\gamma_{n_1}\right\rangle-\left\langle\gamma^\dagger_{n_2}\gamma_{n_2}\right\rangle\right)\right.\\
&+\frac{B_{n_1,n_2}(\mathbf{q})\left[-B^*_{n_1,n_2}(\mathbf{q})-C_{n_1,n_2}(-\mathbf{q})\right]}{\omega+(E_{n_1}+E_{n_2})+i\delta}\left(\left\langle\gamma^\dagger_{n_1}\gamma_{n_1}\right\rangle-\left\langle\gamma_{n_2}\gamma^\dagger_{n_2}\right\rangle\right)\\
&+\frac{C_{n_1,n_2}(\mathbf{q})\left[-C^*_{n_1,n_2}(\mathbf{q})-B_{n_1,n_2}(-\mathbf{q})\right]}{\omega-(E_{n_1}+E_{n_2})+i\delta}\left(\left\langle\gamma_{n_1}\gamma^\dagger_{n_1}\right\rangle-\left\langle\gamma^\dagger_{n_2}\gamma_{n_2}\right\rangle\right)\\
&\left.+\frac{D_{n_1,n_2}(\mathbf{q})\left[-D^*_{n_1,n_2}(\mathbf{q})-A_{n_1,n_2}(-\mathbf{q})\right]}{\omega-(E_{n_1}-E_{n_2})+i\delta}\left(\left\langle\gamma_{n_1}\gamma^\dagger_{n_1}\right\rangle-\left\langle\gamma_{n_2}\gamma^\dagger_{n_2}\right\rangle\right)\right\}\\
=&\frac{1}{N}\sum_{n_1,n_2}\left\{\frac{A_{n_1,n_2}(\mathbf{q})\left[A^*_{n_1,n_2}(\mathbf{q})+D_{n_1,n_2}(-\mathbf{q})\right]}{\omega+(E_{n_1}-E_{n_2})+i\delta}\left[f\left(E_{n_1}\right)-f\left(E_{n_2}\right)\right]\right.\\
&+\frac{B_{n_1,n_2}(\mathbf{q})\left[B^*_{n_1,n_2}(\mathbf{q})+C_{n_1,n_2}(-\mathbf{q})\right]}{\omega+(E_{n_1}+E_{n_2})+i\delta}\left[f\left(E_{n_1}\right)-f\left(-E_{n_2}\right)\right]\\
&+\frac{C_{n_1,n_2}(\mathbf{q})\left[C^*_{n_1,n_2}(\mathbf{q})+B_{n_1,n_2}(-\mathbf{q})\right]}{\omega-(E_{n_1}+E_{n_2})+i\delta}\left[f\left(-E_{n_1}\right)-f\left(E_{n_2}\right)\right]\\
&\left.+\frac{D_{n_1,n_2}(\mathbf{q})\left[D^*_{n_1,n_2}(\mathbf{q})+A_{n_1,n_2}(-\mathbf{q})\right]}{\omega-(E_{n_1}-E_{n_2})+i\delta}\left[f\left(-E_{n_1}\right)-f\left(-E_{n_2}\right)\right]\right\}. \qquad (2.121)
\end{aligned}
$$

Using the symmetry relation of eigenstates for positive and negative eigenvalues in the BdG equation, we can write the Π_{xx} in a simplified form:

$$
\Pi_{xx}(\mathbf{q},\omega)=\frac{1}{N}\sum_{n_1,n_2}\left\{\frac{A_{n_1,n_2}(\mathbf{q})\left[A^*_{n_1,n_2}(\mathbf{q})+D_{n_1,n_2}(-\mathbf{q})\right]}{\omega+(E_{n_1}-E_{n_2})+i\delta}\left[f\left(E_{n_1}\right)-f\left(E_{n_2}\right)\right]\right\}, \qquad (2.122)
$$

where E_n cover all eigenvalues from the BdG equation.
For the optical conductivity and charge stiffness, we set $\mathbf{q}=0$ and obtain:

$$
\Pi_{xx}(\omega)=\frac{1}{N}\sum_{n_1,n_2}\left\{\frac{A_{n_1,n_2}\left[A^*_{n_1,n_2}+D_{n_1,n_2}\right]}{\omega+(E_{n_1}-E_{n_2})+i\delta}\left[f\left(E_{n_1}\right)-f\left(E_{n_2}\right)\right]\right\}, \qquad (2.123)
$$

where $A=A(\mathbf{q}=0)$ and $D=D(\mathbf{q}=0)$.
For the superfluid density, we first set $\omega=0$ and obtain

$$
\Pi_{xx}(\mathbf{q}\to 0)=\frac{1}{N}\sum_{n_1,n_2}\left\{\frac{A_{n_1,n_2}(\mathbf{q}\to 0)\left[A^*_{n_1,n_2}(\mathbf{q}\to 0)+D_{n_1,n_2}(-\mathbf{q}\to 0)\right]}{E_{n_1}-E_{n_2}}\left[f\left(E_{n_1}\right)-f\left(E_{n_2}\right)\right]\right\}. \qquad (2.124)
$$

Alternative derivation

An alternative derivation of the optical conductivity and superfluid can be carried out within the Green function method, which is left for the readers to explore as an exercise. The above formulae for optical conductivity and superfluid density are particularly useful for the study of inhomogeneous superconductors.

9.7.5 2.2 Solution to the Lattice BdG Equations for a Uniform Superconductor

Theory

We consider the case in the absence of spin-orbit coupling and other spin-flip scattering effect, and assume only a superconducting order is present in the system. In the nearest-neighbor hopping approximation for the tight-binding model of a cubic system, the normal-state single-particle energy dispersion is given by

$$\epsilon_{\mathbf{k}} = -2t\left(\cos k_x a + \cos k_y a + \cos k_z a\right) \tag{2.125}$$

for a three-dimensional cubic lattice, while

$$\epsilon_{\mathbf{k}} = -2t\left(\cos k_x a + \cos k_y a\right), \tag{2.126}$$

for a two-dimensional square lattice. Here a is the lattice constant and t is the nearest-neighbor hopping integral. From these dispersions, the normal-state density of states can be numerically evaluated. The results of normal-state density of states are shown in Fig.2.1.

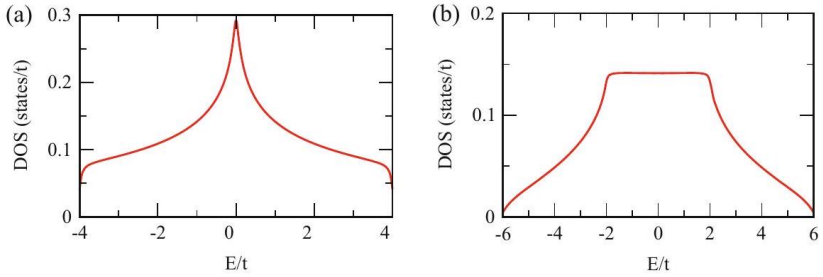

Fig. 2.1 Normal-state single-particle density of states for a two-dimensional (a) and threedimensional (b) system. Lattice size is chosen to be 400×400 for the 2D system and $200 \times 200 \times 200$ for the 3D system. The intrinsic lifetime broadening $\Gamma = 0.05$ is used for the calculation

As one can see, for the 2D system, the DOS exhibits the van Hove singularity. The strong energy dependence of this DOS will influence the magnitude of the superconducting order parameter. For high-temperature cuprate superconductors, the electrons are mostly confined into a two-dimensional Cu square lattice and the energy dispersion for the low-energy $\mathrm{Cu}-3d$ electrons usually includes the next-nearest-neighbor hopping

$$\epsilon_{\mathbf{k}} = -2t\left(\cos k_x a + \cos k_y a\right) - 4t' \cos k_x a \cos k_y a \tag{2.127}$$

We consider a pristine 2D superconductor with an s-wave or $d_{x^2-y^2}$-wave pairing symmetry. In this case, the system is invariant under a translation with a lattice constant a of the square lattice, and the BdG wave functions take the Bloch wavelike:

$$u_i = \frac{1}{\sqrt{N_L}} u_{\mathbf{k}} e^{i\mathbf{k}\cdot\mathbf{r}_i}, \tag{2.128}$$

$$v_i = \frac{1}{\sqrt{N_L}} v_{\mathbf{k}} e^{i\mathbf{k}\cdot\mathbf{r}_i} \tag{2.129}$$

which gives rise to

$$E_{\mathbf{k}} u_{\mathbf{k}} = \xi_{\mathbf{k}} u_{\mathbf{k}} + \Delta_{\mathbf{k}} v_{\mathbf{k}} \tag{2.130a}$$

$$E_{\mathbf{k}} v_{\mathbf{k}} = -\xi_{\mathbf{k}} v_{\mathbf{k}} + \Delta_{\mathbf{k}}^* u_{\mathbf{k}} \tag{2.130b}$$

Here

$$\xi_{\mathbf{k}} = \epsilon_{\mathbf{k}} - \mu \tag{2.131}$$

and

$$\Delta_{\mathbf{k}} = \Delta_s \tag{2.132}$$

for the s-wave pairing symmetry while

$$\Delta_{\mathbf{k}} = (\Delta_d/2)\left(\cos k_x a - \cos k_y a\right) \tag{2.133}$$

for the d-wave pairing symmetry.
A little algebra yields to the eigensolutions

$$\begin{pmatrix} u_{\mathbf{k}} \\ v_{\mathbf{k}} \end{pmatrix} = \begin{pmatrix} u_{\mathbf{k}}^{(0)} e^{i\varphi_{\mathbf{k}}} \\ v_{\mathbf{k}}^{(0)} \end{pmatrix} \tag{2.134}$$

corresponding to the eigenvalue

$$E_{\mathbf{k}} = \sqrt{\xi_{\mathbf{k}}^2 + \left|\Delta_{\mathbf{k}}\right|^2} \tag{2.135}$$

and

$$\begin{pmatrix} u_{\mathbf{k}} \\ v_{\mathbf{k}} \end{pmatrix} = \begin{pmatrix} -v_{\mathbf{k}}^{(0)} e^{i\varphi_{\mathbf{k}}} \\ u_{\mathbf{k}}^{(0)} \end{pmatrix} \tag{2.136}$$

corresponding to the eigenvalue $-E_{\mathbf{k}}$. Here the BdG wave function amplitude is given by

$$\begin{pmatrix} u_{\mathbf{k}}^{(0)} \\ v_{\mathbf{k}}^{(0)} \end{pmatrix} = \begin{pmatrix} \sqrt{\frac{1}{2}\left(1 + \frac{\xi_k}{E_k}\right)} \\ \sqrt{\frac{1}{2}\left(1 - \frac{\xi_k}{E_k}\right)} \end{pmatrix} \tag{2.137}$$

and $\varphi_{\mathbf{k}}$ is the phase angle of $\Delta_{\mathbf{k}}$. Therefore, we obtain the self-consistency equation for the pair potential

$$\Delta_s = \frac{1}{N_L} \sum_{\mathbf{k}} V_s \frac{\Delta_s}{2E_{\mathbf{k}}} \tanh\left(\frac{E_{\mathbf{k}}}{2k_B T}\right), \tag{2.138}$$

for a three-dimensional s-wave superconductor with the quasiparticle excitation energy $E_{\mathbf{k}} = \sqrt{\xi_{\mathbf{k}}^2 + \Delta_s^2}$; and

$$\Delta_d = \frac{1}{N_L} \sum_{\mathbf{k}} V_d \left(\cos k_x a - \cos k_y a\right)^2 \frac{\Delta_d}{2E_{\mathbf{k}}} \tanh\left(\frac{E_{\mathbf{k}}}{2k_B T}\right) \tag{2.139}$$

for a two-dimensional $d_{x^2-y^2}$-wave superconductor with the quasiparticle excitation energy $E_{\mathbf{k}} = \sqrt{\xi_{\mathbf{k}}^2 + \left[\frac{\Delta_d}{2}\left(\cos k_x a - \cos k_y a\right)\right]^2}$. In Fig. 2.2, the temperature dependence of superconducting order parameter for various values of chemical potential is shown.

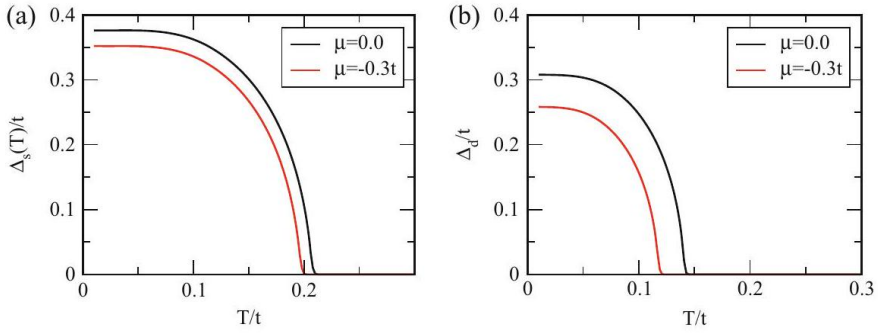

Fig. 2.2 Temperature dependence of the superconducting order parameter for an s-wave (a) and $d_{x^2-y^2}$-wave (b) pairing symmetry for various values of chemical potential in a 2 D tight-binding lattice model with nearest-neighbor hopping. Lattice size is chosen to be 400×400 for the calculations. The energy and temperature (k_BT and k_B is set to 1) are measured in units of t

The results show that the zero-temperature superconducting pair potential and transition temperature are dependent on the location of the chemical potential, at which the intensity of density of states is tuned. In the 2D tight-binding model with nearest-neighbor hopping, the van Hove singularity occurs at the normal state energy $\epsilon = 0$. In Fig. 2.3, we show the typical feature of density of states for a 2D superconductor described by a square-lattice tight-binding model.

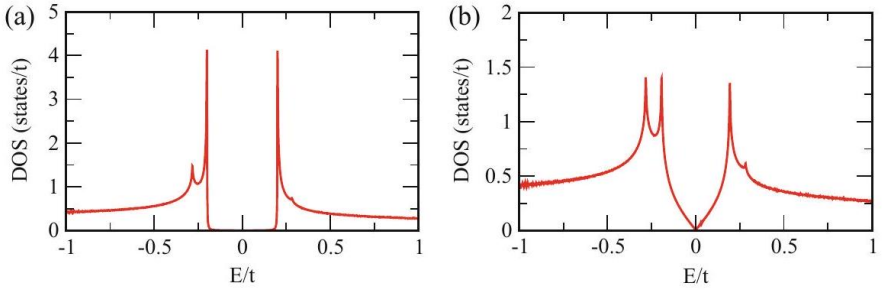

Fig. 2.3 Density of states for a pristine 2D superconductor with s-wave (a) and $d_{x^2-y^2}$-wave (b) pairing symmetry. A square-lattice tight-binding model with normal-state single-particle energy dispersion given by Eq. (2.127) is used. The parameter $t = -0.3t$ and $\mu = -t$, and $\Delta_s = \Delta_d = 0.2t$ are taken. Lattice size is chosen to be 4096×4096 and $\Gamma = 0.001t$ is used for the calculations

The normalstate single-particle energy dispersion given by Eq. (2.127) with $t' = -0.3$t and a chemical potential $\mu = -t$ are considered. For the s-wave pairing symmetry, a well-shape characteristic as marked by the superconducting coherent peaks around the Fermi energy at $E = 0$ is exhibited in the density of states. Instead, for the $d_{x^2-y^2}$-wave pairing symmetry, a V-shape characteristic is exhibited in the density of states around the Fermi energy, which arises from the gapless nodal quasiparticles. In addition, the normal-state van Hove singularity peak is shifted by the superconducting gap opening.

9.7.6 2.3 Lattice Abrikosov-Gorkov Equations

Theory

Similar to the continuum model, we can also establish the Abrikosov-Gorkov theory in the lattice model. Here we generalize it to include the effects of spin-orbit coupling and spin-flip scattering. We first define a 4 -component spinor field operator in the Nambu space

$$\hat{\Psi}_i(\tau) = \begin{pmatrix} c_{i\uparrow}(\tau) \\ c_{i\downarrow}(\tau) \\ c^\dagger_{i\uparrow}(\tau) \\ c^\dagger_{i\downarrow}(\tau) \end{pmatrix}, \tag{2.140}$$

and

$$\hat{\Psi}^\dagger_i(\tau) = \left(c^\dagger_{i\uparrow}(\tau) c^\dagger_{i\downarrow}(\tau) c_{i\uparrow}(\tau) c_{i\downarrow}(\tau) \right), \tag{2.141}$$

where the electronic operators

$$c_{i\sigma}(\tau) = e^{\mathscr{H}_{eff}\tau/\hbar} c_{i\sigma} e^{-\mathscr{H}_{eff}\tau/\hbar}, \tag{2.142}$$

$$c^\dagger_{i\sigma}(\tau) = e^{\mathscr{H}_{eff}\tau/\hbar} c^\dagger_{i\sigma} e^{-\mathscr{H}_{eff}\tau/\hbar}, \tag{2.143}$$

are defined in the imaginary-time space and $\mathscr{H}_{\text{eff}}$ is given by Eq.(2.5).

Why do we use this notation and not other Nambu notation? Because this works. Other notation also works. Right?

Note that $c^\dagger_{i\sigma}(\tau) \neq [c_{i\sigma}(\tau)]^\dagger$. We then introduce the real-space Green's function in the lattice model as

$$\begin{aligned} \mathscr{G}(i\tau; j\tau') &= -\left\langle T_\tau \left(\hat{\Psi}_i(\tau) \otimes \hat{\Psi}^\dagger_j(\tau') \right\rangle \right. \\ &= -\theta(\tau - \tau') \left\langle \hat{\Psi}_i(\tau) \otimes \hat{\Psi}^\dagger_j(\tau') \right\rangle + \theta(\tau' - \tau) \left\langle \hat{\Psi}^\dagger_j(\tau') \otimes \hat{\Psi}_i(\tau) \right\rangle \end{aligned} \tag{2.144}$$

Therefore, in an expanded form, it becomes

$$\mathscr{G}(i\tau; j\tau') = \begin{pmatrix} -\langle T_\tau(c_{i\uparrow}(\tau)c^\dagger_{j\uparrow}(\tau')\rangle - \langle T_\tau(c_{i\uparrow}(\tau)c^\dagger_{j\downarrow}(\tau')\rangle - \langle T_\tau(c_{i\uparrow}(\tau)c_{j\uparrow}(\tau')\rangle - \langle T_\tau(c_{i\uparrow}(\tau)c_{j\downarrow}(\tau')\rangle .... \\ -\langle T_\tau(c_{i\downarrow}(\tau)c^\dagger_{j\uparrow}(\tau')\rangle - \langle T_\tau(c_{i\downarrow}(\tau)c^\dagger_{j\downarrow}(\tau')\rangle - \langle T_\tau(c_{i\downarrow}(\tau)c_{j\uparrow}(\tau')\rangle - \langle T_\tau(c_{i\uparrow}(\tau)c_{j\downarrow}(\tau')\rangle .... \\ -\langle T_\tau(c^\dagger_{i\uparrow}(\tau)c^\dagger_{j\uparrow}(\tau')\rangle - \langle T_\tau(c^\dagger_{i\uparrow}(\tau)c^\dagger_{j\downarrow}(\tau')\rangle - \langle T_\tau(c^\dagger_{i\uparrow}(\tau)c_{j\uparrow}(\tau')\rangle - \langle T_\tau(c^\dagger_{i\uparrow}(\tau)c_{j\downarrow}(\tau')\rangle .... \\ -\langle T_\tau(c^\dagger_{i\downarrow}(\tau)c^\dagger_{j\uparrow}(\tau')\rangle - \langle T_\tau(c^\dagger_{i\downarrow}(\tau)c^\dagger_{j\downarrow}(\tau')\rangle - \langle T_\tau(c^\dagger_{i\downarrow}(\tau)c_{j\uparrow}\tau')\rangle - \langle \tau_\tau(c^\dagger_{i\downarrow}(\tau)c_{j\downarrow}(\tau')\rangle ... \end{pmatrix}. \tag{2.145}$$

(???? how to understand it???)

Since the trace is unchanged upon a cyclic variation of operators, we can easily prove that the Green's function is a function of the difference $\tau - \tau'$, that is,

$$\mathscr{G}(i\tau; j\tau') = \mathscr{G}(i, j; \tau - \tau'), \tag{2.146}$$

with $\tau - \tau'$ restricted in the range of $[-\beta, \beta]$ and the factor $\beta = 1/k_B T$. Therefore, the Fourier transform is given by

$$\mathscr{G}(i, j; i\omega_n) = \int_0^\beta d\tau e^{i\omega_n \tau} \mathscr{G}(i, j; \tau), \tag{2.147}$$

$$\mathscr{G}(i, j; \tau) = \frac{1}{\beta} \sum_n e^{-i\omega_n \tau} \mathscr{G}(i, j; i\omega_n), \tag{2.148}$$

where the Matsubara frequency $\omega_n = (2n+1)\pi k_B T/\hbar$ with $n = -\infty, \ldots, -1, 0, 1, \ldots, \infty$.

Using the equation of motion for $c_{i\sigma}(\tau)$ and $c^\dagger_{i\sigma}(\tau)$:

$$-\hbar\frac{\partial c_{i\sigma}(\tau)}{\partial\tau}=\left[c_{i\sigma}(\tau),\mathscr{H}_{eff}\right]_{-}, \tag{2.149}$$

$$-\hbar\frac{\partial c_{i\sigma}^{\dagger}(\tau)}{\partial\tau}=\left[c_{i\sigma}^{\dagger}(\tau),\mathscr{H}_{eff}\right]_{-}, \tag{2.150}$$

and Eq. (2.10), we can obtain the equation of motion for the Green's function

$$\sum_{j'}\hat{M}_{ij'}(\tau)\mathscr{G}\left(j'\tau;j\tau'\right)=\delta_{ij}\delta\left(\tau-\tau'\right)\hat{1}, \tag{2.151}$$

with

$$\hat{M}_{ij}(\tau)=\begin{pmatrix}-\frac{\partial}{\partial\tau}\delta_{ij}-\tilde{h}_{i\uparrow,j\uparrow} & -\tilde{h}_{i\uparrow,j\downarrow} & 0 & -\Delta_{ij}\\ -\tilde{h}_{i\downarrow,j\uparrow} & -\frac{\partial}{\partial\tau}\delta_{ij}-\tilde{h}_{i\downarrow,j\downarrow} & -\Delta_{ji} & 0\\ 0 & -\Delta_{ij}^{*} & -\frac{\partial}{\partial\tau}\delta_{ij}+\tilde{h}_{i\uparrow,j\uparrow}^{*} & -\tilde{h}_{i\uparrow,j\downarrow}^{*}\\ -\Delta_{ji}^{*} & 0 & -\tilde{h}_{i\uparrow,j\downarrow}^{*} & -\frac{\partial}{\partial\tau}\delta_{ij}+\tilde{h}_{i\downarrow,j\downarrow}^{*}\end{pmatrix} \tag{2.152}$$

for the spin-singlet pairing case, and subject to the self-consistency condition:

$$\Delta_{ij}=-\frac{V}{2}\left[\mathscr{G}_{14}\left(i\tau\rightarrow\tau'+0^{+},j\tau'\right)-\mathscr{G}_{23}\left(i\tau\rightarrow\tau'+0^{+},j\tau'\right)\right], \tag{2.153}$$

$$\Delta_{ij}^{*}=-\frac{V}{2}\left[\mathscr{G}_{41}\left(i\tau\rightarrow\tau'+0^{+},j\tau'\right)-\mathscr{G}_{32}\left(i\tau\rightarrow\tau'+0^{+},j\tau'\right)\right]. \tag{2.154}$$

In the absence of the spin-orbit coupling and spin-flip scattering, we can decouple the equation of motion for the Green's function into two sets:

$$\sum_{j'}\begin{pmatrix}-\frac{\partial}{\partial\tau}\delta_{ij'}-\tilde{h}_{i\uparrow,j'\uparrow} & -\Delta_{ij'}\\ -\Delta_{j'i}^{*} & -\frac{\partial}{\partial\tau}\delta_{ij'}+\tilde{h}_{i\downarrow,j'\downarrow}^{*}\end{pmatrix}\begin{pmatrix}\mathscr{G}_{11}\left(j'\tau;j\tau'\right)\mathscr{G}_{14}\left(j'\tau;j\tau'\right)\\ \mathscr{G}_{41}\left(j'\tau;j\tau'\right)\mathscr{G}_{44}\left(j'\tau;j\tau'\right)\end{pmatrix}=\delta_{ij}\delta\left(\tau-\tau'\right)\hat{1}, \tag{2.155}$$

and

$$\sum_{j'}\begin{pmatrix}-\frac{\partial}{\partial\tau}\delta_{ij'}-\tilde{h}_{i\downarrow\cdot j'\downarrow} & -\Delta_{j'i}\\ -\Delta_{ij'}^{*} & -\frac{\partial}{\partial\tau}\delta_{ij'}+\tilde{h}_{i\uparrow,j'\uparrow}^{*}\end{pmatrix}\begin{pmatrix}\mathscr{G}_{22}\left(j'\tau;j\tau'\right)\mathscr{G}_{23}\left(j'\tau;j\tau'\right)\\ \mathscr{G}_{32}\left(j'\tau;j\tau'\right)\mathscr{G}_{33}\left(j'\tau;j\tau'\right)\end{pmatrix}=\delta_{ij}\delta\left(\tau-\tau'\right)\hat{1}. \tag{2.156}$$

In this case, either one of the above two sets of equations of motion is sufficient to solve the whole problem. More interestingly, there exists a close relation between the Green's function and the BdG eigenfunctions. Specifically, with the time dependence of the quasiparticle operators:

$$\gamma_{n}(\tau)=\gamma_{n}e^{-E_{n}\tau/\hbar} \tag{2.157}$$

$$\gamma_{n}^{\dagger}(\tau)=\gamma_{n}^{\dagger}e^{E_{n}\tau/\hbar} \tag{2.158}$$

and the canonical transformation, we can obtain for the most general case the following matrix elements of the Green's function

$$\begin{aligned}\mathscr{G}_{11}(i,j;\tau) =& -\theta(\tau)\sum_n \left[u_{i\uparrow}^n u_{j\uparrow}^{n*} f\left(-E_n\right) e^{-E_n\tau/\hbar} + v_{i\uparrow}^{n*} v_{j\uparrow}^n f\left(E_n\right) e^{E_n\tau/\hbar}\right] \\ &+\theta(-\tau)\sum_n \left[u_{j\uparrow}^{n*} u_{i\uparrow}^n f\left(E_n\right) e^{-E_n\tau/\hbar} + v_{j\uparrow}^n v_{i\uparrow}^{n*} f\left(-E_n\right) e^{E_n\tau/\hbar}\right] \end{aligned} \tag{2.159}$$

and

$$\begin{aligned}\mathscr{G}_{44}(i,j;\tau) =& -\theta(\tau)\sum_n \left[u_{i\downarrow}^{n*} u_{j\downarrow}^n f\left(E_n\right) e^{E_n\tau/\hbar} + v_{i\downarrow}^n v_{j\downarrow}^{n*} f\left(-E_n\right) e^{-E_n\tau/\hbar}\right] \\ &+\theta(-\tau)\sum_n \left[u_{j\downarrow}^n u_{i\downarrow}^{n*} f\left(-E_n\right) e^{E_n\tau/\hbar} + v_{j\downarrow}^{n*} v_{i\downarrow}^n f\left(E_n\right) e^{-E_n\tau/\hbar}\right]. \end{aligned} \tag{2.160}$$

It is straightforward to obtain the Green's function in the frequency domain

$$\begin{aligned}&\mathscr{G}_{11}\left(i,j;i\omega_n\right) = \int_0^{\beta\hbar} d\tau e^{i\omega_n\tau}\mathscr{G}_{11}(i,j;\tau) \\ =& -\sum_n{}' \left[u_{i\uparrow}^n u_{j\uparrow}^{n*} f\left(-E_n\right)\int_0^{\beta\hbar} d\tau e^{(i\omega_n - E_n/\hbar)\tau} + v_{i\uparrow}^{n*} v_{j\uparrow}^n f\left(E_n\right)\int_0^{\beta\hbar} d\tau e^{(i\omega_n + E_n/\hbar)\tau}\right] \\ =& -\sum_n{}' \left\{\frac{u_{i\uparrow}^n u_{j\uparrow}^{n*}}{i\omega_n - E_n/\hbar} f\left(-E_n\right)\left(e^{\beta\hbar(i\omega_n - E_n/\hbar)} - 1\right) + \frac{v_{i\uparrow}^{n*} v_{j\uparrow}^n}{i\omega_n + E_n/\hbar} f\left(E_n\right)\left(e^{\beta\hbar(i\omega_n + E_n/\hbar)} - 1\right)\right\} \\ =& \sum_n{}' \left[\frac{u_{i\uparrow}^n u_{j\uparrow}^{n*}}{i\omega_n - E_n/\hbar} + \frac{v_{i\uparrow}^{n*} v_{j\uparrow}^n}{i\omega_n + E_n/\hbar}\right] \end{aligned} \tag{2.161}$$

and

$$\begin{aligned}\mathscr{G}_{44}\left(i,j;i\omega_n\right) =& \int_0^{\beta\hbar} d\tau e^{i\omega_n\tau}\mathscr{G}_{44}(i,j;\tau) \\ =& -\sum_n{}' \left[u_{i\downarrow}^{n*} u_{j\downarrow}^n f\left(E_n\right)\int_0^{\beta\hbar} d\tau e^{(i\omega_n + E_n/\hbar)\tau}\right. \\ &\left. + v_{i\downarrow}^n v_{j\downarrow}^{n*} f\left(-E_n\right)\int_0^{\beta\hbar} d\tau e^{(i\omega_n + E_n/\hbar)\tau}\right] \\ =& -\sum_n{}' \left\{\frac{u_{i\downarrow}^{n*} u_{j\downarrow}^n}{i\omega_n + E_n/\hbar} f\left(E_n\right)\left(e^{\beta\hbar(i\omega_n + E_n/\hbar)} - 1\right)\right. \\ &\left. + \frac{v_{i\downarrow}^n v_{j\downarrow}^{n*}}{i\omega_n - E_n/\hbar} f\left(E_n\right)\left(e^{\beta\hbar(i\omega_n - E_n/\hbar)} - 1\right)\right\} \\ =& \sum_n{}' \left[\frac{u_{i\downarrow}^{n*} u_{j\downarrow}^n}{i\omega_n + E_n/\hbar} + \frac{v_{i\downarrow}^n v_{j\downarrow}^{n*}}{i\omega_n - E_n/\hbar}\right] \end{aligned} \tag{2.162}$$

Other matrix elements of the Green's function can be evaluated in the same way, which are left for exercise.

In the absence of the spin-orbit coupling and spin-flip scattering, we can rewrite the Green's matrix elements as

$$\mathscr{G}_{11}\left(i,j;i\omega_n\right)=\sum_{\tilde{n}}{}'\left[\frac{u_{i\uparrow}^{\tilde{n}1}u_{j\uparrow}^{\tilde{n}1*}}{i\omega_n-E_{\tilde{n}1}/\hbar}+\frac{v_{i\uparrow}^{\tilde{n}2*}v_{j\uparrow}^{\tilde{n}2}}{i\omega_n+E_{\tilde{n}2}/\hbar}\right], \tag{2.163}$$

and

$$\mathscr{G}_{44}\left(i,j;i\omega_n\right)=\sum_{\tilde{n}}{}'\left[\frac{u_{i\downarrow}^{\tilde{n}2*}u_{j\downarrow}^{\tilde{n}2}}{i\omega_n+E_{\tilde{n}2}/\hbar}+\frac{v_{i\downarrow}^{\tilde{n}1}\nu_{j\downarrow}^{\tilde{n}1*}}{i\omega_n-E_{\tilde{n}1}/\hbar}\right]. \tag{2.164}$$

In summary, we have demonstrated that once we know the eigensolution of the BdG equations, the Abrikosov-Gorkov Green's function can be expressed rigorously. Conversely, if we know the solution to the Abrikosov-Gorkov equations of motion for the Green's functions, the local density of states can be calculated as

$$\begin{aligned}\rho_{i,\uparrow}(E)&=-\frac{1}{\hbar\pi}\operatorname{Im}\left[\mathscr{G}_{11}\left(i,i;i\omega_n\rightarrow E/\hbar+i0^+\right)\right]\\&=\sum_{\tilde{n}}{}'\left[\left|u_{i\uparrow}^{\tilde{n}1}\right|^2\delta\left(E-E_{\tilde{n}1}\right)+\left|v_{i\uparrow}^{\tilde{n}2}\right|^2\delta\left(E+E_{\tilde{n}2}\right)\right],\end{aligned} \tag{2.165}$$

and

$$\begin{aligned}\rho_{i,\downarrow}(E)&=\frac{1}{\hbar\pi}\operatorname{Im}\left[\mathscr{G}_{44}\left(i,i;-i\omega_n\rightarrow-\left(E/\hbar+i0^+\right)\right)\right]\\&=\sum_{\tilde{n}}{}'\left[\left|u_{i\downarrow}^{\tilde{n}2}\right|^2\delta\left(E-E_{\tilde{n}2}\right)+\left|v_{i\downarrow}^{\tilde{n}1}\right|^2\delta\left(E+E_{\tilde{n}2}\right)\right].\end{aligned} \tag{2.166}$$

The above expressions for the local density of states are the same as those given in terms of the eigensolution to the BdG equations (2.47). As we will show in later chapters, the Green's function technique is very useful and convenient for some situations.

[MOVE TO THE SECTION BEFORE]

The Model

We propose a simple theory for the $I-V$ curves of normal-superconducting microconstriction contacts which describes the crossover from metallic to tunnel junction behavior. The detailed calculations are performed within a generalized semiconductor model, with the use of the Bogoliubov equations to treat the transmission and reflection of particles at the $N-S$ interface. By including a barrier of arbitrary strength at the interface, we have computed a family of $I-V$ curves ranging from the tunnel junction to the metallic limit. Excess current, generated by Andreev reflection, is found to vary smoothly from $4\Delta/3eR_N$ in the metallic case to zero for the tunnel junction. Charge-imbalance generation, previously calculated only for tunnel barriers, has been recalculated for an arbitrary barrier strength, and detailed insight into the conversion of normal current to supercurrent at the interface is obtained. We emphasize that the calculated differential conductance offers a particularly direct experimental test of the predictions of the model.

I. Introduction, conclusion

In recent years there has been much experimental and theoretical work on small-area highcurrent-density superconducting junctions, since such junctions have advantages for certain practical applications. Although the properties (I-V curves, etc.) of classic (high-barrier) tunnel junctions have long been understood in great detail, [1] the properties of metallic (no-barrier) junctions have been studied only more recently [2–4] and in less detail, and the transitional case (small barrier) has received practically no attention at all. Here, we present a new unified treatment which is sufficiently general to embrace both limits, as well as the intermediate regime.

In this paper, we confine our attention primarily to the $N - S$ interface in the context of a generalized Andreev reflection model. This avoids the complications of the Josephson effect, while allowing complete delineation of I - V curves including the so-called "excess currrent" at high voltage, as it increases from zero in tunnel junctions to its limiting value in clean metallic contacts.

The paper begins with a careful clarification of the relation between a general semiconductor model of the superconducting energy levels and the excitations of the BCS model and the Bogoliubov equations. With this in hand, we are quickly led to complete $I - V$ curves for the case of arbitrary barrier strength. We also compute the generalization of the tunnel-injection results for the generation of charge imbalance in the superconductor, and give new insight into the detailed processes involved in the conversion from normal to supercurrent at an N-S interface. Some of the results which we obtain by our simple technique have been obtained earlier by other more mathematically complex theories, but our method gives greater physical insight. Moreover, the simplicity of our method has allowed us to treat a broader range of problems having direct experimental implications. We have also used this model in a previous publication [5] to explain the origin of the excess current and of the subharmonic gap structure which is observed in metallic S-S contacts.

IX. CONCLUSION

We have proposed a simple theory for the $N - S$ microconstriction or point contact that is general enough to describe the complete crossover from metallic to small-area tunnel-junction behavior. From this model, a deeper understanding of the semiconductor picture, excess currents, current conversion, and charge-imbalance processes have emerged, in addition to calculation of $I - V$ curves for arbitrary barrier strength. The latter results are directly accessible to experiment, and should be helpful in interpreting the wide variety of $I - V$ curve shapes observed in the laboratory. The application of this model to the $S - N - S$ case has been presented elsewhere, [5] where it has been shown to offer an explanation of the SGS observed in metallic weak links.

ii. Generalized semiconductor scheme

It has long been conventional to simplify the calculation of tunnel currents by taking advantage of the fact that the BCS coherence factors u_k and v_k drop out of the computation if excitations with the same energy E_k, but with $k < k_F$ and $k > k_F$, are grouped together.

Then a very simple "semiconductor model" can be established, in which only the superconducting density of states $N_s(E)$ distinguishes the superconductor from the situation in the normal state. However, in combining $k_<$and $k_>$for each E_k, information is lost. For instance, the quasiparticle charge imbalance Q^* refers specifically to the imbalance between the two branches $k > k_F$ and $k < k_F$ of the quasiparticle spectrum, a distinction which is completely suppressed in the simplest semiconductor model. Another shortcoming of the elementary semiconductor model is that the density-of-states factor makes no reference to the microscopic nature of the

states. For example, it is clear that the current must be carried toward and away from the junction by waves traveling in the appropriate directions, yet this physical fact is obscured in the usual tunnel-Hamiltonian model.

Here, we describe a generalized semiconductor model specifically designed to avoid this loss of information. The key innovation is the use of the Bogoliubov equations [6] to handle the interface; this treats all cases from a clean metallic interface to a tunnel junction in the same formal way by matching wave functions at the boundary. These results determine the probability current carried by the various excitations characterized by the semiconductor diagram. For simplicity, we restrict attention to metal clean enough to allow use of momentum as a good quantum number for labeling the various waves.

If one considers only energies $E > \Delta$, the Bogoliubov equation solutions (see Appendix for details) for the incident, transmitted, and reflected particles can be identified with the conventional BCS quasiparticle excitations with energy

$$E_k = \left(\Delta^2 + \epsilon_k^2\right)^{1/2} \tag{1}$$

with respect to the electrochemical potential for condensed pairs, where

$$\epsilon_k = \frac{\hbar^2 k^2}{2m} - \epsilon_F \tag{2}$$

Because only the square of ϵ_k enters the expression for E_k, there will be a pair of magnitudes of k associated with each energy, namely,

$$\hbar k^{\pm} = (2m)^{1/2} \left[\epsilon_F \pm \left(E_k^2 - \Delta^2\right)^{1/2}\right]^{1/2} \tag{3}$$

Moreover, because of the BCS pairing of k and $-k$, one must consider both signs of k together, so that there is a fourfold degeneracy of relevant states for each E, as sketched in Fig. 1. Of course there is an additional twofold spin degeneracy, but in the absense of spin-flip processes this affects only normalizations, and it need not concern us here.

The nature of one type of these BCS quasiparticle states is given by the usual Bogoliubov transformation [7] as

$$\gamma_{k0}^* = u_k c_{k\uparrow}^* - v_k c_{-k\downarrow} \tag{4}$$

where the BCS coherence factors are given by

$$u_k^2 = 1 - v_k^2 = \frac{1}{2}\left(1 + \epsilon_k / E_k\right) \tag{5}$$

Although, in general, Eq. (5) determines the magnitudes of u_k and v_k (which can have phase factors), for simplicity we take them to be real and positive. For the $N - S$ case treated here, this involves no loss of generality; only in S - S devices does phase play a role. The excitations described in Eq. (4) consist partly of electrons created at $+k$ (i.e., $u_k c_{k\uparrow}^*$) and partly of holes created at $-k$ (i.e., $v_k c_{-k\downarrow}$, the destruction of an electron at $-k$). Since either term increases the system momentum by $+k$, the subscript k in γ_{k0}^* is a well-defined momentum index suitable for labeling. From Eq. (5) we see that the excitations at $\pm k^+$are predominantly electronlike, while these at $\pm k^-$are predominantly holelike. The other members of the degenerate set are described by including the complementary BCS operator γ_{k1} and also including both senses of k.

In preparation for the application of boundary conditions, we note that the excitation described by Eq. (4) is described in the Bogoliubov-equation formalism (see Appendix for details) as a two-element column vector,

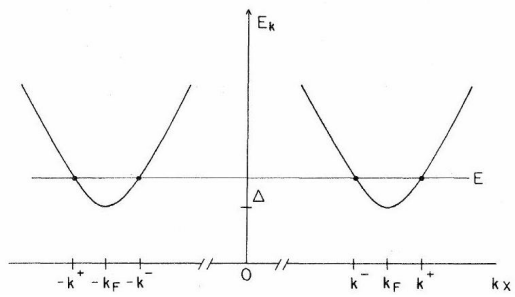

FIG. 1. Schematic plot of excitation energies E_k vs k along an axis passing through the center of the Fermi sphere in the superconducting state. The scale has been greatly expanded near $\pm k_F$.

$$\psi_{k0} = \begin{bmatrix} f_k(x,t) \\ g_k(x,t) \end{bmatrix} \tag{6}$$

Here f_k and g_k satisfy the differential equations

$$\begin{aligned} \left[-\frac{\hbar^2}{2m}\nabla^2 - \mu(x) + V(x)\right] f + \Delta g &= i\hbar\frac{\partial f}{\partial t} \to Ef \\ -\left[-\frac{\hbar^2}{2m}\nabla^2 - \mu(x) + V(x)\right] g + \Delta f &= i\hbar\frac{\partial g}{\partial t} \to Eg \end{aligned} \tag{7}$$

and they are proportional to u_k and v_k, respectively, when $V(x)$ is constant. The time derivatives may be replaced as indicated in solutions for stationary states of energy E.

As written in Eq. (4), the excitations γ^*_{k0} change the charge of the superconductor by the fractional electronic charge $q_k = u_k^2 - v_k^2 = \epsilon_k/E_k = \pm N_s(E)^{-1}$. Since physically allowable operators must conserve charge exactly, it is convenient [7] to introduce operators of the form

$$\gamma^*_{ek0} = u_k c^*_{k\uparrow} - v_k S^* c_{-k\downarrow}, \tag{8a}$$

$$\gamma^*_{hk0} = u_k S c^*_{k\uparrow} - v_k c_{-k\downarrow} = S\gamma^*_{ek0} \tag{8b}$$

where S^* adds a pair to the condensate and S destroys one. These operators create excitations while changing the charge by exactly $\pm e$, corresponding to the subscripts e and h for electron and hole, respectively. Accordingly, they are better adapted to describe the energy levels analogous to those of ordinary electrons. The excitations described by Eqs. (8a) and (8b) are identical, and in no sense cancel as one might suppose for electron and hole operators. The systems resulting from (8a) and (8b) differ only by one condensed pair from the reservoir at the chemical potential.

Now for any system with fermion excitations such as these, the total system energy can be written as

$$E = E_G + \sum_k E_k \gamma^*_k \gamma_k + \mu N \tag{9}$$

where E_G is the ground-state energy, and the sum runs over all the excitations, which have $E_k \geq 0$. The electrochemical potential μ must be introduced explicitly since we are interested in treating processes which change the number N of electrons in a subsystem at given μ by ± 1. In fact, the energy required to make an excitation with charge e is

$$E_{ek} = \mu + E_k, \tag{10a}$$

while that to make an excitation with charge $-e$ differs by 2μ and is

$$E_{hk} = -\mu + E_k = -(\mu - E_k) \tag{10b}$$

We can now tabulate (see Table I) the possible charge-conserving processes involving subsystems 1 and 2, and write down the corresponding condition set by the conservation of energy. There are four distinct cases, each of which conserves energy equally well in reverse, making eight cases in all. As is evident from Table I, all these energetically allowed transitions occur as "horizontal" ones only if we plot both $\pm E_{ki}$ symmetrically about each μ_i, as is motivated by recalling that $\mu - E_k = -E_{hk}$ (see Fig. 2). Further, the four cases of Table I include all the combinations of $\pm E_k$, so that all horizontal transitions in such a "reflected" or semiconductor-model diagram are energetically allowed.

There is, however, another constraint on the system; namely, a particle incident from the left can only produce transmitted particles with positive group velocity ($dE/d\hbar k$) and reflected ones with negative group velocities. In general, there is a finite probability of all the transfers allowed by these considerations to occur, but in the special case of zero barrier and no discontinuity in electronic-band parameters across the $N - S$ interface, it turns out that there is essentially zero crossover between channels inside and outside the Fermi surface, even near the gap edge. It is here that the Bogoliubov equations prove most useful: The semiconductor diagram shows which transitions are energetically allowed; the Bogoliubov equations provide the

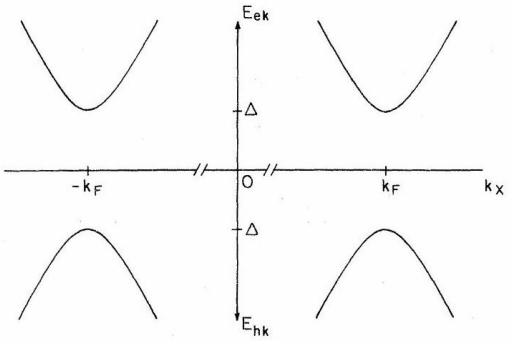

FIG. 2. Semiconductor version of Fig. 1. Inclusion of the quasiparticle branches in the lower half plane allows all the transitions in Table I to be "horizontal."

TABLE I. Processes involving transfer of a single electronic charge.

Process	Energy condition
1. Electron from $1 \to 2$ (or reverse)	$\mu_1 + E_{k1} = \mu_2 + E_{k2}$
2. Hole from $1 \to 2$ (or reverse)	$\mu_1 - E_{k1} = \mu_2 - E_{k2}$
3. Create electron in 1 and hole in 2 (or destroy both)	$\mu_1 + E_{k1} = \mu_2 - E_{k2}$
4. Create hole in 1 and electron in 2 (or destroy both)	$\mu_1 - E_{k1} = \mu_2 + E_{k2}$

quantitative probability that each will occur.

As a final preliminary, we consider the special case of the normal metal, obtained by letting $\Delta \to 0$ in the expressions for the superconducting case. Here the situation simplifies from the superconducting case shown in Fig. 2 because electronlike excitations cannot be made inside the Fermi sphere, since the states there are fully occupied in the ground state, and excitations must be orthogonal to the ground state. Similarly, hole excitations are possible only outside the Fermi sphere. As a result, in the normal metal only the branches shown in Fig. 3 exist.

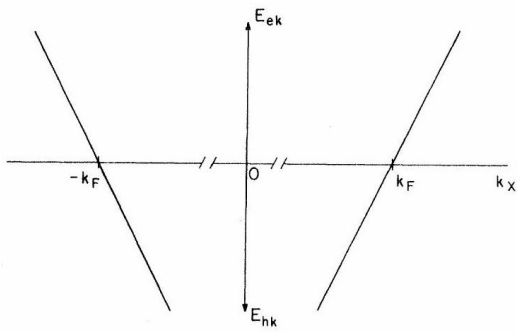

FIG. 3. E_k vs k for the normal state.

iii. The n-s boundary in equilibrium

We start by considering the dynamic equilibrium which exists at an N-S interface with no applied voltage, as sketched in Fig. 4. In this equilibrium situation, all relevant quaisparticle states (such as those labeled $0, 1, 2, 3, 4$, and 5 in the figure) are occupied with the same probability $f_0(E)$, which also gives the probability of a hole in the state 6 at $-E$. Viewed kinematically in a semiclassical approximation, however, particles approach the interface and are transmitted and reflected with certain probabilities, which are given by the products of squared amplitudes of Bogoliubov-equation solutions times their appropriate group velocities. The self-consistency of the equilibrium state provides a useful check on the computed probability coefficients.

To be concrete, consider an electron incident on the interface from the normal state with energy $E > \Delta$, as indicated by the arrow at the state labeled 0 in Fig. 4.

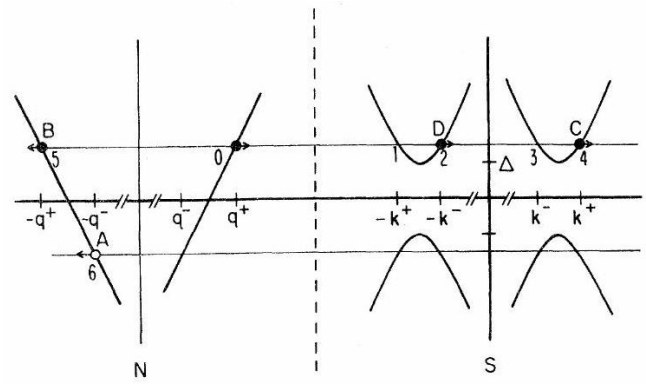

FIG. 4. Schematic diagram of energy vs momentum at $N - S$ interface. The open circles denote holes, the closed circles electrons, and the arrows point in the direction of the group velocity. This figure describes an incident electron at)0), along with the resulting transmitted $(2, 4)$ and reflected $(5, 6)$ particles.

By matching slope and value of the wave function across the interface, one finds the probabilities $A(E), B(E), C(E)$, and $D(E)$ for the four processes indicated by those labels in Fig. 4, i.e., outgoing particles at points $6, 5, 4$, and 2, respectively. In words, $C(E)$ is the probability of transmission through the interface with a wave vector on the same side of the Fermi surface (i.e., $q^+ \to k^+$, not $-k^-$, while $D(E)$ gives the probability of transmission with crossing through the Fermi surface (i.e., $q^+ \to -k^-$). $B(E)$ is the probability of ordinary reflection, while $A(E)$ is the probability of Andreev [8] reflection as a hole on the other side of the Fermi surface. The latter process is not included in Table I, since it involves a transfer of a pair carrying $2e$ across the interface, while the processes in Table I transfer only a single electronic charge. The energy conservation condition appropriate for Andreev reflection is found by equating the energy of the initial electronlike excitation with that of the final holelike excitation plus a Cooper pair at the chemical potential. That is, $E_{ek} = E_{hk} + 2\mu$, from which it follows that

$$|E_e| = |E_h| \tag{11}$$

In other words, the hole is generated as far below μ as the electron was above, as drawn in Fig. 4. Of course, this result is obvious in the excitation representation.

It should be clearly understood that the probabilities A, B, C, and D (and the similar set A', B', C', and D' for quasiparticles incident from the superconducting side) are those appropriate for probability current, taking account of the cancelling effects of state density and group velocity. For example, consider the flow of particles across the interface in the energy range E to $E + dE$, and including only states outside the Fermi surface. From left to right, the current from states at 0 to those at 4 in Fig. 4 is proportional to $v_F C(E) f_0(E) dE$; the balancing current from right to left, i.e., from states at 1 to those at 5, is proportional to $v_F C'(E) f_0(E) N_s(E) dE$, where $N_s(E)$ is the normalized density of states in the superconductor. In equilibrium these flows are exactly equal, so that

$$C'(E) N_s(E) = C(E) \tag{12a}$$

and similarly

$$D'(E) N_s(E) = D(E) \tag{12b}$$

governs the branch-crossing transfers. The results of Eqs. (12) can be derived by direct computation, or by appeal to time-reversal symmetry. For simplicity, in the remainder of the paper we write all expressions in terms of $C(E)$ and $D(E)$, avoiding the need for explicit inclusion of the density-ofstates factor $N_s(E)$ or the quasiparticle group velocity $v_g = N_s^{-1} v_F$ in integrations over energy.

Recognizing the symmetry of the problem about μ, we see that $A(E)$ and $B(E)$ are even functions of E. Similarly, $C(E)$ and $D(E)$ are also even functions of E, provided one uses the convention that $D(E)$ describes processes in which the transmission involves branch crossing, while $C(E)$ governs transmission processes in which the particle stays on the same branch.
It is important to note that the conservation of probability requires that

$$A(E) + B(E) + C(E) + D(E) = 1 \tag{13}$$

This result is particularly useful in simplifying expressions for energies below the gap, $|E| < \Delta$, where there can be no transmitted quasiparticles, so that $C = D = 0$. Then, Eq. (13) reduces simply to $A(E) = 1 - B(E)$, so that a single function of energy is all that is needed.

Now, in general, A, B, C, and D depend on the angle of incidence of the trajectory and on the detailed shape of the scattering potential. For simplicity, we restrict ourselves to a one-dimensional (1D) geometry. For the purposes of this paper, the actual three-dimensional (3D) geometry is invoked only to enforce three boundary conditions on the 1D model: that the junction is well-cooled, and that the energy gap and the electric potential both rise to their full asymptotic values on a scale shorter than ξ on either side of the neck.

To capture the essential effect of any interfacial scattering with a single parameter, we model it by a repulsive potential $H\delta(x)$ located at the interface. This is meant to represent the effect of the typical oxide layer in a point contact, the localized disorder in the neck of a short microbridge, or the intentional oxide barrier in a high-current-density tunnel junction. The calculations with the Bogoliubov equations are quite straighforward, but are given in the Appendix to avoid a digression at this point. The results of the calculations are values of the four coefficients A, B, C, and D as functions of energy and barrier strength. To simplify the formulas, we have introduced a dimensionless barrier strength $Z = k_F H / 2\epsilon_F = H/\hbar v_F$. The significance of this Z is illuminated by noting that the transmission coefficient in the normal state is simply $(1 + Z^2)^{-1}$, and the corresponding reflection coefficient is $Z^2/(1 + Z^2)$.

The expressions for the energy dependences of A, B, C, and D for $E > \Delta$ can be conveniently written in terms of u_0 and v_0, the BCS parameters u and v evaluated on the branch outside the Fermi surface. The results are as given in Table II. For convenience, in addition to the general results we also list the limiting forms of the results for zero barrier ($Z = 0$) and for a strong barrier [$Z^2 (u^2 - v^2) \gg 1$], as well as for $\Delta = 0$ (the normal-metal case). Curves computed using the general results are plotted in Fig. 5 for $Z = 0, 0.3, 1$, and 3. In the special case of $E = \Delta$, one notes from Table II that $A = 1$ and $B = C = D = 0$, independent of Z.

TABLE II. Transmission and reflection coefficients. A gives the probability of Andreev reflection (i.e., reflection with branch crossing), B of ordinary reflection, C of transmission without branch crossing, and D of transmission with branch crossing (see text). $\left(\gamma^2 = \left[u_0^2 + Z^2 (u_0^2 - v_0^2)\right]^2, u_0^2 = 1 - v_0^2 = \frac{1}{2}\left\{1 + \left[(E^2 - \Delta^2)/E^2\right]^{1/2}\right\},$ and $N_s(E) = (u_0^2 - v_0^2)^{-1}$.)

	A	B	C	D
Normal state	0	$\frac{Z^2}{1+Z^2}$	$\frac{1}{1+Z^2}$	0
General form				
$E<\Delta$	$\frac{\Delta^2}{E^2+(\Delta^2-E^2)(1+2Z^2)^2}$	$1-A$	0	0
$E>\Delta$	$\frac{u_0^2 v_0^2}{\gamma^2}$	$\frac{(u_0^2-v_0^2)^2 Z^2(1+Z^2)}{\gamma^2}$	$\frac{u_0^2(u_0^2-v_0^2)(1+Z^2)}{\gamma^2}$	$\frac{v_0^2(u_0^2-v_0^2)Z^2}{\gamma^2}$
No barrier ($Z=0$)				
$E<\Delta$	1	0	0	0
$E>\Delta$	v_0^2/u_0^2	0	$1-A$	0
Strong barrier [$Z^2(u^2-v^2)>>1$]				
$E<\Delta$	$\frac{\Delta^2}{4Z^2(\Delta^2-E^2)}$	$1-A$	0	0
$E>\Delta$	$\frac{u_0^2 v_0^2}{Z^4(u_0^2-v_0^2)^2}$	$1-\frac{1}{Z^2(u_0^2-v_0^2)}$	$\frac{u_0^2}{Z^2(u_0^2-v_0^2)}$	$\frac{v_0^2}{Z^2(u_0^2-v_0^2)}$

Accordingly, except for $Z = 0$, $A(E)$ has a sharp peak at the gap edge, although this peak becomes unobservably narrow for large values of Z.

Although we have developed this technique quite independently, other workers have also employed the Bogoliubov equations, and along similar lines. Andreev [8] in 1964 used them to calculate the thermal-boundary resistance at an $N - S$ interface. Thus, he was essentially concerned with the restriction of quasiparticle flow from N to S caused by the gap. Kümmel [9] expanded the equations to include the condensate phase, and then used them to calculate the momentum balance of electricalcurrent flow near a vortex core. He emphasized the interchange of current between quasiparticles and the pairs in geometries where the gap varied with position. Then, in 1971 Demers and Griffin [10] and Griffin and Demers, [11] calculated the transmission coefficients in $N - S - N$ and $S - N - S$ geometries and made the extension to a δ-function barrier at the interface. Surprisingly, this important work remained essentially unnoticed for a number of years but recently (1977) Entin-Wohlman [12] has drawn on it to develop boundary conditions that she used in solving the Gor'kov gap equation at an N-S interface. Thus, use of the Bogoliubov equations to determine the fraction and type of reflected particles is not new, though perhaps the technique remains underutilized. What is new is our extension of the method to calculations at finite bias voltage (as described in the next section) and our development of a framework that allows the physical consequences of these processes to emerge more clearly.

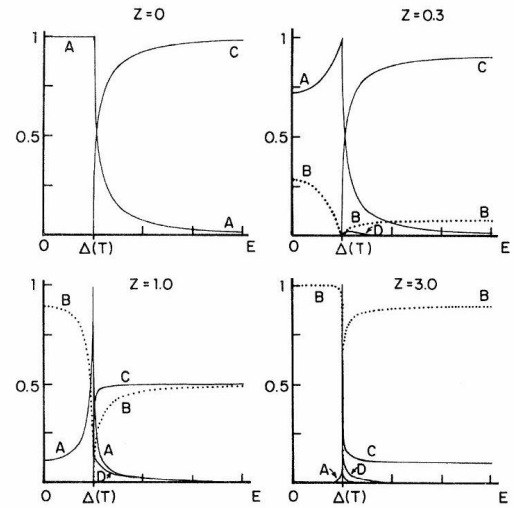

FIG. 5. Plots of transmission and reflection coefficients at N-S interface. A gives probability of Andreev reflection, B gives probability of ordinary reflection, C gives transmission probability without branch crossing, and D gives probability of transmission with branch crossing. The parameter Z measures the barrier strength at the interface.

iv. The n-s boundary at finite voltage: $I - v$ curves

When a voltage is applied, nonequilibrium quasiparticle populations will be generated, which can in general be found only by obtaining a self-consistent solution to a suitable Boltzmann equation. This solution is greatly simplified if one can assume ballistic acceleration of the particles without scattering. This is a good approximation for our case of a small orifice connecting massive electrodes, so long as the diameter of the orifice is small compared to a mean-free path. Moreover, in this regime, Bogoliubov-equation solutions neglecting scattering potentials except at the interface should also be usable. [13] The physical assumption which we use to define the problem is then that the distribution functions of all incoming particles are given by equilibrium Fermi functions, apart from the energy shift due to the accelerating potential. It is convenient to choose the electrochemical potential of the pairs in the superconductor as our reference level, since that remains a welldefined quantity even when the quasiparticle populations are far from equilibrium. Moreover, it is the quantity which defines the location of the "mirror plane" of the semiconductor diagram. With this convention, all incoming electrons from the S side have the distribution function $f_0(E)$, while those coming in from the N side are described by $f_0(E - eV)$.
Since the current must be conserved, it can be calculated in any plane. It is particularly convenient to do so on the N side of the interface, where all current is carried by single particles, and none as a supercurrent. To find the current in our 1D model, we take the difference between $f_{\rightarrow}(E)$ and $f_{\leftarrow}(E)$, the distribution functions at points such as 0 and 5 on Fig. 4, and integrate over E. That is,

$$\begin{aligned} I &= \mathscr{A} J \\ &= 2N(0)ev_F\mathscr{A} \int_{-\infty}^{\infty} [f_{\rightarrow}(E) - f_{\leftarrow}(E)]\, dE \end{aligned} \tag{14}$$

where $\mathscr{A}$ is an effective-neck cross-sectional area, including a numerical factor for angular averaging which will depend on the actual 3D geometry. For example, in the orifice model of a

point contact, $\mathscr{A} = \pi a^2/4$, where a is the radius of the orifice. [14] As usual, $N(0)$ refers to the one-spin density of states at ϵ_F.

With our assumption about incoming populations, it follows that

$$f_{\rightarrow}(E) = f_0(E - eV) \tag{15}$$

while

$$f_{\leftarrow}(E) = A(E)\left[1 - f_{\rightarrow}(-E)\right] + B(E)f_{\rightarrow}(E) + [C(E) + D(E)]f_0(E) \tag{16}$$

In writing Eq. (16), we have chosen to write $f_{\rightarrow}(E)$ instead of $f_0(E - eV)$ in anticipation of later dealing with more complicated problems where $f_{\rightarrow}(E)$ and $f_{\leftarrow}(E)$ must be found self-consistently. Even in such cases, Eq. (16) remains valid as it stands, and serves as a boundary condition for a Boltzmann equation, whose solution would be inserted into the general expression (14) to find the current. However, in the present simple case, we can simply substitute Eqs. (15) and (16) into Eq. (14), obtaining

$$\begin{aligned} I_{NS} &= 2N(0)ev_F\mathscr{A}\int_{-\infty}^{\infty}(f_0(E - eV) - \{\, A(E)f_0(E + eV) + B(E)f_0(E - eV) \\ &\quad + [1 - A(E) - B(E)]f_0(E)\})\, dE \\ &= 2N(0)ev_F\mathscr{A}\int_{-\infty}^{\infty}\left[f_0(E - ev) - f_0(E)\right]\left[1 + A(E) - B(E)\right]dE \end{aligned} \tag{17}$$

In obtaining the final form, we have used the properties that $A + B + C + D = 1, A(E) = A(-E)$, and $f_0(-E) = 1 - f_0(E)$. The quantity $[1 + A(E) - B(E)]$ in Eq. (17) can be referred to as the "transmission coefficient for electrical current." Its form shows that while ordinary reflection [described by $B(E)$] reduces the current, Andreev reflection [described by $A(E)$] increases it by giving up to two transferred electrons (a Cooper pair) for one incident one.

If both sides of the interface are normal metal, $A = 0$ since there is no Andreev reflection, and $1 - B = C = (1 + Z^2)^{-1}$ as noted above, so that Eq. (17) reduces to the simple form

$$I_{NN} = \frac{2N(0)e^2v_F\mathscr{A}}{1 + Z^2}V \equiv \frac{V}{R_N} \tag{18}$$

Note that even in the absence of a barrier ($Z = 0$), there is still a nonzero normal-state resistance. This is the spreading resistance typical of a two-dimensional (2D) or 3D geometry, often referred to as the Sharvin resistance [14] in the present case of a point-contact geometry with infinite mean free path relative to orifice size.

For the more interesting N - S case, we have integrated (17) numerically to obtain $I - V$ curves for a number of barrier strengths at $T = 0$. The results are shown in Fig. 6. The effect of changing the barrier strength is even more dramatic in the differential conductance dI/dV, plotted versus V in Fig. 7, again at $T = 0$. From Figs. 6 and 7, it is clear that barrier strengths $Z \gtrsim 10$ give results essentially indistinguishable from those for classical tunnel junctions, although, as our model demonstrates, there is a continuous variation from the metallic to the tunneling limit. To facilitate the interpretation of experimental dI/dV curves, it is useful to note at $T = 0$, Eq. (17) implies that dI/dV is proportional to the transmission coefficient for electrical current, $1 + A(eV) - B(eV)$, while at $T \neq 0, dI/dV$ is proportional to a thermally smeared version of the same quantity.

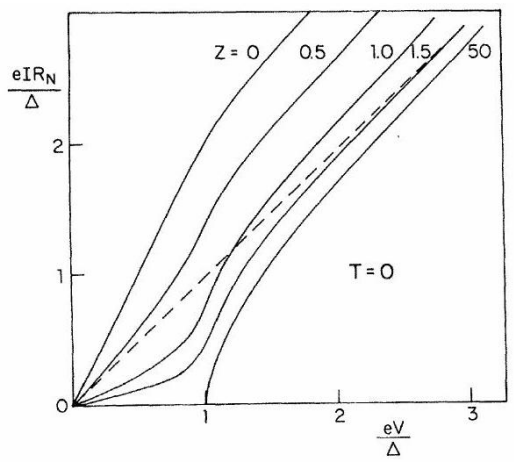

FIG. 6. Current vs voltage for various barrier strengths Z at $T = 0$. These curves attain their asympototic limits only for very high voltages. For example, the tunnel junction ($Z = 50$) curve will be within 1% of the normal-state curve (dotted line) only when $eV \geq 7\Delta$.

[MOVE TO THE SECTION BEFORE]

v. Relation to transfer Hamiltonian approach

With the arbitrary barrier case well in hand, we are in a position to contrast our technique with the more conventional transfer Hamiltonian approach. If one assumes a thick oxide between two banks, to lowest order one can consider the two sides as noninteracting systems, containing electrons in standing-wave states labeled by quantum numbers k_L or k_R. Of course, they are not truly unconnected and there is a small probability that an electron from one side can tunnel to the other side; thus the wave function must actually penetrate through the barrier. Since this penetration will change the energy of the system, many workers have tried to model the resulting change by adding a "transfer" term to the Hamiltonian, although this phenomenological model has never been fully justified. [15] The tunneling transfer matrix element T is tricky to evaluate, since it is a function of the amplitude of the small tail on the penetrating wave and requires some microscopic knowledge of the system. Nonetheless, many workers have calculated T, and the result, for eV much smaller than the barrier height, is an essentially featureless matrix element much like that for an $N - N$ contact.

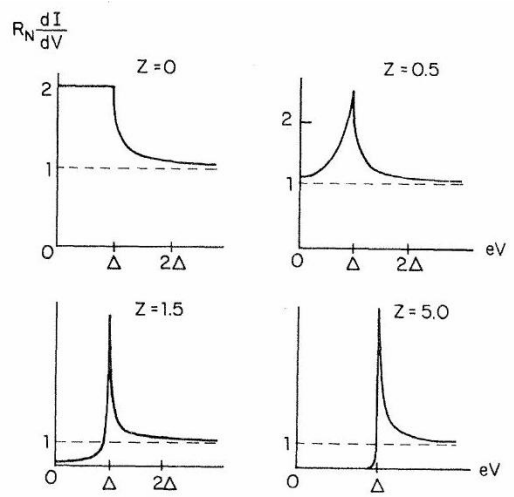

FIG. 7. Differential conductance vs voltage for various barrier strengths Z at $T = 0$. This quantity is proportional to the transmission coefficient for electric current for particles at $E = eV$.

By treating the tunneling as a perturbation, one can calculate the current by using the Golden Rule, and find the electron-transfer rate proportional to a squared matrix element times the number density of unoccupied final states. This is in the origin of the BCS density-of-states factor times the thermal weighting factor $[1-f(E-eV)]$ which appears in the tunneling current, for particles from L to R. When we integrate over all states on the left, an additional $N_L(E)f(E)$ appears, for a total probability (per unit energy) of

$|T|^2 N_L(E)N_R(E-eV)f(E)[1-f(E-eV)]$.

The latter two factors reflect the view that this is a stochastic process involving two independent banks, so that the joint probability for tunneling is proportional to the probability of the initial states being occupied times the probability of final states being unoccupied (i.e., unblocked). When we combine currents in both directions, the cross terms involving products of Fermi functions cancel, and we are left with the usual tunneling result in which the current is proportional to an integral over

$$N_L(E)N_R(E-eV)[f(E-eV)-f(E)]$$

The Bogoliubov equation approach is quite different in spirit. As we saw above, the current transmission coefficient (in contrast to the matrix element squared in the tunnel calculation) varies rapidly for $|E| \approx \Delta$. This is the origin of the density-of-states factor in the final result. In no sense are the two banks decoupled; we associate a given set of wave vectors on the left $(q^+, -q^+, q^-)$ with a specific set on the right (k^+, k^-), regardless of the barrier height. $q^+$is not an "initial" state from which transfer can be blocked by an occupied "final" state k^+. Rather, a wave packet describing an incident particle in q^+evolves continuously into transmitted and reflected wave packets in the completely deterministic way described by Liouville's theorem without scattering. Thus, we associate one distribution function with this entire set of wave vectors. Combining currents originating from both sides gives a difference in Fermi functions just as the transfer Hamiltonian did (after cancellation of cross terms), but the rationale is entirely different in detail. Since we can achieve the same result with a model that has a larger range of validity and usefulness, we have chosen this latter point of view.

vi. Excess current

Although the high-voltage ($eV \gg \Delta$) portion of each $I-V$ characteristic in Fig. 6 is linear with slope R_N, it does not in general fall on the normal-state curve $V = IR_N$ (as it does in a tunnel junction). Rather, it is displaced by a constant amount referred to as the excess current, $I_{\rm exc}$, which can be found by extrapolation back to the $V = 0$ axis. By manipulation of Eqs. (16) and (17), this $I_{\rm exc}$ can be written as

$$I_{\rm exc} \equiv (I_{NS} - I_{NN})|_{eV\gg\Delta} = \frac{1}{eR_N[1-B(\infty)]}\int_0^\infty [A(E) - B(E) + B(\infty)]dE \qquad (19)$$

where from Table II, $B(\infty) = Z^2/(1+Z^2)$ is the reflection coefficient at high energy or in the normal state. Using this expression and those in Table II, we have computed numerically the dependence of $I_{\rm exc}R_N$ (the "insufficient voltage" referred to by Likharev [2]) upon barrier strength Z. Since this high-voltage limit depends on T only through the magnitude of Δ, the normalized quantity $I_{\rm exc}\, R_N/\Delta$ is a function only of barrier strength. This dependence is plotted in Fig. 8. Note the rapid falloff with increasing Z; clearly, excess current will be seen only in relatively barrier-free contacts.

More generally, one can define a voltage-dependent excess current,

$$I_{\rm exc}(V) = I_{NS}(V) - I_{NN}(V) \tag{20}$$

which simply gives the extra current due to the superconductivity. Since $I_{NN}(V)$ is simply V/R_N, finding $I_{\rm exc}\,(V)$ is equivalent to giving the entire I V curve, as was done in Fig. 6. However, it is worth noting that for $Z = 0$ and $\Delta << kT$, the calculation can be carried out analytically, with the result,

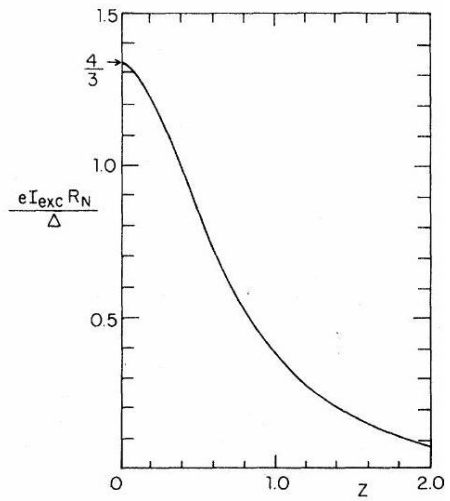

FIG. 8. Excess current (in units of Δ/eR_N) as a function of barrier strength Z. The temperature dependence of the curve is entirely contained within $\Delta(T)$.

$$I_{\rm exc}(V) = (4\Delta/3eR_N)\tanh(eV/2kT), \quad \Delta << kT \tag{21}$$

As noted in our previous work, this result agrees in detail with that obtained by Zaitsev [4] for a clean metallic NS contact, after correcting a factor of 2 in his result.

We can also calculate the excess current for an $S - S'$ contact, by using the $N - S$ result above. As we explained in a previous publication, [5] in the highvoltage limit, the $S - S'$ device can be thought of as a series combination of an $S - N$ and a $N - S'$ microconstriction. The "insufficient voltages" of the two simply add, so that the excess current is the sum of the contributions from the two sides. For example, in the clean contact with $Z = 0$, we find

$$I_{\rm exc} = 4\,(\Delta + \Delta')\,/3eR_N$$

While the excess current has a clear mathematical definition, it may be a difficult quantity to measure reliably, for at least two reasons. First, for voltages greater than the gap, heating will generally distort the $I - V$ curve away from its ideal isothermal shape. [16] There may, in fact, be no linear region at high voltages until heating has driven the contact fully normal. Secondly, even in the absence of heating, care must be taken to carry the measurement to sufficiently high voltages to obtain a true asymptote. For example, the tunnel junction curve in Fig. 6 (i.e., $Z = 50$) appears to have a significant negative (rather than zero) excess current, even at a voltage as high as $eV = 3\Delta$. Of course, if one assumes our computed I - V curves are correct and applicable to the contact at hand, one can determine a value of Z by fitting the measured curves at lower voltages.

vii. Analysis of currents and charge-imbalance generation

In this section we establish a formalism for separating the total current I_{NS} into parts differentiated according to the mechanism of charge transfer. In particular, we distinguish the

part of the current I^*_{NS} associated with the creation of quasiparticle charge imbalance Q^* in the superconductor from the part that is converted directly into supercurrent. We also define linear-response coefficients giving the normalized differential conductance Y and its counterpart Y^*, describing quasiparticle charge injection, and evaluate them as functions of Z and T.

For tunnel junctions, the rate of generation of quasiparticle charge branch imbalance has been discussed in some detail by Tinkham and Clarke [17] (TC), by Tinkham, [18] by Pethick and Smith [19] (PS), and by Clarke, et al. [20] (CESST). The latter authors reviewed carefully the interrelations of the definitions and conventions of the various treatments including the rather different conceptual approach of Schmid and Schön. [21] Using our present method, we can generalize the tunnel results to arbitrary barrier strength, providing a description which covers all cases from the tunnel limit to the ideal metallic contact, and which gives very detailed insight into the process.

To minimize repetition, we refer the reader to CESST for an index of the earlier work, and only summarize the essential points. Noting that quasiparticles at k have a charge

$$q_k = u_k^2 - v_k^2 = \epsilon_k / E_k = \pm N_s \left(E_k\right)^{-1} \tag{22}$$

the total quasiparticle charge (per unit volume, in units of e) is

$$Q^* = \sum_k q_k f_k \tag{23}$$

where f_k is the actual occupation number in a nonequilibrium system. To retain electrical neutrality, there must be an equal and opposite change in the condensate charge, produced by a shift in μ_s. [The quantity Q defined earlier by TC differs from Q^* by replacement of q_k in Eq. (23) by $\operatorname{sgn} q_k = \pm 1$, and represents the numerical population imbalance between the branches. Since Q^* appears to have more general physical significance, we confine our attention to it in this paper.]

To illuminate this problem, it is helpful to rewrite the expression (17) for the current in a form emphasizing the transmitted (rather than reflected) particles by using the sum rule (13) to replace $1 + A - B$ by $2A + C + D$. Thus, we write the total current as

$$I_{NS} = 2N(0)ev_F \mathscr{A} \int_{-\infty}^{\infty} [f_0(E - eV) - f_0(E)] \times [2A(E) + C(E) + D(E)]dE \tag{24}$$

This can be decomposed into two parts by recognizing that the term $2A(E)$ represents the current

$$I^A_{NS} = 2N(0)ev_F \mathscr{A} \int_{-\infty}^{\infty} [f_0(E - eV) - f_0(E)] \times [2A(E)]dE \tag{25}$$

due to Andreev reflection, in which the current in the superconductor is carried entirely by pairs. The remainder of I_{NS} is the current

$$I^{\mathrm{qp}}_{NS} = 2N(0)ev_F \mathscr{A} \int_{-\infty}^{\infty} [f_0(E - eV) - f_0(E)] \times [C(E) + D(E)]dE \tag{26}$$

due to quasiparticle transfer. But even $I_{NS}^{\rm qp}$ does not represent the rate of generation of quasiparticle charge at the interface, which we will call I_{NS}^{*}. To compute that, we must distinguish quasiparticles in the two channels, $k^{+}$and k^{-}, and also take account of their fractional charge $q_k = \pm N_s(E)^{-1}$. Thus,

$$I_{NS}^{*} = 2N(0)ev_F\mathscr{A}\int_{-\infty}^{\infty}[f_0(E-eV)-f_0(E)]\times[C(E)-D(E)]N_s^{-1}(E)dE \tag{27}$$

Finally, since experiments usually involve current bias rather than voltage bias, it has been useful to determine the ratio

$$F^{*} \equiv I^{*}/I \tag{28}$$

giving the charge imbalance generated as a fraction of the injected current. These quantities have been evaluated in the past for tunnel junctions, but now we can evaluate them for arbitrary barrier strength, as a function of V and T.

To make contact with the earlier work on tunnel injection, we note that for strong barriers the results in Table II show that $A \propto Z^{-4} << 1$, so I_{NS}^{A} is negligible and $I_{NS} \approx I_{NS}^{\rm qp}$ reproduces the form of the usual expression for tunnel current, namely,

$$I_{NS}^{\rm qp} = \frac{1}{eR_N}\int_{-\infty}^{\infty}[f_0(E-eV)-f_0(E)]N_s(E)dE, \quad Z^2 \gg 1 \tag{29}$$

The density-of-states factor $N_s(E)$ is not inserted arbitrarily at this point; rather, it arises from the limiting form of $C+D$ given in Table II, namely $Z^{-2}\left(u^2-v^2\right)^{-1}$. As is well known, Eq. (29) shows no excess current; the Andreev term is essential for that, but it is important only for weak barriers.

Again taking the strong barrier limit to evaluate I_{NS}^{*}, we note from Table II that $(C-D) = Z^{-2}$, so that Eq. (27) becomes

$$I_{NS}^{*} = \frac{1}{eR_N}\int_{-\infty}^{\infty}[f_0(E-eV)-f_0(E)]N_s^{-1}(E)dE, \quad Z^2 \gg 1 \tag{30}$$

again exactly equivalent to the standard tunneling result for $\dot{Q}_{\rm inj}^{*}$.

For comparison, we now consider the same quantities in the other limiting case of no barrier, $Z = 0$. Then, as noted in Table II, $B = D = 0$ and $C = 1 - A$. In this case, the total current is

$$I_{NS} = \frac{1}{eR_N}\int_{-\infty}^{\infty}[f_0(E-eV)-f_0(E)][1+A(E)]dE, \quad Z = 0$$

The Andreev portion of the current I_{NS}^{A} is still given by Eq. (25), but $I_{NS}^{\rm qp}$ can be rewritten in terms of $A(E)$ as

$$I_{NS}^{\rm qp} = \frac{1}{eR_N}\int_{-\infty}^{\infty}[f_0(E-eV)-f_0(E)][1-A(E)]dE, \quad Z = 0$$

while

$$I^*_{NS} = \frac{1}{eR_N}\int_{-\infty}^{\infty}[f_0(E-eV)-f_0(E)][1-A(E)]N_s^{-1}(E)dE, \quad Z=0 \tag{33}$$

Note that in Eqs. (32) and (33) there is no contribution to the integrals for $|E|<\Delta$, where $1-A=0$; but in Eq. (31), $1+A=2A=2$ in the gap, where there is a large current derived entirely from the Andreev-reflection process. By contrast, in the strong-barrier limit, there is no current at all in the gap, all current being carried by quasiparticles above the gap. Since Q^* is generated only by quasiparticles, the ratio $F^*=I^*/I$ will in general be smaller for metallic contacts than for tunnel junctions.

In the important special case of very low voltages across the contact ($eV << kT$), we can replace the difference of Fermi functions in the expressions (24) - (27) and (29) - (33) by $eV\,(-\partial f_0/\partial E)$ and define generalized linear-response functions analogous to the Y and Z of CESST. These two functions are the ratios of I_{NS} and I^*_{NS}, respective- ly, to the current I_{NN} at the same small voltage. We now generalize these quatities to include a dependence on barrier strength as well. In doing so, we also change the notation from Y and Z to Y and Y^* to gain in suggestiveness and to avoid confusion with the use of Z for normalized barrier strength in this paper. Specifically, we define

$$Y(Z,T) = \left.\frac{I_{NS}(Z,T)}{I_{NN}(Z)}\right|_{eV\to 0} = \left(1+Z^2\right)\int_{-\infty}^{\infty}\left(-\frac{\partial f_0}{\partial E}\right)[2A(E)+C(E)+D(E)]dE \tag{34}$$

and

$$Y^*(Z,T) = \left.\frac{I^*_{NS}(Z,T)}{I_{NN}(Z)}\right|_{eV\to 0} = \left(1+Z^2\right)\int_{-\infty}^{\infty}\left(-\frac{\partial f_0}{\partial E}\right)[C(E)-D(E)]N_s^{-1}(E)dE \tag{35}$$

In the strong barrier limit, $A\sim Z^{-4}\sim 0$, and using the limiting forms of C and D from Table II as above, we obtain

$$Y(Z\gg 1,T) = \int_{-\infty}^{\infty}\left(-\frac{\partial f_0}{\partial E}\right)N_s(E)dE \tag{36}$$

and

$$Y^*(Z\gg 1,T) = \int_{-\infty}^{\infty}\left[-\frac{\partial f_0}{\partial E}\right)N_s^{-1}(E)dE \tag{37}$$

which are exactly the standard tunneling results given by CESST and others. In the zero barrier limit, $Z=0, B=D=0, C=1-A$, and we have

$$Y(Z=0,T) = \int_{-\infty}^{\infty}\left(-\frac{\partial f_0}{\partial E}\right)[1+A(E)]dE \tag{38}$$

$$Y^*(Z=0,T) = \int_{-\infty}^{\infty}\left(-\frac{\partial f_0}{\partial E}\right)[1-A(E)]N_s^{-1}(E)dE \tag{39}$$

These coefficients Y and Y^*, and their ratio $F^* = Y^*/Y$, are plotted versus T for various values of Z in Figs. 9-11. Note that $Y^*(Z,T)$ is almost independent of the barrier strength Z.

viii. Applications and discussion

A direct application of our results is to fit the temperature dependence of the differential conductance of a point contact at zero voltage, which should be simply $Y(Z,T)/R_N$. This quantity is easily measured, and, unlike the excess current, it is not subject to problems with heating effects.

Although the parameter Z plays a fundamental role in our theory, it cannot be independently determined, and must be inferred from the I - V curve. However, since both $I_{\rm exc}$ and $Y(Z,T)$ depend on Z, we can test the model by comparing these two experimentally accessible quantities against each other. Figure 12 shows $Y(Z,T=0)$ vs $eR_N I_{\rm exc}/\Delta$. They exhibit an approximately linear relationship to each other, as might be expected physically, since both depend linearly on the Andreev-reflection probability.

In addition to our theoretical curve, two other points are displayed in Fig. 12. The point marked Zaitsev-clean is the result found by Zaitsev [4] for a microconstriction with no scattering in the bulk or in the neck, and it agrees exactly with our calculation for $Z = 0$. The point labeled AVZ-dirty is the the result of a calculation by Artemenko, Volkov, and Zaitsev [3] for a microconstriction in the dirty limit ($\tau kT << \hbar$) where the neck is short compared to the nonequilibrium length $\xi(T)(1-t)^{1/4}$. Although our model is not intended to describe diffusive transport in the presence of distributed bulk scattering, a suitable value ($Z \sim 0.55$) of the strength of our 1D δ-function barrier potential gives results very close to those obtained by their

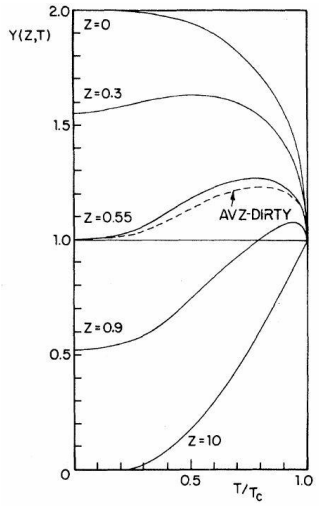

FIG. 9. Y, the zero-voltage differential conductance in units of the normal-state conductance, vs T, for various barrier strengths Z. The curve AVZ-dirty is described in the text.

Green's-function method.

(??? i think, there is no GF method here, just some discussion. Right???)

Our charge-imbalance results may also provide a useful perspective on the work of Hsiang and Clarke [22] on resistance due to charge-imbalance relaxation near an $N-S$ interface. By a physical argument, they reasoned that the appropriate F^* for a clean metallic interface could be approximated by what we call here $Y^*(Z \gg 1)$ as computed for a tunnel junction. Our calculation would instead give $F^* = Y^*(Z=0)/Y(Z=0)$. As just noted above, Y^* is almost independent of barrier strength Z, so $Y^*(Z \gg 1) \approx Y^*(Z=0)$. But the denomina-

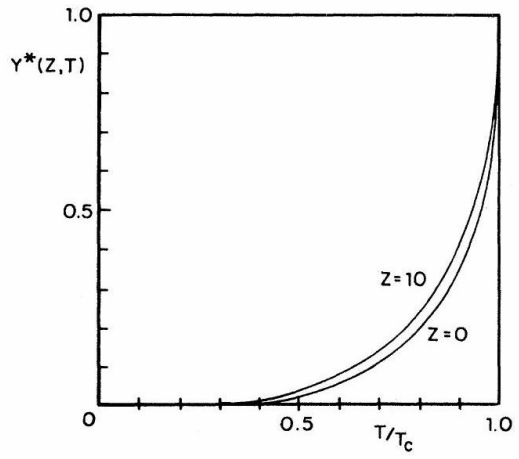

FIG. 10. Y^*, the normalized differential charge imbalance conductance at zero voltage, vs T, for various barrier strengths Z.

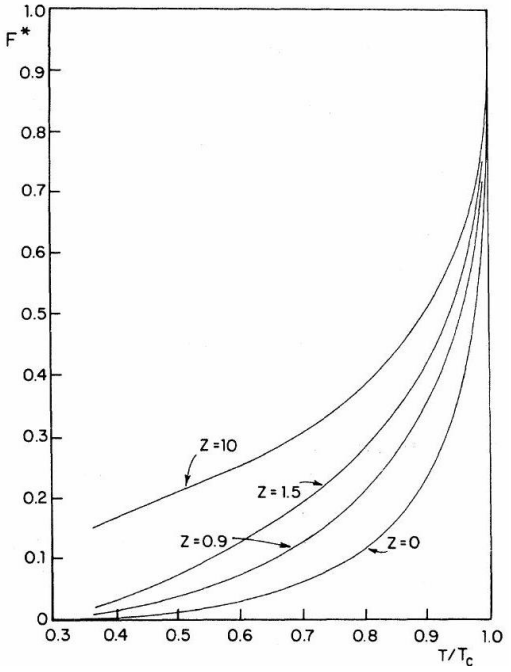

FIG. 11. F^*, the ratio of quasiparticle charge injected to total injected current, as a function of T for various barrier strengths Z.

tor factor $Y(Z = 0)$ varies from 1 at T_c to 2 at $T = 0$, so the resulting T dependence of our F^* is somewhat different from that used by Hsiang and Clarke, although it has the same qualitative shape. Because the interfaces studied by Hsiang and Clarke were not point contacts of the sort we have been treating, however, it is not clear that our results should be expected to describe their data in detail.

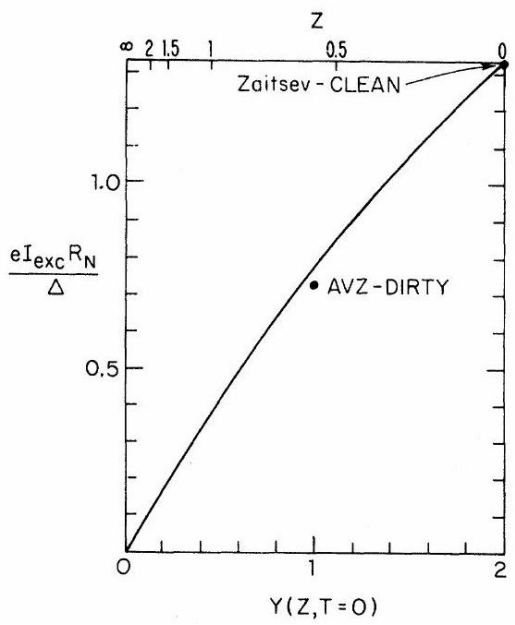

FIG. 12. $eI_{\rm exc}\, R_N/\Delta$ vs $Y(T=0)$ as the barrier strength parameter Z ranges from ∞ to 0. The points AVZ-dirty and Zaitsev-clean are discussed in Sec. VIII.

As noted above, the total current I_{NS} can be expressed as the sum of three terms: I^A_{NS}, the Andreev term with no quasiparticle transfer; I^*_{NS}, the injection rate of quasiparticle charge; and $(I^{\rm qp}_{NS} - I^*_{NS})$, the current carried by the pairs that must flow to compensate for the fractional charges of the quasiparticles. The current I^*_{NS} relaxes to supercurrent over a distance $\Lambda_{Q^*} = (D\tau_{Q^*})^{1/2}$, a diffusion length determined by τ_{Q^*}, the chargeimbalance relaxation time.

The picture described in the previous paragraph corresponds to the viewpoint of TC and PS, in which the current $(I - I^*)$ is viewed as being converted discontinuously to supercurrent at the interface. [23] If one examines the problem more deeply, however, one can obtain a more microscopic view of the conversion process. The key point is that there are solutions of the Bogoliubov equations even for $|E| < \Delta$, but they are evanescent waves which decay in a distance

$$\hbar v_F/2\left(\Delta^2 - E^2\right)^{1/2} \sim \xi(T).$$

(See the Appendix for details.) Thus, even the Andreev current I^A_{NS} is carried for $\sim \xi$ as a quasiparticle current before decaying into a pair current, and the interference of $k^+$and k^-waves causes a similar effect also for the current $I^{\rm qp}_{NS} - I^*_{NS}$ above the gap. This two-step conversion process is shown schematically in Fig. 13. This point of view is reminiscent of that of Schmid and Schön, who treat the entire injected current as a source of

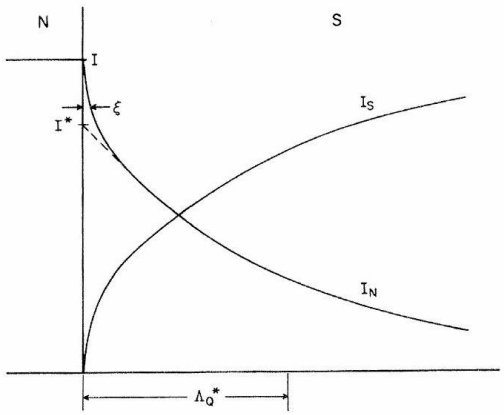

FIG. 13. Schematic diagram of conversion of normal current to supercurrent at $N - S$ interface. The evanescent waves due to Andreev reflection die out over a distance of order ξ,

while the injected quasiparticle charge imbalance relaxes over a charge diffusion length Λ_{Q^*}. charge imbalance, but combine "conversion" terms with τ_{Q^*} relaxation to find a shorter effective relaxation time $\tau_R < \tau_{Q^*}$, which reproduces the same steady-state Q^* as found by the two-step analysis of Tinkham and Clarke [17,18] and of Pethick and Smith. [19] There seems to be a gain in physical insight, however, in distinguishing the two types of processes.

Recognition of the existence of a penetration depth of order ξ for the evanescent quasiparticle waves in the gap also provides a more clear-cut explanation for one aspect of the observations of Octavio et al. [16] on subharmonic gap structure (SGS) in tin variable-thickness bridges (VTB's). They observed voltage-dependent shifts in the positions of the SGS which they attributed to heating. Using the gap shift as a thermometer, with $\Delta_{\rm BCS}(T)$ as the calibration curve, they could infer temperature rises. These temperature increases were roughly proportional to the dissipated power P, but much

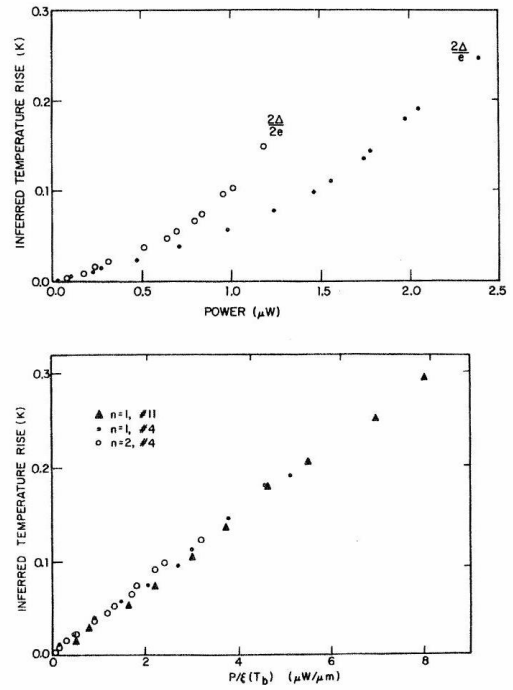

FIG. 14. Temperature rise in tin variable-thickness bridge inferred from depression of energy gap as found from subharmonic gap structure (after Octavio et al.). (a) depicts temperature rise vs power dissipated, P. (b) depicts temperature rise vs $P/\xi(T)$. The superior linear fit in (b) is consistent with observed gap being sensed at a distance $\sim \xi$ from center of bridge.

more precisely proportional to $P/\xi(T)$, as shown by the comparison of Fig. 14(a) and 14(b). Given the 3D cooling of these VTB's, in which the temperature rise is proportional to P/r (where r is the distance from the center of the contact), this observation was interpreted as showing that the energy gap giving the SGS was that in the superconductor at a distance $\sim \xi$ from the center. In a recent paper, [5] we have argued that the SGS arises from multiple Andreev reflections together with the sharp change in $A(E)$ at the gap edge. Given the penetration of the evanescent waves to a depth $\sim \xi(T)$, it is plausible that the gap reflected in the SGS should be that at a similar depth into the bank, as assumed by Octavio et al. on the basis of somewhat different reasoning.

Appendix

The Bogoliubov equations may be written

$$i\hbar\frac{\partial f}{\partial t} = \left[-\frac{\hbar^2\nabla^2}{2m} - \mu(x) + V(x)\right] f(x,t) + \Delta(x)g(x,t) \tag{A1a}$$

$$i\hbar\frac{\partial g}{\partial t} = -\left[\frac{-\hbar^2\nabla^2}{2m} - \mu(x) + V(x)\right] g(x,t) + \Delta(x)f(x,t) \tag{A1 b}$$

where $\Delta(x)$ is the energy gap and $\mu(x)$ is the chemical potential (specifically that of the condensate, in case of nonequilibrium conditions where μ is not uniquely defined). In the normal metal [$\Delta(x) = 0$], Eq. (A1a) is the Schrödinger equation for electrons, while Eq. (A1b) is the time-reversed Schrödinger equation for electrons. Since an electron satisfying the time-reversed Schrödinger equation behaves in many ways like a hole, we will adopt that terminology here.

For $\Delta \neq 0$, the electron and hole wave functions couple together, with two major consequences. First, a gap appears in the E vs k relation, just as it does in elementary BCS theory. To see this result more clearly, we solve Eq. (A1) for a specific geometry. The simplest example is one where $\mu(x), \Delta(x)$, and $V(x)$ are all constant, and the solutions to Eq. (A1) are time-independent plane waves. Taking as our trial solutions $f = \widetilde{u}e^{ikx-iEt/\hbar}$ and $g = \widetilde{v}e^{ikx-iEt/\hbar}$, we find for $V = 0$

$$E\tilde{u} = \left[\frac{\hbar^2k^2}{2m} - \mu\right]\tilde{u} + \Delta\widetilde{v} \tag{A2a}$$

$$E\widetilde{v} = -\left(\frac{\hbar^2k^2}{2m} - \mu\right)\widetilde{v} + \Delta\tilde{u} \tag{A2b}$$

Solving Eqs. (A2a) and (A2b) for E we obtain

$$E^2 = \left(\frac{\hbar^2k^2}{2m} - \mu\right)^2 + \Delta^2 \tag{A3}$$

There are two roots for E. We are concerned with excitations above the ground state ($E \geq 0$), and in this case

$$\widetilde{u}^2 = \frac{1}{2}\left[1 \pm \frac{(E^2 - \Delta^2)^{1/2}}{E}\right] = 1 - \widetilde{v}^2 \tag{A4}$$

$$\hbar k^{\pm} = \sqrt{2m}\left[\mu \pm \left(E^2 - \Delta^2\right)^{1/2}\right]^{1/2} \tag{A5}$$

We also define

$$1 - v_0^2 = u_0^2 = \frac{1}{2}\left(1 + \frac{(E^2 - \Delta^2)^{1/2}}{E}\right)$$

For $|E| < \Delta$, $\tilde{u}$ and $\widetilde{v}$ will be complex conjugates. This definition differs from the usual BCS convention in which u_k and v_k are not defined for $E < \Delta$. Using the notation

$$\psi = \begin{bmatrix} f(x) \\ g(x) \end{bmatrix}$$

the four types of quasiparticle waves for a given energy take the forms

$$\psi_{\pm k^+} = \begin{bmatrix} u_0 \\ v_0 \end{bmatrix} e^{\pm ik^+ x} \tag{A6a}$$

and

$$\psi_{\pm k^-} = \begin{bmatrix} v_0 \\ u_0 \end{bmatrix} e^{\pm ik^- x} \tag{A6b}$$

The ψ 's are the position space representation of the $\gamma^*_{k0} = u_k c^*_{k\uparrow} - v_k c_{-k\downarrow}$ since $c^*_{k\uparrow}$ produces the wave e^{ikx}, while $c_{-k\downarrow}$ destroys an electron at $-k$, leaving the system with a net positive momentum represented by the creation of a hole wave e^{ikx}.

A second consequence, which follows from the $E(k)$ relation (A3), is that the group velocity $v_g = dE/d\hbar k$ goes to zero at the gap edge, even while the phase velocity remains near the normalstate value. This has some interesting consequences, as can best be illustrated by deriving conservation laws for probability and charge.

We define $P(x)$ to be the probability density for finding either an electron or a hole at a particular time and place. Thus, for a solution to Eq. (A1), $P(x,t) = |f|^2 + |g|^2$. Using Eq. (A1) to evaluate $\partial P/\partial t$, we find

$$\frac{\partial P}{\partial t} + \vec{\nabla} \cdot \overrightarrow{\mathrm{J}}_P = 0 \tag{A7}$$

where

$$\overrightarrow{\mathbf{J}}_P = \frac{\hbar}{m} \left[\mathrm{Im}\left(f^* \nabla f\right) - \mathrm{Im}\left(g^* \nabla g\right) \right] \tag{A8}$$

Note that the hole current enters Eq. (A8) with a sign opposite to that of the electron part, just as one expects for a "time-reversed" particle. One can also show that $J_P \propto v_g = \partial E/\partial \hbar k$. Thus, at the gap edge, it is zero.

We can also derive a conservation law for quasiparticle charge. Assigning a unit charge $+e$ to the electron and $-e$ to the hole, the net quasiparticle charge density in one of these excitation waves is $Q = e\left(|f|^2 - |g|^2\right)$. Using Eq. (A1), it is easy to show that

$$\frac{\partial Q}{\partial t} + \vec{\nabla} \cdot \overrightarrow{\mathrm{J}}_Q = \frac{4e\Delta}{\hbar} \mathrm{Im}\left(f^* g\right) \tag{A9}$$

where

$$\overrightarrow{\mathbf{J}}_Q = \frac{e\hbar}{m} \left[\mathrm{Im}\left(f^* \nabla f\right) + \mathrm{Im}\left(g^* \nabla g\right) \right] \tag{A10}$$

The term on the right in Eq. (A9) is a source (or drain) term connecting the quasiparticles with the condensate, and we will see an explicit interchange of currents when treating the $N - S$ case below. However, for now we concentrate on Eq. (A10). Both the electron and hole contribution to the quasiparticle current enter with the same sign, and a moment's thought shows this to be reasonable. An electron ($f \propto e^{ik^+ x}$), moves in the positive direction and carries a positive current. A hole, ($g \propto e^{ik^+ x}$), moves in the negative direction, but also carries a positive current due to the sign of its charge. Thus, while $J_P \propto v_g = 0$ at the gap edge, $J_Q = e v_F$, so one can view the charge current as traveling with the Fermi velocity. Of course, for the normal metal nothing so dramatic occurs, and we always find simply $J_Q = e J_P$.

Starting from the basic Eq. (A1), it is a simple matter to work out the boundary conditions on steady-state plane-wave solutions at an N-S interface. To model the elastic scattering that usually occurs in the orifice, we include a δ-function potential in Eq. (A1), i.e., $V(x) = H\delta(x)$.

The appropriate boundary conditions, for particles traveling from N to S are as follows.

(i) Continuity of ψ at $x = 0$, so $\psi_S(0) = \psi_N(0) \equiv \psi(0)$.

(ii) $(\hbar/2m)\,(\psi'_S - \psi'_N) = H\psi(0)$, the derivative boundary condition appropriate for δ functions.

(iii) Incoming (incident), reflected, and transmitted wave directions are defined by their group velocities. We assume the incoming electron produces only outgoing particles.

Thus,

$$\psi_{\text{inc}} = \begin{bmatrix} 1 \\ 0 \end{bmatrix} e^{iq^+x}, \hbar q^{\pm} = \sqrt{2m}\sqrt{\mu \pm E}$$

$$\psi_{\text{refl}} = a \begin{bmatrix} 0 \\ 1 \end{bmatrix} e^{iq^-x} + b \begin{bmatrix} 1 \\ 0 \end{bmatrix} e^{-iq^+x}$$

$$\psi_{\text{trans}} = c \begin{bmatrix} u_0 \\ v_0 \end{bmatrix} e^{ik^+x} + d \begin{bmatrix} v_0 \\ u_0 \end{bmatrix} e^{-ik^-x}$$

Applying the boundary conditions, and carrying out an algebraic reduction, we find

$$a = \frac{u_0 v_0}{\gamma} \tag{A11a}$$

$$b = -\frac{(u_0^2 - v_0^2)\,(Z^2 + iZ)}{\gamma} \tag{A11b}$$

$$c = \frac{u_0(1 - iZ)}{\gamma} \tag{A11c}$$

$$d = \frac{iv_0 Z}{\gamma} \tag{A11d}$$

where

$$Z = \frac{mH}{\hbar^2 k_F} = H/\hbar v_F$$

and

$$\gamma = u_0^2 + \left(u_0^2 - v_0^2\right) Z^2$$

For simplicity, we have let $k^+ = k^- = q^+ = q^- = k_F$, whenever that substitution did not lead to a qualitative charge. Note that in the absence of a barrier (i.e., $Z = 0$), $b = d = 0$. Physically speaking, this means that all reflection is Andreev reflection and all transmission occurs without branch crossing.

The quantities $A(E), B(E), C(E)$, and $D(E)$ used in the main body of the paper are actually the probability currents, for the particle, measured in units of v_F. For example, $A = J_P^A/v_F = a^*a$, and $D = d^*d\,(u_0^2 - v_0^2)$. Since plane-wave currents are spatially uniform, we need not specify the position at which they are evaluated. However, for $E < \Delta$, $k^+$and k^-in the superconductor have small imaginary parts which lead to an exponential decay on a length scale λ, where

$$\lambda = \frac{\hbar v_F}{2\Delta}\left[1 - \left(\frac{E}{\Delta}\right)^2\right]^{1/2} \tag{A12}$$

Although right at the gap edge the length diverges, the characteristic length is $\hbar v_F/2\Delta = 1.22\xi(T)$. Thus, in order of magnitude terms, one can say that the particles penetrate a depth $\sim \xi(T)$ before the current is converted to a supercurrent carried by the condensate. For clarity,

we have defined $C(E)$ and $D(E)$ as the probability currents at $x > \lambda$, measured in units of v_F. The changeover from full to zero current is described next.

As a simple example of quasiparticle current being converted to condensate current, we consider the case $H = 0$. Then, $b = d = 0, a = u_0/v_0$, and $c = 1/u_0$. For $E < \Delta, a^* a = 1$, which means the incident electron is totally reflected as a hole. Thus, the total charge carried in the normal metal equals $2ev_F$, but in the superconductor J_Q is exponentially small for $x \gg 0$. Explicitly,

$$J_Q^C = (e\hbar/m)\,\mathrm{Im}\left[\left(ce^{ik^+x}\right)^* \nabla \left(ce^{ik^+x}\right)(u_0^* u_0 + v_0^* v_0)\right]$$

Letting $k^+ \approx k_F + i\eta/\hbar v_F$, where $\eta = (\Delta^2 - E^2)^{1/2}$, we have

$$J_Q^C = \frac{|u_0|^2 + |v_0|^2}{|u_0|^2} e v_F e^{-2\eta x/\pi v_F}$$

Below the gap, $|u_0|^2 = |v_0|^2$, so

$$J_Q^C = 2ev_F e^{-2\eta x/\hbar v_F}$$

The "disappearing current" reappears as current carried by the condensate. Rewriting the drain term in Eq. (A9) as

$$-\vec{\nabla} \cdot \overrightarrow{\mathrm{J}}_s \equiv (4e\Delta/\hbar)\,\mathrm{Im}\,(f^* g) \tag{A13}$$

then

$$\begin{aligned} J_s &= \frac{4e\Delta}{\hbar} \int_0^x \mathrm{Im}\left(c^* v_0^* e^{-ik'^*} c u_0 e^{ik+x'}\right) dx' \\ &= \frac{4e\Delta}{\hbar}\,\mathrm{Im}\left[\frac{v_0^* u_0}{u_0^* u_0}\right) \int_0^x e^{-2\eta x'/\hbar v_F} dx' \\ &= 2ev_F\left(1 - e^{-2\eta x/\pi u_F}\right) \end{aligned} \tag{A14}$$

This is the desired result, explicitly showing the supercurrent increasing to an asymptotic value as $x \to \infty$, at the same rate as the quasiparticle current dies away.

What BTK teaches us?

It teaches us how to use formulas for current from BdG.
(??? right?? I'll write later, which exactly formulas are new here?)

10.1.3 Suppression of the Josephson current through a narrow, mesoscopic, semiconductor channel by a single impurity by Bagwell

We study the Josephson current through a ballistic, normal, one-dimensional quantum channel in contact with two superconducting electrodes. A single point impurity having reflection coefficient R is placed in the normal conductor. The impurity couples the Andreev energy levels of forward and reverse moving electrons inside the junction, opening energy gaps in the quasiparticle level spectrum versus superconducting phase difference ϕ. These "Andreev" energy

gaps suppress the Josephson current in much the same way as disorder suppresses the magnetic flux driven currents in a normal mesoscopic ring. Finite temperature "energy averages" the contribution of Andreev levels above the Fermi energy with those below μ, further suppressing the Josephson current. The portion of the Josephson current carried by scattering states outside the superconducting gap is similarly suppressed by disorder and finite temperature.

This is basically a little problem for practice in methods, and it worth our attention, because it is simply formulated and nontrivial.

I Introduction and conclusion

Introduction

The Josephson effect in a clean superconductornormal-superconductor (SNS) junction is very different from the Josephson effect in a tunnel junction. Coherent Andreev reflection, [1] whereby an electron incident on a superconductor from a normal conductor is reflected as a hole, is the mechanism responsible for supercurrent flow in clean SNS junctions. [2] Quasiparticles incident from the normal region of an SNS junction are Andreev reflected off the pair-potential discontinuity at each SN interface, and their wave interference produces a set of resonant levels which carry the Josephson current. Such a description for the Josephson current assumes quasiparticles in the normal region can move without losing phase information, that is, it assumes the SNS junction is a mesoscopic system.

When the normal region of the SNS junction forms a quantum point contact, [3,4] the natural Josephson current scale is $I_c = e\Delta/\hbar$ (Refs. 5 and 6)(2Δ is the energy gap of the superconductor) and the current phase relation is $I(\phi) = I_c \sin(\phi/2)$.[6,7] If a tunnel barrier is then introduced into the normal region of the point contact, electrons often reflect simply as electrons, rather than as a hole. The current through such a dirty SNS point contact then evolves gradually [8–13] with decreasing barrier transmissivity T into the usual Josephson form [14] $I(\phi) = I_c \sin(\phi)$, where $I_c = e\Delta T/2\hbar$. In long and clean SNS junctions, where the extent of the normal region L is longer than the Bardeen-Cooper-Schrieffer (BCS) healing length ξ_0, the natural Josephson current scale is $I_c = ev_F/L$ (Refs. 2 and $15-18$) (v_F is the Fermi velocity) and the current phase relation assumes a triangular shape. These developments, and other calculations where different types of mesoscopic systems are embedded in the normal region of an SNS junction, [18–20] are reviewed in Refs. 21 and 22.

In this paper we apply the Bogoliubov-de Gennes equations [23,24] to describe the Josephson current in both clean SNS junctions and in SNS junctions containing a tunnel barrier. We obtain expressions for the Josephson current versus superconducting phase difference ϕ for both short ($L < \xi_0$) and long ($L > \xi_0$) SNS junctions, and which account for both the bound levels inside the superconducting energy gap and scattering states outside the gap. We show that introducing a tunnel barrier forces quasiparticles in the normal region to form standing waves at $\phi = \pm\pi$, so that the effect of disorder on the Josephson current can be interpreted in a manner very analogous to electrons confined to a normal mesoscopic ring [25,26] or to electrons in a spatially periodic potential. Many magnetic flux sensitive effects predicted for normal mesoscopic rings [27–29] therefore have analogs for the Josephson effect in SNS junctions.

CONCLUSIONS

Bulk supercurrents flow in response to gradients in the phase $\phi(x)$ of the order parameter $\Delta(x) = |\Delta(x)| \exp[i\phi(x)]$, and are maximum when the phase gradient $\nabla\phi(x)$ is large. From this perspective, the Josephson relation for a tunnel junction, $I = I_c \sin(\phi)$, is quite counterintuitive. The Josephson tunneling current $I = I_c \sin(\phi)$ decreases as the driving phase difference increases, and is smallest when the superconducting phase difference is a maximum. The cur-

rent phase relation $I = I_c \sin(\phi)$ is thus analogous to negative differential resistance in a normal conductor, where the normal current decreases as the driving voltage difference increases.

A more intuitive current phase relation exists for clean SNS junctions. For either long or short junctions, the Josephson current always increases as the superconducting phase difference increases, and is maximum when the superconducting phase difference is a maximum. Only when an impurity, tunnel barrier, or geometrical irregularity is present in the junction is the supercurrent zero when the superconducting phase difference is maximum at $\phi = \pm\pi$. The quasiparticle energy gap opening at $\phi = \pm\pi$ in the Andreev level spectrum versus superconducting phase difference when these imperfections are present, and the associated formation of "standing waves" with $dE_n^{\pm}/d\phi = 0$, explain the resulting suppression of the Josephson current. Finite temperature also mixes in a contribution to the Josephson current from the Andreev levels associated with reverse-moving electrons to those of the forward-moving ones, via thermal "energy averaging" instead of directly modifying the energy level spectrum, and therefore has a qualitatively similar effect as disorder on suppressing the Josephson current.

II. SNS junction with an impurity

We model the SNS junction [2] by a step change in the pair potential shown in Fig. 1, namely

$$\Delta(x) = \begin{cases} \Delta e^{i\phi_1}, & x < 0 \\ 0, & 0 < x < L \\ \Delta e^{i\phi_2}, & x > L \end{cases} \tag{1}$$

This model for the pair potential requires that the superconductor widen adiabatically to an infinite width. [6,17] The large superconducting banks can then be viewed as an "order parameter reservoir," where the supercurrent density is effectively zero. In that case, phase gradients of the superconducting order parameter in the contacts, required to support supercurrent flow, are negligible compared to phase gradients near the junction itself. The disorder we describe by a single point impurity placed in the junction

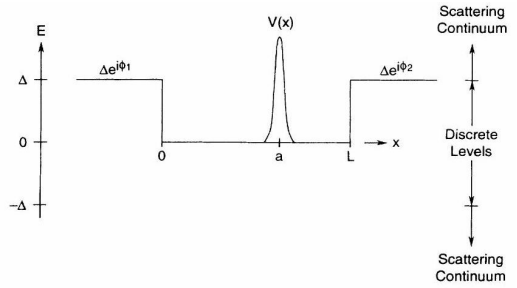

FIG. 1. Scattering potential which describes a mesoscopic Josephson junction. "Andreev" bound states form in the pair potential well. Both the bound levels and scattering states carry parts of the Josephson current.

$$V(x) = V_s \delta(x - a) \tag{2}$$

where $0 \leq a \leq L$.

The potentials $\Delta(x)$ and $V(x)$ enter the Bogoliubov-de Gennes equation of motion for the quasi-particles [23]

$$\begin{pmatrix} H(x) - \mu & \Delta(x) \\ \Delta^*(x) & -[H^*(x) - \mu] \end{pmatrix} \begin{pmatrix} u(x) \\ v(x) \end{pmatrix} = E \begin{pmatrix} u(x) \\ v(x) \end{pmatrix},$$

where the one-electron Hamiltonian $H(x)$ is

$$H(x) = \frac{1}{2m}\left(-i\hbar\frac{d}{dx} - eA(x)\right)^2 + V(x) \tag{4}$$

Equation (3) embodies the quasiparticle dispersion relation for a uniform superconductor,

$$E^2 = \left(\frac{\hbar^2 k^2}{2m} - \mu\right)^2 + \Delta^*\Delta \tag{5}$$

and does not depend on the specific form of the microscopic Hamiltonian giving rise to the pairing potential. We neglect the vector potential A, the electron spin, and the self-consistency condition for $\Delta(x)$. Neglecting the self-consistency condition for $\Delta(x)$ is equivalent to neglecting the proximity effect.

The Andreev levels [the discrete eigenvalues E from Eq. (3) occurring for $|E| < \Delta$] are determined by matching the solutions of Eq. (3) for a spatially uniform pair potential at $x = 0, x = a$, and $x = L$. Details of this procedure are given in Appendix A. For a clean SNS junction this was first done by Kulik, [2] who found the Andreev levels are determined from

$$2\cos^{-1}\left(\frac{E}{\Delta}\right) + \left(\frac{L}{\xi_0}\right)\left(\frac{E}{\Delta}\right) \pm \phi = 2\pi n \tag{6}$$

Here $\xi_0 = \hbar v_F/2\Delta$ is the BCS healing length, $\phi = \phi_2 - \phi_1$ the superconducting phase difference, and $n = 0, \pm 1, \pm 2, \ldots$.

Equation (6) can be interpreted in terms of BohrSommerfeld quantization of the periodic electron-hole orbits in the normal region. [30] The term $2\cos^{-1}(E/\Delta)$ is the phase shift acquired from the evanescent quasiparticle waves penetrating into the superconducting regions. The term $(EL/\Delta\xi_0)$ is the phase shift acquired from free electron and hole propagation in the normal region. Finally the superconducting phase difference ϕ enters Eq. (6) because, in Andreev reflection, the reflected electron and holes acquire an additional phase shift equal to the phase of the superconducting order parameter. Changing ϕ therefore affects the energy levels in a manner similar to changing the size of a confining potential well in ordinary quantum mechanics.

In the presence of a point impurity potential $V(x)$, Eq. (6) is modified to [31]

$$2\cos^{-1}\left(\frac{E}{\Delta}\right) + \left(\frac{L}{\xi_0}\right)\left(\frac{E}{\Delta}\right) \pm \alpha = 2\pi n \tag{7}$$

where the "effective phase" α is determined from

$$\cos(\alpha) = T\cos(\phi) + R\cos\left[\left(\frac{L-2a}{\xi_0}\right)\left(\frac{E}{\Delta}\right)\right] \tag{8}$$

This effective phase α depends on the the normal electron current transmission probability T, given in our point defect model by

$$T = 1 - R = \frac{1}{1 + \left(mV_s/\hbar^2 k_F\right)^2} \tag{9}$$

where $\hbar k_F = \sqrt{2m\mu}$ and μ is the Fermi energy. When $T \to 1$ we recover the Andreev levels for the clean junction, since $\alpha \to \phi$. In the opposite limit of small transmission, where $T \to 0, \alpha$ also becomes small and is nearly independent of the actual phase difference ϕ. If the junction is long compared to the healing length ($L > \xi_0$), and if an impurity is present ($T \neq 1$), α also depends on the particle's energy and the impurity position $|L - 2a|$.

To compute the Josephson current induced by the superconducting phase difference, one must compute both the electrical current $I_n^{\pm}(\phi)$ carried by quasiparticles occupying each Andreev level $E_n^{\pm}(\phi)$ ("discrete" levels with $|E_n^{\pm}| < \Delta$) and the imbalance $I(E, \phi)$ in the electrical

current per unit energy carried by quasiparticles flowing in the "continuum" levels (where $|E| > \Delta$). Once both $I_n^{\pm}(\phi)$ and $I(E,\phi)$ are known, the total current can be written down if one knows the occupation probabilty for these energy levels. Since the Josephson current flows near equilibrium, we assume that the single particle levels are thermally populated according to the Fermi distribution function $f(E)$. We therefore obtain the contribution $I_d(\phi)$ to the Josephson current from the discrete spectrum as

$$I_d(\phi) = \sum_n \left\{ I_n^+(\phi) f\left(E_n^+(\phi)\right) + I_n^-(\phi) f\left(E_n^-(\phi)\right) \right\} \tag{10}$$

and the contribution $I_c(\phi)$ to the Josephson current from the continuous spectrum as

$$I_c(\phi) = \left(\int_{-\infty}^{-\Delta} + \int_{\Delta}^{\infty} \right) I(E,\phi) f(E) dE \tag{11}$$

The total supercurrent $I(\phi)$ is then computed from

$$I(\phi) = I_d(\phi) + I_c(\phi) \tag{12}$$

In this viewpoint only energies below the Fermi energy ($E \leq 0$) contribute to the Josephson current flow at $T = 0$. An additional contribution to the Josephson current results if the pair potential itself changes with superconducting phase difference. 13, 21, 32

For a clean junction ($R = 0$), we obtain the electrical current [24] $I_n^{\pm}(\phi)$ carried by each occupied Andreev level from the normalized quasiparticle wave functions $u(x)$ and $v(x)$ as

$$I_n^{\pm}(\phi) = \mp \frac{e v_F}{L + 2\xi\left(E_n^{\pm}(\phi)\right)} \tag{13}$$

where $\xi(E)$ is the energy dependent healing length [24]

$$\xi(E) = \left(\frac{\hbar v_F}{2\Delta}\right)\left(\frac{\Delta}{\sqrt{\Delta^2 - E^2}}\right) = \xi_0 \left(\frac{\Delta}{\sqrt{\Delta^2 - E^2}}\right) \tag{14}$$

and $E_n^{\pm}(\phi)$ is found from Eq. (6). One could, in principle, perform the same calculation with the impurity present. Unfortunately, the analytical calculation proves intractable. However, if such a calculation could be done, it must yield

$$I_n^{\pm}(\phi) = \mp \frac{e v_F}{L + 2\xi\left(E_n^{\pm}(\phi)\right)} \frac{T \sin(\phi)}{\sin(\alpha)} \frac{1}{\gamma} \tag{15}$$

with $E_n^{\pm}(\phi)$ now found from Eqs. (7) and (8). Here γ is a "feedback" factor

$$\gamma = 1 \pm \left(\frac{\hbar}{2e\Delta}\right)\left(\frac{e v_F}{L + 2\xi\left(E_n^{\pm}(\phi)\right)}\right)\left(\frac{R}{\sin(\alpha)}\right)\left(\frac{L - 2a}{\xi_0}\right) \sin\left(\frac{(L-2a)E_n^{\pm}(\phi)}{\Delta \xi_0}\right) \tag{16}$$

Equations (15) and (16) follow from free energy considerations given below.

The continuous spectrum also contributes to the Josephson current flow in a long SNS junction having $L > \xi_0$. This "continuous spectrum" can be viewed as being composed of "leaky" Andreev levels. [17] When $|E| > \Delta$, it is possible for either the electron or hole composing the Andreev level to escape from the junction by simply transmitting over the pair potential. Although this leakage away from the junction leads to a finite lifetime for the Andreev levels, reducing the total contribution to $I(E,\phi)$ from the continuum Andreev level and spreading it out over a finite-energy range, [18] these broadened Andreev levels nonetheless exist and contribute significantly to the supercurrent flow in long SNS junctions.

We find it most convenient to calculate the continuum current $I_c(\phi)$ using the quasiparticle transmission formalism of van Wees, Lenssen, and Harmans. [18] The method of van Wees, Lenssen, and Harmans is closely analogous to the Landauer-Büttiker transmission formalism [4] for normal currents, and is mathematically equivalent to the transmission formalism of Furusaki, Takayanagi, and Tsukada. [20] Applying this formalism, we find (in Ap- pendix B) the continuum contribution $I_c(\phi)$ for a clean SNS junction to be

$$I_c(\phi) = \frac{2e}{h}\left(\int_{-\infty}^{-\Delta} + \int_{\Delta}^{\infty}\right)\left|u_0^2 - v_0^2\right|\left(\frac{1}{D(E,-\phi)} - \frac{1}{D(E,\phi)}\right)f(E)dE \tag{17}$$

where the function $D(E,\phi)$ is

$$D(E,\phi) = u_0^4 + v_0^4 - 2u_0^2v_0^2\cos\left[\left(\frac{E}{\Delta}\right)\left(\frac{L}{\xi_0}\right) + \phi\right] \tag{18}$$

Here u_0 and v_0 are the standard BCS "coherence" factors

$$2u_0^2 = 1 + \frac{\sqrt{E^2-\Delta^2}}{E} \tag{19}$$

and

$$2v_0^2 = 1 - \frac{\sqrt{E^2-\Delta^2}}{E} \tag{20}$$

The contribution $I_c(\phi)$ to the Josephson current in a clean SNS junction has been calculated previously. [2], 15 – 18, 20 We feel Eq. (17) is probably identical to the analytical results of Ishii, [15] Svidzinski, Antsygina, and Bratus, [16] and Furusaki, Takayanagi, and Tsukada. [20] In the presence of the point impurity, Eq. (17) is modified to

$$I_c(\phi) = \frac{2e}{h}T\left(\int_{-\infty}^{-\Delta} + \int_{\Delta}^{\infty}\right)\left|u_0^2 - v_0^2\right|\left(\frac{1}{D(E,-\alpha)} - \frac{1}{D(E,\alpha)}\right)\frac{\sin(\phi)}{\sin(\alpha)}f(E)dE \tag{21}$$

with the effective phase α defined in Eq. (8). A computation given in Appendix B yields Eq. (21).

Equations (17) and (21) show that the continuous spectrum makes no contribution to the Josephson current if $L \ll \xi_0$, since Eq. (18) gives $D(E,\alpha) = D(E,-\alpha)$ when $L \ll \xi_0$. Further, only energies within a few Δ of the Fermi level make any sizable contribution to $I_c(\phi)$, since the phase sensitive term in Eq. (18) for $D(E,\phi)$ is significant only within a few Δ of the Fermi energy. Thus, the Josephson current at $T = 0$ is not limited to flowing only at the Fermi energy (the case for normal currents at $T = 0$ and small bias voltages), or even limited to flow within an energy range Δ below the Fermi level (false only if $L \ll \xi_0$), but flows over an energy range extending several Δ below the Fermi energy when $L > \xi_0$. Equations (17) and (21) also show that the continuum contribution $I_c(\phi)$ is negligible near $\phi = \pm\pi$, and that $I_c(\phi = \pm\pi) = 0$.

An alternate method to compute Josephson currents requires the change in Helmholtz free energy F with superconducting phase difference [13,21,32,33]

$$I(\phi) = \frac{2e}{\hbar}\frac{dF(\phi)}{d\phi} \tag{22}$$

Equation (22) provides additional insight into the supercurrent formulas presented in this section. Since Eqs. (7)

and (8) hold for the SNS junction with an impurity, our results for the dirty SNS junction follow from those of the clean SNS junction plus the chain rule of differentiation

$$\frac{dF}{d\phi} = \frac{dF}{d\alpha}\frac{d\alpha}{d\phi} \tag{23}$$

where we have from Eq. (8)

$$\left.\frac{\partial\alpha}{\partial\phi}\right|_E = \frac{T\sin(\phi)}{\sin(\alpha)} \tag{24}$$

The factor (24) appears both in our expression (15) for the current $I_n^{\pm}(\phi)$ carried by each Andreev level and in the expression (21) for the continuum supercurrent $I_c(\phi)$. As we argue more precisely in Appendix C, Eq. (23) for the derivative of the free energy, together with Eqs. (7) and (8), implies that Eq. (15) for $I_n^{\pm}(\phi)$ in the dirty junction follows from Eq. (13) for the clean junction. By similar arguments, Eq. (21) for $I_c(\phi)$ in the dirty junction follows from Eq. (17) for the clean junction.

III. Junction shorter than the healing length

In the limit of a "point contact" or "short" junction, for which $L \ll \xi_0$, we immediately find from Eq. (8) that the Andreev level spectrum is determined as

$$E^{\pm} = \pm\Delta\cos(\alpha/2) = \pm\Delta\sqrt{1 - T\sin^2(\phi/2)} \tag{25}$$

where

$$\cos(\alpha) = T\cos(\phi) + R \tag{26}$$

Equation (25) is a special case of the more general expression derived by Beenakker [13] when multiple quantum channels are open.

We graph Eq. (25) in Fig. 2.[34] The dotted lines show

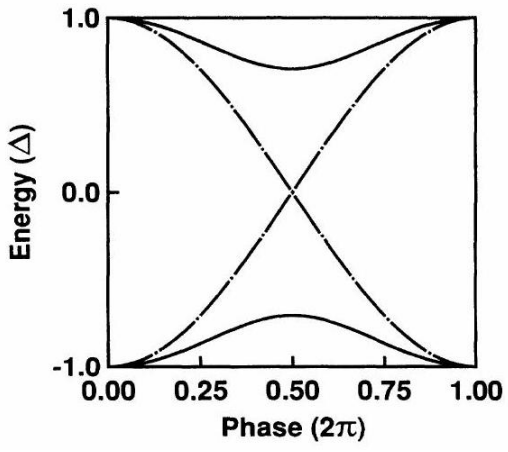

FIG. 2. Andreev levels $E^{\pm}(\phi)$ as a function of superconducting phase difference ϕ for a junction shorter than the healing length ($L \ll \xi_0$). The unperturbed levels in the clean junction (dotted), corresponding to a left-moving (E^+)and right-moving (E^-)electrons, become coupled by the impurity. As a result, the energy degeneracy at $\phi = \pm\pi$ is lifted and an energy gap of size $E_{\rm gap} = 2\Delta\sqrt{R}$ appears in the quasiparticle energy spectrum for the dirty SNS junction (solid). the position of the Andreev levels versus phase difference when no impurities are present. [6,35] The level $E^+(\phi)$ corresponds to an electron traveling in the negative- x direction, while the level $E^-(\phi)$ describes an electron moving along the positive- x direction. These two sets of

Andreev levels are independent when no impurity is present in the junction. However, since the impurity will reflect electrons, it will couple these unperturbed Andreev levels. This effect is most pronounced when the levels are degenerate in energy, i.e., at $\phi = \pm\pi$, so that the impurity opens an energy gap in the Andreev level spectrum versus superconducting phase difference having size

$$E_{\rm gap} = 2\Delta\sqrt{R} \tag{27}$$

Figure 2 is reminiscent of the effects of impurities on the energy level spectrum of a small normal metal ring subject to an Aharonov-Bohm flux, [25,26] and has also been previously suggested for a composite ring made of part normal and part superconducting material when the normal segment is disordered. [36] However, the motion of Andreev reflected electrons in the SNS junction is already periodic, so that a ring geometry (or other type of spatially periodic potential) is not required for $V(x)$ to open gaps in the quasiparticle energy spectrum. It is these "standing waves" forming in the energy level spectrum $E_n^{\pm}(\phi)$, due to the impurity, which suppress the Josephson current.

Using the properties $E^+ = -E^-$and $f\,(E^+) = 1$ - $f\,(E^-)$, we readily obtain from Eqs. (25), (15), and (10)

$$I(\phi) = \frac{e\Delta}{\hbar} T \sin(\alpha/2) \left(\frac{\sin(\phi)}{\sin(\alpha)}\right) \tanh\left(\frac{\Delta}{2kT}\cos(\alpha/2)\right).$$

Writing this in terms of the phase difference ϕ, we find

$$I(\phi) = \frac{e\Delta}{2\hbar} T \left(\frac{\sin(\phi)}{\sqrt{1 - T\sin^2(\phi/2)}}\right) \tanh\left(\frac{\Delta}{2kT}\sqrt{1 - T\sin^2(\phi/2)}\right) \tag{29}$$

again a limiting case of the multichannel formula from Ref. 13. The single-channel formula, Eq. (29), has also been obtained previously. [8–13]

We consider the zero-temperature limit of Eqs. (28) and (29) in Fig. 3, where we can set $\tanh\,(E^+/2kT) = 1$. In the $kT = 0$ case, Eq. (28) becomes

$$I(\phi) = \frac{e\Delta}{\hbar} T \sin(\alpha/2) \left(\frac{\sin(\phi)}{\sin(\alpha)}\right) \tag{30}$$

Equation (30) interpolates nicely between the point contact and tunnel junction, as discussed in Refs. 13 and 21. When the transmission is nearly one, so that the effective phase difference $\alpha \simeq \phi$, we obtain the result [7] for a point contact, $I(\phi) = (\pi G\Delta/e)\sin(\phi/2)$, where $G = 2e^2/h$. In the other limit, where the transmission T is small, the effective phase α is also small and is nearly independent of ϕ. We can then approximate $\sin(\alpha) \simeq \alpha$

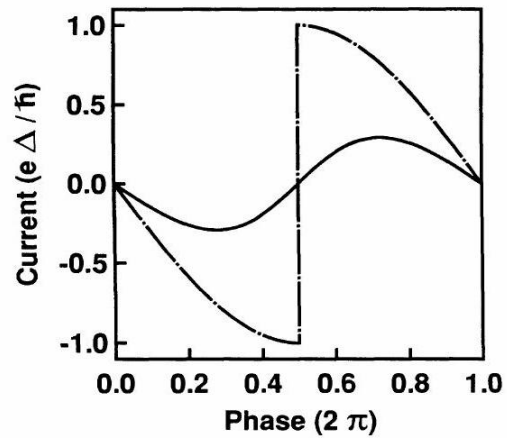

FIG. 3. The "discretized" Josephson current in a clean point contact (dotted) is suppressed by the presence of a tunnel barrier (solid). Regions analogous to "negative differential resistance" in a normal conductor, where the Josephson current decreases as the phase difference increases, are produced by the energy gap in Fig. 2.

so that we obtain the result for a tunnel junction [14] $I(\phi) = (\pi G\Delta/2e)\sin(\phi)$, where the normal conductance is given by a Landauer-type formula $G = 2e^2T/h$.[4]

The effect of finite temperature on the Josephson current is qualitatively similar to that of impurity scattering, since both introduce a mixture of Andreev levels associated with left- and right-moving electrons into the supercurrent. The temperature dependence of Eq. (28) arises from the combination of Fermi factors

$f(E^-) - f(E^+) = 1 - 2f(E^+) = \tanh\left(\frac{E^+}{2kT}\right)$,

so that the temperature dependence of the Josephson current can be viewed as thermally "energy averaging" [37] the contribution of some left-moving electrons above the Fermi energy with right-moving ones below μ. The hightemperature limit of Eq. (28) as $kT \to kT_c$ is [13]

$$I(\phi) = \frac{e\Delta^2}{4\hbar kT_c} T\sin(\phi) \tag{32}$$

which has the same $\sin(\phi)$ dependence as a tunnel junction, again illustrating the similar effects of disorder and finite temperature on the Josephson current. Equation (32) resembles the well-known result of Aslamazov and Larkin [38] for the Josephson current through a point contact calculated from Ginzburg-Landau theory. But since the Ginzburg-Landau theory is valid only near T_c, it will never produce the correct low-temperature form $\sin(\phi/2)$ for the clean point contact.

The sharp discontinuity at $\phi = \pm\pi$ for the clean junction at zero temperature arises from the sharp discontinuity in the Fermi function at $T = 0$.[17] When $\phi = \pi$ the Andreev level E^-(carrying a current $I^- = e\Delta/\hbar$) moves above the Fermi level, while the level E^+(carrying a current $I^+ = -e\Delta/\hbar$) passes below the Fermi level. Thus, the level E^-empties while E^+becomes populated. This change in Andreev level occupation produces a discontinuity in the supercurrent of $2e\Delta/\hbar$. On the other hand, when the transmission T is small, the levels $E^+$and E^- have combined to form a standing wave with $dE^\pm/d\phi = 0$ when $\phi = \pm\pi$, so that the Josephson current falls to zero near $\phi = \pm\pi$.

One would naively predict a critical "depairing current" 23, 39, 40 of order $e\Delta/\hbar$ for a one-dimensional (1D) superconductor. In the presence of a uniform superfluid flow having velocity v_s, the quasiparticle energies are shifted by an amount $\Delta E = p_F \cdot v_s$, where p_F is the Fermi momentum. Thus, the quasiparticle energy gap goes to zero when $\Delta = p_F v_c$, where v_c is the critical "depairing velocity," an argument originally advanced by Landau. [40] All the electrons below the Fermi energy then move at velocity v_c, giving a critical current I_c of

$$I_c = env_c = e\left(\frac{2k_F}{\pi}\right)\left(\frac{\Delta}{p_F}\right) = \left(\frac{e\Delta}{\hbar}\right)\left(\frac{2}{\pi}\right) \tag{33}$$

which is correct to within a numerical factor of order unity. A better treatment [41] would probably slightly increase the numerical value of this current. Thus, the "discretization of the Josephson current" in a superconducting quantum point contact, [6] which follows as a limiting case of Eq. (6), can be understood as simply the Landau depairing current of a 1D superconductor.

IV. Junction longer than the healing length

When the junction length L becomes comparable to the BCS healing length ξ_0, more Andreev levels become bound in the pair potential well and the continuum levels begin to carry a

supercurrent. Despite these differences in detail, the basic picture given in the preceding section is still qualitatively correct. Quasiparticles trapped in the normal region of the SNS junction set up standing waves near $\phi = \pm\pi$ when an impurity is present, suppressing the Josephson current.

Figure 4 shows the Andreev levels [from Eqs. (7) and (8)] in a clean SNS junction (dashed line) and when an impurity is placed in the normal region (solid line). [42] The discrete energy level spectrum is quite similar to the normal mesoscopic ring [26] and to electrons in a periodic lattice. The energy gap near $E = 0$ for $\phi = \pi, a \simeq L/2$, and small R can be found (Appendix D) as

$$E_{\rm gap} \simeq 2\sqrt{R}\,(\hbar v_F/L_{\rm eff}\,) \tag{34}$$

where $L_{\rm eff}^2 = (L+2\xi_0)^2 + R(L-2a)^2$. For both long and short SNS junctions, the Andreev gap therefore obeys

$$\pi E_{\rm gap} \simeq \sqrt{R} I_c \Phi_0 \tag{35}$$

where I_c is the critical current of the clean junction and $\Phi_0 = h/e$ is the normal metal flux quantum. The statement (35) is exact for a short junction.

We plot the Josephson current corresponding to Fig. 4 in Fig. 5. In Fig. 5(a) we recover the known result for the Josephson current (solid) in a long and clean SNS junction. [15–18] The current phase relation is triangular with a critical current $I_c = ev_F/\,(L+2\xi_0)$. The critical current I_c is a consequence solely of the current $I_d(\phi)$ carried by the Andreev levels (short dashes), since Eq. (21) shows the continuum current is zero at $\phi = \pi$. The crit-

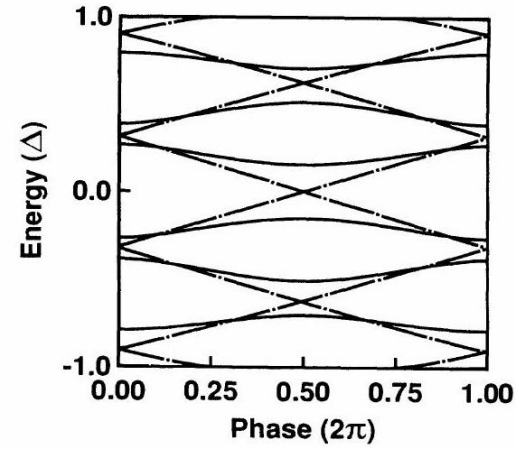

FIG. 4. Andreev levels in a long ($L > \xi_0$) junction with (solid) and without (dashed) an impurity present. As for the short junction, Andreev gaps open in the quasiparticle level spectrum. The analogy with "free electron" and "periodic potential" energy bands is evident in the figure.

ical current $I_c = ev_F/\,(L+2\xi_0)$ follows from Eq. (13) and holds for all values of L, even for $L \ll \xi_0$ when the current phase relation is not triangular. The discretized Josephson current from Sec. III also follows by taking $L \to 0$ in this formula, namely $I_c = ev_F/2\xi_0 = e\Delta/\hbar$.

To obtain the correct dependence of the supercurrent on the phase (triangular as $L \to \infty$), it is necessary to account for the current $I_c(\phi)$ carried in the continuum levels (long dashes). The continuum currents can be understood naively and qualitatively by extrapolating the energy levels from Fig. 4 into the continuum and, ignoring their broadening, treating these continuum Andreev levels "as if" they carried the current from Eqs. (10) and (C4). Thus, the continuum currents $I_c(\phi)$ augment the discrete level currents $I_d(\phi)$ before the first Andreev level moves into the continuum near $\phi \simeq \pi/4$. $I_c(\phi)$ opposes $I_d(\phi)$ after the Andreev level closest to $E = -\Delta$

becomes unbound. (The precise value of ϕ where the lowest Andreev level unbinds depends on the junction length L.) We note the continuum supercurrent $I_c(\phi)$ is not sinusoidal. [15] We also note that $I(\phi)$ is a "small" difference between many larger currents [15–17] carried in each discrete level, along with the larger continuum currents.

The Josephson current through a long and dirty junction is shown in Fig. 5(b). The triangular current phase relation for the clean junction has evolved into an approximately sinusoidal dependence (solid). Neither $I_c(\phi)$ (long dashes) or $I_d(\phi)$ (short dashes) appears to be sinusoidal, although their sum $I(\phi)$ is approximately sinusoidal. For a long and dirty SNS junction, the continuum contribution $I_c(\phi)$ is not only essential to obtain a sinusoidal $I(\phi)$, but is also required to obtain the correct magnitude of the critical current. The continuum levels now contribute to the critical current magnitude, since I_c no longer occurs at $\phi = \pm\pi$. The parameters chosen [42] for this calculation give a transmission probability $T \simeq \frac{1}{2}$, so that comparing Figs. 5(a) and 5(b) reveals (for this cal- culation) that the critical current in the dirty junction is less than $T/2$ times the critical current of the clean junction. For a more transparent impurity, these ratios would be limited by the transmission coefficient T.

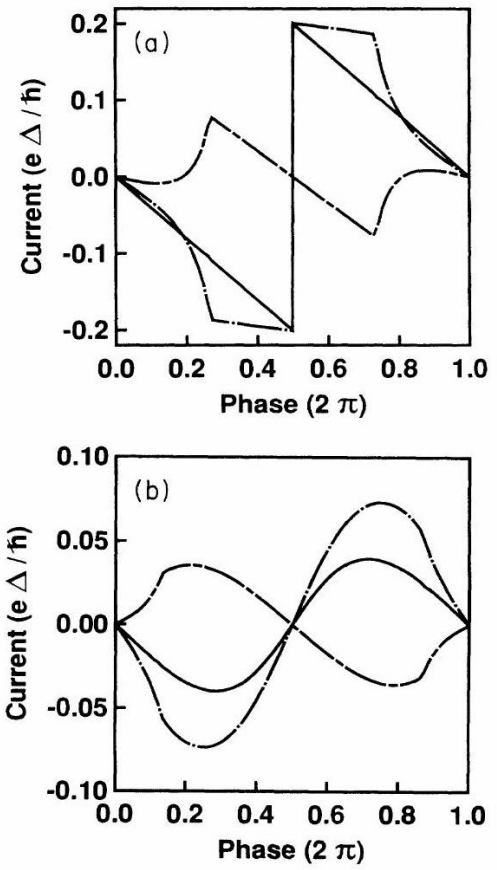

FIG. 5. Josephson current (solid) in a long junction that (a) is clean (b) has an impurity. The impurity rounds the triangular current versus phase relation into a sinusoidal shape, similar to its effect on the short SNS junction. Currents flowing in the scattering continuum (long dashes) and discrete levels (short dashes) combine to give the total Josephson current.

The continuum contribution $I_c(\phi)$ to the Josephson current is suppressed by finite temperature in the same way as the discrete contribution $I_d(\phi)$. Equation (21) can be written as an integral solely over the excitation spectrum as

$$I_c(\phi) = \frac{2e}{h} T \int_{\Delta}^{\infty} \left|u_0^2 - v_0^2\right| \left(\frac{1}{D(E,-\alpha)} - \frac{1}{D(E,\alpha)}\right) \frac{\sin(\phi)}{\sin(\alpha)} [2f(E) - 1] dE \tag{36}$$

The temperature-dependent factor in Eq. (36) is 1 $2f(E) = \tanh(E/2kT)$, implying the same physics of thermal "energy averaging" [37] for currents carried in the continuum levels as that discussed for the discrete levels in Sec. III. Thus, in this viewpoint, all the Josephson current flowing in the continuum at $T = 0$ is carried below the superconducting gap at $E \leq -\Delta$.

One could plausibly argue that moving the single impurity inside the normal region would produce mesoscopic fluctuations [13,43] in the critical current I_c. Equations (7) and (8) show that moving the single impurity will change the Andreev energy levels $E_n^{\pm}$in a long junction ($L \gg \xi_0$). However, it is not obvious that these fluctuating energy levels will cause the Josephson current to fluctuate. For example, it was originally believed from an analogous argument that the critical current would oscillate by varying L even in a clean SNS junction. [2] Later it was realized [15–17] that the critical current does not oscillate, but instead decreases monotonically with L as $I_c = ev_F/(L + 2\xi_0)$. This is because, as the various Andreev levels are forced into the continuum by reducing L, they do not immediately stop carrying a supercurrent. Instead, their contribution to I_c gradually decreases as they move farther outside the superconducting gap. A similar situation holds when moving the single impurity inside the SNS junction.

Moving the impurity away from the center of the junction ($a = L/2$) monotonically reduces the critical current I_c in Fig. 6, [44] showing that I_c does not fluctuate or oscillate with a. As the Andreev levels are forced farther away from the Fermi level by moving the impurity away from the center of the SNS junction, their contribution to I_c gradually decreases. The approximate analysis given in Appendix D agrees with this numerical result. If the impurity is moved a few healing lengths inside one of the superconducting contacts, the critical current should recover its full ballistic value ($I_c^{\text{clean}} = 0.2e\Delta/\hbar$ for the parameters used in Fig. 6), though we have not performed this calculation. In contrast, when the contacts are in their normal state, moving the impurity has no effect on the conductance. The normal state conductance [4] $G = 2e^2T/h$ does not fluctuate as a function of impurity position a, since the transmission coefficient T from Eq. (9) is independent of the impurity position. Therefore, the changing I_c as a function of impurity position a in Fig. 6 is a mesoscopic effect due to the interference of electron waves with the pair potential discontinuities at each SN interface. Mesoscopic fluctuations of the critical current studied in Refs. 13 and 43 have a different origin, arising from the wave interference between multiple impurity scattering events inside the normal region.

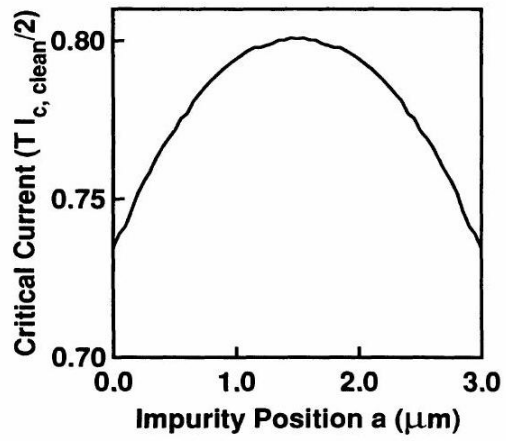

FIG. 6. Moving the lone impurity away from the center of the normal region suppresses the Josephson current in a long SNS junction, even though the normal state conductance of the junction remains unchanged. This mesoscopic effect is due to wave interference of the quasiparticles with the discontinuity in the pairing potential.

10.1.4 Suppression of the Josephson current through a narrow, mesoscopic, semiconductor channel by a single impurity by Bagwell: Calculations

Appendix A: Scattering from the SNS potential

In this appendix we obtain the electrical current [24] transmission amplitude for the scattering of an electronlike excitation incident from the left contact on the potentials $\Delta(x)$ and $V(x)$, shown schematically in Fig. 7.

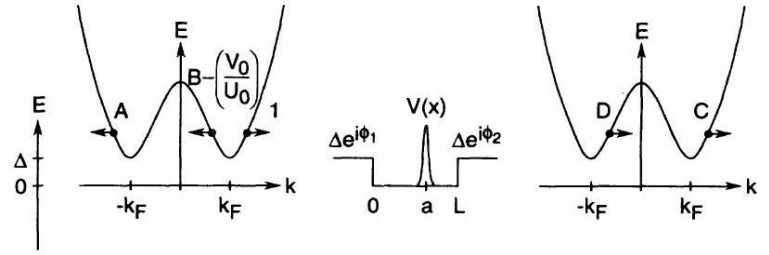

FIG. 7. An electronlike excitation incident from the left contact generates both reflected and transmitted quasiparticles. The transmission amplitudes C and D as a function of the superconducting phase difference $\phi_2 - \phi_1$ determine the Josephson current.

To do this, we match the solutions of Eq. (3) in the regions of uniform pair potential shown in Fig. 1. The poles of this transmission amplitude [45] yield Eqs. (7) and (8) for the discrete Andreev levels, and therefore the electrical current $I_n^{\pm}(\phi)$ carried by the discrete levels. Appendix B shows how the transmission coefficient found in this appendix can be used to obtain Eq. (21) for the continuum current $I_c(\phi)$.

The energy dispersion curve from Eq. (5) can be described by the wave vectors k_e and k_h, where

$$\frac{\hbar^2 k_e^2}{2m} - \mu = \sqrt{E^2 - \Delta^2} \tag{A1}$$

and

$$\frac{\hbar^2 k_h^2}{2m} - \mu = -\sqrt{E^2 - \Delta^2} \tag{A2}$$

with $|k_e| > k_F$ and $|k_h| < k_F$. The "excitation spectrum" of this dispersion law, which includes only the states having $E > 0$, is plotted in Fig. 7.

For a homogeneous superconductor having a pair potential $\Delta(x) = \Delta e^{i\phi_1}$, Eq. (3) has both electronlike solutions for $E > 0$,

$$\begin{pmatrix} u(x) \\ v(x) \end{pmatrix} = \begin{pmatrix} u_0 e^{i\phi_1} \\ v_0 \end{pmatrix} e^{\pm i k_e x} \tag{A3}$$

and holelike solutions for $E > 0$,

$$\begin{pmatrix} u(x) \\ v(x) \end{pmatrix} = \begin{pmatrix} v_0 e^{i\phi_1} \\ u_0 \end{pmatrix} e^{\pm i k_h x} \tag{A4}$$

The "coherence" factors u_0 and v_0 are given by Eqs. (19) and (20). For $E^2 \leq \Delta^2$, $u(x)$ and $v(x)$ decay inside the superconductor [24] with an energy dependent healing length $\xi(E)$ given in Eq. (14). The current carried by normal electrons in the N region (for $E^2 < \Delta^2$) is then converted to a supercurrent within a length $\xi(E)$ inside the superconductor. [24]

We consider now an electronlike excitation incident from the left contact above the superconducting gap, as shown in Fig. 7. The waves generated by this incident electron can be

grouped into four sets (denoted by coefficients A, B, C, and D) which properly include the Andreev reflections. For the electronlike excitations transmitted into right contact we have

$$C\begin{pmatrix} u_0 e^{i\phi_2} \\ v_0 \end{pmatrix} e^{ik_e(x-L)} (x > L) \tag{A5}$$

supported by electrons in the normal region

$$C\begin{pmatrix} u_0 e^{i\phi_2} \\ 0 \end{pmatrix} e^{i\tilde{k}_e(x-L)} (a < x < L) \tag{A6}$$

and holes in the normal region

$$C\begin{pmatrix} 0 \\ v_0 \end{pmatrix} e^{i\tilde{k}_h(x-L)} \quad (a < x < L) \tag{A7}$$

Similarly, for holelike excitations transmitted into the right contact, the waves

$$D\begin{pmatrix} v_0 e^{i\phi_2} \\ u_0 \end{pmatrix} e^{-ik_h(x-L)} \quad (x > L) \tag{A8}$$

$$D\begin{pmatrix} v_0 e^{i\phi_2} \\ 0 \end{pmatrix} e^{-i\tilde{k}_e(x-L)} \quad (a < x < L) \tag{A9}$$

and

$$D\begin{pmatrix} 0 \\ u_0 \end{pmatrix} e^{-i\tilde{k}_h(x-L)} \quad (a < x < L) \tag{A10}$$

are required. I use the notation $\tilde{k}_e$ and $\tilde{k}_h$ to denote the wave vectors in Eqs. (A1) and (A2) when $\Delta = 0$.

A similar procedure applied to the left SN interface is only slightly complicated by the presence of an incident electronlike wave (source term). This source term, which carries an electrical current [24] of $e\hbar k_e/m$, is

$$\begin{pmatrix} u_0 e^{i\phi_1} \\ v_0 \end{pmatrix} e^{ik_e x} \quad (x < 0) \tag{A11}$$

The Andreev reflected holelike excitation is

$$\left(B - \frac{v_0}{u_0}\right)\begin{pmatrix} v_0 e^{i\phi_1} \\ u_0 \end{pmatrix} e^{ik_h x} \quad (x < 0) \tag{A12}$$

The resulting electrons in the normal region are

$$\left(B - \frac{v_0}{u_0} + \frac{u_0}{v_0}\right)\begin{pmatrix} v_0 e^{i\phi_1} \\ 0 \end{pmatrix} e^{i\tilde{k}_e x} \quad (0 < x < a) \tag{A13}$$

and holes

$$B\begin{pmatrix} 0 \\ u_0 \end{pmatrix} e^{i\tilde{k}_h x} \quad (0 < x < a) \tag{A14}$$

The electronlike excitations reflected into the left contact are

$$A\begin{pmatrix} u_0 e^{i\phi_1} \\ v_0 \end{pmatrix} e^{-ik_e x} \quad (x < 0) \tag{A15}$$

supporting electrons in the normal region

$$A\begin{pmatrix} u_0 e^{i\phi_1} \\ 0 \end{pmatrix} e^{-i\tilde{k}_e x} \quad (0 < x < a) \tag{A16}$$

and holes

$$A\begin{pmatrix} 0 \\ v_0 \end{pmatrix} e^{-i\tilde{k}_h x} \quad (0 < x < a) \tag{A17}$$

The scattered waves written above assume $\mu \gg \Delta$, so that we can neglect the difference $(k_e - k_h)$ except when it appears in an exponent. This "Andreev approximation" is usually made in most works on the Josephson effect in SNS junctions.

The scattering matrix [46] (for both electrons and holes) connects the current amplitudes of incoming and outgoing waves at the impurity ($x = a$). The scattering matrix for electrons at $x = a$ gives

$$\begin{pmatrix} C u_0 e^{i\phi_2} e^{i\tilde{k}_e(a-L)} \\ A u_0 e^{i\phi_1} e^{-i\tilde{k}_e a} \end{pmatrix} = \begin{pmatrix} t\left(\tilde{k}_e\right) r\left(\tilde{k}_e\right) \\ r\left(\tilde{k}_e\right) t\left(\tilde{k}_e\right) \end{pmatrix} \begin{pmatrix} \left(B - \frac{v_0}{u_0} + \frac{u_0}{v_0}\right) v_0 e^{i\phi_1} e^{i\tilde{k}_e a} \\ D v_0 e^{i\phi_2} e^{-i\tilde{k}_e(a-L)} \end{pmatrix} \tag{A18}$$

Equation (A18) contains the source term. A similar scattering matrix connects the the hole current amplitudes

$$\begin{pmatrix} D u_0 e^{-i\tilde{k}_h(a-L)} \\ B u_0 e^{i\tilde{k}_h a} \end{pmatrix} = \begin{pmatrix} t^*\left(\tilde{k}_h\right) r^*\left(\tilde{k}_h\right) \\ r^*\left(\tilde{k}_h\right) t^*\left(\tilde{k}_h\right) \end{pmatrix} \begin{pmatrix} A v_0 e^{-i\tilde{k}_h a} \\ C v_0 e^{i\tilde{k}_h}(a - L) \end{pmatrix} \tag{A19}$$

where, for our point scatterer model, the current transmission and reflection amplitudes are

$$t(k) = \frac{1}{1 + i\left(m V_s / \hbar^2 k\right)} \tag{A20}$$

and

$$r(k) = \frac{-i\left(m V_s / \hbar^2 k\right)}{1 + i\left(m V_s / \hbar^2 k\right)} \tag{A21}$$

The electrical current [24] flowing into the right contact, due to the electrical current imposed from the left contact, is

$$J_Q \simeq \frac{e\hbar}{m} \tilde{k}_e \left(|C|^2 - |D|^2\right) \tag{A22}$$

Hence, we must compute the coefficients C and D to obtain the electrical current. The matrix equation for C is

$$\left(\frac{v_0}{u_0}\right)^2 \begin{pmatrix} t\left(\tilde{k}_e\right) r\left(\tilde{k}_e\right) \\ r\left(\tilde{k}_e\right) t\left(\tilde{k}_e\right) \end{pmatrix} \begin{pmatrix} e^{i\left(\tilde{k}_e-\tilde{k}_h\right)a} & 0 \\ 0 & e^{i\phi_e} e^{-i\left(\tilde{k}_e-\tilde{k}_h\right)(a-L)} \end{pmatrix}$$
$$\times \begin{pmatrix} t^*\left(\tilde{k}_h\right) r^*\left(\tilde{k}_h\right) \\ r^*\left(\tilde{k}_h\right) t^*\left(\tilde{k}_h\right) \end{pmatrix} \begin{pmatrix} e^{-i\left(\tilde{k}_e-\tilde{k}_h\right)(a-L)} e^{-i\phi} & 0 \\ 0 & e^{i\left(\tilde{k}_e-\tilde{k}_h\right)a} \end{pmatrix} \begin{pmatrix} C' \\ A' \end{pmatrix} +$$
$$+ \begin{pmatrix} t\left(\tilde{k}_e\right) r\left(\tilde{k}_e\right) \\ r\left(\tilde{k}_e\right) t\left(\tilde{k}_e\right) \end{pmatrix} \left(\begin{bmatrix} 1-\left(\frac{v_0}{u_0}\right)^2 \\ 0 \end{bmatrix} e^{i\tilde{k}_e a} \right)$$
$$= \begin{pmatrix} 10 \\ 0 \quad 1 \end{pmatrix} \begin{pmatrix} C' \\ A' \end{pmatrix}. \tag{A23}$$

Here C' and A' are the same as C and A up to a phase factor, so that $C' = C\exp(i\phi)\exp\left[i\tilde{k}_e(a-L)\right]$ and $A' = A\exp\left(-i\tilde{k}_e a\right)$. The analogous matrix equation for D is

$$\left(\frac{v_0}{u_0}\right)^2 \begin{pmatrix} t^*\left(\tilde{k}_h\right) r^*\left(\tilde{k}_h\right) \\ r^*\left(\tilde{k}_h\right) t^*\left(\tilde{k}_h\right) \end{pmatrix} \begin{pmatrix} e^{-i\left(\tilde{k}_e-\tilde{k}_h\right)(a-L)} e^{-i\phi} & 0 \\ 0 & e^{i\left(\tilde{k}_e-\tilde{k}_h\right)a} \end{pmatrix}$$
$$\times \begin{pmatrix} t\left(\tilde{k}_e\right) r\left(\tilde{k}_e\right) \\ r\left(\tilde{k}_e\right) t\left(\tilde{k}_e\right) \end{pmatrix} \begin{pmatrix} e^{i\left(\tilde{k}_e-\tilde{k}_h\right)a} & 0 \\ 0 & e^{i\phi} e^{-i\left(\tilde{k}_e-\tilde{k}_h\right)(a-L)} \end{pmatrix} \begin{pmatrix} B' \\ D' \end{pmatrix}$$

$$+\left(\tfrac{v_0}{u_0}\right)\begin{pmatrix} t^*(\tilde{k}_h)\, r^*(\tilde{k}_h) \\ r^*(\tilde{k}_h)\, t^*(\tilde{k}_h) \end{pmatrix}\begin{pmatrix} e^{-i(\tilde{k}_e-\tilde{k}_h)(a-L)}e^{-i\phi} & 0 \\ 0 & e^{i(\tilde{k}_e-\tilde{k}_h)a} \end{pmatrix}\begin{pmatrix} t(\tilde{k}_e)\, r(\tilde{k}_e) \\ r(\tilde{k}_e)\, t(\tilde{k}_e) \end{pmatrix}\begin{pmatrix} \left[1-\left(\frac{v_0}{u_0}\right)^2\right] e^{i\tilde{k}_e a} \\ 0 \end{pmatrix}$$

$$= \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} B' \\ D' \end{pmatrix}. \tag{A24}$$

Here B' and D' are the same as B and D up to a phase factor, where $B' = B\exp\left(i\tilde{k}_h a\right)$ and $D' = D\exp\left[-i\tilde{k}_h(a-L)\right]$.

Equations (A23) and (A24) are in a form which can be easily generalized to arbitrary elastic scattering potentials and multiple-moded electron waveguides. Further, Eqs. (A23) and (A24) can be interpreted directly in terms of the phase shifts acquired by the electron and hole Feynman paths multiply reflected from the scatterer and multiply Andreev reflected from the SN boundaries. The remaining considerations here and in Appendix B now specialize to the case where the transmission amplitude is independent of energy.

We directly invert Eqs. (A23) and (A24) to find

$$C' = t\frac{\left[1-\left(\frac{v_0}{u_0}\right)^2 e^{i\phi} e^{i\left(\tilde{k}_e-\tilde{k}_h\right)L}\right]\left[1-\left(\frac{v_0}{u_0}\right)^2\right] e^{i\tilde{k}_e a}}{\left[1-\left(\frac{v_0}{u_0}\right)^2 e^{i\alpha} e^{i\left(\tilde{k}_e-\tilde{k}_h\right)L}\right]\left[1-\left(\frac{v_0}{u_0}\right)^2 e^{-i\alpha} e^{i\left(\tilde{k}_e-\tilde{k}_h\right)L}\right]} \tag{A25}$$

and

$$D' = \left(\frac{v_0}{u_0}\right) \frac{\left(tr^* e^{-i\phi} e^{i\left(\tilde{k}_e - \tilde{k}_h\right)(L-a)} + rt^* e^{i\left(\tilde{k}_e - \tilde{k}_h\right)a}\right)\left[1 - \left(\frac{v_0}{u_0}\right)^2\right] e^{i\tilde{k}_e a}}{\left[1 - \left(\frac{v_0}{u_0}\right)^2 e^{i\alpha} e^{i\left(\tilde{k}_e - \tilde{k}_h\right)L}\right]\left[1 - \left(\frac{v_0}{u_0}\right)^2 e^{-i\alpha} e^{i\left(\tilde{k}_e - \tilde{k}_h\right)L}\right]} \tag{A26}$$

The angle α in Eqs. (A25) and (A26) is determined from
$\cos(\alpha) = T\cos(\phi) + R\cos\left[\left(\tilde{k}_h - \tilde{k}_e\right)(L-2a)\right]$.

If we remove the tunnel barrier ($\alpha \to \phi$ and $t \to 1$) and set the phase difference ϕ to zero, Eq. (A25) gives the result of Demers and Griffin [47] for the transmission amplitude of an electronlike excitation between two superconductors.

The discrete levels in the SNS potential with a tunnel barrier are found [45] by computing the poles of the transmission amplitudes C' or D'. Therefore, the Andreev levels are determined from

$$1 = \left(\frac{v_0}{u_0}\right)^2 e^{\pm i\alpha} e^{i\left(\tilde{k}_e - \tilde{k}_h\right)L} \tag{A28}$$

Since $(v_0/u_0)^2 = \exp\left[2i\cos^{-1}(E/\Delta)\right]$ for $|E| < \Delta$, Eq. (A28) reduces to

$$2\cos^{-1}(E/\Delta) + \left(\tilde{k}_e - \tilde{k}_h\right)L \pm \alpha = 2\pi n \tag{A29}$$

Using $\tilde{k}_e - \tilde{k}_h \simeq k_F E/\mu = E/\Delta\xi_0$, Eqs. (A27) and (A29) reduce to Eqs. (7) and (8).

Equations (7) and (8) also determine the location of the "leaky" Andreev levels in the continuum. In the continuum, the solution of Eqs. (7) and (8) will occur at a complex energy $E = E_R + iE_I$. The imaginary part of this pole can then be interpreted as the lifetime $(\hbar/|E_I|)$ of the leaky Andreev level. The locations of both the discrete poles and the continuum poles of the transmission amplitude are shown in Fig. 8.

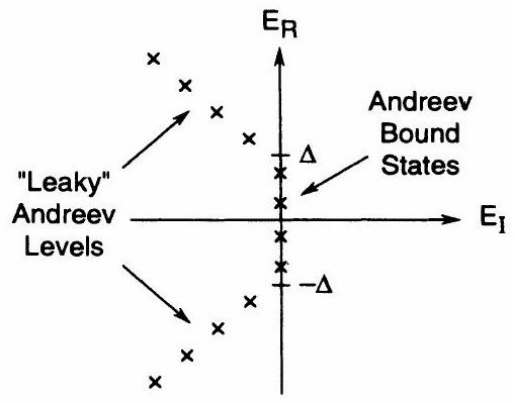

FIG. 8. Poles of the quasiparticle transmission amplitude determine the natural eigenergies of the SNS potential. Welldefined quantum levels exist inside the superconducting energy gap, while scattering resonances outside the gap have a finite lifetime $\hbar/|E_I|$.

Appendix B: Continuum supercurrents

Continuum supercurrents can only flow if there is an imbalance in the electrical currents carried by the quasiparticles incident from the left and right superconducting contacts. The imbalance $I(E,\phi)$ will be proportional to the difference in the transmission coefficients $T^e_{L\to R}(E,\phi) - T^e_{L\leftarrow R}(E,\phi)$ (transmission from left to right minus transmission from right to left) for electrical currents across the SNS junction. This conclusion follows because, near

equilibrium, quantum states in the left and right contacts are equally thermally populated according to the Fermi function $f(E)$ at each energy, and because there are no inelastic scattering processes in the junction.

To obtain the continuum currents we invoke the insights of van Wees, Lenssen, and Harmans. [18] Reference 18 notes that that the electrical current $I(E)$ carried by a single filled quantum state per unit energy is $I(E) = ev_p(E)N_s^+(E)$, where v_p is the phase velocity and $N_s^+(E)$ the superconducting density of states for quasiparticles moving in one direction. We can write this current as $I(E) = e\left(v_p(E)/v_g(E)\right)v_g(E)N_s^+(E)$, where v_g is the group velocity. (Reference 24 defines these phase and group velocities.) Just as in the normal metal, [4] the group velocity times the density of states cancels to $v_g(E)N_s^+(E) = 1/h$. The other factor,

$$v_p(E)/v_g(E) = 1/\left|u_0^2 - v_0^2\right| = N_s^+(E)/N_n^+(E)$$

is simply the ratio of the density of states in the superconductor to the density of states in the normal metal. [This factor $N_s^+(E)/N_n^+(E)$ appears prominently in the study of superconducting tunnel junctions.] The electrical current carried by electronlike excitations in the continuum is therefore

$$I_c^e(\phi) = \frac{2e}{h}\left(\int_{-\infty}^{-\Delta} + \int_{\Delta}^{\infty}\right)\frac{1}{|u_0^2 - v_0^2|}\left[T_{L\to R}^e(E,\phi) - T_{L\leftarrow R}^e(E,\phi)\right]f(E)dE \tag{B1}$$

The additional factor of 2 in Eq. (B1) comes from the electron spin.

We now evaluate the transmission coefficients appearing in Eq. (B1) for our model problem. The transmission coefficient for the electrical currents carried by electronlike excitations incident from the left contact is

$$T_{L\to R}^e(E,\phi) = |C'|^2 - |D'|^2 \tag{B2}$$

with C' and D' determined from Eqs. (A25) and (A26) in Appendix A. Computing these quantities, we find

$$|C'|^2 = T\left|u_0^2 - v_0^2\right|^2 \frac{D(E,\phi)}{D(E,\alpha)D(E,-\alpha)} \tag{B3}$$

and

$$\begin{aligned}|D'|^2 = &\left|u_0^2 - v_0^2\right|^2 \frac{2TRu_0^2v_0^2}{D(E,\alpha)D(E,-\alpha)} \\ &\times\left\{1 + \cos\left[\left(\tilde{k}_e - \tilde{k}_h\right)(L-2a) - \phi\right]\right\}\end{aligned} \tag{B4}$$

where $D(E,\alpha)$ is given by Eq. (18). $T_{L\leftarrow R}^e(E,\phi)$ is easily found from $T_{L\to R}^e(E,\phi)$ by the transformations $\phi \to -\phi$ and $a \to (L-a)$. Therefore,

$$\begin{aligned}T_{L\to R}^e(E,\phi) - &T_{L\leftarrow R}^e(E,\phi) \\ &= T\left|u_0^2 - v_0^2\right|^2 \frac{D(E,\phi) - D(E,-\phi)}{D(E,\alpha)D(E,-\alpha)}\end{aligned} \tag{B5}$$

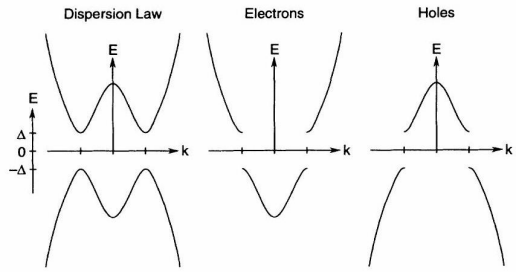
Equation (B5) can be recast as

$$T^e_{L\to R}(E,\phi) - T^e_{L\leftarrow R}(E,\phi) = T\left|u_0^2 - v_0^2\right|^2 \frac{\sin(\phi)}{\sin(\alpha)} \frac{D(E,\alpha) - D(E,-\alpha)}{D(E,\alpha)D(E,-\alpha)} \tag{B6}$$

Combining Eqs. (B6) and (B1), we find

$$I_c^e(\phi)\big|_{E>\Delta} = \frac{2e}{h} T \int_{\Delta}^{\infty} \left|u_0^2 - v_0^2\right| \left(\frac{1}{D(E,-\alpha)} - \frac{1}{D(E,\alpha)}\right) \times \frac{\sin(\phi)}{\sin(\alpha)} f(E)dE \tag{B7}$$

One can now choose several alternate paths to Eq. (21). We have chosen what seems (to us) the most straightforward. Consider the full dispersion relation shown in Fig. 9. It can be separated into an electron branch (standard parabola) and hole branch (inverted parabola). These branches should all be populated according to a Fermi function $f(E)$ at finite temperatures, including



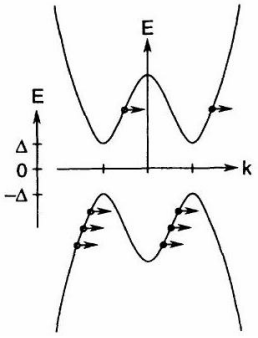


FIG. 9. The total dispersion law for a uniform superconductor can be decomposed into electronlike and holelike states.

Left Contact

Right Contact

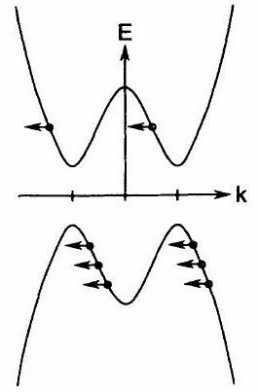

FIG. 10. Both electronlike and holelike states are incident on the SNS potential from all possible branches of the dispersion curve. These quantum levels are populated according to the Fermi function $f(E)$, even in the presence of supercurrent flow.

the hole branches. To compute the Josephson current, one must therefore work also with the negative energy ($E < 0$) solutions of the Bogoliubov-de Gennes equations. We consider quasiparticles incident in all possible branches of the dispersion curve, as shown pictorially in Fig. 10.

Calculating the currents implied from Fig. 10, the total electronlike currents are given by integrating Eq. (B7) over the entire continuum, which is the same as Eq. (21). The hole currents are found to be equal to the electron currents, thereby giving a continuum current too large by a factor of 2. This factor of 2 is easily understood when we note that the dispersion law shown in Fig. 9 contains twice the number of states as the normal metal. We therefore correct for this excess number of quasiparticle states by dividing a factor of 2 into the final result, namely,

$$2I_c(\phi) = I_c^e(\phi) + I_c^h(\phi) \tag{B8}$$

obtaining Eq. (21).

We feel that the physics of Josephson current flow may be less transparent when working solely with the excitation spectrum. Since the excitation spectrum will not be populated at $T = 0$, [18] it is unclear how it can carry the required zero-temperature Josephson current. It was even noted in Ref. 18 that "this seems to prevent the calculation" of the Josephson current at $T = 0$. However, a disadvantage of working with the full dispersion curve is that one must also use the negative energy solutions of Eq. (3). Further, one must compute twice the number of transmission coefficients. Alternatively, one could compute the currents carried by only the electron branch (or only by the hole branch) of the dispersion curve, and still use both positive and negative energies.

Appendix C: supercurrent from free energy

The free energy of a set of independent fermions in the grand canonical ensemble is

$$F = N\mu - kT \sum_E \ln\left(1 + e^{-E/kT}\right) \tag{C1}$$

The derivative of F with respect to the phase difference becomes a sum over the discrete energies $E_n(\phi)$ and integral over the continuum density of states $\rho(E, \phi)$

$$\frac{dF}{d\phi} = \sum_n \frac{dE_n}{d\phi} f\left(E_n\right) + \left(\int_{-\infty}^{-\Delta} + \int_{\Delta}^{\infty} \right) \left. \frac{d\rho(E,\phi)}{d\phi} \right|_E \times \ln\left(1 + e^{-E/kT}\right) dE \tag{C2}$$

The discrete spectrum therefore carries the Josephson current suggested in Sec. II, namely Eq. (10), where

$$I_d(\phi) = \frac{2e}{\hbar} \sum_n \{ \frac{dE_n^+(\phi)}{d\phi} f\left(E_n^+(\phi)\right) + \frac{dE_n^-(\phi)}{d\phi} f\left(E_n^-(\phi)\right) \Big\} \tag{C3}$$

letting us identify the current $I_n^{\pm}(\phi)$ carried by an Andreev level as

$$I_n^{\pm}(\phi) = \frac{2e}{\hbar}\frac{dE_n^{\pm}(\phi)}{d\phi} \tag{C4}$$

Equation (C3) is computationally much simpler than obtaining the current from the quasiparticle wave functions $u(x)$ and $v(x)$, and shows how to easily compute $I_d(\phi)$ when the transmission amplitudes depend on the energy. Further, Eq. (C3) is identical to the current carried by the discrete spectrum from Ref. 13.

We now show how Eq. (15) for the current $I_n^{\pm}(\phi)$ carried by an Andreev level follows from Eq. (C4) combined with Eqs. (7) and (8). We wish to compute

$$\frac{dE_n^{\pm}}{d\phi} = \frac{dE_n^{\pm}}{d\alpha}\frac{d\alpha}{d\phi} \tag{C5}$$

Equation (7) shows how the energy depends on the effective phase α. We find

$$\frac{dE_n^{\pm}}{d\alpha} = \frac{\partial E_n^{\pm}}{\partial \alpha} = \mp\frac{\hbar}{2e}\frac{ev_F}{L + 2\xi\left(E_n^{\pm}\right)} \tag{C6}$$

On the other hand, Eq. (8) shows that $\alpha(E,\phi)$ is a function of both the energy and the phase difference. Therefore

$$d\alpha = \left.\frac{\partial \alpha}{\partial E}\right|_{\phi} dE + \left.\frac{\partial \alpha}{\partial \phi}\right|_{E} d\phi \tag{C7}$$

Combining (C5), (C6), and (C7), we find

$$\frac{dE_n^{\pm}}{d\phi} = \frac{\partial E_n^{\pm}}{\partial \alpha}\left.\frac{\partial \alpha}{\partial \phi}\right|_{E}\frac{1}{\gamma} \tag{C8}$$

where γ is the feedback factor in Eq. (15), namely

$$\gamma = 1 - \left.\frac{\partial E_n^{\pm}}{\partial \alpha}\frac{\partial \alpha}{\partial E}\right|_{\phi} \tag{C9}$$

Equation (8) gives

$$\left.\frac{\partial \alpha}{\partial E}\right|_{\phi} = \left(\frac{R}{\Delta \sin(\alpha)}\right)\left(\frac{L-2a}{\xi_0}\right)\sin\left(\frac{L-2a}{\xi_0}\frac{E}{\Delta}\right) \tag{C10}$$

so that combining (C10) with (24), (C6), (C8), (C9), and (C4) yields Eq. (15).

The continuum contribution to the supercurrent in Eq. (C2) requires the derivative of the continuum density of states with respect to the phase difference

$$\left.\frac{d\rho(E,\phi)}{d\phi}\right|_{E} = \left.\frac{d\rho(E,\alpha)}{d\alpha}\right|_{E}\left.\frac{\partial \alpha}{\partial \phi}\right|_{E} \tag{C11}$$

Equation (C11) implies that we can take the result (17) for $I_c(\phi)$ in the clean junction, replace ϕ by α, then multiply the integrand by (24) to obtain Eq. (21) for $I_c(\phi)$ in the dirty junction. Even though we exploit the continuum contribution of Eq. (C2) to better understand the formulas presented in Sec. II, we do not immediately see the full correspondence between the continuum contribution [13] in Eq. (C2) and the transmission formalism [18] for computing supercurrents carried in the continuum. However, we feel the two methods can probably be shown to be identical.

Appendix D: approximate Andreev levels in a long junction

In this appendix we obtain approximate expressions for the Andreev levels in a long SNS junction with an impurity. Equation (8) can be recast as
$\cos^2(\alpha/2) = 1 - T\sin^2(\phi/2) - R\sin^2[(L-2a)E/2\Delta\xi_0]$.
For $E \ll \Delta$, Eq. (7) becomes

$$E^{\pm} \simeq \left(\frac{\hbar v_F}{2L^*}\right)(2\pi n - \pi \mp \alpha) \tag{D2}$$

with $L^* = L + 2\xi_0$. Taking the impurity exactly in the center of the junction, $a = L/2$, we immediately obtain from Eqs. (D1) and (D2)

$$E^{\pm} \simeq \pi\left(\frac{\hbar v_F}{2L^*}\right)\{2n - 1 \mp \frac{2}{\pi}\cos^{-1}\left[\sqrt{1 - T\sin^2(\phi/2)}\right] \tag{D3}$$

We therefore find the Andreev energy gap near $E = 0$ and $\phi = \pi$ as

$$E_{\rm gap} \simeq 2\pi\left(\frac{\hbar v_F}{2L^*}\right)\left(1 - \frac{2}{\pi}\cos^{-1}\sqrt{R}\right) \tag{D4}$$

which becomes $E_{\rm gap} \simeq (2\sqrt{R})\,(\hbar v_F/L^*)$ for small R. For $T \to 1, E \simeq 0$, and near $\phi \simeq \pi$, we can expand Eq. (D3) as

$$E^{\pm} \simeq \pm 2\left(\frac{\hbar v_F}{2L^*}\right)\sqrt{1 - T\sin^2(\phi/2)} \tag{D5}$$

The slope of the Jospehson current versus phase at $\phi = \pi$ is then approximately

$$\left.\frac{dI}{d\phi}\right|_{\phi=\pi} \simeq \left(\frac{ev_F}{L^*}\right)\left(\frac{T}{2\sqrt{R}}\right).$$

For an impurity which is not centered in the junction, and taking $E \ll \Delta$ and $L - 2a \ll \xi_0$, we can approximate Eq. (D1) as

$$\cos^2(\alpha/2) \simeq 1 - T\sin^2(\phi/2) - R\left((L-2a)E/2\Delta\xi_0\right)^2.$$

Solving Eq. (D7) together with Eq. (D2) for $E^{\pm}$merely replaces $L^* \to L_{\rm eff}$ in Eqs. (D5) and (D6), where $L_{\rm eff}^2 = (L + 2\xi_0)^2 + R(L-2a)^2$. This very approximate analysis confirms Eqs. (34) and (35) in Sec. IV.

10.1.5 Ballistic JC through an asymmetric SNS by Chang, Bagwell

(here will be main method and statement, details will be in the special note)

10.1.6 Josephson and Andreev transport through quantum dots

(see special note about it for now, a very good topic for practice! Later I'll write main statements about it also here)

10.1.7 JJ through a Semiconductor Nanowire

(also, first I'll write it in special note, then - here. There are many articles about it, so I'll select most important ones)

11 Specific Junctions, Applications

11.1 SFS Junction (Junction Through a Ferromagnet)

11.1.1 47*. SFS junction by Shmidt

В разд. 15.2 было показано, что сверхпроводящие пары могут проникать через SN-границу в нормальный металл на глубину ξ_N. Более подробно процесс электропереноса в SNS-переходах будет рассмотрен в 55. Сейчас мы рассмотрим эффект близости в системе сверхпроводник - ферромагнетик (SF) и необычные свойства джозефсоновских SFS-переходов. Но сначала вернемся к эффекту близости в SN-системе и покажем, как оценка длины когерентности ξ_N может быть получена из простых физических соображений. Очевидно, что время жизни τ_p сверхпроводящей пары в несверхпроводящем металле тем меньше, чем больше характерная энергия ΔE процессов, разрушающих пары. Величина τ_p может быть оценена с помощью соотношения неопределенностей:

$$\tau_p \Delta E \sim \hbar \tag{47.1}$$

В нормальном немагнитном металле распаривание происходит за счет тепловых флуктуаций (характерная энергия $\Delta E = k_{\mathrm{B}}T$), т.е. $\tau_p \sim \hbar/k_{\mathrm{B}}T$. В чистый металл пары могут распространяться на глубину порядка $v_{\mathrm{F}}\tau_p \sim \hbar v_{\mathrm{F}}/k_{\mathrm{B}}T$ (ср. с формулой (15.13) для длины затухания параметра порядка в чистом металле). В "грязный» металл пары проникают на длину диффузии за время τ_p, т.е. длина затухания равна $\xi_N \sim \sqrt{D\tau_p} \sim (\hbar D/k_{\mathrm{B}}T)^{1/2}$ (где $D = l_n v_{\mathrm{F}}/3$), что с точностью до $\sqrt{2\pi}$ совпадает с (15.14). В случае SF-контакта в ферромагнетике появляется еще один распаривающий фактор - обменное взаимодействие, которое
пытается выстроить спины электроны в одном направлении, т.е. разрушить пару, которая образована из электронов с противоположно направленными спинами. Если температура Кюри ферромагнетика T_{C} много больше критической температуры T_c сверхпроводника, то средняя обменная энергия в ферромагнетике $E_{ex} \gg k_{\mathrm{B}}T$, и обменное взаимодействие можно считать единственным распаривающим фактором, т.е. $\Delta E \sim E_{\mathrm{ex}}$ в (47.1). В этом случае длина эатухания параметра порядка в "грязном" ферромагнетике $\sqrt{D\tau_p}$ равна

$$\xi_{F1} = \left(\frac{\hbar D}{E_{ex}}\right)^{1/2}, \quad E_{ex} \gg k_{\mathrm{B}}T \tag{47.2}$$

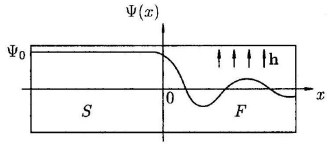
Мы присвоили величине ξ_{F1} дополнительный индекс «1», поскольку длина затухания, как будет показано ниже, - только реальная часть комплексной длины когерентности ξ_F куперовских пар в ферромагнетике. Если наведенный в нормальном металле вблизи SN-границы параметр порядка описывается затухающей экспонентой $\Psi_N(x) = \Psi_{N0}e^{-k_N x}$, где $k_N = 1/\xi_N$, то в SF-случае наведенный параметр порядка не только затухает, но и осциллирует:

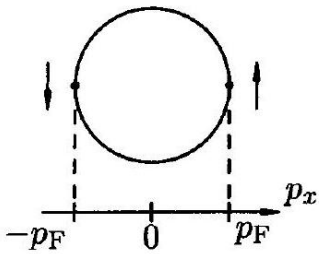
$$\Psi_F(x) = \Psi_{F0}e^{-k_F x} = \Psi_{F0}e^{-k_{F1}x}e^{-ik_{F2}x} \tag{47.3}$$

Здесь Ψ_{F0} - параметр порядка в ферромагнетике на SF-границе, а комплексная величина $k_F = 1/\xi_F = k_{F1} + ik_{F2}$. Ее вещественная часть $k_{F1} = 1/\xi_{F1}$, где ξ_{F1} - введенная ранее длина затухания. Мнимая же часть $k_{F2} = 1/\xi_{F2}$ определяет собой длину волны $2\pi\xi_{F2}$ осцилляций параметра порядка в ферромагнетике, см. рис. 47.1. Можно показать, что в случае "грязного» ферромагнетика без спин-орбитального рассеяния и с

$E_{ex} \gg k_{\mathrm{B}}T$ величины ξ_{F1} и ξ_{F2} равны и описываются формулой (47.2). Комплексную длину когерентности можно тогда записать в виде

$$\xi_F = \left(\frac{\hbar D}{2iE_{ex}}\right)^{1/2} \tag{47.4}$$





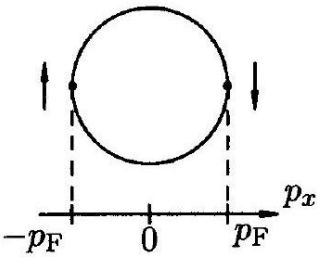


Рис. 47.1. Схематическое изображение поведения параметра порядка вблизи SF-границы; h - обменное поле в ферромагнетике.

а)

б)

ψ

ψ

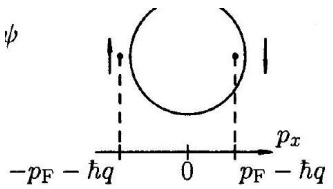

Рис. 47.2. Возникновение ненулевого суммарного импульса пары в ферромагнетике вблизи SF-границы в присутствии обменного поля h. Части а) и б) рисунка соответствуют различным направлениям спинов электронов с положительным и отрицательным импульсами относительно направления обменного поля.

Прежде чем перейти к случаю относительно малых обменных энергий $E_{ex} \geqslant k_{\rm B}T$, попробуем понять физические причины возникновения в ферромагнетике знакопеременного параметра порядка $\Psi_F(x)$. В основе этого явления лежит возможность появления пар с ненулевым суммарным импульсом в присутствии обменного поля, предсказанная для магнитных сверхпроводников в 1964 г. в работах Ларкина и Овчинникова [138], а также Фульде и Феррела [139]. Объемные сверхпроводники с таким состоянием параметра порядка (обозначаемым обычно как LOFF-состояние) пока не обнаружены. Однако вполне реализуемой модификацией LOFF-состояния является осциллирующий параметр порядка вблизи SF-границы, предсказанный позднее в работах [140, 141]. Простая физическая картина появления ненулевого суммарного импульса пары в ферромагнетике, предложенная в работе [142], показана на рис. 47.2. Обсудим здесь слу'ай чистых металлов - сверхпроводника и ферромагнетика. Тог'да пара образована электронами с противоположными (лежащими на ферми-поверхности) импульсами $\hbar\mathbf{k}$ и - $\hbar\mathbf{k}$, так что суммарный импульс пары $\hbar\mathbf{q} = 0$. В ферромагнитной области произойдет изменение энергий электронов пары за счет обменного взаимодействия: тот электрон (назовем его 1 -м), спин которого направлен параллельно обменному полю ферромагнетика, уменьшит свою энергию на E_{ex}, а второй электрон той же пары увеличит свою энергию на E_{ex}. Но энергии электронов, образующих куперовскую пару должны быть равны - казалось бы, это озна'гает немедленное разрушение пары обменным полем! Однако эту проблему можно обойти: увеличим импульс 1 -го электрона до величины $\hbar k_1$ такой, что $\hbar^2 k_1^2/2m - \hbar^2 k^2/2m = E_{ex}$, т.е. $k_1 - k = q_1 \sim E_{ex}/\hbar v_{\rm F}$, а импульс 2-го электрона уменьшим (по абсолютной величине) на такую же величину, - до $\hbar k_2 = \hbar k - \hbar q_1$. 'Тогда противоположные по знаку изменения обменной энергии двух электронов будут скомпенсированы иэменениями их кинетических энергий, а полные энергии останутся одинаковыми, и гара не будет разрушаться. Но такая пара будет теперь иметь ченулевой полный импульс $\hbar q = 2\hbar q_1$, так что ее вклад в параметр порядка будет пропорционален e^{iqx}. Кроме рассмотренной конфигурации спинов в паре возможна и такая, где 1-й электрон (со спином вдоль обменного поля) имеет импульс $-\hbar k$, а 2 -й импульс $\hbar k$. Такая пара приобретет полный импульс $-\hbar q$, и полный параметр порядка будет вести себя как

$$\Psi_F(x) = \Psi_{F0}\left(e^{iqx} + e^{-iqx}\right)/2 = \Psi_{F0}\cos(qx), \tag{47.5}$$

так что длина волны $2\pi\xi_{F2}$ осцилляций параметра порядка равна $2\pi/q \sim \hbar v_F/E_{ex}$. В грязном металле направление импульсов электронов быстро меняется из-за рассеяния на примесях, поэтому зависимость типа (47.5) должна быть усреднена по направлениям вектора q. Аккуратное вычисление [142] показывает, как упоминалось выше, что наряду с осцилляциями параметра порядка появляется и их затухание, причем в грязном пределе $\xi_{F1} = \xi_{F2} = \sqrt{\hbar D/E_{ex}}$.

В связи со знакопеременностью параметра порядка (47.5) естественно ожидать, что в SFS-переходе с толщиной ферромагнетика $d_F \simeq \pi\xi_{F2}$ знаки параметра порядка на сверхпроводящих берегах будут разными, т. е. разность фаз на переходе будет равна π в отсутствие внешнего поля и тока (что не противоречит стационарному уравнению Джозефсона (21.1)). Такой джозефсоновский «л-контакт" был впервые предложен в работе [143] и подробно рассмотрен для SFS-случая в работе [144]. Другой тип π-контакта, возникающего из-за нетривиальной d-волновой симметрии параметра порядка в ВТСП, будет обсуждаться в 49.

На рис. 47.3 представлен результат расчета [145] распределения параметра порядка в грязной ферромагнитной прослойке для различных соотношений толщины слоя d_F и периода осцилляций параметра порядка $2\pi\xi_{F2}$. На следующем рисунке 47.4 изображены зависимости свободных энергий Гинзбурга-Ландау для состояний SFS-перехода с разностями фаз на берегах, равными 0 и π (будем их для краткости называть 0 -состояние и π-состояние). Видно, что π-состояние действительно становится более устойчивым при $d_F \simeq \pi\xi_{F2}$, а затем вновь сменяется обычным 0 -состоянием при дальнейшем увеличении d_F. На рис. 47.3 показано также (штриховой линией) распределение параметра порядка

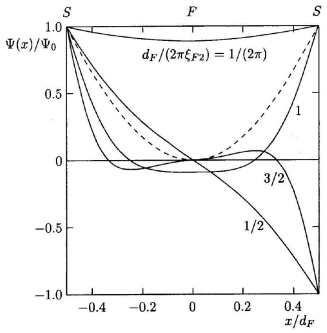

Рис. 47.3. Пространственное распределение параметра порядка в F слое SFS-перехода, вычисленное [145] для различных значений отношения $d_F/2\pi\xi_{F2}$; для отношений, равных $1/2\pi$ и 1, наинизшая энергия достигается в 0 -состоянии, а для отношений $1/2$ и $3/2$ более выгодным оказывается π-состояние.

для 0 -состояния при $d_F = \pi\xi_{F2}$, когда оно имеет более высокую энергию, чем π-состояние (как видно из рисунка, средний квадрат градиента параметра порядка в 0-состоянии выше, чем в π состоянии, что и повышает энергию первого).

Рассмотрим теперь случай относительно малых обменных энергий $E_{ex} \geqslant k_{\mathrm{B}}T$, когда в распаривание дают сравнимый вклад как тепловая энергия, так и обменное поле. Из сравнения выражений (15.14) и (47.4) довольно очевидно (и это можно строго показать), что общее выражение для комплексной длины
F_Γ, отн. ед.

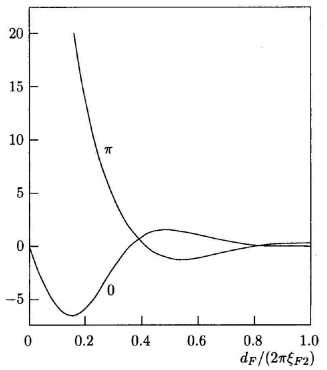

Рис. 47.4. Результат вычислений [145] свободной энергии Гинзбурга Ландау в F-слое для 0 - и π-состояний.

когерентности будет теперь иметь вид

$$\xi_F = \left(\frac{\hbar D}{2\left(\pi k_{\mathrm{B}}T + iE_{ex}\right)}\right)^{1/2} \tag{47.6}$$

Выделяя из этого выражения вещественную и мнимую части для чего удобно записать

$$\pi k_{\mathrm{B}}T + iE_{ex} = \sqrt{(\pi k_{\mathrm{B}}T)^2 + E_{ex}^2}\exp\left(i\,\mathrm{arctg}\left(E_{ex}/\pi k_{\mathrm{B}}T\right)\right)$$

— получим окончательно

$$\xi_{F1,2} = \sqrt{\frac{\hbar D}{\left((\pi k_{\mathrm{B}}T)^2 + E_{ex}^2\right)^{1/2} \pm \pi k_{\mathrm{B}}T}}. \tag{47.7}$$

Это выражение переходит в (47.2) при $E_{ex} \gg k_{\mathrm{B}}T$ и в (15.14) при $E_{ex} = 0$. Важно заметить, что в то время как длина затухания ξ_{F1} растет с понижением температуры (как и для SN контакта), длина волны осцилляций $2\pi\xi_{F2}$ уменьшается. Это дает возможность наблюдать переход SFS-контакта в π-состояние при понижении температуры. Такой эксперимент представлен в работе [145], где в качестве ферромагнитной прослойки был использован сплав CuNi с температурой Кюри около 20 К. На рис. 47.5 представлено семейство измеренных температурных зависимостей критического тока SFS-переходов $\mathrm{Nb-CuNi-Nb}$ с толщиной F-слоя d_F, близкой к $\pi\xi_{F2}$. При наименьшей толщине в 23 нм зависимость $I_c(T)$ не отличается качественно от обычной для SNS-переходов, $I_c \propto e^{-\alpha\sqrt{T}}$. При небольшом увеличении d_F наблюдается насыщение при низких температурах, а потом и немонотонная зависимость $I_c(T)$. Наконец, при толщине $d_F = 27$ нм наблюдается возвратное осциллирующее поведение $I_c(T)$ с обращением в нуль при $T = T_{\text{пер}} \simeq 2$ К. Такое поведение может являться только следствием перехода в π-состояние при $T < T_{\text{пер}}$. В точке этого перехода формальное выражение для $I_c(T)$ проходит через нуль и уходит в отрицательную область. Поскольку в эксперименте измеряется положительно определенная величина критического тока, на зависимости $I_c(T)$ возникает излом в точке $T = T_{\text{пер}}$.

Прямым доказательством перехода SFS-контактов в π-состояние явилось измерение [146] критического тока интерферометра из пяти SFS-контактов, изображенного на рис. 47.6, в зависимости от приложенного магнитного поля. При переходе контактов в π-состояние в каждой ячейке сетки должен возникнуть набег фазы 3π, что в соответствии с (25.2) эквивалентно приложению к сетке магнитного поля с полуцелым потоком на ячейку. Как и в случае двухконтактного интерферометра, описанного

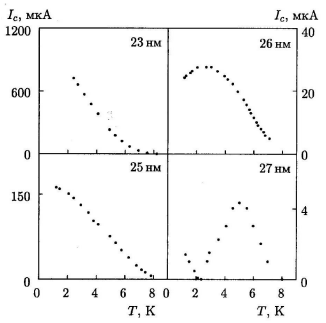

Рис. 47.5. Температурные зависимости критического тока SFS-переходов $\mathrm{Nb-Cu_{0.48}Ni_{0.52}-Nb}$ с толщинами ферромагнитного слоя Cu/Ni от 23 до 27 нм [145].

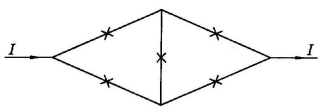

Рис. 47.6. Схематическое изображение треугольной сетки SFS-контактов, состоящей из двух ячеек.

в разд. 25.1, это приведет к смещению зависимости $I_c(H)$ на полпериода. Такой сдвиг, экспериментально обнаруженный при понижении температуры в работе [146], представлен на рис. 47.7.

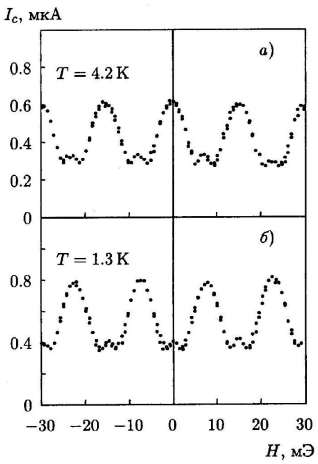

Рис. 47.7. Зависимости $I_c(H)$ двухячеистой сетки SFS-контактов до перехода контактов в π-состояние и после такого перехода ($T_{\text{пер}} = 2.2$ K). Ниже температуры перехода зависимости сдвигаются на полпериода.

11.2 Multiterminal junctions

(first, I'll write this in a separate note)

11.3 Very exotic models and properties of junctions

11.3.1 Casimir froce in Josephson Junctions

(see articles or my special note about it for now)

Casimir-Josephson force in a nutshell

$$F = -\frac{g\hbar v_{\text{F}}}{24\pi L^2}\left(\pi^2 - 3\phi^2\right), \quad |\phi| < \pi$$

$F = -d\Omega/dL$, Ω - free energy.

Why Casimir-Josephson force can be interesting?

- To test some method.
(?? if it give the obtained result by Beenakker. Good theoretical practice!)

Casimir-Josephson force theory

(пока не пишу, потому что тема бесполезная, для прикола вообще ее обсуждать только можно. мб когда-то посмотрю, пока нет в планах)

11.4 Application of Junctions: Main Ideas

11.4.1 4.6 Applications of Weak Superconductivity

The phenomenon of weak superconductivity - renowned for its beautiful physics - is also the basis of a large number of applications. Some of them are outlined below.

We already know that, if the current through a Josephson junction exceeds a critical value, the voltage across the junction has an ac component. The frequency of this component is

defined by (4.21). It is easy to see that, if the junction is exposed to an external rf field and the frequency of the field coincides with the frequency of the Josephson radiation, some sort of resonance must appear. Indeed, in this case, the current-voltage characteristic showing the average values of the current and voltage has the form of a staircase, as in Fig. 4.24. The spacing of the constant voltage steps is exactly $\hbar\omega/2e$. Historically, these steps are called Shapiro steps [30]. Since the frequency can be measured very accurately and the quantities $\hbar$ and e are universal constants, the spacing of the voltage steps on the current-voltage

Josephson junction can be used as a voltage standard [44]. Conversely, the ac Josephson effect can be used to build high-frequency oscillators. Due to the limited radiation power of a single Josephson junction, various types of junction arrays have been proposed in order to increase the output power and to achieve coherent emission of radiation [45].

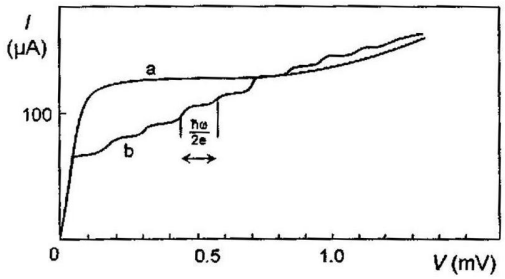

Fig. 4.24. Current-voltage characteristic of a Josephson junction: (a) without external rf electromagnetic field; (b) in the presence of an external of field. The finite slope of the superconducting part is due to a normal film connected in series with the junction [43]

The most celebrated use of SQUIDs is as high-sensitivity magnetometers which are able to register increments of magnetic field of the order of 10^{-10}G in 1 Hz bandwidth. For comparison, recall that the Earth's magnetic field is about 0.5 G . Obviously, the availability of such sensitive devices opens new horizons in various fields of science: geology, geophysics, biophysics, and others. An example is the use of SQUIDs in pioneering studies of the magnetic fields associated with the human heart, the so-called magneto-cardiograms. It turned out that they provide a lot more information about heart problems than the usual electro-cardiograms and therefore promise to become a tool for better diagnostics in this field.

If a SQUID is used as a zero-current device incorporated in an ordinary bridge circuit, it behaves as a voltmeter with sensitivity of about 10^{-15} V. Such voltmeters are already being used in physics laboratories. In addition, Josephson junctions are used in various high-frequency detectors and sensors, in particular, as sensitive elements for detection of millimeter and submillimeter electromagnetic waves in radiotelescopes.

Finally, it is important to mention the use of Josephson junctions as logic and memory elements in digital electronics. They allow much higher operation frequencies (up to hundreds of GHz) than conventional semiconductor-based elements. Another key factor in favor of superconducting digital electronics is the reduced energy consumption as compared to semiconductors. The most ..... –... t.... of lorin is the en.ralled RSFO (ranid single flux quantum) logic which is presently under development in many research laboratories [46].

The sphere of SQUID applications is bound to widen rapidly in the near future and at this particular moment it is impossible to foretell what wonderful results may follow.

Problems

Problem 4.1. Two Josephson junctions with critical currents $I_{c1} = 5 \times 10^{-4}$ A and $I_{c2} = 7 \times 10^{-4}$ A are connected in parallel. The total current through both junctions is 1×10^{-3} A. Find the current through each junction.

Problem 4.2. Find the difference between the maximum and minimum values of V in the plot of Fig. 4.6.

Problem 4.3. Consider a point contact having the critical current $I_c = 10^{-3}$ A and the normal state resistance $R = 2\Omega$. Find the value of the constant voltage across the junction, $\bar{V}$, and the frequency of Josephson radiation, ν, if the current through the contact is $I = 1.2 \times 10^{-3}$ A.
Problem 4.4. Consider a Josephson junction to which a dc current $I_0 = 7 \times 10^{-5}$ A and an ac current of amplitude $I_1 = 2 \times 10^{-6}$ A and frequency $\nu = 10$MHz are applied. That is, the total current applied to the junction is $I = I_0 + I_1 \sin 2\pi\nu t$. The critical current of the junction is $I_c = 10^{-4}$ A. Find the voltage across the junction (in SI units).
Problem 4.5. Consider a tunnel Josephson junction formed by two Pb films. Find the critical field for penetration of a vortex into the junction, H_{cl}, and the field at the center of the vortex. The London magnetic penetration depth for Pb is $\lambda = 400$Å and the critical current density of the junction is $j_c = 10$ A cm^{-2}.
Problem 4.6. Assume that the length of the tunnel junction in Problem 4.5 is $L = 0.2$ mm. Find the external fields corresponding to the first two maxima of the critical current.
Problem 4.7. Consider a single-junction interferometer of inductance 2×10^{-9}H. If the critical current of the junction decreases, the hysteresis in the dependence $\Phi(\Phi_e)$ will disappear at a certain value of the critical current. Find this value.

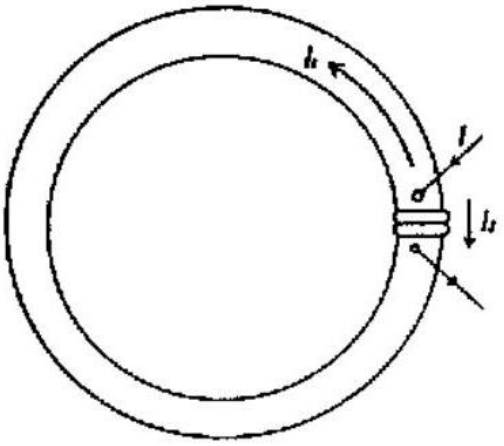

Fig. 4.25. See Problem 4.8. An external source supplies a current I, a part of which, I_r, passes through the ring and the other part, I_J, through the Josephson junction
I, a part of which (I_r) passes through the ring and the other part (I_s) through the Josephson junction, as illustrated in Fig. 4.25. The critical current of the junction is $I_c = 10^{-6}$ A. Find the total current I.

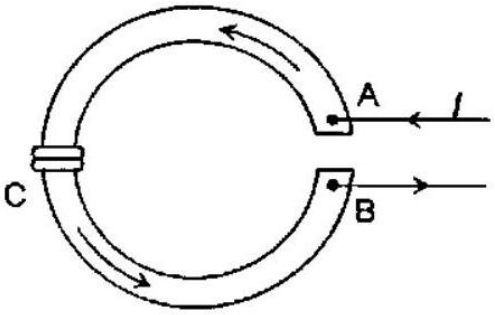

Fig. 4.26. See problem 4.9
Problem 4.9. Consider an SNS Josephson junction with the critical current $I_c = 10^{-6}$ A incorporated in a superconducting ring of inductance $L = 10^{-9}$H. From the side opposite to the junction, a small piece of the ring is cut out, as shown in Fig. 4.26. An external current source connected to the cut supplies a current $I = 0.4 \times 10^{-6}$ A. Find the difference in the phase of the wavefunction between the points A and B, φ_{AB}. Make a plot of the current as a function of the phase difference φ_{AB}.

Part V
Very Useful Methods

12 Methods for BCS SC

12.1 Transformations

12.1.1 Selected GF methods for superconductivity

Assumed formulas for the main derivation of bare Green's function $g^j_{1,1}$ for the discrete model

In quantum mechanics, we can set any set of basis vectors. For the case of a boundary the following set of functions is sufficient

$$\psi_k(n) = \sqrt{\frac{2}{\pi}}\sin(kn), \quad k \in [0,\pi], \quad n \in \mathbb{N}. \tag{12.1}$$

These satisfy

$$\sum_{n=1}^{\infty}\psi_k(n)\psi^\dagger_{k'}(n) = \delta(k-k'), \qquad \int_0^\pi dk\psi^\dagger_k(n)\psi_k(n') = \delta_{n,n'}. \tag{12.2}$$

These are the completeness and the orthogonality relations. After acting with the Hamiltonian $h^{n,n'}_{SC,j} := -\tau_z(t_j\delta_{n',n+1} + t_j\delta_{n',n-1} + \mu\delta_{n',n}) + (\Delta_j e^{i\varphi_j}\tau_+ + \Delta_j e^{-i\varphi_j}\tau_-)\delta_{n',n}$ on these vectors, with help of $\sin x + \sin y = 2\sin\frac{x+y}{2}\cos\frac{x-y}{2}$ one has:

$$\begin{aligned}
\sum_{n'=1}^{\infty} h^{n,n'}_{SC,j}\psi_k(n') &= \sqrt{\frac{2}{\pi}}\sum_{n'=1}^{\infty}\Big[-\tau_z(t_j\delta_{n',n+1} + t_j\delta_{n',n-1} + \mu\delta_{n',n})\sin(kn') + \\
&\qquad + (\Delta_j e^{i\varphi_j}\tau_+ + \Delta_j e^{-i\varphi_j}\tau_-)\delta_{n',n}\sin(kn')\Big] = \\
&= \sqrt{\frac{2}{\pi}}\Big[-\tau_z t_j(\sin(k(n+1)) + \sin(k(n-1))) + \mu\sin(kn) + (\Delta_j e^{i\varphi_j}\tau_+ + \Delta_j e^{-i\varphi_j}\tau_-)\sin(kn)\Big] = \\
&= \sqrt{\frac{2}{\pi}}\Big[-\tau_z t_j\cdot 2\sin(kn)\cos(k) + \mu\sin(kn) + (\Delta_j e^{i\varphi_j}\tau_+ + \Delta_j e^{-i\varphi_j}\tau_-)\sin(kn)\Big] = \\
&= h^j_k\psi_k(n), \qquad\qquad h^j_k := -\tau_z\left(2t_j\cos(k) + \mu\right) + (\Delta_j e^{i\varphi_j}\tau_+ + \Delta_j e^{-i\varphi_j}\tau_-).
\end{aligned}$$

Now, we obtain the expression of the Green's function, that is defined as a solution of

$$zG_{n,n'} - \sum_{n=1}^{\infty} h_{n-n''}G_{n'',n'} = \delta_{n,n'}. \tag{12.3}$$

If we decompose as

$$G_{n,n'} = \int_0^\pi dk\psi_k(n)G_k(n'), \tag{12.4}$$

we will have

$$zG_k(n') - h^j_k G_k(n') = \psi_k(n'), \tag{12.5}$$

$$G_k(n') = \frac{\psi_k(n')}{z - h^j_k}, \tag{12.6}$$

hence

$$G_{n,n'} = \int_0^{\pi} dk \frac{\psi_k(n)\psi_k(n')}{z - h_k^j}. \tag{12.7}$$

This is called Lehmann's representation. This is how the (**??**) was obtained.

12.1.2 Matrix transformations for BCS

Tips for working with matrices in superconductivity

Use Pauli's formula with denominators squared!
(I'll write it later!)

Don't do it by elements of a matrix, it is nonsense!

(write a little example here)

Don't do it by Wolram, it is not working!

(??? why??? but expressions are big and it is a problem. still, it is a question, why he can't compute it???)

Below there is an expression that I tried. (??? why it doesn't work???)

```
A = Inverse[
  z PauliMatrix[0] - (2 t Cos[k] - mu)  PauliMatrix[3] -
   del {{0, Exp[I ph]}, {Exp[-I ph], 0}}]
2/Pi Integrate[Sin[k]^2 A, {k, 0, Pi}]

2/Pi Integrate[
  Sin[k]^2  (-mu + z + 2 t Cos[k])/(-del^2 - mu^2 + z^2 +
    4 mu t Cos[k] - 4 t^2 Cos[k]^2), {k, 0, Pi}]
```

Examples

(I'll add a lot of them here and in the section of problems!)

Derivation of BCS Green's function

12.2 Numerical methods

12.2.1 Typical examples of numerical methods

Numerical Calculation of $\Delta(T)$

[WRITE IT IN WORDS AND GENERAL IDEA, THE EXACTLY CODE IS IN THE SECTION OF PROBLEMS!!!]

Approach 1, by Python

We start from the gap equation and some introduced variables:

$$\eta := \frac{1}{N(0)V}; \quad \eta = \int_0^{\hbar\omega_D} \tanh\frac{\sqrt{\Delta^2+\xi^2}}{2k_BT}\frac{d\xi}{\sqrt{\Delta^2+\xi^2}}; \qquad \Delta_0 \approx 1.76 k_B T_c; \qquad \frac{\hbar\omega_D}{\Delta_0} = \sinh\eta;$$

We transform it as follows:

$$\eta = \int_0^{\hbar\omega_D} \tanh\left(\frac{\Delta_0}{2k_BT_c}\frac{1}{T/T_c}\frac{\Delta}{\Delta_0}\sqrt{1+\xi^2/\Delta^2}\right)\frac{d\xi/\Delta}{\sqrt{1+\xi^2/\Delta^2}}$$
$$\approx \int_0^{\delta^{-1}\sinh\eta} \tanh\left(0.882\frac{\delta}{\tau}\sqrt{1+z^2}\right)\frac{dz}{\sqrt{1+z^2}} \qquad \delta := \Delta(T)/\Delta_0, \qquad \tau := T/T_c$$

here $\hbar\omega_D/\Delta = \Delta_0\hbar\omega_D/(\Delta_0\Delta) = \sinh\eta/\delta$. The number 0.882 is more precise than 1.76/2 for the computer.

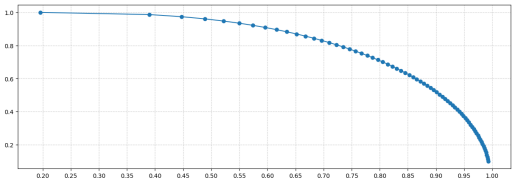
The numerical strategy is as follows. We fix δ and find τ, change δ and solve for $\tau, \ldots$ up to obtain $\delta(\tau)$.

```
import numpy as np
import matplotlib.pyplot as plt
from scipy.integrate import quad
from scipy.optimize import fsolve
from matplotlib.ticker import FormatStrFormatter, MultipleLocator

eta = 1 / 0.35

def bcs_gap_equation(d, t):
    integral, _ = quad(lambda z: np.tanh(0.882 * d * np.sqrt(1 + z**2) / t) / np.sqrt(1 +
    z**2), 0, np.sinh(eta) / d)
    return eta - integral

d_vals = np.linspace(0.1, 0.9999, 70)  # don't set zero here, since we are deviding by d.



t0 = 0.1
t_vals = [fsolve(lambda t: bcs_gap_equation(d, t), t0)[0] for d in d_vals]

plt.figure(figsize=(15, 5))
plt.plot(t_vals, d_vals, marker='o', linestyle='-')
plt.grid(True, linestyle='--', alpha=0.6)

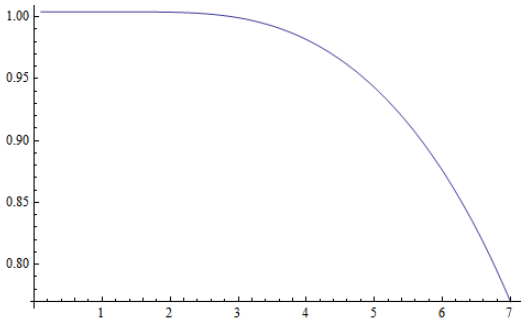
# Set x-axis grid step to 0.05
plt.gca().xaxis.set_major_locator(MultipleLocator(0.05))

plt.gca().xaxis.set_major_formatter(FormatStrFormatter('%.2f'))
plt.show()
```

We get what we expected:

The disadvantage of this approach is that there are no homogeneous points on temperature axes, only on gap axes. But still, it is fine.

(????) This is simpler than first fixing τ to solve for δ, because of the $1/\delta$ in the boundary, but maybe Im wrong on this point. (??? I'll maybe try later it and write here code for this way)



Approach 2, by Wolfram

(????)

```
kb = 1.38 10^(-23);
h = 6.62 10^-34;
hbar = h/2/Pi;
Tc = 9.2;
```

```
Delta0 = 3.528/2*Tc*kb;
omegad = 296*kb/hbar;
Delta[T_]:=
  Block[{a = Log[1.13*hbar*omegad/kb/Tc], b = hbar *omegad/2/kb},
   Return[     FindRoot[     NIntegrate[
         Tanh[b/T*Sqrt[\[Epsilon]^2 + x^2]]/
          Sqrt[\[Epsilon]^2 + x^2], {\[Epsilon], 0, 1},  AccuracyGoal -> 2] - a, {x, 0.01,
    0.1}][[1, 2]]*hbar* omegad]];
Plot[Delta[x]/Delta0, {x, 0.1, 7}]
```

We get what we expected:

(??? there are warnings and the T axes is not normalized. so maybe it is a bad code, but still, it can teach us about using wolfram for superconductivity, so I'll keep it for now.)

13 Bogliubov-de Gennes Equations: Methods and Applications by Jian-Xin Zhu

13.1 3 Local Electronic Structure Around a Single Impurity in Superconductors

Abstract

In this chapter, I am going to discuss the local electronic structure around a single impurity. Both the nonmagnetic and magnetic impurity scattering in conventional s-wave and unconventional d-wave superconductors will be considered. The local electron density of states and the existence of impurity bound or virtual bound states will be explored. The possible realization of Majorana zero-energy modes is discussed for the case of electrons coupled to a spin chain in an s-wave superconductor. These results have a direct relevance to the STM measurements. The results will also be compared with the T-matrix method.

13.1.1 3.1 Introduction

The local electronic structure around a single impurity in a superconductor can provide unique information about the superconducting pairing symmetry [1]. The obtained local density of states can be directly measured by the scanning tunneling microscopy (STM) nowadays. The STM technique has made a significant stride in understanding the pairing symmetry of unconventional superconductors. Theoretically, the study of local electronic structure around a single impurity is also a very important step toward understanding the disorder effect on the bulk superconductivity. The impurity scattering can be either static, which we usually treat as the potential scattering, or dynamic like magnetic impurity or electronic scattering off a local vibrational mode, both of which has internal degrees of freedom. The dynamic scatters cause the inelastic scattering effect of electrons. Here we limit the discussions on the elastic scattering off potential scatters and without loss of generality, consider two-dimensional superconductors, which are described by a tight-binding model on a square lattice.

13.1.2 3.2 Yu-Shiba-Rusinov Impurity States in an s-Wave Superconductor

The condition for the existence of bound state and the spatial oscillations of order parameter and electron density was first studied by Fetter [2] around a spherical impurity in an s-wave superconductor. The existence of bound states due
to resonance scattering in an s-wave superconductor was also considered in an Anderson impurity model by Machida and Shibata [3], Shiba [4], and Machida [5]. For these cases of nonmagnetic impurity scattering, because the product of the bulk superconducting order parameter and the density of states at the Fermi energy is too small (of the order of 10^{-3}), the bound state energy is essentially located near the gap edge. However, the situation becomes very different in the presence of a single magnetic impurity. The quasiparticle scattering off a classical spin was first studied by Yu [6], Shiba [7], and Rusinov [8, 9], who predicted the existence of in-gap bound states, with the energy depending on the exchange coupling between the classical spin and conduction electrons.

The Hamiltonian for an s-wave superconductor with a single-site impurity can be written as

$$\mathscr{H} = \sum_{ij,\sigma} \left[-t_{ij} - \mu\delta_{ij}\right] c^{\dagger}_{i\sigma} c_{j\sigma} + \sum_{i} \left[\Delta_i c^{\dagger}_{i\uparrow} c^{\dagger}_{j\downarrow} + \text{ H.c. } \right] + \sum_{\sigma} \left(\epsilon_I + J\sigma\right) c^{\dagger}_{0\sigma} c_{0\sigma}. \tag{3.1}$$

In principle, as we discussed in earlier chapters, the pair potential Δ_i should be determined self-consistently. However, at this moment, we neglect this selfconsistency and approximate this pair potential by that for the pristine system. As such,

$$\begin{aligned} \mathscr{H}_0 &= \sum_{ij,\sigma} \left[-t_{ij} - \mu\delta_{ij}\right] c^{\dagger}_{i\sigma} c_{j\sigma} + \sum_{i} \left[\Delta_i c^{\dagger}_{i\uparrow} c^{\dagger}_{j\downarrow} + \text{ H.c. } \right] \\ &= \sum_{\mathbf{k}\sigma} \xi_{\mathbf{k}} c^{\dagger}_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma} + \Delta_s \sum_{\mathbf{k}} \left[c^{\dagger}_{\mathbf{k}\uparrow} c^{\dagger}_{-\mathbf{k}\downarrow} + \text{ H.c. } \right] \end{aligned} \tag{3.2}$$

and

$$\mathscr{H}_{imp} = \sum_{\sigma} \left(\epsilon_I + J\sigma\right) c^{\dagger}_{0\sigma} c_{0\sigma} \tag{3.3}$$

Here ϵ_I and J are the strength of the nonmagnetic and ferromagnetic impurity scattering, respectively. Figure 3.1 shows the relative strength of potential in spin up and down channels. In this case, it is particularly convenient to solve the problem in the T-matrix method. By following procedure given in the previous chapter, the

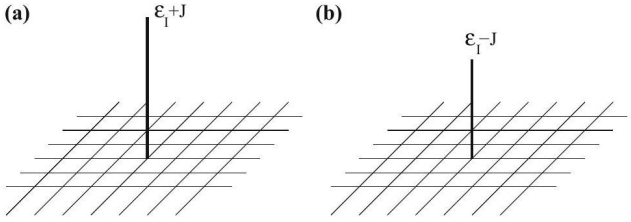


Fig. 3.1 Relative strength of the impurity potential in spin up (a) and spin down (b) channels

Abrikosov-Gorkov equations of motion for the Green's function corresponding to the Hamiltonian equation (3.1) is found to be:

$$\sum_{j'}\left[i\omega_n\delta_{ij'}\hat{\sigma}_0-\hat{h}_{ij'}\right]\mathscr{G}\left(j',j;i\omega_n\right)=\delta_{ij}\hat{\sigma}_0+\hat{V}_{imp}\delta_{i0}\mathscr{G}\left(0,j;i\omega_n\right), \tag{3.4}$$

Because of the non-spin-flip scattering considered here, the Green's function has been redefined from Eq. (2.155) as

$$\mathscr{G}(i,j;\tau)=\begin{pmatrix} -\left\langle T_\tau\left(c_{i\uparrow}(\tau)c_{j\uparrow}^\dagger\right)\right\rangle & -\left\langle T_\tau\left(c_{i\uparrow}(\tau)c_{j\downarrow}\right)\right\rangle \\ -\left\langle T_\tau\left(c_{i\downarrow}^\dagger(\tau)c_{i\uparrow}^\dagger\right)\right\rangle & -\left\langle T_\tau\left(c_{i\downarrow}^\dagger(\tau)c_{j\downarrow}\right)\right\rangle \end{pmatrix}, \tag{3.5}$$

which is a 2×2 matrix in the Nambu space. In Eq. (3.4), the impurity scattering matrix is written as

$$\hat{V}_{imp}=\epsilon_I\hat{\sigma}_3+J\hat{\sigma}_0 \tag{3.6}$$

with the identify matrix

$$\hat{\sigma}_0=\begin{pmatrix}1&0\\0&1\end{pmatrix}, \tag{3.7}$$

and the third component of the Pauli matrix

$$\hat{\sigma}_3=\begin{pmatrix}1&0\\0&-1\end{pmatrix}. \tag{3.8}$$

The single particle Hamiltonian is also a 2×2 matrix

$$\hat{h}_{ij}=\begin{pmatrix}-t_{ij}-\mu\delta_{ij} & \Delta_s\\ \Delta_s & t_{ij}+\mu\delta_{ij}\end{pmatrix}. \tag{3.9}$$

On the other hand, we can also have the Abrikosov-Gorkov equations of motion for the Green's function corresponding to the Hamiltonian equation (3.2):

$$\sum_{j'}\left[i\omega_n\delta_{ij'}\hat{\sigma}_0-\hat{h}_{ij'}\right]G_0\left(j',j;i\omega_n\right)=\delta_{ij}\hat{\sigma}_0, \tag{3.10}$$

where $\mathscr{G}_0\left(i,j';i\omega_n\right)$ is the Fourier transform of

$$\mathscr{G}_0(i,j;\tau)=\begin{pmatrix} -\left\langle T_\tau\left(c_{i\uparrow}(\tau)c_{j\uparrow}^\dagger\right)\right\rangle_0 & -\left\langle T_\tau\left(c_{i\uparrow}(\tau)c_{j\downarrow}\right)\right\rangle_0 \\ -\left\langle T_\tau\left(c_{i\downarrow}^\dagger(\tau)c_{i\uparrow}^\dagger\right)\right\rangle_0 & -\left\langle T_\tau\left(c_{i\downarrow}^\dagger(\tau)c_{j\downarrow}\right)\right\rangle_0 \end{pmatrix}, \tag{3.11}$$

with subscript " 0 " for the statistical average and Heisenberg field operator $c_{i\sigma}(\tau)$ with respect to Eq. (3.2). Since the Hamiltonian equation (3.2) holds the spatial translational invariance, we can find

$$\mathscr{G}_0\left(i,j;i\omega_n\right)=\frac{1}{N_L}\sum_{\mathbf{k}}\mathscr{G}_0\left(\mathbf{k};i\omega_n\right)e^{i\mathbf{k}\cdot\left(\mathbf{r}_i-\mathbf{r}_j\right)} \tag{3.12}$$

with

$$\begin{aligned}\mathscr{G}_0\left(\mathbf{k};i\omega_n\right)&=\begin{bmatrix} i\omega_n-\xi_{\mathbf{k}} & -\Delta_s\\ -\Delta_s & i\omega_n+\xi_{\mathbf{k}}\end{bmatrix}^{-1}\\ &=\frac{1}{\left(i\omega_n-\xi_{\mathbf{k}}\right)\left(i\omega_n+\xi_{\mathbf{k}}\right)-\Delta_s^2}\begin{pmatrix} i\omega_n+\xi_{\mathbf{k}} & \Delta_s\\ \Delta_s & i\omega_n-\xi_{\mathbf{k}}\end{pmatrix}.\end{aligned} \tag{3.13}$$

In a tight-binding model up to the next-nearest-neighbor hopping, the single particle energy dispersion is given by Eq. (2.127) and

$$\xi_{\mathbf{k}} = \epsilon_{\mathbf{k}} - \mu \tag{3.14}$$

The wave vector in the square lattice is given by $\mathbf{k} = k_x \mathbf{e}_x + k_y \mathbf{e}_y$ with $k_{x,y} = \frac{2\pi}{N_L} n_{x,y}$ and $n_{x,y}$ running from $-N_{x,y}/2$ to $N_{x,y}/2 - 1$, the lattice vector in the direct space is given by $\mathbf{r}_i = i_x a \mathbf{e}_x + i_y a \mathbf{e}_y$ with the integers $i_{x,y}$ running from $-N_{x,y}/2$ to $N_{x,y}/2 - 1$. The unit vectors $\mathbf{e}_{x,y}$ are along the bond direction of the square lattice and the $N_L = N_x N_y$.

From Eqs. (3.4) and (3.10), we can obtain the recursion relation:

$$\begin{aligned} \mathscr{G}(i,j;i\omega_n) &= \mathscr{G}_0(i,j;i\omega_n) + \sum_{j'} \mathscr{G}_0(i,j';i\omega_n) \hat{V}_{imp} \delta_{j'0} \mathscr{G}(j',j;i\omega_n) \\ &= \mathscr{G}_0(i,j;i\omega_n) + \mathscr{G}_0(i,0;i\omega_n) \hat{V}_{imp} \mathscr{G}(0,j;i\omega_n) . \end{aligned} \tag{3.15}$$

From Eq. (3.15), we can evaluate the Green's function with site i at the impurity site

$$\mathscr{G}(0,j;i\omega_n) = \mathscr{G}_0(0,j;i\omega_n) + \mathscr{G}_0(0,0;i\omega_n) \hat{V}_{imp} \mathscr{G}(0,j;i\omega_n) , \tag{3.16}$$

which leads to

$$\mathscr{G}(0,j;i\omega_n) = \left[\hat{\sigma}_0 - \mathscr{G}_0(0,0;i\omega_n) \hat{V}_{imp}\right] \mathscr{G}_0(0,j;i\omega_n) . \tag{3.17}$$

We then substitute Eq. (3.17) into Eq. (3.15) and arrive at

$$\mathscr{G}(i,j;i\omega_n) = \mathscr{G}_0(i,j;i\omega_n) + \mathscr{G}_0(i,0;i\omega_n) \hat{T}_{imp}(i\omega_n) \mathscr{G}_0(0,j;i\omega_n) , \tag{3.18}$$

where the T-matrix is given by

$$\hat{T}_{imp}^{-1}(i\omega_n) = \left[\hat{V}_{imp}^{-1} - \mathscr{G}_0(0,0;i\omega_n)\right]^{-1} . \tag{3.19}$$

With the matrix $\hat{V}_{imp}$ given by Eq. (3.6), we can determine the T-matrix to be

$$\hat{T}_{imp}(i\omega_n) = \frac{1}{\Pi(i\omega_n)} \begin{pmatrix} \frac{1}{-\epsilon_I + J} - \mathscr{G}_{22}^0(i\omega_n) & \mathscr{G}_{12}^0(i\omega_n) \\ \mathscr{G}_{21}^0(i\omega_n) & \frac{1}{\epsilon_I + J} - \mathscr{G}_{11}^0(i\omega_n) \end{pmatrix} , \tag{3.20}$$

where

$$\Pi(i\omega_n) = \left(\frac{1}{\epsilon_I + J} - \mathscr{G}_{11}^0(i\omega_n)\right)\left(\frac{1}{-\epsilon_I + J} - \mathscr{G}_{22}^0(i\omega_n)\right) - \mathscr{G}_{12}^0(i\omega_n)\mathscr{G}_{21}^0(i\omega_n) . \tag{3.21}$$

Here we have abbreviated the Green's function $\mathscr{G}_0(0,0;i\omega_n)$ as $\mathscr{G}^0(i\omega_n)$. The pole of the T-matrix with

$$\Pi(i\omega_n \to \omega_c) = 0 \tag{3.22}$$

determines a true or virtual bound state induced by the impurity scattering. Physically, the most direct measure of the possible existence of this kind of states is through the calculation of local density of states (LDOS):

$$\begin{aligned} \rho_i(E) &= \rho_{i\uparrow}(E) + \rho_{i\downarrow}(E) \\ &= -\frac{1}{\pi} \mathrm{Im}\left[\mathscr{G}_{11}\left(i,i;i\omega_n \to E + i0^+\right) - \mathscr{G}_{22}\left(i,i;-i\omega_n \to -\left(E + i0^+\right)\right)\right] \end{aligned} \tag{3.23}$$

which follows from the discussion in Chap. 2.
In Fig. 3.2, we show the energy dependence of LDOS around a single zero-ranged potential scatter in an s-wave superconductor defined on a two-dimensional lattice. The results are obtained within the T-matrix theory, where the self-consistency on the superconducting pair potential is neglected. The lattice is described by a tight-binding model with the hopping parameter included up to the next-nearestneighbors. As is shown, the shape of LDOS for the nonmagnetic impurity remains similar to that for the pristine case (i.e., no impurity scattering). Its intensity on the impurity site (see Fig. 3.2a) suppressed significantly while the LDOS intensity on the nearest-neighboring site to the impurity shows almost no change compared to the pristine case. However, in the presence of a ferromagnetic potential scatter, in-gap quasiparticle states are induced. They are revealed as peaks in the LDOS inside the superconducting gap (see Fig. 3.2b). The location of these in-gap states is dependent on the exchange coupling strength. It first moves toward the Fermi energy with the increased coupling strength and then crosses the Fermi energy when the coupling

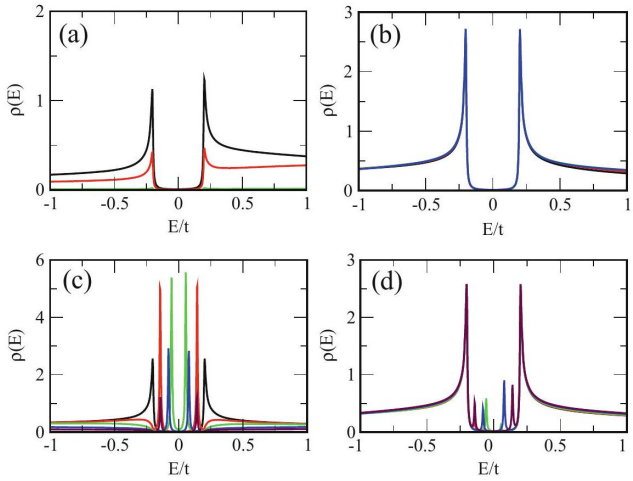

Fig. 3.2 Local density of states around a zero-ranged nonmagnetic ((a)-(b)) and magnetic ((c)(d)) potential scatter in an s-wave superconductor defined on a two-dimensional square lattice. The left column is for the LDOS calculated at the impurity site while the right column is for the LDOS calculated at a site nearest-neighboring to the impurity site. For the nonmagnetic potential scatter $((\mathbf{a})-(\mathbf{b}))$, we take $\varepsilon_I = 1t$ (black), $2t$ (red), $10t$ (green), and 100t (blue) with J fixed at 0 . For the magnetic potential scatter $((\mathbf{c})-(\mathbf{d}))$, we take $J = 0.01$ (black), $0.5t$ (red), $1t$ (green), $2t$ (blue), and $3t$ (maroon) with ε_I fixed at 0 . Here we have used a tight-binding model up to next-nearest neighbor hopping with $t' = -0.2t$ and $\mu = -0.8t$. The pair potential is taken as $\Delta_0 = 0.2t$. The broadening parameter is $\gamma = 0.005t$

strength is further increased. In addition, the spectral weight of the particle and hole in-gap states on the impurity site is nearly symmetric while noticeably asymmetric on the nearest-neighboring sites.

As we have shown above, the T-matrix theory is quite convenient for the study of local quasiparticle properties around a single-site impurity in a uniform background of superconducting order parameter. Rigorously, the superconducting order parameter can be modified near the impurity. In this case, one needs to solve the BdG equations self-consistently. Since a single-site impurity breaks the transitional invariance in space, a very large system size should be considered at a first glance, which presents the computational challenge for diagonalization of the system Hamiltonian. In practice, since the superconducting order parameter around a single impurity varies at a length scale of the superconducting coherence

length ξ, which is inversely proportional to the superconducting energy gap, we can consider a finite area around the impurity. However, this is not generically true for the quasiparticle states, which can be extended into a region further away from the impurity site. To accommo-

date these conditions, one can use a supercell technique. We now consider the single impurity problem as an example of how to use the technique. Consider the supercell containing a single impurity located at the center on a two-dimensional lattice. The cell size is $N_x \times N_y$. Therefore, the entire system now consists of a repeated stacking of these supercells. When the supercell size is sufficiently large that the quasiparticle states induced by the single impurity do not overlap between two nearest-neighboring supercells, the physics from this superlattice should mimick the problem of a single impurity in an otherwise pristine system. For the superlattice, we can apply Bloch theorem to write the BdG wavefunction as

$$\begin{cases} u_{i\sigma} = \frac{1}{\sqrt{M}} \bar{u}_{\tilde{i}\sigma} e^{i\mathbf{K}\cdot\left(\mathbf{R}+\mathbf{r}_{\tilde{i}}\right)}, \\ v_{i\sigma} = \frac{1}{\sqrt{M}} \bar{v}_{i\sigma} e^{i\mathbf{K}\cdot\left(\mathbf{R}+\mathbf{r}_{\tilde{i}}\right)}, \end{cases} \tag{3.24}$$

Here $M = M_x \times M_y$ with $M_x N_x$ and $M_y N_y$ the linear dimension of the entire system. The symbol $\tilde{i}$ labels the sites in a given unit cell. The Bravais lattice $\mathbf{R} = I_x N_x \mathbf{e}_x + I_y N_y \mathbf{e}_y$ with $I_{x(y)}$ integers and $\mathbf{e}_{x(y)}$ unit vectors along the x and y-bond directions. To simplify the discussion, we have taken the unit length $a = 1$. Subjecting the above Block wave function to the periodic boundary condition leads to the wave vectors corresponding to the supercell

$$\mathbf{K} = K_x \mathbf{e}_x + K_y \mathbf{e}_y, \tag{3.25}$$

where $K_x = 2\pi n_x / M_x N_x$ and $K_y = 2\pi n_y / M_y N_y$ with $n_x = -M_x/2, -M_x/2+1, \ldots, M_x/2-2, M_x/2-1$ and $n_y = -M_y/2, -M_y/2+1, \ldots, M_y/2-2, M_y/2-1$ for M_x and M_y even integers. Upon substitution of Eq. (3.24) into Eq. (2.44), we obtain the BdG equations in a tight-binding model with hopping integrals up to the next-nearest neighbors:

$$E_n(\mathbf{K}) u^n_{\tilde{i}\uparrow}(\mathbf{K}) = \sum_{\delta} \tilde{h}_{\tilde{i}\uparrow, i+\delta\uparrow} e^{i\mathbf{K}\cdot\mathbf{r}_\delta} u^n_{i+\delta\uparrow}(\mathbf{K}) + \Delta_{\tilde{i}\tilde{i}} v^n_{\tilde{i}\downarrow}(\mathbf{K}), \tag{3.26}$$

$$E_n(\mathbf{K}) v^n_{\tilde{i}\downarrow}(\mathbf{K}) = -\sum_{\delta} \tilde{h}^*_{\tilde{i}\downarrow, i+\delta\downarrow} e^{i\mathbf{K}\cdot\mathbf{r}_\delta} v^n_{i+\delta\uparrow}(\mathbf{K}) + \Delta^*_{\tilde{i}\tilde{i}\uparrow} u^n_{\tilde{i}}(\mathbf{K}), \tag{3.27}$$

subject to the self-consistency condition:

$$\Delta_{\tilde{i}\tilde{i}} = \frac{U}{2M} \sum_{\mathbf{K},n} u^n_{i\uparrow}(\mathbf{K}) v^{n*}_{\tilde{i}\downarrow}(\mathbf{K}) \tanh\left(\frac{E_n(\mathbf{K})}{2k_B T}\right) \tag{3.28}$$

Once the self-consistent solution is obtained, the local density of states in a given supercell is then evaluated according to

$$\rho_{\tilde{i}}(E) = \frac{1}{M} \sum_{\mathbf{K},n} \left[\left| u^n_{i\uparrow}(\mathbf{K}) \right|^2 \delta\left(E - E_n(\mathbf{K})\right) + \left| v^n_{\tilde{i}\downarrow}(\mathbf{K}) \right|^2 \delta\left(E + E_n(\mathbf{K})\right] . \right) \tag{3.29}$$

Figure 3.3 shows the self-consistent solution of a single impurity in an s-wave superconductor. As we can see, in the presence of a unitary non-magnetic impurity, the superconducting order parameter is indeed strongly suppressed at the impurity site. However, no impurity bound states exist. Instead, in the presence of a ferromagnetic impurity, the superconducting order parameter is suppressed even with an intermediate exchange coupling. In this case, the quasiparticle peaks with energies inside the gap are exhibited in the local density of states. The results are qualitatively consistent with those obtained within the T-matrix theory, suggesting the in-gap states are of Yu-Shiba-Rusinov origin. Therefore, this example demonstrates that

the

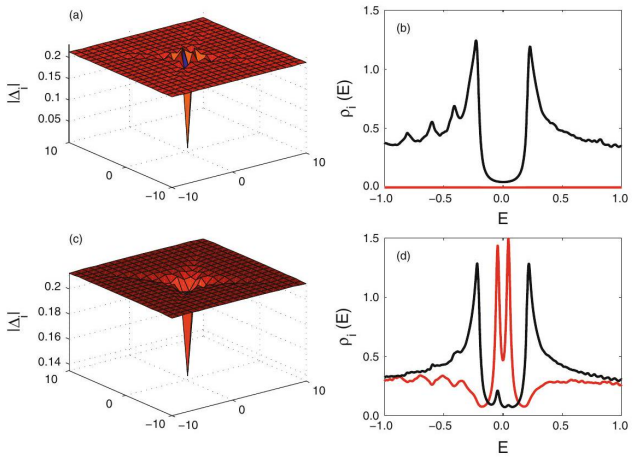

Fig. 3.3 Self-consistent solution to a single impurity in an s-wave superconductor. The top row displays the results of the spatial variation of the superconducting order parameter and the local density of states for a nonmagnetic impurity. The bottom row displays those for a ferromagnetic impurity. For the local density of states, only the results on the impurity site (red line) and on the site nearest neighbor to the impurity site (black line) are plotted. The calculations are carried out for an s-wave superconductor defined on a two-dimensional square lattice. The pairing interaction is taken to be $U = 1.5t$ and the temperature $T = 0.01t$. The supercell size has the dimension of 21 by 21 . The nonmagnetic impurity potential strength $\epsilon_I = 100t$ while the ferromagnetic impurity potential $J = 1t$. Here we have used a tight-binding model up to next-nearest neighbor hopping with $t' = -0.2t$ and $\mu = -0.8t$. The broadening parameter is $\gamma = 0.01t$
fully self-consistent BdG approach can provide more insight into the local electronic structure of a superconductor.

13.1.3 3.3 Majorana Fermion in an s-Wave SC with a Chain of Localized Spins

As we know, the conventional fermions come with a pair of the creation and annihilation operators, $\left(c^\dagger, c\right)$, satisfying the Fermi-Dirac anti-commutation relations $\left\{c, c^\dagger\right\} = 1$. The operators c and $c^\dagger$ are not self-adjoint but they are the adjoint of each other. In contrast to these complex fermions, Majorana fermions are real-valued fermions, that is, they are their own anti-particles and self-adjoint with the property of $c^\dagger = c$. Although these particles may or may not exist in nature as elementary particles, there is intensive interest in their realization in solid state systems [10-13]. In particular, it is proposed that the Majorana fermions can perform better than the complex fermions in keeping the quantum coherence and are proposed as basic building units for quantum computation [14]. For the realization of Majorana fermions in superconductors, a natural strategy is to use the zero-energy or midgap Bogoliubov excitation modes. This observation follows from the particlehole symmetry of Bogoliubov quasiparticles as evident from the BdG equations: The quasiparticle operators $\gamma(E)$ and $\gamma^\dagger(E)$ are related by

$$\gamma(E) = \gamma^\dagger(-E). \tag{3.30}$$

When the quasiparticle excitation energy is zero, we obtain $\gamma = \gamma^\dagger$, suggesting that the particle is its own antiparticle. The search of midgap excitations with the character of Majorana fermions has been made in chiral p-wave superconductors in early years [15, 16] and more recently revived with new proposals [17]. A specific system of interest is that a chain of magnetic atoms on surface of a conventional s-wave superconductor. It has been shown [18-20] that when

the magnetic atoms in the chain form a spiral with the correct pitch, the Yu-Shiba-Rusinov states discussed in previous section can give rise to an effective one-dimensional topological superconductor with Majorana fermions bound to its ends. A schematic setup is shown in Fig. 3.4. The model Hamiltonian is given by

$$\begin{aligned}\mathscr{H} = &\sum_{ij\sigma} \left(-t_{ij} - \delta_{ij}\mu\right) c^\dagger_{i\sigma} c_{j\sigma} + J \sum_{i\in I} \mathbf{S}_i \cdot \left(c^\dagger_{i\sigma} \sigma_{\sigma\sigma'} c_{i\sigma'}\right) \\ &+ \sum_i \left[\Delta_i c^\dagger_{i\uparrow} c^\dagger_{i\downarrow} + \text{ H.c. }\right]. \end{aligned} \tag{3.31}$$

Here the s-wave superconducting pair potential is defined in the BCS mean-field approximation

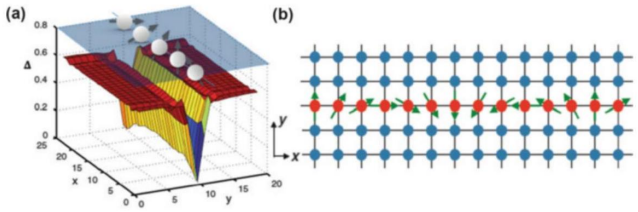

Fig. 3.4 (a) Schematic picture of a chain of magnetic impurities adsorbed on the surface of an s-wave superconductor. Suppression of the superconducting order parameter Δ_i from the selfconsistent BdG solution is also shown. (b) The tight-binding lattice with a row of magnetic atoms. From [21]

$$\Delta_i = U \left\langle c_{i\uparrow} c_{i\downarrow} \right\rangle \tag{3.32}$$

where U is an effective pairing interaction. The third term in the Hamiltonian describes the exchange coupling with strength J of a chain of magnetic spins with the superconducting electrons. We consider a two-dimensional lattice of the dimension $N_L = N_x \times N_y$ for the s-wave superconductor, which lies in the xy plane, and choose the chain of the magnetic atoms aligned along the x-direction. For the case that the magnetic moments form a coplanar spiral at wave vector G, the classical spin can be written as

$$\mathbf{S}_i = S\left(\cos Gx_i, -\sin Gx_i, 0\right) \tag{3.33}$$

where (x_i, y_i) are the coordinate of site i. It represents the spin rotating in the $x-y$ plane. With a periodic condition along the x-direction, it is convenient to perform a spin-dependent gauge transformation to superconducting electron operators:

$$c_{i\sigma} \to c_{i\sigma} = \tilde{c}_{i\sigma} \exp\left[\frac{i}{2}\sigma G x_i\right], \tag{3.34}$$

which effectively aligns the local spin quantization axis for the conduction electrons along the classical spin $\mathbf{S}_i$ and leads to the Hamiltonian

$$\begin{aligned}\mathscr{H} = &\sum_{ij\sigma} \left(-t_{ij} e^{-\frac{i}{2}\sigma G(x_i - x_j)} - \delta_{ij}\mu\right) \tilde{c}^\dagger_{i\sigma} \tilde{c}_{j\sigma} + JS \sum_{i\in I} \tilde{c}^\dagger_{i\sigma} \sigma^x_{\sigma\sigma'} \tilde{c}_{i\sigma'} \Bigg) \\ &+ \sum_i \left[\Delta_i \tilde{c}^\dagger_{i\uparrow} \tilde{c}^\dagger_{i\downarrow} + \text{ H.c. }\right] - \frac{1}{U} \sum_i |\Delta_i|^2 . \end{aligned} \tag{3.35}$$

In the spin reference frame with spin quantized along the x-direction, the effective hopping term becomes spin-dependent $-t_{ij} e^{-\frac{i}{2}\sigma G(x_i - x_j)}$ and can be interpreted as the

hopping with an effective spin-orbit coupling; while the last term in the first line of the above Hamiltonian represents a uniform Zeeman field of the strength JS.

In the one-dimensional limit $N_y = 1$, the entire system is translationally invariant and the pair potential Δ is a constant. We can perform a canonical transformation

$$\tilde{c}_{i\sigma} = \frac{1}{\sqrt{N_L}} \sum_k \tilde{c}_{k\sigma} e^{ikx_i} \tag{3.36}$$

into the Block representation, where k is the wave vector in the first Brillouin zone of the one-dimensional system. The Hamiltonian is then found as

$$\begin{aligned} \mathscr{H} = & \sum_{k\sigma} \xi_{k\sigma} \tilde{c}^\dagger_{k\sigma} \tilde{c}_{k\sigma} + JS \sum_{k\sigma\sigma'} \tilde{c}^\dagger_{k\sigma} \sigma^x_{\sigma\sigma'} \tilde{c}_{k\sigma'} \\ & + \sum_k \left[\Delta \tilde{c}^\dagger_{k\uparrow} \tilde{c}^\dagger_{-k\downarrow} + \text{ H.c. } \right] - \frac{N_x}{U} \Delta^2 \end{aligned} \tag{3.37}$$

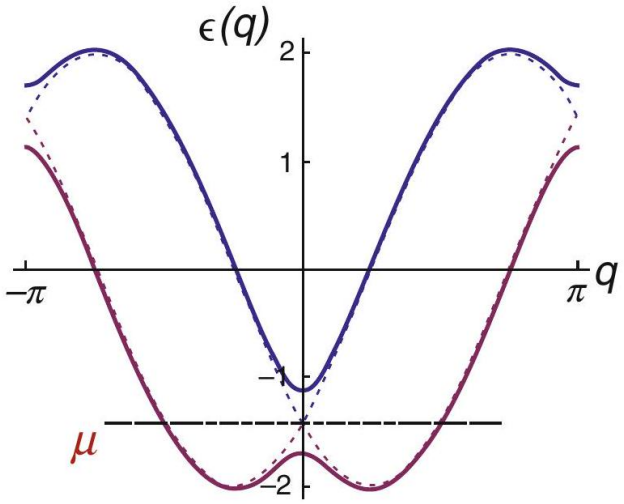
where the spin-dependent energy dispersion in nearest-neighbor hopping model is given by

$$\xi_{k\sigma} = -2t \cos[(k + \sigma G/2)a] - \mu \tag{3.38}$$

with a being the lattice constant. In the normal state ($\Delta = 0$), the single-particle energy dispersion of the system becomes

$$E_k = \xi_{k,+} \pm \sqrt{\xi_{k,-} + J^2 S^2} \tag{3.39}$$

where



$$\xi_{k,\pm} = \frac{1}{2} \left[\xi_{k\uparrow} \pm \xi_{k\downarrow} \right] \tag{3.40}$$

For $k = 0, \pi$ so that $\xi_{k,-} = 0$, the quasiparticle has an excitation gap of JS, as shown in Fig. 3.5. It implies that when the chemical potential lies inside the gap by satisfying the condition

$$|\mu + 2t \cos(Ga/2)| \leq JS, \tag{3.41}$$

there exists a single non-degenerate Fermi point in the right half of the Brillouin zone. The Kitaev criterion [22] then tells that the system is a one-dimensional topological superconductor upon turning on the small superconducting pair potential ($\Delta \neq 0$). It turns out [23-25] that in the one-dimensional system, for an optimized spin spiral pitch G, which minimizes the ground-state energy, the condition Eq. (3.41) is always satisfied.

Fig. 3.5 Normal-state energy dispersion in the one-dimensional electron system coupled to the one-dimensional spin chain. From [21]

For the two-dimensional superconductor, the translation invariance is broken along the y-direction, that is, perpendicular to the spin chain, we can only rely on the numerical simulations to solve the BdG equations

$$\sum_j \tilde{H}_{ij}\Psi_j^n = E_n\Psi_i^n \tag{3.42}$$

where the matrix

$$\tilde{H}_{ij} = \begin{bmatrix} \tilde{h}_{i\uparrow,j\uparrow} & \tilde{h}_{i\uparrow,j\downarrow} & 0 & \delta_{ij}\Delta_i \\ \tilde{h}_{i\downarrow,j\uparrow} & \tilde{h}_{i\downarrow,j\downarrow} & \delta_{ij}\Delta_i & 0 \\ 0 & \delta_{ij}\Delta_i^* & -\tilde{h}^*_{i\uparrow,j\uparrow} & \tilde{h}^*_{i\uparrow,j\downarrow} \\ \delta_{ij}\Delta_i^* & 0 & \tilde{h}^*_{i\downarrow,j\uparrow} & -\tilde{h}^*_{i\downarrow,j\downarrow} \end{bmatrix}, \tag{3.43}$$

and the eigenvector $\Psi_i^n = \left(u_{i\uparrow}^n, u_{i\downarrow}^n, v_{i\uparrow}^n, v_{i\downarrow}^n\right)^{\text{Transpose}}$. Here the matrix normal-state single-particle Hamiltonian matrix is given by

$$\tilde{h}_{ij} = \begin{pmatrix} -t_{ij}e^{-\frac{i}{2}G(x_i-x_j)} - \delta_{ij}\mu & JS\delta_{ij} \\ JS\delta_{ij} & -t_{ij}e^{\frac{i}{2}G(x_i-x_j)} - \delta_{ij}\mu \end{pmatrix}. \tag{3.44}$$

For the bulk system, the closed boundary condition is applicable and the system is still translationally invariant along the x-direction, which allows us to introduce a mixed representation through the transformation

$$\Psi_i^n = \frac{1}{\sqrt{N_x}}\sum_{k_x}\Psi_{i_y}^{\tilde{n}}\left(k_x\right)e^{ik_x i_x a} \tag{3.45}$$

The BdG equations can be block-diagonalized as
with

$$\begin{aligned}&\tilde{h}_{i,j,j_y}\left(k_x\right)\\ &= \begin{pmatrix} -t_{i,j_y} + \left(-2t\cos\left[\left(k_x + G/2\right)a\right] - \mu\right)\delta_{i,j_y} & JS\delta_{i,j_y} \\ JS\delta_{i,j_y} & -t_{i,j_y} + \left(-2t\cos\left[\left(k_x - G/2\right)a\right] - \mu\right)\delta_{i,j_y} \end{pmatrix}.\end{aligned} \tag{3.47}$$

With the aid of these eigensolutions, the ground-state energy can be calculated as a function of the free-parameter G, that is $E_g(G)$, for a given chemical potential, from which the spin spiral pitch G^* can be determined. The typical results are shown in Fig. 3.6 [21]. The strong

suppression of the s-wave superconducting order parameter

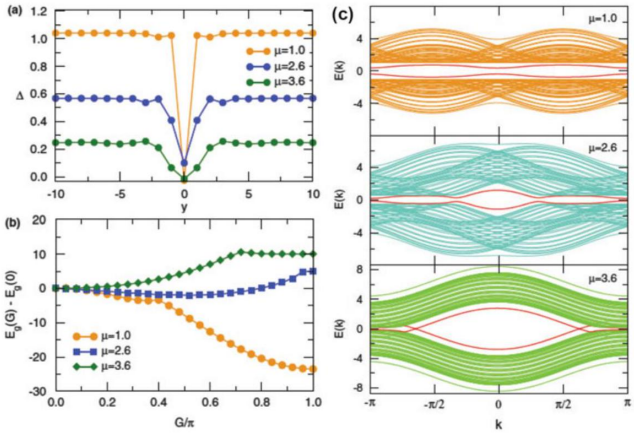


Fig. 3.6 Spatial variation of the superconducting order parameter Δ_{i_y} obtained through the selfconsistent solution to the BdG equations (3.42) (a), the dependence of the ground-state energy on the spiral pitch (b), and band structure on the longitudinal wave vector k_x (c) for various values of the chemical potential $\mu = 1.0, 2.6, 3.6$. The system size is taken to be $N_L = N_x \times N_y = 100 \times 20$. The other parameter values are chosen as $U = 3.6, JS = 2$. The energies are measured in units of nearest neighbor hopping parameter $t = 1$. From [21]
(see Fig. 3.6a) is seen along the spin chain. This superconducting potential quantum well can trap low-energy quasiparticle states. For the chosen chemical potential values, the optimized spiral pitch G_* has the values of $\pi, 0$ and in between (see Fig. 3.6c), corresponding to the antiferromagnetic, ferromagnetic, and topological spiral phases. In all these phases, distinctive Shiba states are obtained (see Fig. 3.6c). These are described by the effective one-dimensional model and the Majorana zeroenergy edge modes can be induced in the system with open boundaries (i.e., at the both ends of the spin chain).

13.1.4 3.4 Impurity Resonance State in a d-Wave Superconductor

The d-wave pairing symmetry, especially, $d_{x^2-y^2}$-wave pairing symmetry, has been observed in high-temperature cuprate superconductors [26, 27]. As we have discussed above, the s-wave superconductivity is not so sensitive to non-magnetic impurity potential scattering, by showing no existence of in-gap states. However, for a d-wave pairing symmetry, the local electronic structure can be quite distinct in the immediate vicinity of an isolated non magnetic impurity [28-40]. It has been theoretically predicted by Balatsky, Salkola and co-workers [31, 32] that, in a d-wave superconductor, a single nonmagnetic impurity can generate quasiparticle resonance states at subgap energies. This prediction has been confirmed by scanning tunneling microscopy experiments [41].

To demonstrate this local properties, we can again employ the T-matrix theory as explained in Sect. 4.2 except that the pair potential is now of the form

$$\Delta_{\mathbf{k}} = \frac{\Delta_0}{2} (\cos k_x - \cos k_y) \tag{3.48}$$

defined in a tight-binding model for a square lattice.
In Fig. 3.7, we show the energy dependence of LDOS around a single zero-ranged potential scatter in a $d_{x^2-y^2}$-wave superconductor defined on a two-dimensional lattice. The results are obtained within the T-matrix theory, where the self-consistency on the superconducting pair potential is neglected. The lattice is described by a tight-binding model with the hopping parameter included up to the next-nearestneighbors. As is shown, the shape of LDOS for the nonmagnetic impurity can change dramatically with the strength of the scattering potential. In particular, due to the locally breaking of the particle-hole symmetry of the electronic states,

the spectral weight for the electron and hole component of quasiparticle resonance peaks is biased. For the repulsive potential scatter, the LDOS resonance state has a dominant hole component on the impurity site (see Fig. 3.7a) while a dominant electron component on the nearest-neighboring site to the impurity (see Fig.3.7b). In contrast, for the attractive potential scatter, the LDOS resonance has a dominant electron component on the impurity site (Fig. 3.7c) but a dominant hole contribution on the nearest-neighboring sites (Fig. 3.7d).

To take into account the full self-consistency of the superconducting order parameter, we use the supercell technique as discussed in Sect.4.2. Now for

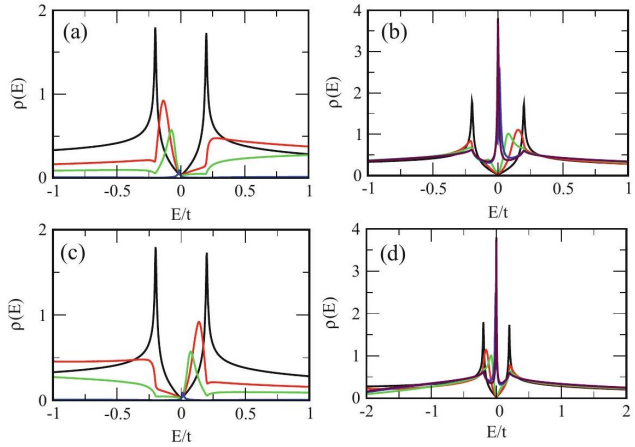

Fig. 3.7 Local density of states around a zero-ranged nonmagnetic potential scatter in a d-wave superconductor defined on a two-dimensional square lattice. The left column is for the LDOS calculated at the impurity site while the right column is for the LDOS calculated at a site nearestneighboring to the impurity site. For the repulsive potential scatter ($(\mathbf{a})-(\mathbf{b})$), we take $\varepsilon_I = 1t$ (red), $2t$ (green), $10t$ (blue), and 100t (maroon). For the attractive potential scatter ((c)-(d)), we take $\varepsilon_I = -1t$ (red), $-2t$ (green), $-10t$ (blue), $-100t$ (maroon). The DOS for the pristine system ($\varepsilon_I = 0$ with black lines) is also shown. Here we have used a tight-binding model up to next-nearest neighbor hopping with $t' = -0.2t$ and $\mu = -0.8t$. The pair potential is taken as $\Delta_0 = 0.2t$. The broadening parameter is $\gamma = 0.005t$

the d-wave superconducting order parameter, the pairing interaction should be of nearest-neighbor type on a square lattice. In the supercell technique, the BdG equations [c.f. Eq. (2.30)] become:

$$E_n(\mathbf{K})u^n_{i\uparrow}(\mathbf{K}) = \sum_{\delta} e^{i\mathbf{K}\cdot\mathbf{r}_\delta}\left[\tilde{h}_{\tilde{i}\uparrow,i+\delta\uparrow}u^n_{\tilde{i}+\delta\uparrow}(\mathbf{K}) + \Delta_{\tilde{i},\tilde{i}+\delta}v^n_{\tilde{i}+\delta\downarrow}(\mathbf{K})\right], \tag{3.49}$$

$$E_n(\mathbf{K})v^n_{i\downarrow}(\mathbf{K}) = \sum_{\delta} e^{i\mathbf{K}\cdot\mathbf{r}_\delta}\left[-\tilde{h}^*_{i\downarrow,i+\delta\downarrow}v^n_{\tilde{i}+\delta\uparrow}(\mathbf{K}) + \Delta^*_{\tilde{i}+\delta,\tilde{i}}u^n_{i+\delta\uparrow}(\mathbf{K})\right], \tag{3.50}$$

subject to the self-consistency condition:

$$\Delta_{\tilde{i}\tilde{i}+\delta} = \frac{V}{4M}\sum_{\mathbf{K},n}\left[u^n_{i\uparrow}(\mathbf{K})v^{n*}_{\tilde{i}+\delta\downarrow}(\mathbf{K})e^{-i\mathbf{K}\cdot\mathbf{r}_\delta} + u^n_{i+\delta,\uparrow}(\mathbf{K})v^{n*}_{i\downarrow}(\mathbf{K})e^{i\mathbf{K}\cdot\mathbf{r}_\delta}\right]\tanh\left(\frac{E_n(\mathbf{K})}{2k_BT}\right). \tag{3.51}$$

The d-wave and the induced extended-s-wave OP components are then defined as

$$\Delta_d(\mathbf{i}) = \frac{1}{4}\left[\Delta_{\hat{x}}(\mathbf{i}) + \Delta_{-\hat{x}}(\mathbf{i}) - \Delta_{\hat{y}}(\mathbf{i}) - \Delta_{-\hat{y}}(\mathbf{i})\right] \tag{3.52}$$

$$\Delta_s(\mathbf{i}) = \frac{1}{4}\left[\Delta_{\hat{x}}(\mathbf{i}) + \Delta_{-\hat{x}}(\mathbf{i}) + \Delta_{\hat{y}}(\mathbf{i}) + \Delta_{-\hat{y}}(\mathbf{i})\right] \tag{3.53}$$

Here $\hat{x}$ and $\hat{y}$ are the unit vectors along x - and y-bond direction of the square lattice. We note that the expression for the LDOS is still the same as that given by Eq. (3.29). In Fig. 3.8, the typical results are shown for a repulsive impurity with the scattering strength in the unitary limit. The d-wave superconducting order parameter is strongly suppressed near the impurity site while a subdominant (extended) s-wave superconducting order parameter is induced around the impurity. In addition, the LDOS near the impurity site exhibits a resonance peak close to the Fermi energy and the spatial dependence of the LDOS at this resonance energy shows tails along the

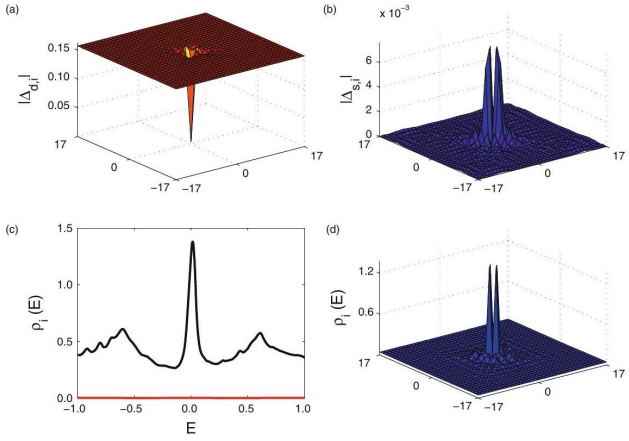

Fig. 3.8 Self-consistent solution to the BdG equations for a single impurity in a d-wave superconductor. The top row displays the spatial variation of the d-wave (a) and induced s-wave (b) components of the superconducting order parameter. The bottom row displays the local density of states on the site nearest neighbor to the impurity site (c) and the spatial dependence of the LDOS at the resonance energy $E_r = 0.014t(\mathbf{d})$. The calculations are carried out for the $d_{x^2-y^2}$ - wave superconductor defined on a two-dimensional square lattice. The pairing interaction is taken to be $V = 1.5t$ and the temperature $T = 0.01t$. The supercell size has the dimension of 35 by 35 . The nonmagnetic impurity potential strength $\epsilon_I = 100t$. Here we have used a tight-binding model up to next-nearest neighbor hopping with $t' = -0.2t$ and $\mu = -0.8t$. The broadening parameter is $\gamma = 0.02t$
nodal direction of the $d_{x^2-y^2}$-wave order parameter. These results are fully consistent with those obtained from the T-matrix theory.

Before closing this chapter, one remark is in order. All of the BdG equations presented so far are derived within an effective BCS theory, which is believed to describe reasonably well the quasiparticles in the superconducting dome even for high-temperature cuprates. Actually, the phase diagram of high-temperature cuprate superconductors is much more complicated with an antiferromagnetic Neel order in its parent compound. These features are mostly discussed in the $t-J$ model, which is a low-energy model derived from the one-band Hubbard model in the localized moment limit. Therefore, it should be appropriate to discuss the superconducting phase within this model. The $t-J$ model Hamiltonian defined on a two-dimensional square lattice can be written as:

$$\begin{aligned}\mathscr{H} = &-\sum_{\langle \mathbf{i}\rangle\sigma} t_{\mathbf{i}j} c^{\dagger}_{\mathbf{i}\sigma} c_{\mathbf{j}\sigma} + \sum_{\mathbf{i}\in I} \varepsilon_{\mathbf{i}} n_{\mathbf{i}} - \mu \sum_{\mathbf{i}} n_{\mathbf{i}} \\ &+ \frac{J}{2} \sum_{\langle \mathbf{ij}\rangle} \left[\mathbf{S}_{\mathbf{i}} \cdot \mathbf{S}_{\mathbf{j}} - \frac{1}{4} n_{\mathbf{i}} n_{\mathbf{j}} \right] + \frac{W}{2} \sum_{\langle \mathbf{ij}\rangle} n_{\mathbf{i}} n_{\mathbf{j}}. \end{aligned} \tag{3.54}$$

Here the electrons are subjected to single occupancy constraint with $\mathbf{S}_{\mathbf{i}}$ the spin- $\frac{1}{2}$ operator on site $\mathbf{i}$. The quantity $n_{\mathbf{i}} = \sum_{\sigma} c^{\dagger}_{\mathbf{i}\sigma} c_{\mathbf{i}\sigma}$ is the electron number operator on site $\mathbf{i}$ and ε_i is the

on-site single-particle potential introduced to describe the impurity scattering or more generally disorder effect. The superexchange interaction $J > 0$ ensures an antiferromagnetic state at zero doping. We have also included a direct nearest-neighbor interaction term so that $W = 0$ and $J/4$ correspond to two versions of the standard $t - J$ model. This term will also adjust the magnitude of the resultant d-wave OP, as will be shown below. Upon doping, the model can be solved within the slave-boson mean-field (SBMF) method [42]. The electron operator as

$$c_{\mathbf{i}\sigma} = b_{\mathbf{i}}^{\dagger} f_{\mathbf{i}\sigma}, \tag{3.55}$$

where $f_{\mathbf{i}\sigma}$ and $b_{\mathbf{i}}$ are the operators for a spinon (a neutral spin- $\frac{1}{2}$ fermion) and a holon (a spinless charged boson). These auxiliary degrees of freedom are subjected to the constraint

$$b_i^{\dagger} b_i + \sum_{\sigma} f_{i\sigma}^{\dagger} f_{i\sigma} \leq 1, \tag{3.56}$$

arising from the single occupancy of electrons $\sum_{\sigma} c_{i\sigma}^{\dagger} c_{i\sigma} \leq 1$. In the SBMF method, this constraint is enforced by introducing a term into the Hamiltonian

$$\sum_i \lambda_i \left[1 - b_i^{\dagger} b_i - \sum_{\sigma} f_{i\sigma}^{\dagger} f_{i\sigma} \right], \tag{3.57}$$

where λ_i is the site-dependent Lagrange multiplier in the presence of impurity scattering potential. In addition, the spin and electron density operators are given
by

$$\mathbf{S}_i = \frac{1}{2} \sum_{\sigma\sigma'} f_{i\sigma}^{\dagger} \boldsymbol{\sigma}_{\sigma\sigma'} f_{i\sigma'} \tag{3.58}$$

with σ being the Pauli matrix, and

$$n_{i\sigma} = f_{i\sigma}^{\dagger} f_{i\sigma} \tag{3.59}$$

By applying the Wick theorem to the interaction terms, we derive a mean-field Hamiltonian

$$\mathscr{H}_{\mathrm{MF}} = \sum_{ij,\sigma} \tilde{h}_{ij} f_{i\sigma}^{\dagger} f_{j\sigma} + \sum_{ij} \left[\Delta_{ij} f_{i\uparrow}^{\dagger} \uparrow_{j\downarrow}^{\dagger} + \text{H.c.} \right] + \sum_i \lambda_i \left(1 - b_i^* b_i \right) \tag{3.60}$$

Here the single-particle Hamiltonian is given by

$$\tilde{h}_{ij} = -t_{ij} b_i b_j^* - \left(\frac{J}{2} + W \right) \chi_{ij} + \left(\varepsilon_i - \mu - \lambda_i \right) \delta_{ij} \tag{3.61}$$

with the resonance valence bond order

$$\chi_{ij} = \frac{1}{4} \sum_{\sigma} \left[\left\langle f_{i\sigma}^{\dagger} f_{j\sigma} \right\rangle + \text{ccc.} \right] \tag{3.62}$$

and the pair potential

$$\Delta_{ij} = \frac{J - W}{2} \left[\langle f_{i\uparrow} f_{i\downarrow} \rangle - \langle f_{i\downarrow} \downarrow f_{j\uparrow} \rangle \right]. \tag{3.63}$$

Due to the holon Bose condensation, which is now treated as a c-number, at low temperatures, the quasiparticles are determined by the spinon degree of freedom only. Without loss of generality, when we take the holon operator as a real number, the application of the Hellmann-Feynman theorem gives rise to the constraints

$$b_i^2 + \sum_\sigma \left\langle f_{i\sigma}^\dagger f_{i\sigma} \right\rangle = 1 \tag{3.64}$$

and

$$\lambda_i = -\sum_j t_{ij}\chi_{ij} b_j / b_i \tag{3.65}$$

Within these mean-field approximations, the BdG equations are derived to be

$$\sum_{\mathbf{j}} \begin{pmatrix} \tilde{h}_{\mathbf{ij}} & \Delta_{\mathrm{ij}} \\ \Delta_{\mathrm{ij}}^\dagger & -\tilde{h}_{\mathbf{ij}}^* \end{pmatrix} \begin{pmatrix} u_{\mathbf{j}}^n \\ v_{\mathbf{j}}^n \end{pmatrix} = E_n \begin{pmatrix} u_{\mathrm{i}}^n \\ v_{\mathbf{i}}^n \end{pmatrix}. \tag{3.66}$$

The local electronic structure around a single nonmagnetic impurity in the $t-J$ model has been studied in the further simplification with a uniform b_i[40, 43]. The results from these studies are qualitatively consistent with those obtained from the above phenomenological BCS model for d-wave superconductors. The full self-consistent solution to the above BdG equations is left for readers to practise.

13.2 4 Disorder Effects on Electronic and Transport Properties in Superconductors

Abstract

In this chapter, we discuss the disorder effects. The disorder comprises of a distribution of nonmagnetic impurities. As such, ensemble averaged effects will be relevant. We focus on the suppression of superconductivity by considering the response of superconducting order parameter, transition temperature, and superfluid density in both s-wave and d-wave superconductors. Finally, we also discuss the localization/delocalization of gapless quasiparticles in a disordered d-wave superconductor within a single-parameter scaling approach.

13.2.1 4.1 Anderson Theorem for Disordered s-Wave Superconductor

A remarkable feature of the isotropic s-wave superconductors is the insensitivity of the superconductivity to the diluted nonmagnetic impurities. This robustness is demonstrated by the Anderson theorem [1]. The theorem states that because the superconductivity arises from the instability of the Fermi surface upon the pairing of time-reversed electronic states, any perturbation should not affect the mean-field superconducting order parameter and transition temperature as long as it does not lift the Kramers degeneracy. We first discuss this theorem within the AbrikosovGorkov theory [2]. For simplicity, we consider the zero-ranged interactions between the conduction electrons and nonmagnetic impurities

$$U(\mathbf{r}) = u_0 \sum_{i\in I} \delta\left(\mathbf{r} - \mathbf{R}_i\right) \tag{4.1}$$

where u_0 is the strength of the scattering potential while $\mathbf{R}_i$ is the position of individual impurities. The Abrikosov-Gorkov equations are derived in Chap. 1 and written as in the continuum limit

$$\begin{aligned} &\left[i\omega_n + \tfrac{\nabla^2}{2m_e} + E_F - U(\mathbf{r})\right] \mathscr{G}\left(\mathbf{r}, \mathbf{r}'; i\omega_n\right) \\ &+ \int d\mathbf{r}'' \Delta\left(\mathbf{r}, \mathbf{r}''\right) \mathscr{F}^\dagger\left(\mathbf{r}'', \mathbf{r}'; i\omega_n\right) = \delta\left(\mathbf{r} - \mathbf{r}'\right) \end{aligned} \tag{4.2a}$$

$$\left[-i\omega_n + \frac{\nabla^2}{2m_e} + E_F - U(\mathbf{r})\right] \mathscr{F}^\dagger(\mathbf{r}, \mathbf{r}'; i\omega_n) + \int d\mathbf{r}'' \Delta^*(\mathbf{r}, \mathbf{r}'') \mathscr{G}(\mathbf{r}'', \mathbf{r}'; i\omega_n) = 0 \tag{4.2b}$$

Here $\omega_n = (2n+1)\pi T$ with n any integer is the Matsubara frequency for electrons, E_F is the Fermi energy, and $\mathscr{G}$ and $\mathscr{F}^\dagger$ are the normal and anomalous Green's functions. The pair potential is given by

$$\Delta^*(\mathbf{r}, \mathbf{r}') = V(\mathbf{r} - \mathbf{r}') T \sum_{\omega_n} \mathscr{F}^\dagger(\mathbf{r}, \mathbf{r}'; i\omega_n), \tag{4.3}$$

where $-V(\mathbf{r} - \mathbf{r}')$ is the pairing interaction. After averaging over the impurity configurations, the transitional invariance is restored so that we can write the above system of equations in the momentum space

$$[i\omega_n - \xi_{\mathbf{p}} - \mathscr{G}_{\omega_n}] \mathscr{G}(\mathbf{p}; i\omega_n) + [\Delta(\mathbf{p}) + \mathscr{F}_{\omega_n}] \mathscr{F}^\dagger(\mathbf{p}; i\omega_n) = 1, \tag{4.4a}$$

$$[i\omega_n + \xi_{\mathbf{p}} + \mathscr{G}_{-\omega_n}] \mathscr{F}^\dagger(\mathbf{p}; i\omega_n) + \left[\Delta^*(\mathbf{p}) + \mathscr{F}^\dagger_{\omega_n}\right] \mathscr{G}(\mathbf{p}; i\omega_n) = 0, \tag{4.4b}$$

where

$$\xi_{\mathbf{p}} = \frac{\mathbf{p}^2}{2m_e} - E_F \tag{4.5}$$

and

$$\mathscr{G}_{\omega_n} = \frac{n_i u_0^2}{(2\pi)^2} \int \mathscr{G}(\mathbf{p}'; i\omega_n) \, d\mathbf{p}' \tag{4.6a}$$

$$\mathscr{F}^\dagger_{\omega_n} = \frac{n_i u_0^2}{(2\pi)^2} \int \mathscr{F}^\dagger(\mathbf{p}'; i\omega_n) \, d\mathbf{p}' \tag{4.6b}$$

with n_i as the density of nonmagnetic impurities. We note that $\mathscr{F}^\dagger_{\omega_n} = (\mathscr{F}_{\omega_n})^*$. We can solve Eq. (4.4) to obtain

$$\mathscr{G}(\mathbf{p}; i\omega_n) = -\frac{i\omega_n - \mathscr{G}_{\omega_n} + \xi_{\mathbf{p}}}{-(i\omega_n - \mathscr{G}_{\omega_n})^2 + \xi_{\mathbf{p}}^2 + \left|\Delta^*(\mathbf{p}) + \mathscr{F}^\dagger_{\omega_n}\right|^2} \tag{4.7a}$$

$$\mathscr{F}^\dagger(\mathbf{p}; i\omega_n) = \frac{\Delta^*(\mathbf{p}) + \mathscr{F}^\dagger_{\omega_n}}{-(i\omega_n - \mathscr{G}_{\omega_n})^2 + \xi_{\mathbf{p}}^2 + \left|\Delta^*(\mathbf{p}) + \mathscr{F}^\dagger_{\omega_n}\right|^2} \tag{4.7b}$$

On substitution of Eq.(4.7) into Eq. (4.6), we find

$$\mathscr{G}_{\omega_n} = \frac{n_i u_0^2}{(2\pi)^2} \int \frac{-(i\omega_n - \mathscr{G}_{\omega_n})}{-(i\omega_n - \mathscr{G}_{\omega_n})^2 + \xi_{\mathbf{p}'}^2 + \left|\Delta^*(\mathbf{p}') + \mathscr{F}^\dagger_{\omega_n}\right|^2} d\mathbf{p}' \tag{4.8a}$$

$$\mathscr{F}^\dagger_{\omega_n} = \frac{n_i u_0^2}{(2\pi)^2} \int \frac{\Delta^*(\mathbf{p}') + \mathscr{F}^\dagger_{\omega_n}}{-(i\omega_n - \mathscr{G}_{\omega_n})^2 + \xi_{\mathbf{p}'}^2 + \left|\Delta^*(\mathbf{p}') + \mathscr{F}^\dagger_{\omega_n}\right|^2} d\mathbf{p}' \tag{4.8b}$$

Here we have dropped the contribution to the integral from the term linear in $\xi_{\mathbf{p}}$ in the numerator of $\mathscr{G}(\mathbf{p}; i\omega_n)$. The pair potential is subjected to the self-consistency:

$$\Delta^*(\mathbf{k}) = T\sum_{i\omega_n}\int \frac{d\mathbf{p}}{(2\pi)^2} V(\mathbf{k}-\mathbf{p})\mathscr{F}^\dagger(\mathbf{p}; i\omega_n) \tag{4.9}$$

In the weak-coupling limit, the pairing interaction is limited to a small range near the Fermi surface. As we discussed in the early chapter, for the s-wave pairing symmetry, the pairing interaction is approximated as

$$V(\mathbf{k}-\mathbf{p}) = V_s. \tag{4.10}$$

From the structure of Eq. (4.8), we can write that for the s-wave pairing symmetry

$$\mathscr{G}_{\omega_n} = -i\omega_n\eta_{\omega_n}, \tag{4.11}$$

and

$$\mathscr{F}_{\omega_n} = \Delta_s\eta_{\omega_n}. \tag{4.12}$$

This gives rise to

$$\begin{aligned}
\eta_{\omega_n} &= \frac{n_i u_0^2}{(2\pi)^2}\int \frac{1+\eta_{\omega_n}}{(\omega_n^2+\Delta_s^2)(1+\eta_{\omega_n})^2+\xi_{\mathbf{p}}^2} d\mathbf{p} \\
&= n_i u_0^2 N(0)\int\frac{d\phi}{2\pi}\int \frac{1+\eta_{\omega_n}}{(\omega_n^2+\Delta_s^2)(1+\eta_{\omega_n})^2+\xi^2} d\xi \qquad (4.13)\\
&= n_i u_0^2 N(0)\int\frac{d\phi}{2\pi}\frac{\pi(1+\eta_{\omega_n})}{\sqrt{(\omega_n^2+\Delta_s^2)(1+\eta_{\omega_n})^2}} \qquad (4.14)\\
&= \frac{1}{2\tau}\frac{1}{\sqrt{\omega_n^2+\Delta_s^2}} \qquad (4.15)
\end{aligned}$$

where $\tau^{-1} = 2\pi n_i u_0^2 N(0)$ with $N(0)$ the density of states per electron spin at the Fermi energy is the impurity scattering rate. Here we have used the integral

$$\int \frac{dx}{1+x^2} = \tan^{-1}(x)$$

The self-consistency solution in the presence of impurity scattering can then be found as

$$\Delta_s = 2g_s\pi T\sum_{i\omega_n}\frac{\Delta_s}{\sqrt{\omega_n^2+\Delta_s^2}} \tag{4.16}$$

where $g_s = N(0)V_s/2$. We note that when the summation over the Matsubara frequency is performed, the cutoff frequency ω_c, which is related to the pairing mechanism, should be introduced. Equation (4.16) indicates that the s-wave superconducting order parameter does not depend on the impurity scattering rate.

The Anderson theorem can also be shown through the BdG equations [3]. As discussed in Chap. 1, the s-wave order parameter is given as

$$\Delta(\mathbf{r}) = V_s\sum_{n(E_n\geq 0)} u_n(\mathbf{r})v_n^*(\mathbf{r})\tanh\left(\frac{E_n}{2k_BT}\right) \tag{4.17}$$

At zero temperature, it is further simplified as

$$\Delta(\mathbf{r}) = V_s \sum_{n(E_n \geq 0)} u_n(\mathbf{r}) v_n^*(\mathbf{r}) \tag{4.18}$$

On the other hand, the BCS variational wave function that pairs electrons in timereversed states is given by

$$\Psi_{\rm BCS}\rangle = \prod_n \left(a_n + b_n c_{n\uparrow}^\dagger c_{\bar{n}\downarrow}^\dagger\right)|0\rangle \tag{4.19}$$

Here $|0\rangle$ stands for the filling Fermi sea, and $c_{n\uparrow}^\dagger$ creates an up-spin electron with wave function $\phi_n(\mathbf{r})$, and $c_{\bar{n}\downarrow}^\dagger$ creates a down-spin electron in $\phi_n(\mathbf{r})^*$, where $\phi_n(\mathbf{r})$ is an eigenfunction of the single-particle Hamiltonian. It thus restricts the trial wave function to the subspace of either doubly occupied or empty levels. The coefficients a_n and b_n are subjected to the normalization condition $|a_n|^2 + |b_n|^2 = 1$. When $\Delta(\mathbf{r})$ is independent of $\mathbf{r}$, we have

$$u_n(\mathbf{r}) = a_n \phi_n(\mathbf{r}) \tag{4.20a}$$
$$v_n(\mathbf{r}) = b_n \phi_n(\mathbf{r}) \tag{4.20b}$$

which leads to

$$\Delta(\mathbf{r}) = V_s \sum_n a_n b_n^* |\phi_n(\mathbf{r})|^2 \tag{4.21}$$

In the absence of a magnetic field, a_n, b_n, and $\phi_n(\mathbf{r})$ can be taken to be real. With the above variational wave function, the energy is given by

$$\begin{aligned} E_G &= \langle \Psi_{\rm BCS}| \mathscr{H} |\Psi_{\rm BCS}\rangle \\ &= \sum_n 2\xi_n - V_s \sum_{n\neq m} a_n a_m b_n b_m \int \phi_n^2(\mathbf{r}) \phi_m^2(\mathbf{r}) d\mathbf{r} \end{aligned} \tag{4.22}$$

subject to the normalization condition for a_n and b_n, where ξ_n is the eigenvalue of the state $\phi_n(\mathbf{r})$. The a_n and b_n can be written as $a_n = \sin\theta_n$ and $b_n = \cos\theta_n$. The variational principle leads to the equation

$$\xi_n \tan(2\theta_n) = \frac{V_s}{2} \sum_{n\neq m} \sin(2\theta_m) \int \phi_n^2(\mathbf{r}) \phi_m^2(\mathbf{r}) d\mathbf{r} \tag{4.23}$$

We now define

$$\tan(2\theta_n) = \frac{\Delta_n}{\xi_n}, \tag{4.24}$$

which implies

$$\sin(2\theta_n) = \frac{\Delta_n}{\sqrt{\xi_n^2 + \Delta_n^2}} = 2a_n b_n \tag{4.25}$$

Equation (4.23) now becomes

$$\Delta_n = V_s \sum_{m\neq n} \frac{\Delta_m}{2\sqrt{\xi_m^2 + \Delta_m^2}} \int \phi_n^2(\mathbf{r}) \phi_m^2(\mathbf{r}) d\mathbf{r} \tag{4.26}$$

Using Eq. (4.21), we obtain

$$\Delta_n = \int \Delta(\mathbf{r})\phi_n^2(\mathbf{r})d\mathbf{r} \tag{4.27}$$

once the condition $m \neq n$ is relaxed.
For a pristine system, $\Delta_n = \Delta(\mathbf{r}) = \Delta_0$. For disordered systems, $\phi_n(\mathbf{r})$ is a complicated wave function. However, if we assume $\Delta(\mathbf{r}) = \tilde{\Delta}$, then the normalization condition $\int \phi_n(\mathbf{r})^2 d\mathbf{r} = 1$ gives rise to $\Delta_n = \tilde{\Delta}$, which is independent
of n. With this condition, the gap equation (4.26) gives

$$\tilde{\Delta} = \int V_s \frac{\tilde{\Delta} N(\epsilon, \mathbf{r})}{\sqrt{\epsilon^2 + \tilde{\Delta}^2}} \phi_n^2(\mathbf{r}) d\mathbf{r} \tag{4.28}$$

where we introduce the normal-state single-particle density of states for the disordered system

$$N(\epsilon, \mathbf{r}) = \sum_m \phi_m^2(\mathbf{r}) \delta(\epsilon - \xi_m) \tag{4.29}$$

In weakly disordered system, $N(\epsilon, \mathbf{r}) \approx N(0)$, the gap equation (4.28) gives $\tilde{\Delta} = \Delta_0$. As such, the transition temperature is also insensitive to the disorder effect. This is the Anderson theorem.

13.2.2 4.2 Suppression of Superconductivity in a Disordered d-Wave Superconductor

For the $d_{x^2-y^2}$-wave pairing symmetry, the pairing interaction can be written as

$$V(\mathbf{k} - \mathbf{p}) = V_d \cos 2\phi \cos 2\phi' \tag{4.30}$$

where the angle $\phi = \tan^{-1}(k_{F,y}/k_{F,x})$ with $k_{F,x(y)}$ the two components of the Fermi wave vector. Correspondingly, the superconducting pair potential is of the form

$$\Delta(\mathbf{k}) = \Delta_d \cos 2\phi \tag{4.31}$$

This special form of the d-wave pairing symmetry leads to the breaking of the scaling law for $\mathscr{F}_{\omega_n}$ and in particular $\mathscr{F}_{\omega_n} = 0$. The self-consistency equation for the d-wave pair potential then becomes

$$\Delta_d = 2g_d \pi T \sum_{i\omega_n} \int \frac{d\phi'}{2\pi} \frac{\Delta_d \cos^2(2\phi')}{\sqrt{\omega_n^2 (1 + \eta_{\omega_n})^2 + (\Delta_d \cos(2\phi'))^2}} \tag{4.32}$$

where $g_d = N(0)V_s/2$ and

$$\eta_{\omega_n} = \frac{1}{2\tau} \int \frac{d\phi'}{2\pi} \frac{1 + \eta_{\omega_n}}{\sqrt{\omega_n^2 (1 + \eta_{\omega_n})^2 + (\Delta_d \cos(2\phi'))^2}} \tag{4.33}$$

Equation (4.32) suggests that the nonmagnetic impurity scattering is pairing breaking and can suppress the transition temperature of the d-wave superconductivity.
The transition temperature from the AG theory is then found [4-7] to be

$$\ln\left(\frac{T_c}{T_{c0}}\right) = \Psi\left(\frac{1}{2}\right) - \Psi\left(\frac{1}{2} + \frac{1}{4\pi\tau T_c}\right). \tag{4.34}$$

Here $\Psi(x)$ is the digamma function and T_{c0} is the transition temperature of a pure system.

The impurity scattering also influences the superfluid density and the penetration depth in a d-wave superconductor. For these quantities, one calculates the electromagnetic response tensor $\mathscr{K}$, relating the current density $\mathbf{j}$ to an applied vector potential $\mathbf{A}$:

$$\mathbf{j} = -\mathscr{K}\,\mathbf{A} \tag{4.35}$$

If the electromagnetic tensor is diagonal $\mathscr{K}_{ij} = \mathscr{K}_{ii}\delta_{ij}$, the penetration depth λ_i for the current flowing in the direction i is given by

$$\lambda_i^{-2} = (4\pi/c)\mathscr{K}_{ii} \tag{4.36}$$

where c is the velocity of light. The AG theory for a disordered BCS d-wave superconductivity then gives the response tensor [4]:

$$\mathscr{K}_{ij} = \frac{e^2}{c}\left\langle v_i(\mathbf{k})v_j(\mathbf{k})\int_0^\infty d\omega \tanh\left(\frac{\omega}{2k_BT}\right)\mathrm{Re}\,\frac{\Delta_k^2}{(\tilde{\omega}^2-\Delta_k^2)^{3/2}}\right\rangle. \tag{4.37}$$

Here $\langle\cdots\rangle \equiv 2(2\pi)^{-2}\int dS_F/|\mathbf{v}(\mathbf{k})|\cdots$ represents an angular average over an arbitrary Fermi surface in a two-dimensional metal, and $\mathbf{v}(\mathbf{k})$ is the Fermi velocity. The renormalized frequency $\tilde{\omega} = \omega - \Sigma_0$ with the impurity self-energy obtained from the T-matrix approximation [8-13]

$$\Sigma_0 = \frac{\Gamma G_0}{(u_0N(0))^{-1} - G_0^2}, \tag{4.38}$$

where $\Gamma = n_i/\pi N(0) = 1/2\tau$ is the scattering rate with n_i being the impurity concentration, and G_0 is the integrated diagonal Green's function averaged over the impurity configuration

$$G_0 = -i\left\langle\frac{\tilde{\omega}}{(\tilde{\omega}^2-\Delta_k^2)^{1/2}}\right\rangle. \tag{4.39}$$

Equation (4.37) can be decomposed into two parts

$$\mathscr{K}_{ij}(T) = \mathscr{K}_{ij}(T=0) + \delta\mathscr{K}_{ij}(T) \tag{4.40}$$

where

$$\mathscr{K}_{ij}(T=0) = \frac{e^2}{c}\left\langle v_i(\mathbf{k})v_j(\mathbf{k})\int_0^\infty d\omega\,\mathrm{Re}\,\frac{\Delta_k^2}{(\tilde{\omega}^2-\Delta_k^2)^{3/2}}\right\rangle, \tag{4.41}$$

and

$$\delta\mathscr{K}_{ij}(T) = \frac{-2e^2}{c}\left\langle v_i(\mathbf{k})v_j(\mathbf{k})\int_0^\infty d\omega f_{\mathrm{FD}}(\omega)\,\mathrm{Re}\,\frac{\Delta_k^2}{(\tilde{\omega}^2-\Delta_k^2)^{3/2}}\right\rangle \tag{4.42}$$

In the impurity-dominated gapless regime, the renormalized frequency takes the form [4] $\tilde{\omega} \to i\gamma + a\omega$, where γ is a constant dependent on the impurity concentration and scattering strength, while the constant $a \sim O(1)$. At low temperatures, it allows us to replace $\tilde{\omega}$ by this limiting form, which gives rise to

$$\delta\mathscr{K}_{ij}(T) = \frac{-e^2}{c}\frac{\pi^2}{2}\gamma a T^2\left\langle v_i(\mathbf{k})v_j(\mathbf{k})\frac{\Delta_k^2}{(\gamma^2+\Delta_k^2)^{5/2}}\right\rangle. \tag{4.43}$$

For the $d_{x^2-y^2}$-wave pairing symmetry, the angular average in the above equation varies as γ^{-2}. It suggests that the coefficient of the T^2-dependence in the penetration depth is proportional to the inverse γ but the T^2 behavior is valid in a very narrow temperature range $\sim \gamma$.

The impurity scattering also affects the zero-temperature tensor $\mathscr{K}_{ij}(T=0)$, which is given by

$$\mathscr{K}_{ij}(T=0) = \mathscr{K}_{ij}(T=0,\Gamma=0) + \frac{e^2}{c}\left\langle v_i(\mathbf{k})v_j(\mathbf{k})\frac{\Delta_k^2}{(\gamma^2+\Delta_k^2)^{1/2}}\right\rangle. \tag{4.44}$$

The scaling relation between the zero-temperature superfluid density $\rho_s \propto \mathscr{K}_{ii}$ and the superconducting transition temperature based on the AG theory for a disordered d-wave superconductor is shown in Fig.4.1. It has been found that for hightemperature cuprate superconductors, the experimentally observed T_c is much more robust than one would expect from the AG theory, when it is measured against the corresponding zero-temperature superfluid density. Originally, the failure has also been ascribed to the mean-field nature of the BCS-type theory in view of the fact that the normal state is a non-Fermi liquid in the optimally doped high-temperature cuprates [15]. It turns out [14] that the discrepancy between the theory and the experiment comes mainly from the inadequacy of the AG theory itself to determine the suppression of the superconducting transition temperature for high-temperature d-wave superconductors. In the AG theory, one crucial assumption in the derivation of the transition temperature is that the spatial dependence of the superconducting order is replaced by an averaged value, as shown in Fig.4.2. This assumption is only valid when the superconducting coherence ξ is much larger than the average distance between impurities l_i. The superconducting coherence length is inversely proportional to the maximal amplitude of the order parameter in the momentum

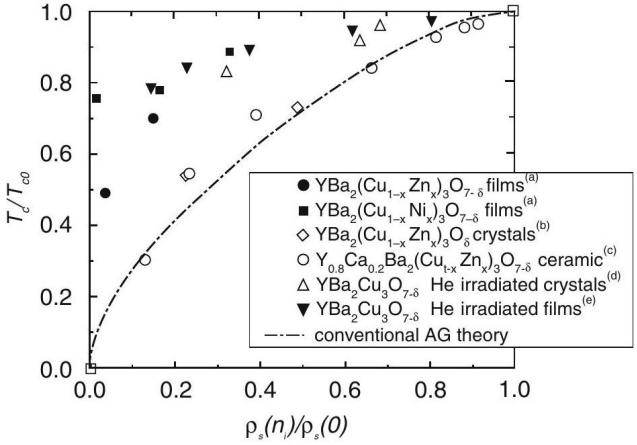

Fig. 4.1 Normalized critical temperature versus the normalized zero-temperature superfluid density. The dashed line denotes the results from the AG theory while the experimental data are represented by symbols. From [14]

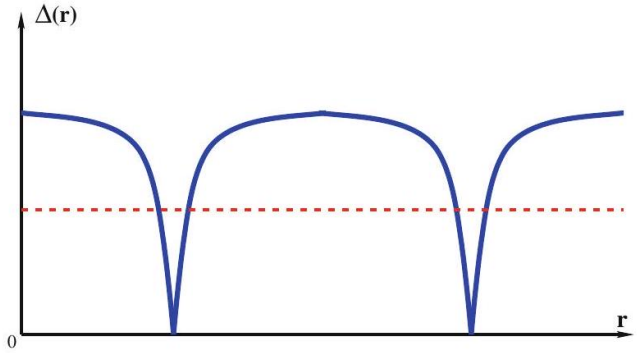

Fig. 4.2 Schematic drawing of the spatial dependence of the superconducting order param-

eter around impurities in a superconductor with a short coherence length (solid blue line). In the AG theory, it is replaced with an averaged value (dashed red line)
space and has the following form:

$$\xi(T) \approx \xi_0 \left(1 - T/T_{c0}\right)^{-1/2} \tag{4.45}$$

For a superconductor with a short coherence length, the superconducting order parameter can be recovered to the bulk value within a distance much shorter than l_i (see solid blue line in Fig. 4.2). As such, the areas of the depressed order parameter around impurities do not overlap, and the superconducting order parameter in most areas of the system is not affected at all. Only when the depressed areas begin to
overlap ($\xi(T) \gg l_i$), the entire system can be affected as if the order parameter is suppressed everywhere. This weakness of the AG theory can be fully overcome by solving the BdG equations self-consistently, in which the inhomogeneity of the superconducting order parameter is fully taken care of.

To be complete, let us re-derive the superfluid density within the lattice model. The derivation follows closely that for the optical properties discussed in Chap. 2. Again we calculate the superfluid stiffness for a current response to a vector potential of wave vector $\mathbf{q}$ and frequency ω along the x-direction in a two-dimensional square lattice through the Kubo formula. By expanding the Hamiltonian to include the interaction between electrons and an electromagnetic field, the time-dependent Hamiltonian is given by

$$\mathscr{H}_t = \mathscr{H}_{BCS} + \mathscr{H}'(t) \tag{4.46}$$

where the BCS Hamiltonian in the tight-binding model has already been discussed in Chap. 2, and $\mathscr{H}'(t)$ describes the coupling of electrons to the external electromagnetic field up to the second order

$$\mathscr{H}'(t) = -ea \sum_i A_x\left(\mathbf{r}_i, t\right) \left(J_x^P\left(\mathbf{r}_i\right) + \frac{ea}{2} A_x\left(\mathbf{r}_i, t\right) K_x\left(\mathbf{r}_i\right) \right), \tag{4.47}$$

where a is the lattice constant, A_x is the vector potential along the x-axis, and the particle current density operator

$$J_x^P\left(\mathbf{r}_i\right) = -i \sum_{\sigma,\delta} \left[t_{i,i+\delta} c_{i\sigma}^\dagger c_{i+\delta,\sigma} - \text{ H.c. } \right], \tag{4.48}$$

and the kinetic energy density operator

$$K_x\left(\mathbf{r}_i\right) = -\sum_{\sigma,\delta} \left[t_{i,i+\delta} c_{i\sigma}^\dagger c_{i+\delta,\sigma} + \text{ H.c } \right] \tag{4.49}$$

The variable $\delta = \hat{x}$ for the nearest-neighbor hopping model and $\delta = \hat{x}, \hat{x} \pm \hat{y}$ for next-nearest-hopping model. The charge current density operator along the x-axis is then found to be

$$J_x^Q\left(\mathbf{r}_i\right) \equiv -\frac{\delta \mathscr{H}'(t)}{\delta A_x\left(\mathbf{r}_i, t\right)} = e J_x^P\left(\mathbf{r}_i\right) + e^2 K_x\left(\mathbf{r}_i\right) A_x\left(\mathbf{r}_i, t\right) \tag{4.50}$$

We then calculate the paramagnetic component of the electric current density to the first order in A_x:

$$\left\langle J_x^P \left(\mathbf{r}_i \langle \right) = -i \int_{-\infty}^{t} \left\langle J_x^P(t), \mathscr{H}'\left(t'\right) \right]_- \right\rangle_0 dt' \tag{4.51}$$

while the diamagnetic part only to the zeroth order, that is, $\langle K_x \rangle_0$. Here $\langle \cdots \rangle_0$ stands for the thermodynamic average with respect to the non-perturbed $\mathscr{H}_{\rm BCS}$. The current response is then obtained as

$$-\frac{J_x^Q(\mathbf{r}_i)}{e^2 A_x(\mathbf{r}_i)} = -ie^{-\mathbf{q}\cdot\mathbf{r}_i}\int_{-\infty}^{t} dt' \left\langle \left[J_x^P(\mathbf{q},t), J_x^P(-\mathbf{q},t')\right]_- \right\rangle_0 - \langle K_x(\mathbf{r}_i)\rangle_0 \tag{4.52}$$

Please keep in mind that the variables t and t' in the vector potential and the integral boundary are the time.

We then perform a lattice average over the spatial variable $\mathbf{r}_i$ to eliminate the atomic-scale fluctuations, and define an effective "Drude weight" as a measure of the superfluid density

$$\rho_s \equiv \frac{D_s}{\pi e^2} = -\langle K_x \rangle_0 + \Pi_{xx}(\mathbf{q}\to 0, \omega = 0) \tag{4.53}$$

Here the first term

$$K_x\rangle_0 = \frac{1}{N_L}\sum_i K_{x,i} \tag{4.54}$$

with the local kinetic energy

$$K_{x,i} = -2t \sum_{n(E_n\geq 0)} \left(f(E_n)\left[u_{i+\hat{x}}^{n*}u_i^n + \text{c.c}\right] + f(-E_n)\left[v_{i+\hat{x}}^n n_i^{n*} + \text{c.c}\right]\right). \tag{4.55}$$

The second term is the current-current correlation function with a double sum over lattice sites

$$\Pi_{xx}(\mathbf{q}\to 0;\omega = 0) = \frac{1}{N_L}\sum_{i,j}\Pi_{xx}^{ij}(\omega = 0), \tag{4.56}$$

where

$$\Pi_{xx}^{ij}(\omega = 0) = \sum_{n_1\left(E_{n_1}\geq 0\right), n_2\left(E_{n_2}\geq 0\right)} A_{n_1,n_2}^i \left[A_{n-1,n_2}^{j*} + D_{n_1,n_2}^j\right] \frac{f(E_{n_1}) - f(E_{n_2})}{E_{n_1} - E_{n_2}} \tag{4.57}$$

with

$$A_{n_1,n_2}^i = 2\left[u_{i+\hat{x}}^{n_1*}u_i^{n_2} - u_i^{n_1*}u_{i+\hat{x}}^{n_2}\right], \tag{4.58a}$$

$$D_{n_1,n_2}^i = 2\left[v_{i+\hat{x}}^{n_1}v_i^{n_2*} - v_i^{n_1}v_{i+\hat{x}}^{n_2*}\right]. \tag{4.58b}$$

Typical results from the solution to the BdG equations are shown in Fig.4.3. As the superconducting coherence length increases, the discrepancy between the

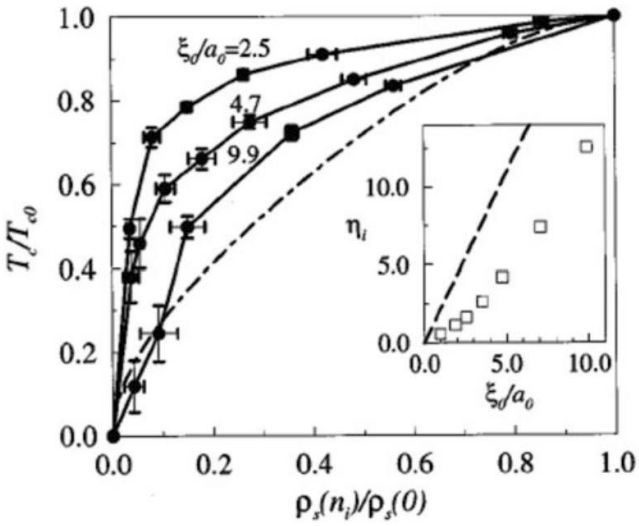

Fig. 4.3 Normalized critical temperature versus the normalized zero-temperature superfluid density obtained from a fully self-consistent solution to the BdG equations in a tight-binding model. The dashed line denotes the results from the AG theory. From [14]

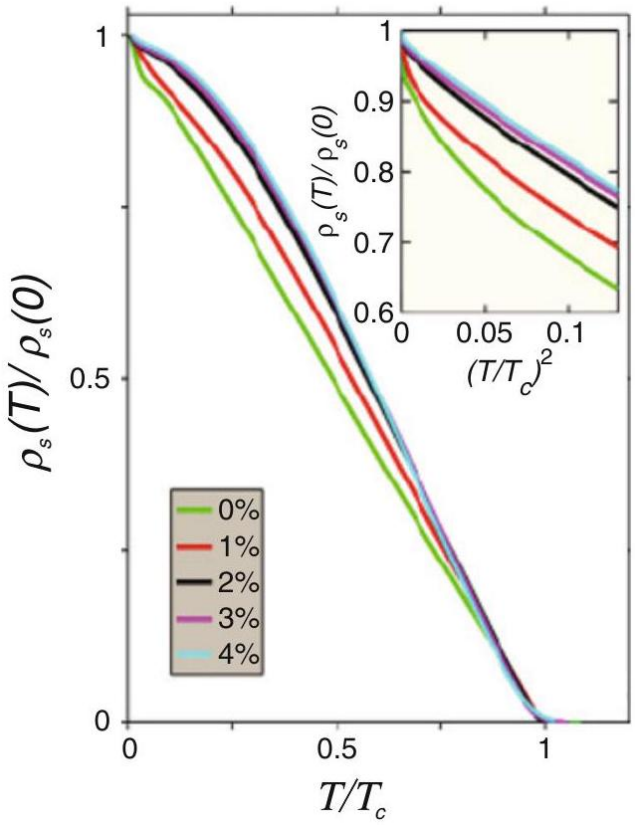
rigorous critical temperature and that from the AG theory diminishes. However, at a very short coherence, the result from the AG theory deviates significantly from the true T_c. In addition, the typical temperature-dependence of the superfluid stiffness is shown in Fig. 4.4. The pileup of the impurity resonance states near the Fermi energy in a disordered d-wave superconductor gives rise to the T^2-dependence of the superfluid stiffness at low temperatures. Increase of the impurity concentration expands the temperature range for the T^2 behavior of ρ_s before it turns into a T linear behavior.

13.2.3 4.3 Quasiparticle Localization in a Disordered d-Wave Superconductor

In Sect. 3.4, we have shown that a single impurity in the unitary scattering limit can produce a zero-energy quasiparticle resonance states. These states have a long decay distance away from the impurity site. A natural question arises as to whether the possible overlap of these states in an ensemble of unitary impurities can create extended low-energy quasiparticle states. We consider this question by using the one-parameter scaling analysis. The one-parameter scaling analysis [17, 18] has been a popular method to study the electronic localization/delocalization in Anderson disordered metals. Our discussion is based on the transfer matrix method and follows that of MacKinnon and Kramer [19] for the disordered solids. To discuss the two-dimensional d-wave disordered superconductors, we first consider a system

Fig. 4.4 Temperature dependence of the normalized superfluid density calculated from a full self-consistent solution to the BdG equations in a two-dimensional lattice model with nearest-neighbor hopping approximation. From [16]



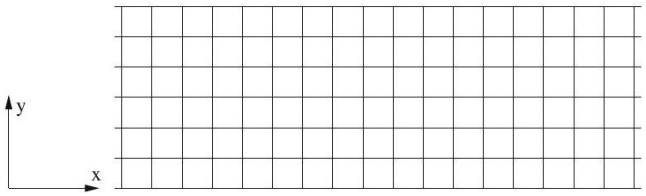


Fig. 4.5 Schematic drawing of a quasi-one-dimensional strip

of electrons defined on a quasi-one-dimensional strip. When the strip width goes to infinity, the strip is expanded into a two-dimensional lattice. The geometry is shown in Fig. 4.5.

We write down the Anderson Hamiltonian as

$$\mathscr{H} = -\sum_{ij} t_{ij} c_i^\dagger c_j + \sum_i \epsilon_i c_i^\dagger c_i \tag{4.59}$$

Here the site index $i = (i_x, i_y)$ with the two components defined in the coordinate system shown in Fig. 4.5 and the variable ϵ_i is on-site potential for the disorder effect. For simplicity of discussion, we have neglected the spin index for electrons. By performing a canonical transformation,

$$c_i = \sum_n \phi_i^n \gamma_n, \tag{4.60}$$

with γ_n is the quasiparticle operator, the problem becomes to solve the Schrödinger equation

$$\sum_j H_{ij}\phi_j = E\phi_i \tag{4.61}$$

In the nearest-neighbor hopping approximation, the expanded form of the above equation is

$$\phi_{i_x+1,i_y} = -E\phi_{i_x,i_y} + \epsilon_{i_x,i_y}\phi_{i_x,i_y} - \phi_{i_x,i_y+1} - \phi_{i_x,i_y-1} - \phi_{i_x-1,i_y}. \tag{4.62}$$

Here we have used the nearest-neighbor hopping parameter $t = 1$ and measured the energy in units of t. We introduce a column vector to denote the coefficients of the i_x-th one-dimensional slice (along the y-direction),

$$\hat{\phi}_{i_x} = \begin{pmatrix} \phi_{i_x,1} \\ \phi_{i_x,2} \\ \cdots \\ \phi_{i_x,M} \end{pmatrix} \tag{4.63}$$

where M is the width of the strip. Equation (4.62) can then be cast into a matrix form

$$\begin{pmatrix} \hat{\phi}_{i_x+1} \\ \hat{\phi}_{i_x} \end{pmatrix} = T_{i_x} \begin{pmatrix} \hat{\phi}_{i_x} \\ \hat{\phi}_{i_x-1} \end{pmatrix}. \tag{4.64}$$

Here the transfer matrix is given by

$$T_{i_x} = \begin{pmatrix} -\left(E\hat{1} - \hat{H}_{i_x}\right) - \hat{1} & \\ \hat{1} & \hat{0} \end{pmatrix} \tag{4.65}$$

where the $\hat{H}_{i_x}$ is the Hamiltonian for the i_x-th slice of the quasi-one-dimensional strip when it is not coupled to the rest. Equation (4.64) gives us a recursion formula for the coefficients $\hat{\phi}_{i_x}$. That is, if we are given the initial coefficients $\hat{\phi}_0$ and $\hat{\phi}_1$, the coefficient $\hat{\phi}_n$ can be obtained through the accumulated transfer matrix

$$P_n = \prod_{i_x=1}^{n} T_{i_x} \tag{4.66}$$

That is,

$$\begin{pmatrix} \hat{\phi}_{n+1} \\ \hat{\phi}_n \end{pmatrix} = P_n \begin{pmatrix} \hat{\phi}_1 \\ \hat{\phi}_0 \end{pmatrix}. \tag{4.67}$$

The matrix P_n satisfies the Oseledec's multiplicative ergodic theorem [20, 21]: For any initial vector

$$\begin{pmatrix} \hat{\phi}_1 \\ \hat{\phi}_0 \end{pmatrix}, \tag{4.68}$$

there exits an orthonormal set of vectors $v_i (1 \leq i \leq 2M)$ such that

$$\gamma_i = \lim_{n\to\infty} \frac{1}{n} \ln \|P_n v_i\| \tag{4.69}$$

exists. Due to the ergodicity of the system, the set of values $\{\gamma_i\}$ are independent on the initial values of the coefficients $\left(\hat{\phi}_1, \hat{\phi}_0\right)^{\text{Transpose}}$, and thus they describe the global properties of the system. The γ_i can be calculated as the log of the eigenvalues of

$$\left[P_n P_n^{\dagger}\right]^{\frac{1}{2n}} \tag{4.70}$$

The vector v_i are now the eigenvectors of $P_n P_n^{\dagger}$ and are indecent of n for large n. In another word, the matrix $\left[P_n P_n^{\dagger}\right]^{\frac{1}{2n}}$ converges to a limiting matrix when $n \to \infty$, which determines the modulus of the eigenvalues of P_n and the corresponding eigenvectors. We note that the matrix P_n is not hermitian and the eigenvalues are in general complex. The eigenvectors v_i can also be called Lyapunov eigenvectors, which determine the properties of electronic states of disordered systems.

With the above introduction, let us turn to the case of disordered d-wave superconductors, where further technical details will be discussed on the calculation of the localization length. In the presence of disorder, the BdG equations (2.30) become

$$\begin{cases} E_n u_i^n = \sum_j h_{ij} u_j^n + \sum_j \Delta_{ij} v_j^n, \\ E_n v_i^n = -\sum_j h_{ij}^* v_j^n + \sum_j \Delta_{ji}^* u_j^n \end{cases} \tag{4.71}$$

where the single particle Hamiltonian

$$h_{ij} = -t_{ij} + (\epsilon_i - \mu)\,\delta_{ij} \tag{4.72}$$

with ϵ_i the on-site potential and μ the chemical potential. We assume the bond pair potential Δ_{ij}^* to be real and neglect the depression effect of the impurity scattering to take $\Delta_{ij} = \Delta$. The above equation in the nearest-neighbor hopping approximation is expanded as:

$$\begin{aligned} \left(E - \left(\epsilon_{i_x,i_y} - \mu\right)\right) u_{i_x,i_y} =& - t u_{i_x+1,iy} - t u_{i_x-1,iy} - t u_{i_x,i_y+1} - t u_{i_x,i_y-1} \\ &+ \Delta v_{i_x+1,iy} + \Delta v_{i_x-1,i_y} + \Delta v_{i_x,i_y+1} \\ &+ \Delta v_{i_x,i_y-1} \end{aligned} \tag{4.73a}$$

$$\begin{aligned} \left(E + \left(\epsilon_{i_x,i_y} - \mu\right)\right) v_{i_x,i_y} =& t v_{i_x+1,iy} + t v_{i_x-1,iy} + t v_{i_x,i_y+1} + t v_{i_x,i_y-1} \\ &+ \Delta u_{i_x+1,i_y} + \Delta u_{i_x-1,i_y} + \Delta u_{i_x,i_y+1} \\ &+ \Delta u_{i_x,i_y-1} \end{aligned} \tag{4.73b}$$

As for the normal state case ($\Delta = 0$), we introduce a column vector

$$\hat{\phi}_{i_x} = \begin{pmatrix} u_{i_x,1} \\ u_{i_x,2} \\ \cdots \\ u_{i_x,M} \\ v_{i_x,1} \\ v_{i_x,2} \\ \cdots \\ v_{i_x,M} \end{pmatrix}. \tag{4.74}$$

Now this vector has a dimension of $2M$. Equations (4.73) can be recast into a matrix form:

$$\begin{pmatrix} \hat{\phi}_{i_x+1} \\ \hat{\phi}_{i_x} \end{pmatrix} = T_{i_x} \begin{pmatrix} \hat{\phi}_{i_x} \\ \hat{\phi}_{i_x-1} \end{pmatrix} \tag{4.75}$$

Here the transfer matrix is

$$T_{i_x} = \begin{pmatrix} -\left(E\hat{1} - \hat{H}_{i_x}\right) - \hat{1} & \\ \hat{1} & 0 \end{pmatrix} \tag{4.76}$$

where

$$\hat{H}_{i_x} = \sum_{j_y} \begin{pmatrix} -t\delta_{j_y,i_y\pm1} + \left(\epsilon_{i_x,i_y} - \mu\right)\delta_{j_y,i_y} & \Delta\delta_{j_y,i_y\pm1} \\ \Delta\delta_{j_y,i_y\pm1} & t\delta_{j_y,i_y\pm1} - \left(\epsilon_{i_x,i_y} - \mu\right)\delta_{j_y,i_y} \end{pmatrix}. \tag{4.77}$$

is the BdG Hamiltonian for the i_x-slice when it is decoupled from the rest. The transfer matrix for the entire strip is given by

$$P_n = \prod_{i_x=1}^{n} T_{i_x} \tag{4.78}$$

connecting the coefficients at the left and right end of the strips

$$\begin{pmatrix} \hat{\phi}_{n+1} \\ \hat{\phi}_n \end{pmatrix} = P_n \begin{pmatrix} \hat{\phi}_1 \\ \hat{\phi}_0 \end{pmatrix}. \tag{4.79}$$

The system transfer matrix satisfies the Oseledec's multiplicative ergodic theorem. It allows to determine the localization length through the eigenvalues of $\left[P_n P_n^\dagger\right]^{1/2n}$ in the limit of $n \to \infty$. Specifically, the matrix

$$\Omega = \ln\left(P_n P_n^\dagger\right), \tag{4.80}$$

leads to $4M$ eigenvalues $\lambda_i (1 \le i \le 4M)$. Lyapunov exponents can then be defined as

$$\gamma_i = \lim_{n\to\infty} \frac{\lambda_i}{2n} \tag{4.81}$$

$$= \lim_{n\to\infty} \tilde{\lambda}_i \tag{4.82}$$

where $\tilde{\lambda}_i$ are the eigenvalues of the matrix $\ln\left(P_n P_n^\dagger\right)^{1/2n}$. Since the matrix P_n is symplectic, the eigenvalues of Ω occur in pairs, which are of opposite sign. The smallest positive Lyapunov exponent is the inverse of the quasi-one dimensional localization length

$$\lambda = \frac{1}{\gamma_{2M}}, \tag{4.83}$$

when we label the exponents in a decreasing order. In practical calculations, the eigenvalues of the matrix $e^\Omega = P_n P_n^\dagger \sim e^{2\gamma_i n}$ rises exponentially with the length of the strip. When the ratio of the eigenvalue closest to the unity from above and the largest eigenvalue becomes comparable to the machine accuracy, this closest to unity eigenvalue is lost. However, it is this eigenvalue that determines the localization length. This difficulty can be overcome by following the GrammSchmidt orthonormalization procedure, which is carried out for each column $B_{n,i}$ of the matrix P_n in succession:

$$\bar{B}_{n,i} = \left(B_{n,i} - \sum_{j<i} \left(\bar{B}_{n,j} \cdot B_{n,i}\right) \bar{B}_{n,j} \right) / b_n^{(i)}, \tag{4.84a}$$

$$b_n^{(i)} = \left| B_{n,i} - \sum_{j<i} \left(\bar{B}_{n,j} \cdot B_{n,i}\right) \bar{B}_{n,j} \right|, \tag{4.84b}$$

for $1 \le i \le 4M$. Through this procedure, each column is orthonormalized to the previous columns. The first column converges to the eigenvector corresponding to the largest eigenvalue, the second column to the second largest and so on. The Gramm-Schmidt transformation can be performed regularly (e.g., every fifth step) but not necessarily at every stage of iteration.

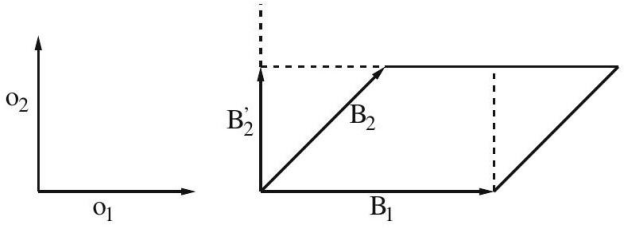

Fig. 4.6 The action of the system transfer matrix on an arbitrary set of orthonormal vectors o_1 and o_2 generates a new set of vectors of B_1 and B_2, which are orthogonalized by the Gramm-Schmidt procedure. However, the area of the parallelogram formed by B_1 and B_2 vectors is preserved

Pictorially, we can think of having P_n acting on a set of orthonormal unit vectors $o_i (1 \leq i \leq 4M)$ to generate a new set of vectors

$$B_i = P_n o^i \tag{4.85}$$

as shown in Fig. 4.6. They are just the columns of the transfer matrix itself. Notice that $B_1 \times B_2' = B_1 \times B_2$ with $B_2' = \bar{B}_2 * b^{(2)}$, and so on. The Gramm-Schmidt orthogonalization procedure preserves the area of a parallelogram formed by two vectors B_i and B_j. This process can be iterated successively through the entire strip, and the eigenvalues are given by

$$e^{n\gamma_1} = b^{(1)}(n_1)\, b^{(1)}(n_2) \ldots, \tag{4.86a}$$
$$e^{n\gamma_2} = b^{(2)}(n_1)\, b^{(2)}(n_2) \ldots, \tag{4.86b}$$
$$\cdots = \cdots, \tag{4.86c}$$
$$e^{n\gamma_{2M}} = b^{(2M)}(n_1)\, b^{(2M)}(n_2) \ldots, \tag{4.86d}$$
$$e^{n\gamma_{2M+1}} = b^{(2M+1)}(n_1)\, b^{(2M)}(n_2) \ldots, \tag{4.86e}$$
$$\cdots = \cdots \tag{4.86f}$$
$$e^{n\gamma_{4M-1}} = b^{(4M-1)}(n_1)\, b^{(4M-1)}(n_2) \ldots, \tag{4.86 g}$$
$$e^{n\gamma_{4M}} = b^{(4M)}(n_1)\, b^{(4M)}(n_2) \ldots, \tag{4.86h}$$

where $n = n_1 + n_2 + \ldots$. For the symplectic matrix P_n, the eigenvalues occur in pairs,

$$n\gamma_1, n\gamma_2, \cdots, n\gamma_{2M}, \frac{1}{n\gamma_{2M}}, \cdots, \frac{1}{n\gamma_2}, \frac{1}{n\gamma_1}, \tag{4.87}$$

where we have arranged them in descending order. As such, we have the following relation

$$n\gamma_{2M} = \frac{n}{\lambda} = \ln b_{n_1}^{(2M)} + \ln b_{n_2}^{(2M)} + \ldots \tag{4.88}$$

from which the localization length can be calculated iteratively

$$\lambda = \frac{n}{c_n^{(2M)}} \tag{4.89}$$

with

$$c_n^{(2M)} = \ln b_n^{(2M)} + c_{n-1}^{(2M)}. \tag{4.90}$$

More generally, we can define a channel dependent localization length

$$\lambda_i = \frac{n}{c_n^{(i)}}, \tag{4.91}$$

with

$$c_n^{(i)} = \ln b_n^{(i)} + c_{n-1}^{(i)}, \tag{4.92}$$

for $1 \leq i \leq 2M$. Since the spin carried by a quasiparticle in a superconductor is conserved [23], these localization lengths can then be used to determine the spin conductance for the strip with width M [24]:

$$g_s(M, n_i) = \sum_{j=1}^{2M} \cosh^{-2} \Lambda_j, \tag{4.93}$$

where $\Lambda_j = \lambda_j / M$ is the localization length in units of the strip width. In Fig. 4.7a, g_s is shown as a function of M and it monotonically decreases with the increase of M at $E = 0$ for each selected impurity density, indicative of a localization in the large M limit. In addition, as shown in Fig. 4.7b, all the data for various values of M at different n_i can be collapsed onto a single curve:

$$g_s(M, n_i) = f\left(\frac{\xi(n_i)}{M}\right) \tag{4.94}$$

so that the one-parameter scaling law is obeyed. The quantity $\xi(n_i)$ is the thermodynamic localization length which only depends on n_i as shown in the inset of Fig. 4.7b, and remains finite for all the disorder density n_i, suggesting that all the

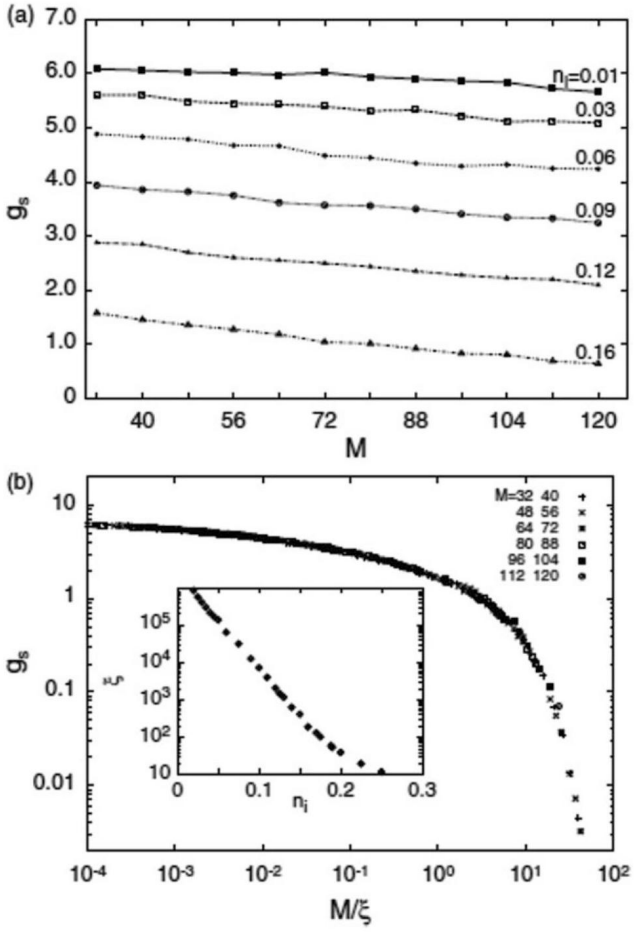

Fig. 4.7 Spin conductance as a function of the strip width M for various values of impurity concentration (a) and as a scaling function of M/ξ (b). Inset of (b): The thermodynamic localization length as a function of impurity concentration n_i. The energy of the quasiparticle state is $E = 0$. From [22]

states are localized even in the unitary limit with the presence of the zero energy resonance peak.

We remark that this scaling approach can also be applied to study the localization and delocalization in disordered topological superconductors.

13.3 5 Local Electronic Structure in Superconductors Under a Magnetic Field

Abstract

In this chapter, the calculation of local electronic structure in the presence of magnetic field is discussed. It starts with the continuum theory for a single vortex and proceeds to the lattice version for the vortex lattices in both conventional s-wave and unconventional d-wave superconductors. A generalization of the BdG formulation for a topological superconductor will be briefly explored. For high- T_c cuprates, the local induction of competing order around a magnetic vortex core is examined. Finally, the Zeeman-field induced FFLO superconducting state is also analyzed in depth.

13.3.1 5.1 Effect of the Magnetic Field

In Chap. 1, we have addressed the non-interacting electron part of the Hamiltonian in the absence of static electric and magnetic field. Since the magnetic field effect on the superconducting properties is unique, we give it an in-depth discussion here. The second quantized Hamiltonian for electrons in the presence of a static magnetic filed is

$$\mathscr{H}_0 = \int d\mathbf{r}\psi_\alpha^\dagger(\mathbf{r})h_\alpha(\mathbf{r})\psi_\alpha(\mathbf{r}) \tag{5.1}$$

Here the single-particle Hamiltonian

$$h_\alpha(\mathbf{r}) = \frac{\left[\frac{\hbar}{i}\nabla_\mathbf{r} + \frac{e}{c}\mathbf{A}(\mathbf{r})\right]^2}{2m_e} + V(\mathbf{r}) + \alpha\mu_B H(\mathbf{r}) - E_F, \tag{5.2}$$

where $\mathbf{A}(\mathbf{r})$ is the vector potential giving rise to the magnetic field $\mathbf{H}(\mathbf{r})$ (assumed to be along the z-direction of the spin axis)

$$\nabla \times \mathbf{A}(\mathbf{r}) = \mathbf{H}(\mathbf{r}) \tag{5.3}$$

$V(\mathbf{r})$ is the Coulomb potential contributed from the nuclear ions, and the third term in Eq. (5.2) describes the coupling of electron spin moment to the magnetic field.

The magnetic field has effects through both electron orbital and spin degrees of freedom. For the purpose of this chapter, we neglect the effect of spin-orbit coupling.

In wide-band systems, where $V(\mathbf{r})$ varies slowly, the free-electron gas approximation is usually made and the continuum model is a choice to study the magnetic field effect. For narrow-band systems, where the band structure effect is important, the tight-binding model is more convenient. Therefore, it is helpful to obtain the single-particle tight-binding Hamiltonian for the orbital effect of the magnetic field. The derivation follows that by Luttinger [1]. In the presence of a magnetic field, we expand the field operators as

$$\psi_\sigma(\mathbf{r}) = \sum_{\mathbf{R}_i} a\left(\mathbf{r} - \mathbf{R}_i\right) e^{-ie\Lambda_i/\hbar c} c_{i\sigma} \tag{5.4}$$

Here $a\left(\mathbf{r} - \mathbf{R}_i\right)$ are either maximally localized Wannier functions or atomic orbitals. They are localized about the lattice site $\mathbf{R}_i$ and drop off rapidly as $\mathbf{r}$ goes away from $\mathbf{R}_i$. The operator $c_{i\sigma}$ annihilates one electron of spin σ at site i. The integral

$$\Lambda_i = \int_{\mathbf{R}_i}^{\mathbf{r}} \mathbf{A}(\boldsymbol{\xi}) \cdot d\boldsymbol{\xi} \tag{5.5a}$$

$$\equiv \int_0^1 \left(\mathbf{r} - \mathbf{R}_i\right) \cdot \mathbf{A}\left(\mathbf{R}_i + \lambda\left(\mathbf{r} - \mathbf{R}_i\right)\right) d\lambda, \tag{5.5b}$$

is taken along the straight line path joining $\mathbf{R}_i$ to $\mathbf{r}$. The exponential factor in Eq. (5.4) has the effect of approximately removing the troublesome $\mathbf{A}\cdot\mathbf{P}$ and $\mathbf{P}\cdot\mathbf{A}$ terms. We consider

$$\left(\mathbf{P}+\frac{e\mathbf{A}(\mathbf{r})}{c}\right)a\left(\mathbf{r}-\mathbf{R}_i\right)e^{-ie\Lambda_i/\hbar c}=e^{-ie\Lambda_i/\hbar c}\left[\mathbf{P}-\frac{e\nabla\Lambda_i}{c}+\frac{e\mathbf{A}(\mathbf{r})}{c}\right]a\left(\mathbf{r}-\mathbf{R}_i\right), \tag{5.6}$$

which leads to

$$\left(\mathbf{P}+\frac{e\mathbf{A}(\mathbf{r})}{c}\right)^2 a\left(\mathbf{r}-\mathbf{R}_i\right)e^{-ie\Lambda_i/\hbar c}=e^{-ie\Lambda_i/\hbar c}\left[\mathbf{P}-\frac{e\nabla\Lambda_i}{c}+\frac{e\mathbf{A}(\mathbf{r})}{c}\right]^2 a\left(\mathbf{r}-\mathbf{R}_i\right) \tag{5.7}$$

We then use the identities

$$\nabla\times\mathbf{r}=0,\quad(\mathbf{A}\cdot\nabla)\mathbf{r}=\mathbf{A} \tag{5.8}$$

$$\nabla\times\mathbf{A}\left(\mathbf{R}_i+\lambda\left(\mathbf{r}-\mathbf{R}_i\right)\right)=\lambda\mathbf{H}\left(\mathbf{R}_i+\lambda\left(\mathbf{r}-\mathbf{R}_i\right)\right), \tag{5.9}$$

while

$$\begin{aligned}\int_0^1\mathbf{A}\left(\mathbf{R}+\lambda\left(\mathbf{r}-\mathbf{R}_i\right)\right)=&\ \lambda\mathbf{A}\left(\mathbf{R}_i+\lambda\left(\mathbf{r}-\mathbf{R}_i\right)\right)\big|_0^1-\int_0^1 d\lambda\lambda\frac{d\mathbf{A}\left(\mathbf{R}_i+\lambda\left(\mathbf{r}-\mathbf{R}_i\right)\right)}{d\lambda}\\&=\mathbf{A}(\mathbf{r})-\int_0^1 d\lambda\left(\left(\mathbf{r}-\mathbf{R}_i\right)\cdot\nabla\right)\mathbf{A}\end{aligned} \tag{5.10}$$

and prove that

$$\nabla\Lambda_i=\mathbf{A}(\mathbf{r})+\int_0^1 d\lambda\lambda\left(\mathbf{r}-\mathbf{R}_i\right)\times\mathbf{H}\left(\mathbf{R}_i+\lambda\left(\mathbf{r}-\mathbf{R}_i\right)\right) \tag{5.11}$$

By substituting Eq.(5.4) into Eq.(5.1), and using the expressions Eq.(5.7) and Eq. (5.11), one arrives at

$$\mathscr{H}_0=\sum_{ij,\sigma}\tilde{h}_{ij}c_{i\sigma}^{\dagger}c_{j\sigma} \tag{5.12}$$

where the field-modified one-electron Hamiltonian is given by

$$\begin{aligned}\tilde{h}_{ij}=\int d\mathbf{r}a^*\left(\mathbf{r}-\mathbf{R}_i\right)e^{ie(\Lambda_i-\Lambda_j)/\hbar c}\Bigg\{\frac{1}{2m_e}\Bigg(\mathbf{P}-\frac{e}{c}\int_0^1 d\lambda\lambda\left(\mathbf{r}-\mathbf{R}_i\right)\times\mathbf{H}\left(\mathbf{R}_j+\lambda\left(\mathbf{r}-\mathbf{R}_j\right)\right)^2\\+V(\mathbf{r})-E_F\Bigg\}a\left(\mathbf{r}-\mathbf{R}_j\right).\end{aligned} \tag{5.13}$$

We may now invoke the fact that the function a_i is localized, which allows us to approximate $\mathbf{r}\approx\mathbf{R}_j$ in the integral over λ in the above integral, as long as the magnetic fields are not varying too rapidly. This approximation leads to

$$\tilde{h}_{ij}=-t_{i\neq j}e^{i\varphi_{ij}}+\left(\epsilon_i-E_F\right)\delta_{ij} \tag{5.14}$$

where

$$t_{ij}=-\int d\mathbf{r}a^*\left(\mathbf{r}-\mathbf{R}_i\right)\left(\frac{\mathbf{p}^2}{2m_e}+V(\mathbf{r})\right)a\left(\mathbf{r}-\mathbf{R}_j\right) \tag{5.15}$$

is the hopping integral in the absence of magnetic field, and the Peierls phase is given by

$$\begin{aligned}\varphi_{ij} &= -\frac{e}{\hbar c}\int_{\mathbf{R}_j}^{\mathbf{R}_i}\mathbf{A}(\boldsymbol{\xi})\cdot\boldsymbol{\xi} \\ &= -\frac{2\pi}{\Phi_0}\int_{\mathbf{R}_j}^{\mathbf{R}_i}\mathbf{A}(\boldsymbol{\xi})\cdot\boldsymbol{\xi}\end{aligned} \tag{5.16}$$

Here the single-electron flux quantum is

$$\Phi_0 = \frac{hc}{e} \tag{5.17}$$

with h the Planck constant. The phase factor modifying the hopping integral is called as the Peierls substitution [2].

The spin Zeeman exchange interaction term can be easily found as

$$\sum_{i\sigma}\sigma\mu_B H_i c_{i\sigma}^{\dagger}c_{i\sigma} \tag{5.18}$$

in the tight-binding model, where H_i is an effective magnetic field at site i.
We conclude this section by summarizing the BdG equations in the presence of magnetic field:

$$\begin{cases} \tilde{h}_{\sigma}(\mathbf{r})u_{\sigma}^{n}(\mathbf{r}) + \int d\mathbf{r}'\Delta\left(\mathbf{r},\mathbf{r}'\right)v_{\bar{\sigma}}^{n}\left(\mathbf{r}'\right) = E_n u_{\sigma}^{n}(\mathbf{r}) \\ \int d\mathbf{r}'\Delta^{*}\left(\mathbf{r}',\mathbf{r}\right)u_{\sigma}^{n}\left(\mathbf{r}'\right) - \tilde{h}_{\bar{\sigma}}^{*}(\mathbf{r})v_{\bar{\sigma}}^{n}(\mathbf{r}) = E_n v_{\bar{\sigma}}^{n}(\mathbf{r}) \end{cases} \tag{5.19}$$

in the continuum limit, and

$$\begin{cases} E_n u_{i\sigma}^{n} = \sum_j \tilde{h}_{ij,\sigma}u_{j\sigma}^{n} + \sum_j \Delta_{ij}v_{j\bar{\sigma}}^{n}, \\ E_n v_{i\bar{\sigma}}^{n} = -\sum_j \tilde{h}_{ij,\bar{\sigma}}^{*}v_{j\bar{\sigma}}^{n} + \sum_j \Delta_{ji}^{*}u_{j\sigma}^{n}, \end{cases} \tag{5.20}$$

in the tight-binding model.

13.3.2 5.2 Vortex Core State in an s-Wave Superconductor

13.3.3 5.2.1 Single Isolated Vortex

The study of the single vortex line of an s-wave superconductor based on the BdG theory has been initiated with the seminal work by Caroli, de Gennes, and Matricon [3-5] and later by Bardeen et al. [6], in which various approximations were used. Later on, Shore et al. [7] and Gygi and Schlüter [8] obtained numerical solutions for quasiparticle amplitudes in a vortex core starting with approximate forms for the pair potential. It is important to note that, in these two calculations, the pair potential used as input was modeled from the experimentally inferred coherence length. The effect of the spatial dependence of the magnetic field was neglected, which seems to be justified when the GL parameter $\kappa \equiv \lambda/\xi$ is large, where λ and ξ are the penetration depth and coherence length, respectively.

Here we consider a single vortex in a two-dimensional s-wave superconductor. When the magnetic field is applied perpendicular to the 2D plane, the orbital effect is dominant over the spin Zeeman effect. By introducing the polar coordinate system
$\mathbf{r} = (r,\theta)$, the pair potential should have the form

$$\Delta(\mathbf{r}) = \Delta(r)e^{-i\theta} \tag{5.21}$$

It suggests that we can write the eigenfunctions as

$$\begin{pmatrix} u_n(\mathbf{r}) \\ v_n(\mathbf{r}) \end{pmatrix} = \begin{pmatrix} u_{j\mu} e^{i(\mu-1/2)\theta} \\ v_{j\mu} e^{i(\mu+1/2)\theta} \end{pmatrix},$$

which leads to the BdG equations

$$\begin{aligned} E_{j\mu} u_{j\mu}(r) =& \frac{\hbar^2}{2m_e} \left(-\frac{d^2 u_{j\mu}(r)}{dr^2} - \frac{1}{r}\frac{du_{j\mu}(r)}{dr} + \frac{(\mu-1/2)^2 u_{j\mu}(r)}{r^2} \right) - E_F u_{j\mu}(r) \\ &+ \Delta(r) v_{j\mu}(r) \qquad (5.22a) \\ E_{j\mu} v_{j\mu}(r) =& -\frac{\hbar^2}{2m_e} \left(-\frac{d^2 v_{j\mu}(r)}{dr^2} - \frac{1}{r}\frac{dv_{j\mu}(r)}{dr} + \frac{(\mu+1/2)^2 v_{j\mu}(r)}{r^2} \right) + E_F v_{j\mu}(r) \\ &+ \Delta(r) u_{j\mu}(r). \qquad (5.22b) \end{aligned}$$

Here the pair potential amplitude

$$\Delta(r) = \frac{U}{2} \sum_{j\mu(|E_{j\mu}| \le \omega_D)} u_{j\mu}(r) v_{j\mu}(r) \tanh\left(\frac{E_{j\mu}}{2k_{BT}} \right) \qquad (5.23)$$

is determined self-consistently, where U is an effective pairing interaction and ω_D is the cutoff. The azimuthal quantum number $|\mu| = \frac{1}{2}, \frac{3}{2}, \frac{5}{2}, \ldots$.

We first focus on solutions to the BdG equations (5.22) by following the original work by Caroli, de Gennes, and Matricon [3] and that in [9] in the assumption that the pair potential is known with a shape schematically drawn in Fig.5.1. Equations (5.22) can be rewritten as:

$$\begin{aligned} &\frac{\hbar^2}{2m_e} \left(-\frac{d^2 u_{j\mu}(r)}{dr^2} - \frac{1}{r}\frac{du_{j\mu}(r)}{dr} + \frac{(\mu^2+1/4)\, u_{j\mu}(r)}{r^2} \right) - E_F u_{j\mu}(r) + \Delta(r) v_{j\mu}(r) \\ &= \left(E_{j\mu} + \frac{\mu\hbar^2}{2m_e r^2} \right) u_{j\mu}(r) \qquad (5.24a) \\ &-\frac{\hbar^2}{2m_e} \left(-\frac{d^2 v_{j\mu}(r)}{dr^2} - \frac{1}{r}\frac{dv_{j\mu}(r)}{dr} + \frac{(\mu^2+1/4)\, v_{j\mu}(r)}{r^2} \right) + E_F v_{j\mu}(r) + \Delta(r) u_{j\mu}(r) \\ &= \left(E_{j\mu} + \frac{\mu\hbar^2}{2m_e r^2} \right) v_{j\mu}(r) \qquad (5.24b) \end{aligned}$$

We now introduce a radius r_c very close to the vortex core center, that is,

$$(\mu + 1/2) k_F^{-1} \ll r_c \ll \xi$$

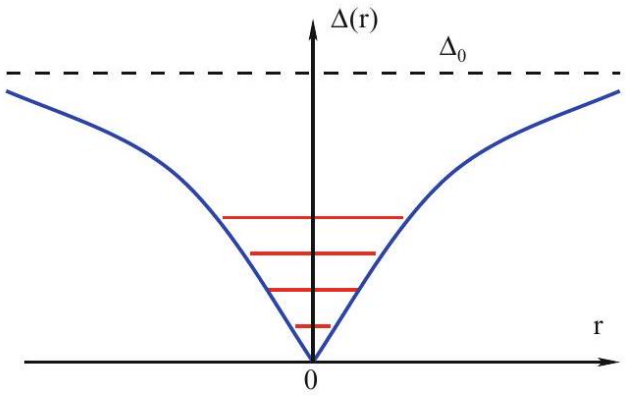

Fig. 5.1 The amplitude of superconducting order parameter $\Delta(r)$ around a single vortex core line. It vanishes at the core center $r = 0$ while rises to the bulk magnitude Δ_0 over a characteristic length ξ. The quasiparticle states with energies (red lines) smaller than the superconducting gap Δ_0 are bound near the vortex core center

For $r < r_c, \Delta(r)$ approaches to zero and we can neglect it in Eqs. (5.24), and obtain the solution as

$$\begin{pmatrix} u_\mu(r) \\ v_\mu(r) \end{pmatrix} = \begin{pmatrix} A_+ J_{\mu-\frac{1}{2}}\left[(k_F+q)\,r\right] \\ A_- J_{\mu+\frac{1}{2}}\left[(k_F-q)\,r\right] \end{pmatrix} \tag{5.25}$$

where k_F is the Fermi wave number, $q = E/\hbar v_F$ with $v_F = \hbar k_F/m_e$, and J_μ is the Bessel function. Here we have used the approximation

$$\left(k_F^2 \pm \frac{2m_e E}{\hbar^2}\right)^{1/2} \approx k_F \pm q \tag{5.26}$$

For $r > r_c$, we use the fact that the Hankel function $H_\mu(k_F r)$ satisfies the Bessel ordinary differential equation:

$$\frac{d^2 H_\mu(k_F r)}{dr^2} + \frac{1}{r}\frac{dH_\mu(k_F r)}{dr} + \left(k_F^2 - \frac{\mu^2}{r^2}\right) H_\mu(k_F r) = 0 \tag{5.27}$$

to separate this fast oscillating component out of the wave function and write in the form

$$\begin{pmatrix} u_\mu(r) \\ v_\mu(r) \end{pmatrix} = \begin{pmatrix} R_+(r) H_{\tilde{\mu}}(k_F r) + \text{ c.c} \\ R_-(r) H_{\tilde{\mu}}(k_F r) + \text{ c.c.} \end{pmatrix} \tag{5.28}$$

where the functions $R_\pm(r)$ are varying slowly in space, and the quantum number $\tilde{\mu} = \sqrt{\mu^2 + 1/4}$. Substituting Eq. (5.28) into Eq. (5.24), we obtain

$$\frac{\hbar^2}{2m_e}\left[-H_{\tilde{\mu}}\frac{d^2R_+(r)}{dr^2} - \left(2H'_{\tilde{\mu}} + \frac{H_{\tilde{\mu}}}{r}\right)\frac{dR_+(r)}{dr}\right] + \Delta(r) H_{\tilde{\mu}} R_-(r)$$

$$= \left(E + \frac{\mu\hbar^2}{2m_e r^2}\right) H_{\tilde{\mu}} R_+(r), \tag{5.29a}$$

$$-\frac{\hbar^2}{2m_e}\left[-H_{\tilde{\mu}}\frac{d^2R_-(r)}{dr^2} - \left(2H'_{\tilde{\mu}} + \frac{H_{\tilde{\mu}}}{r}\right)\frac{dR_-(r)}{dr}\right] + \Delta(r) H_{\tilde{\mu}} R_+(r)$$

$$= \left(E + \frac{\mu\hbar^2}{2m_e r^2}\right) H_{\tilde{\mu}} R_-(r) \tag{5.29b}$$

In the limit that $k_F r \gg 1$, we neglect the terms $HR''_\pm$ and $HR'_\pm/r$, and approximate $H'(k_F r) \approx i k_F H$ from the asymptotic form of the Hankel function

$$H_\mu(x) = \left(\frac{2}{\pi x}\right)^{1/2} \exp\left[i\left(x + \frac{\mu^2}{2x} - \frac{\mu\pi}{2} - \frac{\pi}{4}\right)\right] \tag{5.30}$$

for the limit $r \to \infty$. Equation (5.29) then becomes

$$-i\frac{\hbar^2 k_F}{m_e}\frac{dR_+(r)}{dr} + \Delta(r) R_-(r) = \left(E + \frac{\mu\hbar^2}{2m_e r^2}\right) R_+(r) \tag{5.31a}$$

$$i\frac{\hbar^2 k_F}{m_e}\frac{dR_-(r)}{dr} + \Delta(r) R_+(r) = \left(E + \frac{\mu\hbar^2}{2m_e r^2}\right) R_-(r) \tag{5.31b}$$

For $E \ll \Delta_0$ and $k_F r \gg \mu$, we can treat the right-hand-side of Eq.(5.31) perturbatively. To proceed, we write the envelope functions in the form

$$\begin{pmatrix} R_+(r) \\ R_-(r) \end{pmatrix} = \begin{pmatrix} e^{i\varphi} \\ e^{-i\varphi} \end{pmatrix} e^{-K} \tag{5.32}$$

Substitution of Eq. (5.32) into Eq. (5.31) gives

$$\hbar v_F \left(\frac{1}{2} \frac{d\varphi}{dr} + i \frac{dK}{dr} \right) + \Delta(r) e^{-i\varphi} = E + \frac{\mu \hbar^2}{2 m_e r^2} \tag{5.33a}$$

$$\hbar v_F \left(\frac{1}{2} \frac{d\varphi}{dr} - i \frac{dK}{dr} \right) + \Delta(r) e^{i\varphi} = E + \frac{\mu \hbar^2}{2 m_e r^2} \tag{5.33b}$$

Through addition and subtraction of Eqs. (5.33a) and (5.33b), we find

$$\frac{\hbar v_F}{2} \frac{d\varphi}{dr} + \Delta(r) \cos\varphi = E + \frac{\mu \hbar^2}{2 m_e r^2} \tag{5.34a}$$

$$\hbar v_F \frac{dK}{dr} - \Delta(r) \sin\varphi \tag{5.34b}$$

We further write the solution for φ and K up to the leading order of $E + \frac{\mu \hbar^2}{2 m_e r^2}$:

$$\varphi = \varphi_0 + \varphi_1 \tag{5.35a}$$

$$K = K_0 + K_1 \tag{5.35b}$$

It can be easily found that

$$\varphi_0 = \frac{\pi}{2} \tag{5.36a}$$

$$K_0 = (\hbar v_F)^{-1} \int_0^r \Delta(r')\, dr' \tag{5.36b}$$

Upon substitution of Eq. (5.35) together with Eq. (5.36) into Eq. (5.34), we arrive at

$$\frac{\hbar v_F}{2} \frac{d\varphi_1}{dr} - \Delta(r) \varphi_1 = E + \frac{\mu \hbar^2}{2 m_e r^2} \tag{5.37a}$$

$$K_1 = 0 \tag{5.37b}$$

where we have used the approximation $\sin\varphi_1 \approx \varphi_1$. Equation (5.37a) has the solution

$$\begin{aligned} \varphi_1(r) &= -\int_r^\infty e^{\frac{2}{\hbar v_F}\left[\int_0^r \Delta(r')dr' - \int_0^{r'} \Delta(r'')dr''\right]} \left(2q + \frac{\mu}{k_F r'^2} \right) dr' \\ &= -\int_r^\infty e^{2K_0(r) - 2K_0(r')} \left(2q + \frac{\mu}{k_F r'^2} \right) dr' \end{aligned} \tag{5.38}$$

On the other hand, for $r < r_c$, we can write

$$\varphi_1(r) = a_{-1}/r + a_0 + a_1 r + \dots$$

and

$$\Delta(r) = \left.\frac{d\Delta(r)}{dr}\right|_{r=0} r + \dots$$

and substitute them into Eq. (5.37a). By comparing the coefficients for the r^{-2} term, we have

$$a_{-1} = -\frac{\mu}{k_F}$$

so that

$$\frac{d\varphi_1}{dr} = 2q + \frac{\mu}{k_F r^2} - \frac{2\mu\Delta(r)}{\hbar k_F v_F r} \tag{5.39}$$

for $r < r_c$. We can then obtain

$$\begin{aligned}
\varphi_1(r_c) &= -\int_{r_c}^{\infty} e^{2K_0(r)-2K_0(r')}\left(2q + \frac{\mu}{k_F r'^2}\right) dr' \\
&\approx -\int_0^{\infty} e^{-2K_0(r')}\left(2q + \frac{\mu}{k_F r'^2}\right) dr' - \int_0^{r_c} \frac{d\varphi_1}{dr'} dr' \\
&\approx 2qr_c - \frac{\mu}{k_F r_c} - 2\int_0^{\infty} e^{-2K_0(r')}\left(q - \frac{\mu\Delta(r')}{\hbar k_F v_F r'}\right) dr'.
\end{aligned} \tag{5.40}$$

The final form of the wave function for $r > r_c$ is then

$$\begin{pmatrix} u_\mu(r) \\ v_\mu(r) \end{pmatrix} = \tilde{A} e^{-K_0(r)} \begin{pmatrix} e^{i\frac{\pi}{4}+i\frac{\varphi_1}{2}} H_{\tilde{\mu}}(k_F r) + \text{ c.c} \\ e^{-i\frac{\pi}{4}-i\frac{\varphi_1}{2}} H_{\tilde{\mu}}(k_F r) + \text{ c.c.} \end{pmatrix} \tag{5.41}$$

This wave function must be joined smoothly at $r = r_c$ with that from the region $r < r_c$ given by Eq. (5.25). Using the asymptotic form of the Bessel function

$$J_\mu(x) = \left(\frac{2}{\pi x}\right)^{1/2} \exp\left[x + \frac{\mu^2}{2x} - \frac{\mu\pi}{2} + \frac{\pi}{4}\right] \tag{5.42}$$

for $x \gg 1$ together with that of the Hankel function, Eq. (5.30), we obtain

$$\varphi_1(r_c) = 2qr_c - \frac{\mu}{k_F r_c} \tag{5.43}$$

Comparison of Eq. (5.43) with Eq. (5.40) leads to

$$\int_0^{\infty} e^{-2K_0(r')}\left(q - \frac{\mu\Delta(r')}{\hbar k_F v_F r'}\right) dr' = 0 \tag{5.44}$$

That is,

$$\begin{aligned}
E_\mu &= \frac{\mu}{k_F} \frac{\int_0^{\infty} e^{-2K_0(r')} \frac{\Delta(r')}{r'} dr'}{\int_0^{\infty} e^{-2K_0(r')} dr'} \\
&= \frac{\mu}{k_F} \left.\frac{d\Delta(r)}{dr}\right|_{r=0} g(k_F)
\end{aligned} \tag{5.45}$$

where the dimensionless function $g(k_F)$ depends on the shape of $\Delta(r)$ and is close to one. Using the approximation $\left.\frac{d\Delta(r)}{dr}\right|_{r=0} \approx \frac{\Delta_0}{\xi}$ with the coherence length $\xi = \hbar v_F / 2\Delta_0$, the energies of the vortex core bound states are given by

$$E_\mu = \mu \frac{\Delta_0^2}{E_F} \tag{5.46}$$

These are the Caroli-de Gennes-Matricon vortex core levels. The lowest bound state energy corresponds to $|\mu| = \frac{1}{2}$.

More rigorous solution to the BdG equations can only be obtained through numerical solution, which also determines the pair potential self-consistently [10, 11]. The radial functions are expanded in terms of the set of Bessel functions normalized in a disc of radius R:

$$\begin{pmatrix} u_{j\mu}(r) \\ v_{j\mu}(r) \end{pmatrix} = \sum_i \begin{pmatrix} c_{ji}\phi_{i\mu-\frac{1}{2}}(r) \\ d_{ji}\phi_{i\mu+\frac{1}{2}}(r) \end{pmatrix}, \tag{5.47}$$

where

$$\phi_{im}(r) = \frac{\sqrt{2}}{RJ_m(\alpha_{im})} J_m(\alpha_{im} r/R), \quad i = 1, 2, \ldots, N \tag{5.48}$$

with $m = \mu \mp \frac{1}{2}$ and α_{im} is the i th zero of $J_m(x)$. The BdG equations are now solved separately in each subspace of fixed angular momentum μ, which amounts to solve a $2N \times 2N$ matrix eigenvalue problem. Once the self-consistency solution is obtained, the local density of states as derived in Chap. 1 can be computed.

Typical results are shown in Figs. 5.2 and 5.3. As the temperature decreases, the vortex core size, as defined by $\left.\frac{d\Delta(r)}{dr}\right|_{r\to 0}$, shrinks, as originally predicted by Kramer and Pesch [13]. In addition, at very low-temperatures, the pair potential also exhibits Friedel-like oscillation, which is mainly contributed from the vortex core states. These vortex core states are displayed clearly in the local density of states probed near the core center. For a large zero-temperature coherence length, these core levels

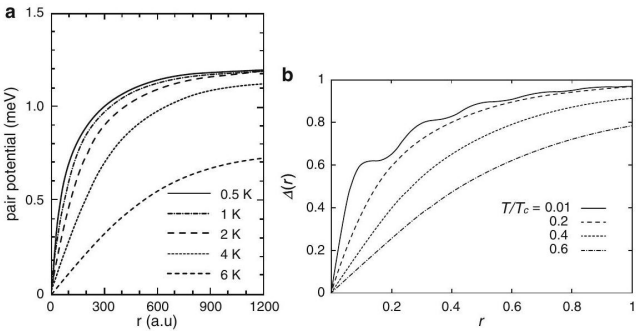

Fig. 5.2 Spatial variation of the pair potential $\Delta(r)$ as a function of distance away from the vortex core center, determined self-consistently, for $k_F\xi = 70$ (a) and 16 (b) for various temperatures. From [11] for (a) and [12] for (b)

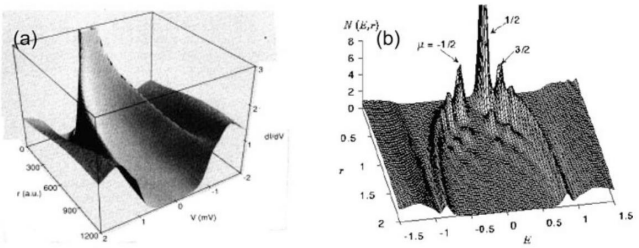

Fig. 5.3 Local density of states as a function of energy and distance from the vortex core center at $T = 0.13T_c$ and $k_F\xi = 70(\mathbf{a})$, and $T = 0.05T_c$ and $k_F\xi = 8(\mathbf{b})$. From [11] for (a) and [12] for (b)

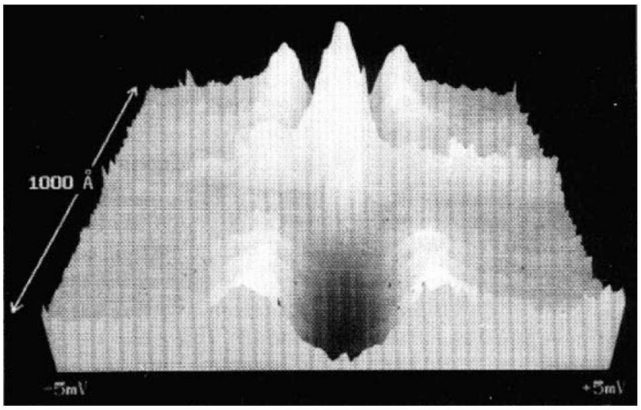

Fig. 5.4 Image of dI/dV on $2H-NbSe_2$ as a function of voltage bias (horizontal axis) and position along a line that intersects a vortex (vertical axis). From [14]

are close in energy and the discretization is thermally smeared, while for a short coherence length, the discretization of the levels is evident. The first experimental evidence for the Caroli-de Gennes-Matricon vortex core states comes from a series of scanning tunneling experiments on a layered hexagonal compound $2H-NbSe_2$ at low temperatures [14-16]. A spatial image of tunneling conductance across a vortex is shown in Fig. 5.4. There a tunneling conductance peak is observed at the vortex core center.

Recently, the STM experiments have also been carried out in a vortex core of a proximity-induced s-wave superconductor in Bi_2Te_3 thin films [17, 18]. The evolution of local tunneling conductance spectra with film thickness has led to a conjecture [18] that the zero-bias conductance peak observed at the core center reveals the existence of Majorana bound states. This conjecture has been supported by a very recent theoretical study [19] by solving a generalized set of BdG equations [20, 21]:

$$\begin{pmatrix} \hat{\mathscr{H}}_{\rm TI}(\mathbf{r}) & \hat{\Delta}(\mathbf{r}) \\ \hat{\Delta}^{\dagger}(\mathbf{r} & -\hat{\mathscr{H}}^{*}_{\rm TI}(\mathbf{r}) \end{pmatrix} \begin{pmatrix} \hat{u}(\mathbf{r}) \\ \hat{v}(\mathbf{r}) \end{pmatrix} = E \begin{pmatrix} \hat{u}(\mathbf{r}) \\ \hat{v}(\mathbf{r}) \end{pmatrix}. \tag{5.49}$$

Here the normal-state effective Hamiltonian of the TI

$$\hat{\mathscr{H}}_{\rm TI} = \epsilon \hat{\sigma}_z - iv_F \left[e^{-i\phi \hat{s}_z} \left(\partial_r \hat{s}_x + \frac{1}{r} \partial_\phi \hat{s}_y \right) + \partial_z \hat{s}_z \right] \hat{\sigma}_x - E_F, \tag{5.50}$$

with $\hat{s}_i$ and $\hat{\sigma}_i$ the Pauli matrices for spin and orbital degrees of freedom, and the Dirac mass

$$\epsilon = -\epsilon_0 - \frac{1}{2m_e} \left(\partial_r^2 + \frac{1}{r} \partial_r + \frac{1}{r^2} \partial_\phi^2 + \partial_z^2 \right), \tag{5.51}$$

in the cylindrical coordinates with the quantity $2\epsilon_0$ describing the bulk gap of the topological insulator. The proximity-induced superconducting gap has the form

$$\hat{\Delta} = e^{i\phi} \Delta_0 \hat{s}_x \tag{5.52}$$

where the superconducting gap Δ_0 is kept as a constant. We note that the BdG wave function $\left[\hat{u}(\mathbf{r}), \hat{v}(\mathbf{r}\right]^{\rm Transpose}$ is a total eight-component vector spanned in a spin-orbital-Nambu space. The BdG quasiparticle wave function around an isolated vortex takes the form

$$\begin{pmatrix} u_j^{s\sigma}(\mathbf{r}) \\ v_j^{s\sigma}(\mathbf{r}) \end{pmatrix} = \begin{pmatrix} e^{i(j-s/2+1/2)} \overline{u^{s\sigma}}(\mathbf{r}) \\ e^{i(j+s/2-1/2)} \bar{v}^{s\sigma}(\mathbf{r}) \end{pmatrix}, \tag{5.53}$$

where the superscripts $s(\pm 1)$ and $\sigma(=1,2)$ on u and v are spin and orbital indices. The coefficients $(\bar{u}^{s\sigma}(\mathbf{r}), \bar{v}^{s\sigma}(\mathbf{r}))$ can be expanded in terms of the Bessel orthonormal functions in

the radial direction [11] while the Gauss-Lobatto functions in the z direction [22]. Numerically, the authors of [19] has used a varying Fermi energy to simulate the thickness dependence of the local density of states around the vortex core. It was found that the local density of states profile evolves from a V-shape to a Y-shape as the Fermi energy level is tuned toward the bulk gap center, in a good agreement with the experimental results.

13.3.4 5.2.2 High Field Limit

The quasiparticle states of a superconductor in the low field limit can be sufficiently described by considering a single isolated vortex. In the high field limit, a vortex lattice is formed as a regular array [23], in which vortices are closely packed. In this limit, the single isolated vortex description is not adequate. Quasiparticle excitations of a superconductor in the high field limit are interesting in the possibility of Landau level quantization, which plays an important role in quantum Hall effect in a semiconductor two-dimensional electron gas.

Different from the single isolated vortex case, in the high magnetic field limit, the vector potential must be treated explicitly in the BdG equations (5.19) with $h(\mathbf{r})$ given by Eq. (5.1). For the extreme type-II superconductors, we can assume the vector potential is entirely determined by the external magnetic field. In the Landau gauge with the vector potential

$$\mathbf{A} = H(-y, 0, 0), \tag{5.54}$$

the pair potential for a triangular Abrikosov lattice has the form

$$\Delta(\mathbf{r}) = \Delta(T, H) \sum_n e^{i\pi a_{2,x} n^2/a_\Delta} e^{i2\pi n x/a_\Delta - (y/l_B + \pi n l_B/a_\Delta)^2}, \tag{5.55}$$

where the position vector $\mathbf{r} = (x, y)$. The unit vectors in the direct space of a triangular vortex lattice are

$$\mathbf{a}_1 = (a_{1,x}, a_{1,y}) = a_\Delta(1, 0), \quad \mathbf{a}_2 = (a_{2,x}, a_{2,y}) = a_\Delta \left(\frac{1}{2}, \frac{\sqrt{3}}{2} \right). \tag{5.56}$$

The magnetic length $l_B = \sqrt{\hbar c/eH}$. This form of the pair potential and the explicit appearance of the vector potential in the BdG equations break the rotational symmetry existing for the single isolated vortex. The BdG wave functions can be expanded as

$$\begin{pmatrix} u_{(\mathbf{r})} \\ v_{(\mathbf{r})} \end{pmatrix} = \sum_{n,\mathbf{q}} \begin{pmatrix} u_{n\mathbf{q}} \\ v_{n\mathbf{q}} \end{pmatrix} \phi_{n,\mathbf{q}}(\mathbf{r}). \tag{5.57}$$

Here $\phi_{n,\mathbf{q}}$ are the eigenfunctions to the single-particle Hamiltonian Eq. (5.1) in the magnetic sublattice representation for a vector potential chosen in the Landau gauge [24]:

$$\begin{aligned} \phi_{n,\mathbf{q}} =& \frac{1}{\sqrt{2^n n! \sqrt{\pi} l_B}} \sqrt{\frac{a_{2,y}}{L_x L_y}} \sum_m e^{i\frac{\pi a_{2,x}}{2a_\Delta} - imq_y a_{2,y}} e^{i(q_x + \pi m/a_\Delta)x - (y/l_B + q_x l_B + \pi m l_B/a_\Delta)^2/2} \\ & \times H_m\left(y/l_B + q_x l_B + \pi m l_B/a_\Delta\right) \end{aligned} \tag{5.58}$$

where $\mathbf{q} = (q_x, q_y)$ is the quasimomenta in the first magnetic Brillouin zone defined by the reciprocal vectors

$$\mathbf{Q}_1 = \left(a_{2,y}, -a_{2.x}\right)/l_B^2, \quad \mathbf{Q}_2 = \left(0, 2a_\Delta\right)/l_B^2 \tag{5.59}$$

L_x and L_y are the linear dimensions of the system, and $H_n(x)$ is the Hermite polynomial of order n. Substitution of Eq. (5.57) into Eq. (5.19) yields

$$\epsilon_n u_{n,\mathbf{q}} + \sum_m \Delta_{nm}(\mathbf{q}) v_{m,\mathbf{q}} = E_{n,\mathbf{q}} u_{n,\mathbf{q}} \tag{5.60a}$$

$$-\epsilon_n v_{n,\mathbf{q}} + \sum_m \Delta^*_{mn}(\mathbf{q}) u_{m,\mathbf{q}} = E_{n,\mathbf{q}} v_{n,\mathbf{q}} \tag{5.60b}$$

Here the normal-state Landau levels are given by

$$\epsilon_n = \left(n + \frac{1}{2}\right)\hbar\omega_c - E_F \tag{5.61}$$

with the cyclotron frequency $\omega_c = eH/m_e c$, and the matrix element for the pair potential is

$$\begin{aligned}\Delta_{nm}(\mathbf{q}) =& \frac{\Delta(T,H)}{\sqrt{2}} \frac{(-1)^m}{2^{n+m}\sqrt{n!m!}} \sum_k e^{i\pi a_{2,x} k^2/a_\Delta + 2ikq_y a_{2,y} - (q_x l_B + \pi k l_B/a_\Delta)^2} \\ & \times H_{n+m}\left[\sqrt{2}\left(q_x + \pi k/a_\Delta\right) l_B\right]\end{aligned} \tag{5.62}$$

Therefore, the BdG equations are now solved in a $2N_c \times 2N_c$ subspace for separate values of quasi momentum q. Due to the complex structure of the pair potential matrix elements, accurate solutions can only be obtained through numerical simulations [25-30]. The numerical results show that when the magnetic field is close to the upper critical field H_{c2}, gapless quasiparticle states can occur at discrete locations of the Fermi surface. We note that the gapless quasiparticle states in the s-wave superconductors are induced from the Cooper pair motion in the high magnetic field. Their existence can be detected by the de Haas-van Alphen oscillations at high magnetic field and low temperatures [31-34].

13.3.5 5.3 Vortex Core States in a d-Wave Superconductor

The study of vortex cores states in a d-wave superconductor finds its immediate relevance when high-temperature cuprates are found to have a d-wave pairing symmetry. A novel feature from a d-wave pairing symmetry is that the superconducting gap function experiences a continuous sign change at some special points of the Fermi energy, showing the existence of nodal quasiparticles. Similar to the previous section, here we first consider the quasiparticle core states in a single isolated vortex in the continuum model and for a vortex lattice in the tight-binding model.

13.3.6 5.3.1 Single Isolated Vortex

We begin with the BdG equations (5.19). The non-local nature of d-wave pairing introduces further complications. We introduce the center-of-mass coordinate system

$$\overline{\mathbf{R}} = \frac{\mathbf{r} + \mathbf{r}'}{2}, \quad \mathbf{s} = \mathbf{r} - \mathbf{r}' \tag{5.63}$$

to rewrite the equations as

$$h_{\mathbf{R}} u(\mathbf{R}) + \int \Delta(\mathbf{R} - \mathbf{s}/2, \mathbf{s}) v(\mathbf{R} - \mathbf{s}) d\mathbf{s} = E u(\mathbf{R}) \tag{5.64a}$$

$$-h^*_{\mathbf{R}} v(\mathbf{R}) + \int \Delta^*(\mathbf{R} - \mathbf{s}/2, \mathbf{s}) u(\mathbf{R} - \mathbf{s}) d\mathbf{s} = E u(\mathbf{R}) \tag{5.64b}$$

Here we have used a new label $\mathbf{R} = \mathbf{r}$ so that the single-particle Hamiltonian becomes

$$h_{\mathbf{R}} = \frac{\hbar^2}{2m_e}\left(\mathbf{p}_{\mathbf{R}} + \frac{e\mathbf{A}(\mathbf{R})}{c}\right) - E_F, \tag{5.65}$$

and

$$\overline{\mathbf{R}} = \mathbf{R} - \frac{\mathbf{s}}{2}, \quad \mathbf{s} = \mathbf{r} - \mathbf{r}' \tag{5.66}$$

The pair potential in the center-of-mass coordinate system is given by

$$\Delta(\overline{\mathbf{R}}, \mathbf{s}) = V(\mathbf{s}) \sum_n \left[u_n(\overline{\mathbf{R}} + \mathbf{s}/2) v_n^*(\overline{\mathbf{R}} - \mathbf{s}/2) + u_n(\overline{\mathbf{R}} - \mathbf{s}/2) v_n^*(\overline{\mathbf{R}} + \mathbf{s}/2) \tanh\left(\frac{E_n}{2k_B T}\right), \right. \tag{5.67}$$

with the energy summation subjected to a cutoff Ω_c in the continuum limit. The pairing interaction is parametrized as

$$V(\mathbf{s}) = V_d g(\varphi) \delta(s - a)/a, \tag{5.68}$$

with $\mathbf{s} = (s, \varphi)$ in the polar coordinates and a as a length scale for nonlocal pairing interaction. For the $d_{x^2-y^2}$-wave pairing symmetry, the angular dependent function

$$g(\varphi) = \cos^2(2\varphi). \tag{5.69}$$

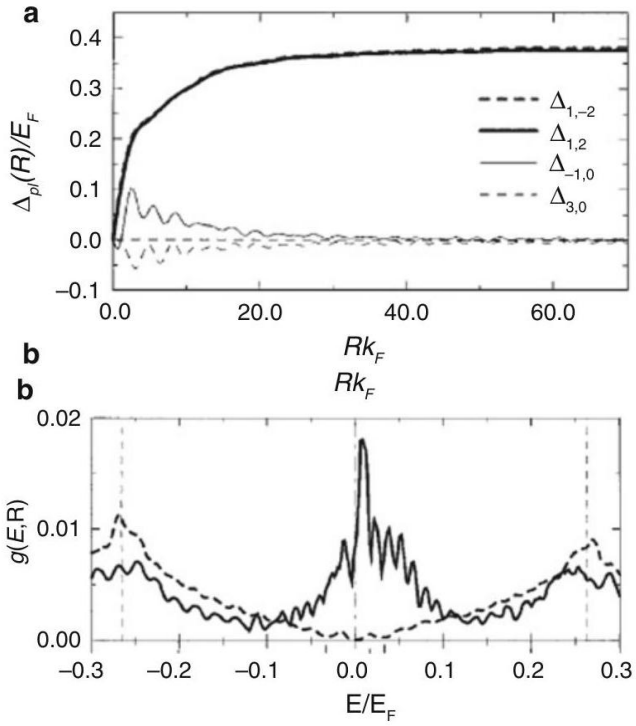
This form of the pair interaction suggests that the d-wave order parameter depends on the relative coordinate s only through its polar angle. Therefore, we can expand it as

$$\Delta(\overline{\mathbf{R}}, \mathbf{s}) = \Delta(\overline{\mathbf{R}}, \theta; \varphi) = \sum_{p,l} e^{ip\theta} e^{il\varphi} \Delta_{pl}(R), \tag{5.70}$$

where $\overline{\mathbf{R}} = (\bar{R}, \theta)$. In this representation, p represents the winding number of the superconducting phase around the vortex and l represents the orbital angular momentum of the relative motion of two paired electrons. For the $d_{x^2-y^2}$-wave pairing symmetry, the order parameter near the single vortex should be contributed dominantly from a linear combination of components with $p = 1$, and $l = \pm 2$ at equal weight $\Delta(\bar{R}, \theta; \varphi) = e^{i\theta}\left[e^{i2\varphi}\Delta_{1,2}(\bar{R}) + e^{-i2\varphi}\Delta_{1,-2}(\bar{R})\right]$.

For the case of singe isolated d-wave vortex, we neglect the vector potential A, which is reasonable for extreme type-II superconductors. We can then follow the same procedure used for the single isolated s-wave vortex to solve the BdG equations (5.64) through the expansion of the wave function as

$$\begin{pmatrix} u_{j\mu}(R) \\ v_{j\mu}(R) \end{pmatrix} = \sum_i \begin{pmatrix} c_{ji}\phi_{i\mu-\frac{1}{2}}(R) \\ d_{ji}\phi_{i\mu+\frac{1}{2}}(R) \end{pmatrix}, \tag{5.71}$$



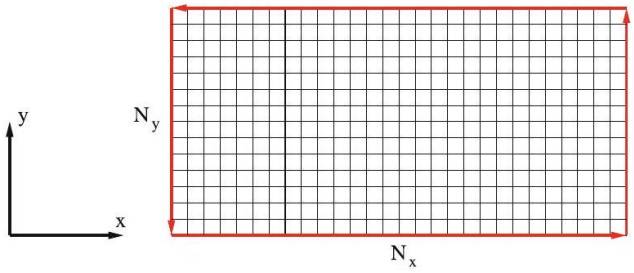
where

$$\phi_{im}(R) = \frac{\sqrt{2}}{R_0 J_m(\alpha_{im})} J_m(\alpha_{im} R/R_0), \quad i = 1, 2, \ldots, N \tag{5.72}$$

with $m = \mu \mp \frac{1}{2}$ and α_{im} is the i th zero of $J_m(x)$, and R_0 is the radius of a disk. The resultant equations can be solved via exact diagonalization with the order parameter obtained through an iteration procedure. Figure 5.5 shows the variation of the dominant component of the superconducting order parameter and the local tunneling conductance at the vortex center [35]. Due to the spatial anisotropy of the dominant $d_{x^2-y^2}$-wave component, other subdominant order parameter components are also induced near the vortex core (see Fig. 5.5a). The calculations

[35] also show that for a short coherence length $k_F\xi_0$ with $\xi_0 = \hbar v_F/\pi\Delta_0$ (Δ_0 is controlled by the pairing interaction strength V_d), the profile for the $d_{x^2-y^2}$-wave order parameter is quite universal and it follows the form $1/R^2$ instead of $\tanh(R/\xi')$ with ξ' a fitting parameter. In addition, a broad peak shows up near the Fermi energy in the local tunneling conductance at the vortex core center (see Fig. 5.5b). For the $d_{x^2-y^2}$-wave vortex core, even for a very short coherence (e.g., $k_F\xi_0 = 2.5$ for Fig. 5.5a), no clear splitting of the core level is obtained, which is in sharp contrast with the case of the s-wave vortex core. This is a clear indication that the nodal quasiparticles preexisting for the $d_{x^2-y^2}$-wave pairing even at zero field play an important role in the nature of vortex core states.

Fig. 5.5 Dominant order parameter component around a d-wave vortex (a) and the theoretically obtained tunneling conductance at the vortex core center. The system size is $k_F R_0 = 120$. The other parameter values are $k_F a = 2, \Omega_c/E_F = 0.3$, $V_d/E_F = 1.6$, and $T = 0$. From [35]



13.3.7 5.3.2 Quasiparticle States in a Mixed-State of d-Wave Superconductors

The order parameter profile for a single $d_{x^2-y^2}$-wave vortex core has also been studied by solving the BdG equations within the tight-binding model [36]. The use of tight-bind model enables one to incorporate band structure of normal-state superconductors, which is especially appropriate for high- T_c cuprates. As in the case of s-wave superconductors, when the magnetic field is much larger than the lower critical field H_{c1}, a vortex lattice is formed also in the d-wave superconductors. The quasiparticle spectrum in the mixed-state within the tight-binding model has been first studied by Wang and MacDonald [37] for a pure $d_{x^2-y^2}$-wave superconductor. It was shown that the local density of states at the d-wave vortex core exhibits a single broad peak at zero energy. The results are supported by the study of the single $d_{x^2-y^2}$-wave vortex line discussed above in the continuum model.

In this high-field limit, we again need to treat the magnetic field effect explicitly, which is described in the BdG equations (5.20). In the mixed state, the magnetic field effect is included through the Peierls phase factor $\varphi_{\mathbf{ij}} = -\frac{2\pi}{\Phi_0}\int_{\mathbf{r_j}}^{\mathbf{r_i}} \mathbf{A}(\mathbf{r})\cdot d\mathbf{r}$, where $\Phi_0 = hc/e(e>0)$ is the single-electron flux quantum. We still assume the superconductor under consideration is in the extreme type-II limit where the Ginzburg-Landau parameter $\kappa = \lambda/\xi$ goes to infinity so

that the screening effect from the supercurrent is negligible. Therefore, the vector potential $\mathbf{A}$ can be approximated by the solution

Fig. 5.6 Schematic drawing of a magnetic unit cell with linear dimensions of N_x and N_y. The red lines form a closed path around the unit cell

$\nabla \times \mathbf{A} = H\hat{\mathbf{z}}$, where H is the magnetic field externally applied along the c axis. The enclosed flux density within each plaquette is given by $\sum_{\square} \varphi_{\mathbf{ij}} = -\frac{2\pi H a^2}{\Phi_0}$.

We choose a Landau gauge to write the vector potential as $\mathbf{A} = (-Hy, 0, 0)$, where y is the y-component of the position vector $\mathbf{r}$. By considering a rectangular lattice, we introduce the magnetic translation operator $\mathscr{T}_{mn}\mathbf{r} = \mathbf{r} + \mathbf{R}$, where the translation vector $\mathbf{R} = mN_x a\hat{\mathbf{e}}_x + nN_y a\hat{\mathbf{e}}_y$ with N_x and N_y the linear dimension of the unit cell of the vortex lattice, as shown in Fig. 5.6. Note that the original crystal lattice is a. To ensure different $\mathscr{T}_{mn}$ to be commutable with each other, we have to take the strength of magnetic field so that the flux enclosed by each unit cell has a single-particle flux quantum, i.e, Φ_0, which is equivalent of two superconducting flux quanta each with $hc/2e$.

Under this condition, we can decouple the translation operator $\mathscr{T}_{mn}$ into two consecutive operations

$$\mathscr{T}_{mn} = \mathscr{T}_{0n}\mathscr{T}_{m0} \tag{5.73}$$

As such, we have

$$\mathbf{A}\left(\mathscr{T}_{m0}\mathbf{r}\right) = \mathbf{A}(\mathbf{r}) = \mathbf{A}(\mathbf{r}) + \nabla\phi_1 \tag{5.74}$$

which gives

$$\phi_1 = 0 \tag{5.75}$$

and

$$\mathbf{A}\left(\mathscr{T}_{0n}\mathbf{r}\right) = -Hy\hat{\mathbf{e}}_x - H\left(nN_y a\right)\hat{\mathbf{e}}_x = \mathbf{A}(\mathbf{r}) + \nabla\phi_2, \tag{5.76}$$

which gives

$$\phi_2 = -HnN_y ax \tag{5.77}$$

Therefore, the transformation $\mathscr{T}_{mn}$ leads to the transformation of the superconducting pair potential as:

$$\begin{aligned}\Delta\left(\mathscr{T}_{mn}\mathbf{r}\right) &= e^{-\frac{i4\pi}{\Phi_0}[-HnN_y a(x+mN_x a)]}e^{-\frac{i4\pi}{\Phi_0}\times 0}\Delta(\mathbf{r}) \\ &= e^{i\chi(\mathbf{r},\mathbf{R})}\Delta(\mathbf{r})\end{aligned} \tag{5.78}$$

where the phase accumulated by the order parameter upon the translation is

$$\chi(\mathbf{r},\mathbf{R}) = -\frac{4\pi}{\Phi_0}\left[-HnN_y a\left(x+mN_x a\right)\right]$$
$$= -\frac{4\pi}{\Phi_0}\mathbf{A}(\mathbf{R})\cdot\mathbf{r} + 4mn\pi \tag{5.79}$$

when $N_x N_y a^2 H = \Phi_0$. If we perform a successive application of four transformations along a closed path around the magnetic unit cell, as shown by the red lines in Fig. 5.6,

$$(0,0) \to (N_x a, 0) \to (N_x a, N_y a) \to (0, N_y a) \to (0,0) \tag{5.80}$$

the accumulated phase on the superconducting order parameter is 4π, which corresponds to two superconducting flux quanta.

From this property, we can obtain the magnetic Bloch theorem for the wavefunction of the BdG equations:

$$\begin{pmatrix} u_{\mathbf{k},\sigma}\left(\mathscr{T}_{mn}\tilde{\mathbf{r}}\right) \\ v_{\mathbf{k},\sigma}\left(\mathscr{T}_{mn}\tilde{\mathbf{r}}\right) \end{pmatrix} = e^{i\mathbf{k}\cdot\mathbf{R}} \begin{pmatrix} e^{i\chi(\mathbf{r},\mathbf{R})/2} u_{\mathbf{k},\sigma}(\tilde{\mathbf{r}}) \\ e^{-i\chi(\mathbf{r},\mathbf{R})/2} v_{\mathbf{k},\sigma}(\tilde{\mathbf{r}}) \end{pmatrix}. \tag{5.81}$$

Here $\tilde{\mathbf{r}}$ is the position vector defined within a given unit cell and $\mathbf{k} = \frac{2\pi l_x}{M_x N_x}\hat{\mathbf{e}}_x + \frac{2\pi l_y}{M_y N_y}\hat{\mathbf{e}}_y$ with $m_{x,y} = 0, 1, \ldots, M_{x,y} - 1$ are the wavevectors defined in the first Brillouin zone of the vortex lattice and $M_x N_x$ and $M_y N_y$ are the linear dimension of the whole system. The vortex carrying the flux quantum $hc/2e$ is the generic feature of the pairing theory for superconductivity. Comparing with the zero-field case but with the similar kind of supercell technique, we can see that the magnetic field also modifies the matching conditions between two neighboring unit cells. Similar type of the magnetic Bloch theorem can also be derived in the symmetry gauge for the vector potential. Typical numerical results are shown in Fig. 5.7 [37]: The d-wave order

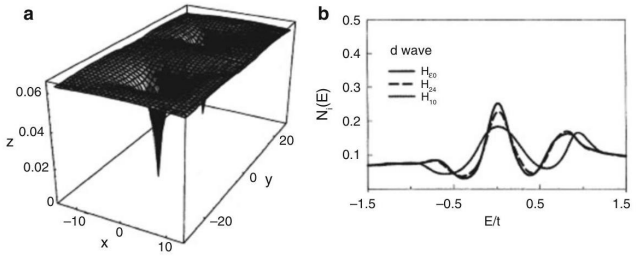


Fig. 5.7 Amplitude of a d-wave order parameter in a magnetic unit cell (a) and the local density of states at the vortex core center. From [37]

parameter as defined by

$$\Delta_d(i) = \frac{1}{4}\left[\Delta_{i,i+\hat{x}} + \Delta_{i,i-\hat{x}} - \Delta_{i,i+\hat{y}} - \Delta_{i,i-\hat{y}}\right], \tag{5.82}$$

is strongly suppressed at the vortex core. The local density of states at the vortex center exhibits a broad peak, which is clearly centered at the Fermi energy. No clear core level splitting is seen. These results are fully supported by the study of a single isolated d-wave vortex core in the continuum model discussed above.

The quasiparticle states near the vortex core can be probed by scanning tunneling microscopy. The unique feature of a pure d-wave pairing symmetry on the mixstate quasiparticles state can also be detected by nuclear magnetic resonance spectroscopy, which is essentially a site-selective probe. The correlation function between the two spin operators at equilibrium is

$$S_{ij}^{\alpha\beta}\left(t-t'\right) = \left\langle S_i^{\alpha}(t) S_j^{\beta}\left(t'\right)\right\rangle. \tag{5.83}$$

Its Fourier transform defines the dynamical structure factor

$$S_{ij}^{\alpha\beta} = \int_{-\infty}^{\infty} e^{i\omega t} S_{ij}^{\alpha\beta}(t) dt$$
$$= \frac{2\pi\hbar}{\mathscr{Z}} \sum_{\mu\nu} e^{-E_\mu/k_B T} \delta\left(E_\mu - E_v + \hbar\omega\right) \langle\mu|S_i^\alpha|v\rangle\langle v|S_j^\beta|\mu\rangle \tag{5.84}$$

where the partition function is given by

$$\mathscr{Z} = \sum_\mu e^{-E_\mu/k_B T} \tag{5.85}$$

If we define the response function

$$R_{ij}^{\alpha\beta}\left(t - t'\right) = -i\theta\left(t - t'\right) \left\langle \left[S_i^\alpha(t), S_j^\beta\left(t'\right) \right] \right\rangle \tag{5.86}$$

where $[A, B]$ denotes a commutator. Its Fourier transform is given by

$$R_{ij}^{\alpha\beta}(\omega + i\eta) = \int_{\infty}^{\infty} dt e^{i(\omega+i\eta)t} R_{ij}^{\alpha\beta}(t)$$
$$= \frac{1}{\mathscr{Z}} \sum_{\mu\nu} \frac{\left(e^{-E_\mu/k_B T} - e^{-E_v/k_B T}\right) \langle\mu|S_i^\alpha|v\rangle\langle v|S_j^\beta|\mu\rangle}{\left(E_\mu - E_v\right) + \hbar\omega + i\eta} \tag{5.87}$$

where η is an infinitesimal. Comparison of Eqs. (5.84) and (5.87) leads to the relation

$$S_{ij}^{\alpha\beta}(\omega) = -\frac{2}{1 - e^{-\hbar\omega/k_B T}} \operatorname{Im} R_{ij}^{\alpha\beta}(\omega). \tag{5.88}$$

In the limit of $\omega \to 0$, we have

$$S_{ij}^{\alpha\beta}(\omega \to 0) = -\frac{2}{\hbar\omega/k_B T} \operatorname{Im} R_{ij}^{\alpha\beta}(\omega \to 0). \tag{5.89}$$

This spin response function can be calculated conveniently in the Matsubara formalism. We are interested in the correlator between

$$S_i^+ = S_i^x + S_i^y = c_{i\uparrow}^\dagger c_{i\downarrow}$$

and

$$S_i^- = S_i^x - iS_i^y = c_{i\downarrow}^\dagger c_{i\uparrow}$$

and write down

$$\mathbf{R}_{ii}^{+-}(\tau) = -\left\langle T_\tau \left(S_i^+(\tau) S_i^-(0) \right) \right\rangle, \tag{5.90}$$

Using the Wick decoupling scheme and performing the Fourier transform, we obtain

$$\mathscr{R}_{ii}^{+-}\left(i\omega_n\right) = \sum_{nn'} u_i^n v_i^{n'} \left[u_i^{n*} v_i^{n'} - v_i^{n*} u_i^{n'} * \right] \frac{f\left(E_n\right) - f\left(-E_{n'}\right)}{i\omega_n + E_n + E_{n'}}, \tag{5.91}$$

from which we arrive at the spin-relaxation rate:

$$\begin{aligned}\frac{1}{T_1} =& \frac{J^2}{2\hbar^2}\mathscr{S}_{ii}^{+-}(\omega \to 0) \\ =& \frac{J^2\pi k_B T}{\hbar^2}\sum_{nn'}\mathrm{Re}\left\{u_i^n v_i^{n'}\left[u_i^{n*}v_i^{n'*} - v_i^{n*}u_i^{n'*}\right]\right\} \\ & \times\left(-\frac{\partial f(E)}{\partial E}\right)\Big|_{E=E_n}\delta\left(E_n + E_{n'}\right)\end{aligned} \tag{5.92}$$

where J is the strength of the coupling between the nuclear spin and the electron spin density on the lattice.

Figure 5.8 shows the temperature dependence of the spin relaxation rate on a few selected probing sites [38]. The results indicate that in the presence of vortices, $1/T_1$ follows $1/T_1 \sim T$ at low temperatures, which deviates from the T^3 behavior at zero field. This T-linear behavior arises from the low-energy states around the vortices. In addition, the temperature range for the T-linear behavior is expanded. This result is in sharp contrast with the $1/T_1 \propto e^{-\Delta_1/T}$ for the s-wave vortex lattice case at low temperature, where $\Delta_1 \sim \Delta_0^2/E_F$ [38]. Its magnitude of $1/T_1$ is also much larger than that for the zero-field case, suggesting a significant contribution from the gapless vortex-core states.

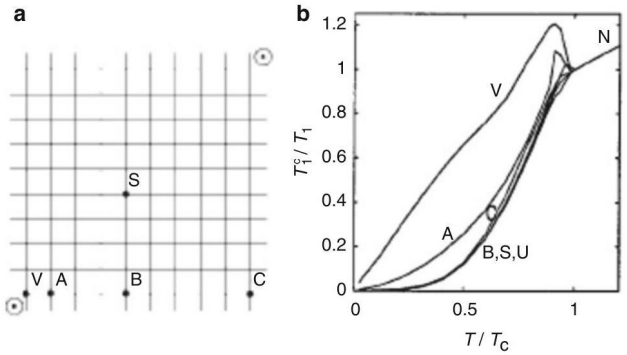

Fig. 5.8 Position of probing sites V, A, B, C, S in the square vortex lattice, where the nearestneighbor vortex is located in the 45° direction from the x-axis (due to the choice of symmetric gauge) (a), and the temperature dependence of spin relaxation rate. Line U shows the zero-field case. The line N is for the normal state at $T > T_c$. From [38]

For high-temperature cuprates, low temperature STM experiments observed a double-peak structure around zero bias in the local differential tunneling conductance at the vortex core center [40, 41]. The discrepancy between the theory and the experiment stimulated interesting theoretical proposals on the quasiparticles in the vortex core of high- T_c cuprates, including the mixed $d_{x^2-y^2} + id_{xy}$-wave pairing symmetry [35, 42], the Landau-level quantization [43], as well as competing order [39, 44-46]. Here we discuss the quasiparticle spectrum within a competing spin-density-wave scenario. Other competing scenarios [47] can be discussed within the same framework.

Beyond the tight-binding model with only a d-wave pairing term, we introduce a Hubbard on-site repulsion

$$H_U = U\sum_i \hat{n}_{i\uparrow}\hat{n}_{\downarrow} \tag{5.93}$$

where $\hat{n}_{i\sigma}$ is the local density operator and U is the strength of the on-site repulsion between two electrons with opposite spin polarization. By assuming that the on-site repulsion is solely responsible for the antiferromagnetism, we have a mean-field decoupling

$$H_{U,\mathrm{MF}} = \sum_{\sigma} m_{i\bar{\sigma}} \hat{n}_{i\sigma} \tag{5.94}$$

where $m_{i\sigma} = U n_{i\sigma}$ is the spin-dependent Hartree-Fock potential. The extended BdG equations can then be derived as:

$$\sum_{\mathbf{j}} \begin{pmatrix} \mathscr{H}_{\mathbf{ij},\sigma} & \Delta_{\mathrm{ij}} \\ \Delta^*_{\mathbf{ij}} & -\mathscr{H}^*_{\mathbf{ij},\bar{\sigma}} \end{pmatrix} \begin{pmatrix} u^n_{\mathbf{j}\sigma} \\ v^n_{\mathbf{j}\bar{\sigma}\bar{\sigma}} \end{pmatrix} = E_n \begin{pmatrix} u^n_{\mathbf{i}\sigma} \\ v^n_{\mathbf{i}\bar{\sigma}} \end{pmatrix}, \tag{5.95}$$

where $(u^n_{\mathbf{i}\sigma}, v^n_{\mathbf{i}\bar{\sigma}})$ is the quasiparticle wavefunction corresponding to the eigenvalue E_n, the single particle Hamiltonian $\mathscr{H}_{\mathbf{i},\sigma} = -t_{ij} e^{i\varphi_{\mathbf{ij}}} \delta_{\mathbf{i}+\delta,\mathbf{j}} + (m_{\mathbf{i},\bar{\sigma}} - \mu)\, \delta_{\mathbf{ij}}$. Notice that the quasiparticle energy is measured with respect to the Fermi energy. The selfconsistent conditions read:

$$m_{\mathbf{i}\sigma} = U \sum_{n} |u^n_{\mathbf{i}\sigma}|^2 f\left(E_n\right), \tag{5.96}$$

and

$$\Delta_{\mathbf{ij}} = \frac{V}{4} \sum_{n} \left(u^n_{\mathbf{i}\uparrow} v^{n*}_{\mathbf{j}\downarrow} + v^{n*}_{\mathbf{i}\downarrow} u^n_{\mathbf{j}\uparrow}\right) \tanh\left(\frac{E_n}{2k_B T}\right), \tag{5.97}$$

where V is the strength of d-wave pairing interaction and the Fermi distribution function $f(E) = 1/\left(e^{E/k_B T} + 1\right)$. Here the summation is also over those eigenstates with negative eigenvalues thanks to the symmetry property of the BdG equation: If $\left(u^n_{\mathbf{i}\uparrow}, u^n_{\mathbf{i}\downarrow}, v^n_{\mathbf{i}\uparrow}, v^n_{\mathbf{i}\downarrow}\right)^{\mathrm{Transpose}}$ is the eigenfunction of the 4×4 equation in the spin space with energy E_n, then $\left(v^{n\,*}_{\mathbf{i}\uparrow}, -v^{n\,*}_{\mathbf{i}\downarrow}, u^{n\,*}_{\mathbf{i}\uparrow}, -u^n_{\mathbf{i}\downarrow}\right)^*$ Transpose up to a global phase factor is the eigenfunction with energy $-E_n$.

For the optimally high- T_c cuprates, since there is no static spin-density-wave (SDW) order at zero field. One can choose the relative strength of Hubbard repulsion and the d-wave pairing interaction such that the antiferromagnetic SDW order is strongly suppressed while the system is only dominated by a pure d-wave superconducting order, which is uniform in real space. As such, the competing nature of the system will be uncovered by suppressing the superconducting order in the form of vortices when a magnetic field is applied. Representative results are shown in Fig. 5.9. With an appropriately chosen strength of the Hubbard repulsion, the SDW order is nucleated at the vortex core center, where the d-wave order parameter is depressed (see the left column of Fig. 5.9). More interestingly, with the SDW order localized at the vortex core center, the near-zero-energy broad peak in the local density of states for a pure d-wave vortex is suppressed with the amplitude of the SDW order (see the left column of Fig. 5.9). The exhibited double-peak structure in the LDOS is consistent with the STM tunneling conductance measured at the vortex core center.

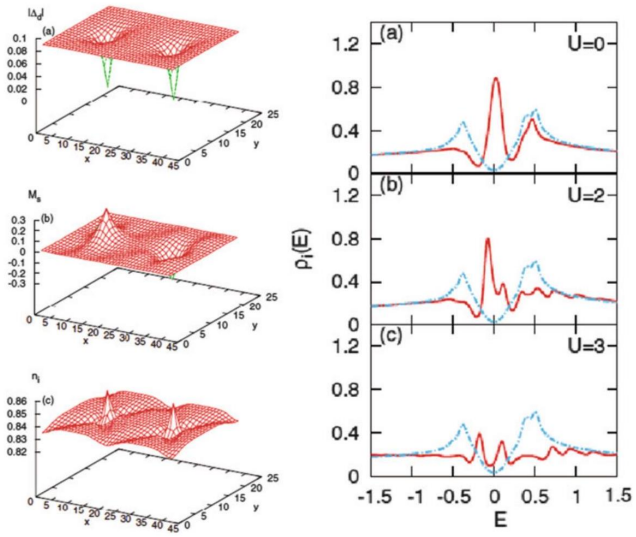

Fig. 5.9 Left column: Spatial variation of the d-wave order parameter (a), staggered spin-densitywave order $M_s = (-1)^i (n_{i\uparrow} - n_{i\downarrow})$ (**b**), and charge density $n_i = n_{i\uparrow} + n_{i\downarrow}$ (c) in a magnetic unit cell of size 42×21 for $V = 1.0$ and $U = 2$. Right column: The local density of states measured at the vortex core center for various values of Hubbard interaction $U = 0$ (a), 2 (b), and 3 (c). The filling factor defined as $\sum_i n_i / N_x N_y = 0.84$. From [39]

13.3.8 5.4 Fulde-Ferrell-Larkin-Ovchinikov State due to a Zeeman Magnetic Field

As we mentioned at the beginning of the chapter, the magnetic field also influences the superconductivity especially with the spin-singlet pairing through the spin Zeeman interaction. This effect is especially important for a low-dimensional system, where the orbital effect of magnetic field when aligned appropriately can be completely quenched. In this section, we will focus on the spin Zeeman effect by neglecting the orbital effect of the magnetic field.

The modification of superconductivity by the external magnetic field through the Zeeman coupling was first studied by Clogston and Chandrasekhar [48, 49]. It is concerned with the bound on the paramagnetic upper critical field by considering the Zeeman interaction alone, that is the Pauli limit, and the nature of the phase boundary. The paramagnetic pair-breaking effect comes from the Zeeman splitting
of the single electron energy bands. When a magnetic field is applied in the normal state, electron band is split into spin-up and spin-down sheets to gain the magnetic energy; while in the superconducting state, this paramagnetism is eliminated by the formation of spin-singlet Cooper pairs. Qualitatively, the destruction of the superconducting state by the Pauli paramagnetic pair breaking occurs when the normal-state paramagnetic energy

$$E_P = \frac{1}{2}\chi_n H_P^2 \tag{5.98}$$

takes over the superconducting condensation energy

$$E_c = \frac{1}{2}N(0)\Delta_{\mathrm{BCS}}^2(T). \tag{5.99}$$

Here the normal-spin susceptibility is given by

$$\chi_n = \frac{1}{2}g^2\mu_B^2 N(0), \tag{5.100}$$

with g being the gyromagnetic ratio, μ_B being the Bohr magneton, and N_0 the density of states at the Fermi energy per spin polarization. The quantity $\Delta_{\rm BCS}$ is the zerofield BCS energy gap. A little algebra yields

$$H_P(T) = \sqrt{2}\Delta_{\rm BCS}(T)/|g|\mu_B \tag{5.101}$$

On the other hand, if one assumes a second-order phase transition and the superconducting order parameter is always uniform in real space, the solution of the BdG equations (5.19) or (5.20) in the Pauli limit (that is, ignoring the orbital effect) will lead to an upper critical field, which will decrease with decreasing temperature below a critical temperature T^+. This transition line is metastable, which suggests that the transition below T^+(with the line defined by $H_P(T)$) becomes the first order. The phase diagram between the Zeeman field and the temperature is shown in Fig. 5.10.

A more unusual state was proposed by Fulde and Ferrell [50], and by Larkin and Ovchinnikov [51], where the pairing state is formed with a finite Cooper pair momentum at a larger Zeeman field. If the normal state is transitioned into this finitemomentum pairing (inhomogeneous in real space) state, the upper critical field can be enhanced. Specifically, the Cooper pairs are formed between electrons at $(\mathbf{k}, \uparrow)$ and those at $(-\mathbf{k}+\mathbf{q}, \downarrow)$, as shown in Fig. 5.11. The shifted momentum q due to the Zeeman field is estimated to be $q \sim 2\mu_B H/\hbar v_F$. The state originally proposed by Fulde and Ferrell has the form

$$\Delta(\mathbf{r}) = \Delta e^{i\mathbf{q}\cdot\mathbf{r}} \tag{5.102}$$

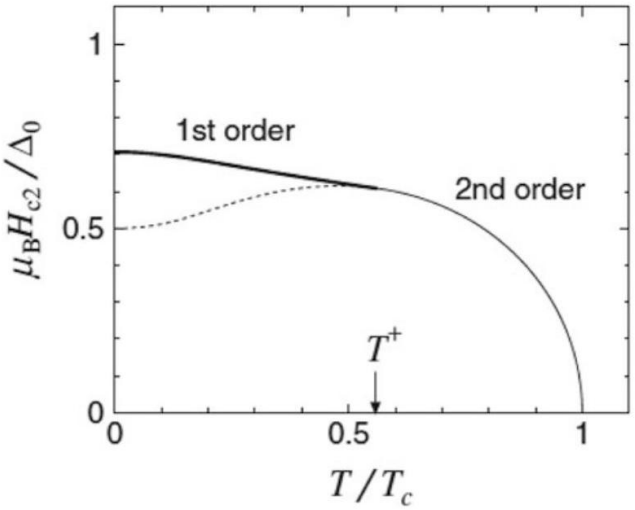

Fig. 5.10 The $H-T$ phase diagram of a two-dimensional superconductor in the pure Pauli limit, which can be realized by applying the field parallel to the plane. Below $T^+(\approx 0.56T_c)$, the transition becomes first order. The broken line represents the metastable transition line. From [52]

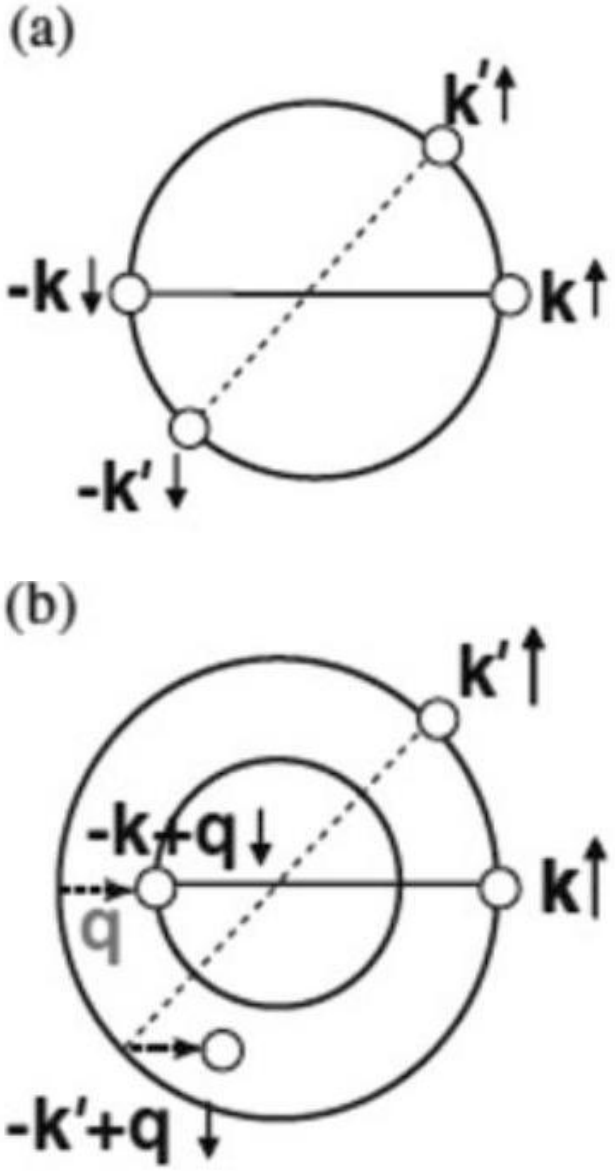

Fig. 5.11 Schematic picture of BCS pairing state ($\mathbf{q} = 0$)(**a**) and FFLO pairing state ($\mathbf{k} \uparrow, -\mathbf{k} + \mathbf{q} \downarrow$)(b). The inner and outer circles represent the Fermi surface of spin-up and spin-down electron bands. From [52]

with the amplitude of the order parameter remaining homogeneous. Note that the functionals $\Delta e^{i\mathbf{q}\cdot\mathbf{r}}$ and $\Delta e^{-i\mathbf{q}\cdot\mathbf{r}}$ are degenerate for a given $\mathbf{q}$, its equal weight linear combination can lift this degeneracy

$$\Delta(\mathbf{r}) = \Delta\left(e^{i\mathbf{q}\cdot\mathbf{r}} + e^{-i\mathbf{q}\cdot\mathbf{r}}\right) = 2\Delta\cos(\mathbf{q}\cdot\mathbf{r}) \tag{5.103}$$

Larkin and Ovchinnikov suggested this form of the order parameter can lead to an even more stable superconducting state in the presence of a larger Zeeman field. Nowadays, this finite-momentum pairing state is called FFLO state [52, 53].

The interest in the FFLO state is recently revived by the observation of a so-called "Q" phase in heavy-fermion $CeCoIn_5$ compound [54], which has a $d_{x^2-y^2}$-wave pairing symmetry at zero field. The problem has recently been numerically studied

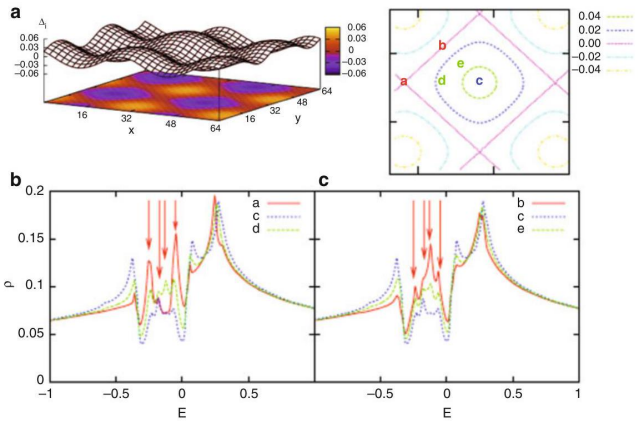

Fig. 5.12 Spatial variation of a d-wave order parameter in the Pauli limit of an external magnetic field (a) and the local density of states (b, c) at the sites marked on the contour plot (upper right panel) of equal magnitude of order parameter. The pairing interaction $V_d = 1.0$, the exchange field $h = H\mu_B = 0.15$, the chemical potential $\mu = -0.4$ in a nearest-neighbor hopping model. From [55]

by solving the BdG equations (5.20) with a d-wave pairing symmetry. Figure 5.12 shows the d-wave order parameter variation as well as the local density of states at several representative sites of the system [55]. The d-wave order parameter at lowtemperatures is stabilized into a square lattice in the form of $\Delta_0 [\cos q_x x + \cos q_y y]$ (see Fig. 5.12a). The spatial variation, especially the sign change of the d-wave order parameter in the real space gives rise to in-gap states exhibited in the local density of states (see Fig. 5.12b, c).

We note that just as interesting quasiparticle states in the mixed state of a superconductor arise from the vortex formation, novel quasiparticle states in the FFLO state through a large external Zeeman field are also due to the variation of order parameter, that is, the collective motion of Cooper pairs. In addition, the BdG formalism is also very powerful in studying the interplay between the Zeeman field and impurities.

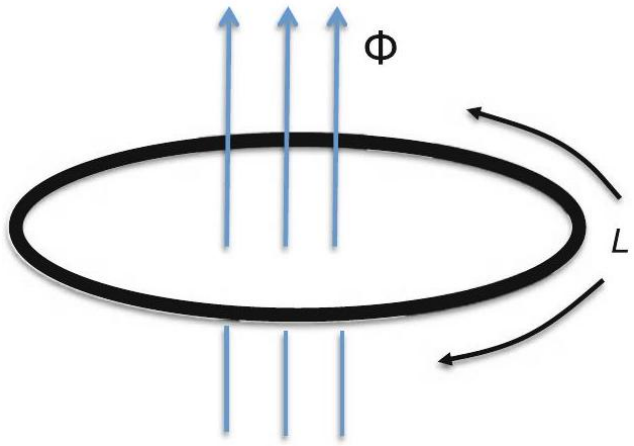
13.4 7 Topological and Quantum Size Effects in SC at Reduced Length Scale

Abstract

The periodicity of persistent currents in multiply connected geometries arising from the Aharonov and Bohm effect is studied for both s-wave superconducting ring and d-wave superconducting cylinder. The loop geometry of a d-wave superconductor is also considered. The solutions of the BdG equations suggest that the hc/e-periodicity is a generic property in s-wave superconductor ring at the mesoscale and in unconventional superconductors. Finally, the theoretical approach to solving the BdG equations is also provided for nanoscale superconductors. The quantum size effects are showcased with the oscillation of transition temperature.

13.4.1 7.1 Persistent Current in a Mesoscopic s-Wave SC Ring

In classical electrodynamics, the Maxwell equations determine directly the behavior of electromagnetic fields $\mathbf{E}$ and $\mathbf{B}$, while the scalar and vector potentials merely play an auxiliary role through the relation



$$\mathbf{E} = -\nabla\varphi(\mathbf{r}), \quad \mathbf{B}(\mathbf{r}) = \nabla \times \mathbf{A}(\mathbf{r}),$$

in the static case. Therefore, the equation of motion of an electron is determined through the Lorentz force

$$\mathbf{F} = -e\left(\mathbf{E} + \frac{\mathbf{v}}{c} \times \mathbf{B}\right),$$

where $\mathbf{v}$ is the electron velocity. However, in quantum mechanics, the scalar and vector potentials enter the Schrödinger equation explicitly and have a direct consequence. In 1959, Aharonov and Bohm (AB) [1] showed that a charged particle can be deflected even when the classical force is absent. This AB effect has now been very well demonstrated by a persistent equilibrium current circulating in an isolated mesoscopic normal-metal ring pierced by an AB flux $\Phi = \oint \mathbf{A} \cdot \mathbf{l}$[2, 3]. This current always has a periodicity of $\Phi_0 = hc/e$, where Φ_0 is the single electron flux quantum. In a superconductor, electrons form Cooper pairs from an effective pairing interaction near the Fermi surface. The flux quantization with $\Phi_0/2$ has been used

Fig. 7.1 Schematic drawing of a one-dimensional superconducting ring of circumference L threaded by a magnetic flux Φ

as a powerful proof for the formation of electron pairs in a macroscopic multiply connected geometries [4-8]. However, we must keep in mind that the Cooper pairs are well defined in momentum space rather than in real space, which makes them distinct from particles with a charge $-2e$. Therefore, there is no reason for one to expect that the persistent current in a superconducting ring should have a periodicity of $\Phi_s = \Phi_0/2$, in particular, when the system is at a mesoscale.

We study this problem by considering a one-dimensional mesoscopic s-wave superconductor ring pierced by a magnetic flux, as shown in Fig. 7.1. Since the flux is restricted to the central hollow region, no magnetic field is experienced by the electrons. The BdG equations are still given by Eq. (5.19) but with no spin Zeeman term and $\nabla \times \mathbf{A} = 0$ on the ring arm. That is, the single-particle Hamiltonian in 1D has the form

$$\tilde{h}(x) = \frac{1}{2m_e}\left(\frac{\hbar}{i}\frac{d}{dx} + \frac{eA(x)}{c}\right)^2 - E_F. \tag{7.1}$$

Here we have used the spatial coordinate $x = 2\pi\theta/L$, where θ is the azimuthal angle, varying between 0 and L. In general, the detailed shape of the ring does not matter. Before we discuss the BdG equations, we first take a look at the wave function to the single-particle Hamiltonian with the Schrödinger equation

$$\tilde{h}(x)\tilde{\varphi}(x) = \epsilon\tilde{\varphi}(x) \tag{7.2}$$

The eigenfunction $\tilde{\varphi}(x)$ satisfies a periodic boundary condition

$$\tilde{\varphi}(x + L) = \tilde{\varphi}(x). \tag{7.3}$$

We introduce a singular gauge transformation

$$\tilde{\varphi}(x) = e^{-ie\chi(x)/\hbar c}\varphi(x) \tag{7.4}$$

Using the identity

$$\left(\frac{\hbar}{i}\frac{d}{dx} + \frac{eA(x)}{c}\right)\tilde{\varphi}(x) = e^{-ie\chi(x)/\hbar c}\left(\frac{\hbar}{i}\frac{d}{dx} + \frac{e}{c}\left(A(x) - \chi'(x)\right)\right)\varphi(x), \tag{7.5}$$

and

$$\left(\frac{\hbar}{i}\frac{d}{dx} + \frac{eA(x)}{c}\right)^2\tilde{\varphi}(x) = e^{-ie\chi(x)/\hbar c}\left(\frac{\hbar}{i}\frac{d}{dx} + \frac{e}{c}\left(A(x) - \chi'(x)\right)\right)^2\varphi(x), \tag{7.6}$$

we obtain

$$\left(\frac{\hbar}{i}\frac{d}{dx} + \frac{e}{c}\left(A(x) - \chi'(x)\right)\right)^2\varphi(x) = \epsilon\varphi(x) \tag{7.7}$$

The choice of the gauge

$$\chi'(x) = A(x), \tag{7.8}$$

leads to

$$-\frac{\hbar^2}{2m_e}\frac{d^2\varphi(x)}{dx^2} = \epsilon\varphi(x). \tag{7.9}$$

Solving Eq. (7.8) yields

$$\chi(x) = \int_0^x A\left(x'\right)dx' \tag{7.10}$$

Therefore, the boundary condition for the new wave function becomes

$$\begin{aligned}\varphi(x+L) &= e^{ie\chi(x+L)/\hbar c}\varphi(x+L)\\ &= e^{\frac{ie}{\hbar c}\int_x^{x+L}A(x')dx'}e^{\frac{ie}{\hbar c}\int_0^x A(x')dx'}\varphi(x)\\ &= e^{i2\pi\Phi/\Phi_0}\varphi(x).\end{aligned} \tag{7.11}$$

Here we have used the identity

$$\int_x^{x+L} A\left(x'\right)dx' = \Phi \tag{7.12}$$

This obervation enables us to apply a singular gauge transformation also to the BdG equations and obtain

$$\begin{pmatrix} h(x) & \Delta(x) \\ \Delta^*(x) & -h^*(x) \end{pmatrix}\begin{pmatrix}u(x)\\ v(x)\end{pmatrix} = E\begin{pmatrix}u(x)\\ v(x)\end{pmatrix}, \tag{7.13}$$

with the periodic boundary condition

$$u(x+L) = e^{i2\pi\Phi/\Phi_0}u(x) \tag{7.14a}$$

$$v(x+L) = e^{-i2\pi\Phi/\Phi_0}v(x) \tag{7.14b}$$

$$\Delta(x+L) = e^{i4\pi\Phi/\Phi_0}\Delta(x) \tag{7.14c}$$

Here the single-particle Hamiltonian is

$$h(x) = -\frac{\hbar^2}{2m_e}\frac{d^2}{dx^2} - E_F. \tag{7.15}$$

If the electron wave vector is k and the wave vector for the collective drift motion (superfluid motion) of the paired electrons is q, the initial Cooper pairing $(k\uparrow, -k\downarrow)$ will occur between electron states $(k+q\uparrow, -k+q\downarrow)$. This allows us to write the wave function and pair potential as

$$\Delta(x) = \Delta e^{2iqx} \tag{7.16a}$$
$$u(x) = u_{k,q}e^{i(k+q)x}, \tag{7.16b}$$
$$v(x) = v_{k,q}e^{i(k-q)x}, \tag{7.16c}$$

A little algebra yields the solution to the BdG equation (7.13) [9]:

$$E^{\pm}_{k,q} = (\hbar k)\frac{\hbar q}{m_e} \pm \sqrt{E_A^2 + \Delta^2} = (\hbar k)\frac{\hbar q}{m_e} \pm E^{(0)}_{k,q} \tag{7.17}$$

with the corresponding eigenfunctions $\left(u^+_{k,q}, v^+_{k,q}\right) = \left(u^{(0)}_{k,q}, v^0_{k,q}\right)$ while $\left(u^-_{k,q}, v^-_{k,q}\right) = \left(v^{(0)}_{k,q}, -u^0_{k,q}\right)$. Here

$$E^{(0)}_{k,q} = \sqrt{E_A^2 + \Delta^2}, \tag{7.18}$$
$$E_A = \frac{\hbar^2}{2m_e}\left(k^2 + q^2\right) - E_F, \tag{7.19}$$

and

$$\begin{pmatrix} u^{(0)}_{k,q} \\ v^{(0)}_{k,q} \end{pmatrix} = \begin{pmatrix} \sqrt{\frac{1}{2}\left(1 + \frac{E_A}{E^{(0)}_{k,q}}\right)} \\ \sqrt{\frac{1}{2}\left(1 - \frac{E_A}{E^{(0)}_{k,q}}\right)} \end{pmatrix} \tag{7.20}$$

The order parameter is then determined by

$$\Delta = \frac{g}{4}\sum_k \frac{\Delta}{E^{(0)}_{k,q}}\left[\tanh\left(\frac{E^{(0)}_{k,q} + \hbar^2 kq/m_e}{2k_BT}\right) + \tanh\left(\frac{E^{(0)}_{k,q} - \hbar^2 kq/m_e}{2k_BT}\right)\right] \tag{7.21}$$

Here the energy cutoff $|E_A| \leq \hbar\omega_D$ is implied in the summation. The boundary condition (7.14) on the wave functions gives

$$k = \frac{\pi}{L}n_k \tag{7.22}$$

and

$$q = \frac{\pi}{L}\left(n_q + \frac{\Phi}{\Phi_s}\right) \tag{7.23}$$

subject to the constraint that $n_k + n_q$ is an even integer and the superconducting flux quantum $\Phi_s = \Phi_0/2$. In addition, from Eq. (6.15), the charge current is now given by

$$I_Q = \frac{2\hbar e}{m_e}\sum_k (k+q)\left[f\left(E^+_{k,q}\right)u^{(0)^2}_{k,q} + f\left(E^{(-)}_{k,q}\right)v^{(0)^2}_{k,q}\right] \tag{7.24}$$

where $f(E)$ is the Fermi-Dirac distribution function.
The drift momentum q defines a superfluid velocity $v_s = \hbar q/m_e$. Equation (7.17) suggests that when the superfluid velocity $v_s = v_d$ with $v_d = \Delta/\hbar v_F$ being the Landau depairing velocity, the gap in the excitation spectrum is closed. The quantity also defines a depairing flux $\Phi_d/\Phi_s = (k_F L/2\pi)(\Delta/E_F)$. This tells us that even if the superconducting gap is not depressed, a gapless quasiparticle state can be induced by the magnetic flux. The numerical results do confirm this intuitive analysis. As shown in Fig. 7.2 (left panel), for a fixed value of ring circumference, when the ration of Δ/E_F is tuned such that $\Phi_d/\Phi_s < 1$, the supercurrent is only a function of magnetic flux with a normal-state period Φ_0. In addition, the selfconsistency solution also shows that the order parameter can be suppressed by an application of the magnetic flux (see Fig. 7.2 (right panel)).

Before we turn to the discussion on the case with a d-wave pairing symmetry, we show a derivation of flux-modified boundary condition for electrons in the 1 D ring

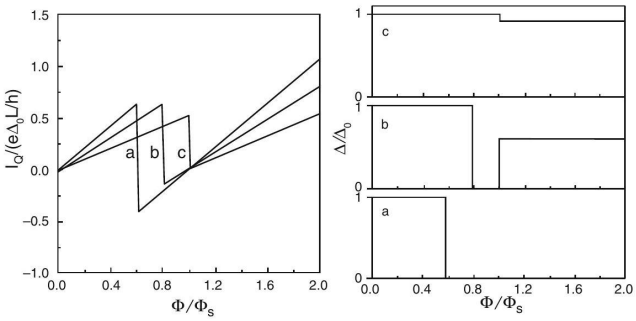


Fig. 7.2 Supercurrent at a fixed amplitude of s-wave order parameter (left panel) and the selfconsistently obtained order parameter as a function of magnetic flux Φ/Φ_S in a mesoscopic ring at $T = 0$ K. For the left panel, the values of $\Delta_0/E_F = 3.0 \times 10^{-3}(a); 4.0 \times 10^{-3}(b); 6 \times 10^{-3}(c)$. For the right panel, the pairing interaction strength is first tuned to give the zero-flux gap value as used for the left panel before it is used for the self-consistent calculations for the flux dependence. The other parameters used are $L = 1000$ nm, and $k_F = 400\pi/L, \hbar\omega_D = 300$ K. Adapted from [9]

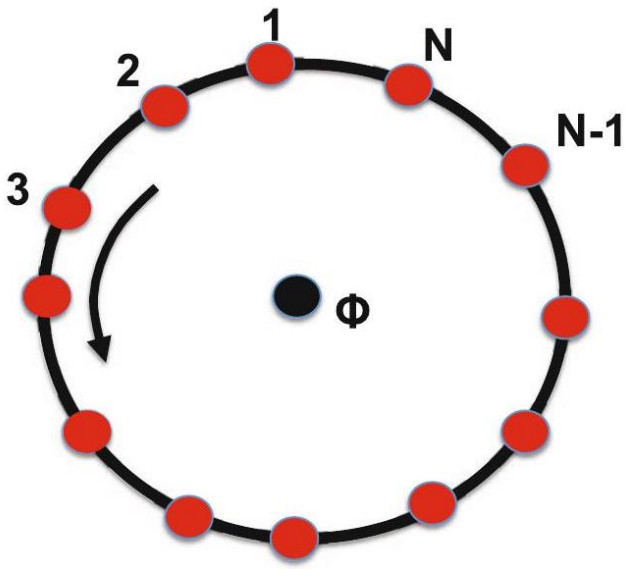

Fig. 7.3 Schematic drawing of a one-dimensional superconducting ring of circumference L threaded by a magnetic flux Φ in a tight-binding model

within a tight-binding model, as shown in Fig. 7.3. The single-particle Hamiltonian is given

by:

$$H = -\sum_{i \neq j} t_{ij} e^{i\theta_{ij}} c_i^\dagger c_j + \sum_i \epsilon_i c_i^\dagger c_i \tag{7.25}$$

where $\theta_{ij} = -\frac{2\pi}{\Phi_0}\int_j^i A(x)dx$ and ϵ is the on-site energy level. Here we have dropped the spin degrees of freedom. Introducing a canonical transformation

$$c_i = \sum_n \varphi_i^n \gamma_n, \tag{7.26}$$

with γ_n being the quasiparticle operator, and within the nearest-neighbor hopping approximation, the Hamiltonian can be diagonalized as

$$\underline{H}\underline{\varphi} = E\underline{\varphi}, \tag{7.27}$$

where

$$\underline{H} = \begin{pmatrix} \epsilon_1 & -te^{i\phi_1} & 0 & 0 & \dots & 0 & -te^{-i\phi_N} \\ -te^{-i\phi_1} & \epsilon_2 & -te^{-i\phi_2} & 0 & \dots & 0 & 0 \\ 0 & -te^{-i\phi_2} & \epsilon_3 & -te^{i\phi_3} & \dots & 0 & 0 \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ -te^{i\phi_N} & 0 & 0 & 0 & \dots & -t^{-i\phi_{N-1}} & \epsilon_N \end{pmatrix}, \tag{7.28}$$

and the eigenvectors $\varphi^{\text{Transpose}} = (\varphi_1, \varphi_2, \varphi_3, \dots \varphi_N)$. Here the accumulated phase for electrons hopping from site j to i has been abbreviated as $\theta_{i,i+1} = \phi_i$ and $\theta_{N,1} = \phi_N$. By performing a uniform transformation

$$\underline{U} = \begin{pmatrix} e^{i\sum_{i=1}^{N-1}\phi_i} & & & & \\ & e^{i\sum_{i=2}^{N-1}\phi_i} & & & \\ & & \dots & & \\ & & & e^{i\phi_{N-1}} & \\ & & & & 1 \end{pmatrix} \tag{7.29}$$

the eigenequation equation becomes

$$\underline{\tilde{H}}\underline{\bar{\varphi}} = E\underline{\bar{\varphi}}, \tag{7.30}$$

where

$$\underline{\hat{H}} = \begin{pmatrix} \epsilon_1 & -t & 0 & 0 & \dots & 0 & -te^{-i\sum_{i=1}^{N}\phi_i} \\ -t & \epsilon_2 & -t & 0 & \dots & 0 & 0 \\ 0 & -t & \epsilon_3 & -t & \dots & 0 & 0 \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ -te^{i\sum_{i=1}^{N}\phi_i} & 0 & 0 & 0 & \dots & -t & \epsilon_N \end{pmatrix}, \tag{7.31}$$

and

$$\overline{\bar{\varphi}} = \underline{U}^\dagger \underline{\varphi}. \tag{7.32}$$

Note that the total phase accumulated across the entire ring is $\sum_i^N \phi_i = 2\pi\Phi/\Phi_0$. Equation (7.31) suggests that the phase factors appearing in the Hamiltonian can be removed by using a modified periodic boundary condition:

$$\bar{\varphi}_{N+1} = \bar{\varphi}_1 \rightarrow \bar{\varphi}'_{N+1} = e^{i2\pi\Phi/\Phi_0}\bar{\varphi}'_1. \tag{7.33}$$

For the BdG equations in the tight-binding model, we can perform the unitary transformation

$$(\underline{U}_{\underline{U}^*})$$

to get the modified periodic boundary conditions for the eigenfunctions. The same procedure can also be applied to the cylindrical geometry, which can be regarded as a stacked array of rings of same radius).

13.4.2 7.2 Current in Multiply Connected Mesoscopic d-Wave SC Geometries

13.4.3 7.2.1 Cylindrical Geometry

For a $d_{x^2-y^2}$-wave pairing symmetry as appropriate to high-temperature cuprates, the pair potential experiences a sign change across the nodal directions and the gapless nodal quasiparticles exist even at zero magnetic field. The question on the periodicity of the supercurrent in a multiply connected geometry with the hollow threaded by a magnetic flux is also intriguing. We first consider the simpler case of a cylindrical geometry as shown in Fig. 7.4. We define the $x-y$ coordinate system

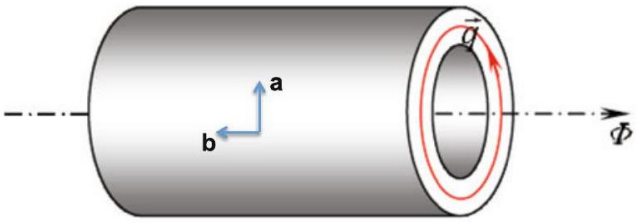

Fig. 7.4 Schematic drawing of a hollow d-wave superconducting cylinder. A magnetic flux Φ threads along the cylinder axis. The vectors **a** and **b** denotes the crystalline axes of an essentially two-dimensional system
to coincide with the crystalline axes, which are perpendicular and parallel to the cylinder axis, respectively. By following the same discussion as in the previous section but now in the tight-binding model, the BdG equations are given as

$$\sum_j \begin{pmatrix} \mathscr{H}_{ij} & \Delta_{ij} \\ \Delta_{ij}^* & -\mathscr{H}_{ij}^* \end{pmatrix} \begin{pmatrix} u_j^n \\ v_j^n \end{pmatrix} = E_n \begin{pmatrix} u_i^n \\ v_i^n \end{pmatrix}, \tag{7.34}$$

subject to the flux-modified boundary condition

$$\begin{pmatrix} u_{i_x+N_x,i_y}^n \\ v_{i_x+N_x,i_y}^n \end{pmatrix} = \begin{pmatrix} e^{i2\pi\Phi/\Phi_0} & 0 \\ 0 & e^{-i2\pi\Phi/\Phi_0} \end{pmatrix} \begin{pmatrix} u_{i_i,i_y}^n \\ v_{i_x,i_y}^n \end{pmatrix}. \tag{7.35}$$

Here (u_i^n, v_i^n) with i denoting the coordinates (i_x, i_y) are the eigenfunctions corresponding to eigenvalues E_n. The single particle Hamiltonian is given by

$$\mathscr{H}_{ij} = -t_{ij} - \mu\delta_{ij}, \tag{7.36}$$

where t_{ij} and μ are the hopping integral and chemical potential, respectively. We take a next-nearest-neighbor hopping approximation with t and t' representing the nearest neighbor and next-nearest neighbor hopping integrals, respectively. The BdG wave function has the form

$$\begin{pmatrix} u_i \\ v_i \end{pmatrix} = \begin{pmatrix} e^{i(\mathbf{k}+\mathbf{q})\cdot\mathbf{r}_i} & 0 \\ 0 & e^{i(\mathbf{k}-\mathbf{q})\cdot\mathbf{r}_i} \end{pmatrix} \begin{pmatrix} u_{\mathbf{k},\mathbf{q}} \\ v_{\mathbf{k},\mathbf{q}} \end{pmatrix}. \tag{7.37}$$

Corresponding to the energy eigenvalues

$$E^{(\pm)}_{\mathbf{k},\mathbf{q}} = Z_{\mathbf{k},\mathbf{q}} \pm E^{(0)}_{\mathbf{k},\mathbf{q}} \tag{7.38}$$

the electron and hole components of the quasiparticle amplitude are given by $(u_{\mathbf{k},\mathbf{q}}, v_{\mathbf{k},\mathbf{q}}) = \left(u^{(0)}_{\mathbf{k},\mathbf{q}}, v^{(0)}_{\mathbf{k},\mathbf{q}}\right)$ and $\left(v^{(0)}_{\mathbf{k},\mathbf{q}}, -u^{(0)}_{\mathbf{k},\mathbf{q}}\right)$ with

$$\left|u^{(0)}_{\mathbf{k},\mathbf{q}}\right|^2 = \frac{1}{2}\left(1 + \frac{Q_{\mathbf{k},\mathbf{q}}}{E^{(0)}_{\mathbf{k},\mathbf{q}}}\right), \quad \left|v^{(0)}_{\mathbf{k},\mathbf{q}}\right|^2 = \frac{1}{2}\left(1 - \frac{Q_{\mathbf{k},\mathbf{q}}}{E^{(0)}_{\mathbf{k},\mathbf{q}}}\right). \tag{7.39}$$

The quantities $Q_{\mathbf{k},\mathbf{q}} = \left[\xi_{\mathbf{k}+\mathbf{q}} + \xi_{\mathbf{k}-\mathbf{q}}\right]/2, Z_{\mathbf{k},\mathbf{q}} = \left[\xi_{\mathbf{k}+\mathbf{q}} - \xi_{\mathbf{k}-\mathbf{q}}\right]/2$, and $E^{(0)}_{\mathbf{k},\mathbf{q}} = \left[Q^2_{\mathbf{k},\mathbf{q}} + |\Delta_{\mathbf{k}}|^2\right]^{1/2}$. In the tight-binding approximation, up to the next-nearest neighbor, the conduction electrons have the normal state dispersion,

$$\xi_{\mathbf{k}} = -2t\left(\cos k_x + \cos k_y\right) - 4t' \cos k_x \cos k_y - \mu \tag{7.40}$$

The d-wave superconducting gap dispersion is given by

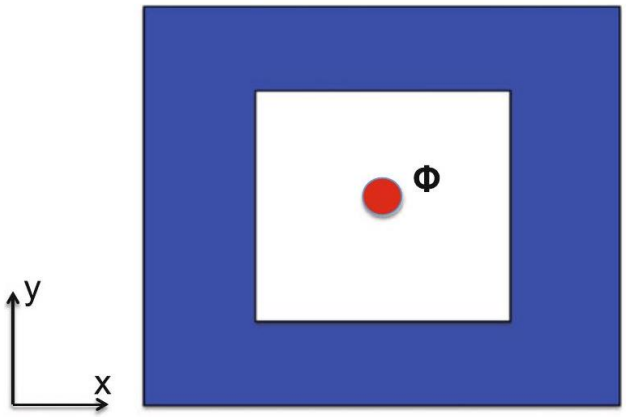
$$\Delta_{\mathbf{k}} = 2\Delta_d \phi(\mathbf{k}) \tag{7.41}$$

where $\phi(\mathbf{k}) = \cos k_x - \cos k_y$, and Δ_d is determined self-consistently:

$$\Delta_d = \frac{V_d}{4N_L} \sum_{\mathbf{k}} \frac{\phi^2(\mathbf{k})\Delta_d}{E^{(0)}_{\mathbf{k},\mathbf{q}}} \times \left[\tanh\left(\frac{E^{(0)}_{\mathbf{k},\mathbf{q}} + Z_{\mathbf{k},\mathbf{q}}}{2k_B T}\right) + \tanh\left(\frac{E^{(0)}_{\mathbf{k},\mathbf{q}} - Z_{\mathbf{k},\mathbf{q}}}{2k_B T}\right)\right] \tag{7.42}$$

where $N_L = N \times N$. Rigorously, the bond order parameters along the x and y directions do not follow the relation $\Delta_x = -\Delta_y$ in the presence of magnetic flux. Here we have imposed the restriction of $\Delta_x = -\Delta_y$ to enforce a rigorous d-wave symmetry. Notice that Δ_d is now a function of Φ/Φ_0. From the boundary condition given by Eq. (7.35), we can find the components of wave vectors $k_x = 2\pi\left(n_x - m/2\right)/N_x, q_x = 2\pi\left(\Phi/\Phi_0 + m/2\right)/N_x$, while $k_y = 2\pi n_y/N_y$, and $q_y = 0$, where $n_{x(y)}$ and m are integers. In particular, m is determined by minimizing $|q_x|$ for a given value of magnetic flux Φ. The electron filling factor and the single nearestneighbor bond current flowing around the cylinder are computed via,

$$n_e = \frac{2}{N_L} \sum_{\mathbf{k}} \left[f\left(E^{(+)}_{\mathbf{k},\mathbf{q}}\right)\left|u^{(0)}_{\mathbf{k},\mathbf{q}}\right|^2 + f\left(E^{(-)}_{\mathbf{k},\mathbf{q}}\right)\left|v^{(0)}_{\mathbf{k},\mathbf{q}}\right|^2\right] \tag{7.43}$$



$$I = \frac{4te}{N_L} \sum_{\mathbf{k}} \left[f\left(E^{(+)}_{\mathbf{k},\mathbf{q}}\right)\left|u^{(0)}_{\mathbf{k},\mathbf{q}}\right|^2 + f\left(E^{(-)}_{\mathbf{k},\mathbf{q}}\right)\left|v^{(0)}_{\mathbf{k},\mathbf{q}}\right|^2\right] \times \left(1 + 2t' \cos k_y/t\right) \sin\left(k_x + q_x\right) \tag{7.44}$$

respectively. A factor of 2 has been included to account for the spin degeneracy. These physical quantities can be numerically evaluated and are reported in [10]. It is found that the order parameter and supercurrent are sensitive to both the system size and electron filling factor. We expect that the current profile should also be dependent on the crystalline orientation with respect to the magnetic flux direction. When the crystalline axes are mis-oriented by 45° away from the cylinder axis, the supercurrent flows along the quasiparticle nodal direction, the study of which is left to readers as an exercise.

13.4.4 7.2.2 Square Loop Geometry

For the smooth multiply geometries, the amplitude of the superconducting order parameter remains homogeneous and the breaking down of the $hc/2e$-periodicity in the supercurrent arises mainly from the competition between the linear dimension of

Fig. 7.5 Schematic drawing of a square loop carved out of a two-dimensional superconductor. A magnetic flux threads through the hole

the system and the superconducting coherence length, which is a typical mesoscopic effect. For unconventional superconductors, the sign change of the superconducting order can have more significant consequence in systems with sharp boundaries like surfaces and interfaces. Near these boundaries, zero-energy modes can be induced. Recently, the periodicity of supercurrent in a square loop has been investigated by solving the BdG equations in real-space within a tight-binding model. The geometry is schematically shown in Fig. 7.5. In this case, it is more convenient to treat directly the Peierls phase factor from the local hopping of electrons in the geometry. Specifically, the vector potential entering Peierls phase given by Eq. (5.16)

$$\varphi_{ij} = -\frac{2\pi}{\Phi_0}\int_j^i \mathbf{A}(\xi)\cdot\xi \tag{7.45}$$

can take the form

$$\mathbf{A}(\mathbf{r}) = \frac{\Phi}{2\pi\left(x^2+y^2\right)}(y,-x,0) \tag{7.46}$$

which ensures the electrons in the arms of the square loop experience only the AB effect.

Figure 7.6 display results from a representative study [11] by solving the BdG equations within a tight-binding model. Energy spectrum is symmetric with respect to the reversal $\Phi \to -\Phi$. Due to the low-energy quasiparticles within the superconducting gap maximum, there are bands inside the gap maximum and they are dispersive with the varying magnetic flux through the AB effect. In addition, the small gap open near the Fermi energy comes from the quantum size effect of the loop. Noticeably, the spectra in the flux region $\Phi \in [0, \Phi_0/4]$ are distinct from those in the region $\Phi \in [\Phi_0/4, \Phi_0/2]$, which leads to very different energy parabolas at $\Phi = 0$ and $\Phi = \Phi_0/2$. Consequently, the $\Phi_0/2$-periodicity is broken down in the supercurrent. Instead only the Φ_0-periodicity is generically satisfied, and should be regarded as a fundamental property of loops formed by unconventional

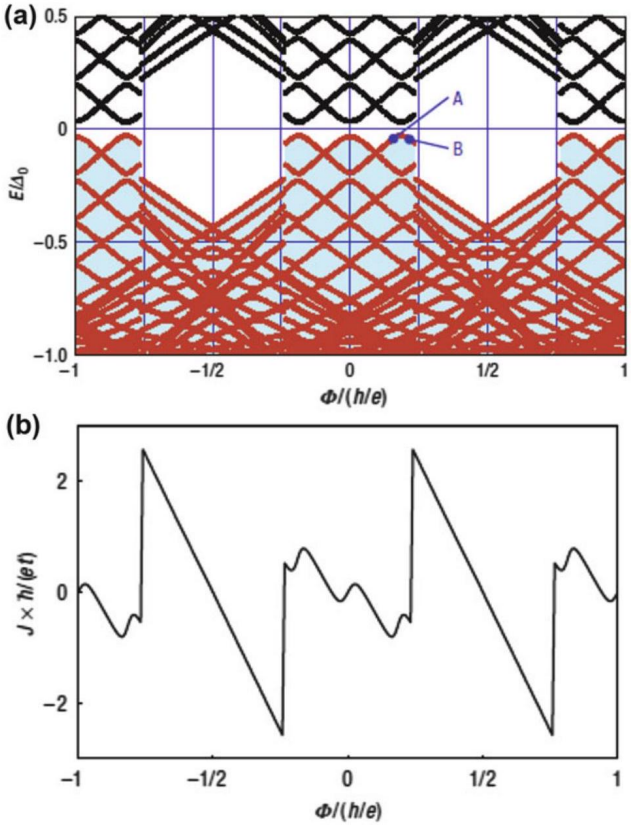


Fig. 7.6 Quasiparticle energy spectrum (a) and supercurrent (b) as a function of the magnetic flux in a square 40×40 loop with a hole of 14×14 unit cells of the original square lattice, obtained by solving the BdG equations self-consistently in a tight-binding model with a nearest-neighbor hopping approximation. The $d_{x^2-y^2}$-wave pairing interaction $0.3t$ is chosen, where t is the nearestneighbor hopping integral. Adapted from [11]

superconducting materials. This periodicity is also shown to survive against the impurity scattering and the change in the loop geometry. This example showcases further the power of the BdG theory when compared with the Ginzburg-Landau theory at a mesoscale.

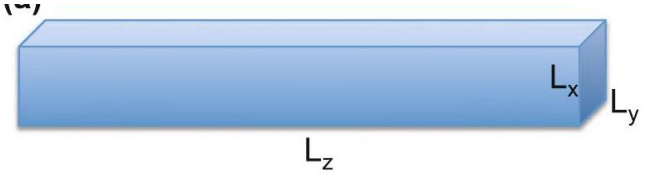
13.4.5 7.3 Quantum Size Effects in Nanoscale Superconductors

Nanoscale metal and semiconductor systems like quantum dots and wires are interesting not only for their unique physical properties but also for their huge potential of technological applications. In these systems, the energy level discretization due to the quantize size effects is one of the key properties. For nanoscale superconductors, the quantum size effects not only set a quantum limit to superconductivity [12, 13], but also are responsible for many new phenomena such as shell effects [1417], which enhance the superconducting energy gap, as well as the oscillation of superconducting transition temperature [18, 19].

Theoretically, the BdG formalism is especially powerful in addressing these quantum size effects. The key idea is to expand the BdG eigenfunctions in terms of the complete set of normal-state single-particle eigenfunctions of the nanoscale systems themselves [20-25]. This approach has also been briefly discussed for the disorder effect and high-field effects in previous chapters. As examples, we consider the continuum model of BdG formalism for s-wave superconducting quantum wires and dots, as shown in Fig. 7.7. For convenience of the discussion, we write the BdG equations for an s-wave superconductor

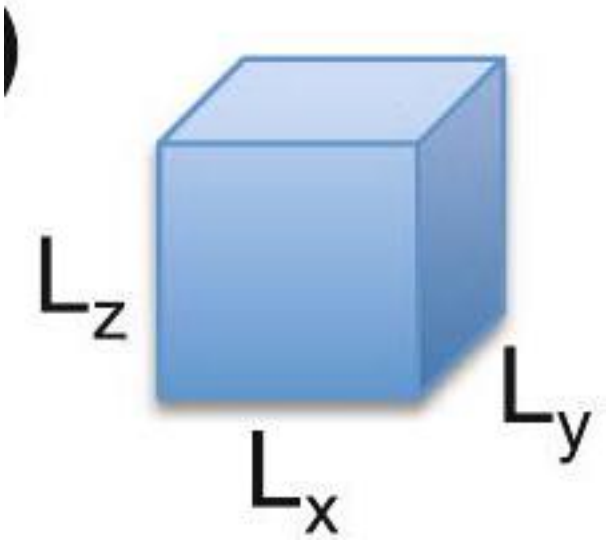
$$\begin{pmatrix} h(\mathbf{r}) & \Delta(\mathbf{r}) \\ \Delta^*(\mathbf{r}) & -h^*(\mathbf{r}) \end{pmatrix} \begin{pmatrix} u_n(\mathbf{r}) \\ v_n(\mathbf{r}) \end{pmatrix} = E_n \begin{pmatrix} u_n(\mathbf{r}) \\ v_n(\mathbf{r}) \end{pmatrix}, \tag{7.47}$$

where the single-particle Hamiltonian is given by



$$h(\mathbf{r}) = -\frac{\hbar^2\nabla^2}{2m_e} + V_c(\mathbf{r}) - E_F, \tag{7.48}$$

and the self-consistency condition is



$$\Delta(\mathbf{r}) = g \sum_{n(E_n>0)} u_n(\mathbf{r}) v_n^*(\mathbf{r}) \tanh\left(\frac{E_n}{2k_BT}\right). \tag{7.49}$$

Fig. 7.7 Schematic drawing of a superconducting quantum wire (a) and a quantum dot(**b**). The variables L_x, L_y, and L_z are the linear dimension of these systems

(a)

(b)

For nanoscale superconductors, the confinement effect is described by the potential $V_c(\mathbf{r})$. For a superconducting quantum wire, the confinement is two-dimensional (e.g., in the $x-y$ plane shown in Fig. 7.7a); while for a superconducting quantum dot, it is three-dimensional (i.e., in all three directions shown in Fig. 7.7b). In the hard-wall approximation, $V(\mathbf{r})$ is

$$V(\mathbf{r}) = \begin{cases} 0, \text{ for } 0 \le x \le L_x, 0 \le |y| \le L_y, \\ \infty, \text{ otherwise} \end{cases} \tag{7.50}$$

for the wire; while

$$V(\mathbf{r}) = \begin{cases} 0, \text{ for } 0 \le x \le L_x, 0 \le |y| \le L_y, 0 \le |z| \le L_z, \\ \infty, \text{ otherwise,} \end{cases} \tag{7.51}$$

for the dot. The corresponding eigenfunctions and eigenvalues for the single-particle Hamiltonian are

$$w_\alpha(\mathbf{r}) = \frac{e^{ik_z z}}{\sqrt{2\pi}} \sqrt{\frac{2}{L_x}} \sqrt{\frac{2}{L_y}} \sin\left(\frac{n_x \pi x}{L_x}\right) \sin\left(\frac{n_y \pi y}{L_y}\right), \tag{7.52}$$

for

$$\epsilon_\alpha = \frac{\hbar^2}{2m_e}\left[\left(\frac{n_x\pi}{L_x}\right)^2 + \left(\frac{n_y\pi}{L_y}\right)^2 + k_z^2\right], \tag{7.53}$$

with α denoting the quantum numbers (n_x, n_y, k_z) for the quantum wire; while

$$w_\alpha(\mathbf{r}) = \sqrt{\frac{2}{L_x}}\sqrt{\frac{2}{L_y}}\sqrt{\frac{2}{L_z}}\sin\left(\frac{n_x\pi x}{L_x}\right)\sin\left(\frac{n_y\pi y}{L_y}\right)\sin\left(\frac{n_z\pi z}{L_z}\right), \tag{7.54}$$

for

$$\epsilon_\alpha = \frac{\hbar^2}{2m_e}\left[\left(\frac{n_x\pi}{L_x}\right)^2 + \left(\frac{n_y\pi}{L_y}\right)^2 + \left(\frac{n_z\pi}{L_z}\right)^2\right], \tag{7.55}$$

with α denoting the quantum numbers (n_x, n_y, n_z) for the quantum dot. We note that the eigenfunctions and eigenvalues for a harmonic potential confinement are also available analytically.

The BdG wavefunctions are then expanded as

$$u_n(\mathbf{r}) = \sum_\alpha u_{n,\alpha} w_\alpha(\mathbf{r}), \tag{7.56a}$$

$$v_n(\mathbf{r}) = \sum_\alpha v_{n,\alpha} w_\alpha(\mathbf{r}). \tag{7.56b}$$

Insertion of Eq. (7.56) into Eq. (7.47) leads to

$$\xi_\alpha u_{n,\alpha} + \sum_\beta \Delta_{\alpha\beta} v_{n,\beta} = E_n u_{n,\alpha}, \tag{7.57a}$$

$$\sum_\beta \Delta^*_{\alpha\beta} u_{n,\beta} - \xi_\alpha v_{n,\alpha} = E_n v_{n,\alpha}, \tag{7.57b}$$

where

$$\xi_\alpha = \epsilon_\alpha - E_F, \tag{7.58}$$

and

$$\Delta_{\alpha\beta} = \int w^*_\alpha(\mathbf{r})\Delta(\mathbf{r})w_\beta(\mathbf{r})d\mathbf{r} \tag{7.59}$$

We note that for a generally irregular wire or dot geometry, there are off-diagonal matrix elements for the single-particle Hamiltonian.

Figure 7.8 displays the numerical results on the superconducting transition temperature with the linear dimension of a square-cross-sectioned quantum wire of Pb, Sn, and Al [22]. It shows clearly the oscillation of transition temperature with the cross-section size. The pronounced resonance feature of the transition temperature is related to the tuning of the density of states in the confinement system. The relative T_c difference between the neighboring peak and valley values is increased with decreasing cross-section size. It also shows that the bulk transition temperature is approached when the linear dimension of the cross-section is several times longer than the bulk superconducting coherence. These results are qualitatively similar to those for cylindrical Al and Sn nano wires [26, 27], suggesting a robust nature of quantum confinement effects. In addition, the same method has also been applied to calculate the local electronic

structure in superconducting quantum wires, from which the quasiparticle interference due to the order parameter inhomogeneity is uncovered [25]. Furthermore, the interplay between the quantum confinement and magnetic field can also be studied in the same framework, which is left for readers as an exercise.

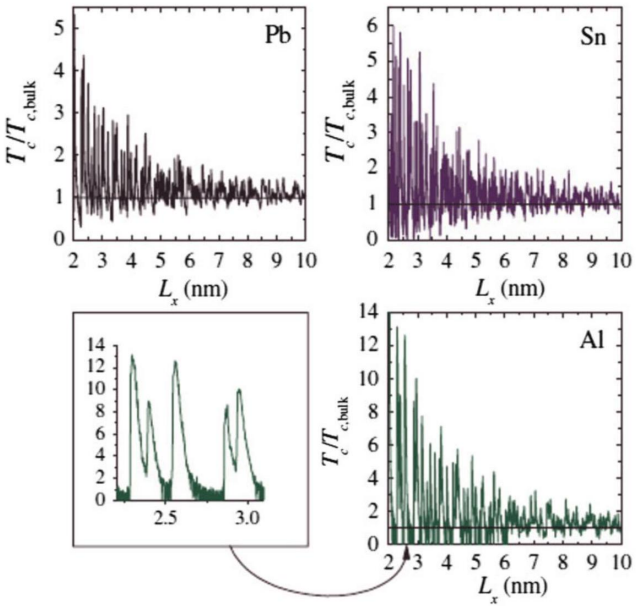


Fig. 7.8 The L_x dependent superconducting critical temperature for Pb, Sn, and Al square-cross-section nano wires. Calculations are with the Debye temperature 96, 195, 375 K and the dimensionless coupling strength $gN(0) = 0.39, 0.25, 0.18$ for Pb, Sn, and Al, respectively. The wire length $L_z = 500$ nm. From [22]

Part VI
Problems and Questions

14 Typical problems

(!!! скорее всего во многих задачах добавлю абзац с теорией, о которой идет речь, прежде чем задается задача! пока это не делаю и теорию продумываю в теор. частях)

14.1 Simplified problems about SC phenomena

(problems from the course of general physics)

14.1.1 Problems about superconductors in magnetic field

(currently, they are written in the note on electrodynamics, later I'll copy them also here)

14.1.2 Qualitative, basic problems about SC 1

O3-5.1 Superconducting ring with decreasing current

A ring with a diameter of $D = 5$cm was rolled from a superconducting wire with a radius of $r = 1$ mm, and the ends of the wire were connected by spot welding. The measurements showed that the contact was not very good, because in one hour the current in the ring decreased by 1% What is the resistance of the ring?

Solution.

(???? нужно подумать про индуктивность сверхпроводника.)
$R = \frac{L}{c^2 t} \ln \frac{\mathcal{J}_0}{\mathcal{J}(t)} \approx 4,4 \cdot 10^{-13}$Ом, где $L = 2\pi D \ln \frac{\pi D}{r}$.

O3-5.2 Superconducting cylinder with decreasing current

A long cylinder with a radius of $a = 1$ cm was rolled from a wide superconducting tape and the edges of the tape were welded along the generatrix. The measurements showed that the electrical contact at the welding site was not very good, because in one hour the current in the cylinder decreased by 1% What is the resistance R of the weld length unit?

Solution.

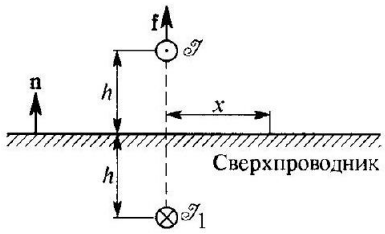
(аналогично прошлой (????))
$R = \frac{L}{c^2 t} \ln \frac{\mathcal{J}_0}{\mathcal{J}(t)} \approx 1,1 \cdot 10^{-13}$Om, где индуктивность единицы ленты $L \approx 4\pi^2 a^2$.

O3-5.3 Wire over superconductor

Find the distribution of surface currents on a flat surface of a superconductor if a rectilinear sufficiently long thin wire parallel to the plane of the superconductor is located at a distance of $h = 1$ cm from it. A current of $\mathcal{J} = 10$ A flows through the wire. Also find the force f acting on a unit length of wire.

Solution.

(????)
$i(x) = \frac{\mathcal{J}h}{\pi(h^2+x^2)}$; $f = \frac{\mathcal{J}^2}{c^2 h} = 1$ дин/см (рис. 236). Поверхностный ток направлен в соответствии с векторным произведением $\mathbf{i} = \frac{c}{4\pi}[\mathbf{nB}]$, т. е. от нас (перпендикулярно плоскости рисунка).



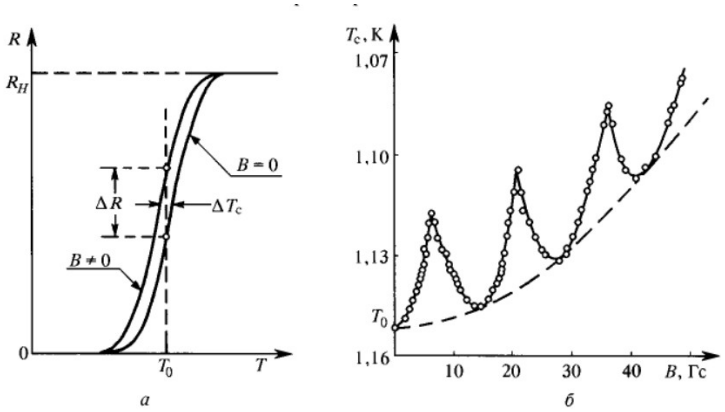


Рис. 236

ОЗ-5.14 Нить с нанесенной сверхпроводящей пленкой

В 1962 г. Литтлом и Парксом была обнаружена осцилляционная зависимость продольного сопротивления пленки сверхпроводника толщиной d, нанесенной на диэлектрическую нить диаметром $D \gg d$, от внешнего магнитного поля $\mathbf{B}$, направленного вдоль нити. Измерения проводились в области сверхпроводящего перехода при постоянной температуре пленки T_0. Зависимость сопротивления пленки от температуры в нулевом и конечном внешнем магнитном поле показана на рис. а). По результатам измерений была построена зависимость критической температуры пленки от магнитного поля (фазовая диаграмма), изображенная на рис. b)

Используя обобщенную формулу квантования Бора-Зоммерфельда $\oint (\mathbf{p}_\mathrm{s} d\mathbf{l}) = 2\pi n\hbar$, ($\mathbf{p}_\mathrm{s} = 2m\mathbf{v}_\mathrm{s} + \frac{2e}{c}\mathbf{A}$ - обобщенный импульс пары), объяснить полученную зависимость $T_\mathrm{c}(B)$ и вычислить диаметр нити. Учесть, что глубина проникновения $\Lambda(T_0) \gg d$, и поэтому эффектом квантования магнитного потока можно пренебречь.

Solution 5.14

(?????)

В силу условий $D \gg d$ и $\Lambda(T_0) \gg d$ можно пренебречь магнитным потоком через пленку и считать, что поле в диэлектрике равно внешнему. Тогда можно записать

$$\oint (\mathbf{p}_\mathrm{s} d\mathbf{l}) = \oint \left(2m\mathbf{v}_\mathrm{s} - \frac{2e}{c}\mathbf{A}\right) d\mathbf{l} = 2\pi n\hbar$$

откуда, используя теорему Стокса, получаем

$$v_\mathrm{s} = \frac{\hbar}{mD}\left(n + \frac{\Phi}{\Phi_0^{\mathrm{sc}}}\right), \qquad \Phi := \frac{\pi D^2}{4}B, \qquad \mathbf{B} := \operatorname{rot}\mathbf{A}, \qquad \Phi_0^{\mathrm{sc}} := \frac{\pi\hbar c}{e}$$

Дополнительная плотность полной энергии сверхпроводника при температуре T_0, обусловленная внешним полем B, равна

$$\Delta w = n_{\text{пар}}\ (T_0)\,\frac{2mv_\mathrm{s}^2}{2} + \frac{B^2}{8\pi}$$

где $n_{\text{пар}}$ - концентрация сверхпроводящих пар, равная $n_{\mathrm{sc}}/2$ (n_{sc} - концентрация сверхпроводящих электронов).

При заданном поле B квадрат скорости сверхпроводящих электронов v_s^2 должен быть минимальным, чтобы обеспечить минимум полной энергии. Таким образом, при увеличении B должна меняться и величина n в условии квантования Бора-Зоммерфельда. Это приводит к периодической зависимости v_s^2 от B (рис. 237).

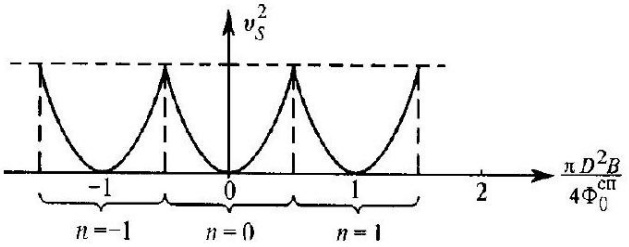

Рис. 237

Поскольку $|\Delta w| \propto k_{\mathbf{b}} \Delta T_{\mathrm{c}}(B)$, то периодическая зависимость v_{s}^2 приводит к периодической зависимости T_c, а член $B^2/(8\pi)$ приводит к монотонному изменению T_{c} (штриховая линия на рис. 82 к условию задачи). Как видно из рисунка, период осцилляций связан с «вхождением» (или «уходом») кванта магнитного потока $\frac{\Delta B \pi D^2}{4} = \Phi_0^{\mathrm{sc}}$, откуда $D = \sqrt{\frac{4\Phi_0^{\mathrm{sc}}}{\pi \Delta B}}$. Из графика находим $\Delta B \simeq 14$ Гс и, следовательно, $D \simeq 1,37 \cdot 10^{-4}$ см.

Сравнить с задачей 4.38 (эксперимент Шарвиных). (????)

O3-5.4 Levitation of the ring

Above the superconducting plane, on an insulating layer with a height of $h = 3$ mm, lies a thin wire ring with a radius of $r = 10$cm. The mass of the ring is $m = 1$ g. A constant current flows through the ring $\mathscr{J}$. Estimate at what value $\mathscr{J}$ the ring will begin to float in the air (levitate).

Solution.

(????)

$\mathcal{J} \geqslant c\sqrt{\frac{mgh}{2\pi r}} = 6,49 \cdot 10^{10}$ ед. СГСЭ $\approx 21,6$ А.

O3-5.5 Oscillations of a magnet over a superconductor

At a distance of a =9 cm above the surface of the superconductor, a thin permanent magnet hovers in the gravity field, the length of which is small compared to the distance of a. If one slightly move the magnet out of equilibrium, it would start to oscillate slowly in the vertical plane. Find the period of these oscillations.

Solution 5.5.

(???)

$T = \pi\sqrt{\frac{a}{g}} = 0,3$с.

O3-5.6 Rotation of a ball over a superconductor

A ball with a mass of $M = 10$ g and a radius of $R = 1$cm, made of a type I superconductor, rests in a magnetic field of $B = 1$ kGs, which is less than critical, at a temperature below the transition point. The temperature of the ball gradually rises such that the superconductivity disappears, and the ball begins to spin. Find the angular velocity ω of the ball's rotation.

Solution 5.6.

(????)

$\omega = \frac{5}{2}\frac{m_e c R B}{M e} = 1.42 \cdot 10^{-5} c^{-1}$.

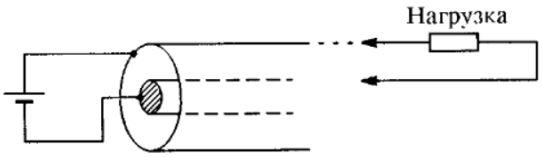
Тут реально носителями тока являются куперовские пары, и для них гиромагнитное отношение $\gamma = \frac{2e}{2 \cdot 2mc} = \frac{e}{2mc}$ совпадает с γ для отдельного электрона.

O3-5.7 Rotation of a superconducting cylinder

In the experiment conducted by I. K. Kikoin, a cylinder made of a superconductor of the first kind with a mass of $M = 80$ g, height of $h = 20$ cm, radius of $R = 0.5$ cm at a temperature below the transition point is suspended vertically on an elastic thread in a magnetic field, which is less than critical one and directed along the axis of the cylinder. The suspension thread is not twisted in its original state. The temperature

is kept constant, and the magnitude of the magnetic field is gradually increased. At a field of $H = 1$ kOe, superconductivity disappears. As a result, the cylinder turns and the thread twists. Determine the maximum twisting angle if the thread's torsion modulus is $\alpha = 1$ erg/rad.

Solution



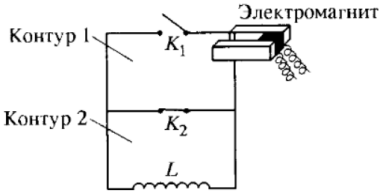
(????)
$\varphi = \frac{m_e c H R h}{e\sqrt{2\alpha M}} = 4,5 \cdot 10^{-5}$ рад.

Носителями тока являются куперовские пары, и для них гиромагнитное отношение $\gamma = \frac{2e}{2 \cdot 2mc} = \frac{e}{2mc}$ совпадает с γ для отдельного электрона.

(??? was there another experiment about it???)

O3-5.8 Using SC in ordinary wires?

Для исключения потерь электроэнергии на джоулево тепло в линиях передачи постоянного тока предложено использовать коаксиальный кабель, внутренняя жила и наружная оболочка которого выполнены из сверхпроводника. Кабель подключен к нагрузке, как это показано на рис. 89.



Максимально допустимые величины магнитной индукции на поверхности сверхпроводника $B = 500$ Гс и напряженности электрического поля изолирующей прослойки кабеля $E = 30$ кВ/см. При каком соотношении диаметров d/D жилы и оболочки можно передать наибольшую мощность W? Найти величину W, приняв диаметр наружной оболочки $D = 20$ см.

Solution 5.8.

$W = \frac{cD^2}{16l} BE = 1,4 \cdot 10^{16}$ эрг /с $= 1,4 \cdot 10^9$В при $\frac{D}{d} = \sqrt{e}$, где e - основание натурального логарифма.

O3-5.9 Магнитный насос (???)

На рис. 90 изображена схема магнитного насоса для «накачки» потока в соленоид.

Насос представляет собой два сверхпроводящих контура с ключами K_1 и K_2. Контур 2 включает в себя соленоид с большой самоиндукцией L, в то время как контур l обладает малой самоиндукцией $l \ll L$. Работа насоса заключается в том, что при закрытом ключе K_2 и открытом ключе K_1 в контуре I с помощью электромагнита создается мощью электромагнита создается магнитное поле. Ключ K_1 замыкается, магнит удаляется и после этого размыкается ключ K_2. Эта операция повторяется много раз. Какого увеличения потока можно достичь в такой системе?

Solution 5.9.

$\left(\frac{\Phi_n}{\Phi_1}\right)_{n\to\infty} = \frac{L}{l}$.

O3-5.10* The London Depth

Find the London penetration depth λ for a typical superconductor of the second kind with a concentration of superconducting electrons $n_{\text{sc}} = 10^{22}\text{cm}^{-3}$.

Solution 5.10*

The formula $\Lambda = \sqrt{\frac{m_e c^2}{4\pi n_{\rm sc} e}} = 0,53 \cdot 10^{-5}$ cm is known, but one can rederive the Meissner effect.

Уравнение движения электрона в сверхпроводнике

$$m\frac{\partial \mathbf{v}}{\partial t} = e\mathbf{E}.$$

Здесь мы заменили полную производную частной, что можно сделать, если пространственные изменения переменных малы ($\frac{d}{dt} = \frac{\partial}{\partial t} + (\mathbf{v}\nabla)$, $\frac{1}{t} \gg \frac{\langle v\rangle}{l}$ или $\omega_{\rm p} \gg \frac{v_{\rm F}}{\Lambda}$, откуда $\frac{v_{\rm F}}{c} \ll 1$).

Так как $\mathbf{E} = -\frac{1}{c}\frac{\partial \mathbf{A}}{\partial t}$ и $\mathbf{j} = en_{\rm sc}\mathbf{v}$, то

$$\mathbf{j} = -\frac{e^2 n_{\rm sc}}{m_{\rm e} c}\mathbf{A} = -\frac{c}{4\pi\Lambda^2}\mathbf{A}, \text{ где } \Lambda = \sqrt{\frac{m_e c^2}{4\pi n_{\rm sc} e^2}} = \frac{c}{\omega_{\rm p}}$$

Это уравнение заменяет закон Ома в сверхпроводниках.

$$\operatorname{rot}\mathbf{j} = -\frac{c}{4\pi\Lambda^2}\operatorname{rot}\mathbf{A} = -\frac{c}{4\pi\Lambda^2}\mathbf{B}$$

Используя уравнение Максвелла $\operatorname{rot}\mathbf{B} = \frac{4\pi}{c}\mathbf{j}$ (в сверхпроводниках $\mathbf{B} \approx \mathbf{H}$, а током смещения в металлах можно пренебречь), получаем

$$\operatorname{rot}\operatorname{rot}\mathbf{B} = \operatorname{grad}\operatorname{div}\mathbf{B} - \nabla^2\mathbf{B} = -\mathbf{B}/\Lambda^2$$

Поскольку $\operatorname{div}\mathbf{B} = 0$, то окончательно

$$\nabla^2\mathbf{B} = \frac{\mathbf{B}}{\Lambda^2}$$

Если однородное внешнее магнитное поле параллельно поверхности сверхпроводника, то уравнение переходит в $\frac{d^2B}{dx^2} = \frac{B}{\Lambda^2}$, где x - координата, направленная вглубь сверхпроводника по нормали к поверхности. Решение этого уравнения $B(x) \propto e^{-x/\Lambda}$, т. е. магнитное поле экспоненциально затухает вглубь сверхпроводника. Поскольку частота внешнего поля не входит в Λ, то результат в полной мере относится к постоянному магнитному полю. Искомая глубина $\Lambda = 5,3 \cdot 10^{-5}$ см.

О3-5.11 Сверхток в пластине

Найти распределение поля и тока в бесконечной пластине сверхпроводника толщиной d, помещенной в однородное параллельное пластине магнитное поле B_0.

Solution 5.11.

$B(x) = B_0\frac{\operatorname{ch}(x/\Lambda)}{\operatorname{ch}[d/(2\Lambda)]}$; $\quad j_{\rm s} = -\frac{cB_0}{4\pi\Lambda}\frac{\operatorname{sh}(x/\Lambda)}{\operatorname{ch}[d/(2\Lambda)]}$, где $\Lambda = \sqrt{\frac{m_e c^2}{4\pi n_{\rm sc} e^2}}$ - лондоновская глубина.

О3-5.12 Длина когерентности по щели

Исходя из соотношения неопределенностей, оценить характерный линейный размер (длину когерентности) электронной пары в сверхпроводнике с энергетической щелью $\Delta = 3$ мэВ в электронном спектре. Учесть, что в образовании пар участвуют электроны вблизи поверхности Ферми, скорость которых принять равной $v_{\rm F} \sim 10^8$ см/с.

Solution 5.12.

(?? this is basic topic in the theory)

$\xi \approx \frac{\hbar v_{\rm F}}{2\Delta} = 10^{-5}$ cm.
$\delta p = \Delta/v_F$ (???)
(in my theory there is no 1/2, but it does not matter)

О3-5.13 Разрушение куперовской пары

В сверхпроводнике электроны образуют пары с противоположно направленными спинами. В каком магнитном поле произойдет разрушение таких пар, сопровождаемое изменением направления спина одного из электронов пары, если в нулевом магнитном поле критическая температура сверхпроводника равна $T_c = 92$ K? Считать, что разрушение пары происходит при $T = 0$ K.

Solution 5.13.

(??? the solution is somewhat equating energy of spin spread and energy that holds together the pair, but I am not sure)
$B \approx \frac{k_B T_c}{\mu_B} \approx 1,4 \cdot 10^6$Гс.

О3-5.15 Maximal surface current

Какой максимальный ток течет по поверхности сверхпроводника I рода, находящегося во внешнем касательном магнитном поле, если величина критического магнитного поля $H_c = 400$ А/см, а лондоновская глубина проникновения $\Lambda = 0,5 \cdot 10^{-5}$ см?

Solution 5.15.

(???)
$j_{\max} = \frac{c}{4\pi}\left(\frac{\partial B}{\partial x}\right)_{\max} = -\frac{cH_c}{4\pi\Lambda} = 8 \cdot 10^7$ A/cm^2, т. е. ток затухает по тому же закону, что и поле.

О3-5.16 Current through a droplet

The current to be measured j flows through a niobium wire with a diameter of $2r_{\text{Nb}} = 0.1$ mm, forming point contacts A and B in a drop of superconducting metal solder Pb + Sn. Due to the presence of an oxide film on the niobium surface, the drop does not completely wet the wire, but only touches the niobium at certain points. Let there be only two such points, A and B, with a distance between them of $l_{AB} = 5$ mm (Fig. below). The thickness of the insulating film on the niobium surface can be considered small compared to the penetration depth.

Estimate the current strength at which one quantum of magnetic flux will pass through the droplet surface. The London lengths for niobium and solder are equal $\Lambda_{\text{Nb}} = 5 \cdot 10^{-6}$ см, $\Lambda_{\text{PbS}} = 10^{-5}$ см.

Solution 5.16*

(??? don't understand the statement. ???)
$\mathscr{E}_{\Phi_0} \approx 0,7$MA.
Решение. Магнитное поле проходит между двумя точечными контактами через поверхность, площадь которой практически равна произведению расстояния между контактами l_{AB} на сумму глубин проникновения в ниобий Λ_{Nb} и припой Λ_{PbSn}.

$$B = \frac{2\mathcal{J}}{cr_{\text{Nb}}}, \qquad \Phi = BS = \frac{2\mathcal{J}}{cr_{\text{Nb}}} l_{AB}\left[\Lambda_{\text{Nb}} + \Lambda_{\text{PbSn}}\right]$$
$$\mathcal{J}_{\Phi_0} = \Phi_0^{\text{sc}} \frac{cr_{\text{Nb}}}{2l_{AB}\left[\Lambda_{\text{Nb}} + \Lambda_{\text{PbSn}}\right]} = 6.9 \cdot 10^{-4} \text{ A} \approx 0,7 \text{ mA}.$$

О3-5.17* Thin film on a thread in a field

A thin film of a type I superconductor with a thickness of $d \ll \Lambda$ is considered, deposited on the surface of a dielectric filament, the radius of which is $R \gg d$. First, the thread is introduced into a longitudinal magnetic field at room temperature, and then the thread temperature drops below the critical temperature T_c. After that, the external magnetic field turns off. How is the magnetic flux captured by the filament and film quantized?
Hint. Use the Bohr-Sommerfeld quantization condition $\oint (\mathbf{p}_s d\mathbf{l}) = 2\pi n\hbar$, where $\mathbf{p}_s$ is the generalized momentum of the pair (see problems 5.14)

Solution 5.17*

Поскольку $d \ll \Lambda$, ток будет распределен по толщине пленки однородно. В силу условия $R \gg d$ магнитное поле в диэлектрике равно

$$B = \frac{4\pi}{c} j_{\text{s}} d$$

(как в соленоиде: $j_{\text{s}}d$ - линейная плотность тока). По определению $j_{\text{s}} = en_{\text{sc}}v_{\text{s}}$, где n_{sc} - плотность сверхпроводящих электронов, v_{s} - скорость центра масс пар. В магнитном поле обощенный импульс пары

$$\mathbf{p_s} = 2m\mathbf{v_s} - \frac{2e}{c}\mathbf{A}$$

Используя условие квантования Бора-Зоммерфельда

$$\oint (\mathbf{p}_{\text{s}} d\text{l}) = 2\pi n\hbar,$$

получаем

$$2\pi n\hbar = \frac{2m2\pi R}{n_{\text{sc}}e} j_{\text{s}} - \frac{2e}{c}\tilde{\Phi},$$

где $\tilde{\Phi} = \int(\text{rot}\,\mathbf{A}d\mathbf{s}) =$ вл R^2 - магнитный поток внутри цилиндра. Исключая j_s, находим:

$$\tilde{\Phi} = n\frac{\Phi_0^{\text{sc}}}{1 + 2\Lambda^2/(Rd)}.$$

Как видно из формулы, при $Rd \gg \Lambda^2$ квантование магнитного потока в тонкостенном цилиндре происходит так же, как и в массивном образце. Но, вообще говоря, «квант потока» всегда меньше Φ_0^{sc}.

Answer: $\Phi = n\Phi_0 \frac{1}{1+2\Lambda^2/(Rd)}$.

O3-5.18 Cryotron (????)

The cryotron is a control device invented by the Buck in 1953 (Fig. 93).
Control current of length $L = 2$ mm with number of turns $N = 20$. A superconducting tantalum wire AB with a diameter of $2a = 0.2$ mm is placed in the solenoid, through which current is passed $\mathscr{J}$. The critical field H_{c} for tantalum at 4.2 K is 100 Gs. By converting the wire from superconducting to normal by the field of the solenoid, the current flowing through the wire can be controlled, Therefore, the cryotron can be used in logic circuits as an active element, as well as as a storage element in computers.
What is the current gain $G = \mathscr{J}/\mathscr{J}'$ can be achieved in this device?

Solution 5.18.

$G = \frac{\mathscr{J}_c}{\mathscr{J}'_{\min}} = 2\pi N\frac{a}{L} \approx 6$, где $\mathscr{J}_c$ - предельный ток прямого провода, создающий разрушающее критическое поле $B_c = \frac{2}{cr}$, $\mathscr{J}'_{\min}$ - предельное (минимальное) значение управляющего тока, переводящего проволоку в нормальное состояние.

O3-5.19 Estimation of a critical field

Tantalum (Ta) crystallizes into a volume-centered cubic lattice with a constant $a = 3\mathring{\text{A}}$ and is a superconductor of the first kind ($T_{\text{c}} = 4,4$ K). Suppose that each Ta atom gives one electron to the conduction band and that the effective mass of it is equal to the mass of a free electron. Estimate from energy considerations the magnitude of the critical magnetic field H_{c} at $T \approx 0$ K, in which Cooper pairs are destroyed.

Solution 5.19.

$H_c \approx \frac{8\cdot 2^{2/3} k_{\text{B}} T_{\text{c}}}{\hbar(3\pi^2)^{1/3}}\sqrt{\frac{m\pi}{a}} \approx 730$Гс.
Плотность энергии сверхпроводника ниже плотности энергии нормального металла на величину плотности энергии связи куперовских пар.

Поскольку энергия связи одной пары равна 2Δ (по Δ на каждый электрон), то $\mathscr{E}_{\text{св}} = n_{\text{пар}}\, 2\Delta = \frac{n_{\text{sc}}}{2} 2\Delta$, где n_{sc} - плотность сверхпроводящих электронов. По аналогии с теплоемкостью металла $n_{\text{sc}} \simeq n\frac{2\Delta}{\varepsilon_{\mathbf{F}}}$

(«размытие распределения» примерно 2Δ), где $n = 2/a^3$ плотность электронов проводимости. Считая, что $\Delta \simeq 2k_{\mathrm{D}}T_{\mathrm{c}}$ (в теории сверхпроводимости Бардина-Купера-Шриффера: $\Delta = 1,76k_BT_c$), получаем

$$\mathscr{E}_{sc} \approx \frac{16\left(k_{\mathrm{B}}T_{\mathrm{c}}\right)^2}{a^3\varepsilon_{\mathrm{F}}} = \frac{32\left(k_{\mathrm{B}}T_{\mathrm{c}}\right)^2 m_{\mathrm{e}}}{a\hbar^2\left(3\pi^2\right)^{2/3}2^{2/3}}$$

Сверхпроводимость «разрушается», когда плотность энергии магнитного поля сравнивается с плотностью энергии связи

$$\frac{H_{\mathrm{c}}^2}{8\pi} = \mathscr{J}_{\mathrm{sc}}, \quad \text{откуда} \quad H_{\mathrm{c}} \approx \frac{8\cdot 2^{2/3}k_{\mathrm{L}}T_{\mathrm{c}}}{\hbar\left(3\pi^2\right)^{1/3}}\sqrt{\frac{m_{\mathrm{e}}\pi}{a}} \approx 730\text{Гс}$$

Отметим, что экспериментальное значение критического поля тантала составляет 830 Гс. Заметим также, что ответ можно выразить и в такой форме

$$H_{\mathrm{c}} \simeq \frac{\Phi_0^{\mathrm{c\Pi}}}{\pi\Lambda\xi}$$

О3-5.20 плотность критического тока распаривания j_{c} при $T = 0$ K для свинца (?????)

Оценить плотность критического тока распаривания j_{c} при $T = 0$ K для свинца, у которого $T_{\mathrm{c}} = 7,2$ K, $n_{\mathrm{sc}} \simeq 3\cdot 10^{22}$ см$^{-3}$, $v_{\mathrm{F}} \approx 10^8$ см/с.

Solution 5.20.

$j_{\mathrm{c}} \simeq \frac{2k_{\mathrm{B}}T_{\mathrm{c}}n_{\mathrm{sc}}e}{m_{\mathrm{e}}v_{\mathrm{F}}} \simeq 10^8$ A/cm^2.

О3-5.21 Расстояние между вихрями по намагниченности

Длинный цилиндр из сверхпроводника II рода, у которого нижнее критическое поле $H_{\mathrm{cl}} = 400$ Э, помещен в магнитное поле $H = 500$ Э, параллельно его образующей, при этом его намагниченность составила половину того значения, которое было при H_{cl}. Оценить среднее расстояние между вихрями магнитного потока в поле H.

Solution 5.21

* $d \approx \sqrt{\frac{\Phi_0^c}{B_2}} \approx 2,6\cdot 10^{-5}$с, где $B_2 = 300$ Гс.

Решение. В первом случае при внешнем поле $H = H_{\mathrm{c1}}$ $B_1 = H + 4\pi I_1 = 0$, откуда намагниченность $4\pi I_1 = -400$ Э. Во втором случае (см. графики на рис. 238) во внешнем поле $H = 500$ Э $B_2 = H + \frac{1}{2}(4\pi I_1) = 500 - 200 = 300$ Гс.

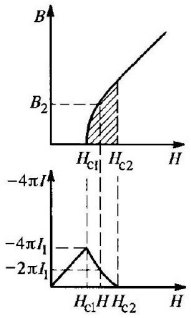


Рис. 238

Поскольку $H > H_{c1}$, то сверхпроводник находится в смешанном состоянии (полагаем, что $H < H_{c2}$). Плотность вихрей, т. е. их число, приходящееся на единицу площади оценим как

$$n = \frac{B_2}{\Phi_0^{\mathrm{cI^{II}}}}$$

Тогда расстояние между вихрями, магнитного потока, называемыми также вихрями Абрикосова,

$$d \approx \frac{1}{\sqrt{n}} = \sqrt{\frac{\Phi_0^{c\pi}}{B_2}} \approx 2,6\cdot 10^{-5}\ \text{cm}$$

Solution

При внешнем поле $H = H_{\text{c}\,1}$ $B_1 = H + 4\pi I_1 = 0$, откуда намагниченность $4\pi I_1 = -400$ Э. Во внешнем же поле $H = 500$ Э $B_2 = H + \frac{1}{2}(4\pi I_1) = 500 - 200 = 300$ Гс. Поскольку $H > H_{\text{c}1}$, то сверхпроводник находится в смешанном состоянии (полагаем, что $H < H_{\text{c}2}$). Плотность вихрей, т. е. их число, приходящееся на единицу площади оценим как

$$n = \frac{B_2}{\Phi_0^{c\pi}}$$

Тогда расстояние между вихрями

$$d \approx \frac{1}{\sqrt{n}} = \sqrt{\frac{\Phi_0^{\text{cT}}}{B_2}} \approx 2,6 \cdot 10^{-5} \text{ cm}$$

Ответ: $d \approx \sqrt{\frac{\Phi_0^{\text{cI}}}{B_2}} \approx 2,6 \cdot 10^{-5}$ cm, где $B_2 = 300$ Гс.

О3-5.22 Поле вихрей по рассеянию нейтронов

В 1964 г. Крибье с сотрудниками с помощью упругого рассеяния нейтронов на ниобии экспериментально подтвердил, что в сверхпроводниках II рода в магнитном поле $B > B_{\text{cI}}$ образуется треугольная вихревая решетка Абрикосова. В опытах наблюдался максимум первого порядка в отражении нейтронов с длиной волны $\lambda = 5$Å под углом $\theta = 20'$ по отношению к падающему пучку от плоскостей, разделенных расстоянием h (высота равностороннего треугольника структуры). В каком магнитном поле проводился эксперимент?

Solution 5.2

2. $B \approx \frac{\sqrt{3}}{2}\frac{\Phi_0^{c\pi}\theta^2}{\lambda^2} = 2430$ Гс, где $\Phi_0^c = \frac{hc}{2e} = 2,07 \cdot 10^{-7}$Гс $\cdot$ с^2 - квант магнитного потока в сверхпроводнике.

О3-5.23 Энергия электронов в вихре

Найти выражение для кинетической энергии $\mathcal{E}$ электронов на единицу длины вихря магнитного потока, проникшего в сверхпроводник II рода при $H > H_{c1}$, считая заданными плотность сверхпроводящих электронов n_{sc} , глубину проникновения Λ и длину когерентности $\xi \ll \Lambda$. Считать, что вихрь занимает по радиусу размер от ξ до Λ, а пары обладают минимально возможной проекцией углового момента.

Solution

По правилу квантования проекции момента импульса $2mv(r)r = \hbar(n = 1)$ находим распределение скоростей центров масс пар в вихре

$$v(r) = \frac{\hbar}{2mr}.$$

Это выражение справедливо при $\xi \ll r \ll \Lambda$, когда можно пренебречь вкладом интеграла $\oint \mathbf{A}d\mathbf{1}$ в правиле квантования Бора-Зоммерфельда (см. задачи 5.14 и 5.17). Если длина вихря равна L, то кинетическая энергия электронных пар в вихре

$$\mathscr{E}_L = \int \frac{2mv^2(r)}{2}\frac{n_{\text{sc}}}{2}dV = L\int_{\xi}^{\Lambda}\frac{\hbar^2}{8mr^2}n_{\text{sc}}2\pi r dr,$$

откуда и следует ответ задачи.

Ответ: 5.23* $\mathscr{E} = \frac{\pi n_{\text{sc}}\hbar^2}{4m}\ln\frac{\Lambda}{\xi}$.

О3-5.24

Найти магнитную энергию единицы длины вихря во внешнем поле $H > H_{\text{cl}}$, считая заданными плотность сверхпроводящих электронов n_{sc} и глубину проникновения $\Lambda \gg \xi$ (длины когерентности). Считать, что вихрь занимает по радиусу размер от ξ до Λ, а пары обладают минимально возможной проекцией углового момента. Получить выражение для H_{cl}, используя результат задачи 5.23.

Solution

$W_{\rm m} = -\mathfrak{M}H$, где $\mathfrak{M} = \mu_{\rm D}\int_{\xi}^{\Lambda}\frac{n_{\rm sc}}{2}2\pi r dr \simeq \frac{\pi n_{\rm sc}}{2}\Lambda^2$ - магнитный момент единицы длины вихря. Из условия $\mathscr{E} + \boldsymbol{W}_{\rm m} = 0$ находим $H_{\rm c1} = \frac{c\hbar}{e\Lambda^2}\ln\frac{\Lambda}{\xi} = \frac{\Phi_0^{\rm sc}}{2\pi\Lambda^2}\ln\frac{\Lambda}{\xi}$ (см. также задачу 5.25).

О3-5.25 Λ и ξ высокотемпературного сверхпроводника

Для высокотемпературного сверхпроводника $YBaCCu_3O_{7-\delta}$, где $\delta < 1$, критические поля $H_{\rm cl} = 10^3$ Э и $H_{\rm c2} = 10^6$ Э. Оценить глубину проникновения Λ и длину когерентности ξ при $T = 0$ К.

Solution

$\Lambda \approx \sqrt{\frac{\Phi_0^{\rm cП}}{\pi H_{\rm cl}}} \approx 0,8\cdot 10^{-5}$ cm; $\xi = \sqrt{\frac{\Phi_0^{\rm cГ}}{\pi H_{\rm c2}}} \approx 3\cdot 10^{-7}$ cm.

О3-5.26

Цилиндр из сверхпроводника II рода массой $M = 25$ г и длиной $l = 10$ см подвешен вдоль оси на тонкой нити. Вдоль оси цилиндра прикладывается такое магнитное поле $H = 10^4 \gg H_{\rm cl}$, что индукция $B \simeq H$. Вначале температура цилиндра $T < T_{\rm c}$, цилиндр покоился, а затем температура увеличилась выше критической. Найти установившуюся угловую частоту вращения цилиндра. Глубина проникновения магнитного поля $\Lambda = 10^{-5}$ см, плотность сверхпроводящих электронов $n_{\rm sc} = 10^{22}$ см$^{-3}$.

Solution

$\omega = \frac{\pi^2 n_{\rm sc}\Lambda^2 hlB}{\Phi_0^{c\pi}M} \approx 2\cdot 10^{-4}\text{c}^{-1}$.

14.1.3 Qualitative, basic problems about SC 2

О3-5.27 Сила на вихрь со стороны дефектов (??)

Плоская лента шириной $b = 0,5$ см из сверхпроводника II рода в смешанном состоянии помещена в магнитное поле $B = 10$ Тл, $H_{\rm cl} \ll B \ll H_{\rm c2}$, перпендикулярное поверхности ленты (рис. 94).

По ленте без диссипации течет ток $\mathcal{J} = 10$ А. При этом вихри неподвижны, удерживаемые структурными дефектами сверхпроводника. Вычислить силу F, действующую на отдельный вихрь со стороны дефектов кристалла. Считать, что ток однородно распределен по образцу, а вихревую структуру создают другие, независимые от (?) токи.

Solution

$F = \frac{1}{c}\frac{\mathcal{E}\Phi_0^{\rm sc}}{b} \approx 4\cdot 10^{-7}$ дин.

О3-5.28 Электрическое поле при вязком течении вихрей (???)

Пластинка из сверхпроводника II рода расположена в магнитном поле H (при этом $H > H_{\rm cl}$), перпендикулярном ее плоскости. Если вдоль пластины пропустить ток плотностью $\mathbf{j}$, то в результате взаимодействия с этим током вихри приходят в движение с конечной скоростью v, определяемой силой трения (приходящейся на единицу длины вихря) $F_{\rm тр} = \eta v$. Такое движение называется вязким течением вихрей. Какое электрическое поле появится в сверхпроводнике?

Solution 5.28

* $E = \frac{1}{c}vB = \frac{\Phi_0^{c\pi}jB}{\eta c^2}$.

Решение. Условием равномерного движения вихря является равенство сил $|\mathbf{F}_{\rm Tp}| = |\mathbf{F}_{\rm A}|$, где сила Ампера, действующая на единицу длины вихря

$$\mathbf{F_A} = \frac{1}{c}\left[\mathbf{j}\mathbf{\Phi}_0^{\text{cn}}\right], \quad \mathbf{\Phi}_0^{\text{cn}} = \frac{hc}{2e}\frac{\mathbf{B}}{B}.$$

Скорость вихря $\mathbf{v}$ образует правую тройку с векторами $\mathbf{j}$ и B. При этом $v = \frac{1}{c}\frac{j\Phi_0^{\text{sc}}}{\eta}$. В системе вихря, движущегося со скоростью $\mathbf{v}$, присутствует только магнитное поле B следовательно в лабараторной системе отсчета имеется также макроскопическое электрическое поле

$$\mathbf{E} = \frac{1}{c}[\mathbf{B}\mathbf{v}].$$

Легко увидеть, что $\mathbf{E}\|\mathrm{j}$ и поэтому $E = \frac{1}{c}vB = \frac{\Phi_0^{\text{sc}} jB}{\eta c^2}$.

О3-5.29* Проводимость при вязком течении вихрей (???)

Найти эффективную проводимость сверхпроводника II рода в режиме вязкого течения вихрей (См. задачу 5.28).

Solution 5.2

9*: $\sigma_{\text{eff}} = \sigma_{\text{n}}\frac{H_{c2}}{B}$, где σ_{n} - проводимость в сердцевине вихря, т. е. проводимость сверхпроводника в нормальном состоянии.

Решение. Как следует из предыдущей задачи (5.28*), $\mathbf{j} = \sigma_{\text{eff}}(B)\mathbf{E}$, где эффективная проводимость $\sigma_{\text{eff}}(B) = \Phi_0^{\text{sc}}/\left(\eta c^2\right)$.

Поскольку при $B = H_{\text{c2}}$ сверхпроводимость исчезает и материал становиться нормальным металлом, то

$$\sigma_{\text{eff}}(H_{\text{c2}}) = \frac{\Phi_0^{\text{cn}} H_{\text{c2}}}{\eta c^2} = \sigma_{\text{n}},$$

откуда $\frac{\Phi_0^{\text{sc}}}{\eta c^2} = \frac{\sigma_{\text{n}}}{H_{\text{c2}}}$ или $\sigma_{\text{eff}}(B) = \sigma_{\text{n}}\frac{B}{H_{\text{c2}}}$.

О3-5.30

В сверхпроводнике, содержащем примеси, электрон упруго рассеивается на примесных атомах без потери фазы. Если среднее расстояние между примесными атомами много меньше длины когерентности ξ, то электрон движется подобно броуновской частице. Исходя из этих соображений, оценить эффективную длину когерентности ξ в сверхпроводнике с постоянной решетки $a = 3$Å, средним расстоянием между примесями $b \simeq 30$Å и критической температурой $T_{\text{c}} = 25$ K.

Solution 5.30.

$\bar{\xi} = \sqrt{6D\tau_{\text{ког}}} \approx \sqrt{\frac{\hbar^2 b}{makT_{\text{c}}}} \approx 1,8 \cdot 10^{-6}$ см, где коэффициент диффузии $D = \frac{1}{3}v_{\text{F}}\lambda \approx \frac{1}{3}v_{\text{F}}b, \left(v_{\text{F}} \simeq \frac{\hbar}{ma}\right), \tau_{\text{ког}} \simeq \frac{\xi}{v_{\text{F}}}$ - время до того момента, когда сбивается фаза электронной волны.

Ш-з.45.2. Coupling constant

Определить константу связи $g = N(0)V$ для олова, если $t_c' = 3.74$ K, а дебаевская температура равна $\Theta_{\text{D}} = 195$ K.

Solution

Используя формулу $k_{\text{B}}T_c = 1.14\hbar\omega_{\text{D}}e^{-1/N(0)V}$, получим $g = \mathbf{0.245}$.

Ш-з.45.3. Critical Temperature of a similar material

Критическая температура смеси изотопов ртути со средним атомным весом 199.7 г равна 4.161 K. На сколько и в какую сторону изменится критическая температура для смеси со средним атомным весом 200.7 г?

Solution

(?? use isotope effect??)
Понизится на 0.01 K.

Ш-з.45.4. Critical Temperature

Туннельный эксперимент дал для индия значение энергетической щели $\Delta_0 = 5.3 \cdot 10^{-4}$ эВ. Какой должна быть согласно теории БКШ критическая температура индия? Сравнить с T_c индия 3.37 K.

Solution

(use that universal relation?)
$T_c = 2\Delta_0/\left(3.52 k_{\mathrm{B}}\right) = 3.49$ K.

О3-5.31

Величину верхнего критического поля H_{c2} для сверхпроводников II рода можно оценить из того условия, что разрушение куперовских пар происходит вследствие их закручивания в магнитном поле. Иначе говоря, пара может сохраняться лишь до тех пор, пока ларморовский радиус больше ее размера. Выразить H_{c2} через длину когерентности ξ и квант магнитного потока Φ_0^{CH}.

Solution 5.31.

$H_{\mathrm{c}2} = \frac{\hbar c}{2e\xi^2} = \frac{\Phi_0^{\mathrm{cП}}}{2\pi\xi^2}$.

О3-5.32

При каком напряжении начнет течь ток через туннельный переход нормальный металл-изолятор-сверхпроводник, если $T_{\mathrm{c}} = 92$ K, а измерения проводятся при $T \ll T_{\mathrm{c}}$?

Solution 5.32.

$V = \frac{\Delta}{e} \approx \frac{kT_{\mathrm{c}}}{e} \approx 0,008$ В. См. приложение II.

О3-5.33 ВАХ системы “алюминий-свинец”

В 1960 г. Гиавер измерил вольт-амперную характеристику сверхпроводящей системы алюминий-свинец при температуре, меньшей критических температур обоих металлов (рис. 95).
(вставлю скоро!)
Она имела максимум при $V_1 = 0,82$ мВ и минимум при $V_2 = 1,4$ мВ. Найти величины энергетических щелей (в эВ) и критические температуры свинца и алюминия.

Solution

Для SIS перехода:

$$eV_1 = eV_{\max} = \Delta_2 - \Delta_1$$
$$eV_2 = eV_{\min} = \Delta_2 + \Delta_1.$$

Мы принимаем минимум - началом возрастания тока при $T = 0$, что на самом деле не совсем так, потому что ток при чуть большем напряжении начнется. Откуда следует:

$$\Delta_2 = e\frac{V_1 + V_2}{2} = 1,11\mathrm{mB}.$$
$$\Delta_1 = e\frac{V_2 - V_1}{2} = 0,29\mathrm{mB}$$

Критическую температуру определяем из соотношения БКШ $k_{\mathrm{G}}T_{\mathrm{c}} = 0.57\Delta$, получаем $T_{\mathrm{c}1} \approx 1,9$ K; $T_{\mathrm{c}2} = 7,3$ K.

Solution 5.33*

Ответ задачи следует из уравнений

$$eV_1 = eV_{\max} = \Delta_2 - \Delta_1$$
$$eV_2 = eV_{\min} = \Delta_2 + \Delta_1.$$

Откуда следует:

$$\Delta_2 = e\frac{V_1 + V_2}{2} = 1,11 \text{ m B} .$$
$$\Delta_1 = e\frac{V_2 - V_1}{2} = 0,29 \text{ m B}$$

Критическую температуру определяем из соотношения $2\Delta = 3,52 k_{\mathrm{F}} T_c$, откуда $T_{\mathrm{c}1} \approx 1,9$ K; $T_{\mathrm{c}2} = 7,3$ K. Подробно эксперименты Гиавера рассмотрены в Приложении II.

O3-5.34

Оценить радиус эффективного взаимодействия сверхпроводящих электронов, исходя из следующих соображений: проходящий около иона электрон «толкает» его, создавая тем самым поляризацию решетки. Радиус взаимодействия соответствует расстоянию, на которое успел уйти этот электрон за время, равное полупериоду колебаний иона. Оценку провести для одновален-тного металла с простой кубической решеткой. Скорость звука $s = 3 \cdot 10^5$ см/с, эффективную массу электрона считать равной массе свободного электрона.

Solution 5.34.

$\xi = \frac{\hbar\pi}{m_e s} = 1,2 \cdot 10^{-5}$ cm $= 1200$Å.

O3-5.35 Penetration of field in metal

For a metal described by the free electron model, find the ratio of the maximum transparency length for electromagnetic waves in the normal state to the London penetration depth in the superconducting state.

Solution 5.35.

(??? what is длина прозрачности???)
5.35. $\lambda \leqslant \lambda_{\mathrm{p}} = 2\pi\sqrt{\frac{m_e c^2}{4\pi n_{\mathrm{se}} e^2}} = 2\pi\Lambda$, т. е. $\frac{\lambda}{\Lambda} \simeq 2\pi$.

O3-5.36 Heat capacity from vortices

In type II superconductors, which are located in an external magnetic field $H_{\mathrm{c}2} > H > H_{\mathrm{c}1}$, the electrons in the vortex crust are in a normal state. How does the contribution of these electrons to the heat capacity of a superconductor depend on the magnitude of the external field and temperature? Consider the correlation length independent of temperature.

Solution 5.36.

(???? need to learn type 2 sc better)
$\Delta C \propto BT$.

O3-5.37 Радиус сверхпроводящего вихря (????)

Решетка квантованных вихрей в сверхпроводниках II рода подобна системе вихревых нитей, возникающих во вращающемся сверхтекучем ^{4}He. Исходя из этой аналогии, оценить на основе критерия сверхтекучести Ландау радиус нормальной сердцевины (кора) магнитного вихря и соответствующую ему плотность тока. Величина энергетической щели сверхпроводника равна $\Delta(T)$, импульс Ферми p_{F}, концентрация сверхпроводящих электронов - $n_{\mathrm{sc}}(T)$.

Solution

Скорость движения центра масс куперовской пары при $r < \Lambda$ (лондоновской глубины) определим как (см. задачу 5.23)

$$v(r) = \frac{\hbar}{2mr}.$$

Если $v(r) \geqslant v_{\text{крит}} = \Delta(T)/p_{\text{F}}$, то сверхпроводимость «разрушается». Таким образом

$$\frac{\hbar}{2mr} \geqslant \frac{\Delta(T)}{p_{\mathbf{F}}}, \text{ откуда } r \leqslant \frac{\hbar v_{\mathbf{F}}}{2\Delta(T)} \simeq \xi(T).$$

Видно, что область нормальной фазы имеет размер порядка длины когерентности ξ. Плотность тока $j(r) = 2en_{\text{s}}v(r) = en_{\text{sc}}v(r)$. При $r = \xi$ получаем

$$j(\xi) = \frac{en_{\text{sc}}\hbar}{2m\xi} \simeq \frac{en_{\text{sc}}\Delta(T)}{\hbar p_{\text{F}}} \sim j_{\text{c}},$$

где j_{c} - ток распаривания (см. задачу 5.20).
Ответ: 5.37*. $r \ll \frac{\hbar v_{\text{F}}}{2\Delta(T)} \simeq \xi(T); j(\xi) \simeq \frac{en_{\text{sc}}\Delta(T)}{\hbar p_{\text{F}}}$.

О3-5.38 Магнитное поле в вихре

Используя полученное в предыдущей задаче выражение для радиальной зависимости плотности сверхпроводящего тока $j(r)$ в вихре (?? какое???), найти распределение магнитного поля $B(r)$ в вихре и оценить поле в его центре. Ответ выразить через квант магнитного потока Φ_0^c и характерные длины Λ и ξ.

Solution

5.38. $B(r) = \frac{\Phi_0^{\text{cm}}}{2\pi\Lambda^2}\ln\frac{\Lambda}{r}; B(0) = B(\xi) = \frac{\Phi_0^{\text{cm}}}{2\pi\Lambda^2}\ln\frac{\Lambda}{\xi} = H_{\text{c1}}$. По теории Абрикосова точное выражение $B(0) = 2H_{\text{c1}}$ (рассматривается область $\xi < r < \Lambda$).

Ш-з.45.1.

Во сколько раз плотность состояний в спектре элементарных возбущдении сверхпроводника больше плотности состояний электронов в вормальом металле около уровня Ферми для энергии возбуждений E, равных соответственно $1.01\Delta_0; 1.5\Delta_0; 2.0\Delta_0$?
(????)
Ответ. $\rho/N(0) = 7.12; 1.34; 1.15$.

14.2 Problems about Typical Methods, Effects

(добавлю из Белоусова и типичного статфиза задачи)

14.2.1 Framework of BCS: Problems about Basic Transformations

me. Mean field approximation of BCS Hamiltonian

Show that the Hamiltonian

$$\widehat{\mathcal{H}} = \sum_p \xi_p a_p^+ a_p - \frac{\lambda}{2}\sum_{pq} a_{p\alpha}^+ a_{-p\beta}^+ a_{q\beta} a_{-q\alpha}.$$

is approximately equivalent to the

$$\widehat{\mathcal{H}} = \sum_p \left(\xi_p\left(a_{p\uparrow}^+ a_{p\uparrow} + a_{p\downarrow}^+ a_{p\downarrow}\right) + \Delta a_{p\downarrow}^+ a_{-p\uparrow}^+ + \Delta^* a_{p\uparrow} a_{-p\downarrow}\right),$$

where Δ is an effective parameter, that is calculated from a operators.
Use Wick's theorem.

Solution by Wick's theorem

(these typical transformations (???))

me. Mean field approximation of BCS Hamiltonian

Show that the Hamiltonian

$$\widehat{\mathcal{H}} = \sum_p \xi_p a_p^+ a_p - \frac{\lambda}{2} \sum_{pq} a_{p\alpha}^+ a_{-p\beta}^+ a_{q\beta} a_{-q\alpha}.$$

is approximately equivalent to the

$$\widehat{\mathcal{H}} = \sum_p \left(\xi_p \left(a_{p\uparrow}^+ a_{p\uparrow} + a_{p\downarrow}^+ a_{p\downarrow} \right) + \Delta a_{p\downarrow}^+ a_{-p\uparrow}^+ + \Delta^* a_{p\uparrow} a_{-p\downarrow} \right),$$

where Δ is an effective parameter, that is calculated from a operators.
Use the path integral approach.

Solution by path integral

(habbard Stratonovich, etc.)

me. Green's function for BCS

For the BCS superconductor described by the $H_{\text{BCS}} = \sum_{\boldsymbol{k}} c_{\boldsymbol{k}\sigma}^\dagger \epsilon_{\boldsymbol{k}} c_{\boldsymbol{k}\sigma} + \Delta \left(c_{\boldsymbol{k}\uparrow} c_{-\boldsymbol{k}\downarrow} + \text{ h.c. } \right)$ where $\epsilon_{\boldsymbol{k}} := \boldsymbol{k}^2/(2m) - \mu$, prove that in the Nambu basis $\psi_{\boldsymbol{k}} = \left(c_{\boldsymbol{k}\uparrow}, c_{-\boldsymbol{k}\downarrow}^\dagger \right)$ the Hamiltonian has a form:

$$H_{\text{BCS}} = \sum_{\boldsymbol{k}} \psi_{\boldsymbol{k}}^\dagger h(\boldsymbol{k}) \psi_{\boldsymbol{k}}; \qquad h(\boldsymbol{k}) := \epsilon_{\boldsymbol{k}} \sigma^3 + \Delta \sigma^1$$

Then prove that the Green's function of the Nambu spinor is given by

$$G(\omega, \boldsymbol{k}) = (\omega - h(\boldsymbol{k}))^{-1} = \frac{\omega \sigma^0 + \epsilon_{\boldsymbol{k}} \sigma^3 + \Delta \sigma^1}{\omega^2 - \epsilon_{\boldsymbol{k}}^2 - \Delta^2}$$

Solution

(???? I'll write it later)

me. Inverse Bogoliubov transformations

In BCS theory, initially the Hamiltonian is written in terms of fermionic operators a and we introduce new operators b as

$$\begin{aligned} \hat{b}_{\mathbf{p}-} &= u_p \hat{a}_{\mathbf{p}-} + v_p \hat{a}_{-\mathbf{p},+}^\dagger, \\ \hat{b}_{\mathbf{p}+} &= u_p \hat{a}_{\mathbf{p}+} - v_p \hat{a}_{-\mathbf{p},-}^\dagger. \end{aligned} \qquad u^2 + v^2 = 1.$$

Find the expression of a operators in terms of b.

Solution

$$\begin{pmatrix} \hat{b}_{-\mathbf{p}-}^\dagger \\ \hat{b}_{\mathbf{p}+} \end{pmatrix} = \begin{pmatrix} u_p & v_p \\ -v_p & u_p \end{pmatrix} \begin{pmatrix} \hat{a}_{-\mathbf{p},-}^\dagger \\ \hat{a}_{\mathbf{p}+} \end{pmatrix} \qquad \Rightarrow \qquad \begin{pmatrix} \hat{a}_{-\mathbf{p},-}^\dagger \\ \hat{a}_{\mathbf{p}+} \end{pmatrix} = \begin{pmatrix} u_p & -v_p \\ v_p & u_p \end{pmatrix} \begin{pmatrix} \hat{b}_{-\mathbf{p}-}^\dagger \\ \hat{b}_{\mathbf{p}+} \end{pmatrix},$$

since $A = \begin{bmatrix} a & b \\ c & d \end{bmatrix} \Rightarrow A^{-1} = \frac{1}{|A|} \begin{bmatrix} d & -b \\ -c & a \end{bmatrix}$.
Result:

$$\begin{aligned} \hat{a}_{\mathbf{p}-} &= u_p \hat{b}_{\mathbf{p}-} - v_p \hat{b}_{-\mathbf{p},+}^\dagger, \\ \hat{a}_{\mathbf{p}+} &= u_p \hat{b}_{\mathbf{p}+} + v_p \hat{b}_{-\mathbf{p},-}^\dagger. \end{aligned}$$

me. Diagonalization of BCS Hamiltonian by basic transformations

Diagonalize the BCS Hamiltonian

$$\hat{H} = \sum_{\mathbf{p}\sigma} \varepsilon_{\mathbf{p}} \hat{a}^{\dagger}_{\mathbf{p}\sigma} \hat{a}_{\mathbf{p}\sigma} + \Delta \sum_{\mathbf{p}} \left[\hat{a}_{\mathbf{p}+} \hat{a}_{-\mathbf{p}-} + \hat{a}^{\dagger}_{-\mathbf{p}-} \hat{a}^{\dagger}_{\mathbf{p}+} \right]$$

by introduction of new fermionic operators b

$$\begin{aligned} \hat{b}_{\mathbf{p}-} &= u_p \hat{a}_{\mathbf{p}-} + v_p \hat{a}^{\dagger}_{-\mathbf{p},+}, \\ \hat{b}_{\mathbf{p}+} &= u_p \hat{a}_{\mathbf{p}+} - v_p \hat{a}^{\dagger}_{-\mathbf{p},-}; \end{aligned} \qquad u^2 + v^2 = 1.$$

Do it by plugging the new operators into the Hamiltonian, then by equating some terms to zero, obtain formulas for u and v.

Solution

We substitute $\hat{a}_{\mathbf{p}-} = u_p \hat{b}_{\mathbf{p}-} - v_p \hat{b}^{\dagger}_{-\mathbf{p},+}, \quad \hat{a}_{\mathbf{p}+} = u_p \hat{b}_{\mathbf{p}+} + v_p \hat{b}^{\dagger}_{-\mathbf{p},-},$

$$\begin{aligned} \varepsilon_{\mathbf{p}} \hat{a}^{\dagger}_{\mathbf{p}+} \hat{a}_{\mathbf{p}+} &= \varepsilon_{\mathbf{p}} (u_p \hat{b}^{\dagger}_{\mathbf{p}+} + v_p \hat{b}_{-\mathbf{p},-})(u_p \hat{b}_{\mathbf{p}+} + v_p \hat{b}^{\dagger}_{-\mathbf{p},-}) = \\ &= \varepsilon_{\mathbf{p}} \left[u_p^2 \hat{b}^{\dagger}_{\mathbf{p}+} \hat{b}_{\mathbf{p}+} + v_p^2 \hat{b}_{-\mathbf{p},-} \hat{b}^{\dagger}_{-\mathbf{p},-} + u_p v_p (\hat{b}_{-\mathbf{p},-} \hat{b}_{\mathbf{p},+} + \hat{b}^{\dagger}_{\mathbf{p},+} \hat{b}^{\dagger}_{-\mathbf{p},-}) \right]; \\ \varepsilon_{\mathbf{p}} \hat{a}^{\dagger}_{\mathbf{p}-} \hat{a}_{\mathbf{p}-} &= \varepsilon_{\mathbf{p}} (u_p \hat{b}^{\dagger}_{\mathbf{p}-} - v_p \hat{b}_{-\mathbf{p},+})(u_p \hat{b}_{\mathbf{p}-} - v_p \hat{b}^{\dagger}_{-\mathbf{p},+}) = \\ &= \varepsilon_{\mathbf{p}} \left[u_p^2 \hat{b}^{\dagger}_{\mathbf{p}-} \hat{b}_{\mathbf{p}-} + v_p^2 \hat{b}_{-\mathbf{p},+} \hat{b}^{\dagger}_{-\mathbf{p},+} - u_p v_p (\hat{b}_{-\mathbf{p},+} \hat{b}_{\mathbf{p}-} + \hat{b}^{\dagger}_{\mathbf{p}-} \hat{b}^{\dagger}_{-\mathbf{p},+}) \right]. \end{aligned}$$

Because of

$$-\sum_{\mathbf{p}} (\hat{b}_{-\mathbf{p},+} \hat{b}_{\mathbf{p}-} + \hat{b}^{\dagger}_{\mathbf{p}-} \hat{b}^{\dagger}_{-\mathbf{p},+}) \overset{\substack{\text{symm} \\ p \text{ region}}}{=} -\sum_{\mathbf{p}} (\hat{b}_{\mathbf{p},+} \hat{b}_{-\mathbf{p}-} + \hat{b}^{\dagger}_{-\mathbf{p}-} \hat{b}^{\dagger}_{\mathbf{p},+}) = \sum_{\mathbf{p}} (\hat{b}_{-\mathbf{p}-} \hat{b}_{\mathbf{p},+} + \hat{b}^{\dagger}_{\mathbf{p},+} \hat{b}^{\dagger}_{-\mathbf{p}-}),$$

the kinetic term is

$$\begin{aligned} &\sum_{\mathbf{p}} \varepsilon_{\mathbf{p}} (\hat{a}^{\dagger}_{\mathbf{p}-} \hat{a}_{\mathbf{p}-} + \hat{a}^{\dagger}_{\mathbf{p}+} \hat{a}_{\mathbf{p}+}) = \sum_{\mathbf{p}} \varepsilon_{\mathbf{p}} \Big[u_p^2 \hat{b}^{\dagger}_{\mathbf{p}+} \hat{b}_{\mathbf{p}+} + v_p^2 \hat{b}_{-\mathbf{p},-} \hat{b}^{\dagger}_{-\mathbf{p},-} + \\ &\qquad + u_p^2 \hat{b}^{\dagger}_{\mathbf{p}-} \hat{b}_{\mathbf{p}-} + v_p^2 \hat{b}_{-\mathbf{p},+} \hat{b}^{\dagger}_{-\mathbf{p},+} + 2u_p v_p (\hat{b}_{-\mathbf{p}-} \hat{b}_{\mathbf{p},+} + \hat{b}^{\dagger}_{\mathbf{p},+} \hat{b}^{\dagger}_{-\mathbf{p}-}) \Big] = \\ &= \sum_{\mathbf{p}} \varepsilon_{\mathbf{p}} \Big[u_p^2 \hat{b}^{\dagger}_{\mathbf{p}+} \hat{b}_{\mathbf{p}+} + v_p^2 (1 - \hat{b}^{\dagger}_{-\mathbf{p},+} \hat{b}_{-\mathbf{p},+}) + v_p^2 (1 - \hat{b}^{\dagger}_{-\mathbf{p},-} \hat{b}_{-\mathbf{p},-}) + u_p^2 \hat{b}^{\dagger}_{\mathbf{p}-} \hat{b}_{\mathbf{p}-} + \\ &\qquad + 2u_p v_p (\hat{b}_{-\mathbf{p}-} \hat{b}_{\mathbf{p},+} + \hat{b}^{\dagger}_{\mathbf{p},+} \hat{b}^{\dagger}_{-\mathbf{p}-}) \Big] = \\ &= \sum_{\mathbf{p}} 2\varepsilon_{\mathbf{p}} v_p^2 + \sum_{\mathbf{p}} \varepsilon_{\mathbf{p}} (u_p^2 - v_p^2)(\hat{b}^{\dagger}_{\mathbf{p}+} \hat{b}_{\mathbf{p}+} + \hat{b}^{\dagger}_{\mathbf{p}-} \hat{b}_{\mathbf{p}-}) + \sum_{\mathbf{p}} 2\varepsilon_{\mathbf{p}} u_p v_p (\hat{b}_{-\mathbf{p}-} \hat{b}_{\mathbf{p},+} + \hat{b}^{\dagger}_{\mathbf{p},+} \hat{b}^{\dagger}_{-\mathbf{p}-}). \end{aligned}$$

The interaction term has

$$\begin{aligned} \hat{a}_{\mathbf{p}+} \hat{a}_{-\mathbf{p}-} &= (u_p \hat{b}_{\mathbf{p}+} + v_p \hat{b}^{\dagger}_{-\mathbf{p},-})(u_p \hat{b}_{-\mathbf{p}-} - v_p \hat{b}^{\dagger}_{\mathbf{p},+}) = \\ &= u_p^2 \hat{b}_{\mathbf{p}+} \hat{b}_{-\mathbf{p}-} - v_p^2 \hat{b}^{\dagger}_{-\mathbf{p},-} \hat{b}^{\dagger}_{\mathbf{p},+} + u_p v_p (\hat{b}^{\dagger}_{-\mathbf{p},-} \hat{b}_{-\mathbf{p}-} - \hat{b}_{\mathbf{p}+} \hat{b}^{\dagger}_{\mathbf{p},+}); \\ \hat{a}^{\dagger}_{-\mathbf{p}-} \hat{a}^{\dagger}_{\mathbf{p}+} &= (u_p \hat{b}^{\dagger}_{-\mathbf{p}-} - v_p \hat{b}_{\mathbf{p},+})(u_p \hat{b}^{\dagger}_{\mathbf{p}+} + v_p \hat{b}_{-\mathbf{p},-}) = \\ &= u_p^2 \hat{b}^{\dagger}_{-\mathbf{p}-} \hat{b}^{\dagger}_{\mathbf{p}+} - v_p^2 \hat{b}_{\mathbf{p},+} \hat{b}_{-\mathbf{p},-} + u_p v_p (\hat{b}^{\dagger}_{-\mathbf{p}-} \hat{b}_{-\mathbf{p},-} - \hat{b}_{\mathbf{p},+} \hat{b}^{\dagger}_{\mathbf{p}+}). \end{aligned}$$

And it has the form

$$\begin{aligned} &\sum_{\mathbf{p}} \left[\Delta \hat{a}_{\mathbf{p}+} \hat{a}_{-\mathbf{p}-} + \Delta \hat{a}^{\dagger}_{-\mathbf{p}-} \hat{a}^{\dagger}_{\mathbf{p}+} \right] = \\ &= \sum_{\mathbf{p}} \left[(u_p^2 \Delta - v_p^2 \Delta) \hat{b}^{\dagger}_{-\mathbf{p}-} \hat{b}^{\dagger}_{\mathbf{p}+} + (u_p^2 \Delta - v_p^2 \Delta) \hat{b}_{\mathbf{p},+} \hat{b}_{-\mathbf{p},-} + u_p v_p (\Delta + \Delta)(\hat{b}^{\dagger}_{-\mathbf{p}-} \hat{b}_{-\mathbf{p},-} - \hat{b}_{\mathbf{p},+} \hat{b}^{\dagger}_{\mathbf{p}+}) \right] \end{aligned}$$

Totally, the Hamiltonian is diagonalized, if we take u_p, v_p such that for each $\mathbf{p}$

$$2\varepsilon_{\mathbf{p}} u_p v_p(\hat{b}_{-\mathbf{p}-}\hat{b}_{\mathbf{p},+} + \hat{b}^\dagger_{\mathbf{p},+}\hat{b}^\dagger_{-\mathbf{p}-}) + (u_p^2\Delta - v_p^2\Delta)\hat{b}^\dagger_{-\mathbf{p}-}\hat{b}^\dagger_{\mathbf{p}+} + (u_p^2\Delta - v_p^2\Delta)\hat{b}_{\mathbf{p},+}\hat{b}_{-\mathbf{p},-} = 0$$

$$\begin{aligned} \hat{b}_{-\mathbf{p}-}\hat{b}_{\mathbf{p},+}: &\qquad 2\varepsilon_{\mathbf{p}} u_p v_p + u_p^2\Delta - v_p^2\Delta = 0 \\ \hat{b}^\dagger_{\mathbf{p},+}\hat{b}^\dagger_{-\mathbf{p}-}: &\qquad 2\varepsilon_{\mathbf{p}} u_p v_p + u_p^2\Delta - v_p^2\Delta = 0 \end{aligned}$$

There are two solutions of the quadratic equation $\frac{u^2}{v^2} + 2\frac{\varepsilon_{\mathbf{p}}}{\Delta}\frac{u}{v} - 1 = 0$. There are two solutions, the first one is

$$\frac{u}{v} = \frac{-2\frac{\varepsilon}{\Delta} - \sqrt{\left(2\frac{\varepsilon}{\Delta}\right)^2 + 4}}{2} = -\frac{\varepsilon}{\Delta} - \sqrt{\frac{\varepsilon^2}{\Delta^2} + 1};$$

$$v^2 = \frac{1}{1 + \left(\frac{\varepsilon}{\Delta} + \sqrt{\frac{\varepsilon^2}{\Delta^2} + 1}\right)^2} = \frac{1}{1 + \frac{\varepsilon^2}{\Delta^2} + \frac{\varepsilon^2}{\Delta^2} + 1 + 2\frac{\varepsilon}{\Delta}\sqrt{\frac{\varepsilon^2}{\Delta^2} + 1}} =$$

$$= \frac{1}{2}\frac{\frac{\varepsilon^2}{\Delta^2} + 1 - \frac{\varepsilon}{\Delta}\sqrt{\frac{\varepsilon^2}{\Delta^2} + 1}}{\left(\frac{\varepsilon^2}{\Delta^2} + 1\right)^2 - \frac{\varepsilon^2}{\Delta^2}\left(\frac{\varepsilon^2}{\Delta^2} + 1\right)} = \frac{1}{2}\frac{\frac{\varepsilon^2}{\Delta^2} + 1 - \frac{\varepsilon}{\Delta}\sqrt{\frac{\varepsilon^2}{\Delta^2} + 1}}{\frac{\varepsilon^2}{\Delta^2} + 1} = \frac{1}{2}\left(1 - \frac{\varepsilon}{\Delta^2 + \varepsilon^2}\right);$$

$$u^2 = 1 - v^2 = \frac{1}{2}\left(1 + \frac{\varepsilon}{\sqrt{\Delta^2 + \varepsilon^2}}\right)$$

The second solution of the quadratic equation gives us the coefficients u, v vice versa. If we plug them into the Hamiltonian, the spectrum will be negative (since there is term $u^2 - v^2$), which is unphysical, so we don't consider this solution.

For real Δ, the Hamiltonian has the form:

$$\begin{aligned} \hat{H} &= \sum_{\mathbf{p}}\Big[2\varepsilon_{\mathbf{p}} v_p^2 + \varepsilon_{\mathbf{p}}(u_p^2 - v_p^2)(\hat{b}^\dagger_{\mathbf{p}+}\hat{b}_{\mathbf{p}+} + \hat{b}^\dagger_{\mathbf{p}-}\hat{b}_{\mathbf{p}-}) + 2u_p v_p\Delta(\hat{b}^\dagger_{-\mathbf{p}-}\hat{b}_{-\mathbf{p},-} + \hat{b}^\dagger_{\mathbf{p}+}\hat{b}_{\mathbf{p},+} - 1)\Big] \\ &= 2\sum_{\mathbf{p}}\Big[\varepsilon_{\mathbf{p}} v_p^2 - u_p v_p\Delta\Big] + \sum_{\mathbf{p}}(\varepsilon_{\mathbf{p}}(u_p^2 - v_p^2) + 2u_p v_p\Delta)\Big[\hat{b}^\dagger_{\mathbf{p}-}\hat{b}_{\mathbf{p},-} + \hat{b}^\dagger_{\mathbf{p}+}\hat{b}_{\mathbf{p},+}\Big] = \\ &= 2\sum_{\mathbf{p}}\Big[\varepsilon_{\mathbf{p}} v_p^2 - u_p v_p\Delta\Big] + \sum_{\mathbf{p}}\left(\varepsilon_{\mathbf{p}}\frac{\varepsilon}{\sqrt{\Delta^2 + \varepsilon^2}} + 2\frac{\Delta}{2\sqrt{\Delta^2 + \varepsilon^2}}\Delta\right)\Big[\hat{b}^\dagger_{\mathbf{p}-}\hat{b}_{\mathbf{p},-} + \hat{b}^\dagger_{\mathbf{p}+}\hat{b}_{\mathbf{p},+}\Big] = \\ &= 2\sum_{\mathbf{p}}\Big[\varepsilon_{\mathbf{p}} v_p^2 - u_p v_p\Delta\Big] + \sum_{\mathbf{p}}\sqrt{\Delta^2 + \varepsilon^2}\Big[\hat{b}^\dagger_{\mathbf{p}-}\hat{b}_{\mathbf{p},-} + \hat{b}^\dagger_{\mathbf{p}+}\hat{b}_{\mathbf{p},+}\Big]. \end{aligned}$$

me. Diagonalization of BCS Hamiltonian for complex Δ by basic transformations

Diagonalize the BCS Hamiltonian

$$\hat{H} = \sum_{\mathbf{p}\sigma}\varepsilon_{\mathbf{p}}\hat{a}^\dagger_{\mathbf{p}\sigma}\hat{a}_{\mathbf{p}\sigma} + \sum_{\mathbf{p}}\Big[\Delta^*\hat{a}_{\mathbf{p}+}\hat{a}_{-\mathbf{p}-} + \Delta\hat{a}^\dagger_{-\mathbf{p}-}\hat{a}^\dagger_{\mathbf{p}+}\Big]$$

by introduction of new fermionic operators b

$$\begin{aligned} \hat{b}_{\mathbf{p}-} &= u_p\hat{a}_{\mathbf{p}-} + v_p\hat{a}^\dagger_{-\mathbf{p},+}, \\ \hat{b}_{\mathbf{p}+} &= u_p\hat{a}_{\mathbf{p}+} - v_p\hat{a}^\dagger_{-\mathbf{p},-}; \end{aligned} \qquad u^2 + v^2 = 1.$$

Do it by plugging the new operators into the Hamiltonian, then by equating some terms to zero, obtain formulas for u and v. Don't assume that Δ is real-valued.

Solution

We substitute $\hat{a}_{\mathbf{p}-} = u_p\hat{b}_{\mathbf{p}-} - v_p\hat{b}^\dagger_{-\mathbf{p},+}, \quad \hat{a}_{\mathbf{p}+} = u_p\hat{b}_{\mathbf{p}+} + v_p\hat{b}^\dagger_{-\mathbf{p},-}$,

$$\begin{aligned} \varepsilon_{\mathbf{p}}\hat{a}^\dagger_{\mathbf{p}+}\hat{a}_{\mathbf{p}+} &= \varepsilon_{\mathbf{p}}(u_p\hat{b}^\dagger_{\mathbf{p}+} + v_p\hat{b}_{-\mathbf{p},-})(u_p\hat{b}_{\mathbf{p}+} + v_p\hat{b}^\dagger_{-\mathbf{p},-}) = \\ &= \varepsilon_{\mathbf{p}}\big[u_p^2\hat{b}^\dagger_{\mathbf{p}+}\hat{b}_{\mathbf{p}+} + v_p^2\hat{b}_{-\mathbf{p},-}\hat{b}^\dagger_{-\mathbf{p},-} + u_p v_p(\hat{b}_{-\mathbf{p},-}\hat{b}_{\mathbf{p},+} + \hat{b}^\dagger_{\mathbf{p},+}\hat{b}^\dagger_{-\mathbf{p},-})\big]; \end{aligned}$$

$$\varepsilon_{\mathbf{p}}\hat{a}^{\dagger}_{\mathbf{p}-}\hat{a}_{\mathbf{p}-} = \varepsilon_{\mathbf{p}}(u_p\hat{b}^{\dagger}_{\mathbf{p}-} - v_p\hat{b}_{-\mathbf{p},+})(u_p\hat{b}_{\mathbf{p}-} - v_p\hat{b}^{\dagger}_{-\mathbf{p},+}) =$$
$$= \varepsilon_{\mathbf{p}}\left[u_p^2\hat{b}^{\dagger}_{\mathbf{p}-}\hat{b}_{\mathbf{p}-} + v_p^2\hat{b}_{-\mathbf{p},+}\hat{b}^{\dagger}_{-\mathbf{p},+} - u_pv_p(\hat{b}_{-\mathbf{p},+}\hat{b}_{\mathbf{p}-} + \hat{b}^{\dagger}_{\mathbf{p}-}\hat{b}^{\dagger}_{-\mathbf{p},+})\right].$$

Because of

$$-\sum_{\mathbf{p}}(\hat{b}_{-\mathbf{p},+}\hat{b}_{\mathbf{p}-} + \hat{b}^{\dagger}_{\mathbf{p}-}\hat{b}^{\dagger}_{-\mathbf{p},+}) \overset{\substack{\text{symm}\\ p \text{ region}}}{=} -\sum_{\mathbf{p}}(\hat{b}_{\mathbf{p},+}\hat{b}_{-\mathbf{p}-} + \hat{b}^{\dagger}_{-\mathbf{p}-}\hat{b}^{\dagger}_{\mathbf{p},+}) = \sum_{\mathbf{p}}(\hat{b}_{-\mathbf{p}-}\hat{b}_{\mathbf{p},+} + \hat{b}^{\dagger}_{\mathbf{p},+}\hat{b}^{\dagger}_{-\mathbf{p}-}),$$

the kinetic term is

$$\sum_{\mathbf{p}}\varepsilon_{\mathbf{p}}(\hat{a}^{\dagger}_{\mathbf{p}-}\hat{a}_{\mathbf{p}-} + \hat{a}^{\dagger}_{\mathbf{p}+}\hat{a}_{\mathbf{p}+}) = \sum_{\mathbf{p}}\varepsilon_{\mathbf{p}}\Big[u_p^2\hat{b}^{\dagger}_{\mathbf{p}+}\hat{b}_{\mathbf{p}+} + v_p^2\hat{b}_{-\mathbf{p},-}\hat{b}^{\dagger}_{-\mathbf{p},-} +$$
$$+ u_p^2\hat{b}^{\dagger}_{\mathbf{p}-}\hat{b}_{\mathbf{p}-} + v_p^2\hat{b}_{-\mathbf{p},+}\hat{b}^{\dagger}_{-\mathbf{p},+} + 2u_pv_p(\hat{b}_{-\mathbf{p}-}\hat{b}_{\mathbf{p},+} + \hat{b}^{\dagger}_{\mathbf{p},+}\hat{b}^{\dagger}_{-\mathbf{p}-})\Big] =$$
$$= \sum_{\mathbf{p}}\varepsilon_{\mathbf{p}}\Big[u_p^2\hat{b}^{\dagger}_{\mathbf{p}+}\hat{b}_{\mathbf{p}+} + v_p^2(1 - \hat{b}^{\dagger}_{-\mathbf{p},+}\hat{b}_{-\mathbf{p},+}) + v_p^2(1 - \hat{b}^{\dagger}_{-\mathbf{p},-}\hat{b}_{-\mathbf{p},-}) + u_p^2\hat{b}^{\dagger}_{\mathbf{p}-}\hat{b}_{\mathbf{p}-} +$$
$$+ 2u_pv_p(\hat{b}_{-\mathbf{p}-}\hat{b}_{\mathbf{p},+} + \hat{b}^{\dagger}_{\mathbf{p},+}\hat{b}^{\dagger}_{-\mathbf{p}-})\Big] =$$
$$= \sum_{\mathbf{p}}2\varepsilon_{\mathbf{p}}v_p^2 + \sum_{\mathbf{p}}\varepsilon_{\mathbf{p}}(u_p^2 - v_p^2)(\hat{b}^{\dagger}_{\mathbf{p}+}\hat{b}_{\mathbf{p}+} + \hat{b}^{\dagger}_{\mathbf{p}-}\hat{b}_{\mathbf{p}-}) + \sum_{\mathbf{p}}2\varepsilon_{\mathbf{p}}u_pv_p(\hat{b}_{-\mathbf{p}-}\hat{b}_{\mathbf{p},+} + \hat{b}^{\dagger}_{\mathbf{p},+}\hat{b}^{\dagger}_{-\mathbf{p}-}).$$

The interaction term has

$$\hat{a}_{\mathbf{p}+}\hat{a}_{-\mathbf{p}-} = (u_p\hat{b}_{\mathbf{p}+} + v_p\hat{b}^{\dagger}_{-\mathbf{p},-})(u_p\hat{b}_{-\mathbf{p}-} - v_p\hat{b}^{\dagger}_{\mathbf{p},+}) =$$
$$= u_p^2\hat{b}_{\mathbf{p}+}\hat{b}_{-\mathbf{p}-} - v_p^2\hat{b}^{\dagger}_{-\mathbf{p},-}\hat{b}^{\dagger}_{\mathbf{p},+} + u_pv_p(\hat{b}^{\dagger}_{-\mathbf{p},-}\hat{b}_{-\mathbf{p}-} - \hat{b}_{\mathbf{p}+}\hat{b}^{\dagger}_{\mathbf{p},+});$$

$$\hat{a}^{\dagger}_{-\mathbf{p}-}\hat{a}^{\dagger}_{\mathbf{p}+} = (u_p\hat{b}^{\dagger}_{-\mathbf{p}-} - v_p\hat{b}_{\mathbf{p},+})(u_p\hat{b}^{\dagger}_{\mathbf{p}+} + v_p\hat{b}_{-\mathbf{p},-}) =$$
$$= u_p^2\hat{b}^{\dagger}_{-\mathbf{p}-}\hat{b}^{\dagger}_{\mathbf{p}+} - v_p^2\hat{b}_{\mathbf{p},+}\hat{b}_{-\mathbf{p},-} + u_pv_p(\hat{b}^{\dagger}_{-\mathbf{p}-}\hat{b}_{-\mathbf{p},-} - \hat{b}_{\mathbf{p},+}\hat{b}^{\dagger}_{\mathbf{p}+}).$$

And it has the form

$$\sum_{\mathbf{p}}\left[\Delta^*\hat{a}_{\mathbf{p}+}\hat{a}_{-\mathbf{p}-} + \Delta\hat{a}^{\dagger}_{-\mathbf{p}-}\hat{a}^{\dagger}_{\mathbf{p}+}\right] =$$
$$= \sum_{\mathbf{p}}\left[(u_p^2\Delta^* - v_p^2\Delta)\hat{b}^{\dagger}_{-\mathbf{p}-}\hat{b}^{\dagger}_{\mathbf{p}+} + (u_p^2\Delta - v_p^2\Delta^*)\hat{b}_{\mathbf{p},+}\hat{b}_{-\mathbf{p},-} + u_pv_p(\Delta + \Delta^*)(\hat{b}^{\dagger}_{-\mathbf{p}-}\hat{b}_{-\mathbf{p},-} - \hat{b}_{\mathbf{p},+}\hat{b}^{\dagger}_{\mathbf{p}+})\right]$$

Totally, the Hamiltonian is diagonalized, if we take u_p, v_p such that for each $\mathbf{p}$

$$2\varepsilon_{\mathbf{p}}u_pv_p(\hat{b}_{-\mathbf{p}-}\hat{b}_{\mathbf{p},+} + \hat{b}^{\dagger}_{\mathbf{p},+}\hat{b}^{\dagger}_{-\mathbf{p}-}) + (u_p^2\Delta^* - v_p^2\Delta)\hat{b}^{\dagger}_{-\mathbf{p}-}\hat{b}^{\dagger}_{\mathbf{p}+} + (u_p^2\Delta - v_p^2\Delta^*)\hat{b}_{\mathbf{p},+}\hat{b}_{-\mathbf{p},-} = 0$$

$$\hat{b}_{-\mathbf{p}-}\hat{b}_{\mathbf{p},+}: \qquad 2\varepsilon_{\mathbf{p}}u_pv_p + u_p^2\Delta - v_p^2\Delta^* = 0$$
$$\hat{b}^{\dagger}_{\mathbf{p},+}\hat{b}^{\dagger}_{-\mathbf{p}-}: \qquad 2\varepsilon_{\mathbf{p}}u_pv_p + u_p^2\Delta^* - v_p^2\Delta = 0$$

(??? now, I am not sure, how to proceed??? anyway, I'll think later, solution for a real Δ is fine)

Chalker,me. Diagonalization of BCS Hamiltonian by matrix notation

Diagonalize the following fermionic Hamiltonian,

$$\mathcal{H} = \epsilon\left(c_1^{\dagger}c_1 + c_2^{\dagger}c_2\right) + \lambda\left(c_1^{\dagger}c_2^{\dagger} + c_2c_1\right),$$

where ϵ and λ are real constants, by matrix notation. Note the opposite ordering of labels in the terms $c_1^{\dagger}c_2^{\dagger}$ and c_2c_1, which is also a requirement of Hermiticity.

Solution

The fermionic Bogoliubov transformation is

$$c_1^\dagger = ud_1^\dagger + vd_2$$
$$c_2^\dagger = ud_2^\dagger - vd_1,$$

where u and v are c-numbers, which we can in fact take to be real, because we have restricted ourselves to real λ. The transformation is useful only if fermionic anticommutation relations apply to both sets of operators. Let us suppose they apply to the operators d and $d^\dagger$, and check the properties of the operators c and $c^\dagger$. The coefficients of the transformation have been chosen to ensure that $\left\{c_1^\dagger, c_2^\dagger\right\} = 0$, while

$$\left\{c_1^\dagger, c_1\right\} = u^2\left\{d_1^\dagger, d_1\right\} + v^2\left\{d_2^\dagger, d_2\right\}$$

and so we must require $u^2 + v^2 = 1$, suggesting the parameterisation $u = \cos\theta, v = \sin\theta$. The remaining step is to substitute in $\mathcal{H}$ for $c^\dagger$ and c in terms of $d^\dagger$ and d, and pick θ so that terms in $d_1^\dagger d_2^\dagger + d_2 d_1$ have vanishing coefficient. The calculation is clearest when it is set out using matrix notation. First, we can write $\mathcal{H}$ as

$$\mathcal{H} = \frac{1}{2}\begin{pmatrix} c_1^\dagger & c_2 & c_2^\dagger & c_1 \end{pmatrix}\begin{pmatrix} \epsilon & \lambda & 0 & 0 \\ \lambda & -\epsilon & 0 & 0 \\ 0 & 0 & \epsilon & -\lambda \\ 0 & 0 & -\lambda & -\epsilon \end{pmatrix}\begin{pmatrix} c_1 \\ c_2^\dagger \\ c_2 \\ c_1^\dagger \end{pmatrix} + \epsilon$$

where we have used the anticommutator to make substitutions of the type $c^\dagger c = 1 - cc^\dagger$. For conciseness, consider just the upper block

$$\begin{pmatrix} c_1^\dagger & c_2 \end{pmatrix}\begin{pmatrix} \epsilon & \lambda \\ \lambda & -\epsilon \end{pmatrix}\begin{pmatrix} c_1 \\ c_2^\dagger \end{pmatrix}$$

and write the Bogoliubov transformation also in matrix form as

$$\begin{pmatrix} c_1 \\ c_2^\dagger \end{pmatrix} = \begin{pmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{pmatrix}\begin{pmatrix} d_1 \\ d_2^\dagger \end{pmatrix}.$$

We pick θ so that

$$\begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix}\begin{pmatrix} \epsilon & \lambda \\ \lambda & -\epsilon \end{pmatrix}\begin{pmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{pmatrix} = \begin{pmatrix} \bar{\epsilon} & 0 \\ 0 & -\bar{\epsilon} \end{pmatrix},$$

where $\tilde{\epsilon} = \sqrt{\epsilon^2 + \lambda^2}$.
(???? check it???)
Including the other 2×2 block of $\mathcal{H}$, we conclude that

$$\mathcal{H} = \bar{\epsilon}\left(d_1^\dagger d_1 + d_2^\dagger d_2\right) + \epsilon - \bar{\epsilon}.$$

(??? how to find the θ???)

Coleman,me. Diagonalization of BCS Hamiltonian by Nambu notation

Diagonalize the following fermionic Hamiltonian,

$$H_{\text{BCS}} = \sum_{\mathbf{k}\sigma}\epsilon_{\mathbf{k}} c_{\mathbf{k}\sigma}^\dagger c_{\mathbf{k}\sigma} + \sum_{\mathbf{k}}\left[\bar{\Delta} c_{-\mathbf{k}\downarrow} c_{\mathbf{k}\uparrow} + c_{\mathbf{k}\uparrow}^\dagger c_{-\mathbf{k}\downarrow}^\dagger \Delta\right]$$

by introduction of Nambu spinors $\psi_{\mathbf{k}} = \binom{c_{\mathbf{k}\uparrow}}{c_{-\mathbf{k}.\downarrow}^\dagger}$.

Solution

The kinetic energy can be written as

$$\sum_{\mathbf{k}} \epsilon_{\mathbf{k}} \left(c^\dagger_{\mathbf{k}\uparrow} c_{\mathbf{k}\uparrow} - c_{-\mathbf{k}\downarrow} c^\dagger_{-\mathbf{k}\downarrow} + 1 \right) = \left(c^\dagger_{\mathbf{k}\uparrow}, c_{-\mathbf{k}\downarrow} \right) \begin{bmatrix} \epsilon_{\mathbf{k}} & 0 \\ 0 & -\epsilon_{\mathbf{k}} \end{bmatrix} \begin{pmatrix} c_{\mathbf{k}\uparrow} \\ \bar{c}^\dagger_{-\mathbf{k}\downarrow} \end{pmatrix} + \sum_{\mathbf{k}} \epsilon_{\mathbf{k}}$$

where the sign reversal in the lower component derives from anticommuting the downspin electron operators. The energy $-\epsilon_{\mathbf{k}}$ is the energy to create a hole. We will drop the constant remainder term $\sum_{\mathbf{k}} \epsilon_{\mathbf{k}}$. We can now combine the kinetic and pairing terms into a single matrix:

$$\begin{aligned} \epsilon_{\mathbf{k}} \sum_{\sigma} c^\dagger_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma} + \left[\bar{\Delta} c_{-\mathbf{k}\downarrow} c_{\mathbf{k}\uparrow} + c^\dagger_{\mathbf{k}\uparrow} c^\dagger_{-\mathbf{k}\downarrow} \Delta \right] &= \left(c^\dagger_{\mathbf{k}\uparrow}, c_{-\mathbf{k}\downarrow} \right) \begin{bmatrix} \epsilon_{\mathbf{k}} & \Delta \\ \bar{\Delta} & -\epsilon_{\mathbf{k}} \end{bmatrix} \begin{pmatrix} c_{\mathbf{k}\uparrow} \\ c^\dagger_{-\mathbf{k}\downarrow} \end{pmatrix} \\ &= \psi^\dagger_{\mathbf{k}} \begin{bmatrix} \epsilon_{\mathbf{k}} & \Delta_1 - i\Delta_2 \\ \Delta_1 + i\Delta_2 & -\epsilon_{\mathbf{k}} \end{bmatrix} \psi_{\mathbf{k}} \end{aligned}$$

And now by finding eigenvalues of a matrix, we get
(?? write it??)

$$E_{\mathbf{k}} \equiv \left| \vec{B}_{\mathbf{k}} \right| = \sqrt{\epsilon^2_{\mathbf{k}} + |\Delta|^2}$$

(??? I'll write it better later!)
So, at this point, one can ask, why we are doing something else, if this method is so compact? Yes, indeed, this is the best approach.

Shnirman.Piasotski.SC-intro.3.1 Diagonalization of BCS Hamiltonian by a ladder operators

Consider the following toy Hamiltonian with Fermionic field operators

$$H = \epsilon \left(c^\dagger_\uparrow c_\uparrow + c^\dagger_\downarrow c_\downarrow \right) + V \left(c^\dagger_\uparrow c^\dagger_\downarrow + c_\downarrow c_\uparrow \right) \qquad \begin{aligned} \{c_\sigma, c_{\sigma'}\} &= \left\{ c^\dagger_\sigma, c^\dagger_{\sigma'} \right\} = 0, \\ \left\{ c_\sigma, c^\dagger_{\sigma'} \right\} &= \delta_{\sigma,\sigma'} \end{aligned} \tag{13}$$

Defining the following objects

$$J_+ = c^\dagger_\uparrow c^\dagger_\downarrow, \quad J_- = c_\downarrow c_\uparrow, \quad J_z = \frac{1}{2}(N-1), \quad N = n_\uparrow + n_\downarrow, \quad n_\sigma = c^\dagger_\sigma c_\sigma \tag{15}$$

demonstrate the following relations hold:

$$[J_+, J_-] = 2J_z, \quad [J_\pm, J_z] = \mp J_\pm \tag{16}$$

Using $J_+ = J^\dagger_-$ we naturally obtain

$$[J_-, J_z] = J_-$$

In other words, we may assert that the operators $J_x = \frac{1}{2}(J_+ + J_-), J_y = \frac{1}{2i}(J_+ - J_-)$, and J_z form a representation of the $\mathfrak{su}(2)$ Lie algebra (note that the representation is reducible since the parity operator $e^{i\pi N}$ is conserved).
Using our definitions (15) we write the Hamiltonian in the language of J-s:

$$H = 2(\epsilon J_z + V J_x) + \epsilon = 2\sqrt{\epsilon^2 + V^2}\,(\cos\vartheta J_z + \sin\vartheta J_x) + \epsilon \tag{19}$$

$$\cos\vartheta = \frac{\epsilon}{\sqrt{\epsilon^2 + V^2}}, \quad \sin\vartheta = \frac{V}{\sqrt{\epsilon^2 + V^2}} \tag{20}$$

Show that the Hamiltonian (19) is diagonalised by the following unitary transformation $U = e^{i\vartheta J_y}$, that is

$$H_d = UHU^\dagger = 2\sqrt{\epsilon^2 + V^2} J_z + \epsilon \tag{21}$$

Next we define the Bogolubov operators

$$\gamma_\sigma = U^\dagger c_\sigma U, \quad \gamma^\dagger_\sigma = U^\dagger c^\dagger_\sigma U \equiv (\gamma_\sigma)^\dagger \tag{28}$$

By virtue of Eq. (21) we have

$$H = U^\dagger H_d U = 2\sqrt{\epsilon^2 + V^2} U^\dagger J_z U + \epsilon = \sqrt{\epsilon^2 + V^2} \left(\gamma^\dagger_\uparrow \gamma_\uparrow + \gamma^\dagger_\downarrow \gamma_\downarrow \right) + \epsilon - \sqrt{\epsilon^2 + V^2} \tag{29}$$

And what is left, is to show, how the new operators are related to the original c-operators. Using BCH formula, or by other way, show that

$$\gamma_\uparrow = \cos\frac{\vartheta}{2} c_\uparrow + \sin\frac{\vartheta}{2} c^\dagger_\downarrow, \qquad \gamma_\downarrow = \cos\frac{\vartheta}{2} c_\downarrow - \sin\frac{\vartheta}{2} c^\dagger_\uparrow. \tag{30}$$

Solution

One has

$$[J_+, J_-] = c_\uparrow^\dagger c_\downarrow^\dagger c_\downarrow c_\uparrow - c_\downarrow c_\uparrow c_\uparrow^\dagger c_\downarrow^\dagger = n_\uparrow n_\downarrow - (1-n_\uparrow)(1-n_\downarrow) = n_\uparrow + n_\downarrow - 1 = N - 1 \equiv 2J_z. \tag{17}$$

Next

$$[J_+, J_z] = \frac{1}{2} c_\uparrow^\dagger c_\downarrow^\dagger \left(c_\uparrow^\dagger c_\uparrow + c_\downarrow^\dagger c_\downarrow \right) - \frac{1}{2} \left(c_\uparrow^\dagger c_\uparrow + c_\downarrow^\dagger c_\downarrow \right) c_\uparrow^\dagger c_\downarrow^\dagger = -\frac{1}{2} \left(c_\uparrow^\dagger c_\downarrow^\dagger + c_\uparrow^\dagger c_\downarrow^\dagger \right) = -J_+. \tag{18}$$

Let us check the inverse transformation

$$U^\dagger J_z U = \cos\vartheta J_z + \sin\vartheta J_x \tag{22}$$

with the help of Baker-Campbell-Hausdor (BCH) formula

$$e^{-i\vartheta J_y} J_z e^{i\vartheta J_y} = \sum_{n=0}^{\infty} (-i\vartheta)^n \frac{[(J_y)^n, J_z]}{n!} \tag{23}$$

where the notation is such that

$$[(J_y)^n, J_z] = \left[J_y, \left[(J_y)^{n-1}, J_z \right] \right] \tag{24}$$

and evaluate

$$\left[(J_y)^{2m}, J_z \right] = \left[J_y, \left[(J_y)^{2m-1}, J_z \right] \right] = J_z \tag{25}$$

$$\left[(J_y)^{2m+1}, J_z \right] = \left[J_y, \left[(J_y)^{2m}, J_z \right] \right] = iJ_x \tag{26}$$

So that:

$$e^{-i\vartheta J_y} J_z e^{i\vartheta J_y} = J_z \sum_{n=0}^{\infty} \frac{(-1)^n \vartheta^{2n}}{(2n)!} + J_x \sum_{n=0}^{\infty} \frac{(-1)^n \vartheta^{2n+1}}{(2n+1)!} = \cos\vartheta J_z + \sin\vartheta J_x \tag{27}$$

In the same notations as before we have

$$\gamma_\sigma = U^\dagger c_\sigma U = \sum_{n=0}^{\infty} \left(-\frac{\theta}{2} \right)^n \frac{[(2iJ_y)^n, c_\sigma]}{n!} \tag{31}$$

First we establish

$$[2iJ_y, c_\uparrow] = -c_\downarrow^\dagger, \quad [2iJ_y, c_\downarrow] = c_\uparrow^\dagger, \tag{32}$$

$$\left[2iJ_y, c_\uparrow^\dagger \right] = -c_\downarrow, \quad \left[2iJ_y, c_\downarrow^\dagger \right] = c_\uparrow. \tag{33}$$

Or, introducing the secular notation, $\sigma = \uparrow \equiv +$ and $\sigma = \downarrow \equiv -$, we compactly write

$$[2iJ_y, c_\sigma] = -\sigma c_{-\sigma}^\dagger, \quad \left[2iJ_y, c_\sigma^\dagger \right] = -\sigma c_{-\sigma} \tag{34}$$

It follows that

$$\left[(2iJ_y)^{2m}, c_\sigma \right] = \left[2iJ_y, \left[(2iJ_y)^{2m-1}, c_\sigma \right] \right] = (-1)^m c_\sigma \tag{35}$$

$$\left[(2iJ_y)^{2m+1}, c_\sigma \right] = \left[2iJ_y, \left[(2iJ_y)^{2m}, c_\sigma \right] \right] = -(-1)^m \sigma c_{-\sigma}^\dagger \tag{36}$$

and hence

$$\gamma_\sigma = c_\sigma \sum_{m=0}^{\infty} \left(\frac{\vartheta}{2} \right)^{2m} \frac{(-1)^m}{(2m)!} + \sigma c_{-\sigma}^\dagger \sum_{m=0}^{\infty} \left(\frac{\vartheta}{2} \right)^{2m+1} \frac{(-1)^m}{(2m+1)!} = c_\sigma \cos\frac{\vartheta}{2} + \sigma c_{-\sigma}^\dagger \cos\frac{\vartheta}{2},$$

exactly what we wanted to show.

How does this relate to the "rotation of a combined particle operators" by the angle θ?

This is a good question, because this solution should be the same as just rotation, but it looks very different. (??????)

me. Obvious question about BCS Hamiltonian

The BCS Hamiltonian has the form:

$$\hat{H} = \int d^3 r \hat{\Psi}_\sigma^+(t,\mathbf{r}) \left(\frac{\left(\hat{\mathbf{p}} - \frac{e}{c}\mathbf{A}\right)^2}{2m} + e\varphi - \mu \right) \hat{\Psi}_\sigma(t,\mathbf{r}) + \\ + \frac{1}{2} \int d^3 r_1 d^3 r_2 \hat{\Psi}_\sigma^+(t,\mathbf{r}_1)\, \hat{\Psi}_{\sigma'}^+(t,\mathbf{r}_2)\, U(\mathbf{r}_1 - \mathbf{r}_2)\, \hat{\Psi}_{\sigma'}(t,\mathbf{r}_2)\, \hat{\Psi}_\sigma(t,\mathbf{r}_1)$$

where the $\hat{\Psi}_\sigma(t,\mathbf{r})$ is an operator of annihilation of an electron, $\hat{\mathbf{p}}$ - operator of the electron's momenta, A, φ - potential of a field.

But often in mathematics, one diagonalizes the Hamiltonian

$$H = \epsilon \left(c_\uparrow^\dagger c_\uparrow + c_\downarrow^\dagger c_\downarrow \right) + V \left(c_\uparrow^\dagger c_\downarrow^\dagger + c_\downarrow c_\uparrow \right) \tag{13}$$

and says that it is related to the BCS Hamiltonian. But how are they related?

Solution

One need to just go to the momenta space, change notation, then do the mean field approximation. Then, V will be the real gap and ϵ is the linearize spectrum.

(?? one can do here the derivation of second one from the first one, but it is rather obvious after going through basics of BCS, so I'll do it later)

me. Transformation of the gap equation

Show that the gap $\Delta = \lambda \cdot \sum_{\mathbf{p}'}' \langle \hat{a}_{-\mathbf{p}',-} \hat{a}_{\mathbf{p}',+} \rangle$ can be reexpressed in terms of the Fermi-Dirac distribution and itself after substituting the canonical transformation

$$\begin{aligned} \hat{a}_{\mathbf{p},-} &= u_p \hat{b}_{\mathbf{p}-} - v_p \hat{b}_{-\mathbf{p},+}^\dagger, \\ \hat{a}_{\mathbf{p},+} &= u_p \hat{b}_{\mathbf{p}+} + v_p \hat{b}_{-\mathbf{p},-}^\dagger, \end{aligned} \qquad u_{\mathrm{p}}^2, v_{\mathrm{p}}^2 = \frac{1}{2} \left(1 \pm \frac{\xi_{\mathrm{p}}}{\sqrt{\xi_{\mathrm{p}}^2 + \Delta^2}} \right);$$

Solution.

$$\begin{aligned} \Delta &= \lambda \sum_{\mathbf{p}'}' \left\langle (u_p \hat{b}_{-\mathbf{p}-} - v_p \hat{b}_{\mathbf{p},+}^\dagger)(u_p \hat{b}_{\mathbf{p}+} + v_p \hat{b}_{-\mathbf{p},-}^\dagger) \right\rangle = \\ &= \lambda \sum_{\mathbf{p}'}' \left\langle u_p^2 \hat{b}_{-\mathbf{p}-} \hat{b}_{\mathbf{p}+} - v_p u_p \hat{b}_{\mathbf{p},+}^\dagger \hat{b}_{\mathbf{p}+} - v_p^2 \hat{b}_{\mathbf{p},+}^\dagger \hat{b}_{-\mathbf{p},-}^\dagger + u_p v_p \hat{b}_{-\mathbf{p}-} \hat{b}_{-\mathbf{p},-}^\dagger \right\rangle = \\ &= \lambda \sum_{\mathbf{p}'}' u_p^2 \underbrace{\left\langle \hat{b}_{-\mathbf{p}-} \hat{b}_{\mathbf{p}+} \right\rangle}_{=0} - v_p u_p \underbrace{\left\langle \hat{b}_{\mathbf{p},+}^\dagger \hat{b}_{\mathbf{p}+} \right\rangle}_{=\bar{n}_{\mathbf{p}}} - v_p^2 \underbrace{\left\langle \hat{b}_{\mathbf{p},+}^\dagger \hat{b}_{-\mathbf{p},-}^\dagger \right\rangle}_{=0} + u_p v_p \underbrace{\left\langle \hat{b}_{-\mathbf{p}-} \hat{b}_{-\mathbf{p},-}^\dagger \right\rangle}_{1-\bar{n}_{\mathbf{p}}} \end{aligned}$$

$$\bar{n}_{\mathbf{p}} := \left\langle \hat{b}_{\mathbf{p}+}^\dagger \hat{b}_{\mathbf{p}+} \right\rangle = \left\langle \hat{b}_{\mathrm{p}-}^\dagger \hat{b}_{\mathbf{p}-} \right\rangle = [\exp(\varepsilon(p)/T) + 1]^{-1}$$

$$\Delta = \lambda \sum_{\mathbf{p}'}' u_p v_p (-\bar{n}_{\mathbf{p}} + 1 - \bar{n}_{\mathbf{p}}) = \lambda \sum_{\mathbf{p}'}' \frac{\Delta}{2\sqrt{\xi_p^2 + \Delta^2}} (1 - 2\bar{n}_{\mathbf{p}}).$$

$$\frac{1}{\lambda} = \frac{1}{2}\sum_{\mathbf{p}}{}' \frac{1-2\bar{n}_{\mathrm{p}}}{\sqrt{\xi_{\mathrm{p}}^2+\Delta^2}}$$

This is the well-known gap equation.

14.2.2 Framework of BCS: Basic, General Properties

Chalker-ex2.Q-2 Number of Particles, Free energy, gap

The BCS Hamiltonian is

$$H = \sum_{k\sigma}\epsilon(k)c_{k\sigma}^{\dagger}c_{k\sigma} - V\sum_{k,q}{}' c_{k\uparrow}^{\dagger}c_{-k\downarrow}^{\dagger}c_{-q\downarrow}c_{q\uparrow}$$

where $c_{k\sigma}^{\dagger}$ and $c_{k\sigma}$ denote fermion creation and annihilation operators for states labelled by wavevector, k, and spin, $\sigma =\uparrow,\downarrow$. The second summation, $\sum_{k,q}{}'$, is restricted to wavevectors k, q of states lying within the Debye energy, $\hbar\omega_D$, of the chemical potential, μ: $|\epsilon(k)$ - $\mu|, |\epsilon(q) - \mu| \leq \hbar\omega_D$. The BCS wavefunction is

$$|\mathrm{BCS}\rangle = \Pi_k\left(u_k + v_k c_{k\uparrow}^{\dagger}c_{-k\downarrow}^{\dagger}\right)|0\rangle,$$

where $|0\rangle$ is the vacuum state and $\{u_k, v_k\}$ are variational parameters, with $|u_k|^2 + |v_k|^2 = 1$. The number operator is

$$N = \sum_{k,\sigma} c_{k\sigma}^{\dagger}c_{k\sigma}$$

(i) Calculate the mean particle number, $\langle\mathrm{BCS}|N|\mathrm{BCS}\rangle$, and its variance,

$$\left\langle \mathrm{BCS}\left|N^2\right|BCS\right\rangle - \langle\mathrm{BCS}|N|\mathrm{BCS}\rangle^2$$

in the BCS wavefunction.

(ii) Show that the free energy of the system in the BCS state is

$$\langle\mathrm{BCS}|H-\mu N|\mathrm{BCS}\rangle = 2\sum_k(\epsilon(k)-\mu)\,|v_k|^2 - \frac{|\Delta|^2}{V}$$

where

$$\Delta = V\sum_k{}' u_k v_k^*$$

(iii) By minimising this free energy with respect to the variational parameters, u_k and v_k, derive the zero-temperature gap equation

$$1 = \frac{V}{2}\sum_k{}' \frac{1}{\left[|\Delta|^2+(\epsilon(k)-\mu)^2\right]^{1/2}}.$$

(iv) Show that, in the weak-coupling limit in which $|\Delta| \ll \hbar\omega_D$, the gap equation has the solution

$$|\Delta| = 2\hbar\omega_D\exp(-1/\nu V)$$

where ν is the density of states at the chemical potential.

Solution to (i)

(?? I'll think about it later. also, I'll write better theory about particle number in SC)

Solution to (ii)

Solution to (iii)

Solution to (iv)

me. Calculation of equation of the coupled two electrons

Two electrons near Fermi surface can be described by the following model:

$$\hat{H}_0(\mathbf{r}_1)\,\psi_{\mathbf{p}}(\mathbf{r}_1) = |\xi_{\mathbf{p}}|\,\psi_{\mathbf{p}}(\mathbf{r}_1), \qquad \psi_{\mathbf{p}}(\mathbf{r}) := V^{-\frac{1}{2}} e^{\frac{i\mathbf{p}\mathbf{r}}{\hbar}}, \qquad \xi_{\mathbf{p}} := v_F(p - p_F).$$

The wave function of two electrons $\psi_{\text{pair}}(\mathbf{r}_1, \mathbf{r}_2) := \sum_{\mathbf{p}} c_{\mathbf{p}} \psi_{\mathbf{p},+}(\mathbf{r}_1)\,\psi_{-\mathbf{p},-}(\mathbf{r}_2)$ obeys the following equation:

$$\left[\hat{H}_0(\mathbf{r}_1) + \hat{H}_0(\mathbf{r}_2) + \hat{V}(\mathbf{r}_1, \mathbf{r}_2)\right]\psi(\mathbf{r}_1, \mathbf{r}_2) = E\psi(\mathbf{r}_1, \mathbf{r}_2).$$

Show that it is equivalent to the following equation:

$$2|\xi_{\mathbf{p}}|\,c_{\mathbf{p}} + \sum_{\mathbf{p}'} V_{\mathbf{p}\mathbf{p}'} c_{\mathbf{p}'} = E c_{\mathbf{p}} \qquad V_{\mathbf{p}\mathbf{p}'} := \left\langle \mathbf{p}, +, -\mathbf{p}, - | \hat{V} | \mathbf{p}', +, -\mathbf{p}', - \right\rangle$$

Solution

One needs just to carefully substitute the ansatz, it is relatively easy, but neatness is still required.

$$\hat{H}_0(\mathbf{r}_1) \sum_{\mathbf{p}} c_{\mathbf{p}} \psi_{\mathbf{p},+}(\mathbf{r}_1)\,\psi_{-\mathbf{p},-}(\mathbf{r}_2) + \hat{H}_0(\mathbf{r}_2) \sum_{\mathbf{p}} c_{\mathbf{p}} \psi_{\mathbf{p},+}(\mathbf{r}_1)\,\psi_{-\mathbf{p},-}(\mathbf{r}_2) + \hat{V}(\mathbf{r}_1, \mathbf{r}_2) \sum_{\mathbf{p}'} c_{\mathbf{p}'} \psi_{\mathbf{p}',+}(\mathbf{r}_1)\,\psi_{-\mathbf{p}',-}(\mathbf{r}_2) =$$
$$= E \sum_{\mathbf{p}} c_{\mathbf{p}} \psi_{\mathbf{p},+}(\mathbf{r}_1)\,\psi_{-\mathbf{p},-}(\mathbf{r}_2).$$

$$|\xi_{\mathbf{p}}|(\mathbf{r}_1) \sum_{\mathbf{p}} c_{\mathbf{p}} \psi_{\mathbf{p},+}(\mathbf{r}_1)\,\psi_{-\mathbf{p},-}(\mathbf{r}_2) + |\xi_{\mathbf{p}}|(\mathbf{r}_2) \sum_{\mathbf{p}} c_{\mathbf{p}} \psi_{\mathbf{p},+}(\mathbf{r}_1)\,\psi_{-\mathbf{p},-}(\mathbf{r}_2) +$$
$$+ \sum_{\mathbf{p}} \psi_{\mathbf{p},+}(\mathbf{r}_1)\,\psi_{-\mathbf{p},-}(\mathbf{r}_2)\,\psi^{\dagger}_{\mathbf{p},+}(\mathbf{r}_1)\,\psi^{\dagger}_{-\mathbf{p},-}(\mathbf{r}_2)\,\hat{V}(\mathbf{r}_1, \mathbf{r}_2) \sum_{\mathbf{p}'} c_{\mathbf{p}'} \psi_{\mathbf{p}',+}(\mathbf{r}_1)\,\psi_{-\mathbf{p}',-}(\mathbf{r}_2) = E \sum_{\mathbf{p}} c_{\mathbf{p}} \psi_{\mathbf{p},+}(\mathbf{r}_1)\,\psi_{-\mathbf{p},-}(\mathbf{r}_2).$$

$$2|\xi_{\mathbf{p}}|\,c_{\mathbf{p}} + \sum_{\mathbf{p}'} V_{\mathbf{p}\mathbf{p}'} c_{\mathbf{p}'} = E c_{\mathbf{p}} \qquad V_{\mathbf{p}\mathbf{p}'} := \left\langle \mathbf{p}, +, -\mathbf{p}, - | \hat{V} | \mathbf{p}', +, -\mathbf{p}', - \right\rangle.$$

Done. Now, this equation can be used to show that indeed electrons are attracted. (??? add words, how exactly. it is already written in the theory)

Shnirman.Piasotski.SC-intro.2(m) Generalized Cooper problem

In the Cooper problem, there were two electrons on top of the full Fermi sea. Consider now a generalization. In this case the excited state is assumed to be a superposition of either of two electrons slightly above the Fermi level or of two holes slightly below the Fermi level (the total number of particles is, thus, not sharply defined). Note that in the grand-canonical description the energies of both electrons and holes are positive. Find the bound state wave function and the binding energy per particle Δ. Compare it with Δ of the BCS theory.

Solution

(????)
We assume the following Ansatz for the wave function

$$|\Psi\rangle = \sum_{-\hbar\omega_D < \xi_k < 0} \alpha(k)\chi(\sigma_1, \sigma_2)\, c_{-k,\sigma_2} c_{k,\sigma_1} |\Psi_0\rangle + \sum_{0 < \xi_k < \hbar\omega_D} \alpha(k)\chi(\sigma_1, \sigma_2)\, c^{\dagger}_{k,\sigma_1} c^{\dagger}_{-k,\sigma_2} |\Psi_0\rangle, \tag{5}$$

where $|\Psi_0\rangle = \prod_{k\leq k_F} c^\dagger_{k,\sigma}|0\rangle$ stands for the fully occupied Fermi sea, and $\xi_k \equiv \epsilon_k - \mu$.
In The wave function (5) includes the hole-like ($\xi_k < 0$) excitation as well as the electron-like ($\xi_k > 0$) ones.
The (BCS) Hamiltonian reads

$$H_{\rm BCS} = \sum_{k,\sigma} \epsilon_k c^\dagger_{k,\sigma} c_{k,\sigma} - \frac{1}{2}\frac{g}{V} \sum_{k,k',\sigma} c^\dagger_{k',\sigma} c^\dagger_{-k',-\sigma} c_{-k,-\sigma} c_{k,\sigma} \tag{6}$$

We will measure the energy of particles relative to the filled Fermi sphere $E_{\rm FS} = 2\sum\limits_{k\leq k_F} \epsilon_k$. Substituting the Ansatz (5) into the Schrödinger equation $(E + E_{\rm FS})\,|\Psi\rangle = H_{\rm BCS}|\Psi\rangle$, we obtain:

$$(2\,\mathrm{sign}\,(\xi_k)\,\epsilon_k - E)\,\alpha(k) = \frac{g}{V} \sum_{-\hbar\omega_D < \xi_{k_1} < \hbar\omega_D} \alpha\,(k_1) \tag{7}$$

Here $\alpha(k)$ for $\xi_k < 0$ describes hole-like excitations and for $\xi_k > 0$ it describes the particle-like excitations.
We introduce

$$C := \frac{1}{V} \sum_{-\hbar\omega_D < \xi_{k_1} < \hbar\omega_D} \alpha(k) \tag{8}$$

substitute it self-consistently and obtain the equation for E

$$\begin{aligned} 1 &= \frac{g}{2} \int\limits_{E_F}^{E_F+\hbar\omega_D} d\omega \frac{\rho(\omega)}{\omega - E/2} - \frac{g}{2} \int\limits_{E_F-\hbar\omega_D}^{E_F} d\omega \frac{\rho(\omega)}{\omega + E/2} \\ &= \frac{g\rho_F}{2} \log\left(\frac{E_F + (\hbar\omega_D - E/2)}{E_F - E/2}\right) + \frac{g\rho_F}{2} \log\left(\frac{E_F - (\hbar\omega_D - E/2)}{E_F + E/2}\right) \end{aligned} \tag{9}$$

Here we have used $1/V\sum\limits_k \to \int \rho(\omega)d\omega$. The density of states in the vicinity of the Fermi surface can be replaced by a constant one $\rho(\omega) \approx \rho_F$.

It follows that

$$\frac{2}{g\rho_F} = \log\left(\frac{E_F^2 - (\hbar\omega_D - E/2)^2}{E_F^2 - E^2/4}\right) \tag{10}$$

Thus for weak coupling $g\rho_F \ll 1$, under the usual condition $E_F \gg \hbar\omega_D$, we obtain

$$E \simeq 2E_F - 2\hbar\omega_D e^{-\frac{1}{g\rho_F}} \tag{11}$$

The binding energy per electron is then found from $E = 2E_F - 2\Delta$

$$\Delta = \hbar\omega_D e^{-\frac{1}{g\rho_F}} \tag{12}$$

(In the typical theory is was $\Delta = \hbar\omega_D e^{-\frac{2}{g\rho_F}}$)

(???? so, where this model is used??? I read something about something similar... I'll add later it here)

Shnirman.Piasotski.BCS.2 Density of states of the BCS quasiparticles

Calculate the density of states of the BCS quasiparticles.

Solution

The density of states (per spin projection) ai given by

$$\rho(E) = \sum_k \delta\,(E - E_k) \tag{7}$$

Here $E_k = \sqrt{\Delta^2 + \xi_k^2}$. We get
(??? what is ρ_0???)

$$\rho(E) = \rho_0 \int d\xi \delta\left(E - \sqrt{\Delta^2 + \xi^2}\right) \tag{8}$$

We define a new integration variable $x = \sqrt{\Delta^2 + \xi^2}$

$$\rho(E) = \rho_0 \int dx \left|\frac{d\xi}{dx}\right| \delta(E - x) \tag{9}$$

Since

$$\frac{dx}{d\xi} = \frac{\xi}{x} = \frac{\sqrt{x^2 - \Delta^2}}{x} \tag{10}$$

we obtain

$$\rho(E) = \frac{2\rho_0 E}{\sqrt{E^2 - \Delta^2}} \tag{11}$$

The factor 2 is due to the fact that ξ and $-\xi$ correspond to the same x. This is of course for $E > \Delta$. For $E < \Delta$ we get $\rho(E) = 0$.

Shnirman.Piasotski.SC-intro.3.2 BCS ground state

Here, we will use notation:

$$\gamma_\uparrow := \cos\frac{\vartheta}{2} c_\uparrow + \sin\frac{\vartheta}{2} c_\downarrow^\dagger, \qquad \gamma_\downarrow := \cos\frac{\vartheta}{2} c_\downarrow - \sin\frac{\vartheta}{2} c_\uparrow^\dagger. \tag{30}$$

$$U = e^{i\vartheta J_y}$$

$$J_+ = c_\uparrow^\dagger c_\downarrow^\dagger, \quad J_- = c_\downarrow c_\uparrow, \quad J_z = \frac{1}{2}(N-1), \quad N = n_\uparrow + n_\downarrow, \quad n_\sigma = c_\sigma^\dagger c_\sigma \tag{15}$$

The ground state is defined via the following condition $\gamma_\sigma|0\rangle_\gamma = 0$. Show that this implies the following relation $U|0\rangle_\gamma = |0\rangle$ where $|0\rangle$ is the vacuum state of original Fermions ($c_\sigma|0\rangle = 0$).
Consider the following representation

$$U^\dagger = e^{-i\vartheta J_y} = e^{a_+ J_+} e^{a_z J_z} e^{a_- J_-} \tag{42}$$

where $a_\pm, a_z$ are functions of the angle ϑ. By differentiating the Eq. (42) with respect to ϑ, establish the following system of non-linear differential equations

$$\frac{d}{d\vartheta} a_+ = -\frac{1}{2} e^{a_z}, \quad \frac{d}{d\vartheta} a_z = a_-, \quad \frac{d}{d\vartheta} a_- = \frac{1}{2}\left(1 + a_-^2\right), \tag{43}$$

$$a_+(0) = a_-(0) = a_z(0) = 0 \tag{44}$$

Show that these are solved by

$$a_\pm(\vartheta) = \mp \tan\frac{\vartheta}{2}, \quad a_z(\vartheta) = -2\log\cos\frac{\vartheta}{2} \tag{54}$$

Using the equation (40) along with the decomposition (42) and the result (54), prove that

$$|0\rangle_\gamma = (1 + a_+ J_+)\, e^{-\frac{1}{2}a_z}|0\rangle \equiv \left(\cos\frac{\vartheta}{2} - \sin\frac{\vartheta}{2} c_\uparrow^\dagger c_\downarrow^\dagger\right)|0\rangle \tag{59}$$

Solution

(????)
Applying the derivative we find

$$\begin{aligned}\frac{d}{d\vartheta} U^\dagger &= -iU^\dagger J_y = e^{a_+ J_+} e^{a_z J_z} e^{a_- J_-} \dot{a}_- J_- + e^{a_+ J_+} e^{a_z J_z} \dot{a}_z J_z e^{a_- J_-} + e^{a_+ J_+} \dot{a}_+ J_+ e^{a_z J_z} e^{a_- J_-} \\ &= U^\dagger J_- \dot{a}_- + U^\dagger e^{-a_- J_-} J_z e^{a_- J_-} \dot{a}_z + U^\dagger e^{-a_- J_-} e^{-a_z J_z} J_+ e^{a_z J_z} e^{a_- J_-} \dot{a}_+ \end{aligned} \tag{45}$$

It follows that

$$-iJ_y = J_- \dot{a}_- + e^{-a_- J_- J_z} e^{a_- J_-} \dot{a}_z + e^{-a_- J_-} e^{-a_z J_z} J_+ e^{a_z J_z} e^{a_- J_-} \dot{a}_+ \tag{46}$$

Now we consider

$$e^{-a_- J_-} J_z e^{a_- J_-} = J_z - a_- [J_-, J_z] = J_z - a_- J_-, \tag{47}$$
$$e^{-a_z J_z} J_+ e^{a_z J_z} = J_+ e^{-a_z} \tag{48}$$
$$e^{-a_- J_-} J_+ e^{a_- J_-} = J_+ + 2a_- J_z - a_-^2 J_- \tag{49}$$

The equality (46) is now

$$-\frac{1}{2}[J_+ - J_-] = J_- \dot{a}_- + (J_z - a_- J_-)\dot{a}_z + \left(J_+ + 2a_- J_z - a_-^2 J_-\right) e^{-a_z} \dot{a}_+ \tag{50}$$

Which yields the following system of ODEs

$$\frac{d}{d\vartheta} a_+ = -\frac{1}{2} e^{a_z}, \quad \frac{d}{d\vartheta} a_z = a_-, \quad \frac{d}{d\vartheta} a_- = \frac{1}{2}\left(1 + a_-^2\right) \tag{51}$$
$$a_+(0) = a_-(0) = a_z(0) = 0 \tag{52}$$

with the initial conditions deduced from the requirement

$$U^\dagger\big|_{\vartheta=0} = 1 \tag{53}$$

Equation (49) is solved by direct integration

$$\frac{da_-}{d\vartheta} = \frac{1}{2}\left(1 + a_-^2\right) \quad \Rightarrow \quad \int^{a_-} \frac{dy}{1+y^2} = \frac{1}{2}(\vartheta - \vartheta_0) \quad \Rightarrow \quad \arctan(a_-) = \frac{1}{2}(\vartheta - \vartheta_0) \quad \Rightarrow \quad a_-(\vartheta) = \tan\left(\frac{\vartheta}{2}\right), \tag{56}$$

where the integration constant is fixed by the initial conditions. Other equations yield

$$a_z(\vartheta) = \int_0^\vartheta d\vartheta' \tan\left(\frac{\vartheta'}{2}\right) = -2\ln\left(\cos\frac{\vartheta}{2}\right) \tag{57}$$

$$a_+(\vartheta) = -\frac{1}{2}\int_0^\vartheta d\vartheta' e^{-2\ln\left(\cos\frac{\vartheta'}{2}\right)} = -\tan\left(\frac{\vartheta}{2}\right) \tag{58}$$

To see this we consider

$$U^\dagger|0\rangle = e^{a_+ J_+} e^{a_z J_z} e^{a_- J_-}|0\rangle = e^{a_+ J_+} e^{a_z J_z}|0\rangle = e^{a_+ J_+} e^{\frac{1}{2}a_z(N-1)}|0\rangle = e^{-\frac{a_z}{2}} e^{a_+ J_+}|0\rangle = e^{-\frac{a_z}{2}}\left(1 + a_+ J_+\right)|0\rangle \tag{60}$$

where we used that $J_+^2|0\rangle = 0$. Now substituting the results of our previous consideration we find that

$$|0\rangle_\gamma = \left(\cos\frac{\vartheta}{2} - \sin\frac{\vartheta}{2} c_\uparrow^\dagger c_\downarrow^\dagger\right)|0\rangle \tag{61}$$

14.2.3 Problems about the Gap Equation

Shnirman.Piasotski.SC-intro.1 **Expectation value of operators in the BCS ground state:**

Following the dream team of Bardeen, Cooper, and Schrieffer, in the class we considered the following family of states as our variational ansatz for the ground state of the BCS Hamiltonian:

$$|\mathrm{BCS}\rangle = \prod_k \left(u_k + v_k c_{k,\uparrow}^\dagger c_{-k,\downarrow}^\dagger\right)|0\rangle \tag{1}$$

Here $|0\rangle$ is the Fermionic vacuum state $c_{k,\sigma}|0\rangle = 0, c_{k,\sigma}^\dagger$ and $c_{k,\sigma}$ are the Fermionic creation and annihilation operators obeying the standard canonical commutation relations

$$\{c_{k,\sigma}, c_{k',\sigma'}\} = \left\{c_{k,\sigma}^\dagger, c_{k',\sigma'}^\dagger\right\} = 0, \qquad \left\{c_{k,\sigma}, c_{k',\sigma'}^\dagger\right\} = \delta_{k,k'}\delta_{\sigma,\sigma'} \tag{2}$$

Prove the following result

$$\left\langle \mathrm{BCS}\left| c_{k',\uparrow}^\dagger c_{-k',\downarrow}^\dagger c_{-k,\downarrow} c_{k,\uparrow}\right|\mathrm{BCS}\right\rangle = u_k v_k u_{k'} v_{k'} \tag{3}$$

Solution

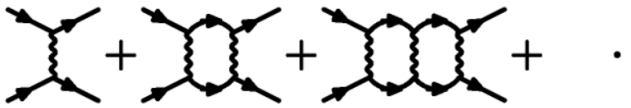
$$\left\langle \mathrm{BCS}\left| c^\dagger_{k',\uparrow} c^\dagger_{-k',\downarrow} c_{-k,\downarrow} c_{k,\uparrow} \right| \mathrm{BCS} \right\rangle =$$

$$= \langle 0| \prod_{k_2 \neq k} \left(u_{k_2} + v_{k_2} c_{k_2,\uparrow} c_{-k_2,\downarrow}\right) \left(u_k + v_k c_{k,\uparrow} c_{-k,\downarrow}\right) c^\dagger_{k',\uparrow} c^\dagger_{-k',\downarrow} c_{-k,\downarrow} c_{k,\uparrow}$$
$$\left(u_k + v_k c^\dagger_{k,\uparrow} c^\dagger_{-k,\downarrow}\right) \prod_{k_1 \neq k} \left(u_{k_1} + v_{k_1} c^\dagger_{k_1,\uparrow} c^\dagger_{-k_1,\downarrow}\right) |0\rangle =$$

$$= v_k \langle 0| \prod_{k_2 \neq k} \left(u_{k_2} + v_{k_2} c_{k_2,\uparrow} c_{-k_2,\downarrow}\right) \left(u_k c^\dagger_{k',\uparrow} c^\dagger_{-k',\downarrow} + v_k c_{k,\uparrow} c_{-k,\downarrow} c^\dagger_{k',\uparrow} c^\dagger_{-k',\downarrow}\right) \prod_{k_1 \neq k} \left(u_{k_1} + v_{k_1} c^\dagger_{k_1,\uparrow} c^\dagger_{-k_1,\downarrow}\right) |0\rangle$$

$$= v_k u_k \langle 0| \prod_{k_2 \neq k,k'} \left(u_{k_2} + v_{k_2} c_{k_2,\uparrow} c_{-k_2,\downarrow}\right) \left(u_{k'} + v_{k'} c_{k',\uparrow} c_{-k',\downarrow}\right) c^\dagger_{k',\uparrow} c^\dagger_{-k',\downarrow}$$
$$\left(u_{k'} + v_{k'} c^\dagger_{k',\uparrow} c^\dagger_{-k',\downarrow}\right) \prod_{k_1 \neq k} \left(u_{k_1} + v_{k_1} c^\dagger_{k_1,\uparrow} c^\dagger_{-k_1,\downarrow}\right) |0\rangle =$$

$$= v_k u_k u_{k'} v_{k'} \langle 0| \prod_{k_2 \neq k,k'} \left(u_{k_2} + v_{k_2} c_{k_2,\uparrow} c_{-k_2,\downarrow}\right) c_{k',\uparrow} c_{-k',\downarrow} c^\dagger_{k',\uparrow} c^\dagger_{-k',\downarrow} \prod_{k_1 \neq k,k'} \left(u_{k_1} + v_{k_1} c^\dagger_{k_1,\uparrow} c^\dagger_{-k_1,\downarrow}\right) |0\rangle =$$



$$= v_k u_k u_{k'} v_{k'} \left\langle 0 \left| \prod_{k_2 \neq k,k'} \left(u_{k_2} + v_{k_2} c_{k_2,\uparrow} c_{-k_2,\downarrow}\right) \prod_{k_1 \neq k,k'} \left(u_{k_1} + v_{k_1} c^\dagger_{k_1,\uparrow}\, \uparrow^\dagger_{-k_1,\downarrow}\right) \right| 0 \right\rangle =$$

$$= v_k u_k u_{k'} v_{k'} \left\langle 0 \left| \prod_{k_1 \neq k,k'} \left(u^2_{k_1} + v^2_{k_1}\right) \right| 0 \right\rangle = v_k u_k u_{k'} v_{k'}$$

ЛШ-58. Scattering in Cooper channel, Bethe-Salpeter equation T_c, Δ_0

(??? write short reminder of the whole formalism)

Рассмотрим мацубаровскую амплитуду рассеяния в куперовском канале $\Gamma^C\left(i\varepsilon, i\varepsilon'\right)$) (энергии сталкивающихся частиц равны $\pm\varepsilon$, а разлетающихся равны $\pm\varepsilon'$). Она дается суммой лестничных графиков, изображенных на рис. ниже

Пусть каждой волнистой линии соответствует множитель $\Gamma^0\left(i\varepsilon, i\varepsilon'\right)$. Будем считать взаимодействие точечным и соответственно пренебрежем зависимостью Γ^C и Γ^0 от импульсов.

а) Суммируя куперовскую лестницу, выведите интегральное уравнение, определяющее $\Gamma^C\left(i\varepsilon, i\varepsilon'\right)$.

б) Рассмотрите модель, в которой $\Gamma^0\left(i\varepsilon, i\varepsilon'\right)$ факторизуется:

$$\Gamma^0\left(i\varepsilon, i\varepsilon'\right) = \lambda v(i\varepsilon) v\left(i\varepsilon'\right)$$

где λ - константа взаимодействия, а функция $v(i\varepsilon)$ - формфактор, определяющий масштаб энергий (спиновая структура опущена). Найдите температуру, при которой Γ^C обращается в бесконечность.

в) В случае, когда

$$v(i\varepsilon) = \frac{\omega_D}{\sqrt{\varepsilon^2 + \omega_D^2}},$$

найдите связь между T_c и ω_D.

Описанная здесь модель нефизична, поскольку настоящее электрон-фононное взаимодействие приводит к затравочной вершине Γ^0, зависящей от переданной энергии $\varepsilon - \varepsilon'$. Тем не менее, поскольку эта модель учитывает запаздывание притяжения между электронами на временах $\approx \omega_D^{-1}$, она дает качественно правильные предсказания.

Solution 58 а.

Выведем уравнение на $\Gamma^C(i\varepsilon, i\varepsilon')$, суммируя диаграммы на рис. из условия. Заметим, что в этих диаграммах сумма 4-импульсов $s = p_1 + p_2$ одинакова в каждой петле. Поэтому интегральное уравнение, соответствующее этим диаграммам, имеет вид

$$\Gamma^C(p, p'; s) = \Gamma^0(p, p') + \int \Gamma^0(p, k) G(k) G(s-k) \Gamma^C(k, p'; s) \frac{d^4k}{(2\pi)^4}$$

(конечно, по частотам следует брать не интеграл, а мацубаровскую сумму). Это уравнение отличается от аналогичного уравнения теории ферми-жидкости знаком перед интегральным членом. (Отличие возникает из-за того, что ферми-жидкостные диаграммы содержат фермионные петли, а куперовские диаграммы - нет.) (?????!!!!)

Положим $s = 0$, пренебрежем зависимостью Γ^0 и Γ^C от пространственного импульса, получим:

$$\Gamma^C(i\varepsilon, i\varepsilon') = \Gamma^0(i\varepsilon, i\varepsilon') + T \sum_{\varepsilon''} \int \frac{d^3p}{(2\pi)^3} \Gamma^0(i\varepsilon, i\varepsilon'') G(i\varepsilon'', \mathbf{p}) G(-i\varepsilon'', -\mathbf{p}) \Gamma^C(i\varepsilon'', i\varepsilon').$$

Интеграл по импульсам вычисляется переходом к интегрированию по ξ:

$$\int \frac{1}{(\varepsilon'')^2 + \xi_p^2} \frac{d^3p}{(2\pi)^3} = \frac{\pi\nu_0}{|\varepsilon''|}$$

(?? check it!)

Поэтому уравнение на куперовскую амплитуду принимает вид

$$\Gamma^C(i\varepsilon, i\varepsilon') = \Gamma^0(i\varepsilon, i\varepsilon') + \pi\nu_0 T \sum_{\varepsilon''} \Gamma^0(i\varepsilon, i\varepsilon'') \Gamma^C(i\varepsilon'', i\varepsilon') / |\varepsilon''|$$

Solution 58 б.

$$\Gamma^0(i\varepsilon, i\varepsilon') = \lambda v(i\varepsilon) v(i\varepsilon')$$

$$\Gamma^C(i\varepsilon, i\varepsilon') = \lambda v(i\varepsilon) \left(v(i\varepsilon') + \pi\nu_0 T \sum_{\varepsilon''} v(i\varepsilon'') \Gamma^C(i\varepsilon'', i\varepsilon') / |\varepsilon''| \right).$$

Из соображений симметрии (??? which???) следует, что

$$\Gamma^C(i\varepsilon, i\varepsilon') = \alpha v(i\varepsilon) v(i\varepsilon'),$$

thus

$$\alpha = \lambda + \pi\nu_0 \alpha\lambda T \sum_{\varepsilon''} v^2(i\varepsilon'') / |\varepsilon''|$$

$$\alpha = \lambda \left(1 - \pi\nu_0 \lambda T \sum_{\varepsilon''} v^2(i\varepsilon'') / |\varepsilon''| \right)^{-1}.$$

$$\alpha = \infty \qquad \Rightarrow \qquad \pi T \sum_{\varepsilon''} v^2(i\varepsilon'') / |\varepsilon''| = 1/\lambda\nu_0$$

Эта формула и определяет температуру перехода T_c.

Solution 58 в. с логарифмической точностью

By this point we know that the equation $\pi T_c \sum_{\varepsilon''} v^2(i\varepsilon'') / |\varepsilon''| = 1/\lambda\nu_0$ should hold.

We plug $v(i\varepsilon) := \omega_D / \left(\omega_D^2 + \varepsilon^2\right)^{1/2} \Rightarrow$ (?? meaning of it???) and fermionic frequencies: $\varepsilon = \omega = (2n+1)\pi T_c$, we have

$$2 \sum_{n=0}^{\infty} \frac{\omega_D^2}{(\omega_D^2 + \pi^2 T_c^2 (2n+1)^2)(2n+1)} = \frac{1}{\lambda\nu_0}.$$

Factor 2 originates from two sums (one from -∞ to 0 and another from 0 to ∞).

Множитель $v^2(i\varepsilon)$ обрезает сумму $\sum_{\varepsilon''} v^2\left(i\varepsilon''\right)/\left|\varepsilon''\right|$ при $n \approx n_{\max} = \omega_D/\pi T_c$. (???????)

Если считать $n_{\max} \gg 1$ и пренебречь множителем $v^2(i\varepsilon)$, заменив верхний предел суммы на $n_{\max}$, получим (то есть мы вообще выкидываем первую скобку из знаменателя, говоря, что она не особо повлияет)

$$\sum_{n=0}^{n_{\max}} \frac{1}{n+1/2} = \ln n_{\max} = \frac{1}{\nu_0 \lambda}$$

$$T_c \approx \frac{\omega_D}{\pi} e^{-1/\lambda\nu_0}$$

Значение коэффициента в этой формуле таким образом найти нельзя, да и, вообще, метод полезен только для быстрой оценки.

Solution 58 в. точно

The T_c comes out of the equation $2\sum_{n=0}^{\infty} \frac{\omega_D^2}{\left(\omega_D^2+\pi^2T_c^2(2n+1)^2\right)(2n+1)} = \frac{1}{\lambda\nu_0}$, so let us evaluate it exactly.

Here, we have два масштаба: T_c и ω_D, причем, $T_c \ll \omega_D$. Поэтому вклады этих масштабов можно разделить, используя следующий стандартный прием. Разобьем сумму на две части: по $n < n_0$ и по $n > n_0$, причем точку разбиения n_0 выберем так, что $n_0 \gg 1$, и одновременно $2\pi T_c n_0 \ll \omega_D$. Найдем сумму по каждой из областей, а затем сложим результаты. В области $n < n_0$ можно заменить функцию $v(i\varepsilon)$ на единицу, после чего эта часть суммы легко вычисляется с помощью тождеств

$$\sum_{k=1}^{\infty}(-1)^{k+1}/k = \ln 2, \quad \lim_{n\to\infty}\left(\sum_{k=1}^{n} 1/k - \ln n\right) = C$$

где $C = 0,577\ldots$ - постоянная Эйлера. Складывая эти два тождества, получаем вклад области $n < n_0$:

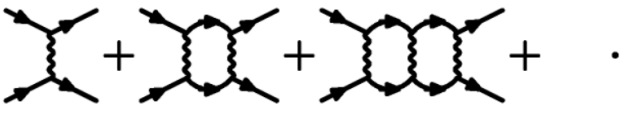
$$S\left(n < n_0\right) = \sum_{n=0}^{n_0} \frac{2}{2n+1} \approx \ln\left(2n_0\right)$$

В высокочастотной области $n > n_0$ можно пренебречь T_c по сравнению с ω_D и заменить сумму интегралом:

$$S\left(n > n_0\right) = \int\limits_{2\pi T n_0}^{\infty} \frac{\omega_D^2}{\varepsilon^2+\omega_D^2}\frac{d\varepsilon}{\varepsilon} = \frac{1}{2}\ln\frac{\varepsilon^2}{\varepsilon^2+\omega_D^2}\Big|_{2\pi T n_0}^{\infty}$$

$$S\left(n > n_0\right)|_{\omega_D \gg 2\pi n_0 T_c} = \ln\frac{\omega_D}{2\pi n_0 T_c}$$

В итоге, суммируя вклады от $n < n_0$ и $n \geqslant n_0$, получаем



$$\frac{1}{\lambda\nu_0} = \ln\frac{\omega_D}{\pi T_c} + C$$

$$T_c = \frac{2\gamma}{\pi}\omega_D e^{-1/\lambda\nu_0}, \qquad \gamma := e^C$$

ЛШ-59. Temperature dependence of the gap $\Delta(T)$

(??? write short reminder of the whole formalism)

Рассмотрим мацубаровскую амплитуду рассеяния в куперовском канале $\Gamma^C\left(i\varepsilon, i\varepsilon'\right)$) (энергии сталкивающихся частиц равны $\pm\varepsilon$, а разлетающихся равны $\pm\varepsilon'$). Она дается суммой лестничных графиков, изображенных на рис. ниже

Пусть каждой волнистой линии соответствует множитель $\Gamma^0\left(i\varepsilon, i\varepsilon'\right)$. Будем считать взаимодействие точечным и соответственно пренебрежем зависимостью Γ^C и Γ^0 от импульсов.

Определите температурную зависимость $\Delta(T)$ для запаздывающего взаимодействия

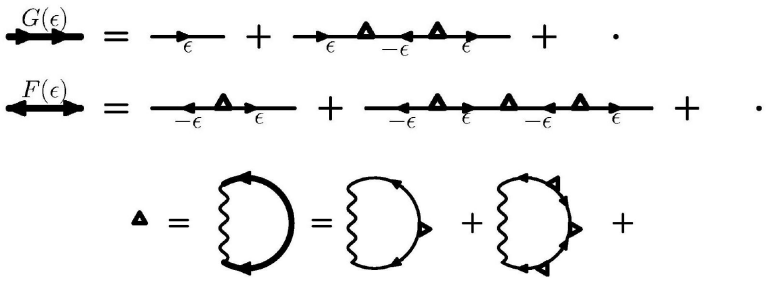
$$\Gamma^0\left(i\varepsilon, i\varepsilon'\right) = \lambda v(i\varepsilon) v\left(i\varepsilon'\right), \qquad v(i\varepsilon) = \frac{\omega_D}{\sqrt{\varepsilon^2+\omega_D^2}}$$

Примите во внимание, что из-за запаздывания щель Δ становится функцией энергии ε спаривающихся частиц.

а) Соответственно рассмотрите величину $\tilde{\Delta}(\varepsilon)$ и, модифицируя уравнения

$$\Delta_{\alpha\beta} = \lambda \int F_{\alpha\beta}(\varepsilon, \mathbf{p}) \frac{d\varepsilon d^3p}{(2\pi)^4},$$

$$\Delta = \lambda T \sum_{\omega_n} \int F\left(i\omega_n, \mathbf{p}\right) \frac{d^3p}{(2\pi)^3} = \lambda T \sum_{\omega_n} \int \frac{\Delta}{\omega_n^2 + \xi_{\mathbf{p}}^2 + \Delta^2} \frac{d^3p}{(2\pi)^3},$$



получите для $\tilde{\Delta}(\varepsilon)$ уравнение самосогласования.

б) В найденном уравнении вычислите интеграл по ξ. Изобразите качественное поведение решения уравнения $\Delta(T)$ на графике. Как $\Delta(T)$ ведет себя при $T \to 0$ и при $T \to T_c$?

в) Найдите сверхпроводящую щель $\Delta(T)$ в пределе низких температур ($T \to 0$) и вблизи точки перехода ($T \to T_c$).

Solution 59 a.

Диаграммы

показывают, что щель Δ возникает в результате свертки аномальной функции $F(i\varepsilon, \mathbf{p})$ и куперовской вершины $\Gamma^0\left(i\varepsilon, i\varepsilon'\right)$.

(???? what is their meaning exactly??? write these formulas. see theory about it for now)

Используем уравнение самосогласования:

$$\tilde{\Delta}(i\varepsilon) = T \sum_{\varepsilon'} \Gamma^0\left(i\varepsilon, i\varepsilon'\right) F\left(i\varepsilon', \mathbf{r}=\mathbf{r}'\right),$$

$$F\left(i\varepsilon, \mathbf{r}=\mathbf{r}'\right) := \int \frac{\tilde{\Delta}(i\varepsilon)}{\varepsilon^2 + \xi_p^2 + \tilde{\Delta}^2(i\varepsilon)} \frac{d^3p}{(2\pi)^3}. \qquad \Gamma^0\left(i\varepsilon, i\varepsilon'\right) = \lambda v(i\varepsilon) v\left(i\varepsilon'\right), \qquad \tilde{\Delta}(i\varepsilon) \equiv \Delta(T) v(i\varepsilon),$$

$$\Delta(T) = \lambda T \sum_{\varepsilon} \int \frac{v^2(i\varepsilon)\Delta(T)}{\varepsilon^2 + \xi_{\mathbf{p}}^2 + v^2(i\varepsilon)\Delta^2(T)} \frac{d^3p}{(2\pi)^3}.$$

Solution 59 б.

Вычисляя интеграл по ξ в $\Delta(T) = \lambda T \sum_{\varepsilon} \int \frac{v^2(i\varepsilon)\Delta(T)}{\varepsilon^2+\xi_{\mathbf{p}}^2+v^2(i\varepsilon)\Delta^2(T)} \frac{d^3p}{(2\pi)^3}$, (??? напишу тут 2 строчки этих преобразований, без слов?) получаем

$$\frac{1}{\lambda\nu_0} = \pi T \sum_{\varepsilon} \frac{v^2(i\varepsilon)}{\sqrt{\varepsilon^2 + \Delta^2(T) v^2(i\varepsilon)}}.$$

Рассмотрим качественно, как ведет себя решение этого уравнения. При $T \ll \Delta(T)$ сумму в правой части можно заменить интегралом. (??? why???)

Таким образом, в этом пределе зависимость от T исчезает, и $\Delta(T)$ стремится к постоянному пределу. Зависимость от T должна быть очень слабой, поскольку для гладкой функции сумма очень хорошо аппроксимирует значение интеграла. Ясно также, что при увеличении температуры величина щели $\Delta(T)$ будет уменьшаться. Формально это следует из того, что сумма в правой части (10.78) переоценивает значение интеграла тем больше, чем больше расстояние между мацубаровскими частотами. Поэтому для того, чтобы удержать правую часть постоянной, рост температуры следует компенсировать убыванием $\Delta(T)$.

Заметим, что при $\Delta = 0$ уравнение (10.78) совпадает с уравнением для определения температуры перехода (10.63), рассмотренным в предыдущей задаче. Это означает, что при $T = T_c$ щель $\Delta(T)$ обратится в нуль. Вблизи этой точки правая часть (10.78) зависит линейно от $T - T_c$ и квадратично от $\Delta(T)$. Поэтому $\Delta(T) \approx \sqrt{T_c - T}$. Из этих рассуждений также следует, что $\Delta(0) \approx T_c$. Полученная таким образом качественная зависимость $\Delta(T)$ согласуется с результатом численного решения уравнения Горькова, изображенном на рис. 10.11

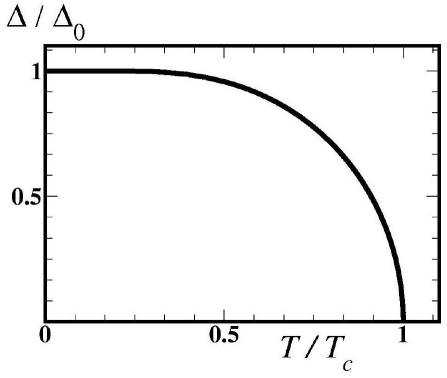


Рис. 10.11

Solution 59 в, Δ_0

Теперь вычислим $\Delta(T)$ при $T \to 0$. Вначале мы просто заменим сумму в $\frac{1}{\lambda\nu_0} = \pi T \sum\limits_{\varepsilon} \frac{v^2(i\varepsilon)}{\sqrt{\varepsilon^2+\Delta^2(T)v^2(i\varepsilon)}}$ интегралом и получим, что $\Delta_0 \equiv \Delta(T=0)$ удовлетворяет уравнению

$$\frac{1}{\nu_0\lambda} = \int\limits_0^\infty \frac{v^2(i\varepsilon)d\varepsilon}{\sqrt{\varepsilon^2 + \Delta_0^2 v^2(i\varepsilon)}}.$$

Найдем этот интеграл для $v(i\varepsilon) = \omega_D / \left(\varepsilon^2 + \omega_D^2\right)^{1/2}$:

$$\frac{1}{\nu_0\lambda} = \int\limits_0^\infty \frac{\omega_D^2 d\varepsilon}{\left(\varepsilon^2 + \omega_D^2\right)\sqrt{\varepsilon^2 + \Delta_0^2\omega_D^2/\left(\varepsilon^2 + \omega_D^2\right)}}.$$

Now, we note that $\Delta_0 \approx T_c \ll \omega_D$. We have a ε, which runs over all values. For $\varepsilon \leq \Delta_0$, we have $v^2(i\varepsilon) \approx 1$, but for $\varepsilon \geq \Delta_0$, we have $\varepsilon^2 \gg \Delta_0^2\omega_D^2/\left(\varepsilon^2 + \omega_D^2\right)$, thus we can just approximate under the square root $\Delta_0^2\omega_D^2/\left(\varepsilon^2 + \omega_D^2\right) \approx \Delta_0^2$:

$$\frac{1}{\nu_0\lambda} \approx \int\limits_0^\infty \frac{\omega_D^2 d\varepsilon}{\left(\varepsilon^2 + \omega_D^2\right)\sqrt{\varepsilon^2 + \Delta_0^2}}.$$

В этом интеграле имеется два существенно разных масштаба энергий: Δ_0 и ω_D. Поэтому можно introduce an energy ε_0, such that $\Delta_0 \ll \varepsilon_0 \ll \omega_D$ and integrate over two parts $\varepsilon < \varepsilon_0$ и $\varepsilon > \varepsilon_0$:

$$\int\limits_0^{\varepsilon_0} \frac{d\varepsilon}{\sqrt{\varepsilon^2 + \Delta_0^2}} + \int\limits_{\varepsilon_0}^\infty \frac{\omega_D^2 d\varepsilon}{\varepsilon\left(\varepsilon^2 + \omega_D^2\right)} = \ln\frac{2\varepsilon_0}{\Delta_0} + \ln\frac{\omega_D}{\varepsilon_0}.$$

Промежуточная энергия ε_0 выпадает. Окончательно получаем

$$\frac{1}{\lambda\nu_0} = \ln\frac{2\omega_D}{\Delta_0}.$$

That is how that complicated integral can be calculated with a little approximation!

Сравнивая это соотношение с выражением (10.73) для температуры перехода T_c, получаем соотношение

$$\Delta_0 = \frac{\gamma}{\pi} T_c$$

Заметим, что коэффициент в формуле (10.73) для T_c связан с конкретной формой обрезания по энергии. Что же касается соотношения (10.83) между Δ_0 и T_c, то при $T_c \ll \omega_D$ оно определяется только физикой низкоэнергетической области $\varepsilon \ll \omega_D$ и поэтому не зависит от выбора обрезающей функции $v(i\varepsilon)$. Кроме того, точно такое же соотношение между Δ_0 и T_c получается и при обрезании по ξ. Таким образом, соотношение (10.83) носит универсальный характер.

Solution 59 в, $\Delta(T)$ approximation at $T \ll T_c$

Now we know, how to evaluate the sum $\frac{1}{\lambda\nu_0} = \pi T \sum\limits_{\varepsilon} \frac{v^2(i\varepsilon)}{\sqrt{\varepsilon^2+\Delta^2(T)v^2(i\varepsilon)}}$, if we have $T = 0$ (because sum changes to the integral). But for low temperatures, we have a sum, so we need to do learn how to do the summation. (?????)

Это можно было бы сделать с помощью формулы суммирования Пуассона (10.47) (????). Однако гораздо проще получить ответ, заметив, что самым малым масштабом, на котором меняется правая часть, является Δ_0. Поэтому при расчете низкотемпературных поправок структурой правой части на масштабе ω_D можно пренебречь.

(???? why???) Тогда можно переписать (10.77) как

$$\frac{1}{\lambda\nu_0} = T \sum_{\varepsilon} \int\limits_{-\infty}^{\infty} \frac{d\xi}{\varepsilon^2 + \xi^2 + \Delta^2}$$

(?? check, maybe there should be π also here???)

$\sum\limits_{n=-\infty}^{\infty} \frac{1}{(2n+1)^2+a^2} = \frac{\pi}{2a} \operatorname{th} \frac{\pi a}{2}$,

$$\frac{1}{\lambda\nu_0} = \int\limits_{0}^{\infty} \operatorname{th} \frac{\sqrt{\xi^2+\Delta^2}}{2T} \frac{d\xi}{\sqrt{\xi^2+\Delta^2}}.$$

Этот интеграл логарифмически расходится, но его значение при $T = 0$ мы уже нашли, и сейчас нас интересуют поправки, возникающие при $T \neq 0$, которые, как мы сейчас увидим, описываются сходящимися интегралами. Минимальное значение аргумента гиперболического тангенса есть $\Delta/(2T) \gg 1$, поэтому $\operatorname{th} x \approx \operatorname{sign} x(1 - 2\exp(-|x|))$,

(??? I am not sure how first term came out, since there is no ω_D in the integral ????)

$$\frac{1}{\lambda\nu_0} = \ln\frac{2\omega_D}{\Delta} - 2\int\limits_{0}^{\infty} \frac{d\xi}{\sqrt{\xi^2+\Delta^2}} \exp\left(-\frac{\sqrt{\xi^2+\Delta^2}}{T}\right).$$

Так как при интегрировании второго члена вклад дают лишь $\xi \ll \Delta$, то $\sqrt{\xi^2+\Delta^2} \approx \Delta + \xi^2/(2\Delta)$,

$$\frac{1}{\nu_0\lambda} = \ln\frac{2\omega_D}{\Delta} - 2e^{-\Delta/T} \int\limits_{0}^{\infty} e^{-\xi^2/2\Delta T} \left(1 - \frac{\xi^2}{2\Delta^2}\right) \frac{d\xi}{\Delta}$$

$$\ln\frac{\Delta}{\Delta_0} = -\sqrt{\frac{2\pi T}{\Delta}} e^{-\Delta/T} \left(1 - \frac{T}{8\Delta}\right),$$

Δ_0 вставлено из замены $1/(\lambda\nu_0) = \ln(2\omega_D/\Delta_0)$.

$$\Delta\,(T \ll T_c) = \Delta_0 \left(1 - \sqrt{\frac{2\pi T}{\Delta_0}} e^{-\Delta_0/T} \left(1 - \frac{T}{8\Delta_0}\right)\right)$$

Выписанная поправка к Δ_0 понадобится нам при вычислении термодинамического потенциала в задаче 60 (???). (Точность выражения (10.88) может показаться чрезмерной, но оказывается, что главный член в выражении (10.88) не дает вклада в термодинамический потенциал, и нам придется учесть выписанную поправку.)

Solution 59 в, $\Delta(T)$ approximation at $T \approx T_c$

Теперь рассмотрим случай $T \to T_c$. В этом пределе $\Delta(T) \ll T$, поэтому правую часть (10.78) можно разложить по Δ:

$$\frac{1}{\lambda\nu_0} = \pi T \sum_{\varepsilon} \left(\frac{v^2(i\varepsilon)}{|\varepsilon|} - \frac{\Delta^2 v^4(i\varepsilon)}{2|\varepsilon|^3} \right)$$

Как показано в задаче 58, первый член в правой части логарифмически зависит от T и сравнивается с левой частью при $T = T_c$. Поэтому его можно объединить с левой частью, получив $\ln T_c/T$.
(??????????)
Что же касается второго члена, пропорционального Δ^2, то он определяется областью $\varepsilon \approx \pi T$, и в нем можно заменить $v^4(i\varepsilon)$ на единицу. Таким образом

$$\ln \frac{T}{T_c} = -\frac{\pi\Delta^2}{2} T \sum_{\varepsilon_n} \frac{1}{|\varepsilon_n|^3}$$

Сумма по мацубаровским частотам легко выражается через ζ-функцию:

$$\zeta(x) = \sum_{n=1}^{\infty} \frac{1}{n^x}, \quad \sum_{n=0}^{\infty} \frac{1}{(2n+1)^x} = \left(1 - \frac{1}{2^x}\right) \zeta(x).$$

(????? change of our sum to the template sum???)

$$\frac{T - T_c}{T_c} = -\frac{7\zeta(3)}{8\pi^2} \frac{\Delta^2}{T_c^2}$$

$$\Delta^2_{T \to T_c} = \frac{8\pi^2}{7\zeta(3)} T_c \left(T_c - T\right)$$

Таким образом, и в этом случае обрезка при $\omega \approx \omega_D$ оказалась несущественной для вычисления щели.

Подводя итог, можно сказать, что конкретный вид обрезания важен в основном для определения T_c. Все остальные физические величины сверхпроводника могут быть выражены через T_c с помощью универсальных соотношений, не зависящих от вида конкретной функции запаздывания $v(i\varepsilon)$. Это происходит потому, что физика сверхпроводника определяется масштабами энергий порядка $T_c \ll \omega_D$. Это оправдывает применение популярной модели, в которой запаздывание на временах порядка ω_D^{-1} учитывается с помощью обрезания интегралов по ξ, а не по ε (???? what is this ε physically????), т. е. запаздывающее взаимодействие заменяется на взаимодействие нелокальное в пространстве.

me. More intuition about BCS

Find $\mathrm{Tr} e^{-\beta H}$, where H is the BCS Hamiltonian

Solution

This is also a basic problem, but details are tricky, so it is a good one.
(Write it later)
(???) One should understand that constant in front of BCS Hamiltonian also has a contribution to the spectrum.

me. More intuition about the gap equation

The gap equation tells us that superconducting gap is obtained by

$$\frac{1}{\lambda} = \frac{1}{2} \sum_{\mathrm{p}}{}' \frac{1 - 2\langle \tilde{n}_p \rangle}{\sqrt{\xi_{\mathrm{p}}^2 + \Delta^2}},$$

where λ is just an input constant of the model; index $'$ indicates that we sum only near the Fermi surface and ξ_{p} is the dispersion, which tells us how kinetic energy of free electron looks like; and $\langle \tilde{n}_p \rangle$ is the averaged number of excitations over superconductive ground state.

Transform this equation to the form of equating averaging of an electron and hole annihilation operators. How this averaging is connected to the gap?

Reminder: $u_p^2 = \frac{1}{2}\left(1 + \frac{\xi_p}{\varepsilon_p}\right), v_p^2 = \frac{1}{2}\left(1 - \frac{\xi_p}{\varepsilon_p}\right)$.

Solution

This is a very easy question, since in the basic theory, there is a derivation from averaging of an electron and hole annihilation operators to the gap equation, so one needs to do just this basic steps to the opposite direction. And the meaning is exactly one, which was in the definition of the gap. However, going backwards is not trivial and it is a good problem for practice, if one don't look at any other theory and just use what is written in the problem statement.

(Write it later here)

14.2.4 Problems about Exotic Transformations in BCS Model

me. Evaluation of a trace

(write background that we work with typical notation in BCS)

For the averaging values, one often calculates traces of the operators. Consider the following transformation:

$$\begin{aligned}\mathrm{Tr}[e^{-\beta H_k}] &= \mathrm{Tr}\Big\{e^{-\beta(\xi_k-\varepsilon_k+\varepsilon_k\left[\hat{b}^\dagger_{\mathbf{k}-}\hat{b}_{\mathbf{k},-}+\hat{b}^\dagger_{\mathbf{k}+}\hat{b}_{\mathbf{k},+}\right])}\Big\} = \\ &= \mathrm{Tr}\Big\{e^{-\beta(\xi_k-\varepsilon_k)}\Big\}\mathrm{Tr}\Big\{e^{-\beta(\varepsilon_k\left[\hat{b}^\dagger_{\mathbf{k}-}\hat{b}_{\mathbf{k},-}+\hat{b}^\dagger_{\mathbf{k}+}\hat{b}_{\mathbf{k},+}\right])}\Big\} \\ &= 4e^{-\beta(\xi_k-\varepsilon_k)}(1+e^{-\beta\varepsilon_k}+e^{-\beta\varepsilon_k}+e^{-2\beta\varepsilon_k}) = \\ &= 4e^{-2\beta(\xi_k-\varepsilon_k)}(1+e^{-\beta\varepsilon_k})^2\end{aligned}$$

and 4 originates from four states: nothing is occupied, spin up is occupied, spin down is occupied and both spins are occupied.

Is it correct? If no, how to fix it?

Solution

No, it is not correct.

(???? I forgot the explanation, why. it was something about that if we have a constant, no states are for it, so trace does not produce 4. but I forgot, why exactly?)

(??? what to do with constant in front, it is maybe also not correct)

Zala,me. More intuition about constant term in the BCS

In the gap equation, one can do the following transformation:

$$\begin{aligned}&\mathrm{Tr}[\frac{\exp\Big[-\beta H\Big]}{\mathrm{Tr}[e^{-\beta H}]}c_{k,+}c_{-k,-}] = \\ &= \mathrm{Tr}[\frac{\exp\left[-\beta\sum_p\left\{-2\Big[\xi_p v_p^2-u_p v_p\Delta\Big]+\begin{pmatrix}c_{p\uparrow} & c^\dagger_{-p\downarrow}\end{pmatrix}\begin{bmatrix}\xi_p & \Delta(t)\\ \Delta(t) & -\xi_p\end{bmatrix}\begin{pmatrix}c_{p\uparrow}\\ c^\dagger_{-p\downarrow}\end{pmatrix}\right\}\right]}{\mathrm{Tr}[e^{-\beta H}]}c_{k,+}c_{-k,-}]\end{aligned}$$

Now, to evaluate this trace we need to work with the constant term, which $2\Big[\xi_p v_p^2-u_p v_p\Delta\Big]$.

(??? here, most likely the constant is wrong, I'll check later!!!)

One can say "this is just a constant, so I'll put it out exponent of it and it will be just a factor in front of the rest expression".

Another approach to the constant is by saying "this constant in matrix notation is actually the identity matrix", thus exponent of it will be an exponent of the constant times the identity matrix, so by taking the trace it will pop out ot the game at all".

Following one logic, constant plays role, following another - does not. What is the correct approach for the constant?

Solution

It is a good, but purely mathematical question.

(anyway, solution will be "the correct transformations will be such that the correct well-known equation is obtained at the end")

How to take properly constant term out: by just constant or by unit matrix?

(write formulas for both!)
These two approaches have a different outcome, since we take later 01 component. So, what is the correct one?

me. Checking trivial evolution of the density matrix

Write the equation of trivial evolution of superconductor's density matrix, if it is not perturbed by anything external. Show that even though time passes and density matrix evolves, the gap does not change.

Solution

This problem is good for application of the density matrix formalism, however, of course, it is useless and asks one about only understanding the formalism.

(write that first part about the formalism!!!!)

(does density matrix gather a trivial phase in its evolution????? write it in the theory of QM!!!)

For the case of the trivial evolution, we have:

$$\begin{aligned}\rho(t+\delta t) = \prod_p \exp\left[-\beta\Big(\epsilon_{\mathbf{k}} - 2\Big[\varepsilon_{\mathbf{p}} v_p^2 - u_p v_p \Delta\Big]\Big)\right]\cdot \\ \cdot \exp\left[-i \begin{pmatrix} c^\dagger_{p\uparrow}, c_{-p\downarrow}\end{pmatrix} \begin{bmatrix} \xi_p & \bar{\Delta} \\ \Delta & -\xi_p \end{bmatrix} \begin{pmatrix} c_{p\uparrow} \\ c^\dagger_{-p\downarrow}\end{pmatrix} \delta t\right]\cdot \\ \cdot \exp\left[-\beta \begin{pmatrix} c^\dagger_{\mathbf{k}\uparrow}, c_{-\mathbf{k}\downarrow}\end{pmatrix} \begin{bmatrix} \epsilon_{\mathbf{k}} & \bar{\Delta} \\ \Delta & -\epsilon_{\mathbf{k}} \end{bmatrix} \begin{pmatrix} c_{\mathbf{k}\uparrow} \\ c^\dagger_{-\mathbf{k}\downarrow}\end{pmatrix}\right]\cdot \\ \cdot \exp\left[i \begin{pmatrix} c^\dagger_{p\uparrow}, c_{-p\downarrow}\end{pmatrix} \begin{bmatrix} \xi_p & \bar{\Delta} \\ \Delta & -\xi_p \end{bmatrix} \begin{pmatrix} c_{p\uparrow} \\ c^\dagger_{-p\downarrow}\end{pmatrix} \delta t\right] / \mathrm{Tr}[e^{-\sum_{q\sigma'} \mu_q n_{p\sigma'}(t)}] \\ = \\ \prod_p \exp\left[-\beta\Big(\epsilon_{\mathbf{k}} - 2\Big[\varepsilon_{\mathbf{p}} v_p^2 - u_p v_p \Delta\Big]\Big)\right]\cdot \\ \cdot \exp\left[\begin{pmatrix} c^\dagger_{p\uparrow}, c_{-p\downarrow}\end{pmatrix} \Big(-i \begin{bmatrix} \xi_p & \bar{\Delta} \\ \Delta & -\xi_p \end{bmatrix} \delta t - \beta \begin{bmatrix} \epsilon_{\mathbf{k}} & \bar{\Delta} \\ \Delta & -\epsilon_{\mathbf{k}} \end{bmatrix} + i \begin{bmatrix} \xi_p & \Delta \\ \bar{\Delta} & -\xi_p \end{bmatrix} \delta t\Big) \begin{pmatrix} c_{p\uparrow} \\ c^\dagger_{-p\downarrow}\end{pmatrix} + \right. \\ \left. + \begin{pmatrix} c^\dagger_{p\uparrow}, c_{-p\downarrow}\end{pmatrix} \mathrm{Kommutators} \begin{pmatrix} c_{p\uparrow} \\ c^\dagger_{-p\downarrow}\end{pmatrix} + \cdots \right] / \mathrm{Tr}[e^{-\sum_{q\sigma'} \beta\varepsilon_{p\sigma'} n_{p\sigma'}(t)}]\end{aligned}$$

where here I defined

$$\begin{aligned}\mathrm{Kommutators} = \frac{1}{2}\left[-i \begin{bmatrix} \xi_p & \bar{\Delta} \\ \Delta & -\xi_p \end{bmatrix} \delta t, -\beta \begin{bmatrix} \epsilon_{\mathbf{k}} & \bar{\Delta} \\ \Delta & -\epsilon_{\mathbf{k}} \end{bmatrix}\right] + \\ + \frac{1}{2}\left[-i \begin{bmatrix} \xi_p & \bar{\Delta} \\ \Delta & -\xi_p \end{bmatrix} \delta t, i \begin{bmatrix} \xi_p & \bar{\Delta} \\ \Delta & -\xi_p \end{bmatrix} \delta t\right] + \\ + \frac{1}{2}\left[-\beta \begin{bmatrix} \epsilon_{\mathbf{k}} & \bar{\Delta} \\ \Delta & -\epsilon_{\mathbf{k}} \end{bmatrix}, i \begin{bmatrix} \xi_p & \bar{\Delta} \\ \Delta & -\xi_p \end{bmatrix} \delta t\right],\end{aligned}$$

where square brackets (with a comma inside) mean the commutator, not a matrix! And the "..." mean higher commutators, which will have a very long expression and I have no idea how to deal with them. Luckily, for the trivial evolution, we have

$$\mathrm{Kommutators} = 0,$$

because all operators under it are the same up to a constant (and also two commutators are zero together, because one is (-1) times another), so we will have

$$\rho(t+\delta t) = \prod_p \exp\left[-\beta\Big(\epsilon_{\mathbf{k}} - 2\Big[\varepsilon_{\mathbf{p}} v_p^2 - u_p v_p \Delta\Big]\Big)\right] \cdot$$
$$\cdot \exp\left[-\beta \begin{pmatrix} c^\dagger_{p\uparrow}, c_{-p\downarrow} \end{pmatrix} \begin{bmatrix} \epsilon_{\mathbf{k}} & \bar{\Delta} \\ \Delta & -\epsilon_{\mathbf{k}} \end{bmatrix} \begin{pmatrix} c_{p\uparrow} \\ c^\dagger_{-p\downarrow} \end{pmatrix}\right] / \mathrm{Tr}[e^{-\sum_{q\sigma'} \beta \varepsilon_{p\sigma'} n_{p\sigma'}(t)}] =$$
$$= \prod_p \exp\left[-\sum_{q\sigma'} \beta \varepsilon_{p\sigma'} n_{p\sigma'}(t)\right] / \mathrm{Tr}[e^{-\sum_{q\sigma'} \beta \varepsilon_{p\sigma'} n_{p\sigma'}(t)}].$$

The terms are combined back exactly as they combined into the initial expression. So, in other words, the density matrix does not evolve in the equilibrium.

Now, we can use our density matrix for getting the gap:
(I need to write that Denis's derivation in this notation)
(anyway, we have a one matrix in the numerator, so it is straightforward how to transform it)

14.2.5 Problems about Numerical Computations in BCS Model

Known,me. Numerical evaluation of gap equation by bisection method

Calculate the gap as a function of temperature numerically, using the bisection and sum terms without changing the sum to the integral.
(remind, what is the gap eq.)
(remind, what is the bisection method)

Solution

General input:

```
import numpy as np
import matplotlib.pyplot as plt
from scipy.optimize import bisect

# Parameters
tttt = 0.3        # hopping parameter
mu = 0.0          # chemical potential
lambd = 1.0       # coupling strength
cutoff = 0.1      # energy window near Fermi surface
N = 1000          # number of momentum points
p_vals = np.linspace(-np.pi, np.pi, N)

def disp(p):
    return -2 * tttt * np.cos(p)

def fermi(E, beta):
    x = beta * E
    x = np.clip(x, -700, 700)  # safe range to avoid overflow
    return 1 / (np.exp(x) + 1)

def gap_eq_func(Delta, T):
    beta = 1 / T
    sum_val = 0.0
    for p in p_vals:
        xi = disp(p) - mu
        if abs(xi) > cutoff:
            continue
        Ep = np.sqrt(xi**2 + Delta**2)
        f = fermi(Ep, beta)
        sum_val += (1 - 2 * f) / Ep
    return 0.5 * sum_val / N - 1 / lambd
```

Estimate critical temperature Tc (limit Delta -> 0):

```
def linearized_gap_eq(T):
    beta = 1 / T
    sum_val = 0.0
```

```
    for p in p_vals:
        xi = disp(p) - mu
        if abs(xi) > cutoff:
            continue
        Ep = abs(xi)
        f = fermi(Ep, beta)
        sum_val += (1 - 2 * f) / Ep
    return 0.5 * sum_val / N - 1 / lambd

from scipy.optimize import brentq
Tc = brentq(linearized_gap_eq, 0.001, 0.1)
```

Compute Delta(T) using bisection method:

```
T_vals = np.linspace(0.001, Tc, 200)
Delta_vals = []

for T in T_vals:
    try:
        Delta_T = bisect(gap_eq_func, 1e-6, 1.0, args=(T,), xtol=1e-6)
    except ValueError:
        Delta_T = 0.0  # Bisection failed; gap = 0
    Delta_vals.append(Delta_T)
```

Normalize:

```
Delta_vals = np.array(Delta_vals)
Delta_0 = Delta_vals[0]
T_norm = T_vals / Tc
Delta_norm = Delta_vals / Delta_0
```

Plot:

```
plt.figure(figsize=(8, 5))
plt.plot(T_norm, Delta_norm, label=r'$\Delta(T)/\Delta(0)$')
plt.xlabel(r'Normalized Temperature $T/T_c$')
plt.ylabel(r'Normalized Gap $\Delta(T)/\Delta(0)$')
plt.title('Superconducting Gap vs Temperature (Bisection Method)')
plt.grid(True)
plt.legend()
plt.tight_layout()
plt.show()
```

```
print(f"Estimated Tc = {Tc:.5f}, Delta(0) = {Delta_0:.5f}")
```

Known,me. Numerical evaluation of gap equation by iterations

Calculate the gap as a function of temperature numerically, using iterations and sum terms without changing the sum to the integral.
(remind, what is the gap eq.)
(remind, what is the iteration method)

Solution

(one needs to just multiply the gap eq. by the gap, such that the l.h.s. will be the updated gap. the rest is relatively trivial)

Known,me. Numerical evaluation of gap equation by changing to the integral

Calculate the gap as a function of temperature numerically by changing the sum to the integral and use the inbuilt commands of a popular programming language.
(remind, what is the gap eq.)
(remind, some function in python, for example)

Solution 1, by Python

We start from the gap equation and some introduced variables:

$$\eta := \frac{1}{N(0)V}; \quad \eta = \int_0^{\hbar\omega_D} \tanh \frac{\sqrt{\Delta^2+\xi^2}}{2k_BT} \frac{d\xi}{\sqrt{\Delta^2+\xi^2}}; \qquad \Delta_0 \approx 1.76 k_B T_c; \qquad \frac{\hbar\omega_D}{\Delta_0} = \sinh\eta;$$

We transform it as follows:

$$\eta = \int_0^{\hbar\omega_D} \tanh\left(\frac{\Delta_0}{2k_BT_c}\frac{1}{T/T_c}\frac{\Delta}{\Delta_0}\sqrt{1+\xi^2/\Delta^2}\right)\frac{d\xi/\Delta}{\sqrt{1+\xi^2/\Delta^2}}$$
$$\approx \int_0^{\delta^{-1}\sinh\eta} \tanh\left(0.882\frac{\delta}{\tau}\sqrt{1+z^2}\right)\frac{dz}{\sqrt{1+z^2}} \qquad \delta := \Delta(T)/\Delta_0, \qquad \tau := T/T_c$$

here $\hbar\omega_D/\Delta = \Delta_0\hbar\omega_D/(\Delta_0\Delta) = \sinh\eta/\delta$. The number 0.882 is more precise than 1.76/2 for the computer.

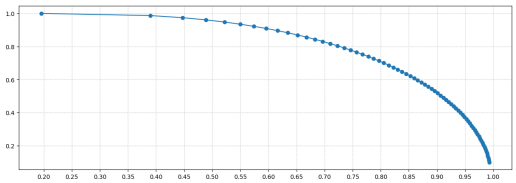
The numerical strategy is as follows. We fix δ and find τ, change δ and solve for $\tau, \ldots$ up to obtain $\delta(\tau)$.

```
import numpy as np
import matplotlib.pyplot as plt
from scipy.integrate import quad
from scipy.optimize import fsolve
from matplotlib.ticker import FormatStrFormatter, MultipleLocator

eta = 1 / 0.35

def bcs_gap_equation(d, t):
    integral, _ = quad(lambda z: np.tanh(0.882 * d * np.sqrt(1 + z**2) / t) / np.sqrt(1 +
    z**2), 0, np.sinh(eta) / d)
    return eta - integral

d_vals = np.linspace(0.1, 0.9999, 70)  # don't set zero here, since we are deviding by d.



t0 = 0.1
t_vals = [fsolve(lambda t: bcs_gap_equation(d, t), t0)[0] for d in d_vals]

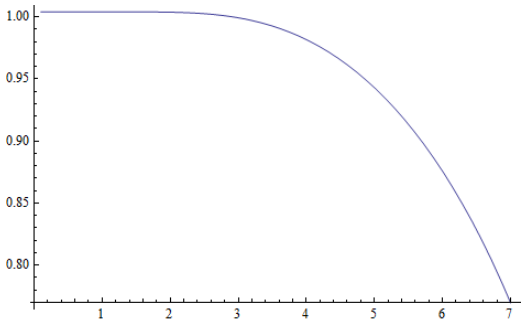
plt.figure(figsize=(15, 5))
plt.plot(t_vals, d_vals, marker='o', linestyle='-')
plt.grid(True, linestyle='--', alpha=0.6)

# Set x-axis grid step to 0.05
plt.gca().xaxis.set_major_locator(MultipleLocator(0.05))

plt.gca().xaxis.set_major_formatter(FormatStrFormatter('%.2f'))
plt.show()
```

We get what we expected:

The disadvantage of this approach is that there are no homogeneous points on temperature axes, only on gap axes. But still, it is fine.



(????) This is simpler than first fixing τ to solve for δ, because of the $1/\delta$ in the boundary, but maybe Im wrong on this point. (??? I'll maybe try later it and write here code for this way)

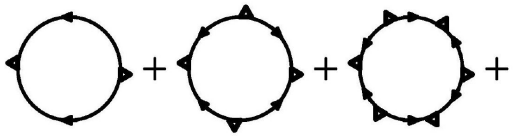
Solution 2, by Wolfram

(???? write about FindRoot[] and NIntegrate[] commands, how do they work?)

```
kb = 1.38 10^(-23);
h = 6.62 10^-34;
hbar = h/2/Pi;
Tc = 9.2;
Delta0 = 3.528/2*Tc*kb;
omegad = 296*kb/hbar;
Delta[T_]:=
  Block[{a = Log[1.13*hbar*omegad/kb/Tc], b = hbar *omegad/2/kb},
   Return[     FindRoot[     NIntegrate[
         Tanh[b/T*Sqrt[\[Epsilon]^2 + x^2]]/
          Sqrt[\[Epsilon]^2 + x^2], {\[Epsilon], 0, 1},  AccuracyGoal -> 2] - a, {x, 0.01,
    0.1}][[1, 2]]*hbar* omegad]];
Plot[Delta[x]/Delta0, {x, 0.1, 7}]
```

We get what we expected:

(??? there are warnings and the T axes is not normalized. so maybe it is a bad code, but still, it can teach us about using wolfram for superconductivity, so I'll keep it for now.)



14.2.6 Questions about Applicability of Formulas

(here, there will be a questions like "I want to describe this phenomena, which formulas I should use?" Later I'll collect this from articles)

14.2.7 Problems about phenomena in the theoretical BCS 1

ЛШ-60. Heat capacity at $T < T_c$

(??? write short reminder of the whole formalism)
Покажите, что вклад электронов в термодинамический потенциал Ω сверхпроводящего металла дается диграммным рядом, показанным на рис. ниже.

Какие выражения сопоставляются различным диаграммам?
Выразите эту сумму графиков через функцию $\Delta(T)$, считая ее известной. Найдите температурную зависимость теплоемкости сверхпроводника:

а) при $T \ll T_c$

б) при $T \to T_c$. В этом случае достаточно взять первый график, показанный на рис. 10.9, поскольку вблизи T_c величина Δ мала. Сравните ответ с теплоемкостью нормального металла (см. [1], 36).

Hint: Вычисляя мацубаровскую сумму при низких температурах, удобно пользоваться формулой суммирования Пуассона $\sum_{n=-\infty}^{\infty} f(n) = \sum_{k=-\infty}^{\infty} \int_{-\infty}^{\infty} f(x) e^{2\pi i k x} dx$, оставляя в сумме по k лишь члены с $k = 0, \pm 1$. Напомним, что применять формулу Пуассона следует с осторожностью, поскольку она справедлива лишь для функций, аналитических на всей вещественной оси.

Solution 60. in general

Характерный масштаб энергий, дающих вклад в термодинамику, оказывается порядка $\max\{\Delta_0, T_c\}$, и следовательно эффектами запаздывания на временах порядка ω_D^{-1} можно пренебречь, выражая все величины через T_c или Δ_0.
Рассмотрим диаграммное разложение термодинамического потенциала, показанное на рис. 10.9. Как обычно, продифференцируем термодинамический потенциал по константе связи λ для того, чтобы убрать множитель $1/n$ перед диаграммами.
(????? why is it a typical approach????)
Как нетрудно заметить, если в каждой из диаграмм на рис. 10.9 перерезать одну из электронных линий, то получается одна из диаграмм на рис. 10.6, причем соответствие взаимнооднозначное. Поэтому

$$\frac{\lambda}{V}\frac{\partial\Omega}{\partial\lambda} = T\sum_{\omega_n}\int G_0^{-1}\left(i\omega_n,\mathbf{p}\right)\left(G\left(i\omega_n,\mathbf{p}\right)-G_0\left(i\omega_n,\mathbf{p}\right)\right)\frac{d^3p}{(2\pi)^3} =$$
$$= -T\sum_{\omega_n}\int \Delta^* F\left(i\omega_n,\mathbf{p}\right)\frac{d^3p}{(2\pi)^3} = -\frac{|\Delta|^2}{\lambda}.$$

Делая преобразование, мы воспользовались соотношениями $G_{\alpha\beta}(\varepsilon,\mathbf{p}) = G^0_{\alpha\beta}(\varepsilon,\mathbf{p}) + G^0_{\alpha\lambda}(\varepsilon,\mathbf{p})\Delta^*_{\lambda\mu}F_{\mu\beta}(\varepsilon,\mathbf{p})$ и $\Delta = \lambda T\sum_{\omega_n}\int\frac{\Delta}{\omega_n^2+\xi_{\mathbf{p}}^2+\Delta^2}\frac{d^3p}{(2\pi)^3}$.

Термодинамический потенциал получается интегрированием $\partial\Omega/\partial\lambda$ по λ от $\lambda = 0$ до истинного значения. Чтобы проинтегрировать по λ, выразим $d\lambda$ через $d\Delta$ с помощью $\Delta = \lambda T\sum_{\omega_n}\int\frac{\Delta}{\omega_n^2+\xi_{\mathbf{p}}^2+\Delta^2}\frac{d^3p}{(2\pi)^3}$:

$$\frac{d\lambda}{\lambda^2} = T\sum_{\omega_n}\int\frac{2\Delta d\Delta}{\left(\omega_n^2+\xi_{\mathbf{p}}+\Delta^2\right)^2}\frac{d^3p}{(2\pi)^3}$$

Поэтому

$$\frac{\Omega_s-\Omega_n}{V} = -2\int_0^{\Delta} T\sum_{\omega_n}\int\frac{\Delta^3 d\Delta}{\left(\omega_n^2+\xi_{\mathbf{p}}^2+\Delta^2\right)^2}\frac{d^3p}{(2\pi)^3}$$

Интегрируя по ξ и Δ, получим
(!??!?!??!!?!? a place for good calculations!!!!)

$$\frac{\Omega_s-\Omega_n}{V} = -\pi\nu_0 T\sum_{\omega_n}\left(\sqrt{\omega_n^2+\Delta^2}+\frac{\omega_n^2}{\sqrt{\omega_n^2+\Delta^2}}-2\left|\omega_n\right|\right).$$

Снова рассмотрим предельные случаи.

Approximation at $T\to 0$

$T\sum\limits_{\omega_n}\ldots \approx \int\ldots\frac{d\omega}{2\pi}$,

$$\sum_n f(n) \approx \int f(x)dx + \int e^{2\pi i x}f(x)dx + \int e^{-2\pi i x}f(x)dx + \ldots$$

$$f(x) := \sqrt{(2\pi Tx)^2+\Delta^2}+\frac{\Delta^2}{\sqrt{(2\pi Tx)^2+\Delta^2}} - 4\pi T|x|$$

Здесь неаналитичность $|x|$ не мешает использовать формулу Пуассона, поскольку для последнего слагаемого сумму в формуле Пуассона можно вычислить явно, не делая никаких приближений. (????)
(?????? a place for a calculation!!!!)
Вычислим сумму в (10.98) при $T\to 0$. Согласно формуле суммирования Пуассона,

$$\frac{\Omega_s-\Omega_n}{V} = -\pi\nu_0\sum_{k=-\infty}^{\infty}\int_{-\infty}^{\infty}\left(\sqrt{\omega^2+\Delta^2}+\frac{\omega_n^2}{\sqrt{\omega^2+\Delta^2}}-2|\omega|\right)ve^{ik\omega/T}\frac{d\omega}{2\pi}$$

Заметим, что первые два члена - плавные функции ω, поэтому интегралы от них экспоненциально малы. Поэтому нам достаточно удержать их лишь при $k = 0,\pm 1$. Что же касается последнего члена, то интеграл от него легко вычисляется и равен $-4T^2/k^2$. В результате выражение для термодинамического потенциала приводится к виду

$$\frac{\Omega_s-\Omega_n}{V} = -\nu_0\left[\int_0^{\infty}\left(\sqrt{\omega^2+\Delta^2}+\frac{\omega^2}{\sqrt{\omega^2+\Delta^2}}-2\omega\right)d\omega + \int_{-\infty}^{\infty}\left(\sqrt{\omega^2+\Delta^2}+\frac{\omega^2}{\sqrt{\omega^2+\Delta^2}}\right)\cos\frac{\omega}{T}d\omega - 2\sum_{k=1}^{\infty}\frac{T^2}{k^2}\right].$$

$$\int_0^{\infty}\left(\sqrt{\omega^2+\Delta^2}+\frac{\omega^2}{\sqrt{\omega^2+\Delta^2}}-2\omega\right)d\omega = \frac{\Delta^2}{2} \qquad\qquad \sum_{k=1}^{\infty}\frac{1}{k^2} = \frac{\pi^2}{6}$$

```
Integrate[(Sqrt[x^2 + d^2] + x^2/Sqrt[x^2 + d^2] - 2 x), {x, 0, Infinity}]
```

We are left with computation of $I := \int\limits_{-\infty}^{\infty} \left(\sqrt{\omega^2+\Delta^2} + \frac{\omega^2}{\sqrt{\omega^2+\Delta^2}}\right) \cos\frac{\omega}{T} d\omega$. Функция $\sqrt{\omega^2+\Delta^2}$ имеет скачок на разрезе от точки $i\Delta$ до бесконечности. В остальной же части верхней полуплоскости функция аналитична, поэтому контур интегрирования можно деформировать так, чтобы он огибал этот разрез (рис. 10.12)

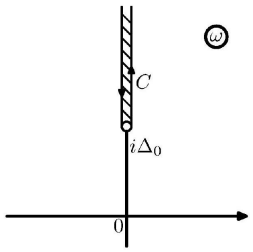


Рис. 10.12

$$\omega := i\Delta + iu,$$

(????? I don't know what happened???)

$$I = 2\int\limits_0^{\infty} \frac{\Delta^2 + 2u^2 + 4u\Delta}{\sqrt{2\Delta u + u^2}} e^{-(\Delta+u)/T} du$$

В этот интеграл дают вклад $u \approx T$, поэтому подынтегральное выражение можно разложить по u:

$$2\Delta^2 e^{-\Delta/T} \int\limits_0^{\infty} \left(1 + \frac{15}{4}\frac{u}{\Delta}\right) e^{-u/T} \frac{du}{\sqrt{2\Delta u}} = \sqrt{2\pi T\Delta^3} e^{-\Delta/T} \left(1 + \frac{15}{8}\frac{T}{\Delta}\right)$$

Finally:

$$\frac{\Omega_s - \Omega_n}{V} = -\frac{\nu_0\Delta^2}{2}\left(1 + 2\sqrt{\frac{2\pi T}{\Delta}} e^{-\Delta/T}\left(1 + \frac{15}{8}\frac{T}{\Delta}\right)\right) + \frac{\pi^2\nu_0 T^2}{3}.$$

Заметим, что последний член в этой формуле это взятый с обратным знаком термодинамический потенциал нормального металла. (???? why????)

Finally,

$$\Omega_s = -\frac{V\nu_0\Delta^2}{2}\left(1 + 2\sqrt{\frac{2\pi T}{\Delta}} e^{-\Delta/T}\left(1 + \frac{15}{8}\frac{T}{\Delta}\right)\right)$$

$\Delta\left(T \ll T_c\right) = \Delta_0\left(1 - \sqrt{\frac{2\pi T}{\Delta_0}} e^{-\Delta_0/T}\left(1 - \frac{T}{8\Delta_0}\right)\right)$,

$$\Omega_s = -\frac{\nu_0 V\Delta_0^2}{2}\left(1 + 4\sqrt{\frac{2\pi T^3}{\Delta_0^3}} e^{-\Delta_0/T}\right),$$

Обратим внимание на происходящее здесь сокращение главного температурнозависящего члена (??).

Then

(??? did we neglect other terms after second derivative wrt to T? why they are much less then one that survived???)

$$C_s = T\frac{\partial S_s}{\partial T} = -T\frac{\partial^2\Omega_s}{\partial T^2} = 2\nu_0 V\sqrt{\frac{2\pi\Delta_0^5}{T^3}} e^{-\Delta_0/T}.$$

Approximation at $T \to T_c$

Разложим $\frac{\Omega_s - \Omega_n}{V} = -\pi\nu_0 T\sum\limits_{\omega_n}\left(\sqrt{\omega_n^2+\Delta^2} + \frac{\omega_n^2}{\sqrt{\omega_n^2+\Delta^2}} - 2\left|\omega_n\right|\right)$ до четвертого порядка по Δ (член второго порядка обращается в нуль): (?? check!)

$$\frac{\Omega_s - \Omega_n}{V} = -\pi\nu_0\Delta^4 T\sum_{\omega_n}\frac{1}{\left|\omega_n\right|^3}$$

Сумма, как и в задаче 59, выражается через ζ-функцию: (?? check!)

$$\frac{\Omega_s - \Omega_n}{V} = -\frac{7\zeta(3)}{16\pi^2}\frac{\nu_0\Delta^4}{T_c^2}$$

Подставляя сюда Δ из (10.94), получим

$$\Omega_s - \Omega_n = -\frac{4\pi^2}{7\zeta(3)} V\nu_0 \left(T - T_c\right)^2$$

$$C_s - C_n = \frac{8\pi^2}{7\zeta(3)}\nu_0 T_c V,$$

$C_n := C_{\text{normal metal}} = \frac{2\pi^2}{3}\nu_0 VT$,

$$\frac{C_s - C_n}{C_n} = \frac{12}{7\zeta(3)}$$

Solution 2 (???)

Кстати, эту задачу можно решить, вычисляя термодинамический потенциал идеального газа квазичастиц со спектром (10.37). (?? попробую!)

ЛШ-61. The impact of the Coulomb interaction on superconductivity

Типично говорится, что влияние кулоновского взаимодействия на сверхпроводимость невелико благодаря сильному запаздыванию фононов. Рассмотрим вопрос об относительной важности электрон-электронного и электрон-фононного взаимодействий более подробно.

Оказывается удобным ввести упрощенную модель взаимодействия, в которой между электронами имеется мгновенное отталкивание и запаздывающее притяжение, причем как отталкивание, так и притяжение считаются точечными. При этом затравочная амплитуда рассеяния в куперовском канале имеет вид

$$\Gamma^0\left(i\varepsilon, i\varepsilon'\right) = \lambda v(i\varepsilon) v\left(i\varepsilon'\right) - \mu$$

где параметр μ характеризует величину отталкивания между электронами.

Найдите температуру, при которой амплитуда рассеяния в куперовском канале обращается в бесконечность. Покажите, что эффект отталкивания сводится к замене константы λ в выражении (10.30) для T_c на

$$\lambda_* = \lambda - \frac{\mu}{1 + \nu_0\mu \ln\left(\varepsilon_F/\omega_D\right)}.$$

Безразмерная величина кулоновского взаимодействия в металле есть $\nu_0\mu \approx e^2/\hbar v_F$ в пределе высокой электронной плотности и $\nu_0\mu \approx 1$ при обычных значениях плотности. Соответственно максимально возможная поправка к эффективной константе взаимодействия λ_*, согласно (10.49), имеет относительную малость $1/\ln\left(\varepsilon_F/\omega_D\right)$. Поэтому кулоновское взаимодействие в нормальном металле не может превратить притяжение в отталкивание и, следовательно, не подавляет сверхпроводимость.

Чтобы установить соответствие между моделью (10.48) и реальным кулоновским взаимодействием $V(\mathbf{q})$ в первом приближении достаточно подставить вместо μ среднее значение $V(\mathbf{q})$ в s-канале. Для случая экранированного кулоновского взаимодействия

$$V(\mathbf{q}) = \frac{4\pi e^2}{q^2 + \varkappa^2}; \quad \varkappa^2 = 8\pi\nu_0 e^2$$

(см. задачу 45) получаем следующее выражение:

$$\mu = \left\langle V_c\left(\mathbf{p} - \mathbf{p}'\right)\right\rangle = \frac{\pi e^2}{p_0^2}\ln\left(1 + \frac{4p_0^2}{\varkappa^2}\right),$$

где усреднение производится по положениям импульсов $\mathbf{p}$ и $\mathbf{p}'$ на ферми-поверхности.

Solution 61.

Рассмотрим уравнение (10.58) для куперовской амплитуды рассеяния, полученное в решении задачи 58. Если куперовская амплитуда $\Gamma^C(i\varepsilon, i\varepsilon')$ имеет полюс при $T \to T_c$, то в уравнении (10.58) можно пренебречь свободным членом:

$$\Gamma^C(i\varepsilon, i\varepsilon') = \pi\nu_0 T \sum_{\varepsilon''} \Gamma^0(i\varepsilon, i\varepsilon'')\,\Gamma^C(i\varepsilon'', i\varepsilon')\,/\,|\varepsilon''|$$

Зависимость от ε' в этом уравнении «сокращается». Поэтому можно считать, что решение факторизуется: (???? maybe it is vice versa, we want that ε' will not play role, thus we substitute: (??))

$$\Gamma^C(i\varepsilon, i\varepsilon') = \Phi(i\varepsilon)\Phi(i\varepsilon')$$

(Зависимость Γ^C от ε и ε' должна быть одинаковой ввиду симметрии куперовской лестницы.) Тогда функция $\Phi(\varepsilon)$ удовлетворяет уравнению

$$\Phi(i\varepsilon) = \pi\nu_0 T \sum_{\varepsilon'} \left(\Gamma^0(i\varepsilon, i\varepsilon')\,/\,|\varepsilon'|\right)\Phi(i\varepsilon')$$

Для Γ^0 из условия задачи это интегральное уравнение оказывается вырожденным и легко решается. Видно, что функция $\Phi(\varepsilon)$ содержит два члена: пропорциональный $v(i\varepsilon)$ и не зависящий от ε. Ищем решение в виде

$$\Phi(\varepsilon) = av(i\varepsilon) + b$$

Подставляя это выражение в (10.119) и приравнивая коэффициенты перед $v(i\varepsilon)$ и перед константой, получаем

$$a = \pi\lambda\nu_0 T \sum_{\varepsilon'} \left[av^2(i\varepsilon') + bv(i\varepsilon')\right]/\,|\varepsilon'|\,,$$
$$b = -\pi\mu\nu_0 T \sum_{\varepsilon'} [av(i\varepsilon) + b]/\,|\varepsilon'|\,.$$

На этот раз мы не будем заниматься точным вычислением сумм в этом выражении, а найдем их с логарифмической точностью, поскольку основной интерес будут представлять величины, стоящие перед логарифмами. Суммы, содержащие $v(i\varepsilon)$ и $v^2(i\varepsilon)$ следует обрезать сверху при $\varepsilon \approx \omega_D$. Сумму, не содержащую факторов запаздывания, мы обрежем сверху при $\varepsilon \approx \omega_p\,(\approx \varepsilon_F)$ - на плазменной частоте, которая играет в физике электрон-электронного взаимодействия роль, аналогичную ω_D для электрон-фононного взаимодействия. Таким образом, получаем

$$a = \nu_0\lambda \ln\frac{\omega_D}{T}(a+b)$$
$$b = -\mu\nu_0\left[a\ln\frac{\omega_D}{T} + b\left(\ln\frac{\omega_D}{T} + \ln\frac{\omega_p}{\omega_D}\right)\right].$$

Перенося во втором уравнении член с $\ln(\omega_p/\omega_D)$ в левую часть, можно переписать его в таком виде, что оно становится похоже на первое:

$$b = -\nu_0\mu_* \ln\frac{\omega_D}{T}(a+b); \quad \mu_* = \frac{\mu}{1+\nu_0\mu\ln(\omega_p/\omega_D)}$$

Мы ввели здесь эффективную куперовскую амплитуду μ_*, которая отличается от μ из-за запаздывания фононов.

Now, we sum similar equations for a and b and get the condition for their compatibility:

$$1 = (\lambda - \mu_*)\ln\frac{\omega_D}{T}$$

из которого находим температуру перехода:

$$T_c \approx \omega_D e^{-1/\lambda_*\nu_0}, \quad \lambda_* = \lambda - \mu_*$$

Таким образом, кулоновское взаимодействие действительно понижает температуру сверхпроводящего перехода, но не очень сильно. При $\nu_0\mu\ln\varepsilon_F/\omega_D \gg 1$ относительная поправка к λ мала как $1/\ln(\varepsilon_F/\omega_D)$.

(??? how many degrees is changed if one takes into account Coulomb???)

ЛШ-62. Response and susceptibility of electrons to the field

(??? write about задачу 51, what is going on there??? why the formalism is that we need to calculate the response for the susceptibility?? connection of χ and Q???)

При вычислении электромагнитного отклика сверхпроводника центральное место занимает рассмотренное в гл. 9 тождество Уорда

$$\Pi_{\alpha\beta}(\omega,\mathbf{k})|_{\mathbf{k}=0,\omega\to 0}=-\frac{ne^2}{m}\delta_{\alpha\beta},$$

где поляризационный оператор в частотно-импульсном представлении это $\Pi_{\alpha\beta}(\omega,\mathbf{k}) = \int \Pi_{\alpha\beta}(\omega,\mathbf{r})e^{-i\mathbf{kr}}d^3\mathbf{r}$, следующее из калибровочной инвариантности. Оно приводит к сокращению градиентного и диамагнитного вкладов в электрический ток, с которым мы уже сталкивались в задаче 51 при выводе формулы Друде. Прежде чем заниматься электродинамикой сверхпроводников, изучим тождество Уорда более подробно в случае нормального металла.

а) (Тождество Уорда в нормальном металле) Рассмотрим линейный отклик тока $\mathbf{j}$ в идеальном ферми-газе электронов на неоднородный статический векторный потенциал $\mathbf{A}$. В импульсном представлении линейное соотношение $\mathbf{j}$ и $\mathbf{A}$ записывается как

$$\mathbf{j}_\mathbf{k}=Q(\mathbf{k})\mathbf{A}_\mathbf{k}.$$

Калибровочная инвариантность требует, чтобы для ядра $Q(\mathbf{k})$ выполнялось свойство

$$Q(\mathbf{k})|_{k=0}=0.$$

Согласно тождеству Уорда, это равенство обеспечивается сокращением градиентной $\langle \mathbf{v}G\mathbf{v}G\rangle$ и диамагнитной частей тока $\mathbf{j}=-\frac{e}{mc}\left\langle\psi^+(\mathbf{r})\psi(\mathbf{r})\right\rangle\mathbf{A}(\mathbf{r})$ (см. задачу 51).

Проверьте это сокращение еще раз в более общем виде, не предполагая спектр электронов $\xi(\mathbf{p})$ квадратичным, а считая его произвольной функцией. Используйте соотношение $\mathbf{v}(\mathbf{p})=\nabla_\mathbf{p}\xi(\mathbf{p})$.

б) (Диамагнетизм Ландау.) С помощью тождества Уорда можно найти орбитальную магнитную восприимчивость χ_0 газа невзаимодействующих электронов. Согласно результату части а), разложение $Q(\mathbf{k})$ по $\mathbf{k}$ начинается с члена второй степени: $Q(\mathbf{k})=a\mathbf{k}^2+\mathrm{O}\left(\mathbf{k}^4\right)$.

Разложите петлю, показанную на рис. 10.10,

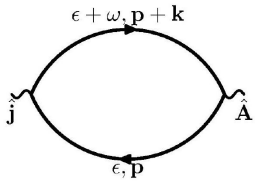

Рис. 10.10

по $\mathbf{k}$ и определите константу a. Как a связана с χ_0? Проверьте, что $\chi_0=-\frac{1}{3}\chi_{\text{пара}}$, где $\chi_{\text{пара}}$ - парамагнитная восприимчивость, найденная в задаче 23 (!?!???!?!?).

Если бы нас интересовало не сокращение $Q(0)$, а одно только вычисление χ_0, можно было бы действовать иначе. Рассмотрим оператор орбитального магнитного момента. $\mu=\frac{e}{mc}[\mathbf{r}\times\mathbf{p}]$ и найдем его среднее, используя функцию Грина в слабом магнитном поле: $G_H\left(E,\mathbf{r}_1,\mathbf{r}_2\right) = \exp\left(\frac{e}{\hbar c}\int\mathbf{A}\left(\mathbf{r}'\right)\mathbf{dr}'\right)G_0\left(E,\mathbf{r}_1,\mathbf{r}_2\right)$. (Интеграл берется по прямому пути, соединяющему $\mathbf{r}_1$ и $\mathbf{r}_2$.) Восприимчивость χ_0 получится, если выделить из G_H линейный по H член.

Solution 62 a.

Прежде чем вычислять $Q(0)$ для произвольного электронного спектра $\xi(\mathbf{p})$, уточним выражение для тока. Гамильтониан частиц со спектром $\xi(\mathbf{p})$ во внешнем магнитном поле $\mathbf{A}(\mathbf{r})$ есть

$$\widehat{\mathcal{H}}=\int\psi^+(\mathbf{r})\xi\left(\widehat{\mathbf{p}}-\frac{e}{c}\mathbf{A}\right)\psi(\mathbf{r})d^3\mathbf{r}$$

где $\widehat{\mathbf{p}}=-i\nabla_\mathbf{r}$. Ток, согласно общим принципам, получается варьированием гамильтониана по $\mathbf{A}$:

$$\widehat{\mathbf{j}}=e\psi^+(\mathbf{r})\nabla_\mathbf{p}\xi\left(\mathbf{p}-\frac{e}{c}\mathbf{A}\right)\psi(\mathbf{r})$$

(??? derive)

Выделим линейный по $\mathbf{A}$ член:

$$\widehat{\mathbf{j}} \approx e\psi^+(\mathbf{r})\nabla_{\mathbf{p}}\xi(\mathbf{p})\psi(\mathbf{r}) - \frac{e^2}{c}\psi^+(\mathbf{r})\nabla_{\mathbf{p}}\left[(\mathbf{A}\nabla_{\mathbf{p}})\,\xi(\mathbf{p})\right]\psi(\mathbf{r})$$

(??? i think, I was deriving it long time ago, I'll do it again)

При $\xi(\mathbf{p}) = \mathbf{p}^2/2m - E_F$ это выражение для тока переходит в обычную квантовомеханическую формулу. (??? check)

Проще всего вычисляется вклад в $Q(0)$ второго члена:

(???? why averaging is here???)

$$Q^{(2)}_{\alpha\beta}(\mathbf{k}) = -\frac{e^2}{c}\left\langle \psi^+ \frac{\partial^2\xi(\mathbf{p})}{\partial p_\alpha \partial p_\beta}\psi \right\rangle = -\frac{e^2}{c}\int \frac{\partial^2\xi(\mathbf{p})}{\partial p_\alpha \partial p_\beta} n_F(\xi(\mathbf{p}))\frac{2d^3p}{(2\pi)^3}$$

We are putting $\mathbf{A}$ outside the $\nabla_{\mathbf{p}}$, because it does not depend on coordinates. (??? right??)

Чтобы найти вклад первого члена, поступим стандартным образом:

$$\widehat{\mathcal{H}}_{\text{int}} \approx -\frac{1}{c}\int \widehat{\mathbf{j}}(\mathbf{r})\mathbf{A}(\mathbf{r})d^3r$$

Находя, как обычно, (??????????) поправку первого порядка к функции Грина и вычисляя с ее помощью $\langle\mathbf{j}\rangle$, получаем, что этот вклад дается петлей:

$$Q^{(1)}_{\alpha\beta}(i\Omega,\mathbf{k}) = -\frac{e^2}{c}\lim_{\tau\to+0} T\sum_{\omega_n}\int \frac{v_\alpha(\mathbf{p})v_\beta(\mathbf{p})}{i\omega_n - \xi(\mathbf{p})}\frac{e^{i\omega_n\tau}}{i\omega_n + i\Omega - \xi(\mathbf{p}+\mathbf{k})}\frac{2d^3p}{(2\pi)^3}$$

Мы ввели здесь множитель сходимости $e^{i\omega_n\tau}(\tau\to+0)$, который отвечает за правильный порядок ψ и ψ^+(ср. с задачей 35 (??????????????)).

$$\begin{aligned}
Q^{(1)}_{\alpha\beta}(\Omega=0,\mathbf{k}=0) &= -\frac{e^2}{c}\lim_{\tau\to+0} T\sum_{\omega_n} e^{i\omega_n\tau}\int \frac{v_\alpha(\mathbf{p})v_\beta(\mathbf{p})}{(i\omega_n - \xi(\mathbf{p}))^2}\frac{2d^3p}{(2\pi)^3} \overset{\mathbf{v}=\nabla_{\mathbf{p}}\xi(\mathbf{p})}{=} \\
&= -\frac{e^2}{c}\lim_{\tau\to+0} T\sum_{\omega_n} e^{i\omega_n\tau}\int v_\alpha(\mathbf{p})\nabla_\beta\frac{1}{i\omega_n - \xi(\mathbf{p})}\frac{2d^3p}{(2\pi)^3} \overset{\text{i b p}}{=} \\
&= +\frac{e^2}{c}\lim_{\tau\to+0} T\sum_{\omega_n} e^{i\omega_n\tau}\int \nabla_\beta v_\alpha(\mathbf{p})\frac{1}{i\omega_n - \xi(\mathbf{p})}\frac{2d^3p}{(2\pi)^3} = -Q^{(2)}_{\alpha\beta}
\end{aligned}$$

In the first transformation, we just noted that $\nabla_\beta\xi(\mathbf{p})/\left(i\omega_n - \xi(\mathbf{p})\right)^2 = \nabla_\beta\frac{1}{i\omega_n - \xi(\mathbf{p})}$.

(суммирование по мацубаровским частотам производится так же, как в выражении (7.59) в решении задачи 35). (!?!???! do the derivations?!? see problem 35!!????? I don't know, why formulas are the same?)

Итак, $Q_{\alpha\beta}(0) = 0$.

Solution 62 б. (????)

Чтобы найти диамагнитную восприимчивость ферми-газа χ_0, свяжем ее с константой a в разложении $Q(\mathbf{k}) = a\mathbf{k}^2 + \ldots$ По определению $Q(\mathbf{k})$,

$$\mathbf{j} = \widehat{Q}\mathbf{A} = -a\nabla^2\mathbf{A}$$

С другой стороны, ток связан с намагниченностью:

$$\mathbf{j} = c\,\mathrm{rot}\,\mathbf{M} = c\,\mathrm{rot}\,\chi_0\mathbf{B} = \chi_0 c\,\mathrm{rot}\,\mathrm{rot}\,\mathbf{A}.$$

Поскольку $\mathrm{div}\,\mathbf{A} = 0$, ток можно записать так:

$$\mathbf{j} = -\chi_0 c\nabla^2\mathbf{A}$$

Отсюда находим $\chi_0 = a/c$.

Теперь вычислим a. Предположим, что волновой вектор $\mathbf{k}$ направлен вдоль оси z, и найдем Q_{xx}:

$$Q_{xx} = -\lim_{\tau\to+0}\frac{e^2}{c}T\sum_{\omega_n} e^{i\omega_n\tau}\int \frac{v_x(\mathbf{p}+\mathbf{k})v_x(\mathbf{p})}{(i\omega_n - \xi_{\mathbf{p}+\mathbf{k}})\,(i\omega_n - \xi_{\mathbf{p}})}\frac{2d^3p}{(2\pi)^3}$$

В отличие от спиновой восприимчивости, орбитальная восприимчивость определяется не только окрестностью поверхности Ферми, но и всеми состояниями под ней, потому что квантование Ландау затрагивает все состояния с $E < E_F$, и конечная восприимчивость χ_0 возникает из-за отличия суммы квантованных энергий от интеграла по непрерывному спектру. Поэтому мы ограничимся случаем $\xi(\mathbf{p}) = \mathbf{p}^2/2m - E_F$. Разлагая $Q(k)$ по $k_z = k$, и имея в виду, что для квадратичного спектра $v_x(\mathbf{p}+\mathbf{k}) = v_x(\mathbf{p}) = p_x/m$, запишем

$$Q_{xx} = -\frac{e^2k^2}{c} T\sum_{\omega_n} e^{i\omega_n\tau} \int \frac{v_x^2}{i\omega_n - \xi_{\mathbf{p}}} \frac{\partial^2}{\partial p_z^2} \frac{1}{i\omega_n - \xi_{\mathbf{p}}} \frac{2d^3p}{(2\pi)^3}.$$

Проинтегрировав по частям, получим

$$\chi_0 = \frac{e^2}{c^2} T\sum_{\omega_n} e^{i\omega_n\tau} \int \frac{v_x^2 v_z^2}{\left(i\omega_n - \xi_{\mathbf{p}}\right)^4} \frac{2d^3p}{(2\pi)^3}.$$

Then, we average $\left\langle v_x^2 v_z^2 \right\rangle = v^4/15$ and get:

$$\chi_0 = \frac{e^2}{15c^2m^4} T\sum_{\omega_n} e^{i\omega_n\tau} \int \frac{p^4}{\left(i\omega_n - \xi_{\mathbf{p}}\right)^4} \frac{2d^3p}{(2\pi)^3}.$$

Here

$$\int_0^\infty \frac{p^6 dp}{\left(i\omega_n + E_F - p^2/2m\right)^4} \overset{\text{3x i b p}}{=} -\frac{5m^3}{2} \int_0^\infty \frac{dp}{i\omega_n + E_F - p^2/2m}$$

Proof. (I'll add formulas here, I did it long time ago) □

после чего суммирование по ω_n дает, как обычно, распределение Ферми (см. формулу (7.59) в з. 35) (???? do it???/):

$$\chi_0 = -\frac{e^2}{12\pi^2 mc^2} \int_0^\infty n_F\left(\xi_p\right) dp = -\frac{e^2 p_0}{12\pi^2 mc^2}$$

Используя выражение для спиновой восприимчивости, найденное в задаче 24 (??? comment, how we get it???)

$$\chi_{\text{para}} = 2\mu_B^2 \nu_0 = \frac{e^2}{4m^2c^2} \frac{mp_0}{\pi^2}$$

находим соотношение между орбитальной и спиновой восприимчивостью:

$$\chi_0 = -\frac{1}{3}\chi_{\text{para}}$$

Однако, это соотношение не универсально. Как видно из нашего вычисления, вклад в χ_0 дает весь спектр, а не только поверхность Ферми. Поэтому полученное соотношение между χ_0 и $\chi_{\text{пара}}$ верно лишь для квадратичного спектра. При более общем законе дисперсии $\xi(\mathbf{p})$ восприимчивость χ_0 по величине может оказаться даже больше, чем $\chi_{\text{пара}}$. В этом случае нормальный металл оказывается диамагнетиком.

ЛШ-63. London's equation from BCS

Найдите отклик тока в сверхпроводнике на статический векторный потенциал. Отличие от задачи 62 состоит в том, что теперь сокращения при $\mathbf{q} = 0$ нет. Положив $\mathbf{q} = 0$ в соотношении $\mathbf{j}_\mathbf{q} = Q(\mathbf{q})\mathbf{A}_\mathbf{q}$, получим так называемое уравнение Лондонов:

$$\mathbf{j}(\mathbf{r}) = -\frac{e^2}{mc} n_s \mathbf{A}(\mathbf{r}).$$

Величина n_s называется сверхтекучей плотностью. Как связаны n_s и Δ при $|T - T_c| \ll T_c$?

Физическая причина отсутствия сокращения вкладов в $Q(0)$ заключается в том, что калибровочная инвариантность в сверхпроводнике спонтанно нарушена. В нормальном металле сокращение $Q(0)$ обеспечивается тождеством Уорда (9.16), следующим из калибровочной инвариантности. А в сверхпроводнике калибровочная инвариантность отсутствует.

Определите глубину проникновения магнитного поля в сверхпроводник. Для этого с помощью уравнения Лондонов решите задачу о проникновении магнитного поля в объем сверхпроводника вблизи поверхности. Покажите, что магнитное поле затухает в глубину по экспоненциальному закону: $H(x) = H(0)\exp\left(-x/\delta_\Lambda\right), x > 0$, и найдите связь δ_Λ с n_S.

Покажите, что пренебрегать зависимостью ядра $Q(q)$ от q законно, если лондоновская глубина проникновения δ_Λ достаточно велика: $\delta_\Lambda \gg \xi_0 = \hbar v_F/\Delta_0$.

Solution 63.

(!! remind the formalism here!!!)
В этой задаче мы вычислим $Q(0)$ для сверхпроводника. При этом основное отличие от вычисления для нормального металла, проделанного в задаче 62, возникает из-за необходимости учесть как нормальные, так и аномальные средние.

Среднее от диамагнитного вклада в ток есть просто (?? why???)

$$Q^{(2)}(0) = -ne^2/mc$$

Градиентный вклад $Q^{(1)}_{\alpha\beta}(i\Omega, \mathbf{k})$ получается усреднением произведения токов и дается следующим выражением: (??? where does it originate????)

$$Q^{(1)}_{\alpha\beta}(i\Omega_s, \mathbf{k}) = \frac{1}{2c}\sum_{\sigma,\sigma'}\int_{-\beta}^{\beta} e^{i\Omega\tau}d\tau \int e^{i\mathbf{kr}}\left\langle \mathrm{T}_\tau \psi^+_\sigma(\mathbf{r},\tau)\hat{j}_\alpha\psi_\sigma(\mathbf{r},\tau)\psi^+_{\sigma'}(0,0)\widehat{j}_\beta\psi_{\sigma'}(0,0)\right\rangle d^3\mathbf{r}$$

где σ, σ' - спиновые индексы, а $\mathbf{j} = -i\frac{e}{m}\nabla_{\mathbf{r}}$.
For its computation, необходимо спарить ψ-операторы, учитывая как нормальные, так и аномальные средние. При этом теорема Вика по-прежнему справедлива, поскольку операторы ψ и ψ^+можно выразить линейным образом через операторы рождения и уничтожения квазичастиц сверхпроводника, для которых аномальные средние равны нулю. Таким образом,

$$\left\langle \mathrm{T}_\tau \psi^+_\sigma(\mathbf{r},\tau)\widehat{j}_\alpha\psi_\sigma(\mathbf{r},\tau)\psi^+_{\sigma'}(0,0)\widehat{j}_\beta\psi_{\sigma'}(0,0)\right\rangle = -\widehat{j}_\alpha G_{\sigma\sigma'}(\mathbf{r},\tau)\widehat{j}_\beta G_{\sigma'\sigma}(-\mathbf{r},-\tau) - \widehat{j}_\alpha F^+_{\sigma\sigma'}(\mathbf{r},\tau)\widehat{j}_\beta F_{\sigma'\sigma}(-\mathbf{r},-\tau)$$

Тогда $Q^{(1)}_{\alpha\beta}(i\Omega, \mathbf{k})$ принимает вид

$$Q^{(1)}_{\alpha\beta}(i\Omega, \mathbf{k}) = -\frac{1}{2c}\int_{-\beta}^{\beta} e^{i\Omega\tau}d\tau \int d^3r e^{i\mathbf{kr}}\left[2\widehat{j}_\alpha G(\mathbf{r},\tau)\widehat{j}_\beta G(-\mathbf{r},-\tau) + 2\widehat{j}_\alpha F(\mathbf{r},\tau)\widehat{j}_\beta F^*(-\mathbf{r},-\tau)\right]$$

Знаки петель, содержащих функции G и F, оказываются одинаковыми. Переписывая выражение (10.150) в импульсном представлении, получаем

$$Q^{(1)}_{\alpha\beta}(i\Omega, \mathbf{k}) = -\frac{Te^2}{c}\sum_{\omega_n}\int v_\alpha\left(\mathbf{p}-\frac{\mathbf{k}}{2}\right)v_\beta\left(\mathbf{p}+\frac{\mathbf{k}}{2}\right)\times$$
$$\times\left\{G\left(i\omega_n, \mathbf{p}-\frac{\mathbf{k}}{2}\right)G\left(i\omega_n+i\Omega, \mathbf{p}+\frac{\mathbf{k}}{2}\right) + F\left(i\omega_n, \mathbf{p}-\frac{\mathbf{k}}{2}\right)F^*\left(i\omega_n+i\Omega, \mathbf{p}+\frac{\mathbf{k}}{2}\right)\right\}\frac{2d^3p}{(2\pi)^3}.$$

thus

$$Q^{(1)}(\mathbf{k}=0) = \frac{1}{3}Q^{(1)}_{\alpha\alpha}(0) = -\frac{e^2T}{3m^2c}\sum_{\omega_n}\int \mathbf{p}^2\left(G^2(i\omega_n,\mathbf{p}) + |F(i\omega_n,\mathbf{p})|^2\right)\frac{2d^3p}{(2\pi)^3}.$$

Собирая вместе $Q^{(1)}$ и $Q^{(2)}$ и учитывая определение n_s, получим

$$n - n_s = -\frac{2T\nu_0 p_0^2}{3m}\sum_{\omega_n}\int_{-\infty}^{\infty}\frac{\Delta^2+\xi^2-\omega_n^2}{\left(\omega_n^2+\xi^2+\Delta^2\right)^2}d\xi$$

Here, при интегрировании по ω the integral обращается в нуль (??? why????), в то время как при интегрировании по ξ этого не происходит. Следовательно, оно не вполне корректно определено. Дело в том, что эта величина не «сидит» на поверхности Ферми, и для правильного учета состояний вдали от уровня Ферми следовало бы брать плотность состояний, зависящую от энергии. Однако сверхтекучая плотность, несомненно, определяется поверхностью Ферми, потому что только там и происходит перестройка электронных состояний. В глубине же фермиевского моря (т.е. при $\xi \sim E_F$) ничего не происходит.
(?????)
Поэтому можно поступить так: вычесть из этого выражения аналогичное с $\Delta = 0$, т. е. для нормального металла. Тогда вклад глубоких состояний выпадет. При этом, как мы знаем, для нормального металла $n_s = 0$. В результате

$$n_s = \frac{2\nu_0 p_0^2}{3m}T\sum_{\omega_n}\int_{-\infty}^{\infty}\left[\frac{\xi^2-\omega_n^2}{\left(\xi^2+\omega_n^2\right)^2} - \frac{\xi^2-\omega_n^2+\Delta^2}{\left(\xi^2+\omega_n^2+\Delta^2\right)^2}\right]d\xi.$$

Получившееся выражение можно интегрировать в любом порядке. Лучше всего сначала проинтегрировать по ξ. При этом оказываются полезными следующие соотношения:

$$\int\limits_{-\infty}^{\infty} \frac{dx}{\left(x^2+a^2\right)^2} = \frac{\pi}{2a^3}, \quad \int\limits_{-\infty}^{\infty} \frac{x^2 dx}{\left(x^2+a^2\right)^2} = \frac{\pi}{2a}$$

После интегрирования получаем ответ: (??? check???)

$$n_s = \frac{2\nu_0 p_0^2}{3m} T \sum_{\omega_n} \frac{\pi\Delta^2}{\left(\omega_n^2+\Delta^2\right)^{3/2}}.$$

Рассмотрим различные предельные случаи.

а) Case $T \to 0$.

Заменим сумму интегралом:

$$n_s = \frac{2\nu_0 p_0^2}{3m} \frac{\pi\Delta^2}{2\pi} \int\limits_{-\infty}^{\infty} \frac{d\omega}{\left(\omega^2+\Delta^2\right)^{3/2}} = \frac{2\nu_0 p_0^2}{3m} = \frac{p_0^3}{3\pi^2} = n.$$

Видим, что при $T = 0$ сверхтекучая плотность равна полной, как и должно быть в трансляционно-инвариантной системе.

б) Case $T \to T_c$.

В этом случае достаточно пренебречь Δ в знаменателе. Тогда сумма выражается через ζ-функцию (см. задачу 59), что дает

$$\frac{n_s}{n} = \frac{7\Delta^2}{4\pi^2 T_c^2} = 2\left(1 - \frac{T}{T_c}\right).$$

Таким образом, при $T \to T_c$ сверхтекучая плотность уменьшается до нуля.
Теперь свяжем n_s с глубиной проникновения. Запишем закон Ампера:

$$\operatorname{rot} \mathbf{H} = \frac{4\pi}{c}\mathbf{j} = -\frac{4\pi n_s e^2}{mc^2}\mathbf{A}$$

Поскольку $\mathbf{H} = \operatorname{rot} \mathbf{A}$, имеем

$$\nabla^2 \mathbf{A} = \frac{4\pi n_s e^2}{mc^2}\mathbf{A}$$

Пусть граница образца перпендикулярна оси x, а магнитное поле параллельно оси z. Тогда

$$A_y(x) = A_y(0) e^{-x/\delta_\Lambda}, \qquad \delta_\Lambda^2 := \frac{mc^2}{4\pi n_s e^2}$$

Отсюда получаем, что магнитное поле

$$H_z = -\frac{\partial A_y}{\partial x} = \frac{A_y(0)}{\delta_\Lambda} e^{-x/\delta_\Lambda} = H_z(0) e^{-x/\delta_\Lambda}$$

экспоненциально затухает в глубь сверхпроводника, причем глубина проникновения равна δ_Λ.
В нашем расчете мы пренебрегали дисперсией $Q(k)$. Выясним, при каких условиях это законно, или, иными словами, каков масштаб пространственной дисперсии в сверхпроводнике. Чтобы определить этот масштаб, следует сравнить kv (это и есть величина, которой мы пренебрегли) со всеми остальными величинами в знаменателях функций G и F в (10.151). Сравнивая ξ с Δ, получаем характерный волновой вектор $k_0 \approx \xi^{-1}(T) \approx \Delta(T)/(\hbar v_F)$. Заметим, однако, что при $T \to T_c \Delta(T) \to 0$ и основную роль в знаменателе играет $\omega_{n=0} = \pi T_c \approx \Delta_0$. Поэтому на самом деле характерный волновой вектор при любых температурах есть $k_0 \approx \xi_0^{-1} \approx \Delta_0/(\hbar v_F)$. Для того чтобы наш расчет был применим, должно быть $\delta_\Lambda \gg \xi_0$. В этом случае сверхпроводник называют лондоновским. Противоположный предельный случай называется пиппардовским.
Оказывается, что в сверхпроводниках есть два пространственных масштаба. Один из них, $\xi(T)$, - это масштаб корреляций параметра порядка Δ. Другой, ξ_0, это размер куперовской пары. При $T \to T_c$ различие между ними становится весьма ощутимым, поскольку при приближении T к T_c корреляционная длина $\xi(T)$ расходится, в то время как размер пары ξ_0 (он же масштаб пространственной дисперсии) при этом остается конечным.

Solution через матричную форму

Покажем, как производить подобные расчеты с помощью матричной функции Грина

$$\widehat{G} = \begin{bmatrix} G_{\uparrow\uparrow} & F_{\uparrow\downarrow} \\ F_{\downarrow\uparrow} & G_{\downarrow\downarrow} \end{bmatrix}$$

Она удовлетворяет такому уравнению:

$$(i\omega - \xi(\mathbf{p})\tau_z - \Delta_1\tau_x - \Delta_2\tau_y)\,\widehat{G} = \widehat{1}$$

($\Delta = \Delta_1 + i\Delta_2$).

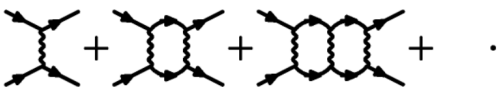
$$\widehat{\mathbf{j}} = c\frac{\delta\widehat{G}^{-1}}{\delta\mathbf{A}} = e\mathbf{v}(\mathbf{p})\hat{1} - \frac{e^2}{mc}\mathbf{A}\tau_z, \qquad \widehat{G} := -\frac{1}{\omega_n^2 + \xi^2 + \Delta^2}\begin{pmatrix} i\omega_n + \xi & \Delta \\ \Delta^* & i\omega_n - \xi \end{pmatrix};$$

Вычисляя

$$\operatorname{Tr}\left(\widehat{j}_\alpha\hat{G}\,(i\omega_n, \mathbf{p})\,\hat{j}_\beta\hat{G}\,(i\omega_n, \mathbf{p})\right) = \frac{e^2 v_\alpha(\mathbf{p})v_\beta(\mathbf{p})}{\left(\omega_n^2 + \xi^2 + \Delta^2\right)^2}\operatorname{Tr}\left(\left(i\omega_n + \xi\tau_z + \Delta\tau_x\right)\left(i\omega_n + \xi\tau_z + \Delta\tau_x\right)\right) =$$
$$= 2e^2 v_\alpha(\mathbf{p})v_\beta(\mathbf{p})\frac{\Delta^2 + \xi^2 - \omega_n^2}{\left(\omega_n^2 + \xi^2 + \Delta^2\right)^2},$$

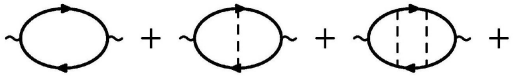
получим то же выражение, что и ранее (см. (10.156)).

14.2.8 Dirty Superconductors: Basic Problems 1



(I'll write here many problems about "how to describe this or that model")

ЛШ-64. Disorder doesn't change T_c



(?? remind the background!)

Обычно говорят, что куперовские пары образованы электронами с противоположными импульсами и спинами. Оказывается, беспорядок не разрушает куперовские пары, хоть импульс и становится плохим квантовым числом. Качественно это можно пояснить так. В присутствии примесей электроны двигаются по ломаным, от одной примеси к другой. За каждым электроном вдоль линии его движения остается деформация решетки, представляющая собой шлейф из виртуальных фононов, рассасывающийся за время порядка ω_D^{-1}. Этот «ароматический след» притягивает другие электроны, причем эффект притяжения максимален для электрона, движущегося в точности по той же траектории, но в обратном направлении. Такие состояния есть при любой степени беспорядка, поскольку увеличение концентрации примесей лишь делает траектории более изломанными, но не выделяет определенного направления движения на каждой из них (в отличие, скажем, от траекторий в магнитном поле). Из этого рассуждения видно, что чисто потенциальное рассеяние на примесях, оставляющее систему инвариантной по отношению к обращению времени, не подавляет сверхпроводимость. А магнитное поле, например, подавляет.

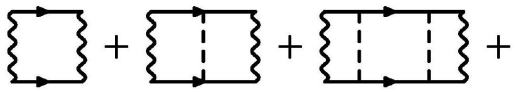
Рассмотрите куперовскую восприимчивость χ_C в присутствии примесей. Чтобы получить χ_C, усредните по беспорядку диаграммы куперовской лестницы

При этом каждый блок куперовской лестницы превращается в диффузионную лестницу, подобную

Покажите, что наличие примесей не меняет $\chi_C(\mathbf{k} = 0)$ и, следовательно, не приводит к изменению T_c.

Solution 64.

Для того чтобы изучить влияние примесей на T_c, рассмотрим диаграммы, образующие один блок куперовской лестницы, и усредним их по беспорядку:



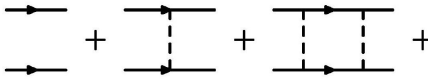


Рис. 10.13

Они имеют ту же структуру, что и диаграммы  . Отличие состоит в том, что куперовская петля теперь содержит примесную лестницу, описывающую рассеяние куперовской пары на примесях. Поэтому

$$\Gamma^C = -\frac{\lambda}{1+\lambda\Pi_c}, \qquad \Pi_c =$$

По сути дела, такая сумма уже была вычислена нами в задаче 54. Напомним, что усредненная по беспорядку функция Грина в грязном металле равна

$$G\left(i\omega_n, \mathbf{p}\right) = \frac{1}{i\omega_n - \xi_p + \frac{1}{2\tau}\operatorname{sign}\omega_n}.$$

Каждая ступенька куперовской лестницы, состоящая из двух функций Грина, взятая при $\Omega = 0, \mathbf{s} = 0$, есть

$$B_c\left(i\omega_n\right) = \int G\left(i\omega_n, \mathbf{p}\right) G\left(-i\omega_n, -\mathbf{p}\right) \frac{d^3p}{(2\pi)^3} = \int\limits_{-\infty}^{\infty} \frac{\nu_0 d\xi}{\left(\omega_n + \frac{1}{2\tau}\operatorname{sign}\omega_n\right)^2 + \xi^2} = \frac{2\pi\nu_0\tau}{1+2\tau\left|\omega_n\right|}$$

Суммировать B_c по ω_n не следует, поскольку столкновения с примесями - упругие. (????)

Теперь вычислим всю примесную лестницу. При этом полезно вспомнить, что примесная штриховая линия равна $nu_0^2 = \left(2\pi\nu_0\tau\right)^{-1}$ (см. гл. 9). (???????)
Суммируя геометрическую прогрессию, получаем

$$L\left(i\omega_n\right) = B_c\left(i\omega_n\right) + \frac{1}{2\pi\nu_0\tau}B_c^2\left(i\omega_n\right) + \ldots = \frac{B_c\left(i\omega_n\right)}{1 - B_c\left(i\omega_n\right)/\left(2\pi\nu_0\tau\right)} = \frac{\pi\nu_0}{\left|\omega_n\right|}$$

Как мы видим, τ полностью исчезло из этой формулы. Отметим, что выпадение τ из ответа формально обязано тому же сокращению, которое обеспечивает сохранение числа частиц при вычислении коррелятора плотность-плотность в ферми газе с примесями:

$$\langle n(\omega, \mathbf{q}) n(-\omega, -\mathbf{q})\rangle_{\mathbf{q}=0} = \pi\nu_0/(i\omega)$$

(см. задачу 52). Находим куперовскую петлю:

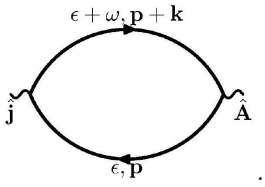
$$\Pi_c = -T\sum_{\omega_n} L\left(i\omega_n\right) = -2\pi\nu_0 T \sum_{\omega_n > 0} \frac{1}{\left|\omega_n\right|} = -\nu_0 \ln\frac{2\gamma\omega_D}{\pi T}$$

Поэтому

$$T_c = \frac{2\gamma}{\pi}\omega_D e^{-1/\lambda\nu_0}$$

как и в отсутствие примесей.

ЛШ-65*. London length in alloy



(?? remind the background!)
Рассеяние на примесях уменьшает сверхтекучую плотность n_s в формуле Лондонов (10.52). Чтобы найти зависимость n_s от концентрации примесей, определим ядро $Q(0)$ с учетом беспорядка. Процедура усреднения по беспорядку аналогична рассмотренной в задачах 50 и 51 (!?!?!?!??), с той только разницей, что вместо функций Грина свободных фермионов в сверхпроводнике надо использовать нормальную и аномальную функции (10.35) и (10.36).

a) Усредните по примесям матричную функцию Грина $\widehat{G}$. Используйте введенную в гл. 9 (???) модель δ-функционных примесей. Получите формулу

$$\langle\widehat{G}(i\omega, p)\rangle = \left(\widehat{G}_0(i\omega, \mathbf{p})^{-1} + \frac{i\omega - \Delta\tau_x}{2\tau\left(\omega^2 + \Delta^2\right)^{1/2}}\right)^{-1}$$

Не теряя общности, вычисления можно упростить, считая $\Delta^* = \Delta$. При этом в матричной записи $\widehat{G}_0^{-1}(i\omega, \mathbf{p}) = i\omega - \tau_z\xi(\mathbf{p}) - \Delta\tau_x$.

b) Усредните по беспорядку диаграмму для $Q(\mathbf{k})$, имеющую вид

Вычислив $\mathrm{Tr}(\widehat{j}\widehat{G}\widehat{j}\widehat{G})$ получите $Q(\mathbf{k})$, после чего по $Q(\mathbf{k}=0)$ определите сверхтекучую плотность.

Solution 65 a.

(!?!??!? все полностью опирается на задачи 50, 51)

Начнем с усреднения функций Грина сверхпроводника по примесям. Для этого мы вычислим матричную собственно-энергетическую часть

Рис. 10.15

При этом матричное выражение для примесной линии таково:

$$nu_0^2 \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} = \frac{1}{2\pi\nu_0\tau}\widehat{1}$$

(примеси одинаково хорошо рассеивают как электроны, бегущие вперед, так и назад, и при этом не переводят одно из спаривающихся состояний в другое, поскольку у них разный спин). Вычисляем собственно-энергетическую часть в первом порядке по концентрации примесей, следуя методу задачи 50:

$$\widehat{\Sigma}\left(i\omega_n\right) = \frac{1}{2\pi\nu_0\tau}\int \widehat{G}\left(i\omega_n, \mathbf{p}\right)\frac{d^3p}{(2\pi)^3} = -\frac{1}{2\pi\nu_0\tau}\int \frac{i\omega_n\widehat{1} + \xi_{\mathbf{p}}\widehat{\tau}_z - \Delta\widehat{\tau}_x}{\omega_n^2 + \Delta^2 + \xi_{\mathbf{p}}^2}\frac{d^3p}{(2\pi)^3}$$

Интегрируя по ξ, (!!! do it!!) получаем

$$\widehat{\Sigma}\left(i\omega_n\right) = -\frac{1}{2\tau}\frac{i\omega_n\widehat{1} + \Delta\widehat{\tau}_x}{\sqrt{\omega_n^2+\Delta^2}}$$

Таким образом

$$\widehat{G}^{-1} = \widehat{G}_0^{-1} - \widehat{\Sigma} = i\tilde{\omega}_n\widehat{1} - \xi\widehat{\tau}_z - \tilde{\Delta}\widehat{\tau}_x,$$

$$\tilde{\omega}_n := \omega_n\left(1 + \frac{1}{2\tau\sqrt{\omega_n^2+\Delta^2}}\right), \qquad \tilde{\Delta} := \Delta\left(1 + \frac{1}{2\tau\sqrt{\omega_n^2+\Delta^2}}\right)$$

Обратим внимание, что

$$\tilde{\omega}_n/\tilde{\Delta} = \omega_n/\Delta$$

Как мы убедимся в дальнейшем, это свойство очень важно.

При вычислении $\widehat{\Sigma}$ мы использовали затравочные функции Грина G и F. Что произойдет, если теперь подставить исправленные функции Грина в выражение для $\widehat{\Sigma}$? Оказывается, $\widehat{\Sigma}$ при этом не изменится. Это легко видно из (10.178), поскольку при изменении в этом выражении ω_n и Δ в одно и то же число раз величина $\widehat{\Sigma}$ не меняется. Поэтому полученный нами ответ автоматически оказался решением интегрального уравнения для $\widehat{\Sigma}$, точно так же, как и для нормального металла (см. задачу 50).

В принципе, щель в грязном сверхпроводнике следует определять заново, решая уравнение самосогласования $\Delta_{\alpha\beta} = \lambda\int F_{\alpha\beta}(\varepsilon, \mathbf{p})\frac{d\varepsilon d^3p}{(2\pi)^4}$, принимающее вид

$$\Delta = \lambda T\sum_{\omega_n}\int_{-\infty}^{\infty}\frac{\nu_0 d\xi\tilde{\Delta}}{\tilde{\omega}_n^2 + \tilde{\Delta}^2 + \xi^2}$$

$$\Delta = \pi\lambda\nu_0 T\sum_{\omega_n}\frac{\tilde{\Delta}}{\sqrt{\tilde{\omega}_n^2+\tilde{\Delta}^2}} = \pi\lambda\nu_0 T\sum_{\omega_n}\frac{\Delta}{\sqrt{\omega_n^2+\Delta^2}}$$

не содержащему концентрации примесей. (Во втором равенстве мы использовали (10.181).) Таким образом, примеси не влияют не только на T_c, но и на термодинамику сверхпроводника вообще. Так происходит потому, что для термодинамических свойств существенна лишь полная плотность состояний (или, грубо говоря, сколько длин волн укладывается на каждой квазичастичной траектории) и совершенно не важно, как эти состояния устроены (т. е. по каким конкретно траекториям движутся квазичастицы, по прямым, или по ломаным, рассеиваясь на примесях).

Solution 65 б.

Теперь рассмотрим отклик сверхтекучего тока на внешнее магнитное поле. В отличие от T_c, эта величина гораздо более чувствительна к форме траекторий и сильно изменяется даже при малых концентрациях примесей. (Достаточно, чтобы длина свободного пробега стала меньше, чем размер куперовской пары ξ_0). Определим сверхтекучую плотность. Как и в задаче 51, для вычисления отклика достаточно провести вычисления с усредненными по примесям функциями Грина, потому что диаграмма с примесной линией, соединяющей разные функции Грина, равна нулю (из-за того, что вершина взаимодействия с электромагнитным полем векторная).

Усредненные же функции Грина отличаются от затравочных лишь заменой $\omega_n \to \tilde{\omega}_n, \Delta \to \tilde{\Delta}$. Поэтому можно сразу написать формулу для n_s по аналогии с задачей 50:

$$\frac{n-n_s}{n} = T\sum_{\omega_n} \int\limits_{-\infty}^{\infty} \frac{\xi^2 + \tilde{\Delta} - \tilde{\omega}_n^2}{\left(\xi^2 + \tilde{\Delta} + \tilde{\omega}_n^2\right)^2} d\xi$$

Исключим вклад ферми-моря, вычтя из этого выражения его значение при $\Delta = 0, \tau = \infty$, и проинтегрируем по ξ:

$$\frac{n_s}{n} = \pi T \sum_{\omega_n} \frac{\tilde{\Delta}^2}{\left(\tilde{\omega}^2 + \tilde{\Delta}^2\right)^{3/2}}$$

$$\frac{n_s}{n} = \pi T \sum_{\omega_n} \frac{\Delta^2}{\left(\omega_n^2 + \Delta^2\right)^{3/2}\left(1 + \frac{1}{2\tau\sqrt{\omega_n^2+\Delta^2}}\right)}.$$

$\tau\Delta_0 \gg 1 \quad \Rightarrow \quad$ результат задачи 63 (??),
$\tau\Delta_0 \ll 1 \quad \Rightarrow$

$$\frac{n_s}{n} = 2\pi\tau T \sum_{\omega_n} \frac{\Delta^2}{\left(\omega_n^2 + \Delta^2\right)^2} = \pi\tau\Delta \,\mathrm{th}\, \frac{\Delta}{2T}.$$

Интересно, что в грязном сверхпроводнике даже при $T \to 0$ сверхтекучая плотность много меньше полной:

$$\frac{n_s(T\to 0)}{n} = \pi\tau\Delta_0 \ll 1$$

Это связано с нарушением трансляционной инвариантности и «торможением» электронов примесями. Подставляя n_s в формулу для глубины проникновения δ_Λ (???), получаем

$$\delta_\Lambda = \frac{1}{2\pi}\sqrt{mc^2/\left[e^2\Delta\tau \,\mathrm{th}(\Delta/2T)\right]}$$

ЛШ-66*. Influence of magnetic impurities on superconductivity

(?? remind the background!)
Пусть кроме обычных примесей имеются также и магнитные:

$$H_{int} = \sum_{\mathbf{r}_a} J\psi^+(\mathbf{r}_a)\ \widehat{\sigma}^k\ \widehat{S}_a^k\ \psi(\mathbf{r}_a).$$

Здесь $\widehat{S}_a^k$ - оператор спина a-й примеси. Спины примесей будем считать некоррелированными. Такие примеси нарушают симметрию по отношению к обращению времени и поэтому легко подавляют сверхпроводимость. Найдите T_c как функцию концентрации примесей $n_{\text{маг.}}$ Покажите, что сверхпроводимость подавляется при относительно малой концентрации $n_{\text{маг}} \approx T_c/(v_F\sigma)$, где σ - сечение рассеяния на магнитной примеси.

Solution 66.

(!?!??!? суть решения напишу обязательно тут!!!)
Вначале найдем усредненную по парамагнитным примесям функцию Грина. Для того чтобы ее вычислить, мы используем модифицированную крестовую технику. Введем четырехкомпонентные функции Грина

$$\widehat{G} = -\begin{pmatrix} \langle \mathrm{T}_\tau \psi_\alpha^+(\mathbf{r},\tau)\psi_\beta(0,0)\rangle & \langle \mathrm{T}_\tau \psi_\alpha(\mathbf{r},\tau)\psi_\beta(0,0)\rangle \\ \left\langle \mathrm{T}_\tau \psi_\alpha^+(\mathbf{r},\tau)\psi_\beta^+(0,0)\right\rangle & \left\langle \mathrm{T}_\tau \psi_\alpha(\mathbf{r},\tau)\widehat{\psi}_\beta^+(0,0)\right\rangle \end{pmatrix}$$

(α и β - спиновые индексы). При этом функция Грина в отсутствие примесей равна

$$\widehat{G}_0 = -\frac{1}{\omega_n^2+\xi^2+\Delta^2}\begin{pmatrix} (i\omega_n+\xi)\,\delta_{\alpha\beta} & -\Delta_{\alpha\beta} \\ -\Delta_{\alpha\beta}^+ & (i\omega_n-\xi)\,\delta_{\alpha\beta} \end{pmatrix}$$

а $\Delta_{\alpha\beta} = i\Delta\sigma^y_{\alpha\beta}$ ($\sigma^i_{\alpha\beta}$– спиновые матрицы Паули). Как и в предыдущей задаче, найдем собственно-энергетическую часть из диаграммы на рис. 10.16:

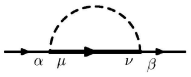


Рис. 10.16
В случае парамагнитных примесей штриховая линия имеет нетривиальную спиновую структуру. Ее можно найти, вычислив коррелятор флуктуаций примесного потенциала:

$$\left\langle \sum_a J\delta\left(\mathbf{r}-\mathbf{r}_a\right)\sigma^i_{\alpha\beta}S_i^a \sum_b J\delta\left(\mathbf{r}'-\mathbf{r}_b\right)\sigma^k_{\mu\nu}S_k^b \right\rangle = n_{\mathrm{mag}}J^2\delta\left(\mathbf{r}-\mathbf{r}'\right)\left\langle S^iS^k\right\rangle\sigma^i_{\alpha\beta}\sigma^k_{\mu\nu} =$$
$$= \frac{S(S+1)}{3}n_{\mathrm{mag}}J^2\delta\left(\mathbf{r}-\mathbf{r}'\right)\sigma^i_{\alpha\beta}\sigma^i_{\mu\nu}$$

Стоящее здесь скалярное произведение матриц Паули можно преобразовать, используя тождество Фирца: $\sigma^i_{\alpha\beta}\sigma^i_{\mu\nu} = 2\delta_{\alpha\nu}\delta_{\beta\mu} - \delta_{\alpha\beta}\delta_{\mu\nu}$. Получаем:

$$\widehat{\Sigma}_{\alpha\beta}\left(i\omega_n\right) = -\frac{n_{\mathrm{mag}}}{3}J^2S(S+1)\left(2\delta_{\alpha\beta}\delta_{\mu\nu}-\delta_{\alpha\mu}\delta_{\beta\nu}\right)\int\limits_{-\infty}^{\infty}\widehat{G}_{\mu\nu}\left(i\omega_n,\xi\right)\nu_0 d\xi$$

Подставим вначале в этот интеграл $\widehat{G}_0$. (?? why??)
Интегрирование производится довольно просто (?? do it!!), и мы получаем

$$\widehat{\Sigma}_{\alpha\beta}\left(i\omega_n\right) = -\frac{1}{2\pi\tau_s}\frac{i\omega_n\widehat{1}-2\delta_{\alpha\beta}\Delta_{\mu\nu}\delta_{\mu\nu}\widehat{\tau}_x+\Delta_{\alpha\beta}\widehat{\tau}_x}{\sqrt{\omega_n^2+\Delta^2}}$$

где $\tau_s = \frac{3}{\pi\nu_0 n_{\mathrm{mag}}J^2S(S+1)}$ - время релаксации спина на примесях. Поскольку $\Delta_{\mu\nu}\delta_{\mu\nu}=0$, то мы получаем таким образом, что $\widehat{G}^{-1} = \widehat{G}_0^{-1} - \widehat{\Sigma}$ отличается от $\widehat{G}_0$ заменой ω_n и Δ на

$$\tilde{\omega}_n = \omega_n\left(1+\frac{1}{2\tau_s\sqrt{\omega_n^2+\Delta^2}}\right), \qquad \tilde{\Delta} = \Delta\left(1-\frac{1}{2\tau_s\sqrt{\omega_n^2+\Delta^2}}\right)$$

Однако заметим, что теперь, в отличие от задачи 64,

$$\tilde{\omega}/\tilde{\Delta} \neq \omega/\Delta.$$

Поэтому если теперь подставить $\widehat{G}$ в (10.194), то получится другое значение $\widehat{\Sigma}$. Попробуем решить задачу самосогласованно, подставляя в (10.194) $\widehat{G}$ с неизвестными $\tilde{\omega}$ и $\tilde{\Delta}$. Тогда

$$\widehat{\Sigma}_{\alpha\beta}\left(i\omega_n\right) = -\frac{1}{2\pi\tau_s}\frac{i\tilde{\omega}_n\widehat{1}-\tilde{\Delta}_{\alpha\beta}\widehat{\tau}_x}{\sqrt{\tilde{\omega}_n^2+\tilde{\Delta}^2}}.$$

Уравнение Дайсона теперь приводит к условию самосогласования, определяющему $\tilde{\omega}$ и $\tilde{\Delta}$:

$$\tilde{\omega} = \omega + \frac{\tilde{\omega}}{2\tau_s\sqrt{\tilde{\omega}^2+\tilde{\Delta}^2}}, \qquad \tilde{\Delta} = \Delta - \frac{\tilde{\Delta}}{2\tau_s\sqrt{\tilde{\omega}^2+\tilde{\Delta}^2}}.$$

Теперь запишем уравнение Горькова, определяющее щель:

$$\Delta = \lambda T\sum_{\omega_n}\int\limits_{-\infty}^{\infty}\nu_0 d\xi F\left(i\omega_n,\xi\right) = \lambda T\sum_{\omega_n}\int\limits_{-\infty}^{\infty}\frac{\tilde{\Delta}\nu_0 d\xi}{\tilde{\omega}_n^2+\tilde{\Delta}^2+\xi^2} = \pi\lambda\nu_0 T\sum_{\omega_n}\frac{\tilde{\Delta}}{\sqrt{\tilde{\omega}_n{}^2+\tilde{\Delta}^2}}.$$

Из-за того, что $\tilde{\omega}/\tilde{\Delta} \neq \omega/\Delta$, это уравнение отличается от уравнения для чистого сверхпроводника.

Выведем отсюда уравнение, определяющее температуру перехода сверхпроводника с парамагнитными примесями T_c^*. Полагая $\Delta \to 0$, решим полученные уравнения $\tilde{\omega} = \omega + \frac{\tilde{\omega}}{2\tau_s\sqrt{\tilde{\omega}^2+\tilde{\Delta}^2}}$, и $\tilde{\Delta} = \Delta - \frac{\tilde{\Delta}}{2\tau_s\sqrt{\tilde{\omega}^2+\tilde{\Delta}^2}}$:

$$\tilde{\omega} = \omega + \frac{1}{2\tau_s}\operatorname{sign}\omega, \quad \tilde{\Delta}\left(1+\frac{1}{2\tau_s|\tilde{\omega}|}\right) = \Delta.$$

Тогда уравнение на T_c^* имеет вид:

$$1 = 2\pi\lambda\nu_0 T_c^*\sum_{\omega_n>0}\frac{\tilde{\Delta}}{\Delta\tilde{\omega}_n} = 2\pi\lambda\nu_0 T_c^*\sum_{\omega_n>0}\frac{1}{\tilde{\omega}_n+1/2\tau_s} = 2\pi\lambda\nu_0 T_c^*\sum_{\omega_n>0}\frac{1}{\omega_n+1/\tau_s}.$$

Остановимся на физическом смысле этой формулы. При рассеянии на парамагнитной примеси спин электрона может перевернуться, и τ_s есть среднее время между двумя переворотами спина, т.е. время жизни куперовской пары. Знаменатель в (10.204) описывает развал куперовских пар из-за рассеяния на магнитных примесях и уменьшение эффективного времени взаимодействия.

Если τ_s велико по сравнению с h/T_c^*, то парамагнитные примеси лишь слегка сдвигают T_c. Но при $\tau_s \approx \hbar/T_c^*$ сверхпроводимость полностью подавляется. Найдем критическое τ_s^*, полагая $T_c^* = 0$ и заменяя сумму на интеграл:

$$\frac{1}{\lambda\nu_0} = \ln\frac{2\gamma\omega_D}{\pi T_c} = \int\limits_0^{\omega_D}\frac{d\omega}{\omega+1/\tau_s^*} = \ln\left(\omega_D\tau_s^*\right)$$

откуда

$$\tau_s^* = 2\gamma\hbar/\left(\pi T_c\right)$$

Таким образом, парамагнитные примеси даже в малых концентрациях могут существенно повлиять на свойства сверхпроводника и даже полностью подавить сверхпроводимость. При этом оказывается, что в определенном интервале по концентрации примесей существует режим так называемой бесщелевой сверхпроводимости, в котором сопротивление металла равно нулю, но энергетическая щель отсутствует. Так получается из-за того, что примеси меняют энергию связи электронов в паре по-разному в разных частях образца. (???? add it to later parts of theory)

14.2.9 Dirty Superconductors: Basic Problems 2

ЛШ-67*. Верхнее критическое поле в грязном сверхпроводнике

Сверхпроводимость можно подавить магнитным полем, поскольку оно нарушает симметрию по отношению к обращению времени. Как именно происходит это подавление, зависит от характеристик сверхпроводника. Рассмотрим грязный сверхпроводник, в котором $l \ll \xi_0$, и, начиная с сильного поля H, в котором сверхпроводимость подавлена, будем постепенно уменьшать величину H и определим пороговое значение H, при котором сверхпроводимость восстанавливается. Оказывается, для Этого нужно изучить устойчивость системы по отношению к малым неоднородньим флуктуациям $\Delta(\mathbf{r})$. Формально, для этого надо рассмотреть куперовскую лестницу в слабом статическом поле $\mathbf{A}(\mathbf{r})$, таком что $\operatorname{rot}\mathbf{A} = \mathbf{H}$. Записав для этого случая уравнение самосогласования $\Delta_{\alpha\beta} = \lambda\int F_{\alpha\beta}(\varepsilon,\mathbf{p})\frac{d\varepsilon d^3p}{(2\pi)^4}$ в пределе $\Delta \to 0$, найдите, при каком поле существует нетривиальное решение этого уравнения. Это поле называется верхним критическим полем H_{c2}.

Solution 67.

(!?!??!? суть решения напишу обязательно тут!!!)

Как и в задаче 64, мы вначале найдем куперовскую примесную лестницу, а затем подставим ее в уравнение самосогласования. Вычисление куперовской лестницы во внешнем магнитном поле в общем случае довольно сложно. Однако если поле медленно меняется на длине свободного пробега, эта задача сильно упрощается. Заметим, что две ступеньки примесной лестницы находятся друг от друга на расстоянии порядка l. Это позволяет пренебречь изменением поля на одной ступеньке и рассмотреть ступеньку в постоянном поле. Изменение поля мы учтем, переходя к суммированию ступенек, каждая из которых чувствует магнитное поле на своем отрезке траектории.

Поскольку нас интересуют неоднородные решения уравнения самосогласования, мы вначале вычислим примесную лестницу при ненулевом суммарном импульсе $\mathbf{s}$ в нулевом магнитном поле. Это можно сделать так же, как и в задаче 54. Одна ступенька лестницы вычисляется точно так же:

$$B_c = \iint \frac{d\Omega}{4\pi} \frac{\nu_0 d\xi}{\left(i\omega - \xi + \frac{i}{2\tau}\operatorname{sign}\omega\right)\left(-i\omega - \xi + \mathbf{sv} - \frac{i}{2\tau}\operatorname{sign}\omega\right)} = \int \frac{d\Omega}{4\pi} \frac{2\pi\nu_0\tau}{1 + 2|\omega|\tau + i\tau\mathbf{sv}} = \frac{2\pi\nu_0\tau}{1 + 2|\omega|\tau + \tau D\mathbf{s}^2}$$

где D - коэффициент диффузии. Суммируя лестницу, получаем

$$C_\omega(\mathbf{s}) = \frac{B_c}{1 - B_c/2\pi\nu_0\tau} = \frac{2\pi\nu_0}{2|\omega| + D\mathbf{s}^2}$$

Теперь учтем магнитное поле. Пусть сначала его векторный потенциал $\mathbf{A}(\mathbf{r})$ постоянен. Тогда его учет сведется к сдвигу импульсов $\mathbf{p} \to \mathbf{p} - e\mathbf{A}/c$ в функциях Грина. Поэтому в примесной лестнице $\mathbf{s}$ заменится на $\mathbf{s} - 2e\mathbf{A}/c$:

$$\widehat{C}_\omega = \frac{2\pi\nu_0}{2|\omega| + D\left(\mathbf{s} - \frac{2e}{c}\mathbf{A}\right)^2}.$$

Удобно записать это выражение в координатном представлении. Будем считать $C_\omega(\mathbf{r}, \mathbf{r}')$ функцией начальной и конечной точек. Заменяя $\mathbf{s}$ на $-i\nabla_{\mathbf{r}}$, перепишем выражение для куперона в форме дифференциального уравнения:

$$\left[2|\omega| + D\left(-i\frac{\partial}{\partial\mathbf{r}} - \frac{2e}{c}\mathbf{A}\right)^2\right] C_\omega(\mathbf{r}, \mathbf{r}') = 2\pi\nu_0\delta(\mathbf{r} - \mathbf{r}').$$

Что изменится, если $\mathbf{A}(\mathbf{r})$ - медленно меняющаяся функция? Если мы намерены учитывать лишь первые два порядка по $\mathbf{A}$ в знаменателе (10.209), то легко понять, что все возможные усложнения связаны с появлением членов, зависящих от $\operatorname{div}\mathbf{A}$, поскольку это единственная вращательно инвариантная комбинация из производных A. (Иными словами, если $\mathbf{A}$ становится функцией $\mathbf{r}$, возникает вопрос о порядке операторов $\mathbf{A}(\mathbf{r})$ и ∇ в купероне.) Но выбирая калибровку, в которой $\operatorname{div}\mathbf{A} = 0$, мы всегда можем добиться исчезновения подобных поправок. Поэтому для того, чтобы вычислить примесную лестницу, достаточно решить уравнение

$$\left[2|\omega| + D\left(-i\frac{\partial}{\partial\mathbf{r}} - \frac{2e}{c}\mathbf{A}(\mathbf{r})\right)^2\right] C_\omega(\mathbf{r}, \mathbf{r}') = 2\pi\nu_0\delta(\mathbf{r} - \mathbf{r}').$$

Это уравнение можно вывести и напрямую. Для этого надо рассмотреть такие поправки к одной «ступеньке»:

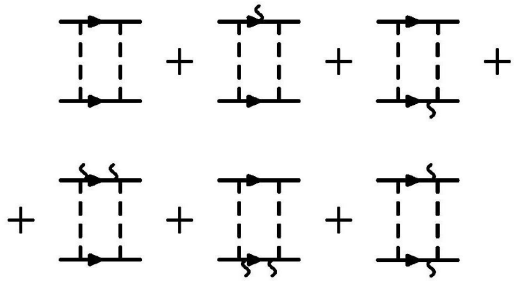

Рис. 10.17

(Волнистые линии на этом рисунке изображают взаимодействие с внешним магнитным полем.) После этого суммирование лестницы дает уравнение (10.211). Теперь запишем уравнение самосогласования, полагая $\Delta \to 0$. Вблизи H_{c2} состояние неоднородно, поэтому Δ зависит от $\mathbf{r}$. Уравнение Горькова имеет вид

$$\Delta(\mathbf{r}) = \lambda \int_{-\infty}^{\infty} F(\omega, \mathbf{r}, \mathbf{r}) \frac{d\omega}{2\pi}$$

Аномальная гриновская функция $F(\omega, \mathbf{r}, \mathbf{r})$ дается при $\Delta \to 0$ единственной диаграммой:

Рис. 10.18

Сравнивая ее с диаграммой для примесной лестницы, находим

$$F(\omega, \mathbf{r}, \mathbf{r}) = \int \Delta(\mathbf{r}')\, C_\omega(\mathbf{r}, \mathbf{r}')\, d^3 r'$$

Поэтому уравнение самосогласования записывается так:

$$\Delta(\mathbf{r}) = \lambda \int\limits_{-\infty}^{\infty} \frac{d\omega}{2\pi} \int C_\omega(\mathbf{r}, \mathbf{r}')\, \Delta(\mathbf{r}')\, d^3 r'$$

Чтобы найти его решения, удобно разложить $\Delta(\mathbf{r})$ по нормированным собственным функциям $\varphi_n(\mathbf{r})$ оператора в левой части (10.211). Эти функции обладают такими свойствами:

$$D\left(-i\frac{\partial}{\partial \mathbf{r}} - \frac{2e}{c}\mathbf{A}(\mathbf{r})\right)^2 \varphi_n(\mathbf{r}) = \mu_n \varphi_n(\mathbf{r}),$$

$$\int \varphi_n(\mathbf{r}) \varphi_m^*(\mathbf{r}) d^3 r = \delta_{nm}$$

($\mu_n - n$-е собственное значение). Запишем $\Delta(\mathbf{r})$ в виде

$$\Delta(\mathbf{r}) = \sum_n \Delta_n \varphi_n(\mathbf{r})$$

Куперон можно выразить через $\varphi_n(\mathbf{r})$:

$$C_\omega(\mathbf{r}, \mathbf{r}') = 2\pi\nu_0 \sum_n \frac{\varphi_n(\mathbf{r}) \varphi_n^*(\mathbf{r}')}{2|\omega| + \mu_n}$$

Это соотношение легко проверить, заметив, что эта функция в силу (10.215) удовлетворяет уравнению при $\mathbf{r} \neq \mathbf{r}'$, а при $\mathbf{r} \to \mathbf{r}'$ левая часть уравнения совпадает с δ-функцией, поскольку интеграл от нее по $\mathbf{r}$ равен 1 в силу (10.216). Тогда уравнение (10.214) перепишется так:

$$\Delta_n = \int\limits_{-\infty}^{\infty} \frac{2\pi\nu_0 \lambda \Delta_n}{2|\omega| + \mu_n} \frac{d\omega}{2\pi}.$$

Оно имеет нетривиальное решение при

$$\frac{1}{\nu_0 \lambda} = \int\limits_{-\infty}^{\infty} \frac{d\omega}{2|\omega| + \mu_n}$$

Интеграл следует обрезать сверху при $\omega = \omega_D$, как и ранее. В результате

$$\frac{1}{\nu_0 \lambda} = \ln \frac{2\omega_D}{\mu_n}.$$

Найдем собственные значения μ_n. Для этого нужно решить уравнение (10.215). Выберем калибровку $A_y = -Hx$. Тогда можно заметить, что уравнение (10.215) совпадает с уравнением Шредингера для частицы с массой $m = (2D)^{-1}$, зарядом $q = 2e$ и энергией μ_n в магнитном поле H. Из квантовой механики известно, что в этом случае собственные знвчения таковы:

$$E_n = \omega_H \left(n + \frac{1}{2}\right) + \frac{\hbar^2 k_z^2}{2m}; \quad \omega_H = \frac{qH}{mc}.$$

Это означает, что

$$\mu_n = \frac{4DeH}{c}\left(n + \frac{1}{2}\right) + Dk_z^2.$$

Поскольку собственные значения растут с ростом H, критическое магнитное поле определяется наименьшим собственным значением. Оно равно $\mu_0 = 2DeH/c$. Таким образом

$$\frac{1}{\nu_0 \lambda} = \ln \frac{\omega_D c}{DeH_{c2}}.$$

Выражая λ через T_c с помощью (10.73), получаем окончательно

$$H_{c2} = \frac{\pi}{2\gamma}\frac{T_c c}{De} = \frac{\pi}{\gamma}\frac{T_c}{\hbar D}\Phi_0$$

где $\Phi_0 = \hbar c/2e$ - квант потока.

Заметим, что собственные функции, отвечающие минимальному собственному значению, локализованы:

$$\varphi_{n,k_y}(x,y,z) = \frac{1}{\pi^{1/4} l_H^{1/2}} e^{ik_y y} e^{-(x-x_0)^2/2l_H^2},$$

Гπe

$$l_H = \sqrt{\hbar c/(qH)}, \quad x_0 = ck_y/(qH).$$

Таким образом, сверхпроводимость возникает в «нитях» толщины l_H. При понижении поля концентрация нитей быстро возрастает, пока они не заполнят собой весь объем.

В каких случаях переход от сверхпроводимости к нормальному металлу в магнитном поле устроен так, как описано в решении? Чтобы ответить на этот вопрос, надо сравнить магнитные поля, соответствующие различным сценариям разрушения сверхпроводимости. Мы вычислили магнитное поле, соответствующее разрушению сверхпроводимости неоднородным образом. Оценим поле, соответствующее разрушению сверхпроводимости сразу во всем объеме. Для этого надо сравнить энергию магнитного поля в объеме сверхпроводника с энергией конденсации. Энергия магнитного поля на единицу объема есть

$$E_{\text{mag}} = H^2/8\pi$$

Энергию конденсации легко оценить, считая, что частицы в интервале энергий Δ за счет конденсации понижают свою энергию на Δ. Число таких частиц в единице объема есть $\nu_0\Delta$, поэтому энергия конденсации равна

$$E_c \approx \nu_0\Delta^2 \approx \nu_0 T_c^2$$

Таким образом, магнитное поле, соответствующее однородному разрушению сверхпроводимости (термодинамическое критическое поле), есть

$$H_c \approx T_c\sqrt{\nu_0}$$

Сравним его с H_{c2}

$$\frac{H_c}{H_{c2}} \approx \sqrt{De\nu_0}c \approx \frac{v_F l\sqrt{mp_F/\hbar^3}}{c} \approx l\sqrt{\frac{e^2p_F^3}{mc^3\hbar^3}} \approx \frac{l}{\delta_\Lambda}$$

где δ_Λ - лондоновская глубина проникновения в чистом сверхпроводнике, определенная в (10.162). Таким образом, $H_{c2} \gg H_c$ при $l \ll \delta_\Lambda$. В этом случае H_{c2} действительно определяет границу сверхпроводящей фазы. Если же $H_{c2} \ll H_c$ (т. е. $\delta_\Lambda \ll l$), то переход происходит однородно по всему объему при поле H_c. В этом случае при $H = H_{c2} < H_c$ ничего особенного не происходит.

ЛШ-71. Плотность состояний в грязном металле

В неупорядоченном металле туннельная плотность состояний $\nu(\varepsilon)$ имеет особенность на уровне Ферми. Сингулярность $\nu(\varepsilon)$ при $\varepsilon \to E_F$ свидетельствует о том, что ферми-жидкостное состояние в металле в присутствии рассеяния на случайном потенциале весьма сильно модифицируется. Чтобы найти поправку к туннельной плотности состояний, возникающую из-за кулоновского взаимодействия, проделайте следующее.

а) Вычислите вершину взаимодействия электрона с электрическим полем с учетом беспорядка, используя мацубаровскую технику; просуммируйте для этого диаграммы на рис. 11.7.

Рис. 11.7

Считайте, что переданный импульс $\mathbf{q}$ и переданная энергия ω_n удовлетворяют условиям $|\mathbf{q}| \ll 1, \omega_n\tau \ll 1$, где τ и l - время и длина свободного пробега. Покажите, что вершинная часть равна

$$\Gamma(\varepsilon_m, \omega_n, \mathbf{q}) = \begin{cases} 1/\left[\tau\left(|\omega_n| + D\mathbf{q}^2\right)\right] & \text{при } \varepsilon_m(\varepsilon_m - \omega_n) < 0 \\ 1 & \text{при } \varepsilon_m(\varepsilon_m - \omega_n) > 0 \end{cases}$$

где D - коэффициент диффузии. Диффузионный полюс выражения (11.35) описывает эффект усиления взаимодействия с внешним полем вследствие диффузии.

Изменение величины взаимодействия можно качественно объяснить тем, что изза диффузионного замедления динамики электроны проводят больше времени в области действия внешнего поля и поэтому

взаимодействуют с ним более сильно. То, насколько сильно диффузия замедляет динамику, зависит от размерности системы. Как мы знаем из задачи 9, критической размерностью является $D = 2$, поскольку при $D \leqslant 2$ число возвратов диффузионной траектории в исходную точку расходится, а при $D > 2$ - сходится. Поэтому эффекты усиления взаимодействия в грязном металле оказываются наиболее интересными в двумерном случае.

б) Найдите эффективное электрон-электронное взаимодействие $V(\omega_n, \mathbf{q})$ с учетом динамической экранировки. Для этого вычислите сумму диаграмм на рис. 8.3 и покажите, что заэкранированное взаимодействие есть

$$V(\omega_n, \mathbf{q}) = V_0(\mathbf{q}) \frac{|\omega_n| + D\mathbf{q}^2}{|\omega_n| + D\mathbf{q}^2 + \nu D\mathbf{q}^2 V_0(\mathbf{q})}$$

где $V_0(\mathbf{q})$ - затравочное взаимодействие. В качестве поляризационного оператора используйте мацубаровский коррелятор плотность-плотность, найденный в задаче 52.
(???? добавлю формулы!!!)

в) Найдите собственно-энергетическую поправку к функции Грина первого порядка по заэкранированному взаимодействию $V(\omega_n, \mathbf{q})$, соответствующую диаграмме на рис. 11.8.

Рис. 11.8
Используя найденное выражение, найдите поправку $\delta\nu(\varepsilon)$ к плотности состояний двумерного металла в случае кулоновского взаимодействия $V_0(\mathbf{r}) = e^2/|\mathbf{r}|$. Покажите, что в этом случае поправка к плотности состояний есть

$$\frac{\delta\nu(\varepsilon)}{\nu} = -\frac{e^2}{8\pi^2\hbar\sigma} \ln\frac{1}{|\varepsilon|\tau} \ln\frac{\tau D^2 \left(\nu e^2\right)^4}{|\varepsilon|},$$

где σ - двумерная проводимость. Расходимость $\delta\nu(\varepsilon)$ при $\varepsilon \to 0$ означает, что квазичастицы в двумерной неупорядоченной ферми-системе сильно отличаются от свободных фермионов. Усиление эффектов взаимодействия в плотности состояний (11.37) при малых ε свидетельствует о неприменимости теории возмущений в двумерном неупорядоченном металле при энергиях вблизи уровня Ферми.

(чуть лучше напишу условие! укажу, что у нас происходит, где появляется туннельная плотность!)

Solution 71 a.

Короче, знать нужно все, что выше, задача полностью опирается на пару ранее задач.

Рассмотрим вершинную часть взаимодействия электрона с внешним полем. Затравочная вершинная часть (в отсутствие примесей) равна единице. Вычислим вершинную часть, дающуюся диаграммами на рис. , используя усредненные по беспорядку мацубаровские функции Грина (см. (9.17)). Рассмотрим вначале поправку к вершине, соответствующую изображенной на рис. 11.9 диаграмме с одной примесной линией:

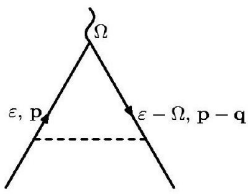

Рис. 11.9
Интересующее нас выражение

$$\Gamma^{(1)}(\varepsilon_m, \omega_n, \mathbf{q}) = \frac{1}{2\pi\nu_0\tau} \int \frac{1}{\left(i\varepsilon_m - \xi_{\mathbf{p}} + \frac{i}{2\tau}\operatorname{sign}\varepsilon_m\right)} \cdot \frac{1}{\left(i\varepsilon_m - i\omega_n - \xi_{\mathbf{p}-\mathbf{q}} + \frac{i}{2\tau}\operatorname{sign}(\varepsilon_m - \omega_n)\right)} \frac{d^2\mathbf{p}}{(2\pi)^2}$$

вычисляется таким же образом, как ступенька примесной лестницы в задаче 52. Заменяя интеграл по $d^2\mathbf{p}$ интегралом по ξ и вычисляя его методом вычетов, нетрудно показать, что выражение отлично от нуля только в том случае, когда знаки энергий ε_m и $\varepsilon_m - \omega_n$ различаются. (В противном случае оба вычета интегрируемого выражения попадают в одну и ту же полуплоскость комплексного ξ.)

В случае, когда знаки энергий различны и $\omega_n > 0$, получаем выражение

$$\Gamma^{(1)}(\varepsilon_m, \omega_n, \mathbf{q}) = \frac{1}{1 + \tau\omega_n + \tau D\mathbf{q}^2}$$

подобное найденному в задаче 52.

Теперь просуммируем всю примесную лестницу  .

Как и в задаче 52, интересующий нас лестничный ряд образует геометрическую прогрессию. Поэтому

$$\Gamma(\varepsilon_m, \omega_n, \mathbf{q}) = \frac{1}{1 - \Gamma^{(1)}} \approx \frac{1}{\tau(\omega_n + D\mathbf{q}^2)}$$

Рассматривая аналогично случай $\omega_n < 0$, можно убедиться в том, что ω_n в (11.76) следует заменить на $|\omega_n|$.

Если же знаки энергий ε_m и $\varepsilon_m - \omega_n$ в функциях Грина в (11.74) совпадают, то зануляется не только первая поправка $\Gamma^{(1)}$, но, как нетрудно видеть, и все остальные члены диаграммного ряда на рис.  .

Это является следствием общего правила, отмеченного в гл. 9 - примесная лестница отлична от нуля только если энергии в функциях Грина имеют разные знаки.

Solution 71 б.

Эффективное взаимодействие с учетом динамической экранировки вычисляется суммированием последовательности «пузырьковых» диаграмм (см. задачу 45):

$$V(\omega_n, \mathbf{q}) = \frac{V_0(\mathbf{q})}{1 - \Pi(\omega_n, \mathbf{q})\, V_0(\mathbf{q})}$$

где $\Pi(\omega_n, \mathbf{q})$ - поляризационный оператор, а $V_0(\mathbf{q})$ - затравочное взаимодействие. Подставляя поляризационный оператор $\Pi(\omega_n, \mathbf{q}) = -\nu D\mathbf{q}^2 / \left(|\omega_n| + D\mathbf{q}^2\right)$ из (9.23), получаем искомое выражение (11.36).

Для дальнейших вычислений нам понадобится двумерный фурье-образ кулоновского потенциала взаимодействия. Его проще всего найти, проинтегрировав известный фурье-образ трехмерного кулоновского потенциала по q_z:

$$V_0^{(2)}(\mathbf{q}) = V_0^{(3)}(q_x, q_y, z = 0) = \int\limits_{-\infty}^{\infty} \left(\frac{e^2}{|\mathbf{r}|}\right)_{\mathbf{q}} \frac{dq_z}{2\pi} = \int\limits_{-\infty}^{\infty} \frac{4\pi e^2}{\mathbf{q}^2 + q_z^2} \frac{dq_z}{2\pi} = \frac{2\pi e^2}{|\mathbf{q}|}$$

где $\mathbf{q} = (q_x, q_y)$

Solution 71 в.

Поправка к туннельной плотности состояний $\nu(\varepsilon)$ получается из поправки к функции Грина интегрированием по импульсам, которое можно заменить интегрированием по ξ:

$$\frac{\delta\nu(\varepsilon)}{\nu_0} = -\frac{1}{\pi} \int \delta G(\varepsilon, \xi) d\xi$$

Вычислим $\delta G(i\varepsilon, \mathbf{p})$ при $T = 0$, заменяя суммы по мацубаровским частотам интегралами. Будем для определенности считать, что $\varepsilon > 0$. Выражение, соответствующее диаграмме на рис. 11.8, есть

$$\delta G(i\varepsilon, \mathbf{p}) = G_0^2(i\varepsilon, \mathbf{p}) \iint \Gamma^2(\varepsilon, \omega, \mathbf{q}) V(\omega, \mathbf{q}) G(i\varepsilon - i\omega, \mathbf{p} - \mathbf{q}) \frac{d\omega d^2q}{(2\pi)^3}.$$

Наибольший вклад в интеграл по энергии возникает от области $\omega > \varepsilon$, так как в этой области вершинная часть $\Gamma(\varepsilon, \omega, \mathbf{q})$ имеет диффузионный полюс и поэтому велика - см. (11.35). Пренебрегая вкладом области $\omega < \varepsilon$, имеем

$$\delta G(i\varepsilon, \mathbf{p}) = \frac{1}{\left(i\varepsilon - \xi_{\mathbf{p}} + \frac{i}{2\tau}\right)^2} \int\limits_{\varepsilon}^{\infty} \frac{d\omega}{2\pi} \int \frac{1}{\left(i\varepsilon - i\omega - \xi - \mathbf{q}\mathbf{v}_{\mathbf{p}} - \frac{i}{2\tau}\right)} \frac{V_0(\mathbf{q})}{(\omega + D\mathbf{q}^2)\left(\omega + D\mathbf{q}^2 + \nu D\mathbf{q}^2 V_0(\mathbf{q})\right)} \frac{d^2\mathbf{q}}{(2\pi)^2}.$$

Удобно сразу проинтегрировать это выражение по ξ. При этом мы пренебрегаем членами ω и $\mathbf{qv}$ в знаменателе по сравнению с τ^{-1}, поскольку нас интересует вклад малых энергий и импульсов. (do this, it should be easy!!!)

Таким образом, получаем

$$\int \delta G(i\varepsilon,\xi)d\xi = 2\int\limits_{\varepsilon}^{\infty} d\omega \int \frac{V_0(\mathbf{q})}{(\omega+D\mathbf{q}^2)\left(\omega+D\mathbf{q}^2+\nu D\mathbf{q}^2V_0(\mathbf{q})\right)}\frac{d^2\mathbf{q}}{(2\pi)^2}.$$

Подставляя в это выражение фурье-образ затравочного взаимодействия (11.78), получаем

$$\int \delta G(i\varepsilon,\xi)d\xi = -2e^2\int\limits_{\varepsilon}^{\infty} d\omega \int\limits_{0}^{\infty} \frac{dq}{(\omega+Dq^2)\left(\omega+Dq^2+2\pi\nu e^2Dq\right)}$$

Проинтегрируем найденное выражение по q. Наибольший вклад в интеграл вносит область (??? why??)

$$\frac{\omega}{2\pi\nu De^2} \le q \le \sqrt{\frac{\omega}{D}}$$

в которой можно пренебречь Dq^2 по сравнению с ω, и ω - по сравнению с νe^2Dq. Обрезая логарифмически расходящийся интеграл на границах области (11.84), получаем

$$\int \delta G(i\varepsilon,\xi)d\xi = \frac{1}{4\pi\nu D}\int\limits_{\varepsilon}^{\infty} \ln\frac{\left(\nu e^2\right)^2}{D\omega}\frac{d\omega}{\omega}$$

Интеграл по частотам также логарифмически расходится на верхнем пределе. Чтобы получить вклад диффузионной области обрежем интеграл по ω на $\omega\tau \approx 1$, (При больших значениях ω электроны движутся баллистически, поэтому эта область описывается теорией ферми-жидкости и не приводит к сингулярности в плотности состояний.) Вычисляя интеграл по ω и удерживая при аналитическом продолжении с мнимых частот на вещественные лишь главный дважды логарифмический член, получаем поправку к туннельной плотности состояний:

$$\frac{\delta\nu(\varepsilon)}{\nu} = -\frac{1}{8\pi^2\nu D}\ln\frac{\left(\nu e^2\right)^4\tau D^2}{|\varepsilon|}\ln\frac{1}{|\varepsilon|\tau}.$$

Вклад (11.86) в плотность состояний имеет отрицательный знак и сингулярен на малых энергиях $\varepsilon \to 0$. С помощью соотношения Эйнштейна $\sigma = e^2\nu D$ произведение νD можно выразить через проводимость, что дает искомое выражение (11.37) для плотности состояний двумерного металла.

Discussion of the result

Остановимся на физическом смысле результата (11.86). Туннельная плотность состояний описывает реакцию электронной жидкости на добавление в нее электрона. Роль кулоновского взаимодействия в этом процессе состоит в следующем. Сразу после того, как электрон протуннелировал в металл, его заряд незаэкранирован и создает кулоновское поле. Под действием этого поля остальные электроны начинают двигаться так, чтобы заэкранировать вновь прибывший электрон. Макроскопически этот процесс приводит к максвелловской релаксации заряда. Таким образом, туннелирование одного электрона сопровождается коллективным растеканием заряда многих других электронов, что приводит к уменьшению вероятности туннелирования. В чистом металле максвелловская релаксация происходит почти мгновенно (за время порядка обратной плазменной частоты). Соответственно в этом случае поправки к $G(t-t')$ из-за взаимодействия достаточно быстро затухают на больших временах, и сингулярности в $G(\varepsilon)$ при $\varepsilon \to 0$ не возникает. В то же время в неупорядоченной системе, характеризующейся омической проводимостью, максвелловская релаксация происходит более медленно. Поэтому в этом случае влияние индуцированного туннелирующим электроном растекания заряда на амплитуду туннелирования оказывается существенным и соответствующая поправка к плотности состояний расходится на малых энергиях. Можно сказать, что плохо проводящая система сильнее «сопротивляется» попыткам добавить в нее электрон. Этот эффект и приводит к уменьшению одночастичной плотности состояний.

Поправка (11.86) приводит к специфической температурной зависимости туннельного тока, а также к его неомичности. Повторив проделанное выше вычисление $\delta\nu(\varepsilon)$ при конечной температуре, нетрудно убедиться в том, что результат (11.86) остается в силе с точностью до замены $\varepsilon \to \varepsilon_m = \pi T(2m+1)$. Соответствующая зависимость туннельного тока от T и V оказывается следующей:

$$G = \frac{dI}{dV} = G_0\left(1+\frac{\delta\nu\left(\varepsilon_{T,eV}\right)}{\nu}\right), \quad \varepsilon_{T,eV} = \max[T,eV]$$

Как видно из этого выражения, при уменьшении температуры и напряжения имеет место подавление туннельного тока, причем насыщения при $eV, T \to 0$ не происходит. Сингулярное поведение туннельного сопротивления при малых температурах или напряжениях, возникающее вследствие сингулярности $\nu(\varepsilon)$ при $\varepsilon \to E_F$, называется туннельной аномалией.

14.2.10 Problems about tunneling, junctions 1: Basic Models

me. Integral in the RSJ model

Find how much time is needed for the phase to change by 2π in the Josephson junction with resistance for the currents $I_c < I$.

Solution

One needs to remember the model and then compute a not so trivial integral.

$$I = \frac{V}{R} + I_c \sin(\phi) = \frac{\hbar}{2eR}\frac{\partial \phi}{\partial t} + I_c \sin(\phi)$$

(???)

$$\frac{\hbar}{2eR}\frac{d\phi}{I - I_c \sin(\phi)} = dt \qquad \Rightarrow \qquad \int_0^{t_0}, \int_0^{2\pi} \qquad \Rightarrow$$

```
Integrate[1/(A - Sin[x]), {x, 0, 2 Pi}]
```

(?? later maybe I'll solve it analytically, currently it is also fine to know how to get it with Wolfram)

$$t_0 = \frac{\hbar}{2eR}\frac{2\pi}{\sqrt{I^2 - I_c^2}}$$

ЛШ-68. Microscopic Framework of Tunneling

а) Выведите формулу для туннельного тока

$$I(V) = 4e\sum_{\mathbf{p},\mathbf{p}'} |T_{\mathbf{p}\mathbf{p}'}|^2 \int_{-\infty}^{\infty} \operatorname{Im} G_a^R(\mathbf{p}, \varepsilon + eV) \operatorname{Im} G_b^R(\mathbf{p}', \varepsilon) \left[n_F(\varepsilon) - n_F(\varepsilon + eV)\right] \frac{d\varepsilon}{\pi}$$

где $n_F(\varepsilon)$ - фермиевская функция распределения, а $G_a^R(\mathbf{p}, \varepsilon) = -i\int_0^{\infty} \left\langle \left[a_{\mathbf{p}}^+(t), a_{\mathbf{p}}(0)\right]\right\rangle e^{i\varepsilon t} dt$, используя мацубаровскую технику.

Для этого рассмотрите отклик туннельного тока $\widehat{I} = i\widehat{X}e^{ieVt} - i\widehat{X}^+ e^{-ieVt}$ на поле, пропорциональное туннельному оператору $X = \sum_{\mathbf{p},\mathbf{p}'} T_{\mathbf{p}\mathbf{p}'}\widehat{a}_{\mathbf{p}}^+ \widehat{b}_{\mathbf{p}'}$. Используя аналитические свойства мацубаровских функций Грина, перейдите от мнимых частот к вещественным и тем самым свяжите функцию отклика с величинами в реальном времени.

б) Рассмотрите туннелирование между двумя идеальными ферми-газами с постоянной плотностью состояний. Покажите, что при eV $\ll E_F$ вольт-амперная характеристика линейна, т. е. выполняется закон Ома $V = RI$, причем сопротивление контакта R не зависит от температуры и определяется соотношением

$$R^{-1} = 4\pi e^2 \nu_a \nu_b |T_0|^2$$

где ν_a и ν_b - плотности состояний берегов контакта.

в) Пусть в одном из ферми-газов имеется взаимодействие между частицами, так что собственно-энергетическая часть оказывается равной

$$\Sigma(\xi, \varepsilon) = a\xi - b\varepsilon$$

где ε - энергия частицы, а $\xi = v_F(p - p_0)$, причем $\xi, \varepsilon \ll E_F$. Найдите туннельное сопротивление.

Указание: Для электрон-фононного взаимодействия собственно-энергетическая часть есть функция ε, а от ξ не зависит (см. гл. 6). Поэтому в этом случае $a = 0$. Для электрон-электронного взаимодействия собственно-энергетическая часть зависит как от ξ, так и от ε, и поэтому $a \neq 0$ и $b \neq 0$. (????!??!)

Solution 68 a.

Согласно формуле Кубо, среднее от оператора туннельного тока (11.13) в низшем порядке теории возмущений по туннельному гамильтониану (11.11) равно

$$I(t) = i \int\limits_{-\infty}^{t} \left\langle \left[\widehat{H}_T\left(t'\right), \widehat{I}(t) \right] \right\rangle dt'.$$

Благодаря фазовым множителям $e^{\pm ieVt}$ операторы $\widehat{H}_T(t)$ и $\widehat{I}(t)$ явно зависят от времени. Чтобы свести задачу вычисления туннельного тока к стандартной задаче о нахождении функции отклика в равновесном состоянии, введем обобщенную воспри- имчивость $\chi(\omega)$

$$\chi(\omega) = i \int\limits_{0}^{\infty} \langle [\widehat{X}(t), \widehat{I}(0)] \rangle e^{i\omega t} dt$$

описывающую отклик туннельного тока на поле $\widehat{X}$, определенное соотношением (11.12). Нетрудно видеть, что туннельный ток как функция напряжения V на туннельном контакте связан с $\chi(\omega)$ следующим соотношением:

$$I(V) = 2 \operatorname{Re} \chi(\omega = eV)$$

Чтобы вычислить $\chi(\omega)$, найдем мацубаровскую восприимчивость

$$\chi_M\left(i\Omega_n\right) = \frac{1}{2} \int\limits_{-\beta}^{\beta} \left\langle \mathrm{T}_\tau \widehat{X}(\tau) \widehat{I}(0) \right\rangle e^{i\Omega_n \tau} d\tau$$

а затем продолжим ее на вещественные частоты. Раскроем среднее с помощью определений $\widehat{I} = \dot{\widehat{Q}}_a = ie \sum\limits_{\mathbf{p},\mathbf{p}'} T_{\mathbf{p}\mathbf{p}'} \widehat{a}^+_{\mathbf{p}} \widehat{b}_{\mathbf{p}'} +$ h.c., $X = \sum\limits_{\mathbf{p},\mathbf{p}'} T_{\mathbf{p}\mathbf{p}'} \widehat{a}^+_{\mathbf{p}} \widehat{b}_{\mathbf{p}'}$ получим

$$\left\langle \mathrm{T}_\tau \widehat{X}(\tau) \widehat{I}(0) \right\rangle = \sum_{\mathbf{p}_1,\mathbf{p}'_1,\mathbf{p}_2,\mathbf{p}'_2} T_{\mathbf{p}_1\mathbf{p}'_1} \left\langle \mathrm{T}_\tau \widehat{a}^+_{\mathbf{p}_1}(\tau) \widehat{b}_{\mathbf{p}'_1}(\tau) \left(T_{\mathbf{p}_2\mathbf{p}'_2} \widehat{a}^+_{\mathbf{p}_2}(0) \widehat{b}_{\mathbf{p}'_2}(0) - T^*_{\mathbf{p}_2\mathbf{p}'_2} \widehat{a}_{\mathbf{p}_2}(0) \widehat{b}^+_{\mathbf{p}'_2}(0) \right) \right\rangle.$$

В отсутствие сверхпроводящих корреляций в пробнике и образце средние вида $\left\langle \widehat{a}^+_{\mathbf{p}} \widehat{a}^+_{\mathbf{p}'} \right\rangle$ и $\left\langle \widehat{b}_{\mathbf{p}} \widehat{b}_{\mathbf{p}'} \right\rangle$ равны нулю. Поэтому только вклад второго члена в $\left\langle \mathrm{T}_\tau \widehat{X}(\tau) \widehat{I}(0) \right\rangle$ оказывается отличным от нуля. Далее, спаривая операторы, находим (????? почему минус в второй функции Грина?)

$$\left\langle \mathrm{T}_\tau \widehat{X}(\tau) \widehat{I}(0) \right\rangle = -ie \sum_{\mathbf{p}\mathbf{p}'} \left| T_{\mathbf{p}\mathbf{p}'} \right|^2 G_a(\tau, \mathbf{p}) G_b\left(-\tau, \mathbf{p}'\right)$$

где $G_a(\tau, \mathbf{p}) = -\left\langle \mathrm{T}_\tau \widehat{a}_{\mathbf{p}}(\tau) \widehat{a}^+_{\mathbf{p}}(0) \right\rangle$ и $G_b(\tau, \mathbf{p}) = -\left\langle \mathrm{T}_\tau \widehat{b}_{\mathbf{p}}(\tau) \widehat{b}^+_{\mathbf{p}}(0) \right\rangle$ - мацубаровские функции Грина соответственно пробника и образца. Записав функции Грина в частотном представлении (???) подставив в $\chi_M\left(i\Omega_n\right)$, получим

$$\chi_M\left(i\Omega_n\right) = -2ieT \sum_{\omega_m} \sum_{\mathbf{p}\mathbf{p}'} \left| T_{\mathbf{p}\mathbf{p}'} \right|^2 G_a\left(i\omega_m + i\Omega_n, \mathbf{p}\right) G_b\left(i\omega_m, \mathbf{p}'\right)$$

где множитель 2 учитывает суммирование по проекциям спина.

Теперь выполним аналитическое продолжение с помощью интегрального представления $G\left(i\varepsilon_n, \mathbf{r}_1, \mathbf{r}_2\right) = \frac{1}{\pi} \int\limits_{-\infty}^{\infty} \frac{\operatorname{Im} G^R(\varepsilon, \mathbf{r}_1, \mathbf{r}_2)}{\varepsilon - i\varepsilon_n} d\varepsilon$, с помощью которого мацубаровские функции Грина выражаются через мнимые части запаздывающих функций. В результате получим:

$$\chi_M\left(i\Omega_n\right) = -2ieT \sum_{\omega_m} \sum_{\mathbf{p}\mathbf{p}'} \left| T_{\mathbf{p}\mathbf{p}'} \right|^2 \int\limits_{-\infty}^{\infty} \int \frac{\operatorname{Im} G^R_a(\varepsilon, \mathbf{p}) \operatorname{Im} G^R_b\left(\varepsilon', \mathbf{p}'\right)}{\left(i\omega_m + i\Omega_n - \varepsilon\right)\left(i\omega_m - \varepsilon'\right)} \frac{d\varepsilon d\varepsilon'}{\pi^2}$$

$T\sum\limits_{\omega_m}\frac{1}{(i\omega_m+i\omega_n-\xi_{p+k})(i\omega_m-\xi_p)}=\frac{n_F(\xi_{p+k})-n_F(\xi_p)}{i\omega_n-\xi_{p+k}+\xi_p}\qquad\Rightarrow$

$$\chi_M\left(i\Omega_n\right)=-\frac{2ie}{\pi^2}\sum_{\mathbf{pp}'}\left|T_{\mathbf{pp}'}\right|^2\int\limits_{-\infty}^{\infty}\int\limits_{-\infty}^{\infty}\operatorname{Im}G_a^R(\varepsilon,\mathbf{p})\operatorname{Im}G_b^R\left(\varepsilon',\mathbf{p}'\right)\frac{n_F(\varepsilon)-n_F\left(\varepsilon'\right)}{\varepsilon'-\varepsilon+i\Omega_n}d\varepsilon d\varepsilon'.$$

Аналитическое продолжение (11.46) на вещественные частоты достигается заменой $i\Omega_n$ на $\omega+i0$. Вещественная часть полученного выражения дает туннельный ток

$$I(V)=\frac{4e}{\pi}\sum_{\mathbf{pp}'}\left|T_{\mathbf{pp}'}\right|^2\iint\limits_{-\infty}^{\infty}\delta\left(\varepsilon'-\varepsilon-eV\right)\operatorname{Im}G_a^R(\varepsilon,\mathbf{p})\operatorname{Im}G_b^R\left(\varepsilon',\mathbf{p}'\right)\left(n_F(\varepsilon)-n_F\left(\varepsilon'\right)\right)d\varepsilon d\varepsilon'=$$

$$=\frac{4e}{\pi}\sum_{\mathbf{pp}'}\left|T_{\mathbf{pp}'}\right|^2\int\limits_{-\infty}^{\infty}\operatorname{Im}G_a^R(\varepsilon+eV,\mathbf{p})\operatorname{Im}G_b^R\left(\varepsilon,\mathbf{p}'\right)\left(n_F(\varepsilon)-n_F(\varepsilon+eV)\right)d\varepsilon$$

Эта формула имеет совершенно общий характер, поскольку при её выводе не делалось никаких предположений о спектре и характере взаимодействия в пробнике и образце.

(???? or maybe it works only for noninteracting models?)

Solution 68 б.

Применим общую формулу

$$I(V)=\frac{4e}{\pi}\sum_{\mathbf{pp}'}\left|T_{\mathbf{pp}'}\right|^2\int\limits_{-\infty}^{\infty}\operatorname{Im}G_a^R(\varepsilon+eV,\mathbf{p})\operatorname{Im}G_b^R\left(\varepsilon,\mathbf{p}'\right)\left(n_F(\varepsilon)-n_F(\varepsilon+eV)\right)d\varepsilon$$

к задаче о туннельном контакте между двумя нормальными металлами. Мнимая часть запаздывающей функции Грина $G^R(\varepsilon,\mathbf{p})=\left(\varepsilon-\xi_{\mathbf{p}}+i0\right)^{-1}$ равна

$$\operatorname{Im}G^R(\varepsilon,\mathbf{p})=-\pi\delta\left(\varepsilon-\xi_{\mathbf{p}}\right)$$

(since $\lim_{\varepsilon\to0^+}\frac{1}{x\pm i\varepsilon}=\mp i\pi\delta(x)+\mathcal{P}\left(\frac{1}{x}\right)$).

Рассмотрим более простой случай шероховатого барьера, когда туннельный матричный элемент не зависит от импульсов: $T_{\mathbf{pp}'}=T_0$. Величина T_0 есть значение туннельного матричного элемента при энергии вблизи E_F. При этом каждая из двух функций Грина в общей формуле для тока через контакт интегрируется по импульсам отдельно (this is how we get rid of two sums, we just have two integrals) и соответственно вклад каждой из них есть

$$\int\operatorname{Im}G_{a(b)}^R(\varepsilon,\mathbf{p})\frac{d^3p}{(2\pi)^3}=-\pi\nu_{a(b)}$$

где $\nu_{a(b)}$ - плотность состояний с одной проекцией спина (??? why???).

Нетрудно проверить, что

$$\int\left(n_F(\varepsilon)-n_F(\varepsilon+eV)\right)d\varepsilon=eV$$

при произвольной температуре.

(???? no, I can't do it??? add this to the note on mathematics and typical methods of condensed matter.)

```
Integrate[(1/(Exp[ ve] + 1) - 1/(Exp[ ve + c] + 1)), {ve, -Infinity, Infinity}]
```

Yes, it gives the stated result, but why β disappears from the answer? Also, Wolfram counts with $4\pi i$, which might be not a problem (???).

For analytical calculation, there is a problem, because subtracted integrals at the negative axes are divergent themselves, so we need to work together with them. One can introduce a variable $a:=e^{\varepsilon}$, then come to

```
Integrate[(Exp[b]-1)/((a + 1) (a + Exp[b])), {a, 0, Infinity}]
```

and then neglect imaginary parts from Wolfram. (??? still, I don't understand it well)

Thus, the current can be expressed as

$$I(V)=V/R,\qquad R:=\left(4\pi e^2\left|T_0\right|^2\nu_a\nu_b\right)^{-1}.$$

R is сопротивление туннельного контакта. Таким образом, для контакта между нормальными металлами справедлив закон Ома, причем сопротивление при $T \ll E_F$ не зависит от температуры.

Нетрудно убедиться в том, что закон Ома с независящим от температуры сопротивлением получается и при произвольной зависимости туннельного матричного элемента $T_{\mathbf{pp}'}$ от импульсов $\mathbf{p}$ и $\mathbf{p}'$. Интересно, что даже в случае туннелирования через идеально гладкий барьер, при котором сохраняется параллельная барьеру компонента импульса, закон Ома по-прежнему имеет место при $T \ll E_F$. Эффект сохранения импульса при туннелировании существенно влияет на характер зависимости $I(V)$ при $eV, T \ll E_F$ только в тех случаях, когда и образец, и пробник представляют собой достаточно низкоразмерные системы.

Solution 68 в.

Одночастичная функция Грина с собственно-энергетической частью вида (11.31) имеет вид

$$G(\varepsilon, \mathbf{p}) = \frac{1}{G_0^{-1}(\varepsilon, \mathbf{p}) - \Sigma(\varepsilon, \mathbf{p})} = \frac{1}{\varepsilon(1+b) - \xi_{\mathbf{p}}(1+a) + i0}$$

При этом туннельная плотность состояний (??? check!)

$$\nu(\varepsilon) = -\frac{1}{\pi} \int \operatorname{Im} G(\varepsilon, \mathbf{p}) \frac{d^3\mathbf{p}}{(2\pi)^3} = \int \delta\left(\varepsilon(1+b) - \xi_{\mathbf{p}}(1+a)\right) \frac{d^3\mathbf{p}}{(2\pi)^3} = \frac{\nu_0}{1+a},$$

где ν_0 - плотность состояний без учета взаимодействия. Таким образом оказывается, что туннельная плотность состояний не зависит от константы b.

Полезно сравнить этот ответ с перенормировкой спектра квазичастиц. Функция Грина имеет полюс при

$$\varepsilon = \varepsilon_0(\mathbf{p}) = \frac{1+a}{1+b} v_F \left(|\mathbf{p}| - p_0\right)$$

Таким образом, константа b дает вклад в перенормировку спектра, не меняя при этом туннельный ток. Так происходит потому, что константа b определяет величину скачка в распределении частиц по импульсам на ферми-поверхности, равную вычету функции Грина в квазичастичном полюсе

$$Z = 1/(1+b)$$

Но поскольку перенормировка туннельной плотности состояний пропорциональна

$$\nu(\varepsilon) \approx Z(\partial\varepsilon/\partial\xi)^{-1}$$

вклады константы b в эффективную массу и в вычет Z взаимно сокращаются. Таким образом, туннельный ток зависит не только от перенормированного спектра квазичастиц $\varepsilon = \xi(p)$, но и от их структуры, описываемой величиной Z.

В случае электрон-фононного взаимодействия $a = 0$, и поэтому туннельный ток оказывается точно таким же, как и в отсутствие взаимодействия. Качественно это объясняется адиабатичностью фононов. Туннелирование электрона в металл происходит мгновенно, поэтому при туннелировании решетку можно считать неподвижной. Таким образом, вероятность туннелирования определяется свойствами свободных электронов. Фононы же затем за время порядка ω_D^{-1} подстраиваются под конечное состояние электронов после туннелирования, каким бы оно ни было.

Заметим, что наш вывод об отсутствии влияния электрон-фононного взаимодействия на туннельный ток имеет весьма общий характер. Как нетрудно видеть, туннельная плотность состояний (11.54) не меняется, если собственно-энергетическая часть $\Sigma(\varepsilon)$ зависит от энергии ε произвольным образом. Для полного сокращения эффектов взаимодействия требуется лишь отсутствие зависимости Σ от p, которое в случае электрон-фононного взаимодействия обеспечивается адиабатичностью фононов.

ЛШ-69. Туннельный ток в NS-контакте

Рассмотрим туннельный контакт между нормальным металлом и сверхпроводником, к которому приложено напряжение V. Выразите туннельный ток при $T < T_c$ через сопротивление контакта R в нормальном состоянии, т. е. при $T > T_c$. Покажите, что при нулевой температуре зависимость туннельного тока от V имеет порог:

$$I = \frac{1}{R}\sqrt{V^2 - (\Delta/e)^2}\,\operatorname{sign} V,$$

где Δ - сверхпроводящая щель при $T = 0$.

Найдите зависимость туннельного тока от температуры при $0 < T < T_c$?

Solution 69 в общем случае

Для нахождения туннельного тока между номальным металлом и сверхпроводником можно воспользоваться общим соотношением

$$\left\langle \mathrm{T}_\tau \widehat{X}(\tau)\widehat{I}(0)\right\rangle = \sum_{\mathbf{p}_1,\mathbf{p}_1',\mathbf{p}_2,\mathbf{p}_2'} T_{\mathbf{p}_1\mathbf{p}_1'} \left\langle \mathrm{T}_\tau \widehat{a}^+_{\mathbf{p}_1}(\tau)\widehat{b}_{\mathbf{p}_1'}(\tau)\left(T_{\mathbf{p}_2\mathbf{p}_2'}\widehat{a}^+_{\mathbf{p}_2}(0)\widehat{b}_{\mathbf{p}_2'}(0) - T^*_{\mathbf{p}_2\mathbf{p}_2'}\widehat{a}_{\mathbf{p}_2}(0)\widehat{b}^+_{\mathbf{p}_2'}(0)\right)\right\rangle.$$

При этом в сверхпроводнике аномальные средние вида $\left\langle \widehat{a}^+_{\mathbf{p}_1}\widehat{a}^+_{\mathbf{p}_2}\right\rangle$ отличны от нуля, и поэтому требуется заново проанализировать вклад двух членов под усреднением в туннельный ток. Однако, оказывается, что поскольку в номальном металле средние $\left\langle \widehat{b}_{\mathbf{p}_1'}\widehat{b}_{\mathbf{p}_2'}\right\rangle$ равны нулю, первый член в $\left\langle \mathrm{T}_\tau \widehat{X}(\tau)\widehat{I}(0)\right\rangle = \sum\limits_{\dots} T_{\mathbf{p}_1\mathbf{p}_1'}\langle\dots\rangle$ по-прежнему обращается в нуль при усреднении. Поэтому, как и в задаче 68, можно перейти от $\left\langle \mathrm{T}_\tau \widehat{X}(\tau)\widehat{I}(0)\right\rangle = \sum\limits_{\dots} T_{\mathbf{p}_1\mathbf{p}_1'}\langle\dots\rangle$ к выражению (11.48), в которое входят туннельные плотности состояний пробника и образца.

Туннельная плотность состояний дается мнимой частью функции Грина. Аналитическое продолжение функции Грина сверхпроводника (10.35) с положительных мацубаровских частот на вещественную ось дает

$$G^R(\varepsilon,\mathbf{p}) = \frac{\varepsilon+\xi_{\mathbf{p}}}{\varepsilon^2-\xi^2_{\mathbf{p}}-\Delta^2+i0\,\mathrm{sign}\,\varepsilon}$$

Следовательно туннельная плотность состояний есть

$$\nu(\varepsilon) = -\frac{1}{\pi}\int \mathrm{Im}\, G^R(\varepsilon,\mathbf{p})\frac{d^3p}{(2\pi)^3} = \nu_0\int\limits_{-\infty}^{\infty}(\varepsilon+\xi)\delta\left(\varepsilon^2-\xi^2-\Delta^2\right)\mathrm{sign}\,\varepsilon d\xi$$

Вычисляя интеграл от δ-функции, находим (shoul be easy, I'll check later)

$$\nu(\varepsilon) = \begin{cases} \nu_0|\varepsilon|/\left(\varepsilon^2-\Delta^2\right)^{1/2} & \text{при } |\varepsilon|>\Delta \\ 0 & \text{при } |\varepsilon|<\Delta \end{cases}$$

Этот результат может быть записан в виде $\pi\nu_0\partial\xi/\partial\varepsilon$, т.е. как плотность состояний квазичастиц с законом дисперсии $\varepsilon^2 = \Delta^2+\xi^2$. Хотя такой подход игнорирует различие между туннелирующими электронами и квазичастицами, в которые они превращаются в сверхпроводнике, результат в данном случае оказывается верным. Причина состоит в том, что квазичастицы теории БКШ состоят из двух электронов с одинаковой энергией. Их вклады в туннельную плотность состояний равны $|u_p|^2$ и $|v_p|^2$, где u_p и v_p - коэффициенты преобразования Боголюбова. Но поскольку $u_p^2+v_p^2=1$, суммарный вклад двух компонент квазичастицы в туннельный ток определяется только свойствами квазичастичного спектра. Так происходит потому, что эффекты взаимодействия в теории БКШ учитываются только в рамках теории среднего поля, и поэтому многочастичные эффекты оказываются относительно простыми.

Подставляем туннельную плотность состояний (11.60) в (11.48), находим туннельный ток:

$$I_{N-S}(V) = 4\pi e\nu_a\nu_b|T_0|^2\int\limits_{|\omega|>\Delta}(n_F(\omega)-n_F(\omega+eV))\frac{|\omega|d\omega}{\sqrt{\omega^2-\Delta^2}}.$$

Случай нулевой температуры.

Пусть eV > 0. Тогда интегрирование по энергиям производится в интервале $-eV<\varepsilon<0$ (??? why negative???). При eV < Δ интеграл (11.61) обращается в нуль, поскольку в этой области не выполнено условие $|\varepsilon|>\Delta$ (?? can we see it from formulas, or it is from common sense??). Для $eV>\Delta$ находим

$$I_{N-S}(V) = \frac{1}{eR}\int\limits_{-eV}^{-\Delta}\frac{|\varepsilon|d\varepsilon}{\sqrt{\varepsilon^2-\Delta^2}} = \frac{\sqrt{(eV)^2-\Delta^2}}{eR}$$

Таким образом, зависимость туннельного тока от напряжения имеет порог, равный Δ/e. Рассматривая аналогично случай $eV<0$, получаем искомую зависимость (11.32), обладающую свойством антисимметрии: $I_{N-S}(-V) = -I_{N-S}(V)$.

Случай малой температуры

Порог при $eV = \Delta$ является резким только при нулевой температуре. При конечной температуре в нормальном металле всегда имеются квазичастицы с энергией $\varepsilon > \Delta$, которые могут туннелировать в сверхпроводник. Поэтому естественно ожидать, что при $T > 0$ корневая особенность размывается и туннельный ток оказывается отличным от нуля при всех напряжениях.

Чтобы убедиться в том, что это действительно так, най дем туннельный ток под порогом при малых температурах $T \ll \Delta$. Интеграл в (11.61) при таких T определяется окрестностями точек $\varepsilon = \pm\Delta$. Введем обозначение $\varepsilon = \pm(\Delta + x)$ в каждой из областей. Как будет ясно из дальнейших вычислений, характерное значение x оказывается порядка T, поэтому можно разложить плотность состояний по x/Δ, then

$$I_{N-S}(V,T) = 4\pi e\nu_a\nu_b\,|T_0|^2 \int\limits_0^\infty \Big[n_F(\Delta + x) + n_F(-\Delta - x) - n_F(\Delta + eV + x) - n_F(-\Delta - x + eV)\Big]\frac{\Delta dx}{\sqrt{2\Delta x}}.$$

$n_F(-\varepsilon) = 1 - n_F(\varepsilon)$,

$$I_{N-S}(V,T) = \frac{1}{eR}\int\limits_0^\infty [n_F(\Delta - eV + x) - n_F(\Delta + x + eV)]\sqrt{\frac{\Delta}{2x}}dx.$$

(мы выразили туннельный матричный элемент T_0 через сопротивление контакта в нормальном состоянии, add this formla from the previous problem).

При больших положительных значениях энергии фермиевская функция распределения переходит в больцмановскую,

$$n_F(\varepsilon) \overset{\varepsilon \gg T}{\approx} e^{-\varepsilon/T}$$

и поэтому выражение для туннельного тока принимает следующий вид after a very trivial transformation:

$$I_{N-S}(V,T) = \frac{1}{eR}e^{-\Delta/T}\,\mathrm{sh}\,\frac{eV}{T}\cdot\int\limits_0^\infty \sqrt{\frac{2\Delta}{x}}e^{-x/T}dx$$

We trivially introduce $x' = x/T$, use $\Gamma(1/2) = \int x^{\frac{1}{2}-1}e^{-x}dx = \sqrt{\pi}$, and get

$$I_{N-S}(V,T) = \frac{\sqrt{2\pi\Delta T}}{eR}e^{-\Delta/T}\,\mathrm{sh}\,\frac{eV}{T}$$

Это выражение неприменимо в узкой окрестности порога при $(eV - \Delta) \sim T$, поскольку при таких напряжениях приближение $n_F(\varepsilon \gg T) \approx e^{-\varepsilon/T}$ нельзя применять к первому члену в (11.64).

Итак, при $0 < T \ll \Delta$ ток (11.61) при $eV < \Delta$ экспоненциально мал. По мере роста температуры ток под порогом $eV < \Delta$ возрастает, и когда температура достигает T_c, вольт-амперная характеристика становится омической, как для контакта между двумя нормальными металлами.

Помимо термоактивационного вклада в ток, описываемого $I_{N-S}(V,T) = \frac{\sqrt{2\pi\Delta T}}{eR}e^{-\Delta/T}\,\mathrm{sh}\,\frac{eV}{T}$, под порогом $eV = \Delta$ существует еще один весьма интересный вклад, не исчезающий при $T \to 0$. Он связан с когерентным туннелированием пары электронов с противоположными импульсами и спинами.

(??? add before that we don't consider two paericle tunnelings. why???)

Оказавшись в сверхпроводнике, такие два электрона могут образовать куперовскую пару. Туннелирование пары, в отличие от одночастичного туннелирования, не требует затраты энергии Δ на каждую частицу, и поэтому такой вклад не «вымерзает» при низких температурах. Когерентное туннелирование пар электронов часто называют андреевским отражением, поскольку описанный процесс перехода двух электронов из нормального металла в сверхпроводник можно рассматривать как превращение электрона в дырку при отражении от поверхности сверхпроводника. Вероятность двухчастичного туннелирования пропорциональна $|T_0|^4$, а не $|T_0|^2$, как для одночастичного туннелирования. Поэтому при $|T_0| \ll 1$ и не слишком низкой температуре двухчастичные процессы очень редки по сравнению с одночастичными. Вследствие этого андреевское отражение вносит существенный вклад в туннельный ток лишь при достаточно низких температурах.

ЛШ-70. Эффект Джозефсона.

В контакте двух сверхпроводников помимо одночастичного вклада в ток, рассмотренного в задачах 68 и 69 (! впишу формулы!), появляется дополнительный вклад, связанный с туннелированием куперовских пар. Формально этот вклад можно описать, заменив нормальные функции Грина в диаграмме на рис. 11.3 на аномальные - см. рис. 11.6.

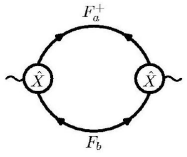

Рис. 11.6

Таким образом, туннельный эксперимент позволяет «измерить» аномальную функцию Грина в сверхпроводнике.

Покажите, что в равновесии, при $V = 0$, двухчастичный ток отличен от нуля и равен

$$I = I_0 \sin(\varphi_a - \varphi_b)$$

где $\varphi_{a(b)}$ - значения фазы сверхпроводящего параметра порядка $\Delta_{a(b)} = \left|\Delta_{a(b)}\right| e^{i\varphi_{a(b)}}$ на разных берегах контакта. Туннельный контакт между двумя сверхпроводниками, в котором имеет место эффект Джозефсона ($I = I_0 \sin(\varphi_a - \varphi_b)$), называется соответственно джозефсоновским контактом.

Рассмотрите случай, когда сверхпроводники по обе стороны контакта одинаковые, т.е. $\Delta_{a(b)} = \Delta e^{i\varphi_{a(b)}}$. Получите т.н. соотношение Амбегаокара-Баратова. для максимального тока в джозефсоновском контакте:

$$I_0(R) = \frac{\pi\Delta}{2eR} \operatorname{th} \frac{\Delta}{2T}$$

где R - сопротивление контакта при $T > T_c$.

Solution 70.

(??? remind background!!!)

Поскольку теперь у нас с обеих сторон контакта находятся сверхпроводники, первый член в выражении

$$\left\langle \mathrm{T}_\tau \widehat{X}(\tau)\widehat{I}(0)\right\rangle = \sum_{\mathbf{p}_1,\mathbf{p}_1',\mathbf{p}_2,\mathbf{p}_2'} T_{\mathbf{p}_1\mathbf{p}_1'} \left\langle \mathrm{T}_\tau \widehat{a}^+_{\mathbf{p}_1}(\tau)\widehat{b}_{\mathbf{p}_1'}(\tau)\left(T_{\mathbf{p}_2\mathbf{p}_2'}\widehat{a}^+_{\mathbf{p}_2}(0)\widehat{b}_{\mathbf{p}_2'}(0) - T^*_{\mathbf{p}_2\mathbf{p}_2'}\widehat{a}_{\mathbf{p}_2}(0)\widehat{b}^+_{\mathbf{p}_2'}(0)\right)\right\rangle.$$

оказывается отличным от нуля и усреднение необходимо выполнить заново. Как нетрудно видеть, первый член усредняется так же, как и раньше, с единственной разницей, состоящей в замене нормальных средних на аномальные.

Соответствующий вклад в восприимчивость χ_M выписывается по аналогии с задачей 68

(???? write here the derivation!!!)

и оказывается равным

$$\chi_{M,S-S}(i\Omega_n) = ieT\sum_{\omega_m}\sum_{\mathbf{pp}'} |T_{\mathbf{pp}'}|^2 F^+_{a,\mu\nu}(i\Omega_n + i\omega_m, \mathbf{p}) F_{b,\nu\mu}(i\omega_m, \mathbf{p}')$$

где $F_a(i\varepsilon_n, \mathbf{p})$ и $F_b(i\varepsilon_n, \mathbf{p})$ - аномальные функции Грина берегов контакта, а μ и ν - спиновые индексы. Суммируя по μ и ν с учетом спиновой структуры аномальных функций Грина, получаем выражение по виду сходное с (11.45) с точностью до замены нормальных функций Грина на аномальные:

$$\chi_{M,S-S}(i\Omega_n) = -2ieT\sum_{\omega_m}\sum_{\mathbf{pk}} |T_{\mathbf{pk}}|^2 F^+_a(i\Omega_n + i\omega_m, \mathbf{p}) F_b(i\omega_m, \mathbf{k})$$

Обратим внимание на то, что знаки выражений (11.45) и (11.69) совпадают. Это соответствует общему наблюдению о совпадении знаков «нормальных» ии «аномальных» петель, сделанному в решении задачи 63. (???? which????)

Поскольку, как мы увидим, джозефсоновский ток отличен от нуля в равновесии, т. е. при $V = 0$, нам будет достаточно вычислить $\chi_{M,S-S}(i\Omega_n)$ при $\Omega_n = 0$. Аналитическое продолжение оказывается ненужным, и можно сразу записать выражение для туннельного тока:

$$I_{S-S} = 4e|T_0|^2 T \operatorname{Im}\sum_{\omega_m}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \frac{\Delta_a^*\nu_a d\xi_b}{\omega_m^2 + \xi_a^2 + |\Delta_a|^2}\frac{\Delta_b\nu_b d\xi_b}{\omega_m^2 + \xi_b^2 + |\Delta_b|^2} =$$

$$= 4\pi^2 e|T_0|^2 \nu_a\nu_b T \operatorname{Im}\sum_{\omega_m} \frac{\Delta_a^*\Delta_b}{\sqrt{\omega_m^2 + |\Delta_a|^2}\sqrt{\omega_m^2 + |\Delta_b|^2}}$$

Полученное выражение отлично от нуля когда фазы параметра порядка по разные стороны контакта различны. Пусть $\Delta_{a,b} = |\Delta_{a,b}| e^{i\varphi_{a,b}}$. Выражая туннельный матричный элемент T_0 через сопротивление контакта в нормальном состоянии, получаем соотношение Джозефсона:

$$I = I_0 \sin(\varphi_b - \varphi_a), \qquad I_0 = \frac{\pi}{eR} T \sum_{\omega_m} \frac{|\Delta_a| |\Delta_b|}{\sqrt{\omega_m^2 + |\Delta_a|^2}\sqrt{\omega_m^2 + |\Delta_b|^2}},$$

Отметим еще раз, что, в отличие от других разновидностей туннельного тока, джозефсоновский ток не связан с релаксацией к равновесному состоянию. Эффект Джозефсона ($I = I_0 \sin(\varphi_a - \varphi_b)$) имеет место в термодинамическом равновесии, и соответственно ток (11.71) между двумя сверхпроводниками с различающимися фазами параметра порядка может течь неограниченно долго.

Из-за того, что джозефсоновский ток отличен от нуля в равновесии также мы не рассматриваем вклад в туннельный ток $\left\langle \mathrm{T}_\tau \widehat{X}(\tau)\widehat{I}(0)\right\rangle = \sum_{...} T_{\mathbf{p}_1\mathbf{p}_1'} \langle ... \rangle$, содержащий нормальные средние. Как мы видели в задачах 68 и 69, такой вклад описывает некогерентное туннелирование отдельных электронов и приводит к току, исчезающему при $V = 0$ (???? why exactly, add formulas???).

Если $|\Delta_a| = |\Delta_b| \equiv \Delta$,

$$I_0 = \frac{\pi}{eR} T \sum_{\omega_m} \frac{\Delta^2}{\omega_m^2 + \Delta^2},$$

$\sum_{n=-\infty}^{\infty} \frac{1}{(2n+1)^2+a^2} = \frac{\pi}{2a} \operatorname{th} \frac{\pi a}{2}$ $\Rightarrow$

$$I_0(R) = \frac{\pi\Delta}{2eR} \operatorname{th} \frac{\Delta}{2T}$$

Фйг-7.1. Критический ток SNS перехода

Найти основную температурную зависимость критического тока SNS перехода при $T \to T_c$, используя теорию Гинзбурга-Ландау. Рассмотреть случая одинаковых и разных сверхпроводящих металлов.

Solution

(??? it is done before in BCS, but I don't know, how to do in in GL framework yet. it is interesting to see later, that if these results are the same? they should be...)

Фйг-7.2 Критический ток и ток захвата

Найти отношение критического тока I_c к току захвата I_r в джозефсоновском туннельном контакте с большим параметром Мак-Камбера $\beta_C \gg 1$.

Reminder: (??? what is this parameter?? what is the current of захват??)

Solution

(???)

14.2.11 Problems about tunneling, junctions 2: Basic Models

Фйг-7.3 Высота n-ой ступеньки Шапиро

Найти зависимость высоты n-ой ступеньки Шапиро от ее номера n для простейшей резистивной модели джожефсоновского контакта.

Reminder: (??? what is this ступенька??)

Solution

(???)

Фйг-7.4 Критический ток и поле для короткого SNS контакта

Вывести зависимость $I_c(B)$ критического тока от магнитного поля для короткого джозефсоновского перехода длины $L \leq \lambda_J$, где λ_J джозефсоновская глубина проникновения.

Solution

(??? maybe shmidt's theory is the best for it?? I have no idea, how to do it in BCS)

Фйг-7.5 Критический ток в двухконтактном СКВИДе

Для двухконтактного СКВИДа найти зависимость критического тока I_c от магнитного потока в катушке Φ_{ext} в двух предельных случаях: большого и малого параметра $\beta_L = 2\pi\mathcal{L}I_c/\Phi_0$, где $\mathcal{L}$ - индуктивность петли СКВИДа.

Solution

(??? maybe it is done in theory?)

Фйг-7.6* Джозефсоновский переход с флуктуациями сверхтока

Для длинного джозефсоновского перехода с длиной $L \gg \lambda_J$ плотность сверхтока в котором испытывает флуктуации по длине перехода, $j_c(x) = j_0 + \delta j(x)$, где среднее от $\delta j(x)$ равно 0, а коррелятор $\langle \delta j(x)\delta j(x')\rangle = D\delta(x-x')$, найти зависимость полного критического тока от магнитного поля B при больших полях, когда в области перехода находится много вихрей Джозефсона.

Solution

(??? if averaged now, then why there will be an impact?? I'll add a theory about such fluctuations later)

(?? is it a physical model???)

Фйг-13.2.Andreev level at $\phi = \pi$

Показать, что SNS контакт при разности фаз $\phi = \pi$ всегда содержит андреевский уровень с энергией $E = 0$.

Solution

(??? one can remember the CPR plot and it is always zero. so maybe basic derivation of Josephson relation is enough? anyway, I'll write an explicit answer later)

Фйг-13.3. Electronic heat capacity in the mixed state of type I SC

Найти электронную теплоемкость в смешанном состоянии сверхпроводника I рода, считая, что нормальные домены имеют плоскую форму и их толщина равна $d_N \gg \hbar v_F/\Delta$, а температура $T \ll T_c$.

Solution

(??? is there at all a mixed state of type I SC???? I'll listen to the lecture later. A. F. Andreev and P. Tekel wrote "Theory of a Surface "Mixed" State in Type I Superconductors", so there might be it.... I'll create a section in theory about it)

14.2.12 Problems about tunneling, junctions 3: Basic Models

Фйг-13.4. Эффективная масса возбуждений в вихре

Найти эффективную массу M_z возбуждений в коре абрикосовского вихря для произвольного отношения электронных масс $m_z/m_\perp$.
Reminder: (??? what is mass in the vortex)

Solution

(??? what is mass in the vortex)

Фйг-13.5. Mixed state, big field

Найти плотность электронных состояний в s-сверхпроводнике в смешанном состоянии с магнитным полем $B \ll H_{c2}$ при малых энергиях $E \ll \Delta$, и его теплоемкость при $T \ll T_c$.

Solution

(???)

Фйг-13.1. Андреевские уровни в SNS контакте

Найти низколежащие андреевские уровни в плоском SNS контакте в зависимости от разности фаз χ на сверхпроводящих берегах и при произвольном соотношении $\hbar v_F/\Delta$ и толщины нормальной области d.

Solution

(I think, there is a well-known formula, which should be in the beginning of my theory of Andreev reflection. Don't know it yet)

Shnirman, Piasotski.KIT.2024-5.1(m) ABS in an ideal long SNS

Consider a long SNS contact of length L. Provide a derivation for the Andreev reflection amplitude in the the left interface. Obtain the quantization condition and try to estimate the energies and the number of the Andreev bound states.

Solution

We need to just solve BdG equations. (??? need to write theory about it better!!)

We consider

$$H = \tau_z \left(\frac{p^2}{2m} - \mu \right) + (\Delta(x)\tau_+ + \text{h.c. }) \tag{1}$$

$$\Delta(x) = \Delta \left[\Theta(-x) + \Theta(x-L)e^{i\varphi} \right] \tag{2}$$

(???Why do they have v^*, not v?)
Left and right of the interface we have the following fundamental solutions

$$\psi_L(x) = \psi_k e^{ikx}, \quad \psi_R(x) = U\psi_k e^{ikx} \tag{3}$$

where

$$\psi_k = \begin{pmatrix} \Delta \\ \epsilon + \mu - \frac{k^2}{2m} \end{pmatrix}, \qquad \left(\frac{k^2}{2m} - \mu \right)^2 = -\Delta^2 + \epsilon^2, \qquad U := e^{i\varphi\tau_z/2} \tag{4}$$

We search for the bound state solutions, such that

$$\lim_{x\to-\infty} \psi_L(x) = \lim_{x\to\infty} \psi_R(x) = 0 \tag{5}$$

This forces us to choose

$$\psi_L(x) = c_+^L \psi_{-k_+} e^{-ik_+ x} + c_-^L \psi_{-k_-} e^{-ik_- x} = \begin{pmatrix} \psi_{-k_+} e^{-ik_+ x} & \psi_{-k_-} e^{-ik_- x} \end{pmatrix} \begin{pmatrix} c_+^L \\ c_-^L \end{pmatrix} \tag{6}$$

$$\psi_R(x) = c_+^R U \psi_{k_+} e^{ik_+(x-L)} + c_-^R U \psi_{k_-} e^{ik_-(x-L)} = U \begin{pmatrix} \psi_{k_+} e^{ik_+(x-L)} & \psi_{k_-} e^{ik_-(x-L)} \end{pmatrix} \begin{pmatrix} c_+^R \\ c_-^R \end{pmatrix} \tag{8}$$

$$k_\pm = \pm\sqrt{2m\mu \pm 2mi\sqrt{\Delta^2 - \epsilon^2}} \tag{9}$$

In the central section, all four fundamental solutions are admissible, so

$$\psi_C(x) = \left[c_{p+} e^{ik_N^p x} + c_{p-} e^{-ik_N^p x}\right] \begin{pmatrix} 1 \\ 0 \end{pmatrix} + \left[c_{h+} e^{ik_N^h x} + c_{h-} e^{-ik_N^h x}\right] \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \tag{10}$$

$$k_N^p = \sqrt{2m(\mu + \epsilon)}, \quad k_N^h = \sqrt{2m(\mu - \epsilon).} \tag{11}$$

(!!! change what is below to true matrix notation!!!)
Now we apply the boundary conditions on the lhs

$$\begin{pmatrix} 0 & \begin{pmatrix} \psi_{-k_+} & \psi_{-k_-} \end{pmatrix} \\ 0 & -i \begin{pmatrix} k_+ \psi_{-k_+} & k_- \psi_{-k_-} \end{pmatrix} \end{pmatrix} \begin{pmatrix} c_+^R \\ c_-^R \\ c_+^L \\ c_-^L \end{pmatrix} = \begin{pmatrix} 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 \\ ik_N^p & -ik_N^p & 0 & 0 \\ 0 & 0 & ik_N^h & -ik_N^h \end{pmatrix} \begin{pmatrix} c_{p+} \\ c_{p-} \\ c_{h+} \\ c_{h-} \end{pmatrix}.$$

Now we apply the boundary conditions on the rhs

$$\begin{pmatrix} U \begin{pmatrix} \psi_{k_+} & \psi_{k_-} \end{pmatrix} & 0 \\ iU \begin{pmatrix} k_+ \psi_{k_+} & k_- \psi_{k_-} \end{pmatrix} & 0 \end{pmatrix} \begin{pmatrix} c_+^R \\ c_-^R \\ c_+^L \\ c_-^L \end{pmatrix} = \begin{pmatrix} e^{ik_N^p L} & e^{-ik_N^p L} & 0 & 0 \\ 0 & 0 & e^{ik_N^h L} & e^{-ik_N^h L} \\ ik_N^p e^{ik_N^p L} & -ik_N^p e^{-ik_N^p L} & 0 & 0 \\ 0 & 0 & ik_N^h e^{ik_N^h L} & -ik_N^h e^{-ik_N^h L} \end{pmatrix} \begin{pmatrix} c_{p+} \\ c_{p-} \\ c_{h+} \\ c_{h-} \end{pmatrix} \tag{14}$$

$$\begin{pmatrix} c_{p+} \\ c_{p-} \\ c_{h+} \\ c_{h-} \end{pmatrix} = \begin{pmatrix} 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 \\ ik_N^p & -ik_N^p & 0 & 0 \\ 0 & 0 & ik_N^h & -ik_N^h \end{pmatrix}^{-1} \begin{pmatrix} 0 & \begin{pmatrix} \psi_{-k_+} & \psi_{-k_-} \end{pmatrix} \\ 0 & -i \begin{pmatrix} k_+ \psi_{-k_+} & k_- \psi_{-k_-} \end{pmatrix} \end{pmatrix} \begin{pmatrix} c_+^R \\ c_-^R \\ c_+^L \\ c_-^L \end{pmatrix} \tag{15}$$

$$\begin{pmatrix} U \begin{pmatrix} \psi_{k_+} & \psi_{k_-} \end{pmatrix} & 0 \\ iU \begin{pmatrix} k_+ \psi_{k_+} & k_- \psi_{k_-} \end{pmatrix} & 0 \end{pmatrix} \begin{pmatrix} c_+^R \\ c_-^R \\ c_+^L \\ c_-^L \end{pmatrix} - M \begin{pmatrix} 0 & \begin{pmatrix} \psi_{-k_+} & \psi_{-k_-} \end{pmatrix} \\ 0 & -i \begin{pmatrix} k_+ \psi_{-k_+} & k_- \psi_{-k_-} \end{pmatrix} \end{pmatrix} \begin{pmatrix} c_+^R \\ c_-^R \\ c_+^L \\ c_-^L \end{pmatrix} = 0, \tag{16}$$

$$M := \begin{pmatrix} \cos\left(k_N^p L\right) & 0 & \sin\left(k_N^p L\right)/k_N^p & 0 \\ 0 & \cos\left(k_N^h L\right) & 0 & \sin\left(k_N^h L\right)/k_N^h \\ -k_N^p \sin\left(k_N^p L\right) & 0 & \cos\left(k_N^p L\right) & 0 \\ 0 & -k_N^h \sin\left(k_N^h L\right) & 0 & \cos\left(k_N^h L\right) \end{pmatrix} \tag{17}$$

It follows that we have the condition

$$\det \begin{pmatrix} UJ & -CJ + iSK^{-1}JK_S \\ iUJK_S & SKJ + iCJK_S \end{pmatrix} = 0 \tag{18}$$

where

$$C = \begin{pmatrix} \cos\left(k_N^p L\right) & 0 \\ 0 & \cos\left(k_N^h L\right) \end{pmatrix}, \quad S = \begin{pmatrix} \sin\left(k_N^p L\right) & 0 \\ 0 & \sin\left(k_N^h L\right) \end{pmatrix} \tag{19}$$

$$K = \begin{pmatrix} k_N^p & 0 \\ 0 & k_N^h \end{pmatrix}, \quad K_S = \begin{pmatrix} k_+ & 0 \\ 0 & k_- \end{pmatrix}, \tag{20}$$

$$J = \begin{pmatrix} \psi_{k_+} & \psi_{k_-} \end{pmatrix} = \begin{pmatrix} \Delta & \Delta \\ \epsilon - i\sqrt{\Delta^2 - \epsilon^2} & \epsilon + i\sqrt{\Delta^2 - \epsilon^2} \end{pmatrix}. \tag{21}$$

To obtain the desired result we approximate $k_N^p \approx k_N^h \approx k_+ \approx -k_- \approx k_F$ everywhere apart from the phases. In this connection, the secular equation (19) simplifies to
(!!!! this is the important point, how exactly it is done??? try to to it!!!)

$$\det\begin{pmatrix} UJ & -CJ+iSJ\tau_z \\ ik_F UJ\tau_z & k_F\left[SJ+iCJ\tau_z\right] \end{pmatrix} = \det\left[UJk_F\right]\det\left[SJ+iCJ\tau_z+iUJ\tau_z(J)^{-1}U^\dagger\left(CJ-iSJ\tau_z\right)\right]=0 \quad (23)$$

This yields the condition
(?? check!)

$$\left(\Delta^2-2\epsilon^2\right)\cos\left(\left[k_N^p-k_N^h\right]L\right)+\Delta^2\cos\varphi-2\epsilon\sqrt{\Delta^2-\epsilon^2}\sin\left(\left[k_N^p-k_N^h\right]L\right)=0. \quad (24)$$

If we parametrise the energies inside of the gap as $\epsilon=\Delta\cos\chi$, we find that

$$\cos\varphi=\cos\left(\left[k_N^p-k_N^h\right]L-2S_\chi\chi\right),\quad S_\chi=\frac{\sin(\chi)}{|\sin(\chi)|} \quad (25)$$

which is the condition discussed in the class

$$\varphi=\left[k_N^p-k_N^h\right]L-2S_\chi\chi \mod 2\pi \quad (26)$$

(??? what is the meaning of this formula???)

Shnirman, Piasotski.KIT.2024-5.2(m),BTK NS contact with δ-barrier

Consider NS contact with one transverse channel (effectively one-dimensional wire), where the superconducting order parameter vanishes for $x<0$ and is equal to $|\Delta|e^{i\phi}$ for $x>0$. Let us add a δ-potential barrier at $x=0$, namely $V(x)=H\delta(x)$. Write down the BdG equations for this case and find the scattering amplitudes in all possible scattering channels for an incoming (from the normal side) electron with energy E. Consider both cases $E<|\Delta|$ and $E>|\Delta|$.

Solution

The BdG equations read

$$\begin{pmatrix} -\frac{\hbar^2\nabla_x^2}{2m}+V(x)-\tilde{\mu} & \Delta(x) \\ \Delta^*(x) & \frac{\hbar^2\nabla_x^2}{2m}-V(x)+\tilde{\mu} \end{pmatrix}\begin{pmatrix} u \\ v^* \end{pmatrix}=E\begin{pmatrix} u \\ v^* \end{pmatrix} \quad (27)$$

This gives

$$\begin{pmatrix} -\frac{\hbar^2\nabla_x^2}{2m}+H\delta(x)-\tilde{\mu} & \Delta(x) \\ \Delta^*(x) & \frac{\hbar^2\nabla_x^2}{2m}-H\delta(x)+\tilde{\mu} \end{pmatrix}\begin{pmatrix} u \\ v^* \end{pmatrix}=E\begin{pmatrix} u \\ v^* \end{pmatrix} \quad (28)$$

The delta-function can only be compensated by a jump in the first derivative. Thus, instead of continuity of the first derivative we obtain a new boundary condition

$$\left.\frac{du}{dx}\right|_{x=+0}-\left.\frac{du}{dx}\right|_{x=-0}=\frac{2mH}{\hbar^2}u(x=0) \quad (29)$$

$$\left.\frac{dv^*}{dx}\right|_{x=+0}-\left.\frac{dv^*}{dx}\right|_{x=-0}=\frac{2mH}{\hbar^2}v^*(x=0) \quad (30)$$

These are in addition to the continuity of the wave functions themselves:

$$u(x=+0)=u(x=-0)\quad,\quad v^*(x=+0)=v^*(x=-0) \quad (31)$$

Case $E<|\Delta|$
As in the script the solution for $x<0$ reads

$$\Psi(x<0)=\frac{1}{\sqrt{v_F}}\begin{pmatrix}1\\0\end{pmatrix}e^{ik_e x}+\frac{r_N}{\sqrt{v_F}}\begin{pmatrix}1\\0\end{pmatrix}e^{-ik_e x}+\frac{r_A}{\sqrt{v_F}}\begin{pmatrix}0\\1\end{pmatrix}e^{ik_h x} \quad (32)$$

and the solution for $x>0$ reads

$$\Psi(x>0)=A\begin{pmatrix}U_g\\e^{-i\phi}U_g^*\end{pmatrix}e^{ik_1 x}+B\begin{pmatrix}U_g^*\\e^{-i\phi}U_g\end{pmatrix}e^{ik_2 x} \quad (33)$$

where

$$U_g \equiv \sqrt{\frac{E + i\sqrt{|\Delta|^2 - E^2}}{2E}} \tag{34}$$

$$k_1 = k_F \sqrt{1 + i\frac{\sqrt{|\Delta|^2 - E^2}}{\tilde{\mu}}} \tag{35}$$

$$k_2 = -k_F \sqrt{1 - i\frac{\sqrt{|\Delta|^2 - E^2}}{\tilde{\mu}}} \tag{36}$$

The continuity of the wave functions gives

$$\begin{aligned} \frac{1 + r_N}{\sqrt{v_F}} &= AU_g + BU_g^* \\ \frac{r_A}{\sqrt{v_F}} &= \left(AU_g^* + BU_g\right) e^{-i\phi} \end{aligned} \tag{37}$$

For the derivatives we approximately put $|k_e| \approx |k_h| \approx |k_1| \approx |k_2| \approx k_F$. Then

$$\begin{aligned} \frac{1 - r_N}{\sqrt{v_F}} + \frac{2mH}{ik_F\hbar^2}\left[\frac{1 + r_N}{\sqrt{v_F}}\right] &= AU_g - BU_g^* \\ \frac{r_A}{\sqrt{v_F}} + \frac{2mH}{ik_F\hbar^2}\left[\frac{r_A}{\sqrt{v_F}}\right] &= \left(AU_g^* - BU_g\right) e^{-i\phi} \end{aligned} \tag{38}$$

Adding and subtracting we obtain

$$AU_g = 1/\sqrt{v_F} + \frac{mH}{ik_F\hbar^2}\left[\frac{1 + r_N}{\sqrt{v_F}}\right] \tag{39}$$

$$AU_g^* e^{-i\phi} = r_A/\sqrt{v_F}\left[1 + \frac{mH}{ik_F\hbar^2}\right] \tag{40}$$

$$BU_g^* = r_N/\sqrt{v_F} - \frac{mH}{ik_F\hbar^2}\left[\frac{1 + r_N}{\sqrt{v_F}}\right] \tag{41}$$

$$BU_g e^{-i\phi} = -\frac{mH}{ik_F\hbar^2}\left[\frac{r_A}{\sqrt{v_F}}\right] \tag{42}$$

Excluding A from the first two equations we get

$$r_A\left[1 + \frac{mH}{ik_F\hbar^2}\right] = e^{-i\phi}e^{-i\gamma}\left[1 + \frac{mH}{ik_F\hbar^2}\left(1 + r_N\right)\right] \tag{43}$$

Here $\gamma(E) \equiv \arccos(E/|\Delta|)$ and $e^{-i\gamma} = U_g^*/U_g$. From the second pair of equations we exclude B and obtain

$$r_A\left[-\frac{mH}{ik_F\hbar^2}\right] = e^{-i\phi}e^{i\gamma}\left[r_N - \frac{mH}{ik_F\hbar^2}\left(1 + r_N\right)\right] \tag{44}$$

Let us introduce

$$Z = \frac{mH}{k_F\hbar^2} \tag{45}$$

Then the equations read

$$r_A[1 - iZ] = e^{-i\phi}e^{-i\gamma}\left[1 - iZ\left(1 + r_N\right)\right] \tag{46}$$

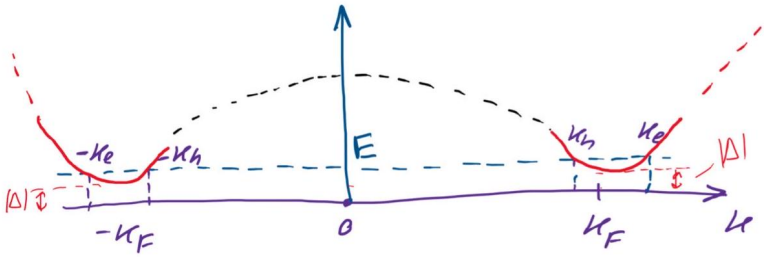
$$r_A iZ = e^{-i\phi}e^{i\gamma}\left[r_N + iZ\left(1 + r_N\right)\right] \tag{47}$$

Excluding r_N we obtain

$$r_A = \frac{e^{-i\phi}}{(1+Z^2)\,e^{i\gamma} - Z^2 e^{-i\gamma}} \tag{48}$$

The probability of Andreev reflection is equal to

$$|r_A|^2 = \frac{1}{\cos^2\gamma + (1+2Z^2)^2 \sin^2\gamma} \leq 1 \tag{49}$$



Of course one has $|r_N|^2 + |r_A|^2 = 1$.
Case $E > |\Delta|$
In this case the waves propagate further at $x > 0$. The possible solutions (propagating to the right) are the ones with $k = k_e$ and $k = -k_h$ in Fig. 1. The the solution for $x > 0$ reads

$$\Psi(x>0) = \frac{A}{\sqrt{v_g}} \begin{pmatrix} u_0 \\ e^{-i\phi} v_0 \end{pmatrix} e^{ik_e^{(s)} x} + \frac{B}{\sqrt{v_g}} \begin{pmatrix} v_0 \\ e^{-i\phi} u_0 \end{pmatrix} e^{-ik_h^{(s)} x} \tag{50}$$

where

$$u_0 \equiv \sqrt{\frac{E - \sqrt{E^2 - |\Delta|^2}}{2E}} \tag{51}$$

$$v_0 \equiv \sqrt{\frac{E + \sqrt{E^2 - |\Delta|^2}}{2E}} \tag{52}$$

Spectrum on the superconducting side of the NS contact.
The group velocity of these solutions reads (here $\xi_k > 0$)

$$v_g = \frac{1}{\hbar}\frac{\partial E_k}{\partial k} = \frac{1}{\hbar}\frac{\partial \sqrt{|\Delta|^2 + \xi_k^2}}{\partial k} = \frac{1}{\hbar}\frac{\xi_k}{E_k}\frac{\partial \xi_k}{\partial k} \approx \left(v_0^2 - u_0^2\right) v_F \tag{53}$$

The continuity of the wave functions at $x = 0$ gives

$$\begin{aligned} \frac{1 + r_N}{\sqrt{v_F}} &= \frac{A u_0 + B v_0}{\sqrt{v_g}} \\ \frac{r_A}{\sqrt{v_F}} &= \frac{A v_0 + B u_0}{\sqrt{v_g}} e^{-i\phi} \end{aligned} \tag{54}$$

For the derivatives we approximately put $|k_e| \approx |k_h| \approx \left|k_e^{(s)}\right| \approx \left|k_h^{(s)}\right| \approx k_F$. Then

$$\begin{aligned} \frac{1 - r_N}{\sqrt{v_F}} + \frac{2mH}{ik_F\hbar^2}\left[\frac{1 + r_N}{\sqrt{v_F}}\right] &= \frac{A u_0 - B v_0}{\sqrt{v_g}} \\ \frac{r_A}{\sqrt{v_F}} + \frac{2mH}{ik_F\hbar^2}\left[\frac{r_A}{\sqrt{v_F}}\right] &= \frac{A v_0 - B u_0}{\sqrt{v_g}} e^{-i\phi} \end{aligned} \tag{55}$$

```
expr = (1 + Z^2) Exp[I g] - Z^2 Exp[-I g];
Simplify[ComplexExpand@Abs@expr]
```

(??? Why do they have v^*, not v?)

S_1NS_2 Junction

Solution

(??? I'll add some question from Chang, Bagwell...)

Фйг-13.6. Maximal SC dot in normal metal

Рассмотреть гранулу очень малого размера a из сверхпроводящего металла. Найти (используя стандартную модель БКШ) оценку для величины a, при которой конечность размера гранулы начинает заметно влиять на условие для куперовской неустойчивости нормального металлического состояния.

Solution

(??? maybe it changes the Fermi energy? I have no idea, the whole BCS model does not take into account size of the material)

14.2.13 Ginzburg-Landau Formalism: Problems about phenomena [SEE COND MATT]

Б-3.4.5. Квантование потока

Комплексность сверхпроводящего параметра порядка $\psi = |\psi| \times \times \exp(i\theta)$ приводит к эффекту квантования магнитного потока в сверхпроводнике. Наряду с вектор-потенциалом $\mathbf{A}(\mathbf{r})$ градиент фазы $\nabla\theta$ также дает вклад в плотность сверхпроводящего тока:

$$\mathrm{j}_s = \frac{c}{4\pi\delta^2}\left(\frac{\hbar c}{2e}\nabla\theta - \mathbf{A}\right).$$

Доказать, что поток магнитного поля Φ через замкнутый контур C, на котором сверхпроводящий ток тождественно равен нулю $\mathbf{j}_s = 0$ и параметр порядка отличен от нуля $\psi \neq 0$, всегда кратен целому числу n квантов магнитного потока $\phi_0 = \pi\hbar c/e$. Найти пример простейшего вихревого состояния, несущего несколько квантов магнитного потока.

FOR PROBLEMS IN BELOUSOV SEE COND MATTER FOR NOW

Solution

(???)

Фйг-2.2. Квантование потока внутри тонкой пленки

Найти, как квантуется магнитный поток внутри тонкой ($d \ll \lambda$) сверхпроводящей пленки, нанесенной на поверхность цилиндрической нити радиуса $R \gg (d, \lambda)$.

Solution

(???)

Б-3.4.9. Тонкая пластина

Имеется тонкая пластина сверхпроводника первого рода с параметром Гинзбурга-Ландау $\varkappa \ll 1$ и толщиной D. Пластина находится во внешнем магнитном поле H_0, параллельном плоскостям пластины. Найти распределение сверхпроводящего тока и магнитного поля в пластине и определить критическое значение толщины пластины, при которой изменяется род фазового перехода в магнитном поле.

Solution

(???)

Б-3.4.10 Критический ток тонкой пленки

Определить критическую плотность сверхпроводящего тока j_s, который может протекать по тонкой пленке сверхпроводника толщиной d, много меньшей корреляционной длины ξ и глубины проникновения магнитного поля δ. Считать плотность сверхпроводящего тока однородной по сечению пленки.

Solution

(???)

FOR PROBLEMS IN BELOUSOV SEE COND MATTER FOR NOW

Б-3.4.6. Энергия в вихре и первое критическое поле

Для предельного сверхпроводника второго рода с параметром Гинзбурга-Ландау $\varkappa \gg 1$ найти:
а) энергию на единицу длины прямолинейного квантового вихря;
б) нижнее или первое критическое магнитное поле H_{c1}.

Solution

(???)

Б-3.4.7. Анизотропия верхнего критического поля

Коэффициент γ перед градиентным членом в разложении Гинзбурга-Ландау для свободной энергии сверхпроводящего кристалла должен отражать анизотропию направлений в кристалле и представляет собой тензор второго ранга $\gamma_{ij}(i,j = 1,2,3)$. В одноосном кристалле с тетрагональной или с гексагональной симметрией он равен

$$\gamma_{ij} = (\delta_{ij} - n_i n_j)\,\gamma_\perp + n_i n_j \gamma_\parallel,$$

где $\mathbf{n}$ - единичный вектор в направленин оси симметрин кристалла. (В кристаллах с кубической симметрией $\gamma_\perp = \gamma_\parallel$..) Рассмотреть анизотропию верхнего критического поля, т. е. зависимость поля H_{c2} от угла θ между осью симметрии кристалла $\mathbf{n}$ и направлением внешнего магнитного поля.

Solution

(???)

Б-3.4.8. Поверхностная сверхпроводимость

Параллельно плоской поверхности сверхпроводника приложено внешнее магнитное поле. Показать, что образование сверхпроводящей фазы начинается в приповерхностном слое сверхпроводника, и оценить соответствующее поверхностное критическое поле H_{c3}. Найти диапазон магнитных полей, в котором возможно явление поверхностной сверхпроводимости, заключающееся в наличии сверхпроводящей фазы в приповерхностном слое и ее отсутствии в объеме сверхпроводника.

FOR PROBLEMS IN BELOUSOV SEE COND MATTER FOR NOW

Б-3.4.11 эффект Литтла-Паркса

Определить период осцилляций температуры сверхпроводящего перехода тонкого полого цилиндра радиуса R и толщиной $d \ll \xi, \delta, R$ в зависимости от величины потока магнитного поля $\Phi = \pi R^2 H$, направленного вдоль оси цилиндра (эффект Литтла-Паркса).

Фйг-2.1. Эффект Литтла-Паркса

Найти зависимость T_c сверхпроводящего цилиндра с толщиной стенок d и радиусом $R \gg d \geq \xi_0$ от магнитного поля, направленного вдоль оси цилиндра (эффект Литтла-Паркса).

Б-3.4.12 Поверхностное натяжение in SN contact

Определить коэффициент поверхностного натяжения для границы между сверхпроводящей и нормальной фазами в сверхпроводнике первого рода с предельно малым параметром Гинзбурга-Ландау $\varkappa \ll 1$, когда можно пренебречь глубиной проникновения магнитного поля и считать, что магнитное поле не проникает в сверхпроводящую область.

Solution

(???)

FOR PROBLEMS IN BELOUSOV SEE COND MATTER FOR NOW

Б-3.4.13 Взаимодействие двух вихревых линий (!?!?!?!?)

Найти в сверхпроводнике второго рода с $\varkappa \gg 1$ энергию и силу взаимодействия двух параллельных вихревых линий, расположенных на расстоянии $r \gg \xi$ друг от друга. Показать, что квантованные вихри с одинаковым направлением циркуляции сверхпроводящего тока отталкиваются, а с противоположно направленными - притягиваются.

Б-3.4.14 Притяжение вихревой линии

Показать, что вихревая линия, параллельная поверхности сверхпроводника, притягивается к его поверхности. Определить силу притяжения.

Solution

(???)

Б-3.4.15. Фазовая диаграмма состояний в ферромагнитном сверхпроводнике

Металл с магнитными атомами, в котором могут сосуществовать и конкурировать два явления: сверхпроводимость и ферромагнетизм, можно назвать ферромагнитным сверхпроводником. Например, халькогениды $HoMo_6S_8, HoMo_6Se_8$ и борид $ErRh_4B_4$. Считая температуры сверхпроводящего перехода T_c и Кюри θ близкими, ферромагнитный сверхпроводник можно описать в рамках теории функционала Гинзбурга-Ландау с двумя взаимодействующими параметрами порядка: сверхпроводящим $\psi(\mathbf{r})$ и намагниченностью $\mathbf{M}(\mathbf{r})$, используя следующее разложение для плотности свободной энергии, отсчитанной от нормального состояния:

$$\Delta F = \alpha(T)|\psi|^2 + \frac{\beta}{2}|\psi|^4 + \frac{A(T)}{2}\mathbf{M}^2 + \frac{B}{4}\mathbf{M}^4 + G\mathbf{M}^2|\psi|^2$$

Константа взаимодействия $G > 0$, что соответствует подавлению сверхпроводимости при появлении ферромагнитного упорядочения. Коэффициенты разложения $\alpha(T) = \alpha_0\,(T - T_c)$ и $A(T) = A_0(T - \theta)$, а остальные не зависят от температуры. Для случая $T_c > \theta$ определить возможные фазы, найти род фазовых переходов и построить фазовую диаграмму состояний в зависимости от константы взаимодействия. Считать, что ферромагнитное состояние энергетически гораздо выгоднее, чем сверхпроводящее.

Solution

(???)

FOR PROBLEMS IN BELOUSOV SEE COND MATTER FOR NOW

Б-3.4.16 Антиферромагнитный геликоид

Пусть в изотропном ферромагнитном сверхпроводнике одновременно реализуются ферромагнитное и сверхпроводящее состояния. С учетом энергии магнитного поля величиной $\mathbf{h} = \operatorname{rot}\mathbf{A}$ и энергий

неоднородности функционал Гинзбурга-Ландау имеет вид

$$\Delta\mathcal{F} = \int d^3r \Delta F\left(\mathbf{M}(\mathbf{r}), \psi(\mathbf{r}), \psi^*(\mathbf{r}), \mathbf{A}(\mathbf{r})\right),$$

$$\Delta F = \frac{C_m}{2}(\nabla\mathbf{M})^2 + \frac{A(T)}{2}\mathbf{M}^2 + \frac{B}{4}\mathbf{M}^4 + \frac{(\mathbf{h}-4\pi\mathbf{M})^2}{8\pi} + \frac{\gamma}{2}\left|\left(-i\hbar\nabla - \frac{2e}{c}\mathbf{A}\right)\psi\right|^2 + \alpha(T)|\psi|^2 + \frac{\beta}{2}|\psi|^4 + G\mathbf{M}^2|\psi|^2.$$

При температурах заметно ниже точки Кюри θ и сверхпроводящего перехода T_c абсолютные величины вектора намагниченности $\mathbf{M}$ и сверхпроводящего параметра ψ можно считать фиксированными. Найти условие на коэффициент магнитной жесткости C_m, при котором однородное ферромагнитное упорядочение становится неустойчивым и возникает спин-спиральная фаза, в которой вектор намагниченности $\mathbf{M}$ равномерно поворачивается в плоскости, перпендикулярной выделенной оси при движении вдоль этой оси. Такая магнитная структура называется антиферромагнитным геликоидом. Определить период геликоида (шаг спирали) в зависимости от глубины проникновения магнитного поля δ. Возможность состояний с квантованными вихрями не рассматривать.

Solution

(???)

Б-3.4.17. Корреляции ψ

В нормальной фазе при температуре выше температуры сверхпроводящего перехода возможны флуктуации сверхпроводящего параметра порядка $\psi(\mathbf{r})$. Определить пространственную корреляционную функцию $\langle\psi(\mathbf{r})\psi^*(\mathbf{r}')\rangle$, пренебрегая членом четвертого порядка в функционале Гинзбурга-Ландау.

Solution

(???)

Б-3.4.18. Diamagnetic susceptibility of granules due to Cooper pairs

Возможность флуктуационного рождения сверхпроводящих куперовских пар в нормальной фазе при температуре выше температуры сверхпроводящего перехода T_c создает дополнительный вклад в диамагнитную восприимчивость металла. Вычислить флуктуационную поправку к диамагнитной восприимчивости во внешнем магнитном поле H при $T > T_c$ для нульмерного сверхпроводника (сферической гранулы малого радиуса: $R \ll \xi$ и $R \ll \delta$).

FOR PROBLEMS IN BELOUSOV SEE COND MATTER FOR NOW

Б-3.4.19. Размытие фазового перехода в 0D сверхпроводнике

В нульмерном сверхпроводнике - малой грануле с характерным размером $R \ll \xi(T)$ - найти поведение квадрата модуля сверхпроводящего параметра порядка $|\psi_0(T)|^2$ в области температур, близких к критической точке перехода T_c в объемном сверхпроводнике. Найти условие малости размытия фазового перехода, если объем гранулы V, а среднее расстояние между уровнями энергий вследствие размерного квантования равно $\delta\varepsilon$.

Фйг-2.3. Parallel critical field and thin film current

Найти параллельное критическое магнитное поле и критический ток для тонкой сверхпроводящей пленки (толщина $d \ll \lambda$).

Фйг-2.4. Change of transition temperature in a thin film

Пленка сверхпроводящего металла толщины d нанесена на толстый слой нормального металла. Граница S/N полностью прозрачна для электронов. Длина когерентности $\xi(T) = \xi_0\left(1 - T/T_{c0}\right)^{-1/2}$, причем $\xi_0 \ll d$. Найти сдвиг температуры перехода в зависимости от толщины d. Длину когерентости в нормальном металле ξ_n при $T \sim T_{c0}$ считать постоянной.

Фйг-2.5. Prove that $H_{c2}(T) > H_c(T)$

Показать, что при $\kappa > 1/\sqrt{2}$ неустойчивость нормального состояния по отношению к образованию сверхпроводящего параметра порядка наступает при поле $H_{c2}(T) > H_c(T)$.

14.2.14 Type II superconductors: Basic Problems 1

Фйг-3.1. Vortices in thin film

Найти зависимость плотности тока $j(r)$ на расстоянии r от центра вихря в тонкой пленке толщины $d \ll \lambda$, затем вычислить энергию такого вихря и энергию взаимодействия вихря и анти-вихря на расстоянии $r \gg \lambda$. Вычисления довести до конца в двух предельных случаях, $r \ll \lambda^2/d$ и $r \gg \lambda^2/d$.

Solution

(???)

(потом допишу, типичные хорошие вопросы)

1. Фазовым переходом какого рода является сверхпроводящий переход?

Answer:

2. Запишите выражение для спектра возбуждений $\varepsilon(p)$ в модели Бардина-Купера-Шриффера.

Answer:

3. Какова связь между энергетической щелью $\Delta(0)$ и критической температурой сверхпроводника T_c?

Answer:

4. Как зависит от константы взаимодействия λ энергетическая щель $\Delta(0)$ при нулевой температуре? Аналитична ли эта зависимость?

Answer:

5. Чему равна энергия связи куперовской пары при константе взаимодействия λ?

Answer:

6. Как связаны энергетическая щель Δ и концентрация сверхпроводящих электронов n_s?

Answer:

7. Как зависит от температуры энергетическая щель сверхпроводника $\Delta(T)$ вблизи точки перехода T_c?

Answer:

8. Как зависит от температуры T критический ток $j_c(T)$ сверхпроводника вблизи точки перехода T_c?

Answer:

9. Как зависит от температуры T критическое магнитное поле $\mathcal{H}_c(T)$ сверхпроводника вблизи точки перехода T_c?

Answer:

10. Как зависит от температуры T теплоемкость сверхпроводника $C_s(T)$ ниже точки перехода T_c?

Answer:

1. Запишите выражение для функционала Гинзбурга-Ландау Ω_s.

Answer:

2. Запишите уравнение Гинзбурга-Ландау для комплексного параметра порядка $\psi(\mathbf{r})$.

Answer:

3. Запишите уравнение Гинзбурга-Ландау для векторного потенциала $\mathcal{A}(\mathbf{r})$.

Answer:

4. Как зависит от температуры T корреляционная длина ξ вблизи точки перехода T_c? Чему равен размер куперовской пары?

Answer:

Как зависит от температуры T лондоновская глубина проникновения λ вблизи точки перехода T_c?

Answer:
(copy the well-known formulas)
(?? explain, why it is so by intuition and from what formulas this comes?)

6. Запишите выражение для плотности сверхпроводящего тока j_s.

Answer:

7. Запишите равенство, выражающее сущность эффекта Мейсснера.

Answer:

8. Запишите выражения для кванта магнитного потока Φ_0 и магнитного потока через полость сверхпроводника Ф.

Answer:

8. How many there are phonons at $T = 0$? Are they anough to couple all electrons near Fermi surface?

Answer:
There are zero phonons.
(??? why???)
They are not used for superconductivity because there, the virtual phonons are used.
(??? what are virtual phonons - I don't know, but there is paragraph about it in theory)

9. В каком соотношении находятся корреляционная длина ξ и лондоновская глубина проникновения магнитного поля λ для сверхпроводников II рода?

Answer:

10. Запишите оценочные выражения для верхнего $\mathcal{H}_{c2}$, нижнего $\mathcal{H}_{c1}$ и термодинамического $\mathcal{H}_c$ критических магнитных полей.

Answer:

11. Возможно ли проникновение в сверхпроводник нормального к поверхности магнитного поля?

Answer:
yes, this is the Meissner effect.

12. Возможно ли проникновение в сверхпроводник электрического поля?

Answer:
depends on dielectric properties (???)

14.3.2 Questions about Understanding Basics 2

(maybe I'll add reminders before answers for people not to look for some basics if they forgot the answer)

2. Какой эксперимент, основанный на использовании внешнего магнитного поля, позволяет отличить сверхпроводник от гипотетического идеального проводника (с $R = 0$)?

Answer:

3. Какие классы веществ, проявляющие SC свойства, известны на данный момент?

Answer:

4. Нарисуйте типичную для SC зависимость $R(T)$. Три способа определения критической T_c.

Answer:

5. Нарисуйте зависимости $H_c(T)$ и $n_s(T)$. Какими формулами они приближенно описываются?

Answer:

6. Переходом какого рода является переход в SC состояние?

Answer:

7. Каков физический смысл параметров сверхпроводящего состояния Δ_0 и ξ?

Answer:

Write the London equations. What is the physical meaning of λ_L? How are j_c and $H_c(0)$ related?

Answer:
(??? are these questions related?)

What is the radius of the core of the apricot vortex? What is the energy of a single apricot vortex and what does it consist of?

(maybe I'll add reminder here for people not to look for some basics if they forgot the answer)

Answer:

Question about basic properties of SC

10. В чём заключается и что однозначно доказывает изотопический эффект у SC?

Answer:

11. What is the energy ratio that describes the so-called "quasi-classical approximation" in BCS?

Answer:

ACTUALLY, IT IS A GOOD IDEA TO CREATE QUESTIONS LIKE "WHAT IS (SOMETHING)", and this something is not explained in the theory, but it is easily restored by the common sense, if one knows the theory!!!

I'll add some these questions later.

12. Как меняется вид зависимости плотности электронных состояний от энергии $N(E)$ и спектр возбуждений носителей $E(p)$ при переходе металл - SC (при $T \to 0$)? Какие формулы описывают их в рамках теории БКШ?

Answer:

13. Как вводятся константы электрон-фононного взаимодействия λ и кулоновского отталкивания μ^*? В чём заключается перенормировка λ в приближении сильной связи?

Answer:

14. Какое выражение для SC щели Δ_0 даёт теория БКШ (в пределе слабой связи)? Нарисуйте типичные зависимости $\Delta_0(\lambda)$ и $\Delta(T)$.

Answer:

15. Какое выражение для $T_\mathbf{c}$ даёт теория Элиашберга (в случае сильной эл.-фононной связи)?

Answer:

16. Как SC щель Δ_0 соотносится с такими физическими величинами как $T_\mathrm{c}, \xi_0, v_\mathrm{c}, j_\mathrm{c}, H_\mathrm{c}$?

Answer:

Question about zero gap

The gap equation $\Delta = \lambda \sum'_{\mathbf{p}'} u_p v_p \Big(-\bar{n}_\mathbf{p} + (1-\bar{n}_\mathbf{p}) \Big) = \lambda \sum'_{\mathbf{p}'} \frac{\Delta}{2\sqrt{\xi_p^2+\Delta^2}} (1-2\bar{n}_\mathbf{p})$ has two solutions, one is the $\Delta = 0$ and another is the well-known, which depends on the temperature. Why do we say that there is a superconductivity? Why the solution of $\Delta = 0$ is not good?

Answer:
The point is that the superconductor will be in a state with lower energy. Ans the ground state of $\Delta = 0$ has more energy then with $\Delta \neq 0$.
(I'll add later also formulas from the theory about the energy of the ground state)
Fun fact: In nonequilibrium this argument does not work since the energy of the superconductor is not conserved: it interacts with the external system creating the nonequilibrium.
(??? how to answer this question - see Stability of nonequilibrium Fermi distributions with respect to Cooper pairing by A. G. Aronov and V. L. Gurevich, I'll write later)

What is the energy density of Bose-Einstein condensation?

(maybe I'll add reminder here for people not to look for some basics if they forgot the answer)

Answer:
(??? I don't know. Is it related to SC?)

Question about basic properties of SC

Draw typical dependences of thermal conductivity $\varkappa$ and heat capacity C on temperature. What is the relative magnitude of the heat capacity jump?

Answer:
so, heat capacity has a jump and it is known.
thermal conductivity - (??? no, I should study it better)

Question about basic properties of theories of SC

What is a characteristic relation in BCS theory and the Ginzburg-Levanyuk criterion?

Answer:
characteristic relation
Ginzburg-Levanyuk - see theory, some relation, I'll write later

14.3.3 Questions about Understanding Basics 3

me. What is the analog between 2D potential well and BCS theory?

Answer:
(write here explicitly, what is in one case and what is in another and compare)

me. Why do we write BCS theory in Fourier space?

Answer:
(discuss second quantization, the same idea is everywhere, right? (????))

me. Averaging in BCS

Show that $\langle a_{q\downarrow} a_{-q\uparrow} \rangle$ is nonzero.

Solution

$$\langle a_{q\downarrow} a_{-q\uparrow} \rangle \sim \mathrm{tr} a_{q\downarrow} a_{-q\uparrow} e^{-\beta(\sum\limits_{\mathbf{p}\sigma} \xi_{\mathbf{p}} \hat{a}^\dagger_{\mathbf{p}\sigma} \hat{a}_{\mathbf{p}\sigma} + \frac{1}{\lambda}|\Delta|^2 + \sum\limits_{\mathbf{p}} [\Delta^* \hat{a}_{\mathbf{p}+} \hat{a}_{-\mathbf{p}-} + \Delta \hat{a}^\dagger_{-\mathbf{p}-} \hat{a}^\dagger_{\mathbf{p}+}])} \sim$$
$$\sim \mathrm{tr} a_{q\downarrow} a_{-q\uparrow} e^{-\beta \sum\limits_{\mathbf{p}} [\Delta^* \hat{a}_{\mathbf{p}+} \hat{a}_{-\mathbf{p}-}]} = ???$$

(????)

20. Как связаны параметры порядка теории БКШ и теории Гинзбурга - Ландау?

Answer:
(add that formula)

21. Как связаны λ_{GL} и H_{cl1} в теории Гинзбурга-Ландау? Как λ_{GL} зависит от длины свободного пробега и температуры?

Answer:

22. Как связаны $\xi_{\mathbf{gL}}$ и H_{c2} в теории Гинзбурга - Ландау? Как $\xi_{\mathbf{gL}}$ зависит от длины свободного пробега и температуры?

Answer:

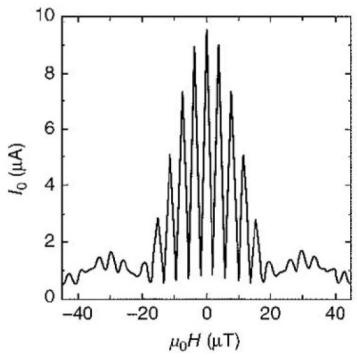
23. Как связаны критические магнитные поля H_c, H_{cI} и H_{c2} друг с другом и с $\lambda_{\mathrm{GL}}, \xi_{\mathrm{GL}}$?

Answer:

24. Напишите уравнения Джозефсона, а также соотношение Амбегаокара и Баратова.

Answer:

25. Чему равен коэффициент пропорциональности между частотой и смещением в SISконтакте? Как предельная частота сверхтока зависит от величины SC щели Δ_0?



Answer:

14.3.4 Questions about Understanding Typical Phenomena 1

(discuss easy experiment and ask to explain it)

KUL-lect.joseph.eff Diffraction and interference in a YBaCuO SQUID structure (???)

We see results of (??? some experiment)

Can you explain the observed oscillations? Can you estimate the ratio ASQUID /AJJ?

Solution (????)

(don't know yet....)

14.3.5 Questions about Understanding Typical Phenomena 2

(discuss easy experiment and ask to explain it)

14.3.6 Questions about Understanding Special Models

(потом добавлю, книги по ним написаны, выделю хотя бы какие-то известные потом)

14.3.7 Problems about Understanding Special Effects

(есть куча статей, просто от туда беру графики, спрашиваю почему так? пока теор. части додумывать нужно, потом займусь сборкой этих задач.)

14.3.8 Hypothetical questions about сверхпроводниках

(из курса Фейгальмана скорее всего много вопросов можно найти.)

Когда могут быть кванты потока более чем 1? (????)

(хз, там какя-то умная теория на это.)

Когда могут быть решетки абрикосова не треугольные? (????)

(хз, там какя-то умная теория на это.)

Когда могут быть не s-спаривания? (????)

(хз, там какя-то умная теория на это.)

Когда могут быть? (????)

(хз, там какя-то умная теория на это.)

Когда могут быть? (????)

(хз, там какя-то умная теория на это.)

Когда могут быть? (????)

(хз, там какя-то умная теория на это.)

14.4 Other Questions about Superconductivity

14.4.1 Questions about what is exactly going on in BCS?

All these questions are discussed in detail in theory, but I'll collect them also here to have a nice "FAQ" section.

What is a Cooper pair operator?

Is, for example, is $c^\dagger_{p,+}c^\dagger_{-p,p}$ (where $c^\dagger$ is an electron creation operator) a Cooper pair operator?
Answer:
(?????)
This operator creates two excitations, however, a Cooper pair is in the ground state, so it is not an excitation, so my answer is that no, it is not a Cooper pair operator.
(??? TODO: write theory about it better, then write here how the real one looks like)

15 Problems about specific phenomena and properties

15.1 Problems about Special Useful Methods

15.1.1 Problems about GF Special Methods for SC 1

me. the Heisenberg equations for the discrete model

Here we will derive the Heisenberg equations for the Nambu fields $C_{n,j}$ and D.

Solution

We will use $i\frac{d}{dt}C_{n,ja}(t) = [C_{n,ja}(t), H_{\rm tot}]$ and we will change the names of inner indices $j \to p, n \to k, n' \to l$, we compute:

$$[C_{nja}, H_D] = \frac{1}{2}\left(C_{nja}D^\dagger_b h^{bc}_D D_c - D^\dagger_b h^{bc}_D D_c C_{nja} = C_{nja}D^\dagger_b h^{bc}_D D_c - (-1)^2 D^\dagger_b h^{bc}_D D_c C_{nja}\right) = 0;$$

$$[C_{n,ja}, H_{SC}] = \frac{1}{2}\left[C_{n,ja}\sum_{p,k,l} C^\dagger_{k,pb}\,[h^{k,l}_{SC,p}]^{bc}\,C_{l,pc} - \sum_{p,k,l} C^\dagger_{k,pb}\,[h^{k,l}_{SC,p}]^{bc}\,C_{l,pc}C_{n,ja}\right] =$$

$$= \tfrac{1}{2}\left[\textstyle\sum_{p,k,l}(-C^\dagger_{k,pb}C_{n,ja} + \delta_{kn}\delta_{pj}\delta_{ab})\,[h^{k,l}_{SC,p}]^{bc}\,C_{l,pc} - \sum_{p,k,l}\underbrace{C^\dagger_{k,pb}}_{=C_{k,pr}P_{rb}}\,[h^{k,l}_{SC,p}]^{bc}\,(P_{ac}\delta_{jp}\delta_{nl} - C_{n,ja}C_{l,pc})\right] =$$

$$= \tfrac{1}{2}\Big[-\sum_{p,k,l} C^\dagger_{k,pb}C_{n,ja}\,[h^{k,l}_{SC,p}]^{bc}\,C_{l,pc} + \sum_l [h^{n,l}_{SC,j}]^{ac}\,C_{l,jc} - \sum_k C_{k,jr}\underbrace{P_{rb}\,[h^{k,n}_{SC,j}]^{bc}\,P_{ac}}_{=-[h^{k,n}_{SC,j}]^{ra*}=-[h^{k,n}_{SC,j}]^{ar}} + \sum_{p,k,l} C^\dagger_{k,pb}\,[h^{k,l}_{SC,p}]^{bc}\,C_{n,ja}C_{l,pc}\Big] =$$

$$= \sum_l [h^{n,l}_{SC,j}]^{ac}\,C_{l,jc} = \Big[\sum_l [h^{n,l}_{SC,j}]\,C_{l,j}\Big]_a.$$

Let us remind, that here each $h^{k,l}_{SC,p}$ operator is a matrix of 4×4 dimensions, so two extra indices mean taking the row's and column's element. At the last step of the transformation we notice that the first and the fourth terms are the same but with different sign.

$$[C_{n,ja}, H_T] = -\tfrac{1}{2}\Big[C_{n,ja}\sum_{p=1} t'_p C^\dagger_{1,pb}\tau^{bc}_z D_c + C_{n,ja}\sum_{p=1} t'_p D^\dagger_b \tau^{bc}_z C_{1,pc} - \sum_{p=1} t'_p C^\dagger_{1,pb}\tau^{bc}_z D_c C_{n,ja} - \sum_{p=1} t'_p D^\dagger_b \tau^{bc}_z C_{1,pc}C_{n,ja}\Big] =$$

$$= -\frac{1}{2}\Big[\sum_{p=1} t'_p(-C^\dagger_{1,pb}C_{n,ja} + \delta_{n,1}\delta_{pj}\delta_{ab})\tau^{bc}_z D_c + \sum_{p=1} t'_p(-D^\dagger_b C_{n,ja})\tau^{bc}_z C_{1,pc} -$$

$$- \sum_{p=1} t'_p C^\dagger_{1,pb}\tau^{bc}_z \underbrace{D_c C_{n,ja}}_{=-C_{n,ja}D_c} - \sum_{p=1} t'_p \underbrace{D^\dagger_b}_{=D_d P_{db}}\tau^{bc}_z C_{1,pc}C_{n,ja}\Big] =$$

$$= -\frac{1}{2}\Big[t'_j\delta_{n,1}\tau^{ac}_z D_c - \sum_{p=1} t'_p D_d \underbrace{P_{db}\tau^{bc}_z P_{ca}}_{-\tau^{da}_z}\delta_{n1}\delta_{pj}\Big] =$$

$$= [-\delta_{n,1}\ t'_j\ \tau_z\ D]_a.$$

After restoring t-dependence and summing terms, we have

$$i\frac{d}{dt}C_{nj}(t) = \sum_l\ h^{n,l}_{SC,j}\ C_{l,j}(t) - \delta_{n,1}\ t'_j\ \tau_z\ D(t).$$

And this is the (**??**) The Eq. (**??**) is derived by exactly the same approach.

me. the Dyson equation for Green's functions for the discrete model

The Dyson equation for $[G^{0,0}_{0,0}(t)]_{a,b} := -i\Theta(t)\langle\{D_a(t),\ D^\dagger_b(0)\}\rangle$ is derived as follows.

Solution

We evaluate:

$$
\begin{aligned}
i\frac{d}{dt}[G^{0,0}_{0,0}(t)]_{a,b} = & \underbrace{\delta(t)\langle\{D_a(t),\ D^\dagger_b(0)\}\rangle}_{=\delta(t)\langle\{D_a(0),\ D^\dagger_b(0)\}\rangle=\delta_{ab}\delta(t)} - i\Theta(t)\langle\{i\frac{dD_a(t)}{dt},\ D^\dagger_b(0)\}\rangle \\
&= \delta(t)\delta_{ab} - i\Theta(t)\langle\{h^{ac}_D D_c(t),\ D^\dagger_b(0)\}\rangle - i\Theta(t)\langle\{\sum_{j=1}(-1)t'_j\tau^{ac}_z C_{1,jc}(t),\ D^\dagger_b(0)\}\rangle = \\
&= \delta(t)\delta_{ab} - i\Theta(t)h^{ac}_D\underbrace{\langle\{D_c(t),\ D^\dagger_b(0)\}\rangle}_{=[G^{0,0}_{0,0}(t)]_{a,b}} - \sum_{j=1}t'_j\tau^{ac}_z\underbrace{(-i)\Theta(t)\langle\{C_{1,jc}(t),\ D^\dagger_b(0)\}\rangle}_{=[G^{j,0}_{1,0}(t)]_{cb}}.
\end{aligned}
$$

Thus, in the matrix form we will get

$$
\left(i\frac{d}{dt} - h_D\right)G^{0,0}_{0,0}(t) + \sum_{j=1}t'_j\tau_z G^{j,0}_{1,0}(t) = \delta(t)
$$

Now, to use transformation $F[f](z) := \int_0^\infty dt e^{izt}f(t)$, the formulas below are used:

$$
\begin{aligned}
F[i\frac{d}{dt}[G^{0,0}_{0,0}(t)]_{a,b}](z) &= \int_0^\infty dt e^{izt} i\frac{d}{dt}[G^{0,0}_{0,0}(t)]_{a,b} = \\
&= ie^{izt}[G^{0,0}_{0,0}(t)]_{a,b}|^\infty_0 - i\cdot iz\int_0^\infty dt e^{izt}[G^{0,0}_{0,0}(t)]_{a,b} = z[G^{0,0}_{0,0}(z)]_{a,b}, \\
F[h_D[G^{0,0}_{0,0}(t)]_{a,b}](z) &= h_D[G^{0,0}_{0,0}(z)]_{a,b}, \\
F[\sum_{j=1}t'_j\tau_z[G^{j,0}_{1,0}(t)]_{ab}](z) &= \sum_{j=1}t'_j\tau_z[G^{j,0}_{1,0}(z)]_{ab}. \\
F[\delta(t)](z) &= 1,
\end{aligned}
$$

and we will have:

$$
[z - h_D]G^{0,0}_{0,0}(\omega) + \sum_{j=1}^{N}t'_j\tau_z G^{j,0}_{1,0}(\omega) = 1,
$$

Now, we will derive the Dyson eq. for $[G^{j,j'}_{n,n'}(t)]_{a,b} := -i\Theta(t)\langle\{C_{n,j,a}(t),\ C^\dagger_{n',j',b}(0)\}\rangle$, we evaluate:

$$
\begin{aligned}
i\frac{d}{dt}[G^{j,j'}_{n,n'}(t)]_{a,b} &= \delta(t)\underbrace{\langle\{C_{n,j,a}(t),\ C^\dagger_{n',j',b}(0)\}\rangle}_{=\delta_{nn'}\delta_{jj'}\delta_{ab}} - i\Theta(t)\langle\{i\frac{dC_{n,j,a}(t)}{dt},\ C^\dagger_{n',j',b}(0)\}\rangle = \\
&= \delta(t)\delta_{nn'}\delta_{jj'}\delta_{ab} + \textstyle\sum_l(-i\Theta(t))\langle\{[h^{n,l}_{SC,j}]^{ad}\ C_{l,jd}(t), C^\dagger_{n',j',b}(0)\}\rangle - (-i\Theta(t))\langle\{\delta_{n,1}t'_j\tau^{ad}_z D_d(t), C^\dagger_{n',j',b}(0)\}\rangle = \\
&= \delta(t)\delta_{nn'}\delta_{jj'}\delta_{ab} + \textstyle\sum_l[h^{n,l}_{SC,j}]^{ad}\ \underbrace{(-i\Theta(t))\langle\{C_{l,jd}(t), C^\dagger_{n',j',b}(0)\}\rangle}_{=[G^{j,j'}_{l,n'}]_{db}} - \delta_{n,1}t'_j\tau^{ad}_z\underbrace{(-i\Theta(t))\langle\{D_d(t), C^\dagger_{n',j',b}(0)\}\rangle}_{=[G^{0,j'}_{0,n'}]_{db}}.
\end{aligned}
$$

Also, $i\frac{d}{dt}[G^{j,j'}_{n,n'}(t)]_{a,b} \equiv \sum_l i\frac{d}{dt}[G^{j,j'}_{l,n'}(t)]_{a,b}\delta_{l,n}$, thus in matrix notation we will have:

$$
\sum_l i\frac{d}{dt}G^{j,j'}_{l,n'}(t)\delta_{l,n} = \delta(t)\delta_{nn'}\delta_{jj'}\delta_{ab} + \sum_l h^{n,l}_{SC,j}\ G^{j,j'}_{l,n'} - \delta_{n,1}t'_j\tau_z G^{0,j'}_{0,n'} \tag{15.1}
$$

$$
\sum_l\left[i\delta_{l,n}\frac{d}{dt} - h^{n,l}_{SC,j}\right]G^{j,j'}_{l,n'} + \delta_{n,1}t'_j\tau_z G^{0,j'}_{0,n'} = \delta(t)\delta_{nn'}\delta_{jj'}. \tag{15.2}
$$

The Fourier transform is done exactly as for the example above.

The other two Dyson equations (**??**) can be derived the same way.

me. $G^{j,0}_{n,0}(\omega)$ in terms of $-g^{j}_{n,1}(\omega)$

Solution

We define $g^{j}_{n'',n'}(\omega)$ as a solution of

$$\sum_{n''}[z\delta_{n,n''} - h^{n,n''}_{SC,j}]g^{j}_{n'',n'}(\omega) = \delta_{n,n'}. \tag{15.3}$$

To work with the it we need to understand this equation well. Here only n, n' are external indices, we can treat them as a matrix indices and imagine l.h.s. as a product of a matrix $[z - h_{SC,j}]$ and a vector-column $g^{j}(\omega)$, and the r.h.s. as the identity matrix. Thus, in this notation, $g^{j}(\omega) = [z - h_{SC,j}]^{-1}$ and has a type of a matrix (or in index notation $[g^{j}(\omega)]_{n,n''} = g^{j}_{n,n''}(\omega) = \left[[z - h_{SC,j}]^{-1}\right]_{n,n'}$). Another important feature of $g^{j}_{n'',n'}(\omega)$ is that it doesn't have same number of indices as $G^{j,j'}_{n'',n'}(\omega)$. This is because it describes only two pints (n and n') in j-th SC lead. Now, the Eq. (**??**) can be transformed as

$$\sum_{n''}[z\delta_{n,n''} - h^{n,n''}_{SC,j}]G^{j,0}_{n'',0}(\omega) = -\delta_{n,1}t'_j\tau_z G^{0,0}_{0,0}(\omega), \tag{15.4}$$

$$\sum_{n} g^{j}_{n',n}(\omega)\cdot\sum_{n''}\left[z\delta_{n,n''} - h^{n,n''}_{SC,j}\right]G^{j,0}_{n'',0}(\omega) = -\sum_{n} g^{j}_{n',n}(\omega)\ \delta_{n,1}\ t'_j\ \tau_z G^{0,0}_{0,0}(\omega) \tag{15.5}$$

$$\sum_{n''}\sum_{n}\left[z\delta_{n,n''} - h^{n,n''}_{SC,j}\right]g^{j}_{n',n}(\omega)G^{j,0}_{n'',0}(\omega) = -\sum_{n} g^{j}_{n',n}(\omega)\cdot\ \delta_{n,1}\ t'_j\ \tau_z G^{0,0}_{0,0}(\omega) \tag{15.6}$$

$$\sum_{n''}\delta_{n',n''}G^{j,0}_{n'',0}(\omega) = -\sum_{n} g^{j}_{n',n}(\omega)\ \delta_{n,1}\ t'_j\ \tau_z G^{0,0}_{0,0}(\omega) \tag{15.7}$$

$$G^{j,0}_{n',0}(\omega) = -g^{j}_{n',1}(\omega)t'_j\tau_z G^{0,0}_{0,0}(\omega) \tag{15.8}$$

$$G^{j,0}_{n,0}(\omega) = -g^{j}_{n,1}(\omega)t'_j\tau_z G^{0,0}_{0,0}(\omega), \quad j \neq 0. \tag{15.9}$$

At the second line we multiplied the whole sum (with fixed n) by $g^{j}_{n',n}(\omega)$ (with some unknown fixed n') and then summed all possible l.h.s. and r.h.s. over all n. Thus the (**??**) is proven.

me. Boundary Green's function $g^{j}_{1,1}$ for discrete model

The BGF approach proposes the calculation of the GF of 1D superconductor near its end by the following formula

$$G_{1,1} = G^{(0)}_0 - G^{(0)}_1[G^{(0)}_0]^{-1}G^{(0)}_{-1}, \tag{15.10}$$

where the translationally invariant SC GF is

$$G^{(0)}_{n-n'}(z) := \int_{-\pi}^{\pi}\frac{dk}{2\pi}\frac{e^{ik(n-n')}}{z - (-2t\cos k - \mu)\tau_z - \Delta_j\left[e^{i\varphi_j}\tau_+ + e^{-i\varphi_j}\tau_-\right]}. \tag{15.11}$$

Solution

(???? write what is going on???)

Here compared to main theory we have a basis of plane waves $|\psi\rangle = \frac{e^{ikn}}{\sqrt{2\pi}}$. For only this calculation we will introduce $\bar{\mathbf{\Delta}} := \Delta_j\left[e^{i\varphi_j}\tau_+ + e^{-i\varphi_j}\tau_-\right]$ to make formulas shorter. Considering this integral in the wide-band limit $t \gg \Delta_j$, we approximate it by linearizing near the Fermi points $\mu = 0$, $k = \pm\frac{\pi}{2}$:

$$G^{(0)}_{n-n'}(z) \approx e^{i\frac{\pi}{2}(n-n')}\int_{-\infty}^{\infty}\frac{dq}{2\pi}\frac{e^{iq(n-n')}}{z - 2tq\tau_z - \bar{\mathbf{\Delta}}} + e^{-i\frac{\pi}{2}(n-n')}\int_{-\infty}^{\infty}\frac{dq}{2\pi}\frac{e^{iq(n-n')}}{z + 2tq\tau_z - \bar{\mathbf{\Delta}}}. \tag{15.12}$$

We are interested in

$$G^{(0)}_0(z) \approx \frac{1}{t}\int_{-\infty}^{\infty}\frac{d\bar{q}}{2\pi}\frac{z + \bar{\mathbf{\Delta}}}{z^2 - \bar{q}^2 - \Delta_j^2} = -\frac{1}{t}\int_{-\infty}^{\infty}\frac{d\bar{q}}{2\pi}\frac{z + \bar{\mathbf{\Delta}}}{(\bar{q} - k_+)(\bar{q} - k_-)}; \qquad k_\pm(z) := \pm z\sqrt{1 - \frac{\Delta_0^2}{z^2}}. \tag{15.13}$$

The inversion is done the same way like in the main derivation. Closing the integration contour in the upper half-plane, we obtain

$$G_0^{(0)}(z) \approx -\frac{i}{2t}\frac{z+\bar{\mathbf{\Delta}}}{k_+} = -\frac{i}{2t}\frac{1+\frac{\bar{\mathbf{\Delta}}}{z}}{\sqrt{1-\frac{\Delta_j^2}{z^2}}}; \qquad [G_0^{(0)}(z)]^{-1} = 2ti\frac{1-\frac{\bar{\mathbf{\Delta}}}{z}}{\sqrt{1-\frac{\Delta_j^2}{z^2}}}. \tag{15.14}$$

Analogously,

$$G_1^{(0)}(z) \approx \frac{i\tau_z}{t}\int_{-\infty}^{\infty}\frac{d\bar{q}}{2\pi}\frac{\bar{q}e^{i\frac{\bar{q}}{2t}}}{z^2-\bar{q}^2-\Delta_j^2} = -\frac{i\tau_z}{t}\int_{-\infty}^{\infty}\frac{d\bar{q}}{2\pi}\frac{\bar{q}e^{i\frac{\bar{q}}{2t}}}{(\bar{q}-k_+)(\bar{q}-k_-)} \approx \frac{\tau_z}{2t}; \tag{15.15}$$

$$G_{-1}^{(0)}(z) \approx -\frac{i\tau_z}{t}\int_{-\infty}^{\infty}\frac{d\bar{q}}{2\pi}\frac{\bar{q}e^{-i\frac{\bar{q}}{2t}}}{z^2-\bar{q}^2-\Delta_j^2} = G_1^{(0)}(z), \tag{15.16}$$

where the last equality is obtained by re-defining the integration variable $\bar{q} \to -\bar{q}$. Collecting together all the contribution, we have

$$G_{1,1} = -\frac{i}{2t}\frac{1+\frac{\bar{\mathbf{\Delta}}}{z}}{\sqrt{1-\frac{\Delta_j^2}{z^2}}} - \frac{\tau_z}{2t}2ti\frac{1-\frac{\bar{\mathbf{\Delta}}}{z}}{\sqrt{1-\frac{\Delta_j^2}{z^2}}}\frac{\tau_z}{2t} = -\frac{i}{t}\frac{1+\frac{1}{z}\Delta_j\left[e^{i\varphi_j}\tau_+ + e^{-i\varphi_j}\tau_-\right]}{\sqrt{1-\frac{\Delta_j^2}{z^2}}}. \tag{15.17}$$

And this is the same result (**??**).

15.1.2 Problems about GF Special Methods for SC 1

me.* Density ABS for multiterminal QD junction

Here we will derive the DOS for the QD model (**??**).
(!!! write arguments, why one expects this formula!!!)
Hint:
(write useful math formulas for it!!)

Solution

(!!! more background is required for this derivation!!!!)
This is a complicated derivation.
The density of states $\rho(\omega) = \int \delta(\omega - E_s)$ can be obtained by the fundamental relation (**??**), which for our discrete model looks like:

$$\rho(\omega) = -\frac{1}{\pi}\sum_{\forall m}\text{Im tr}\,\widehat{G}_{m,m}(\omega+i\eta). \tag{15.18}$$

Here the trace is taken over the spin and particle-hole indices, and $\widehat{G}_{m,m'}(\omega+i\eta)$ is the full retarded ($z=\omega+i\eta$) Green's function of the system. In another words, in this notation we consider m and m' as all allowed points in our "sun-junction" **??**, so

$$\rho(\omega) = -\frac{1}{\pi}\text{Im tr}G_{0,0}^{0,0}(\omega+i\eta) - \frac{1}{\pi}\sum_{j=1}^{N}\sum_{n=1}^{\infty}\text{Im tr}G_{n,n}^{j,j}(\omega+i\eta). \tag{15.19}$$

To calculate it, we continue to exploit the Dyson equations (**??**), (**??**),(**??**) and (**??**). From them we have

$$G_{n,n'}^{j,j'}(\omega) = g_{n,n'}^{j}(\omega)\delta_{j,j'} - t'_j g_{n,1}^{j}(\omega)\tau_z G_{0,n'}^{0,j'}(\omega), \tag{15.20}$$

$$G_{0,n'}^{0,j'}(\omega) = -\,g_D(\omega)\sum_{j''=1}^{N} t'_{j''}\tau_z G_{1,n'}^{j'',j'}(\omega), \tag{15.21}$$

where the dot's GF is defined as a solution of

$$[z-h_D]g_D(\omega) = 1. \tag{15.22}$$

Derivation of (15.20) is easily done by looking at l.h.s. of (**??**) as on matrix equation and by inverting matrices. Together these equations give

$$G^{j,j'}_{n,n'}(\omega) = g^{j}_{n,n'}(\omega)\delta_{j,j'} + \sum_{j''=1}^{N} t'_j t'_{j''} g^{j}_{n,1}(\omega)\tau_z g_D(\omega)\tau_z G^{j'',j'}_{1,n'}(\omega). \tag{15.23}$$

From this, we find by setting $n = 1$ that

$$G^{j,j'}_{1,n'}(\omega) = g^{j}_{1,n'}(\omega)\delta_{j,j'} + \sum_{j''=1}^{N} g^{j}_{1,1}(\omega)\cdot t'_j t'_{j''}\tau_z g_D(\omega)\tau_z \cdot G^{j'',j'}_{1,n'}(\omega). \tag{15.24}$$

Now, we switch to the fully matrix notation. We define the block matrices

$$\hat{g}_{j,j'}(n,n') := g^{j}_{n,n'}(\omega)\delta_{j,j'}, \qquad \hat{t}_{j,j''} := t'_j t'_{j''}\tau_z g_D(\omega)\tau_z, \qquad \hat{G}_{j,j'}(n,n') := G^{j,j'}_{n,n'}(\omega). \tag{15.25}$$

We think about arguments in brackets as indices of the matrix, that is determined by each j and each j'. The sum in (15.24) is a tensor contraction by index j'', thus in matrix notation it is a multiplication of a matrix to the hatted $\hat{G}$. Thus we write a solution as

$$\hat{G}(1,n') = (1-\hat{g}(1,1)\hat{t})^{-1}\hat{g}(1,n'), \tag{15.26}$$

This formula in matrix notation gives the GF from (15.20) as

$$\hat{G}(n,n') = \hat{g}(n,n') + \hat{g}(n,1)\hat{t}(1-\hat{g}(1,1)\hat{t})^{-1}\hat{g}(1,n'). \tag{15.27}$$

Now we are ready to compute the DOS. We substitute the known already (**??**) and the $\hat{G}(n,n')$ and transform:

$$\begin{aligned}
\rho(\omega) =& -\frac{1}{\pi}\mathrm{Im}\,\mathrm{tr}[z - h_D - \Sigma(\omega)]^{-1} - \frac{1}{\pi}\sum_{n=1}^{\infty}\mathrm{Im}\,\mathrm{Tr}\hat{G}(n,n) = \\
=& \rho^{(0)}_{SC}(\omega) - \frac{1}{\pi}\mathrm{Im}\,\mathrm{tr}[z - h_D - \Sigma(\omega)]^{-1} - \frac{1}{\pi}\mathrm{Im}\,\mathrm{Tr}\left[\hat{t}(1-\hat{g}(1,1)\hat{t})^{-1}\sum_{n=1}^{\infty}\hat{g}(1,n)\hat{g}(n,1)\right] = \\
=& \rho^{(0)}_{SC}(\omega) - \frac{1}{\pi}\mathrm{Im}\,\mathrm{tr}[g_D^{-1}(\omega) - \Sigma(\omega)]^{-1} + \frac{1}{\pi}\mathrm{Im}\,\mathrm{Tr}\left[\hat{t}(1-\hat{g}(1,1)\hat{t})^{-1}\frac{\partial\hat{g}(1,1)}{\partial\omega}\right].
\end{aligned} \tag{15.28}$$

Here we have used the widely-known for GF specialists identity $\sum_{n=1}^{N} G_{1,n}G_{n,1} = -\frac{\partial G_{1,1}}{\partial\omega}$ (see[**?**]). Now we do the final transformation. We define $\mathcal{T}_j := t'_j\tau_z$ and rewrite

$$\hat{t} \equiv \mathcal{T} g_D(\omega)\mathcal{T}^T. \tag{15.29}$$

Now indices of $\hat{t}$ are distributed between $\mathcal{T}_j$ matrices. The sign "transpose" makes the column-vector $\mathcal{T}_j$ a row, such that by indices j, j'' we have a number (1×1 object). Now, by applying Woodbury matrix identity

$$(A+UCV)^{-1} = A^{-1} - A^{-1}U\left(C^{-1} + VA^{-1}U\right)^{-1}VA^{-1}$$

and identifying $\Sigma(\omega) := \mathcal{T}^T\hat{g}(1,1)\mathcal{T}$ (in the previous notation the definition looked like $\Sigma(\omega) := \sum_{j=1}^{N}\left(t'_j\right)^2\tau_z g^{j}_{1,1}(\omega)\tau_z$) the multiplier under trace will be

$$\begin{aligned}
(1-\hat{g}(1,1)\mathcal{T}g_D(\omega)\mathcal{T}^T)^{-1} &= (\hat{g}^{-1}(1,1) - \mathcal{T}g_D(\omega)\mathcal{T}^T)^{-1}\hat{g}^{-1}(1,1) = \\
&= 1 + \hat{g}(1,1)\mathcal{T}(g_D^{-1}(\omega) - \mathcal{T}^T\hat{g}(1,1)\mathcal{T})^{-1}\mathcal{T}^T = \\
&= 1 + \hat{g}(1,1)\mathcal{T}(g_D^{-1}(\omega) - \Sigma(\omega))^{-1}\mathcal{T}^T.
\end{aligned} \tag{15.30}$$

And we do the final step of the final transformation:

$$\rho(\omega) = \rho_{SC}^{(0)}(\omega) - \frac{1}{\pi}\mathrm{Im\,tr}[g_D^{-1}(\omega) - \Sigma(\omega)]^{-1} + \frac{1}{\pi}\mathrm{Im\,tr}\left[g_D(\omega)\Big(1 + \Sigma(\omega)(g_D^{-1}(\omega) - \Sigma(\omega))^{-1}\Big)\frac{\partial\Sigma(\omega)}{\partial\omega}\right] = \tag{15.31}$$

$$= \rho_{SC}^{(0)}(\omega) - \tfrac{1}{\pi}\mathrm{Im\,tr}\left[\left(g_D^{-1}(\omega) - \Sigma(\omega)\right)^{-1}\underbrace{\frac{\partial g_D^{-1}(\omega)}{\partial\omega}}_{\equiv 1}\right] + \tfrac{1}{\pi}\mathrm{Im\,tr}\left[\left(g_D^{-1}(\omega) - \Sigma(\omega)\right)^{-1}\tfrac{\partial\Sigma(\omega)}{\partial\omega}\right] =$$

$$= \rho_{SC}^{(0)}(\omega) - \frac{1}{\pi}\mathrm{Im\,tr}\left[\frac{\partial}{\partial\omega}\log\left(g_D^{-1}(\omega) - \Sigma(\omega)\right)\right] =$$

$$= \rho_{SC}^{(0)}(\omega) - \frac{1}{\pi}\mathrm{Im}\,\frac{\partial}{\partial\omega}\log\det\left[g_D^{-1}(\omega) - \Sigma(\omega)\right] =$$

$$= \underbrace{\rho_{SC}^{(0)}(\omega) + \rho_D^{(0)}(\omega)}_{\text{bare DOS}} + \underbrace{\left(-\frac{1}{\pi}\mathrm{Im}\,\frac{\partial}{\partial\omega}\log\det\left[1 - g_D(\omega)\Sigma(\omega)\right]\right)}_{\text{tunneling contribution}}. \tag{15.32}$$

Thus we have proven (**??**).

15.2 Problems about Special Effects

15.2.1 Problems about Nambu Notation for Applications

me. Nambu formalism

Show that

$$H_D := \sum_{\sigma=\pm}(V + \sigma\Delta_Z)d_\sigma^\dagger d_\sigma, \qquad \Leftrightarrow \qquad H_D = \frac{1}{2}D^\dagger\Big[V\tau_z + \Delta_Z\sigma_z\Big]D + \mathrm{const}; \quad D := \begin{pmatrix} d_+ \\ d_- \\ d_-^\dagger \\ -d_+^\dagger \end{pmatrix}.$$

Solution

Let us do it in the opposite direction.

$$H_D = \frac{1}{2}D^\dagger\Big[V\tau_z + \Delta_Z\sigma_z\Big]D =$$

$$= \frac{1}{2}\begin{pmatrix} d_+^\dagger & d_-^\dagger & d_- & -d_+ \end{pmatrix}\begin{pmatrix} \Delta_Z + V & 0 & 0 & 0 \\ 0 & V - \Delta_Z & 0 & 0 \\ 0 & 0 & \Delta_Z - V & 0 \\ 0 & 0 & 0 & -\Delta_Z - V \end{pmatrix}\begin{pmatrix} d_+ \\ d_- \\ d_-^\dagger \\ -d_+^\dagger \end{pmatrix} =$$

$$= \frac{1}{2}\Big((\Delta_Z + V)d_+^\dagger d_+ + (V - \Delta_Z)d_-^\dagger d_- + (\Delta_Z - V)d_- d_-^\dagger + (-\Delta_Z - V)(-d_+)(-d_+^\dagger)\Big) =$$

$$= \frac{1}{2}\Big((\Delta_Z + V)d_+^\dagger d_+ + (V - \Delta_Z)d_-^\dagger d_- + (\Delta_Z - V)(1 - d_- d_-^\dagger) + (-\Delta_Z - V)(1 - d_+ d_+^\dagger)\Big) =$$

$$= (\Delta_Z + V)d_+^\dagger d_+ + (V - \Delta_Z)d_-^\dagger d_- - V.$$

me. Nambu formalism

Show that

$$H_{SC} := \sum_{j=1}^{N}\left(-t_j\sum_{n=1}^{\infty}\sum_{\sigma=\pm}(c_{n,\sigma,j}^\dagger c_{n+1,\sigma,j} + c_{n+1,\sigma,j}^\dagger c_{n,\sigma,j}) + \Delta_j\sum_{n=1}^{\infty}(e^{i\varphi_j}c_{n,+,j}^\dagger c_{n,-,j}^\dagger + \mathrm{h.c.}) - \right.$$

$$\left. - \mu\sum_{\sigma=\pm}\sum_{n=1}^{\infty}c_{n,\sigma,j}^\dagger c_{n,\sigma,j}\right)$$

is equivalent to one in terms of $C_{n,j} := \begin{pmatrix} c_{n,+,j} & c_{n,-j} & c^\dagger_{n,-j} & -c^\dagger_{n,+j} \end{pmatrix}^T$:

$$H_{SC} = \frac{1}{2}\sum_{j=1}^{N}\left(-t_j\sum_{n=1}^{\infty}(C^\dagger_{n,j}\tau_z C_{n+1,j} + C^\dagger_{n+1,j}\tau_z C_{n,j}) + \Delta_j\sum_{n=1}^{\infty}(e^{i\varphi_j}C^\dagger_{n,j}\tau_+ C_{n,j} + \text{h.c.}) - \right.$$
$$\left. -\mu\sum_{n=1}^{\infty}C^\dagger_{n,j}\tau_z C_{n,j}\right) + \text{const.}$$

Solution

We will do in the opposite direction and by each part in the sum over j. The first part:

$$\frac{1}{2}(C^\dagger_{n,j}\tau_z C_{n+1,j} + C^\dagger_{n+1,j}\tau_z C_{n,j}) =$$
$$= \tfrac{1}{2}(c^\dagger_{n,+,j}\ c^\dagger_{n,-j}\ c_{n,-j}\ -c_{n,+j})\begin{pmatrix}1&0&0&0\\0&1&0&0\\0&0&-1&0\\0&0&0&-1\end{pmatrix}\begin{pmatrix}c_{n+1,+,j}\\c_{n+1,-j}\\c^\dagger_{n+1,-j}\\-c^\dagger_{n+1,+j}\end{pmatrix} + \tfrac{1}{2}(c^\dagger_{n+1,+,j}\ c^\dagger_{n+1,-j}\ c_{n+1,-j}\ -c_{n+1,+j})\begin{pmatrix}1&0&0&0\\0&1&0&0\\0&0&-1&0\\0&0&0&-1\end{pmatrix}\begin{pmatrix}c_{n,+,j}\\c_{n,-j}\\c^\dagger_{n,-j}\\-c^\dagger_{n,+j}\end{pmatrix} =$$
$$= \frac{1}{2}\Big(c^\dagger_{n,+,j}c_{n+1,+,j} + c^\dagger_{n,-j}c_{n+1,-j} - c_{n,-j}c^\dagger_{n+1,-j} - (-c_{n,+j})(-c^\dagger_{n+1,+j}) +$$
$$+ c^\dagger_{n+1,+,j}c_{n,+,j} + c^\dagger_{n+1,-j}c_{n,-j} - c_{n+1,-j}c^\dagger_{n,-j} - (-c_{n+1,+j})(-c^\dagger_{n,+j})\Big) =$$
$$= c^\dagger_{n+1,+,j}c_{n,+,j} + c^\dagger_{n+1,-j}c_{n,-j} - c_{n+1,-j}c^\dagger_{n,-j} - c_{n+1,+j}c^\dagger_{n,+j}.$$

This the exactly the term we needed. All was easy, since all operators in each term commute (the key transformation is the anticommutation relation). Now, the second part:

$$\frac{1}{2}(e^{i\varphi_j}C^\dagger_{n,j}\tau_+ C_{n,j} + \text{h.c.}) =$$
$$= \tfrac{1}{2}e^{i\varphi_j}(c^\dagger_{n,+,j}\ c^\dagger_{n,-j}\ c_{n,-j}\ -c_{n,+j})\begin{pmatrix}0&0&1&0\\0&0&0&1\\0&0&0&0\\0&0&0&0\end{pmatrix}\begin{pmatrix}c_{n,+,j}\\c_{n,-j}\\c^\dagger_{n,-j}\\-c^\dagger_{n,+j}\end{pmatrix} + \tfrac{1}{2}e^{-i\varphi_j}(c^\dagger_{n,+,j}\ c^\dagger_{n,-j}\ c_{n,-j}\ -c_{n,+j})\begin{pmatrix}0&0&0&0\\0&0&0&0\\1&0&0&0\\0&1&0&0\end{pmatrix}\begin{pmatrix}c_{n,+,j}\\c_{n,-j}\\c^\dagger_{n,-j}\\-c^\dagger_{n,+j}\end{pmatrix} =$$
$$= \frac{1}{2}e^{i\varphi_j}\left(c^\dagger_{n,+,j}c^\dagger_{n,-j} + c^\dagger_{n,-j}(-c^\dagger_{n,+j})\right) + \frac{1}{2}e^{-i\varphi_j}\left(c_{n,-j}c_{n,+,j} + (-c_{n,+j})c_{n,-j}\right) =$$
$$= \frac{1}{2}e^{i\varphi_j}\left(c^\dagger_{n,+,j}c^\dagger_{n,-j} + c^\dagger_{n,+,j}c^\dagger_{n,-j}\right) + \frac{1}{2}e^{-i\varphi_j}\left(c_{n,-j}c_{n,+,j} + c_{n,-j}c_{n,+,j}\right) =$$
$$= e^{i\varphi_j}c^\dagger_{n,+,j}c^\dagger_{n,-j} + e^{-i\varphi_j}c_{n,-j}c_{n,+,j}.$$

Another, slightly simpler way is to obtain only the first term and then to take h.c. of it to get the second term. Also, note that this is the place where we wee exactly, why there is a minus sign in the last component of the Nambu spinor, it generates the essential minus to obtain the required term. Finally, the last term:

$$\frac{1}{2}C^\dagger_{n,j}\tau_z C_{n,j} = \frac{1}{2}\begin{pmatrix}c^\dagger_{n,+,j} & c^\dagger_{n,-j} & c_{n,-j} & -c_{n,+j}\end{pmatrix}\begin{pmatrix}1&0&0&0\\0&1&0&0\\0&0&-1&0\\0&0&0&-1\end{pmatrix}\begin{pmatrix}c_{n,+,j}\\c_{n,-j}\\c^\dagger_{n,-j}\\-c^\dagger_{n,+j}\end{pmatrix} =$$
$$= \frac{1}{2}(c^\dagger_{n,+,j}c_{n,+,j} + c^\dagger_{n,-j}c_{n,-j} - c_{n,-j}c^\dagger_{n,-j} - (-c_{n,+j})(-c^\dagger_{n,+j})) =$$
$$= \frac{1}{2}(c^\dagger_{n,+,j}c_{n,+,j} - c_{n,+j}c^\dagger_{n,+j} + c^\dagger_{n,-j}c_{n,-j} - c_{n,-j}c^\dagger_{n,-j}) =$$
$$= \frac{1}{2}(c^\dagger_{n,+,j}c_{n,+,j} - (-c^\dagger_{n,+j}c_{n,+j} + 1) + c^\dagger_{n,-j}c_{n,-j} - (-c^\dagger_{n,-j}c_{n,-j} + 1)) =$$
$$= c^\dagger_{n,+,j}c_{n,+,j} + c^\dagger_{n,-j}c_{n,-j} - 1.$$

me. Nambu formalism

Prove that

$$H_T := -\sum_{j=1}^{N}t'_j\sum_{\sigma=\pm}(c^\dagger_{1,\sigma,j}d_\sigma + d^\dagger_\sigma c_{1,\sigma,j}). \qquad \Leftrightarrow \qquad H_T = -\frac{1}{2}\sum_{j=1}^{N}t'_j\sum_{\sigma=\pm}(C^\dagger_{1,j}\tau_z D + D^\dagger\tau_z C_{1,j}),$$

where $C_{n,j} := \begin{pmatrix} c_{n,+,j} & c_{n,-j} & c^\dagger_{n,-j} & -c^\dagger_{n,+j}\end{pmatrix}^T$ and $D := \begin{pmatrix} d_+ & d_- & d^\dagger_- & -d^\dagger_+\end{pmatrix}^T$.

Solution

We do it again from the opposite direction:

$$H_T = -\tfrac{1}{2}(c^\dagger_{1,+,j}\ c^\dagger_{1,-j}\ c_{1,-j}\ -c_{1,+j}) \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix} \begin{pmatrix} d_+ \\ d_- \\ d^\dagger_- \\ -d^\dagger_+ \end{pmatrix} - \tfrac{1}{2}(d^\dagger_+\ d^\dagger_-\ d_-\ -d_+) \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix} \begin{pmatrix} c_{1,+,j} \\ c_{1,-j} \\ c^\dagger_{1,-j} \\ -c^\dagger_{1,+j} \end{pmatrix} =$$

$$= -\frac{1}{2}(c^\dagger_{1,+,j}d_+ + c^\dagger_{1,-j}d_- - c_{1,-j}d^\dagger_- - c_{1,+j}d^\dagger_+ + d^\dagger_+ c_{1,+,j} + d^\dagger_- c_{1,-j} - d_- c^\dagger_{1,-j} - d_+ c^\dagger_{1,+j}) =$$

$$= -\frac{1}{2}(c^\dagger_{1,+,j}d_+ + c^\dagger_{1,-j}d_- - c_{1,-j}d^\dagger_- - c_{1,+j}d^\dagger_+).$$

This is the term in non-Nambu formalism (**??**).

me. normal Hamiltonian in Nambu space for the continuous model

(!! write better what is going on!!!???)
Prove that

$$H_{\mathrm{n}} = \sum_{\sigma,\sigma'=\pm} \int_\Omega dx \hat\psi^\dagger_\sigma(x) h_{\sigma,\sigma'}(p,x) \hat\psi_{\sigma'}(x) \qquad \Leftrightarrow \qquad H_{\mathrm{n}} \equiv \frac{1}{2}\int_\Omega dx\ \hat\Psi^\dagger(x) \mathcal{H}_{\mathrm{n}}(p,x) \hat\Psi(x),$$

where $\mathcal{H}_{\mathrm{n}}(p,x) := \begin{pmatrix} h(p,x) & 0 \\ 0 & -\sigma_y h^*(p,x)\sigma_y \end{pmatrix}$;
$h(p,x) := \sum\limits_{\sigma,\sigma'=\pm} h_{\sigma,\sigma'}(p,x)|\sigma\rangle\langle\sigma'|$;
$\hat\Psi(x) := \begin{pmatrix} \hat\psi(x) \\ i\sigma_y \left[\hat\psi^\dagger(x)\right]^T \end{pmatrix}$;
$\hat\psi(x) := \sum\limits_{\sigma=\pm} \hat\psi_\sigma(x)|\sigma\rangle$.

Solution

We will omit the arguments (p,x), (x) and prove to the other direction:

$$\hat\Psi^\dagger \mathcal{H}_{\mathrm{n}} \hat\Psi = (\hat\psi^\dagger_+ \quad \hat\psi^\dagger_- \quad \hat\psi_- \quad -\hat\psi_+) \begin{pmatrix} h_{++} & h_{+-} & 0 & 0 \\ h_{-+} & h_{--} & 0 & 0 \\ 0 & 0 & -h_{--} & h^*_{-+} \\ 0 & 0 & h^*_{+-} & -h_{++} \end{pmatrix} \begin{pmatrix} \hat\psi_+ \\ \hat\psi_- \\ \hat\psi^\dagger_- \\ -\hat\psi^\dagger_+ \end{pmatrix} =$$

$$= \begin{pmatrix} \hat\psi^\dagger_+ h_{++} + \hat\psi^\dagger_- h_{+-} & \hat\psi^\dagger_+ h_{-+} + \hat\psi^\dagger_- h_{--} & -\hat\psi_- h_{--} - \hat\psi_+ h^*_{-+} & \hat\psi_- h^*_{+-} - (-\hat\psi_+) h_{++} \end{pmatrix} \begin{pmatrix} \hat\psi_+ \\ \hat\psi_- \\ \hat\psi^\dagger_- \\ -\hat\psi^\dagger_+ \end{pmatrix} =$$

$$= \hat\psi^\dagger_+ h_{++} \hat\psi_+ + \hat\psi^\dagger_- h_{+-} \hat\psi_+ + \hat\psi^\dagger_+ h_{-+} \hat\psi_- + \hat\psi^\dagger_- h_{--} \hat\psi_- - \hat\psi_- h_{--} \hat\psi^\dagger_- - \hat\psi_+ h^*_{-+} \hat\psi^\dagger_- - \hat\psi_- h^*_{+-} \hat\psi^\dagger_+ - \hat\psi_+ h_{++} \hat\psi^\dagger_+ =$$

$$= 2\left(\hat\psi^\dagger_+ h_{++} \hat\psi_+ + \hat\psi^\dagger_- h_{+-} \hat\psi_+ + \hat\psi^\dagger_+ h_{-+} \hat\psi_- + \hat\psi^\dagger_- h_{--} \hat\psi_-\right) + \mathrm{const}\cdot\delta(0),$$

where at the last step we used anticommutative identities and the hermiticity of the Hamiltonian ($H = H^{*T}$) Because of which, for example, $h^*_{-+} = h_{+-}$. We remind that h-s are just complex functions, so ψ-s can go through it. Then, the factor 2 cancels with factor $1/2$ from the Nambu Hamiltonian and we get the exactly the term under the integral of non-Nambu Hamiltonian (**??**).

me. SC Hamiltonian in Nambu space for the continuous model

(!! write better what is going on!!!???)
Here we will prove that

$$H_{\mathrm{SC}} := \sum_{\sigma=\pm} \int_0^\infty dx \hat\chi^\dagger_\sigma(x) \left[\frac{p^2}{2m} - \mu\right] \hat\chi_\sigma(x) + \int_0^\infty dx \left[\Delta \hat\chi^\dagger_+(x) \hat\chi^\dagger_-(x) + \Delta^* \hat\chi_-(x) \hat\chi_+(x)\right]$$

is equivalent to

$$H_{\rm SC}=\frac{1}{2}\int_0^\infty dx\hat{\Upsilon}^\dagger(x)\mathcal{H}_{\rm SC}(p,x)\hat{\Upsilon}(x),\quad \mathcal{H}_{\rm SC}(p,x)=\begin{pmatrix}\left[\frac{p^2}{2m}-\mu\right] & i\Delta\sigma_y\\ -i\Delta^*\sigma_y & -\left[\frac{p^2}{2m}-\mu\right]\end{pmatrix},$$

where $\hat{\Upsilon}(x)=\begin{pmatrix}\hat{\chi}(x)\\ i\sigma_y\left[\hat{\chi}^\dagger(x)\right]^T\end{pmatrix}$, $\hat{\chi}(x)=\sum_{\sigma=\pm}\hat{\chi}_\sigma(x)|\sigma\rangle$.

Solution

We will omit dependence on $(p,x),(x)$ and do as before:

$$\hat{\Upsilon}^\dagger\mathcal{H}_{\rm SC}\hat{\Upsilon}=\begin{pmatrix}\hat{\chi}^\dagger & \hat{\chi}^T(-i\sigma_y)\end{pmatrix}\begin{pmatrix}\left[\frac{p^2}{2m}-\mu\right] & \Delta\\ \Delta^* & -\left[\frac{p^2}{2m}-\mu\right]\end{pmatrix}\begin{pmatrix}\hat{\chi}\\ i\sigma_y\hat{\chi}^{\dagger T}\end{pmatrix}=$$
$$=\begin{pmatrix}\hat{\chi}^\dagger\left[\frac{p^2}{2m}-\mu\right]+\hat{\chi}^T(-i\sigma_y)\Delta^* & \hat{\chi}^\dagger\Delta-(\hat{\chi}^T(-i\sigma_y))\left[\frac{p^2}{2m}-\mu\right]\end{pmatrix}\begin{pmatrix}\hat{\chi}\\ i\sigma_y\hat{\chi}^{\dagger T}\end{pmatrix}=$$
$$=\hat{\chi}^\dagger\left[\frac{p^2}{2m}-\mu\right]\hat{\chi}+\hat{\chi}^T(-i\sigma_y)\Delta^*\hat{\chi}+\hat{\chi}^\dagger\Delta(i\sigma_y\hat{\chi}^{\dagger T})-(\hat{\chi}^T(-i\sigma_y))\left[\frac{p^2}{2m}-\mu\right](i\sigma_y\hat{\chi}^{\dagger T})=$$
$$=\hat{\chi}^\dagger\left[\tfrac{p^2}{2m}-\mu\right]\hat{\chi}+\Delta^*\begin{pmatrix}\chi_+ & \chi_-\end{pmatrix}\begin{pmatrix}0 & -1\\ 1 & 0\end{pmatrix}\begin{pmatrix}\chi_+\\ \chi_-\end{pmatrix}+\Delta\begin{pmatrix}\chi_+^\dagger & \chi_-^\dagger\end{pmatrix}\begin{pmatrix}0 & 1\\ -1 & 0\end{pmatrix}\begin{pmatrix}\chi_+^\dagger\\ \chi_-^\dagger\end{pmatrix}-\left[\tfrac{p^2}{2m}-\mu\right]\begin{pmatrix}\chi_+ & \chi_-\end{pmatrix}\begin{pmatrix}\chi_+^\dagger\\ \chi_-^\dagger\end{pmatrix}=$$
$$=\left[\tfrac{p^2}{2m}-\mu\right](\chi_+^\dagger\chi_++\chi_-^\dagger\chi_-)+\Delta^*(\chi_-\chi_+-\chi_+\chi_-)+\Delta(-\chi_-^\dagger\chi_+^\dagger+\chi_+^\dagger\chi_-^\dagger)+\left[\tfrac{p^2}{2m}-\mu\right](-\chi_+\chi_+^\dagger-\chi_-\chi_-^\dagger)=$$
$$=2\left(\left[\frac{p^2}{2m}-\mu\right](\chi_+^\dagger\chi_++\chi_-^\dagger\chi_-)+\Delta\chi_+^\dagger\chi_-^\dagger+\Delta^*\chi_-\chi_+\right).$$

Now the equivalence with (**??**) is obvious. Also, this formula can also be found, for example, in [**?**] and the similar one in [**?**].

me. the Heisenberg equations for the continuous model

(!! write better what is going on!!!???)
Here we will derive the Heisenberg equations for the Nambu fields $\hat{\Psi}$ and $\hat{\Upsilon}$.

Solution

We will use $i\frac{d}{dt}\hat{\Upsilon}(x,t)=\left[\hat{\Upsilon}(x,t),H_{\rm tot}\right]$ and for it we compute:

$$\left[\hat{\Upsilon}_a(x),H_n\right]=\int_\Omega dx'\hat{\Upsilon}_a(x)\frac{1}{2}\hat{\Psi}_b^\dagger(x')\mathcal{H}_{\rm n}^{bc}(p',x')\hat{\Psi}_c(x')-\int_\Omega dx'\frac{1}{2}\hat{\Psi}_b^\dagger(x')\mathcal{H}_{\rm n}^{bc}(p',x')\hat{\Psi}_c(x')\hat{\Upsilon}_a(x)=$$
$$=\int_\Omega dx'\hat{\Upsilon}_a(x)\frac{1}{2}\hat{\Psi}_b^\dagger(x')\mathcal{H}_{\rm n}^{bc}(p',x')\hat{\Psi}_c(x')-\int_\Omega dx'(-1)^2\frac{1}{2}\hat{\Upsilon}_a(x)\hat{\Psi}_b^\dagger(x')\mathcal{H}_{\rm n}^{bc}(p',x')\hat{\Psi}_c(x')=0;$$

$$\left[\hat{\Upsilon}_a(x),H_{SC}\right]=\hat{\Upsilon}_a(x)\int dx'\frac{1}{2}\hat{\Upsilon}_b^\dagger(x')\mathcal{H}_{\rm SC}^{bc}(p',x')\hat{\Upsilon}_c(x')-\int dx'\frac{1}{2}\hat{\Upsilon}_b^\dagger(x')\mathcal{H}_{\rm SC}^{bc}(p',x')\hat{\Upsilon}_c(x')\hat{\Upsilon}_a(x)=$$
$$=\int dx'\frac{1}{2}(-\hat{\Upsilon}_b^\dagger(x')\hat{\Upsilon}_a(x)+\delta_{ab}\delta(x-x'))\mathcal{H}_{\rm SC}^{bc}(p',x')\hat{\Upsilon}_c(x')-$$
$$-\int dx'\frac{1}{2}\hat{\Upsilon}_b^\dagger(x')\mathcal{H}_{\rm SC}^{bc}(p',x')(-\hat{\Upsilon}_a(x)\hat{\Upsilon}_c(x')+\mathcal{C}_{ca}\delta(x-x'))=$$
$$=-\int dx'\frac{1}{2}\hat{\Upsilon}_b^\dagger(x')\hat{\Upsilon}_a(x)\mathcal{H}_{\rm SC}^{bc}(p',x')\hat{\Upsilon}_c(x')+\frac{1}{2}\mathcal{H}_{\rm SC}^{ac}(p,x)\hat{\Upsilon}_c(x)+$$
$$+\int dx'\frac{1}{2}\hat{\Upsilon}_b^\dagger(x')\mathcal{H}_{\rm SC}^{bc}(p',x')\hat{\Upsilon}_a(x)\hat{\Upsilon}_c(x')-\frac{1}{2}\hat{\Upsilon}_b^\dagger(x)\mathcal{H}_{\rm SC}^{bc}(p,x)\mathcal{C}_{ca}=$$

$$= -\int dx' \frac{1}{2}\hat{\Upsilon}_b^\dagger(x')\hat{\Upsilon}_a(x)\mathcal{H}_{\rm SC}^{bc}(p',x')\hat{\Upsilon}_c(x') + \int dx' \frac{1}{2}\hat{\Upsilon}_b^\dagger(x')\mathcal{H}_{\rm SC}^{bc}(p',x')\hat{\Upsilon}_a(x)\hat{\Upsilon}_c(x')$$
$$+ \frac{1}{2}\mathcal{H}_{\rm SC}^{ac}(p,x)\hat{\Upsilon}_c(x) - \frac{1}{2}\underbrace{\hat{\Upsilon}_b^\dagger(x)}_{=\hat{\Upsilon}_d C_{bd}}\mathcal{H}_{\rm SC}^{bc}(p,x)\mathcal{C}_{ca} =$$
$$= \int dx' \frac{1}{2}\hat{\Upsilon}_b^\dagger(x')\underbrace{[\mathcal{H}_{\rm SC}^{bc}(p',x'),\hat{\Upsilon}_a(x)]}_{=0}\hat{\Upsilon}_c(x') + \frac{1}{2}\mathcal{H}_{\rm SC}^{ac}(p,x)\hat{\Upsilon}_c(x) - \frac{1}{2}\hat{\Upsilon}_a\underbrace{\mathcal{C}_{bd}\mathcal{H}_{\rm SC}^{bc}(p,x)\mathcal{C}_{ca}}_{=-\mathcal{H}_{\rm SC}^{da*}=-\mathcal{H}_{\rm SC}^{ad}} =$$
$$= \mathcal{H}_{\rm SC}^{ac}(p,x)\hat{\Upsilon}_c(x) \equiv [\mathcal{H}_{\rm SC}(p,x)\hat{\Upsilon}(x)]_a.$$

Here we used the fact that each component $\mathcal{H}_{\rm SC}^{bc}$ is a scalar function, so it commutes with spinor $\hat{\Upsilon}_c(x)$ and that from charge-symmetry properties ($C_{ab}\hat{\Upsilon}_b^\dagger = \hat{\Upsilon}_a$) we have $\hat{\Upsilon}_b C_{ab} = \hat{\Upsilon}_b^\dagger$, since $C_{ab}^\dagger = C_{ab}$.

To be more mathematically strict, one can also agree about the positions of row and column indices of spinors (Ψ and Υ). We are not fixing much attention to it, since in case of doubt one can imagine matrices, rows, columns. Also, we omit upper-lower position of indices and agree that we sum over each repeated index despite its position.

Also, it is important to use the fact that that $\mathcal{H}_{\rm SC}$ is Hermitian, since this is the main property to use the transformations like $\mathcal{C}_{bd}\mathcal{H}_{\rm SC}^{bc}(p,x)\mathcal{C}_{ca} = -\mathcal{H}_{\rm SC}^{da*} = \mathcal{H}_{\rm SC}^{ad}$.

$$\left[\hat{\Upsilon}_a(x), H_T\right] = \frac{1}{2}\Big(\hat{\Upsilon}_a(x)\hat{\Upsilon}_b^\dagger(a)\mathcal{W}^{bc}\hat{\Psi}_c(\tilde{R}) + \underbrace{\hat{\Upsilon}_a(x)\hat{\Psi}_b^\dagger(\tilde{R})}_{=-\hat{\Psi}_b^\dagger(\tilde{R})\hat{\Upsilon}_a(x)}\mathcal{W}^{\dagger bc}\hat{\Upsilon}_c(a) -$$
$$- \hat{\Upsilon}_b^\dagger(a)\mathcal{W}^{bc}\underbrace{\hat{\Psi}_c(\tilde{R})\hat{\Upsilon}_a(x)}_{=-\hat{\Upsilon}_a(x)\hat{\Psi}_c(\tilde{R})} - \hat{\Psi}_b^\dagger(\tilde{R})\mathcal{W}^{\dagger bc}\hat{\Upsilon}_c(a)\hat{\Upsilon}_a(x)\Big) =$$
$$= \frac{1}{2}\Big(\delta_{ab}\delta(x-a)\mathcal{W}^{bc}\hat{\Psi}_c(\tilde{R}) - \hat{\Psi}_b^\dagger(\tilde{R})\mathcal{W}^{\dagger bc}\mathcal{C}_{ab}\delta(x-a)\Big) =$$
$$= \frac{1}{2}\Big(\delta_{ab}\delta(x-a)\mathcal{W}^{bc}\hat{\Psi}_c(\tilde{R}) - \hat{\Psi}_r(\tilde{R})\underbrace{\mathcal{C}_{br}\mathcal{W}^{\dagger bc}\mathcal{C}_{ab}}_{-\mathcal{W}^{ra*}=-\mathcal{W}^{ar}}\delta(x-a)\Big) =$$
$$= \delta(x-a)\mathcal{W}^{ac}\hat{\Psi}_c(\tilde{R}) \equiv [\delta(x-a)\mathcal{W}\hat{\Psi}(\tilde{R})]_a$$

After collecting terms and restoring t-dependence, we got

$$i\frac{d}{dt}\hat{\Upsilon}(x,t) = \mathcal{H}_{\rm SC}(p,x)\hat{\Upsilon}(x,t) + \delta(x-a)\mathcal{W}\hat{\Psi}(\tilde{R},t),$$

which is the Eq. (**??**). Analogous we get the Eq. (**??**). There is no value of writing the analogous derivation and as the one before, it is straightforward and bulky.

me. Derivative of the Dyson equations for the continuous model

(!! write better what is going on!!!???)

Here we will find the Dyson equation for $[G_{\rm NN}(x,x'|t)]_{ab} := -i\Theta(t)\langle\{\hat{\Psi}_a(x,t),\hat{\Psi}_b^\dagger(x',0)\}\rangle$.

Solution

We evaluate:

$$i\frac{d}{dt}[G_{\rm NN}(x,x'|t)]_{ab} = \underbrace{\delta(t)\langle\{\hat{\Psi}_a(x,t),\hat{\Psi}_b^\dagger(x',0)\}\rangle}_{=\delta(t)\langle\{\hat{\Psi}_a(x,0),\hat{\Psi}_b^\dagger(x',0)\}\rangle=\delta(t)\delta(x-x')\delta_{ab}} - i\Theta(t)\langle\{i\frac{d\hat{\Psi}_a(x,t)}{dt},\hat{\Psi}_b^\dagger(x',0)\}\rangle =$$
$$= \delta(t)\delta(x-x')\delta_{ab} - i\Theta(t)\langle\{\mathcal{H}_{\rm n}^{ac}(p,x)\hat{\Psi}_c(x,t),\hat{\Psi}_b^\dagger(x',0)\}\rangle - i\Theta(t)\langle\{\delta(x-\tilde{R})\mathcal{W}^{\dagger ac}\hat{\Upsilon}_c(a,t),\hat{\Psi}_b^\dagger(x',0)\}\rangle =$$
$$= \delta(t)\delta(x-x')\delta_{ab} + \mathcal{H}_{\rm n}^{ac}(p,x)\underbrace{(-i\Theta(t))\langle\{\hat{\Psi}_c(x,t),\hat{\Psi}_b^\dagger(x',0)\}\rangle}_{=[G_{NN}(x,x'|t)]_{cb}} + \delta(x-\tilde{R})\mathcal{W}^{\dagger ac}\underbrace{(-i\Theta(t))\langle\{\hat{\Upsilon}_c(a,t),\hat{\Psi}_b^\dagger(x',0)\}\rangle}_{=[G_{SN}(a,x'|t)]_{cb}}.$$

Note that purely the expression $\langle\{\hat{\Psi}_a(x,t),\hat{\Psi}_b^\dagger(x',0)\}\rangle$ is in general case complex to evaluate and the $\delta(t)$ and $\Theta(t)$ allow us to proceed. Also, we consider the Hamiltonian as a complex function, thus we can easily take it out of averaging. Thus in matrix form, we have

$$\left(i\frac{d}{dt} - \mathcal{H}_{\rm n}(p,x)\right)G_{\rm NN}(x,x'|t) = \delta(x-\tilde{R})\mathcal{W}^\dagger G_{SN}(a,x'|t) + \delta(t)\delta(x-x'). \tag{15.33}$$

Exactly the same way other Dyson Eq. (**??**) can be proven. To use transformation $F[f](z) := \int_0^\infty dt e^{izt} f(t)$, we prepare, for example, like

$$\begin{aligned} F[i\frac{d}{dt}G_{\rm NS}](z) &= \int_0^\infty dt e^{izt} i\frac{d}{dt}G_{\rm NS}(t) = ie^{izt}G_{\rm NS}(t)|_0^\infty - i\cdot iz\int_0^\infty dt e^{izt}G_{\rm NS} = zG_{\rm NS}(z), \\ F[\mathcal{H}_{\rm n}G_{\rm NS}](z) &= \mathcal{H}_{\rm n}G_{\rm NS}(z), \\ F[\delta(x-\tilde{R})\mathcal{W}^\dagger G_{\rm SS}](z) &= \delta(x-\tilde{R})\mathcal{W}^\dagger G_{\rm SS}(z). \end{aligned}$$

Now, the eq. $\left(i\frac{d}{dt} - \mathcal{H}_{\rm n}(p,x)\right) G_{\rm NS}(x,x'|t) = \delta(x-\tilde{R})\mathcal{W}^\dagger G_{\rm SS}(a,x'|t)$ will be transformed as

$$(z-\mathcal{H}_{\rm n})G_{\rm NS}(z) = \delta(x-\tilde{R})\mathcal{W}^\dagger G_{\rm SS}(z).$$

Other Dyson eq. (**??**) are transformed the same way.

15.2.2 Problems Transformations of SC Green's functions

me. spectral density for the continuous model

(!! write better what is going on!!!???)
Here we will find the formula for the $\rho_{\rm n}(\omega)$.

Solution

Fist, we notice that (we use $z := \omega + i\eta, \eta \to 0$)

$$\begin{aligned} \frac{\partial}{\partial z}\big[z-\mathcal{H}_{\rm n}(p,x)\big]m(x,x') &= \frac{\partial}{\partial z}\delta(x-x'), \\ m(x,x') + \big[z-\mathcal{H}_{\rm n}(p,x)\big]\frac{\partial m(x,x')}{\partial z} &= 0, \\ \frac{\partial m(x,x')}{\partial z} &= -\frac{1}{\big[z-\mathcal{H}_{\rm n}(p,x)\big]}m(x,x') \\ \frac{\partial m(x,x')}{\partial z}\delta(x'-x) &= -\frac{\delta(x'-x)}{\big[z-\mathcal{H}_{\rm n}(p,x)\big]}m(x,x') \\ \frac{\partial m(x,x')}{\partial z}\delta(x'-x) &= -m(x',x)m(x,x'). \end{aligned}$$

Here we see the importance of $m(x',x) \neq m(x,x')$ Analogously, the same formula for g is obtained. Now, with the help of $G_{\rm NN}(x,x') = m(x,x') + +m(x,\tilde{R})\mathcal{W}^\dagger g(a,a)\mathcal{W}D^{-1}m(\tilde{R},x')$ we will find the formula for $\rho_{\rm n}(\omega)$:

$$\begin{aligned} \rho_{\rm n}(\omega) =& -\frac{1}{\pi}{\rm Im}\int_\Omega dx {\rm tr} G_{\rm NN}(x,x) \\ =& \underbrace{-\frac{1}{\pi}{\rm Im}\int_\Omega dx {\rm tr} m(x,x)}_{=:\rho_{\rm n}^{(0)}(\omega)} - \frac{1}{\pi}{\rm Im}\,{\rm tr}\Big[m(x,\tilde{R})\mathcal{W}^\dagger g(a,a)\mathcal{W}D^{-1}\int_\Omega dx m(\tilde{R},x)\Big] \\ =& \rho_{\rm n}^{(0)}(\omega) - \frac{1}{\pi}{\rm Im}\,{\rm tr}\Big[m(x,\tilde{R})\mathcal{W}^\dagger g(a,a)\mathcal{W}D^{-1}\int_\Omega dx m(\tilde{R},x)\Big] = \\ =& \rho_{\rm n}^{(0)}(\omega) - \frac{1}{\pi}{\rm Im}\int_\Omega dx {\rm tr}\Big[\mathcal{W}^\dagger g(a,a)\mathcal{W}D^{-1}\int_\Omega dx m(\tilde{R},x)m(x,\tilde{R})\Big] = \\ =& \rho_{\rm n}^{(0)}(\omega) - \frac{1}{\pi}{\rm Im}\,{\rm tr}\Big[\mathcal{W}^\dagger g(a,a)\mathcal{W}D^{-1}\int_\Omega dx m(\tilde{R},x)m(x,\tilde{R})\Big] = \\ =& \rho_{\rm n}^{(0)}(\omega) + \frac{1}{\pi}{\rm Im}\,{\rm tr}\ \mathcal{W}^\dagger\ g(a,a)\ \mathcal{W}\ D^{-1}\ \frac{\partial m(\tilde{R},\tilde{R})}{\partial z}. \end{aligned}$$

Thus we have proven the (**??**).

Now, with the help of $G_{\rm SS}(x,x') = g(x,x') + g(x,a)\mathcal{M}[1-g(a,a)\mathcal{M}]^{-1}g(a,x')$ find a formula for the $\rho_{\rm SC}(\omega)$:

$$\begin{aligned}
\rho_{\rm SC}(\omega) &= -\frac{1}{\pi}{\rm Im}\int_0^\infty dx {\rm tr}\{G_{\rm SS}(x,x)\} = \\
&= \underbrace{-\frac{1}{\pi}{\rm Im}\int_0^\infty dx {\rm tr}\{g(x,x)\}}_{=:\rho^{(0)}_{\rm SC}(\omega)} - \frac{1}{\pi}{\rm Im}\int_0^\infty dx {\rm tr}\Big[g(x,a)\mathcal{M}[1-g(a,a)\mathcal{M}]^{-1}g(a,x)\Big] \\
&= \rho^{(0)}_{\rm SC}(\omega) - \frac{1}{\pi}{\rm Im}\ {\rm tr}\Big[\mathcal{M}[1-g(a,a)\mathcal{M}]^{-1}\int_0^\infty dx g(a,x)g(x,a)\Big] \\
&= \rho^{(0)}_{\rm SC}(\omega) + \frac{1}{\pi}{\rm Im}\ {\rm tr}\Big[\mathcal{M}[1-g(a,a)\mathcal{M}]^{-1}\frac{\partial g(a,a)}{\partial\omega}\Big] \\
&= \rho^{(0)}_{\rm SC}(\omega) + \frac{1}{\pi}{\rm Im}\ {\rm tr}\Big[\mathcal{W}m(\tilde{R},\tilde{R})\mathcal{W}^\dagger[1-g(a,a)\mathcal{W}m(\tilde{R},\tilde{R})\mathcal{W}^\dagger]^{-1}\frac{\partial g(a,a)}{\partial\omega}\Big].
\end{aligned}$$

Finally, one needs to use $(ABC)^{-1} = C^{-1}B^{-1}A^{-1}$ to simplify the expression under tr:

$$\begin{aligned}
&\mathcal{W}m(\tilde{R},\tilde{R})\mathcal{W}^\dagger[(m(\tilde{R},\tilde{R})\mathcal{W}^\dagger)^{-1}m(\tilde{R},\tilde{R})\mathcal{W}^\dagger - (m(\tilde{R},\tilde{R})\mathcal{W}^\dagger)^{-1}m(\tilde{R},\tilde{R})\mathcal{W}^\dagger g(a,a)\mathcal{W}m(\tilde{R},\tilde{R})\mathcal{W}^\dagger]^{-1}\tfrac{\partial g(a,a)}{\partial\omega}\Big] = \\
&= \mathcal{W}m(\tilde{R},\tilde{R})\mathcal{W}^\dagger(m(\tilde{R},\tilde{R})\mathcal{W}^\dagger)^{-1}[1-m(\tilde{R},\tilde{R})\mathcal{W}^\dagger g(a,a)\mathcal{W}]^{-1}(m(\tilde{R},\tilde{R})\mathcal{W}^\dagger)\frac{\partial g(a,a)}{\partial\omega} = \\
&= \mathcal{W}D^{-1}m(\tilde{R},\tilde{R})\mathcal{W}^\dagger\frac{\partial g(a,a)}{\partial\omega}
\end{aligned}$$

and finish our little proof:

$$\rho_{\rm SC}(\omega) = \rho^{(0)}_{\rm SC}(\omega) + \frac{1}{\pi}{\rm Im}\ {\rm tr}\Big[\mathcal{W}D^{-1}m(\tilde{R},\tilde{R})\mathcal{W}^\dagger\frac{\partial g(a,a)}{\partial\omega}\Big]. \tag{15.34}$$

$$= \rho^{(0)}_{\rm SC}(\omega) + \frac{1}{\pi}{\rm Im}\ {\rm tr}D^{-1}m(\tilde{R},\tilde{R})\frac{\partial\mathcal{W}^\dagger g(a,a)\mathcal{W}}{\partial\omega}. \tag{15.35}$$

We hope that by this point reader felt the whole beauty of the mathematical transformations.

15.2.3 Problems about флуктуационные эффекты в слабых контактах

Фйг-8.1. Напряжение при проскальзывании фазы

Найти среднее напряжение на джозефсоновском контакте с током $I < I_c$, возникающее из-за термически индуцированных процессов проскальзывания фазы (емкостью контакта пренебречь). Температуру считать малой по сравнению с E_J.

Solution

(???)

Фйг-8.2. $\bar{V}(I)$ в квантовом джозефсоновском контакте

Найти в квазиклассическом приближении при $T = 0$ зависимость среднего напряжения $\bar{V}(I)$ в квантовом джозефсоновском контакте с $E_J \gg E_C$ и $1/R = 0$, от тока в контакте I, при $I_c - I \ll I_c$.

Solution

(???)

Фйг-8.3. $\bar{V}(I)$ в квантовом джозефсоновском контакте

Найти в квазиклассическом приближении при $T = 0$ зависимость среднего напряжения $\bar{V}(I)$ в квантовом джозефсоновском контакте с $E_J \gg E_C$ и $1/R = 0$, от тока в контакте I, при условии $I \ll I_c$.

Solution

(???)

Фйг-8.4. Гамильтониан и ДУС из кольца с SNS котактом

Рассмотреть сверхпроводящее кольцо индуктивности L, замкнутое на квантовый джозефсоновский контакт энергии E_J и емкости C. Для случая, когда параметр $\beta_L = 2\pi L I_c/c\Phi_0$ слегка превышает 1, вывести эффективный гамильтониан двухуровневой квантовой системы. Найти условия на параметры задачи, при которых нижние 2 состояния будут заметно отделены по энергии от более высоких возбужденных состояний.

Solution

(???)

15.2.4 Problems about GF Special Methods for SC

me. Current in three-terminal junction

(!! rewrite it!!)
There are several ways to describe multiterminal junctions. For the mutlitermianl junction with a two-level system in the center (quantum dot), one way is to write density of states as

$$\rho(\omega) = \underbrace{\rho^{(0)}_{SC}(\omega) + \rho^{(0)}_{D}(\omega)}_{\text{bare DOS}} + \underbrace{\left(-\frac{1}{\pi} \mathrm{Im} \frac{\partial}{\partial \omega} \log\det\left[1 - g_D(\omega)\Sigma(\omega)\right] \right)}_{\text{tunneling contribution}}.$$

(?? where parameters mean??? also write the impostance of the self energy, since it will be used in the final formula)
Proof of this formula is complicated and requires some background of condensed matter. But we ca just use this formula and compute the current by calculation of free energy

$$F = -k_{\mathrm{B}}T \int_0^\infty d\varepsilon \rho(\varepsilon) \ln\left[2\cosh\left(\varepsilon/2k_{\mathrm{B}}T\right)\right]$$

and then the formula $I = \frac{2e}{\hbar}\frac{\partial F}{\partial \varphi}$. Do this calculation and obtain the current as a function of phase difference φ.
Hint: (write formula for the derivative of the log det)

Solution

One needs first to simplify the basic formula for the current, then take the derivative using formula from linear algebra, rewrite imaginary part as two terms and use the residue theorem to evaluate each (remembering, where are the poles of the Fermi function).
(!!! I need to redo it again!!!)

$$J_j(\varphi) = -\frac{2e}{h\beta} \int_0^\infty d\omega \ln\left(2\cosh\frac{\beta\omega}{2}\right) \frac{\partial}{\partial\varphi} \delta\rho(\omega,\varphi) \overset{[}{\Phi}_0 = \frac{h}{2e} \equiv \frac{\pi\hbar}{e}]\text{i b p} = \tag{15.36}$$

$$= -\frac{1}{\Phi_0} \mathrm{Im} \int_0^\infty d\omega \tanh\frac{\beta\omega}{2} \frac{\partial}{\partial\varphi} \ln\det d\left(\omega + i\eta, \varphi\right) \overset{f(\omega)=\frac{1}{e^{\beta\omega}+1}}{=} \tag{15.37}$$

$$= \frac{1}{\Phi_0} \mathrm{Im} \int_{-\infty}^{+\infty} d\omega f(\omega) \mathrm{tr} \frac{\partial}{\partial\varphi} \ln\det(\omega + i\eta - h_D - \Sigma(\omega + i\eta)) = \tag{15.38}$$

$$= \frac{1}{\Phi_0} \mathrm{Im} \int_{-\infty}^{+\infty} d\omega f(\omega) \mathrm{tr} \frac{1}{\omega + i\eta - h_D - \Sigma(\omega + i\eta)} \frac{\partial\Sigma(\omega + i\eta)}{\partial\varphi_j} = \tag{15.39}$$

$$= \frac{1}{2i\Phi_0} \int d\omega f(\omega) \,\mathrm{tr}\, \frac{1}{\omega + i\eta - h_D - \Sigma(\omega + i\eta)} \frac{\partial\Sigma(\omega + i\eta)}{\partial\varphi_j} - \tag{15.40}$$

$$- \frac{1}{2i\Phi_0} \int d\omega f(\omega) \,\mathrm{tr}\, \frac{1}{\omega - i\eta - h_D - \Sigma(\omega - i\eta)} \frac{\partial\Sigma(\omega - i\eta)}{\partial\varphi_j}. \tag{15.41}$$

The poles of the integrand allows one to make a simplification. The Fermi function produces fermionic poles. The first integral because of $\omega + i\eta$ has poles from the propagator in the lower-half of the complex plane, thus we need to close the contour to the upper-half. In this region we have only poles from Fermi's function (when $e^{\beta\omega} = -1$). It means, $\beta\omega = \pi + 2\pi n, n = 0, 1, 2, 3...$ The second integral should be closed in the lower part of the plane, where the poles are $\beta\omega = \pi + 2\pi n, n = -1, -2, -3..$, because of $\omega - i\eta$ in it. As a result,

$$J_j(\varphi) = \frac{1}{2i\Phi_0} \cdot 2\pi i \sum_{\omega_n \geq 0} \underbrace{\mathrm{res}(f(\omega))}_{-1/\beta} \mathrm{tr}\, \frac{1}{\omega + i\eta - h_D - \Sigma(\omega + i\eta)} \frac{\partial \Sigma(\omega + i\eta)}{\partial \varphi_j} - \tag{15.42}$$

$$- \frac{1}{2i\Phi_0} \cdot (-2\pi i) \sum_{\omega_n < 0} \underbrace{\mathrm{res}(f(\omega))}_{-1/\beta} \mathrm{tr}\, \frac{1}{\omega - i\eta - h_D - \Sigma(\omega - i\eta)} \frac{\partial \Sigma(\omega - i\eta)}{\partial \varphi_j} = \tag{15.43}$$

$$= -\frac{\pi}{\Phi_0} \frac{1}{\beta} \sum_{\omega_n} \mathrm{tr} \frac{1}{i\omega_n - h_D - \Sigma(i\omega_n)} \frac{\partial \Sigma(i\omega_n)}{\partial \varphi_j}. \tag{15.44}$$

At $T = 0$ the sum is changed to the integral:

$$J_j(\varphi, T = 0) = -\frac{1}{2\Phi_0} \int d\omega\ \mathrm{tr} \frac{1}{i\omega - h_D - \Sigma(i\omega)} \frac{\partial \Sigma(i\omega)}{\partial \varphi_j}. \tag{15.45}$$

From this equation, the Ambegoakar-Baratoff's formula can be obtained if one neglects $\Sigma(i\omega)$ in the denominator (this is the tunneling limit). This is because $\Sigma \sim \Gamma$, so after decomposition of the denominator into series, the terms from Σ from the denominator will be of the highest order in Γ.

me. the approximation of the current for two terminals

The general expression for the Josephson current (15.67) can be simplified for the case of two terminals by usage of the Sokhotski–Plemelj theorem as follows:

$$I_1 = \frac{1}{\Phi_0} \mathrm{Im} \int_{-\infty}^{+\infty} d\omega f(\omega) \mathrm{tr} \frac{1}{\omega + i\eta - h_D - \Sigma(\omega)} \frac{\partial \Sigma(\omega + i\eta)}{\partial \varphi_1} = \tag{15.46}$$

$$= -\frac{\pi}{\Phi_0} \sum_{\tau,\sigma=\pm} \int d\omega f(\omega) \delta\left(\omega - \tau\omega_A - \sigma E_Z\right) \frac{\partial}{\partial \varphi_1} \left(\Sigma(0) + \omega \left. \frac{d\Sigma(\omega)}{d\omega} \right|_{\omega=0} \right) = \tag{15.47}$$

$$= -\frac{\pi}{\Phi_0} \Big(f(\omega_A + E_Z) + f(\omega_A - E_Z) - f(-\omega_A + E_Z) - f(-\omega_A - E_Z) \Big) \frac{\partial}{\partial \varphi_1} \omega_A = \tag{15.48}$$

$$= -\frac{\pi}{\Phi_0} \Big(- \frac{2\mathrm{sh}(\beta\omega_A)}{\mathrm{ch}(\beta\omega_A) + \mathrm{ch}(\beta E_Z)} \Big) \frac{\partial}{\partial \varphi_1} \omega_A = \tag{15.49}$$

$$= \frac{2\pi E_J}{\Phi_0} \frac{\mathrm{sh}(\beta\omega_A)}{\mathrm{ch}(\beta\omega_A) + \mathrm{ch}(\beta E_Z)} \frac{\partial \sqrt{1 - D\sin^2 \frac{\varphi}{2}}}{\partial \varphi_1} \overset{\varphi := \varphi_2 - \varphi_1}{=} \tag{15.50}$$

$$= \frac{2\pi E_J}{\Phi_0} \frac{\mathrm{sh}(\beta\omega_A)}{\mathrm{ch}(\beta\omega_A) + \mathrm{ch}(\beta E_Z)} \frac{D \cdot 2 \sin \frac{\varphi}{2} \cos \frac{\varphi}{2}}{4\sqrt{1 - D\sin^2 \frac{\varphi}{2}}} = \tag{15.51}$$

$$= \frac{\pi D E_J}{2\Phi_0} \frac{\mathrm{sh}(\beta\omega_A)}{\mathrm{ch}(\beta\omega_A) + \mathrm{ch}(\beta E_Z)} \frac{\sin\varphi}{\sqrt{1 - D\sin^2 \frac{\varphi}{2}}}. \tag{15.52}$$

Thus we have (**??**).

me. spectrum in two terminals for the discrete model

Solution

$$E_{\tau,\sigma} = \tau\left[1+\frac{\Gamma_1}{\Delta_1}+\frac{\Gamma_2}{\Delta_2}\right]^{-1}\left(\sqrt{V^2+|\Gamma_1 e^{i\varphi_1}+\Gamma_2 e^{i\varphi_2}|^2}+\sigma\Delta_Z\right) = \tag{15.53}$$

$$= \frac{\tau}{1+\frac{\Gamma_1}{\Delta_1}+\frac{\Gamma_2}{\Delta_2}}\sqrt{V^2+\Gamma_1^2+\Gamma_2^2+2\Gamma_1\Gamma_2\cos(\varphi_1-\varphi_2)}+\sigma\frac{\Delta_Z}{1+\frac{\Gamma_1}{\Delta_1}+\frac{\Gamma_2}{\Delta_2}} \tag{15.54}$$

$$= \frac{\tau}{1+\frac{\Gamma_1}{\Delta_1}+\frac{\Gamma_2}{\Delta_2}}\sqrt{V^2+(\Gamma_1+\Gamma_2)^2-2\Gamma_1\Gamma_2+2\Gamma_1\Gamma_2\cos(\varphi_1-\varphi_2)}+\sigma E_Z, \tag{15.55}$$

$$= \frac{\sqrt{V^2+(\Gamma_1+\Gamma_2)^2}\tau}{1+\frac{\Gamma_1}{\Delta_1}+\frac{\Gamma_2}{\Delta_2}}\sqrt{1-2\Gamma_1\Gamma_2\frac{1}{V^2+(\Gamma_1+\Gamma_2)^2}\cdot 2\frac{1-\cos\varphi}{2}}+\sigma E_Z, \tag{15.56}$$

$$= \tau E_J\sqrt{1-D\sin^2\frac{\varphi}{2}}+\sigma E_Z, \tag{15.57}$$

where

$$E_J := \frac{\sqrt{V^2+(\Gamma_1+\Gamma_2)^2}}{1+\frac{\Gamma_1}{\Delta_1}+\frac{\Gamma_2}{\Delta_2}}, \qquad D := \frac{4\Gamma_2\Gamma_1}{V^2+(\Gamma_1+\Gamma_2)^2}, \qquad E_Z := \frac{\Delta_Z}{1+\frac{\Gamma_1}{\Delta_1}+\frac{\Gamma_2}{\Delta_2}}. \tag{15.58}$$

This is the (**??**).

me. spectrum in three terminals for the discrete model

Solution

$$E_{\tau,\sigma} = \tau\left[1+3\frac{\Gamma}{\Delta}\right]^{-1}\left(\sqrt{V^2+\Gamma^2(3+2\cos(\varphi-\chi)+2\cos\varphi+2\cos\chi)}+\sigma\Delta_Z\right) =$$

$$= \tau\left[1+3\frac{\Gamma}{\Delta}\right]^{-1}\left(\sqrt{V^2+3\Gamma^2-4\Gamma^2\left(-\frac{3}{2}+\frac{1-\cos(\varphi-\chi)}{2}+\frac{1-\cos\varphi}{2}+\frac{1-\cos\chi}{2}\right)}+\sigma\Delta_Z\right) =$$

$$= \tau\left[1+3\frac{\Gamma}{\Delta}\right]^{-1}\left(\sqrt{V^2+9\Gamma^2-4\Gamma^2\left(\sin^2\frac{(\varphi-\chi)}{2}+\sin^2\frac{\varphi}{2}+\sin^2\frac{\chi}{2}\right)}+\sigma\Delta_Z\right).$$

Thus

$$E_{\tau,\sigma} = \tau E_J\sqrt{1-D\Phi(\varphi,\chi)}+\sigma\tilde{\Delta}_Z, \tag{15.59}$$

where we introduce $\Phi(\varphi,\chi)$ and D with special coefficients, such that $D\in[0,1]$,

$$E_J := \left[1+3\frac{\Gamma}{\Delta}\right]^{-1}\sqrt{V^2+9\Gamma^2}, \tag{15.60}$$

$$D := \frac{9\Gamma^2}{V^2+9\Gamma^2}, \tag{15.61}$$

$$\Phi(\varphi,\chi) := \frac{4}{9}\left(\sin^2\varphi/2+\sin^2\chi/2+\sin^2(\varphi/2-\chi/2)\right), \tag{15.62}$$

$$\tilde{\Delta}_Z := \frac{\Delta_Z}{1+3\frac{\Gamma}{\Delta}}. \tag{15.63}$$

And we have (**??**). Note that with ore definition, the function $\Phi(\varphi,\chi)$ has a maximal value of 1, and the D is allowed to be from 0 to 1.

15.2.5 Problems about Majorana states in SC-s

(there are many articles about it, so there will be enough good question for like 10 pages... It is not important now)

15.2.6 Problems about vortices

(ADD LATER HERE PROBLEMS FROM BELOUSOV)

Фйг-5.1. Дрейф вихрей в пленке

Имеется пленка высокотемпературного сверхпроводника YBaCuO с $T_c = 93.5°\text{K}$. Толщина пленки 100 nm. В поперечном поле $B = 8T$ при температуре $T = 90.5°\text{K}$ измерено удельное сопротивление $0.5\mu\Omega \cdot \text{cm}$. Найти среднюю скорость дрейфа вихрей v_v, если через пленку течет транспортный ток с плотностью $j = 10^4$ A/cm^2. Найти также коэффициент диффузии вихрей D, размерность коего cm^2/s.

Solution

(???)

Фйг-5.2. $j_c(T)$ при пиннинге на цилиндрических отверстиях

Найти зависимость критического тока $j_c(T)$ от температуры вблизи критической, $T \to T_c - 0$, при наличии слабого магнитного поля, индуцирующего вихри, для случая пиннинга вихрей на цилиндрических отверстиях диаметра $d > \xi_0$.

Пояснение: учесть рост $\xi(T)$ вблизи T_c. Двумерную плотность отверстий n_2 считать самым малым параметром задачи.

Solution

(???)

Фйг-5.3. $j_c(T)$ при пинниге на изотропных слабых дефектах

Найти зависимость критического тока $j_c(T)$ от температуры вблизи критической, $T \to T_c - 0$, при наличии слабого магнитного поля, индуцирующего вихри. Пинниг вихрей возникает теперь из-за изотропных слабых дефектов. Объемная плотность дефектов n_3 велика, $n_3\xi_0^3 \gg 1$.

Solution

(???)

Фйг-5.4. Пленка с дыркой при тепловых изгибных флуктуациях

Один вихрь находится в сверхпроводящей пленке, поперечно ее плоскости,и зацепляется за одно цилиндрическое отверстие диаметра $d > \xi_0$, ось которого параллельна направлению магнитного поля. Толщину пленки считать сколь угодно большой. При достаточно высокой температуре T, близкой к T_c, тепловые изгибные флуктуации вихря становятся заметными, т.е. их типичная амплитуда $u_T = \left(\left\langle u^2 \right\rangle\right)^{1/2}$ превышает величину d. В такой ситуации сила пиннинга вихря резко падает, но остается ненулевой. Найти зависимость критического тока $j_c(T)$ в этом режиме от температуры.

Solution

(???)

Фйг-6.1. $B(H)$ при флуктуациях положений вихревых линий

К относительно тонкой пленке сверхпроводника (толщина $d \gg \xi$, но при этом $d \ll a_0 = \sqrt{\Phi_0/B}\Big)$ приложено слабое параллельное магнитное поле, создающее двумерную решетку из вихревых линий, расположенных в плоскости пленки, со средним расстоянием между вихрями $a_0 \gg \lambda$. Считать что все стандартные параметры сверхпроводника $-\xi, \lambda$ - известны. В пленке имеются точечные дефекты, приводящие к флуктуациям положения вихревых линий, в частности, поперечный "уход" $|u(z) - u(0)| \propto z^{2/3}$. Кроме того, дефекты приводят к ненулевой величине критического тока пленки j_c, которая много меньше тока распаривания j_0. Требуется найти, как меняется зависимость $B(H)$ в области $B \ll H_{c1}$ из-за наличия дефектов.

Solution

(???)

Фйг-6.2. Сопротивление по критическому току

Для сверхпроводника с $\xi \ll \lambda$ в магнитном поле B находящемся в интервале $H_{c1} \ll B \ll H_{c2}$ задан критический ток j_c малый по сравнению с током распаривания j_0. Величина j_c определяется пиннингом на слабых изотропных дефектах. Эти же дефекты приводят к разрушению дальнего порядка решетки вихрей на расстояниях $R_c \gg \lambda \gg a_0$. Оценить величину R_c, считая остальные параметры заданными.

Solution

(???)

Фйг-6.3. Температура плавления вихревой решетки

Для решетки точечных вихрей в тонкой пленке сверхпроводника, находящейся в поперечном поле $B \ll H_{c2}$, найти температуру плавления T_M вихревой решетки. Все параметры считать заданными, толщина $d \leq \xi \ll \lambda$.

Solution

(???)

Фйг-13.7. Уровни в вихре с p-спариванием

Найти уровни ϵ_μ в вихре в сверхпроводнике с p-спариванием типа $d_\pm(k) \propto k_x \pm i k_y$ (как в A-фазе ^{3}He), для случая магнитного поля направленного вдоль оси z.

Solution

(???)

15.2.7 Problems about fluctuation effects

Фйг-4.1. Параметр Гинзбурга Gi для типичных случаев

Получить по порядку величины параметра Гинзбурга Gi для сверхпроводников размерности d $= 1, 2, 3$, как в чистом так и в чистом и грязном пределах, выразив их через параметры металла (k_F и длина пробега l), поперечные размеры (для $d = 1, 2$) и температуру перехода T_c.

Solution

(У Варламова Ларкина решена, почитаю, додумаю, впишу!)

Фйг-4.2. Флуктуационная диамагнитная восприимчивость

Вычислить отношение χ_{fl}/χ_0 флуктуационной диамагнитной восприимчивости к восприимчивости металла для трехмерного сверхпроводника.

Solution

(???)

Фйг-4.3. Ширина флуктуационной области вблизи $H_{c2}(T)$

Оценить ширину $\mathrm{Gi}(B)$ флуктуационной области вблизи линии $H_{c2}(T)$ при достаточно сильных магнитных полях, $B \gg \mathrm{Gi}H_{c2}(0)$.

Solution

(???)

Фйг-4.4. $T_{c0} - T_{BKT}$ для слоистого ВТСП

Оценить величину температурного интервала $T_{c0} - T_{BKT}$ для слоистого ВТСП семейства BiCaSrCuO исходя из данных по сопротивлению вдоль слоев при температуре порядка $1.5T_c$.
(данные найти самостоятельно в литературе, например с помощью библиографии в книге В.В.Шмидта I'll change the formulation, add some data!!!)

Solution

(???)

Фйг-4.5. Сопротивление "пирловских" вихрей

Для тонкой пленки свепрохпроводника (толщина $d \ll \lambda$) оценить величину линейного сопротивления $(dV/dI)|_{I\to 0}$ при $T < T_c$, возникающего из-за ненулевой концентрации "пирловских" вихрей.
(??? add explanation, what are they???)

Solution

(???)

Фйг-4.6*. Ренормгруппа Костерлица для перехода распаривания вихрей

Вывести и решить уравнения ренормгруппы Костерлица для фазового перехода распаривания вихрей в пленке, найти зависимость $R_c(T)$ при $T \to T_c - 0$.

(see Mineev Samokhin for now, it is a big topic)

15.3 Creation of Special Models

15.3.1 Problems about Creation of a Model for Special Superconductors 1

(I'll summarize many things from articles here)

Create model for superconductor that is open to the surroundings

(just a framework for open SC)

Solution

Create model for superconductor that is in non-thermal state

(discuss that we want it to be not in thermal state, thus we introduce such openness. explain, what do we mean by this??)

Solution

Superconductor between two baths

Create model for superconductor that is between two baths with different temperatures.

Solution for 1D superconductor

(??? currently, it is a not really solved problem...)

First of all, the superconductor itself will be described by

$$H_0 = \sum_{k,\sigma} \Big(\xi_k c^\dagger_{k\sigma} c_{k\sigma} + \Delta \big(c_{k\uparrow} c_{-k\downarrow} + c^\dagger_{-k\downarrow} c^\dagger_{k\uparrow} \big) \Big);$$

To make it an open system, we will use the density matrix.
(??? did it act before on a wave function?? maybe... (???))
The Hamiltonian is nearly integrable
(??? write what it means???)
So we can use the GGE anzatz for it:

$$\rho_{\boldsymbol{\mu}}(t) = \frac{e^{-\sum_{q,\sigma} \mu_q(t) n_{q,\sigma}}}{\mathrm{Tr}[e^{-\sum_{q,\sigma} \mu_q(t) n_{q,\sigma}}]}$$

(??? write what the parameter here mean???)
By "can" we mean that the error from the exact computation will be little (??? how much??).
And as all open system the density matrix obey the following Lindblad equation:

$$\frac{d\rho}{dt} = -i[H_0, \rho] + \hat{\mathcal{D}}[\rho],$$

$$\hat{\mathcal{D}}[\rho] := \epsilon \sum_{\alpha} \left(L_\alpha \rho L_\alpha^\dagger - \frac{1}{2}\{L_\alpha^\dagger L_\alpha, \rho\} \right);$$

Here α is a multi-index, which is $\alpha = \{i, k_1, k_2\}$, where i means the type of Lindblad operator below, k is the momenta index (so we have sum over all the momenta).

The Lindblad operators will be

$$\begin{aligned} L_{1,k_1k_2} &= \sqrt{\gamma_{1,k_1k_2}}\, b^\dagger_{k_1,p_1} b_{k_2p_2}, & \gamma_{1,k_1k_2} &= e^{-(\varepsilon_{k_1,p_1} - \varepsilon_{k_2,p_2})/2T_b} \\ L_{2,k_1k_2} &= \sqrt{\gamma_{2,k_1k_2}}\, b^\dagger_{k_1,p_1} b^\dagger_{k_2p_2}, & \gamma_{2,k_1k_2} &= e^{-(\varepsilon_{k_1,p_1} + \varepsilon_{k_2,p_2})/2T_b} \\ L_{3,k_1k_2} &= \sqrt{\gamma_{3,k_1k_2}}\, b_{k_1,p_1} b_{k_2,p_2}, & \gamma_{3,k_1k_2} &= e^{+(\varepsilon_{k_1,p_1} + \varepsilon_{k_2,p_2})/2T_b} \end{aligned}$$

(???????????????? why there are so????????)

Note that the Lindblad operators depend on the spectrum ε, which depends on the gap Δ, which is changed in time. So, the Lindblad operators depend on time. (??? maybe it means that they can't be in this form??)

And here, the b operators are Bogoliubov ones:

$$\begin{aligned} \widehat{b}_{k,-} &= u_k \widehat{c}_{k,-} + v_k \widehat{c}^\dagger_{-k,+} & \widehat{c}_{k,+} &= u_k \widehat{b}_{k,+} + v_k \widehat{b}^\dagger_{-k,-} \\ \widehat{b}_{k,+} &= u_k \widehat{c}_{k,+} - v_k \widehat{c}^\dagger_{-k,-} & \widehat{c}_{k,-} &= u_k \widehat{b}_{k,-} - v_k \widehat{b}^\dagger_{-k,+} \end{aligned}$$

where the coefficients are

$$u_p^2 = \frac{1}{2}\left(1 + \frac{\xi_p}{\sqrt{\xi_p^2 + |\Delta|^2}}\right), \qquad v_p^2 = \frac{1}{2}\left(1 - \frac{\xi_p}{\sqrt{\xi_p^2 + |\Delta|^2}}\right)$$

in which there is the gap that obey self-consistency equation

$$\Delta := \lambda \sum_k \mathrm{Tr}\left(e^{-\sum_r \mu_r(\Delta) b_r^\dagger b_r} c_{k\uparrow} c_{-k\downarrow}\right); \qquad \widehat{\mathcal{H}} = E_0 + \sum_{k,\sigma} \varepsilon_{k,\sigma} b^\dagger_{k,\sigma} b_{k,\sigma}; \qquad \varepsilon_k = \sqrt{\xi_k^2 + |\Delta|^2}$$

(by which we mean that it is obtained from H, which also has Δ)

Now, what is left is to write, how one would solve the Liouville equation and how to obtain all physical parameters from the density matrix.

Solution for 1D superconductor (with another method (???))

(??? how to do it in another way?? read articles and write it here)

Solution for 3D superconductor

(??? I have no idea about it at all)

Solution

(???)

15.5.5 Problems about Special Junctions 1

(write from articles some transformations in their calculations. for now I write it in special note for them)

me. Calculation of Josephson current

(write that in MTJJ there is this and that formula for the current and density of states)
Find the current.
(point out that we have a GF in 4x4 matrix and the main point of the exercise is to understand how to work with it! delete or explain all that is related only to cond matter)

Solution

The current can be determined from the Gibbs free energy, which, in its turn, is derived from the density of states ρ (see review in Sec. **??**). More precisely, ρ is obtained from d matrix by $\rho(\omega,\varphi) = -\frac{1}{\pi}\operatorname{Im}\frac{\partial}{\partial\omega}\ln\det d\,(\omega,\varphi)$, and the d matrix is obtained from GF of the model by (**??**). Thus, the current in the j^{th} lead can be determined by some careful transformations:

$$J_j(\varphi) = -\frac{2e}{h\beta}\int_0^\infty d\omega \ln\left(2\cosh\frac{\beta\omega}{2}\right)\frac{\partial}{\partial\varphi}\delta\rho(\omega,\varphi) \overset{[}{\Phi_0}= \frac{h}{2e}\equiv\frac{\pi\hbar}{e}]\text{i b p}= \tag{15.64}$$

$$= -\frac{1}{\Phi_0}\operatorname{Im}\int_0^\infty d\omega\tanh\frac{\beta\omega}{2}\frac{\partial}{\partial\varphi}\ln\det d\,(\omega+i\eta,\varphi) \overset{f(\omega)=\frac{1}{e^{\beta\omega}+1}}{=} \tag{15.65}$$

$$= \frac{1}{\Phi_0}\operatorname{Im}\int_{-\infty}^{+\infty} d\omega f(\omega)\operatorname{tr}\frac{\partial}{\partial\varphi}\ln\det(\omega+i\eta-h_D-\Sigma(\omega+i\eta)) = \tag{15.66}$$

$$= \frac{1}{\Phi_0}\operatorname{Im}\int_{-\infty}^{+\infty} d\omega f(\omega)\operatorname{tr}\frac{1}{\omega+i\eta-h_D-\Sigma(\omega+i\eta)}\frac{\partial\Sigma(\omega+i\eta)}{\partial\varphi_j} = \tag{15.67}$$

$$= \frac{1}{2i\Phi_0}\int d\omega f(\omega)\operatorname{tr}\frac{1}{\omega+i\eta-h_D-\Sigma(\omega+i\eta)}\frac{\partial\Sigma(\omega+i\eta)}{\partial\varphi_j} - \tag{15.68}$$

$$- \frac{1}{2i\Phi_0}\int d\omega f(\omega)\operatorname{tr}\frac{1}{\omega-i\eta-h_D-\Sigma(\omega-i\eta)}\frac{\partial\Sigma(\omega-i\eta)}{\partial\varphi_j}. \tag{15.69}$$

The poles of the integrand allows one to make a simplification. The Fermi function produces fermionic poles. The first integral because of $\omega+i\eta$ has poles from the propagator in the lower-half of the complex plane, thus we need to close the contour to the upper-half. In this region we have only poles from Fermi's function (when $e^{\beta\omega}=-1$). It means, $\beta\omega=\pi+2\pi n, n=0,1,2,3...$ The second integral should be closed in the lower part of the plane, where the poles are $\beta\omega=\pi+2\pi n, n=-1,-2,-3..$, because of $\omega-i\eta$ in it. As a result,

$$J_j(\varphi) = \frac{1}{2i\Phi_0}\cdot 2\pi i\sum_{\omega_n\geq 0}\underbrace{\operatorname{res}(f(\omega))}_{-1/\beta}\operatorname{tr}\frac{1}{\omega+i\eta-h_D-\Sigma(\omega+i\eta)}\frac{\partial\Sigma(\omega+i\eta)}{\partial\varphi_j} - \tag{15.70}$$

$$- \frac{1}{2i\Phi_0}\cdot(-2\pi i)\sum_{\omega_n<0}\underbrace{\operatorname{res}(f(\omega))}_{-1/\beta}\operatorname{tr}\frac{1}{\omega-i\eta-h_D-\Sigma(\omega-i\eta)}\frac{\partial\Sigma(\omega-i\eta)}{\partial\varphi_j} = \tag{15.71}$$

$$= -\frac{\pi}{\Phi_0}\frac{1}{\beta}\sum_{\omega_n}\operatorname{tr}\frac{1}{i\omega_n-h_D-\Sigma(i\omega_n)}\frac{\partial\Sigma(i\omega_n)}{\partial\varphi_j}. \tag{15.72}$$

At $T=0$ the sum is changed to the integral[1]:

$$J_j(\varphi, T=0) = -\frac{1}{2\Phi_0}\int d\omega\ \operatorname{tr}\frac{1}{i\omega-h_D-\Sigma(i\omega)}\frac{\partial\Sigma(i\omega)}{\partial\varphi_j}. \tag{15.73}$$

From this equation, the Ambegoakar-Baratoff's formula can be obtained if one neglects $\Sigma(i\omega)$ in the denominator (this is the tunneling limit). This is because $\Sigma\sim\Gamma$, so after decomposition of the denominator into series, the terms from Σ from the denominator will be of the highest order in Γ.

To compute currents from j-th contact to j'-th we need to compute $J_j - J_{j'}$. Soon the results of this formula will be presented.

15.5.6 Problems about Special Junctions 2

(write from articles some transformations in their calculations. for now I write it in special note for them)

[1] See, for example, Eq. (89) in [**?**]

15.5.7 Problems about Special Junctions 3

(write from articles some transformations in their calculations. for now I write it in special note for them)

15.5.8 Problems about MTJJ

(I'll write it first in the note on MTJJ. that there is this or that setup, solve something in it. there are very many setup and it is a good challenge to derive something there)

Part VII
Specific Superconductivity in a Nutshell

16 Special also useful theories and properties

16.1 Details of general properties of superconductors

При нулевой температуре все электроны сверхпроводящие (????)

Вывод этого утверждения по Пухову следующий. Плотность электронов в сверхпроводнике n делится на нормальную n_n и сверхтекучую n_s части. Из теории ферми-жидкости (разложением и усреднением) $\mathbf{P} = -\mathbf{v}\frac{4\pi}{3(2\pi\hbar)^3}\int\limits_0^\infty dpp^4\frac{dn_B(\varepsilon)}{d\varepsilon}$, подставим фермиевское распределение и умножим на 2 (от спина), получаем

$$\rho_n = -\frac{8\pi}{3(2\pi\hbar)^3}\int\limits_0^\infty \frac{dn_F}{dp}p^4dp \overset{\text{around } p\approx p_F}{=} -\frac{p_F^4}{3\pi^2\hbar^3 v_F}\int\limits_{-\infty}^{+\infty}\frac{dn_F}{d\varepsilon}d\xi.$$

$\rho = mN/V = p_F^3 m/3\pi^2\hbar^3 \equiv \rho_n + \rho_s$,

$$\frac{\rho_n}{\rho} = -2\int\limits_0^{+\infty}\frac{dn_F}{d\varepsilon}d\xi.$$

Тут интеграл определяется температурной зависимостью щели $\Delta(T)$. Дифференцируем $\frac{1}{\lambda} = \frac{1}{2}\sum\limits_{\mathbf{p}}\cdot\frac{1+2\bar{n}_{\mathrm{p}}}{\sqrt{\xi_{\mathrm{p}}^2+\Delta^2}}$ по T и подставляем, получаем (!!! сделаю это уже очень скоро!!!)

$$\frac{\rho}{\rho_n} = 1 - \frac{d\ln T}{d\ln\Delta}.$$

Поэтому при $T\to 0$ плотность нормальной компоненты обращается в ноль $\rho_n \to 0$. Другими словами, при нулевой температуре все электроны становятся сверхпроводящими и $\frac{\rho_s}{\rho} = -\frac{d\ln T}{d\ln(\Delta/T)} \overset{x\to 0}{\to} 1$ 1.

(???? пока это вопрос, а то в другом месте написано, что нет, не все, ибо ферми сфера заполнена, рассеяние не может быть)

Общие важные вопросы про теории сверхпроводимости

Связи теорий сверхпроводимости друг с другом (????)

(??? оставшийся важный вопрос, потом пойму, пока прописать сами теории нужно еще)

Переходы между одними и другими типами сверхпроводников за счет изменения их параметров (????)

(укажу про эти задачи потом, что как доказать, что меняя такой-то параметр такие-то эффекты поменяются. пока тренируюсь в этом.)

Почему вообще классическая теория ГЛ работает для квантовых явлений? (????)

(тоже, стану умнее - допишу)

Как конкретно экспериментальные факты указывают на верную теорию сверхпроводимости?

1. Притяжение между электронами обеспечивается фононами решетки. Это взаимодействие не прямое, а опосредованное и не может выражаться потенциальной функцией $U(\mathbf{r}_1 - \mathbf{r}_2)$.

2. Для существования связанного состояния двух электронов нужна двумерность. Она обеспечивается тем, что движение электронов происходит на фоне заполненной ферми-сферы.

Эффективно взаимодействие выражается в рассеянии электрона на электроне. Чтобы электрон мог перейти из состояния $\mathbf{p}$ в состояние $\mathbf{p}'$, последнее, согласно принципу Паули, должно быть свободно. Это возможно лишь для состояний вблизи поверхности Ферми. Ширина области, в которой электроны могут притягиваться друг к другу $\sim \hbar\omega_D$, поскольку это максимальная энергия фононов, которую можно передать. Остальные электроны, находящиеся в глубине ферми-сферы, не могут изменить свой импульс.

В мелкой трёхмерной яме уровня, соответствующего связанному состоянию, нет. Он появляется только, если яма достаточно глубока и число Борна больше единицы. Откуда же появляется «низкоразмерность» движения, обеспечивающая существование пары? У нас не об изолированные частицы в 3D-пространстве, а о квазичастицы на фоне заполненной ферми-сферы. Испускание и поглощение фонона приводит лишь к повороту импульса электрона, его положение описывается только двумя углами на ферми-сфере, а величина импульса остаётся практически неизменной $p \approx p_F$. Наличие заполненной ферми-сферы делает задачу эффективно двумерной. Кроме того, мы заменяем плотность состояний вблизи поверхности Ферми на постоянную величину, что также соответствует двумерному случаю. В мелкой двумерной яме уровень, соответствующий связанному состоянию, есть всегда. Энергия связи экспоненциально мала по константе взаимодействия, что и объясняет малую величину температуры сверхпроводящего перехода (?? почему???).

Другие принципиальные свойства сверхпроводников

Вычисление сил, действующих на сверхпроводник в магнитном поле

(см ЛЛ8, еще додумать нужно. Вроде в общефизе тоже про это задачи были)

Самоиндукция сверхпроводников

(см ЛЛ8, еще додумать нужно. добавлю задачи про это в каталог)

Теоретическое доказательство, что проводимость сверхпроводника равна ровно бесконечности (?????)

(??? непонятно, почему все другие процессы дают ровно нулевой вклад в проводимость. а так- через переход к ур Лондонов это можно показать, допишу позже.)

16.2 Details of basic theories

16.2.1 Details of GL theory

Флуктуационная поправка к теплоемкости по ГЛ

(I'll summarize details about it here)

GL theory by Chelkatshev

(????)

$$F[\Delta(\mathbf{r})] = F_{n0} + \int d\mathbf{r}\frac{\mathbf{B}^2}{8\pi} + a\int d\mathbf{r}\Delta^*\left[\frac{\hbar}{\tau_{\mathrm{GL}}} - \hbar D\left(\nabla_{\mathbf{r}} - i\frac{2e}{\hbar c}\mathbf{A}\right)^2 + \frac{b}{2T_c}|\Delta|^2\right]\Delta,$$

τ_{GL} имеет размерность времени и меняет знак в точке сверхпроводящего перехода,

$$\frac{\hbar}{\tau_{\mathrm{GL}}} = \alpha\left(T - T_c\right),$$

Удобно нормировать параметр порядка так, чтобы его модуль совпадал с щелью в квазичастичной плотности состояний объёмного образца. Коэффициенты a, α, D и b слабо зависят от температуры, и их можно найти из БКШ. Для грязного предела (например, в сверхпроводящих сплавах с примесями), когда длина свободного пробега электрона l много меньше, чем $\xi_0 = \sqrt{\hbar D/T_c}$ (характерный размер куперовской пары при $T = 0$), D совпадает с коэффициентом диффузии электрона на уровне Ферми ($D = v_F l/3$),

$$a = \frac{\nu\pi}{8T_c}, \quad \alpha = \frac{8}{\pi}, \quad b = \frac{7\zeta(3)}{\pi^3}, \qquad \text{Kopnin N. B "Non-eq. SC"}$$

$\nu = mp_F/2\pi^2\hbar^3$, $\zeta(3) \approx 1.2$.

Условие применимости разложения $F[\Delta(\mathbf{r})]$ это $\Delta \ll \Delta(T \ll T_c) \equiv \Delta_0 \sim T_c$ и $\Delta \sim \sqrt{\hbar T_c/\tau_{\mathrm{GL}}} \sim \sqrt{(T_c - T)\,T_c}$, откуда следует условие $|T - T_c| \ll T_c$. Кроме того, Δ должна меняться в пространстве не слишком быстро (на расстояниях много больших ξ_0).

Для чистого случая:

$$a = 7\zeta(3)n/8\pi^2T_c^2, \qquad \alpha = 6\pi^2T_c/7\zeta(3)E_F, \qquad D = \hbar/4m, \qquad b = 3T_c/4E_F,$$

$n = p_F^3/3\pi^2\hbar^3$ - плотность электронов, $E_F = p_F^2/2m$ - энергия Ферми, m - масса электрона.

(??? тут у нас всегда обычная масса, не эффективная? этот вопрос не четко обсуждается в литературе, додумать нужно)

Микроскопический вывод функционала Гинзбурга Ландау по Враламову и Ларкину

6. 1. Функционал Гинзбурга — Ландау традиционного сверхпроводника

6. 2. Функционал Гинзбурга —Ландау для сверхпроводника с нетривиальной симметрией параметра порядка

О критерии Гинзбурга-Леванюка в разных случаях

(??? Когда-то доучу это!!!!)

$$Gi_{(D)} = \frac{1}{\alpha}\left[\frac{V_D}{V}\vartheta_D b(4m)^{\frac{D}{2}} T_{\mathrm{c}}^{\frac{D}{2}-1}\right]^{\frac{2}{4-D}}.$$

(???? верная ли формула эта???)

Подставим в эту формулу следующие из микроскопического рассмотрения значения параметров теории Гинзбурга - Ландау (2.6)(допишу их!!!), тогда

$$Gi_{(D)} = \left[\frac{7\zeta(3)\vartheta_D}{8\pi^2}\left(\frac{V_D}{V}\right)\frac{1}{\nu_D T_{\mathrm{c}}\xi^D}\right]^{\frac{2}{4-D}}$$

Так как $\nu_D T_{\mathrm{c}} \sim \nu_D v_F/\xi_c \sim p_F^{D-1}\xi_c^{-1} \sim \mathfrak{a}^{1-D}\xi_c^{-1}$, то

$$Gi_{(D)} \sim \left[\frac{7\zeta(3)\vartheta_D}{8\pi^2}\left(\frac{V_D}{V}\right)\frac{\xi_c \mathfrak{a}^{D-1}}{\xi^D}\right]^{\frac{2}{4-D}}$$

Также:

$$Gi_{(2)} = \frac{7\zeta(3)}{32\pi^3}\frac{1}{\nu_2 T_{\mathrm{c}}\xi^2}$$

$$Gi_{(3)} = \left[\frac{7\zeta(3)}{64\pi^3}\frac{1}{\nu_3 T_{\mathrm{c}}\xi^3}\right]^2$$

$\mathfrak{a}$ есть межатомное расстояние. Как уже упоминалось, в массивных традиционных сверхпроводниках ввиду большой величины корреляционной длины ($\xi_c \sim 10^{-6} \div 10^{-4}$ cm), которая намного превышает межатомное расстояние ($\mathfrak{a} \sim 10^{-8}$ см), флуктуационная поправка к теплоемкости оказывается чрезвычайно малой.

(!!!! нужно переписать таблицу, кривая получилась!!!)

$Gi_{(3)}$	$Gi_{(2)}$
$80\left(\frac{T_{\mathrm{c}}}{E_F}\right)^4, (c)$ $\frac{1{,}6}{(p_F l)^3}\left(\frac{T_{\mathrm{c}}}{E_F}\right), (d)$	$\left(\frac{T_{\mathrm{c}}}{E_F}\right), (d)$ $\frac{0{,}27}{p_F l}, (d)$
$Gi_{(1)}$	$\frac{1{,}3}{p_F^2 l d}, (d)$ film
$Gi_{(0)}$	
$0,5, (d)$ $1,3\left(p_F^2 S\right)^{-2/3}\left(T_{\mathrm{c}}\tau\right)^{-1/3}, (d)$ wire $2,3\left(p_F^2 S\right)^{-2/3}, (d)$ whisker	$\frac{\sqrt{7\zeta(3)}}{2\pi}\frac{1}{\sqrt{\nu T_{\mathrm{c}} V}} \approx$

Имеется связь между найденным числом Гинзбурга - Леванюка для грязного $2D$ случая $Gi_{(2)}^{(d)}$ и безразмерным кондактансом

$$G_\square = \frac{\hbar}{e^2 R_\square},$$

(???)

Другие определения

Уширение критической области магнитным полем

(потом когда-то дочитаю)

16.2.2 Details of BCS theory

Other forms of BCS hamiltonian

(write those from my master's thesis here!)

Size of a Cooper pair

$$\Delta \approx \left| \frac{p^2}{2m} - \frac{p_F^2}{2m} \right| \approx v_F \delta p.$$

Размер - это неопределенность координаты, из соотношения неопределённости:

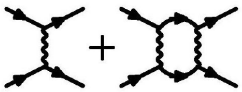
$$\xi \approx \frac{\hbar v_F}{\Delta}.$$

Поскольку 2Δ есть энергия связи двух электронов,

$$\Delta \approx \left| \frac{p_2^2}{2m} - \frac{p_1^2}{2m} \right| \approx \frac{p_F \delta p}{m}, \quad (v_i \approx v_F)$$

Размер куперовской пары можно оценить также из щели в спектре: $\varepsilon(p) = \sqrt{\Delta^2 + v_F^2 (p - p_F)^2}$. Вдали от ферми-уровня $v_F |p - p_F| \gg \Delta$ спектр совпадает с случаем нормального металла: $\varepsilon(p) = v_F |p - p_F|$. Это значит, что эффект спаривания оказывает влияние только на электроны с импульсами в области шириной $\delta p \approx \Delta / v_F$. Соответственно, пространственный масштаб куперовской корреляции составляет $\xi \approx \hbar / \delta p \approx \hbar v_F / \Delta$.

$$\xi(v_F \approx 10^8 \text{ cm/c}, \Delta \approx 10K) \approx 2 \cdot 10^{-4}\text{см} \gg a = n^{-1/3} \approx 2 \cdot 10^{-8}\text{с}.$$



Пары проникают друг через друга, их нельзя представлять себе как классический газ частиц, расстояние между которыми больше их размеров.

Proof that all electrons are superconductive at $T = 0$

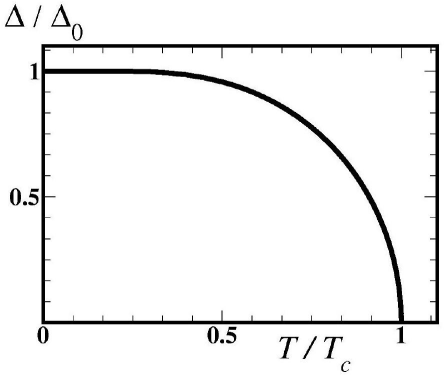
Determining $\Delta(T)$ in general case

$$\Gamma^0\left(i\varepsilon, i\varepsilon'\right) = \lambda v(i\varepsilon) v\left(i\varepsilon'\right), \qquad v(i\varepsilon) = \frac{\omega_D}{\sqrt{\varepsilon^2 + \omega_D^2}}$$

$$\Delta_{\alpha\beta} = \lambda \int F_{\alpha\beta}(\varepsilon, \mathbf{p}) \frac{d\varepsilon d^3p}{(2\pi)^4},$$

$$\Delta = \lambda T \sum_{\omega_n} \int F\left(i\omega_n, \mathbf{p}\right) \frac{d^3p}{(2\pi)^3} = \lambda T \sum_{\omega_n} \int \frac{\Delta}{\omega_n^2 + \xi_{\mathbf{p}}^2 + \Delta^2} \frac{d^3p}{(2\pi)^3},$$



$$\tilde{\Delta}(i\varepsilon) = T \sum_{\varepsilon'} \Gamma^0\left(i\varepsilon, i\varepsilon'\right) F\left(i\varepsilon', \mathbf{r} = \mathbf{r}'\right),$$

$$F\left(i\varepsilon, \mathbf{r} = \mathbf{r}'\right) = \int \frac{\tilde{\Delta}(i\varepsilon)}{\varepsilon^2 + \xi_p^2 + \tilde{\Delta}^2(i\varepsilon)} \frac{d^3p}{(2\pi)^3}.$$

$$\tilde{\Delta}(i\varepsilon) = \Delta(T) v(i\varepsilon)$$

$$\Delta(T) = \lambda T \sum_{\varepsilon} \int \frac{v^2(i\varepsilon)\Delta(T)}{\varepsilon^2 + \xi_{\mathbf{p}}^2 + v^2(i\varepsilon)\Delta^2(T)} \frac{d^3p}{(2\pi)^3}.$$

$$\frac{1}{\lambda\nu_0} = \pi T \sum_{\varepsilon} \frac{v^2(i\varepsilon)}{\sqrt{\varepsilon^2 + \Delta^2(T) v^2(i\varepsilon)}}.$$

Determining Δ_0

$$\frac{1}{\nu_0\lambda} = \int_0^{\infty} \frac{v^2(i\varepsilon) d\varepsilon}{\sqrt{\varepsilon^2 + \Delta_0^2 v^2(i\varepsilon)}}. \qquad v(i\varepsilon) := \omega_D / \left(\varepsilon^2 + \omega_D^2\right)^{1/2}$$

$$\frac{1}{\nu_0\lambda} = \int\limits_0^\infty \frac{\omega_D^2 d\varepsilon}{(\varepsilon^2+\omega_D^2)\sqrt{\varepsilon^2+\Delta_0^2}}.$$

$$\int\limits_0^{\varepsilon_0} \frac{d\varepsilon}{\sqrt{\varepsilon^2+\Delta_0^2}} + \int\limits_{\varepsilon_0}^\infty \frac{\omega_D^2 d\varepsilon}{\varepsilon\,(\varepsilon^2+\omega_D^2)} = \ln\frac{2\varepsilon_0}{\Delta_0} + \ln\frac{\omega_D}{\varepsilon_0}.$$

$$\frac{1}{\lambda\nu_0} = \ln\frac{2\omega_D}{\Delta_0}.$$

$$\Delta_0 = \frac{\gamma}{\pi}T_c \qquad T_c = \frac{2\gamma}{\pi}\omega_D e^{-1/\lambda\nu_0}$$

Determining $\Delta(T)$ for $T \ll T_c$

$$\frac{1}{\lambda\nu_0} = T\sum_\varepsilon \int\limits_{-\infty}^\infty \frac{d\xi}{\varepsilon^2+\xi^2+\Delta^2} \qquad \sum_{n=-\infty}^{\infty} \frac{1}{(2n+1)^2+a^2} = \frac{\pi}{2a}\,\mathrm{th}\,\frac{\pi a}{2}$$

$$\frac{1}{\lambda\nu_0} = \int\limits_0^\infty \mathrm{th}\,\frac{\sqrt{\xi^2+\Delta^2}}{2T}\frac{d\xi}{\sqrt{\xi^2+\Delta^2}}.$$

$$\frac{1}{\lambda\nu_0} = \ln\frac{2\omega_D}{\Delta} - 2\int\limits_0^\infty \frac{d\xi}{\sqrt{\xi^2+\Delta^2}}\exp\left(-\frac{\sqrt{\xi^2+\Delta^2}}{T}\right).$$

$$\frac{1}{\nu_0\lambda} = \ln\frac{2\omega_D}{\Delta} - 2e^{-\Delta/T}\int\limits_0^\infty e^{-\xi^2/2\Delta T}\left(1-\frac{\xi^2}{2\Delta^2}\right)\frac{d\xi}{\Delta}$$

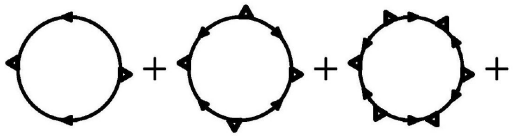
$$\ln\frac{\Delta}{\Delta_0} = -\sqrt{\frac{2\pi T}{\Delta}}e^{-\Delta/T}\left(1-\frac{T}{8\Delta}\right) \qquad \Delta_0 = \gamma T_c/\pi$$

$$\Delta\,(T\ll T_c) = \Delta_0\left(1-\sqrt{\frac{2\pi T}{\Delta_0}}e^{-\Delta_0/T}\left(1-\frac{T}{8\Delta_0}\right)\right)$$

Determining $\Delta(T)$ for $T \approx T_c$

$$\frac{1}{\lambda\nu_0} = \pi T\sum_\varepsilon \frac{v^2(i\varepsilon)}{\sqrt{\varepsilon^2+\Delta^2(T)v^2(i\varepsilon)}}.$$

$$\frac{1}{\lambda\nu_0} = \pi T\sum_\varepsilon\left(\frac{v^2(i\varepsilon)}{|\varepsilon|} - \frac{\Delta^2 v^4(i\varepsilon)}{2|\varepsilon|^3}\right)$$



$$\ln\frac{T}{T_c} = -\frac{\pi\Delta^2}{2}T\sum_{\varepsilon_n}\frac{1}{|\varepsilon_n|^3}$$

$$\zeta(x) = \sum_{n=1}^\infty \frac{1}{n^x}, \quad \sum_{n=0}^\infty \frac{1}{(2n+1)^x} = \left(1-\frac{1}{2^x}\right)\zeta(x).$$

$$\frac{T-T_c}{T_c} = -\frac{7\zeta(3)}{8\pi^2}\frac{\Delta^2}{T_c^2}$$

$$\Delta^2_{T\to T_c} = \frac{8\pi^2}{7\zeta(3)} T_c \left(T_c - T\right)$$

Heat capacitance at $T < T_c$

$$\frac{\lambda}{V}\frac{\partial\Omega}{\partial\lambda} = T\sum_{\omega_n}\int G_0^{-1}\left(i\omega_n,\mathbf{p}\right)\left(G\left(i\omega_n,\mathbf{p}\right) - G_0\left(i\omega_n,\mathbf{p}\right)\right)\frac{d^3p}{(2\pi)^3} =$$

$$= -T\sum_{\omega_n}\int \Delta^* F\left(i\omega_n,\mathbf{p}\right)\frac{d^3p}{(2\pi)^3} = -\frac{|\Delta|^2}{\lambda}.$$

$$\frac{d\lambda}{\lambda^2} = T\sum_{\omega_n}\int \frac{2\Delta d\Delta}{\left(\omega_n^2 + \xi_{\mathbf{p}} + \Delta^2\right)^2}\frac{d^3p}{(2\pi)^3}$$

$$\frac{\Omega_s - \Omega_n}{V} = -2\int_0^{\Delta} T\sum_{\omega_n}\int \frac{\Delta^3 d\Delta}{\left(\omega_n^2 + \xi_{\mathbf{p}}^2 + \Delta^2\right)^2}\frac{d^3p}{(2\pi)^3}$$

$$\frac{\Omega_s - \Omega_n}{V} = -\pi\nu_0 T\sum_{\omega_n}\left(\sqrt{\omega_n^2+\Delta^2} + \frac{\omega_n^2}{\sqrt{\omega_n^2+\Delta^2}} - 2\left|\omega_n\right|\right).$$

а) $T \to 0$.

$\sum_n f(n) \approx \int f(x)dx + \int e^{2\pi i x} f(x)dx + \int e^{-2\pi i x} f(x)dx + \dots \qquad f(x) := \sqrt{(2\pi T x)^2 + \Delta^2} + \frac{\Delta^2}{\sqrt{(2\pi T x)^2+\Delta^2}} - 4\pi T|x|$

$$\Omega_s = -\frac{V\nu_0\Delta^2}{2}\left(1 + 2\sqrt{\frac{2\pi T}{\Delta}}e^{-\Delta/T}\left(1 + \frac{15}{8}\frac{T}{\Delta}\right)\right)$$

$$\Omega_s = -\frac{\nu_0 V\Delta_0^2}{2}\left(1 + 4\sqrt{\frac{2\pi T^3}{\Delta_0^3}}e^{-\Delta_0/T}\right)$$

$$C_s = T\frac{\partial S_s}{\partial T} = -T\frac{\partial^2\Omega_s}{\partial T^2} = 2\nu_0 V\sqrt{\frac{2\pi\Delta_0^5}{T^3}}e^{-\Delta_0/T}.$$

б) $T \to T_c$.

$$\frac{\Omega_s - \Omega_n}{V} = -\pi\nu_0\Delta^4 T\sum_{\omega_n}\frac{1}{\left|\omega_n\right|^3} \overset{\text{typ summ}}{=} -\frac{7\zeta(3)}{16\pi^2}\frac{\nu_0\Delta^4}{T_c^2}$$

$$\Omega_s - \Omega_n = -\frac{4\pi^2}{7\zeta(3)} V\nu_0\left(T - T_c\right)^2$$

$$C_s - C_n = \frac{8\pi^2}{7\zeta(3)}\nu_0 T_c V, \qquad C_n = \frac{2\pi^2}{3}\nu_0 VT$$

$$\frac{C_s - C_n}{C_n} = \frac{12}{7\zeta(3)}$$

Impact of Coulomb interaction on superconductivity

Кулоновское взаимодействие действительно понижает температуру сверхпроводящего перехода, но не очень сильно. При $\nu_0\mu \ln \varepsilon_F/\omega_D \gg 1$ относительная поправка к λ мала как $1/\ln(\varepsilon_F/\omega_D)$.

Proof:

$$\Gamma^0(i\varepsilon, i\varepsilon') = \lambda v(i\varepsilon) v(i\varepsilon') - \mu$$

$$\lambda_* = \lambda - \frac{\mu}{1 + \nu_0\mu \ln(\varepsilon_F/\omega_D)}.$$

$$E_{\mathbf{k},\pm}:=\sqrt{\xi_k^2+\Delta^2\left(|\,\mathrm{d}(\mathbf{k})|^2\pm|\mathrm{m}(\mathbf{k})|\right)} \tag{17.16}$$

For tempr order par we use self-cons eq:

$$\Delta_{\alpha\beta}(\mathbf{k}) = -T\sum_{n}\sum_{k'} V_{\beta\alpha,\gamma\delta}\left(\mathbf{k},\mathbf{k}'\right)\frac{\Delta_{\gamma\delta}\left(\mathbf{k}'\right)}{\omega_n^2+\xi_{k'}^2+\Delta_{\mathbf{k}'}^2} \tag{17.17}$$

$\sum_{n=-\infty}^{\infty}\frac{1}{(2n+1)^2\pi^2+x^2} = \frac{1}{2x}\ln\frac{x}{2} \Rightarrow$

$$\Delta_{\alpha\beta}(\mathrm{k}) = -\sum_{\mathbf{k}'} V_{\beta\alpha,\gamma\delta}\left(\mathrm{k},\mathrm{k}'\right)\Delta_{\gamma\delta}\left(\mathrm{k}'\right)\frac{1}{2E_{\mathrm{k}'}}\,\mathrm{th}\left(\frac{E_{\mathrm{k}'}}{2T}\right) \tag{17.19}$$

Add eq. 6.5, 6.6 here!!!

Now, matrix form:

$$\hat{G}\left(\mathbf{k}_1,\mathbf{k}_2;\omega_n\right) = -\int_0^{1/T} d\tau e^{i\omega_n\tau}\left\langle T_\tau A_{\mathbf{k}_1}(\tau)A^+_{\mathbf{k}_2}(0)\right\rangle = \begin{pmatrix} G_{\alpha\beta}\left(\mathbf{k}_1,\mathbf{k}_2;\omega_n\right) & -F_{\alpha\beta}\left(\mathbf{k}_1,\mathbf{k}_2;\omega_n\right) \\ -F^+_{\alpha\beta}\left(\mathbf{k}_1,\mathbf{k}_2;\omega_n\right) & -G_{\beta\alpha}\left(-\mathbf{k}_2,-\mathbf{k}_1;-\omega_n\right)\end{pmatrix} \tag{17.20}$$

$$\hat{G}_0\left(\mathbf{k},\omega_n\right) = -\frac{1}{\omega_n^2+\xi_k^2+\Delta_k^2}\begin{pmatrix}\left(i\omega_n+\xi_k\right)\delta_{\alpha\beta} & \Delta_{\alpha\beta}(\mathbf{k}) \\ \Delta^+_{\alpha\beta}(\mathbf{k}) & \left(i\omega_n-\xi_k\right)\delta_{\alpha\beta}\end{pmatrix} = -\frac{i\omega_n\hat{\tau}_0+\xi_k\hat{\tau}_3+\dot{\Delta}(\mathbf{k})}{\omega_n^2+\xi_k^2+\Delta_k^2} \tag{17.21}$$

Now, spectral decomposition:

$$\hat{G}\left(\mathbf{k},\omega_n\right) = \int_{-\infty}^{+\infty}\frac{dz}{2\pi}\frac{\hat{\rho}(\mathbf{k},z)}{i\omega_n-z}$$

$$T\sum_n\frac{1}{i\omega_n-z} = \frac{1}{2}\,\mathrm{th}\,\frac{z}{2T} \tag{17.22}$$

$$\hat{\rho}(\mathbf{k},\omega) = -2\,\mathrm{Im}\,\hat{G}^R(\mathbf{k},\omega) = i\left(\hat{G}^R(\mathbf{k},\omega)-\hat{G}^A(\mathbf{k},\omega)\right)$$

$$\hat{G}^{R(\boldsymbol{A})}(\mathbf{k},\omega) = \hat{G}\left(\mathbf{k},\omega_n\right)\Big|_{i\omega_n\to\omega\pm i0} \tag{17.23}$$

$$\det\left\|E^2-\xi_k^2-\Delta(\mathbf{k})\Delta^+(\mathbf{k})\right\| = 0 \qquad \text{spectr} \tag{17.24}$$

$$E_{\mathbf{k}} = \sqrt{\xi_k^2+\Delta^2|g(\mathbf{k})|^2} \qquad \text{singl}$$

$$E_{\mathbf{k}} = \sqrt{\xi_k^2+\Delta^2|\,\mathrm{d}(\mathbf{k})|^2} \qquad \text{unit ph, tripl}$$

$$E_{\mathrm{k},\pm} = \sqrt{\xi_k^2+\Delta^2\left(|\,\mathrm{d}(\mathbf{k})|^2 \pm |\mathrm{d}^*(\mathbf{k})\times\mathrm{d}(\mathbf{k})|\right)} \qquad \text{non-unit ph, tripl} \tag{17.25}$$

T.e. нули спектра возбуждений для любых фаз триплетного спаривания определяется $\det \Delta(k) = 0$, то есть $\mathrm{d}^2(\mathbf{k}) = 0$.

Now, density of states:

$$N(E) := \sum_{\mathbf{k}\alpha} \delta\left(E - E_{\mathbf{k}}\right) \tag{17.26}$$

$$N(E) = \frac{1}{2\pi} \sum_{\mathbf{k}\alpha} \rho(\mathbf{k}, E) = -\frac{1}{\pi} \operatorname{Im} \sum_{\mathbf{k}\alpha} G\left(\mathbf{k}, \omega_n\right) \Big|_{i\omega_n \to E + i0} \tag{17.27}$$

(?? 5.29???)

$$\begin{aligned} N\left(E'\right) &= 2 \int \frac{d^3k}{(2\pi)^3} \delta\left(E - E_{\mathbf{k}}\right) = 2N_0 \int \frac{d\Omega}{4\pi} \int d\xi \delta\left(E - E_{\mathbf{k}}\right) = \\ &= 2N_0 \int \frac{d\Omega}{4\pi} \frac{dE'' E'}{\sqrt{E'^2 - \Delta_{\mathbf{k}}^2}} \delta\left(E' - E'\right) = 2N_0 \int \frac{d\Omega}{4\pi} \frac{E}{\sqrt{E^2 - \Delta_{\mathbf{k}}^2}} \end{aligned} \tag{17.28}$$

int over angles in $\Delta_{\mathbf{k}}^2 < E^2$.

(isotr, s-copl) $$N(E) = 2N_0 \begin{cases} 0, & E < \Delta \\ \frac{E}{\sqrt{E^2 - \Delta^2}}, & E > \Delta \end{cases}$$

And if there are zeros in spectrum:

$$N(E) = 2N_0 \int \frac{d\Omega}{4\pi} \frac{E}{\sqrt{E^2 - \Delta^2 \left(\hat{k}_x^2 + \hat{k}_y^2\right)}} = N_0 \int \sin\theta d\theta \frac{E}{\sqrt{E^2 - \Delta^2 \sin^2\theta}}$$

$$N(E) \approx N_0 \int_0^{E/\Delta} \theta d\theta \frac{E}{\sqrt{E^2 - \Delta^2\theta^2}} \sim N_0 \left(\frac{E}{\Delta}\right)^2 \tag{17.30}$$

(???)

Line of zeros $\Rightarrow$ $$N(E) \sim N_0 \frac{E}{\Delta}. \tag{17.31}$$

Подобные степенные зависимости плотности состояний квазичастиц от энергии приводят к степенному (а не экспоненциальному) температурному поведению термодинамических и кинетических характеристик необычных сверхпроводников.

16.2.5 General details of theories of SC

Connection of The Ginzburg-landau and BCS theories

Теория Асламазова и Ларкина о геометрическом сужении в сверхпроводниках

(см Щелкочева, там хорошо написано, пока не до этого)

Двухчастичный эффект Джозефсона по ЛШ

(add formalism from Levitov Shitov about these calculations)
(??? idea of it???)

$$I = I_0 \sin(\varphi_a - \varphi_b)$$

(add here summary from LS)

On fabrication of Josephson Junctions

(not important)

Критический ток и «ток возврата» в JJ

(??? хз пока что)

Other basic properties of JJ s

(хз, что это, потом когда-то додумаю.)

(write about and Ferrell-Prange equation some words from Shmidt, no one knows this equation, but 4 lines for it is fine)

Josephson vertex by Shmidt (!??!)
(по идее тут ничего не должно быть нового, разве что так вот поле вихрями попадает, ну и окей. потом дочитаю.)

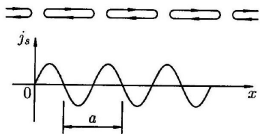

Рис. 24.4. а) Схематическое изображение смешанного состояния джозефсоновского туннельного перехода-плотно сжатая цепочка вихрей; б) распределение туннельного сверхтока через переход, которое при этом возникает.

Josephson radiation (???)

• DC bias current → AC response fd=3 GHz
• Power generated typically low & difficult to couple to external circuit (impedance mismatch)
• Nice recent experiment: direct detection of the emitted radiation.
(??? хз, что это такое, но есть статья про это, нужно будет - буду изучать, пока ничего такого не понимаю.)

16.3.2 RCSJ, SQUID: other methods and properties

Other properties of RCSJ model

Other about Shapiro steps

C. C. Grimes and S. Shapiro obtained such steps for different power of fields:

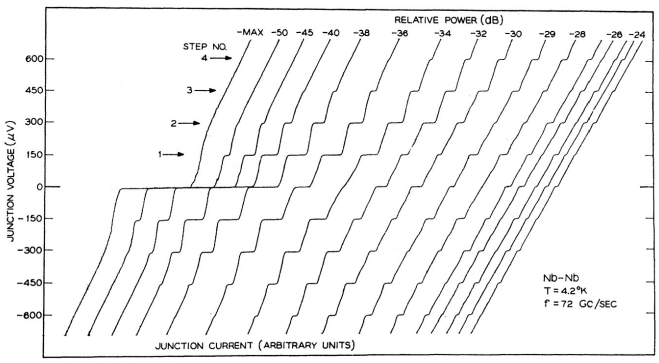

FIG. 1. Voltage-current curves for a Nb-Nb point-contact Josephson junction exposed to a 72-Gc/sec signal at various power levels.

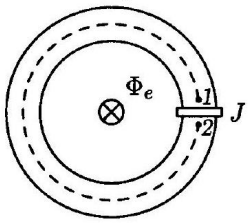
Shapiro steps have been observed in nanotube Josephson junctions, superconducting nanowires and High-Temperature superconductors with additional interesting effects.

Fractional Shapiro steps have been observed in circuits with several Josephson junctions although all fractions can not be explained.



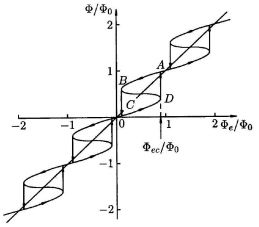
(??? maybe in later parts of this part I'll write about it, currently I don't need it)

Rf SQUID

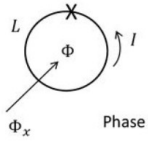
(??? I have never needed it, so I'll just put it here)

ring. No d.c voltage may be established across rf squids.

We have properties as follows:



- non-linear inductance of Josephson junction gives a periodic modulation of the resonance frequency of the tank circuit



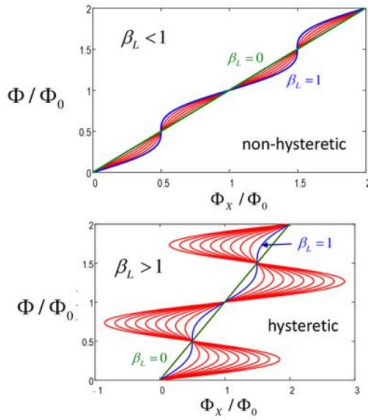
- these changes follow the amplitude of the rf current for a given working frequency response variies with $\Phi_o = h/2e = 2,0710^{-15}$Vs

- advantage: no electrical contacts

- disadvantage: noise of tank curcuit and amplifier large than intrinsic SQUID noise

rf SQUID (Superconducting Quantum interference Device) --- not a SQUID (no interference)

Phase coherence: $\phi + \frac{2\pi\Phi}{\Phi_0} = 0$



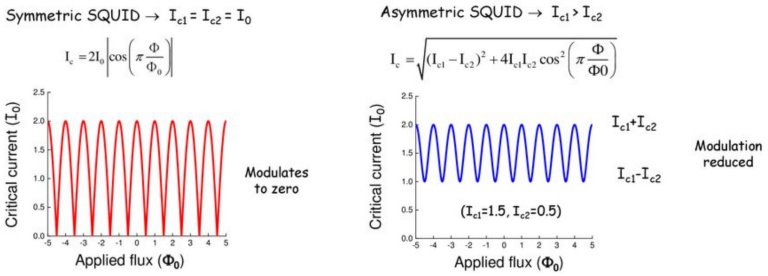
$$\Phi = \Phi_x + LI_c = \Phi_x + LI\sin\phi$$

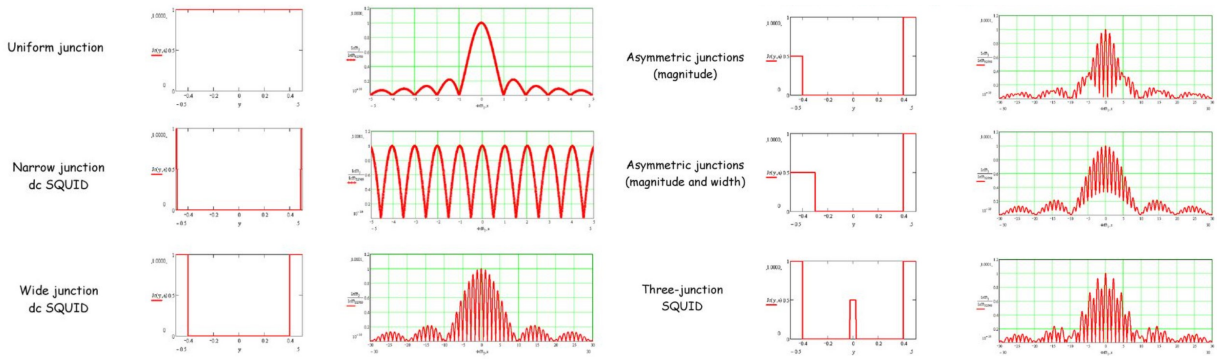
$$\Phi = \Phi_x - LI\sin\left(\frac{2\pi\Phi}{\Phi_0}\right)$$

$$\frac{\Phi_x}{\Phi_0} = \frac{\Phi}{\Phi_0} + \left(\frac{LI_c}{\Phi_0}\right)\sin\left(\frac{2\pi\Phi}{\Phi_0}\right)$$

$$= \frac{\Phi}{\Phi_0} + \frac{1}{2\pi}\beta_L \sin\left(\frac{2\pi\Phi}{\Phi_0}\right)$$

Single-junction inductance parameter $\beta_L = \frac{2\pi LI_c}{\Phi}$

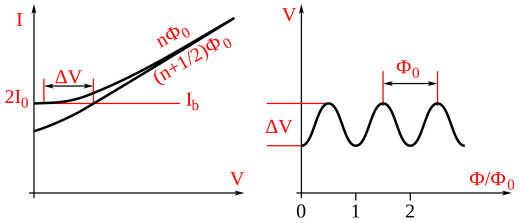




slope at half-integer Φ_0 $\frac{d\Phi}{d\Phi_x} = \frac{1}{1-\beta_L}$

Other about SQUID-s

Properties of modified SQUID-s



Asymmetric SQUID will shift current up:

(???)

Overview of applications of SQUID-s

(all applications will be reviewed in the end of this part, here there is a general summary, but with some meaningful information!)

16.3.3 Superconductors of II kind: other well-known properties

35* Анизотропные сверхпроводники II рода

(??)

36* Разрушение сверхпроводимости в тонкой пленке тепловыми вихрями, БКТ переход

Длина экранировки:

$$\lambda_{2d} = \frac{2\lambda^2}{d}.$$

$L^k_{\square} = 2\pi\lambda_{\text{eff}}$,
λ_{eff} равно либо λ, либо λ_{2d}.
$R \ll \lambda_{2d} \qquad \Rightarrow$
$U_2(R) = 2q_1q_2d\epsilon_0 \ln(R/\lambda_{2d})$,
$U_1 = d\epsilon_0 \ln(\lambda_{2d}/\xi)$,

$$U_{\text{pair}}(R) = 2\epsilon_0 d \ln\frac{R}{\xi} = \frac{\Phi_0^2}{4\pi^2\lambda_{2d}} \ln\frac{R}{\xi}.$$

В тонких пленках λ_{2d} может достигать макроскопических размеров. Так, при $\lambda = 3$ мкм (что легко достигается в близкой окрестности T_{c0}) и толщине пленки $d = 50$Å получим $\lambda_{2d} \simeq \simeq 3.6$ мм. При этом энергия кора вихря, $U_{\text{core}} = d\epsilon_0$, мала: $U_{\text{core}}/k_{\text{B}} \simeq 10$ K, в то время как полная энергия гораздо больше, $U_1/k_{\text{B}} \simeq 100$ K (мы выбрали здесь для оценки $\xi \simeq 0.1$ мкм).

$$n(L) \simeq (L/\xi)^2 \exp(-U_1(L)/T) = (L/\xi)^{2-\alpha},$$

$\alpha = \epsilon_0 d/k_{\text{B}}T = \Phi_0^2/(8\pi^2\lambda_{2d}k_{\text{B}}T)$.

$$\frac{1}{\lambda_{2d}(T_{\text{BKT}})} = \frac{d}{2\lambda_-^2(T_{\text{BKT}})} = \frac{16\pi^2 k_{\text{B}}T_{\text{BKT}}}{\Phi_0^2}.$$

$$n_s^{(2),\min} = \frac{8mk_{\text{B}}T_{\text{BKT}}}{\pi\hbar^2}$$

$$\ln\frac{R_c(T)}{\xi} = b\left(\frac{\text{Gi}^{(2D)}T}{T - T_{\text{BKT}}}\right)^{1/2},$$

(???)

37* Плавление решетки вихрей

$$B_m(T) \propto \frac{\Phi_0}{(k_{\text{B}}T)^2}\left(\frac{\Phi_0}{4\pi\lambda}\right)^4 \propto (1 - T/T_c)^2 \qquad \text{при} \qquad T \to T_c.$$

Поле плавления решетки убывает с повышением температуры быстрее, чем верхнее (и нижнее) критическое поле, которое ведет себя линейно вблизи температуры перехода, $H_{c2} \propto (1 - T/T_c)$.

$$\frac{B_m(T)}{H_{c2}(T)} = \alpha_m \frac{1 - T/T_c}{\text{Gi}}$$

α_m - number.

38 Критический ток в сверхпроводниках второго рода. Критическое состояние

39 Взаимодействие вихрей с центрами пиннинга

(??? допишу, если будет нужно)

$$F_{\text{возвр}} = \frac{2|M|\Phi_0}{\lambda a_0^2}\delta x.$$

$$F_{\text{возвр}} = \frac{2|M|B}{\lambda}\delta x.$$

$$\mathcal{F}_{\text{L}} = \frac{1}{c} I_{\text{Tp}} B,$$

$$I_c = \frac{2c|M|\sqrt{\Phi_0}}{\lambda\sqrt{B}}.$$

$$j_c = \frac{2c|M|\sqrt{\Phi_0}}{\lambda\sqrt{B}d}.$$

40 Резистивное состояние

(??? допишу, если будет нужно)

41* Коллективный пиннинг вихрей слабыми дефектами

(??? допишу, если будет нужно)

42* Крип магнитного потока и нелинейная проводимость в ВТСП.

(??? допишу, если будет нужно)

16.4 Other well-known methods for SC junctions

16.4.1 Tight-binding SC models

16.4.2 Overview of other tunneling properties

(collection of other famous results, but not so important ones)

Current and Ambeogakar-Baratoff's formula from Sauls

A Sharvin contact is a small constriction between two conductors where electron transport occurs ballistically without scattering, typically when the constriction size is smaller than the electron mean free path.

The total supercurrent at the point contact is obtained from Eq.

$$\mathbf{J}_e = 2N_f \int \frac{d\Omega_{\hat{\mathbf{p}}}}{4\pi} e\mathbf{v}_\mathbf{p} T \sum_n \frac{1}{4} \mathrm{Tr}\left\{\widehat{\tau}_3 \widehat{\mathfrak{G}}^{\mathrm{M}}\left(\mathbf{r}, \mathbf{p}; \varepsilon_n\right)\right\}$$

and the cross-section of the Sharvin contact,

$$I_s = \left(\pi a^2\right) 2N_f \int_{\hat{\mathbf{p}}\cdot\hat{\mathbf{n}}>0} \frac{d\Omega_\mathbf{p}}{4\pi} 2\hat{\mathbf{n}}\cdot\mathbf{v}_p \frac{\pi}{2} T \sum_n \frac{|\Delta|^2 \sin\vartheta}{\varepsilon_n^2 + |\Delta|^2 \cos^2(\vartheta/2)}$$

The normal-state Sharvin conductance, $G_\mathrm{N} = \frac{\pi a^2}{2} e^2 N_f v_f$, valid in the ballistic limit $\ell \gg a$, is determined by the area of the aperature, the density of states and Fermi velocity for quasiparticle charge transport. Thus, in terms of the contact resistance, $R_\mathrm{N} = 1/G_\mathrm{N}$,

$$I_s = \frac{\pi}{eR_\mathrm{N}} T \sum_n \frac{|\Delta|^2 \sin\vartheta}{\varepsilon_n^2 + |\Delta|^2 \cos^2(\vartheta/2)} = \frac{\pi|\Delta|}{eR_\mathrm{N}} \sin(\vartheta/2) \tanh\left(\frac{|\Delta|\cos(\vartheta/2)}{2T}\right)$$

where the last form is obtained using $\tanh(z) = 8z\sum_{k=1}^{\infty} \frac{1}{\pi^2(2k-1)^2+4z^2}$. This is the result for the current-phase relation originally obtained by K-O. It reduces to the current-phase relation for a Josephson tunnel junction, $I_s = I_c \sin\vartheta$, in the limit $T \to T_c$, where the critical current,

$$I_c = \frac{\pi|\Delta|^2}{4eR_\mathrm{N}T_c} \propto (1 - T/T_c), \quad |T - T_c| \ll T_c$$

is the result obtained by Ambegaokar and Baratoff, except that the tunnelling conductance is replaced by the Sharvin conductance. However, at low temperatures the current-phase becomes increasingly asymmetric near $\vartheta = \pi$ as shown in Fig. 2, and discontinuous at $T = 0$,

$$I_s(T=0) = \frac{\pi\Delta(0)}{eR_\mathrm{N}} \sin(\vartheta/2)\,\mathrm{sgn}(\cos(\vartheta/2))$$

In addition to the divergence of the slope $dI_s/\,d\vartheta|_{\vartheta=\pi}$ as $T \to 0$, the K-O result predicts a critical current that is twice that of the Ambegaokar-Baratoff result.

Heat conductance

$\varepsilon > \Delta$

$$\kappa_\mathrm{NS} = \frac{1}{2} N_f v_f \mathcal{A} \int_{|\Delta|}^{\infty} d\varepsilon \frac{\varepsilon^2/4T^2}{\cosh^2(\varepsilon/2T)} \left[1 - |r_\mathrm{A}(\varepsilon)|^2\right]$$

where $\mathcal{A}$ is an area of the contact (cf. For an N-N contact $\kappa_\mathrm{N} = \mathcal{A}\frac{\pi^2}{12} N_f v_f T\Big)$.

16.4.3 BTK Method

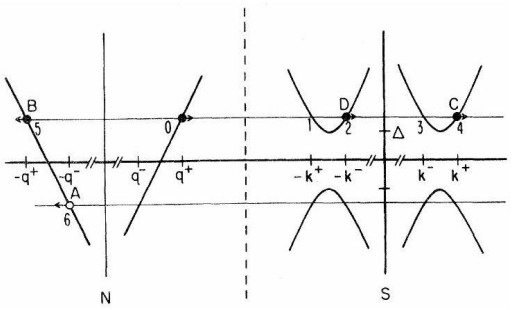
BTK Formalism and Basic Contacts

NS **Boundary**

$\psi_k = [u_k(x.t), v_k(x,t)]^T$ looks as follows:

$$\left[-\frac{\hbar^2}{2m}\nabla^2 + V(x) - \mu(x)\right] u_k(x,t) + \Delta(x) v_k(x,t) = i\hbar \frac{\partial u_k(x,t)}{\partial t} \tag{16.1}$$

$$-\left[-\frac{\hbar^2}{2m}\nabla^2 + V(x) - \mu(x)\right] v_k(x,t) + \Delta^*(x) u_k(x,t) = i\hbar \frac{\partial v_k(x,t)}{\partial t}, \tag{16.2}$$



$u_k(x,t) \equiv u_k e^{ikx - iE_k t/\hbar}$
$v_k(x,t) \equiv v_k e^{ikx - iE_k t/\hbar}$
$\frac{\hbar^2 k_\pm^2}{2m} = \mu \pm \sqrt{E_k^2 - |\Delta|^2}.$

$$\psi_{\text{inc}}^N = \begin{bmatrix} 1 \\ 0 \end{bmatrix} e^{ik_+ x}, \tag{16.3}$$

$$\psi_{\text{refl}}^N = a \begin{bmatrix} 0 \\ 1 \end{bmatrix} e^{ik_- x} + b \begin{bmatrix} 1 \\ 0 \end{bmatrix} e^{-ik_+ x}, \tag{16.4}$$

$$\psi_{\text{trans}}^S = c \begin{bmatrix} u_0^2 \\ v_0^2 \end{bmatrix} e^{ik_+ x} + d \begin{bmatrix} v_0^2 \\ u_0^2 \end{bmatrix} e^{-ik_- x}, \tag{16.5}$$

$1 - v_0^2 = u_0^2 = \frac{1}{2}\left(1 + \frac{\left(E^2 - \Delta^2\right)^{1/2}}{E}\right)$

$\psi^N(0) = \psi^S(0) = \psi(0)$
$\frac{\hbar}{2m}\frac{d\psi^S(0)}{dx} - \frac{\hbar}{2m}\frac{d\psi^N(0)}{dx} = H\psi(0)$

$$I(\phi) = \frac{e\Delta}{\hbar} T \sin(\alpha/2) \frac{\sin(\phi)}{\sin(\alpha)}, \tag{16.21}$$

16.4.4 Beenakker's Determinant Method

$$\rho(\varepsilon) = -\frac{1}{\pi} \operatorname{Im} \frac{d}{d\varepsilon} \ln\det\left[1 - R_{\rm A}(\varepsilon + i0^+) S_{\rm N}(\varepsilon + i0^+)\right] + \rho_0(\varepsilon). \tag{16.22}$$

$$S_{\rm N}(\varepsilon) := \begin{pmatrix} s_0(\varepsilon) & 0 \\ 0 & s_0^*(-\varepsilon) \end{pmatrix}, \tag{16.23}$$

$$R_{\rm A}(\varepsilon) := i\alpha(\varepsilon) \begin{pmatrix} 0 & r_{\rm A} \\ r_{\rm A}^* & 0 \end{pmatrix}, \qquad r_{\rm A} := \begin{pmatrix} e^{i\phi/2}\sigma_y & 0 \\ 0 & e^{-i\phi/2}\sigma_y \end{pmatrix},$$
$$\alpha(\varepsilon) = e^{-i \arccos(\varepsilon/\Delta_0)} = \varepsilon/\Delta_0 - i\sqrt{1 - \varepsilon^2/\Delta_0^2}. \tag{16.24}$$

$$\rho(\varepsilon) = -\frac{1}{\pi} \operatorname{Im} \frac{d}{d\varepsilon} \ln\det\left[1 - M(\varepsilon + i0^+)\right] + \rho_0(\varepsilon), \qquad M(\varepsilon) := -\alpha(\varepsilon)^2 r_{\rm A}^* s_0^*(-\varepsilon) r_{\rm A} s_0(\varepsilon). \tag{16.25}$$

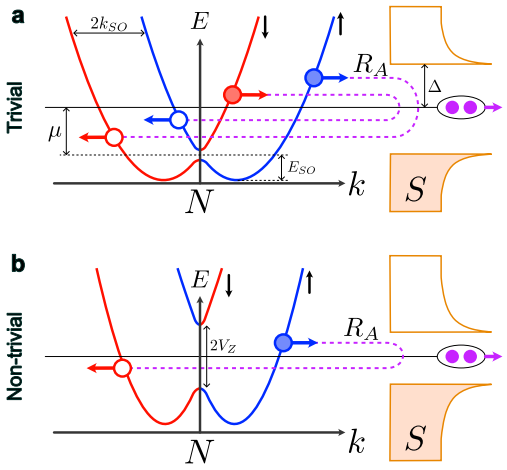
$F = -k_{\rm B}T \int_0^\infty d\varepsilon\, \rho(\varepsilon) \ln\left[2\cosh(\varepsilon/2k_{\rm B}T)\right],$

$$F = \frac{i}{4\pi} \int_{-\infty}^{\infty} d\varepsilon\, \tanh(\varepsilon/2k_{\rm B}T) \ln\det\left[1 - M(\varepsilon + i0^+)\right] + F_0, \tag{16.26}$$

$$F = -k_{\rm B}T \sum_{p=0}^{\infty} \ln\det\left[1 - M\left(i\omega_p + i\gamma\right)\right], \qquad \omega_p = (2p+1)\pi k_{\rm B}T. \tag{16.27}$$

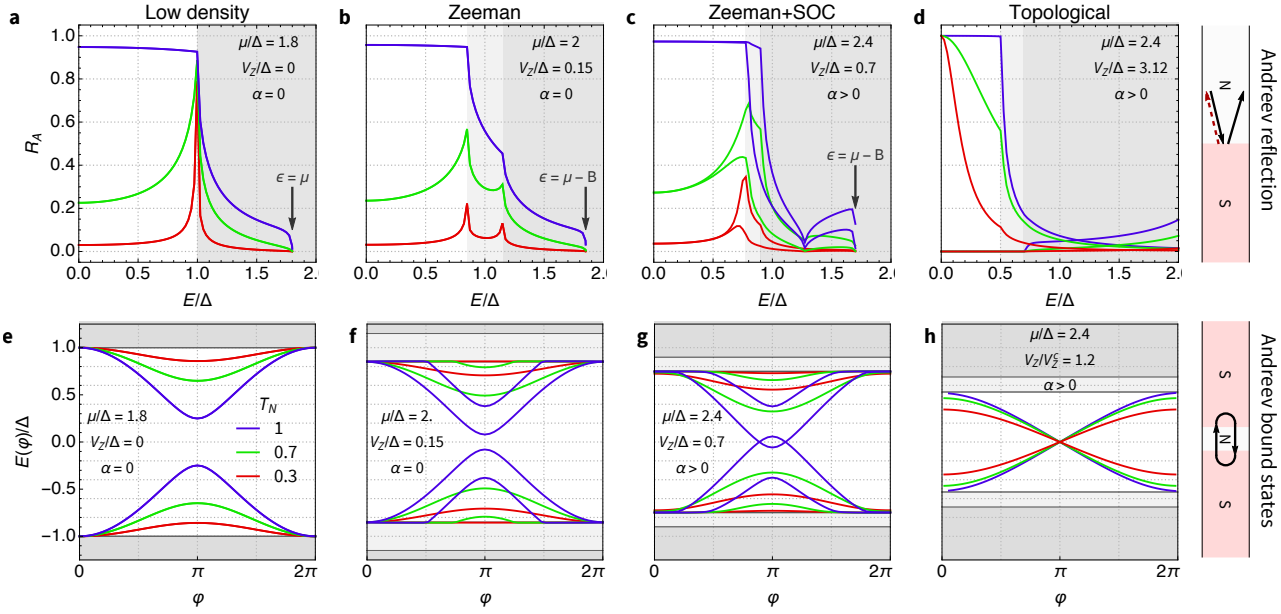
$$\frac{E}{\Delta} = \pm\frac{1}{2}\sqrt{1 + \operatorname{Tr}\left(S\mathbf{e}^{i\phi}S^*\mathbf{e}^{-i\phi}\right)}, \tag{16.28}$$

$$E = \pm\frac{\Delta}{2}\sqrt{1 + \sum_{l,j} T_{lj} e^{-i(\phi_l - \phi_j)}}, \tag{16.29}$$



For example, for $H = \begin{pmatrix} -i\sigma_z\hat{v}\partial/\partial x & \Delta \\ \Delta^* & --i\sigma_z\hat{v}\partial/\partial x \end{pmatrix}$

$$I = -\frac{e}{\hbar}\frac{\partial}{\partial\varphi}T\sum_{\omega}\ln\det\left[1 - S_N S_A(\omega)\right],$$



$S_N := \begin{pmatrix} S & 0 \\ 0 & -S^* \end{pmatrix}$, $S := \begin{pmatrix} r_L & t_{LR} \\ t_{RL} & r_R \end{pmatrix}$ $S_A = -i\begin{pmatrix} 0 & r_A \\ r_A^* & 0 \end{pmatrix}$ $r_A := \begin{pmatrix} e^{-\theta_L+i\varphi_L} & 0 \\ 0 & e^{-\theta_R+i\varphi_R} \end{pmatrix}$, $\theta := \operatorname{arcsinh}\frac{\omega}{\Delta}$.

16.4.5 Majorana wires and junctions

Main plots and formulas of Majorana wires

(???)
(write formulas for Hamiltonian, with which plot below is assumed)

Models of Majorana wires

(write Hamiltonians and show what is important about it)

$$H_w := \frac{1}{2}\int dx \Psi^\dagger(x)\mathcal{H}(x)\Psi(x), \qquad \mathcal{H}_w(x) := \left(-\frac{\hbar^2\partial_x^2}{2m^*} - \mu - i\alpha\partial_x\sigma_y\right)\tau_z + V_Z\sigma_x; \tag{16.30}$$

$$H_{\rm SC} = \int_{-\infty}^{\infty} dx \left(\Delta(x)\psi_\uparrow^\dagger(x)\psi_\downarrow^\dagger(x) + h.c.\right). \tag{16.31}$$

The SM Hamiltonian takes into account the so-called Rashba spinorbit (SO) interaction (term $i\alpha\partial_x\sigma_y$) and the existence of parallel to the nanowire axis magnetic field B (term $V_Z\sigma_x$, where $V_Z = \frac{1}{2}g\mu_B B$ is the usual Zeeman energy with effective g-factor). The usual Nambu notation is assumed (for example, the wave function $\Psi(x) = (\psi_\uparrow^\dagger, \psi_\downarrow^\dagger, \psi_\downarrow, -\psi_\uparrow)$ is a Nambu spinor).

Another model with Majoranas that will be used in our review and for which our method can be applicable is a model of topological superconductors They can be modeled, for example, as a low-energy limit of a Kitaev chain, and its Hamiltonian looks as follows:

$$H_{TS} = \int_0^\infty dx \Psi_{TS}^\dagger(x)\left(-iv_F\partial_x\sigma_z + \Delta\sigma_y\right)\Psi_{TS}(x). \tag{16.32}$$

Here the pairing gap Δ is induced by proximity effect and can be considered as real and positive; $\Psi_{TS}(x) = \left(c_r, c_l^\dagger\right)^T$ is the Nambu spinor, it contains right- and left-moving fermion operators $c_{r,l}(x)$. One can see that the difference between the conventional SC is the dispersion relation.

The model (16.30) has a discretized version, which looks as follows [**?**]:

$$H_{\rm wire} = \frac{1}{2}\sum_j \left[\Psi_j^\dagger\hat{h}\Psi_j + \left(\Psi_j^\dagger\hat{t}\Psi_{j+1} + \text{h.c.}\right)\right], \qquad \begin{aligned} \hat{h} &:= (2t-\mu)\sigma_z\tau_0 + V_x\sigma_0\tau_x + \Delta\sigma_x\tau_0, \\ \hat{t} &:= -t\sigma_z\tau_0 + i\alpha\sigma_z\tau_z, \\ \Psi_j^T &= \left(c_{j\uparrow}, c_{j\downarrow}, c_{j\downarrow}^\dagger, -c_{j\uparrow}^\dagger\right). \end{aligned}$$

Here $\hat{h}$ is responsible for a on-site energy and the $\hat{t}$ is a hopping matrix. Often the discretized models are analyzed more conveniently, and after one can take a continuous limit (as done in the main part of this thesis).

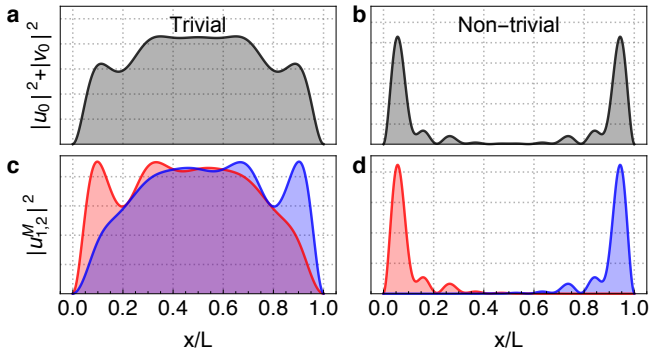


Figure 16.5: Wavefunction of the lowest energy state ψ_0 in a uniform $L = 1\mu$m Majorana nanowire for a trivial $V_Z = 0.5V_Z^c$ (a) and a non-trivial $V_Z = 1.4V_Z^c$ (b) cases. (c,d) Wavefunctions of the corresponding Majorana components $u_{1,2}^M(x)$ in the Majorana basis. In the trivial regime the left (red) and right (blue) Majorana components strongly overlap (c), whereas in the topological regime they move apart and concentrate at the ends of the nanowire (d). Credit: [**?**].

One can find a lot of physics from these Hamiltonians, was was reviewed in the introduction. The excitations of this model can be described by self-conjugation operators (which are known

from field theory as Majorana operators) $\gamma_1 := \gamma_1^\dagger$ and $\gamma_2 := \gamma_2^\dagger$. These can be obtained from unitary rotation $\gamma_1 := \psi_0^\dagger + \psi_0$, $\gamma_2 := i(\psi_0^\dagger - \psi_0)$, where the later operators are defined from the wave function in the model as $\psi_n := \int dx \sum_\sigma \left[u_{n\sigma}(x)\psi_\sigma(x) + v_{n\sigma}(x)\psi_\sigma^\dagger(x)\right]$. Here and $u_{n\sigma}(x), v_{n\sigma}(x)$ are the wavefunctions of electron and hole. The "big" value of V_Z is crucial for having the localization of the Majorana modes: if $V_Z > V_Z^c$ then we have a non-trivial topological regime and the wave-functions are localized. If $V_Z < V_Z^c$ then the regime is non-topological and the wave-functions are overlap strongly. This is illustrated in Fig. 16.5.

GF-s of Majorana wires

$$G(\tau) := -\langle \mathcal{T}_\tau \Psi_{\rm TS}(\tau)\Psi_{\rm TS}^\dagger(0)\rangle_0 = T\sum_\omega e^{-i\omega\tau}G_j(\omega); \qquad G(\omega) = \frac{1}{i\omega}\left(\sqrt{\omega^2+\Delta^2}\,\tau_0 + \Delta\tau_x\right).$$

Here $\Psi_{\rm TS} = (\psi\ \psi^\dagger)^T$ is a Nambu spinor and $\mathcal{T}_\tau$ is the time-ordering operator. The frequencies ω are the fermionic Matsubara frequencies ($\omega = 2\pi(n+1/2)/\beta$). This function can be used for description of multiterminal junctions with topological superconductors.

16.4.6 Fluctuation effects in weak contacts

Thermal fluctuations in the Josephson transition, phase slippage and I(V,T).

Macroscopic quantum effects: "phase tunneling" and transition to a resistive state.

Macroscopic quantum coherence in SQUIDS.

Aslamazov-Larkin increasement of cunductivity near T_c because of fluctuations

1. Постановка вопроса (421).

2. Остаточное сопротивление нормального металла (423).

3. Электромагнитные свойства сверхпроводящих сплавов (432).

16.5.3 Other experimental hints for a true SC theory

(??? I'll write it very not soon, since it is not important)
Little–Parks oscillations, as a hit for BCS
(напишу тут, как из этого догадаться про BCS (???))

16.5.4 Effects of Temperature and Magnetic Field

Δ(T) при нетривиальном спаривании.
Теплоемкость и спиновая восприимчивость сверхпроводника.
Парамагнитный предел для синглетного сверхпроводника.
Диамагнитный отклик, глубина проникновения поля и ее температурная зависимость.

16.5.5 Eliashberg Theory of Electron–Phonon Interaction (???)

Обзор теории Элиашберга

Eliashberg theory is a theory of superconductivity that describes the role of phonons in providing the attractive interaction between two electrons. Phonon dynamics are taken into account, thus giving rise to retardation effects that impact the electrons, in the form of a frequency-dependent electron self-energy. Now the order parameter is frequency dependent (not static as in BCS).

Гамильтониан электрон-фононного взаимодействия и уравнения Дайсона.

(У Левитова Шитова же теория про это уже известна)

Формальное решение для функций Грина, спектральное представление и усреднение по ферми-поверхности.

(??)

Интегральное уравнение для параметра порядка $\Delta(\omega)$ и анализ его решения.

(У Левитова Шитова же уже это решалось, да?)

Роль кулоновского взаимодействия.

(задача Лев-в Шит-в)

Простое применение: изотопический эффект в сверхпроводимости.

(!!)

16.6 Unconventional Superconductivity in a Nutshell

(!!!!!! добавлю потом деление по типам тем!!!)

16.6.1 Overview of UC SC

(main all about it)

16.6.2 Fundamentals of UC SC

Formation of Cooper pair for UC SC

$$\Psi^l_{\text{pair}} = g_1(\mathbf{k})|\Pi\uparrow\rangle + g_2(\mathbf{k})(|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle) + g_3(\mathbf{k})|\downarrow\downarrow\rangle = \begin{pmatrix} g_1(\mathbf{k}) & g_2(\mathbf{k}) \\ g_2(\mathbf{k}) & g_3(\mathbf{k}) \end{pmatrix}.$$

$$g_\alpha(\mathbf{k}) = \sum_{m=-1}^{1} a^\alpha_{lm} Y_{lm}(\hat{\mathbf{k}})$$

- амплитуды состояний с $S_z = 1, 0$ и -1, соответственно.

Или через базиса симметричные матрицы $i\sigma\sigma_y = (i\sigma_x\sigma_y, i\sigma_y\sigma_y, i\sigma_z\sigma_y)$:

$$\Psi'_{\text{pair}} = i(\mathbf{d}(\mathbf{k})\boldsymbol{\sigma})\sigma_y = (d_x(\mathbf{k})\sigma_x + d_y(\mathbf{k})\sigma_y + d_z(\mathbf{k})\sigma_z)\, i\sigma_y = \\ = \begin{pmatrix} -d_x(\mathbf{k}) + id_y(\mathbf{k}) & d_z(\mathbf{k}) \\ d_z(\mathbf{k}) & d_x(\mathbf{k}) + id_y(\mathbf{k}) \end{pmatrix}$$

$$g_1 = -d_x + id_y, g_2 = d_z, g_3 = d_x + id_y$$

$$d_\alpha(\mathbf{k}) = \sum_{m=-l}^{1} b^\alpha_{lm} Y_{lm}(\hat{\mathbf{k}}).$$

Среднее значение спина пары:

$$\mathbf{S} = i\hbar \int \frac{d\Omega}{4\pi} \mathrm{d}^*(\mathbf{k}) \times \mathrm{d}(\mathbf{k});$$

Среднее значение орбитального момента пары:

$$\mathbf{L} = i\hbar \int \frac{d\Omega}{4\pi} \mathbf{d}^*(\mathbf{k}) \left[\mathbf{k} \times \frac{\partial}{\partial \mathbf{k}}\right] \mathbf{d}(\mathbf{k}).$$

Singlets, Triplets, other states

Operation	Singlet	Triplet
Fermion exchange	$\psi(\vec{k}) = \psi(-\vec{k})$	$\vec{d}(\vec{k}) = -\vec{d}(-\vec{k})$
Orbital rotation	$g\psi(\vec{k}) = \psi(R(g)\vec{k})$	$g\vec{d}(\vec{k}) = \vec{d}(R(g)\vec{k})$
Spin rotation	$g\psi(\vec{k}) = \psi(\vec{k})$	$g\vec{d}(\vec{k}) = \tilde{R}(g)\vec{d}(\vec{k})$
Time-reversal	$\widehat{K}\psi(\vec{k}) = \psi^*(-\vec{k})$	$\widehat{K}\vec{d}(\vec{k}) = -\vec{d}^*(-\vec{k})$
$U(1)$-gauge	$\widehat{\Phi}\psi(\vec{k}) = e^{i\phi}\psi(\vec{k})$	$\widehat{\Phi}\vec{d}(\vec{k}) = e^{i\phi}\vec{d}(\vec{k})$

2 Spin Structure of Paired States

(see Mineev)

3 Phases of Superfluid Helium-3

4 Superconducting States in Crystals

Energy of Elementary Excitations in Superconductors

$$V_{\alpha\beta,\lambda\mu}\left(\mathbf{k},\mathbf{k}'\right)=\frac{1}{2}V_{\Gamma}\left(k,k'\right)\sum_{i=1}^{d_{\Gamma}}\left(\psi_i(\hat{\mathbf{k}})\mathbf{g}_{\alpha\beta}\right)\left(\boldsymbol{\psi}_i^{*}\left(\hat{\mathbf{k}}'\right)\mathbf{g}_{\lambda\mu}^{+}\right)$$

$$\Psi=\prod_{\mathbf{k}}\left(u_{\mathbf{k}}+v_{\mathbf{k}}a_{\mathbf{k}\uparrow}^{+}a_{-\mathbf{k}\downarrow}^{+}\right)|\mathrm{vac}\rangle$$

$$T=0\quad\Rightarrow\quad\begin{array}{l}F_{\mathbf{k},\uparrow\downarrow}=\langle\Psi\left|a_{\mathbf{k}\uparrow}a_{-k\downarrow}\right|\Psi\rangle,\\ F_{\mathbf{k},\uparrow\downarrow}^{+}=\left\langle\Psi\left|a_{-k\uparrow}^{+}a_{k\downarrow}^{+}\right|\Psi\right\rangle.\end{array}\qquad T\neq 0\quad\Rightarrow\quad\begin{array}{l}F_{\mathbf{k},\alpha\beta}=\langle a_{\mathbf{k}\alpha}a_{-\mathbf{k}\beta}\rangle,\\ F_{\mathbf{k},\alpha\beta}^{+}=\left\langle a_{-k\alpha}^{+}a_{\mathbf{k}\beta}^{+}\right\rangle.\end{array}$$

Для нечетного потепциала взаимодействия $\Delta_{\mathbf{k},\alpha\beta}$ и $F_{\mathbf{k},\alpha\beta}$ также нечетны и описывают триплетное спаривание:

$$\Delta_{\mathbf{k},\alpha\beta}=\Delta\mathbf{d}(\mathbf{k})\left(i\sigma\sigma_y\right)_{\alpha,\beta}.$$

$$\mathbf{d}(\mathbf{k})=\mathbf{d}^{l}(\mathbf{k})=\sum_{m=-l}^{1}\mathbf{b}_{lm}(k)Y_{lm}(\dot{k})\qquad\int\frac{d\Omega}{4\pi}|\mathrm{d}(\mathbf{k})|^2=1$$

Для сверхпроводника с триплетным спариванием:

$$E_{\mathbf{k}}=\sqrt{\xi_k^2+\Delta^2|\mathbf{d}(\mathbf{k})|^2}$$

В B-фазе $\mathbf{d}=\hat{\mathbf{k}}$

$$E_k^B=\sqrt{\xi_k^2+|\Delta|^2}$$

то есть, как и в случае s-спаривания, на всей ферми-поверхности имеется щель, не зависящая от направления $\mathbf{k}$.

В A-фазе $\mathbf{d}=\sqrt{3/2}\left(\hat{k}_x+i\hat{k}_y,0,0\right)$

$$E_{\mathbf{k}}^A=\sqrt{\xi_k^2+\frac{3}{2}\Delta^2\left(\hat{k}_x^2+\hat{k}_y^2\right)}=\sqrt{\xi_k^2+\frac{3}{2}\Delta^2\sin^2\theta}$$

то есть щель в спектре обращается в нуль на северном и южном полюсах ($\theta=0,\pi$) ферми-сферы.

Gap in the Spectrum of Elementary Excitations and Critical Temperature

(??? основная идея???)

$$\Delta_{\mathbf{k},\alpha\beta}=-\sum_{\mathbf{k}'}V_{\beta\alpha,\lambda\mu}\left(\mathbf{k},\mathbf{k}'\right)F_{\mathbf{k}',\lambda\mu}\tag{6.1}$$

$$F_{\mathbf{k},\lambda\mu}=\langle a_{\mathbf{k}\lambda}a_{-\mathbf{k}\mu}\rangle=\left\langle\left(u_{\mathbf{k},\lambda\gamma}b_{\mathbf{k}\gamma}+v_{\mathbf{k},\lambda\gamma}b_{-\mathbf{k}\gamma}^{+}\right)\left(u_{-\mathbf{k},\mu\delta}b_{-\mathbf{k}\delta}+v_{-\mathbf{k}}\mu\delta b_{\mathbf{k}\delta}^{+}\right)\right\rangle$$

$$u_{\mathbf{k},\alpha\beta}=u_{\mathbf{k}}\delta_{\alpha\beta},\quad v_{\mathbf{k},\alpha\beta}=-v_{-\mathbf{k},\beta\alpha}$$

$$\langle b_{-\mathbf{k}\alpha}b_{\mathbf{k}\beta}\rangle=\left\langle b_{\mathbf{k}\alpha}^{+}b_{-\mathbf{k}\beta}^{+}\right\rangle=0$$

$$\left\langle b_{\mathbf{k}\alpha}^{+}b_{\mathbf{k}\beta}\right\rangle=\delta_{\alpha\beta}-\left\langle b_{\mathbf{k}\beta}b_{\mathbf{k}\alpha}^{+}\right\rangle=f_{\mathbf{k}}\delta_{\alpha\beta}\qquad f_{\mathrm{k}}=f\left(E_{\mathrm{k}}\right)=\frac{1}{\exp\left(E_{\mathrm{k}}/T\right)+1}$$

$$F_{\mathbf{k},\lambda\mu} = -u_{\mathbf{k}} v_{\mathbf{k},\lambda\mu} \left(1 - 2f_{\mathbf{k}}\right) = \frac{\Delta_{k,\lambda\mu}}{2E_{\mathbf{k}}} \left(1 - 2f_{\mathbf{k}}\right) \tag{6.3}$$

$$\Delta_{\mathbf{k},\alpha\beta} = -\sum_{\mathbf{k}'} V_{\beta\alpha,\lambda\mu}\left(\mathbf{k},\mathbf{k}'\right) \frac{1 - 2f_{\mathbf{k}'}}{2E_{\mathbf{k}'}} \Delta_{\mathbf{k}',\lambda\mu} \tag{6.4}$$

$$g(\mathbf{k}) = -\sum_{\mathbf{k}'} \frac{V\left(\mathbf{k},\mathbf{k}'\right)\left(1 - 2f_{\mathbf{k}'}\right)}{2\sqrt{\xi_{k'}^2 + \Delta^2 \left|g\left(\mathbf{k}'\right)\right|^2}} g\left(\mathbf{k}'\right) \qquad \text{singl} \tag{6.5}$$

$$\mathbf{d}(\mathbf{k}) = -\sum_{\mathbf{k}'} \frac{V\left(\mathbf{k},\mathbf{k}'\right)\left(1 - 2f_{\mathbf{k}'}\right)}{2\sqrt{\xi_{k'}^2 + \Delta^2 \left|\mathbf{d}\left(\mathbf{k}'\right)\right|^2}} \mathrm{d}\left(\mathbf{k}'\right) \qquad \text{tripl} \tag{6.6}$$

Solutions: (???????)

$$g(\mathbf{k}) = \sum_{m=-l}^{l} a_{lm} Y_{lm}(\hat{\mathbf{k}}) \tag{6.7}$$

$$\mathrm{d}(\mathbf{k}) = \sum_{m=-l}^{l} \mathrm{b}_{lm} Y_{lm}(\hat{\mathbf{k}}) \tag{6.8}$$

(??? how we come to temperature???)

$$1 = N_0 V_i \int_0^{\varepsilon_i} d\xi \frac{\mathrm{th}\left(|\xi|/2T_c\right)}{|\xi|} \tag{6.9}$$

$$1 = N_0 V_l \left(\ln \frac{\varepsilon_l}{2T_\mathrm{c}} - \int_0^{\infty} dx \frac{\ln x}{\mathrm{ch}^2\, x} \right)$$

$$T_\mathrm{C} = \frac{2\gamma}{\pi} \varepsilon_l \exp\left(-\frac{1}{N_0 V_l}\right) \tag{6.10}$$

$2\gamma/\pi \approx 1.14$, $\ln \gamma = C \approx 0.577$

$$a_{lm}(T) = N_0 V_i \int_0^{\varepsilon_1} d\xi \int \frac{d\Omega}{4\pi} \frac{\mathrm{th}\left(\sqrt{\xi^2 + \Delta^2(T)|g(\mathbf{k})|^2}/2T\right)}{\sqrt{\xi^2 + \Delta^2\left(T'\right)|g(\mathbf{k})|^2}} Y_{lm}^*(\hat{\mathbf{k}}) g(\mathbf{k}) \qquad \text{singl} \tag{6.11}$$

$$\mathbf{b}_{lm}(T) = N_0 V_l \int_0^{\varepsilon_1} d\xi \int \frac{d\Omega}{4\pi} \frac{\mathrm{th}\left(\sqrt{\xi^2 + \Delta^2(T)|\mathbf{d}(\mathbf{k})|^2}/2T\right)}{\sqrt{\xi^2 + \Delta^2(T)|\mathrm{d}(\mathbf{k})|^2}} Y_{im}^*(\hat{\mathbf{k}}) \mathrm{d}(\mathbf{k}) \qquad \text{tripl} \tag{6.12}$$

For s-coupl, $T = 0$:

$$\frac{1}{N_0 V_0} = \int_0^{\varepsilon_0} \frac{d\xi}{\sqrt{\xi^2 + \Delta_0^2}} \approx \ln \frac{2\varepsilon_0}{\Delta_0} \tag{6.13}$$

$$\Delta_0 = \Delta(T = 0) = 2\varepsilon_0 \exp\left(-\frac{1}{N_0 V_0}\right) \tag{6.14}$$

$$\Delta_0 = \frac{\pi}{\gamma} T_c \approx 1,75 T_c \tag{6.15}$$

$$\frac{1}{N_0 V_0} = \int_0^{\varepsilon_0} \frac{d\xi}{\sqrt{\xi^2 + \Delta^2}} - 2 \int_0^{\varepsilon_0} \frac{f(E) d\xi}{\sqrt{\xi^2 + \Delta^2}}$$

$$\ln \frac{2\varepsilon_0}{\Delta_0} = \ln \frac{2\varepsilon_0}{\Delta} - 2 \int_0^{\varepsilon_0} \frac{f(E) d\xi}{\sqrt{\xi^2 + \Delta^2}}$$

$$\ln \frac{\Delta_0}{\Delta} = 2 \int_0^{\varepsilon_0} \frac{d\xi}{\left(\exp\left(\sqrt{\xi^2 + \Delta^2}/T\right) + 1\right) \sqrt{\xi^2 + \Delta^2}} \tag{6.16}$$

$\varepsilon \approx \infty, T \approx 0,$

$$\ln \frac{\Delta_0}{\Delta} \approx \frac{2}{\Delta_1} e^{-\Delta_0/T} \int_0^{\infty} e^{-\xi^2/(2\Delta T)} d\xi = \sqrt{2\pi \frac{T}{\Delta}} e^{-\Delta_0/T}$$

$$\Delta = \Delta_0 \left(1 - \sqrt{\frac{2\pi T}{\Delta}} e^{-\Delta_0/T}\right) \tag{6.17}$$

$$\ln \frac{\Delta_0}{\Delta} = \ln \frac{\pi T}{\gamma \Delta} + \frac{7\zeta(3)}{8\pi^2} \left(\frac{\Delta}{T}\right)^2 + \dots$$

$\Delta_0 = \pi T_c / \gamma,$

$$\ln \frac{T_c}{T} \approx \frac{T\zeta(3)}{8\pi^2} \left(\frac{\Delta}{T}\right)^2$$

$$\Delta(T) \approx \left(\frac{8\pi^2}{7\zeta(3)}\right)^{1/2} T_{\mathrm{c}} \left(\frac{T_{\mathrm{c}} - T}{T_{\mathrm{c}}}\right)^{1/2} \tag{6.18}$$

The Seebeck effect in a superconductor and the possibility of measuring it.

“Superconducting thermocouple” and the magnetic flux in it.

The Nernst effect in the mixed state of a superconductor and the problem of entropy per vortex.

The Nernst fluctuation effect is above the transition point.

(???)

16.7.2 Heat Capacity from Fluctuation, Diamagnetism of SC II kind

Флуктуации вблизи температуры перехода (оценка ширины флуктуационной области, диамагнетизм, парапроводимость).

Переход Березинского-Костерлица-Таулеса в тонкой пленке.

(По Варламову Ларкину создам параграфы потом!)

2.2. Вклад флуктуаций в теплоемкость

2.2.1. Точное решение задачи в случае размерности $D = 0$
2.2.2. Произвольная размерность: случай $T \geqslant T_c$
2.2.3. Произвольная размерность: случай $T < T_c$

2.3. Флуктуационный диамагнетизм

2.3.1. Предварительные замечания

Что касается трехмерных образцов, то следует отметить, что выражение (1.10), будучи представленным посредством корреляционной длины $\xi(T)$, оказывается справедливым в области более широкой, чем обсуждаемая выше область слабых флуктуаций (ГЛ-область). Действительно, в ГЛ-области ($|\epsilon| \gtrsim Gi$) $\xi(\epsilon) \sim \epsilon^{-1/2}$ и такое представление тривиально. Ситуация изменяется в непосредственной близости точки перехода, где становится существенным взаимодействие флуктуаций. Здесь само присутствие куперовских пар начинает влиять на корреляционную длину. Согласно скэйлинговой гипотезе (которую мы подробно обсудим ниже) вблизи перехода единственным масштабом в системе остается корреляционная длина, по-прежнему степенным образом зависящая от температуры: $\xi(\epsilon) \sim \epsilon^{-\nu}$, однако взаимодействие флуктуаций изменяет критический индекс по сравнению с его ГЛ-величиной $\nu = 1/2$. Та же скэйлинговая гипотеза позволяет записать для диамагнитной восприимчивости общее соотношение:

$$\chi_{(3)} \sim -e^2 T \xi(T) \sim -\chi_P \epsilon^{-1/2} \begin{cases} 1, & \epsilon \gtrsim Gi \\ \left(\frac{\epsilon}{Gi}\right)^{1/2-\nu}, & \epsilon \lesssim Gi, \end{cases}$$

$$\chi_{(3c)} \left(T \gg T_c\right) \sim -e^2 T \xi(T) \sim -\chi_P$$

В двумерном случае выражение (1.10) применимо для оценки $\chi_{(2)}$, когда магнитное поле приложено перпендикулярно плоскости, позволяя флуктуационным куперовским парам вращаться в ней:

$$\chi_{(2c)}(T) \sim e^2 \frac{n}{m} < R^2 > \sim e^2 T \xi^2(T) \sim -\chi_P \frac{E_F}{T - T_c}.$$

$$\chi_{(\text{layer },\perp)}(\epsilon, H \to 0) \sim -e^2 T \frac{\xi_x(\epsilon)\xi_y(\epsilon)}{\max\{s, \xi_z(\epsilon)\}}$$

Из этой формулы очевидно существование кроссовера между $2D$ и $3D$ температурными режимами: по мере того, как температура приближается к T_c, зависимость диамагнитной восприимчивости от ϵ меняется с $1/\epsilon$ на $1/\sqrt{\epsilon}$. Это происходит тогда, когда приведенная температура достигает значения $\epsilon_{cr} = r\left(\xi_z\left(\epsilon_{cr}\right) \sim s\right)$. Параметр анизотропии:

$$r = \frac{4\xi_z^2(0)}{s^2} = \frac{J^2}{T} \begin{cases} \frac{\pi\tau}{4}, & T\tau \ll 1 \\ \frac{7\zeta(3)}{8\pi^2 T}, & T\tau \gg 1 \end{cases}$$

играет важную роль в теории слоистых сверхпроводников [5].

2.3.2. Флуктуационный диамагнетизм нульмерного образца

$$T_c(H) = T_c(0)\left(1 - \frac{4\pi^2\xi^2}{\Phi_0^2}\left\langle \mathbf{A}^2 \right\rangle\right)$$

По этой причине для описания сверхпроводящей гранулы в магнитном поле можно воспользоваться статистической суммой в той же форме (2.25), как и в его отсутствие, но с перенормированным параметром $a(H) = a + \frac{e^2}{m}\langle \mathbf{A}^2 \rangle$:

$$Z_{(0)}(H) = \pi \int d\,|\Psi_0|^2 \exp\left(-\frac{\left[a+\frac{e^2}{m}\left\langle \mathbf{A}^2\right\rangle\right]|\Psi_0|^2+\frac{b}{2V}|\Psi_0|^4}{T}\right) = \\ = \sqrt{\frac{\pi^3 VT}{2b}}\exp\left[\frac{a^2(H)V}{2bT}\right]\left\{1-\operatorname{erf}\left[a(H)\sqrt{\frac{V}{2bT}}\right]\right\}.$$

В области слабых флуктуаций $Gi_{(0)} \lesssim \epsilon$ для свободной энергии можно выписать асимптотическое выражение (2.27):

$$F_{(0)}(\epsilon, H) = -T\ln\frac{\pi}{\alpha\left(\epsilon + \frac{4\pi^2\xi^2}{\Phi_0^2}\langle \mathbf{A}^2\rangle\right)}$$

$$M_{(0)}(\epsilon, H) = -\frac{1}{V}\frac{\partial F_{(0)}(\epsilon, H)}{\partial H} = -\frac{6\pi T\xi^2}{5\Phi_0^2 d}\frac{H}{\left(\epsilon + \frac{\pi^2\xi^2}{10\Phi_0^2}H^2d^2\right)}$$

Легко видеть, что флуктуационная намагниченность отрицательна и линейно возрастает по абсолютной величине вплоть до некоторого поля кроссовера, при котором она достигает минимума. Это поле мы назовем температурно зависящим критическим полем гранулы $H_{c2(0)}(\epsilon) \sim \frac{\Phi_0}{d\xi(\epsilon)} \sim \sim \frac{\xi}{d}H_{c2}(0)\sqrt{\epsilon}$[7].

$$\chi_{(D)}(\epsilon) = -2\pi\frac{\xi T}{v_F}\chi_P\begin{cases}\frac{1}{\sqrt{\epsilon}}, & \text{проволока в параллельном}\\ \frac{2}{\sqrt{\epsilon}}, & \text{поле,}\\ \frac{d}{3\xi}\ln\frac{1}{\epsilon}, & \text{проволока в перпендикулярном}\end{cases}$$

2.3.3. Флуктуационный диамагнетизм в двумерном случае

$$F(\epsilon, H) = -\frac{SH}{\Phi_0}T\sum_{n,k_z}\ln\frac{\pi T}{\alpha T_c\epsilon + \omega_c\left(n+\frac{1}{2}\right)}.$$

Здесь S есть площадь сечения, перпендикулярного полю, а учет вырожденности уровней привел к появлению множителя HS/Φ_0, равного числу квантовых состояний, соответствующих определенной паре квантовых чисел n и k_z. Поскольку мы будем интересоваться лишь флуктуационным вкладом, сингулярным по степени близости системы к точке перехода, то, в интересующем нас случае тонкой пленки ($d \ll \xi_z(T)$), при суммировании по k_z в выражении (2.71) следует оставить лишь член с $k_z = 0$. Это приводит к появлению множителя $1/d$.

Выражение (2.51) удобно переписать, введя безразмерное магнитное поле:

$$h = \frac{\omega_c}{\alpha T_c} = \frac{eH}{2m\alpha T_c} = \frac{H}{\widetilde{H}_{c2}(0)}$$

после чего флуктуационная часть свободной энергии $2D$ сверхпроводника принимает вид:

$$F_{(2)}(\epsilon, H) = -\frac{TS}{2\pi\xi_{xy}^2}h\sum_{n=0}^{n_c-1}\ln\frac{\pi}{\alpha\left[\epsilon + 2h\left(n+\frac{1}{2}\right)\right]}$$

Мы ввели здесь удобное для нашего дальнейшего рассмотрения определение верхнего критического поля

$$\widetilde{H}_{c2}(0) = \frac{2m\alpha T_{\rm c}}{e} = \frac{\Phi_0}{2\pi\xi^2}$$

(??? дальше словами. Плюс указания на эти действия выше обязательно должны быть!!!)

2.4. Слоистый сверхпроводник в магнитном поле

2.4.1. Модель Лоуренса - Дониака

Обобщение функционала Гинзбурга - Ландау на случай слоистого сверхпроводника (функционал Лоуренса - Дониака, ЛД-функционал [50]) в перпендикулярном магнитном поле может быть записано в виде

$$\mathcal{F}_{LD}[\Psi] = \sum_l \int d^2r \left(a\left|\Psi_l\right|^2 + \frac{b}{2}\left|\Psi_l\right|^4 + \frac{1}{4m}\left|\left(\nabla_\parallel - 2ie\mathbf{A}_\parallel\right)\Psi_l\right|^2 + \mathcal{J}\left|\Psi_{l+1} - \Psi_l\right|^2 \right),$$

Ψ_l - параметр порядка в l-м сверхпроводящем слое, а феноменологический параметр $\mathcal{J}$ пропорционален энергии джозефсоновской связи между соседними слоями.

(дальше словами какие-то свойства напишу и указания на ходы. Вроде что-то похожее на типичные ходы дальше идет, но тут прямо специфика.)

2.4.2. Общая формула для флуктуационного вклада в свободную энергию в произвольном магнитном поле

(словами напишу, тут специфика)

2.4.3. Флуктуационная намагниченность и ее кроссоверы

2.4.4. Флуктуационная теплоемкость в магнитном поле

Дифференцирование общего выражения для флуктуационного вклада в свободную энергию слоистого сверхпроводника (2.74) по приведенной температуре позволяет найти наиболее сингулярную часть флуктуационной теплоемкости в магнитном поле:

$$C_{\rm LD}(\epsilon, h) = -\frac{1}{VT}\frac{\partial^2}{\partial^2\epsilon}F_{\rm LD}(\epsilon, h) = \frac{1}{4\pi s\xi_{xy}^2}\frac{1}{2h}\int\limits_0^{2\pi}\frac{d\theta}{2\pi}\psi^{(1)}\left(\frac{1}{2} + \frac{\widetilde{\epsilon}(\theta)}{2h}\right).$$

2.6. Скейлинг и ренормализационная группа

2.7. Влияние флуктуаций на сверхтекучую плот ность и критическую температуру

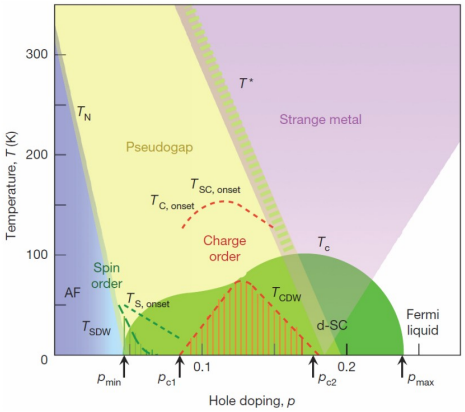
17.1.6 Overview of other not so used methods for SC contacts

Andreeev's equation

$$|\varphi(\mathbf{r})\rangle = e^{i\mathbf{p}_F\cdot\mathbf{r}/\hbar}|\Psi_{\mathbf{p}}(\mathbf{r})\rangle$$

$$\left[\varepsilon\widehat{\tau}_3 - \widehat{\Delta}(\mathbf{p},\mathbf{r})\right]|\Psi_{\mathbf{p}}(\mathbf{r})\rangle + i\hbar\mathbf{v}_{\mathbf{p}}\cdot\left(\boldsymbol{\nabla} - i\frac{2e}{\hbar c}\mathbf{A}(\mathbf{r})\right)|\Psi_{\mathbf{p}}(\mathbf{r})\rangle = 0. \tag{17.7}$$

Here $\mathbf{p}_F$ is the Fermi momenta, $\widehat{\tau}_3$ is the third Pauli's matrix, $\mathbf{p} = p_F\hat{\mathbf{p}}$ and $\mathbf{v}_\mathbf{p} = v_F\hat{\mathbf{p}}$, $\mathbf{v}_\mathbf{p}$ is a Fermi momenta and velocity at different unit directions $\hat{\mathbf{p}}$, and $\widehat{\Delta}$ is a matrix with Δ parameters (it is different for different parity of the Cooper pairs). Finally, $|\Psi_\mathbf{p}(\mathbf{r})\rangle$ should ba understood as the Andreev spinor $|\Psi_\mathbf{p}(\mathbf{r})\rangle := \mathrm{col}\,(u_{\mathbf{p}\uparrow}(\mathbf{r})\ u_{\mathbf{p}\downarrow}(\mathbf{r})\ v_{\mathbf{p}\uparrow}(\mathbf{r})\ v_{\mathbf{p}\downarrow}(\mathbf{r}))$.

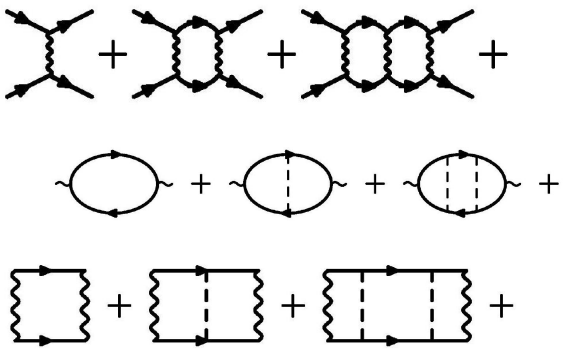


(see de Gennes book for example of application of it to the vortex. I don't know other applications of it.)

PPS's Green's functions method

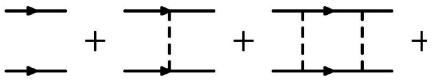
(see my special note about it for now. it is a strange method, which is hard to use.)

17.2 Disorder in Superconductors in a Nutshell



(нужно будет - прочитаю, сделаю потом подразделы)

Потенциальные примеси и их влияние на обычное s-спаривание.
Зависимость критических магнитных полей от беспорядка.
Спин-орбитальное примесное рассеяние и парамагнитный предел.
Нарушение T-инвариантности и распаривающий фактор.
Подавление сверхпроводимости магнитным полем. Бесщелевая сверхпроводимость.
Разрушение «необычных» сверхпроводящих фаз потенциальными примесями.



17.2.1 Disorder of superconductors: Basic Models

Теорема Андерсона.

$$\Gamma^C = -\frac{\lambda}{1+\lambda\Pi_c}$$

Π_c =

$$G\left(i\omega_n, \mathbf{p}\right) = \frac{1}{i\omega_n - \xi_p + \frac{1}{2\tau}\operatorname{sign}\omega_n}.$$

$$B_c\left(i\omega_n\right) = \int G\left(i\omega_n, \mathbf{p}\right) G\left(-i\omega_n, -\mathbf{p}\right) \frac{d^3p}{(2\pi)^3} = \int\limits_{-\infty}^{\infty} \frac{\nu_0 d\xi}{\left(\omega_n + \frac{1}{2\tau}\operatorname{sign}\omega_n\right)^2 + \xi^2} = \frac{2\pi\nu_0\tau}{1+2\tau\left|\omega_n\right|}$$

$$L\left(i\omega_n\right) = B_c\left(i\omega_n\right) + \frac{1}{2\pi\nu_0\tau}B_c^2\left(i\omega_n\right) + \ldots = \frac{B_c\left(i\omega_n\right)}{1 - B_c\left(i\omega_n\right)/\left(2\pi\nu_0\tau\right)} = \frac{\pi\nu_0}{\left|\omega_n\right|}$$

$$\langle n(\omega, \mathbf{q}) n(-\omega, -\mathbf{q})\rangle_{\mathbf{q}=0} = \pi\nu_0/(i\omega)$$

$$\Pi_c = -T\sum_{\omega_n} L\left(i\omega_n\right) = -2\pi\nu_0 T \sum_{\omega_n>0} \frac{1}{\left|\omega_n\right|} = -\nu_0 \ln\frac{2\gamma\omega_D}{\pi T}$$

$$T_c = \frac{2\gamma}{\pi}\omega_D e^{-1/\lambda\nu_0}$$

О методе матричных функций Грина и уравнении Намбу-Горькова

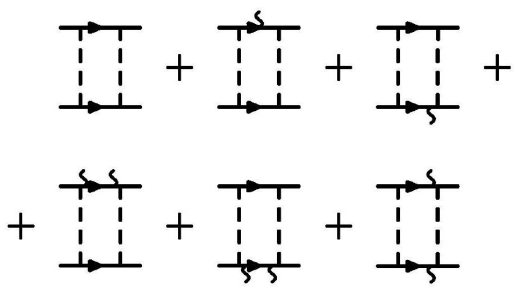
$$\frac{1}{\lambda\nu_0} = \ln \frac{2\gamma\omega_D}{\pi T_c} = \int_0^{\omega_D} \frac{d\omega}{\omega + 1/\tau_s^*} = \ln\left(\omega_D \tau_s^*\right)$$

$$\tau_s^* = 2\gamma\hbar/\left(\pi T_c\right)$$

Верхнее критическое поле в грязном сверхпроводнике

(???)
Proof:

$$B_c = \iint \frac{d\Omega}{4\pi} \frac{\nu_0 d\xi}{\left(i\omega - \xi + \frac{i}{2\tau}\operatorname{sign}\omega\right)\left(-i\omega - \xi + \mathbf{sv} - \frac{i}{2\tau}\operatorname{sign}\omega\right)} = \int \frac{d\Omega}{4\pi} \frac{2\pi\nu_0\tau}{1 + 2|\omega|\tau + i\tau\mathbf{sv}} =$$
$$= \frac{2\pi\nu_0\tau}{1 + 2|\omega|\tau + \tau D\mathbf{s}^2}$$



$$C_\omega(\mathbf{s}) = \frac{B_c}{1 - B_c/2\pi\nu_0\tau} = \frac{2\pi\nu_0}{2|\omega| + D\mathbf{s}^2}$$

$\mathbf{p} \to \mathbf{p} - e\mathbf{A}/c$

$$\widehat{C}_\omega = \frac{2\pi\nu_0}{2|\omega| + D\left(\mathbf{s} - \frac{2e}{c}\mathbf{A}\right)^2}.$$

$$\left[2|\omega| + D\left(-i\frac{\partial}{\partial\mathbf{r}} - \frac{2e}{c}\mathbf{A}\right)^2\right] C_\omega\left(\mathbf{r}\mathbf{r}'\right) = 2\pi\nu_0\delta\left(\mathbf{r} - \mathbf{r}'\right).$$

$$\left[2|\omega| + D\left(-i\frac{\partial}{\partial\mathbf{r}} - \frac{2e}{c}\mathbf{A}(\mathbf{r})\right)^2\right] C_\omega\left(\mathbf{r}\mathbf{r}'\right) = 2\pi\nu_0\delta\left(\mathbf{r} - \mathbf{r}'\right).$$

$$\Delta(\mathbf{r}) = \lambda \int\limits_{-\infty}^{\infty} F(\omega \mathbf{r}\mathbf{r}) \frac{d\omega}{2\pi}$$

$$F(\omega \mathbf{r}\mathbf{r}) = \int \Delta\left(\mathbf{r}'\right) C_\omega\left(\mathbf{r}\mathbf{r}'\right) d^3 r'$$

$$\Delta(\mathbf{r}) = \lambda \int\limits_{-\infty}^{\infty} \frac{d\omega}{2\pi} \int C_\omega\left(\mathbf{r}\mathbf{r}'\right) \Delta\left(\mathbf{r}'\right) d^3 r'$$

$$D\left(-i\frac{\partial}{\partial \mathbf{r}} - \frac{2e}{c}\mathbf{A}(\mathbf{r})\right)^2 \varphi_n(\mathbf{r}) = \mu_n \varphi_n(\mathbf{r})$$

$$\int \varphi_n(\mathbf{r}) \varphi_m^*(\mathbf{r}) d^3 r = \delta_{nm}$$

$$\Delta(\mathbf{r}) = \sum_n \Delta_n \varphi_n(\mathbf{r})$$

$$C_\omega\left(\mathbf{r}\mathbf{r}'\right) = 2\pi\nu_0 \sum_n \frac{\varphi_n(\mathbf{r}) \varphi_n^*\left(\mathbf{r}'\right)}{2|\omega| + \mu_n}$$

$$\Delta_n = \int\limits_{-\infty}^{\infty} \frac{2\pi\nu_0 \lambda \Delta_n}{2|\omega| + \mu_n} \frac{d\omega}{2\pi}.$$

$$\frac{1}{\nu_0 \lambda} = \int\limits_{-\infty}^{\infty} \frac{d\omega}{2|\omega| + \mu_n}$$

$\omega = \omega_D$.

$$\frac{1}{\nu_0 \lambda} = \ln \frac{2\omega_D}{\mu_n}.$$

$$E_n = \omega_H \left(n + \frac{1}{2}\right) + \frac{\hbar^2 k_z^2}{2m}; \quad \omega_H = \frac{qH}{mc}.$$

$$\mu_n = \frac{4DeH}{c}\left(n + \frac{1}{2}\right) + Dk_z^2.$$

$\mu_0 = 2DeH/c.$

$$\frac{1}{\nu_0\lambda} = \ln\frac{\omega_D c}{DeH_{c2}}.$$

$$H_{c2} = \frac{\pi}{2\gamma}\frac{T_c c}{De} = \frac{\pi}{\gamma}\frac{T_c}{\hbar D}\Phi_0$$

$\Phi_0 = \hbar c/2e$

$$\varphi_{nk_y}(xyz) = \frac{1}{\pi^{1/4}l_H^{1/2}}e^{ik_y y}e^{-(x-x_0)^2/2l_H^2}$$

$$l_H = \sqrt{\hbar c/(qH)} \quad x_0 = ck_y/(qH).$$

$$E_{\text{mag}} = H^2/8\pi$$

$$E_c \approx \nu_0\Delta^2 \approx \nu_0 T_c^2$$

$$H_c \approx T_c\sqrt{\nu_0}$$

$$\frac{H_c}{H_{c2}} \approx \sqrt{De\nu_0}c \approx \frac{v_F l\sqrt{mp_F/\hbar^3}}{c} \approx l\sqrt{\frac{e^2p_F^3}{mc^3\hbar^3}} \approx \frac{l}{\delta_\Lambda}$$

17.2.2 Superconductor-insulator Phase Transition

(a widely discussed topic)

Most Important Experimental Facts

(?? see some artivles about it, not important for now)

17.2.3 2D Superconductors

(there are a lot of experiments about it, I'll write later)

17.2.4 Materials with Localization and SC

(SC when there is a lot of disorder, the wf are localized. this is a research topic. how to combine BCS and localization?)

17.2.5 Superconductivity of a Graph

(see Feigelman's article)

Main Experimental Parameters

(remember what Khvaluk told me)

Main Experimental Facts for Materials

(see what Feigelman wrote)
And this is the only thing that we can describe by this whole theory.

Main Methods of the Theory

(main idea of Feigelman's theory)

17.3 Less currently applicable, but potentially useful theories

17.3.1 Kitaev's 1D chain

17.3.2 Majorana Fermions in a Superconductors

(много статей про это есть, выпишу что-то важное)

On Quantizing Majorana Fermions in a Superconductor C. Chamon, R. Jackiw, Y. Nishida, S.-Y. Pi, L. Santos

(выпишу основные потом формулы)

17.3.3 London's theory

(допишу потом, даже не знаю, где это нужно в настоящее время)

Уравнения Лондонов в двух словах

$$\mathbf{B} + \lambda_L^2 \text{ rot } \text{rot}\, \mathbf{B} = 0 \qquad \text{(ур. Лондонов)}$$

Суть их в том, что (?? мы описываем нелинейную электродинамику в сверхпроводнике??)
(!?!? абзац про связь их с ур Максвелла?? так и не додумал, потом додумаю!)
Получаются уравнения Лондонов так:

$$\text{rot}\, \mathbf{B} = \frac{4\pi}{c}\mathbf{j}_s, \qquad \mathbf{j}_s(\mathbf{r}) := n_s e \mathbf{v}(\mathbf{r})$$
$$\text{div}\, \mathbf{B} = 0.$$

$$\mathcal{F} = \int F_s dV + E_{kin} + E_{\text{mag}}\,,$$

$$E_{kin} = \frac{1}{2}\int n_s m v^2 dV = \frac{1}{2}\int n_s m \left(\frac{c}{4\pi n_s e}\,\text{rot}\,\mathbf{B}\right)^2 dV,$$

$$E_{\text{mag}} = \int \frac{\mathbf{B}^2}{8\pi} dV$$

В итоге:

$$\mathcal{F} = \int dV \left[\mathcal{F}_s + \frac{1}{8\pi}\left(\mathbf{B}^2 + \lambda_L^2 (\text{rot}\,\mathbf{B})^2\right)\right], \qquad \lambda_L := \left(\frac{mc^2}{4\pi n_s e^2}\right)^{1/2} \sim 10^{-5} \div 10^{-6}\text{cm}.$$

Варьируем (????), получаем уравнение Лондонов:

$$\mathbf{B} + \lambda_L^2 \text{ rot } \text{rot}\, \mathbf{B} = 0$$

(тут еще калибровку можно сделать, кстати.(????))

$$\text{rotrot}\, \mathbf{A} = -\frac{1}{\lambda_L^2}\mathbf{A},$$

О границе применимости уравнений Лондонов (????)

(напишу четко потом)

Вывод уравнений Лондонов и их свойств

(выпишу из Шмидта, все про них)

6. Глубина проникновения магнитного поля по Лондонам

Лондоновская глубина проникновения для некоторых сверхпроводников по Шмидту, со ссылкой на [Линтон Э. Сверхпроводимость. М.: Мир, 1971.]:

Элемент	Al	Cd	Hg	In	Nb	Pb	Sn	Tl
$\lambda(0), \text{Å}$	500	1300	$380 \div 450$ (анизотропия)	640	470	390	510	920

(?!!! проверю расчетами!)

Нелокальная электродинамика сверхпроводников по Шмидту

В общем виде нелокальная связь между j_s и $\mathbf{A}$ может быть записана в виде

$$\mathbf{j}_s(\mathbf{r}) = \int \widehat{Q}\left(\mathbf{r}-\mathbf{r}'\right)\mathbf{A}\left(\mathbf{r}'\right)d\mathbf{r}',$$

$\widehat{Q}$ - некоторый оператор, который, действуя на вектор $\mathbf{A}$, превращает его в вектор $\widehat{Q}\mathbf{A}$. Радиус действия оператора $\widehat{Q}(\mathbf{r}$ - $\mathbf{r}')$ берется равным ξ_0, т.е. $\widehat{Q}\left(\mathbf{r}-\mathbf{r}'\right)$ отличен от нуля только при $|\mathbf{r}-\mathbf{r}'| \lesssim \xi_0$. Так происходит усреднение действия вектора $\mathbf{A}$ на частицу (носитель сверхтока) больших размеров. Если этот размер устремить к нулю, то $\widehat{Q}$ превратится в δ-функцию, и мы вернемся к локальной электродинамике. Пиппард предложил $\widehat{Q}\mathbf{A}$ выбрать в виде

$$\widehat{Q}\left(\mathbf{r}-\mathbf{r}'\right)\mathbf{A}\left(\mathbf{r}'\right) = -\frac{3n_s e^2}{4\pi mc\xi_0}\frac{\left(\mathbf{r}-\mathbf{r}'\right)}{\left(\mathbf{r}-\mathbf{r}'\right)^4}\left(\mathbf{A}\left(\mathbf{r}'\right),\mathbf{r}-\mathbf{r}'\right)e^{-|\mathbf{r}-\mathbf{r}'|/\xi_0}$$

$$\lambda = \frac{1}{H_0}\int\limits_0^\infty H dx.$$

$H_0 = H_{\text{surface}}$

$$\mathbf{j}_s = -\frac{c}{4\pi\lambda^2}\frac{\lambda_{\mathrm{P}}}{\xi_0}\mathbf{A}.$$

$$= -\frac{c}{4\pi\lambda_{\mathrm{P}}^2}\mathbf{A},$$

$$\lambda_{\mathrm{P}} \simeq \left(\lambda^2\xi_0\right)^{1/3}.$$

Квантовое обобщение уравнения Лондонов. Квантование магнитного потока по Лондонам

$$\hbar\nabla\theta = 2m\mathbf{v}_s + \frac{2e}{c}\mathbf{A}$$

$$\mathbf{j}_s = n_s e\mathbf{v}_s$$

$$\mathbf{j}_s = \frac{1}{c\Lambda}\left(\frac{\Phi_0}{2\pi}\nabla\theta - \mathbf{A}\right)$$

$$\frac{\Phi_0}{2\pi}\oint_C \nabla\theta d\mathbf{l} = \oint_C \mathbf{A}d\mathbf{l}.$$

$$\oint_C \mathbf{A}d\mathrm{l} = \Phi,$$

$$\Phi = (\Phi_0/2\pi)\oint_C \nabla\theta d\mathbf{l}.$$

$$\Phi = n\Phi_0,$$

$$\Phi_0 = \frac{\pi\hbar c}{e} = \frac{hc}{2e}.$$

17.3.4 London equations, consequences

(все указания про них - тут. из Кириченко выпишу всё, когда дойду)

Пока считаю, что это почти бесполезная теория, окей, объясняет диамагнетизм, и не знаю, что больше из неё можно получить.

- The London equation

$$\mathbf{j} = -\frac{c}{4\pi\lambda_L^2}\mathbf{A} \quad \Leftrightarrow \quad \operatorname{curl}\mathbf{j} = -\frac{c}{4\pi\lambda_L^2}\mathbf{B}$$

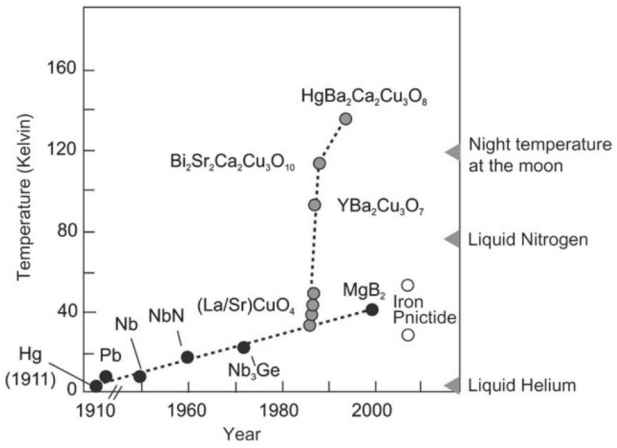
leads to the Meissner effect through the penetration equation $\nabla^2 B = B/\lambda_L^2$, where $\lambda_L \approx (mc^2/4\pi ne^2)^{1/2}$ is the London penetration depth.

- In the London equation $\mathbf{A}$ or $\mathbf{B}$ should be a weighted average over the coherence length ξ. The intrinsic coherence length $\xi_0 = 2\hbar v_p/\pi E_g$.

17.3.5 On 1D superconductors

(есть статья Бычкова Горькова Дзялошинского, мб когда-то отвечу на этот вопрос. Говорят, что она может быть, но это спорно и при сильном кулоновском взаимодействии (???))

17.3.6 BCS-BEC Crossover



(??? what is it???)

17.4 High-T SC

(нужно будет - прочитаю, сделаю потом подразделы)

High-T SC: main methods

Overview of high-T sup cond

Compound	T_C(K)
$La_{2-x}Sr_xCuO_4$	38
$YBa_2Cu_3O_{7-x}$	92
$Bi_2Sr_2CaCu_2O_{8+x}$	110
$Tl_2Ba_2Ca_2Cu_3O_{10+x}$	125
$HgBa_2Ca_2Cu_3O_{8+x}$	133

(ниже пара тем курса “Введение в сверхпроводимость” от КАФЕДРы ФИЗИКИ НИЗКИХ ТЕМПЕРАТУР И сверхпроводимости МГУ)

№16, 2 часа.

Квазидвумерные и квазиодномерные системы.

Усиление электрон–фононного взаимодействия в системах с переменной валентностью.

Нефононные механизмы сверхпроводимости.

d-спаривание.

Main materials for high-T SC

18 Overview of special phenomena and applications

18.1 Other Phenomena In a Nutshell

18.1.1 Thermoelectric Effects in Superconductors

Эффект Зеебека в сверхпроводнике и возможность его измерения.

«Сверхпроводящая термопара» и магнитный поток в ней.

Эффект Нернста в смешанном состоянии сверхпроводника и проблема энтропии, приходящейся на один вихрь.

Флуктуационный эффект Нернста выше точки перехода.

18.1.2 Vortex Lattice Melting and Pinning in a Nutshell

Вихрь в потенциале точечных дефектов.

Скейлинговые соотношения.

Решетка вихрей: упругие модули.

Плавление решетки вихрей тепловыми флуктуациями.

Разрушение дальнего порядка решетки примесями и критический ток.

Крип магнитного потока и нелинейная проводимость в ВТСП.

18.1.3 Fluctuation Effects by Varlamov, Larkin in a Nutshell (????)

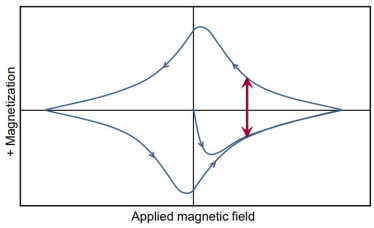
(по Варламову Ларкину, I'll write the most important concepts)

Fluctuations in Nanostructures and Special Superconducting Systems (????)

(по Варламову Ларкину. их часть 4. там огромное задротство)

18.1.4 Other Magnetic Phenomena

(пока как-то не актуально про них думать, но слышал про них)



Magnetization curve of hard superconductors

(я не понял это, когда-то подумаю еще раз, все равно никакими формулами нас не обучали)

If flux lines are pinned in hard superconductors, their thermodynamic equilibrium positions can not settle, which results in irreversible magnetization curves with higher magnetization values.

Close relation between irreversible magnetization and critical current The 'Bean critical state model"' explains that under certain assumptions:

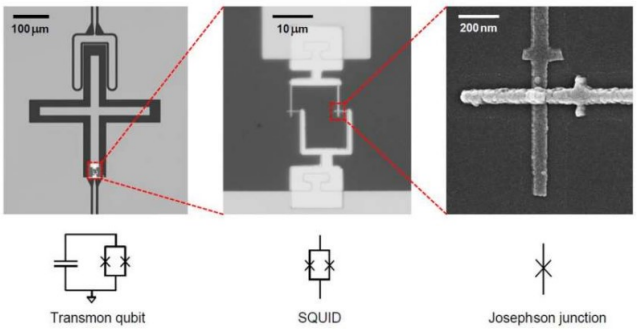
$$|M(B_a)| \sim \boldsymbol{j_c}(\boldsymbol{B_a})$$

18.1.5 On induced superconductivity of 2D materials (???)

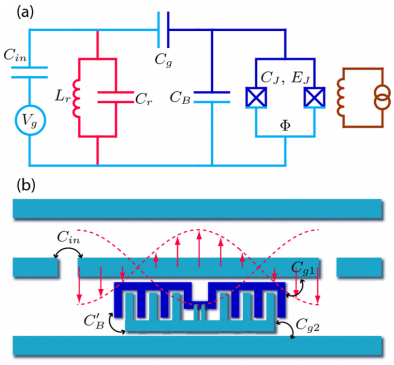
(maybe I'll look later)

18.2 Superconductivity for quantum computation (???)

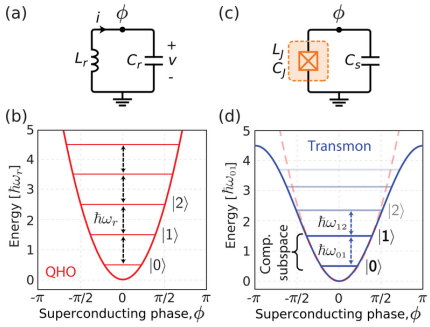
(тут очень многое можно указать потом)



18.3 Applications of superconductivity



(из Applied Superconductivity: Josephson Effect and Superconducting Electronics by Prof. Dr. Rudolf Gross, пока не актуально в этом разбираться.)



18.3.1 On superconductivity for qubits and quantum computers

(это же в кв теор инф)

Transmon qubits

LC circuit $E_{tot} = \frac{Q^2}{2C} + \frac{1}{2L}\Phi^2 = \frac{1}{2}C\dot{\Phi}^2 + \frac{1}{2}C\frac{1}{LC}\Phi^2 \quad \widehat{H} = \frac{Q^2}{2C} + \frac{1}{2L}\widehat{\Phi}^2$

$$E_n = \hbar\omega_0\left(n + \frac{1}{2}\right) \quad \omega_0 = \frac{1}{\sqrt{LC}}$$

Non-linear inductance $L_J = \frac{\hbar}{2eI_c\cos(\varphi)} = \pm L_c \frac{1}{\cos(\varphi)}$ Energy in JJ $E = E_J[1-\cos(\varphi)]$ $E_J \equiv \frac{\Phi_0}{2\pi} I_c$ $E_c = e^2/2C$ Transmon

$$\widehat{H} = \frac{\hat{Q}^2}{2C} + E_J[1-\cos(\hat{\varphi})]$$
$$\widehat{H} = 4E_c\hat{n}^2 + E_J[1-\cos(\hat{\varphi})] \qquad hf_{01} \approx \sqrt{8E_JE_c} - E_c$$
$$\widehat{H} = 4E_c\hat{n}^2 + E_J\frac{\widehat{\varphi}^2}{2} - E_J\frac{\widehat{\varphi}^4}{24} + \cdots \qquad hf_{12} \approx hf_{01} - E_c$$

Time dependence

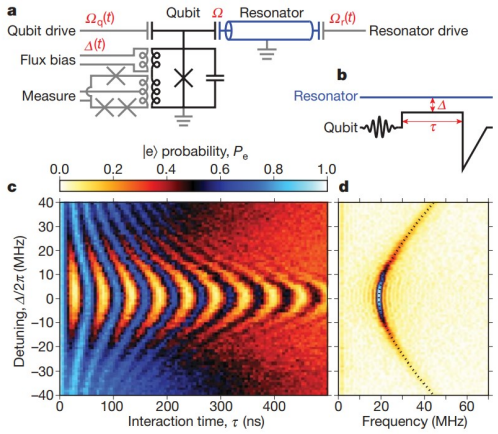
$$|\Psi(t)\rangle = c_0(t)e^{-\frac{i\varepsilon_0 t}{\hbar}}|0\rangle + c_1(t)e^{-\frac{i\varepsilon_1 t}{\hbar}}|1\rangle$$
$$c_0(t) = e^{-i\Delta t/2}\left[\cos\frac{\Omega t}{2} + i\frac{\Delta}{\Omega}\sin\frac{\Omega t}{2}\right]$$
$$c_1(t) = i\frac{A}{\Omega\hbar}e^{i\Delta t/2}\sin\frac{\Omega t}{2} \qquad P_1(t) = |c_1(t)|^2 = \frac{A^2}{\hbar^2\Omega^2}\sin^2\left(\frac{\Omega}{2}t\right)$$

Rabi frequency $\Omega = \sqrt{\Delta^2 + A^2/\hbar^2}$ Detuning $\Delta = \omega_{01} - \omega$
Resonator $\omega_r = 2\pi\frac{v_p}{\lambda_n} = 2\pi\frac{1}{\sqrt{LC}}\frac{(n+1)}{2\ell}$ FWHM: $\kappa = \frac{\omega_r}{Q}$
Dispersive readout $\omega_r \pm \frac{g^2}{\Delta}$
(??? так пока и не разобрался, как это работает???)
Anharmonicity is required to isolate two levels
(тут абзац про эту идею)
We need an anharmonic energy spectrum
Non-linear circuit elements are required (diodes, transistors,) But typical non-linear elements are dissipating
Solution: Josephson junction The energy levels will be non-equidistant
A Josephson junction is a non-linear inductor
Inductance of a JJ:

$$V = L_J\frac{dI_S}{dt}$$
$$I_S = I_c\sin\varphi \Leftrightarrow \frac{dI_S}{dt} = I_c\cos\varphi\frac{d\varphi}{dt} = \frac{2eV}{\hbar}I_c\cos\varphi \quad L_J = \frac{\hbar}{2eI_C\cos\varphi}$$

voltage-phase relation: $\frac{d\varphi}{dt} = \frac{2\mathrm{eV}}{\hbar}$; $\cos\varphi = \pm\sqrt{1-\left(\frac{I_s}{I_c}\right)^2}$ the inductance of a JJ depends on the current (via the phase difference φ)
Total energy $\rightarrow$ Hamiltonian:

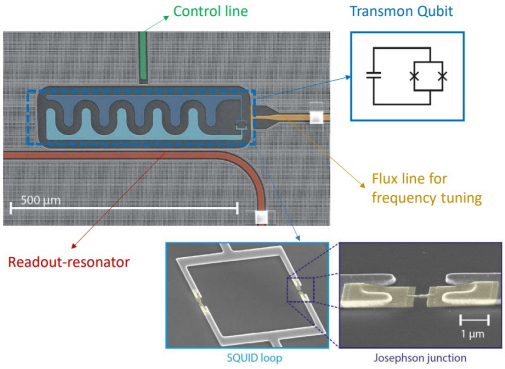
$$\widehat{H} = \frac{\widehat{Q}^2}{2C} + E_J[1-\cos\hat{\varphi}]$$
$$\widehat{H} = 4E_c\hat{n}^2 + E_J[1-\cos\hat{\varphi}]$$



We consider $\varphi \ll 1$ and $E_J > E_C$ i.e. the transmon regime

$$\hat{H} = 4E_c\hat{n}^2 + E_J\left[1-\left(1-\frac{\hat{\varphi}^2}{2}+\frac{\hat{\varphi}^4}{24}\ldots\right)\right] \approx 4E_c\hat{n}^2 + E_J\frac{\hat{\varphi}^2}{2} - E_J\frac{\hat{\varphi}^4}{24}$$

Stored energy in JJ:



$$E = \int_0^t IV\,dt = \int_0^\varphi I_C\sin\varphi\frac{\hbar}{2e}d\varphi$$
$$E = \frac{\Phi_0}{2\pi}I_C[1-\cos(\varphi)] = E_J[1-\cos(\varphi)] \qquad E_J := \frac{\Phi_0}{2\pi}I_C = \text{ "Josephson energy"}$$

Two-level systems, basic quantum optics for quantum computing

Superconducting circuits as artificial atoms: frequency range

General circuit is as follows:

Qubit control

(допишу скоро уже, там минут 20 и сделаю это)

Qubit readout

When a qubit is coupled to a superconducting CPW resonator, dispersive readout allows to determine the qubit state: under the conditions:

- Strong coupling regime

$$\text{i.e. } g \gg \kappa, \frac{1}{T_1}, \frac{1}{T_2} \quad \left(\frac{1}{g} \sim 50 \text{ ns} \ll T_1,\ T_2 \right)$$

- Dispersive regime (detuned regime)

$$\text{i.e. } g \ll \omega_{\text{resonator}} - \omega_{\text{qubit}} \equiv \Delta$$

- Low photon numbers in cavity: $<< \Delta^2/4\ g^{2\sim100}$

18.3.2 Overview of typical applications of superconductivity

Part VIII
Other Properties, Theories and Effects

19 Other Known Phenomena and Models

19.1 Unconventional Superconductivity by Mineev, V.P. Samokhin, K., part 1

19.1.1 1. Cooper Pairing in General

Сверхпроводимость - полное исчезновение электрического сопротивления постоянному току - наблодается во многих металлах при достаточно низких температурах. О сверхпроводимости можно говорить как о сверхтекучести, то есть полном исчезновении вязкости в жидкости, состоящей из электронов проводимости. Подобное явление имеет место и в ряде друтих квантовых жидкостен: сверхтекучих ^{4}He и ^{3}He, атомных ядрах и нейтронных звездах.

Теоретическое изучение сверхтекучих ферми-систем началось со времени создания в 1957 г. Дж. Бардиным, Л. Купером и Дж. Шриффером [1] геории сверхпроводимости (здесь и далее - теории БКШ). В основе этой теории лежит утверждение Л. Купера о нсустойчивости основного состояния электронного газа со сколь угодно слабым притяжением между частицами по отношению х образованию связанных состояний - пар электронов. Межэлектронное

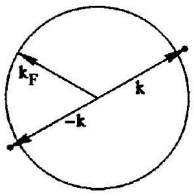

Рис. 1. Два электрона с противоположными импульсами над сферои Ферми притяжение, превосходящее кулоновское отталкивание, в большинстве сверхпроводников обязано своим происхождепием взаимодействию электронов с колебаниями кристаллической решетки (фононами), приводящему к образованиоо области избыточного положительного заряда, окружающщего данный электрон. Такое взаимодействие практически изотропно, поэтому куперовские пары образуются в состоянии с нулевым орбитальным момегтом (s-спаривание). Иначе дело обстоит в сверхтекучем ^{3}He, где куперовское спаривание возникает благодаря взаимодействию ядерных спинов атомов гетия-3 с флуктуациями намагниченности жидкости (парамагнонами). Парамагнонное взаимодействие существенно анизотропно и приводит к образованию куперовских пар с орбитальным моментом $L = 1$ (p-спаривание).

Несмотря на значительную разницу в природе притяжения между частицами, куперовское спаривание является общим механизмом, ответствеппыым за формирование сверхтекучего состояния в различных ферми-системах. Слепуя работе [2], рассмотрим квантово-мсханическую задачу о двух электронах в нормальном металле при нулево температуре. Будем считать, что пара электронов взаимодействует между собой посредством потенциала $V(\mathbf{r}_1 - \mathbf{r}_2)$, не зависящето от их спинов, а наличие остапьних электронов, заполняющих все состояния нисже уровня Ферми, проявляется только чсрез приншип Паули
(рис. 1). Для определения уровней эiергии и волновых функций $\psi(\mathbf{r}_1, \mathbf{r}_2)$ электроніо пары нсобходимо рсшшить уравеение Шредингера

$$-\frac{\hbar^2}{2m}\left(\boldsymbol{\nabla}_1^2+\boldsymbol{\nabla}_2^2\right)\dot{\psi}\left(\mathbf{r}_1,\mathbf{r}_2\right)+V\left(\mathbf{r}_1-\mathbf{r}_2\right)\psi\left(\mathbf{r}_1,\mathbf{r}_2\right)=\left(\Delta+\frac{\hbar^2k_F^2}{m}\right)\psi\left(\mathbf{r}_1,\mathbf{r}_2\right) \tag{1.1}$$

где Δ - эдергия электронной пары, отсчитанная от энергии двух свободныхх электронов, т. е. удвоенной энергии Ферми $h^2k_{\mathrm{F}}^2/m$.

Or координат электронов $\mathbf{r}_1$ и $\mathbf{r}_2$ можно перейти к координатам центра инерции $\mathbf{R}=\left(\mathbf{r}_1+\mathbf{r}_2\right)/2$ и относительного движения $\mathbf{r}=\mathbf{r}_1-\mathbf{r}_2$. Если счщтать, что центр инерции пары покоится, иными словами, что импульсы электронов противоположны ($\mathbf{k}$ и $-\mathbf{k}$), то зависимость ψ от $\mathbf{R}$ можно опустить, и уравнение Шредиигсра перепишется в виде

$$-\frac{\hbar^2}{m}\frac{\partial^2\psi(\mathrm{r})}{\partial\mathrm{r}^2}+V(\mathbf{r})\psi(\mathbf{r})=\left(\Delta+\frac{\hbar^2k_F^2}{m}\right)\psi(\mathbf{r}) \tag{1.2}$$

Персходя к импупьсному представлениго

$$g(\mathbf{k})=\int d^3re^{-i\mathbf{kr}}\psi(\mathbf{r}) \tag{1.3}$$

получаем:

$$\frac{\hbar^2}{m}h^2g(\mathbf{k})+\int\frac{d^3k'}{(2\pi)^3}V\left(\mathbf{k}-\mathbf{k}'\right)g\left(\mathbf{k}'\right)=\left(\Delta+\frac{\hbar^2k_F^2}{m}\right)g(\mathbf{k}) \tag{1.4}$$

Взаимодействие

$$V\left(\mathbf{k}-\mathbf{k}'\right)=\int d^3re^{-i(\mathbf{k}-\mathbf{k}')\mathbf{r}}V(\mathbf{r}) \tag{1.5}$$

зависящее от направлений импульсов

$$V\left(\mathbf{k}-\mathbf{k}'\right)=\sum_{l=0}^{\infty}V_l\left(k,k'\right)\sum_{m=-1}^{1}Y_{lm}(\hat{\mathbf{k}})Y_{lm}^*\left(\hat{\mathbf{k}}'\right) \tag{1.6}$$

будем считать притяжением в узком слое толщиной $\varepsilon_l\ll\varepsilon_{\mathrm{F}}=\hbar^2k_{\mathrm{F}}^2/(2\ \mathrm{m})$ над поверхностыо Ферми

$$V_l\left(k,k'\right)=\begin{cases}-V_l, & \text{при } \varepsilon_{\mathrm{F}}<\frac{\hbar^2k^2}{2m},\frac{\hbar^2k'^2}{2m}<\varepsilon_{\mathrm{F}}+\varepsilon_l\\ 0, & \text{вне интервала } \left(\varepsilon_{\mathrm{F}},\varepsilon_{\mathrm{F}}+\varepsilon_l\right)\end{cases} \tag{1.7}$$

Здесь $Y_{lm}(\hat{\mathbf{k}})$ - сферические функции с орбитадыным моментом l и его проекцией m на ось z, а $\hat{\mathbf{k}}=\mathbf{k}/k_{\mathrm{F}}$.

Осуществим в (1.4) обычный переход от интегрирования по волновому вектору к интегрированию по энергии $\xi=\hbar^2k^2/2m-\varepsilon_{\mathrm{E}}$ и направлениям $\mathbf{k}$

$$\int\frac{d^3k}{(2\pi)^3}\to N_0\int d\xi\int\frac{d\Omega}{4\pi} \tag{1.8}$$

где

$$N_0=\frac{mk_F}{2\pi^2\hbar^2} \tag{1.9}$$

• плотность состояний на поверхности Ферми на одну проекцию спина электрона. Имеем:

$$\left[\frac{\hbar^2}{m}\left(k^2-k_{\mathrm{F}}^2\right)-\Delta\right]_{\varepsilon_l} g(\mathbf{k})-$$
$$-N_0\int\limits_0^d d\xi'\int\frac{d\Omega'}{4\pi}\sum_{i=0}^{\infty}V_l\sum_{m=-1}^{1}Y_{im}(\hat{\mathbf{k}})Y_{lm}^*\left(\hat{\mathbf{k}}'\right)g\left(\mathbf{k}'\right)=0 \tag{1.10}$$

Нетрудно убедиться, что каждому значению орбитального момснта l соответствует определенное собственное состояние $\{g_l(\mathbf{k}),\Delta_l\}$ уравнения (1.10). Действительно, подставдяя разложение

$$g(\mathbf{k})=g_{l'}(\mathbf{k})=\sum_{m'=-l'}^{l'}a_{l'm'}(k)Y_{l'm'}(\hat{\mathbf{k}})$$

в (1.10) и попьзуясь ортонормированностью сферических функций

$$\int\frac{d\Omega'}{4\pi}Y_{lm}^*\left(\hat{k}'\right)Y_{l'm'}\left(\hat{k}'\right)=\delta_{ll}\delta_{mm'} \tag{1.11}$$

полупим:

$$\left[\frac{\hbar^2}{m}\left(k^2-k_{\Gamma}^2\right)-\Delta_l\right]g_l(\mathbf{k})-N_0V_l\int\limits_0^{\varepsilon_l}d\xi g_l(\mathbf{k})=0$$

Следоватетьно,

$$g_l(\mathbf{k})=\frac{N_0V_i\int\limits_0^{c_1}d\xi g_l(\mathbf{k})}{2\xi-\Delta_l} \tag{1.12}$$

Интегрируя по ξ левую и правуіо части этого уравнения, получим

$$1=N_0V_l\int\limits_0^{\varepsilon_l}\frac{d\xi}{2\xi-\Delta_l}=\frac{N_0V_l}{2}\ln\frac{\varepsilon_l-\frac{\Delta_l}{2}}{-\frac{\Delta_l}{2}}$$

Отсюда, полагая взаимодействие слабым $N_0V_1\ll 1$, находим

$$\Delta_l=-2\varepsilon_l\exp\left(-\frac{2}{N_0V_l}\right) \tag{1.13}$$

Итак, при сколб угодно слабом притяжении между двумя электронами возникает связаннос состояние, энергия которого зависит от орбитального момента.

Данное утверждение, доказаннюе для двух электронов, сохраняет свою силу и в многоэлектронной задаче (см. 6). Именно, сверхпроводящие состояния, соответствуошие куперовскому спариванипо с различными значениями орбитального момента, имеют различную критическую температуру. Сверхпроводящие состояния

$$g_l(\mathbf{k})=\sum_{m=-1}^{1}a_{lm}(k)Y_{lm}(\hat{\mathbf{k}}) \tag{1.14}$$

с данным l, отличагощиеся наборами коэффициентов $\{a_{3m}(k)\}$, имеют одинаковую критическуі температуру. Из всех таких состоянй при опредсленной температуре и определенном давлении реализуется наиболее эпергетически выгодіное.

Размер куперовской пары. Характерный интервал δk, на котором изменяюотя коэффициенты $a_{lm}(k)$, связан соотношешием неопрсделенности $\xi_0 \delta k \geq 1$ с характерным размером ξ_0 волновой функции в координатном пространстве - размером куперовской пары [1]. Неопределенность волнового вектора δk можно оценить через энсргиго связи пары:

$$\Delta \sim \delta\varepsilon \sim \frac{\hbar^2}{m} k_{\mathrm{F}} \delta k \sim \hbar v_{\mathrm{F}} \delta k$$

Следовательно,

$$\xi_0 \sim \frac{\hbar v_{\mathrm{F}}}{\Delta} \tag{1.15}$$

Неустойчивость нормального ферми-газа по отношению к куперовскому спариванио, очевидно, должпа проявляться при температуре ' $T_{\mathrm{c}} \sim \Delta$. Фермиевская скорость оценивается терез среднее расстояние между фермионами $n^{-1/3}$ (n - копцентрация) как $v_F \sim \hbar n^{1/3}/\mathrm{m}$. Для обычных сверхпроводников T_c порядка нескольких градусов, а масса электронов проводимости, грубо говоря, совпадает с массой электронов в вакууме, и $\xi_0 \approx 10^{-5}$ cm. В ^{3} Не критическая температура нххе на три порядка, но и масса атомов ^{3}Не в несколько тысяч раз больше массы электронов, поэтому $\xi_0 \approx 10^{-6}$с. В тяжелофермионних соединениях эффективная масса электронов в $10 - 100$ раз больше массы электронов в вакууме, а в высокотемпературных сверхпроводниках T_c достигает десятков и сотен градусов. Поэтому в этих соединениях $\xi_0 \approx 10^{-6} - 10^{-7}$ cm.

Во всех персчислснных случаях $\xi_0 \gg n^{-1/3}$, то есть изолированных куперовских пар нс существует, и задача о возникновении сверхпроводящего состояния является существенно многочастичной.

19.1.2 2. Spin Structure of Paired States

Во всех известіннх к пастоящему моменту сверхтекучих ферми-жидкостях куперовские пары состоят из частиц со спином $1/2$. Спиновое состояние пары может характеризоваться значением полного спина $S = 0$ (синглет) или $S = 1$ (триплет), либо же представлять суперпозицию этих двух состояний. Для сверхпроводяших систем, обладаюощих определенной пространственной четностью, последняя возможность искппочается. Удобно рассмотреть этот вопрос для сверхпроводящих состояний с определенным орбиташным моментом.

Орбитальная волновая функшия (1.14) является четной для четдых значений орбитального момента l и нечетной ддя нечетных l:

$$g_l(-\mathbf{k}) = (-1)^l g_i(\mathbf{k}) \tag{2.1}$$

В то же время, согласно принципу Паули, полная волновая функция пары, состояшая из произведений вида $g(\mathbf{k})\chi_{12}$, где χ_{12} - спиноовая волютовая фунаия частиц 1 и 2, должна менять знак при их перестановкс:

$$g(-\mathbf{k})\chi_{21} = -g(\mathbf{k})\chi_{12} \tag{2.2}$$

Из соотношений (2.1) и (2.2) следует, что спиновое состояние пары с четным (нечетным) орбитатьным моментом / должно быть антисимметричньмм (симметричным) по отношснио к перестановке частиц.

Спиновые состояния двух частиц со спином $1/2$ строятся из спиновых состояний

[11] Точнос шыражение $\xi_0 = \hbar v_F / (2\pi T_c)$ для размера куперовской пары будет получено в \$18.

$$\alpha_\lambda = \begin{pmatrix}1\\0\end{pmatrix} = |\uparrow\rangle \quad \text{и} \quad \beta_\lambda = \begin{pmatrix}0\\1\end{pmatrix} = |\downarrow\rangle$$

одной частицы, являющихся собственнціми для операторов квадрата спина s^2 и проекшии спина s_z на ось z:

$$s_z = \frac{h}{2}\begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix}, \quad s_z\alpha_\lambda = \frac{\hbar}{2}\alpha_\lambda, \quad s_z\beta_\lambda = -\frac{\hbar}{2}\beta_\lambda$$

Собственная функция спин-синглетного состояния пары, для которого $S = 0$, $S_z = 0$ (где $\mathbf{S} = \mathbf{s}_1 + \mathbf{s}_2$), антисимметричная по отношению к перестановке частиц, имеет вид

$$\alpha_{1\lambda}\beta_{2\mu} - \beta_{1\lambda}\alpha_{2\mu} = |\uparrow|\rangle - \left|\nu\vdots\right\rangle = \begin{pmatrix}0 & 1\\ -1 & 0\end{pmatrix} = \left\langle i\sigma_{\psi_{i\mu}}\right.$$

то есть выражается черсз матрицу Паули σ_y[1]. Полная волновая функиия пары с $S = 0$ выглядит при этом следующим образом:

$$\Psi^l_{\text{pair}} = g(\mathbf{k})i\sigma_y = \sum_{m=-l}^{1} a_{lm}Y_{lm}(\hat{\mathbf{k}})i\sigma_y \tag{2.3}$$

где l может принимать значения $0, 2, 4, \ldots$ Соответствующие парные состояния, как это принято в атомной физике, носят названия $s, d, g, \ldots$ состояний.

Комплексные коэффициенты a_{im}, входлшие в формулу (2.3), одинаковые для всех куперовских пар данного сверхпроводящего состояния, представляют собой параметр порядка сверхпроводника. В слабо неоднородиьх состояниях параметр порядка зависит or координат, то есть коэффициенты a_{lm} являются функциями r. Так, параметром порядка для сверхпроводника с s-спариванием спужит одна комплексная фупкдия

$$a_{00}(\mathbf{r}) = \psi(\mathbf{r}) = |\dot{\psi}|e^{i\varphi} \tag{2.4}$$

а, например, для сверхпроводника с d-спариванием ($l = 2$) таких функций пять.

Для спин-триплетного состояния пары ($S = 1$) волновые функции, соответствующие трем различным проекдиям спина пары иа ось квантования и симметричные по отiошенито к перестановке частиц, имеiот вид

$$S_z = \begin{cases} 1, & \alpha_{1\lambda}\alpha_{2\mu} = |\uparrow\uparrow\rangle = \begin{pmatrix}1 & 0\\ 0 & 0\end{pmatrix} \\ 0, & \alpha_{1\lambda}\beta_{2\mu} + \beta_{1\lambda}\alpha_{2\mu} = |\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle = \begin{pmatrix}0 & 1\\ 1 & 0\end{pmatrix}, \\ -1, & \beta_{1\lambda}\beta_{2\mu} = |\downarrow\rangle = \begin{pmatrix}0 & 0\\ 0 & 1\end{pmatrix} \end{cases}$$

то есть являются симметричными матрицами. Полная волновая функция пары представляет собой линсйную комбинациюо этих состояний:

$$\Psi^l_{\text{pair}} = g_1(\mathbf{k})|\uparrow\uparrow\rangle + g_2(\mathbf{k})(|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle) + g_3(\mathbf{k})|\downarrow\rangle = \begin{pmatrix}g_1(\mathbf{k}) & g_2(\mathbf{k})\\ g_2(\mathbf{k}) & g_3(\mathbf{k})\end{pmatrix} \tag{2.5}$$

[11] Напомним опрелеление магриц Паули:

$$\sigma_x = \begin{pmatrix}0 & 1\\ 1 & 0\end{pmatrix}, \quad \sigma_y = \begin{pmatrix}0 & -i\\ i & 0\end{pmatrix}, \quad \sigma_z = \begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix}$$

Здесь

$$g_\alpha(\mathbf{k}) = \sum_{m=-1}^{1} a^\alpha_{lm} Y_{Im}(\hat{\mathbf{k}}) \tag{2.6}$$

• ампиитуды состояний с $S_z = 1, 0$ и -1, соответственно.

Квантовое число / в формуле (2.6) можст приниматъ значения $1, 3, \ldots$ Соответствующие состояния называют сверхпроводящими состояниями с $p, f, \ldots$ спариванием. Друтая форма записи выражения (2.5) связана с использованием базиса симметричных матриц $i\sigma\sigma_y = (i\sigma_x\sigma_y, i\sigma_y\sigma_y, i\sigma_z\sigma_y)$. Имеем:

$$\begin{aligned}\Psi'_{\text{pair}} &= i(\,\mathrm{d}(\mathbf{k})\sigma)\sigma_y = (d_x(\mathbf{k})\sigma_x + d_y(\mathbf{k})\sigma_y + d_x(\mathbf{k})\sigma_z)\, i\sigma_y = \\ &= \begin{pmatrix} -d_x(\mathbf{k}) + id_y(\mathbf{k}) & d_z(\mathbf{k}) \\ d_z(\mathbf{k}) & d_x(\mathbf{k}) + id_y(\mathbf{k}) \end{pmatrix}\end{aligned} \tag{2.7}$$

Компоненты всктора $\mathrm{d}(\mathbf{k})$, линейно выражающиеся через ампиитуды $g_\alpha(\mathbf{k})$:

$$g_1 = -d_x + id_y, \quad g_2 = d_2, \quad g_3 = d_x + id_y$$

могут быть разложены по сферическим гармоникам:

$$d_\alpha(\mathbf{k}) = \sum_{m=-1}^{1} b^\alpha_{lm} Y_{lm}(\hat{\mathbf{k}}) \tag{2.8}$$

Коэффициенты b^α_{lm} играют роль параметра порядка сверхпроводника с данным типом спаривания, то есть с данным значением квантового числа l. Так, в простейшем случае p-спаривания параметром порядка является набор девяти комплексных функиий $b^\alpha_{lm}(m = -1, 0, 1)$.

Упражнешие. Используя выражение (2.7) для спшиновой волновой функции триплетного состояния, доказать формулы для

а) среднего значения спина пары:

$$\mathbf{S} = i\hbar \int \frac{d\Omega}{4\pi} \mathrm{d}^*(\mathbf{k}) \times \mathrm{d}(\mathbf{k}) \tag{2.9}$$

б) срешлего значения орбитального момента пары:

$$\mathbf{L} = i\hbar \int \frac{d\Omega}{4\pi} \mathbf{d}^*(\mathbf{k}) \left[\mathbf{k} \times \frac{\partial}{\partial \mathbf{k}}\right] \mathbf{d}(\mathbf{k}) \tag{2.10}$$

19.1.3 3. Phases of Superfluid Helium-3

Сферические гармоники $Y_{\mathrm{lm}}(\hat{k})$ с $l = 1$

$$Y_{11}(\hat{\mathbf{k}}) \propto \left(\hat{k}_x + i\hat{k}_y\right)$$
$$Y_{1-1}(\hat{\mathbf{k}}) \propto \left(\hat{k}_x - i\hat{k}_y\right), \quad Y_{10}(\hat{\mathbf{k}}) \propto \hat{k}_x$$

линейно выражаются через компоненты вектора $\hat{\mathbf{k}}$, что порождает еще одну форму записи вектора d:

$$d_\alpha(\mathbf{k}) = A_{\alpha i}\hat{k}_i \tag{3.1}$$

Комплексная 3 × 3 матрица $A_{\alpha i}$ суть параметр порядка в сверхтекучих ферми-жидкостях с p-спариванием. Именно такой тип спаривания осуществляется в сверхтекучем ^{3} He [3-6], фазовая диаграмма которого изображена на рис. 2.

Вектор d в выражении (3.1) зависит от компонент вектора k в некоторой фиксированной системе координат. Пользуясь тем, что при трехмсрных по-

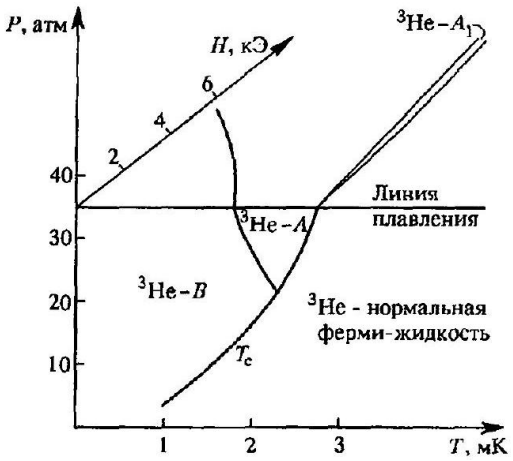

Рис. 2. Фазовая диаграмма жидкого гелия-3 в координатах: температура $-T$ (мК), давление P (атм), магнитное поле - H (кЭ)

воротах $\hat{R}^S$ и $\hat{R}^O$ в стиновом и орбитаном (координатном) пространствах, соответственно, компоненты векторов **d** и **k** линейно прсобразуются через самих себя, то есть

$$d_\alpha \to \tilde{d}_i = R^{\mathrm{S}}_{\alpha\beta} d_\beta$$
$$k_i \to \tilde{k}_i = R^{\mathrm{o}}_{ij} k_j$$

мы можем записать параметр порядка в произвольной сисгеме координат.

Перечислим возможные фазы сверхтекучей жидкости с p-спариванием, различалишиеся видом спшнового вектора d (или матрицы $A_{\alpha i}$).

B-фаза:

$$\mathrm{d}(\mathbf{k}) \propto \hat{\mathbf{k}} \tag{3.2}$$

то есть $A_{\alpha i} \propto \delta_{\alpha i}$ (в произвольной сисгеме координат $A_{\alpha i} \propto R_{\alpha i}$, где $\hat{R}$ матрица трехмерных вращений). Волновая функция пары (см. (2.7)) имеет в ХХд

$$\begin{aligned}\mathbf{\Psi}^B_{\mathrm{pair}} &\propto \begin{pmatrix} -\hat{k}_x + i\hat{k}_y & \hat{k}_z \\ \hat{k}_z & \hat{k}_x + i\hat{k}_y \end{pmatrix} = \\ &= \left(-\hat{k}_x + i\hat{k}_y\right)|\Pi\rangle + \hat{k}_z\left(\left|\prod \downarrow\right\rangle + |\,\lfloor\uparrow\rangle\right) + \left(\hat{k}_x + i\hat{k}_y\right)|\downarrow\downarrow\rangle\end{aligned} \tag{3.3}$$

Таким образом, B-фаза предсгавляет собой линеейную комбинацию трех равновероятных состояний $|S_z = +1, m = -1\rangle, |S_z = 0, m = 0\}$ и $|S_z = -1,\ m = +1\rangle$.

Имеюотся еше пве фазы, в которых реализуется часть состояний, из которых состоит B-фаза.

Планарная фаза:

$$\mathrm{d}(\mathbf{k}) \propto \left(\hat{k}_x, \hat{k}_y, 0\right) \tag{3.4}$$

Отсiода

$$\Psi_{\text{pair}}^{\text{pl}} \propto \left(-\hat{k}_x + i\hat{k}_y\right) |\Uparrow\rangle\Big\rangle + \left(\hat{k}_x + i\hat{k}_y\right) |U\rangle. \tag{3.5}$$

Планарная фаза является смесыо двух состояний: $|S_z = +1, m = -1\rangle$ и $|S_z = -1, m = +1\rangle$.

Полярпая фаза:

$$\mathbf{d}(\mathbf{k}) \propto \left(0, 0, \hat{k}_z\right) \tag{3.6}$$

Отсюода

$$\Psi_{\text{pair}}^{\text{pol}} \propto \hat{k}_z(|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle) \tag{3.7}$$

Полярная фаза состоит из пар с $S_z = 0$ и $m = 0$.

Имеются также фазы с ненулевыми орбитальным и спиновым моментами.

А-фаза:

$$\mathbf{d}(\mathbf{k}) \propto \left(\hat{k}_x + i\hat{k}_y, 0, 0\right) \tag{3.8}$$

то есть $A_{\alpha i}^{A} \propto V_\alpha \left(\Delta_i' + i\Delta_i''\right)$, где $\mathbf{V} = (1,0,0), \Delta' = (1,0,0), \Delta'' = (0,1,0)$. В произвольной систсме координат: V - единичныпи вектор в спиновом пространстве, а Δ' и Δ'' - единиqные взаимно перпендикулярные векторы в координатном пространстве. Парная волновая функция имеет вид

$$\Psi_{\text{pair}}^{A} \propto \left(\hat{k}_x + i\hat{k}_y\right) \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix} \propto \left(\hat{k}_x + i\hat{k}_y\right) \left(|\uparrow\rangle\rangle - |\downarrow\rangle\right\rangle \tag{3.9}$$

Таким образом, A-фаза представляет собой линейную комбинацино двух равновероятных состояний $|S_z = +1, m = 1\rangle$ и $|S_z = -1, m = 1\rangle$. Спиновый момент в этой фазе отсутствует. Орбитальный момент сосуда с A-фазой в основном состоянии должен быть порядка $N\hbar$, где N - число куперовских пар.

A_1 - фаза:

$$\mathbf{d}(\mathbf{k}) \propto \left(\hat{k}_x + i\hat{k}_y, i\left(\hat{k}_x + i\hat{k}_y\right), 0\right) \tag{3.10}$$

Отсюда $A_{\alpha i}^{A_1} \propto \left(V_\alpha' + iV_\alpha''\right)\left(\Delta_i' + i\Delta_i''\right)$, причем в произвольной системе координат $\mathbf{V}'$ и $\mathbf{V}''$ - единичные взаимно перпендикулярные спиновые векторы,
а Δ' и Δ'' опредепяюотся апалогично A-фазе. Парная волновая функиия имеет вид

$$\Psi_{\text{pair}}^{A_2} \propto \left(\hat{k}_x + i\hat{k}_y\right) \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} = \left(\hat{k}_x + i\hat{k}_y\right) |\Pi\rangle \tag{3.11}$$

Следовательно, A_1-фаза состоит щз пар с $S_z = 1$ и $m = 1$. Эта фаза обладает как орбитальным, так и спиновым магнитным моментом.

$\beta - \phi aa$:

$$\mathrm{d}(\mathbf{k}) \propto \left(\hat{k}_x, i\hat{k}_x, 0\right) \tag{3.12}$$

Отсiода $A_{\alpha i}^{\beta} \propto \left(V_\alpha' + iV_\alpha''\right)\Delta_i$, и

$$\Psi_{\text{pair}}^{\beta} \propto \hat{k}_x \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} = \left(\left(\hat{k}_x + i\hat{k}_y\right) + \left(\hat{k}_x - i\hat{k}_y\right)\right) |\Pi\rangle \tag{3.13}$$

то есть β-фаза состоит из пар с $S_z = 1, m = +1$ и $S_z = 1, m = -1$ и обладает ненулевым спиновым момснтом.

19.1.4 4. Superconducting States in Crystals

Из рассмотрсния в 2 следует, что свсрхпроводящие состояния, обладаэщие определениой пространственной четностыю, могут быть тибо спинсинглетными, либо спин-триплетными. Именно, парная волновая функция для пространственно-четных состояний

$$\Psi^{\mathrm{s}}_{\mathrm{pair}} \propto g(\mathbf{k}) i\sigma_y \tag{4.1}$$

$$g(\mathbf{k}) = g(-\mathbf{k}) \tag{4.2}$$

соответствует $S = 0$, а для пространственно-нечетных состоянид $S = 1$, то есть

$$\Psi^{\mathrm{t}}_{\mathrm{pair}} \propto (\mathbf{d}(\mathbf{k})\sigma) i\sigma_y \tag{4.3}$$

$$\mathbf{d}(\mathbf{k}) = -\mathrm{d}(-\mathbf{k}) \tag{4.4}$$

Симметрия системы в сверхпроводящем состоянии включает в себя пространственную инверсию, если парная волновая функция Ψ_{pair} под деюствием оператора инверсии I не менятся:

$$I\Psi_{\mathrm{pair}} = \Psi_{\mathrm{pair}} \tag{4.5}$$

что соответствует синглетному спариванию, или меняет знак:

$$I\Psi_{\mathrm{pair}} = -\Psi_{\mathrm{pair}} \tag{4.6}$$

при триплетном спаривании. Смешанные сверхпроводящие состояния вида

$$a\Psi^{\mathrm{s}} + b\Psi^{\mathrm{t}} \tag{4.7}$$

в этом случае запрещены.

Если же симметрия нормального состояния не включает пространственпууо инверсипо (кристалшi без цештра инверсии), или симметрия по отношению к инверсии нарушается при переходе в сверхпроводящее состояние (специальный вид спаривающего взаимодействия), то состояния типа (4.7) в
принципе могут реализовываться [7]. Мы будем предполагать наличие пространственной инверсии и работать со свсрхпроводящими состояниями вида (4.1) либо (4.3).

Как было показано в 1, в изотропном веществе темпсратуры перехода в сверхпроводящие состояния с разными зачениями орбитального момепта куперовских пар различны, то есть $T_{\mathrm{c}} = T_{\mathrm{c}}(l)$. Функции $g(\mathbf{k})$ и $\mathbf{d}(\mathbf{k})$ для синглетного и триплстного состояний, соотвстственно, имегт вид линейных комбинаций сферических функиий с даницм l:

$$g^l(\mathbf{k}) = \sum_{m=-l}^{l} a_{lm} Y_{lm}(\hat{k}), \qquad \text{при } l = 0, 2, 4, \ldots \tag{4.8}$$

$$\mathrm{d}^l(\mathbf{k}) = \sum_{m=-l}^{l} \mathrm{b}_{lm} Y_{lm}(\hat{\mathrm{k}}), \qquad \text{при } l = 1, 3, 5, \ldots \tag{4.9}$$

Как отмечалось в предыдущем параграфе, выбор системы координат, в которой записываются функции $Y_{lm}(\hat{k})$, роли не играет, поскольку при переходе от одного базиса

$(\hat{x}, \hat{y}, \hat{z})$ к другому $(\hat{x}', \hat{y}', \hat{z}')$, то есть при пространстзснных вращениях систсмы координат, функции $Y_{lm}\left(\hat{\mathbf{k}}'\right)$ линейно выражаются через сферические гармоники с тем же значением l:

$$Y_{lm}\left(\hat{\mathbf{k}}'\right) = \sum_{m'=-1}^{i} \Gamma_{mm'} Y_{lm'}(\hat{\mathbf{k}})$$

В общем стучас говорят, что набор функций $\{\psi_i(\mathbf{r})\}$ образует базис нсприводимого представления нскоторой трупшы пространственной симметрии G, если функции данного набора при любом преобразовании симметрии g из этой группы линейно выражаются только через самих себя [8]:

$$\psi_i(g\cdot) = \psi_i\left(\mathbf{r}'\right) = \sum_{j=1}^{d} c_{ij}\psi_j(\mathbf{r})$$

В изотропной системе, инвариантной относительно любшх пространственнвіх вращений, то есть преобразований из группы SO_3, неприводимые представления нумеруются значением орбитального момента l, а набор из $2l+1$ сферических гармоник с данным l образует базис представления. Типы куперовского спаривания при этом находятся во взаимнооднозначном соответствии с неприводимыми представлениями группы трехмерных вращений.

Принцип классификации сверхпроводпщих состояний согласно различным представлениям группы симметрии системы в нормальном состоянии полностью сохраняется и в присутствии кристаллической аиизотропии [9-14]. Именно, сверхпроводящие состояния с различными критическими температурами описываготся базисными функиими различных неприводимых представлении Γ группы G точечной симметрии кристалла [1], причем $T_c = T_c(\Gamma)$.

Разложения (4.8), (4.9) в этом случае принимают вид:

$$g(\mathbf{k}) = \sum_{i=1}^{d_\Gamma} \eta_i \psi_i^{\Gamma_s}(\hat{\mathbf{k}}) \tag{4.10}$$

$$\mathbf{d}(\mathbf{k}) = \sum_{i=1}^{d_\mathrm{r}} \eta_i \psi_i^{\Gamma_u}(\hat{\mathbf{k}}) \tag{4.11}$$

где $\psi_i^{\Gamma_\mathrm{s}}(\hat{\mathbf{k}})$ и $\psi_i^{\Gamma_\mathrm{u}}(\hat{\mathbf{k}})$ - базисные функции (g - четтые, au - нечетные по $\hat{\mathbf{k}}$) неприводимых представлений Γ размерности d_Γ группны G.

Для пренебрежимо малого спин-орбитального взаимодсйствия имеется вырождение состояний по отношенип к вращениям стиновьх векторов:

$$\eta_i^\alpha \to \tilde{\eta}_i^\alpha = R^S_{\alpha\beta}\eta_i^\beta.$$

В случае сильного спшн-орбиталного взаимодействия, которое имеет место в соединениях, содержащих элсменты с большими атомными номерами, удобно представить (4.11) в виде разложения

[11] Пространствешая группа симметрии кристалия вкточает комбинации операций точечной симметрии и трангляций. Постсдние мохно не принмать по внимание, так как никакой цопо:нительной пространствснноі модуляции при переходе в сверхпроводящсе состояине не возникаст.

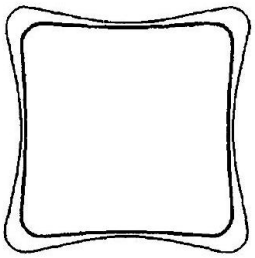
$$\mathbf{d}^{\mathrm{I}}(\mathbf{k}) = \sum_{i=1}^{d_\Gamma} \eta_i \psi_i^{\Gamma_{\mathrm{u}}}(\hat{\mathbf{k}}) \tag{4.12}$$

по векторным базисным функциям

$$\begin{gathered}\psi_i^{\Gamma_u}(\hat{\mathbf{k}}) = \psi_i^x(\hat{\mathbf{k}})\hat{x} + \psi_i^y(\hat{\mathbf{k}})\hat{y} + \psi_i^z(\hat{\mathbf{k}})\hat{z} \\ \psi_i^{\Gamma_u}(-\hat{\mathbf{k}}) = -\psi_i^{\Gamma_u}(\hat{\mathbf{k}})\end{gathered} \tag{4.13}$$

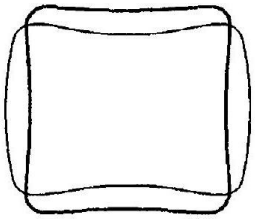
неприводимого представления Г. Базис в спиновом пространстве задается единичными аксиалыпыми векторами $\hat{x}, \hat{y}, \hat{z}$, жестко связанными с кристаллическими осями. Здесь необходимо сделать слелующее замечание. Несмотря на то, что в кристаллах с сильным спин-орбитальным взаимодействием спиnі электрона становится «ллохим» квантовым числом, электронные состояния тем не менее остаются двукратно вырожденными (крамсрсовское вырождение - следствие симметрии по отношению к обращениоо времени), что позволяет характеризовать их «псевдоспином». В этом же смыслс следует понимать термин «спин-синглетное» или «спин-триплетное» сверхпроводящие состояния.

Совокупность комплексных коэффициентов η_i (или η_i) в разложениях (4.10), (4.11) или (4.12) прсдставляет собой параметр порядка в кристаллических сверхпроводниках. Таким образом, возможны как сверхпроводящие состояния с однокомпонентными параметрами порядка $\eta = |\eta|e^{i\varphi}$, так и с многокомпонентными параметрами порядка.



Помимо точечных преобразований, группа симметрии нормального состояния $\mathcal{G}$ включает операцию обращения времени R и калибровочные преобразования $U(1)$[2]:

$$\mathcal{G} = U(1) \times R \times G$$



Переход в сверхгекулее или сверхпроводяшсе состояние означает появление фазовой когерентіости, то есть различия между состояниями с различными фазами φ параметра порядка $|\eta|e^{i\varphi}$, о чем говорят как о спонтанном нарушении калибровочной симметрии $U(1)$. При переходе в данное сверхтекучее состояние могут нарушаться также и другие симметрии из $\mathcal{G}$ (необыиная сверхмекучесть или сверхпроводимость). В результате сохраняется инвариантность лишгь по отношению к преобразованиям, образующим подгруппу H (сверхироводящий класс) группы $\mathcal{G}$. Таким образом, задача перечисления всех возможных сверхпроводящих (или сверхтекулих) фаз сводится к нахождению сверхпроводящих классов, соответствующих различным нарушенным симетриям нормалыной фазы [9].

Среди допустимьх по симметрии сверхпроводящих состояний следует выделять те, которые могут возникпуть непосредственно из нормальной фазы [3]. Согласно общей теории фазовых переходов Ландау, параметры порядка таких состояний должны преобразовываться по одному из неприводимых представлений точечной группы симметрии G нормальной фазы [9]. Обычное сверхпроводящее состояние обладает полной точечной симметрией кристалла, то есть относится к единичному представлению A_{1g} и описывается тривиальным сверхпроводящим классом $H = R \times G$. Точечная симметрия всех остальных сверхпроводящих состояний, относящихся к неслиничнцм представлениям

[12] В отсутствие спин-орбитального взаимодействия в группу $\mathcal{G}$ необходимо включать также преобразования свободных трехмериых вращений спинов, образуюиих группу SO_3^S.

a

6

Рис.3. Сечение ферми-поверхности (жирная линия) в базисной плоскости тетрагонаиного кристалла (группа симметрии D_{4h}. Тонкой линисй изображемы: а) аминитуда параметра порялка обычного сверхпроводящего состояния (прецставление Λ_{1g}), б) амплитуда парамстра порядка одного из нсобычиых снсрхироводяших состояний (представтение B_{1g}), поннжающего точечную симметрию кристаліа до D_{2h}

(или нечетному единичному представлению A_{1u}), нарушсна, и они пазываются нетривиальными или необычньми сверхпроводящими состоянияии (рис. 3).

В случае однокомпонентіого параметра порядка имеется взамнооднозначное соответствие между одномерными представлениями группы G и сверхпроводящими классами. Напротив, неодномерные представления порохдают несколько сверхпроводящих состояний, относящихся к различным сверхпроводяшшм классам и имеющих одинаковую критическуго температуру, но разную свободную энсргио (подробнее об этом см. 11). Это имеет место, нагример, для фаз с p-спариванисм, персисленнЬIX в 3.

Сверхпроводящие классы в гексагональном кристалле. В качестве примера, важного с точки зрения приложений к сверхпроводящему соединению с гяжельми фермионами LPt_3, обсудим сверхпроводящие состояния в кристалле с гексагонатьной симметрией, для которого $G = D_{6h} = D_6 \times I$, где I - преобразование инверсии. Здесь имеется 6 неприводимых представлений: 4 одномерных (A_1, A_2, B_1, B_2) и 2 пвумерных (E_1, E_2). Симметрия каждого сверхпроводящего состояния должна описываться подгруппой группы $\mathcal{G} = U(1) \times R \times D_{6h}$.

Группа $D_6 = \{C_n, U_n\}$ сосгоит из шести операций поворота C_n вокруг оси $\hat{z}$ на угол $\pi n/3$ $(n = 0, 1, \ldots, 5; C_0 = E$ - единичный элемент группы) и вращений U_n на угол π вокруг шести осей

$$- - \hat{x} \sin \frac{\pi n}{3} + \hat{y} \cos \frac{\pi n}{3}$$

Среди подгрупп группы $\mathcal{G}$ имеются четыре подгруппы H, которые соответствуот сверхпроводящим состояниям, описываемым функциями четырех одномерных представлений D_6. Это подтруппы $D_6 \times R, D_6\,(C_6) \times R$, $D_6\,(D_3) \times R$, и $D_6\,(D_3') \times R$.

[13] Сверхпроводящие классы, не относяицииеся к данной катсгория, соответствуот состояния, которые могут вознпкууть при дополиительных фазовых переходах внутри свсрхпроводяцей фазы.

Подгруппа, указанная в скобках, объединяет те элементы группы D_{6h}, которые не умножагтся на фазовый множитель из $U(1)$, то есть

$$D_6\left(C_6\right) = \left\{C_n, e^{i\pi}U_n\right\}$$
$$D_6\left(D_3\right) = \left\{C_{2k}, U_{2k}, e^{i\pi}C_{2k+1}, e^{i\pi}U_{2k+1}\right\}$$
$$D_6\left(D_3'\right) = \left\{C_{2k}, U_{2k+1}, e^{i\pi}C_{2k+1}, e^{i\pi}U_{2k}\right\}$$

гдс $k = 0, 1, 2$. Легко видеть, что подгруппа D_6 соответствует единичному представлснию A_1. Ровно половина элементов подгруппы $D_6\left(C_6\right)$ (или $D_6\left(D_3\right), D_5\left(D_3'\right)$) есть элементы группы D_6, друтая половина - комбинации операций точечной симметрии и калибровочного преобразования $c^{i\pi}$. Так, точечные преобразования U_n мсняют знак параметра порядка свсрхпроводящсго состояния с симметрией $D_6\left(C_6\right)$, которое, тем самым, соответствуст неединичному представлению A_2 групш D_6 (аналогично, $D_6\left(D_3\right)$ соответствует B_1, а $D_6\left(D_3'\right)$ соответствует B_2).

Высокотемпературиые сверхпроводиики. Еще одним примером необимной сверхпроводимости являются высокотемпературные сверхпроводники, к которым относятся металлооксидные материалы с T_c в пределах от 7 K до 100 K. Наиболее изученные представители этого класса - соединения $La_{2-x}Sr_xCuO_4$ и $YBa_2Cu_3O_{7-x}$, - обладают тетрагональной симметрией кристаллической решетки, то есть $G = D_{4h} = D_4 \times I$. В иттрий-бариевых соединениях имеются неболшие (порядка одного процента) орторомбические искажения кристалличсской рсшетки, влияние которых мы рассмотрим несколько ниже.

Группа D_4, вкпючаоошая операции поворотов C_n вокрут оси $\hat{z}$ на утол $\pi n/2$ и поворотов U_n на угол π вокруг осей

$$\hat{x}\cos\frac{\pi n}{2} + \hat{y}\sin\frac{\pi n}{2}$$

где $n = 0, 1, 2, 3$, имеет 5 неприводимых представлений: четыре одномерных (A_1, A_2, B_1, B_2) и одно двумерное (E).

Совокупность данных о низкотемпературном повепении тсрмолинамических характеристик [15, 16], а также измерения угловой зависимости амплитуды фотоэмиссии (ARPES) [17] и фазочувствительные SQUID-эксперименты [18-20] (см. 16) позволяют сделать вывод о том, что сверхпроводящцее состояние в этих соединсниях описывается однокомпонентным нетривиальным параметром порядка, отвечающим синглетному спариванито и преобразуіоциммся в соответствии с представлением B_{1g}, то есть

$$g(\mathbf{k}) \propto \hat{k}_x^2 - \hat{k}_y^2 \tag{4.14}$$

В устоявшейся терминологии такая импухьсная зависимость называется «dспариванием», что, однако, не совсем точно, поскольку в кристаллах нет классификации состояний по орбиталному момснту. В соответствуюощем сверхпроводящсм классе

$$\therefore \quad D_4\left(D_2\right) \times R = \left\{C_{2k}, U_{2k}, e^{i\pi}C_{2k+1}, e^{i\pi}U_{2k+1}\right\} \times R \quad (k = 0, 1)$$

фазовые множители $e^{i\pi} = -1$ компенсируют смену знака базиспой функшии при действии операцжй тотечной симметрии.

Орторомбичсскис кристаллы характеризуются группой симметрии $G = D_{2h}$, имеющей четыре одномерных неприводимьх представления. Простейшее из них - едипичное A_{1g}, соответствующсе обычной сверхпроводимости, описывается параметром порядка, инвариантным относительно вращений на угол π вокруг направлений $\hat{x}, \hat{y}, \hat{z}$. Для синглетного спаривания такими свойствами, в частности, обладает функция

$$g(\mathbf{k}) \propto a + b\left(\hat{k}_x^2 - \hat{k}_y^2\right)$$

представляющая собой смесь s и d-состояний - параметр порядка сверхпроводимости с так назьваемьм «s $+d$-спариванием». Интересно отметить, что это вполне обычное сверхпроводящее состояние в орторомбическом кристалле может оказаться довольно «близким» к необычному сверхпроводящему состоянию B_{1g} в тетрагональном кристалле. Так будет, когда неболыше орторомбические искажения в тетрагональном кристалле вызывают примешивание s-компонепты к исходной d - компоненте параметра порядка (4.14). Другое, часто фигурирующее в литературе «s $+id$-состояние», мы обсудим в следующем подразделе.

Мапнитные сверхпроводящие влассы. Приведенные выше примеры сверхпроводяших классов явно содержат операдию R, то есть соответствующие состояния инвариантны по отношению к обращению времени. Эго, в свою очередь, означает отсутствие спонтанного магнетизма куперовских пар. Однако действие операций точечной группы на параметр порядка может быть скомпенсировано умножснием не толкко на фазовый множитель из калибровочной группы $U(1)$, но и на операцито R, которая сводится к комплексному сопряжению: $g(\mathbf{k}) \to g^*(\mathbf{k})$ или $\mathbf{d}(\mathbf{k}) \to \mathbf{d}^*(\mathbf{k})$. Тем самым инвариантность по отношению к обращенио времени оказывается нарушенной, и симметрия таких сверхпроводящих состояний описывается магнитныии сверхпроводящими классами [9].

Легко видеть, что непосредственный переход из нормаьной фазы в сверхпроводяшую с однокомпонентвым параме тром порядка и нарушеннод симметрией по отношению к обращенио времени невозможен. В самом деле, вблизи
криттческой температуры сверхпроводящие классы находятся во взаимнооднозначном соответствии с представлениями точечной группы G, а операшия R переводит базисную функциі представления в комплексно-сопряженную и поэтому требует, чтобы размерность прсдставления d_Γ была не меньше двух.

Детальное обсуждение вопроса о магнетизме сверхпроводящих фаз с многокомпонентными параметрами порядка мы отложим до 15, а здесь приведем лишь один пример магнитного сверхпроводящего класса для тетрагонального кристалла. Нетрудно убедиться в том, что у группы $\mathcal{G} = U(1) \times R \times D_{4h}$ имеется подгруппа:

$$D_4\,(D_2) = \{C_{2k}, U_{2k}, RC_{2k+1}, RU_{2k+1}\} \quad (k = 0, 1)$$

содержащая операцию обращения времени лишь в комбинации с поворотами вокруг осей симметрии тетрагональной решетки. Указанной симметрией обладает, например, сверхпроводящая фаза синглетного спаривания с параметром порядка $g(\mathbf{k}) = \left(\Delta_s + i\Delta_d\left(\hat{k}_x^2 - \hat{k}_y^2\right)\right)e^{i\varphi}$, где Δ_s и Δ_d - произвольные когстанты. Такое состояние (тасто называемое $s + id$-спариванисм) может возникнуть в результате двух последоватешных фазовых переходов: сначала из нормальной фазы в сверхпроводящую с однокомпонентным параметром порядка $g_1(\mathbf{k}) = \Delta_s e^{i\varphi}$, соответствующим представлению $A_{1\ \mathrm{g}}$, а затем, при более низкой температуре - в другую сверхпроводяшую фазу, в которой к $g_1(\mathbf{k})$ примешивается параметр порядка $g_2(\mathbf{k}) = \Delta_d\left(\hat{k}_x^2 - \hat{k}_y^2\right)e^{i\varphi}$, соответствующий представлению $B_{1\ \mathrm{g}}$.

Нули в спектре элементарных возбуждений. Наличие нетривиальных элементов симметрии, вкпочающих калибровочное прсобразование, приводит к важному слелствию - существованито нулей параметра порядка. Обсудим это свойство для спин-синглетного параметра порядка $g(\mathbf{k})$ с симметрией $D_6\,(C_6) \times R$:

$$C_n g(\mathbf{k}) = g(\mathbf{k}) \tag{4.15}$$

$$e^{i\pi} U_n g(\mathbf{k}) = g(\mathbf{k}) \tag{4.16}$$

$$g(-\mathbf{k}) = g(\mathbf{k}) \tag{4.17}$$

В частности, значсний параметра порядка на плоскости (k_x, k_z), перпендикулярной оси $\hat{y}$, вокрут которой осуществляется поворот U_0, из (4.16) имеем:

$$U_0 g\left(k_x, k_z\right) = -g\left(k_x, k_z\right) \tag{4.18}$$

С друтой стороны, $U_0 k_x = -k_x, U_0 k_z = -k_z$, и

$$U_0 g\left(k_x, k_z\right) = g\left(-k_x, -k_z\right)$$

Используя свойство (4.17), получаем:

$$U_0 g\left(k_x, k_z\right) = g\left(k_x, k_z\right) \tag{4.19}$$

Равенства (4.18) и (4.19) могут быть выполнены ошіовременно лишь при условии

$$g\left(k_x, k_z\right) = 0 \tag{4.20}$$

Таким образом, параметр порядка обращается в нуль на плоскости (k_x, k_x), более того, он меняет знак при се пересечении. То же самое верно для всех плоскостей, перпендикулярных к осям поворотов U_n.

2	E_{2u}	$k_x\hat{x} - k_y\hat{y}, k_x\hat{y} + k_y\hat{x}$ или $\hat{z}k_x\left(k_x^2 - k_y^2\right), 2\hat{z}k_xk_xk_y$	

Таблица 2. Базисныс функции нечетных ($S = 1$, слабос спиц-орбиталыюо взаимодействие) представлений группы D_{6h}

d	Γ	$\psi_i^\Gamma(\hat{\mathbf{k}})$	H
1	A_{1u}	$k_z\left(k_x^3 - 3k_xk_y^2\right)\left(k_y^3 - 3k_yk_x^2\right)$	$D_6 \times R \times SO_3^{\text{S}}$
1	$A_{2\text{u}}$	k_z	$D_6\left(C_6\right) \times R \times SO_3^{\text{s}}$
1	B_{1u}	$k_y^3 - 3k_yk_x^2$	$D_5\left(D_3\right) \times R \times SO_3^3$
1	B_{2u}	$k_x^3 - 3k_xk_y^2$	$D_6\left(D_3'\right) \times R \times SO_3^S$
2	E_{1u}	k_x, k_y	
2	E_{2u}	$k_z\left(k_x^2 - k_y^2\right), 2k_xk_yk_z$	

Щель в спектре элементарных возбуждений сверхпроводника пропорционална модуло параметра порядка [4]:

$$\Delta_{\mathbf{k}} \sim |g(\mathbf{k})| \quad \text{при } S=0, \quad \Delta_{\mathrm{k}} \sim |\mathbf{d}(\mathbf{k})| \quad \text{при } S=1$$

(см. ниже 5). Поэтому энергетический спектр квазичастиц в сверхпроводящем состоянии с симметрией $D_6\,(C_6) \times R$ является бесшелевым на линиях пересечения поверхности Ферми и плоскостей, перпендикулярных к осям поворотов U_n.

Для спин-триплетного параметра порядка $\mathbf{d}(\mathbf{k})$ с симметриеи $D_6\,(C_6) \times R$ имеем:

$$C_n\ \mathrm{d}(\mathbf{k}) = \mathrm{d}(\mathbf{k}) \tag{4.21}$$

$$e^{i\pi} U_n\ \mathrm{d}(\mathbf{k}) = \mathrm{d}(\mathbf{k}) \tag{4.22}$$

$$\mathrm{d}(-\mathbf{k}) = -\mathrm{d}(\mathbf{k}) \tag{4.23}$$

Таблица 3. Базисныс функции четных ($S=0$) и нечетных ($S=1$, силыое спинорбитальное взаимодействые) представлений группы $D_{4\text{ д}}$

d	Γ	$\psi_i^{\Gamma}(\hat{k}), \psi_1^{\Gamma}(\hat{k})$	H
1	$A_{1\text{ g}}$	$ak_z^2 + b\left(k_x^2 + k_y^2\right)$	$D_4 \times R$

1	A_{2g}	$k_x k_y\left(k_x^2 - k_y^2\right)($	$D_4\,(C_4) \times R$
1	A_{2u}	$u\left(\hat{x}k_y + \hat{y}k_x\right)\left(k_x^2 - k_y^2\right) + b\left(\hat{x}k_y - \hat{y}k_x\right)$	
1	$B_{1\text{ g}}$	$k_x^2 - k_y^2$	$D_4\,(D_2) \times R$
1	B_{1u}	$a\left(\hat{x}k_x - \hat{y}k_y\right) + b\hat{z}k_x\left(k_x^2 - k_y^2\right)$	
1	B_{2g}	$k_x k_y$	$D_4\,(D_2') \times R$
1	B_{2u}	$u\left(\hat{x}k_y + \hat{y}k_x\right) + b\hat{z}k_x k_y k_z$	
2	E_g	$k_z k_x, k_z k_y$	
2	E_u	$\hat{z}k_x, \hat{z}k_y$	

Таблица 4. Базисные функции нечетных ($S=1$. слабое спин-орбитальнос взаимодействие) представлений трутпы D_{4h}

d	Γ	$\psi_i^{V_{\mathrm{s}}}(\hat{\mathrm{k}})$	H
1	A_{1u}	$k_x k_y k_x\left(k_x^2 - k_y^2\right)$	$D_4 \times R \times SO_3^{\mathrm{s}}$
1	A_{2u}	k_x	$D_4\,(C_4) \times R \times SO_3^{\mathrm{s}}$
1	B_{1u}	$k_x k_3 k_z$	$D_4\,(D_2) \times R \times SO_3^5$
1	B_{2u}	$k_z\left(k_x^2 - k_y^2\right)$	$D_4\,(D_2') \times R \times SO_3^5$
2	E_u	k_x, k_y	

Инвариантность параметра порядха по отношению к вращениям C_n означает, что для импульсов, направленных вдоль оси $\hat{z}$, отлична от нуля только z-компонента вектора $\mathrm{d}(\mathrm{k})$:

$$\mathbf{d}\,(k_z) = \hat{z}\psi^z\left(\hat{k}_z\right) \tag{4.24}$$

Из (4.22)

$$U_0 \mathbf{d}\,(k_z) = -\mathbf{d}\,(k_z) \tag{4.25}$$

но в то же время из (4.23) и (4.24) получаем:

[14] Данное утверждение справедливо аля уиитарных свгрхпроводящих состояний в отсутствие примесей (см. сноску 6 в 5 и 17).

$$U_0\mathbf{d}\left(k_z\right)=U_0\hat{z}\psi^z\left(\hat{k}_z\right)=-\hat{z}\psi^z\left(-\hat{k}_z\right)=\hat{z}\psi^z\left(\hat{k}_z\right)=\mathbf{d}\left(k_z\right) \tag{4.26}$$

Из сравнения соотношений (4.25) и (4.26) следует, что

$$\mathbf{d}\left(k_z\right)=0 \tag{4.27}$$

то есть параметр порядка равен нулоо на оси $\ddot{z}$, и поэтому спектр квазичастиц является бесщелевым на северном и южном полюсах ферми-поверхности.

Таким образом, имеется общая особенность сверхпроводяших состояний, симметрия которых включает комбинации точечных и калибровочных преобразований (или точечных преобразований и операции обращения времени). А именно, спектр элементарных возбуждений в таких сверхпроводниках является бесщелевым. Нули параметра порядка расположены на
